Spectral Shift of Band Origins in the Near Ultraviolet Absorption Spectra of Some 2- and 3-Substituted Pyridines

G. S. KASTHA and S. C. BAG

Optics Department, Indian Association for the Cultivation of Science, Calcutta 32, India

(Received April 30, 1971)

The relative shifts in the position of band origin of the lowest singlet π-electron transition in some 2- and 3-substituted pyridines, and monosubstituted benzenes with similar substituents, with respect to those of the parent molecules have been calculated by the method of localized orbitals with configuration interaction. Under certain assumptions, the calculated relative shifts in the 2- and 3-substituted pyridines are found to bear a linear relationship with that of the corresponding monosubstituted benzenes. The experimental data are found to be in agreement with the theoretical expectation.

The close similarity between the near ultraviolet π-electronic absorption spectra of monosubstituted benzenes and similarly substituted pyridines is well known. From the available values of the position of the O–O band of the lowest singlet $\pi\rightarrow\pi^*$ transitions in these compounds in the vapour phase, it is seen that the shifts of the band origin in the near ultraviolet absorption spectra of 2- and 3-substituted pyridines from that of pyridine are closely parallel to those of corresponding monoderivatives of benzene with respect to that of benzene. The π-electronic energy levels of some monosubstituted benzene molecules have been calculated from localized orbital model with configuration interaction by Kimura, Tsubomura, and Nagakura[1] and by Kimura and Nagakura.[2] Similar calculations including inductive effect of the substituent have been made by Favini, Gamba, and Bellobono[3] in amino- and nitro-substituted pyridines. With reasonable values of the ionization potential of the substituent, the electron affinity of benzene and pyridine molecules to which the substituent is attached and the resonance integrals between the substituent and the carbon atom of the respective molecules, these authors have obtained fair agreement between the calculated and experimentally observed values of the π-electronic energy levels in these molecules. SCF calculations of the π-electronic energy level of monosubstituted benzenes have also been reported by several workers.[4–6]

We have applied the localized orbital model with configuration interaction to explain the observed parallelism of the shifts of band origins in the near ultraviolet absorption spectra of some monosubstituted benzenes and 2- and 3-substituted pyridines with the same substituent without going into the actual calculations of the lowest π-electronic energy levels of all these molecules.

Theoretical Considerations

a) Monosubstituted Benzenes. The energy of the lowest excited π-electronic level E_a^X of monosubstituted benzenes with substituent X corresponding to E_a the energy of the α-band in benzene has been obtained from an approximate solution of the 3×3 determinantal equation (which is equivalent to a second order perturbation calculation) of B-species given by Kimura and Nagakura[2] for monosubstituted benzenes, and is given by

$$E_a^X = E_a + \frac{\frac{1}{6}\beta_X^2}{E_a - E_{C.T,b}} \qquad (1)$$

where β_X is the resonance integral corresponding to $\beta+\beta'$ of Kimura and Nagakura[2] and $E_{C.T,b}=I_X-A-Q_2$ is the energy of the charge transfer state. All these quantities are given in electron volts and the notations used are those of Kimura and Nagakura.[2]

The validity of Eq. (1) is seen from Table 1 where a comparison of the exact values of this energy level in a number of monosubstituted benzene molecules calculated by Kimura and Nagakura[2] and those for the corresponding molecules obtained from Eq. (1) is given. All these values have been calculated with the parameters given by Kimura and Nagalura.[2]

TABLE 1. COMPARISON OF THE ENERGY OF THE LOWEST EXCITED STATE IN MONOSUBSTITUTED BENZENES

(All values in eV)

Substituent	F	Cl	Br	OH	NH_2
Kimura and Nagakura[2]	4.80	4.70	4.53	4.68	4.40
Equation (1)	4.80	4.71	4.53	4.68	4.35

If the lowering of the ground state energy is neglected, the shift in the position of α-band of benzene with substitution is given by:

$$\Delta E_a^X = E_a - E_a^X,$$

and from Eq. (1) we get

$$\beta_X^2 = 6\Delta E_a^X (E_{C.T,b} - E_a) \qquad (2)$$

b) Monosubstituted Pyridines. The method of calculating the lowest excited π-electron energy levels in 2- and 3-substituted pyridines is the same as that used by Favini, Gamba, and Bellobono[3] in the case of aminopyridines. But instead of solving the 7×7 determinantal equation exactly, an approximate solution as in the case of monosubstituted benzenes has been used for obtaining the energy of the lowest excited state in each of the 2- and 3-substituted pyridines with the

substituent X. These are respectively given by the following equations:
For 2-substituted pyridines:

$$E_1^{X(2)} = E_1 - 0.017I_\pi^X + \frac{0.166\beta_X^2}{E_1 - E_5^{(2)} - 0.132I_\pi^X} + \frac{0.011\beta_X^2}{E_1 - E_6^{(2)} - 0.27I_\pi^X} \quad (3)$$

and for 3-substituted pyridines:

$$E_1^{X(3)} = E_1 - 0.083I_\pi^X + \frac{0.171\beta_X^2}{E_1 - E_5^{(3)} - 0.157I_\pi^X} + \frac{0.042\beta_X^2}{E_1 - E_6^{(3)} - 0.33I_\pi^X} \quad (4)$$

where E_1 is the energy of the lowest excited state (A_1) of pyridine, $E_1^{X(2)}$ and $E_1^{X(3)}$ are those of 2- and 3-substituted pyridines, respectively, I_π^X is the inductive parameter of the substituent X given by Godfrey and Murrell,[7] the quantities containing β_X^2 are the square of the Hamiltonian matrix elements between the lowest excited state (A_1) of pyridine and the appropriate charge transfer state $T_D{}^4$ and $T_D{}^5$ according to the notations used by Favini, Gamba, and Bellobono.[3]

For the two types of substituted pyridines, the following are the energies of these two charge transfer states.

$$\left.\begin{aligned} E_5^{(2)} &= I^X - A - Q_5{}^{(5)}; \quad E_6^{(2)} = I^X - A - Q_6{}^{(2)} \\ E_5^{(3)} &= I^X - A - Q_5{}^{(3)}; \quad E_6^{(3)} = I^X - A - Q_6{}^{(3)} \end{aligned}\right\} \quad (5)$$

If the lowering of the ground state energy is neglected, the substitution of β_X^2 from Eq. (2) into Eqs. (3) and (4) yields, for the values of the shift of the lowest excited energy level for the two kinds of substituted pyridines, the following expressions:

$$\Delta E_2^X = E_1 - E_1^{X(2)} = 0.017I_\pi^X + \left[\frac{E_{C.T,b} - E_a}{E_5^{(2)} - E_1 + 0.132I_\pi^X} + \frac{0.066(E_{C.T,b} - E_a)}{E_6^{(2)} - E_1 + 0.27I_\pi^X}\right]\Delta E_a^X \quad (6)$$

and

$$\Delta E_3^X = E_1 - E_1^{X(3)} = 0.083I_\pi^X + \left[\frac{1.026(E_{C.T,b} - E_a)}{E_5^{(3)} - E_1 + 0.157I_\pi^X} + \frac{0.252(E_{C.T,b} - E_a)}{E_6^{(3)} - E_1 + 0.33I_\pi^X}\right]\Delta E_a^X \quad (7)$$

Assuming that the molecules of monosubstituted benzene and the two types of substituted pyridine as regular hexagons with bond distances 1.39 Å, the values for the bond lengths between the substituent and the substituted carbon atom as those given by Kimura and Nagakura[2] and a point charge approximation for the evaluation of the electrostatic energies Q, it is found $Q_5{}^{(2)} \approx Q_5{}^{(3)}$, $Q_6{}^{(2)} \approx Q_6{}^{(3)}$, and $Q_6 > Q_5 > Q_2$, Q_6 being greater than Q_5 by about 10% and Q_5 greater than Q_2 by the same amount.

If we assume that for a given substituent $I^X - A$ has the same value for the monosubstituted benzene and the corresponding 2- and 3-substituted pyridines and observing that $E_a \approx E_1$ the Eqs. (6) and (7) may be further simplified. The quantities $(E_{C.T,b} - E_a)/(E_5^{(2)} - E_1 + 0.132I_\pi^X)$ etc. will be somewhat larger than unity while though the terms like $(E_{C.T,b} - E_a)/(E_6^{(3)} - E_1 + 0.271_\pi^X)$ have values appreciably greater than unity their effects will be reduced because in each case they are multiplied by small quantities. Hence the coefficients of ΔE_a^X in Eqs. (6) and (7) will be a little larger than 1.066 and 1.278, respectively. These equations may, therefore, be written as

$$\Delta E_2^X = 0.017I_\pi^X + 1.1\Delta E_a^X \quad (8)$$

and

$$\Delta E_3^X = 0.083I_\pi^X + 1.3\Delta E_a^X \quad (9)$$

Further, if we assume that I_π^X for the different substituents may be represented by an average value I_π for both types of pyridine molecules considered, then it follows from Eqs. (8) and (9) that the plots of ΔE_2^X and ΔE_3^X *vs.* ΔE_a^X are straight lines with slopes 1.1 for the 2-pyridines and 1.3 for the 3-pyridines and the intercepts have values $0.017\,I_\pi$ and $0.083\,I_\pi$, respectively.

Comparison with Experiment

In order to find out how far the conclusions drawn from the theoretical considerations agree with the experimental data obtained by various workers[8–22] the shifts in the positions of O-O band (expressed in units of electron volt) for the 2- and 3-substituted pyridines with respect to that of pyridine are plotted against

TABLE 2. POSITION OF O–O BAND (cm^{-1}) IN THE NEAR ULTRAVIOLET ABSORPTION SPECTRA OF BENZENE, MONOSUBSTITUTED BENZENES, PYRIDINE, 2-SUBSTITUTED AND 3-SUBSTITUTED PYRIDINES

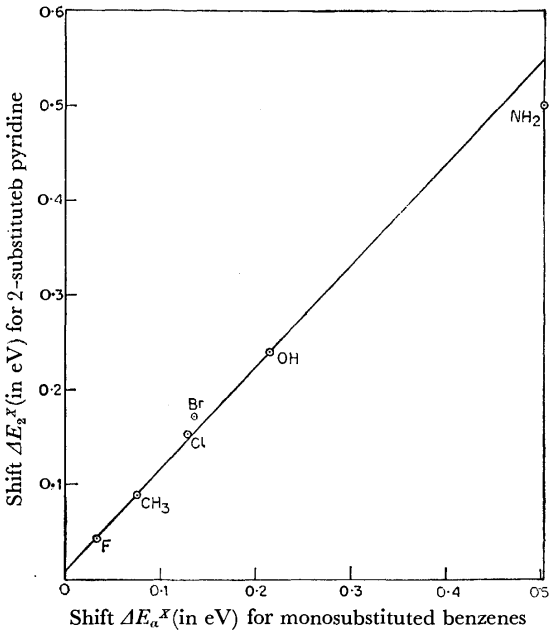

Fig. 1.

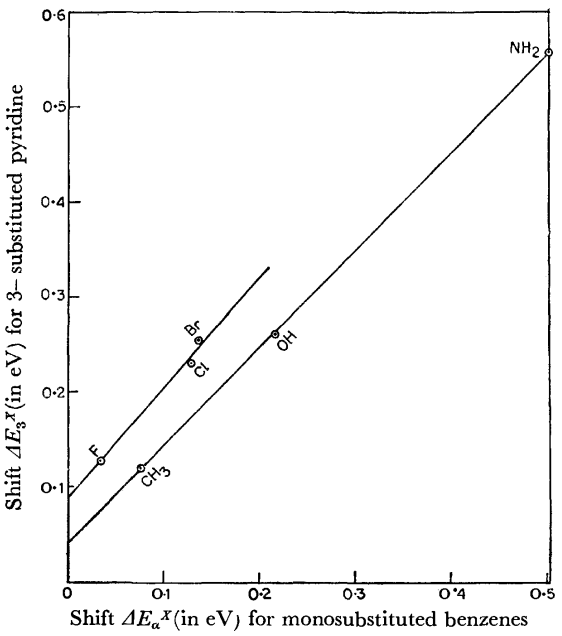

Fig. 2.

those of the corresponding monosubstituted benzene with respect to benzene in Figs. 1 and 2, respectively. For this purpose the positions of the O–O band in the near ultraviolet absorption spectra of monosubstituted benzenes and some 2- and 3-substituted pyridines with similar substitutions, taken from available data, are shown in Table 2.

It is seen from Figs. 1 and 2 that the plots of ΔE_2^X *vs.* ΔE_α^X and ΔE_3^X *vs.* ΔE_α^X give straingt lines. In the case of 2-substituted pyridines all the points corresponding to different substituents fall on the same line (Fig. 1) with a slope of 1.07 and an intercept of 0.01 eV. This value of the slope compares favourably with the expected value 1.1 of Eq. (8). The average value of I_π obtained from the same equation is about 0.6 eV. For the 3-substituted pyridines the points corresponding to F, Cl, and Br as substituents and those with CH_3, OH, and NH_2 as substituents fall on two different straight lines (Fig. 2). The former has an inclination of 1.16 and an intercept of 0.09 eV while for the latter these values are 1.02 and 0.04 eV, respectively. The value of the slope for either of the straight lines is smaller than 1.3 expected from Eq. (9) while the average values of I_π for the two groups of compounds are respectively about 1.0 and 0.5 eV. The value 0.6 eV of I_π obtained from 2-substituted pyridine compares favourably with the values 1.0 eV and 0.5 eV for this quantity in the case of 3-substituted pyridines. The values of I_π^X given by Godfrey and Murrell[7] for these substituents vary from 0.54 eV for the methyl group to 1.74 eV for the amino group. The values obtained in the present case lie within these limits.

Far Infrared Spectra and the Calculation of Lattice Vibrations of Benzoic Acid[1]

Shunsuke MESHITSUKA, Hiroaki TAKAHASHI, Keniti HIGASI, and Bernhard SCHRADER*

Department of Chemistry, School of Science and Engineering, Waseda University, Tokyo

**Institut für Spektrochemie und angewandte Spektroskopie, Dortmund, Germany*

(Received December 27, 1971)

Polarized far infrared spectra from 400 to 30 cm^{-1} of benzoic acid single crystals have been measured. Three bands polarized parallel to the C_2^5 screw axis *b* were observed at 104, 86, and 62 cm^{-1}, and three bands polarized parallel to the *a*-axis at 106, 76, and 65 cm^{-1}. The lattice vibrations of benzoic acid have been calculated assuming the rigidity of the molecule during the lattice vibrations and applying a simple force field. The bands at 104, 86, and 62 cm^{-1} were assigned to the rotational vibrations of A_u symmetry species: the O–H···O stretching, the ring torsional and the O–H···O out-of-plane bending modes, respectively, and the bands at 106, 76, and 65 cm^{-1} to those of B_u symmetry species. The force constant K(O···H) related to the hydrogen bonds in the cyclic dimer was calculated to be 0.35 mdyn/Å.

The far infrared spectra of carboxylic acid dimers in the vapor phase and in solutions have been studied by several investigators.[2–9] It has been well established in both formic and acetic acids[3,5,8] that the three infrared active vibrations associated with the hydrogen bonds in the cyclic dimer are, from the higher frequencies, the O···H stretching+O–H···O in-plane bending, the O–H···O out-of-plane bending and the ring torsional modes; they are approximately rotational vibrations of the monomers.

Only a few works have been carried out on the low frequency Raman spectra of dimeric carboxylic acids.[10,11] The three Raman active hydrogen-bond vibrations would be the O···H stretching, the O–H···O in-plane bending and the O–H···O out-of-plane bending modes; they can be regarded as translational vibrations of the monomers.

In crystalline solids, provided that the Bravais unit cell contains more than two dimers, translational vibrations of the dimers are also expected to appear in the far infrared spectra and rotational vibrations of the dimers in the low frequency Raman spectra. In such a crystalline state, the low frequency vibrational modes would become complicated due to the interactions between the rotational and translational motions.

Thus it is interesting to study the low frequency vibrational spectra of carboxylic acid dimers in crystalline solids. Simple carboxylic acids such as formic and acetic acids do not exist as hydrogen-bonded dimers in the crystal; they are chain polymers. Benzoic acid is a suitable sample for this purpose because its Bravais unit cell contains two dimers.

The low frequency vibrational spectra of benzoic acid single crystals have been studied by Stanevich,[6] Statz and Lippert,[9] and Maier and Schifferdecker.[12] Recently Wyncke *et al.*[13] measured polarized far infrared spectra of single crystals and proposed an assignment for the infrared active lattice vibrations. Their assignment is based on the assumption that the frequencies of the rotational vibrations of the monomers are in the inverse order of the corresponding moment of inertia. The assumption, however, is not appropriate in the case of benzoic acid because of the strong hydrogen bonds in the dimer.

More recently, Colombo and Furic[14] observed polarized Raman spectra and gave an assignment of the Raman active lattice vibrations. They separated translational vibrations of the monomers from rotational vibrations of the dimers by the difference in the temperature dependence of these two groups of vibrations. The separation, however, does not seem convincing.[15]

The purpose of this paper is to give an assignment for the lattice vibrations of benzoic acid based on the normal coordinate calculations as well as the polarized far infrared spectra of the single crystals.

Experimental

Single crystals of benzoic acid were grown from a saturated ethanol solution by slow evaporation at 30°C. The evaporation rate was adjusted so that crystals of centimeter dimensions were formed over a period of several weeks. The crystals were obtained as fine needles with *b* as needle axis, sometimes as small rectangular plates developed on (001).

X-Ray measurements were carried out with CuK_α radiation by using oscillation and Weissenberg photographic methods. Oscillation photographs indicated that the C_2^5

screw axis (b-axis) was always along the longer edge of the rectangular crystal plates. The cell dimensions obtained are: $a \cdot sin\beta = 5.44$, $b = 5.14$, and $c \cdot sin\beta = 21.8$ Å, which are in good agreement with the values reported by Sim *et al.*[16]

The infrared spectra were recorded with a Hitachi FIS-3 far infrared spectrometer. For the infrared polarization measurements a polarizer made up of a stack of polyethylene sheets was used and the sample, about 20 mm long, 10 mm wide and 0.2 mm thick, prepared by cleaving a suitable crystal plate, was attached to the slit 45° tilted with respect to the vertical in order to minimize the polarization effects in the spectrometer. The spectrum of the powder was recorded in a Nujol mull between silicon plates.

Calculation of Lattice Vibrations

The crystal structure of benzoic acid is monoclinic $P2_1/c-C_{2h}^5$, with two cyclic dimers in a Bravais unit cell (Fig. 1). The cell dimensions are: $a=5.52\pm0.02$, $b=5.14\pm0.02$, $c=21.90\pm0.05$ Å and $\beta=97°$.[16] The O···O distance of the two hydrogen bonds in the dimer is 2.65 Å. The bond length O–H and C–H were assumed to be 1.03 and 1.08 Å, respectively, in this frequency calculation.

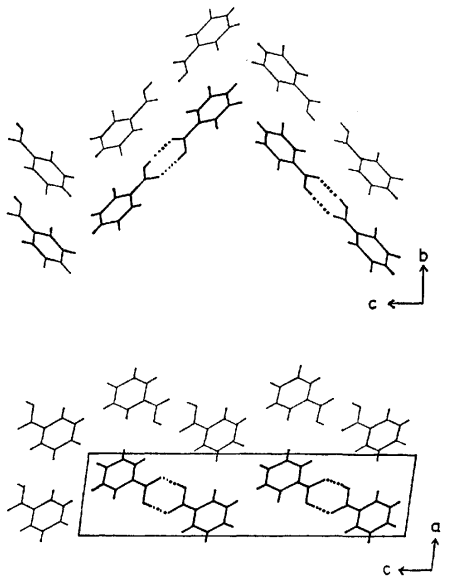

Fig. 1. Crystal structure of benzoic acid.

The calculation of the lattice vibrations has been carried out using the method developed by Shimanouchi *et al.*[17] and assuming that the molecule is not distorted during the vibrations. The intermolecular potential can be expressed as the sum of the potential associated with the hydrogen bonds in the dimer V_h, and the potential representing the interactions between the atoms of different dimers V_t. The interactions between atoms more than 3 Å apart were neglected,

$$V = V_h + V_t$$

$$V_h = (1/2)\sum_i K(\text{O}\cdots\text{H})\Delta q_i^2 + (1/2)\sum_i H_{//}(\text{O–H}\cdots\text{O}) r_{\text{OH}} q_{\text{OH}} \Delta\alpha_i^2 + (1/2)\sum_i H_{\perp}(\text{O–H}\cdots\text{O}) r_{\text{OH}} q_{\text{OH}} \Delta\beta_i^2 + (1/2)\sum_i H(\text{C=O}\cdots\text{H}) r_{\text{CO}} q_{\text{OH}} \Delta\gamma_i^2 + (1/2)\sum_i Y(\text{C=O})\Delta\tau_i^2 + \sum_{i\neq j} p(\text{O}\cdots\text{H, O}\cdots\text{H})\Delta q_i \Delta q_j$$

$$V_t = (1/2)\sum_i F_t(\text{O}\cdots\text{H})\Delta q_{1i}^2 + (1/2)\sum_i F_t(\text{C}\cdots\text{H})\Delta q_{2i}^2 + (1/2)\sum_i F_t(\text{H}\cdots\text{H})\Delta q_{3i}^2$$

where $Y(\text{C=O})$ is the force constant of the torsion around the C=O bond and $p(\text{O}\cdots\text{H, O}\cdots\text{H})$ is the force constant representing the resonance interaction between the two O···H bonds in the dimer.

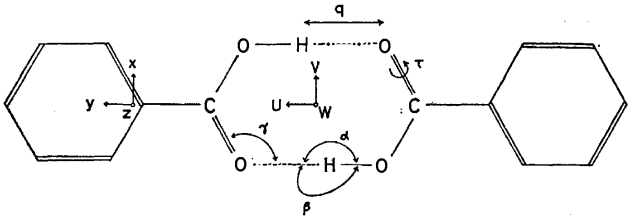

Fig. 2. Coordinates related to the hydrogen bonds in the cyclic dimer.

Results and Discussion

1. Infrared Active Lattice Vibrations. The far infrared spectrum from 400 to 30 cm^{-1} of benzoic acid powder suspended in Nujol is given in Fig. 3. The bands at 106, 78, and 63 cm^{-1} are reduced to weak and broad bands in the spectrum of cyclohexane solution, as shown in Fig. 4. These bands are therefore considered to be due to lattice vibrations. Although

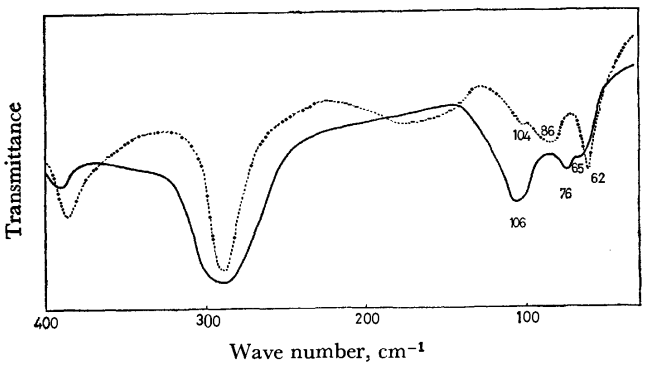

Fig. 5. Polarized far-infrared spectra of benzoic acid single crystals.
·····Electric vector parallel to the *b*-axis
——Electric vector perpendicular to the *b*-axis (parallel to the *a*-axis)

Wyncke *et al.*[13] reported two weak bands at 36 and 29 cm^{-1}, we could find no bands between 60 to 30 cm^{-1}.

In the polarized spectrum of the single crystal shown in Fig. 5, the lattice vibrations occur at 104, 86, and 62 cm^{-1}, when the electric vector of the incident light is parallel to the *b*-axis (C_2^s screw axis) and at 106, 76, and 65 cm^{-1}, when the electric vector is parallel to the *a*-axis. Thus the bands at 104, 86, and 62 cm^{-1} are assigned to the lattice modes of symmetry species A_u, while the bands at 106, 76, and 65 cm^{-1} to those of B_u species. The polarization measurement, however, does not agree with the observation of Wyncke *et al*;[13] their *a* and *b* axes correspond to our *b* and *a* axes, respectively.

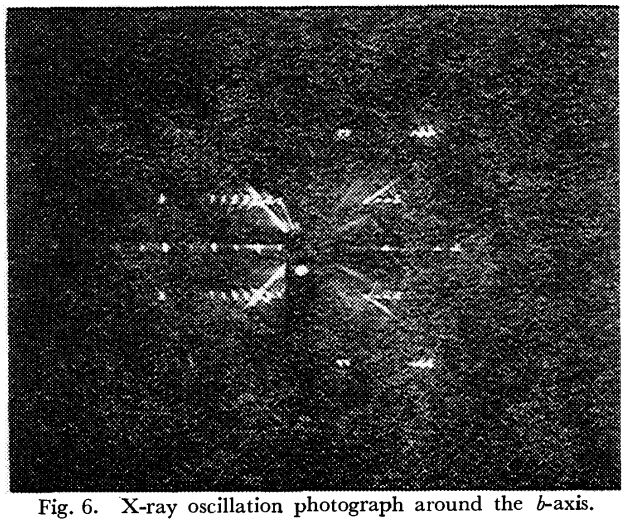

Fig. 6. X-ray oscillation photograph around the *b*-axis.

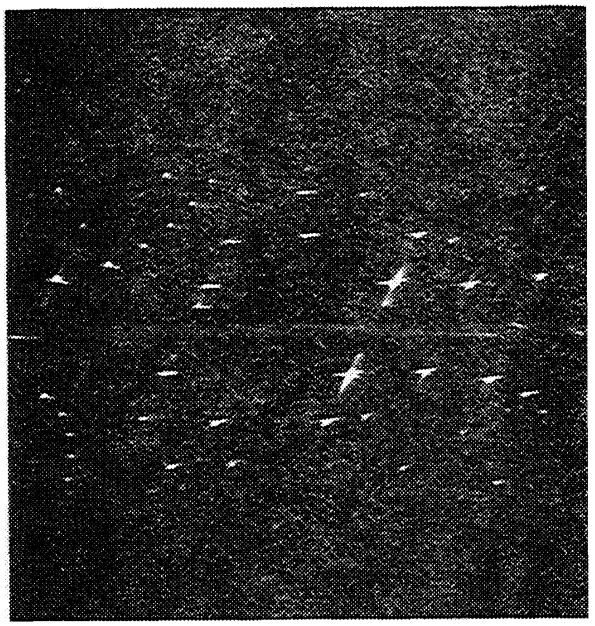

Fig. 7. Weissenberg photograph around the *b*-axis.

The X-ray oscillation photograph around our *b*-axis which is parallel to the longer edge of the rectangular crystal is given in Fig. 6. The photograph clearly shows that the screw axis C_2^s lies along our *b*-axis. Moreover, the cell dimensions, $a \cdot sin\beta = 5.44$, $b = 5.14$, and $c \cdot sin\beta = 21.8$ Å, calculated from this photograph and the Weissenberg photograph (Fig. 7) are in substantial agreement with the results $a = 5.52$, $b = 5.14$, $c = 21.90$ Å, and $\beta = 97°$ obtained by Sim *et al.*[16] This suggests that Wyncke's *a* and *b* axes should be interchanged.

Infrared active lattice vibrations of benzoic acid are approximately described as rotational vibrations of the monomers R_x, R_y, and R_z and translational vibrations of the dimers T_U, T_V, and T_W (Fig. 2). The former can be regarded as the O–H···O out-of-plane bending, the O–H···O torsional and the O···H stretching+O–H···O in-plane bending vibrations, respectively. The frequencies of the former depend mainly on the force constants related to the hydrogen bonds in the cyclic dimer, while the frequencies of the latter are determined mainly by interaction force constants between atoms of different dimers. Accordingly, the

frequencies of rotational vibrations of the monomers are anticipated to be higher than those of translational vibrations of the dimers, because hydrogen bonding forces are usually stronger than non-bonding interaction forces.

The principal moment of inertia of the monomer are in the order $I_z>I_x>I_y$. If we assume that the force field around each monomer has spherical symmetry, *viz.*, the effective force constants for R_x, R_y, and R_z are approximately the same, the frequencies of the rotational vibrations of the monomer would be in the order $\nu(R_y)>\nu(R_x)>\nu(R_z)$. Actually the assumption is not acceptable because two monomers are combined together by strong hydrogen bonds to form a cyclic dimer in the crystal, and the largest hydrogen-bond force constant K(O···H) is almost solely effective for R_z. This suggests that the frequency of R_z is the highest in spite of the biggest moment of inertia I_z. It is not easy to tell, *a priori*, which frequency is higher, $\nu(R_x)$ or $\nu(R_y)$. The effective force constant for R_x might be slightly larger than that for R_y, whereas the moment of inertia for R_y is smaller than that for R_x.

2. Raman Active Lattice Vibrations. Raman active lattice vibrations of benzoic acid can be classified approximately into two groups: translational vibrations of the monomers T_x, T_y, and T_z, and rotational vibrations of the dimers R_U, R_V, and R_W. The former are in other expressions, the O–H···O in-plane bending, O···H stretching and the O–H···O out-of-plane bending vibrations, respectively. For the same reason as that for infrared active lattice vibrations, the frequencies of translational vibrations of the monomers are supposed to be higher than those of rotational vibrations of the dimers, and the highest frequency of these vibrations would be the O···H stretch $\nu(T_y)$.

The moment of inertia of the dimer is in the order

$I_W > I_V > I_U$. The effective force constants for R R_V, and R_W would not differ much from each other, because it is highly improbable that some strong interaction forces are operative along particular directions between the dimers. Thus, the rotational vibrations of the dimers would be in the order $\nu(R_U) > \nu(R_V) > \nu(R_W)$.

3. Assignment of Lattice Modes. The observed and calculated frequencies along with their approximate lattice modes are listed in Table 1. The Raman frequencies (A_g and B_g species) are those measured by Colombo *et al.*[14] The calculated frequencies are in fairly good agreement with the observed. In the frequency calculation, it was assumed that the molecule of benzoic acid was not distorted during lattice vibrations; in other words, the coupling between intramolecular vibrations and lattice vibrations was ignored. This might be a good approximation when the frequencies of all the intra-molecular vibrations are high and are far apart from the frequencies of lattice vibrations. In the case of benzoic acid, the frequencies of the C–C torsion and the C–O torsion, which are intramolecular vibrations, are very low, presumably around 200 cm^{-1}, and the interactions between these two intramolecular vibrations and the lattice vibrations can not be neglected. This could be one reason why we see minor discrepancies between calculated and observed frequencies.

The lattice modes assigned to the observed and calculated frequencies are more or less approximate ones. The actual lattice mode should be expressed as a linear combination of these approximate modes. However, only the mode of largest weight or contribution is given in the table. Hydrogen-bond vibrations of several carboxylic acids are summerized in Table 2. We see that in formic and acetic acids $\nu(R_x)$ is higher than $\nu(R_y)$, while in benzoic acid $\nu(R_x)$ is lower than $\nu(R_y)$. This is probably attributed to the fact that in formic and acetic acids the difference between I_x and I_y is smaller than that in benzoic acid, and the effect of the difference in the force constants becomes important. Besides this, the frequencies of formic and acetic acids given in the table are those of isolated dimers in the vapor phase and are free from interaction forces between the dimers, while in benzoic acid crystals the effects of these interaction forces can no longer be neglected.

4. Force Constants. The intermolecular force constants obtained from the calculation of the lattice vibrations are shown in Table 3. The non-bonding interaction force constants F(H···H) and F(C···H) were fixed to the values reported for benzene and naphthalene.[20] Other force constants were determined by a least square method to get the best fit between observed and calculated frequencies.

A resonance interaction force constant p(O···H, O···H) between the two O···H bonds in the cyclic dimer was introduced in this calculation. The same type of force constant has been used in the calculation of 1-methylthymine ($p = -0.09$ mdyn/Å).[21] Without this force constant the Raman active O···H stretching (T_y) frequencies 122 and 126 cm^{-1}, and the infrared active O···H stretching+O–H···O in-plane bending (R_x) frequencies 104 and 106 cm^{-1} cannot be explained simultaneously. This resonance force constant is not used in the normal-coordinate calculation of formic and acetic acid dimers (Table 4). This is probably because the Raman active frequencies of these acids are not exactly known (Table 2), and the hydrogen-bond force constants were determined using infrared frequencies alone. The negative value of this force constant is consistent with the physical meaning of "resonance interaction", *i.e.* the potential energy of the configuration in which the two O···H distances in the cyclic dimer are lengthened or shortened simultaneously is lower than that of the configuration in which one O···H is lengthened while at the same time the other is shortened.

We thank Dr. Midori Goto of the Government Chemical Industrial Research Institute Tokyo for the measurement of X-ray photographs.

The Abnormal Absorption Intensity of the C-H Stretching Vibration Band in Chloroform Vapor. II.

Tomoo MIYAZAKI and Hiroshi YAMAMOTO

Department of Applied Chemistry, Faculty of Science and Engineering, Waseda University, Nishi-Ohkubo, Shinjuku-ku, Tokyo

(Received January 18, 1972)

By CNDO calculations considering the 3*d* orbitals of the chlorine atom, the infrared absorption intensity of the C–H stretching vibration band in chloroform vapor has been discussed in comparison with those of methyl chloride and methylene chloride. The absolute intensities of the fundamental and the first-overtone bands of these compounds have been calculated in view of the mechanical and the electrical anharmoniciteis of the vibrating bond. From the results of these calculations, it was revealed that the contribution of the electrical properties of the vibrating bond to the abnormal absorption intensity of the C–H stretching vibration band in chloroform vapor is really greater than that of the mechanical anharmonicity.

In a previous paper,[1] the abnormal infrared absorption intensity of the C–H stretching vibration band in chloroform vapor was discussed in terms of the electrical properties of the vibrating bond. By CNDO calculations involving the 3*d* orbitals of the chlorine atom,[2] the absolute intensities of the fundamental and the first-overtone bands of the C–H stretching vibrations in CH_3Cl, CH_2Cl_2, and $CHCl_3$ were calculated from the values of the first and the second derivatives of the dipole moment with respect to the normal coordinates. The calculated relative intensities of the fundamental bands of these compounds were in satisfactory agreement with the observed values. The calculated absolute intensity of the first-overtone band of the C–H stretching vibration in chloroform was stronger than that of the fundamental band, and the $A^*_{1\leftarrow0}/A^*_{2\leftarrow0}$ ratio was 0.558, where $A^*_{1\leftarrow0}$ and $A^*_{2\leftarrow0}$ are the absolute intensities of the fundamental and the first-overtone bands in a harmonic oscillator approximation respectively. From the results of the calculations, it was learned that the electrical properties of the vibrating bond are the effective factors in bringing about the abnormal absorption intensity of the C–H stretching vibration band in chloroform vapor. However, the calculated absolute intensity of the first-overtone band in chloroform was smaller than the observed one. (The $A^*_{1\leftarrow0}/A^*_{2\leftarrow0}$ ratio calculated from the observed values has been reported to be 0.16—0.2.[3,4]) Therefore, in this paper, the fundamental and the first-overtone band intensities of the C–H stretching vibrations of CH_3Cl, CH_2Cl_2, and $CHCl_3$ have been calculated in view of the mechanical anharmonicity of the vibrating bond.

Methods of Calculation

The mechanical anharmonicity of the molecular vibration can be discussed on the basis of an analysis of the potential energy expanded by the normal coordinate. The treatment of the subject in this work is simplified because the normal modes considered are approximately equal to the pure C–H symmetric stretching modes, as has been described in the previous paper.[1]

The CNDO method, involving the 3*d* orbitals of the chlorine atom, used in this work was described in detail in the previous paper of this series.[1] From the results of the CNDO calculations for the molecules distorted in the manner dictated by the C–H symmetric coordinates (S_{CH}), the potential energy function for the C–H vibration was obtained by fitting the total energy of the molecule to a quartic function with respect to the S_{CH} coordinate. The potential energy functions thus obtained are as follows:

$$V_{CH}(CH_3Cl) = 62.1720 \times 10^4 S_{CH}^2 - 52.5935 \times 10^{12} S_{CH}^3 + 27.2339 \times 10^{20} S_{CH}^4, \quad (1)$$

$$V_{CH}(CH_2Cl_2) = 60.8290 \times 10^4 S_{CH}^2 - 61.2499 \times 10^{12} S_{CH}^3 - 1.59167 \times 10^{20} S_{CH}^4, \quad (2)$$

$$V_{CH}(CHCl_3) = 58.9394 \times 10^4 S_{CH}^2 - 83.4185 \times 10^{12} S_{CH}^3 + 31.8084 \times 10^{20} S_{CH}^4, \quad (3)$$

where the S'_{CH}s in Eqs. (1), (2), and (3) are equal to $(1/\sqrt{3})$ $(\Delta r'_{CH}+\Delta r''_{CH}+\Delta r'''_{CH})$, $(1/\sqrt{2})$ $(\Delta r'_{CH}+\Delta r''_{CH})$, and Δr_{CH} respectively. The units of the V_{CH} and the S_{CH} are [erg] and [cm] respectively. For our present object, the potential energy as a function of the normal coordinate (Q_k) alone will be sufficient; here the Q_k involves the C–H symmetric stretching vibration as the main constituent. Since there is a singularity about the vibration mode considered in this work, as has been described above, the energy functions can be obtained from Eqs. (1), (2), and (3) as a function of the normal coordinate, Q_k:

$$V_k(CH_3Cl) = (1/2) \times 7.60852 \times 10^{29} Q_k^2 - 2.51736 \times 10^{49} Q_k^3 + 1.01967 \times 10^{69} Q_k^4, \quad (4)$$

$$V_k(CH_2Cl_2) = (1/2) \times 7.65022 \times 10^{29} Q_k^2 - 3.05426 \times 10^{49} Q_k^3 - 0.062939 \times 10^{69} Q_k^4, \quad (5)$$

$$V_k(CHCl_3) = (1/2) \times 7.63400 \times 10^{29} Q_k^2 - 4.34747 \times 10^{49} Q_k^3 + 1.33405 \times 10^{69} Q_k^4, \quad (6)$$

where the units of the V_k and the Q_k are [erg] and [erg$^{1/2}$sec] respectively. In the above equations, the Q_ks differ from each other, but they are not distin-

guished in expression in order to avoid complexity. In rewriting the above, the Ls(CH)'s were taken to be $1.00797\times\sqrt{N_A}$, $1.02183\times\sqrt{N_A}$, and $1.03698\times\sqrt{N_A}$ in [$g^{-1/2}$] units for CH_3Cl, CH_2Cl_2, and $CHCl_3$ respectively, where the Ls(CH)'s are the elements of the $\boldsymbol{L}$ matrix which relate the symmetry coordinate to the normal coordinate, and where the N_A is Avogadro's number. Unfortunately, however, the calculated potential energy for the stretching vibration by the CNDO method is not appropriate since the energy increase with the displacement from the equilibrium distance is too much larger than that generally found. In other words, the force constant of the stretching vibration calculated by the CNDO method is too large (2—3 times). Therefore, in order to determine the appropriate potential energy of the vibration considered, we assumed that each potential energy function of Eqs. (4)—(6) can be rewritten by multiplying the coefficients by the constant (α) determined in comparison with the observed frequency of the actual vibration. To determine the constant (α), trial calculations were performed until the difference between energy levels, which were calculated by the Rayleigh-Ritz method, as will be indicated below, coincided with the observed frequency of the fundamental band. In these calculations, the wave functions, ψ_v's, involving the mechanical anharmonicity were described as linear combinations of harmonic oscillator wave functions, φ_i^0's:

$$\psi_v = \sum_{i=0}^{n} c_{vi}\varphi_i^0. \tag{7}$$

The variational treatment of the coefficient, c_{vi}, leads to this equation:

$$\sum_j c_{vj}(H_{ij}-\varepsilon_v\delta_{ij}) = 0 \qquad i = 0, 1, 2, \cdots, n, \tag{8}$$

where:

$$H_{ij} = T_{ij} + V_{ij},$$
$$T_{ij} = \left\langle \varphi_i^0 \middle| -\frac{\boldsymbol{h}^2}{8\pi^2}\frac{\partial^2}{\partial Q_k^2} \middle| \varphi_j^0 \right\rangle, \tag{9}$$
$$V_{ij} = \left\langle \varphi_i^0 \middle| \frac{1}{2}\lambda_k Q_k^2 + g_k Q_k^3 + h_k Q_k^4 \middle| \varphi_j^0 \right\rangle.$$

In Eq. (8), ε_v is the energy for the wave function, ψ_v. H_{ij} is the matrix element of the Hamiltonian, including the kinetic (T_{ij}) and the potential (V_{ij}) energies for the vibrating system. The energies (ε_v's) are the roots of the secular equation. Practically, the n in Eq. (7) was taken to be 11, since the further addition of φ_i^0 no longer changed the eigenvalues (ε_0, ε_1, ε_2, and ε_3) within an order of six significant figures. It should also be noted that the constant (α) is set appropriately at the first step of this calculation. The calculated energies and wave functions are listed in Table 2, in which the potential energy functions are also indicated.

Dipole Moments and Their Derivatives. The formulas used to calculate the dipole moments, in view of the atomic polarization, were given in the previous paper.[1] The dipole moments were calculated for the molecules distorted in the manner dictated by the symmetry coordinate including the C–H symmetric stretching modes. The numerical values required to calculate the absorption intensity were obtained by fitting the calculated dipole moments to a quartic function with respect to the C–H distance, and by taking the first and the second derivatives at the C–H equilibrium distance. They are listed in Table 1, in which the dipole-moment derivatives at the observed and the calculated equilibrium distances are also indicated. Although there are two distinct evaluations of the numerical values required, this problem will be dealt with in the following discussion.

Absolute Absorption Intensities. The absolute absorption intensities of the fundamental and the first-overtone bands, in view of the mechanical and the electrical anharmonicities, can be calculated by the following equation:

$$A_{v+n\leftarrow v} = \frac{8\pi^3}{3c\boldsymbol{h}}\left(\frac{N_v}{N_t}-\frac{N_{v+n}}{N_t}\right)\nu_{v+n,v}\sum_{i=x,y,z}|(\mu_i)_v^{v+n}|^2, \tag{10}$$

$$N_v = N_0\exp\left(-(\varepsilon_v-\varepsilon_0)\right)/\boldsymbol{k}T, \tag{11}$$

$$N_t = N_0\sum_{v=0}^{\infty}\exp\left(-(\varepsilon_v-\varepsilon_0)\right)/\boldsymbol{k}T, \tag{12}$$

$$(\mu_i)_v^{v+n} = \left\langle \psi_v \middle| \mu_i^0 + \left(\frac{\partial\mu_i}{\partial Q_k}\right)_0 Q_k + \frac{1}{2}\left(\frac{\partial^2\mu_i}{\partial Q_k^2}\right)_0 Q_k^2 \middle| \psi_{v+n} \right\rangle, \tag{13}$$

where N_0 and N_v are the numbers of the molecules which are involved at the energy levels of ε_0 and ε_v respectively, and where N_t is the total number of molecules. Also, c is the velocity of light, $\boldsymbol{h}$ is Planck's constant, and $\boldsymbol{k}$ is Boltzmann's constant. In this calculation, the T was taken to be 300°K. μ_i^0 is the i-component of the dipole moment, and $\nu_{v+n,v}$ is the

transition energy in [sec^{-1}] units from the energy level (v) to the energy level ($v+n$). The summation in Eq. (12) was terminated under the condition that a further increase in the i no longer changed the absolute intensity (A), as calculated from Eq. (10), within an order of six significant figures. In the previous paper, since the vibration was approximated to be harmonic, the absolute intensity of the fundamental band, $A_{1\leftarrow 0}$*, was calculated by the summation of $A_{1\leftarrow 0}$, $A_{2\leftarrow 1}$, $A_{3\leftarrow 2}$, *etc.* In this calculation, however, we cannot treat the problem in the same way in view of the mechanical anharmonicity. Fortunately, the mechod of approach to this problem was simplified, since the values of $A_{2\leftarrow 1}$ and $A_{3\leftarrow 1}$ were negligibly small in comparison with the values of $A_{1\leftarrow 0}$ and $A_{2\leftarrow 0}$ respectively.

Results and Discussion

In the treatment of this work, there are some problems which have been left unsolved. In the first place, the equilibrium distance obtained by the total energy minimization disagrees with the observed one. Consequently, the dipole moment calculated in the observed geometry differs from that at the calculated equilibrium distance. It is the same in the dipole-moment derivatives. Generally, the theoretical dipole moment has been calculated by many investigators at the observed equilibrium distance. Also, in the previous paper we discussed the absolute infrared absorption intensity of the C-H stretching vibration band in chloroform by the use of the dipole-moment derivatives at the observed equilibrium distance. In this paper, however, the dipole-moment derivatives were calculated at both the observed and the calculated equilibrium distances. Between these values, a considerable discrepancy was noted in the first derivative of the dipole moment of $CHCl_3$ as is indicated in Table 1. However, as indicated in Table 3, the absolute intensities calculated by these values were not contradictory to each other

in terms of the general tendency of the problem. Second, the force constant calculated by the CNDO method is too large, as has been stated above. That is, the absorption bands calculated from the coefficients of Q^2 in Eqs. (4), (5), and (6) are by far larger than the observed values in frequency; therefore, we rewrote the potential energy by multiplying the coefficients of the function by the constant (α). The values of the constants for CH_3Cl, CH_2Cl_2, and $CHCl_3$ were 0.417, 0.435, and 0.460 respectively. In estimating the constants (α's), we made it a condition that the differences between energy levels of the vibration had to be in agreement with the observed values, where the energy levels were calculated by the variational method de-

scribed in the method of calculation. The potential energies used in this calculation are indicated in Table 2. The frequencies of the fundamental and the first–overtone bands calculated from the energy levels for the C–H vibration of $CHCl_3$ were in good agreement with the observed values: Calcd. 3033 cm^{-1}, Obsd. 3033 cm^{-1} for the fundamental band, and Calcd. 5942 cm^{-1}, Obsd. 5945 cm^{-1} for the first–overtone band. The calculated energy levels and wave functions are listed in Table 2. Therefore, we consider that it is reasonable to calculate the absolute infrared absorption intensity by considering the mechanical anharmonicity for the C–H stretching vibration of $CHCl_3$ by the use of the wave functions associated with these energy levels. The calculated absolute intensities of the fundamental and the first–overtone bands are summarized in Table 3. It is sufficient to consider the values of $A_{1\leftarrow 0}$ and $A_{2\leftarrow 0}$ alone in order to obtain the fundamental and the first–overtone band intensities, because the values of $A_{2\leftarrow 1}$ and $A_{3\leftarrow 1}$ were quite small. The absolute intensity of the fundamental band of the C–H stretching vibration in chloroform is much weaker than those of the symmetric C–H stretching vibration bands of CH_3Cl and CH_2Cl_2. The absolute intensity of the first–overtone band of this vibration in $CHCl_3$ is stronger than those of CH_3Cl and CH_2Cl_2. The $A_{1\leftarrow 0}/A_{2\leftarrow 0}$ ratios for these compounds are indicated in Table 4. The ratio for chloroform is in good agreement with the observed one.

In Table 5, the absolute intensities calculated from the integrals, $\langle\psi_0|\mu_i^0+(\partial\mu_i/\partial Q_k)_0 Q_k|\psi_v\rangle$ and $\langle\psi_0|\mu_i^0+(\partial\mu_i^0/\partial Q_k)_0 Q_k+1/2\,(\partial^2\mu_i/\partial Q_k^2)_0 Q_k^2|\psi_v\rangle$, are compared with the previous results,[1] which are calculated on the basis of the electrical anharmonicity alone. This comparative table clarifies the contribu-

tion of the mechanical anharmonicity of the vibration to the fundamental and the first–overtone band intensities. Furthermore, in Table 6, the numerical values of the terms effective in calculating the absolute absorption intensities are indicated. Thus, it is found that the abnormal absorption intensity of the C–H stretching vibration band in chloroform vapor arises, mainly, from the electrical properties of the vibrating bond.

Conclusion

The absolute infrared absorption intensities of the fundamental and the first–overtone bands of the C–H stretching vibration in chloroform were calculated in view of the mechanical and the electrical anharmonicities of the vibrating bond. These absolute infrared absorption intensities were then compared with those of the C–H symmetric stretching vibration bands in methyl chloride and methylene chloride. The contribution of the mechanical anharmonicity of the vibrating bond to the abnormal absorption intensity of the C–H stretching vibration band in chloroform vapor was compared with that of the electrical anharmonicity. From the results of these calculations, it was confirmed that the abnormal absorption intensity of the C–H stretching vibration band in chloroform vapor arises from the electrical properties of the vibrating bond.

The authors would like to acknowledge the continuing encouragement of Professor K. Higasi. They are also indebted to Professor H. Takahashi for drawing their attention to this problem. Several helpful discussions with Mr. H. Shinida are gratefully acknowledged. In their calculations, they were helped by "the university contribution" of I.B.M. Japan, Ltd.

The n-π^* Absorption and Phosphorescnce of Terephthalaldehyde

Yoshio MURAKAMI, Ryoichi SHIMADA and Yoshiya KANDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received December 17, 1971)

The $n\rightarrow\pi^*$ absorption spectrum of terephthalaldehyde (TPA) has been studied. The $f_{n\rightarrow\pi^*}$-value observed in cyclohexane at room temperature was 1.3×10^{-3}, which was 2.4 times that of benzaldehyde (BA). Vibrational analyses of the absorption and phosphorescence spectra of TPA indicate that the CHO-torsional, CHO-wagging, aldehyde H-wagging, and out-of-plane ring deformation vibrations are important in the vibronic perturbation between (n,π^*) and (π,π^*) states. The spectral structures and the results of CNDO computations of the $f_{n\rightarrow\pi^*}$-values of the $n\rightarrow\pi^*$ absorptions of TPA and BA suggest that the intensity enhancement in the TPA absorption is due to an increase in the vibronic perturbation between (n,π^*) and (π,π^*) states as well as to an increase in the electronically-allowed character in TPA in comparison with that in BA.

Since McMurry's study was published in 1941, a number of investigations have been carried out on the singlet-singlet electronic $n\rightarrow\pi^*$ systems of various aliphatic and aromatic carbonyls. Especially, the $n\rightarrow\pi^*$ absorptions of benzaldehyde and its derivatives have been a major object of interest.

It has been shown that the $n\rightarrow\pi^*$ transition of benzaldehyde is electronically allowed by the formal destruction of the C_{2v} symmetry of its parent molecule, formaldhyde, but a significant amount of the intensity is induced by $\pi\rightarrow\pi^*$ transitions through vibronic interaction between (n,π^*) and (π,π^*) states.

From the nature of the vibronic interactions, the out-of-plane vibrations of the CHO group are known to be important in promoting vibronic intensification.[1-4] Goodman *et al.* found out-of-plane CHO-torsional, CHO-wagging, and ring deformation vibrations in the $n\rightarrow\pi^*$ absorption and concluded that these vibrations are most effective in the intensification.[5-10]

It is interesting to study the $n\rightarrow\pi^*$ absorption of terephthalaldehyde(TPA), which is composed of a benzene ring and two CHO groups. TPA gives an absorption spectrum in the near ultraviolet region quite similar to that of benzaldehyde(BA), but the intensity of the $n\rightarrow\pi^*$ absorption is about 2.4 times greater than that of BA. Two main sources of the intensification of the $n\rightarrow\pi^*$ absorption in TPA may be considered to be (1) an increase in the intrinsic

$n\rightarrow\pi^*$-allowed character and (2) an increase in vibronic interaction between the (n,π^*) and (π,π^*) states. TPA has two nearly degenerate (n,π^*) states; one gives an electronically-allowed transition, and the other, a forbidden $n\rightarrow\pi^*$ transition. The forbidden transition may be also perturbed by $\pi\rightarrow\pi^*$ transitions, and this perturbation may contribute to the intensity-enhancement of the $n\rightarrow\pi^*$ absorption.

The purpose of this paper is to discuss the nature of the $n\rightarrow\pi^*$ absorption of TPA and to show the probable sources for the intensification of the absorption.

The phosphorescence spectrum of TPA will also be studied because the absorption and phosphorescence are both due to the $n\rightarrow\pi^*$ transition and because their spectral structures are very similar to each other. The information obtained from the study of the phosphorescence spectrum of TPA will be useful in understanding the nature of the $n\rightarrow\pi^*$ absorptions.

Experimental

The TPA was prepared through the dehydration reaction of tetrabromo-*p*-xylene, which had been synthesized by means of *p*-xylene and bromine.[11] The crude TPA was purified by repeated recrystallization from 10% hot methanol and by repeated vacuum sublimation. Cyclohexane, methylcyclohexane, ethyl ether, isopentane, and ethanol were purified by ordinary methods.[12]

The near-ultraviolet absorption spectrum of TPA was studied in cyclohexane at room temperature and in EPA at 77°K with a Shimadzu multipurpose recording spectrophotometer MPS-50L and in the vapor with a recording spectrophotometer made of a Bausch & Lomb 500-mm grating monochromator, an RCA 1P28 photomultiplier tube, an RCA amplifier WV-84C, and a recorder. A 500-W xenon short-arc lamp and a tungsten lamp were used as the continuous-light sources. The vapor pressure of TPA in a vapor cell 45 cm in length was controlled by changing the temperature of the cell from 80 to 100°C. The infrared spectrum was recorded with a Hitachi-Perkin-Elmer infrared spectrophotometer, type 225, for the 200—4000 cm^{-1} region in the KBr disk. The Raman spectrum of the TPA crystal was recorded in the 250—4000 cm^{-1} region with a JRS-U1 laser Raman spectrophotometer equipped with a JEOL argon-ion laser, JLG-A4. The depolarization factor of the Raman lines was also measured in ethanol.

The phosphorescence spectra were studied in methylcyclohexane at 4.2 and 77°K with a Hilger E2 spectrograph. The degree of polarization of the phosphorescence was measured in EPA at 77°K by the usual method.[13]

Results and Discussion

Phosphorescence. The near-ultraviolet absorption spectra of TPA and BA[4] observed in EPA at 77°K are shown in Fig. 1. By analogy with the BA absorption, the three main absorption bands of TPA appearing in the 3900—3200, 3200—2800, and 2800—2300 Å

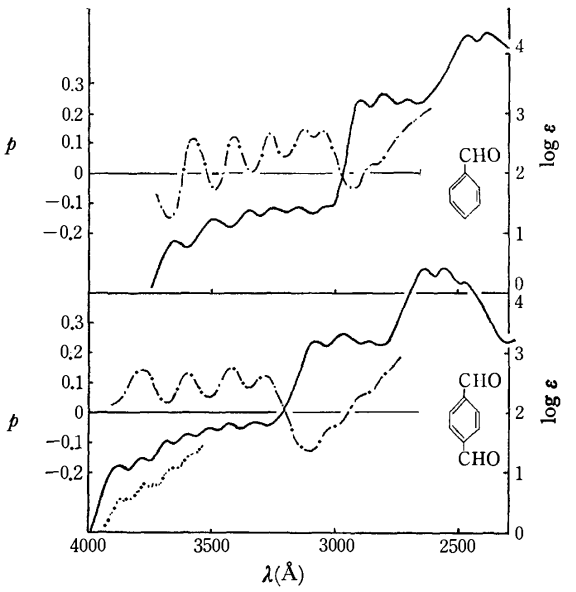

Fig. 1. The absorption spectra in EPA at 77°K (——) and the excitation polarization spectra (-·-·-) obtained relative to the O–O band of the phosphorescence of BA and TPA in EPA at 77°K. The $n\rightarrow\pi^*$ absorption spectrum of TPA observed in the vapor is also shown (------).

regions can be ascribed to $^1U(n,\pi^*)\leftarrow S_0$, $^1L_b(\pi,\pi^*)\leftarrow S_0$, and $^1L_a(\pi,\pi^*)\leftarrow S_0$ transitions respectively.

TPA emits a weak blue-green phosphorescence with a lifetime of 2.01×10^{-2} sec in EPA at 77°K. The phosphorescence is negatively polarized relative to the $^1L_b(\pi,\pi^*)$ excitation and positively polarized relative to the $^1L_a(\pi,\pi^*)$ excitation, as can be seen in Fig. 1. The polarized phosphorescence spectrum is shown in Fig. 2; it has been observed with respect to the excitation into the O–O band at 2700 Å of the $^1L_a(\pi,\pi^*)$ system in EPA at 77°K. The most remarkable feature of the spectrum is a progression of about 1700 cm^{-1}; this frequency can be assigned to the totally symmetric C=O stretching vibration. The shortest wavelength band at 4350 Å was taken as the O–O band. The separation between this band and the longest-wavelength band at 3880 Å in the S′←S absorption observed in EPA at 77°K, which was taken as the O–O band of the $^1U(n,\pi^*)\leftarrow S_0$ absorption system, is about 2600 cm^{-1}. These characteristic features of the phosphorescence are consistent with the lowest triplet state of TPA being a $^3U(n,\pi^*)$ state.

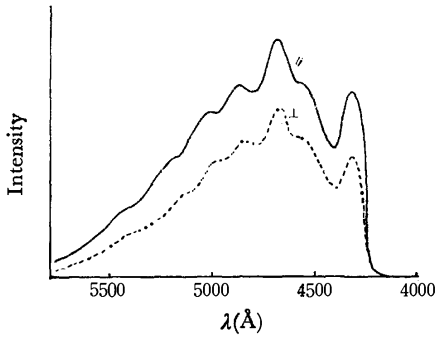

Fig. 2. The polarized phosphorescence spectrum of TPA in EPA at 77°K. Excitation was made into the O–O band of the $^1L_a(\pi,\pi^*)$ band.

13) Y. Murakami, R. Shimada, and Y. Kanda, "Molecular Luminescence," ed. by E. C. Lim, Benjamin, New York (1969), p. 119.

The phosphorescence spectrum was also observed in methylcyclohexane at 4.2°K. A part of the spectral structure is given in Fig. 3, along with the phosphorescence spectrum and the phosphorescence polarization spectra measured with respect to the excitation into the O–O bands of the $^1L_b(\pi,\pi^*)$ and $^1L_a(\pi,\pi^*)$ systems in EPA at 77°K. The phosphorescence observed in methylcyclohexane at 77°K gives almost the same spectrum as that observed in EPA at 77°K. The spectrum observed in methylcyclohexane at 4.2°K shows a well-resolved fine structure. The shortest-wavelength band at 4331.8 Å, which is the strongest in the spectrum, was taken as the O–O band of the system. The observed vibrational frequencies are given in Table 1, along with their intensities. The infrared and Raman spectral data are given in the same table. Clearly polarized Raman bands are indicated by a letter, *p*.

The prominent vibrational frequency of 1715 cm^{-1}, which constitutes the main progression in the phos-

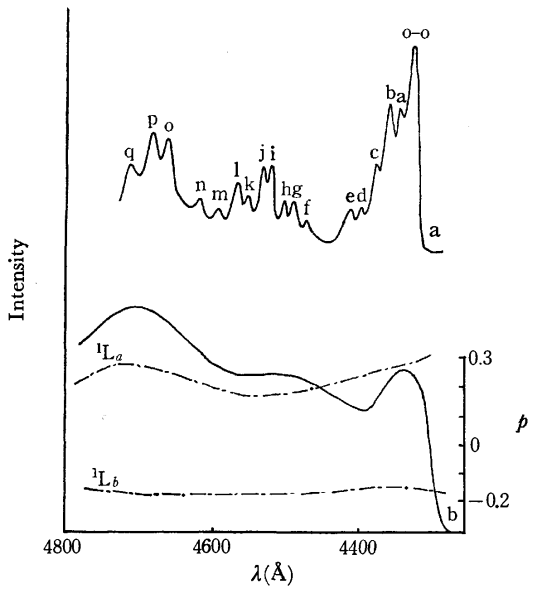

Fig. 3. A part of the phosphorescence spectra (——) of TPA at 4.2°K, a, and in EPA at 77°K, b. The phosphorescence polarization spectra (-·-·-) were obtained with respect to the O–O bands of the ^1L_a and ^1L_b bands.

phorescence spectrum, was assigned to the totally symmetric C=O stretching vibration. Two strong and polarized Raman bands were observed in the C=O stretching frequency region. These are 1695 and 1708 cm^{-1} in frequency and are nearly equal in intensity. This doublet was attributed to a Fermi resonance between a totally symmetric combination and the C=O stretching vibration. The in-plane CHO-bending vibration is expected to appear in the 230—240 cm^{-1} region. A combination of the overtone of this vibration and the ring-CHO stretching vibration, to which a strong and polarized Raman band of 1210 cm^{-1} was assigned, gives a frequency of about 1700 cm^{-1}. The C=O stretching vibration may be mechanically coupled with this combination vibration through the carbonyl carbon atom. Fermi resonances in the C=O stretching vibration are observed in various carbonyl compounds. The fairly strong bands at 150, 235, 970, and 1010 cm^{-1} were assigned to the out-of-plane CHO-torsional, CHO-wagging, ring deformation, ν_5,[14] and aldehyde H-wagging vibrations respectively. The other bands, at 870, 1170, 1415, and 1610 cm^{-1}, were ascribed to the totally symmetric vibrations, ν_1, ν_{9a}, aldehyde C–H bending, and ν_{8a} respectively. The degree of polarization of the phosphorescence, measured relative to the ^1L_b excitation, is negative and is approximately uniform throughout the phosphorescence region, while the degree of polarization measured relative to the ^1L_a excitation gives a minimum around the 1000 cm^{-1} region, although the overall value is positive, as can be seen in Fig. 3. This observation is consistent with the above vibrational assignment. Detailed vibrational analyses of the infrared and Raman spectra will be reported in the near future.

14) The notations of the normal modes of vibrations characteristic of the benzene ring are according to Langseth and Lord.[15]

15) A. Langseth and R. C. Lord, *Kgl. Danske Videnskab. Selskab. Math-Fys. Medd.*, **16**, 1 (1938).

It should be noted that only a few vibrational frequencies were observed in both the infrared and Raman spectra. Such a mutually exclusive relation between infrared and Raman spectra must hold only for the *trans*-form of this molecule. However, the distance between two CHO groups is long enough for there to be a possibility that TPA has both *trans*- and *cis*-conformations. In this connection, the two conformations are calculated to have almost the same ground-state energy, as can be seen in Table 2. Although the CHO plane may deviate from the plane of the benzene ring by repulsion between H atoms of the benzene ring and H and O atoms of the carbonyl group, the deviation may be minimized by the conjugation of the π-electrons. Thus, the TPA molecule may be assumed to have an almost planar structure in the ground state. The *trans*-form of the TPA molecule belongs to the C_{2h} point group and the *cis*-form belongs to the C_{2v} point group. The z axis was taken to be perpendicular to the molecular plane and the y axis to be along the long axis for the C_{2h} point group, while the z axis was taken to be along the C_2 axis and the y axis to be perpendicular to the molecular plane for the C_{2v}.

TPA has two low-lying $^3U(n,\pi^*)$ states, $^3A_u(n,\pi^*)$ and $^3B_g(n,\pi^*)$ states for the *trans*-form, and $^3B_2(n,\pi^*)$ and $^3A_2(n,\pi^*)$ states for the *cis*-form. The electronically-allowed $n\leftarrow\pi^*$ character of the phosphorescence clearly indicates that the lowest triplet state in the *trans*-form is a $^3A_u(n,\pi^*)$ state; thus, the lowest triplet in the *cis*-form is a $^3B_2(n,\pi^*)$ state. CNDO SCF CI calculations, which will be described later, suggest that the lowest $^3A_u(n,\pi^*)$ and $^3B_2(n,\pi^*)$ states are strongly perturbed by the $^1L_a(\pi,\pi^*)$ state, but that the perturbations by the $^1L_b(\pi,\pi^*)$ state are negligibly small, as can be seen in Table 3. In TPA, the $^3L_a(\pi,\pi^*)$ state is expected to be located just above the emitting $^3U_A(n,\pi^*)$ state; thus, the $^3U_A(n,\pi^*)$ state may be perturbed by the $^1U_A(n,\pi^*)$ state through second-order spin-orbit-vibronic coupling. The out-of-plane vibrations observed in the phosphorescence spectrum should be due to the strong vibronic coupling between the $^3L_a(\pi,\pi^*)$ and $^3U_A(n,\pi^*)$ states through b_g or a_2 vibrations. The same phenomenon was observed in the phosphorescence spectrum of BA.[8-10]

$n\rightarrow\pi^*$ Absorption. The near-ultraviolet absorption spectrum and the excitation polarization spectrum measured with respect to the O–O band of the phosphorescence spectrum of TPA in EPA at 77°K are shown in Fig. 1. The corresponding spectra of BA[4] are also given in the same figure. The $n\rightarrow\pi^*$ absorption spectrum of TPA consists of two main progressions. One starts from the longest-wavelength band, located at 3880 Å, with an interval of 1385 cm^{-1}, while the other starts from a band separated by 695 cm^{-1} from the 3880 Å band toward the shorter-wavelength side, with the same interval. The first progression has polarization minima requiring negative polarization, even though the sign of the observed polarization is positive, while the second progression shows positive polarization maxima. No band could be observed on the longer-wavelength side of the 3880 Å band at 77°K, even though a concentrated TPA solution was used. This definitely indicates that the 3880 Å band is a O–O

band of the $n\rightarrow\pi^*$ absorption.

The absorption spectrum of TPA observed in cyclohexane at room temperature is almost the same as that observed in EPA at 77°K. The oscillator strengths of the $n\rightarrow\pi^*$ and $\pi\rightarrow\pi^*$ absorption bands are given in Tables 2 and 3, together with the data for BA. A question immediately arises why the $f_{n\rightarrow\pi^*}$-value of TPA is 2.4 times that of BA. Three possible reasons for the intensification of the $n\rightarrow\pi^*$ absorption in TPA may be considered:

(1) The $n\rightarrow\pi^*$ absorption of TPA has a more electronically allowed character.

(2) The $n\rightarrow\pi^*$ absorption of TPA is more vibronically intensified by strong $\pi\rightarrow\pi^*$ absorptions.

(3) TPA has two CHO groups, and thus two $n\rightarrow\pi^*$ absorptions can be expected to be observed in this region, one electronically allowed and the other forbidden. The observed $n\rightarrow\pi^*$ absorption is the superposition of these two systems.

In order to study the nature of the $n\rightarrow\pi^*$ absorption of TPA in detail, the absorption spectrum was observed in the vapor phase. The $n\rightarrow\pi^*$ vapor absorption, which is given in Fig. 1, shows a rather simple spectral structure, and the individual bands are not sharp enough. The CHO plane may deviate from the plane of the benzene ring somewhat freely in the vapor phase, and this may cause the diffuseness of the spectral structure. The longest-wavelength band at 3857 Å was taken as the O–O band of the $n\rightarrow\pi^*$ absorption. A weak and diffuse band was observed at 3830 Å, separated by 180 cm^{-1} from the O–O band. This band may be ascribed to the superposition of the CHO-torsional and CHO-wagging vibrational bands, whose ground-state vibrational frequencies are 150 and 235 cm^{-1} respectively. The second band observed in the solution spectra splits into two bands in this vapor spectrum. The observed frequencies of 740 and 880 cm^{-1} were assigned to the out-of-plane ring deformation, ν_5, and aldehyde H-wagging vibrations, whose ground-state vibrational frequencies are 970 and 1010 cm^{-1} respectively. A rather strong band was observed at 3660 Å, separated by 1395 cm^{-1} from the O–O band corresponding to the third band of the solution spectra. A frequency of 1395 cm^{-1} was assigned to the totally symmetric C=O stretching vibration in the excited state.

It should be noted that the spectral structures of the n-π^* absorption and phosphorescence spectra are very similar to one another. This means that the $^1U_A(n,\pi^*)\leftarrow S_0$ transition is perturbed by the $^1L_a(\pi,\pi^*)\leftarrow S_0$ transition through exactly the same out-of-plane vibrations as are involved in the vibronic coupling between the emitting $^3U_A(n,\pi^*)$ and the low-lying $^3L_a(\pi,\pi^*)$ states. From the electronically-allowed character of the spectral structure, the $n\rightarrow\pi^*$ absorption of TPA can be ascribed to a $^1A_u(n,\pi^*)\leftarrow S_0$ transition for *trans*-TPA and to a $^1B_2(n,\pi^*)\leftarrow S_0$ transition for *cis*-TPA.

The intensities of the $n\rightarrow\pi^*$ absorptions of TPA and BA were calculated by the CNDO SCF CI method, using Pople's parameter.[16,17] In the CI calculations, seven higher-lying occupied molecular orbitals and seven lower-lying vacant molecular orbitals were employed. All the calculations were made on the basis of an assumption that the conformations of TPA and BA molecules were both planar. The geometries of the molecular structure used in the calculation were:

ring C–C = 1.396 Å, ring C–H = 1.084 Å,
ring – aldehyde C–C = 1.490 Å,
aldehyde C–O = 1.240 Å, aldehyde C–H = 1.114 Å,
ring ∠C–C–C = 120°, ring ∠H–C–C = 120°,
ring – aldehyde ∠C–C–C = 120°,
aldehyde ∠O–C–C = 123°, and
aldehyde ∠O–C–H = 120°.

The calculated state functions of the ^1L_a, ^1L_b, and ^1U ($=^3U$ in CNDO approximation) states for the *trans*- and *cis*-forms of TPA and BA are as follows:

for *trans*-TPA,

$$\Psi_{^1B_u(\pi,\pi^*);\,L_a} = 0.931(\phi_{24},\phi_{26}) - 0.293(\phi_{21},\phi_{27}) - 0.091(\phi_{24},\phi_{29}) + 0.067(\phi_{20},\phi_{31}) + 0.063(\phi_{23},\phi_{30}) + \cdots$$

$$\Psi_{^1B_u(\pi,\pi^*);\,L_b} = 0.761(\phi_{21},\phi_{26}) + 0.619(\phi_{24},\phi_{27}) - 0.187(\phi_{21},\phi_{29}) + \cdots$$

$$\Psi_{^1A_u(n,\pi^*);\,U_A} = 0.681(\phi_{25},\phi_{26}) + 0.600(\phi_{23},\phi_{28}) + 0.266(\phi_{20},\phi_{26}) + 0.259(\phi_{25},\phi_{29}) + 0.196(\phi_{20},\phi_{29}) + \cdots$$

$$\Psi_{^1B_g(n,\pi^*);\,U_F} = 0.698(\phi_{23},\phi_{26}) + 0.556(\phi_{25},\phi_{28}) + 0.355(\phi_{23},\phi_{29}) + 0.302(\phi_{20},\phi_{28}) + \cdots$$

for *cis*-TPA,

$$\Psi_{^1B_1(\pi,\pi^*);\,L_a} = 0.932(\phi_{24},\phi_{26}) - 0.294(\phi_{22},\phi_{27}) + 0.150(\phi_{19},\phi_{28}) - 0.091(\phi_{24},\phi_{29}) + \cdots$$

$$\Psi_{^1A_1(\pi,\pi^*);\,L_b} = 0.764(\phi_{22},\phi_{26}) + 0.617(\phi_{24},\phi_{27}) - 0.187(\phi_{22},\phi_{29}) + \cdots$$

$$\Psi_{^1B_2(n,\pi^*);\,U_A} = 0.692(\phi_{25},\phi_{26}) + 0.532(\phi_{23},\phi_{28}) - 0.273(\phi_{21},\phi_{28}) + 0.256(\phi_{25},\phi_{29}) + 0.251(\phi_{20},\phi_{26}) + 0.187(\phi_{20},\phi_{29}) + \cdots$$

$$\Psi_{^1A_2(n,\pi^*);\,U_F} = 0.633(\phi_{23},\phi_{26}) + 0.559(\phi_{25},\phi_{28}) - 0.306(\phi_{21},\phi_{26}) + 0.292(\phi_{23},\phi_{29}) + 0.287(\phi_{20},\phi_{28}) + \cdots$$

and for BA,

$$\Psi_{^1A'(\pi,\pi^*);\,L_a} = 0.868(\phi_{19},\phi_{21}) + 0.418(\phi_{17},\phi_{22}) - 0.150(\phi_{15},\phi_{23}) - 0.106(\phi_{17},\phi_{21}) - 0.100(\phi_{19},\phi_{23}) + \cdots$$

$$\Psi_{^1A'(\pi,\pi^*);\,L_b} = 0.703(\phi_{17},\phi_{21}) - 0.645(\phi_{19},\phi_{22}) - 0.231(\phi_{17},\phi_{23}) - 0.144(\phi_{15},\phi_{22}) + 0.108(\phi_{19},\phi_{21}) + \cdots$$

$$\Psi_{^1A''(n,\pi^*);\,U} = 0.776(\phi_{20},\phi_{21}) + 0.444(\phi_{20},\phi_{24}) - 0.351(\phi_{16},\phi_{21}) - 0.278(\phi_{16},\phi_{23}) + \cdots$$

Table 3. $f_{T\leftarrow S}$-values contributed from the two perturbing paths in TPA and BA

	Perturbing transition	$\tilde{\nu}^{obs.}_{\pi\to\pi^*0\text{-}0}$ (cm^{-1})	$f^{obs.}_{\pi\to\pi^*}$	Emitting triplet state	$f^{calc.}_{T\leftarrow S}$ a)
trans-TPA	$^1L_a(\pi,\pi^*)$-S_0	37,600	3.51×10^{-1}	$^3A_u(n,\pi^*)$	5.44×10^{-6}
	$^1L_b(\pi,\pi^*)$-S_0	32,450	2.47×10^{-2}	$^3A_u(n,\pi^*)$	1.22×10^{-9}
cis-TPA	$^1L_a(\pi,\pi^*)$-S_0	37,600	3.51×10^{-1}	$^3B_2(n,\pi^*)$	3.24×10^{-6}
	$^1L_b(\pi,\pi^*)$-S_0	32,450	2.47×10^{-2}	$^3B_2(n,\pi^*)$	1.43×10^{-9}
BA	$^1L_a(\pi,\pi^*)$-S_0	40,500	2.56×10^{-1}	$^3A''(n,\pi^*)$	2.93×10^{-6}
	$^1L_b(\pi,\pi^*)$-S_0	34,600	2.02×10^{-2}	$^3A''(n,\pi^*)$	1.18×10^{-8}

a) The $f^{calc.}_{T\leftarrow S}$-value was calculated with the following equations and observed values:

$$M_{T\leftarrow S}=M_{^1L_a \text{ or } ^1L_b\text{-}S_0}\frac{\langle\psi_{^1L_a \text{ or } ^1L_b}|H_{so}|\psi_{^3U_A}\rangle}{E_{^1L_a \text{ or } ^1L_b}-E_{^3U_A}}$$

$$f_{T\leftarrow S}=1.08\times10^{-5}\times\tilde{\nu}(cm^{-1})\times G\times M^2_{T\leftarrow S},$$

$E^{TPA}_{^3U_A}=23{,}100\ cm^{-1}$, and

$E^{BA}_{^3U}=25{,}150\ cm^{-1}$.

These state functions were used for the calculations of the transition moments of the $n\to\pi^*$ absorptions and the spin-orbit couplings between the $^3U_A(n,\pi^*)$ states and the $^1L_a(\pi,\pi^*)$ and $^1L_b(\pi,\pi^*)$ states for TPA and BA; the results are listed in Tables 2 and 3. The calculated $f_{n\to\pi^*}$-values of TPA and BA are listed in Table 2, together with the $f_{n\to\pi^*}$-values observed in cyclohexane at room temperature. The $f_{n\to\pi^*}$-values were also calculated by the use of Jaffé's parameter;[18] the results are given in the same table. Although Jaffé's parameter gives $f_{n\to\pi^*}$-values about one half of those obtained with Pople's parameter, the ratios of the calculated $f_{n\to\pi^*}$-values of TPA to those of BA are almost all the same. The values were 1.4 and 1.7 for *trans*-TPA and 1.6 and 1.8 for *cis*-TPA with Pople's and Jaffé's parameters respectively, as is shown in Table 2.

$$f_{n\to\pi^*}(\textit{trans}\text{-TPA})/f_{n\to\pi^*}(\text{BA})\approx 1.6 \text{ and}$$

$$f_{n\to\pi^*}(\textit{cis}\text{-TPA})/f_{n\to\pi^*}(\text{BA})\approx 1.7.$$

The calculation shows that *cis*-TPA gives an $f_{n\to\pi^*}$-value slightly greater than that of *trans*-TPA. The molecular extinction coefficients of the O–O bands of the $n\to\pi^*$ absorptions of TPA and BA measured in cyclohexane at room temperature are 18 and 11 respectively, the ratio being 1.6: 1. This value cannot be directly equal to the ratio of the electronically-allowed characteristics of the $n\to\pi^*$ absorptions of TPA and BA because the O–O band observed in solution generally involves non-totally symmetric vibrational bands of a low frequency, and the Frank-Condon factors of the n-π^* transitions of TPA and BA may be different. The calculated and experimental ratios both give values greater than unity. Hence, this leads to the conclusion that the $n\to\pi^*$ absorption of TPA has a fairly stronger electronically-allowed character than that of BA.

It is well known that the greater part of the observed intensity of the $n\to\pi^*$ absorption of BA is vibronically induced. The ratio of the observed $f_{n\to\pi^*}$-values of TPA and BA, 2.4: 1, may suggest that the $n\to\pi^*$ absorption of TPA is much more intensified vibronically than that of BA. This may be supported by the experimental fact that the second progression of the $n\to\pi^*$ absorption of TPA, which contains vibronic bands due to the out-of-plane ring deformation, ν_5, and aldehyde H-wagging vibrations, is remarkably enhanced in intensity compared with that of BA. This may result in an increase in the degree of polarization of the first band of the second progression of TPA to +0.15 from +0.10 for BA.

It should be noted that the degree of polarization of the first progression of TPA is markedly increased compared with that of BA. The degree of polarization of the first band of the progression of BA is −0.15, while that of TPA is +0.02. It was observed in the vapor absorption that the first band of TPA contains not only the O–O band, but also vibronic bands due to the CHO-torsional and CHO-wagging vibrations. These out-of-plane vibrations may increase the degree of polarization of the first progression of TPA. Since they increase the intensity of the first band of the first progression, the experimental ratio of $\varepsilon^{TPA}_{0\text{-}0}/\varepsilon^{BA}_{0\text{-}0}$, 1.6: 1, seems a little greater than the ratio in an ideal case where no out-of-plane vibrations are involved. The calculations of the transition densities between $^1U_A(n,\pi^*)$ and $^1L_a(\pi,\pi^*)$, and between $^1U_A(n,\pi^*)$ and $^1L_b(\pi,\pi^*)$ with the state functions given above suggest that the n-π^* transition in TPA is preferentially perturbed by $^1L_a(\pi,\pi^*)$. The ratio of intensity incre-

ments of the $n\rightarrow\pi^*$ absorptions due to the vibronic perturbation in TPA and BA is given by:

$$\frac{f^{\mathrm{TPA}}_{^1U_A(n,\pi^*)_{\mathrm{vib}}}}{f^{\mathrm{BA}}_{^1U(n,\pi^*)_{\mathrm{vib}}}} = \frac{f^{\mathrm{TPA}}_{^1L_a}}{f^{\mathrm{BA}}_{^1L_a}} \cdot \frac{E^{\mathrm{TPA}}_{^1U_A}}{E^{\mathrm{BA}}_{^1U}} \cdot \frac{E^{\mathrm{BA}}_{^1L_a}}{E^{\mathrm{TPA}}_{^1L_a}} \times \frac{\{E^{\mathrm{BA}}_{^1U} - E^{\mathrm{BA}}_{^1L_a}\}^2}{\{E^{\mathrm{TPA}}_{^1U_A} - E^{\mathrm{TPA}}_{^1L_a}\}^2} \frac{(W^{\mathrm{TPA}}_{^1U_A{}^1L_a})^2}{(W^{\mathrm{BA}}_{^1U^1L_a})^2} \approx 1.7 \times \frac{(W^{\mathrm{TPA}}_{^1U_A{}^1L_a})^2}{(W^{\mathrm{BA}}_{^1U^1L_a})^2}$$

where $W_{^1U^1L_a}$ is the vibronic interaction energy matrix element between ^1U and ^1L_a states.[19] The ratio of $W^{TPA}_{^1U_A{}^1L_a}/W^{BA}_{^1U^1L_a}$ is suggested to be greater than unity by a rough estimation of the value of the energy matrix element. Therefore, the above relation clearly explains the increase in the vibronic intensification of the $n\rightarrow\pi^*$ absorption of TPA.

The CNDO calculation indicates that the forbidden $n\rightarrow\pi^*$ transition is also strongly perturbed by the $^1L_a(\pi,\pi^*)\leftarrow S_0$ transition; thus, a_u or b_2 vibrations can be expected to appear in the $n\rightarrow\pi^*$ absorption. These vibronic bands give a positive polarization and should have different vibrational frequencies from those of the b_g or a_2 vibrations which are found in the allowed $n\rightarrow\pi^*$ absorption. Therefore, the observed $n\rightarrow\pi^*$ absorption and excitation polarization spectra can be expected to have very complicated patterns if a_u or b_2 vibrations are present. The $n\rightarrow\pi^*$ absorption spectrum of TPA was carefully studied in the vapor phase and in the crystal matrix at a low temperature in order to find the vibronic bands due to the electronically-forbidden $n\rightarrow\pi^*$ transition, but no positive evidence for the existence of these bands could be found. This indicates that the enhancement of the $n\rightarrow\pi^*$ absorptions due to the forbidden $n\rightarrow\pi^*$ transition is negligible.

The authors wish to thank Mr. Anjin Matsuda for his very helpful collaboration, and Mr. Hajime Ishii for his help in the theoretical calculations. The authors are also grateful to the Japan Electron Optics Laboratory Co., Ltd., for the measurement of the Raman spectrum of TPA.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1679—1682(1972)

Mössbauer Effect of ^{119}Sn in Tetracarbonylcobalt Derivatives of Tin(IV) Halides

Sumio Ichiba, Motomi Katada, and Hisao Negita
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received October 18, 1971)

The ^{119}Sn Mössbauer effect was studied in tetracarbonylcobalt derivatives of tin(IV) halides, $X_nSn[Co(CO)_4]_{4-n}$, where X=Cl, Br or I, and $n=0\sim4$. The isomer shift in each halogen series increased as the halogen atom was successively replaced by the $Co(CO)_4$ group. The values of the isomer shift were between those of tin(IV) halides and $XSn[Co(CO)_4]_3$ and did not change lineraly with the number of halogen atoms. The values of the quadrupole splitting were smaller than those of the corresponding organotin halides, X_nSnR_{4-n}, and attained their maximum at dihalides. From the Mössbauer parameters, the chemical bonds in the compounds, especially the Sn–Co bond, were discussed.

A large number of compounds containing metal-metal bonds between a Group IV element and a transition element have been synthesized, and the nature of the bonds and chemical properties of the compounds have been investigated by many workers.[1-5] Recently, Mössbauer spectroscopy has become available for compounds containing tin atoms, and the compounds containing a Sn–M bond, such as Sn–Fe, Sn–Co, Sn–Mn, and Sn–Re, have been studied by this method.[6-13] In particular, compounds containing metalcarbonyl have been investigated in the studies of metal-metal bonding. Karasyov *et al.*[13] have studied $A_nSn(C_6H_5)_{4-n}$ ($A=Mn(CO)_5$, $Re(CO)_5$, or $Co(CO)_4$, and $n=1\sim3$) by Mössbauer spectroscopy and elucidated the electron-donating nature of $Mn(CO)_5$ and $Re(CO)_5$ and accepting nature of $Co(CO)_4$

as compared to C_6H_5. Goldandkii *et al.*[13] have studied the A_nSnCl_{4-n}, $[C_5H_5Fe(CO)_2]_nSn(C_6H_5)_{4-n}$, and $[C_5H_5Fe(CO)_2]_nSnCl_{4-n}$ compounds and reported that in them metalcarbonyl groups act as electron acceptors. Onaka *et al.*[10] have studied $R_{3-n}X_nSn[Mn(CO)_5]$ and reported that the $Mn(CO)_5$ group is a stronger electron donor than the methyl, phenyl, and halogen groups. Spencer *et al.*[14] have studied $X_nSn[Co(CO)_4]_{4-n}$ and $R_nSn[Co(CO)_4]_{4-n}$ by ^{59}Co nuclear quadrupole resonance (NQR) and reported that there are Sn–Co π-interactions and that $Co(CO)_4$ is more electron-withdrawing than the methyl group. In the present studies, the Mössbauer effects of ^{119}Sn in $X_nSn[Co(CO)_4]_{4-n}$, where X=Cl, Br, or I, and n=0~4, were investigated in order to study the chemical bond, especially the Sn–Co bond.

Experimental

Materials. Tin(IV) halides and dicobalt octacarbonyl were obtained commercially. Tin(II) chloride was dehydrated completely by heating it in a nitrogen atmosphere. Tin(II) bromide was prepared by dissolving tin metal powder in concentrated hydrobromic acid. Tin(II) iodide was purified by sublimation in a nitrogen atmosphere. The purity of the tin(II) halides was checked by means of the Mössbauer spectrum.

Preparation of the Compounds. The compounds studied were prepared by the method of Patmore and Graham.[1] All the reactions were carried out under a nitrogen atmosphere because of their reactivity with air. The compounds were identified by their melting points and infrared spectra.

Measurements. The measurements were made as has been described previously.[15] The γ-ray source of barium stannate was used at room temperature, whereas the absorber was cooled with liquid nitrogen. The thickness of the absorber was about 20 mg/cm^2 for tin.

Results and Discussion

The Mössbauer spectrum of $Cl_3Sn[Co(CO)_4]$ is shown in Fig. 1, as an example. The solid line in the figure is the computer fit of the experimental points to the Lorentzian curve by the least-squares method. From the curves, the Mössbauer parameters, such as

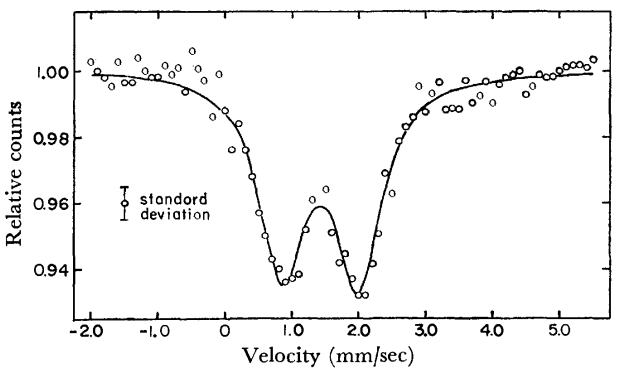

Fig. 1. The Mössbauer spectrum of $Cl_3Sn[Co(CO)_4]$.

Table 1. Mössbauer parameters for tin compounds

Compounds	δ[a] (mm/sec)	2ε (mm/sec)	Γ (mm/sec)

a) Isomer shift with respect to $BaSnO_3$.
b) Ref. 8).

the isomer shift (δ), the quadrupole splitting (2ε), and the half width (Γ), were derived. The values of these parameters are summarized in Table 1.

Isomer Shift. According to Cordey-Hayes,[16] the isomer shift of tin (IV) compounds is lower than the value of gray tin, which is completely quadrivalent, with the hybridized configuration $(5s)(5p)^3$, and which is sensitive to the s-electron density at the tin nucleus in such a way that the decrease in the value is closely related to the increase in the partial ionic character of the bond. The screening effects of the s-electrons by the $5s$, $5p$ and, in some cases, $5d$ electrons are also taken into account.

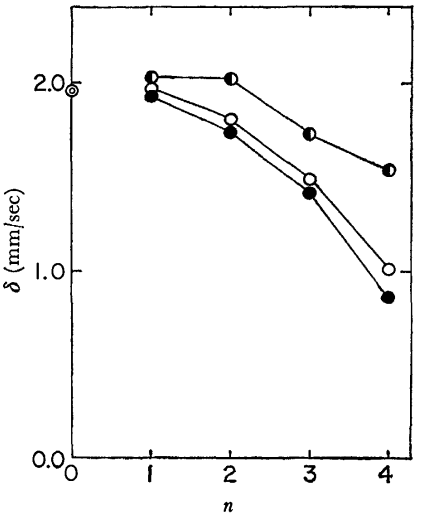

Fig. 2. The isomer shift *vs.* the number of halogens, n, in $X_nSn[Co(CO)_4]_{4-n}$ series.
●: Cl, ○: Br, ◐: I and ◎: $Sn[Co(CO)_4]_4$.

In Table 1, the values of the isomer shift of tin tetrahalides agree with the literature values,[13] and the values of the $X_nSn[Co(CO)_4]_{4-n}$ compounds (X=Cl, Br, or I, and n=1~3) increase as the electronegativities of the halogen atoms decrease. The plots of the values of the isomer shift *versus* the number of halogens, n,

16) M. Cordey-Hayes, *J. Inorg. Nucl. Chem.*, **26**, 915 (1964).

are shown in Fig. 2. Since the value of the isomer shift of $Sn[Co(CO)_4]_4$ is higher than that of each tin (IV) halide, the bonding character of the Sn–Co must be more covalent than those of Sn–X. The values of the isomer shift of the compounds in each series of halogen are between the values of $XSn[Co(CO)_4]_3$ and SnX_4. In each curve, it is observed that the changes in the isomer shift *versus* the number of halogens are not linear. That is, the change in the isomer shift becomes smaller as the number of halogens, n, decreases. On the other hand, it has been reported that the ionic character in the Sn–Cl bond increases with the decrease in the n, as is shown by the findings concerning the NQR due to ^{35}Cl in $Cl_nSn[Co(CO)_4]_{4-n}$ (n=2~4).[17-19] Thus, the electrons on the tin atom are more withdrawn to chlorine atoms as their number, n, decreases. Furthermore, according to Spencer *et al.*,[14] more π-electrons transfer to the tin atom from $Co(CO)_4$ and, in turn, decrease the isomer shift of tin, as their number, n, increases. The observed isomer shift must be the result of the competition of the ionic character in the Sn–X bond with the π-bonding in the Sn–Co bond as the number, n, changes.

The same tendency of the isomer shift has been observed in the $[C_5H_5Fe(CO)_2]_nSnCl_{4-n}$ and $[C_5H_5Fe(CO)_2]_nSn(C_6H_5)_{4-n}$ (n=0~3) series of compounds.[7]

Quadrupole Splitting. In tin(IV) compounds, large quadrupole splittings are generally observed when there is an unequal electron population at the three $5p$ or four $5sp^3$ orbitals. Sizable quadrupole splittings are observed in the $X_nSn[Co(CO)_4]_{4-n}$ compounds (X=Cl, Br, or I, and n=1~3), as is shown in Table 1. Thus, in these compounds there is an unequal electron population at the three $5p$ orbitals, so that the bonding characters of Sn–X and Sn–Co are considerably different. Many workers have studied the quadrupole splitting of organotin compounds of the type of X_nSnR_{4-n} (R=alkyl or aryl, X=halogen, and n=1~3).[13,20-22] The results show that the quadrupole splitting in the organotin compound becomes smaller as the electronegativity of the organic group, R, approaches that of the halogen atom. Because the quadrupole splittings of the $X_nSn[Co(CO)_4]_{4-n}$ compounds are smaller than the values of the corresponding organotin compounds, the $Co(CO)_4$ group is more electronegative than the alkyl or aryl group. This result agrees with the conclusions of the NQR study of the compounds by Spencer *et al.*[14] and the Mössbauer study of the $(C_6H_5)_nSn[Co(CO)_4]_{4-n}$ series by Karasyov *et al.*[13]

Bir'yukov *et al.*[23] reported that the Co–Sn–Cl angle in $ClSn[Co(CO)_4]_3$ is 104°, as determined by the X-ray diffraction method. Boer *et al.*[24] reported that, in $Cl_2Sn[Co(CO)_2C_7H_8]_2$ or $(C_6H_5)_2Sn[Co(CO)_2C_7H_8]_2$, the Co–Sn–Co angle is larger than Cl–Sn–Cl or C_6H_5–Sn–C_6H_5, as determined by the X-ray diffraction method. Patmore and Graham[25] reported that the Co–Sn–Co angle in $Cl_2Sn[Co(CO)_4]_2$ is larger than the tetrahedral angle, as determined by IR spectroscopy. They also studied the $(CH_3)_nSn[Co(CO)_4]_{4-n}$ compounds by NMR spectroscopy and showed, from the coupling constants, $J(^{117}Sn-CH_3)$ and $J(^{119}Sn-CH_3)$, that an increase in the s-character is observed in the Sn–Co bond. All those results may be summarized by Bent's rule,[26] which suggests that the s-character is concentrated in the orbitals directed toward more electropositive substituents. In the light of Bent's rule, it is plausible that the s-character is concentrated in the Sn–Co bonds, while the p-character is concentrated in the Sn–X bonds. In consequence, the Co–Sn–Co bond angle becomes larger than the tetrahedral angle, while the X–Sn–X angle becomes smaller. The resultant imbalance in p-electron populations is manifested by quadrupole splitting.

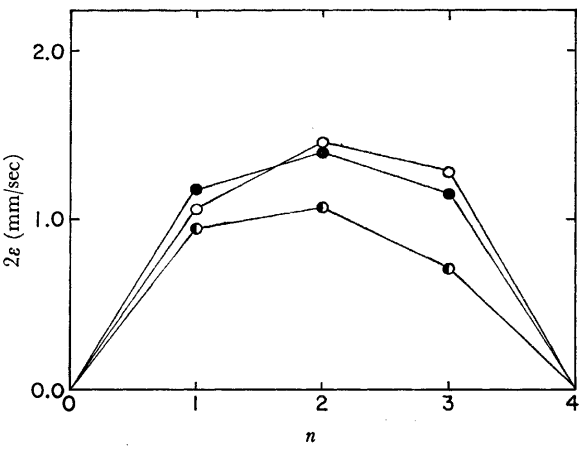

Fig. 3. The quadrupole splitting *vs.* the number of halogens, n, in $X_nSn[Co(CO)_4]_{4-n}$ series.
●: Cl, ○: Br, and ◐: I.

In Fig. 3, the values of the quadrupole splitting are plotted *versus* the number of halogen atoms, n. From the electronegativity of halogen, it can be expected that the values of the quadrupole splitting will decrease in the order of Cl>Br>I, but this is not true of bromine. The anomaly of bromine compounds seems to result from the distorted tetrahedral structure of tin tetrabromide,[27,28] in accordance with its broad line width.

The values of the quadrupole splitting attain their maximum at n=2 in all series of the compounds. An explanation of this phenomenon was attempted using a simple point-charge model. According to Parish and Platt,[21] the coordinates and arrangements of the

(a) X_3SnY(or $XSnY_3$) (b) X_2SnY_2

Fig. 4. Point-charge models of the tetrahedral bonding.

tetrahedral point-charge model of the X_nSnY_{4-n} type, in which X is the halogen atom and Y is the $Co(CO)_4$ group in the present case, are as is shown in Fig. 4.

The quadrupole splitting of ^{119}Sn, which has spin states of the excited and ground states of the nuclei, 3/2 and 1/2, is given by:

$$2\varepsilon = KV_{zz}(1+\eta^2/3)^{1/2} \quad (1)$$

Where V_{zz} is the electric-field gradient in the direction of the principal axis, which is taken as the z axis, and where the asymmetry parameter, η, is defined by:

$$\eta = \frac{V_{xx}-V_{yy}}{V_{zz}} \quad (2)$$

The electric-field gradients, V_{xx}, V_{yy}, and V_{zz}, can be expressed as follows:

$$\begin{aligned} V_{xx} &= \sum_L (3\sin^2\theta_L\cos^2\phi_L - 1)[L] \\ V_{yy} &= \sum_L (3\sin^2\theta_L\sin^2\phi_L - 1)[L] \\ V_{zz} &= \sum_L (3\cos^2\theta_L - 1)[L] \end{aligned} \quad (3)$$

where [L] represents the nature of the ligand contributing to the electric-field gradient, and where θ_L and ϕ_L are the polar and azimuthal angles of the ligand respectively. Using the three Eqs., (1), (2), and (3), the relative values of the quadrupole splitting for the tetrahedral point-charge model of X_nSnY_{4-n} ($n=1\sim3$) are calculated as follows:

X_3SnY	tetrahedral	$2\varepsilon\sim2[Y]-2[X]$
X_2SnY_2	tetrahedral	$2\varepsilon\sim1.15(2[Y]-2[X])(\eta=1)$
$XSnY_3$	tetrahedral	$2\varepsilon\sim-2[Y]+2[X]$

where [X] and [Y] are the parameters of the contributions to the electric-field gradient by the X and Y ligands.

In this interpretation, the dihalides should have a quadrupole splitting larger by 15% than that for the monohalide or trihalide, which have the same value but the opposite sign. The experimental data are consistent with the results of the point-charge treatment for the maximum value at dihalide. However, the values of $X_3Sn[Co(CO)_4]$ and $XSn[Co(CO)_4]_3$ are not equal. This can be explained on the basis of the deviation of the bond angle from the tetrahedral angle. As has been stated above, the X–Sn–Co bond angle is larger than the tetrahedral angle in $X_3Sn[Co(CO)_4]$ and is smaller in $XSn[Co(CO)_4]_3$. The electric-field gradient arises from the imbalances in the charges on the ligands as well as in the valence electron, but the latter is far more effective than the former. Therefore, the sign of the electric-field gradient in the tetrahedral compound, $XSn[Co(CO)_4]_3$, would be positive, because the valence shell of the tin atom will have more electron density concentrated in the x- and y-directions (Sn–Co) than in the z-direction (Sn–X), and the sign in $X_3Sn[Co(CO)_4]$ would be negative. The parameters of the quadrupole splitting are:

$2[X] - 2[Y] > 0$ in tetrahedral $XSn[Co(CO)_4]_3$

$2[Y] - 2[X] < 0$ in tetrahedral $X_3Sn[Co(CO)_4]$

If the X–Sn–Co bond angle were smaller than the tetrahedral angle in $XSn[Co(CO)_4]_3$ and larger in $X_3Sn[Co(CO)_4]$, the values of the parameter of the quadrupole splitting in both compounds would be decreased. However, the decreasing rate of the quadrupole splitting in $X_3Sn[Co(CO)_4]$ with the increase in the X–Sn–Co angle would be larger than that in $XSn[Co(CO)_4]_3$ with the decrease in the X–Sn–Co angle, because the value of $3(3\cos^2\theta-1)$ decreases more rapidly as θ increases in the neighborhood of the tetrahedral angle and [X]>[Y]. Furthermore, it is expected that the parameter, [X], of $XSn[Co(CO)_4]_3$ would become larger than that of $X_3Sn[Co(CO)_4]$. This is the case with the compounds of chloride and iodide.

When all the molecules in the series of the X_nSnY_{4-n} compound are obtained in an isolated state in solid or frozen solutions, the data of quadrupole splitting provide valuable information about the molecular structure, as is shown in the present study. In view of this, the Mössbauer studies of organic tin halides in a frozen solution would be interesting, for in that way all the molecules may be isolated, while it is difficult to discuss the molecular structure from the data in the solid state, where some association occurs.

Polarography of Uranyl Complex with *p*-Aminothiophenoxyacetic Acid in Dimethyl Sulfoxide Solution

Tsai-Teh LAI and Jan-Chin YANG

Department of Chemical Engineering, Cheng Kung University, Tainan, Taiwan, China

(Received September 22, 1970)

The polarography of uranyl ion in dimethyl sulfoxide (DMSO) was investigated in the DMSO concentration range 40—99 vol%. The complex species identified is $UO_2(DMSO)_6^{2+}$; it is transformed into $UO_2(DMSO)_2^+$ and UO_2^+ after the electrode reduction. In the presence of *p*-aminothiophenoxyacetic acid, the uranyl ion in the DMSO medium produces a two-step wave at lower pH and higher concentration of DMSO. The limiting current of the wave is controlled partially by the kinetics of the preceding chemical reaction and partially by the diffusion of the complex. The rate constant and diffusion coefficient of the reduction process were determined. At pH around 4, the formation of binuclear uranyl complexes was confirmed.

Gutman and Shoeber were the first to study the polarography of a number of inorganic ions in dimethyl sulfoxide solution.[1-3] They found that many polarographic reductions appeared to be irreversible in dimethyl sulfoxide. The polarography of uranyl complex with fumarate in a dimethyl sulfoxide concentration up to 40 vol% has been studied.[4]

Because of difficult solubility of *p*-aminothiopenoxyacetic acid in water, dimethyl sulfoxide was chosen as a solvent to study the complex of uranium(VI) with *p*-aminothiophenoxyacetic acid. The concentration range of dimethyl sulfoxide was 40—99 vol%.

Experimental

Apparatus. The polarograph and technique used in this work have been reported.[5] The capillary characteristics were: $m=1.307$ mg/sec and $t=4.88$ sec/drop at $H=67.3$ cm in 1.0 mM $UO_2(ClO_4)_2$, 70 vol% dimethyl sulfoxide, 0.08M *p*-aminothiophenoxyacetic acid, 0.15M $NaClO_4$ and 0.002% Triton X-100 at closed circuit. The hydrogen used for deaeration of the polarographic solution was presaturated with dimethyl sulfoxide by passing through a bottle filled with 70 vol% dimethyl sulfoxide solution. All polarograms were taken at 30±0.1°C.

Chemicals. *p*-Aminothiophenoxyacetic acid (P-ATPAA) was of research grade, Aldrich Chemical Co., and the solution was freshly prepared for each run.

Dimethyl sulfoxide (DMSO) was of chemical pure reagent (Wako Pure Chemical Industries Co.) and was not further purified.

All the polarograhic solutions contained 0.15M $NaClO_4$ as supporting electrolyte and 0.002% Triton X-100 as maximum suppressor.

Results and Discussion

Uranyl Ion in DMSO in the Absence of p-*ATPAA.* The polarographic behavior of uranyl ion in DMSO was studied in the DMSO concentration range 40—99 vol% over the pH range 2.40—5.25. Beyond this pH range, the waves become less well-defined. Above DMSO concentration 90 vol%, a strong maximum appears and the concentration of Triton X-100 must be increased from 0.002% to 0.03% to suppress the maximum.

TABLE 1. WAVE CHARACTERISTICS OF URANYL ION IN DMSO (1.0 mM $UO_2(ClO_4)_2$, 0.15M $NaClO_4$, 0.002% Triton X-100)

C_{DMSO} vol %	pH	$-E_{1/2}$ V *vs.* SCE	i_d μA	$E_{1/4}-E_{3/4}$

	4.95	0.492	1.14	0.066

a) 0.03% Triton X-100

The values of $E_{1/4}-E_{3/4}$ are in the range 0.055—0.067 (Table 1); the temperature coefficients of half-wave potential and diffusion current are −0.3 mV/°C and 1.5%/°C, respectively, in the temperature range 24—36°C. The results indicate that the electrode reductions are one-electron reversible and diffusion-controlled reduction process.

The dependence of the half-wave potential of uranyl ion on pH value in various concentrations of DMSO is shown in Fig. 1. The breaking point on the plots of $-E_{1/2}$ *vs.* pH is a function of the concentration of DMSO. Above 70 vol% DMSO, the breaking points are at pH 4.0; and at pH 3.0 for 50—60 vol% DMSO. However, below 40 vol% DMSO no breaking point appeared indicating that no hydrogen ion is invloved in the electrode reaction for any pH value of solution. The slope of the plots at pH<4.0 is also a function of DMSO concentration. The slope reaches 0.051 at 90 vol% DMSO. It indicates that one hydrogen ion is involved

●80 vol%; ×90 vol%; ○99 vol%.

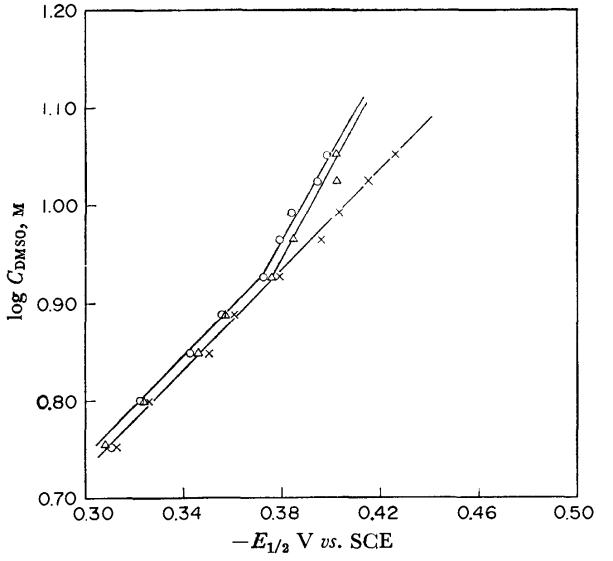

Fig. 2. Plots of log C_{DMSO} *vs.* $-E_{1/2}$ for uranyl ion in DMSO.
1.0 mM $UO_2(ClO_4)_2$, 0.15 M $NaClO_4$ and 0.002% Triton X-100.
× pH 4.00; △ pH 3.00; ○ pH 2.75.

in the electrode reaction. At pH>4.0 no hydrogen ion takes part in the electrode reaction for any concentration of DMSO.

Figure 2 shows the half-wave potential of uranyl ion in DMSO as a function of the lograrithmic concentration of DMSO. At pH≥4.0 and [DMSO]<80 vol%, a straight line with a slope 0.377 was obtained. At pH<4.0, breaking points were found; the slopes are 0.377 and 0.230 for 40 vol%<[DMSO]<60 vol% and 60 vol%<[DMSO]<80 vol%, respectively.

Introducing these values of slopes into the half-wave potential equation

$$(E_{1/2})_c = \text{const.} - (p-q)0.060 \log C_{DMSO} - 0.060a\,\text{pH} \quad (1)$$

for the electrode reaction

$$UO_2(DMSO)_p^{2+} + aH^+ + e = UO_2(DMSO)_q^+ + a\text{DMSO}\cdot H^+ + (p-q-a)\text{DMSO} \quad (2)$$

the values of (p-q) become equal to 6 at pH>4.0 and equal to 6 and 4 at pH<4.0.

The coordination between uranyl ion and DMSO has been proved by the donation of a lone pair of electrons on oxygen atom of DMSO of a monodentate ligand.[6]

Thus, it was inferred that the uranyl-DMSO complex species formed is $UO_2(DMSO)_6^{2+}$, proving that the uranyl ion is solvated completely by six molecules of DMSO in the presence of an excess DMSO. However, it is transformed into $UO_2(DMSO)_2^+$ and UO_2^+ after it undergoes the electrode reduction.

Uranyl Ion in DMSO in the Presence of p-*ATPAA.*

The polarographic behavior of the uranyl-DMSO-*p*-ATPAA system was studied systematically in the pH range 2.75—6.00 with DMSO concentration 65—99 vol% and *p*-ATPAA concentration 0.01—0.12M.

Typical current-potential curves for the polarographic solution containing 1.0 mM $UO_2(ClO_4)_2$, 0.08M *p*-ATPAA, 90 vol% DMSO, 0.15M $NaClO_4$ and 0.002% Triton X-100 at various pH values are presented in Fig. 3. At pH 4.80, a single well-defined wave was obtained; however, at pH<4.30, two-step waves were observed. The electrocapillary curves are shown in Fig. 4. A large decrease in the drop time of the capillary was observed by the addition of *p*-ATPAA proving the existence of adsorption of *p*-ATPAA on the dropping mercury electrode. The formation of two-step waves was attributed to the adsorption of *p*-ATPAA on the dropping mercury

electrode.[7] The lower pH value and higher DMSO concentration favor the formation of two-step waves.

The effect of the concentration of DMSO and *p*-ATPAA on the limiting currents of the two waves is shown in Fig. 5 and the wave parameters of the two-step waves in Table 2. The limiting current of the first wave increases with the concentrations of DMSO and *p*-ATPAA; however, the limiting current of the second wave is independent of the concentration of *p*-ATPAA and increases with the concentration of DMSO.

Nature of the Limiting Current. A preceding chemical reaction takes place between the $UO_2(DMSO)_6^{2+}$ complex and *p*-ATPAA producing a mixed ligand complex and reaches a chemical equilibrium; then an electrode reaction occurs to the mixed ligand complex.

In an attempt to determine both the kinetic parameter of the preceding chemical reaction and the nature of the limiting current of the polarogram of the mixed ligand complex, the following equation[8] was applied

$$\bar{i} = r \cdot 1255nm^{2/3}\tau^{2/3}\mathrm{Co}k\left[1 - \mathrm{erf}\left(k\sqrt{\frac{\tau}{D}}\right)\right]\exp\left[\frac{k^2\tau}{D}\right] \quad (3)$$

where k is the rate constant, r the ratio of the average limiting current to the maximum limiting current and a function of τ and $kD^{-1/2}$, and other notations have their usual meaning.

Introducing $m=m_0H$ and $\tau_0=\tau H$; Eq. (3) becomes;

$$i = r \cdot 1255nm_0^{2/3}\tau_0^{2/3}\mathrm{Co}k\left[1 - \mathrm{erf}\left(k\sqrt{\frac{\tau_0}{HD}}\right)\right]\exp\left[\frac{k^2\tau_0}{HD}\right] \quad (4)$$

and

$$\frac{\bar{i}}{\bar{i}_0} = \frac{r}{r_0}\frac{\left[1 - \mathrm{erf}\left(k\sqrt{\frac{\tau_0}{HD}}\right)\right]}{\left[1 - \mathrm{erf}\left(k\sqrt{\frac{\tau_0}{H_0D}}\right)\right]}\exp\left[\frac{k^2\tau_0}{HD} - \frac{k^2\tau_0}{H_0D}\right] \quad (5)$$

The plots of $\bar{i}/\bar{i}_0$ against mercury head H using $kD^{-1/2}$ as parameter are shown in Fig. 6, in which $\bar{i}_0$ is the average limiting current for the polarograms ob-

tained from a given polarographic solution at $H=$ 40 cm and $\tau_0=2700$ sec-mm/drop. We see that the limiting current is practically diffusion-controlled when $kD^{-1/2}$ is larger than 1.0 $sec^{-1/2}$. At $k=\infty$, the error function should be expanded into a series and Eq. (3) can be reduced to Ilkovic equation.[9] On the contrary, the limiting current is essentially rate-controlled when $kD^{-1/2}$ is smaller than 0.01 $sec^{-1/2}$. When $kD^{-1/2}$ is between 0.01 and 1.00 $sec^{-1/2}$, the limiting current is controlled partially by diffusion and partially by the rate of the preceding chemical reaction.

The variations of $kD^{-1/2}$ values as a function of the concentration of *p*-ATPAA and as a function of pH value are demonstrated in Figs. 7 and 8, respectively. The values of $kD^{-1/2}$ were evaluated by determining the $\bar{i}/\bar{i}_0$ values by varying mercury head and by applying Fig. 6.

It is obvious from Fig. 7 that in the absence of *p*-ATPAA, irrespective of the concentration of DMSO and the pH value, the value of $kD^{-1/2}$ is infinite, indicating that the electrode reduction of the uranyl-DMSO complexes is completely diffusion-controlled. This result is in accord with that obtained from the temperature coefficient of diffusion current. The $kD^{-1/2}$ value decreases with the increase of the concentration of *p*-ATPAA and DMSO. This reveals that the higher concentrations of DMSO and *p*-ATPAA enhance the rate-controlled character of the electrode reduction process of uranyl-DMSO-*p*-ATPAA complexes.

A complete diffusion-controlled reduction process of uranyl-DMSO-*p*-ATPAA complex is obtained in the pH range 3.7—4.5 at 30°C (Fig. 8). Polynuclear complexes are formed in the pH range and the increment of viscosity of the polarographic solution rendered the electrode reduction to be diffusion-controlled.[10] However, beyond this pH range, a rate-controlled character takes part in the reduction of the complex.

It can be expected that at higher temperature the adsorption is hindered and no rate-controlled phenomenon appeared even at pH<3.7 (curve II, Fig. 8).

Formation of Polynuclear Complexes. The temperature coefficient of the half-wave potential is determined to be 0.6 mV/°C in a polarographic solution containing 1.0 mM $UO_2(ClO_4)_2$, 70 vol% DMSO, 0.08M *p*-ATPAA, 0.15M $NaClO_4$, and 0.002% Triton X-100 at pH 4.30 in temperature range 18.0—39.5°C. This indicates that the electrode process is reversible. However, as shown in Table 3, in the vicinity of pH 4, the mean $E_{1/4}-E_{3/4}$ value is 0.039; the deviation of this value from the

90 vol% DMSO; 0.08M *p*-ATPAA	3.30	0.30	0.68	1.99×10^{-3}	4.42×10^{-5}

heoretical value of 0.057 V for one-electron reversible reduction was no doubt due to the asymmetry of the polarogram which arose from the polymerization effect.[11]

The polymerization degree for the polynuclear complexes formed was determined by the same method as described previously.[11] The results are shown in Table 3, in which a and b denote the polymerization degree of the oxidized and reduced form of the uranium complex, respectively. It is obvious from Table 3 that a binuclear uranyl complex was formed in the vicinity of pH 4.

Rate Constant and Diffusion Coefficient. The rate constant k of the preceding chemical reaction and the diffusion coefficient D of the uranyl complex can be determined by applying Eq. (4) for $m_0=2.734\times10^{-3}$ mg/sec-mm, $\tau_0=2.7\times10^3$ sec-mm/drop and $n=1$ values. Table 4 lists some data of k and D of the uranyl complexes. The $kD^{-1/2}=1.00$ and $k\gg D$ for uranyl-DMSO and uranyl-DMSO-*p*-ATPAA (70 vol% DMSO; 0.08M *p*-ATPAA) systems show again that the electrode reaction is diffusion-controlled. However, the data obtained for uranyl-DMSO-*p*-ATPAA (90 vol% DMSO; 0.08M *p*-ATPAA) system indicate a partial kinetic-controlled character. These results support the deduction.

Fluorescence Emission in the Gas Phase of Several Aromatic Hydrocarbons

Akira NAKAJIMA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received December 13, 1971)

The fluorescence and excitation spectra of several condensed aromatic hydrocarbons were measured in the gas phase at low pressures. The emission from the second excited singlet state (S_2 emission) could be observed with some of the compounds studied, in which the first weak absorption band is located close to the second much stronger band. The relative yield of the S_2 emission always increased with the increase in the excitation wavenumber. It has been shown that the occurrence of the S_2 emission can be explained in a qualitative way by the state densities and the radiative rates. In coronene, an emission to be regarded as originating from the third excited singlet state was observed.

It is well known that radiationless transitions from higher excited singlet states to the first excited singlet state in most complex molecules occur with such a high efficiency that usually fluorescence arises solely from the lowest excited singlet state.[1-8] Recent theoretical studies[9-12] have indicated that, in large molecules, internal conversion can take place even in the isolated state. Although the emission from the second excited singlet state (S_2 emission) of a large molecule[8] has been considered to be extremely weak on account of the very fast internal conversion,[4-7] it may be detected in principle by means of a highly sensitive spectroscopic device and by the use of a favorable compound satisfying certain conditions.

The fluorescence originating from the second excited singlet state of pyrene in the gas phase at low pressures

was found independently by Geldof *et al.*[13] and by the present author *et al.*[14] With the aid of a very sensitive emission spectrometer,[15] Geldof *et al.* observed anomalous emission bands in the short-wavelength region of the fluorescence spectrum of a rarified pyrene gas excited in the second absorption band; these bands are to be ascribed to the S_2 emission.[13] They also studied the effect of the inert gas and the temperature on the relative yield of this emission and estimated the rate constants for the internal conversion and the reverse process.[13] On the other hand, the present author *et al.* measured the fluorescence and excitation spectra of pyrene gas, paying special attention to the S_2 emission, and showed a very remarkable increase in its relative quantum efficiency with excitation into successively higher excited singlet states.[14]

It seems to be established that the 'anomalous' emission can be regarded as quite intrinsic and not due to impurities, because no impurity band was detected in the fluorescence and excitation spectra in the solutions of the highly purified sample employed, because its excitation spectrum corresponds well in wavenumber to the absorption spectrum of pyrene gas,[14,16] because its relative intensity is reduced by the vibrational relaxation on the addition of an inert (non-electronically-quenching) gas such as nitrogen[17] and cyclohexane,[16] and further, because such emissions have also been observed with deuteropyrene[17] and methylpyrenes.[18]

Moreover, it has been reported that fluorescence from the second excited singlet state can be observed with 3,4-benzpyrene[13,19] both in the gas phase and in solution, 1,2-benzanthracene[19] in solution, and 1,12-benzperylene[20] in plastics.

In particular, in all of these 'abnormal' molecules, as we can recognize, the very weak first absorption band is situated in the immediate vicinity of the much stronger second band. In this respect, the weakness of the first band should be regarded as more significant than would be desirable for reducing self-absorption.[13,19]

In view of these facts, the following empirical criteria for the occurrence of the S_2 emission may be proposed:

(1) The rate of emission from the second excited singlet is sufficiently large compared to that from the first excited singlet.

(2) The energy separation between the first and second excited singlets is relatively small.

The purpose of this work is to test these criteria on a number of condensed aromatic hydrocarbons by making attempts to detect S_2 emission in the short-wavelength tail of their 'normal' fluorescence spectra. In addition, the influence of the internal conversion rates on the behavior of the S_2 emission has been considered in connection with the vibrational level densities for the relevant states.

Experimental

Naphthalene and phenanthrene were recrystallized from ethanol and zone-refined. 1-Methoxynaphthalene was distilled under reduced pressure. 1-Naphthol was recrystallized from ethanol. Biphenyl was recrystallized from ethanol, zone-refined, and sublimed *in vacuo*. Anthracene was recrystallized from xylene, zone-refined, and sublimed *in vacuo*. Chrysene was recrystallized from benzene and zone-refined. Perylene was chromatographed and sublimed *in vacuo*. Triphenylene, tetracene, 1,2-benzanthracene, 20-methylcholanthrene, 1,12-benzperylene, and coronene were sublimed *in vacuo*. Spectroscopic-grade benzene was used as a solvent without further purification. The purities of the samples were carefully checked by observing the excitation spectra. If, unfortunately, an impurity band was found in the excitation spectrum, the emission spectra were not measured with excitation in the neighborhood of that band.

The fluorescence and excitation spectra were measured with a Hitachi MPF-2A spectrofluorometer, to which an electric furnace was attached in the cell compartment. The square, non-fluorescent quartz cell containing a small amount of the sample was evacuated and sealed off. The furnace in which the gas cell was placed was constructed of brass blocks and was covered with asbestine slates as insulators. It consists of a lower part with two quartz windows and an upper, windowless part; the temperatures of the two parts were separately controlled. The vapor pressure of the compound was assessed utilizing the published data,[21,22] with the temperature of the upper part always set at a somewhat lower temperature. The vapor pressures at which the experiments were carried out were 0.01—1 Torr, except for 1-methoxynaphthalene and biphenyl, whose pressures were raised to 5 Torr.

The fluorescence spectra were corrected for the spectral sensitivity of the instrument by the use of the standard fluorescence spectra of quinine sulfate, 2-naphthol, and phenol.[23-25] The excitation spectra were also corrected using rhodamine B as the standard substance.[25,26]

Results and Discussion

Since the experiments were made at such low vapor pressures that the lifetime of the excited molecule was considerably shorter than the time interval between molecular collisions, during the processes of internal conversion the excitation energy was conserved, with part of it reserved as excess vibrational energy. It may be assumed that the internal conversion to the second excited singlet state from a higher excited singlet state, in which the molecule is initially prepared by

photon absorption, occurs very rapidly and irreversively. The resultant molecule in the high vibronic levels of the second excited singlet state (S_2) either emits the S_2 emission or is isoenergetically converted into the high vibronic levels of the first excited singlet state (S_1), from which it may in turn emit the 'normal' S_1 emission or pass nonradiatively into the highly-excited vibrational levels of the triplet or ground state (S_0). If the radiative lifetime in the high vibronic levels of S_1 is relatively long, then the returning process from S_1 to S_2 can take place.[13] Thus, the yield of the S_2 emission can be considered to be composed of a direct, short-lived component occurring before internal conversion and an indirect, long-lived component derived from the reverse process.[13,16]

By a simple consideration of the kinetics based on this scheme,[16] the ratio of the quantum yield of the S_2 emission, Φ_2, to that of the S_1 emission, Φ_1, is obtained as follows:

$$\Phi_2/\Phi_1 = k_2(k_{1f}+k_{1q}+k_{rp})/k_{1f}k_{ic}, \quad (1)$$

where k_{1f} and k_2 are the rate constants for the emissions from S_1 and S_2 respectively, where k_{ic} and k_{rp} are those for the internal conversion and the reverse process respectively, and where k_{1q} is the overall rate constant for the nonradiative (quenching) processes from S_1.

The radiative rate constants, k_i, were estimated from the S_0—S_1 absorption spectra in solution, using the following well-known equation:[3,4,6,7]

$$k = 2.88 \times 10^{-9} n^2 \bar{\nu}_m^2 \int \varepsilon d\bar{\nu}, \quad (2)$$

or by the aid of a simpler expression:[27]

$$k \sim 8.6 \times 10^{-6} n^2 \bar{\nu}_m^2 \varepsilon_{max}, \quad (3)$$

where ε is the molar extinction coefficient, and n, the refractive index of the solvent.

The rate constant of internal conversion, k_{ic}, can be formulated as:[7,9-12,28]

$$k_{ic} = (2\pi/\hbar)v^2\rho_1, \quad (4)$$

where v is the coupling matrix element between the zero-order Born-Oppenheimer states for the perturbation inducing internal conversion and where ρ_1 is the density of the final vibronic states (in S_1) at resonance with the initial state (in S_2). For the reverse process, the rate constant, k_{rp}, is expressed in a similar form:[16]

$$k_{rp} = (2\pi/\hbar)v^2\rho_2, \quad (5)$$

where ρ_2 is the density of states in S_2.

Using these expressions, Eq. (1) can be reduced to:

$$\Phi_2/\Phi_1 = (k_2/k_1)(\rho_2/\rho_1) + k_2/k_{ic}\phi_1, \quad (6)$$

where ϕ_1 is the quantum yield of S_1 fluorescence caused by excitation in the first excited singlet or within high-pressure limits. It is assumed here that ϕ_1 can be approximated by the quantum yield in solution.

Internal conversion in a large molecule has been thought to occur in 10^{-11}—10^{-13} sec.[1,4-7] Recently, the rate constant, k_{ic}, was estimated for pyrene in the gas phase as $\sim 10^{12}$ sec^{-1} by Geldof *et al.*[13] and as 5.8×10^{11} sec^{-1} by us.[16,29] In the present study, no attempt was made to determine the value of k_{ic}, *e.g.*, by performing the inert-gas experiments[13,16] when S_2 emission could be observed. Instead, for all the molecules under consideration k_{ic} was assumed to take a value similar to that estimated for pyrene, *i.e.*, 10^{12} sec^{-1}.[1,4,7,12] Because of this large k_{ic} value, the contribution of the second term in Eq. (6) may be comparatively small for most 'abnormal' molecules.

The density of vibrational states, ρ, was computed by the use of Haarhoff's formula.[30] As we have no definite knowledge at the present stage about the effectiveness of the vibrational modes in giving rise to radiationless transitions, the contributions of all the modes are taken into account equally. Since the vibrational assignments are not available for most of the compounds studied, a scaling method has been adopted;[31,32] that is, for an aromatic hydrocarbon, C_mH_n, there are n degenerate CH stretching modes assigned at 3050 cm^{-1}, n in-plane CH bending modes at 1100 cm^{-1}, n out-of-plane CH bending modes at 900 cm^{-1}, $m-1$ ring stretching modes at 1500 cm^{-1}, $m-2$ in-plane ring deformation modes at 700 cm^{-1}, and $m-3$ out-of-plane ring deformation modes at 500 cm^{-1}. The values of ρ calculated by this method were compared with those obtained by direct calculation using the observed frequencies; the differences were only 15% for benzene,[33] less than 6 times for naphthalene,[34] and up to 100 times for anthracene[35] and pyrene.[36] Although the difference in ρ increases rapidly with the number of atoms, yet the difference in the ratio between ρ's is satisfactorily smaller, *e.g.*, within a factor of only two for anthracene. It should be kept in mind, however, that the value computed by Haarhoff's approximation becomes inaccurate at smaller energies.[30]

Below, the results of observations of the fluorescence and excitation spectra in the gas phase will be illustrated and the possibility of the appearance of S_2 emission will be investigated by means of the rate constants evaluated in the manner described above.

Naphthalene, 1-Naphthol, and 1-Methoxynaphthalene. Since the lowest excited singlet state (^1L_b), which gives rise to a weak absorption band, is located close to the

27) The half-width of an absorption band was taken as 6.0 kK, and the mean wavenumber, $\bar{\nu}_m$, and the maximum extinction coefficient, ε_{max}, were used.

29) In this connection, it is of interest to note that k_{ic} seems to vary only slightly with the excess vibrational energy; despite the large difference between the excitation energies (10.5 kK), the value of k_{ic} obtained by Geldof *et al.* is not very different from ours. Since the term for electronic interaction, β, may be assumed to be constant, and since $v^2=\beta^2\bar{F}$,[7,9,28] the product of the averaged Franck-Condon factor, $\bar{F}$, and the density of states, ρ, can be considered as a relatively slowly-decreasing function of the excitation energy.

second excited singlet state (^1L_a), which gives rise to a relatively strong band, naphthalene may be considered to meet the aforesaid criteria. The gas-phase fluorescence of naphthalene has thus far been studied by a number of workers,[31,37-39] some of whom attempted, but failed, to detect fluorescence from the second excited singlet state with ordinary exciting light sources.[31,38] The present author also examined the short-wavelength region of the fluorescence spectra, while varying the excitation wavelength, but no emission from an excited singlet state other than the first could be observed. The observed fluorescence and excitation spectra of naphthalene vapor, being similar to those already reported,[31,37,38] will not be presented here.

It can be expected that, by the substitution of an electron-donating group (-OH, -OCH_3) into the naphthalene ring, the ^1L_a state will come close in energy to the ^1L_b state, while the absorption intensities of the ^1L_b and ^1L_a bands and, hence, the associated radiative rates will also vary to some extent. In order to observe such substituent effects on the emissivity, the fluorescence spectra of 1-naphthol and 1-methoxynaphthalene were measured. As may be seen from Figs. 1 and 2, no emission from the ^1L_a state could be observed.

The reason why S_2 emission could not be found in these compounds can be considered in terms of the

b) Hereafter, $\bar{\nu}_{exc}$ will denote the excitation wavenumber at which the actual observation of the emissions was made.

estimated values of the radiative rate constants, the densities of states, and the related parameters listed in Table 1. The values of ρ for 1-naphthol and 1-methoxynaphthalene were assumed to be the same as that for naphthalene. As is indicated in Table 1, the calculated quantum yield ratios are so small compared with those of 'abnormal' molecules (*vide infra*) that the intensity of the S_2 emission may be expected to be too weak to be observed with conventional instruments. However, a more sensitive technique may permit its detection. In fact, quite recently Wannier *et al.*[40] could observe the resonance fluorescence from the second excited singlet state of naphthalene in the gas phase by utilizing a laser excitation source. It should be added, however, that the emission mechanism considered by them is very different from ours.[16]

Biphenyl, Phenanthrene, Triphenylene, and Chrysene. The absorption spectrum of biphenyl in solution shows a structureless intense band at about 40.5 kK and a weak band observed as a slight inflection around 36 kK.[41] It is thus interesting to see whether or not S_2 emission occurs in the gaseous state. As is shown in Fig. 3, the 35—42 kK region of the fluorescence spectrum does not vary with an increase in the excita-

c) An assumed wavenumber at which no fluorescence spectrum was observed.

tion energy. The observed large Stokes shift (4 kK) may be due to the change in the molecular geometry in the excited state.[41] The absence of S_2 emission in biphenyl is considered to be ultimately ascribable to the small ρ_2/ρ_1 values arising from the somewhat large energy separation between the first and second singlet states (~5 kK), as may be seen from Table 2.

Phenanthrene exhibits fairly well-structured fluorescence spectra on low-energy excitation and considerably broadened and red-shifted spectra on high-energy excitation, as is illustrated in Fig. 4. The spectral changes observed are uniform and gradual. In the 29—35 kK range of these spectra, however, no trace of S_2 emission can be found. The fluorescence spectra of triphenylene with excitation at various wavelengths are shown in Fig. 5. As the excitation wavenumber increases, the spectrum gradually becomes broader, and in the 29—35 kK range no S_2 emission is found. The reason for the absence of S_2 emission in phenanthrene and triphenylene is that the energy difference between S_1 and S_2 is quite large (6.0 and 6.2 kK respectively), as is indicated in Table 2.

The emission spectra of chrysene excited at several wavenumbers are shown in Fig. 6. The whole spectrum

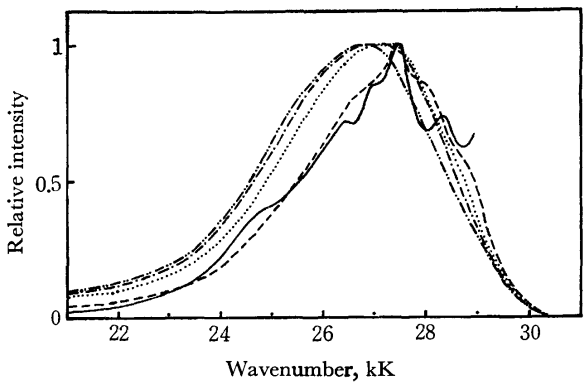

Fig. 4. The gas-phase fluorescence spectra of phenanthrene. Excitations at 30.3 kK (——), 35.2 kK (----), 39.2 kK (·····), 41.1 kK (-·-·), and 43.5 kK (-···-). At 113°C (~0.9 Torr).

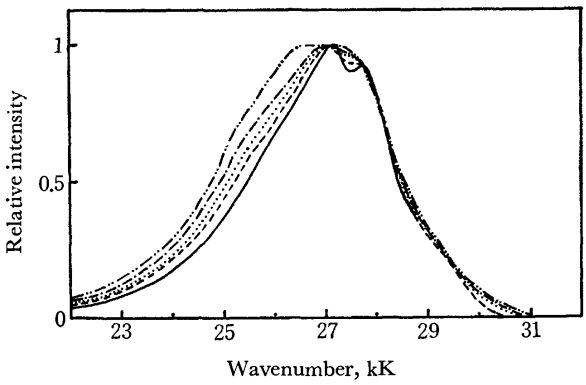

Fig. 5. The gas-phase fluorescence spectra of triphenylene. Excitations at 31.3 kK (——), 33.3 kK (----), 35.7 kK (·····), 38.5 kK (-·-·), and 41.7 kK (-···-). At 200°C (~0.032 Torr).

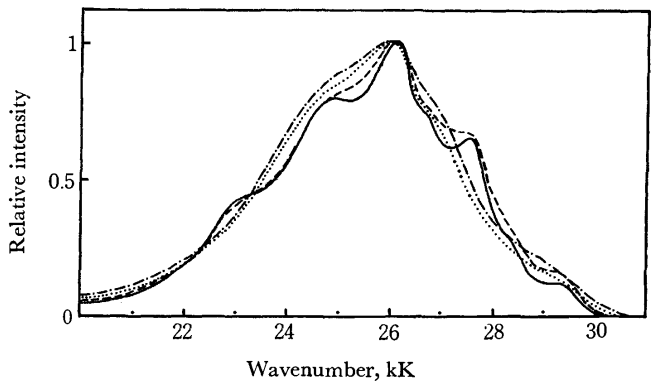

Fig. 6. The gas-phase fluorescence spectra of chrysene. Excitations at 32.5 kK (——), 35.0 kK (----), 38.5 kK (·····), and 40.8 kK (-·-·). At 212°C (~0.7 Torr).

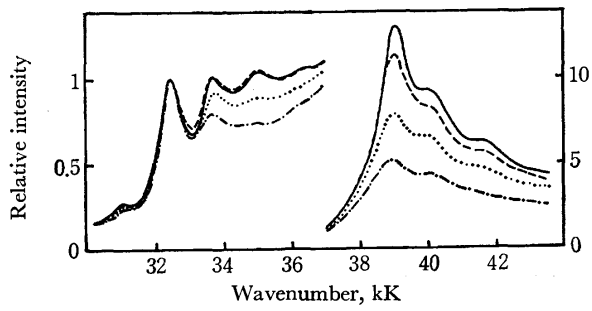

Fig. 7. The excitation spectra of chrysene gas. Emission observed at 25.0 and 26.3 kK (——), 27.5 kK (----), 28.6 kK (·····), and 29.2 kK (-·-·). At 210°C (~0.7 Torr).

41) H. Suzuki, "Electronic Absorption Spectra and Geometry of Organic Molecules," Academic Press, New York (1967).

becomes more diffuse on excitation at higher energies. The relatively well-resolved band at about 29.3 kK might be assigned to an S_2-emission band. However, this band is situated too far from the position of the second absorption band at about 32.5 kK; further, the behavior of the excitation spectrum is quite anomalous in that its relative intensity decreases with the increase in the monitoring wavenumber, as is shown in Fig. 7. Moreover, Table 2 indicates that the calculated Φ_2/Φ_1 values for chrysene are appreciably smaller than those of, for example, 1,2-benzanthracene (*vide infra*). This is also due to the large S_1—S_2 energy difference (4.9 kK). These facts imply that some impurity is possibly responsible for the emission observed around 29.3 kK.[42]

1,2-Benzanthracene and 20-Methylcholanthrene. As the criteria are well satisfied by 1,2-benzanthracene and its derivative, 20-methylcholanthrene, it is tempting to test the presence of S_2 emission in these molecules. The observation of the emission from the second excited singlet state of 1,2-benzanthracene in *n*-heptane solutions was reported by Easterly *et al.*[19] According to their interpretation. the emission arises from the thermal population of S_2 from S_1.[19] In the present study, the gas-phase fluorescence spectra of 1,2-benzanthracene and 20-methylcholanthrene were measured at various excitation wavenumbers; these are shown in Figs. 8 and 9. The observed spectra are relatively sharp and well-structured with low energy excitations. On excitation at higher wavenumbers, however, the spectrum broadens and shifts to the red, and the intensity on its short-wavelength tail increases appreciably. On the basis of its band position and spectral behavior, the emission appearing in the high-wavenumber region can be assigned to the S_2 emission.

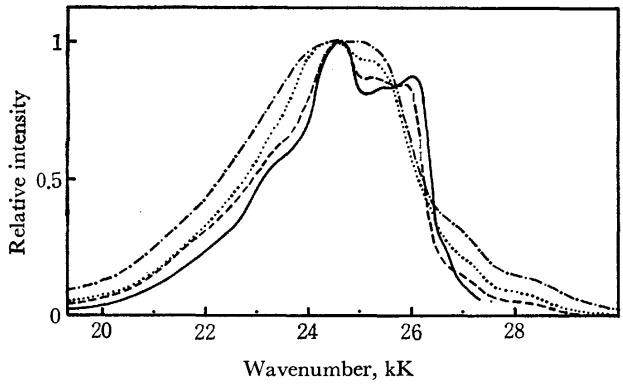

Fig. 8. The gas-phase fluorescence spectra of 1,2-benzanthracene. Excitations at 28.9 kK (——), 31.5 kK (——), 36.4 kK (·····), and 41.7 kK (-·-·). At 152°C (~0.01 Torr).

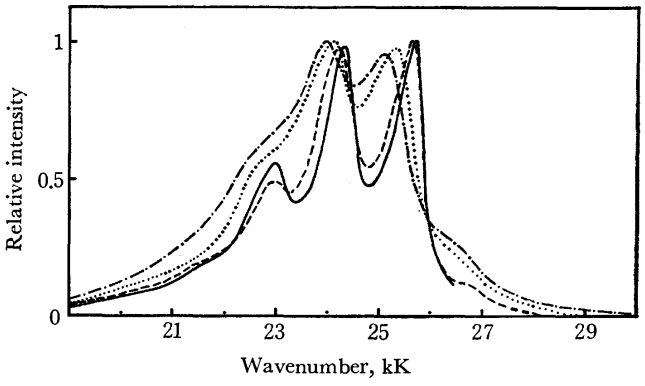

Fig. 9. The gas-phase fluorescence spectra of 20-methylcholanthrene. Excitations at 27.2 kK (——), 28.7 kK (——), 35.5 kK (·····), and 40.0 kK (-·-·). At 190°C (~0.065 Torr).

42) An alternative explanation may be that this band arises from the v—$v-1$ resonance fluorescence and that the anomaly in its excitation spectrum is caused by the considerable broadening of the band.

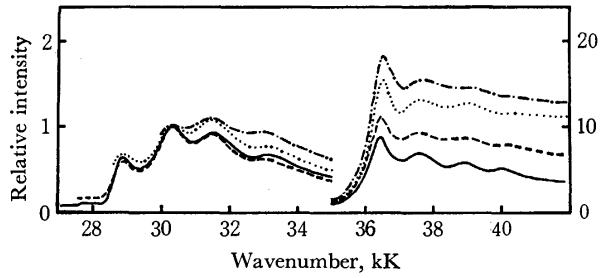

Fig. 10. The excitation spectra of 1,2-benzanthracene gas. Emission observed at 25.0 kK (——), 27.0 kK (——), 27.8 kK (·····), and 28.6 kK (-·-·). At 167°C (~0.024 Torr).

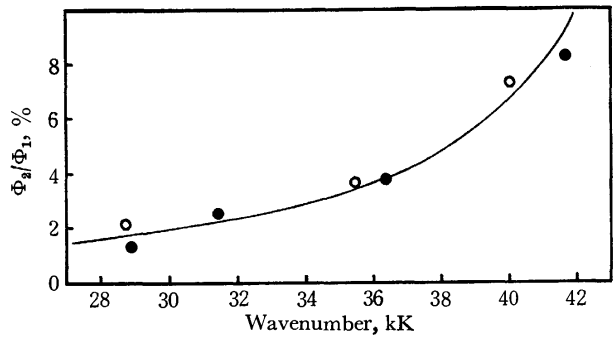

Fig. 11. The observed Φ_2/Φ_1 value *vs.* excitation wavenumber, for 1,2-benzanthracene (●) and 20-methylcholanthrene (○).

Figure 10 shows the excitation spectra of 1,2-benzanthracene, indicating that the relative intensity of the S_2 emission increases with the excitation energy. In Fig. 11, the observed ratio Φ_2/Φ_1 for 1,2-benzanthracene and 20-methylcholanthrene is plotted against the excitation wavenumber, showing the progressive increase in the former with the increase in the latter. Interestingly, the data on 20-methylcholanthrene give almost the same curve as those on 1,2-benzanthracene, as Fig. 11 shows.

The radiative rate constants, state densities, and related parameters are given in Table 3. The ρ values for 1,2-benzanthracene were substituted for those for 20-methylcholanthrene. As is shown in Table 3, the calculated relative yields of the S_2 emission are very large in these molecules, suggesting that the expectation regarding the appearance of the S_2 emission is quite realistic. The great enhancement of the S_2 emission by the substituent effects to be expected with 20-methylcholanthrene was not actually observed, however, as is shown in Fig. 9.

1,12-Benzperylene and Coronene. Dawson and Kropp reported an S_2 emission due to thermal repopulation

with 1,12-benzperylene in a poly (methyl methacrylate) matrix.[20] 1,12-Benzperylene shows absorption spectra with a very weak first band, followed by a much stronger second band, well satisfying the criteria. In coronene, the first and second absorption bands are extremely weak and closely spaced (α-band), accompanied by an intense third band (p-band).[43] This assignment was made in view of the relatively complicated structure of the 'α-band' and the theoretical results.[44-46]

The fluorescence spectra of 1,12-benzperylene and coronene measured in the gas phase and in benzene solutions are shown in Figs. 12 and 13. In benzene solutions the spectra exhibit quite distinct vibrational structures, with an enhanced 0—0 band indicative of the so-called Ham effect recently studied by the present author;[47] this effect can be utilized in the assignment of the vibronic bands.

As may be seen from Fig. 12, the gas-phase fluorescence of 1,12-benzperylene has an interesting feature. On the short-wavelength side of the weak 0—0 band observed as a small peak at 24.6 kK, a band corresponding to the solution band around 25 kK appears at about 25.1 kK, with an appreciably high intensity. In addition to this, another relatively intense band can be observed around 26.4 kK upon excitation at higher wavenumbers.

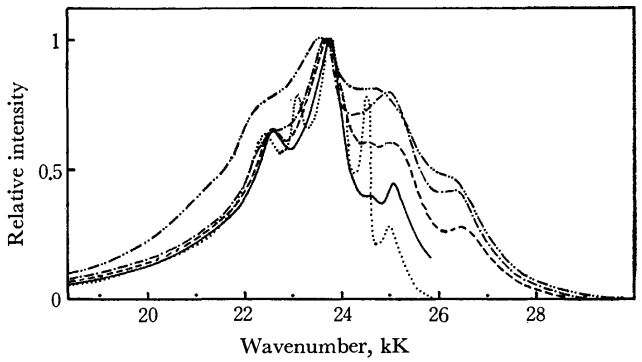

Fig. 12. The fluorescence spectra of 1,12-benzperylene. In the gas phase: excitations at 27.0 kK (——), 29.9 kK (----), 34.5 kK (-·-·), and 40.0 kK (-···-···-); at 210°C (~0.02 Torr). In the benzene solution: excitation at 28.6 kK (·····); at room temperature.

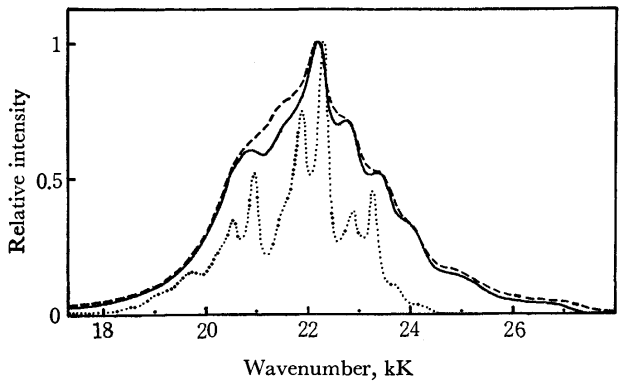

Fig. 13. The fluorescence spectra of coronene. In the gas phase: excitations at 30.1 kK (——) and 34.2 kK (----); at 285°C (~0.09 Torr). In the benzene solution: excitation at 29.5 kK (·····); at room temperature.

The excitation spectra monitoring on the three bands is shown in Fig. 14. Though these spectra differ considerably in relative intensity in the high-wavenumber region, their agreement with one another in wavenumber is very good, implying that these three bands originate from the same molecular species and not from impurities.

The emission observed around 25 kK in solution was

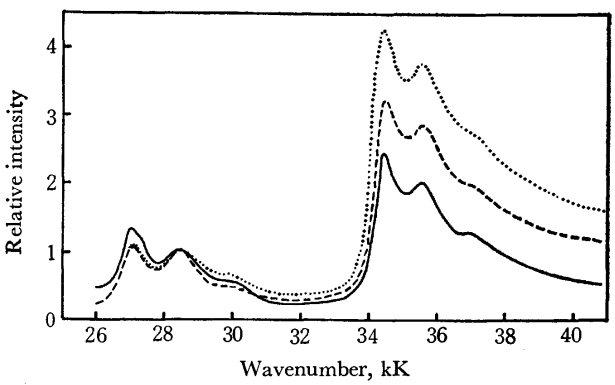

Fig. 14. The excitation spectra of 1,12-benzperylene gas. Emission observed at 23.7 kK (——), 25.0 kK (----), and 26.5 kK (·····). At 210°C (~0.02 Torr).

assigned by Kropp and Dawson[20] to the S_2 emission. If this is true, the bands appearing around 25.1 kK and 26.4 kK might be attributable to the S_2 and S_3 emissions respectively. However, the 0—0 absorption band of the second electronic transition is observed in the gas phase at 27.0 kK (see Fig. 14). Accordingly, it is preferable to assign the 26.4 kK band[48] to the S_2 emission. The 25 kK band, on the other hand, may be considered to be the 1—0 resonance emission band, overlapped by the higher vibrational components of the S_2 emission. This explanation seems to be consistent with the observation in the condensed phase by Kropp and Dawson of the temperature-dependent anti-Stokes band, which may, in our opinion, occur from an excited vibronic level.

The relative yields of the S_2 emission were estimated from the areas under the emission curves obtained on the assumption of a mirror-image relationship. The observed and calculated yield ratios are given in Table 4, showing that these ratios have appreciably large values and that they increase with the excitation energy.

The fluorescence spectra of coronene are also interesting, as is shown in Fig. 13. Excitation was made at the limited peaks (30.1 and 34.3 kK), because a weak impurity band was observed with excitation at lower wavenumbers and because the purification of coronene is notoriously difficult.[49] The fluorescence tail extending to the higher-energy region (24—29 kK) may be composed of S_2 and S_3 emissions. Since the relative intensities of these emissions could not be estimated separately, their yields were treated as a sum. As is shown in Table 4, the values of $(\Phi_2+\Phi_3)/\Phi_1$ observed are of a reasonable order of magnitude in comparison with those calculated in the manner described in the Appendix. The calculated value of Φ_3/Φ_1 was relatively small, of the order of 10^{-3}.

Anthracene, Tetracene, and Perylene. Since the second absorption band (^1L_b) in anthracene, tetracene, and perylene is quite weak compared to the first band (^1L_a), this is a case where the criteria are not satisfied. The gas-phase fluorescence spectra of these compounds were also measured, while varying the excitation wavelength, and the absence of any S_2 emission was shown. The spectral results were almost the same as those obtained by other workers[50-55] and so are not given in this paper. The failure of any S_2 emission to appear can be well understood by the very small values of Φ_2/Φ_1 calculated to be as is shown in Table 5.

TABLE 5. THE VALUES GIVEN FOR ANTHRACENE, TETRACENE, AND PERYLENE

a) Ref. 7.

Concluding Remarks

It has been shown that the density of states can play an important role in radiationless transitions; this is in contrast with the view of Siebrand,[56] who places more emphasis on the Franck-Condon factors. Despite our simple model, the tendency for the relative yield of the S_2 emission to increase with the excitation energy can be interpreted, though qualitatively, in terms of

48) The band seems to be affected by the reabsorption by the strong second absorption band.

the appropriately evaluated values of the state densities and the radiative rate constants. All the results obtained have proved consistent with the criteria previously mentioned, which can be restated on the basis of the first term in Eq. (6) that the S_2 emission can occur because of the large values of k_2/k_{1f} and ρ_2/ρ_1, the latter of which depends strongly on the energy difference. The contribution of the second term in Eq. (6), on the other hand, has been estimated to be comparatively small ($\lesssim 5\times10^{-3}$). In the case of azulene, it can be considered that k_{rp}/k_{ic} is very small because of the anomalously large S_1—S_2 energy separation, but k_{ic} is nearly comparable to k_2 because of the small Franck-Condon factors, so that the large second term permits the fluorescence emission from S_2. According to our results, in the molecule whose Φ_2/Φ_1 value is evaluated to be larger than about 0.01, there is a possibility for the S_2 emission to occur; this emission is essentially of an indirect nature. A strong laser excitation source would, however, be very useful for detecting a much weaker S_2 emission in a variety of compounds, including those studied in this work.

The participation of the triplet state has been neglected, but the vibrational relaxation by molecular collisions is so fast and complete during the sufficiently long lifetime of the triplet state that the molecule resulting in this state may contribute only to the quenching process.

The discrepancy between the observed and calculated yield ratios and, especially, the too great dependence of the calculated Φ_2/Φ_1 values on the excitation energy may be improved to some extent by considering the differences in the Franck-Condon overlap integrals for the individual vibrational modes; this must be done in a more elaborate study, irrespective of the model assumed.

Attention should be called to the assignment of the S_2 emission, which is generally made on the basis of the observations that it occurs in the short-wavelength region of the normal fluorescence and that its excitation spectrum almost agrees with the absorption spectrum. As has been suggested in the case of 1,12-benzperylene (and chrysene[42]), such behavior can be exhibited by the v—v—i resonance fluorescence in the gas phase or the thermally-excited vibronic band (hot band) in the condensed phase. This possibility requires further investigations designed to establish a method for an unambiguous identification.

In view of the interesting spectral features observed in 1,12-benzperylene and coronene, it seems worthwhile to make further studies of their gas-phase emissions.

The author wishes to express his thanks to Professors Junji Aoki and Hiroo Inokuchi for the gift of the sample of 1,12-benzperylene. His tahnks are also due to Mr. Masakatsu Aoi for his helpful discussions.

Appendix

The kinetics involving the third excited singlet state is considered, in which it is assumed that the direct conversion process between S_1 and S_3 is negligible. In Fig. 15 the

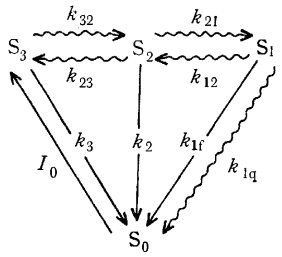

Fig. 15. Three-state scheme, with the rate constants for various radiative (——) and nonradiative (~~~) processes.

radiative and nonradiative processes concerned are represented, along with the definitions of the rate constants. According to this scheme, the rate equations can be expressed as follows:

$$dS_1/dt = k_{21}S_2 - (k_{1f}+k_{1q}+k_{12})S_1 \quad (7)$$

$$dS_2/dt = k_{32}S_3 + k_{12}S_1 - (k_2+k_{21}+k_{23})S_2 \quad (8)$$

$$dS_3/dt = I_0 + k_{23}S_2 - (k_3+k_{32})S_3 \quad (9)$$

where S_i is the concentration of the molecules in S_i. Under photostationary conditions, $dS_1/dt = dS_2/dt = dS_3/dt = 0$, from which the following formulae can be obtained:

$$\Phi_2/\Phi_1 = (k_2/k_{1f})(k_{12}/k_{21}) + k_2/k_{21}\phi_1 = \text{Eq. (1)} \quad (10)$$

$$\begin{aligned}\Phi_3/\Phi_1 &= (k_3k_{12}/k_{1f}k_{21})(k_{23}/k_{32}+k_2/k_{32}) + (k_3k_{23}/k_{21}k_{32} \\ &\quad + k_3k_2/k_{21}k_{32}+k_3/k_{32})(k_{1f}+k_{1q})/k_{1f} \\ &= (k_3/k_{1f})(\rho_2/\rho_1)(\rho_3/\rho_2+k_2/k_{32}) \\ &\quad + [(k_3/k_{21})(\rho_3/\rho_2)+k_2k_3/k_{21}k_{32}+k_3/k_{32}]/\phi_1, \end{aligned} \quad (11)$$

where the rate constants for the forward and backward conversion processes have been given by

$$k_{ij}/\rho_j = k_{ji}/\rho_i = (2\pi/\hbar)v_{ij}^2. \quad (12)$$

The Φ_2/Φ_1 ratio obtained by neglecting the S_1—S_3 conversion process and the quenching process from S_2 is identical to that given before for the two-state scheme, as is indicated by Eq. (10). On the basis of these expressions, the quantum-yield ratios for coronene are evaluated using the rate constants and state densities listed in Table 4. It was assumed that $k_{32}\sim k_{21}\sim 10^{12}$ (sec^{-1}).

Dielectric Dispersion at Meter Waves of 1-Hexanol and 1-Octanol in Cyclohexane Solutions

Hitoshi KOMOOKA

School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo

(Received January 13, 1972)

The dielectric constants and losses of 1-hexanol and 1-octanol in cyclohexane solutions were measured in the frequency range 60—480 MHz at various temperatures. The values $\varepsilon_0-\varepsilon_\infty$ deviate widely from the linear dependence on concentration. The curve of $(\varepsilon_0-\varepsilon_\infty)/c$ plotted against concentration c falls rapidly as c decreases. Its value seems to be zero at the concentration of 1 mol/*l*. A comparison with the values of higher alcohols given in literature shows that the curve is almost uniquely determined for each temperature as a function of the concentration of hydroxyl group alone, irrespective of the length of C–C chain in alkyl group of alcohols. As shown by Ibbitson and Moore, there exist considerable amounts of dimers, trimers and cyclic polymers in the dilute solutions of 1% by weight. The cause for the large values of dielectric constant cannot be merely attributed to the formation of hydrogen-bonded aggregates of molecules. A possible structure of the aggregates is discussed.

Since Mizushima[1] investigated the dielectric dispersion of alcohols in 1927, studies in this field have been made by several authors with various methods. Lebrun[2] measured the dielectric constants and losses of 1-heptanol, 1-octanol, 1-nonanol, and 1-decanol at 20°C in the frequency range $1—9.5\times10^3$ MHz, obtaining two relaxation times. Garg and Smyth[3] measured those of ten normal alcohols from propyl through dodecyl in the wavelength range 30,000—0.22 cm. They analyzed the dispersion into three separate regions. The dispersion process with the longest relaxation time was attributed to the breaking of the hydrogen bonds in molecular aggregates followed by the rotation of alcohol molecules.

Measurements on dilute solutions of alcohols were carried out by Johari and Smyth.[4] It was shown that normal alcohols in dilute benzene solutions have two relaxation processes instead of three, lacking the one attributable to the associated molecules.

Theoretical studies on the dielectric constant of liquid were made by Onsager, Kirkwood[5] and others. Kirkwood succeeded at least qualitatively in explaining the large values for alcohol. His theory is by no means satisfactory. It does not take into account the existence of three relaxation processes in liquid alcohols. The lowest frequency relaxation process dominates in the dispersion region. A study on the process would help elucidate complicated problems with regard to liquid structure.

The dielectric constants and losses of alcohols have been determined. Cyclohexane was selected as a solvent among others, because the value $\varepsilon_0—\varepsilon_\infty$ for the solution of an alcohol is nearly equal to that of the other, if the concentrations of hydroxyl group are equal to each other, although the relaxation frequencies are quite different.

Experimental

Purification of Materials. 1-Hexanol was washed with a 10% solution of sodium hydroxide and distilled through a 50 cm column under reduced pressure. The middle portion was distilled fractionally through a 1 m column packed with Dixon packings at 30 Torr. About 20% of the distillates was separated off at a reflux ratio of 180: 1, in which at least four impurities were found to be present by gas chromatography with a column containing Silicone Oil SE-30 as a fixed phase liquid. Removal of one of them was difficult,[6] and seemed almost impossible by distillation at 50 Torr. In the middle fraction, there was no perceptible peak originating from impurity in its chromatogram. Molecular Sieve 5A was used as a drying agent.

1-Octanol was purified by the same method as described above except that it was distilled fractionally at 15 Torr. The gas chromatograms resembled those of 1-hexanol when the temperature of the column was elevated.

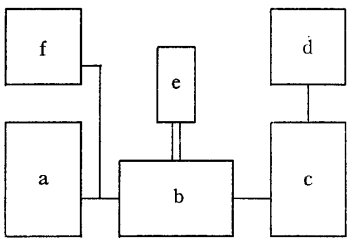

Fig. 1. Block diagram of the apparatus. a: signal generator hp 608C, b: VHF bridge hp 803A, c: VHF detector hp 417A, d: null detector hp 415E, e: sample holder, f: frequency counter.

Cyclohexane was washed with concentrated sulfuric acid, with mixed acid and again with sulfuric acid. It was distilled fractionally through a 1 m column packed with Helipack packings and dried with calcium hydride. Density 0.7738, n_D 1.4235, ε_0 2.016 at 25°C.

Apparatus. Dielectric constants and losses were measured with a Hewlet-Packard Type 803A VHF bridge which operates as a Byrne bridge. The setup for measurement is shown by a block diagram in Fig. 1. The error in the measurement of impedance, according to the specifications, may be within 2% in magnitude and within 1.2° in phase angle when the necessary corrections are made to the bridge readings.

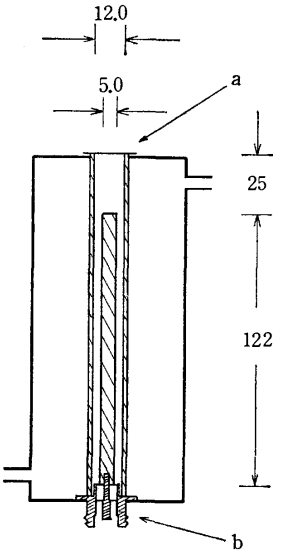

Fig. 2. Sample holder. a: thin glass plate, b: type-N jack. All dimensions in mm.

with dimensions in Fig. 2. Made of brass, it is an open-circuited coaxial line equipped with a N-female type connector at one end. As the outer conductor is 2.5 cm longer than the inner one, leakage of high frequency signals is effectively prevented. The electrical length and characteristic impedance of the cell were so determined that the measured values of the dielectric constant of cyclohexane, benzene and chlorobenzene agree with the values at low frequencies reported in various papers. The electrical length thus obtained is 12.5 cm, which is 0.3 cm longer than the physical length of the inner conductor. The characteristic impedance is 52.5Ω, which agrees with the value calculated from the dimensions of the cell.

The electrical length of the transmission line which connects the cell to bridge was about 9.2 cm. This showed slight variations with frequency within 0.1 cm.

Method of Calculations. The imput admittance Y of an open-circuited cell of coaxial type is given by

$$Y = i\frac{\sqrt{\varepsilon}}{Z_0}\tan\frac{2\pi\sqrt{\varepsilon}fl}{c} \tag{1}$$

if wall losses are neglected, where $\varepsilon(=\varepsilon'-i\varepsilon'')$ is the complex dielectric constant of a substance filled in the cell, c light velocity; Z_0 and l the characteristic impedance and electrical length of the cell, respectively. If we put

$$a = \frac{2\pi ifl Z_0}{c}Y \text{ and } z = \frac{2\pi i\sqrt{\varepsilon}fl}{c}, \tag{2}$$

a and z are complex numbers and fulfill the following equations:

$$a = z\tanh z \tag{3}$$

or

$$z = a\coth z. \tag{3'}$$

Equation (3') can be solved easily by means of successive approximations. If z_i is the i-th approximate value of z, the $(i+1)$-th approximation is given by

$$z_{i+1} = a - \frac{2z_i+\sinh 2z_i}{2a-1+\cosh 2z_i}. \tag{4}$$

Static value ε_0 and high frequency limit ε_∞ of dielectric constant and relaxation frequency f_r are calculated in the following way. By Debye's theory the following equations hold at each frequency f:

$$\varepsilon' = \varepsilon_\infty + (\varepsilon_0-\varepsilon_\infty)\frac{1}{1+(f/f_r)^2} \tag{5}$$

$$\varepsilon'' = (\varepsilon_0-\varepsilon_\infty)\frac{f/f_r}{1+(f/f_r)^2}. \tag{6}$$

From these equations, the relation

$$\varepsilon'' = \frac{1}{f_r}\varepsilon' f - \frac{\varepsilon_\infty}{f_r}f \tag{7}$$

can be derived. According to the method of least squares, we can choose $1/f_r$ and ε_∞/f_r so that the following expression is minimum:

$$\sum_i\left(\varepsilon_i'' - \frac{1}{f_r}\varepsilon_i' f_i + \frac{\varepsilon_\infty}{f_r}f_i\right)^2 = \min. \tag{8}$$

where ε_i' and ε_i'' are experimental values at frequency f_i. Then, ε_0 is calculated from

$$\sum_i(\varepsilon_i'-\varepsilon_\infty) = (\varepsilon_0-\varepsilon_\infty)\sum_i\frac{1}{1+(f_i/f_r)^2}. \tag{9}$$

Measurements. Dielectric constants and losses were measured at the frequencies 60, 80, 100, 150, 200, 250, 300, 400, and 480 MHz. Frequencies were controlled to be within ±0.1% of the specified values. Temperatures were kept constant by circulation of water from a thermostat through a jacket around the cell. No measurements were made for dilute solutions with relaxation frequency out of the frequency range.

Results

Some typical plots of complex dielectric constant $\varepsilon=\varepsilon'-i\varepsilon''$ for 1-hexanol and solutions are shown in Fig. 3. The plots for each liquid are on a semicircle within experimental error. It is sufficient if we consider a single dispersion process in each liquid in the frequency range where measurements are made. The observed dielectric constant and loss of 1-hexanol at 25°C are given in Table 1 with the calculated values from Eqs. (5) and (6).

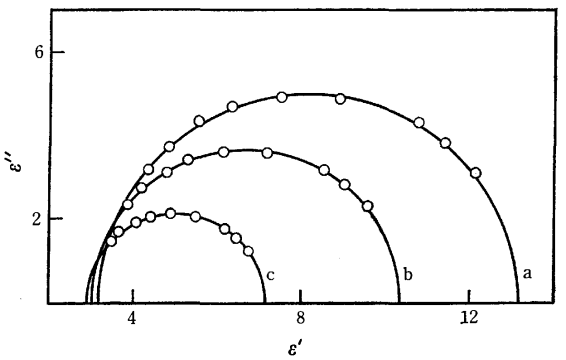

Fig. 3. Complex dielectric constants of 1-hexanol in cyclohexane soltuions at 25°C. a: 100%, b: 80.12%, c: 60.44%.

The dielectric parameters calculated from Eqs. (8) and (9) of pure 1-hexanol and 1-octanol and cyclohexane solutions are given in Tables 2 and 3, together with the refractive indices measured by use of a Pulfrich refractometer and with densities.

Discussion

The value $\varepsilon_0-\varepsilon_\infty$ decreases rapidly with the decrease in the concentration of alcohol, as seen from Table 2 or 3. The ratio $(\varepsilon_0-\varepsilon_\infty)/c$ at 25°C is plotted against concentration c for both alcohols in Fig. 4. We see a large dependence of $\varepsilon_0-\varepsilon_\infty$ on concentration. The two curves are situated closely to each other; especially at low concentration below 4 mol/l they coincide within experimental error. This indicates that the magnitude of $\varepsilon_0-\varepsilon_\infty$ is mainly determined by the concentration of

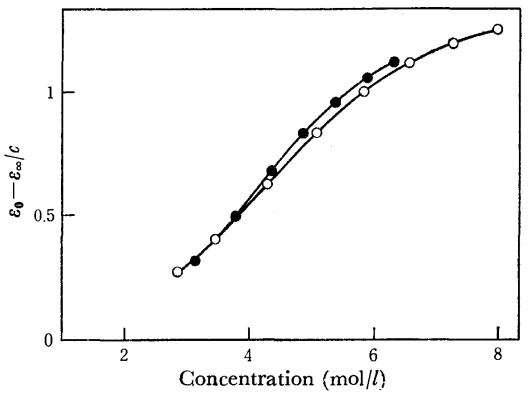

Fig. 4. Comparison of 1-hexanol and 1-octanol at 25°C. ○: 1-hexanol, ●: 1-octanol.

hydroxyl group irrespective of the length of C–C chain in alkyl group of alcohols. If it is proportional to the number of alcohol molecules per unit volume, these curves can be interpreted as representing the concentration dependence of the contribution of a molecule to dielectric dispersion. We see from Tables 2 and 3 that the variation of refractive indices of the solutions is so small that its influence can be ignored. It is suggested that a large change in the properties of alcohol molecules takes place in the concentration range 2—7 mol/*l*.

The situation stated above remains unchanged if we examine the concentration dependecne of

$$\frac{(\varepsilon_0-\varepsilon_\infty)(2\varepsilon_0+\varepsilon_\infty)\,T}{\varepsilon_0(\varepsilon_\infty+2)^2c}$$

according to Onsager's equation in which ε_∞ is used in place of n^2. The two curves plotted in Fig. 5 represent the relation. We cannot consider these curves to represent the concentration dependence of Kirkwood's *g*-factor. The value 31.6 for pure 1-octanol becomes 8.4 at the concentration of 2.4 mol/*l*; the ratio 31.6/8.4= 3.76 is much greater than the value 2.57 of *g*-factor calculated for normal alcohols.[7] Other equations for the dielectric constant of liquid will give the same conclusion.

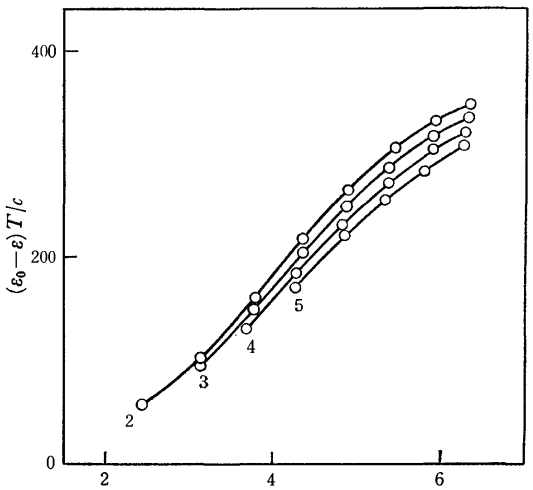

Fig. 7. Plots of $(\varepsilon_0-\varepsilon_\infty)T/c$ for 1-octanol against concentration.

In Figs. 6 and 7, the values $(\varepsilon_0-\varepsilon_\infty)T/c$ are plotted against *c* at various temperatures for 1-hexanol and 1-octanol in cyclohexane solutions, respectively. In order to facilitate comparison of the curves at different temperatures, the values in the ordinates are multiplied by the absolute temperature. The slope of these curves at middle concentration is steep at low temperature. With increasing temperature, it becomes gradual and the curve shifts toward high concentration side as a whole. If we extrapolate the curves to lower concentration, their values vanish in the vicinity of 1 mol/*l*.

The curves seem to indicate that the mechanism of association to hydrogen-bonded polymers which have an anomalously large dielectric constant is of co-operative nature. At sufficiently low concentration, the percentage of alcohol molecules which form the polymers will be zero; when the concentration reaches a certain value near 1 mol/*l*, the percentage will begin to increase; with increasing concentration, the percentage increases rapidly and finally it would attain a saturated value if the concentration increased further beyond that of pure alcohols. It is easy to explain the large temperature dependence of dielectric constant of the alcohols if we assume the mechanism of co-operative nature.

Ibbitson and Moore[8] reported that alcohols in the dilute solution of 1% by weight have two near infrared absorption bands besides the one attributable to monomers. The two bands were attributed to the presence of dimers, trimers and cyclic polymers. They also found that, with the appearance of the two bands, the solute polarization began to decrease from a constant value at lower concentrations. Therefore, we cannot expect a considerable amount of molecules to form the polymers with large dielectric constant at such concentration.

8) D. A. Ibbitson and L. F. Moore, *J. Chem. Soc B*, **1967**, 76.

The saturation property can be inferred from the values $(\varepsilon_0-\varepsilon_\infty)\,T/c$ for pure alcohols. The calculated values from the data by Saxton *et al.*[9] are 331 and 354 at 20°C for methanol and ethanol, respectively; 382 for 1-propanol, 395 for 1-butanol and 378 for 1-pentanol from the data tabulated by Brot, Magat, and Reinisch[10] at the same temperature. Smaller values for methanol and ethanol might be due to the smallness of their refractive indices.

The points for 1-heptanol, 1-nonanol, and 1-decanol calculated from Lebrun's experiments lie approximately on our curve as seen from Fig. 6.

The polymers are supposed to have the structure of nets composed of alcohol molecules bridged by hydrogen bonds. The two dimensional spread is necessary for co-operative phenomenon. It can be easily imagined that chain multimers and cyclic polymers join together to form a net when concentration increases.

The author is grateful to Professor Hideo Okabayashi for his kind guidance and encouragement throughout this work, and to Mr. Takei and Mr. Shinomiya for their advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1700—1704(1972)

Mass Spectrometric Analysis of Water-insoluble Yellow Monoazo Pigments

Kousuke KOBAYASHI and Kazutoyo HIROSE

Dai-Nippon Ink Institute of Chemical Research, Kamikizaki, Urawa, Saitama

(Received May 19, 1971)

Water-insoluble Yellow Monoazo Pigments were examined in order to establish a new analytical system using mass spectrometry. The characteristic ions observed were as follows: molecular ions, amine-component ions which are formed by the scission of the amide bond with hydrogen transfer and which are the most intense ones, ions at *m/e*: 43, and, in some cases, further-decomposed ions from the amine-component ions. A new analytical system was established on the basis of the analysis of the mass fragmentations of 27 samples, and applied to three unknown samples. The structure of these pigments can be deduced from the low-resolution mass spectra for those derived from substituted anilines, and from the high-resolution spectra for those derived from other amines.

Organic pigments have been widely used in many fields, such as printing inks, paints, plastics, and coatings. There have been many reports on the syntheses and physical properties of these pigments, but only a few on their analysis.[1] They are usually analysed by chemical methods, by infrared spectrometry, or by the X-ray diffraction method. The chemical analysis does not always give successful results in spite of its difficulty and its slowness. The latter two instrumental methods give information which can be compared with the known data, but not enough to elucidate their chemical structure.

On the other hand, mass spectrometry, developed recently in the field of organic chemistry, can be expected to give some information about the structure of organic pigments, because the pigments give molecular ions (as they have a long conjugated system in their structure) and because their chemical compositions can be practically determined by the high-resolution measurements. The final object of our research is to establish software for typing out the chemical structure of organic pigments after feeding the mass-spectrometric data into a computer. Some examples of such autoanalysis have already been reported in the cases of ketones[2] and fatty acid esters.[3] As the first step of our series of studies, we examined the mass-spectrometric analysis of Water-insoluble Yellow Monoazo Pigments (YMP) in order to find some characteristic peaks which differentiate them from other types of organic pigments, such as Water-insoluble Red Monoazo Pigments, and to determine the kind and location of the substituents.

Experimental

Apparatus and Measurement. The spectra were obtained using a JMS-O1SG double-focussing mass spectrometer (Japan Electron Optics Laboratory Co., Ltd.). Using 75 eV electrons at a regulated emission current of 200 μA, all the experiments were made by the electrical detection method under low-resolution conditions (*ca.* 1600); some results were also examined by the photo-plate detection method, using perfluoro kerosene under high-resolution conditions (*ca.* 20000), in order to confirm the elemental composition of the ions. Samples were introduced through a direct sample

Results and Discussion

Fragmentation Process. Some examples of the mass spectra of YMP are shown in Fig. 1. In all cases except YMP-12, the most intense peak was the amine-component ion (Am^+) formed by the scission of the amide bond with hydrogen transfer. Furthermore, the molecular ion (M^+) and the ion at *m/e*: 43 ($Ac^+=CH_3CO^+$) were observed in every sample. When Am^+ has a methoxy or carbomethoxy group, a further-decomposed ion (Ad^+) was also observed at an appreciable intensity. The pattern coefficient, based on Am^+, and the sample-vaporizing temperature of each sample are shown in Table 2. The intensities of M^+, Ad^+, and Ac^+ were 10—50%, 10—40%, and 10—60%, respectively, based upon that of the base peak with some exceptions.

The fact that the scission of the amide bond with hydrogen transfer gives the most intense peak was also observed in *N,N*-diphenyl phenylacetamide.[4] In diphenyl acetanilide, an ion which arises from the scission of the amide bond with reverse hydrogen transfer was observed.[4] The cleavage of both sides of the carbonyl

a) An ion of this formula was not observed.

group in β-diketone[5] and that of both sides of the azo group in substituted azo benzene[6] have also been reported.

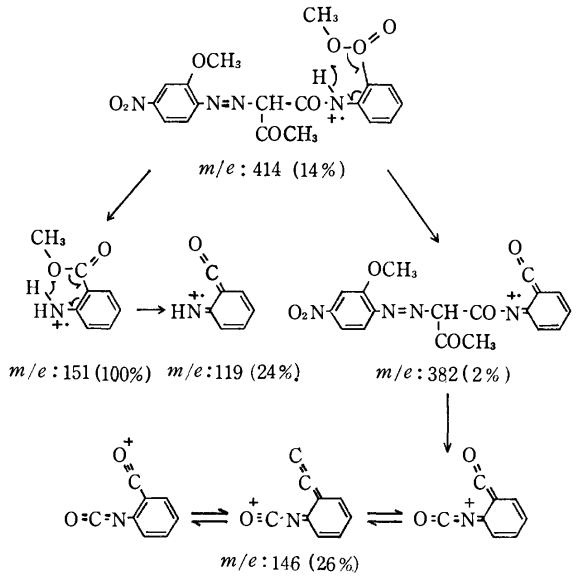
All the apparent peaks in each spectrum were examined by the high-resolution method; some of them are shown in Table 3 in the cases of YMP-1 and -10. The mean intensities of the ions were as follows (the intensity obtained is shown in parentheses):

Ar(Ai)–N=N–CH(COCH$_3$)–CO$^+$ (1)
Ar(Ai)$^+$ (<1)
Ar(Ai)–N=N$^+$ (1)
Ar(Bj)–NH$_2^{+\cdot}$ (100)
Ar(Bj)–N=C=O$^{+\cdot}$ (5)
Ar(Bj)–NH$^+$ (<1)
Ar(Bj)–NH–CO–CH(COCH$_3$)$^+$ (1)
Ar(Bj)–NH–CO$^+$ (2)
(M–43)$^+$ (3)
Ac$^+$ (49)
(M–17)$^+$ (<1)
Ar(Ai)–NH$^+$ (2)
Ar(Ai)–NH$_2^{+\cdot}$ (3)

The last ion, Ar(Ai)–NH$_2^{+\cdot}$, is assumed to be produced from the enol form of M$^+$ with hydrogen scrambling.[7] The formation of these ions can be similarly explained by the scission described in the above literature.[4-6]

When Am$^+$ has a methoxy group at the *ortho* or *para* position, Ad$^+$ was observed in every case at a position of 15 mass units lower than Am$^+$. Compounds possessing a carbomethoxy group at the *ortho* position showed two typical ions at *m/e*: 119 and 146. The formation of these unusual ions can reasonably be explained by the fragmentation process shown in Scheme 1. The transformation of Am$^+$ (*m/e*: 151) into Ad$^+$ (*m/e*: 119) is known as the *ortho* effect.[8]

Analytical Method of YMP. As has been mentioned above, M$^+$, Am$^+$, Ad$^+$, and Ac$^+$ are typical ions in the mass spectra of YMP. Ac$^+$ is a specific ion by which YMP can be distinguished from other types of organic pigments. The only exceptions are Water-insoluble Yellow Disazo Pigments, but they can easily be differentiated by their high molecular weights (over 600).



Scheme 1. Fragmentation process of YMP-7.

Usually YMP are synthesized from two aromatic amines. For example, a pigment with the general formula is synthesized from two amines, Ar(Ai)–NH$_2$ and Ar(Bj)–NH$_2$. If these amines are limited to substituted anilines, such as anisidine or toluidine, the structure of YMP can be decided on the basis of low-resolution mass-spectrometric measurements alone. The substituents, Ai and Bj, can be easily deduced from the following equations. The correlation in the mass among M$^+$, Am$^+$, and substituents is given by Eqs. (1) and (2), where M(X) represents the mass of X, and where m and n represent the number of substituents:

$$\sum_{i=1}^{m} M(\mathrm{Ai}) + \sum_{j=1}^{n} M(\mathrm{Bj}) = M(\mathrm{M}^+) - 281 + m + n \quad (1)$$

7) R. G. Cooks, I. Howe, and D. H. Williams, *Org. Mass Spectrom.*, **2**, 137 (1969).
8) H. Budzikiewicz, C. Djerassi, and D. H. Williams, "Mass Spectrometry of Organic Compounds," Holden-Day, San Francisco (1967), pp. 197, 279, 516, 636.

$$\sum_{j=1}^{n} M(\mathrm{Bj}) = M(\mathrm{Am}^+) - 93 + n \quad (2)$$

Equations (3) and (4) are obtained from Eqs. (1) and (2):

$$\sum_{j=1}^{n}(M(\mathrm{Bj})-1) = M(\mathrm{Am}^+) - 93 \quad (3)$$

$$\sum_{i=1}^{m}(M(\mathrm{Ai})-1) = M(\mathrm{M}^+) - M(\mathrm{Am}^+) - 188 \quad (4)$$

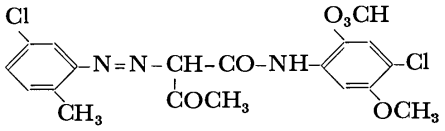
If Ai or Bj is the chlorine or bromine atom, the number and kind of these halogen atoms can be decided from the intensities of the isotope peaks of these ions. The methoxy or carbomethoxy group can be deduced from Ad^+, and the number of nitrogen atoms also be easily deduced by the application of the nitrogen rule.[9] If no appropriate combination can be found, the amines seem not to be simple substituted anilines. In this case, a precise mass determination would be very useful.

The position of the substituent cannot usually be decided on the basis of the mass spectrum, except in the cases of the methoxy and carbomethoxy groups mentioned above. However, the positions of the substituents are limited to some extent because of the difficulty of synthesis and the inferiority of the physical properties. We surveyed the literature and can now presume the position of the substituent from its structure with some statistical probability. In the case of the dimethylamino group, for example, *p-N,N*-dimethylaminoaniline alone has been used as the starting material.

Application to Unknown Samples (Fig. 2). *X-1*: M^+ and Am^+ were observed at *m/e*: 423 and 187 respectively. M^+ contains two chlorine atoms, and Am^+ contains one chlorine atom, showing that both substituents, Ai and Bj, contain one chlorine atom. Equations (3) and (4) give the following values:

$$\sum(M(\mathrm{Bj})-1) = 94, \quad \sum(M(\mathrm{Ai})-1) = 48$$

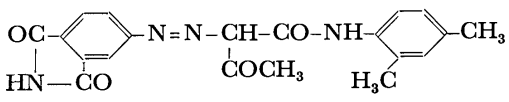
It is conclusively deduced that Ai consists of one chlorine atom and one methyl group, and that Bj consists of one chlorine atom and two methoxy groups, one of which is considered to be at the *ortho* of *para* position from the presence of Ad^+ at *m/e*: 172. The following structure was, then, considered most probable from the statistical viewpoint; it was confirmed by comparison with the compound synthesized.



X-2: M^+ and Am^+ were observed at *m/e*: 378 and 121 respectively. Neither ion contains a halogen atom. As Ad^+ was not observed, the methoxy and carbomethoxy groups are absent. The summation of the mass of substituents may be given as follows:

$$\sum(M(\mathrm{Bj})-1) = 28, \quad \sum(M(\mathrm{Ai})-1) = 69$$

Obviously Bj consists of two methyl groups or one ethyl group, but ethyl aniline has never been used as a starting material. As an appropriate combination of substituents for 69 mass units could not be found, the amine, $Ar(Ai)–NH_2$, used as the starting material seemed not to be a simple substituted aniline. The elemental composition of M^+ was determined to be $C_{20}H_{18}N_4O_4$ (calcd: 378.135, obsd: 378.133) by a precise mass determination. Therefore, the 69 mass units corresponding to $C_2H_{-1}NO_2$ may be presumed to be an imide group or acetylene plus a nitro group. The latter can, however, be rejected because of the absence of the 2200 cm^{-1} band in its infrared spectrum. Thus, the –CO–NH–CO– grouping appears to be most probable. Although the positions of methyl groups cannot be decided on the basis of the experimental results, 2,4-dimethylaniline seemed to be the most probable starting material. The following structure was, then, suggested; it was confirmed by comparison with the compound synthesized.



X-3: M^+ is an ion at *m/e*: 450 and contains two chlorine atoms. Am^+ is an ion at *m/e*: 221 or 194 and contains no chlorine atoms. Therefore, two chlorine atoms are contained in Ai. If Am^+ is an ion at *m/e*: 221, $\sum(M(\mathrm{Ai})—1)$ must be 41 mass units, which conflicts with the foregoing result. Therefore, Am^+ must be an ion at *m/e*: 194, and the mass numbers of the substituents may be calculated as follows:

$$\sum(M(\mathrm{Ai})-1) = 68, \quad \sum(M(\mathrm{Bj})-1) = 101$$

Ad^+ was observed at *m/e*: 166 and 165, which correspond to the loss of an ethylene and an ethyl radical from Am^+ respectively. From this fact, it was assumed that Am^+ contains an ethoxy group at the *ortho* or *para*

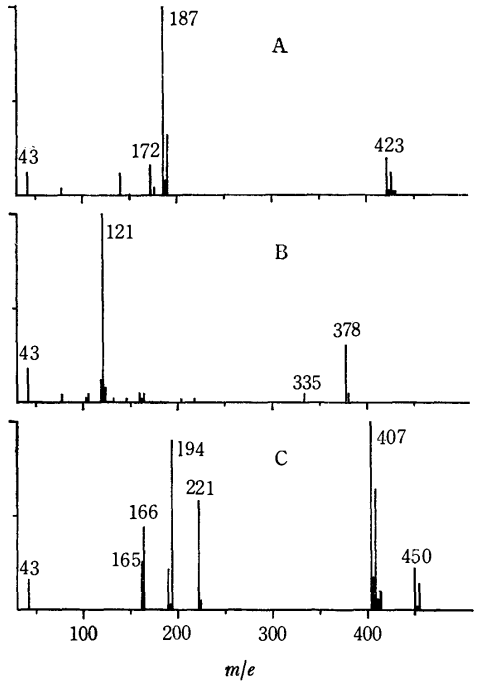


Fig. 2. Mass spectra of unknown samples.

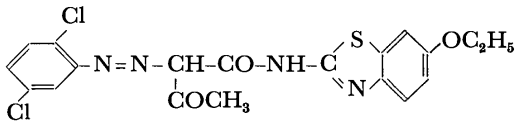
TABLE 4. HIGH RESOLUTION MASS MEASUREMENT OF X-3

Observed mass	Formula	Calculated mass	Standard ion structure
450.032	$C_{10}H_{16}N_4O_3SCl_2$	450.032	M^+
221.040	$C_{10}H_9N_2O_2S$	221.038	$Ar(Bj)-NH-CO^+$
194.053	$C_9H_{10}N_2OS$	194.051	Am^+
166.019	$C_7H_6N_2OS$	166.020	$Ad^+:Am^+-C_2H_4$
165.010	$C_7H_5N_2OS$	165.012	$Ad^+:Am_+-C_2H_5$

position.[10] By subtracting the mass of the ethoxy group from 101, the total mass of Bj becomes 57 mass units, which corresponds to methyl plus an amide group. As the combination of ethoxy, methyl, and amide groups has never been used, the elemental composition of M^+ was examined. The elemental composition of M^+ was $C_{19}H_{16}N_4O_5Cl_2S$ (Table 4); the 57 mass units described above corresponded to $CH_{-1}NS$, suggesting a thioisocyanate or thiazole ring.

10) K. Kobayashi, unpublished work (1970).

The former was rejected on the basis of its high reactivity. The following structure was, then, proposed as the most probable one and was confirmed by comparison with the compound synthesized:



Ions at *m/e*: 407 and 211, corresponding to $(M—43)^+$ and $Ar(Bj)-NH-CO^+$ respectively, were observed as intense peaks in this case alone.

The authors wish to express their thanks to Mr. K. Kurihara for his technical assistance and to Mr. K. Takagi and Mr. H. Sakai of Dai-Nippon Ink and Chemicals, Inc., for their generous support of this work. We are also sincerely grateful to Professor T. Takeuchi of Nagoya University for his constant interest and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1704—1708(1972)

Activation Analysis of Arsenic, Copper, and Antimony in Sea Water

Shiro GOHDA

Atomic Energy Research Institute, Kinki University, Kowakae, Higashi-Osaka

(Received September 16, 1971)

Arsenic, copper, and antimony in sea water were determined by the thermal neutron activation analysis. Convenient pre- and post-irradiation procedures were proposed and some samples were analyzed. Arsenic, copper, and antimony were collected by the cocrystallization with thionalide, and were irradiated for 30 min in the neutron flux of 2×10^{13} n/cm^2/sec. After the thionalide complex was decomposed with nitric acid, the copper and antimony were separated from the arsenic by precipitating with oxine, and the arsenic in the filtrate was coprecipitated with ferric hydroxide. Gamma-ray spectra were obtained and the decays of the 0.44—0.67 MeV photo peak of ^{64}Cu plus ^{122}Sb and the 0.55 MeV peak of ^{76}As were followed. The arsenic, copper, and antimony contents in sea water were estimated to be 1.12—1.71 μg As/l, 1.49—3.35 μg Cu/l, and 0.22—0.57 μg Sb/l.

Many workers have studied on the amount of arsenic and copper in sea water. Gorgy *et al.*,[1] Rakestraw and Lutz.[2] and Ishibashi *et al.*[3] determined the total amount of arsenic in sea water by the arsenomolybdate blue method or Gutzeit method, and found 15—35 μg As/l, 6—28 μg As/l, and 3—6 μg As/l, respectively. However, these methods give generally high values, that may result from arsenic impurity contained in the zinc and the acid employed, which sometimes exceeds the amount of arsenic in sea water. Smales and Pate[4,5] stated that the activation analysis could minimize the errors caused by the contamination from the reagents, and they found 1.6—5 μg As/l in sea water. Portmann and Riley[6] also gave the value of 2 μg As/l in sea water spectrophotometrically by molybdenum blue method, after concentrating arsenic by the thionalide cocrystallization.

The copper content in sea water have been reported to be in the range 1—20 μg Cu/l. Riley[7] searched for the favorable method for the determination of copper in such a low concentration, and pointed out that much of the earlier works were unreliable because of the poor analytical technique and the contamination. Brooks *et al.*[8] applied the atomic absorption spectrophotometry, and found 0.7—1.5 μg Cu/l in sea water; the value was in good agreement with Riley and Shinhaseni's data.[9] On the antimony content in sea

water, a few reports[10-12] have been published. Portmann[10] analyzed the Irish sea water samples spectrophotometrically and estimated to be 0.13—0.40 μg Sb/l.

Since the concentration of arsenic, copper, and antimony in sea water are very low, as described above, a suitable concentrating technique and sensitive analytical method have been desired. The neutron activation coupled with the thionalide cocrystallization seems to be one of the most attractive techniques, because of the simple and rapid procedure, the high sensitivity, and the minimum contamination. But ^{64}Cu, ^{76}As, and ^{122}Sb, which are available radioactive nuclides for the analysis, show the gamma photo peaks in the similar energy region. Moreover, the half-lives of ^{64}Cu (12.8 h) and ^{76}As (26.5 h) are too close to be used in the decay curve analysis. In this research, a simple and convenient chemical procedure for the neutron activation analysis of arsenic, copper, and antimony in sea water was recommended. These elements were concentrated by means of the thionalide cocrystallization, and after the neutron irradiation, copper and antimony were precipitated with oxine, arsenic was coprecipitated with ferric hydroxide, and the ^{76}As, ^{64}Cu, and ^{122}Sb activities were measured by the gamma-ray spectrometry. Some sea water samples were analyzed by this method, and furthermore, to search on the dissolved form of these elements, the particle size distribution of the elements was also investigated.

Experimental

Materials. Thionalide solution, 2% (w/v); 2 g of thionalide (Thioglycollic-β-aminonaphthalide) was dissolved in acetone and diluted to 100 ml with acetone. The solution was freshly prepared as required.

Sulfuric acid, 6N; Arsenic-free sulfuric acid was diluted with water.

Standard solution of arsenic, 10 μg/ml; 0.1607 g of arsenic trioxide was dissolved in diluted sodium hydroxide solution, which was neutralized with diluted sulfuric acid and diluted to 100 ml with water. This stock solution (1 mg As per ml) was diluted to make a working standard solution containing 10 μg of arsenic per ml.

Standard solution of antimony, 10 μg/ml; 0.2669g of potassium antimonyl tartrate ($K[Sb(C_4H_2O_6)(H_2O)]$) was dissolved in sulfuric acid and diluted to 100 ml with 6N sulfuric acid. This stock solution (1 mg Sb per ml) was diluted with 6N sulfuric acid to make a standard solution containing 10 μg of antimony per ml.

Standard solution of copper, 10 μg/ml; 0.3929 g of copper sulfate ($CuSO_4 \cdot 5H_2O$) was dissolved in water, and after 5 ml of 6N sulfuric acid was added, diluted to 100 ml with water. The stock solution was diluted to get a solution containing 10 μg of copper per ml.

Oxine solution, 2% (w/v); 2 g of 8-quinolinol was dissolved in 7 ml of glacial acetic acid and diluted to 100 ml with water.

All the other reagents were the reagent grade, and employed without the further purification. Redistilled water was used in all the procedures.

Apparatus. Gamma-ray spectra were obtained with a well-type 3″×3″ NaI(Tl) scintillation detector connected to a Hitachi Gammascope, Model RAH-403 (a 400 channel pulse height analyzer), and the radioactivity measurements in the tracer experiments were made with a 2″×2″ NaI(Tl) detector connected to a Hitachi scalor, Model RC-2.

Procedure. *Pre-irradiation*: Immediately after the sampling, 1 l of sea water was successively filtered through a 8 μ pore-size Millipore filter and a 0.45 μ pore-size Millipore filter. To the filtered sample was added 0.3 g of ascorbic acid, and the solution was heated just under the boiling point, for 30 min (to reduce arsenic(V) to arsenic(III)). After 5 ml of 6N sulfuric acid and 8 ml of 2% thionalide acetone solution were added to the cooled solution with vigorous stirring, and the solution was boiled for about 30 min and then allowed to stand overnight at room temperature. The precipitate was filtered with a Millipore filter (pore size; 0.45 μ) and washed with water.

Irradiation: Two Millipore filters employed for the filtration of sea water sample and the filter including the thionalide precipitate were separately packed in three polyethylene capsule (8 mm long×12 mm in diameter), which were stuffed in a polyethylene rabbit tube. The sample and the standard material were irradiated for 30 minutes in a neutron flux of 2×10^{13} n/cm^2·sec in KUR.

Post-irradiation: After cooling a few hours, the irradiated sample was treated with 20 ml of nitric acid containing 5 mg of copper, 1 mg of arsenic, and 0.3 mg of antimony carriers, and was decomposed by fuming to almost dryness. The residue was dissolved with 3 ml of 1N nitric acid, and copper and antimony were precipitated as the oxinates by adding 5 ml of 2% oxine solution at pH 7—8. Arsenic remaining in the filtrate was coprecipitated with ferric hydroxide at pH 8 by adding 10 mg of ferric ion, after the excess oxine was removed as the copper chelate (10 mg of copper was added).

Radioactivity Measurement: The copper and antimony oxinates and the ferric hydroxide precipitates were used for the gamma ray spectrometry of ^{64}Cu, ^{122}Sb, and ^{76}As. For the hydroxide precipitate, the 0.55 MeV photo peak of the gamma rays following to the decay of ^{76}As was measured. For the oxinates precipitate, the decay of the photo peak area from 0.44 to 0.67 MeV, which was the sum of the 0.51 MeV annihilation gamma rays of ^{64}Cu and the 0.57 MeV gamma rays of ^{122}Sb, was followed for one week.

Results

Thionalide Cocrystallization of Copper, Arsenic, and Antimony. In order to establish the pre-irradiation procedure, the conditions for the cocrystallization, such as the acidity of sulfuric acid and the amount of thionalide, were studied by using the radioactive tracers, ^{64}Cu, ^{76}As, and ^{124}Sb.

The tracer and 5 μg of the carrier were added to 1 l of sea water, and the recovery of the cocrystallization with thionalide was obtained by comparing the gamma activity with that of the original tracer solution.

1) Effect of Sulfuric Acid Concentration: The effect of sulfuric acid concentration on the recovery is shown in Fig. 1.

Copper(II), arsenic(III), and antimony(III), (V) are

almost quantitatively recovered in the range from 0.01N to 0.5N sulfuric acid concentration, while the recovery of arsenic(V) is incomplete in this range, and reaches to a maximum value (about 97%) at 0.5N sulfuric acid. The volume of sulfuric acid used must be as small as possible, for minimizing the contamination from the acid, and therefore, arsenic(V) is reduced to arsenic(III) with ascorbic acid, and the acidity is maintained at 0.03N.

TABLE 1. RECOVERY OF ARSENIC, COPPER AND ANTIMONY USING VARIOUS VOLUME OF 2% THIONALIDE

Volume of thionalide added (m*l*)	% Recovery		
	As	Cu	Sb
3	62.8		
5	95.8	96.2	94.8
7	98.3	98.3	98.6
8	98.6	98.9	98.6
10	99.4		99.3
12	99.8	99.2	99.5
15	99.8		

2) Effect of the Amount of Thionalide on the Cocrystallization: The effect of the thionalide amount was studied by adding the different amount of 2% thionalide solution to 1 *l* of sea water containing the tracer, 5 μg of the carrier and ascorbic acid, which was kept at 0.03N with sulfuric acid. The results are presented in Table 1. The recovery of more than 98 per cent can be obtained by addition of 7 m*l* or more of 2% thionalide solution, and therefore, in the further experiments, 8 m*l* of 2% thionalide is employed per 1 *l* of sea water.

Chemical Separation with Oxine. Because ^{64}Cu and ^{76}As emit the gamma rays of the similar energies and have the half lives not so different from each other, neither the gamma ray spectrometry nor the decay curve analysis was successful to estimate the activity of each of the nuclides. The post-irradiation procedure, described above, was designed and preliminarily tested by the tracer experiments. The precipitate of oxinates was filtered with a glass filter, then dissolved into hydrochloric acid solution of a constant volume

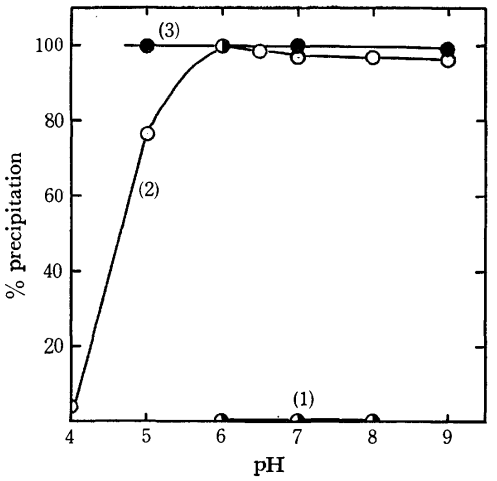

Fig. 2. Effect of pH on the precipitation of oxinates.
(1): As, (2): Sb-oxinate, (3): Cu-oxinate

and the gamma activity of the solution was compared with that of the same volume of original tracer solution. The percentage of precipitation *vs.* pH curves are shown in Fig. 2.

Copper and antimony are almost quantitatively precipitated in the pH range from 6 to 9, but arsenic remains in the solution, which is readily recovered by coprecipitation with ferric hydroxide at a pH between 6 and 9. The overall recovery in the pre- and post-irradiation procedures is to be 98.6±3.5%.

Analysis of Sea Water Samples. Sea water samples were collected from 11 stations, 137—139° E and 31—34° N. At the station No. 5, six samples were obtained from the surface to a depth of 500 m. Samples at stations No. 9, No. 10, and No. 11 were used for the study of the adsorption of arsenic, copper, and antimony on the vessel wall in the storage.

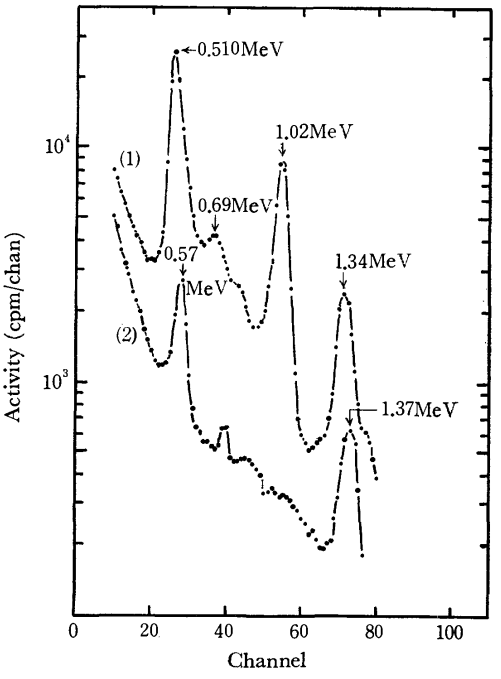

Fig. 3. Gamma-rays spectra of $^{64}Cu+^{122}Sb$ in sample (1): 10 h, (2): 125 h after irradiation.

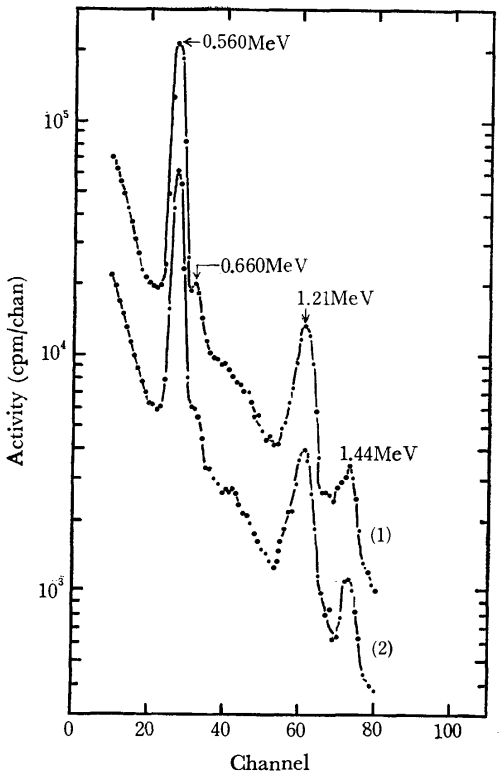

Fig. 4. Gamma-rays spectra of ^{76}As in sample (1): 10 h, (2): 25 h after irradiation.

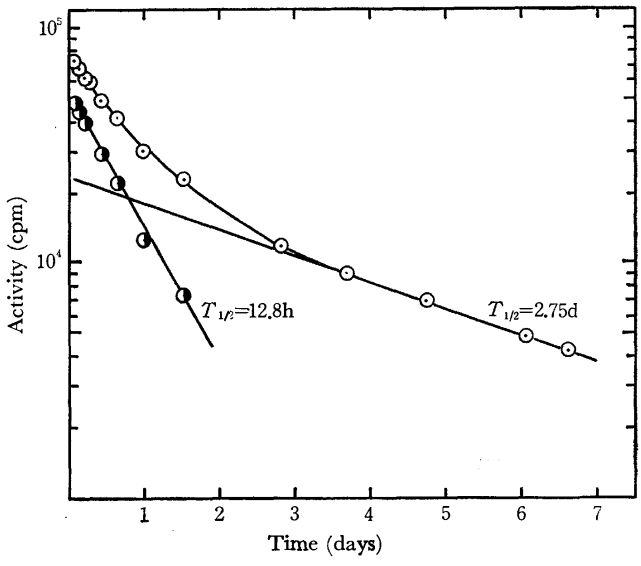

Fig. 5. Decay curves of $^{64}Cu(T_{1/2}=12.8\ h)$ and $^{122}Sb(T_{1/2}=2.75\ d)$.

These samples were analyzed according to the procedure described above. The typical gamma ray spectra of the copper and antimony fraction and the arsenic fraction are shown in Figs. 3 and 4, and the decay curves are presented in Figs. 5 and 6 respectively.

By the present procedures, 0.01 μg of arsenic, copper and antimony could be detected. However, the results of the blank test were as follows; As: 0.01—0.03 μg, Cu: 0.02 μg, Sb: 0.007—0.01 μg. The analytical results are summarized in Table 2. The relative error of the duplicated analysis was estimated to be within $\pm$5%.

Discussion

The total contents of these elements in sea water are in the range of 1.12—1.71 μg As/l, 1.49—3.35 μg Cu/l, and 0.22—0.57 μg Sb/l. The concentration of arsenic well agrees with the value of Portmann and Riley,[6] and the content of antimony also agrees with

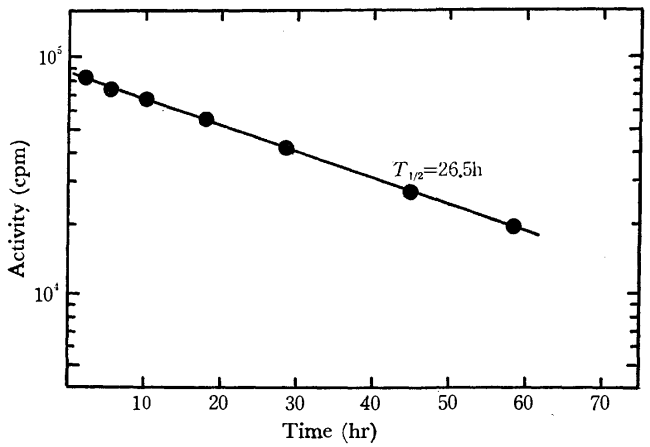

Fig. 6. Decay curve of $^{76}As(T_{1/2}=26.5$ h).

those of Noddack and Noddack,[11] Schutz and Turekian,[12] and Portmann and Riley.[10] The amount of copper is in the good agreement with the results of Fabricand *et al.*,[13] Riley and Shinhaseni.[9] and Brooks *et al.*[8]

The particle-size distribution suggests that the most parts of arsenic and antimony occur in soluble ionic state, passing through the 0.45 μ pore-size filter. 70—80% of copper exists in the particle species (about 50% distribution in the particles of larger than 8 μ, and 20—30%, in the particles of 0.45—8 μ), except for samples at station No. 4 and No. 5, in which about a half part of copper exists in the soluble ionic state. This phenomenon might be caused by the fact that the stations No. 4 and No. 5 were influenced by the Kuroshio Stream.

The vertical distributions of these elements were obtained at the station No.5. The total content and the particle size distribution slightly varried from the surface to 100 m depth, but in more than 100 m depth, they seemed to be almost changeless. After sample No. 9 was stored for 80 days, arsenic, copper, and antimony remaining in the solution and adsorbed on to the vessel wall were separately determined. For sample No. 10 and No. 11, the sample water was filtered with a 0.65 μ pore-size Millipore filter after the 30 days storage, and the analysis was made on the filtrate, the Millipore filter and the vessel wall. The results are shown in Table 3, from which it was deduced that the samples should be analyzed within a few days after the sampling.

Spectrophotometric Studies and Analytical Applications of Vanadium(IV) Chelates with 4-(2-Pyridylazo)resorcinol and 1-(2-Pyridylazo)-2-naphthol

S. P. MUSHRAN, Om PRAKASH, and J. R. VERMA
Chemical Laboratories, University of Allahabad, Allahabad, India
(Received May 1, 1971)

Oxovanadium(IV), VO^{2+}, gives sensitive colour reactions with 4-(2-pyridylazo)resorcinol ($\varepsilon=2.54\times10^4$ at λ_{max} 550 nm) and 1-(2-pyridylazo)-2-naphthol ($\varepsilon=1.02\times10^4$ at λ_{max} 560 nm). The composition of the complexes VO^{2+}: PAN or PAR was established by the continuous variations, mole ratio, and Asmus straight line methods. Lambert-Beer's law range, Ringbom optimum range, pH stability range, photometric error, and stability constant values were also evaluated.

The formation of coloured chelates of VO^{2+} with Alizarin red S,[1] chrome azurol S,[2] Pyrocatechol violet,[3] and Pyrogallol red[4] have recently been reported. Pyridylazo dyes particularly 4-(2-pyridylazo)resorcinol (PAR) and 1-(2-pyridylazo)-2-naphthol (PAN) have assumed importance in analytical chemistry as metallochromic indicators and colorimetric reagents for the microdetermination of a number of metal ions.[5-8] The present paper describes spectrophotometric studies on the composition, stability and analytical applications of VO^{2+} chelates with PAR and PAN.

Experimental

The metal salt ($VOSO_4\cdot H_2O$, Anala R. B.D.H.) solution prepared in water was standardized by titration with permanganate. The solution was flushed with pure nitrogen to check aerial oxidation of the metal ion. The solutions of PAR and PAN (E. Merck) were prepared in doubly distilled water and ethanol, respectively. Acetate buffer of pH 5.0 and 4.4 was used in VO^{2+}-PAR and VO^{2+}-PAN systems, respectively. Ionic strength was adjusted to 0.1 in VO^{2+}-PAR system and 0.05 in VO^{2+}-PAN system by the addition of sodium perchlorate solution.

A Beckman (DU) spectrophotometer with 10 mm^2 quartz cells was used for all absorbance measurements. For pH measurements a Leeds and Northrup direct reading pH meter with glass-calomel electrode assembly was used.

All mixtures were flushed with pure nitrogen and kept at 12°C in a water bath for 15 minutes and then absorbance was recorded. The total volume was kept at 25 *ml*. The VO^{2+}-PAR system was studied in aqueous medium and VO^{2+}-PAN system in 30% ethanol.

Results and Discussion

At pH>3 a water soluble red VO^{2+}-PAR chelate is formed and at pH 5—7 the colour of the chelate is red-violet and is intensified by the addition of excess of metal ion. The VO^{2+}-PAN chelate formation starts at pH>2 and a red violet chelate is formed at pH>3.5. The reagents are coloured yellow under these conditions. The pH *versus* λ_{max} plots (Fig. 1) show that the VO^{2+}-PAR system is stable at pH 5—7 and VO^{2+}-PAN at pH 4.7.

The absorption curves for the reagents PAR and PAN and their chelates with VO^{2+} were obtained by the method of Vosburgh and Cooper[9] (Fig. 2). At pH 5.0 λ_{max} of PAR is 410 nm and of VO^{2+}-PAR chelate 550 nm. The λ_{max} of PAN and VO^{2+}-PAN chelate at pH 4.4 are 470 nm and 560 nm, respectively. The λ_{max} of the chelates remain unchanged in small excess of reagent or large excess of metal concentrations showing the existence of only one chelate.

The composition of the chelate was studied by continuous variations (Fig. 3), mole ratio (Fig. 4) methods. The composition 1 : 1 (VO^{2+}: PAR or PAN) was established by the above methods. Application of Asmus[10] straight line method as extended by Klausen and Langmyhr[11] shows straight line at $m=1$ and $n=1$ (Figs. 5 and 6, where m and n are the number of metal atoms and ligand molecules, respectively, in a chelate molecule) establishing the formation of only one mononuclear chelate in each system having the composition 1 : 1 (VO^{2+}: PAR or PAN).

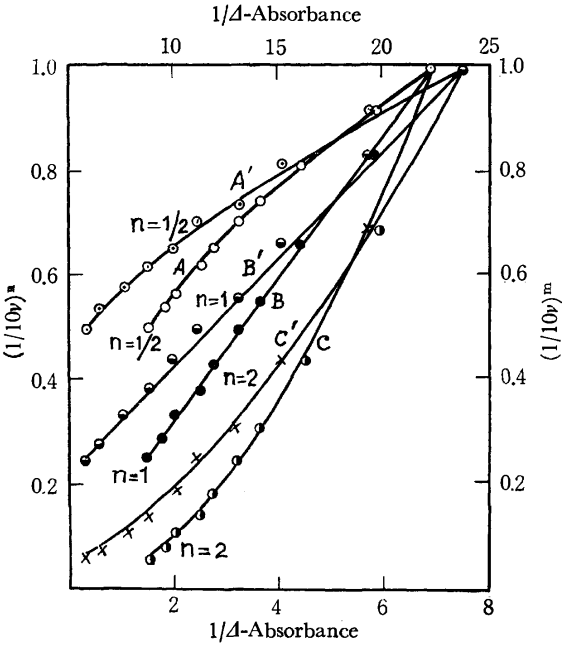

Fig. 5. Straight line plots, A, B, and C, VO^{2+}-PAR chelate in excess of $VOSO_4$ at pH 5.0, λ_{max} 550 nm, CM=2.0×10^{-3}M (1.0 ml), CR=2.0×10^{-3}M (0.1 —0.4 ml); A′, B′, and C′, VO^{2+}-PAN chelate in excess of $VOSO_4$ at pH 4.4, λ_{max} 560 nm, CM=1.0×10^{-3}M (1.0 ml), CR=1.0×10^{-3}M (0.1—0.4 ml).

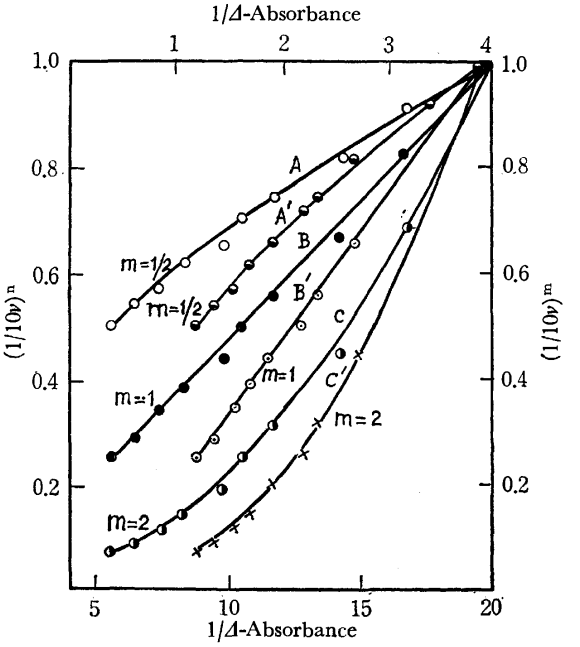

Fig. 6. Straight line plots, A, B, and C, VO^{2+}-PAR chelate in excess of $VOSO_4$ at pH 5.0, λ_{max} 550 nm, CR=2.0×10^{-3}M (1.0 ml), CM=2.0×10^{-3}M (0.1 —0.4 ml); A′, B′, and C′, VO^{2+}-PAN chelate in excess of $VOSO_4$ at pH 4.4, λ_{max} 560 nm, CM=1.0×10^{-3}M (1.0 ml), CR=1.0×10^{-3}M (0.1—0.4 ml).

The conditional stability constant values were evaluated by two different methods, (a) continuous variations using non equimolar solutions and (b) mole ratio. The stability constant (K) values along with the change in free energy of formation (ΔG) are summarised in the following table.

Table 1. Values of log K and ΔG of VO^{2+}-PAR and VO^{2+}-PAN chelates
(Temp., 12°C; μ=0.1 $NaClO_4$)

VO^{2+} complex with	Average log K	$\Delta G=-RT\log K$ (kcal/mol)	Method
PAR	6.3	−8.2	(a)
	7.2	−9.4	(b)
PAN	6.0	−7.8	(a)
	6.7	−8.7	(b)

For the photometric determination of vanadium(IV) with PAR and PAN, ranges of Beer's law were determined. These are VO^{2+}-PAR: 2.5—0.2 and VO^{2+}-PAN: 3.5—0.1 ppm of vanadium. For more accurate analysis the Ringbom[12] optimum range was determined by plotting log [V^{4+}] in ppm against % transmittance. The Ringbom optimum range of analysis for VO^{2+}-PAR system was found to be 2.0—0.3 and for VO^{2+}-PAN system it was computed as 3.0—0.6 ppm of vanadium. The photometric error was computed from the Ringbom plot using the Ayres[13] equation. The minimum % relative error per 1% photometric error was 0.3 for VO^{2+}-PAR system and 0.8 for VO^{2+}-PAN system. The sensitivity values in Sandell units are VO^{2+}-PAR 0.002 γ/cm^2 (at 550 nm) and VO^{2+}-PAN 0.005 γ/cm^2 (at 560 nm). The molar absorptivity values computed at the same wavelengths are 2.54×10^4 for the system VO^{2+}-PAR and 1.02×10^4 for the system VO^{2+}-PAN.

Procedure

For the determination of 2.0—0.3 ppm of vanadium(IV), take PAR in five times excess. Fix the pH at 5.0 using acetate buffer and flush with nitrogen. Measure the absorbance at 550 nm and compare with calibration plot. For the determination of vanadium(IV) in 3.0—0.6 ppm range, PAN is a suitable reagent. When using PAN, the mixture should contain at least-30% ethanol. The pH should be fixed at 4.4. The procedure is similar to that for PAR.

Effect of Diverse Ions

In the determination of vanadium (IV) with PAR at pH 5.0, V^{5+}, Nb^{5+}, Ta^{5+}, U^{6+}, Zr^{4+}, In^{3+}, Ga^{3+}, Al^{3+}, La^{3+}, Bi^{3+}, Y^{3+}, Sc^{3+}, Mn^{2+}, Zn^{2+}, Cu^{2+}, Co^{2+}, Ni^{2+}, Hg^{2+}, and Pb^{2+} give positive errors and Cr^{6+}, Mo^{6+}, W^{6+}, Th^{4+}, Cd^{2+}, Fe^{3+}, Mg^{2+}, Ca^{2+}, Ba^{2+}, Sr^{2+} do not interfere and interferences by Zr^{4+}, Y^{3+}, Al^{3+} are masked by adding 1 m*l* 0.4% fluoride solution.

In determination with PAN at pH 4.4, Mo^{6+}, W^{6+}, Os^{8+}, Nb^{5+}, Ta^{5+}, Ti^{4+}, Zr^{4+}, Th^{4+}, Al^{3+}, La^{3+}, Sc^{3+}, Y^{3+}, Fe^{3+}, Cr^{6+}, As^{3+}, Be^{2+}, Ca^{2+}, Ba^{2+}, Sr^{2+}, Mn^{2+}, Pb^{2+}, Cd^{2+}, Sn^{4+}, Mg^{2+}, Tl^{+} do not interfere while U^{6+}, V^{5+}, Ga^{3+}, In^{3+}, Bi^{3+}, Co^{2+}, Ni^{2+}, Hg^{2+}, Zn^{2+}, Cu^{2+} give positive errors.

In the determination of vanadium(IV) with PAR and PAN 100 fold excess of F^-, Cl^-, Br^-, I^-, SO_3^{2-}, NO_3^-, SCN^-, IO_3^-, NO_2^-, $S_2O_8^{2-}$, PO_4^{3-}, $B_4O_7^{2-}$ do not interfere.

The authors are grateful to the Council of Scientific and Industrial Research, New Delhi, for supporting the work and providing financial assistance to J.R.V.

Electron-transfer Reactions of Multidentate Ligand Cobalt(III) Complexes. IV. The Reductions of Cobalt(III) Complexes of Amino Acids by Iron(II) in Aqueous and Water-methanol Solutions

Kousaburo OHASHI, Katsumi YAMAMOTO, Ichiro HIRAKO, and Yoshimi KURIMURA*

Department of Chemistry, Ibaraki University, Mito

**College of General Education, Ibaraki University, Mito*

(Received September 17, 1971)

The kinetics of the Fe(II) reductions of *trans*(O,Cl)-Co(dien)(am)Cl^+ (am=glycine, α-alanine, β-alanine, leucine, and proline) and *trans*(N)-$Co(am)_2(ox)^-$ (am=glycine, α-alanine, β-alanine, ox=oxalate, and dien=diethylenetriamine) have been made spectrophotometrically in an aqueous solution. Except for the β-alanine complex, the reactivities of the Co(III) complexes are not very different when the amino acid is replaced by the other one. The greater reactivities of the β-alanine complexes may be due to the steric strain on the six-membered β-alanine chelate ring. The rates of the reductions of *cis*(N)-$Co(\alpha\text{-ala})_2(ox)^-$ and *cis*(N)-$Co(\beta\text{-ala})_2(ox)^-$ by Fe(II) are greatly affected by the addition of methanol to the aqueous solutions; the rate increases with an increase in the mol fraction of methanol. The replacement of water molecules in the solvation sphere of the reductant by the methanol molecules is considered to be one of the reasons for the greater rate in water-methanol solutions.

In the electron-transfer reactions of Co(III) complexes which proceed *via* the inner-sphere and outer-sphere activated states, the nonbridging ligand can appreciably affect the reaction rates.[1,6,7,9,10] The nonbridging ligand effect has been investigated mostly on the metal complexes with a uni-dentate bridging ligand.[1-10] Kinetic studies of the Fe(II) rdeuctions of Co(III) complexes, with oxalate ions as the bridging ligand, are very few, and the effects of amino acids as the nonbridging ligand in the Fe(II) reductions of Co(III) complexes have not been examined. In this connection, the Fe(II) reductions of *trans*(N)-$Co(am)_2(ox)^-$, and *trans*(O,Cl)-Co(dien)(am)Cl^+ were investigated.

The effect of organic solvents on the reduction rate of *cis*-$Co(en)_2NH_2CH_2CH_2OHCl^{2+}$ by Fe(II) was also examined previously.[11] In this study, we observed the increase in the rate upon the addition of such organic solvents as ethanol, acetone, dimethylformamide, and dimethylsulfoxide to the aqueous solutions. The reactivity of the Co(III) complex in an ethanol-water (0.5 mol fraction of ethanol) is about 10 times grater than that in an aqueous solution at $[H^+]=0.080$M. The reason for this grater reactivity is, however, yet uncertain. A further investigation of the Fe(II) reduction of Co(III) complexes in methanol-water was carried out using anionic Co(III) complexes such as *cis*(N)-$Co(\alpha\text{-ala})_2(ox)^-$ and *cis*(N)-$Co(\beta\text{-ala})_2(ox)^-$ in a methanol-water medium; those results will be also reported in this paper.

Experimental

Preparation of Complexes. The *trans*(O,Cl)-[Co(dien)(gly)Cl]ClO_4, *trans*(O,Cl)-[Co(dien)(α-ala)Cl]$ClO_4\cdot H_2O$, *trans*(O,Cl)-[Co(dien)(β-ala)Cl]ClO_4, *trans*(O,Cl)-[Co(dien)(leu)Cl]ClO_4, and *trans*(O,Cl)-[Co(dien)(pro)Cl]ClO_4[12] used as the oxidants were prepared by a method established by Ohkawa.[13] The configurations of these complexes with respect to diethylenetriamine were ascertained by means of the NMR spectra.[14] The coordinated chlorine atom in the *trans*(O,Cl)-Co(dien)(am)Cl^+ is located at the *trans*-positions to the coordinated oxygen atom of amino acid, and the diethylenetriamine occupies the *cis-trans* (mer) position in these complexes (Fig. 1).

16) This complex has two geometrical isomers. The linear behavior of the log (A_t-A_∞) *vs.* time plot for the Fe(II) reductions of this complex in aqueous solution indicates that the reactivities of the two isomers with Fe(II) are of almost the same degree or that the content of one isomer is relatively small as compared with that of the other one.

K[$Co(α\text{-}ala)_2(ox)$],[15] and *cis*(N)-,[16] and *trans*(N)-K[$Co(β\text{-}ala)_2(ox)$][17] compounds were prepared by the methods cited in the references. The purities and identities of the complexes were ascertained by microanalysis for carbon, hydrogen, and nitrogen and by comparing the absorption spectra with those reported in the literature.

The results of the microanalysis of carbon, hydrogen, and nitrogen for the complexes are presented in Table 1.

Materials. The preparation of the iron(II) solution and the determinations of the concentrations of the iron(II), hydrogen, and perchlorate ions in this solution were carried out by methods similar to those described in a previous paper.[6] Methanol of Tokyo Kasei, spectroscopic-grade, was distilled before use. The other chemicals used were G. R.-grade reagents. The concentration of the perchlorate anion in the reaction mixture was adjusted to 1.0M by the addition of sodium perchlorate.

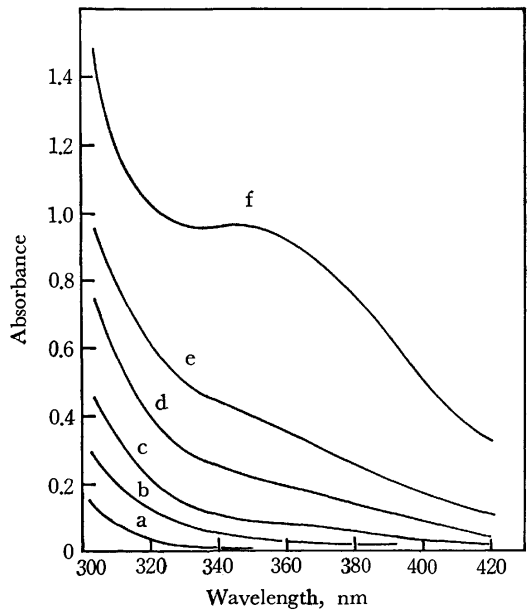

Fig. 2. Absorption spectra of ferric perchlorate in aqueous solution of methanol.

Measurement of Reaction Rate in Aqueous Solutions. The reduction rate was followed by the usual spectrophotometric method. The wavelengths used were the first absorption maxima of the complexes. For all the complexes, the kinetic runs were carried out under pseudo-first-order conditions.

Measurement of the Reaction Rate in Water-methanol Mixtures. The kinetic runs for *cis*(N)-$Co(α\text{-}ala)_2(ox)^-$ and *cis*(N)-$Co(β\text{-}ala)_2(ox)^-$ were carried out under pseudo-first-order and second order conditions respectively. The wavelengths used for the determinations of the rate constants were 535 nm for *cis*(N)-$Co(α\text{-}ala)_2(ox)^-$ and 550 nm for *cis*(N)-$Co(β\text{-}ala)_2(ox)^-$.

Absorption Spectra of Ferric Perchlorate in Methanol-water Mixtures. The absorption spectra of ferric perchlorate in aqueous solutions of methanol are represented in Fig. 2. The absorbances of the solutions in the near-ultraviolet region increase with an increase in the mol fraction of methanol. Such increases in absorbance were also observed previously by the addition of ethanol, acetone, dimethylsulfoxide, and dimethylformamide to an aqueous solution of ferric perchlorate.[11]

Results and Discussion

Reductions in Aqueous Solutions. The rate data obtained with $Co(dien)(am)Cl^+$ and $Co(am)_2(ox)^-$ listed in Table 2 show that; a) the β-alanine complexes have greater effectiveness than other complexes in the $Co(dien)(am)Cl^+$ and $Co(am)_2(ox)^-$ series; for example, the rate constants of the β-alanine complexes are greater than those of the corresponding α-alanine complexes by 114—140 times; b) the patterns of reactivity with respect to the amino acids are very similar in the two series; the ratios of the rate constant of the Co(III) complexes to the corresponding glycine complex (represented) by R values for α-alanine and glycine complex are in the ranges of 0.24—0.41 and 33—42 respectively; c) except for the β-alanine complexes, the reactivities of the amino acid complexes are not very different within the same series. The activation parameters for the reductions which were obtained from the temperature dependence of the rate constant are also listed in Table 2.

Since an oxalate-bridged mechanism has been demonstrated for the Fe(II) reductions of $Co(ox)_3^{3-}$ and

c) R_1 and R_2 represent the ratios of the rate constants to the corresponding glycine complexes.

$Co(NH_3)_3(H_2O)(ox)^+$ by observing the spectrum of Fe(III) product and by determining its rate of formation and decay,[18] and since the reactivity of $Co(NH)_4(gly)^{2+}$ with Fe(II) is negligibly small as compared with that $Co(NH_3)_4(ox)^+$,[19] it is reasonable to assume that the Fe(II) reductions of the $Co(am)_2(ox)^-$ proceed *via* oxalate-bridged activated states. For Co(dien)(am)-Cl^+, since the rate of the $Co(NH_3)_4(am)^{2+}$ with Fe(II) can be again ignored as compared with that of Co-$(NH_3)_5Cl^{2+}$ ($k=1.6\times10^{-3}M^{-1}sec^{-1}$, 25°C, $\mu=1.7$),[20] there is little doubt that the Cl^- is the bridging ligand.

These results, (a)—(c), seem to indicate the effect of the nonbridging ligand on the electron-transfer reaction. It is interesting to note here that the reactivity of the β-alanine complex is remarkably greater than that of the corresponding glycine and α-alanine complexes. The greater reactivity of the Co(III) complex with a six-membered chelate ring as compared with that of a five-membered one may be due to strain on the six-membered ring. Such a steric strain on the six-membered ring would reduce the energy needed for the reorganization of the nonbridging ligand in the Co(III) complex for the electron-transfer. The smaller enthalpies of the activation for the β-alanine complexes relative to those for other amino acid complexes seem to be responsible for the smaller reorganization energy for the β-alanine complexes. A part of the energy may consist of the energy for stretching the nonbridging β-alanine ligand away from the Co(III) center.[1,6]

Reduction in an Aqueous Solution of Methanol. The reductions of *cis*(N)-Co(α-ala)$_2$(ox)$^-$ and *cis*(N)-Co(β-ala)$_2$(ox)$^-$ by Fe(II) in a methanol-water mixture obey the first order dependence of the Fe(II) and Co(III) concentrations respectively. In an aqueous solution of methanol, the reactivities of these complexes increase sharply upon the addition of methanol to the aqueous solution (Fig. 3). In the previous work, it was found that the reduction rates of the cationic Co(III) complex, *cis*-$Co(en)_2NH_2CH_2CH_2OHCl^{2+}$, with Fe(II) in aqueous solution is accelerated in the presence of such organic solvents as dimethylformamide, dimethylsulfoxide, ethanol, and acetone.[11] Such an increase in the rate in a mixed solvent medium is contrary to the trend of electron-transfer reactions, such as $Co(phen)_3^{2+}$–Co-

$(phen)_3^{3+}$[21] and Fe^{2+}–Fe^{3+}.[22,23] The ratio of the rate constants in water (k_{H_2O}) and isopropanol (k_{alc}) for the Fe^{2+}–Fe^{3+} reaction was calculated by Sutin by assuming that the iron species are not changed in the two solvents. The obtained values of k_{alc}/k_{H_2O} are about 10^{-9} for the Fe^{2+}–Fe^{3+} reaction and about 10^{-6} for the Fe^{2+}–$FeOH^{2+}$ reaction.[22a] These values agree satisfactorily with that experimentally obtained when $[H^+]=0.01$M. However, Sutin pointed out that the predominat species may be quite different in the two solvents, as was suggested by the spectrophotometric measurements. If the reactants have larger differences in configuration in isopropanol than in water, the reorganization energy may be much greater in alcohol.[22a]

Though the formation of the mixed-ligand Fe(II), $Fe(H_2O)_{6-n}(CH_3OH)_n^{2+}$, has not been ascertained, the

progressive change in the absorption spectra of the Fe(III) perchlorate solution upon the addition of methanol to an aqueous solution (Fig. 2) would suggest the formation of a mixed-ligand complex such as $Fe(H_2O)_{6-n}(CH_3OH)_n^{2+}$.

The results of the present and of previous studies suggest that the rate increase with an increase in the concentration of organic solvents in the Fe(II) reductions of the cationic Co(III) complex, *cis*-$Co(en)_2NH_2CH_2CH_2OHCl^{2+}$, and anionic Co(III) complexes, *cis*(N)-$Co(\alpha\text{-ala})_2(ox)^-$ and *cis*(N)-$Co(\beta\text{-ala})_2(ox)^-$ proceed *via* the bridged activated states. In the organic substance-water media, the first coordination sphere of the ferrous ion may be changed from that in water; on the other hand, the replacement of the ligands in the Co(III) complex ions by the organic substance need hardly be considered because of the inertness of the complexes.

Consequently, the replacement of the water molecules in only the first coordination sphere of the reductant by organic solvent molecules is considered to be one of the most important reasons for the acceleration of the rate. However, no further discussion about the increase in the rate of electron-transfer reactions between the Co(III)-oxalate complexes and Fe(II) with an increase in the concentration of methanol in an aqueous solution could be made because of the present lack of much kinetic data on these effects.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1715—1719(1972)

The Reactions of ^{80}Br Activated by the (n, γ) Process with Methane

Masakatsu SAEKI, Kenshi NUMAKURA,* and Enzo TACHIKAWA
Division of Chemistry, Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken

(Received September 20, 1971)

The reactions of ^{80}Br activated by the (n,γ) process with CH_4 have been examined. By assuming that the limiting yields of products at 1.0 m.f. of the Kr-moderator is due to thermal ionic processes, the kinetic yields were tentatively determined to be the 12.4% for total organic, 11.4% for $CH_3{}^{80}Br$, and 1.0% for $CH_2{}^{80}BrBr$. A similar treatment of the results from the reactions with CD_4 gives 5.1% for total organic, 3.9% for $CD_3{}^{80}Br$, and 1.2% for $CD_2{}^{80}BrBr$. When the $CH_3{}^{80}Br$ yield was compared with that from the reactions of ^{80}Br from the (I.T.) activation, a noticeable difference was noticed; it was roughly 3 times as large as in the latter system. Furthermore, the pressure effects on the $CH_3{}^{80}Br$ show that a fraction of $CH_3{}^{80}Br$ is highly excited and is able to decompose even at a pressure of 1920 mmHg. This suggests that the distribution of ^{80}Br in the reaction energy range extends to a higher energy than in the case of ^{80}Br activated by the (I.T.) process.

The ^{80}Br atom activated by isomeric transition has a charge distribution ranging from +1 to +14, with a peak at +7 and an excess kinetic energy, as a result of a molecular explosion.[1,2] In previous papers[3-5] it was concluded that, in the reactions with CH_4, both kinetic-energy and kinetic-energy-independent processes are involved in the formation of organic products.

The (n,γ) activation process, on the other hand, results in ^{80}Br atoms and ions of a maximum kinetic energy equal to 358 eV when the ^{79}Br is a free atom. The maximum energy of ^{80}Br depends principally on the mass of the radical to which ^{79}Br is bonded.[6,7] However, the partial cancellation of prompt gamma-cascade momenta could result in a distribution of ^{80}Br from zero to the maximum, although most of the ^{80}Br energies will probably be formed with energies in a large excess of the reaction energy range, 18% of which is in a singly-charged state.[8] Thus, the study of the reactions of ^{80}Br from the (n,γ) activation is interesting with a view to comparing the reactivity of ^{80}Br activated by the (I.T.) process.

Rack and Gordus[9] investigated the reactions of ^{80}Br from the (n,γ) activation with gaseous CH_4 in an attempt to determine whether the reaction occurs principally because of the positive charge or because of the γ-recoil kinetic energy acquired by the ^{80}Br. The conclusion reached was that the reactions with CH_4 occur principally, if not completely, as a result of the recoil kinetic energy acquired by the atom in the activation. Later, Spicer and Gordus[10] conducted a gas-chromatographic analysis of the products and observed that 89% of the organic activity was due to $CH_3{}^{80}Br$, and 11%, to $CH_2{}^{80}BrBr$, and that the limiting organic yields at zero m.f. of Br_2 were 10.7% $CH_3{}^{80}Br$ and 1.3% $CH_2{}^{80}BrBr$.

However, in Rack's experiments,[9] the highest m.f. of

the moderator reached was 0.7. The previous work[5] in the (I.T.) experiments suggested that their extrapolation of the yields of the products to 1.0 m.f. of the moderator did not necessarily reflect the real yield-curve in highly-moderated systems.

The prime object of this paper is to examine the product-distribution from the reactions of ^{80}Br from the (n,γ) activation with CH_4 over the whole m.f. range of an inert moderator, Kr. The results obtained will be discussed in comparison with those in the (I.T.) experiments. Some experiments have also been performed on the isotopic variation between CH_4 and CD_4.

Experimental

The methane and Kr were supplied by the Takachiho Chemical Co., while the deuterated methane was supplied by Merck of Canada (its nominal purity was 99%). Those gases were used without purification.

Samples prepared in 18.5 m*l* silica bubblets usually contained about 1—10 mmHg of Br_2. The total pressure was kept constant at 500 ± 10 mmHg, except in the series of experiments where the yield variations of the products were measured as a function of the total pressure. Energetic (n,γ) activated ^{80}Br was formed by irradiating the samples for 5—60 sec in the JRR-4 reactor. The thermal neutron flux at the irradiation port was 2×10^{12} n/cm^2/sec. After irradiation, the ampoule was dipped into liq. N_2 within 1 min in order to stop further reactions; this was followed by the isomeric transition of ^{80m}Br. After the sample had been thawed by inserting it into warm water, it was divided into two portions using a vacuum-line technique. One portion was used to measure the decay of activities in the sample to obtain the total ^{80}Br activity involved. The other was directly injected into radio-gas chromatography. The relative yields of the individual products were obtained by dividing the activities in the radio-gas chromatograms by the total ^{80}Br activity.

The total organic yield was measured with samples with no additive. Separation into organic and inorganic fractions was achieved by the usual solvent extraction method.[5] The organic phase contained an activity, of which at least 98% was ^{80}Br, thus indicating that a proper chemical separation was achieved. After applying decay corrections, the total organic yield, O.Y. = 100 × organic activity/(organic + inorganic activities), was calculated. All the relative yields of the individual products have been corrected to percentage yields, using a correction factor determined from the sum of the relative yields and the total organic yield found in the sample with no additive.

The concomitant irradiation of Kr added as a moderator yields various radioactive Kr-isotopes. However, the species which must be taken into account in the irradiation 5 to 60 sec in duration are ^{85m}Kr, ^{87}Kr, and ^{79}Kr, the relative activities of which are 1.00, 0.633, and 0.016. The uncertainty as to the total ^{80}Br activity caused by their simultaneous presence was not significant, less than a few percent.

A contamination of the results from the $^{80m}Br(I.T.)^{80}Br$ process can be anticipated. When the isomeric transition occurred while the sample was dipped in a liq. N_2 bath, the reaction of the newly-formed ^{80}Br with the reactant can be ignored because of the clamping effect.[11] Thus, the error resulting from the isomeric transition can be estimated to be less than 1%.

11) J. A. Merrigan, W. K. Ellgren, Jr., and E. P. Rack, *J. Chem. Phys.*, **44**, 174 (1966).

The most serious error in this work seems to result from the non-uniformity of the components among the two divided portions. The accuracy of the present results is usually limited to ±10%. For most of the samples, 2 to 3 samples were made and worked with. The data are usually consistent within the limits of experimental error.

Results

The radio-gas chromatographic analysis of samples has shown that the main products from the reactions of (n,γ)-activated ^{80}Br with CH_4 or CD_4 are $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ or their isotropic analogues, much as in the (I.T.) experiments.

Table 1. The total pressure effect on products from the ^{80}Br–CH_4 system

Total Pressure (mmHg)	$CH_3{}^{80}Br$ (%)	$CH_2{}^{80}BrBr$ (%)
55	11.1±1.1	1.1±0.1
110	11.5±1.2	1.1±0.1
210	10.5±1.1	1.2±0.1
310	—	1.5±0.2
500	12.3±0.4	1.6±0.3
710	12.9±0.4	1.8±0.2
890	—	2.5±0.3
930	13.8±1.4	1.9±0.2
1560	14.9±1.5	2.3±0.2
1920	15.8±0.6	2.1±0.2

Table 1 summarizes the yields of the individual products obtained under various total pressures. In all cases, the Br_2/CH_4 ratio is in the range from 0.02 to 0.03. The $CH_3{}^{80}Br$ yield increases with an increase in the total pressure, at least up to 1920 mmHg; $CH_2{}^{80}BrBr$ increases at the beginning, but a further increase in pressure has no measurable effect on it.

Table 2. The percentage yields of products from the Kr-moderated ^{80}Br–CH_4 and ^{80}Br–CD_4 systems

m.f. of Kr	Reactant CH_4		Reactant CD_4	
	$CH_3{}^{80}Br$ (%)	$CH_2{}^{80}BrBr$ (%)	$CD_3{}^{80}Br$ (%)	$CD_2{}^{80}BrBr$ (%)
0.00	12.3 ±0.4	1.5 ±0.4	4.6 ±0.4	1.7 ±0.2
0.10	8.5 ±0.9	0.82±0.07	3.8 ±0.4	1.5 ±0.15
0.19	9.4 ±0.9	1.4 ±0.2	2.0 ±0.2	0.87±0.09
0.24	6.4 ±0.6	0.95±0.10	—	—
0.30	6.7 ±0.7	—	1.6 ±0.2	0.80±0.08
0.42	3.7 ±0.4	0.96±0.10	1.6 ±0.2	0.90±0.09
0.51	2.2 ±0.2	0.66±0.07	—	—
0.60	1.7 ±0.6	0.81±0.28	0.88±0.09	0.88±0.09
0.71	1.1 ±0.1	0.51±0.05	0.69±0.07	0.83±0.08
0.80	0.78±0.08	0.47±0.05	0.60±0.06	0.64±0.06
0.90	0.93±0.10	0.54±0.08	0.72±0.07	0.47±0.05

The moderator effects of Kr in these products have been examined while keeping the Br_2/CH_4 ratio in the range from 0.02 to 0.05. The results obtained are summarized in Table 2. The yields of the total organic products and of the individual products in the ^{80}Br–CH_4 system were 13.8±0.6% total organic, 12.3±0.4% $CH_3{}^{80}Br$, and 1.5±0.2% $CH_2{}^{80}BrBr$. In the ^{80}Br–CD_4

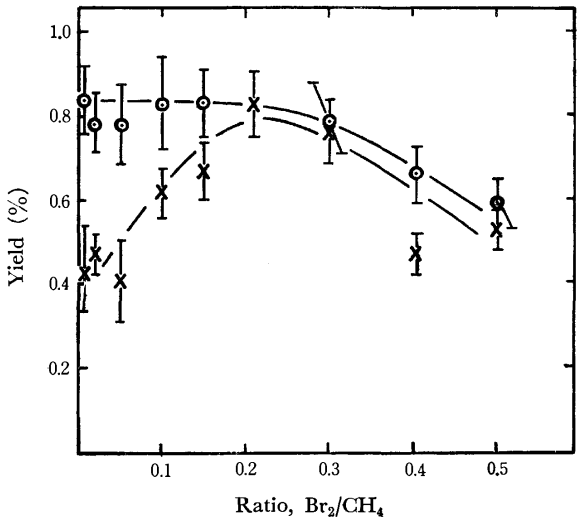

Fig. 1. Variations in $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ with the Br_2/CH_4 ratio in the reaction system in the constant presence of 100 mmHg of CH_4. (The total pressure was kept at 500±10 mmHg by adding Kr.)
⊙: $CH_3{}^{80}Br$, ×: $CH_2{}^{80}BrBr$

system, the yields were 6.3±0.6% total organic, 4.6±0.4% $CD_3{}^{80}Br$, and 1.7±0.2% $CD_2{}^{80}BrBr$. As the dilution of the reaction system by Kr proceeds, the yields decreased; the limiting values at 1.0 m.f. of Kr were 0.9±0.1% $CH_3{}^{80}Br$ and 0.5±0.1% $CH_2{}^{80}BrBr$, 0.7±0.1% $CD_3{}^{80}Br$ and 0.5±0.1% $CD_2{}^{80}BrBr$.

In order to make a comparison with the results obtained in the ^{80m}Br–CH_4 system,[5] the variation in $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ as a function of the ratio of Br_2/CH_4 has also been examined; the results are graphically depicted in Fig. 1. In all cases, the pressure of CH_4 was kept constant at 100 mmHg and Kr was added until the total pressure reached 500±10 mmHg. Under these conditions, the variation in Kr (400—350 mmHg) concomitantly with the increase in the Br concentration has no significant effect on the kinetic energy moderation of the energetic ^{80}Br, since Kr is as good a kinetic energy moderator as Br_2. Thus, the yield-curve of $CH_2{}^{80}BrBr$, showing a maximum, is related directly with the increase in Br_2, but not with the concomitant decrease in the amount of Kr in the system.

Discussion

The total organic yields found in the present work are in agreement with the values (12.0±1.0% from ^{80}Br–CH_4 and 6.4±1.0% ^{80}Br–CD_4) previously reported by Spicer and Gordus[10,12] and with the value of 13.3±0.5% from ^{80}Br–CH_4 reported by Rack and Gordus.[9,12] Furthermore, the percentage yields of individual products also show a reasonable agreement with the values,[10] 10.7% for $CH_3{}^{80}Br$ and 1.3% for $CH_2{}^{80}BrBr$, and 4.9% for $CD_3{}^{80}Br$ and 1.5% for $CD_2{}^{80}BrBr$. If one estimates the kinetic energy yield by simply subtracting the limiting yield at 1.0 m.f. of Kr from that obtained with no additive, 13.8−1.4=12.4% for the total organic products, 12.3−0.9=11.4% for $CH_3{}^{80}Br$, and 1.5−0.5=1.0% for $CH_2{}^{80}BrBr$ are obtained. A similar treatment of the results from the ^{80}Br–CD_4 system yields 6.3−1.2=5.1% for the total organic products, 4.6−0.7=3.9% for $CD_3{}^{80}Br$, and 1.7−0.5=1.2% for $CD_2{}^{80}BrBr$. The value of 12.3% for $CH_3{}^{80}Br$ is roughly 3 times that found in the (I.T.) experiments.[5] As has been discussed in a previous paper,[5] an additional formation of products due to the thermal ionic processes is possible in the highly Kr-moderated ^{80m}Br–CH_4 system. There is no "*a priori*" reason to believe that this additional formation does not occur in the present ^{80}Br–CH_4 or CD_4 systems. Thus, the values obtained for the kinetic energy yields in the above calculation should be taken to be minimum values.

Comparison of the Results with Those from the (I.T.) Experiments. The higher yield of $CH_3{}^{80}Br$ from the kinetic energy process in the (n,γ) experiment than in the (I.T.) experiments results from the difference in the physical nature of the ^{80}Br from the two types of activation. Since the ^{80}Br atom from the (n,γ) activation has a kinetic-energy distribution ranging up to E_{max}, while a fraction of the charged atom is of the order of 18%,[8] mostly singly-charged, the kinetic energy is a more important factor in the course of the reactions than is the positive charge. When products are formed *via* energetic processes, they are excited and so can undergo a secondary decomposition or isomerization, as detected by a pressure-dependent competition between the collisional deactivation and the unimolecular decomposition. The results in Table 1 agree with the above expectation, indicating that a fraction of $CH_3{}^{80}Br$ is highly excited and that it is subjected to a secondary decomposition, even under a total pressure of 1920 mmHg, although a large fraction is easily stabilized and is essentially pressure-independent. This is in great contrast with the results of the (I.T.) experiments, where $CH_3{}^{80}Br$ increases with the pressure at the beginning, but tends to level off at around 500 mmHg.[3] This is indicative that a fraction of the $CH_3{}^{80}Br$ in the (n,γ) experiment stays in somewhat higher excitation states than that in the (I.T.) experiment. Since the excitation energy of the products is a good measure of the energetic state of the reacting atom at the time of the reactions,[13] it may be pointed out that the possible collisions which can lead to energetic reactions of ^{80}Br are available to a higher energy in the present (n,γ) experiments, than in the (I.T.) experiments.

When one compares the $CH_2{}^{80}BrBr$ yield with that in the (I.T.) experiments, it is noticeable that a higher yield is obtained from the latter (2.1±0.2% in the (I.T.) experiments). This trend is very different from that found in $CH_3{}^{80}Br$ and implies that an appreciable amount of $CH_2{}^{80}BrBr$ is formed *via* a thermal ionic process in the (I.T.) experiments.

One attempt to evaluate the maximum yield of

12) These values were obtained by extrapolating to zero additive, while in the present work they are the percentage yields in the presence of 1—5 mmHg Br_2. However, the presence of this amount of Br_2 does not affect the yield beyond the range of experimental uncertainty. Thus, the direct comparison of the present values with the reported values is rather reasonable.

13) C. F. McKnight and J. W. Root, *J. Phys. Chem.*, **73**, 4430 (1971).

$CH_2{}^{80}BrBr$ in the (I.T.) experiments proceeds on the assumption that the energetic formations of $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ occur in the same energy range. On this assumption, the ratio of the yields of products, $CH_3{}^{80}Br/CH_2{}^{80}BrBr$, from the energetic reactions of ^{80}Br can be considered to be the same for both types of activation of ^{80}Br. The maximum value of the energetic yield of $CH_2{}^{80}BrBr$ in the (I.T.) experiments can, thus, be estimated by the calculation:

$$(CH_2{}^{80}BrBr/CH_3{}^{80}Br) \text{ in } (n,\gamma) \text{ work} \times (CH_3{}^{80}Br \text{ in (I.T.) work}) = (1.0/11.4) \times (3.9) = 0.34$$

The experimental uncertainty in the (I.T.) experiments[5] did not allow us to detect definitely the kinetic energy moderation of $CH_2{}^{80}BrBr$ by Kr, both because of its small yield and because of its additional formation in the Kr-moderated system. Although the above calculation does not involve any certainty, it may be considered that the kinetic energy formation of $CH_2{}^{80}BrBr$ is less important in the (I.T.) experiments.[4]

Another important observation regards the yields of products in the highly Kr-moderated system. While the limiting yields of $CH_3{}^{80}Br$ at 1.0 m.f. of Kr are $0.9\pm0.1\%$ for the (n,γ) activation and $0.5\pm0.1\%$ for the (I.T.) activation, a significant difference is noticed in the limiting yields of $CH_2{}^{80}BrBr$ between the two types of activations. In the (n,γ) activation, $CH_2{}^{80}BrBr$ decreases from 1.5% with the m.f. of Kr and can be extrapolated to 0.5% at 1.0 m.f. of Kr, but in the (I.T.) activation an additional, noticeable formation occurs when the m.f. of Kr exceeds 0.5 and can be extrapolated to 2.9%.[5]

The fraction of the charged ^{80}Br from the (n,γ) activation is mostly singly-charged. Thus, the thermal ionic yield of $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ must be due to the reactions of thermal Br^{1+}. If this species is also the most important reacting one in the limiting conditions of 1.0 m.f. of Kr in the (I.T.) experiments, there exists no plausible explanation of the higher yield of $CH_2{}^{80}BrBr$ and the lower yield of $CH_3{}^{80}Br$, relative to those in the (n,γ) experiments. A possible explanation, thus, would involve another kind of reacting species of ^{80}Br for the formation of products *via* kinetic-energy-independent processes in the (I.T.) experiments. This is very concievable when one considers that a large fraction of ^{80}Br is formed with multiple charges and little excess kinetic energy as a result of successive internal conversions.[14] As the dilution of the reaction system with Kr proceeds, the distribution of the charge and the energy tends to be controlled through collisions with Kr. At least the fractions of ^{80}Br may be in different charge and energy states from those in the (n,γ) experiments[15] and may react with CH_4 *via* a kinetic-energy-independent process. However, further study will be required before we can describe a real working process which can explain these results.

Formation of $CH_2{}^{80}BrBr$. The yield curve shown in Fig. 1 is very similar to that found in the (I.T.) experiments and can also be explained in terms of the competition of two types of reactions: 1) the formation of $CH_2{}^{80}BrBr$ through the reaction of $\cdot CH_2{}^{80}Br + Br_2 \rightarrow CH_2{}^{80}BrBr + Br$, and 2) the scavenging reaction of Br_2 for the reacting ^{80}Br atom.

However, the shift of the maximum from 0.08 to 0.2, a higher value of Br_2/CH_4 than in the (I.T.) experiments is indicative that the energy state of $\cdot CH_2{}^{80}Br$ is different in the two kinds of activation of ^{80}Br; $\cdot CH_2{}^{80}Br$ in the present (n,γ) activation is rather excited and is less sensitive to Br_2 than in the previous (I.T.) activation. This is possible if they are formed by different reaction processes. However, this is not the time to explore this problem further, although Kr may play a role in the formation of $\cdot CH_2{}^{80}Br$ in the (I.T.) activation.[16]

In the unmoderated systems, at least 2/3 of the $CH_2{}^{80}BrBr$ is formed *via* an energetic process of ^{80}Br. Thus, it is worthwhile to discuss its formation process on the basis of the model previously presented[17-19] by assuming that, in the energetic process, $\cdot CH_2{}^{80}Br$ exists as an intermediate in the formation of $CH_2{}^{80}BrBr$. Wolfgang[17] proposed a direct-double-displacement process to explain the formation of CH_2TI from the reaction of the recoil tritium atom with CH_4 in the iodine-scavenged systems. Later, Tang and Rowland[18] concluded that the process is of minor importance in the reaction of the recoil tritium atom. In the energetic reaction of ^{80}Br, however, the process is rather probable, since the greater the mass of the reacting species is, the larger is the linear momentum transfer into a product in collision, although some ambiguity concerning the time interval between the leaving of the two H atoms remains.[19] The following two reaction schemes can be suggested:

1) single-step double-replacement reaction

$$^{80}Br^* + CH_4 \longrightarrow \cdot CH_2{}^{80}Br + 2H$$

2) two-step single-replacement reaction

$$^{80}Br^* + CH_4 \longrightarrow (CH_3{}^{80}Br)^* + H$$
$$(CH_3{}^{80}Br)^* \longrightarrow \cdot CH_2{}^{80}Br + H$$

The implication of a double displacement occurring in a single step is that the entire reaction process is complete on a time scale comparable to that of the single-substitution processes, *i.e.*, $<10^{-13}$ sec. The two-step process, on the other hand, describes a situation in

14) E. Tachikawa, This Bulletin, **43**, 63 (1970).

15) This consideration is consistent with observations in the reactions of ^{80}Br and ^{82}Br activated by (I.T.) processes with CH_3Br. The moderator curve of the products from the reactions of ^{82}Br can be extrapolated to zero % at 1.0 m.f. of Kr, while those from the reaction of ^{80}Br can be extrapolated to some finite value. This difference can also be ascribed to the difference in the decay schemes of ^{80m}Br and ^{82m}Br: the latter decays to the ground state in a single transition, and the resulting ^{82}Br has a high excess kinetic energy as well as a high charge. Ref. T. Kobaysahi, unpublished data; J. Okamoto and E. Tachikawa, This Bulletin, **42**, 1504 (1969); D. W. Oates, R. L. Ayres, R. W. Helton, K. S. Schwartz, and E. P. Rack, *Radiochem. Radioanal. Lett.*, **4**, 123 (1970).

16) This is possible, since the ^{80}Br from the (I.T.) activation is highly ionized with a relatively low kinetic energy. In the ^{80m}Br–C_2H_6 system, the amount of one of the products, $CH_3{}^{80}Br$, very much depends upon the moderator used (see Ref. 21).

which the excited molecule formed in the first step has sufficient time for some vibrations and/or rotations of individual groups in the molecule on prior to the bond breaking. The two-step mechanism is normally determined through the pressure dependence of the yields of the decomposition products relative to that of the single-displacement products. In the present case, if $CH_2{}^{80}BrBr$ is mainly formed by a two-step mechanism, the ratio of $CH_2{}^{80}BrBr/CH_3{}^{80}Br$ must decrease with an increase in the total pressure. This is in great contrast to the results shown in Fig. 2, which

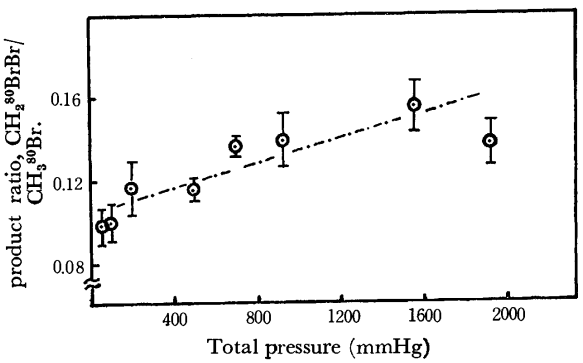

Fig. 2. The product ratio, $CH_2{}^{80}BrBr/CH_3{}^{80}Br$, as a function of the total pressure ($Br_2/CH_4=0.02$—0.03).

shows the plot of the $CH_2{}^{80}BrBr/CH_3{}^{80}Br$ ratio against the total pressure (using the results in Table 1). Although a quantitative treatment of the results requires a correct knowledge of the energetics of the individual reaction path as well as of a ^{80}Br-energy spectrum, qualitatively it is evident that the $\cdot CH_2{}^{80}Br$ radical is indeed formed largely by the one-step mechanism. However, the contribution, if any, by the two-step mechanism to the formation of this radical cannot be estimated.

Isotope Effect. The isotope effect has been observed in the $CH_3{}^{80}Br$–$CD_3{}^{80}Br$ pair; its value is 2.7 in the unmoderated system, decreases with the m.f. of Kr, and becomes close to unity when the m.f. of Kr becomes over 0.8. The difference in the yields between $CH_2{}^{80}BrBr$ and $CD_2{}^{80}BrBr$ does not exceed the experimental fluctuation over the range of the m.f. of Kr studied.

By tentatively identifying the kinetic energy yield of $CH_3{}^{80}Br$ and $CD_3{}^{80}Br$ as 11.4% and 3.9%, the value of 2.9 ± 0.3 can be obtained as the kinetic isotope effect. When one compares these results with those obtained in the (I.T.) experiments, the ratio is found to be comparable with the 2.7 ± 0.3 for $CH_3{}^{80}Br/CD_3{}^{80}Br$ in the latter experiments.[3] Furthermore, the non-existence of any isotope variation between $CH_2{}^{80}BrBr$ and $CD_2{}^{80}BrBr$ within the range of experimental uncertainty shows an agreement between them.[3] The present isotope effect is due to the reactivity integral isotope effect,[20] and the contribution of the moderator isotope effect is not significant, as has been discussed previously.[3]

The results in Table 2 show that at least 2/3 of the $CH_2{}^{80}BrBr$ is formed *via* an energetic process. Thus, if a similar value of isotope effects presents in the energetic formation of $CH_2{}^{80}BrBr$, the present experimental method will provide a method of detecting the isotopic variation between $CH_2{}^{80}BrBr$ and its isotopic analogue, contrary to the experimental results. The current set of experiments in our laboratory shows that the kinetic isotope effect in C_2H_6–C_2D_6[21] and C_3H_8-isotopic analogues[22] ranges from 1.3 to 1.5. These results suggest that the chemical and/or physical natures of the residual and leaving groups play a role in the isotope effect. If the kinetic isotope effect in the present $CH_2{}^{80}BrBr$–$CD_2{}^{80}BrBr$ remains in this range, the difference in the yields might be overshadowed by the experimental fluctuation. This is possible, since their formations will involve the breaks of two C–H or D bonds. In conclusion, it can only be said that the isotope effect in $CH_2{}^{80}BrBr$–$CD_2{}^{80}BrBr$, if it exists, is much less than that in the $CH_3{}^{80}Br$–$CD_3{}^{80}Br$ pair.

Crystal Growth of β-Hopeite on (0001) Plane of a Single Crystal of Zinc

Akitsugu OKUWAKI, Jinichi NINAGAWA, Taijiro OKABE, and Keiichi OMORI

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai
**Institute of Mineralogy, Petrology and Economic Geology, Tohoku University, Sendai*

(Received September 22, 1971)

The epitaxy and the orientation of β-hopeite grown on the (0001) plane of a single crystal of zinc were studied. The epitaxy was found to be (0001)-Zn//(010)-β-hopeite, and the orientation was [10.0]//[100] or [12.0]//[100]. The nature of the chemical bond between β-hopeite and zinc is considered to be similar to that of the wurtzite type rather than to that of the wüstite type in view of the structure of the boundary surfaces.

One of the present authors previously studied the influence of impurities on the phosphatizing of steel,[1,2] the composition and the orientation of phsophate,[3] and also the electrochemical behavior of phosphatizing.[4] Machu,[5] Jaenicke and Lorenz,[6] and Khain[7] have studied the mechanism of phosphatization, and Neuhaus and Gebhardt[8–10] have presented a unique opinion on the epitaxies of phosphate coated on such base metals as Fe, Zn, and Cu.

From the above-mentioned investigations into the orientation of β-hopeite, $Zn_3(PO_4)_2 \cdot 4H_2O$, on iron and steel, it has become obvious that the (010) plane of β-hopeite combines with the metal surface. In those studies, however, since polycrystalline pieces have been used as the base metal, the experimental determination of the epitaxies between phosphate and metal was difficult. Consequently, their estimation was carried out from their lattice constants. In order to examine the orientation and epitaxy between coating and metal precisely, the use of a single crystal as the base metal is necessary. In the present paper the following investigations will be reported: the orientation and the epitaxy of β-hopeite grown on the (0001) plane of zinc single crystal were studied by a microscopic observation of the crystal growth of β-hopeite, based on our experimental results and the crystal structure of β-hopeite, an adhesive mechanism between β-hopeite and zinc was also investigated.

Experimental

Phosphatizing Solution. The phosphatizing solution was prepared from a 0.1 mol/*l* solution of phosphoric acid by adjusting its pH with anhydrous sodium carbonate.

Microscopic Observation of the Crystal Growth. A single crystal of zinc (3 mm × 3 mm × 100 mm) was prepared by a modification of the method of Czochralski', the *c*-axis of zinc in the single crystal is perpendicular to the base plane. It was split just before the experiment, and a split chip of 2 mm was dipped in the phosphatizing solution, and held in a crystallizing dish. Then, under a microscope whose object glass was immersed into the phosphatizing solution, the crystal growth was observed, photographed, and filmed using a FUJICA Single 8, Z 2-type 8 mm movie camera by means of the memo-motion technique.

Results and Discussion

Observation of the Growth Direction of β-Hopeite. Photographs of crystals grown on the (0001) plane of zinc treated with the phosphatizing solution at various pH's are shown in Figs. 1—4. At pH 3.5, β-hopeite did not form, except for the appearance of etch pits. In the pH range of 4.5—5.0, the growth of a relatively large crystal of β-hopeite was observed.

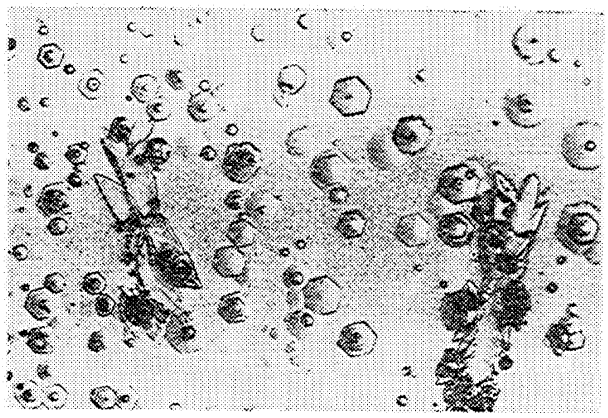

Fig. 8. Crystal growth of β-hopeite on the (0001)-Zn at pH 4.72 (40 min). (×180)

The series of microscopic photographs shown in Figs. 5 to 8 are the crystal growth of β-hopeite on the (0001) plane of zinc at pH 4.72, 20°C. The orientation of the *a*-axis on the (0001) plane of zinc can easily be recognized from the etch pits formed. Yamamoto and Watanabe[11] reported that etch pits appeared as regular hexagons when the (0001) plane of zinc was etched with a dilute hydrogen chloride solution. In these cases, the three *a*-axes of the zinc crystal are at right angles to the sides of the hexagon. When a zinc single crystal revealing a (0001) plane was dipped in the phosphatizing solution, etch pits with the same orientation as has been described above appeared, as is shown in Fig. 1. In Figs. 9 and 10, obtained by tracing Figs. 4 and 7 respectively, the directions of the crystal growth of β-hopeite are shown as dotted lines, and the three *a*-axes, a_1, a_2, and a_3, of the zinc crystal are drawn on an enlarged regular hexagon of the etch pit.

Two kinds of direction of the crystal growth can be observed in these figures; one of them coincides with the direction of the three *a*-axes, while the other makes an angle of 30° with the *a*-axes. From these results, it can be said that β-hopeite crystal grows along the [10.0] or [12.0] direction on the (0001) plane of zinc.

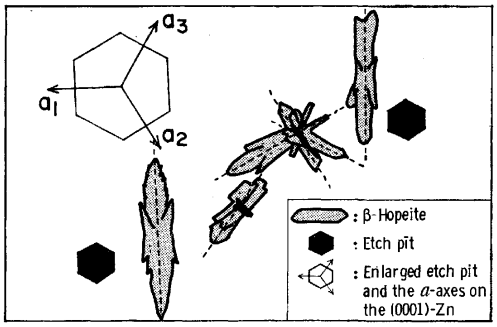

Fig. 9. Relation between the direction of crystal growth and that of the a-axes on the (0001)-Zn.

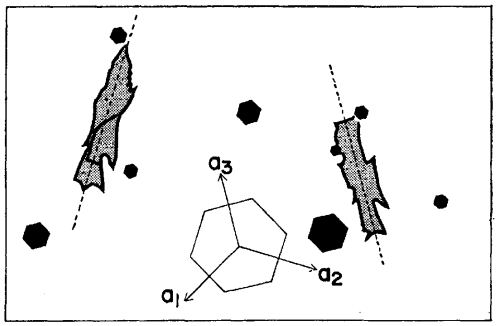

Fig. 10. Relation between the direction of crystal growth and that of the a-axes on the (0001)-Zn.
The illustrations of shapes are the same as in Fig. 9

Epitaxy. The epitaxies of β-hopeite on the (0001) plane of zinc are shown by two modes in Fig. 11 and Table 1. The black spots in Fig. 11 are zinc atoms on the (0001) plane, while the regular hexagon and the rectangle with perimeters of thick lines indicate an etch pit and the unit cell of β-hopeite projected on the (010) plane respectively.

The length of the a-axis in β-hopeite is equivalent to

Table 1. Epitaxies between β-hopeite and zinc

Mode	Epitaxy Zinc	Epitaxy β-Hopeite	Period Zinc	Period β-Hopeite	Misfitting (%)
1	$[1\bar{2}10]$	// [100]	10.66	10.64	0
	$[10\bar{1}0]$	// [001]	4.62	5.04	+9
1′	$[10\bar{1}0]$	// [001]	10.01	10.08	+1
2	$[01\bar{1}0]$	// [100]	10.01	10.64	+6
	$[\bar{2}110]$	// [001]	5.33	5.04	−5

4 times the a-axis in zinc in the 1 mode. This mode of orientation accords with that published by Neuhaus and Gebhardt.[9] As for the direction of the c-axis in β-hopeite, considering zinc atoms on the (0002) plane in relation to such epitaxy as the 1′ mode, the misfitting in the epitaxy becomes smaller than that in the 1 mode, as is shown in Table 1. In the 2 mode, β-hopeite grows along the [12.0] direction; perhaps this relation is a new finding. Although, many other modes can be observed in the epitaxies between β-hopeite and zinc, the two modes described above seem to be the simplest ones, with the least misfitting.

The growth of crystals of a fin shape is observed in some figures of this paper; the crystal joins at an angle of about 30° with the [001] direction of β-hopeite. The angle between [100] and [101] in β-hopeite is smaller than 30°, that between [10.0] and [12.0] in zinc, therefore, the rate of crystal growth in the direction of [001] is more rapid than that in the direction of [101] in a β-hopeite crystal. Seemingly, the quantity of β-hopeite formed on the (0001) plane of zinc by the epitaxies of either mode, 1 or 1′, is larger than that formed by the epitaxy of the 2 mode, and the growth rate of the former is larger than that of the latter judging from an observation of Figs. 4—8 and several other photographs and movies, although some of them are not cited here. This may be due to the fact that the misfitting in the 1 or 1′ mode is smaller than that in the 2 mode.

Adhesive Mechanism. Neuhaus and Gebhardt have found that the (010) plane of β-hopeite usually combines with the surface of metals in phosphatization.[9] Such phenomena seem to be attributable to the crystal structure of β-hopeite, which was analysed by Gamidov and Galovachev.[12] The projection of the phosphate

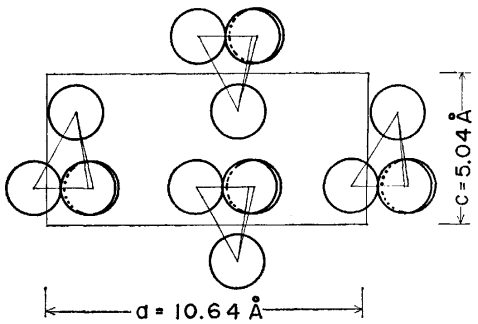

Fig. 12. The projection of phosphate ion on the (010) plane of β-hopeite.

11) M. Yamamoto and J. Watanabe, *J. Japan Inst. Metals*, **17**, 628 (1953).
12) R. S. Gamidov and V. P. Galovachev, *Dokl. Akad. Nauk. USSR*, **150**, 381 (1963).

ion to the (010) plane is shown in Fig. 12 in aid in the consideration of the adhesive mechanism.

As it is impossible to project all the atoms because of the mutual hindrance, only phosphate ions combined to metallic zinc are projected.

A brief explanation of the combination of the (010) plane of β-hopeite with a metal surface is given below from the standpoints of the density and the distribution of oxygen atoms, and the bond length and the coordination between metal and oxygen atoms of the phosphate ion in β-hopeite. On the (001) plane, all the oxygen atoms are located on the 1/4 and 3/4 *c* levels; therefore, it is difficult for this plane to combine with the metal surface. Similarly, on the (100) plane, the low density of the oxygen atom and its localization at one corner are observed. On the (010) plane, however, the density of the oxygen atom is the highest, and the distribution of these atoms is relatively uniform, as is shown in Fig. 12, consequently, the strongest combination is that between the (0001) plane of zinc and the (010) plane of β-hopeite occurs, as is indicated in Figs. 13 and 14.

The positions of the oxygen atom of phosphate in these figures were determined so that the bond distance between the oxygen and zinc atoms was about 2 Å. The lattices, however, combine with each other in a

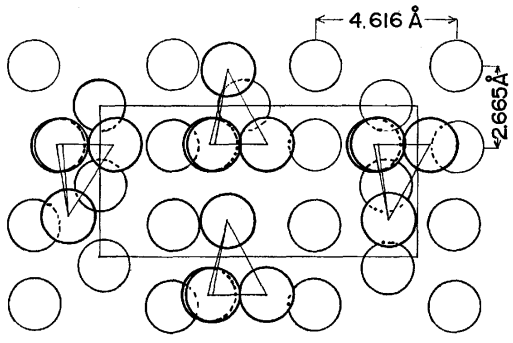

Fig. 13. Overlapped projection of the (010) plane of β-hopeite and the (0001) plane of zinc.

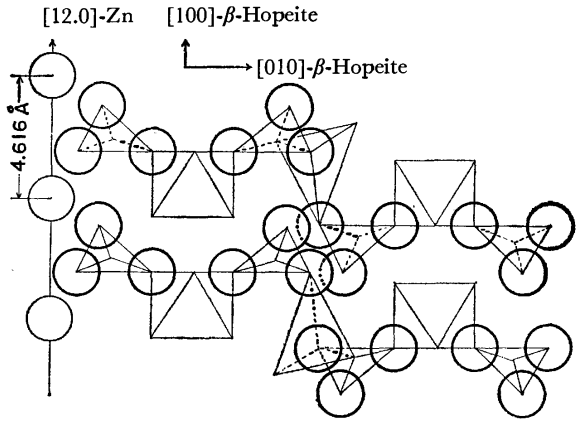

$Zn[PO_4][ZnO_2(H_2O)_4][PO_4][ZnO_4]$

Fig. 14. Side view of the overlapped projection.

rather distorted manner, and the nature of the chemical bond may be of a strong chemisorption. Neuhaus and Gebhardt[13] have proposed that the chemical bond between β-hopeite and the metal surface is of the wüstite type and that a mesomery exists between $Me^{(+)}\cdots O^{(-)}\cdots PO_3$ and $MeO^{(-)}\cdots P^{(+)}\cdots O_3$. It is, however, reasonable that the bond is not of an wüstite type but of an wurtzite one for the following reasons:

1. Zinc atoms are abundant on the boundary surface between β-hopeite and zinc, as is shown in Fig. 13. This may be analogous to an wurtzite enriched with zinc atoms, having an oxygen vacancy and behaving as a negative semiconductor. On the other hand, an wüstite enriched with oxygen atoms is positive.[14]
2. It is reasonable to say that zinc combined with the oxygen in the phosphate ion located at the boundary has a coordination number of 4, in the light of the crystal structures of β-hopeite and wurtzite.

The Characterization of Oligomeric Iron(II)-tetraoxime Complexes

Joseph BACKES, ISAO MASUDA, and Koichiro SHINRA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka

(Received September 29, 1971)

Several polymeric iron(II) chelates with tetraoxime ligands,

$$CH_3C(NOH)C(NOH)-\overset{(\alpha)}{CH_2}-\overset{(\beta)}{CH_2}-(CH_2)_n-\overset{(\beta)}{CH_2}-\overset{(\alpha)}{CH_2}-C(NOH)C(NOH)CH_3,$$

where $n=2$ and 6, were characterized. They show a ligand-to-iron molar ratio of 1:1, corresponding to a planar arrangement of the ferrous ion and the four oxime nitrogens; two pyridine or methylpyridine substituents are axially coordinated to the central metal ion. The complexes are diamagnetic in the solid state, and their absorption spectra closely resemble those of the monomeric ferrous dimethylglyoxime compounds. The molecular weight, determined in a pyridine solution by vapor-pressure osmometry (2800 for $-(CH_2)_2-$ and 3100 for $-(CH_2)_6-$), corresponds to 5 or 6 Fe–N_4 units within the polymer chain. An NMR investigation including tetraoxime ligands with both aliphatic and aromatic linkages, as well as the corresponding chelates, shows that the protons in the α or in the β position to the oxime groups do not undergo any shift upon chelation. The electronic spectral data and NMR data provide no evidence that the Fe(II) chelate rings within the polymer chain are affected by one another.

In a recent work,[1] polymeric ferrous tetraoxime complexes with aromatic groups as linkage between the two α-dioxime ligand units have been synthesized and characterized. In the present study, two low-molecular-weight ferrous tetraoxime polymers with methylene bridges, $-(CH_2)_6-$ and $-(CH_2)_{10}-$, will be described. The molecular model shows that, because of the extended methylene chain, the α-dioxime groups are situated at random in space, this results in a structure far less rigid than the one incorporating phenyl- or similar bridging groups. An NMR study shows that the chelation of the oxime nitrogens does not cause any shift to the protons adjacent to the chelate ring. The polymer chain is thus considered to be formed of Fe–N_4 units independent of one another.

The properties and the structures of these new chelates are compared with those of the monomeric iron(II)-α-dioxime complexes, as well as with those of the previously-reported polymeric chelates.

Experimental

Preparation of the Tetraoxime Ligands. Dodecane-2,3,10,11-tetraone-tetraoxime, and hexadecane-2,3,14,15-tetraone-tetraoxime were prepared according to the methods described by Murahashi and Kubota.[2] The products obtained showed the following characteristics.

Dodecane-2,3,10,11-tetraone-tetraoxime. White crystals; soluble in DMSO, DMF, pyridine, and other organic solvents; mp 251—253°C. (Found: C, 50.41; H, 7.61; N, 19.33%.)

Hexadecane-2,3,14,15-tetraone-tetraoxime. White crystals; soluble in DMSO, DMF, and pyridine; insoluble in ethanol, methanol, *etc.*; mp 240—241°C. (Found: C, 56.18; H, 8.72; N, 16.28%.)

Preparation of the Complexes. One millimole of an iron(II) salt (Mohr's salt) was dissolved under nitrogen in 20 m*l* of water; to this solution we then added, at room temperature, a solution of 0.5 mmol of a tetraoxime ligand in 5 m*l* of the base (pyridine, methylpyridine). An intensely-red-colored precipitate immediately formed. The reaction mixture was stirred for five hours. The product was then filtered, washed extensively with water and ethanol, and then dried *in vacuo* at room temperature.

The red powders obtained were all soluble in pyridine. They were only slightly soluble in other organic bases and were extremely unstable in common organic solvents (DMF, DMSO, *etc.*). The yield was quantitative. The analytical data are shown in Table 1.

Apparatus and Procedures. The molecular weight was determined in a pyridine solution at 25°C, using a Mechrolab vapor-pressure osmometer, Model 302.

a) Tetraoximes will be abbreviated as $(CH_2)_n$ TOH_4.
b) Temperature at which the compounds turn black without melting.
c) "Py," "β-Pic," and "γ-Pic" stand for pyridine, β-picoline, and γ-picoline respectively.

1) J. Backes, I. Masuda, and K. Shinra, This Bulletin, **45**, 1061 (1972).

2) S. Murahashi and H. Kubota, *ibid.*, **35**, 1465 (1962).

The NMR spectra were obtained with a Japan Electron Optics JNM-3H-60 spectrometer at 60 Mc/sec, using tetramethylsilane as the internal reference. Under a nitrogen atmosphere, equimolar amounts of the tetraoxime ligand and an iron(II) salt were dissolved in 1 m*l* of deuterated pyridine; the solution was kept at room temperature for 5 hours before recording. We used solutions of 10% for the ligands and up to 20% for the ferrous complexes. The addition of D_2O caused the disappearance of the oxime protons of the free ligands at a low field.

The apparatus and techniques concerning the infrared and electronic spectra, the thermogravimetric analyses, and the magnetic properties have been described previously.[1)]

Results and Discussion

Table 1 shows the anlytical data of the different chelate polymers. They indicate a tetraoxime ligand-to-iron molar ratio of 1 : 1, and thus a structure where two α-dioxime groups and the ferrous ion form a planar arrangement and where the pyridine ligands (pyridine and methylpyridine) are axially substituted. This structure is further supported by the following thermogravimetric and spectral data.

The thermogravimetric curve (*cf.* Fig. 1) shows the characteristic pattern expected for the release of two coordinated pyridine molecules. The weight loss observed (29.9%) is in fair agreement with the calculated value (31.7%).

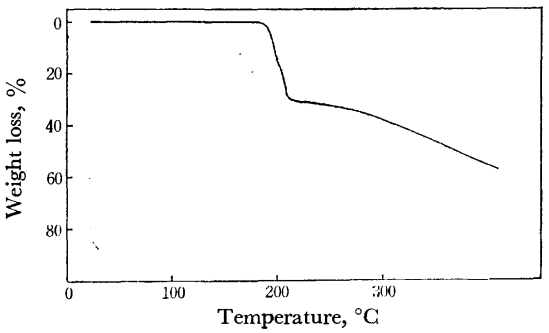

Fig. 1. Thermogravimetric analysis of $(CH_2)_6TOH_2\cdot Fe\cdot(Py)_2$ under nitrogen atmosphere.

Fig. 2. *) Concentration inaccurate due to low solubility.

While, for the tetraoxime polymers with aromatic linkages, no pyridine and pyridine-like bases were found to be axially coordinated in the solid state,[1)] the present polymers readily underwent this axial substitution.

The polymers are soluble in pyridine. The absorp-

tion spectra in a pyridine solution (*cf.* Fig. 2) bear a close resemblance to those of the monomeric ferrous dimethylglyoxime compounds, $(DmgH)_2\cdot Fe\cdot(Py)_2$, for which two intense absorption bands are found at 19.6 and 26.0 kK; they are assigned to the Fe→oxime and the Fe→pyridine charge transfers respectively.[3,4,5] The absorption bands of the tetraoxime complexes with axial pyridine are found in the same region (*cf.* Table 3). In monomeric ferrous complexes involving aromatic dioxime ligands (*i.e.*, α-benzil-dioxime or α-furil-dioxime), as well as in the polymeric chelates with aromatic bridges, the Fe→oxime charge-transfer bands undergo almost the same shifts as the dimethylglyoxime compounds (Table 3). The fact that no considerable shifts occur upon the linking together of several of these $Fe-N_4$ units indicates further that the different chelate rings within the polymer chain are independent of one another and that the iron(II) $d\pi$-electrons do not engage into an extended π-delocalization in the case of aromatic linkage groups. The effect of substitution on the axially-coordinated pyridine is the same in the monomeric as in the polymeric compounds (*cf.* Table 2 and Ref. 4). The electronic states of the ferrous ion in the monomer and in the polymer may thus be considered to be quite similar.

The absorption spectra at different pH values, ranging ftom pH 8.9 to pH 4.9 fail to show one single isosbestic point; this indicates a two-step dissociation of the axial base. A look at the thermogravimetric curve supports this assumption.

The ferrous tetraoxime compounds with aromatic linkages were all paramagnetic in the solid state. Upon dissolution in pyridine, these compounds are considered to undergo spin-pairing to form octahedrally-substituted diamagnetic complexes.[1] The present tetraoxime chelates with axial pyridine substituents were all found to have negative susceptibilities at room temperature in the solid state; this indicates a low-spin ferrous ion in the complexes. This is consistent with the high extinction coefficient of the absorption bands in the visible region (Fig. 2).[3]

The infrared spectra of the ligands exhibit a broad absorption band between 1620 and 1680 cm^{-1}. Upon coordination with iron(II), a strong band appears in

Table 4. NMR spectral data[a] of the bis(α-ketoxime) ligands, $CH_3C(NOH)CO-R-COC(NOH)CH_3$ and $CH_3COC(NOH)CH_2-R'-CH_2C(NOH)COCH_3$

a), b): see Table 4.

the 1620 cm^{-1} region; its position changes only slightly from one chelate to another. This band is attributed to the C=N stretching mode within the chelate. In both the free ligands and the chelate compounds, the OH stretching vibrations are found around 3200 cm^{-1} indicating the presence of free end-group oximes in the latter.

The solubility of these ferrous tetraoxime polymers in pyridine permitted vapor-pressure osmometry measurements. For the chelates with $-(CH_2)_6-$, the molecular weight values were found at 2800 ± 50, and for the chelates with $-(CH_2)_{10}-$, at 3100 ± 50, thus indicating a chain-length of 5 to 6 units.

For neither of the coordination compounds could an X-ray diffraction pattern, indicating an inherent crystalline structure, be found; this is in agreement with the polymeric character of the complexes.

NMR Spectra. This investigation was carried out in order to determine whether the complexing of the four oxime nitrogens with a ferrous ion had an effect on the protons close to this chelate ring.

Compounds involving keto-oxime groups have been the subject of extensive NMR studies[7,8] because of their properties to form *syn-anti* isomers. In the case of α-ketoximes, several isomeric structures can be theoretically conceived; this number increases considerably when the tetraoxime compounds are considered. However, the results obtained for the present compounds show no evidence of the presence of different isomers.

The spectral data of the bis(α-ketoxime) compounds incorporating aromatic as well as methylene linkages are shown in Table 4. They are taken as a basis for assigning the protons in the tetraoxime compounds. The protons of the aromatic rings appear as two doublets in the region between 1 and 3 ppm (τ-scale); this pattern is characteristic of a *para*-substituted species.

E: $(CH_2)_{10}TOH_4$ in C_5D_5N
F: $(CH_2)_{10}TOH_2$·Fe in C_5D_5N

The oxime protons are found as sharp signals at a low field in DMSO; they are shifted to a lower field in pyridine. Through all of these spectra a common effect of the pyridine solvent is found, as all the signals undergo a shift, varying from 0.5 to 2.5 ppm toward a lower field than in the case of the spectra in DMSO. Further, the oxime protons appear as very sharp signals in DMSO, while in a pyridine solution the shape changes and the intensity decreases considerably.

The bis(α-ketoxime) compounds with methylene linkages show a broad absorption of the protons in the chain, extending over 1 ppm. The protons in the position α to the oxime C=N bond are shifted to a lower field. The oxime protons are found in the same region as those of the ketoximes with aromatic links. A similar solvent effect due to pyridine can be seen.

The spectra of the tetraoxime ligands are quite similar to those of the α-ketoxime compounds (*cf.* Table 5). The methyl protons appear as one sharp singlet (*cf.* Figs. 3 and 4). The oxime protons are found at a higher field than the monoxime compounds and appear either as a sharp singlet or as two less intense singlets, the latter at a lower field, in DMSO and in pyridine respectively.

Upon chelation in a pyridine solution, the position of neither the methyl protons nor the aromatic protons is altered (*cf.* Fig. 3); only the resolution decreases, and the oxime protons cannot be detected any more down to −20 ppm. For a series of monomeric Co(III) dimethylglyoxime compounds, the hydrogen-bond protons have been found to range between −8.1 and −8.5 ppm, depending on the nature of the complex.[9]

For the methylene-bridged tetraoxime chelate compounds, a similar spectral pattern is found (*cf.* Fig. 4). The positions of neither the methyl nor the methylene protons changes, while the oxime protons are no more detected down to −20 ppm.

The conclusion which can be drawn from these NMR data is that the protons in the α or in the β position relative to the oxime groups remain unaffected upon chelation with iron(II). Thus, no indication is found for an extended π-delocalization within the polymer chain involving the Fe(II)-*dπ* electrons.

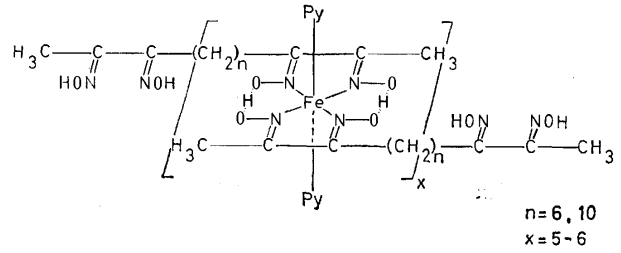

Fig. 5. Schematic representation of the pyridine-substituted, ferrous, methylene-bridged tetraoxime polymers.

Murahashi and Kubota[3] have suggested linear and cyclic structures for the nickel chelates of methylene- and phenyl-bridged tetraoximes. In a previous work we proposed a linear structure for the ferrous polymer chelates with aromatic linkages. This structure has been confirmed for the present methylene-bridged compounds (*cf.* Fig. 5). The infrared data as well as the molecular-weight data make it possible to eliminate the cyclic structures postulated by the above authors.

The Polarography of *N,N'*-Ethylenebis(acetylacetoniminato) and *N,N'*-Ethylenebis(salicylaldehydeiminato) Complexes of Cobalt(III), Nickel(II), and Copper(II) in an *N,N*-Dimethylformamide Solution

Mutsuo KODAMA, Yuki FUJII, and Mitsuo SAKURAI
Department of Chemistry, Ibaraki University, Bunkyo, Mito, Ibaraki

(Received September 30, 1971)

The polarographic behavior of *N,N'*-ethylenebis(acetylacetoniminato) (baen) and *N,N'*-ethylenebis(salicylaldehydeiminato) (bisaen) complexes of cobalt(III), nickel(II), and copper(II) in DMF solutions was studied thoroughly. At the dropping mercury electrode, these metal complexes give well-defined cathodic waves corresponding to the reduction of metal(II) to metal(I). A careful and systematic study of the polarographic behavior of *β-cis* and *trans* cobalt(III)-baen and -bisaen complexes of the general formulae: $CoZY^{1-a}$ and $CoZX_2^{1-2b}$, and that of nickel(II)- and copper(II)-baen complexes, revealed that the unusual stability of the metal(I)-baen and -bisaen complexes can be ascribed mainly to the stable square-planar nature of baen and bisaen. The effect of the replacement of the ligand by the halogen atom was also investigated.

Recently, Olson, and Vasilevskis[1-3] reported, in their polarographic investigation of cyclic amine complexes of nickel(II), copper(II), and cobalt(II), that these complexes give single well-defined polarographic steps corresponding to the reduction of metal(II) to metal(I), and that the unusual stability of cyclic amine complexes containing the metal formally in the +1 oxidation state can be ascribed to the cyclic nature of ligands. In our laboratory, a series of mixed *β-cis* and *trans* cobalt(III)-*N,N'*-ethylenebis(acetylacetoniminato) (baen) and -*N,N'*-ethylenebis(salicylaldehydeiminato) (bisaen) complexes containing ammonia, amino acids, acetylacetone, and 2,2'-dipyridyl were prepared by oxidizing the cobalt(II)-baen and -bisaen complexes, which have long been known to be oxygen carriers.[4-6] These baen and bisaen-cobalt(III) complexes and their cobalt(II) complexes in the *N,N*-dimethylformamide (DMF) give a reversible cathodic step corresponding to the reduction of cobalt(II) to cobalt(I), as in the cases of metal(II)-cyclic amine complexes. In this paper, we will study systematically the polarographic behavior of the mixed cobalt(III)-baen and -bisaen complexes in DMF and will discuss the nature of baen and bisaen, which can trap the metal ion in an uncommon oxidation state. Some comparisons will also be made between the cabalt and copper and nickel complexes in order to describe the precise nature of baen and bisaen as ligands.

Experimental

Reagents. The *N,N*-dimethylformamide (DMF) used for the polarographic work was purified by a procedure described by Fujinaga *et al.*[7] The supporting electrolyte, tetraethylammonium perchlorate (TEAP), was prepared by the method given by Fujinaga, Izutsu, and Takaoka.[8] Baen, bisaen, and their cobalt(II) complexes were prepared by the methods given by Morgan and Smith[9] and by Diehl and Hach.[10] The cobalt(III)-baen and -bisaen complexes used in this study were prepared by oxidizing the cobalt(II)-baen and -bisaen complexes with hydrogen peroxide in solutions containing ammonia, amino acids, acetylacetone, or 2,2'-dipyridyl. The detailed ways of preparing them, the determination of their stereochemical configuration, and the elemental analyses will be described in a future paper. All the other chemicals used were reagent-grade and were used without further purification.

Apparatus and Experimental Procedures. The DC polarographic waves were measured by using a manual polarograph similar to that of Kolthoff and Lingane[11] or Yanagimoto pen-recording polarograph PA-102. All the AC polarograms were also recorded automatically by employing the above pen-recording polarograph. The DC polarographic data given in this paper were corrected for the residual current and the ohmic drop of the cell circuit (4.1 kΩ). For all the measurements, we used three dropping mercury electrodes. They have *m* values of 0.7396, 0.9153, and 0.5836 mg/sec, and drop times, t_d's, of 4.10, 5.10, and 4.40 sec respectively, in an air-free DMF (0.15 M TEAP) solution at the mercury height of 70.0 cm and with an open circuit. A saturated calomel electrode (SCE) with a large area was used as the reference electrode and was connected to the cell solution through the salt bridge proposed by Takaoka.[12] In the AC polarographic measurements, a 200-μF condenser was used to minimize the effect of cell resistance.[13] All the polarographic studies were carried out at 20°C using sample solutions containing no free ligand. The oxygen dissolved in the sample solutions was removed by bubbling pure nitrogen gas saturated with pure DMF through the solution. All the free ligands, except *N,N'*-ethylenebis-(3-bromoacetylacetonimine) (baen-Br_2), used in this study were found to give no reduction wave under the present experimental conditions.

Results and Discussion

As is illustrated by the DC polaragrams in Figs. 1 and 2, the cobalt(III)-baen and -bisaen complexes in

a DMF solution give two cathodic waves, the limiting currents of which are exactly proportional to their bulk concentration and to the square-root of the effective pressure on the DME (Tables 1 and 2). The peak-heights of the AC polarograms in Figs. 1 and 2 show that the electrode reaction at the first step of these complexes is irreversible, but that at the second wave, reversible in a polarographic sense. Furthermore, the diffusion current constants, I_d's ($=i_d/C\ m^{2/3}\ t_d^{1/6}$), of both steps were found to be nearly identical to that for the reduction wave of the trisacetylacetonatocobalt(III) complex in the DMF solution (Table 3). It was also found that cobalt(II)-baen and -bisaen complexes give a single reversible reduction wave, the reduction potential of which agrees

well within several milivolts with that of the second step of the corresponding cobalt(III) complex, and that their I_d values are nearly identical to that of the cobalt(III) complex (Figs. 3 and 4). All the above polarographic evidence indicates that the first and second steps of cobalt(III) complexes correspond, respectively, to the one-electron reduction of cobalt(III) to cobalt(II) and that of cobalt(II) to cobalt(I). The polarographic data on cobalt(III)-baen and -bisaen complexes studied in this paper are summarized in Table 4, together with those on nickel(II) and copper(II)-bean complexes.

As is shown by the data in Table 4, the first waves of the *β-cis* complexes with the general formula $CoZY^{1-a}$ give log-plot (E *vs.* $\log(i/(i_d-i))$) slopes larger than those of *trans* complexes, $CoZX_2^{1-2b}$. Although the details of the determination of the configuration have not been described in this paper, the NMR study confirmed that all the cobalt(III) complexes of the general formula $CoZY^{1-a}$ have the *β-cis* configuration, and the $CoZX_2^{1-2b}$ complexes the *trans* configuration.

An electrode reaction accompanied by a change in the configuration of the reactant is generally believed to be slow.[14] Therefore, the above finding may imply that the electrode reaction at the first step of the *β-cis* complex is accompanied by a change in its configuration or by a loosening of its structure. This would also explain well the reversible property of the second reduction step of the *β-cis* complex. However, in the case of the irreversible polarographic reduction, from the theoretical point of view the log-plot examination can not be expected to provide many useful information on the electrode reaction mechanism or on the formula of the reduction product. Therefore, we can not describe more precisely the nature of the first wave on the basis of the log-plot examination. On the other hand, in the case of the second step, because of its perfect reversible nature, we can determine exactly the electrode reaction mechanism and, hence, formulate the reduction product by performing a careful log-plot examination (E *vs.* $\log(i^n/(i_d-i))$ plot). The polarographic data gives in Table 4 also indicate that the second waves of the mixed cobalt(III) complexes of baen and bisaen containing bidentate ligands give exclusively straight lines, with reciprocal slopes of about 65 mV, close to the theoretical value of 58 mV for the reversible one-electron reduction in the plot of the DC potential, E, against $\log(i^2/(i_d-i))$ (Fig. 5). As has been stated previously, the sample solutions used in this study contained no free ligand. Therefore, the above linear relation between E and $\log(i^2/(i_d-i))$ implies that one molecule of the ligand will be liberated in the course of the reduction of the complex. Considering the polarographic evidence that the second wave appears at the potential nearly identical to the reduction potential of the corresponding cobalt(II) complex, the ligand liberated in the course of the reduction may be concluded to be the bidentate one. Consequently, the electrode reactions for the reduction of the *β-cis* cobalt(III)-baen and -bisaen complexes at the DME can be formulated as:

$$CoZY^{1-a} + e^- \rightleftharpoons CoZY^{a-}$$

$$CoZY^{a-} + e^- \rightleftharpoons CoZ^- + Y^{a-}$$

On the other hand, in the polarography of a series of mixed cobalt(III)-baen and -bisaen complexes involving amino acids or ammonia (the general formula is $CoZX_2^{1-2b}$), which have the *trans* configuration, the plot of E against $\log(i/(i_d-i))$ for the second step gave straight lines, with slopes falling in the range from 60 to 70 mV, corresponding to the reversible one-electron reduction (Fig. 6). By the addition of lithium(I) perchlorate to the sample solution, the reduction step was shifted remarkably to less negative potentials, and the plot of E against $\log(i^3/(i_d-i))$ in place of $\log(i/(i_d-i))$ gave a straight line with a slope of 57 mV. A typical result is shown in Fig. 7. The above positive shift of the reduction potential and the linear relation between the E and $\log(i^3/(i_d-i))$ can be reasonably explained in terms of the interaction of a lithium(I) ion with the reduction product, the cobalt(I) complex, that is, the coordinative relaxation of the amino acid anion from the cobalt(I)-baen or -bisaen complex.[15] Although the dependence of the potential shift on the concentration of the lithium(I) ion was examined in only a qualitative way, because of the lack of an association constant in the DMF solu-

0.15 M TEAP, 20°C

tion, the finding that the reduction potential is shifted to less negative potentials with an increase in the lithium(I) ion concentration also supports the present authors' explanation. Thus, the above linear relation between E and $\log(i^3/(i_d-i))$ suggests the following reaction mechanism for the relaxation process:

$$CoZX_2^{2-} + e^- + 2Li^+ \rightleftharpoons CoZ^- + 2LiX$$

where Z^{2-} and X^- mean the baen or bisaen anion and the amino acid anion. Therefore, the reduction process of *trans* cobalt(III)-baen and -bisaen complexes involving amino acids or ammonia in solutions not containing lithium(I) salt can be formulated as:

$$CoZX_2^- + e^- \rightleftharpoons CoZX_2^{2-} \quad \text{irreversible}$$

$$CoZX_2^{2-} + e^- \rightleftharpoons CoZX_2^{3-} \quad \text{reversible}$$

The addition of calcium(II) salt to the trans cobalt(III)-baen and -bisaen complex solutions also caused a similar coordinative relaxation. That is, in the presence of the calcium(II) ion, the second wave gave a straight line with a slope of 60 mV between E and $\log(i^2/(i_d-i))$. Those results are not shown here.

We have mentioned earlier that a series of *trans* cobalt(III)-baen and -bisaen complexes with the general formula of $CoZX_2^{1-2b}$ all give the reduction product $CoZX_2^{-(1+2b)}$, which has an atomic configuration similar to that of $CoZX_2^{1-2b}$, in their polarographic reduction at the DME. On the other hand, a series of *β-cis* cobalt(III) complexes with the general formula of $CoZY^{1-a}$ are reduced to the cobalt(I) to give the CoZ^-, thus, liberating the bidentate ligand, Y^{a-}. The coordination of a bidentate ligand such as the acetylacetonate anion and 2,2′-dipyridyl to the metal ion force the baen and bisaen to take a *β-cis* configuration in the octahedral complex. Therefore, the dissociation of bidentate Y^{a-} from the metal will allow the baen and bisaen to be in a *trans* configuration, which has less strain than the *β-cis* configuration.

The concentration of Cu(baen)^0 = 1.74 mM

Square-planar nickel(II) and copper(II)-baen complexes also gave single cathodic waves corresponding to the one-electron reduction of the metal(II) complex (see the I_d values in Table 3). Typical polarograms are reproduced in Figs. 8 and 9. The plot of E against $\log(i/(i_d-i))$ also gave linear relations, with slopes of about 70 mV, corresponding to the following reversible one-electron reduction:

$$MZ^0 + e^- \rightleftharpoons MZ^- \quad \text{reversible}$$

From the above experimental results and the discussion of them, it can be stated that the unusual stability of baen and bisaen complexes containing the metal ion formally in the +1 oxidation state is ascribable to the stable planar configuration of the ligands. The possibility of the formation of cobalt, nickel, and copper metals in the course of the reductions of baen, and bisaen complexes was disproved by the α-nitroso-β-naphthol, dimethylglyoxime, and ammonia tests of

aqueous solutions obtained by treating the mercury metal used in the polarographic study with concentrated hydrochloric acid and by then neutralizing the resulted solutions.

The influence of the replacement of the ligand by the halogen atom on the polarographic behavior of baen complexes was also studied. As is shown by the data in Tables 3 and 4, the introduction of the halogen atom on the ligand causes a remarkable positive shift of polarographic waves. However, *N,N'*-ethylene-bis(3-halogenoacetylacetoniminato) (baen-X_2) complexes also gave well-defined polarographic steps which correspond to the reversible reduction of M(II) to M(I). Although the influence of such a substitution on the coordinated ligand can be discussed from various points of view, as a first approximation the introduction of a halogen atom may be considered to have a remarkable effect on the delocalized π system of the ligand. In considering that the cobalt(III) ethylenediaminetetraacetate complex gives only one reduction step, corresponding to the reduction from Co(III) to Co(II) under the present experimental conditions (Table 4), we can not completely neglect the possibility that the delocalized π system of the baen or bisaen contributes to some extent to the stabilization of the M(I) oxidation state. Therefore, the finding that the metal(II)- baen-X_2 complexes also give polarographic steps which correspond to the reduction of M(II) to M(I) seems to indicate that the delocalized π system of the acetylacetone segment in the baen and bisaen plays only a minor role in the stabilization of the M(I) oxidation state. Furthermore, we can mention the following two facts (Table 4):

1) The first step of the *β-cis* cobalt(III)-baen or -bisaen complex appears at less negative potentials than that of the *trans* complex, $CoZX_2$[1-2b].

2) The reduction steps of the bisaen complexes appear at less negative potentials than those of corresponding baen complexes.

The former can be ascribed to the asymmetric structure of the *β-cis* complex and to the coordination of the bisentate ligand with a delocalized π system.[14] The latter fact, that the reduction wave of bisaen complex is located at a less negative potential than that of the baen complex, is ascribable to the benzene ring of bisaen.[14]

Olson and Vasilevskis[1-3] stated in their electrochemical and synthetic studies of cyclic amine complexes of nickel(II), copper(II), and cobalt(II) that probably the major factor responsible for the unusual stability of the cyclic amine complexes containing the metal ion in the +1 oxidation state is the cyclic nature of the ligands. However, all the experimental evidence obtained in this polarographic study of the metal complexes of noncyclic Schiff bases, baen and bisaen, leads to the conclusion that the unusual stability of metal(I) complexes can be attributed to the rigid and stable square-planar nature of tetradentate ligands. Here, we can not disregard the role played by the stable environment provided by the inert aprotic solvent, DMF.

Ionic Equilibria in Mixed Solvents. VII. Hydrolysis of Copper(II) Ion in Dioxane-Water Mixtures containing 3 M (Li)ClO_4 as an Ionic Medium

Hitoshi OHTAKI and Takayoshi KAWAI

Department of Electrochemistry, Tokyo Institute of Technology, O-okayama, Meguro, Tokyo

(Received October 2, 1971)

The hydrolytic reactions of copper(II) ion were studied at 25°C in water, in 0.1 and 0.5 mole fraction dioxane-water mixtures, each containing 3 M (Li)ClO_4 as an ionic medium. Emf measurements were carried out in the range of the total copper(II) concentration of 0.01125—0.07106 M (in water), 0.01548—0.1356 M (in the 0.1 mole fraction dioxane-water mixture), and 0.02257—0.1231 M (in the 0.5 mole fraction dioxane-water mixture), respectively. Species formed and their formation constants determined (log $*\beta_{p,q}$) are: CuOH (-7.54 ± 0.02), Cu_2OH (-6.22 ± 0.02), $Cu_2(OH)_2$ (-11.12 ± 0.05), and $Cu_3(OH)_2$ (-10.36 ± 0.05) in water; CuOH (-7.44 ± 0.02), Cu_2OH (-6.22 ± 0.02), $Cu_2(OH)_2$ (-11.35 ± 0.05), and $Cu_3(OH)_2$ (-10.12 ± 0.08) in the 0.1 mole fraction dioxane-water mixture; CuOH (-7.74 ± 0.02), and Cu_2OH (-6.40 ± 0.02) in the 0.5 mole fraction dioxane-water mixture.

From the hydrolytic reaction of beryllium ion in dioxane-water mixtures, Ohtaki and Kato[1,2] found that the composition and formation constants of hydrolyzed species of beryllium ions change little even though the dioxane concentration is varied from zero to 0.2 mole fraction (55.01 wt%). Thus, dissociation constants of aquated metal ions, which are weak acids, vary in different manner from those of carboxylic acids[3,4] and of ammonium ions[5,6].

In the present work, the hydrolytic reaction of copper(II) ion was studied by emf measurements in water, in 0.1 and 0.5 mole fraction dioxane-water mixtures, and the chemical species formed and their formation constants were determined.

If we neglect solvated solvent molecules and electric charges of the species for the sake of simplification, the hydrolytic reaction of copper(II) ions can be written as follows, no association of perchlorate ions with any species being assumed;

$$qCu + pH_2O = Cu_q(OH)_p + pH \qquad *\beta_{p,q} = [Cu_q(OH)_p][H]^p/[Cu]^q \qquad (1)$$

h Hydrogen ion concentration in equilibrium.
H Analytical excess of hydrogen ion concentration $=[ClO_4]=2B=[Li]$.
B Total concentration of copper(II) ion.
b Concentration of free copper(II) ion.
Z Average number of hydrogen ions set free per copper ion $=(h-H)/B$.
p Number of hydroxyl groups bound to hydrolyzed species.
q Number of copper atoms present in hydrolyzed species.
$*\beta_{p,q}$ Equilibrium constant for the formation of $Cu_q(OH)_p$.
E Emf.
[ ] Concentration.

The Method of Measurements. B was kept constant during the course of potentiometric titration. Lithium perchlorate was used as an ionic medium in order to keep the total ionic equivalent concentration constant (3 M). Potentiometric titrations were carried out by the following two methods.

1) Water and the 0.1 mole fraction dioxane-water mixture. Ordinary titration method was employed for the cases of water and the 0.1 mole fraction dioxane-water mixture. Thus a titrant was added from a buret to a test solution prepared as follows. Copper(II) perchlorate solution was neutralized with an alkaline solution prepared by electrolysis, until a certain amount of copper hydroxide was precipitated. The turbid solution was bubbled for several days with nitrogen gas which was presaturated with solvent vapor. The solution was then filtered through G3 and G4 glas filters covered with platinum powder, a clear test solution being obtained. The total concentration of copper(II) ion in this solution was determined by means of gravimetry with salicylaldoxime.[7] An acidic titrant with the same concentration of copper(II) ion as that of the test solution was added. The composition of the titrant was B M of $Cu(ClO_4)_2$, H_0 M of $HClO_4$ and $(3-2B-H_0)$ M of $LiClO_4$.

2) In a system of a 0.5 mole fraction dioxane-water mixture, hydrogen ions were generated coulometrically, because solubility of copper hydroxo complexes was so low that a fairly small amount of hydrogen ions had to be added for carrying out measurements and the solution was so viscous that addition of a titrant from a buret gave rise to erroneous results. The electric circuit for coulometry was as follows.

(−) Pt | 0.10 M $AgClO_4$, 2.90 M $LiClO_4$ in water | 3 M $LiClO_4$ in water | 3 M $LiClO_4$ in mixture | Test soln | Pt (+)

Neither precipitation nor turbidity was observed during the course of experiments. A constant emf was obtained within 10 min after addition of a titrant, and remained unchanged for at least 5 hours within the accuracy 0.1 mV.

6) M. H. Miles and E. M. Eyring, *J. Phys. Chem.*, **69**, 467 (1965).
7) F. J. Welcher, "Organic Anayltical Reagents," Vol. III. 2nd ed. D. Van Nostrand C., Inc., New York, N. Y. (1947), p. 262.

The hydrogen ion concentration was determined by means of the cell

$$\text{Ref} \mid \text{Test Solution} \mid \text{GE}, \qquad \text{(A)}$$

where GE denotes a glass electrode and Ref, the reference half cell (B)

$$\left|\begin{array}{l|l|l} 3.000\ \text{M}\ LiClO_4 & 2.990\ \text{M}\ LiClO_4 & \text{AgCl-Ag} \\ \text{in mixture} & 0.010\ \text{M}\ AgClO_4 & \\ & \text{in water} & \end{array}\right| \qquad \text{(B)}$$

The emf of cell (A) can be written (at 25°C) as

$$E = E_0' + 59.15 \log h + 59.15 \log f_H + E_j(h, B), \qquad (2)$$

where E_0' is a constant and f_H represents the activity coefficient of hydrogen ion. The standard state is so defined that f_H as well as the activity coefficients of the reacting species tends to unity as the composition approaches 3 M $LiClO_4$ in a given solvent. $E_j(h, B)$ denotes the liquid junction potential at the junction, test solution | 3 M $LiClO_4$ aqueous solution. The liquid junction potential at the other junction, 3 M $LiClO_4$ in the aqueous or mixed solvent | 2.99 M $LiClO_4$, 0.01 M $AgClO_4$ aqueous solution, can be assumed to be constant throughout the course of titration.

In such a case where the total ionic concentration B, and the solvent composition are kept constant, constancy of f_H can be assumed in the course of a series of potentiometric measurements. When h is small and the total copper ion concentration is kept $E_j(h, B)$ can be a constant and Eq. (2) may be written as follows[2].

$$E = E_0 + 59.15 \log h \qquad (3)$$

where

$$E_0 = E_0' + 59.15 \log f_H + E_j(h, B)$$

This was used to determine the hydrogen ion concentration from emf data.

Experimental

Reagents and Analysis. *Copper(II) perchlorate*: Reagent grade copper(II) nitrate recrystallized twice from water was heated under an infrared lamp until no evolution of NO_2 gas could be recognized, and then in an electric oven for 1 day at 800°C. The copper(II) oxide thus prepared was dissolved in a hot perchloric acid solution and then filtered. Copper(II) perchlorate crystals were obtained by recrystallization. The stock solution of copper perchlorate was prepared by dissolving the crystals in water. pH of the solution was about 2. The acid concentration in the stock solution was determined in the following way. An aliquot (about 50 ml) of aqueous 3 M $LiClO_4$ solution containing about 10^{-3} M $HClO_4$ was gradually neutralized coulometrically. As the volume change is negligible during the course of coulometric titration, the end point was located by plotting $10^{E/59.15}$ against microfaradays passed (Gran plot[8]). A small and known amount of the stock solution of copper(II) perchlorate was then added to the vessel from a weighing buret and the solution was gradually acidified by means of a coulometric generation of hydrogen ions. The amount of acid present in the solution could be estimated from a similar plot of $10^{E/59.15}$ *vs.* microfaradays.

The total perchloric acid concentration determined by the ion exchange method agreed satisfactorily with the sum of equivalent concentrations of copper(II) and hydrogen ions in the solution.

Lithium perchlorate was prepared by the method described by Biedermann and Ciavatta.[9]

Dioxane was purified by the method described elsewhere.[1]

Apparatus. *Glass electrode and pH meter*: Beckman No. 40498 glass electrodes were used in combination with Radiometer PHM-4d pH meter (Copenhagen).

The Wilhelm-type of the half-cell described by Forsling, Hietanen, and Sillén[10] was used for emf measurements.

A coulometric analyzer (Leeds & Northrup Co., Philadelphia, Pa.) was employed as a current power source. Constant currents of 0.643 and 6.43 mA were used; the currents were held constant within ±0.05 and ±0.1%, respectively. Emf measurements were carried out at 25.00±0.01°C in a paraffin oil thermostat in a room thermostated at 25±1°C.

Results

Values of Z and $-\log h$ in each series of B calculated from the emf data are represented graphically in Figs. 1, 2, and 3. The compositions and the formation constants of the species were evaluated on the basis of the data.

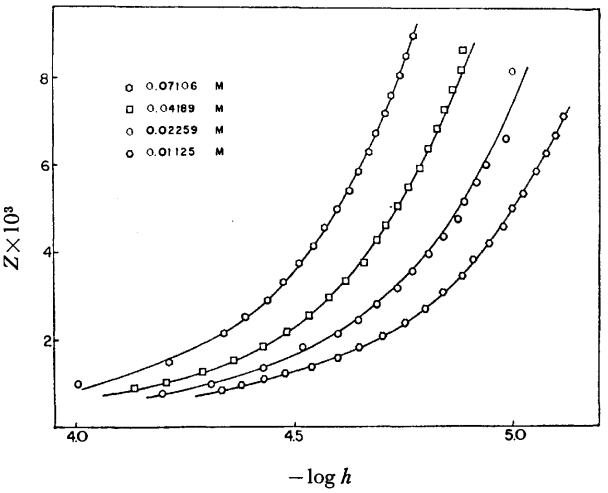

Fig. 1. Values of Z *vs.* $-\log h$ in the aqueous solution. Solid lines show calculated curves of Z with formation constants of $\log {}^*\beta_{1,1} = -7.54$, $\log {}^*\beta_{1,2} = -6.22$, $\log {}^*\beta_{2,2} = -11.12$ and $\log {}^*\beta_{2,3} = -10.36$.

The concentration of hydrogen ion set free by hydrolysis BZ is given by the general formula

$$BZ = \sum_p \sum_q p[Cu_q(OH)_p] = \sum_p \sum_q p {}^*\beta_{p,q} b^q h^{-p} \qquad (4)$$

In the case where maximum value of Z is very low, we can, without introducing any appreciable error, simplify the preliminary calculations by employing the approximation

$$[Cu^{2+}] = b \approx B \qquad (5)$$

Applying the approximation to Eq. (4) and rearrang-

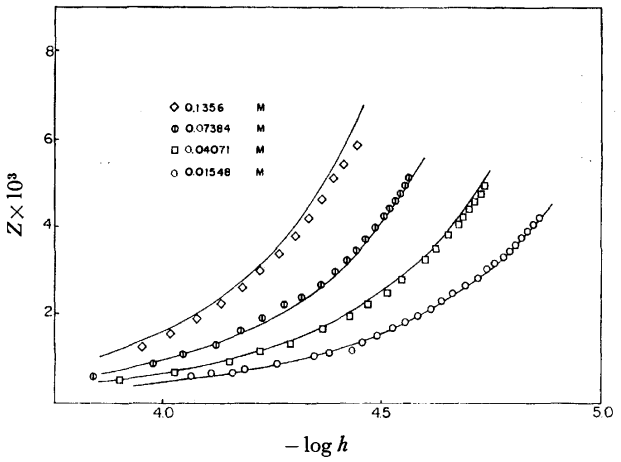

Fig. 2. Values of Z *vs.* $-\log h$ in the solution of a 0.1 mole fraction dioxane-water mixture. Solid lines show calculated curves of Z with formation constants of $\log {}^*\beta_{1,1}=-7.44$, $\log {}^*\beta_{1,2}=-6.22$, $\log {}^*\beta_{2,2}=-11.35$, and $\log {}^*\beta_{2,3}=-10.12$.

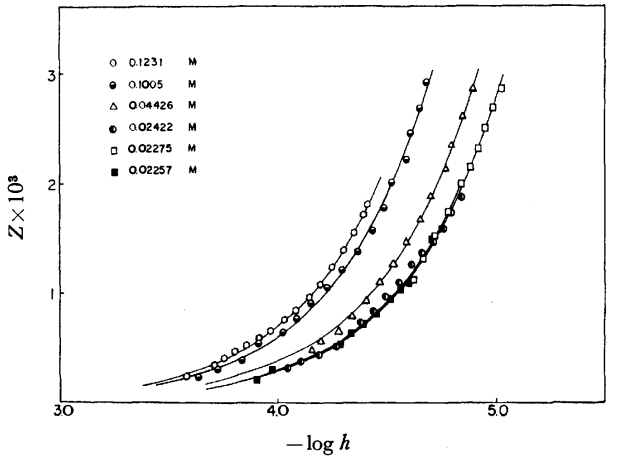

Fig. 3. Values of Z *vs.* $-\log h$ in the solution of a 0.5 mole fraction dioxane-water mixture. Solid lines show calculated curves of Z with formation constants of $\log {}^*\beta_{1,1}=-7.74$ and $\log {}^*\beta_{1,2}=-6.40$.

ing it, we have

$$Zh = \sum_p pK_p h^{-(p-1)} \tag{6}$$

where

$$K_p = \sum_q {}^*\beta_{p,q} B^{q-1} \tag{7}$$

By plotting Zh against h^{-1} we obtain sets of straight lines with various slopes in the system of water and a 0.1 mole fraction dioxane-water mixture, and a set of horizontal lines in the system of the 0.5 mole fraction dioxane-water mixture. We see that there are homoligandic complexes with one and two hydroxo groups in water and in the 0.1 mole fraction dioxane-water mixture, whereas homoligandic complexes with one hydroxo group are formed in the 0.5 mole fraction dioxane water mixture. Plots of $K_1=\sum_q {}^*\beta_{1,q}B^{q-1}$ *vs.* B gave a straight line in each solvent system, which showed that q is equal to 1 and 2 at $p=1$; thus, CuOH and Cu_2OH are present in all solvent compositions examined. The formation constants of the CuOH and Cu_2OH complexes can be obtained from the intercept and the slope of the plot in each solvent system.

The values of the slope ($K_2=2\sum_q {}^*\beta_{2,q}B^{q-1}$) are plotted against B in the case of water and a 0.1 mole fraction dioxane-water mixture. The plot gave a smooth curve with zero intercept. If values of K_2 divided by B were plotted against B, a straight line was obtained in both solvent systems. The result indicates that q is equal to 2 and 3 at $p=2$; the $Cu_2(OH)_2$ and $Cu_3(OH)_2$ complexes exist as dihydroxo complexes. From the intercepts and slopes of these plots the formation constants of the $Cu_2(OH)_2$ and $Cu_3(OH)_2$ complexes are obtained. No other complexes have been detected.

The species formed by hydrolysis of copper(II) ion are found to be CuOH, Cu_2OH, $Cu_2(OH)_2$, and $Cu_3(OH)_2$ in water and in the 0.1 mole fraction dioxane-water mixture, and CuOH and Cu_2OH in the 0.5 mole fraction dioxane-water mixture. Thus, Eq. (4) can be written as

$$BZ = {}^*\beta_{1,1}h^{-1}b + {}^*\beta_{1,2}h^{-1}b^2 + 2{}^*\beta_{2,2}h^{-2}b^2 + 2{}^*\beta_{2,3}h^{-2}b^3 \tag{8}$$

for the systems of water and 0.1 mole fraction dioxane-water mixture and,

$$BZ = {}^*\beta_{1,1}h^{-1}b + {}^*\beta_{1,2}h^{-1}b^2 \tag{8'}$$

for the system of 0.5 mole fraction dioxane-water mixture.

The data were treated by a generalized least-squares method with an electronic computer, HITAC 5020E, in order to make the error square sum $U=\sum(Z-Z_{\text{calcd}})^2$ a minimum for the set of formation constants ${}^*\beta_{p,q}$.

The final values of the constants obtained by computer calculation and their uncertainties estimated are collected in Table 1.

Discussion

Several workers[9,11,12] proposed the formation of $CuOH^+$ and $Cu_2(OH)_2^{2+}$ complexes in aqueous 3 M (Li or Na) ClO_4 solution. Pedersen[13] reported formation of the $CuOH^+$, Cu_2OH^{3+}, and $Cu_2(OH)_2^{2+}$ complexes. Mahapatra[14] confirmed the formation of higher polynuclear complexes.

In the present study we have found the formation of the $Cu_3(OH)_2^{4+}$ complex as well as complexes found by previous workers.[9,11-13] Addition of dioxane, however, prevents the formation of higher complexes.

The difference between $\log {}^*\beta_{1,1}$ and $\log {}^*\beta_{1,2}$ is close to that between $\log {}^*\beta_{2,2}$ and $\log {}^*\beta_{2,3}$. This shows that the stabilization of the Cu_2OH^{3+} complex formed by the combination of a copper ion with an OH^- group in the $CuOH^+$ complex is similar to that of the $Cu_3(OH)_2^{4+}$ complex formed by the combination of a copper ion with the $Cu_2(OH)_2^{2+}$ complex. This

0.5 m.f. dioxane-H_2O	-7.74 ± 0.02	-6.40 ± 0.02	—	—

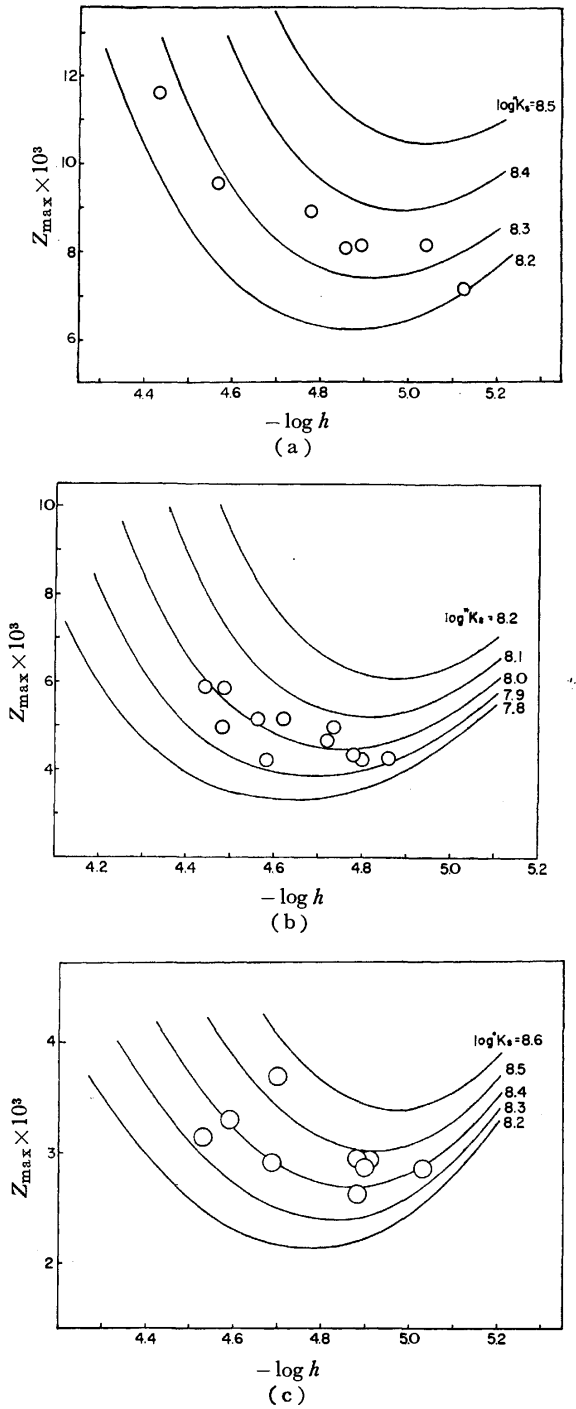

Fig. 4. Z_{max} plotted against $-\log h$. Solid lines are calculated curves of Z_{max} at various values of K_s. a) Water, b) the 0.1 mole fraction dioxane-water mixture, c) the 0.5 mole fraction dioxane-water mixture.

suggests that in the latter reaction the copper ion makes a bond with one OH^- group which is connected with only one copper atom, as in the case of a copper atom combining with one OH^- group in the Cu_2OH^{3+} complex in the former reaction. Thus, the $Cu_2(OH)_2^{2+}$ complex can take a linear form but not a ring form and the $Cu_3(OH)_2^{4+}$ complex can have two single OH^- bridges in the molecule.

In the range of concentration of dioxane up to 0.2 mole fraction, the composition of species produced and their formation constants were scarcely affected by solvent compositions. However, in the 0.5 mole fraction (83.5 wt%) dioxane-water mixture, dihydroxo complexes disappeared while monohydroxo complexes existed without appreciable change in formation constants.

The maximum value of Z, *i.e.*, Z_{max}, at a given B depends on the solubility product of copper hydroxide as well as the formation constants of the complexes in the solution, provided that the solution is equilibrated with copper hydroxide precipitates. If the solubility product ${}^*K_s$ is defined by

$$ {}^*K_s = [Cu^{2+}][H^+]^{-2} = bh^{-2} \simeq Bh^{-2} \quad (9) $$

we get the following equations by substituting this relation into Eqs. (8) and (8'), respectively;

$$ Z_{max} \simeq {}^*\beta_{1,1}h_{max}^{-1} + {}^*\beta_{1,2}{}^*K_s h_{max} + 2{}^*\beta_{2,2}{}^*K_s + 2{}^*\beta_{2,3}{}^*K_s{}^2 h^2{}_{max} \quad (10) $$

for systems of water and 0.1 mole fraction dioxane-water mixture, and

$$ Z_{max} \simeq {}^*\beta_{1,1}h_{max}^{-1} + {}^*\beta_{1,2}{}^*K_s h_{max} \quad (10') $$

for the system of 0.5 mole fraction dioxane-water mixture.

Some supplementary experiments have been achieved to determine Z_{max} at various values of B in these solvents. Since no appreciable increase in Z_{max} was observed when agitation of a solution with copper hydroxide precipitates was continued for 3—7 days, we regarded the solution as a saturated solution with copper hydroxide. Values of Z_{max} thus found are plotted against $-\log h$ in Fig. 4. They are compared with values of Z_{max} calculated by Eqs. (10) and (10') with various values of ${}^*K_s$. From these plots the most probable values of $\log {}^*K_s$ were estimated to be 8.3 ± 0.2 in the aqueous solution, 8.0 ± 0.2 in the 0.1 mole fraction dioxane-water mixture and 8.4 ± 0.2 in the 0.5 mole fraction dioxane-water mixture containing 3M $LiClO_4$ as an ionic medium. From these results it is seen that the solubility product of $Cu(OH)_2$ given in terms of ${}^*K_s$ is practically independent of solvent composition as is so the formation constant of the $Cu_q(OH)_p^{(2p-q)+}$ complex described in terms of ${}^*\beta_{p,q}$.

The authors thank Prof. M. Tanaka, Nagoya University, for his advice. They are indebted to Dr. M. Maeda for valuable discussions.

Interaction between Organoaluminum Compounds and Ditertiary Phosphines Studied by Proton Magnetic Resonance

Teruhiko KAGAWA and Harukichi HASHIMOTO*

Department of Synthetic Chemistry, The University of Tokyo, Bunkyo-ku, Tokyo

**Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai*

(Received October 14, 1971)

The adduct formation of triethylaluminum or diethylaluminum chloride with ditertiary phosphines ($Ph_2P(CH_2)_nPPh_2$ $n=1,2,3,4$, and 6) in benzene solution was investigated by PMR. The adducts have a composition of $(AlEt_3)_2$ (diphosphine) except in the case of $Ph_2PCH_2PPh_2$, which makes two kinds of adducts (1 : 1 and 2 : 1). Electronegativity of the complexed aluminum is also calculated from Dailey-Shoolery equation.

During the course of an investigation of the effect of ligands on butadiene-ethylene codimerization reaction catalyzed by $CoCl_2(Ph_2P(CH_2)_nPPh_2)$-$AlEt_3$,[1] it became desirable to study the interaction of ditertiary phosphine ligand with triethylaluminum. In such catalyst system, the organoaluminum compound may be considered not only to reduce the metal to low oxidation state, but also to activate the low oxidation state complex to make the coordination site(s) vacant.[2] Such activation may be caused by the interaction of ditertiary phosphine(Lewis base) with organoaluminum compound(Lewis acid).

On the other hand, interaction of Lewis bases such as ethers and tertiary amines with organoaluminum compounds has been extensively studied.[3] But much less is studied about the interaction with phosphines,[4] especially ditertiary phosphines.

The object of this paper is to describe the interaction of triethylaluminum or diethylaluminum chloride with ditertiary phosphines $Ph_2P(CH_2)_nPPh_2$ ($n=1,2,3,4$, and 6) by PMR and to discuss the effect of the methylene chain length of phosphines.

Experimental

All operations were performed under dry nitrogen atmosphere.

Reagent. $AlEt_3$ and $AlEt_2Cl$(Ethyl Corp., USA) were distilled under vacuum and ditertiary phosphines $Ph_2P(CH_2)_nPPh_2$ ($n=1,2,3,4,6$)[5] were synthesized according to the method of Hewertson and Watson,[6] and purified toluene and benzene were stored under dry nitrogen.

Procedure. An appropriate amount of 14.5 wt% benzene solution of triethylaluminum was mixed with an appropriate amount of ditertiary phosphine and a small amount of toluene as an internal standard, and this homogeneous solution was poured into 5.0 mm diameter pyrex tube by syringe and the tube was sealed off. Proton magnetic resonance spectra were run at room temperature on Hitachi Perkin-Elmer R-20A at 60 MHz.

Results and Discussion

PMR Spectra of Ditertiary Phosphines and Organoaluminum Compounds. Spectra of 1,1-bis(diphenylphosphino)methane and 1,2-bis(diphenylphosphino)-ethane in benzene solution were observed as a triplet due to the coupling between ^{31}P and ^{1}H, and the coupling constants were as follows; DPM: $|\,^2J_{PH}\,| = 1.8$ cps, DPE: $|\,^2J_{PH}+{}^3J_{PH}\,| = ca.$ 8.4 cps. The methylene proton resonaces of other longer methylene chain ditertiary phosphines occurred as a broad band and were not analysed further.

The signals of methyl and methylene protons of triethylaluminum, which has been analysed as A_2B_3 system,[7] were simply analysed as triplet and quartet respectively in this paper.

Ditertiary Phosphines-Organoaluminum Compounds Systems. Spectrum of ditertiary phosphine-$AlEt_3$ system consists of singnals due to methylene protons of ditertiary phosphine, a triplet of methyl protons and a quartet of methylene protons of $AlEt_3$. The chemical shift and the coupling constant (^1H-^{31}P) of ditertiary phosphines and the chemical shift of two kinds of protons of $AlEt_3$ vary with molar ratio of ditertiary phosphine/$AlEt_3$. This is considered to be a result of adduct formation by the interaction of diphosphine as a Lewis base with triethylaluminum as a Lewis acid in solution. Consequently, a composition of this adduct will be estimated from the variation of these parameters (namely chemical shift and coupling constant) with molar ratio.

The variation in the chemical shift of methylene protons of DPE, and of methyl and methylene protons of aluminum compounds with DPE/Al molar ratio in DPE-$AlEt_3$ or $AlEt_2Cl$ systems is shown in Fig. 1. The chemical shift of DPE is constant until the molar ratio becomes 0.5, but that of methyl- and methylene protons of aluminum are linearly increased. On the further addition of DPE a monotonous and nearly linear decrease in chemical shift of DPE is observed,

○ P-C$\underline{H}_2$-P, △ Al-C-C$\underline{H}_3$, □ Al-C$\underline{H}_2$-C

but the ethyl signals of aluminum part are almost constant. This may show that DPE and $AlEt_3$ form 1 : 2 adduct in solution. Similar behavior has been observed in a system of $AlEt_3$-PMe_3 by Cullingworth and co-workers[4b] and a change of chemical shift occurs at the molar ratio of 1 : 1. The variation of these parameters in the system of DPM-$AlEt_3$ is slightly different from that of DPE system and shown in Fig. 2. In this case the parameters vary at molar ratio of 0.5 and 1.0, and two kinds of adduct, *i.e.*, 1 : 2 and 1 : 1, may be present.

Other ditertiary phosphines (DPP, DPB, and DPH) were examined with combination of triethylaluminum and the results are the same as DPE system. Using triphenylphosphine as a monophosphine, chemical shifts of $AlEt_3$ vary at 1 : 1 molar ratio like PMe_3.

The coupling constants J_{PH} of DPE and DPM changed also with the molar ratio and this variation

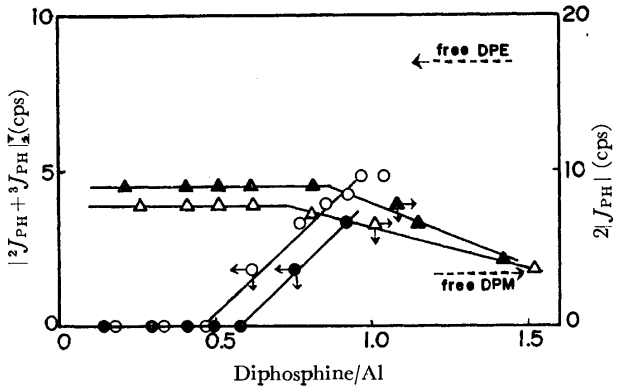

Fig. 3. Change in coupling constant ($^1H-^{31}P$) of DPM and DPE.
DPM: △ $AlEt_3$ ▲ $AlEt_2Cl$
DPE: ○ $AlEt_3$ ● $AlEt_2Cl$

is given in Fig. 3. As seen in Fig. 3, the change in DPE system occurs at the ratio of 0.5 in a similar manner to the chemical shift described above, and this is a piece of evidence in support of the formation of 1 : 2 adduct. But the changing point in the DPM system is at molar ratio of ca 0.8 and this may also show that there are two kinds of adduct in solution. The reasons why $|\,^2J_{PH}\,|$ of complexed DPM is larger than that of free one and why $|\,^2J_{PH}+{}^3J_{PH}\,|$ of complexed DPE is smaller than that of free ligand are not clear. It may be necessary to know the sign of coupling constants between ^1H and ^{31}P.

It is now concluded by the variations of chemical shift and the coupling constant with molar ratio that ditertiary phosphines ($Ph_2P(CH_2)_nPPh_2$, n=2,3,4,6) form 1 : 2 adduct with triethylaluminum in solution, while DPM forms 1 : 1 and 1 : 2 adducts. These results are similar to those of ditertiary amine-trimethylaluminum systems[10], in which $Me_2NCH_2NMe_2$ forms 1 : 1 complex, and $Me_2N(CH_2)_2NMe_2$ and $Me_2N(CH_2)_3NMe_2$ form 1 : 2 complex. The relationship between composition of the adduct and the methylene chain length*(n)* is same in both cases except n=1.

An empirical linear relationship between the electronegativity χ of a metal atom (CH_3CH_2M) and its internal shift Δ: a difference in the chemical shift of methylene and methyl protons, was known as Dailey-Shoolery equation and this equation has been useful in studying the change of electronegativity with coordination of donor molecules.[11]

$$\chi = 0.62\Delta + 2.07$$

11) T. Takeshita and W. E. Frankle, *Tetrahedron Lett.*, **1968**, 5913.

The Lewis acidity of aluminum coordinated with diphosphine was evaluated by application of Dailey-Shoolery equation to ditertiary phosphine-$AlEt_3$ system. The variation in the internal shift with the molar ratio of diphosphine/$AlEt_3$ was calculated from above data and shown in Fig. 4. As expected, the complex formation with phosphine results in decreasing the electronegativity of aluminum. The effect of the length of methylene chain in the ditertirary phosphines is not so remarkable but the following order of donor ability to aluminum was obtained: DPP>DPB≈DPH≳DPE>DPM.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1741—1746 (1972)

The Dissolution of Olivine in Aqueous Solutions of Inorganic Acids[1)]

Isao SANEMASA, Minoru YOSHIDA, and Takejiro OZAWA

Department of Chemistry, Faculty of Science,
Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 17, 1971)

The dissolution of olivine was studied in aqueous solutions of inorganic acids at temperatures of 35, 50, and 65°C in order to obtain basic information about the alteration and leaching processes in acid hot spring regions. The rates of dissolution have been determined by measuring the change in the concentrations of silica, magnesium, and the total iron leached in the solutions as a function of the time. Olivine dissolved in stirred aqueous solutions of 0.05—2N perchloric, hydrochloric, and sulphuric acids without any selective dissolution of components in the mineral. The rate at which olivine dissolved was found to be two-thirds of the reaction order with respect to the sample-powder (10—20 μ in diameter) weight (*i.e.*, first order with respect to the surface area) and to decrease in the order of $H_2SO_4 \gg HCl > HClO_4$. HSO_4^- enchanced the rate remarkably. The complexing affinity of the anions did not play an important part in the reaction with olivine powder.

Studies of the leaching of chemical elements from rocks and minerals from various points of view have been reported by many investigators.[2-5)] Olivine is a common and important rock-forming mineral; it is particularly characteristic of basic and ultrabasic igneous rocks. The minerals of the olivine group are very susceptible to hydrothermal alteration, low-grade metamorphism, and weathering.[6)] As a result, olivine has been observed to be more altered than magnetite, the glassy part, and pyroxene in natural altered rocks found in acid hot spring regions.[7)]

Heterogeneous reactions between inorganic materials and aqueous solutions are important in discussing the alteration and weathering of rocks and minerals and the formation of ores and thermal waters. The kinetics of the dissolution of ferric oxide[8,9)] and gibbsite[10)] in aqueous solutions have been studied, while silicate minerals,[11-13)] especially feldspars,[14,15)] have also been investigated, mainly from the practical point of view. It is somewhat difficult to study the rate at which silicate minerals go into a solution, since their structures are complicated.

The olivine group has a fundamental structure in silicate minerals, which consist of independent $[SiO_4]^{4-}$ tetrahedra linked by divalent ions in a six-fold coordination. Leaching and hydrothermal alteration experiments of olivine have been carried out in order to clarify the origin of chemical species in natural waters,[16)] the mechanism of weathering,[17)] and alteration at high temperatures.[18)]

The object of this paper is to obtain some basic information on the kinetic behavior of olivine in acid hot spring regions.

Experimental

Materials. The olivine (Fo_{91}) sample used in the present study was separated from dunite[19] from Takashima, Karatsu, Saga Prefecture. The dunite was constituted of 94, 3, 3, and 0.1 vol% of olivine, spinels, clinopyroxene, and orthopyroxene respectively. The dunite was crushed in a steel Ellis mortar and powdered in an agate mortar. The fraction containing particles between 150 and 200 meshes was collected, washed with distilled water, and dried at 110°C. After this treatment, the olivine was separated by means of an iso-dynamic magnetic separator (S. G. Frantz Co., INC, Model L-1). This fraction will hereafter be called Sample A. This sample was further finely pulverized in an agate mortar again. This powder was sized by sedimentation in distilled water to 10—20 μ, and then dried at 110°C. This fraction will be called Sample B. The chemical composition of the olivine sample is given in Table 1. Accord-

Table 1. Chemical composition of olivine

Constituent	Content (%)

H_2O (−)	0.0
H_2O (+)	0.0
P_2O_5	trace
Total	100.45

ing to Dr. Kiyoshi Ishibashi, who examined this olivine sample microscopically, the spinel-group minerals (mainly chromite) and pyroxene comprized less than 3—4 vol%, while no hydrous minerals were observed as alteration products. The purity of the sample is sufficient for the present purposes.

Reagents. All the chemicals used were of analytical-reagent quality. Concentrated perchloric, hydrochloric, and sulphuric acid were diluted to the desired concentrations with redistilled water; the concentrations of the acid in the dilute solutions were determined by titration against a standard sodium carbonate solution. A sodium hydrogen sulphate solution (0.45 M) was prepared by adding a sodium hydroxide solution to a sulphuric acid standard solution in just half the volume required for neutralization.

Equipment. The reaction vessel was a 300-m*l* glass flask with four necks; the center neck was connected with a water-sealed stirring rod, while the other three were fitted with a nitrogen-introducing tube, a condenser, and a stopper. The stoppered neck was utilized to add the sample powder to the aqueous solution and to take out the sample solution. The container was placed on a water bath thermostated at from 35—65°C to 0.1°C.

Measurements of Reaction Kinetics. The sample powder, 200 mg for Sample A and 100 mg for B, was disperesed in 200 m*l* of an aqueous acid solution in the reaction vessel, into which nitrogen gas had previously been introduced continuously. The mixture was then stirred at about 1000 rpm. The preliminary experiments revealed that the stirring speed, over the range of about 200 to 2000 rpm, did not affect the rate of dissolution of the sample powder. After various times, 2-m*l* aliquots of the sample solution were withdrawn for analysis in the following manner. When Sample A was used, the stirring was stopped for 30 sec before each desired time. The sample particles were allowed to settle on the bottom of the reaction vessel; then the supernatant was pippetted off at the prescribed time, and it was submitted to chemical analysis. On the other hand, when Sample B was used, a portion of the reaction solution containing sample particles was pippetted off immediately at each desired time with continuous stirring. The mixture was then filtered and washed with redistilled water through a membrane filter(having a porous size of 0.45 μ) with suction into a 25-m*l* volumetric flask.

Chemical Analysis of the Reaction Solution. The silica was determined photometrically by the silico-molybdate yellow method.[20] We found no colloidal silica under the present experimental conditions. The total iron was estimated photometrically with α,α'-dipyridyl after the reduction of all the iron to the ferrous state using sodium thioglycolate. The magnesium was determined by the Xylidyl blue-II[21] photometric method,[22] with some modifications.

Results and Discussion

The Amount of Each Element Dissolved from Olivine. Tarutani[16] reported, in his leaching studies in the pH range from 1.5 to 10 with or without organic acid (EDTA and citric acid), that olivine dissolved in the same ratio as that in the mineral into a solution of pH 1.5 and into solutions with the organic acids except at pH 10. However, his experiments lacked sufficient data, since his major attention was devoted to the effects of organic acids on the leaching process. On the contray, Hoppe,[17] who studied the question from the view of the weathering of rocks, assumed the presence of a residual layer rich in iron.

Figures 1, 2, and 3 show how amounts of silica,

○: SiO_2 ◐: Mg ●: Fe

magnesium, and iron dissolved from olivine (Sample B) increase against the time of the reaction in 0.1 N perchloric, hydrochloric, and sulphuric acid solutions (200 ml) at 50°C.

The initial amount of each component presented in the olivine sample, W_0, can be calculated from Table 1, *i.e.*, 40.2 mg as SiO_2, 30.2 mg as Mg, and 7.49 mg as Fe for 100 mg of Sample B. Table 2 shows the amount of each component dissolved in a 0.1 N perchloric acid solution at different times, $(\Delta W)_{sol}$, and the ratios of each $(\Delta W)_{sol}$ to W_0. The amount of Fe is the sum of Fe^{2+} and Fe^{3+}. The $(\Delta W)_{sol}/W_0$ ratios for SiO_2, Mg, and Fe in solution are shown to be in fairly good agreement at any time of reaction. This suggests that olivine is dissolved in an acid inorganic solution without any selective dissolution of the components in the mineral, as was pointed out by Tarutani.[16] The selective dissolution of silica and magnesium, resulting in a residual layer rich in iron, was not observed under the present experimental conditions.

(a): $(\Delta W)_{sol}$, mg. (b): $(\Delta W)_{sol}/W_0$

Dissolution Rate of Olivine. When the reaction at the solid surface is the rate-determining step, the reaction rate, dw/dt, is said to be given by the following equation:[23]

$$-dw/dt = k_0SC \quad (1)$$

where w and S indicate, respectively, the weight and the surface area of the particles remaining at the reaction time, t, where k_0 is the rate constant per unit of surface area, and where C is the concentration of the reactant. Spherical particles of W_0 grams, the average radius of which is r_0, are used as the initial material. The rate can be shown by Equation (2):

$$-dw/dt = 3k_0W_0^{1/3}W^{2/3}C/r_0d_s \quad (2)$$

where d_s is the specific gravity of the solid. As $3k_0W_0^{1/3}C/r_0d_s$ is constant, we can obtain Equation (3) by integrating Eq. (2):

$$W_0^{1/3} - W^{1/3} = 1/3\,kt \quad (3)$$

where k is constant. By substituting Eq. (3) for $W=W_0(1-\alpha)$, we obtain:

$$1-(1-\alpha)^{1/3} = 1/3\,kW_0^{-1/3}t \quad (4)$$

Since $1/3\,kW_0^{-1/3}$ is a constant, we can obtain a straight-line relationship by plotting $1-(1-\alpha)^{1/3}$ *vs.* t.

From the definition of α, $\alpha=(W_0-W)/W_0=(\Delta W)_{t,sol}/W_0$, where $(\Delta W)_{t,sol}$ is the weight loss of the mineral into a solution at time t. Olivine, $(Mg, Fe)_2SiO_4$, dissolves into aqueous solutions of acids to form soluble aquo-magnesium and ferrous (ferric in part) cations and silicic acid.[24] Theoretical-

ly, the sum of the components in a solution should be equal to the weight loss of the solid. The results obtained, given in Table 3, confirmed the material balance among them. Thus, $(\Delta W)_{t,sol}$ is equal to the sum of the amounts of each component dissolved in the solution at time t. The amounts of the other components in olivine are negligibly small compared with those of the three components. The plots of $1-(1-\alpha)^{1/3}$ against time t, in 0.1 N perchloric, hydrochloric, and sulphuric acid solutions at 35, 50, and 65°C, are shown in Figs. 4 and 5, which give straight lines up to about 85% dissolution. These results suggest that olivine powder (10—20 μ) reacts with well-stirred aqueous perchloric, hydrochloric, and sulphuric acid solutions according to a two-thirds reaction order with respect to the powder weight; that is, the reaction is first-order with respect to the surface area. It may be seen from Figs. 4 and 5 that the rate at which olivine goes into $HClO_4$ solutions is almost the same as that at which it goes into HCl solutions, but it is apparently enhanced in H_2SO_4 solutions under the same reaction conditions.

The Estimation of the Activation Energy. The relation between the slopes of the straight lines in Figs. 4 and 5 and the reaction temperatures is illustrated in Fig. 6 according to the Arrhenius plot. The apparent activation energy, 14 Kcal/mol, obtained for

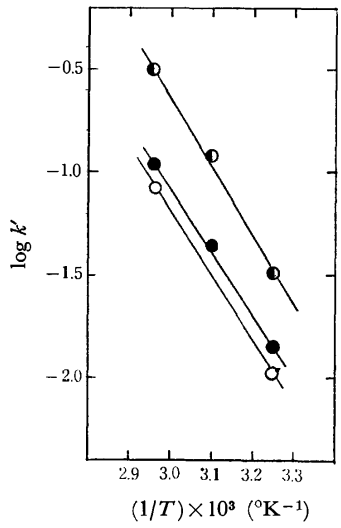

Fig. 6. Arrhenius plots for the dissolution of olivine in $HClO_4$, HCl, and H_2SO_4 solutions. k' corresponds to 1/3 $k\ W_0^{-1/3}$ in Eq. (4).
○: $HClO_4$, ●: HCl, ◐: H_2SO_4

the reaction with $HClO_4$ is similar to that for the reaction with HCl. For the reaction with H_2SO_4, it is somewhat higher, *i.e.*, 16 Kcal/mol. That is, the enhanced rate of the reaction with a sulphuric acid solution corresponds to the increase in the pre-exponential term in the Arrhenius equation.

In the subsequent experiments, Sample A was used; its particle size was larger than that of Sample B. The rate of the reaction was measured by estimating only the total iron dissolved in the solution at various times. The rate of dissolution was interpreted by comparing it with the slopes of straight lines for the range where a plot of the amount of total iron against the time is linear.

Effect of the HSO_4^- Ion. The dissolution curves at 50°C for $HClO_4$ with a concentration of 0.05—2 N, HCl with one of 0.05—1 N, and H_2SO_4 with one of 0.05—1 N are illustrated in Figs. 7, 8, and 9 respectively. The straight lines break early in the reaction at an about 5% dissolution. These breaks are also observed in the cases of silica and magnesium. No explanation for these bends can be offered at the

Table 4. Acid normalities and slopes of straight lines

N	Slopes of straight lines (mg/hr)		
	$HClO_4$	HCl	H_2SO_4
0.05	0.18	0.22	0.50
0.1	0.24	0.26	0.78
0.2	0.29		0.93
0.5	0.41	0.53	1.2
1	0.61	0.75	1.5
2	0.80		

present time. The slopes of these lines, ranging from about 5 to 35% dissolution at various acid normalities, are listed in Table 4. Table 4 shows that the values for HCl are somewhat greater than those for $HClO_4$, while those for H_2SO_4 are markedly greater than those $HClO_4$ and HCl with the same hydrogen-ion concentration.

In order to confirm the remarkable enhancement in the sulphuric acid solution, experiments were made in

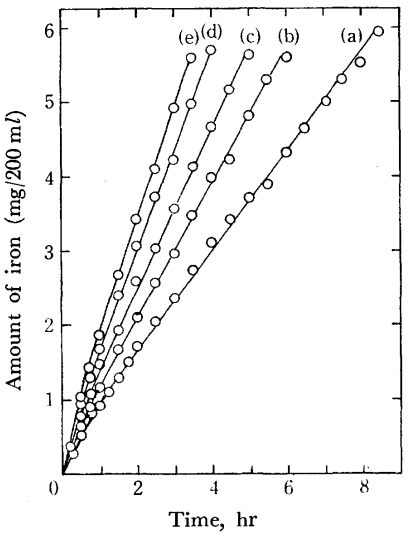

Fig. 10. Effect of the HSO_4^- ion on the dissolution of olivine at 50°C.
(a): 1 M $HClO_4$
(b): 1 M $HClO_4$+0.98×10^{-3} M $NaHSO_4$
(c): 1 M $HClO_4$+0.49×10^{-2} M $NaHSO_4$
(d): 1 M $HClO_4$+0.49×10^{-1} M $NaHSO_4$
(e): 1 M $HClO_4$+0.2 M $NaHSO_4$

solutions containing 1 M $HClO_4$ and $NaHSO_4$ in various concentrations. At such a high hydrogen-ion concentration, the dissociation of the HSO_4^- ion is negligible. The results obtained are shown in Fig. 10. It is apparent from Fig. 10 that the presence of the HSO_4^- ion in only one-thousandth the concentration of $HClO_4$ promotes the dissolution rate considerably.

According to the studies of the dissolution of hydrous ferric oxide by Furuichi *et al.*[25] and of α-ferric oxide by Pryor *et al.*[9] and Azuma,[8] each in aqueous acid solutions, the rate of dissolution is in accord with the order of decrease in the complexing affinity of the anions for the ferric ion, *i.e.*, $HCl > H_2SO_4 > HClO_4$. On the other hand, Packter *et al.*[10] observed that the rate of the dissolution of gibbsite in the H_2SO_4 solution was markedly enhanced as compared to those in the HCl and $HClO_4$ solutions. They attributed the promoting effect of sulphuric acid to dipole interaction between the HSO_4^- ion or $H^+\cdots SO_4^{2-}$ ion-paris and active sites on the solid surface. Our study of olivine showed the effect of sulphuric acid to be similar to the case of gibbsite.

Effect of Cl^- and ClO_4^- ions. The rate of dissolution was measured in 0.2 M $HClO_4$ solutions with varying NaCl concentrations, and was also measured in 0.1 M $HClO_4$ solutions containing an adequate amount of $NaClO_4$. The results are shown in Fig. 11 and 12. The rate of the dissolution of olivine was found to be greater in the solutions containing the ClO_4^- ion as well as Cl^- ion than in the solutions without them. The effects of the Cl^- and ClO_4^- ions were, however, very small compared with that of the HSO_4^- ion. The roles of each anion, HSO_4^-, Cl^-, and ClO_4^-, in the reaction of dissolution may be

Distribution Studies of the Potassium Salts with Hexanitrodiphenylamine and Analogous Acids

Tadashi IWACHIDO

College of Liberal Arts, Okayama University, Tsushima, Okayama

(Received December 16, 1971)

The association constants of potassium salts with 2,4,6,2′,4′,6′-hexanitrodiphenylamine (hexyl), *N*-(2,4,6-trinitrobenzo)-2,4-dinitro-1-naphthylamine (α-hexyl), and 1,3,7,9-tetranitrophenothiazine-5-oxide (thiohexyl) in the nitrobenzene phase were determined conductometrically. The distribution constants and the association constants of these salts in an aqueous phase were determined simultaneously by means of solvent extraction. The dissociation constants in the aqueous phase and the distribution constants of the acids were estimated from an analysis of the curve obtained by plotting the distribution ratios of the metal or the acids against the pH. The results show that these salts exist mainly in the dissociated form in both phases. The applicability of the proposed distribution mechanism was also discussed.

In a previous paper,[1] the extraction mechanism of the alkali metal picrates into nitrobenzene has been discussed. This paper will show that the distribution of alkali metals or picric acid can well be explained in terms of the association constants of the salts in both the aqueous and the nitrobenzene phases, in terms of the dissociation constant of picric acid in the aqueous phase, and in terms of the distribution constants of the salts.

The distribution ratio of the alkali metals increases with a decrease in the association constant in the nitrobenzene phase and with an increase in that in the aqueous phase. In an earlier work,[2] it has been shown that some amine derivatives have a high extractability for potassium (% E=60 or more), even in the presence of much greater amounts of lithium ions (added as a buffer solution, $[Li^+]/[K^+]=100—1000$), which is quite different from the case of potassium picrates (%E=2, when $[Li^+]/[K^+]=100$). The present paper will describe how the extraction mechanism established for alkali metal picrates is also useful for weak and bulky acids, such as hexyl, α-hexyl, and thiohexyl. The amounts of lithium ions in the aqueous phase are decisive for the determination of the

2) T. Iwachido, *ibid.*, **44**, 1835 (1971).

distribution ratio of potassium, especially at an alkaline pH.

Experimental

Reagents. Potassium salt with hexyl was prepared by dissolving commercially-available hexyl into a hot aqueous solution containing potassium carbonate. The resultant precipitates were recrystallized three times from water containing a small amount of potassium carbonate. α-Hexyl was prepared by the nitration of the condensation product of picrylchloride with 1-naphthylamine[3], and thiohexyl, by the nitration of phenothiazine.[4,5] Potassium salts with these acids were prepared by dissolving these substances into a hot mixture of alcohol and water containing potassium carbonate; then the precipitates were recrystallized three times from such a mixture.

Acetic acid-lithium acetate buffers (0.01 M) and 0.01 M phosphoric acid-lithium phosphate buffers were used to adjust the pH values of the solution to pH 4—5.5 and pH 6—8 respectively. More alkaline solutions (pH 9—11) were prepared with a 0.005 M lithium carbonate solution and hydrochloric acid and a pH 12 solution, with a 0.01 M lithium hydroxide solution.

Extraction. Into a 50-m*l* centrifuge tube equipped with a stopper, 10 m*l* of a 0.01 M buffer solution and 10 m*l* of water were transferred; then 20 m*l* of a nitrobenzene solution containing potassium salts of these acids (1×10^{-3} M) was added. The resultant mixture of the aqueous and nitrobenzene solutions was shaken moderately for two hours at 25°C and then centrifuged at the same temperature. The preparation of the aqueous phase was slightly modified when the association constant and the distribution constant in the aqueous phase had been determined: 10 m*l* of an 8×10^{-4} M potassium hydroxide solution was mixed with 10 m*l* of a potassium chloride solution, the concentration ranging from 0 to 2×10^{-3} M. The resultant solutions were then treated as before.

Determination of Potassium, Lithium, and the Acids. The concentration of potassium remaining in the aqueous phase after equilibration and that of lithium extracted into nitrobenzene were determined using an atomic absorption spectrophotometer (Nippon Jarrell Ash, Type AA-1); the concentrations of the acids in the aqueous phase were determined spectrophotometrically (Hitachi Ltd.; Spectrophotometer, Type 124) using matched 50-mm cells at 425, 445, and 463 mμ for hexyl, α-hexyl, and thiohexyl respectively, while the solution was kept sufficiently alkaline (pH 13) to avoid the hydrolysis of the salts. The pH of the aqueous solution was also measured in order to analyse the distribution equilibria.

Conductance Measurements in the Nitrobenzene Solution. Nitrobenzene of a guaranteed-grade was washed with an aqueous solution of sodium carbonate and then distilled water, and subsequently dried over calcium chloride for two days. The nitrobenzene was then distilled under reduced pressure. A fraction boiling at 75°C/5 mmHg, with a specific conductance of 0.02 μ℧/cm, was collected. The specific conductance of the water-saturated or wet nitrobenzene was about 20 times that of the dry nitrobenzene. The conductance of the nitrobenzene solution placed in a jacketted vessel equipped with platinized platinum electrodes and a thermometer (a thermocouple; Cu-Con.) was measured by using a conductometer (Ando Electric Co. Ltd., LCR-10, Universal Bridge), while the temperature of the solution was kept at 25±0.005°C by circulating the thermostated water. In order to obtain the $\Lambda-\sqrt{C}$ plot, a dilution method using a weighing buret was adopted.

Theoretical

By writing the formulae for the hexyl, α-hexyl, and thiohexyl acids and the potassium salts of these acids as HR and MR respectively, the equilibria involved can be represented schematically as in Fig. 1:

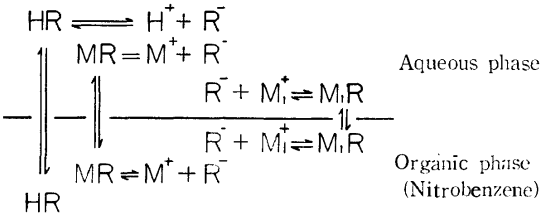

Fig. 1. Schematic representation of the equilibria involved in the extraction.

1) Dissociation of the Acids:

$$HR \rightleftharpoons H^+ + R^- \qquad K_a^{HR} = \frac{[H^+]_a[R^-]_a}{[HR]_a} \tag{1}$$

2) Association of Potassium Salts:

$$M^+ + R^- \rightleftharpoons MR \qquad K_a^{MR} = \frac{[MR]_a}{[M^+]_a[R^-]_a} \tag{2}$$

$$K_o^{MR} = \frac{[MR]_o}{[M^+]_o[R^-]_o} \tag{3}$$

$$M_I^+ + R^- \rightleftharpoons M_IR \qquad K_a^{M_IR} = \frac{[M_IR]_a}{[M_I^+]_a[R^-]_a} \tag{4}$$

$$K_o^{M_IR} = \frac{[M_IR]_o}{[M_I^+]_o[R^-]_o} \tag{5}$$

3) Distribution of the Neutral Molecules:

$$D^{HR} = \frac{[HR]_o}{[HR]_a} \tag{6}$$

$$D^{MR} = \frac{[MR]_o}{[MR]_a} \tag{7}$$

$$D^{M_IR} = \frac{[M_IR]_o}{[M_IR]_a} \tag{8}$$

In these equilibrium expressions, the subscripts a and o refer to the aqueous and the organic phases respectively; the brackets, to the molar concentration, and M_I^+, to a competing cation. As the competing cation, it is desirable to choose the lithium ion, because the extractability of the lithium salts with the acids is much lower than that of the potassium salts.

i) Association Constant, K_o^{MR}. The association constants of these salts in a nitrobenzene solution were determined by the method of Shedlovsky.[6] The conductances, Λ, were related to the concentration of the electrolytes, C, by the following equation:

$$\frac{1}{\Lambda S} = \frac{1}{\Lambda_\infty} + \frac{K_o^{MR}C\Lambda S f_o^2}{\Lambda_\infty^2} \qquad S \equiv \left[\frac{Z}{2} + \sqrt{1+\left(\frac{Z}{2}\right)^2}\right]^2 \qquad Z = \frac{\alpha\sqrt{C\Lambda}}{\Lambda_\infty^{3/2}} \tag{9}$$

where Λ_∞ refers to the limiting conductance; f, to the mean activity coefficient, and α, to the Onsager

6) T. Shedlovsky, *J. Franklin Inst.*, **225**, 739 (1938).

coefficient.

ii) Association Constant, K_a^{MR}, and Distribution Constant, D^{MR}. The distribution ratio of the acid, q^R, in a sufficiently alkaline solution can be written as:

$$q^R = \frac{[MR]_o + [R^-]_o}{[MR]_a + [R^-]_a} \tag{10}$$

In this case only, the pH of the solution was adjusted by the use of potassium hydroxide instead of the lithium buffers. Hence, the terms of lithium in neither phase appears in the expression (cf. Eq. (13)).

The combination of Eqs. (2), (3), and (7) leads to the following equation:

$$\frac{Y}{q^R} = \frac{1}{D^{MR}} + \frac{1}{D^{MR}K_a^{MR}f_a^2[M^+]_a}$$

$$Y = \frac{\sqrt{0.25 + C_oK_o^{MR}f_o^2} + 0.5}{C_oK_o^{MR}f_o^2} + 1 \tag{11}$$

The values of the mean activity coefficient, f, in both the aqueous (ε=78.54) and the nitrobenzene (ε=34.8) phases were approximated by the Debye-Hückel limiting law:

$$-\log f^2 = \frac{3.6494 \times 10^6 \sqrt{I}}{(\varepsilon T)^{3/2}} \tag{12}$$

where I denotes the ionic strength.

iii) Distribution of the Acids. The distribution ratio of the acid at equilibrium between the two phases can be written as:

$$q^R = \frac{[HR]_o + [MR]_o + [M_IR]_o + [R^-]_o}{[HR]_a + [MR]_a + [M_IR]_a + [R^-]_a} \tag{13}$$

The substitution of the equilibrium constants defined by Eqs. (1) to (8) into Eq. (13) gives this equation:

$$q^R = D^{HR}\frac{\left[1 + \left\{\left(1 + \frac{1}{K_o^{MR}[M^+]_o}\right)D^{MR}K_a^{MR}[M^+]_a + D^{M_IR}K_a^{M_IR}[M_I^+]_a\right\}\frac{K_a^{HR}}{D^{HR}[H^+]_a}\right]}{\left\{1 + \left(1 + K_a^{MR}[M^+]_a + K_a^{M_IR}[M_I^+]_a\right)\frac{K_a^{HR}}{[H^+]_a}\right\}} \tag{14}$$

iv) Distribution of Potassium. At equilibrium the distribution of potassium between the two phases can be written as:

$$q^M = \frac{[MR]_o + [M^+]_o}{[MR]_a + [M^+]_a} \tag{15}$$

The total concentrations of the reagent, C^R, and of potassium, C^M, are represented as:

$$C^R = [HR]_a + [HR]_o + [MR]_a + [MR]_o + [M_IR]_a + [M_IR]_o + [R^-]_a + [R^-]_o \tag{16}$$

$$C^M = [MR]_a + [MR]_o + [M^+]_a + [M^+]_o \tag{17}$$

The electroneutrality condition in the organic phase is expressed as:

$$[R^-]_o = [M^+]_o + [M_I^+]_o \tag{18}$$

Combining Eqs. (16), (17), and (18) and solving for $[R^-]_a$ gives:

$$\frac{1}{[R^-]_a} = \frac{1 + \frac{1 + D^{HR}}{K_a^{HR}}[H^+]_a + (1 + D^{M_IR})K_a^{M_IR}[M_I^+]_a}{C^R - C^M + [M^+]_a - [M_I^+]_o} \tag{19}$$

On the other hand, the rearrangement of Eq. (15) gives:

$$q^M = D^{MR}\left(\frac{1 + \frac{1}{K_o^{MR}[R^-]_o}}{1 + \frac{1}{K_a^{MR}[R^-]_a}}\right) \tag{20}$$

The substitution of Eq. (19) into Eq. (20) gives this useful expression:

$$q^M = D^{MR}\frac{\left(1 + \frac{1}{K_o^{MR}([M^+]_o + [M_I^+]_o)}\right)}{\left\{1 + \frac{1 + (1 + D^{HR})[H^+]_a/K_a^{HR} + (1 + D^{M_IR})K_a^{M_IR}[M_I^+]_a}{K_a^{MR}(C^R - C^M + [M^+]_a - [M_I^+]_o)}\right\}} \tag{21}$$

It must be noted that all the experiments were carried out under such a condition as $C^R - C^M = 0$, which can easily and exactly be realized by the use of the salt as the source of the reagent and the metal species. This is also advantageous in simplifing Eq. (21).

Results and Discussion

i) Equilibria Involved in the Extraction System. The equilibria shown in Fig. 1 are fundamental ones. Certainly, some other equilibria also exist in the two phases, such as the dissociation of the acids in nitrobenzene, the homoconjugation reaction (as has been mentioned in connection with picric acid in nitrobenzene),[7] the dimerization of the acids in both phases, *etc.* Lin[8] has suggested that the polymerization of hexylate ions in the aqueous phase does not occur until the concentration of hexylate exceeds 10^{-2} M.

The present studies of the distribution of potassium or the acids between the aqueous and the nitrobenzene phases show that the neglect of the reactions mentioned above does not cause any trouble in explaining the experimental results. This fact supports the idea that these equilibria are of minor importance.

ii) Association Constants of Potassium Salts in Nitrobenzene, K_o^{MR}. The conductance measurements were carried out with a cell devised for dilution runs, the concentrations ranging from about 0.5×10^{-4} to 7×10^{-4} M. A plot of Λ *vs.* $\sqrt{C}$ gives good straight lines, the intercepts on the Λ-axis for potassium salts with hexyl, α-hexyl, and thiohexyl being 31.42, 30.89, and 29.90 respectively, and the slope giving a value almost equal to Onsager's coefficient for each salt. The Shedlovsky plot (Fig. 2) was obtained by the the following calculations. First, z (Eq. (9)) is calculated from the Λ_∞ evaluated approximately by extrapolating the above linear $\Lambda-\sqrt{C}$ plot to the Λ-axis, and then the Shedlovsky plot is made by the help of Eq. (12). The reciprocal of the intercept of the plot on the $1/(\Lambda S)$-axis gives the second approximation for Λ_∞. The process is repeated until the Λ_∞ thus obtained is no longer altered. The final plots are shown in Fig. 2. The values of Λ_∞ and K_o^{MR} can be determined simultaneously from the plot. The value of K_o^{MR} in the wet nitrobenzene solution is calculated in the same manner, because the saturation of water (about 0.1 M) does not alter the dielectric constant of nitrobenzene (34.8) practically. Table 1 shows that the saturation of water causes about a 1.5-hold increase in Λ_∞ and a large decrease in K_o^{MR}. Taking into consideration the fact that the Λ_∞ values of potassium picrate are 34.7 and 40.3 for dry and the wet nitrobenzene solutions respectively, the sequence of Λ_∞ may well account for the bulkiness of the conjugate base, R^-.

iii) Distribution Coefficients, D^{MR}, *and Association Constants of Potassium Salts in the Aqueous Phase,* K_a^{MR}. The pH values of the aqueous solution were kept at pH 10.46±0.03, 10.14±0.02, and 11.67±0.01 for hexyl, α-hexyl, and thiohexyl respectively. A plot of Y/q^M *vs.* $1/(f_a^2[M^+]_a)$ (Fig. 3) shows a line in accordance with the theoretical requirements. However, the enlarged plot for thiohexyl shows that the line curves slightly downwards at the upper part.

For potassium picrate, it has been reported that the values of K_a^{MR} and D^{MR} are 44 and 0.014 respectively.[1] A comparison of the present results with those of the picrates shows that the structural difference (for example, in a functional group or bulkiness) be-

tween the picrates and the acids much more significantly influences the value of D^{MR} than that of K_a^{MR}. It may, however, be difficult to point out such a correlation between K_a^{MR} or D^{MR} and the structural factors among these three acids.

iv) Distribution of Potassium, q^M. Figures 4, 5, and 6 show a plot of log q^M *vs.* pH by means of solid circles. Each curve consists of two constant-slope portions; that is, one is a line with a slope exactly 1/2, and the other, a horizontal line independent of the pH.

The appearance of the horizontal line can be explained from Eq. (21) by assuming that the potassium or lithium concentration in both phases attains a certain constant value characteristic of the acids in a sufficiently high pH region. The $(1+D^{HR})[H^+]_a/K_a^{HR}$ term is, of course, much smaller than unity and smaller than the $(1+D^{M_IR})[M^+]_a$ term. If the $[M^+]_a$ term can be assumed to be much larger than $[M_I^+]_o$, Eq. (21) reduces to a much simpler expression, as has been pointed out in the case of alkali metal picrates,[1] as:

$$(q^M)^2 = \frac{K_a^{MR} D^{MR}}{K_o^{MR}} \qquad (22)$$

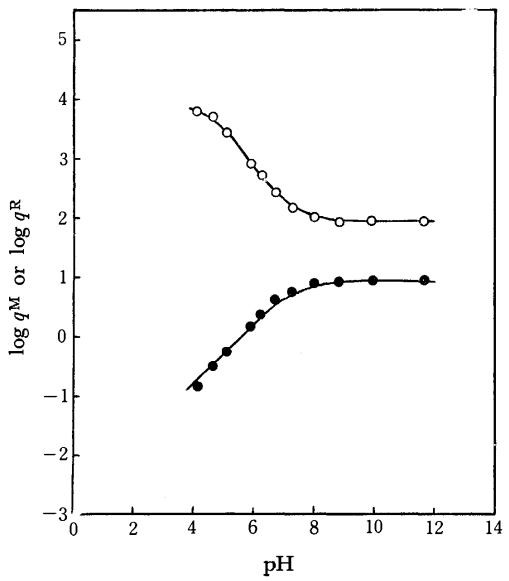

Fig. 4. The distribution of the potassium salt with hexyl,

Solid circles: log q^M – pH curve.

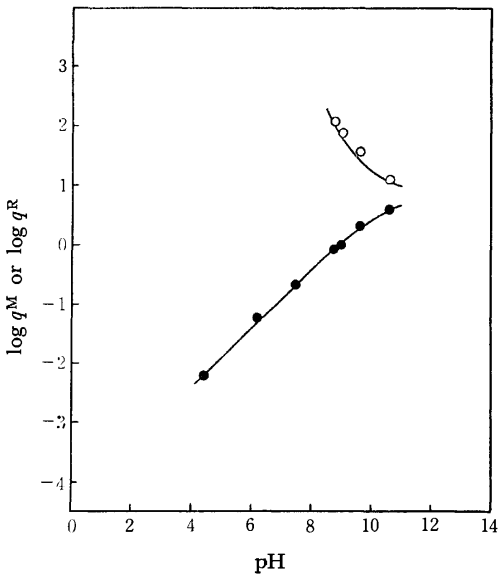

Fig. 6. The distribution of the potassium salt with thiohexyl,
Open circles: log q^R – pH curve
Solid circles: log q^M – pH curve.

Figures 4 and 5 show that the q^M values measured at sufficiently high pH values are considerably smaller than those to be expected from Eq. (22), as shown in Table 1. Such a result can well be understood by taking into account the effect of the concentration of the lithium extracted, $[M_I^+]_o$. In fact, the results of the atomic absorption spectrophotometric measurements show that the extractabilities of potassium salts by these acids are so high that the concentration of potassium in the aqueous phase, $[M^+]_a$, decreases to about 10^{-4} M. The value is only slightly larger than that of the lithium extracted, $[M_I^+]_o$, though the extractability of lithium ions still remains much lower than that of potassium. Therefore, the neglect of the $[M_I^+]_o$ term compared to the $[M^+]_a$ term causes a large deviation between the measured q^M values and q^M values estimated by means of the much simpler expression. An atomic absorption spectrophotometric method might not always be satisfactory in finding out such a small difference.

Thiohexyl reveals no horizontal line below pH 11.5. With a more alkaline solution (pH 12.69), a slightly small q^M value was obtained (log q^M=0.356). The decrease in q^M value can also be explained from Eq. (21) by taking into account the increased value of $[M_I^+]_o$. The log q^M value thus obtained is 0.3564. The good agreement between the measured and calculated q^M values may prove the usefulness of Eq. (21).

On the other hand, when the aqueous solution is acidic, potassium as well as lithium ions will remain

almost unextracted in the aqueous phase to satisfy the condition $[M^+]_a \gg [M_I^+]_o$. Accordingly, under such a condition a useful approximation for q^M may be obtained from Eq. (21) by making the following assumptions:

$$[M^+]_o \gg [M_I^+]_o,\ D^{M_IR} \ll 1,\ D^{HR} \gg 1, \text{ and } q^M \approx \frac{[M^+]_o}{[M^+]_a}$$

In this manner, Eq. (21) can be simplified to the following expression:

$$(q^M)^2 = \frac{[M^+]_o + \frac{1}{K_o^{MR}}}{[M^+]_a + \frac{1}{K_a^{MR}}\left(1 + \frac{D^{HR}}{K_a^{HR}}[H^+]_a + K_a^{M_IR}[M_I^+]_a\right)} \quad (23)$$

Under sufficiently acidic conditions, Eq. (21) is further simplified, yielding:

$$(q^M)^2 = \frac{D^{MR}K_a^{MR}K_a^{HR}}{K_o^{MR}D^{HR}} \cdot \frac{1}{[H^+]_a} \quad (24)$$

A plot of log q^M *vs.* pH gives a straight line with a slope of 1/2; the intercept on the Y/q^M-axis is given by $1/2(\log K_a^{MR}D^{MR}K_a^{HR}/K_o^{MR}D^{HR})$. In Figs. 4, 5, and 6, it is shown that the above relation holds well in the acidic region. The solid line in each figure was drawn by means of Eq. (21) so as to fit well with the experimental values (solid circles) by choosing an appropriate value for K_a^{HR}/D^{HR} (Table 1).

v) Distribution of the Acids, q^R. The dependence of the distribution ratio of the acid upon pH is expressed by Eq. (14). This equation may well be understood by dividing it into two equations on the basis of appropriate assumptions; that is, an equation which holds in a sufficiently alkaline pH:

$$q^R = \frac{\left(1 + \frac{1}{K_o^{MR}[M^+]_o}\right)D^{MR}K_a^{MR}[M^+]_a + D^{M_IR}K_a^{M_IR}[M_I^+]_a}{1 + K_a^{MR}[M^+]_a + K_a^{M_IR}[M_I^+]_a} \quad (25)$$

and one which holds in a sufficiently acidic pH:

$$q^R = D^{HR} \quad (26)$$

When the aqueous solution is sufficiently alkaline, the amounts of potassium in both phases attain a certain constant value, as has been mentioned before. Accordingly, from Eq. (25) it can be expected that log q^R will also attain a certain constant value. Figures 4 and 5 show that Eq. (25) holds well in such an alkaline solution. Thiohexyl (Fig. 6) does not show such a constant portion below pH 11.5.

On the other hand, when the aqueous solution is sufficiently acidic, it can be expected from Eq. (26) that the log q^R value will also attain a constant value. Only hexyl reveals incompletely the presence of such a constant. The distribution behavior in a more acidic region can be shown only when more sensitive methods than spectrophotometry are available for the determination of the acid in the aqueous phase.

When the pH value of the solution is comparable with that of pK_a^{HR} ($K_a^{HR}/[H^+]_a \approx 1$), no terms (except lithium terms) can be neglected. Therefore, it is impossible to make such an illustrative statement about the distribution curves.

When appropriate values for K_a^{HR} and D^{HR} are chosen, a theoretical q^R—pH curve which fits well with the experimental values should be obtained. In Figs. 4, 5, and 6 the calculated curves are shown by solid lines. The fit is the best for the hexyl salt. In the remaining two salts, the experimental q^R values are so few that the K_a^{HR} and D^{HR} values can not be determined exactly, because the data on q^R in the acidic region (which are lacking in the experiment) are dominant in determining these values. This can easily be understood from the fact mentioned above; that is, the q^R values in the alkaline region do not depend upon K_a^{HR} or D^{HR} (cf. Eq. (25)). The K_a^{HR} value thus obtained for hexyl agrees well with that reported by Lin[9] ($pK_a = 5.4$). It is noticeable, however, that the K_a^{HR} values reported by Grunwald,[10] Glover,[11] and O'Donnell[12] are much larger than that of the present work.

vi) Association Constants, $K_a^{M_IR}$, and Distribution Constants, D^{M_IR}, for the Lithium Salts. The values of $K_a^{M_IR}$ and D^{M_IR} for these salts have not been reported, except in the case of hexyl salt ($K_a^{M_IR} = 8.9$, $D^{M_IR} = 0.5$[13]). The atomic absorption spectrophotometric measurements proved that the distribution ratio of lithium was almost the same for hexyl and α-hexyl and was considerably smaller for thiohexyl. This fact supports the idea that the terms containing these constants are negligibly small, as is the case with hexyl. Therefore, for α-hexyl and thiohexyl the theoretical q^R—pH and the q^M—pH curves are calculated by means of Eqs. (14) and (21) respectively, disregarding these terms.

In conclusion, the present work has made it clear that the distribution mechanism proposed for alkali metal picrates is valid also for the acids which show a high extractability. However, it must be noted that the application of this method suffers some limitations from the properties of the acid used. The acids favorable for such distribution studies are sufficiently acidic in nature to prevent the hydrolysis of the salts in wet nitrobenzene. The hydrolysis makes it impossible to determine the association constant of the salt by conductometry. Another important requirement is that the acids must have a moderate q^R or q^M value. For example, with an acid having an extremely high q^R value the method fails to determine a dissociation constant and a distribution constant, as has been mentioned in connection with α-hexyl and thiohexyl.

The author wishes to express his gratitude to Professor Kyoji Tôei for his guidance throughout the course of this work.

Kinetic Studies of the Nickel Malate Complex Formation in Solution by the Pressure-jump Method

Shoji HARADA, Katsuyoshi AMIDAIJI, and Tatsuya YASUNAGA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received December 21, 1971)

The nickel malate complex formation reaction in an aqueous solution, $Ni^{2+}+Mal^{2-} \underset{k_d}{\overset{k_f}{\rightleftharpoons}} NiMal$, where Mal^{2-} represents the malate ion, was studied by the pressure-jump method. The following rate constants and the equilibrium constant were obtained: $k_f=5.6\times10^5$ M^{-1} sec^{-1}, $k_d=17$ sec^{-1} and $K=3\times10^4$ M^{-1} at 25°C and $\mu\rightarrow0$. Studies at various temperatures between 12 and 30.5°C gave the thermodynamic parameters. In comparison with the results on other ligand complexes, the ligand effects seem to be found not in the formation rate constant, but in the dissociation rate constant. The results indicate that the rate-determining step of the complex formation is the release of the water molecule from the inner coordination sphere of the nickel ion.

The development of the relaxation method has made it possible to study kinetically the fast metal complex formation reactions.[1] Some of the complex formations of the nickel(II) ion have been studied by the flow method,[2] the temperature-jump method,[3] the pressure-jump method[4], and most recently by the pressure-shock method.[5] These studies have revealed that the step-by-step association picture proposed by Eigen[6] *et al.* for the complex formation reaction is valid and that the rate-determining step is the release of the water molecule from the inner coordination sphere of the nickel ion. In the case of the complex formation with a bidentate ligand, however, two water molecules on the nickel ion should be replaced, and the reaction mechanism is more complicated.

The present study was undertaken in order to obtain kinetic information on the nickel malate complex formation reaction and in order to compare the ligand effects on the kinetic parameters with those of other bidentate ligands. Another purpose was to test the operation of a newly-built device at the beginning of the pressure-jump study.

Experimental

All of the chemicals used were of a reagent grade. A stock solution of nickel malate was prepared by mixing a stoichiometric amount of $NiSO_4$ with malic acid, and then it was titrated with a solution of $Ba(OH)_2$ until all the sulfate ion had precipitated as $BaSO_4$. The solid $BaSO_4$ was removed by filtration. The concentration of the nickel malate of the resultant solution was determined by a dimethylglyoxime titration. Each solution studied was prepared by diluting the stock solution to the desired concentration. The pH values of the solutions were $\geq$6.5 where most of the ligand was in the dissociated form. In order to reduce the cavitation effects, the solutions were degassed by sonoration with a 400 KHz transducer under reduced pressure.

The pressure-jump apparatus used was a modification of that described by Macri and Petrucci.[7] The pressure-jump cell is shown in Fig. 1. N_2 gas was introduced from

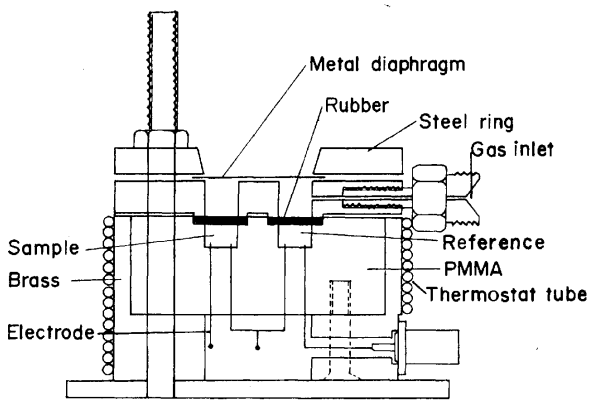

Fig. 1. Pressure-jump cell.

the gas inlet until a brass diaphragm burst at a pressure of approximately 25 atm. The pressure of the two cells, one containing the sample solution and the other containing the reference KCl solution, decreases abruptly from 25 to 1 atm. The concentration changes of the species were followed by means of the electric conductivity method; *i.e.*, the two cells were in separate arms of a Wheatstone bridge circuit fed from a 150 KHz oscillator. To calibrate the time constant of the apparatus, a 0.02 M $MgSO_4$ solution which exhibites a relaxation effect faster than 1 μsec was used. From the trace obtained (Fig. 2a), the apparatus has been proved to be useful for kinetic studies of reactions with relaxation times down to 100 μsec. The temperature of the sample cell was controlled to $\pm$0.5°C by circulating the water from a thermostat through a copper tube spiraled around the cell.

In all the nickel malate solutions, the relaxation spectrum was characterised by a single relaxation time. A representative relaxation spectrum is shown in Fig. 2b. The reciprocal relaxation time was calculated from a plot of $-\log \Delta C$ *vs.* the time, where ΔC is the deviation of the concentration from its equilibrium value. The quoted relaxation times and the rate constants are the mean values of several runs.

Results

In the present studies, the complex formation reaction may be expressed as follows:

$$M^{2+} + L^{2-} \underset{k_d}{\overset{k_f}{\rightleftharpoons}} ML \qquad (1)$$

where M^{2+} is the metal ion, L^{2-} is the ligand, and ML is the complex. The rate constants are related to the relaxation time, τ, by the following equation:

$$1/\tau = k_d + k_f\gamma_{\pm}^2(C_M + C_L) \qquad (2)$$

where C_M and C_L are the concentrations of M^{2+} and L^{2-} respectively and where $\gamma_{\pm}$ is the mean activity coefficient of the free ions. The experimental conditions and the observed relaxation times at 25°C are shown in Table 1.

The complex formation constant, $K(=k_f/k_d)$, of nickel malate was not, unfortunately, given in the literature, so the values of k_f, k_d, and K were calculated from the kinetic data. As the first approximation, a value of K which had been roughly estimated from those of nickel malonate and succinate[8] was used to calculate the ionic concentrations. The activity coefficients of the ions were calculated by means of the Kielland equation.[9] The $1/\tau$ values were plotted against $\gamma_{\pm}^2(C_M+C_L)$ to give k_f and k_d from the slope and the intercept of the line respectively. Here, the ratio of k_f and k_d should coincide with the first estimated K value. The same procedures were repeated until a constant K value was obtained. The final results are shown in Fig. 3, and the following rate and equilibrium constants were obtained: $k_f=5.6\times10^5$ M^{-1} sec^{-1}, $k_d=17$ sec^{-1}, and $K=3\times10^4$ M^{-1} at 25°C $\mu\to0$.

a) C_o refers to the total stoichiometric concentrations of nickel malate.

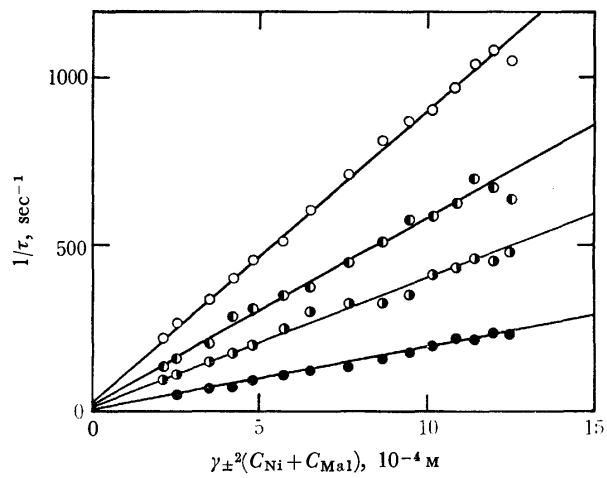

Fig. 3. $1/\tau$ *vs.* $\gamma_{\pm}^2(C_{Ni}+C_{Mal})$ plot at 12°C (●), 20°C (◑), 25°C (◐), and 30.5°C (○).

In order to determine the energies of activation, a series of experiments was run covering the temperature range from 12 to 30.5°C. The rate constants, k_f, and k_d, and the equilibrium constants at each temperature were obtained from Fig. 3. The Arrhenius energy of activation, $\Delta E_f^{\ddagger}$, was obtained from the plot of $\log k_f$ against $1/T$, as is shown in Fig. 4. The entropy of activation, $\Delta S_f^{\ddagger}$, the enthalpy of activation, $\Delta H_f^{\ddagger}$, and the free energy of activation, $\Delta G_f^{\ddagger}$, were calculated from the next

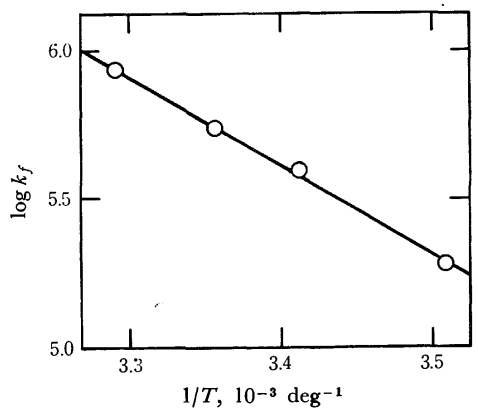

Fig. 4. Temperature dependence of k_f.

$$\log A = \log \frac{eRT}{Nh} + \frac{\Delta S_f^{\neq}}{2.3R} \tag{3}$$

$$\Delta H_f^{\neq} = \Delta E_f^{\neq} - RT \tag{4}$$

$$\Delta G_f^{\neq} = \Delta H_f^{\neq} - T\Delta S_f^{\neq} \tag{5}$$

where A is the frequency factor.

Discussion

The kinetic data obtained for the nickel malate systems are compared with those for similar systems in Table 3. The values of k_f lie in approximately the same order, $\sim10^5$ M^{-1} sec^{-1}, irrespective of the nature of the ligand, and the ligand effects are found not in the value of k_f, but in the values of k_d and K.

Eigen and his co-workeers have proposed[6] a mechanism of complex formation reaction *via* rapid ion-pair formation, followed by the rate-determining loss of a water molecule in the inner coordination sphere of the metal ion:

$$\underset{\text{I}}{Ni(H_2O)_6^{2+} + Mal^{2-}} \overset{K_0}{\rightleftharpoons} \underset{\text{(II)}}{[(H_2O)_5Ni(H_2O)Mal]} \overset{k_{12}}{\underset{k_{21}}{\rightleftharpoons}} \underset{\text{(III)}}{[(H_2O)_5NiMal]} \overset{k_{23}}{\underset{k_{32}}{\rightleftharpoons}} \underset{\text{(IV)}}{[(H_2O)_4NiMal]} \tag{6}$$

where state (I) is the free ions, state (II) is the ion-pair, state (III) is the half-bonded intermediate, state (IV) is the bidentated complex, and K_0 is the ion-pair association constant.

On the assumptions that the intermediate state (III) is in a steady state and that $k_{23} \gg k_{21}$, the rate constant in Eq. (6) may be thus related to the formation rate constant in Eq. (1):

$$k_f = K_0 \cdot k_{12} \tag{7}$$

K_0 cannot be determined experimentally, so it has become customary to estimate it by means of the Fuoss equation.[3,8] For 2—2 electrolytes, K_0 can be calculated to be about 25 M^{-1}. The rate constant for the rate-determining process of Reaction (6), k_{12}, was, then, calculated to be 2.2×10^4 sec^{-1} by means of Eq. (7).

As may be seen in Table 4, this value has become of interest in comparison with the case of other ligand complexes, *i.e.*, the rate constants of the rate-deter-

mining process of the nickel complex formation lie approximately 10^3—10^4 sec^{-1} irrespective of the nature of the entering ligand. The small difference between them may be due to the approximation in calculating K_0. These facts indicate that the loss of a water molecule in the inner coordination sphere of the nickel ion is the rate-determining process of the complex fomration reaction.

Activation parameters can be reevaluated as follows for the detailed mechanism of complex formation in considering the variation in the free energy (ΔG_0), the entoropy (ΔS_0), and the enthalpy (ΔH_0) for the ion-pair formation:

$$\Delta G_0 = -RT \ln K_0 \tag{8}$$

$$\Delta S_0 = -19.4\, Z_- Z_+ / a = \Delta S^* - \Delta S_{12}^* \tag{9}$$

$$\Delta H_0 = \Delta G_0 + T\Delta S_0 = \Delta H^* - \Delta H_{12}^* \tag{10}$$

where Z is the valence of the ion and where a is the distance of the closest approach of the ion-pair partners (5Å). The results are listed in Table 2. In comparison with the complexes of other ligands, the thermodynamic parameters calculated are of the same order of magnitude, despite the large differences in the nature of the ligands, *e.g.*, the carbon number and the acidity. This fact also suggests that the rate-determining step of the complex formation is the release of the water molecule from the inner-sphere of the nickel ion.

In acid solutions, another path of the nickel malate complex formation can be proposed:

$$Ni^{2+} + HMal^- \rightleftharpoons NiMal + H^+ \tag{11}$$

In this experiment, however, the relaxation effect has become small with an increase in the concentration of $HMal^-$. Therefore, we could not obtain very precisely the dependency of τ on the hydrogen-ion concentration, as was done in the nickel malonate complex formation reaction.[11]

The authors wish to express their thanks to Mr. Takayasu Goto for the assistance he has given in the construction of the apparatus.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1755—1759 (1972)

The Crystal Structure of $(-)_{589}$-Dinitrobis(ethylenediamine)cobalt(III) $(+)_{589}$-Bis(malonato)ethylenediaminecobaltate(III)

Keiji MATSUMOTO and Hisao KUROYA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received December 24, 1971)

The crystal structure of $(-)_{589}$-[$Co(NO_2)_2en_2$] $(+)_{589}$-[Co mal_2 en] has been investigated by the X-ray method. Crystal data: triclinic, space group $P\bar{1}$; $a=10.58(2)$Å, $b=7.98(1)$Å, $c=7.99(1)$Å, $\alpha=122.8(2)°$, $\beta=105.3(2)°$, $\gamma=74.6(2)°$; $Z=1$. The crystal structure was determined by the Fourier technique and was refined by the least-squares method to an R factor of 0.101. The Δ configuration has been assigned to both the complex cation and anion, $(-)_{589}$-$[Co(NO_2)_2en_2]^+$ and $(+)_{589}$-[Co $mal_2en]^-$. The two Co-mal chelate rings are nearly planar. The O–Co–O angle in this ring is 96°, slightly larger than the N–Co–N angle observed in the cobalt(III)-trimethylenediamine chelate ring. All the ethylenediamine ligands in the two complex ions have the *ob*-conformation.

The absolute configuration of $(-)_{589}$-[Co $mal_2en]^-$ (mal=malonate ion) was studied by Douglas and his co-workers[1] by means of the ORD and CD spectra. They identified the lowest frequency CD peak with a positive sign as the A component by referring to the ORD and CD spectra of $(+)_{589}$-[Co $ox_2en]^-$ and $(-)_{546}$-[Co EDTA]$^-$; thus, they assigned the Δ configuration to $(-)_{589}$-[Co $mal_2en]^-$ on the basis of Mason's empirical rule.[2]

Recently, Judkins and Royer[3] measured the CD spectrum of $\Delta(+)_{589}$-[Co $tn_3]^{3+}$ in a signle crystal, showed that the relative positions of the E_a and A_2 bands in this complex are reversed as compared with those found in $\Delta(-)_{589}$-[Co $en_3]^{3+}$, and concluded that the sign of the Cotton effect should change when the coordination angle (θ) in the chelate ring goes from less than to greater than 90°, as had been predicted by Piper.[4] If such is the case with the Δtris(malonato)-cobalt(III) (possibly $\theta>90°$; this complex has not yet been prepared) and the Δtris(oxalato)coablt(III) complexes, the CD signs of their E_a components will be the opposite of each other. On the other hand, the rotational strength of the A component, $R(A)$, of the bis-complex seems to have a sign reflecting that of the R (E_a) of the parent tris-complex.[5] Therefore, the sign of the A component of $\Delta(-)_{589}$-[Co $mal_2en]^-$ should be the reverse of that of $\Delta(+)_{589}$[Co $ox_2en]^-$. These circumstances were not taken into account by Douglas *et al.* in making the assignment of the absolute configuration of $(-)_{589}$-[Co $mal_2en]^-$. In order to re-examine and determine its configuration directly,

we carried out a crystal-structure analysis of $(-)_{589}$-$[Co(NO_2)_2en_2]$ $(+)_{589}$-[Co mal_2en].

Experimental

The complex compound, $(-)_{589}$-$[Co(NO_2)_2en_2]$ $(+)_{589}$-[Co mal_2en], was prepared following the method of Dwyer *et al.*[6]; subsequent recrystallization from an aqueous solution yielded brown crystals suitable for X-ray work. Using Cu$K\alpha$ radiation, the unit-cell dimensions were determined from higher angle reflections of Weissenberg photographs, on which aluminum powder diffraction lines were superimposed for calibration. Oscillation and Weissenberg photographs did not show any special symmetry or systematic absences, indicating that the space group is $P1$ or $P\bar{1}$. Only the former is, however, consistent with the optical activity of the specimen. The crystal data are as follows:

Triclinic
$a=10.58(0.02)$Å
$b=7.98(0.01)$Å
$c=7.99(0.01)$Å
$\alpha=122.8(0.2)°$
$\beta=105.3(0.2)°$
$\gamma=74.6(0.2)°$
Space group $P1$
$Z=1$ ($D_m=1.81$, $D_c=1.82$ g cm^{-3})
$\mu=35.9$ cm^{-1} for Ni$K\alpha$

Multiple-film, equi-inclination Weissenberg photographs were taken about the c (0 to 4th layers) and a axes (0 to 3rd layers) using Ni$K\alpha$ radiation. The intensities of 1442 independent reflections were estimated visually with the standard calibrated scales, but 71 of these were too weak to be measured: therefore, their intensities were assumed to be zero. The intensities were corrected for the usual L_p factor and spot shape,[7] but not for absorption. The crystal specimen used for the data collection had dimensions of $0.1\times0.04\times0.4$ mm.

Determination of the Crystal Structure

The positions of the two cobalt atoms were readily determined from the three-dimensional Patterson map. Their positional and thermal parameters were refined by the least-squares method. At this stage, the R factor was 0.411. The two nitro groups and one malonate ligand were found on the Fourier map phased by the two heavy atoms (Co_1 and Co_2). Then, the parameters of the 15 atoms thus obtained were refined and the structure factors were computed by their use. The subseuqent Fourier synthesis of the electron density showed the locations of all the remaining atoms. The five cycles of the least-squares refinement with an individual isotropic temperature factor reduced the R value to 0.101 for 1371 observed reflections. The weighting scheme employed was:

$w=0.3$ for $F_0<3.8$
$w=1.0$ for $3.8\leq F_0\leq 25.9$
$w=25.9/F_0$ for $F_0>25.9$

The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[8] The real part of the anomalous disperison correction for Co was taken into account.[9] A subsequent refinement, in which anisotropic vibrations were permitted to the two cobalt atoms, improved neither the R factor nor the e.s.d.'s of the parameters. A difference synthesis computed at this stage did not show peaks corresponding to any of the hydrogen atoms. The final atomic coordinates, the temperature factors, and their e.s.d.'s are given in Table 1. The observed and calculated structure factors are preserved by the Chemical Society of Japan.[10]

were determined by using the anomalous dispersion effects of the cobalt atoms for Cu$K\alpha$ radiation. The right-handed coordinate system was used in the indexing of the Weissenberg photographs throughout the present work. The intensities of the $hk0$ reflections were compared with those of $\bar{h}\bar{k}0$ on Weissenberg photographs around the c axis. The inequality relationships which were observed for some Bijvoet pairs are shown in Table 2. In this table the calculated intensities which were obtained by the use of the atomic coordinates shown in Table 1 are also listed. The values of $\Delta f'_{Co}$ and $\Delta f''_{Co}$ were taken from the International Tables for X-ray Crystallography.[8] A comparison of the observed inequality relationships with the calculated ones indicates that the set of the atomic coordinates shown in Table 1 represents the absolute structure of the crystal.

Results and Discussion

Projections of the crystal structure of an symmetric unit along the c and b axes are presented in Figs. 1 and 2 respectively. The crystal is composed of $(-)_{589}$-$[Co(NO_2)_2en_2]^+$ and $(+)_{589}$-$[Co\ mal_2en]^-$ ions, which are linked to each other by hydrogen bonds. In order to confirm the hydrogen bonds which exist between the amine groups of the coordinated ethylenediamine ligands and the oxygen atoms of the malonate ions, the positions of the hydrogen atoms were computed on the assumption that the $>NH_2$ groups have the tetrahedral geometry and the N–H bond distance is 1.03 Å.[11] The hydrogen bonds are summarized in Table 3. In the $(-)_{589}$-$[Co(NO_2)_2en_2]^+$ cation, all of the $H(NH_2)$'s of the ethylenediamine ligands participate in the hydrogen bonding. The N_4–H···O_8 and N_6–H···O_5 bonds seem to be stronger than the other six bonds. In the $(+)_{589}$-$[Co\ mal_2en]^-$ anion, only one hydrogen atom of the individual NH_2 group takes part in the hydrogen bonding; these N–H···O bonds are as strong as the N_4–H···O_8 and N_6–H···O_5 bonds.

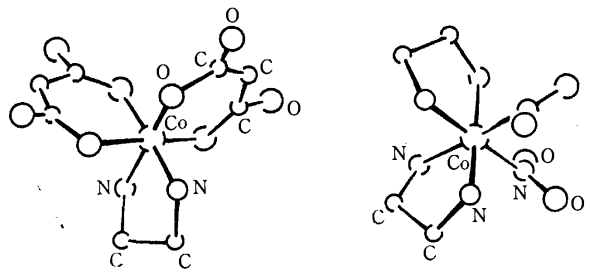
The perspectives of $(-)_{589}$-$[Co(NO_2)_2en_2]^+$ and $(+)_{589}$-$[Co\ mal_2en]^-$ are depicted in Fig. 3. It has been elucidated by the present work that both the complex ions have the same configuration, *i.e.*, Λ.[12]



$(+)_{589}$-$[Co\ mal_2en]^-$ $(-)_{589}$-$[Co(NO_2)_2en_2]^+$

Fig. 3. The absolute configurations of the complex ions.

The absolute configuration of $(+)_{589}$-$[Co\ mal_2en]^-$ is consistent with the assignment made by Douglas *et al.*[1] Their spectral assignment of the *A* transition is possibly correct. On the other hand, if Piper's model is also applicable in the case of the tris(malonato)-coablt(III) complex,[4] the sign of the rotational strength, $R(A)$, of $\Lambda(+)_{589}$-$[Co\ mal_2en]^-$ should be reversed to that of $\Lambda(-)_{589}$-$[Co\ ox_2en]^-$, as has already been stated. Douglas *et al.* gave the negative sign to the rotational strengths of the *A* components of these two complexes. Therefore, their assignment of the *A* component is not entirely satisfactory.

The Λ configuration of $(-)_{589}$-$[Co\ (NO_2)_2en_2]^+$ established in the present work has already been assigned by some workers on the basis of the CD[5,13,14] and ORD[15] data. It is possible that the sign of the major CD peak in the first-absorption-band region is to be regarded as a diagnostic of the absolute configuration of the dissymmetric *cis*-$[CoL_2en_2]$ complexes (the ligands, L, are unidentate).[5,16,17]

The bond distances and angles in the complex ions are listed in Table 4. The approximate symmetry of $(-)_{589}$-$[Co(NO_2)_2en_2]^+$ and $(+)_{589}$-$[Co\ mal_2en]^-$ is C_2. All the ethylenediamine molecules in both com-

plexes are of the *ob*-conformation. The role of the hydrogen bonding in $(-)_{589}$-$[Co(NO_2)_2en_2]^+$ may be important in stabilizing the unstable *ob-ob* conformer.[11] The two Co-mal chelate rings are approximately planar (Fig. 4). The maximum deviation of the atom from mean plane is 0.23 Å. The presence of N–H···O hydrogen bonds seems to be significant in the formation of the nearly planar Co-mal chelate rings.[12] The average O–Co–O angle is 96°, slightly larger than the N–Co–N angle (94°) found in $(-)_{589}$-$[Co\ tn_3]^{3+}$.[18] The C–C–C angle (125°) is far from the tetrahedral angle, indicating that there is much strain in this bond angle. The C–O (coordinated to the Co atom) distances in the carboxyl groups are likely to be slightly larger than in the uncoordinated C–O bonds.

The authors wish to express their thanks to Mr. K. Hirotsu, who adapted the HBLS-4 and the RSSFR-3 computer programs to the FACOM 270—30 computer at Osaka City University. Binuclear Metal Complexes. III.[1] Preparation and Properties of Mononuclear and Binuclear Copper(II) and Nickel(II) Complexes of New Macrocycles and Their Related Ligands[2]

Hisashi Okawa and Sigeo Kida

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received January 5, 1972)

The syntheses and properties of copper(II) and nickel(II) complexes of *N,N'*-alkylenebis(3-formyl-5-methylsalicylaldimine (alkylene=ethylene, propylene, or trimethylene) are described. By the reaction of these complexes with other alkylenediamines (ethylenediamine or trimethylenediamine), mononuclear copper(II) and nickel(II) complexes of new N_4O_2-type macrocycles have been synthesized. These complexes react with additional copper(II) or nickel(II) ions to form binuclear copper(II) or nickel(II) complexes. The geometries and properties of these new complexes are discussed.

It is known that the syntheses of macrocyclic, polydentate ligands are much facilitated by the template effect of metal ions.[3] In recent years considerable efforts have been directed towards syntheses of new macrocycles and their metal complexes. However, it appears that most of the work in this area dealt with mononuclear complexes of macrocycles, and only a few macrocycles making a binuclear metal complex have been reported.[4-7]

It is known that *N,N'*-ethylenebis(salicyclaldimino)-copper(II) reacts with copper(II) and other divalent metal ions to form a binuclear or trinuclear complex.[8] It is also well established that binuclear copper(II) complexes are obtained when copper(II) chloride or bromide is allowed to react with bis-(*N*-R-salicylaldimino)copper(II),[9] where R is an alkyl or a phenyl group attached to the imino nitrogen. Formation of these complexes is based on the fact that a phenolic oxygen atom can form bonds with two metal ions. Binuclear copper(II) complexes of 2,6-diformyl-4-4-methylphenol[10] and its Schiff base derivatives[10,11,12] have also been reported, where the phenolic oxygen acts as a bridge and the two formyl oxygens or imino nitrogens coordinate to copper(II) ions.

We have attempted to prepare new macrocycles which form a nearly planar, binuclear metal complex in such a way that two phenolic oxygens in the macrocyclic moiety bridge two metal ions. We prepared the copper(II) and nickel(II) complexes of *N,N'*-alkylenebis(3-formyl-5-methylsalicylaldimine) (alkylene=ethylene, propylene, or trimethylene) and then the mononuclear copper(II) and nickel(II) complexes of new N_4O_2-type macrocycles, using the above complexes as starting materials. The four macrocycles obtained are: 23,24-dihydroxy-10,21-dimethyl-3,6,14,17-tetraazatricyclo[17,3,1,$1^{8,12}$]tetracosa-1(23),2,6,8(24),9,11,13,17,19,21-decaene (abbreviated to

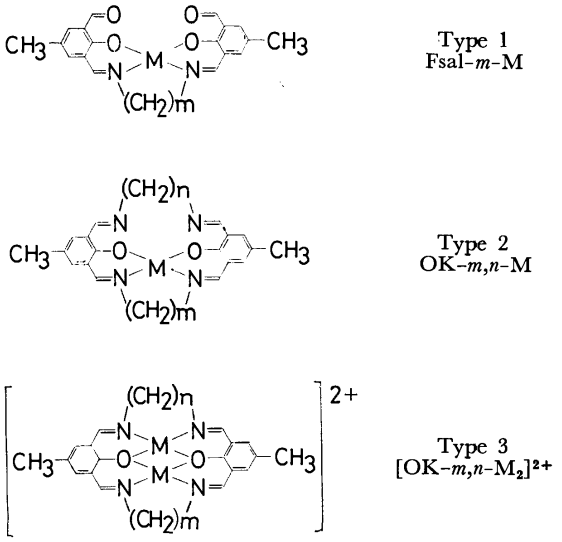
Fig. 1. Structures of macrocycles.

Three types of complexes have been prepared. The strucutral formulas are given in Fig. 2. The metal complexes of *N,N'*-alkylenebis(3-formyl-5-methylsalicylaldimine) (type 1) are abbreviated to Fsal-*m*-M, where *m* is 2 or 3 and M stands for copper or nickel. OK-*m,n*-M indicates the mononuclear metal complex of the macrocycles, in which *m* and *n* denote the number of methylene groups in the chelate ring and the number of the methylene groups in the bridge combining the two uncoordinated nitrogens, respectively. In the case where *l*-propylenediamine is included in the ligand instead of ethylenediamine, the macrocycle is abbreviated to OK-2-(*l*-pn),3. $[OK\text{-}m,n\text{-}M_2]^{2+}$ represents the binuclear metal complex of the macrocycle.



Type 1
Fsal-*m*-M

Type 2
OK-*m,n*-M

Type 3

Fig. 2. Structures of three types of complexes.

Experimental

Syntheses. 2,6-*diformyl*-4-*methylphenol*: Denton and Suschitzky's method[13] was modified for the preparation of 2,6-diformyl-4-methylphenol. *p*-Cresol (50 g) and hexamethylenetetramine (50 g) were mixed in a mortar. The pulverized mixture was added to polyphosphoric acid (500 g) at 160°C under vigorous stirring. The reaction mixture was cooled and hydrolyzed with water, and the product was isolated by steam distillation. Chameleon chemical grade polyphosphoric acid is suitable for this reaction. The yield was 8—11%, which is superior to that reported in literature.[13]

Fsal-2: 2,6-diformyl-4-methylphenol (9.85 g) and ethylenediamine (1.8 g) were mixed in ethanol. The orange prisms which separated were collected and recrystallized from dioxane to give yellow prisms with a melting point of 190—193°C.

Found: C, 68.05; H, 5.90; N, 8.49%. Calcd for $C_{20}H_{20}N_2O_4$: C, 68.17; H, 5.72; N, 7.95%.

Fsal-3: This compound was prepared by treating 2,6-diformyl-4-methylphenol (9.85 g) with 1,3-diaminopropane (2.22 g) in ethanol. The precipitate was collected and recrystallized from dioxane as yellow prisms. It melts at 144—147°C.

Found: C, 69.10; H, 6.02; N, 7.67%. Calcd for $C_{21}H_{22}N_2O_4$: C, 68.84; H, 6.05; N, 7.65%.

Fsal-m-M type Complexes: Copper(II) and nickel(II) complexes of Fsal-2 and Fsal-3 were synthesized. Methods of preparation for these complexes are the same in principle. A typical procedure is as follows. An aqueous solution of a slight excess of copper(II) acetate monohydrate was added to a solution of Fsal-2 in warm ethanol. Soon brown needles separated. They were collected and washed with ethanol.

The complexes can be prepared by treating stoichiometric amounts of 2,6-diformyl-4-methylphenol, diamine, and metal acetate in ethanol. Fsal-2(*l*-pn)-Cu was synthesized by this method.

Fsal-2-Cu and Fsal-2(*l*-pn)-Cu form greenish brown needles and Fsal-3-Cu green needles. The nickel(II) complexes form orange needles. Elemental analyses of the complexes are given in Table 1.

Table 1. Analyses of Fsal-*m*-M type complexes

	Found(%)			Calcd(%)		
Fsal-*m*-M[a]	C	H	N	C	H	N
Fsal-2-Cu	57.79	4.50	6.86	58.04	4.38	6.77
Fsal-2(*l*-pn)-Cu	58.81	4.78	6.39	58.94	4.71	6.55
Fsal-3-Cu	58.56	4.61	6.10	58.94	4.71	6.55
Fsal-2-Ni·1/2H_2O	57.18	4.53	6.60	57.46	4.58	6.70
Fsal-3-Ni	59.42	4.78	6.41	59.61	4.76	6.62

a) Fsal-2=$C_{20}H_{18}N_2O_4$; Fsal-2(*l*-pn) and Fsal-3=$C_{21}H_{20}N_2O_4$.

OK-m,n-M type Complexes: These were synthesized by the reaction of Fsal-*m*-M and ethylenediamine or 1,3-diaminopropane in *N,N*-dimethylformamide. The general synthetic method for macrocyclic complexes is given for OK-2,2-Cu as an example. Ethylenediamine (120 mg) was added to a vigorously stirred, hot solution of Fsal-2-Cu (828 mg) in *N,N*-dimethylformamide (800 m*l*) for thirty seconds. Stirring was continued for ten minutes and the reaction mixture was allowed to stand overnight. The brown prisms which separated were collected and washed with ethanol.

OK-2,3-Cu and OK-3,3-Cu form greenish brown and green prisms, respectively. OK-2,2-Ni and OK-2,3-Ni form orange prisms. The elemental analyses of the complexes are given in Table 2.

$[OK\text{-}m,n\text{-}M_2]^{2+}$ *type Complexes*: These were synthesized when an equimolar quantity of OK-*m,n*-M and M(II) salt

were treated in methanol. A typical procedure is given for $[OK\text{-}3,3\text{-}Cu_2]Cl_2\cdot H_2O$. Copper(II) chloride dihydrate (35 mg) was added to a suspension of OK-3,3-Cu (120 mg) in methanol (20 m*l*), and the mixture was heated on a water bath. A clean solution was filtered, concentrated to 5 m*l* and diluted with ethanol (5 m*l*) to give green needles. They were collected and washed with a small amount of ethanol.

The results of elemental analyses of binuclear complexes of macrocycles are given in Table 3.

Measurements. Electronic spectra were determined in solution and in solid with a Hitachi EPS-3T recording spectrophotometer. A reflectance attachment was used for the measurements on the solid samples. Infrared spectra were measured with a Hitachi EPI-S2 spectrophotometer in the region from 4000 to 650 cm^{-1}, using the KBr disk method. Magnetic susceptibilities were measured by the Gouy method at room temperature, where Pascal's constants were used for diamagnetic correction. Circular dichroism spectra were recorded with a JASCO ORD/SP optical rotatary dispersion recorder.

Results and Discussion

Fsal-m-M type Complexes. Condensation of two molecules of 2,6-diformyl-4-methylphenol with one molecule of ethylenediamine or 1,3-diaminopropane affords the monomeric Schiff base, Fsal-2 or Fsal-3, in quantitative yield with no formation of polymer. Copper(II) and nickel(II) complexes of Fsal-2 and Fsal-3 were synthesized. Their IR and visible spectral bands and magnetic moments are given in Table 4.

In the IR spectra, the bands around 1670 and 1635—1628 cm^{-1} can be assigned to the C=O and C=N stretching vibrations, respectively. A new band appeared around 1545 cm^{-1} upon complex formation. The band can be assigned to the skeletal vibration of the aromatic ring.[15]

The ligand field bands of Fsal-2-Cu and Fsal-3-Cu were observed at 17.5 and 16.6 kK, respectively. The *d-d* band for Fsal-3-Cu was found at a lower energy region than that for Fsal-2-Cu, which is thought to be a typical square-planarr copper(II) complex.[21-23] Since it is well established that the red shift in the d-d band takes place when the configuration around the copper(II) ion is distorted from planarity,[17,24-26] Fsal-3-Cu is assumed to possess a slightly distorted structure. The distortion of the configuration around the copper(II) ion in Fsal-3-Cu may also be demonstrated by its large magnetic moment of 2.01 B.M.

14) This band had previously been assigned to $\nu_{C=N}$[15], but it is known from N^{15} data that the band due to $\nu_{C=N}$ is located at a higher frequency.[16] Now the band around 1545 cm^{-1} is attributed to the phenolic C–O vibration[17] or the C–C vibration of the aromatic ring.[4] However, the former assignment is inconsistent with the assignment of the band near 1340 cm^{-1} to the phenolic C–O vibration.[4,18,19] Recently it has been reported that anilato complexes also show a similar band around 1530 cm^{-1}.[20] From this fact it seems reasonable to assign this new band to the skeletal vibration of the aromatic ring.

OK-3,3-Cu	1630	1625	1545	16.9	1.92
OK-2,2-Ni·1/2H_2O	1645	1627	1547	18.2	diamag.
OK-2,3-Ni	1628		1547	18.1	diamag.

as compared with 1.81 B.M. for Fsal-2-Cu, since it is well known that the distortion from planar towards tetrahedral configuration gives rise to an increase in μ_{eff} value.[17] The large magnetic moment of 2.01 B.M. for Fsal-3-Cu as compared with 1.90 B.M. for *N*,*N*′-1,3-propylenebis(salicylaldimino)copper(II)[17] can be attributed to the greater distortion caused by the steric repulsion between its formyl groups, which are in the ortho-position relative to phenol oxygen.

Fsal-2-Ni and Fsal-3-Ni are diamagnetic and have only one ligand field band at 18.2 and 16.7 kK, respectively (in DMF). Thus it is evident that these complexes have a planar configuration. This agrees with the fact that Ni-salen families (salen=*N*,*N*′-ethylenebis(salicylaldimine)) retain the planar structure even if the number of methylene groups is increased to 3, 4, or 5.[28,29] However, it appears that the configuration around the nickel(II) ion in Fsal-3-Ni is slightly distorted judging from the position of its d-d band which is lower in energy than that of Fsal-2-Ni.

OK-m,n-M type Complexes. In the case of Fsal-*m*-*M* type complexes, the two uncoordinated formyl groups are sufficiently close to each other to allow an intramolecular cyclization by treatment with other molecules such as ethylenediamine or 1,3-diaminopropane (kinetic template reaction). The complexes employed as starting matetials for the syntheses of OK-m,n-M were Fsal-2-Cu, Fsal-3-Cu and Fsal-2-Ni. Fsal-3-Ni was not used because of its limited amount. Since OK-*m*,*n*-M type complexes are sparingly soluble in any solvent, their molecular weight could not be determined. The yields of the macrocyclic complexes were nearly quantitative. Their IR and electronic specta and magnetic moments are given in Table 5.

The IR spectra show two bands in the region from 1645 to 1625 cm^{-1} in the case of the same methylene chain (*i.e.* $n=m$), and no band due to the $\nu_{C=O}$ mode. The bands can be attributed to the coordinated and uncoordinated azomethine groups, respectively. On the other hand, in the case of OK-2,3-Cu and OK-2,3-Ni the bands due to the coordinated and uncoordinated azomethine groups do not appear as well-resolved bands. No appreciable shift of the skeletal vibration of the aromatic ring was observed by clcyization.

The powder reflectance spectra of OK-2,2-Cu, OK-2,3-Cu and OK-3,3-Cu possess *d-d* bands at 17.5, 17.3 and 16.9 kK, respectively. The magnetic moments of OK-2,2-Cu, OK-2,3-Cu and OK-3,3-Cu are 1.92, 1.81, and 1.80 B.M., respectively. The sequences of these *d-d* bands and magnetic moments are compatible with each other and agreee in the order of distortion from a square planar configuration, which is effected by the increase in numbers, *n*(and *m*), of methylene groups. A similar trend in the *d-d* bands is found in the copper(II), nickel(II) and cobalt(II) complexes of N_4-macrocycles.[30]

OK-2,2-Ni and OK-2,3-Ni are undoubtedly planar complexes, since they are diamagnetic and have only one *d-d* band around 18.1—18.2 kK. They are insoluble in polar solvents such as pyridine. This implies that coordination bonds in the tetragonal plane are strong enough to exclude the fifth and sixth coordination of the solvent molecules in the axial position. A similar behavior has been observed in Ni-salen,[31] in Ni-amben series[32] (amben=*N*,*N*′-ethylenebis(*o*-aminobenzylideneimine) and in nickel-

(II) complexes of N_4-macrocycles.[30]

In order to obtain „OK-3,2,-Cu" with 6-6-6 condensed ring system, Fsal-3-Cu and ethylenediamine were allowed to react in *N,N*-dimethylformamide. The product obtained, however, showed identical IR and visivle spectra and the same magnetic moment as OK-2,3-Cu. Thus it can be concluded that „OK-3,2-Cu" and OK-2,3-Cu are the same compound. It seems that the copper(II) ion migrates during the cyclization process to form a stable 6-5-6 condensed ring system. For the sake of confirmation, Fsal-2-(*l*-pn)-Cu, OK-2(*l*-pn),3-Cu and „OK-3,2(*l*-pn)-Cu" were prepared by using *l*-propylenediamine instead of ethylenediamine, and their CD spectra were compared (Fig. 3). The CD spectra of OK-2(*l*-pn),3-Cu and

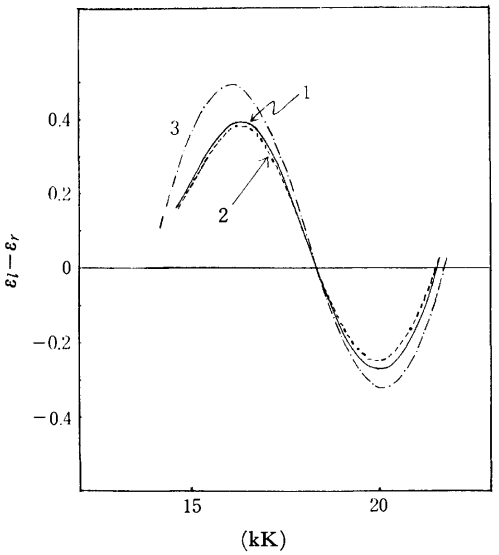

Fig. 3. CD spectra of OK-2(*l*-pn), 3-Cu(1), „OK-3,2(*l*-pn)-Cu"(2) and Fsal-2(*l*-pn)-Cu(3)(in *N,N*-dimethylformamide).

„OK-3,2(*l*-pn)-Cu" were found to be practically the same and very similar to that of Fsal-2(*l*-pn)-Cu in intensity as well as in sign. This indicates that they all possess the 6-5-6 condensed ring system, which is more stable than the 6-6-6 condensed ring system. Our results are consistent with the conclusion of Nakahara *et al.*[33] that *N,N'*-ethylenebis(salicylaldimino)-copper(II) is more stable than *N,N'*-1,3-propylenebis-(salicylaldimino)copper(II). It seems that the reaction carried out in hot N,N-dimethylformamide causes copper(II) ion migration.

[OK-m,n-M_2]$^{2+}$ type Complexes. The ligand field bands and some IR bands of complexes of this type are given in Table 6. Their magnetic moments were not measured because of limited amounts.

Infrared spectra show only one band for the C=N stretching vibration. The marked difference in IR spectra between OK-*m,n*-M and [OK-*m,n*-M_2]$^{2+}$ is seen in the frequencies of the skeletal vibration of the benzene ring; 1540 cm^{-1} for the former and 1560—1565 cm^{-1} for the latter with the exception of [OK-2,2-Cu_2]$Cl_2 \cdot C_2H_5OH \cdot 2H_2O$. A similar behavior was found in a complex where a phenolic oxygen atom bridges two copper(II) ion.[34,35] Thus such a behavior in the skeletal vibration appears to be characteristic of this type of binuclear structure. However, [OK-2,2-Cu_2]$Cl_2 \cdot C_2H_5OH \cdot 2H_2O$ shows a band due to a skeletal vibration of the aromatic ring at 1540 cm^{-1}, which is difficult to explain at present.

The reflectance and absorption spectra of [OK-2,2-Cu_2]$Cl_2 \cdot C_2H_5OH \cdot 2H_2O$ show one ligand field band at 18.1 and 17.4 kK, respectively, which are higher in energy than that of OK-2,2-Cu. In both the solid and solution spectra of [OK-2,3-Cu_2]$Cl_2 \cdot 2H_2O$ a very broad band was observed in the range from 15 to 18 kK. This may be due to the presence of two copper(II) ions with enivornments of different steric geometry. The reflectance spectra of [OK-3,3-Cu_2]$Cl_2 \cdot H_2O$ and [OK-3,3-Cu_2]$SO_4 \cdot 2H_2O$ show one ligand field band at 15.3 and 15.6 kK, respectively, while their solution spectra show a main peak at 16.5 kK and a discernible shoulder at the longer wavelength side of the main absorption band. Recently Pilkington and Robson[3] prepared $LCu_2Cl_2 \cdot 6H_2O$ and $LCu_2SO_4 \cdot 2H_2O$ (L is their abbreviation for OK-3,3) by another method. $LCu_2SO_4 \cdot 2H_2O$ and our

Table 6. IR and *d-d* bands of [OK-*m,n*-M_2]$^{2+}$ type complexes

	IR bands (cm^{-1})		*d-d* bands (kK)		
			Solutions		Powder
	C=N	Skeletal	MeOH	Py	
[OK-2,2-Cu_2]$Cl_2 \cdot C_2H_5OH \cdot 2H_2O$	1630	1540	18.1		17.4
[OK-2,3-Cu_2]$Cl_2 \cdot 2H_2O$	1641	1560	15—18		15—17.5
[OK-3,3-Cu_2]$Cl_2 \cdot H_2O$	1635	1565	16.5 (14.5)		15.3
[OK-3,3-Cu_2]$SO_4 \cdot 2H_2O$	1633	1563	16.5 (14.5)		15.6
[OK-2,2-Ni_2]$Cl_2 \cdot 3H_2O$	1633	1565	18.2	18.2	18.3
[OK-2,3-Ni_2]$Cl_2 \cdot 2H_2O$	1632	1563	18.0	18.1	18.2

Bands in parenthesis appear as a shoulder.

33) A. Nakahara, H. Yamamoto, and H. Matsumoto, This Bulletin, **37**, 1137 (1964).
34) C. M. Harris, J. M. James, P, J. Milham, and E. Sinn, *Inorg. Chim. Acta*, **3**, 81 (1969).
35) B. Coles, C. M. Harris, and E. Sinn, *Inorg. Chem.*, **8**, 2607 (1969).

$[OK\text{-}3,3\text{-}Cu_2]SO_4\cdot 2H_2O$ are undoubtedly the same complex, since they have the same composition and show very similar IR and visible spectra. Furthermore, $LCu_2Cl_2\cdot 6H_2O$ and $[OK\text{-}3,3\text{-}Cu_2]Cl_2\cdot H_2O$ are the same complex except for water of crystallization, because their IR and visible absorption peaks are practically the same. Pilkington and Robson[3] suggested on the basis of X-ray analysis that $LCu_2Cl_2\cdot 6H_2O$ has a square-pyramidal structure with a chlorine or a water molecule in apical positions. According to Ciampolini,[36] the copper(II) ion in a square pyramidal environment shows two distinguishable *d-d* bands, their main peak appearing on the shorter wave-length side with a shoulder on the longer wave-length side, but in the case of trigonal bipyramidal copper(II) complexes the band on the longer wave-length side is the main peak. Thus, $[OK\text{-}3,3\text{-}Cu_2]Cl_2\cdot H_2O$ and $[OK\text{-}3,3\text{-}Cu_2]SO_4\cdot 2H_2O$ probably keep a square-pyramidal, five-coordinate configuration in methanol solution.

36) M. Ciampolini, *Structure and Bonding*, **6**, 52 (1969).

$[OK\text{-}2,2\text{-}Ni_2]Cl_2\cdot 3H_2O$ and $[OK\text{-}2,3\text{-}Ni_2]Cl_2\cdot 2H_2O$ form orange prisms. Their visible spectra possess only one d-d band in the region from 18.3 to 18.0 kK. No absorption is found up to 2000 mμ. Thus it is expected that they are low-spin, square-planare binuclear complexes. It might be concluded that both complexes retain the planar geometry in a polar solvent such as pyridine, since there is no significant difference in electronic spectra between solid state, methanol solution and pyridine solution (Table 6). On the other hand, they differ from $LNi_2Cl_2\cdot 2H_2O$ (corresponding to „$[OK\text{-}3,3\text{-}Ni_2]Cl_2\cdot 2H_2O$") prepared by Pilkington and Robson,[3] in that the latter is dark-green and para-magnetic. Thus it can be concluded that nickel(II) ions in $[OK\text{-}2,2,\text{-}Ni_2]Cl_2\cdot 3H_2O$ and $[OK\text{-}2,3\text{-}Ni_2]Cl_2\cdot 2H_2O$ keep the square-planar configuration even in pyridine owing to the sufficiently strong ligand field, but that in $LNi_2Cl_2\cdot 2H_2O$ ($=[OK\text{-}3,3\text{-}Ni_2]Cl_2\cdot 2H_2O$) a chloride ion or water molecule can coordinate to apical positions, consistent with the decrease in the ligand field caused by an increase in the number of methylene groups.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1764—1766 (1972)

Studies on Stable Free Radicals. XI. ESR Spectra of Stable Nitroxide Biradicals

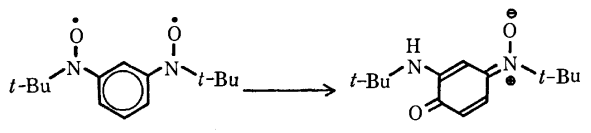
Toshimasa TODA, Eiko MORI, and Keisuke MURAYAMA

Central Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo

(Received October 5, 1971)

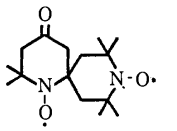
The ESR spectra of the triplet state of stable nitroxide biradicals, 1,9-diaza-2,2,8,8,10,10-hexamethyl-4-oxo-spiro[5.5]-undecane-1,9-dioxyl (III), cyclohexane-1-spiro-2′-(4′-oxoimidazolidine)-5′-spiro-4″-(2″,2″,6″,6″-tetramethylpiperidine)-1′,1″-dioxyl (IV) and cyclohexane-1-spiro-2′-(3′-oxoimidazolidine)-5′-spiro-4″-(2″,2″,-6″,6″-tetramethylpiperidine)-1′,1″-dioxyl (V) have been observed in a frozen MTHF glass. The biradicals have $2\mathbf{D} \simeq 500$ and $\mathbf{E} \simeq 0$ gauss. The distance ($r \simeq 5$ Å) between the two radical sites in these biradicals indicates that one piperidine ring can exist in chair form and the other in twisted form in III, and both in the twisted form in IV and V. The biradical, 2,2,6,6-tetramethylpiperidine-4-spiro-2′-(4′-oxoimidazolidine)-5′-spiro-4″-(2″,2″,-6″,6″-tetramethylpiperidine)-1,1″-dioxyl (VI) in a MTHF frozen glass shows no spectrum corresponding to a triplet state.

The electron spin resonance spectra of the stable biradicals and in particular nitroxide biradicals[2] with a small scalar electron spin-spin interaction are well known. However, cases of very large interaction are less common.[3] Calder and his co-workers[4] reported on the ESR spectrum of the nitroxide biradical (I) of this type. The crystalline samples of the triplet I undergoes a spontaneous topochemical change to the aminoquinone imine *N*-oxide (II).



(I) (II)

We have isolated four stable nitroxide biradicals, III–VI.[5,6] They are very stable and no change have taken place on standing at room teaperature over several years.



(III)

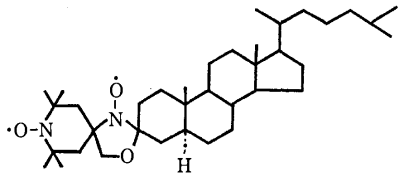
5) K. Murayama, S. Morimura, O. Amakasu, T. Toda, and E. Yamao, *Nippon Kagaku Zasshi*, **90**, 296 (1969).

6) T. Toda, S. Morimura, E. Mori, H. Horiuchi, and K. Murayama, This Bulletin, **44**, 3445 (1971).

Since the molecular models of these nitroxide biradicals indicate that the two radical sites in the molecule can approach each other closely, and the molecules are relatively rigid, the direct intramolecular interactions of the two radical sites are expected to be larger than those of the nitroxide biradicals in which the two nitroxide radical subunits are connected to each other by flexible chains.[2a,7]

In this paper, we wish to report on the ESR spectra of the nitroxide biradicals III—VI.

After our work had been completed, Keana and Dinerstein[8] published a report on the ESR spectrum of stable nitroxide biradical (VII), which is compatible with ours.



(VII)

Results and Discussion

The nitroxide biradical, 1,9-diaza-2,2,8,8,10,10-hexamethyl-4-oxo-spiro[5.5]undecane-1,9-dioxyl (III) in solution and frozen 2-methyltetrahydrofuran (MTHF) gave the spectra shown in Fig. 1. Since the spectrum in the transition of $\Delta m=\pm 2$ could be observed in a rigid glass state, the spectrum in Fig. 1-b gives a typical triplet state in a randomly oriented molecule.[9]

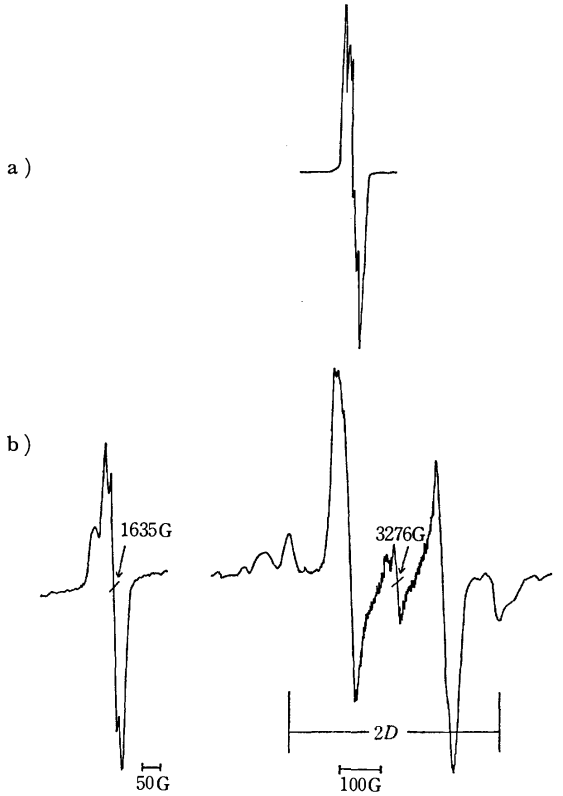


Fig. 1. ESR Spectra of III in 10^{-3} mol/l MTHF solution. a): at room temperature and b): at −196°C (measured in liquid nitrogen Dewar vessel).

The Hamiltonian for a biradical is

$$H = H_{\text{Zeeman}} + H_{\text{hyperfine}} + H_{\text{exchange}} + H_{\text{dipolar}}$$

The anisotropic effect observed in Fig. 1 is due to H_{dipolar}, where $H_{\text{dipolar}}=\mathbf{D}(S_z^2-1/3\cdot S^2)+\mathbf{E}(S_x^2-S_y^2)$. The zero field splitting parameter **D** can be estimated from the rigid glass spectrum as shown in Fig. 1, in which the separation between the outermost of lines in the spectrum is 2**D**.

The frozen MTHF glass spectrum of cyclohexane-1-spiro-2′-(4′-oxoimidazolidine)-5′-spiro-4″-(2″,2″,6″,6″-tetramethylpiperidine)-1′,1″-dioxyl (IV) is given in Fig. 2.

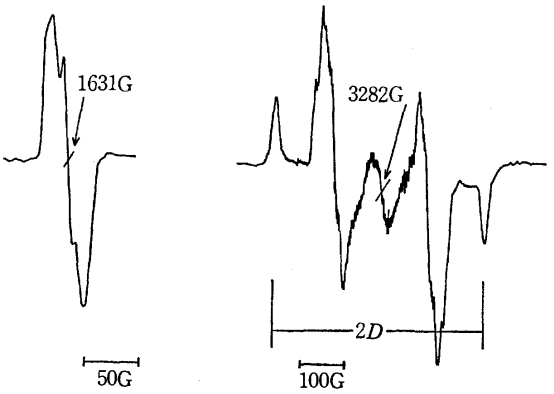

Fig. 2. ESR spectrum of IV in MTHF rigid glass at −196°C.

The spectrum of cyclohexane-1-spiro-2′-(3′-oxoimidazolidine)-5′-spiro-4″-(2″,2″,6″,6″-tetramethylpiperidine)-1′,1″-dioxyl (V) in a rigid glass of MTHF (not shown) exhibited a shape similar to the spectrum of IV.

The parameter **D** for the biradicals IV and V can also be estimated from these spectra. The exact calculations of **E** for the nitroxide biradicals III, IV and V are not possible from our data, but it is clear that $|\mathbf{E}|\ll|\mathbf{D}|$ in each of the biradicals.

In the point dipole approximation, 2**D** is related to the distance r between the >N–O· groups by the equation.[10]

$$2\mathbf{D} = 55600 \times r^{-3} \qquad (1)$$

The zero field splitting parameter **D** and the distance r for the nitroxide biradicals are given in Table 1.

Table 1. The values of zero field parameter **D** and distance between two >N–O· groups r

Biradical	$2\cdot\mathbf{D}$ (gauss)[a]	r (Å)[b]
III	532	4.72
IV	487	4.85
V	530	4.71

a) accuracy ±7 gauss.
b) accuracy ±0.02Å, from calculation by equation (1).

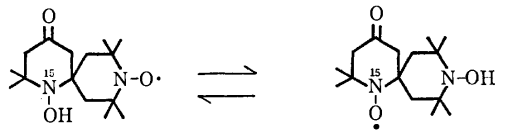
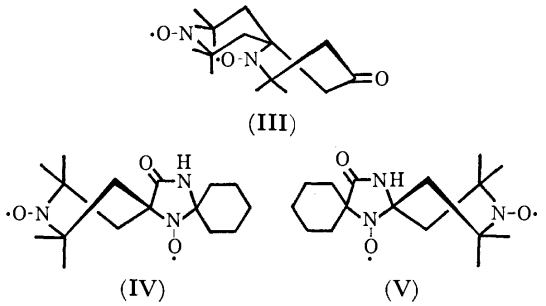
Measurements on molecular models of III with various conformations for two piperidine rings provide values of 4—6 Å for r which is the distance between each oxygen of two >N–O· groups. It was reported[11] distribution of spin density of unpaired electron is 73% on oxygen atom and 27% on nitrogen atom in the nitroxide radical, 2,2,6,6-tetramethylpiperidine-1-oxyl. When one piperidine ring is in a twisted form[11] and the other in a chair form[12] in III, as shown in Fig. 3, r is about 5 Å, in agreement with the value estimated from its ESR spectrum. When two piperidine rings are in boat forms in III, r is about 6 Å and 2**D** is 257 gauss; in chair forms, 4 Å and 869 gauss.

We reported on the intramolecular hydrogen transfer between the >N–OH and >N–O· groups in 1,9-diaza-(1-^{15}N)-2,2,8,8,10,10-hexamethyl-4-oxo-spiro[5.5]undecane-1-hydroxy-9-oxyl (VIII) corresponding to the precursor of the nitroxide biradical, III.[13] This was found from the ESR spectrum of VIII in toluene solution in which the intensity of the doublet lines resulting from a ^{15}N nucleus increased at high temperatures and decreased at low temperatures.



(VIIIa) (VIIIb)

From the intramolecular hydrogen transfer in VIII, it seems that the distance between two radical sites in III is 4.8 Å, because the distance between the hydrogen of >N–OH group and the oxygen of >N–O· group in VIII could approach that of van der Waals radius if the conformation of VIII corresponds to that of III. On the other hand, the values of r obtained for IV and V from these spectra in a MTHF frozen glass are in agreement with those measured from their molecular models in which the conformation of each



(III)

(IV) (V)

Fig. 3. Conformation of biradicals III, IV, and V.

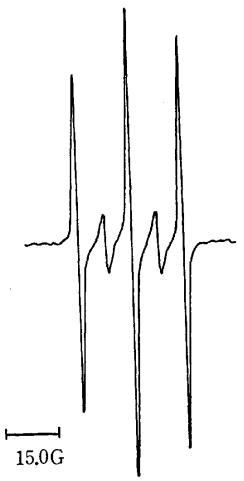


Fig. 4. ESR spectrum of VI in 10^{-3} mol/l toluene solution at room temperature.

piperidine ring is in a twisted form as shown in Fig. 3.

The spectrum of 2,2,6,6-tetramethylpiperidine-4-spiro-2′-(4′-oxoimidazolidine)-5′-spiro-4″-(2″,2″6″6″-tetramethylpiperidine)-1,1″-dioxyl (VI) in toluene solution at room temperature give quintet lines just like the spectrum of the carbonate diester of 4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl[2a] as shown in Fig. 4.

The frozen glass spectrum of VI does not correspond to that of a crystalline triplet. The distance between the two radical sites in VI may be longer than those of the other nitroxide biradicals III—V. The molecular model of VI indicates that two radical sites can approach each other in the molecule when both piperidine rings exist in boat form. However, such a conformation would not be predominant in VI.

Experiments for estimating the values of the triplet-singlet separation **J** in these nitroxide biradicals were not successful since there is no suitable solvent to measure the signal intensity of these solid state spectra at various temperatures.

Experimental

ESR measurements. The spectra were recorded with a Hitachi MES 4001 type X-band spectrometer equipped with the cavity of TE_{011} mode employing 100 kc modulation. The magnetic field was monitored by a Hitachi M 4704 digital gauss meter using a Hall element.

Materials. The nitroxide biradicals were prepared by oxidation of amines with hydrogen peroxide or *m*-chloroperbenzoic acid.[5,6,13]

We would like to thank Dr. Genshun Sunagawa, the director, for his encouragement.

Effect of Ring Size on the Mass Spectral Fragmentation of Cyclic Sulfoxides

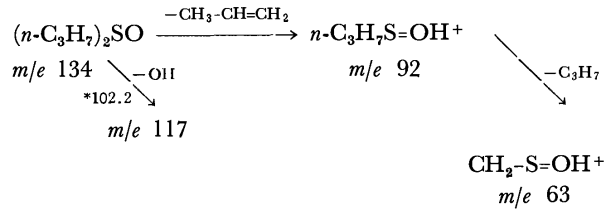
Seizo TAMAGAKI and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received February 1, 1971)

Mass spectra of six cyclic sulfoxides were determined in order to study the effects of ring size on the rate of OH-elimination from molecular ions. The ratios of the rates for the OH loss, $[M^+-OH]/[M^+]$, are: trimethylene sulfoxide: 0.23 /tetramethylene sulfoxide: 0.06 /pentamethylene sulfoxide: 0.24 /hexamethylene sulfoxide: 1.21 /9-thiamonoxybicyclo[3.3.1]nonane: 3.14 /7-thiamonoxybicyclo[2.2.1]heptane: 0.02. These findings were explained in terms of the difference in the closest approaching distance between the sulfinyl oxygen and the β- or γ-hydrogen atoms. Geometry of the ionized molecular ions appears to be an important factor in determining these ratios. The loss of HSO was also disucssed.

Although the electron impact fragmentations of open chain alkyl sulfoxides have been scrutinized in detail[1] and their common features can be illustrated as shown below by di-*n*-butyl sulfoxide as an example, no spectrometric study on cyclic sulfoxides has been



made in connection with the effect of ring size on their fragmentation.

It has been well known that the ejection of simple molecules such as H_2O or HCl from the molecular ion of cyclohexyl alcohol or chloride produced by electron impact does not necessarily take place by way of 1,2-elimination but displays a different behavior from that of the thermal process[2] where usually the elimination occurs exclusively *via* 1,2-elimination process resulting in the concomitant formation of a double bond. While, in the mass spectral fragmentation the extent of the ejection of small molecule or radical has been known to depend on the geometry or structure of molecules. For example, in a series of studies on rigid steroid ketone, Djerassi found that the Mclafferty rearrangement proceeds only if the interatomic distance between the carbonyl oxygen and γ-hydrogen is less than 1.8 Å.[3]

Very recently, Green and his coworkers[4] studies the electron impact induced elimination reactions involving the loss of small molecules, by employing specifically deuterium-labeled cyclohexyl or cycloheptyl chlorides and concluded that the ground-state interatomic distance may be extrapolated to the ionized state and thereby used to predict the position from which the hydrogen arised.

In this work, we have also re-examined the aforementioned Green's posturate in alicyclic sulfoxides from which the OH group is expelled and found that the hydrogen abstraction markedly depends upon the ring-size. For further information concerning the position of hydrogen to be removed, not only the monocyclic but also bicyclic sulfoxides were synthesized and subjected for the study.

Experimental

Synthesis of Alicyclic Sulfoxides. The cyclic sulfoxides were synthesized by the usual methods described in the literatures[5-7] and the sulfides were oxidized to the corresponding sulfoxides with sodium metaperiodate, usually

in ethanol except the oxidation of four-membered cyclic trimethylene sulfide where methanol was found to be the best solvent. The boiling (melting) points are: trimethylene sulfoxide: 91°/14 mmHg; tetramethylene: 113—114°/14 mmHg; pentamethylene: 124—125°/14 mmHg; hexamethylene: 144—145°/14 mmHg; 7-thiamonoxybicyclo [2.2.1]heptane: 205—208°C; 9-thiamonoxybicyclo[3.3.1]-nonane: 140°C/15 mmHg (sublimation temp).

Deuterium Labeling. The deuteration of the α-position to the sulfinyl group was accomplished by heating the corresponding ordinary sulfoxide of 500 mg with deuterium oxide of 5 g dissolving small pieces of sodium metal in a sealed tube at around 100°C for 2 or 3 days. After heating, the solvent was distilled off and the residue was extracted repeatedly with chloroform. The chloroform layer was concentrated and distilled off under reduced nitrogen atmosphere. The typical NMR spectrum of five-membered cyclic sulfoxide is shown in Fig. 1.

Measurement. Hitachi RMU-6E single focus mass spectrometer set at normal (80 eV) ionizing voltages and emission current of 110 mA was used to record the spectra. Samples were introduced into the ionizing chamber through a glass inlet system (141-B) prepared for heating around 200°C.

Results and Discussion

The main decomposition paths are illustrated in Figs. 2—7 and Schemes 1—2, and the main features

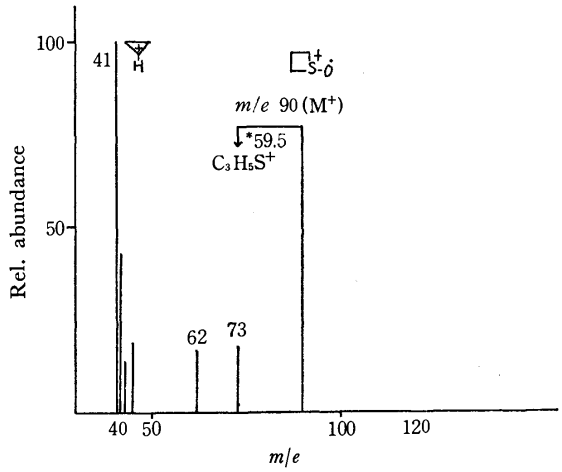

Fig. 2. Mass spectrum of trimethylene sulfoxide.

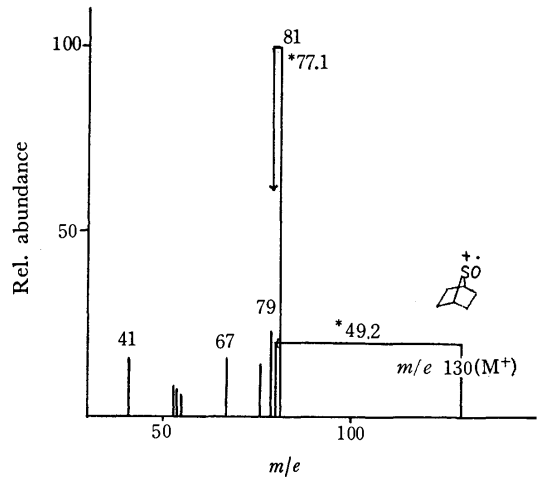

Fig. 6. Mass spectrum of 7-Thiamonoxybicyclo[2.2.1]-heptane at 80 eV.

of the mass spectra of these compounds are summerized as follows: (1) in every case, the molecular ion gives relatively higher peak height. (2) Surprisingly, in contrast to methyl phenyl sulfoxide and pyridine *N*-oxide both bearing similar semipolar linkages, no measurable deoxygenation appears to take place with

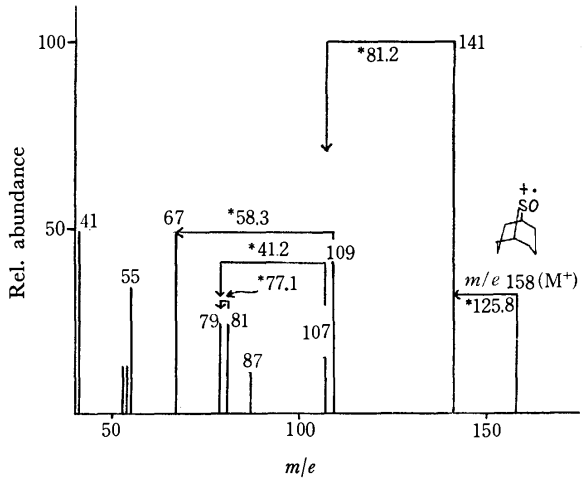

Fig. 7. Mass spectrum of 9-Thiamonoxybicyclo[3.3.1.] nonane at 80 eV.

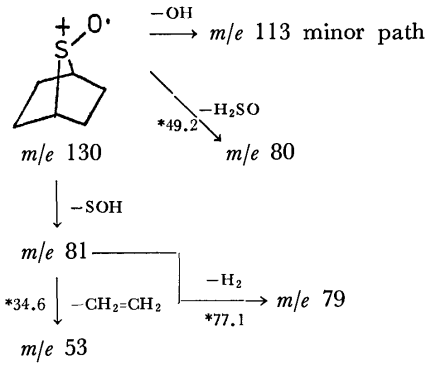
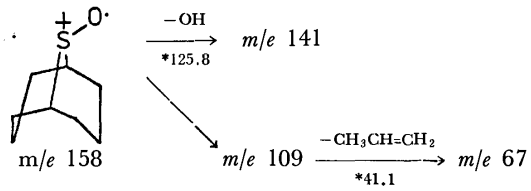
alicyclic sulfoxides at such high electron ionizing voltage as 80 eV. (3) Instead, the loss of OH and/or SOH takes place with all these sulfoxides although the extent of elimination for these simple molecules depends upon the nature of the sulfoxides. This will be discussed later in detail in connection with the effect of ring size on the dehydroxylation.

The bicyclic sulfoxides such as 7-thiamonoxybicyclo[2.2.1]heptane and 9-thiamonoxybicyclo[3.3.1]-nonane exhibit quite special and interesting behavior along the successive fragmentations.

The decomposition patterns for these compounds are shown as in Schemes 1 and 2, depicted below:



Scheme 1.



Scheme 2.

From inspection of these spectra, as for the OH loss the appearance of the metastable peaks seems to indicate that the elimination of OH radical proceeds by way of the noticeably similar mechanism for all the compounds investigated except the [2.2.1]bicyclic sulfoxide in which the OH loss is relatively a minor route. While, the elimination of HSO appears to give the corresponding metastable peaks only in the case of the monocyclic compounds with an exception of trimethylene sulfoxide. With the bicyclic derivatives the corresponding metastable peaks are

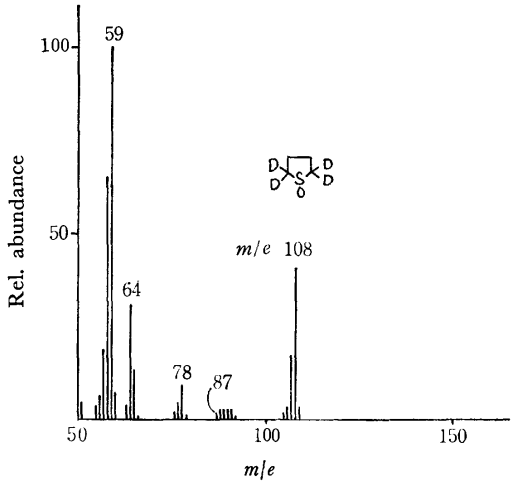


Fig. 8. Mass spectrum of tetramethylene sulfoxide-d_4 at 80 eV.

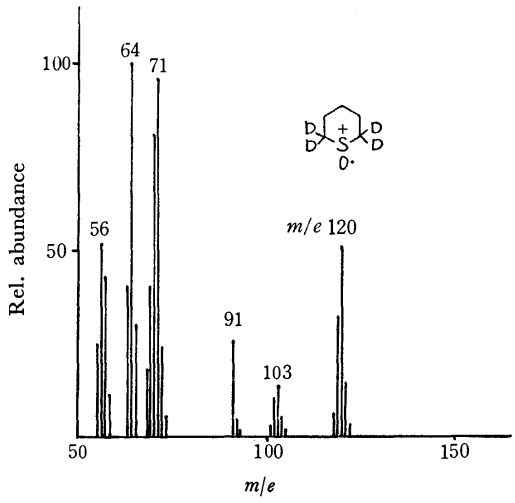

Fig. 9. Mass spectrum of pentamethylene sulfoxide-d_4 at 80 eV.

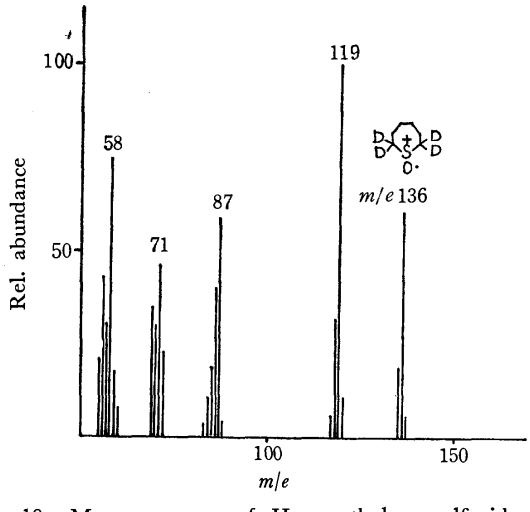

Fig. 10. Mass spectrum of Hexamethylene sulfoxide-d_4 at 80 eV.

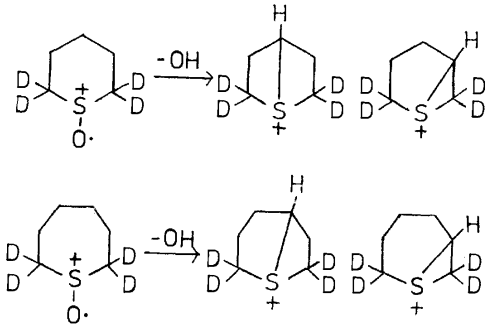
not detected at all. At present it is not clear what factors introduce such phenomena.

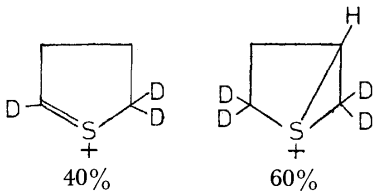
In order to dislose the origin of hydrogen abstracted in the elimination processes, a few sulfoxides deuterated were subjected to the electron impact analyses and the mass spectra of deuterated sulfoxides are shown in Figs. 8—10.

The deuterium labeling experiments confirm that the six- and seven-membered ring analogs undergo OH elimination reaction predominantly from the site other than the α-positions to the sulfinyl groups (Scheme 3).



Scheme 3.

Whereas, the behavior of the five-membered ring compound is much different. Abstraction of deuterium or hydrogen from α- and β-positions occurs concomitantly at the ratio of 40 to 60, respectively, resulting in the formation of such ion as:



As the deuterium labeling experiments indicate, with all the five-, six-, and seven-membered cyclic sulfoxides, elimination of HSO radical does occur predominantly by abstracting the hydrogen rather than the deuterium. These facts are just consistent with expectation that the OH elimination takes place without destruction of sulfoxide ring, while as for the HSO elimination ring openings prerequisite to ejection of HSO. The deuterium contents in various peaks were calculated and listed in Table 1.

TABLE 1. DEUTERIUM CONTENTS IN VARIOUS PEAKS

Sulfoxide	Peak	Relative Deuterium content,[a] %	Relative Deuterium content, %
Tetramethylene	M^+	87.8	100
	M^+-OH	52.4	59.7
	M^+-HSO	82.5	94.0
Pentamethylene	M^+	42.2	100
	M^+-OH	43.5	100
	M^+-HSO	31.7	75.1[b]
Hexamethylene	M^+	94.7	100
	M^+-OH	91.8	96.9
	M^+-HSO	83.5	88.2

a) Values after corrected for isotope peaks due to ^{13}C and ^{35}S.

b) This low value may be due to uncorrectness for the neighboring peak not attributed to HSO elimination.

Effect of Ring-Size on the Rate of Elimination. When the relative intensity ratios of peak heights of $[M^+ -OH]$ ions to the peak heights of the parent ions, *i.e.*, $[M^+ -OH]/[M^+]$, are plotted against the ring-size as shown in Fig. 11, we can get an upward concave curvature with the value of the five-membered ring sulfoxide being at minimum. The ratio ranges from a low figure of 0.06 for the five-membered sulfoxide to a high one of 1.21 for the seven-membered analog.

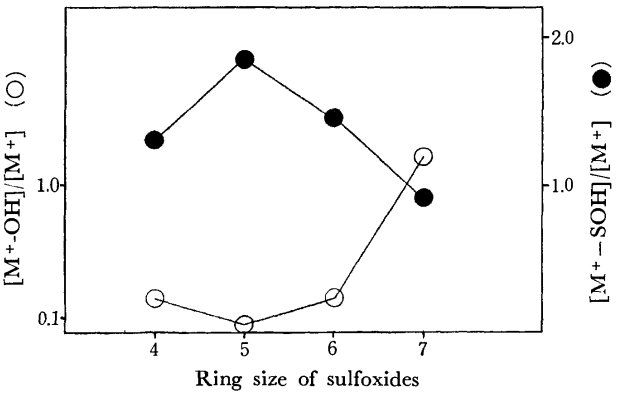


Fig. 11. Plot of intensity of OH- or SOH- eliminated fragment against ring size.

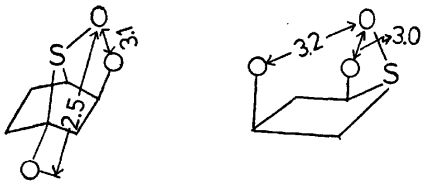
While, the plot of $[M^+ -HSO]$ intensities against those of molecular peaks, $[M^+ -HSO]/[M^+]$, is entirely different in shape from those of the above mentioned, as shown in Fig. 11 where no regularity can be seen in the plot of the $[M^+ -OH]$. Besides, the ratio of the maximum to the minimum values does not exceed only a little more than 2. Different features can be observed in the case of the bicyclic compounds. Even with the [3.3.1] bicyclic sulfoxide, the $[M^+-HSO]/[M^+]$ ratio increased up to 1.31, which is not much different from that of the monocyclic analogs. While, the ratio, $[M^+-OH]/[M^+]$, increased to as much as 3.14. On the other hand, the [2.2.1] bicyclic sulfoxide underwent much more facile HSO elimination, giving rise to the ratio of 8.70. However, $[M^+-OH]/[M^+]$ ratio was found to be negligibly small, *i.e.*, 0.03.

These observations imply that the HSO elimination does not depend so sharply upon the change of the ring size, but the ease of the expulsion of the OH group is markedly dependent on the number of methylene group. The latter finding can be readily rationalized on the basis of the strained structures. Since the five-membered and the [2.2.1] bicyclic sulfoxides are very strained and have only small degrees of freedom, the sulfoxide oxygen atom of these compounds can not easily get close enough to the β-hydrogen for elimination. In fact, on the basis of the molecular models, the closest distance between the center of the oxygen and that of each hydrogen atoms exceeds 3.0



Å with all these ring systems. This explanation may be supported further by the following observation that in the spectra for both compounds taken at 20 eV (Fig. 12) the number of ions attributed to the OH loss is far less than that of the ions arised from loss of oxygen. Namely, the sulfinyl oxygen that cannot find hydrogen atom in close vicinity has to cleave off itself (Scheme 4).

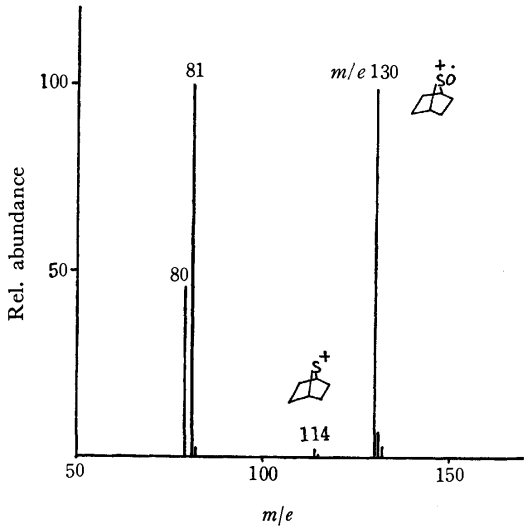


Fig. 12. Mass spectrum of 7-thiamonoxybicyclo[2.2.1]-heptane at 20 eV.

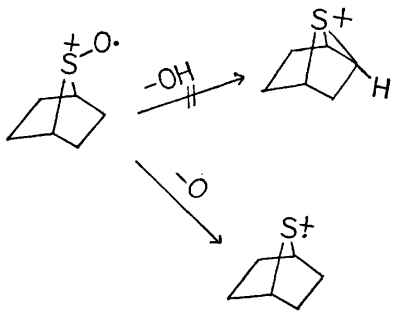
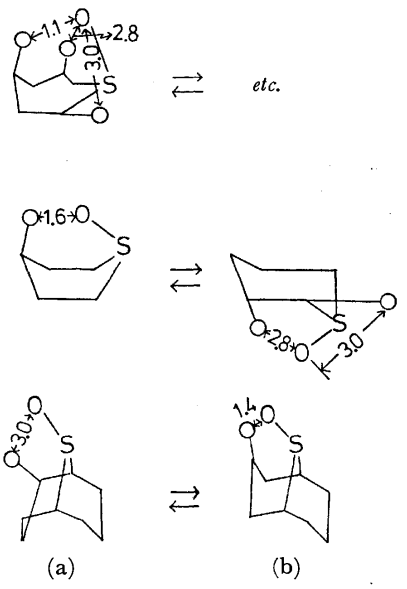


Scheme 4.

As for the more flexible six- and seven-membered cyclic sulfoxides, relative intensities of the dehydroxylated mass peaks against these of the parent ions are considerably higher than those of the strained sulfoxide and loss of OH for the seven-membered analog is more evident than for the six-membered system. All these observations seem to suggest strongly that not only the distances between hydrogen and oxygen in ground state geometry as Green and his coworkers have advocated but also the molecular motions are important for determining the extent of the OH elimination.

This is in keeping with our recent finding in the Ei reactions undergoing via five-membered cyclic transition state.[9] The distances between oxygen and hydrogen for some of possible conformations for the individual compounds studied are shown below:



In the first place, the distance between the sulfinyl oxygen and the nearest hydrogen atom in the molecule appears to determine the ease of the loss of OH. In the second place, the factor controlling the OH elimination seems to depend on the statistical stability of the molecular geometry which must satisfy the first condition for the OH elimination.

This latter condition is explicitly exemplified by the comparison of the mass pattern of the seven-membered sulfoxide with that of [3.3.1] bicyclic sulfoxide. The shortest distances between the two atoms calculated from the geometries for these two sulfoxides are 1.0 Å and 1.4 Å, respectively. On the contrary the $[M^+-OH]/[M^+]$ratios increased from 1.18 for the seven membered ring system to 3.12 for the [3.3.1] bicyclic sulfoxide. This is apparently apprehended by the assumption of the geometrical mobility toward the favorable conformation for eliminations under

Table 2. Distance between oxygen and nearest hydrogen atom in various sulfoxides and ratio of $[M^+-OH]/[M^+]$ or $[M^+-HSO]/]M^+]$

Sulfoxide	Å	$[M^+$-OH$]/[M^+]$		$[M^+$-HSO$]/[M^+]$	
4	3.0	0.23		1.30	
5	3.0	0.06	(0.02)	1.85	(0.33)

such a higher temperature as around 200°C in the inlet chamber room. Although the [3.3.1] bicyclic sulfoxide have been said to exist in the conformation (a) in which both six-membered rings are in the chair forms at around the room temperature,[10] at a higher temperature the steric repulsion between two hydrogens on the 3- and 7- positions would force the molecule to assume the conformations of one chair and one boat six-membered rings (b).

Such a conformation, considered to be favorable for the elimination of OH-group, would not be statistically stable in the case of the seven-membered system, because the 7-membered ring is very flexible.

Meanwhile, the behavior of the HSO elimination was found to differ from that of OH elimination. The fact that the OH loss does not depend on the change of the ring-size, *i.e.*, nor even on whether the sulfoxides are mono or bicyclic sulfoxides, may not be accounted for without the hypothesis that the molecular ions of the sulfoxides undergo OH-elimination, keeping the original skeleton, while the HSO loss does not take place without the destruction of the initial structure of the sulfoxide molecules. The C–S bond rupture at the initial step would lead molecular ions to convert to the corresponding open-chain structures.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1772—1776 (1972)

Liquid Crystalline Properties of Terminally Substituted Benzylideneanilines[1]

Kei MURASE

Ibaraki Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Tokai, Naka-gun, Ibaraki

(Received March 25, 1971)

The preparation and mesomorphic characteristics of certain anils (*p*-alkoxybenzylidene-*p'*-alkylanilines and *p*-alkoxybenzylidene-*p'*-alkoxyanilines) are described. Fifteen new compounds were found to exhibit nematic behavior below 100°C. The structural effects of the terminal substituents on nematic temperature range are discussed. It has been found that the anils containing *n*-alkyl substituents in the *p*-position of the aniline moiety exhibit mesophases in a much lower temperature range than those containing *n*-alkoxy substituents. Among *p*-isoalkoxybenzylideneanilines, all compounds except one are non-mesomorphic.

Recently, the electro-optic properties of liquid crystals have attracted considerable attention because of their application for display.[2] The term liquid crystal or mesomorphic state means a unique state of matter intermediate between a crystalline solid and a normal isotropic liquid.[3] A special class of mesomorphic material called nematic liquid crystal changes its transparency when an electric field is applied to its thin film.

Since low temperature nematic materials are desirable for a practical display device, efforts have been made for their preparation.[4–6] With this purpose in view, we prepared and characterized twenty three new anils, three of which were reported[5,6] as low temperature mesomorphic materials.

Results and Discussion

The terminally substituted anils we prepared are given in Table 1 along with their transition temperatures. The compounds are classified into the following three types according to their molecular constitutions.

I: *p-n*-Alkoxybenzylidene-*p'-n*-alkylanilines
II: *p*-Isoalkoxybenzylidene-*p'-n*-alkylanilines
III: *p*-Isoalkoxybenzylidene-*p'-n*-alkoxyanilines

A great number of *p-n*-alkoxybenzylidene-*p'-n*-alkoxyanilines (type IV) are known to exhibit mesomorphisms.[7,8] However, mesomorphic properties of other anils with less polar or branched substituents are scarcely known.

The compounds of type I contain no oxygen atom in the substituent of the aniline moiety. As the atom is polar and considered to contribute to intermolecular terminal cohesion between ordered mesomorphic molecules, it is of great interest to investigate the mesomorphic properties of the compounds. In this study, sixteen new compounds of this type were synthesized. Elemental analyses of most of them are given in Table 2.

Weygand and Gabler[9] studied *p-n*-nonyloxybenzylidene-*p'-n*-alkylanilines, which were found to exhibit smectic mesophases and no nematic mesophase when they have an ethyl or higher alkyl substituent in aniline moiety. Almost all the compounds of type I presented here, however, exhibit enantiotropic mesophases, as shown in Table 1.

It is notable that in homologous series of *p-n*-alkoxy-

benzylidene-*p'*-ethylanilines and *p*-*n*-alkoxybenzylidene-*p'*-*n*-propylanilines the smectic phase first appears at C_7-ether[10] and C_6-ether, respectively, while in the series of *p*-*n*-alkoxybenzylidene-*p'*-ethoxyanilines[7] and *p*-*n*-alkoxybenzylidene-*p'*-*n*-propoxyanilines[8] the smectic properties begin at their respective C_9-ethers.

The compounds of type II, which are characterized by their terminal substituents of bulky branched groups as well as less polar *n*-alkyl groups, are non-mesomorphic in two cases.

The compounds of type III have a branched and a *n*-alkoxy substituent. Five compounds of this type were prepared. Only one compound IIIu exhibited monotropic nematic behavior.

Effect of Alkyl Substituents. Various transition temperatures for the homologous series of *p*-*n*-alkoxybenzylidene-*p'*-ethylanilines (type I) and *p*-*n*-alkoxybenzylidene-*p'*-ethoxyanilines (type IV) *vs.* the length of their alkoxy chain (total carbon and oxygen atoms) are plotted in Fig. 1. Those of *p*-*n*-alkoxybenzylidene-*p'*-*n*-propylanilines (type I) and *p*-*n*-alkoxy-

10) Flannery and Haas report the smectic phase of C_4-ether[6].

(Data for nonyloxy derivative in (2) are referred from Ref. 9.)

benzylidene-*p'-n*-propoxyanilines (type IV) are similarly plotted in Fig. 2.

From a comparison of crystal-mesomorphic and nematic-isotropic transition temperatures for the corresponding compounds of type I and type IV, it was found that both transition temperatures for each compound of type I are much lower than those for the corresponding compound of type IV. The features for the compounds of the former type are considered to be due to the decrease of the terminal intermolecular attraction resulting from the lack of a polar oxygen atom in the substituent of aniline moiety. As a matter of fact, smectic phases appear at a shorter alkoxy chain length in these compounds than in the compounds of type IV, because smectic stability increases when terminal attraction decreases and lateral interaction becomes relatively predominant.

It is known that nematic-isotropic transition temperatures for a homologous series lie on two smooth curves, one related to the members with an even-numbered chain and the other to those with an odd-numbered chain. In Figs. 1 and 2, dotted lines are drawn in the middle of the above mentioned two curves. The lines show that the temperatures for the compounds of type I have an unusual rising tendency with the growing chain length, while those for the compounds of type IV have a usual[11,12] falling tendency.

These phenomena can be explained by assuming a

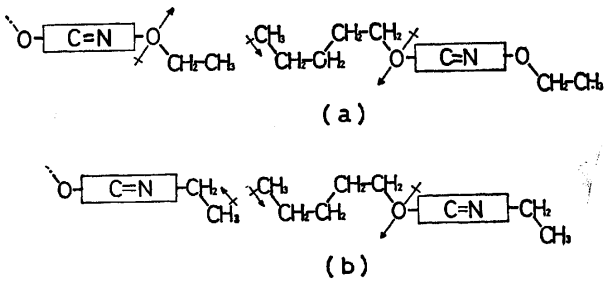

Fig. 3. Head-to-tail arrangement of neighboring molecules (a) compounds of the type IV (b) compounds of the type I.

head-to-tail molecular arrangement in which central C=N bondings of neighboring anils are in the same direction.[13] In the compounds of type IV as shown in Fig. 3(a), the terminal attraction between neighboring molecules is caused mostly by the interaction between dipoles of C–O–C groups. The contribution of other kinds of interactions such as related to the induced dipole moment of terminal methyl group are probably smaller. The nematic-isotropic transition temperatures for these compounds have falling tendency with the growing chain length because of decrease of the interaction between the dipoles. On the other hand, in the compounds of type I as shown in Fig. 3(b), the terminal attraction between

13) The possibility of a head-to-head or tail-to-tail molecular arrangement, where the C=N bondings of neighboring molecules are in opposite direction to each other, cannot be ruled out. However, it will be impossible to explain the phenomena by assuming this arrangement.

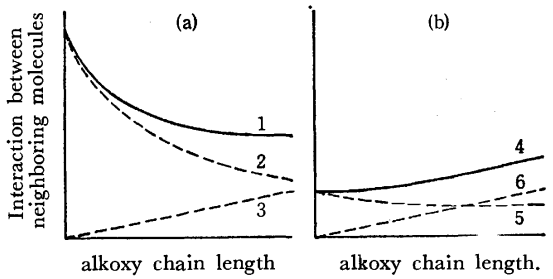

Fig. 4. Terminal interaction *vs.* alkoxy chain length (a) for the compounds of type IV, (b) for the compounds of the type I, curve 1 and 4: total interaction, curve 2: interaction related to two O atoms, curve 3: interaction such as related to polalizability of terminal CH_3 group, curve 5: interaction related to terminal CH_3 group and O atom, curve 6: interaction to two terminal CH_3 group

neighboring molecules is caused by the interaction between the dipole of the C–O–C group in one molecule and the induced dipole of the terminal methyl group in the other molecule and by the interaction between the induced dipoles of the terminal methyl groups in both molecules. The former interaction becomes weaker with the growing alkoxy chain length, but the latter becames stronger because of increase of the induced dipole. The rising tendency is considered to be due to the superiority of the latter interaction. A schematic explanation is given in Fig. 4.

Effect of Odd- and Even-numbered Length of Terminal Chain. In Figs. 1 and 2, the well known change of nematic-isotropic transition temperatures can be seen between homologues containing odd and even numbers of carbon atoms in the terminal substituent of benzylidene moiety. Figure 5 gives the plots of nematic-isotropic transition temperatures for several series of *p*-*n*-alkoxybenzylidene-*p'*-*n*-alkylanilines. Similar changes are found also with regard to the terminal chain length of aniline moiety.

When the alkoxy chain length is defined as the number of oxygen plus carbon atoms, and the alkyl chain length as that of carbon atoms, curves of nematic-isotropic transition temperatures related to an odd-numbered chain length lie always above those related to an even-numbered chain length. It is notable that the feature is decided by the altered chain length of one moiety, independent of the chain length of the other moiety.

The behavior can be explained by considering the direction of polarizability of terminal methyl group as suggested by Gray.[12] Using the cog-wheel conformation for the substituted chain, the terminal C–C bond in the odd-numbered chain lies in the direction of the preferred axis of the molecules, but in the even-numbered chain it makes an angle with this axis. Therefore, the terminal intermolecular attraction is considered to be stronger in the molecules containing odd-numbered terminal chain. It is inferred that an oxygen atom in ether bonding makes one unit like a methylene group in this conformation and its polarity has nothing to do with the alternative behavior of the transition temperatures.

Let us consider curves 1 and 2 in Fig. 5. The terminal situations of neighboring molecules are exhibited schematically in Figs. 6 and 7 for the compounds related to curves 1 and 2, respectively. (A), (B) and (C) represent 2, 3, and 4 of alkyl chain length of aniline moiety. It is understood that the terminal intermolecular cohesion of the odd-numbered chain of the aniline moiety should be stronger than that of the even-numbered chain, independent of the chain length of the benzylidene moiety. As the terminal C–C bond of the benzylidene moiety of compounds in Fig. 7 lies in the direction of the preferred axis of the molecule, the terminal cohesion in these compounds should be stronger than that of corresponding compounds in Fig. 6. Thus, a compound with the terminal situation of (A) or (C) has a lower nematic-isotropic transition temperature than a homologous one with

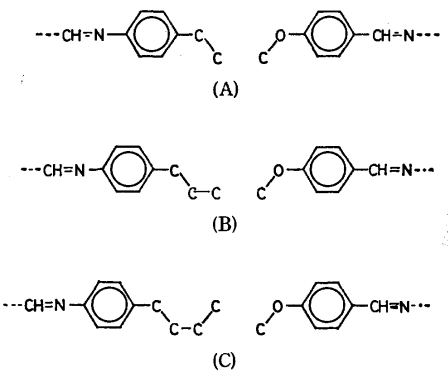

Fig. 6. Terminal situation of neighboring molecules of *p*-methoxybenzylidene-*p*-alkylanilines.

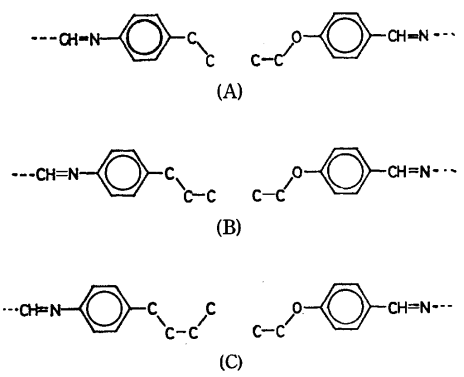

Fig. 7. Terminal situation of neighboring molecules of *p*-ethoxybenzylidene-*p'*-alkylanilines.

terminal situation of (B). The series in Fig. 6 exhibit the transition at a lower temperature than that in Fig. 7.

The consideration is in line with the aspects of curves 1 and 2 of Fig. 5. All the other data on the alternation of nematic-isotropic transition temperatures of anils can be explained as well.

Effect of Branched Chain Substituent. The bulky effect of the branched substituent was expected to weaken the intermolecular cohesion and to make the mesomorphic transition temperatures of type II and III compounds low as was the case with 4'-isoalkoxybenzylidene-1-aminonaphthyl-4-azobenzene.[11] However, all the compounds of these types do not exhibit mesomorphic behavior except for IIIu. The results suggest that the compounds do not possess sufficient intermolecular cohesion for mesomorphic ordering because of too bulky effect.

However, both the nematic-isotropic and the crystal-nematic transition temperatures of the compound IIIu are actually lower than those of the corresponding compound of type IV by about ten degrees. If the melting point of non-mesomorphic materials can be assumed to correspond to the crystal-mesomorphic transition temperature of mesomorphic ones, similar lowering effects are found in a comparison of these temperatures of the compounds of type II or III and the corresponding compounds of type I or IV.[7,8]

Experimental

Materials. p-*Alkoxybenzaldehydes*: *p-n*-Propoxybenzaldehyde (bp 91—92°C/2 mmHg), *p*-isopropoxybenzaldehyde[14], *p-n*-butoxybenzaldehyde (bp 111—112°C/2 mmHg), *p-n*-amyloxybenzaldehyde (bp 114—116°C/2 mmHg), *p*-isoamyloxybenzaldehyde (bp 110—111°C/2 mmHg), *p-n*-hexyloxybenzaldehyde[14], *p-n*-heptyloxybenzaldehyde (bp 136—137°C/2 mmHg), *p-n*-octyloxybenzaldehyde (bp 152—154°C/2 mmHg) and *p-n*-hexadecyloxybenzaldehyde[14] were prepared from *p*-hydroxybenzaldehyde and the corresponding alkylbromide by refluxing in ethanol.[15] The yields were 60—80%. All the aldehydes obtained were identified by IR-spectroscopy, and exhibited the following peaks: ν_{max}^{film} 2925, 2850 (aliphatic C–H), 2730 (aldehyde C=H), 1695 (C=O), 830 cm^{-1} (*p*-substituted).

p-*alkoxyanilines*: *p*-Anisidine and *p*-phenetidine were obtained from commercial sources and distilled. *p-n*-Butoxyaniline was prepared by the reduction of *p-n*-butoxynitrobenzene.[16]

p-*Alkylanilines*: *p*-Toluidine and *p*-ethylaniline were obtained from commercial sources and distilled. *p-n*-Propylaniline and *p-n*-butylaniline were prepared by a method similar to that of Read and Mullin[17] (bp 74—76, 80—86°C/2 mmHg, respectively).

Preparation of Substituted Benzylideneanilines. Equimolar quantities of the appropriate benzaldehyde and aniline were mixed, warmed at about 50°C for a quarter of an hour and then cooled to room temperature until crystalline products appeared. It was necessary to cool the mixture with dry ice-acetone for the synthesis of Ib and Ip.

Since no crystals appeared in the syntnesis of Ih and IIr, the mixture was dissolved in benzene containing a catalytic amount of benzenesulfonic acid, and refluxed for about three hours to remove water azeotropically.[4] After the removal of solvent, the residue was cooled in dry ice-acetane to crystallize.

The products were purified by recrystallization from ethanol. All anils were obtained in 60—85% yield after recrystallization. The absorption band at 1625—1630 cm^{-1} (C=N stretching[18]) in IR-spectra, not belonging to raw materials, confirms the formation of anils.

Determination of Transition Temperature. The melting point and mesomorphic transition temperature were determined with an electrically heated microscope block in conjugation with a projection system. The mesomorphic states of the compounds were readily distinguished by their typical textures.[19]

The author wishes to thank Dr. K. Nakagawa, Dr. H. Toyoda, and Dr. H. Katsuraki for their encouragement, and T. Wachi for his cooperation.

Structure and Reactivity of Small Ring Compounds. IV.[1] Photochemistry of Spirocyclopropyl Ketones[2]

Akio SONODA, Ichiro MORITANI, Jo MIKI, Takashi TSUJI*, and Shinya NISHIDA*

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received May 10, 1971)

The photochemical transformations of a series of spriocyclopropyl ketones (**1**—**4**) have been investigated in dilute *n*-hexane solutions. Spirocyclopropyl ketones **1** and **2** give mainly the 'Type I' photoproducts of cycloalkanones, *i.e.*, 1-(2'-propenyl)cyclopropanecarboxaldehyde (**5**, 34%) and 1-(3'-butenyl)cyclopropanecarboxaldehyde (**7**, 37%), respectively, in marked contrast to the usual photochemical cleavage of cyclopropyl ketones. Ethylidenecycloalkanones are not detected, but their hydrogenated derivatives, 2-ethylcycloalkanones, are produced in a small amount.

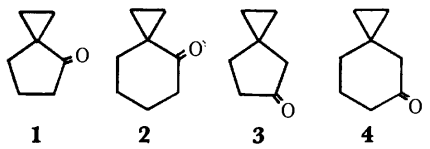
The photoreaction of **1** has been found to be quenched by piperylene, so that it is highly probable that the reaction products are derived from the n–π^* triplet states of the ketones.

The irradiations of nonconjugated spiroketones **3** and **4** afford ring-enlarged 4-methylenecycloalkanones, **9** and **10**, respectively.

The preferential photoisomerization of conjugated cyclopropyl ketones to enones has been extensively studied both in gas and liquid phases.[3] It has been thought that in this characteristic photoisomerization, transfer of the excitation energy absorbed by the carbonyl chromophore to a highly strained cyclopropane ring through a conjugative interaction causes the homolytic ring fission to give the enones.[4]

In order to elucidate this interesting photochemical process on the basis of conformational aspect, we have investigated the photochemistry of some spirocyclopropyl ketones (**1**—**4**). In compounds **1** and **2** bearing a cyclopropane ring in an adjacent position to a carbonyl group, the cyclopropane ring and carbonyl group are fixed to permit the maximum conjugative interaction from their geometry.[5] On the other hand, compounds **3** and **4** are nonconjugated.

In a preliminary paper,[2] we reported the unusual photochemical behaviors of these spiroketones. Recently, Crandall and Seidewand[6], and Turro *et al.*[7] also reported the photoreactions of **1** and **2** in different solvents. In the present paper, we describe the detailed results and discuss the photochemistry of cyclopropyl ketones.

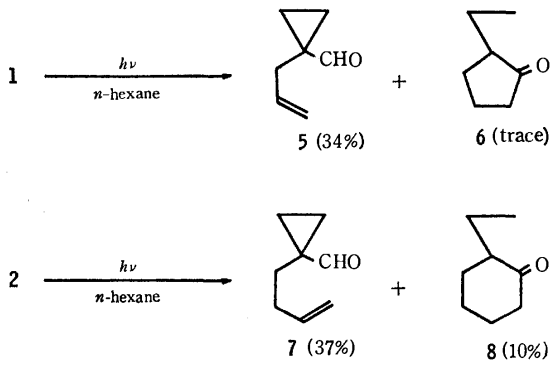


1 **2** **3** **4**

Fig. 1.

Results

Photochemistry of Spiro[2.4]heptan-4-one (1). Irradiation of a *n*-hexane solution of **1** (0.11 mol/*l*) by a high pressure mercury lamp gave 1-(2'-propenyl)-cyclopropanecarboxaldehyde (**5**) and a trace amount of 2-ethylcyclopentanone with a considerable amount of polymeric materials. The prolonged irradiation caused the polymerization. Under optimized reaction conditions (40 hr irradiation) the aldehyde **5** was isolated in 34% yield by means of preparative vpc. The structure of **5** was determined by elemental analysis, IR, and NMR spectra. 2-Ethylcyclopentanone which was obtained in too small a quantity to be isolated was assigned by comparison of its retention times of vpc with an authentic sample.[8]



Scheme 1.

Oxygen Effect and Quenching Experiments. On irradiation of ketone **1**, the presence of oxygen caused marked retardation of the photoconversion. In addition, piperylene quenched the photochemical reaction of **1**. These results are shown in Table 1.

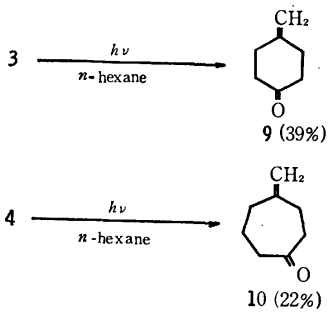
a) Irradiated by means of 3130 Å using potassium chromate filter solution ($5\times10^{-4}M$, path length 5 cm).
b) Determined by the relative area of vpc.
c) In concentration of 0.16 mole/*l* *n*-hexane.

Photochemistry of Spiro[2.5]octan-4-one (2). Irradiation of ketone **2** in *n*-hexane under the conditions similar to those employed in the photolysis of **1** afforded 1-(3′-butenyl)cyclopropanecarboxyaldehyde (**7**) and 2-ethylcyclohexanone (**8**) in 37% and 10% yields, respectively. The structure of **7** was established by elemental analysis, NMR, and IR spectra. The minor product **8** was identified by comparisons of its IR and NMR spectra with those of an authentic sample.[9]

Irradiation of **2** in diethyl ether for 50 hr also gave **7** and **8** in 23% and 16% yields, respectively. The irradiation through a Pyrex filter did not affect the reaction (after 50 hr, **7** and **8** were produced in 17% and 9% yields, respectively).

Photochemistry of Spiro[2.4]heptane-5-one (3) and Spiro[2.5]octan-5-one (4). Irradiation of a *n*-hexane solution of **3** in a quartz vessel gave only polymeric materials after 20 hr. On irradiation through a Pyrex filter, the ring-enlarged product, 4-methylenecyclohexanone (**9**) was obtained in 39% yield after 3 hr. The structure of **9** was established by the comparison with an authentic sample.[10]

Irradiation of **4** in *n*-hexane produced 4-methylenecycloheptanone (**10**) in 22% yield after 20 hr. The structure of **10** was also confirmed by IR and NMR spectra and elemental analysis. Hydrogenation of **10** gave 4-methylcycloheptanone.[11]



Scheme 2.

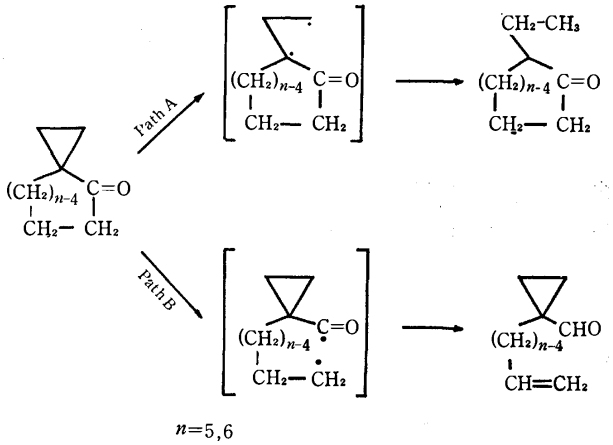
Discussion

The photochemistry of **1** and **2** has been studied by three research groups.[2,6,7] Although their results are slightly different in detail according to the reaction conditions, the most important observation in these studies is that the cyclopropane cleavage (Path A) is not the major path, but the α-cleavage of the bond away from the cyclopropyl group (Path B) is actually the preferred process.[12]



Scheme 3.

Accordingly, it can be concluded that the retention of cyclopropane ring is characteristic for the photoconversions of conjugated spirocyclopropyl ketones. This is a striking contrast to the predominant photocleavage of a cyclopropane ring observed in numbers of cyclopropyl ketones.[3]

The present investigation showed that the irradiation of **1** in *n*-hexane gives 1-(2′-propenyl)cyclopropanecarboxaldehyde (**5**) almost exclusively, whereas the irradiation of **2** in the same solvent produced 1-(3′-butenyl)cyclopropanecarboxaldehyde (**7**, 37%) accompanied by a considerable amount of 2-ethylcyclohexanone (**8**, 10%). The latter compound might be formed *via* a diradical followed by abstraction of hydrogen atoms from the solvent (Scheme 3). This is supported by the fact that the yield of **8** is substantially increased (16%), when **2** is treated in diethyl ether. It becomes apparent that the cyclopropane cleavage is hardly found in the photolysis of **1**, but in **2** it competes with 'Type I'[13] cleavage.

The photochemical cleavage of cyclopropyl ketones to enones is rationalized by the concept that photoexcitation energy is transferred to the cyclopropyl group through conjugative interaction and the strained ring is cleaved by its excess energy.[4] However, this concept would not be able to explain the difference in the photochemical behavior between

11) C. Djerassi, B. F. Burrows, G. G. Overberger, T. Takekoshi, C. D. Gutsche, and C. T. Chang, *J. Amer. Chem. Soc.*, **85**, 949 (1963).
12) In addition to **1** and **2**, Turro *et al.*[7] reported that 1,1-dimethylspiro[2.3]hexan-4-one gives cyclopropane ring-retained acetals as exclusive photoproducts in methanol.
13) J. G. Calvert and J. N. Pitts, Jr., "Photochemistry," John Wiley & Sons, Inc., New York, N. Y. (1966), p. 368—427.

spiroketones and other cyclopropyl ketones. According to Kosower and Ito,[5] the spiroketone **1** has higher degree of conjugation between the cyclopropyl and carbonyl groups than bicyclo[3.1.0]hexan-2-one. This would lead that the spiroketone suffers the cyclopropane cleavage more efficiently than the bicyclic ketone. However, the reverse is true in our case.

We determined the π–π^* absorption maxima of **1** and **2** in ethanol, and compared them with those of corresponding methylene- and dimethyl-cycloalkanones and nonconjugated spiroketones **3** and **4** (Table 2). The result indicates that the spiroketones **1** and **2** have similar conjugative interaction. Again this cannot help to understand the difference in their photochemical transformations.

TABLE 2. UV DATA OF SPIRO[2. *n*]ALKANONES (n=4, 5) AND RELATED KETONES

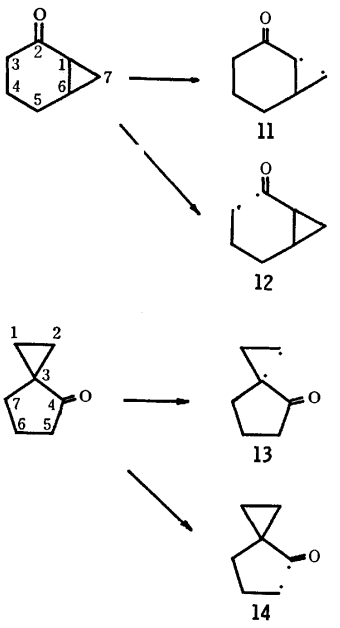
b) Prepared by the known method.[15]
c) Prepared by the known method.[9]

In the photochemistry of bicyclo[4.1.0]heptan-3-ones, Dauben and his coworkers[3c,f] showed that only when a methyl group is substituted at C–3 position, the α-cleavage away from the cyclopropyl group (C-2—C-3) becomes a predominant reaction path. However, this substituent effect to stabilize the radical generated in the photolysis cannot also be the factor controlling the direction of bond fission in these spiroketones. In the bicyclic ketones, the diradical **11**, which is primary–secondary, is proposed to be more stable than diradical **12**.[3c,f] The diradical **13** expected from the cyclopropane cleavage of spiroketone **1** is a primary-tertiary one. The α-cleavage of **1** will give **14**, which may be comparable in its stability with **12**. There will be no reason to expect that the diradical **13** is less stable than **11**, and hence **13** is less stable than **14**.

Crandall and Seidewand[6] have suggested that the apparent resistance of the cyclopropyl group to photochemical ring fission is due to the reversible recombination to the ring. Actually, the cyclopropane ring fission is reversible in several instances,[16] but there



Scheme 4.

may be no reason why such a recombination process is particularly important only in the spiroketones and not so in other cyclopropyl ketones such as bicyclo [n.1.0]alkanones. Therefore, we believe that this explanation is not sufficient enough to account for the present results.

It was demonstrated that the photolysis of **1** using Pyrex-filtered light (>280 nm) proceeds similarly to the direct photolysis, and the photoreaction is quenched by piperylene. These results strongly indicate that the photoreaction of **1** as well as **2** proceeds *via* the n–π^* triplet state.[17] In many cases, the cleavage of cyclopropane ring proceeds through the triplet state.[18]

We would like to propose a hypothesis to rationalize the features of the photochemical behavior of spiroketones of **1** and **2**. Since the present photoreactions are regarded as a triplet reaction, the photoexcitation of these spiroketones leads to their triplet diradical state, where both the carbonyl carbon and the oxygen atoms may behave as a radical-like species.[19] The cyclopropane cleavage would subsequently occur through merely a dark reaction of the cyclopropylcarbinyl radical. Thus, the radical-like carbonyl-carbon would attack the cyclopropyl bond in an intramolecular S_H2 fashion to cleave the cyclopropyl ring giving an enolic diradical which is

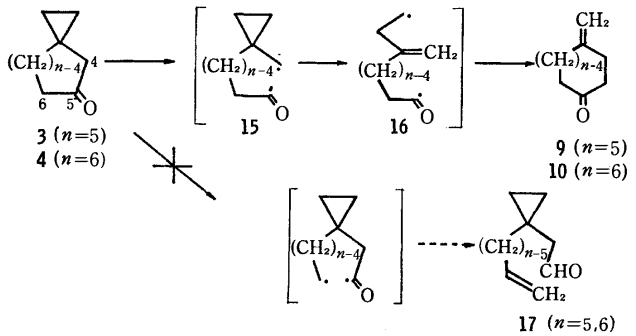
followed by abstraction or migration of hydrogen atoms. In the S_H2 process[20], the attack would take place from the backside of the dissociating cyclopropyl bond, and hence the relative geometry between the cyclopropyl bond and *p*-orbital at the carbonyl carbon will be important.

The examination of the molecular models of these spiroketones indicates that in ketone **2**, the overlapping of the backside bond of the cyclopropyl bond and *p*-orbital of the carbonyl carbon in a *p*-σ manner might be possible to some extent, whereas in ketone **1**, the two orbitals are so arranged spacially as not to allow significant overlapping because of the rigid conformation of the cyclopentanone structure. The flexibility of the cyclohexane-ring structure in ketone **2** makes this sort of *p*-σ overlapping possible to a certain degree, but not fully as those of acyclic and bicyclic cyclopropyl ketones. Therefore, in the photolysis of **2**, the cyclopropane cleavage would compete with the α-cleavage.

Irradiation of nonconjugated spiroketones, **3** and **4**, afforded the ring-enlarged products, 4-methylenecycloalkanones, **9** and **10**, respectively. The cyclopropane ring was cleaved in these ketones. The reaction could be explained in a following way. The diradical **15** formed by the α-cleavage at C-4—C-5 gives the second diradical **16** *via* the induced ring opening of the cyclopropylcarbinyl radical, and finally the diradical cyclize intramolecularly to afford the reaction product. The ring-opening of the cyclopropylcarbinyl radical to form the second cyclic compound has been demonstrated in the photoreaction of several β-cyclopropyl cyclic ketones[21].

In the reaction of **3** and **4**, the formation of aldehyde **17** expected from the cleavage at C-5—C-6 could not be detected. This fact may suggest that the C-4—C-5 bond fission forming cyclopropylcarbinyl radicals occurs in preference to the C-5—C-6 cleavage.



Scheme 5.

Experimental

The IR spectra were recorded on a Hitachi EPI-S2 spectrophotometer. The UV spectra were obtained with a Hitachi EPS-2U spectrophotometer. The NMR spectra were obtained with a JEOLCO JNM-MH-60 or JNM-4H-100 spectrometer at 60 MHz and 100 MHz, respectively, using TMS as an internal standard. The analytic and preparative vpc were carried out using a Yanagimoto GCG-5DH gas chromatograph. All irradiations were conducted with a Eikosha PIH-500 (High pressure mercury lamp, 500 W). All temperatures are uncorrected.

Materials. Spiro[2.4]heptan-4-one (**1**) and spiro[2.5]octan-4-one (**2**) were prepared by sodium dichromate oxidation of the corresponding carbinols[22] as described previously.[1]

Spiro[2.4]heptan-5-one (**3**) was prepared by the known method[23] from spiro[2.4]heptan-5-ol. Bp 58°C/18 mmHg, IR (liquid film): 1743 cm^{-1} (C=O), UV (ethanol): λ_{max} 290 nm (ε=35), NMR (60 MHz, CCl_4): 7.86 τ (2H, s, methylene of cyclopentanone), 7.5—8.3 τ (4H, m, methylenes of cyclopentanone), and 9.43 τ (4H, s, cyclopropane). Found: C, 76.08; H, 9.26%. Calcd for $C_7H_{10}O$: C, 76.32; H, 9.15%.

Spiro[2.5]octane-5-one (**4**) was prepared by the oxidation of spiro[2.5]octan-5-ol which was reported previously.[24] IR (liquid film): 1718 cm^{-1} (C=O). UV (ethanol): λ_{max} 288 nm (ε=35). NMR (60 MHz, CCl_4): 7.91 τ (2H, s, methylene of cyclohexanone), 7.5—8.5 τ (6H, m, methylenes of cyclohexanone), and 9.69 τ (4H, s, cyclopropane).

The spiroketones, starting materials, were purified by either fractional distillation or preparative vpc. Solvent *n*-hexane was purified by treating with fuming sulfuric acid followed by distillation. Diethyl ether and 2-propanol were purified by fractional distillation before use.

Irradiation of **2** *in* n-*hexane.* A solution of 15.0 g of **2** in 450 m*l* of *n*-hexane was irradiated through a quartz vessel under continuous slow bubbling of pure nitrogen. The reaction was monitored periodically by removing aliquots and then analyzing by vpc (Apiezon L at 130°C). When about the half of the starting ketone had been consumed, irradiation was stopped (40 hr). After solvent was evaporated through a short column, the residual oil (14.4 g) was subjected to fractional distillation under reduced pressure. The distillate (11.8 g) was separated by vpc (Apiezon L) into three components. The first compound (2.75 g) was characterized as an aldehyde **7** (37% yield based on consumed **2**) by the analysis, functional tests and the spectral data. IR (liquid film): 2730 cm^{-1} (C–H, aldehyde) 3070, 1025 cm^{-1} (C–H, cyclopropane), 1705 cm^{-1} (C=O), 1635, 900 cm^{-1} (terminal olefin). UV (ethanol): λ_{max} 211 nm (ε=2400), and 280 nm (ε=67). NMR (100 MHz, CCl_4): 1.4 τ (1H, s, aldehyde), 4.25 and 5.05 τ(1H, and 2H, ABC pattern of vinyl), 7.86 τ (2H, q, methylene), 8.35 τ (2H, overlapped d, methylene), and 8.93 and 9.12 τ (2H+2H, AA'BB' pattern of cyclopropane). Found: C, 77.03; H, 9.79%. Calcd for $C_8H_{12}O$: C, 77.37; H, 9.74%. Bp. 60—61°C/7 mmHg. n_D^{20} 1.4612. Olefin test (Br_2, $KMnO_4$) positive. 2,4-Dinitrophenylhydrazone; mp 133—134°C.

The second product (0.76 g, 10% yield) was identified to be 2-ethylcyclohexanone (**8**) by comparisons of IR, retention times of vpc (Apiezon L and Carbowax 6000) with an authentic sample.[9] IR (liquid film): 1710 cm^{-1} (C=O), and 1382 cm^{-1} (CH_3). NMR (100 MHz, CCl_4): 9.20 τ (3H, t, methyl). Found: C, 75.75; H, 11.03%. Calcd for $C_8H_{14}O$: C, 76.14; H, 11.18%. Bp 51—52°C/8 mmHg. Semicarbazone, mp 157—157.5°C. The mixed mp of the semicarbazone with an authentic sample showed no depression.

The last component was unchanged **2** (7.58 g).

Irradiation of **2** in diethyl ether using a Pyrex reaction vessel for 50 hr afforded a volatile reaction mixture which was composed of **7** (24%), **8** (12%) and **2** (64%).

Irradiation of ***1*** *in* n-*hexane.* A solution of **1** (7.0 g) in *n*-hexane (500 m*l*) was similarly irradiated for 40 hr. The volatile reaction mixture (4.3 g) was separated with a preparative vpc (Apiezon L) into two components. The first eluted product (1.23 g, 34% yield) was characterized as an aldehyde **5**. Bp 34°C/7 mmHg. n_D^{20} 1.4608. UV (ethanol): λ_{max} 211 nm (ε=2700), 260 nm (ε=82). IR (liquid film): 3080, 1030 cm^{-1} (cyclopropane), 2725, 1690 cm^{-1} (aldehyde), 1630, 1410, 995, and 910 cm^{-1} (terminal olefin). NMR (100 MHz, CCl_4): 1.35 τ (1H, s, aldehyde), 4.3 τ (1H, m, vinyl), 4.99 and 5.12 τ (2H, two multiplet peaks, vinyl), 7.68 τ (2H, d, J=6.5 Hz, methylene), and 9.03 τ (4H, AA'BB' pattern, cyclopropane). Found: C, 76.09; H, 9.16%. Calcd for $C_7H_{10}O$: C, 76.32; H, 9.15%. 2,4-Dinitrophenylhydrazone, mp 139—139.5°C. Found: C, 53.96; H, 5.13; N, 19.26%. Calcd for $C_{13}H_{14}O_4N_4$: C, 53.79; H, 4.86; N, 19.26%. The second component was **1** unchanged (3.4 g). The existence of **6** was observed in vpc, but **6** was not isolated. The structure of **6** was confirmed by the identity of retention time (Apiezon L, diglycerol and Carbowax 20 M) with that of authentic 2-ethylcyclopentanone.[8] The yield of **6** was estimated to be less than 0.5%. The photolyses of **1** in diethyl ether, 2-propanol, benzene, and *n*-hexane, respectively, with a Pyrex filter afforded almost the same results as above.

Quenching of photoreaction of **1**. Three *n*-hexane solution of **1**; (A: **1**, 0.16 M), (B: **1**, 0.16 M and piperylene, 0.16 M) and (C: **1**, 0.16 M and piperylene 1.6 M) were degassed by the freeze-thaw method and irradiated in quartz tubes under nitrogen on a round table (5 cm from 500 W mercury lamp) immersed in an aqueous K_2CrO_4 filter solution (5×10^{-4} M). Periodical sampled aliquots of these solutions were subjected to the vpc analysis. While **1** converted to **5** in solution A (16% of **5** formed after 5 hr), in solution B there was observed marked quenching effect as shown in Table 1. In solution C, the photolysis of **1** was found to be completely quenched.

Irradiation of **3** *in* n-*hexane.* A solution of **3** (0.200 g) in *n*-hexane (10 m*l*) was irradiated for 3 hr in a Pyrex tube. After careful removal of the solvent, reaction mixture was subjected to a preparative vpc. Besides unreacted **3** (0.094 g), compound **9** was separated from several minor products. The compound **9** was characterized to be 4-methylenecyclohexanone (0.042 g, 39% yield). IR (liquid film): 1715 cm^{-1} (C=O), 1650, 895 cm^{-1} (olefinic). NMR (60 MHz, CCl_4): 5.15 τ (2H, s, vinyl), 7.55 τ (8H, m, methylene). UV (ethanol): λ_{max} 210 nm (ε=2800) and λ_{max} 283 nm (ε=30). Found: C, 76.44; H, 9.18%. Calcd for $C_7H_{10}O$: C, 76.32; H, 9.15%. The comparisons of **9** with an authentic sample which was prepared by the oxidation of 4-methylenecyclohexanol showed good identity in retention times of vpc (Apiezon L and Carbowax 6000) and in the mixed mp test of the 2,4-dinitrophenylhydrazones (mp 154—155°C).

Irradiation of ***4*** *in* n-*hexane.* A solution of **4** (0.572 g) in *n*-hexane (15 m*l*) was irradiated in a quartz tube for 20 hr. After the reaction mixture was treated as usual, 0.18 g of **4** and 0.086 g of **10** were isolated by vpc (Carbowax 6000). Compound **10** was characterized as 4-methylenecycloheptanone (22% yield). IR (liquid film): 1710 cm^{-1} (C=O), 1640, 890 cm^{-1} (olefinic). UV (ethanol): λ_{max} 286 nm (ε=20). NMR (60 MHz, CCl_4): 5.18 τ (2H, s, vinyl), 7.55 τ (8H, m, methylene) and 8.20 τ (2H, m, methylene). Found: C, 77.01; H, 10.09%. Calcd for $C_8H_{12}O$: C, 77.37; H, 9.74%. The 2,4-dinitrophenylhydrazone, mp 148—149°C.

Compound **10** (0.020 g) was hydrogenated in methanol on Pd-black (0.005 g). The hydrogenated product was identified as 4-methylcycloheptanone by the comparisons of the IR spectra and retention times of vpc (Apiezon L and Carbowax 6000) with an authentic sample.[9]

Studies on the Voges-Proskauer Reaction. II. The Structure of a Pigment from the Diacetyl Reaction of 1-Benzyl-1-methylguanidine[1]

Tamio NISHIMURA, Chiji YAMAZAKI, Tetsuro UENO, Shinichi KITAJIMA, and Koichi ISHIGE

Department of Chemistry, School of Hygienic Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo

(Received July 13, 1971)

A pigment formed in the diacetyl reaction of 1-benzyl-1-methylguanidine was isolated as reddish purple prisms. The reduced pigment was colorless and rapidly converted back to the original pigment on exposure to the air. On the basis of IR, NMR, and mass spectral evidence, the structures of the pigment and the reduced one were established to be 2-(*N*-benzyl-*N*-methylamino)-4-methyl-5-(1-oxo-1,2-dihydro-2-naphthylidenemethyl)-imidazole and 2-(*N*-benzyl-*N*-methylamino)-4-methyl-5-(1-hydroxy-2-naphthylmethyl)imidazole, respectively.

Voges and Proskauer[2] found that glucose peptone cultures of a certain microorganism produced a pink color on addition of aqueous potassium hydroxide solution. It was shown that the coloration occurs as a result of the reaction between acetoin and creatine or certain similar substances, and the former is converted into diacetyl during the course of reaction.[3,4] Barritt[5] modified the reaction by the addition of 1-naphthol, which resulted in a great intensification of the color. This reaction has been called the diacetyl reaction. It has been demonstrated by several investigators that the color reaction is characteristic of 1,1-disubstituted, mono-, and unsubstituted guanidines and the intensity of coloration decreased in the order mentioned.[5-10] It is also obvious from literature[5,11,12] that the ketonic component should be α-diketone having at least one methyl group attached to the carbonyl carbon atom. Although Eggleton *et al.*[6] obtained a crude coloring matter in the diacetyl reaction of creatine, the pigment has not yet been isolated in a pure crystalline form and consequently its structure has remained unknown. The present work deals with the structure determination of a pigment produced in the diacetyl reaction of 1-benzyl-1-methylguanidine as the first step for elucidation of the mechanism of this color reaction.

Results and Discussion

The crude pigment from creatine according to Eggleton's method gave numerous coloring bands on column chromatography, which made it impossible to obtain a pure pigment. Thus we selected 1-benzyl-1-methylguanidine in expectation of ease in isolation of the aimed pigment, because of its expected good solubility in non-polar solvents in addition to good stability of coloration.[10]

Preliminary experiments revealed that the yield of pigment was best, when the guanidine, diacetyl, and 1-naphthol were allowed to react in water in a molar ratio of 1 : 2 : 5. The pigment was formed by the addition of 1-naphthol in 2.5 N sodium hydroxide to a mixture of diacetyl and the guanidine hydrochloride in water, followed by agitation of the mixture at room temperature. The crude pigment was obtained either by adjusting the reaction mixture to pH 10 with hydrochloric acid, or by extracting the sodium chloride-saturated mixture with benzene. The pigment was purified by column chromatography on silica gel with benzene, giving dark reddish purple prisms with mp 149—149.5°C in about 2% yields on the basis of the guanidine employed. It was also obtained in about 5% yields by conducting the reaction in chloroform with an equimolar proportion of reactants. The pigment thus isolated gave a visible spectrum having the same maximum absorption as and a similar shape to that obtained under the conditions of quantitative determination.[10]

Elemental analysis and mass spectrometry of the pigment gave the molecular formula $C_{23}H_{21}ON_3$. NMR data showed the presence of *N*-methyl (3.21

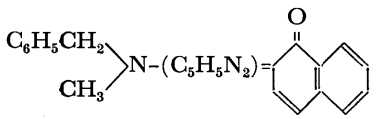
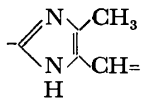
s), *N*-methylene (4.80, s), phenyl (7.32, s), and naphthalene nucleus (7.0—8.4, m) as shown in Fig. 2a.

The IR spectrum of the pigment showed strong peaks at 1630 cm^{-1} (C=O) and 800 cm^{-1} (ring hydrogen out-of-plane vibration) as shown in Fig. 3a. The 800 cm^{-1} band was observed in 1,2-naphthoquinone but not in 1,4-naphthoquinone suggesting the presence of 1,2-naphthoquinoidal system. The pigment absorbed hydrogen on catalytic hydrogenation and yielded a colorless solution, which rapidly restored the original reddish color upon exposure to the air. The recovered pigment gave the same IR spectrum as that of the original pigment. The reduced pigment showed an associated O–H stretching band at 3150—3270 cm^{-1} in KBr disk and a sharp unassociated band at 3460 cm^{-1} in carbon tetrachloride, with simultaneous disappearance of the carbonyl band (Fig. 3b). It also showed a C–O stretching band at 1250 cm^{-1} (in CCl_4) or 1260 cm^{-1} (in KBr). The UV spectrum of the reduced pigment (Fig. 1) was similar to that of 1-naphthol. The hydrogenated pigment should therefore have a naphthol structure. The fact that it has no signal in the neighborhood of 6.7 ppm (Fig. 2b) at which 2-proton of 1-naphthols[13] usually resonates, further suggests that the reduced pigment is 2-substituted 1-naphthol. The absence of this signal in 2-substituted 1-naphthol was confirmed by comparing the NMR spectrum of 2-chloro-1-naphthol with that of 4-chloro-1-naphthol. On the basis of these findings, it was inferred that the pigment has the structure I.

In the NMR spectrum of the reduced pigment (Fig. 2b), the =CH– signal (6.69 ppm) disappeared and a new signal ($-CH_2-$) was observed at 3.62 ppm. In consideration of the presence of an aromatic C-methyl (2.51 ppm, s) and of the highly probable preservation of the guanidine structure in the pigment, it might be reasonable to conclude that the unknown moiety $C_5H_5N_2$ in I is II.



I



II

An NH chemical shift in imidazole has been reported to be in 11.10—13.50 ppm,[14] whereas the NH signal of the pigment was found in a markedly lower field (16.69 ppm, disappearing on addition of CH_3OD). The exceptional down-field shift and the unusual low frequencies of both N–H (3040—3090 cm^{-1}, independent of concentrations in CCl_4 and the intensity reduced on treatment with CH_3OD) and C=O stretching vibrations in the IR spectrum might be interpreted as the result of intramolecular hydrogen bonding between the NH and carbonyl oxygen atom and might provide an additional evidence supporting the presence of 1,2-quinoid structure. Thus the fol-

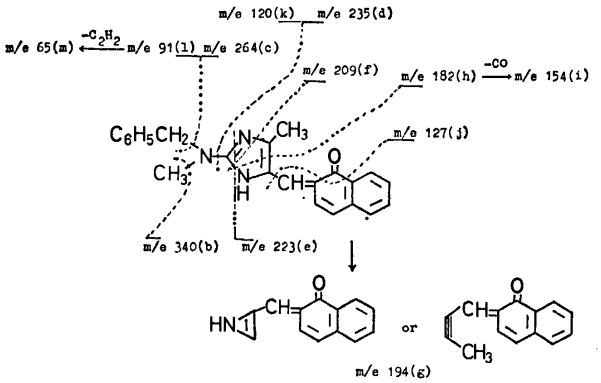
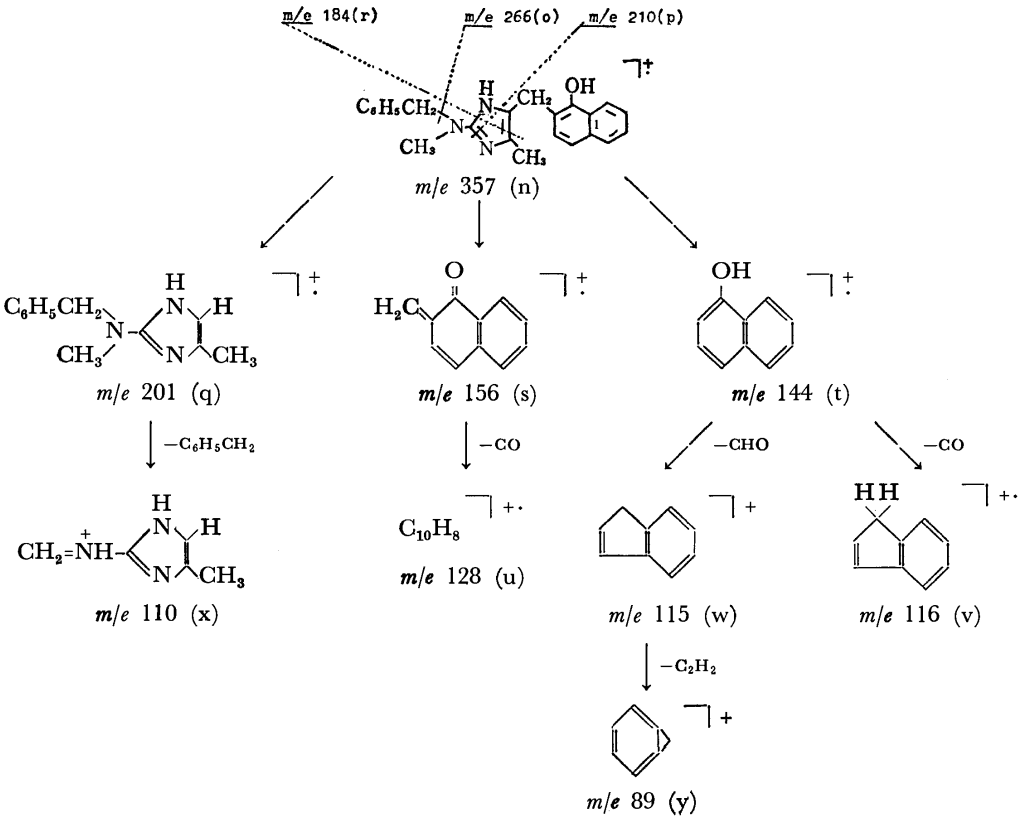
The mass spectrum of the pigment was consistent with the structure III as shown in the following fragmentation scheme:





Treatment of the pigment with CH_3OD resulted in the significant increase in M+1 and *m/e* 183 ion peaks, indicating that deuteration occurred at position 1. Thus the methyl group can be located at position 4 in the imidazole ring from the latter peak.

The mass spectrum of the reduced pigment can be explained by the following fragmentation scheme: The ions q, s, and t may arise from the molecular ion n by the hydrogen rearrangement-dissociation reaction by analogy with the fragmentation of diarylmethanes containing *o*-methyl or *o*-hydroxyl substituent,[15] and the presence of the former two ions substantiates the reduced pigment to be 2-substituted-1-naphthol.

From the foregoing discussions it is concluded that the pigment produced in the diacetyl reaction of 1-benzyl-1-methylguanidine is 2-(*N*-benzyl-*N*-methylamino)-4-methyl-5-(1-oxo-1,2-dihydro-2-naphthylidenemethyl)imidazole (III), and the reduced form should be 2-(*N*-benzyl-*N*-methylamino)-4-methyl-5-(1-hydroxy-2-naphthylmethyl)imidazole (IV). Thus it becomes evident that the pigment produced by Barritt's or Eggleton's method differs from that formed by the original Voges-Proskauer reaction carried out in the absence of 1-naphthol.

Recently, Sakaguchi *et al.*[16] reported that the Voges-Proskauer reaction of diacetyl, 1,1-dimethyl guanidine and 1-naphthol by Eggleton's method gives two spots A (reddish purple, R_f 0.76) and B (red, R_f 0.62) on tlc (silica gel, benzene–AcOEt–EtOH (3 : 1 : 1)), and the major product is pigment B. Our pigment corresponds to Sakaguchi's pigment A in view of the color and the R_f value. Isolation of the pigment corresponding to Sakaguchi's pigment B was not successful, because of its instability.

Experimental

Melting points are uncorrected. NMR spectra were obtained on a Japan Electron Optics JNM-100 or Hitachi 3H-60 spectrometer. Chemical shifts are reported as δ values using tetramethylsilane as an internal standard. Abbreviations used in NMR data are: s, singlet; m, complex multiplet. The mass spectra were determined on a Japan Electron Optics JMS-01S high resolution mass spectrometer (Mattauch-Herzog type) operating with an ionizing energy of 70 eV by the direct inlet procedure. The source temperatures were 220°C for the pigment and 170°C for the reduced one. Exact mass measurement was carried out with perfluorokerosene to provide reference masses. Infrared spectra were obtained with a Hitachi recording spectrophotometer EPI G_2. Visible and ultraviolet spectra were obtained with a Hitachi spectrophotometer 101 or EPS-2.

Materials. Commercially available 1-naphthol and 1,4-naphthoquinone were purified by steam distillation and column chromatography on silica gel with benzene, respectively. 2-Chloro-1-naphthol,[17] 4-chloro-1-naphthol,[18] 1,2-naphthoquinone,[19] and 1-benzyl-1-methylguanidine hydrochloride[10] (mp 134—135°C)[20] were prepared according to the known procedures.

Preparation of Pigment. (a) To a solution of 1-benzyl-1-methylguanidine (1.63 g, 0.01 mol) in chloroform (25 m*l*) were added successively diacetyl (0.86 g, 0.01 mol) in chloroform (3 m*l*) and 1-naphthol (1.44 g, 0.01 mol) in chloroform (10 m*l*). The mixture was stirred at 24°C for 6 hr and then allowed to stand at room temperature for 16 hr. The resulting deep red solution was evaporated at about 40°C and the residue, after being dissolved in a small amount of benzene, was charged onto a column (made from 100 g of about 300 mesh Wako-gel, 60 mm diameter and 68 mm depth) and then eluted with benzene. After the first 850 m*l* fraction containing 1-naphthol and unidentified substances had been removed, the main fraction (about 2,800 m*l*) corresponding to a deep reddish purple band of the chromatogram was collected and evaporated at 37°C to give crude pigment (532 mg), which was found to consist of the desired pigment and three other minor components by means of tlc (silica gel, benzene). A reddish purple amorphous product showing a single spot on tlc was obtained by repeated chromatographic purification. The product dissolved in a small amount of benzene gave 182 mg of dark reddish purple prisms, mp 149—149.5°C, on addition of several drops of *n*-hexane and refrigeration. The pigment was readily soluble in ethyl acetate, carbon disulfide, benzene, and carbon tetrachloride; moderately in methanol, ethanol, and dilute aqueous alkali solution; insoluble in water. Found: C, 77.59; H, 6.54; N, 11.62%. Calcd for $C_{23}H_{21}N_3O$: C, 77.72; H, 5.96; N, 11.82%. UV: λ_{max} 535 mμ (ε=37200) in aqueous NaOH+Na_2CO_3.[10]

(b) To a mixture of 1-benzyl-1-methylguanidine hydrochloride (1.50 g, 7.5 mmol) in water (300 m*l*) and diacetyl (1.31 g, 15 mmol) in water (350 m*l*) was added a solution of 1-naphthol (5.41 g, 37.5 mmol) in 2.5 N NaOH (300 m*l*) under stirring at room temperature. The resulting reddish purple solution was stirred at room temperature for 10 min and then saturated with sodium chloride. After 20 min, the solution was separated by decantation from a dark purple gummy precipitate which did not contain the desired pigment. The solution was extracted several times with benzene, and the combined extracts (3500 m*l*) were dried over anhydrous sodium sulfate for 12 hr and then concentrated at 42—45°C to a small volume. The concentrate was purified in the same manner as above to give the pure pigment (131 mg).

Catalytic Hydrogenation of Pigment. A solution of pigment (50 mg) in benzene (50 m*l*) was hydrogenated in the presence of platinic oxide (20 mg) at ambient pressure and temperature. The red color of the pigment disappeared within 100 min, after which the solution was evaporated under reduced pressure to give a glass. Similar results were obtained in combinations of methanol–Pd/C and methanol–PtO_2.

Intramolecular Hydrogen Bonds. XVIII.[1] Intramolecular Hydrogen Bonding in Ethyl α- and β-Alkylamino-alkanoates[2]

Nobuo Mori, Masanori Aihara, Yoshihiro Asabe, and Yojiro Tsuzuki

Department of Chemistry, Science University of Tokyo, Shinjuku-ku, Tokyo

(Received July 28, 1971)

The intramolecular hydrogen bonding in ethyl ω-alkylamino-acetates and -propionates in dilute carbon tetrachloride solutions has been investigated through the measurement of the NH and CO stretching absorption spectra. In the α-esters, the spectral data give no evidence regarding the hydrogen-bond formation. In the β-esters, though, the hydrogen bonding occurs, probably predominantly between the NH and the CO group.

It is known[3] that the hydrogen-donating nature of an amino group is much lower than that of a hydroxyl group, but higher than that of a mercapto group. Infrared spectroscopic investigations indicate that ethyl α- and β-hydroxyalkanoates[4,5] form an intramolecular hydrogen bond, exclusively between the OH and the CO group: thereby, their absorption bands are largely shifted to the lower-frequency side. In the corresponding mercapto-esters,[1] however, there is no spectral evidence for any hydrogen-bond formation between the SH and the ester group, indicating the very poor hydrogen-donating nature of the mercapto group, which is generally recognized.[6] These results have prompted us to investigate the intramolecular hydrogen bonding in the corresponding alkylaminoalkanoates as well.

Experimental

Samples. Ethyl alkylamino- and dialkylamino-acetates were prepared from the corresponding alkylamino-acetonitriles[7] by the usual method.[8] Ethyl β-alkylamino- and β-dialkylamino-propionates were synthesized by the addition of alkylamines to ethyl acrylate in ethanol.[9] The ethyl ethers of ω-ethylaminoalkanols were obtained by the reaction of ω-ethoxyalkyl bromides with ethylamine. They were then purified by several fractional distillations in an atmosphere of nitrogen immediately before the infrared measurement; their purity was checked by means of IR and/or NMR spectroscopy. Some of the samples are unknown compounds, whose analytical data and physical constants are summarized in Table 1. The solvents used were dried over phosphorus pentoxide and distilled.

Infrared Measurements. This was carried out at 20°C, using a grating spectrophotometer of the Japan Spectroscopic Co.[7] The concentrations used were 0.003 mol/*l* (NH spectra; cell-thickness: 5.0 cm) and 0.001 or 0.01 mol/*l* (CO spectra; cell-thickness: 1.1 or 0.1 cm), unless otherwise noted. The calculated spectral slit width was 1.5 cm^{-1} at the wave numbers of 3300 and 1700 cm^{-1}.

Results and Discussion

The analytical data of the unknown compounds are summarized in Table 1.

Table 1. Analytical data of unknown compounds

Compound	R	Bp °C/mmHg	n_D^{20}	Anal. of N, % Found	Calcd

	t-Bu	76/6	1.4254	8.07	8.09

In order to determine the level of concentration below which the intermolecular association is negligible, the concentration dependence has been examined. Figures 1 and 2 show the spectra of two esters in various concentrations in carbon tetrachloride in the NH stretching region. At higher concentrations, three absorptions appear. On dilution, the lowest-frequency band practically disappears, the middle-frequency band increases in its intensity and frequency, and the highest-frequency band remains almost unchanged. Below a certain concentration, the relative intensity of the last two bands remains constant; from their frequencies and intensities, the

band near 3350 cm^{-1} can be assigned to the monomeric NH species, and the other, near 3450 cm^{-1}, probably to the carbonyl overtone.[10] Furthermore, these esters are practically monomeric in concentrations of 0.01 mol/*l* or less.

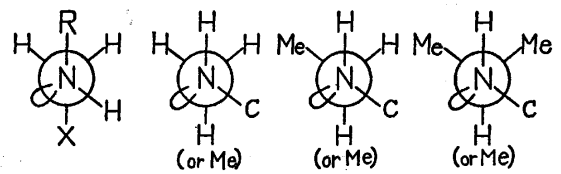
The NH Spectra. As Fig. 3A shows, the bands of ethyl alkylaminoacetates, when the alkyl group is methyl, isopropyl, or *t*-butyl, are very slightly broadened on the higher-frequency side, while the ethyl-

10) L. Joris and P. von R. Schleyer, *ibid.*, **90**, 4599 (1968).

amino-ester shows a highly unsymmetric band. On the other hand, the band of each β-alkylamino-propionate is very much broadened at a frequency higher by *ca.* 20 cm^{-1} than the maximum position (Fig. 3B). The apparent spectral data are summarized in Table 2.

In discussing the data, it may be convenient to examine the molecular model with respect to the rotational isomerism around the N–C bonds. In this examination, the following assumptions were made:[7] (1) the tricovalently-bound nitrogen atom takes a tetrahedron-like structure, (2) the molecule exists in a staggered conformation, but not in an eclipsed one, and (3) the lone electron-pair on the nitrogen atom is practically equal in steric size to the hydrogen atom.

In Fig. 4, the projections, IA and IB, are made along the N–C_α bond of ethyl alkylaminoacetates and along the N–C_β bond of ethyl β-alkylaminopropionates respectively, while the projections, II, III, and IV, are those along the N–C_R bond, where C_R denotes the carbon atom of an alkyl group, R, directly attached to the amino-nitrogen atom; the circle denotes the C_α atom in IA, the C_β atom in IB, or the C_R atom in II, III, and IV.



IA: X=COOEt II III IV
IB: X=CH_2COOEt

Fig. 4. Projections along the N–C_α (IA) or the N–C_β bond (IB) and along the N–C_R bond (II, III and IV).

All the acetates may sterically prefer the same conformation, IA, with respect to the C_α–N bond, in which the bulky groups, R and X, are *trans*. The observed differences in peak frequencies may be explained by the steric effect of R, as has previously been done for similar phenomena observed in alkylmethylamines[7] and *N*-alkylanilines.[11] When R is methyl or *t*-butyl, the amino-hydrogen atom always exists in the environment, II or IV respectively, in any rotational position about the N–C_R bond to be favored. In the case of *t*-butyl, thus, the lowering of the NH frequency by 23 cm^{-1} seems attributable to the presence of the two methyl groups *skew* to the NH group. When R is ethyl, there are two steric environments, II and III, around the NH group; the latter may be sterically preferable because of the methyl and the C-group being *trans*. In view of the steric preference, thus, the major component of the unsymmetric band can be assigned to III, and the minor component at the higher frequency can be assigned to II and may correspond to the band of ethyl methylaminoacetate. Finally, when R is isopropyl, two environments, III and IV, are likewise possible; they are practically indiscriminative in steric preference. Thus, the observed, almost symmetric band probably consists of two bands corresponding to these environments, III and IV. The same explanation can apply to the case of the β-esters, because the same steric environments around the NH group are expected.

In addition to the steric stabilization, the conformations, IA and IB, can probably involve a further stabilization resulting from the possible hydrogen bonding between the NH and the COOEt group, as would be expected from a similar situation in the corresponding α- and β-hydroxyalkanoates, which are exclusively internally bonded.[4,5] In the case of the aminoacetates, however, the NH spectral data give no striking evidence for the hydrogen-bond formation. That is, (1) there is no appreciable band-shift from the ν_{NH} values of alkylmethylamines[7] to the lower-frequency side, (2) the half-band widths are very close to those of alkylmethylamines,[7] and (3) the high band-intensites, as compared with those of the latter amines,[7] may also be caused by the electron-attractive nature of the ethoxycarbonyl group. On the other hand, ethyl β-alkylaminopropionates may be internally bonded, as can be evidenced by their lower NH frequencies and high band intensities. A similar result is found in α- and β-alkylaminoalkanonitriles.[7] These findings, particularly the absence of hydrogen bonding in the α-esters, are not expected from the fact that the ethyl ethers of ω-ethylamino-ethanol and -propanol are internally bonded, with similar 5- and 6-membered rings being formed through the bonding.

Recent infrared investigations indicate that an intramolecular hydrogen bonding occurs in *o*-substituted anilines,[12] pyrrolic esters,[13] 2-methylamino-ethanol,[14] acetylureas,[15] and *N*-ω-phenoxyalkyl-anilines.[16] In these cases, the shifts observed in the NH frequencies are very small as compared with those in the corresponding OH bondings, indicating a considerably weaker hydrogen bond, although the frequency shifts of the hydrogen-acceptor groups are larger than those which would be expected from the NH shifts, indicating a considerably strong bond. For example, in methyl *N*-methylanthranilate,[17] the $\Delta\nu_{NH}$ is 81 cm^{-1} from the free ν_{NH} assumed to be equal to the ν_{NH} of 3442 cm^{-1} of *N*-methylaniline, while the $\Delta\nu_{CO}$ is 45 cm^{-1} from the ν_{CO} of 1730 cm^{-1} of methyl *N,N*-dimethylanthranilate (*cf.*, in methyl salicylate, $\Delta\nu_{OH}$: *ca.* 430 cm^{-1}; $\Delta\nu_{CO}$: *ca.* 40 cm^{-1}).[17,18] In the present case, accordingly, an examination of the carbonyl spectra has been carried out.

The Carbonyl Spectra. Ethyl dialkylamino-

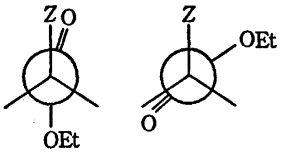
acetates show, in carbon tetrachloride, two overlapped bands with a spacing of about 15 cm^{-1}, and the intensity of the higher-frequency band increases in acetonitrile relative to that of the lower-frequency band (Fig. 5A). By analogy with the cases of α-halogeno-[19] and α-alkoxy-carbonyl compounds,[5,20] this band splitting can be suitably explained by the rotational isomerism around the C_1–C_2 bond. Thus, the two bands can be assigned to the *cis* and the the *gauche* forms respectively:



cis-Form with a higher ν_{CO} *gauche*-Form with a lower ν_{CO}

In carbon tetrachloride, the relative intensity (*cis* to *gauche*) increases with the α-substituents in the order: Et_2N (0.6) < Me_2N (0.9). Thus, the diethylamino group is larger in steric size than the dimethyl amino group if the steric size of the α-substituent is the most important factor in determining the *cis-gauche* equilibrium[20]

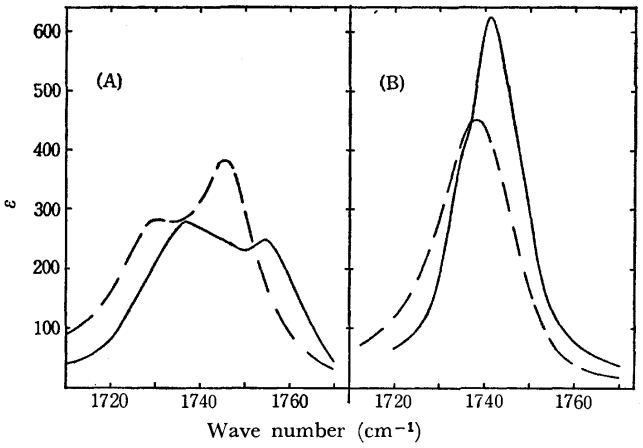


Fig. 5. Carbonyl spectra of ethyl dimethylaminoacetate (A) and of ethyl monomethylaminoacetate (B) in acetonitrile (——) and carbon tetrachloride (——): concentration 0.01 mol/*l*; cell 0.11 cm.

On the other hand, ethyl monoalkylaminoacetates show, in carbon tetrachloride, a strong band at 1742 cm^{-1}, with a very weak shoulder centered near 1736 cm^{-1}. In acetonitrile, a single, somewhat broadened band appears at 1738 cm^{-1}; this band corresponds to the higher-frequency band observed in carbon tetrachloride, since a more polar solvent has the effect of decreasing the ν_{CO}. If no intramolecular hydrogen bonding occurs in carbon tetrachloride, as has been suggested from the NH data, the unsymmetry of the band may again be attributed to the *cis-gauche* isomerism. If this is true, the following two points should be noticed: (1) the band spacing in each

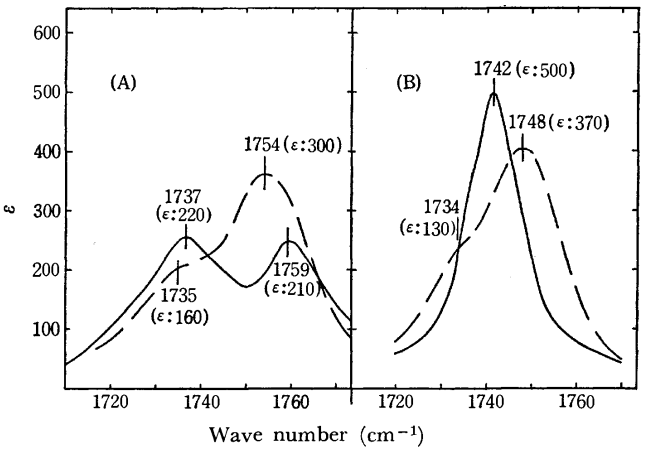

Fig. 6. Carbonyl spectra of ethyl methoxyacetate (A) and of ethyl glycolate (B) in acetonitrile (——) and carbon tetrachloride (——): concentration 0.01 mol/*l*; cell 0.11 cm. The ε values of the band components are given in parentheses.

solvent is smaller than those of the corresponding dialkylaminoacetates, or the peak-frequency in each solvent is lower than those of the *cis* form of the latter esters (the same trend is found in the cases of ethyl glycolate and methoxyacetate), and (2) the intensity ratio (*cis* to *gauche*) of *ca.* 6 is so high as to be not expected, unless an intramolecular hydrogen bonding or attractive interaction occurs to stabilize the *cis* form. The first point can, at least in part, be explained in terms of the lower electron density on the monoalkylamino-nitrogen atom, since the C–N dipole with a lower electron density on the N atom should have the lower field effect of decreasing the double-bond character (or ν_{CO}) of the carbonyl group in the *cis* form.

As for the second point, if the *cis-gauche* equilibrium is determined predominantly by the size of the α-substituent,[20] and if the nonomethylamino group is smaller in size than the dimethylamino group, the former group can be expected to give an intensity ratio higher than the 0.9 of the latter. This expectation agrees with our observation, but the observed ratio of 6 seems too high to be attributed to the decreased steric effect only,[1] since such a high ratio is generally found in internally-bonded carbonyl compounds such as α-hydroxyalkanoates.[5] The high ratio in carbon tetrachloride may be suitably explained by taking account of an attractive interaction which may be operative between the NH and the CO group in the *cis* form in that solvent, but not in acetonitrile, which associates with the NH group to prevent the intramolecular interaction (observed ν_{NH}: 3340 cm^{-1} lower by 8 cm^{-1} than in CCl_4).[21] It is not evident whether the interaction is the usual hydrogen bonding or the electrostatical attraction, but it is probably the latter, because no lowering of the NH frequency is observed. In this connection, it should be mentioned that ethyl glycolate shows, in carbon tetrachloride, an unsymmetric band, because a

19) L. J. Bellamy, "The Infrared Spectra of Complex Molecules," Methuen and Co., London (1958), p. 400.
20) T. L. Brown, *J. Amer. Chem. Soc.*, **80**, 3513 (1958).
21) Aliphatic secondary amines have spectral shifts of at most 10 cm^{-1} in acetone from the free ν_{NH}'s in CCl_4.[22]
22) D. Hagži (Ed.), "Hydrogen Bonding," Pergamon Press, New York (1959), p. 181.

strong hydrogen bond is formed exclusively between the OH and the CO group in the *cis* form (ν_{OH}: 3550 cm^{-1}).[4] In acetonitrile, the bonding to the carbonyl is prevented by the intermolecular association with the solvent (observed ν_{OH}: 3480 cm^{-1}), and two carbonyl bands appear with an intensity ratio of 2.8 (Fig. 6): this ratio is larger than the value of 2 of ethyl methoxyacetate (probably because of the smaller size of the hydroxyl group), but it is only half of the 5.5 of ethyl monomethylaminoacetate, although the hydroxyl group is expected to be smaller in size (hence, to give a higher intensity ratio) than the methylamino group. As one of the reasons for this, there can be considered an electrostatic repulsion between the dipoles in the *cis* form;[23] this repulsion is expected to be less operative between the C–N and the C=O dipole than between the C=O and the C–O dipole, because the C–N, especially the C–N(HCH_3), dipole may have a lower field effect on the C=O dipole, as is suggested by the order in which the band spacing in acetonitrile increases with the α-substituents: $NHCH_3$ (11 cm^{-1}) < $N(CH_3)_2$ (15 cm^{-1}) = OH (14 cm^{-1}) < OCH_3 (19 cm^{-1}). It is, of course, not evident whether this repulsion has such a high effect on the *cis-gauche* equilibrium.

Finally, β-dialkylamino, and also β-monoalkylamino, groups have practically no field effect on the carbonyl group, since ethyl β-diethylaminopropionate shows a single, symmetric CO band at the usual position of 1740 cm^{-1}. Furthermore, the ν_{CO} values, lower by 4 cm^{-1}, of ethyl monoalkylaminopropionates indicate that internal bonding to the carbonyl group occurs.

23) S. Mizushima, T. Shimanouchi, I. Ichishima, T. Miyazawa, I. Nakagawa, and T. Araki, *J. Amer. Chem. Soc.*, **78**, 2038 (1956). The importance of the steric factor in determining the equilibrium was indicated by Brown[20] for highly electronegative groups, such as halogens and alkoxy groups, but the electrostatic factor should be further considered when the electronegativities of the substituents are very different (*cf.*, usually, μ_{C-N}: 0.22; μ_{C-O}: 0.74).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1790—1794 (1972)

Studies on Separation of Amino Acids and Related Compounds. VII. Separation of L-Aspartyl-(α,β)-L-histidine and of L-Glutamyl-(α,γ)-L-histidine[1,2]

Mitsuteru HIRATA,* Kosaku NODA,** and Nobuo IZUMIYA***

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received July 29, 1971)

As control compounds, the structural α- and ω-isomers of L-aspartyl- and L-glutamyl-L-histidine were synthesized by a conventional manner. The experiments on a column chromatography of Dowex 50 were carried out with a model mixture containing α- and ω-isomer, and the complete separation of the isomers was observed at acidic condition. A mixture of α- and ω-isomers of L-aspartyl- or L-glutamyl-L-histidine prepared through the coupling of benzyloxycarbonyl-L-aspartic or glutamic acid anhydride with L-histidine were separated into each isomer with a large column in moderate yields.

An α-aspartyl or α-glutamyl dipeptide is synthesized without any special difficulty by the coupling of benzyloxycarbonyl-ω-benzyl-aspartic or -glutamic acid with an amino acid benzyl ester and subsequent deprotection from a coupling product.[3] Similarly, benzyloxycarbonyl-α-benzyl-aspartic or -glutamic acid is used for synthesis of a β-aspartyl or γ-glutamyl peptide.[3] An intramolecular anhydride[4] (XIV) is derived from benzyloxycarbonyl-L-aspartic acid by the action of acetic anhydride. Coupling reaction of the anhydride (XIV) with an amino acid ester produces a mixture of α- and β-dipeptide derivative, and the latter can be removed from the reaction mixture by extraction with sodium bicarbonate solution.[3] Similarly, benzyloxycarbonyl-L-glutamic acid anhydride[5] (XVI) is used for synthesis of α- and γ-glutamyl peptide.[3] Although the preparation of the anhydride (XIV or XVI) is much easier than that of benzyloxycarbonyl-α or ω-benzyl-aspartic or glutamic acid, the application of the anhydride for synthesis of α- or ω-peptide is restricted by the low yields and the elaborate preparative efforts.

We attempted to develop a convenient procedure separating α- and ω-structural isomers of L-aspartyl or L-glutamyl dipeptide by a column chromatography. We selected L-aspartyl- and L-glutamyl-L-histidine in this study because some of these dipeptides seemed interesting from the stand point of biochemical materials; β-L-aspartyl-L-histidine (VII) is a normal constituent of human urine,[6] and the VII and α-L-glutamyl-L-histidine (VI) possess tetanus toxic activities.[7]

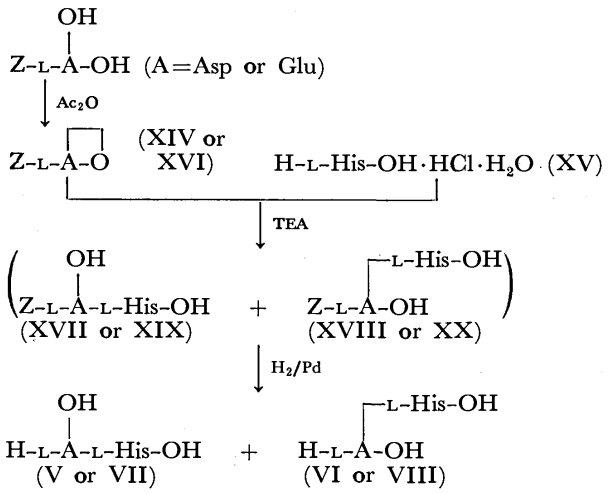
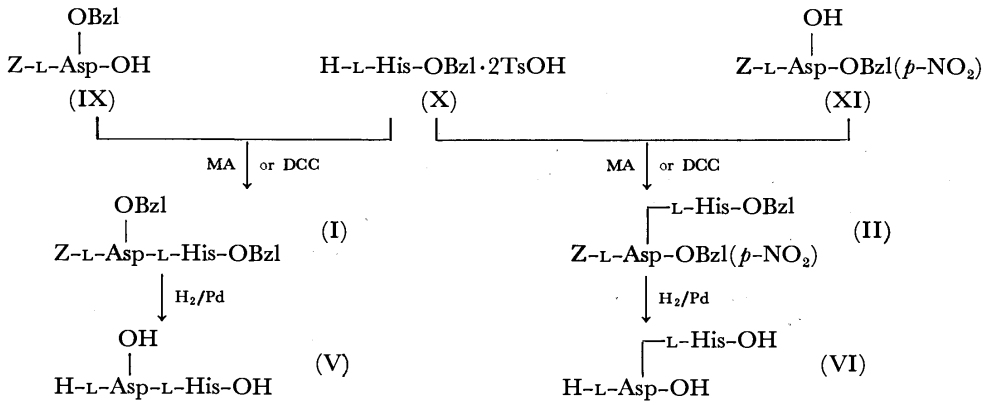


Scheme 1.

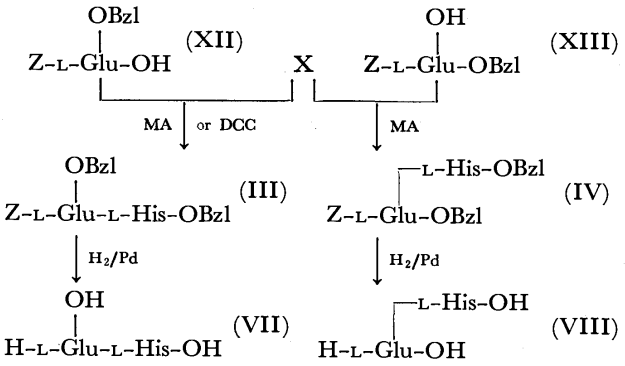
The reaction route in this study is shown in Scheme 1.[8] A coupling reaction of the anhydride (XIV or XVI) and L-histidine will produce a mixture of XVII and XVIII or XIX and XX. A whole reaction mixture is subjected to hydrogenolysis and each isomer in a hydrogenated mixture is attempted to separate by the application of a Dowex 50 column.

It should be noted that Kornguth *et al.* reported the separation of a mixture of ε-(α-L-glutamyl)-L-lysine and ε-(γ-L-glutamyl)-L-lysine by an amino acid analyzer.[9] We reported the experimental results to separate the leucyl dipeptide diastereomers by a Dowex column in the analytical and preparative scale,[10] and to separate glycyl tripeptide diastereomers by an amino acid analyzer.[11]

Each isomer of L-aspartyl- and L-glutamyl-L-histidine were prepared in the conventional manner



Scheme 2.



Scheme 3.

shown in Schems 2 and 3. The acid (XI) was used instead of benzyloxycarbonyl-α-benzyl-L-aspartic acid because the preparation[12] of the latter is considerably troublesome compared with that of XI or XIII. It was indicated that a synthetic isomer gave single spot on a paper chromatogram, but the R_f value was different from that of the corresponding isomer (Table 1).

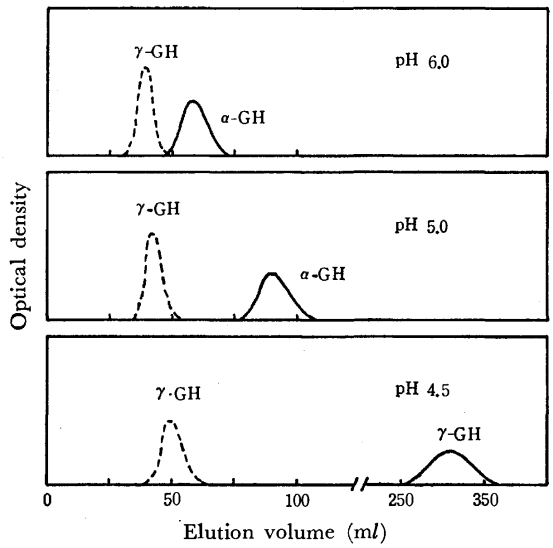

Fig. 2. Effect of pH in buffer system on separation of Glu-His.

Preliminary experiments on a model mixture were performed with a small column (0.9×50 cm) of Dowex 50 using 0.2 N ammonium acetate buffers at different pH, in order to find an optimal condition for the separation. The elution patterns of a model mixture composed of two isomers in the same amount were indicated in Figs. 1 and 2. The α- and γ-isomer of glutamyl-histidine in the mixture were separated each other more efficiently in general than the α- and β-aspartyl-histidine. It was observed that peaks of the free amino acids, aspartic acid and histidine, did not overlap with those of α- and β-aspartyl-histidine when a buffer of pH 4.0 or 5.0 was used. Similarly, peaks of glutamic acid and histidine did not overlap with those of the α- and γ-dipeptide when a buffer of pH 4.5, 5.0 or 6.0 was used.

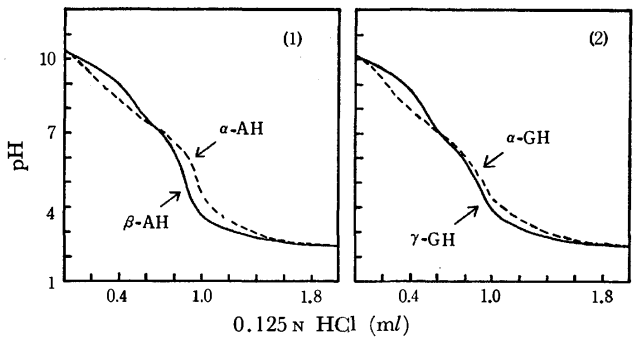

Fig. 3. pH Titration curve of Asp-His (1) and Glu-His (2).

In a previous paper,[10] it was observed that an L-L diastereomer of leucyl-alanine with a solvent of pH 4.5 in a Dowex 50 column was eluted more slowly than the corresponding L-D isomer, whereas the L-L isomer with a solvent of pH 5.5 was eluted rapidly than the L-D. It was also observed that the titration curves for the diastereomers crossed each other around pH 5.0. Then, it was suggested that the positions of peaks were correlated with the pH titration curves. In this study, the titration of α- and ω-isomer or L-aspartyl- or L-glutamyl-L-histidine indicated that the titration curves crossed each other around pH 7 in both cases (Fig. 3). Therefore, separation studies of the model mixture with the small column were performed with solvents of pH 7.0, 8.0 and 9.0; it was found that each of the peptides was eluted very rapidly near to a void volume and not separated each other. Thus, the correlation between the peak positions and the pH titration curves by α- and ω-isomer in this study could not be established.

As the experiments on a preparative scale, two materials which prepared following Scheme 1 were tried to separate into α- and ω-isomer with a large column (1.8×110 cm) of Dowex 50. Each material was composed of four ninhydrin positive components, namely α- and ω-isomer of L-aspartyl or L-glutamyl-L-histidine as majors and aspartic or glutamic acid and histidine as minors. Although a buffer of pH 4.0 or 4.5 might be an efficient solvent for complete separation (see, Figs. 1 and 2), we used a pH 5.0 buffer for an economy of running time. When the material derived from 5 mmol of benzyloxycarbonyl-L-aspartic acid anhydride (XIV) was applied for the column with the pH 5.0 buffer, pure α- and β-L-aspartyl-L-histidine were isolated in 31% and 22% yield respectively. In the similar manner, pure α- and γ-L-glutamyl-L-histidine were isolated in 21% and 28%. Thus, it was indicated that the structural isomers of L-aspartyl- and L-glutamyl-L-histidine can be prepared conveniently by the use of the anhydride and following application of a column chromatography.

Experimental

The R_f(tlc) refers to thin layer chromatography with a solvent of chloroform–methanol (5 : 1, v/v).

α-(Benzyloxycarbonyl-β-benzyl)-L-aspartyl-L-histidine Benzyl Ester (I). *(a) By MA Method*: To a solution of benzyloxycarbonyl-β-benzyl-L-aspartic acid[13] (IX) (3.57 g, 10 mmol) and TEA (1.4 ml, 10 mmol) in THF (20 ml) at −5°C was added isobutyl chloroformate (1.31 ml, 10 mmol). After 15 min, a mixture of L-histidine benzyl ester di-*p*-toluenesulfonate[14] (X) (5.90 g, 10 mmol) and TEA (2.8 ml, 20 mmol) in DMF (20 ml) was added to the solution. The mixture was allowed to stand overnight at room temperature, and then evaporated to dryness *in vacuo*. After the residue was dissolved in ethyl acetate (30 ml), the solution was washed successively with 4% sodium bicarbonate and water, dried over sodium sulfate, and then evaporated. The product was obtained as a semi-solid; yield, 3.1 g (53%); R_f (tlc) 0.59.

(b) By DCC Method: To a solution of IX (0.71 g, 2 mmol) and X (1.18 g, 2 mmol) in DMF (10 ml) were added TEA (0.56 ml, 4 mmol) and DCC (0.41 g, 2 mmol) at 0°C. After the mixture had been stirred overnight at room temperature, it was evaporated and ethyl acetate was added to residue. After dicyclohexylurea was filtered off, the filtrate was washed with 4% sodium bicarbonate and water, dried, and evaporated to give a semi-solid; 0.78 g (67%); R_f(tlc) 0.59.

β-(Benzyloxycarbonyl-α-p-nitrobenzyl)-L-aspartyl-L-histidine Benzyl Ester (II). Benzyloxycarbonyl-α-*p*-nitrobenzyl-L-aspartic acid[15] (XI) (4.02 g, 10 mmol) and X (5.9 g, 10 mmol) were coupled by the MA method as described for the preparation (method a) of I; yield of an oily product, 3.28 g (52%); R_f (tlc) 0.61. The same compound (II) was prepared by the DCC method from XI and X as described for the preparation (method b) of I; yield of an oil, 57%; R_f (tlc) 0.61.

α-(Benzyloxycarbonyl-γ-benzyl)-L-glutamyl-L-histidine Benzyl Ester (III). (a) By MA Method: Benzyloxycarbonyl-γ-benzyl-L-glutamic acid[16] (XII) (3.71 g, 10 mmol) and X (5.9 g, 10 mmol) was coupled as described for the preparation (method a) of I, and the resulting crude product was recrystallized from ethyl acetate–ether–petroleum ether; yield, 2.7 g (45%); mp 92—93°C; $[\alpha]_D^{25}$ −11.0° (*c* 2, ethanol); R_f (tlc) 0.54.

Found: C, 65.70; H, 5.95; N, 9.36%. Calcd for $C_{33}H_{34}O_7N_4$: C, 65.51; H, 5.84; N, 9.55%.

(b) By DCC Method: III was prepared from XII and X; yield, 39%; mp 93—94°C; $[\alpha]_D^{25}$ −11.5° (*c* 2, ethanol); R_f (tlc) 0.54 (Found: C, 65.55; H, 5.91; N, 9.32%).

γ-(Benzyloxycarbonyl-α-benzyl)-L-glutamyl-L-histidine Benzyl Ester (IV). This was obtained from benzyloxycarbonyl-α-benzyl-L-glutamic acid[17] (XIII) (3.71 g, 10 mmol) and X (10 mmol) by the MA method; yield, 2.04 g (34%); mp 130—132°C; $[\alpha]_D^{25}$ −13.2° (*c* 2, ethanol); R_f (tlc) 0.52.

Found: C, 65.82; H, 6.02; N, 9.27%. Calcd for $C_{33}H_{34}O_7N_4$: C, 65.51; H, 5.84; N, 9.55%.

α-L-Aspartyl-L-histidine (α-Asp-His or α-AH) (V). A solution of I (2.92 g, 5 mmol) in 90% acetic acid (25 m*l*) was treated with hydrogen in the presence of palladium black. The filtrate from the catalyst was evaporated to dryness. The residual crystals were recrystallized from water-ethanol; yield, 1.15 g (80%); mp 205—207°C (decomp.); $[\alpha]_D^{25}$ +12.0° (*c* 2, water) (Found as monohydrate: C, 41.45; H, 5.81; N, 19.66%). (lit,[6]; mp 190—194°C; $[\alpha]_D$ +9.7° (water).)

β-L-Aspartyl-L-histidine (β-Asp-His or β-AH) (VI). This was obtained by hydrogenolysis of II (1.89 g, 3 mmol) as described above; yield, 0.354 g (41%); mp 234—238°C (decomp.); $[\alpha]_D^{25}$ +36.8° (*c* 2, water) (Found as monohydrate: C, 41.37; H, 5.66; N, 19.63%). (lit.[18]; mp 235—240°C; $[\alpha]_D$ +38° (water).)

α-L-Glutamyl-L-histidine (α-Glu-His or α-GH) (VII). This was obtained from III (1.8 g, 3 mmol); yield, 0.707 g (78%); mp 199—204°C (decomp.); $[\alpha]_D^{25}$ +18.5° (*c* 2, water) (Found as monohydrate: C, 43.84; H, 6.08; N, 18.26%). (lit,[19]; mp 177—178°C.)

γ-L-Glutamyl-L-histidine (γ-Glu-His or γ-GH) (VIII). This was obtained from IV (1.8 g, 3 mmol); yield, 0.435 g (48%); mp 203—205°C (decomp.); $[\alpha]_D^{25}$ +12.3° (*c* 2, water).

Found: C, 44.01; H, 6.13; N, 18.37%. Calcd for $C_{11}H_{16}O_5N_4 \cdot H_2O$: C, 43.70; H, 6.00; N, 18.54%.

Paper Chromatography of the Dipeptides. The experiments were carried out with ascending technique with Toyo Roshi No. 52 paper, and a peptide on the paper was developed with ninhydrin. It was observed that each (V, VI, VII or VIII) of synthetic dipeptides showed single spot with three different solvents. As recognized from Table 1, the isomers of Asp-His or Glu-His were clearly separated on a chromatogram.

Table 1. R_f values of dipeptides on paper chromatography

Dipeptide	R_f		
	BAPW[a]	BPA[b]	PW[c]
α-Asp-His	0.13	0.17	0.16
β-Asp-His	0.09	0.12	0.11
α-Glu-His	0.19	0.19	0.18
γ-Glu-His	0.12	0.13	0.14

a) *n*-butanol - acetic acid - pyridine - water; 4 : 1 : 1 : 2, v/v.
b) *n*-butanol - acetic acid - water; 3 : 1 : 1, v/v.
c) pyridine - water; 4 : 1, v/v.

Column Chromatography of Model Mixture Composed of Isomeric Dipeptides. A model mixture of Asp-His was made by dissolving each 0.05 mmol of V and VI in water (0.5 m*l*). Similarly, a model mixture of Glu-His (VII and VIII) was prepared. A column (0.9×50 cm) with Dowex 50×8 (200—400 mesh), NH_4^+ form, was equilibrated by washing with 0.2 N ammonium acetate buffer of a definite pH (4.0, 4.5, 5.0 or 6.0), and a model mixture was applied to a column. The column was eluted with the same buffer at room temperature, and two m*l* fractions were collected at a flow rate of about 20 m*l*/hr. Approximately 0.01 m*l* from each tube was spotted on a strip of filter paper. The strip was dried at 100°C for 5 min, immersed in a 0.2% ninhydrin-acetone solution, and again heated. The degrees of coloration developed were determined by a densitometer as described previously.[20] The resulting patterns are shown in Figs. 1 and 2. The nature of a peptide in each peak in Figs. 1 and 2 was identified by means of paper chromatography after the corresponding fractions were concentrated by evaporation.

pH Titration Curve of the Dipeptides. Each isomer (0.05 mmol) of Asp-His and Glu-His was dissolved in 0.1 N sodium hydroxide (1 m*l*), and an automatic titration was carried out with 0.125 N hydrochloric acid with Radiomer pH-stat, model TTT-1, at room temperature. The resulting patterns are shown in Fig. 3.

Preparative Separation of α-Asp-His and β-Asp-His from a Mixture. A solution of benzyloxycarbonyl-L-aspartic acid anhydride[4] (XIV) (1.25 g, 5 mmol) in THF (5 m*l*) was added to a solution of L-histidine monohydrochloride monohydrate (XV) (1.05 g, 5 mmol) and TEA (2.8 m*l*, 20 mmol) in water (10 m*l*) under vigorous stirring at room temperature. After 15 min, the reaction mixture was evaporated to dryness and the residue was dissolved in 90% acetic acid (30 m*l*). The solution was treated with hydrogen in the presence of palladium black. Paper chromatography on the hydrogenated solution showed the presence of α-Asp-His, β-Asp-His, aspartic acid and histidine. The filtrate from the catalyst was evaporated to dryness, and the residue was dissolved in 0.2 N ammonium acetate buffer (1 m*l*) of pH 5.0. The solution was put on a column (1.8×110 cm) of Dowex 50×8 treated previously with the same buffer. The column was eluted with the same buffer (650 m*l*) at a flow rate of 60 m*l*/hr, and each 10 m*l* was fractionated (No. 1—No. 65). Then, the eluting solvent was changed to 2 N ammonium hydroxide. The material in each fraction was identified by means of paper chromatography; it was found

that the fractions 13—15 contained aspartic acid, the 28—40 β-Asp-His, the 48—61 α-Asp-His and the 70—73 histidine. The fractions from tube number 48 to 61 were evaporated *in vacuo* to dryness. To remove the ammonium acetate contaminated, the residue dissolved in water was treated with a column of Dowex 50×8, H^+ form, and the column was washed with water and eluted with aqueous ammonium hydroxide. The eluate was evaporated, and the residual crystals were recrystallized from water–ethanol; yield of α-Asp-His monohydrate, 440 mg (31% from XIV); mp 205—208°C (decomp.); $[\alpha]_D^{25}$ +12.5° (*c* 2, water) (Found: C, 41.37; H, 5.64; N, 19.70%). A mixture of this product and an authentic sample obtained from I showed a single spot in paper chromatography with different solvent systems.

The fractions from 28 to 40 were treated in the same manner described above to give pure β-Asp-His monohydrate, 308 mg (22% from XIV); mp 234—237°C (decomp.); $[\alpha]_D^{25}$ +37.2° (*c* 2, water) (Found: C, 41.42; H, 5.51; N, 19.66%).

Preparative Separation of α-Glu-His and γ-Glu-His from a Mixture. Benzyloxycarbonyl-L-glutamic acid anhydride[5] (XVI) (1.32 g, 5 mmol) was coupled with XV (5 mmol), and the reaction mixture was treated exactly in the same manner as described above. As only one exception, the eluting solvent was changed from 0.2 N ammonium acetate buffer (pH 5.0) to 2 N ammonium hydroxide at the fraction number 85. It was found that the fractions 10—12 contained glutamic acid, the 16—24 γ-Glu-His, the 59—81 α-Glu-His and the 90—94 histidine. The fractions from 59 to 81 were treated in the same manner as described above to give pure α-Glu-His monohydrate, 314 mg (21% from XVI); mp 202—205°C (decomp.); $[\alpha]_D^{25}$ +18.2° (*c* 2, water) (Found: C, 43.60; H, 6.19; N, 18.75%).

The fractions from 16 to 24 yielded 409 mg (28%) of pure γ-Glu-His monohydrate; mp 205—207°C (decomp.); $[\alpha]_D^{25}$ +11.6° (*c* 2, water) (Found: C, 43.52; H, 6.12; N, 18.66%).

The authors wish to thank Mr. Toshiyasu Matsuo, Morishita Pharmaceutical Co., for his valuable technical assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1794—1797 (1972)

Chemical Constituents of *Alnus sieboldiana* (BETULACEAE). III. The Synthesis and Stereochemistry of Yashabushiketols

Yoshinori ASAKAWA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received August 30, 1971)

Dihydroyashabushiketol (**2**), isolated previously from the male flower of *Alnus sieboldiana*, has been synthesized by the condensation of benzaldehyde with acetylacetone, followed by hydrogenation. The absolute configuration at C_5 of yashabushiketol (**1**) and **2** has been identified as S. The geometry between the *trans* double bond and the carbonyl group in **1** was established to be *s-cis*. Eleven more minor components of a known aromatic compound were identified at the same time.

Preceding studies[1,2] of the male flower constituents of *Alnus sieboldiana* belonging to the Betulaceae family have shown the presence of two new ketols, yashabushiketol (**1**) and dihydroyashabushiketol (**2**), with the biosynthetically interesting C_6-C_7-C_6 skeleton and four new flavonoids, together with various phenylpropanoids. The present paper will describe the synthesis of **2**, the stereochemistry of **1** and **2**, and the isolation of other phenylpropanoids from the male flower of *A. sieboldiana*.

Results and Discussion

Synthesis of Dihydroyashabushiketol (2). In connection with the study of the biosynthesis of two new ketols, **1** and **2**, we have examined the synthesis of **2**. The reaction of benzaldehyde with a complex of acetylacetone and boron trioxide in the presence of triisopropyl borate and *n*-butylamine gave dicinnamoylmethane (**3**) in a good yield. The catalytic hydrogenation of **3** over platinum oxide afforded dihydroyashabushiketol (**2**) (the *dl* form of **2**), along with saturated diketone (**4**). The sodium borohydride reduction of the diketone (**4**) easily afforded diol (**5**), which has also been prepared from **2** by the same procedure. The oxidation of **2** with active manganese dioxide gave the diketone (**4**).

Stereochemistry of Yashabushiketol (1) and Dihydroyashabushiketol (2). The absolute configuration at C_5 of **1** and **2** was determined by applying the benzoate rule[3] and Horeau's asymmetric synthesis.[4] The benzoylation of **1** with benzoyl chloride and with 3,5-dinitrobenzoylchloride yielded the corresponding benzoates. The benzoate rule predicts that its benzoates would be more dextrorotatory if the configuration at C_5 had S. Actually, the difference in the molecular rotation ($[M]_{Benzoate}$—$[M]_{Alc.}$) between the benzoates and the ketol (**1**) was positive. It follows that the configuration at C_5 is S. This was corroborated by the asymmetric esterification employing α-phenylbutyric anhydride. The reaction of **1** with an excess of (±)-α-phenylbutyric anhydride resulted in recovery of (−)-α-phenylbutyric acid.

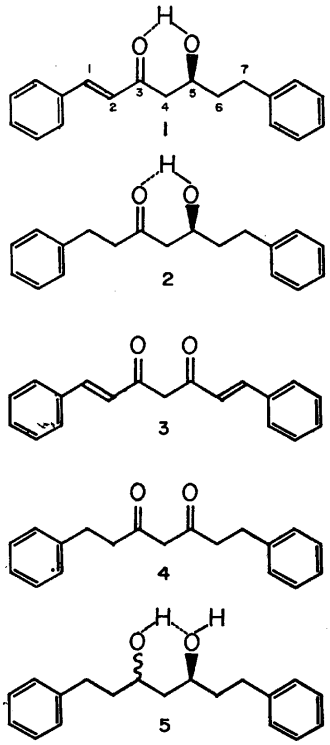

Fig. 1.

Hence, the configuration at C_5 may be deduced to be S. The configuration at C_5 of **2** was also established to be S by the method described above.

Yashabushiketol (**1**) may exist in two geometries, s-*cis* and s-*trans*, with respect to the C_2-C_3 single bond. An inspection of the molecular model predicted that the former form, with a planar zig-zag arrangement of the carbon chain, will be energetically favored over the latter. The infrared spectrum of **1** in nujol mull showed two intense carbonyl bands ($\nu_{C=O}$ 1703 cm^{-1} and $\nu_{C=O}$ 1678 cm^{-1}) and a more intense band of the *trans* ethylenic bond[5] ($\nu_{C=C}$ 1607 cm^{-1}). The arithmetical differences[6] in frequency between $\nu_{C=O}$ and $\nu_{C=C}$ are 96 cm^{-1} and 71 cm^{-1}. These data indicate that **1** is in the *s-cis* form. The infrared spectrum in the hydroxyl strechng region of **1** in carbon tetrachloride showed a concentration-independent band at 3520 cm^{-1} (ε, 32). This surely indicates the existence of an intramolecular hydrogen bonding between the hydroxyl group and the lone-pair electron on the carbonyl oxygen, thus supporting the special arrangement shown in Formula 1.

Previously-known Aromatic Compounds. The isolation of eleven minor components, benzaldehyde, γ-phenylpropyl acetate, cinnamyl acetate, coumarin, cinnamyl cinnamate, β-phenylethyl-β-phenylpropionate, methyl cinnamate, benzoic acid,[7] phenylacetic acid, β-phenylpropionic acid, and eugenol, was performed by a combination of column and preparative thin-layer chromatographies. All the compounds isolated were identified by direct comparisons (mixed mp, UV, IR, NMR and mass spectra) with authentic specimens. It is characteristic that almost all the compounds isolated from the male flower of *A. sieboldiana* carry one or two of the monosubstituted benzene-rings which would arise from shikimic acid. From the viewpoint of biosynthesis it is also interesting that the male flower of *A. sieboldiana* contains only benzaldehyde, whereas that of *A. pendula* contains only cinnamaldehyde.[8]

Experimental

All the melting points are uncorrected. The UV, IR, NMR, and mass spectra and the gas chromatograms were measured in the same manner as reported in the preceding paper.[1c] The optical rotations were measured on a Japan Spectroscopic Co., Ltd., automatically-recording spectropolarimeter, Model ORD/UV-5.

*Dicinnamoylmethane (**3**).* The preparation of dicinnamoylmethane was performed on one-tenth the scale of the Pabon's procedure[9]; 42% yield; mp 141—142°C (lit,[9] 140.5°C); λ_{max}^{EtOH} 235 nm (log ε, 3.41), 310 (3.48), 395 (4.04), 418 (3.87); ν_{max}^{Nujol} 1626 (CO-CH=COH), 1148, 1143, 980 (*trans* CH=CH), 878, 795, 723, 690 cm^{-1}; δ_{ppm} ($CDCl_3$) 5.82 (s, 1H), 6.11 (d, J=16 Hz, 2H), 7.42 (m, 10H), 7.67 (d, J=16 Hz, 2H); *m/e* 276 (M^+), 258 ($M-H_2O$), 248 (M–CO), 199, 171, 157, 145, 144, 131 (base), 117, 115, 103, 91, 77, 69, 51.

Found: C, 82.37; H, 5.81%. Calcd for $C_{19}H_{16}O_2$: C, 82.58; H, 5.84%.

*Hydrogenation of Dicinnamoylmethane (**3**).* Dicinnamoylmethane (**3**) (307 mg) was hydrogenated over a prereduced PtO_2 (68 mg) in methanol for 9 hr under ambient conditions. After the catalyst had been filtered off, the filtrate was evaporated *in vacuo*. The product showed two spots on tlc; it was subjected to preparative thin-layer chromatography, using a 4 : 1 mixture of *n*-hexane and ethyl acetate to give diketone (**4**) (197 mg) as yellow oil and dihydroyashabushiketol (**2**) (90 mg) mp 69—70.5°C (from *n*-hexane); $[\alpha]_D^{25}$ ±0° (*c* 1.6, in $CHCl_3$). The diketone (**4**) showed the following properties: λ_{max}^{EtOH} 272 (4.35), $\lambda_{max}^{n\text{-Hexane}}$ 279 (3.96), $\lambda_{max}^{n\text{-Hexane+NaOH}}$ 297 (4.25); $\nu_{max}^{Liq.}$ 3450, 3026, 1726, 1706, 1626, 1606, 1498, 1455, 751, 704; δ_{ppm} ($CDCl_3$) 2.32—3.08 (m), 3.45 (s, CO–CH$_2$–CO), 5.41 (s, CO–CH=C–), 7.22 (s, 10H); *m/e* 280 (M^+), 262 ($M-H_2O$), 175, 133, 105, 104, 91 (base), 77, 65, 51, 43, 39.

Found: C, 81.58; H, 7.10%. Calcd for $C_{19}H_{20}O_2$: C, 81.39; H, 7.19%.

*Reduction of Diketone **4** to Diol **5**.* Into a solution of **4** (140 mg) in dioxane–water (50 m*l*, 4 : 1 by volume) we stirred sodium borohydride (500 mg) dissolved in dioxane (25 m*l*), and then the mixture was allowed to stand overnight. The mixture was acidified with 1 N hydrochloric acid, and then the solvent was removed *in vacuo*. The residue, after water (10 m*l*) had been added, was extracted with chloroform. The removal of the solvent from the dried extract gave **5** as a colorless oil (130 mg): $[\alpha]_D^{25}$ ±0° (*c* 2.0, in $CHCl_3$); λ_{max}^{EtOH} 247 (2.47), 253 (2.59), 255 (2.59), 259 (2.66), 262 (2.68), 265 (2.56), 269 (2.60); $\nu_{max}^{Liq.}$ 3356, 1601, 1496, 1416, 1336, 1130, 746, 699; δ_{ppm} ($CDCl_3$) 1.30 (m,

6H), 2.70 (m, 4H), 3.90 (s, 2 OH), 3.85 (quin. 2H, J=6 Hz), 7.23 (s, 10H); *m/e* 284 (M^+), 266 ($M-H_2O$), 248, 149, 91 (base), 77.

Found: C, 80.56; H, 8.59%. Calcd for $C_{19}H_{24}O_2$: C, 80.24; H, 8.51%.

*Reduction of Dihydroyashabushiketol (**2**) to Diol (**5**).* The reduction of **2** (62 mg) with sodium borohydride (250 mg) in the manner described in the preceding paragraph gave a yellow oil (48 mg): $[\alpha]_D^{25}$ +0.66 (*c* 2.6, in $CHCl_3$); $\nu_{max}^{CCl_4(0.0060\ mol)}$ 3665 (ε, 78), 3538 (ε, 20). This oil was identical in all respects to the **5** derived from the diketone (**4**).

*Oxidation of Dihydroyashabushiketol (**2**) to Diketone (**4**).* A solution of **2** (50 mg) in dry chloroform (20 m*l*) was stirred with activated manganese dioxide (0.920 g) at room temperature over a 5-day period. The mixture was filtered, and the precipitate was washed thoroughly with chloroform. The combined filtrate was evaporated *in vacuo* to give a yellow oil (15 mg) which was identical in all respects to **4**.

*The Benzoate of Yashabushiketol (**1**).* Into a solution of **1** (42 mg) in a mixture of dry benzene (1.5 m*l*) and dry pyridine (0.15 m*l*), we stirred benzoyl chloride (0.3 m*l*) at 0°C. The mixture, after having been allowed to stand overnight, was worked up as usual to give the benzoate (30 mg): mp 94—95°C (from *n*-hexane); $[M]_{Benzoate}$ +61.69; $[M]_{Benzoate}-[M]_{Alc.}=+6.42$; λ_{max}^{EtOH} 280 (3.49); ν_{max}^{Nujol} 1715, 1280, 740, 695; M^+ 384 ($C_{26}H_{24}O_3$).

*The 3,5-Dinitrobenzoate of Yashabushiketol (**1**).* The benzoylation was performed using 50 mg of **1**, 92 mg of 3,5-dinitrobenzoyl chloride, 25 m*l* of benzene, and 1.0 m*l* of pyridine in the same manner as above. The crude product was purified on TLC to give the benzoate as a pale yellow oil (77 mg): $[M]_{Benzoate}$+92.20; $[M]_{Benzoate}-[M]_{Alc.}=+36.93$; λ_{max}^{EtOH} 300 (3.98); $\nu_{max}^{Liq.}$ 1725, 1280, 755, 720, 708, M^+ 474 ($C_{26}H_{22}O_7N_2$).

*The Benzoate of Dihydroyashabushiketol (Natural Product) (**2**).* The method described above was employed using 80 mg of **2** and 50 mg of benzoylchloride; it gave the benzoate (105 mg): $[M]_{Benzoate}$+45.93; $[M]_{Benzoate}-[M]_{Alc.}=+38.16$; λ_{max}^{EtOH} 282 (2.08); $\nu_{max}^{Liq.}$ 1725, 1280, 1114, 755, 720, 708; M^+ 386 ($C_{26}H_{26}O_3$).

*The 3,5-Dinitrobenzoate of Dihydroyashabushiketol (**2**).* The benzoylation of **2** (50 mg) with 3,5-dinitrobenzoyl-chloride (92 mg) in dry pyridine gave the benzoate as a yellow oil (72 mg): $[M]_{Benzoate}$+73.56; $[M]_{Benzoate}-[M]_{Alc.}=+65.78$; λ_{max}^{EtOH} 295 (3.38); $\nu_{max}^{Liq.}$ 1730, 1450, 1354, 1285, 1170; M^+ 476 ($C_{26}H_{24}O_7N_2$).

The benzoates and 3,5-dinitrobenzoates of **1** and **2** described above are very unstable compounds. After having been allowed to stand at room temperature for 2 or 3 days, all the benzoates decomposed and showed two spots on tlc. All attempted elemental analyses of these benzoates failed to obtain satisfactory values.

*Reaction of Yashabushiketol (**1**) with α-Phenylbutyric anhydride.* A solution of **1** (2.14×10^{-4} mol) and α-phenylbutyric anhydride (5.83×10^{-4} mol), prepared by refluxing α-phenylbutyric acid with acetic anhydride, in pyridine (2.5 m*l*) was allowed to stand overnight. The excess anhydride was decomposed by adding water, and then the solution was allowed to stand 7 hr at room temperature. The solution was extracted with ether. The ether extract was washed successively with water, 5% sodium bicarbonate (10 m*l*×3), and water (three times). The combined aqueous extract was washed with chloroform and acidified with 1 N sulfuric acid. The acidified solution was extracted with chloroform, after which the chloroform extract was dried and evaporated. α-Phenylbutyric acid (96 mg) was recovered: $[\alpha]_D^{25}$ −3.12° (*c* 1.92, in benzene), theoretical[4] $[\alpha]_D=96.5°/2(2.71)-1=-21.5°$. The optical yield was, therefore, 3.12/21.5=14.5% (−).

The neutral fraction in the ether solution was washed thoroughly with water, 1 N sulfuric acid, and water successively. The removal of the solvent from the ether solution gave the ester (54 mg), which was then purified by tlc to give the pure ester (44 mg): λ_{max}^{EtOH} 300 (3.95); $\nu_{max}^{Liq.}$ 1725, 1168, 750, 701; M^+ 426.

Found: C, 81.20; H, 6.90%. Calcd for $C_{29}H_{30}O_3$: C, 81.66; H, 7.09%.

*Reaction of Dihydroyashabushiketol (**2**) with α-Phenylbutyric anhydride.* The method described above was employed, using **2** (3.3×10^{-4} mol) and α-phenylbutyric anhydride (1.01×10^{-3} mol). The recovered α-phenylbutyric acid weighed 209 mg: $[\alpha]_D^{25}$ −0.34° (*c* 2.90, in benzene); the optical yield was 1.5% (−). On the other hand, the ether extract was worked up as above to obtain the ester (64 mg): λ_{max}^{EtOH} 293 (2.47); $\nu_{max}^{Liq.}$ 1727, 1496, 1170, 746, 709; M^+ 428.

Found: C, 82.78; H, 7.46%. Calcd for $C_{29}H_{32}O_3$: C, 82.27; H, 7.53%.

Extraction and Isolation. The benzene extract (750 g) of the male flower of *A. sieboldiana* was extracted first with a saturated sodium bisulfite solution to isolate the aldehyde fraction (1.24 g), and then it was separated into a neutral fraction (50 g), an acidic fraction (8.0 g), and a phenolic fraction (8.4 g), as has been shown previously.[2b]

Benzaldehyde: The decomposition of the sodium bisulfite solution with 20% sodium hydroxide, followed by extraction with ether, yielded a pale yellow oil (1.24 g); this oil showed one peak on the gas chromatogram and one spot on tlc. The spectral data were completely identical with those of authentic benzaldehyde. The 2,4-dinitrophenylhydrazone derivative melted at 240—241°C.

γ-Phenylpropyl Acetate, β-Phenylethyl β-Phenylpropionate, Coumarin, Cinnamyl Acetate, Cinnamyl Cinnamate, and Methyl Cinnamate: After the isolation of the major components, β-phenylethyl cinnamate, pinostrobin, pinosylvin dimethyl ether and ketols, **1** and **2**, from the neutral fraction, the brown oil (845 mg) remaining unidentified was further chromatographed carefully on silica gel using a mixture of *n*-hexane and ethyl acetate. From the 19 : 1 (by volume) *n*-hexane - ethyl acetate fraction, a colorless oil (80 mg) was obtained. This oil was then subjected to preparative thin-layer chromatography to give γ-phenylpropyl acetate (18 mg) and β-phenylethyl β-phenylpropionate (24 mg). γ-Phenylpropyl acetate: λ_{max}^{EtOH} 260 (3.34); $\nu_{max}^{Liq.}$ 1735, 1240; δ_{ppm} ($CDCl_3$) 2.03 (s, 3H), 1.92 (q, J=8 Hz, 2H), 2.70 (t, J=8 Hz, 2H), 4.08 (t, J=8 Hz, 2H), 7.24 (s, 5H). β-Phenylethyl β-phenylpropionate: $\nu_{max}^{Liq.}$ 1735; δ_{ppm} ($CDCl_3$) 2.49 and 2.85 (t, J=7.5 and 1.5 Hz, A_2B_2, 4H, C_6H_5-C<u>H</u>$_2$-C<u>H</u>$_2$-CO), 2.81 (t, J=7.5 Hz, 2H, C_6H_5–C<u>H</u>$_2$–CH_2–O–), 4.18 (t, J=7.5 Hz, 2H, –CH_2–C<u>H</u>$_2$–O–), 7.11 (s, 10H); *m/e* 254 (M^+), 133, 105, 91 (base).

A pale yellow oil (500 mg) obtained from the 4 : 1 *n*-hexane - ethyl acetate fraction was further subjected to column chromatography on silica gel using a mixture of *n*-hexane, benzene, and ethyl acetate to give coumarin (10 mg), cinnamyl acetate (22 mg), cinnamyl cinnamate (100 mg), and methyl cinnamate (47 mg). Coumarin: mp 70—71°C; δ_{ppm} ($CDCl_3$) 6.42 (d, J=9 Hz, 1H), 7.00 (d, J=9 Hz, 1H), 7.41 (m, 4H). Cinnamyl acetate: λ_{max}^{EtOH} 250 (3.68); $\nu_{max}^{Liq.}$ 1735, 1240; δ_{ppm} ($CDCl_3$) 2.06 (s, 3H), 4.70 (d, J=6 Hz, 2H), 6.17 (d, J_{AB}=16 Hz, t, J_{BX}=6 Hz, 1H), 6.69 (d, J_{AB}=16 Hz, 1H), 7.33 (s, 5H). Cinnamyl cinnamate: mp 40—41°C; λ_{max}^{EtOH} 255 (4.09), 275 (4.13);

$\nu_{max}^{Liq.}$ 1710, 1635, 1450, 1165, 965; δ_{ppm} ($CDCl_3$) 4.84 (d, J_{BX}=6 Hz, 2H), 6.30 (d, J_{AB}=16 Hz, t, J_{BX}=6 Hz, 1H), 6.45 (d, J=16 Hz, 1H), 6.63 (d, J=16 Hz, 1H), 7.43 (m, 10H), 7.74 (d, J=16 Hz, 1H). The hydrolysis of the ester with an alcoholic potassium hydroxide solution gave cinnamic acid and cinnamyl alcohol. Methyl cinnamate: $\nu_{max}^{Liq.}$ 1712, 976; δ_{ppm} ($CDCl_3$) 3.82 (s, 3H), 6.45 (d, J=16 Hz, 1H), 7.49 (m, 5H), 7.78 (d, J=16 Hz, 1H).

Benzoic Acid, Phenylacetic Acid, and β-Phenylpropionic Acid. These acids were identified as their methyl esters. After the isolation of alnustinol (3,5,7-trihydroxy-6-methoxyflavanone) from the acidic fraction by crystallization, the combined filtrate was methylated with diazomethane. The main component of methyl cinnamate was removed by crystallization, and the residual oil (320 mg) was chromatographed on silica gel using a mixture of *n*-hexane, benzene, and ethyl acetate to give methyl benzoate (25 mg), methyl phenylacetate (8 mg), and methyl β-phenylpropionate (80 mg). Methyl benzoate: $\nu_{max}^{Liq.}$ 1740, 1257, 1161; δ_{ppm} ($CDCl_3$) 3.90 (s, 3H), 7.50 (m, 3H), 8.15 (m, 2H). Methyl phenylacetate: $\nu_{max}^{Liq.}$ 1725, 1274, 1109; δ_{ppm} ($CDCl_3$) 3.63 (s, 2H), 3.70 (s, 3H), 7.37 (s, 5H); *m/e* 150 (M^+), 91 (base). Methyl β-phenylpropionate: $\nu_{max}^{Liq.}$ 1740, 1169, 748; δ_{ppm} ($CDCl_3$) 3.77 (s, 3H), 2.82 (m, 4H), 7.28 (s, 5H); *m/e* 164 (M^+), 133, 105, 104 (base), 91.

Eugenol: After the isolation of flavonoids from the phenolic fraction by crystallization, the filtrate (60 mg) was converted into the trimethylsilyl derivative, which was then subjected to gas chromatography and tlc to identify eugenol.

The author wishes to express his hearty gratitude to Professor Kenji Fukui and Dr. Takayuki Suga of Hiroshima University for their guidance and encouragement.

Imidothiocarbonates. V.[1] Preparations and Properties of Novel Azomethine Ylides and Thiocarbonyl Ylides from Sulfur-contained Heterocycles

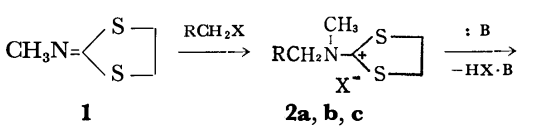
Yoshio Ueno and Makoto Okawara

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro, Tokyo

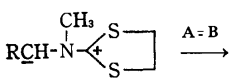
(Received September 28, 1971)

Preparations and properties of some novel azomethine ylides and thiocarbonyl ylides containing 1,3-dithiolanium moiety have been studied. Azomethine ylides, **3a**, **b**, and **c**, were prepared by deprotonation of 2-(*N*-methyl-*N*-phenacyl)amino-(**2a**)), 2-(*N*-*p*-nitrobenzyl-*N*-methyl)amino-(**2b**), and 2-(*N*-carbethoxymethyl-*N*-methyl)-amino-1,3-dithiolanium salt (**2c**), respectively. Azomethine ylides **3a**, **b** reacted with benzaldehydes to give 1,3-dipolar cycloadducts which are new class of spiro orthocarbonates, otherwise it is difficult to obtain. Elimination of ethylene sulfide from the spiro orthocarbonates easily occurred to give thiocarbonyl compounds. In the absence of dipolarophiles, **3a** cyclized intramolecularly to give 1,3-oxazoline-2-thione derivative. Formation of the thiocarbonyl ylides by deproptonation of 2-phenacylthio-1,3-oxazolium and 2-*p*-bromophenacylthio-1,3-dithiolanium salts, and their different cyclization to spiro compounds were also studied. Reaction of thiocarbonyl ylides **16** with *p*-nitrobenzaldehyde afforded *p*-nitrochalcone. Mechanisms of these interesting reactions and their synthetic utility were discussed.

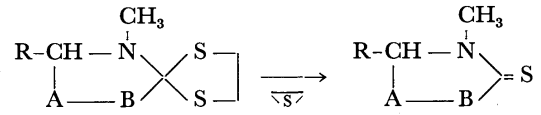
In continuation of our studies on iminodithiocarbonates, we have explored the formation of 2-(*N*,*N*-dialkylamino)-1,3-dithiolanium salts (**2**) from 2-methylimino-1,3-dithiolane (**1**) in high yield.[1] We consider here the possibility of the preparation of new azomethine ylides[2] (**3**) by deprotonation of the iminium salts **2**. It is expected that such an azomethine ylide may react with appropriate dipolarophiles (A=B) to yield spiro orthocarbonates. Moreover, such spiro orthocarbonates are expected to give heterocyclic thiocarbonyl compounds with a release of ethylene sulfide, because we have shown that spiro orthocarbonates containing 1,3-dithiolane or 1,3-oxathiolane ring, easily eliminate ethylene sulfide to produce thiocarbonyl or carbonyl compounds.[3,4]



1 **2a, b, c**



3a R=PhCO
b R=*p*-$NO_2C_6H_4$
c R=EtOCO



A compound in which the *N*-methyl group of ylide **3** is replaced by sulfur atom is also a new class of compounds named as thiocarbonyl ylide.[5]

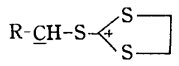
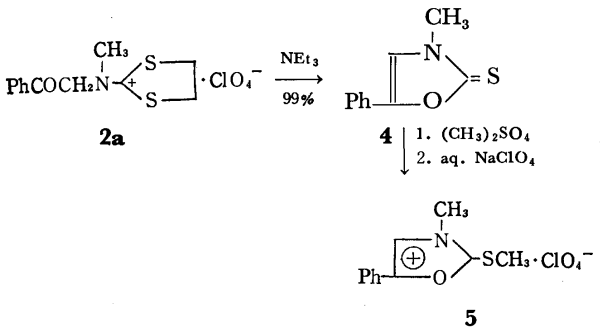
This paper describes the formation of novel azomethine ylides and thiocarbonyl ylides and their interesting reactions.

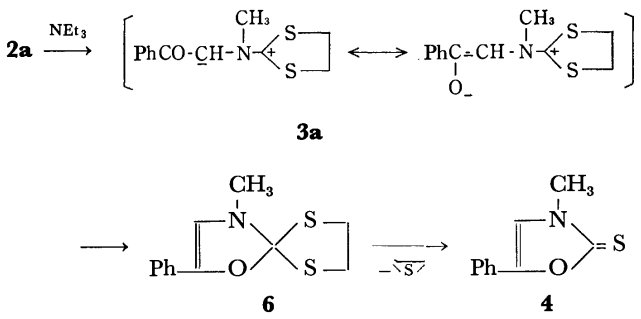


Results and Discussion

Formation of Azomethine Ylides and Their Properties. When 2-(*N*-methyl-*N*-phenacylamino)-1,3-dithiolanium perchlorate (**2a**) was treated with triethylamine in acetonitrile, 3-methyl-5-phenyl-1,3-oxazoline-2-thione (**4**) was obtained in quantitative yield. The infrared spectrum of **4** shows the characteristic bands at 3100 cm^{-1} (–CH=C〈), at 1492, 1462 cm^{-1} (thioamide II), and at 1210, 1195 cm^{-1} (thioamide I). The structure of **4** was further characterized by the formation of the oxazolium salt **5**. Thus methylation of **4** with dimethyl sulfate afforded 2-methylthio-3-methyl-5-phenyl-1,3-oxazolium perchlorate (**5**).

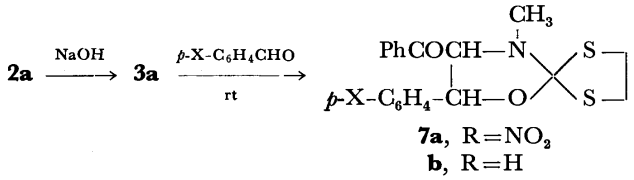


We postulate a mechanism involving prior formation of azomethine ylide **3a**, followed by intramolecular cyclization into spiro orthocarbonate **6**, and then elimination of ethylene sulfide, giving the final product **4** as formulated in Scheme 1.



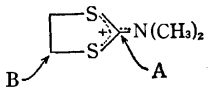
Scheme 1.

Attempts to trap the postulated intermediate, azomethine ylide **3a**, by 1,3-dipolar cycloaddition using phenyl isothiocyanate, carbon disulfide, or diethyl fumarate gave, instead, the intramolecular cyclization product **4** as the only isolated product. On the other hand, when *p*-nitrobenzaldehyde was employed as dipolarophile, 1,3-dipolar cycloaddition to the azomethine ylide **3a** occurred to give spiro orthocarbonate **7a** in 62% yield instead of **4**. Similarly benzaldehyde gave the cycloadduct **7b** in 55% yield.



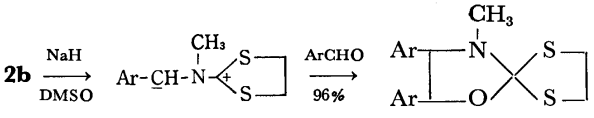
The infrared spectrum of **7a** shows a carbonyl vibrations at 1670 cm^{-1} those of nitro at 1520 and 1350 cm^{-1} and reveals the absence of thiocarbonyl group observed in the compound **4**.

Reactivities of the azomethine ylide **3a** towards dipolarophiles seem to be dependent upon that of the cationic part of **3a**. Thus we have explored that tri(hetero)substituted carbonium ions are greatly stabilized by nitrogen or sulfur atoms and that they have more than two reaction sites.[6] For example, it was shown that 2-(*N*,*N*-dimethylamino)-1,3-dithiolanium salt **8** reacts with various nucleophiles at two sites, A or B, and that whether the reactions take place at A or B, chiefly depends upon the nature of nucleophiles. In general, hard-nucleophiles (HO^-, RO^-) are most powerful to attack at A, whereas soft-nucleophiles (RS^-, $R_2NC(=S)S^-$) at B. Nitrogen-containing nucleophiles are intermediate between the two (aniline at A and triethylamine at B).



These facts are consistent with the observation that benzaldehydes (hard nucleophile) react with ylide **3a** to give 1,3-dipolar cycloaddition product **7**, and that the other dipolarophiles such as phenyl isothiocyanate, carbon disulfide, and diethyl fumarate (soft-nucleophiles) do not react.

When **2b** was treated with sodium hydride or potassium *t*-butoxide in dimethyl sulfoxide (DMSO) or acetonitrile, the reaction mixture turned to deep violet and returned to colorless by the addition of hydrochloric acid. This deep colored material seems to be the azomethine ylide **3b**. This was confirmed by 1,3-dipolar cycloaddition of *p*-nitrobenzaldehyde to the deep colored material. Thus a mixture of **2b** and *p*-nitrobenzaldehyde in DMSO was treated with sodium hydride at room temperature to produce the spiro orthocarbonate **9** in almost quantitative yield.

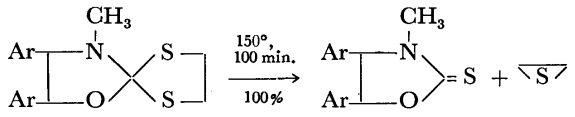


(Ar=*p*-$NO_2C_6H_4$)

The infrared spectrum of **9** reveals the presence of a nitro group (1530, 1350 cm^{-1}) and an etheral group (1062 cm^{-1}). The NMR spectrum in $(CD_3)_2SO$ exibits singlet peak at τ 7.70 (N-CH_3, 3H), triplet peaks at τ 7.60 (CH_2CH_2, 4H), a singlet peak at τ 7.06 (〉CH–

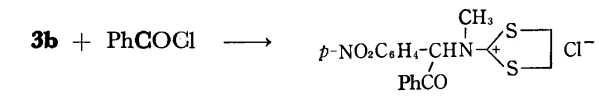
6) T. Nakai, Y. Ueno, and M. Okawara, This Bulletin, **43**, 3175 (1970).

CH〈, 2H), and two multiplet peaks centered at 2.45 and 1.75 (aromatic protons, each 4H). It was found that, as expected, the spiro orthocarbonate **9** afforded 1,3-oxazolidine-2-thione derivative **10** at the temperature above its melting point with a release of ethylene sulfide in quantitative yield.



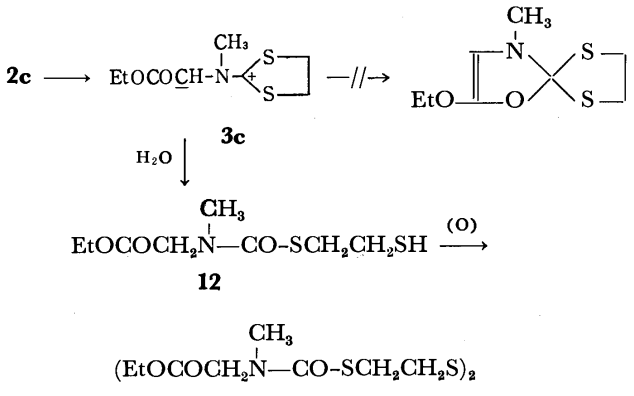
9 **10**

Acylation of the azomethine ylide **3b** with benzoyl chloride gave *C*-benzoylated product **11**, of which infrared spectrum shows the presence of a carbonyl group (1660 cm^{-1}). **11** was stable salt and recovered unchanged on heating at 180°C for 30 min.



11

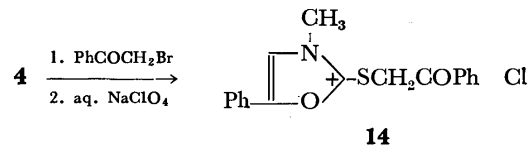
An attempt to cyclize the azomethine ylide **3c**, derived from the iminium salt **2c**, into spiro orthocarbonate in a similar manner as in the case of azomethine ylide **3a** failed. It was observed that only the hydrolysis of the salt **2c** by the water added after the reaction,



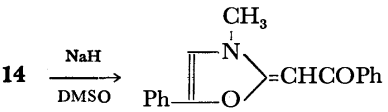
3c **12** **13**

and subsequent air-oxidation of the resulting mercaptan derivative **12** to disulfide **13**. The infrared spectrum of **13** reveals the presence of ester group (1750, 1200 cm^{-1}), and the amide carbonyl (1660 cm^{-1}), and the absence of thiol group. Similar hydrolysis of the iminium salt **8** into mercaptan or disulfide derivative has been reported.[7] No formation of spiro orthocarbonate from **3c** may be explained by the less reactivity of ester carbonyl towards carbonium ion in comparison with ketonic carbonyl of **3a**.

Formation of Thiocarbonyl Ylides and Their Properties. As described above, 1,3-oxazoline-2-thione **4** was easily alkylated to 2-methylthio-1,3-oxazolium salt **5** with deimethyl sulfate. When phenacyl bromide was employed in place of dimethyl sulfate, 2-phenacylthio-1,3-oxazolium salt **14** was obtained in 68% yield. Oxazolium salt **14** was expected to produce a new interesting thiocarbonyl ylide by deprotonation with base. Upon treatment of **14** with sodium hydride in DMSO at room temperature afforded 2-phenacylidene-3-methyl-5-phenyl-1,3-oxazoline **15** in 75% yield.



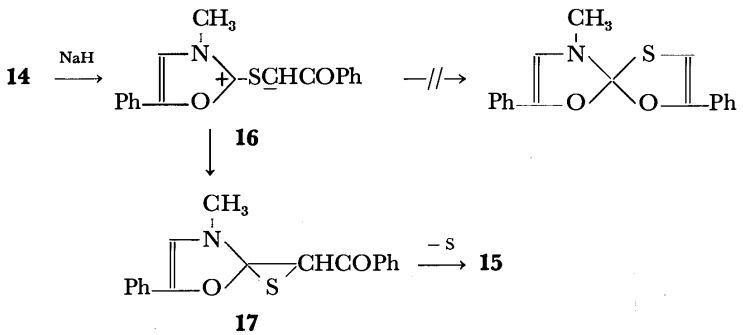
14



15

A possible reaction sequence for the formation of **15** was indicated in Scheme 2. Thus the thiocarbonyl ylide **16** derived from **14** cyclized into the thiirane derivative[8] **17**, instead to the five-membered ring as observed in azomethine ylide **3a**. The thiirane **17** afforded **15** with liberation of elemental sulfur.

On the other hand, it was found that the thiocarbonyl ylide **19**, derived from 2-(*p*-bromophenacylthio)-1,3-dithiolanium bromide,[9] cyclized into spiro orthocarbonate **20** instead to the thiirane derivative



16 **17**

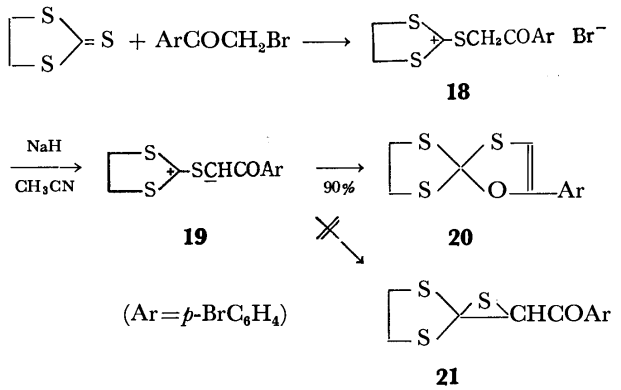
Scheme 2.

7) T. Nakai and M. Okawara, *ibid.*, **43**, 1864 (1970).

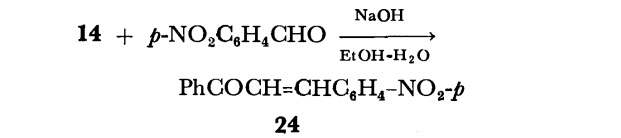
8) Takaku *et al.* reported the following reaction, in which thiirane derivative was postulated as intermediate to the isomerized product: $(Me_2N)_2\overset{+}{C}\text{–}SCH_2R\ X^- \xrightarrow{:B} (Me_2N)_2\overset{+}{C}\text{–}S\text{–}\overset{-}{C}HR$ **25** $\longrightarrow (Me_2N)_2C\text{—}CHR \xrightarrow{-O} (Me_2N)_2C{=}C(SH)R$, M. Takaku, S, Mitamura, and H. Nozaki, *Tetrahedron Lett.*, **1969**, 3651.

9) R. Mayer and K. Schafer, *J. Prakt. Chem.*, (4) **26**, 279 (1964).

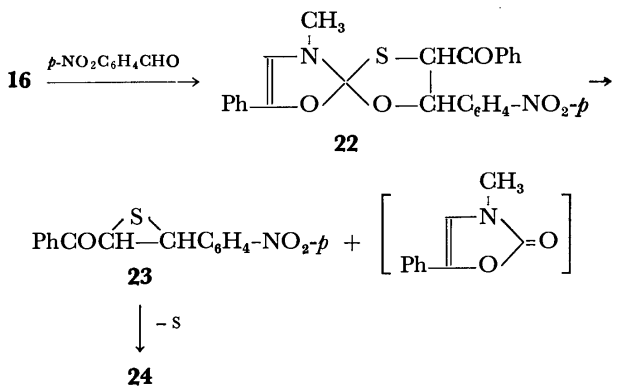
21. The IR spectrum of **20** shows no absorption bands in carbonyl region. The NMR spectrum in CCl_4 exhibits a singlet peak at τ 6.46 (SCH_2-CH_2S, 4H), a singlet peak at τ 3.97 (CH=, 1H), and multiplet peaks centered at τ 2.65 (aromatic protons, 4H).



Finally, 1,3-dipolar cycloaddition of thiocarbonyl ylide **16** was undertaken. Thus **14** was treated with sodium hydroxide in the presence of *p*-nitrobenzaldehyde at room temperature to give *p*-nitrochalcone **24** in 85% yield.

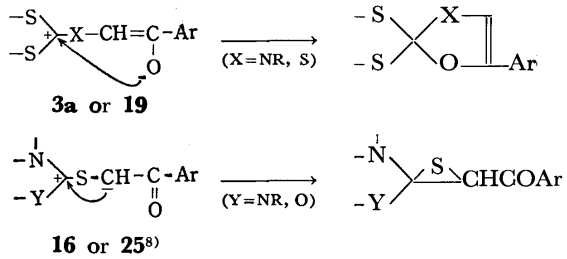


Facile elimination of thiirane from spiro orthocarbonates seems to be a general property of these types of compounds as observed above or as reported previously.[3,4] Moreover, it is well known that some kinds of thiiranes are quite readily decomposed to olefins with liberation of elemental sulfur. On the basis of these facts, a possible reaction mechanism may be illustrated in Scheme 3. Although the fate of the fragmented oxazolone group has not been established, the reaction seems to proceed *via* 1,3-dipolar cycloaddition of *p*-nitrobenzaldehyde to the thiocarbonyl ylide **16**, giving the spiro orthocarbonate **22**, which readily decomposes to the thiirane **23** and, possibly, the oxazolone derivative. The thiirane **23** finally decomposes to *p*-nitrochalcone **24** with liberation of elemental sulfur.

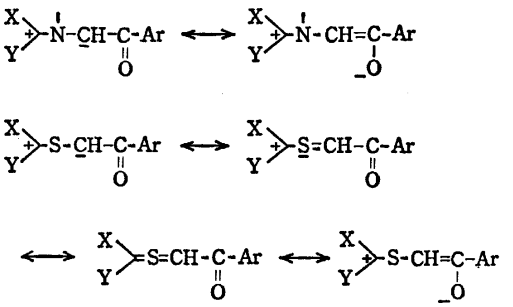


Scheme 3

Differences in the Intramolecular Cyclization Mode between Azomethine Ylides and Thiocarbonyl Ylides. It is quite interesting that two kinds of intramolecular cyclization modes of the azomethine and thiocarbonyl ylides were found. Thus the azomethine ylide **3a** and thiocarbonyl ylide **19** cyclized to five-membered ring at oxygen anion, whereas the thiocarbonyl ylide **16** cyclized to three-membered ring at carbanion as illustrated below.



These differences can not be clearly explained at the present stage. However we assume that the formation of thiirane derivatives, which are sterically unfavorable because of their subsequent facile occurrence of elimination or isomerization[8] of sulfur atom, is related to the stabilization or carbanion by sulfur atom in thiocarbonyl ylides. Thus in contrast to the azomethine ylides, the larger contribution of the carbanion-structure is postulated in thiocarbonyl ylides, if in which the carbanion can be stabilized by vacant *d*-orbitals of bivalent sulfur atom. The cyclization at the carbanion to the thiirane derivatives seems to become feasible only in such a case.



In thiocarbonyl ylide **19**, however, other factors seem to be operative for the cyclization.

Experimental

All the melting points were uncorrected. The IR spectra were recorded on Japan Optics JNL 4H-100 spectrometer using tetramethylsilane (TMS) as an internal standard. All experiments on ylides were carried out under nitrogen atmosphere.

Materials. 2-(*N*-Methyl-*N*-phenacyl)amino-(**2a**), 2-(*N*-*p*-nitrobenzyl-*N*-methyl)amino-(**2b**), and 2-(*N*-carbethoxymethyl-*N*-methyl)amino-1,3-dithiolanium salt (**2c**) were prepared from 2-methylimino-1,3-dithiolane (**1**) and corresponding alkyl bromides, respectively, as previously reported.[1]

Intramolecular Cyclization of Azomethine Ylide ***3a***. A mixture of 1.7 g (4.8 mmol) of 2-(*N*-methyl-*N*-phenacyl)-amino-1,3-dithiolanium perchlorate (**2a**) and 1 m*l* of triethylamine in 20 m*l* of acetonitrile was heated at 60°C for 5 hr. Addition of water, extraction with ether, drying with sodium sulfate, and then concentrating the etheral solution af-

forded 0.9 g (99%) of 3-methyl-5-phenyl-1,3-oxazoline-2-thione (4) : mp 140—141°C (recrystallized from acetonitrile ether)

Found: C, 62.41; H, 4.63; N, 7.32%. Calcd for $C_{10}H_9NOS$: C. 62.82; H, 4.75; N, 7.33%.

The compound **4** was also formed in quantitative yield when the salt **2a** was treated with sodium hydride in dioxane at room temperature for 0.5 hr. Under similar conditions **4** was obtained in almost the same yield even in the presence of the dipolarophiles such as phenyl isothiocyanate, carbon disulfide, or diethyl fumarate.

Methylation of 3-Methyl-5-phenyl-1,3-oxazoline-2-thione ***4***. A mixture of equimolar amount of **4** and dimethyl sulfate was heated at 60°C for 1 hr, followed by treatment with aqueous sodium perchlorate, afforded 2-methylthio-3-methyl-5-phenyl-1,3-oxazolium perchlorate (**5**) in 70% yield: mp 189—190°. IR 1080 cm^{-1} (ClO_4^-).

Found: C, 43.01; H, 3.75; N, 4.47%. Calcd for $C_{11}H_{12}NO_5SCl$: C, 43.22; H, 3.96; N, 4.58%.

Reaction of Azomethine Ylide ***3a*** *with Benzaldehydes.*

A. p-*Nitrobenzaldehyde*: To a mixture of 1.3 g (3.7 mmol) of the 1,3-dithiolanium salt **2a** and 1 g (6.6 mmol) of *p*-nitrobenzaldehyde in 80 m*l* of ethanol and 40 m*l* of water, was added with stirring 0.36 m*l* of 10 N aqueous sodium hydroxide solution. After about 30 min, white solid precipitated out was collected by filtration. Recrystallization from ethanol-acetone solution afforded 0.9 g (62%) of the spiro orthocarbonate **7a** : mp 132—133°C; IR, 1670 cm^{-1} (C=O), 1520, 1350 cm^{-1} (NO_2).

Found: C, 56.44; H, 4.43; N, 6.61%. Calcd for $C_{19}H_{18}N_2O_4S_2$: C, 56.71; H, 4.51; N, 6.96%.

B. Benzaldehyde: Similarly, **3a** reacted with benzaldehyde to give the spiro orthocarbonate **7b** in 54% yield: mp 84—85°C (recrystallized from ether): IR 1690 cm^{-1} (C=O).

Found: N, 3.96%. Calcd for $C_{19}H_{19}NO_2S_2$: N, 3.92%.

Reaction of the Azomethine Ylide ***3b*** *with* p-*Nitrobenzaldehyde.* To a mixture of 0.7 g (2 mmol) of 1,3-dithiolanium bromide **2b** and 0.3 g (2 mmol) of *p*-nitrobenzaldehyde in 10 m*l* of DMSO was added 0.1 g of 50% sodium hydride at room temperature. The reaction mixture turned to deep violet with evolution of hydrogen. The reaction mixture was stirred at room temperature for 2 hr and then poured into 50 m*l* of water to give 0.8 g (96%) of the cycloadduct **9** : mp 142—143°C (recrystallized from ethyl acetate); IR 1530, 1350 cm^{-1} (NO_2).

Found: C, 51.17; H, 3.99; N, 9.64%. Calcd for $C_{16}H_{13}N_3O_5S$: C, 51.15; H, 4.09; N, 10.02%.

Pyrolysis of the Spiro Orthocarbonate ***9***. Pyrolysis of **9** (1 g) at 150—160°C for 15 min. gave 0.85 g (100%) of 3-methyl-4,5-di(*p*-nitrophenyl)-1,3-oxazolidine-2-thione (10): mp 198—199°C (recrystallized from boiling acetone); IR 1505 (thioamide), 1530, 1350 cm^{-1} (NO_2).

Found: C, 53.80; H, 3.48; N, 11.43%. Calcd for $C_{16}H_{13}N_3O_5S$: C, 53.48; H, 3.65; N, 11.70%.

Reaction of the Azomethine Ylide ***3b*** *with Benzoyl Chloride.* *C*-Benzoylated product **11** was isolated in 21% yield in the reaction of the ylide **3b** with benzoyl choride in acetonitrile at room temperature for 3 hr: mp 80—81°C (recrystallized from methanol); IR 1660 cm^{-1} (C=O).

Found: C, 54.94; H, 4.62; N, 6.94; S, 16.59%. Calcd for $C_{18}H_{17}ClN_2O_3S_2$: C, 55.04; H, 4.36; N, 7.13; S, 16.29%.

Hydrolysis of the Azomethine Ylide ***3c***. A solution of 2.8 g (9.9 mmol) of the 1,3-dithiolanium perchlorate **2c** in 10 m*l* of acetonitrile was treated with 4 m*l* of triethylamine at 60°C for 4 hr. Water was added to the reaction mixture and extracted with ether, drying with sodium sulfate and evaporation of the solvent and trituration of the residue with a small amount of ether - *n*-hexane afforded 1 g (43%) of disulfide **13**: mp 75—76°C (recrystallized from ether); IR 1750 (ester C=O), 1660 (amide C=O), and 1200 cm^{-1} (C–O–C).

Found; C, 41.25; H, 6.08; N, 5.87%. Calcd for $C_{16}H_{28}N_2O_6S_4$: C, 40.67; H, 5.95; N, 5.95%.

Alkylation of 3-Methyl-5-phenyl-1,3-oxazoline-2-thione ***4*** *with Phenacyl Bromide.* A mixture of 2.9 g (15 mmol) of **4** and 3 g (15 mmol) of phenacyl bromide in 30 m*l* of tetrahydrofuran (THF) was allowed to stand at room temperature for 2 days. Treatment of the reaction mixture with aqueous sodium perchlorate solution gave 4.26 g (68%) of 2-phenacylthio-3-methyl-5-phenyl-1,3-oxazolium perchlorate **14**: mp 208—209°C (d.) (recrystallized from acetonitrile); IR 1680 cm^{-1} (C=O).

Found; C, 53.39; H, 3.90; N, 3.58%. Calcd for $C_{18}H_{16}ClNO_6S$: C, 52.76; H, 3.94; N, 3.42%.

Formation of 2-Phenacylidene-1,3-oxazoline ***15***. A solution of 1.0 g (2.5 mmol) of oxazolium salt **14** in 10 m*l* of DMSO was treated with 0.12 g of 50% sodium hydride at room temperature. The reaction mixture turned to red with evolution of hydrogen. After standing at room temperature over one night, the mixture was poured into excess water to give 0.5 g (75%) of 2-phenacylidene-3-methyl-5-phenyl-1,3-oxazoline **15**: mp 196—197°C (d). (recrystallized from acetone); IR 1530 cm^{-1} (C=O); NMR ($CDCl_3$) τ 6.65 (s, 3H, *N*-CH_3), τ 4.55 (s, 1H, –CH=), τ 3.21 (s, 1H, –CH=), and τ 2.4 (m, 10H, phenyl protons).

Found: C, 76.95; H, 5.10; N, 4.78%. Calcd for $C_{18}H_{15}NO_2$: C, 77.96; H, 5.45; N, 5.05%.

Intramolecular Cyclization of the Thiocarbonyl Ylide ***19***. To a suspension of 1.24 g (3 mmol) of 2-(*p*-bromophenacylthio)-1,3-dithiolanium bromide (prepared by the method of Mayer[9]) in 40 m*l* of acetonitrile, was added 0.2 g of 50% sodium hydride. The reaction mixture turned to reddish-brown, was stirred at room temperature for 3 hr and then was poured into water (*ca.* 500 m*l*) with stirring to give 0.9 g (90%) of spiro orthocarbonate **20**; mp 85—86°C (d.) (recrystallized from n-hexane–ether).

Found: C, 39.84; H, 2.87%. Calcd for $C_{11}H_9BrOS_3$: C, 39.66; H, 2.72%.

The NMR spectral data of **20** was described in the text.

Reaction of Thiocarbonyl Ylide **16** *with p-Nitrobenzaldehyde.* To a suspension of 0.8 g (2 mmol) of 14 and 0.4 g (2.6 mmol) of *p*-nitrobenzaldehyde in 70 m*l* of water and 50 m*l* of ethanol, was added 0.2 m*l* of aqueous solution of 10 N sodium hydroxide. The reaction mixture turned to orange-brown and deposited the brown precipitates, which were collected by filtration after 2 hr. Recrystallization from ether - ethyl acetate afforded yellowish-brown solid **24** (85): mp 162.0—162.5°C (lit,[10] 162.5°); IR 1655 cm^{-1} (C=O).

Found: C, 70.85; H, 4.14; N, 5.33%. Calcd for $C_{15}H_{11}NO_3$: C, 71.14; H, 4.37; N, 5.53%.

Studies on Stable Free Radicals. X.[1] Photolysis of Hindered *N*-Chloroamines

Toshimasa TODA, Eiko MORI, Hideo HORIUCHI, and Keisuke MURAYAMA
Central Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo

(Received October 5, 1971)

Photolysis of the hindered *N*-Chloroamines, 1-chloro-2,2,6,6-tetramethyl-4-oxopiperidine (IIa), 1-chloro-2,2,6,6-tetramethylpiperidine (IIb), and 1-chloro-2,2,5,5-tetramethyl-4-oxoimidazolidine (IIc), in benzene solution were carried out in an ESR spectrometer cavity. The ESR spectra of the corresponding amino radicals IIIa, IIIb, and IIIc were observed in evacuated solutions. In solutions containing oxygen, it was found that amino radicals IIIb and IIIc readily reacted with oxygen to give the corresponding stable nitroxide radicals IVb and IVc, from the shapes of spectra and *g*-values. Amino radical IIIa did not react with oxygen. Although the amino radicals could not be isolated, their formation was confirmed by the isolation of a coupling product with a benzyl radical generated from dibenzylmercury.

Although syntheses and studies of the properties of stable nitroxide radicals have been carried out extensively,[2] stable amino radicals which can be isolated, analyzed and presented for a long time are scarcely known except for the diphenylpicrylhydrazyl and verdazyl radicals,[3] whose stability seems to result from the delocalization of the unpaired electron. The ESR spectra of diaryl amino radicals generated from corresponding hydrazines by pyrolysis in solution can be observed even at high temperatures,[4] but those of dialkyl amino radicals with no conjugated system for the unpaired electron, obtained by photolysis of tetraalkyltetrazenes in solution can be detected only at low temperatures.[5]

It has been reported that dialkyl amino radicals are relatively poor dehydrogenating agents, *e.g.*, dimethylamino radicals give dimethylamine and *N*-methylformaldimine by disproportionation at high temperatures.[6]

$$2\cdot Me_2N\cdot \rightarrow Me_2NH + CH_2 = NMe$$

Thus, a hindered amino radical lacking hydrogen on the α-carbon of the radical group is expected to be more stable than a dimethylamino radical.

Sholle *et al.* succeeded in observing the ESR spectrum of 2,2,6,6-tetramethyl-4-oxo-1-piperidyl radical (IIIa) at room temperature, but it was also unstable.[7]

Although this amino radical has no hydrogen on the α-carbons of the radical group, the hydrogens at the α-positions of the keto group in piperidine ring are easily abstracted.[8]

We have prepared hindered *N*-chloroamines containing no easily abstracted hydrogen and observed the ESR spectra of the corresponding amino radicals generated directly by photolysis of the *N*-chloroamines in a cavity of the ESR spectrometer. The amino radicals thus obtained were sensitive to oxygen and gave the corresponding stable nitroxide radicals.

Results and Discussion

We prepared 1-chloro-2,2,6,6-tetramethyl-4-oxopiperidine (IIa) by the reaction of the corresponding amine (Ia) with sodium hypochlorite,[9] but IIa was unstable. On keeping it to stand 2,2,6,6-tetramethyl-4-oxopiperidine hydrochloride (Ia′) separated as a precipitate.

Formation of Ia′ is plausible, if IIa decomposes into amino radical IIIa and Cl· by homolysis, and both radicals abstract hydrogens from keto α-methylene group in IIa or IIIa to give amine (Ia) hydrogen chloride. The assumption seems reasonable from the consideration that 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxyl (IVa) abstracted hydrogens from keto α-methylene group of IVa to give 1-hydroxy-2,2,6,6-tetramethyl-4-oxopiperidine and phorone under reflux in benzene, while 2,2,6,6-tetramethylpiperidine-1-oxyl (IVb) was recovered unchanged under the same reaction conditions.[8]

We therefore prepared 1-chloro-2,2,6,6-tetramethylpiperidine (IIb) and 1-chloro-2,2,5,5-tetramethyl-4-oxoimidazolidine (IIc) which have no ketonic α-methylene hydrogens, by the reaction of these amines with sodium hypochlorite. Chloroamines IIb and IIc were more stable than IIa.

The ESR spectra of the radicals generated directly from the chloroamines by photolysis in an ESR spectrometer cavity were recorded at room temperature under two conditions, *viz.*, in the presence and absence of oxygen.

Photolysis of Chloroamine IIa. The radical generated by UV irradiation of IIa in evacuated benzene solution gave the spectrum shown in Fig. 1a. Triplet lines, due to the interaction of a ^{14}N nucleus and supplementary splitting of each component of the triplet caused by the interaction with 12 protons of four methyl substituents in amino radical IIIa, were observed. The radicals generated by UV irradiation of IIa in benzene (containing oxygen) and in toluene (containing or not containing oxygen), gave the same spectrum as that of Fig. 1a. After cessation of UV irradiation, the spectra remained observable for a certain period and then disappeared gradually.

Photolysis of Chloroamine IIb. The radical generated by photolysis of IIb in an evacuated benzene solution gave the spectrum shown in Fig. 1b. Supplementary splittings resulting from 12 protons of four methyl substituents in amino radical IIIb were observed. The spectrum disappeared immediately when UV irradiation was terminated. In an evacuated toluene solution, photolysis of IIb gave no spectrum.

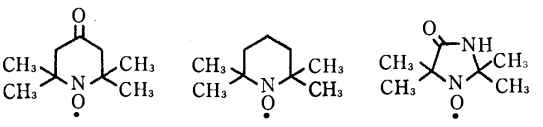
The spectrum of the radical generated by photolysis of IIb in benzene (containing oxygen) is given in Fig. 2. Only triplet lines due to a ^{14}N nucleus were observed. The spectrum remained observable for a long time after cessation of UV irradiation. In toluene (containing oxygen), photolysis of IIb gave a spectrum of triplet lines similar to that in Fig. 2.

Fig. 2. ESR spectrum of Nitroxide Radical IVb generated by the photolysis of IIb in undegassed benzene solution at room temperature.

Photolysis of Chloroamine IIc. The spectrum of the radical obtained from IIc in an evacuated benzene solution is shown in Fig. 1c. Triplet lines due to a ^{14}N nucleus and further splittings caused by the interaction with 12 protons of four methyl substituents in the amino radical IIIc were observed. The interaction with another ^{14}N at the 3-position in IIIc was not observed (Fig. 1c). When UV irradiation was stopped, the spectrum as well as that given in Fig. 1b disappeared immediately. No spectrum was observed in an evacuated toluene solution. The spectra of the radicals generated from IIc in benzene and in toluene (each containing oxygen) gave triplet lines as the spectrum in Fig. 2.

The splitting constants and *g*-values of the radicals obtained in this study were determined from the spectra and are listed in Table 1.

The ESR spectra of the corresponding nitroxide radicals IVa,[10] IVb[10], and IVc[11] were also measured. Each spectrum showed triplet lines as in Fig. 2. Values for their splitting constants and *g*-values are listed in Table 2.



(IVa) (IVb) (IVc)

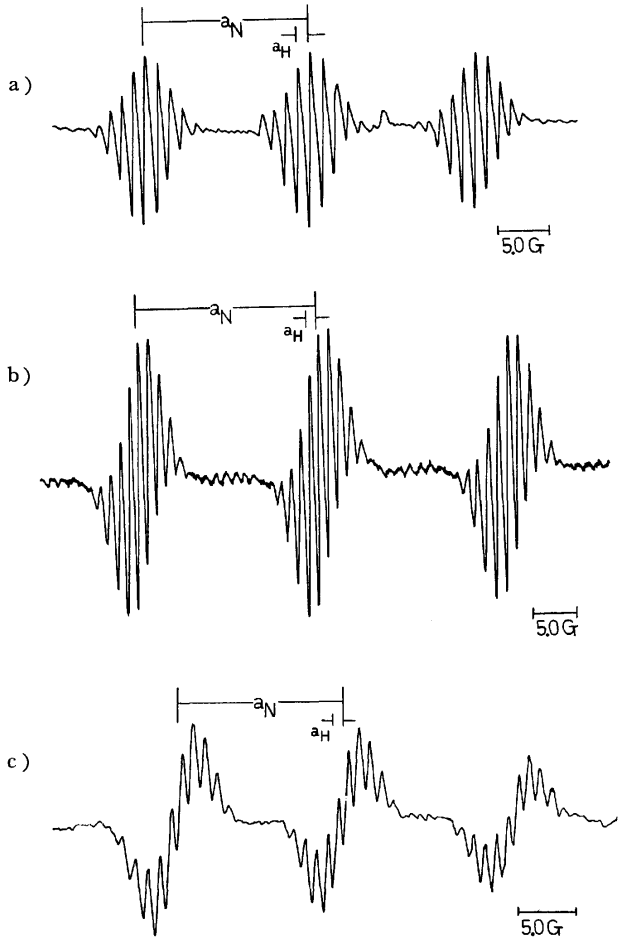


Fig. 1. ESR spectra of Amino Radicals genrated by the photolysis of *N*-chloroamines in degassed benzene solution at room temperature: a) from IIa. b) from IIb. c) from IIc.

Table 1. Values of hyperfine splitting constants and g-values of the radicals generated by photolysis on N-chloroamines[a]

Chloro-amine	Amino radical[b]			Nitroxide radical[c]		
	a_N[d]	a_H[d]	g-value[e]	a_N[d]	a_H[d]	g-value[e]
IIa	15.0	1.2	2.0027	15.0[g]	1.2[g]	2.0043[g]
IIb	14.3	0.78	2.0041	15.0	f)	2.0056
IIc	14.3	1.2	2.0038	14.0	f)	2.0053

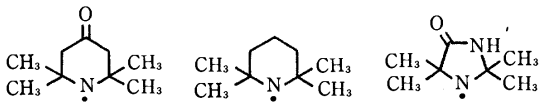
a): measured in benzene solution at room temperature. b): in degassed solution. c): in undegassed solution. d): unit in gauss. accuracy ±0.1 gauss. e): accuracy ±0.0001. f): not resolved. g): corresponding amino radical.

Table 2. The values of hyperfine splitting constants and g-values of the nitroxide radicals[a]

Radical	a_N[b]	a_H	g-value[c]
IVa	14.3	d)	2.0055
IVb	15.0	d)	2.0056
IVc	14.0	d)	2.0052

a): measured in benzene at room temperature. The two values obtained in degassed and undegassed solutions were the same. b): unit in gauss. accuracy ±0.1 gauss. c): accuracy ±0.0001. d): not resolved.

The radicals obtained in the absence of oxygen appear to be amino radicals IIIa, IIIb, and IIIc from the following considerations.



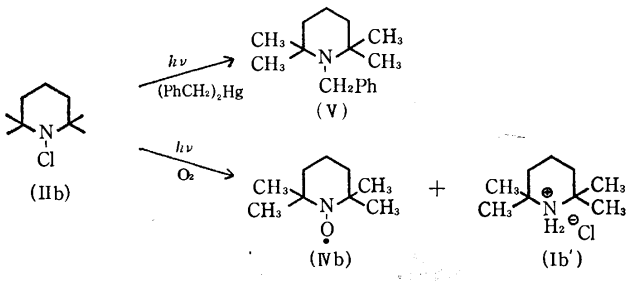
(IIIa) (IIIb) (IIIc)

Supplementary splittings were observed besides the triplet lines in each ESR spectrum as shown in Fig. 1 a-c, while only triplet lines were observed for the corresponding nitroxide radicals. Values for the coupling constants of a ^{14}N nucleus in the amino radicals IIIa and IIIc are larger than those for the corresponding nitroxide radicals (except for radical IIIb). This can be accounted for by the consideration that the density of each unpaired electron is almost entirely localized on the nitrogen atom, while in the corresponding nitroxide radical, each unpaired electron can be delocalized, $>N-O\cdot \leftrightarrow >\overset{\oplus}{N}-\overset{\ominus}{O}$.[12] g-Values for the amino radicals are smaller than those for the corresponding nitroxide radical as shown in Tables 1 and 2. This might be due to the difference in the spin-orbit coupling constants and has been pointed out in the cases of the di-p-tolyl-amino radical[4] and the di-p-tolyl nitroxide radical.[13]

In the presence of oxygen, the radicals obtained from IIb and IIc appear to be nitroxide radicals IVb and IVc, because splittings resulting from protons of the methyl substituents in these compounds were not observed in the ESR spectra, and g-values agreed with those of the corresponding nitroxide radicals. The radicals obtained from IIa in benzene or in toluene (each containing or not containing oxygen) appear to be amino radical IIIa, because their ESR spectra agreed with the spectrum of amino radical IIIa as shown in Fig. 1a.

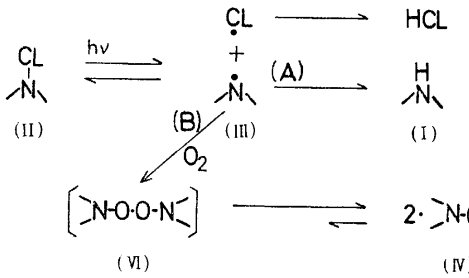
The following experiments were carried out in order to confirm the formation of the amino radical and the nitroxide radical in photolysis of the chloroamine.

We obtained 1-benzyl-2,2,6,6-tetramethylpiperidine (V) by the photolysis of a mixture of IIb and dibenzylmercury[14] in benzene with bubbling argon gas. The reaction did not proceed in dark. Photodecomposition of IIb in benzene with bubbling oxygen gas gave 2,2,6,6-tetramethylpiperidine-1-oxyl (IVb) and 2,2,6,6-tetramethylpiperidine hydrochloride (Ib').



(IIb) (V) (IVb) (Ib')

Thus, the photolysis of the hindered N-chloroamine would proceed as shown in Chart 1.



(II) (III) (I) (VI) (IV)

Chart 1

Processes A and B are considered to be competitive reactions for the following reasons. (1) the photodecomposition of IIb in benzene with bubbling oxygen gas gave nitroxide radical IVb and salt Ib'; and (2) no ESR spectra were observed in the photolyses of IIb and IIc in evacuated toluene solutions and the radicals obtained from IIb and IIc in toluene containing oxygen were the corresponding nitroxide radicals IVb and IVc, respectively.

Amino radical IIIa does not react with oxygen and would mainly abstract hydrogens to give corresponding amine Ia, because the radical obtained by photolysis of IIa even in the presence of oxygen was the amino radical IIIa. Salt Ia' was obtained on keeping IIa to stand.

From the fact that amino radicals IIIb and IIIc are converted into nitroxide radicals IVb and IVc in the presence of oxygen, it seems reasonable to assume

12) see Ref. 1b. p. 127.

the existence of peroxide (VI), precursor of the nitroxide radical as shown in Chart 1. Such a peroxide has been suggested in the photolysis of perfluoro-*N*-fluoropiperidine.[15] We consider that there may be an equilibrium between peroxide VI and nitroxide radical IV in solution[16], but the equilibrium lies far on the side of the radical.

The results suggest that even hindered amino radicals cannot be isolated, because they are sensitive towards oxygen to give the corresponding nitroxide radicals and readily abstract a hydrogen from media or another radical to give the amines, even though these radicals have no hydrogen on the α-carbon in the radical group.

Table 1 shows that the nitrogen coupling constant of IIIb is smaller than that of the corresponding nitroxide radical IVb. This seems to be correlated with the result that amino radical IIIa does not react with oxygen, which would be caused by the effect of 4-oxo group in piperidine ring.

Experimental

Melting points and boiling points are uncorrected. IR spectra were determined by means of Nujol mulls and liquid films. NMR spectra were obtained with a Varian A-60 NMR spectrometer using tetramethylsilane as an internal standard at 32°C. Mass spectra were obtained with a JEOL-JMS-OIS spectrometer at 75 eV.

ESR Measurements. ESR spectra were recorded on a Hitachi MES 4001 type X-band spectrometer employing 100 kHz modulation at room temperature. Degassed samples were prepared in the usual manner. Samples containing *ca.* 5% of dissolved *N*-chloroamine were irradiated with an USIO projector equipped with xenon 2 kw lamp. Splitting constants and *g*-values were measured relative to the aqueous solution of Fremy's salt.

Preparation of N-Chloroamines. The solution of aqueous sodium hypochlorite was prepared by passing chlorine gas (24 g) into a cold solution of sodium hydroxide (36 g) in 300m*l* of water at 0°C.[9]

1-Chloro-2,2,6,6-tetramethyl-4-oxopiperidine (IIa). To a stirred solution of 31.0 g (0.2 mml) of 2,2,6,6-tetramethyl-4-oxopiperidine (Ia)[6,17] and 20 g of aqueous solution of hydrogen chloride (35%) in 200 m*l* of water was added slowly 250 m*l* of aqueous sodium hypochlorite at 0—5°C. After the addition was completed, stirring was continued for 10 min at 0—5°C. The solution was shaken with 300 m*l* of ether. The ether layer was dried over sodium sulfate and evaporated under reduced pressure at room temperature. The residual oil was distilled to give 19.0 g (50.0%) of IIa: bp 63—64°C/0.3 mmHg. Found: C, 56.80; H, 8.61; N, 7.34; Cl, 18.62%. Calcd for $C_9H_{16}ONCl$: C, 56.99; H, 8.50; N, 7.38; Cl, 18.69%. IR(cm^{-1}): $\nu_{C=O}$ 1728. 2,2,6,6-Tetramethyl-4-oxopiperidine hydrochloride (Ia') was precipitated from the distilled oil on standing at room temperature. This was confirmed by comparison of the melting point and IR spectrum with those of the authentic sample prepared by the reaction of Ia with hydrogen chloride in ethanol. Recrystallization from ethanol gave a pure sample: mp 197°C (decomposition). Found: C, 56.41; H, 9.45; N, 7.33; Cl, 18.46%. Calcd for $C_9H_{18}ONCl$: C, 56.39; H, 9.47; N, 7.31; Cl, 18.49%.

1-Chloro-2,2,6,6-tetramethylpiperidine (IIb). In the same way as mentioned above, 34.0 g (96.5%) of IIb was obtained from 28.0 g (0.2 mml) of 2,2,6,6-tetramethylpiperidine (Ib)[10]: bp 65°C/7 mmHg. Found: C, 61.52; H, 10.34; N, 8.23; Cl, 19.69%. Calcd for $C_9H_{18}NCl$: C, 61.52; H, 10.34; N, 8.23; Cl, 19.69%. Calcd for $C_9H_{18}NCl$: C, 61.52; H, 10.32; N, 7.97; Cl, 20.18%. NMR (τ) (in CCl_4): 8.41, broad (6H). 8.80, siglet (12H).

1-Chloro-2,2,5,5-tetramethyl-4-oxoimidazolidine (IIc). To a stirred solution of 1.4 g (10 mmol) of 2,2,5,5-tetramethyl-4-oxoimidazolidine (Ic)[11] in 20 m*l* of water was added slowly 20 m*l* of aquoeus sodium hypochlorite at 0—5°C. The solution was stirred for additional 20 min at 0—5°C, and extracted with 100 m*l* of ether. The ethereal solution was dried over sodium sulfate and evaporated under reduced pressure to give 1.7 g of IIc. Recrystallization from benzene gave an analytically pure sample: mp 153—154°C. Found: C, 48.06; H, 7.66; N, 15.83; Cl, 20.05%. Calcd for $C_7H_{13}ON_2Cl$: C, 47.60; H, 7.42; N, 15.86; Cl, 20.07%. IR(cm^{-1}): $\nu_{C=O}$ 1678 and 1730, ν_{NH} 3150.

Reaction of IIb. a). A solution of 7.75 g (44 mmol) of IIb and 8.45 g (22 mmol) of dibenzylmercury[14] in 170 m*l* of dry benzene with bubbling argon gas was irradiated with a high pressure mercury lamp (Hanovia, 450 W) for 8 hr at 0—5°C. After cessation of UV irradiation, the solution was decanted into a separatory funnel, shaken with 80 m*l* of 10% hydrochloric acid and separated. The aqueous layer was concentrated to half volume under reduced pressure, neutralized with aqueous solution of potassium hydroxide (40%), extracted with 100 m*l* of benzene and dried over potassium carbonate. After evaporating the solvent, the resulting oil was chromatographed on 50 g of aluminum oxide. Eluting with petroleum ether afforded 1.2 g of 1-benzyl-2,2,6,6-tetramethylpiperidine (V). Recrystallization from petroleum ether gave a pure sample: mp 39—40°C. Found: C, 82.91; H, 11.07; N, 5.87%. Calcd for $C_{16}H_{25}N$: C, 83.05; H, 10.89; N, 6.05%. NMR (τ) (in CCl_4): 2.5—3.0 (5H), 6.20 singlet (2H), 8.45 broad (6H), 8.97 singlet (12H). mass spectrum: $M^+=231$ (231). Picrate: mp 170—171°C (from ethanol). Found: C, 57.10; H, 6.14; N, 11.91%. Calcd for $C_{22}H_{28}O_7N_4$: C, 57.38; H, 6.13; N, 12.17%. The benzene layer was concentrated in a vacuum to give 2.5 g of crystallline solids. Recrystallization from ethanol gave dibenzyl melting at 52—53°C (mp 52°C).

b). A solution of 17.6 g (0.1 mol) of IIb in 140 m*l* of dry benzene with bubbling oxygen gas was irradiated with a high pressure mercury lamp (Hanovia, 450 W) for 2 hr at 0—5°C. After cessation of UV irradiation, 5.0 g of 2,2,6,6-tetramethylpiperidine hydrochloride (Ib') was separated from the solution by filtration. This was confirmed by comparison of the melting point and IR spectrum with those of the sample prepared by the reaction of Ib with hydrogen chloride in ethanol. Recrystallization from ethanol gave a pure sample: mp 295°C (decomposition). Found: C, 60.78; H, 11.40; N, 7.85; Cl, 19.91%. Calcd for for $C_9H_{20}NCl$: C, 60.83; H, 11.34; N, 7.88; Cl, 19.95%. The filtrate was concentrated under reduced pressure. The oily residue was chromatographed on a column of aluminum oxide and the column eluted successively with petroleum ether, benzene, and methanol. From petroleum ether eluates, 3.5 g of the starting

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1806—1812 (1972)

On the Configuration of Branched-Chain Derivatives of 1,2 : 5,6-Di-*O*-isopropylidene-*α*-D-*ribo*-hexofuranos-3-ulose

Juji YOSHIMURA, Kazuhiko KOBAYASHI, Ken-ichi SATO, and Masuo FUNABASHI

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 7, 1971)

In order to obtain a 3-*C*-hydroxymethyl-D-glucose derivative some nucleophilic reactions of 1,2 : 5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose (**1**) and the configurations of products have been examined. *Gluco*- and *allo*-configurations of known 3-*C*-nitromethyl derivatives of **1** were confirmed by the fact that 3-*C*-acetaminomethyl-1,2-*O*-isopropylidene-α-D-*xylo*- and *ribo*-pentodialdofuranoses, derived by four successive transformations, showed the absence and presence of the aminal-ring formation between the aldehyde and acetamino groups, respectively. A 3-*C*-carbethoxymethyl derivative obtained by the Reformatsky reaction of **1** with ethyl bromoacetate was proved to be of *allo*-configuration by the lactone-formation between C_5-hydroxyl and carboxyl groups. The configuration of 3-*C*-hydroxymethyl derivative (**15**) obtained by treatment of known 3-*C*-methylene derivative of **1** with permanganate was proved to be of *gluco*-type by comparison of the corresponding 3-*C*-aminomethyl derivative (**5**), derived by three-step conversions, with that obtained from 3-*C*-nitromethyl derivatives. **15** was also obtained by epoxidation of **1** with diazomethane followed by ring-opening with alkali. Treatment of **5** and its *allo*-epimer with nitrous acid gave, respectively, a ring-expanded product and the 3′,5-anhydride, the former being also recognized in the epoxidation products. Structures of new compounds were examined by NMR spectra and stereoselectivity of reactions discussed.

Studies are increasingly being made on branched-sugars rarely found in nature[1], and on osuloses as important intermediates for synthesis of deoxy-, amino-, and branched-sugars[2].

In order to obtain a 3-*C*-hydroxymethyl derivative of D-glucose as an intermediate for a total synthesis of tetrodotoxin[3], we examined nitromethane-condensation, the Reformatsky reaction and diazomethane-condensation of 1,2 : 5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose (**1**)[4] and the configurations of the products. The compound was obtained by treatment of 3-*C*-methylene derivative of **1** with permanganate or by diazomethane-condensation of **1**, followed by ring-opening of the resulting epoxide.

Results and Discussion

Nitromethane Condensation and the Reformatsky Reaction. It is known that the nitromethane condensation of **1** afforded 1,2 : 5,6-di-*O*-isopropylidene-3-*C*-nitromethyl-α-D-allofuranose (**2**) or a mixture of **2** and the corresponding 3-epimer (**3**), depending on the conditions[5-7]. The structure of **2** and **3** was confirmed from the fact that 1,2-*O*-isopropylidene-3-*C*-nitromethyl-α-D-pentofuranose derived from **3** by oxidative elimination of atom at position 6 gave the corresponding 3,5-*O*-isopropylidene ring[7] and that a part of **3** was converted into **2** through 3-dehydro-3-deoxy-1,2 : 5,6-di-*O*-isopropylidene-3-*C*-nitromethylene-α-D-*ribo*-hexofuranose[6]. Their structures were confirmed by examining whether the corresponding 3-*C*-acetaminomethyl-1,2-*O*-isopropylidene-α-D-*ribo*-hexofuranose[6]. Their structures were confirmed by examining whether the corresponding 3-*C*-acetaminomethyl-1,2-*O*-isorpopylidene-α-D-pentodialdofuranoses can form an aminal-ring between the aldehyde and

acetamino groups. Hydrogenation of **2** and **3** in the presence of palladium-charcoal gave the corresponding 3-*C*-aminomethyl derivatives (**4**) and (**5**), respectively. They were then converted into 3-*C*-acetaminomethyl derivatives (**6**) and (**7**) by acetylation in ethanol. The compounds were obtained in crystalline state, and characterized by NMR. The results for **6** and **7** are given in Figs. 1—3.

The first-order analysis of the original spectrum of **6** was hindered by overlapping of proton signals. However, deuteration of the amido and hydroxyl protons and addition of a few drops of benzene to cause a shift in several peaks (Fig. 1) made it easy to assingn $H_{3'a}$ and H_{6b} protons. Other protons were assigned from the intensities and coupling constants. The coupling constant between H_4 and H_5 was also determined by the examination of pseudo-contact

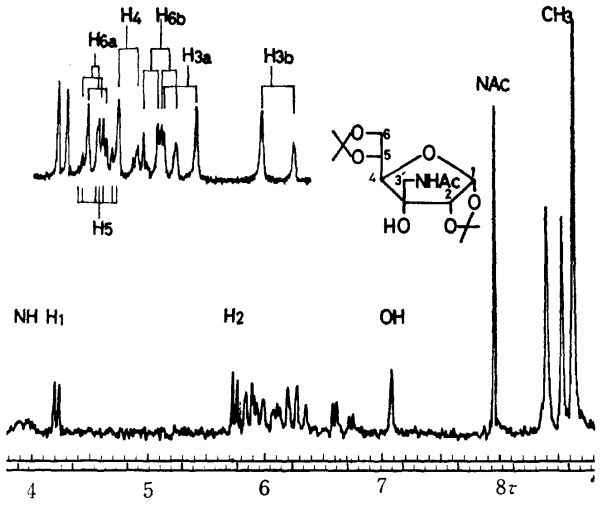

Fig. 1. NMR spectrum of **6** in $CDCl_3$.

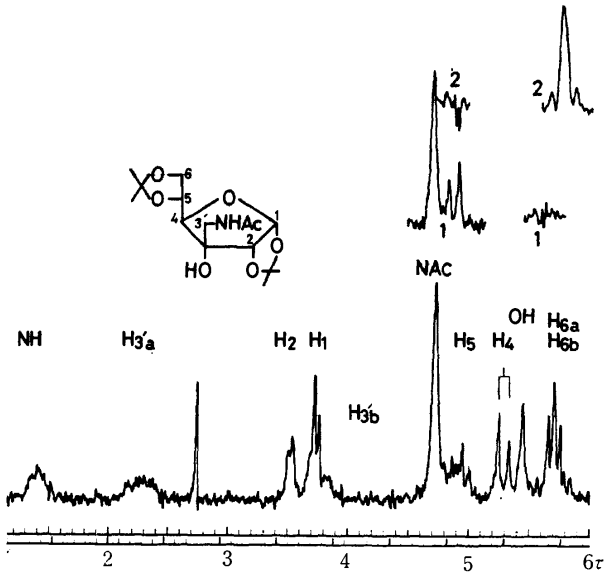

Fig. 2. NMR spectrum of **6** (16 mg) in the presence of $Eu(fod)_3$ (10 mg).

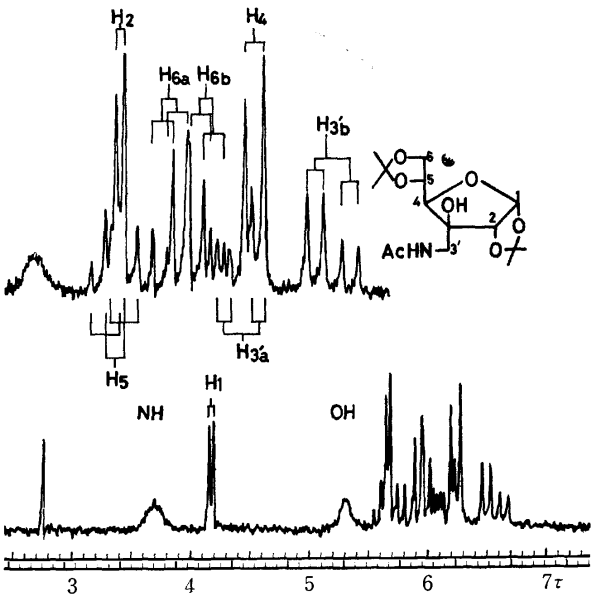

Fig. 3. NMR spectrum of **7** in $CDCl_3$.

shift (Fig. 2) with tris(1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedionato)-europium (III)[8] [Eu(fod)$_3$]. Tickling of H_6 protons caused H_5 proton signal to disclose a large coupling corresponding to that of H_4, and irradiation of H_5 changes H_{6a} and H_{6b} signals to a broadened AB quartet from AB part of an ABX system. From a comparison of the magnitude of contact shifts of several kinds of protons, it is concluded that nitrogen atom in **6** is the more predominant ligand than oxygen of *tert*-hydroxyl group.

Signals in the NMR spectrum of **7** (Fig. 3) were assigned only by means of double-resonance technique. Such a difference in D-*allo* and D-*gluco* derivatives was generally observed.

Hydrolyses of 5,6-*O*-isopropylidene groups of **6** and **7** were performed by treatment with 0.01 N sulfuric acid for 2 hr, and the products were directly oxidized with periodate to give 1,2-*O*-isopropylidene-3-*C*-acetaminomethyl-α-D-*xylo*- and and D-*ribo*-pentodialdofuranose (**8**) and (**9**), respectively. **8** showed charac-

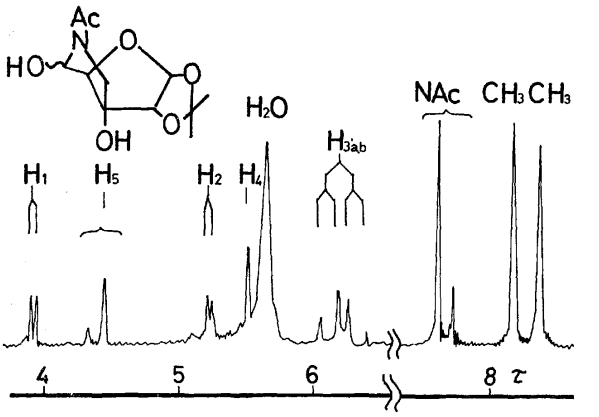

Fig. 4. NMR spectrum of **8** in $CDCl_3$.

8) R. E. Rondeau and R. E. Sievers, *J. Amer. Chem. Soc.*, **93**, 1522 (1971).

teristic absorptions of tertiary amide (1605 and 1615 cm^{-1}) in IR spectrum, and showed no aldehyde proton signal in NMR spectrum (Fig. 4). The existence of two singlets for both *N*-acetyl and H_5 protons which could not collapse at 60°C indicates that **8** exists in aminal structures (**8'**) in which two configurations are possible at C_5. **9** also showed a secondary amide absorption (1640 and 1540 cm^{-1}) and an aldehyde proton signal at τ 0.37 (Fig. 5). The configurations of **2** and **3** were confirmed.

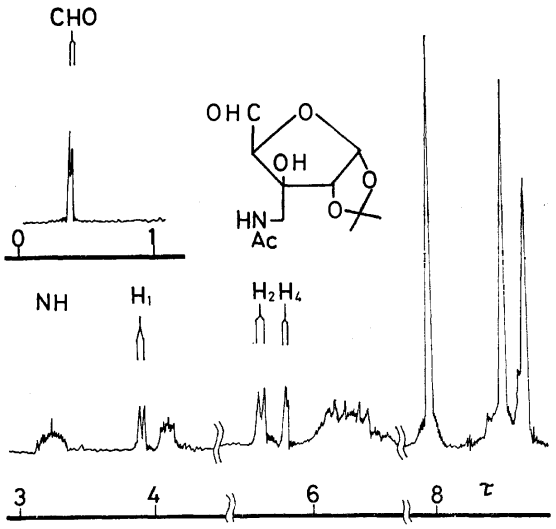

Fig. 5. NMR spectrum of **9** in $CDCl_3$.

Acetylation of **2** with acetic anhydride in the presence of *p*-toluenesulfonic acid gave 3,5,6-tri-*O*-acetyl-1,2-*O*-isopropylidene-3-*C*-nitromethyl-α-D-allofuranose (**10**). However, conversion of **10** into the corresponding 3-*C*-nitromethylene derivative[7] was unsuccessful. Deamination of **4** and **5** was attempted. Treatment of **4** with barium nitrite in acetic acid at 0°C for 12 hr gave 1,2-*O*-isopropylidene-3',5-anhydro-3-*C*-hydroxymethyl-α-D-allofuranose (**11**) in 20% yield. Disappearance of the characteristic absorption of an amino (1580 cm^{-1}) and appearance of that of hydroxyl (3250 and 3410 cm^{-1}) group in IR spectrum, and the presence of H_4 signal as singlet and H_5 as triplet supports the structure (Fig. 6). A similar treatment of **5** gave a sirup. The presence of a six-membered ketone was deduced by IR spectrum (1730 cm^{-1}) and NMR spectrum (two kinds of H_1 signals at τ 4.08 and 4.25, and two quartet at τ 7.1—7.7). The spectral information was also confirmed on a sirup obtained from the mother liquor of **11**. Thus it is concluded that deamination of **4** and **5** induced ring-expansion C_3'-carbonium ion, and a part of carbonium ion cyclized with sterically close C_5-oxygen in the case of **4**.

Treatment of **1** with ethyl bromoacetate in the presence of zinc metal and catalytic amount of iodine, followed by chromatographic separation of the product on a silica gel column gave the corresponding 3-*C*-

carbethoxymethyl derivative (**12**) as a sirup and a small amount of 1,2-*O*-isopropylidene-3-*C*-carboxymethyl-α-D-allofuranose-3′,5-lactone (**13**) as crystals. Treatment of **12** with alkali gave the corresponding 3-*C*-carboxymethyl derivative (**14**). However, application of dehydrative decarboxylation of β-hydroxy-carboxylic acid in quinoline with copper powder[9] to **14** gave unchanged product and again a small amount of **13**. This proves that **12** and **14** have the *allo*-configuration. IR spectrum of **12**, **13** and **14** showed, respectively, characteristic absorption bands of ester (1725 cm^{-1}), lactone (1735 cm^{-1}), and carboxylic acid (1695 cm^{-1}). The presence of much less hindered C_6-methylene signals in the NMR spectrum of **13** also supports the structure (Fig. 7).

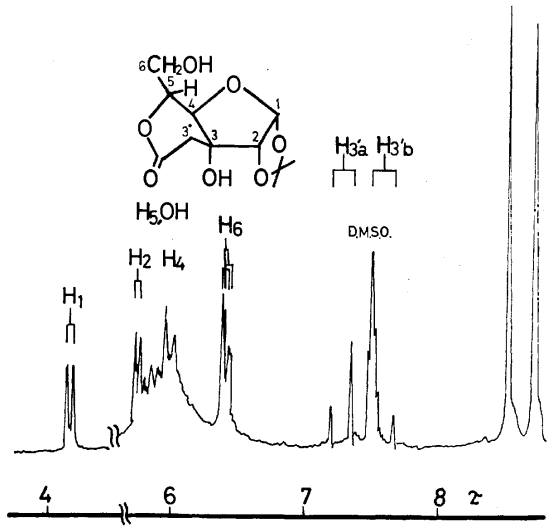

Fig. 7. NMR spectrum of **13** in DMSO.

Synthesis of 3-C-Hydroxymethyl-1,2: 5,6-di-O-isopropylidene-α-D-glucofuranose by means of the Wittig or Diazomethane Reaction. It has been reported that the reaction of **1** with methylenetriphenylphosphorane in dimethyl sulfoxide or in ether gave the corresponding 3-*C*-methylene derivative[10,11]. Treatment of this compound with potassium permanganate gave 3-*C*-hydroxymethyl-1,2 : 5,6-di-*O*-isopropylidene-α-D-glucofuranose (**15**) in 70% yield. The NMR spectrum of **15** gave a pattern close to that of **7**, except for the $C_{3'}$-methylene protons which appeared as a singlet at τ 6.15. The configuration at C_3 was proved chemically as follows. Partial tosylation of **15** gave a monotosylate (**16**) whose tosylated position was deduced to be $C_{3'}$ from the lower shift of $C_{3'}$-methylene signals (at τ 5.05 and 5.80 as AB quartet) in the NMR spectrum. The compound was converted into the corresponding azide, and then hydrogenated to give the corresponding 3-*C*-aminomethyl derivative which was identical with **5** in melting point and spectral data.

As another synthetic method of **15**, direct epoxidation of **1** with diazomethane was tried, followed by ring-opening with alkali and the product was examined by gas liquid chromatography (Fig. 8). When epoxidation was carried out in ether or methanol, the product contained many species, but the products obtained by the reaction in benzene contained the desired compound (peak c) as the main product. In fact, **15** was separated in 25% yield which was identical with the authentic specimen in melting point and spectral data. Three trimethylsilylated species of **1** indicated the occurrence of two kinds of enolization[12] to some extent. The glpc of the sirup obtained from the mother liquor showed nearly complete separation of **15** (peak c) by simple crystallization. Peaks d and b were respectively deduced to be 3-epimer of **15** and a ring expanded product mentioned in the case of the deamination of **4**. However, it could not be isolated.

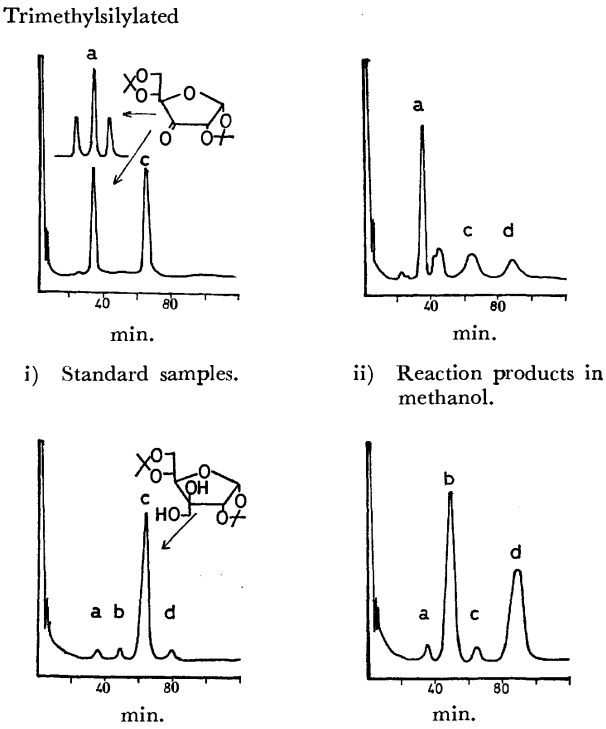

Fig. 8. Gas chromatograms of the reaction products of **1** with diazomethane.
(1.5% OV-17 on Shimalite; 115°C: N_2 flow rate, 60 ml/min.)

The configurations of reaction products obtained can be understood by the attacking of nucleophiles from the outside of the V-shaped fused five-membered ring in **1**, except in the reaction of diazomethane in benzene. Such stereoselectivities have also been recognized in the Grignard reaction of 5-deoxy-1,2-*O*-isopropylidene-β-L-*threo*-pentofuranos-3-ulose[13] and in hydrogenation of **1**[14] or the corresponding

cyclohexylidene dreivative[15].

The abnormal stereoselectivity of the reaction of diazomethane in benzene can be explained only by assuming an interaction between oxygen atoms in 1,2-*O*-isopropylidene group of **1** and the polarized structure of diazomethane[16].

Experimenal

All boiling and melting points are uncorrected. The solutions were evaporated under diminished pressure at a bath temperature not exceeding 45°C. Specific rotations were measured in a 0.5-dm tube, with a Carl Zeiss LEP Al Polarimeter. The IR spectra were recorded with a Hitachi Model EPI-GS grating IR spectrophotometer. The NMR spectra were taken in deuteriochloroform unless otherwise stated with a JMN-4H-100 MHz and partly with Varian XL-100 Spectrometer using tetramethylsilane as an internal standard. Chemical shifts and coupling constants were recorded in τ and Hz units, and frequencies in cm^{-1}.

*3-*C*-Aminomethyl-1,2: 5,6-di-*O*-isopropylidene-α-*D*-allofuranose (**4**) and -glucofuranose (**5**).* A solution of 1,2 : 5,6-di-*O*-isopropylidene-3-*C*-nitromethyl-α-D-allofuranose (**2**) or -glucofuranose (**3**) (5 g, 15.6 mmol) in methanol-water (100 ml) was hydrogenated in the presence of palladium-charcoal (5%, 2.5 g). After hydrogenation, the solution was filtered and methanol was evaportaed. The water layer was then extracted with chroloform. The extract was washed with water, dried, and concentrated to give crystals which was recrystallized from methanol-ether. The yield was 4.26 g (94%) in both cases.

Found: C, 54.36; H, 8.04; N, 5.18%. Calcd for $C_{13}H_{23}NO_6$: C, 53.96; H, 8.01; N, 4.84%.

Compound **5**: mp 114—115°C; $[\alpha]_D^{23}$ +28.8° (*c* 1.0, ethanol). IR: 3330 and 3280 (NH_2), 1615 (C-N); NMR: 4.13 (H_1; d, $J_{1,2}$=3.5), 5.69 (H_2; d), 6.23 (H_4; d, $J_{4,5}$=7.9), 5.66 (H_5; sex, $J_{5,6a}$=5.6), 5.84 (H_{6a}; q, $J_{5,6b}$=5.7), 5.96 (H_{6b}; q, $J_{6a,6b}$=8.3), 6.90 ($H_{3'a}$; d, $J_{3'a,b}$=13.2), 7.03 ($H_{3'b}$; d), 7.88 (OH and NH, s), 8.49 8.58, 8.65 and 8.68 (4 C-CH_3).

Found: C, 52.58; H, 8.30; N, 4.62%. Calcd for $C_{13}H_{23}NO_6 \cdot 1/2H_2O$; C, 52.40; H, 8.06; N, 4.70%.

*3-*C*-Acetaminomethyl-1,2 : 5,6-di-*O*-isopropylidene-α-*D*-allofuranose (**6**) and -glucofuranose (**7**).* Acetic anhydride (0.5 g, 4.9 mmol) was added to a solution of **4** or **5** (0.3 g, 1.04 mmol) in methanol (3 m*l*) and then kept at room temperature for one day. The solution was treated by the usual procedure to give crystals which were recrystallized from ether-*n*-hexane. Yields were nearly quantitative in both cases.

Compound **6**: mp 156—156.5°C; $[\alpha]_D^{23}$ +56.3° (*c* 1.0, ethanol). IR: 3450 (OH), 3375 (NH), 1645 and 1515 (NHAc); NMR: 4.22 (H_1; d, $J_{1,2}$=4.0), 5.75 (H_2; d), 3.92 (NH), *ca.* 5.88 (H_{6a}; q, $J_{5,6a}$=2.0), *ca.* 5.89 (H_5; sex), 6.01 (H_4; *d*, $J_{4,5}$=8.4), 6.16 (H_{6b}; q, $J_{6a,b}$=8.0, $J_{6b,5}$=6.3), 6.27 ($H_{3'b}$), 6.64 ($H_{3'b}$; q, $J_{a,b}$=13.6, $J_{3'b,NH}$=3.8), 7.08 (OH, s), 7.97 (NAc; s), 8.41, 8.54 and 8.64 (4 C-CH_3).

Found: C, 54.21; H, 7.70; N, 4.08%. Calcd for $C_{15}H_{25}NO_7$: C, 54.37; H, 7.61; N, 4.23%.

The pseudocontact shift was measured in the presence of 5 or 10 mg of Eu(fod)$_3$ to 16 mg of **6**. The extent and order of shift (ppm) of protons in the latter case were as follows; NAc (4.24) > $H_{3'b}$ (3.67) > $H_{3'a}$ (2.84) > NH (2.54) > H_2 (2.23) > OH (1.64) > H_5 (0.09) > H_4 (0.73) > H_1 and H_{6b} (0.47), C-CH_3 (0.30, 0.28, 0.23 and 0.14), H_{6a} (0.18).

Compound **7**: mp 120—121°C, $[\alpha]_D^{23}$ +63.8° (*c* 1.44, ethanol). IR: 1650 and 1542 (NHAc); NMR: 3.55 (NH; broad s), 4.16 (H_1; d, $J_{1,2}$=4.5), 5.29 (OH; s), 5.66 (H_2; d), 5.65 (H_5; q, $J_{5,6b}$=5.8), 5.88 (H_{6a}; q, $J_{5,6a}$=5.9), 6.04 (H_{6b}; q, J_{ab}=8.6), 6.24 (H_4; d, $J_{4,5}$=7.8), 6.22 and 6.55 ($H_{3'ab}$; each q, J_{ab}=14.7, $J_{3'b,NH}$=5 5, $J_{3'b,NH}$= 6.8), 7.96 (NAc; s), 8.50, 8.59, 8.64 and 8.69 (4 C-CH_3).

Found: C, 54.51; H, 7.59; N, 4.20%. Calcd for $C_{15}H_{25}NO_7$: C, 54.37; H, 7.61; N, 4.23%.

*3-*C*-Acetaminomethyl-1,2-*O*-isopropylidene-α-*D*-ribo-pentodialdofuranose-5,*N*-aminal (**8'**).* A solution of **6** (1.5 g, 4.5 mmol) in 0.1 N-sulfuric acid (50 m*l*) was kept at room temperature for 2 hr, neutralized with barium hydroxide and then filtered. The filtrate was extracted with chloroform, and the extract was evaporated to give a sirup (1.10 g). Oxidation of the sirup in water with sodium periodate (0.81 g, 3.78 mmol) gave crystals (0.4 g, 34%) soluble in dimethyl sulfoxide, but insoluble in usual organic solvents. Mp 219.5—220.7°C; $[\alpha]_D^{23}$ +25.4°→+29.7° (after 24 hr, c 1.0, water). IR: 3480 (OH), 1607 and 1625 (=NAc): NMR (DMSO-d_6): 3.92 (H_1; d, $J_{1,2}$=3.1), 4.32 and 4.44 H_5; two kinds of s), 5.23 (H_2; d), 5.52 (H_4; s), 6.12 and 6.33 ($H_{3'ab}$; ABq, $J_{a,b}$=14.0), 7.62 and 7.72 (NAc; two kinds of s), 8.17 and 8.36 (2 C-CH_3).

Found: C, 50.61; H, 6.60; N, 5.37%. Calcd for $C_{11}H_{17}NO_6$: C, 50.96; H, 6.61; N, 5.40%.

*3-*C*-Acetaminomethyl-1,2-*O*-isopropylidene-α-*D*-xylo-pentodialdofuranose (**9**).* A solution of 3-*C*-acetaminomethyl-1,2-*O*-isopropylidene-α-D-glucofuranose (0.5 g, 1.73 mmol) and sodium periodate (0.4 g 1.87 mmol) in water (50 m*l*) was allowed to stand for 5 hr, and the sodium iodate separated by addition of ethanol was filtered off. After evaporation of ethanol from the filtrate, the water layer was extracted with chloroform to give a sirup which could not be crystallized. The amount of sirup was too small for its physical constants to be determined. However, satisfactory spectral information was obtained to deduce the structure without any further purification.

IR: 1725 (CHO), 1640 and 1540 (NHAc); NMR: 0.41 (CHO; d, $J_{4,CHO}$=2.0), 3.81 (H_1; d, $J_{1,2}$=4.0), 5.62 (H_2; d), 5.81 (H_4; d), *ca.* 6.00—6.65 (OH, $H_{3'a}$, $H_{3'b}$), 7.97 (NAc; s), 8.51 and 8.67 (2 C-CH_3).

*3,5,6-Tri-*O*-acetyl-1,2-*O*-isopropylidene-3-*C*-nitromethyl-α-*D*-allofuranose (**10**).* A solution of **2** (6.0 g, 18.8 mmol) and a catalytic amount of *p*-toluenesulfonic acid in acetic anhydride (9.6 g, 95 mmol) was allowed to stand for one day, and poured into excess sodium bicarbonate in water. Extraction of the aqueous solution with chloroform gave crystals which were recrystallized from ethanol. Yield, 3.0 g (39.4%) mp 165—166°C, $[\alpha]_D^{23}$ +77.0° (*c* 1.0, ethanol). IR: 1750, 1730 (OAc), 1560, 1540 (NO_2); NMR: 4.28 (H_1; d, $J_{1,2}$= 4.0), 4.67 (H_2; d), 4.45—4.65 (H_5; m), 4.94 and 5.15 ($H_{3'ab}$; ABq, $J_{a,b}$=11.7), 5.76 (H_4; d, $J_{4,5}$=8.0), 5.05 and 5.83 H_{6ab}; q and q, $J_{5,6a}$=3.0, $J_{5,6b}$=5.5, $J_{a,b}$=12.0), 7.92 and 7.94 (3 OAc), 8.45 and 8.65 (2 C-CH_3).

Found: C, 47.17; H, 5.88; N, 3.30%. Calcd for $C_{16}H_{23}NO_{11}$: C, 47.41; H, 5.72; N, 3.46%.

Treatment of this compound in benzene with sodium bicarbonate at 80°C gave only an intractable sirup.

*3',5-Anhydro-3-C-hydroxymethyl-1,2-O-isopropylidene-α-D-allofuranose (**11**).* To an ice-cooled solution of **4** (0.6 g, 2.08 mmol) and acetic acid (0.763 m*l*) in water (5 m*l*) was added dropwise barium nitrite monohydrate (0.95 g, 3.84 mmol) in water (5 m*l*) with stirring for 20 min, and the resulting solution was allowed to stand for 12 hr at 10°C. Extraction of the reaction mixture with chloroform gave crystals which were recrystallized from ethanol-*n*-hexane. Yield, 0.1 g (20.6%); mp 115.8—116°C; $[\alpha]_D^{23}$ +73.8° (*c* 1.0, chloroform). IR: 3410 and 3250 (OH); NMR: 4.06 (H_1; d, $J_{1,2}$=4.5), 5.61 (H_2; d), 5.62 (H_4; s), 5.80 (H_5; t, $J_{5,6}$=5.0), 5.92 and 6.27 ($H_{3'ab}$; ABq, $J_{a,b}$=10.5), 6.24 (H_6; d), 6.88 (OH; s), 8.40 and 8.61 (s C-CH_3).

Found: C, 51.63; H, 7.00%. Calcd for $C_{10}H_{16}O_6$: C, 51.72; H, 6.94%.

*Reformatsky Reaction of **1** with Ethyl Bromoacetate.* A suspension of **1** (1.2 g 4.65 mmol), ethyl bromoacetate (3.7 g, 22.2 mmol) and zinc metal (2.1 g, 31.9 mmol) in tetrahydrofuran (11 m*l*) was refluxed for 1.5 hr in the presence of a catalytic amount of iodine and then filtered. The filtrate was poured into ice water containing acetic acid (1.2 m*l*), and extracted with chloroform. The pale yellow sirup 1.2 g) obtained by evaporation of the extracts was fractionated on a silica gel C-100 (20 g) column. The column was succesively eluted with ligroin, ligroin-benzene (1 : 1), benzene, benzene-acetone (5 : 1) and acetone. Concentration of ligroin-benzene and benzene solution gave 3-*C*-carbethoxymethyl-1,2 : 5,6-di-*O*-isopropylidene-α-D-allofuranose (**12**) as a sirup (0.5 g, 29.5%), and 3-*C*-carboxymethyl-1,2-*O*-isopropylidene-α-D-allofuranose 3',5-lactone (**13**) as crystals (0.3 g, 22.4%).

Compound **12**: IR: 1735 (ester); NMR: 4.26 (H_1; d, $J_{1,2}$=3.75), 5.21 (H_2; d), 5.65—6.20 (CH_2, H_4, H_5, H_{6a}, H_{6b}), 7.10 and 7.53 ($H_{3'ab}$; ABq, $J_{a,b}$=15.0), 7.83 (OH; s), 8.41, 8.54 and 8.63 (4 C-CH_3), 8.72 (CH_3 in ethyl; t, J=5.0).

Found: C, 54.95; H, 7.23%. Calcd for $C_{16}H_{26}O_8$: C, 55.48; H, 7.57%.

Compound **13**: mp 195—195.5°C; $[\alpha]_D^{23}$ +136.6° (*c* 1.0, acetone). IR: 1735 (lactone); NMR (DMSO): 4.16 (H_1; d, $J_{1,2}$=4.2), 5.76 (H_2; d), 5.98 (H_4; d, $J_{4,5}$=5.0), 5.78—6.20 (H_4, H_5, OH), 6.40 and 6.42 (H_{6ab}; two d, $J_{5,6}$=5.0), 7.30 and 7.52 ($H_{3'ab}$; ABq, $J_{a,b}$=15.5), 8.51 and 8.20 (2 C-CH_3).

Found: C, 50.62; H, 6.30%. Calcd for $C_{11}H_{16}O_7$: C, 50.77; H, 6.20%.

*3-C-Carboxymethyl-1,2 : 5,6-di-O-isopropylidene-α-D-allofuranose (**14**).* 0.1 N Sodium hydroxide (5 m*l*) was added to a solution of **12** (4.0 g, 10.9 mmol) in water (50 m*l*) which was then allowed to stand for 2 hr. The solution was acidified with acetic acid and extracted with chloroform. Evaporation of the extracts gave crystals which were recrystallized from petroleum ether. Yield, 2.8 g (80%), mp 111.5—112.5°C; $[\alpha]_D^{23}$ +22.7° (*c* 0.54, chloroform). IR: 1695 (COOH); NMR: 4.26 (H_1; d, $J_{1,2}$=4.0), 5.30 (H_2: d), 5.80—6.25 (H_4, H_5, H_{6a}, H_{6b}, OH), 7.04 and 7.52 ($H_{3'ab}$; ABq, $J_{a,b}$=15.0), 8.42, 8.56 and 8.64 (4 C-CH_3).

Found: C, 52.64; H, 6.85%. Calcd for $C_{14}H_{22}O_8$: C, 52.82; H, 6.97%.

An attempted dehydrative decarboxylation of **14** by refluxing in quinoline in the presence of copper powder for 10 hr gave unchanged **14** and a small amount of **13**.

*3-C-Hydroxymethyl-1,2 : 5,6-di-O-isopropylidene-α-D-glucofuranose **15**.* A) To a suspension of 1,2 : 5,6-di-*O*-isopropylidene-3-*C*-methylene-α-D-ribo-hexofuranose (3.4 g, 13.25 mmol) in water (30 m*l*) was added dropwise potassium permanganate (2.6 g, 15.4 mmol) in water (130 m*l*) for 30 min with stirring. After 1 hr, the solution was filtered and the filtrate was extracted with chloroform. The sirup obtained by evaporation of the extracts was crystallized from hexane. Yield, 2.71 g (70.3%); mp 84—86°C; $[\alpha]_D^{23}$ +21.8° (*c* 1.0, chloroform). NMR: 4.12 (H_1; d, $J_{1,2}$=4.0), 5.58 (H_2; d), 5.68 (H_5; m), 5.84 ($H_6{}^a$; q, $J_{5,6a}$=4.8, $J_{6a,6b}$=8.0), 5.96 (H_{6b}; q, $J_{5,6b}$=5.0), 6.15 ($H_{3'ab}$; s), 6.18 (H_4; d, $J_{4,5}$=7.0), 6.45 (OH; s), 8.48, 8.56, 8.63, 8.68 (4 C-CH_3).

Found: C, 54.59; H, 8.22%. Calcd for $C_{13}H_{22}O_7$: C, 53.78; H, 7.64%.

B) Dried diazomethane (0.726 g, 1.2 equivalent calculated from nitrosomethylurea) was added to a solution of **1** (3.42 g, 14.4 mmol) in benzene (40 m*l*), which was then evaporated. A solution of the resulting sirup in acetone-water (100 ml, 1 : 1 v/v) containing potassium hydroxide (0.5 g) was refluxed for 3 hr, and acetone was evaporated. Extraction of the water layer with chloroform gave a sirup which was extracted with hot *n*-hexane to give crystals. Yield, 0.95 g (25%); mp 86.0—86.5°C. It showed no depression of melting point by admixture with an authentic sample. The IR spectral data were found to be identical.

*3-C-Hydroxymethyl-1,2 : 5,6-di-O-isopropylidene-3'-O-(p-toluenesulfonyl)-α-D-glucofuranose (**16**).* To a solution of **15** (0.5 g, 1.72 mmol) was added *p*-toluenesulfonyl chloride (0.36 g, 2.27 mmol) with stirring. After standing overnight, the solution was poured into ice-water and extracted with chloroform. The extract was washed with cold N hydrochloric acid, saturated sodium bicarbonate solution and water. Evaporation of the extracts gave a sirup which was crystallized from ether-*n*-hexane. Yield, 0.66 g (86.4%); mp 116.5—117.5°C; $[\alpha]_D^{23}$ +98.4° (*c* 1.01, chloroform). NMR: 4.18 (H_1; d, $J_{1,2}$=3.5), 5.05 and 5.80 ($H_{3'ab}$; ABq, $J_{a,b}$=10.0), 5.66 (H_2; d), 5.92 (H_{6a}; q, $J_{5,6a}$=6.0, $J_{6a,6b}$=8.0), 6.36 (H_4; d, $J_{4,5}$=8.0), 6.60 (H_{6b}; q, $J_{5,6b}$=6.0), 7.25 (OH; broad s), 8.63, 8.67, 8.70 and 8.77 (4 C-CH_3).

Found: C, 54.52; H, 6.39; S, 7.47%. Calcd for $C_{20}H_{28}O_9S$: C, 54.05; H, 6.35; S, 7.21%.

*Preparation of **5** from **16**.* A solution of **16** (0.5 g, 1.13 mmol) and sodium azide (0.15 g, 2.26 mmol) in dimethylformamide (20 ml) was refluxed for 4 hr at 173°C, then poured into ice-water. The resulting solution was extracted with chloroform. Evaporation of the extracts gave a sirup which could not be completely separated from dimethylformamide. However, it gave a characteristic absorption of azide (2100 cm^{-1}) in IR spectrum. NMR: 4.13 (H_1; d, $J_{1,2}$=3.4), 5.58 (H_2; d), *ca.* 5.71 (H_5; m), 5.88 (H_{6a}; q, $J_{5,6a}$=5.5, $J_{6a,7b}$=7.9), 6.00 (H_{6b}; q, $J_{5,6b}$=4.6), 6.29 and 6.32 ($H_{3'ab}$; ABq, $J_{a,b}$=10.2), *ca.* 6.26 (H_4; d), 8.48, 8.85 and 8.65 (4 C-CH_3).

Hydrogenation of the sirup in ethanol (20 m*l*) in the presence of Raney nickel (0.5 g) at 40°C and 30 atm. gave the corresponding 3-*C*-aminomethyl derivative as crystals. Yield, 0.25 g (61%); mp 113—115°C. The spectral data of the crystals were identical with those of **5**.

*3-C-Hydroxymethyl-1,2 : 3,3' : 5,6-tri-O-isopropylidene-α-D-glucofuranose (**17**).* A suspension of **15** (1 g, 3.45 mmol) and anhydrous copper sulfate (3 g) in acetone (50 m*l*) was refluxed for 72 hr, filtered through active carbon, and the filtrate was evaporated. The sirup crystallized gradually, but it could not be recrystallized because of its small solubility in organic solvents. Yield, 0.8 g (70%); mp 54—56°C; $[\alpha]_D^{23}$ +23.1° (*c* 0.6, ethanol); NMR: 4.18 (H_1; d, $J_{1,2}$=3.5), 5.66 (H_2; d), 6.08 (H_4; d, $J_{4,5}$=13.0), 5.56—6.06 (H_5, H_{6ab} and $H_{3'ab}$), 8.52, 8.58, 8.60, 7.66 and 8.68 (6 C-CH_3).

Found: C, 58.05; H, 7.99%. Calcd for $C_{16}H_{26}O_7$:

C, 58.17; H, 7.93%.

*3-C-Hydroxymethyl-1,2 : 5,6-di-O-isopropylidene-α-D-glucofuranose 3,3'-carbonate (**18**).* To a solution of 15 (1 g, 3.45 mmol) in pyridine (10 ml) was bubbled excess phosgene under cooling. After standing for 1 hr the solution was poured into ice-water and extracted with chloroform. Evaporation of the extracts gave a sirup in 90% (0.98 g) yield. $[\alpha]_D^{23}$ +25.8° (*c* 0.1, chloroform); IR: 1820 (carbonate) NMR: 4.05 (H_1; d, $J_{1,2}$=4.4), 5.41 (H_2; d), 5.32 and 5.45 ($H_{3'ab}$; ABq, $J_{a,b}$=9.0), 5.72 (H_5: m), 5.87 (H_{6a}; q, $J_{5,6a}$=2.9), 5.99 (H_{6b}; q, $J_{6a,6b}$=8.4, $J_{5,6b}$=4.5), 6.10 (H_4; d, $J_{4,5}$=8.4), 8.49, 8.56, 8.65 and 8.66 (4 C-CH_3).

Found: C, 52.55; H, 6.35%. Calcd for $C_{14}H_{20}O_8$: C, 53.16; H, 6.37%.

The authors are grateful to Mr. Masatsune Kainosho and Mr. Katsumi Ajisaka of Ajinomoto Co. for measurement of part of the NMR spectra, to Miss Fumie Hattori for glpc and members of the Laboratory of Organic Analysis for elemental analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1812—1816 (1972)

The Reduction of Stereoisomeric 6-*tert*-Butyl-3-methoxy-3-methylcyclohexenes with Lithium in Ethylamine

Tadashi MASAMUNE, Hajime MATSUE, and Matsuo FUJII

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received October 12, 1971)

The synthesis and reduction with lithium in ethylamine of the entitled stereoisomeric allyl ethers **1** and **2** are described. The reaction of both the isomers occurred very readily with concomitant cleavage of the methoxy groups, and gave the same products, 4-*tert*-butyl-1-methylcyclohexene (**13**), and *c*- and *t*-3-*tert*-butyl-6-methylcyclohex-1-enes (**14** and **15**), in the same ratio (87 : 4 : 9), indicating that the respective reactions involved a common intermediate (**16**). Moreover, the reduction of the *cis*-isomer **1** with an axial methoxy group proceeded much more rapidly than that of the *trans*-isomer **2** with an equatorial methoxy.

Although the metal-in-ammonia reduction of aromatic carbocycles or heterocycles has been extensively investigated,[1] comparatively little is known about the corresponding reduction of allyl ethers and, especially, its stereochemistry.[2] In the studies aimed at establishment of C_9-configuration of jervine,[3] we found that "jervine-11β-ol" or 11-deoxojervine produced both Δ^{12}-olefin with 17β-hydrogen[4] and $\Delta^{13(17)}$-olefin with 12α-hydrogen[3] by the Birch reduction, but not any stereoisomers of the olefins. This result led us to have interest in and examine the relevant reaction of simpler, stereoisomeric allyl ethers. In this paper we describe the synthesis and chemical behavior under the Birch conditions of *c*- and *t*-6-*tert*-butyl-*r*-3-methoxy-3-methylcyclohex-1-enes (**1** and **2**).[5]

Treatment of 4-*tert*-butylanisole[6] (**3**) with lithium in liquid ammonia[7] followed by distillation afforded a mixture of dihydro compounds (**4**), bp 86—87°C/8 mmHg, in 74% yield. This on acid hydrolysis gave a 4 : 1 mixture (checked by gas chromatography; abbr., vpc) of $\alpha\beta$- and $\beta\gamma$-unsaturated ketones (**5** and **6**) in 91% yield, from which **5**, bp 101—102°C/11 mmHg, and **6**, bp 95—97°C/9 mmHg, were isolated in 42 and 14% yields, respectively, by column chromatography over silicic acid.[8] In accordance with the assigned structures, the former **5** exhibited absorptions at 224 mμ (ε 10500), at 1691 and 1618 cm^{-1}, and at τ 3.99 and 2.98 (two olefinic protons) in the UV, IR and NMR spectra, while the latter **6** those at 1720 cm^{-1} and at τ 4.48 (only one olefinic proton).

$\beta\gamma$-Unsaturated ketone **6** manifested itself to be untenable to oxidation. When allowed to stand in the air at room temperature, **6** spontaneously formed a beautiful crystalline compound (**7**), mp 106—107°C, which was analyzed for $C_{10}H_{16}O_3$, a molecular formula

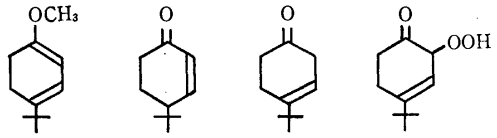
8) Lewis and Williams recently prepared these ketones **5** and **6** to determine the equilibrium ratio between them. However, the authors reported no physical constants to characterize the compounds and also the ratio in question to be 1 to 1 (vpc). K. G. Lewis and G. J. Williams, *Tetrahedron Lett.* **1965**, 4573.

corresponding to the sum of **6** and an oxygen molecule. In the IR spectrum absorption maxima appeared newly at 3200 and 1660 cm^{-1} instead of that at 1720 cm^{-1} of **6**. Similarly, in the NMR spectrum one-proton singlet and doublet were observed at τ 1.10 and 3.06 instead of the triplet at τ 4.48 of **6**. While compound **7** resisted acetylation under the usual conditions, it was reduced with sodium borohydride to give a mixture, from which a glycol (**7a**), mp 108.5—109.5°C, could be isolated in good yield by preparative tlc. This was readily converted into the acetonide (**7b**), oil, in 60% yield by treatment with acetone and silica gel (Wakogel Q-23). These findings indicated the compound to be formulated by structure **7**.

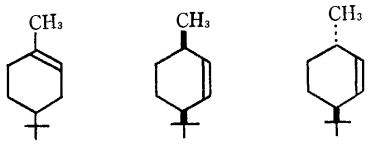


4 **5** **6** **7**

$\alpha\beta$-Unsaturated ketone **5** was treated with methyl lithium in ether[9] to produce a mixture of stereoisomeric tertiary alcohols, which were separated by column chromatography over alumina to give *cis*- and *trans*-alcohols (**8** and **9**), mp 36—37°C and 57—58°C, in 32 and 43% yields, respectively. The same treatment of $\beta\gamma$-unsaturated ketone **6** afforded the corresponding tertiary alcohol (**10**), mp 64—66°C, only in a low yield. The configurations of **8** and **9** were tentatively assigned on the basis of the R_f values on tlc or the elution sequence in column chromatography[10] as well as the predominant axial attack by Grignard reagents on unhindered ketones.[11] This assignment proved to be correct by derivation of these alcohols to the known compounds; hydrogenation of **8** and **9** over platinum yielded quantitatively the corresponding saturated alcohols (**11** and **12**), mp 65.5—67°C and 95—96°C, which were identified as *c*- and *t*-4-*tert*-butyl-1-methyl-*r*-1-cyclohexanols.[12] The olefinic alcohols **8** and **9** were then converted with methyl iodide and sodium hydride into the respective methyl ethers **1** and **2**, bp 76—78°C/25 mmHg and 88—89°C/17 mmHg, in 60 and 70% yields.

The reduction of *cis*-ether **1** with excess of lithium in ethylamine at *ca.* −70°C for 1 hr produced a 87 : 4 : 9 mixture (vpc) of three compounds (**13**, **14** and **15**), which were separated by preparative vpc into the main product **13** and the mixture of minor products **14** and **15** in 72 and 10% yields. Compound **13** was identified as 4-*tert*-butyl-1-methylcyclohexene by comparison of the authentic sample.[13] The mixture in question displayed in the NMR spectrum a broad multiplet and a sharp singlet at τ 4.43 and τ 9.13 due to *two* olefinic and *tert*-butyl protons, indicating that it consisted of stereoisomeric 3-*tert*-butyl-6-methylcyclohex-1-enes. Hydrogenation of the mixture over palladium followed by examination of the resulting saturated hydrocarbons[13] by vpc proved the minor and major components to be *cis*- and *trans*-isomers **14** and **15**, respectively.

The same reaction of *trans*-ether **2** led to the same result; formation of a 87 : 4 : 9 mixture of **13**, **14** and **15**, indicating the products to be formed through a *common* intermediate (**16**) from both the ethers **1** and **2**.



13 **14** with Δ **15** with Δ
21 without Δ **22** without Δ

The reduction was next followed by vpc with time. Thus, excess of lithium was added to a solution of *trans*-ether **2** in ethylamine at *ca.* −70°C, and a small portion of the mixture was picked up and the product components were determined in a short interval of time, after the blue color appeared. It was found that (1) the reduction was extremely fast; while 25% of the starting ether remained unchanged after 30 sec, the reaction had been completed after 50 sec, and (2) the ratio of the reaction products **13**, **14** and **15** was constant (87 : 4 : 9) before and after the starting ether reacted completely. As expected, the compound **13** or the mixture of **14** and **15** itself was recovered unchanged on treatment for 2 hr under the conditions used.

Finally it was attempted to examine the relative rates of *cis*- (**1**, axial methoxy) and *trans*-ether (**2**, equatorial methoxy); that is, equal amounts of **1** and **2** in ethylamine were reacted with excess of lithium. Interestingly, the reduction of *cis*-isomer **1** proceeded much more fast, at least with the rate of 50 times, than that of *trans*-isomer **2**, although the ratio could not be determined quantitatively owing to the extreme rapidness. These results were summarized as shown in Scheme 1.

In this Scheme, the processes of **1** or **2** to allyl radical **19** or allyl anion **16**[14] must involve the rate-determining step and would probably contain some complexes formed between metal or electron and allyl ethers such as **17** or **18**, since the reactions of **1** and **2** proceeded with the different rates and led to the same results. In view of the difficulty of reduction of an isolated double bond and of reductive cleavage of a saturated alkyl ether, it would be very improbable that the processes either consisted of two steps, addition

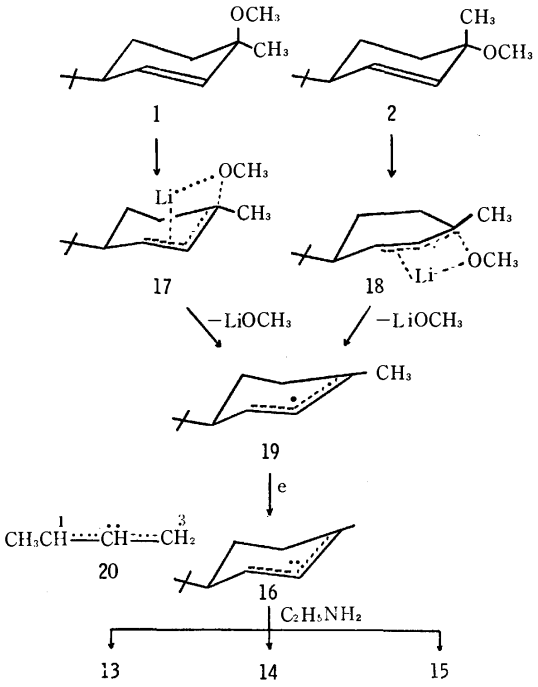
14) The transformation of **19** to **16** would proceed very readily, as the energy level of the highest half-occupied orbital of methylallyl radical corresponding to the anion **20** would be very low ($-0.10\sim-0.20\beta$). We are indebted to Mr. H. Kashiwagi in our Department for calculation as to methylallyl radical.



Scheme 1

of an electron to the double bond (the energy of lowest unoccupied molecular orbital,[15] -1.0β) and subsequent removal of the methoxy anion, or direct expulsion of the methoxy group by metal or an electron. The following step, the irreversible protonation of anion **16**, would occur most preferably at the site with the highest total π-electron density.[16] The distribution of π-electron of methylallyl anion **20** was calculated[17] by the Hückel MO orbital method, using more or less standard parameters.[18] The result showed that the site in question was the carbon atom (C_3 of **20**) unsubstituted by the methyl group (the difference in total π-electron density between C_1 and C_3, 0.15—0.25 electron). Thus the predominant formation of compound **13** would be reasonably interpreted by assuming that the afore-mentioned calculation with model **20** could be applied for the present intermediate **16**. On the other hand, the difference in formation of **14** and **15** might be rationalized on the basis of the difference in continued maximum overlap[19] between the axially oriented π-orbitals at C_1, C_2 and C_3 of **16** on approach of the proton of ethylamine, or of that in steric hindrance between the transition states leading to the products **14** and **15** from **16**. Further investigations concerning which factor is generally more or exclusively important are now in progress.

Experimental

The melting points were measured in open capillaries and uncorrected. Homogenity of each compound was always checked by tlc on silica gel (Wakogel B-5) and/or alumina (Merck G), and also by vpc (PEG-6000) with Hitachi Gas Chromatograph Model K53. The UV and IR spectra were taken in 99% ethanol and in liquid state, unless otherwise stated. The NMR spectra were measured in deuterochloroform at 60 and/or 100 MHz, TMS being used as an internal standard, unless otherwise stated. The abbreviations "s, d, t, q, br and m" in the NMR spectra denote "singlet, doublet, triplet, quartet, broad and multiplet," respectively.

4-tert-*Butylanisole (3).* 4-*tert*-Butylphenol was converted into **3** in 80% yield by the method of Olson *et al.*,[6] bp 87—88°C/8 mmHg (lit,[6] bp 232.2°C/760 mmHg); IR, ν_{max} 1610, 1247, 1183 and 1039 cm^{-1}; NMR, τ 8.71 (9H, s, *tert*-butyl), 6.23 (3H, s, $OC\underline{H}_3$), and 3.17 and 2.71 (each 1H, ABq J=9 Hz, $\underline{H}$ at C_2 and C_3).

4-tert-*Butyldihydroanisole (4).* Compound **3** was reduced under the conditions similar to those of the Birch reduction of the corresponding isopropyl derivative;[7] small pieces of lithium (6 g) were added under vigorous stirring to a solution of liquid ammonia (300 m*l*) containing **3** (20 g) in dry ether (130 m*l*) cooled with dry ice-acetone. The mixture was stirred for 30 min after the blue color appeared. The color gradually disappeared on addition of ethanol (70 m*l*). After removal of ammonia, the residue was mixed with water and extracted with ether. The ether solution was dried over anhydrous sodium sulfate, evaporated and then distilled to give **4** (14.8 g), which was used for the next reaction without further purification, bp 86—87°C/8 mmHg; IR, ν_{max} 1695, 1658 and 1608 cm^{-1}; NMR, τ 8.94 (9H, s, *tert*-butyl), 7.78 (4H, s, $\underline{H}$ at C_5 and C_6), 6.43 (3H, s, $OC\underline{H}_3$), and 5.08 and 4.37 (each 1H, ABq J=6.5 Hz, $\underline{H}$ at C_2 and C_3). The NMR spectrum indicated that the product (a single peak by vpc) would be the 5,6-dihydro derivative rather than the expected compound, 4-*tert*-butyl-3,6-dihydroanisole.

4-tert-*Butylcyclohex*-2-*en*-1-*one (5) and 4*-tert-*Butylcyclohex*-3-*en*-1-*one (6).* Compound **4** (7.4 g) was refluxed in 5% hydrochloric acid (bath temperature, 140°C) for 10 hr.[8,20] After being cooled, the mixture was treated with ether. The ether solution was washed with 5% sodium carbonate solution and water, dried and evaporated to leave oily residue, which proved to be a 79 : 21 mixture of **5** and **6** by vpc. The residue (6.27 g) was submitted to column chromatography over a mixture of silicic acid (120 g) and celite (35 g), each fraction being checked by vpc. Fractions eluted with benzene, showing a single peak, were collected and purified by distillation to give $\beta\gamma$-unsaturated ketone **6** (1.0 g), bp 95—97°C/9 mmHg; IR, ν_{max} 1720 and 809 cm^{-1}; NMR, τ 8.90 (9H, s, *tert*-butyl), 7.20 (2H, d, J= 3.5 Hz, $\underline{H}$ at C_2), and 4.48 (1H, t, J=3.5 Hz, $\underline{H}$ at C_3).

Found: C, 78.65; H, 10.88%. Calcd for $C_{10}H_{16}O$; C, 78.89; H, 10.59%.

Fractions eluted withb enzene - ether (4 : 1), showing a single peak, were treated in the same manner as mentioned above and afforded $\alpha\beta$-unsaturated ketone **5** (3.0 g), bp 101—102°C/11 mmHg; UV, λ_{max} 224 mμ (ε 10500); IR, ν_{max} 1691 and 1618 cm^{-1}; NMR, τ 9.12 (9H, s, *tert*-butyl), 3.99 (1H, double d, J=10.5 and 2.5 Hz, $\underline{H}$ at C_2), and 2.98 (1H, dobule t, J=10.8, 2.0 and 2.0 Hz, $\underline{H}$ at C_3).

Found: C, 78.77; H, 10.63%. Calcd for $C_{10}H_{16}O$: C, 78.89; H, 10.59%.

The composition ratio of **5** and **6** in the product was about 1 to 1 after 5 hr reflux in 5% hydrochloric acid, and changed

to 4 to 1 after 10 hr reflux. This ratio (4 : 1) was obtained after 3 hr reflux in 7.5% hydrochloric acid.

4-tert-*Butyl-2-hydroperoxycyclohex-3-en-1-one* (**7**). When compound **6** was allowed to stand in the air at room temperature, a crystalline substance gradually separated out. After one month compound **6** became completely crystalline. Recrystallization from carbon tetrachloride afforded hydroperoxide **7**, mp 106—107°C, UV, λ_{max} 216 mμ (ε 12600); IR (Nujol), ν_{max} 3200, 1660 and 871 cm^{-1}; NMR, τ 8.91 (9H, s, *tert*-butyl), 3.78 (1H, d, J=10.5 Hz, H at C_2), 3.06 (1H, d, J=10.5 Hz, H at C_3), and 1.10 (1H, s, OOH).

Found: C, 65.13; H, 8.84%. Calcd for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75%.

A solution of **7** (300 mg) in methanol (20 m*l*) was treated with sodium borohydride (100 mg) under cooling with ice-water and stirring for 1 hr. After addition of acetic acid (0.6 m*l*) and water (50 m*l*), the mixture was extracted with ether. The ether solution was dried and evaporated to leave crystalline substance, which showed two spots on tlc. The main product (**7a**) was obtained by preparative tlc, had mp 108.5—109.5°C, and amounted to 160 mg. Recrystallization from ether afforded an analytical sample, mp 108.5—109.5°C; IR (Nujol), ν_{max} 3250, 1050 and 951 cm^{-1}.

Found: C, 70.21; H, 11.03%. Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%.

Compound **7a** (40 mg) dissolved in a small volume of acetone was poured onto a column filled with silica gel (Wako-gel Q-23, 5.0 g) freshly washed with acetone and then with *n*-hexane, and eluted successively with *n*-hexane, and *n*-hexane - acetone (97 : 3, 95 : 5 and 92 : 8). Eluates from the solvent mixtures were purified by preparative tlc (chloroform) to give the acetonide (**7b**, 26 mg), oil; IR, ν_{max} 1060, 1030, 882, and 856 cm^{-1}; NMR, τ 8.90 (9H, s, *tert*-butyl), 8.64 (6H, s, *gem*-CH$_3$), 5.80 and 5.57 (each 1H, br, m, H at C_4 and C_3), and 4.55 (1H, br, d, J=4 Hz, H at C_2).

Found: C, 74.56; H, 10.34%. Calcd for $C_{13}H_{22}O_2$; C, 74.24; H, 10.54%.

c- *and* t-*4*-tert-*Butyl-1-methylcyclohex-2-en*-r-*1-ol* (*8 and 9*). To a cooled, suspended mixture of small pieces of lithium (7.3 g) in dry ether (200 m*l*) was added methyl iodide (30 m*l*) in dry ether (40 m*l*) under stirring and under a stream of nitrogen. The mixture was refluxed for 4 hr and then filtered rapidly through glass-wool.[9] After dropwise addition of $\alpha\beta$-unsaturated ketone **5** (10.1 g) dissolved in ether (50 m*l*) to the filtrate, the whole mixture was stirred at room temperature for 1 hr, then treated with a solution of sodium sulfate (8.0 g) and sodium thiosulfate (0.5 g) in water (100 m*l*) under cooling to decompose excess of the lithium, and extracted with ether. The ether solution was dried and evaporated to leave oily residue (11.8 g), showing two spots on tlc (benzene - ether, 5 : 1 or 4 : 1). This was separated by column chromatography over alumina (standard, active II—III, 130 g). Fractions eluted with *n*-hexane and *n*-hexane - benzene (10 : 1), showing a single spot with higher R_f value were collected and evaporated to give crystalline *cis*-alcohol (**8**, 3.45 g), which on sublimation had mp 36—37°C; IR (CS_2), ν_{max} 3620, 3400, 1100, 902 and 735 cm^{-1}; NMR, τ 9.04 (9H, s, *tert*-butyl), 8.75 (3H, s, CH$_3$ at C_1), and 4.28 (2H, br s, H at C_2 and C_3).

Found: C, 78.29; H, 11.91%. Calcd for $C_{11}H_{20}O$: C, 78.51; H, 11.98%.

Fractions eluted with *n*-hexane - benzene (10 : 1, 8 : 2, 6 : 4 and 1 : 1) showed two spots on tlc. The following fractions eluted with benzene showed a single spot with lower R_f value on tlc and afforded *trans*-alcohol **9** (4.7 g), which on sublimation had mp 57—58°C; IR (CS_2), ν_{max} 3620, 3400, 1120, 918 and 752 cm^{-1}; NMR, τ 9.09 (9H, s, *tert*-butyl), 8.76 (3H, s, CH$_3$ at C_1), and 7.81 (1H, s, OH), and 4.41 (2H, s, H at C_2 and C_3).

Found: C, 78.49; H, 11.97%. Calcd for $C_{11}H_{20}O$: C, 78.51; H, 11.98%.

cis-Alcohol **8** (50 mg) was hydrogenated over rhodium-platinum (30 mg) in ethanol (5 m*l*) for 24 hr. After filtration of the catalysis the solution was evaporated and then extracted with ether. The ether solution was washed with water, dried and evaporated to leave oily residue, which crystallized on trituration with *n*-hexane, had mp 61—63°C and amounted to 48 mg. This was distilled for purification to give *c*-4-*tert*-butyl-1-methyl-*r*-1-cyclohexanol (**11**), mp 65.5—67°C (lit,[12] mp 66—67°C); IR (CS_2), ν_{max} 3600, 1198, 1098, 1026, 990, 925, and 904 cm^{-1} (lit,[12] ν_{max} 1200, 1100, 1031, 995, 923, and 909 cm^{-1}); NMR, τ 9.14 (9H, s, *tert*-butyl) and 8.87 (3H, s, CH$_3$ at C_1).

trans-Alcohol **9** (50 mg) was hydrogenated over platinum (50 mg as PtO_2–H_2O) in methanol (5 m*l*) for 2 hr. The mixture was worked up as usual to give *t*-4-*tert*-butyl-1-methyl-*r*-1-cyclohexanol[12] (**12**, 48 mg), mp 91—93°C, which on recrystallization from aqueous methanol had mp 95—96°C (lit,[12] mp 89—90°C); IR (CS_2), ν_{max} 3600, 3340, 1137, 1100, 977, and 913 cm^{-1} (lit,[12] ν_{max} 1142, 1103, 979, and 914 cm^{-1}); NMR, τ 9.14 (9H, s, *tert*-butyl) and 8.88 (3H, s, CH$_3$ at C_1).

4-tert-*Butyl-1-methylcyclohex-3-en-1-ol* (**10**). To methyl lithium, prepared from methyl iodide (20 g), lithium (2.0 g) and dry ether (60 ml) was dropwise added $\beta\gamma$-unsaturated ketone **6** (1.0 g) in dry ether (20 m*l*). The mixture was refluxed for 25 hr under stirring and then worked up in the same manner as the case of **5** to give oily substance (1.18 g). A part (380 mg) of the oil was purified by preparative tlc (benzene - ether, 4 : 1) to yield crystalline alcohol **10** (137 mg), mp 38—40°C, which on further purification by sublimation had mp 64—66°C and amounted to 82 mg; IR (Nujol), ν_{max} 3320, 1128, 1104, and 884 cm^{-1}; NMR, τ 8.96 (9H, s, *tert*-butyl), 8.82 (3H, s, CH$_3$ at C_1), and 4.66 (1H, m, H at C_3).

Found: C, 78.35; H, 11.85%. Calcd for $C_{11}H_{20}O$: C, 78.51; H, 11.98%.

c- *and* t-*6*-tert-*Butyl*-r-*3-methoxy-3-methylcyclohex-1-enes* (*1 and 2*). A mixture of *cis*-alcohol **8** (2.7 g) and sodium hydride (2.5 g), washed with *n*-hexane repeatedly, was stirred vigorously in dry ether (180 m*l*) at room temperature for 19 hr under a stream of nitrogen. After addition of methyl iodide (50 m*l*), the whole mixture was refluxed overnight under stirring and then filtered. The filtrate was washed with water, dried, evaporated, and then distilled to give the methyl ether (**1**, 1.75 g), showing a single peak by vpc, bp 76—78°C/25 mmHg; IR ($CHCl_3$), ν_{max} 1371, 1110, 1073, 868, and 822 cm^{-1}; NMR, τ 9.10 (9H, s, *tert*-butyl), 8.81 (3H, s, CH$_3$ at C_3), 6.80 (3H, s, OCH$_3$), and 4.34 and 4.08 (each 1H, ABq, J=11 Hz, H at C_1 and C_2 or *vice versa*).

Found: C, 79.35; H, 11.98%. Calcd for $C_{12}H_{22}O$: C, 79.06; H, 12.16%.

trans-Alcohol **9** (3.2 g) was treated in the same manner (sodium hydride 2.6 g, methyl iodide 50 m*l*, and ether 200 ml) as **8**, and afforded the methyl ether (**2**, 2.40 g) after distillation, bp 88—89°C/17 mmHg; IR, ν_{max} 1368, 1110, 1078, 868, and 830 cm^{-1}; NMR, τ 9.11 (9H, s, *tert*-butyl), 8.79 (3H, s, CH$_3$ at C_3), 7.80 (3H, s, OCH$_3$), and 4.43 and 4.18 (each 1H, ABq, J=11 Hz, H at C_3 and C_2).

Found: C, 79.30; H, 11.87%. Calcd for $C_{12}H_{22}O$: C, 79.06; H, 12.16%.

Reduction of cis- *and* trans-*ethers* ***1*** *and* ***2***. To a solution of *cis*-ether **1** (2.2 g) in ethylamine (70 m*l*) cooled with dry ice - acetone (*ca.* −70°C) were added small pieces of lithium (1.0 g) under stirring, and the blue color appeared after 10 min. The mixture was further stirred for 1 hr and the reaction was stopped by addition of ammonium chloride. After removal of the ethylamine, the residue was treated with ether and water, and the ether solution was dried and evaporated carefully to leave oily substance (1.7 g), which was decolorized by passing through alumina column and proved to be a 87 : 4 : 9 mixture of three components by vpc (PEG-6000, 70°C, and nitrogen 0.9 kg/cm^2). A part (1.0 g) of the oily product was separated into the main product (0.59 g) and the mixture of two minor products (84 mg) by preparative vpc with Varian Aerograph Autoprep 700, using DGSP and helium gas (60 m*l*/min) at 60°C. The former was identified as 4-*tert*-butyl-1-methylcyclohex-1-ene (**13**) by comparison (vpc and NMR) with the authentic sample;[13] NMR, τ 9.15 (9H, s, *tert*-butyl), 8.37 (3H, br s, C$\underline{H}_3$ at C_1), and 4.70 (1H, br, $\underline{H}$ at C_2). This compound **13** (290 mg) was hydrogenated over palladium charcoal (12 mg) in ethanol (5 m*l*) according to the known procedure.[13] The vpc analysis showed the product to be a 32 : 68 mixture of *c*- and *t-r*-1-*tert*-butyl-4-methylcyclohexanes (**21** and **22**) (lit,[13] the ratio, 27 : 73).

The latter mixture was supposed to consist of stereoisomeric 3-*tert*-butyl-6-methylcyclohex-1-enes (**14** and **15**) on the basis of the NMR spectrum: τ 9.13 (9H, s, *tert*-butyl), 9.07 (3H, d, J=6 Hz, C$\underline{H}_3$ at C_6), and 4.43 (2H, br m, $\underline{H}$ at C_1 and C_2). This was supported in the following: hydrogenation of the mixture (20 mg) in the same manner as **13** produced a 31 : 69 (*ca.* 4 : 9) mixture (vpc) of the corresponding saturated *cis*- and *trans*-hydrocarbons **21** and **22**.

The reduction of *trans*-ether **2** was carried out in the same manner as that of the *cis*-isomer **1** and gave a 87 : 4 : 9 mixture of **13**, **14**, and **15**. Hydrogenation of the relevant mixture of two minor products afforded a 27 : 73 (*ca.* 4 : 9) mixture (vpc) of **21** and **22**.

To a solution of *trans*-ether **2** (2.2 g) in ethylamine (100 m*l*) cooled at *ca.* −70°C were added small pieces of lithium (0.8 g). A small fraction of the mixture was picked up in a small interval of time (30 and 50 sec, 1, 5, 10, 15, and 20 min, 1 and 1.5 hr) after the blue color appeared, and the composition of each fraction was checked by vpc. The first fraction, picked up after 30 sec, was found to contain **2**, **13**, **14**, and **15** in the ratio of *ca.* 25, 65, 3, and 7. All other fractions consisted only of **13**, **14**, and **15** with the ratio of 87, 4, and 9.

To a solution of equal amounts (150 mg) of *cis*- and *trans*-ethers (**1** and **2**) in ethylamine (30 m*l*) cooled at *ca.* −70°C was added lithium (300 mg) under vigorous stirring. A part of the mixture was taken up as soon as the blue color appeared and the components were determined by vpc, when *cis*-ether **1** practically disappeared and the ratio in area of **2** and **1** was over 50.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1816—1820 (1972)

Methylene Analogs of Cyclobutenedione. III.[1] The Reaction of 2-Bromo- and 2,2-Dibromo-3,4-bis(diphenylmethylene)cyclobutanone with Alcoholic Potassium Hydroxide

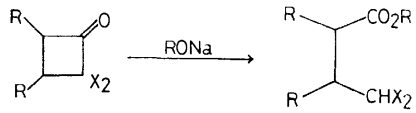
Fumio TODA and Yoshikazu TAKEHIRA

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama

(Received October 19, 1971)

The reactions of 2-bromo-3,4-bis(diphenylmethylene)cyclobutanone (III) with methanolic and 2-propanolic potassium hydroxide afforded methyl 4-methoxy-2,3-bis(diphenylmethylene)butyrate (VIII) and 3,4-bis-(diphenylmethylene)-γ-lactone (XXI) respectively. The reaction of the 2,2-dibromo analog of III (XXV) with methanolic potassium hydroxide afforded methyl 4-methoxy-4-bromo-2,3-bis(diphenylmethylene)butyrate (XXVIIIa) and methyl 4,4-diphenyl-3-formyl-2-diphenylmethylenebut-3-enate (XXIIIa) in approximately equal yields. However, the reaction of XXV with 2-propanolic potassium hydroxide afforded XXIIIc exclusively. The reaction mechanism was disclosed to be that the haloester intermediates V and XXVII initially formed from III and XXV respectively, by the addition of alcohol to the carbonyl followed by the ring-opening, react with the alkoxy and hydroxy anions competitively.

It has been reported that the reaction of 2-halo-,[2] 2,4-dihalo,[2] and 2,2-dihalocyclobutanone[3] with a base affords the corresponding cyclopropane carboxylic acid *via* a Favorskii transformation. It has also been reported that the treatment of 2,2-dihalocyclobutanone (I) with a base affords the ring-opened product (II).[3-6]



(I) (II)

1) Part II: F. Toda and K. Akagi, *Tetrahedron*, **27**, 2801 (1971). Note the change in the title of the series of publications to "Methylene Analogs of Cyclobutenedione" instead of the previously-used "Methylene Analogs of Cyclobutadienequinone." Since cyclobutadiene is not an aromatic compound, its dicarbonyl derivative is not a real quinone.

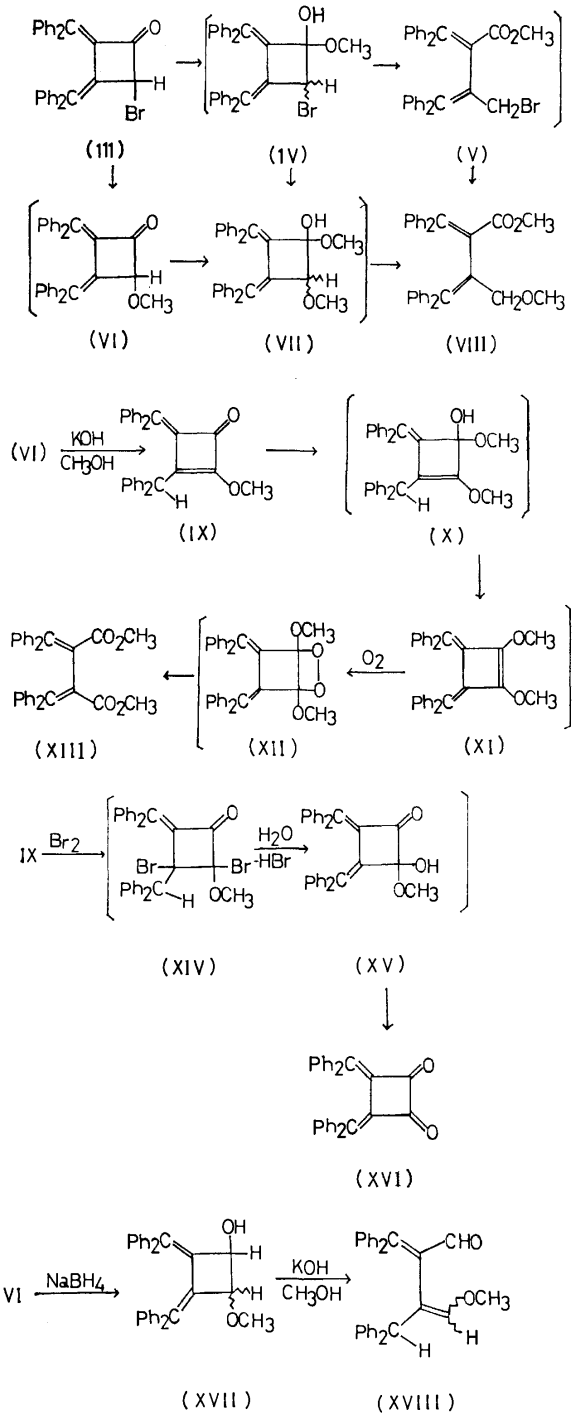
6) T. R. Patts and R. E. Harmon, *J. Org. Chem.*, **34**, 2792 (1970).

In connection with these facts, we are interested in the reaction of 2-bromo- (III) and 2,2-dibromo-3,4-bis(diphenylmethylene)cyclobutanone(XXV) with alcoholic potassium hydroxide. The actual products were compounds that were derived by the reaction of both the carbonyl and the bromine of III and XXV with the base. Therefore, of particularly interest to us the determination of the reaction site which the base attacks initially.

The reaction of III[1] with methanolic potassium hydroxide at room temperature for 6 hr afforded VIII in a 93% yield. The structure of VIII was determined by means of the spectral data described in the Experimental section. For the reaction, the two main paths are considerable, as is shown in Scheme 1. One of them proceeds *via* the VI produced by the substitution. The other one proceeds *via* the IV produced by the addition. However, any possibility of the formation of VI in the reaction is neglected, since the reaction of VI, prepared according to a previously-reported method,[1] with methanolic potassium hydroxide afforded IX and XIII in 30 and 43% yields respectively, but no detectable VIII. The structure of IX was identified by means of the spectral data shown in the Experimental section. The UV spectrum of IX in C_2H_5OH, 293 nm (ε, 17600), was comparable to that of the analogous compound, 4-diphenylmethylene-3-diphenylhydroxymethylcyclobut-2-enone in C_2H_5OH, 280 nm (ε, 15400).[1,7] The structure of IX was further identified by the reaction with bromine in chloroform to afford XVI[1] in a 30% yield. The reaction may proceed *via* XIV and XV, as is shown in Scheme 1. The structure of XIII was identified by a comparison of its spectral data with those of an authentic sample prepared by the reaction of XVI with methanol in the presence of a catalytic amount of bromine.[8]



Scheme 1.

It was proven that the IX initially produced by the 1,3-hydrogen shift of VI reacts further with sodium methoxide in the presence of oxygen and finally affords XIII, probably *via* X, XI, and XII. When VI was treated with sodium methoxide under nitrogen, IX was obtained in a 65% yield, besides a small amount of XIII (1%). The treatment of IX with the base under oxygen afforded XIII exclusively. It is probable that XI reacts with oxygen and affords XIII, since it has been established that the analogous compound, 3,4-bis(diphenylmethylene)cyclobutene, reacts with oxygen rapidly even in the course of recrystallization and affords 3,4-bis(diphenylmethylene)butanedial.[9]

On the basis of the results obtained above, the reaction path which proceeds *via* IV was established as reasonable. Nevertheless, there is still the problem to be resolved of whether the conversion of IV into VIII proceeds *via* V or VII. The possibility that VII is an intermediate can, however, be ruled out, since XVII, which is analogous to VII, showed a different type of reaction with the base. The reaction of XVII, prepared by the sodium borohydride reduction of VI, with the base afforded the vinyl ether XVIII, but no compound analogous to VIII.[10]

The reaction of III with 2-propanolic potassium hydroxide to afford XXI exclusively can also be interpreted by assuming XIX as an intermediate. The hydroxy ester, XX, produced by the reaction of XIX with the hydroxy anion undergoes intramolecular cyclization to XXI. The cyclization of XX to XXI is reasonable, since the sodium borohydride reduction of XXIIIa prepared by the reaction of XVI with

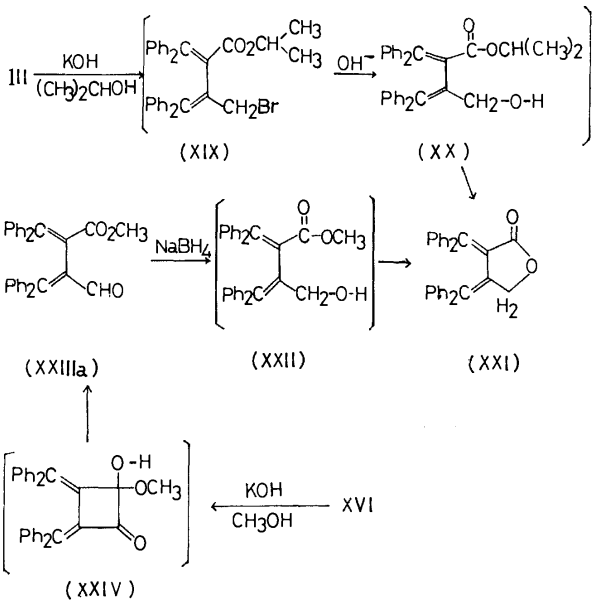
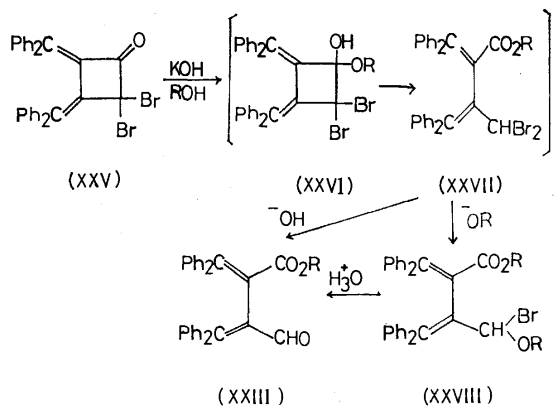


Scheme 2.

methanolic potassium hydroxide afforded XXI quantitatively, probably *via* XXII, which is analogous to XX, and since it has been established that the sodium borohydride reduction of γ-keto ester afford γ-lactones.[11,12]

Finally, the most reasonable path from III to VIII is that which proceeds successively *via* IV and V. Therefore, the reaction type of III with the base is similar to that of I to afford II.[3-6]

The reaction of XXV[1] with methanolic potassium hydroxide at room temperature for 6 hr afforded XXVIIIa and XXIIIa in 48 and 52% yields respectively. The structure of XXVIIIa was identified by means of the spectral data described in the Experimental section.

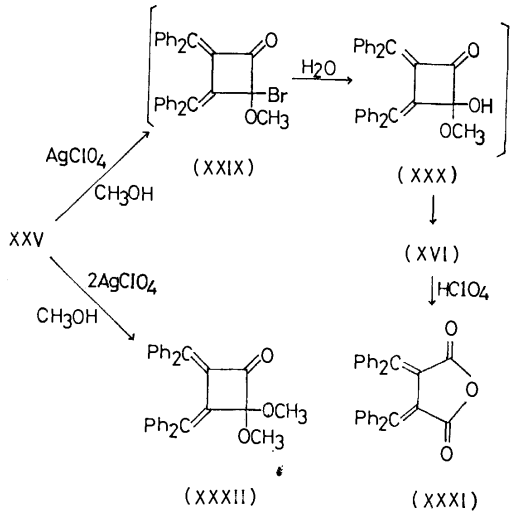


a : $R=CH_3$
b : $R=C_2H_5$
c : $R=CH(CH_3)_2$

Scheme 3.

Under the reaction conditions employed for XXV, XXVIIIa was not converted to XXIIIa, but was recovered unchanged, even though the heating of XXVIIIa with hydrochloric acid in methanol afforded XXIIIa in a 52% yield.

Since XXVIIIa is analogous to the VIII produced by the reaction of III with methanolic potassium hydroxide, a similar reaction mechanism is applicable. As is shown in Scheme 3, the XXVI initially produced by the attack of the methoxy anion on the carbonyl of XXV undergoes ring-opening to afford XXVII. The two competing reactions of XXVII with the methoxy and hydroxy anions afford XXVIII and XXIII respectively. Evidence for the presence of the competing reactions was obtained by the following experiments. When XXV was treated with ethanolic potassium hydroxide. XXVIIIb and XXIIIb were isolated in 15 and 85% yields respectively. However, the same treatment of XXV with 2-propanolic potassium hydroxide afforded XXIIIc exclusively (80% yield). The spectral data of XXVIIIb (Experimental section) were comparable to those of XXVIIIa. The spectral data of XXIIIb and XXIIIc (Experimental section) were also comparable to those of XXIIIa.



Scheme 4.

The type of the reaction of XXV with the base to afford XXVIII and XXIII *via* XXVII is also similar to that of III and of I. The monomethoxy ketone XXIX, analogous to VI, which was ruled out as a possible intermediate in the reaction of III, is probably not an intermediate for the following reasons. The reaction of XXV with an equimolar amount of silver perchlorate in wet methanol at room temperature afforded XVI and XXXI in 16 and 30% yields respectively. A reasonable reaction path is that shown in Scheme 4, since the reaction of XXV with two molar amounts of silver perchlorate in wet methanol afforded XXXII in a 55% yield, and since the oxidation of XVI into XXXI by perchloric acid has been established.[1] The high reactivity of the bromine of XXIX

12) P. de Mayo, E. Y. Spencer, and R. W. White, *Can. J. Chem.*, **41**, 2996 (1963).

13) All the IR and NMR spectra were measured in Nujol mull and $CDCl_3$ respectively.

in the acidic media suggests that XXIX in methanolic potassium hydroxide affords a halogen-free product instead of XXVIIIa.

Experimental[13]

The Reaction of III with Methanolic Potassium Hydroxide. A suspension of finely-powdered III[1] (0.35 g) in 5% methanolic potassium hydroxide (30 ml) was stirred at room temperature for 6 hr. The crude product obtained by the addition of water to the reaction mixture was collected by filtration, washed with water, and dried. The crude product was recrystallized from cyclohexane to afford VIII as colorless prisms; 0.25 g (93%); mp 152—153°C. IR, 1710 (C=O), 1435 (ester CH_3), 1265 and 1245 (ester) and 1105 cm^{-1} (C-O-C); UV, ($CHCl_3$), 234 (26400), 260 sh (16200) and 314 nm (ε, 8400); NMR, 2.7—3.2 (m, C_6H_5, 20H), 6.03 (s, CH_2, 2H), 6.53 (s, CO_2CH_3, 3H) and 6.63 τ (s, OCH_3, 3H).

Found: C, 83.38; H, 5.99%. Calcd for $C_{32}H_{28}O_3$: C, 83.48; H, 6.10%.

The Reaction of VI with Methanolic Potassium Hydroxide. A suspension of finely-powdered VI[1] (0.5 g) in 5% methanolic potassium hydroxide (20 ml) was stirred at room temperature for 20 hr. The yellow crystals which separated out were collected by filtration, washed with methanol, and recrystallized from acetone to afford XIII as yellow needles; 0.24 g (43%); mp 233—234°C (lit,[8] 233—234°C). The spectral data were identical with those of an authentic sample prepared by a separate method.[8]

The addition of water to the mother liquor remaining after the separation of the crude crystals of XIII by filtration afforded crude crystals. The recrystallization of the crude crystals from cyclohexane afforded IX as colorless prisms; 0.15 g (30%); mp 126—127°C. IR, 1760 (C=O), 1650 (*exo* C=C), 1590 (*endo* C=C), 1290 (=C-O-) and 1080 and 1060 cm^{-1} (C-O-C); UV (C_2H_5OH), 293 nm (ε, 17600); NMR, 2.6—3.2 (m, C_6H_5, 20H), 5.33 (s, CH, 1H) and 5.95 τ (s, CH_3, 3H).

Found: C, 86.27; H, 5.51%. Calcd for $C_{31}H_{24}O_2$: C, 86.89; H, 5.65%.

When a suspension of VI (0.2 g) in 5% methanolic potassium hydroxide (50 ml) was stirred for 24 hr at room temperature under nitrogen, and when the reaction mixture was then treated as above, 0.13 g (65%) of IX and 2 mg (1%) of XIII were isolated.

The Reaction of IX with Methanolic Potassium Hydroxide under Oxygen. A solution of IX (0.12 g) in 5% methanolic potassium hydroxide (20 ml) was stirred at room temperature under oxygen for 24 hr. The yellow crystals which separated out were collected and recrystallized from acetone to afford XIII as yellow needles; 0.05 g (40%); mp 233—234°C.

The Reaction of IX with Bromide. One drop of bromine was added to a solution of IX (0.05 g) in chloroform (5 ml). The crude product which remained after the evaporation of the solvent was recrystallized from cyclohexane to afford XVI as green needles; 0.015 g (30%); mp 206—207°C (lit,[1] 206—207°C). The spectral data were identical with those reported.[1]

The Preparation of XXIIIa. A suspension of XVI[1] (0.4 g) in 5% methanolic potassium hydroxide (20 ml) was heated under reflux for 10 min. The crude product obtained by the addition of water to the reaction mixture was collected by filtration, washed with water, and dried. The recrystallization of the crude product from cyclohexane afforded XXIIIa as pale yellow prisms; 0.35 g (80%); mp 160—161°C. IR, 2780 (CHO), 1700 (ester C=O), 1660 (aldehyde C=O) and 1265 cm^{-1} (ester); UV (CH_3OH), 236 (20500), 289 (13700) and 335 nm (ε, 7500); NMR, 0.52 (s, CHO, 1H), 2.5—3.1 (m, C_6H_5, 18H), 3.35 (m, C_6H_5, 2H) and 6.50 τ (s, CH_3, 3H).

Found: C, 83.41; H, 5.38%; Mol wt (benzene), 436. Calcd for $C_{31}H_{24}O_3$: C, 83.76; H, 5.44%. Mol wt, 444.

The Preparation of XXI. To a solution of XXIIIa (0.55 g) in tetrahydrofuran (10 ml), we added an excess of sodium borohydride (0.2 g). The reaction mixture was decomposed with water and extracted with benzene. The benzene solution was washed with water and dried over sodium sulfate. The crude product obtained by the evaporation of the solvent was recrystallized from methanol to afford XXI as yellow prisms; 0.32 g (62%); mp 221—222°C. IR, 1750 (C=O), 1580 (C=C) and 1130 cm^{-1} (lactone); UV (C_2H_5OH), 258 (22200) and 388 nm (ε, 9200); NMR, 2.5—3.6 (m, C_6H_5, 20 H) and 5.02 τ (s, CH_2, 2H).

Found: C, 86.37; H, 5.28%; Mol wt (*m/e*), 414. Calcd for $C_{30}H_{22}O_2$: C, 86.93; H, 5.35%; Mol wt, 414.

The Reaction of III with 2-propanolic Potassium Hydroxide. A suspension of finely-powdered III (0.5 g) in 5% 2-propanolic potassium hydroxide (50 ml) was stirred at room temperature for 4 hr. The recrystallization of the crude product obtained by the addition of water to the reaction mixture from cyclohexane afforded XXI as yellow prisms; 0.15 g (35%); mp 221—222°C. Its spectral data were identical with those described above.

The Reaction of XXV with Methanolic Potassium Hydroxide. A suspension of finely-powered XXV (0.58 g) in 5% methanolic potassium hydroxide was stirred at room temperature for 6 hr. The crude product thus formed was collected by filtration, washed with water, and recrystallized from benzene-petroleum ether (bp 70—80°C) to afford XXVIIIa as colorless prisms; 0.28 g (48%); mp 182—183°C. IR, 1720 (C=O), 1240 (ester) and 1090 and 1080 cm^{-1} (C-O-C); UV ($CHCl_3$), 272 nm (ε, 9100); NMR, 2.6—3.0 (m, C_6H_5, 20H), 3.65 (s, CH, 1H), 6.85 (s, CH_3, 3H) and 7.08 τ (s, CH_3, 3H).

Found: C, 71.34; H, 5.36%; Mol wt (benzene), 525. Calcd for $C_{32}H_{27}O_3Br$: C, 71.14; H, 5.04%; Mol wt, 539.

The mother liquor remaining after the separation of the crude XXVIIIa by filtration was diluted with water. The crude crystals which separated out were recrystallized from cyclohexane to afford XXIIIa as pale yellow prisms; 0.28 g (52%); mp 160—161°C. Its spectral data were identical with those recorded for an authentic sample prepared from XVI.

The Reaction of XXV with Ethanolic Potassium Hydroxide. When a suspension of XXV (0.46 g) in 5% ethanolic potassium hydroxide (50 ml) was treated by the same procedure employed for the reaction of XXV with methanolic potassium hydroxide, 0.07 g (15%) of XXVIIIb, mp 175—176°C and 0.35 g (85%) of XXIIIb, mp 165—166°C were obtained.

The structure of XXVIIIb was identified by means of the following spectral and analytical data. IR, 1695 (C=O), 1250 (ester) and 1065 cm^{-1} (C-O-C); UV ($CHCl_3$), 275 nm (ε, 8700); NMR, 2.5—3.2 (m, C_6H_5, 20 H), 3.65 (s, CH, 1H), 6.35 (q, J=7.5 Hz, CH_2, 2H), 7.08 (q, J=7.5 Hz, CH_2, 2H), 8.93 (t, J=7.5 Hz, CH_3, 3H), and 9.25 τ (t, J= 7.5 Hz, CH_3, 3H).

Found: C, 71.24; H, 5.09%; Mol wt (benzene), 549. Calcd for $C_{34}H_{31}O_3Br$: C, 71.86; H, 5.49; Mol wt, 567.

The structure of XXIIIb was identified by means of the following spectral and analytical data. IR, 2720 (CHO), 1690 (ester C=O), 1650 (aldehyde C=O) and 1260 cm^{-1}

(ester); UV (C_2H_5OH), 236 (19300), 289 (12100) and 332 sh nm (ε, 6700); NMR, 0.94 (s, CHO, 1H), 2.85 (m, C_6H_5, 18H), 3.40 (m, C_6H_5, 2H), 6.01 (q, J=7.5 Hz, CH_2, 2H) and 9.15 τ (t, J=7.5 Hz, CH_3, 3H).

Found: C, 84.35; H, 5.62%. Calcd for $C_{32}H_{26}O_3$: C, 83.84; H, 5.68%.

The Reaction of XXV with 2-Propanolic Potassium Hydroxide. A suspension of finely-powdered XXV (0.5 g) in 5% 2-propanolic potassium hydroxide (50 m*l*) was stirred at room temperature for 6 hr. The crude product formed by the addition of water to the reaction mixture was recrystallized from cyclohexane to afford XXIIIc as pale yellow prisms; 0.3 g (80%); mp 115—116°C. IR, 2720 (CHO), 1685 (ester C=O) 1650 (aldehyde C=O) and 1260 cm^{-1} (ester). The IR spectrum was comparable to those of XXIIIa and XXIIIb.

Found: C, 83.65; H, 5.82%. Calcd for $C_{33}H_{28}O_3$: C, 83.87; H, 5.97%.

The Acid-catalyzed Hydrolysis of XXVIII. A solution of XXVIIIa (0.15 g) in methanol (50 m*l*) containing five drops of concentrated hydrochloric acid was heated under reflux for 3 hr. The crude product which remained after the evaporation of the solvent to dryness was recrystallized from cyclohexane to afford XXIIIa; 0.064 g (52%).

The same treatment of XXVIIIb (0.21 g) afforded XXIIIb; 0.1 g (60%).

The Reaction of XXV with Methanol in the Presence of Silver Perchlorate. To a solution of XXV (0.6 g) in methanol (5 m*l*) - tetrahydrofuran (5 m*l*), we added an equimolar amount of silver perchlorate (0.2 g). After the removal of the silver bromide formed by filtration, the filtrate was evaporated to dryness. The residue was taken up in ether (100 m*l*), and the ether solution was washed successively with aqueous sodium chloride and water and dried over sodium sulfate. The evaporation of the solvent afforded a mixture of red and green crystals. After the recrystallization from cyclohexane, this mixture was separated mechanically into components. Each component was further recrystallized from cyclohexane. Red rhombs (0.14 g (30%)) were identified as the anhydride XXXI by a comparison of its spectral data with those recorded for an authentic sample[1]. Green needles (0.07 g (16%)) were found to be the diketone XVI[1] by the same spectroscopic method.

When XXV (0.6 g) was treated with two molar amounts of silver perchlorate (0.4 g) by the same procedure as that employed for the reaction of XXV with an equimolar amount of silver perchlorate, 0.27 g (55%) of XXXII was obtained as the sole product. The structure of XXXII was identified by a comparison of its spectral data with those of an authentic sample prepared according to a previously-reported method.[1]

The authors wish to express their thanks to Mr. Shoichi Kato for the elemental analyses, to Miss Shizuko Konomi for her measurement of the NMR spectra, and to Miss Sayumi Asakawa for her measurement of the UV spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1820—1824 (1972)

Methylene Analogs of Cyclobutenedione. IV.[1] The Reaction of 3,4-Bis(diphenylmethylene)cyclobutanedione Monoacetal and Its Derivatives with Methanolic Potassium Hydroxide

Fumio TODA and Nobuhiro OOI

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama

(Received October 19, 1971)

The reaction of 2,2-dimethoxy-3,4-bis(diphenylmethylene)cyclobutanone (II), 2,2-dimethoxy-3,4-bis(diphenylmethylene)cyclobutanol (III), 2-hydroxy-3,4-bis(diphenylmethylene)cyclobutanone (IV), and 2-methoxy-3,4-bis(diphenylmethylene)cyclobutanol (VIII) with methanolic potassium hydroxide was studied. The three methoxy compounds, II, III, and VIII, afforded the ring-opened products, methyl 4,4-dimethoxy-2-diphenylmethylene-3-diphenylmethylbut-3-enate (X), 4,4-dimethoxy-2-diphenylmethylene-3-diphenylmethylbut-3-enal (XIII), and 4-methoxy-2-diphenylmethylene-3-diphenylmethylbut-3-enal (XVI) respectively. However, the ketoalcohol IV afforded the enolizable cyclobutenedione, 3,4-bis(diphenylmethyl)cyclobutenedione (XXI).

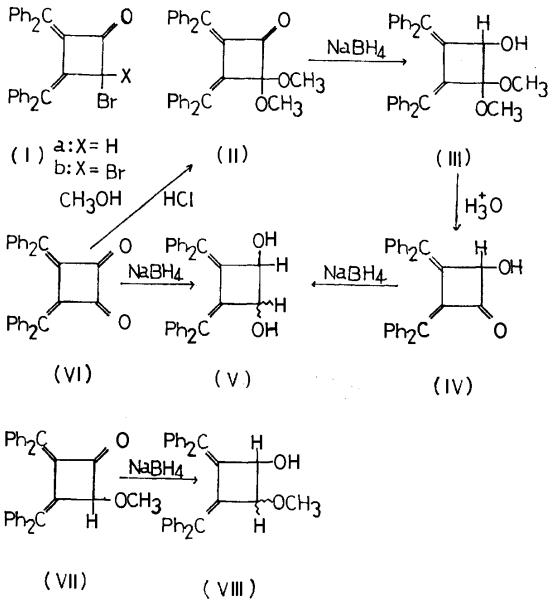
In a previous paper of this series,[1] we have reported the reaction of 2-bromo- (Ia) and 2,2-dibromo-3,4-bis(diphenylmethylene)cyclobutanone (Ib) with alcoholic potassium hydroxide to afford ring-opened products. In the reaction, it has been established that the base attacks the carbonyl initially. In order to certify the generality of the reaction mode, we have studied the reactions of II, III, IV, and VIII with methanolic potassium hydroxide.

Preparation of Compounds II, III, IV, and VIII. The ketoketal II was prepared in a 73% yield according to a previously-reported method,[2] the heating of Ib with methanol. The compound was also prepared in a 91% yield by the heating of a solution of 3,4-bis(diphenylmethylene)cyclobutanedione (VI)[2] in methanol containing a catalytic amount of hydrogen chloride.

The reduction of II in methanol with sodium borohydride afforded the corresponding alcohol III in almost a quantitative yield. The structure of III was identified by means of the spectral data[3] described in the Experimental section. Particularly, the elec-

1) Part III, F. Toda and Y. Takehira, This Bulletin, **45**, 1816 (1972).

2) F. Toda and K. Akagi, *Tetrahedron*, **27**, 2801 (1971).



Scheme 1.

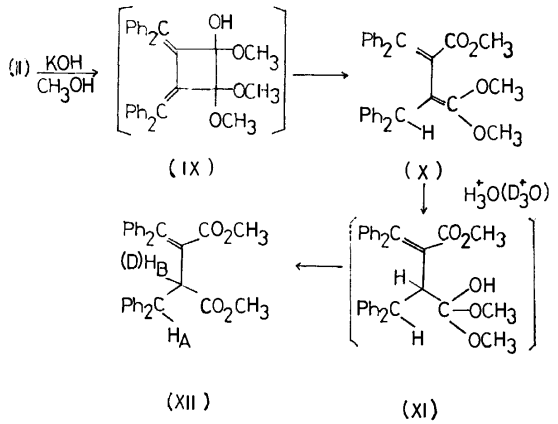
tronic absorption band of III, 365 nm (ε, 16800), was comparable to those of various 1,2-bis(diphenylmethylene)cyclobutane derivatives, 357—400 nm (ε, 15000—20000).[2,4]

The acid-catalyzed hydrolysis of III afforded the keto alcohol IV in a quantitative yield. The structure of IV was determined by means of the spectral data (Experimental section).

The structure of IV was further confirmed by the sodium borohydride reduction to the corresponding diol V, the spectral data of which were identical with those recorded for the diol[2,5] prepared by the sodium borohydride reduction of VI. Of the three compounds prepared, II, III, and IV, III differs in stability from the other two. In an atmosphere, III decomposed gradually and was converted finally into IV.

Monomethoxycyclobutanol VIII was obtained in a 46% yield by the sodium borohydride reduction of VII, which had been prepared by the reaction of Ia with methanol in the presence of silver perchlorate according to a previously-reported procedure.[2] The structure of VIII was identified by means of the spectral data (Experimental section), even though the configurational relationship between hydroxy and methoxy was not clear.

The Reaction with Methanolic Potassium Hydroxide. The heating of a solution of II and potassium hydroxide in methanol under reflux for 17 hr afforded X in a 72% yield. The structure of X was determined by means of the spectral data (Experimental section). In the NMR spectrum, X showed two methoxy methyl signals at 6.58 and 7.24 τ. The nonequivalence of the two methoxy methyls agrees with the structure bearing a *gem*-dimethoxy ethylene moiety. The structure of X was further identified by an acid-catalyzed hydrolysis, which afforded dimethyl 2-diphenylmethyl-3-diphenylmethylenesuccinate (XII), probably *via* the intermediate XI (Scheme 2). The structure of XII was identified by means of the spectral data described in the Experimental section. The assignment of the two AB-type doublets, 4.90 and 5.40 τ, was performed with using the monodeutero compound XII-*d*, prepared by the reaction of X with DCl in D_2O. Since XII-*d* showed a singlet at 4.92 τ, the doublet at the lower field (4.90 τ) can be assigned to the benzylic methine proton, H_A.



Scheme 2.

The reaction of II with methanolic potassium hydroxide to afford X can be interpreted by assuming the trimethoxy alcohol IX, as an intermediate. Therefore, the alcohol IX, initially produced by the action of methoxy anion on the carbonyl of II can be led to X by ketonization, accompanied by ring-opened, as is shown in Scheme 2. If the assumption is correct, the alcohols III and VIII would react with methanolic potassium hydroxide in the same fashion as that of II.

The reaction of III with methanolic potassium hydroxide under the same conditions as those employed for II was completed in 1 hr and afforded XIII in a quantitative yield. The structure of XIII was identified by means of the spectral data. IR, 2720 (CHO), 1665—1650 (C=O and C=C) and 1240 and 1230 cm^{-1} (C=C–O); UV, 291 (8700) and 356 nm (ε, 3800); NMR, 0.66 (s, CHO, 1H), 2.5—3.5 (m, C_6H_5, 20H), 5.51 (s, CH, 1H), 6.51 (s, OCH_3, 3H) and 7.22 τ (s, OCH_3, 3H). The UV spectrum of XIII was comparable to that of X. Since the two absorption bands of $\nu_{C=O}$ and $\nu_{C=C}$ overlapped and appeared at 1665—1650 cm^{-1} as a broad band, it was impossible to assign each band. The presence of a methoxy-substituted ethylene was certified for the 4,4-dimethoxy-3-diphenylmethyl-2-diphenylmethylene-but-3-enol (XV) obtained quantitatively by the sodium borohydride reduction of XIII. The alcohol XV showed a strong band at 1665 cm^{-1} which was assignable to the methoxy-substituted ethylene.

Further structural proof for XIII was obtained by means of its acid-catalyzed reaction. The treatment of XIII with hydrochloric acid under the same condi-

3) All the IR, UV, and NMR spectra were recorded in Nujol mull, ethanol, and $CDCl_3$ respectively.

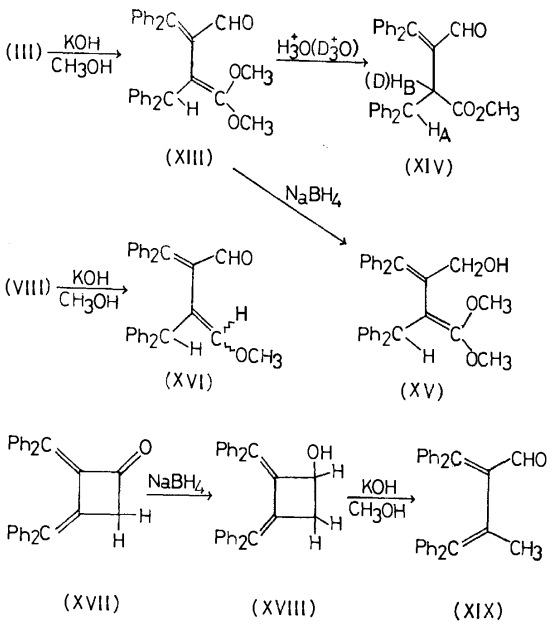


Scheme 3.

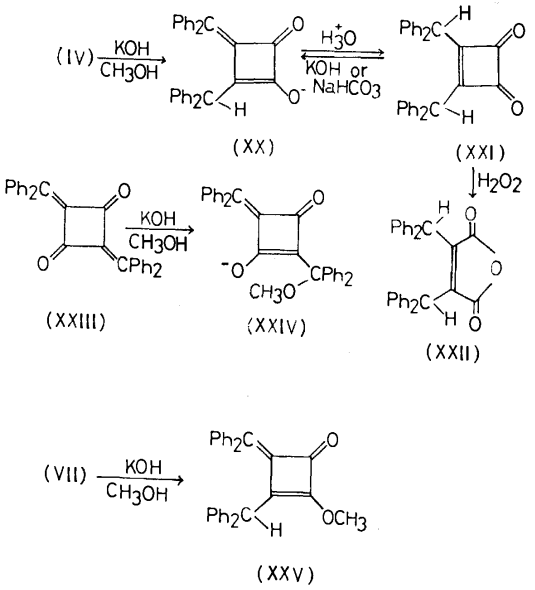
tions as those employed for X afforded methyl 2-diphenylmethyl-3-formyl-4,4-diphenylbut-3-enate (XIV) quantitatively. The structure of XIV was determined by means of the spectral data described in the Experimental section. The assignment of the two AB-type doublets of XIV, 4.88 and 5.34 τ, was performed again on the monodeutero derivative, XIV-*d*, prepared by the reaction of XIII with DCl in D_2O. Since XIV-*d* showed a singlet at 4.89 τ, but no other methine proton signal, the signal at 4.88 τ of XIII can be assigned to the benzylic methine proton, H_A.

The same reaction mode as that of II and III was observed in the case of VIII. The heating of VIII with methanolic potassium hydroxide under reflux for 5 hr afforded 4-methoxy-3-diphenylmethyl-2-diphenylmethylenebut-3-enal (XVI) in a 56% yield. The structure of XVI was identified by means of the spectral data. IR, 2720 (CHO), 1670 (C=O) and 1640 cm^{-1} (C=C); UV, 248 (16200), 299 (8600) and 370 sh nm (ε, 3600); NMR, 0.76 (s, CHO, 1H), 2.81 (m, C_6H_5, 18H), 3.34 (m, C_6H_5, 2H), 4.52 (d, J=0.7 Hz, =CH, 1H), 5.41 (d, J=0.7 Hz, CH, 1H) and 6.48 τ (s, CH_3, 3H). The NMR spectral data show the presence of a coupling between the methine proton and the vinyl proton. Since the long-range coupling across one double and three single bonds is well established as an allylic coupling,[6] the NMR spectrum of XVI can be well interpreted by its structure. However, the geometry around the double bond bearing the methoxy group was not determined.

A comparison of the three reactions of II, III, and VIII with methanolic potassium hydroxide makes it clear that the ketone II reacts more slowly than do the alcohols III and VIII. However, it is not clear which, the addition of methanol to the carbonyl of II or the ring-opening of IX, is more retarded.

All the three products, X, XIII, and XVI, have a vinylether structure. It is reasonable to consider that the double bonds of those products are stabilized by one or two methoxy groups, because the reaction of XVIII with methanolic potassium hydroxide afforded 2,3-bis(diphenylmethylene)butan-1-al (XIX). The reaction of XVIII prepared by the sodium borohydride reduction of 2,3-bis(diphenylmethylene)-cyclobutanone (XVII) according to a reported method,[2] with methanolic potassium hydroxide under the same conditions as those employed for VIII, was finished within 10 min and afforded XIX in an 80% yield. The structure of XIX was identified by means of the spectral data (Experimental section).

In order to clarify which, the addition of methanol to the carbonyl of II or the ketonization of IX, occurs more easily, the keto alcohol IV, was reacted with methanolic potassium hydroxide. Contrary to expectations, IV did not give any ring-opened product. Although IV is almost insoluble in methanol, it dissolved in methanolic potassium hydroxide easily. The acidification of the solution afforded 3,4-bis(diphenylmethyl)cyclobutenedione (XXI) in a 62% yield.



Scheme 4.

The UV spectrum of IV (or of XXI) in 5% methanolic potassium hydroxide, 330 nm (ε, 21700), was comparable to that of the enolate anion (XXIV) obtained by dissolving 2,4-bis(diphenylmethylene)-cyclobutanedione (XXIII) in 5% methanolic potassium hydroxide, 324 nm (ε, 24600).[7] Therefore, IV and XXI must dissolve in the base in the form of the enolate anion, XX. Since the base-catalyzed rearrangement of VII to 4-diphenylmethylene-3-diphenylmethyl-2-methoxycyclobut-2-enone (XXV) has been reported,[1] the base-catalyzed 1,3-hydrogen shift may be characteristic for a system such as IV or VII.

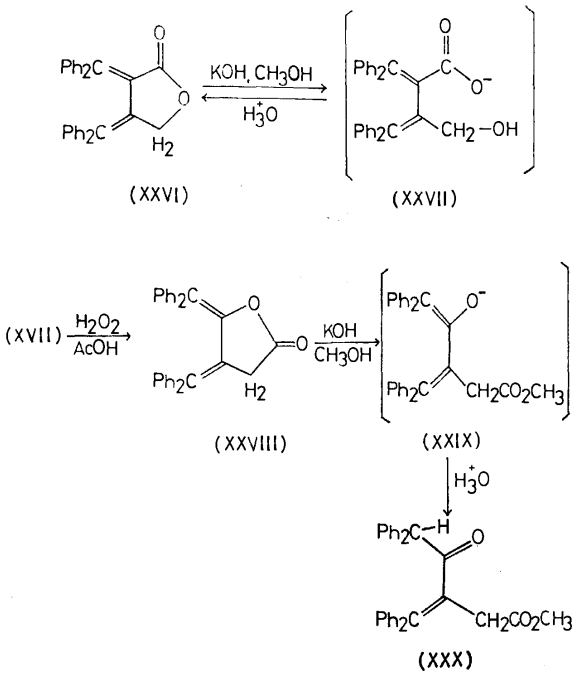
7) G. A. Taylor, *J. Chem. Soc.*, *C*, **1969**, 1755.

All the cyclobutenediones except squaric acid and its derivatives which have been reported to date are sensitive to the base, and all undergo ring-cleavage.[8] The enolization of XXI in the base without ring cleavage differs widely from these facts. The acidity of the benzylic hydrogen of XXI is relatively strong, and XXI dissolves in even methanolic sodium bicarbonate. In connection with the strong acidity[9] of squaric acid, the acidic nature of the hydrogen of XXI is interesting.

Further structural proof for XXI was obtained by oxidation with neutral hydrogen peroxide which afforded bis(diphenylmethyl)maleic anhydride (XXII) in a 24% yield. It is well established that cyclobutenediones undergo a Baeyer-Villiger oxidation with neutral hydrogen peroxide to afford the corresponding maleic anhydrides.[8]



Scheme 5.

Any possibility that the compound derived from IV is a γ-lactone, such as XXVI or XXVIII, is ruled out. 3,4-Bis(diphenylmethylene)-γ-lactone (XXVI) was prepared according to the reported method;[1] it was dissolved in methanolic potassium hydroxide, probably by the formation of a carboxylate anion like XXVII, and XXVI was reformed by acidification. The behavior is similar to that of XXI; however, the spectral data which have been recorded for XXVI differ from those of XXI. 4,5-Bis(diphenylmethylene)-γ-lactone (XXVIII), prepared by the oxidation of XVII according to Corey's procedure,[10] was also dissolved in methanolic potassium hydroxide, probably in the form of an enolate anion like XXIX. However, the ketone XXX was obtained by the acidification of the alkaline solution. Both the spectral data of XXVIII and of XXX are also different from those of XXI (Experimental section).

Experimental[3]

Preparation of III. A suspension of II (5.00 g) in ethanol (100 m*l*) was treated with a large excess of sodium borohydride at 50—60°C for 1 hr. After the reaction mixture had been decomposed with water, the crude product which was separated out was collected by filtration, washed with water, and dried to afford III; 4.71 g (94%). The recrystallization of the product from ethyl acetate gave an analytical pure sample as pale yellow prisms; 4.0 g (80%); mp 131—132°C. IR, 3480 cm^{-1} (OH); UV, 365 nm (ε, 16800); NMR, 2.83 (d, C_6H_5, 10H), 3.18 (d, C_6H_5, 10H), 4.87 (d, J=10 Hz, CH, 1H), 6.53 (s, OCH_3, 3H), 6.83 (s, OCH_3, 3H) and 7.60 τ (d, J=10 Hz, OH, 1H).

Found: C, 83.30; H, 5.97%. Calcd for $C_{32}H_{28}O_3$: C, 83.45; H, 6.13%.

Preparation of IV. To a solution of III (0.60 g) in acetone (10 m*l*), several drops of concentrated hydrochloric acid were added. Crude crystals formed by the addition of water to the reaction mixture were collected by filtration, washed with water, and dried to afford IV; 0.53 g (99%). Recrystallization of the crude crystals from ethyl acetate afforded a pure sample as fine orange needles; 0.425 g (79%); mp 185—186°C. IR, 3420 (OH) and 1775 cm^{-1} (C=O); UV, 271 (15600), 329 (5000) and 422 nm (ε, 9200); NMR, 2.68 (d, C_6H_5, 10H), 3.18 (d, C_6H_5, 10H), 4.44 (s, CH, 1H) and 7.63 τ (s, OH, 1H).

Found: C, 86.74; H, 5.18%. Calcd for $C_{30}H_{22}O_2$; C, 86.93; H, 5.35%.

A suspension of IV (0.25 g) in ethanol (10 m*l*) was treated with a large excess of sodium borohydride at room temperature for 5 min. The crystals formed were collected by filtration, washed with water, and dried to afford V as pale yellow needles; 0.23 g (92%); mp 222—223°C (lit,[2,4] mp 222—223°C). The spectral data were identical with those of an authentic sample prepared according to a previously-reported method.[2,4]

Preparation of VIII. The treatment of VII[2] (0.50 g) in methanol (10 m*l*) with sodium borohydride by the same method as that employed for III afforded VIII as yellow needles; 0.23 g (46%); mp 167—170°C. IR, 3420 cm^{-1} (OH); UV, 365 nm (ε, 17400); NMR, 2.25 (s, C_6H_5, 10H), 3.22 (s, C_6H_5, 10H), 5.18 (d, J=5 Hz, CH, 1H), 5.53 (d, J=5 Hz, CH, 1H), 6.69 (s, CH_3, 3H) and 7.2 τ (broad, OH, 1H).

Found: C, 86.00; H, 5.84%. Calcd for $C_{31}H_{26}O_2$: C, 86.48; H, 6.09%.

Ring-opening Reaction of II. A solution of II (0.30 g) and a large excess of potassium hydroxide (2.5 g) in THF (15 m*l*) - methanol (35 m*l*) was heated under reflux for 17 hr. After decomposition with water, the crude crystals which separated out were collected by filtration, washed with water, and dried to give X; 0.23 g (74%). Recrystallization from cyclohexane gave pure X as colorless prisms; mp 118—119°C. IR, 1710 (C=O), 1655 (C=C), 1240 (ester) and 1250 cm^{-1} (=C–O–); UV, 238 sh (18300) and 315 nm (ε, 6300); NMR, 2.7—3.2 (m, C_6H_5, 20H), 5.45 (s, CH, 1H), 6.58 (s, OCH_3, 3H), 6.68 (s, CO_2CH_3, 3H) and 7.24 τ (s, OCH_3, 3H).

Found: C, 80.97; H, 6.55%; Calcd for $C_{33}H_{30}O_4$; C, 80.79; H, 6.16%.

Acid-catalyzed Hydrolysis of X. A solution of X (0.09 g) in acetone (5 ml) containing a catalytic amount of hydrochloric acid was heated at 50—60°C for 5 min. The crude crystals formed by the addition of water were filtered, washed with water, and dried to yield XII; 0.08 g (92%). Recrystallization of the crude crystals from methanol gave pure XII as colorless prisms; mp 164—165°C. IR, 1738 (C=O), 1725 (C=O), 1260 (ester) and 1240 cm^{-1} (ester); UV, 264 nm (ε, 7100); NMR, 2.6—3.3 (m, C_6H_5, 20H), 4.90 (d, J=12 Hz, H_A, 1H), 5.40 (d, J=12 Hz, H_B, 1H), 6.45 (s, CO_2CH_3, 3H) and 6.62 τ (s, CO_2CH_3, 3H).

Found: C, 80.22; H, 5.86%. Calcd for $C_{32}H_{28}O_4$: C, 80.64; H, 5.92%.

Ring-opening Reaction of III. A suspension of III (0.50 g) and potassium hydroxide (0.4 g) in methanol (10 ml) was heated under reflux for 1 hr. After decomposition with water, the crude crystals which had formed were filtered, washed with water, and dried to afford XIII; 0.49 g (98%). The recrystallization of the crystals from ethyl acetate yielded pure XIII as yellow prisms; mp 113—114°C.

Found: C, 83.37; H, 5.99%. Calcd for $C_{32}H_{28}O_3$: C, 83.45; H, 6.13%.

The aldehyde XIII (0.09 g) in methanol (5 ml) was treated with an excess of sodium borohydride at 50—60°C for 5 min. Crude crystals (0.09 g (100%)) obtained by the decomposition of the reaction mixture were recrystallized from methanol to afford pure XV as colorless prisms; mp 148—148.5°C. IR, 3520 (OH), 1665 (C=C) and 1240 cm^{-1} (=C–O); UV, 237 sh (9500), 271 sh (4200) and 279 sh nm (ε, 3500); NMR, 2.5—3.5 (m, C_6H_5, 20H), 5.45 (s, CH, 1H), 6.05 (d, J=6 Hz, CH_2, 2H), 6.42 (s, OCH_3, 3H), 7.33 (s, OCH_3, 3H) and 8.87 τ (t, J=6 Hz, OH, 1H).

Found: C, 83.06; H, 6.47%. Calcd for $C_{32}H_{30}O_3$: C, 83.01; H, 6.54%.

Acid-catalyzed Hydrolysis of XIII. To a solution of XIII (0.14 g) in acetone, a few drops of concentrated hydrochloric acid were added, and then the mixture was heated at 50—60°C for 5 min. Crystals (0.13 g (96%)) obtained by the addition of water to the reaction mixture were recrystallized from cyclohexane to afford pure XIV as colorless needles; mp 204—205°C. IR, 2720 (CHO), 1745 (CO_2CH_3), 1660 (CHO) and 1240 cm^{-1} (ester); UV, 238 sh (18300) and 315 nm (ε, 6300); NMR, 0.83 (s, CHO, 1H), 2.4—3.7 (m, C_6H_5, 20H), 4.88 (d, J=11 Hz, H_B, 1H), 5.34 (d, J=11 Hz, H_A, 1H) and 6.36 τ (s, CH_3, 3H).

Found: C, 83.71; H, 5.81%. Calcd for $C_{31}H_{26}O_3$: C, 83.38; H, 5.87%.

To a solution of XIII (0.10 g) in THF (5 ml), was added a few drops of concentrated deuterochloric acid, and then the mixture was heated at 50—60°C for 5 min. The same treatment of the reaction mixture as above afforded XIV-*d* after recrystallization from cyclohexane; 0.08 g (82%).

Ring-opening Reaction of VIII. A solution of VIII (0.32 g) and potassium hydroxide (0.5 g) in methanol (10 ml) was heated under reflux for 5 hr. Crude crystals obtained by the addition of water to the reaction mixture were recrystallized from benzene to afford XVI as yellow prisms; 0.18 g (56%); mp 187°C.

Found: C, 86.25; H, 6.07%. Calcd for $C_{31}H_{26}O_2$: C, 86.48; H, 6.09%.

Ring-opening Reaction of XVIII. A mixture of XVIII (0.40 g), potassium hydroxide (0.5 g), and methanol (20 ml) was heated under reflux for 10 min. Crude crystals obtained by the decomposition of the reaction mixture were recrystallized from petroleum ether (bp 60—70°C) to afford XIX as pale yellow plates; 0.32 g (80%); mp 141—142°C. IR, 2720 (CHO) and 1655 cm^{-1} (C=O); UV, 235 sh (22100), 270 sh (14300) and 305 sh nm (ε, 8600); NMR, 0.55 (s, CHO, 1H), 2.6—3.4 (m, C_6H_5, 20 H) and 7.98 τ (s, CH_3, 3H).

Found: C, 89.60; H, 5.88%. Calcd for $C_{30}H_{24}O$: C, 89.96; H, 6.04%.

Isomerization of IV to XXI. A mixture of IV (1.65 g), potassium hydroxide (1.0 g), and methanol (15 ml) was heated under reflux for 5 min to afford a clear solution. The crude crystals obtained by the acidification of the clear solution with hydrochloric acid were recrystallized from methanol to afford XXI as colorless prisms; 1.02 g (62%); mp 130—131°C. IR, 1790 and 1770 (unsplit doublet, C=O) and 1580 cm^{-1} (C=C); UV, 258 sh (9000), 267 sh (7600) and 276 sh nm (ε, 6200); NMR, 2.5—3.0 (m, C_6H_5, 20H) and 4.73 τ (s, CH, 2H).

Found: C, 86.97; H, 5.15%. Calcd for $C_{30}H_{22}O_2$: C, 86.93; H, 5.35%.

Oxidation of XXI. A mixture of XXI (0.2 g), 30% aqueous hydrogen peroxide (1.5 ml), and acetic acid (60 ml) was stirred at room temperature for 24 hr. The crude crystals formed by the addition of water to the reaction mixture were recrystallized from methanol to afford XXII as colorless prisms; 0.1 g (48%); mp 171—172°C. IR, 1825 and 1770 (C=O) and 1645 cm^{-1} (C=C); UV, 253 sh (6500), 259 sh (5800) and 282 sh nm (ε, 4000); NMR, 2.85 (d, C_6H_5, 20H) and 4.63 τ (s, CH, 2H).

Found: C, 83.85; H, 5.07%. Calcd for $C_{30}H_{22}O_3$: C, 83.70; H, 5.15%.

The same reaction in acetone for 86 hr afforded XXII in a 24% yield.

Preparation of XXVIII. A mixture of XVII (0.66 g), 30% aqueous hydrogen peroxide (1 ml), and acetic acid (60 ml) was stirred at 65°C for 10 hr. The crude crystals formed by the addition of water to the reaction mixture were recrystallized from methanol to afford XXVIII as yellow prisms; 0.07 g (10%); mp 216—217°C. IR, 1795 (C=O) and 1620 cm^{-1} (C=C); UV, 251 (29300) and 345 nm (ε, 11100); NMR, 2.6—3.6 (m, C_6H_5, 20H) and 6.53 τ (s, CH_2, 2H).

Found: C, 86.41; H, 5.11%. Calcd for $C_{30}H_{22}O_2$: C, 86.93; H, 5.35%.

Reaction of XXVIII with Methanolic Potassium Hydroxide. A mixture of XXVIII (0.05 g), potassium hydroxide (0.04 g), and methanol (20 ml) was heated under reflux for 15 min. The crude crystals formed by the decomposition of the reaction mixture were collected by filtration and were then recrystallized from methanol to afford XXX as colorless prisms; 0.025 g (46%); mp 106—107°C. IR, 1740 (C=O) and 1670 cm^{-1} (C=O); 290 nm (ε, 4900); NMR, 2.85 (m, C_6H_5, 20H), 5.15 (s, CH, 1H), 6.62 (s, CH_3, 3H) and 6.75 τ (s, CH_2, 2H).

Found: C, 83.72; H, 5.80%. Calcd for $C_{31}H_{26}O_3$: C, 83.38; H, 5.87%.

The authors wish to express their thanks to Mr. Shoichi Kato for the elemental analyses, to Miss Shizuko Konomi for her measurement of the NMR spectra, and to Miss Sayumi Asakawa for her measurement of the UV spectra.

Layered Compounds. V.[1] Synthesis and Properties of [*m.n*]Paracyclophadiynes

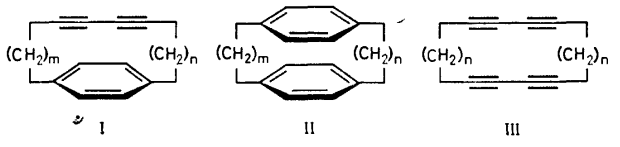
Takahiro MATSUOKA, Taichi NEGI, Tetsuo OTSUBO, Yoshiteru SAKATA, and Soichi MISUMI

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

(Received October 22, 1971)

A series of bisethynyl compounds, IX and XII, were prepared by a modified ethynylation using *N*-methyl-2-pyrrolidone in good yields. Intramolecular oxidative coupling of the bisethynyl compounds has been achieved with high-dilution technique to give relatively good yields of highly strained or strainless [*m.n*]paracyclophadiynes I and cyclic diacetylenes XIII. From the comparison of the electronic spectra of these diacetylenic compounds, it is concluded that abnormal spectra of Ic and Id are attributed to the transannular π-electronic interaction between benzene nucleus and diacetylenic unit rather than the ring strain in the molecules. In addition, a marked down-field shift of aromatic protons in Ic compared with the other paracyclophadiynes is explained in terms of the transannular shielding effect of diacetylenic linkage.

In various types of bridged systems[2], two or more chromophoric groups separated from each other frequently exhibit anomalous behavior when they are forced to bring close together as in the case of [*m.n*]-paracyclophanes. Since an increased proximity of the groups necessarily brings about a severe strain in the molecule owing to a mutual π-orbital repulsion, the resulting strain sometimes makes it difficult to explain the anomalous physical properties of such distorted molecules in terms of a transannular interaction of π-orbitals.

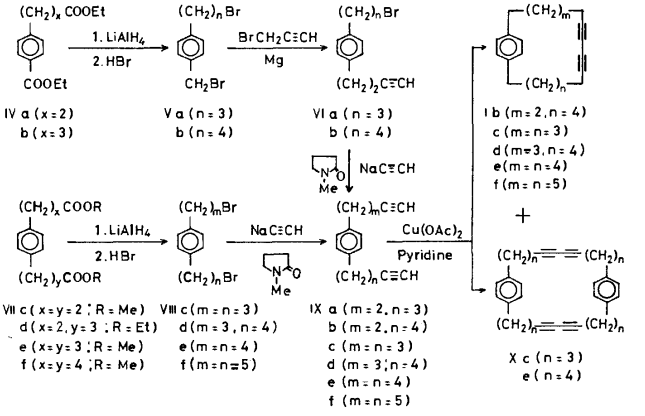


There have been systematic surveys of [*m.n*]paracyclophanes (II),[3] cyclic tetraacetylenes(III),[4] and multilayered cyclophanes[5] in view-points of the transannular interaction and the strain effect. They showed unambiguous evidences supporting the transannular interaction. On the other hand, there are only a few studies on the interaction in bridged compounds containing different chromophoric groups, since a superposition of absorption bands due to both groups often makes a spectral elucidation difficult. Cram and Antar[6] reported two of [*n*]paracyclophyne containing a monoacetylene group in its bridge chain. However, any evidence for transannular electronic interaction could not be observed there.

From examinations of scale models, it has been expected that paracyclophadiynes I are well suitable model compounds for the study of the transannular electronic interaction between a benzene nucleus and a conjugated diacetylene group. It is well known that a variety of highly strained diacetylenic compounds could have been prepared by oxidative coupling reaction of terminal bisethynyl compounds like IX.[7] Thus we have undertaken to investigate a relationship among methylene chain length and the physical properties of paracyclophadiynes I. In this paper we report the synthesis and the spectral properties of I. The name "[*m.n*]paracyclophadiyne" is used here in place of *a,b*-[*n'*]paracyclophadiyne for convenience, in which *m* and *n* are numbers of methylene group, *e.g.* for Ic [3.3]paracyclophadiyne instead of 4,6-[10]paracyclophadiyne.

Results and Discussion

Synthesis. All of the paracyclophadiynes (I) were prepared by the general synthetic sequence outlined in Scheme 1. Cyclic diacetylenes XIII and tetraacetylenes XIV were synthesized as spectral reference compounds (Scheme 2).



Scheme 1. A synthesis of paracyclophadiynes.

In some preliminary experiments, bisethynyl compounds IX were obtained by bisethynylation of dibromides VIII in ether with liquid ammonia solution of sodium acetylide in autoclave at room temperature in reasonable yields, 79% for $m=n=3$ and

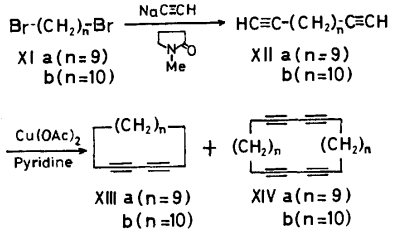

Scheme 2. A synthesis of cyclic acetylenes.

74% for $m=n=4$, accompanied with a small amount of olefinic compounds. After examining several experimental conditions, we observed a more convenient procedure by which the bisethynyl compounds IX were likewise afforded in good yields at atmospheric pressure by the use of *N*-methyl-2-pyrrolidone in place of ether as a co-solvent. This facile procedure was also applied to permit good yields of bisethynyl alkanes XII as shown in Table 1.

On the other hand, bisethynyl compounds, IXa and IXb, each containing a butynyl group were synthesized through stepwise ethynylations as shown in Scheme 1. Thus monoethynyl bromoderivatives VI (a and b) were obtained by the reaction of dibromides V with propargylmagnesium bromide in 80 and 96% yields, respectively. The following ethynylation of VI gave bisethynyl compounds IX (a and b), 77% and 89%, in a same manner stated above. Analytical data and the physical properties of the bisethynyl compounds IX and XII are shown in Table 1.

The paracyclophadiynes I were obtained by Eglinton's oxidative reaction[8] of IX with a high-dilution

technique for intramolecular cyclization. The oxidative coupling reaction was achieved with dropwise addition of dilute ether solution of IX for a period of 80—110 hr to anhydrous cupric acetate in pyridine at 85—95°C under nitrogen atmosphere. Chromatography of the coupling products on alumina gave the desired cyclic monomers Ib—f in relatively good yields (47—21%) together with by-product, cyclic dimers X. It is noteworthy that nitrogen atmosphere during the oxidative coupling is presumably necessary to avoid air oxidation of the coupling products, because the coupling reaction of IX in air atmosphere gave a low yield of I, *e.g.* only 8% yield of Ie from IXe. As cyclic diacetylenes, XIIIa and XIIIb, were also afforded by this procedure in 55 and 72% yields, the procedure is excellently applicable to general preparation of cyclic conjugated diacetylenes. The latter compound XIIIb had been previously synthesized under normal Eglinton's condition in a 17% yield.[8] A new compound XIIIa, 1,3-cyclotridecadiyne, is the smallest one of monocyclic conjugated diacetylenes known so far and is highly strained on consideration with a skeletal model. It was observed that this compound is thereby unstable and becomes rapidly orange after isolation, but the dilute solution can be kept for a month at −20°C. All of the paracyclophadiynes I obtained above can be kept without decomposition in diffused light at room temperature.

An attempted synthesis of extremely strained paracyclophadiyne I with $m=2$, $n=3$ failed, but afforded a mixture of cyclic dimer X consisted of two possible isomers.

Analytical data and the physical properties of cyclic di- and tetra-acetylenes I, X, XIII, and XIV are summarized in Table 2.

Geometry of Paracyclophadiynes. An examination of Stuart-Briegleb model for paracyclophadiynes Id—f reveals that in each molecule a benzene nucleus is held parallel to a diacetylene group in the bridge chain and its mutual distance becomes shorter with decreasing number of methylenes in the diacetylene bridge as shown in Fig. 1. [3.3]- and [2.4]-Paracyclophadiynes can not be constructed with this type of model. On the other hand, examination with Dreiding model suggests that two isomeric forms should be present in a highly strained molecule, [3.3]-paracyclophadiyne Ic (Fig. 2). The cyclophadiyne Ic, however, exhibits no evidence for the presence of such isomers on the NMR spectrum even at low temperature as described below. Therefore, it is quite interesting to investigate the mutual arrangement of

the benzene nucleus and the diacetylene group in the molecule.

Recently the exact molecular structure of [3.3]-paracyclophadiyne was determined with X-ray by Tanaka *et al.*[10] (Fig. 3 and 4). The figures show that the structure of the molecule is characterized as follows: a) atomic group C–C≡C–C≡C–C in Ic is forced to bend by 6—11° from its normal linear arrangement. Both the triple bonds are held with shorter bond lengths than that (1.208 Å)[11] in dimethyldiacetylene, b) the benzene nucleus is less distorted than the benzene nuclei in [3.3]paracyclophane, c) a particular bond angle in the trimethylene chain is unusually greater than the normal, *i.e.* 120.1° or 126.7°, d) the C–C≡C–C≡C–C group is parallel to an axis linked through substituted benzene atoms, C_{11} and C_{14}, as opposed to the examination of Dreiding model (see Fig. 4), e) two shortest distances between

both π-electron systems, 3.067 and 3.077 Å, are much shorter than a minimum distance (3.14 Å)[12] between two benzene nuclei in [3.3]paracyclophane.

The structural features of [3.3]paracyclophadiyne above-stated are most likely interpreted on the basis of a repulsive force arising from enormous π-orbital overlap between the diacetylene group and the benzene nucleus. Of several highly strained cyclic compounds containing a diacetylenic linkage isolated from the other chromophoric groups, [3.3]paracyclophadiyne is the first one of which exact structure was determined.

Nuclear Magnetic Resonance Spectra. The NMR spectra of [*m.n*]paracyclophadiynes I, cyclic dimers X, and open chain compound IX are illustrated in Table 3. It shows that chemical shifts of aromatic protons other than the Ic aromatic protons are about the same as that of the open chain compounds IX. Thus it can be considered that there is no appreciable effect of diacetylenic linkage on the chemical shifts of Id—f because of elongated distances. The aromatic protons of [2.4]homologue Ib appeared also at nearly the same position, indicating that the magnetic effect of diacetylenic linkage is negligible even in such a highly strained molecule. It was observed in a series of [*n*]paracyclophanes[13] that the chemical shift of aromatic protons was little varied even if the benzene ring is highly distorted.

Xc	2.88	s	8
Xe	3.01	s	8

Concentration a) 0.14 M, b) 0.06 M.

In the other strained cyclophadiyne Ic, on the other hand, the aromatic protons were found to appear at down-field by *ca.* 0.2 ppm compared with strainless homologues (Table 3). Therefore, this down-field shift should be attributed to the transannular shielding effect from magnetic anisotropy of diacetylenic bond. It remains questionable that the aromatic protons of Id appeared as an expected AA'BB' pattern but those of Ib unexpectedly as a sharp singlet, in same relationship observed for the aromatic protons of [2.4]- and [3.4]-paracyclophanes.[14]

The spectra of methylene protons in I are showed in Fig. 5. The three signals in Ie and If are respectively assigned to benzylic, propargylic, and the rest methylene protons from lower field. The benzylic protons of I appear in a range of 6.9—7.7 τ as complexed multiplets. Unsymmetric paracyclophadiyne Id showed two multiplets at 7.1—7.3 and 7.3—7.6 τ, in which benzylic protons in trimethylene bridge and in tetramethylene bridge respectively were assigned from comparison with [3.3]- and [4.4]-homologues. In the spectrum of Ib a complexed signal at 7.3—7.7 τ is explainable by which the higher field counterpart of A_2B_2 pattern of the dimethylene bridge protons is superimposed with the benzylic protons in the tetramethylene bridge. The propargylic protons in the tetramethylene bridge appeared at 8.1 τ. A remarkable difference between the chemical shifts of two pairs of propargylic protons in Ib seems to be attributed to a difference in shielding effect of benzene ring due to methylene bridge length.

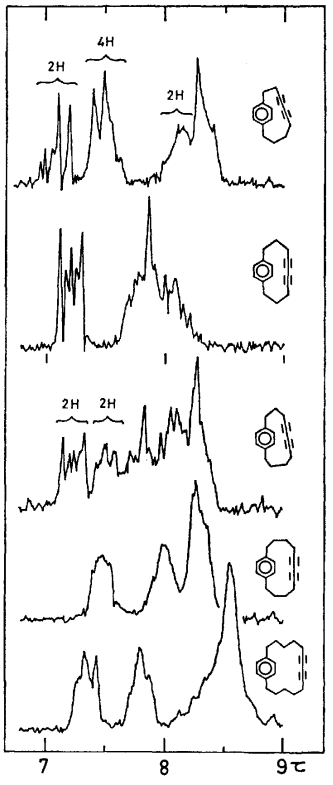

Fig. 5. The NMR spectra of the methylene protons in paracyclophadiynes (60 MHz, in CCl_4, at room temp.).

A long-range shielding effect of diacetylenic linkage is probably responsible to slight down-field shifts of benzylic protons in Ic and in shorter methylene bridges of Ib and Id. In order to confirm this shielding effect, cyclic diacetylenes XIII, in which the majority of protons might be located above the diacetylene linkage, were chosen to examine. Table 4 records the chemical shifts of the propargylic protons and the other methylene protons (τ-values at absorption maxima) in XIII and XIV together with cycloalkanes. Although the propargylic protons of XIII and XIVb

a) shoulder

appear at nearly the same position, the other methylene protons (broad singlet) of XIIIa and XIIIb are shifted by 0.17 ppm to down-field from those of XIVb and cycloalkanes. Since XIIIa would considerably be strained and XIIIb be strainless from the examination of model, same chemical shift for the methylene protons of XIIIa and XIIIb provided further evidence that the strain in diacetylenic linkage has little influence on the shielding effect of the linkage. Accordingly, the above-mentioned down-field shift should be mainly attributed to the shielding of diacetylenic linkage. And also the down-field shift (*ca.* 0.2 ppm) of aromatic protons in Ic stated before is possibly ascribed to the same effect.

The spectra of Ic were determined at 70, 35, and −70°C to study the conformational equilibrium (a⇄b in Fig. 2). But the signals of the aromatic protons were kept sharp singlet even at −70°C. This finding is consistent with that the molecule in solution has the same geometry as in crystals (Fig. 4). It is presumed that the relative arrangement of the benzene ring and the diacetylene linkage undergoes no significant change even if an interconversion between a chair form and a boat form arises from the conversion of both trimethylene bridges.

Electronic Spectra. Figure 6 and Table 5 record the electronic spectra of the [*m.n*]paracyclophadiynes I, in which the number of *m* and *n* are varied stepwise. In those spectra, a cyclic dimer Xe, 5,7,23,25-[12.12]paracyclophatetrayne, is a reference compound, in which the interaction between the two chromophores may be unexpected. The spectra show obvious features as follows: a) disappearance of vibrational fine structures with the decrease of

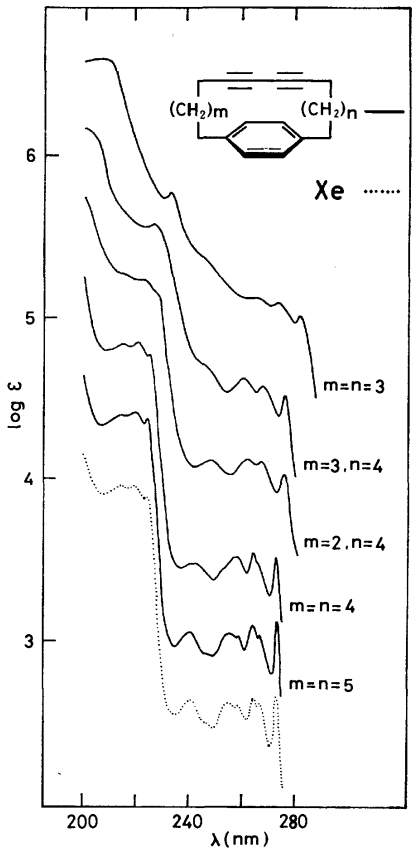

Fig. 6. The electronic spectra of paracyclophadiynes in cyclohexane. The ε-value of the cyclic dimer Xe is reduced to give the value for the unit chromophoric groups, *i.e.*, ε/2. The curves are displaced upward successively by 0.5 log ε unit from the curve immediately below.

methylene number, and then broadening of the curves, b) bathochromic shifts of the longest wavelength absorption bands, and c) appearance of a new peak at 233 nm for Ic and at 227 nm for Id, respectively.

The spectral features are explainable by two plausible elucidations, distortion in the two chromophores and transannular interaction between those. It was reported in the spectra of [*n*]paracyclophanes[16] that the distortion of benzene ring resulted in a disappearance of fine structure and a bathochromic shift of absorption band. However, there has not been investigated the spectral properties of distorted cyclic molecules containing only a conjugated diacetylenic linkage. Figure 7 shows that a strain-free cyclic diacetylene XIIIb exhibits a characteristic fine structure, whereas a strained one XIIIa does a broad absorption maximum, and that there is no significant difference between the positions of absorption bands of both spectra. Upon these facts, a) and b) may be explained by the strain effect of the chromophores, mainly of benzene ring, but c) not by only the strain effect. The reason is that the spectrum of less strained [3.4]paracyclophadiyne Id resembles the spectrum of more strained [3.3]homologue Ic, whereas highly strained one Ib shows an absorption curve similar to the reference compound Xe rather than to [3.3]homologue.

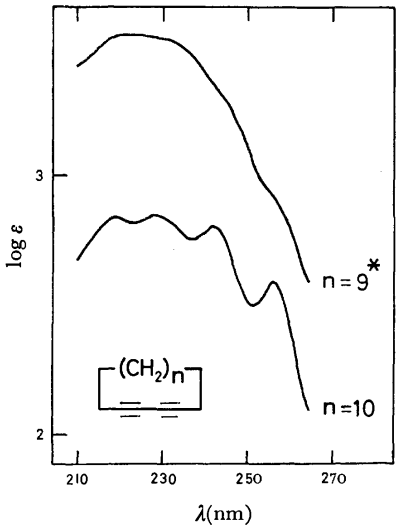

Fig. 7. The electronic spectra of cyclic diacetylenes in cyclohexane. * Qualitative.

Accordingly, it is suggested that new absorption peaks, at 233 nm of Ic and at 227 nm of Id, of the smaller paracyclophadiynes might be ascribed to the transannular interaction between the two chromophores. As is illustrated in Fig. 3, the closest interatomic distances between the two groups, 3.067 Å of C_7—C_{11} and 3.077 Å of C_4—C_{14}, are remarkably small as compared with a minimum interplanar distance of approximately 3.4 Å known for a variety of non-distorted aromatic substances. Thus the overlap of the π-electron orbitals must be particularly significant both at C_7—C_{11} and C_4—C_{14}. On the other hand, [2.4]homologue should be highly strained and less overlapped at the tetramethylene bridge site than in [3.3]homologue from the examination of molecular model. Consequently, it is concluded that the abnormal spectra of [3.3]- and [3.4]-paracyclophadiynes, Ic and Id, are best explained in terms of transannular π-electron interation caused by closely overlapped two chromophores.

[4.4]Paracyclophadiyne Ie shows absorption bands at about same wavelengths as those of the reference compound Xe, but with 0.7—0.8 times of the intensity ($\varepsilon/2$) for each pair of the chromophores as can be seen from Table 5. Such lower intensity was invariably observed on repeated measurements and with various runs of the specimen, indicating noncontamination of impurities. This phenomenon on the intensity has been also observed by Nakagawa and Ando[17] and explained in terms of the dispersion force interaction between excited dipoles by Tinoco[18] and Rhodes.[19] Accordingly, the intensity of the spectrum of Ie seems to be explained in terms of the dispersion force interaction or dipole-dipole interaction rather than the overlap of π-orbitals unlike in the cases of [3.3]- and [3.4]-homologues.

A similarity of the If spectrum to that of Xe is suggestive of the absence of the interaction between the two chromophores. Low intensity bands, occured at 285—295 nm in each spectrum of Ib, Ie, and If, at 285 nm for XIIIb and at 288 nm for XIVa, are considered as an excitation of the diacetylene bond alone.

19) W. Rhodes, *ibid.*, **83**, 3609 (1961).

The electronic spectra of paracyclophadiyne-tetracyanoethylene complexes will be reported in near future.

Infrared Spectra. Figure 8 shows the infrared spectra in a range of 2300—2100 cm^{-1} for cyclic acetylenic compounds, I, X, XIII, and XIV. The cyclic monomers I and XIII exhibit stronger higher-frequency band than lower-frequency one, whereas the cyclic dimers X and XIV are *vice versa*. This phenomenon is related probably to the very structure of the molecules and not to intermolecular interaction since the same relationship is observed between spectra of solid state and of solution.

Experimental

Melting points and boiling points are uncorrected. The UV, IR, NMR, and mass spectra were measured with a Hitachi EPS-3T autorecording spectrophotometer, a Hitachi EPI-G2 spectrometer, a Hitachi R-20 spectrometer, and a Hitachi RMU-7 spectrometer, respectively.

Ethyl p-*Ethoxycarbonylhydrocinnamate (IVa).* Acetylation of ethyl hydrocinnamate was accomplished by the procedure of Borshe and Sinn[20] except for using carbon tetrachloride as a solvent, yield 86.0%, bp 144—146°C/3 mmHg (lit,[20] bp 194—197°C/16 mmHg).

To an alkaline solution of sodium hypobromite, prepared from sodium hydroxide (230 g, 5.75 mol) and bromine (310 g, 1.94 mol) in water (1.9 *l*), 65 g (0.30 mol) of ethyl *p*-acetylhydrocinnamate was added over a period of 10 min with stirring keeping the temperature below 0°C. After the addition the mixture was kept at 60°C for 3 hr with stirring. The reaction mixture was cooled and washed well with ether and then acidified with 150 m*l* of conc. sulfuric acid, successively. The acid precipitate was collected, washed well with water and dried in vacuum over calcium chloride to give white crystals (53.7 g, 93%). For analysis a small amount of the sample was recrystallized from acetic acid and then sublimed (bath temp. *ca.* 200°C/3 mmHg) to give white powder, mp 296—297°C (in sealed tube), (Found: C, 61.39; H, 6.05%) (lit,[21] mp 284°C).

p-Carboxyhydrocinnamic acid was converted to diethyl ester *via* acid chloride according to the usual method. From 63.9 g of the dicarboxylic acid was obtained 70.0 g (84.5%) of the diethyl ester IVa as a colorless liquid, bp 148—153°C/4 mmHg. For analysis a sample was distilled under reduced pressure to give a colorless liquid, bp 157—158°C/4 mmHg. Found: C, 67.12; H, 7.26%. Calcd for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25%.

p-*(3-Hydroxypropyl)benzyl Alcohol.* The ester IVa (81.0 g, 0.32 mol) in 200 m*l* of ether was added dropwise over a period of 1.5 hr with stirring to a suspension of 24.4 g (0.64 mol) of lithium aluminum hydride in 800 m*l* of ether. The mixture was kept at reflux with stirring for 4 hr. To the cooled reaction mixture a small amount of water was carefully added dropwise to decompose the excess reducing agent. After addition of 2 N hydrochloric acid (1.8 *l*) and salting out, the mixture was extracted with ether (500 m*l*). The ether solution was washed twice with succesive, 100 m*l* portions of saturated sodium chloride, dilute sodium bicarbonate solution saturated with sodium chloride, and saturated sodium chloride, respectively. The solution was dried over anhydrous sodium sulfate and concentrated under reduced pressure to yield an opaque pale yellow viscous oil (54.0 g).

The bis-*p*-nitrobenzoate of this material was prepared by the usual pyridine-*p*-nitrobenzoyl chloride method, mp 111.5—112.5°C (from ethanol). Found: C, 62.04; H, 4.42; N, 5.90%. Calcd for $C_{24}H_{20}N_2O_8$: C, 62.06; H, 4.34; N, 6.03%.

p-*(3-Bromopropyl)benzyl Bromide (Va).* *p*-(3-Hydroxypropyl)benzyl alcohol (54.0 g) was converted to the dibromide Va (41.5 g, 43.7%) according to the usual method,[22] bp 142—147°C/3 mmHg. For analysis a sample was distilled under reduced pressure to give a colorless liquid, bp 117—119°C/0.08 mmHg; IR (liquid film), 608 and 563 cm^{-1} (C-Br). Found: C, 41.38; H, 4.21%. Calcd for $C_{10}H_{12}Br_2$: C, 41.13; H, 4.14%.

*4-(*p-*(3'-Bromopropyl)phenyl)-1-butyne (VIa).* To a solution of propargylmagnesium bromide,[23] prepared from magnesium (1.3 g, 0.054 mol) and propargyl bromide (6.4 g, 0.054 mol) in ether (15 m*l*) under nitrogen atmosphere, a solution of the dibromide Va (8.7 g, 0.030 mol) in 20 m*l* of ether was quickly added with vigorous stirring. The mixture was stirred for 6 hr at room temperature and then poured into a mixture of crashed ice (100 g) and ether (100 m*l*), and 50 m*l* of 6 N hydrochloric acid was added. The resulting mixture was extracted with ether. The ether solution was washed with a saturated sodium chloride and dried over anhydrous sodium sulfate. The solution was concentrated under reduced pressure to yield an orange liquid (7.38 g). This residue was chromatographed on 30 g of neutral alumina using petroleum ether as an eluent to yield a colorless liquid (6.0 g, 80.0%). For analysis a sample was distilled under reduced pressure to give a colorless liquid, bp 108—110°C/0.08 mmHg; IR (liquid film), 3287, 2120 and 644 (-C≡CH), 573 cm^{-1} (C-Br); NMR (CCl_4), τ: 2.97 (s, 4H), 6.73 (t, J=6 cps, 2H), 7.1—8.1 (m, 8H), 8.19 (t, J=2 cps, 1H). Found: C, 62.22; H, 6.21%. Calcd for $C_{13}H_{15}Br$: C, 62.16; H, 6.02%.

Ethyl p-*(3-Ethoxycarbonylpropyl)benzoate (IVb).* *p*-(3-Ethoxycarbonylpropyl)acetophenone was obtained according to Baddeley and Williamson.[21]

Oxidation of the acetophenone derivative with sodium hypobromite was carried out in the same manner described for the preparation of *p*-carboxyhydrocinnamic acid. From 104 g of the acetophenone derivative was obtained 82.2 g (89.0%) of *p*-(3-carboxypropyl)benzoic acid, mp 184—190°C. A small amount of sample was recrystallized from 50% acetic acid to yield white needles, mp 195.5—196°C (lit,[21] mp 194—195°C).

The dicarboxylic acid was converted to diethyl ester *via* acid chloride according to the usual method. From 65.1 g of the acid was obtained 72.8 g (88.0%) of ethyl *p*-(3-ethoxycarbonylpropyl)benzoate(IVb) as a pale yellow liquid, bp 156—160°C/2 mmHg. For analysis a sample was distilled under reduced pressure to give a colorless liquid, bp 153—155°C/1 mmHg. Found: C, 68.00; H, 7.77%. Calcd for $C_{15}H_{20}O_4$: C, 68.16; H, 7.63%.

p-*(4-Hydroxybutyl)benzyl Alcohol.* Reduction of the ester IVb with lithium aluminum hydride was accomplished in a similar manner described for the preparation of *p*-(3-hydroxypropyl)benzyl alcohol. From 90 g of IVb was obtained 63.7 g of the crude diol as an opaque pale yellow viscous oil. The bis-*p*-nitrobenzoate of this diol was prepared, mp 99—100°C (from ethanol). Found: C, 63.00; H, 4.65; N, 5.75%. Calcd for $C_{25}H_{22}N_2O_8$: C, 62.76; H, 4.64; N, 5.86%.

p-*(4-Bromobutyl)benzyl Bromide (Vb).* *p*-(4-Hydroxybutyl)benzyl alcohol (62.0 g) was converted to the di-

21) G. Baddeley and R. Williamson, *J. Chem. Soc.*, **1956**, 4647.

bromide Vb (63.5 g, 60.5%) according to the usual method,[22] bp 149—153°C/3 mmHg. For analysis a sample was distilled under reduced pressure to give a colorless liquid, bp 126—128°C/0.08 mmHg; IR (liquid film), 608 and 561 cm^{-1} (C–Br). Found: C, 43.34; H, 4.63; Br, 51.91%. Calcd for $C_{11}H_{14}Br_2$: C, 43.17; H, 4.61; Br, 52.22%.

*4-(*p*-(4'-Bromobutyl)phenyl)-1-butyne (VIb).* Propynylation of the dibromide Vb with propargylmagnesium bromide[23] was accomplished in a manner to that described for the propynylation of the dibromide Va. From 20 g of the dibromide Vb was obtained 16.6 g (96.0%) of the monoethynyl compound VIb as a pale yellow liquid after chromatographic treament. For analysis a sample was distilled under reduced pressure to give a colorless liquid, bp 118—120°C/0.09 mmHg; IR (liquid film), 3287, 2120 and 645 (–C≡CH), 563 cm^{-1} (C–Br); NMR (CCl_4), τ: 3.03 (s, 4H), 6.70 (t, J=6 cps, 2H), 7.1—7.8 (m, 6H), 8.1—8.3 (m, 5H). Found: C, 63.24; H, 6.53%. Calcd for $C_{14}H_{17}Br$: C, 63.40; H, 6.46%.

p-Bis(β-methoxycarbonylethyl)benzene (VIIc). A mixture of 36.9 g of dimethyl β,β'-(*p*-phenylene)diacrylate,[24] 360 m*l* of tetrahydrofuran and 3.6 g of 5% palladium-carbon catalyst was shaken in an atmosphere of hydrogen for 3 hr at about 60°C to take up theoretical amount of hydrogen. The hot mixture was filtered through an extraction thimble and the residual material in the thimble was extracted with tetrahydrofuran using a Soxhlet extractor. The combined solution was cooled to 0°C. The precipitated diester VIIc was collected and dried in vacuum, brilliant white scaly crystals (36.6 g, 97.6%), mp 116—118°C (lit,[25] mp 117—118°C).

p-Bis(3-bromopropyl)benzene (VIIIc). Reduction of the dimethyl ester VIIc, which was slightly soluble in ether, with lithium aluminum hydride was carried out by the technique of Nystrom and Brown.[26] From 30 g of VIIc was obtained 20.5 g (88.0%) of *p*-bis(3-hydroxypropyl)-benzene as white crystals, mp 60—61.5°C. A small amount of the sample was recrystallized from benzene to give colorless plates, mp 60.5—61.5°C (lit,[27] mp 61°C).

Bromination of the above diol was accomplished by the method of Ruzicka *et al.*[24] From 20 g of the diol was obtained 24.9 g (75.5%) of the dibromide VIIIc as a colorless liquid, bp 156—160°C/1 mmHg (lit,[24] bp 158—162°C/1 mmHg).

Ethyl p-(3-Ethoxycarbonylpropyl)hydrocinnamate (VIId). 108 g of β-(*p*-(2-carboxyethyl)benzoyl)propionic acid[28] was reduced by the modified Wolff-Kishner method[29] to yield 76.4 g (75.0%) of the *p*-(3-carboxypropyl)hydrocinnamic acid, mp 142—144°C (lit,[28] mp 143—144°C).

This dicarboxylic acid (66.4 g) was converted to the diethyl ester (69.6 g, 85.0%) by the usual acid-ethanol method, bp 165—168°C/2 mmHg. For analysis a sample was distilled under reduced pressure to give a colorless liquid, bp 173—174°C/3 mmHg. Found: C, 69.73; H, 8.51%. Calcd for $C_{17}H_{24}O_4$: C, 69.83; H, 8.27%.

*4-(*p*-(3'-Bromopropyl)phenyl)butyl Bromide (VIIId).* Reduction of VIId with lithium aluminum hydride was accomplished in a similar manner described for the preparation of *p*-(3-hydroxypropyl)benzyl alcohol. From 64.5 g of VIId was obtained 47.9 g of 4-(*p*-3'-hydroxypropyl)-phenyl)butyl alcohol as an opaque pale yellow viscous oil. The bis-*p*-nitrobenzoate of this diol was prepared, mp 100.5—101.5°C (from ethanol). Found: C, 64.07; H, 5.22; N, 5.46%. Calcd for $C_{27}H_{26}N_2O_8$: C, 64.02; H, 5.17; N, 5.53%.

Bromination of the above diol was achieved by the usual dry hydrogen bromide method.[30] From 26.1 g of the diol was obtained 32.9 g (78.7%) of the dibromide VIIId as a colorless liquid, bp 151—155°C/1 mmHg. For analysis a sample was distilled under reduced pressure to give a colorless liquid, bp 174—176°C/3 mmHg. Found: C, 46.78; H, 5.34%. Calcd for $C_{13}H_{18}Br_2$: C, 46.73; H, 5.43%.

p-Bis(4-bromobutyl)benzene (VIIIe). A series of reactions leading to the formation of dibromide VIIIe *via* diethyl ester VIIe was carried out by the method of Cram *et al.*[31]

p-Bis(5-bromopentyl)benzene (VIIIf). Bromination of *p*-bis(5-hydroxypentyl)benzene, which was prepared from dimethyl ester VIIf by the method of Cram and Daeniker,[32] was accomplished by the usual method.[30] From 33.0 g of the diol was obtained 41.5 g (83%) of the dibromide VIIIf as a colorless liquid, bp 188—190°C/3 mmHg. For analysis a sample was chromatographed on alumina using petroleum ether as an eluent and then distilled under reduced pressure to give a colorless liquid, bp 144°C/0.02 mmHg. Found: C, 50.99; H, 6.50; Br, 42.28%. Calcd for $C_{16}H_{24}Br_2$: C, 51.08; H, 6.43; Br, 42.49%.

Ethynylation of VI, VIII, and XI. To a solution of monosodium acetylide, prepared from 3.6 g (0.16 mol) of sodium in liquid ammonia (100 m*l*), a solution of 10 g (0.029 mol) of dibromide VIIIe in 100 m*l* of *N*-methyl-2-pyrrolidone, which was distilled at atmospheric pressure, was added dropwise over a period of 50 min. During this period the bottom of the reaction flask was kept cool on a dry ice-alcohol bath, and vigorous stirring was continued with passage of a slow stream of acetylene. After the addition of VIIIe and the introduction of acetylene were over, stirring was continued overnight at room temperature to allow the evaporation of nearly all the ammonia. To the reaction mixture a small amount of water was carefully added to decompose excess sodium acetylide. After further addition of water (1 *l*) and salting-out, the reaction mixture was extracted with ether. The ether extract was washed well with water, dilute sulfuric acid, dilute sodium bicarbonate solution, and again with water, successively and dried over calcium chloride. The solution was concentrated under reduced pressure to yield 6.4 g of a yellow oil, for which Beilstein's test was negative. This residue was chromatographed on 50 g of alumina using petroleum ether as an eluent to yield 6.0 g (87.7%) of 6-(*p*-(4'-ethynylbutyl)phenyl)-1-hexyne (IXe) as a colorless liquid. For analysis a small amount of the sample was crystallized from petroleum ether at −20°C to give colorless crystals, mp 18—19°C. Bisethynyl compound IXc, IXd, IXf, XIIa, and XIIb were also prepared in good yields from corresponding dibromides by the method described above. VIa and VIb were also ethynylated in a similar method except that two gram atoms of sodium were

used to 1 mol of the monobromide VI.

Analytical data, yields, and physical properties of these bisethynyl compounds IX and XII were summarized in Table 1.

General Procedure for the Oxidative Coupling of IX and XII. In a 3 *l* separable flask, equipped with a vibromixer, a 1 *l* dropping funnel fitted with a capillary, and a gas inlet tube, are placed 1.3 *l* of pyridine and 20 g (0.11 mol) of anhydrous cupric acetate. The mixture was heated on an oil-bath with vigorous stirring and passage of a slow stream of nitrogen. Keeping the temperature of the bath at about 95°C, the solution of the bisethynyl compound IXe (3.0 g, 0.013 mol) in 2 *l* of ether was added dropwise through the capillary of the dropping funnel into the reaction flask. The addition was completed for 110 hr. During this period vigorous stirring and passage of nitrogen were continued and two 5 g portions of the cupric salt were added at nearly equal intervals. After the addition the reaction mixture was permitted to stand at room temperature for more than 6 hr and poured into a cooled mixture of crashed ice (2.4 kg), conc. sulfuric acid (540 m*l*) and ether (650 m*l*). Then brown insoluble material was filtered, the organic layer was separated and the water layer was extracted with 1 *l* of ether. The combined etherial solution was washed well with dilute sulfuric acid, dilute sodium bicarbonate solution and water, successively and dried over calcium chloride. The solution was concentrated under reduced pressure to yield a red oil (6.8 g) which gave no band at *ca.* 3300 cm^{-1} due to ethynyl group. The residue was dissolved in 10 m*l* of benzene and chromatographed on 200 g of alumina to yield two compounds. The first (1.39 g, 46.6%) was eluted with petroleum ether - ether (40 : 1); it was the cyclic monomer, [4.4]-paracyclophadiyne (Ie). For analysis a small amount of the sample was crystallized from *n*-pentane at −20°C, colorless plates, mp 72—73°C. On the crystallization, however, the alternative colorless thick plates were often obtained, they showed mp 76—77°C. The latter shows identical UV and NMR spectra with those of the former. Once the lower melting point crystals were melted and then solidified, it showed mp 76—77°C. On the other hand, in the case of the higher melting point crystals such phenomenon was not observed in this process. This phenomenon is explainable in terms of a polymorphism. Analytical data and physical properties of the cyclic monomer Ie are shown in Tables 2, 3 and 5 and Figs. 5, 6 and 8. The second substance (0.370 g, 12.4%) was eluted with petroleum ether - benzene (2 : 1); it was the cyclic dimer, 5,7,23,25-[12.12]paracyclophatetrayne (Xe). For analysis a small amount of the sample was recrystallized from cyclohexane, white needles, mp 163—164°C. Analytical data and physical properties of this cyclic dimer are shown in Tables 2, 3 and 5 and Figs. 6 and 8.

In a preliminary experiment, the linear dimer, (HC≡C–$(CH_2)_4$– –$(CH_2)_4$C≡C–)$_2$, was obtained; colorless needles, mp 76—77°C; λ_{max} 219.5 nm (ε 20200), 241.5 (518) and 274 (936) (in cyclohexane); IR 3265, 2320 and 2110 cm^{-1} (KBr disk). Found: C, 91.37; H, 8.83%; mol wt, 457 (osmometry in benzene). Calcd for $C_{36}H_{42}$: C, 91.08; H, 8.92%; mol wt, 475.

The Oxidative Coupling of IXa. The oxidative coupling of IXa (Table 6) resulted in a red oil (7.1 g). Chromatography on silica gel, followed by recrystallization from cyclohexane gave a mixture of two possible cyclic dimers, 3,5,18,20-[9.9]- and 3,5,18,20-[8.10]-paracyclophatetraynes, in poor yield; white needles, mp 159—162°C. Found: C, 92.94; H, 7.35%. Calcd for $C_{30}H_{28}$: C, 92.74; H, 7.26%. Mol wt, Found: 388 (mass spectrometry). Calcd for $C_{30}H_{28}$: 388. UV: (in cyclohexane) λ_{max} 214, 220, 225, 242.5, 256.5, 264, and 273 nm.

Hydrogenation of XIII. 1,3-Cyclotridecadiyne (XIIIa, 704 mg), which was purified by chromatography in *n*-pentane on alumina at *ca.* 5°C, took up 96% of the calculated volume of hydrogen in ethyl acetate (5% Pd-C). The crude product was chromatographed in petroleum ether on alumina, followed by distillation (*ca.* 80°C (bath temp.)/2 mmHg), to give cyclotridecane[33] (430 mg, 60%) as a colorless oil. Found: C, 84.81; H, 14.99% mol wt (mass spectroscopy) 182.

1,3-Cyclotetradecadiyne[8] (XIIIb, 563 mg) similarly gave cyclotetradecane (419 mg, 73%, mp 48—52°C), which was recrystallized from ethanol as colorless needles, mp 56—56.5°C (lit,[33] 53.5—54°C). Found: C, 85.33; H, 14.62%, mol wt (mass spectroscopy) 196.

Isolation and Structure Proof of Dinitrocyclohexenones Formed in the Nitration of Polyalkylbenzenes with Fuming Nitric Acid[1]

Hitomi SUZUKI,* Mikio SAWAKI,** and Reiji SAKIMOTO**

*Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

**Research Institute, Nihon Soda Co., Ltd., Kohdzu, Odawara

(Received October 22, 1971)

Action of fuming nitric acid upon 1,2,3,5-tetramethylbenzene and 2-ethyl-1,3,5-trimethylbenzene at low temperature was found to yield small amounts of dinitrocyclohexenones in addition to the ring nitration and side-chain nitrooxylation products. Chromatographic separation over silica gel followed by spectral investigation established the structures of these nitro-ketones to be 2,3,4,6-tetramethyl-5,6-dinitro-3-cyclohexen-1-one and 2,4,6-trimethyl-3-ethyl-5,6-dinitro-3-cyclohexen-1-one respectively. The mechanistic interpretation of their formation was briefly discussed.

Treatment of polyalkylbenzenes with fuming nitric acid at low temperature often yields a mixture of ring nitration and side-chain nitrooxylation products.[2] This unusual reaction has an electrophilic feature and is characterized for its peculiar orientation and high positional selectivity.[3] When the samples of the product mixtures from the nitration of polyalkylbenzenes were directly subjected to infrared analyses, it was usually noted that in addition to the major bands due to aromatic nitro compounds and benzyl nitrates, some weak absorptions occur in the regions attributable to carbonyl and aliphatic nitro group stretching vibrations. Carbonyl absorption would at first sight appear to arise from benzaldehydes which could be derived from benzyl nitrates under the influence of acid catalyst,[4] while absorptions owing to aliphatic nitro group would be attributed to phenylnitromethanes, the presence of which was confirmed in some nitration products.[5] However, some of these bands often appear in the regions of too higher frequencies (1370—1380 and 1560—1570 cm^{-1} for nitro group, and 1740—1750 cm^{-1} for carbonyl group) to make such spectral assignment unanimously acceptable. PMR spectra of the crude nitration products from polymethylbenzenes also exhibited weak peaks at quite high field 8.5—9.0 τ, indicating the presence of protons of highly alkane character. These puzzling features of infrared and PMR spectra are now explained by the isolation of alicyclic nitro-ketones, 2,3,4,6-tetraalkyl-5,6-dinitro-3-cyclohexen-1-ones, from the nitration products of isodurene (1,2,3,5-tetramethylbenzene) and ethylmesitylene (2-ethyl-1,3,5-trimethylbenzene), respectively. The structural proof of these unusual products will be the major subject of the present report.

In the preceding paper,[6] we have reported that the chromatographic treatment on silica gel of the nitration product from ethylmesitylene gave from benzene eluates some nitro-carbonyl compounds as a syrupy substance, from which a new nitro-carbonyl compound was obtained as fine colorless needles melting at 140—141°C. The result of elemental analysis and the appearance of a very weak molecular ion at m/e 256 in the mass spectrum indicated that the compound had a molecular formula $C_{11}H_{16}N_2O_5$. Its infrared spectrum revealed the presence of two different nitro groups (1568, 1549, 1379, and 1340 cm^{-1}), a carbonyl group (1737 cm^{-1}), and a double bond (1688 cm^{-1}, weak). The double bond should not be conjugated with carbonyl group nor nitro group, since the ultraviolet spectrum in methanol showed only one weak and broad absorption band at 287—288 nm (ε=265). Nitro groups seem to be attached to the carbon atoms adjacent to the carbonyl group and the double bond, respectively, because the $n\rightarrow\pi^*$ transition at 287—288 nm was appreciably intensified and the carbonyl stretching vibration was substantially shifted to higher wave number. The presence of cyclic structure was confirmed by the examination of the mass spectrum, which exhibited prominent peaks at m/e 210 (M^+-NO_2), 180 ($M^+-NO_2-C_2H_6$), 164 (M^+-2NO_2), 149 ($M^+-2NO_2-CH_3$), 135 ($M^+-2NO_2-CH_3-CH_2$), 121 ($M^+-2NO_2-CH_3-2CH_2$), 107 ($C_7H_6OH^+$), 105 ($C_7H_6CH_3^+$), and 79 ($C_6H_7^+$). The structural detail was obtained from the PMR spectrum, which depicted the presence of one ethyl group (3H 9.12 t, 2H 8.42 q; J=7 Hz. A two-proton quartet was further coupled slightly to the lower-field one proton quartet at 3.91 τ), three methyl groups (3H 8.78 s; 3H 8.15 s; 3H 7.89 d, J=1.7 Hz), and two methine protons (1H 5.01 s; 1H 3.91 q, J=1.6 Hz. A one-proton quartet at 3.91 τ was coupled slightly to the methylene quartet at 8.42 τ). The PMR data offer the partial structures -C(Me)=C(Et)-CH(Me)-, -CH-, and -CMe-, which were compatible with the spectral evidences only when the product was formulated as 2,4,6-trimethyl-3-ethyl-5,6-dinitro-3-cyclohexen-1-one. The appearance of some methyl and methine protons at quite

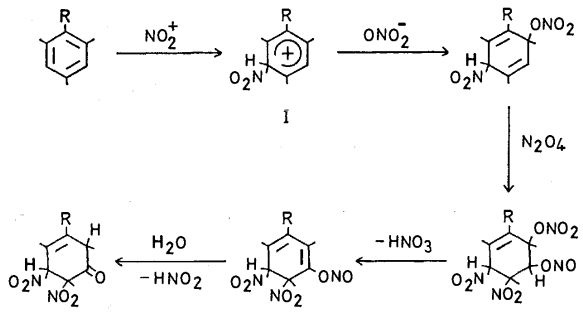
high field in the PMR spectrum can be understood in terms of anisotropic effect of neighboring nitro groups.

Nitration of isodurene has been reported to yield mononitro or dinitro compounds.[7] However, the products were not as simple as had generally been thought, and besides normal ring nitration products, were obtained appreciable amounts of a non-crystallizable syrupy substance, which could be separated into two major fractions on silica gel chromatography; one containing side-chain nitrooxylated products and the other containing nitrocarbonyl compounds. Further treatment of the latter fraction on silica gel chromatography gave a nitro-ketone with the composition $C_{10}H_{14}N_2O_5$ as the main isolable product. It crystallized from ethanol as fine needles melting at 137—138°C. Its infrared spectrum contained absorption bands at 1738 (C=O), 1680 (C=C, weak), 1573 (NO_2), 1553 (NO_2), 1448, 1380 (NO_2), 1340 (NO_2), 1280, 1038, 1003, and 858 cm^{-1}, and its ultraviolet spectrum (in MeOH) showed a weak band at 285 nm (ε=327), which was characteristic of unconjugated ketones with $n\rightarrow\pi^*$ transition appreciably intensified by the presence of auxiliary chromophores. The PMR spectrum showed three methyl singlets at 8.72, 8.69, and 8.11 τ; one methyl doublet at 7.90 τ coupled to a lower-field methine quartet at 3.92 τ (J=1.5 Hz); and one methine singlet at 5.05 τ. These spectral data and the result of elemental analysis were only consistent with the formulation of the product as 2,3,4,6-tetramethyl-5,6-dinitro-3-cyclohexen-1-one. The assigned structure was further confirmed by the mass spectrum which showed the expected peaks at *m/e* 196 (M^+-NO_2), 166 ($M^+-NO_2-2CH_3$), 150 (M^+-2NO_2), 135 ($M^+-2NO_2-CH_3$), 121 ($M^+-2NO_2-CH_3-CH_2$), 107 ($C_7H_6OH^+$), 105 ($C_7H_6-CH_3^+$), 91 ($C_7H_7^+$), and 79 ($C_6H_7^+$).

The formation of nitrocyclohexenones seems to be general in the nitration of highly alkylated benzenes, although these nitro-carbonyl compounds derived from various hydrocarbons are in most cases a non-crystallizable oil of complicated character, which gradually turned to a dark sticky substance on either repeated attempts to crystallize from solvents or prolonged standing.

The present result is of special interest, not only because it provides a novel mode of abnormal nitration but also because it seems to suggest the possibility of the addition-elimination sequence to be involved partly in the nitration of polyalkylbenzenes, which has generally been accepted to proceed through the S_E2 mechanism. The reaction sequence for the formation of 5,6-dinitro-3-cyclohexen-1-ones may be explained in terms of the addition-elimination mechanism which involves nitronium ion as electrophile and nitrate ion as nucleophile at the initial stage of the reaction. One of the plausible sequences is depicted in Scheme 1. The carbonium ionic intermediate (I) may be stabilized by the favorable orientation of alkyl substituents to such an extent that the addition process in which the nucleophile is captured can compete well with the ordinary substitution process. The process is supported by the recent observation[8] that the nitration of 1,2,3-trimethylbenzene and 4-bromo-*o*-xylene with acetic anhydride-nitric acid, a system containing a strong nucleophile, can lead to the extensive formation of 1-nitro-4-acetoxycyclohexa-2,5-dienes.



Scheme 1

Experimental

Infrared spectra were run as KBr disc on a Jasco DS-402G spectrophotometer and only prominent peaks are recorded. PMR measurements were carried out on a Varian A-60A and HA-100 spectrometer with deuteriochloroform as solvent and TMS as internal standard. Ultraviolet spectra were determined in methanol solutions on a Shimadzu QV-50 spectrophotometer. Mass spectra were obtained by Dr. A. Ohno of Sagami Chemical Research Center.

Isolation of Dinitrocyclohexenones. General procedures for the nitration of polyalkylbenzenes were described in the preceding paper. Although alumina chromatography was an efficient tool for the separation of side-chain substitution products from ordinary ring nitro compounds, it proved to be unsatisfactory for the isolation of dinitrocyclohexenones in crystallizable state from the crude nitration product mixtures. The oily nitration product was passed through a column of silica gel using light petroleum as eluant to give a mixture of nitro compounds and benzyl nitrates. Further elution with a mixture of benzene and light petroleum gave a fraction containing nitro-carbonyl compound as a yellow syrupy substance, which on trituration with ethanol gave a white powder in the crude yield of 2—4%. It was recrystallized several times from ethanol to give the nitro-ketone as colorless fine needles.

2,3,4,6-tetramethyl-5,6-dinitro-3-cyclohexen-1-one: mp 137—138°C.

The Photo-Beckmann Rearrangement of 3α,5-Cyclo-5α-cholestan-6-one Oxime[1,2]

Hiroshi SUGINOME, Hajime TAKAHASHI, and Tadashi MASAMUNE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received October 23, 1972)

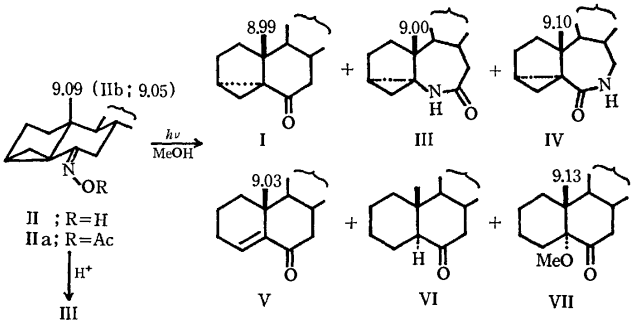
Photolysis of 3α,5-cyclo-5α-cholestan-6-one oxime affords two isomeric lactams with cyclopropane rings arising from photo-Beckmann rearrangement although the yields are poor. The result gives further support to our view on the C→N migration process in photo-Beckmann rearrangement. The major part of the products of the reaction consisted of the parent ketone and several products probably derived from it. The results are compared with those obtained in our photolysis of 5α-cholestan-6-one oxime and the isomeric 5β-cholestan-6-one oximes. The poor yields of the lactams is probably ascribable to the presence of the cyclopropane ring in this conjugated cyclopropyl ketone oxime.

Since the first paper[3] on the photochemical Beckmann rearrangement on arylaldoximes, additional results on aliphatic ketone oximes,[4] alicyclic ketone oximes[4,5,6,9] and α,β-unsaturated ketone oximes[7,8] have been reported. Mechanistic aspects of the reaction have been extensively investigated[8,9,10] and the intermediacy of oxaziridine in this reaction has been confirmed.[8,10]

We have shown[9] that in the photo-Beckmann rearrangement of 5α-cholestan-6-one oxime and the isomeric 5β-cholestan-6-one oximes the bond migration from the intermediary oxaziridines to amides proceeds in a stereospecific manner, the migration of C-5 occurring with retention of the configuration.

With regard to the effect of substituents on the migrating carbon it has been shown[11] that mono-, di-, or tri-substituted α-carbon atom migrates to yield the corresponding lactams and that the migration of the more alkyl-substituted α-carbon atom occurs predominantly, although the irradiation of a certain strained oxime with bridge-head tri-substituted α-carbon leads to the photo-Beckmann fission.[12]

In this paper, we report on the photolysis of 3α,5-cyclo-5α-cholestan-6-one oxime (II). Although the distinct difference in the mode of photolysis between conjugated cyclopropyl ketones and alkyl ketones has been clarified,[13] no investigation has so far been carried out on the photolysis of the conjugated cyclopropyl ketone oxime. Results of the photolysis of II may afford additional information on the bond migration process and also on the synthetic utility of this photochemical reaction.



Arabic numerals denote chemical shifts (τ) of 19-methyl protons.

Results

Oxime[14] of 3α,5-cyclo-5α-cholestan-6-one (I) was described by Wallis *et al.* and repetition of this work was found to give the corresponding *single* oxime (II). This revealed the $\pi\rightarrow\pi^*$ band[15] at λ_{max} 197—200 nm (*n*-hexane, ε; 9440).[16] In order to confirm the configuration of the oximino group, II was submitted to the ground state Beckmann rearrangement with polyphosphoric acid.[17] This led to an amorphous single lactam III in 65% yield.[18] The structure of III should be either (III) or (IV). Compound III exhibited one-proton singlet at τ 4.18 which is exchangeable with deuterium and a single-proton quartet centered at τ 9.56. The former is ascribable to lactam NH and the chemical shift of the latter corresponds to proton attached to cyclopropane ring.[19]

On the basis of this NMR spectrum, structure III, 6-aza-3α,5-cyclo-*B*-homo-5α-cholestan-7-one, is found to be correct. The configuration of the oximino group of II is, therefore, safely assigned as an anti-

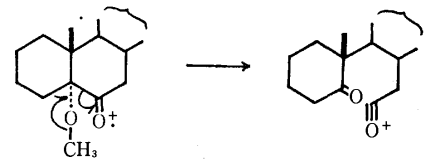
C_5C_6 bond. This assignment is conclusive since it is extremely unlikely that in the ground state Beckmann rearrangement of II, a complete isomerization from *syn* to *anti* takes place before the rearrangement. Hydrogen atoms attached to carbon α to oximino group are known to appear downfield[20] in the NMR spectrum of saturated oximes. 100 MHz NMR spectrum of II revealed a double doublet at τ 6.70 with J=12.2 Hz and 2.3 Hz and the coupling constant requires that the singnal should be assignable to 7α-equatorial hydrogen deshielded by OH of the oximino group. The acetyl derivative IIa (mp 99—101°C) of II showed only a doublet due to 7α-hydrogen at τ 6.76 with J=10.9 Hz.

Compound II (5g) in dry methanol (300 m*l*) was irradiated for 31 hr with a 150-W low pressure mercury arc lamp. Since further irradiation caused transformation of the initial products, it was stopped at this stage. Extensive column chromatography and the preparative tlc of a complex mixture of the products led to the isolation of six products, besides recovery of the starting oxime (31%).[21] They were 3α,5-cyclo-5α-cholestan-6-one (I)[22] (8%), amorphous III (3%), amorphous IV (2%), cholest-4-en-6-one (V)[23] (1%), 5α-cholestan-6-one (VI)[24] (1%), and compound (VII), mp 134—138°C (2%).

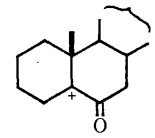
Compound III proved to be identical with lactam III obtained by the ground state Beckmann rearrangement of II. The mass spectrum of IV (the molecular ion at 399) and elemental analysis disclosed that it was isomeric with II having the molecular formula $C_{27}H_{45}ON$. The infrared spectrum of IV demonstrated typical lactam carbonyl bands at 1635 cm^{-1}. While the NMR spectrum of III revealed a signal due to lactam as a singlet, that of IV showed the corresponding signal as a triplet at τ 3.93 (J=5.9 Hz). Moreover, two single-proton double doublets appeared at τ 6.4 (J=5.9 Hz and 14.9 Hz) and at τ 7.06 (J=5.9 Hz and 14.9 Hz). These two protons are ascribable to CH_2 protons α to the lactam nitrogen. On addition of D_2O, the two double doublets coalesced into two doublets centered at the same position (J=14.9 Hz) and the NH signal vanished. It is therefore, evident that the smaller splitting is due to a coupling between CH_2 protons and a proton attached to nitrogen. Thus, structure IV, 7-aza-3α,5-cyclo-*B*-homo-5α-cholestan-6-one is assigned to the compound. The observed two doublets are ascribable to geminal protons attached to C-7 and the magnitude of splitting (J_{AB}= 14.9 Hz) is in agreement with geminal coupling. Although these geminal protons may appear as AB part of ABX system in which X is the C-8 proton, the observed doublet signal shows $J_{AX}=J_{BX}\simeq 0$ Hz, and suggests that dihedral angles between C-7α and C-7β protons and C-8β proton are about 60° and the C-8 proton approximately bisects the angle between the C-7-methylene protons. Protons attached to the cyclopropane ring were not observable since they would be hidden in the methylene envelope.[25]

The mass spectrum (molecular ion 416) and elemental analysis of VII were in agreement with $C_{28}H_{48}O_2$. The presence of a methoxyl group in VII was proved by the NMR spectrum which showed a three-proton singlet at τ 6.64. The infrared spectrum of VII revealed a 6-membered ring ketone at 1714 cm^{-1} but no hydroxyl group. It is clear that the carbonyl group was generated from the oximino group since generation of the parent carbonyl group from the oximino group was found to be usual.[4,8,11] Thus VII might be 3-, 4- or 5-methoxycholestan-6-one formed by the addition of methanol[26] to either I or V. Since in the NMR spectrum of VII we could find no signal attributable to a proton attached to a carbon atom with a OCH_3 group, the methoxyl group should be located at the carbon bearing no hydrogen. Therefore, VII is 5-methoxycholestan-6-one. Since a comparison of chemical shifts of 19-methyl protons of VI (τ 9.25) and VII (τ 9.31) reveals no deshielding of 19-methyl protons in VII by the newly introduced methoxyl group, the structure of VII should be 5α-methoxycholestan-6-one (VII). The mass spectrum of VII showed the base peak at *m/e* 401 and a prominent peak at *m/e* 385 (79%). It seems somewhat unusual that the expulsion of methyl group from aliphatic methyl ether gives a base peak. However, $M-CH_3$ base peak perhaps originates from the cleavage of acyl-carbon bond[27] followed by the loss of methyl unit to afford the following fragment ion A.



A: *m/e* 401 (100%)

Fragment ion 385 corresponds to fragment B.



B: *m/e* 385 (79%)

Discussion

The results we obtained demonstrate that the photo-Beckmann rearrangment can be achieved even in the conjugated cyclopropanone oxime and affords the corresponding lactams with cyclopropane ring. However, the yields of lactams were poor and the major portion of the products was the parent ketone arising

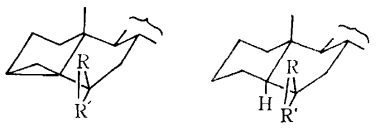
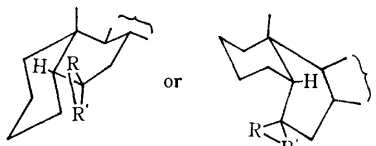
from the elimination of the nitrogen moiety of the intermediary oxaziridine. Thus, compared with the results of the photo-Beckmann rearrangements of 5α-cholestan-6-one oxime and the isomeric 5β-cholestan-6-one oximes[9] the effects of the presence of cyclopropane ring and those of steric origin are evident.



VIII IX



X

R=O, R'=NH or R=NH, R'=O

This would imply that in the intermediate oxaziridine VIII the rearrangement into lactam becomes less easy, owing to the presence of cyclopropane ring, than in the case of oxaziridine IX, and the elimination of nitrogen as N_2, hydrazine[8] or ammonia[11] becomes dominant in the present case. Compared with the isomeric 5β-cholestan-6-one oximes (plausible conformation of the intermediate oxaziridine is depicted as is X) less easy formation of lactams from 5α-isomer is mainly attributable to the conformational factors. Formation of two lactams with cyclopropane ring gives additional support to our view[9] on the C→N migration process in the photo-Beckmann rearrangement.

With regard to the mode of formation of three ketones V, VI and VII obtained as the minor products, it is almost certain that V was derived from I since the formation of α,β-unsaturated ketone from the conjugated cyclopropyl ketone was recognized as general[13,28] and the mode of reaction was recently investigated in detail.[13,29] The other two ketones VI and VII can be derived either directly from I or through the formation of V by photo-reduction as well as photo-addition. Several investigators encountered the photo-reduction of double bond of α,β-unsaturated ketons. Addition of methanol to α,β-unsaturated carbonyl compound generally gives β-methoxy-carbonyl compound[30] and therefore the formation of VII is better understandable by the direct addition of methanol to cyclopropyl ketone (I).

Experimental

All mps were determined by a Yanagimoto type hot-stage and uncorrected. Unless otherwise stated, IR was determined in Nujol using a Jasco model IR-E spectrophotometer. Except for compound VII, all NMR spectra were determined on a Japan Electron Optics PS-100 high resolution NMR spectrometer in $CDCl_3$ solution using TMS as an internal reference. NMR spectrum of compound VII was taken with a Hitachi H-60 high resolution NMR spectrometer. Mallinckrodt silicic acid (100 mesh) was used for column chromatography and Wakogel B-5 for preparative tlc. The progress of the reactions was followed by tlc.

3α,5-Cyclo-5α-cholestan-6-one Oxime.[14] *(II).* Oximation of I by the usual procedure was found to give a single oxime, mp 125—126°C. Literature mp 143—144°C.[14] (from EtOH), $[\alpha]_D^{25}$ ($CHCl_3$) +83.3°. Mass M^+ 399. NMR: τ 9.31 (18-CH_3), τ 9.09 (19-CH_3). Acetate (IIa): *O*-acetate was prepared by the usual method. mp 99—101°C. NMR: τ 6.76 (d, J=10.9 Hz) (7αH), τ9.31 (s, 18-CH_3) τ 9.05 (s, 19-CH_3) τ 7.84 (s, O-Ac).

Beckmann Rearrangement of 3α-5-Cyclo-5α-cholestan-6-one Oxime. II (200 mg) was added to polyphosphoric acid (2 g) which was kept at *ca.* 100°C. The mixture was stirred for 10 min. After cooling the mixture was poured into 10% aqueous sodium carbonate solution. The mixture was extracted with ether. After the usual work up, tlc of the residue (200 mg) showed two spots and the major and more polar compound was purified by preparative tlc ($CHCl_3$ - ether 1 : 1). III (130 mg, 65%) was obtained in an amorphous form. (Found: C, 81.04; H, 11.60; N, 3.63%. Calcd for $C_{27}H_{45}ON$: C, 81.14; H, 11.35; N, 3.51%). IR ($CHCl_3$): 1656 cm^{-1} (CONH). NMR: τ 4.18 (s, NH), τ 9.00 (s, 19-methyl), τ 9.31 (s, 18-methyl). (τ 9.56 quartet J=8.2 and 4.8 Hz) C-4α or C-4βH (τ 7.71, broad s) C-7 methylene. Mass. M^+ 399.

Photolysis of 3α,5-Cyclo-5α-cholestan-6-one Oxime. II (5 g) in dry methanol (300 m*l*) was photolyzed for 31 hours by a 150 W low pressure Hg arc lamp under a nitrogen atmosphere. After removal of the solvent the residue was dissolved in ether (150 m*l*). The ethereal solution was washed with water, dried and evaporated. The residue was subjected to column chromatography by using 100 g of adsorbent. Elution was first made with *n*-hexane and then with a mixture of *n*-hexane and benzene with an increasing amount of benzene (*n*-hexane, 300 m*l*, hexane - benzene 9:1, 300 m*l* hexane - benzene 8:2, 300 m*l*, hexane - benzene 7 : 3, 700 m*l*, hexane - benzene 6 : 4, 600 m*l*, hexane - benzene 5 : 5, 400 m*l*), affording fraction A (1.4 g). Elution was then continued with *n*-hexane - benzene (3 : 7) (300 m*l*), pure benzene (200 m*l*) and finally benzene - $CHCl_3$ (8 : 2) (400 m*l*) to afford fraction B (1.6 g). Elution was continued with benzene - $CHCl_3$ (6 : 4) (200 m*l*), benzene - $CHCl_3$ (4 : 6) (200 m*l*) and benzene - $CHCl_3$ (2 : 8) (300 m*l*) to afford fraction C (0.24 g).

Elution was further carried out with $CHCl_3$ (200 m*l*), $CHCl_3$ - ether (8 : 2) (200 m*l*) and $CHCl_3$ - ether (6 : 4) (200 m*l*) to afford fraction D (1.3 g). Finally, elution was carried out with $CHCl_3$ - ether (4 : 6) (200 m*l*), $CHCl_3$ - ether (2 : 8) (100 m*l*), $CHCl_3$ - ether (1 : 1) (100 m*l*) and ether (200 m*l*) to give fraction E (0.9 g). Fractions A, B, C, and D were subjected to further separation as follows. Fraction A: This was again chromatographed with 26 g of adsorbent, some fractions obtained being further purified by preparative tlc to afford four products. The least polar compound was recrystallized from ethanol to afford 5α-cholestan-6-one (VI), mp 95—97°C,[31] identical with authentic specimen. (30 mg, 0.6%). The second least polar fraction (620 mg) was recrystallized from ethanol to yield 3α,5-cyclo-5α-cholestan-6-

30) R. Stoermer and H. Stockmann, *Ber.*, **48**, 1786 (1914).

31) The literature mps for 5α-cholestan-6-one are mp 98.5—99.5°C[22] and mp 96°C (D. N. Jones, J. R. Lewis, C. W. Shoppee, and G. H. R. Summers, *J. Chem. Soc.*, **1955**, 2876.

one (I) (392 mg, 8%). The third least polar fraction (130 mg) yielded 62 mg (1.3%) of crystals mp 104—106°C, NMR: τ 3.65 (C-4H) (t, J=3.0 Hz), τ 9.30 (s, 18-CH_3) and τ 9.03 (s, 19-CH_3) which were identical with cholest-4-en-6-one.[23] The most polar fraction (200 mg) afforded crystals of the starting oxime (130 mg). Fraction B: This was recrystallized from ethanol to yield the starting oxime (1.4 g) which was then combined with oxime from fraction A. Total yield of pure recovered oxime was thus 31%. Fraction C: This was purified by preparative tlc ($CHCl_3$ containing a small amount of ether). Oily material obtained was recrystallized from ethanol to yield 5α-methoxycholestan-6-one, mp 134—138°C (110 mg, 2%). (Found: C, 80.70; H, 11.64%; Calcd for $C_{28}H_{48}O_2$: C, 80.71; H, 11.61%). IR: 1714 cm^{-1} (6-membered cyclic ketone) 1090 cm^{-1} (C-O). NMR: τ 6.65 (s, OCH_3), τ 9.31 (s, 19-CH_3) τ 9.36 (s, 18-CH_3). Mass: M^+ 416. Fraction D: This was purified by column chromatography (adsorbent 26 g; solvent, benzene - chloroform). Preparative tlc of the eluates with chloroform containing a small amount of ether then afforded 300 mg of crude material which was subjected again to preparative tlc (ethyl acetate - ether - benzene 3 : 2 : 1) to afford two amorphous compounds. Less polar compound IV (100 mg; 2%) (Found: C, 81.11; H, 11.29; N, 3.55%. Calcd for $C_{27}H_{45}ON$: C, 81.14; H, 11.35; N, 3.51%). IR ($CHCl_3$): 1635 cm^{-1} (NHCO), 3420 cm^{-1} (NH). More polar compound III (160 mg; 3%) was identical with the lactam obtained by the ground-state Beckmann rearrangement.

We are grateful to Mrs. S. Araki in this department for the measurements of NMR spectra, also to the staffs of the laboratories for mass spectrometric analysis and elemental analysis of the Faculty of Pharmaceutical Sciences of this University, for the mass spectral determinations and the elemental analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1839—1843 (1972)

The Structure of κ-Carrageenan from *Gigartina Tenella*

Susumu HIRASE and Kyoko WATANABE

Department of Chemistry, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Kyoto

(Received October 25, 1971)

An alkaline treatment of κ-carrageenan from *Gigartina tenella* resulted in the change of the proportions of galactose, 3,6-anhydro-galactose and sulfate from 100 : 91 : 124 to 95 : 96 : 119. Fragmentation of the methylated polysaccharide gave 2,4,6-tri-*O*-, 2,6-di-*O*-, and mono-*O*-methyl-D-galactose in the molar proportions of 1 : 18 : 0.8 together with 3,6-anhydro-D-galactose and its 2-*O*-methyl-derivative in the molar proportion of 1 : 4. From these and other data, it is concluded that the polysaccharide is composed of the residues of 1,3-linked β-D-galactose 4-sulfate (95 mol), 1,4-linked α-D-galactose 6-sulfate (5 mol), and 1,4-linked 3,6-anhydro-α-D-galactose (67 mol) and its 2-sulfate (24 mol), and that the 1,3- and 1,4-linked residues are repeated alternatingly to form a chain macro-molecule.

The chemical structure of κ-carrageenan obtainable from several species of red seaweeds of the *Chondrus and Gigartina* families has been extensively investigated by many workers.[1)]

Our previous studies on the κ-carrageenan from *G. tenella*[2)] showed the presence of D-galactose, 3,6-anhydro-D-galactose and ester sulfate in the molar proportions of 100 : 98 : 117, together with very small amounts of L-galactose and D-xylose. Partial methanolysis provided evidence that carrabiose (3,6-anhydro-4-*O*-β-D-galactopyranosyl-D-galactose) represented the repeating units of the backbone structure of the sulfated polysaccharide. In the present paper, further details of the structure have been investigated by means of alkali-treatment, methylation and IR spectroscopic measurement.

The κ-carrageenan used in this work has been prepared in the same manner as that described in the preceding paper.[2)] On analysis it contained galactose, 3,6-anhydro-galactose and sulfate in the molar proportions of 100 : 91 : 124, the proportions being in approximate agreement with those of the previous preparations. When this polysaccharide sample was treated with alkaline borohydride according to the method of Rees,[3)] the molar proportions of the components changed from those described above to 95 : 96 : 119. It is apparent that both galactose and sulfate decreased by 5 mol with concurrent increase of an equimolar amount of the anhydro-sugar. This could be explained by the presence of 2-linked galactose 3-or 6- sulfate or 4-linked galactose 3- or 6-sulfate residues, any of which could be convertible into 3,6-anhydro-galactose residues by the alkali treatment. However, from the general concept[4)] of chemical structures, based on extensive investigations of a variety of sulfated polysaccharides of red seaweed origin, it is most probable that 5 mol of 4-linked galactose 6-sulfate residues exist in the sulfated polysaccharide under investigation.

The sulfated polysaccharide was then methylated ten times with dimethyl sulfate and sodium hydroxide solution. The product contained 17.3% of methoxyl groups and 16.7% of sulfate groups. If the methylation was complete for the alkali-modified polysaccharide, 4-linked galactose 6-sulfate residues should have been converted into 3,6-anhydro-galactose re-

sidues, and consequently, the product would contain 17.2% of methoxyl groups and 20.6% of sulfate groups. That the observed sulfate content was lower than the expected one suggested that additional desulfation had occurred during the methylation.

TABLE 1. FRAGMENTATION OF METHYLATED κ-CARRAGEENAN

Methylated sugar	Molar ratio
2,4,6-Tri-*O*-methyl-D-galactose	1.0
2,6-Di-*O*-methyl-D-galactose	18.0
Mono-*O*-methyl-D-galactose	0.8
2-*O*-Methyl-3,6-anhydro-D-galactose	4.0
3,6-Anhydro-D-galactose	1.0

The complete degradation of the methylated polysaccharide gave the products shown in Table 1. 2,4,6-Tri-*O*-methyl-D-galactose and 2,6-di-*O*-methyl-D-galactose were identified by the isolation of crystalline reducing sugars. Mono-*O*-methylgalactoses were shown to be mainly 2-*O*-methyl- and 6-*O*-methyl derivatives by paper chromatography, gas liquid chromatography and paper electrophoresis. 3,6-Anhydro-D-galactose was obtained as a syrupy dimethylacetal, and was then converted into crystalline diphenylhydrazone. 2-*O*-Methyl-3,6-anhydro-D-galactose was identified by the isolation of its crystalline methyl β-glycoside. In addition, a trace amount of 2,4-di-*O*-methyl-D-galactose was also shown to be present.

Among the partially methylated D-galactoses obtained above, 2,6-di-*O*-methyl-D-galactose was the major product in accordance with the cases of κ-carrageenans of other origin.[5] This product is derived either from 3-linked D-galactose 4-sulfate or 4-linked D-galactose 3-sulfate residues. But the latter possibility is completely excluded, because the 3-sulfate residues would have been converted into 3,6-anhydro-D-galactose residues by the action of alkali during methylation. The formation of 2,4,6-tri-*O*-methylgalactose appears to indicate the presence of non-sulfated, 3-linked D-galactose residues. However, on the basis that the yield was as small as one eighteenth of that of 2,6-di-*O*-methyl-D-galactose, and also that some desulfation occurred during methylation as discussed above, it seems more probable that this tri-*O*-methylgalactose has been derived by desulfation followed by methylation from 3-linked D-galactose 4-sulfate residues. The yield of the tri-*O*-methylgalactose relative to that of the di-*O*-methylgalactose indicated that 5% of the 4-sulfate residues were desulfated during methylation. The formation of small amounts of 2-*O*-, and 6-*O*-methylgalactose could be accounted for by incomplete methylation of 3-linked D-galactose 4-sulfate residues. 2,4-Di-*O*-methyl-D-galactose was formed in so small an amount that it had no structural significance. After all, all the D-galactose residues seem to be joined 1,3 with sulfate groups on C_4 in the native polysaccharide.

On the other hand, the formation of 2-*O*-methyl-3,6-anhydro-D-galactose and non-methylated 3,6-anhydro-D-galactose as the cleavage fragments from the methylated polysaccharide indicates that all the anhydro-sugar residues are joined 1,4 as has been proved by the isolation of carrabiose derivatives in high yield[2], and also that some of the anhydro-sugar residues are 2-sulfated. The proportion of the 2-sulfated residues to the non-sulfated residues may not be directly evaluated from the relative yields of the anhydro-sugar fragments from the methylated polysaccharide, because a part of the 2-sulfate groups might have possibly been released during methylation. This possibility is supported by the fact[6] that the treatment of methyl 2-*O*-p-toluensulfonyl-3,6-anhydro-D-galactoside with strong alkali resulted in complete desulfonation without configurational inversion.

Now the problems to be solved are concerned with the proportion of 2-sulfation on anhydro-sugar residues in the native polysaccharide and also with the proportion of desulfation of these sulfate groups during methylation. These problems have been tentatively solved as shown in Table 2, which includes the summary of discussion as well. As has been already mentioned, the native polysaccharide contains galactose, anhydrogalactose and sulfate in the molar proportions of 100 : 91 : 124. Since, on the basis of the results of alkali treatment, 5 mol per 100 mol of galactose residues are joined 1,4 with 6-sulfate groups, as has been mentioned above, the residual 95 mol are joined 1,3 with 4-sulfate groups. These two residues account for 100 mol per 124 mol of total sulfate groups so that

TABLE 2. STRUCTURAL FEATURES OF THE κ-CARRAGEENAN

κ-Carrageenan	Residues in relative moles

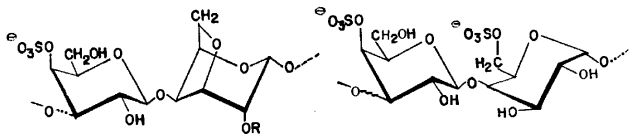
24 mol of sulfate groups could exist on C_2 of anhydro-sugar residues. Then the non-sulfated anhydro-sugar residues exist by 67 mol, the proportion of 2-sulfation to non-sulfation being approximately 1 : 3. When the polysaccharide was methylated, 5 mol per 95 mol of galactose 4-sulfate residues seems to have been desulfated, as was discussed above. Similarly, if it is presumed that 5 mol per 24 mol of anhydro-sugar 2-sulfate residues were desulfated during methylation, fragmentation of the methylated polysaccharide would produce 3,6-anhydro-D-galactose and its 2-methyl ether in the molar proportion of 77 : 19, which agrees with the experimental result (4 : 1), Furthermore, when such desulfation as discussed above are taken into consideration, the molar proportion of methoxyl groups to sulfate groups should be 2.48 for the completely methylated polysaccharide. This value is again reasonable for the experimental result (2.67).

In conclusion, the κ-carrageenan under investigation is a hybrid consisting of three structural units a (70%), b (25%), and c (5%) shown in Fig. 1, the α-linkages being presumed from the positive value of optical rotation of the native polysaccharide.[2] Although the indicated proportions between the units are based on the discussion about Table 2, the κ-carrageenan seems to contain a family of related polysaccharide molecules, which differ more or less in the proportions of a, b, and c, as has been pointed out by Anderson and his co-workers[7]. The structure proposed above is similar in outline to that reported for the κ-carrageenan from *Gigartina stellata* as well as from *Chondrus crisps*.[5]



(a) R=H
(b) R=$SO_3^{\ominus}$ (c)

Fig. 1. The possible structure of the κ-carrgeenan from *G. tenella*

The proposed structure is also supported by infrared spectrum, which showed absorption bands at 850 cm^{-1} and 805 cm^{-1}. The former band is attributed to the sulfate groups attached to secondary axial hydroxyl groups[8] (C_4 of D-galactose residues), while the latter band is characteristic to the 2-sulfate groups on anhydro-sugar residues.[7] The band (820 cm^{-1}) due to the sulfate groups on primary hydroxyl groups (C_6 of galactose residues) was not observed. The 6-sulfated residues exist in so small amounts that the band may be masked in the broadening region of neighboring bands.

Experimental

General Method. Solutions were concentrated under reduced pressure at 40°C in a rotary evaporator. Melting points were measured on Yanagimoto apparatus Model MP-S2. Paper electrophoresis was performed on Toyo filter paper No. 51 with 0.1 M sodium borate buffer (pH 10) and a potential gradient of 17 volts/cm. Infrared spectra were recorded with Hitachi Infrared Spectrophotometer Model 215 (sample as a potassium bromide disk).

Paper Chromatography (pc) and Thin Layer Chromatography (tlc). Pc was performed on Toyo-filter paper No. 51, and the solvents (in v/v) used were as follows: A) 1-butanol - acetic acid - water (4 : 1 : 2); B) 1-butanol - ethanol-water (5 : 1 : 4, upper layer); C) butanone - 28% ammonium hydroxide - water (20 : 0.1 : 1.7); D) cyclohexanol saturated with water; E) 1-butanol - pyridine - water (10 : 3 : 3); F) benzene - ethanol (5 : 1) saturated with water; G) ethyl acetate - pyridine - water saturated with ammonium borate (12 : 4.5 : 3); and H) 1-butanol-water saturated with ammonium borate (4 : 1 : 2). In the case of the solvents G and H, filter paper was dipped into ammonium borate solution and dried before use. Spray reagents used were a) aniline hydrogen phthalate,[9] b) *p*-anisidine hydrochloride,[10] and c) *o*-aminophenol phosphate.[11] Tlc was carried out on glass plates (20 cm in length) coated with silica gel G containing calcium sulfate as binder, using the solvents J ethyl acetate-pyridine-water (30 : 2 : 1), and K benzene-ethanol-water (40 : 15 : 1). Chromatograms were sprayed with 2N-methanolic sulfuric acid and heated at 110°C.

Gas Liquid Chromatography (glc). The apparatus used was a Hitachi Gas Chromatograph Model K53 equipped with a hydrogen flame ionization detecter, using nitrogen as a carrier gas. Analyses were carried out by the following methods depending upon the purpose: Method A: For the general purpose, methyl glycosides and dimethyl acetals of methylated sugars were analysed on a column (3 mm × 1 m) packed with 2.5% neopentylglycol succinate on chromosorb W (100—200 mesh) at 160°C. This method has the disadvantage that some of the peaks are overlapped each other especially in the analysis of a complicated mixture. Method B: For the purpose of identifying anhydro-sugar derivatives, a mixture (10 mg) of methyl glycosides and dimethyl acetals of methylated sugars was dissolved in concentrated hydrochloric acid (0.2 m*l*) at 0°C, ethanethiol (0.1 m*l*) added, and the mixture was vigorously stirred at 0°C for 15 min. By this treatment, anhydro-sugar derivatives were converted into diethyl dithioacetals, while methylated methyl galactosides were mostly unchanged. The reaction mixture was neutralized with saturated sodium bicarbonate solution, evaporated to dryness, and the trimethylsilylated with pyridine (0.5 m*l*), trimethylchlorosilane (0.1 m*l*), and hexamethyldisilazane (0.2 m*l*). The products in chloroform (3 m*l*) were washed three times with cold water (1 m*l*), dried with anhydrous magnesium sulfate, evaporated, and then analysed on a column (1 m) packed with 5% neopentyl glycol succinate on chromosorb W (100—200 mesh) at 160°C. Retention times of trimethylsilylated diethyl dithioacetals were much higher than those of trimethylsililated methyl galactosides. Method C: For the purpose of identifying galactose derivatives, the sample to be analysed was hydrolysed with 1 N-sulfuric acid at 100°C for 5 hr. During this treatment, anhydro-sugar derivatives are, if present, completely degraded. The remaining methylated galactoses were converted into alditol acetates, which were then analysed on a column (2 m)

packed with 3% ECNSS-M on chromosorb W.[12,13]

Column Chromatography. Effluents were collected in an automatic fraction collector, and examined for their contents by pc, tlc, and/or coloration with an anthrone-sulfuric acid reagent and a resorcinol-hydrochloric acid reagent.[14] Fractions containing the same contents were combined, evaporated and again examined by pc, tlc and/or glc.

Alkali Treatment of Polysaccharide. According to the method of Rees,[3] the polysaccharide (0.42 g) dissolved in water (250 m*l*) was treated with sodium borohydride (0.1 g) at room temperature for 24 hr. Sodium hydroxide (10 g) and sodium borohydride (1.5 g) were then added, and the mixture was heated at 80°C for 3 hr. The solution was neutralized with acetic acid, dialysed against running tap water for 2 days, concentrated, precipitated with ethanol, and finally dried *in vacuo*; yield, 0.33 g (78.5%).

The product, as well as the sample before alkali treatment, was analysed for sugars by the colorimetric method with a resorcinol reagent and an anthrone reagent after Yaphe,[14] and for sulfate by the volumetric method[15] modified as follows: the sample (2—5 mg) to be analysed was dissolved in water (3—10 m*l*), and about 0.005 N glycol chitosan solution (2 m*l*) was added in excess to precipitate the polysaccharide sulfate in a stoichiometric reaction. To this mixture, 1 N-hydrochloric acid (0.5 m*l*) and one or two drops of 0.2% toluidine blue indicator solution were added. The excess of the glycol chitosan was titrated with a standard 0.0025 N potassium polyvinyl alcohol sulfate solution (equivalent 162) until the indicator changed from blue to reddish purple. The sulfate content of the sample was calculated from the difference between the titration value and the blank value. The results were as follows: the molar proportions of galactose, 3,6-anhydro-galactose and sulfate were 1 : 0.91 : 1.24 in the native polysaccharide, and 0.95 : 0.96 : 1.19 (1 : 1.01 : 1.25) in the alkali-treated sample.

Methylation of Polysaccharide. To a solution of polysaccharide (12.4 g) in water (150 m*l*) treated with sodium borohydride (0.5 g) overnight at room temperature was added dimethyl sulfate (50 g) and 30% sodium hydroxide (80 m*l*) dropwise with vigorous stirring during 6 hr at 60°C under at atmosphere of nitrogen. The reaction mixture was left overnight. Dimethyl sulfate (50 g) and 30% alkali (80 m*l*) were again added in the same manner. The reaction mixture was left overnight, then heated at 80°C for 1 hr to decompose the excess of dimethyl sulfate, neutralized with 2 N-sulfuric acid, dialysed against running tap water for 50 hr, and concentrated. The resulting solution was treated four more times with dimethyl sulfate and alkali in the same manner as above-mentioned. Finally, the methylated polysaccharide was precipitated with 99% ethanol and dried *in vacuo*; yield, 10 g; $[\alpha]_D^{10}$ +57.3° (*c* 0.79, water), (Found: OCH_3, 17.3; SO_3, 16.7%).

Methanolysis of Methylated Polysaccharide. The methylated polysaccharide (8.1 g) was treated with 3% methanolic hydrogen chloride at 80°C for 20 hr. The reaction mixture was then neutralized with silver carbonate, filtered and evaporated. The resulting syrup was treated with 0.2 N-barium hydroxide solution (100 m*l*) at 60°C for 2 hr, neutralized with carbon dioxide, and filtered. The filtrate was passed through Amberlite IR-120 (200 m*l*) and IR-45 (300 m*l*) in succession, and the deionized solution was evaporated to a syrup; yield, 4.82 g.

Analysis of the Methanolysis Products. Examination of the methanolysis products obtained above by pc (solvent D, spray reagent c) indicated the presence of 3,6-anhydro-galactose dimethyl acetal (**1**), its 2-methyl ether (**2**), and the methyl β-glycopyranoside (**3**) corresponding to **2**. Analysis by glc (method B) showed two peaks of diethyl dithioacetals, one of which was derived from **1**, and the other from **2**. and **3**. From the peak areas measured and the molar response factor determined for authentic samples, it was shown that 3,6-anhydrogalactose and its 2-methyl ether existed in the molar proportion 1 : 4.

On the other hand, when a portion of the methanolysis products was hydrolysed and examined by pc (solvent A, B and C; spray reagent a and b), there were detected 2,6-di-*O*-methylgalactose (**4**) together with small amounts of 2,4,6-tri-*O*-methylgalactose (**5**) and mono-*O*-methylgalactose (**6**). Analysis by glc (method C) showed that **4**, **5** and **6** existed in the molar proportions of 1 : 18 : 0.8, the figure being based on the peak areas and molar response factors.

Separation of the Methanolysis Products. Methanolysis products (1.3 g) obtained above were applied to a Dowex 1×4 column (OH form, 5×36 cm) and eluted first with distilled water to give fractions I, II, and III. The column was then eluted with 0.2 M-ammonium carbonate aqueous solution, and the effluent was deionized with Amberlite IR-120 and IR-45 resins, and evaporated to give fraction IV. All the fractions were obtained in syrups.

Fraction I: Yield, 0.61 g. This fraction should be a mixture of methyl glycosides of partially methylated galactoses, as it showed color reaction with an anthrone reagent and no color reaction with a resorcinol reagent. It was combined with a similar fraction obtained by the same procedure as that mentioned above, and the resulting mixture (1.4 g) was hydrolysed with 1 N-sulfuric acid (20 m*l*) at 100°C for 30 hr. The resulting mixture of reducing sugars (1.08 g) was separated on a cellulose powder column (5×40 cm), which was eluted first with a benzene-ethanol (5 : 1) mixture saturated with water, to give fractions I-1 (0.24 g), and I-2 (0.88 g) in syrups. The proportion of the solvent mixture was then changed to 3 : 1 to give fraction I-3 (0.04 g) in a syrup.

Examination of the fraction I-1 by pc (solvent F, spray reagent b) showed two spots, one (R_f 0.73, pink brown) corresponding to 2,4,6-tri-*O*-methylgalactose, and the other (R_f 0.63, pale brown) corresponding to an unidentified compound. In tlc (solvent J and K), the former component gave a darker spot with slightly higher R_f value than the latter component. The mixture was separated to the components on an Avicel column (3×92 cm) with a benzene-ethanol (5 : 1) mixture saturated with water. The faster moving component (0.077 g) was identified as 2,4,6-tri-*O*-methyl-D-galactose, which was crystallized from ether; mp and mmp 102—103.5°C,[16] $[\alpha]_D^{10}$ +116.9°→+79.8°[16,19] (*c* 0.46, water), (Found: C, 48.66; H, 8.19%). The slower-moving component (0.07 g) was not examined further.

Fraction I-2 (0.88 g) gave a single spot corresponding to 2,6-di-*O*-methylgalactose both in pc (solvent B and C, spray reagent b) and tlc (solvent K). It crystallized readily and was recrystallized from ethanol - petroleum ether, 2,6-di-*O*-

methyl-D-galactose was obtained as plates; mp and mmp 118—119.5°C,[17,18] $[\alpha]_D^{10}$ +47.7°→+90.7°[17,18] (*c* 0.73, water), (Found: C, 46.16; H, 7.91%).

Fraction I-3 (0.04 g) was shown by pc (solvent C and F, spray reagent b) to be a mixture of 2,6-di-*O*-methylgalactose, 2,4-di-*O*-methylgalactose and mono-*O*-methylgalactose. The mixture was separated to the components on an Avicel column (2×30 cm), which was first eluted with benzene-ethanol (5 : 1) saturated with water to give two fractions. The proportion of the solvent mixture was then changed to 3 : 1 to give an additional fraction. The first fraction (0.11 g) on crystallisation gave 2,6-di-*O*-methyl-D-galactose; mp and mmp 118—119.5°C, $[\alpha]_D^{12}$ +45.3°→+88.5° (*c* 0.46, water). The second fraction (0.005 g), $[\alpha]_D^{28}$ +76.7° (*c* 0.45, water),[18] was obtained as a syrup, which showed exactly the same behavior as that of an authentic sample of 2,4-di-*O*-methyl-D-galactose both in pc[18] (solvent C and F, spray reagent b) and glc (method C). This fraction was obtained in too small an amount to be crystallized. The last fraction (0.025 g) was obtained as a syrup, which was shown to be a mixture of 2-*O*-, 3-*O*-, 4-*O*-, and 6-*O*-methylgalactoses both by paper electrophoresis and glc (method C), the first and last components being predominant. Isolation of the components was not attempted.

Fraction II. Yield, 0.48 g; $[\alpha]_D^{23}$ −21.6° (*c* 0.85, water). Examination of the fraction II by pc and tlc with any solvent system, detected a single spot, respectively. But examination by glc (method A) revealed the presence of three components, one of which had exactly the same retention time as that of an authentic sample of 2-*O*-methyl-3,6-anhydro-galactose dimethyl acetal. The other two seemed to be methyl 2,6-di-*O*-methyl-α- and -β-galactofuranosides. The negative value of optical rotation of this fraction II supported the above view. As the mobilities of these three were identical both on a filter paper and a thin layer chromatogram with any solvent system, the separation on a column was not attempted. Instead, the fraction was treated with methanolic hydrogen chloride to give an equilibrium mixture in the following manner. The fraction was combined with a similar fraction (1.2 g) obtained from the methanolysis products of the methylated polysaccharide, and the resulting mixture (1.68 g) was heated with 1.5% methanolic hydrogen chloride (20 m*l*) at 80°C for 23 hr, at which time optical rotation of the reaction solution reached a constant value (α_D −2.5→+0.8°). The reaction solution was treated in the usual manner, and the products were chromatographed on a Dowex 1×4 column (OH form, 3×46 cm) with distilled water as a eluting solvent, three fractions being obtained. The first fraction (0.41 g), $[\alpha]_D^{15}$ +120.2° (*c* 0.88, water) was identified as methyl 2,6-di-*O*-methyl-α- and -β-D-galactopyranosides, which on hydrolysis with N-sulfuric acid at 100°C for 5 hr gave 2,6-di-*O*-methyl-D-galactose; mp and mmp 118—119°C, $[\alpha]_D^{10}$ +47°→+86° (*c* 0.52, water). The second fraction (0.75 g), $[\alpha]_D^{15}$ −18.2° (*c* 0.61, water) was a mixture of the same components as those of the fraction II itself. The last fraction (0.29 g) was identified as methyl 2-*O*-methyl-3,6-anhydro-β-D-galactopyranoside, which was crystallized from ether; mp 65.5°C, $[\alpha]_D^{10}$ −65.1° (*c* 0.87, water).

Fraction III. Yield, 0.126 g; $[\alpha]_D^{23}$ −44.0° (*c* 1.45, water). In pc (solvent D, spray reagent c) the fraction III showed a single spot. It crystallized on standing. Recrystallization from ether gave methyl 2-*O*-methyl-3,6-anhydro-β-D-galactopyranoside. This is the first information of this compound, although its enantiomorph was reported before;[19] mp 65—65.5°C, $[\alpha]_D^{10}$ −66.3° (*c* 0.79, water), (Found: C, 50.52; H, 7.5%).

Fraction IV. Yield, 0.061 g; $[\alpha]_D^{23}$ +24.0° (*c* 1.1, water). This fraction was identified as 3,6-anhydro-D-galactose dimethyl acetal[2,20,21] by the optical rotation, pc (solvent A, B, and D, spray reagent c) and also by the hydrolysis with 0.1 N-sulfuric acid at 100°C for 2 hr to the reducing sugar, which was then converted into the diphenylhydrazone;[20] mp and mmp 156—157.5°C, $[\alpha]_D^{10}$ +40.0°→+31.9° (*c* 0.26, methanol), (Found: C, 66.07; H, 5.75; N, 7.94%).

The authors are grateful to the Ministry of Education for a Grant in Aid for Scientific Research.

The Synthesis of 3,6-Anhydro-5-*O*-methyl-D-galactose

Susumu HIRASE and Kyoko WATANABE

Department of Chemistry, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Kyoto

(Received November 6, 1971)

3,6-Anhydro-5-*O*-methyl-D-galactose has been synthesized for the first time through a series of reactions composed of blocking the hydroxyl groups at C_2 and C_4 of methyl 3,6-anhydro-α-D-galactopyranoside with the phenylcarbamoyl groups, converting the resulting derivative of the methyl glycoside into the corresponding dimethyl acetal, methylating the newly formed hydroxyl group at C_5, removing the blocking substituents, and finally hydrolysing the dimethyl acetal. The partially methylated anhydro-sugar obtained was uncrystallizable, and was characterized by its crystalline dimethyl acetal and crystalline aldonamide.

3,6-Anhydro-D- and -L-galactoses occur in a variety of red seaweed polysaccharides as their component sugars.[1] In a course of our structural investigation on some of these polysaccharides, 3,6-anhydro-5-*O*-methyl-D-galactose has been needed as a reference compound. This partially methylated anhydro-sugar has never appeared in literatures, although its isomeric 2-*O*-methyl[2,3] and 4-*O*-methyl[4] derivatives have been described. Its synthesis has been carried out for the first time through the route described below.

Methyl 3,6-anhydro-α-D-galactopyranoside(I) has been used as a starting compound. Its hydroxyl groups at C_2 and C_4 were blocked with the phenylcarbamoyl groups. The resulting phenylcarbamoylated methyl glycoside(II) was converted into the corresponding dimethyl acetal(III) with the open chain structure by an action of boiling methanolic hydrogen chloride. This opening of the pyranose ring has been reported to be an unusual property of 3,6-anhydro-galactosides.[5,6] The newly formed hydroxyl group at C_5 was then methylated(III→IV). Reductive removal of the blocking substituents[7] from IV gave crystalline 3,6-anhydro-5-*O*-methyl-D-galactose dimethyl acetal(V), which was further characterized by its crystalline *p*-nitrobenzoate. Three isomers are possible for 3,6-anhydro-mono-*O*-methyl-D-galactose dimethyl acetal in respect to the position of the *O*-methyl group. As the dimethyl acetal obtained above was distinguished in properties from the 2-*O*-methyl and 4-*O*-methyl isomers, the *O*-methyl group of the dimethyl acetal should exist on C_5 as expected. Mild hydrolysis of the dimethyl acetal(V) afforded 3,6-anhydro-5-*O*-methyl-D-galactose, which was uncrystallizable. Any other reducing derivatives of the anhydro-sugar as well as the anhydro-sugar itself have never been crystallized.

The partially methylated anhydro-sugar obtained above showed a ketose reaction, reduced a Fehling's solution at room temperature, and restored the color to a Schiff's reagent. These properties are in agreement with those of the parent anhydro-sugar.[5] When oxidized with bromine, the partially methylated anhydro-sugar gave 3,6-anhydro-5-*O*-methyl-D-galactonic acid, which was characterized by its crystalline amide. This amide was again distinguishable from the 2-*O*-methyl and 4-*O*-methyl isomers.

Experimental

General Methods. Solutions were concentrated under reduced pressure below 40°C with a rotary evaporator. Melting points were determined on a micro hot stage with Yanagimoto apparatus Model MP-S2. Paper chromatography was carried out on Toyo filter paper No. 51 with, unless otherwise stated, 1-butanol - acetic acid - water(4 : 1 : 2 v/v) as a solvent. Spots were located with an *o*-aminophenol reagent.[8]

Methyl 3,6-Anhydro-2,4-di-O-phenylcarbamoyl-α-D-galactopyranoside(II). To a solution of methyl 3,6-anhydro-α-D-galactopyranoside(I)[9] (2.0 g) in dry pyridine(20 m*l*) was added phenylisocyanate(3.5 g) and the mixture was heated at 100°C for 2 hr. A small amount of methanol was added to destroy the excess of the reagent, the mixture concentrated, and the residual syrup was dissolved in methanol(20 m*l*). Diphenylurea, which crystallized on standing, was removed by filtration and the filtrate was concentrated to a glass (4.7 g); $[\alpha]_D^{25}$ +50.8° (*c* 1.24 in methanol), $[\alpha]_D^{25}$ +44.6° (*c* 1.04 in chloroform), (Found: N, 6.95; OCH_3, 7.18%. Calcd for $C_{21}H_{22}O_7N_2$: N, 6.76; OCH_3, 7.49%).

3,6-Anhydro-2,4-di-O-phenylcarbamoyl-D-galactose Dimethyl Acetal(III). A solution of II(4.7 g) in 1% methanolic hydrogen chloride(50 m*l*) was refluxed for 1.5 hr, when the optical rotation of the solution reached a constant value

TABLE 1. PROPERTIES OF THE DERIVATIVES OF 3,6-ANHYDRO-MONO-*O*-METHYL-D-GALACTOSES

Derivative	Properties	2-*O*-Methyl[a]	4-*O*-Methyl[4]	5-*O*-Methyl
Dimethyl acetal	Mp (°C)	liquid	liquid	53—54
	$[\alpha]_D$ (°) (H_2O)	−31.1	+33.9	+45.3 (*c* 0.93, 25°C)
	R_f[b]	0.61	0.68	0.53
	Retention time (min)[c]	5.5	3.0	4.4
Aldonamide	Mp (°C)	171—172	111	47—48 (monohydrate)
	$[\alpha]_D$ (°) (H_2O)	−75.4	+82.66	+65.5 (*c* 1.80, 25°C)

a) The values reported for L-compounds[2] are cited herein, as the corresponding D-compounds have not been reported so far.
b) Paper chromatograms were irrigated with cyclohexanol saturated with water.[2]
c) Gas liquid chromatography was carried out on a column (1 m) packed with 3% ECNSS-M on Chromosorb-W at 160 °C. Xylitol pentaacetate, added as an internal marker, showed the retention time 9.2 min.

($[\alpha]_D$ +51°→39°). The solution was neutralized with silver carbonate, filtered, and concentrated to a colorless thick syrup(4.7 g); $[\alpha]_D^{25}$ +30.0° (*c* 0.40 in methanol), $[\alpha]_D^{25}$ +53.4° (*c* 0.88 in chloroform). The slightly lower value of the methoxyl content indicated that the product was contaminated with a small amount of II and its β-isomer, which had been in equilibrium with III during the reaction. (Found: N, 6.40; OCH_3, 13.10%. Calcd for $C_{22}H_{26}O_8N_2$: N, 6.28; OCH_3, 13.90%).

3,6-Anhydro-5-O-methyl-2,4-di-O-(N-methylphenylcarbamoyl)-D-galactose Dimethyl Acetal (IV). The syrup (4.6 g) obtained above, was methylated twice with iodomethane (10 m*l*) and silver oxide(10 g) in *N,N*-dimethylformamide (40 m*l*) according to the method of Kuhn and his coworkers.[10] The product(IV) was obtained as a slightly colored syrup (5.0 g); $[\alpha]_D^{25}$ +34.5° (*c* 1.51 in methanol), $[\alpha]_D^{25}$ +28.4° (*c* 0.81 in chloroform). (Found: OCH_3, 18.51%. Calcd for $C_{25}H_{32}O_8N_2$: OCH_3 19.06%).

3,6-Anhydro-5-O-methyl-D-galactose Dimethyl Acetal(V). Accroding to the procedure of Bouveng,[7] IV(5.0 g) was treated with lithium aluminum hydride (2.0 g) in boiling tetrahydrofuran(100 m*l*) for 3 hr. The crude product obtained was purified by dissolution in water(20 m*l*) and extraction with hexane to remove an oily by-product. Evaporation of the aqueous solution gave a colorless syrup(1.8 g). Paper chromatographic examination of this syrup showed the presence of a small amount of methyl 3,6-anhydro-galactosides (R_f 0.68) in addition to V(R_f 0.75). The mixture was separated on a charcoal-Celite column(4.6×33 cm), which was eluted first with 2% ethanol(4.7 *l*) and then 5% ethanol (15 *l*). The methyl glycosides together with a small amount of V were eluted with the former eluant. Concentration of the effluent containing V gave a syrup, which was further purified by solution in acetone, filtration and re-concentration. V was obtained as a colorless syrup, which crystallized on standing for several months; yield 1.2 g (48% based on I). It was recrystallized twice from ethyl acetate-benzene-hexane(1 : 1 : 2). Its mp, specific optical rotation, R_f value in paper chromatography, and retention time in gas liquid chromatography are recorded in Table 1. These properties are distinguishable from those of 2-*O*-methyl and 4-*O*-methyl isomers, as compared in the same table.

Found: C, 48.46; H, 8.17; OCH_3, 41.60%. Calcd for $C_9H_{18}O_6$: C, 48.64; H, 8.16; OCH_3, 41.90%.

3,6-Anhydro-5-O-methyl-D-galactose Dimethyl Acetal 2,4-Di-p-nitrobenzoate. A mixture of V(0.10 g), *p*-nitrobenzoyl chloride(0.50 g), and dry pyridine(5 m*l*) was allowed to stand at room temperature for 24 hr. Water (0.5 m*l*) was added to hydrolyse the excess of the reagent, and a saturated sodium bicarbonate solution(50 m*l*) was then added with strirring. The *p*-nitrobenzoate(0.24 g), which was precipitated, was recrystallized twice from ethanol; mp 145—146°C, $[\alpha]_D^{27}$ +69.7° (*c* 0.76 in chloroform).

Found: C, 52.89; H, 4.61; N, 5.31%. Calcd for $C_{23}H_{24}O_{12}N_2$: C, 53.08; H, 4.65; N, 5.38%.

3,6-Anhydro-5-O-methyl-D-galactose. The dimethyl acetal(V) (0.80 g) was hydrolysed with 0.02 N sulfuric acid (30 m*l*) at 100°C for 1.5 hr. The product, isolated in the usual manner, was further purified by dissolution in methanol, filtration and concentration to give the reducing sugar as a colorless syrup(0.60 g). It showed a Seliwanoff's ketose reaction, reduced a Fehling's solution at room temperature and restored the color to a Schiff's reagent; $[\alpha]_D^{28}$ +23.2°→+26.8° (*c* 0.56 in water). (Found: OCH_3, 17.26%. Calcd for $C_7H_{12}O_5$: OCH_3, 17.61%).

3,6-Anhydro-5-O-methyl-D-galactonamide. The reducing sugar (0.58 g) obtained above was oxidized with bromine (0.40 m*l*) in water(10 m*l*) in the dark at room temperature for 24 hr. The excess of the oxidant was removed by aeration, and the solution was neutralized with silver carbonate and filtered. The filtrate was passed through a column of Amberlite IR-120(H^+ form)(10 m*l*), and then neutralized with a barium hydroxide solution. Concentration of the solution gave the barium salt, which was purified by dissolution in ethanol, filtration, and precipitation with acetone. The salt was then dissolved in water and treated with Amberlite IR-120(H^+ form) (10 m*l*). Evaporation of the solution gave 3,6-anhydro-5-*O*-methyl-D-galactonic acid as a colorless syrup (0.50 g); $[\alpha]_D^{25}$ +25.4° (*c* 0.63 in water). Crystallization was unsuccessful. This acid was converted into the methyl ester by reaction with boiling 3% methanolic hydrogen chloride(5 m*l*) for 4 hr. The product was purified by dissolution in ethyl acetate, filtration, and concentration. The ester was obtained as a colorless syrup(0.40 g); $[\alpha]_D^{25}$ +22.7° (*c* 0.66 in water). Crystallization was again unsuccessful.

The methyl ester obtained above was dissolved in cold methanol(8 m*l*) saturated with dry ammonia, and the mixture was left to stand in a refrigerator for 24 hr. Concentration of the reaction solution gave a syrup, which crystallized on addition of a drop of water. Solids were collected on a porous plate, and recrystallized twice by dissolving in 2-propanol(0.5 m*l*) and adding ethyl acetate saturated with water(2.0 m*l*). The amide was obtained as tetragonal monohydrate. The physical constants are recorded in Table 1, and compared with those of 2-*O*-methyl and 4-*O*-methyl isomers.

Found: C, 40.05; H, 7.49; N, 6.82%. Calcd for $C_7H_{13}O_5N\cdot H_2O$: C, 40.19; H, 7.23; N, 6.70%.

We are grateful to the Ministry of Education for a Grant in Aid for Scientific Research.

Propiolamidines I. Syntheses of *N,N'*-Disubstituted Phenylpropiolamidines and New Routes to 5-*N*-Substituted Amino-3-phenylisoxazoles and 5-*N*-Substituted Amino-1,3-diphenylpyrazoles

Hiroshi FUJITA, Rokuro ENDO, Akira AOYAMA, and Takeshi ICHII

Central Research Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo

(Received November 9, 1971)

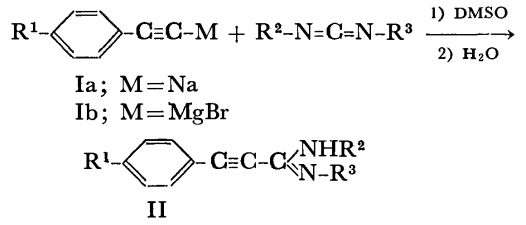
N,N'-Disubstituted phenylpropiolamidines were synthesized from phenylacetylene and carbodiimides. They were inert toward nucleophiles in a neutral or basic medium, but reactive in an acidic one. They reacted in the presence of hydrogen chloride with hydroxylamine, hydrazine, and arylhydrazines to give 5-*N*-substituted amino-3-phenylisoxazoles, 5-*N*-substituted amino-3-phenylpyrazole and 5-*N*-substituted amino-1-aryl-3-phenylpyrazoles, respectively, by nucleophilic addition followed by cyclization. The reaction mechanism is discussed on the basis of the structures of these heterocyclic compounds.

Although syntheses and reactions of amidines have been investigated in detail,[1] amidines conjugated with a carbon-carbon triple bond have not yet been reported. Even in the category of imidic acid derivatives, only two examples are known, namely substituted propiolimidates[2] and phenylpropiolamidoxime.[3]

In the present paper, syntheses and reactions of *N,N'*-disubstituted phenylpropiolamidines are described. Reaction of these amidines with hydroxylamine and hydrazines constitutes a new route to 5-*N*-substituted amino-isoxazoles and -pyrazoles, respectively.

Results and Discussion

Syntheses of N,N'-*Disubstituted Phenylpropiolamidines.* Preparation of the propiolamidines was accomplished as shown in Scheme 1. In general, sodium phenylacetylide (Ia) reacted satisfactorily with carbodiimides to give amidines (Method A), but in a few cases, the Grignard reagent (Ib) was preferred (Method B).



Scheme 1.

Phenylacetylene was added to metallic sodium dispersed in xylene to afford sodium phenylacetylide. The presence of tertiary amines, *e. g.*, triethylamine, *N,N*-dimethylaniline or *N,N,N',N'*-tetramethylethylenediamine, exerted a remarkable effect on the smooth formation of the acetylide at a moderate temperature in hydrocarbon solvents. The tertiary amines may stabilize the acetylide by coordination in non-polar solvents.

When dimethylsulfoxide (DMSO) was added to the sodium phenylacetylide dispersion, complex formation took place as suggested by Kriz *et al*,[4] and nucleophilic attack of the acetylide anion on carbodiimides was accelerated. No significant reaction seems to take place if no DMSO is present.

The phenylpropiolamidines were obtained as crystals, which showed infrared absorption maxima in the 2200 cm^{-1} region for acetylenic bond and near 3200 cm^{-1} attributable to N-H stretching vibration.

N,N'-Bis(*p*-nitrophenyl)phenylpropiolamidine (IIf) was not obtained from the sodium acetylide, probably because of the susceptibility of *N,N'*-bis(*p*-nitrophenyl)carbodiimide to base, but was synthesized by a reaction with the Grignard reagent of phenylacetylene.

Reactions with Hydroxylamine. Amidines are known to react with hydroxylamine in the presence

of acid to form amidoximes[1] and phenylpropiolamidoxime readily cyclizes to give 3-amino-5-phenylisoxazole.[3] A reaction of the propiolamidine (II) with hydroxylamine would, therefore, be presumed to proceed according to Scheme 2 to give III; but the reaction afforded a 5-*N*-substituted amino-3-phenylisoxazole (IV) and released an amine hydrochloride.

Consequently, the nucleophilic addition of hydroxylamine to the triple bond followed by cyclization might occur according to Scheme 3.

The structures of these isoxazoles (IV) were characterized on the basis of their mass and NMR spectra. The isoxazole, thus derived from IIa, was concluded to be 5-cyclohexylamino-3-phenylisoxazole (IVa), by comparison of the fragmentation pattern in the mass spectrum (Fig. 1) and the chemical shift of the C-4 proton in the NMR spectrum with those of 3-amino-5-phenyl- and 5-amino-3-phenylisoxazole.[5] As shown in Fig. 1, IVa readily released cyclohexene to give an aminoisoxazole which gave the same fragmentation pattern as that of 5-amino-3-phenylisoxazole and which was inconsistent with that of 3-amino-5-phenylisoxazole.

The NMR spectral data of IVa also supported the 5-aminoisoxazole structure. The signal at 5.26 ppm, assigned to C-4 proton of IVa, was comparable to 5-amino-3-phenylisoxazole.

The signals due to C-4 protons of 5-arylamino-3-phenylisoxazoles appeared at a reasonably lower field on account of the anisotropic effect of the phenyl ring. The chemical shift of the C-4 proton of several 5-*N*-substituted amino-3-phenylisoxazoles is given in Table 2.

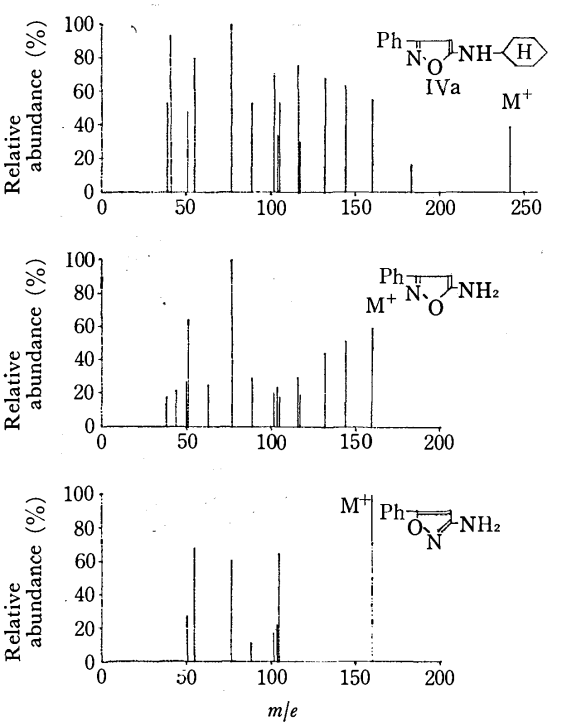

Fig. 1. Mass fragmentation patterns of 5-cyclohexylamino-3-phenylisoxazole (IVa), 5-amino-3-phenylisoxazole and 3-amino-5-phenylisoxazole.

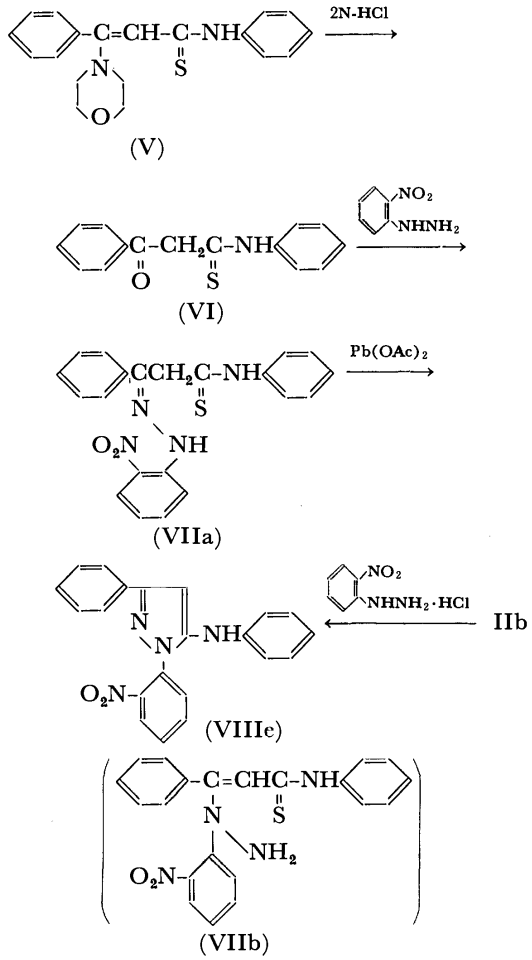
Reactions with Hydrazines. It is well-known that some acetylenic compounds readily undergo addition-cyclization reactions with hydrazines to give pyrazole derivatives such as pyrazolones[6,7] and aminopyrazoles.[8]

Reactions of the propiolamidines with hydrazines were therefore carried out in a similar manner to that for the isoxazole synthesis. In the presence of sodium ethoxide, as well as under neutral conditions, phenylpropiolamidine (IIb) was chiefly recovered in a reaction of IIb with phenylhydrazine; but in the reaction with phenylhydrazine hydrochloride, the expected product, a pyrazole, was obtained together with eliminated aniline. The reaction of IIb with phenylhydrazine hydrochloride afforded predominantly a single isomer (VIIIc) of an anilinodiphenylpyrazole; namely 3-anilino-1,5-diphenyl-[9] or 5-anilino-1,3-diphenylpyrazole.[10] Both structures were assigned to the pyrazole derived from benzoylthioacetanilide and phenylhydrazine,[9,10] and exhibited the same melting point as that of VIIIc. Pocar and his co-workers[10] reported some intermediate hydrazones but presented no spectral data regarding their structures. It was supposed that these intermediates could be another structure such as VIIb in Scheme 4, whose formation was attributable to the nucleophilic attack of the α-nitrogen in phenylhydrazine at the β-acetylenic carbon and was postulated under acidic conditions[7] as in Pocar's case. We therefore confirmed the structure of an intermediate (VIIa) obtained from benzoylthioacetanilide (VI) and *o*-nitrophenylhydrazine, and compared the pyrazole cyclized from VIIa with the one derived from the amidine IIb as shown in Scheme 4.



Scheme 4.

As indicated in Table 3, the structure of the intermediate is undoubtedly the hydrazone VIIa. Consequently, the cyclization of VIIa should give 5-anilino-1-(*o*-nitrophenyl)-3-phenylpyrazole, which is completely consistent with the product from IIb and *o*-nitrophenylhydrazine hydrochloride in terms of the IR, mass and NMR spectra and melting point.

Table 3. NMR data of V, VI, and VIIa.[a]

No.	$-CH_2-$	=CH-	Enolic OH or =N-NH-	Solvent
V	—	5.91	—	$CDCl_3$
VI	4.62	6.25[b]	14.80[b]	$CDCl_3$
VIIa	4.55	—	11.05	$(CD_3)_2CO$

a) δ value from TMS.
b) Due to the presence of the enolic tautomer.

The pyrazoles homologous to 5-anilino-1,3-diphenylpyrazole were also presumed to be produced predominantly in reactions of the propiolamidines with arylhydrazines. An exception was the two isomeric pyrazoles found in the case of the reaction of *N,N'*-bis(*p*-tolyl)phenylpropiolamidine (IIc) with phenylhydrazine hydrochloride. The main product was assigned as VIIIg, by analogy with the other pyrazoles (VIII) in the reaction scheme and in spectral data, so the minor product was assumed to be 1,5-diphenyl-

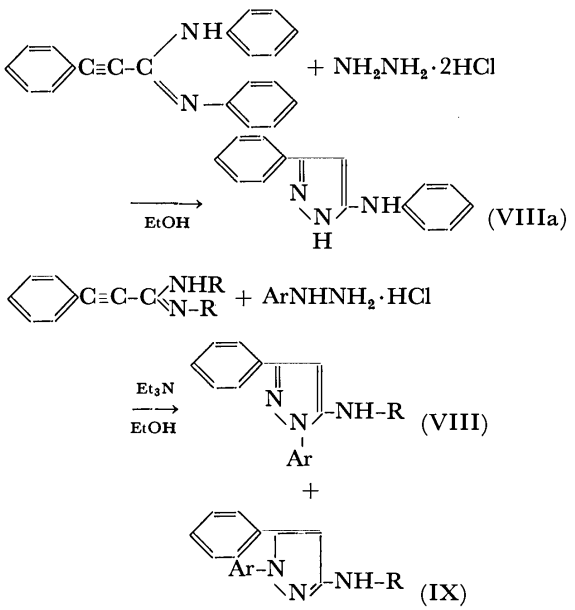
Table 4. Aminopyrazoles

No.	R	Ar	Mp, °C	Yield, %	Chemical shift of C-4 proton[a]
VIIIa		H	153.5—155[b]	49	6.32[f]
VIIIb	H		67—68.5	50	5.87
VIIIc			153.5—154.5[c]	50	6.46
VIIId			141—142.5	38	6.34[e]
VIIIe			165—166[d]	69	6.64[f]
VIIIf			103—104	54	6.30
VIIIg			94—95	40	6.43
VIIIh			100—101	34	6.45
IXg			180—181.5	7	6.24

a) δ value from TMS in $CDCl_3$. b) Lit, mp 152.5—153.5°C (Ref. 9). c) Lit, mp 153°C (Ref. 10). d) Lit, mp 164—165°C (Ref. 10). e) in CCl_4. f) in acetone-d_6.

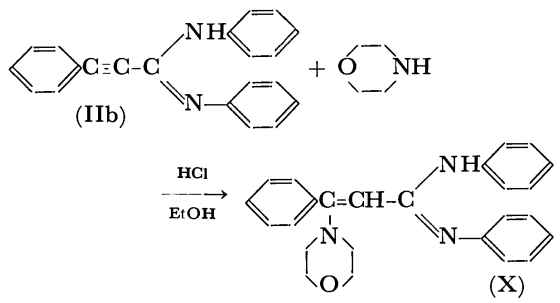


Scheme 5.

3-(*p*-toluidino)pyrazole (IXg).

Reaction Mechanism. As described above, the reactions of the propiolamidines with nucleophiles took place under acidic conditions and the acetylenic β-carbon rather than the amidino carbon was preferentially attacked. This situation was confirmed by the reaction of IIb with morpholine in the presence of hydrogen chloride resulting in addition to the triple bond giving *N,N'*-diphenyl-β-morpholinocinnamamidine (X) in preference to the addition-elimination to the amidino carbon (Scheme 6).

Consequently, as shown in Scheme 3, the propiolamidine would be activated by the protonation at the amidine nitrogen to form the diaminoallene cation, and readily attacked by a nucleophile, such as hydroxylamine, to give the adduct. The central carbon atom of allene in the adduct corresponds to β-carbon of enamines, so that the prototropic change to the enamino amidine intermediate might take place smoothly. The cyclization process would also be prompted by protonation, and an protonated amino group in the cyclic product would be released to give the amine hydrochloride together with an isoxazole, since the more basic amine, cyclohexylamine, was recovered predominantly in the reaction of *N*-cyclohexyl-*N'*-phenylphenylpropiolamidine (IIi) with hydroxylamine hydrochloride.



Scheme 6.

Experimental

All melting points are uncorrected. The NMR spectra were measured with a Varian A-60 NMR spectrometer, using tetramethylsilane as an internal standard. The mass spectra were obtained using a JEOL-JMS-OIS Mass spectrometer. The IR spectra were determined by means of nujol mulls or liquid films.

Materials. *N,N'*-Dicyclohexylcarbodiimide was obtained commercially, *N,N'*-bis(*p*-methoxyphenyl)carbodiimide was derived from *N,N'*-bis(*p*-methoxyphenyl)chloroformamidiniumchloride,[11] *N,N'*-bis(*p*-nitrophenyl)carbodiimide was synthesized from *p*-nitrophenylisocyanate using 3-methyl-1-phenyl-1-phospha-3-cyclopenten-1-oxide as a catalyst.[12] The other carbodiimides were prepared from the corresponding thioureas employing yellow mercuric oxide.

Preparation of N,N'-*Disubstituted Phenylpropiolamidines (II). Method A: General Procedure*: Metallic sodium (1.15 g, 50 mg-atom) was dispersed in 50 m*l* dry xylene by means of a Sodium Dispersator (Taneda Co., Ltd., Toyama city) at about 110°C in the presence of one drop of oleic acid under dry nitrogen. After cooling to 60°C, triethylamine (5.0 g, 50 mmol) was added, followed by dropwise addition of phenylacetylene (5.2 g, 51 mmol) in 10 m*l* of xylene at a rate so that the reaction temperature was kept at about 60°C. Acetylide formation took place immediately. After the exothermic reaction ceased, the mixture was warmed at the same temperature for 30 min. The corresponding carbodiimide (50 mmol) in 10 m*l* xylene was introduced dropwise at room temperature for 10 min, but no significant change was observed. When dimethylsulfoxide (3.9 g, 50 mmol) in 10 m*l* xylene was added with cooling in a cold water bath, the reaction mixture almost dissolved and turned dark brown.[13] After 30 min, the mixture was poured into ice water, the organic layer was separated and the aqueous layer was extracted twice with ethyl acetate. The combined organic layers were washed with saturated aqueous sodium chloride, dried over anhydrous sodium sulfate and concentrated *in vacuo*. The concentrate was purified by silica gel column chromatography and/or recrystallization.

N,N'-*Dicyclohexylphenylpropiolamidine (IIa)*. A yellow viscous oil. IR: 3400 (NH), 2200 (C≡C) cm^{-1}. Further purification on a silica gel column (benzene - ethanol 50 : 1) was not successful. Picrate: mp 187—188°C (decomp., from ethanol). Found: C, 60.55; H, 5.95; N, 12.84%. Calcd for $C_{27}H_{31}N_5O_7$: C, 60.32; H, 5.81; N, 13.03%. IR: 2190 (C≡C) cm^{-1}.

N,N'-*Diphenylphenylpropiolamidine (IIb)*. Yellow needles (from *n*-hexane); mp 122—123.5°C. Found: C, 84.89; H, 5.43; N, 9.41%. Calcd for $C_{21}H_{16}N_2$: C, 85.11; H, 5.44; N, 9.45%. IR: 3200 (NH), 2200 (C≡C) cm^{-1}. Picrate: mp 198—200°C (decomp., from methanol). Found: C, 61.52; H, 3.77; N, 13.24%. Calcd for $C_{27}H_{19}N_5O_7$: C, 61.71; H, 3.64; N, 13.33%. IR: 2200 (C≡C) cm^{-1}.

N,N'-*Bis(*p-*tolyl)phenylpropiolamidine (IIc)*. Yellow needles (from ethanol); mp 140.5—141°C. Found: C, 84.93; H, 6.20; N, 8.58%. Calcd for $C_{23}H_{20}N_2$: C, 85.15; H, 6.21; N, 8.64%. IR: 3230 (NH), 2220 (C≡C) cm^{-1}. NMR (δ in CCl_4): 2.30 (6H, s, CH_3), 6.85—7.3 (phenyl protons).

N,N'-*Bis(*p-*methoxyphenyl)phenylpropiolamidine (IId)*. Yellow needles (from ethanol); mp 122—123°C. Found: C, 77.44; H, 5.75; N, 7.82%. Calcd for $C_{23}H_{20}N_2O_2$: C, 77.50; H, 5.66; N, 7.86%. IR: 3350 (NH), 2210 (C≡C) cm^{-1}. NMR (δ in $CDCl_3$): 3.97 (6H, s, OCH_3).

N,N'-*Bis(*p-*chlorophenyl)phenylpropiolamidine (IIe)*. Colorless needles (from ethanol-*n*-hexane); mp 153—154°C. Found: C, 69.40; H, 3.86; N, 7.50; Cl, 19.41%. Calcd for $C_{21}H_{14}N_2Cl_2$: C, 69.05; H, 3.86; N, 7.67; Cl, 19.41%. IR: 3240, 3160 (NH), 2260 (C≡C) cm^{-1}. NMR (δ in CCl_4): 7.26 (s, phenyl protons).

N,N'-*Dibenzylphenylpropiolamidine (IIg)*. Viscous oil. IR: 2200 (C≡C) cm^{-1}. Further purification of this material was not successful, so it was converted into the picrate and characterized. Picrate: mp 190—191°C (decomp., from ethanol). Found: C, 62.71; H, 4.12; N, 12.39%. Calcd for $C_{29}H_{23}N_5O_7$: C, 62.92; H, 4.19; N, 12.65%. IR: 2230 (C≡C) cm^{-1}. NMR (δ in DMSO-d_6): 4.74, 4.88 (4H, benzyl protons).

N,N'-*Dicyclohexyl*-p-*tolylpropiolamidine (IIh)*. *p*-Tolylacetylene, instead of phenylacetylene, was converted into sodium acetylide and reacted with *N,N'*-dicyclohexylcarbodiimide in a similar way. A oily crude amidine was crystallized as the benzoate. Benzoate: Colorless crystals (from 50% ethanol); mp 141—142°C. Found: C, 78.08; H, 8.32; N, 6.60%. Calcd for $C_{29}H_{36}N_2O_2$: C, 78.34; H, 8.16; N, 6.30%. IR: 2190 (C≡C) cm^{-1}. NMR (δ in $CDCl_3$): 2.43 (3H, s, CH_3), 3.66 (2H, broad bands,).

N-*Cyclohexyl*-N'-*phenylphenylpropiolamidine (IIi)*. White needles (from *n*-hexane); mp 113—114°C. Found: C, 83.52; H, 7.28; N, 9.14%. Calcd for $C_{21}H_{22}N_2$: C, 83.40; H, 7.33; N, 9.26%. IR: 3190, 3090 (NH), 2190 (C≡C) cm^{-1}. Benzoate: White crystals (from 50% ethanol); mp 115—116°C. Found: C, 79.11; H, 6.57; N, 6.38%. Calcd. for $C_{28}H_{28}N_2O_2$: C, 79.21; H, 6.65; N, 6.60%. IR: 2220 (C≡C) cm^{-1}.

N-n-*Butyl*-N'-*phenylphenylpropiolamidine (IIj)*. Yellow needles (from *n*-hexane); mp 55—56°C. Found: C, 82.50; H, 7.31; N, 10.05%. Calcd for $C_{19}H_{20}N_2$: C, 82.57; H, 7.29; N, 10.14%. IR: 3200 (NH), 2200 (C≡C) cm^{-1}. Picrate: mp 169—170°C (decomp., from ethanol). Found: C, 59.24; H, 4.63; N, 13.67%. Calcd for $C_{25}H_{23}N_5O_7$: C, 59.40; H, 4.59; N, 13.86%. IR: 2190 (C≡C) cm^{-1}.

N-*Benzyl*-N'-*phenylphenylpropiolamidine (IIk)*. Yellow needles (from *n*-hexane); mp 94—95°C. Found: C, 85.17; H, 5.78; N, 9.18%. Calcd for $C_{22}H_{18}N_2$: C, 85.13; H, 5.85; N, 9.03%. IR: 3200 (NH), 2200 (C≡C) cm^{-1}. NMR (δ in $CDCl_3$): 4.95 (2H, s, CH_2).

Method B: N,N'-*Bis(*p-*nitrophenyl)phenylpropiolamidine (IIf)*. Phenylethynylmagnesium bromide was prepared from ethylmagnesium bromide and phenylacetylene in ether in the usual way. One equimolar of *N,N'*-bis(*p*-nitrophenyl)-carbodiimide in tetrahydrofuran and then DMSO (two equimolar) were introduced subsequently at room temperature. The mixture was stirred for 45 min and poured into ice water. After the precipitate was filtered off, the filtrate was extracted with ether. The precipitate and extract were crystallized from ethyl acetate to afford crude amidine. Recrystallization from dimethylformamide gave yellow crystals. Mp 264—265°C (decomp.). Found: C, 65.45; H, 3.88; N, 14.71%. Calcd for $C_{21}H_{14}N_4O_4$: C, 65.28; H, 3.65; N, 14.50%. IR: 3350 (NH), 2210 (C≡C) cm^{-1}.

*Syntheses of 5-*N-*Substituted Amino-3-phenylisoxazoles. General Procedure*: A mixture of the phenylpropiolamidine (II) and a slight excess of hydroxylamine hydrochloride in ethanol was refluxed for several hours. After removal of the solvent under reduced pressure, the residue was treated as usual with hot benzene to recover the eliminated amine hydrochloride and the benzene soluble materials were subjected to silica gel column chromatography using a suitable solvent system or purified by recrystallization.

11) H. Eilingsfeld, G. Neubauer, M. Seefelder, and H. Weidinger, *Chem. Ber.*, **97**, 1237 (1964).

12) T. W. Campbell, J. J. Monagle, and V. S. Fordi, *J. Amer. Chem. Soc.*, **84**, 3673 (1962).

13) In some cases, DMSO was added to the sodium acetylide suspension before addition of a carbodiimide solution. In this case, the sodium phenylacetylide-DMSO complex was observed.[4] However, the order of addition does not seem to affect the yield of amidines.

5-Cyclohexylamino-3-phenylisoxazole (IVa). Colorless needles (from *n*-hexane); mp 128—129.5°C. Found: C, 74.42; H, 7.64; N, 11.78%. Calcd for $C_{15}H_{18}N_2O$: C, 74.35; H, 7.49; N, 11.56%. IR: 3370 (NH), 1622, 1501 cm^{-1}. NMR (δ in $CDCl_3$): 5.26 (1H, s, C-4 proton), 4.46 (1H, broad band, NH), 3.25 (1H, broad band, ). Mass (*m/e*): 242 (M^+), 160 (M− ),144, 132, 116, 89, 77.

5-Anilino-3-phenylisoxazole (IVb).[14] Pale yellow plates (from ethanol); mp 136—137°C. Found: C, 76.13; H, 5.28; N, 11.76%. Calcd for $C_{15}H_{12}N_2O$: C, 76.25; H, 5.12; N, 11.86%. IR: 3290, 3210 (NH), 1650, 1497, 1473 cm^{-1}. NMR (δ in $CDCl_3$): 5.85 (1H, s, C-4 proton). Mass (*m/e*): 236 (M^+). Aniline hydrochloride, characterized by the IR spectrum, was recovered in 82% yield.

3-Phenyl-5-p-toluidinoisoxazole (IVc). Colorless crystals (from ethanol); mp 145—146°C. Found: C, 76.67; H, 5.63; N, 11.05%. Calcd for $C_{16}H_{14}N_2O$: C, 76.78; H, 5.64; N, 11.19%. IR: 3280, 3200 (NH), 1645, 1510, 1485, 1475 cm^{-1}. NMR (δ in $CDCl_3$): 5.76 (1H, s, C-4 proton), 2.33 (3H, s, CH_3).

5-p-Anisidino-3-phenylisoxazole (IVd). Colorless needles (from ethanol); mp 150—151°C. Found: C, 72.01; H, 5.24; N, 10.72%. Calcd for $C_{16}H_{14}N_2O_2$: C, 72.16; H, 5.30; N, 10.52%. IR: 3330, 3260 (NH), 1658, 1518, 1502, 1483, 1464 cm^{-1}. NMR (δ in $CDCl_3$): 5.65 (1H, s, C-4 proton), 3.80 (3H, s, OCH_3).

Reaction of IIi with Hydroxylamine hydrochloride. An ethanolic solution of IIi and excess hydroxylamine hydrochloride was refluxed for 5 hr. After removal of the solvent, the concentrate was treated with benzene to separate the released amine hydrochloride, which was characterized by IR spectrum as cyclohexylamine hydrochloride (IR spectrum showed no absorption maximum attributable to the phenyl ring). The soluble material was chromatographed on a silica gel column (benzene - ethanol 50 : 1). The eluted isoxazole was recrystallized from ethanol. Mp 136—137°C. The IR spectrum was identical with that of IVb.

Synthesis of 5-Anilino-1-o-nitrophenyl-3-phenylpyrazole (VIIIe) from β-Morpholinothiocinnamanilide (V).[10] *β-Morpholinothiocinnamanilide (V):*[15] The reaction of 1-morpholino-1-phenylethylene (9.5 g) with phenylisothiocyanate (6.75 g) in ethyl acetate afforded yellow needles of V (12.8 g, 79%), followed by recrystallization from the same solvent to give an analytically pure sample having mp 154.5—156.5°C (decomp.). Found: C, 70.36; H, 6.31; N, 8.77; S, 9.88%. Calcd for $C_{19}H_{20}N_2OS$: C, 70.34; H, 6.21; N, 8.63; S, 9.88%. NMR (δ in $CDCl_3$): 5.91 (1H, s, =CH).

Benzoylthioacetanilide (VI):[15] V (9.72 g) in 60 m*l* hot ethanol was treated with 16 m*l* of 2N-HCl and left overnight in a refrigerator. The precipitate was collected and recrystallized from 50% ethanol repeatedly. Yield: 63%. Colorless powder. Mp 78—79.5°C. Found: C, 70.84; H, 5.17; N, 5.59; S, 12.60%. Calcd for $C_{15}H_{13}NOS$: C, 70.56; H, 5.13; N, 5.49; S, 12.56%. NMR (δ in $CDCl_3$): 4.62 (s, CH_2), 6.25 (s, =CH), 14.80 (s, enolic OH).

o-Nitrophenylhydrazone of VI (VIIa):[10] To an ethanolic solution of VI (1.72 g), *o*-nitrophenylhydrazine (1.03 g) dissolved in 50% aqueous acetic acid was added and the mixture was heated at 95°C for 5 min. The resulting deposit was filtered off and triturated with ethyl acetate - petroleum ether to give an orange solid (2.1 g, 80%). Recrystallization from ethyl acetate three times afforded orange needles. Mp 169.5—172.5°C (decomp.). Found: C, 64.84; H, 4.70; N, 14.55; S, 8.30%. Calcd for $C_{21}H_{18}N_4O_2S$: C, 64.60; H, 4.65; N, 14.35; S, 8.20%. NMR (δ in acetone-d_6): 4.55 (2H, s, CH_2), 11.05 (1H, broad band, NH).

5-Anilino-1-o-nitrophenyl-3-phenylpyrazole (VIIIe) from VIIa:[10] VIIa (0.78 g) was cyclized by lead diacetate trihydrate (0.76 g) in a gently refluxing aqueous acetic acid. After 30 min, the mixture was filtered, the filtrate poured into ice water, and the yellow precipitate of VIIIe was collected and washed with water. Yield: 46%. Repeated recrystallization from ethanol afforded yellow needles. Mp 164—165°C. Mixed mp with one derived from IIb; 165—166°C. The respective IR, NMR, and mass spectra of both samples were also superimposable.

Syntheses of 5-N-Substituted amino-3-phenylpyrazoles. 5-Anilino-3-phenylpyrazole (VIIIa):[9] IIb (1.0 g) reacted with hydrazine dihydrochloride in the presence of an equimolar amount of triethylamine in boiling ethanol for 3 hr. A benzene soluble red oil was triturated with benzene - *n*-hexane to yield a yellow solid, followed by recrystallization from dilute ethanol to give crystalline powders of VIIIa (278 mg, 35%). Mp 153.5—155°C. Found: C, 76.25; H, 5.56; N, 17.60%. Calcd for $C_{15}H_{13}N_3$: C, 76.57; H, 5.57; N, 17.86%. NMR (δ in acetone-d_6): 6.32 (1H, s, C-4 proton).

General Procedure for Syntheses of 1-Aryl-3-phenyl-5-N-substituted Aminopyrazoles. Phenylpropiolamidine (II) and a slight excess of arylhydrazine hydrochloride were refluxed in ethanol for several hours. After the solvent was distilled off, the residual material was treated with hot benzene in order to recover the eliminated amine hydrochloride. Benzene soluble materials were purified by silica gel column chromatography and/or recrystallization using suitable solvents.

5-Cyclohexylamino-1,3-diphenylpyrazole (VIIIb): Cyclohexylamine hydrochloride (61%) was recovered. After being separated by silica gel column (benzene - ethanol 50 : 1), crude VIIIb was recrystallized from petroleum ether (bp 30—70°C) to afford colorless prisms having mp 67—68.5°C. Yield: 50%. Found: C, 79.75; H, 7.41; N, 13.14%. Calcd for $C_{21}H_{23}N_3$: C, 79.46; H, 7.30; N, 13.24%. NMR (δ in $CDCl_3$): 5.87 (1H, s, C-4 proton).

5-Anilino-1,3-diphenylpyrazole (VIIIc):[10] After separation of aniline hydrochloride [73%, mp 197.5—199°C (decomp.) Lit, mp 198°C. Found: C, 55.36; H, 6.28; N, 10.92; Cl, 27.08%], VIIIc was solidified with *n*-hexane and recrystallization from ethanol to give colorless prisms. Mp 153.5—154.5°C. Found: C, 80.92; H, 5.55; N, 13.55%. Calcd for $C_{21}H_{17}N_3$: C, 81.00; H, 5.50; N, 13.50%. NMR (δ in $CDCl_3$): 6.46 (1H, s, C-4 proton).

5-Anilino-3-phenyl-1-p-tolylpyrazole (VIIId): Colorless crystals (from ethanol); mp 141—142.5°C. Found: C, 80.82; H, 5.86; N, 12.66%. Calcd for $C_{22}H_{19}N_3$: C, 81,20; H, 5.89; N, 12.91%. NMR (δ in CCl_4): 6.34 (1H, s, C-4 proton), 2.25 (3H, s, CH_3).

5-Anilino-1-o-nitrophenyl-3-phenylpyrazole (VIIIe):[10] Yellow needles (from ethanol); mp 165—166°C. Found: C, 70.42; H, 4.65; N, 15.74%. Calcd for $C_{21}H_{16}N_4O_2$: C, 70.77; H, 4.53; N, 15.72%. NMR (δ in acetone-d_6): 6.64 (1H, s, C-4 proton). Mass (*m/e*): 356 (M^+), 310, 207, 102, 77. Aniline hydrochloride was also recovered (73%).

5-Anisidino-1,3-diphenylpyrazole (VIIIf): Colorless prisms (from benzene - *n*-hexane); mp 103—104°C. Found: C, 77.28; H, 5.62; N, 12.41%. Calcd for $C_{22}H_{19}N_3O$: C, 77.39; H, 5.61; N, 12.31%. NMR (δ in $CDCl_3$): 6.30 (1H, s, C-4 proton), 3.76 (3H, s, OCH_3).

14) A. Umani-Ronchi, M. Acampora, G. Gaudiano, and A. Selva, *Chim. Ind.* (Milan), **1967**, 388.

15) S. Hünig, K. Hübner, and E. Benzing, *Chem. Ber.*, **95**, 926 (1962).

5-p-*Toluidino-1,3-diphenylpyrazole (VIIIg) and 3*-p-*Toluidino-1,5-diphenylpyrazole (IXg)*: After removal of *p*-toluidine hydrochloride (82%), benzene soluble materials were chromatographed on a silica gel column. VIIIg was first eluted with benzene and then IXg with the same solvent. Both were recrystallized from *n*-hexane - benzene to afford analytical samples. VIIIg: Colorless needles. Yield: 40%. Mp 94—95°C. Found: C, 80.95; H, 5.82; N, 13.19%. Calcd for $C_{22}H_{19}N_3$: C, 81.20; H, 5.89; N, 12.91%. NMR (δ in $CDCl_3$): 6.43 (1H, s, C-4 proton), 2.29 (3H, s, CH_3). IXg: Colorless crystals. Yield: 7%. Mp 180—181.5°C. Found: 81.49; H, 6.05; N, 12.88%. NMR (δ in $CDCl_3$): 6.24 (1H, s, C-4 proton), 2.29 (3H, s, CH_3).

5-p-*Chloroanilino-1,3-diphenylpyrazole (VIIIh)*: Colorless prisms (from ethanol); mp 100—101°C. Found: C, 73.25; H, 4.57; N, 12.03; Cl, 10.18%. Calcd for $C_{21}H_{16}N_3Cl$: C, 72.93; H, 4.66; N, 12.15; Cl, 10.25%. NMR (δ in $CDCl_3$): 6.45 (1H, s, C-4 proton).

A Reaction of IIb with Morpholine. A mixture of IIb (7.4 g) and morpholine (2.18 g) in 60 m*l* ethanol was heated for 5.5 hr in the presence of one equivalent of hydrogen chloride. After distilling off the solvent, the residue was suspended in benzene and shaken with aqueous potassium carbonate solution. The resulting benzene solution was washed with water, dried over anhydrous sodium sulfate and concentrated. Recrystallization of the residual solid from ethanol afforded yellow prisms of *N,N'*-diphenyl-*β*-morpholinocinnamamidine (X, 5.0 g, 52%). Mp 137—138°C. Found: C, 78.10; H, 6.58; N, 10.98%. Calcd for $C_{25}H_{25}N_3O$: C, 78.30; H, 6.57; N, 10.96%. NMR (δ in $CDCl_3$): 2.80 and 3.64 (8H, CH_2 in morpholine), 5.04 (1H, s, =CH), 6.9—7.5 (phenyl protons).

The authors are grateful to Prof. Makoto Okawara, Tokyo Institute of Technology, for his valuable comments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1852—1854 (1972)

Studies on Stable Free Radicals. XII.[1] ESR Spectra of 2-*t*-Butylaminotropone *N*-Oxyl Radicals

Toshimasa TODA, Eiko MORI, and Keisuke MURAYAMA
Central Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo

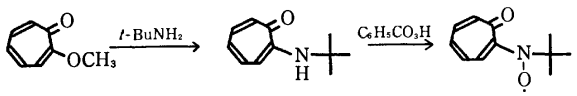
(Received November 15, 1971)

We observed a well resolved ESR spectrum of 2-*t*-butylaminotropone *N*-oxyl radical generated by the oxidation of the corresponding amine with perbenzoic acid, and assigned the values of hyperfine coupling constants of protons in the tropone ring by a comparison with the ESR spectra of deuterium substituted 2-*t*-butylaminotropone *N*-oxyl radicals: $a_N = 12.7$ gauss, $a_H{}^3 = a_H{}^5 = a_H{}^7 = 1.86$ gauss and $a_H{}^4 = a_H{}^6 = 0.93$ gauss for protons on tropone ring.

ESR spectra of arylnitroxide radicals, such as diphenylnitroxide radical[2] or *t*-butylphenylnitroxide radical[3] have been reported. However, the ESR spectrum of the nitroxide radical having aromatic seven-membered ring has not yet been reported. We observed the ESR spectrum of 2-*t*-butylaminotropone *N*-oxyl radical (IIa) and assigned the values of hyperfine splitting constants of protons on the tropone ring in IIa by a comparison with the ESR spectra of deuterium substituted 2-*t*-butylaminotropone *N*-oxyl radicals.

Results

We prepared 2-*t*-butylaminotropone (Ia) by the reaction[4] of 2-methoxytropone[5] with *t*-butylamine and obtained the corresponding nitroxide radical (IIa) by the oxidation of Ia with perbenzoic acid.[6]



(Ia) (IIa)

Since the nitroxide radical IIa is unstable and unisolable, we measured the ESR spectrum of IIa obtained by mixing a solution of Ia in benzene and perbenzoic acid in the ESR sample tube directly at room temperature.

The ESR spectrum of IIa is presented in Fig. 1-a. Triplet lines due to the interaction of a ^{14}N (12.7 gauss) and nine lines (0.93 gauss, the intensity ratio is 1 : 2 : 4 : 6 : 6 : 6 : 4 : 2 : 1) of each component of the triplet were observed. Further splittings in each component of the triplet would be caused by the interaction with protons on the tropone ring, because no interaction with protons of *t*-butyl group in *t*-butylphenylnitroxide radical have been observed in the ESR spectrum.[3]

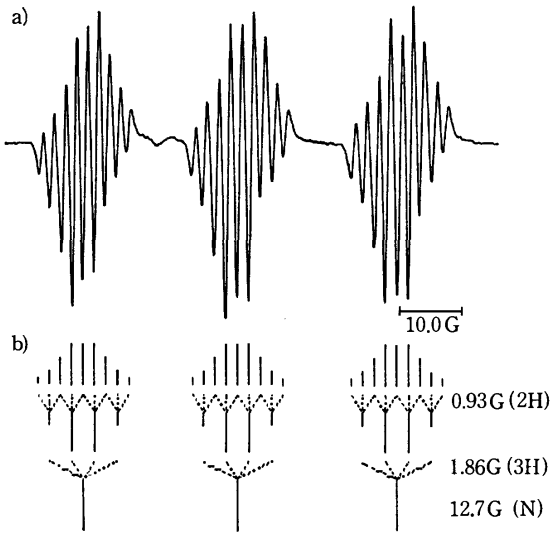

Fig. 1. ESR spectra of 2-*t*-butylaminotropone *N*-oxyl radicals (IIa).
a): Spectrum observed in benzene at room temperature.
b): Stick spectrum consisting of the values of the assigned splitting constants.

To assign the values of coupling constants of protons on the tropone ring in IIa, we prepared deuterium substituted 2-*t*-butylaminotropones (Ib, Ic, and Id) as shown in Chart 1 and measured the ESR spectra of the corresponding nitroxide radicals (IIb, IIc, and IId).

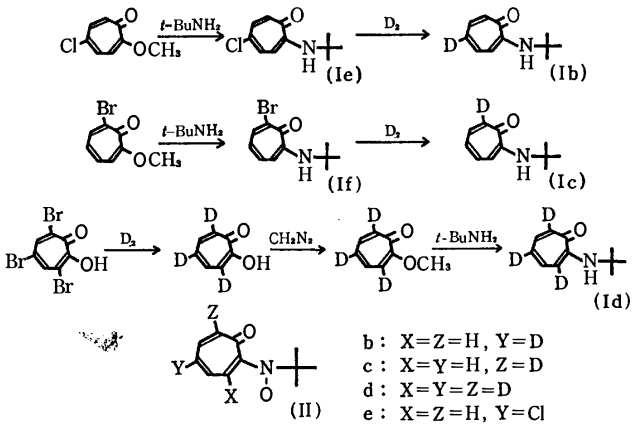

Chart 1

The nitroxide radical IIb gave the spectrum shown in Fig. 2, in which seven lines (splitting at 0.93 gauss, 1 : 3 : 3 : 4 : 3 : 3 : 1) were observed in each component of the triplet. Radical IIc also showed a spectrum (each component of the triplet was split into seven lines at 0.93 gauss) similar to that of IIb. Similarity of both spectra of IIb and IIc suggests that each value for the coupling constants of protons at the 5- and 7-positions on the ring in IIa is the same.

We observed slightly broadened triplet lines (a_N= 12.7 gauss) in the spectrum of IId as shown in Fig. 3. Each component of the triplet lines would not be resolved in the ESR spectrum because of small coupling constant values of the protons at the 4- and 6-positions and of deuterium at the 3-, 5- and 7-positions on the ring in IId.

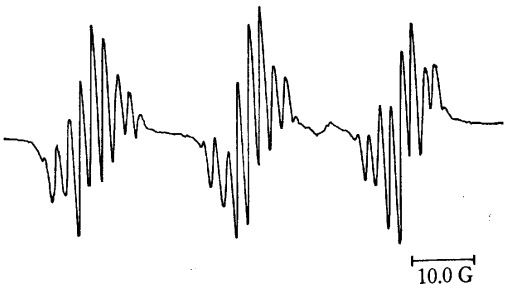

Fig. 2. ESR spectrum of 2-*t*-butylamino-5-*d*-tropone *N*-oxyl radical (IIb).

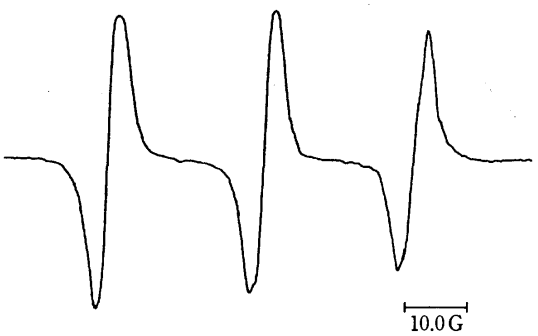

Fig. 3. ESR spectrum of 2-*t*-butylamino-3,5,7-tri-*d*-tropne *N*-oxyl radical (IId).

From the results, we assigned the values of the coupling constants of protons on the tropone ring and of nitrogen in IIa as follows: $a_H^3=a_H^5=a_H^7=$ 1.86 gauss, $a_H^4=a_H^6=0.93$ gauss and $a_N=12.7$ gauss. The stick spectrum consisting of these values is shown in Fig. 1-b and agrees with the observed spectrum of IIa.

The results obtained for IIa are comparable with those for *t*-butylphenylnitroxide radical ($a_H^4=a_H^2=a_H^6=2\cdot a_H^3=2\cdot a_H^5=1.9$ gauss and $a_N=13.4$ gauss).[3]

We obtained the following values for the coupling constants of nitrogen and the protons in 2-*t*-butylamino-5-chlorotropone *N*-oxyl radical, IIe : $a_N=12.4$ gauss and $a_H^3=a_H^7=2\cdot a_H^4=2\cdot a_H^6=1.98$ gauss. The spectrum is given in Fig. 4. The values are also comparable to those of the *t*-butyl-*p*-chlorophenylnitroxide radical ($a_N=13$ gauss and $a_H^2=a_H^6=2\cdot a_H^3=2\cdot a_H^5=2.01$ gauss).[3]

Fig. 4. ESR spectrum of 2-*t*-butylamino-5-chlorotropone *N*-oxyl radical (IIe).

The results indicate that the distribution of an unpaired electron at the 3—7 positions on the tropone

ring in IIa is similar to that at the 2—6 positions on the phenyl ring in the *t*-butylphenylnitroxide radical.

Experimental

Melting points and boiling points are uncorrected.

ESR Measurements. ESR spectra were obtained with a Hitachi MES 4001 type X-band spectrometer employing 100 kHz modulation. The samples prepared by mixing the solution of the amines (*ca.* 3%) in benzene and perbenzoic acid (*ca.* 5 mg) in an ESR sample tube were fully degassed and sealed. The splitting constants were measured relative to the aqueous solution of Fremy's salt.

2-t-Butylaminotropone (Ia). A solution of 13.6 g (0.1 mol) of 2-methoxytropone[5] and 14.6 g (0.2 mol) of *t*-butylamine in 100 m*l* of ethanol was heated under reflux for 24 hr. After removal of ethanol, the resulting oil was distilled: bp 122—133°C/2 mmHg. Yield, 12.7 g (68.3%). The distilled oil solidified on standing. Recrystallization from cyclohexane gave an analytically pure sample: mp 61—62°C. Found: C, 74.28; H, 8.56; N, 7.78%. Calcd for $C_{11}H_{15}ON$: C, 74.54; H, 8.53; N, 7.90%. IR (cm^{-1}) (Nujol): 3250, 1604 and 1597. UV (mμ): λ_{max}^{EtOH} 248, 338 and 407. NMR (τ) (in CCl_4): 2.95—3.50(5H) and 8.50 (9H).

2-t-Butylamino-5-chlorotropone (Ie). A solution of 8.0 g (45 mmol) of 2-methoxy-5-chlorotropone[7] and 6.6 g (90 mmol) of *t*-butylamine in 100 m*l* of ethanol was heated under reflux for 24 hr. After removal of ethanol, the redidue was chromatographed on an alumina column. Eluting with ethanol afforded 6.2 g (65.0%) of Ie. Recrystallization from petroleum ether gave a pure sample: mp 81.5—83°C. Found: C, 62.42; H, 6.68; N, 6.67; Cl, 16.75%. Calcd for $C_{11}H_{14}ONCl$: C, 62.40; H, 6.66; N, 6.64; Cl, 16.74%.

2-t-Butylamino-7-bromotropone (If). A solution of 8.6 g (40 mmol) of 2-methoxy-7-bromotropone[5] and 6.0 g (83 mmol) of *t*-butylamine in 100 m*l* of ethanol was refluxed for 27 hr. After ethanol was removed under reduced pressure, the resulting crystalline solid was recrystallized from methanol to give 6.1 g (59.5%) of If: mp 138.5—140°C. Found: C, 51.35; H, 5.52; N, 5.41; Br, 30.90%. Calcd for $C_{11}H_{14}ONBr$: C, 51.57; H, 5.51; N, 5.49; Br, 31.19%.

2-t-Butylamino-5-d-tropone (Ib). A solution of 4.3 g (20 mmol) of Ie and 3.0 g of triethylamine in dry dioxane was shaken with 1.0 g of anhydrous palladium chloride and 6 m*l* of deuterium oxide in an atmosphere of deuterium. After about 130 m*l* of deuterium was absorbed, the reaction mixture was filtered to separated a precipitate. The filtrate was concentrated under reduced pressure and the residue was distilled: bp 126—130°C/2 mmHg. The distilled oil solidified on standing. Recrystallization from cyclohexane furnished a pure sample: mp 61.0—62.5°C. Yield, 2.1 g (59.0%). Found: C, 74.20; H(D), 9.19; N, 7.85%. Calcd for $C_{11}H_{14}DON$: C, 74.12; H(D), 9.07; N, 7.89%.

2-t-Butylamino-7-d-tropone (Ic). By a method similar to the above, 2.6 g (73.0%) of Ic was obtained from 5.1 g (20 mmol) of If: mp 61.5—62.5°C. Found: C, 73.91; H(D), 9.05; N, 7.81%. Calcd for $C_{11}H_{14}DON$: C, 74.12; H(D), 9.07; N, 7.89%.

2-t-Butylamino-3,5,7-tri-d-tropone (Id). A solution of 35.8 g (0.1 mol) of 3,5,7-tribromotropolone[8] and 40.0 g of triethylamine in 300 m*l* of dry dioxane was shaken with 5.0 g of anhydrous palladium chloride and 30 m*l* of deuterium oxide in an atmosphere of deuterium. After about 7 *l* of deuterium was absorbed during 4 hr, the reaction mixture was filtered to separate a precipitate. The precipitate was dissolved in 60 m*l* of aqueous sodium hydroxide (50%) and extracted with 200 m*l* of chloroform. The filtrate and the chloroform layer were combined, dried over sodium carbonate and concentrated under reduced pressure. The residue was distilled to give 6.5 g of 3,5,7-tri-*d*-tropolone: bp 106—110°C/12 mmHg. The oil solidified on standing. Recrystallization from benzene gave a pure sample: mp 51.5—53°C. Found: C, 66.99; H(D), 7.75%. Calcd for $C_7H_3D_3O_2$: 67.19; H(D), 7.25%. NMR (τ) (in CCl_4): 1.50(1H) and 2.78(2H). To a solution of 2.9 g (23 mmol) of 3,5,7-tri-*d*-tropolone in 50 m*l* of ether was added a solution of diazomethane (3 g) in 100 m*l* of ether dropwise with ice bath cooling. The solution was allowed to stand overnight at room temperature. After removal of ether, the resulting oil was distilled to give 2.0 g (57.5%) of 2-methoxy-3,5,7-tri-*d*-tropone: bp 138—142°C/5 mmHg. By a similar procedure used for Ia, 1.6 g (61.4%) of Id was obtained from 2.0 g (14 mmol) of 2-methoxy-3,5,7-tri-*d*-tropone: mp 60.0—62°C. Found: C, 73.07; H(D), 10.36; N, 7.59%. Calcd for $C_{11}H_{12}D_3ON$: C, 73.28; H(D), 10.05; N, 7.78%.

Perbenzoic Acid. Perbenzoic acid was prepared by the usual way[9] and purified by sublimation under reduced pressure: 35—40°C/4 mmHg.

The authors are grateful to Dr. Nobuo Soma for his helpful suggestions in the preparation of the amines, and to Dr. Genshun Sunagawa, the director, for his encouragement.

Studies on Stable Free Radicals. XIII.[1] Synthesis and ESR Spectral Properties of Hindered Piperazine *N*-Oxyls

Takao YOSHIOKA, Eiko MORI, and Keisuke MURAYAMA

Central Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo

(Received November 15, 1971)

New hindered 3,5-dioxopiperazines (VII, IX), hindered piperazines (VIII, X), and the corresponding *N*-oxyls (XI, XIII, XII, and XIV) were synthesized. The substituent and solvent effects of the nitrogen coupling constants (a_N) in the *N*-oxyls were measured and compared with each other; the introduction of carbonyl groups at the *C*-3 and *C*-5 ring positions decreased these values, which increased in a protic polar solvent.

Many papers have recently reported synthetic methods for and the properties of extremely stable free radicals.[2] Especially, the introduction of *N*-oxyl into such heterocyclic rings as pyrrolines (I), pyrrolidines (II), piperidines (III), oxazolines (IV),[3] imidazolines (V),[4] and imidazolidines (VI)[5] were synthesized in number (Chart 1), and some of them were found useful as a radical scavenger,[5] and oxidizing agent,[5] and a spin labeling compound.[6]

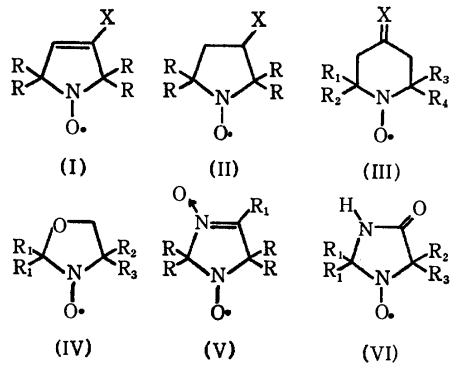

Chart 1.

However, piperazine *N*-oxyls have not as yet been reported, although some hindered piperazines are known;[7] this may be because of the difficulties in the direct oxidation of such hindered piperazines, as will be discussed later.

This paper will describe the synthesis of new hindered piperazine *N*-oxyls, their chemical properties, and their ESR coupling constants (a_N). The substituent and solvent effects on the coupling constant in the *N*-oxyls are of interest in connection with those of the piperidine *N*-oxyls (III).[8] Chart 2 summarizes starting hindered amines and the corresponding *N*-oxyls.

Results and Discussion

I. The Synthesis of 3,5-Dioxopiperazines, VII and IX. The starting amine, IX_H (R=H), was synthesized from bis(1-cyanocyclohexyl)amine (XV), itself derived from an aminonitrile of cyclohexanone, in a concentrated sulfuric acid solution according to a literature procedure.[7] Although the application of this method to the synthesis of VII_H met with failure, the following method, using basic conditions, successfully led to the formation of VII_H (Chart 3): the treatment of an aminonitrile of acetone with potassium hydroxide in refluxing methanol gave VII_H, plus 2,2,5,5-tetramethyl-4-oxoimidazolidine (XVI).[5] The alkylation or acylation of VII_H or IX_H gave the corresponding 4-substituted derivatives; after VII_H or IX_H was treated with sodium hydride in *N*,*N*-dimethylformamide (DMF), benzylation or carbethoxylation of the resulting Na-salts gave VII_B, IX_B (R=$CH_2C_6H_5$), VII_C, IX_C (R=COOEt) (Chart 4).

Piperazines $VIII_{H,B}$ and $X_{H,B}$ were synthesized by

Chart 4.

II. Oxidation of the Dioxopiperazines VII and IX to the Corresponding N-*Oxyls, XI and XIII.* The direct oxidation of the 4-unsubstituted dioxopiperazines, VII_H and IX_H, to XI_H and $XIII_H$ respectively was unsuccessful (Chart 4.); when *m*-chloroperbenzoic acid (CPBA) was used as an oxidizing agent, a rapid decomposition of VII_H and IX_H occurred with blue coloration, and none of the desired *N*-oxyls XI_H and $XIII_H$ were formed. Using 30% aqueous hydrogen peroxide in the presence of EDTA and sodium tungstate did not afford the desired products. However, the 4-substituted dioxopiperazines, $VII_{B,C}$ and $IX_{B,C}$, were oxidized with CPBA or 30% aqueous hydrogen peroxide to give the desired *N*-oxyls, $XI_{B,C}$ and $XIII_{B,C}$ respectively. The relative ease of the formation of the cyclohexane-spiro-piperazine-*N*-oxyl, $XIII_B$, was observed by comparing the degree of orange coloration; it was smaller than that of the tetramethyl-*N*-oxyl XI_B upon the oxidation of the corresponding amines with 30% aqueous hydrogen peroxide in methanol in the presence of the catalysts.

The 4-unsubstituted derivatives, VII_H and IX_H, were synthesized by the hydrolysis of XI_C and $XIII_C$, respectively, followed by spontaneous decarboxylation.

III. Oxidation of the VIII and X Piperazines to the XII and XIV N-*Oxyls.* The direct oxidation of the VIII and X piperazines should require controlled reaction conditions because of the presence of the *tert*-amine group. In fact, the oxidation of $XIII_B$ and X_B with CPBA met with failure; a rapid decomposition occurred, with a green coloration, and one of the the desrifed *N*-oxyls XII or XIV were obtained. On the other hand, the oxidation of $VIII_B$ (the tetramethylpiperazine derivative) with 30% aqueous hydrogen peroxide in the presence of the catalyst *in methanol* was successful in producing the desired *N*-oxyl, XII_B. The application of this procedure to the oxidation of X_B (cyclohexane-spiro-piperazine derivative) was, however, unsuccessful; X_B was recovered quantitatively under the same reaction conditions.

The difference in the reactivity between $VIII_B$ and X_B, or that between VII_B and IX_B, described above, may be explained by the steric effect at *C*-2 and *C*-6 in the ring. The same relationship has been observed in the imidazolidine series[5] and in the piperidine series.[9]

The oxidation of X_B with 30% aqueous hydrogen peroxide in the presence of the catalyst gave an undesirable product, N^1-oxyl-N^4-oxide ($XVII_B$) *in acetic acid.*

Since the direct oxidation of X_B failed to produce XIV_B, another route was attempted; we reduced[10] the 3,5-dioxo derivative, $XIII_B$, with LAH to give the corresponding hydroxylamine (XVIII), which was then oxidized with air[11], thus affording the dseired *N*-oxyl, XIV_B.

IV. Coupling Constants (a_N) in the ESR Spectra. The ESR spectra of the piperazine *N*-oxyls were measured in a 10^{-3} M solution, using Fremy's salt as the reference. Table 1 summarizes the substituent effects on the nitrogen-coupling constant (a_N) in the piperazine *N*-oxyls, and shows that carbonyl groups at *C*-3 and *C*-5 or a nitroxide group at *N*-4 decrease the value by about 1.0 gauss, *e.g.*, XI_B, XII_B, and $XVII_B$. This suggests that the unpaired electron distribution is altered to a small extent by a dipolar field effect. A similar trend has been observed with the ipperidine *N*-oxyl series.[8] Anomalously, the *N*-oxyl $XIII_C$

exhibited a relative low value (13.7); no reasonable explanation of this has been proposed because of the uncertainty of the conformation.

Table 2 shows solvent effects which are attributable to the hydrogen bonding between the *N*-oxyl and solvent (HS), altering the unpaired electron distirbution in favor of the (B) form, *i.e.*, the form with the more nucleophilic oxygen atom,[8] as is shown in Chart 5.

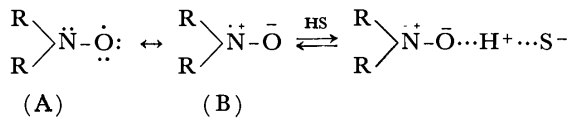

Chart 5.

Experimental

All the melting points are uncorrected.

Unless otherwise stated, the IR spectra were taken with a Hitachi EPI-S2 spectrometer (Nujol mull); the NMR spectra, with a Varian A-60 using tetramethylsilane as the internal standard; the Mass spectra, with a JEOL-JMS-OIS app aratus, and the ESR spectra, with a Hitachi MES 4001 type X-band spectrometer employing 100 kc modulation. Table 3 shows the formula molecular ion peak, mp, bp, yield, and result of elemental analysis of all the prdoucts; the IR spectra are shown in Table 4, and the NMR in Table 5.

2,2,6,6-Tetramethyl-3,5-dioxopiperazine (VII_H). A solution of 100 g (1.19 mol) of an aminonitrile of acetone and 26.6 g (474 mmol) of potassium hydroxide in 1000 m*l* of methanol was refluxed for 7 hr. Then 49.2 g (479 mmol) of a 35% aqueous hydrochloric acid solution was added into the reaction mixture to neutralize the used potassium hydroxide with stirring at 20°C. After 1 hr, the potassium chloride thus produced was removed by filtration; the filtrate was evaporated *in vacuo* to give a semi-solid, which was then washed at room temperature with 1000 m*l* of benzene in order to separate the oxoimidazolidine, XVI. The treatment of the obtained insoluble solid with a solution of 90.1 g of 35% aqueous hydrochloric acid in 180 m*l* of methanol gave 40.2 g of the monohydrochloride of VII_H. Recrystallization from water gave pure prisms. The hydrochloride was dissolved in water on heating and was neutarlized with potassium carbonate. The extract with chloroform from the mixture was dried over anhydrous magnesium sulfate and evaporated *in vacuo* to give the free base, VII_H, which was subsequently recrystallized from DMF to give colorless needles.

2,2,6,6-Tetramethyl-3,5-dioxo-4-benzylpiperazine (VII_B). Into a solution of 28.5 g (168 mmol) of VII_H in 500 m*l* of dry DMF, were added thirteen 0.5 g-portions (9.65 g, 201 mmol) of 50% sodium hydride (Nujol dispersion) with stirring at 40°C. After the vigorous evolution of hydrogen had ceased, the reaction mixture was stirred for 1 hr at 40°C. Into the mixture we then added a solution of 28.4 g (224 mmol) of benzyl chloride in 50 m*l* of dry DMF at 45—50°C. After stirring overnight at room temperature, the DMF was evaporated *in vacuo* to give a residue, which was dissolved in benzene (200 m*l*) and water (200 m*l*). The separated benzene layer was washed with water, dried over anhydrous magnesium sulfate, and treated with active charcoal. The evaporation of the benzene *in cacuo* left an oil, which was then dissolved in petroleum benzine and cooled

at 5°C to give 27.4 g of colorless prisms of VII_B.

2,2,6,6-Tetramethyl-3,5-dioxo-4-carbethoxypiperazine (VII_C). This was prepared from VII_H and ethyl chlorocarbonate in a manner similar to that described above; the extract with benzene from the reaction mixture was washed with ice-water (7—10°C).

2,2,6,6-Tetramethylpiperazine ($VIII_H$). To a suspension of 9.1 g (240 mmol) of LAH in 1000 m*l* of dry ether, we added twenty 0.5-g portions (58.8 mmol) of VII_H at 5—8°C. The resulting solution was stirred for 30 min at 5°C and then refluxed for 1 hr. On cooling to room temperature, a solution of 34.3 g of ethyl acetate in 60 m*l* of ether was added to the resulting mixture in order to decompose the excess LAH. After the reaction mixture had been kept at room temperature for 1 hr, a solution of 2.3 g of sodium hydroxide in 45 m*l* of water was added at 5°C into the mixture, and then the mixture was stirred for 1 hr at room temperature. The ether layer was separated and dried over anhydrous magnesium sulfate. The evaporation of the ether give 5.1 g of crude crystals, which readily sublimed *in vacuo*. The amine, $VIII_H$, turned yellow on exposure to air.

2,2,6,6-Tetramethyl-4-benzylpiperazine ($VIII_B$) was synthesized from VII_B in a manner similar to that described above (in tetrahydrofuran (THF), at 15—20°C).

Cyclohexane-1-spiro-2'-(3',5'-dioxopiperazine)-6'-spiro-1''-cyclohexane (IX_H) was synthesized by the literature procedure.[7]

Cyclohexane-1-spiro-2'-(3',5'-dioxo-4'-benzylpiperazine)-6'-spiro-1''-cyclohexane (IX_B) was prepared from IX_H at 65°C as colorless prisms by a procedure similar to that used in the synthesis of VII_B.

Cyclohexane-1-spiro-2'-piperazine-6'-spiro-1''-cyclohexane (X_H) was prepared from IX_H in ether at 5—8°C in a manner similar to that used in the synthesis of $VIII_H$.

Cyclohexane-1-spiro-2'-(4'-benzylpiperazine)-6'-spiro-1''-cyclohexane (X_B) was similarly prepared from IX_B in ether at 5—8°C.

Oxidation of the Piperazines. 2,2,6,6-Tetramethyl-3,5-dioxopiperazine-1-oxyl (XI_H). By the Direct Oxidation of VII_H. i) With 30% Aqueous Hydrogen Peroxide in the Presence of EDTA and Sodium Tungstate (HPO) in Methanol: Into a suspension of 0.1 g (0.589 mmol) of VII_H in 3.0 g of methanol, was slowly added 1.5 g (13.2 mmol) of HPO. The solution was allowed to stand for 5 days at room temperature. No desired reddish-orange solution, which would indicate the formation of *N*-oxyls, was obtained; the mixture merely turned pale yellow. The methanol was evaporated *in vacuo*, and 15 m*l* of benzene and 0.5 g of potassium carbonate were added to the mixture in order to decompose the excess hydrogen peroxide. The resulting mixture was stirred at room temperature overnight. When the benzene layer, separated from the reaction mixture, was evaporated *in vacuo*, it gave none of the desired prroduct, XI_H.

ii) With HPO in Acetic Acid: None of the desired product ws obtained.

iii) With CPBA in Dichloromethane: Into a solution of 0.1 g (0.589 mmol) of VII_H in 10 m*l* of dichloromethane, was slowly added 0.3 g (1.74 mmol) of CPBA at room temperature. The solution gradually turned blue and then discolored; none of the desired reddish-orange solution was observed. When the dichloromethane was evaporated *in vacuo* after washing with a 10% aqueous solution of potassium carbonate, it gave no *N*-oxyl.

By Hydrolysis Followed by the Decarboxylation of VII_C. Into 2.5 g of a 9.15×10^{-3}% solution (0.264 μmol) of potassium hydroxide in methanol, was added 67.7 mg (0.264 μmol) of VII_C at room temperature. The mixture was allowed to stand for 1 hr at room temperature; then the methanol was evaporated *in vacuo* below room temperature to leave a residue, which was washed with ether three times to remove the VII_C. The residue was then dissolved in methanol and treated with a solution of an equimolar hydrogen chloride in methanol at 10°C. The methanol was removed *in vacuo*, and the resuting residue was extracted with ether. The concentration of the extract gave yellow prisms. A small piece of the prisms gradually sublimed at 150—160°C (on the hot plate of a micro melting-point apparatus).

2,2,6,6-Tetramethyl-3,5-dioxo-4-benzylpiperazine-1-oxyl (XI_B). To a solution of 3.0 g (11.5 mmol) of VII_B in 10 m*l* of acetic acid, was added dropwise 5.25 g (46.2 mmol) of HPO at 20°C. The solution was then allowed to stand at room temperature. After 3 days the solution began to turn reddish. After standing for additional 4 days, 100 m*l* of benzene and 23.7 g potassium carbonate were added to the reaction mixture below 15°C in order to neutralize the acetic acid employed as a solvent and in order to decompose the excess hydrogen peroxide. The suspension was stirred for 2 hr at room temperature. Separation, drying over potassium carbonate, and the evaporation of the benzene gave 4.1 g of a reddish oil, which was then chromatographed on 100 g Brockmann aluminum oxide, using petroleum benzine as the eluent. The subsequent evaporation of the elute *in vacuo* left a reddish oil, which crystallized on standing overnight (1.5 g). Recrystallization gave reddish-orange neeldes. As a by-product along with XI_B, *2,2,6,6-tetramethyl-3,5-dioxo-4-benzyl-1-hydroxypiperazine* was obtained from an ether-elute; mp 97—98°C (from petroleum ether); (1.2 g, 44%). Found: C, 64.95, H; 7.29, N; 9.96%. Calcd for $C_{15}H_{20}N_2O_3$: C, 65.22, H; 7.32, N; 10.14%. IR(cm^{-1}): 3450, 1735, 1675, 735, and 700.

2,2,6,6-Tetramethyl-3,5-dioxo-4-carbethoxypiperazine-1-oxyl (XI_C) was prepared by the oxidation of VII_C with CPBA in a procedure similar to that described above; the extract was washed with water below 10°C.

2,2,6,6-Tetramethyl-4-benzylpiperazine-1-oxyl (XII_B). i) Oxidation of $VIII_B$ with CPBA: As soon as a solution of 0.6 g (3.48 mmol) of CPBA in 10 m*l* of dichloromethane was added dropwise to a solution of 0.25 g (1.08 mmol) of $VIII_B$ in 10 m*l* of dichloromethane at 15°C, a rapid decomposition of $VIII_B$ occurred with green coloration; none of the desired *N*-oxyl was obtained.

ii) Oxidation of $VIII_B$ with HPO in Methanol: To a solution of 1.92 g (8.28 mmol) of $VIII_B$ in 5 m*l* of methanol, was added dropwise 3.0 g (26.5 mmol) of HPO at room temperature. After the reaction mixture had been allowed to stand for 20 hr at room temperature, 10 more grams of HPO were added to the mixture. After standing overnight, a reddish oil separated spontaneously. To the mixture was then added 50 ml of benzene and 5 g of potassium carbonate. Vigorous stirring was continued for 3 hr, and then the benzene layer was separated, washed with water saturated with sodium chloride, and dried over anhydrous magnesium sulfate. The subsequent removal of the benzene left 1.7 g of a reddish oil, which was chromatographed on 100 g of a silica gel (M. WOELM for Dry-Column Chromatography) using petroleum benzine as the eluent. The evaporation of the elute *in vacuo* gave 0.6 g of reddish crystals.

Cyclohexane-1-spiro-2'-(3',5'-dioxopiperazine-1'-oxyl)-6'-spiro-1''-cyclohexane ($XIII_H$). The direct oxidation of IX_H with HPO or CPBA failed to produce $XIII_H$ in a manner similar to that used for the oxidation of VII_H. However, hydrolysis, followed by decarboxylation of $XIII_C$, gave $XIII_H$ in a procedure similar to that used for VII_C.

Cyclohexane-1-spiro-2'-(3',5'-dioxo-4'-benzylpiperazine-1'-oxyl)-6'-spiro-1''-cyclohexane ($XIII_B$). i) To a suspension of 0.1 g (0.294 mmol) of IX_B in 0.7 m*l* of acetic acid, was added dropwise 0.35 g (3.08 mmol) of HPO. The suspension was then stirred at room temperature. After 2 days, a reddish oil separated spontaneously from the acetic acid. To the mixture, after 4 days, were addde 5 m*l* of benzene and 0.2 g of potassium carbonate at room temperature in order to neutralize the acetic acid and in order to decompose the excess hydrogen peroxide. The resulting suspension was stirred at room temperature for 2 hr. The benzene was then evaporated *in vacuo* to give 0.109 g of a reddish oil. The oil was dissolved in a small amount of *n*-hexane and cooled at −5—0°C overnight to give reddish crystals.

ii) To a solution of 4.0 g (11.7 mmol) of IX_B in 800 m*l* of dichloromethane, was gradually added 8.0 g (46.6 mmol) of crystals of CPBA at room temperature. The reaction mixture immediately turned red, and was then kept for 5 days at room temperature. The resulting solution was washed with 200 m*l* of a 10% aqueous potassium carbonate solution three times and with water. After the solution had then been dried over potassium carbonate, the removal of the solvent left a reddish oil, which was chromatographed on 100 g of Brockmann aluminum oxide using petroleum benzine as the eluent. The evaporation of the elute gave 2.5 g of crude crystals, which were recrystallized to give pure reddish crystals. The physical data completely accorded with those of the sample obtained by *Method i)* above.

Cyclohexane-1-spiro-2'-(3',5'-dioxo-4'-carbethoxypiperazine-1'-oxyl)-6'-spiro-1''-cyclohexane ($XIII_C$) was synthesized from IX_C in a manner similar to that used in the synthesis of XI_C; a reddish oil obtained by the evaporation of the extract solidified during 3 days' storage at −10—0°C. The solid was washed with cold (−50°C) *n*-hexane and chromatographed on silica gel using *n*-hexane–ether (9 : 1) to give reddish-orange prisms.

Cyclohexane-1-spiro-2'-(4'-benzylpiperazine-1'-oxyl)-6'-spiro-1''-cyclohexane (XIV_B). i) Oxidation of X_B with CPBA: An attempt to do this in a manner similar to that used in the oxidation of $VIII_B$ met with failure.

ii) Oxidation of X_B with HPO in Methanol: A mixture of 0.2 g (0.641 mmol) of X_B, 0.5 g (4.42 mmol) of HPO and 2 m*l* of methanol was stirred at room temperature. After 6 days, the starting amine was quantitatively revovered.

iii) Oxidation of X_B with HPO in Acetic Acid: This gave none of the desired product, but another product, *cyclohexane-1-spiro-2'-(4'-benzylpiperazine-1'-oxyl-4'-oxide)-6'-spiro-1''-cyclohexane ($XVII_B$)*, when conducted in a manner similar to that used in the preparation of $XIII_B$.

iv) Reduction of $XIII_B$ with LAH Followed by the Air-Oxidation of the Resulting Hydroxyl Amine (XVIII): Into a suspension of 0.248 g (6.5 mmol) of LAH in 6 ml of dry ether, was gradually added 0.5 g (1.41 mmol) of $XIII_B$ at room temperature. The ether was refluxed for 30 min and then allowed to stand at room temperature. After 12 hr, the

reddish solution gradually became colorless. The discolored solution was poured into ice-water, and the mixture was stirred at room temperature for 3 days while being exposed to air. The ether layer gradually turned red again and was separated, washed with water three times, dried over anhydrous magnesium sulfate, treated with active charcoal, and evaporated *in vacuo* to give 0.437 g of crude crystals, which gave reddish crystals upon recrystallization.

We wish to thank Dr. Genshun Sunagawa, the Director of these laboratories, for his encouragement and Mr. Tsutomu Kanai for his technical assistance during the course of this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1860—1863 (1972)

Steric Effect in the Nucleophilic Attack of Bromide Anion on Diaryl- and Aryl-2-thienyliodonium Ions

Yorinobu YAMADA and Makoto OKAWARA

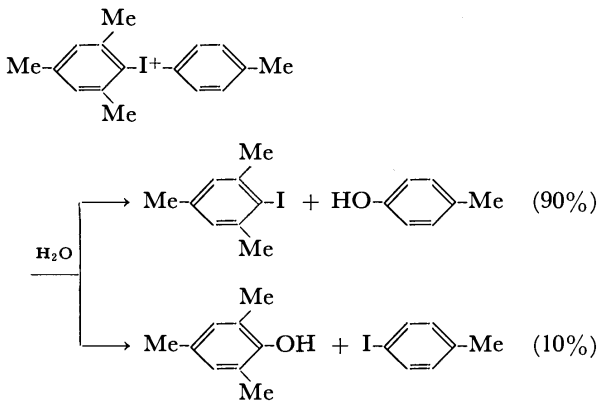
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 15, 1971)

Duryl-, mesityl-, and *o*-tolyl-phenyl- and 2-thienyliodonium bromides have been synthesized. When these substances were allowed to decompose in molten (235°C) and solution (100°C) states, the nucleophile (bromide anion) preferentially attacked the substituted phenyl ring. Steric and electronic effects of phenomena have been discussed.

The nucleophilic substitution reaction on the aryl ring of diaryliodonium salts is usually influenced by the inductive and resonance effects of the substituent group.[1] Generally, the nucleophile preferentially attacks the phenyl ring containing the electron-withdrawing group. The site of the nucleophilic attack, however, is influenced by the steric hindrance of the substituent group.

Le Count and Reid reported on the steric effect by the *ortho*-methyl group in the reaction of diaryliodonium salts.[2] Hydrolysis of *p*-tolylmesityliodonium bisulfate which contains two methyl groups *ortho* to the iodine atom, gives 90% of iodomesitylene and 10% iodotoluene.



We showed that the nucleophile (bromide and chloride ions) attacks the aryl ring rather than the thienyl ring in the reaction of aryl-2-thienyliodonium halides.[3] The reaction seems to be an aromatic bimolecular substitution reaction and to proceed *via* the π-p orbital interaction of the aryl ring and halide ion in the trigonal-bipyramidal structure of iodonium salt. However, if the methyl group is introduced into the *ortho*-position on the phenyl ring of phenyl-2-thienyliodonium salt, it can be expected that the nucleophile attacks the thienyl ring predominantly. The same situation can be expected in the case of diaryliodonium salt. The present paper describes the steric effect in the reaction of substituted diphenyl- and substituted phenyl-2-thienyliodonium bromides containing the *ortho*-methyl substituent on the phenyl ring.

Results and Discussion

Substituted phenyl-2-thienyl- (I) and substituted diphenyl-iodonium bromides (II) were synthesized from substituted phenyliodoso acetate and thiophene or benzene in a mixture of acetic anhydride and concentrated sulfuric acid, respectively. The products are summarized in Table 1.

The thermal decomposition of the iodonium salts I and II was carried out in the molten state (23±55°C) for 5 min and the reaction products aryl halides and 2-thienyl halides were confirmed by gas chromatography in comparison with their authentic samples. The reaction of I and II proceeds along the following paths, the bromide ion competitively attacking the aryl ring or the thienyl ring (or phenyl ring.) The results are given in Table 2. The results in the solution state (100°C) of the iodonium bromides in *N*,*N*-dimethylformamide (DMF) and DMF-dioxane

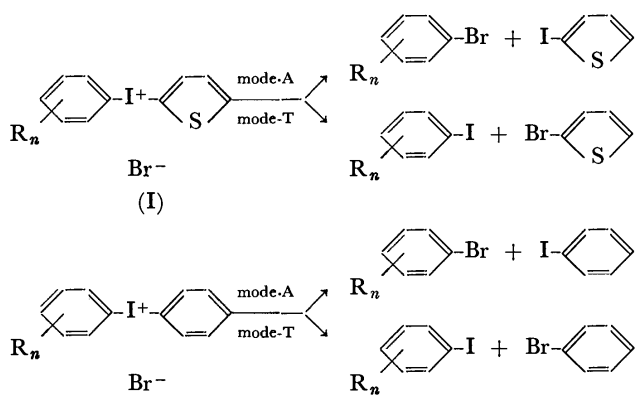
Th-: Thienyl ring; Ph-: Phenyl ring



R=Methyl group, $n=1, 3, 4$

are summarized in Table 3. They are similar to those in the molten state. In every case the reaction proceeded without side reaction.

We see from Table 2 that the mode-A reaction, in which the nucleophile attacks the aryl ring, takes place completely for Ib and Ic and it is accompanied by the mode-T reaction, in which the nucleophile attacks the thienyl ring, only in the case of Ia. Similarly, for II the mode-A reaction takes place more predominantly than mode-B, in which the nucleophile attacks the phenyl ring. The reaction of II, however, does not proceed so selectively as that of I. The results are in contrast to those in the hydrolysis of *p*-tolylmesityliodonium salt reported by Le Count and Reid.

An aromatic bimolecular substitution mechanism has been proposed for *m*- or *p*-substituted phenyl-2-thienyl- and *p*-tolyliodonium salts.[5] If an aromatic bimolecular substitution mechanism is operative in the present case, the reaction of II should give unsubstituted phenyl bromide rather than methyl substituted phenyl bromide, but the result is the opposite. Thus, the *ortho*-methyl group is effective in the intramolecular strain to facilitate the dissociation of the bond between substituted phenyl 1-carbon and iodine. The substituted phenyl cation produced seems to be

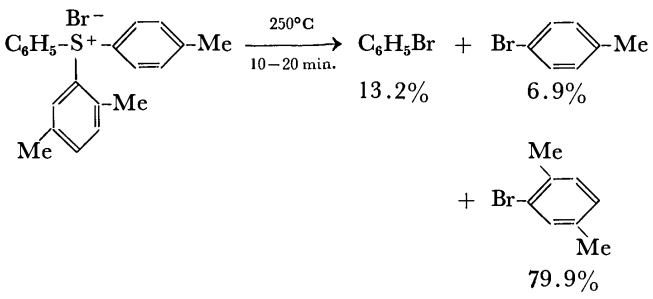
o-Tolyl (a)	DMF	100 : 0	86.8 : 13.2
Mesityl (b)	DMF	100 : 0	96.0 : 4.0
Duryl (c)	DMF	100 : 0	100 : 0
o-Tolyl (a)	Dioxane-DMF (1 : 1)	100 : 0	92.3 : **7.7**
Mesityl (b)	Dioxane-DMF (1 : 1)	100 : 0	*ca.* 100 : trace
Duryl (c)	Dioxane-DMF (1 : 1)	100 : 0	100 : 0

Th-: Thienyl ring; Ph-: Phenyl ring

stabilized by some methyl groups, and an analogous mechanism to an aromatic S_N1 is plausible. Similar results have been observed in the case of *m*- or *p*-substituted phenyl-2-thienyliodonium salts. However, there is a slight difference in the reaction tendency between I and II, *viz.*, the mode-T reaction takes place unfavorably compared to mode-B. Thus, it is very difficult for the thienyl ring to be attacked by the halide ion regardless of the position of the substituent group in the phenyl nucleus. A remarkable distinction between the reactions of the iodonium bromides containing one *ortho*-methyl group (Ia and IIa) and two *ortho*-methyl groups (Ib, c and IIb,c) was not observed either in the molten or solution states. This suggests that even the one *ortho*-methyl group affords a considerable steric strain enough to break the substituted phenyl 1-carbon-iodine bond.

Wiegand and McEwen reported on the steric effect in the pyrolysis reaction of triarylsulfonium bromides.[6] The reaction of phenyl-*p*-tolyl-2,5-dimethylphenylsulfonium bromide gives aryl bromides in the order of preference of 2,5-dimethylbromobenzene > bromobenzene > *p*-bromotoluene. This is explained by the



fact that the sulfonium bromide decomposes preferentially in such a manner as to give maximum relief of steric strain.

Thus, it is reasonable to assume that the reaction of the iodonium bromides containing *ortho*-methyl groups proceeds by an analogous mechanism to an aromatic S_N1.

When the substituted phenyl-2-thienyliodonium bromide (I) was allowed to react in the solvent, only the mode-A reaction took place. DMF and dioxane act to stabilize the substituted phenyl cation and help the dissociation of the substituted phenyl 1-carbon-iodine bond. In the case of substituted diphenyliodonium bromide (II), the mode-A reaction increases to some extent in DMF and dioxane, but the remarkable solvent effect was not observed compared to the reactions of Ia and II is attributed to the greater reactivity of phenyl ring than that of thienyl ring.

Experimental

Substituted Phenyl Iodide. Subsittuted phenyl iodides were prepared from substituted benzene by the usual method.[7]

Subsitituted Phenyliodoso Acetate. Iodosobenzene diacetate was prepared by the oxidation of iodobenzene in a mixture of hydroge nperoxide and acetic anhydride.[8] Other subsitituted phenyliodoso acetates were prepared by a procedure like that given for mesityliodoso acetate.[9] To 24.6 g (0.1 mol) of iodomesitylene in 50 m*l* of ethyl acetate was added dropwise with stirring 95 g (0.25 mol) of 20% peracteic acid in acetic acid and ethyl acetate. The flask was chilled with an ice-water bath during the course of addition (30 min). The solution was then stirred for two hours below 10°C and allowed to stand overnight at room temperature. The solvent was removed under reduced pressure. The white crystals were washed with ether and dried overnight, giving 27.8 g of mesityliodoso acetate (yield, 78.5%), mp 110—125°C. (See Table 4 for melting points and yield data).

TABLE 4. ARYLIODOSO ACETATE

Aryl group	Mp (°C)	Yield (%)
o-Tolyl	145—148	69.2
Mesityl	110—120	78.5
Duryl	130—137	77.9

o-*Tolylphenyliodonium Bromide.* To a suspension of 3.4 g (10 mmol) of *o*-tolyliodoso acetate and 5 m*l* of benzene in 100 ml of acetic anhydride was added 5 m*l* of concd. sulfuric acid with stirring below 10°C. After stirring for one hour, the reaction mixture was allowed to stand for 5 hr at room temperature. The mixture was poured into 200 m*l* of ice water and extracted with two 50 m*l* portions of ether. The aqueous layer was treated with activated carbon and 30 g of sodium bromide in 100 m*l* of water. The precipitate was washed with water and with methanol and then dried to give 1.8 g of *o*-tolylphenyliodonium bromide. Recrystal-

lization from methanol gave a pure product.

Mesitylphenyliodonium Bromide. To a well-stirred mixture of 11 g (34 mmol) of phenyliodoso acetate, 3.6 g (30 mmol) of mesitylene and 150 m*l* of acetic anhydride kept below 10°C was added 10 m*l* of concd. sulfuric acid over 30 min. After the mixture had been stirred for 6 hr at room temperature, 200 m*l* of ice-water was added, and the mixture was extracted with two 50 m*l* portions of ether. The aqueous layer was treated with activated carbon and then with 30 g of sodium bromide in 100 m*l* of water. The precipitate was recrystallized from methanol to give 8.3 g of mesitylphenyliodonium bromide.

Durylphenyliodonium Bromide. In a similar way the reaction of phenyliodoso acetate (9 g, 28 mmol) with durene (3 g, 22 mmol) gave 8.3 g of durylphenyliodonium bromide.

o-*Tolyl-2-thienyliodonium Bromide.* To a well-stirred mixture of 100 m*l* of acetic anhydride, 6.7 g (20 mmol) of *o*-tolyliodoso acetate and 5.0 g (60 mmol) of thiophene, 5 m*l* of concd. sulfuric acid was added dropwise below 10°C. After 4 hr, 200 m*l* of ice-water was added. Extraction twice with 50 m*l* portions of ether followed by treatment with activated carbon produced an almost colorless solution, which was treated with 20 g of sodium bromide in 100 m*l* of water. The precipitates were collected and crystallized from methanol to give 2.6 g of *o*-tolyl-2-thienyliodonium bromide.

Mesityl-2-thienyliodonium Bromide. To a vigorously stirred solution of 8.2 g (22 mmol) of mesityliodoso acetate, 2.8 g (33 mmol) of thiophene and 200 m*l* of acetic anhydride, was added 5 m*l* of concd. sulfuric acid below 10°C. Subsequent treatments were carried out in the same way to give 8.8 g of mesityl-2-thienyliodonium bromide.

Duryl-2-thienyliodonium Bromide. In a similar way 2.3 g of duryl-2-thienyliodonium bromide was obtained from 4.5 g (12 mmol) of duryliodoso acetate and 2.5 g (30 mmol) of thiophene.

Pyrolysis Reaction of Iodonium Bromides (I and II). 0.25 g of substituted phenyl-2-thienyliodonium bromide (I) was enclosed in a pyrex ampoule. The ampoule was then placed in an oil bath kept at 235°C for 5 min. After the end of the pyrolysis the pyrolysate was dissolved in a small quantity of ether, and the amounts of 2-iodothiophene and 2-bromothiophene were determined by a Hitachi Gas Chromatograph 025—5051 on a 1 m column packed with Silicone SE-30 at 100°C. Chlorobenzene was used as an internal standard.

The pyrolysis reaction of substituted diphenyliodonium bromide (II) was also carried out in a similar way. Amounts of iodobenzene and bromobenzene were determined in the same way.

Reaction of Iodonium Bromides (I and II) in DMF and DMF-Dioxane. The reaction of iodonium bromides was carried out by a procedure similar to that given for *o*-tolylphenyliodonium bromide. *o*-Tolylphenyliodonium bromide (0.469 g, 1.25 mmol) dissolved in 100 m*l* of DMF was held at 100°C for 5 hr. At the end of the reaction the mixture was poured into cold water, extracted twice with ether and the extract was dried over anhydrous magnesium sulfate. After removing the solvent by distillation, the residue was redissolved in a small quantity of ether and the amounts of iodobenzene and bromobenzene were determined by means of gas chromatography. Subseuqent treatment was carried out in a similar way to that for the pyrolysis reaction. In every case the concentration was kept at 0.125 mmol/*l*.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1863—1866 (1972)

The Photolysis and Thermolysis of Ethyl Azidoformate in the Presence of Ketones

Tamejiro HIYAMA, Hiroaki TAGUCHI, Shinsaku FUJITA, and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Yosida, Kyoto

(Received November 29, 1971)

The photochemical decomposition of ethyl azidoformate (I) in an acetone solution gives the nitrene adduct, oxazirane II, whereas the thermolysis of the solution gives a C–H insertion product, III. The photolysis of I in cyclohexanone gives an α-insertion product, IX, while the thermolysis affords a β-insertion product, X, and an oxazole, XIII, in addition to IX. The multiplicity of the reactive species is examined in terms of the heavy-atom effect.

In contrast with carbene chemistry, few examples have been reported of the reactions of nitrenes with *n*-bases.[1,2] An arylnitrene has been observed to react intramolecularly with a carbonyl group to produce anthranil,[3] but the attempted intermolecular reaction of benzenesulfonylnitrene with cyclohexanone failed to afford any products arising from nitrene-addition.[4] We wish now to report that ethoxycarbonylnitrene generated by photolysis or thermolysis has been incorporated into acetone and cyclohexanone.

Table 1 lists the reaction conditions and product distributions in the reaction of ethyl azidoformate (I) with acetone. The irradiation[5] of an acetone solution of I gave 2-ethoxycarbonyl-3,3-dimethyloxazirane (II), hexane-2,5-dione (IV), and ethyl carbamate (V). The thermally labile oxazirane II polymerized upon slight heating and gave no satisfactory analyses, but the exact mass was compatible with the molecular formula of $C_6H_{11}NO_3$. The hydrolysis of II gave an

5) Since the solution of I in acetone showed none of the UV absorptions which are absent in those of the components, the possibility of the formation of a CT-complex under the photolysis may be excluded.

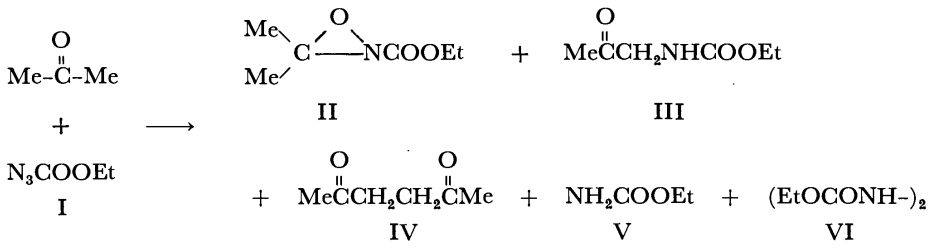

Table 1. Photolysis and thermolysis of I in acetone

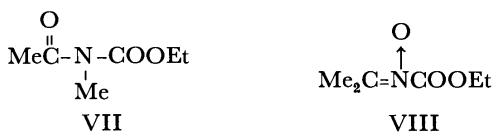
Condition	Solvent	Reaction time (hr)	Products (%)[a]				
			II	III	IV	V	VI
$h\nu$[b]	none	40	60	0	4	23	0
$h\nu$[b]	CH_2Cl_2[c]	45	0	27	0	15	0
Δ[d]	none	4	0	26	0	5	4
Δ[d]	CH_2Cl_2[c]	3	0	45	0	11	0

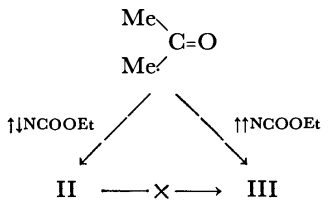
a) All products were isolated by column chromatography, and the isolation yields are given.
b) An 0.4 M acetone solution of I was irradiated by means of a 200-W high-pressure mercury lamp externally at room temperature.
c) An 0.4 M acetone solution of I was diluted with an equi-volume of dichloromethane.
d) Thermolysis was performed in an autoclave at 180°C.



acetone identified as the 2,4-dinitrophenylhydrazone. The NMR spectrum (see Experimental section) may also be explained by two alternative structures, VII and VIII, but both are unlikely.[6]

When the photolysis was carried out in dichloromethane, ethyl acetonylcarbamate (III)[9] and V were obtained, but no trace of II was isolated (Table 1). The solvent effect[2,10] observed in the formation of II probably indicates that the formation of oxazirane II is to be ascribed to attack of the singlet nitrene on acetone. On the other hand, triplet nitrene is involved in the formation of III. The formation of IV and V can be understood in terms of the hydrogen-abstraction reaction of the triplet nitrene.

The thermal decomposition of I in acetone yielded III, V, and *N,N'*-diethoxycarbonylhydrazide (VI), while the reaction under dilution with dichloromethane resulted in increased yield of III and V (Table 1). This indicates that the carbamates are possibly derived from the triplet nitrene. As is shown in Scheme 1, we may assume that the reaction of the singlet nitrene yields oxazirane II, while the triplet nitrene gives carbamate III. The possible formation of III *via* II was excluded, as the heating of the crude II at 180°C gave no carbamate III, but only polymeric products.



Scheme 1

The reactions in a cyclohexanone solution are summarized in Table 2. Photolysis gave 2-ethoxycarbonylaminocyclohexanone (IX),[11] bicyclohexyl-2,2'-dione (XI),[12] and V, while the photoreaction in a dichloromethane solution gave 3-ethoxycarbonylaminocyclohexanone (X)[13] in addition to IX, V, and 2-(1-cyclohexenyl)cyclohexanone (XII).

The thermolysis of I in cyclohexanone yielded another novel compound, 2-ethoxy-4,5-tetramethyleneoxazole (XIII), which exhibited an IR band at 1597 cm^{-1} and a UV absorption at 265 nm (log ε 1.48), both characteristic of oxazoles.

6) An authentic sample of VII prepared from *N*-methylurethane[7] was not identical with II. Another possibility, VIII, may be rejected because a strong absorption between 1050—1200 cm^{-1} due to nitrones[8] is absent in the IR spectrum of II and because the photochemistry of nitrones is known to give rise to oxaziranes. Further, the structure of VIII implies a positive charge on the nitrogen atom bearing an electronegative ethoxycarbonyl group; this is not possible.

13) The authentic sample was obtained in an independent study by the ethoxycarbonylation of *m*-aminophenol, followed by hydrogenation and oxidation. In a similar manner, 4-ethoxycarbonylaminocyclohexanone was prepared. Details of the syntheses will be given elsewhere in the near future.

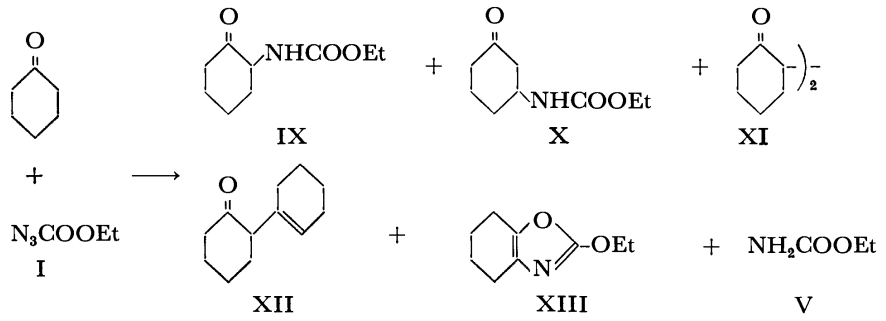

Table 2. Photolysis and thermolysis of I in cyclohexanone

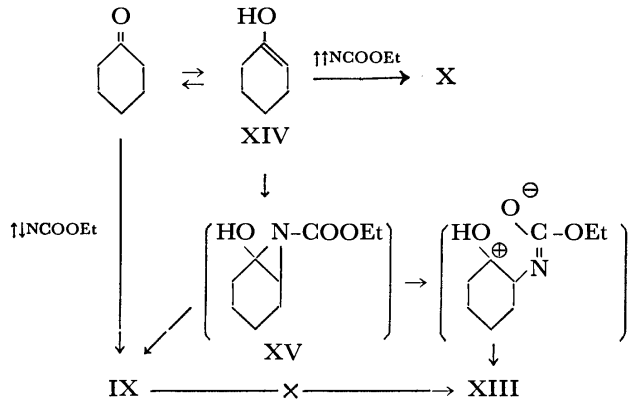
Condition	Solvent	Reaction time (hr)	Products (%)[a]					
			IX	X	XI	XII	XIII	V
$h\nu$[b]	none	40	8	0	5	0	0	22
$h\nu$[b]	CH_2Cl_2[c]	45	15	8	0	24	0	7
Δ[d]	none	2	29	11	2	0	17	4
Δ[e]	CH_2Cl_2[c]	3	18	7	2	0	13	4

a) All products were isolated by column chromatography, and the isolation yields are given.
b) A 0.4 M solution of I in cyclohexanone was irradiated by means of a 200-W high-pressure mercury lamp externally at room temperature.
c) A 0.4 M cyclohexanone solution of I was diluted with an equi-volume of dichloromethane.
d) Thermolysis was performed by adding I to cyclohexanone at 156°C.
e) Thermolysis was performed in an autoclave at 150°C.

A possible account of the products is given in Scheme 2. The formation of XIII should involve the attack of I or the nitrene on the *enol* form, XIV, of cyclohexanone,[14] since IX could not be converted to XIII under thermolytic conditions. The precursor of XIII may be a 1,3-dipolar adduct, hydroxyaziridine XV, and/or a triazoline, but no conclusive data are yet available.



Scheme 2.

The observed heavy-atom effect implies that X is derived from the triplet nitrene. The absence of 4-ethoxycarbonylaminocyclohexanone in the products suggests that the allylic insertion of triplet nitrene into the enolized cyclohexanone led to X. The reactive species in the formation of IX is either singlet nitrene or hydroxyaziridine, XV.[15]

14) Cyclohexanone involves several percentages of the enol form at room temperature; this form is often the reactive species.
15) The photolysis of ethyl azidoformate in 1-cyclohexenyl acetate gives the acetate of the hydroxyaziridine XV, which is transformed to IX on hydrolysis.[9]

Experimental

All the melting points are uncorrected. The infrared spectra were recorded on a Shimadzu spectrophotometer IR-27-G, the ultraviolet spectra, on a Hitachi EPS-2 spectrometer, the nuclear magnetic resonance spectra on a JEOL C-60-H spectrometer, and the mass spectra, on a Hitachi RMU-6L spectrometer.

Photolysis of Ethyl Azidoformate in Acetone. A mixture of acetone (20 ml) and ethyl azidoformate (1.00 g, 8.7 mmol) was placed in a quartz tube, degassed by bubbling nitrogen and irradiated externally at room temperature with a 200-W high-pressure mercury lamp until nitrogen evolution had ceased and the characteristic IR bands at 2185 and 2137 cm^{-1} due to the azide group had disappeared (*ca.* 40 hr). After the removal of the excess acetone under reduced pressure, the yellow oily residue (1.5 g) was separated by column chromatography on silica gel. Elution with *n*-hexane, benzene, and finally with ether gave 2-ethoxycarbonyl-3,3-dimethyloxazirane (II) (0.76 g, 60%); bp 100°C (bath temperature) at 2 mmHg. IR (neat): 1715, 1400, 1375, 1327, 1212, 1004 cm^{-1}; NMR (CCl_4): δ 1.35 (t, 3H, $\underline{CH_3}CH_2$-), 1.45 (s, 3H, $C\underline{H_3}$-), 1.52 (s, 3H, $C\underline{H_3}$-), 4.12 (q,2 H, $CH_3\underline{CH_2}$); MS: *m/e* 145 (19%), 73 (100), 59 (73), 58 (72).

Found: *m/e* 145.075 (M^+). Calcd for $C_6H_{11}NO_3$: *m/e* 145.074.

Further elution gave hexane-2,5-dione (IV) (0.04 g, 4%) and ethyl carbamate (V) (0.18 g, 23%). Both IV and V were identified by a comparison of their infrared spectra and retention times on gas chromatography with those of authentic samples.

Photolysis of Ethyl Azidoformate in an Acetone-dichloromethane Mixture. A solution of ethyl azidoformate (0.50 g, 4.4 mmol) in acetone (10 ml) and dichloromethane (10 ml) was irradiated as has been described above. After concentration, the residual mixture was separated by column chro-

matography on alumina. Successive elution with *n*-hexane, benzene, and ether gave ethyl acetonylcarbamate (III) (0.11 g, 27%). IR (neat): 3350, 1705, 1525, 1330, 1065 cm^{-1}; NMR (CCl_4): δ 1.26 (t, 3H, $\underline{CH_3}CH_2$-), 2.17 (s, 3H, CH_3-), 3.9—4.3 (m, 4H, doublet at δ 4.00, -CH_2-, quartet at δ 4.10, $CH_3\underline{CH_2}$-), 5.59 (broad s, 1H, NH); MS: *m/e* 145 (M^+, 3%), 102 (39), 78 (19), 74 (18), 62 (58), 44 (100). Ethyl carbamate (V) (0.07 g, 15%) was obtained as a by-product.

Hydrolysis of Oxazirane II. A mixture of 2,4-dinitrophenylhydrazine (0.70 g), concentrated sulfuric acid (3 m*l*), water (3 m*l*), and ethanol (10 m*l*) was added, drop by drop, to a solution of oxazirane (0.45 g, 3.1 mmol) in ethanol (5 m*l*). The reaction mixture was then allowed to stand at 50°C overnight, and the red crystals thus precipitated were filtered; mp 119—120°C. The mixed melting point with acetone 2,4-dinitrophenylhydrazone was 119—120°C.

Thermolysis of Ethyl Azidoformate in Acetone. Ethyl azidoformate (2.00 g, 17.4 mmol) dissolved in acetone (40 m*l*) was heated under a nitrogen atmosphere in an autoclave at 180°C for 4 hr. The removal of the excess acetone *in vacuo* gave a dark-colored residue (2.38 g), which then was subjected to chromatography on an alumina column. Elution with benzene and ether gave ethyl acetonylcarbamate (III) (0.67 g, 26%), *N,N'*-diethoxycarbonylhydrazide (VI) (0.12 g, 4%), and ethyl carbamate (V) (0.07 g, 5%).

Thermolysis of Ethyl Azidoformate in Acetone-dichloromethane. A solution of ethyl azidoformate (1.00 g, 8.7 mmol) in acetone (20 m*l*) and dichloromethane (20 m*l*) was placed in an autoclave and heated at 160—180°C for 3 hr. The subsequent separation of the crude mixture by chromatography on a column of silica gel afforded III (0.51 g, 45%), and V (0.08 g, 11%).

Photolysis of Ethyl Azidoformate in Cyclohexanone. Ethyl azidoformate (1.00 g, 8.7 mmol) in cyclohexanone (20 m*l*) was irradiated in a manner similar to that described above (*ca.* 40 hr). The subsequent removal of the excess cyclohexanone *in vacuo* afforded a yellow oil, which was separated by chromatography on an alumina column. Elution with benzene and ether gave bicyclohexyl-2,2'-dione (XI) (0.08 g, 5%); mp 70—71°C (*n*-hexane) (lit,[12] 70—71°C). IR (neat): 1705, 1220, 1125 cm^{-1}; NMR (CCl_4): δ 1.2—2.1 (m, 12H, methylene), 2.2—2.6 (m, 4H, methylene), 2.6—3.1 (m, 2H, methine); MS: *m/e* 194 (M^+, 17%), 98 (100). Further elution with ether afforded 2-ethoxycarbonylaminocyclohexanone (IX)[11] (0.14 g, 8%), IR (neat): 3330, 1710, 1510, 1257, 1052 cm^{-1}; NMR (CCl_4): δ 1.20 (t, 3H, $\underline{CH_3}CH_2$-), 1.5—2.8 (m, 8H, methylene), 4.02 (q, 2H, $CH_3\underline{CH_2}$-), 4.0—4.4 (m, 1H, methine), 5.73 (broad d, 1H, NH); MS: *m/e* 185 (M^+, 8%), 157 (8), 141 (10), 128 (51), 62 (34), 56 (49), 44 (100), and ethyl carbamate (V) (0.15 g, 22%).

Photolysis of Ethyl Azidoformate in Cyclohexanone-dichloromethane. A solution of ethyl azidoformate (0.50 g, 4.4 mmol) in cyclohexanone (10 m*l*) and dichloromethane (10 m*l*) was irradiated much as has been described above. Work-up and chromatography on alumina gave 2-(1-cyclohexenyl)cyclohexanone (XII) (0.18 g, 24%), IR (neat): 3050, 1717, 1120, 678 cm^{-1}; NMR (CCl_4): δ 0.7—3.0 (m, 17H, methylene and methine), 5.4—5.5 (m, 1H, olefinic); MS: *m/e* 178 (M^+, 57%), 149 (100), 81 (70), 79 (69), 67 (67). Subsequent elution with ether gave 2-ethoxycarbonylaminocyclohexanone (IX) (0.12 g, 15%), 3-ethoxycarbonylaminocyclohexanone (X) (0.06 g, 8%), IR (neat): 3370, 1700, 1535, 1268, 1244, 1217, 1046 cm^{-1}; NMR (CCl_4): δ 1.22 (t, 3H, $\underline{CH_3}CH_2$-), 1.6—2.9 (m, 8H, methylene), 3.5—4.2 (m, 1H, methine), 4.04 (q, 2H, $CH_2\underline{CH_3}$-), 5.8—5.9 (broad s, 1H, NH); MS: *m/e* 185 (M^+, 9%), 156 (57), 128 (79), 96 (84), 43 (100), and ethyl carbamate (V) (0.02 g, 7%).

Thermolysis of Ethyl Azidoformate in Cyclohexanone. A mixture of ethyl azidoformate (1.00 g, 8.7 mmol) and cyclohexanone (5 m*l*) was added, drop by drop, to refluxing cyclohexanone (*ca.* 1 hr) After an additional hour of refluxing, the excess cyclohexanone was removed *in vacuo*. The subsequent work-up of the residual mixture and chromatography on an alumina column afforded 2-ethoxy-4,5-tetramethylene oxazole (XIII) (0.25 g, 17%). IR (neat): 1712, 1597, 1450, 1387, 1315, 1210 cm^{-1}; NMR (CCl_4): δ 1.40 (t, 3H, $\underline{CH_3}CH_2$–), 1.5—2.1 (m, 4H, methylene), 2.1—2.7 (m, 4H, methylene), 4.36 (q, 2H, $CH_3\underline{CH_2}$–); MS: *m/e* 167 (M^+, 44%), 139 (97), 111 (100), 66 (85), 55 (60); UV: λ_{max} (EtOH) 265 nm (log ε 1.48), $<$220 nm (log $\varepsilon$$>$2.54).

Found: C, 64.5; H, 8.1; N, 8.2%. Calcd for $C_9H_{13}NO_2$: C, 64.7; H, 7.8; N, 8.4%.

The subsequent eluants were 2-ethoxycarbonylaminocyclohexanone (IX) (0.47 g, 29%), 3-ethoxycarbonylaminocyclohexanone (X) (0.18 g, 11%), bicyclohexyl-2,2'-dione (XI) (0.04 g, 2%), and ethyl carbamate (V) (0.04 g, 4%).

Thermolysis of Ethyl Azidoformate in Cyclohexanone-dichloromethane. A mixture of ethyl azidoformate (1.00 g, 8.7 mmol), cyclohexanone (20 m*l*), and dichloromethane (20 m*l*) was heated at 150°C in an autoclave for 3 hr. A subsequent work-up gave the oxazole XIII (0.18 g, 13%), XI (0.03 g, 2%), IX (0.29 g, 18%), X (0.11 g, 7%), and V (0.03 g, 4%).

Chemistry of Nitrosoimines. II.[1] Photolysis of 2-Nitrosoimino-2,3-dihydrothiazoles

Kin-ya AKIBA, Isaburo FUKAWA, Noboru NOMURA, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received November 30, 1971)

Irradiation of 3-substituted 2-nitrosoimino-2,3-dihydrobenzothiazoles (I) with a medium pressure mercury lamp gave bis[*o*-(*N*-substituted cyanamino)phenyl] disulfides (III) in high yields. Irradiation of 4,5-diphenyl-2-nitrosoimino-2,3-dihydrothiazole (VI) gave bis[(2-phenyl-2-*N*-phenylcyanamino)vinyl] disulfide (VIII).

The photolysis was shown to be due to the π-π^* excitation from the results of specific irradiation to π-π^* and n-π^* bands. The relative rates of photolysis of 2-nitrosoimino-3-phenyl-2,3-dihydrobenzothiazole (Ia) were measured in several solvents. The mechanism has been discussed in connection with that in alkyl nitrites and nitrosamines.

Simple *N*-nitrosoimines were not known until recently since they are unstable and decompose into the corresponding carbonyl compounds and nitrogen. In 1968, Thoman and Hunsberger prepared sterically hindered *N*-nitrosoketimines.[2] However, a few heterocyclic compounds carrying the nitrosoimino group stabilized by conjugation have been known to be stable at room temperature. They also decompose into the corresponding carbonyl compounds and nitrogen in refluxing toluene.[3]

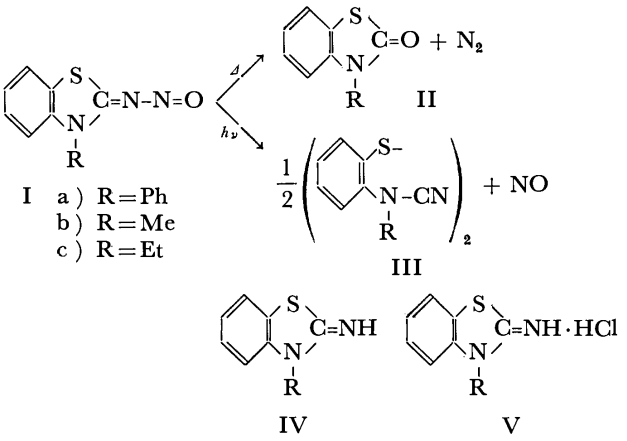
We wish to report that the photolysis of 2-nitrosoimino-2,3-dihydrothiazoles gives the corresponding disulfides through π-π^* excitation accompanied by the C-S bond cleavage and nitric oxide formation.

Results and Discussion

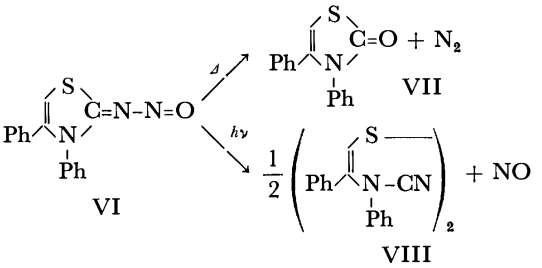
Reaction Products. 2-Nitrosoimino-3-phenyl-2,3-dihydrobenzothiazole (Ia) in benzene-dichloromethane was irradiated with a medium-pressure mercury lamp (100W) through a pyrex filter under nitrogen for 5 hr at about 10°C. Evolution of nitric oxide was observed during the irradiation. Bis[*o*-(*N*-phenylcyanamino)phenyl] disulfide (IIIa) was obtained in 74% yield.

In the cases of 3-methyl- (Ib) and 3-ethyl-2-nitrosoimino-2,3-dihydrobenzothiazoles (Ic), the photolyses proceeded considerably more slowly than that of Ia. In order to suppress further decomposition of the resulting disulfides (IIIb and IIIc), irradiation was discontinued after 13—15 hr, during which time 50—60% of the starting nitrosoimines was consumed. The products were IIIb (48%) and IIIc (45%) together with 2-imino-2,3-dihydrobenzothiazoles (IVb, 17%, IVc, 5%). Irradiation of Ib for a longer period (20—25 hr) gave IVb (15%) and the corresponding immonium chloride (Vb, 37%), the formation of which showed formation of hydrogen chloride due to the decomposition of dichloromethane.

Photolysis of nitrosoimines (I) gave no 3-substituted 2,3-dihydro-2-benzothiazolones (II), showing that the photochemical reaction differs completely from that of a thermal one.



3,4-Diphenyl-2-nitrosoimino-2,3-dihydrothiazole (VI) was also irradiated in acetonitrile for 30 min, 51% of VI being decomposed. Bis[(2-phenyl-2-*N*-phenylcyanamino)vinyl] disulfide (VIII) was obtained in 50% yield based on photolyzed VI. When it was irradiated for 50 min for completion, several compounds were detected by thin layer chromatography. Thiazolone (VII), the product in thermal decomposition of VI, was not produced at all during the photolysis.



Irradiation of nitrosoimine (Ia) in benzene-dichloromethane in the presence of cyclohexane (ten times of Ia in mol) gave the nitrate of 2-imino-3-phenyl-2,3-dihydrobenzothiazole in 20% yield, the structure of which was determined by elemental analysis and quantitative nitrosation to Ia with sodium nitrite and acetic acid. Formation of nitric acid may be due to the reaction of nitric oxide with hydrogen donor, cyclohexene, as shown in the following.

$$NO + C_6H_{10} \rightarrow HNO + C_6H_9\cdot$$

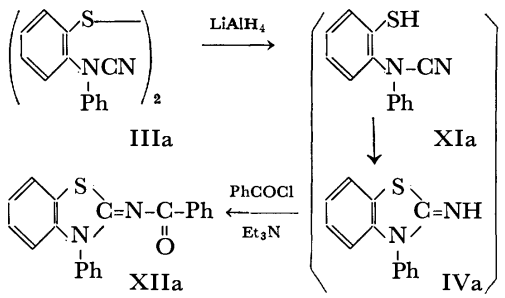
$$HNO + 2\,NO \rightarrow HNO_3 + N_2$$

The second reaction seems to be analogous to the formation of benzenediazonium nitrate from nitrosobenzene and nitric oxide.[4] Only black tar was obtained when oxygen was passed through the solution during the photolysis.

We propose a general scheme as given above.

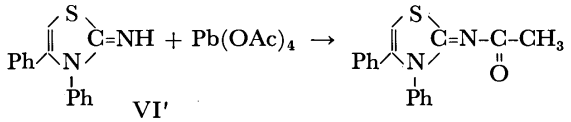
The presence of thiyl radical (X) is quite clear because of the formation of disulfide (III). Whether imino radical (IX) exists as a primary intermediate to give thiyl radical (X) or not cannot be determined in spite of isolation of imines (IV), because *o*-cyanaminothiophenol (XI) tends to cyclize to imine (IV) rapidly as shown below.

When IIIa was reduced with lithium aluminum hydride in tetrahydrofuran (THF) and benzoylated soon after with benzoyl chloride and triethylamine, 2-benzoylimino-3-phenyl-2,3-dihydrobenzothiazole (XII) was obtained in 68% yield. This shows that the intermediate thiophenol (XI) forms 2,3-dihydrothiazole ring (IVa) before it undergoes benzoylation.[5]

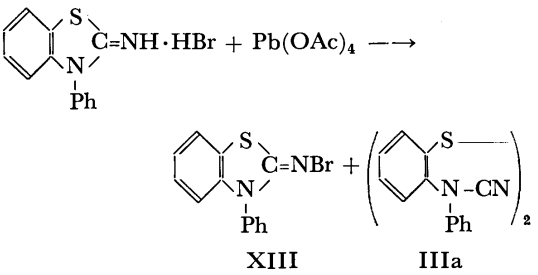


The results of oxidation of imines with lead tetraacetate are worth mentioning, although direct correlation between the oxidation and the proposed mechanism is not clear.

Oxidation of 3,4-diphenyl-2-imino-2,3-dihydrothiazole (VI') with lead tetraacetate in benzene gave 2-acetylimino-3,4-diphenyl-2,3-dihydrothiazole in 35% yield with some unidentified products. In the case of the hydrochloride of imine VI', the 2-acetylimino compound was obtained in 19% yield.



A similar oxidation of 2-imino-3-phenyl-2,3-dihydrobenzothiazole hydrobromide gave 2-*N*-bromoimino compound (XIII) and disulfide (IIIa) in 50% and 6.7% yields, respectively.



Kinetic Study. Ultraviolet and visible absorptions of 2-nitrosoimino-2,3-dihydrothiazoles (I and VI) are summarized in Table 1. Other absorptions of Ia in chloroform at 265 (ε 6.43×10^3), 273 (6.55×10^3) and 289 nm (4.21×10^3) are common to those of other compounds listed in Table 1 and attributed to excitation of the 2,3-dihydrothiazole ring.

Table 1. Ultraviolet and visible absorptions of 2-nitrosoimino-2,3-dihydrothiazoles

Compound	Solvent	λ_{max} (nm)	ε	λ_{max} (nm)	ε
Ia	$CHCl_3$	354	1.18×10^4	506	62.2
Ib	$CHCl_3$	350	1.45×10^4	496	68.2
Ic	$CHCl_3$	350	1.28×10^4	496	65.0
VI	CH_3CN	350	1.08×10^4	454	111.0

Visible absorptions (450—520 nm) of the nitrosoimines shift toward the shorter wavelength (blue shift) by changing solvents from non-polar to polar ones (see Table 3), and are assigned to the n-π^* transition of the nitrosoimino group. The most intense absorptions at about 350 nm, which are not affected by

4) E. Bamberger, *Ber.*, **30**, 506 (1897).

5) E. H. Rodd, "Chemistry of Carbon Compounds", Vol. IVa, Elsevier Publishing Co., Amsterdam (1957) p 425.

the polarity of the solvent (see Table 3), were assigned to the π-π^* transition of the nitrosoimino group, which is conjugated to the 2,3-dihydrothiazole ring. These assignments were supported by the fact that such absorptions were absent in the spectra of the corresponding 2-imino compounds. As an example, 2-imino-3-phenyl-2,3-dihydrobenzothiazole (IVa) showed the following absorption in chloroform: 281 (ε 5.3×10^3) and 288 nm (5.9×10^3).

2-Nitrosoimino-3-phenyl-2,3-dihydrobenzothiazole (Ia) was chosen as the substrate for most of the kinetic study, since its photolysis in various solvents produced disulfide (IIIa) in high yield (72—79%) and the π-π^* and n-π^* absorption bands were completely separate from one another.

Specific irradiation of the π-π^* and n-π^* bands of Ia was carried out in order to decide which excitation initiated the reaction (see Experimental). Irradiation of the π-π^* absorption region at 365 nm showed the same relative decomposition rates as those by a pyrex filter as shown in Table 2.

Table 2. Relative rates of photolysis of Ia with filters

Solvent	Filter		
	Pyrex	365 nm[a]	546 nm[b]
C_6H_6	2.3	2.3	—
CH_2Cl_2	1.0	1.0	—
CH_3CN	1.0	1.0	—

a) Aqueous solution of cobaltous sulfate and cupric sulfate.
b) Aqueous solution of calcium chloride and cupric chloride.

On the other hand, irradiation of the n-π^* absorption region at 546 nm for 5 hr did not initiate photoreaction at all, and led to complete recovery of the starting nitrosoimine (Ia), both in benzene and dichloromethane. Thus, the photoreaction of nitrosoimine (Ia) is completely due to the π-π^* excitation.

Quantum yield (0.38) was measured in acetonitrile by irradiation with 365 nm light.

The photolysis rates of I were then measured in various solvents with a pyrex filter. We chose the rate of Ia in acetonitrile (4.3×10^{-2} mmol/min) to be the standard value 1.0.

As shown in Fig. 1, plots of the nitrosoimine concentration against time showed a straight line. The linearity indicates that the amount of nitrosoimine (I) decomposed per unit time was constant. Because of intense π-π^* absorption, the solution of I absorbs 100% effective incident radiation at 365 nm.

As shown in Table 3, a greater decomposition rate of Ia was observed in aromatic solvents such as benzene, toluene and anisole, and the rates in non-aromatic solvents were almost constant in spite of the wide change of dielectric constants of the solvents. The decomposition rates of Ib and Ic were considerably less than that of Ia, and the rate of Ic was scarcely accelerated at all in benzene.

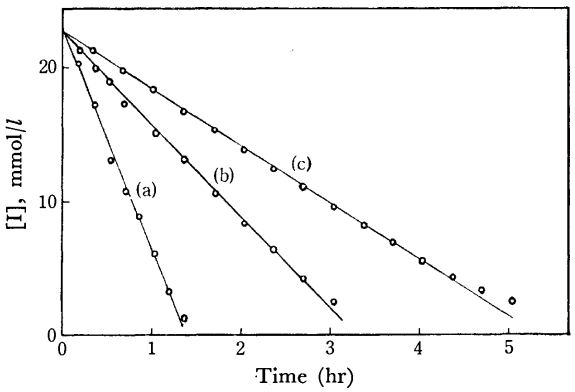


Fig. 1. Photolysis of the nitrosoimines (I).
(a) Ia in C_6H_6; (b) Ia in CH_3CN; (c) Ic in CH_3CN

Aromatic solvents might not act as a photosensitizer for Ia, because the rate in a mixture of benzene and acetonitrile is equal to that in acetonitrile. Benzene is completely transparent and not photochemically

Table 3. Relative photolysis rates and electronic spectra of 3-substituted 2-nitrosoimino-2,3-dihydrobenzothiazole(I) in various solvents (λ_{max} by nm)

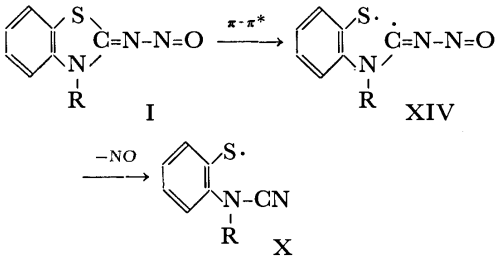
a) The present work. b) Unpublished result.

excited at all by irradiation with 365 nm.

Since an interaction of *N*-nitrosamines with the solvent benzene was observed by NMR,[6] the solvent effect on the decomposition rate of Ia might also be ascribed to an interaction of nitrosoimine with the aromatic solvents. However, this explanation is not consistent with the fact that the rate of Ic is scarcely accelerated at all in benzene. The reason for the specific acceleration of photolysis rate of Ia in aromatic solvents is not yet clear.

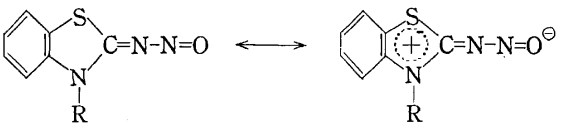
From the results, we propose that the photolysis of the nitrosoimines is due to π-π^* excitation, and some radical intermediate (X) is produced according to the ring opening followed by loss of nitric oxide from the resulting biradical (XIV).



General Discussion. Compounds containing the double-bonded nitrogen group, such as nitroso, azo, and imino compounds, have weak absorptions in the longer wavelengths due to the n-π^* excitation of the non-bonding nitrogen electrons, as shown in Table 4.

Thoman and Hunsberger reported that the absorption spectra of di(*p*-chlorophenyl)-nitrosoiminomethane showed two visible absorptions at 596 and 522 nm, probably due to the n-π^* excitations of nitrogens of the nitroso and imino parts of the nitrosoimino group, respectively.[2] On the other hand, heterocyclic nitrosoimino compounds show apparently only one n-π^* absorption at a shorter wavelength than di(*p*-chlorophenyl)-nitrosoiminomethane.

In the case of the heterocyclic nitrosoimino compounds such as I, the two lone pairs of N-atoms might be nearly equivalent with respect to their electronic energy and the two n-π^* bands might overlap each other. As a result, only one apparent n-π^* excitation was observed as with the azo compound, indicating that the resonance structure (I′) appears to be predominant.



A large contribution of I′ is supported by the fact that 2,3-dihydrothiazoles are one of the "π-electron excess aromatic compounds". The thermal stability of I is consistent with resonance stabilization. The nitrosoimino group of I shows the π-π^* absorption at a longer wavelength (*ca.* 350 nm) than that of di(*p*-chlorophenyl)-nitrosoiminomethane (*ca.* 306 nm), indicating a high degree of conjugation with the 2,3-dihydrothiazole ring. The fact that absorption bands of di(diphenylamino)-nitrosoiminomethane lie between those of the above two cases shows resonance contribution of nitrogens in the diphenylamino group.

Thus, the photoreaction of I is due to π-π^* excitation, but does not occur by the irradiation of n-π^* absorption. This result is in significant contrast to photoreactions of nitrites[8] or nitrosoalkanes[9] which lead to the cleavage of RO-NO bond or C-NO bond with high quantum yield even by the irradiation of their n-π^* bands to give alkoxyl or alkyl radical together with nitric oxide, respectively.

The different behavior of nitrosoimine is ascribable to the fact that its N-N bond has a strong double bond character with a larger bond energy than O-N and C-N bond of the nitrites and the nitrosoalkanes, respectively.

N-Nitrosamines are inert for photolysis in neutral

9) K. D. Anderson, C. J. Crumpler, and D. L. Hammick, *J. Chem. Soc.*, **1935**, 1679.

and in strong acidic media.[10] This is explained by a similar double bond character of the N-N bond both in the photoexcited state and in strong acidic media as shown below.

$$\begin{matrix}R\\R\end{matrix}\!\!>\!N\text{-}N\!=\!O \longleftrightarrow \begin{matrix}R\\R\end{matrix}\!\!>\!\overset{+}{N}\!=\!N\text{-}\overset{-}{O}$$

These considerations support the idea that the π-π^* irradiation of nitrosoimine induces a cleavage of the C-S bond of the 2,3-dihydrothiazole ring followed by that of N-N bond of the nitrosoimino group to give directly thiyl radical (X) and nitric oxide. However, there is no definite evidence at present to exclude the mechanism involving the photochemical cleavage of the N-N bond of the nitrosoimino group to give nitric oxide and the vibrationally excited imino radical (IX), which isomerizes into more stable thiyl radical (X).

Experimental

Materials. 2-Imino-3-phenyl-2,3-dihydrobenzothiazole (IVa) was prepared by the method of Passing,[3a] mp 73—74°C (lit, 74—75°C). 2-Nitrosoimino-3-phenyl-2,3-dihydrobenzothiazole (Ia) was prepared by nitrosation of IVa in acetic acid with a concentrated aqueous solution of sodium nitrite, and then reprecipitated twice from dichloromethane solution by adding petroleum ether, mp 138°C (decomp.) (lit,[3a] mp 141°C). 2-Imino-3-methyl- (IVb) and 3-ethyl-2-imino-2,3-dihydrobenzothiazole (IVc), 3-methyl-2-nitrosoimino- (Ib) and 3-ethyl-2-nitrosoimino-2,3-dihydrobenzothiazole (Ic) were prepared according to reported procedures.[3b,3c] IVb: mp 122—123°C (lit, 123°C), IVc: mp 86—87°C (lit, 86°C), Ib: 104—105°C (decomp.) (lit, 103—104°C), and Ic: mp 108—109°C (decomp.) (lit, 110°C).

3,4-Diphenyl-2-imino-2,3-dihydrothiazole hydrochloride and the corresponding free imine (mp 107°C, lit, 111°C) were prepared according to the method of Beyer and Ruling.[11] 3,4-Diphenyl-2-nitrosoimino-2,3-dihydrothiazole (VI) was prepared by nitrosation of hydrochloride in 42% yield, mp 152—153°C (decomp.).

Found: C, 63.74; H, 4.20; N, 14.67%. Calcd for $C_{15}H_{11}N_3SO$: C, 64.04; H, 3.93; N, 14.94%.

General Procedure of Photolysis. The nitrosoimines were irradiated through a pyrex filter with a 100W medium-pressure mercury lamp immersed in the reaction solution. The temperature of the solution was kept at *ca.* 10°C with a water-cooled jacket around a lamp and an external ice bath. Nitrogen was passed through the solution during irradiation.

Photolysis of 2-Nitrosoimino-3-phenyl-2,3-dihydrobenzothiazole (Ia). a) Nitrosoimine (Ia, 4.0 g, 15.7 mmol) in a mixture of benzene (50 m*l*)-dichloromethane (100 m*l*) was irradiated. Irradiation was stopped when the absorption at 350—360 nm region disappeared completely. The crystalline product obtained after evaporation of the solvent was recrystallized from ethanol to give bis[*o*-(*N*-phenylcyanamino)phenyl] disulfide (IIIa, 2.2 g, 5.8 mmol, 74%); mp 151.5—152.0°C and IR: 2200 cm^{-1} (C≡N).

Found: C, 69.15; H, 4.16; N, 12.64; S, 14.23%. mol wt (Rast), 410. Calcd for $C_{26}H_{18}N_4S_2$: C, 69.31; H, 4.03; N, 12.44; S, 14.23%; mol wt, 450.

b) Nitrosoimine (Ia, 4.0 g, 15.7 mmol) in a mixture of benzene (50 m*l*)-dichloromethane (100 m*l*) was irradiated in the presence of cyclohexene (157 mmol). Removal of volatile materials gave the immonium nitrate of 2-imino-3-phenyl-2,3-dihydrobenzothiazole (3.1 mmol, 20%), mp 198°C (decomp.), after washing with benzene.

Found: C, 53.77; H, 3.54; N, 14.89%. Calcd for $C_{13}H_{11}N_3SO_3$: C, 53.97; H, 3.83; N, 14.51%.

Nitrosation of the immonium nitrate with sodium nitrite and acetic acid gave Ia quantitatively. The benzene washings were evaporated and the brown residual oil was chromatographed on alumina. No crystalline product was obtained. The infrared spectrum of the oil showed a strong absorption at 2200 cm^{-1} (C≡N) indicating the presence of IIIa.

Reduction of Disulfide (IIIa) with $LiAlH_4$. A solution of lithium aluminum hydride (0.5 g, 33.3 mmol) in THF (50 m*l*) was added in small portions to the disulfide (IIIa, 1.5 g, 3.3 mmol) in THF (50 m*l*) cooled with an ice bath. After the addition had been completed, the reaction mixture was stirred for 1 hr. The remaining lithium aluminum hydride was decomposed by adding aqueous solution of sodium hydroxide (20%, 1 m*l*) and then water (15 m*l*). After filtration, the precipitates were extracted with dichloromethane (150 m*l*) and the combined solution was dried over anhydrous sodium sulfate. The concentrated solution (50 m*l*) was refluxed with triethylamine (1.5 g, 16.4 mmol) and benzoyl chloride (1.5 g, 10.7 mmol) for 1 hr, and 100 m*l* of dichloromethane was then added. After shaking several times with 1 N aqueous solution of sodium hydroxide (40 m*l*) to remove excess benzoyl chloride, the dichloromethane layer was washed with water and dried over anhydrous sodium sulfate. The pale yellow solid obtained after evaporation of the solvent was recrystallized from ethanol to give 2-benzoylimino-3-phenyl-2,3-dihydrobenzothiazole (XIIa, 1.5 g, 4.5 mmol, 68%), mp 205.5—206.5°C. IR: 1620 cm^{-1} (C=O).

Found: C, 72.72; H, 3.99; N, 8.50%. Calcd for $C_{20}H_{14}N_2SO$: C, 72.70; H, 4.28; N, 8.48%. XIIa was identified by comparison with the melting point and IR spectrum of an authentic sample, prepared by a similar benzoylation of 2-imino-3-phenyl-2,3-dihydrobenzothiazole (IVa).

Photolysis of 3-Methyl-2-nitrosoimino-2,3-dihydrobenzothiazole (Ib). Nitrosoimine (Ib, 6.0 g, 30.9 mmol) in a mixture of benzene (50 m*l*) and dichloromethane (100 m*l*) was irradiated for 17 hr, during which time 60% of Ib was consumed. After evaporation of the solvent, the residue was extracted with petroleum ether (200 m*l*). The extract was concentrated *in vacuo* at room temperature and the resulting precipitates were recrystallized from petroleum ether to give 2-imino-3-methyl-2,3-dihydrobezothiazole (IVb, 0.6 g, 3.1 mmol, 17%), mp 122—123°C. The remaining crystalline residue was refluxed in ethanol for 8 hr to decompose the remaining nitrosoimine (Ib) into 3-methyl-2,3-dihydro-2-benzothiazolone (IIb). After evaporation of the solvent, the residue was extracted repeatedly with petroleum ether to remove IIb. The remaining white solid was recrystallized from ethanol to give bis[*o*-(*N*-methylcyanamino)-phenyl] disulfide (IIIb, 1.4 g, 4.3 mmol, 48%), mp 140.0—141.0°C. IR: 2200 cm^{-1} (C≡N).

Found: C, 58.90; H, 4.34; N, 17.27; S, 19.52%; mol wt (Rast), 376. Calcd for $C_{16}H_{14}N_4S_2$: C, 58.87; H, 4.32; N, 17.17; S, 19.64%; mol wt, 326.

Photolysis of 3-Ethyl-2-nitrosoimino-2,3-dihydrobenzothiazole (Ic). Ic (6.0 g, 29.2 mmol) was irradiated in a mixture of benzene (50 m*l*) and dichloromethane (100 m*l*) for 13 hr, 60% of Ic being consumed. A treatment similar to that

11) H. Beyer and G. Ruling, *Chem. Ber.*, **89**, 107 (1956).

for Ib gave 3-ethyl-2-imino-2,3-dihydrobenzothiazole (IVc, 0.2 g, 0.9 mmol, 5%), mp 86—87°C, and bis[*o*-(*N*-ethylcyanamino)phenyl] disulfide (IIIc, 1.4 g, 4.0 mmol, 45%), mp 83.0—84.0°C, and IR: 2200 cm^{-1} (C≡N).

Found: C, 60.97; H, 5.17; N, 15.67; S, 17.83%; mol wt (Rast), 364. Calcd for $C_{18}H_{18}N_4S_2$: C, 60.81; H, 5.39; N, 15.76; S, 18.04%; mol wt 354.

Photolysis of 3,4-Diphenyl-2-nitrosoimino-2,3-dihydrothiazole (VI). A solution of nitrosoimine (VI, 1.165 g, 4.15 mmol) in acetonitrile (250 m*l*) was irradiated for 30 min, 51% of the starting material being photolyzed. Photolysis on the same scale was repeated four times. Solutions from two runs were combined and treated as follows.

The solvent (500 m*l*) was evaporated with a rotary evaporator to 50 m*l*. The resulting yellow precipitates (0.728 g, VI) were filtered and the filtrate was condensed to almost dryness. A mixture of petroleum ether (110 m*l*) and ethanol (10 m*l*) was added to the residue and the resulting precipitates (0.484 g, VI) were filtered. White crystalline product (0.643 g, almost pure VIII) and brown tar (0.6 g) were obtained from the filtrate by condesation. In order to purify the crystalline product, the main fractions of R_f 0.6—0.7 (with chloroform) were collected on silica gel thin layer chromatograms and extracted with methanol (30 m*l*). The extract was condensed to 10 m*l* to give bis[(2-phenyl-2-phenylcyanamino)vinyl] disulfide (VIII, 0.510 g), mp 141.0—142.0°C. IR: 2210 cm^{-1} (C≡N), UV: $\lambda_{max}^{CHCl_3}$ 280 nm (ε 3.47×10^4) and MS: 476 (5.5%, M^+-CN), 251 (62, 1/2 M^+), 180 (99, $PhC{\equiv}\overset{+}{N}Ph$), 134 (26, $PhCHCS^+$), 91 (10.5, PhN^+), 77 (100, Ph^+), and 26 (50, CN^+).

The parent peak (M^+, 502) could not be detected in spite of some change in the ionization voltage. The yield of VIII was 50% based on the photolyzed material.

Thermal Decomposition of 3,4-Diphenyl-2-nitrosoimino-2,3-dihydrothiazole (VI). Nitrosoimine (VI, 1.02 g, 3.63 mmol) was refluxed in xylene (50 m*l*) until the orange-red color of VI disappeared. Removal of the solvent gave 0.67 g (2.65 mmol, 73%) of the corresponding thiazolone (VII) as colorless crystals, mp 121.5—123°C. IR (nujol): 1640 cm^{-1} (C=O). Found: C, 71.00; H, 4.35; N, 5.28; S, 12.70%. Calcd for $C_{15}H_{11}NOS$: C, 71.12; H, 4.38; N, 5.53; S, 12.66%.

Oxidation of 3,4-Diphenyl-2-imino-2,3-dihydrothiazole (VI') with Lead Tetraacetate. To a benzene solution (40 m*l*) of the imine (VI', 4.0 g, 16.0 mmol), lead tetraacetate (5.5 g, 12.4 mmol) was added portionwise at 0°C with stirring which was continued overnight at room temperature. After filtration of yellow crystals (lead acetate, 3.5 g), the filtrate was condensed with a rotary evaporator. The condensate was chromatographed on silica gel to give 2-acetylimino-3,4-diphenyl-2,3-dihydrothiazole (1.66 g, 4.34 mmol), mp 200°C, in 35% yield, which was eluted with dichloromethane-ether (4 : 1). An authentic sample of 2-acetylimino compound (mp 200°C) was prepared according to the method of Beyer and Ruling.[11] There were some unidentified products.

The hydrochloride of imine (VI') was oxidized with lead tetraacetate in a similar way to that above. The 2-acetylimino compound was obtained in 19.0% yield with some unidentified products.

Oxidation of 2-Imino-3-phenyl-2,3-dihydrobenzothiazole Hydrobromide with Lead Tetraacetate. To a suspension of the imine hydrobromide (4.0 g, 13.0 mmol) in benzene (30 m*l*), lead tetraacetate (4.0 g, 18.2 mmol) was added portionwise at room temperature with stirring, which was continued overnight. Lead tetraacetate was consumed completely as confirmed by iodometry. After the yellow precipitates, lead acetate (3.64 g), were filtered, the filtrate was condensed and the condensate was chromatographed on silica gel. *N*-Bromoimino-3-phenyl-2,3-dihydrobenzothiazole (XIII, 2.0 g, 6.5 mmol, 50% yield) was eluted with benzene and the disulfide (IIIc, 0.20 g, 2.1 mmol, 6.7%) was eluted with benzene-dichloromethane. XIII: mp 139°C (decomp.), UV: $\lambda_{max}^{CH_3CN}$ 263 nm (ε 1.48×10^4) and MS: 306 (M^+), 304 (M^+) and 225 (M^+-Br, 100).

Found: C, 51.10; H, 2.78; N, 9.41; S, 10.13%. Calcd for $C_{13}H_9N_2SBr$: C, 51.16; H, 2.77; N, 9.18; S, 10.50%.

Kinetic Studies. The photolysis rates of the nitrosoimines (I, 7.8 mmol) were measured in several solvents (350 m*l*) with the same apparatus. The concentration of the remaining nitrosoimines (I) was measured by UV absorption at *ca.* 350 nm at appropriate intervals. Because of the poor solubility of I in alcohols, the mixed solvents of ethanol (250 m*l*)-dichloromethane (100 m*l*) were used. The electronic spectra of nitrosoimine (Ia) in alcohols were not affected by the addition of dichloromethane. 3.9 mmol of Ia was used in the case of toluene (350 m*l*).

The decomposition rate of Ia in acetonitrile (4.31×10^{-2} mmol/min) was chosen to be the standard relative rate 1.0. Two filter solutions were used for the specific irradiation of π-π^* and n-π^* absorption bands. They were cooled with an ice bath and circulated through a cooling jacket (path length 1 cm) around the lamp, instead of with water. An aqueous solution of cobaltous sulfate and cupric sulfate (a mixture of 490 g of $CoSO_4\cdot7H_2O$, 100 g of $CuSO_4\cdot5H_2O$ and 900 m*l* of H_2O)[12] was used as one filter solution for isolation of 365 nm radiation from a medium-pressure mercury lamp.

The decomposition rates of Ia in benzene solution with unfiltered light and filtered light (π-π^* irradiation) were 9.3×10^{-2} and 8.5×10^{-2} mmol/min, respectively. The reduced rate of the latter corresponds to the transmittance of the filter solution (Fig. 2).

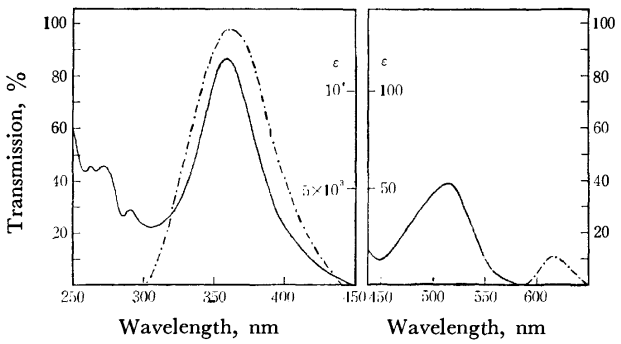

Fig. 2. Electronic spectrum of Ia in $CHCl_3$ (solid line) and transmission of the filter solution (dotted line; $CoSO_4$-$CuSO_4$)

An aqueous solution of cupric chloride and calcium chloride (100 g of $CuCl_2$, 300 g of $CaCl_2$ in 1 *l* of aqueous solution, slightly acidified with HCl) was used as the other filter solution for the isolation of the n-π^* absorption band at 546 nm. This filter solution transmitted 60% at 546 nm and 25% at 577 nm and no light was transmitted at either a wavelength shorter than 500 nm or one longer than 600 nm. No photodecomposition of Ia was observed with the use of this filter solution both in benzene and in dichloromethane. The transmission of both filters remained unchanged with time.

Quantum Yield Measurement. The isolation of 365 nm radiation from a medium-pressure mercury lamp (100 W) was accomplished by a combination of the filter solution

12) J. G. Calvert and J. N. Pitts, "Photochemistry," Chapter 7, John Wiley & Sons, Inc., New York (1967).

(120 g of $Cu(NO_3)_2$ in 100 m*l* of H_2O, path length 1 cm) and a Corning glass filter(No. CS-7-607). The transmission was 0% below 355 nm, 57% at 365 nm, and 0% above 400 nm. The light intensity was measured by potassium ferrioxalate actinometry[13] and was 2×10^7 Einstein l^{-1} sec^{-1}. The quantum yields of photolysis of Ia in acetonitrile were 0.384 and 0.372 by repeated determinations.

The Oxidation of (+)-3-Carene and the Related Compounds with *t*-Butyl Chromate[1,2]

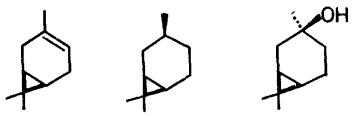
Takayuki SUGA, Tsuyoshi SHISHIBORI, and Tamon MATSUURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received October 11, 1971)

The oxidation of (+)-3-carene with *t*-butyl chromate was found to afford 3,α-dimethylstyrene (**2**), eucarvone (**3**), 1,1,4-trimethylcyclohepta-2,4-dien-6-one (**4**), 3-methylacetophenone (**5**), 8-hydroxy-*m*-cymene (**6**), car-3-en-2-one (**7**), (−)-car-3-en-5-one (**8**), and (−)-car-3-ene-2,5-dione (**9**). The aromatized compound (**6**) was a major product in the oxidation in an acidic medium, whereas the oxidation in the neutral and the basic media gave the enedione (**9**) and the enone (**8**) as major products. It was, furthermore, proved that methylenes adjacent to the cyclopropane ring of (−)-*cis*-carane (**10**) and (+)-caran-3β-ol (**11**) were scarcely attacked by *t*-butyl chromate.

Recently the oxidation of (+)-3-carene (**1**) with permanganate[3] or with chromium trioxide[4] has been reported. The *t*-butyl chromate oxidation of a compound with a cyclopropane ring has not yet been examined, although the endocyclic mono-[5] and di-unsaturated[6,7] compounds have been subjected to this oxidation. We have now examined the oxidation of (+)-3-carene (**1**), (−)-*cis*-carane (**10**), and (+)-caran-3β-ol (**11**) in order to establish further details of the oxidative behavior of *t*-butyl chromate in relation to compounds with both a cyclopropane ring



(**1**) (**10**) (**11**)

and an ethylenic bond. While we were preparing the manuscript of this report on our results, there appeared a brief paper[8] reporting the oxidation of **1** with *t*-butyl chromate. This prompted us to publish our paper involving the results of a more detailed examination of the reaction conditions which control the yield of products in the oxidation of (+)-3-carene (**1**) with *t*-butyl chromate.

Results and Discussion

(+)-3-Carene (**1**) was oxidized at 50°C for 48 hr under the reaction conditions shown in Table 1, with an equimolar or with three molar equivalents of the oxidant in various solvents, such as benzene, a mixture of benzene, glacial acetic acid and acetic anhydride, benzene admixed with pyridine. After the usual treatment[9] or the reaction mixture, the gas-liquid chromatographic analysis of a neutral product showed the presence of at least eight components, in a different ratio of the components in every oxidation. The neutral fraction was subjected to separation, purification, and identification as based on a combination of fractional distillation, column chromatography, analytical and preparative glc, spectroscopic analyses, comparisons of its physical data with those of known specimens, and the preparation of the crystalline derivatives. The procedure indicated neutral products to be composed of such compounds as 3,α-dimethylstyrene (**2**), eucarvone (**3**), 1,1,4-trimethylcyclohepta-2,4-dien-6-one (**4**), 3-methylacetophenone (**5**), 8-hydroxy-*m*-cymene (**6**), car-3-en-2-one (**7**), (−)-car-3-en-5-one (**8**), and (−)-car-3-ene-2,5-dione (**9**). The results are shown in Table 1. In addition to the formation of compounds **2**, **6**, **7**, **8**, and **9**, which have recently been reported by another group,[8] compounds **3**, **4**, and **5** were newly identified in this study.

8-Hydroxy-*m*-cymene (**6**) was the main reaction product in Experiments 1 and 2, in which the oxidation was carried out in an acidic medium. The yield

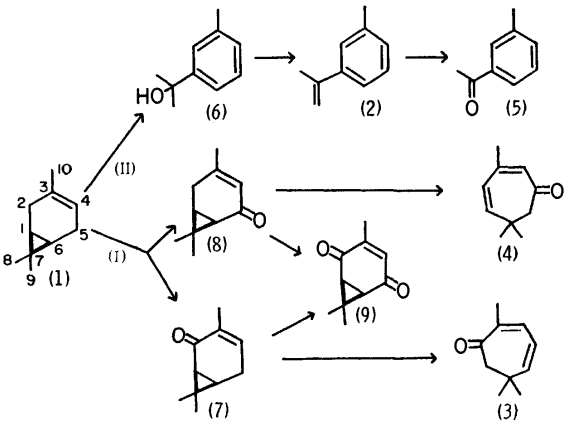
a) A denotes *t*-butyl chromate dissolved in benzene, B does the chromate dissolved in a mixture of benzene, glacial acetic acid and acetic anhydride, and C does the chromate dissolved in benzene containing pyridine.
b) The yield is based on the sample, (+)-3-carene, taken.
c) The yield of products is based on the peak area on the glc of the neutral product.
d) 'I/II' denotes the ratio of the sum of percentages of **3**, **4**, **7**, **8**, and **9** to the sum of these of **2**, **5**, and **6**.

of **6** is, however, reduced to nearly a half in Experiments 3 and 4, and to nearly a quarter in Experiments 5 and 6, which employed a mixture of benzene and pyridine as the solvent. The same incident as above was also observed for the formation of 3,α-dimethylstyrene (**2**). This seems to suggest the initial opening of the cyclopropane ring, followed by the formation of the aromatized compounds. The formation of increased amounts of car-3-en-5-one (**8**) was observed upon oxidation in a rather basic medium. This indicates that the oxidation in the basic status is favorable for the allylic oxidation at the C-5 position of 3-carene (**1**). The same tendency was observed in the formation of car-3-ene-2,5-dione (**9**). The oxidation using three molar equivalents of the oxidant in the presence of pyridine afforded a neutral product in the highest yield, which was almost entirely composed of the dione (**9**). The seven-membered ring compounds, (**3**) and (**4**), might have resulted from the isomerization of the bicyclic ketones, (**7**) and (**8**), as in the case of the oxidation of **1** with permanganate[3] or with chromium trioxide.[4] In all the experiments, **7** and **3** were produced in lower yields than **8** and **4** respectively.

The oxidation of (−)-*cis*-carane (**10**) and (+)-caran-3β-ol (**11**) was carried out with three molar equivalents of the oxidant containing glacial acetic acid and acetic anhydride respectively over a 48-hr period. However, scarcely no oxidation products were produced, rather the starting material was recovered almost unchanged. It has been shown that *t*-butyl chromate does not attack methylenes adjacent to only the cyclopropane ring.

The following conclusions may be drawn from the results. The oxidation of 3-carene with *t*-butyl chromate involves two pathways, (I) and (II). Route I is mainly concerned with the oxidation of an allylic methylene to a carbonyl group, while Route II involves the aromatization of carene, followed by the subsequent oxidation of the benzillic position. As is shown in Scheme 1, the unsaturated ketones, (**7**), (**8**), and (**9**), may be given from **1** through Route I. The aromatized compounds, (**6**), (**2**), and (**5**), seem to be formed through Route II, such as has been observed previously in the oxidation of α-terpinene.[6] The ratio (I/II) of the respective total sum of the yields of compounds produced by the two routes was larger



Scheme 1.

in a basic medium than in an acidic one (Table 1). By considering the results of the oxidation of *cis*-carane (**10**) and caran-3β-ol (**11**), as well as endocyclic monounsaturated compounds,[5] it seems that the double bond would contribute more than the cyclopropane ring to the formation of the α,β-unsaturated ketones, (**7**) and (**8**), and of the diketone, (**9**), by the preferential attack of the methylene situated between an ethylenic bond and a cyclopropane ring.

Experimental

Measurements. The melting points are uncorrected. The IR spectra were measured on a Hitachi, EPI-S, Infrared Spectrophotometer. The UV spectra were obtained on a JASCO, ORD/UV-5, Spectrophotometer. The NMR spectra were recorded on a Hitachi Perkin-Elmer, R-20, High-resolution Spectrometer at 60 MHz, using tetramethylsilane as the internal standard. Analytical glc was carried out on a Hitachi Perkin-Elmer, F6-D, Gas Chromatograph equipped with a flame-ionization detector at 160°, with a flow rate of nitrogen of 50 ml/min and using a 10% Carbowax column (3 mm × 2 m). Preparative glc was performed on a Shimadzu, GC-1A, Gas Chromatograph, using a 10% Carbowax column (10 mm × 2 m). The silica gel used was Kieselgel (Merck) (less than 0.08 mm).

Oxidation and Treatment of the Reaction Mixture.
Exp. 1: A *t*-butyl chromate solution was prepared from chromium trioxide (10.0 g, 0.1 mol), *t*-butyl alcohol (22.2 g, 0.3 mol), benzene (60 ml), acetic anhydride (10.2 g, 0.1 mol), and glacial acetic acid (6.0 g, 0.1 mol) in the same

manner as in the previous report.[5,9] The oxidant solution was added, drop by drop, to (+)-3-carene (**1**) (13.6 g, 0.1 mol) (bp 168.0—168.5°C, d_4^{25} 0.8601, $[\alpha]_D^{25}$ +13.9°, neat) over a period of 4 hr, with agitation at 50°C, and then the mixture was maintained at the same temperature for 44 hr while being stirred in an atmosphere of dry nitrogen. The treatment of the mixture in the same manner as in our previous reports[9,10] afforded a neutral oily product (3.5 g); the reaction products were then identified.

Exp. 2: A solution of three molar equivalents of the oxidant with the same concentration as in Exp. 1 was added to **1** (50 g) in the same manner as in Exp. 1. The subsequent treatment of the reaction mixture in the same manner as above gave a neutral product (35.5 g).

Exp. 3: A benzene solution, not containing acetic anhydride and glacial acetic acid, of the equimolar oxidant was added to **1** (13.6 g) in the same manner as in Exp. 1. A neutral oily product (11.5 g) was then obtained from the reaction mixture by the same treatment as above.

Exp. 4: The oxidation was carried out using a benzene solution of three molar equivalents of the oxidant and 8.0 g of **1** in the same manner as above. Thus, 2.83 g of a neutral product was obtained.

Exp. 5: A benzene solution of *t*-butyl chromate was prepared by adding chromium trioxide (2.21 g) to *t*-butyl alcohol (4.90 g), after which the solution was diluted with benzene (24 m*l*) as above. The solution, after having been dried over anhydrous sodium sulfate, was concentrated to 20 m*l*, and then pyridine (0.5 g) was added. To the oxidant solution, 3.0 g of **1** dissolved in 25 m*l* of benzene was added, drop by drop, over a 4-hr period at 50°C. The mixture was maintained at the same temperature for a further 44 hr with stirring. The subsequent treatment of the reaction mixture in a manner similar to that used in Exp. 1 gave 2.75 g of a neutral product.

Exp. 6: To an oxidant solution prepared in the same manner as in Exp. 5, 1.0 g of **1** dissolved in 25 m*l* of benzene was added. After 48 hr, the similar treatment of the reaction mixture gave a neutral product (0.87 g).

In each experiment, the glc of the neutral product showed the presence of at least eight components, **2** (retention time, 2.5 min), **3** (4.4), **4** (6.8), **5** (7.8), **6** (9.0), **7** (11.0), **8** (13.9), and **9** (16.9). The retention times of the peaks on the glc were the same in every experiment.

Identification of Reaction Products. The identification of the products is exemplified by Exp. 2, shown below. The distillation of a neutral product (25 g) gave 14.6 g of a distillate with a boiling point of 50—115°C/10 mmHg and 3.5 g of a residue which was almost entirely composed of yellow crystals (mp 100—102°C). The distillate was chromatographed on a silica-gel column with mixtures of *n*-hexane and increasing amounts of ethyl acetate; we thus separated it into eight eluates.

*3,α-Dimethylstyrene (**2**)*: This hydrocarbon was obtained as the first eluate of the column chromatography. Its IR spectrum was identical with that of 3,α-dimethylstyrene reported[11] and derived from 8-hydroxy-*m*-cymene (see below) by dehydration with phosphorous oxychloride. Ozonization of **2** afforded 3-methylacetophenone (the 2,4-dinitrophenylhydrazone, mp and mixed mp 207—208°C) and formaldehyde (the same phenylhydrazone derivative, mp and mixed mp 165—166°C).

*Eucarvone (**3**)*: The second eluate was identical in respects of the retention time on the glc and the IR spectrum with a specimen of eucarvone.[12] The 2,4-dinitrophenylhydrazone (mp 151—152°C) showed no depression of the melting point on admixed with the known specimen.

*1,1,4-Trimethylcyclohepta-2,4-dien-6-one (**4**)*: This compound was isolated as the third eluate. This eluate, after purified further by the preparative glc, gave a pale yellow oil: λ_{max}^{EtOH} 294 nm (log ε 3.31). The IR (1631 and 1575 cm^{-1}) and the NMR (1.10, 2.02, 2.51, 5.63, 5.91, and 6.03 ppm) spectra were identical with those of **4** reported.[3] The 2,4-dinitrophenylhydrazone melted at 176.5—177.5°C (lit,[3] mp 175—176°C).

*3-Methylacetophenone (**5**)*: The fourth eluate afforded an oil: ν_{max}^{liq} 1682 cm^{-1} (C=O); δ ($CDCl_3$) 2.36 (s, 3H, Ar–CH_3), 2.54 (s, 3H, $COCH_3$), and 7.0—7.8 ppm (m, 4H, Ar–H). The oil gave a 2,4-dinitrophenylhydrazone derivative (mp 207—208°C), which was identified as that[13] of 3-methylacetophenone by a mixed-melting-point determination.

*8-Hydroxy-*m*-cymene (**6**)*: The fifth eluate was the main component of the neutral part and gave an oil: mass *m/e* 150 (M^+); ν_{max}^{liq} 3381 (OH), 3027, 1618, and 1598 (benzene ring), 824, 789, and 710 cm^{-1} (1,3-disubst. benzene); δ ($CDCl_3$) 1.53 (s, 6H, $(CH_3)_2C$), 1.75 (s, 1H, OH exchanged with D_2O), 2.31 (s, 3H, Ar–CH_3), and *ca.* 7.1 ppm (m, 4H, Ar–H). These spectral data coincided with those[3,13] reported for **6**. The 3,5-dinitrobenzoate derivative showed a mp of 93—94°C (lit,[3] mp 93—94°C): (Found: C, 59.31; H, 4.59; N, 8.23%. Calcd for $C_{17}H_{16}N_2O_6$: C, 59.30; H, 4.68; N, 8.14%).

*Car-3-en-2-one (**7**)*: The sixth eluate showed a certainly different retention time from that of eucarvone upon glc. However, in the course of performing the preparative glc, the compound changed to eucarvone (**3**). It was, therefore, judged that the compound obtained from the sixth eluate was probably car-3-en-2-one (**7**).

*(−)-Car-3-en-5-one (**8**)*: The seventh eluate gave an oil showing $[\alpha]_D^{25}$ −265° (*c* 0.5, EtOH) and λ_{max}^{EtOH} 227 nm (log ε 3.55). Its IR and NMR spectral data were identical with those of car-3-en-5-one (**8**) previously reported.[3]

*(−)-Car-3-ene-2,5-dione (**9**)*: This was isolated, both from the residue in the distillation of the neutral product and from the last eluate in the column chromatography, as yellow crystals: mp 102—102.5°C, $[\alpha]_D^{25}$ −15.1° (*c* 0.3, EtOH); mass 164 (M^+); λ_{max}^{EtOH} 241 nm (log ε 4.11), 226 (sh. 4.03). The melting point and the IR and NMR spectra were identical with those reported for **9**.[3]

Found: C, 72.88; H, 7.56%. Calcd for $C_{10}H_{12}O_2$; C, 73.17; H, 7.32%.

*Oxidation of (−)-*cis*-Carane (**10**).* (−)-*cis*-Carane (bp 99—101°C/130 mmHg, n_D^{25} 1.4558, $[\alpha]_D^{25}$ −35.1° (*c* 1.1, *n*-hexane)) was prepared from (+)-3-carene (**1**) following the literature method.[14] The oxidation of **10** (1.0 g) was performed in the same manner as in Exp. 2. The molar ratio of **10** to the oxidant was 1 to 3. The same treatment of the reaction mixture as in Exp. 1 gave an oil (0.61 g). Glc and tlc analyses showed the presence of only a little oxygenated compound, but the sample was recovered.

*Oxidation of (+)-Caran-3β-ol (**11**).* (+)-3-Carene (**1**) was hydrated by the oxymercuration-demercuration.[15]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1876—1880 (1972)

Mass-spectral Fragmentation of 3-(5-Nitro-2-furyl)-1,2,4-triazoles[1]

Yasuhiko KATO and Ichiro HIRAO

Laboratory of Organic Synthesis, Department of Chemical Engineering, Kyushu Institute of Technology, Tobata-ku, Kita-Kyushu

(Received October 23, 1971)

The mass spectra of 3-(5-nitro-2-furyl)- (I), 5-methyl-3-(5-nitro-2-furyl)- (II), 5-ethyl-3-(5-nitro-2-furyl)- (III), and 5-trideuteriomethyl-3-(5-nitro-2-furyl)-1,2,4-triazole (IV) and their 1-acetyl, 1-trideuterioacetyl, and 1-propionyl derivatives were examined. The mother compounds, I–IV, gave the most prominent molecular ions and showed the same fragmentation pattern. The molecular ions undergo two modes of cleavages; one is the elimination of NO (1) and CO (2), followed by the loss of C_2H_2 (3), thus giving the M−84 ions which include the 5-substituents of the triazole ring, while the other is the loss of NO_2-CO, which directly gives rise to the fragment M−74 ions. The 1-acyl derivatives gave extremely weak molecular ion peaks. In the first step of the fission of the molecular ions, the elimination of an acyl group occurred, with the rearrangement of a hydrogen atom, thus giving rise to prominent ions. These ions correspond to the molecular ions of the mother compounds, I–IV, and are expected to show a similar fragmentation pathway. The fragmentation of these compounds was also considered to occur in view of the existence of meta-stable ion peaks. The meta-stable peaks appearing at the transition of the loss of NO are flat-topped, releasing kinetic energy of 0.78±0.04 eV.

The mass spectra of simple furans were investigated, and the fragmentation has been established,[2-5] but no systematic mass-spectral investigation concerning more complex nitrofuran derivatives has yet been reported.

3-(5-Nitro-2-furyl)- and 5-alkyl-3-(5-nitro-2-furyl)-1,2,4-triazoles and their 1-acyl derivatives are easily prepared by the reactions of 5-nitro-2-furimidoylhydrazine derivatives with acid anhydrides (or ethyl orthoformate).[6,7] We have prepared nine derivatives of of 3-(5-nitro-2-furyl)-1,2,4-triazole and its seven deuterium-labeled compounds by the reported methods[6,7] and have examined their mass spectra in order to describe the fragmentation schemes of the compounds.

Experimental

Mass-spectral Measurement. The mass spectra were obtained on a Hitachi mass spectrometer, Model RMU-6L, except for two compounds, Ia and Ic, for which a Japan Electron Optics Co., JEOL-OlSG mass spectrometer with a direct inlet was used. The operating conditions were as follows:

	RMU-6L	JEOL-01SG
Ionizing energy (eV)	70	70
Accelerating voltage (kV)	3.20	1.75
Total electron current (μA)	80	80
Temperature of ionization chamber (°C)	220	210
Temperature for vaporization (°C)	110—150	100
Vapor pressure (mmHg)	2.0×10^{-6}	5.0×10^{-7}

Samples. The samples employed in this experiment were prepared by the methods previously reported.[6,7] All the deuterium-labeled compounds except for the 1-deuterated compound (V) were also obtained in a similar manner, by the use of hexadeuterioacetic anhydride. V was obtained by refluxing II or by the hydrolysis of acetyl-II with D_2O for 2—3 hr, and then crystallized from D_2O. The compounds thus obtained were found by mass-spectrometric analysis to be 99% deuterated for Ib-IIIb, IV, IVa, and IVc, and 85% deuterated for V. The mps of the unpublished compounds are shown in Table 1.

Results and Discussion

3-(5-Nitro-2-furyl)-1,2,4-triazoles. The mass spectra of 3-(5-nitro-2-furyl)- (I), 5-methyl-3-(5-nitro-2-furyl)- (II), and 5-ethyl-3-(5-nitro-2-furyl)-1,2,4-triazole (III) are shown in Fig. 1 and Table 2. The compounds give the most prominent molecular ions (M^+) (the base peaks) with masses of 180, 194, and 208 respectively, as would be predicted from the presence of the stabilized heteroaromatic nucleus. The distinct fragment ions (M−30) of the masses at 150, 164, and 178 are formed by the elimination of NO from the molecular ions; this differs somewhat from nitrobenzene in that the M−46 (NO_2) fragment is weak, and is similar to the behavior of 5-nitro-2-bromofuran.[8] The M−30 ions may lose carbon monoxide[9] to give ion peaks (M−58) with masses of 122, 136, and 150 respectively. The subsequent loss of an acetylene molecule would lead to M−84 ion peaks (*m/e* I: 96, II: 110, and III: 124). There is a three-step process concerned with the fission of the furan ring in the molecular ions. The M−84 ions undergo two modes of cleavage of the triazole ring to give two distinct ions, RCN_2H^+ (*m/e* 42, 56, and 70) and $RCNH^+$ (*m/e* 28, 42, and 56) respectively.

The occurrence of another process of cleavage of the furan ring in the molecular ions is confirmed on the basis of the appearance of the meta-stable ion peaks. The molecular ions lose NO_2 and CO fragments by a one-step process to give M−74 ions at the masses of 106, 120, and 134 respectively. The M−74 ions show four modes of cleavage and give *m/e* 79 (common to all spectra), 65, 64, and M−103 (77, 91, and 105) ions by, respectively, the loss of RCN, $(R-H)CN_2H$, RCN_2H, and N_2H fragments. The common ion (79) gives two fragment ions at the masses of 51 and 50 from its two modes of cleavage, and the M−103 ions lose RCN to give the *m/e* 50 ion.

To define more precisely the mechanism and ions involved, the 5-trideuteriomethyl compound was synthesized and the hydrogen atom on the triazole nucleus on II was exchanged by equilibration with D_2O. In the mass spectra of 5-trideuteriomethyl-3-(5-nitro-2-furyl)-1,2,4-triazole (IV) and 5-methyl-3-

8) R. Grigg, M. V. Sargent, D. H. Williams, and J. A. Knight, *Tetrahedron*, **21**, 3441 (1965).

9) The possibility of the loss of N_2 in this pathway was eliminated because the mass spectra of 5-nitro-2-bromofuran (Ref. 8) and 5-nitro-2-furonitrile (measured under the same experimental conditions) showed a fragmentation step which corresponds to the loss of 28 amu. The mass-spectral fragmentation of 5-nitro-2-furonitrile may be shown as follows:

$$m/e\ 138\ (M^+) \xrightarrow{-30} m/e\ 108 \xrightarrow{-28} m/e\ 80 \xrightarrow{-26} m/e\ 54 \xrightarrow{-27} m/e\ 27$$

(m*: meta-stable ion observed)

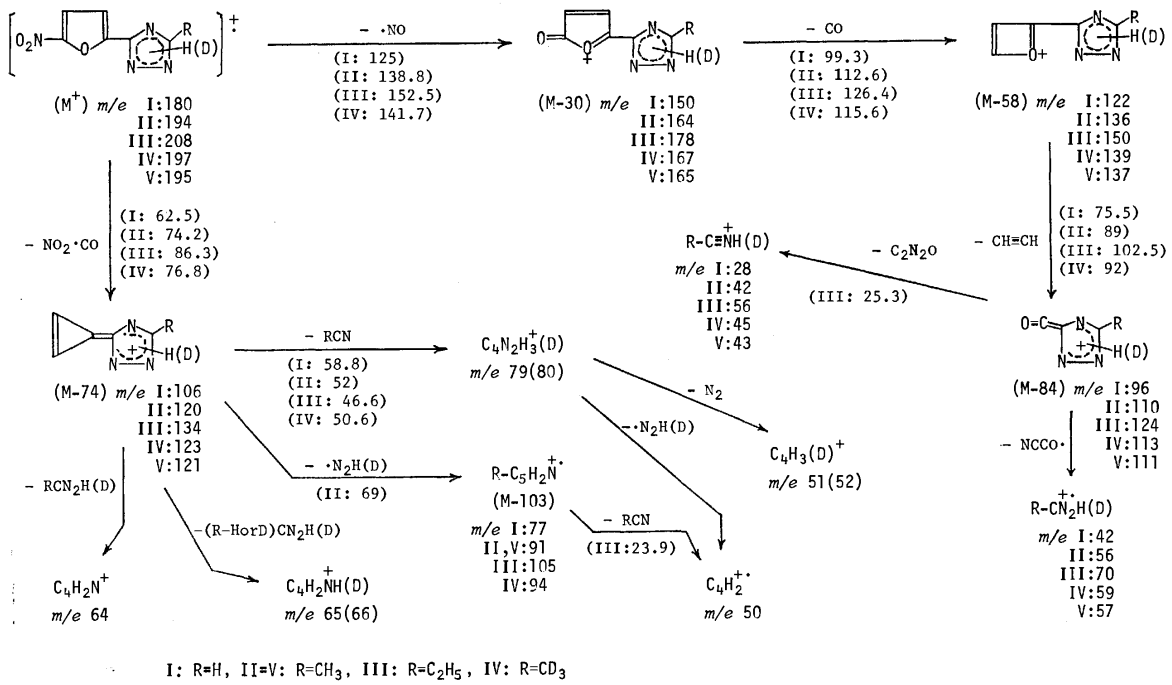

Scheme 1. Fragmentation of I, II, III, IV, and V.

(5-nitro-2-furyl)-1-deuterio-1,2,4-triazole (V) (Table 2), *m/e* 194, 164, 136, 110, 56, and 42 are shifted completely to *m/e* 197, 167, 139, 113, 59, and 45, and to *m/e* 195, 165, 137, 111, 57, and 43, respectively. Moreover, the two peaks at *m/e* 79 and 51 in the spectrum of II are shifted to, respectively, *m/e* 80 and 52 in that of V, while *m/e* 91 and 64 remain without being shifted. We may conclude, therefore, that the fragmentation pathways in the foregoing occur for I, II, III, and IV.

The major fragmentation, common to I–V, is postulated in Scheme 1. Some of the pathways of the fragmentation were confirmed by the presence of meta-stable ion pekas.

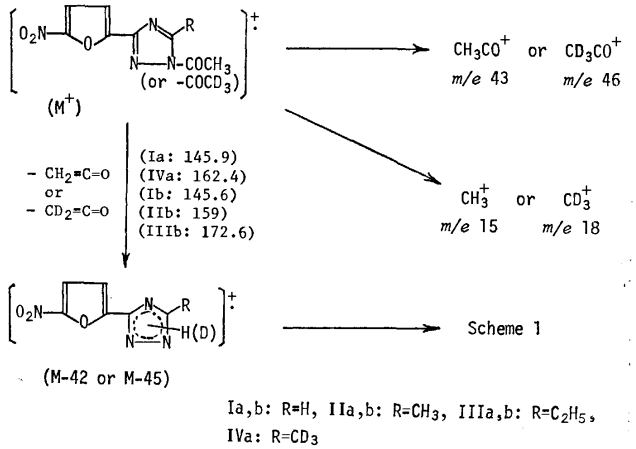
1,2,4-triazole (IVa) are summerized in Table 3 (Ia, in Fig. 1). The 1-acetyl compounds, Ia–IVa, give weak molecular-ion peaks (10—15% of the base peak). The elimination of an acetyl group from the molecular ion occurs in the following processes. One process, by the rearrangement of a hydrogen atom, produces base peaks at M—42, which are consistent with the masses of the molecular ion of I, II, III, or IV, by the loss of a ketene (CH_2=C=O). The other process, without any rearrangement, produces a strong peak with a mass of 43 due to $CH_3C{\equiv}O^+$ and a distinct peak of the CH_3^+ ion at mass 15. The M—42 ions of the masses at 180, 194, and 208 may undergo the same fragmentation as the corresponding mother compound (I, II, III, or IV), as has been described above. On the other hand, in the mass spectra of 1-trideuterioacetyl compounds, Ib–IIIb, the molecular ions are extremely weak (5—6% of the base peak). The



Scheme 2. Fragmentation of 1-acetyl (Ia-IVa) and 1-trideuterioacetyl (Ib-IIIb) compounds.

peaks corresponding to M—42 in Ia-IIIa are shifted completely to one atomic mass unit (amu); those corresponding to *m/e* 43 and 15 are consistent with a mass shift of 3 amu. This suggests that a similar mode of the cleavage of the trideuterioacetyl group also occurs, with or without the rearrangement of a deuterium atom, giving the prominent peaks (M—44) by the loss of CD_2=C=O, the base peak at mass 46 ($CD_3C{\equiv}O^+$), and a fragment ion peak with mass 18 (CD_3^+) by N^1-CO and α-bond cleavages (Scheme 2). It might, therefore, be expected that a mode of fragmentation similar to that of V would occur for the M—44 ions with the masses of 181, 195, and 209.

1-Propionyl Derivatives of I, II, III, and IV. The mass-spectral data of 1-propionyl- (Ic), 5-methyl-1-propionyl- (IIc), 5-ethyl-1-propionyl- (IIIc), and 5-trideuteriomethyl-1-propionyl-3-(5-nitro-2-furyl)-1,2,4-triazole (IVc) are shown in Table 4. The molecular ions here are also weak (10—15% of the base peak). In the first step of the fission of the molecular ions, as is shown in Scheme 3, there are four modes of the elimination of the propionyl group. With the rearrangement of one or two atoms of hydrogen, strong peaks (the base peak of IIIc) at M—56 result from the eliminations of (1) the CH_3CH=C=O (or CH_2=CHCHO) molecule and (2) the CH_2=CHC=O radical, successively a hydrogen atom. On the other hand, cleavage occurs without any rearrangment, giving (3) the base peaks (except for IIIc) at the mass 57 ($C_2H_5C{\equiv}O^+$) and (4) a prominent ion ($C_2H_5^+$) at mass 29, which also might come somewhat from the cleavage of the ion *m/e* 57. The M—56 ions correspond to the molecular ions of I—IV and may be expected to show the same fragmentation as that of the corresponding compounds, as is indicated in Shceme 1.

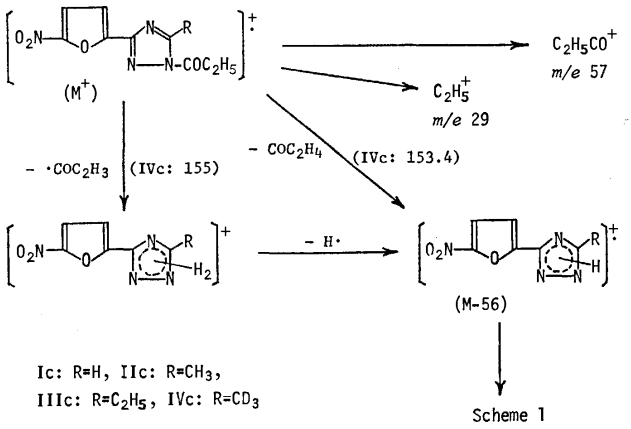
The molecular ions in the spectra of I–IV and the ions of $[M-(R'CO-H \text{ or } D)]^+$ in the spectra of the acyl compounds decompose to yield meta-stable ion peaks corresponding to the following transitions:

$$M^+ \rightarrow (M\text{-}30)^+ + NO$$



Scheme 3. Fragmentation of 1-propionyl compounds (Ic-IVc).

$$[M-(R'CO-H \text{ or } D)]^+ \rightarrow [M-(R'CO-H \text{ or } D)-30]^+ + NO$$

The meta-stable peaks in these transitions are flat-topped, indicating a formation with a release of kinetic energy.[10] As is shown in Table 5, the energy values found for these compounds correspond approximately to that of *o*-nitrophenol[10a] and are 2.5 times that of 5-nitro-2-furonitrile.

The authors wish to thank Massrs. Y. Takigawa, K. Umeno, and Y. Ohotani, staff members of the Research and Development Department of Mitsubishi Industrial Co., Ltd., for the mass spectral measurements and useful discussions. Thanks are due to the Ministry of Education for its financial aid.

The 1-Methylene Derivatives of [7](2,6)Pyridinophane. Preparative and Conformational Studies

Shinsaku FUJITA, Kazuo IMAMURA, and Hitosi NOZAKI

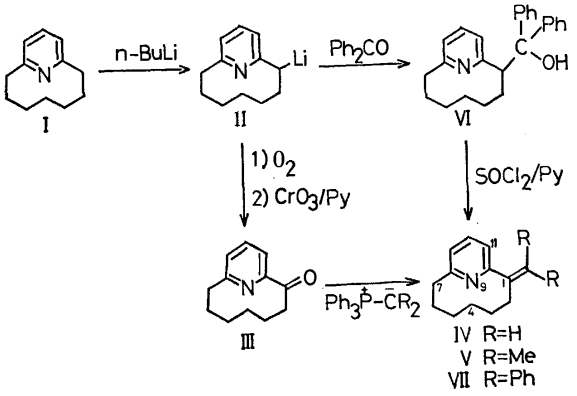
Department of Industrial Chemistry, Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received December 1, 1971)

The 1-*exo*-methylene derivatives (IV, V and VII) of [7](2,6)pyridinophane (I) are synthesized by Wittig's reaction of [7](2,6)pyridinophan-1-one (III) or by the dehydration of the corresponding carbinol (VI). The C-4 protons are all shielded magnetically to varying extents, depending on their respective 1-substituents. The shielding effect is ascribed to the anisotropy of the pyridine ring. The signals of the C-4 protons are temperature-dependent, and the energy barriers for the conformational changes are estimated to be 8.7 for III, 9.1 for IV, 9.1 for V and 9.8 kcal/mol for VII.

Dynamic NMR spectrometry has revealed the conformational details of [7](2,6)pyridinophane (I), particularly the flipping of the heptamethylene chain.[1,2] The present report will describe the synthesis of several 1-π derivatives (IV, V, and VII) of I and the conformational changes induced by the incorporation of a trigonal (sp^2) carbon on C-1.

The Synthesis of 1-Methylene[7](2,6)pyridinophanes. The treatment of [7](2,6)pyridinophane (I) with *n*-butyllithium gave an orange-red solution of 1-lithio-[7](2,6)pyridinophane (II), which afforded [7](2,6)-pyridinophan-1-one (III) upon quenching with oxygen and subsequent Cornforth oxidation.[1] The reaction of III with methylenetriphenylphosphorane yielded 1-methylene[7](2,6)pyridinophane (IV), which exhibited IR bands characteristic of an *exo*-methylene double bond at 1633 and 894 cm^{-1}. A similar Wittig reaction of III with isopropylidenetriphenylphosphorane gave 1-isopropylidene[7](2,6)pyridinophane (V). The IR absorptions characteristic of an isopropylidene group appeared at 1642, 1373, and 1365 cm^{-1}. The reaction of the 1-lithio derivative (II) with benzophenone afforded 1-(α-hydroxybenzhydryl)[7](2,6)pyridinophane (VI). 1-Diphenylmethylene[7](2,6)pyridinophane (VII) was obtained by the dehydration of VI with thionyl chloride in pyridine. All the new compounds gave elemental analyses and spectral data consistent with the assigned structures.



Dynamic NMR Spectrometry and Conformational Changes of 1-Oxo- and 1-exo-Methylene[7](2,6)pyridinophanes. The NMR spectra of IV, V, and VII at room temperature are shown in Fig. 1. The C-4 protons are magnetically shielded to various extents, depending on their 1-substituents (Table 1).[3] The chemical shift of the C-4 protons of IV (δ 0.92 ppm) is comparable to the value of 1-ketone III (δ 1.07 ppm),[1] and the stereochemical requirements of the oxo and methylene groups are similar to each other. The conjugation of the pyridine ring of IV with the 1-*exo*-methylene group should favor such an extreme conformer as VIII, in which one of the C-4 protons, H_x, is above, but slightly out of the center of the pyridine ring as

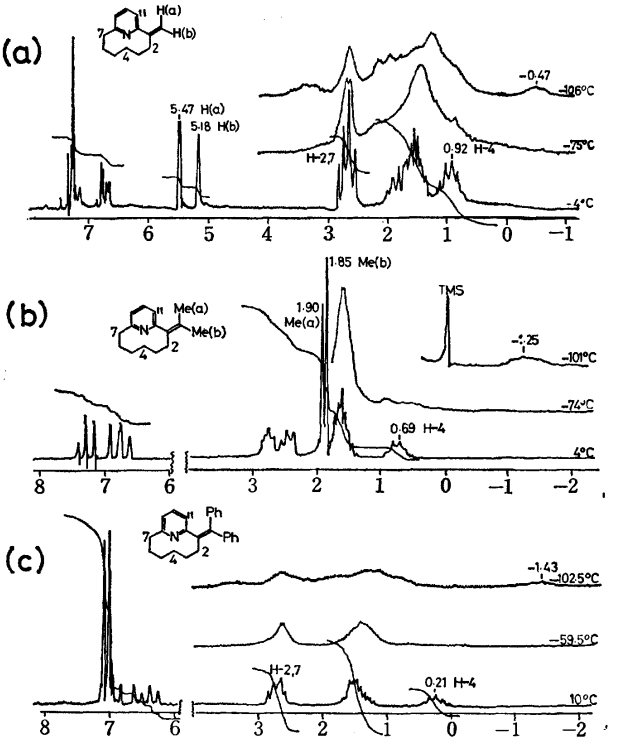


Fig. 1. Dynamic NMR spectra of IV (a), V (b) and VII (c); 60 MHz in $CFCl_3$, TMS as an internal standard.

d) Reported in Ref. 1.

compared with the corresponding proton of I.[4)] However, the C-4 protons of VII are more shielded than those of III and IV, and the chemical shift (δ 0.21 ppm) is comparable to that (δ 0.22 ppm) of unsubstituted [7](2,6)pyridinophane (I) itself. In the case of VII, steric hindrance arising from the H-11 of the pyridine ring and the phenyl group should influence the coplanarity of the pyridine and the *exo*-methylene group and consequently, the conformation of the heptamethylene bridge. The chemical shift (δ 0.69 ppm) of V is intermediate between those of IV and VII.

The NMR signals of the heptamethylene chain of IV are temperature-dependent as is illustrated in Fig. 1a. At room temperature, the heptamethylene bridge flips up and down (VIII⇄VIII') and its protons show an average chemical shift. At low temperatures, one of the C-4 protons (δ −0.47 at −106°C) of IV is more shielded than at room temperature. This fact indicates the fixation of the heptamethylene bridge to an extreme conformation such as VIII. The bridges of the other 1-π derivatives exhibited similar dynamic NMR spectra (Figs. 1b and 1c).

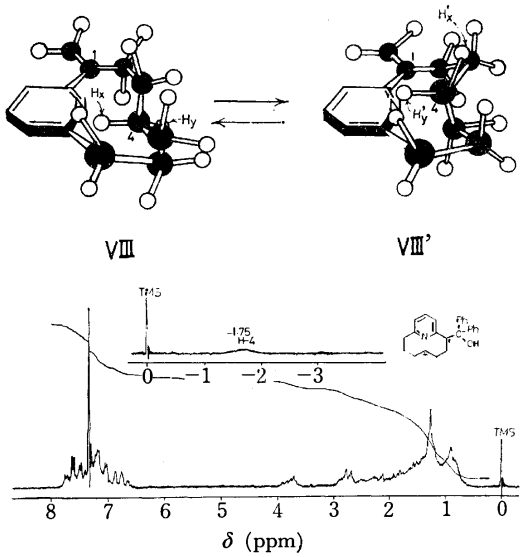

Fig. 2. The NMR spectrum of VI (24°C, 60 MHz in $CDCl_3$).

The estimated energy barriers for the conformational changes of 1-π-[7](2,6)pyridinophanes are shown in Table 1 as well as that of the mother compound (I). The introduction of π-bonds on C-1 reduces the energy barriers for the flipping of the heptamethylene chains, as is exemplified in III. In the *exo*-methylene derivatives, the steric crowding between H-11 and the 1-substituents compensates the above-mentioned reduction by the incorporation of π-bonds on C-1. Thus, the coalescence temperature (T_c) and the $\Delta G^{\neq}_c$ values of IV and V are comparable to those of the unsubstituted pyridinophane (I) itself. Moreover, those of VII are much higher and indicate that the steric hindrance becomes dominant. In conclusion, the chemical shifts of the C-4 protons, the coalescence temperature, and the $\Delta G^{\neq}_c$ values may be regarded as adequate measures of the relative steric bulkiness of 1-substituents.

The NMR spectrum of the carbinol VI (Fig. 2) is an extreme case as compared with those of other 1-monosubstituted [7](2,6)pyridinophanes.[1)] The one proton on C-4 is highly shielded (δ −1.75 ppm in $CDCl_3$) even at room temperature. In contrast, the two C-4 protons of [7](2,6)pyridinophan-1-ol have been reported to show an average signal at δ −0.08 ppm ($CDCl_3$) at room temperature.[1)] Probably, the bulky 1-substituent ($Ph_2(HO)C$-) prevents the flipping of the heptamethylene chain of VI.

Experimental

The dynamic NMR spectra were determined on a JEOL C-60-H spectrometer at 60 MHz, using fluorotrichloromethane ($CFCl_3$) as the solvent and tetramethylsilane (TMS) as the internal standard unless otherwise stated. The mass spectra were obtained on a Hitachi RMU-6L spectrometer.

1-Methylene[7](2,6)pyridinophane (IV). A solution (1.0 N, 4.0 *ml*) of *n*-butyllithium in *n*-hexane was added at room temperature under a nitrogen atmosphere to a suspension of triphenylmethylphosphonium bromide[6)] (1.29 g,

4) The anisotropy of the pyridine rings should be dependent upon the electron densities of the respective pyridine rings conjugated by π bonds.

3.6 mmol) in tetrahydrofuran (15 ml). After stirring under nitrogen for 2 hr, the resulting red solution was added to a solution of III[1] (0.57 g, 3.0 mmol) in tetrahydrofuran (25 ml), after which stirring was continued for 24 hr. The reaction mixture was then poured into water and extracted with ether (200 ml). The combined extracts were dried over sodium sulfate and concentrated *in vacuo*. The oily residue was separated by preparative-scale thin layer chromatography (TLC) on silica gel, using *n*-hexane-benzene (1 : 3) as the solvent. The crude product was distilled to give IV (0.15 g, 26%); bp 70°C (bath temperature)/2 mmHg. IR (neat): 3055, 2924, 2840, 1633, 1580, 1461, 894, 838, 821, 799, 745, and 725 cm^{-1}. MS *m/e* (relative abundance): 187 (88), 186 (43), 172 (78), 159 (100), 158 (79), 146 (21), 144 (35), 133 (65), 130 (22), 117 (23), 77 (22), 65 (22), 39 (29). UV $\lambda_{max}^{n\text{-hexane}}$ (log ε): 246 nm (3.94), 277 nm (3.74). The NMR spectrum is shown in Fig. 1a.

Found: C, 83.6; H, 9.4; N, 7.4%. Calcd for $C_{13}H_{17}N$: C, 83.4; H, 9.2; N, 7.5%.

1-Isopropylidene[7](2,6)pyridinophane (V). A red solution of phosphorane, prepared from triphenylisopropylphosphonium bromide[7] (1.39 g, 3.6 mmol) and *n*-butyllithim (1.0 N, 4.5 ml), was added to a solution of III (0.57 g, 3.0 mmol) in tetrahydrofuran (25 ml). After stirring for 24 hr under nitrogen, the white precipitates were filtered off and the filtrate was concentrated. The residual oil was separated by preparative TLC (silica gel, *n*-hexane-benzene (1 : 3)) and distilled to give V (0.21 g, 33%); bp 117—118°C/0.5 mmHg. IR (neat): 3055, 2924, 2840, 1642, 1579, 1455, 1373, 1365, 1190, 1160, 853, 826, 801, 787, 753, and 731 cm^{-1}. MS *m/e* (relative abundance): 215 (100), 214 (63), 200 (62), 187 (85), 186 (88), 174 (20), 172 (48), 161 (34), 158 (27), 144 (30), 131 (24), 130 (21), UV $\lambda_{max}^{n\text{ hexane}}$ (log ε): 250.5 nm (3.92), 274 nm (3.80). The NMR spectrum is shown in Fig. 1b.

Found: C, 83.8; H, 9.9; N, 6.4%. Calcd for $C_{15}H_{21}N$: C, 83.7; H, 9.8; N, 6.5%.

1-(α-Hydroxybenzhydryl)[7](2,6)pyridinophane (VI). A solution (0.90 N, 4.4 ml) of *n*-butyllithium in *n*-hexane was added to solution of I[1] (0.70 g, 4.0 mmol) in tetrahydrofuran (75 ml) at room temperature. After stirring under a nitrogen atmosphere for 30 min, a solution of benzophenone (0.73 g, 4.0 mmol) in tetrahydrofuran (25 ml) was added to the resulting orange-red solution of II. The reaction mixture was stirred for 2 hr and then treated with aqueous ammonium chloride (100 ml), extracted with ether, and dried over sodium sulfate. Concentration and recrystallization gave VI (1.42 g, quantitative); mp 162—163°C (benzene). IR (KBr disk): 3300, 3050, 2960, 2940, 2885, 2810, 1593, 1570, 1495, 1463, 1450, 1412, 1350, 1279, 1174, 1049, 1031, 999, 960, 943, 930, 908, 889, 864, 853, 845, 810, 784, 775, 765, 757, 746, 728, 700, 689, 671, 640, 601 cm^{-1}. The NMR may be found in Fig. 2.

Found: C, 83.9; H, 7.5; N, 4.0%. Calcd for $C_{25}H_{27}NO$: C, 84.0; H, 7.6; N, 3.9%.

1-Diphenylmethylene[7](2,6)pyridinophane (VII). Thionyl chloride (1.0 ml) was added in one portion under nitrogen to a solution of VI (0.17 g, 0.5 mmol) in pyridine (10 ml), and then the solution was heated at 50°C for 5 hr. The reaction mixture was subsequently poured onto ice, extracted with ether, and dried over sodium sulfate. After the removal of the ether, the residual solid was recrystallized from *n*-hexane to afford VI as white crystals (0.14 g, 85%); mp 116—118°C. IR (KBr disk); 3075, 3050, 3015, 2960, 2950, 2910, 2840, 1597, 1582, 1567, 1494, 1454, 1444, 1203, 870, 838, 815, 794, 769, 760, 754, 736, 827, 714, 702, 674, 630, and 602 cm^{-1}. MS *m/e* (relative abundance): 339 (100), 338 (98), 311 (47), 310 (76), 182 (37), 105 (100), 77 (76), 57 (20), 51 (35). UV $\lambda_{max}^{n\text{-hexane}}$ (log ε): 236 nm (4.21), 309.5 nm (4.16). The NMR spectrum is shown in Fig. 1c.

Found: C, 88.3; H, 7.4; N, 4.3%. Calcd for $C_{25}H_{25}N$: C, 88.5; H, 7.4; N, 4.1%.

Synthetic Reactions by Complex Catalysts. XXVI.[1] The Copper-catalyzed Reaction of α,β-Unsaturated Isocyanide with Active Methylene Compounds

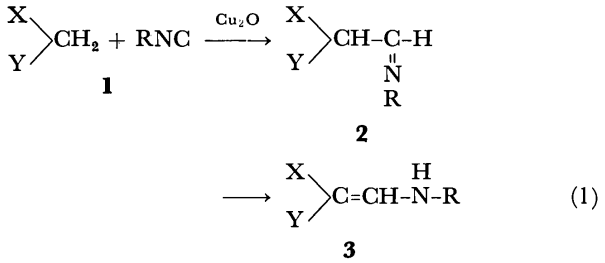
Takeo SAEGUSA, Ichiki MURASE, and Yoshihiko ITO

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received December 13, 1971)

The Cu_2O-catalyzed reaction of α,β-unsaturated isonitrile with active methylene compound is described. Vinyl isocyanide (VIC) and propenyl isocyanide (PPIC) were employed as the isocyanide components. In addition, allyl isocyanide (AIC), which has been known to be rearranged readily to PPIC by Cu_2O, was also used as a precursor of PPIC. Five types of products were isolated and identified. These products were explained by a scheme starting with an intermediate of the organocopper-isonitrile complex (**9**) derived from the active methylene compound.

In a previous communication,[2] we have described a new formimidation of active methylene compounds with isonitrile in the presence of a *catalytic amount* of Cu_2O. In the formimidation, isonitrile is inserted between the C–H bond of active methylene compounds (**1**), thus leading to the transient species (**2**), which then rearranges readily to the tautomeric isomer (**3**) (Eq. (1)).



(1)

The formimidation was possible only with aryl and α,β-alkenyl isocyanides. Saturated alkyl isocyanide did not react with active methylene compounds under the conditions of our study.

When the amount of Cu_2O catalyst was increased in the reaction of alkenyl isocyanide with the active methylene compound, some other reactions occurred and the selectivity of the formimidation was lowered. The present paper will describe this reaction as a whole. As the α,β-unsaturated alkenyl isocyanides, vinyl isocyanide (VIP), and propenyl isocyanide (PPIC) were employed. In addition, allyl isocyanide (AIC) was used as a convenient precursor of PPIC, because it was known to be rearranged very readily to PPIC by the Cu_2O catalyst.[3]

$$CH_2{=}CHCH_2NC \rightarrow CH_3{-}CH{=}CHNC \qquad (2)$$

The types of products are **3**, **5**, **6** (or **7**), and **8**. The relative amounts of these products are dependent upon the nature of the active methylene compound.

Results and Discussion

In the reactions of alkenyl isocyanides (VIC, PPIC and AIC) with diethyl malonate in the presence of increasing amounts of the Cu_2O catalyst, cyclopropane derivatives of **5a** and **5b** were obtained in significant yields. Both PPIC and AIC gave the same product of **5b**. This fact can be well explained by the rapid isomerization of AIC to PPIC by Cu_2O (Eq. (2),) which takes place prior to the reaction with diethyl malonate. The amounts of olefinic products, **7a** and **6b**, were small. Presumbaly, **7a** was formed by the double-bond isomerization of **6a**.[4] Under the present reaction conditions, saturated alkyl isocyanide does not react with the active methylene compound.[1] The reactions of VIC with some other active methylene compounds (*i.e.*, methyl acetoacetate, ethyl acetoacetate and acetylacetone) were also examined. The results are shown in Table 1.

The relative ratios of **5** to the combined yield of the four products decrease as the acid strength of the active methylene compound is increased; *i.e.*, $CH_3COCH_2COCH_3$ — $CH_3COCH_2CO_2C_2H_5$ — $C_2H_5O_2C$-

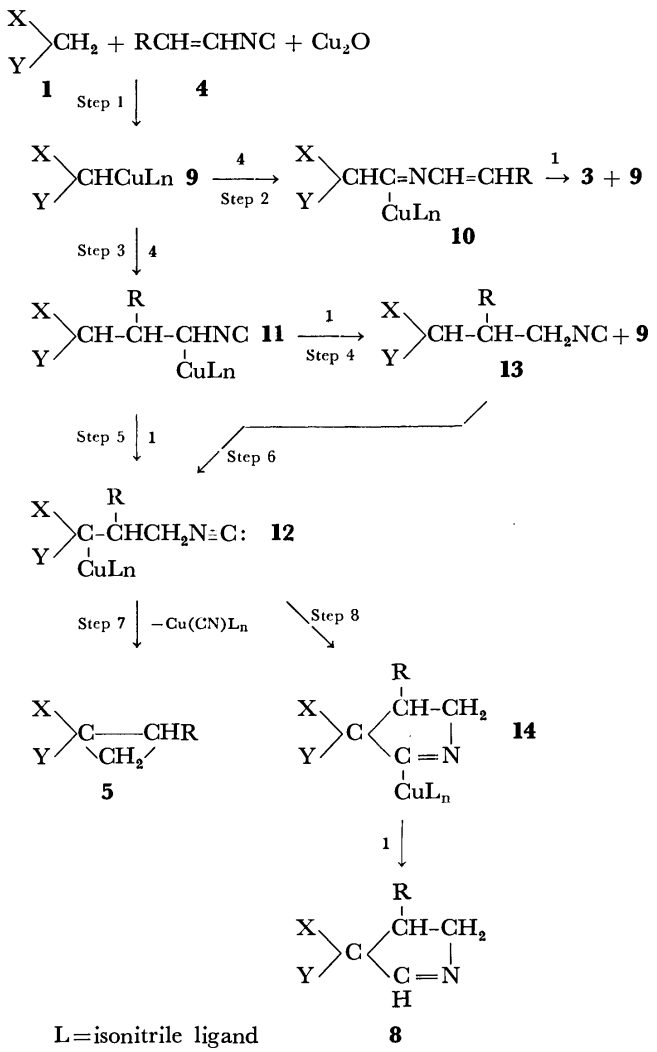
a) An equimolecular mixture of active methylene compounds and isonitrile was employed. VIC=vinyl isocyanide, AIC=allyl isocyanide, PPIC=propenyl isocyanide
b) The yield was based upon the amount of the product isolated by distillation.
c) The reaction was carried out in *N,N*-dimethylformamide.
d) The type of product was **7a**.

$CH_2CO_2C_2H_5$. Probably, active methylene compounds with more acidic hydrogen undergo formimidation more readily.

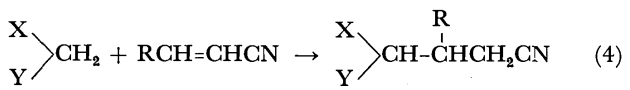
These products may be explained by the following reaction scheme.



L=isonitrile ligand

The first step is the formation of an organocopper complex (**9**)[5], which possibly has the ligand of isonitrile (Step 1). The hydrogen abstraction from the active methylene compound (**1**) by Cu_2O-isonitrile has been proposed and well supported in the Michael-type addition reaction induced by the Cu_2O-isonitrile system.[5,6] The α,α-addition of organocopper of **9** to the terminal carbon atom of the isonitrile group gives **10**, which then abstracts a hydrogen atom from another molecule of **1** to produce the formimidation product, **3**, and the key intermediate of organocopper (**9**)[2] (Step 2).

The α,β-addition of organocopper of **9** to the olefinic double bond of alkenyl isocyanide affords **11** (Step 3), and the subsequent step of the hydrogen abstraction by **11** (Step 5) gives rise to the adduct, **13**, and the intermediate, **9**. The combination of Steps 3 and 4 corresponds to the addition of the active methylene compound to α,β-unsaturated isonitrile, which may interestingly be compared with the corresponding Michael addition to α,β-unsaturated nitrile[6] (Eq. (4)):



It has been reported[7] that the terminal carbon atom of the vinyl group of VIC has an increased electron density due to a canonical form of $^-CH_2-CH=\overset{+}{N}=C:$. The polarization character of VIC is opposite to that of acrylonitrile. Consequently, the nucleophilic addition to VIC may not be a favorable reaction. The addition of diethyl malonate to VIC was not observed in the presence of the *tert*-BuOK catalyst under the

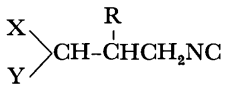
conditions shown in Table 1. The polarization character of VIC, however, may be much changed by its coordination through the termical carbon atom of the isocyano group to copper. In each of the reaction mixtures of VIC and AIC with methyl phenylacetate with the Cu_2O catalyst, the Michael addition products, **15f** and **15g**, were actually isolated.



15

f. X=C_6H_5, Y=CO_2Me, R=H
f. X=C_6H_5, Y=CO_2Me, R=Me

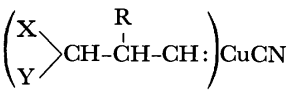
When the reaction of VIC with methyl phenylacetate was carried out in dimethylformamide, **15f** was not formed, but **5f** and **8f** were produced (see Table 1). Complex **12** is formed by the 1,3-rearrangement of **11** (Step 5) or from **13** (Step 6), which has an active hydrogen at the γ-carbon. The elimination of CuCN from **12** gives rise to the formation of **5** (Step 7). Step 7 is closely related to the following reaction of CuCN elimination:[8]

$$EtO_2CCH_2CH_2NC + \frac{1}{2}Cu_2O \rightarrow EtO_2CCH{=}CH_2 + CuCN + \frac{1}{2}H_2O$$

$$EtO_2CCH_2\underset{\displaystyle CH_3}{\underset{|}{C}}HNC + \frac{1}{2}Cu_2O \rightarrow EtO_2CCH{=}CHCH_3 + CuCN + \frac{1}{2}H_2O$$

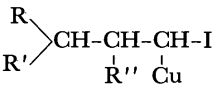
On the other hand, the insertion of the isocyano group into the carbon-copper band in **12** is a cyclization process[9] (Step 8) which produces **14**, which in turn abstracts hydrogen from another molecule of **1** to give **8** and **9**. The olefinic compound, **6**, is a minor product, whose formation has not yet been elucidated.

The production of olefin suggests another possibility for the formation of the cyclopropane derivative.



16

It seems likely that a carbene intermediate (**16**) is formed by the α,α-elimination from α-isocyanoorganocopper (**11**), which may be regarded as a kind of copper carbenoid. Kirmse and Wächtershäuser[10] reported that cyclopropane and olefin were obtained in the reaction of 1,1-diiodoneoalkanes with copper. This reaction has been explained in terms of a process involving a copper carbenoid (**17**).



17

Experimental

Reagent. VIC was prepared according to Matteson's procedure.[7] AIC was prepared according to Ugi's procedure,[11] while PPIC was prepared by the isomerization of

AIC with a Cu_2O catalyst.[4] The active methylene compounds were all commercial reagents and were purified by distillation under nitrogen. The Cu_2O was a commercial reagent of an analytical reagent grade and was dried under nitrogen prior to use.

Reactions of Isonitriles with Active Methylene Compounds. A mixture of equimolecular amounts of isonitrile and an active methylene compound, together with Cu_2O in benzene, was heated under nitrogen. Then, the excess solid Cu_2O was removed by filtration and wahed with CH_2Cl_2. The filtrate and washings were combined and treated with a 4 N KCN aqueous solution. The organic layer was subjected to distillation under reduced pressure. The products were purified by preparative glpc. The product structures were determined by studying the IR, NMR, and Mass spectra and by elemental analysis. The identification data of the products are summarized in Table 2.

The Synthesis of an Etiojervane Analog of Corticosterone.[1]

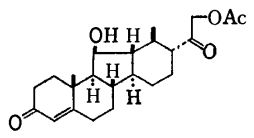
Tadashi MASAMUNE and Takako ORITO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

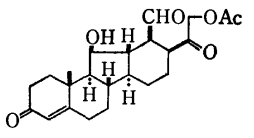
(Received December 20, 1971)

The synthesis of C-nor-D-homo-17-epicorticosterone 21-acetate (**1**) from jervine (**3**), which possesses the corticosterone configuration at each of the ring junctions, is described. Etiojerv-5-ene-3β,11β-diol-17-one (**4**), obtained by a seven-step process from **3**, was subjected to the Darzens reaction and afforded glycidic ester (**7**), which was converted by treatment with boron trifluoride into olefin (**9**). Catalytic hydrogenation followed by reduction with lithium aluminum hydride gave rise to tetraol (**15**), which was isolated as the acetonide (**16**). After Oppenauer oxidation of **16**, acid hydrolysis and subsequent partial acetylation, the resulting monoacetate (**19**) was oxidized with dicyclohexylcarbodiimide in dimethylsulfoxide to give compound **1**. Spectral and chemical evidence are presented for configurational assignment to both the compound and the synthetic intermediates.

Interest continues in the search for analogs with enhanced or more specific pharmacological properties in the synthesis of modified steroid hormones. During the last few years etiojervane analogs of cortisone,[2] progesterone,[3,4a] testosterone,[4b,5,6] estrone,[4c,5,7] and others[8-11] have been prepared. We describe herewith the synthesis of C-nor-D-homo-17-epicorticosterone 21-acetate (**1**), which possesses the corticosterone configuration at each ring junction and differs from the corresponding aldosterone (**2**) only in the function at C_{18} and the configuration at C_{17}.



1



2

The readily available veratrum alkaloid jervine (**3**) was converted by a seven-step process into etiojerv-5-ene-3β,11β-diol-17-one[2] (**4**) *via* trienone[4b,12] (**5**) in an over-all yield of 13.5%. Compound **4** was selected as the starting material for the following reasons. (1) A synthetic route[3,13] *via* hydration of the 17,20-double bond of **5** followed by selective oxidation at C_{20} to the *17-acetyl group* would be impractical, in view of the instability of a closely related compound, 17α-acetyletiojerva-5,12-dien-3β-ol[14] (**6**), owing to the facile oxidative cleavage. (2) Dihydrojervine derivatives with *trans*-fused C/D linkage and open ring E, obtained by the double Birch reductions of **3**[3,15,16] or by acetolysis of 12,13-dihydrojervine and subsequent hydrogenation,[16,17] led to formation of the corresponding 17α-*acetyl* (*not* 17β) derivatives by the fragmentation of ring E.[18,19] However, selective introduction of a hydroxyl or an acetoxyl group

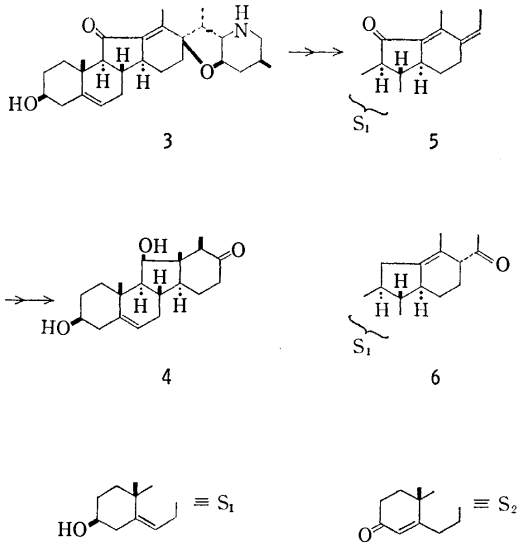
into C_{21} in a final stage of the synthesis would be difficult.



Alkylation at C_{17}, the most important step, was carried out under various conditions. The Wittig reaction of **4** with carbethoxymethylenetriphenylphosphorane[2] and the Darzens reaction under the conditions used for steroidal 3-ketones[20] were attempted for preparing compounds with 17-substituents convertible to the side chain of corticosterone, but proved to be unsuccessful, most of the starting compound **4** being recovered unchanged. However, treatment of **4** by a modified procedure of the latter reaction, using ethyl chloroacetate (8 mol) and sodium ethoxide (5 mol) in dimethyl sulfoxide (DMSO) at room temperature, resulted in formation of glycidic ester (**7**), mp 176—178°C, in 36% yield after chromatographic separation, along with an almost equal amount of the unreacted compound **4**. Compound **7** displayed a peak at *m/e* 390 due to the molecular ion and absorptions at 1747 cm^{-1} and at τ 8.84 (triplet) and 5.75 (quartet) due to the carbethoxy group in the mass, IR, and NMR spectra, respectively, which were consistent with the structure. The configuration of the side chain at C_{17} was assigned β (α-epoxide) on the analogy of the Grignard reactions in unhindered ketones[21] and, especially, of the ethynylation of C-nor-D-homocortisone synthesis (17β-ethynyl 40% and 17α-ethynyl 5%).[2]

Glycidic ester **7**, on treatment with boron trifluoride etherate in a refluxing solution of tetrahydrofuran (THF) and DMSO, afforded a 1 : 2 mixture of two allyl alcohols. The mixture was subjected to separation by preparative thin layer chromatography (tlc) to give **8**, mp 150—151°C, and **9**, mp 152—153°C, in 23 and 40% yields, respectively. The former showed a signal (singlet) due to the methyl protons attached to the 13,17-double bond at τ 8.07, and the latter one (W_H=12 Hz) due to the new olefinic proton at τ 4.11 in the NMR spectrum. The presence of a double bond at C_{12}–C_{13} of **8** was excluded, because the 18-methyl protons of etiojerv-12-en-11β-ol derivatives appeared at a higher field over τ 8.20.[14]

Kupchan and El-Haj[4a] obtained etiojerva-4,16-dien-20-ol-3,11-dione (**10**) as the only isolable product by treatment of a compound with an epoxy function at C_{17} and C_{20} (**11**) under almost the same conditions. They assigned the β-configuration to the relevant epoxy group on the basis of this reaction result, which was rationalized by a concerted cleavage of the diaxially oriented C_{17}–O and C_{16}–H bonds.[22] In view of the stereochemical peculiarity in C and D rings of etiojervanes, the rationalization leading to the preferential elimination of proton from the less hindered carbon C_{16} would not be unreasonable. Contrary to expectation, the present result differed from theirs in the formation of two olefins **8** and **9**. This would be explicable on the premise of a two-step elimination mechanism; cleavage of the presumed α-epoxy group at C_{17} followed by removal of one of the protons on two adjacent carbons C_{13} and C_{16}. It would be improbable that the reaction proceeded with a concerted mechanism, whereby compounds with two *trans*-fused five-membered rings should result from contraction of the D ring.[23] It is to be noted that compound **8** is the first etiojervane derivative with both the 13,17-double bond and *trans*-fused C/D linkage (12βH, 14αH).

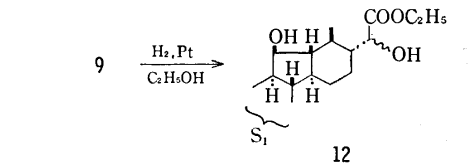
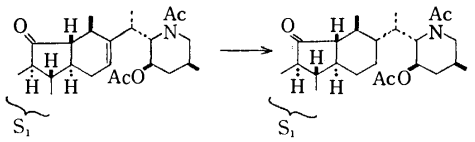
Hydrogenation of olefin **9** over platinum in ethanol took place selectively, giving the 16,17-dihydro derivative (**12**), mp 177—179°C, in 81% yield. A signal at τ 4.11 due to the proton at C_{16} of **9** disappeared in the NMR spectrum of **12**. On the other hand, compound **8** with the tetra-substituted double bond remained unchanged by the same treatment. The side chain configuration at C_{17} of **12** was tentatively assigned to α on the basis that (1) hydrogenation of an imino-jervane derivative (**13**) with the double bond at C_{16} and C_{17} as well as the *trans*-fused C/D linkage produced a compound (**14**) with the 17α-side chain, resulting from attack of hydrogen from the upper (β) side,[16] and (2) adsorption of the double bond in question on the catalyst would possibly occur at the same side as the fixed 11-hydroxy group rather than the rotatable 20-hydroxyl.[24]



12



13 3-Acetate 14 3-Acetate

Reduction of ester **12** with lithium aluminum hydride (LAH) gave rise to etiojerv-5-ene-3β,11β,20ξ,-21-tetrol (**15**) as crystalline state, which was scarcely soluble in the usual organic solvents, and without further purification, converted by treatment with acetone and *p*-toluenesulfonic acid (PTS) into the acetonide (**16**), mp 217—220°C in 47% yield from **12**. The mass (*m/e* 390, M$^+$), IR (ν_{max} 1068 and 1052 cm^{-1}) and NMR spectra (τ 8.62, 6H, singlet) were in good accord with the structure. The Oppenauer oxidation[13] of acetonide **16** proceeded without any change of the 11β-hydroxy group and afforded an $\alpha\beta$-unsaturated ketone (**17**), mp 160—162°C, in 85% yield, which showed strong absorption maxima at 1650 and 1610 cm^{-1} in the IR spectrum.

Acetonide **17** was then subjected to hydrolysis with acid to give triol (**18**), which was also hardly soluble in the usual organic solvents and used for the next reaction without further purification. Treatment of **18** with acetic anhydride (1.3 mol) in dioxane effected partial acetylation at C_{21}, giving monoacetate (**19**), oil, after separation by preparative tlc. Selective oxidation of the 20-hydroxyl to the oxo function by the usual procedures, using anhydrous chromic acid in acetic acid or in pyridine or Jones' reagent,[25] failed owing to the susceptibility of the 11β-hydroxyl group to oxidation. However, oxidation was achieved by treatment of **19** with dicyclohexylcarbodiimide (DCC), trifluoroacetic acid and pyridine in DMSO at room temperature.[26] The resulting product (**1**) mp 209—211°C, isolated in 30% yield from **17** by preparative tlc, was analyzed for $C_{23}H_{32}O_5$, which was supported by the mass spectrum (*m/e* 388, M$^+$). In accordance with the assigned structure, the compound exhibited absorption maxima at 3420, 1748, 1728, 1665, and 1610 cm^{-1} due to the hydroxyl and carbonyl functions in the IR spectrum, and two singlets at τ 8.60 and 7.88 (19-CH_3 and $OCOCH_3$), a doublet with J of 6 Hz at τ 9.05 (18-CH_3), a multiplet and a singlet at τ 5.35 and 4.38 (H at C_{11} and C_4) in the NMR spectrum. The CD and ORD curves of **1** clearly exhibited a positive Cotton effect, as compared with those of acetonide **17** (Fig. 1). Analogous with the fact that two epimeric, well established etiojervanes (**20** and **21**) with the 17β- and 17α-acetyl group displayed negative and positive Cotton effects (a=−91° and +61°), respectively.[14] The positive Cotton effect due to the 20-oxo function of **1** indicated the 17-substituent to be α-oriented, supporting the hydrogenation result of **9**. Accordingly, compound **1** is regarded as C-nor-D-homo-17-epicorticosterone 21-acetate. Since functionalization of the 18-methyl group of related compounds has been achieved,[27] compound **1** or the synthetic intermediates would be useful for the synthesis of etiojervane analogs of aldosterone. The present synthesis involves 16 steps and the over-all yield from jervine **3** is 0.3%. Improved syntheses of **1** and **2** are now in progress.

Experimental

The melting points were measured in open capillaries and uncorrected. Homogeneity of each compound was always checked by TLC on silica gel (Wakogel B-5) and/or alumina (Merck G). The optical rotations and IR spectra were taken in methanol and in Nujol unless otherwise stated. The NMR spectra were measured in deuterochloroform at 60 and/or 100 MHz, tetramethylsilane being used as an internal reference, unless otherwise sated. The abbreviations s, d, t, q, br, and m in the NMR spectra denote singlet, doublet, tripelt, quartet, broad, and multiplet, respectively.

17β-Carbethoxymethylen-17α,20ξ-expoxyetiojerv 5-ene-3β,11β-diol-(7). To a solution of etiojerv-5-ene-3β,11β-diol-17-one[2] (**4**, 9.14 g), 194—195°C, in DMSO (400 m*l*), freshly distilled at bp 95°C/35 mmHg over sodium hydride, were added ethyl chloroacetate (13.5 m*l*) and sodium ethoxide (11.7 g) under cooling, and the mixture was stirred at room temperature for 48 hr in a sealed tube. The mixture was shaken with water (400 m*l*) and chloroform (200 m*l*). After separation of the chloroform layer, the aqueous solution was extracted with chloroform (3×100 m*l*). All the chloroform solutions were combined, washed with an aqueous sodium chloride solution and water, dried over anhydrous sodium sulfate, and evaporated to leave brown oil. The oil (14.35 g) was chromatographed over alumina (Merck, neutral 250 g), using benzene, benzene-ether, ether, and acetone as eluents. Fractions eluted with benzene-ether and ether amounted to 9.66 g after removal of the solvents and, on trituration with acetone-ether, yielded crystalline material (**7**, 3.07 g), which was collected by filtration and showed a single spot. The filtrate was evaporated off to leave amorphous residue (4.68 g), which was again chromatographed over silica gel (Merck, 70—325 mesh, 181 g), using the same solvents as mentioned above. Eluates with benzene-ether contained **7** (checked by tlc) and crystallized partially on trituration with ether or ether-acetone. The crystalline substance (**7**, 1.11 g), collected by filtration, was combined with the afore-mentioned and recrystallized from ether-acetone for analysis to give **7** (3.80 g), mp 176—178°C; $[\alpha]_D$ −58.9°; mass, *m/e* 390 (M^+); IR, ν_{max} 3470 and 1747 cm^{-1}; NMR, τ 9.11 (3H, d, J=7 Hz, 18-CH_3), 8.84 (3H, t, J=7 Hz, $COOCH_2CH_3$), 8.76 (3H, s, 19-CH_3), 6.50 (1H, m, *H* at C_3), 5.75 (2H, q, J=7 Hz, $COOCH_2CH_3$), 5.70 (1H, m, *H* at C_{11}), 4.77 (1H, br s, *H* at C_6), and 4.43 (1H, s, *H* at C_{20}).

Found: C, 70.45; H, 8.73%. Calcd for $C_{23}H_{34}O_5$: C, 70.45; H, 8.78%.

Examination of the mother liquors obtained on removal of **7** by tlc indicated the presence of an almost equal amount of **4**.

17-Carbethoxymethylenetiojerva-5,13(17)-diene-3β,11β,20-ξ-triol (8) and 17-carbethoxymethylenetiojerva-5,16-diene-3β,11β,20ξ-triol (9). A solution of **7** (500 mg) in dry THF (25 m*l*) and DMSO (25 m*l*) was refluxed with boron trifluoride etherate (0.5 m*l*) for 5 hr and for another 3 hr after addition of the same fluoride (0.5 m*l*). After being cooled, the solution was mixed with water (150 m*l*) and then extracted with chloroform (50, 25, and 25 m*l*). The chloroform solutions were dried and evaporated under reduced pressure to leave amorphous residue (506 mg). This was separated into 2 parts by preparative tlc using ether and 18 plates; each plate was made of silica gel (Wakogel B-5, 10 g) with an area 20×20 cm^2. A less mobile fraction showing a single spot was extracted with acetone-methanol and gave amorphous substance (140 mg) after removal of the solvent, which crystallized on trituration with acetone-ether to yield **8** (115 mg), mp 149—150°C. This was recrystallized from the same solvent for analysis; mp 150—151°C; $[\alpha]_D$ −146.9°; IR, ν_{max} 3370, 3270 (shoulder), 1749 and 1295 cm^{-1}; NMR, τ 8.65 (3H, s, 19-CH_3), 8.65 (3H, t, J=7 Hz, $COOCH_2CH_3$), 8.07 (3H, s, 18-CH_3), 6.50 (1H, m, *H* at C_3), 5.75 (2H, q, J=7 Hz, $COOCH_2CH_3$), 5.70 (1H, m, *H* at C_{11}), 4.94 (1H, s, *H* at C_{20}), and 4.72 (1H, br s, *H* at C_6).

Found: C, 70.54; H, 8.72%. Calcd for $C_{23}H_{34}O_5$: C, 70.74; H, 8.78%.

The more mobile fraction (288 mg) showing a single spot crystallized on trituration with acetone-ether to give **9** (199 mg), mp 147—149°C. This was recrystallized from the same solvent for analysis; mp 152—153°C; $[\alpha]_D$ −145.3°; IR, ν_{max} 3520, 3390, 3210, 1723, and 1285 cm^{-1}; NMR, τ 8.82 (3H, d, J=6 Hz, 18-CH_3), 8.72 (3H, s, 19-CH_3), 8.72 (3H, t J=7 Hz, $COOCH_2CH_3$), 6.50 (1H, m, *H* at C_3), 5.75 (2H, q, J=7 Hz, $COOCH_2CH_3$), 5.70 (1H, m, *H* at C_{11}), 5.36 (1H, s, *H* at C_{20}), 4.75 (1H, br s, *H* at C_6), and 4.11 (1H, br s W_H=12 Hz, *H* at C_{16}).

Found: C, 70.66; H, 9.07%. Calcd for $C_{23}H_{34}O_5$: C, 70.74; H, 8.78%.

17α-Carbethoxymethylenetiojerv-5-ene-3β,11β,20ξ-triol (12). Compound **9** (1.70 g) was hydrogenated over prereduced Adams platinum (800 mg as $PtO \cdot H_2O$) in ethanol (125 m*l*) at room temperature for 2 days, when 100 m*l* of hydrogen (1 mol) had been absorbed. The reaction was continued for 3.5 days. After removal of the catalyst and the solvent, the residue was dissolved in chloroform. The solution was washed with an aqueous sodium chloride solution and water, dried and evaporated to leave amorphous residue (1.97 g), which crystallized on trituration with acetone-ether to give **12** (1.49 g), mp 167—170°C, showing a single spot. This was recrystallized from the same solvent for analysis; mp 177—179°C; $[\alpha]_D$ −53.5°; IR, ν_{max} 3470, 1717 and 1240 cm^{-1}; NMR, τ 8.98 (3H, d, J=6Hz, 18-CH_3), 8.77 (3H, s, 19-CH_3), 8.72 (3H, t, J=7 Hz, $COOCH_2CH_3$), 6.50 (1H,

m, *H* at C_3), 5.76 (2H, q, J=7 Hz, $COOCH_2CH_3$), 5.72 (2H, m, *H* at C_{11} and C_{20}), and 4.75 (1H, br s, H at C_6).

Found: C, 70.21; H. 9.43%. Calcd for $C_{23}H_{36}O_5$: C, 70.37; H, 9.24%.

*17α-Ethyletiojerv-5-ene-3β,11β,20ξ,21-tetrol 20,21-Acetonide (**16**).* To a suspension of LAH (500 mg) in dry THF (40 m*l*) was added compound **12** (500 mg) in dry THF (35 m*l*) under stirring during 50 min, and the mixture was stirred at room temperature for 1 hr. To the cooled mixture were added dropwise methanol (2 m*l*) and water (20 m*l*) under stirring to decompose excess of the LAH, and then 1 N hydrochloric acid to dissolve the resulting aluminum hydroxide. The mixture was extracted with ethyl acetate (3×20 m*l*), and the solution was washed with water. The aqueous washings were again extracted with ethyl acetate (20 m*l*). All the acetate solutions were combined, evaporated and dried over phosphorus pentoxide under reduced pressure to leave crystalline material (crude tetrol **15**, 427 mg), which was used for the next reaction without further purification.

A solution of the crude tetrol **15** in acetone (40 m*l*), freshly distilled over potassium carbonate after reflux with potassium permanganate, was stirred with PTS (400 mg) at room temperature for 10 min, when the spot of **15** had disappeared. After 40 min, the solution was mixed with an aqueous, saturated sodium bicarbonate solution and extracted with chloroform (3×40 m*l*). The chloroform solution was washed with water, dried and evaporated to leave amorphous residue (513 mg), which showed 2 spots on tlc and was separated by preparative tlc (ether and 13 plates). The more mobile, main fraction gave amorphous substance which was crystallized and recrystallized from acetone-ether to give **16** (237 mg), mp 217—220°C; $[\alpha]_D$ −49.2°; mass, *m/e* 390 (M^+); IR, ν_{max} 3430, 1068, and 1052 cm^{-1}; NMR, τ 8.85 (3H, d, J=5 Hz, 18-CH_3), 8.75 (3H, s, 19-CH_3). 8.62 (6H, s, CH_3CCH_3), 6.50 (1H, m, *H* at C_3), 6.00 (3H, m, *H* at C_{20} and C_{21}), 5.70 (1H, m, *H* at C_{11}), and 4.75 (1*H*, br s, *H* at C_6).

Found: C, 73.87; H, 9.74%. Calcd for $C_{24}H_{38}O_4$: C, 73.80; H, 9.81.

*17α-Ethyletiojerv-4-ene-11β,20ξ,21-triol-3-one 20,21-Acetonide (**17**).* A solution of compound **16** (200 mg) in toluene (55 m*l*) containing cyclohexanone (5 m*l*) was heated under stirring until 28 m*l* of the toluene was removed. After addition of aluminum isopropoxide (480 mg), the whole mixture was refluxed for 3.7 hr and cooled. After addition of acetone (8 m*l*) and water (8 m*l*), the mixture was stirred at room temperature overnight and filtered. The filtrate was subjected to steam distillation to give oily residue which was extracted with chloroform repeatedly. The extracts yielded amorphous substance (225 mg) which crystallized on trituration with ether to give **17** (168 mg), mp 156—158°C. This was recrystallized from acetone-ether for analysis; mp 160—162°C; $[\alpha]_D$ +100.0°; IR, ν_{max} 3410, 1650, 1610, 1075, and 1060 cm^{-1}; NMR, τ 8.87 (3H, d, J=5 Hz, 18-CH_3), 8.64 (6H, s, CH_3CCH_3), 8.59 (3H, s, 19-CH_3), 6.05 (4H, m, *H* at C_{11}, C_{20}, and C_{21}), and 4.28 (1H, s, *H* at C_4).

Found: C, 74.10; H, 9.26%. Calcd for $C_{24}H_{36}O_4$: C, 74.19; H, 9.34%.

*17α-Ethyletiojerv-4-ene-11β,21-diol-20-one 21-Acetate (C-Nor-D-homo-17-epicorticosterone 21-Acetate, **1**).* A solution of compound **17** (100 mg) in methanol (8 ml) containing concentrated hydrochloric acid (4 drops) was stirred at room temperature for 1.5 hr. After removal of the methanol below 40°C, the residue was extracted with chloroform, and the chloroform solution was evaporated and dried over phosphorus pentoxide under reduced pressure to leave resinous substance (crude **18**, 93 mg).

The resin was dissolved in pyridine (0.2 m*l*) and treated with acetic anhydride (36 m*l*) in dioxane (0.4 m*l*) at room temperature for 15 hr. The mixture was poured into ice-water (70 m*l*) and extracted with chloroform repeatedly. The chloroform solution was washed with 1 N hydrochloric acid and water, dried and evaporated to leave oily residue (126 mg) which was separated by preparative tlc (ether and 3 plates). The main fraction afforded oil (crude **19**, 60 mg) which was used for the next reaction without further purification.

A solution of the oil (50 mg) in a 1 : 3 mixture of dry DMSO and benzene (0.64 m*l*) was treated with DCC (80 mg, 3 equiv) and 0.5 M trifluoroacetic acid and 1 M pyridine in DMSO (0.13 m*l*) at room temperature for 3.5 hr in a sealed tube. On addition of ether, precipitates separated out and were removed by filtration. The ether filtrate was washed with water, dried and evpaorated to leave amorphous residue (66 mg) which was separated into 3 parts by preparative TLC (ether and 1 plate). The main fraction gave crystalline material (**1**, 20 mg), mp 208—211°C, on removal of the solvent. This was recrystallized from acetone-ether for analysis; mp 209—211°C; CD and ORD (Fig. 1); mass, *m/e* 388 (M^+); IR, ν_{max} 3420, 1748, 1728, 1665, and 1610 cm^{-1}; NMR, τ 9.05 (3H, d, J=6 Hz, 18-CH_3), 8.60 (3H, s, 19-CH_3), 7.88 (3H, s, $OCOCH_3$), 5.80 (1H, m, *H* at C_{11}), 5.35 (2H, s, *H* at C_{21}), and 4.38 (1H, s, *H* at C_4).

Found: C, 70.88; H, 8.43%. Calcd for $C_{23}H_{32}O_5$: C, 71.10; H, 8.30%.

The authors are grateful to Mr. Shigezo Shimokawa for the measurement of NMR, to Mr. Naofumi Hanabusa for that of CD and ORD curves, to Miss Masako Takahashi for that of mass spectra, and also to Misses Hiroko Kakizaki and Motoko Sato for the microanalysis.

The Synthesis of the 1,2,4-Thiadiazine-1,1-dioxides[1]

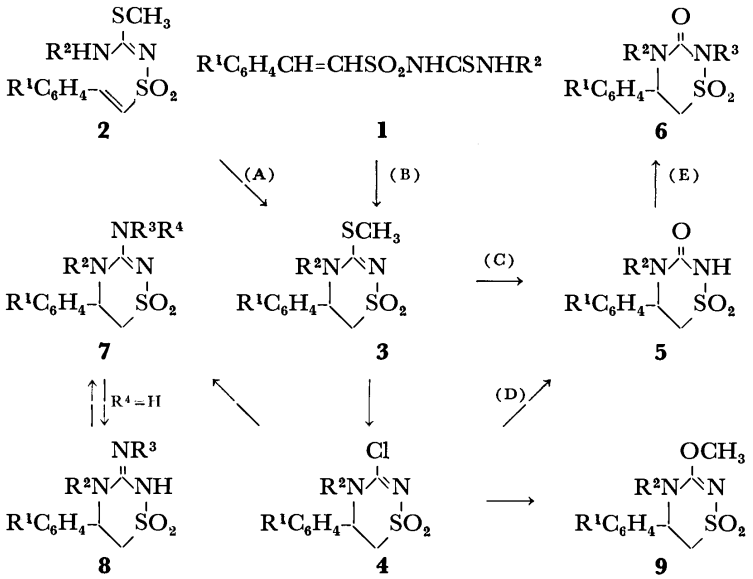
Kiyoshi HASEGAWA and Syuzi HIROOKA

Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Takaoka-shi

(Received January 5, 1972)

N-(2-Phenylethene-1-sulfonyl)-*N'*-monoalkyl *S*-methylisothioureas, **2**, were ring-closed to yield Michael cycloadducts, 3-methylthio-4-alkyl-5-phenyl-1,1-dioxo-5,6-dihydro-1,2,4-thiadiazines, **3**. Bulky *N'*-alkyl groups hindered the cycloaddition. The base-catalyzed hydrolysis of **3** and 3-chloro-derivatives **4** gave 4-methyl-5-phenyl-2,3,5,6-tetrahydro-1,1,3-trioxo-1,2,4-thiadiazines, **5**, which in turn underwent *N*-alkylation to give **6**. The reaction of **4** with amines or with sodium methoxide yielded 3-amino-, **7**, or 3-methoxy-thiadiazine derivatives, **9**.

Recently we have reported[2,3] the synthesis of a new heterocyclic system, 5,6-dihydro-1,4,2-dithiazine-1,1-dioxide, by the intramolecular Michael cycloaddition of *N*-(2-phenylethene-1-sulfonyl)-*N'*-alkylthioureas, dithiocarbamates, and *O*-alkyl thiocarbamates. This paper will describe a new route to the little-known 1,2,4-thiadiazine-1,1-dioxide derivatives,[4] starting from the substituted isothioureas. The process is outlined below.



Results and Discussion

The reaction of *N*-(2-phenylethene-1-sulfonyl)-*N'*-monoalkylthioureas (**1**) with dimethyl sulfate in DMF afforded *N*-(2-phenylethene-1-sulfonyl)-*N'*-alkyl *S*-methylisothioureas (**2**) (Table 1). They were ring-closed in ethanol containing catalytic amounts of sodium hydroxide to yield intramolecular cycloadducts, 3-methylthio-4-alkyl-5-phenyl-1,1-dioxo-1,2,4-thiadiazines (**3**) (Table 2, Method (A)). The IR spectrum of **3a** displayed a strong band at 1530 cm^{-1} due to the N=C bond, but no absorption due to the NH bond was observed. In the NMR pattern of **3a**, ring protons, $H_AH_CH_B$, showed an ABX pattern consisting of three quartets of H_A centered at δ 3.36, H_C 3.53, and H_B 5.03 (J_{AC}=13.5 Hz, J_{AB}=10.5 Hz, J_{BC}=6.0 Hz) (Fig. 1). The peak at *m/e* 118.066 in the mass spectrum was in complete agreement with the fragment ion, $C_6H_5CN^+CH_3$, derived from only the six-membered heterocycle, **3**. The structures of **3b**—**3h** were inferred because they were analogous with **3a** in their preparations and spectral data.

Cycloaddition is subject to steric hindrance, and it was unsuccessful here when the alkyl group, R^2, in **2** was bulky or branched, like the cyclohexyl, isopropyl, *s*-, and *t*-butyl groups. The amounts of a base required to complete the cycloaddition of **2**'s in 6 hr at 25—30°C were determined. Table 2 shows that only from a sixth to a third equivalent of the base was sufficient to effect the cycloaddition of **2** when R^2 was the methyl group, while more bases were required when R^2 became bulky. The *N'*-dialkylisothiourea could not be ring-closed, presumably because of the lack of a hydrogen atom at the *N'*-position. The reaction of **1** with dimethyl sulfate and sodium hydroxide in ethanol afforded **3** directly (Table 2, Method (B)). The C–N bond in **3** could not be cleaved by a strong base at elevated temperatures, but hydrolytic products, 4-methyl-5-phenyl-2,3,5,6-tetrahydro-1,1,3-trioxo-1,2,4-thiadiazines (**5**) resulted (Table 4, Method (C)). They were identified by

means of the IR (1650 cm^{-1} for C=O, 2960 cm^{-1} for NH), NMR (δ 3.30 for NH) and mass spectra, and also by means of the results of elemental analyses. The methylthio group in **3** was replaced by a chlorine atom to give 3-chloro-derivatives (**4**) (Table 3). The base-catalyzed hydrolysis of **4** gave **5** (Table 4, Method (D)), and **5** was readily methylated to afford 2,4-dimethyl-5-phenyl-2,3,5,6-tetrahydro-1,1,3-trioxo-1,2,4-thiadiazine (**6**) (Table 4, Method (E)). The reaction of **4** with various amines or with sodium methoxide yielded 3-alkylamino- or -hydrazino- (**7**), or 3-methoxy-derivatives (**9**) (Table 3). When the R^4 in **7** is a hydrogen atom, the tautomerism between **7** and **8** can be expected. The possibility that the solid product is an alternative isomer, **8**, was discounted by its insolubility in alkali, thereby demonstrating the absence of the SO_2NH group. The IR

spectra of **7a** and **7b** in KBr tablets displayed absorption peaks in the same region as the N=C group in **7c** and **7d**. However, NMR studies of **7a**, **7g**, and **7i** dissolved in DMSO-d_6 offered evidence for the presence of the **8** isomer in a tautomeric mixture in the solution. In the $NHCH_3$ group in **7a**, methyl protons showed a doublet at δ 2.71 (J=4.0 Hz), and a NH proton, a broad quartet at δ 6.94 (J=4.0 Hz), with a peak area of 0.52H. In addition, there was a sharp singlet at δ 2.70, assignable to the $=NCH_3$ protons in **8** between a doublet methyl signal. However, a sulfonamide NH proton of **8** could not be observed because of overlapping with a signal of water contained in DMSO-d_6 at 3.34. After the treatment with D_2O, the NH proton signal (δ 6.94) was eliminated and only a sharp singlet due to the $=NCH_3$ protons appeared. The relative peak areas of the methyl and NH peaks assignable to the structures of **7** and **8** indicated that **7a** consisted of about a 50 : 50 mixture of **7** and **8** in DMSO-d_6.

Experimental

The melting points were determined on a Yanagimoto micro-melting-point measuring apparatus, MP-S2, and are uncorrected. The IR spectra were recored on a JASCO IRA-1 spectrometer. The NMR spectra were determined with a Varian HA-100 spectrometer, with TMS as the internal standard, and the mass spectra, with a JMS-OlSG spectrometer.

*N-(2-Phenylethene-1-sulfonyl)-N'-methyl S-Methylisothiourea (**2a**).* To a stirred solution of *N*-(2-phenylethene-1-sulfonyl)-*N'*-methylthiourea (1.20 g, 0.0040 mol) in DMF (10 m*l*), we added a 1 N NaOH solution (9.6 m*l*, 0.0096 mol) and dimethyl sulfate (0.61 g, 0.0048 mol), drop by drop, at 0—10°C. After being stirred for 3 hr at room temperature, the reaction mixture was poured into ice water (100 m*l*) and kept overnight. The precipitated white solid was filtered to give 0.96 g (89%) of **2a**. Recrystallization from benzene-petroleum ether gave colorless crystals. IR (KBr): 3330 (NH), 3040 (=CH), 1610 (C=C), 1560 (N=C),

1335, and 1115 (SO_2) cm^{-1}. NMR ($CDCl_3$): δ 2.44 (s, 1H, SCH_3), 2.99 (d, J_{NHCH_3}=5.0 Hz, 3H, $NHCH_3$), 6.93 (d, J_{AB}=15.5 Hz, 1H, H_A), 7.54 (d, J_{AB}=15.5 Hz, 1H, H_B), 7.45±0.02 (m, 5H, phenyl), 8.10 (broad, 1H, NH). Mass spectrum *m/e*: 270 (M^+).

*3-Methylthio-4-methyl-5-phenyl-1,1-dioxo-5,6-dihydro-1,2,4-thiadiazine (**3a**).* *Method (A)*: To a solution of **2a** (0.54 g, 0.0020 mol) in ethanol (20 m*l*), we added a 1 N NaOH solution (0.34 m*l*, 0.00033 mol), after which the mixture was stirred for 6 hr at 25—30°C. An ethanol solution containing white precipitates was concentrated *in vacuo*, water (5 m*l*) was added, and the precipitates were collected to obtain 0.44 g (82%) of **3a**. Recrystallization from ethanol gave colorless crystals. IR (KBr): 1530 (N=C), 1300, and 1140 (SO_2) cm^{-1}. NMR ($CDCl_3$): δ 2.47 (s, 3H, SCH_3), 2.86 (s, 3H, NCH_3), 3.36 (q, J_{AC}=13.5 Hz, J_{AB}=10.5 Hz, 1H, H_A), 3.53 (q, J_{AC}=13.5 Hz, J_{BC}=6.0 Hz, 1H, H_C), 5.03 (q, J_{AB}=10.5 Hz, J_{BC}=6.0 Hz, 1H, H_B), 7.34±0.12 (m, 5H, phenyl). Mass spectrum (75 eV) *m/e* (rel intensity): 77 (17), 78 (13), 91 (10), 104 (100), 105 (10), 118.066 (12), 119 (6), 132 (6), 159 (6), 173 (3), 191 (4), 206 (5), 207 (10), 270.105 (calculated molecular weight, 270.106, 10).

Method (B): Into a solution of *N*-(2-phenylethene-1-sulfonyl)-*N'*-methylthiourea (10.25 g, 0.0400 mol) in a 1 N NaOH solution (80 m*l*, 0.0800 mol) and ethanol (80 m*l*), we stirred, drop by drop, dimethyl sulfate (6.40 g, 0.050 mol) at 0—10°C. Stirring was continued for a further 4 hr at room temperature. An ethanol solution containing white precipitates was concentrated *in vacuo*, and the precipitates were collected to afford 7.50 g (69%) of **3a**. The aqueous filtrate was acidified with concentrated hydrochloric acid to give 2.20 g of **5a**.

*3-Chloro-4-methyl-5-phenyl-1,1-dioxo-5,6-dihydro-1,2,4-thiadiazine (**4a**).* Into a solution of **3a** (2.70 g, 0.0100 mol) in chloroform (20 m*l*) we bubbled excess chlorine at 30—40°C until the colorless solution turned orange. The evaporation of the chloroform left white precipitates, which were recrystallized from methanol to obtain 2.40 g (92%) of colorless crystals. IR (KBr): 1590 and 1575 (N=C), 1330 and 1150 (SO_2) cm^{-1}. NMR ($CDCl_3$): δ 3.04 (s, 3H, CH_3), 3.48 (q, J_{AC}=14.0 Hz, J_{AB}=9.5 Hz, 1H, H_A), 3.63 (q, J_{AC}=14.0 Hz, J_{BC}=7.0 Hz, 1H, H_C), 5.18 (q, J_{AB}=9.5 Hz, J_{BC}=7.0 Hz, 1H, H_B), 7.44 (s, 5H, phenyl). Mass spectrum *m/e*: 258.088 (calculated molecular weight, 258.082).

*4-Methyl-5-phenyl-2,3,5,6-tetrahydro-1,1,3-trioxo-1,2,4-thiadiazine (**5a**).* *Method (C)*: To a solution of **3a** (0.54 g, 0.0020 mol) in acetone (10 m*l*), we added a 1 N NaOH solution (4.0 m*l*, 0.0040 mol), after which the reaction mixture was refluxed for 2 hr. The acetone was evaporated *in vacuo*, and the solution was acidified with concentrated hydrochloric acid to afford 0.44 g (82%) of **5a**. Recrystallization from ethanol gave colorless crystals. IR (KBr): 2960 (NH), 1650 (C=O), 1340, 1320, and 1140 (SO_2) cm^{-1}. NMR (DMSO-d_6): δ 2.59 (s, 3H, NCH_3), 3.30 (broad, 1H, NH), 3.73 (q, J_{AC}=13.7 Hz, J_{AB}=9.8 Hz, 1H, H_A), 3.94 (q, J_{AC}=13.7 Hz, J_{BC}=5.6 Hz, 1H, H_C), 4.89 (q, J_{AB}=9.8 Hz, J_{BC}=5.6 Hz, 1H, H_B), 7.38 (s, 5H, phenyl). Mass spectrum *m/e*: 240.083 (calculated molecular weight, 240.085).

Method (D): To a solution of **4a** (0.52 g, 0.0020 mol) in acetone (20 m*l*), we added a 1 N NaOH solution (4.0 m*l*, 0.0040 mol), after which the reaction mixture was stirred for 1 hr at room temperature. The acetone was evaporated *in vacuo*, and water (10 m*l*) was added to the residue. The solution was then acidified with concentrated hydrochloric acid to afford 0.46 g (96%) of **5a**.

*2,4-Dimethyl-5-phenyl-2,3,5,6-tetrahydro-1,1,3-trioxo-1,2,4-thiadiazine (**6a**).* Into a solution of **5a** (0.64 g, 0.0027 mol) in a 1 N NaOH solution (5.5 m*l*, 0.0054 mol) and ethanol (5.5 m*l*), we stirred, drop by drop, dimethyl sulfate (0.40 g, 0.0032 mol) over a 4-hr period at room temperature. The alkaline solution containing white precipitates was concentrated and collected to obtain 0.35 g (52%) of **6a**. Recrystallization from aqueous methanol gave colorless crystals. IR (KBr): 1650 (C=O), 1350, 1340, and 1145 (SO_2) cm^{-1}. NMR ($CDCl_3$): δ 2.77 (s, 3H, $C_6H_5\underset{|}{C}HN(\underline{CH_3})$-), 3.24 (s, 3H, $-N(CH_3)SO_2-$), 3.43 (q, J_{AC}=13.2 Hz, J_{AB}=12.0 Hz, 1H, H_A), 3.65 (q, J_{AC}=13.2 Hz, J_{BC}=6.0 Hz, 1H, H_C), 4.81 (q, J_{AB}=12.0 Hz, J_{BC}=6.0 Hz, 1H, H_B), 7.37±0.1 (m, 5H, phenyl). Mass spectrum *m/e*: 254.075 (calculated molecular weight, 254.073).

*3-Methylamino-4-methyl-5-phenyl-1,1-dioxo-5,6-dihydro-1,2,4-thiadiazine (**7a**).* To a stirred solution of **4a** (1.03 g, 0.0040 mol) in chloroform (10 m*l*), we added a 30% aqueous methylamine solution (0.83 g, 0.0080 mol) at room temperature, and then the mixture was stirred for 1 hr. The chloroform was evaporated *in vacuo*, and water (10 m*l*) was added to the residue. The cooled precipitates were collected to obtain 0.82 g (81%) of **7a**. Recrystallization from chloroform–petroleum ether gave colorless crystals. IR (KBr): 3350 (NH), 1560—1530 (N=C), 1340 and 1115 (SO_2) cm^{-1}. NMR (DMSO-d_6): δ 2.65 (s, 3H, NCH_3), 2.71 (d, J_{NHCH_3}=4.0 Hz, $NHCH_3$), 2.70 (s, $=NCH_3$), 3.20 (q, J_{AC}=13.5 Hz, J_{AB}=10.0 Hz, 1H, H_A), 3.45 (q, J_{AC}=13.5 Hz, J_{BC}=6.0 Hz, 1H, H_C), 4.89 (q, J_{AB}=10.0 Hz, J_{BC}=6.0 Hz, 1H, H_B), 6.94 (q, J_{NHCH_3}=4.0 Hz, 0.52H,NH), 3.34 (SO_2NH), 7.34 (s, 5H, phenyl). Mass spectrum *m/e*: 253.116 (calculated molecular weight, 253.118).

*3-Methoxy-4-methyl-5-phenyl-1,1-dioxo-5,6-dihydro-1,2,4-thiadiazine (**9a**).* To a solution containing sodium metal (0.3 g) dissolved in methanol (4 m*l*), we added **4a** (0.78 g, 0.0030 mol) in portions over a 30-min period at room temperature. The mixture was then allowed to stand for 2 hr, water (10 m*l*) was added, and the precipitates (0.27 g (37%) of **9a**) were collected. The filtrate was acidified with concentrated hydrochloric acid to afford 0.28 g of a hydrolytic product of **4a**. Recrystallization of **9a** from methanol gave colorless crystals. IR (KBr): 1570 (N=C), 1300, and 1130 (SO_2) cm^{-1}. NMR ($CDCl_3$): δ 2.73 (s, 3H, NCH_3), 3.90 (s, 3H, OCH_3), 3.25 (q, J_{AC}=15.0 Hz, J_{AB}=10.4 Hz, 1H, H_A), 3.54 (q, J_{AC}=15.0 Hz, J_{BC}=6.0 Hz, 1H, H_C), 4.97 (q, J_{AB}=10.4 Hz, J_{BC}=6.0 Hz, 1H, H_B), 7.38±0.05 (m, 5H, phenyl). Mass spectrum *m/e*: 254 (M^+).

Automatic Problem Solving Applied to Synthetic Chemistry

Malcolm BERSOHN
Department of Chemistry, University of Toronto, Toronto 181, Ontario, Canada
(Received September 24, 1970)

The first computer program that plans multi-step organic syntheses has been written. In the course of its operation the program generates partially complete synthetic pathways and ranks them as to efficiency. At each stage the program develops that partially complete route which it judges to be the most efficient, and extends it by one step. Partially complete routes which lose too much material are discarded. After each tolerably efficient pathway from available starting materials to the goal molecule is completed, the entire pathway is printed, together with the yield of each step and the overall yield.

The Information Structure of a Synthesis Problem

The various alternative methods of synthesizing a substance can be represented by a diagram like that of Fig. 1. Note that the figure is by no means a complete statement of all of the possible ways of making benzene from cheaper or simpler substances. For clarity, small molecules like CO_2, O_2, H_2, H_2O etc. are omitted from the diagram.

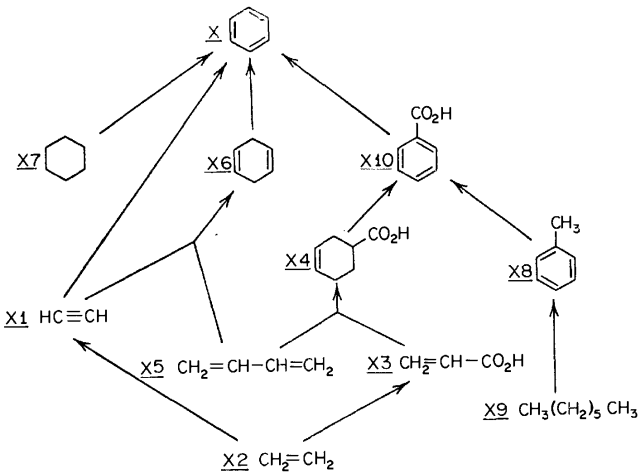

Fig. 1.

Such a two dimensional diagram can become very difficult to decipher because the more pathways that are included the more intersecting lines are possible. In addition, we will have more and more cases like X2, which is both four steps and two steps removed from the goal molecule. Hence there is no well defined level structure or generation structure. Also, evidently, we cannot describe the structure as a tree since there are cycles in it, such as X, X1, X2, X3, X4, and X10. A tree in a forest has no such rings and the tree of graph theory is also acyclic. Nonetheless, despite the unsuitability of two dimensional diagrams for representing it and the absence of a familiar name, the structure does have definite properties, as follows:

(1) Every molecule except the goal molecule has at least one successor molecule.
(2) Every molecule except the starting molecules has at least one parent molecule.
(3) Some molecules have coreactants with which they react to form their common successor molecule. For example, acetylene is the coreactant of butadiene and butadiene is the coreactant of acetylene in the problem of Fig. 1.

These three kinds of relationships link all the molecules of the problem together and these links must be suitably represented in the memory of a computer.

The Strategy Used by Chemists for Finding Good Synthetic Routes

Suppose that we wish to synthesize a molecule named M, starting from readily available molecules. The usual way of attacking this problem is to consider all possible synthetic reactions which could directly produce M. Suppose, for example that L1 and L2 react to form M, L3 can be rearranged to give M, L4 and L5 also react to produce M, all with satisfactory yield. Then we must next consider ways to make the set of molecules {L1, L2, L3, L4, L5}. For example, L1 can be made from K1 and K2; it can also be prepared by isomerization of K3 or K4 etc. We keep on moving backwards in this fashion until available substances are reached, *e.g.* the set {C1, C2, C3, B1, B3, A1, ···, A12}. Some of the pathways found from available substances to M have higher yield and consequently are cheaper to execute than others; we select the most efficient synthetic route(s) for experimental trial.

There are two major difficulties in the carrying out of the above method for planning a synthesis. The first difficulty is that our memory may fail us when considering how to make an intermediate substance, *e.g.* K3; we may not recall a particularly good reaction that could produce K3 from, let us say, J27.

The second difficulty is much greater. Even when and if we remember all relevant synthetic reactions, the complete set of possible pathways is too enormous for human consideration. Suppose, for example, that we have a molecule as complicated as the anti-biotic aureomycin, and assume there exists at least "some" possible synthetic routes which can produce aureomycin in 20 steps. If we assume that at each step there are five possible ways to produce a given intermediate in one step, then there are not only "some" possible routes but actually there are something like 5^{20} possible routes capable of being carried out experimentally. Some of these routes are grossly inefficient; neglecting then is no loss. But some that we do not consider may be much more efficient than the route that we choose to test experimentally.

Elimination of Bad Pathways

We can improve our performance with the following trick. Let us decide on a cutoff overall yield, *i.e.* an overall yield such that if a given incomplete pathway has a lower overall yield than this cutoff value, then we are no longer interested in further developing this pathway. For example, if the series of reactions that convert K3 to M has an overall yield less than the cutoff overall yield, then we will not concern ourselves with the problem of how to synthesize K3. In other words, we will neglect all pathways through K3. A realistic value for the cutoff overall value yield depends on the difficulty of synthesizing the molecule M, and the selection of this value must utilize the experience of the pharmaceutical companies. 0.2% is perhaps the right order of magnitude for a difficult molecule.

This one trick will eliminate most of the possible pathways. But considering that we are dealing with numbers like 5^{20}, we must neglect still more of the pathways. Let us reluctantly decide that we have only time to consider the most promising pathways. Those incomplete pathways have the maximum promise which have demonstrated the greatest simplification in the molecule at lowest cost in some monetary unit. The units of simplification depend on the increase, in going from the given intermediate to M, in the number of rings, number of functional groups and number of non-hydrogenic atoms. Based on this criterion, simplification/cost, we give each intermediate molecule a score. Using this score, at any given time we can confine our efforts to the intermediate substance which at the moment has the highest score. If K3 has the highest score, *i.e.* the route from K3 to M is more efficient than any other route from an intermediate substance to M so far discovered, then we will obtain all possible parents of K3. Suppose the possible parents of K3 are called J1, J2, J3, and J4, and suppose also that J1, J2, J3, and J4 are all less promising (have a lower score) than K6, which is now the most promising of all the intermediate molecules for which we do not have parent molecules. In this case the next thing to do is to look for all possible parents of K6. In this scheme some molecules will be generated and then never considered again because the routes through them never look as promising as other routes. Finally one must terminate the synthesis planning when a pre-decided number of apparently useful synthetic routes have been produced and/or a pre-decided number of man days have been consumed in the search.

Implementation of the Strategy by a Computer Program

The essence of the foregoing scheme has been programmed and run for a number of cases on a computer. For convenience the program was written in the LISP language. A sample problem solved by the program is shown in Fig. 2.

Cost. The cost of doing the problem of Fig. 2 on an IBM 360/65 Computer in 1971 is the equivalent of about 1800 yen. The actual computer time is about six seconds. This relatively high cost suggests that in the future the program must be translated into the most economical type of computer language, assembly language.

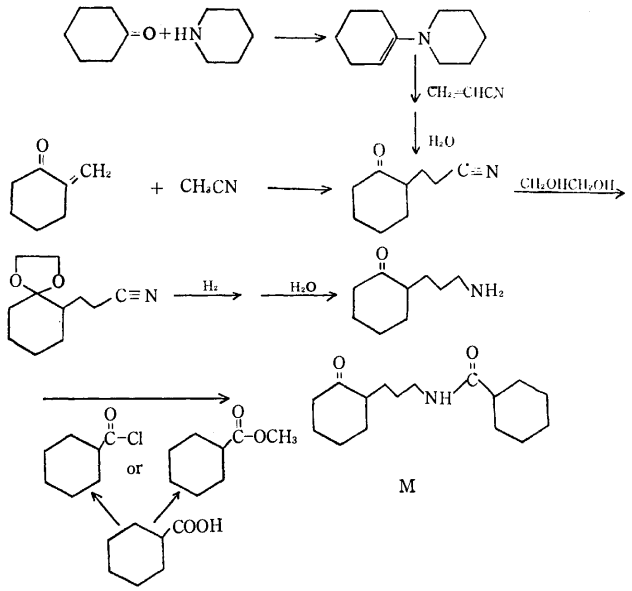

Fig. 2. A sample problem solved by a computer.

Representation of Molecular Structure in a Computer

Three dimensional molecular structures can be represented in the one dimensional memories of computers in a variety of ways. In this section I describe the representation used in this program. Each non-hydrogenic atom is given a name. The name given makes no difference whatsoever provided that no two atoms have the same name. For example, the non-hydrogenic atoms of 1-propanal could be named as follows:

$$\underset{\text{C1}}{CH_3}—\underset{\text{C2}}{CH_2}—\underset{\text{C3}}{CH}=\underset{\text{C4}}{O}$$

The structure of a molecule is representable as a list of sublists. To take the case of 1-propanal, the list is:

```
(C 1 carbon 3 ((C 2 1)       ))
(C 2 carbon 2 ((C 3 1)(C 1 1)))
(C 3 carbon 1 ((C 2 1)(O 4 2)))
(O 4 oxygen 0 ((C 3 2)       ))
```

We use parentheses here to mark the beginning and end of lists and sublists. A program in assembly language does not need this parenthesis notation.

Let us consider the first sublist: (C1 carbon 3 ((C2 1))). The first symbol, C1, is the name of an atom. It is convenient, but certainly not necessary to refer to carbon atoms with a name that begins with C. The second symbol, carbon, is the name of the element of which the atom C1 is an example. The third symbol, 3, is the number of hydrogen atoms bonded to C1. The last item in the sublist is a list of pairs. In this case there is only one such pair, (C2 1). This means that C2 is singly bonded to C1. The pair (C2 3) would mean that C2 is triply bonded to C1. An aro-

matic bond between C1 and C2 would be shown as (C2 0).

The reader will note various redundancies in this representation. It is obvious that since C1 is bonded to only one non-hydrogenic atom, and by a single bond, then C1 must have three attached hydrogen atoms. Hence, if we neglect stable radicals, the number of hydrogen atoms need not be entered. The program could compute this number when needed. I have temporarily taken the view that time is more important than space so the present program stores this redundant number for quick retrieval. Another redundancy may be noted: the sublist for C1 contains the pair (C1 1) which tells us that C2 is singly bonded to C1. The sublist for C2 contains the pair (C1 1), which conveys the same information. In fact all such bonding information is stored in two places. For another example, (O4 2) in the C3 sublist conveys the same information as (C3 2) in the O4 list. Here again, speed of retrieval has been the dominant consideration. Similarly, in a machine or assembly language program it would be simple to recognize the C in C2 and infer that it is a carbon atom. In a higher level language such as LISP, breaking off the alphabetic part of a name from the numerical part consumes computer time.

Let us call this kind of list of sublists a molecular structure list. Since each sublist refers to a particular non-hydrogenic atom, we can call the sublists atomic property lists. We mention in passing that *cis-trans*, chirality, and isotopic labelling information can be added to an atomic property list when necessary.

The reader will find it instructive to write down the Kekule structure, with appropriate labels, corresponding to the following molecular structure list:

```
((C 1 carbon 0 ((C 2 0)(C 6 0)(C 7 1)))
 (C 2 carbon 1 ((C 1 0)(C 3 0)      ))
 (C 3 carbon 1 ((C 2 0)(C 4 0)      ))
 (C 4 carbon 1 ((C 3 0)(C 5 0)      ))
 (C 5 carbon 1 ((C 4 0)(C 6 0)      ))
 (C 6 carbon 1 ((C 5 0)(C 1 0)      ))
 (C 7 carbon 0 ((C 1 1)(O 8 2)(O 9 1)))
 (O 8 oxygen 0 ((C 7 2)             ))
 (O 9 oxygen 1 ((C 7 1)             )))
```

Representation of Chemical Reactions in a Computer

From the above discussion it is apparent that a molecular structure list, which is conveniently one dimensional, can be put into a computer to represent molecular structure unambiguously. Chemical reactions can then be represented in a computer as transformations of these molecular structure lists. The four basic transformations of the program are called ADDH (add a hydrogen atom), REMOVEH (remove a hydrogen atom), MAKEBOND, and BREAKBOND. In addition, changes of chirality or of *cis-trans* arrangement of allylic atoms or of ring junctions are made on the atomic property lists of the parent molecules whenever the reaction concerned requires this.

We define the programming term *subroutine*. A subroutine is a set of instructions inside a program which form a unit and carry out a particular function. The subroutine is given one or more symbols, numbers or structures as input. It produces one or more symbols, numbers or structures as results. These results are then used by the section of the program which called upon the subroutine for answer(s). Typically a subroutine is called upon to produce an answer at several places in a program; hence, it is executed several or many times in the course of running the program, each time with different input. An example from this program is a subroutine called RINGCOUNT which, given the structure list of a molecule as input, returns an integer as answer, telling how many rings the molecule has. Another example is a subroutine CARBON which given the name of an atom as input, states as output (after searching the atomic property list for the second item, the element name) whether it is true or false that the given atom is a carbon atom.

Subroutines that represent chemical reactions always have as one of their inputs the name of a molecule. These subroutines usually begin by making a copy of the molecular structure list of the input molecule. The transformations are then performed on this copy. In this way the structure of the input molecule is always preserved in memory.

The subroutine HYDROGENATE is supplied with the names of two non-hydrogenic atoms as well as the name of the molecule to which the two atoms belong. For each of the two atoms the subroutine calls upon ADDH to increase the number of bonded hydrogens by one. It also changes the number 2 in the atomic property lists into the number 1, unless the two atoms are triply bonded to each other in which case it changes the number 3 to 2 in both of the atomic property lists. (Complete hydrogenation of a triple bond requires the use of this subroutine twice). If the two atoms are aromatically bonded to each other the subroutine HYDROGENATE makes them singly bonded to each other and changes the bonding of the other atoms in the same ring, which are not part of another aromatic ring, from aromatic to double bonding. If the two atoms are not bonded to each other the subroutine sends an error message.

Suppose the program's internal name for 1-propanal is X51. Then the command "HYDROGENATE C3 O4 X51" results in the following new molecular structure list:

```
(C 1 carbon 3 ((C 2 1)      ))
(C 2 carbon 2 ((C 3 1)(C 1 1)))
(C 3 carbon 2 ((C 2 1)(O 4 1)))
(O 4 oxygen 1 ((C 3 1)      ))
```

The program gives this new structure a unique but arbitrary name. DEHYDROGENATE is also given the names of two non-hydrogenic atoms and the name of the molecule to which they belong as input. Thus, if X51 is 1-propanal as before, then the command "DEHYDROGENATE C1 C2 X51" results in the acrolein molecular structure list:

```
(C 1 carbon 2 ((C 2 2)      ))
(C 2 carbon 1 ((C 3 1)(C 1 2)))
(C 3 carbon 1 ((C 2 1)(O 4 2)))
(O 4 oxygen 0 ((C 3 2)      ))
```

This new substance is similarly given some temporary internal name by the program, not any chemical name.

To illustrate the operations MAKEBOND and BREAKBOND, let us consider the case of benzoic acid, whose molecular structure list was given above. We examine the reaction

$$C_6H_5Br \xrightarrow[\substack{2\ CO_2\\3\ H_2O}]{1\ Mg\ or\ Li} C_6H_5CO_2H$$

The program allows this type of reaction only when the product is a monocarboxylic acid. Let us call benzoic acid B1. Let us further introduce a variable Q, which will exist only inside of this subroutine. *Initially* we will set Q equal to B1, that is Q will initially have the same structure as benzoic acid. The structure list of Q will be successively modified by four commands of the subroutine for this type of carboxylation. The end result will be to re-organize the final structure list of Q into the structure lists of the parents of B1.

The first of the four commands is "BREAKBOND C1 C7 Q." The reslut of this first operation is to produce the following modified structure list for Q:

(C 1 carbon 0 ((C 2 0)(C 6 0)))
(C 2 carbon 1 ((C 1 0)(C 3 0)))
(C 3 carbon 1 ((C 2 0)(C 4 0)))
(C 4 carbon 1 ((C 3 0)(C 5 0)))
(C 5 carbon 1 ((C 4 0)(C 6 0)))
(C 6 carbon 1 ((C 5 0)(C 1 0)))
(C 7 carbon 0 ((O 8 2)(O 9 1)))
(O 8 oxygen 0 ((C 7 2)))
(O 9 oxygen 1 ((C 7 1)))

In the atomic property list of C7 the subroutine has removed any reference to C1; in the atomic property list of C1 the reference to C7 has also been removed. In the structure list of Q the bond has now been broken. At the next command in the subroutine "MAKEBOND C1 BR10 Q" the structure list of Q is modified again. The name BR10 is chosen by the program for convenience. After execution of this MAKEBOND command the structure list of Q is:

(C 1 carbon 0 ((BR10 1)(C 2 0)(C 6 0)))
(C 2 carbon 1 ((C 1 0)(C 3 0)))
(C 3 carbon 1 ((C 2 0)(C 4 0)))
(C 4 carbon 1 ((C 3 0)(C 5 0)))
(C 5 carbon 1 ((C 4 0)(C 6 0)))
(C 6 carbon 1 ((C 5 0)(C 1 0)))
(C 7 carbon 0 ((O 8 2)(O 9 1)))
(O 8 oxygen 0 ((C 7 2)))
(O 9 oxygen 1 ((C 7 1)))
(BR10 bromine 0 ((C 7 1)))

We remark in passing that the input to the BREAKBOND subroutine is the names of two atoms followed by the name of the molecule to which they belong; the arguments of the MAKEBOND subroutine, however, are the names of two atoms followed by the name of the molecule to which the *first* mentioned atom belongs. Thus, in the command just discussed, MAKEBOND C1 BR10 Q is correct but MAKEBOND BR10 C1 Q is syntactically incorrect.

For the third command we introduce the variable K which refers to the hydroxyl oxygen of the carboxyl group in question, namely O9, in this case. The execution of the command MAKEBOND C7 K Q results in the following structure list for Q:

(C 1 carbon 0 ((BR10 1)(C 2 0)(C 6 0)))
(C 2 carbon 1 ((C 1 0)(C 3 0)))
(C 3 carbon 1 ((C 2 0)(C 4 0)))
(C 4 carbon 1 ((C 3 0)(C 5 0)))
(C 5 carbon 1 ((C 4 0)(C 6 0)))
(C 6 carbon 1 ((C 5 0)(C 1 0)))
(C 7 carbon 0 ((O 8 2)(O 9 2)))
(O 8 oxygen 0 ((C 7 2)))
(O 9 oxygen 1 ((C 7 2)))
(BR10 bromine 0 ((C 1 1)))

If the inputs to MAKEBOND are atoms which are singly bonded to each other, MAKEBOND adds one more bond, making then doubly bonded.

The last command is "REMOVEH K." This command results in the final structure list for Q:

(C 1 carbon 0 ((BR10 1)(C 2 0)(C 6 0)))
(C 2 carbon 1 ((C 1 0)(C 3 0)))
(C 3 carbon 1 ((C 2 0)(C 4 0)))
(C 4 carbon 1 ((C 3 0)(C 5 0)))
(C 5 carbon 1 ((C 4 0)(C 6 0)))
(C 6 carbon 1 ((C 5 0)(C 1 0)))
(C 7 carbon 0 ((O 8 2)(O 9 2)))
(O 8 carbon 0 ((C 7 2)))
(O 9 carbon 0 ((C 7 2)))
(BR10 bromine 0 ((C 1 1)))

The generation is now complete. After each generation is complete, a subroutine called REORGANIZE is called in to form, out of the changed copy of the original structure list (*i.e.* out of the final structure list for Q), one or more parent structure lists consisting of connected atoms. (In some reactions, like the esterification of a dicarboxylic acid, there are more than two "parent" molecules.) Here the subroutine REORGANIZE finds one group of three connected atoms and another group of seven connected atoms. REORGANIZE then forms two new structure lists, as follows:

I (C 7 carbon 0 ((O 8 2)(O 9 2)))
(O 8 oxygen 0 ((C 7 2)))
(O 9 oxygen 0 ((C 7 2)))

The program does not know that this molecule is called carbon dioxide; it gives it an arbitrary name such as B2. The program does know, as we shall see, that a molecule this small can be considered to be available.

II (C 1 carbon 0 ((BR10 1)(C 2 0)(C 6 0)))
(C 2 carbon 1 ((C 1 0)(C 3 0)))
(C 3 carbon 1 ((C 2 0)(C 4 0)))
(C 4 carbon 1 ((C 3 0)(C 5 0)))
(C 5 carbon 1 ((C 4 0)(C 6 0)))
(C 6 carbon 1 ((C 5 0)(C 1 0)))
(BR10 bromine 1 ((C 1 1)))

This parent, bromobenzene, is given an arbitrary name, such as B3. The names Q and K and L and their associated information are discarded as we exit from the reaction subroutine. REORGANIZE also attaches to the name B3 the names B1 as successor and B2 as coreactant. To the name B1 is attached the name B3 as parent. B2 is formally also a parent but it is not

marked as such by the program, because it is the smaller parent. B2 has attached to it the name B3 as coreactant. To the largest parent, B3, is also attached the name of the reaction, BROMIDECARBOXYLATION, which causes the relationships. Yield information is also inserted at this point. In the present program all the yields supplied by the reaction subroutines are average values from the literature. In future versions of the program subroutines like STERICHINDRANCE (which calculates degree of branching near a site) will be called in to calculate the estimated deviation of the yield from the average yield, so that chemical experience can be fully utilized.

A Generalized Form for Writing the Chemical Transformations of a Reaction Subroutine

In the previous discussion of the reaction BROMIDECARBOXYLATION, the first command given was BREAKBOND C1 C7 Q. Actually this is the content of the command at a comparatively low level. The initial, *i.e.* the highest level version of this command merely says something like BREAKBOND CARBON-NEXT-TO CARBOXYL-CARBON CARBOXYL-CARBON Q. It is left to the detailed operation of the subroutine as it calls in other subroutines to find that C7 is a carboxyl carbon and that C1 is its neighbouring carbon atom. Similarly "MAKEBOND C1 BR10 Q" is originally something equivalent to "MAKEBOND CARBON-NEXT-TO-CARBOXYL-CARBON INVENTED-NAME-FOR-BROMINE-ATOM Q." The command MAKEBOND C7 O9 Q is at the higher level also essentially MAKEBOND CARBOXYL-CARBON HYDROXYL-OXYGEN-NEXT-TO-CARBOXYL-CARBON Q. It is apparent from this that if we just provide a subroutine with the simple $-C-CO_2H$ structure and give directions for converting it to $-C-Br$ and CO_2 then the reaction subroutine can be made more compact. The useful procedure GENREACTION takes as its arguments (inputs) a general "structure," such as $-C-CO_2H$ Br, in the form of a structure list, a list of pairs of atoms in the general structure between which we should break a bond, a list of pairs of atoms of the general structure between which we should make a bond, a list of the atoms of the general structure to which we should add a hydrogen atom and a list of atoms of the general structure from which we should remove a hydrogen atom. Some of these lists may be empty. The output of GENREACTION will be the required predecessor(s).

Thus in the latest version of the program, inside of the BROMIDECARBOXYLATION subroutine is the command

```
GENREACTION (E1 C 0 ((E2.1)))
            (E2 C 0 ((E1.1)(E3.2)(E4.1)))
            (E3 O 0 ((E2.2)))
            (E4 O 1 ((E2.1)))
            (E5 Br 0 nil))
     ((E1.E2)) ((E2.E4) (E1.E5)) nil (E4).
```

In the future the program will be modified to "learn" synthetic reactions at a rapid rate. All this means is that the program will accept input data in the form of: *name of the reaction, model structure list, lists of atom pairs from the model structure list* for BREAKBOND and MAKEBOND, *lists of atoms of the model structure* for ADDH and REMOVEH, *yield, structural conditions* which decrease the yield, *presence of acid, base, oxidizers or reducing agents* among reagents of the reaction. The program will then convert this input data into appropriately named subroutines and add the subroutines to itself permanently. (The new expanded program will be written onto a disk file or punched out onto cards.) The program must also insert the name of the new subroutine into the proper list, *e.g.* carbonyl reactions, so that it will be called when appropriate. It is evident that compact procedures like GENREACTION will be required for this "learning" of chemistry by the program.

Minimizing of Repetition

Hydrogenation and dehydrogenation subroutines are available in the program. In order to prevent a long series consisting of useless alternate addition and removal of hydrogen the dehydrogenation subroutine is defined so that it cannot be used to cancel the effect of an immediately adjacent hydrogenation. At least one other chemical reaction must intervene between a hydrogenation and a dehydrogenation. Similarly hydrolysis may not immediately follow or precede ketal formation or esterification. Also, wherever possible, the temporary attachment and subsequent removal of a blocking, protective, activating or solubilizing group is treated together with the reaction that requires this as a single reaction.

The program indeed performs much useless hydrogenation and dehydrogenation but pathways along which this occurs automatically get a lower score than otherwise identical pathways along which the useless reactions did not occur.

The Operation of the Program

The general operation of the program can be summarized in the following three steps.

1. Put goal molecule on NEWLIST. Examine goal molecule.
2. GENERATEPREDECESSORS of the first molecule on NEWLIST.
3. If NEWLIST is empty then STOP. Otherwise go to Step 2.

Newlist and Oldlist. A list named NEWLIST is maintained which consists of the names of all of the molecules whose predecessors we do not know. There is a corresponding list called OLDLIST which consists of the names of all of the molecules which are not available but for which we have found all possible immediate predecessors.

Beginning of the Program. The program begins by establishing NEWLIST, with a single item on it, *i.e.* the name of the goal molecule M. It then calls in the subroutine EXAMINE to survey the goal molecule,

noting all structural features and combinations of structural feature, *i.e.* relations of functional groups to one another and to rings, etc. A list of these features is attached to the name of the molecule.

Main Part of the Program. In the next step of the program the first item on NEWLIST is subjected to the action of a subroutine called GENERATEPREDECESSORS. This subroutine will be repeatedly called and does the main work of the program. Initially, of course, the first item on NEWLIST is the only item on NEWLIST, *i.e.* the name of the goal molecule. For generality let us call the input molecule to GENERATEPREDECESSORS by the name X. GENERATEPREDECESSORS first decides whether or not it has previously seen this molecule in the solution of this problem. It searches for an isomer of X on OLDLIST. If there are no such isomers we proceed to the next phase. All isomers of X on OLDLIST are subjected to a detailed examination to see if they have exactly the same structure as X. If there is a molecule, *e.g.* by the name of Y, which is on OLDLIST but which has the same structure as X then there must exist two separate pathways from this structure to the goal molecule. The pathway of higher score, *i.e.* greater efficiency, is chosen. The other one is erased from memory. If X is erased we go back to get the first item on NEWLIST and subject it in turn to GENERATEPREDECESSORS etc. If Y is erased we continue with the next phase of GENERATEPREDECESSORS.

Generation Stage. GENERATEPREDECESSORS now collects the list of reactions associated with each structural feature of X. (For example if X has the amide functional group, there are associated with this functional group the list of two reactions: aminolysis of methyl ester and aminolysis of acyl chloride.) For each reaction there is a reaction subroutine which is immediately used to generate the appropriate predecessor(s). An example is the generation of bromobenzene as a predecessor of benzoic acid by the reaction subroutine BROMIDECARBOXYLATION. To take another example, if a certain diene and a dienophile can react in a Diels-Alder reaction to give X then the DIELSALDER reaction subroutine generates the diene and a dienophile structures in response to the input of X. For this to happen the procedure EXAMINE must have found a cyclohexenyl group in X with a -M group just outside of the ring, three atoms away from the nearer of the two vinyl carbons in the ring.

Case Where the Program is Baffled. If no predecessor of X can be generated, *i.e.* the EXAMINE subroutine has failed to detect a feature familiar to it and the program is therefore unable to find an applicable reaction subroutine, then the structure and the arbitrary name of X are printed out together with the question, "How do you make this?"

Disposition of the Predecessors. As soon as each predecessor is generated it is disposed of in some way. Let us call the predecessor Z. There are four cases.

A. If the overall yield from Z to the goal molecule is less than the cutoff value discussed previously then the pathway and yield are printed out together with the comment that the overall yield is inadequate to justify further development of this pathway. Then the pathway is removed from the computer memory, "erased," an absolutely necessary step to preserve unfilled memory space.

B. If Z is available *and* all necessary coreactants on the path to the goal molecule are also either available or can be synthesized by a method now known to the program, then the entire pathway from the available predecessor to the goal molecule is printed out together with the yield of each step, the name of each reaction and the overall yield. The program recognizes as available any molecule which satisfies any one of the following three criteria:

1. It has no more than eight non-hydrogenic atoms.
2. It is an ester or a carboxylic acid, or it has only one heteroatom, and it has nine non-hydrogenic atoms.
3. A molecule with identical structure appears on a list called AVAILABLELIST.

The last criterion is important in practice because very often we have a large number of byproducts of other processes available to us. If the program knows about them much computer time will be saved.

C. If Z is available but on the pathway to the goal molecule there are necessary coreactants which are neither available nor does the program yet have a synthesis for them, then no action is taken in regard to Z. The information that Z is a predecessor of X is permanently attached to the name of X. In this way information about Z can be easily retrieved when and if the entire synthetic route has been generated.

D. If Z is not available and the yield from Z to M is not less than the cutoff value, then Z is put onto NEWLIST. This is the most usual case.

Scoring. Just before being put on NEWLIST the predecessor Z must be scored. In the program at present the cost part of the scoring procedure has not yet been reduced to specific monetary units. It is assumed for the present that cost depends on the overall yield, the number of steps required and the amount of material carried through the route. To illustrate the last point we note that a reaction with a 50% yield followed by a reaction with a 100% yield is cheaper, other things being equal, than a two step sequence consisting of a reaction with a 100% yield followed by a reaction with a 50% yield. The overall yield is the same in both cases but in the first case there is less material carried into the second reaction.

A procedure called SCORE considers all these aspects in calculating a somewhat arbitrary cost. The program knows a yield for each reaction; in some cases this yield depends on the structure of the molecules involved. A monetary cost could also be easily inserted if the necessary chemical engineering data were available.

When there are two or more coreactants generated as predecessors SCORE gives all of them the same score which is that calculated for the largest of the molecules. SCORE calculates the cost expended for the amount of simplification achieved in the largest of the coreactants. The cost is the cost of going from Z to M and the "simplification" is really the number of atoms and

functional groups added in going from Z to M.

Hierarchy of NEWLIST. Each predecessor of X is placed on NEWLIST in a definite position which depends upon its score. All molecules closer to the front of the list than Z must have a score greater or equal to that of Z. All molecules which follow Z on NEWLIST must have a lower score than Z or the same score that Z has. In this way when the program takes the first molecule on NEWLIST for processing by GENERATEPREDECESSORS it is really considering the most promising incomplete pathway.

End of GENERATEPREDECESSORS. When, within the limits of the repertory of reactions of the program, all possible predecessors of X have been generated and suitably placed, the name of X is taken off NEWLIST and placed on OLDLIST.

Table 1.

Cycle[a]	NEWLIST	OLDLIST	Available Molecules Generated
0			
1			
2			3			
4			5			
a) cycle: the number of times the subroutine has been called

Example of the Operation of the Program

In the example of Fig. 2 GENERATEPREDECESSORS was called five times. The result of each application of this subroutine is shown in Table 1. In this case EXAMINE found that M is an amide and hence GENERATEPREDECESSORS calls in the subroutines for acylating an amine with a methyl ester and with an acyl chloride and generates the corresponding amine and methyl ester and acyl chloride. In the next cycle the methyl ester stands at the head of NEWLIST. EXAMINE has found out that it is an ester, hence the reaction subroutine for esterification is called in, and it generates the carboxylic acid and methanol. The carboxylic acid is available hence it is not put on OLDLIST. The CH_2NH_2 functional group is related to the reaction subroutine called HYDROGENATENITRILE. This latter subroutine generates the corresponding nitrile, but recognizes the simultaneous presence of an active carbonyl group that needs to be protected, the ketone group, and a note is included for the final printout that the ketone group must be protected from hydrogenation by a ketal before the reaction is done and that this ketal is to be removed after the reaction is finished. EXAMINE has seen that in the nitrile there are exactly three saturated carbons between two -M groups and hence an alpha-beta addition is suggested. The corresponding subroutine is quite complicated since it generates cyclohexanone and acrylonitrile which can react *via* the Stork enamine reaction[1] to obtain the nitrile. The subroutine also generates acetonitrile and α-methylenecyclohexanone. In one case a ketone adds across the double bond of an unsaturated nitrile; in the other case a nitrile adds across the double bond of an unsaturated ketone. A note is added in the case of the enamine reaction that the enamine must be prepared first. The yield is also different in the two similar reactions. Since all of the predecessors are available the synthesis of M can be effected in an overall yield of 58%, or 51% depending on the pathway. The successful pathways are printed out.

In the fifth and final cycle of GENERATEPREDECESSORS, cyclohexane carboxylic acid is generated, as the predecessor of the corresponding acyl chloride.

The reader will note that there was no attempt to generate a secondary alcohol, *i.e.* to synthesize the ketone from a secondary alcohol. The reason is that since we do not wish to oxidize alcohols indiscriminately, the exact conditions under which we want to do this should be specified in the routine. At the time of running of this example I had not yet thought out the matter to completion, hence the alcohol oxidation reaction subroutine had not yet been written. (The conclusion now reached is that it is perfectly satisfactory to oxidize any alcohol to the corresponding aldehyde or ketone, provided that the next reaction step is not hydrogenation of the aldehyde or ketone.)

Conslusion

Computing synthetic pathways is now possible without human intervention at any intermediate stage. The process is expensive, however, and only when it is made cheap will a computer program become indispensable to the synthetic chemist.

Studies on Stable Free Radicals. IX.[1] Peroxy Acid Oxidation of Hindered Secondary Amines to Nitroxide Radicals

Toshimasa TODA, Eiko MORI, and Keisuke MURAYAMA

Central Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo

(Received August 21, 1971)

The hindered secondary amines, 2,2,6,6-tetramethyl-4-oxopiperidine (II) and 1,9-diaza-2,2,8,8,10,10-hexamethyl-4-oxo-spiro[5.5]undecane (VI), were oxidized with *m*-chloroperbenzoic acid, and the corresponding hydroxylamine (III) and *N*-oxyl-hydroxylamine (VIII), respectively, were isolated. The further oxidation of III and VIII with the peracid afforded the corresponding nitroxide radical IV and IX, in good yields respectively. The stoichiometry of the oxidation reaction of the hydroxylamine III to the nitroxide radical IV was elucidated on the basis of the ESR signal intensities of oxidation products at various molar ratios with the peracid and III. An ESR study of the 1-^{15}N-labelled *N*-oxyl-hydroxylamine (XII) indicated that there was an intramolecular hydrogen transfer between >N–OH and >N–O· groups in the *N*-oxyl-hydroxylamines VIII and XII.

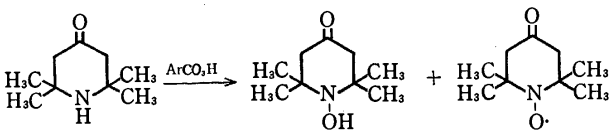
The peracid oxidation of organic molecules in a solution are known to proceed *via* heterolytic[2] or homolytic[3] processes. Organic peracids have been found to be good reagents for the oxidation of hindered secondary amines to the corresponding nitroxide radicals.[4,5] Recently, Duynstee and his co-workers[6] studied the oxidation of a hindered secondary amine (I) with perbenzoic acid to the corresponding nitroxide radical and suggested that the reaction proceeds through the corresponding hydroxylamine, although no hydroxylamine intermediate was isolated.

(I)

In the present work, we isolated the intermediate hydroxyl-amine (III) and *N*-oxyl-hydroxylamine (VIII) in the oxidation of 2,2,6,6-tetramethyl-4-oxopiperidine (triacetonamine) (II) and 1,9-diaza-2,2,8,8,10,10-hexamethyl-4-oxo-spiro[5.5]undecane (pentacetonediamine) (VI)[7] with *m*-chloroperbenzoic acid respectively, and found that when the *N*-oxyl-hydroxylamine VIII resulted, there was an intramolecular hydrogen transfer between the >N–OH and >N–O· groups.

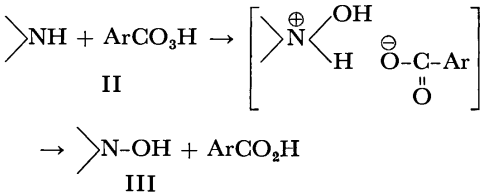
Results and Discussion

Oxidation of Triacetonamine (II). The reaction of the amine II with 1 mol-equivalent of *m*-chloroperbenzoic acid in chloroform at room temperature afforded 1-hydroxy-2,2,6,6-tetramethyl-4-oxopiperidine (III) (40.7%), the corresponding nitroxide radical (IV) (30.3%), and some unchanged amine II (16.0%).



(II) (III) (IV)

Using 2 mol-equivalents of the peracid under the same reaction conditions, the amine II formed the nitroxide radical IV in good yield (91.0%). The formation of the hydroxylamine III must be due to a nucleophilic attack of the amine II on a hydroxy group of the peracid, by analogy to the oxidation of aniline with the peracid to phenylhydroxylamine.[8]



The further oxidation of the hydroxylamine III with 1 mol-equivalent of the peracid gave the nitroxide radical IV quantitatively. We attempted to follow this peracid oxidation process of the hydroxylamine III to the nitroxide radical IV in detail. Attempts to titrate the remaining peracid in the reaction mixture by means of iodometry were unsuccessful, since the nitroxide radical formed also liberated iodine from potassium iodide. Therefore, we estimated the yield of the nitroxide radical IV by comparing its ESR signal intensities with those of a standard sample IV. Table 1 summarizes the results of this estimation and proves the stoichiometry of this oxidation reaction to be as follows:

$$2\,\rangle\text{N–OH} + \text{ArCO}_3\text{H} \rightarrow 2\,\rangle\text{N–O}\cdot + \text{ArCO}_2\text{H} + \text{H}_2\text{O}.$$

This shows that the yield of the nitroxide radical IV is not affected by the addition of an efficient radical scavenger, 1,3,5-trinitrobenzene.[9] Moreover, in the oxidation reaction, the coupled product[10] of the

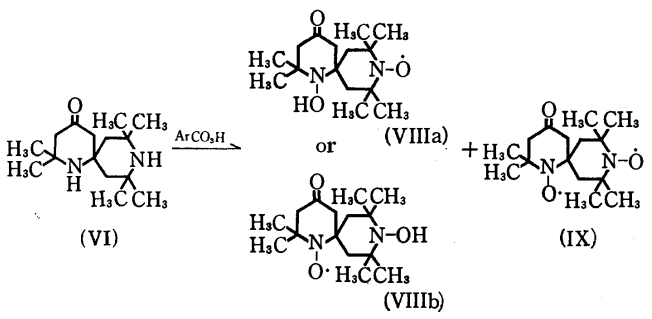
Table 1. Stoichiometry of the reaction of the hydroxylamine III with the peracid in benzene

Molar concentration × 10^3		
Solution[a]		Nitroxide radical (IV)[b,c]
Hydroxylamine	Peracid	
3	4	3
3	3	3
3[d]	3	3
3	1.5	3
3[d]	1.5	3
3	1	2[e]

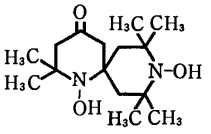
a) A solution of the hydroxylamine III (5 m*l*, 6×10^{-3} M) and a solution of the peracid were combined to 10 m*l* total volume.
b) Measurements were carried out in the same sample tube under the same conditions after 100 sec reaction time at room temperature.
c) The ESR signal intensities were compared with those of the pure nitroxide radical IV in the same sample tube under the same conditions.
d) 1,3,5-Trinitrobenzene (50 mg) was added. The ESR signal intensity of the pure nitroxide radical IV itself in solution was not influenced by an addition of 1,3,5-trinitrobenzene.
e) The ESR signal intensity did not increased after an additional 1 hr reaction time.

free radical IV with a phenyl radical arising from the peracid was not found, and no evolution of carbon dioxide was observed. From these results, this oxidation reaction is presumed to proceed through an ionic process[11], but we have no conclusive proof for this reaction mechanism.

Oxidation of Pentacetonediamine (VI). The similar treatment of pentacetonediamine (VI) with *m*-chloroperbenzoic acid in chloroform afforded two products melting at 113°C (A) and at 145°C (B). The product A was identified as 1,9-diaza-2,2,8,8,-10,10-hexamethyl-4-oxo-spiro[5.5]undecane-1,9-dioxyl



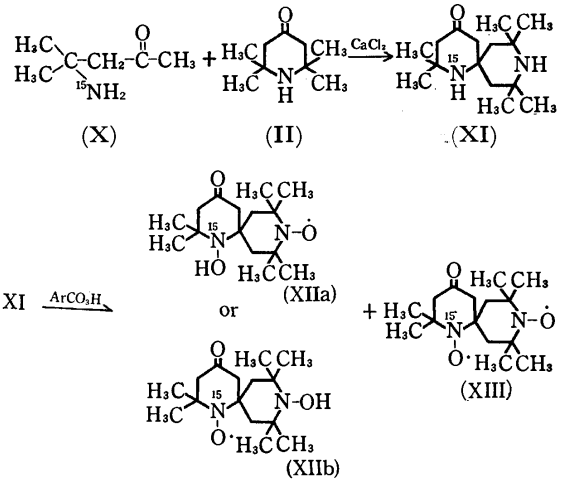
(IX) by elementary analysis and by an IR spectral comparison with an authentic sample.[7] The product B was formulated as $C_{15}H_{27}O_3N_2$ and shown to be a *N*-oxyl-hydroxylamine (VIIIa) or (VIIIb) by its spectral data (mass, IR, and ESR). No other possible intermediary products including dihydroxylamine (VII) were obtained under the present reaction conditions. As in the case of the hydroxylamine III, the further peracid oxidation of VIII gave the nitroxide biradical IX in a good yield.



(VII)

In order to determine the structure of VIII, the following isotope-labelling experiments were carried out.

The 1-^{15}N-labelled pentacetonediamine (XI) was prepared by the reaction of 4-amino(^{15}N)-4-methyl-pentan-2-one (X) with II and then, submitted to peracid oxidation to give a biradical (XIII) and a *N*-oxyl-hydroxylamine compound (XIIa or XIIb).



The structure of *N*-oxyl-hydroxylamine XII may be determined by the ESR measurements, since triplet lines due to the interaction with the ^{14}N-nucleus can be expected for the structure XIIa, while doublet lines due to the interaction of the ^{15}N-nucleus can be expected for the structure XIIb. The ESR spectrum of the product XII (Fig. 1) showed five lines, suggesting the existence of mixture of these isomers XIIa and XIIb, but the intensity of the doublet lines (due to ^{15}N-nucleus) increased at higher temperatures and decreased at lower temperatures reversibly. This suggests the existence of an equilibrium between XIIa and XIIb in solution; such as equilibrium may result from an intramolecular hydrogen exchange between >N–OH and >N–O· groups in a solution of a 10^{-4} M concentration. The equilibrium constants were obtained from the ratio of the area of triplet lines to that of doublet lines at various temperatures; they are plotted to determine the equilibrium enthalpy and entropy in Fig. 2.

Since the difference in the structures of the two isomers is very small, the small enthalpy and entropy values seem to be reasonable. The molecular model of VIII indicates that the >N–OH and >N–O· groups can approach each other closely when one

11) Blackly and Reinhard [*J. Amer. Chem. Soc.*, **87**, 802 (1965)] have reported that bis(trifluoromethyl)nitroxide radicals exist in equilibrium wtith its dimer in $CFCl_3$:
$2(CF_3)_2N\text{-}O\cdot \rightleftarrows (CF_3)_2N\text{-}O\text{-}O\text{-}N(CF_3)_2$.
In this oxidation process, homolysis of the peroxide (V) might be involved: >N-O-O-N< (V) ⟶ 2 >N-O· (IV).

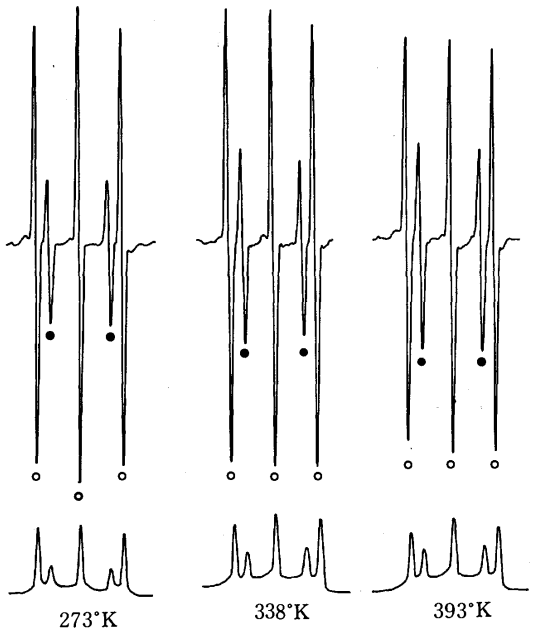


Fig. 1. ESR spectra of XII in toluene at 10^{-4} M concentration.
In the bottom half of the figure are given the integrated spectra: ○ triplet lines due to ^{14}N nucleus ($a_{^{14}N}=15.2$ G).
● doublet lines due to ^{15}N nucleus ($a_{^{15}N}=23.3$ G).

$\Delta H_0=-1.09$ kcal/mol
$\Delta S=0.253$ e.u.

piperidine ring is twisted[12] and the other piperidine ring is in a chair form,[13] and *vice versa*. Therefore, it may be considered that such an intramolecular transfer of a hydrogen between >N–OH and >N–O· groups in VIII is possible and that the structure VIIIa is a predominant isomer at ordinary temperatures; these conclusions are based on the results of the ESR measurement of XII at various temperatures.

Recently, Poindexter and Glazer[14] have suggested, on the basis of studies of dynamic nuclear polarizability, that a nitroxide radical III and dimethyl phosphite form a transient hydrogen bond between P–H and ·O–N<. Our results concerned the intramolecular hydrogen exchange also suggest the formation of a transient hydrogen bond between >N–OH and >N–O· groups in the transition state.

It has been reported[6,15] that the mass spectra of stable nitroxide radicals exhibit a characteristic peak corresponding to $(M+1)^+$ in addition to the molecular ion peak; the $(M+1)^+$ peak was assigned to hydroxylamine formed by the hydrogen abstraction of the nitroxide radical from water or the free radical compound. In VIII, a prominent $(M+1)^+$ peak was observed, as is shown in Fig. 3, but the mass spectrum

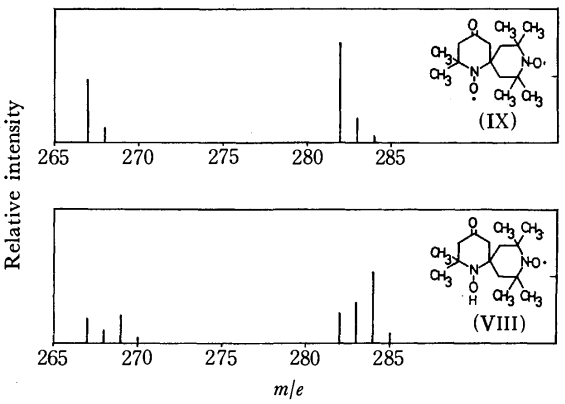

Fig. 3. Mass spectra of VIIIa and IX.

of the biradical IX did not show such a characteristic $(M+1)^+$ peak. This suggests that a hydrogen of the hydroxy group in VIII may be easily abstracted to give the dihydroxylamine VII and the biradical IX in a mass spectrometer.

Experimental

The melting points are uncorrected. The IR spectra were determined by means of Nujol mulls or liquid films. The mass spectra were obtained using a JEOL-JMS-OIS mass spectrometer at 75 eV. The ESR spectra were recorded using a Hitachi MES 4001 spectrometer employing 100 kc modulation at X-band in conjunction with a Hitachi MES 4701 thermo controller, the sample temperature being measured with a copper-constantan thermocouple. The integrated curves were obtained using a Hitachi 4703 integrator. The splitting constants and g-values were measured relative to the aqueous solution of Fremy's salt.

m-Chloroperbenzoic Acid. The commercially-available *m*-chloroperbenzoic acid (PBA) used here had a purity of 85.5%, as determined by iodometric analysis.

Oxidation of 2,2,6,6-Tetramethyl-4-oxopiperidine (II). a): A solution of 8.1 g (40 mmol) of PBA in 60 m*l* of chloroform was slowly stirred into a solution of 6.2 g (40 mmol) of 2,2,6,6-tetramethyl-4-oxopiperidine (II) in 50 m*l* of chloroform at ice-water-bath temperature. The solu-

tion was allowed to stand for an additional 24 hr at room temperature. Then, the solution was washed with 100 ml of aqueous sodium hydroxide (40%), dried over potassium carbonate, and freed of the solvent by evaporation under reduced pressure. The oily residue (6.0 g) was chromatographed on a column of aluminum oxide, and the column was eluted successively with petroleum ether, benzene, and methanol.

1). From petroleum ether eluates, 1.0 g (16.0%) of II was recovered. Confirmation was done by means of an IR spectral comparison with the starting material.

2). From benzene eluates, 2.1 g (30.3%) of 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxyl (IV) was obtained. It was identified by a comparison of the melting point (36°C) and the IR and ESR spectra with those of an authentic sample.[7]

3). From methanol eluates, 2.8 g (40.7%) of 1-hydroxy-2,2,6,6-tetramethyl-4-oxopiperidine (III) was isolated; it was identified by comparing its melting point (mp 90—91°C) and IR spectrum with those of an authentic sample.[10] Found: C, 63.06; H, 10.01; N, 8.18%. Calcd for $C_9H_{17}O_2N$: C, 63.13; H, 10.00; N, 8.18%.

b): In a way similar to that described above, the reaction of 6.2 g (40 mmol) of II with 16.2 g (80 mmol) of PBA in chloroform gave 6.3 g of an oily residue. By column chromatography on aluminum oxide, 6.2 g (91.0%) of IV was obtained. It was identified by means of its melting point (mp 36°C), and IR and ESR spectra.

Oxidation of 1-Hydroxy-2,2,6,6-tetramethyl-4-oxopiperidine (III). The reactions described below were carried out under a nitrogen atmosphere, leading to a trap filled with an aqueous barium hydroxide solution.

a): A solution of 1.0 g (5 mmol) of PBA in 60 ml of chloroform was stirred into a solution of 1.7 g (10 mmol) of III in 40 ml of chloroform at room temperature. The solution was then stirred for an additional 3 hr at room temperature.

At this point, the yield of IV was 67%, as was determined by comparing the ESR signal intensity of the reaction mixture with that of the standard sample IV in chloroform. Then, the solution was washed with 40 ml of aqueous sodium hydroxide (40%), dried over potassium carbonate, and evaporated under vacuum. The resulting oil was chromatographed on a column of aluminum oxide. The benzene eluates afforded 1.1 g (64.6%) of IV, and the methanol eluates gave 0.2 g (11.7%) of the unchanged starting hydroxylamine III. These compounds were identified by a comparison of the IR spectra and the melting points with those of the respective authentic samples.

b): A solution of 1.0 g (5 mmol) of PBA in 60 ml of benzene was stirred into a solution of 1.7 g (10 mmol) of III in 40 ml of benzene at room temperature. The solution was then stirred for an additional 1.5 hr at room temperature. At this point, the yield of IV was 100%, as was determined by comparing the ESR signal intensity of the reaction mixture with that of the standard sample IV in benzene. The column chromatography of the oily material obtained in a a way similar to that described above gave 1.3 g (75.0%) of IV. In these reactions a) and b), no detectable precipitates of barium carbonate were observed in the trap.

Oxidation of 1,9-Diaza-2,2,8,8,10,10-hexamethyl-4-oxo-spiro[5.5]undecane (VI).[7] A solution of 6.1 g (30 mmol) of PBA in 60 ml of chloroform was added to a stirred solution of 2.5 g (10 mmol) of VI in 50 ml of chloroform under ice-water cooling and the solution was stirred for an additional 15 min under ice-water cooling. The solution was washed with 70 ml of aqueous sodium hydroxide (40%), dried over potassium carbonate, and evaporated under vacuum. The resulting oil solidified upon the addition of petroleum ether and 1.6 g of the crystalline solid was separated by filtration. This crude material was dissolved in 5 ml of benzene and placed onto a column of aluminum oxide. The column was eluted successively with petroleum ether, benzene, and methanol. The benzene eluates afforded 0.8 g (28.4%) of 1,9-diaza-2,2,8,8,10,10-hexamethyl-4-oxo-spiro[5.5]-undecane-1,9-dioxyl (IX). Recrystallization from petroleum benzine gave a pure sample; mp 112—113°C. Found: C, 63.81; H, 9.35; N, 10.04%. Calcd for $C_{15}H_{26}O_3N_2$: C, 63.80; H, 9.28; N, 9.92%. IR (cm^{-1}): $\nu_{C=O}$ 1728. From the methanol eluates, 0.6 g (21.2%) of 1,9-diaza-1-hydroxy-2,2,8,8,10,10-hexamethyl-4-oxo-spiro[5.5]undecane-9-oxyl (VIIIa) was obtained. By the recrystallization of the crude material from cyclohexane, an analytically pure sample was obtained; mp 145—146°C. Found: C, 63.58; H, 9.60; N, 9.76%. Calcd for $C_{15}H_{27}O_3N_2$: C, 63.57; H, 9.60; N, 9.88%. IR (cm^{-1}): $\nu_{C=O}$ 1728, ν_{OH} 3400. ESR (in toluene): $a_N=15.0\pm0.1$ gauss. $g=2.0060\pm0.0001$.

Oxidation of 1,9-Diaza-1-hydroxy-2,2,8,8,10,10-hexamethyl-4-oxo-spiro[5.5]undecane-9-oxyl (VIIIa). A solution of 1.2 g (6 mmol) of PBA in 20 ml of benzene was stirred into a solution of 1.7 g (6 mmol) of VIIIa in 20 ml of benzene at room temperature, after which the solution was stirred for an additional 3 hr at room temperature. The solution was then treated by a procedure similar to that described above, and the resulting oil was chromatographed on a column of aluminum oxide. The benzene eluates afforded 1.3 g (71.5%) of IX, which was identified by comparing its melting point (mp 112—113°C) and IR spectrum with those of an authentic sample.

Oxidation of 1,9-Diaza(1-^{15}N)-2,2,8,8,10,10-hexamethyl-4-oxo-spiro[5.5]undecane (XI). Similarly as described above, 1.0 g of the crystalline solid was obtained from 2.5 g (10 mmol) of XI. By means of column chromatography, from 1.0 g of the crystalline solid, 0.35 g (12.7%) of XIII and 0.65 g (23.0%) of XIIa were obtained. Pure samples were obtained by recrystallization. XIII : mp 112—113°C (from petroleum benzine). XIIa : mp 145—146°C (from cyclohexane), ESR (in toluene): $a_{^{14}N}=15.2\pm0.1$ gauss. $a_{^{15}N}=23.3\pm0.1$ gauss. $g=2.0056\pm0.0001$.

Synthesis of 2-Amino-^{15}N-2-methylpentan-4-one (X). To a stirred solution of 14.1 g (0.26 mol) of ammonium chloride-^{15}N (90% ^{15}N contents)[16] and 14.6 g (0.26 mmol) of potassium hydroxide in 50 ml of water at room temperature was added 14.7 g (0.15 mol) of mesityl oxide. The solution was then stirred continuously for 18 hr at room temperature, after which 10.0 g of potassium carbonate was added into the stirred solution at 0—5°C. An oil separated and was extracted into 100 ml of ether, dried over potassium carbonate, and evaporated under reduced pressure. The resulting oil was distilled to give X; bp 55—58°C/15 mmHg; yield, 10.8 g (62.1%). IR (cm^{-1}): $\nu_{C=O}$ 1760, ν_{NH} 3550, 3360 and 3280.

Synthesis of 1,9-Diaza(1-^{15}N)-2,2,8,8,10,10-hexamethyl-4-oxo-spiro[5.5]undecane (XI). By the reaction of 10.8 g (94 mmol) of X and 8.3 g (54 mmol) of II with calcium chloride (0.3 g), 4.6 g (50.0%) of XI was obtained in the same way as has been reported previously.[7] The recrystallization from cyclohexane gave an analytically pure sample; mp 91—95°C (This mp corresponds to that of the monohydrate of XI). Found: C, 66.31; H, 11.12; N, 10.85%.

The Preparation and General Properties of Ion-exchange Carbon Fiber

Sugio OTANI, Masao TAMURA, Yatsuo YOSHIDA, and Yoshio TSUJI

Faculty of Technology, Gunma University, Kiryu, Gunma

(Received November 17, 1971)

Cation-exchange carbon fibers were prepared from pitch-based carbon fiber by oxidizing treatment with a mixture of $K_2Cr_2O_7$, HNO_3, and water. Their most characteristic properties were a large electric conductivity, a large thermal stability, and their shape. Their exchanging properties varied with the composition of the mixture and the treating conditions. The following composition and the conditions were adopted as standard.

Composition of the mixture: $K_2Cr_2O_7$, 10 g; HNO_3, 20 m*l*; H_2O, 80 m*l*

Condition of the treatment: temperature, 104°C; period, 2.5 hr

Amount of carbon fiber: carbon fiber prepared at 1000°C 1 g

The cation-exchange capacity obtained by the standard procedure was 2.0 ± 0.1 mequiv/g. Carbon fiber prepared at 1000°C was a better material than that prepared at 2000°C. Even after the exchangers were heated at 220°C in air, no change was observed in the capacity measured at room temperature. The electric resistivity increased from 7×10^{-3} ohm-cm to 8×10^{-2} ohm-cm with an increase in the capacity, and no difference was obserbed between exchangers of the acidic form and the sodium form. The tensile strength of the filament(1.9 mequiv/g in the capacity) was 6.7×10^{6} g/cm^2, and the breaking load of the spinning yarn of 1300 den. (2.0 mequiv./g) was 3.0 kg.

A number of investigations have been carried out on the preparation of high-modulus or high-strength carbon fibers and their applications. On the other hand, it seems that little attention has been paid to improving the application of low-modulus carbon fibers. However, we thought that the application of the low-modulus carbon fibers should also be developed as fully as possible. The present paper will, then, deal with ion-exchange carbon fibers prepared from low-modulus carbon fibers.

As compared with other ion-exchangers, the ion-exchange carbon fibers are characterized by their electric conductivity, their thermal stability, and their flexibility. Ion-exchange carbon fibers were prepared by oxidation. For the purpose of the surface treatment of high-modulus carbon fibers, the oxidation of carbon fibers has been attempted by various manners.[1] However, the ion-exchange capacity of the resulting carbon fibers is only less than 0.02 milliequivalents per gram. Therefore, the previous manners are not very good for preparing ion-exchangers.

On the other hand, some attempts have been reported to prepare the ion-exchangers by sulfonation from such carbonaceous materials as coal or char.[2,3] Sulfonation is effective for carbonaceous materials which contain same hydrogen atoms, but it does not give satisfactory results for carbon fibers practically composed only of carbon atoms.

After several preliminary examinations, it has been found that oxidizing treatment with a mixture of $K_2Cr_2O_7$, HNO_3 and water is a promising method for the preparation of ion-exchange carbon fiber without any intensive deterioration of its mechanical properties.

Experimental and Results

Preparation. The present ion-exchangers were prepared by the procedure shown in Fig. 1. This procedure is characterized by the use of a mixture of nitric acid, potassium dichromate, and water, and

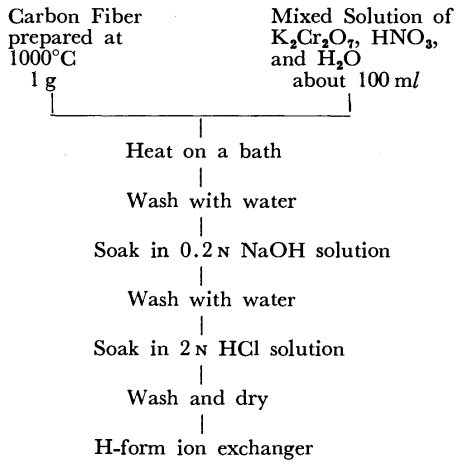

Fig. 1. Procedure of preparation.

1) D. W. McKee and V. J. Mimeault, General Electric Technical Information Series ICMT JUSE No 1/4, Nov., 6, 1970.
2) M. Roy, *J. Appl. Chem.*, **6**, 335 (1956).

by the use of carbon fibers prepared at 1000°C from pitch material. The cation-exchange capacity of the resulting exchangers was affected by several conditions, for example, the composition of the mixed solution, the oxidizing temperature, and the period. In this work, most of the cation-exchange capacities have been measured with sodium ions. Therefore, the cation-exchange capacity will be represented by the exchange capacity with sodium ions. Unless otherwise stated, the measurement of the capacity was carried out as follows: about 1 g of the exchangers, weighed exactly, was allowed to stand in a 0.2 N NaOH solution for 24 hours, and then the decrease in alkali was determined by titration with hydrochloric acid. Figure 2 shows the relationship between the composition of the mixed solution and the exchange

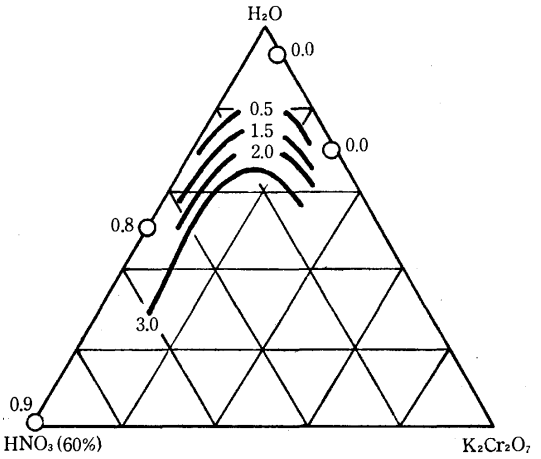

Fig. 2. Relationship between the composition of the mixed solution and the exchange capacity of the resulting fibers.

capacity of the fibers finally obtained. The numbers in Fig. 2 represent the capacity. In this experiment, the weight of the original carbon fibers used was about 1 g, the oxidizing temperature was 104°C, and the oxidizing period was 2.5 hr. By the use of mixtures having compositions lower than the line denoted by 3.0, capacities larger than 3.0 mequiv/g were obtained. However, those fibers were remarkably weak in tensile strength, and some soluble matters were formes in an alkaline solution. Therefore, the composition and the conditions shown in Table 1 were adopted as standard. This standard procedure gave the exchange capacity of 2.0±0.1 mequiv/g.

Table 1. Standard composition and conditions

Composition of the treating mixture	HNO_3	20 m*l*
	$K_2Cr_2O_7$	10 g
	H_2O	80 m*l*

period	2.5 hr	
Amount of carbon fiber		
Carbon fiber prepared at 1000°C		1 g

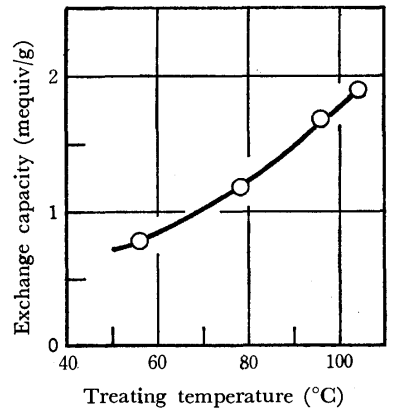

Fig. 3. Effect of the treating temperature. (Other treating conditions and composition of the mixture were the same as those of the standard procedure shown in Table 1.)

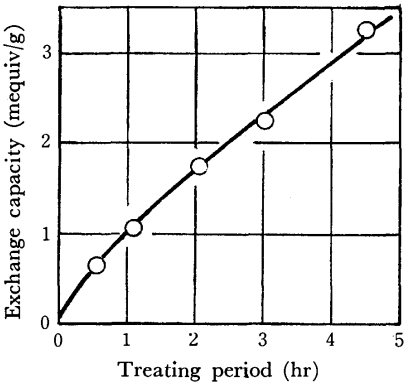

Fig. 4. Effect of the treating period. (Other treating conditions and composition of the mixture were the same as those of the standard procedure shown in Table 1.

Figures 3 and 4 show the effects of the oxidizing temperature and the oxidizing period respectively. These results indicate that it was possible to control the capacity of the fibrous exchangers by selecting well the composition of the mixed solution, the oxidizing temperature, and the oxidizing period.

Chemical Composition and Structure. The chemical composition and infrared spectrum of a typical ion-exchanger having a capacity of 2.0 mequiv/g are shown in Table 2 and Fig. 5 respectively.

The original carbon fiber had, before treatment, a carbon content of 99.2 wt%, and it had no characteristic absorption band in its infrared spectrum. By

Table 2. Chemical composition of ion exchange carbon fiber

TABLE 3. CHANGES OF d_{002} AND L_c BY THE OXIDIZING TREATMENT

State	Original	Exchanger	
		H-form	Na-form
Inter-layer distance	3.7_7	3.6_7	3.6_3
Crystalline thickness	17	19	18

the oxidizing treatment, the weight of the fiber increased by about 10% in the case of preparing a fibrous exchanger with a capacity of 2.0 mequiv/g. The resulting ion-exchange carbon fiber was very hydroscopic and was found to take up water of about 10 wt% upon exposure to the atmosphere. Its infrared spectrum indicates that some carbonyl and hydroxyl groups were introduced by the treatment.

In order to get some information on the structural changes upon treatment, the powdered samples were used for X-ray diffraction analysis. X-ray diffraction profiles of the original and the treated carbon fibers were composed of (002) and (10) diffraction bands. The two bands were very broad in all cases. The structural parameters of the original one, calculated from the (002) diffraction band, were 3.7_7 Å in inter-layer distance, d_{002}, and 17 Å in the crystalline thickness, L_c. By the oxidizing treatment, the (10) band was weakened to some extent, and the inter-layer distance was decreased slightly, as is shown in Table 3. On the basis of these data, it seems that the structure was not affected very much by the oxidizing treatment.

Exchanging Properties. The first examination of the exchanging properties consisted of measuring the variation in the exchange capacity upon a repetition of the cycle of exchanging and regenerating. The H-form carbon fiber was allowed to stand in a 0.2 N NaOH solution for one day to measure the exchange capacity, and then the resulting carbon fiber-(Na-form fiber) was regenerated with the 0.2 N HCl

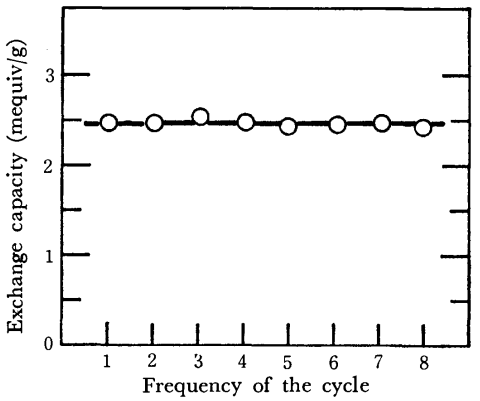

Fig. 6. Variation of the capacity by repeating the cycle of exchanging and regenerating.

solution over a one-day period. The exchange capacity of the regenerated H-form fiber was again measured by the above method, and then the cycles of the exchanging and regenerating were repeated. As is shown in Fig. 6, even after the cycles had been repeated 8 times, the exchange capacity remained at the same value as that of the original exchanger.

In order to determine the exchanging rate, a 50-m*l* portion of the 0.2 N NaOH solution was placed in each of 7 flasks, and one gram of the H-form exchanger was taken into each alkaline solutions, then the decreases in alkali after 5, 10, 15, 20, 30, 40, and 50 min were determined by titration with the 0.2 N HCl solution. The results are shown in Fig. 7. Two curves, (1) and (2), were obtained for the present ion exchangers, while curve (3) was that of a weakly acidic exchange resin obtained commercially. The value of 100% exchange was considered to be reached at the end of 2 days.

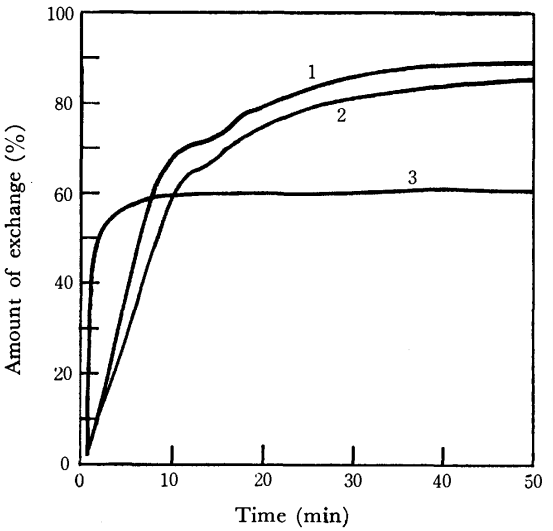

Fig. 7. Rate of ion exchange
1) exchange carbon fiber, 2.1 mequiv/g in the capacity
2) exchange carbon fiber, 1.9 mequiv/g in the capacity
3) weakly acidic exchange resin (as control)

When one gram of the exchange carbon fiber in 100 m*l* of distilled water was titrated with the 0.2 N NaOH solution, the pH of the solution varied as is shown in Fig. 8. The curve (a) is the result of a blank

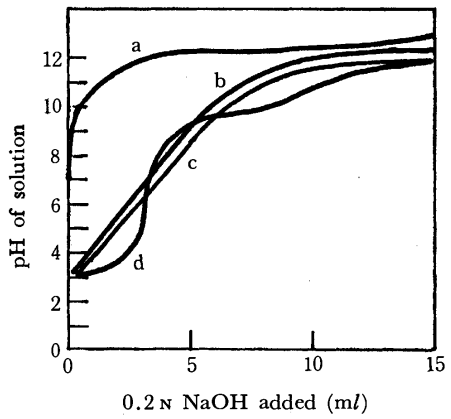

Fig. 8. Titration curves with NaOH solution.
a) pure water (blank test)
b) exchange carbon fiber, 2.1 mequiv/g in the capacity
c) exchange carbon fiber, 3.5 mequiv/g in the capacity
d) mixture of strongly acidic and weakly acidic exchange resins (as control)

test with distilled water alone, while curve (d) is that on a mixture of strongly acidic and weakly acidic exchangers obtained commercially. The titration curves of the present carbon fibers gradually rose from 3 to 12 in pH value.

Figure 9 shows the thermal stability of the present ion-exchange carbon fiber. After heating in air for one hour, the ion-exchange capacity was measured at room temperature. Until the heating temperature was over 220°C, no change was observed in the capacity, at 320°C, the capacity decreased by 20%.

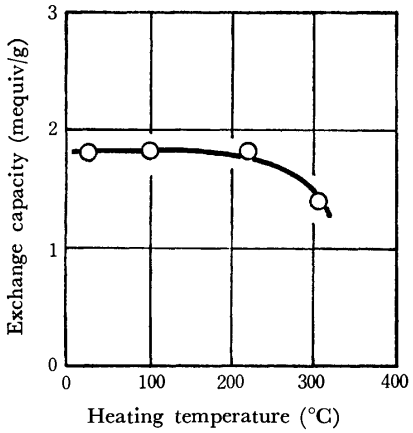

Fig. 9. Change of the exchange capacity after heating in air for one hour.

The effect of the exchanging temperature is shown in Fig. 10. Since the experimental error was about ±0.1 mequiv/g, it seems that an increase in the exchanging temperature up to 100°C caused scarcely no change in the capacity.

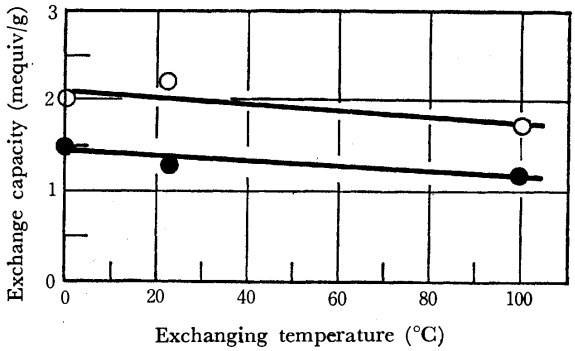

Fig. 10. Effect of the exchanging temperature.

Electric and Mechanical properties. The electric resistivity of the present exchangers is shown in Fig. 11. The measurement was carried out at room temperature by the use of the Universal Bridge TF 1313A made by Marconi Instrument, Ltd. As is shown in Fig. 11, the electric resistivity increased with the increase in the capacity, and no difference was observed between the H-form and the Na-form.

The mechanical properties of a typical ion-exchanger

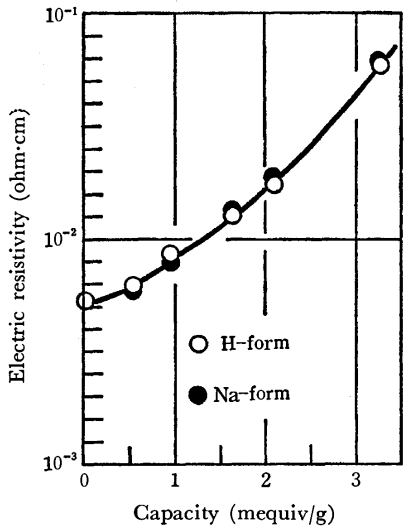

Fig. 11. Relationship between elecctric resistivity and the ion exchange capacity.

Table 4. Mechanical properties of the original and the ion exchange carbon fiber

Sample	Tensile strength ($\times 10^6$ g/cm^2)	Breaking load (Kg)	Elongation (%)	Young's modulus ($\times 10^6$ g/cm^2)
Filament				
original	8.7	—	2.1	420
ion exchanger (1.9 mequiv/g)	6.7	—	2.5	260
Spinning yarn (1300 den.)				
original	—	4.0	—	—
ion exchanger (2.0 mequiv/g)	—	3.0	—	—

are shown in Table 4. The tensile strength decreased by 20% as compared with that of the original carbon fiber, and Young's modulus decreased by 33%. When the graphite fiber prepared at 2000°C was used as the original fiber in the standard procedure, the resulting fibrous exchanger had a tensile strength of only one half of these values and an exchange capacity of less than one third. Carbon fiber heated at 1000°C was a much better material for the exchanger than that prepared at 2000°C.

Discussion

From the results presented above, it has been found that the new ion-exchangers can easily be prepared from carbon fiber. The resulting fibrous exchangers have a satisfactory tensile strength for common use and several other characteristic properties. The most interesting properties other than their shape and mechanical properties are their large electric conductivity and their large thermal stability.

The exchanging properties shown in Fig. 8 resemble those of amorphous zirconium phosphate[4] rather than a commercial strongly or weakly acidic resin exchanger which has a single functional group. From this result, it seems that the ion-exchange carbon fibers have many kinds of functional groups and/or exchanging mechanisms. It is a well known fact that graphite oxide is formed from graphite crystallites or graphitized carbon materials by oxidizing treatment with various agents, such as a mixed solution of phosphoric acid and sulfuric acid.[5,6] Graphite oxide, however, is a very complicating material, and its chemical composition and structure are not known definitely. According to Hofmann *et al.*,[7,8] the chemical composition can be represented by $C_8O_2(OH)_2$ and oxygen atoms exist in both the *keto*-type and the *enol*-type. The inter-layer distance, d_{002}, of the graphite oxide was expanded to 7.96 Å even in a dry state. However, on the basis of the results obtained in the present work, it is doubtful that the previous considerations of the graphite oxide are applicable to the present investigation. In the present work, use was made of a new oxidizing agent and the carbon material not graphitized. Carbon fiber prepared at 1000°C had a larger exchange capacity than that produced from carbon fiber prepared at 2000°C. The inter-layer distance of the exchanger, in spite of the large amount of oxygen introduced, kept almost the same value as that of the original fiber. The exchangers have acidic functional groups, and their infrared spectra indicate the presence of carbonyl and hydroxyl groups. Moreover, it is also well known that mellitic acid is formed from carbon materials by oxidation with some oxidizing agents, such as nitric acid. From these results, it seems most reasonable to assume that the ion-exchange properties are due mainly to the carboxyl groups substituted at various positions of the carbon structure.

The Allylic Oxidation of Thujopsene

Masaaki Ito, Kazuo Abe, and Hitoshi Takeshita*

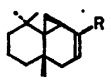
Department of Industrial Chemistry, Kitami Institute of Technology, Kitami, Hokkaido

** Department of Chemistry, Faculty of Science, Tohoku University, Sendai*

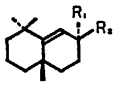
(Received June 30, 1971)

The allylic oxidation[1] of olefins to their acetate by mercuric acetate in acetic acid or other solvents occurs by means of an electrophilic addition. Brown[2] has shown that the oxymercuration-demercuration of olefins is an excellent method of obtaining alcohols. The procedure achieves the Markovnikov hydration of carbon-carbon double bonds without rearrangement, and it results in the preferential formation of *exo* hydroxyl derivatives.

Although several attempts to prepare a saturated alcohol by Brown's procedure have been unsuccessful with regard to thujopsene (**1**), we have obtained some findings on the reaction of thujopsene **1**, with mercuric acetate in acetic acid. Thus, it may be seen that, besides a skeletal conversion to give a bicyclic acetate (**4**), an allylic oxidation occurs at the methyl group, while these are no Markovnikov addition to **1**. Thus, **1** was first mercurated by heating it with mercuric acetate in acetic acid at 70°C for 3 hr; it was then demercurated by heating at 100—120°C for 3—4 hr. Glpc and tlc analyses of the reaction mixture showed two major products, (**2**) and (**3**), and a minor product, **4**. Samples of the three products were readily isolated from the mixture by means of preparative tlc.



1 : R=CH_3
2 : R=CH_2OAc
3 : R=CH_2OH



4 : R_1=CH_2OAc, R_2=CH_3
6 : R_1=CH_3, R_2=CH_2Br

The **2** product was a colorless liquid; its IR spectrum showed a presence of an acetoxyl group, while the NMR spectrum indicated the cyclopropane ring intact and the replacement of a methyl group by an acetoxymethyl group. The structure assigned to this product, **2**, was verified when the hydrolysis of **2** afforded thujopsenol (**5**).[3]

The **3** product, pale yellow crystals, was identified as thujopsenal by a direct comparison of its melting point and IR and NMR spectra with those of an authentic sample.

The minor product, **4**, a colorless liquid, was analyzed to be $C_{17}H_{28}O_2$. The NMR spectrum revealed the absence of any cyclopropane ring and the presence of an acetoxymethyl group. Because of the close resemblance of the NMR data to the related compound (**6**),[4] the structure of **4** was deduced to be as depicted.

Whenever the reaction carried out in an atmosphere of nitrogen or oxygen, the ratio of the yield of **3** to **2** was not affected. Although the reaction was attempted in various solvents (*e.g.*, in acetic acid-acetic anhydride, tetrahydrofuran-water, and acetic acid, acetone-water) the reaction products were almost always the same. The reaction in the presence of silver acetate[5] or hydroquinone does not seem to improve the yield.

Experimental

Materials and Methods. The thujopsene was obtained from Hiba (*Thujopsis dolabrata* Sieb. et Zucc.) oil. Thin-layer chromatography (tlc) and preparative tlc were performed on silica gel Merck G. The equipment used in this study was a Varian A-60 NMR spectrometer, a Shimadzu IR-27G grating IR spectrometer, a Shimadzu MPS-50 multipurpose UV spectrometer, and a Shimadzu UM-2 elemental-analyses apparatus.

Allylic Oxidation of Thujopsene. A solution of 5.8 g (28 mmol) of thujopsene in 10 m*l* of acetic acid was treated with a solution of 9.6 g (30 mmol) of mercuric acetate in 40 m*l* of acetic acid. The mixture was heated at 70°C for 3 hr. After the mercuration, the reaction temperature was elevated to 120°C, and then the solution was maintained at that temperature for 4 hr. The reaction mixture was cooled, treated with water, and extracted with ether. The ether solution was dried and evaporated, and the residue was distilled. After the removal of the unchanged hydrocarbon, these products, **2**, **3**, and **4**, were isolated by preparative tlc using a mixed solvent of *n*-hexane and ethyl acetate (9 : 1, by volume).

The sample of **2** (0.53 g, 14.4%) was a colorless liquid and showed the following spectral data: UV λ_{max}^{EtOH} 222 (ε 4509), λ_{max}^{Hexane} 221.5 mμ(ε 4488); IR (CCl_4) 1728 (C=O), 1227 (CH_3CO), 3011 cm^{-1} (cyclopropyl); NMR (CCl_4) 0.63 (s, 3, CH_3), 1.12 (s, 3, CH_3), 1.15 (s, 3, CH_3), 2.01 (s, 3,$OC-OCH_3$), 4.50 (s, 2 CH_3OAc), 5.25 ppm (m, 1, olefinic proton).

Found C, 77.68; H, 9.89%. Calcd for $C_{17}H_{26}O_2$: C, 77.82; H, 9.99%.

The sample of **3** (0.34 g, 11.1%) consisted of pale yellow crystals; mp 75°C; IR (CCl_4) 1692 (C=O), 1649 cm^{-1} (C=C).

The sample of **4** (0.2 g, 5.4%) was a colorless liquid and showed the following spectral data: UV λ_{max}^{EtOH} 208 mμ. IR (CCl_4) 1730 (C=O), 1237 cm^{-1} (CH_3CO–), and NMR (CCl_4) 1.06 (d, 6, $2CH_3$), 1.14 (s, 3, CH_3), 1.20 (s, 3, CH_3),

The Autocatalytic Oxidation of Thujopsene. A Facile Synthesis of Mayurone

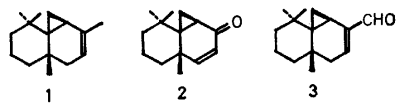
Masaaki Ito, Terumi Nishimura, and Kazuo Abe

Department of Industrial Chemistry, Kitami Institute of Technology, Kitami, Hokkaido

(Received June 30, 1971)

The autoxidation of cyclic terpenes, including an allyl methyl moiety, is known to give a small amount of a preferential product, accompanied by minor products. For example, the autoxidation of limonene[1] produces carveol, carvone, 8-*p*-menthene-1,2-diol, and limonene 1,2-oxide. Our interest in the autocatalytic oxidation and in the chemistry of thujopsene has led us to seek favorable catalysts for the autocatalytic oxidation of thujopsene to mayurone.

In the course of our investigations utilizing metal chelate catalysts for synthetic purposes, it has been found that the oxidation of thujopsene (**1**) with molecular oxygen in dioxane gives mayurone (**2**) and an unidentified product (**4**) in poor yields, but the oxidation was accelerated in the presence of metal chelate catalysts, as is shown in Table 1. $CoCl_2$–dioxane[2] was most effective in giving **2**, **3**, and **4**. In this system, however, the products were not obtained in good yields in the absence of the catalysts and the solvent. From this observation, it seems that the chelate complex formed from $CoCl_2$ and dioxane has a remarkably catalytic effect. Also, catalysts composed of a metallic salt, and a synthetic organic adsorbent showed a catalytic effect, affording the same products. This study promised to be of interest because of the possibility of effecting a new type of chelate-catalyzed reactions. New types of catalysts were realized. The results are summarized in Table 1.



1 2 3

The IR and NMR spectra of **2** were all consistent with those of an authentic sample, which has been prepared by the potassium permanganate and sodium perchromate oxidation[3] and the photosensitized oxidation[4] of thujopsene, and which has also been isolated from several conifers.[5,6,7] Compound **3** was identified by glpc analysis with thujopsenal which had been prepared by the selenium dioxide oxidation

of thujopsene Compound **4** was not identified.

Experimental

The melting point was determined on a Büchi melting-point apparatus. The NMR spectrum was recorded on a Hitachi R-20A spectrometer at 60 MHz, using tetramethylsilane as the internal standard. The IR spectrum was determined on a Shimadzu IR-27G spectrophotometer. The UV spectrum was recorded on a Shimadzu MPS-50 spectrophotometer. Glpc analyses were performed on a Shimadzu GC-1C gas chromatograph with a 1.1-m stainless-steel column packed with 15% OV-17, at 180°C.

Materials. The thujopsene used was purified by the careful distillation of Cedar H oil (Takasago Perfumery Co., Ltd.) through a concentric column and had a boiling point of 119°C/10 mmHg, showing no trace of an impurity upon glpc analysis. The inorganic salts used for preparing the catalysts were commercial, extra-pure reagents.

Preparation of the Chelate Catalysts. Some of the catalysts shown in Table 1 were prepared according to the reported method for preparing kieselguhr using synthetic organic absorbents, GHP[8] or N-GHP[9]. For example, a 1.5-g portion of N-GHP dissolved in 6 m*l* of water was added to a solution of 0.158 g of $RuCl_3$-xH_2O in 2 m*l* of ethyl alcohol, after which the mixture was kneaded in a mortar. The slurry was washed with water and dried at 100°C.

General Procedure for Autocatalytic Oxidation. Into a stirred mixture of 3.0 g of thujopsene and 0.2 or 0.015 g of the catalyst in 10 m*l* of dioxane or without the solvent, we passed a stream of dry oxygen at a rate of 62 m*l*/min for 21 hr. The mixture was then chilled, filtered, and evaporated. The components of the reaction mixture were analyzed by means of glpc. Thier yields were accounted on the basis of the area ratio of peaks on a chromatogram, regarding the peak area of hydrocarbons in the reaction mixtures as 100. The yield of mayurone was found to be 20% by glpc, using naphthalene as the internal standard; the retention times were 18 min for mayurone (**2**), 15 min for thujopsenal (**3**), and 11 min for the unidentified product (**4**).

*Isolation of Mayurone (**2**).* Into a stirred mixture of 20.4 g (0.1 mol) of thujopsene and 1.0 g of the $RuCl_3$-N-GHP catalyst in 300 m*l* of dioxane, we passed a stream of dry oxygen at a rate of 408 m*l*/min at 70°C for 29 hr. The mixture was then chilled and filtered. After the removal of the solvent, the reaction mixture thus obtained was distilled through a concentric column to collect the distillate with a bp of 150°C/7.5 mmHg, which deposited a crystalline matter on chilling. Two recrystallizations of the crystals from petroleum ether (bp 30—40°C) gave 1.45 g of **2** as colorless crystals; mp 70.0—71.0°C; $[\alpha]_D^{27}$ +221.0 (*c* 10.0 CCl_4); MW 201.86 (benzene) (calcd 204.16); NMR (CCl_4) 0.66 (CH_3), 1.11 (CH_3), 1.30 (CH_3), 1.30 (CH_3), 5.44 (1H, J=11.9 Hz), 6.00 (1H, J=11.0 Hz); IR (CCl_4) 3010 (cyclopropyl), 1661 (conj. C=O). 1619 cm^{-1} (conj. C=C); UV $\lambda_{max}^{cyclohexane}$ 226 mμ(ε 6646).

Reaction of Urea with Ethylene in the Presence of Oxygen and a Nitrile-Sodium Tetrachloropalladate-Cupric Chloride Catalyst System

Tadashi INOUE, Hiroshi HARADA, and Shingo MIYAJIMA

The Central Research Laboratories, Chisso Corporation, Kamariya, Kanazawa-ku, Yokohama

(Received August 12, 1971)

The reactions of amines and amides with olefins in the presence of palladium chloride are generally complicated because of the fact that both the nucleophiles and the products form complexes with palladium chloride.[1-3] By hydrogenation of the resulting complexes Stern and Spector demonstrated the addition of nitrogen functions to olefins.[1] Hirai and Sawai reported the formation of *N*-vinylamides along with their complexes with palladium chloride by the reaction of ethylene-palladium(II) chloride complex with some cyclic amides in tetrahydrofuran.[3]

We found that urea in an acidic aqueous solution reacts with ethylene at room temperature to yield acetylurea in the presence of oxygen and a nitrile-sodium tetrachloropalladate-cupric chloride catalyst system. Sodium tetrachloropalladate was stirred in acetonitrile or benzonitrile for 1 to 3 hr. Most of the palladate dissolved to form a reddish-orange solution of the nitrile-palladium(II) chloride complex[4] leaving precipitates of sodium chloride. Toluene and an aqueous hydrochloric acid solution of urea and cupric chloride were added, and the mixture was stirred while ethylene and oxygen were bubbled through.[5] Crystals of crude acetylurea separated. The results are summarized in Table 1. In the absence of nitrile, Pd(II) readily combined with urea to form precipitates of bis(urea)dichloropalladium(II), which could not catalyze the reaction.

When the reaction temperature was above 30°C, formation of 6-methyl-2-oxo-4-hexahydropyrimidinylurea became predominant. There is hardly any doubt that this compound results from the condensation of urea with acetaldehyde formed by the oxidation of ethylene with Pd(II), since it is known that the

a) Reactions were carried out at room temperature and at flow rates of ethylene and oxygen, 0.25 and 0.5 mol/hr, respectively, unless otherwise stated.
b) The yields are given based on Pd(II), assuming the stoichiometry of 1 mole of acetylurea per 2 moles of Pd(II).
c) The value indicates the pH of the aqueous phase containing $CuCl_2$ and urea.
d) The value indicates the pH of aqueous hydrochloric acid, in which $CuCl_2$ and urea were dissolved.
e) Flow rate was 0.3 mol/hr for both ethylene and oxygen.
f) 10.7 g of a mixture of acetylurea and 6-methyl-2-oxo-4-hexahydropyrimidinylurea was obtained.
g) Reaction was carried out at 0—5°C.

condesnation leads to the cyclic product in an acidic aqueous solution and at an elevated temperature.[6)]

N-vinylation (Eq. 1) rather than ethylolation of urea (Eq. 2) might be involved in acetylurea formation:[3)] Acetaldehyde in place of ethylene gives no acetylurea under otherwise similar reaction conditions.

$$CH_2{=}CH_2 + H_2NCONH_2 \xrightarrow{Pd^{++}} [CH_2{=}CHNHCONH_2] + 2H^+ + Pd^0$$

Experimental

Melting points are uncorrected. The infrared spectra were obtained with a Nihon Bunko Model IR-S spectrophotometer using KBr disks.

Typical Procedure. Acetylurea (Expt. 2): Sodium tetrachloropalladate (1.34 g, 4.55 mmol) was stirred in acetonitrile (50 m*l*) for 1 hr at room temperature. Toluene (50 m*l*) and an aqueous solution (200 ml) containing cupric chloride (anhydrous, 2.5 g) and urea (15 g, 0.25 mol) and adjusted at pH 1.4 with hydrochloric acid were added. The mixture was stirred at room temperature while ethylene and oxygen were bubbled through the mixture. After 18 hr, the crude crystals of acetylurea were filtered, washed successively with cold water, methanol and ether, and dried. The yield was 7.3 g. Recrystallization from ethanol gave needles, mp 215—216°C (lit,[7)] 216—217°C, corrected).

Found: C, 35.32; H, 5.99; N, 27.31%. Calcd for $C_3H_6N_2O_2$: C, 35.29; H, 5.92; N, 27.44%.

The IR spectrum was identical with that of acetylurea reported.[8)] A mixture melting point with the authentic sample showed no depression.

The yield was calculated on the basis of the crude product, which amounted to 29% based on starting urea, corresponding to 3150% based on Pd(II) charged; the crude product was proved to be pure by its IR spectrum.

6-Methyl-2-oxo-4-hexahydropyrimidinylurea: Sodium tetrachloropalladat e(3.4 g, 0.0116 mol) was stirred with benzonitrile (130 m*l*) for 3 hr and ethylene was bubbled for about 30 min. The temperature was raised to 50—60°C and a solution of cupric chloride (5.5 g) and urea (15 g, 0.25 mol) in aqueous hydrochloric acid (25 m*l*; pH, 1.5) was added. The mixture was stirred at 50—60°C, while ethylene and oxygen were bubbled through the mixture each at a flow rate of 0.3 mol/hr. After 6.5 hr, the crude crystals of 6-methyl-2-oxo-4-hexahydropyrimidinylurea were collected, washed with cold water, methanol and ether, and dried (8.4 g). Analytical sample was obtained by recrystallization from water, mp 238°C (lit,[6)] 245°C).

Found: C, 41.86; H, 7.14; N, 32.39%. Calcd for $C_6H_{12}N_4O_2$: C, 41.85; H, 7.03; N, 32.54%.

The IR spectrum was identical with that of the authentic sample prepared from crotonaldehyde and urea.[9)] A mixture melting point determination showed no depression.

The yield of the crude product, the IR spectrum of which was apparently the same as that of the pure one, was 39% based on starting urea, corresponding to 840% based on Pd(II).

Attempted Reaction Using Acetaldehyde in Place of Ethylene. Pd(II) Catalyst: Sodium tetrachloropalladate (1.3 g) was treated with acetonitrile (50 m*l*). Toluene (100 m*l*) and a solution of cupric chloride (2.5 g) and acetaldehyde (5.5 g) in aqueous hydrochloric acid (30 m*l*; pH, 1.3) were added. With the mixture kept at 0—6°C, oxygen was introduced and a solution of urea (7 g) in aqueous hydrochloric acid (20 m*l*; pH, 1.3) was gradually added under stirring. After 13 hr at 0—6°C and additional 2 hr at 15°C, the reaction was stopped. No crystals separated. On standing at room temperature overnight, some crystals deposited from the reaction mixture (1.1 g). The IR spectrum revealed

that the product was hexahydro-6-methyl-2-oxo-4-pyrimidinylurea free from acetylurea.

Metallic Palladium Catalyst: Sodium tetrachloropalladate (3.4 g) was treated with benzonitrile (75 m*l*) and ethylene was bubbled through to form ethylene-palladium(II) chloride complex. Metallic palladium was formed when a solution of acetaldehyde (22 g) in aqueous hydrochloric acid (50 m*l*; pH, 1.5) was added and the mixture was stirred for some time. A solution of urea (15 g) in aqueous hydrochloric acid (50 m*l*; pH, 1.5) was gradually added, while oxygen was bubbled through at 0—5°C. The supply of oxygen was continued for 13 hr at 0—5°C under stirring. The precipitate was filtered, which proved to be only metallic palladium.

The Synthetic Intermediate of Pyridoxine. III.[1] The Simple Synthesis of Ethyl *N*-Ethoxalylalaninate and Ethyl *N*-Formylalaninate

Itsutoshi MAEDA, Soichiro ASAI, Hideshi MIYAYASHIKI, and Ryonosuke YOSHIDA

Central Research Laboratories, Ajinomoto Co., Inc. Suzuki-cho, Kawasaki

(Received August 18, 1971)

Ethyl *N*-ethoxalylalaninate (I), which is an important intermediate on the synthesis of pyridoxine, had been obtained from alanine through two steps. That is compound I had been prepared by the treatment of ethyl alaninate hydrochloride with ethoxalyl chloride[2] or with diethyloxalate in the presence of triethylamine, as was in our previous paper.[3] Our further investigation was undertaken to determine a simple method. Compound I and ethyl *N*-formylalaninate (II) could be obtained by heating a mixture of alanine, oxalic acid, and ethanol at various temperatures, as is shown in Fig. 1.

The yield of Compound I increased when the mixture was heated in the range from 110 to 140°C, while at temperatures above 150°C the yield of Compound I decreased and that of Compound II increased remarkably. After the water formed and the unreacted ethanol had been distilled off from the reaction mixture, ethanol was added again to the residue and the

a) *N*-Formylamino acid ester.
b) *N*-Alkoxalylamino acid ester.
c) Alanine (0.15 mol), oxalic acid (0.15 mol), diethyl oxalate (0.75 mol), and ethanol (138 g) were used.

1) Part II of this series: I. Maeda, M. Takehara and R. Yoshida, This Bulletin, **44**, 1407 (1971).
2) W. Kerp and K. Unger, *Ber.*, **30**, 579 (1897).
3) I. Maeda, M. Takehara, K. Togo, S. Asai, and R. Yoshida, This Bulletin, **42**, 1435 (1969).

mixture was heated again. When the mixture was heated at 120°C and the above treatment was repeated three times, the yield of Compound I amounted to 58.0%, while the yield of Compound II was 10.6%. A mixture of alanine (0.15 mol), oxalic acid (0.15 mol), diethyl oxalate (0.75 mol), and ethanol was heated at 120°C, and the treatment described above was repeated three times. The yield of Compound I was 70.1%, while the amount of Compound II was a trace. The results of these methods preparing *N*-alkoxalylamino acid esters are shown in Table 1.

Compound II, which is also an important intermediate for the synthesis of pyridoxine, can be obtained by heating a mixture of alanine, formic acid, and ethanol. *N*-Formylamino acid esters have been prepared from amino acids in two steps. In general, they are prepared by the esterification of *N*-formylamino acids with diazomethane[4] or by the formylation of amino acid esters with formic acid and acetic anhydride.[5]

By a similar simple method, these various *N*-formylamino acid esters could be synthesized from amino acid, formic acid, and alcohol in one step. The results are shown in Table 2.

a) Based on amino acid.

Experimental[6]

Ethyl N-ethoxalylalaninate. A mixture of DL-alanine (13.35 g, 0.15 mol), oxalic acid (39.5 g, 0.45 mol), and ethanol (138 g) was put into a 300-m*l* autoclave. The autoclave was kept at 120°C by electrical heating for 3 hr, and then it was chilled. The ethanol and water formed in the reaction mixture were distilled off under reduced pressure. Then ethanol (138 g) was added to the residue, and the mixture was again treated in a manner similar to that used in the experiment described above. This treatment was repeated three times. After the unreacted ethanol and diethyl oxalate, which was one of the by-products, had been removed, the residue was distilled under reduced pressure to afford ethyl *N*-formylalaninate (bp 115—120°C/4 mmHg; yield, 2.3 g; 10.6%) and ethyl *N*-ethoxaylalaninate (bp 140—145°C/4 mmHg; yield, 18.9 g; 58.0%). The following *N*-alkoxylalamino acid esters were prepared by the same method. Ethyl *N*-ethoxalylglycinate (bp 135—138°C/5 mmHg; yield, 24.6 g; 80.9%). Found: C, 47.31; H, 6.65; N, 7.04%. Calcd for $C_8H_{13}NO_5$: C, 47.29; H, 6.45; N, 6.89%. Ethyl *N*-ethoxalylleucinate (bp 150—154°C/4 mmHg; yield, 29.1 g; 74.8%). Found: C, 55.89; H, 8.40; N, 5.69%. Calcd for $C_{12}H_{21}NO_5$: C, 55.58; H, 8.16; N, 5.40%. Ethyl *N*-ethoxalylphenylalaninate (bp 180—185°C/1 mmHg; yield, 5.7 g; 12.9%). The results are summarized in Table 1.

The investigation of the reaction temperature and time shown in Fig. 1 was carried out as follows. A mixture of DL-alanine (4.45 g, 0.05 mol), oxalic acid (13.5 g, 0.15 mol), and ethanol (46.0 g, 1 mol) was put into a 100-ml autoclave. The reaction was then carried out at 110—180°C at intervals of 10°C for 1, 3, or 5 hr respectively. The reaction mixtures were diluted with ethanol to 100 m*l* after which the amounts of ethyl *N*-formylalaninate and ethyl *N*-ethoxalylalaninate were analyzed by gas chromatography, which was carried out with 4% Versamid 900 on Chromosorb T (4 mmϕ × 1 m; column temperature, 190°C; flow rate of He, 60 m*l*/min; internal standard, benzophenone).

N-Formylamino Acid Esters. A mixture of amino acid (0.2 mol), 98.5% formic acid (0.6 mol), and ethanol (4 mol) was put into a 300-m*l* autoclave. The autoclave was then kept under the conditions listed in Table 2. After the removal of the solvent from the reaction mixture, the product was obtained as a syrup; the *N*-formylamino acid ester was then distilled at reduced pressure, as will be described below.

Methyl *N*-formylalaninate (bp 102—105°C/2 mmHg. Found: C, 45.79; H, 7.18; N, 10.82%). Ethyl *N*-formylalaninate (bp 110°C/2 mmHg. Found: C, 49.84; H, 7.91; N, 9.61%). Butyl *N*-formylalaninate (bp 131—133°C/2 mmHg. Found: C, 55.51; H, 9.02; N, 8.29%. Calcd for $C_8H_{15}O_3N$: C, 55.47; H, 8.73; N, 8.09%). Ethyl *N*-formylleucinate (bp 143°C/8 mmHg. Found: C, 58.09; H, 9.45; N, 7.60%). Methyl *N*-formylglycinate (bp 137°C/28 mmHg. Found: C, 41.26; H, 6.43; N, 11.76%). Ethyl *N*-formylglycinate (bp 136°C/5 mmHg. Found: C, 45.61; H, 7.22; N, 10.87%). Ethyl *N*-formylphenylalaninate (bp 158—159°C/1 mmHg. Found: C, 65.29; H, 7.07; N, 6.50%). Methyl *N*-formylmethionate (bp 152—153°C/1 mmHg. Found: C, 44.05; H, 7.02; N, 7.22%).

The authors wish to thank Professor Dr. Masanao Matsui of The University of Tokyo for his many helpful discussions and suggestions.

Electronic Spectra and Structures of 3-Substituted 1,2-Diphenylcyclopropenyl Cations

Zen-ichi Yoshida and Hideki Miyahara

Department of Synthetic Chemistry, Kyoto University, Yoshida, Kyoto, 606

(Received September 2, 1971)

The simplest and most strained non-benzenoid aromatic, cyclopropenyl cation($2\pi 3c$) system is expected to have unique electronic properties. Thus, the electron donating σ-inductive effect of an attached *n*-propyl group is more significant for the stabilization of this carbonium ion than the electron donating π-conjugative effect of an attached phenyl group,[1] in contrast to most other carbonium ions. The ^{13}C–H coupling constant of parent cyclopropenyl cation indicates that the orbital used for bonding with the hydrogens is *sp* hybrid.[2]

Only a few papers[3] have appeared on the electronic spectra and structures of the cyclopropenyl system. This paper deals with the electronic spectra and structures of 3-substituted 1,2-diphenylcyclopropenyl system (Fig. 1) obtained by using the variable integrals method I (VI/I)[4] devised to contain only one arbitrary molecular parameter.

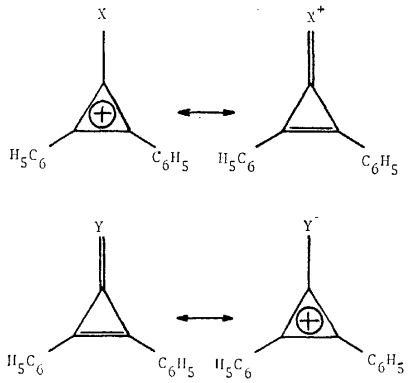

Fig. 1. 3-Substituted-1,2-diphenylcyclopropenyl system taken up in this study.

Experimental

Materials. 1,2-Diphenylcyclopropenone[5] (**1**), 1,2-diphenyl-3-ethoxycyclopropenyl tetrafluoroborate[5] (**2**), 1,2-diphenylcyclopropenethione[6] (**3**), and 1,2-diphenyl-3-dimethylaminocyclopropenyl tetrafluoroborate[5] (**5**) were prepared according to literature. 1,2-Diphenyl-3-ethylthiocyclopropenyl tetrafluoroborate (**4**), mp 149—150°C (decomp.) (Anal. Found: C, 60.20; H, 4.54%; Calcd for $C_{17}H_{15}BF_4$: C, 60.37; H, 4.47%) was prepared from **3** and triethyloxonium tetrafluoroborate in 70% yield in a similar manner to that for **2**.

Measurements of Spectra. Ultraviolet spectra were taken on a Hitachi Model ESP-3T spectrometer. Solvents used were of spectrograde from E. Merck & Co.

Method of Calculation

Details of the VI/I method have been described.[4] In order to assume reasonable geometries of the molecules the linear bond order(p) - bond length(l) relationships are used in each iteration step of the SCF procedure.[7] For the three membered ring the reference of the double bond length was taken to be equal to that of cyclopropene[8]:

$$l_{C-C} = 1.477 - 0.177p \quad (1)$$

The procedure is known to give satisfactory bond lengths for fulvenes *etc.*[7] The molecules were assumed to be planar. Numbering of atoms in the molecules are giving in Fig. 2. The CI calculations were made on the singly excited configurations for which inner orbitals of five occupied and five unoccupied levels are responsible.

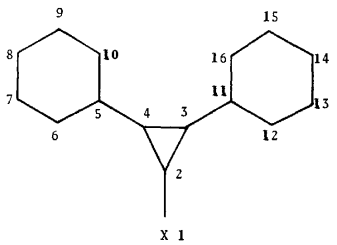

Fig. 2. Numberings of the atoms.

Results and Discussion

The observed electronic spectra of **1** and **3** in cyclohexane and **2**, **4**, and **5** in methylene chloride solutions are given in Table 1 with calculated transition energies. For **1** and **3** the weak least energy bands were obviously assigned to the n-π^* bands which shifted toward higher energy in ethanol.[3a,9] This is not included in our calculation.

We see that the agreement between calculated and observed values is relatively satisfactory and the reasonable assignments of the bands could be made

using the forms of the CI wave functions. The least energy $^1\pi$-$^1\pi^*$ bands for **1**—**4** have a characteristic of the stilbene chromophore[10] with fine structurs due to vibrational levels, though the corresponding band for **5** appears broad. The second allowed lower energy $^1\pi$-$^1\pi^*$ bands in **3**, **4** and **5** are interesting. The strong band in **3** observed near 4.3 eV might be due to the intramolecular charge-transfer transition from ring to sulfur. The 4.40 eV band observed in **4** and 4.85 eV band observed in **5** could also be assigned to the intramolecular charge-transfer transition from heteroatom to ring. In **1** and **2**, however, no intramolecular charge-transfer transitions as above were observed being in line with the prediction from calculations that the bands in question would be shifted toward relatively higher energy. This trend of the substituents at 3-position in these systems for the interaction with the diphenylcyclopropenyl ring is similar to that found in monosubstituted benzenes, in which thiol and amino groups interact strongly with the benzene ring, in contrast to weakly interacting hydroxyl group.[11] The observed $^1\pi$-$^1\pi^*$ bands of **1** show essentially no solvent shift, in ethanol. However, those of ethanol solution of **3** are noticeably shifted to higher energy, and those of **2**, **4**, and **5** in ethanol containing sulfuric acid exhibited slight blue shifts. The spectral features toward solvent polarity can be explained by large polarization in the ground state of these molecules. This can be understood by the calculated formal charges and dipole moments shown in Table 2. It seems that the geometries of these molecules are nearly planar in their dominant conformation in solution.[12]

Photosensitive Ionomer. IV. Preparation of Mercurous Copoly(vinyl alcohol-methacrylate) and Properties of the Plate

Kazuyuki SUGITA, Masahide HASE*, and Shin SUZUKI

Department of Graphic Engineering, Faculty of Engineering, Chiba University, 1-33, Yayoi-cho, Chiba

(Received September 13, 1971)

Mercurous copoly(vinyl alcohol-acrylate) was studied in order to produce a new type of photosensitive system by applying the disproportionation reaction of mercurous acetate to an ionically crosslinked polymer.[1,2] It was found that the plate prepared thereform was sensitive to ultraviolet light, and that a dark brown relief image was formed by a printing-out process. The latent image could be amplified by reducing development; visible image formation was due to metallic mercury which was isolated as a product of the disproportionation and reduction of mercurous ion. The latent image was also intensified by oxidizing development; relief image formation was ascribed to the ionic crosslinking by mercuric ion formed in the disproportionation and oxidation of mercurous ion. We have studied mercurous copoly(vinyl alcohol-methacrylate), comparing its image-forming characteristics with those of copoly(vinyl alcohol-acrylate).

Experimental

Preparation of Mercurous Copoly(vinyl alcohol-methacrylate) and Photosensitive Plates. Various copolymers of methacrylic acid with vinyl alcohol were prepared from methacrylic acid, vinyl acetate and xylene in the quantities given in Table 1, in the same way as copolymers of acrylic acid.[1] One g of copolymer of methacrylic acid with vinyl alcohol was dissolved in 50 m*l* of water and exactly neutralized with 0.5 N sodium hydroxide. Under vigorous agitation in the dark, the mercurous nitrate solution was added to the sodium copoly(vinyl alcohol-methacrylate) solution. The solution turned into a milky white emulsion. The mercurous salt of the copolymer was separated by centrifugation at 10000 rpm. The mercurous salt precipitated was again uniformly dispersed in a small quantity of water, spread over glass plates, and left to dry.

Results and Discussion

Film Formation and Spectral Sensitivity. In preparing the emulsion, the volume of the mercurous nitrate solution was at first so controlled that an equimolar amount of nitrate and sodium ions was sustained in the copolymer solution. However, the emulsion did not dry up to a smooth, transparent layer and could not be used as a photosensitive layer. The volume of the mercurous nitrate solution was therefore determined in order to obtain a good photosensitive layer, taking into consideration the fact that too much mercurous methacrylate decreased the film-forming ability of the copolymer and too small an amount of it did not bring about the fixing ability. The wedge spec-

a) 0.1 g of benzoyl peroxide was used as an initiator in each case.
b) A reduced viscosity, η_{sp}/C, was measured at 30°C on an aqueous solution of the copolymer (0.25 g/100 m*l*).
c) Calculated value (in wt%) by assuming that the quantity of mercurous ions in the nitrate solution was quantitatively fixed to side chains of each copolymer.

trogram showed that the layer turned dark brown on exposure to light ranging from 250 to 315 nm. Irradiation was performed with a low-pressure mercury lamp.

Photosensitivity and Reducing Development. Each photosensitive plate was divided into three parts, the first part being irradiated for 50 min, the second for 1—2 min, and the third not at all. The first turned dark brown, and a photographic image was formed on the plate by a printing-out process. The second remained transparent and could not be distinguished from the third. The plate was immersed in a hydroquinone solution (1 g in 20 m*l* of water and 80 m*l* of alcohol). In a few minutes, the second part became dark grey, but not the third. Development was completed in 10—15 min. This means that irradiation for 1—2 min formed a latent image which could be developed into a visible image on the plate.

Fixation and Oxidizing Development. The plate made from Copolymer 1005 (see Table 1) was stepwise irradiated for 50, 5, and 0 min, respectively, and placed in a mixed solvent of acetic acid (15 m*l*), water (15 m*l*), and alcohol (70 m*l*). In 10—15 min the photosensitive layer of the second and third parts swelled and became detached from the plate, but that of the first part was unchanged. The polymer remaining on the plate formed a relief image. In the case of the plates from Copolymer 510, 1002, and 1010, the layer of the first part was swollen and partly dissolved away. The exposed layers which were made from Copolymer 501, 502, 505, and 1001 and irradiated for 50 min, were dissolved away and the image could not be fixed.

The plate which was irradiated stepwise by changing exposing duration was immersed in a potassium permanganate solution (0.05 g in 30 m*l* of acetic acid and 70 m*l* of water). The layer in the exposed area for 50 min exposure remained on the plate. Though the surface of the layer for 5 min exposure turned insoluble, the inner part of the layer remained soluble, and the latent image could not be intesnified to a relief image by oxidizing development.

Comparison with Acrylate Plates. When the image-forming characteristics of mercurous copoly(vinyl alcohol-methacrylate) are compared with those of mercurous copoly(vinyl alcohol-acrylate), smaller photosensitivity, imperfect fixation, and failure of oxidizing development are notable. Irradiation for 30—50 min gave the methacrylate plate a print-out image and that for 1—2 min a latent image. On the other hand, irradiations for 20—30 min and for 0.5—1 min were sufficient to form a print-out image and a latent image, respectively, on the acrylate plate under the same exposing conditions. A relief image was fixed on the methacrylate plate made from Copolymer 1005, but the areas of the plate from which the photosensitive layers had become detached were not perfectly transparent, some residual layers being left. The selective swelling of unexposed layer was deduced to be due to the difference in bond strength of ionic crosslinkages.[1] The methyl substituent of methacrylate group may decrease the difference in bond strength.

Failure of oxidizing development can be explained by the intrinsic optical property of copoly(vinyl alcohol-methacrylic acid); this copolymer partly absorbed ultraviolet light ranging from 250 to 350 nm. It might be difficult for disproportionation to occur in the inner part of the photosensitive layer on exposure.

The authors wish to thank Prof. Takahiro Tsunoda, Chiba University, for allowing the use of the monochromator.

Iron Compounds Formed by the Aerial Oxidation of Ferrous Salt Solutions

Masao KIYAMA and Toshio TAKADA

Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received September 23, 1971)

Many reports have been published on the formation of iron compounds, α-FeOOH, γ-FeOOH, and Fe_3O_4, by the oxidation of aqueous suspensions of ferrous precipitates, such as hydroxide, carbonate, and basic sulfate.[1-5] Accroding to these reports, their formation depends on the oxidation rate, the temperature, the pH, *etc.* However, no detailed report has yet been presented on the formation of iron compounds by the oxidation of ferrous salt solutions in which no ferrous precipitate is present. In this note experimental results will be reported on the formation of iron compounds by the aerial oxidation of such ferrous salt solutions.

Experimental

Procedure. Aqueous solutions of ferrous salts were prepared by dissolving ferrous salt of an analytical grade in water. Three liters of each solution were poured into a round flask with a capacity of about 4 *l*. This flask had four inlet necks, into which a thermometer, a reflux condenser, a temperature regulator, and an air-introducing tube (0.7 cm in internal diameter) were inserted. The flask was quickly heated up to a given temperature. Compressed air was then blown into it at the rate of 200 *l*/hr so as to oxidize and stir the solution. During oxidation the temperature was kept constant. Each iron compound precipitated was filtered, washed with water, and then dried at about 105°C.

Identification. Each iron compound obtained was examined by a usual chemical analysis and by the X-ray diffraction method using Mn filtered Fe-K_α radiation.

Results and Discussion

Table 1 shows the kind of iron compounds formed by the oxidation of ferrous salt solutions at 70°C for 30 hr. In connection with the starting solution, in a $FeSO_4$ solution only α-FeOOH is obtained; in the other solutions, mixtures of α-FeOOH and the other compounds are obtained, depending on the kinds and concentrations of the anions present. It is expected that the content of each compound in the mixture depends on the oxidation time by which the composition of the solution is determined. In order to verify this, the following experiments were conducted by use of a fractional precipitation method.

Table 1. Iron compounds formed by the aerial oxidation of ferrous salt solutions with 0.72 M in the ferrous ion at 70°C for 30 hr

Starting solution	pH value	Iron compounds formed
$FeSO_4$	1.9	α-FeOOH
$FeSO_4(NH_4)_2SO_4$	1.8	α-FeOOH≈(NH_4)-$Fe_3(OH)_6(SO_4)_2$
$FeCl_2$	1.7	β-FeOOH≈α-FeOOH
$FeCl_2(NH_4Cl)_2$	1.2	β-FeOOH>α-FeOOH
$FeBr_2$	1.6	α-FeOOH>γ-FeOOH>α-Fe_2O_3

0.72 M-$FeCl_2$ and 0.72 M-$FeSO_4$ solutions were oxidized at 70°C. After 20 hr, the precipitates formed were sufficiently separated from the solutions by filtration, after which the whole filtrates were further oxidized at 70°C for 20 hr. This treatment was repeated several times every 20 hr. With repeated oxidation, the concentration of the free acid in each filtrate, HCl or H_2SO_4, and its Fe^{3+}/Fe^{2+} ratio increased. Table 2 shows the iron compounds fractionally precipitated for different oxidation times. After the first 60 hr of the total oxidation time has passed, only a basic sulfate is formed in the $FeSO_4$ solution, whereas in the $FeCl_2$ solution β-FeOOH is formed with a slight amount of α-FeOOH even after 100 hr. The X-ray diffraction pattern of the basic sulfate obtained (Fig. 1) shows that it differs sharply from a jarosite-type basic sulfate, as will be described later. Its composition was $(Fe_2O_3)_2SO_3(H_2O)_5$ (Found: Fe_2O_3, 65.3; SO_3, 16.8; H_2O, 17.9 wt%).

Table 2. Iron compounds fractionally precipitated by the oxidation of 0.72 M-$FeCl_2$ and 0.72 M-$FeSO_4$ solutions for different times at 70°C

Time (hr)	$FeCl_2$ solution	$FeSO_4$ solution
to 20	α-FeOOH≈β-FeOOH	α-FeOOH
20 to 40	β-FeOOH>α-FeOOH	α-FeOOH>basic sulphate[a]
40 to 60	β-FeOOH>α-FeOOH	basic sulphate[a]>α-FeOOH
60 to 80	β-FeOOH>α-FeOOH	only basic sulphate[a]
80 to 100	β-FeOOH≫α-FeOOH	
100 to 120	β-FeOOH≫α-FeOOH	

a) Its chemical composition was $(Fe_2O_3)_2SO_3(H_2O)_5$.

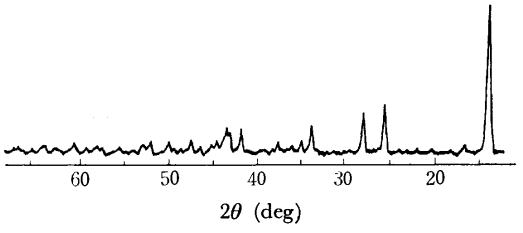

Fig. 1. X-Ray diffraction pattern of the $(Fe_2O_3)_2SO_3(H_2O)_5$ by using Fe-Kα radiation.

The addition of NH_4Cl to the $FeCl_2$ solution and that of a sulfate to the $FeSO_4$ solution favorably affected the formation of β-FeOOH and a basic sulfate respectively. Only β-FeOOH began to be formed at 70°C in the filtrate obtained by oxidizing a mixture of 0.72 M-$FeCl_2$ and 1.44 M-NH_4Cl solutions at 70°C for 20 hr. Also, only a basic sulfate began to be formed at 70°C in the filtrate obtained from a mixture of a 0.72 M-$FeSO_4$ solution and one of 0.72 M-K_2SO_4, Na_2SO_4 or $(NH_4)_2SO_4$ solution at 70°C for 20 hr. Its composition was $RFe_3(SO_4)_2(OH)_5$(R= K, Na, or NH_4), and its crystal structure was of the jarosite type.[6]

By blowing the air into the chloride or the sulfate solution, some of the ferrous ions in it are oxidized to ferric ions, which are then hydrolyzed to form both the acid, HCl or H_2SO_4, and α-FeOOH as the first precipitate. As oxidation progresses, the concentration of the ferric chloride or ferric sulfate increases with an increase in that of HCl or H_2SO_4, and β-FeOOH or the basic sulfate begins to be formed as the second precipitate. This may indicate that their formation is closely connected with the kinds and concentrations of the ferric complex ions in such solutions.

The kinds of the iron compounds formed in the chloride or the sulfate solutions did not depend strongly on the temperature, but that of the iron compounds formed in a ferrous bromide solution did. When the temperature was decreased, an amorphous compound was formed instead of α-FeOOH in the former solutions. Table 3 shows the iron compounds which were formed by the oxidation of a 0.33 M-$FeBr_2$ solution at various temperatures for 20 hr. It was also found that γ-FeOOH, α-FeOOH, β-FeOOH, and α-Fe_2O_3 were all formed by oxidizing a mixture of $FeCl_2$ and excess NaI solutions under conditions similar to the above.

Table 3. Iron compounds formed by the aerial oxidation of a 0.33 M-$FeBr_2$ solution at various temperatures for 20 hr

Temp. (°C)	Iron compounds obtained
10	β-FeOOH
20	β-FeOOH$>\alpha$-FeOOH
40	γ-FeOOH$\approx\alpha$-FeOOH
65	α-FeOOH$>\gamma$-FeOOH$>\alpha$-Fe_2O_3
80	α-$Fe_2O_3\approx\alpha$-FeOOH$>\gamma$-FeOOH

It is known that, on the slow oxidation of $Fe(OH)_2$ in a ferrous salt solution with a pH of about 7, γ-FeOOH can be obtained by selecting the proper oxidizing conditions. In this case a dark green compound, called a green rust, I or II, is always formed before the formation of γ-FeOOH. Accordingly, the presence of the green rust has so far been considered to be indispensable for the formation of γ-FeOOH. Since the solutions of $FeBr_2$ and the mixture of $FeCl_2$ and NaI were acidic (pH<3), no iron compound containing ferrous ions was formed as the intermediate one. In conclusion, γ-FeOOH can be formed not only by the slow oxidation of the green rust in the solution, but also by that of the ferrous salt solution by selecting the proper conditions.

Synthesis of (4-Pyridyl)-1,2-ethanediol and α-Acetoxy-4-vinylpyridine

Toshiyuki FURUYAMA, Koichi MORI, and Ryoichi WAKASA

Technical Research Laboratory, Asahi Chemical Industry Co. Ltd., Nakadai, Itabashi-ku, Tokyo

(Received October 5, 1971)

Aaron *et al.*[1] synthesized (4-pyridyl)-1,2-ethanediol as an intermeidate compound in the process of obtaining 3-quinuclidiol using 4-vinylpyridine and potassium permanganate. Haas *et al.*[2] similarly carried out the synthesis and obtained (4-pyridyl)-1,2-ethanediol as a pasty mass which could not be readily purified. They produced α-acetoxy-4-vinylpyridine by the reaction of (4-pyridyl)-1,2-ethanediol with acetic anhydride[2] and polymerized it with azobisisobutyronitrile as an initiator. Both the above procedures gave a low yield of the compound.

The present authors investigated the synthetic process of (4-pyridyl)-1,2-ethanediol and α-acetoxy-4-vinylpyridine, and found a very much improved route in comparison with the above synthetic methods[1,2]. By our process the polymeriaztion grade of α-acetoxy-4-vinylpyridine is easily obtained. The α-acetoxy-4-vinylpyridine was polymerized with γ-rays, and its physical properties were studied. Results of the polymerization have been presented elsewhere[3].

Results and Discussion

It is known that glycol synthesis from a C=C double bond with permanganates proceeeds favorably in an alkaline condition[4]. If the synthesis is carried out in

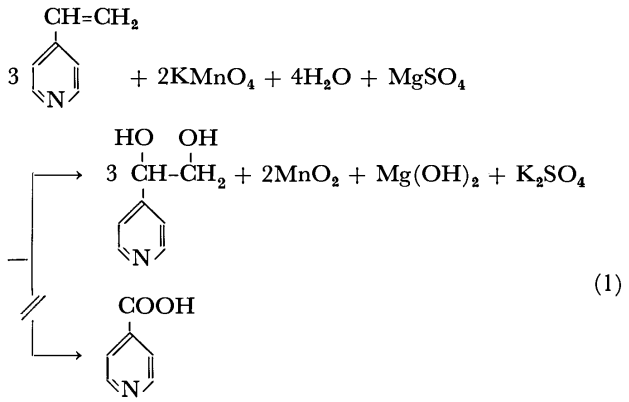
3) T. Furuyama, K. Mori, and R. Wakasa, *J. Polym. Sci., Part A*, **9**, 3411 (1971).

4) Y. Ogata, "Oxidation and Reduction", Nankodo, Tokyo (1963), pp. 348—403.

either acidic or neutral conditions, the main product turns out to be an oxidized material which could be produced by cleavage of the C=C[4].

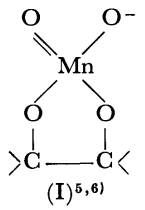
In the initial experiments we carried out glycol synthesis with a potassium hydroxide solution (alkaline condition), and, contrary to expectation, obtained isonicotinic acid as the main product. When we used water as a solvent (neutral condition), potassium hydroxide formed from the consumed potassium permanganate facilitated the formation of isonicotinic acid. It can be concluded that the methods of Aaron *et al.* and Haas *et al.* give an appreciable amount of isonicotinic acid together with (4-pyridyl)-1,2-ethanediol.

We used magnesium sulfate as a scavenger of the potassium hydroxide formed, as shown in reaction scheme (1), and obtained (4-pyridyl)-1,2-ethanediol in an exceptionally high yield, 84% or quantitatively.



(1)

As regards the mechanism of the reaction of potassium permanganate with a C=C, Wiberg and Saegabarth[5] discussed a mechanism based upon the formation of a cyclic ester between the permanganate ion and the C=C[6], as shown in (I).



(I)[5,6]

In 4-vinylpyridine, the proton abstraction reaction may easily take place with the attack of the hydroxyl ion on a similar cyclic ester, which may lead to the formation of isonicotinic acid, the cleavage product.

The solubility of (4-pyridyl)-1,2-ethanediol is summarized in Table 1 against Hildebrand's solubility parameter. (4-Pyridyl)-1,2-ethanediol seems to dissolve in solvents with a solubility parameter greater than 12.7. Our results make us doubtful of those given by Aaron *et al.*[1] with respect to the solubility and melting point of (4-pyridyl)-1,2-ethanediol. Haas *et al.*[2] also indicated a similar doubt.

With respect to the synthesis of α-acetoxy-4-vinylpyridine (II), we carried out a method similar to that of Haas *et al.*[2] except for one difference, removal of

Table 1. Solubility of (4-pyridyl)-1,2-ethanediol

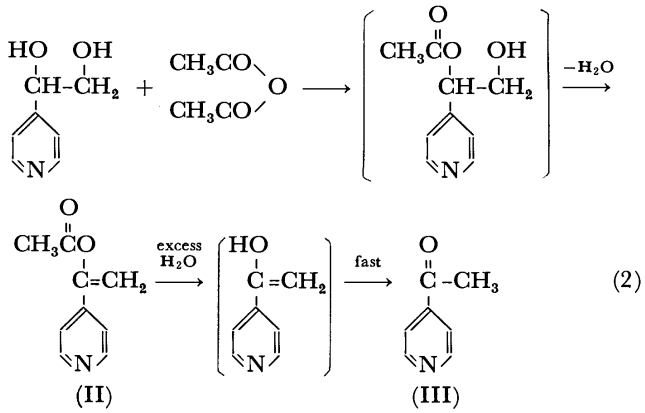
contaminated water. This water seems to facilitate the formation of the by-product 4-acetylpyridine (III) according to reaction scheme (2):



(II) (III)

(2)

Repetition of azeotropic removal of water elevates the yield of α-acetoxy-4-vinylpyridine to a great extent. In the NMR spectrum of α-acetoxy-4-vinylpyridine, the coupling constant of the vinyl protons indicates that the acetoxy group is on α-carbon.

Experimental

(4-Pyridyl)-1,2-ethanediol. 25.2 g (0.24 mol) of 4-vinylpyridine was dissolved in 300 m*l* of acetone. The resulting solution was maintained at 2—5°C under strong magnetic stirring. 25.3 g of potassium permanganate (0.16 mol) and 9.6 g of anhydrous magnesium sulfate (0.08 mol) were dissolved in 500 m*l* of water. The solution was added dropwise from a dropping funnel onto the above acetone solution over a period of 20 min. Mechanical agitation was continued for an additional 10 min and the temperature of the reaction system was raised to room temperature. After addition of a very small amount of hydroquinone, the mixture was filtered with a glass filter. The solid material, manganese dioxide and magnesium hydroxide, was discarded. The clear pale yellow filtrate was concentrated under nitrogen atmosphere with a bath temperature of 50°C under reduced pressure. When the amount of the concentrate became approximately 50 m*l*, 200 m*l* of ethanol was added to the precipitate potassium sulfate, and the solution was kept in a refrigerator overnight. After filtration of the resulting potassium sulfate, (4-pyridyl)-1,2-ethanediol was condensed from the ethanol solution as a pale yellow viscous liquid. Yield, 84% or quantitative. NMR (60 MHz, DSS reference, in D_2O at 80°C): $H_{(a)}$, δ3.83; $H_{(b)}$, 4.40; $H_{(c)}$, 4.90; $H_{(d)}=H_{(d')}$, 7.50; $H_{(e)}=H_{(e')}$, 8.57.

α-Acetoxy-4-vinylpyridine. 100 g of (4-pyridyl)-1,2-ethanediol was dissolved in 300 m*l* of ethanol and 100 m*l* of benzene was added. The ethanol and benzene were removed under reduced pressure. The azeotropic procedure was repeated three times. 500 g of acetic anhydride was added to the dried (4-pyridyl)-1,2-ethanediol and the mixture was subjected to gentle boiling overnight. Acetylation was exothermic and no external heating was required at the initial stage of the reaction. Excess acetic anhydride was removed under reduced pressure. The following high vacuum distillation gave α-acetoxy-4-vinylpyridine. In order to obtain the polymerization grade of α-acetoxy-4-vinylpyridine, high vacuum distillation was repeated twice. The yield of polymerization grade material was 50%. Bp 80°C/0.58 mmHg. Found: C, 66.3; H, 5.6; N, 8.4%. Calcd for $C_9H_9O_2N$: C, 66.2; H, 5.6; N, 8.6%. NMR (60 MHz, TMS reference, in $CDCl_3$ at room temperature): $H_{(a)}$, δ2.25; $H_{(b)}$, 5.28; $H_{(c)}$, 5.80; $H_{(d)}=H_{(d')}$, 7.42; $H_{(e)}=H_{(e')}$, 8.70; $|J_{(b)(c)}|$, 2.5 Hz.

Catalytic Hydrogenolysis of 7-Chloro-7-fluorobicyclo[4.1.0]heptane in the Presence of Ethylenediamine

Hideki KANO, Kazuo KOBAYASHI, and Koji ISOGAI
Faculty of Engineering, Niigata University, Gakko-cho, Nagaoka, Niigata

(Received October 22, 1971)

During the course of an investigation on the catalytic hydrogenolysis of *gem*-dichlorocyclopropanes to monochlorocyclopropanes,[1] it became desirable to confirm the stereochemical behavior of the substrates in the formation of *endo* and *exo* isomers of monochlorocyclopropanes. Ando *et al.*[2] reported that cyclopropyl radical is formed and partly inverted in the reduction of some *gem*-chlorofluorocyclopropanes with tri-*n*-butyltin hydride. The behavior of *gem*-halofluorocyclopropanes in their catalytic hydrogenolyses seemed of interest to investigate. This paper deals with the catalytic hydrogenolysis of 7-chloro-6-fluorobicyclo-[4.1.0]heptane (**1**) with Raney nickel catalyst (R–Ni) in the presence of various basic additives.

7-*exo*-Chloro-7-*endo*-fluorobicyclo[4.1.0]heptane (*exo*-Cl-**1**), 7-*endo*-chloro-7-*exo*-fluorobicyclo[4.1.0]heptane (*endo*-Cl-**1**), and a mixture of isomers (*mixture*-**1**, *exo*-Cl-**1**/*endo*-Cl-**1**=43/57) were catalytically hydrogenolyzed with R-Ni in a methanol solution in the presence of sodium hydroxide, potassium hydroxide, lithium hydroxide, ethylamine, diethylamine, triethylamine, piperidine, ethylenediamine, trimethylenediamine, hexamethylenediamine, benzylamine, and monoethanolamine under ordinary conditions. 7-Fluorobicyclo[4.1.0]heptane (**2**) was obtained predominantly without monochlorocyclopropane only in the presence of ethylenediamine as an additive, with considerable evolution of hydrogen. No reaction occurred in the presence of other basic additives.

The results of catalytic hydrogenolyses of *exo*-Cl-**1** and *endo*-Cl-**1** are shown in Table 1. Hydrogenolyses proceeded stereospecifically with retention of configuration and gave 7-*endo*-fluorobicyclo[4.1.0]heptane (*endo*-F-**2**) and 7-*exo*-fluorobicyclo[4.1.0]heptane (*exo*-F-**2**) from *exo*-Cl-**1** and *endo*-Cl-**1** respectively. *Exo*-Cl-**1** was hydrogenolyzed more easily than *endo*-Cl-**1**. The difference seems to be attributable to the effect of hindrance of condensed ring.

TABLE 1. CATALYTIC HYDROGENOLYSIS OF *exo*-Cl-**1** AND *endo*-Cl-**1**

Substrate: 0.005 mol, Catalyst: 2.5 g as Ni, Additive: $NH_2(CH_2)_2NH_2$ 0.03 mol, Reaction time: 24 hr

endo-Cl-**1**	5	—	17	78

Hydrogenolysis of *mixture*-**1** with various amount of R-Ni and ethylenediamine is shown in Table 2. Increase in the amounts of R-Ni and ethylenediamine gave rise to the increase of hydrogenolyzed products.

It is of interest that *gem*-dichlorocyclopropanes are hydrogenolyzed readily in the presence of common amines and alkali hydroxides[1], whereas **1** is hydrogenolyzed gradually only in the presence of ethylenediamine. Poor reactivity of **1** may be caused by the

polarizability of C-F bond and the weak affinity to the catalyst surface. By stirring the methanol solution of ethylenediamine with R–Ni, a colored complex was formed which dissolved into the solution with the evolution of hydrogen. The catalytic hydrogenolysis of **1** was retarded when ethylenediamine and R–Ni were stirred in the reaction medium for several hours before addition of **1**. The behavior of ethylenediamine is not clear, but it might be explained as follows: chlorine atom adsorbed on the catalyst is extracted by the complex formed from ethylenediamine and R-Ni, and concerted reduction takes place simultaneously by the transfer of electron to the substrate in the transition from Ni(0) to Ni(II).

Experimental[3]

*Preparation of 7-Chloro-7-fluorobicyclo[4.1.0]heptane (**1**).* The compound was prepared by the method of Ando *et al.*[4] To a mixture of cyclohexene, sodium hydride and methyl dichlorofluoroacetate, methanol was added gradually at 0°C. A mixture of *endo*-chloro and *exo*-chloro isomers of **1** (*mixture*-**1**; *exo*-Cl/*endo*-Cl=43/57) was obtained in 30% yield, bp 23.5—25°C/4 mmHg. Found: C, 57.02; H, 6.87%; Calcd for $C_7H_{10}ClF$: C, 56.98; H, 6.83%. Isomer ratio of **1** was identified by NMR and vpc. ^{19}F NMR of isomers; *exo*-Cl-**1** (R_t: 6.4 min): δ 80.0 (J=5 Hz); *endo*-Cl-**1** (R_t: 7.3 min): δ 45.1 (J=19 Hz). Isolation of two isomers of **1** was carried out by preparative vpc.

*7-Fluorobicyclo[4.1.0]heptane (**2**).* A mixture of *endo*- and *exo*-fluoro isomers of **2** isolated from hydrogenolyzed products of *mixture*-**1** by preparative vpc gave satisfactory ^1H NMR and data of elemental analysis. NMR; *exo*-F-**2** (R_t: 3.6 min); δ 4.12 (J=2 Hz); *endo*-F-2 (R_t: 4.0 min): δ 4.38 (J=7 Hz). Found: C, 73.58; H, 9.76%. Calcd for $C_7H_{11}F$: C, 73.65; H, 9.71%.

General Procedure of Catalytic Hydrogenation. A mixture of chlorofluorocyclopropane (0.005 mol), R–Ni (2.5 g as Ni), methanol (50 m*l*) and commercial amine or alkali hydroxide (0.03 mol) was stirred under ordinary pressure of hydrogen at 18—22°C for 24 hr. The solution was separated from catalyst, poured into 500 m*l* of water and extracted with ether. Ether solution was washed with dilute HCl and water, and then dried (Na_2SO_4). After removal of ether, the residue was identified and determined by vpc.

The authors wish to thank Prof. Ichiro Murata, Osaka University, for the elemental analysis.

3) ^1H NMR spectrum was obtained with a JEOLCO JNM-4H-100 spectrometer in CCl_4 with TMS as an internal reference. ^{19}F NMR spectrum was obtained with a JEOLCO JNM-4H-100 spectrometer (94 MHz) in CCl_4 with trifluoroacetic acid as an external reference. Vpc analyses and separations were performed with an OHKURA MODEL 6000 or an OHKURA MODEL 1200 gas chromatograph. For analytical purposes, a 3 mm×2 m column with 15% TCP on 60—80 Celite 545 or a 3 mm×3 m column with 15% HV grease on 60—80 Celite 545 was used. As carrier gas, hydrogen was used at a rate of 60 ml/min. For preparative purposes, a 8 mm×5 m column was used with 30% HV grease or 30% TCP on 40—60 Celite 545.

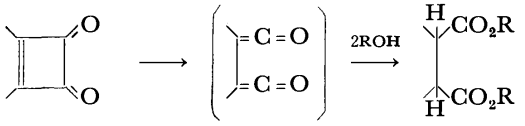
Methylene Analogs of Cyclobutenedione. V.[1] The Reactions of 3,4-Bis(diphenylmethylene)cyclobutanedione with Water, Alcohol, and Amine in the Presence of Bromine. The Approach to a Bisketene

Fumio TODA and Junji FUJITA

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama

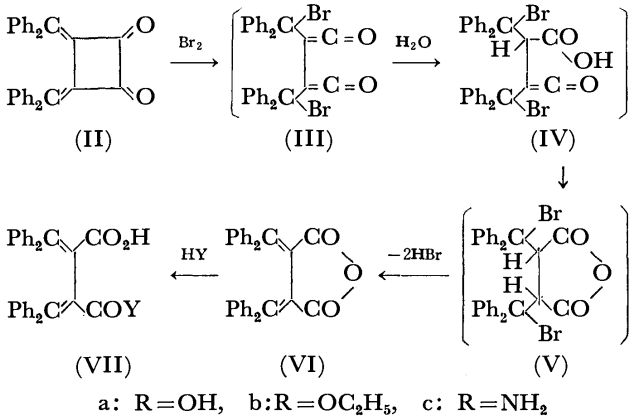
(Received November 10, 1971)

The approach to the bisketene (I) is an interesting subject. Evidence for the formation of I as an intermediate has been reported by several investigators. Both the ethanolysis of diphenylcyclobutenedione[2] and the photolysis of phenylcyclobutenedione[3] in methanol to afford diethyl 2,3-diphenylsuccinate and dimethyl 2-phenylsuccinate respecitvely have been interpreted as proceeding *via* the corresponding bisketene intermediate (I). A similar photochemical transformation of benzocyclobutenedione to a bisketene intermediate has also been reported.[4,5]



(I)

On the contrary, 3,4-bis(diphenylmethylene)-cyclobutanedione (II)[6] was stable in methanol for 24 hr, whereas under the same conditions diphenyl cyclobutenedione was completely destroyed within 12 hr[2]. The stability of II is probably the result of the impossibility of its transformation into a bisketene intermediate. If this assumption is correct, a reagent which localizes the π-electrons of the diene system of II will promote the transformation of II into a bisketene intermediate. This expectation was confirmed using bromine, and II was converted, probably *via* a bisketene intermediate into various products depending on the nucleophiles added.



a: R=OH, b: R=OC_2H_5, c: R=NH_2

Scheme 1

The heating of a solution of II in wet carbon tetrachloride containing about 2.5 molar amounts of bromine under reflux for 30 min afforded VI. VI was identified by a comparison of its IR spectrum with that of an authentic sample prepared accroding to a previously-reported method[6]. The structure of VI was further confirmed by its hydrolysis, ethanolysis, and ammonolysis, which afforded VIIa, VIIb, and VIIc respectively.

The formation of VI can be well interpreted by assuming the bisketene (III) as an intermediate, even though it is not clear whether or not the C–Br bond of III is a real σ-bond. A possible reaction mechanism of the formation of VI from III is an intramolecular cyclization of the IV initially produced by the addition of water to III, accompanied by dehydrobromination, as is shown in Scheme 1, even though it is again not clear whether or not the intramolecular cyclization of IV into V precedes the dehydrobromination of IV.

The reactions of II with alcohol and amine in the presence of bromine to afford the diester IX and the succinimide X respectively can also be interpreted by assuming the bisketen III as an intermediate. The heating of a solution of II in dry carbon tetrachloride containing methanol and bromine under reflux for 30 min afforded IXa in a 68% yield. By a similar procedure, IXb was obtained in a 71% yield. IX was identified by means of the spectral data described in the Experimental section. The reaction of II with *n*-propyl-, isopropyl-, and *n*-butylamine in dry carbon tetrachloride containing a small amount of bromine at room temperature for 30 min afforded three succinimides, Xc, Xd, and Xe, in 63, 58, and 59% yields respectively. X was identified by means of the spectral data described in the Experimental section.

Experimental

The Reaction of II with Water. A solution of II (0.5 g) and bromine (0.3 g) in wet carbon tetrachloride (50 m*l*) was refluxed for 30 min. The crude crystals obtained by the subsequent evaporation of the solvent were recrystallized from acetonitrile to afford VI as red rhombs; 0.385 g (74%); mp 230—231°C (lit,[6] mp 230°C). IR (Nujol), 1795 and 1755 (C=O) and 1545 cm^{-1} (C=C). The IR spectrum was identical with that of an authentic sample prepared according to a previously-reported method.[6]

The Hydrolysis, Ethanolysis, and Ammonolysis of VI. A mixture of VI (0.25 g), KOH (0.04 g), and acetone (25 m*l*)-water (5 m*l*) was refluxed for 2 hr. The reaction mixture was concentrated to *ca.* 10 m*l* and was acidified with hydrochloric acid. The solid thus formed was collected by filtration, washed with water, and recrystallized from ethanol to leave VIIa as pale yellow needles; 0.165 g (63%); mp 233—234°C. IR (Nujol), 1695 and 1670 cm^{-1} (C=O); UV (EtOH), 228 (20300), 266 (11700), and 320 sh nm (ε, 6800).

Found: C, 80.40; H, 4.76%. Calcd for $C_{30}H_{22}O_4$: C, 80.70; H, 4.97%.

A mixture of VI (0.15 g), KOH (0.05 g), and ethanol (3 m*l*) was refluxed. The solid obtained by the same treatment of tlie reaction mixture as that employed for the hydrolysis of VI was recrystallized from cyclohexane to afford VIIb as colorless needles; 0.12 g (68%); mp 188—189°C. IR (Nujol), 1735 and 1665 (C=O) and 1230 cm^{-1} (ester); UV (EtOH), 232 (22300), 267 (13300) and 320 nm (ε, 7600).

Found: C, 81.10; H, 5.65%. Calcd for $C_{32}H_{26}O_4$: C, 80.99; H, 5.52%.

Through a solution of VI (0.1 g) in chloroform (30 m*l*), ammonia was bubbled for 30 min. The crude product which remained after the evaporation of the solvent was recrystallized from acetone to afford VIIc as colorless needles; 0.07 g (67%); mp 243—244°C. IR (Nujol), 3320 and 3200 (NH) and 1675 cm^{-1} (C=O); UV (EtOH), 232 (11600), 265 (6500) and 320 sh nm (ε, 4100).

Found: C, 80.65; H, 5.31%. Calcd for $C_{30}H_{23}O_3N$: C, 80.88; H, 5.20%.

The Reaction of II with Alcohol. A solution of II (0.5 g) and bromine (0.3 g) in carbon tetrachloride (dried over P_2O_5) (50 m*l*)-methanol (5 m*l*) was heated under reflux for 30 min. The crude product obtained by the evaporation of the solvent was recrystallized from acetone to yield IXa as yellow needles; 0.39 g (68%); mp 233—234°C. IR (Nujol), 1700 (C=O), and 1240 and 1270 cm^{-1} (ester); UV ($CHCl_3$), 246 (22700), 272 (14500), and 330 nm (ε, 8600).

Found: C, 81.22; H, 5.56%. Calcd for $C_{32}H_{26}O_4$: C, 80.99; H, 5.52%.

The heating of a solution of II (0.25 g) and bromine (0.2 g) in carbon tetrachloride (dried over P_2O_5) (30 m*l*)-ethanol (5 m*l*) under reflux for 30 min afforded IXb as pale yellow prisms; 0.22 g (71%); mp 210—211°C. IR (Nujol), 1690 (C=O), and 1245 and 1270 cm^{-1} (ester); UV ($CHCl_3$), 245 245 (21400), 270 (14400), and 326 nm (ε, 7400); NMR ($CDCl_3$), 2.8—3.2 (m, Ph, 20H), 6.13 (q, CH_2, 4H), and 9.18 τ (t, CH_3, 6H).

Found: C, 81.37; H, 5.99%. Calcd for $C_{34}H_{30}O_4$: C, 81.24; H, 6.02%.

The Reaction of II with Amine. A mixture of II (0.3 g), bromine (0.2 g), carbon tetrachloride (dried over P_2O_5) (30 m*l*) and *n*-propylamine (1 g) was stirred at room temperature for 30 min. After the removal of the amine salt by filtration, the mother liquor was concentrated to dryness. The crude product which remained was recrystallized from acetone to afford Xa as yellow needles; 0.215 g (63%); mp 249—250°C. IR (Nujol), 1740 and 1685 cm^{-1} (C=O); UV ($CHCl_3$), 258 (20800), 310 (14600), and 400 nm (ε, 8700).

Found: C, 84.14; H, 5.57%. Calcd for $C_{33}H_{27}O_2N$: C, 84.40; H, 5.80%.

By the same treatment of II with isopropylamine as above, Xb was obtained as yellow needles in a 58% yield; mp 256—257°C. IR (Nujol), 1747 and 1685 cm^{-1} (C=O); UV ($CHCl_3$); 258 (22100), 310 (15600), and 400 nm (ε 9500).

Found: C, 84.12; H, 5.58%. Calcd for $C_{33}H_{27}O_2N$: C, 84.40; H, 5.80%.

By the same treatment of II with *n*-butylamine as above. Xc was obtained as yellow needles in a 59% yield; mp 234—235°C. IR (Nujol), 1750 and 1690 cm^{-1} (C=O); UV ($CHCl_3$); 258 (21600), 310 (15200) and 400 nm (ε, 9000).

Found: C, 84.36; H, 5.81%. Calcd for $C_{34}H_{29}O_2N$: C, 84.44; H, 6.04%.

Kinetic Studies of Copper(II) Chloroacetate Complex Formation Reaction in Aqueous Solutions

Shoji HARADA, Yoshikuni TSUJI, and Tatsuya YASUNAGA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received November 15, 1971)

Rate constant of the complex formation reaction depends on the nature of the metal ion, *e.g.*, on the charge, the electronic configuration, the ionic radius, and the coordination structure.[1] The development of the relaxation methods has made it possible to study kinetically on many complex formation reactions which proceed too fast to be studied by the conventional method. On copper(II) complex formation reaction, however, relatively few kinetic studies have been carried out.[2,3] This is presumably because of the fast rate of the reaction and ease of the formation of hydroxy species even at relatively low pH's. The purpose of the present investigation is to study on the copper(II) chloroacetate complex formation reaction, which can be studied at low pH's, with the help of the ultrasonic absorption method.

Experimental

Reagent-grade copper nitrate, chloroacetic acid, sodium hydroxide, and sodium perchlorate were used. The ionic strength of the solutions was adjusted to 1.0 by an addition of sodium perchlorate. Ultrasonic absorption measurements were carried out at 25°C by the pulse method over the frequency range from 5.5 to 220 MHz. Details of the apparatus have been described elsewhere.[4]

Theoretical

The metal ion and the ligand are hydrated in an aqueous solution. In the case of the complex formation, therefore, two or three-step mechanisms, the rate-determining step of which is the release of a water molecule from the metal ion, have been proposed;[5]

$$\underset{\text{(I)}}{M^{m+}_{aq} + L^{n-}_{aq}} \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} \underset{\text{(II)}}{\left[M^{m+}O\langle^{H}_{H}L^{n-}\right]_{aq}} \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} \underset{\text{(III)}}{[ML]^{m-n}_{aq}} \quad (1)$$

where M is the metal ion, L is the ligand, state I is free ions, state II is the ion-pair, and state III is the complex, and the subscript means that the ions are hydrated. Step I—II represents the diffusion of the ions to form the ion-pair and the rate constants, k_{12}, k_{21}, seem to be very fast. Step II—III is the rate-determining process of the inner-sphere complex formation. With the assumption that k_{12}, $k_{21} \gg k_{23}$, k_{32}, the relaxation frequency, f_r, for the step II—III is related to the rate constants and the ionic concentrations by the following form;

$$2\pi f_r = k_{32} + k_{23}\{1 + k_{21}/k_{12}(C_M + C_L)\}^{-1} \quad (2)$$

where C_M and C_L are the concentrations of M and L respectively. The relaxation absorption is expressed by the single relaxation equation;

$$\alpha/f^2 = A\{1 + (f/f_r)^2\}^{-1} + B \quad (3)$$

where α is the absorption coefficient, f is the frequency, and A and B are constants.

Results and Discussion

The concentrations of the species, which were calculated by the use of the formation constants of copper(II) chloroacetate[6] are summarized in Table 1. Representative absorption curves are shown in Fig. 1. The relaxation frequencies obtained are also listed in

TABLE 1. EXPERIMENTAL CONDITIONS AND THE RELAXATION FREQUENCY OF THE SOLUTION

Sample number	$\sum$Cu (10^{-1} M)	$\sum$L (10^{-1} M)	Ionic concentrations (10^{-3} M)					f_r (MHz)

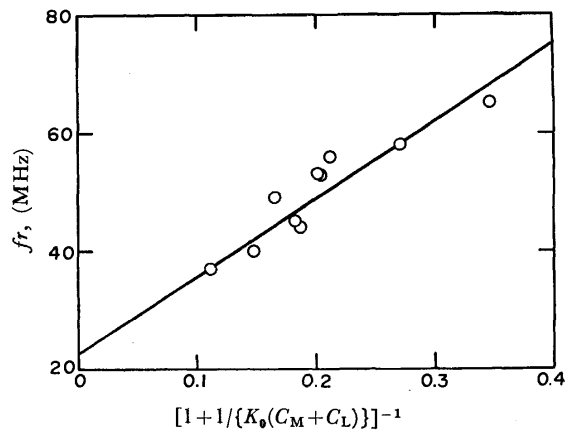

Fig. 2. Plot of relaxation frequency (f_r) *vs.* $[1+1/\{K_0(C_M+C_L)\}]^{-1}$.

Table 1. To ensure that the observed relaxation absorption is due to the complex formation reaction of copper(II) chloroacetate, blank experiments were carried out with solutions containing copper(II) nitrate or chloroacetic acid in the same conditions. In no case was a relaxation absorption observed.

The principal equilibria between copper and chloroacetate ions at low concentrations are;

$$Cu^{2+} + ClAc^- \rightleftharpoons Cu(ClAc)^+ \quad (4)$$

$$Cu(ClAc)^+ + ClAc^- \rightleftharpoons Cu(ClAc)_2 \quad (5)$$

where $ClAc^-$ means the chloroacetate ion. $Cu(ClAc)_3^-$ and higher-order complexes may exist, but the concentrations are very low. Both of the equations have been investigated in trying to correlate the experimental data. In applying Eq. (2) to Eq. (4), the ratio k_{12}/k_{21}, which is the ion-pair constant K_0, can be estimated using the Fuoss equation.[7,8] At ionic strength 1.0, K_0 is calculated to be about 1 for the 2—1 electrolytes. With the data in Table 1 and K_0, f_r is plotted against $[1+1/\{K_0(C_{Cu^{2+}}+C_{ClAc^-})\}]^{-1}$ in Fig. 2. From the slope and the intercept of the line in Fig. 2, k_{23} and k_{32} were obtained; $k_{23}=8.5\times10^8$ sec^{-1}, and $k_{32}=1.4\times10^8$ sec^{-1}. Over-all formation constant, K, can be approximately given by $K_0(1+k_{23}/k_{32})$ and is calculated to be; 7.1 M^{-1}. Taking into account the uncertainty of K_0, this value is in good agreement with the value reported in Ref. 6, 8.1 M^{-1}, which had been previously used in the calculation of the ionic concentrations. On the other hand, the same plots for Eq. (5) do not show a linear relation. These results suggest that Eq. (4) is responsible for the present absorption.

By the ultransonic absorption measurements in the aqueous solution of copper(II) acetate, the rate constant of water substitution of Cu^{2+} ion is reported[9]; $k_{H_2O}=(1—2)\times10^9$ sec^{-1}.

The rate constant k_{23} of copper(II) chloroacetate complex formation reaction obtained above is very close to the value in the case where the ligand is acetate. Moreover the rate constant k_{23} is also close to the water substitution rate studied by the NMR; $k_{ex}\gtrsim3\times10^9$ sec^{-1}. These facts show that the rate-determining step of the complex formation reaction is the loss of a water molecule from the inner-sphere of the metal ion.

As is well known, the d^9 copper(II) ion is subject to Jahn-Teller distortion, and the axial water molecules are in a great lability. Consequently, the fast water substitution rate of copper(II) obtained above may be mainly caused by its peculiar electronic configuration.

An Electrochemical Study of the Photosensitivity of Poly-*N*-vinylcarbazole

Hiroshi YONEYAMA, Masatoshi HIRAI, and Hideo TAMURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received December 6, 1971)

Recently, the photosensitization of ZnO by dyes was studied by means of an electrochemical method, in which dyes were dissolved into a solution and the ZnO crystal was used as a test electrode; it was found that the photosensitization of ZnO by dyes is due to direct electron transfer from excited dyes to ZnO.[1-6] These studies also showed the usefulness of the electrochemical method for the investigation of the photosensitivity of a semiconductor material. In this communication, the application of the electrochemical method to the study of the photosensitivity of poly-*N*-vinylcarbazole (PVCz) will be reported. As is well known, PVCz has a high electronic resistivity, which causes various difficulties in the electrochemical measurements. However, the usefulness of this method will be demonstrated in this paper. The improvement of the photosensitivity of PVCz by the addition of dyes has already been reported[7-9] for a mixed solid system of PVCz and dyes.

Experimental

The PVCz film was prepared by the method described by Okamote *et al.*,[7] using commercial PVCz (Lubican M 170). Evaporated gold or silver paste was used as the electrical contact. No remarkable difference due to the contact material was found. The assembly of the PVCz electrode is shown in Fig. 1, in which a cell assembly is also shown. The PVCz electrode was dipped in a 2 N H_2SO_4 aqueous solution for at least 2 hr before being set in a cell which contained a 0.1 N H_2SO_4 aqueous solution. A freshly-prepared electrode was used for each measurement.

The current was measured by means of a pico-ammeter equipped with a current compensator for the residual current. Measurements were made at 25°C by means of the circuit schematically shown in Fig. 1. No reference electrode was used in this study, and the potential differemce between the PVCz electrode and the counter electrode was recorded. As will be described below, the current was so small that the polarization of the counter electrode was almost negligible. In this case, the platinized platinum counter electrode probably acts as an oxygen electrode[10] or as a hydrogen peroxide electrode.[11]

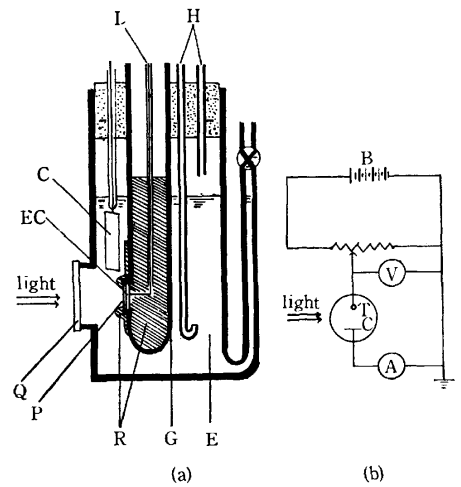

Fig. 1. Schematic illustration of a cell assembly (a) and a circuit for measurements (b). P: PVCz, EC: electrical contact, R: epoxy resin, G: glass tube, C: counter electrode (platinized platinum), E: electrolyte, L: lead wire, Q: quartz plate, H: nitrogen inlet and outlet, B: dry battery, V: voltmeter (input resistance 10^{11} Ω), A: pico-ammeter

A 500 W xenon arc lamp was used as the light source. Various color glass filters, different by 50—60 nm in cut-off wavelength, were chosen for the measurements of the spectral sensitization of PVCz by Rhodamine B.

Result

Figure 2 shows the *I-V* curves of the PVCz electrode in 0.1N H_2SO_4. The photocurrent in this figure was measured under the illumination of a xenon lamp without any filters. It may be observed in this figure that the anodic current was larger than the cathodic current for the same polarization voltage. Figure 3

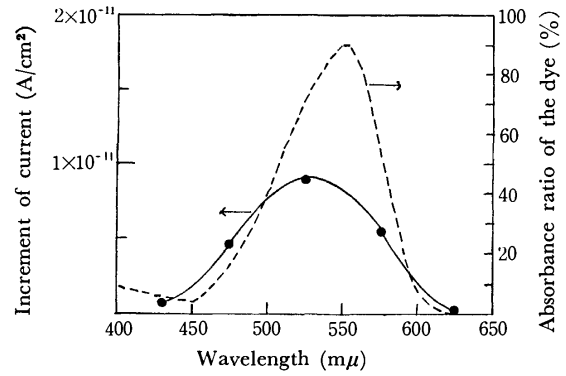

Fig. 4. Spectral sensitization of PVCz by addition of 10^{-5} M Rhodamine B to 0.1N H_2SO_4.
Solid line: increment of the cathodic current
Dotted line: absorption spectrum of the dye

shows the ratio of the photocurrent to the dark one, which was estimated on the basis of Fig. 2. This figure clearly shows that the ratio was by far larger for the cathodic than for the anodic polarization. The current ratio obtained on the PVCz electrode containing 1 mol% tetracyanoethylene (TCNE) as an electron acceptor[12] is also shown in the figure.

12) H. Meier, W. Albrecht, and U. Tschirwitz, *Ber. Bunsenges. Phys. Chem.*, **73**, 795 (1969).

A noticeable spectral sensitization, one which accords with the absorption spectrum of the dye, was observed in the electrolyte containing 10^{-5} M Rhodamine B when the electrode was polarized cathodically. Figure 4 shows the increment of the cathodic photocurrent at −250V by the addition of the dye. No increase of the anodic current by the addition of the dye was observed.

Discussion

When the PVCz electrode was polarized cathodically, the electron energy in the surface region of the electrode becomes lower than that in the bulk of the electrode. Therefore, there must exist an electric field which drifts free electrons from the bulk to the surface and positive holes from the surface to the bulk. In this case, the free electrons, which move from the bulk to the surface and then transfer to a species in the electrolyte, will increase in number upon illumination if the illumination produces the large number of electrons as well as positive holes. On the other hand, if no excited species is produced in the electrolyte by the illumination, the cathodic current due to positive holes will not be influenced by the illumination. Similarly, free holes produced by the illumination will increase the anodic current, while this current will not be increased by photogenerated free electrons if the illumination does not produce any excited species in the electrolyte. Hence, it can be said, from the *I-V* curves in the electrolyte without dyes (Fig. 2), that the cathodic current and the anodic current are carried by electrons and holes respectively. The high current gain upon the illumination which was observed on the cathodic polarization is ascribed to the fact that the electrons are the minority carriers.

On the basis of such considerations, the increase of the cathodic current caused by the excited dye indicates that the injection of a positive hole from Rhodamine B into the PVCz electrode occurred, while the injection of an electron from the dye to the electrode probably did not occur.

ESR Study of γ-Irradiated Isobutylene-Silica Gel System

Siro NAGAI, Shun-ichi OHNISHI, and Isamu NITTA

Osaka Laboratory for Radiation Chemistry, Japan Atomic Energy Research Institute, 508 Mii, Neyagawa-shi, Osaka

(Received December 14, 1971)

In a previous paper,[1] we reported that monomer and dimer cations of some methylbenzenes are produced in the adsorbed states upon γ-irradiation. Isobutylene is known to be a vinyl monomer polymerizing through a cationic mechanism. The present study was undertaken to examine the possibility of observing isobutylene radical cation. A detailed study of the nature of the adsorbed radicals seems to be of importance.

We describe our ESR study of free radicals produced in the γ-irradiated isobutylene-silica gel system. It is seen that the well-resolved spectra observed under certain conditions not only make the identification of radicals possible but also show the phenomena of asymmetric linewidth variation of the hf lines.

Experimental

Silica gel was the same as that reported.[1] Isobutylene (99.0%) was obtained from Takachiho Trading Co. Ltd., and was used without further purification. All experimental procedures were the same as described.[2] The isobutylene contents in the adsorbed samples were in the range 1—20% of the monolayer value.

Results and Discussion

A typical spectrum of adsorbed isobutylene observed at −196°C consists of 10 lines with 22.4 gauss splitting and of several weak lines as shown in Fig. 1a. The 10-line spectrum was assigned to *t*-butyl radical $\dot{C}(CH_3)_3$ from the hyperfine splitting constant.

It should be noted that the linewidths of individual hf lines differ from each other. The $M_I=-1/2$ line is the narrowest of the 10 lines throughout the whole temperature range investigated, and gives the partially resolved second-order structure even at −196°C. At higher temperatures, the structures of the other two lines, $M_I=1/2$ and $-3/2$ become observable (Fig. 1b). The spacings of the second-order components of the $M_I=-1/2$ line at −60°C are 0.70, 0.50, 0.39, and 0.25 gauss which agree with the data in liquid phase.[3] The asymmetric linewidth variation can be explained in terms of a modulation of the anisotropic hyperfine and g-tensor interactions.[4]

The ESR spectrum becomes well-resolved at higher temperatures. The main part of the spectrum (±70 gauss) is shown in Fig. 2a. In this region 6 lines of the 10-line spectrum of the *t*-butyl radical appeared.

4) J. H. Freed and G. K. Fraenkel, *ibid.*, **39**, 326 (1963).

The weak signals at −196°C (Fig. 1a) are well-resolved and the 36 lines (3×3×4) drawn by sticks were assigned to 2-methylallyl radical $CH_2{=}C(CH_3){-}CH_2$. The hf splitting constants measured at −80°C were $a(CH_2)=13.8$ gauss, $a'(CH_2)=14.6$ gauss and $a(CH_3)=3.2$ gauss. The splitting values of methylenic protons show a good correspondence with $a(CH_2)=13.93$ gauss and $a'(CH_2)=14.83$ gauss of the unsubstituted allyl radical.[3]

The asymmetric linewidth variation is appreciable in the spectrum due to the 2-methylallyl radical (Fig. 2b). Qualitative examination of the spectrum shows that the methyl proton lines are broader on the high-field side of the spectrum than on the low-field side. The behavior may be explained on the basis of the theory of ESR linewidth developed by Freed and Fraenkel,[4] provided that the theory is applicable to the spectra of adsorbed radicals. Detailed analyses, however, have not been made because of overlapping of the hf lines with those of two other radicals.

In addition to the 36-line spectrum, we note other lines indicated by arrows in Fig. 2a. The widths of the lines are broader than those of the other two radicals. They may be regarded as a part of the spectrum of the propagating radical $\dot{C}(CH_3)_2{-}CH_2{-}R$ on the basis of the approximate hf splitting values of 22 gauss for methyl protons and 12 gauss for methylene protons. A similar propagating radical on silica gel was found from adsorbed ethylene.[5] From the fact that the signal intensity decreases with the rise of temperature, the propagating radicals are considered to be formed at −196°C during irradiation. It is reasonable to assume that the condensation of isobutylene molecules occurs inhomogeneously on the surface of silica gel before irradiation. The related phenomena were observed in the formation of benzene dimer cations from adsorbed benzene,[1,6] and also in that of benzene monomer cations from adsorbed acetylene.[2]

ESR spectra from the samples with amounts of adsorption less than 2.0 cc STP/g are mainly due to positive holes in irradiated silica gel.[7] With the rise of temperature, the intensity of the spectrum of the *t*-butyl radical is found to increase slightly at the expense of the silica gel signal, suggesting the formation of the *t*-butyl radical partly through a cationic mechanism.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1935—1936 (1972)

6β-Acetoxyfuranoeremophilan-3α-yl Angelate and 6β-Hydroxyfuranoeremophilan-3α-yl Angelate.[1] New Furanoeremophilane Derivatives from *Farfugium hiberniflorum* Kitamura

Hajime NAGANO and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo

(Received December 18, 1971)

In connection with the structural studies of farfugin A and farfugin B isolated from *Farfugium japonicum* Kitamura (=*Ligularia tussilaginea* Makino; Tsuwabuki in Japanese),[2] we have examined the constituents of *Farfugium hiberniflorum* Kitamura (=*Liguralia hiberniflora* Makino; Kan-tsuwabuki in Japanese) and isolated 6β-acetoxyfuranoeremophilan-3α-yl angelate (I) and 6β-hydroxyfuranoeremophilan-3α-yl angelate (II),[1] which constitute two new furanoeremophilane derivatives related to furanofukinol (III).[3]

Compound I, $C_{22}H_{30}O_5$ (M^+ at m/e 374), a viscous oil, was positive to the Ehrlich test. IR, UV, PMR, and mass spectra (see Experimental) suggest the presence of a furan, a secondary and a tertiary methyl, and also that of partial structures: $CH_3COO-\underset{|}{C}H$

	R_1	R_2
(I)	-OC(CH$_3$)=CH-CH$_3$	Ac
(II)	-OC(CH$_3$)=CH-CH$_3$	H
(III)	H	H
(IV)	H	-OC(CH$_3$)=CH-CH$_3$

1) The structures refer to those of relative configurations.

2) H. Nagano, Y. Moriyama, Y. Tanahashi, T. Takahashi, M. Fukuyama, and K. Sato, *Chem. Lett.*, **1972**, 13.

3) K. Naya, M. Nakagawa, M. Hayashi, K. Tsuji and M. Naito, *Tetrahedron Lett.*, **1971**, 2961.

and $CH_3CH{=}C(CH_3)COO{-}\underset{|}{C}H$. The latter moiety was determined as angelyl group by benzene induced solvent shift[4] ($\delta^{CDCl_3} - \delta^{C_6D_6} = 0.44$ ppm) of the olefinic proton found to be *trans* to the ester group. Reduction of I with lithium aluminum hydride gave a diol $C_{15}H_{22}O_3$ identical (IR, PMR, and tlc) with furanofukinol (III)[3] (3α,6β-dihydroxyfuranoeremcphilane) isolated by Naya *et al.* from *Petasites japonicus* Maxim. Thus, compound I is either 6β-acetoxyfuranoeremophilan-3α-yl angelate (I) or 3α-acetoxyfuranoeremophilan-6β-yl angelate.[1]

Acetylation of II, $C_{20}H_{28}O_4$, an oil, with acetic anhydride and pyridine afforded a monoacetate identical (IR, vpc and tlc) with I. On reduction with lithium aluminum hydride, II gave III. However, spectral data of II differ from those of 6-angelylfuranofukinol (IV)[3] (3α-hydroxyfuranoeremophilan-6β-yl angelate).

Thus substances I and II should be represented by 6β-acetoxyfuranoeremophilan-3α-yl angelate and 6β-hydroxyfuranoeremophilan-3α-yl angelate,[1,5] respectively.

Experimental

Isolation. The dried roots of *Farfugium hiberniflorum* Kitamura (100 g) were extracted three times with boiling benzene (each 400 m*l*). The roots were then powdered and further extracted with boiling benzene. The combined extracts (1.6 g) were chromatographed on silica gel (Wako-gel, C-200; 120 g) with light petroleum-ether (5 : 1) as eluent to give a pale yellow oil containing I. Successive elution with light petroleum-ether (3 : 1) afforded crude II. Pure I (60 mg) and II (100 mg) were obtained by repeated chromatography of each crude oil on silica gel.

6β-Acetoxyfuranoeremophilan-3α-yl Angelate (I). Spectral data of I, $C_{22}H_{30}O_5$, an oil, are as follows; UV: λ_{max}^{EtOH} 215 nm (ε 17000); IR: $\nu_{max}^{CHCl_3}$ 1730, 1710, 1640, 1560, 1235, and 1160 cm^{-1}; PMR ($CDCl_3$): δ 0.97 (d, J=7 Hz, $C_{(4)}$-CH_3), 1.03 (s, $C_{(5)}$-CH_3), 1.87 (d, J=1.5 Hz, $C_{(11)}$-CH_3), 1.87 [s, $CH_3CH{=}C(CH_3)COO$-], 1.97[d,[6] J=7 Hz, $CH_3CH{=}C(CH_3)COO$-], 2.12 (s, CH_3CO-), 5.37 (m, $C_{(3)}$-H), 6.01[q,[6] J=7 Hz, $CH_3CH{=}C(CH_3)COO$-], 6.37 (br. s, $C_{(6)}$-H), and 7.05 ppm (m, $C_{(12)}$-H); PMR (C_6D_6): δ 0.90 (d, J=7 Hz, $C_{(4)}$-CH_3), 0.95 (s, $C_{(5)}$-CH_3), 1.76 (s, CH_3-CO-), 1.8—2.2[$C_{(11)}$-CH_3, $CH_3CH{=}C(CH_3)COO$- and $CH_3CH{=}C(CH_3)COO$-], 5.57[m, $C_{(3)}$-H and $CH_3CH{=}C(CH_3)COO$-], 6.51 (br. s, $C_{(6)}$-H) and 6.95 ppm (m, $C_{(12)}$-H); MS: *m/e* 374 (relative intensity 2%, M^+), *m/e* 124 (100%, *retro*-Diels-Alder fragment), *m/e* 83 (82%, $[CH_3CH{=}C(CH_3)CO]^+$), *m/e* 55 (70%, $[CH_3CH{=}CCH_3]^+$) and *m/e* 43 (80%, $[CH_3CO]^+$).

6β-Hydroxyfuranoeremophilan-3α-yl Angelate (II). Characterization of II, $C_{20}H_{28}O_4$, an oil, is as follows; IR: $\nu_{max}^{CHCl_3}$ 3450, 1700, 1640, 1560, 1240 and 1160 cm^{-1}; PMR ($CDCl_3$): 0.95 (s, $C_{(5)}$-CH_3), 1.00 (d, J=7 Hz, $C_{(4)}$-CH_3), 1.8—2.1 [$C_{(11)}$-CH_3, $CH_3CH{=}C(CH_3)COO$- and $CH_3CH{=}C(CH_3)COO$-], 5.07 (br. s, $C_{(6)}$-H), 5.30 (m, $C_{(3)}$-H), 6.05 [m, $CH_3CH{=}C(CH_3)COO$-] and 7.04 ppm (m, $C_{(12)}$-H).

Reduction of 6β-Acetoxyfuranoeremophilan-3α-yl Angelate (I) with Lithium Aluminum Hydride. A solution of I (43 mg) in dry ether was added to a suspension of lithium aluminum hydride (50 mg) in dry ether and the reaction mixture was refluxed for 1.5 hr under nitrogen atmosphere. The usual treatment gave a crystalline material (34 mg), which was purified by chromatography on silica gel to afford furanofukinol (III), UV: λ_{max}^{EtOH} 219 nm (ε 6200); IR: ν_{max}^{Nujol} 3375 and 3320 cm^{-1}; PMR (DMSO-d_6): 0.77 (s, $C_{(5)}$-CH_3), 0.84 (d, J=7 Hz, $C_{(4)}$-CH_3), 1.98 (d, J=*ca.* 1 Hz, $C_{(11)}$-CH_3), and 7.14 ppm (m, $C_{(12)}$-H); MS: *m/e* 250 (3%, M^+) and *m/e* 124 (100%, *retro*-Diels-Alder fragment).

6β-Hydroxyfuranoeremophilan-3α-yl angelate (II) was reduced with lithium aluminum hydride to give furanofukinol (III) by the same procedure as abave.

The authors wish to thank Prof. K. Naya, Kwansei Gakuin University, for the gift of the authentic sample of furanofukinol, and also for the PMR and IR spectra of furanofukinol and its derivatives.

4) J. Ronayne and D. H. Williams, *J. Chem. Soc., C*, **1967**, 2642.

5) Since no optical rotation data were described for furanofukinol (III),[2] absolute configurations of compounds I and II are left undetermined. From biogenetic considerations, absolute configurations of I and II are plausible for compounds I and II.

6) Further long-range couplings are observed for these signals.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1937—1938 (1972)

The Temperature Dependence of the Fluorescence and Polarization Spectra of 1-Naphthol

Satoshi SUZUKI, Tsuneo FUJII, and Kohei SATO

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano

(Received January 10, 1972)

In general, the fluorescence of an organic compound in a condensed medium originates from the lowest excited singlet state, because the internal conversion between excited singlet states is fast compared with the fluorescence emission. If two excited singlet levels are closely situated in the region of the lowest absorption band, a dual emission is expected to be observed.[1-5] On the other hand, it is well accepted that a molecule in a fluid solution is first excited to the Franck-Condon excited state, and that it then passes into the equilibrium excited state from which the fluorescence emission occurs. At sufficiently low temperatures, such a relaxation process cannot take place during the fluorescence lifetime because of the high viscosity of a solvent. As a result of this phenomenon, the fluorescence emission originates from the Franck-Condon excited state and, hence, shifts to the blue. This note will report the inversion of the fluorescent state in 1-naphthol caused by a lowering of the temperature.

Experimental

1-Naphthol was recrystallized three times from water and then sublimed *in vacuo*. Glycerin (Wako Pure Chemical Industiries, Inc., JIS S grade) was used without further purification.

The absorption spectra were recorded on a Hitachi EPS-2 recording spectrophotometer. The fluorescence and excitation spectra were obtained by means of a Hitachi MPF-2A fluorescence spectrophotometer. The temperatures of the solutions were controlled by using a cryostat (Torisha Laboratory, Ltd.) with an accuracy of about ±1 K. The degree of polarization, P, was measured by the method of photoselection.[6-8]

Results and Discussion

The temperature dependence of the fluorescence spectra for 1-naphthol in a glycerin solution is shown in Fig. 1, together with the absorption and polarization spectra.

1-Naphthol has four absorption bands in the near-ultraviolet region. The lowest frequency band with a sharp fine structure is assigned to the ^1L_b transition, the broad band near 3.4 kK which overlaps the ^1L_b, to the ^1L_a transition, and the other two strong bands at higher frequencies than 4 kK, to the ^1B_b transition.[9-11] The moments of the ^1L_b and ^1B_b transitions lie nearly along the direction of the long axis of the molecule, while the moment of the ^1L_a transition is nearly along the short axis.[11-13]

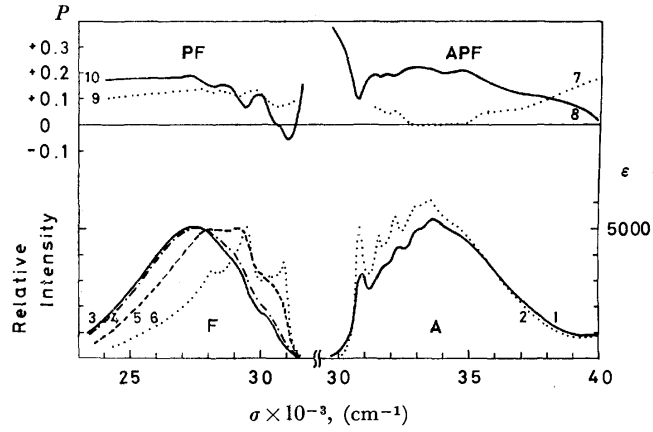

Fig. 1. Temperature dependence of the absorption, fluorescence, and polarization spectra of 1-naphthol in glycerin. a) Absorption spectra(A) 1: 299 K; 2: 135 K. b) Fluorescence spectra(F) Excitation wavelength: 297 nm; 3: 329 K; 4: 261 K; 5: 242 K; 6: 168 K. c) Fluorescence excitation polarizarion spectra(APF) 7: 200 K, observed at 325 nm; 8: 200 K, observed at 360 nm. d) Fluorescence polarization spectra (PF) Excitation wavelength: 297 nm; 9: 283 K; 10: 195 K.

At room temperatures, 1-naphthol has a broad, structureless fluorescence band. In the excitation polarization spectrum at 200 K, obtained by monitoring the fluorescence at the wavelength of 360 nm, which corresponds to the maximum of the broad fluorescence band, the peaks of the ^1L_b-absorption band correspond to the polarization minima, whereas the polarization spectrum has large positive P values in the ^1L_a-band region. Further, the degree of polarization is negative in the region of the ^1B_b transition. Such behavior in the excitation polarization spectrum is very similar to that observed in the system of 1-naphthol and triethylamine.[4] The fluorescence polarization curve obtained with excitation at the ^1L_a band has nearly the same positive P values over the whole region of the fluorescence band. These observations indicate that the polari-

zation of the broad fluorescence transition is parallel to that of the ^1L_a and that, hence, the fluorescent state is the ^1L_a state.

As the temperature is lowered, the fluorescence spectrum shifts to the blue and changes to a structured band, the peaks of which lie in mirror-symmetry positions with respect to the ^1L_b absorption peaks.

At a low temperature, the excitation polarization spectrum obtained by monitoring the highest-frequency peak of the fluorescence band exhibits minima at the wavelengths corresponding to the region of the ^1L_a-absorption band. The degree of polarization is positive in the region of the ^1B_b-absorption band. The degree of polarization of the fluorescence emission obtained with an excitation wavelength of 297 nm shows a considerable decrease in the short-wavelength region. The wavelengths at which the minima of the polarization curve occur coincide with the peaks of the fluorescence band. The behavior of the polarization spectra confirms that the fluorescence emission from 1-naphthol in glycerin at sufficiently low temperatures is predominantly from the ^1L_b state. The same temperature dependence of fluorescence and polarization spectra was observed in both propylene glycol and ethanol solvents.

The results may be interpreted as follows. In the equilibrium excited state, the interaction of a solute molecule with solvent molecules lowers the ^1L_a energy below the ^1L_b, so that the broad ^1L_a fluorescence is observed. At a sufficiently low temperature, where the solute and solvent molecules do not have enough time to relax to the equilibrium configuration, the ^1L_a state lie above the ^1L_b, therefore, the blue-shifted ^1L_b fluorescence is observed. This interpretation is consistent with the finding of the theoretical calculation that the π-moment of the ^1L_a state is larger than that of the ^1L_b.[12]

The degree of polarization in glycerin increases to a maximum value at 10°C. This means that 1-naphthol cannot re-orient itself during its fluorescence lifetime at a temperature below 10°C. It should be noted that the temperature at which the fluorescence from the ^1L_b state becomes appreciable is lower by about 30 degrees than that at which the re-orientation of the solute ceases. The effects of molecular motions on the fluorescent state will be discussed later.

The Syntheses and Properties of Chloro(acrylonitrile) Complexes of Platinum(0)

Keinosuke SUZUKI and Hideshi OKUDA

Inorganic Chemistry Laboratory, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received January 10, 1972)

In the reaction of $Pt(PPh_3)_4$ with haloolefins, the formation of two kinds of complexes, *i.e.*, the olefin complex and the vinyl complex, has been reported.[1)]

Olefin complex Vinyl complex

This paper will deal with the reaction of $Pt(PPh_3)_4$ and $Pt(AsPh_3)_4$ with chloroacrylonitrile, CH_2=CClCN, and with the structures of the complexes formed; the discussion will be based on the spectroscopic data.

The treatment of the benzene solution of $Pt(PPh_3)_4$ with chloroacrylonitrile resulted in a pale yellow solution, from which $Pt(PPh_3)_2(CH_2CClCN)$ (I) was subsequently isolated. A similar treatment of $Pt(AsPh_3)_4$ with the same ligand gave a pale yellow substance formulated as $Pt(AsPh_3)_2(CH_2CClCN)$ (II). Both complexes, (I) and (II), are stable in air; they decompose at 160—170 and 160—165°C respectively. The infrared and proton magnetic resonance spectra data of the two complexes are summarized in Table 1. As is clear from the table, the stretching frequency, $\nu_{C=C}$ disappeared upon the complex formation, while ν_{C-Cl} was still present. Since Bland and Kemmitt[1)] proposed the coordination of the double bond, *i.e.* the formation of the olefin complex on the basis of the disappearance of $\nu_{C=C}$, it may be reasonable to assume the formation of olefin complexes for both the complexes studied here. The far-infrared spectral data also indirectly support the above assumption, because the stretching frequency, ν_{Pt-Cl}, expected for the product of the oxidative addition was not observed. For the complex II this was not clear due to the strong ligand absorption in the region 320—350 cm^{-1}.

The proton magnetic resonance spectra of methylene protons in the complexes I and II are shown in Fig. 1. For these complexes, it was difficult to obtain well-resolved spectra because of their low solubility in common organic solvents.

Furthermore, the non-equivalence of the methylene protons caused another difficulty in interpreting the spectra. The CH_2 protons of the coordinated ligand showed a high-field shift in both complexes, indicating the formation of olefin complexes, and the satellite due to the coupling with ^{195}Pt was also observed. In the complex I, the central peak of the CH_2 proton appeared as a complicated multiplet centered at around $\tau = \sim 7.6$ ppm. This complex signal may be

1) W. J. Bland and R. D. W. Kemmitt, *J. Chem. Soc., A*, **1969**, 2062.

II: $Pt(AsPh_3)_2(CH_2$=CClCN)

due to the existence of an AB pattern, which is, in turn, able to couple with two non-equivalent phosphorus atoms. Since the CH_2 protons do not couple with an arsenic atom, the signal of the complex II can be expected to be much simpler than that of the complex I. However, as is shown in Fig. 1, the central peak of the CH_2 signal appeared as a triplet with the intensity ratio of 1 : 28 : 1. We interpret this triplet as being the case when the inside peakes of an AB quartet come very close to one another and as being a quartet changed into a triplet. To obtain accurate values of the coupling constant and chemical shift, the use of an AB quartet pattern is required, but the signal obtained could not be further resolved. Consequently, the $J(H_a-H_b)$ value was approximated to the difference in the values of the two signals, 1 and 2, and τ, to the value of the signal 2 in Fig. 1.

The electronic spectra of the complexes were measured in the 220—360 nm, region. They are quite similar to each other; there are three absorption maxima at 36.5, 39.7, and 43.2×10^3 cm^{-1} ($\varepsilon=1.8\times10^4$ sh, 2.6×10^4, and 3.8×10^4) far the complex I and at 35.8, 39.7, and 44.4×10^3 cm^{-1} ($\varepsilon=1.1\times10^4$ sh, 2.6×10^4, and 4.7×10^4) for the complex II. From these results, the formation of the olefin complexes is concluded for both cases. We further tried to prepare a vinyl complex by refluxing the complex I in ethanol but without success.

2) S. B. Lie and P. Klaboe, *Spectrochem. Acta*, **26A**, 1191 (1970).

Experimental

Materials. The $Pt(PPh_3)_4$ and $Pt(AsPh_3)_4$ were prepared by a method previously reported by other authors.[3,4]

Chloroacrylonitrilebis(triphenylphosphine)platinum(O)=(I). 2-Chloroacrylonitrile (0.2 m*l*, 2 mmol) was added to a solution of tetrakis(triphenylphosphine)platinum (12. g, 1 mmol) in benzene (100 m*l*) under nitrogen. The reddish-brown color of the original solution turned to a pale yellow, and a white substance was obtained on concentrating the solution. It was reprecipitated from a mixture of chloroform and ethyl ether as a white powder; mp 160—170°C (decomp.). Found: C, 57.86; H, 3.61: N, 1.35%. Calcd for $C_{39}H_{32}NClP_2Pt$≡$Pt(PPh_3)_2(CH_2CClCN)$: C, 58.03; H, 4.00; N, 1.74%.

Chloroacrylonitrilebis(triphenylarsine)platinum(O)=(II). To a suspension of tetrakis(triphenylarsine)platinum (1.4 g, 1 mmol) we added 0.2 m*l* (2 mmol) of 2-chloroacrylintirile. The suspension changed to a pale yellow solution in about 30 min. After the solution had then been stirred for 2 hr, it was filtered and the filtrate was concentrated under reduced pressure to give a pale yellow compound. It was precipitated from a mixture of dichloromethane and ethyl ether as a pale yellow powder; mp 160—165°C (decomp.). Found: C, 51.49; H, 3.48; N, 1.37%. Calcd for $C_{39}H_{32}NClAs_2Pt$≡$Pt(PPh_3)_2(CH_2CClCN)$: C, 52.33; H, 3.60; N, 1.57%.

Measurements. The infrared spectra were recorded with JASCO-DS-402G and HITACHI EPI-L2 spectrophotometers. The electronic spectra in the CH_3CN solution were obtained with a HITACHI 323 spectrometer. The proton magnetic resonance spectra were obtained with a JEOL C-60H spectrometer, using $CDCl_3$ as the solvent and TMS as the internal standard.

(Received December 13, 1971)

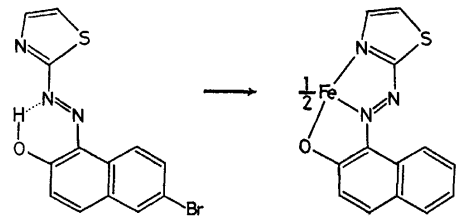
The crystal structures of 1-(2-thiazolylazo)-6-bromo-2-naphthol(TAN-Br) and bis(1-(2-thiazolylazo)-2-naphthol)iron(II) ([Fe[TAN)$_2$]) have been determined by X-ray diffraction. Our main interest lies in the reactions of thiazolylazo-naphthol(TAN) with various metal ions as an analytical reagent. 6-Bromo-derivative of TAN was chosen for the elucidation of structure by the heavy atom method.

The crystals of TAN-Br were grown by sublimation of crude materials. Crystal data are: $C_{13}H_8N_3OSBr$, M.W. 334.2, mp 189°C, orthorhombic, $a=19.07\pm0.03$, $b=32.08\pm0.05$, $c=4.22\pm0.01$ Å. $Dm=1.72$g·cm^{-3}, $Z=8$, $Dx=1.72$ g·cm^{-3}; space group $P2_12_12_1$. Intensities of the three-dimensional reflections were measured visually from equi-inclination Weissenberg photographs for 0—3 layers around the c-axis and 0th layer around the a-axis. In total, 2074 independent reflections were collected and converted into $|F|$ values in the usual way. The structure was solved by the heavy atom method. Parameters were refined by the least-squares method and the R value was reduced to 0.12.

Crystal data of [Fe(TAN)$_2$] are: $[Fe(C_{13}H_8N_3OS)_2]\cdot CHCl_3\cdot C_2H_5OH\cdot H_2O$, F.W. 784.0, triclinic, $a=12.63$, $b=11.97$, $c=10.52$ Å, $\alpha=87°12'$, $\beta=99°36'$, $\gamma=104°46'$. $Dm=1.63$ g.cm^{-3}, $Z=2$, $Dx=1.64$ g.cm^{-3}; space group $P\bar{1}$. Using Cu$K\alpha$ radiation, 3318 intensity data were collected by photographic method for 0—8 layers around the c-axis and 0—2 layers around the a-axis. The structure was solved by the heavy atom method and refined by the block-diagonal least-squares method. R factor was found to be 0.18.

The two crystallographically independent TAN-Br molecules are similar in shape and size. They are planar within a deviation of ±0.03 and ±0.15 Å. Both molecules conform to the chemical formula presented in Fig. 1a. The N···O distance of 2.50 Å suggests an intramolecular hydrogen bonding between N and O atoms as indicated in Fig. 1a.

The structure of [Fe(TAN)$_2$] is shown in Figs. 1b and 2. The TAN acts as a terdentate ligand. One Fe(II) ion is bonded octahedrally to two phenolic



a TAN-Br b [Fe(TAN)$_2$]

Fig. 1. Comparison between TAN-Br and [Fe(TAN)$_2$].

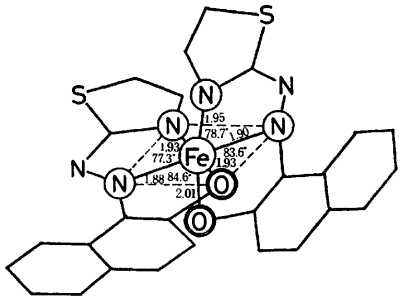


Fig. 2. The Structure of Fe(II) chelate [Fe(TAN)$_2$].

oxygens, two azo nitrogens adjacent to the naphthol ring and two thiazole nitrogens to form four five-membered chelate rings. The ligand molecules are very nearly planar and the mean planes of the ligands are perpendicular to each other. The two ligands are in *mer* coordination. Thus the structure determined from the measurement of stability constant and absorption spectra has been verified. Since the structure of TAN-Br and probably also of TAN is as shown in Fig. 1a, 180° rotation around the two N–C bonds should occur in chelate ring formation and turn the structure into that shown in Fig. 1b.

The general feature of coordination of TAN to Fe(II) is very similar to that of 1-(2-pyridylazo)-2-naphthol(PAN) observed in crystals of [Cu(PAN)-H_2O]·ClO_4.[1]

The Complex of Poly-α,L-glutamic Acid with Acridine Orange in the Neutral and Alkaline pH Region

Yukio SATO, Michio YONEYAMA, and Masahiro HATANO
The Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai
(Received December 10, 1971)

It is well known that an extrinsic optical activity is induced in the region corresponding to the absorption bands of acridine orange (AO) only when the dye combines with helical form of poly-α,-L-glutamic acid (PLGA).[1-3] Myhr and Foss,[4] and Eyring and Yang[5] reported that the Cotton effect could be induced for the complex even at pH 8.0, where the structure of PLGA is regarded to be a random coil form. The cause of the induced circular dichroism (CD) of the PLGA-AO complexes and their structures are, however, not yet completely clarified.

In this communication, we present preliminary results on the optical activities and structures of the complexes in the PLGA-AO system for R/D values smaller than 10. It was found that, in the cases of R/D of around unity, complexes with ordered structures can be formed in the neutral and alkaline pH region.

The complexes were prepared by adding an aqueous solution of AO to that of PLGA with pH of 4.5. The pH of the complex solutions was brought to the desired value by addition of NaOH. The total molarity of AO was fixed at 2×10^{-5} M. The CD curves of these complexes were recorded at several R/D values for various pH. When R/D exceeds 4, the intensity of the induced CD was found to diminish in the neutral and alkaline pH regions. However, the induced CD spectra were observed even in the neutral and alkaline pH regions for R/D of around unity (Fig. 1).

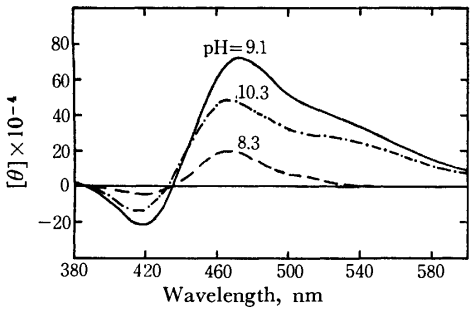

Fig. 1. pH dependence of CD spectra of PLGA-AO system at $R/D=1$.

As shown in Fig. 1, the induced CD which starts to develop at pH of about 6 reaches a maximum intensity at pH of about 9 and diminishes at pH of about 12. It is likely that the induced CD spectra developed in the neutral and alkaline pH regions for the case of R/D of around unity are due to the ordered structures of the complexes.

For the sake of confirmation, we also measured the specific viscosity η_{sp} of PLGA with various degrees of polymerization (DP) at pH of 4.5 and those of PLGA-AO complexes of R/D of unity at pH of 9.0. By means of the following Simha equation, J values were calculated from specific viscosity.

$$\frac{\eta_{sp}}{\Phi} = \frac{J^2}{15(\ln 2J-1.5)} + \frac{J^2}{5(\ln 2J-0.5)} + \frac{14}{15} \qquad (1)$$

where J is the axial ratio of a postulated ellipsoid of the polymer and Φ is the volume fraction of the polymer in the solution. As shown in Fig. 2, J values of PLGA-AO complexes are proportional to the DP of PLGA. These results indicate that PLGA-AO complexes with R/D of unity at pH 9.0 have rigid rod-like structures, *e.g.*, helical structures.

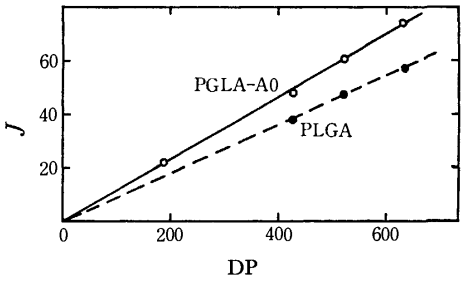

Fig. 2. Simha's J values as a function of degree of polymerization (DP) for PLGA in H_2O (pH 4.5) and PLGA-AO complex of $R/D=1$ in MeOH:H_2O (5:3) (pH 9.0).

In the case of R/D of unity, almost all available AO molecules can be bound to PLGA by ionic bonds between the cationic ring nitrogen atoms of AO molecules and ionized carboxyl groups of the side chains of PLGA in the neutral and alkaline pH regions. As a result of neutralization of the side chains of PLGA by the AO cations, PLGA can be compelled to form a helical structure with AO molecules around it. In the strong alkaline region above the pK_a value of AO,[6] the molecules are deprotonated to be neutral. It seems to be difficult for AO molecules to be bound to PLGA and to stabilize the helical structure of PLGA. Ballard *et al.*[2] inferred, in the case of R/D larger than 20 at pH of 4.5, the presence of a left-handed super-helix of AO molecules around the right-handed helix of PLGA on the basis of a negative CD band polarized parallel to the helix axis at 470 nm. In comparing our results with theirs, we tentatively conclude that AO molecules bound to the carboxylate groups of the side chains of PLGA are arranged to form a right-handed super-helix surrounding the core of the right-handed helix of PLGA, since in this case a positive CD band at about 470 nm is observed.

The Flexibility of the Tribenzylamine Molecule in Both Solution and the Solid State as Revealed by NMR Measurements

Ariyuki AIHARA and Masatoki YOKOI*

Department of Materials Science, Denki-Tsushin University, Chofu, Tokyo

** Department of Chemistry, Faculty of Science, Shinshu University, Matsumoto*

(Received January 7, 1972)

The molecule of tribenzylamine has a possibility of taking a number of conformations due to the intramolecular rotation of the moieties of the molecule about various axes of rotation; there is also the possibility of the molecular inversion of the pyramidal structure of N–$(CH_2)_3$ bonds.[1,2] We have performed NMR measurements of tribenzylamine in the crystalline state as well as in solution in order to get some knowledge about the flexibility of this molecule.

A JNM-4H-100 spectrometer (100 MHz)[3] has been used to measure the high-resolution NMR absorption in the CCl_4 solution, while the measurement of the broad-line NMR was done with a conventional autodyne spectrometer constructed in our laboratory,[4] operating at a frequency of 19.8 MHz (proton) and with a modulating field of 35 Hz superimposed on the main magnetic field.

Despite a presumed complication of the molecular conformation, the NMR spectrum of tribenzylamine dissolved in CCl_4 exhibits only a single sharp absorption signal of methylene protons (δ=3.52 ppm, ref. TMS). This fact suggests that the molecule must be undergoing some flexing motions in such a way that all the protons of methylene groups become magnetically equivalent on the average. In Table 1, the δ values of methylene protons as well as those of phenyl protons are compared with the chemical shift data of mono- and dibenzylamine, and also of dibenzylmethylamine, observed in CCl_4 solutions. The values are all corrected for possible intermolecular interactions by extrapolating the measured δ's at several concentrations to an infinite dilution.

It is interesting to see that the signal of the C_6H_5 protons in tribenzylamine shows somewhat complicated features, with three main peaks at δ=7.16, 7.22, and 7.28 ppm, while those of mono- and dibenzylamine are rather simple. Dibenzylmethylamine seems to behave much like tribenzylamine so far as the chemical shift is concerned.

TABLE 1. THE CHEMICAL SHIFT DATA OF MONO-, DI-, AND TRIBENZYLAMINE, AND ALSO OF DIBENZYLMETHYLAMINE
(in CCl_4 solutions at 25°C; δ in ppm, and the reference is TMS)

Compounds	δ (NH,NH_2,CH_3)	$\delta(CH_2)$	$\delta(C_6H_5)$
$NH_2(CH_2C_6H_5)$	1.21(NH_2)	3.76	7.18
$NH(CH_2C_6H_5)_2$	1.37(NH)	3.74	7.22
$N(CH_2C_6H_5)_3$	—	3.52	7.16, 7.22, 7.28
$N(CH_2C_6H_5)_2CH_3$	2.13(CH_3)	3.47	7.16, 7.22, 7.27

The results of the broad-line NMR measurements add further evidence that this molecule is flexible even in the crystalline state: the magnitude of the second moment at 29°C, 6.23±0.10 Gauss^2 (corrected for modulation broadening after Andrew[5]), is smaller than the theoretical value of the intramolecular contribution to the second moment, 7.38 Gauss^2, which is calculated with the molecular structure data obtained by Drs. Fujiko and Hitoshi Iwasaki from the three-dimensional X-ray crystal structure analysis,[6] assuming the molecule to be rigid in the crystal. It is almost certain, without calculating further the intermolecular contribution to the second moment, that the molecule has some degrees of freedom of motion in the crystal even at room temperature. The width of the absorption spectrum shows a tendency to decrease gradually with the rise in the temperature up to ~70°C.

In view of the bulky molecular structure in a rather loose-packed crystal lattice of tribenzylamine,[6] a tentative calculation has been made of the reduction in the intramolecular contribution to the second moment due to the rotational movement of the phenyl groups about axes joining them to methylene carbons to each other; this rotational motion does not cause any translational shift of the molecule as a whole.

Following the equation introduced by Gutowsky and Pake[7] to correlate the reduction of the second moment due to the rotation of a pair of protons with the angle, γ_{jk}, between the line joining the j and k protons and the axis of rotation;

$$F(\gamma_{jk}) = (3\cos^2\gamma_{jk} - 1)^2/4,$$

we get 5.97 Gauss^2 as the reduced intramolecular contribution to the second moment due to the phenyl-group rotation. This value is slightly less than the observed value of the second moment, 6.23 Gauss^2, the difference being due to the intermolecular contribution to the second moment in a non-rigid lattice. Any intramolecular movements other than that postulated above are improbable, for they would cause a shift of the center of mass of the molecule in the crystal lattice. The details will be published later in this Bulletin.

A Cation-dependent Conformational Change of the 2,2′:6′,2″-Terpyridine Anion Radical

Kazuo NAKAMURA

Department of Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya

(Received January 20, 1972)

Although the structure of the ion pair between the aromatic anion radical and the alkali metal cation in solution has been extensively studied by means of ESR and optical spectra, the case in which the conformation of the anion radical varied with the species of the counter cation has not yet been reported. In the present work, the visible spectra of the 2,2′ : 6′,2″-terpyridine anion radical revealed the presence of two species of ion pairs. The solvent and cationic dependence of the equilibrium between the two species indicated that the species can be distinguished by means of the conformation of the anion.

The visible spectrum of the anion radical produced with lithium in tetrahydrofuran (THF) exhibited an absorption maximum in the 610-mμ range, together with a slight shoulder in the 560-mμ range. With the change in the alkali metal in the order of increasing cationic radius, the shoulder was developed at the expense of the peak in the 610-mμ range. In the spectrum of the cesium-produced radical, the intensity in the 560-mμ range exceeded that in the 610-mμ range. The relative intensity of two peaks also depended on the solvent. The use of 2-methyl tetrahydrofuran (MTHF) enhanced the intensity of the peak in the 610-mμ range, while the use of dimethoxyethane (DME) weaken the intensity of the same peak. The maximum in the 610-mμ range almost disappeared in the spectrum of the cesium-produced radical in DME. The spectrum of the radical in dimethylformamide showed a single maximum, at 573-mμ, which was independent of the metal used. This absoprtion certainly arises from the free terpyridine anion. ESR studies of the nitrogen-hetrocyclic anion radicals have proved that those anions existed as ion pairs in an ethereal solvent.[1-5] Each of the two separated bands in the ranges of 560 mμ and 610 mμ should be assigned to one of the structurally-different ion pair. Examples of the spectra are presented in Fig. 1.

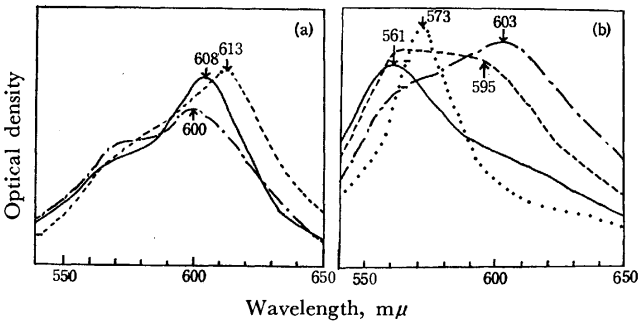

Fig. 1. Visible spectra of the terpyridine anion.
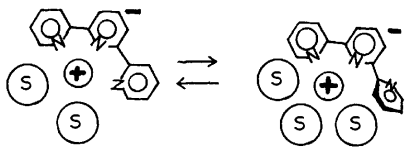
(a): Cationic dependence of the spectra in THF.
----, Li; ——, Na; – – –, Rb.
(b): Solvent dependence of the spectra of the cesium-produced radical.
——, DME; ----, THF; – – –, MTHF; ·····, DMF.
Concentration of the radical, $(1-5)\times10^{-3}$ mol/l.

The repulsions among the nonbonding and antibonding electrons on the three nitrogen atoms of the terpyridine anion keep those atoms far from each other. This situation holds with regard to the conformation of the free terpyridine anion. Three nitrogen atoms are able to coordinate to a cation only when the interaction of the cation with nitrogen atoms is strong enough to compensate for the above repulsions. The interaction of a cation with an anion, especially with the nonbonding electrons on the anion, is intensified by a decrease in the cationic size, while an increase in the solvation of the cation in the order of MTHF<THF<DME[6] weakens such interactions. Both the solvent dependence and the cationic dependence of the relative intensities of the two peaks, therefore, strongly suggested that, in the species exhibiting the peak of the 610-mμ range, the cation is enclosed by three nitrogen atoms and several solvent molecules. When an additional solvent molecule participates this first layer surrounding the cation, one of the nitrogen atoms will become free from coordination to the cation, as is schematically shown in Fig. 2. In such a case, an appreciable change in the spectrum can be expected. The shift of the absorption maximum from the 610-mμ range to the 560-mμ range is due to this conformational change.



(A) (B)

Fig. 2. Possible structures of the ion pair.
The species with absorption maximum in 610 mμ range (A) and in 560 mμ range (B).

Contrary to the case observed thus far, the increase in the cationic field, which resulted from the decrease in the cationic size or in the solvation of the cation, caused a red shift of the absorption maximum in the 610-mμ range.

Promoting Effect of Zirconium Compound on Catalytic Activity for Oxychlorination of Butadiene

Hiroyuki HAGIWARA and Naoyuki TODO

Government Chemical Industrial Research Institute, Tokyo, Mita, Meguro-ku, Tokyo

(Received January 28, 1972)

It is generally accepted that certain carriers not only display a large exposed surface of active constituent but also modify the catalytic activity or the selectivity of the active agent. It has been suggested that the surface compound can be formed between the carrier and the supported material giving a complex which has better catalytic properties.[1-2] During the course of studies on the catalyst for the oxychlorination of butadiene to get 1,2- or 3,4-dichlorobutene, a material of chloroprene monomer, it was found that the activities of the catalysts we developed, $CuCl_2$-LiCl-H_3PO_4 supported on sintered commercial alumina-silica carriers, depend considerably on the amount of contaminant zirconium compound on the carriers.

This communication reports on some characteristic effects of the zirconium compound on activity. The carriers used were sintered alumina-silica ($S<1 m^2/g$) of low surface area, obtained from Fujimi Kenmazai Kogyo Co. (SNO3) and Tokai Konetsu Kogyo Ltd. (TA124). Their approximate chemical compositions were Al_2O_3-10 wt% SiO_2 containing zirconium to some extent or practically none. The catalysts were prepared by the usual coimpregnation method. The amounts of $CuCl_2$, LiCl, and H_3PO_4 supported were 1.81 wt%, 0.21 wt%, and 0.08 wt%, respectively. The activity was measured by a conventional flow type apparatus at a space velocity of 210 per hour at temperatures 160—250°C. A stoichiometric reactant mixture was used. Prior to the activity measurement, the catalysts were preactivated at 300°C for 3 hours under the atmosphere of nitrogen. It is shown in Table 1 that the conversion of butadiene depends obviously on the zirconium content in the carriers: the catalyst prepared from SNO3 revealed a much higher conversion than that prepared from TA124. Its ability was modified by treating the carrier with a concentrated hydrochloric acid to reduce the zirconium content. The amount of zirconium is optimum when the activity of the catalyst is maximum. Thus, in order to get the quantitative relationship between activity and zirconium content, we measured the activity of a series of catalysts prepared from a carrier impregnated with various amounts of zirconium oxychloride by calcination at 700°C prior to supporting the active components.

TABLE 1. ACTIVITIES OF THE CATALYST PREPARED BY USING VARIOUS CARRIERS

Carrier	Conversion of butadiene (%)	Selectivity to 1,2- and 3,4-dichlorobutene (%)
SNO3	52.1	94.4
SNO3 treated with HCl	73.0	96.2
TA124	15.8	94.8

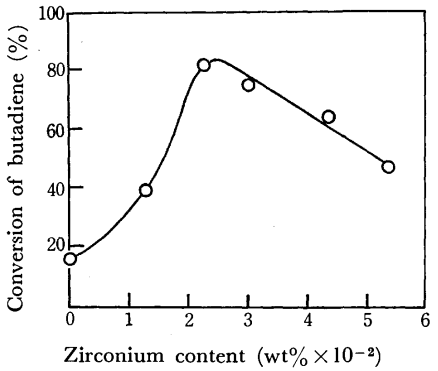

Fig. 1. Effect of zirconium content on the catalytic activity.

We see from Fig. 1 that the addition of an optimum amount of zirconium gave rise to an increase in conversion about five times as high as that obtained without addition of zirconium salts. In contrast, the activity of the catalyst prepared by using silicon carbide as a carrier was not improved by the addition of zirconium salts. The alumina-silica surface might play an important role in cooperation with the zirconium ion for the formation of an active compound composed of $CuCl_2$, LiCl, and H_3PO_4, although neither the structure nor the promoting mechanism of zirconium have been made clear as yet.

3*H*-2,1-Benzoxathiole-1,1-dioxide, an Unusual By-Product from the Jacobsen Reaction[1]

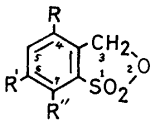
Hitomi Suzuki and Kiyoshi Kawamura

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received March 13, 1972)

Since the discovery of the non-conventional chlorination of hexamethylbenzene,[2] substitution on the alkyl side-chain of polyalkyl aromatics under ionic conditions has been a problem of interest. However, the character and scope of the unusual reaction have not yet fully been understood because of the paucity of relevant findings.[3] We would like to report on an example of anomalous substitution product, 3*H*-2,1-*benzoxathiole*-1,1-*dioxide*, which has been obtained from the Jacobsen reaction of some dichloroxylenes and monochlorotrimethylbenzenes.

2,5-Dichloro-*p*-xylene was dissolved in 20%-fuming sulfuric acid and the dark mixture was kept at 65—70°C for 14 hr to complete isomerization. Quenching with water, extraction of the insoluble part with ether and the subsequent removal of the solvent gave a light brown crystalline solid which was recrystallized from ethanol to yield white needles (*ca.* 1—2%), mp 170—171°C. The elemental analysis was in good agreement with the composition $C_8H_6Cl_2O_3S$ (M= 253; Found: C, 37.98; H, 2.30; O, 19.24; S, 12.34%. Calcd for $C_8H_6Cl_2O_3S$: C, 37.94; H, 2.37; O, 18.97; S, 12.65%); its mass spectrum showed revealing fragment ion peaks at *m/e* 252, 187, 176, 159, 141, and 125. Its infrared spectrum (KBr disk) contained absorptions at 755, 870, 896, 975, 1120 (CH_2–O), 1191 (SO_2), 1242, 1278, 1358 (SO_2), and 1453 cm^{-1}. Its ^1H NMR spectrum (100 MHz, $CDCl_3$) exhibited three singlet peaks at 7.51 (CH_3), 4.60 (CH_2), and 2.45 τ (aromatic H) of relative intensities 3 : 2 : 1. The elemental analysis and spectral data were compatible only with the structure of dichloro-methyl-3*H*-2,1-benzoxathiole-1,1-dioxide, and ^1H NMR spectral comparison with the reference compounds allowed for the ring substituents to be arranged as shown in formula I (R=R′ ′=Cl, R′=CH_3). Similar products were obtained from 4,5-dichloro-*o*-xylene and 4,6-dichloro-*m*-xylene in a smaller amount.



(I)

Ease of the formation of the cyclic ester seems to depend on the orientation of substituents. Thus, 5-chloropseudocumene gave a mixture of three isomeric sultones, of which 4-chloro-6,7-dimethyl-3H-2,1-benzoxathiole-1,1-dioxide (I, R=Cl, R′=R″ =CH_3) was the major component, while chloromesitylene and 5-chlorohemimellitene did not afford any detectable amount of ester but were mostly converted into intractable polymeric substance. Some physical properties of these cyclic esters are summarized in the Table. A noteworthy feature of these products is the preferential sulfo-oxylation on the methyl group attached to the more positively polarized ring carbon ortho to chlorine atom. Similar trends have been observed in the diarylmethane formation,[4] as well as the side-chain nitro-oxylation of polyalkylbenzene derivatives.[5] The sultones were usually formed in a small amount and their separation from the accompanying polymeric by-product was often troublesome. The cyclic ester may share the intermediate with diarylmethane,[6] but the mode of its formation is not clear at present.

Table 1. Physical properties of some 3*H*-2,1-benzoxathiole-1,1-dioxides formed in the Jacobsen reaction of dichloroxylenes and monochlorotrimethylbenzenes[a]

3*H*-2,1-Benzoxathiole-1,1-dioxide (I)			Mp (°C)	^1H NMR spectra ($CDCl_3$, τ)

A Free Radical Mechanism for the Formation of Zinc-Carbenoid Reagent from Diethylzinc and Chloroiodomethane

Sotaro MIYANO, Junzo YAMASHITA, and Harukichi HASHIMOTO
Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki, Sendai

(Received February 28, 1972)

Chloroiodomethane is useful as a methylene source for the cyclopropanation of olefins by the oxygen catalyzed zinc-carbenoid reaction.[1] Cyclohexene (99%), cyclooctene (99%), 1-heptene (79%), 2-heptene (94%), and 1-octene (88%) gave the corresponding cyclopropane in the yields given in parentheses.

We wish to present the possibility of a radical mechanism for the formation of the zinc-carbenoid reagent from diethylzinc and chloroiodomethane. Chloroiodomethane (38 mmol) was allowed to react with diethylzinc (25 mmol) in the presence of styrene (25 mmol) in benzene (20 m*l*) at 50°C under nitrogen atmosphere. The starting materials were recovered unchanged after 3 hr indicating that no reaction took place. By passing oxygen into the space above the reaction mixture at a rate of 10 m*l*/min, chloroiodomethane completely reacted within 1.5 hr giving phenylcyclopropane in 66% yield. When oxygen was introduced just after the addition of chloroiodomethane, the reaction was also completed within 1.5 hr giving phenylcyclopropane in 70% yield. AIBN and UV light also catalyzed the cyclopropanation of styrene (Table 1). Without diethylzinc, chloroiodomethane did not cyclopropanate styrene in the presence of AIBN or UV light, though peroxides[2] or UV light[3] catalyzed the cyclopropanation of olefins with diiodomethane.

TABLE 1. CYCLOPROPANATION OF STYRENE[a]

Catalyst	Reaction		Phenylcyclopropane
	Time (h)	Temp (°C)	Yield (%)
—[b]	3	50	0
—	4	70	0
—	7	70	3.7
Oxygen[b]	1.5	50	70
AIBN[c,d]	2	70	46
AIBN[c]	4.5	70	22
UV light[e]	1.5	23	73

a) Reactions were carried out under nitrogen atmosphere. Styrene 50 mmol; CH_2ClI 60 mmol; Et_2Zn 50 mmol; benzene 50 m*l*.
b) Styrene 25 mmol; CH_2ClI 38 mmol; Et_2Zn 25 mmol; benzene 20 m*l*.
c) AIBN 2.5 mmol.
d) CH_2ClI 94 mmol.
e) In 150 m*l* of benzene. High pressure mercury lamp (100 W) was used.

When a mixture of styrene, chloroiodomethane and diethylzinc in *n*-hexane was irradiated with a UV light at −70°C, chloroiodomethane reacted with diethylzinc with the formation of ethyl iodide in equivalent amount to the reacted chloroiodomethane, while styrene remained unchanged. When the light was turned off and the reaction mixture was allowed to stand at room temperature, an exothermic reaction took place, and phenylcyclopropane was obtained in 50% yield within 1 hr. This indicates the following reaction sequences (R=Et or CH_2Cl);[4]

$$ClCH_2I + Et_2Zn \xrightarrow{\text{Initiator or } h\nu} \underset{\text{(I)}}{ClCH_2ZnEt} + EtI$$

$$CH_2ClI + \text{(I)} \xrightarrow{\text{Initiator or } h\nu} \underset{\text{(II)}}{(ClCH_2)_2Zn} + EtI$$

$$\text{(I) or (II)} + PhCH{=}CH_2 \rightarrow Ph\text{-}\triangleleft + ClZnR$$

There are evidences that ethyl radical is formed by the reaction of diethylzinc with oxygen[6] or by the decomposition of AIBN in the presence of diethylzinc.[7]

This suggests that the zinc-carbenoid reagent is formed via free radical processes from diethylzinc and chloroiodomethane. The methylene transfer step from the zinc-carbenoid reagent to olefins seems to be a conventional, one-step and three-centered carbenoid reaction if we consider the stereospecific methylene addition to 2-heptenes, the absence of C–H insertion products, and the fact that the formed zinc-carbenoid reagent can cyclopropanate styrene without any free radical catalyst.

Dimerization and Electronic Absorption Spectra of Tetracyanoethylene Anion in Solution and in Solid

Michiya Itoh

Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received May 6, 1971)

The 2-methyltetrahydrofuran solutions of several alkali tetracyanoethylenides (M^+, $TCNE^-$, where M=Na, K, Rb, and Cs) show strong visible absorption spectra at low temperature which might be considered to be charge-transfer bands between two TCNE anions. Temperature dependence of the electronic absorption and ESR spectra of $TCNE^-$ in solution yields the monomer-dimer equilibrium of the TCNE anion. The heat of dimer formation of the anion was found to decrease in the order $Na^+ > K^+ > Rb^+ > Cs^+$ with the size of the counter ions. The heat of dimer formation in $Na^+(TCNE)^-$ also depends considerably on the solvent system. The absorption spectra of the solid TCNE anions were found to resemble the spectrum of the TCNE anion dimer $(TCNE^-)_2$ in solution to a great extent. A comparison of the electronic absorption and ESR spectra of $M^+(TCNE)^-$ in solution and in solid demonstrates that the solid $TCNE^-$ is almost diamagnetic, and the anion dimer can be the unit of structure in the solid salts.

Numerous studies were carried out on the electronic and magnetic properties of radical dimer $(TCNQ^-)_2$ and dimer radical $(TCNQ)_2^-$ of 7,7,8,8-tetracyanoquinodimethane anion $(TCNQ)^-$ in solution[1] and in solid[2-4]. However, few spectroscopic studies of the TCNE anion dimer have been reported since the first preparation of the solid TCNE anion by Webster *et al.*[5] Phillips and Powell[6] suggested complex formation taking place between the TCNE anion and its parent molecule $(TCNE)_2^-$ on the basis of the reversible color change of the THF solution with decreasing temperature. In a previous paper,[7] the present author erroneously proposed the formation of the dimer radical in the MTHF solution at low temperature by means of electronic absorption spectroscopy for which a MTHF solution of TCNE anion containing neutral TCNE was used. Subsequently, the author came to observe the electronic absorption spectra of the solid TCNE anion, ($M^+(TCNE)^-$, M=Na, K, Rb, and Cs), which were very similar to the low temperature spectra of the MTHF solution of $TCNE^-$. Recently, Chang[8] has proposed the formation of the TCNE anion dimer in MTHF by ESR spectroscopy.

The author investigated the solid TCNE anion, and reinvestigated the anion in solution by both optical and ESR spectroscopies. The results indicate the formation of the radical dimer in solution at a low temperature, and suggest that the dimer of $TCNE^-$ can be the unit of structure in solid $M^+(TCNE)^-$. The heat of dimer formation of $TCNE^-$ depends largely on the counter cation (Na^+, K^+, Rb^+, and Cs^+) and also on the solvent composition. The electronic absorption spectra of $TCNE^-$ and $(TCNE^-)_2$ were discussed.

Experimental

Preparation and Materials. To a degassed acetonitrile solution (~8 ml) of TCNE (~0.3 g) was added NaCN or KCN (~1.5 g) in a sealed vessel. The dark brown reaction solution was stirred on a magnetic stirrer at 5°C for 3—4 days. The reaction mixture was filtered through a glass filter, and the solvent (CH_3CN) was removed by vacuum evaporation. The solid residue was washed two or three times with THF (~5 ml). Dark brown or black solid $Na^+(TCNE)^-$ or $K^+(TCNE)^-$ was obtained. Each procedure was performed in a sealed glass vessel in a vacuum.

$Rb^+(TCNE)^-$ and $Cs^+(TCNE)^-$ were prepared by the same procedures as for $Na^+(TCNE)^-$ from RbI and CsI, respectively. The compositions of the solid salts were confirmed by the elementary analysis of carbon and nitrogen.

$M^+(TCNE)^-$ film was prepared in a quartz optical cell (1 mm or 1 cm) by vacuum evaporation of the solvent from the CH_3CN solution of the salt. Reddish blue or purple film was obtained.

Purification of the solvent was carried out in the same manner as described previously.[7]

Measurements. Electronic absorption spectra were determined with a Cary recording spectrophotometer Model 11. However, spectroscopic study of the monomer-dimer equilibrium was made on a Beckman DK-2U spectrophotometer.[7] All the ESR measurements were made on a JEOLCO P-10 ESR spectrometer (100 kc modulation) with a variable temperature equipment.

Results and Discussion

Electronic Absorption Spectra and ESR in Solid TCNE Anion. Since Webster *et al.*[5] reported the solid formation of metal tetracyanoethylenides from an acetonitrile solution of TCNE and metal iodide or cyanide, few spectroscopic studies of the solid TCNE anion have been reported. This seems to be due to the fact that the preparation of solid $M^+(TCNE)^-$ is more difficult than that of the 7,7,8,8-tetracyanoquinodimethane anion or Würster's salt. In this work, electronic absorption spectra of the pure samples of $M^+(TCNE)^-$ were determined in film and in KBr pellet. The spectra of the solid salts in KBr pellets, shown in Fig. 1, are almost unaltered by changing

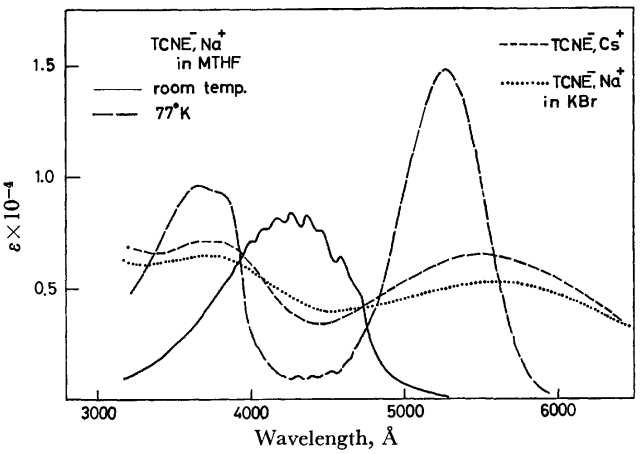

Fig. 1. Electronic absorption spectra of the solid TCNE anions in KBr pellets, and of the MTHF solution of $Na^+(TCNE)^-$ at room temperature and at liquid nitrogen temperature. The ordinate for the spectra of the solid salts is in an arbitary scale.

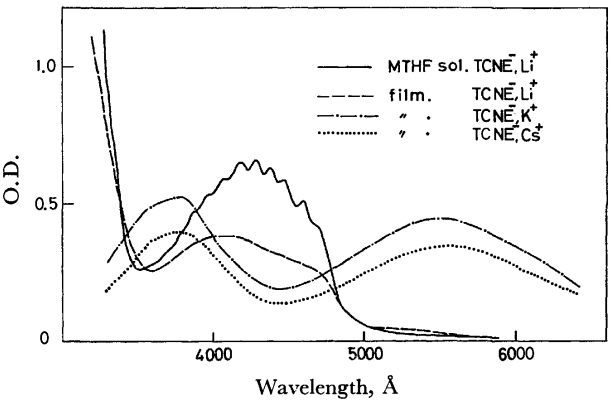

Fig. 2. Electronic absorption spectra of $M^+(TCNE)^-$ (M= Li, K, and Cs) in films at room temperature, and of the MTHF solution of $Li^+(TCNE)^-$ at room temperature.

M^+. It is noteworthy that these spectra of solid $M^+(TCNE)^-$ are differ remarkably from those in solution at room temperature, but are similar to the low temperature spectra (77°K) of the anion in MTHF.

Chesnut and Phillips[3] explained the temperature dependence of ESR intensity of the solid $Na^+(TCNE)^-$ by a singlet-triplet model with $J=0.26$ eV. The apparent relative concentration of paramagnetic species in the solid $M^+(TCNE)^-$ (Na^+, K^+, Rb^+, and Cs^+) were determined to be only 0.1—0.01 mol%. In powdered sample of the solid $M^+(TCNE)^-$, apparent relative concentration of paramagnetic species showed a slight change with temperature (123—380°K). It seems that this paramagnetic species in the salt is impurity or one with defect in solid.

The absorption spectrum of $Li^+(TCNE)^-$ in film, shown in Fig. 2, was determined to be similar to that in solution at room temperature. No significant temperature dependences were observed with the ESR and absorption spectra in the MTHF solution of $Li^+(TCNE)^-$. Thus $Li^+(TCNE)^-$ is considered to be monomeric both in solid and in solution even at a low temperature. Repeated attempts of preparation and isolation of the solid $Li^+(TCNE)^-$ failed.

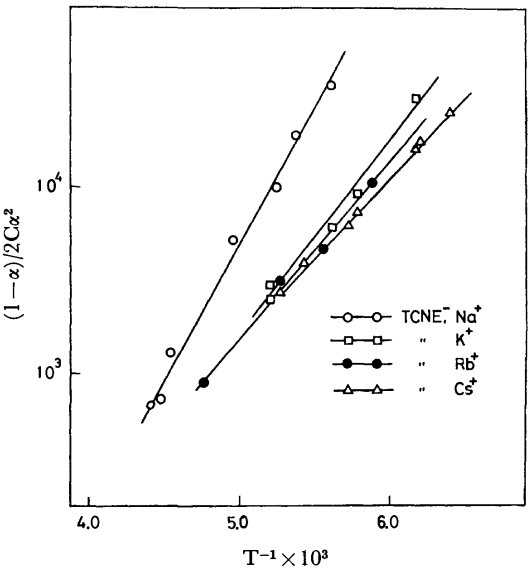

Fig. 3. Plots of log $(1-\alpha)/2C\alpha^2$ against 1/T in the MTHF solutions of $M^+(TCNE)^-$.

Monomer-Dimer Equilibrium Determined by ESR. A procedure similar to that for the investigation of the dimerization of Würster's cation by Kawamori *et al.*[9] was applied to the temperature dependence of ESR signal strength in the MTHF solution of $M^+(TCNE)^-$. Monomer-dimer equilibrium constant $K=K_0\exp(-\Delta H/RT)=(1-\alpha)/2C\alpha^2$, where C is the concentration of the TCNE anion and α is the fractional concentration of the monomer at a certain temperature, which is given by IT/C; I is the relative ESR intensity. Figure 3 shows the plots of log $(1-\alpha)/2C\alpha^2$ against $1/T$ in the MTHF solutions of the Na, K, Rb, and Cs salts. The slope of the straight line which suggests the dimerization of $TCNE^-$ gave the heat of dimer formation. The results are summarized in Table 1.

Table 1. Heat of dimer formation of $M^+(TCNE)^-$

M^+	Na^+	K^+	Rb^+	Cs^+
$-\Delta H$, kcal	7.1	4.8	4.3	4.0

Values of $-\Delta H$ (*l*/mol) depend considerably on the counter ion in the order $Na^+>K^+>Rb^+>Cs^+$. The value of $-\Delta H$ obtained in $Na^+(TCNE)^-$ (7.1 kcal) agrees well with that obtained by Chang (8 kcal), and is comparable to the value (10 kcal) obtained by Boyd and Phillips for the dimerization of $TCNQ^-$ in an aqueous solution. If the difference of solvent system in the formation of $(TCNE^-)_2$ and $(TCNQ^-)_2$ is taken into account, $-\Delta H$ might be smaller in the former.

Reinvestigation of the Monomer-Dimer Equilibrium by Electronic Absorption Spectra. The absorption spectra of the MTHF solution of $Na^+(TCNE)^-$ (analytically pure) were determined at room temperature and at 77°K, as shown in Fig. 1. A strong absorption band at 5400 Å region was tentatively assigned to be a charge-transfer band between two TCNE anions. This

9) A. Kawamori, A. Honda, K. Suzuki, and Y. Ooshika, *J. Chem. Phys.* **44**, 4363 (1966).

absorption at low temperature was confirmed to be independent of the neutral TCNE by the addition of TCNE to the solution of anion. The previous results[7] were reinvestigated by assuming the monomer-dimer equilibrium of $TCNE^-$ at low temperature. Itoh and Nagakura[10] demonstrated the dimerization of the substituted pyridinyl radicals by means of the equation $\log K = \log \varepsilon \cdot \varepsilon_d / 2a(\varepsilon_d - \varepsilon)^2$, where K is equilibrium constant of dimerization and a is stoichiometric concentration of the monomer; a was determined from optical absorbance at 4500 Å of the MTHF solution of $M^+(TCNE)^-$ at room temperature, assuming the TCNE anion to be entirely monomer at room temperature. The values, ε and ε_d are apparent absorption coefficient and molar absorption coefficient of the absorption maxima at 5400 Å at various temperatures, respectively. The absorption of monomer at 5400 Å region was neglected. If $TCNE^-$ in a considerably concentrated solution of MTHF is assumed to be in the dimer form $(TCNE^-)_2$ at 77°K (see Fig. 1), ε_d is evaluated to be 15,000 at 77°K. However, while the oscillator strength (f-value) of the absorption band of the dimer was assumed to be independent of temperature, ε_d at absorption maxima gradually increased but a half-width decreased with decreasing temperature, as shown in Fig. 4.

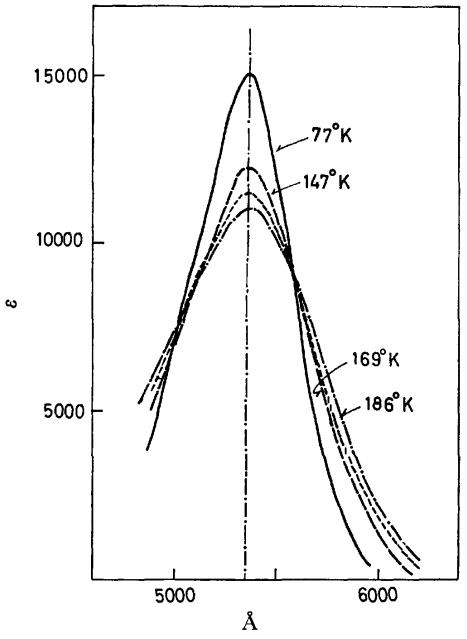

Fig. 4. Temperature dependence of the molar absorption coefficient, ε_d, of the charge-transfer band in $(TCNE^-)_2$, determination of which was made as follows. The molar absorption coefficient ($\varepsilon_{d_{77}}$) and intensity (I_{77}) at 77°K were evaluated by assuming that Na^+ $(TCNE)^-$ in a highly concentrated solution (MTHF) was entirely dimeric at 77°K. The absorption spectra of the MTHF solution of the salts were measured at several temperatures. Apparent absorbance (ε_d') and intensity (I') of the charge-transfer band were determined at a certain temperature. The molar absorption coefficient (ε_d) at a certain temperature was obtained by the equation $\varepsilon_d = \varepsilon_d' \cdot I_{77}/I'$, where the integrated intensity ($I \propto f$-value) of charge-transfer band was assumed to be independent of temperature.

10) M. Itoh and S. Nagakura, *J. Amer. Chem. Soc.*, **89**, 3959 (1967).

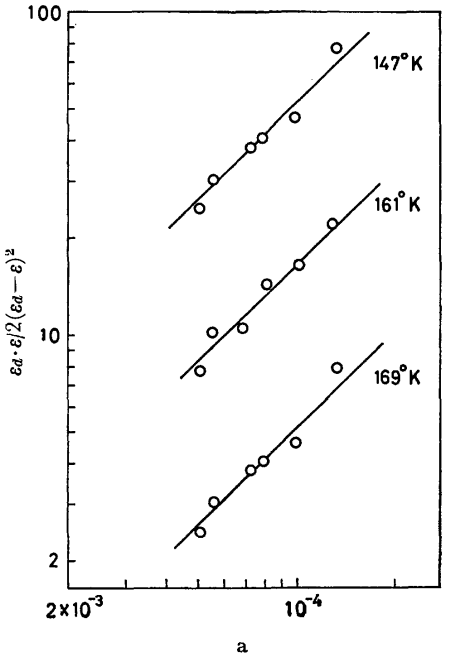

Fig. 5. Plots of $\log \varepsilon \cdot \varepsilon_d/2\ (\varepsilon_d-\varepsilon)^2$ against $1/T$ in the MTHF solution of Na^+ $(TCNE)^-$ at various temperatures.

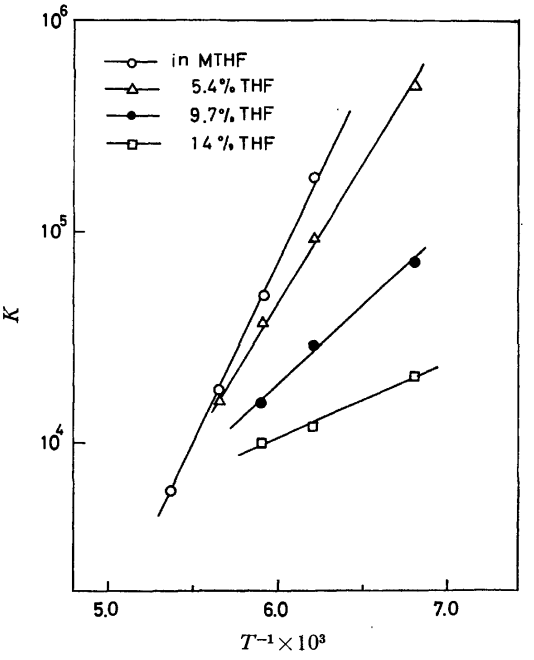

Fig. 6. Temperature dependence of the monomer-dimer equilibrium constant K in MTHF and THF-MTHF mixed systems.

Using ε_d obtained at several temperatures, straight lines close to a slope were obtained in the plots, $\log \varepsilon \cdot \varepsilon_d/2(\varepsilon_d-\varepsilon)^2$ against $\log a$, as shown in Fig. 5. The slope=1 suggests the monomer-dimer equilibrium of $TCNE^-$ at various temperatures. Equilibrium constant K (l/mol) at several temperatures was obtained by a least-squares fit. Figure 6 shows temperature dependence of K in the MTHF and MTHF-THF mixed systems. Heats of dimer formation for $Na^+(TCNE)^-$ were obtained from slopes of the straight lines of each solvent system. The results are sum-

Table 2. Thermodynamic data for the formation of $(Na^+)_2$ $(TCNE^-)_2$ by means of electronic absorption spectroscopy

Solvent	MTHF	5.4% THF	9.6% THF	14.5% THF
K, mol^{-1} (169°K)	5.0×10^4	3.6×10^4	1.5×10^4	1.0×10^4
$-\Delta H$, kcal	7.6	5.7	3.4	1.8
ΔS, eu	−11.8	−6.5	−0.5	3.7

marized in Table 2. As for $Na^+(TCNE)^-$ in MTHF, the value of $-\Delta H$ obtained by absorption spectroscopy was in good agreement with that obtained by ESR, as shown in Tables 1 and 2. However, the values of K corresponding to log $(1-\alpha)/2C\alpha^2$ in Fig. 3 show considerable deviation from those of absorption spectra. Although $-\Delta H$ obtained by ESR might be fairly accurate, the values of K by ESR seem to be much less accurate than those by absorption spectra. The value, $-\Delta H$ in $Na^+(TCNE)^-$ is largely dependent upon the solvent system (Table 2). When MTHF was mixed with a small amount of THF which is more polar than MTHF, $-\Delta H$ decreased remarkably while the entropy change increased. The decrease in $-\Delta H$ and the increase in ΔS (from large minus to plus) with increasing solvent polarity were observed in the dimer formation of the ketyl radicals reported by Hirota and Weissman.[11] These results seem to be attributed to the greater solvation in monomer than in dimer.

Electronic Absorption Spectra of Monomer and Dimer of TCNE$^-$. The MTHF solution of $TCNE^-$ shows a broad absorption spectrum with a vibrational structure at 3600—4700 Å region. From the shape of absorption, it seems that the absorption spectrum of $TCNE^-$ at 3600—4700 Å region consists of two electronic transitions. This is supported by an open shell SCF MO calculation of $TCNE^-$. The observed and calculated data are summarized in Table 3.

From the experimental results of $TCNE^-$ both in solution and in solid, it is clearly seen that the strong absorption spectrum at 5300—5500 Å region and another absorption at 3500—4000 Å region are attributed to the dimer. From the standpoint of charge-transfer interaction in the radical dimer, the visible absorption at ~5400 Å observed for the TCNE anion dimer can be interpreted to be the charge-transfer band between two $TCNE^-$ and the shorter wavelength absorption with two maxima is ascribed to the shifted local excitations.

Table 3. Observed and calculated electronic transition energies and oscillator strengths (f-values)

Obsd		Calcd	
E(eV)	f	E(eV)	f
2.7, 2.8	0.21	2.2	0.11
		2.4	0.08
—	—	3.4	0.42

The electronic absorption spectra of the solid $M^+(TCNE)^-$ were found to greatly resemble the spectra of the dimer in solution. The magnetic and optical properties of the solid salt suggest that the TCNE radical dimer is the unit of structure in the solid state where the spin exchange interaction in the dimer is extremely great in a considerably wide range of temperature (123—380°K) in comparison with those of Würster's salt,[12-14] ethylphenazyl[15] and other radical salts.[3,4,16]

The author wishes to express his sincere thanks to Professor R. S. Mulliken for giving him the opportunity to work at the University of Chicago where a part of this work was done. He wishes to thank Professor S. Nagakura for reading the manuscript. Thanks are also due to Dr. S. Iwata, the Institute of Physical and Chemical Research, for computation of the open shell SCF MO of TCNE anion.

Photo-decoloration Process of the Reverse Photochromic Spirans

Eiichi INOUE, Hiroshi KOKADO, Isamu SHIMIZU, Hajime KOBAYASHI, and Yohnosuke TAKAHASHI

Imaging Science and Engineering Laboratory, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received July 30, 1971)

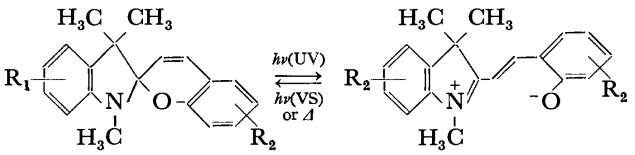
The unstable colorless form (A′) of the reverse photochromic spiran (SP-3) (1,3,3-trimethyl-5-methoxyspiro[indoline-2,2′-benzopyran]-8′-carboxylic acid) was obtained in a stable state by vacuum evaporation (10^{-5} Torr) on a KBr substrate. It was confirmed by IR spectral analysis that reverse photochromism occurred between the colored (B′; merocyanine-like structure) and the colorless forms (A′; spiropyran). A colorless transient intermediate (X) was observed in the photo-decoloration process of the (SP-3). X was transformed into both A′ and B′. Thus the photo-decoloration efficiency ($\phi_{B'\to A'}$) depends on the ratio of the conversion from X to A′. State (B′) is stabilized in a polar or proton donative solvent. The life time of X is greatly influenced by the solvent as well as the stability of B′. The photo-decoloration efficiency ($\phi_{B'\to A'}$) of the spirans is effectively improved by substituting SP-2 with (methoxyl group) at 5-position. Whether X is observable or not depends on the substituent and its position. The reversibility of photochromic cycle of the spirans was restricted by the photobleaching of B′ by UV irradiation. It was observed that the photo-bleaching of B′ is accelerated in a degassed solution.

Derivatives of 1,3,3-trimethylspiro[indoline-2,2′-benzopyran] (SP-1) are well-known photochromic materials.[1]

The mechanism and kinetics of photo-coloration of spirans have been studied,[2] but detailed discussions on photo-decoloration process do not seem to have been made. This might be due to the unstability of the colored species of the photochromic spirans. It has been found that a compound substituted with –COOH at 8′-position (SP-2) exhibited reverse photochromism.[3] The colored form is more stable than the spiran form. The photo-induced bleaching of SP-2 and its derivatives were studied by means of flash photolysis.

The structure of the colored species of the reverse photochromic spirans is like that of a merocyanine dye, the colored form of the normal photochromic spirans. The color changes corresponding to the intramolecular transformation as follows.

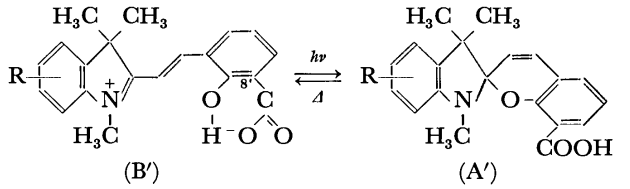
(a) normal photochromism



(A′) (B′)

Stable, colorless Unstable, colored

(b) reverse photochromism



(B′) (A′)

Stable, colored Unstable, colorless

Symbols A′ and B′ denote the colorless and the colored forms, respectively.

The existence of a colorless transient intermediate (X) was observed during the photo-decoloration of a reverse photochromic spiran (SP-3). In this paper, we propose a reaction scheme for the photo-decoloration process of the spirans.

We also describe the influence of both solvents and substituents on the photo-transformation and the effect of oxygen on the reversibility of the reverse photochromic process.

Experimental

Experiments were carried out with a set of flash spectrographic instrument (USHIO UFP-1). The half width of flash was 18 μsec with a power of 200 Joule/pulse. A quartz cell, 7 mmφ and 100 mm thick, was used at room temperature. The temperature of the solution during the measurement was kept constant in a range 5—60°C by using a doubly sealed quartz tube, in which water at constant temperature is circulated from a thermoregulated bath (Fig. 1).

The spirans are listed in Table 1. The photo-decoloration efficiency ($\phi_{B'\to A'}$) was obtained at a sufficiently low temperature (−40°C) to avoid thermal recoloration during measurements.

SP-10	5-Cl

be induced from intramolecular transformation between colorless spiropyran (A′) and colored merocyanine (B′) by irradiation of light. The colored form was formed on the rupture of C_{spiro}–O bond.

The photo-generated colored form (B′) was unstable, and the color diminished spontaneously when illumination was stopped. SP-1 substituted by –COOH at 8′-position (SP-2) and its derivatives are known to be "reverse photochromic" spirans. The colored form (B′) was more stable than the colorless one (A′) and was converted into A′ by irradiation with visible light. The color reappeared gradually when illumination was stopped.

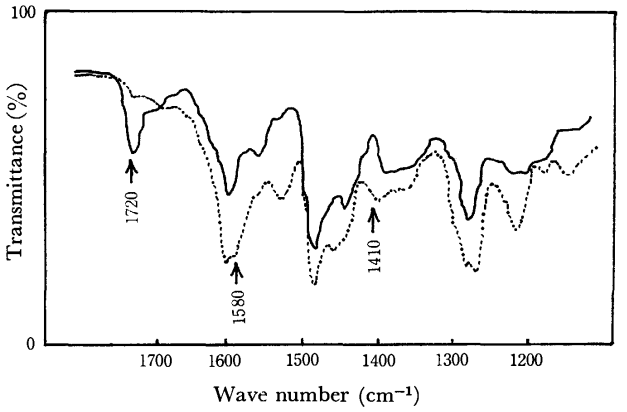

Fig. 2. I.R. spectra of the evaporated film of (SP-3) in the colorless and colored species on KBr.
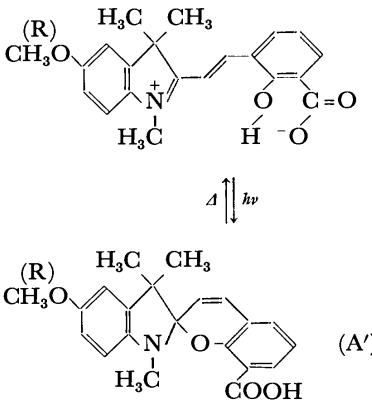
(a): ——colorless (b): ·····colored

When a layer of SP-3 (1,3,3-trimethyl-5-methoxy spiro[indoline-2,2′-benzopyran]-8′-carboxylic acid) was formed on a KBr crystal surface by vacuum evaporation, its (A′) state was preserved for a long time at room temperature. The IR spectra of A′ and B′ forms of SP-3 are shown in Fig. 2. The spectrum (a) almost coincided with that of the colorless form of SP-1 except for the bands at 1720 cm^{-1} and 3000—4000 cm^{-1} which are assigned to –COOH group. The colorless film on KBr crystal became gradually colored in the dark, and the IR spectrum was also transformed from (a) to (b) in the colored form. The band at 1720 cm^{-1} in (b) diminished and new bands due to CO_2^- appeared at 1580 cm^{-1} and 1410 cm^{-1}. The others were almost the same as the spectrum of colored form of SP-1. The structures of the colorless and colored forms (SP-3) were estimated as follows.



The stable colored form may be stabilized by a six membered ring between $-CO_2^-$ and –OH groups. The stable colored form was observed in all derivatives (presented in Eq. (2′)) having –COOH group at 8′-position. Thus the reverse photochromism of (SP-2) and its derivatives are given by Eq. (2′).

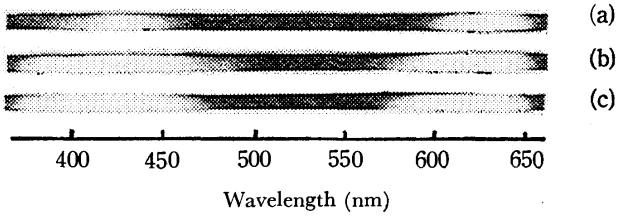


Fig. 3. Spectrographies of (SP-3) in acetone at each delay time (t) after illumination with flash light.
(a) before illumination.
(b) t=30 μsec.
(c) t=30 msec.

Photo-decoloration Process of SP-3. The color of the solution (ethanol, acetone, *etc.*) of SP-3 disappeared by irradiation with visible or ultraviolet light. Spectrograms of SP-3 in acetone at each delay time after illumination with flash light are shown in Fig. 3. Absorption band at visible range (near 550 nm) decreased just after illumination (delay time 30 μsec). The color reappeared partly within 30 msec after the illumination.

By photochemical analysis in the steady state, the coloration rate (A′→B′) k has been obtained at the same temperature in several solvents as shown in Table 2. Thus, there are fast and slow processes in the

TABLE 2. SPECIFIC RATE CONSTANTS ($k_{A'\to B'}$) OF SP-3 IN VARIOUS SOLVENTS (at room temperature)

Solvent	$k_{A'\to B'}$ (sec^{-1})
Methanol	1.82×10^{-3}
Ethanol	7.91×10^{-4}
2-Propanol	8.81×10^{-3}
Acetone	3.59×10^{-3}
Acetonitrile	5.45×10^{-3}

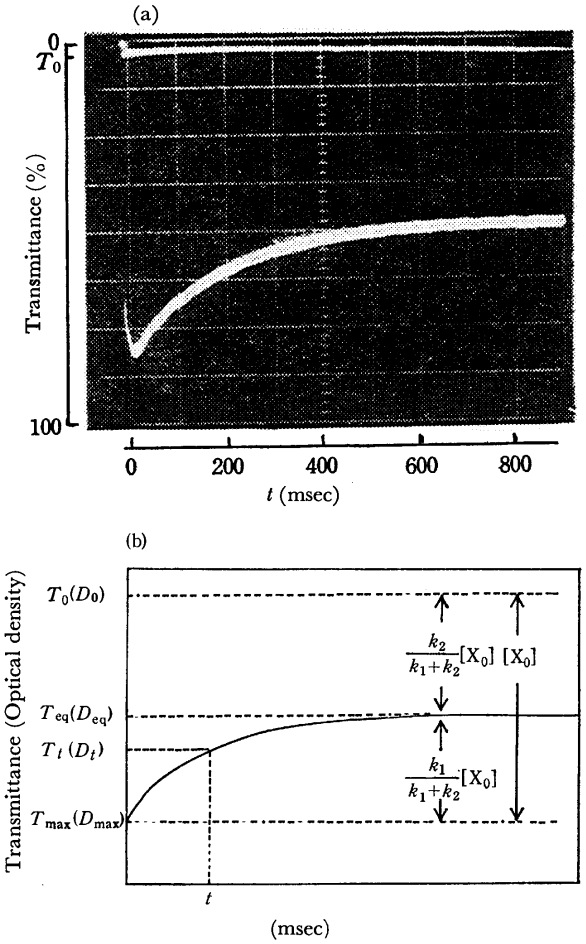

Fig. 4. Typical curve tracing the change in transmittance at λ_{max}(475 mμ) on the synchroscope and its diagram for the analysis.
(a): curve of SP-3 ethanol solution.
(b): diagram for analyzing of the curve.

recoloration of SP-3 solution. From the results, we assumed the existence of an intermediate state (X) during the course of photo-decoloration. Since no new band except for A''s and B''s could be observed, the absorption spectrum of X should resemble that of the colorless form.

When the change of B′ after illumination was traced at the absorption maximum (470 nm) by a synchroscope, a typical recoloration curve was obtained as shown in Fig. 4 (a).

The photo-decoloration process can be assumed as follows.

$$B' + h\nu \longrightarrow B^* \quad (3)$$

$$B^* \xrightarrow{\text{fast}} X \quad (4)$$

$$X \xrightarrow{k_1} B' \quad (5)$$

$$X \xrightarrow{k_2} A' \quad (6)$$

where $h\nu$, $k_1(k_2)$, and B* represent light quantum, specific rate of X→B′ (X→A′) process and the excited species of B′, respectively. The specific rates (k_1 and k_2) were obtained by the analysis of the recoloration curves as follows.

The rate equation for the reaction is

$$-\frac{d[X]}{dt} = (k_1+k_2)[X] \quad (7)$$

By integrating, we have

$$\frac{[X]}{[X]_0} = e^{-(k_1+k_2)t} \quad (8)$$

where [X] and [X_0] denote the concentration of X at t(sec) and initial state just after flash. The values of [X_0] and [X] are converted into the optical density (D) at λ_{max} of B′ by means of the following equations.

$$[X_0] = \frac{1}{\varepsilon_{B'} l}(D_{eq} - D_{max})\frac{k_1+k_2}{k_1} \quad (9)$$

$$[X] = \frac{1}{\varepsilon_{B'} l}(D_{eq} - D_t)\frac{k_1+k_2}{k_1} \quad (10)$$

where $\varepsilon_{B'}$ and l denote the absorption coefficient of B′ at λ_{max} and cell length, respectively. D_0, D_{eq}, D_{max}, and D_t give optical density as shown in Fig. 4(b).

From Eqs. (8), (9), and (10), we get

$$\ln\left(\frac{D_{eq} - D_t}{D_{eq} - D_{max}}\right) = -(k_1+k_2)t \quad (11)$$

A plot of $\ln(D_{eq}-D_t/D_{eq}-D_{max})$ against time t was linear for the photo-decoloration of SP-3 in ethanol as shown in Fig. 5. The slope gives the specific rate (k_1+k_2) 2.9 sec^{-1} at room temperature.

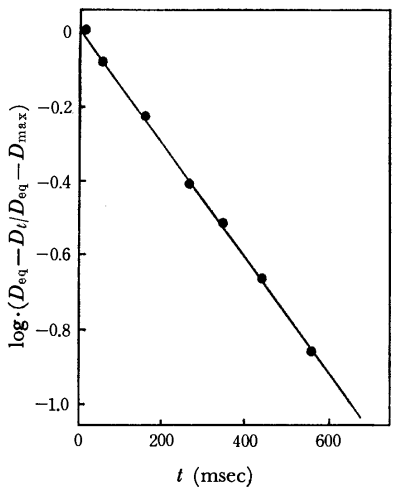

Fig. 5. A plot of log ($D_{eq}-D_t/D_{eq}-D_{max}$) against time ($t$) for SP-3 in ethanol at room temperature.

The ratio of the specific rates k_2/k_1 is given by

$$\frac{k_2}{k_1} = \frac{D_0 - D_{eq}}{D_{eq} - D_{max}} \quad (12)$$

The values obtained for the photo-decoloration of SP-3 in ethanol are summarized in Table 3.

Arrhenius' plots for the specific rates k_1 and k_2 (Fig. 6) showed good linearity. Activation energy ΔE^* and

the pre-exponential factor A were calculated (Table 3) from these slopes and Arrhenius' law

$$k = Ae^{-\Delta E^*/RT} \qquad (13)$$

An energy scheme for the photo-decoloration of SP-3 was assumed as given in Fig. 7. Colorless intermediate species (X) can be formed from the photo-excited state of B'. According to this assumption, X is transformed into the unstable colorless one A' in the ratio (k_2/k_1+k_2). Therefore, the photo-decoloration efficiency of B' seems to be determined by the product of the transition probability from B* to X and the conversion ratio (k_2/k_1+k_2) from X to A'.

Solvent Effect. The absorption band of B' in the visible region shifted towards longer wavelength in polar solvents, especially in proton donative solvents such as alcohol. Stokes' shift was observed in the fluorescence spectrum of an alcohol solution of B'. Typical curves of absorption and fluorescence spectra of B' are shown in Fig. 8. The ground state of B' which was supposed to be of Zwitter-ionic structure can be stabilized by interaction with polar solvents. The largest stability of B' was observed in an alcohol solution. This implies that the hydrogen bond would be formed between B' and alcohol. Stabilization of B' by solvent was supposed to cause the blue shift of the absorption band. Stokes' shift in alcohol was uncommonly large compared with that in acetone. This implies that some structural change of the system occurred in the equilibrium state of the excited species. Since the stabilized ground state of B' is supposed to be a hydrogen-bonded form ($B^{+\delta}\cdots H\cdots OR^{-\delta}$), it is considered that the rupture of the hydrogen bond (B' HOR) might occur in the excited equilibrium state. A schematic diagram is shown in Fig. 9 to illustrate the large Stokes' shift.

When the Brønsted acid such as hydrochloric acid was added, the colored species (B') was transformed into a yellow salt-type species (C; $B^+H\cdots X^-$).[4] C was photochemically converted into A' with a quantum yield of nearly 1. On the other hand, the quantum yield of photo-conversion from B' to A' was higher in proton donative solvents such as alcohol than in

Table 4. Life time of the transient intermediate (X) and the conversion ratio of the reaction (X→A′) of (SP-3) in various solvents (at room temperature)

Solvent	$k(1/\tau)$, sec^{-1}	$\eta_2(k_2/k_1+k_2)$

other solvents. The results also supported the view that the structure of ($B^{+\delta}\cdots H\cdots OR^{-\delta}$) was described as a hydrogen-bonded form in the alcohol solution of B′.

It is to be noticed that the life time (τsec) of X observed during the photo-decoloration of the reverse photochromic spirans was also influenced by solvents. Table 4 shows the specific rate constants ($k_1+k_2=k$ (sec^{-1})) and the conversion ratios ($\eta_2=k_2/(k_1+k_2)$) of the reaction to A′ from X of the SP-3 in various solvents. The value (k) was much smaller in alcoholic solvents compared with that in solvents such as acetone. X was stabilized with both the acidity as proton donor and the polarity of solvents. The value (η_2) was almost constant in alcohols and decreased in acetone and acetonitrile. The solvent effect on η_2 was less distinct than that on (k).

Table 5. Kinetic data on the reactions (X→A′, X→B′) of (SP-3) in various solvents.

Solvent	$\Delta E^{\ddagger}$ (kcal/mol)		A (sec^{-1})		$\Delta G^{\ddagger}$ (kcal/mol)	
	$\Delta E^{\ddagger}_{X\to A'}$	$\Delta E^{\ddagger}_{X\to B'}$	$A_{X\to B'}$	$A_{X\to B'}$	$\Delta G^{\ddagger}_{X\to A'}$	$\Delta G^{\ddagger}_{X\to B'}$
Ethanol	20.3	18.6	$10^{15.2}$	$10^{13.2}$	17.3	18.4
2-Propanol	19.8	22.5	$10^{15.5}$	$10^{16.6}$	16.3	17.3
Acetone	18.9	18.9	$10^{16.6}$	$10^{16.1}$	13.8	14.6

Kinetic data on the temperature dependence on the specific rate constants (k_1, k_2) in various solvents are summarized in Table 5. The large pre-exponential factor (A) and the high activation energy ($\Delta E^{\ddagger}$) were the inherent characteristics of the thermal transformations of the spirans (*e.g.* A′→B′, X→A′, and X→B′). The activated free energy ($\Delta G^{\ddagger}$) of the reactions increased in ethanol owing to the effect of the stabilization of X by the proton donative solvent.

The photo-decoloration efficiency ($\phi_{B'\to A'}$) of the reverse photochromic spirans should be determined by the product of η_1 and η_2 which are the ratios of the interconversions B*→X and X→A′ under the hypothetical reaction scheme for photo-decoloration. Because of the difficulty to determine the absolute value of η_1, we measured the relative value (η_{1rel}) for (SP-3) in various solvents. The results are given in Table 6. The relative efficiencies (ϕ_{rel}) obtained with the steady light coincided qualitatively with the relative values ($S_{rel}=\eta_{rel}/(\eta_{rel})_{ethanol}$) as shown in Table 6. The deviation between ϕ_{rel} and S_{rel} might be

caused by the neglect of the temperature effect on η_2.

Effect of Substituents. Photo-decoloration efficiency was influenced by the substituent in the indoline part of the reverse photochromic spiran (SP-2). Existence of X also depended on the substituent.

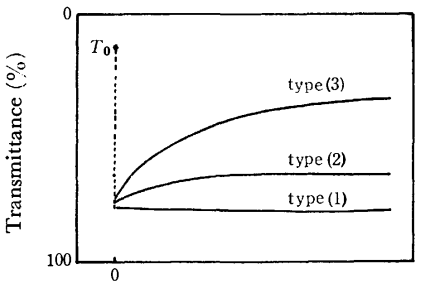

Fig. 10. Typical curves showing the changes of trasmittance at λ_{max}, against time after flash illumination. T; transmittance before illumination.

Typical curves of transmittance at the absorption maximum after the flash illumination are shown in Fig. 10. They can be classified into three groups. SP-2, 9, and 10 are of type 1, in which X could not be observed. It seemed that the photo-decoloration occurred in the process from B* to A′, or the energy barrier between X and A′ or B′ could be neglected. X was observed in SP-3, 4, 5, and 6 which are of type 3. SP-7 and 8 are of type 2, in which X was hardly detected at all by analysis. No explanation has been given on the influence of the substituents on the process.

Kinetic data on X of the spirans belonging to the type 3 are shown in Table 7. The longer the life time of X, the higher the interconversion ratio (η_2).

It was found that the photo-decoloration efficiency ($\phi_{B'\to A'}$) of the spiran substituted with an electron-

Table 7. Life time and conversion ratio (η_2) of the reverse photochromic spirans

Spiran	Solvent	$k(sec)^{-1}$	$\eta_2(k_2/k_1+k_2)$

releasing group ($-OCH_3$) was higher than that with an electron attractive substituent (–Br). These substituent effects were similar to those on stability of the colored form of the spirans of type 3 as given in Table 7.

Effect of the Dissolved O_2 on the Photo-bleaching of Spirans. Reversibility of spirans gradually decreased during repetition of the photo-interconversion between A′ and B′. The term "fatigue" of the photochromism was given to such a phenomenon. The fatigue process of reverse photochromic spirans depended largely on the dissolved oxygen and the photon energy of the light.

When a degassed ethanol solution of SP-3 was irradiated with a flash pulse with no filter, the existence of X was recognized during the decoloration process, but coloration was not completely restored. After the illumination of 4 pulses, no photo-decoloration occurred. The fatigue phenomenon was scarcely noticeable in a solution saturated with air.

No fatigue was observed even in the degassed sample when visible light (with a UV cut off filter) was passed on the solution. It was supposed that the fatigue from the irradiation of UV light, *viz.*, irreversible bleaching of the color was induced from the higher excited state. Deactivation from the higher excited state to the lower state may be accelerated by the dissolved oxygen in high efficiency.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1956—1960(1972)

Mechanism of Hydrogen Exchange Reactions on 1:2 Electron Donor-Acceptor Complexes of Anthracene with Sodium

Masaru ICHIKAWA,* Sadao TANAKA,** Shuichi NAITO,* Takahiro NAKAMURA, Mitsuyuki SOMA, Takaharu ONISHI, and Kenzi TAMARU

Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received August 25, 1971)

The mechanisms of the H_2–D_2 and D_2–HZ exchange reactions over 1:2 Electron Donor-Acceptor (EDA) complexes of anthracene with sodium, where HZ denotes the EDA complexes, were studied kinetically and spectroscopically in the temperature range 20—90°C. It was found that molecular hydrogen exchanges directly with the hydrogen of the complexes ($An^{2-}2Na^+$ or An^-Na^+) and also with the monohydroanion complex (AnH^-Na^+), which is formed by the dissociative adsorption of hydrogen. The H_2–D_2 exchange reaction proceeded *via* not only the σ-bonded hydrogen of the complexes, but also homolytically dissociated "mobile" hydrogen.

The reactions of hydrogen over various electron donor-acceptor (EDA) complexes of various aromatic compounds, such as aromatic hydrocarbons, their substituted compounds[1a] and phthalocyanines,[1b] with alkali metals were studied previously. It was found that H_2–D_2 and D_2–HZ exchange reactions (HZ denotes the EDA complexes) took place at room temperature at considerable rates, hydrogen being dissociatively adsorbed. It is of interest to elucidate the reasons for this reactivity which appears on the formation of the EDA complexes.

The composition of the complexes studied so far[1a] was not always well defined. In this study, however, stoichiometric complex films were employed, and the role of the chemisorbed hydrogen on the EDA complexes was studied. The active intermediates for the hydrogen exchange reactions were determined by NMR and UV spectroscopic techniques.

Experimental

Stoichiometric complex films of anthracene with sodium ($An^{2-}Na^+$ and An^-Na^+: An=anthracene) were prepared from their stoichiometric tetrahydrofuran (THF) solutions by evaporating the solvent.[2,3]

The formation and composition of the complexes as films or in solution[4] were confirmed by their characteristic absorption spectra. The complex films were evacuated at about 100°C for one day, prior to the experiments. Anthracene was purified by repeated recrystallization and the zone-melting method. Sodium was purified by distillation. In the hydrogen exchange reactions the isotopic hydrogen mixtures were analyzed by gas chromatography using an activated alumina column.

The reactions were carried out in a closed circulating system, which included a U-type reaction vessel.

Results and Discussion

Hydrogen Exchange Reaction between D_2 and the Hydrogen of 1:2 Anthracene-sodium Complex Film (D_2–HZ Exchange

Reaction). When D_2 (40 cmHg) was introduced onto the film of $An^{2-}2Na^+$, 5.6×10^{-3} mol, at temperatures between 20 and 90°C, a considerable amount of D_2 was adsorbed, and at the same time the gaseous deuterium was diluted by hydrogen from the complex forming HD in the gas phase, as shown in Fig. 1.

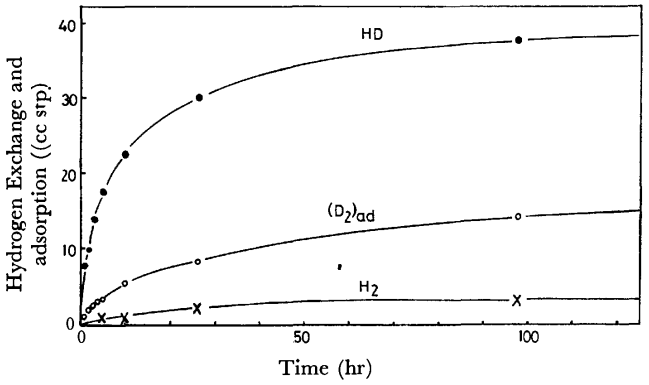

Fig. 1. The kinetics of the D_2-HZ exchange reaction and the hydrogen adsorption $(D_2)_{ads}$ over $An^{2-}2Na^+$ complex film at 80°C, $P_{D_2}=40$ cmHg.

The hydrogen adsorbed over the $An^{2-}2Na^+$ film could be completely removed by evacuating the system at 100°C for 20 hr. Reproducible results were obtained for the D_2–HZ reaction and the hydrogen adsorption.

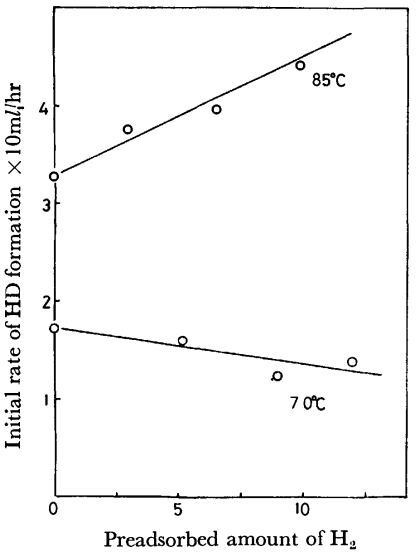

Fig. 2. Intial rates of HD formation *versus* the amount of preadsorbed hydrogen, $(H_2)_{abs}$ over an An^{2-} $2Na^+$ film (5×10^{-3} mol). $P_{D_2}=20$ cmHg.

The behaviour of the hydrogen adsorbed on the $An^{2-}2Na^+$ film in the hydrogen exchange reaction was examined at temperatures between 25 and 85°C, and by admitting D_2 (20 cmHg) onto a film (5×10^{-3} mol) deposited on silica wool on which various amounts of H_2 (from 2 to 42 m*l* stp) had been preadsorbed. The desorption of hydrogen was very slow at lower temperatures. We see from the results given in Fig. 2 that at lower temperatures (25 to 70°C) the rate of HD formation decreased slightly with increasing amounts of preadsorbed hydrogen. On the other hand, at higher temperatures such as 85°C, the rates increased slightly with increasing amount of the preadsorbed hydrogen. The initial rates of HD formation for all temperatures extrapolated to zero H_2 adsorption are not zero, but correspond to those observed over the fresh $An^{2-}2Na^+$ films. These results suggest that at least in the initial stage of the reaction the D_2–HZ exchange reaction takes place directly between the gas phase D_2 and the hydrogen of the $An^{2-}2Na^+$ complex, not through the hydrogen chemisorbed on the complex. This is also supported by the fact that the rate of HD formation was faster than that of D_2 adsorption (Fig. 1).

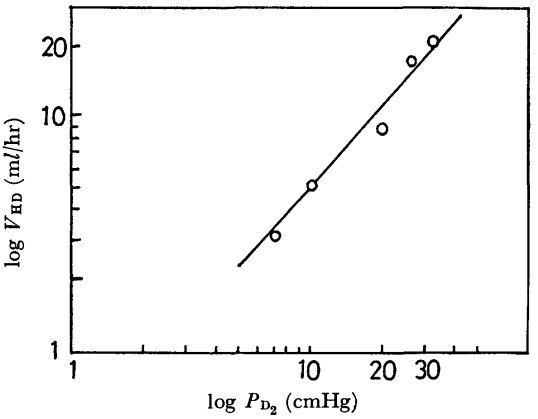

Fig. 3a. Dependence of the D_2-$(H_2)_{ads}$ exchange reaction rate upon the deuterium pressure over An^{2-} $2Na^+$ which had been adsorbed with H_2 (42 cc stp) at 62°C.

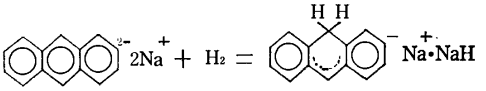
The exchange reaction between D_2 (20 cm) and an almost saturated adsorbed hydrogen layer, $[(H_2)_{ads}/(An^{2-}2Na^+)_0=0.9]$ was studied at temperatures between 20 and 90°C. Near saturation the kinetics of the HD formation were represented by the following equation (Fig. 3a).

$$-d(HD)/dt = kP_{D_2}(H_2)_{ads}$$

To determine the position of the hydrogen taking part in the D_2–HZ exchange, the complex film was decomposed by oxygen after exchange with D_2, and the resulting anthracene was analyzed by mass and NMR spectrometry. The results suggested that the mono-deuterated (9-position of the anthracene) product was obtained in the initial exchange ($d_0=80$, $d_1=18$, $d_2=2$, $d_3=0\%$).

As was suggested previously,[2,3] 9-monohydroanthracenium sodium (AnH^-Na^+) and sodium hydride were produced by hydrogen adsorption over the $An^{2-}2Na^+$ film.



AnH^-Na^+ was also separately prepared by reacting $An^{2-}2Na^+$ and 9,10-dihydroanthracene (AnH_2) in THF at 25°C;[3]

$$An^{2-}2Na^+ + AnH_2 = 2AnH^-Na^+$$

The AnH^-Na^+ thus prepared (identified by its charac-

5) M. Ichikawa, M. Soma, T. Onishi, and K. Tamaru, This Bulletin, **43**, 3672 (1970).

teristic electronic absorption band at 432 mμ) was deposited on the wall of the reaction vessel (270 ml) by evaporating the solvent at 25°C. The film of AnH^-Na^+ was stable at temperatures below 80°C, but when strongly evacuated for several hours above 80°C it slowly changed to the monoanion anthracene complex by giving off hydrogen;

$$2AnH^-Na^+ = 2An^-Na^+ + H_2$$

When 20 cmHg of D_2 was introduced onto the AnH^-Na^+ film at temperatures between 20 and 80°C, the reversible HD formation proceeded following first-order kinetics, and attained an equilibrium value. The apparent activation energy for the hydrogen exchange between D_2 and the AnH^-Na^+ film was determined to be 10 kcal/mol. It was also found that at 65°C the rate of HD formation in the D_2–AnH^-Na^+ exchange reaction was proportional to the pressure of D_2 (6.5 to 45 cmHg) and to the amount of exchangeable AnH^-Na^+ (Fig. 3b).

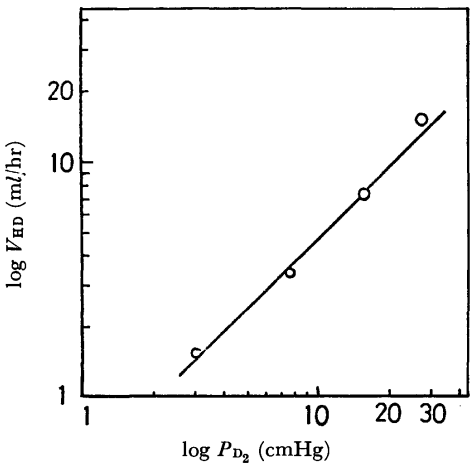


Fig. 3b. Depencence of the D_2-AnH^-Na^+ exchange reaction rate upon the deuterium pressure at 65°C.
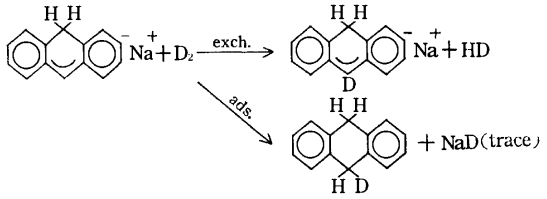
AnH^-Na^+ (7×10^{-3} mol)

AnH^-Na^+ dissolved in d_8-tetrahydrofuran (from Merck Co., 98% pure) was completely exchanged with D_2 at 65°C, and the complex solution was analyzed by NMR spectrometry. It was found that the deuterium exchange took place selectively at the 10-position of the 9-monohydroanthracenium sodium, and a small amount of monodeuterated 9,10-dihydroanthracene was formed in the resulting solution. Interpretation of the spectra was carried out using the results obtained by Schneider.[6] The deuterium exchanged monohydroanthracene was evacuated ($AnH^-Na^+ = An^-Na^+ + 1/2\ H_2$), decomposed by oxygen, collected by sublimation and analyzed by mass and NMR spectrometry. It was shown that monodeuterio(9-position) anthracene was the major product.

d_0-anthracene = 10, d_1 = 88, d_2 = 2, and d_3 = 0%

The results seem to indicate that the monohydroanthracenium complex participates in the hydrogen exchange reaction at the carbon atom opposite to the one where hydrogen was added, and during the course of the hydrogen exchange reaction desorption of the added hydrogen takes place rather slowly. Thus, only the d_1 species is produced to any extent by the deuteration, and no marked mixing at two equivalent carbon atoms (9- and 10-positions) was observed. From these results it is suggested that the D_2–AnH^-Na^+ exchange reaction proceeds as follows.



To clarify the role of the NaH in the hydrogen exchange reaction, a slight excess sodium hydride (or NaD) (75 mg, 3×10^{-3} mol) was added to the AnH^-Na^+ (2.8×10^{-3} mol) in THF, and a mixed film of AnH^-Na^+ and NaH was thus deposited on silica wool (The hydrogen exchange reaction did not proceed over the NaH alone under these reaction conditions).

The hydrogen exchange reaction was carried out in the three different systems as follows:

$$(AnH^-Na^+, NaH) + D_2 \longrightarrow HD \quad d(HD)/dt = r_1$$

$$(AnH^-Na^+, NaD) + D_2 \longrightarrow HD \quad r_2$$

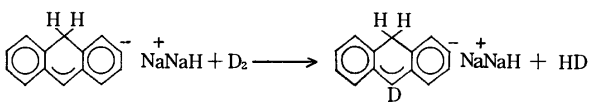
$$(AnH^-Na^+, NaD) + H_2 \longrightarrow HD \quad r_3$$

where AnH^-Na^+ (3×10^{-3} mol) and AnH or NaD (*ca.* 1 g, 4×10^{-2} mol) were employed to make the mixed films. The rates, r_1 and r_2, were found to be almost equal (*ca.* 4 ml/hr), whereas r_3 was negligibly small at 65°C under the same reaction conditions.

When an adduct film of AnH^-Na^+ (3×10^{-3} mol) and NaD (*ca.* 4×10^{-2} mol) was heated at 85°C for several hours *in vacuo*, a small amount of hydrogen gas was collected. Gas chromatographic analysis gave its composition as H_2=2%, HD=87%, and D_2=11%. From UV-spectroscopic measurements it was found that $An^{2-}2Na^+$ was regenerated and AnH^-Na^+ decreased by eliminating hydrogen:

$$AnH^-Na^+ + NaD \longrightarrow An^{2-}2Na^+ + HD$$

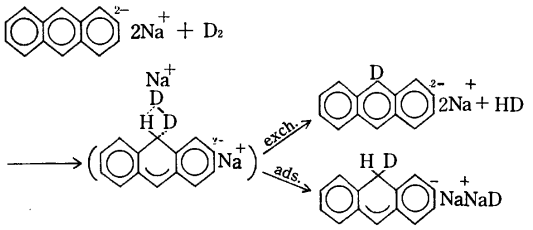
The results suggest that it is the hydrogen in the AnH^-Na^+ which participates in the exchange with molecular hydrogen, the hydrogen of NaH being unreactive for the exchange reaction at the temperatures studied.



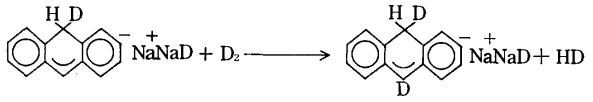
It was therefore concluded that the overall process for the D_2–HZ exchange reaction occurred simultaneously with D_2 adsorption on the $An^{2-}2Na^+$ film as follows.

i) Direct hydrogen exchange between $An^{2-}2Na^+$ and D_2 accompanied by dissociative chemisorption:

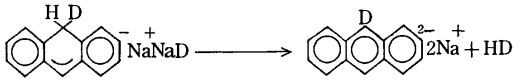
6) W. G. Schneider, Nucl. Magnetic Resonance Chem. Proc. Symp., (Cagliari, Italy, 1964).



ii) Direct hydrogen exchange of D_2 with AnD^-Na^+ which was formed by the D_2 adsorption:



iii) At temperatures above 85°C the desorption process also contributes to the hydrogen exchange reaction, *viz.*,



The H_2–D_2 Exchange Reaction over the 1:2 Anthracene-sodium Complex Film. When a 1:1 mixture of H_2 and D_2 (total pressure 20 cmHg) was admitted onto a fresh $An^{2-}2Na^+$ film (5.2×10^{-3} mol) deposited on silica wool, HD was produced and total deuterium content in the gas phase decreased as shown in Fig. 4.

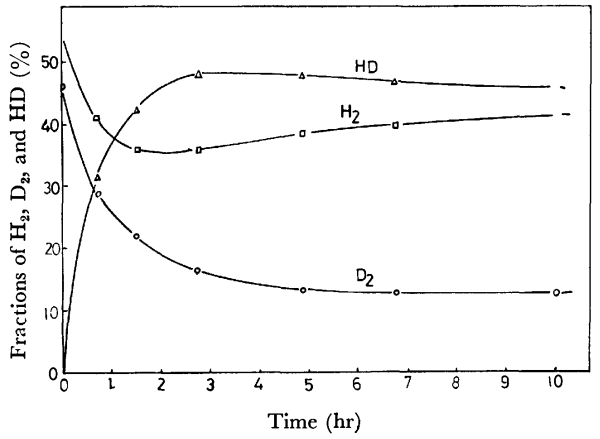


Fig. 4. The kinetics of the H_2-D_2 exchange reaction over an An^{2-} $2Na^+$ film (5.2×10^{-3} mol) at 82°C.
$p_{H_2+D_2}$=20 cmHg.

The initial rate of HD formation in the H_2–D_2 exchange reaction was studied after the complete evacuation of the residual adsorbed hydrogen and was compared with that of the D_2–HZ reaction, which lead to the following conclusions: Above 82°C the temperature dependence and the initial rate of HD formation from a H_2–D_2 mixture were similar to those of the D_2–HZ exchange reaction (P_{D_2}=20 cmHg) as shown in Fig. 5. The HD formation in the H_2–D_2 exchange reaction thus results mainly from the following two exchange reactions which involve the bonded hydrogen of the $An^{2-}2Na^+$ complex.

$$D_2 + HZ = HD + DZ$$

$$H_2 + DZ = HD + HZ$$

HZ: $An^{2-}2Na^+$ or AnH^-Na^+

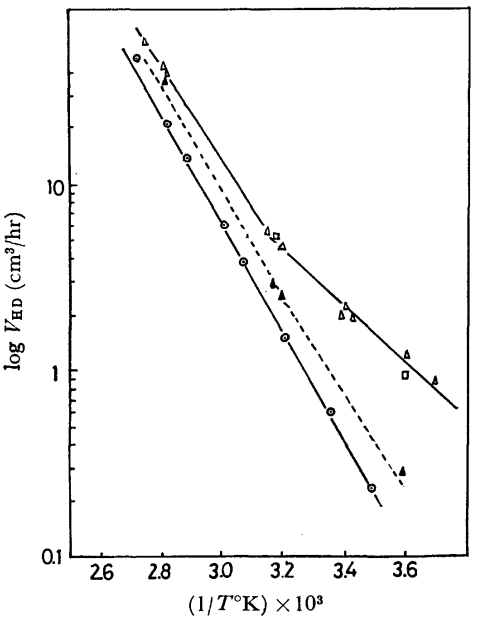

Fig. 5. Arrhenius' plot for the initial HD formation in the H_2-D_2 exchange reaction over $An^{2-}2Na^+$ films (-△-△-), and in the D_2HZ (HZ=$An^{2-}2Na^+$) exchange reaction (-○-○-). The rates of HD formation in the H_2-D_2 exchange reaction after the preadsorption of CO (*ca.* 4.5 cc) (-▲-▲-), and after evacuation of the preadsorbed CO from the complex film (-□-□-).

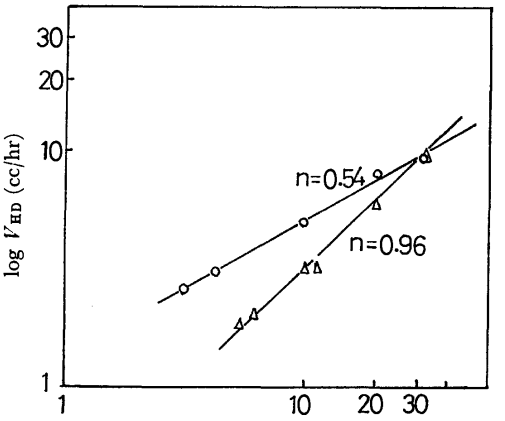

Fig. 6. Dependence of the H_2-D_2 exchange reaction rate upon the total pressure of H_2+D_2 (1:1) mixture and the deuterium pressure (P_{H_2}=10 cmHg) over $An^{2-}2Na^+$ (5.2×10^{-3} mol) film at 45°C.
-○- log P_{D_2} (cmHg) -△- log $P_{H_2+D_2}$ (cmHg)

On the other hand, at lower temperatures, *e.g.* 42°C, the HD formation from a H_2–D_2 mixture was faster than in the D_2–HZ exchange reaction (Fig. 5). The initial rate of HD formation could not be explained by the above mentioned bonded mechanism alone and the H_2–D_2 exchange reaction almost reached thermal equilibrium in the gas phase. The pressure dependence of the rates of the H_2–D_2 exchange reaction at 45°C was found to be proportional to the total pressure of the H_2–D_2 mixture (1 : 1), and to the square root of each of the H_2 and D_2 pressures as shown in Fig. 6.

$$d(HD)/dt = kP_{H_2}^{1/2}P_{D_2}^{1/2}$$

It is thus suggested that at lower temperatures the

H_2–D_2 exchange reaction takes place mainly *via* the recombination of "mobile" hydrogen chemisorbed on the complex film:

$$\left.\begin{array}{l} D_2 \rightleftarrows 2D(a) \\ H_2 \rightleftarrows 2H(a) \end{array}\right\} \rightleftarrows 2HD$$

It should be noted that when the $An^{2-}2Na^{+}$ film adsorbed carbon monoxide (4.5 and 16 m*l* stp) at 40°C, the HD formation from the H_2–D_2 exchange reaction decreased markedly, and the initial rates of HD formation became almost equal to those obtained at similar temperatures for the D_2–HZ exchange reaction. After evacuation of the complex film at 85—100°C for 20 hr, the activity of the film for the H_2–D_2 exchange reaction was completely restored as shown in Fig. 5. It is suggested that CO effectively inhibited the "weakly chemisorbed hydrogen" mechanism, but had negligible effect on the exchange between D_2 and the hydrogen of the complex molecule.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1960—1972(1972)

Calorimetric Study of the Glassy State. VII. Phase Changes between the Crystalline Phases of Cycloheptanol with Various Degrees of Stability

Keiichiro ADACHI, Hiroshi SUGA, and Syûzô SEKI
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka, Japan
(Received November 8, 1971)

The heat capacities of 8 kinds of stable and meta-stable crystalline phases including the glassy crystal of cycloheptanol were measured at temperatures from 13 to 300 K. The crystalline phases have been named crystals I, II, II′, III, III′, III″, I_β, and glassy crystal. Transition temperatures between crystals II and I, III and II, II′ and II, III′ and III, III″ and III were determined to be 258.45, 227.26, 172.23, 152.30, and 128.2 K, respectively. The melting point and glass transition point of the glassy crystal were determined to be 280.30 and 140 K, respectively. The heats of transition between crystals II and I, III and II, III′ and III and the heat of melting were determined to be 876, 554, 58.1, and 1604 $Jmol^{-1}$, respectively. The residual entropy of the glassy crystal was found to be 0.7 $JK^{-1}mol^{-1}$ assuming that of crystal III′ to be zero. The stabilization phenomenon in the glassy crystalline state was also studied from the measurements of enthalpy relaxation. The stability of the various phases was determined by calculating their free energies. The degree of freedom which is frozen in the glassy crystalline state was discussed from molecular viewpoints. Classification of various phase transitions found in this material was also made from the viewpoint of thermodynamical stability.

In general the glassy state results from an elongation of a relaxation time by cooling a material which is in a supercooled metastable state. Thus, the glassy state is looked upon as a non-equilibrium state in a thermodynamic sense.[1] We measured the heat capacities of the quenched high-temperature crystalline phases of cyclohexanol and 2,3-dimethylbutane and concluded that these crystalline phases have definite residual entropies at 0 K and exhibit glass transition phenomena characteristic of non-equilibrium glassy states.[2,3,4] We proposed the term "*glassy crystal*" for defining the glassy crystalline state as the non-equilibrium frozen-in state of crystals which have glass transition points. The present paper describes the results of measurements of heat capacity for cycloheptanol expected to form the glassy crystal from a preliminary study of the differential thermal analyses (DTA).

In previous studies,[2,3] we attempted to explain the residual entropies in terms of the degrees of freedom frozen-in below the glass transition points and proposed two possible explanations, the orientational degree of freedom of the molecules and the conformational one. However, the residual entropies were so small that they were accounted for only by taking into consideration the conformational degree of freedom frozen below the glass transition point. An important feature of the present investigation may be found in the fact that the molecule of cycloheptanol can be expected to have more kinds of possible conformations than that of cyclohexanol or 2,3-dimethylbutane. We can expect 42 kinds of distinguishable conformations for this molecule. Although we do not know much about the energy difference between these conformers, we can expect the conformational degree of freedom to contribute greatly to the residual entropy of the glassy crystal of this material, if the conformational degree of freedom is frozen at or below the glass transition point.

The influence of the complicated molecular structure on the behaviors of phase transitions is also of interest. Various metastable phases were found and some thermodynamic functions were determined for them.[2,3,4] In the present study we have also found the occurrence of 8 kinds of stable and metastable crystalline phases from DTA measurement and clarified the relation of

the instability by measuring their heat capacities.

It is well-known that the glassy state is not a completely frozen-in state but is stabilized very gradually into an equilibrium state. In this respect we measured the enthalpy relaxation time of the stabilization process.

We also measured the Raman and IR spectra in order to analyze the magnitude of the heat capacities. From the results the magnitude of heat capacity due to internal vibrations was calculated and that due to the change of the configuration of molecules was estimated. Variation in the magnitude of heat capacity caused by annealing in the glassy crystalline state was also examined.

Experimental

Material. The sample employed was synthesized by reducing cycloheptanone prepared by the reaction of cyclohexanone with diazomethane. The equations of the chemical reactions are as follows.

$$C_6H_{10}O + CH_2N_2 \longrightarrow C_7H_{12}O$$
$$C_7H_{12}O + LiAlH_4 \longrightarrow C_7H_{13}OH.$$

Cycloheptanone was synthesized by adding 550 g of nitrosomethylurethane little by little with violent stirring into a mixture of 400 g of cyclohexanone, 2 *l* of ethylether and 1200 g of 50% KOH aqueous solution. The temperature of the reacting system was regulated to 10±5°C. It took about 6 hr to complete the reaction. Fractional distillation of the reaction product yielded about 200 m*l* of pure cycloheptanone. Hydrogenation of the cycloheptanone was carried out with the aid of $LiAlH_4$ in an ethylether solution by the usual method. The reaction product was then purified by repeating fractional distillation. About 50 m*l* of the purified cycloheptanol was obtained. In order to remove the trace of water, vacuum distillation was craried out over baked CaO. The absolute purity of the sample was finally determined to be 99.932% from the equilibrium temperatures in the melting process.

Apparatus. The measurement of the heat capacity was made with an adiabatic calorimeter.[5] The cryostat was reconstructed in such a way that liquid nitrogen could be introduced into the inside of the inner jacket when the sample was required to be quenched. The platinum resistance thermometer was calibrated after the completion of investigation by comparison with the laboratory standard thermometer which had been calibrated at the US National Bureau of Standards. The deviation of the temperature scale was, however, too small to cause any error in spite of severe thermal treatment. The sample cell contained 26.774 g of the sample as well as a small amount of helium gas for heat exchange medium (1 atm at room temperature).

The Raman spectra were obtained with a Nihon Bunko Co. Raman spectrometer model R 1000 and the IR spectra with a Nihon Bunko Co. Double beam spectrometer model DS 402 G. The apparatus for DTA was reported previously.[6]

Results

DTA. Thermal behaviors were studied preliminarily by means of DTA before the precise measurements of heat capacity. The results are shown in Fig.

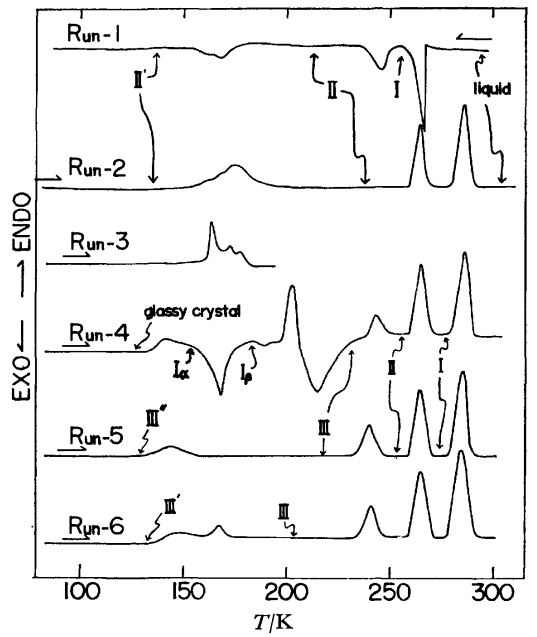

Fig. 1. DTA curves of cycloheptanol.

1. Run 1 is the cooling curve measured at a rate of about −1.5 K/min. A sharp exothermic peak due to abrupt crystallization was observed at 267 K followed by a phase transition at about 245 K. A small exothermic anomaly was observed at about 165 K on further cooling. Run 2 is the heating curve measured after the specimen had been slowly cooled down to 80 K from 280 K. The heating rate was about 2 K/min. A small and broad anomaly with two shoulders was observed at about 170 K and peaks due to a phase transition and melting followed at 259 and 278 K, respectively. We named the phases as follows, table between 259 and 278 K, Crystal I; between 170 and 259 K, Crystal II; below 170 K, Crystal II′. The heating curve taken after crystal II had been rapidly chilled at a rate of about 4 K/sec by steeping the DTA sample container in liquid nitrogen is shown in Run 3. The DTA curve taken after crystal I had been chilled rapidly by the same procedure is shown in Run 4. When the specimen in the liquid state was chilled at the same cooling rate, nearly the same DTA diagram as for Run 3 was obtained. In Run 4 an anomaly resembling that for glass transition was observed at 140 K. This is considered to be the glass transition. We thus called the phase below 140 K the glassy crystal. On further heating, an exothermic transition followed around 167 K. We named the phase between 140 and 160 K Crystal I_α and that established by the transition around 167 K Crystal I_β. A phase change took place from crystal I_β to another unknown phase at 197 K. A small exothermic anomaly was recognized around 190 K. The phase to which crystal I_β was transformed at 197 K was unstable and irreversibly transformed into the more stable one at about 210 K. A new peak appeared at 239 K which was not observed in Run 2. Above 250 K, nearly the same thermogram as in Run 2 was obtained. We named the phase with transition point at about 239 K Crystal III. In order to obtain crystal III as a pure

phase, crystal II was annealed at dry ice temperature for 3 days. Run 5 is a heating curve taken after the annealing. A small and broad anomaly was observed around 130 K. The peak at about 240 K is slightly larger than the one in Run 4. Since no peak due to the transition from crystal II′ to crystal II appeared at 170 K, it was concluded that crystal III had been established in pure state by the annealing. By annealing at 140±3 K for 5 days, crystal III changed to another phase, the DTA thermogram for which is represented by Run 6. However, when crystal III was annealed at 115—125 K for 5 days, nearly the same thermogram as in Run 5 was obtained. The phases appearing at the lowest temperature in Runs 5 and 6 were named Crystals III′ and III″, respectively.

Heat Capacity Measurements. Selected values of the heat capacity data are listed in Table 1; a complete set of the heat capacity data is preserved by the Chemical Society of Japan.[7] These heat capacity data are plotted against temperature in Fig. 2. In Series 1, the heat capacities were measured after the liquid specimen at room temperature had been chilled at a rate of about −50 K/min (Series 1). Under these conditions, it was expected from DTA that crystal I would be supercooled and the glassy crystalline state established below 140 K. The data listed in Series 2 and 2′ were taken before measurement of the enthalpy relaxation in annealing treatment, *i.e.* determination of the points D and E shown in Fig. 8. In Series 1, 2, and 2′, the heat evolution or absorption due to a stabilization effect near T_g was subtracted by correction of temperature drift. In the II′—II transition temperature region (Series 3′, 3″) the heat capacity changed slightly with thermal history. Measurements were carried out after the following thermal histories. In Series 3′ crystal II was cooled down to 100 K at the rate of −6 K/min and then annealed for 18 hr at 138 K. In Series 3″ the specimen was annealed for 12 hr at 156 K after cooling. Measurements for the supercooled crystal II in the temperature region 200—215 K were somewhat difficult on account of the exo-thermic transition from this phase to crystal III. Crystal III (Series 4) was prepared under the same conditions as for DTA (Run 5, Fig. 1). When it was annealed at 140 K for 3 days, it was transformed irreversibly into another phase which showed a phase transition to crystal III at 152.3 K. We named this phase crystal III′ (Run 6, Fig. 1). At the ordinary cooling rate (−1 K/min), crystal III was supercooled easily with no III′—III transition. The heat capacity curve of the supercooled crystal III showed a small anomaly at about 128 K. We named the supercooled phase below 128 K crystal III″ (Run 6 Fig. 1). The results for crystal III′ and crystal III″ are listed in Series 5 and 6, respectively. Crystl I (Series 9) was prepared from the results of DTA (Run 4, Fig. 1). The results for crystal III′ and crystal III″ are listed in Series 5 and 6 respectively. Crystal I_β (Series 9) was prepared from the results of DTA (Run 4, Fig. 1). Measurements for I_β were carried out after the phase had been annealed at 123 K for 15 hr (Series 9′). The aim of these measurements was to check a possible relaxation phenomenon of I_β having different thermal histories. However, no such effect was observed.

Determination of the Transition Points and the Heats and Entropies of Transition. *(1) II—I Transition*: The transition point was determined to be 258.45 K from the heat capacity measurement. Determination of the heat of transition was carried out for three series of independent measurement. As is shown in Table 2, the values obtained in experiments 1 and 3 were smaller than those of experiment 2. The deviation is beyond experimental error. This might have been caused by the thermal history of crystal II. In Expts. 1 and 3, measurements were carried out for crystal II (fresh sample produced by cooling crystal I to about 245 K), whereas in Expt. 2 crystal II prepared from crystal III was employed. It was expected that a small amount of crystal I was included in crystal II in Expts. 1 and 3 and caused a decrease in the magnitude of the heat of transition. Accordingly the values from Expts. 1 and 3 were abandoned and those from Expt. 2 were taken for calculation of the thermodynamic variables.

(2) II′—II Transition: Figure 2 indicates that, the heat capacity curve in this transition region has two maxima at 167.88 and 172.33 K, respectively, of which the latter is taken as the true transition point. Since the transition takes place over a wide temperature range, it is difficult to determine the exact heat of transition owing to the difficulty in estimation of the

7) The complete data of the heat capacity are kept as Document No. 7207 at the office of the Bulletin of the Chemical Society of Japan. 'normal' heat capacity. We thus calculated only the difference of enthalpy between crystal II′ at 162.5 K and crystal II at 176.5 K as given in Table 2.

(3) III—II Transition: The transition point could not be determined on account of the superheating effect of crystal III above the transition point. Thus the determination was carried out by measuring the magnitude of the temperature drift which was brought about by a spontaneous heat evolution or absorption due to the transition between crystals II and III. For this purpose a mixture of crystals II and III in the ratio about 1 : 1 was used since the rate of transition is expected to be maximum at this ratio where the best sensitivity is expected for the measurement. The temperature dependence of the drift for this specimen was measured at the temperature region 215—240 K and the transition point was determined as shown in

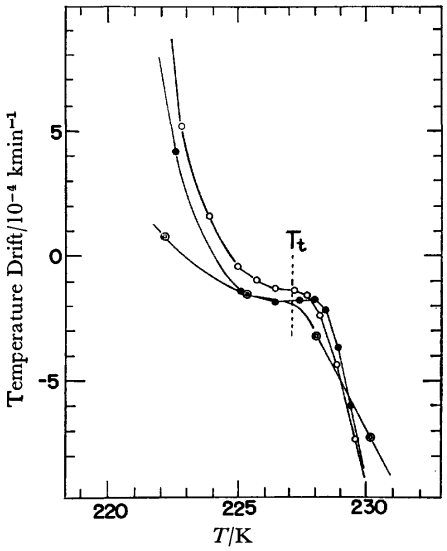

Fig. 3. Determination of the transition point between the crystal-II and III.

Fig. 3. The heat of transition was measured twice and the results are shown in Table 2. The values from Expt. 1 were determined by measuring the enthalpy difference between superheated crystal III (at 230.1 K) and crystal II at 239.7 K, since we did not know the superheating effect at that stage. The measurement in Expt. 2 was carried out between 226 and 240 K.

(4) III′—III Transition: The transition point was determined to be the temperature at which the heat capacity curve reaches a maximum value. Although this curve has a shape similar to that of second order phase transition, it took more than one hour to attain equilibrium after heating was over. The heat and entropy of transition are given in Table 2.

(5) III″—III Transition: The transition is considered to be that of higher order judging from the shape of the heat capacity curve. In contrast to the III′—III transition, equilibrium temperature was attained in a few minutes. As in the case of the II—II′ transition, estimation of contribution from the lattice part was difficult and no accurate determination

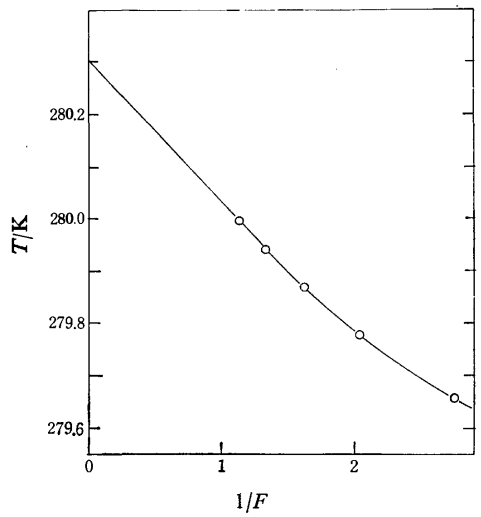

Fig. 4. Melting curve for cycloheptaol

of the entropy of transition could be made. The transition point was determined to be 128.2 K from the heat capacity curve.

(6) Melting Process: The data of fractional melting are plotted in Fig. 4. The melting point and the content of impurities which do not form solid solution with crystal I were determined from the curve. The melting point is the value obtained under the pressure of about 1 atm since the calorimeter cell contained helium gas. The difference between this and the triple point cannot be calculated since the data of the volume change at the melting is not available. The purity of the specimen was found to be 99.932%. The value of the enthalpy of melting is given in Table 2.

Estimation of the Heat Capacity of Crystal I_α Between 140 and 258 K. The heat capacity of crystal I_α (supercooled crystal I) between the temperature region 145—258 K could not be measured on account of its instability. Thus it was estimated in such a way that the difference of the enthalpy between 145 and 258 K agrees with that determined experimentally. The result is given in Fig. 2 by dashed line. Between 228 and 258 K, the heat capacity curve of crystal I is estimated to be parallel to that of crystal II and represented as follows.

$$C_p(\mathrm{I}) = C_p(\mathrm{II}) + 4.30. \quad (1)$$

Between 145 and 288 K, the interpolation equation is estimated to be;

$$C_p(\mathrm{I}_\alpha) = 180.35 - 0.45888T + 1.8769 \times 10^{-3}T^2. \quad (2)$$

By these equations the enthalpy of crystal I_α at 144.097 K is calculated to be 9036 J mol^{-1}. Here the enthalpy of crystal III′ at 0 K was taken as the reference point of enthalpy. The value obtained by direct measurement was 9010 J mol^{-1} which is in good agreement with that calculated by Eqs. 1 and 2. The procedure of the direct measurement was reported previously.[3]

Estimation of the Heat of Transition Between Crystal I and the Unidentified Phase. From DTA, it was found that crystal I_α is transformed into an unidentified phase at 197 K. We attempted to calculate the heat of transition for this phase change assuming that the unidentified phase was either crystal I or crystal II. For this purpose it is necessary to determine the enthalpies for crystals I_α, I_β, and II at 197 K. The values for crystals I_α and II were calculated to be 17.35 and 16.71 kJ mol^{-1}, respectively, from the above data. The value for crystal I_β was determined directly[3] at 163.9 K to be 11.48 kJ mol^{-1}. The value at 197 K was then calculated to be 16.49 kJ mol^{-1} by means of the following equation which was estimated to be between 165 and 197 K as

$$C_p = 0.291T + 99. \quad (3)$$

The heat of transition is thus determined to be either 0.86 ± 0.05 or 0.22 ± 0.05 kJ mol^{-1} by assuming that the unidentified phase is either crystal I_α or crystal II. It is reasonable, however, to consider the value of transition between I_β and the unidentified phase to be close to that of the II—I transition (0.875 kJ mol^{-1}) from a comparison of the peak areas of DTA thermogram (Run 4, Fig. 1). Accordingly, we estimated that the phase into which crystal I_β is transformed would be

TABLE 3. CALCULATION OF THIRD LAW ENTROPIES.

1) The third law entropy of crystal I at 258.45 K *via* III′—III, III—II, and II—I transition

Temperature	Contribution	ΔS / $JK^{-1}mol^{-1}$
0 — 12.5	Debye extrapolation θ_D=112.9	1.73
12.5—152.30	$\int C_p(III')\, d\ln T$	114.04
152.30	Transition $\left(\frac{58.07}{152.30}\right)$	0.38

	$\sum$ =	204.76

2) The third law entropy of crystal I_α at 258.45K *via* crystal I.

0 — 13.5	Debye extrapolation θ_D=112.7	2.17
13.5 — 145.5	$\int C_p$(Glassy cryst.) $d\ln T$	107.07
145.5 —258.45	$\int C_p(I_\alpha)\, d\ln T$	94.82
	$\sum$ =	204.06

a) Equations 18 and 19 were used for the calculation.

3) The third law entropy of crystal II at 227.26K *via* crystal II′

Temperature	Contribution	ΔS
0 — 13.5	Debye extrapolation θ_D=114.2	2.09
13.5 — 162.5	$\int C_p(II')\, d\ln T$	118.65
162.5 — 177.5	Transition region	18.15
177.5 —227.26	$\int C_p(II)\, d\ln T$	39.97
	$\sum$ =	178.86

4) The third law entropy of crystal III at 152.30K

Temperature	Contribution	ΔS
0 — 13.5	Debye extrapolation	2.31
13.5 —152.30	$\int C_p(III'')\, d\ln T$	114.41
	$\sum$ =	116.41

5) Zero-point entropy calculated by assuming that of crystal III′ to be zero.

Glassy crystal	0.70
Crystal II′	—0.19
Crystal III″	—0.26

crystal I_α and the heat of transition between the phases 860±50 J mol^{-1}.

Residual Entropies of Various Phases. Assuming the entropy of crystal III′ at 0 K to be zero, we calculated the zero-point entropies for various other phases. The calculation for glassy crystal and crystal I_β are based on the above estimations. The results are given in Table 3. Below 13 K, the entropy changes were calculated with use of the Debye equation assuming

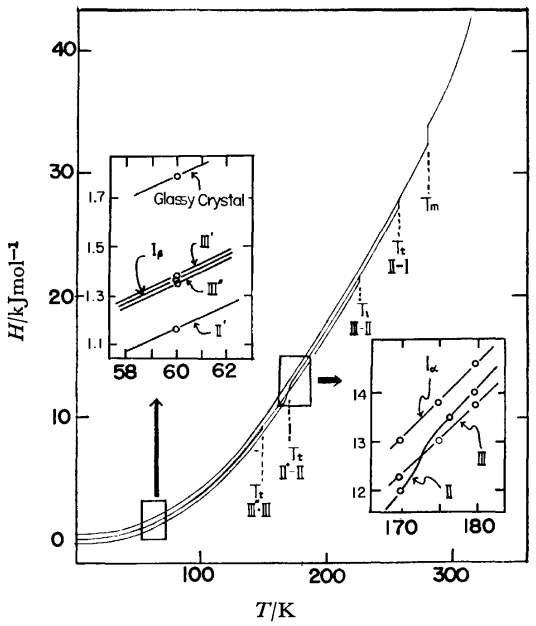

Fig. 5. Enthalpy curves of cycloheptanol.

6 degrees of freedom. The Debye temperatures are given in Table 3. The residual entropy determined for glassy crystalline state amounts to 0.70 $JK^{-1}mol^{-1}$, whereas the zero point entropies of other phases can be considered to be zero within experimental error.

Thermodynamic Functions of Various Phases. The thermodynamic functions derived from the data are given in Table 4 and the enthalpies in Fig. 5. The enthalpy curves are close to each other on account of small heats of transition. The entropy curves behave in a similar way. The relative Gibbs energies as well as the relative enthalpies of each phase with reference to crystals III′ and III are plotted in Figs. 6 and 7 for comparison of the stabilities of various phases. We see in Fig. 6, that crystal II′ is more stable than crystal III′ below 150 K. Thus the phase transformation from crystal III′ or III″ to crystal II′ should take place by annealing crystal III′ or III″ below 150 K. However, annealing of crystal III′ for 6 days at 140 K gave no such an effect by DTA study. The enthalpies of crystals II and III become equal at about 170 K

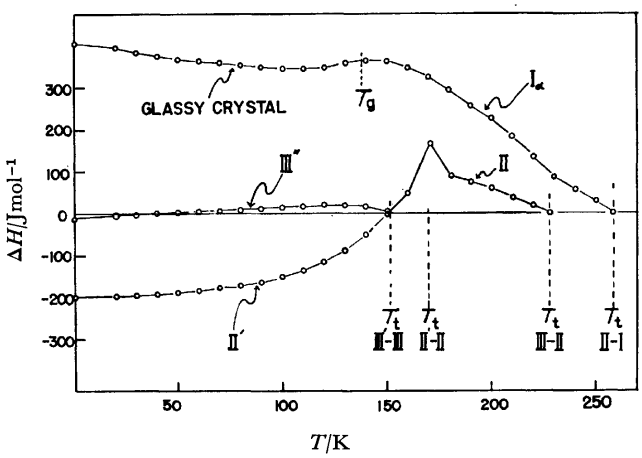

Fig. 6. Difference in Gibbs energy between the crystal-III′ and the other various phases.

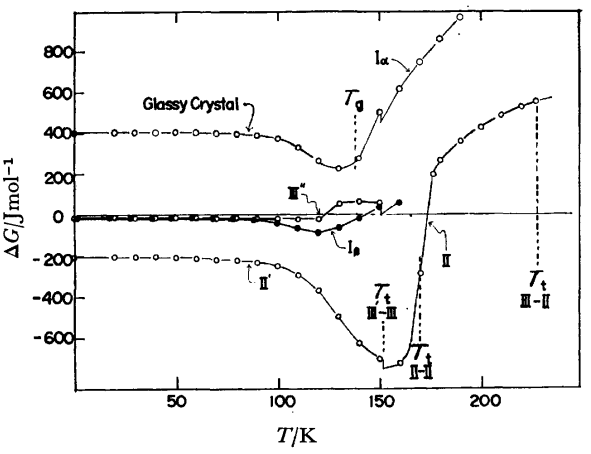

Fig. 7. Difference in enthalpy between the crystal-III' and the other various phases.

as shown in Fig. 7. The irreversible phase change might take place at this temperature, with neither heat evolution nor heat absorption. It was found, however, that the annealing of crystal II at about 170 K (II'—II transition region) for several days caused no phase change in crystal III. The Gibbs energy of crystal III'' is slightly smaller than that of crystal III'. This might be due to experimental error.

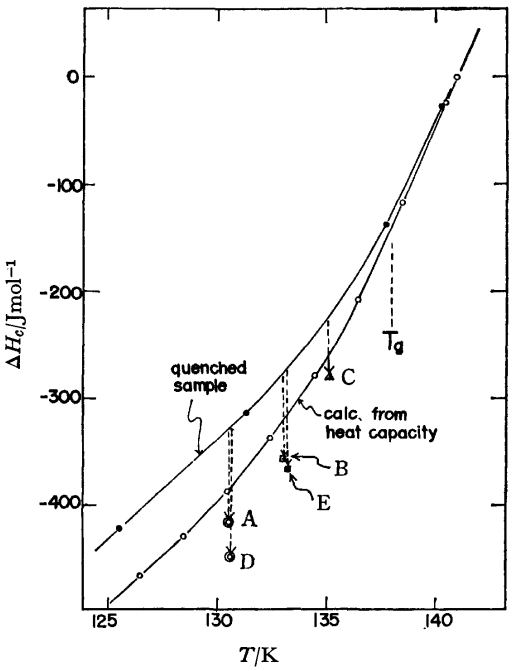

Fig. 8. Decrease of the configurational enthalpy of the glassy crystal by annealing treatment.

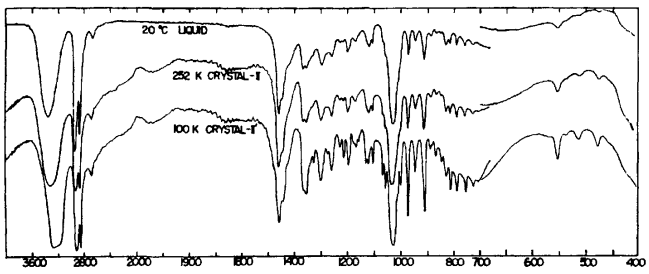
Relaxation Phenomenon of Enthalpy. The relaxation of the enthalpy of the glassy crystalline state was investigated by annealing for 20 hr at 130.6, 133.0, and 135.2 K. The values of the enthalpy decrease during the treatments are given by points A, B, and C in Fig. 8 where the ordinate indicates the configurational enthalpy for the sake of convenience. The method of calculation of the configurational enthalpy has been given.[2,3] For the calculation it was necessary to estimate the heat capacity due to lattice and internal vibrations. This is difficult on account of the gradual increase of the heat capacity curve below T_g (Fig. 2), but it was estimated by the equation

$$C(\text{vib}) = 0.7197T + 4.62. \quad (4)$$

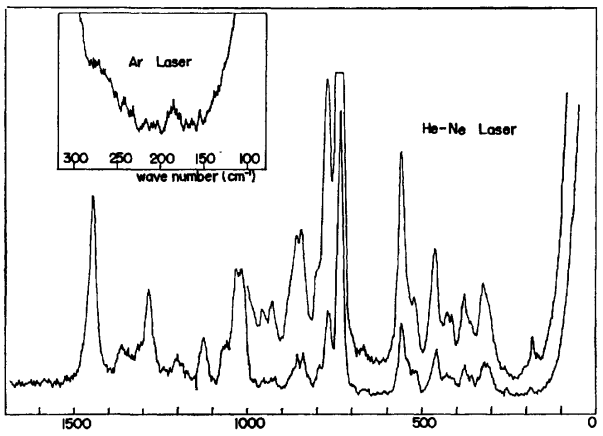
Point D represents the value of the enthalpy after annealing for 75 hr at 130.7±0.5 K and point E stands for the value after the annealing for 68 hr at 133.3 K. From the results, the conventional relaxation times were calculated to be 24 hr at 130.7 K on the assumption that the enthalpy decreased exponentially. This might not be correct since it was found that the relaxation in the glassy crystalline state of 2,3-dimethylbutane is not the genuine exponential type.[3] Thus the present data of the relaxation time give only approximate values of the time constant.

Measurements of Raman and IR Spectra. In order to estimate the contribution of internal vibrations to heat capacities, the Raman and IR spectra were



Wave number (cm^{-1})

Fig. 9. Infrared spectra of cycloheptanol.



Wave number (cm^{-1})

Fig. 10. Raman spectra of cycloheptanol.

measured in liquid state. The observed Raman and IR spectra are shown in Figs. 9 and 10, respectively. The frequencies of bands are as follows;

Raman: 179, 255, 295, 319, 355, 372, 410, 420, 456, 516, 553, 661, 725, 764, 790, 835, 853, 922,

IR: 455, 474, 512, 535, 552, 570, 725, 730, 760, 790, 816, 813, 850, cm^{-1}.

Since the band at 179 cm^{-1} was observed by using both a He–Ne laser and an Ar laser as a light source, it was not a noise accompanied by a He–Ne laser. The weak infrared bands at 474, 535, and 570 cm^{-1} were assigned to combination bands, *i.e.* 179+295=474, 179+355=534, and 255+319=574. From the results, the frequencies of the normal modes were estimated. Among the possible 60 modes, the following 37 modes are assigned empirically (Table 5). The remaining 23 modes are assigned to the CH_2 rocking ($\times 6$) and skeletal modes ($\times 17$). Since the molecule of cycloheptane belongs to a symmetry group of C_s or C_2,[8] it is expected that it has at most only a mirror plane for a symmetry element and that all of the modes are not degenerate and active both in the IR and Raman spectra. We therefore adopted the following 15 bands; 179, 255, 295, 319, 355, 372, 410, 421, 456, 516, 553, 661, 725, 764, and 790 cm^{-1} as the normal modes which are not degenerate. There still remain 8 modes. Since it is known empirically that the CH_2 rocking modes have frequency below 1100 cm^{-1}, we assumed 4 modes with an average frequency of 900 cm^{-1} and other 4 modes with one of 1100 cm^{-1}. Since the heat capacity due to the mode whose frequency is greater than 800 cm^{-1} is small below 200 K, ambiguity in the estimation causes no trouble.

CO stretching	1030	×1

Discussion

Residual Entropy. We have used a term "glassy crystal" for the phase which was established below 140 K by rapid cooling of crystal I. The residual entropy of this crystalline phase amounted to 0.7 $Jmol^{-1}K^{-1}$. This is too small to claim that the phase has a residual entropy because its magnitude is the same order as that of the experimental error. However, we can give several reasons for assuming that the phase should be in a glassy crystalline state. First, it is possible that the value we obtained for the residual entropy is not correct, since it was determined on the assumption that crystal III′ has no residual entropy. It is necessary to determine the absolute value of the entropy from a comparison of the entropy in the gaseous state determined by thermal method with that determined from spectroscopic data. Second, the stabilization phenomenon characteristic of glassy state was actually observed in this phase. Thus it can be concluded that the phase is in a non-equilibrium state. Third, if crystal II′ is taken as the reference state with no residual entropy (Table 3 and Fig. 6), the value of the residual entropy increases to 0.9 $Jmol^{-1}K^{-1}$. This value is slightly larger than the limit of experimental error (0.6 J $mol^{-1}K^{-1}$) and might indicate the presence of the residual entropy. Fourth, the shapes of the heat capacity curve and the DTA diagram closely resemble those of known glassy crystals.[2,3,4] The empirical rule for the glassy crystals states that the ratio of T_g and T_2 is nearly constant (1.15—1.20).[3] Here T_2 is the temperature defined by Gibbs and DiMarzio,[9] at wihch the configurational entropy of supercooled liquid vanishes. By means of the rule we attempted to estimate the true value of the residual entropy of the glassy crystalline state. The value of a ratio between T_g and T_2 is related to a residual entropy S_0 by the following equation.

$$\Delta C_p \ln (T_g/T_2) = S_0. \quad (5)$$

Here ΔC_p is the jump of the heat capacity at the glass

9) J. H. Gibbs and E. A. DiMarzio, *J. Chem. Phys.*, **28**, 373 (1958).

transition point. Since the value of T_g/T_2 is known to be 1.15—1.20 for the glassy crystals and the ΔC_p for the present glassy crystal amounts to about 30 $JK^{-1}mol^{-1}$, the value of S_0 is determined to be 5.0 $JK^{-1}mol^{-1}$ from the equation. If this is correct, all the other phases also have a residual entropy of about 5 $JK^{-1}mol^{-1}$. We therefore consider that the residual entropy of glassy crystal is not so large as compared with 5 $JK^{-1}mol^{-1}$. The order of magnitude seems to be too small since this molecule has the following conformations.

If one assumes a chair form, there are seven distinguishable conformations with respect to the carbon atom on which a hydroxyl group is bonded. Furthermore, there are two positions to locate the hydroxyl group on the carbon atom *i.e.* an equatorial position and an axial one. Thus we can anticipate at least 14 conformations. If the position of a hydrogen atom of the hydroxyl group is considered with respect to its internal rotation, the number of conformations may increase further by a factor of three *i.e.* 42 kinds of conformations. The value of $R\ln(14)$ and/or $R\ln(42)$ amount to 22 and/or 31 $JK^{-1}mol^{-1}$ respectively. Here R reprensents the gas constant. Although we do not know the energy difference between the conformations, we can expect that the configurational degree of freedom will contribute greatly if they are frozen at the glass transition point. Thus it seems to be reasonable to consider that not all of these conformational degrees of freedom are frozen at the T_g. It is suggested that some motional degrees of freedom exist even below T_g. This might be explained in terms of interconversions between the molecules with various conformations in the glassy crystalline state.

The Plastic Crystalline State. Since the value of the entropy of melting is 5.72 $JK^{-1}mol^{-1}$, crystal I is considered to be plastic. The sum of the values of the entropy of melting and those of I—II transition amounts to 11.6 $JK^{-1}mol^{-1}$. Since this is still smaller than that of the Timmermans criterion,[9] crystals II and III might also be considered to be plastic. This is supported further by the motional narrowing phenomenon of the NMR spectra for these phases and the magnitude of the heat capacities. We see in Fig. 2 that the supercooled states of crystals II and III show no anomaly similar to that in glass transition in their heat capacity curves. In contrast to the glassy crystal, the high degree of configurational degrees of freedom for crystals II and III give rise to the λ-type phase transitions as shown in Fig. 2. We suggested that crystals II and III have residual entropy and these phases are also looked upon as frozen-in states at low temperatures. However, since no glass transition phenomenon could be observed for the crystals down to the lowest temperature, we are not convinced that we can call them glassy crystals. We might say that plastic crystals such as II or III do not always show the glass transition when they are cooled down without irreversible transformation into other more stable phases. In order to solve the so-called Kauzmann paradox,[1] Gibbs and DiMarzio postulated that a supercooled liquid will show the second order phase transition with infinitely slow cooling rate.[9,11] If we adopt this point of view for crystal I and cool it down very slowly below T_g, this phase might also have a second order phase transition similar to that of crystal II or III as far as the internal equilibrium is maintained below 140 K.

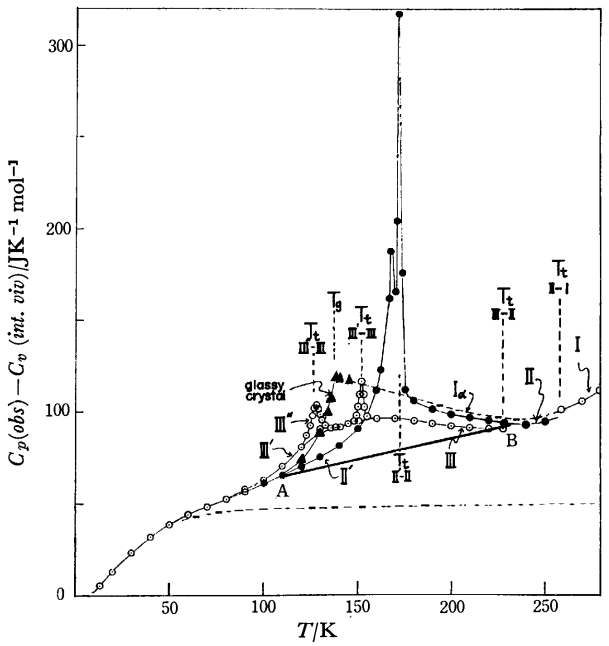

Fig. 11. Plot of C_p(obs)–C_v(internal vib.).

Analysis of Heat Capacities. From the data of Raman and IR spectra, the magnitude of contribution of internal vibrations to the heat capacity was calculated. The value was then subtracted from the observed total heat capacities. The result is shown in Fig. 11. The dashed line represents the heat capacity due to the lattice vibration calculated by using the Debye model with 6 degrees of freedom. The difference between the plotted value of (C_p(obs)—C_v(int)) and the value of the dashed line is explained as the sum of anomalous heat capacity C(an) and (C_p—C_v). The C(an) becomes noticeable above around 70 K and amounts to about 50 $JK^{-1}mol^{-1}$ around 200 K for all the phases. This is considered to be another evidence for these phases to be plastic crystals which are generally known to have a large heat capacity whose magnitude can not be explained in terms of only a contribution of vibrations and (C_p—C_v). It is known that the material belonging to the plastic crystals has first order phase transition point in its crystalline state and that the entropy of transition is much larger than that of melting. On the contrary, the entropy of transition of cycloheptanol does not amount to such a large value and the magnitude of the heat capacity of the low temperature form (crystal III) is too large to be explained only from vibrational contribution. This should indicate the evidence of continuous ordering of the molecular orientation and conformations with decreasing temperature. Although the magnitude of

10) J. Timmermans, *J. Phys. Chem. Solids*, **18**, 1 (1961).

11) G. Adam and J. H. Gibbs, *J. Chem. Phys.*, **43**, 139 (1965).

the C(an) is not explained from the molecular motions, we might expect that the changes of configurations and conformations cause this effect.

II—II′ Transition. The difficulty of determining the entropy change for II—II′ transition has been already pointed out. As is shown in Fig. 11, the heat capacity due to the change of configuration does not vanish at temperatures far above the transition point. We calculated the entropy of transition assuming that the "normal" heat capacity is given by the straight line A—B. The procedure is based on an assumption that the configurational heat capacity can be separated into two parts *i.e.* the configurational heat capacity accompanied by the phase transition and that independent of the transition. The entropy of transition thus determined amounted to 17.2 $Jmol^{-1}K^{-1}$ (Rln 7.9).

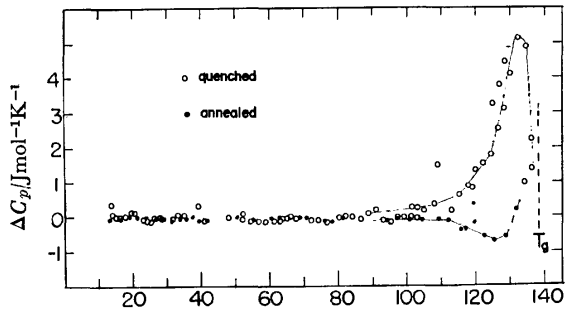

Fig. 12. The deviation of the heat capacities of the quenched glassy crystal and annealed one from the smoothed values.

Difference Between the Heat Capacity of Annealed Glassy Crystal and the Quenched One. The heat capacity of the glassy crystalline state was measured with the specimens which was annealed below T_g and then quenched. The aim of this measurement is to detect the difference in heat capacities of specimens. The difference is shown in Fig. 12. Hardly any difference can be seen below 100 K. However above this temperature it becomes noticeable with a maximum value of 5 $JK^{-1}mol^{-1}$ around 130 K. As a possible explanation, an experimental error might be considered at first since the heat evolution or absorption due to the stablilization effect disturbed the measurements of the heat capacity around 130 K. However, the observed temperature drift due to this effect was not so large as to account for the actual difference at least below 130 K. Thus the fact can be ascribed to the variation of the configurational heat capacity caused by annealing since the anomalous heat capacity was recognized in the glassy crystalline state above 70 K as is seen in Fig. 11. Existence of the degree of freedom not frozen below the glass transition point was confirmed in the glassy crystalline state of cyclohexanol and 2,3-dimethylbutane in the study of broad line NMR and dielectric loss. The decrement of the anomalous heat capacity in the glassy crystalline state caused by annealing can be explained in terms of the variation of the shape and size of the potential energy curves for various conformations caused by annealing.

Crystal I_β. Run-4 in Fig. 1 shows that crystal I_α is transformed into a meta-stable phase around 170 K. Similar phenomena of the supercooled plastic crystals transformed into other meta-stable phases just above their glass transition points were also observed for cyclohexanol[2] and 2,3-dimethylbutane.[3] The heat capacity curve of crystal I_β showed an anomalous increase around 130 K. However, this is not as steep as in the case of glass transition (Fig. 2). The heat capacity curve of the meta-stable phase of 2,3-dimethylbutane also shows a similar hump. The residual entropy of crystal I_β was calculated to be -1.0 ± 1 $JK^{-1}mol^{-1}$ based on the above assumption. On the other hand, the residual entropy of the meta-stable phase of 2,3-dimethylbutane was found to be 2.7 $JK^{-1}mol^{-1}$. In order to see whether this meta-stable phase can be considered as a glassy crystal or not below the temperature at which the anomaly was observed, we measured the heat capacity of crystal I_β in two series subjected to different thermal histories. No change was detected in the magnitude of the heat capacity due to the difference in thermal history. Thus the anomalous increase of the heat capacity can not be attributed to the relaxation phenomenon. It would be noted that this phase does not show any phase transition as in the case of crystal II or III. We may regard this phase as a plastic crystal above 140 K from the magnitude of its heat capacity.

Phase Transition Between Phases with Various Degrees of Stability. In general the degree of stability of a material system can be classified into three steps, *i.e.* stable, meta-stable, and non-equilibrium states. A stable state is the state in which free energy is at its absolute minimum. The meta-stable state is the state in which free energy is at the minimum, but not absolute minimum. The two states are, however, classified as thermodynamically equilibrium states. On the other hand, non-equilibrium state is the state at which free energy is not in its minimum. From this point of view, the phase changes which occur in cycloheptanol can be classified into five groups as shown in Table 6.

Table 6. Classification of phase transitions from the standpoint of thermodynamical stabilities

Type	Stability relation	Example
	Irreversible Transitions	
(1)	non-equilibrium→metastable	Glassy crystal → I_α
(2)	metastable→metastable or stable	$I_\alpha \rightarrow I_\beta$ $I_\alpha \rightarrow$ II II→III
	Reversible Transitions	
(3)	metastable⇌metastable	III″⇌III III′⇌III $I_\beta \rightleftharpoons I_\alpha$
(4)	stable⇌metastable	II′⇌II
(5)	stable⇌stable	III⇌II II⇌I I⇌liquid

(1) includes phase changes between non-equilibrium and meta-stable states. A typical example might be the so-called glass transition, although this is a kind of relaxation phenomenon and not a "phase transition" in a strict sense. In cycloheptanol, the glass transition

between glassy crystal and crystal I_α corresponds to this group. Since the state of glassy crystal changes gradually and continuously with time, the transition is regarded to be irreversible.

(2) includes irreversible transitions between a meta-stable and a stable state or between one meta-stable and another meta-stable phase. These phase transitions are considered to be exo-thermic peaks of the thermogram of DTA (Run 4, Fig. 1).

(3), (4), and (5) include various kinds of reversible phase changes. An example of group (3) can, however, be classified into group (1), since crystals III′, III″, and I_β can be in a non-equilibrium state with residual entropy. At the present stage of investigation, however these phases may be regarded as meta-stable since no thermal histories were detected. The example in (4) might be peculiar in the sense that we can follow the phase transition from each side of the starting phase. Usually we know only the examples from right to left with exothermic effect.

In the previous papers,[2,3,4] we have reported that various kinds of supercooled plastic crystals are transformed stepwise into more stable states. The phenomenon is known as "Ostwald's law of stage" (or step rule). Transitions of this type are those between the discrete states in the phase space and the transitions proceed at the boundary of the phases. There also exists a transition which occurs continuously between the different states in the phase space. This phase change takes place homogeneously. When it happens to occur irreversibly, then one of two phases between which the transition proceeds should be invariably in a non-equilibrium state. Cycloheptanol shows both these trends depending on the thermal histories, and provides good examples for a study of phase changes from thermodynamic or statistical-mechanical as well as kinetic aspects.

Summary

(1) The heat capacities of cycloheptanol were measured from 13 to 300 K. It was found that there exist 8 crystalline phases *i.e.* Crystals I, II, II′, III, III′, III″, I_β, and glassy crystal.

(2) The transition points for transitions II—I, III—II, II′—II, III′—III, and III″—III were determined to be 258.45, 227.26, 127.23, 152.30, and 128.2 K, respectively. Melting point and the glass transition point of glassy crystal were also determined to be 280.30 and 240 K, respectively.

(3) Heats of transition for transitions II—I, III—II, and III′—III and the heat of melting were determined to be 876, 554, 58.1, and 1604 $Jmol^{-1}$, respectively. The entropies of transition corresponding to these phase changes were calculated to be 3.39, 2.44, 0.38, and 5.72 $JK^{-1}mol^{-1}$, respectively.

(4) The residual entropies were also determined for glassy crystal, crystals II and III″ to be 0.70, −0.19, and −0.26 $JK^{-1}mol^{-1}$, respectively, assuming that crystal III′ has no residual entropy.

(5) The free energies and enthalpies of the various crystalline phases were calculated, the instability being determined by comparison of their free energies. It was concluded that crystal II′ was most stable in the temperature region below 170 K, III between 170 and 227.26 K, II between 227.26 and 258.45 K and I between 258.45 and 280.30 K.

(6) Relaxation of the enthalpy in the glassy crystalline state was studied and the relaxation time was determined to be about 24 hr at 133.3 K.

(7) The degree of freedom frozen in the glassy crystalline state was discussed from the viewpoint of conformations of the molecule.

(8) The heat capacities due to internal vibrations were calculated from the data of IR and Raman spectra and the magnitude of heat capacities in the various phases were discussed.

(9) Various kinds of phase transitions found in cycloheptanol were classified from the viewpoint of thermodynamical stabilities.

The authors wish to thank Mr. Shinichi Ishikawa and Mr. Mitsuo Ohama for the measurements of infrared and Raman spectra.

Exciton-Exciton Interaction and Exciton Migration in Anthracene, Pyrene, and Perylene Crystals

Akinori INOUE, Keitaro YOSHIHARA,* and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo

**The Institute of Physical and Chemical Research, Wako, Saitama*

(Received November 17, 1971)

The bimolecular annihilation of singlet excitons in pyrene, perylene, and anthracene crystals was studied by the aid of a nitrogen gas laser. The rate constant, γ, for bimolecular annihilation was estimated at 293°K to be 9×10^{-15} and 8×10^{-14} $cm^3\,sec^{-1}$ for pyrene and perylene, respectively. The temperature dependence of γ was measured with the result that it increases with the increasing temperature for the pyrene and perylene crystals, while it is almost independent of temperature for anthracene between 77°K and 293°K. The difference in the temperature dependence of γ was attributed to the difference in the mechanism of the exciton migration of the crystals. The method developed by the present authors for studying the exciton migration based on the exciton bimolecular annihilation was compared with that obtained previously by the use of mixed crystals.

In the last decade, a number of studies have been made of the singlet-exciton migration in aromatic hydrocarbon crystals;[1-5] most of them have been concerned with the fluorescence from host or guest molecules in mixed crystals. However, in the study of the exciton migration, it is desirable to use pure crystals to avoid specific host-guest interaction, the reflection of excitons by guest molecules, and the reabsorption of host fluorescence by guest molecules.[5] The exciton-exciton collision annihilation first sutdied by Bergman, Levine, and Jortner[6] may be useful for this purpose. They studied this phenomenon by observing the radiative decay of the fluorescence from a densely-excited anthracene crystal. Bimolecular collision annihilation was also observed for the pyrene crystal.[7]

The mechanism of the bimolecular exciton annihilation involves the exciton-transfer process followed by a collision ionization of an exciton pair through the autoionization level.[8] Since the former process may be rate-determining,[9,10] the exciton transfer in molecular crystals may be studied by measuring the rate constant, γ, for the bimolecular annihilation. In the present work, the γ value was estimated by measuring the fluorescence decay of densely-excited pyrene and perylene crystals. Furthermore, its temperature dependence was studied for anthracene, pyrene, and perylene crystals in order to clarify the mechanism of the exciton migration.

Experimental

Pyrene and anthracene were purified by vacuum sublimation and zone refining. Pure perylene was obtained by recrystallization of the synthetic material from a toluene solution.[11] Single crystals and polycrystalline samples of these materials were used for the experiment. The samples were excited by pulse radiations with half-widths of about 4 nsec at 3371 Å from a coaxial nitrogen laser.[12,13] The laser power of ~20 kW was measured by the chemical actinometry[14] in each experiment, in order to evaluate the exciton density. The laser beam was focused on a spot about 0.8 mm of diameter on the crystal surface. Filters were used in order to attenuate the intensity of the laser beam. The fluorescence from the samples was passed through a Bausch and Lomb monochromator and was detected by an RCA 1P28 photomultiplier, a Toshiba UV-39 filter being set in front of the entrance slit of the monochromator to eliminate the scattered laser light. By the use of neutral density filters, the photomultiplier pulse current was adjusted to be of the order of magnitude of a few mA, far below its saturation current. The decay curves were displayed on a Tektronix 585 oscilloscope and were photographed. The bimolecular rate constant was estimated by the least-squares method.

Results and Discussion

Estimation of γ Values. Some typical oscilloscope tracings of the fluorescence decays at the low- and high-density excitations are shown in Fig. 1, taking the perylene at 293°K as an example. Semilogarithmic plots of the decay curves are shown in Fig. 2. The decay curve deviates pronouncedly from an exponential decay at the high-density excitation, while it is regarded as exponential at the low-density excitation. The results can be interpreted in terms of the exciton-exciton annihilation. When the bimolecular annihilation of excitons takes place, the singlet-exciton density, n, after the termination of the laser may be represented by Eq. (1):

$$dn/dt = -\alpha n - \gamma n^2 \quad (1)$$

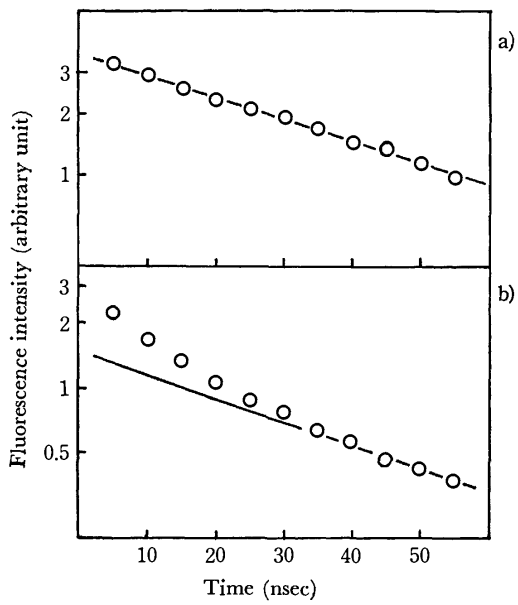

Fig. 2. Semilogarithmic plots of perylene fluorescence intensity *versus* time at low (a) and high (b) exciton density at 293°K.

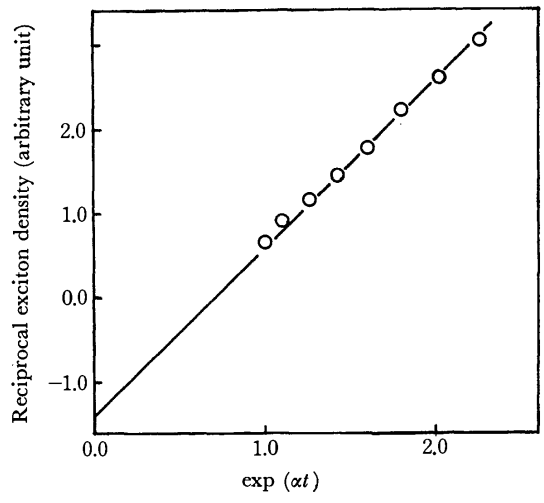

Fig. 3. A plot of the reciprocal exciton density *versus* $\exp(\alpha t)$ of perylene crystal at 293°K.

Integration of Eq. (1) gives the following equation:

$$1/n = (1/n_0 + \gamma/\alpha)\exp(\alpha t) - \gamma/\alpha \qquad (2)$$

where n_0 is the initial exciton density. A linear relationship is expected to be satisfied between $1/n$ and $\exp(\alpha t)$. This relationship was found to be satisfied for the perylene and pyrene crystals at 293°K. The result for the perylene crystal taken as an example is shown in Fig. 3. The γ value was obtained from γ/α corresponding to the intercept of the straight line with the ordinate and from the monomolecular decay constant, α, obtained by the low-density excitation.

The initial exciton densities, n_0's, were estimated for the pyrene and perylene crystals on the following three assumptions. (1) Since the life-times of singlet excitons in the crystal are much longer than the pulse duration of the nitrogen laser, the time dependence of the excitation pulse may be represented by a delta function. (2) The crystals absorb the laser-pulse photons following the Lambert-Beer law. The initial exciton density (cm^{-3}) can be written:

$$n_0 = (N_0/S)(1 - 1/10^{\varepsilon cl})/l \qquad (3)$$

Here, N_0, S, and ε are the number of photons in a laser pulse, the area of the crystal surface illuminated by the laser beam, and the molar extinction coefficient of the crystal, respectively. Furthermore, c is the molar concentration of the crystal, as determined from the crystal data.[15] By determining the penetration depth, l, in such a way that $10^{\varepsilon cl}$ equals e, the mean exciton density in a volume of Sl was calculated. (3) Since the unpolarized laser beam was irradiated perpendicular to the *ab* plane of the perylene single crystal, the molar extinction coefficient was estimated by averaging the polarized values in this plane observed by Hochstrasser.[16] For pyrene, the molar extinction coefficient of the solution[17] was used, since the fluorescence decay was observed for a multicrystalline sample. In the case of anthracene, the exciton may not stay within the irradiated volume during the measurement time, since its migration rate is considered to be very fast. This makes it difficult to determine the accurate value of n_0 and prevents us from determining the γ value for anthracene.

The γ values at 293°K were estimated to be 9×10^{-15} and 8×10^{-14} cm^3sec^{-1} for the pyrene and perylene crystals, respectively.

Mechanism of Exciton Transfer. It is a central question whether the band model or the hopping model is applicable to the energy transfer in molecular crystals. The applicability of these two models is dependent upon the strength of the molecular interaction in the crystals.[18] Under the framework of the band model, the efficienty of energy transfer may be expected to decrease with the increasing temperature since the phonon scatters the coherent diffusion of the

15) For perylene crystal; D. M. Donaldson, J. M. Robertson, and J.G. White, *Proc. Roy. Soc., Ser. A*, **220**, 311 (1953). For pyrene crystal; J. M. Robertson and J. G. White, *J. Chem. Soc.*, **1947**, 358.

exciton and limits the mean free path of the exciton.[19] This has actually been found by Hammer and Wolf[20] for naphthalene in the temperature range from 100°K to 6°K. In careful experiments adopting the host-guest systems, no indication of a thermally activated energy transfer process was found in such monomeric molecular crystals as anthracene and naphthalene.[3]

The magnitude of the molecular interaction in the crystal is related with that of the jump time. The time for pyrene was determined to be 2×10^{-11} sec at room temperature from an impurity-quenching experiment.[4] This value is larger by two orders of magnitude than that of anthracene (2×10^{-13} sec) which was obtained from the Davydov-splitting or impurity-quenching experiment.[3] This means that the exciton diffusion is slower by two orders of magnitude for pyrene than for anthracene.

When the free path approaches the distance between neighboring molecules, the hopping model may be a good approximation for the energy transfer. In such dimeric crystals as pyrene and perylene, the lowest excited singlet state is an excited dimer state.[21] Since the electronic interaction between an excited dimer and a ground state dimer is weak,[22] the hopping model may be applicable to this case. Hence, the transfer of the dimer exciton will be assisted by the thermal activation through the lattice phonon.

We measured the temperature dependence of γ; the results are shown in Figs. 4 and 5, which give the plots of log γ *versus* $1/T$ for the pyrene and perylene crystals, respectively. From the slopes of the straight lines, we determined the apparent activation energies to be 330 and 290 cm^{-1} for the pyrene and perylene crystals, respectively.

These results are consistent with the recent studies by Klöpffer and Bauser.[4] They measured the fluorescence

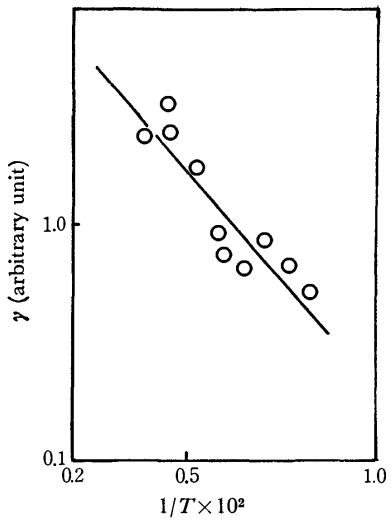

Fig. 4. A plot of log γ *versus* $1/T$ of pyrene multicrystalline sample.

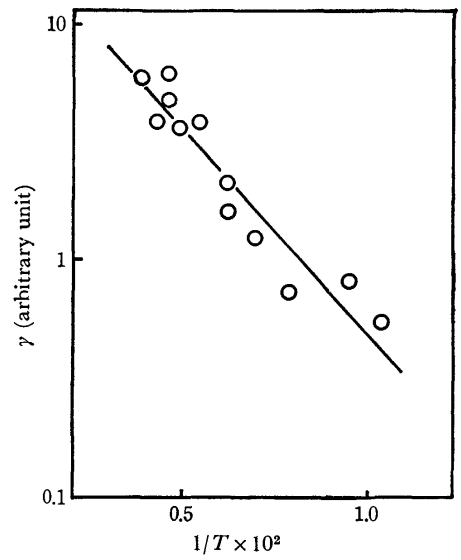

Fig. 5. A plot of log γ *versus* $1/T$ of perylene single crystal.

spectra of the mixed crystal of 10^{-3} mol/mol coronene in pyrene and observed structured coronene fluorescence spectra at 298°K, while at 77°K the only broad fluorescence spectrum of pyrene was observed. This result shows that the energy transfer in the pyrene crystal is completely frozen-in at low temperature.

The anthracene crystal takes the monomeric structure and no excited dimer is formed in the crystal. The electronic interaction between the excited singlet state and the ground state is very strong. The energy transfer is accomplished by the diffusion of monomer excitons due to the dipole-dipole and exchange interactions, and it requires no thermal activation energy. The band model may be applicable to this case. As is seen in Fig. 6, the γ value is almost independent of temperature in the range of 77—293°K. This result is also consistent with the study of energy transfer in a mixed crystal done by Geschwendtner and Wolf.[2] The fluorescence intensity of the guest tetracene molecule in the host anthracene crystal was temperature-independent between 45—80°K, indicating a small coupling of phonon for the energy-transfer process in the anthracene crystal.

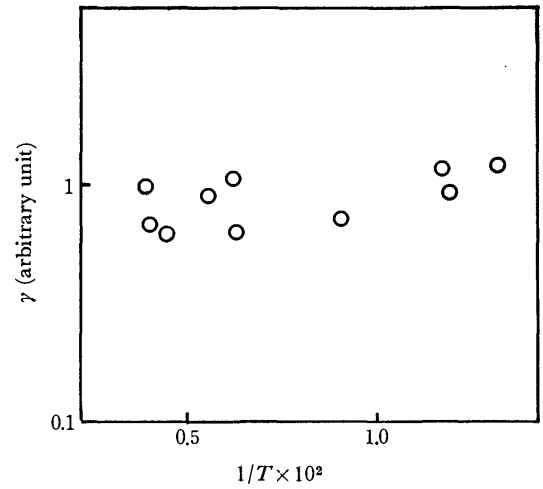

Fig. 6. A plot of log γ *versus* $1/T$ of anthracene single crystal.

The present study of the exciton interaction based on the exciton-transfer process gives the results consistent with those obtained by previous studies using guest molecules in host crystals. In our opinion, however, the present method may be superior to the host-guest systems since it deals with pure crystals. This avoids specific host-guest interactions, the reflection of the excitons by guest molecules, and the reabsorption of the host fluorescence by guest molecules.[5] It is also in favor of the present method that there is no difficulty in choosing the proper guest substances; therefore, we can remove the limitation that the energy-transfer experiment have been made for only a few molecular crystals.

The authors wish to express their thanks to Professor Satoru Iwashima, Meisei University, and Professor Hiroo Inokuchi, The University of Tokyo, for their kind offer of pure materials. Their thanks are also due to Mr. Takayoshi Kobayashi for his helpful discussion.

An Electron Spin Resonance Study of the Tropone Anion Radical

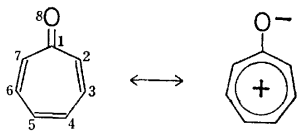
Yusaku IKEGAMI, Hidetoshi WATANABE, and Shuichi SETO

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-2-chome, Sendai

(Received December 14, 1971)

The ESR spectrum of the tropone anion radical has been examined. The radical was generated from the neutral species by the electrolytic reduction in *N,N*-dimethylformamide. Splitting constants are satisfactorily explained in terms of the calculated spin densities by the McLachlan procedure, confirming that the unpaired spin orbital belongs to an a_2 symmetrical species. The complete delocalization of the π-electrons was assumed for the anion radical.

The physico-chemical properties of tropone (I) have been studied by means of various techniques such as dipole moment,[1] vapor-phase electron diffraction,[2] ionization potential,[3] and infrared and Raman spectra.[4] Theoretical treatments of the electronic spectrum have also been discussed by some investigators.[5-6] It has been clarified from the above results and the chemical properties of troponoid compounds[7] that tropone has a planar C_{2v} symmetrical structure possessing both the unsaturated character as a conjugate ketone (Ia) and the aromatic character of a 6π-electron ring system (Ib) caused by the polarization of the carbonyl group. The magentic resonance of tropone, however, has been little studied until recently.[8] The measurement and analysis of the nuclear magnetic resonance of tropone were reported in detail by Bertelli *et al.*,[9] proposing a reevaluation of the question of aromatic character of tropone as well as its derivatives.



Ia Ib

The ESR study is interesting from two points of view. One is related to the stability of the radical in which an extra electron is added to a seven-membered ring. Since the instable character is known for some seven-membered aromatic radicals such as cycloheptatrienyl,[10] tropolonyl,[11] and cycloheptatriene anion,[12] the stability would be related to whether the radical has a ketyl structure as seen in the stable benzophenone radical anions. The other point is the expectation that the splitting constants, if observed, might be related to the calculated spin densities at the carbon atoms of the radical. This would be a good approach to getting the relationship between the experiments and the molecular orbital calculations.

We have measured the ESR spectrum of the tropone

anion radical.[13] Details of the study will be reported.

Results and Discussion

Generation and ESR Spectrum of Tropone Anion Radical. Treatment of tropone with lithium, sodium, or potassium metal in degassed tetrahydrofuran or 1,2-dimethoxyethane caused immediate change in color to reddish violet at temperatures above −40°C. However, no ESR signal was observed at temperatures above −75°C. On the other hand, the electrolytic reduction of tropone solution in degassed *N,N*-dimethylformamide (DMF) at room temperature gave the spectrum shown in Fig. 1. The radical was not stable so that the signal intensity decreased to one half during 15 minutes at room temperature after the current was turned off. The color of the solution changed gradually to a reddish brown during the electrolysis. The use of acetonitrile as the solvent did not favor the generation of the radical.

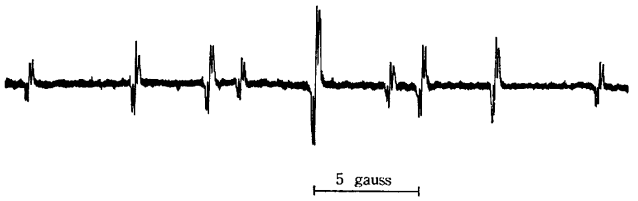

Fig. 1. ESR spectrum of tropone anion radical generated by electrolytic reduction of tropone in DMF at room temperature.

Hyperfine structure of the spectrum is readily analyzed with three splitting constants as expected for the symmetrical structure of I. Assignments for the constants are reasonably made by comparison with calculated spin densities. The observed splitting constants and the experimental spin densities calculated by the relation, $a_i^H = Q_{CH}^H \rho_i$,[14] where $|Q_{HC}^H| = 23.7$ gauss, are given in Table 1.

Table 1. Observed splitting constants (a_i) and calculated spin densities (ρ_i) for tropone anion radical

Position	a_i gauss	Spin density, ρ_i Exptl[a]	Calcd Hückel	Calcd McLachlan[b] (1)	Calcd McLachlan[b] (2)

Calculation of Spin Densities. Calculation of unpaired spin densities (ρ_i) for the anion radical was carried out by employing the Hückel MO theory and the approximate configuration interaction treatment proposed by McLachlan.[15] The bond alternation parameter k was introduced in order to represent the aromaticity of the tropone molecule. It is defined by $k = \beta_s/\beta_d$, where β denotes the resonance integral parameter, and the subscripts s and d the single and double bond in Ia, respectively. $k = 1$ means complete delocalization and $k = 0$ complete localization of π-electrons. The Coulomb and resonance integral parameters for the carbonyl group were chosen.

It was shown from the calculations that, if $k = 1$, the calculated spin densities by the Hückel MO theory are independent of the Coulomb and resonance integral parameters for the carbonyl group, because the unpaired spin orbital for the radical belongs to an a_2 symmetrical species of C_{2v} symmetrical structure. The effects of the carbonyl parameters appear slightly at second hand in the McLachlan spin densities. Two calculations using different parameters for the carbonyl group are included in Table 1 togehter with the Hückel spin densities. The McLachlan procedure showed better values than by Hückel MO calculation.

Dependence of the orbital energies of tropone on k-parameter is shown in Figs. 2a and 3a for the cases of two different Coulomb integral parameters. It is assumed that $\beta_{C=O} = \beta_{C=C}$. These figures disclose that the reduction of k-parameter replaces the unpaired spin orbital by the b_2 symmetrical one. The replacement of the orbitals is unavoidable unless one adopts the unusually small parameter α_8 for the carbonyl oxygen. The spin density at the carbonyl group in the b_2 orbital is so large that the total extent of the ESR spectrum can not be rationalized. It is thus concluded that the k-parameter must be close to 1, which means the complete delocalization of π-electrons in the tropone anion radical.

Total Binding Energy. The above conclusion for the anion radical is inconsistent with the considerations

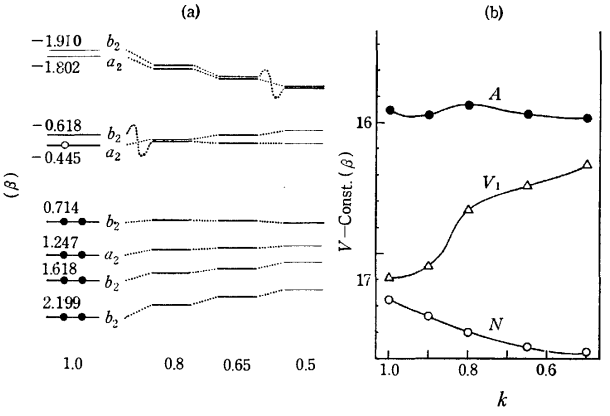

Fig. 2. Dependence of the Hückel molecular orbitals and total binding energy (V) on the bond alternation parameter k. $\beta_{1,8} = 1\beta$, $\alpha_8 = \alpha + 1\beta$.
(a): Orbital energy. (b): V-k Curves for tropone (N), the lowest excited state (V_1), and tropone anion radical (A). All the energies are in terms of β.

15) A. D. McLachlan, *Mol. Phys.*, **3**, 233 (1960).

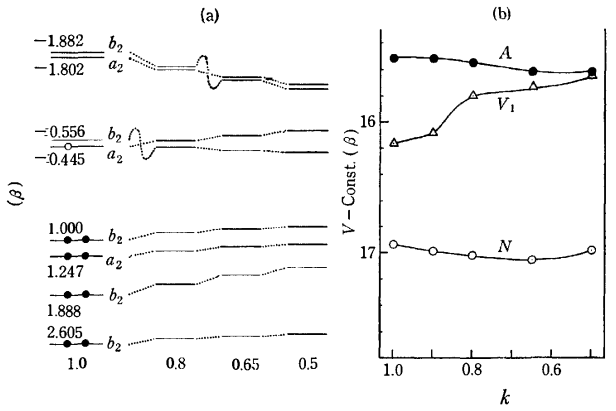

Fig. 3. Dependence of the Hückel molecular orbitals and total binding energy on the bond alternation parameter. $\beta_{1,8}=1\beta$, $\alpha_8=\alpha+2\beta$. Representation is the same as for Fig. 2.

for the neutral molecule by Yamaguchi *et al.*[6] and Bertelli *et al.*[9] who emphasized the reduced delocalization of the π-electrons in tropone. It is considered that a comparison between the *V-k* curves for tropone and the anion radical might provide information on the difference in the bond alternations. The *V-k* curve depicts the dependence of the total binding energy on *k*-parameter. We thus examined the curves for both species. The total binding energies (V) were calculated by the procedure by Longuet-Higgins and Salem,[16] adapted to non-benzenoid aromatic compounds by Nakajima and Katagiri.[17] The procedure is as follows.

Bond lengths r are given by

$$r(\text{in Å}) = 1.520 - ap$$

$$a = 0.186$$

where p designates the bond orders. Resonance integral $\beta(r)$ is given as an exponential function of the form

$$\beta(r) = \beta \exp[b(1.397-r)]$$

with

$$b = 4.599\,\text{Å}^{-1}.$$

The total binding energy of the molecule is given by

$$V = E_\pi + E_\sigma = (2/ab)\sum_{i<j}\beta_{ij} + \sum_i q_i\alpha_i + \text{const}$$

with

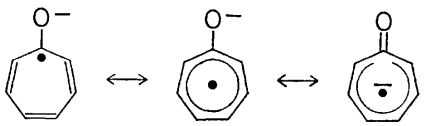
$$\alpha_i = \alpha + \omega(1-q_i)\beta$$

in which α designates the Coulomb integral parameter, q_i the electron density, and ω a proportionality coefficient here taken to be unity. β_{ij} corresponds to the $\beta(r)$ calculated for the bond between the i- and j-atoms. Calculations using the above equation afforded the *V-k* curves shown in Figs. 2b and 3b for the ground states of the neutral molecule (N) and the anion radical (A). For comparison, the curves for the lowest excited states (V_1) are included in the figures.

16) H. C. Longuet-Higgins and L. Salem, *Proc. Roy. Soc.*, (London), *Ser. A*, **251**, 172 (1959).

It is to be noticed in that the total binding energy of the anion radical is little affected by the bond alternation parameter k, while the other two states, N and V_1, show a distinct dependency like that for some non-benzenoid aromatic molecules.[17] Since the variation of the energy with *k*-parameter for the anion radical is estimated to be few kilocalories which can be covered by thermal energy at normal temperature, the calculations do not permit assumption of the stable electronical configuration for the anion radical. This implies that the electronical configuration of the radical is largely affected by the counter-ion and the supporting electrolyte.

Conclusion. It is clear that the unpaired spin orbital belongs to an a_2 species and the spin is located mainly on the seven-membered ring. Thus the structure IIc is predominant over the ketyl forms IIa and IIb for the radical. As the radical was generated at room temperature, it is more stable than the cycloheptatriene anion radical,[12] which could only be generated at low temperature and was assumed to have a nonplanar boat conformation. The considerable stability of the tropone anion radical might be attributed to the environmental factors besides the complete delocalization of π-electrons in a planar tropone structure.



IIa IIb IIc

Experimental

Tropone was carefully purified by distillation in a high vacuum. *N,N*-Dimethylformamide was degassed by at least five freezing-pumping cycles after being purified and distilled on to a Molecular Sieve 4A which had been flame-dried in a vacuum.

The technique employed in the electrolytic generation of the free radical is similar to that used by Hirayama.[18] A cell with platinum electrodes was constructed so that electrolysis could be performed within a cavity for the preparation of radical unstable at room temperature. Electrolysis was performed with a concentration less than 0.7% in DMF, using tetra-*n*-propylammonium perchlorate as a supporting electrolyte.

The ESR spectrum was measured with a Hitachi X-band ESR spectrometer Model MPU-3B using a field modulation of 100 kHz.

The authors wish to express their appreciation to Professor T. Isobe and Dr. H. Yokoi for helpful discussions.

Electronic Absorption Spectra and Geometry of Molecule Ions Generated from Stilbene and Related Compounds. I. Dianions

Hiroshi SUZUKI, Kinko KOYANO,

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

and Tosiyasu L. KUNII

Information Science Laboratory, Faculty of Science, and Computer Centre, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received December 27, 1971)

Stilbene and some of its alkyl-substituted derivatives were reduced with alkali metals to dianions in 1,2-dimethoxyethane. From comparison of the electronic absorption spectra of these dianions with one another and with the results of semiempirical SCF-MO-CI calculation of the π-electronic state, the geometries of the dianions were inferred to be as follows: (a) the preferred geometry of a sterically unhindered dianion, such as the dianion of stilbene, is probably planar or nearly planar; (b) when alkyl substituents are introduced into the central ethylenic carbon atoms, the steric interference caused by the substituents is relieved chiefly by the rotation about the central ethylenic bond; (c) the steric interference caused by *ortho* methyl substituents seems to be comparatively small or to be relieved by the rotation about the bonds connecting benzene rings to the ethylenic carbon atoms as well as the ethylenic bond. From the influence of alkali-metal cations on the spectra of the dianions, it was inferred that the dianions exist mainly as contact ion aggregates in which the counter-ions are located near the central ethylenic bond, one probably almost above an ethylenic carbon atom and the other almost below the other ethylenic carbon atom.

Aromatic hydrocarbons are reduced with alkali metals in ethereal solvents to mononegative ion radicals (anion radicals) and, further, in some cases, to dinegative ions (dianions). Geometries of these ions are probably not always similar to those of the parent molecules. The question of how the molecular geometry changes with charge state is of interest, but information on the geometry of the ions is scarce. As regards the ions generated from stilbene, a planar geometry has been proposed for the anion radical,[1] and a nonplanar geometry in which the two benzylidene moieties are rotated about the central ethylenic bond (the α—α' bond) to make an angle of about 90° has been proposed for the dianion.[2] However, direct evidence does not seem to have been given.

One of us (H. S.) studied the relation between the electronic absorption spectrum and the molecular geometry of the neutral molecules of stilbene and related compounds.[3-8] The purpose of the present study is to disclose the corresponding relation for the negative and positive ions generated from stilbene and related compounds and to answer partly the above question. We have studied the geometries and spectra of the dianions by means of semiempirical SCF–MO–CI calculation.

Experimental

A deaerated solution of *trans*-stilbene in 1,2-dimethoxyethane (DME) cooled in ice was contacted with a potassium mirror in a vacuum line system, essentially similar to the one described by Ishitani *et al.*[9] After a while, the solution turned yellowish brown, and exhibited a distinct ESR signal with fine structure; its electronic absorption spectrum has main bands at about 701 and 494 nm, as shown in Fig. 1 (1) (curve b), and closely resembles the spectrum of the anion radical produced by γ-ray irradiation of a glassy solution of *trans*-stilbene in 2-methyltetrahydrofuran (MTHF) at 77°K.[10] The yellowish brown solution is considered to contain the stilbene anion radical and the neutral stilbene as main components. After the solution had been kept cool and in contact with a potassium mirror for a sufficiently long time (about one day), the color turned a beautiful red. This red solution exhibited substantially no ESR signal. Its electronic absorption spectrum has a broad intense band with a peak at about 503 nm and no intense bands in the near ultraviolet region, as shown by curve c in Fig. 1 (1). The solution decolored when it was brought into contact with air. The electronic absorption and NMR spectra of the decolored solution were essentially the same as those of the solution of neutral *trans*-stilbene. When anthracene was dissolved into the red solution, the color of the solution changed to blue, and the solution showed electronic absorption and ESR spectra characteristic of the anthracene anion radical. It is evident that the red solution contains the stilbene dianion as the main component and does not contain the neutral molecule and anion radical of stilbene in any significant amounts.

Some alkyl-substituted derivatives of stilbene were reduced by procedures similar to the one described above. The electronic absorption spectra of stilbene and its derivatives in various reduction stages, measured by the use of cells of path length 10 mm at room temperature, are shown in Figs. 1 (1)—(8). In each figure, curve a is the spectrum of the neutral molecule (S) in *n*-heptane, curve b that of a DME

10) The spectra of the anion radicals produced by γ-ray irradiation were measured by Dr. Tadamasa Shida of the Institute of Physical and Chemical Research, Yamato-machi, Saitama, to whom the authors are greatly indebted.

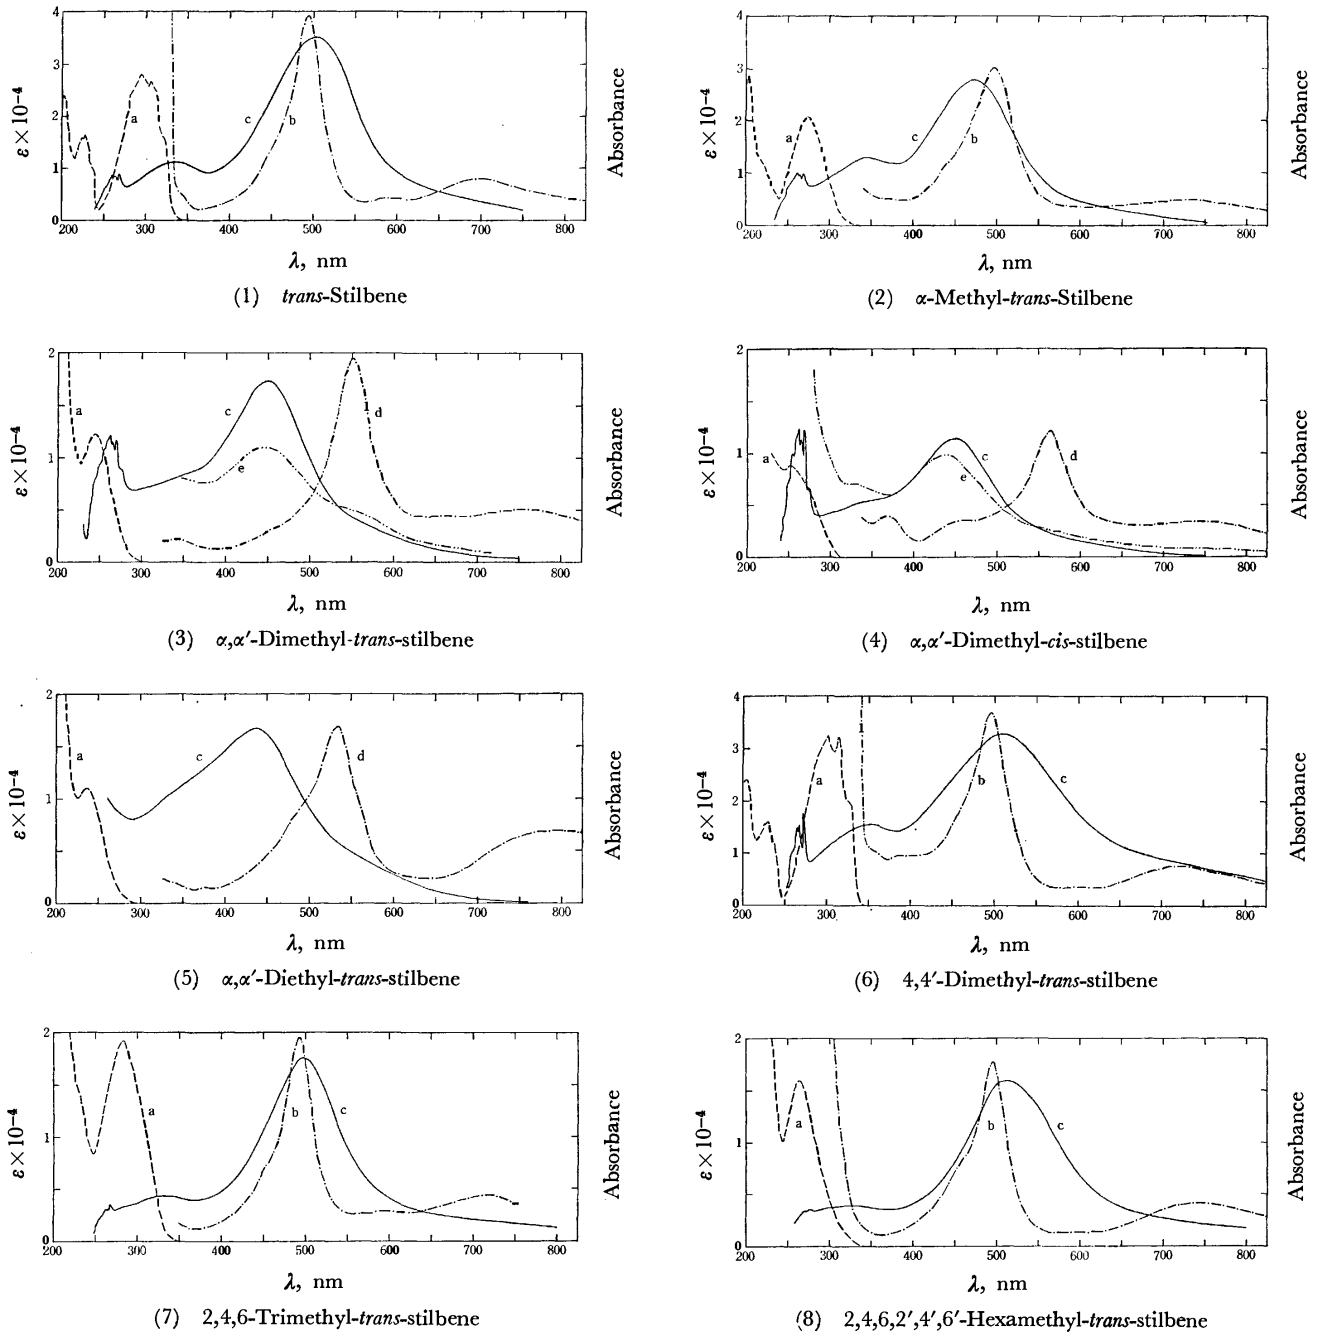

Fig. 1. Electronic absorption spectra of stilbenes (S) and their anion radicals (S^-) and dianions (S^{2-}). Curve a is the spectrum of S dissolved in *n*-heptane. Curve c is the spectrum of a DME solution in which S has been reduced with K to S^{2-}. For explanation of other cruves, see text. For curve a the intensity is represented with the molar absorptivity (ε); for other curves it is represented with the absorbance on arbitrary scale.

solution which is considered to contain the anion radical (S^-) and the neutral parent compound S as main solutes, and curve c that of a DME solution containing the dianion (S^{2-}) as the most important solute and not S^- and S in any significant amounts. Intensity is represented by the molar absorptivity for curve a, and by absorbance in a different arbitrary scale for all other curves. Each spectrum represented by curve b closely resembles that of the anion radical produced by γ-ray irradiation,[10] except that the former is slightly broader. The wavelengths of the main absorption maxima (λ_{max}) and some relevant data are given in Table 1.

In the case of α,α'-dialkylstilbenes the spectra of the anion radicals could not be obtained by means of alkali-metal reduction. In Figs. 1 (3)—(5), the spectra of the anion radicals produced by γ-ray irradiation[10] are shown by curve d, and those of DME solutions in which reduction with potassium has not sufficiently occurred exhibiting weak and broad ESR signals by curve e. These spectra indicate that each solution corresponding to curve e contains the neutral molecule of the stilbene derivative in a large amount, the dianion in a fair amount and the anion radical in a very small amount. This means that the equilibrium constant (K_{disp}) of the disproportionation

$$2S^- \rightleftarrows S + S^{2-}$$

is much greater for these derivatives than for *trans*-stilbene and other derivatives. It has been found that even the K_{disp} value for α-methylstilbene is greater than that for stilbene.[2] It is noteworthy that the spectra of the dianions generated from *trans*- and *cis*-α,α′-dimethylstilbene are essentially the same as each other, while the spectra of the anion radicals produced from these isomers by γ-ray irradiation distinctly differ from each other.

Reductions with sodium and with cesium were also carried out for most of the compounds. As a whole, the spectra of the dianions produced by the use of these alkali metals are closely similar to those obtained by the use of potassium, except for comparatively small differences in the position of the absorption maximum.

In contrast to the α,α′-dialkyl derivatives, it was difficult to reduce the derivatives bearing methyl substituents on the benzene nuclei to dianions, but not to anion radicals. With the 4,4′-dimethyl and 2,4,6-trimethyl derivatives, when the spectra of the anion radicals were measured a broad absorption band having a peak at about 790 or 800 nm often developed and the color of the solutions changed from yellowish brown to deep blue. The species responsible for this band could not be identified; it is certain that it is neither the anion radical nor the dianion. The 2,4,6,2′,4′,6′-hexamethyl derivative was also readily reduced to the anion radical by the use of any alkali metal, but all attempts to reduce it to the dianion with sodium and with cesium were unsuccessful. The spectra of the solutions kept in contact with the alkali metal for a sufficiently long time were those of the anion radical. There were no signs of bands due to the dianion or to the neutral molecule. A spectrum considered to be due to the dianion was obtained by the use of potassium. However, it changed its shape in a comparatively short time. It is therefore questionable whether the spectrum shown as curve c in Fig. 1 (8) can be regarded as that of the pure dianion. The corresponding λ_{max} value in Table 1 is also questionable. With these nuclear-methylated derivatives the values of K_{disp} appear to be very small. According to qualitative observations, the value for 4,4′-dimethylstilbene appears to become larger to some extent as the temperature is lowered. This tendency, if true, is quite the opposite of that reported for reduction of tetraphenylethylene with sodium in tetrahydrofuran.[11-16]

MO Calculation

It is assumed that all the tervalent carbon atoms in the dianions have sp^2 hybrid orbitals and the π-electron approximation is applicable. This seems to be reasonable, although the possibility of rehybridization should be taken into consideration in the case of smaller systems such as ethylene,[17] and in cases where the reductant is, for example, lithium and where on association of the dianion with the alkali-metal cations the ethylenic carbon atoms might be linked to the alkali-metal atoms with bonds having partially covalent character. Semiempirical SCF–MO–CI calculation of the π-electronic states of the dianions was carried out on many geometrical models designed to represent rotations about the central CC "double" bond (the α—α′ bond) and the two CC "single" bonds (the α—1 and the α′—1′ bond). The carbon skeleton of the stilbene π-system is illustrated in Fig. 2, together with the numbering of the carbon atoms and the coordinate system.

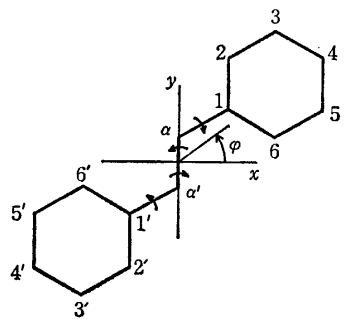

Fig. 2. The skeleton of the stilbene π-system. The planar *trans* form, that is, geometry (0,0,0), is shown.

The length of CC bond p—q is denoted by R_{pq} (Å), and the angle of twist of this bond, *viz.*, the dihedral angle between the σ-skeleton planes of carbon atoms p and q, is denoted by θ_{pq}. The value of $\theta_{aa'}$ is taken to be 0° for the *trans* form, and 180° for the *cis* form. For the sake of convenience, essentially the same assumptions as those made for the treatment of neutral stilbenes are made on the geometry.[3,4,8] Thus, the following relations are assumed:[18]

$$R_{a1} = 1.517 - 0.067 \times |\cos\theta_{a1}|$$
$$R_{a'1'} = 1.517 - 0.067 \times |\cos\theta_{a'1'}|$$
$$R_{aa'} = 1.517 - 0.177 \times |\cos\theta_{aa'}|$$

All bond angles are assumed to be 120°, and all CC bond lengths in the benzene rings 1.397 Å. Thus the geometry of the π-system can be described as a function

of angles of twist θ_{a1}, $\theta_{a'1'}$, and $\theta_{aa'}$. Hereafter geometries are represented as $(\theta_{a1}, \theta_{a'1'}, \theta_{aa'})$. As an example, geometry (0,0,0) represents the geometry in which $\theta_{a1}=\theta_{a'1'}=\theta_{aa'}=0°$. The calculations were carried out for geometries in which $\theta_{a1}=\theta_{a'1'}$ and which belong to symmetry group C_2, with the exception of geometries (0,0,0) and (0,0,180), which belong to symmetry groups C_{2h} and C_{2v}, respectively.[19]

Calculation was carried out by means of the Pariser-Parr-Pople method, using an HITAC 5020E at the computer Centre, the University of Tokyo. The parameter values were taken as proposed by Nishimoto and Forster.[20] Thus, for all the carbon π-centers, the values of the one-center core integral (α_p) and one-center repulsion integral (γ_{pp}) were taken to be -11.16 and 11.13 eV, respectively. The two-center core integral (β_{pq}) was taken to be zero for nonneighboring π-centers, and was estimated for neighboring π-centers by the use of a modification of the Nishimoto-Forster equation,[20]

$$\beta_{pq}(\text{in eV}) = -(2.04+0.51P_{pq})\times|\cos\theta_{pq}|,$$

where P_{pq} represents the π-bond order of the p—q bond calculated from the starting set of MO's. The two-center repulsion integral (γ_{pq}) was estimated by the use of the following Nishimoto-Mataga type equation[21] for all the pairs of π-centers:

$$\gamma_{pq}(\text{in eV}) = 14.397/(1.294+R_{pq})$$

Satisfactory self-consistency was attained after 10 iterations in SCF–MO calculation. In the iterations the geometry and all the values of β_{pq} and γ_{pq} were kept fixed, and no interaction between the π-electron distribution and the σ-electron distribution was taken into consideration.

The values of the resonance integral (β^0_{pq}) for neighboring π-centers were determined by the use of the equation

$$\beta^0_{pq} = k_{pq}\beta^0,$$

where

$$k_{pq} = [S(R_{pq}, 0°)/S(1.397\text{Å}, 0°)]\times|\cos\theta_{pq}|.$$

$S(R,0°)$ represents the π–π overlap integral for a CC bond whose length is R and whose angle of twist is 0°. For the values of S the values calculated by Mulliken and others[22] for Slater atomic orbitals were used.

19) Calculation was also carried out for geometries (a, $-a$, 0) and (a, $-a$, 180), which belong to symmetry groups S_2 and C_s, respectively. The calculated values of energies and oscillator strengths of electronic transitions and of the ground-state energy of the π-electronic system coincide almost completely with those for the corresponding C_2 geometries, (a, a, 0) and (a, a, 180). The S_2 geometries (a, $-a$, 0) seem to be almost as probable as the corresponding C_2 geometries (a, a, 0). The C_s geometries (a, $-a$, 180), however, seem to be much less probable than the corresponding C_2 geometries (a, a, 180), since the steric repulsion between the two phenyl groups must be much stronger in the former than in the latter. Geometries (a, $-a$, b) with b different from 0 and 180 have no symmetry elements. The probability of these geometries also seems to be small.

a) Coefficient with which the electron configuration appears in the state function.

b) Electron configuration that makes the most important contribution to the state. (i—j) denotes the singlet electron configuration arising from the ground configuration by promotion of an electron from π orbital ψ_i to ψ_j. The orbital index i takes the increasing integer from 1 for the lowest orbital to 14 for the highest orbital in the order of increasing energy.

c) Energy of the excited state relative to the ground state (S_0) in eV.

d) Oscillator strength of the transition from the ground state to the excited state.

e) Direction of the transition moment: φ represents the angle that the transition moment makes with the x axis in the xy plane (see Fig. 2).

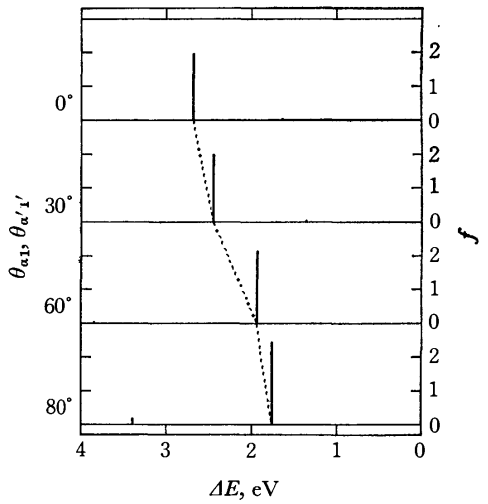

Fig. 3. The calculated energies (ΔE) and oscillator strengths (f) of transitions from the ground state to singlet excited states in the stilbene dianion for various values of θ_{a1} and $\theta_{a'1'}$ when $\theta_{aa'}$ is fixed at 0°.

In the CI calculation 30 singlet and 30 triplet lowest-energy singly excited electron configurations were taken into account.

Some results of the calculation are shown in Table 2 and Figs. 3 and 4. In Table 2 are listed the energies and some other data of the lowest singlet excited states of the dianion of geometry (0,0,0). Figures 3 and 4 illustrate the variations in the energies (ΔE) and oscillator strengths (f) of the transitions from the ground state to the lowest singlet excited states associated with the variations in geometry.

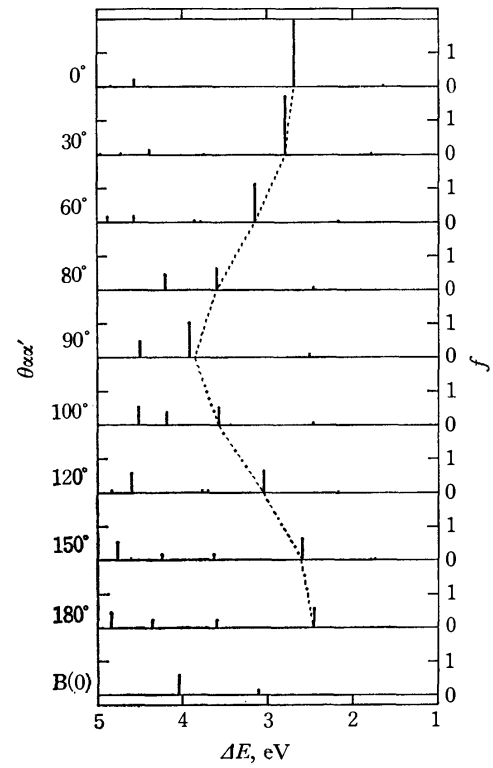

Fig. 4. The calculated energies (ΔE) and oscillator strengths (f) of transitions from the ground state to singlet excited states in the stilbene dianion for various values of $\theta_{\alpha\alpha'}$ when $\theta_{\alpha 1}$ and $\theta_{c'1'}$ are fixed at 0°. For comparison, the corresponding quantities in the benzyl anion of a planar geometry are also shown, being indicated by B(0). In every case there is no singlet excited state having energy lower than 1 eV.

Discussion

Band A. As shown in Fig. 1 and Table 1, each dianion has an intense absorption band with its maximum in the region of about 420—520 nm (according to Zabolotny and Garst,[23] for the dianion generated from *trans*-stilbene, $\lambda_{max}=504$ nm, and $\varepsilon_{max}=ca.\ 3.8\times10^4$). Hereafter, attention is focused on this band, which is referred to as band *A*. It should be noted that in every case this band is structureless and very wide.

Besides this band, most of the "dianion spectra" (curve c, Fig. 1) show a very broad band in the region of 330—350 nm and a comparatively weak band with fine structure in the region of 260—270 nm. It is somewhat questionable whether all these weak absorptions are due to the dianions.

Regarding the position of band *A*, the following facts should be noted: (1) band *A* of the 4,4'-dimethylstilbene dianion is at slightly longer wavelength than that of the stilbene dianion; (2) the position of band *A* of the 2,4,6-trimethyl- and 2,4,6,2',4',6'-hexamethylstilbene dianions does not differ much from that of the stilbene dianion, in spite of the presence of a number of methyl substituents; (3) band *A* shifts progressively to shorter wavelengths as alkyl substituents are introduced to the α and α' positions, in the order stilbene, α-methylstilbene, α,α'-dimethylstilbene, and α,α'-diethylstilbene.

Band *A* can undoubtedly be attributed to the transition from the ground state (S_0) to the singlet excited state to which the singlet electron configuration arising from one-electron transition from the 8th orbital (the highest occupied orbital) to the 11th orbital, (8—11), makes the most important contribution (see Table 2). In geometries (0,0,0) and (0,0,180), this excited state is the 3rd singlet excited state S_3 belonging to symmetry species B_u and B_2, respectively. In other geometries of symmetry C_2 this state belongs to symmetry species B. Hereafter, this state is called the *A* state, and the transition from the ground state to this state is called the *A* transition.

There seem to be at least three factors influencing the position of band *A*: (1) the geometry of the dianion, (2) the electronic effect of alkyl substituents, and (3) the effect of the counter-ion. The purpose of the present paper is to infer the geometry of the dianions from the position of their *A* bands, but before proceeding to such a discussion, it seems necessary to examine other factors.

The Electronic Effect of Alkyl Substituents. Band *A* of the 4,4'-dimethylstilbene dianion is at longer wavelength than that of the stilbene dianion by about 6 nm. If additivity is assumed, the bathochromic shift due to one methyl substituent at the *para* position is about 120 cm^{-1}.

The electronic effect of a methyl substituent on the energy of a π-electronic transition is usually ascribed to the inductive and the hyperconjugative effect, and can be approximately treated by perturbation theory.[24] Roughly speaking, the change in wavenumber at the absorption maximum caused by introduction of one methyl substituent $\Delta\nu$ depends on the change in the π-electron density at the substitution position (p) upon the electronic transition ΔP_{pp} in the following way. When the value of ΔP_{pp} is negative, the value of $\Delta\nu$ is also negative (the shift is bathochromic); the larger the absolute value of ΔP_{pp}, the larger the absolute value of $\Delta\nu$; when the value of ΔP_{pp} is zero, or positive (if small amount) the value of $\Delta\nu$ can be negative owing to the hyperconjugative effect; when the value of ΔP_{pp} is positive and very large, the value of $\Delta\nu$ can be positive (the shift can be hypsochromic).

Table 3. The calculated π-electron densities in the ground and *A* states of the stilbene dianion of geometry (0,0,0)

Position (p)	$P_{pp(G)}$	$P_{pp(A)}$	$\Delta P_{pp(GA)}$

24) See, for example, H. Suzuki, the book cited in Ref. 8, pp. 408—410; A. Streitwieser, Jr., "Molecular Orbital Theory for Organic Chemists," John Wiley & Sons, Inc., New York, N.Y. (1961), pp. 131—134.

In Table 3 are shown the values of the π-electron densities (P_{pp}) in the ground and A states, together with the values of the π-electron density changes (ΔP_{pp}) associated with the A transition, calculated for geometry (0,0,0). It should be noted that the value of ΔP_{pp} is negative at the α and *ortho* positions and positive at the *para* positions. Essentially the same tendency is found in other geometries such as (0,0,30) and (30,30,0). Since the electronic effect of a methyl substituent on band A is bathochromic even at the *para* position, it must be bathochromic to much greater extent at the α and *ortho* positions. Accordingly, if it were not for the electronic effect of the methyl (or ethyl) substituents, the hypsochromic shift of band A associated with progressive introduction of alkyl substituents into the α and α' positions should be greater than observed. Even in the series of stilbene, 2,4,6-trimethyl-, and 2,4,6,2′,4′,6′-hexamethylstilbene, band A would shift hypsochromically, though the extent of the shift might be comparatively small, with increasing introduction of methyl substituents.

Table 4. Dependence of the position of the A band maximum on the counter-ion

trans-Stilbene	λ_{max}, nm (in DME)		
	Na^+	K^+	Cs^+
Unsubstituted	500	503	513
α,α′-Dimethyl-	436	450	457.5
α,α′-Diethyl-	427	437	440

Effect of the Counter-ion. The spectra of the dianion generated from the same compound by reduction with different alkali metals are similar to one another in shape, but the position of band A differs for different alkali metals. Table 4 shows that in every case the A band maximum shifts to longer wavelengths as the alkali metal becomes larger, in the order Na, K, and Cs.

If the dianions existed as unassociated ions or as so-called solvent-separated ion aggregates, the spectra would be substantially independent of the kind of the counter-ion.[25,26] The fact that the position of the absorption maximum varies depending on the kind of the alkali metal indicates that the dianions S^{2-} exist at least for a great part as contact ion aggregates (S^{2-}, $2M^+$) (called triple ions or diassociates), being associated with the alkali-metal ions M^+, although DME, the solvent used, is said to be a powerful solvating agent for alkali-metal ions and hence a very suitable solvent for making solvent-separated ion aggregates[25,26] or unassociated ions.[27]

In addition to the contact diassociates, possibly some other species, such as solvent-separated diassociates, contact and solvent-separated monoassociates (S^{2-},M^+), and unassociated dianions, may exist, though probably in much smaller amounts. The contact ion aggregates may assume various geometries around the equilibrium geometry. These might be responsible at least partly for the broadness of band A.

The fact that the band shifts to longer wavelengths with increasing size of the counter-ion suggests that band A of the unassociated dianion is located at a still longer wavelength than that of the same dianion associated with cesium ions. As is seen in Table 4, for every alkali metal the band shifts to shorter wavelengths with increasing alkyl substitution, in the order stilbene, α,α′-dimethyl-, and α,α′-diethylstilbene. It is plausible that the order will also be maintained in the spectra of the unassociated dianions.

Geometry of the Dianions. It might be said that, if it were not for the electronic effect of alkyl substituents and the effect of the counter-ions, band A would behave as follows: (1) it shifts comparatively rapidly to shorter wavelengths as the α and α' positions are increasingly substituted with alkyl groups; (2) it shifts comparatively slowly to shorter wavelengths as the *ortho* positions are increasingly substituted with methyl groups. These behaviors should be related to the geometry of the dianions.

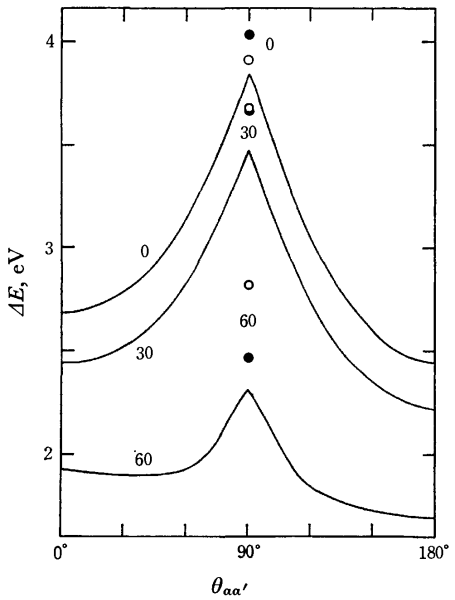

Fig. 5. The relationship of the calculated energy of the A transition of the stilbene dianion (ΔE) to angles of twist $\theta_{\alpha 1}$, $\theta_{\alpha' 1'}$, and $\theta_{\alpha\alpha'}$. The numerals written near curves and circles indicate the values of $\theta_{\alpha 1}$ ($=\theta_{\alpha' 1'}$) in units of degree. For geometries with $\theta_{\alpha\alpha'}=90°$, the A transition being forbidden, the energies of the main allowed transition are also shown with open circles. These are to be compared with the energies of the main allowed transition of the benzyl anion of the corresponding geometries, which are shown with black spots.

As is seen in Figs. 3 and 4, the results of calculation show that the energy of the A transition decreases with increasing deviation of $\theta_{\alpha 1}$ and $\theta_{\alpha' 1'}$ from 0° and increases with increasing deviation of $\theta_{\alpha\alpha'}$ from 0° or from 180°. These tendencies can be seen more clearly in Fig. 5, in which the energy of the A transition is plotted against $\theta_{\alpha\alpha'}$ for various values of $\theta_{\alpha 1}$ and $\theta_{\alpha' 1'}$. The π-electronic state of the stilbene dianion having a geometry in which $\theta_{\alpha\alpha'}=90°$ is considered to resemble that of two mutually independent benzyl anions. For the sake of comparison,

Table 5. The main absorption band maximum of the benzyl anion in tetrahydrofuran

Counter-ion	λ_{max}, nm	ε_{max}	Ref.
Li^+	330	9.6×10^3	23)
Na^+	354.6	1.2×10^4	22)
Na^+	350	3.5×10^3	24)
Cs^+	356	—	24)

results of a similar calculation for the benzyl anion are also given in Figs. 4 and 5.

The benzyl anion has been reported to have its first intense absorption band at about 350 nm,[28-30] as shown in Table 5. This position is of much shorter wavelength than that of band *A* of the stilbene dianion. The stilbene dianion is iso-π-electronic with hydrazobenzene, and the benzyl anion with aniline. The spectral resemblance of hydrazobenzene and aniline suggests that the most preferred geometry of hydrazobenzene is probably a nonplanar conformation in which the central NN bond is twisted.[31] The situation is quite different in the case of the stilbene dianion and the benzyl anion.

We thus conclude as follows. The most preferred geometry of a sterically unhindered dianion such as the dianions of stilbene and 4,4′-dimethylstilbene is probably planar or nearly planar. It is probably the *trans* form, in view of the result of calculation of the total energy.

When alkyl substituents are introduced into the α and α' positions, the steric interference caused by the substitution are probably relieved chiefly by partial rotation about the α—α' bond. From examination of the electronic absorption spectra of α-methyl- and *cis*-β-methylstyrene and *cis*- and *trans*-α-methylstilbene it has been concluded that a phenyl group in such a system sterically interacts more strongly with a methyl group at the *cis*-β position than with a methyl group at the α position.[32,33] This leads to the inference that in the planar *trans* form of the α,α'-dimethylstilbene dianion the steric interference of the α-phenyl group with the α'-methyl group is probably stronger than that with the α-methyl group. The former can be relieved by comparatively small rotation about the α—α' bond. This means that major part of the steric interference in the dianion can be relieved by rotation about the α—α' bond. The rotation about the α—α' bond is, of course, not the only possible mode of geometry change relieving the steric interference. Rotation about the α—1 and the α'—1′ bonds and some other modes of geometry change probably take place to smaller extents. The possibility also cannot entirely be excluded that a small change in hybridization of the valence orbitals of the α and α' carbon atoms, resulting in a small deviation of the geometry about these atoms from planarity, may contribute to the relief of the steric interference.

The fact that the dianion spectra of *cis*- and *trans*-α,α'-dimethylstilbene are essentially the same indicates that the same dianion, probably of a *trans*-like geometry, is produced from either isomer.

The steric effect of introduction of methyl groups into the *ortho* positions is apparently smaller than that of introduction of methyl groups into the α and α' positions. This is rather surprising, in view of the fact that in the case of neutral molecules the steric effect of the *ortho* substitution is almost comparable to that of the α and α' substitution.[6] This is considered to indicate one of the following two possible causes: (1) in the dianions the steric interference caused by the *ortho* substitution is much smaller than that caused by the α and α' substitution; (2) the former cannot be relieved by rotation about the α—α' bond as effectively as the latter, and can be relieved more effectively by rotation about the α—1 and α'—1′ bonds; consequently, the values of $\theta_{\alpha 1}$ and $\theta_{\alpha' 1'}$ in the 2,4,6,2′,4′,6′-hexamethylstilbene dianion, for example, are larger than those in the α,α'-dimethylstilbene dianion and the value of $\theta_{\alpha\alpha'}$ in the former is smaller than that in the latter. The second possibility seems to be more plausible.

In the dianion the increase in the total energy associated with deviation of $\theta_{\alpha 1}$ and $\theta_{\alpha' 1'}$ from 0° is considered to be much larger than that associated with deviation of the same extent of $\theta_{\alpha\alpha'}$ from 0°. The fact that the formation of the dianion is difficult with the nuclear-substituted stilbenes but easy with the α,α'-substituted stilbenes may have some connection with the possible difference in the extent of the steric interference involved or that in the manner in which the steric interference is relieved, in addition to the possible difference in the magnitude of the electron-donating effect of the substituents at different positions. The relative difficulty of the dianion formation is due to many factors, such as the energy of formation of the aggregates of the dianion and anion radical with the counter-ion and of external and internal solvation of the ion aggregates, besides that of formation of the unassociated dianion from the unassociated anion radical, and deserves further investigation.

Total Energy and π-Bond Order. The phenomenon that the main absorption band shifts to shorter wavelengths with increasing steric interference is very similar to that observed with the neutral molecules of stilbenes.[3-8] However, while in the neutral molecules the steric interference is relieved chiefly by rotation about the α—1 and α'—1′ "single" bonds, in the corresponding dianions it is inferred as above to be relieved chiefly by rotation about the α—α' "double" bond. The difference is understandable in terms of calculated values of the total energy as well as the π-bond order.

Table 6. The calculated total energies of the stilbene molecule and dianion of various geometries in the ground state

α—1; α'—1′	0.3413	0.7109	0.3825	0.4867	0.5908

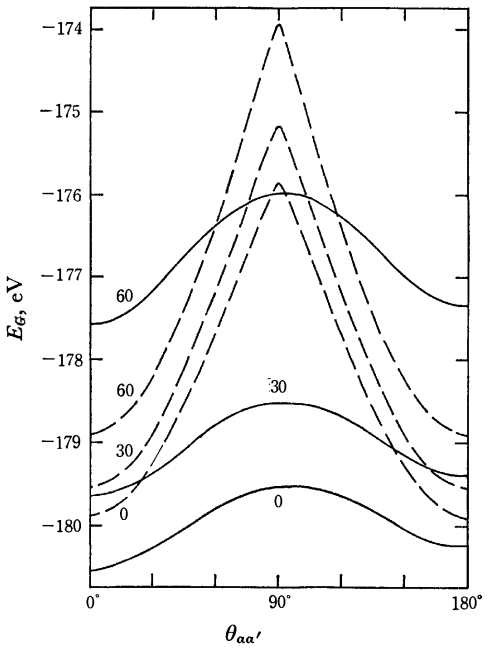

Fig. 6. The relationship of the calculated total energies (E_G) of the stilbene molecule (— — —) and dianion (———) in the ground state to angles of twist $\theta_{\alpha 1}$, $\theta_{\alpha' 1'}$, and $\theta_{\alpha\alpha'}$. The numerals written near curves indicate the values of $\theta_{\alpha 1}$ ($=\theta_{\alpha' 1'}$) in terms of degree.

In Fig. 6 and Table 6 are shown results of the SCF calculation of the total energy of the ground state, as the sum of the π-electron energy and the energy of core-core interaction, for the stilbene dianion and molecule of various geometries. In the calculation the energy of core-core interaction was assumed to be given by

$$\sum_p \sum_{q \neq p} \gamma_{pq},$$

where γ_{pq} is the two-center repulsion integral for the $2p\pi$ atomic orbitals centered at carbon atoms p and q.

From the results, both for the dianion and the molecule, geometries (0,0,0) and (0,0,180) correspond to the energy minima. In addition, the results show that in the case of the dianion the α—α' bond is twisted with a smaller energy increase than the α—1 and α'—1′ bonds, while in the case of the molecule the reverse is true. These tendencies agree with those expected from correlation diagrams[34] connecting the HMO levels of the planar stilbene π-system with those of two non-interacting benzyl groups and those of non-interacting two benzene rings and one ethylenic bond.

In Table 7 are shown the π-bond orders calculated for geometry (0,0,0). In the dianion the π-bond order of the α—α' bond is smaller than that of the α—1 as well as the α'—1′ bond, while in the molecule the reverse is true. The π-bond orders of bonds of the anion radical (as well as the cation radical) must be intermediate between those of the corresponding bonds of the molecule and the dianion (as well as the dication). Therefore, it is of interest to examine how steric interferences affect the geometry and the spectrum in the case of these ion radicals.

It is noteworthy that in the case of the dianion the calculated ground-state energy of geometry (0,0,0) is lower by as much as about 0.3 eV than that of geometry (0,0,180), while in the case of the molecule the energy of geometry (0,0,0) is slightly higher than that of geometry (0,0,180). Even in the case of the molecule, *trans*-stilbene is more stable than its *cis* isomer by about 3[35,36] or 6[37] kcal/mol. In the *cis*-stilbene molecule the two phenyl groups cannot be simultaneously coplanar with the central ethylenic bond plane, owing to steric interference, and the most preferred geometry of this molecule is considered to be close to geometry (30,30,180).[3,4,8,38] According to the results of calculation, the energy of this geometry is higher by about 0.3 eV than that of geometry (0,0,0). Thus, it may be said that the present calculation gives quite adequate results. It seems reasonable to infer that the most preferred geometry of the dianion is the *trans* form, at least if steric interference is absent or small.

Location of the Alkali-Metal Cations in the Contact Ion Aggregates. The geometry of the contact ion aggregates (S^{2-},$2M^+$), the location of M^+'s with respect to S^{2-} in (S^{2-},$2M^+$), is examined.

Schlenk and Bergmann found that addition of carbon dioxide to products resulting from the reduction of *trans*-stilbene with alkali metals, followed by hydrolysis, gave α,α'-diphenylsuccinic acid, which was the racemic mixture when the alkali metal was lithium and the *meso* isomer when the alkali metal was sodium or potassium.[39] These stereochemical findings suggest that, in the reduction with lithium, two lithium atoms undergo *cis* addition to the α and α' carbon atoms of stilbene with bonds possessing covalent character to a large extent, and that in the reduction with sodium or potassium the product exists for a great part as ion aggregates (S^{2-},$2M^+$) which are in equilibrium with the unassociated ions. The thermodynamically most stable geome-

try of the ion aggregate is probably a geometry in which one of the two cations is located on one side of the dianion plane and the other on the opposite side.

The energy of interaction between the ions in the contact aggregate of the dianion in the ground state with the cations ΔE_G and the change in the energy of the A transition of the dianion caused by the ion aggregation $\Delta\Delta E_{GA}$ were tentatively calculated for various locations of the cations in the following approximate manner. In the calculation solvent effects were not considered.

It is assumed that two alkali-metal cations are located symmetrically with respect to the origin of the coordinate system assigned to the dianion (see Fig. 2). That is, if the coordinate of one of the two cations is denoted by (x_M, y_M, z_M), that of the other is assumed to be $(-x_M, -y_M, -z_M)$. The energy of interaction between the ions in the aggregate of the two cations with the dianion in the ith π-electronic state ΔE_i is given by

$$\Delta E_i = 2(E_{\text{core,M}} - E_{\pi(i),M}) + E_{MM'},$$

where $E_{\text{core,M}}$ is the energy of repulsive interaction between the cores of the dianion and one of the cations, $E_{\pi(i),M}$ is that of attractive interaction between the π-electronic cloud of the dianion and one of the cations, and $E_{MM'}$ is that of repulsive interaction between the two cations. These quantities are assumed to be given by the following equations:[40]

$$E_{\text{core,M}} = e^2 \sum_p (1/R_{pM})$$

$$E_{\pi(i),M} = e^2 \sum_p (P_{pp(i)}/R_{pM})$$

$$E_{MM'} = e^2/R_{MM'},$$

where e is the quantum of electricity, R_{pM} the distance between the pth carbon π-center of the dianion and one of the cations, $P_{pp(i)}$ the π-electron density at the pth carbon π-center of the dianion in the ith π-electronic state, $R_{MM'}$ the distance between the two cations, and the summations are carried out over all the π-centers. The change in the energy of transition from the ith to the jth π-electronic state associated with the aggregation $\Delta\Delta E_{ij}$ is given by

$$\Delta\Delta E_{ij} = 2(E_{\pi(i),M} - E_{\pi(j),M}).$$

The calculation was carried out for the dianion of geometry (0,0,0), by the use of the values of π-electron densities $P_{pp(G)}$ and $P_{pp(A)}$ shown in Table 3. After Hush and Rowlands,[41] the perpendicular distance of a cation from the plane of the dianion z_M was assumed to be given by

$$z_M = r_{M^+} + 2.5(\text{Å}),$$

where r_{M^+}, the Goldschmidt ionic radius of the alkali-metal cation, was taken to be 0.97, 1.33, and 1.70 Å for Na^+, K^+, and Cs^+, respectively. The results of the calculation for various locations of the cations are shown in Fig. 7.

The A band maximum shifts to shorter wavelengths as the alkali metal is changed from Cs to K, and further to Na. From comparison of this fact with the result of the calculation of $\Delta\Delta E_{GA}$ shown in Fig. 7(2) and inspection of the result of the calculation of ΔE_G shown in Fig. 7(1), the possibility of geometries in which the alkali-metal cations are located near the benzene rings is excluded. It is inferred that the cations are located near the ethylenic bond. The results show that geometries a and b have large and nearly equal probabilities.

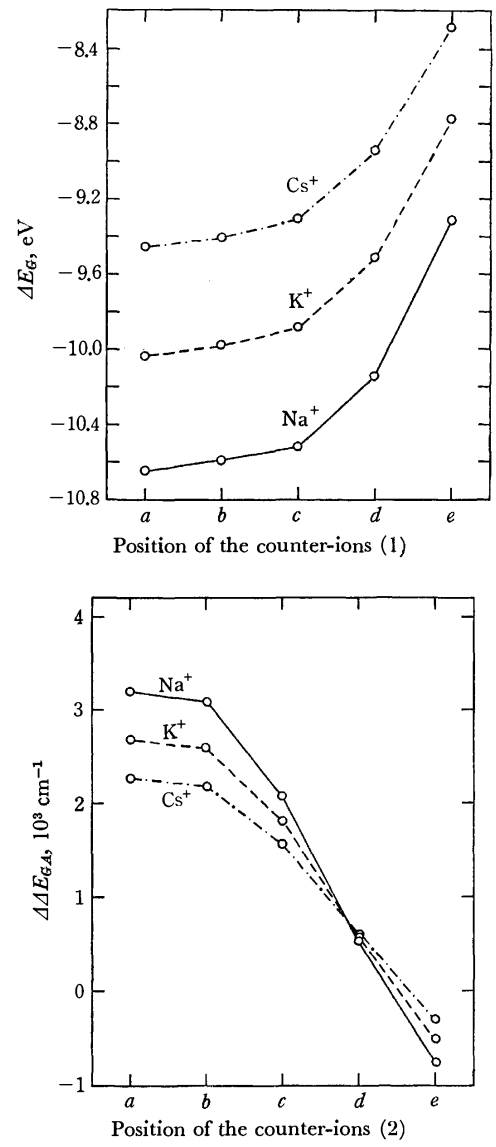

Fig. 7. The relationship of (1) ΔE_G and (2) $\Delta\Delta E_{GA}$ of the stilbene dianion of geometry (0,0,0) to the location of the counter-ions. The positions of the counter-ions are represented by the projection of one of them on the plane of the dianion as follows: (*a*) the center of the α-α' bond; (*b*) the position of carbon atom α; (*c*) the position of carbon atom 1; (*d*) the center of a benzene ring; (*e*) the position of carbon atom 4. The perpendicular distances of the counter-ions from the dianion plane are taken as described in text.

In addition to the electrostatic interaction between the ions, charge transfer from the dianion to the alkali-metal cations seems to make a minor contribution to the stability of the ion aggregate. The most important component of the charge-transfer interaction is probably the interaction between the highest occupied orbital (the 8th π orbital) of the dianion and the lowest vacant orbital (an s orbital) of each cation. Since the former

40) For justification of adopting the point-charge approximation, see Ref. 41.

41) N. S. Hush and J. R. Rowlands, *Mol. Phys.*, **6**, 201 (1963).

has a nodal plane bisecting the α—α′ bond perpendicularly and the latter is centrosymmetric, if the cations were located near the center of the α—α′ bond (geometry *a*), the charge-transfer interaction would make substantially no contribution to the stability. It is therefore concluded that the most preferred or equilibrium geometry of the ion aggregate is probably close to geometry *b*, that is, the geometry in which one of the cations is located above carbon atom α and the other below carbon atom α′.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1988—1992(1972)

The Effect of the Wavelength of an Exciting Light on Four-center-type Photopolymerization in the Crystalline State

Takashi TAMAKI, Yasuzo SUZUKI, and Masaki HASEGAWA
Research Institute for Polymers and Textiles, Kanagawa-ku, Yokohama
(Received March 12, 1971)

The effect of the wavelength of an exciting light on four-center-type photopolymerization in the crystalline state has been investigated. 2,5-Distyrylpyrazine (DSP), 1,4-bis[β-pyridyl-(2)vinyl]benzene (P2VB), *p*-phenylenediacrylic acid (*p*-PDA) dimethyl ester were converted quantitatively into highly crystalline oligomers (pentamers on the average) on irradiation at the long-wavelength edge of the absorption of the monomer. On subsequent exposure to the light which is absorbed by each oligomer, the oligomer crystals *as*-polymerized were converted quantitatively into high polymer crystals. The polymer thus obtained was found to be identical with the polymer produced by the light of a xenon or a high-pressure mercury lamp. The quantum yields for the oligomerization and polymerization reactions of DSP and the *p*-PDA dimethyl ester were found to be between 1 and 2 on the basis of the number of olefinic double bonds consumed to form the cyclobutane ring. These results confirmed that the four-center-type photopolymerization in the crystalline state consists of two kinds of separable, step-by-step addition mechanisms: an oligomerization of the diolefinic compound and a growth reaction of the terminal group in the growing chain. From the crystallographic information on the DSP oligomer, the oligomerization as well as the polymerization process of DSP were concluded to proceed by a monomer lattice-controlled mechanism.

The method of investigating four-center-type photopolymerization in the crystalline state of diolefinic compounds, such as 2,5-distyrylpyrazine (DSP), its related compounds, *p*-phenylenediacrylic acid (*p*-PDA) derivatives, and *p*-benzene (α-cyano)diacrylic acid (*p*-BCA) derivatives, has recently been developed in this laboratory.[1-8]

Many diolefinic compounds which are photopolymerizable in the crystalline state have been synthesized.[1-4] They can be roughly classified into high and low photopolymerizable compounds according to their reaction times. For example, DSP and the *p*-PDA dimethyl ester belong to the former type, and 1,4-bis[β-pyridyl-(2) vinyl]benzene (P2VB) belongs to the latter.

A previously-reported kinetic study[5] of the photopolymerization of DSP in the crystalline state has shown that the reduced viscosity of the polymer increases with the reaction time, that it continues to rise on irradiation even after the conversion is completed, and that the molecular weight of the polymer at a low conversion is widely distributed. From these facts, it has been concluded that the polymerization follows a step-by-step mechanism.

Recently in a X-ray crystallographic study of DSP the photopolymerization of DSP in the crystalline state was concluded to be a topochemical reaction which is lattice-controlled and which is strictly governed by the spatial arrangement of monomer molecules in a crystal.

In this paper the effects of the wavelength of an irradiating light on four-center-type photopolymerization and the quantum yields are described. The mechanism of the polymerization is discussed in terms of the oligomerization process and the growth process producing a high polymer.

Experimental

Preparation of the Monomers. DSP, P2VB, and the *p*-PDA dimethyl ester were prepared and recrystallized as has been described in earlier papers.[2,3]

Optical Measurements. To examine the effect of the wavelength of an exciting light on the polymerization of each monomer in the crystalline state, UV and IR spectral changes were measured during polymerization upon irradiation with monochromatic light. For the UV measurements the monomer crystals were deposited on a quartz plate in

the form of a thin layer by slow evaporation from a concentrated solution, while for the IR measurements KBr pellets containing the monomer crystals were prepared.

The exciting light was furnished by a spectroirradiator (Jasco) composed of a 2000-W xenon lamp as the light source and a grating monochromator.

To attenuate the scattered light, the UV measurements were performed by the method of an integrating sphere attached to a spectrophotometer.

The disappearing rate of the olefinic double bonds during the oligomerization and the polymerization was followed by IR analysis. In the case of the oligomerization, KBr pellets (150 mg) containing 1.5 mg of monomer crystals were prepared by pressing in an evacuated die at 9 kbars for 4 min. In the case of the polymerization of the oligomer, KBr pellets containing 6—7 mg of monomer crystals were prepared in the same way, before the measurement they were exposed to the light at the long-wavelength edge of the absorption of the monomer until the monomer was completely converted into the oligomer.

The excitation light for the measurement of the quantum yields was furnished by a grating monochromator (Shimadzu Bausch and Lomb), to which a 450 W high-pressure mercury lamp was attached as a light source. The light intensity was measured by potassium ferrioxalate actinometry.[9] The actinometric estimates were checked with a thermopile (Eppley).

Preparation of the Oligomer and the Polymer. Fine crystals of the monomer (200 mg) were dispersed in 50 m*l* of water-methanol (4: 6) in a Pyrex flask; they were then irradiated for one hour at room temperature by means of a 450-W high-pressure mercury lamp with a suitable cut-off filter—for example, Corning 3-73 for DSP and P2VB, and Corning 0-52 for the *p*-PDA dimethyl ester.

In order to check the photopolymerizability of the oligomer molecules in the crystalline state, they were exposed to the light of a high-pressure mercury lamp without any color filter.

The oligomer and the polymer thus obtained were identified by means of their melting points, IR and NMR spectra, and reduced viscosities (360 mg in 100 m*l* of CF_3COOH).

Results and Discussion

Wavelength Effect on the Photopolymerization. The crystalline UV absorption of DSP, as measured in a thin layer deposited on a quartz plate, is shown in Fig. 1a (Curve 1). DSP molecules in the crystal (*orthorhombic*, P_{bca}) are piled up plane-to-plane along the *c*-axis, to which the long axis of the molecules makes an angle of about 30°; the distance between olefinic double bonds of the nearest neighbouring molecules in 3.94 Å.[6] From these facts, a dipole-dipole interaction may be supposed to exist among DSP molecules in the crystal, as in the case of *trans*-cinnamic acid.[10]

It was found that, on the irradiation of crystalline DSP at a wavelength longer than 400 mμ, the UV absorption spectrum was changed into one with peaks at 350 mμ and 290 mμ, as may be seen in Fig. 1a (Curve 2), in which the band at 430 mμ was excited. Under those conditions, an IR absorption band at 970 cm^{-1} corresponding to the ν_{CH} of the *trans* HC=CH bond

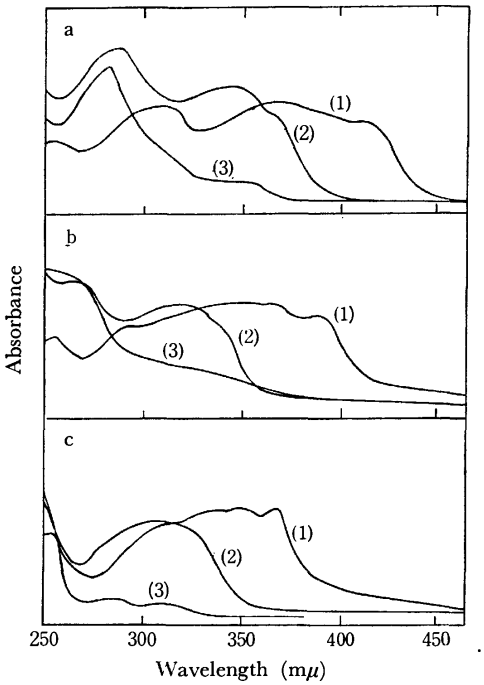

Fig. 1. The crystalline UV spectra of DSP (a): (1) non-irradiated, (2) irradiated at 430 mμ and (3) successively irradiated at 350 mμ, of P2VB (b): (1) non-irradiated, (2) irradiated at 410 mμ and (3) successively irradiated at 350 mμ, and of the *p*-PDA dimethyl ester (c): (1) non-irradiated, (2) irradiated at 360 mμ and (3) successively irradiated at 310 mμ.

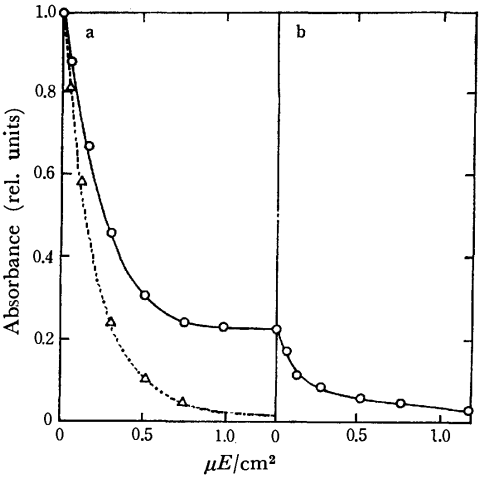

Fig. 2. Kinetics of polymerization of DSP in KBr irradiated (a) at 430 mμ and (b) at 350 mμ: the figure (—○—) corresponds to IR absorbance measurement at 970 cm^{-1}, and the one (---△---) to UV absorbance measurement at 384 mμ taken after dissolution of irradiated pellets in 95% EtOH.

gradually decreased, and then reached a constant level about one-fifth of the initial value, while the monomer in KBr pellets, as measured by UV analysis at 384 mμ after dissolving each pellet in 95% ethanol, decreased and finally almost disappeared, as is shown in Fig. 2a.

These facts imply that crystalline DSP is converted into the oligomer on irradiation at a wavelength longer than 400 mμ. To confirm this, the preparative experiment described in the Experimental section was performed, and the characteristics of the product were examined.

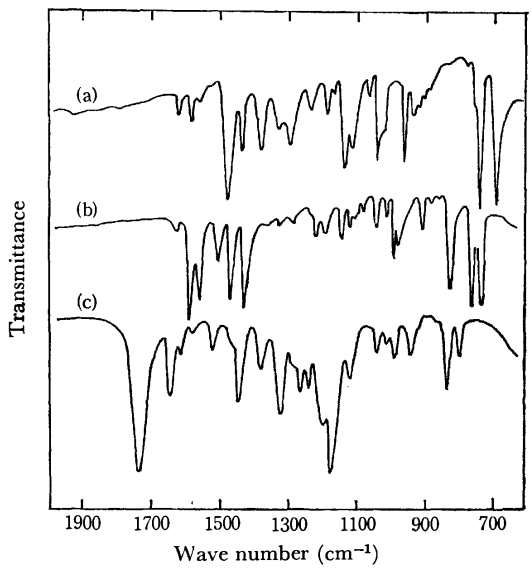

Fig. 3. IR spectra of (a) the DSP oligomer, (b) the P2VB oligomer and (c) the *p*-PDA dimethyl ester oligomer.

The product was quantitatively obtained from DSP, and it melted at 285—290°C. In the IR absorption spectrum, shown in Fig. 3(a), bands attributable to the olefinic double bond are recognized both at 970 cm^{-1} and 1630 cm^{-1}; they completely disappear in that of poly-DSP, as was demonstrated previously.[2] Assuming that the absorption coefficient of the product at 970 cm^{-1} is the same as that of the monomer, the product can be said to correspond to a pentamer, on the average, because the absorbance remains at one-fifth of the initial level (Fig. 2a).

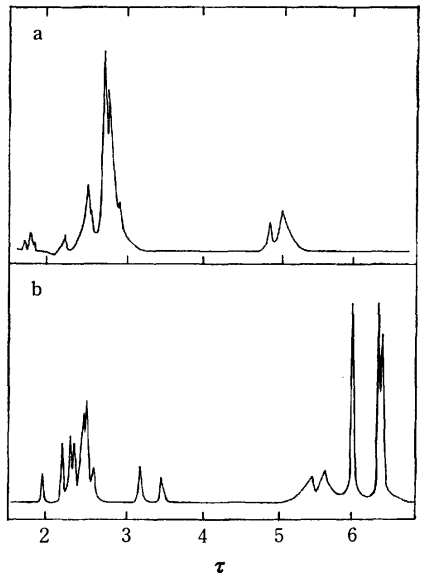

Fig. 4. NMR spectra of (a) the DSP oligomer and (b) the *p*-PDA dimethyl ester oligomer.

The NMR spectrum in Fig. 4a shows the peaks of protons attached to the cyclobutane ring near 5 τ, and those attached to aromatic rings at 2—3 τ. The degree of polymerization, as calculated from the ratio of the number of cyclobutane-ring protons *vs.* that of the other, was equal to about one-fifth. This value corresponds to a pentamer, in good agreement with that estimated by the IR measurements.

Upon the further irradiation of the DSP oligomer at a wavelength longer than 400 mμ, no change was any longer observed. This is reasonable because the oligomer is transparent in that wavelength region. However, the oligomer was found to be converted into a high polymer by exposure to the light at a wavelength shorter than 400 mμ. For example, the excitation at 350 mμ induced a decrease in an UV absorption band at 350 mμ, while leaving the one at 290 mμ unchanged, as may be seen in Fig. 1a (Curve 3). At the same time, the IR absorbance at 970 cm^{-1} decreased, and then completely disappeared (Fig. 2b). The product preparatively obtained was identical with the poly-DSP described previously.[2]

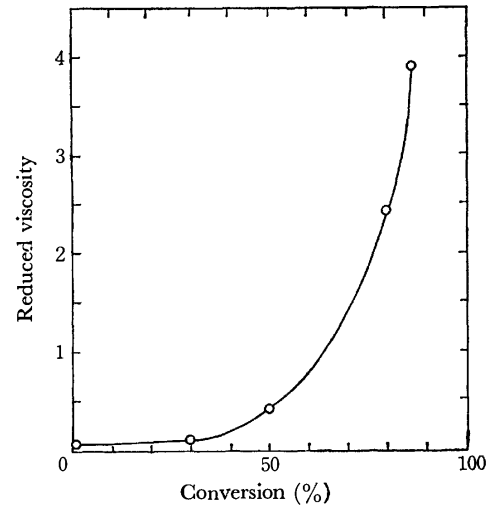

Fig. 5. The reduced viscosity as a function of conversion of olefinic double bonds (measured by IR analysis) during polymerization of the DSP oligomer.

Figure 5 shows the plot of the reduced viscosity *vs.* the conversion during the polymerization of the DSP oligomer. The reduced viscosity increased with an increase in the conversion, as in the case previously reported.[5] This demonstrates that the polymerization of the DSP oligomer proceeds by the step-by-step addition of the terminal group.

When DSP monomer crystals were irradiated at 350 mμ from the beginning, the UV and IR absorption spectra were gradually changed into those of the polymer, without apparently showing those of the oligomer on the way.

It may be concluded that, on irradiation at a wavelength longer than 400 mμ, crystalline DSP was not converted into a high polymer, but quantitatively into the oligomer (a pentamer, on the average), and that a wavelength shorter than 400 mμ was required for the further growth of the terminal group in the oligomer.

It was found that P2VB and the *p*-PDA dimethyl ester, which are photopolymerizable,[2,3] also oligomerized in the crystalline state on irradiation at the long-wavelength edge of the absorption (Fig. 1b, c, 3b, c, and 4b), and that each oligomer polymerized to give a high polymer on irradiation, as may be seen in Fig. 1b and

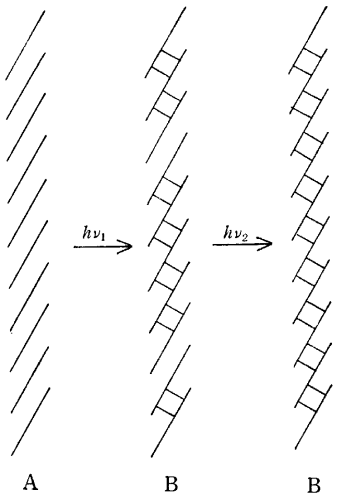

Fig. 6. The scheme of four-center-type photopolymerization in the crystalline state (see text for details).

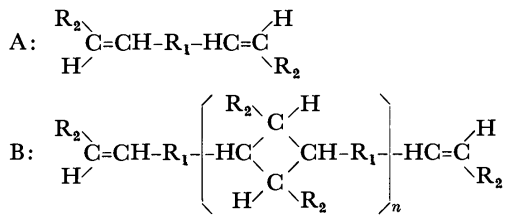
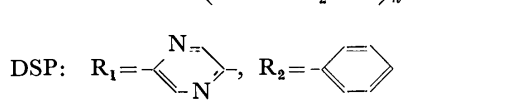
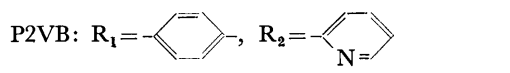
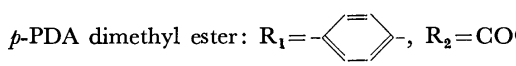
c. The NMR spectrum of the P2VB oligomer thus obtained was almost the same as that of the poly-P2VB shown in the previous paper.[2]

The effect of the wavelength of an exciting light on the four-center-type photopolymerization confirms the step-by-step mechanism in the polymerization suggested in a previously-reported kinetic study.[5] The polymerization reaction in the crystalline state is schematically illustrated in Fig. 6, where A and B represent the monomer molecule and the molecule larger than the dimer with a cyclobutane ring in the main chain respectively.









The reaction scheme is as follows:

$$A + h\nu_1 \longrightarrow A^* \quad (1)$$

$$A + A^* \xrightarrow{k_1} B \quad (2)$$

$$A^* + B \xrightarrow{k_2} B \quad (3)$$

$$B + h\nu_2 \longrightarrow B^* \quad (4)$$

$$B + B^* \xrightarrow{k_3} B \quad (5)$$

where A* and B* represent A and B in the excited state respectively. Equation (2) represents a dimerization reaction, while Eqs. (3) and (5) represent growth reactions.

Since the π-electron conjugation of A is interrupted by the formation of the cyclobutane ring to produce B, the π–π^* electronic transition energy of B can be expected to be higher than that of A (Fig. 1). Therefore, it is possible to excite A alone on irradiation at the long-wavelength edge of the absorption of A ($h\nu_1$), leaving B in the ground state.

Under those conditions, A is converted into B through Eqs. (2) and (3). This first reaction stage is designated as an oligomerization process, because the B produced in this stage is equivalent to a pentamer.

On successive irradiation with the light ($h\nu_2$) which excites B, a high polymer is produced through Eq. (5), a growth reaction of the terminal group in the growing chain. The second reaction stage is designated as a higher polymerization process.

Exposure to the light which excites both A and B from the beginning can induce the oligomerization and the polymerization reaction through Eqs. (1) to (5) successively to give a high polymer. At this time, a A+B*→B reaction may also proceed.

The rate constants, k_1 and k_2, of these elemental reactions in the oligomerization of DSP can be estimated from the kinetic data shown in Fig. 2a. From Eqs. (2) and (3), Eq. (6) is given:

$$-\mathrm{d[A]}/\mathrm{d}t = 2k_1[\mathrm{A}][\mathrm{A}^*] + k_2[\mathrm{A}^*][\mathrm{B}] \quad (6)$$

Since these reactions proceed in the crystalline state, Eq. (6) does not strictly hold good in this system. However, it may be sufficient to evaluate the ratio of k_1 and k_2. It is supposed that [A*] is proportional to the absorbed light intensity, *i.e.*, $[\mathrm{A}^*] \propto 1-\exp(-\kappa[\mathrm{A}])$, in which κ is the constant related to the absorption coefficient and the light-path length. By replacing A* with $1-\exp(-\kappa[\mathrm{A}])$, Eq. (6) can be integrated to give Eq. (7):

$$[\mathrm{A}_0] - [\mathrm{A}] = (2k_1 - k_2)\int_0^t [\mathrm{A}]\mathrm{d}t + k_2\int_0^t [\mathrm{C}]\mathrm{d}t \quad (7)$$

where $[\mathrm{A}_0]$ is the initial concentration of A in a pellet, [C] is the sum of [A] and [B], and $\exp(\kappa[\mathrm{A}]) > 1$ is assumed. The conversion of [A] was followed by UV measurements, and that of [C], by IR measurements, as is shown in Fig. 2a.

The result that $k_2/k_1 \simeq 10$ was obtained. This result is reasonable considering that the B produced in the oligomerization process corresponds to a pentamer. The reason why k_2 is larger than k_1 could not be thoroughly explained. One possible explanation for this acceleration is that the distance between the olefinic double bonds of A and B becomes shorter than that between A and A as a result of the molecular rearrangement from A to B. However, other alternatives may be acceptable.

Quantum Yields. The quantum yields for the oligomerization and the polymerization of DSP, P2VB, and the *p*-PDA dimethyl ester were measured. The quantum yield, (ϕ), is defined by the equation:

$$\phi = -(\mathrm{d[double\ bonds]}/\mathrm{d}t)/I_{abs} \quad (8)$$

where $-(\mathrm{d[double\ bonds]}/\mathrm{d}t)$ is the disappearing rate of the olefinic double bond per unit of volume, and where I_{abs} is the rate at which the incident light is absorbed per unit of volume of a pellet containing the sample.

There are two IR absorption bands, at 970 cm^{-1} and

at 1630 cm^{-1}, attributable to the olefinic double bond. The former can be used for the measurement in DSP and P2VB, and the latter, in the *p*-PDA dimethyl ester, because they are more intense than the others.

ε_A, an IR absorption coefficient of A, was exactly determined from the calibration curve of the IR absorbance *vs.* the monomer concentration in a pellet. However, ε_B, that of B, could not be determined since B was not a homogeneous species, but an oligomer mixture with various degrees of polymerization. Hence, we assumed that $\varepsilon_B=\varepsilon_A$. This may be approximately correct because the substitutions of the olefinic double bonds in A and B are similar.

I_{abs} could not be precisely evaluated because of the ambiguity in the amount of scattered light. I_{abs} should be equal to the intermediate value between two extreme ones calculated on the assumption that the scattered light is either all lost or not lost at all.[11] The extreme values are calculated as the difference between the intensity of the radiation transmitted through a pure KBr pellet (I_{KBr}) and a pellet containing the sample (I_{sam}) in the former case, and between the incident light intensity (I_0) and I_{sam} in the latter case. I_{KBr} was about 70% of I_0 at 365 mμ under these experimental conditions.

The substitution of the upper limit of I_{abs}, I_0-I_{sam}, in the denominator of Eq. (8) gives the quantum yield at the lower limit, and *vice versa*.

The initial quantum yields for the oligomerization and the polymerization of DSP, P2VB, and the *p*-PDA dimethyl ester are summarized in Table 1. These are the values at the lower limit.

TABLE 1. QUANTUM YIELDS OF OLIGOMERIZATION AND POLYMERIZATION OF DSP, P2VB, AND THE *p*-PDA DIMETHYL ESTER

	Oligomerization		Polymerization	
	Excitation (mμ)	ϕ	Excitation (mμ)	ϕ
DSP	436	1.2	365	1.6
P2VB	405	0.04	—	—
p-PDA dimethyl ester	365	1.2	313	0.7

The quantum yields of DSP and the *p*-PDA dimethyl ester were all between 1 and 2 except for that of the polymerization of the latter. This indicates that these photoreactions all belong to one type of reaction in which, theoretically, the maximum value is equal to 2, and that they proceed very efficiently compared with the model compounds photodimerizable in the crystalline state, such as stilbazole[12] and *trans*-cinnamic acid.[13]

The true value of the quantum yield may be expected to be larger than those listed in Table 1. One of the quantum yields calculated at the upper limit was beyond 2, but the other was not. At least mechanistically, the quantum yield which is beyond 2 cannot be visualized for this kind of photopolymerization.

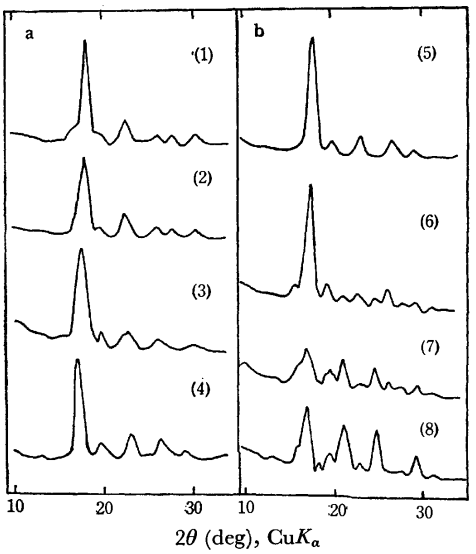


Fig. 7. The changes of X-ray diffraction diagram (a) during oligomerization of DSP: (1) monomer crystals, (2) 35% of conversion, (3) 65% and (4) 100% (*as*-oligomerized), and (b) during polymerization of the oligomer: (5) oligomer crystals, (6) 46% (7) 83% and (8) 100% (*as*-polymerized). Conversion was followed by measuring an IR absorbance at 970 cm^{-1}.

The quantum yield for the oligomerization of P2VB was 0.04. That for the polymerization could not be measured because several bands near 970 cm^{-1} overlap each other and the absorption coefficient at 1630 cm^{-1} is too low in the IR absorption spectrum of the oligomer.

The reason for the difference between the quantum yields in DSP and P2VB cannot be explained until more detailed studies of the crystal structure and the photochemical behavior of these compounds are made.

Structure of the DSP Oligomer. Figure 7 shows the changes in the X-ray diffraction diagram of DSP during the oligomerization and the polymerization. The diffraction diagram of the oligomer is clearly different from those of the monomer and the polymer.

It is noteworthy that the crystallinity of the oligomer (*as*-polymerized) is very high. Once the oligomer is dissolved in a solution, the same crystal structure cannot be reproduced by reprecipitation. In contrast to the DSP oligomer crystal (*as*-polymerized), the recrystallized oligomer could not be photopolymerized. This observation suggests that the thermodynamically quasi-stable oligomer crystals are produced, as in the case of the high polymer crystals *as*-polymerized.[7]

From these facts it is evident that both the oligomerization and the polymerization proceed through a direct rearrangement from the monomer crystals to the polymer crystals by means of a three-dimensional, monomer-lattice-controlled mechanism.

Conformations of the Esters. VI.[1] The Conformations of Monothiocarbonates

Michinori Ōki and Hiroshi Nakanishi

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received September 3, 1971)

The presence of two or three conformational isomers in monothiocarbonates has been confirmed by nuclear magnetic resonance and infrared spectroscopies and by dipole moment techniques. The data can best be interpreted by assuming that the conformations involving the *s-cis* conformation are more stable than that of *s-trans, s-trans*.

It has been confirmed recently that some formates[2] and carbonates[1] exist as both *s-cis* and *s-trans* conformers with respect to the ester group, and the stability of the two conformational isomers has been discussed. As a natural extension of the study of the conformational analysis of carbonates, the conformations of monothiocarbonates have now been studied.

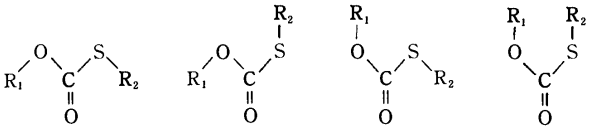

Fig. 1. Conformations of monothiocarbonate.

The following conformational isomers of monothiocarbonates may be considered: *s-trans,s-trans* (A), *s-trans, s-cis* (B), *s-cis,s-trans* (C), and *s-cis,s-cis* (D) (Fig. 1). The conformer D is unstable because of the steric repulsion between R_1 and R_2 groups, although the repulsion should be somewhat smaller in monothiocarbonates than in ordinary carbonates because the C–S bond distance is greater than that of C–O, (C–S, 1.82 Å; C–O, 1.42 Å).[3] Therefore, the conformer D can be neglected.

The chief factors governing the conformations of the ester and the carbonate have been described in previous papers.[1,2] The same factors may be considered for the monothiocarbonates, although there are some points which are different in the monothiocarbonates from the carbonates: 1) the bond moment[4] of the C–S (0.9 D) is a little larger than that of the C–O (0.85 D); 2) the sulfur atom has a larger van der Waals radius (1.85 Å) than oxygen (1.4 Å);[5] 3) the distance of the C–S bond (1.82 Å) is larger than that of the C–O (1.42 Å).

Regarding the first factor, the dipole-dipole interaction between the C=O and the C–S bonds or the C–O and the C–S bonds will be somewhat larger in the monothiocarbonates than in ordinary carbonates (Fig. 2(1)). The second factor necessarily increases the repulsion between sulfur and oxygen in monothiocarbonates, although a part of the repulsion may be released by the third factor. Therefore, the coformer C may be a little more stable than the conformers A and B (Fig. 2(2)). Regarding the third factor, it may be postulated that, in determining the preference of the conformations, the contributions of the steric repulsion between C=O and the R_2 group in the conformers A and C, that between O_{ether} and the R_2 group in the conformer B, and that between the R_1 group and S in the conformer C are smaller in monothiocarbonates than in the carbonates (Fig. 2(3)).

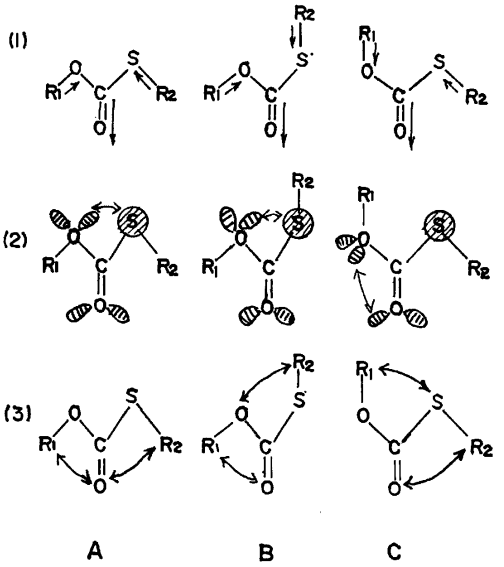

Fig. 2. Factors governing the conformations of monothiocarbonate.

In addition to the above considerations, the sulfur atom may influence the stability of these conformers because its polarizability is larger than that of oxygen.

The purpose of this paper is to present the results of nuclear magnetic resonance and infrared spectral studies and dipole moment measurements undertaken to confirm the existence of conformational isomers in monothiocarbonates.

Experimental

Materials. General Procedure: The sodium thiolate, which was prepared by refluxing sodium in thiol and dry ether for several days, was poured into methyl chloroformate in dry ether with ice cooling. The solution was freed from the precipitate, and the monothiocarbonate was distilled.

Dimethyl Monothiocarbonate: bp 63°C/93 mmHg. NMR (τ): OCH_3, 6.13; SCH_3, 6.34.

S-*Ethyl Methyl Monothiocarbonate*: bp 66—67°C/81 mmHg. NMR (τ): OCH_3, 6.12; $C\underline{H}_2CH_3$, 7.07; $CH_2C\underline{H}_3$, 8.62.

S-*Isopropyl Methyl Monothiocarbonate*: bp 50.5°C/20 mmHg. NMR (τ): OCH_3, 6.20; $C\underline{H}(CH_3)_2$, 6.53; $CH(C\underline{H}_3)_2$, 8.64.

S-t-*Butyl Methyl Monothiocarbonate*: bp 86—87°C/72 mmHg. NMR (τ): OCH_3, 6.25; $C(C\underline{H}_3)_3$, 8.53.

S-*Phenyl Methyl Monothiocarbonate*: bp 125.5°C/20 mmHg. NMR (τ): OCH_3, 6.25; aromatic H, 2.60.

Found: C, 57.36; H, 4.66%. Calcd for $C_8H_8O_2S$: C, 57.14; H, 4.80%.

The purities of these compounds were checked by gas chromatography and by studying the infrared spectra and the NMR spectra. The infrared and NMR spectra were measured with the spectrometers previously described.[1] The dipole moment was measured in a benzene solution by the heterodyne beat method.

Results and Discussion

Nuclear Magnetic Resonance Spectra. The NMR spectra of several methyl monothiocarbonates were measured in a carbon tetrachloride solution at room temperature. The results are shown in Table 1. The chemical shifts of the methoxy methyl protons of alkyl methyl monothiocarbonates from TMS change from compound to compound. Since it is difficult to consider that this large shift is due merely to the difference in electronic effects of the alkylthio group, the authors should like to claim that the change is attributable to the change in the population of conformational isomers by the steric effect.

Table 1. NMR spectral data of monothiocarbonates MeOCOSR in CCl_4 ($c=15\%$)

	R	$OC\underline{H}_3$
I	Me	6.10(τ)
II	Et	6.12
III	*i*-Pr	6.20
IV	*t*-Bu	6.25
V	Ph	6.25

In order to obtain further information on the existence of conformational isomers, the NMR spectra of *S*-*t*-butyl methyl monothiocarbonate were measured at low temperatures in CS_2–CH_2Cl_2. The results are shown in Table 2 and Fig. 3. The peak heights of the methoxy and *t*-butyl protons decrease as the temperature is lowered: the peak height of the methoxy proton at −110°C is 57% of that at 34°C, while that of the *t*-butyl

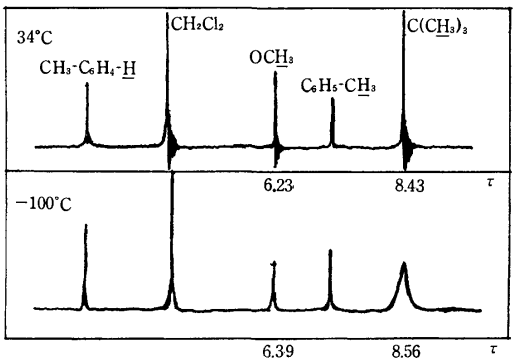

Fig. 3. NMR spectra of MeOCOS-*t*-Bu in $CS_2+CH_2Cl_2+CH_3C_6H_5$.

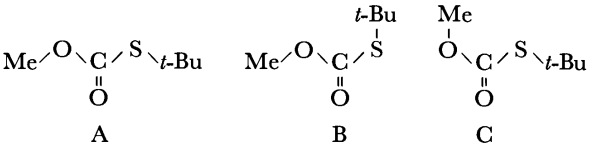
is merely 21% (Fig. 3). These results may best be interpreted by assuming the presence of two or three conformers in this compound and by assuming that the exchange rate among the conformers is slow on the NMR time scale at this low temperature. The broadening both in the peaks of methoxy and *t*-butyl groups may mean the coexistence of three conformers, A, B, and C, or two conformers, B and C, because the chemical shift of the methoxy protons in the conformer A can be considered to be almost the same as that of the conformer B and the same would be true for the chemical shifts of *t*-butyl protons in the conformers A and C, provided that the anisotropic effect of the carbonyl group is the most important in determining the chemical shifts.



Infrared Spectra. Only a few infrared spectra of carbonyl absorptions of monothiocarbonates have been reported so far;[6,7] only one carbonyl absorption has been reported. However, as was pointed out earlier,[1,2,8] by using an infrared spectrophotometer with a high resolution, we may find two or three carbonyl absorptions for the monothiocarbonates, especially because of the NMR behavior described above. Thus, infrared spectra of carbonyl stretching vibration absorptions of monothiocarbonates were measured in hexane, carbon tetrachloride, and acetonitrile.

II	Et	1713 (106)	1707 (41)	1701 (91)
		1720 (1712)	1715 (600)	1713 (1065)
III	*i*-Pr	1712 (174)	1705 (92)	1698 (114)
		1718 (2000)	1714 (787)	1712 (1050)
IV	*t*-Bu	—	1705 (74)	1700 (114)
			1713 (739)	1711 (928)
V	Ph	1718 (330)	1711 (112)	1702 (148)
		1728 (64)	1722 (46)	1715 (86)
		1736 (1711)	1730 (715)	1728 (918)

The results confirmed our expectations: monothiocarbonates show unsymmetrical carbonyl absorptions, although the shape of the absorption is not that of the multiple peaks, as is shown in Fig. 4. These unsymmetrical absorptions were graphically separated into two symmetrical peaks.[9] The results are shown in Table 3. With compounds II, III, and IV, the band at a higher frequency is stronger than the lower one in both polar and nonpolar solvents. Apparently in these solvents, the effect of the bulkiness of alkyl groups does not play an important role in determining the conformation of the ester group in contrast to the case of carbonates. From the NMR data, the existing conformers are considered to be B and C or A, B, and C. The directions of the bond dipoles of C=O and C–O or C–S in various conformations suggest that the wave number of the carbonyl absorption of the conformer A is the lowest among the three conformations. However, at the present time, it is not known which of the two conformers, B and C, gives the carbonyl absorption at a higher frequency. Therefore, the most stable conformation cannot be known from the infrared spectral data, although the conformation A is clearly the most unstable.

Compound V has three absorptions in these three solvents, probably indicating that three conformations, A, B, and C, are present. However, since there is a possibility that the third band arises because of the enhancement due to the Fermi resonance, it is necessary to obtain further information. Thus, the infrared spectra of the carbonyl overtone absorptions of *S*-alkyl methyl monothiocarbonate were measured. The results are given in Fig. 5 and Table 4.

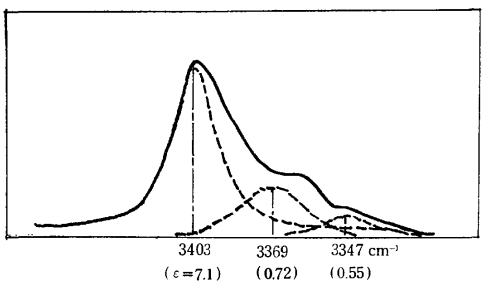

Fig. 5. Carbonyl overtone spectra of MeOCOS-*t*-Bu in CCl_4 C=0.0097 mol/*l*.

Table 4. Carbonyl overtone absorptions of monothiocarbonates MeOCOSR in CCl_4 $C=0.01$ mol/*l*

	R	cm^{-1}	(ε)
I	Me	3388	(0.41)
		3397	(0.34)
		3416	(3.81)
II	Et	3362	(0.20)
		3380	(0.36)
		3409	(4.51)
III	*i*-Pr	3368	(0.66)
		3389	(1.28)
		3406	(4.73)
IV	*t*-Bu	3347	(0.55)
		3369	(0.72)
		3403	(7.10)

The shapes of the absorption curves of compounds I—V are unsymmetrical, and the curves fit best when three rather than two overlapping absorptions are considered.[10] These results strongly suggest that these compounds really show three carbonyl absorptions.

Dipole Moment. The temperature dependency of the dipole moment of *S*-*t*-butyl methyl thiocarbonate (IV) was measured in order to obtain information about the stability of these conformers. The results are given in Table 5.

Table 5. Dipole moment of *t*-BuSCOMe in benzene

T°C	16	32	53
(D)	1.01	0.95	0.83

The calculated dipole moment values of *S*-*t*-butyl methyl monothiocarbonate are 0.1 D for the *s-trans, s-trans* conformer (A), 2.1 D for the *s-trans,s-cis* conformer (B), and 2.0 D for the *s-cis,s-trans* conformer (C).[11] The dipole moment of compound IV decreases as the temperature of the measurement is raised. Since the calculated dipole moment of the conformer B is not very different from that of the conformer C, the results may mean that the *s-trans,s-trans* conformer (A) is present, that A is the most unstable, and that the *s-cis* conformers, B and/or C, are the main conformers.

In conclusion, all the data presented above suggest that, among the three possible conformations, the conformation A is the least stable. Thus, although it has not been possible to determine which of the conformations, B and C, is the most stable, it is apparent that the conformations involving the *s-cis* part are more stable than the *s-trans,s-trans* conformation. It may be pointed out, as a difference between carbonates and thiocarbonates, that even the simplest example of the latter, dimethyl monothiocarbonate, shows signs of the presence of the three conformers, while the simplest example of the former, ethyl methyl carbonate, gives no such sign.

9) The possibility of an absorption including three bands cannot be ruled out. This is especially so when the intensity of the second band is very small and its wave number is close to that of the strong band.

10) The decomposition of the absorption curves into the component bands is more easily performed in the overtone region because the separation of the components becomes larger.

11) The calculation was made using the bond moments of 2.4 D for C–O and 0.4 D for C–H. The values for C–O and C–S were cited earlier (See Ref. 4).

Ligand Effects in the Cooligomerization of Butadiene and Ethylene by a Nickel-based Catalyst System[1]

(Received October 12, 1971)

The cooligomerization of butadiene and ethylene catalyzed by a $NiCl_2$–$AlEt_3$–phosphine system was investigated. The cooligomerization product was 1,*cis*-4-hexadiene or/and 1,*trans*-4,9-decatriene. Bidentate ditertiary phosphines had remarkable effects on the reaction. The effects of ditertiary phosphines are also described.

Several complex catalyst systems for the cooligomerization of a conjugated diene and a monoolefin have been reported. Iwamoto reported the codimerization of butadiene and ethylene to give 1,*cis*-4-hexadiene by means of a catalyst system composed of cobalt chloride, ditertiary phosphine, and triethylaluminum.[2] An iron-based catalyst system for the synthesis of 1,*cis*-hexadiene has also been reported.[3] Müller and his coworkers found the reaction of butadiene and ethylene to give 1,5,9-decatriene.[4] Wilke reported a cotrimerization of butadiene and ethylene giving *trans*-1,*cis*-5-cyclodecadiene and 1,*trans*-4,9-decatriene by means of a nickel acetylacetonate-diethylaluminum ethoxide catalyst system.[5] The addition of α-olefins to conjugated dienes was accomplished by means of a catalyst derived from the interaction of bis(tri-*n*-butylphosphine) nickel chloride, and diisobutylaluminum chloride.[6] Linear 1,4-dienes were the primary products. The synthesis of 1,*trans*-4-hexadiene with rhodium trichloride was reported by Alderson.[7] A detailed study of the reaction of butadiene and ethylene catalyzed by a nickel hydride complex, $HNi(P(OEt)_3)_4^+$, was also reported.[8]

In a previous paper, the present authors reported briefly on the cooligomerization of butadiene and ethylene by means of a nickel-based catalyst system;[9] in this paper, they will describe the effects of ditertiary phosphine in the catalyst system.

Experimental

Reagents. The toluene was purified by washing it with sulfuric acid and by then distilling it over sodium under a nitrogen atmosphere. The triethylaluminum and ethylene were used without further purification. The butadiene was dried by passing it through columns of calcium chloride and of silica gel. The nickel chloride and triphenylphosphine were commercial reagents. The ditertiary phosphines were prepared according to the method described by Hewertson and Watson.[10] Nickel complexes of the phosphines were prepared by adding nickel chloride to an alcoholic solution of the phosphines.

Ditertiary phosphine	Mp (°C)
$Ph_2P(CH_2)_nPPh_2$	
$n=1$	119.9—120.9(120.5—121.5)[10]
$n=2$	139.6—140.9(143—144)[10]
$n=3$	63.3—65.3(61—62)[2,11]
$n=4$	133.8—133.9(137—139)[12]
$n=5$	43.1—46.1(liquid)[12]
$n=6$	125.2—126.0
$Ph_2PCH_2OCH_2PPh_2$	90.3—95.3
$Ph_2PCH_2CH_2OCH_2CH_2PPh_2$	liquid (liquid)[12]

Procedure. A 100 m*l* stainless-steel autoclave equipped with a magnetic stirrer was charged with nickel chloride, ditertiary phosphine (or its nickel complex), toluene (with or without), butadiene, and triethylaluminum in a glass ampoule under a nitrogen atmosphere. At room temperature, ethylene was introduced until a pressure of *ca.* 20 kg/cm² was reached, after which the ampoule of triethylaluminum was broken with agitation. Then the autoclave was heated to 110°C, where the reaction pressure reached approximately 50 kg/cm²; this pressure was maintained during the reaction by introducing ethylene. After 3 hr, the autoclave was cooled to room temperature and the catalyst was quenched by adding a small amount of methanol. The reaction mixture was washed with water and dried with anhydrous sodium sulfate. The products were analyzed by gas chromatography.

*Product Analysis. 1,*trans*-4,9-Decatriene*: 1,*trans*-4,9-Decatriene was distilled from the reaction mixture at 83°C/52 mmHg. The IR spectrum of the compound exhibited absorption bands at 3065, 1637, 987, 965, and 910 cm^{-1}, showing the existence of terminal vinyl and *trans* double-bond groups. No peak attributable to conjugated diene was observed. NMR spectrum showed a very complicated pattern. The signals at τ=3.7—4.6(4H), 4.7—5.2(4H), 7.1—7.5(2H), 7.6—8.2(4H), and 8.3—8.9(2H) were attributable to $-C=CH-$, $-C=CH_2$, $=C-CH_2-C=$, $-C-CH_2-C=$, and $-C-CH_2-C-$ respectively. Hydrogenation was carried out in methanol at 50°C by means of a palladium black catalyst under an atmospheric hydrogen pressure. Three moles of hydrogen were absorbed, and *n*-decane was obtained.

The gas chromatogram of the reaction mixture showed a shoulder peak on that of 1,4,9-decatriene, the fraction of which was separated by preparative gas chromatography. The IR spectrum of the compound exhibited a pattern fairly similar to that of 1,4,9-decatriene. The peaks at 3075, 1634, 1374, 989, 965, and 912 cm^{-1} showed the existence of terminal vinyl, *trans* double-bond, and methyl groups. No peak attributable to conjugated diene was observed. The peaks at 989 and 912 cm^{-1}, attributable to the terminal vinyl group, were weaker than those of 1,4,9-decatriene. On the hydrogenation of a mixture of the compound and 1,4,9-decatriene, only *n*-decane was formed. The compound is presumed to be 1,4,8-decatriene.

*1,*cis*-4-Hexadiene*: 1,*cis*-4-Hexadiene was distilled from a reaction mixture at 66.5—67.0°C. Its IR and NMR spectra were identical with those of an authentic sample of the *cis* isomer.

4-Vinylcyclohexene, 1,5-cyclooctadiene, and 1,5,9-cyclododecatriene were identified by gas chromatography, and by IR and NMR spectroscopy.

Results and Discussion

1. $NiCl_2$–$AlEt_3$ System. In the reaction of butadiene and ethylene with this catalyst system, the main products were higher oligomers. 4-Vinylcyclohexene(VCH), 1,5-cyclooctadiene(COD), 1,4,9-decatriene(DT), and 1,5,9-cyclododecatriene(CDT) were also produced. The selectivity of the DT(DT(g)/products (g)) was about 25 wt%. The yield of 1,4-hexadiene (HD) was negligible.

2. PPh_3–$NiCl_2$–$AlEt_3$ System. In this catalyst system, the main products were also higher oligomers. The increase in triphenylphosphine suppressed the formation of DT and CDT.

3. $Ph_2PCH_2PPh_2$(DPM)–$NiCl_2$–$AlEt_3$ System. The main cooligomerization product was 1,4,9-decatriene, plus some 1,4,8-decatriene. The yield of 1,4-hexadiene was also negligible.

When the molar ratio of DPM to $NiCl_2$ reached 3, the reaction stopped almost completely.

4. $Ph_2PCH_2CH_2PPh_2$(DPE)–$NiCl_2$–$AlEt_3$ System. The main cooligomerization product was 1,4,9-decatriene when the molar ratio of DPE to $NiCl_2$ was less than unity. However, when the ratio exceeded unity, the sole cooligomerization product was 1,4-hexadiene. When the molar ratio of DPE to $NiCl_2$ reached 3, the reaction stopped almost completely at 110°C. If the reaction temperature was elevated to 130°C, the catalytic activity was observed even though the molar ratio of DPE to $NiCl_2$ was 4.

It was expected that triethylaluminum took an important role in the cooligomerization reaction of butadiene and ethylene. To ascertain the effect of triethylaluminum, the molar ratio of triethylaluminum to nickel chloride was gradually changed at DPE/$NiCl_2$=0.5 and the distribution of the products was examined.

Table 4. Effects of $AlEt_3$
$NiCl_2=6.02\times10^{-4}$ mol, DPE/Ni=0.5, 110°C, 3 hr, 50 kg/cm^2

8.3	27	27	0.4	3.1	4.2	27	9.3	+
19.6	34	35	trace	4.4	4.0	51	17	+

When the molar ratio of triethylaluminum to nickel chloride was 19.5, 1,4-hexadiene was not produced; 1,4,9-decatriene was obtained as the main cooligomerization product. However, the molar ratio of triethyl aluminum to nickel chloride became 3.1, 1, 4-hexadiene and 1,4,9-decatriene were obtained together. There was a tendency for the yield of 1,4-hexadiene to increase as the molar ratio of triethylaluminum to nickel chloride became smaller.

As was suggested in discussing the reaction of buta-

diene with ethylene catalyzed by the $HCo(Ph_2PCH_2CH_2PPh_2)_2$–triethylaluminum system,[13] it seems that triethylaluminum can interact with the coordinated phosphorus atom, release it from the metal atom, and make a coordinatively unsaturated state. This interaction should be more effective at a higher concentration of triethylaluminum. The coordinatively unsaturated state would promote the reaction of butadiene with ethylene. It would depend on the degree of unsaturation whether 1,4,9-decatriene or 1,4-hexadiene was produced. Clearly, the formation of 1,4,9-decatriene requires a higher unsaturated state around the nickel atom than that of 1,4-hexadiene, and so it is always accompanied by other products, such as VCH, COD, and CDT.

It is very interesting to note that the $Ni(DPE)Cl_2$–$AlEt_3$ system showed no catalytic activity for the cooligomerization of butadiene and ethylene. However, the addition of $NiCl_2$ to the catalyst system caused the catalytic activity for the butadiene-ethylene reaction to recover and 1,4,9-decatriene was yielded. A Lewis acid such as $AlCl_3$ or $FeCl_3$ was ineffective, unlike $NiCl_2$. On the other hand, the addition of DEP to the $Ni(DPE)Cl_2$–$AlEt_3$ system did not cause any catalytic activity. The effect of the added $NiCl_2$ is shown in Table 5.

Table 5. Effects of $NiCl_2$ added to $Ni(DPE)Cl_2$–$AlEt_3$ system
$Ni(DPE)Cl_2=5.68\times10^{-4}$ mol, Al/Ni(DPE)Cl_2=18.5—20.2, 110°C, 3 hr, 50 kg/cm²

$NiCl_2$/Ni(DPE)Cl_2 (mol/mol)	BD (g)	Yield (g)	DT (g)
3.1	36	0.5	trace
6.8	32	9.0	5.1
13.5	40	27.0	12.0
27.0	34	27.5	15.0

5. $Ph_2P(CH_2)_3PPh_2$(DPP)–$NiCl_2$–$AlEt_3$ System.
The DPP ligand showed almost the same catalytic effect as DPE; *i.e.*, when the molar ratio of DPP to $NiCl_2$ was less than unity, the main cooligomerization product was 1,4,9-decatriene and 1,4-hexadiene was produced. When it was more than unity, 1,4,9-decatriene was not produced and 1,4-hexadiene was the sole cooligomerization product. In contrast with the catalyst system containing DPE, the reaction did not stop even at DPP/$NiCl_2$=5 at 110°C.

6. $Ph_2P(CH_2)_4PPh_2$(DPB)–$NiCl_2$–$AlEt_3$ System.
In this reaction system, the main products were higher oligomers, and no formation of 1,4-hexadiene was observed.

7. Other Bidentate Ligands–$NiCl_2$–$AlEt_3$ Systems.
In the reaction of the complexes coordinated with $Ph_2P(CH_2)_nPPh_2$ (n=5,6), $Ph_2PCH_2OCH_2PPh_2$, and $Ph_2PCH_2CH_2OCH_2CH_2PPh_2$, no ligand effects were observed distinctly. The distribution of products resembled that of the $NiCl_2$–$AlEt_3$ system.

In the present study, the added or coordinated ditertiary phosphine had a great influence on the distribution of products. When the molar ratio of DPE or DPP to $NiCl_2$ became unity, a great change in the distribution of products was observed.

Generally, a phosphine ligand coordinates to a low-valent nickel atom which is produced by reduction with an organoaluminum compound, and stabilizes it. This function of a phosphorus atom is stronger with bidentate ditertiary phosphine than with monodentate phosphine because of its chelating effect. Especially, the chelation of the ditertiary phosphines, $Ph_2P(CH_2)_nPPh_2$ (n=2,3), is stronger than those of the other ditertiary phosphines because of the easy formation of a five- or six-membered chelate ring. The high coordinating ability of DPE and DPP is supposed to be the promoting power for the selective formation of 1,4-hexadiene.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1999—2003(1972)

Generation and Cycloaddition of 8,8-Dimethylisobenzofulvene[1]

Hiroshi TANIDA,* Tadashi IRIE, and Kazuo TORI
Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received December 3, 1971)

Transient 8,8-dimethylisobenzofulvene (**5**) was generated by thermal decomposition of two materials; one is formally an adduct of cyclopentadienone with 9-isopropylidenebenzonorbornadiene (**6**), and the other an adduct of 3,6-di(2′-pyridyl)-*S*-tetrazine with **6**. The former was prepared by cycloaddition of **6** to tetrachlorodimethoxycyclopentadiene followed by dechlorination giving a ketal, then hydrolysis of the ketal function. Generation without any trapping reagent instantaneously yielded one kind of dimer of a stereospecific structure. In the presence of dimethyl maleate, dimethyl 9-isopropylidenebenzonorbornene-*exo,cis*-2,3-dicarboxylate and its *endo-cis* isomer were formed. In the presence of dimethyl fumarate, the *trans* isomer was obtained. Trapping with tropone led to a 1 : 1 adduct resulting from participation of the exocyclic C_2–C_8 double bond in **5**. All attempts to isolate **5** or prepare a stable metal complex of **5** by conventional means were unsuccessful.

The preparation and properties of non-planar valence bond isomers of benzene and its derivatives such as the Dewar benzenes (bicyclo[2.2.0]hexa-2,5-dienes), benzvalenes (tricyclo[3.1.0.0^{2,6}]hex-3-enes) and prismanes (tetracyclo[2.2.0.0^{2,6}.0^{3,5}]hexanes) have received considerable attention in recent years.[2-4] The planar fulvene is the most classical valence isomer and has been known for more than seventy years.[5] Benzo derivatives of these compounds can be considered as valence bond isomers of naphthalene, of which benzobenzvalene (or naphthvalene)[4] and benzofulvene (**1**)[6] are known. The isoconjugate isomer of **1**, benzoisofulvene (**2**), is of considerable interest, being isoelectronic with both the recently prepared isobenzofuran (**4a**)[7], and isobenzothiophene (**4b**)[8] known for some

Z = O, S

years. Hafner[9] was the first to succeed in the isolation of a derivative of this ring system. He isolated *N,N*-dimethyl-*N*-(1,3-diphenyl-2-indenylidenemethyl)amine (**3**) and reported on the observation of transient *N,N*-dimethyl-*N*-(2-indenylidenemethyl)amine. In connection with this, we are interested in the preparation and reactivity of 8,8-dimethylisobenzofulvene **5**.

Results

The preparation of **5** was tried through two independent sequences starting from 9-isopropylidenebenzonorbornadiene (**6**), obtained by the addition of benzyne to 6,6-dimethylfulvene.[10] The first was modelled after the method of Mackenjie.[11] Heating **6** with 1,2,3,4-tetrachloro-5,5-dimethoxycyclopentadiene (**7**) at 165°C for 5 hr yielded the 1 : 1 adduct (**8**)

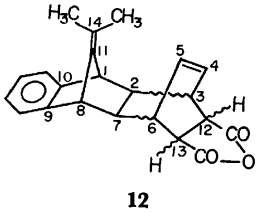
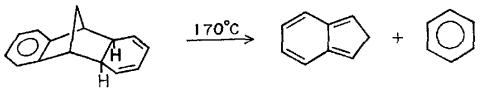
in 87% yield. Dechlorination of **8** with sodium in *t*-butyl alcohol-tetrahydrofuran gave ketal **9**, hydrolysis of which with 70% aqueous acetic acid provided ketone **10**. Stereochemistry of these compounds was determined from their PMR spectra as indicated in the chart, principally following the assignments[11b] presented for closely related compounds; the addition compounds of norbornene or benzonorbornadiene to **7**, and their derivatives. In the stereochemistry, it is of importance that the signal assigned to H_2 (H_7) in the adduct **8** appears as a singlet at δ 2.59 ppm indicating the absence of significant spin-coupling to H_1 (H_8), and that the signal at δ 2.30 ppm due to H_2 (H_7) in the dechlorinated ketal **9** is a multiplet indicative of spin-coupling to H_3 (H_6). These observations led to the configuration in which H_2 and H_7 are *endo* to the benzonorbornene ring and *exo* to the norbornene ketal ring.

Decarbonylation of **10** in a dioxane solution proceeded at 100°C at a fair rate. Attempts to isolate the diene **11** by conventional methods were unsuccessful due to the subsequent reverse cycloaddition liberating benzene and **5**, but its formation was confirmed by the addition of maleic anhydride which rapidly forms the adduct **12**. Evidence for the indicated structure **12**



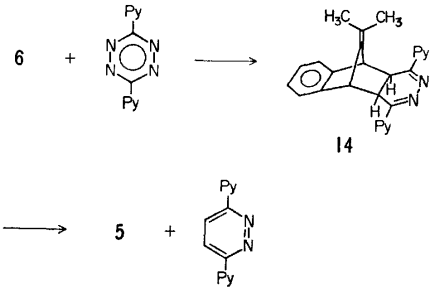
12



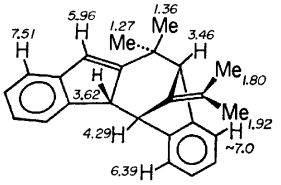
13

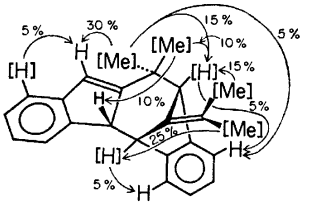
was provided by the PMR spectrum (see Experimental). A related compound **13** prepared through the same reaction sequence starting from benzonorbornadiene instead of **6**, has been reported to require a temperature of 170°C for thermal decomposition leading to indene (presumably *via* isoindene) and benzene.[11c] The large difference in reactivity between **11** and **13** clearly demonstrates a significant participation of the isopropylidene group in **11** in the transition state of thermal decomposition.

The second route for **5** began with the reaction of a suspension of 3,6-di(2′-pyridyl)-*S*-tetrazine[12] with **6** in dioxane solution at room temperature (exothermic, N_2 elimination). In the dioxane solution the adduct **14** decomposed rapidly at about 50°C and slowly in the solid state on storage.



The thermal decomposition of both **10** and **14** in the absence of any trapping reagent instantaneously and quantitatively yielded only one kind of dimer (**15**, Fig. 1) displaying a remarkable stereochemical preference in dimerization. The parent peaks in the mass spectrum and elementary analysis are consistent with the formula $(C_{12}H_{14})_2$. Although the catalytic reduction of **15** resulted in no up-take of hydrogen, the Raman spectrum in chloroform revealed three kinds of unsaturated bonds at 1582(m),[13] 1616(s), and 1708(m) cm^{-1}, assignable to unsaturation due, respectively, to a benzene ring, a cyclopentenyl double bond, and an isopropylidene double bond.[14] The UV spectrum





15

(λ_{max}^{ether} 262 mμ (ε 12810), 268 (12490), and 274 (10750)) is compatible with the existence of a double bond conjugated with a benzene ring. Confirmatory evidence for the structure was obtained by a detailed analysis of the 100 MHz PMR spectrum in $CDCl_3$. The signal assignments were made on the basis of spin-decoupling

12) J. F. Geldard and F. Lions, *J. Org. Chem.*, **30**, 318 (1965),
13) m=medium, s=strong, and w=weak.
14) Raman $\nu_{C=C}$ in chloroform appear, for 7-isopropylidenebenzonorbornene,[9] at 1725 (w) cm^{-1} (isopropylidene) and, for benzonorbornadiene, at 1620 (w) (C=C), 1607 (w) (C=C and/or benzene), and 1578 (m) (benzene). Infrared spectrum of **15** shows no absorption at 1708 cm^{-1}.

and nuclear Overhauser effect (NOE).[15,16] Chemical shifts and the positive NOE value observed are shown in Fig. 1.[17] When the signals marked by brackets were saturated with double irradiation, the positive enhancement of intensities was observed at the signals marked by arrows. It is considered that the anisotropy effect of the benzene ring of the indene moiety is responsible for the shift of the proton on the other benzene being at such a high field (δ 6.39 ppm); likewise the anisotropy effect of this latter benzene ring causes a high value for the shift of the vinyl proton (δ 5.96 ppm). Furthermore, orientation of the methine proton at position 3 of the indene moiety was established as β by the NOE results. Some coupling constants are given in Experimental. All our attempts to isolate **5** or to prepare a stable metal complex of **5** were unsuccessful. Experiments carried out are thermal decomposition of **10** and **14** under reduced pressure (1×10^{-3} mm) using a cold finger, thermal decomposition of **10** and **14** in the presence of iron pentacarbonyl, and photochemical decomposition of **10** and **14** in the absence and presence of iron pentacarbonyl. The only product characterized on these treatments was **15**.

Trapping of 5 with Dienophiles. Generation of **5** was carried out by warming dioxane solutions of **10** at 100°C (method A, Table 1) and of **14** at 50°C (method B, Table 1) in the presence of dimethyl maleate. The products were *exo-cis* adduct (**16**), *endo-cis* adduct (**17**), and dimer **15**. No detectable amount of *trans* adduct (**18**) was found by vpc. Structures of the adducts were established by their PMR spectra (Experimental). The yields of the three products varied with the amount of dimethyl maleate added (Table 1). Although the yield of **15** decreased on increasing the mole ratio of dimethyl maleate to **10** or **14**, the relative yield ratio of **16** to **17** was nearly independent of the amount of dimethyl maleate and the methods of generation. The constancy of ratio indicates the existence of an identical intermediate **5** in the decompositions of **10** and **14**. The formation of **18** but no other adduct was observed in the reaction of **10** or **14** with dimethyl fumarate.

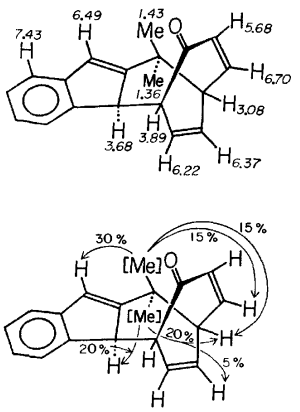

Fig. 2. Chemical shifts (δ in ppm downfield from TMS) and nuclear Overhauser effects (indicated by arrows) in the PMR spectrum of the tropone adduct **19** in $CDCl_3$.

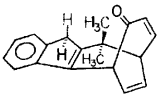
Trapping with Tropone. Decomposition of **10** was carried out at 120°C in the presence of ten equivalents of tropone. Distillation of excess of tropone under reduced pressure left a crystalline 1 : 1 adduct in an almost quantitative yield. The IR carbonyl absorption at 1657 cm^{-1} is compatible with the presence of cyclohepta-2,5-diene but not a cyclohepta-3,5-dienone moiety. The 100-MHz PMR spectrum in $CDCl_3$ included singlet methyl signals at δ 1.36 and 1.43 ppm and five olefinic proton resonances, as well as all other signals in agreement with structure **19**, given in Fig. 2 with chemical shifts and positive NOE values observed. Appearance of the vinyl proton α to the carbonyl at such a high field as δ 5.68 ppm is thought to be due to the anisotropy effects of benzene and the ethylene bridge. Orientation of the methine proton at position 3 of the indene moiety was established as α by the NOE experiments. The proton readily underwent a base-catalyzed 1,3-shift to give **20**.



20

Thus we see that **5** acts as a 6π electron addend due to participation of the exocyclic π bond in both dimerization and the tropone reaction though the mode of addition of **5** toward the 4π reactants (**5** and tropone) is just the reverse. The orbital-symmetry rule of

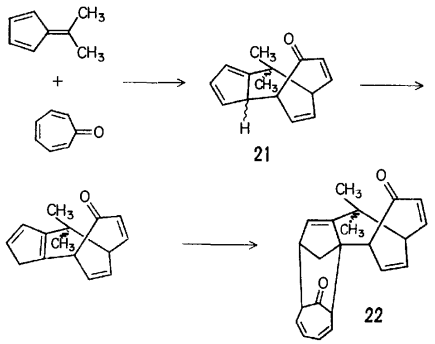
17) The indicated structure was consistent with the results from X-ray analysis.

Woodward and Hoffmann[18] suggests that the concerted [6+4] cycloaddition reaction has a preference for *exo* addition as far as symmetry factors are dominant. Some evidences have been reported. The tropone adduct **19** bearing the α hydrogen at position 3 might be an additional evidence, but not the dimer **15** having β hydrogen. However, the mechanism of neither reaction, whether concerted or stepwise *via* diradicals, has yet been established.

During the course of this investigation, Houk *et al.*[19] reported a cycloaddition reaction between dimethylfulvene and tropone analogous to the present reaction with tropone.[19] However, the initial adduct (**21**) is very labile because of the fact that the resulting cyclopentadiene system undergoes further addition to tropone. Thus the main product finally obtained in a stable form is a 1:2 adduct of dimethylfulvene and tropone (**22**). Their overall results are therefore very complicated. Nevertheless, their mechanistic interpretation is compatible with ours. It is suggested that the first addition of dimethylfulvene to tropone to form **21**, though not yet proven, takes place from *exo* direction.



Experimental

Melting points were taken by capillary and are corrected. Boiling points are uncorrected. Infrared spectra were determined with a Nippon Bunko IR-S spectrometer, ultraviolet spectra with a Hitachi EPS-3T spectrometer, PMR spectra with Varian A-60A and HA-100 spectrometers, and mass spectra with a Hitachi RMU-6 mass spectrometer. VPC analysis was carried out on a Hitachi gas chromatograph K-53 equipped with a hydrogen flame ionization detector and a 15 m capillary column coated with butanediol succinate or a 2 m×4 mm glass column packed with 3% diethylene glycol succinate on Chromosorb W.

Addition of 9-Isopropylidenebenzonorbornadiene (6) to 1,2,3,4-Tetrachloro-5,5-dimethoxycyclopentadiene (7). A mixture of 3.65 g (0.02 mol) of **6** and 13.2 g (0.05 mol) of **7** was heated at 165°C under nitrogen with stirring for 5 hr. After removal of excess of **7** under reduced pressure, the residue was recrystallized from pentane giving the 1:1 adduct (**8**) in 87% yield, mp 176.5—177.5°C; PMR (CCl_4) δ: ~7.00 (4, aromatic), 3.71 (s, 2, C_1,C_8–H), 3.48 (s, 6, CH_3O), 2.59 (s, 2, C_2, C_7–H), and 1.65 ppm (s, 6, CH_3).

Found: C, 56.80; H, 4.58; Cl, 31.72%. Calcd for $C_{21}H_{20}Cl_4O_2$: C, 56.52; H, 4.52; Cl, 31.79%.

Ketal 9 from 8. To a solution of 4.46 g (0.01 mol) of **8** in 10 ml of anhydrous tetrahydrofuran was added 2.76 g (0.12 g-atom) of sodium metal and 8.90 g (0.12 mol) of *t*-butyl alcohol, and the mixture was refluxed for 6 hr with stirring. After destruction of the remaining sodium by addition of methanol, the reaction mixture was concentrated by distillation of the solvent and extracted with ether. The ether solution was washed with a saturated sodium chloride solution and water, dried over sodium sulfate and evaporated. Recrystallization of the residue (2.99 g, 97% yield) from *n*-hexane yielded a pure sample of **9**, mp 155—160°C (decomp.); PMR ($CDCl_3$) δ: ~7.01 (4, aromatic), 5.88 (t, 2, CH=CH), 3.45 (2, s, C_1,C_8–H), 3.09 (s, 6, CH_3O), 2.91 (2, m, C_3,C_6–H), 2.30 (2, qua, C_2,C_7–H), and 1.44 ppm (s, 6, CH_3).

Found: C, 81.80; H, 8.01%. Calcd for $C_{21}H_{24}O_2$: C, 81.78; H, 7.84%.

Ketone 10. A suspension of 1.5 g of ketal (**9**) in 50 ml of 70% aqueous acetic acid was warmed at 80°C for 30 min. After dissolution of the crystals, new crystals gradually separated, which were then extracted with ether. The ether extract was washed with saturated sodium chloride solution and with water, dried and evaporated. Recrystallization of the residue (1.3 g) from a mixture of hexane and methylene chloride gave 1.07 g of **10** (83.6%), mp 140—141°C (decomp.); UV max (95% C_2H_5OH): 264 mμ (ε 1840), 270 (2700), and 276 (2810); IR (CCl_4) cm^{-1}: 1775 and 1800 (C=O); PMR ($CDCl_3$) δ: ~7.05 (4, aromatic), 6.20 (t, 2, CH=CH), 3.66 (2, s, C_1,C_8–H), 3.10 (qui, 2, C_3,C_6–H), 2.29 (qua, 2, C_2,C_7–H), and 1.45 (s, 6, CH_3).

Found: C, 86.77; H, 6.92%. Calcd for $C_{19}H_{18}O$: C, 86.98; H, 6.91%.

Thermal Decomposition of 10 in the Presence of Maleic Anhydride. A solution of **10** (525 mg, 0.002 mol) and maleic anhydride (1.96 g, 0.02 mol) in 50 ml of dioxane was heated under reflux for 16 hr. Evaporation of the solvent followed by washing with ether to remove excess maleic anhydride yielded 478 mg of the adduct **12**. Recrystallization from a mixed solvent of methylene chloride and ether gave a pure sample, mp>230°C; IR ($CHCl_3$) cm^{-1}: 1756 and 1776 (acid anhydride); PMR ($CDCl_3$) δ: 6.10 (qua, 2, CH=CH), 3.52 (s, 2, C_1,C_8–H), 3.35 (broad m, 2, C_3,C_6–H), 3.00 (t, 2, COCH–CHCO), 1.90 (broad s, 2, C_2,C_7–H), 1.45 (s, 6, CH_3).

Found: C, 79.22; H, 6.18%. Calcd for $C_{22}H_{20}O_3$: C, 79.49; H, 6.06%.

Generation of Dimethylisobenzofulvene (5) and its Dimer (15). Method A. A solution of 510 mg of ketone **10** in 50 ml of dioxane was heated under reflux for 16 hr. Evaporation of the solvent yielded 333 mg of **15**, mp 155—156°C (ether-petroleum ether); mass spectrum (70 eV) *m/e* 312 (parent peak); molecular weight by osmometry 321; UV max (ether): 262 mμ (ε 12800), 268 (12500), and 274 (10800); PMR ($CDCl_3$) for δ, see Fig. 1; $J_{1.29,3.62}$=3.5 Hz[20] and positive allylic coupling $J_{3.62,5.96}$ and metabenzylic coupling $J_{7.51,3.62}$.

Found: C, 92.54; H, 8.04%. Calcd for $C_{21}H_{21}$: C, 92.26; H, 7.74%.

The decomposition of **10** was completed within 2 hr in boiling *o*-dichlorobenzene.

Method B. To a solution of 182 mg of 9-isopropylidenebenzonorbornadiene (**6**) in 5 ml of dioxane were added portionwise crystals of 236 mg of 3,6-di(2'-pyridyl)-*S*-tetrazine which dissolved gradually. The reaction proceeded with evolution of nitrogen to give the adduct **14**. Heating the

dioxane solution at 50°C caused decomposition of **14**, giving **15** and 3,6-di(2′-pyridyl)pyridazine, mp 176—177°C in the absence of a trapping reagent.

Reaction of **5** *with Dimethyl Maleate.* Generation of **5** was conducted in the presence of dimethyl maleate by heating a dioxane solution of **10** at 100°C or one of **14** at 50°C. The results obtained are given in Table 1. The product was isolated by preparative vpc performed on a Yanagimoto gas chromatograph GCG-3 equipped with a 1 m × 14 mm stainless steel column packed with 5% diethylene glycol succinate on Chromosorb W.

The *exo-cis* adduct **16**, mp 157—158°C; UV max (95% C_2H_5OH): 262 mμ (ε 1340), 268 (2010), and 274 (2080); IR (CCl_4) cm^{-1}: 1749 (COOMe); PMR ($CDCl_3$) δ: ~7.13 (4, aromatic), 4.08 (2, s, C_1,C_4–H), 2.79 (s, 2, C_2,C_3–H), and 1.71 ppm (s, 6, $C\underline{H}_3$).

Found: C, 71.83; H, 6.56%. Calcd for $C_{18}H_{20}O_4$: C, 71.98; H, 6.71%.

The *endo-cis* adduct **17**, mp 145.5—146°C; UV max (95% C_2H_5OH): 261 mμ (ε 995), 267 (1510), and 274 (1510); IR (CCl_4) cm^{-1}: 1749 and 1731 (COOMe); PMR ($CDCl_3$) δ: 7.18 (4, aromatic), 4.05 (split t, 2, C_1,C_4–H), 3.40 (overlapped with $COOC\underline{H}_3$, 2, C_2,C_3–H), and 1.61 ppm (s, 6, $C\underline{H}_3$).

Found: C, 72.04; H, 6.76%.

The presence of dimethyl fumarate yielded the *trans* adduct **18**, mp 89—90°C; UV max (95% C_2H_5OH): 261 mμ (ε 1120), 267 (1680), and 274 (1720); IR (CCl_4) cm^{-1}: 1740 (COOMe); PMR ($CDCl_3$) δ: 7.20 (4, aromatic), 4.19 (s, 1, C_1–H), 4.15 (X part of AMX type, 1, C_4–H), 3.55 (M of AMX, 1, C_3–H), 2.95 (A of AMX (doublet), 1, C_2–H), 1.68 (s, 3, $C\underline{H}_3$), and 1.60 (s, 3, $C\underline{H}_3$).

Found: C, 72.08; H, 6.64%.

Reaction of **5** *with Tropone.* A mixture of 1 g (0.382 mmol) of **10** and 4.05 g (3.82 mmol) of tropone was heated at 120°C in the dark under argon atmosphere for 30 min. Removal of excess of tropone under reduced pressure left 1.02 g of crystals which were recrystallized from ether to yield a pure sample of **19**, mp 120.5—121.5°C; UV max (95% C_2H_5OH): 224 mμ (ε 21400) and 259 (11100); IR (CCl_4) cm^{-1}: 1657 (C=O); PMR ($CDCl_3$) for δ, see Fig. 2; $J_{5.68,6.70}$=12.0 Hz, $J_{6.70,3.08}$=8.7, $J_{5.68,3.08}$≈0.2, $J_{3.89,5.68}$=1.7, $J_{6.22,6.37}$=11.5, $J_{6.22,3.89}$≈8, $J_{3.08,6.37}$≈8, $J_{3.08,6.22}$=1.7, $J_{3.89,6.37}$=1.7, and positive allylic coupling $J_{6.49,3.68}$.

Found: C, 86.75; H, 6.89%. Calcd for $C_{19}H_{18}O$: C, 86.98; H, 6.91%.

Passing **19** through an alumina column gave the double bond isomer **20**; mp 107—108.5°C; UV max (95% C_2H_5OH): 238 mμ (ε 10100) and 261 (8950); IR (CCl_4) cm^{-1}: 1680 and 1662 (one split absorption, C=O); PMR ($CDCl_3$) δ: ~6.75 (m, 1, vinyl β to CO), ~6.2 (m, 2, $C\underline{H}$=$C\underline{H}$), 5.85 (d of d, 1, vinyl α to CO), 4.37 (d of m, 1, bridgehead α to CO in cycloheptadienone moiety), 3.37 (s, 2, benzyl), and 3.19 ppm (m, 1, bridgehead γ to CO in cycloheptadienone moiety).

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka

(Received December 15, 1971)

The oxidation of styryl acetate, vinyl acetate, vinyl propionate, methyl acrylate, and methyl cinnamate with $RhCl(PPh_3)_3$ catalyst has been studied. The reaction is remarkably affected by the substituent on an olefinic carbon atom. The oxidation mechanism was discussed in connection with decarbonylation.

Recently we reported on the oxidation of olefins catalyzed by rhodium complexes to give carbonyl compounds.[1] Oxidation products could be classified into two types, the carbon-carbon double bond cleavage products and the noncleavage products. The carbonyl compounds formed by olefin oxidation underwent decarbonylation.

We investigated rhodium complex catalyzed oxidation of some vinyl esters bearing a carbonyl group in connection with decarbonylation reaction. It was found that the formation of two type oxidation products is greatly affected by the site of the carbonyl group on olefins.

In this paper the oxidation of vinyl esters is described and discussed in relation to the substituent effect of olefins.

Results and Discussion

The olefin oxidation catalyzed by rhodium complex was carried out by heating mixtures of the reactant vinyl ester and the rhodium complex in toluene or ethanol for 8 hr under a constant bubbling of oxygen. The results are summarized in Table 1, showing that $RhCl(PPh_3)_3$ complex is a good catalyst.

Oxidation of Styryl Acetate. Heating of styryl ace-

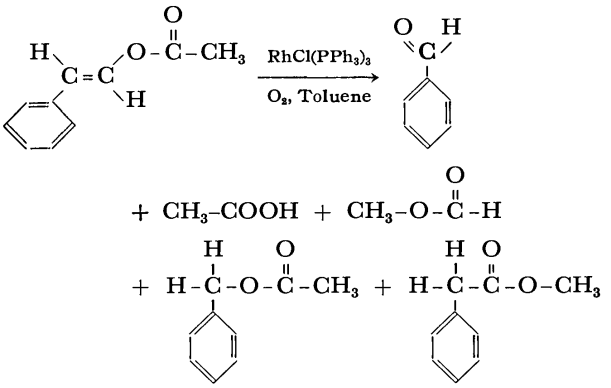
Table 1. Oxidation of vinyl esters by $RhCl(PPh_3)_3$

Olefin	Solvent	Oxidation products: C=C bond cleavage	Oxidation products: Noncleavage	Decarbonylation products
Styryl acetate[b]	Toluene	Benzaldehyde (403%)[a]	Benzyl acetate (10%)	
		Acetic acid (240)	Methyl phenylacetate	
		Methyl formate (157)	(trace)	
	Ethanol	Benzaldehyde (trace)	Benzyl acetate (56)	Benzyl methyl ketone (29%)
			Methyl phenylacetate (trace)	
Vinyl acetate[c]	Toluene		Methyl acetate (24)	Acetone (93)
				Propionaldehyde (15)
				Methyl vinyl ether (trace)
	Ethanol		Methyl acetate (238)	Acetone (110)
				Propionaldehyde (trace)
				Methyl vinylether (trace)
Vinyl propionate[c]	Toluene		Ethyl acetate (91)	Methyl ethyl ketone (83)
			Methyl propionate (trace)	Ethyl vinyl ether (10)
				Butyraldehyde (5)
Methyl cinnamate[b]	Toluene	Benzaldehyde (125)	Methyl phenylacetate (20)	
		Methyl formate (110)		
	Ethanol	Benzaldehyde (5)	Methyl phenylacetate (93)	
		Methyl formate (trace)		
Methyl acrylate[c]	Toluene		Methyl acetate (315)	
	Ethanol		Methyl acetate (837)	

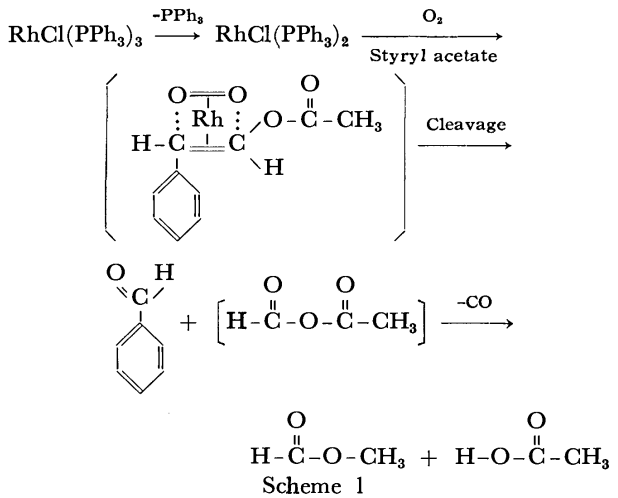
a) Yields are based on the catalyst utilized.
b) Olefin (30 mmol), $RhCl(PPh_3)_3$ (1.3 mmol), Reaction temp. 80°C, Reaction time 8 hr.
c) Olefin (60 mmol), $RhCl(PPh_3)_3$ (1. 3mmol),Reaction temp. 70°C, Reaction time 8 hr.

tate (*cis* and *trans* mixture) in toluene gave benzaldehyde (403%),[2] acetic acid (240%), and methyl formate (157%) as the main product with benzyl acetate (10%), and methyl phenylacetate (trace).



The formation of these oxidation products might be explained in the following way: The main products such as benzaldehyde, acetic acid and methyl formate are derived from the double bond cleavage of styryl acetate. Presumably a four-center intermediate in which both oxygen molecule and olefin coordinate to rhodium(I) is formed as shown in scheme 1.

The cleavage of C=C and O=O bonds of the intermediate would give benzaldehyde and acid anhydride of formic and acetic acids. This four-center type intermediate has been proposed in the reaction of singlet oxygen molecule and indene.[3] The acid anhydride of



Scheme 1

formic and acetic acids formed would undergo decarbonylation by the rhodium complex to give acetic acid and methyl formate. From the solid phase of the reaction mixture, $RhCl(CO)(PPh_3)_2$ and unidentified complexes (ν_{CO}: 2055 cm^{-1}) were obtained. We confirmed that acid anhydrides, such as acetic anhydride could be easily decarbonylated to give ester compounds by $RhCl(PPh_3)_3$.[4]

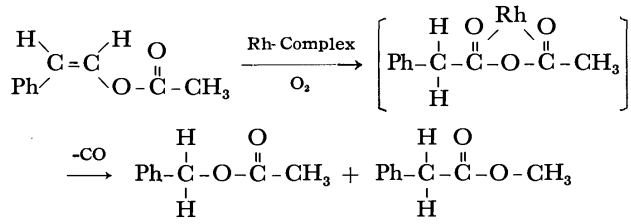
The formation of a small amount of benzyl acetate and methyl phenylacetate classified as the noncleavage oxidation products might take place in the following way: the addition of oxygen to bond of styryl acetate followed by a hydrogen shift would give an anhydride of acetic and phenylacetic acids. The anhydride would be further decarbonylated to benzyl ace-

2) Yields of the oxidation products which appear hereafter in this paper are all based on the amount of the complexes used.

3) W. Fenical, D. R. Kearns, and P. Radlick, *J. Amer. Chem. Soc.*, **91**, 3396 (1969).

4) J. Blum and Z. Lipshes, *J. Org. Chem.*, **34**, 3076 (1969).

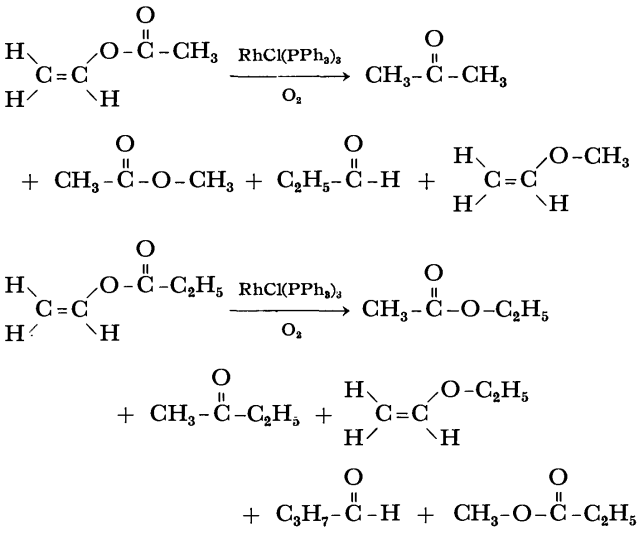
tate and methyl phenylacetate as shown below.



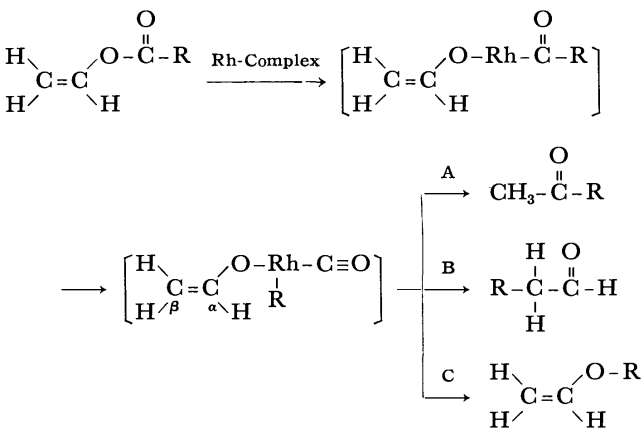
Scheme 2

Table 1 also shows that the oxidation of styryl acetate undergoes a similar remarkable solvent effect as styrene.[1b] In ethanol solvent, the double bond cleavage hardly takes place at all.

Oxydation of Vinyl Acetate and Propionate. In the oxidation of vinyl acetate and propionate in toluene, no double bond cleavage products were obtained. However, acetone (93%) and methyl ethyl ketone (83%) were obtained in marked contrast to the case of styryl acetate.



The products acetone, propionaldehyde and methyl vinyl ether from vinyl acetate, and methyl ethyl ketone, butyraldehyde and ethyl vinyl ether from vinyl propionate might be explained in terms of decarbonylation of the starting vinyl carboxylates as shown in scheme 3.



Scheme 3

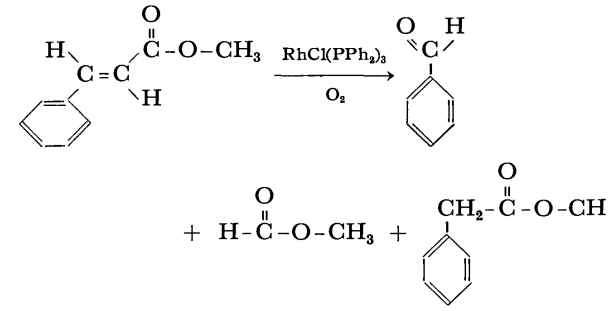
Presumably vinyl propionate is added oxidatively to the rhodium complex $RhCl(PPh_3)_2$ forming a vinyloxy acyl-rhodium complex. The acyl complex would then be converted into an alkyl carbonyl complex through acyl-alkyl rearrangement.[5] The decomposition of the complex followed by the recombination of the ligands would give the products.[6]

Ethyl acetate and methyl propionate may be derived from the noncleavage oxidation of vinyl propionate. Similarly methyl acetate from vinyl acetate as in the case of styryl acetate oxidation.

It should be noted that styryl acetate undergoes oxidation with the C=C bond cleavage, but not vinyl acetate or vinyl propionate. It might be that styryl acetate having an electron withdrawing phenyl group can form more easily the four-center intermediate described above than vinyl carboxylates.[7]

Oxydation of Methyl Cinnamate and Acrylate. Methyl cinnamate and acrylate were chosen as the reactant in order to investigate the conjugation effect between the C=C and C=O groups on oxidation and decarbonylation.

Oxidation of methyl cinnamate in toluene gave benzaldehyde (125%), methyl formate (110%) and methyl phenylacetate (20%). In contrast to the oxidation of vinyl esters bearing no carbonyl group on an olefinic atom, no decarbonylation products was obtained. No C=C bond cleavage oxidation was observed in the case of methyl acrylate which has no phenyl group on the olefinic carbon atom.



The result suggests that the conjugation of the carbonyl group with the C=C bond prevents decarbonylation reaction.

In conclusion, vinyl esters undergo oxidation smoothly by the rhodium triphenylphosphine complex, and the product distribution is influenced by the substituent on olefins.

Experimental

Materials and Analysis. All the temperatures were uncorrected. The IR spectra were recorded on a JASCO IR-E spectrometer. The NMR spectra were measured on a Japan Electron Optics JNM-4H-100 spectrometer. Chemical shifts are given in τ units together with splitting patterns

6) No reaction occurring in argon atmosphere in place of O_2 suggests that O_2 plays an important role. Details of the behavior, however, are not apparent yet.

7) M. S. Kharash, R. C. Seyler, and F. R. Mayo, *J. Amer. Chem. Soc.*, **60**, 882 (1938).

and relative integrated area. Vpc analysis was carried out with a Yanagimoto G-8 gas chromatograph using Apiezon-L, Silicone OV-17, diethyl phthalate columms. $PhCl(PPh_3)_3$ was prepared by the method of Osborn *et al.*[8] Styryl acetate (*cis* and *trans* mixture) was prepared according to the method of Semmler.[9] Vinyl acetate, vinyl propionate, methyl cinnamate, and methyl acrylate were of commercial grade and dried over anhydrous magnesium sulfate and distilled before use. Toluene and ethanol were purified as mentioned previously.[1]

Oxidation of Styryl Acetate. In a flask described previously,[1] was charged a mixture of 1.21 g (1.3 mmol) of $RhCl(PPh_3)_3$, 4.96 g (30 mmol) of styryl acetate (*cis* and *trans* mixture) and 75 m*l* of toluene. The mixture was heated at 80°C with a constant bubbling of oxygen for 8 hr. The resulting mixture was concentrated and the liquid phase was analyzed and isolated by vpc to give 0.555 g (403%) of benzaldehyde (I), 0.187 g (240%) of acetic acid (II), 0.122 g (157%) of methyl formate (III), 0.020 g (10%) of benzyl acetate (IV) and a trace of methyl phenylacetate (V). These compounds were identified by comparison with authentic samples. Compound I: IR (neat): 685, 744, 1200, and 1675 cm^{-1}; NMR (CCl_4): 0.15 (s, 1) and 2.10—2.70 (m, 5). Compound II: NMR (CCl_4): —1.35 (s, 1) and 7.90 (s, 3). Compound III: NMR (CCl_4): 1.92 (s, 1) and 6.23 (s, 3). Compound IV: IR (neat): 710, 765, 1240, 1380, and 1740 cm^{-1}; NMR (CCl_4): 2.73 (s, 5), 4.99 (s, 2), 7.99 (s, 3).

The residual solid material was chromatographed on a silica gel column (50 g). Elution with benzene (300 m*l*) gave dark brown carbonyl complexes. Separation of the complexes by column chromatography (silica gel, 15 g) gave $RhCl(CO)(PPh_3)_2$ (0.1 g) and unidentified complexes (ν_{CO}: 2055 cm^{-1}) (0.5 g). Further elution with ether (300 m*l*) gave triphenylphosphine oxide.

Oxidation of Vinyl Acetate. The same procedure was used as for styryl acetate. Reaction products were methyl acetate (VI), acetone (VII), propionaldehyde (VIII), and methyl vinyl ether (IX). These compounds were assigned by comparison of NMR spectra and retention times with those of authentic samples. Compound VI: NMR (CCl_4): 6.35 (s, 3) and 7.99 (s, 3). Compound VII: NMR (CCl_4): 7.94 (s).

Oxidation of Vinyl Propionate. The same procedure was used as above. Reaction products were ethyl acetate (X), methyl ethyl ketone (XI), ethyl vinyl ether (XII), butyraldehyde (XIII), and methyl propionate (XIV). The compounds were identified by a comparison of NMR and retention time with those of authentic samples. Compound X: NMR (CCl_4): 5.94 (q, 2), 8.05 (s, 3), and 8.77 (t, 3). Compound XI: NMR (CCl_4): 7.53 (q, 2), 7.87 (s, 3), and 8.95 (t, 3).

Reaction of Acetic Anhydride with Rhodium Complex. In a flask as described above was placed a mixture containing 0.61 g (0.65 mmol) of $RhCl(PPh_3)_3$, 6.12 g (60 mmol) of acetic anhydride and 50 m*l* of toluene. The reaction was carried out at 80°C with a constant bubbling of oxygen for 8 hr. The resulting reaction mixture was treated as usual and the liquid phase was analyzed and separated by vpc to give 3.76 g (2.550%) of methyl acetate. The solid phase was chromatographed on silica gel (25 g) to give triphenylphosphine oxide and $RhCl(CO)(PPh_3)_2$ (0.40 g).

The Additive Effect of Triphenylphosphine on the Polymerization of Vinyl Monomers by Copper(II) Chelates

Toshiyuki SHONO, Yuko YAMASHOJI, and Koichiro SHINRA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-Kami, Suita, Osaka

(Received November 1, 1971)

Various copper(II) chelates were found to be effective initiators in the polymerization reaction of the methyl methacrylate in the presence of triphenylphosphine. The conversion increases with an increase in the concentration of triphenylphosphine, reaching a constant level at the ratio of 1 : 2 between copper chelates and triphenylphosphine. Di-μ-methoxo-bis(ethylacetoacetato)dicopper(II) was the most effective initiator. The dependence of the rate of the polymerization on the square root of the concentration of the complexes suggests that the polymerization by this initiation system proceeds *via* a radical mechanism. It can be assumed that the copper chelate coordinated the triphenylphosphine and that homolytic fission occurred to give a free ligand radical, accompanied by the reduction of the central copper atom. Stable copper(I) mixed chelates were obtained under conditions similar to those of the polymerization.

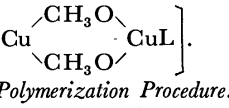
The radical polymerization of vinyl monomers by using copper acetylacetonate [$Cu(acac)_2$] and its derivatives as catalysts has been reported.[1-3] The solvent effects and effects resulting from the additives, as well as a high order with respect to the monomer, are characteristic of these polymerization reactions. These characteristics indicate the participation of monomers and additives in the initiation step. Recently, Bamford and Ferrar[4] showed by radiochemical investigations that donor additives enhance the rates of the initiation of free radical polymerization by transition-metal acetylacetonate and that the propagating chain carries one acetylacetonate residue, but that the fragments derived from the additives are incorporated in the polymer to only a minor extent.

In the present study, various copper(II) chelates were found to be effective initiators in the polymerization reaction of the vinyl monomer in the presence of triphenylphosphine.

During the initiating step, a ligand displacement is supposed to occur, with the simultaneous reduction of Cu(II)→Cu(I). Various Cu(I) triphenylphosphine mixed chelates were separated.

Experimental

Materials. The monomer was purified by the usual method and was distilled under reduced pressure before use. The triphenylphosphine was recrystallized several times from ether. The methoxo-copper(II) chelates were synthesized according to the method of Bertrand[5]; that is, the copper chelate, CuL_2, was allowed to react with potassium hydroxide in methanol to produce the methoxo complexes,



Polymerization Procedure. A copper chelate, the monomer, and the solvent were placed in a glass tube. After the tube had been degassed by repeated freezing, evacuating, and thawing, it was sealed off. Polymerization was carried out under shaking in a thermostat maintained at a given temperature. The resulting polymers were precipitated in methanol containing hydrochloric acid, filtered, and dried *in vacuo* to a constant weight.

Measurements. The NMR spectra were measured in order to determine the tacticities of the poly(methyl methacrylates) according to the method of Kato.[6]

Polarographic measurements were carried out in acetonitrile with a Yanagimoto potential-controlled Polarograph at 25°C. Tetrabutylammonium perchlorate was used as the supporting electrolyte, and Triton X was added to each solution in order to diminish the maximum wave.

Result and Discussion

Additive Effect of Triphenylphosphine. Copper(II) acetylacetonate and di-μ-methoxo-bis(acetylacetonato)-dicopper(II) $[Cu(acac)OCH_3]_2$ each has its own accelerative effect on the polymerization of various vinyl monomers in organic solvents. Tables 1 and 2 show the remarkable accelerative effects of triphenylphosphine on the polymerization of methyl methacrylate (MMA) by copper(II) chelates. The accelerative effects of μ-methoxo copper(II) complexes were superior to those of the original copper(II) chelates. The methoxo ethyl acetoacetate chelate was the most effective.

The stereoregularity of the resulting polymer was calculated from the NMR spectra. The syndiotacticities were slightly higher than those of ordinary polymers

obtained by radical polymerization. (74.0%, polymerized by $[Cu(eacac)OCH_3]_2$ at 20°C; 68.8%, polymerized by $Cu(acac)_2$ at 50°C; 65.6%, at 70°C.)

Figure 1 shows the dependence of the conversion on the concentration of triphenylphosphine. The conversion increases with an increase in the concentration of triphenylphosphine, reaching a constant level at the ratio of 1:2 of the copper chelate and triphenylphosphine. Above this ratio, the polymerizing mixture loses its blue color at the end of the polymerization. In the absence of copper(II) chelates, traces of the polymer were obtained in the presence of 0.1 mol/l of triphenylphosphine ([MMA]: 5 mol/l).

TABLE 3. SOLVENT EFFECTS ON THE POLYMERIZATION RATE IN $[Cu(acac)OCH_3]_2$–PPh_3 SYSTEM

Solvent	Rate of polymerization (mol/l/sec)
Acetonitrile	7.09×10^{-5}

be stabilized by acetonitrile.[7]

Kinetics. From the straight line in the time-conversion plots, the rates of polymerization were evaluated by graphically determining a tangent at a given time. The dependences of the rate of polymerization on the square root of the concentrations of the four complexes are shown in Fig. 2. Figure 3 shows the rate of polymerization as a function of the monomer concentration at a constant concentration of copper chelates and additives. From the slopes of these straight lines, the order with respect to the monomer was found to be 1.0. Judging from this order, the coordination of the monomer to the copper chelate cannot be considered at the initiation step. It can be assumed that the Cu(II) chelate coordinated the triphenylphosphine and that homolytic fission occurred to give a free-ligand radical or an alkoxy radical, accompanied by the reduction of the central copper atom.

The reduction potentials of the copper(II) chelates were measured and plotted against the rate of polymerization. A good linearity was obtained (see Fig. 4).

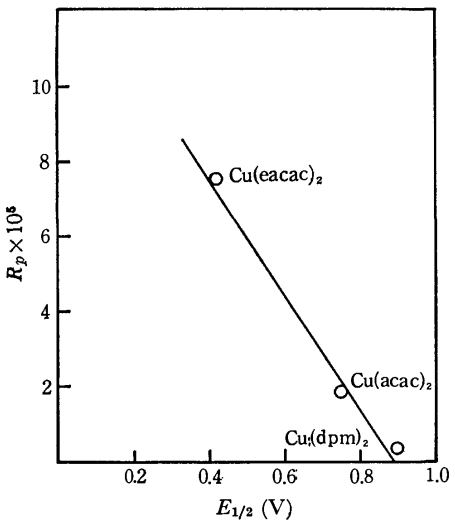

Fig. 4. The relationship between the reduction potentials of the copper(II) chelates and the rate of polymerization (Table 2).

(Received December 18, 1971)

The reaction of 2-dimethoxymethyl-3-methoxypropionitrile (**1**) with acetamidine produces pyrimidopyrimidine (**8**) *via* the consecutive process of **1**→an intermediate→**8**. The intermediate was not isolated, but two structures have been proposed for it. We have now succeeded in the isolation of the intermediate and determined it to be 2-methyl-4-amino-5-dimethoxymethyl-5,6-dihydropyrimidine (**4**). Several key intermediates were also successfully isolated. The novel reaction pathway for the title reaction was concluded to be as follows: the elimination of methanol from **1**, followed by the addition of acetamidine affords 3-acetamidinopropionitrile (**3**), the subsequent quick cyclization of which produces the intermediate, **4**; the further elimination of methanol from **4**, followed by a replacement reaction with acetamidine, gives an acetamidinomethylene compound (**6**), which is converted into the final product, **8**, *via* an intermediate (**7**). Some minor pathways will also be presented.

Although it has been known that enol ether and acetal derivatives of α-formylnitriles react with amidines to give the same final products,[3-5] Takamizawa and his co-workers have reported an unusual result on 2-formyl-3-alkoxypropionitriles.[6] When treated with acetamidine, 2-methoxymethylene-3-methoxypropionitrile (**12**) of an enol ether-type affords 2-methyl-4-amino-5-methoxymethylpyrimidine (**13**) of the usual type,[7] but 2-dimethoxymethyl-3-methoxypropionitrile (**1**) of an acetal type yields 2,7-dimethyl-5,6-dihydropyrimido-[4,5-*d*]pyrimidine (**8**) *via* an intermediate showing the absorption maximum at 262 mμ in methanol in the UV spectrum. An unusual product, **8**, is also obtained from 2-dimethoxymethylacrylonitrile (**2**); this reaction can be explained in terms of the fast conversion of **2** into **1** at the initial stage. As the hydrolyses of **8** give 2-methyl-4-amino-5-acetamidomethyl- (**9**) and 2-methyl-4-amino-5-aminomethylpyrimidine (**10**) quantitatively,[8] the reaction of **1** (or **2**) is very important for thiamine production. However, the reaction mechanism is not unequivocally established because of the unsuccessful isolation of the intermediate. For the structure of the intermediate, 2-acetamidinomethylene-3-methoxypropionitrile (**14**) has been proposed on the basis of a comparison with the reaction of 2-aminomethylene-3-alkoxypropionitrile with methyl acetimidate.[6] On the other hand, in view of the behavior of **1** under basic conditions we have proposed a revised structure, 2-methyl-4-amino-5-dimethoxymethyl-5,6-dihydropyrimidine (**4**), which would be formed *via* the pathway of **1**→**2**→2-dimethoxymethyl-3-acetamidinopropionitrile (**3**)→**4**.[1] The present investigation was carried out in order to establish the exclusive reaction pathway by isolating the intermediate.

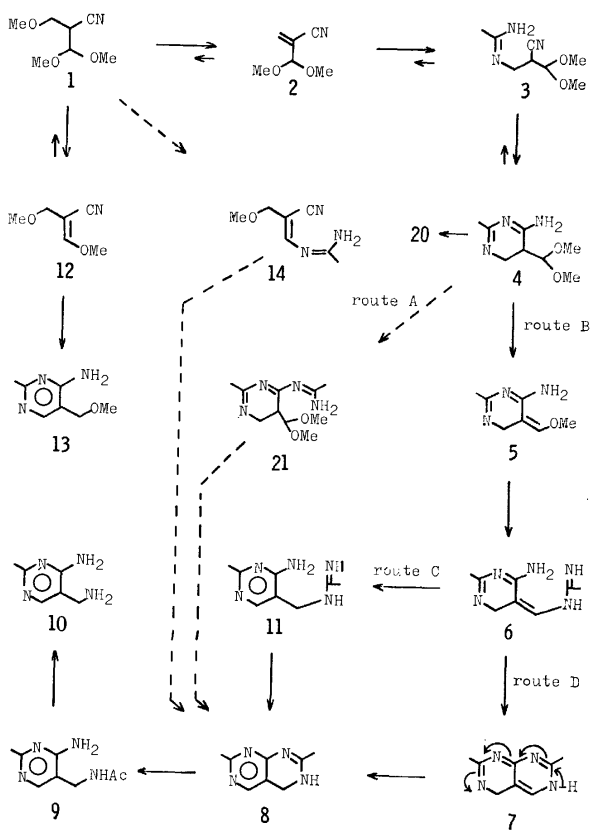

Chart 1

The reaction of **1** with acetamidine in methanol can be generalized into the equation of **1**→the intermediate →**8**.[6] Although the first step of this consecutive process proceeds even at room temperature to some extent, a reflux temperature and another one mole of acetamidine are required to conclude the second step. For the iso-

lation of the intermediate, the retardation of the rate of second step is naturally necessary, so it seemed to be desirable to use a relatively low reaction temperature and to deactivate the remaining acetamidine by neutralizing it when the formation of the intermediate to a considerable amount was observed.

The lack of success in the isolation of the intermediate has long been attributed to its instability. If the intermediate is **4**, it is conventionally isolated as a hydrochloride, since 4-amino-5,6-dihydropyrimidines are stable as hydrochlorides.[9] On the preparation of hydrochloride of **4**, however, the presence of moisture and an excess of hydrogen chloride should be avoided, because 4-amino- and 5-dimethoxymethyl (acetal) groups of **4** can easily be hydrolyzed under acidic conditions.[1]

When a solution of **1** and acetamidine in anhydrous methanol was kept at 55°C for 1 hr, the characteristic band due to the intermediate appeared strongly in the UV spectrum. To the solution, methanolic hydrogen chloride was added in amounts strictly equimolar with the acetamidine used, and then the solution was concentrated. The repeated recrystallization of the crystals which appeared gave a hydrochloride whose analytical data corresponded to those of the hydrochloride of **4**. The yield was about 44%. Its UV spectrum in methanol showed an absorption maximum at 278 mμ which was shifted to 262 mμ on neutralization. The reaction of the hydrochloride with acetamidine showed a consecutive increase in the absorbancy due to **8** at 305 mμ, and from the reaction mixture **8** was isolated. Therefore, the hydrochloride was identified as the hydrochloride of the intermediate.

The spectral data suggested that the intermediate was **4**. It showed a behavior similar to that of 2-methyl-4-amino-5,6-dihydropyrimidine (**18**)[1] in the UV spectrum, as has been described above, signals due to an acetal group (two singlets due to methyls at 3.32 δ and 3.37 δ and one doublet (J=7.5 Hz) due to the methine proton (H_Y) at 4.48 δ) in the NMR (DMSO-d_6), but no characteristic band due to a nitrile group in the IR. The signals of the remaining protons in the NMR also consisted of **4**. The H_6 signals constitute the AB portion (3.75 δ and 3.63 δ) of an ABXY system, whose X and Y portions are H_5 (3.10—3.40 δ) and H_Y respectively. The 2-methyl signal appears at 2.33 δ as a broad singlet due to homoallylic coupling with H_6.[1]

The treatment of the intermediate with p-quinone in benzene gave 2-methyl-4-amino-5-dimethoxymethylpyrimidine (**15**).[10] Therefore, the structure of the intermediate was established as **4**. Much as in the acid-catalyzed hydrolysis of **18** to 2-methyl-3*H*-4-oxo-5,6-dihydropyrimidine (**19**),[1] **4** was easily hydrolyzed to a 4-oxo-compound (**16**), whose structure was confirmed by the UV spectrum in methanol to show behavior similar to that of **19** and by the NMR spectrum to show a pattern quite similar to that of **4**. The reaction of **4** with methylamine gave a transaminated compound (**17**). The presence of an *N*-methyl signal[11] in the NMR supported this structure. Further, the treatment of **4** with sodium methoxide gave **13**. Therefore, the structure of the intermediate was unequivocally established as **4**.

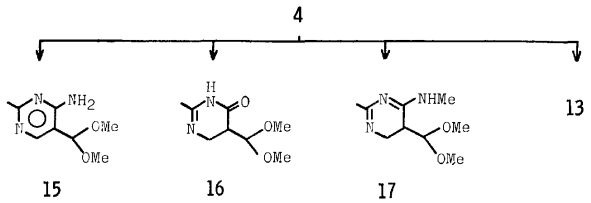

Chart 2

The establishment of the structure of the intermediate clearly supported our idea that the first step in the reaction of **1** with acetamidine proceeds *via* the pathway of **1**→**2**→**3**→**4**.[1]

The treatment of **2** with acetamidine at 0°C in the absence of methanol, followed by neutralization with hydrogen chloride, gave another hydrochloride, whose elementary analytical data agreed with those of the hydrochloride of **4**. This hydrochloride showed the characteristic band due to a non-conjugate nitrile group in the IR spectrum and was quickly converted into **4** upon neutralization. Therefore, it was identified as the hydrochloride of **3**. The UV spectrum, showing an absorption maximum similar to that of acetamidine hydrochloride, and the NMR, showing the presence of an acetal group, a CH_2–$\underset{|}{\overset{|}{C}}$–H moiety, and a C-methyl group, also supported the structure. The fast reactions of **2**→**3** and **3**→**4** suggested that the step, **1**→**2**, was rate-determining in the first step. The fact that **2** was hardly detected in the tlc of the reaction of **1** with acetamidine also supported this idea.

The heating of **4** in the absence of acetamidine, followed by hydrolysis, gave **9** in a 25% yield. This means the existence of the reverse reaction of **4**, that is **4**→**3**→**2**+acetamidine, which reacted with **4**. Therefore, the first step, **1**→**4**, should be expressed as follows: **1**⇌**2**⇌**3**⇌**4**.

A minor product (**20**) was isolated from the above reaction. The analytical data and mass spectrum determined that it was a dimeric substance, $C_{14}H_{22}N_6O_2 \cdot HCl$, which was thought to be formed from the dimerization of **4** by the elimination of two moles of methanol. The compound **20** was also detected in the reaction of **1** or **4** with acetamidine to a limited extent. Studies of the structure of **20** will be reported separately.

A small amount of **13** was newly obtained from the reaction of **1** with acetamidine. However, it was not isolated from the reaction of **4**. This fact suggested that **13** was formed *via* the pathway of **1**→**12**→**13**. Consequently, the existence of an equilibrium **1**⇌**12** under basic conditions due to the presence of an acetamidine base was confirmed.

On the basis of above facts, the reaction process of **1** with acetamidine should be **1**⇌**2**⇌**3**⇌**4**→**8**, in which

$$\begin{array}{ccc} \mathbf{1} & \rightleftarrows & \mathbf{2} \\ \Downarrow & & \\ \mathbf{12} & \rightarrow & \mathbf{13} \end{array} \qquad \begin{array}{ccc} \rightleftarrows & \mathbf{3} & \rightleftarrows & \mathbf{4} & \rightarrow & \mathbf{8}, \\ & & & \downarrow & & \\ & & & \mathbf{20} & & \end{array}$$

1→**2**→**3**→**4**→**8** is most important.

11) R. H. Bible, "Interpretation of NMR Spectra," Plenum Press, New York (1965), p. 16.

The second step, **4**→**8**, presented further interesting problems. For this step, two pathways route A (**4**→**21**→**8**) and route B (**4**→**5**→**6**→**8**), are possible (see Chart 1). If the reaction proceeds *via* route A, the reaction of **4** with methyl acetimidate can be expected to give **8** in a yield similar to that in the reaction with acetamidine.[8,12] However, the yield of **8** in the reaction with acetimidate was only 17%, which was similar to that from the reverse reaction of **4**. Further, the starting materials were recovered from the reaction of **18** or its phenyl analog **22**[13] with acetamidine. No transaminated compounds, such as **23** and **24**, were obtained from either reaction. Therefore, the possibility of the reaction pathway *via* route A was excluded.

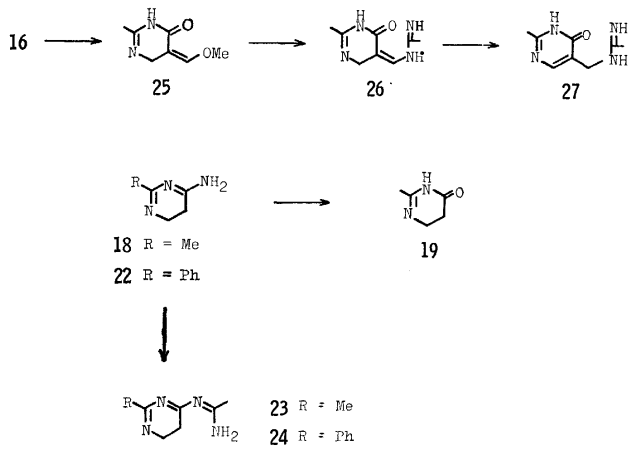

Chart 3

To examine the possibility of the pathway *via* route B, the reaction of a deaminated compound, **16**, was attempted. When treated with acetamidine in methanol at reflux temperature, **16** gave **27**, which was then purified as its dihydrochloride, $C_8H_{12}N_4O \cdot 2HCl$. The spectral data suggested that it was 2-methyl-3*H*-4-oxo-5-acetamidinomethylpyrimidine. The UV spectrum showed the characteristic band due to 2-methyl-4-hydroxypyrimidines in acidic or in alkaline media,[14,15] while the NMR spectrum showed signals due to methyl groups at C_2 position, and at the acetamidino moiety, the 5-methylene group and the pyrimidine-ring proton. It is quite natural to consider that the reaction of **16** proceeds *via* the pathway of **16**→**25**→**26**→**27**. Consequently, route B can be proposed as a reliable pathway. If this idea is probable, **16** and **4** can be said to react with acetamidine at comparable rates. By heating a mixture of one mole each of **4**, **16**, and acetamidine in methanol, **8** and **27** were formed in a 1 : 1 ratio, as expected. Therefore, the second step was confirmed to proceed *via* route B.

Two more pathways can be proposed for the final step of route B. One is route C (**6**→**11**→**8**), and the other is route D (**6**→**7**→**8**) (see Chart 1). For the determination of the predominant pathway, the reaction of **4** with propioamidine was carried out, in

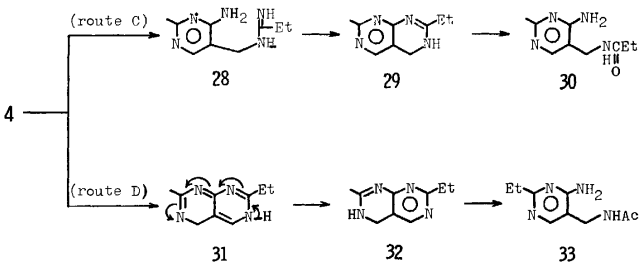

Chart 4

which the reaction product **29** should be formed when the reaction proceeds *via* route C, and **32**, when it proceeds *via* route D (see Chart 4). Both products, **29** and **32**, were easily identified by hydrolysis to 5-propioamidomethylpyrimidine (**30**) and 5-acetamidomethylpyrimidine (**33**) respectively. The heating of **4** and propioamidine in methanol, followed by hydrolysis, gave a mixture of the two pyrimidines in high yields. The major pyrimidine was isolated in a pure state. As the NMR spectrum showed a 3-proton singlet due to an acetyl methyl group, the major one was identified as **33**. The remaining signals also supported the structure; signals due to the ethyl group and singlets due to the methylene group and the pyrimidine-ring proton were observed. The attempt to isolate the minor pyrimidine was unsuccessful because of its low yield and because its solubilities are similar to those of **33**. However, it was identified as **30** by a comparison of the retention times in the gas chromatograms. The authentic sample of **30** was prepared by the propionylation of **10**. The relative ratio of **30** and **33** was about 8 : 92, as determined by gas chromatography. This result clearly revealed that route D is predominant. The existence of a minor route, C, was also supported by the isolation of **11** from a reaction mixture of **1** and acetamidine, though its yield was very poor. Proof of the structure of **11** was provided by a comparison of the IR and mass spectra of an authentic sample, which was prepared by the reaction of **10**[7] with methyl acetimidate.

The presence of an acid, usually acetamidine hydrochloride, was desirable for the accelation of the second step **4**→**8**. This fact seemed to suggest that the elimination of methanol, **4**→**5**, was the rate-determining step. A detailed discussion on the reaction mechanism will be presented kinetically in a following paper.

In conclusion, the reaction of **1** with acetamidine has been established to proceed *via* the major pathway of **1**⇌**2**⇌**3**⇌**4**→**5**→**6**→**7**→**8**, along with the minor one of **6**→**11**→**8** and two side pathways of **1**→**12**→**13** and **4**→**20**.

Experimental

All the melting points were recorded on a Kofler block and have been uncorrected. The NMR spectra were taken with a Varian A-60-A spectrometer, using tetramethylsilane as the internal reference; the chemical shifts were expressed in δ unit (s: singlet, d: doublet, t: triplet, q: quartet, m: multiplet, bs: broad singlet). The UV spectra were observed in methanol. The solvents used were removed under a reduced pressure. The percentages of methanolic sodium methoxide and hydrogen chloride are shown in w/w and the ratios of solvent systems used for the purification, in v/v.

2-Methyl-4-amino-5-dimethoxymethyl-5,6-dihydropyrimidine (4). *(1) Isolation as Its Hydrochloride (4·HCl)*: 2-Dimethoxymethyl-3-methoxypropionitrile (**1**; 147 g) was added to an acetamidine solution, prepared from acetamidine hydrochloride (256 g) and 22% methanolic sodium methoxide (697 g), after which the solution was kept at 55°C. After 1 hr, 30% methanolic hydrogen chloride (220 g) was added to the solution below 10°C. After the concentration of the solution to 450 g, crystals appeared; they were collected by filtration. The repeated recrystallization of the crystals from methanol-ether (9: 1) gave cubics of **4·HCl** (89.7 g), mp 155—160°C (decomp.). UV: 278 (ε 11500); (+NaOH) 262 mμ (ε 7500). Found: C, 43.32; H, 7.45; N, 18.78%. Calcd for $C_8H_{15}N_3O_2\cdot HCl$: C, 43.34; H, 7.28; N, 18.95%.

(2) Reaction with Acetamidine: *(i) Isolation of the Product*: To a solution of sodium (517 mg) in methanol (20 m*l*), we added hydrochlorides of acetamidine (2.125 g) and **4** (1.662 g). The solution was refluxed for 4 hr, filtered from precipitated sodium chloride, and then evaporated to dryness. A solution of the residue in water (5 m*l*) was heated on a boiling-water bath for 1 hr and then evaporated to dryness. The recrystallization of the residue from water gave 2-methyl-4-amino-5-acetamidomethylpyrimidine (**9**; 652 mg); mp 208—209°C.[6]

(ii) Effect of the Presence of Acetamidine Hydrochloride: (a) Hydrochlorides of acetamidine (283 mg) and **4** (321 mg) were added to 6 m*l* of methanolic sodium methoxide [a methanol solution (20 m*l*) containing sodium (431 mg)]. The solution was diluted to 20 m*l* with methanol and then refluxed for 1.5 hr. The yield of **8** was 35%, which was determined using the absorption maximum of **8** at 310 mμ in the UV spectrum. (b) Hydrochlorides of acetamidine (425 mg) and **4** (329 mg) were dissolved in 10 m*l* of methanolic sodium methoxide [a methanol solution (50 m*l*) containing sodium (517 mg)] and then diluted to 20 m*l* with methanol. The solution was refluxed for 1.5 hr, after which the yield of **8** was determined. The yield was 76%.

(3) Dehydrogenation with p-Quinone: The hydrochloride (**4·HCl**, 4.42 g) was neutralized with methanolic sodium methoxide, which had been prepared from sodium (460 mg) and methanol (10 m*l*). The methanol solution was shaken for a few minutes, and quickly filtered from the precipitated sodium chloride, and the methanol was removed. To a benzene solution (250 m*l*) of the residue, we then added *p*-quinone (2.5 g) dissolved in benzene (20 m*l*), after which the solution was refluxed for 3 hr. After cooling, the insoluble materials were eliminated by decantation. The benzene layer was washed with 1N sodium hydroxide (10 m*l*×2) and water (10 m*l*×1), and dried, and the solvent was removed. The subsequent recrystallization of the residue from benzene and *n*-hexane gave 2-methyl-4-amino-5-dimethoxymethylpyrimidine (**15**, 53 mg), mp 107—108°C.[10]

(4) Hydrolysis: 21% Methanolic hydrogen chloride (890 mg) was added to a solution of **4·HCl** (1.1 g) in methanol (20 m*l*) containing water (90 mg) at −30°C. The solution was kept at 0°C for 2 hr, and then the solvent was removed. The recrystallization of the residue gave the hydrochloride of 2-methyl-3*H*-4-oxo-5-dimethoxymethyl-5,6-dihydropyrimidine (**16**) as needles; mp 212—213°C (decomp.). The yield was 816 mg. UV: 228 (ε 6500); (+NaOH) 220 mμ. NMR (DMSO-d_6): 4.75 (d, 1H, C$\underline{H}$(OMe)$_2$, J=4 Hz), 3.37 (s, 6H, OMe), 3.1—3.4 (m, 1H, H_5), 3.6—3.8 (m, 2H, H_6), 2.23 (bs, 3H, –C(–)–Me). Found: C, 43.38; H, 6.34; N, 12.48%. Calcd for $C_8H_{14}N_2O_3\cdot HCl$: C, 43.15; H, 6.74; N, 12.58%.

(5) Reaction with Methylamine: The hydrochloride of **4** (395 mg) was neutralized with methanolic sodium methoxide, which had been prepared from sodium (41 mg) and methanol (17 m*l*). To the solution we then added methylamine (4.6 g) in methanol (30 m*l*). The mixture was kept at room temperature for 2 days, neutralized with 1% methanolic hydrogen chloride (3.5 g), and filtered from the precipitates, and the solvent was removed. The residue was extracted with chloroform. The subsequent removal of the chloroform gave the syrup of 2-methyl-4-methylamino-5-dimethoxymethyl-5,6-dihydropyrimidine hydrochloride (**17·HCl**; 318 mg). No satisfactory elementary analysis was obtained for **17·HCl** because of its hydroscopicities, but the UV and NMR data supported the structure. UV: 280; (+NaOH) 260 mμ. NMR (methanol-d_4): 4.55 (d, 1H, –C$\underline{H}$(OMe)$_2$, J=7 Hz), 3.7—3.5 (m, 2H, H_6), 3.40 (s, 6H, OMe), 3.08 (s, 3H, N–Me), 2.25 (t, 3H, C–Me, $J\fallingdotseq$1 Hz).

(6) Treatment with Sodium Methoxide: The hydrochloride of **4** (1.88 g) was neutralzed with methanolic sodium methoxide, which had been prepared from sodium (1.67 g) and methanol (26 m*l*), and then the solution was refluxed. After 8 hr, the solution was neutralized with methanolic hydrogen chloride, filtered from precipitated sodium chloride, and evaporated to dryness. The residue was chromatographed on silica gel (Wakogel Q-23, 100—200 mesh, 40 g). Elution with acetone (100 m*l*) and, subsequently, with acetone-methanol (20: 1, 400 m*l*) gave 2-methyl-4-amino-5-methoxymethylpyrimidine (**13**, 913 mg), mp 118—120°C.[16]

(7) Reverse Reaction (The Formation of 8 and 20): A solution of **4·HCl** (590 mg) was added to a sodium methoxide solution, which had been prepared from sodium (46 mg) and methanol (6 m*l*), and then the mixture was warmed at 60°C for 7 hr. After cooling, the solution was filtered from precipitated sodium chloride and the solvent was removed. The yellow residue was chromatographed over alumina (Wako activated alumina, 300 mesh, 9.2 g). Elution with ethyl acetate-benzene-methanol (2: 1: 1) gave **8** (144 mg) as the first fraction (500 m*l*), a mixture of **8** and **20** (285 mg) as the second one (300 m*l*), and **8** (133 mg) as the third one (30 m*l*). The second crop was further chromatographed over the alumina (10 g). Elution with benzene-methanol (50: 1, 100 m*l*) gave **8** (54 mg), while subsequent elution with benzene-methanol (25: 1, 100 m*l*) gave **20** (153 mg). This **20** was purified by recrystallization from methanol and ethyl acetate. Mp 208—210°C (decomp.). MS 306 (M^+). Found: C, 49.04; H, 6.65; N, 24.36; Cl, 10.63%. Calcd for $C_{14}H_{22}N_6O_2\cdot HCl$: C, 49.13; H, 6.78; N, 24.58; Cl, 10.37%.

(8) Reaction with Methyl Acetimidate: i) Hydrochlorides of methyl acetimidate (3.28 g) and **4** (2.217 g) were added to methanolic sodium methoxide, which had been prepared from sodium (690 mg) and methanol (20 g). After the removal of the precipitated sodium chloride by filtration, the total weight of the filtrate was made to 21 g by adding methanol, and then the solution was refluxed. The reaction mixture was quenched with acetic acid, and the yield of **8** was determined by gas chromatography (30% Apiezon grease L; column temperature, 236.5°C; flow rate, 90 m*l*/min; carrier gas, He; retention time of **8**, 2.2 min) as follows: 13.1% (after 0.5 hr), 13.1% (after 2 hr), and 13.1% (after 3 hr). ii) Hydrochlorides of methyl acetimidate (1.64 g) and **4** (1.11 g) were neutralized with a sodium methoxide solution, which had been prepared from sodium (450 mg) and methanol (15 m*l*). The mixture was worked up in a way similar to the above. The yield of **8** was 16.7% (after 1 hr) and 13.3% (after 2 hr).

(9) Reaction with Propioamidine: A solution of sodium methoxide in methanol, which had been prepared from

16) A. Takamizawa and R. Maeda, *ibid.*, **74**, 746 (1954).

sodium (138 mg) and methanol (6 ml), was added to a mixture of hydrochlorides of propioamidine (651 mg) and **4** (443 mg) and then quickly filtered from the precipitated sodium chloride. The filtrate was refluxed for 5 hr and then evaporated to dryness. To the residue we added water (8 ml), after which the aqueous solution was heated on a boiling-water bath for 1 hr. The removal of the water gave syrupy crystals (1.01 g) of a mixture of 2-methyl-4-amino-5-propioamidomethyl- (**30**) and 2-ethyl-4-amino-5-acetamidomethylpyrimidine (**33**). The relative ratio of **30** and **33** was 8:92, which was determined by means of the peak height in the gas chromatogram (4% polyethyleneglycol 20M; column temperature, 240°C; flow rate, 100 ml/min; carrier gas, He; retention time, **30**: 13 min and **33**: 11 min). After a part of the syrupy crystals (120 mg) had been used for gas-chromatographic analysis, the crystals were collected by filtration. The subsequent recrystallization of the crystals from acetone gave leaflets of **33** (111 mg); mp 206.5—207.5°C. UV: 236 (ε 8900), 275 (ε 5400); (+HCl) 251 mμ. NMR (methanol-d_4): 7.93 (s, 1H, H_6), 4.28 (s, 2H, $-CH_2-$), 2.69 (q, 2H), 1.23 (t, 3H) (C_2H_5, J=7 Hz), 1.93 (s, 3H, CH_3CO). Found: C, 55.87; H, 7.07; N, 28.68%. Calcd for $C_9H_{14}N_4O$: C, 55.65; H, 7.27; N, 28.85%.

The mother liquors of the filtration of the syrupy crystals and the recrystallization of **33** were combined, and the combined solution was evaporated to dryness. The residue was chromatographed over the alumina (12 g). Elution with benzene-methanol (50:3, 100 ml) gave **33** (180 mg), while further elution with the same solvent-system gave a syrup (170 mg) which contained **30** and/or **33** (46.5 mg), as determined by studying UV spectrum.

*2-Methyl-4-amino-5-propionylamidomethylpyrimidine (**30**).* Freshly-distilled propionyl chloride (750 mg) was added to a solution of 2-methyl-4-amino-5-aminomethylpyrimidine (**10**; 850 mg)[7] in pyridine under cooling, and the mixture was kept in a refrigerator overnight. The solvent was then removed. The residue was neutralized with N sodium hydroxide and then evaporated to dryness. The recrystallization of the residue from acetone gave needles of **30** (320 mg); mp 181°C. UV: 236 (ε 11400), 275 (ε 7100); (+HCl) 250 mμ. NMR (chloroform-d): 7.80 (s, 1H, H_6); 4.30 (s, 1H), 5.82 (s, 1H) ($-CH_2-$); 2.25 (q, 2H, J=7.3 Hz), 1.25 (t, 3H) (C_2H_5-). Found: C, 55.66; H, 7.29; N, 28.67%. Calcd for $C_9H_{14}N_4O$: C, 55.65; H, 7.25; N, 28.85%.

*2-Dimethoxymethyl-3-acetamidinopropionitrile (**3**).* *(1) Isolation*: Acetamidine hydrochloride (4.2 g) was added to a solution of sodium (0.95 g) in methanol (20 ml); the mixture was shaken and quickly filtered from the precipitated sodium chloride, and then the methanol was removed. Under stirring, 2-dimethoxymethylacrylonitrile (**2**; 3 g) was added drop by drop, to a solution of the residue in 1,2-dimethoxyethane (17 ml) at 0°C. After 3 hrs' stirring, the solution was kept in a refrigerator for 2 days and then neutralized with 30% methanolic hydrogen chloride (4.5 g). The crystals which appeared (5.4 g) were collected by filtration and recrystallized from ethanol. Cubics of the hydrochloride of **3** (2.97 g) were obtained; mp 144—146°C. UV: 206 mμ (ε 6170). IR_{KBr}: 2256 cm^{-1} (non-conjugate nitrile). NMR (methanol-d_4): 2.32 (s, 3H, C–CH_3), 3.8—3.14 (m, 3H, CH_2–CH), 4.70 [d, 1H, CH(OMe)$_2$, J=5 Hz], 3.51 (s, 6H, C(OMe)$_2$]. Found: C, 43.16; H, 7.08; N, 19.00%. Calcd for $C_8H_{15}N_3O_2\cdot HCl$: C, 43.34; H, 7.28; N, 18.95%.

*(2) Cyclization to **4***: The hydrochloride of **3** (350 mg) was neutralized with methanolic sodium methoxide, prepared from sodium (46 mg) and methanol (5 g), and kept at room temperature for 2 hr. The solution was neutralized with 36% methanolic hydrogen chloride (300 mg) and filtered from the precipitated sodium chloride, and then the methanol was removed. The recrystallization of the residue (511 mg) from ether and methanol gave **4**·**HCl** (200 mg).

*2-Methyl-4-amino-5-acetamidinomethylpyrimidine (**11**).* *(1) Isolation*: Acetamidine hydrochloride (20 g) and **1** (26 g) were added to methanolic sodium methoxide, which had been prepared from sodium (3.68 g) and methanol (58 ml), and the mixture was stirred at 43°C for 3 hr. After cooling, 43% methanolic hydrogen chloride (9.2 g) was added to the solution. The yellow crystals which appeared were collected by filtration and washed with ethyl acetate (100 ml). The residue was dissolved with hot methanol, and the methanol solution was cooled to 0°C. The precipitates (the monohydrochloride of **11**) were collected by filtration and washed with a small portion of methanol. The yield was 134 mg; mp 246—250°C (decomp.). UV: 233 (ε 10900), 273 (ε 4930); (+HCl) 246 mμ. MS: 179 (M^+), 162 (M^+-NH_3), 122 ($M^+-NH-\overset{NH}{\overset{\|}{C}}-Me$). Found: C, 44.26; H, 6.68; N, 31.75%. Calcd for $C_8H_{13}N_5\cdot HCl$: C, 44.55; H, 6.54; N, 32.47%.

(2) Synthesis: A solution of 2-methyl-4-amino-5-aminomethylpyrimidine (**10**, 13.8 g)[7] in methanol (30 ml) was added, drop by drop and over a 20-min period, to a solution of methyl acetimidate hydrochloride (11 g) in methanol (5 ml) at 15°C. After stirring at 15°C for 1 hr, precipitates which appeared (the monohydrochloride of **11**) were collected by filtration and washed with a mixture of methanol (9 ml) and pyridine (5 ml). The yield was 870 mg; mp 246—250°C (decomp.).

*Reaction of 2-Methyl-4-amino-5,6-dihydropyrimidine (**18**) with Acetamidine.* (1) Acetamidine hydrochloride (473 mg) and **18** (556 mg)[1] were added to a solution of sodium methoxide, prepared from sodium (115 mg) and methanol (14 g), and then filtered from the precipitated sodium chloride. The solution was refluxed for 4 hr and then evaporated to dryness. The residue was extracted with acetonitrile (100 ml), and the acetonitrile was removed. The recrystallization of the residue from acetonitrile gave **18** (113 mg).

(2) A solution of acetamidine hydrochloride (945 g) and **18** (555 mg) in methanol (5 ml) was refluxed for 4 hr. The UV spectrum of the reaction mixture showed only the characteristic band due to the hydrochloride of **18**.

*Reaction of 2-Phenyl-4-amino-5,6-dihydropyrimidine (**22**) with Acetamidine.* A solution of acetamidine hydrochloride (510 mg) and **22** (467 mg)[13] in methanol (5 g) was refluxed for 5 hr. The UV spectrum of the reaction mixture showed only the characteristic band due to the hydrochloride of **22**.

*Reaction of 2-Methyl-3H-4-oxo-5-dimethoxymethyl-5,6-dihydropyrimidine (**16**) with Acetamidine.* Hydrochlorides of **16** (550 mg) and acetamidine (630 mg) were added to methanolic sodium methoxide, prepared from sodium (204 mg) and methanol (20 ml), and then filtered from the sodium chloride thus precipitated. The solution was refluxed for 2 hr and then evaporated to dryness. The recrystallization of the residue from ethanol gave needles of 2-methyl-4-hydroxy-5-acetamidinomethylpyrimidine (**27**; 250 mg), (mp 218—238°C (decomp.)), which was subsequently purified as its dihydrochloride (mp 197—202°C (decomp.)). UV: 207 (ε 9000), 220 (shoulder), 278 (ε 5540); (+HCl) 224, 262; (+NaOH) 232, 262 mμ. NMR (methanol-d_4): 8.13 (s, 1H, H_6), 4.39 (s, 2H, $-CH_2-$), 2.28 (s, 3H, >C–Me), 2.68 (s, 3H, 2-Me). Found: C, 38.01; H, 5.67; N, 22.26; Cl, 28.70%. Calcd for $C_8H_{12}N_4O\cdot 2HCl$: C, 37.95; H, 5.53; N, 22.13; Cl, 28.01%.

*Reaction of 2-Methyl-4-amino-5-dimethoxymethyl- (**4**) and 2-Methyl-3H-4-oxo-5-dimethoxymethyl-5,6-dihydropyrimidine (**16**) with Acetamidine.* Hydrochlorides of **4** (372 mg), **16**

(372 mg) and acetamidine were added to a solution of sodium methoxide, which had been prepared from sodium (157 mg) and methanol (10 m*l*) and the mixture was refluxed for 5 hr. After cooling, the solution was filtered from the precipitated sodium chloride and then evaporated to dryness. A mixture of **8** and **27** was obtained as a yellow powder (708 mg). The relative ratio of **8** and **27** was about 1: 1, as determined from the NMR spectrum of the mixture in methanol-d_4. Singlets due to the methylene group of **8** at 4.95 and to that of **27** at 4.18 δ were used for the determination.

*Isolation of 2-Methyl-4-amino-5-methoxymethylpyrimidine (**13**) from the Reaction of 2-Dimethoxymethyl-3-methoxypropionitrile (**1**) with Acetamidine.* To methanolic sodium methoxide, prepared from sodium (0.64 g) and methanol (7 m*l*), we added **1** (1.6 g). The solution was refluxed for 4 hr, filtered from the precipitated sodium chloride, and then evaporated to dryness. The aqueous solution (6 m*l*) of the residue was warmed at 100°C for 1 hr and then evaporated to dryness. 48% Sodium hydroxide (3 g) was added to the residue, and the crystals which appeared were collected by filtration and washed with water and then with ethyl acetate. The evaporation of the ethyl acetate gave syrupy crystals, from which **13** was isolated by preparative tlc (a silica gel plate, chloroform-ethyl acetate, 1: 1). The recrystallization of crude **13** from benzene gave a pure product 141 mg); mp 118—120°C.[16]

The authors wish to express their deep gratitude to Professor Toshihiko Okamoto, the University of Tokyo, for his interest.

The Reaction of Aspartyl Dipeptide Esters with Ketones

Yasuo ARIYOSHI and Naotake SATO

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki, Kanagawa

(Received December 18, 1971)

The methyl and ethyl esters of α-L-aspartyl-L-phenylalanine (I and II), -L-tyrosine (III and IV), -L-(β-cyclohexyl)alanine (V and VI), and -L-[β-(4-hydroxycyclohexyl)]alanine (VII and VIII) have been found to react with ketones (acetone, methyl ethyl ketone, and cyclohexanone), in the absence of any catalysts, to give the corresponding 4-imidazolidinone derivatives (XVII—XXX). The NMR spectra of the imidazolidinones with an aromatic side chain (XVII—XXVIII) have indicated that these compounds exist in the folded conformation (in which the aromatic ring faces the imidazolidinone ring) in the solution. The imidazolidinones (XVII—XXX) were hydrolyzed with hot water to give the peptide esters (I—VIII), all in their original optical purity. On the other hand, the β-isomers of the peptide esters (IX—XVI) did not react with these ketones under the same conditions. These characteristics were used successfully in the separation of the two structural isomers of these peptide esters.

The methyl and ethyl esters of α-L-aspartyl-L-phenylalanine (I and II), -L-tyrosine (III and IV), -L-(β-cyclohexyl)alanine (V and VI), and -L-[β-(4-hydroxycyclohexyl)]alanine (VII and VIII) all have a sweet taste very similar to that of sucrose, and they have recently become well known as sweetening agents.[1,2]

In the course of studies of these sweet peptides, it was found that the dipeptide esters (I—IV) readily reacted with ketones, such as acetone, methyl ethyl ketone, and cyclohexanone, in the absence of any catalysts, to give crystalline 4-imidazolidinone derivatives (XVII—XXVIII) (Fig. 1 and Table 2). However, most of the reactions of the hexahydroderivatives (V—VIII), obtained by the hydrogenation of the aromatic rings of the corresponding dipeptide esters (I—IV) with hydrogen and platinum catalyst, with these ketones gave oily products. Among them, only the reactions of V and VI with acetone gave analytically pure crystalline products (XXIX and XXX). Similar reactions have been observed in the cases of carbobenzoxyamino acid amides,[3] ampicillin,[4] and oxytocin.[5]

The structures of the reaction products (XVII—XXX) were determined on the basis of their analytical and spectral data and their chemical behavior. The results of the elemental analyses of the reaction products were in agreement with the values calculated for the imidazolidinones (XVII—XXX) (Table 2). The IR spectra of the imidazolidinones containing the phenylalanyl or the β-cyclohexylalanyl residue (XVII—XXII, XXIX, and XXX) showed two carbonyl absorptions at 1740—1750 cm^{-1} (ester) and at 1700—1703 cm^{-1} (a composite band of the amide and carboxyl groups), whereas the imidazolidinones containing the tyrosyl residue (XXIII—XXVIII) showed two carbonyl absorptions at 1720—1725 cm^{-1} (a composite band of the ester and carboxyl groups) and 1695 cm^{-1} (amide). All of these imidazolidinones (XVII—XXX) lacked amide-II absorptions of the starting materials in the region of 1500—1600 cm^{-1}.

Fig. 1. Dipeptides and 4-imidazolidinones

When the NMR spectra of the compounds with an aromatic side chain (XVII—XXVIII) were measured in acetone-d_6 or dimethyl sulfoxide-d_6, the protons of one of the two alkyl groups on the C-2 carbon were found to be shifted to a higher field (appearing at δ 0.4—0.6 ppm) by the magnetic shielding effect of the aromatic ring; for example, the H_a and H_b protons of the 2,2-dimethyl group of XVII appeared at δ 0.57 ppm (3H, singlet) and δ 1.33 ppm (3H, singlet) respectively in acetone-d_6, whereas the corresponding six protons of the hexahydroderivative (XXIX) were found at δ 1.45 ppm as a singlet. The two protons on the β-carbon atom of the aspartyl residue of XVII were almost unaffected (Fig. 2). Therefore, this shift suggests that

a) Raised rapidly. b) Decomposition.

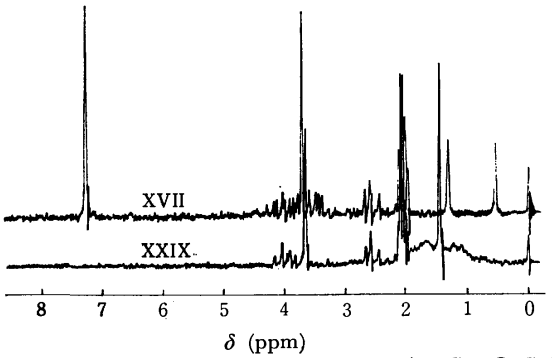

Fig. 2. NMR spectra of XVII and XXIX (in CD_3COCD_3).

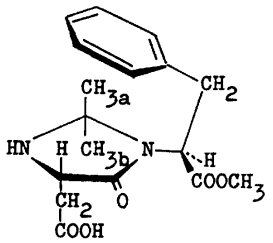

Fig. 3. Preferred conformation of XVII

compound XVII takes the folded conformation, in which the aromatic ring faces the imidazolidinone ring, as is shown in Fig. 3.

In boiling water, all the imidazolidinones except for the spiroderivatives were completely hydrolyzed within twenty minutes to give the corresponding peptide esters in their original optical purity. The spiroderivatives (XIX, XXII, XXV, and XXVIII) were much more stable to hydrolysis. Under the same conditions, they were only partly hydrolyzed to the corresponding peptide esters. Some two hours were required for their complete hydrolysis.

The reactions of the peptide esters (I—VIII) with aldehydes, such as acetaldehyde, propionaldehyde, or isobutylaldehyde, failed to give crystalline products.

The corresponding β-isomers of the peptide esters (IX—XVI), which have a bitter taste, did not react with these ketones under the same conditions. These characteristics were used successfully in the separation of the two structural isomers of these sweet peptide esters. When these peptides were conveniently prepared by the condensation of such *N*-protected aspartic anhydrides as carbobenzoxy-L-aspartic anhydride with the appropriate amino acid esters, followed by deprotection, they were always mixtures of α- and β-aspartyl peptides. Several methods of separating α- and β-aspartyl peptides have been reported, including techniques of fractional extraction,[6] column chromatography,[7] and selective precipitation.[8]

When a mixture of the α- and β-aspartyl peptide esters (I and IX, II and X, III and XI, IV and XII, V and XIII, or VIII and XVI) was treated in acetone, the α-isomer changed to the corresponding soluble imidazolidinone, whereas the unchanged β-isomer remained insoluble. The β-isomer was filtered and recrystallized from water to give the pure β-isomer. The filtrate from the β-isomer was concentrated to dryness to give the imidazolidinone, which was then hydrolyzed with hot water to afford the pure α-isomer. The results are summarized in Table 3.

Experimental

All the melting points are uncorrected. The IR spectra were recorded in Nujol mull with a Jasco IR-S spectrometer. The NMR spectra were obtained with a Varian T-60 spectrometer at 60 MHz, and the chemical shifts are given from tetramethylsilane as the internal reference. The structural isomers were determined by a method described previously.[8]

Preparation of the Starting Materials. The α-L-aspartyl-L-phenylalanine methyl and ethyl esters (I and II), and the α-L-aspartyl-L-tyrosine methyl and ethyl esters (III and IV) were prepared by the condensation of β-benzyl *N*-carbobenzoxy-L-aspartate[9] and the appropriate amino acid esters

with ethyl chloroformate, followed by deprotection. A typical run (I in Table 1) was as follows: To a chilled solution of β-benzyl *N*-carbobenzoxy-L-aspartate (17.9 g) and triethylamine (5.1 g) in chloroform (120 ml) was added ethyl chloroformate (5.5 g) at −5——10°C with stirring. After the solution had been stirred for 20 min at this temperature, a chilled mixture of methyl L-phenylalaninate hydrochloride (11.9 g) and triethylamine (6.5 g) in chloroform (150 ml) was stirred into the mixed anhydride solution at −5——10°C. Stirring was continued for 3 hr at room temperature. The reaction mixture was washed with N hydrochloric acid and then water, and dried over sodium sulfate. The solvent was removed by distillation *in vacuo*, and the residue was recrystallized from ethyl acetate-petroleum ether to give β-benzyl *N*-carbobenzoxy-L-aspartyl-L-phenylalanine methyl ester as needles; yield, 21 g (81%); mp 114.5—115.5°C. (Found: C, 67.16; H, 6.13; N, 5.43%). lit, 116—117°C,[10] 118.5—119.5°C.[1] A solution of the dipeptide ester (8.3 g) in 75% aqueous acetic acid (150 ml) was hydrogenated in the presence of 5% palladium on charcoal (1.0 g) for 6 hr. The filtrate from the catalyst was then concentrated *in vacuo*, and the residual crystals were recrystallized from water to give I as needles; yield, 4.0 g (83%). The data are given in Table 1.

The β-L-aspartyl-L-phenylalanine methyl and ethyl esters (IX and X), and the β-L-aspartyl-L-tyrosine methyl and ethyl esters (XI and XII) were prepared from α-benzyl *N*-carbobenzoxy-L-aspartate[11] and the appropriate amino acid esters according to the method used in the preparation of the α-isomers. A typical run (IX in Table 1) was as follows: α-Benzyl *N*-carbobenzoxy-L-aspartate (7.2 g) was condensed with methyl L-phenylalaninate hydrochloride (5.2 g) by the method described in the preparation of the α-isomers; this gave 7.8 g (75%) of α-benzyl *N*-carbobenzoxy-L-aspartyl-L-phenylalanine methyl ester; mp 121—122°C. lit,[1] mp 131—133°C. (Found: C, 67.37; H, 6.05; N, 5.45%). The hydrogenolysis of 10 g of the dipeptide ester gave 3.8 g of IX. All of the compounds (IX—XII) were hygroscopic. The data are given in Table 1.

The α-L-aspartyl-L-(β-cyclohexyl)alanine methyl and ethyl esters (V and VI), the α-L-aspartyl-L-[β-(4-hydroxycyclohexyl)]alanine methyl and ethyl esters (VII and VIII), the β-L-aspartyl-L-(β-cyclohexyl)alanine methyl and ethyl esters (XIII and XIV), and the β-L-aspartyl-L-[β-(4-hydroxycyclohexyl)]alanine methyl and ethyl esters (XV and XVI) were obtained by the hydrogenation of the aromatic ring of the corresponding dipeptides (I—IV and IX—XII). A typical run (V in Table 1) was as follows: A solution of I (5.0 g) in 0.1 M aqueous acetic acid (250 ml) was hydrogenated in the presence of platinum oxide (1.0 g) at atmospheric pressure and room temperature. The filtrate from the catalyst was then concentrated to dryness *in vacuo*. The residue was triturated with ether to give V as a crystalline powder, which was then recrystallized from water to give platelets; 4.8 g (94%).

VIII, XIV, XV, and XVI were hygroscopic. The data are given in Table 1.

4-Imidazolidinones (XVII—XXX). The imidazolidinones (XVII—XXX) were prepared by the condensation of the dipeptides (I—VIII) with acetone, methyl ethyl ketone, or cyclohexanone at 25—100°C for 0.5—12 hr. A typical run (XVII in Table 2) was as follows: A suspension of I (6.0 g) in acetone (100 ml) was heated under reflux for 30 min. The insoluble crystals (1.5 g) were then filtered off. The crystals were identified with I by studying the IR spectrum. After the filtrate had been kept in a refrigerator overnight, the crystals thus formed were collected by filtration; yield, 3.0 g. The second crop (1.0 g) was recovered from the mother liquor; total yield, 4.0 g (61%); mp 145°C (raised rapidly); $[\alpha]_D^{25}$ −157.5° (*c* 1, acetone); IR: 3310 (NH), 1750 (ester), and 1703 (amide-I and carboxyl group) cm^{-1}; NMR (CD_3COCD_3): δ 0.57 (s, 3H, $-CH_3$), 1.33 (s, 3H, $-CH_3$), 2.57 (m, 2H, $-CH_2COO$), 3.50 (m, 2H, $-CH_2C_6H_5$), 3.73 (s, 3H, $-COOCH_3$), 3.50—4.20 (m, 2H, 2 $-CH\langle$), 4.37 (broad s, NH), and 7.30 (s, 5H, $-C_6H_5$) ppm. For the NMR spectrum, see also Fig. 2. For anal. and mp, see Table 2.

Separation of the α- and β-Isomers with Acetone. A typical run (No. 1 in Table 3) was as follows: A suspension mixture of I (4 g) and IX (4 g) in acetone (200 ml) was stirred for 15 hr at room temperature. An insoluble, amorphous material was then collected by filtration. The compound was identified as anhydrous IX by studying the IR spectrum, which failed to absorb the water of crystallization of the starting material. The compound was recrystallized from water (40 ml) to give 3.3 g (83%) of IX as needles, which were found by paper electrophoresis to be free from the α-isomer; mp 198—199°C (decomp.); $[\alpha]_D^{22}$ +40.5° (*c* 1, acetic acid).

On the other hand, the filtrate from the β-isomer was concentrated to dryness *in vacuo*. The residual crystals were dissolved in hot water, concentrated to dryness *in vacuo*, and then recrystallized from water (40 ml) to give 3.3 g (83%) of I as needles; mp 235—236°C (decomp.); $[\alpha]_D^{25}$ +32.0° (*c* 1, acetic acid). These results showed that no racemization occurred during the reaction. The crystals were found by paper electrophoresis to be free from the β-isomer. The results are summarized in Table 3.

The Reaction of Sulfilimine with Phenyl Grignard Reagent*,[1]

Shigeru OAE, Toshiaki YOSHIMURA, and Naomichi FURUKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimotocho, Sumiyoshi-ku, Osaka

(Received December 27, 1971)

The reactions of diphenyl (I), phenyl benzyl (II), and phenyl methyl *N*-*p*-tosylsulfilimines (III) with phenylmagnesium bromide were carried out. (I) gave biphenyl and diphenyl sulfide in high yields. A tracer experiment with diphenyl sulfilimine-1-^{14}C revealed that the reaction proceeds *via* the initial formation of triphenylsulfonium salt upon which the attack of phenylmagnesium bromide affords the products. "Benzyne" mechanism is ruled out. (II) and (III) gave various compounds, the major products being α-phenylated sulfides which are presumed to be formed by the Pummerer type rearrangement initiated by the abstraction of α-proton by the Grignard reagent.

N-*p*-Tosylsulfilimines can generally be prepared by allowing the corresponding sulfides to react with chloramine-T[2] (sodium salt of *N*-chloro *p*-toluenesulfonamide). Spectroscopic analysis indicates that the sulfilimine has a semipolar S–N bond similar to the S–O bond in sulfoxides.[3] In contrast to the massive works on sulfoxides,[4] the chemical properties of sulfilimines have not been explored. Recently Cram *et al.*[5] and Johnson *et al.*[6] studied the stereochemistry of nucleophilic substitution reactions of sulfilimines while Petranek and Vecera investigated the sigmatropic rearrangement of allylic *N*-*p*-tosylsulfilimines.[7] We have also studied the substitution,[8] elimination,[9] E*i* reaction[10], and pyrolysis reactions of sulfilimines.[10] Since sulfilimines have a labile S–N bond they are as reactive as the corresponding sulfoxides, and are, therefore, good substrates for examining the possible reactions which occur on the trivalent sulfur atom. This paper describes a detailed account of the reaction of *N*-*p*-tosylsulfilimines with phenyl Grignard reagent.

Reaction of Diphenyl Sulfilimine with Phenylmagnesium Bromide. Diphenyl *N*-*p*-tosylsulfilimine was dissolved in anhydrous THF. Into the resulting solution was added 5 mol excess of phenylmagnesium bromide. When the mixture was allowed to stand at room temperature, no reaction occurred and the sulfilimine was recovered almost quantitatively. The mixture was therefore refluxed in an oil bath for several hours. The reaction mixture was then decomposed with water, and the products were isolated and identified as shown in Table 1.

TABLE 1. PRODUCTS AND YIELDS OF THE REACTION OF $PhS\overset{+}{\underset{-}{\underset{|}{N}}}TsPh$ WITH PhMgBr

Products	Yield (%)

$(Ph)_3S^+X^-$	not identified	not identified

A; Carried out at room temperature.
B; Carried out by refluxing in THF.

Contrary to expectation, the major products are biphenyl and diphenyl sulfide, no sulfonium salt being isolated. Both biphenyl and diphenyl sulfide are known to be obtained by the attack of phenyl anion on triphenylsulfonium salt[12] incipiently formed during the reaction. The mechanism of the reaction was investigated. In a previous paper, it was shown that sulfilimine has two attacking sites, *i.e.* S and N for nucleophiles.[13] If the attack of the Grignard reagent takes place on the sulfur (IV) atom (Path (A), Fig. 1), triphenylsulfonium salt might be formed as an incipient intermediate which is then attacked by another molecule of the Grignard reagent either at the *ortho* proton to form benzyne and diphenyl sulfide (Path (A)-(a)) or at the phenyl carbon attached to the sulfur atom to form directly biphenyl and diphenyl sulfide (Path (A)-(b)). If the attacking site is the sulfilimino nitrogen (Path (B)), diphenyl sulfide would be obtained directly while biphenyl would result from the reaction between *N*-phenyltosylamide and phenylmagnesium bromide. Another alternative path (Path (C)), would be the one which involves the initial attack of the Grignard reagent on the α-hydrogen atom of the sulfilimine giving

* Recently, Manya *et al.* reported the same sort of reaction. They obtained nearly the same results as ours but they could isolate the triphenylsulfonium salt. P. Manya, S. Sekera, and P. Rumpf, *Bull. Soc. Chim. Fr.*, **1971**, 286.

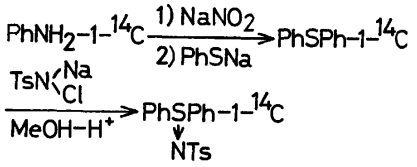

Fig. 2. The synthetic method of sulfilimine-1-^{14}C.

benzyne and *N*-phenylmercaptotosylamide upon which the attack of the Grignard reagent[14] produces diphenyl sulfide. The above four mechanistic schemes are shown in Fig. 1. In order to make a choice from the four mechanisms, the sulfilimine labeled with ^{14}C at 1-position was synthesized and allowed to react with phenylmagnesium bromide. The synthetic procedure to prepare the *N*-*p*-tosylsulfilimine-1-^{14}C is shown in Fig. 2. If the reaction proceeds *via* the formation of triphenylsulfonium ion (Path (A), either (a) or (b)), the original ^{14}C activity of the sulfilimine should be distributed between diphenyl sulfide and biphenyl, 2/3 (66.7%) for the sulfide and 1/3 (33.3%) for biphenyl, if the ^{14}C isotope effect is neglected. The reaction that proceeds *via* path (B) will require all the ^{14}C activity to be found in the diphenyl sulfide alone, that *via* path (C) 50% each in both diphenyl sulfide and biphenyl. A choice between paths (a) and (b) can be made by tracing the ^{14}C activity within the molecule of biphenyl by means of degradation. Thus, diphenyl sulfilimine-1-^{14}C was treated with phenylmagnesium bromide. The ^{14}C analytical data obtained from the above experiment are shown in Table 2.

The distribution of ^{14}C activity among the products indicates that *ca.* 70% is in diphenyl sulfide the rest in biphenyl. These data rule out (B) and (C), leaving the first two plausible mechanisms that involve the initial formation of triphenylsulfonium salt. (A) is consistent with the mechanism proposed by Andersen[15] for the reaction between diphenyl sulfoxide with phenyllithium.

TABLE 2. ^{14}C DISTRIBUTION IN THE PRODUCTS

Compound	^{14}C Activities dpm/mM	(%)
Ph–Ph	4.80×10^{6}	30.0
Ph–S–Ph[a]	1.11×10^{6}	69.2
Ph–S–Ph	1.60×10^{6}	(100)
↓ NTs		
(original)		
(recovered)[b]	1.57×10^{6}	98.2
Ph–S–Ph[c]		
(original)	1.65×10^{6}	(100)
(recovered)	1.61×10^{6}	97.6

a) The activity of diphenyl sulfide was measured, after its oxidation to diphenyl sulfone with H_2O_2.
b) The reaction was interrupted and the activity of the recovered sulfilimine measured.
c) Diphenyl sulfide-1-^{14}C was treated with phenylmagnesium bromide in order to check a possible ^{14}C exchange reaction between the diphenyl sulfide formed and phenyl Grignard reagent.

The fact that the ^{14}C activity of the recovered sulfilimine is practically the same as that of the original one, seems to indicate that the decomposition of the intermediate triphenylsulfonium salt to diphenyl sulfide is faster than the possible reverse reaction to the sulfilimine. Under the same conditions, diphenyl sulfide does not undergo phenyl exchange with phenyl Grignard reagent. Thus, the ^{14}C activity of diphenyl sulfide should come from the sulfilimine alone. All these data support the mechanism involving the initial formation of triphenylsulfonium ion. However, the question still remains through which of the paths (a) and (b) the reaction proceeds.

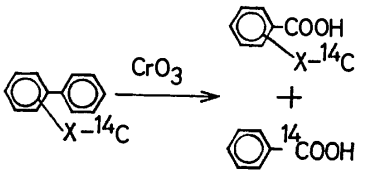

Fig. 3. The degradation of biphenyl.

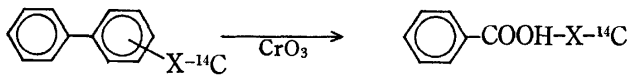
In order to ascertain this, biphenyl-X-^{14}C obtained from the above experiment was allowed to degrade by the following method.

As shown in Fig. 1, if the reaction proceeds by the nucleophilic attack of phenyl anion at the sulfonium salt (Path (b)), the ^{14}C activity found in biphenyl-X-^{14}C should be the same as that found in benzoic acid-X-^{14}C, since no ^{14}C migration occurs at all during the reaction. On the other hand, the benzyne route (a) requires the ^{14}C activity of benzoic acid to be 3/4 of that of biphenyl. The results obtained from the degradation are shown in Table 3, and indicate that the reaction proceeds *via* path (A)-(b).

Table 3. Degradation data of biphenyl-X-^{14}C



Theor. (%)		
For (Aa)	(100)	(75)
For (Ab)		(100)
Found		
Activities (dmp/mM)		
1.53×10^4		1.58×10^4
	(100)	(103)

The result seems to contradict our earlier observation[16] and also that of Franzen's[17] on the reaction of triarylsulfonium salt with phenyllithium where benzyne route is confirmed. The difference between the above two reactions might be due to the less basic nature of the Grignard reagent than phenyllithium. Namely, phenyllithium is so strong a base that it can attack a proton *ortho* to the sulfonio group to form "benzyne", while the Grignard reagent is not a powerful base but a good nucleophile to attack the phenyl carbon.

Reactions of Phenyl Methyl and Phenyl Benzyl N-*Tosylsulfilimines with Phenylmagnesium Bromide.* These two reactions were carried out in a similar way to that of diphenyl *N*-tosylsulfilimine and phenylmagnesium bromide. After the reaction, the products were separated through a column packed with silica gel. The products and their yields obtained from the above sulfilimines are shown in Table 4.

We see that no sulfonium salt was isolated, however, the products are rather complicated. The results are in a marked contrast to those of diphenyl *N*-*p*-tosylsulfilimine. The pattern of distribution of the products is very close to that for the reaction of the corresponding sulfoxide with phenylmagnesium bromide.[18]

In the case of phenyl benzyl *N*-*p*-tosylsulfilimine, the major product is *N*-benzhydryl-*p*-toluenesulfonamide which was identified by comparing the IR, NMR, and mass spectra with those of the authentic sample prepared from benzhydrylamine and *p*-tosyl chloride. In addition to the *N*-benzhydryl-*p*-toluenesulfonamide, diphenyl sulfide and phenyl benzyl sulfide were isolated, identified and their yields were determined. With the present data only, it is difficult to postulate any plausible mechanism for the reaction. However, as in the case of the sulfoxides α-hydrogen abstraction by phenyl anion (or radical) might be the initial step followed by either the Pummerer or Stevens-type rearrangement as shown

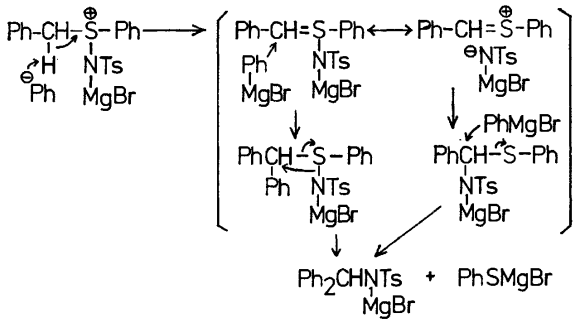


Fig. 4. The mechansim of the reaction.

below. A large excess of the Grignard reagent and a prolonged reaction time gave diphenyl sulfide in an increasing yield and diphenyl disulfide in a smaller amount. Diphenyl sulfide is probably obtained from diphenyl disulfide and not from the direct attack by phenylmagnesium bromide on sulfinyl sulfur. This was

found to be the case for the reaction with the diphenyl sulfilimine. In the case of phenyl methyl *N-p*-tosylsulfilimine, the major product is phenyl benzyl sulfide which might be formed by a Pummerer type rearrangement.

Experimental

Preparation of N-p-*Tosylsulfilimines.* The sulfilimines used in the study were prepared according to the known method.[19]

Reaction of Diphenyl N-p-*Tosylsulfilimine with Phenylmagnesium Bromide.* Diphenyl *N-p*-tosylsulfilimine (1 g) was dissolved in 30 m*l* anhydrous THF. To this was added 20 m*l* solution of phenylmagnesium bromide prepared from bromobenzene (1.6 g) and magnesium (0.25 g) in 20 m*l* anhydrous THF. The solution was then refluxed for 12 hr. After the reaction, the solution was decomposed with water and then with dilute hydrochloric acid. The aqueous solution was then extracted with chloroform. The chloroform extract was separated, washed with water, extracted again with 10% of aqueous sodium hydroxide, washed with water and then dried over anhydrous sodium sulfate. After removing the solvent, the residue was chromatographed through a column packed with silica gel.

The chromatogram indicated two spots, each of which was nicely separated; diphenyl sulfide and biphenyl were identified by glc from the first layer and the sulfilimine from the second layer. *p*-Tosylamide was isolated from the aqueous layer after acidifying the solution with hydrochloric acid. All the products were identified by comparing their IR, NMR, and glc with those of the authentic samples. The yields are shown in Table 1.

^{14}C Tracer Study with Diphenyl N-p-*Tosylsulfilimine-1-^{14}C with Phenylmagnesium Bromide.* N-p-*Tosylsulfilimine-1-^{14}C*: Diphenyl sulfide-1-^{14}C (3 g) prepared from diazotizing of aniline-1-^{14}C and thiophenol[20] was dissolved in 10 m*l* methanol containing a drop of acetic acid. To the solution was added 4.6 g of chloramine-T in 5 m*l* methanol. After being kept standing for 1 hr, the solution was poured into ice water. To this was added 10% of aqueous sodium hydroxide. The precipitates were separated. The crude sulfilimine was recrystallized from ethanol, yield 5 g, mp 111—112°C.

Exchange Reaction of Diphenyl Sulfide-1-^{14}C with Phenylmagnesium Bromide. In order to confirm the possibility of phenyl group interchange between the sulfide and phenyl Grignard reagent, a mixture of 0.6 g of diphenyl sulfide-1-^{14}C and phenylmagnesium bromide prepared from bromobenzene (1.6 g) and magnesium (0.24 g) in 10 m*l* of anhydrous THF was treated under the same conditions applied for the above reaction. After the reaction, diphenyl sulfide was recovered and oxidized to diphenyl sulfone by hydrogen peroxide for treatment such as degradation and ^{14}C activity determination.

Degradation of Diphenyl Sulfide-1-^{14}C.[21] In order to locate the specific position of ^{14}C activity of diphenyl sulfide-1-^{14}C the sulfide was oxidized first to the diphenyl sulfone which was then irradiated with 150 W UV lamp in benzene solution for 42 hr to afford biphenyl. After biphenyl was isolated and purified by sublimation, biphenyl (0.55 g) was oxidized by anhydrous chromic acid to benzoic acid, yield 0.16 g (37%). During those reactions no ^{14}C migration was observed. By the above method the labeled position and amount of ^{14}C activity in the diphenyl sulfide were found.

Degradation of Biphenyl-x-^{14}C. Biphenyl-x-^{14}C prepared from the sulfilimine and phenylmagnesium bromide was degraded similarly. After oxidation of biphenyl, benzoic acid-x-^{14}C was obtained in 58% yield. Both biphenyl and benzoic acid were purified by sublimation.

Measurement of ^{14}C Activity. The ^{14}C activity of the products obtained from the above reactions was measured by means of a Packard Tri Carb liquid scintillation counter by dissolving aliquot amounts of the samples in toluene. POP and POPOP were used as scintillators.

Reaction of Phenyl Benzyl N-p-*Tosylsulfilimine with Phenylmagnesium Bromide.* A typical experiment is as follows. Phenyl benzyl *N-p*-tosylsulfilimine (1 g prepared from the sulfide and chloramine-T) was dissolved in 20 m*l* anhydrous THF. To this solution was added phenylmagnesium bromide (2: 1 mol of sulfilimine) in anhydrous THF, and the solution was stirred overnight at room temperature. The solution was then decomposed with aqueous hydrochloric acid solution. The aqueous solution was extracted with chloroform. The chloroform solution was extracted again with an aqueous alkaline solution. The chloroform extract was condensed and the residue was chromatographed through a column packed with silica gel. From the chloroform eluent, a mixture of the sulfide and biphenyl was separated and the sulfilimine was recovered. The mixture was separated by means of glc (diethylene glycol succinate polyester on Neosorb). Their yields were determined by glc. After eluting the above mixture, chloroform was used to separate the polar compounds from which *N*-benzhydryl-*p*-tosylamide was obtained together with the recovered sulfilimine. *N*-Benzhydryl-*p*-tosylamide: mp 152°C; IR νSO_2 1165, 1320 cm^{-1}, νNH 3260 cm^{-1}; NMR methyl proton 7.57, methine C–H and N–H protons 4.30, phenyl protons 2.1—3.0 τ.

Found: C, 70.83; H, 5.81; N, 4.04%. Calcd for $C_{20}H_{19}SNO_2$: C, 71.20; H, 5.67; N, 4.15%.

From the alkaline extract only *p*-tosylamide was isolated.

Reaction of Phenyl Methyl N-p-*Tosylsulfilimine with Phenylmagnesium Bromide.* The reaction was carried out by the same method as for phenyl benzyl sulfilimine and after the usual work up the products given in Table IV were isolated.

Reaction of α-Chloro Sulfoxides with Carbonyl and Thiocarbonyl Compounds

Gen-ichi TSUCHIHASHI and Katsuyuki OGURA

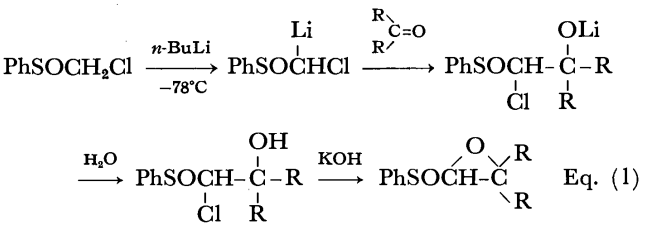
Sagami Chemical Research Center, Ohnuma, Sagamihara, Kanagawa 229

(Received January 18, 1972)

Chloromethyl methyl sulfoxide undergoes a Darzens-type reaction with carbonyl compounds in the presence of potassium *t*-butoxide in *t*-butanol to afford methylsulfinyloxirane derivatives. The stereochemistry of this reaction has been studied. The reaction with a symmetrical ketone appeared to proceed stereospecifically to give only one isomer. On the other hand, the reaction with unsymmetrical ketones such as pinacolone or acetophenone produced a mixture of two diastereoisomers, in which a thermodynamically unstable isomer was predominant. The reaction with thiobenzophenone gave 1,1-diphenyl-2-methylsulfinylethylene which seems to have been formed from the intermediacy of 2,2-diphenyl-3-methylsulfinylthiirane. Mechanisms of these reactions are also discussed.

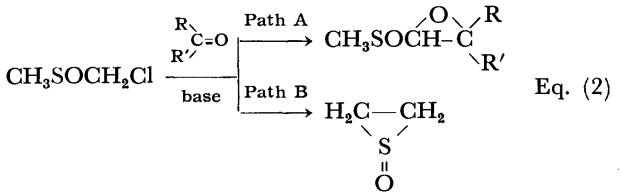
Preparation of α-chlorosulfoxides can be readily accomplished by the reaction of sulfoxides with ordinary chlorinating agents such as chlorine,[1] sulfuryl chloride,[2] *t*-butyl hypochlorite,[3] or *N*-chlorosuccinimide.[4] We have examined the synthetic utility of these α-chlorosulfoxides, particularly chloromethyl methyl sulfoxide, in order to find a way to obtain sulfoxide derivatives of a new type. Application of Darzens-type condensation to α-chlorosulfoxide, *i.e.*, the reaction with carbonyl compounds in the presence of a base, is of considerable interest.

In 1969, Durst reported that the metallation of chloromethyl phenyl sulfoxide followed by the addition to ketones, hydrolysis and successive dehydrochlorination with a base gave phenylsulfinyloxiranes as shown in the following.[5]



Eq. (1)

When alkyl chloromethyl sulfoxide is subjected to reaction with carbonyl compounds, two reactions as shown in Eq. 2 should be taken into consideration, a Darzens-



Eq. (2)

type (Path A) and a Ramberg-Bäcklund-type (Path B). We studied the reaction of chloromethyl methyl sulfoxide with carbonyl compounds in the presence of a base in order to see which reaction this sulfoxide favors.

During the course of our investigation, Tavares and his co-workers reported that chloromethyl *p*-tolyl sulfoxide is directly converted into *p*-tolylsulfinyloxiranes by treatment with carbonyl compounds and potassium *t*-butoxide in *t*-butanol–ether.[6] However, Durst and Tin pointed out that Tavares' procedure might be restricted to the sulfoxides which cannot undergo the Ramberg-Bäcklund-type reaction and they prepared methylsulfinyloxiranes by a procedure similar to that shown in Eq. (1).[7]

We found that the reaction of chloromethyl methyl sulfoxide with carbonyl compounds in the presence of potassium *t*-butoxide resulted in the formation of methylsulfinyloxiranes. The application of this reaction to unsymmetrical ketones was investigated. Two diastereomeric isomers of methylsulfinyloxiranes were obtained, and the stereochemistry of these isomers was studied in order to elucidate the steric course of the reaction. In the present paper, we describe the results as well as a study on the reaction with thiobenzophenone.

Results and Discussion

Potassium *t*-butoxide was added to a solution of *t*-butanol containing chloromethyl methyl sulfoxide and benzophenone, and the solution was kept at room temperature with stirring. After the usual work-up, colorless crystals, mp 109—110°C, were obtained in a 62% yield. The IR spectrum of the product showed an absorption at 1034 cm^{-1}, characteristic of a sulfinyl group, and no absorption around 4000—3000 cm^{-1} and 1800—1600 cm^{-1}, indicating that the product has neither hydroxyl nor carbonyl group. In its NMR spectrum, four singlets appeared at δ 7.37 (5H), 7.35 (5H), 4.58 (1H), and 2.57 (3H, CH_3SO).[8] These data as well as the following facts show the structure of this material to be 2,2-diphenyl-3-methylsulfinyloxirane (**1**). The reduction of **1** with lithium aluminum hydride gave 1,1-diphenyl-2-methylthioethanol, which was independently synthesized by the reduction of 1,1-diphenyl-2-

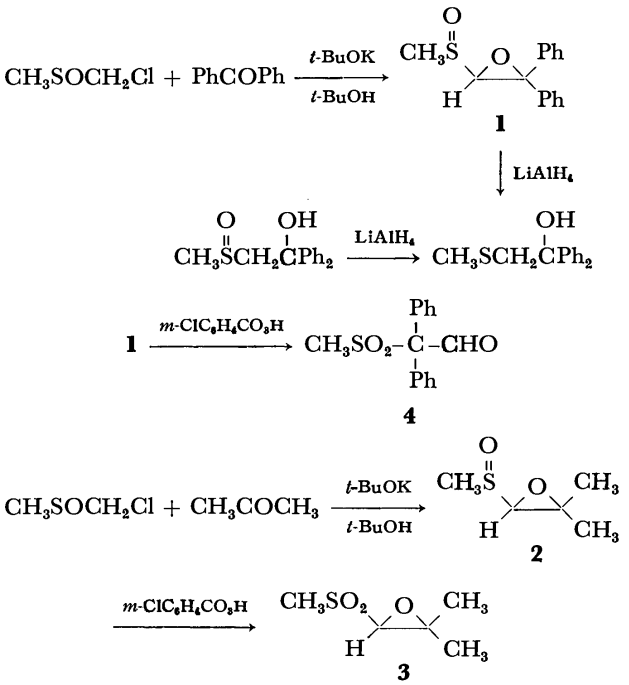
8) The protons of a normal methylsulfinyl group showed an NMR signal near δ 2.6. For example, dimethyl sulfoxide: δ 2.62; methyl methylthiomethyl sulfoxide: δ 2.59.

methylsulfinylethanol.[9]

Similarly, acetone reacted with chloromethyl methyl sulfoxide in the presence of potassium *t*-butoxide to afford a methylsulfinyloxirane in a 95% yield, its structure being assigned to 2,2-dimethyl-3-methylsulfinyloxirane (**2**) from its physical properties [IR (KBr): 1039 cm^{-1}, NMR (in CCl_4): δ 3.80 (s, 1H), 2.66 (s, 3H), 1.48 (s, 3H), and 1.45 (s, 3H)]. Oxidation of **2** gave the corresponding sulfone **3**.[10]



Scheme 1

When pinacolone was subjected to this Darzens-type reaction of chloromethyl methyl sulfoxide, a mixture shown by NMR analysis to consist of two isomeric methylsulfinyloxiranes **5** and **6** (3: 1) was formed in a 66% yield. One isomer (the major component) could be isolated, showing four singlets at δ 3.78 (1H), 2.58 (3H), 1.48 (3H), and 1.00 (9H) in its NMR spectrum and an absorption at 1034 cm^{-1} in its IR spectrum. In the NMR spectrum of the other isomer, four singlets also appeared at δ 3.44 (1H), 2.88 (3H), 1.40 (3H), and 1.08 (9H). These data are consistent with the structures given in formulas **5** and **6**. The stereochemical structure of the major component was unambiguously determined on the basis of the result of an intramolecular nuclear Overhauser effect. It was found that irradiation of the methyl signal in the NMR spectrum of the major component caused a significant increase (15%) in the intensity of the methine proton which was not effected by irradiation of the *t*-butyl signal, as shown in Fig. 1. This indicates that the methyl group and the

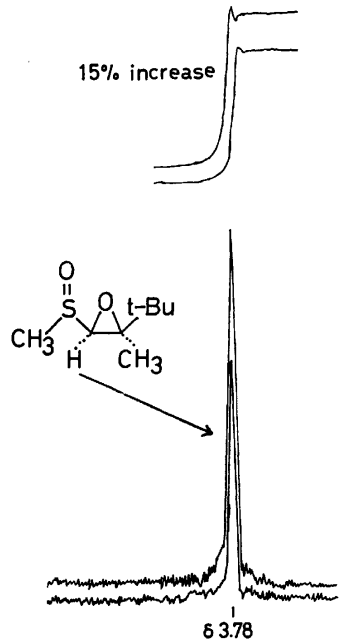


Fig. 1. Intramolecular Overhauser Effect of **5**. irradiation of the methyl signal (δ 1.41)

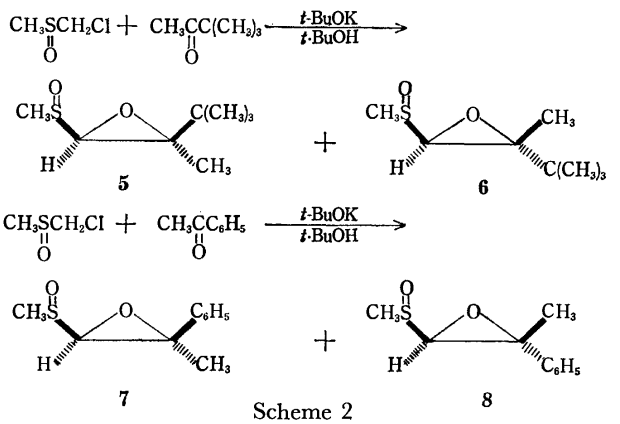
methine proton of the major component are close together in space. Thus its stereochemical structure was assigned to be **5** in which hydrogen atom and methyl group are in *cis* position.

Acetophenone reacted with chloromethyl methyl sulfoxide by an action of potassium *t*-butoxide to afford a mixture of two diastereoisomers, **7** and **8** (3: 2) in a 60% yield. We tentatively assigned the stereochemical formulas **7** and **8** to the structures of the major and the minor products, respectively, by considering a similar stereochemical course to that of the reaction of pinacolone with chloromethyl methyl sulfoxide.

The reaction of thiobenzophenone with chloromethyl methyl sulfoxide in the presence of potassium *t*-butoxide did not give the expected product, 2,2-diphenyl-3-methylsulfinylthiirane **9**, but an α,β-unsaturated sulfoxide (**10**) in a 38% yield.

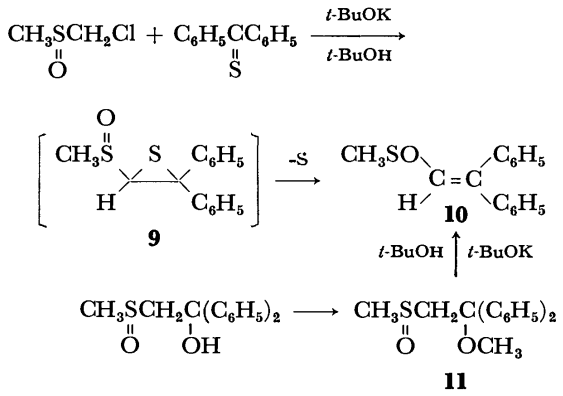
The structure of **10** was determined from its IR (1021 cm^{-1}) and NMR (δ 7.28 (s, 10H), 6.88 (s, 1H), and 2.59 (s, 3H)) spectra. The structure was further confirmed by an independent synthesis. The treatment of the methyl ether (**11**) derived from 1,1-diphenyl-2-methylsulfinylethanol with potassium *t*-butoxide af-



Scheme 2

9) E. J. Corey and M. Chaykovsky, *J. Amer. Chem. Soc.*, **87**, 1345 (1965).

10) The oxidation of **1** with *m*-chloroperbenzoic acid, accompanied by a rearrangement, yielded diphenyl(methylsulfonyl)-acetaldehyde(**4**), of which the structure was assigned by its physical properties (see Experimental Section). The analogous rearrangements of α-epoxy sulfoxides and α-epoxy sulfones to the corresponding aldehydes were already reported.[6,7]



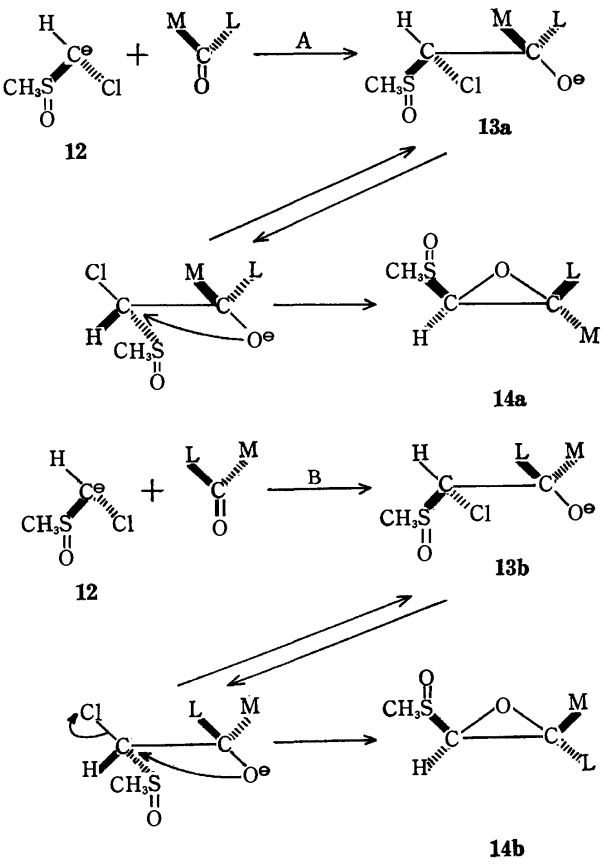
Scheme 3

forded **10**. It is reasonable to assume that **10** was formed by the desulfurization of the expected product **9**.

It should be noted that only one isomer was given in the reaction of chloromethyl methyl sulfoxide with symmetrical ketones such as benzophenone or acetone. This is in line with the result reported by Durst who found a high stereoselectivity in the Darzens-type reaction of chloromethyl phenyl sulfoxide with cyclohexanone, acetone or benzophenone.[5] On the other hand, when an unsymmetrical ketone such as pinacolone or acetophenone was used as a carbonyl component, two diastereoisomers were produced. It is of interest that a thermodynamically unstable isomer, **5** or **7**, was predominantly formed as described above. This tendency was also reported by Tavares and his co-workers. They stated that chloromethyl *p*-tolyl sulfoxide reacted with benzaldehyde to yield mainly *cis*-2-phenyl-3-(*p*-tolylsulfinyl)oxirane whose structure was assigned tentatively from the NMR coupling constant between the methine protons in the oxirane ring. They explained that their result can be attributed to precipitation of a less soluble *cis* isomer. This does not hold in our observation because the reaction condition is homogeneous. We would like to propose a plausible mechanism for the formation of a thermodynamically unstable isomer in the Darzens-type reaction of chloromethyl methyl sulfoxide with an unsymmetrical ketone. The carbanion (**12**) derived from chloromethyl methyl sulfoxide attacks a carbonyl compound to form an intermediate (**13**) in the first step of the reaction. We assume that this step is not reversible. The formation of **13a** proceeds through a less hindered transition state than the formation of **13b**, owing to the difference in bulkiness between M and L (M<L). If the oxy anion in **13a** attacks the carbon atom bearing chlorine atom from behind, as in the usual ring-closure reaction of chlorohydrins, the thermodynamically unstable isomer (**14a**) will be formed from the kinetically preferred intermediate (**13a**).

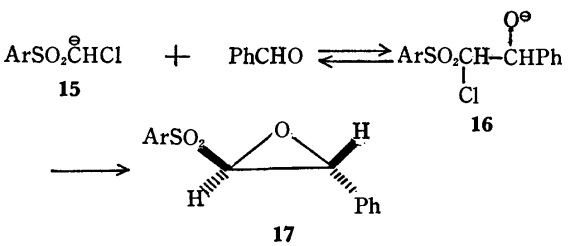
It is interesting to compare this result with that of Darzens-type condensation of α-halosulfones studied by Vogt and Tavares.[11] According to their report, a thermodynamically stable isomer, *i.e. trans* isomer, was produced exclusively. They assume that the initial nucleophilic attack upon a carbonyl compound is

11) P. F. Vogt and D. F. Tavares, *Can. J. Chem.*, **47**, 2875 (1969).



Scheme 4

rapidly reversible and the product determining step is the ring closure (**16**→**17**). The thermodynamically stable isomer was formed predominantly, passing through the preferred transition state, from the dynamic equilibrium between two diastereoisomers of **16**.



We believe that the conflicting behaviors in α-halosulfoxides and α-halosulfones can be ascribed to the difference of stability in anions **12** and **15**. Anion **15** is much more stable than anion **12**.

Experimental

Reaction of Chloromethyl Methyl Sulfoxide with Benzophenone. To a solution containing 550 mg of chloromethyl methyl sulfoxide and 970 mg of benzophenone in 5 m*l* of *t*-butanol, 10 m*l* of potassium *t*-butoxide solution (0.77N) in *t*-butanol was added and the resulting solution was stirred for 6 hr at room temperature. The solid deposited by the addition of methylene chloride (50 m*l*) was filtered off and the filtrate was evaporated under reduced pressure. The residue was crystallized from carbon tetrachloride to give 780 mg of 2,2-diphenyl-3-methylsulfinyloxirane **1** as colorless crystals.

An analytical sample was obtained by recrystallization from methylene chloride-carbon tetrachloride (mp 109—110°C); IR (neat): 1034 cm^{-1}, NMR ($CDCl_3$): δ 7.37 (s, 5H), 7.35 (s, 5H), 4.58 (s, 1H), and 2.57 (s, 3H).

Found: C, 69.61; H, 5.43; S, 12.45%. Calcd for $C_{15}H_{14}O_2S$: C, 69.74; H, 5.46; S, 12.39%.

Reduction of **1** *with Lithium Aluminum Hydride.* To a solution containing 200 mg of **1** in 10 m*l* of ether, 150 mg of lithium aluminum hydride was added and the reaction mixture was stirred for 40 hr at room temperature. After the addition of 3N sulfuric acid (3 m*l*), the mixture was extracted with methylene chloride. The organic layer was dried over anhydrous sodium sulfate and evaporated under reduced pressure. The residue was purified by column-chromatography (on silica gel, elution with benzene) to afford 96 mg of a colorless oil. This oil was identical with the product obtained by the reduction of 1,1-diphenyl-2-methylsulfinylethanol[9] with lithium aluminum hydride; bp 120°C/0.2 mmHg, NMR (CCl_4): δ 7.5—7.0 (m, 10H), 3.54 (s, 1H, OH), 3.29 (s, 2H), and 1.98 (s, 3H).

Found: C, 73.97; H, 6.47; S, 13.15%. Calcd for $C_{15}H_{16}OS$: C, 73.73; H, 6.60; S, 13.12%.

Oxidation of **1** *with* m-*Chloroperbenzoic Acid.* *m*-Chloroperbenzoic acid (175 mg) was added to a solution containing 208 mg of **1** in 15 m*l* of methylene chloride and the mixture was stirred for 1 hr under cooling with ice water. After the addition of sodium carbonate (200 mg) to the mixture and stirring for 1 hr at room temperature, insoluble material was filtered off and the filtrate was evaporated under reduced pressure. The residual crystals were recrystallized from carbon tetrachloride-*n*-hexane to yield 100 mg of the aldehyde **4** as colorless crystals; mp 125—126°C, IR (KBr): 1715, 1303, and 1136 cm^{-1}, NMR (CCl_4): δ 9.94 (s, 1H), 7.7—7.2 (m, 10H), and 2.74 (s, 3H), MS (70 eV): *m/e* 274 (M^+), 195 (base peak), 167 (69%), 166 (20%), 165 (51%), and 152 (18%).

Found: C, 65.39; H, 5.17; S, 11.67%. Calcd for $C_{15}H_{14}O_3S$: C, 65.67; H, 5.14; S, 11.69%.

Reaction of Chloromethyl Methyl Sulfoxide with Acetone. To a solution containing 815 mg of chloromethyl methyl sulfoxide in 2.5 m*l* of acetone, 12 m*l* of potassium *t*-butoxide (0.77N) in *t*-butanol was added and the solution was stirred for 11 hr at room temperature. After the addition of methylene chloride (50 m*l*), the deposited solid was filtered off and the filtrate was evaporated under reduced pressure. The residue was chromatographed on silica gel (elution with methylene chloride and methanol-ethyl acetate (1: 5)) to afford 924 mg (95%) of pale yellow crystals which were recrystallized from carbon tetrachloride to give **2** as colorless crystals; mp 88—89°C, IR (KBr): 1039 cm^{-1}, NMR (CCl_4): δ 3.80 (s, 1H), 2.66 (s, 3H), 1.48 (s, 3H), and 1.45 (s, 3H).

Found: C, 44.82; H, 7.50; S, 23.77%. Calcd for $C_5H_{10}O_2S$: C, 44.75; H, 7.51; S, 23.89%.

Oxidation of **2** by *m*-chloroperbenzoic acid was carried out in methylene chloride to yield the corresponding sulfone **3** as a colorless oil; IR (neat): 1317 and 1150 cm^{-1}, NMR ($CDCl_3$): δ 3.85 (s, 1H), 3.00 (s, 3H), 1.72 (s, 3H) and 1.46 (s, 3H).

Found: C, 39.38; H, 6.74; S, 21.10%. Calcd for $C_5H_{10}O_3S$: C, 39.98; H, 6.71; S, 21.35%.

Reaction of Chloromethyl Methyl Sulfoxide with Pinacolone. To a mixture containing 580 mg of chloromethyl methyl sulfoxide and 1.65 g of pinacolone, 10 m*l* of 0.77N potassium *t*-butoxide solution in *t*-butanol was added and the solution was stirred for 11 hr at room temperature. After the addition of 100 m*l* of methylene chloride and 1 m*l* of water, the mixture was dried over anhydrous sodium sulfate. After filtration, the filtrate was evaporated under reduced pressure. The residue was shown by NMR analysis to contain **5** and **6** in a ratio of 74: 26, and was chromatographed on Florisil to give 244 mg of a mixture consisting of **5** and **6** (5: 3), and 247 mg of **5**. An analytical sample of **5** was obtained by recrystallization from methylene chloride-*n*-hexane as colorless crystals; mp 79—81°C, IR (KBr): 1034 cm^{-1}, NMR (CCl_4): δ 3.78 (s, 1H), 2.58 (s, 3H), 1.48 (s, 3H), and 1.00 (s, 9H).

Found: C, 54.60; H, 9.09; S, 18.16%. Calcd for $C_8H_{16}O_2S$: C, 54.51; H, 9.15; S, 18.19%.

Although **6** was not isolated, a compound whose NMR signals (CCl_4) appeared at δ 3.44 (s, 1H), 2.88 (s, 3H), 1.40 (s, 3H), and 1.08 (s, 9H) was assigned to be **6**.

Reaction of Chloromethyl Methyl Sulfoxide with Acetophenone. To a solution containing 365 mg of chloromethyl methyl sulfoxide and 412 mg of acetophenone in 5 m*l* of *t*-butanol, 6 m*l* of 0.77N potassium *t*-butoxide in *t*-butanol was added and the reaction mixture was stirred for 1 hr at room temperature. After the addition of 90 m*l* of methylene chloride and a small amount of activated charcoal, the insoluble solid was filtered off. The filtrate was evaporated under reduced pressure, and the residue was crystallized from carbon tetrachloride - *n*-hexane to give 383 mg (60%) of pale yellow crystals which were shown by NMR analysis to consist of **7** and **8** (3: 2). An analytical sample was obtained by successive recrystallization from carbon tetrachloride and water as a colorless solid; mp 124—128°C, IR (KBr): 1036 cm^{-1}. The NMR signals ($CDCl_3$) of **7** appeared at δ 7.36 (s, 5H), 3.92 (s, 1H), 2.71 (s, 3H), and 1.87 (s, 3H). The NMR of **8** showed the absorption ($CDCl_3$) at δ 7.36 (s, 5H), 4.16 (s, 1H), 2.40 (s, 3H), and 1.80 (s, 3H).

Found: C, 61.04; H, 6.41; S, 16.37%. Calcd for $C_{10}H_{12}O_2S$: C, 61.19; H, 6.16; S, 16.34%.

Reaction of Chloromethyl Methyl Sulfoxide with Thiobenzophenone. To 3.5 m*l* of potassium *t*-butoxide solution (0.77N) in *t*-butanol, 245 mg of chloromethyl methyl sulfoxide and 310 mg of thiobenzophenone were added and the reaction mixture was stirred for 15 min at room temperature. The solid deposited by the addition of 50 m*l* of methylene chloride was filtered off and the filtrate was evaporated under reduced pressure. Crystallization of the residue from *n*-hexane gave 165 mg of colorless crystals. These crystals were dissolved in methanol-methylene chloride. After separation of insoluble crystals, the mother liquor was evaporated under reduced pressure to give 145 mg (38%) of colorless crystals. An analytical sample was obtained by recrystallization from methylene chloride - *n*-hexane; mp 106—107°C, IR (KBr): 1021 cm^{-1}, NMR (CCl_4): δ 7.28 (broad s, 10H), 6.88 (s, 1H), and 2.59 (s, 3H).

Found: C, 74.53; H, 5.91; S, 13.23%. Calcd for $C_{15}H_{14}OS$: C, 74.34; H, 5.82; S, 13.23%.

Independent Synthesis of 1,1-Diphenyl-2-methylsulfinylethylene. Sodium hydride (185 mg) was added to a solution of 1,1-diphenyl-2-methylsulfinylethanol[9] (1.04 g) in 15 m*l* of tetrahydrofuran and the mixture was stirred for 20 min at room temperature. Methyl iodide (3 m*l*) was added and the solution was kept for 30 min at room temperature with stirring. After the addition of water (10 m*l*), the reaction mixture was extracted with methylene chloride. The organic layer was dried over anhydrous sodium sulfate and evaporated under reduced pressure to give colorless crystals which were recrystallized from *n*-hexane to give the corresponding methyl ether (**11**), mp 130.5—132.5°C.

A mixture containing 150 mg of **11** and 2 m*l* of 0.77N potassium *t*-butoxide in *t*-butanol was refluxed for 3.5 hr. After removal of the solvent under reduced pressure, the

residue was chromatographed on silica gel (elution with methylene chloride and ethyl acetate) to afford 39 mg of **9** as colorless crystals, mp 107—107.5°C. These crystals were identical with those obtained by the reaction of chloromethyl methyl sulfoxide with thiobenzophenone (by IR and mixture mp).

We thank Mr. K. Sato and Dr. M. Fukuyama for measurement of the intramolecular nuclear Overhauser effect.

We are grateful for financial support from the Kawakami Memorial Foundation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2027—2032(1972)

Aminosugars. XX. Synthesis of Some Derivatives of 2-Acetamido-2-deoxy-D-mannose[1]

Juji YOSHIMURA, Hideo SAKAI, Nobuteru ODA, and Hironobu HASHIMOTO

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received January 11, 1972)

Preparation of 2-acetamido-2-deoxy-D-mannose (**2**) by epimerization of the corresponding D-glucose was improved by addition of Ni^{2+} ion to the equilibration system, and several derivatives of **2** were synthesized. *N*-glycosides were obtained by using ammonium chloride as a catalyst, and *p*-nitrophenyl glycoside by a fusion method. The composition of four isomers in benzylglycosidation of **2** was determined to be 66% α-pyranoside (**6**), 11% β-pyranoside, 16% α-furanoside (**5**) and 7% β-furanoside. Benzylidenation of **6** gave the corresponding 4,6-*O*-benzylidene derivative which was converted into the 3-*O*-acetate (**8**) by acetylation, and to the corresponding 2-amino-2-deoxy derivative by treatment with ethanolic potassium hydroxide. Oxidation of **6** with oxygen in the presence of platinum-charcoal and following esterification gave the corresponding methyl uronate which was derived to the di-*O*-acetate (**11**). Periodate oxidation and the following hydrogenation of **5** gave benzyl 2-acetamido-2-deoxy-α-D-lyxofuranoside which was then derived to di-*O*-acetate (**13**). Nitromethane condensation of **2** in barium hydroxide solution gave one isomeric 1-*C*-nitro-1-deoxy-D-heptitol which was converted into methyl 3-acetamido-3-deoxy-D-*glycero*-D-*galacto*-α-heptopyranoside (**18**). First-order analyses of NMR spectra of **8**, **11**, **13**, and tetra-*O*-acetate of **18** are described.

Of the 2-aminosugars found in nature 2-amino-2-deoxy-D-glucose and -D-galactose derivatives have been extensively studied.[2] However, the corresponding D-mannose derivatives have been scarcely investigated at all due to difficulty of availability from both natural and synthetic resources. In addition, 2-acetamido-2-deoxy-D-mannose (**2**) is known to be a component of *N*-acetyl-neuraminic acid,[3] and the corresponding uronic acid was recently found in polysaccharides of bacterial cell walls.[4-6] The authors studied an improved preparation of **2** by the epimerization of 2-acetamido-2-deoxy-D-glucose (**1**), and have synthesized several derivatives.

Results and Discussion

The epimerization of **1** in alkaline mediums such as sodium or ammonium hydroxide solution has been examined,[7-9] but, the formation of **2** at the pseudo-equilibrium did not exceed *ca.* 15%. Considering the yield would increase if the equilibrium was shifted toward **2** by a complex formation with metallic ions, we examined their effect on the epimerization of **1** in ammonium hydroxide solution by PPC. Ions such as Mg^{2+}, Cu^{2+}, $Cr_2O_7^{2-}$, Ca^{2+}, Zn^{2+}, or Ba^{2+} decreased and MoO_4^{2-}, Ni^{2+}, Mn^{2+}, Fe^{3+}, Co^{2+}, or Pb^{2+} ion increased the formation of **2**. Effects of the latter were studied in detail by glc. The results given in Fig. 1 indicate that the addition of nickel ion increased markedly the yield of **2** up to 25%. Though the mechanism is not yet clear, it is obvious that the coexistence of metallic ion change more or less the equilibration between **1** and **2**. From the equilibration mixture, **2** was isolated by an improved method of Carlo *et al.*[10]

As derivatives of **2**, some *N*-glycosides were first prepared in the usual way.[11] When ethanol solution of **2** and aromatic amines (aniline, *o*-toluidine, *m*- and *p*-nitroaniline, and α- and β-naphthylamine) were refluxed

(1): $NiCO_3 \cdot Ni(OH)_2$, (2): $Fe_2(SO_4)_3$, (3): $Co(OAc)_2$, (4): $(NH_4)_2MoO_4$, (5): Without metallic salt. (6): $MnSO_4$

in the presence of ammonium chloride as a catalyst, the corresponding *N*-glycosides (**3a**—**f**) were obtained as crystals. However, in the cases of *o*-nitroaniline, 2,4-dinitroaniline and diphenylamine, the starting materials were recovered. Anomeric configuration of **3a**—**f** was deduced to be β from their negative optical rotations. Their physical constants are summarized in Table 1. *p*-Nitrophenyl glycoside (**4**) of **2** was newly prepared from the corresponding *N,O*-pentaacetate by a fusion method[12] in 20.8% yield.

On the other hand, in the benzylglycosidation of **2** in the presence of boron trifluoride and hydrogen chloride carried out by Plimmer *et al.*,[13] only the corresponding α-furanoside (**5**) was isolated as the tri-*O*-acetate in a low yield after acetylation of the products. We repeated the experiment and proved the composition of the corresponding α-pyranoside, β-pyranoside, α-furanoside, and β-furanoside in the product to be 66%, 11%, 16%, and 7%, respectively. After benzylglycosidation, the reaction mixture was poured into water and extracted with ether. Concentration of the aqueous solution gave crystalline benzyl 2-acetamido-2-deoxy-α-D-mannopyranoside (**6**) in 31.7% yield, which was identical with that derived *via* 4,5-(3,4,6-tri-*O*-acetyl-2-deoxy-D-mannopyrano)-2-methyl-Δ^2-oxazoline.[14] The ether extracts were re-extracted with water. Evaporation of the resulting solution gave **5** in 0.5% yield. In order to elucidate the ratio of the four isomers, sirups A and B obtained from the mother liquors of **6** and **5**, respectively, were examined by glc. Sirups A and B showed four and three peaks, respectively, in the ratio given in Fig. 2, and peaks a and d were identified with **6** and **5**, respectively. The other two peaks b and c were deduced to be β-pyranoside and β-furanoside, respectively, from their retention times. The ratio of the four isomers of benzyl glycoside mentioned above was calculated from the yields of **5** and **6**, the area ratio of each peak and the amount of sirup A and B. The results are consistent with the fact that Gross *et al.*[15] isolated ethyl 2-acetamido-2-deoxy-α-D-mannopyranoside from the glycosidation mixture by column chromatography in 62% yield.

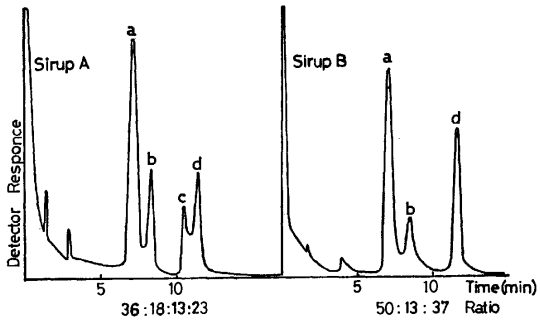

Fig. 2. Gas chromatogram of sirup A and sirup B.
(Column: 1.5% OV-17 on Chromosorb G, 2m×4 mm; carrier gas: N_2, 60 ml/min; temperature: 235°C).

Benzylidenation of **6** gave benzyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-mannopyranoside (**7**), whose structure was ascertained by the NMR spectrum of its 3-*O*-acetyl derivative (**8**). *N*-Deacetylation of **7** with potassium hydroxide in ethanol gave benzyl 2-amino-4,6-*O*-benzylidene-2-deoxy-α-D-mannopyranoside (**9**). Catalytic oxidation of **6** with oxygen in the presence of platinum-charcoal gave benzyl 2-acetamido-2-deoxy-α-D-mannopyranosiduronic acid (**10**), whose structure was ascertained by the NMR spectrum of the corresponding methyl 3,4-di-*O*-acetyl-uronate (**11**). In addition, **5** was converted into benzyl 2-acetamido-2-

In a previous paper, one of the authors (J. Y.) reported that nitromethane condensation of D-glucose was accomplished only in water in the presence of barium hydroxide as a catalyst, but not that of **1**.[16] However, 1-*C*-nitro-1-deoxy derivative (**14**) from **2** was easily obtained under the same conditions, which gave the corresponding tetra-*O*-acetate (**15**). The configuration at *C*-2 of **14** was determined by conversion into the corresponding 3-acetamido-3-deoxy-D-heptose (**16**) by the Nef reaction, which was nearly the same as 3-acetamido-3-deoxy-D-*glycero*-D-*galacto*-heptose synthesized by the cyanohydrin method.[9] Methyl-glycosidation of **16** with 3% methanolic hydrogen chloride was accompanied by de-*N*-acetylation to give the corresponding methyl α,β-glycoside hydrochloride (**17**). *N*-Acetylation and per-acetylation of **17** gave pure *N*-acetate (**18**)[9] and *N*,*O*-pentaacetate (**19**) of the corresponding methyl α-D-glycoside, respectively. The configuration of **19** was proved to be methyl 3-acetamido-3-deoxy-D-*glycero*-D-*galacto*-α-heptopyranoside by the analysis of NMR spectrum (Fig. 3). The irradiation of NH or H_4 caused H_3 proton signals to change from an octet to a quartet. However, no change of H_5 proton signals indicates that $J_{4,5}$ is nearly zero. Moreover, irradiation of H_7 caused $H_{7'}$ proton signals to collapse to a doublet and changed the appearance of H_2 and H_6 proton signals. Assignments of H_2 and H_6 protons were also supported by the fact that their tickling caused H_7 and $H_{7'}$ proton signals to collapse to a doublet, and H_5 to a singlet. It would be rational that proton signals attached to carbons having secondary acetoxyl groups appear in lower magnetic field than that of others. NMR parameters of **8**, **11**, **13**, and **19** are summarized in Table 2. We see that coupling constants of ring protons in **8** and **11** present the characteristics of the configuration of α-D-mannopyranoside. The same value for $J_{2,3}$ and $J_{3,4}$ in **13** indicates that it exists in a twist conformation in which C_2 and C_3 atoms are displaced in the opposite sense to the plane of the other ring atoms.[17,18] Similarly, the value for $J_{2,3}$ of **19** is consistent with the di-axial relationship of the D-*glycero*-D-*galacto*-heptopyranoside configuration. It should be noted that distortion of the pyranoside-ring in **19** is suggested by the values for $J_{4,5}$ and $J_{1,2}$.

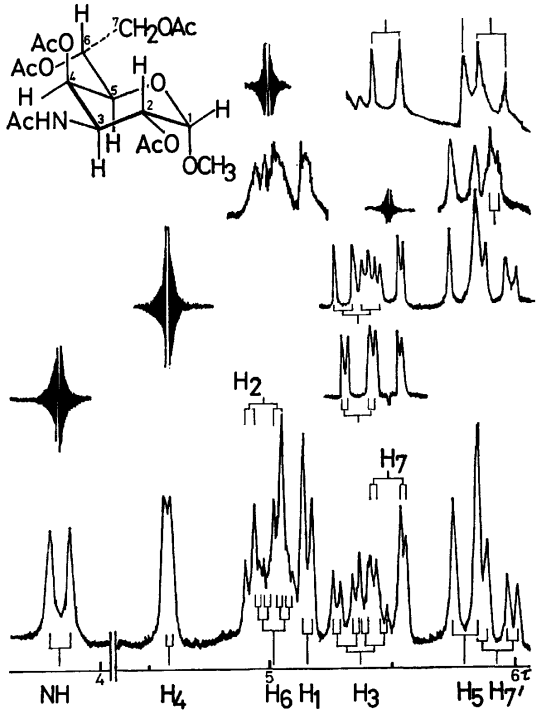

Fig. 3. NMR spectrum of methyl 3-acetamido-3-deoxy-2,4,6,7-tetra-*O*-acetyl-D-*glycero*-D-*galacto*-α-heptopyranoside (100 MHz, $CDCl_3$).

Experimental

The melting points were determined on a sulfuric acid bath and uncorrected. Optical rotations were measured in 0.5 or 0.2-dm tubes with a Carl Zeiss Photoelectric Polarimeter. NMR spectra were recorded at 100 MHz with a JNM 4H-100 Spectrometer, with tetramethylsilane as an internal standard. Glc was carried out with a Shimadzu 4-A Chromatograph using a flame ionization detector. IR spectra were recorded with a Hitachi Model EPI-GS Spectrophotometer. Chemical shifts and coupling constants were recorded in τ and Hz scales, and IR frequencies in cm^{-1}.

Examination of the Effect of Metallic Ions on the Epimerization of 2-Acetamido-2-deoxy-D-glucose (1). *(i) Paper Chromatography*: An aqueous solution of **1** (10 mg) and one of the metallic salts (5 mg) described below was adjusted with

a) Compound **8** was measured in pyridine-d_5 and the others in chloroform-d_1.
b) The peaks of H_4, H_5, and H_5 were analyzed as an AB_2 system.

ammonia (*ca.* 1 m*l*) to pH 11, allowed to stand at room temperature for 24 hr, and examined by ppc with a borated paper of Tokyo Filter Paper No. 50A and 1-butanol-pyridine-water (6:4:3, v/v) as a developing solvent. R_f values of **1** and 2-acetamido-2-deoxy-D-mannose were 0.58 and 0.16, respectively, and the amounts of both compounds were roughly estimated by visual comparison of both spots developed with aniline hydrogen phthalate. Metallic salts such as nickel carbonate, ferric sulfate, lead acetate, manganese sulfate, cobalt sulfate, and ammonium molybdate (Group A) increased, and barium hydroxide, magnesium acetate, cupric acetate, calcium acetate, zinc chloride, and potassium dichromate (Group B) decreased the formation of **2**.

(ii) Gas-Liquid Chromatography: A solution of a metallic salt (0.5 g) of group A, **1** (5.0 g), and concentrated aqueous ammonia (0.4 m*l*) in water (15 m*l*) was allowed to stand at room temperature. An aliquot (0.2 m*l*) of the reaction mixture was evaporated to dryness at suitable intervals, and the residue was subjected to gas-liquid chromatography after trimethylsilylation. The yield of **2** was calculated from the ratio of peak areas of **1** and **2**. The retention times of **1** and **2** were 9.2 and 5 min, respectively, under the following conditions. Column: 1.5% OV-17 on Chromosorb G, 3 m×3 mm. Carrier gas: N_2, 1.12 kg/cm^2. Temp.: 165°C.

Preparation of 2-Acetamido-2-deoxy-D-mannose (2). A solution of **1** (500 g) and nickel carbonate (25 g) in water (1.5 *l*) was adjusted to pH 11 with concentrated ammonia (*ca.* 15 m*l*), allowed to stand at room temperature for 3 days under nitrogen atmosphere, and then neutralized by addition of dry ice. Nickel ions were removed from the reaction mixture as sulfide, and the aqueous solution was evaporated. Unchanged **1** deposited during the course of the concentration was recovered by filtration. The sirup remained was dried on phosphorus pentoxide, extracted several times with hot ethanol (each 150 m*l*), and the combined extracts were evaporated after filtration of **1** precipitated. The residual sirup was crystallized from aqueous ethanol (50%)-acetone, and recrystallized from water-acetone. Yield, 100 g (20%); mp 124—126°C (lit,[10] mp 127—128°C).

N-Aryl 2-Acetamido-2-deoxy-β-D-mannopyranosyl Amines (3a—f). A solution of **2** (200 mg), an amine (4 molar equivalent), and ammonium chloride (4 mg) in absolute ethanol (6 m*l*) was refluxed for 1 hr. Partial evaporation of ethanol (4 or 5 m*l*) and addition of ether gave crystals. *N*-Glycosides were recrystallized from ethanol–ether. The results are shown in Table 1. The compounds show characteristic IR absorptions of an amide and aromatics, respectively.

p-Nitrophenyl 2-Acetamido-2-deoxy-α-D-mannopyranoside (4). Acetylation of **2** with a mixture of acetic anhydride and pyridine gave 2-acetamido-2-deoxy-1,3,4,6-tetra-*O*-acetyl-β-D-mannopyranose[12] in 53% yield. To a fused mixture of this acetate (200 mg, 0.51 mmol) and *p*-nitrophenol (287 mg, 2.1 mmol) was added a mixture of acetic acid and acetic anhydride (1 m*l*; 19: 1 v/v) containing *p*-toluenesulfonic acid (4 mg), and heated for 75 min at 120—125°C, with continuous evacuation by a water pump to remove acetic acid. A chloroform solution of the reaction mixture was then washed with water, N-sodium hydroxide, and again water, and concentrated to a sirup. To a solution of the dried sirup in absolute methanol was added metallic sodium (10 mg) under cooling and the reaction mixture was allowed to stand for 2 hr at room temperature, neutralized with Amberlite IR-120 (H^+), and concentrated to a sirup crystallized from ethyl acetate. Yield, 40 mg (20.8%); mp 101—102.5°C; $[\alpha]_D^{23}$ +65.4° (*c* 1.0, methanol). IR: 1640 and 1540 (NHAc), 1590 and 1505 (phenyl), and 1500 (NO_2).

Found: C, 48.26; H, 5.53; N, 7.92%. Calcd for $C_{14}H_{18}N_2O_8 \cdot 1/3H_2O$: C, 48.28; H, 5.40; N, 8.04%.

Benzylglycosidation of 2-Acetamido-2-deoxy-α-D-mannose. An admixture of **2** (100 g, 0.42 mol), distilled benzyl alcohol (920 m*l*) and boron trifluoride etherate (10 m*l*) was heated at 100—105°C for 1 hr under stirring and the reaction was continued for 1 hr after the addition of hydrochloric acid (5 g). The reaction mixture was evaporated *in vacuo* to give a sirup, which was dissolved in water and extracted with ether to remove benzyl alcohol. The water layer was passed through a column of Amberlite IRA-410 (OH^-), decolorized and concentrated to a loose sirup from which benzyl 2-acetamido-2-deoxy-α-D-mannopyranoside (**6**) was deposited. **6** was recrystallized from water; yield, 40.3 g (31%); mp 76—79°C; $[\alpha]_D^{23}$+97.5° (*c* 0.6, chloroform), (lit,[14] mp 73—78°C; $[\alpha]_D^{20}$+97.3°). IR: 1630 and 1560 (NHAc).

Found: C, 57.99; H, 7.10; N, 4.50%. Calcd for $C_{15}H_{21}NO_6$: C, 57.86; H, 6.80; N, 4.50%.

When **6** could not be obtained as crystals, benzylidenation of a part of the dried sirup easily gave benzyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-mannopyranoside (**7**) as crys-

tals in *ca.* 30% yield, and hydrolysis of **7** with 60—70% aqueous acetic acid gave **6** as crystals available for seeding.

The ether extract was re-extracted with water, and the water solution was neutralized with Amberlite IRA-410 and concentrated to a sirup, which was crystallized from methanol–*n*-hexane to give benzyl 2-acetamido-2-deoxy-α-D-mannofuranoside (**5**) as crystals. Yield, 0.65 g (0.5%); mp 167—168°C; $[\alpha]_D^{23}$+134.7° (*c* 0.5, methanol), (lit,[13] mp 172—173°C, $[\alpha]_D^{20}$+132°). IR: 1620 and 1560 (NHAc).

Found: C, 58.07; H, 6.91; N, 4.46%. Calcd for $C_{15}H_{21}NO_6$: C, 57.86; H, 6.80; N, 4.50%.

A pure sample of **5** also could be obtained by the purification of crude products *via* 5,6-*O*-isopropylidenation and de-5,6-*O*-isopropylidenation, but the isopropylidene derivative could not be crystallized.

The results of the analysis of sirup obtained from the mother liquor of **5** and **6** by glc are given in Fig. 2.

*Benzyl 2-Acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-mannopyranoside (**7**).* A mixture of **6** (10 g, 32 mmol), benzaldehyde (100 m*l*) and zinc chloride (21 g) was shaken for one day at room temperature, and then poured into ice-water (200 m*l*). The resulting mixture was allowed to stand for 2 hr under occasional stirring, and the water layer was decanted off. An oily liquid which remained was triturated three times with petroleum ether to give a powder, which was washed with ether and crystallized from methanol. Yield, 9.0 g (70%); mp 210—211.5°C; $[\alpha]_D^{23}$+45.6° (*c* 0.8, methanol). IR: 3350 (NH), 1640 and 1520 (NHAc).

Found: C, 66.34; H, 6.42; N, 3.65%. Calcd for $C_{22}H_{25}NO_6$: C, 66.15; H, 6.31; N, 3.51%.

*Benzyl 2-Acetamido-3-*O*-acetyl-4,6-*O*-benzylidene-2-deoxy-α-D-mannopyranoside (**8**).* A sample of **7** (200 mg, 0.5 mmol) was acetylated with acetic anhydride (2 m*l*, 20 mmol) and pyridine (2 m*l*) in the usual way to give **8** quantitatively; mp 221—222°C; $[\alpha]_D^{23}$+61.4° (*c* 1.0, methanol). IR: 3375 (NH), 1715 (OAc), 1670 and 1515 (NHAc).

Found: C, 65.17; H, 6.03; N, 3.26%. Calcd for $C_{24}H_{27}NO_7$: C, 65.29; H, 6.16; N, 3.17%.

*Benzyl 2-Amino-4,6-*O*-benzylidene-2-deoxy-α-D-mannopyranoside (**9**).* A solution of **7** (14.6 g) and potassium hydroxide (39 g) in ethanol (150 m*l*) was refluxed for 16 hr, and then poured into ice-water. The resulting precipitate was filtered, washed with water and recrystallized from ethanol-petroleum ether to give crystals in 78% (10.1 g) yield. Mp 133—134°C; $[\alpha]_D^{23}$+64.7° (*c* 0.6, methanol). IR: 3375, 3310, 1570 (NH_2); NMR ($CDCl_3$): 2.69 (phenyl), 4.52 (methine), 5.24 (H_1; s), 5.35 and 5.56 (–CH_2–; ABq, J=11.8), 6.78 (H_2; d, $J_{2,3}$=4.9), 5.48 (H_3; q, $J_{3,4}$=8.5), 7.78 (OH and NH_2).

Found: C, 67.21; H, 6.84; N, 4.12%. Calcd for $C_{20}H_{23}NO_5$: C, 67.21; H, 6.49; N, 3.92%.

*Benzyl 2-Acetamido-2-deoxy-α-D-mannopyranosiduronic Acid (**10**).* A suspension of **6** (30 g, 96 mmol) and platinum-charcoal (10%, 20 g) in water (600 m*l*) was stirred on a bath at 89—93°C with bubbling of oxygen gas. The pH of the reaction mixture was occasionally adjusted to 7.0—7.8 by the addition of sodium bicarbonate solution, and over oxidation was controlled by the addition of *sec*-butanol. The reaction was followed by tlch wit 1-butanol–water–acetic acid (4:5:1, upper phase), and stopped when a spot of the starting material disappeared. The undissolved materials were then filtered off, and the filtrate was treated with Amberlite IR-120 (H^+) to remove sodium ions, decolorized and concentrated to give a solid which was crystallized from water; yield, 16.0 g (51%), mp 197°C (decomp.), $[\alpha]_D^{23}$+52.6° (*c* 0.5, water). IR: 1705 (COOH), 1615 and 1540 (NHAc).

Found: C, 55.67; H, 5.85; N, 4.25%. Calcd for $C_{15}H_{19}NO_7$: C, 55.38; H, 5.89; N, 4.31%.

*Methyl (Benzyl 2-Acetamido-3,4-di-*O*-acetyl-α-D-mannopyranoside)uronate (**11**).* To a solution of **10** (1.0 g, 3.1 mmol) in methanol (70 m*l*) was added diazomethane (*ca.* 1.1 g, 26 mmol) in ether (15 m*l*) under ice-cooling, and the reaction mixture was allowed to stand for 1 hr at room temperature, and then evaporated to give a sirup which showed two spots on a tlc. An aqueous solution of the sirup was extracted with ether to remove impurities, and concentrated. The resulting sirup was dried and acetylated by the usual method to give **11** as a sirup. Yield, 0.85 g (65%); $[\alpha]_D^{22}$+77.3° (*c* 0.8, methanol). IR: 3280 (NH), 1750 (OAc), 1650 and 1540 (NHAc).

Found: C, 57.20; H, 6.49; N, 3.02%. Calcd for $C_{20}H_{25}NO_9$: C, 56.73; H, 5.95; N, 3.31%.

*Benzyl 2-Acetamido-2-deoxy-α-D-lyxofuranoside (**12**).* To a solution of **5** (1.0 g, 3.2 mmol) in water (16 m*l*) was added sodium metaperiodate (0.76 g, 3.5 mmol) in water (10 m*l*), and the reaction mixture was allowed to stand for 1 hr at room temperature and then sodium borohydride (0.21 g, 5.5 mmol) in water (5 m*l*) was added dropwise under stirring. The resulting solution was deionized with Amberlite IR-120B and IRA-410 and concentrated. The sirup obtained was decolorized in methanol. Evaporation of methanol gave crystals which was recrystallized from methanol–petroleum ether. Yield, 0.8 g (90%); mp 127—128°C; $[\alpha]_D^{23}$+76.7° (*c* 0.26, methanol); IR: 1635 and 1540 (NHAc).

Found: C, 59.39; H, 6.74; N, 4.94%. Calcd for $C_{14}H_{19}NO_5$: C, 59.77; H, 6.81; N, 4.98%.

*Benzyl 2-Acetamido-3,5-di-*O*-acetyl-2-deoxy-α-D-lyxofuranoside (**13**).* Acetylation of **12** (99 mg, 0.35 mmol) with acetic anhydride (1 m*l*, 10 mmol) and pyridine (1 m*l*) gave **13** in 78.6% (102 mg) yield. The substance was recrystallized from ether; mp 122—124°C; $[\alpha]_D^{21}$+99.8° (*c* 0.6, methanol); IR: 3280 (NH), 1750 (OAc), 1650 and 1540 (NHAc).

Found: C, 59.39; H, 6.35; N, 3.79%. Calcd for $C_{18}H_{23}NO_7$: C, 59.18; H, 6.33; N, 3.83%.

*3-Acetamido-1,3-dideoxy-1-*C*-nitro-*D*-glycero-*D*-galacto-heptitol (**14**).* To a mixed solution of **2** (40 g, 167 mmol) in water (80 m*l*) and nitromethane (100 m*l*, 1.85 mol) was added barium hydroxide octahydrate (112 g, 356 mmol) under cooling and stirring. The reaction mixture was stirred for 1 hr at 40—45°C. Ethanol (120 m*l*) was then added to precipitate barium salts. The mixture was allowed to stand overnight in a refrigerator, and the supernatant layer was decanted off, from which **2** was recovered (11.6 g, 29%). The precipitate was dissolved in 2N-acetic acid, and barium ions were immediately removed by addition of 2N-sulfuric acid and filtration. The filtrate was concentrated to give **15** as crystals. When **15** could not be obtained as crystals, the sirup was dissolved in water (50 m*l*) and impurities were extracted with ethyl acetate. The solution was then concentrated again to give **15** as crystals. The product was recrystallized from water-ethanol; yield, 8.4 g (26%); mp 213—214°C (decomp.); $[\alpha]_D^{23}$−50.1° (*c* 1.2, water). IR: 1620 and 1550 (NHAc), 1520 (NO_2).

Found: C, 38.02; H, 6.24; N, 10.20%. Calcd for $C_9H_{18}N_2O_8$: C, 38.30; H, 6.43; N, 9.93%.

*3-Acetamido-2,4,6,7-tetra-*O*-acetyl-1-*C*-nitro-1,3-dideoxy-*D*-glycero-*D*-galacto-heptitol (**12**).* To a suspension of **14** (100 mg, 0.36 mmol) in acetic anhydride (2 m*l*, 19 mmol) was added one drop of concentrated sulfuric acid. The mixture was allowed to stand overnight at room temperature, poured into ice-water (30 m*l*) and extracted with chloroform. The extract was washed with water thorougly and concentrated to give crystals quantitatively, which were recrystallized from

ethanol-ether; mp 131—132°C; $[\alpha]_D^{23}$ −13.7° (*c* 1.04, methanol). IR: 1745 (OAc), 1650 and 1550 (NHAc), 1520 and 1365 (NO_2).

Found: C, 45.98; H, 5.80; N, 5.68%. Calcd for $C_{19}H_{28}N_2O_{13}$: C, 46.35; H, 5.73; N, 5.69%.

3-Acetamido-3-deoxy-D-glycero-D-galacto-*heptose (**16**)*. A solution of **14** (4.0 g, 14.2 mmol) in 2N-sodium hydroxide (50 m*l*) was added dropwise to 14.4N-sulfuric acid (100 m*l*) at a temperature controlled under 2°C. Ice-water (250 m*l*) was poured into the reaction mixture in order to prevent temperature rise. Barium carbonate (284 g) was added to remove sulfate ions, and the mixture was stirred for 6 hr. After the precipitate was filtered off, the filtrate was treated with Amberlite IR-120 (H^+), concentrated to give a residue which was crystallized and recrystallized from water-ethanol. Yield, 3.07 g (86%); mp 215—216°C (decomp.); $[\alpha]_D^{23}$ +162° (5 min), +116° (24 hr), (*c* 0.48, water), (lit,[9] mp 223—225°C, $[\alpha]_D$ +150°→+110°). IR: 1605 and 1555 (NHAc).

Found: C, 42.74; H, 6.81; N, 5.53%. Calcd for $C_9H_{17}NO_7$: C, 43.02; H, 6.82; N, 5.58%.

Methyl 3-Amino-3-deoxy-D-glycero-D-galacto-*α,β-heptopyranoside Hydrochloride (**17**)*. A suspension of dried **16** (1.5 g, 48 mmol) and Drierite (1 g) in methanol (46 m*l*) containing hydrochloric acid (3%) was refluxed for 50 hr, and filtered and the filtrate was evaporated. Hydrochloric acid was completely removed by evaporation three times of a methanol solution of the residue and the residue was crystallized from methanol-ethyl acetate. Yield, 0.90 g (55.8%); mp 212°C (decomp.); $[\alpha]_D^{22}$ +126° (*c* 0.5, water). IR: 1605 and 1520 (NH_3^+).

Found: C, 36.71; H, 7.01; N, 5.62%. Calcd for $C_8H_{17}NO_6 \cdot HCl$: C, 37.00; H, 6.99; N, 5.39%.

Methyl 3-Acetamido-3-deoxy-D-glycero-D-galacto-*α-heptopyranoside (**18**)*. To a solution of **17** (330 mg, 1.27 mmol) in methanol (30 m*l*) containing 31 mg (1.35 mmol) of sodium metal was added acetic anhydride (0.14 m*l*) under stirring. After standing for 1 hr at room temperature, the reaction mixture was treated with silver carbonate (0.3 g) and filtered. The filtrate was deionized with Amberlite IR-120B (H^+), and evaporated to give crystals (326 mg, 97%), which were recrystallized from methanol-ethyl acetate-petroleum ether. Yield, 200 mg (60%): mp 224°C (decomp.); $[\alpha]_D^{22}$ +203° (*c* 0.5, water), (lit,[9] mp 233—236°C, $[\alpha]_D^{23}$ +207°). IR: 3300 (NH), 1640 and 1550 (NHAc).

Found: C, 45.55; H, 7.33; N, 5.56%. Calcd for $C_{10}H_{19}NO_7$: C, 45.28; H, 7.22; N, 5.28%.

Methyl 3-Acetamido-3-deoxy-2,4,6,7-tetra-O-*acetyl*-D-glycero-D-galacto-*α-heptopyranoside (**19**)*. Acetylation of **17** by the usual method gave the corresponding tetraacetate which was recrystallized from ether, in 53.8% yield. Mp 184—186°C; $[\alpha]_D^{21}$ +172° (*c* 1.01, methanol). IR: 3350 (NH), 1740 (OAc), 1660 and 1535 (NHAc).

Found: C, 49.61; H, 6.34; N, 3.00%. Calcd for $C_{18}H_{27}NO_{11}$: C, 49.88; H, 6.28; N, 3.23%.

Kinetic Study on Homolysis of Aryl Arylazo Sulfones[1)]

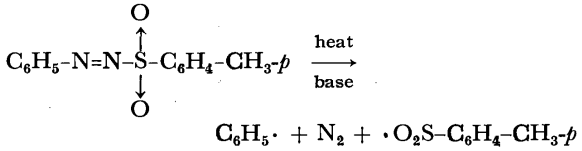
Minoru KOJIMA, Hiroshi MINATO, and Michio KOBAYASHI*

Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo

(Received December 7, 1971)

Aryl arylazo sulfones were prepared, and the rates of homolyses in chlorobenzene were determined in the presence of a base for suppression of acid catalysis at 80—118°C. An isokinetic relationship was found to hold between $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ (β=101.0°C). The substituents on the benzenesulfonyl group influenced the rates very little, whereas the substituents on the phenylazo group decreased the rates (especially the electron-releasing substituents).

Phenylazo *p*-tolyl sulfone was found to undergo homolysis when such bases as pyridine, quinoline, and magnesium oxide were present for suppression of heterolysis catalyzed by acidic products.[2)]



$$C_6H_5\text{-}N{=}N\text{-}\overset{\overset{O}{\uparrow}}{\underset{\underset{O}{\downarrow}}{S}}\text{-}C_6H_4\text{-}CH_3\text{-}p \xrightarrow[\text{base}]{\text{heat}} C_6H_5\cdot + N_2 + \cdot O_2S\text{-}C_6H_4\text{-}CH_3\text{-}p$$

Rates of homolyses of substituted phenylazotriphenylmethanes[3)] and aryl arylazo sulfides[4)] were reported. In contrast to the case of substituted benzoyl peroxides, the rates of decomposition of these azo compounds containing electron-releasing and electron-withdrawing substituents (except that with *p*-methyl) were smaller than that of the non-substituted azo compounds. The effect of the substituents of aryl arylazo sulfones on the rates of decomposition appears to be of great interest, and kinetic studies have been carried out in chlorobenzene. The results will be described in the present paper.

Experimental

Materials. Aryl arylazo sulfones except the *p*-dimethylamino derivative were prepared from substituted benzenediazonium chlorides and sodium salts of substituted benzenesulfinic acids according to the method of Hantzsch.[5]

p-Dimethylaminophenylazo *p*-tolyl sulfone was prepared by isolating *p*-dimethylaminobenzenediazonium fluoroborate[6] and letting it react with sodium *p*-toluenesulfinate in water.

Kinetic Measurements. Since the thermal homolyses of aryl arylazo sulfones are complicated because of the occurrence of the heterolyses catalysed by the acidic products (sulfonic acids, sulfinic acids),[2] the rates of decomposition were determined in the presence of pyridine (3 mol per mol of an azosulfone) except the *p*-dimethylamino azosulfone. The rates of decomposition of *p*-dimethylaminophenylazo *p*-tolyl sulfone were determined in the presence of triethylamine (3 mol per mol of the azosulfone), since the azosulfone itself possesses a basicity comparable to that of pyridine.

An azosulfone (3 mmol) was dissolved in a mixture of chlorobenzene (60 m*l*) and pyridine (or triethylamine) in a flask placed in a constant-temperature bath. Decomposition was followed by determining the amount of nitrogen gas evolved by use of a gas buret. The evolution of nitrogen was almost quantitative (more than 90%) with all the azosulfones.

Results and Discussion

Aryl arylazo sulfones prepared are summarized in Table 1. The rates of decomposition of these azosulfones followed first-order equations when a base was present. Some examples are shown in Fig. 1. From

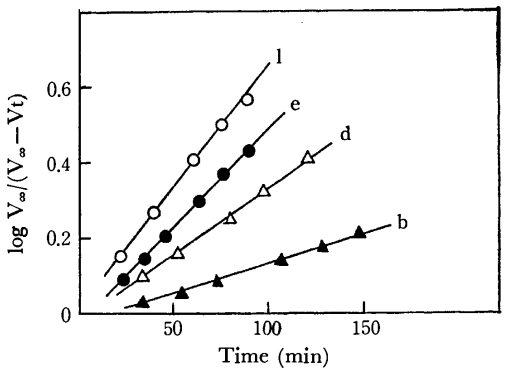

Fig. 1. Typical plots for the rates of decomposition of aryl arylazo sulfones in chlorobenzene at 90.6°C. (Letters in the figure correspond to the compounds described in Table 1. V_∞ and V_t are the volumes of the nitrogen evolved at time ∞ and time t, respectively.)

the rate constants at four or five different temperatures, activation parameters were obtained. Tables 2 and 3 show the rate constants and activation parameters. Figure 2 shows that an isokinetic relationship holds

between the $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values, and β is equal to 101.0°C. This fact suggests that all the azosulfones decompose by the same mechanism.

Figure 3 is the plots of log k_X/k_H *versus* the Hammett σ values for substituted phenylazo *p*-tolyl sulfones at 90.6°C. It is remarkable that the rates of all the substituted azosulfones are smaller than that of phenylazo *p*-tolyl sulfone itself, and the rates of the azosulfones with electron-releasing substituents are especially small. A

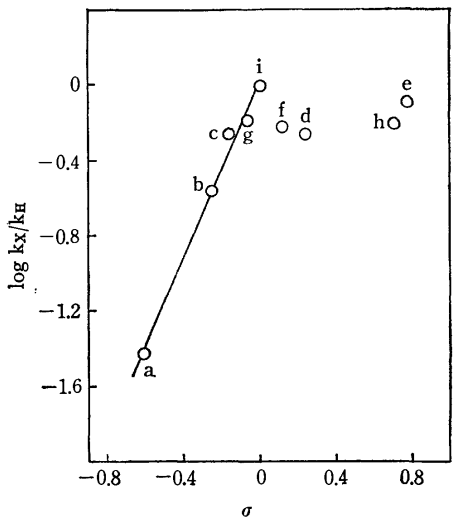

Fig. 3. Relationship between σ values and log k_X/k_H (90.6°C) (Letters in the figure correpond to the compounds described in Table 1. The value for a was calculated from those at higher temperatures.)

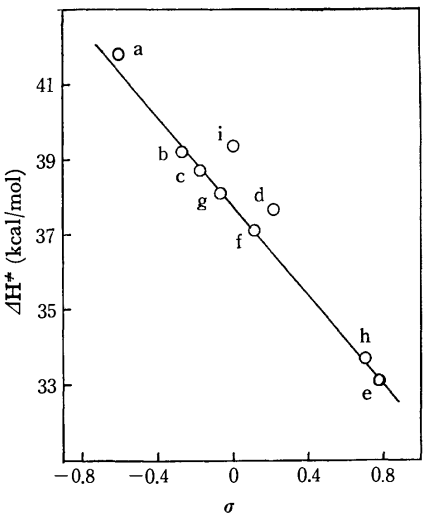

Fig. 4. Relationship between $\Delta H^{\ddagger}$ and σ values. (Letters in the figure correspond to the compounds described in Table 1.)

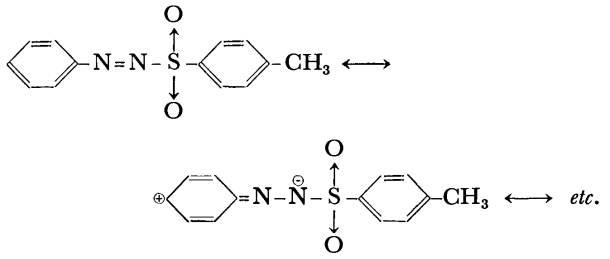
linear relationship seems to hold for azosulfones containing electron-releasing substituents, but not for those with electron-withdrawing substituents. These findings are in contrast with the results with substituted phenylazotriphenylmethanes and aryl arylazo sulfides; in the latter cases, the rates of the azo compounds containing electron-withdrawing substituents were especially small.

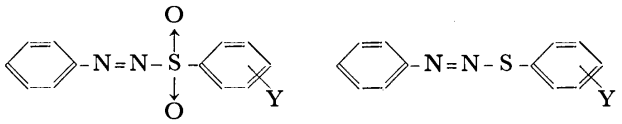
Figure 4 shows that a fair linear relationship holds between $\Delta H^{\ddagger}$ and the Hammett σ values.

The $\Delta S^{\ddagger}$ values for these azosulfones are much greater than those of other azo compounds. It is likely that in the ground states, these azosulfones are greatly polarized and strongly solvated, whereas in their transition states the C–N and S–N bonds are stretched and the extent



of solvation is much smaller, and therefore the $\Delta S^{\ddagger}$ values are very large.

Table 3 summarizes the rate constants of aryl phenylazo sulfones. The rate constants do not vary greatly with the substituents. These results are in contrast with those of p-MeC_6H_4–N=N–S–C_6H_4–Y (for example, $k_H/k_{p\text{-}NO_2}$ is equal to about 20).[4]



It is reasonable that the strength of the N–S bond of the azosulfide is greatly influenced by the resonance involving the S lone pair and the electrophilic substituents on the benzene ring, whereas the strength of the N–S bond of the azosulfone is very little affected by the substituents across the sulfonyl group.

Aryl arylazo sulfones can be synthesized very easily and are fairly stable (no decomposition for several months at 0°C). Therefore, they are very useful as a source of substituted phenyl free radicals.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2035—2039(1972)

Aroyl Arenesulfonyl Peroxides. V. Mechanisms of the Reactions of Benzoyl *p*-Toluenesulfonyl Peroxide with Several Nucleophiles[1)]

Ryuki HISADA, Michio KOBAYASHI, and Hiroshi MINATO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo

(Received January 14, 1972)

Reactions of benzoyl *p*-toluenesulfonyl peroxide (BTP) with several nucleophiles were investigated. The reaction with triphenylphosphine gave benzoyl *p*-toluenesulfonate and triphenylphosphine oxide, that with diphenyl sulfide gave benzoyl *p*-toluenesulfonate and diphenyl sulfoxide, and that with *p*-tolylmagnesium bromide gave *p*-tolyl *p*-toluenesulfonate and benzoic acid. In the reaction of BTP[carbonyl-^{18}O] with triphenylphosphine, 88% of carbonyl oxygen-18 was retained as the carbonyl oxygen of the benzoyl *p*-toluenesulfonate formed, whereas in the reaction of BTP[carbonyl-^{18}O] with diphenyl sulfide only 58% of the label in the starting peroxide was found in the carbonyl oxygen of the benzoyl *p*-toluenesulfonate formed. In the reaction of BTP[sulfonyl-^{18}O] with *p*-tolylmagnesium bromide, it was found that the two sulfonyl oxygens of BTP were completely retained in the two sulfonyl oxygens of the *p*-tolyl *p*-toluenesulfonate formed. Possible mechanisms of these reactions are discussed.

Benzoyl *p*-toluenesulfonyl peroxide (BTP) has been synthesized in our laboratories. Investigation on its decomposition under various conditions has revealed that the O–O bond of BTP tends to undergo heterolytic cleavage, and that the heterolysis is the main reaction unless some base is present in the medium for suppression of autocatalysis.[2)]

Diacyl and diaroyl peroxides are known to react with such nucleophiles as triphenylphosphine.[3)] The reactions of BTP with various nucleophiles seem to be of great interest. Detailed investigation was carried out in order to determine which of the two peroxidic oxygen atoms is attacked and what products are formed from this unsymmetrical peroxide. The results are given in this paper.

Results and Discussion

When a carbon tetrachloride solution of triphenylphosphine or diphenyl sulfide was stirred into a carbon tetrachloride solution of benzoyl *p*-toluenesulfonyl peroxide (BTP) at 10°C, the mixture became turbid in five minutes, and fine needles precipitated. When such a mixture was heated at 30°C for 30 min, it became transparent again. The completion of the reaction was

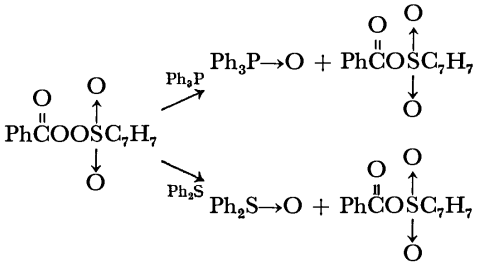
d) Probably formed by hydrolysis during the reaction with aniline.
e) Determined as BzOH.

shown by disappearance of the infrared absorption of the peroxidic carbonyl group of BTP. The reaction was completed in about one hour with triphenylphosphine, but it took about 6 hr with diphenyl sulfide. The main product was identified to be benzoic *p*-toluenesulfonic anhydride, on the basis of a comparison of its infrared spectrum with that of an authentic sample prepared by the method of Karger and Mazur.[4] Since the anhydride is unstable toward hydrolysis, it was determined by converting it into BzNHPh and TsOH or BzOH and TsOH. The results are shown in Table 1. The reactions can be expressed as follows.



In order to investigate the detailed mechanism of these reactions, BTP [carbonyl-^{18}O] was synthesized

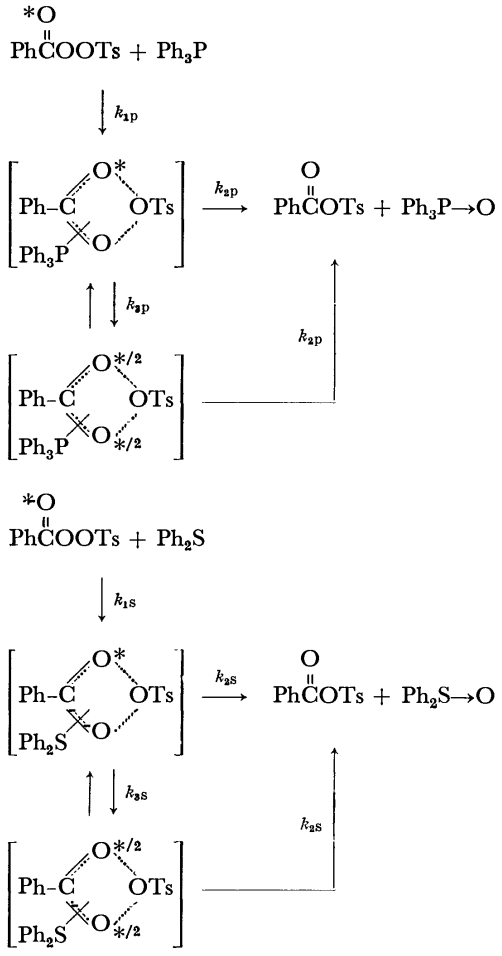
a) Experimental error in two experiments for the same sample was within ±0.02 excess atom %.
b) Calculated on the assumption that the carbonyl oxygen of BTP becomes the carbonyl oxygen of the anhydride without scrambling.
c) Not determined.

4) M. H. Karger and Y. Mazur, *J. Org. Chem.*, **36**, 528 (1971).

and the products of its reaction with triphenylphosphine and diphenyl sulfide were analyzed. The oxygen-18 contents of compounds (I)—(VIII) shown in the above scheme were determined. The results are shown in Table 2.

Benzanilide (V) formed from the anhydride obtained by the reaction with triphenylphosphine contains 88% of the excess oxygen-18 in the original BTP, whereas benzanilide (VII) formed from the anhydride obtained by the reaction with diphenyl sulfide contains only 58% of the excess oxygen-18 in the original BTP. This means that during the reaction with triphenylphosphine the carbonyl oxygen of the original BTP is retained as the carbonyl oxygen of the anhydride to a considerable extent, whereas the carbonyl oxygen of BTP is almost completely scrambled during the reaction with diphenyl sulfide.

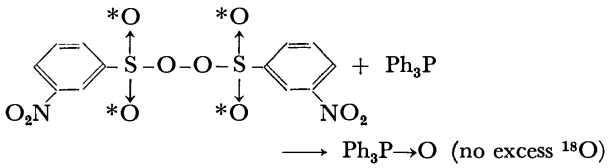
These reactions can be expressed as follows.



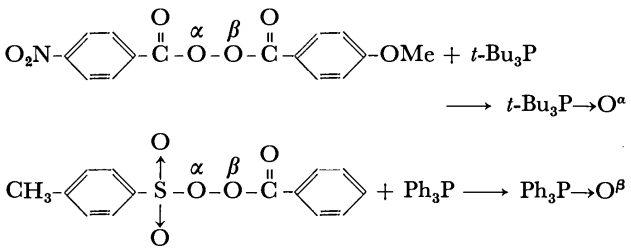
In this scheme, k_{1p} (or k_{1s}) is the rate of the complex formation between BTP and the nucleophile, k_{3p} (or k_{3s}) that of the oxygen scrambling in the complex, and k_{2p} (or k_{2s}) the rate of the formation of the final products from the complex. The exact nature of the complex has not been clarified as yet.

The results of ^{18}O analyses indicate that k_{2p} is greater than k_{3p} whereas k_{2s} is smaller than k_{3s}.

The fact that both triphenylphosphine oxide and diphenyl sulfoxide contain some excess oxygen-18 can be explained by the assumption that (a) the nucleophiles attack both the carbonyl and peroxidic oxygen atoms, or (b) the nucleophiles attack the peroxidic oxygen atom and then some scrambling takes place before the anhydride is formed. Although the possibility (a) cannot be strictly excluded, it is less likely since both benzoyl peroxide[3b] and *m*-nitrobenzenesulfonyl peroxide[5] react with triphenylphosphine at their peroxidic oxygen atoms.



It is interesting to note that in the reactions of BTP with triphenylphosphine and diphenyl sulfide the peroxidic oxygen atom attacked is the one adjacent to the benzoyl group, and not the one adjacent to the more electron-withdrawing tosyl group. Denney and Greenbaum[3c] studied the reaction of *p*-nitrobenzoyl *p'*-methoxy-benzoyl peroxide with tri-*t*-butylphosphine, and showed that the peroxidic oxygen atom adjacent to the more electron-withdrawing *p*-nitrobenzoyl group was attacked by tri-*t*-butylphosphine.



p-Tolylmagnesium bromide was chosen as another nucleophile and its reaction with BTP was investigated. When an ethereal solution of *p*-tolylmagnesium bromide was stirred into an ethereal solution of BTP under a nitrogen atmosphere at 3°C, white precipitates were formed immediately. The products were analyzed after stirring for 3 hr. Results: benzoic acid (91%), *p*-tolyl *p*-toluenesulfonate (41%) and *p*-toluenesulfonic acid (46%).

In order to study the mechanism of this reaction in detail, BTP [sulfonyl-^{18}O] was synthesized and its reaction with *p*-tolylmagnesium bromide investigated. The distribution of the excess oxygen-18 in *p*-tolyl *p*-toluenesulfonate formed was determined by converting it into *p*-cresol and *p*-toluenesulfonic acid, according to the scheme (next page). The results are summarized in Table 3.

The data in Table 3 show that the sulfonyl oxygen of BTP is completely retained as the sulfonyl oxygen of *p*-tolyl *p*-toluenesulfonate within experimental error. This indicates that the following mechanism (next page) is plausible.

The reaction with the Grignard reagent is in contrast to the reactions with triphenylphosphine and diphenyl sulfide; and coordination between the basic carbonyl oxygen atom and the electrophilic magnesium atom takes place first, probably determining the course of the reaction. It is known that carbonyl oxygen atoms are much more basic than sulfonyl oxygen atoms.

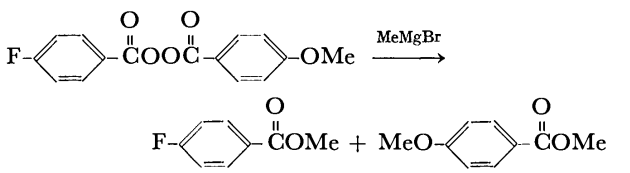
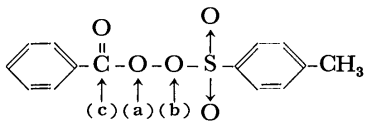
Ōkubo, Maruyama, and Ōsugi[6)] studied the reactions of substituted benzoyl peroxides with Grignard reagents, and found that even *p*-fluorobenzoyl *p'*-methoxybenzoyl peroxide is attacked at both the peroxidic oxygens yielding two esters.



6) M. Ōkubo, K. Maruyama, and J. Ōsugi, This Bulletin **44**, 125 (1971).

When BTP is mixed with excess anhydrous hydrazine, its carbonyl carbon atom is attacked by the nucleophile, benzhydrazide being formed in 67% yield. Sodium methoxide reacts with BTP in a similar manner, producing methyl benzoate.

Thus, benzoyl *p*-toluenesulfonyl peroxide is attacked by nucleophiles at three different positions, *viz.*, a) the peroxidic oxygen atom adjacent to the benzoyl group (Ph_3P and Ph_2S), b) the peroxidic oxygen atom adjacent to the sulfonyl group (RMgBr) and c) the carbonyl carbon atom (N_2H_4 and NaOMe).



Experimental

Materials. Triphenylphosphine, extra pure grade of Wako Chemicals, was used without further purification. Diphenyl sulfide was prepared according to the procedure of Hartman, Smith and Dickey[7)] and distilled under reduced pressure; the fraction boiling at 162—163°C/18 mmHg was collected and used. The preparation of BTP[carbonyl-^{18}O] and BTP[sulfonyl-^{18}O] was described in a previous paper.[8)] *p*-Tolylmagnesium bromide was prepared according to the procedure of Lawesson and Yang.[9)]

Reaction of BTP[carbonyl-^{18}O] with Triphenylphosphine. To 1.46 g (5 mmol) of BTP[carbonyl-^{18}O] dissolved in 200 m*l* of carbon tetrachloride was added 1.44 g (5.5 mmol) of triphenylphosphine in 50 m*l* of carbon tetrachloride with stirring at 10°C. The reaction mixture was then warmed up to 30°C and allowed to stand for 15 hr. After 1.12 g (12 mmol) of freshly distilled aniline was added to the reaction mixture, it was refluxed for 30 min, washed successively with water, dilute hydrochloric acid and water, and then dried over anhydrous magnesium sulfate. Carbon tetrachloride

7) W. W. Hartman, L. A. Smith, and J. B. Dickey, "Organic Syntheses," Coll. Vol. II, p. 242.
8) R. Hisada, H. Minato, and M. Kobayashi, submitted to This Bulletin.
9) S. O. Lawesson and N. C. Yang, *J. Amer. Chem. Soc.*, **81**, 4230 (1959).

was evaporated under reduced pressure. The residue was chromatographed on active alumina (300 mesh).

Benzanilide (86% yield), mp 162—163°C (lit,[10] 160—161°C) and triphenylphosphine oxide (96% yield), mp 153°C (lit,[11] 153.5°C) were obtained and recrystallized three times from a mixture of benzene and ether. They were subjected to the determination of ^{18}O-contents, according to the method described previously.[5] From the aqueous layer, benzoic acid was isolated and weighed (11% yield) and *p*-toluenesulfonic acid was weighed as its *S*-benzylisothiuronium salt (98% yield).

Reaction of BTP[carbonyl-^{18}O] with Diphenyl Sulfide. To 1.46 g (5 mmol) of BTP[carbonyl-^{18}O] dissolved in 200 m*l* of carbon tetrachloride was added 1.02 g (5.5 mmol) of diphenyl sulfide in 50 m*l* of carbon tetrachloride with stirring at 10°C. The mixture was treated in a manner similar to that for the reaction with triphenylphosphine.

Benzanilide and diphenyl sulfoxide obtained from the reaction mixture of BTP[carbonyl-^{18}O]-diphenyl sulfide-aniline could not be completely separated from each other by elution chromatography. They were purified by repeated recrystallizations from a mixture of benzene and *n*-hexane; BzNHPh, mp 162°C, and Ph_2SO, mp 70°C (lit,[12] 70—71°C).

Since the yields could not be determined by this technique, unlabeled BTP was allowed to react with diphenyl sulfide, and benzoic *p*-toluenesulfonic anhydride produced was hydrolyzed to benzoic acid and *p*-toluenesulfonic acid; the former was weighed (98% yield), and the latter was converted into its *S*-benzylisothiuronium salt and weighed (96% yield). Diphenyl sulfoxide and unreacted diphenyl sulfide were determined by gas chromatography (column: silicone oil SE 30, 1 m; 190°C; internal standard, *p*-tolyl benzoate), yield, 81% and 13%, respectively.

Reaction of BTP[sulfonyl-^{18}O] and p-*Tolylmagnesium Bromide.* To 2.64 g (9 mmol) of BTP[sulfonyl-^{18}O] in 100 m*l* of anhydrous ether was added 9 mmol of *p*-tolylmagnesium bromide in 50 m*l* of ether under a nitrogen atmosphere at 3°C with stirring. After the reaction mixture was allowed to stand at 3—5°C for 3 hr with stirring, water was added. The ethereal layer was separated from the aqueous layer, washed successively with a 10% sodium hydrogen carbonate solution and water, and dried over anhydrous magnesium sulfate. After the ether was removed under reduced pressure, the residue was chromatographed on silica gel (Wako Gel Q 22). *p*-Tolyl *p*-toluenesulfonate isolated (41% yield) was recrystallized three times from *n*-hexane, mp 69—69.5°C (lit,[13] 69—70°C). The aqueous layer was acidified with hydrochloric acid and extracted with ether. After the combined extracts were dried over anhydrous magnesium sulfate, the solvent was evaporated and the benzoic acid isolated was weighed (91% yield). *p*-Toluenesulfonic acid was determined as its *S*-benzylisothiuronium salt (46% yield).

p-Tolyl *p*-toluenesulfonate was hydrolyzed to *p*-cresol and *p*-toluenesulfonic acid. *p*-Cresol was converted by bromine water into 2,6-dibromo-*p*-cresol, which was purified twice by sublimation, mp 48—49°C (lit,[14] 49°C). *p*-Toluenesulfonic acid was obtained as *S*-benzylisothiuronium salt, and recrystallized three times from water, mp 180—181°C.

Photolysis of Phenylazo *p*-Tolyl Sulfones[1)]

Michio KOBAYASHI, Sadao FUJII, and Hiroshi MINATO

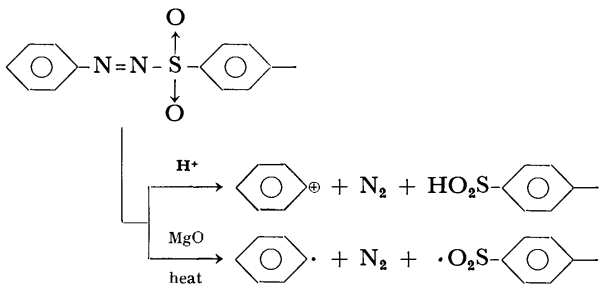
Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo

(Received January 14, 1972)

Photolysis of phenylazo *p*-tolyl sulfone and *p*-chlorophenylazo *p'*-tolyl sulfone in aromatic solvents at room temperature was investigated. The products were analyzed, and the isomer distribution and partial rate factors in arylation of mono-substituted benzenes were determined. The results indicate that the photolysis involves formation of aryl radicals and *p*-tolylsulfonyl radicals.

Arylazo aryl sulfones are interesting compounds; they undergo both heterolysis and homolysis. As an example, when phenylazo *p*-tolyl sulfone (I) is placed in an acidic medium, phenyl cation is formed,[2)] whereas I yields phenyl radical when it is heated in a medium containing magnesium oxide, pyridine, or quinoline which captures *p*-toluene sulfonic acid.[3)]

Thermal decomposition of I in a non-acidic medium is not so fast, and the half-life at 60°C is about 20 hr



($\Delta H^{\ddagger}$=30.8 kcal/mol, $\Delta S^{\ddagger}$=10.7 e.u./mol)[3)] in ethylbenzene.

Since azosulfones absorb at wavelength over 400 nm owing to the n-π^* transition of the azo group, they are

3) M. Kobayashi, H. Minato, M. Kojima, and N. Kobori, *ibid.*, **44**, 2501 (1971).

expected to undergo photolysis. The photolyses of I and *p*-chlorophenylazo *p'*-tolyl sulfone (II) have been investigated in aromatic solvents, and the results are described in this paper.

Results and Discussion

Solutions of I in equimolar mixtures of benzene and a monosubstituted benzene were degassed and irradiated with a high pressure mercury lamp at room temperature. Considerable amounts of biaryls were isolated when reaction mixtures were washed with water and the organic layers were subjected to column chromatographic separation on Florisil or alumina. Quantitative determination of biphenyl and substituted biphenyl isomers were carried out by gas chromatography, and the partial rate factors were calculated. As regards anisole or nitrobenzene, photolysis was performed in a mixture with chlorobenzene instead of benzene, and the amounts of substituted biphenyls formed were determined. The partial rate factors in these solvents were calculated by using the partial rate factors in chlorobenzene. The results are summarized in Table 1.

TABLE 1. ISOMER DISTRIBUTIONS AND PARTIAL RATE FACTORS IN PHENYLATION WITH I

Substrate	Isomer distribution (%)			Partial rate factors		
	o	*m*	*p*	*o*	*m*	*p*
Anisole	72.6	13.5	13.9	4.99	0.94	1.92
Ethylbenzene	54.8	29.6	15.6	2.41	1.30	1.37
Chlorobenzene	62.5	22.5	15.0	2.95	1.06	1.42
Benzonitrile	50.0	20.0	30.0	3.64	1.46	4.37
Nitrobenzene	61.7	13.2	25.1	5.34	1.14	4.37

When the values of log (partial rate factors at para positions) were plotted *versus* the Hammett σ-values, a V-shaped line was obtained as shown in Fig. 1. The ρ value for the right half was +0.90 (γ, 0.988), which is comparable to the ρ value (1.21) obtained by the thermal homolysis of I.[3] The isomer distributions and partial rate factors shown in Table 1 are similar to those obtained with phenyl radical (Table 2 (a)), but quite different from those with phenyl cation (Table 2 (b)).[2]

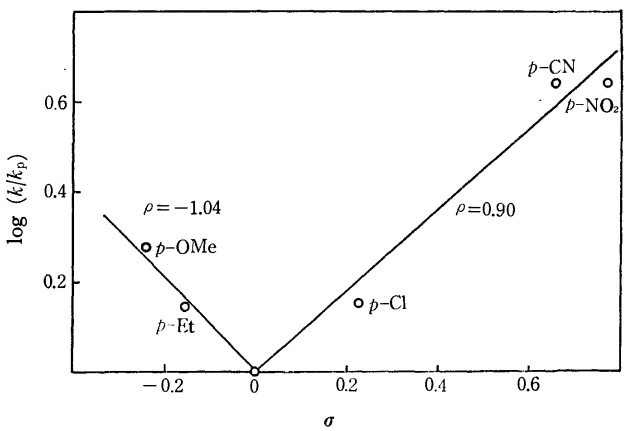

Fig. 1. The Hammett plots for phenylation of substituted benzenes by phenylazo *p*-tolyl sulfone

These data indicate that the biphenyls shown in Table 1 arose from the attack of phenyl radical on aromatic solvents. The free-radical nature of the substitution is exemplified by the values in benzonitrile and nitrobenzene; –CN and $-NO_2$ are *o*,*p*-directors and the partial rate factors are greater than unity.

TABLE 2. ISOMER DISTRIBUTIONS AND PARTIAL RATE FACTORS IN PHENYLATION WITH (a) PHENYL RADICAL AND (b) PHENYL CATION

(a) Phenyl Radical (from I in a non-acidic medium)[3]

Substrate	Isomer distribution (%)			Partial rate factors

Nitrobenzene	26.0	68.9	5.1	0.08	0.20	0.03

In order to determine the mechanism of photolysis of phenylazo sulfones, photochemical and thermal decompositions of *p*-chlorophenylazo *p'*-tolyl sulfone (II) in benzene were investigated. The products are shown in Table 3. Although II absorbs at 226 (ε=29000), 305 (ε=15000) and 430 nm (ε=190), the results of photo-

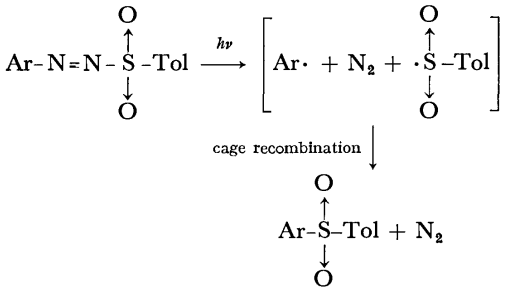
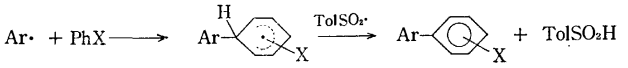
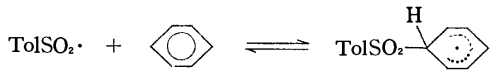
lyses in a quartz vessel and in a pyrex vessel were similar. Thus, the absorption at 430 nm is mainly responsible for the photolysis.

Formation of the products of the photolysis of II can be explained by the following scheme.





Yields of phenyl *p*-chlorophenyl sulfone were very small both in photolysis and thermolysis (less than 1 mol % by glc). This indicates that *p*-toluenesulfonyl radical functions only as a hydrogen abstractor. However, it is possible that the sulfonyl radical adds to benzene, forming a sulfonylcyclohexadienyl radical in the following equilibrium.



Such a possibility is not rejected by the experimental results. It is likely that the life of the sulfonyl radical is prolonged by existence of such equilibrium.

When a sulfonyl radical abstracts hydrogen, a sulfinic acid should be produced. However, a sulfinic acid was not detected in the reaction mixture, though a sulfonic acid and a thiolsulfonate were found. It is known that a sulfinic acid disproportionates easily, forming such products.[4]

$$3\ p\text{-TolSO}_2\text{H} \longrightarrow p\text{-TolSO}_3\text{H} + p\text{-TolSO}_2\text{S-Tol-}p$$

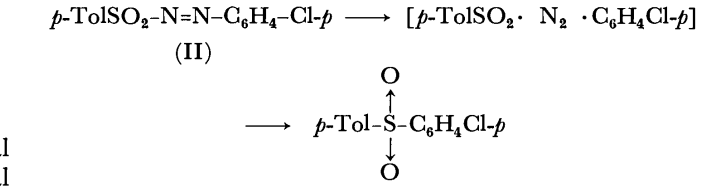
Isomer distributions and partial rate factors in phenylation of substituted benzenes, shown in Table 1, are in general similar to those of thermal homolysis shown in Table 2(a), and are characteristic of free radical reactions. However, the values are somewhat different and the differences in partial rate factors being fairly large in the case of benzonitrile and nitrobenzene.

It is known that sulfones undergo photolysis in aromatic solvents, yielding biphenyls,[5] and occurrence of such photolysis could be the cause for the difference in partial rate factors. However, when a benzene solution of phenyl *p*-tolyl sulfone was degassed and irradiated for 45 hr, the yield of biphenyl was only 9%. Since the yield of *p*-chlorophenyl *p'*-tolyl sulfone in the photolysis of II was only 15%, photolysis of the sulfone so produced cannot influence the partial rate factors greatly.

Photolysis was carried out at room temperature (20°C), and thermolysis at 80°C. However, it was established by a previous investigation that isomer distribution and partial rate factors in phenylation by phenyl radical do not vary much with the reaction temperature.[3] Thus, the cause for the difference in phenylations by photolysis and thermal homolysis cannot be the difference in reaction temperature.

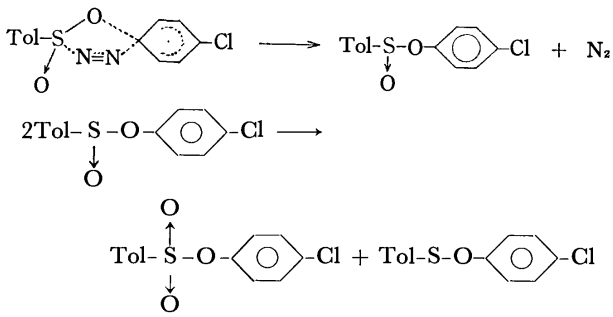
A most probable explanation for the difference is as follows. In photolysis, the azosulfone is photolyzed by the n-π^* transition, yielding free phenyl radical and free *p*-toluenesulfonyl radical; the free phenyl radical adds to a substituted benzene, yielding phenylcyclohexadienyl radical. In thermal homolysis, a π-complex between the azosulfone and the solvent is formed prior to the cleavage of the C–N and S–N bonds, and the bond between phenyl radical and the solvent molecule is formed concertedly with the cleavage of the C–N and S–N bonds.

The yield of *p*-chlorophenyl *p'*-tolyl sulfone in photolysis was very much greater than that in thermolysis as shown in Table 3. The difference can also be explained in terms of the free phenyl radical in the photolysis and the solvated free phenyl radical in the thermolysis. In photolysis, free *p*-chlorophenyl radical and free *p*-toluenesulfonyl radical recombine in a solvent cage and form the sulfone in a fair yield.

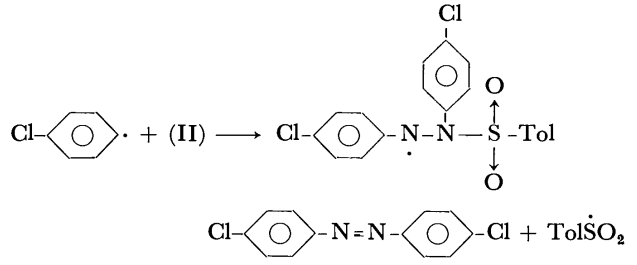


In the thermolysis, cleavages of the C–N and S–N bonds are aided by formation of weak bonds between solvent molecules and the radicals being produced, and therefore the yield of the sulfone is much smaller.

Formation of *p*-chlorophenyl *p'*-toluenesulfonate cannot be easily explained. A plausible route is disproportionation of *p*-chlorophenyl *p'*-toluenesulfinate formed in the following way.



Formation of 4,4'-dichloroazobenzene can be explained in terms of the addition of *p*-chlorophenyl radical to the starting azosulfone.



4) J. L. Kice and K. W. Bowers, *J. Amer. Chem. Soc.*, **84**, 605 (1962).

5) N. Kharasch and A. I. A. Khodair, *Chem. Commun.*, **1967**, 98.

The reaction is analogous to the attack of phenyl radical to phenylazotriphenylmethane. In both cases, a less stable radical adds to the azo bond, and a more stable radical is released.

$$Ph\cdot + Ph\text{-}N{=}N\text{-}CPh_3 \longrightarrow Ph\text{-}\underset{\cdot}{N}\text{-}\underset{\displaystyle Ph}{N}\text{-}CPh_3 \longrightarrow Ph\text{-}N{=}N\text{-}Ph + Ph_3C\cdot$$

Experimental

Materials. Phenylazo *p*-tolyl sulfone was synthesized by the method described previously.[3] UV, λ_{max} (hexane) 221 nm (ε, 19000), 287 nm (ε, 16000), 432 nm (ε, 150). *p*-Chlorophenylazo *p'*-tolyl sulfone (II) was synthesized by the reaction between *p*-chlorobenzenediazonium chloride and sodium *p*-toluenesulfinate in water, and recrystallized from methanol; mp 118.5—119.0°C (decomp.). UV, λ_{max} (hexane) 226 nm (ε, 29000), 305 nm (ε, 15000), 430 nm (ε, 190).

Determinations of Biaryls Formed by Photolysis of I. About 3 mmol of I was dissolved in a mixture of 1/8 mol each of benzene (or chlorobenzene) and a substituted benzene, and the solution was degassed by the freezing-evacuation technique. The solution was irradiated with a high-pressure mercury lamp for 15—60 hr (irradiation was continued for 5 hr after the evolution of nitrogen ceased). An internal standard (bibenzyl) was added, and the reaction mixture was washed with water, a 5% sodium carbonate solution and then concentrated by evaporation of the solvent. When azobenzene formed in a small yield interfered glc determinations, it was removed by reduction with zinc and hydrochloric acid in methanol. The amounts of biaryl isomers were determined with a Hitachi K-53 Flame Ionization Gas Chromatograph (Apiezon L column, 4 m).

Products of Photolysis of p-*Chlorophenylazo* p'-*Tolyl Sulfone (II) in Benzene.* A solution of II (35.4 mmol) in benzene (450 m*l*) was photolyzed with a high-pressure mercury lamp for 25.5 hr at 20°C under nitrogen. A considerable amount of *p*-toluenesulfonic acid precipitated. After the reaction mixture was washed with a 5% sodium carbonate solution and then concentrated, the products in the residue were separated by elution chromatography on alumina or Florisil. Products separated were rechromatographed when necessary. Each product was identified by its mp, IR and/or NMR spectra.

The sodium carbonate extracts were concentrated under reduced pressure, made weakly acidic by addition of hydrochloric acid, and the *p*-toluenesulfonic acid in the solution was precipitated as its *S*-benzylisothiuronium salt. No *p*-toluenesulfinic acid was detected.

4,4'-Dichloroazobenzene was determined by use of its absorption at 444 nm (ε, 880) after column-chromatographic separation.

Products of Thermal Decomposition of II in Benzene. A solution of II (35.4 mmol) in benzene (600 m*l*) containing CaO powder (5.4 g) was kept at 70°C for 82 hr under nitrogen. The products of decomposition were analyzed by the procedure described for photolysis.

By a separate experiment, the rate of decomposition of II was determined (II, 3.260 mmol; benzene, 60 m*l*; CaO, 0.54 g). The rate of evolution of nitrogen showed that rate constant k is equal to 2.1×10^{-5} sec^{-1} at 70.0°C.

(Received March 21, 1972)

Anisole-4*d*, chlorobenzene-4*d*, chlorobenzene-d_5, nitrobenzene-d_5, *m*-dinitrobenzene-d_4, and 1,3,5-tri-*t*-butylbenzene-d_3 were phenylated with phenyl radical generated from PhN_2BF_4–$NaNO_2$, *N*-nitrosoacetanilide or phenylazotriphenylmethane(PAT), and the isotope effect in these phenylations was determined. The values of k_H/k_D in the phenylations of chlorobenzene and 1,3,5-tri-*t*-butylbenzene are not so larger than unity, whereas that in the phenylation at the 2-position of *m*-dinitrobenzene with PAT was very large ($\sim$11).

Large isotope effect was observed in the phenylation of arenes with the phenyl radical generated from benzoyl peroxide (BPO) in highly diluted solutions (k_H/k_D=6.6),[1] whereas no isotope effect was observed in the phenylations with *N*-nitrosoacetanilide (NNA) or phenylazotriphenylmethane.[2] It has been proposed that in highly diluted solutions of BPO the hydrogen-abstraction from the cyclohexadienyl radicals produced proceeds slowly by disproportionation between the cyclohexadienyl radicals themselves since benzoyloxy radical is ineffective due to its low concentration,[1] whereas in the phenylations with NNA or PAT no isotope effect is observed since the hydrogen-abstraction from the cyclohexadienyl radicals proceeds quickly by the presence of efficient hydrogen abstractors in rather high concentrations.[2]

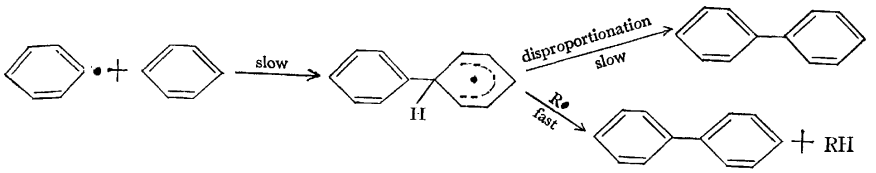
2) E. L. Eliel, M. Eberhardt, O. Simamura, and S. Meyerson, *Tetrahedron Lett.*, **1962**, 749; E. L. Eliel, J. G. Saha, and S. Meyerson, *J. Org. Chem.*, **30**, 2451 (1965).



A previous paper from our laboratories described the generation of phenyl radical from PhN_2BF_4–$NaNO_2$ in DMSO according to the following scheme, and an isotope effect was observed in the phenylation of arenes with this system.[3]

$$PhN_2BF_4 + NaNO_2 \longrightarrow PhN{=}N{-}O{-}N{=}O + NaBF_4$$
$$PhN{=}N{-}O{-}N{=}O \longrightarrow Ph\cdot + N_2 + NO_2$$
or
$$2PhN{=}N{-}O{-}N{=}O \longrightarrow PhN{=}N{-}O{-}N{=}NPh + N_2O_3$$
$$PhN{=}N{-}O{-}N{=}NPh \longrightarrow Ph\cdot + N_2 + \cdot ON{=}NPh$$

In this system, abstraction of the hydrogen atom from the cyclohexadienyl radicals is efficiently carried out either by NO_2 or PhN=NO·, the latter radical being the hydrogen abstractor in the phenylation with NNA.[4] Existence of isotope effect in the phenylation in the presence of an efficient hydrogen-abstractor contradicts with the interpretation proposed by Eliel *et al.*[2] In an attempt to gain further understanding in this problem, various deuterated arenes have been phenylated with phenyl radicals produced from PhN_2BF_4–$NaNO_2$, BPO, NNA and PAT, and the results will be described in this paper.

Table 1. Isomer distributions and partial rate factors in the phenylation of PhX and deuterated PhX with PhN_2BF_4–$NaNO_2$ in DMSO at 20°C[a]

Substrate	Isomer distributions (%)			Partial rate factors		
	o-,	*m*-,	*p*-,	k_o/k	k_m/k	k_p/k
$PhOCH_3$	72.4	14.2	13.4			
$PhOCH_3$-4*d*	71.6	14.3	14.1			
PhCl	56.5	23.5	20.0	3.45	1.44	2.44
PhCl-4*d*	55.3	24.2	20.5			
PhCl-d_5	58.2	23.4	18.4	3.13	1.26	1.98
$PhNO_2$	77.4	5.9	16.7	19.8	1.51	8.55
$PhNO_2$-d_5	73.4	6.8	19.8	12.3	1.14	6.62

a) The average values of two experiments.

Results and Discussion

Table 1 shows the isomer distributions and partial rate factors in the phenylation of arenes and deuterated arenes. The isomer distributions in phenylated $PhOCH_3$-4*d* and PhCl-4*d* are not too much different from those in the corresponding methyldiphenyls and chlorodiphenyls. From the partial rate factors in the phenylations of PhCl-d_5, PhCl, $PhNO_2$-d_5, and $PhNO_2$, the values of k_H/k_D at the *ortho*, *meta* and *para* positions were calculated. The results are shown in Table 2.

Table 2. Kinetic isotope effect in the phenylation with phenyl radical

Substrate	k_H/k_D in the formation of substituted diphenyls[a]		
	2-,	3-,	4-,
PhCl-d_5	1.10	1.14	1.23
$PhNO_2$-d_5	1.61	1.32	1.29

a) These values were calculated from the partial rate factors listed in Table 1. Experimental errors were ±0.10

Isotope effect is fairly small in the case of chlorobenzene (k_H/k_D=1.10~1.23), whereas it is considerably large in the case of nitrobenzene (k_H/k_D=1.29~1.61). It is interesting that the k_H/k_D values are different at different positions of these arenes.

The fact that isotope effect was observed in the presence of an efficient hydrogen-abstractor (PhN=NO· or NO_2) contradicts with the explanation proposed by Eliel *et al.*[2] In order to determine isotope effect more directly and in greater details, competitive phenylations of an arene and the corresponding deuterated arene were carried out by use of the phenyl radicals generated from PhN_2BF_4–$NaNO_2$, *N*-nitrosoacetanilide and phenylazotriphenylmethane. The results are shown in Table 3.

In the phenylation of $C_6D_5NO_2$–$C_6H_5NO_2$, the k_H/k_D values at *para* position were nearly unity regardless of the phenyl radical source, whereas those at *ortho* position were fairly large in the cases of PhN_2BF_4–$NaNO_2$ and NNA (k_H/k_D=2.36 and 2.02). It appears strange that no isotope effect was observed at *ortho* position of nitrobenzene when PAT was used as the radical source.

In the phenylation of *m*-$C_6D_4(NO_2)_2$–*m*-$C_6H_4(NO_2)_2$, isotope effects were observed both at 4 and 2 positions with the phenyl radicals generated from all the sources. In the case of the phenylation with PAT, the k_H/k_D value at the more crowded 2 position was greater than that expected from the zero-point energies of the C–H and C–D bonds ($k_H/k_D \fallingdotseq 11$).

Bromberg, Muszkat, and Fischer observed an unusually large isotope effect (k_H/k_D=95) in the initiation step of the reaction of 4a,4b-dihydrophenanthrene with oxygen.[5] They stated that the large kinetic isotope effect is due to both a considerable loss of zero-point energy of stretching and bending vibration in the transition state and a large contribution from quantum-mechanical tunnelling.

Shih, Hey, and Williams reported absence of isotope effect in the phenylation of tritiated benzene with benzoyl peroxide,[6] and Price and Convery also reported absence of isotope effect in the phenylation of 2,4-

m-$C_6D_4(NO_2)_2$+m-$C_6H_5(NO_2)_2$	BPO[d]	80±0.1	2.53		e

a) The average values of two experiments; experimental errors were ±0.10.
b) Yields of the meta isomer were low, and isolation was not possible.
c) Without solvent. d) In acetonitrile. e) Yields of 2,6-isomers were low, and they were not isolated.

dinitrotritiobenzene with benzoyl peroxide.[7] Both of these groups used benzoyl peroxide in rather large concentrations, and it is conceivable that many benzoyloxy radicals (a highly active hydrogen-abstractor) are present in the media and effectively abstract hydrogens of the intermediate cyclohexadienyl radicals. In an attempt to establish whether or not isotope effect exists under such conditions, the experiment of Price and Convery was repeated with benzoyl peroxide in a m-$C_6H_4(NO_2)_2$–m-$C_6D_4(NO_2)_2$ mixture. As shown in Table 3, k_H/k_D was found to be 2.03. Since the conditions of this experiment are somewhat drastic (a solid mixture of benzoyl peroxide and m-dinitrobenzene is heated up over 90°C for melting and decomposition), a similar mixture was dissolved in acetonitrile and the homogeneous solution was let to decompose at 80°C. Again, isotope effect was observed (k_H/k_D=2.53). In the experiment with a solid mixture of BPO and m-dinitrobenzene, some decomposition of BPO must have taken place in solid phase before melting, and therefore the result is somewhat ambiguous. In the experiment with an acetonitrile solution, however, the result clearly shows that isotope effect exists in phenylation of m-dinitrobenzene with BPO.

It has been said that there is no isotope effect in nitration of arenes. However, recently Myhre, Beug, and James have observed kinetic isotope effects in nitrodeprotonation of a series of 1-X-2,4,6-tri-t-butylbenzenes and reported that the k_H/k_D values changed from 1.0 to 3.8 as X is varied from H to CH_3.[8] Such a correlation between isotope effect and the size of the substituent may exist in our systems too, since 1) almost no isotope effect at the *para* positions and greater isotope effect was observed at *ortho* positions, and 2) a very large isotope effect (~11) was observed with the phenylation of m-dinitrobenzene at its 2-position with the phenyl radical produced from PAT (the hydrogen abstractor is bulky trityl radical).

In order to clarify the relationship between isotope effect and the size of the substituents, 1,3,5-tri-t-butylbenzene and 1,3,5-tri-t-butylbenzene-2,4,6-d_3 were competitively phenylated with the phenyl radicals generated from NNA and PAT. However, the k_H/k_D values obtained were 1.06 and 1.01, and thus there is no definite correlation between isotope effect and the size of the substituents in free-radical phenylation of arenes.

TABLE 4. ISOMER DISTRIBUTIONS IN THE PHENYLATION OF m-DINITROBENZENE AND m-DINITROBENZENE-d_4

Substrate	Radical source	Temperature (°C)	Yields of dinitrodiphenyls (%)	
			2,6-	2,4-
m-$C_6H_4(NO_2)_2$	PhN_2BF_4–$NaNO_2$	20±3	67.1	32.9
m-$C_6H_4(NO_2)_2$	$PhN{=}NCPh_3$	60±0.1	36.5	63.5
m-$C_6D_4(NO_2)_2$	$PhN{=}NCPh_3$	60±0.1	14.5	85.5

In an attempt to gain further understanding on this problem, m-dinitrobenzene and m-dinitrobenzene-d_4 were phenylated with the phenyl radicals produced from PhN_2BF_4–$NaNO_2$ and PAT, and the isomer distributions of the dinitrodiphenyls were determined. The results are shown in Table 4. In the case of m-$C_6H_4(NO_2)_2$–PhN_2BF_4–$NaNO_2$, the amount of 2,6-dinitrodiphenyl produced was 67%, whereas in the case of m-$C_6H_4(NO_2)_2$–PAT it decreased to 36.5%. This finding can be rationalized by assuming that very bulky trityl radical abstracts the hydrogen at the crowded 2 position of the 1,3-dinitro-2-phenylcyclohexadienyl radical much more slowly than that at the less crowded 4 position of the 1,3-dinitro-4-phenylcyclo-

7) C. C. Price and R. J. Convery, *J. Amer. Chem. Soc.*, **79**, 2941 (1957); **80**, 4101 (1958).
8) P. C. Myhre, M. Beug, and L. L. James, *ibid.*, **90**, 2105 (1968).

hexadienyl radical. The amount of 2,6-dinitrodiphenyl produced further decreased to 14.5% in the case of m-$C_6D_4(NO_2)_2$–PAT. These data are consistent with the abnormally large k_H/k_D value (~11) observed in the case of m-$C_6H_4(NO_2)_2$–m-$C_6D_4(NO_2)_2$–PAT (Table 3).

Thus, a very large isotope effect was observed in free-radical phenylation at the crowded 2-position of m-dinitrobenzene, and not at the crowded 2-position of 1,3,5-tri-t-butylbenzene. Resonance stabilization of the intermediate cyclohexadienyl radical must be taken into consideration in addition to the bulkiness of the substituents. The more resonance-stabilized is the cyclohexadienyl radical, the more slowly proceeds the following hydrogen-abstraction step. If this is so, it is reasonable that no isotope effect was shown by t-butyl group which is bulky but possesses no ability of resonance-stabilization.

The k_H/k_D value observed for phenylation at the 2-position of m-dinitrobenzene (~11) was greater than the value expected from the zero-point energy of the C–H bond (6~7). This finding can be rationalized only by assuming a large contribution from quantum-mechanical tunnelling effect or assuming that in the free-radical substitution at such an overcrowded position the activation entropy factor varies with isotopes.

Experimental

Materials. Benzenediazonium tetrafluoroborate was prepared according to the directions described previously.[9] *N*-Nitrosoacetanilide was prepared by the method reported in the literature[10] and dried in a desiccator which was kept in a refrigerator; mp 75°C (decomp.). Phenylazotriphenylmethane (PAT) was prepared by the bromine-water oxidation of phenylhydrazotriphenylmethane,[11] which was synthesized from phenylhydrazine and triphenylmethyl chloride in ether.[12] Crude PAT was recrystallized from benzene-ethanol; mp 111—112°C (decomp.). Dimethyl sulfoxide was dried with calcium hydride and distilled; bp 86°C/25 mmHg. Benzene and chlorobenzene were washed with concentrated sulfuric acid and water successively, dried over calcium chloride, and distilled; bp 80 and 131°C, respectively. Anisole was washed with an aqueous sodium hydroxide solution and water, dried over calcium chloride, and distilled; bp 153°C. Nitrobenzene was washed repeatedly with a potassium dichromate solution, dried over calcium chloride, and distilled; bp 95.5°C/18 mmHg.

Authentic samples of substituted diphenyls were prepared by the methods described previously.[13] Anisole-4*d* was prepared by the hydrolysis of p-methoxyphenylmagnesium bromide in D_2O (isotopic purity, 99.75%, E. Merck AG, Darmstadt); bp 58°C/15 mmHg. Its isotopic purity was determined to be 92% by mass spectrometry. Chlorobenzene-4*d* was prepared in a similar manner from p-bromochlorobenzene; bp 131°C. Its isotopic purity was 90%. Chlorobenzene-d_5 and nitrobenzene-d_5 of CIBA Limited were used without further purification. Isotopic purity was 98.5% and 99%, respectively. m-Dinitrobenzene-d_4 was prepared by the nitration of benzene-d_6 (isotopic purity>99 atom % D, E. Merck AG, Darmstadt) with anhydrous potassium nitrate and sulfuric acid-d_2, which was produced from sulfuric anhydride and deuterium oxide-d_2 (isotopic purity, 99.75%, E. Merck AG, Darmstadt). Crude m-dinitrobenzene-d_4 was recrystallized from ethanol; mp 89°C. Its isotopic purity was determined to be 97.5% by mass spectrometry. 1,3,5-tri-t-butylbenzene was prepared by the method described in the literature;[14] mp 72—73°C (from methanol). 1,3,5-tri-t-butylbenzene-2,4,6-d_3 was obtained by hydrogen-deuterium exchange (six times was needed) from 1,3,5-tri-t-butylbenzene and trifluoroacetic acid-d_1 which was prepared from trifluoroacetic anhydride (Aldrich Chemical Co., Inc.) and deuterium oxide-d_2 (E. Merck AG, Darmstadt, isotopic purity: 99.75%) in carbon tetrachloride according to the method described in the literature.[8] After the exchange reaction was repeated for six times, exchange was shown to be 98% complete by its NMR spectrum (comparison of its integrated signal with that of the known amount of ferrocene as an internal standard).

*Phenylation of Anisole, Anisole-4*d, *Chlorobenzene or Chlorobenzene-4*d *with Benzenediazonium Tetrafluoroborate-Sodium Nitrite.* Under a nitrogen atmosphere a solution of 0.25 g (1.3 mmol) of benzenediazonium tetrafluoroborate dissolved in DMSO (2.0 g) was added drop by drop at 20°C into a vigorously stirred solution of sodium nitrite (3 mol/mol of PhN_2BF_4) and an aromatic substrate (anisole, anisole-4*d*, chlorobenzene or chlorobenzene-4*d*; 50 mol/mol of PhN_2BF_4) in 10 g of DMSO. Evolution of nitrogen was instantaneous upon addition of each drop of the diazonium salt solution, and the addition was completed in about five minutes. Treatment of the reaction mixtures and the quantitative determination of the diphenyl isomers produced were made according to the method reported previously.[3]

Competitive Phenylation of Chlorobenzene–Benzene and Chlorobenzene-d_5*–Benzene.* Under a nitrogen atmosphere a solution of 0.2 g of benzenediazonium tetrafluoroborate in DMSO (2.0 g) was added drop by drop at 20°C into a vigorously stirred solution of sodium nitrite (3 mol/mol of PhN_2BF_4) in 6.0 g of DMSO and an equimolar mixture of benzene and chlorobenzene (or benzene and chlorobenzene-d_5; 50 mol/mol of PhN_2BF_4). The reaction mixture was treated according to the method described previously.[3]

Competitive Phenylation of Nitrobenzene–Chlorobenzene and Nitrobenzene-d_5*–Chlorobenzene.* Competitive phenylation of nitrobenzene-chlorobenzene (or nitrobenzene-d_5–chlorobenzene) with benzenediazonium tetrafluoroborate-sodium nitrite were carried out in a manner similar to that described above, and the diphenyl isomers produced were determined by glc.

Partial rate factors in the phenylation at each position of an arene were calculated by using the following equation.

$$k_x/k = (k_x/k_{o\text{-}Cl}) \times (k_{o\text{-}Cl}/k)$$

where,

k_x/k: the partial rate factor in the phenylation of PhX at the x (o-, m-, or p-) position

k_x/k_{o-Cl}: the ratio of the phenylation rate at the x position of PhX *versus* that at the *ortho* position of chlorobenzene

k_{o-Cl}/k: the partial rate factor in the phenylation at the *ortho* position of chlorobenzene

Competitive Phenylation of Nitrobenzene–Nitrobenzene-d_5. An equimolar mixture of nitrobenzene (40 mmol) and nitrobenzene-d_5 (40 mmol) was phenylated by using 8 mmol of a phenylating agent (PhN_2BF_4–$NaNO_2$–DMSO (150 g) or *N*-Nitrosoacetanilide or PAT) under a nitrogen atmosphere. The reaction mixture was dissolved in ether and washed with water. The solvent was removed under reduced pressure, and elution chromatography of the residue on alumina yielded an *o*-nitrodiphenyl–*o*-nitrodiphenyl-d_4 mixture and a *p*-nitrodiphenyl–*p*-nitrodiphenyl-d_4 mixture. The *m*-isomer mixture could not be isolated because of its low yield. The kinetic isotope effect was calculated from the parent peak ratio (I_{199}/I_{203}) of the mass spectrum of each mixture (Hitachi Mass Spectrometer RM-60).

$$\frac{\text{yield of } PhC_6H_4NO_2}{\text{yield of } PhC_6D_4NO_2} = \frac{k_H}{k_D} \times \frac{[C_6H_5NO_2]}{[C_6D_5NO_2]}$$

Competitive Phenylation of m-*Dinitrobenzene–*m-*Dinitrobenzene-*d_4. *m*-Dinitrobenzene (25 mmol) and *m*-dinitrobenzene-d_4 (25 mmol) were phenylated by using 5 mmol of a phenylating agent (PhN_2BF_4–$NaNO_2$, *N*-nitrosoacetanilide or PAT) in DMSO (150 g) under a nitrogen atmosphere. The reaction mixture was dissolved in chloroform and washed with water to remove DMSO. Evaporation under reduced pressure removed chloroform and then unreacted *m*-dinitrobenzene and *m*-dinitrobenzene-d_4. Elution chromatography of the residue on alumina gave a 2,4-dinitrodiphenyl–2,4-dinitrodiphenyl-d_3 mixture and a 2,6-dinitrodiphenyl–2,6-dinitrodiphenyl-d_3 mixture. The kinetic isotope effect was calculated from the parent peak ratio (I_{244}/I_{247}). It was ascertained that the parent peak ratio did not change when ionization potential was changed from 15 to 70 eV.

*Competitive Phenylation of 1,3,5-tri-*t*-butylbenzene–1,3,5-tri-*t*-butylbenzene-2,4,6-*d_3. 1,3,5-tri-*t*-butylbenzene (7.0 mmol) and 1,3,5-tri-*t*-butylbenzene-2,4,6-d_3 (7.0 mmol) were phenylated under nitrogen either by NNA (2 mmol) in acetonitrile (20 g) or by PAT (2 mmol) in benzene (18 g). The reaction mixture was dissolved in ether and washed with water. After the ether was removed, most of the unreacted 1,3,5-tri-*t*-butylbenzene and 1,3,5-tri-*t*-butylbenzene-2,4,6-d_3 was removed by chromatography on alumina. The substituted diphenyl fraction was subjected to a Hitachi glc K-53 (column: Apiezon L, 1 m) which is connected with a Hitachi Mass Spectrometer RM-60. The k_H/k_D value was calculated from the parent peak ratio (I_{322}/I_{324}) of 2,4,6-tri-*t*-butyldiphenyl and 2,4,6-tri-*t*-butyldiphenyl-3,5-d_2.

Phenylation of m-*Dinitrobenzene and* m-*Dinitrobenzene-*d_4 *with PAT or* PhN_2BF_4–$NaNO_2$. Ten mmol of *m*-dinitrobenzene (or *m*-dinitrobenzene-d_4) was phenylated with 1 mmol of PAT (or PhN_2BF_4–$NaNO_2$) in 50 g of DMSO under a nitrogen atmosphere. The reaction mixture was diluted with ether, washed with water, and dried over anhydrous magnesium sulfate. The ether and about 70% of the unreacted *m*-dinitrobenzene (or *m*-dinitrobenzene-d_4) was distilled off under reduced pressure. The residual *m*-dinitrodiphenyl isomers were analyzed by a Hitachi glc K-53 (column: Apiezon L, 10%, 1 m on Chromosorb W).

Phenylation of m-$C_6H_4(NO_2)_2$–m-$C_6D_4(NO_2)_2$ *with BPO.*
1) A solid mixture of BPO (3 mmol), *m*-$C_6H_4(NO_2)_2$ (17 mmol) and *m*-$C_6D_4(NO_2)_2$ (17 mmol) was placed in an oil bath at 90°C, and then heated up to and kept at 100°C for one day.

2) An acetonitrile solution (60 g) of BPO (2 mmol), *m*-$C_6H_4(NO_2)_2$ (26 mmol) and *m*-$C_6D_4(NO_2)_2$ (26 mmol) was let to decompose at 80 ± 0.1°C under nitrogen for one day.

The two reaction mixtures were subjected to distillation under reduced pressure for removal of *m*-dinitrobenzenes (and acetonitrile). Elution chromatography of the residue gave a mixture of 2,4-dinitrodiphenyl and 2,4-dinitrodiphenyl-d_3. Isotope effect was calculated from the ratio of the parent peaks (I_{244}/I_{247}).

The authors are indebted to Messrs. Kisaburo Yamazaki and Takamichi Ichimura at the Central Research Laboratories of Yamanouchi Pharmacy Co., Limited for mass spectrometric measurements.

Cationic Arylation. V. Reaction of Substituted Benzenes with *p*-Nitrophenyl Cation

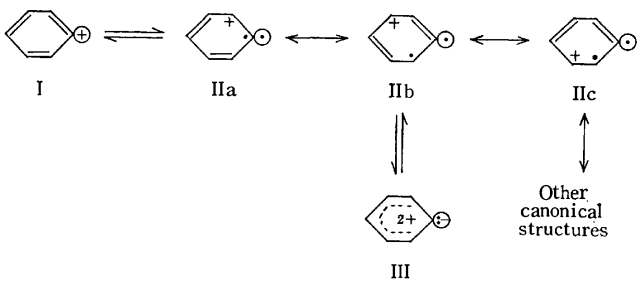
Nobumasa KAMIGATA, Michio KOBAYASHI, and Hiroshi MINATO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo

(Received March 24, 1972)

The cationic arylation of substituted benzenes was investigated with *p*-nitrophenyl cation generated from *p*-nitrobenzenediazonium tetrafluoroborate in acetonitrile and from *p*-nitrophenylazo *p'*-tolyl sulfone in the presence of trifluoroacetic acid. The isomer distribution of substituted nitrobiphenyls produced and the partial rate factors indicated electrophilic character of the *p*-nitrophenyl cation. Selectivity of *p*-nitrophenyl cation is low compared with those of nitronium or sulfonyl cation, and similar to that of phenyl cation. These facts suggest that the *p*-nitrophenyl cation functions as a cation diradical with concerted uncoupling of a pair of π-electrons, one of which falls into the vacant sp^2 σ-orbital.

Benzenediazonium tetrafluoroborate undergoes heterolysis in aprotic polar solvents, and substituted diphenyls are produced when some substituted benzene was present. The partial rate factors in this phenylation are of electrophilic nature, and hence the reactive intermediate produced is considered to be phenyl cation.[1] However, the positional selectivity of phenyl cation is considerably different from those of nitro, sulfonyl, alkyl, or acyl cations in ordinary electrophilic substitutions on arenes.[2] Abramovitch *et al.*[3] modified a proposal originally made by Taft[4] concerning the stabilization of the *m*-methoxyphenyl cation, and suggested that aryl cation (I) initially formed in the thermal decomposition of diazonium salts may isomerize to a diradical cation (II) with concerted uncoupling of a pair of π-electrons, one of which falls into the vacant sp^2 σ-orbital, and that the resulting species would be expected to behave like a highly electrophilic free radical in aromatic substitution reactions. Canonical structures (II) would have the properties of a triplet carbene. If a second π-electron fell into the σ-orbital, the species (III) resulted might behave as a singlet carbene.



Preliminary molecular-orbital calculations made by Absar and McEwen[5] indicate the order of stabilization (II)>(III)>(I) for the phenyl cation itself, the triplet diradical cation (II) being the ground state.

In an attempt to study further the electronic state of phenyl cation, the isomer distributions and partial rate factors in substitutions of arenes with *p*-nitrophenyl cation have been investigated. The results will be described in this paper.

Results and Discussion

p-Nitrophenyl cation was generated from *p*-nitrobenzenediazonium tetrafluoroborate in acetonitrile or from *p*-nitrophenylazo *p'*-tolyl sulfone and trifluoroacetic acid. A substituted benzene was mixed with the *p*-nitrophenyl cation source, and the isomer distributions and partial rate factors in the *p*-nitrophenylation were determined. Table 1 and 2 show the results, together with the data on phenyl cation[1b,6] and *p*-nitrophenyl radical[7] for comparison.

The data in Table 1 show that *p*-nitrophenyl cation, not *p*-nitrophenyl radical, is produced, since with nitrobenzene as the substrate the *meta* position of the nitrobenzene is substituted extensively and the partial rate factors are much smaller than unity and quite different from those with *p*-nitrophenyl radical.

Zollinger reported that when *p*-nitrobenzenediazonium tetrafluoroborate was decomposed in a mixture of nitrobenzene and DMSO, the isomer distribution of the 4,X'-dinitrodiphenyls produced was *ortho* 65.3, *meta* 9.5 and *para* 25.2%.[8] Since this isomer distribution is similar to that with *p*-nitrophenyl radical produced from *p*-nitrobenzoyl peroxide, he proposed that *p*-nitrobenzenediazonium cation combines with DMSO, forming an intermediate, which then decomposes to *p*-nitrophenyl radical, nitrogen and DMSO cation radical. Our results are quite different from Zollinger's, and the difference can be ascribed to the solvents; all the data are in agreement with the interpretation that in acetonitrile *p*-nitrobenzenediazonium ion forms *p*-nitrophenyl cation whereas it forms *p*-nitrophenyl radical in DMSO.

When the partial rate factors with phenyl cation and

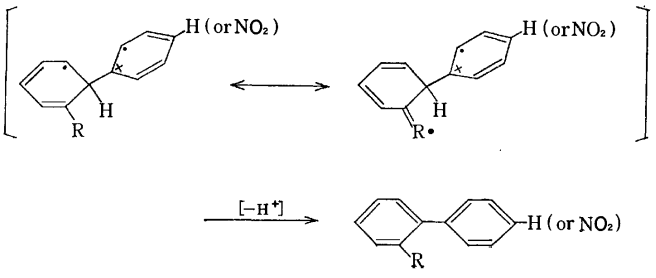
a) Ref. 6 b) This work c) Ref. 7

those with *p*-nitrophenyl cation are compared, the latter are greater with all the substrates (except f_p with nitrobenzene). *p*-Nitrophenyl cation is more selective than phenyl cation, and according to Brown's selectivity rule *p*-nitrophenyl cation is considered to be less reactive than phenyl cation.

When the *m*/*p* ratios are compared in order to examine the selectivity within a molecule, they are always greater with *p*-nitrophenyl cation than with phenyl cation. This finding also shows that *p*-nitrophenyl cation is less reactive than phenyl cation. This intramolecular selectivity is greater with the substrate with an electron-withdrawing substituent and hence less prone to make a bond with an aryl cation. This is reasonable since the activation energy is greater with less reactive substrates, the transition state is at a later stage on the reaction coordinate and hence the intramolecular selectivity is greater.



The yields of *ortho* isomers are always great, and this shows the radical nature of aryl cations. An intermediate σ-complex can be expressed as shown in the above structural formula and it roughly approximates the transition state. The more stable structure is that possessing the substituent R at the end of the resonance system of the cyclohexadienyl radical, and it gives rise to the *ortho* isomer.

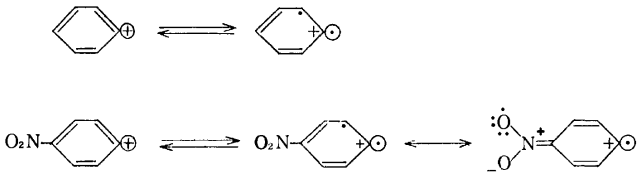
The data shown in Table 2 also indicate that both the intermolecular (the partial rate factors) and intramolecular (the *m*/*p* ratios) selectivities of *p*-nitrophenyl cation are in general greater than those of phenyl cation. Hence, *p*-nitrophenyl cation is less reactive than phenyl cation.

The comparison of the data in Table 1 and 2 reveals that the isomer distributions and partial rate factors somewhat differ when the source and the medium are different. Such differences could be ascribed to the following reasons. 1) Difference of the counter anions: The counter anion is BF_4^- in the case of the diazonium salts and $CF_3CO_2^-$ (or $ArSO_2^-$) in the case of the azosulfones. The tightness of the ion pairs naturally differs. 2) Difference in the rates of abstraction of proton from the σ-complex: Since the basicities of the counter anions differ, the rates of proton abstraction may be different. However, no isotope effect was observed as reported in a previous paper,[1b] and hence the rate-determining step must be the forma-

tion of the σ-complex. 3) Difference in the solvents: The diazonium salts are decomposed in acetonitrile which is fairly basic, and therefore fairly extensive solvation is expected at the transition state although smaller than that at the ground state. The medium in which azosulfones are decomposed contains about 20% trifluoroacetic acid, and the solvation is expected to be very little. The fact that f_m and f_p are smaller with azosulfones could be ascribed to lack of stabilization by solvation at the transition state.

The reactivities at the *ortho* positions are somewhat greater in azosulfones than those in diazonium salts, and especially the values with *p*-nitrophenyl cation toward the *ortho* position of nitrobenzene are unusually great. At present, it is not possible to give an adequate explanation to this finding.

The fact that *p*-nitrophenyl cation is more selective and less reactive than phenyl cation in reactions with arenes could be explained as follows. If phenyl cation and *p*-nitrophenyl cation do not possess diradical cation nature, certainly *p*-nitrophenyl cation would be less stable and more reactive than phenyl cation. However, *p*-nitrophenyl cation is stabilized considerably by resonance with the nitro group as shown below. Thus, because of the diradical cation nature of the aryl cations, *p*-nitrophenyl cation is more stable and less reactive than phenyl cation.



Experimental

Materials. Acetonitrile was purified according to the method in the literature[9] and distilled; bp 81.5°C. Trifluoroacetic acid of Wako Pure Chemical Industries Limited was used without further purification. Benzene and chlorobenzene were washed with concentrated sulfuric acid and water successively, dried over calcium chloride and distilled. Boiling points were 80 and 131°C, respectively. Anisole was washed with an aqueous sodium hydroxide solution and water, dried over calcium chloride, and distilled; bp 153°C. Nitrobenzene was washed repeatedly with a potassium dichromate solution, dried over calcium chloride, and distilled; bp 95.5°C/18 mmHg.

p-Nitrobenzenediazonium tetrafluoroborate was prepared according to the method described in the literature.[10]

p-Nitrophenylazo *p'*-tolyl sulfone was prepared according to the method described previously.[11]

4-Nitrodiphenyl was prepared by nitration of diphenyl according to the method of Maki and Obayashi,[12] mp 112.8—113°C (from methanol).

2-Methoxy-4'-nitrodiphenyl was prepared from *N*-nitroso-*p*-nitroacetanilide[13] and anisole, and was purified by elution chromatography and recrystallized from methanol, mp 63—64°C.

3-Methoxy-4'-nitrodiphenyl was prepared from diazotized *m*-anisidine and nitrobenzene by the Gomberg reaction. After removal of the solvent from the reaction mixture, the residue was distilled with superheated steam. The crystals obtained were then fractionated by chromatography on alumina in *n*-hexane–benzene (1: 1), mp 90—91°C (from methanol).

4-Methoxy-4'-nitrodiphenyl was prepared from *N*-nitroso-*p*-acetanisidide[12] and nitrobenzene, and was purified by elution chromatography on alumina in *n*-hexane–benzene and recrystallized from methanol, mp 110°C.

2-Chloro-4'-nitrodiphenyl was prepared by reaction of *N*-nitroso-*p*-nitroacetanilide[13] with chlorobenzene. After removal of chlorobenzene under reduced pressure, distillation with superheated steam and then elution chromatography on alumina (*n*-hexane–benzene, 4:1), yielded the product, mp 79—80°C (from methanol).

3-Chlorodiphenyl and 4-chlorodiphenyl were prepared by the method reported previously.[14]

3-Chloro-4'-nitrodiphenyl was prepared by the nitration of 3-chlorodiphenyl with fuming nitric acid in acetic anhydride. The crude oily product was fractionally distilled under reduced pressure (bp 157—160°C/1 mmHg) and purified by elution chromatography on alumina in *n*-hexane–benzene (4: 1); mp 93—94°C (from methanol).

4-Chloro-4'-nitrodiphenyl was prepared by the nitration[15] of 4-chlorodiphenyl, and was then purified by elution chromatography on alumina in *n*-hexane–benzene and recrystallized from ethanol; mp 145.5°C.

2,4'- and 4,4'-Dinitrodiphenyl were prepared by the nitration of 4-nitrodiphenyl according to the method of Maki and Obayashi.[12] The 2,4'-isomer was recrystallized from ethanol (mp 93.5—94°C), and the 4,4'-isomer from acetone (mp 237°C).

3-Nitrodiphenyl was prepared by the method described in the literature.[16]

3,4'-Dinitrodiphenyl was prepared by the nitration of 3-nitrodiphenyl according to the method reported in the literature,[17] mp 188.5°C (from ethanol).

General Procedure for p-*Nitrophenylation with* p-*Nitrobenzenediazonium Tetrafluoroborate.* In acetonitrile (70.0 g) *p*-nitrobenzenediazonium tetrafluoroborate (2.1 g) was dissolved, and the solution was diluted with an equimolar mixture of benzene and monosubstituted benzene (50 mol of the total substrate/mol of p-$NO_2C_6H_4N_2BF_4$). The homogeneous solution was placed in a bath at 60±0.1°C, and the decomposition was followed by measuring the evolution of nitrogen. After the evolution of nitrogen ceased, the mixture was diluted with ether and triphenylmethane was added as an internal standard for the glc analyses. The ethereal solution was washed with water to remove the acetonitrile,

washed with a 5% sodium hydroxide solution to remove acidic products, and water successively, and dried over anhydrous magnesium sulfate.

General Procedure for p-*Nitrophenylation with* p-*Nitrophenylazo* p'-*Tolyl Sulfone in the Presence of Trifluoroacetic Acid.* *p*-Nitrophenylazo *p'*-tolyl sulfone (2.0 g, 6.6 mmol) was dissolved in a mixture of benzene (0.250 mol) and a substituted benzene (0.250 mol), and then trifluoroacetic acid (6.0 g, 52.6 mmol) was added to this homogeneous solution. The mixture was decomposed in a constant temperature bath at 60 ± 0.1°C. After the decomposition was over, the reaction mixture was treated in a manner similar to that described for the reaction with *p*-nitrobenzenediazonium tetrafluoroborate.

Quantitative Analyses. The substituted nitrodiphenyl isomers produced in the *p*-nitrophenylation were separated by gas chromatography. The compounds corresponding to the individual peaks were identified by comparing their retention times with those of the authentic specimens and their amounts were determined by use of calibration curves. The columns used were packed with Apiezon L (10%) on Chromosorb W, 1 m.

The Migratory Aptitudes in the 1,3-Dipolar Cycloadducts of Substitiuted 1-Benzoyliminopyridinium Ylides with Dimethyl Acetylenedicarboxylate[1]

Tadashi SASAKI, Ken KANEMATSU, Akikazu KAKEHI, and Gin-ichi ITO

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa, Nagoya, 464

(Received November 4, 1971)

The 1,3-dipolar cycloaddition of substituted 1-benzoyliminopyridinium ylides (**1**, **6**, and **9**) with dimethyl acetylenedicarboxylate (DAC) produced the corresponding rearrangement compounds (**3**, **4**, **7**, **8**, and **10**). On the other hand, the similar reaction of **11** with DAC in acetonitrile gave **12**, accompanied with a Sommelet-type rearrangement compound, **13**. The structural elucidation of these products was accomplished by spectral inspections.

In continuation of our previous work,[2] we wish to report here on a comparative study of the cycloaddition reactions of 1-benzoyliminopyridinium ylides[3] with DAC.

Results and Discussion

In the reaction of 2-methyl-1-benzoyliminopyridinium ylide (**1**) with DAC in benzene at room temperature, the products were characterized as 1-benzoyl-2,3-bis(methoxycarbonyl)-3a-methyl-1,3a-dihydropyrazolo[1,5-*a*]pyridine (**2**) (5%) and a mixture of two rearranged isomers, dimethyl α-(2-methyl-3-pyridyl)-α'-benzoylaminomaleate (**3**) and dimethyl α-(2-methyl-5-pyridyl)-α'-benzoylaminomaleate (**4**) (9%) in a ratio of 7: 2.[4] An unstable compound (**2**) was spontaneously transformed, after 3 days at room temperature, into a mixture of **3** and **4**, and the reaction of **2** with tetracyanoethylene in benzene afforded a crystalline Diels-Alder adduct, **5**.

Thus, the isomeric products, **3** and **4**, may be assumed to be formed through Path **a** *via* 1,2-migration (intermediates **A**→**B**) in competition with Path **b** *via* 1,4-migration (intermediates **C**→**D**) by the rearrangement of **2**.

The 2,4-dimethyl compound, **6**, did not react with DAC in benzene under the above conditions. The present reactions were carried out in refluxing benzene, they gave an isomeric mixture of the rearranged products, **7** and **8** (51%) in a ratio of 1: 1.2 (as determined by nmr analyses).

A similar reaction of **9** with DAC in benzene or acetonitrile at 60—65°C afforded the expected rearranged product, **10** (28%).

These results are summarized in Scheme 1.

The reaction of 2,6-dimethyl-1-benzoyliminopyridinium ylide (**11**) with DAC in benzene at room temperature afforded the rearranged product, **12**, in a 74% yield. The NMR spectrum showed signals at τ 7.65 (s, 3H, Me), 7.44 (s, 3H, Me), 6.01 (s, 3H, COOMe), 6.30 (s, 3H, COOMe), 2.92 (d, 1H, C_5-H), 2.3—2.8 (m, 6H, Ph and C_4-H), and 2.32 (br s, 1H, NH, exchanged by D_2O), suggesting the intermediacy of dihydropyrazolopyridine, which might then rapidly rearrange into a stable compound, **12**. However, in acetonitrile, two products, **12** and **13**, were produced in 44 and 10% yields respectively. The NMR spectrum of **13** showed signals of one methyl proton at τ 7.63 (s, 3H), of pyridine ring protons at τ 3.00 (dd, 2H, overlapped with each proton at C_3- and C_5-H), of methylene

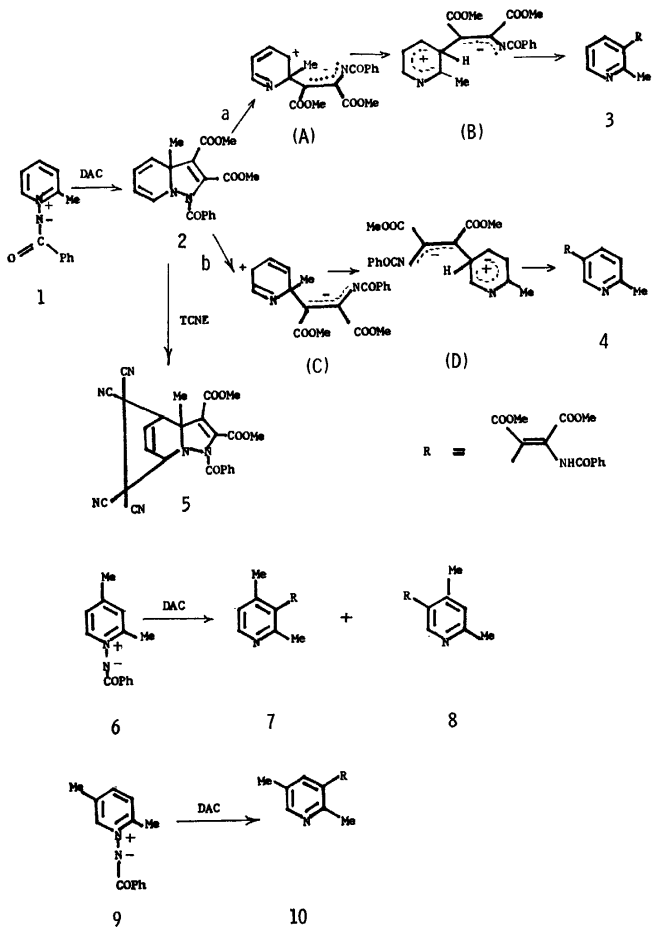
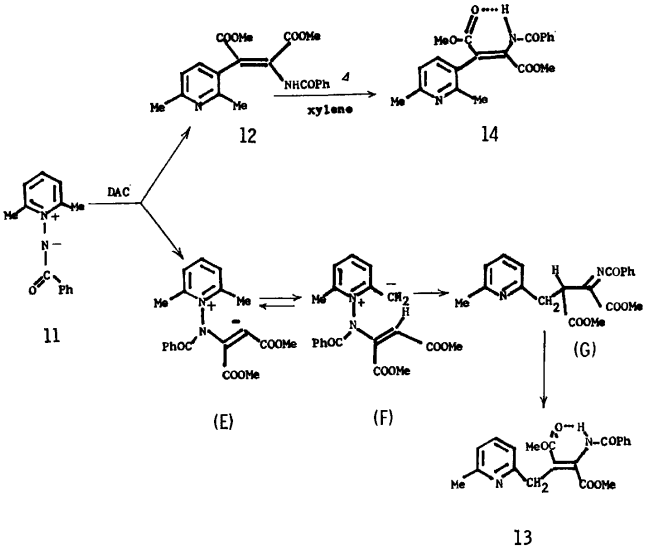
3) Several ring-substituted 1-benzoyliminopyridinium ylides have been prepared by a modification of the Gösl method; see T. Okamoto, M. Hirobe, C. Mizushima, and A. Osawa, *Yakugaku Zasshi*, **83**, 308 (1963).

4) These products were assigned on the basis of the foregoing data; see Ref. 2.



Scheme 1.

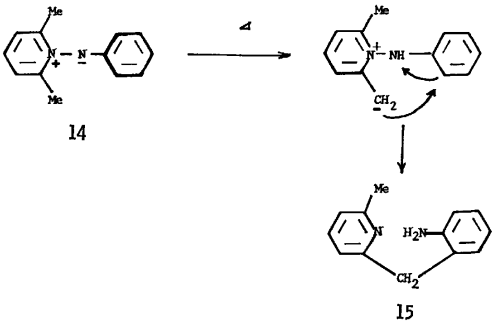
protons at τ 6.08 (s, 2H), of phenyl protons and C_4-H at τ 1.75—2.80 (m, 6H), of two methoxycarbonyl protons at τ 6.12 (s, 3H) and 6.20 (s, 3H), and of NH proton at τ −2.02 (br s, 1H, exchanged by D_2O). In particular, the singlet signal at τ 6.08 clearly arises from the methylene group at the 2-position in the pyridine moiety, suggesting that a Sommelet-type rearrangement has occurred. Moreover, a signal at τ −2.02 indicates the presence of a hydrogen-bonding amido group, showing that *cis-trans* isomerization has occurred. The heating of **12** in xylene at reflux for 5 hr afforded **14**, suggesting the presence of a hydrogen-bonding amido group at τ −2.09 (br s, exchanged by D_2O) by NMR. These results are summarized in Scheme 2.



Scheme 2.

Finally, an additional discussion may be made of these studies. The mechanisms of the formations of the several rearranged products were discussed in our previous report.[2] However, the rearrangement behaviour is different from that of the substituents between the alkoxycarbonyl and benzoyl groups attached to the iminopyridinium moiety. The former undergoes rearrangement in the 1,4-fashion, but the latter proceeds competitively in the 1,2- and 1,4-fashions.

In addition, a Sommelet-type rearrangement product, **13**, was obtained by the reaction of **11** with DAC; this reaction might be initiated by a prototropic shift *via* intermediates, **E**→**F**→**G**, followed by a rearrangement to **13**, as is illustrated in Scheme 2. A similar rearrangement has been observed in the case of 2,6-dimethyl-1-phenyliminopyridinium ylide (**14**) as is shown in Scheme 3.[5]



Scheme 3.

Experimental[6]

The 1,3-Dipolar Cycloaddition Reactions of the Ylides with DAC. General Method: Into a benzene or acetonitrile solution of DAC, an equimolar amount of the ylide was stirred at room temperature or at the reflux temperature. After the disappearance of the deep color of the solution, the solvent was removed *in vacuo* and the oily mixture was separated by column chromatography (silica gel), using benzene as the eluent.

Reaction of 1 with DAC. From 0.64 g of **1** and 0.43 g of DAC, we obtained **2** (0.055 g, 5%) as a pale yellow oil; ν_{max}^{neat} 1663, 1715, 1742 cm^{-1}, τ (CCl_4) 2.00—2.25 (m, 2H, 2,6-protons of C_6H_5), 2.40—2.80 (m, 3H, 3,4,5-protons of C_6H_5 and 1H, H_7), 4.30 (m, 2H, H_4 and H_5), 5.06 (m, 1H, H_6), 6.16 (s, 3H, OCH_3), 6.28 (s, 3H, OCH_3), 8.44 (s, 3H,

5) K. Dimroth, G. L. Buchanan, A. S. von Eichen, and G. Schiffler, *Ann. Chem.*, **604**, 221 (1947).

6) The melting points were measured with a Yanagimoto micromelting point apparatus and are uncorrected. Microanalyses were performed on a Perkin-Elmer 240 Elemental Analyser. The UV spectra were determined with a JASCO Model ORD/UV-5 recorder. The NMR spectra were taken with a Japan Electric Optics Lab. Co., Ltd., Model C-60-XL NMR spectrometer and with a Varian A-60 recording spectrometer, with tetramethylsilane as the internal standard. The chemical shifts are expressed in τ values. The IR spectra were taken with a JASCO Model IR-S spectrophotometer.

CH_3), and a mixture of **3** and **4** (mp 163—169°C, 0.096 g, 9%), which was identified as a 7:2 mixture because the integrated areas for the ring-substituted methyl protons and the C_2–H of the pyridine ring appeared at τ 7.57 (s) and 1.46 (br d) in **3** and at 7.45 (s) and 1.71 (br s) in **4**. The isomers could not be separated either by column chromatography or by repeated recrystallization.

Found: C, 64.46; H, 5.13; N, 7.84%. Calcd for $C_{19}H_{18}O_5N_2$: C, 64.40; H, 5.12; N, 7.91%.

Preparation of the Adduct, 5. A solution of 0.05 g of **2** and 0.02 g of tetracyanoethylene in 20 m*l* of benzene was stirred at room temperature for 3 hr. The precipitated solid was collected by filtration and recrystallized from methanol to give **5** (0.02 g, 29%); mp 182—184°C; τ ($CDCl_3$) 8.43 (s, 3H, CH_3), 6.23 (s, 3H, $COOCH_3$), 6.26 (s, 3H, $COOCH_3$), 5.78 (dd, $J_{4,5}$ 7.5 Hz, $J_{4,6}$ 1.5 Hz, 1H, H_4), 5.54 (dd, $J_{7,6}$ 7.0 Hz, $J_{7,5}$ 1.5 Hz, 1H, H_7), 3.48 (br t, $J_{5,6}$ 7.5 Hz, $J_{6,7}$ 7.0 Hz, 1H, H_6), 3.18 (br t, $J_{5,4}$ 7.5 Hz, $J_{5,6}$ 7.5 Hz, 1H, H_5), 2.10—2.80 (m, 5H, C_6H_5).

Found: C, 62.24; H, 3.85; N, 17.52%. Calcd for $C_{25}H_{18}N_6O_5$: C, 62.24; H, 3.76; N, 17.42%.

Reaction of 6 with DAC. From 0.68 g of **6** and 0.43 g of DAC (in benzene at 80°C), we obtained a mixture of **7** and **8** (mp 169—171°C, 0.56 g, 51%), which was identified as a 1:1.2 mixture because the integrated areas for the methyl protons and the C_2 proton of the pyridine ring appeared at τ 7.63 (s, CH_3 at C_2) and 1.77 (d, $J_{5,6}$ 7.5 Hz, H_6) in **7**, and at τ 7.52 (s, CH_3 at C_2) and 1.83 (s, H_6) in **8**. The mixture could not be separated either by column chromatography or by repeated recrystallization, but it gave a satisfactory analytical value.

Found: C, 65.41; H, 5.46; N, 7.42%. Calcd for $C_{20}H_{20}O_5N_2$: C, 65.21; H, 5.47; N, 7.61%.

Reaction of 9 with DAC. From 1.2 g of **9** and 0.7 g of DAC (in benzene or acetonitrile at 65°C), we obtained **10** (mp 186—188°C, 0.51 g 28%); ν_{max}^{KBr} (C=O) 1671, 1719, 1739 cm^{-1}, τ ($CDCl_3$) 7.68 (s, 3H, CH_3), 7.58 (s, 3H, CH_3), 6.02 (s, 3H, $COOCH_3$), 6.30 (s, 3H, $COOCH_3$), 2.4—2.9 (m, 7H, 5H of C_6H_5, 1H of ring proton of C_4 and 1H of NH).

Found: C, 65.30; H, 5.50; N, 7.48%. Calcd for $C_{20}H_{20}O_5N_2$: C, 65.21; H, 5.47; N, 7.61%.

Reaction of 11 with DAC. 1) From 0.68 g of **11** and 0.43 g of DAC (in benzene at room temperature for 1.5 hr), we obtained **12** (mp 208—211°C, 0.83 g, 74%); ν_{max}^{KBr} (C=O) 1677, 1708, 1731 cm^{-1}, τ ($CDCl_3$) 7.65 (s, 3H, CH_3), 7.44 (s, 3H, CH_3), 6.01 (s, 3H, $COOCH_3$), 6.30 (s, 3H, $COOCH_3$), 2.92 (d, $J_{4,5}$ 8.0 Hz, 1H, H_5), 2.30—2.80 (m, 6H, 5H of C_6H_5 and 1H or H_4), 2.32 (br s, 1H, NH).

Found: C, 65.10; H, 5.52; N, 7.40%. Calcd for $C_{20}H_{20}O_5N_2$: C, 65.21; H, 5.47; N, 7.61%. 2) From 0.68 g of **11** and 0.43 g of DAC (in acetonitrile at room temperature for 1.6 hr), we obtained **12** (0.26 g, 44%) and **13** (mp 172—176°C, 0.06 g, 10%); ν_{max}^{KBr} (C=O) 1680, 1706, 1730 cm^{-1}, τ ($CDCl_3$) 7.63 (s, 3H, CH_3), 6.20 (s, 3H, $COOCH_3$), 6.12 (s, 3H, $COOCH_3$), 6.08 (s, 2H, CH_2), 3.00 (dd, $J_{3,4}=J_{4,5}$ 7.5 Hz, 2H, H_3 and H_5), 1.75—2.00 and 2.30—2.80 (br m, 6H, 5H of C_6H_5 and 1H of H_4), −2.02 (br s, 1H, NH).

Thermal Isomerization of 12. A solution of 0.33 g of **12** in 20 m*l* of xylene was heated in an oil bath at 140—145°C for 5 hr. The solvent was then removed under reduced pressure, and the residue was purified by silica-gel chromatography, with benzene as the eluent, to give colorless crystals; **14** (0.20 g, 65%); mp 152—153°C; τ ($CDCl_3$) 7.56 (s, 3H, CH_3), 7.46 (s, 3H, CH_3), 6.45 (s, 3H, $COOCH_3$), 6.27 (s, 3H, $COOCH_3$), 3.07 (d, $J_{4,5}$ 8.0 Hz, 1H, H_5), 1.91—2.19 and 2.33—2.76 (br m, 6H, 5H of C_6H_5 and 1H of H_4), −2.09 (br s, 1H, NH, exchanged by D_2O .

Found: C, 65.41; H, 5.45; N, 7.57%. Calcd for $C_{20}H_{20}O_5N_2$: C, 65.21; H, 5.47; N, 7.61%.

Reactive Species Produced by Laser Irradiation. The Reaction of CN Radicals with Hydrocarbons

Ko Taki, Pil Hyon Kim, and Susumu Namba
The Institute of Physical and Chemical Research, Wako-shi, Saitama
(Received January 17, 1972)

The reactive species, CN radicals, were produced by the irradiation of the focused laser beam on the metal cyanide target. The reaction of CN radicals with low-molecular-weight hydrocarbons gave fragmented hydrocarbons and CN (and NC) compounds, while that with hydrogen gave hydrogen cyanide. From the experimental results, it seems that the products may be formed mainly by the reaction of the reactive species with fragment hydrocarbon radicals which are produced by the collision of the high-temperature reactive species (CN*) with the parent hydrocarbons.

When the intense laser beam is focused upon a suitable target, its surface material is rapidly heated and then vaporized or decomposed.[1] It is of interest to study the chemical reaction of an organic compound with decomposed reactive species produced by laser irradiation. As has previously been shown,[2] in a binary system, such as metal compounds and hydrocarbons, the laser beam decomposes metal compounds selectively, because it is absorbed by the metal compounds only. The reaction of decomposed reactive

2) K. Taki, P. H. Kim, and S. Namba, This Bulletin, **43**, 1450 (1970).

species with some substrates present may then be observed.

In this experiment, copper cyanide and some other metal cyanides were decomposed by laser heating to form CN radicals, and the reaction of the CN radicals thus obtained with hydrocarbons was investigated.

Free CN radicals in the gaseous state have been formed from cyanogen by electric discharge,[3] thermal decomposition,[4] photodissociation,[5] and reaction with nitrogen.[6] It has also been found that carbon atoms produced by laser irradiation on carbon target[7] react with nitrogen to produce CN, as in the case of the carbon arc.[8] However, little work has been reported on the reaction[9,10] of CN with hydrocarbons in the gaseous state.

Experimental

1) Preparation of Copper Cyanide.[11] A potassium cyanide solution was added to a copper sulphate solution at 60°C in order to precipitate CuCN. The elemental analysis of this copper cyanide showed C, 13.70% and N, 15.73%. It has the empirical formula of CuCN (Calcd: C, 13.41; N, 15.61%). The freshly-prepared CuCN was used for decomposition. AgCN (prepared from $AgNO_3$ and KCN) powder was also used.

2) Laser Irradiation. Copper cyanide powder or other metal cyanides in a 7-cc cell filled with substrate gas (700—760 Torr) was irradiated by a ruby laser beam focused by a lens 10 cm in focal length. The ruby laser used was a normal laser, the output energy and pulse duration of which were 3 J and 0.5 msec respectively. The temperature of the irradiated region on metal cyanide is estimated to be above 1000°C, and the heated region of the target surface is about 10^{-2} cm^2.

3) Analysis. The volatile products were collected and analysed by gas chromatography using dioctyl phthalate, dinonyl phthalate, silica gel, and squalane columns. The reliable value in detection was about 10^{-8} mol.

Results

1) Decomposition of Copper Cyanide. The noncondensable products at −196°C (one-fifth of all the products) were analysed mass spectrometrically; they were found to be nitrogen and small amounts of oxygen and carbon monoxide. The condensable gas was almost pure cyanogen, like that produced by the conventional heating.[12] Therefore, the decomposition may show the formation of CN, which then gives cyanogen by the combination of two CN radicals. (AgCN was also decomposed. The products were almost the same as those from copper cyanide.)

The presence of the N_2 and CO[13] gases in the products suggested that the decomposition of copper cyanide might produce N and C atoms. However, their yields are small and N and O atoms do not play any significant role in the reaction with hydrocarbons.[7,14]

Table 1. Product yield in the reaction of CN with low molecular weight hydrocarbons for 6 pulse laser irradiations

Substrate	Product	Yield (10^{-6}mol)
Methane	C_2N_2	0.20
	CH_3CN	0.007
	CH_3NC	0.03
	C_2H_6	trace
Ethane	C_2N_2	0.20
	CH_3CN	0.03
	CH_3NC	0.03
	C_2H_5CN	0.003
	C_2H_5NC	0.006
	C_2H_3CN	0.02
	CH_4	0.10
	C_2H_4	0.40
	C_2H_2	0.20
Ethylene	C_2N_2	0.20
	C_2H_3CN	0.05
	CH_4	0.02
	C_2H_6	0.03
	C_2H_2	0.60
	Vinylacetylene	trace
	Diacetylene	trace

2) Reaction of CN with Low-molecular-weight Hydrocarbons. In the presence of methane, the products were acetonitrile, methyl isocyanide, and some other hydrocarbons (small amounts of ethane). In ethane, the products were methyl isocyanide,[15] acetonitrile, propionitrile, ethyl isocyanide, and other hydrocarbons. In ethylene, acrylonitrile and propionitrile were produced. The results are summarized in Table 1. In the table, the data of the noncondensable products (N_2, O_2, H_2, and CO) and HCN (see Appendix) are excluded. In the reaction with acetylene, small amounts of ethyl isocyanide, propionitrile, acrylonitrile, and black polymeric products were observed, but cyanoacetylene and dicyanoacetylene were not detected.

3) Reaction of CN with Other Substrates. In the reaction of propylene and cyclohexane, the low-molecular-weight cyanides and isocyanides (CH_3CN, CH_3NC,

C_2H_5CN, C_2H_5NC), hydrocarbons, and C_2N_2 were produced, but the cyanides or isocyanides of the parent molecules were not obtained. The reaction with benzene produced benzonitrile and phenyl isocyanide[17] in an almost equivalent yield ($0.7-2\times10^{-8}$ mol for 7 pulses), hydrocarbons (mainly C_2H_2), and C_2N_2. In the reaction with toluene, benzyl cyanide was not obtained, but benzonitrile, phenyl isocyanide, hydrocarbons, and C_2N_2 were obtained.

Discussion

From the reaction products, it may be considered that the formation process of nitrile and isonitrile is the combination of alkyl radicals with CN. The formation of alkyl radicals may be brought about either by hydrogen abstraction by CN, resulting in the formation of hydrogen cyanide,[9] or by the decomposition of the hydrocarbons mentioned below.

It seems that the CN radicals produced by laser irradiation are probably in the high-temperature state at the moment of production, and that they collide with the hydrocarbons and decompose them thermally into fragments. The CN radicals may react with the fragments thus produced near the target surface, because the mean free path of CN vapor is about 10^{-5} cm at 1 atm; subsequently, low-molecular-weight CN (and NC) compounds and hydrocarbons may be formed. The formation of benzonitrile may be due to the stability of the benzene ring.

The thermal decomposition at the target surface may be negligible for the following reasons; the hydrocarbon may not decompose at the heated surface during the time of CN vaporization because the hydrocarbon can not collide with the heated surface because of the vapor pressure of the CN species, and the reaction of the CN species with the fragmented hydrocarbon produced before the vaporization of CN may also be negligible because the life-time of a fragmented hydrocarbon (such as CH, CH_2,$\cdots$) is much shorter than the vaporization time ($\sim10^{-4}$ sec).

The collisional and thermal decomposition may be supported by the fact that the laser irradiation on nickel plate in ethane gives the products of hydrocarbon listed in Table 2.

Table 2. Product yield in the reaction of Ni vapor with ethane (about 700 torr) for 7 pulse irradiations

Substrate	Product	Yield (10^{-6}mol)
Ethane	CH_4	0.32
	C_2H_4	0.77
	C_2H_2	0.37
	C_3H_8	0.10

From the above considerations, the formation of CN products may follow the thermal (collisional) decomposition caused by the high-temperature CN radicals or the hydrogen abstraction caused by CN radicals, as follows:

[1] $CuCN \xrightarrow{\text{laser heating}} CN^*$ species and others[19]

[2] $2CN^* \longrightarrow C_2N_2$

[3] $CN^* + RH \longrightarrow [RHCN]^*$

[4] $[RHCN]^* \xrightarrow{\text{fragmentation}}$ CN; H_2, C_2N_2; HCN, CN(or NC) compounds; hydrocarbon products

[5] $RH + CN \longrightarrow R\cdot + HCN$; CN(or NC) compounds

CN*; CN at the high-temperature state

The authors wish to acknowledge the enthusiastic assistance of Miss K. Motegi in carrying out this work; they wish also to express their appreciation to Mr. S. Satooka for his mass-spectroscopic analysis.

Appendix

Reaction of CN with Hydrogen. The laser irradiation on freshly-prepared copper cyanide in the presence of hydrogen shows the formation of hydrogen cyanide, as in the reaction of hydrocarbons with the CN radicals formed by the photolysis of ICN.[5] However, when the copper cyanide was aged the yield of hydrogen cyanide decreased with the time; at last no hydrogen cyanide was given after about a week. The above copper cyanide, when heated at 100—200°C under a vacuum, gave hydrogen cyanide again. Moreover, the yield of cyanogen was not changed by the time of the ageing of copper cyanide. The copper cyanide obtained from $Cu[Cu(CN)_2]_2$ and $Cu[Cu(CN)_3]$ by thermal decomposition also gave hydrogen cyanide, and when the decomposition temperature was at about 150°C, the ratio of hydrogen cyanide to cyanogen showed the highest value, as is shown in Fig. 1. No differences in these samples were found in the X-ray diffraction pattern or in emission spectrum excited by the laser irradiation.

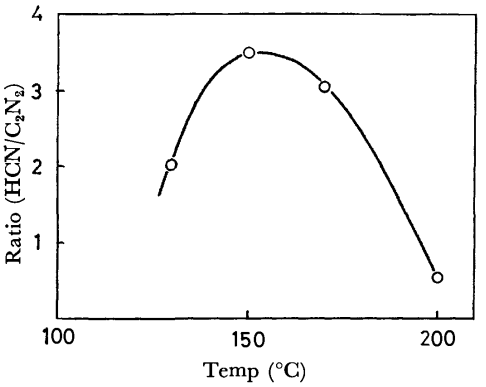

Fig. 1. The ratio of HCN to C_2N_2 in the reaction of hydrogen with CN produced by the laser irradiation on CuCN prepared from $Cu[Cu(CN)_2]_2$ and $Cu[Cu(CN)_3]$ at various temperatures. The yield of C_2N_2 is about 0.2×10^{-6} mol for 6 pulses.

17) The phenyl isocyanide was prepared by the method of Ref. 18.

18) J. U. Nef, *Liebig's Ann. Chem.*, **270**, 275 (1892).

19) All the high-temperature species (CuO, Cu, $\cdots$) except CN radicals may also decompose the substrate.

In order to examine the formation of hydrogen cyanide, several experiments were performed. The laser irradiation on a carbon target[20] in a mixture of hydrogen and nitrogen gave the hydrogen cyanide. The addition of a small amount of oxygen in this case caused a decrease in the yields of hydrogen cyanide and cyanogen. Oxygen molecules react with CN radicals quickly, resulting in a decrease in the yields of hydrogen cyanide and cyanogen. Moreover, it was found that hydrogen cyanide does not react with copper oxide, but that it does react with copper hydroxide quickly and disappears. It seems that the failure to detect hydrogen cyanide when ageing copper cyanide is used may be caused by the presence of copper hydroxide formed in the air. This consideration is supported by the fact that the copper cyanide prepared by an excess of a potassium cyanide solution with a copper sulfate solution did not give hydrogen cyanide, because a small amount of copper hydroxide may be formed in the alkali solution.

By using copper cyanide containing a trace of copper hydroxide on its surface in the reaction with various substrates, the yield of hydrogen cyanide is affected, but the yield of the other CN products may not be affected, because these CN products are not reactive with copper hydroxide.

20) The laser irradiation of a carbon target in nitrogen gives CN radicals.[7]

Studies of the Synthesis of Furan Compounds. XXVII.[1] Derivatives of 3-(5-Nitro-2-furyl)acrylonitrile

Ichiro HIRAO and Yasuhiko KATO

Laboratory of Organic Synthesis, Department of Chemical Engineering, Kyushu Institute of Technology, Tobata-ku, Kita-Kyushu

(Received January 17, 1972)

In a continuation of our previous papers[2,3] concerning the syntheses with 5-nitro-2-furonitrile, 2-(5-nitro-2-furyl)vinyl-1,2,4-oxadiazoles and -1,2,3-triazoles were prepared from 3-(5-nitro-2-furyl)acrylonitrile (I). When I was treated with diazomethane in ether, 4-[2-(5-nitro-2-furyl)vinyl]-1,2,3-triazole (II) was obtained. II gave *N*-acetyl (IIa) and *N*-morpholinomethyl (IIb) compounds when treated with acetic anhydride and when the Mannich reaction was utilized respectively. 3-(5-Nitro-2-furyl)acrylamide oxime (III) was prepared by the usual method from I and hydroxylamine. The treatment of III with benzaldehyde and acid anhydrides or chlorides afforded 3-[2-(5-nitro-2-furyl)vinyl]-5-phenyl-4,5-dihydro-1,2,4-oxadiazoline (IV) and *O*-acyl-3-(5-nitro-2-furyl)acrylamide oximes (IIIa—IIIe) respectively. The *O*-acyl-amide oximes were found to cyclize to 3-[2-(5-nitro-2-furyl)vinyl]-5-alkyl-1,2,4-oxadiazole (V—VII) in their thermal analyses.

3-(5-Nitro-2-furyl)acrylonitrile (I) has been prepared from 3-(5-nitro-2-furyl)acrolein oxime acetate and pyridine,[4] by the dehydration of the corresponding acid amide with *p*-toluenesulfonyl chloride,[5] and by the Wittig reaction of 5-nitrofurfural with cyanomethylenetriphenylphosphorane.[6] However, the above procedures may be supposed to be unsuitable for supplying I as a synthetic raw material from the following points of view: 1) the low yields of the product, 2) the lack in the economy, and 3) the complicated procedure necessary because of the isomerization of the product. Therefore, a better procedure for the preparation of I and the synthesis of its derivatives shall be described in this paper.

Results and Discussion

3-(5-Nitro-2-furyl)acrylonitrile (I) was prepared in a good yield by the reaction of 3-(5-nitro-2-furyl)acrylamide with phosphoryl chloride. When treated with diazomethane in ether, I cyclized to 4-[2-(5-nitro-2-furyl)vinyl]-1,2,3-triazole (II). The structure of this compound was confirmed on the basis of its analytical and IR spectral data. By heating II with acetic anhydride or with 37% formaldehyde and morpholine, *N*-acetyl (IIa) and *N*-morpholinomethyl (IIb) compounds were obtained respectively, though the position of the substituents on the triazole ring was uncertain. 3-(5-Nitro-2-furyl)acrylamide oxime (III) was readily obtained from I and hydroxylamine in the usual way.[2,7,8] The IR spectrum of III exhibited two N–H stretching bands, one at 3448 and the other at 3405 cm^{-1}, besides a broad absorption at 2807 cm^{-1} which might be assumed to be a intramolecular chelated[9] O–H stretching frequency.

3-(5-Nitro-2-furyl)acrylamide was prepared from *trans*-3-(5-nitro-2-furyl)acrylic acid[10] by the usual method. In comparing the NMR spectrum of the acrylamide with that of the *trans*-acrylic acid, the *trans*

configuration of the acrylamide can be deduced from a coupling constant ($J_{\alpha\beta}$) of the ethylene-bonding α- and β-protons similar to that of the *trans*-acrylic acid ($J_{\alpha\beta}$=15.8 Hz). In the NMR spectra of I and III, the observed $J_{\alpha\beta}$ values were approximately the same as that of the starting acrylamide. Therefore, the geometrical configuration was confirmed to be retained during the process of acrylamide→I→III.

When amide oximes are heated with aldehydes, they are converted to 4,5-dihydro-1,2,4-oxadiazolines.[11] Thus, III reacted with benzaldehyde to afford 3-[2-(5-nitro-2-furyl)vinyl]-5-phenyl-4,5-dihydro-1,2,4-oxadiazoline (IV). On the treatment of III with acid anhydrides or chlorides in the usual manner, *O*-acyl-3-(5-nitro-2-furyl)acrylamide oximes (IIIa—IIIe) were produced. The assignment of the *O*-acyl structures to IIIa—IIIe is based on their IR spectra. As in the case of the *N*-acylamide oxime, only one sharp band is observed in the 3400 cm^{-1} region.[12] On the other hand, in the IR spectra of IIIa—IIIe these compounds showed two absorptions, at about 3460 and 3350 cm^{-1}, presumably due to the N–H stretching of the primary amino group, and a C=O absorption at about 1750 cm^{-1}. Furthermore, the characteristic O–H absorption at 2807 cm^{-1} in the mother compound, III, disappeared.

The results of differential thermal analysis (DTA) and thermogravimetric analysis (TGA) indicated that IIIa—IIIc underwent a cyclization reaction, with the release of a molecule of water; this was supported by the absence of the C=O and NH_2 absorptions in the IR spectra of the heating residues of IIIa—IIIc. The DTA curves show an endothermic peak at 173°C for IIIa, at 161°C for IIIb, and at 156°C for IIIc. These peaks coincide with the melting points of each of the corresponding compounds, and are in agreement with a stage in the reduction of the weight at 172—190°C for IIIa, at 160—187°C for IIIb, and at 155—184°C for IIIc, as shown by the TGA curves. About 8.0, 7.4, and 7.1% losses of the weight were observed for IIIa, IIIb, and IIIc respectively at this stage; these losses correspond to the loss of a molecule of water (theoretical: IIIa 7.5, IIIb 7.1, and IIIc 6.7%). Thus, the cyclization reaction was successfully carried out when IIIa—IIIc were heated at the corresponding melting point in a nitrogen stream to give 5-methyl (V), 5-ethyl (VI), and 5-propyl-3-[2-(5-nitro-2-furyl)vinyl]-1,2,4-oxadiazole (VII) respectively.

The geometrical configurations of the compounds, IIIa—IIIe and V—VII, were concluded to be *trans* by a comparison of the $J_{\alpha\beta}$ values of IIId and VI with that of I or III.

Experimental

All the melting points are uncorrected. The elemental analyses were carried out with a Yanagimoto CHN Corder, MT-2 type. The infrared absorption spectra (IR) were performed on a JASCO Model IRA-2 grating infrared spectrophotometer. The nuclear magnetic resonance spectra (NMR) were determined by means of a Japan Electron Optics NMR spectrometer, JNM-C-60HL (60 MHz). All the spectra were measured in DMSO-d_6 (concentration, 7—8 wt%), with tetramethylsilane as the internal reference; the peak positions were expressed in δ-values. The thermal analyses were carried out with a Chyo Balance and with Rigaku Denki Thermoflex in a nitrogen stream.

trans-*3-(5-Nitro-2-furyl)acrylonitrile (I).* A mixture of 18.2 g (0.1 mol) of *trans*-3-(5-nitro-2-furyl)acrylamide, 35 m*l* of phosphoryl chloride, and 2—3 drops of *N,N*-dimethylaniline was heated at 65—70°C for 1.5 hr. After cooling, the reaction mixture was poured onto crushed ice, and the precipitates were collected by filtration, washed with cold water, and dried. They were then recrystallized from ethanol to afford 14 g (84.7%) of the pure nitrile (I) as yellow needles; mp 110°C. IR (KBr) cm^{-1}: 2218 (C≡N). NMR (DMSO-d_6) δ: 6.41 (d, 1H, J=16.3 Hz, ethylene bond C_α–H), 7.18 (d, 1H, J=4.0 Hz, furan ring C_3–H), 7.57 (d, 1H, J=16.3 Hz, ethylene bond C_β–H), and 7.67 (d, 1H, J=4.0 Hz, furan ring C_4–H).

Found: 51.49; H, 2.01; N, 17.05%. Calcd for $C_7H_4N_2O_3$: C, 51.22; H, 2.44; N, 17.07%.

The NMR data of the ethylenic protons of the *trans*-acrylic acid and acrylamide were obtained as follows:

trans-acrylic acid: α-H 6.53, β-H 7.42, J=15.8 Hz. acrylamide: α-H 6.68, β-H 7.23, J=15.8 Hz.

4-[2-(5-Nitro-2-furyl)vinyl]-1,2,3-triazole (II). To a stirred suspension of I (5 g, 30 mmol) in 100 m*l* of ether, we added an ethereal solution containing 32 mmol of diazomethane. The mixture was refluxed for 4 hr, and then the insoluble material was filtered off. The filtrate was taken to dryness *in vacuo*, and the residue was washed with boiling ligroin. Recrystallization from benzene gave 1 g (16.2%) of II as ochreous granules which melted at 133—134°C. IR (KBr) cm^{-1}: 3500 (N–H).

Found: C, 46.61; H, 2.86; N, 27.38%. Calcd for $C_8H_6N_4O_3$: C, 46.60; H, 2.91; N, 27.18%.

4-[2-(5-Nitro-2-furyl)vinyl]-N-acetyl-1,2,3-triazole (IIa). A mixture of II (0.3 g, 1.5 mmol) and acetic anhydride (0.5 g)

11) F. Tiemann, *Ber.*, **22**, 2412 (1889).

12) F. Floy, R. Lenears, and C. Moussebois, *Helv. Chim. Acta*, **45**, 437 (1962).

in 10 ml of dioxane was refluxed for 2 hr. The resulting solution was taken to dryness *in vacuo*, and the residue was washed with water and then dried. Crystallization from benzene gave 0.28 g (76%) of IIa as yellow needles; mp 146—148°C. IR (KBr) cm^{-1}: 1670 (C=O).

Found: C, 48.14; H, 3.43; N, 22.69%. Calcd for $C_{10}H_8N_4O_4$: C, 48.38; H, 3.22; N, 22.58%.

4-[2-(5-Nitro-2-furyl)vinyl]-N-morpholinomethyl-1,2,3-triazole (IIb). A mixture of II (0.3 g, 1.5 mmol), 37% formaldehyde (0.15 g), morpholine (0.15 g), *N,N*-dimethylformamide (0.15 g), and dioxane (10 ml) was stirred at 10—12°C for 1 hr. The resulting mixture was poured onto ice water, and the precipitates were collected on a filter. Recrystallization from methanol afforded pale yellow granules (IIb) which melted at 62—63°C and which weighed 0.2 g (43.7%).

Found: C, 51.52; H, 5.07; N, 23.30%. Calcd for $C_{13}H_{15}N_5O_4$: C, 51.15; H, 4.92; N, 22.95%.

trans-*3-(5-Nitro-2-furyl)acrylamide oxime (III).* To a stirred, warmed (50—55°C) mixture of I (1.64 g, 10 mmol), *N,N*-dimethylaniline (2 drops), and ethanol (50 ml) was added a solution of hydroxylamine hydrochloride (2.1 g, 30 mmol) and sodium hydroxide (0.96 g, 24 mmol) in 10 ml of water over a period of 15—20 min. After the addition, the mixture was stirred at 60°C for an additional hour. On cooling, the precipitated product was filtered and dried. Recrystallization from ethanol afforded 1.58 g (80.2%) of III as orange needles; mp 217—218°C. IR (KBr) cm^{-1}: 3448, 3405 (NH_2), and 2807 (O–H···NH_2). NMR (DMSO-d_6) δ: 5.78 (s, 2H, NH_2 proton), 6.61 (d, 1H, J=16.3 Hz, ethylene bond C_α–H), 7.00 (d, 1H, J=4.0 Hz, furan ring C_3–H), 7.05 (d, 1H, J=16.3 Hz, ethylene bond C_β–H), and 7.68 (d, 1H, J=4.0 Hz, furan ring C_4–H).

Found: C, 42.77; H, 3.37; N, 21.49%. Calcd for $C_7H_7N_3O_4$: C, 42.64; H, 3.55; N, 21.32%.

3-[2-(5-Nitro-2-furyl)vinyl]-5-phenyl-4,5-dihydro-1,2,4-oxadiazoline (IV). A 10-mmol (1.97 g) portion of III was heated with benzaldehyde (50 ml) at 100°C for 4 hr. The resulting solution was taken to dryness *in vacuo*, and the residue was washed with ether and then dried. Recrystallization from methanol gave 1.6 g (56.1%) of IV as ochre-colored needles; mp 158—159°C.

Found: C, 59.09; H, 3.77; N, 14.73%. Calcd for $C_{14}H_{12}N_3O_4$: C, 58.94; H, 2.86; N, 14.73%.

trans-O-*Acetyl-3-(5-nitro-2-furyl)acrylamide oxime (IIIa).* A mixture of acetic anhydride (20 ml) and III (0.99 g, 5 mmol) was heated at 60—65°C for 0.5—1 hr. After cooling, water was added to decompose the surplus acid anhydride, and the precipitated product was filtered, washed with water, and dried. It was then recrystallized from dioxane to give 0.88 g (73.4%) of IIIa as yellow leaflets; mp 171—172°C. IR (KBr) cm^{-1}: 3457, 3350 (NH_2), and 1745 (C=O). Thermal analysis: 173°C (DTA; endothermic), 172—190°C (TGA; weight loss 8.0%).

Found: C, 45.03; H, 3.80; N, 17.26%. Calcd for $C_9H_9N_3O_5$: C, 45.19; H, 3.76; N, 17.57%.

trans-O-*Propionyl-3-(5-nitro-2-furyl)acrylamide oxime (IIIb).* This was prepared by the method used for IIIa, using 20 ml of propionic anhydride. Work up as above afforded 0.91 g (72%) of pure IIIb as yellow leaflets; mp 157—158°C (from dioxane). IR (KBr) cm^{-1}: 3455, 3350 (NH_2), and 1745 (C=O). Thermal analysis: 161°C (DTA; endothermic), 160—187°C (TGA; weight loss 7.4%).

Found: C, 47.09; H, 4.32; N, 16.15%. Calcd for $C_{10}H_{11}N_3O_5$: C, 47.43; H, 4.37; N, 16.60%.

trans-O-*Butyryl-3-(5-nitro-2-furyl)acrylamide oxime (IIIc).* The procedure described above for IIIa was employed using butyric anhydride (35 ml). The resulting solution was kept standing at room temperature until the product was isolated. The product was obtained as yellow leaflets; mp 153—154°C (from dioxane); weight, 1.1 g (78.7%). IR (KBr) cm^{-1}: 3455, 3350 (NH_2), 2970, 2885 (CH_2, CH_3), and 1745 (C=O). Thermal analysis: 156°C (DTA; endothermic), 155—184°C (TGA; weight loss 7.1%).

Found: C, 49.39; H, 4.95; N, 15.43%. Calcd for $C_{11}H_{13}N_3O_5$: C, 49.44; H, 4.86; N, 15.73%.

trans-O-*Chloraocetyl-3-(5-nitro-2-furyl)acrylamide oxime (IIId).* To a stirred, warmed (50—60°C) mixture of III (0.99 g, 5 mmol), sodium bicarbonate (1.05 g, 12.4 mmol), and dioxane (20 ml), we added, drop by drop, a solution of chloroacetyl chloride (0.57 g, 5.1 mmol) in 10 ml of dioxane. The resulting mixture was stirred for an additional hour, and then it was poured into ice water. The precipitates were collected, washed with water, and dried. Crystallization from ethanol afforded 1.1 g (80.4%) of IIId as yellow-ochre needles; mp 147—148°C. IR (KBr) cm^{-1}: 3465, 3345 (NH_2), 1767 (C=O), and 1285 (CH_2Cl). NMR (DMSO-d_6) δ: 4.46 (s, 2H, $COCH_2Cl$ proton), 6.57 (d, 1H, J=16.3 Hz, ethylene bond C_α–H), 6.86 (broad s, 2H, NH_2 proton), 7.12 (d, 1H, J=4.0 Hz, furan ring C_3–H), 7.28 (d, 1H, J=16.3 Hz, ethylene bond C_β–H), and 7.68 (d, 1H, J=4.0 Hz, furan ring C_4–H).

Found: C, 39.62; H, 3.15; N, 15.09%. Calcd for $C_9H_8N_3O_5Cl$: C, 39.41; H, 2.92; N, 15.32%.

trans-O-*Benzoyl-3-(5-nitro-2-furyl)acrylamide oxime (IIIe).* This was prepared in the same way as IIId, but using benzoyl chloride (1.4 g). In this way, 1.1 g (73.4%) of IIIe were obtained; mp 197°C. Recrystallization from dioxane gave a yellow powder; mp 200—201°C. Yield: 1.8 g (59.2%). IR (KBr) cm^{-1}: 3470, 3345 (NH_2), and 1726 (C=O).

Found: C, 55.97; H, 3.69; N, 13.46%. Calcd for $C_{14}H_{11}N_3O_5$: C, 55.81; H, 3.65; N, 13.95%.

trans-*3-[2-(5-Nitro-2-furyl)vinyl]-5-methyl-1,2,4-oxadiazole (V).* Compound IIIa (0.55 g, 2.3 mmol) was heated at 173—175°C under a nitrogen stream for 5 min, by which time the evolution of water had ceased. The residue was then recrystallized from ethanol to give 0.23 g (45.6%) of V as yellow-ochre granules; mp 189—190°C.

Found: C, 48.48; H, 3.19; N, 18.73%. Calcd for $C_9H_7N_3O_4$: C, 48.87; H, 3.16; N, 19.00%.

trans-*3-[2-(5-Nitro-2-furyl)vinyl]-5-ethyl-1,2,4-oxadiazole (VI).* The method used here was virtually identical with that described for V; 0.75 g (2.9 mmol) of IIIb was heated at 162—164°C. Work-up as above afforded 0.4 g (58.6%) of VI as yellow needles; mp 123—125°C (from ethanol). NMR (DMSO-d_6) δ: 1.30 (t, 3H, J=7.2 Hz, $-CH_2-C\underline{H}_3$ proton), 2.91 (q, 2H, J=7.2 Hz, $-C\underline{H}_2-CH_3$ proton), 7.12 (d, 1H, J=16.9 Hz, ethylene bond C_α–H), 7.18 (d, 1H, J=4.0 Hz, furan ring C_3–H), 7.43 (d, 1H, J=16.9 Hz, ethylene bond C_β–H), and 7.66 (d, 1H, J=4.0 Hz, furan ring C_4–H).

Found: C, 50.62; H, 3.73; N, 17.67%. Calcd for $C_{10}H_9N_3O_4$: C, 51.06; H, 3.83; N, 17.87%.

trans-*3-[2-(5-Nitro-2-furyl)vinyl]-5-propyl-1,2,4-oxadiazole (VII).* The method used here was virtually identical with that used for V; a 2.1-g (7.9 mmol) portion of IIIc was heated at 155—156°C. Ochre-colored leaflets; mp 67—68°C (from ethanol). Yield: 0.65 g (43.3%). IR (KBr) cm^{-1}: 2971, 2940, and 2880 (CH_2, CH_3).

Found: C, 53.14; H, 4.56; N, 16.71%. Calcd for $C_{11}H_{11}N_3O_4$: C, 53.01; H, 4.41; N, 16.88%.

The authors are indebted to Mr. S. Iwasaki and Mr. Y. Hanada for their technical assistance, to Mr. T. Uchida for the infrared spectral measurements, and to Mr. Y. Uemura for the elemental analysis.

Chemical Constituents of the Male Flower of *Alnus pendula* (BETULACEAE)

Takayuki SUGA, Nobuo IWATA, and Yoshinori ASAKAWA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received January 26, 1972)

The structure of alnustone (**1**) isolated from the male flower of *Alnus pendula* Matsum. has been established to be 1,7-diphenyl-1,3-heptadien-5-one. Previously-known compounds, β-phenylethyl cinnamate (**6**), cinnamaldehyde, benzylacetone, β-phenylethyl alcohol, pinocembrin (**7**), pinostrobin (**8**), alpinetin (**9**), galangin (**11**), pinosylvin (**13**), and its monomethyl ether (**14**), eugenol, chavicol, cinnamic acid, β-phenylpropionic acid, and benzoic acid, were identified along with the above new ketone.

Alnus pendula Matsum. (*A. multinervis* Call.)[1] belongs to Betulaceae and can be used as a water-erosion-control plant. Previous studies[2-6] of the chemical constituents of the male flower of *Alnus sieboldiana* (Betulaceae) have shown the presence of two new ketols, yashabushiketol (**4**) and dihydroyashabushiketol (**5**), with a biosynthetically interesting skeleton, four new flavonoids, together with twenty-five aromatic compounds, and small amounts of aliphatic and isoprenoid compounds. The present paper will describe the isolation and structure elucidation of a new ketone, named alnustone (**1**),[7] with the same Ph–C_7–Ph skeleton as that of the ketols (**4**) and (**5**) and the identification of fifteen aromatic compounds from the male flower of *A. pendula*. From the viewpoint of biosynthesis and chemotaxonomy, the chemical constituents of the male flower of *A. pendula* will also be compared with those of *A. sieboldiana*.

Results and Discussion

The benzene extraction of a viscous material secreted on the fresh male flower (catkin) of *A. pendula* Matsum. gave a brown viscous oil. After the removal of the acidic and phenolic constituents, a neutral fraction was separated into three fractions by silica gel column chromatography, using *n*-hexane, benzene, and ethyl acetate successively as eluents.

Alnustone (**1**). The chromatography of the benzene-elution fraction over silica gel yielded alnustone (**1**) in fairly considerable amounts as pale yellow needles (mp 61.0—62.5°C). Its formula, $C_{19}H_{18}O$, was based on the high-resolution mass spectral analysis of the molecular ion. The spectral properties indicated that alnustone possessed a *trans, trans*-dienone group (ν_{max} 1665 and 990 cm^{-1}; λ_{max} 325 nm (log ε 4.40) and two monosubstituted benzene-rings (ν_{max} 750 and 700 cm^{-1}; δ 7.11 (s, 5H) and 7.20 ppm (m, 5H)). The base peak (*m/e* 157) and the signals at δ 6.11 (d, 1H, –CH=CH–CO–), 6.77 (m, 2H, =CH–CH=), and 7.18 ppm (m, 1H, overlapped with the signals of benzene-ring protons, Ph–CH=CH–) indicated the presence of the Ph–CH=CH–CH=CH–CO– group. The presence of the Ph–CH_2–CH_2–CO– group was confirmed by the NMR signals at δ 2.82 ppm (m, 4H). The hydrogenation of **1** over the platinum oxide catalyst readily gave the tetrahydroderivative (**2**), $C_{19}H_{22}O$, which was established on the bases of the disappearance of absorption bands due to the *trans, trans*-dienone moiety and the newly-appearing absorption bands of an isolated carbonyl group. On the other hand, the reduction of **1** by sodium borohydride afforded a secondary alcohol (**3**) with a conjugated diene group adjacent to the benzene ring, judging from its spectral data. Thus, alnustone has been confirmed to be *trans, trans*-1,7-diphenyl-1,3-heptadien-5-one (**1**).

Known Aromatic Compounds. *a) Neutral Components*: The isolation of β-phenylethyl cinnamate (**6**), cinnamaldehyde, benzylacetone, and β-phenylethyl alcohol was performed by a combination of the silica gel column chromatography and the preparative thin-layer chromatography of the neutral fractions. All the compounds isolated were identified by a direct comparison of their physical and spectral data with those of the authentic samples or with those reported in our previous papers.[2-6]

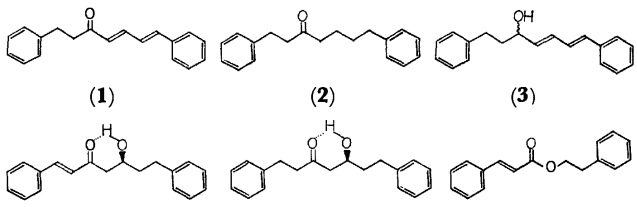

Fig. 1.

b) Phenolic and Acidic Components: Four flavonoids, pinocembrin (**7**), pinostrobin (**8**), alpinetin (**9**), and galangin (**11**), two stilbenes, pinosylvin (**13**) and pinosylvin monomethyl ether (**14**), and two phenols, eugenol and chavicol, were isolated from the phenolic fraction and subsequently identified by the above method. As acidic components, cinnamic acid, β-phenylpropionic acid, and benzoic acid were identified by a direct comparison of their retention times in gas chromatography and of the spectra of the methyl esters of authentic specimens.

A Comparison between the Constituents of the Male Flower of A. pendula and A. sieboldiana. The first object of this study was to compare the occurrence and distribution of the Ph–C_3 compounds in *A. pendula* with those

Fig. 2.

of the compounds in *A. sieboldiana* from the points of view of biosynthesis and chemotaxonomy. β-Phenylethyl cinnamate (**6**) was most abundant in the male flower of both plants. Alnustone (**1**) was found in *A. pendula*, but not in *A. sieboldiana*. On the other hand, yashabushiketol (**4**) and dihydroyashabushiketol (**5**) appeared only in *A. sieboldiana*. These facts are very interesting with respect to the biosynthesis of these three components. The co-occurrence of flavonoids and stilbenes was found in both plants. Four flavonoids with the $C_{(6)}$–OMe group, such as alnustinol (**10**) and alnusin (**12**), have been found in *A. sieboldiana*, in contrast with the case of *A. pendula*. One of the most significant discoveries of the present survey is that the great majority of components isolated from *A. pendula* are composed of simple aromatic compounds with one or two Ph–C_3 skeletons, in the same manner as in *A. sieboldiana*, with the exception of eugenol and chavicol. In addition to the above aromatic constituents, small amounts of *n*-paraffins, α-olefins, triterpenes (taraxerone, β-amyrenone, and a triterpenic acid), unsaturated aliphatic ketones, and fatty acids are commonly present in both plants. Thus, it is clear that the two plants belong to closely related species from the viewpoint of chemotaxonomy.

Experimental

All the melting points are uncorrected. The UV spectra were measured by means of a Japan Spectroscopic Co., Ltd., ORD/UV-5 Spectropolarimeter in ethanol. The mass spectra were recorded on a Hitachi, RMS-4, Mass Spectrometer. The high-resolution mass spectra were obtained by means of a Hitachi, RMU-TL, Mass Spectrometer. The NMR spectra (100 MHz) were recorded on a JEOL, JNM-4H-100, High-Resolution Spectrometer in a carbon tetrachloride solution, using tetramethylsilane as the internal standard. The measurements of the IR and NMR (60 MHz) spectra and the glc were performed in the same manner as was reported in our preceding paper.[4]

Extraction and Isolation. Male flowers (6.59 kg) of *A. pendula* grown in the suburbs of Hiroshima were collected in March in 1970 and were, after having been minched mechanically, extracted with benzene over a two-month period. The evaporation of the solvent gave a brown viscous oil (3.6%). This viscous oil was successively extracted with a 5% sodium bicarbonate solution (Acid), a 5% sodium carbonate solution (Phenol I), a 0.4% sodium hydroxide solution (Phenol II), and a 5% sodium hydroxide solution (Phenol III); the subsequent acidification of each fraction with 5% hydrochloric acid gave an acidic fraction (2.3 g) and three phenolic fractions, Phenol I (2.5 g), Phenol II (38.2 g), and Phenol III (7.7 g). After the removal of the acidic and phenolic constituents, the neutral fraction (184 g) was obtained. A part (13 g) of it was fractionated into two fractions by silica gel column chromatography using *n*-hexane (Fraction 1) and benzene (Fraction 2). The Fraction 2 was further subjected to silica gel column chromatography to separate it into three fractions (i), (ii), and (iii), using benzene as the eluting agent.

Alnustone (1). From the fraction (i), a conjugated ketone (**1**) was isolated as pale yellow needles (236 mg): mp 61.0—62.5°C (from ethanol); *m/e* 262.1360 (calcd for $C_{19}H_{18}O$: 262.1357), 171 (Ph–CH=CH–CH=CH–CO–CH_2)$^+$, 157 (base, Ph–CH=CH–CH=CH–CO)$^+$, 129 (Ph–CH=CH–CH=CH)$^+$, 105 (Ph–CH_2–CH_2)$^+$, 103 (Ph–CH=CH)$^+$, 91 (C_7H_7)$^+$, 77 (C_6H_5)$^+$. These fragment ions were identified on the basis of a high-resolution mass-spectral analysis.

Found: C, 86.60; H, 7.19%. Calcd for $C_{19}H_{18}O$: C, 86.98; H, 6.91%.

The Catalytic Hydrogenation of Alnustone (1). Alnustone (**1**) (42 mg) was hydrogenated over a prereduced PtO_2 catalyst (10 mg) in ethanol for 1 hr under ambient conditions. After the catalyst had then been filtered off, the removal of the solvent from the filtrate gave the tetrahydroderivative (**2**) (34 mg): λ_{max}^{EtOH} 288 nm (log ε 1.99); $\nu_{max}^{liq.}$ 1710 cm^{-1}; δ ($CDCl_3$) 1.4—1.9 (m, 4H, Ph–CH_2–C$\underline{H}_2$–C$\underline{H}_2$–CH_2–CO–), 2.2—3.0 (m, 8H, 2×Ph–C$\underline{H}_2$– and –C$\underline{H}_2$–CO–C$\underline{H}_2$–), 7.21 ppm (s, 10H); *m/e* 266 (M$^+$), 175 (Ph–CH_2–CH_2–CH_2–CH_2–CO–CH_2)$^+$ or (Ph–CH_2–CH_2–CO–CH_2–CH_2–CH_2)$^+$, 161 (Ph–CH_2–CH_2–CH_2–CH_2–CO)$^+$, 133 (Ph–CH_2–CH_2–CO)$^+$, 105 (Ph–CH_2–CH_2)$^+$, 91 (base, C_7H_7)$^+$, 77 (C_6H_5)$^+$.

The Reduction of Alnustone (1) with Sodium Borohydride. Into a solution of **1** (140 mg) in methanol (20 m*l*), we stirred sodium borohydride (60 mg) dissolved in methanol (10 m*l*) at 0°C. The mixture was then stirred for 1 hr. The reaction mixture was acidified with 1N hydrochloric acid, and then the solvent was removed *in vacuo*. The product, after water (10 m*l*) had been added, was extracted with ether. The removal of the solvent from the dried extract gave a secondary alcohol (**3**) (134 mg): λ_{max}^{EtOH} 222 (log ε 4.06), 228 (4.06), 235 (3.94), 288 nm (4.50); $\nu_{max}^{liq.}$ 3400, 1100 (OH), 1640, 990 (*trans*-CH=CH–CH=CH–), 750, 690 cm^{-1} (monosubst. benzene-ring); δ ($CDCl_3$) *ca.* 1.9 (m, 2H, –CH(OH)–C$\underline{H}_2$–CH_2–Ph), 2.08 (bs, 1H, O$\underline{H}$, disappeared upon the addition of D_2O), *ca.* 2.7 (m, 2H, Ph–C$\underline{H}_2$–), 4.10 (q, *J*=7 Hz, 1H, =CH–C$\underline{H}$(OH)–CH_2–), 5.80 (dd, *J*=15 Hz and 7 Hz, 1H, –CH=C$\underline{H}$–CH(OH)–), 6.1—6.8 (m, 3H, Ph–C$\underline{H}$=C$\underline{H}$–C$\underline{H}$=), 7.24 (s, 5H, $C_6\underline{H}_5$–CH_2–), 7.33 ppm (m, 5H, $C_6\underline{H}_5$–CH=); *m/e* 264 (M$^+$), 246 (M−H_2O), 173 (Ph–CH=CH–CH=CH–CHOH–CH_2)$^+$, 159 (Ph–CH=CH–CH=CH–CHOH)$^+$, 155 (Ph–CH=CH–CH=CH–CH=CH)$^+$, 129 (Ph–CH=CH–CH=CH)$^+$, 117 (Ph–CH_2–CH=CH)$^+$, 105 (Ph–CH_2–CH_2)$^+$, 91 (C_7H_7)$^+$, 77 (C_6H_5)$^+$, 65 (C_5H_5)$^+$.

n-Paraffins, α-Olefins, Unsaturated Aliphatic Ketones, and Triterpenes (Taraxerone and β-Amyrenone). The Fraction 1, when eluted with *n*-hexane, gave a mixture of *n*-paraffins and α-olefins, (1.5 g). The *n*-paraffins (C_{21}–C_{31}: C_{27} main) and α-olefins, (C_{23}–C_{29}) were identified by a comparison

with the retention times in gas chromatography of authentic samples and by the hydrogenation of the mixture. After the isolation of alnustone (**1**) from the fraction (i), the filtrate which showed three spots on tlc was purified by preparative thin-layer chromatography to give a mixture of unsaturated aliphatic ketones (10 mg), mp 71—74°C, β-amyrenone (44 mg), and taraxerone (127 mg).

β-Amyrenone: mp 178—179°C (lit,[8] mp 178—179°C); ν_{max}^{Nujol} 1710 cm^{-1}; *m/e* 424 (M^+) 409, 218 (base), 203, 189. All the spectral and physical data of this compound agreed with those of β-amyrenone derived from β-amyrin.

Taraxerone: mp 233—235°C (lit,[9] mp 237—238°C); ν_{max}^{Nujol} 1705 cm^{-1}; *m/e* 424 (M^+), 409, 300, 285, 204 (base), 218, 189, 133.[9]

*Pinostrobin (**8**), β-Phenylethyl Cinnamate (**6**), β-Phenylethyl Alcohol, Benzylacetone, and Cinnamaldehyde.* The fraction (ii) afforded a colorless viscous oil, which was then further chromatographed on a silica gel column, using a mixture of *n*-hexane and ethyl acetate, to give β-phenylethyl cinnamate (2.170 g), mp 51—52°C, pinostrobin (96 mg), mp 91—92.5°C, and β-phenylethyl alcohol (220 mg). The fraction (iii) gave a pale yellow oil (30 mg) which showed two spots on tlc and two peaks (1 : 1) on the gas chromatogram (R_t=4.0 and 7.1, 10% PEG 6000 on Diasolid L (60—80 mesh) at 180°C). The chromatographic separation of the oil by tlc gave cinnamaldehyde (R_t=7.1) and benzylacetone (R_t=4.0). All of the spectral data of the compounds were identical with those of the authentic samples.

*Pinocembrin (**7**) and Galangin (**11**).* The Phenol I (2.5 g) was chromatographed on a silica gel column, using ethyl acetate as the eluting agent, to give pinocembrin (340 mg), mp 201—202.5°C (lit,[6] mp 200—201°C) and galangin (460 mg), mp 220—222°C (lit,[10] 214—215°C). The 3,7-dimethylether derivative: mp 145—147°C (lit,[11] 145—146°C). The spectral data of these compounds coincided completely with those of the known specimens.

*Pinosylvin (**13**), Pinosylvin Monomethyl Ether (**14**), Alpinetin (**9**), Eugenol, Chavicol, a Triterpenic Acid, and Benzoic Acid.* The chromatography of the Phenol II (15.5 g) on a silica gel column using a mixture of *n*-hexane and ethyl acetate gave pinosylvin (250 mg), mp 158—159°C (lit,[6] 156—158°C), pinosylvin monomethyl ether (3.5 g), mp 122—122.5°C (lit,[6] 119—120°C), alpinetin (1.18 g), mp 224—225.5°C (lit,[4] mp 224.5—225.0°C), eugenol (140 mg), n_D^{25} 1.5410, chavicol (60 mg), n_D^{25} 1.5405, benzoic acid (1.93 g), mp and mixed mp 122—123°C, and an unidentified triterpenic acid (50 mg), mp 195—196°C, M^+ 470. The identities were established by a comparison of their spectral data.

Pinosylvin monomethyl ether (1.54 g) and benzoic acid (840 mg) were also isolated from the Phenol III (7.7 g).

β-Phenylpropionic Acid, Cinnamic Acid, and Fatty Acids. The acidic fraction (2.3 g) was methylated with diazomethane. The methyl ester was then chromatographed on silica gel to give methyl cinnamate (50 mg), minute amounts of methyl β-phenylpropionate and methyl benzoate, and a trace amount of a mixture of methyl myristate, methyl palmitate, and methyl stearate. These compounds were identified by a direct comparison of their retention times in glc (10% SE-30 and 10% DEGS on Diasolid L (60—80 mesh) at 100°C) and their IR spectra with those of authentic samples.

Stereochemical Studies of Monoterpene Compounds. XVIII.[1] A Conformational Study of Monoterpene α,β-Unsaturated Ketones by Means of the Temperature-dependent Circular Dichroism

Takayuki SUGA and Kiyoshi IMAMURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received January 31, 1972)

The conformations of flexible, cyclic α,β-unsaturated ketones, (−)-*p*-menth-3-en-5-one (**1**), (+)-carvone (**2**), (−)-piperitone (**3**), (−)-carvenone (**4**), and (+)-pulegone (**5**), were examined by means of the temperature-dependent circular dichroism (CD) in the region of the n-π^* transition. In polar solvents, the simultaneous occurrence of the conformational equilibrium and the asymmetric solvation was observed markedly for the compound **1** of these compounds, along with a change in the large rotational strength at lower temperatures.

In the region of the ultraviolet absorption, α,β-unsaturated ketones generally exhibit three optically-active, absorption bands:[2] the first band (320—350 nm) is ascribed to the n-π^* transition, and the others (240 nm and 210 nm), to the π-π^* transition. The sign of a Cotton effect of the third band has been correlated[3] with the chirality contribution of the α′-pseudo-axial bond. On the other hand, the sign of a

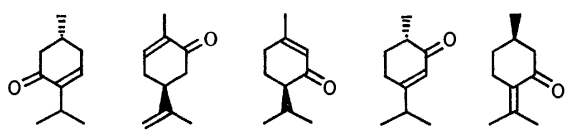
1) Part XVII of this series: T. Hirata, *J. Sci. Hiroshima Univ. Ser. A*, **35**, 239 (1971).

2) L. Velluz and M. Legrand, *Angew. Chem.*, **77**, 842 (1965).

3) A. W. Burgstahler and R. C. Barkhurst, *J. Amer. Chem. Soc.*, **92**, 7601 (1970).

Cotton effect of the second band has been interpreted[4] on the basis of the chirality, or sense of twist, of the enone system, compared with the diene system, while the other one has been related[5] to a normal octant rule for the cisoid enone system and to a reverse octant rule for the transoid one. However, it has recently been shown[6-8] that the sign of a Cotton effect of the last two bands varies irregularly in dependence on the α-axial and the γ-axial substituents, regardless of the alteration in the conformation.

We have now examined the conformations of five *s-trans* and *s-cis* α,β-unsaturated ketones, (−)-*p*-menth-3-en-5-one (**1**), (+)-carvone (**2**), (−)-piperitone (**3**), (−)-carvenone (**4**), and (+)-pulegone (**5**), by means of the temperature-dependent CD in the region of the *n*-π* transition; we chose this region because of the availability and the facility of the band in it.



1 **2** **3** **4** **5**

Results and Discussion

The predictions of the sign of a Cotton effect for each conformer have been based on the rule[5] of the correlation between the chirality of an enone system and its sign of a Cotton effect for the *n*-π* transition. The alteration of the magnitude of a Cotton effect in the optical rotatory dispersion (ORD) and the CD curves of α,β-unsaturated ketones with a change in the temperature results from the following factors: (i) the conformational alteration, *i.e.*, the increase or the decrease in the population of a conformation with the opposite sign of a Cotton effect, as in the cases of *trans*-2-chloro-5-methylcyclohexane,[9] (−)-menthone, and 1-hydroxymenthone,[10] (ii) the asymmetric solvation,[11] *i.e.*, the association of a solvent molecule, which is more strengthened at lower temperatures, in the asymmetric manner, and (iii) the vibronic effect.[12] The contribution of the last factor is negligible, however, because the compounds used here showed a remarkable increase in the rotational strength at the lower temperature rather than an enhancement of a fine structure.

A half-chair form of four possible conformations of a cyclohexenone ring has been suggested[13] as being stable on the basis of the conformational analysis of the cyclohexene ring. Therefore, (−)-*p*-menth-3-en-5-one (**1**) and (+)-carvone (**2**), 2,5-disubstituted cyclohexenone, may exist in two interconvertible half-chair conformations, **1a** and **1b**, and **2a** and **2b**, respectively (Fig. 1). A positive Cotton effect may be predicted for the **1a** and **2b** conformers, whereas the opposite one may be predicted for the **1b** and **2a** conformers. The CD curves of the compounds **1** and **2** showed the double-humped

Cotton effect with an increase in the positive rotational strength for the compound **1** and the negative one for the compound **2** in the shorter-wavelength region with a lowering of the temperature in both the MI solvent and decalin (Figs. 2 and 3). These observations indicate a conformational alteration, but not an asymmetric solvation and, accordingly, the predominance of the **1a** conformer with an *eq*-methyl group and the **2a** conformer with an *eq*-isopropenyl group in the conformational equilibrium, as is shown in Fig. 1.

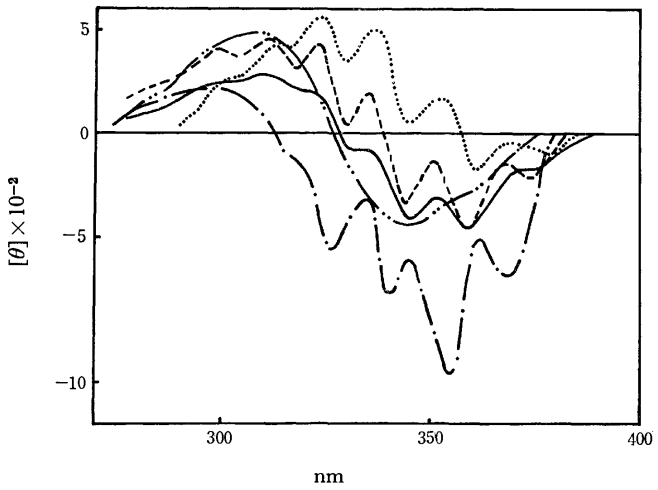

Fig. 4. CD curves of (−)-*p*-menth-3-en-5-one (**1**): ·····, at 25°C in isooctane, —··—, at 25°C in ethanol, and —, at 25°C, ----, at −92°C, and —·—, at −186°C in the EPA solvent.

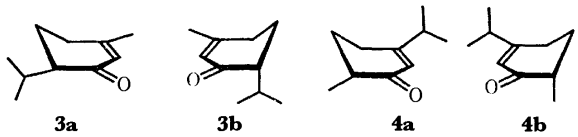
However, the compound **1** showed unexpected temperature-dependent CD curves in the EPA solvent (Fig. 4); the positive rotational strength in the shorter-wavelength region increased with a change in the temperature from 25 to −92°C, while the negative one in the longer-wavelength region increased at the expense of the positive one with the hypsochromic shift of the band when the temperature was further lowered from −92 to −186°C. Considering the conformational equilibrium between the **1a** and **1b** conformers, this phenomenon may be explained as follows: a lowering of the temperature to −92°C increases the population of the unsolvated conformer **1a** with a positive Cotton effect, rather than resulting in an increase in the solvated species, but a further lowering of the temperature to −186°C favors the solvated form **1b** with a negative Cotton effect, as has been shown for pulegone oxide.[14] With changing a solvent from a nonpolar solvent to a polar one, the magnitude of a negative Cotton effect of the compound **1** in the longer-wavelength region remarkably increased with the hypsochromic shift of the band; this suggests an asymmetric solvation, but not a conformational change (Fig. 4). These observations of the temperature-dependent CD curves seem to indicate that the asymmetric solvation principally contributes to the preference of the conformation of *p*-menth-3-en-5-one in the polar solvents. For the compound **2**, such a phenomenon was also observed, but it was very small in magnitude in a comparison with that of the compound **1**.



3a **3b** **4a** **4b**

Fig. 5. Preferred conformation of (−)-piperitone (**3**) and (−)-carvenone (**4**).

(−)-Piperitone (**3**) and (−)-carvenone (**4**), 3,6-disubstituted cyclohexenone, may also exist in two interconvertible half-chair conformations, **3a** and **3b**, and **4a** and **4b**, respectively (Fig. 5). The predicted Cotton effect is positive for the **3a** and **4a** conformers and negative for the **3b** and **4b** conformers.

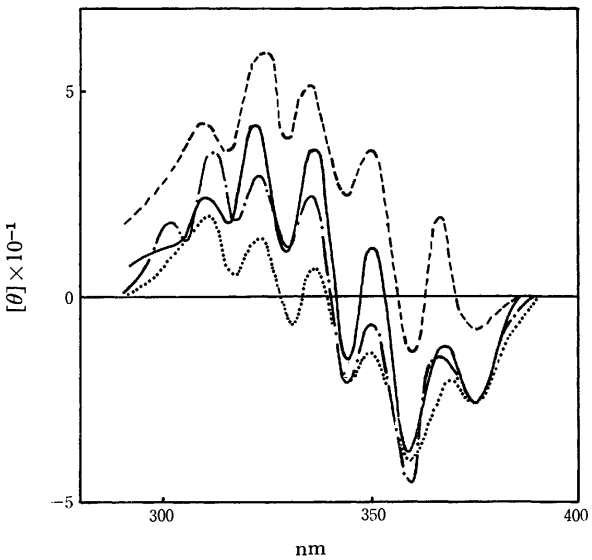


Fig. 6. CD curves of (−)-piperitone (**3**): —, at 25°C and ----, at −92°C in the MI solvent, and —·—, at 25°C and ·····, at 146°C in decalin.

The CD curves of the compound **3** showed a double-humped Cotton effect at 25°C in both the MI solvent and decalin. The positive rotational strength of the Cotton effect in the shorter-wavelength region increased at the expense of the negative one in the longer-wavelength region with a lowering of the temperature in both the solvents (Fig. 6). This indicates the preference of the **3a** conformer with an *eq*-isopropyl group in the conformational equilibrium between **3a** and **3b**.

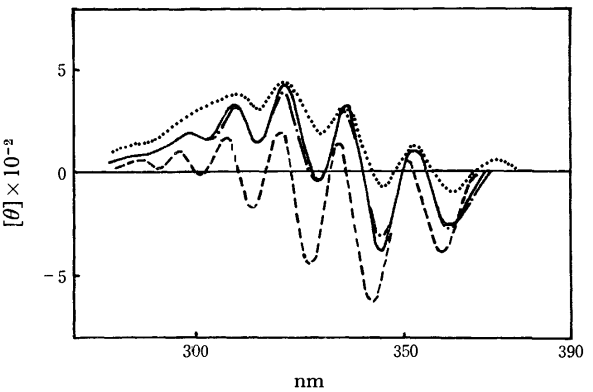

Fig. 7. CD curves of (−)-carvenone (**4**): —, at 25°C and ----, at −127°C in the MI solvent, and —·—, at 25°C and ·····, at 149°C in decalin.

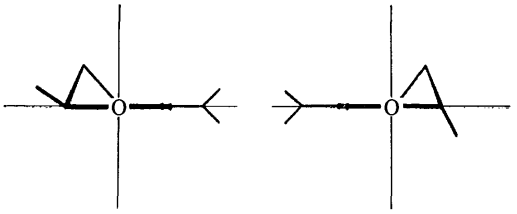
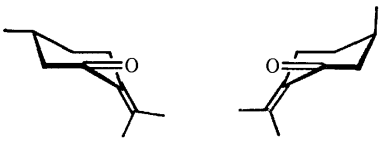
On the other hand, the compound **4** also showed a double-humped Cotton effect, but a less amplified one, on its CD curves (Fig. 7) in the MI solvent at room temperature. The curves exhibited an increase in the negative rotational strength in the longer-wavelength region with a lowering of the temperature in both the MI solvent and decalin. These facts seem to imply the preference of the **4b** conformer with an *ax*-methyl group in the conformational equilibrium between **4a** and **4b**. However, a small shift ($\delta^{CDCl_3}-\delta^{C_6H_6}=0.00$ ppm and $\delta^{CCl_4}-\delta^{C_5H_5N}=-0.09$ ppm) of the α-methyl signal of the compound **4** was observed in the examination of the NMR solvent effects.[15,16] This fact favors the conformer with an *eq*-methyl group, which has been recognized to be more stable energetically.[17] These observations may be successfully explained in terms of a conformational equilibrium between the two envelope forms,[18] **4c** and **4d**, where the planes of the C=C and C=O double bonds are coplanar. From the energetic point of view, the conformational energy between the envelope form and the half-chair one of a cyclohexenone system is small. The reverse octant rule can be applied[5] to the envelope forms; it predicts a negative Cotton effect for the **4c** conformer and a positive one for the **4d** conformer (Fig. 8). Thus, the CD and NMR spectral data indicate the predominance of the **4c** conformer with the *eq*-methyl group in the conformational equilibrium between **4c** and **4d**. This is also supported by the rotational strength, which is smaller than that of the other compounds at lower temperatures.



4c **4d**

Fig. 8. The octant projection diagrams of the envelope forms, (**4c**) and (**4d**), of (−)-carvenone (**4**).

(+)-Pulegone (**5**), a *s-cis*, α,β-unsaturated ketone, may exist in two interconvertible half-chair conformations, (**5a**) and (**5b**), as is shown in Fig. 9. A positive Cotton effect is predicted for the **5a** conformer, and a negative one, for the **5b** conformer. The CD curves of



5a **5b**

Fig. 9. Preferred conformation of (+)-pulegone (**5**).

the compound **5** exhibited a positive Cotton effect without the double hump and a fine structure in both the MI solvent and decalin at various temperatures (Fig. 10). The increase in the positive rotational strength with a lowering of the temperature indicates the predominance of the **5a** conformer with an *eq*-methyl group in the conformational equilibrium between **5a** and **5b**. We have recently estimated[19] the conformational energy in this equilibrium to be 1.1 kcal/mol; we also estimated the rotational strengths of the **5a** and **5b** conformers.

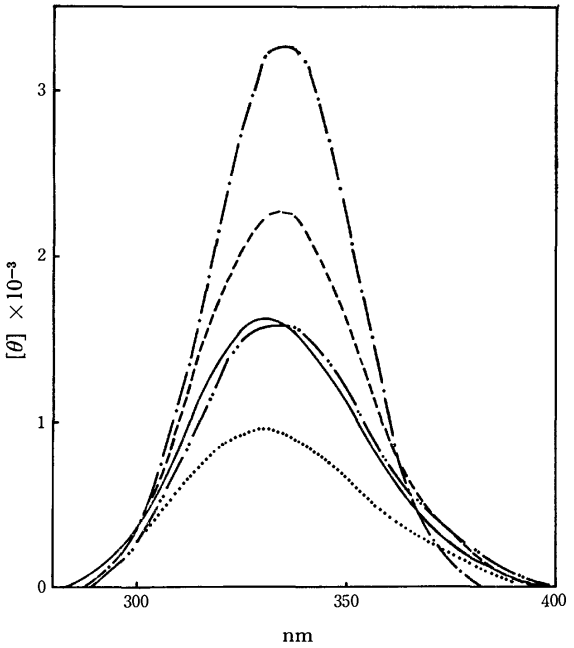


Fig. 10. CD curves of (+)-pulegone (**5**): —, at 25°C and – – –, at −67°C, and —·—, at −186°C in the MI solvent, and —··—, at 25°C and ·····, at 152°C in decalin.

The temperature-dependent CD curves of the compounds **3**, **4**, and **5** in the EPA solvent acted the same as in both the MI solvent and decalin at various temperatures. Thus, it may be said that temperature-dependent CD measurements offer useful information about the conformational alteration of the optically-active, flexible α,β-unsaturated ketones. However, it should be noted that there is a possibility of the occurrence of such unexpected behavior as in cases of (−)-*p*-menth-3-en-5-one (**1**) and (+)-carvone (**2**), on the CD curves of the α,β-unsaturated ketones in the polar solvent because of the asymmetric solvation.

Experimental

Measurements. The temperature-dependent CD curves were measured by means of a Japan Spectroscopic Co. Ltd., ORD/UV-5, automatically-recording spectrometer equipped with a CD attachment in the MI solvent (methylcyclohexane-isopentane, 1 : 3 by volume), the EPA solvent (ether–isopentane–ethyl alcohol, 5:5:2 by volume), and decalin, using a variable-temperature CD cell. The NMR spectra were recorded on a Hitachi Perkin-Elmer, R-20, high-resolution spectrometer at 60 MHz, using tetramethylsilane as the

internal standard. Gas chromatography was carried out on a Hitachi Perkin-Elmer, F-6D, apparatus attached with a column packed with 20% DEGS on Diasolid L (60—80 mesh) and with 20% PEG 6000 on Celite (60—80 mesh) at 120°C.

Materials. *(−)-p-Menth-3-en-5-one (1)*: Into a pyridine (45 ml) solution of 4-hydroxy-menthone (1.0 g) prepared from 3-*p*-menthene following the method reported in the literature,[20] we dropped phosphorus oxychloride (23 ml) at 0°C. The reaction mixture was left at room temperature for 36 hr and then treated in the usual manner. The refinement of the product by column chromatography on silica gel gave the compound **1** (0.23 g) in a 100% purity (as determined on the basis of analytical glc) and with the following properties: bp 55.0°C/2 mmHg, $[\alpha]_D^{25}-72.4°$ (*c* 2.78, ethanol) (lit,[21] $[\alpha]_D^{20}-78.0°$, neat).

(+)-Carvone (2): A commercial sample was purified by converting it to the sodium bisulfite adduct and by also rectifying the regenerated oil. The compound **2** thus obtained was 100% pure (as determined on the basis of analytical glc) and showed the following properties: bp 74.0—77.0°C/4 mmHg, n_D^{25} 1.4967, d_4^{25} 0.9567, $[\alpha]_D^{25}+61.7°$ (neat) (lit,[22] $[\alpha]_D^{20}+62.3°$, neat).

(−)-Piperitone (3): A commercial sample was purified by rectification under a reduced pressure to give the compound **3** (95.0% pure by analytical glc), with the following properties: bp 94.0°C/8 mmHg, n_D^{25} 1.4808, d_4^{25} 0.9280, $[\alpha]_D^{25}$ −5.20° (neat) (lit,[23] $[\alpha]_D^{20}-51.5°$, neat).

(−)-Carvenone (4): (−)-Dihydrocarvone (2.0 g; bp 105.0—106.5°C/18 mmHg, n_D^{25} 1.4685, d_4^{25} 0.9227, $[\alpha]_D^{25}-18.6°$ (neat), prepared[24] by the reduction of (+)-carvone, was treated with a mixture of acetic acid (25.6 ml) and hydrobromic acid (25.6 ml) for 30 min at room temperature. The reaction mixture was then poured into water and extracted with ether. The oil (1.97 g) obtained after the removal of the solvent was refined by column chromatography on silica gel. The compound **4** (100% pure by analytical glc) showed the following properties: bp 70.0—72.0°C/4.5 mmHg, n_D^{25} 1.4799, d_4^{25} 0.9231, $[\alpha]_D^{25}-41.0°$ (neat) (lit,[25] $[\alpha]_D^{25}+45.4°$ (neat) for the enantiomer of **4**).

The NMR spectra of the methyl proton signal at the 1-position appeared at δ 1.13 in both deuterochloroform and benzene, at 1.06 in carbon tetrachloride, and at 1.15 ppm in pyridine.

(+)-Pulegone (5): The purification of pennyroyal oil by means of the formation of the sodium bisulfite adduct, followed by regeneration and then distillation, gave the compound **5**, with the following properties: bp 65.5°C/2.5 mmHg, n_D^{25} 1.4845, d_4^{25} 0.9352, $[\alpha]_D^{25}+22.7°$ (neat) (lit,[26] $[\alpha]_D^{20}+23.4°$, neat).

The authors are indebted to the Takasago Perfumery Co., Ltd., Tokyo, for the gift of samples of carvone, piperitone, and pulegone.

A Negative Ion-molecule Reaction in Nitroethylene

Tetsuo SHIGA and Hitoshi YAMAOKA*
Department of Polymer Chemistry, Kyoto University, Kyoto
Kazuo ARAKAWA and Toshio SUGIURA
Takasaki Radiation Chemistry Research Establishment, Japan Atomic Energy Research Institute, Takasaki, Gunma
(Received November 4, 1970)

The formation of negative ions and the negative ion-molecule reaction in nitroethylene by electron impact have been studied. The nondissociative resonance electron capture of the nitroethylene molecule led to the formation of the molecular negative ion. The ionization efficiency curves and the appearance potentials of several fragment negative ions and the molecular negative ion were measured. The dimer negative ion of nitroethylene was found to be formed by the ion-molecule reaction between the molecular negative ion and a neutral nitroethylene molecule, and the rate constant of this ion-molecule reaction was estimated to be approximately 3.2×10^{-13} cc molecule^{-1}sec^{-1}.

A number of studies of ion-molecule reactions for positive ions done by the use of a mass spectrometer have been reported in recent years. Such investigations have provided useful information on those radiation-induced chemical reactions where more than one-half of the product formation usually results from the reactions of intermediate ions. For negative ion-molecule reactions, however, detailed studies have been limited to reactions which occur in oxygen and other gases of ionospheric interest,[1-6] although negative ions have also been considered to play an important role as active species in radiation-induced reactions.

In the course of investigations of radiation-induced polymerizations, it has been elucidated on the basis of the results of kinetic experiments[7] that the polymerization of nitroethylene proceeds by a free anionic mechanism through negative intermediates. An ESR study[8] and preliminary mass spectrometric observations[9] of nitroethylene have indicated that the polymerization was initiated by anion radicals of nitroethylene formed by the capture of electrons.

In the present study done by the use of a mass spectrometer, the formation of negative ions from nitroethylene and the dimer-negative-ion formation of nitroethylene by the ion-molecule reaction were investigated in order to obtain some information on the initial process of the radiation-induced polymerization of nitroethylene.

Experimental

The apparatus used for this study was a 90° single-focusing Hitachi RMU-6D mass spectrometer which had been modified to measure negative ions as described in a previous paper.[10] A conventional-type electron gun was used without paying any attention to the energy spread of the impact electrons. A 10-stage Ag–Mg electron multiplier combined with a DC amplifier was used as the ion detector, and the output current was recorded by means of a Rikadenki B-34 three-pen recorder. The minimum detectable ion current was 5×10^{-19}A. During the experiments, except when studying the effect of the ion-accelerating potential, the ion-acceleration voltage and the voltage supplied to the conversion dynode of the electron multiplier were kept at —3.5 and —1.5 kV respectively. The electron-trap voltage was maintained at the same potential as the ionization chamber. The repeller potential was always adjusted to 0 V in order to obtain the molecular negative ions of nitroethylene with thermal velocity. A source magnet, which had a flux intensity of 150 gausses, was also used for the collimation of the electron beam. The total emission was maintained at 100 μA throughout the energy range of the electron impact, and then the 40% trap current was obtained above 10 eV electron energies. The electron-accelerating potentials were read at each 1/50 V by means of a 10-turn precision Helipot variable resister in the range from 0 to 20 V; the resister had previously been well calibrated by means of a Yokokawa DC Voltage Standard GOS-11.

Sulfur hexafluoride and oxygen were used to calibrate the electron-energy scale. The appearance potentials of the SF_6^- ion from sulfur hexafluoride and the O^- ion from oxygen were taken as 0.03 eV[11] and 4.53 eV[12] respectively. The appearance potentials of the negative ions formed by the resonance-capture process were determined by the linear extraporation method.

The pressure in the ionization chamber was determined indirectly from the pressure in the sample reservoir, which was measured by means of a manometer, a McLeod gauge, and a CEC 23-105 Micro-Manometer. The ratio of the

sample pressure of the steady state in the ionization chamber to that in the reservoir was determined by the static operation of the inert gases (He, Ne, and Ar[13]) in the energy range in which the ion intensity of the resonance-electron capture was linearly proportional to the pressure.

Nitroethylene was prepared by the dehydration of 2-nitroethanol and purified as has been described previously.[7b] Sulfur hexafluoride (Allied Chemical Co.) was purified by trap-to-trap distillation in a vacuum. Oxygen and methane (Takachiho Chemical Ind.) were used without further purification.

Results

Formation of Negative Ions. A large number of negative ions were observed to be formed from nitroethylene by an electron impact of 100 eV. The relative abundance of the main negative ions, which were normalized to the intensity of NO_2^-, is shown in Table 1.

TABLE 1. RELATIVE ABUNDANCE OF THE MAIN NEGATIVE IONS PRODUCED FROM NITROETHYLENE BY ELECTRON IMPACT OF 100 eV

m/e	Ion	Source pressure (mmHg) 2.6×10^{-6}	Source pressure (mmHg) 9×10^{-3}
16	O^-	7.4	6.8
17	OH^-	6.8	9.1
25	C_2H^-	19	22
30	NO^-	0.93	0.96
42	CNO^-	3.4	7.3
46	NO_2^-	100	100
55	C_2HNO^-	0.62	0.85
