99	$C_2H_3NO_2C_2H_2^-$	—	0.6
146	$(C_2H_3NO_2)_2^-$	—	0.1
219	$(C_2H_3NO_2)_3^-$	—	2×10^{-4}

The molecular negative ion of nitroethylene, $C_2H_3NO_2^-$, was found at a pressure of 2.6×10^{-6} mmHg, and the relative abundance of $C_2H_3NO_2^-$ increased remarkably with the increase in the source pressure. At a pressure of 9×10^{-3} mmHg, the dimer negative ion of nitroethylene, $(C_2H_3NO_2)_2^-$, and the trimer negative ion, $(C_2H_3NO_2)_3^-$, were also observed, although the intensity of the trimer ion was very low.

The ionization efficiency curves of the main negative ions from nitroethylene, such as O^-, C_2H^-, NO_2^-, and $C_2H_3NO_2^-$, and that of SF_6^- from sulfur hexafluoride are shown in Fig. 1. The intensity of these negative ions in the electron-energy region less than 10 eV was proportional to the pressure of nitroethylene in the ionization chamber. From these curves, the appearance potentials and the apparent energy widths of the resonance-electron-capture processes from the molecular and fragment ions were obtained. The main results are summarized in Table 2. The appearance potential

73	$C_2H_3NO_2^-$	0	0.7

of NO_2^- in this study is higher than that of the NO_2^- from nitroalkanes (below 1 eV[14]).

From the ionization efficiency curve of $C_2H_3NO_2^-$ shown in Fig. 1, it is clear that the appearance potential is about 0 eV and that the width of the resonance capture is very narrow; both of those properties are also exhibited in the molecular negative ion of sulfur hexafluoride. These facts indicate that the nitroethylene molecule has the ability to capture thermal electrons easily by means of nondissociative process. Similar results in the cases of nitrocompounds of benzene derivatives have been reported by Christophorou *et al.*[15] and Jäger and Henglein.[16] The width of the nondissociative resonance capture of nitroethylene seems to be due to the energy spread of the impact electrons used, since the energy spread of the resonance-electron-capture process of SF_6 has been considered to be narrower than 0.05 eV.[11]

Compton *et al.*[17] measured the lifetimes of the molecular negative ions for SF_6, $C_6H_5NO_2$ and $(CH_3CO)_2$ by the use of a time-of-flight mass spectrometer. For the molecular negative ion of nitroethylene, an attempt to estimate the mean lifetime was made using the following procedures. The ion intensity of $C_2H_3NO_2^-$ was remarkably dependent upon the ion-accelerating potential. As is shown in Fig. 2, the dependence of the ion-accelerating potential on the ion intensity was measured for $C_2H_3NO_2^-$ and SF_6^- by using a Faraday cage as the ion detector. The dotted lines in Fig. 2 are the first differential curves obtained from the relations between the ion intensity and the ion-accelerating potential. Neglecting the change in the ion-collection efficiency with the variation in the accelerating potential, the sum of the residence time of the ions in the ionization chamber and the flight time of the ions at the peak of the first differential curve can be approximately considered as the mean lifetime of the ions. From the results of Fig. 2 and the estimated residence times in the ionization chamber to be described in the next section, the mean lifetimes for $C_2H_3NO_2^-$ and SF_6^- were calculated to be 14 μ sec and 28 μ sec respectively. The value for SF_6^- shows a close agreement with the result obtained by Compton *et al.* (25 μ sec[17]).

Dimer-negative-ion Formation by Ion-molecule Reaction. In the case of an electron impact of 100 eV, many secondary products of ion-molecule reactions were observed. However, at an electron energy of less than 1 eV, the secondary ions were the only products obtained by the reaction with $C_2H_3NO_2^-$; the mass numbers of the main secondary ions were 99, 119, and 146.

From the viewpoint of studying the initial process of the polymerization, special attention was paid to the formation process of the dimer negative ion. The ionization efficiency curves of $C_2H_3NO_2^-$ and $(C_2H_3NO_2)_2^-$ are shown in Fig. 3. The close agreement of the shapes of the two peaks indicates that the precursor of $(C_2H_3NO_2)_2^-$ is $C_2H_3NO_2^-$. The intensity of $(C_2H_3NO_2)_2^-$ at the peak in Fig. 3 was proportional to the square of the pressure of nitroethylene, whereas that of $C_2H_3NO_2^-$ was linear to the pressure, as is shown in Fig. 4. The plots of the $(C_2H_3NO_2)_2^-/C_2H_3NO_2^-$ ratio *vs.* the pressure of nitroethylene give a linear relation, as is shown in Fig. 5. From these results, it is evident that $(C_2H_3$-

17) R. N. Compton, L. G. Christophorou, G. S. Hurst, and P. W. Reinhardt, *J. Chem. Phys.*, **45**, 4634 (1966).

$NO_2)_2^-$ is produced by the ion-molecule reaction of the molecular ion with a neutral nitroethylene molecule, which can be demonstrated as follows:

$$C_2H_3NO_2^- + C_2H_3NO_2 \xrightarrow{k} (C_2H_3NO_2)_2^- \quad (a)$$

The rate constant of the (a) reaction was estimated by the following procedures. Assuming that the source pressure is low and that the fraction of the molecular ion which reacts is very small, Eq. (1) is obtained by introducing a treatment similar to that developed by Koyano *et al.*[18] for a reaction cross section:

$$g\left(\frac{I_D}{I_P}\right) = k[C_2H_3NO_2]\tau_N \quad (1)$$

where I_D/I_P is the ratio of the intensities of the dimer ion and the molecular ion, $[C_2H_3NO_2]$ is the concentration of nitroethylene, τ_N is the residence time of the molecular ion in the ionization chamber, and g is the ratio of the electron-multiplier gain of I_D to that of I_P. g was experimentally obtained as $1/\sqrt{2}$. For the estimation of τ_N, the ion-molecule reaction of the methane positive ions, represented by the (b) formula, was taken as a standard:

$$CH_4^+ + CH_4 \longrightarrow CH_5^+ + CH_3 \quad (b)$$

Using the published value of the rate constant for this reaction (1.1×10^{-9} cc mol^{-1}sec^{-1} [19]), the residence time of CH_4^+ in this apparatus ($\tau_{CH_4^+}$) was determined to be 2.1 μ sec from the slope of the linear relation between $I_{CH_5^+}/I_{CH_4^+}$ and the pressure of methane in the ionization chamber. It is generally known that the residence time of ions in the ionization chamber is a function of the mass of ions, the field strength in the chamber, and the distance from the electron beam to the exit slit of the chamber. In both the (a) and (b) reactions, the distance from the electron beam to the exit slit is the same, and the field strength is considered to be equal for positive and negative ions, although the signs of the gradients are the opposite. Consequently, the residence time of ions in this study is only a function of the mass of ions. By multiplying $\tau_{CH_4^+}$ by the square root of the mass ratio of $C_2H_3NO_2^-$ and CH_4^+, τ_N was estimated as 4.6 μ sec. Since $k\tau_N$ in Eq. (1) was obtained from the slope of Fig. 5, the rate constant of Reaction (a) was determined to be 3.2×10^{-13} cc mol^{-1}sec^{-1}.

Discussion

The results presented in Table 2 clearly show that many of the fragment ions from nitroethylene have appearance potentials which are almost identical. It might be expected that some of them result from ion-molecule reactions. However, the experimental evidence that the intensities of the ions increase linearly with the increase in the pressure in the ionization chamber indicates that these fragment ions are not produced by ion-molecule reactions, but are formed by the dissociative-resonance-capture processes.

It is interesting that the molecular negative ion of nitroethylene is observed at a lower pressure in the ionization chamber. The formation of molecular negative ions is generally classified into two different processes as has been pointed out by Compton *et al.*[17]: (i) metastable molecular negative ion formation, and (ii) molecular negative ion formation, in which the ion is stabilized by collision or radiation.

In the present study, the intensity of the molecular negative ion of nitroethylene is also proportional to the pressure by an electron impact of less than 1 eV. This fact indicates that the molecular negative ion is predominantly formed by the (i) process, in which the molecule is able to capture thermal electrons while maintaining its interatomic distances. The exact cross section of the electron capture can not be determined by the apparatus used. However, the relative intensity of the molecular ion of nitroethylene in the energy range of the resonance capture was about 1/200 of that for SF_6^- at a normalized pressure. Several values for the cross section of SF_6^- formation by nondissociative electron attachment have been reported.[11,17,20-24] Among them, the value of 2.6×10^{-14} cm^2 determined by Mahan and Young[24] was chosen as the most reliable one. Consequently the cross section of the nondissociative resonance capture of nitroethylene was estimated to be approximately 1.3×10^{-16} cm^2.

Now, the technique used in the present study for determining the ion lifetime should be discussed, since it has not been clearly established. As is well known, there is a strong tendency toward defocusing as the ion accelerating potential is reduced, and, of course, the beam will tend to spread as the retention time in the analyzer tube is increased. It is, therefore, necessary to obtain some information on the effect of the ion-accelerating voltage upon the collected current of several positive ions. In an attempt to correct some uncertain effects, the dependence of the accelerating voltage on the ion intensities of Ar^+ and SF_6^- was measured by changing the sign of the supplied voltage. The ion-intensity ratio of SF_6^-/Ar^+ changed in almost the same manner as is shown in Fig. 2 with the variation in the accelerating voltage. This fact, and the close agreement of the lifetime for SF_6^- between the values obtained by Compton[17] and by ourselves seem to imply that the method in the present study is still valid despite the limitations imposed by the obvious oversimplification.

The lifetime of the molecular negative ion thus formed is closely related to the electron affinity of the molecule.[17] Kamiyama *et al.*[25] calculated the electronic configurations, matrix elements, and energy levels for the molecular negative ion of nitroethylene by a semi-empirical MO method; they also gave the value of

1.53 eV as the electron affinity of nitroethylene. The observed long lifetime of the molecular negative ion of nitroethylene may be given by this positive electron affinity and the stable molecular configuration in the electron attachment.[25] The nature of the nitroethylene molecule as a strong electron acceptor shown in this study is in reasonable agreement with those suggested by the ESR[8] and the optical investigations.[25] On the other hand, in the case of the electron impact with 100 eV, the remarkable increase in the molecular negative ion at higher pressures shown in Table 1 seems to be caused by the (ii) process or by other processes.

It is clear from the results shown in Figs. 2 and 3 that the precursor of the dimer negative ion is the molecular negative ion of nitroethylene, and that the dimer negative ion is formed by the ion-molecule reaction of the molecular ion with a neutral nitroethylene molecule. The theoretical kinetic equation of ion-molecule reactions was first derived by Gioumousis and Stevenson[26] on the basis of an ion-induced-dipole model. Moran and Hamill[27] have considered the interaction of an ion with a molecule possessing a permanent dipole. Using a similar model, Harridon *et al.*[28] have proposed a modified collision theory including the effect of ion-dipole interaction. They have shown that the mean rate constant for collisions where both an ion and a neutral molecule have thermal velocities is given by the following equation:

$$\bar{k}_{\text{therm}} = 2\pi e\left(\frac{\alpha}{\mu}\right)^{1/2} + \frac{2\pi e\mu_D}{\mu}\left(\frac{2\mu}{\pi kT}\right)^{1/2}$$

where e is the electron charge, μ is the reduced mass of the colliding pair, α is the polarizability of the molecule, μ_D is the dipole moment of the molecule, and kT is the thermal kinetic energy.

According to this theory, the rate constant for the dimerization reaction of nitroethylene was calculated. Although the polarizability and the dipole moment of the nitroethylene molecule are unknown, it can be assumed that they are in the same order as those of nitroethane. The calculated values are 6.2×10^{-9} and 5.9×10^{-9} cc mol^{-1}sec^{-1} at 323°K and 373°K respectively. The rate constant measured experimentally (3.2×10^{-13} cc mol^{-1}sec^{-1}) is several orders of magnitude smaller than that predicted by the theory. This may indicate that a great portion of collisions do not give rise to dimerization reactions. The reasons for the apparent low rate constant of the dimerization reaction are not clear. One possible explanation is that the collisions lead to other ion-molecule reactions. However, the secondary ions observed at an electron energy of less than 1 eV are not abundant, as has already been mentioned. It would appear, therefore, that the contribution of other ion-molecule reactions is not very large. Alternatively, the apparent low rate constant could be explained by the occurrence of a charge transfer or a collision-induced electron detachment from the molecular negative ion which was not detected in the present study. A more likely explanation is that the model used does not adequately describe the ion-molecule collision since it contains no consideration of the electronic structures of the interacting species. Recently, Schaefer and Henis[29] have presented a qualitative description of low-energy ion-molecule reactions based on the assumption that the probability of reaction can be described by the change in the electron density around the nulcear centers involved. For the dimerization reaction of nitroethylene, however, this description cannot be applied because of the difficulty in calculating the detailed electron density distribution in complicated reaction systems.

In general, the mass-discrimination effect must be considered in determining the rate constants of ion-molecule reactions. However, this effect, caused by the repeller potential, was not present in the present study, where the repeller potential was always kept at 0 V. Other factors in the mass-discrimination effect, such as the space charge, the surface potential, and the source magnet in the ionization chamber, were not taken into consideration.

No experiment on the polymerization in the gas phase has yet been carried out, since the vapor pressure of nitroethylene is extremely low at room temperature. The rate constant of the polymerization in the liquid phase was determined from the kinetic experiments to be 6.7×10^{-14} cc mol^{-1}sec^{-1} at 20°C.[7b]

For the trimer negative ion, the measurements of the ionization efficiency curve and the dependence of the source pressure were difficult because of the low intensity of the trimer ion. In the positive-ion mass spectra, however, neither dimer nor trimer positive ions were observed in the pressure range examined. This fact also indicates that neither the dimer nor the trimer negative ions are produced by a direct electron capture process of a neutral nitroethylene dimer or trimer; rather, both are formed as secondary products. Consequently, the formation process of the trimer negative ion can involve only a consecutive reaction:

$$(C_2H_3NO_2)_2^- + C_2H_3NO_2 \longrightarrow (C_2H_3NO_2)_3^- \qquad (c)$$

Although only a limited range of the pressure was examined, the mass spectrometric observation mentioned above supports the concept that the precursor of the radiation-induced polymerization of nitroethylene is the molecular negative ion.

The authors wish to express their appreciation to Professor Koichiro Hayashi for his valuable advice and helpful discussions. They are also indebted to Professor Seizo Okamura and Dr. Hirobumi Danno for their continous encouragement during the course of this work.

The Solid Complex of Aminomalonic Acid with β-Alanine and Its Thermal Decomposition[1]

Juziro NISHIJO, Isamu IMANISHI, and Genzo HASHIZUME*
Kobe Womens College of Pharmacy, Higashinada-ku, Kobe
(Received June 25, 1971)

For the crystallization of aminomalonic acid with several amino acids from an aqueous solution, solid complex formation was studied by means of an X-ray diffractometer. No complex formation of aminomalonic acid with α-alanine, *dl*-α-amino-*n*-butyric acid, *l*-isoleucine, *l*-leucine, *dl*-serine, *dl*-norleucine, α-amino-iso-butyric acid, *dl*-valine, *dl*-threonine, or *dl*-norvaline was observed. However, with β-alanine, the formation of a solid complex with a molar ratio of 1:1 was ascertained. When this solid complex was analyzed by the differential thermogravimetric method in air at a heating rate of 1.4°C/min, a decarboxylation reaction, accompanied by endothermic and exothermic peaks, was observed at 115—133°C. On the other hand, the decarboxylation of aminomalonic acid alone occurred in the temperature range of 112—138°C. The areas of the endothermic peak, which was attributed to the decarboxylation, and the endothermic peak, which was attributed to the crystallization energies of γ-glycine and β-alanine, were, respectively, about 3 and 3/2 times those of the peaks observed in the case of aminomalonic acid. It was also observed that the exothermic process proceeded in two steps. The X-ray analysis of the products of the decarboxylation process suggested that the complex first melted to become amorphous to X-rays, and that it was then decarboxylated to amorphous glycine and amorphous β-alanine with these subsequent crystallization. The two-step exothermic process was explained in terms of a somewhat earlier crystallization of amorphous glycine than in terms of that of the amorphous β-alanine. The activation energy of the solid complex was estimated to 119.2 kcal/mol from the thermogravimetric curve. This large value of the apparent activation energy may be considered to result because the solid complex turns to an amorphous phase much more sensitive to decarboxylation prior to decomposition, and the steep slope of the thermogravimetric curve which results from the rapid decarboxylation of the amorphous gives the large apparent activation energy.

The present authors have previously reported[2] that aminomalonic acid reacted with glycine to form a solid complex with a 1:1 molar ratio when they were crystallized from an aqueous solution, and that the complex was thermally more stable than aminomalonic aicd alone. This paper will describe the solid-complex formation of aminomalonic acid with several other amino acid, and the thermal characteristics of the complex, if formed, will be compared with those of aminomalonic acid.

Experimental

Materials. Aminomalonic acid purified by recrystallization and various amino acids (special grade chemicals) were dissolved (in a molar ratio of 1:1) into water. By then evaporating the solvent at 25°C under a pressure of 3—5 mmHg, and easily crystallizable or a highly viscous residue was obtained. When the highly viscous residue was allowed to stand in air, a crystalline powder was obtained. This crystalline powder was pulverized in an agate mortar and was then used as the sample.

Analysis. The X-ray analysis was carried out with an X-ray diffractometer, Rigaku Denki Geigerflex, using Ni filter-CuK_α radiation. The infrared absorption spectra were measured with a Nihon Bunko Grating Infrared Spectrophotometer, type DS-402G. The Nujol-mull method was adopted in the measurements. DTA-TGA was carried out by an apparatus previously reported.[3] Measurements were carried out in air, because no significant difference had been observed in air as in a nitrogen stream. Samples of 200—500 meshes were used for the measurements.

Determination of Aminomalonic Acid and β-Alanine by the X-ray Diffraction Technique. Aminomalonic acid was mixed with a solid complex, AM_1-β-AL_1 (AM: aminomalonic acid, AL: β-alanine, the subscripts refer to the molar ratio), in order to obtain samples with various weight ratios of aminomalonic acid to AM_1-β-AL_1. The mixture was triturated well in a mortar to diminish the orientation of the crystals. Then, the sample was set in a sample holder (the same sample holder was used throughout this work). The intensity [(half width) × (height)] of the diffraction peak due to aminomalonic acid at 24.1° (2θ) in these samples was measured in order to obtain a calibration curve, which was then used for the determination of the aminomalonic acid content (Fig. 3). The measuring conditions were as follows: 40 kV—1.5 mA;[4] full scale, 400 count/sec; time constant, 4: scanning speed, 0.5°(2θ)/min, and chart speed, 20 mm/min. The determination of β-alanine was carried out by the same method as that used for aminomalonic acid and under analogous condition, except for 40 kV—3 mA[4] and a chart speed of 40 mm. In this case, the height of the diffraction peak of β-alanine at 24.1° (2θ) was adopted as its intensity (Fig. 4).

Results and Discussion

Solid Complex-formation Ability. The solid complex-formation abilities of aminomalonic acid with several amino acids, studied by X-ray analysis, are shown in Table 1. The absence of any solid-complex formation is shown by the sign ×. In these cases, only the diffraction patterns of aminomalonic acid were observed. In the cases shown with the sign ○, a new diffraction pattern, different from those of the component amino acids, was observed, indicating a complex

formation. In the cases shown with the sign △, diffraction pattern consisted of the peaks due to unknown species and those of the component amino acid, (aminomalonic acid or added amino acid). The former were found to correspond to the diffraction peaks of the hydrate of aminomalonic acid or the added amino acid. Thus, we concluded that no complex is formed in these cases.

The fact that aminomalonic acid can form solid complexes with β-alanine and glycine, but not with α-substituted amino acids, seems to suggest that steric factors in the neighborhood of amino and carboxyl groups of amino acids have a bearing on the complex-formation ability of aminomalonic acid with other amino acids.

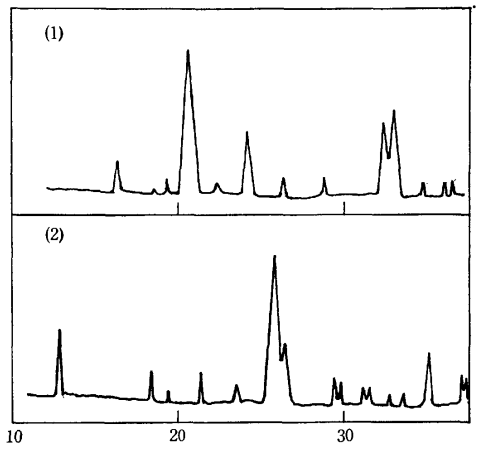

Fig. 1. X-ray diffraction patterns of aminomalonic acid (1) and β-alanine (2).

Solid Complex of Aminomalonic Acid with β-Alanine. The X-ray diffraction patterns of aminomalonic acid and β-alanine are shown in Fig. 1, while those of the samples, whose molar ratios of aminomalonic acid to β-alanines are 1 : 1, 2 : 1, and 1 : 2, are shown in Fig. 2. In the case of AM_1-β-AL_1, a new diffraction pattern, different from those of the components, aminomalonic acid and β-alanine, was obtained, while in the cases of AM_2-β-AL_1 and AM_1-β-AL_2, diffraction patterns of AM_1-β-AL_1 with those of aminomalonic acid or β-alanine respectively were observed. Also, AM_3-β-AL_2 and AM_4-β-AL_3 gave patterns of AM_1-β-AL_1 and

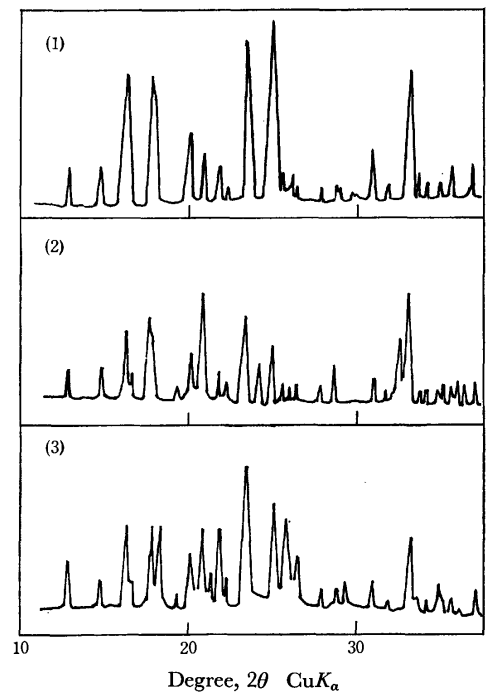

Fig. 2. X-ray diffraction patterns of AM_1-β-AL_1 (1), AM_2-β-AL_1 (2) and AM_1-β-AL_2 (3).

aminomalonic acid, while AM_2-β-AL_3 and AM_3-β-AL_4 gave patterns of AM_1-β-AL_1 and β-alanine. To determine the molar ratio of aminomalonic acid to β-alanine in the complex, the content of aminomalonic acid in AM_2-β-AL_1, AM_3-β-AL_2, and AM_4-β-AL_3, and that of β-alanine in AM_1-β-AL_2, AM_2-β-AL_3, AM_3-β-AL_4, were estimated by using the calibration curves (Figs. 3, 4). The contents of aminomalonic acid and β-alanine, which exist excessively in these samples, were calculated by assuming that the crystals corresponding to the diffraction pattern of AM_1-β-AL_1 were composed of aminomalonic acid and β-alanine in a molar ratio of 1 : 1. These calculated values agreed fairly well with the found values, as shown in Table 2. It was concluded

that aminomalonic acid reacts with β-alanine in a 1:1 molar ratio to produce a solid complex which gives the diffraction pattern of AM_1-β-AL_1.

The infrared absorption spectra of aminomalonic acid, β-alanine, and AM_1-β-AL_1 are shown in Fig. 5. In the spectrum of AM_1-β-AL_1, absorption bands observed in the neighborhood of 820, 910, and 1100 cm^{-1} were especially different from those of aminomalonic acid or β-alanine. In addition, the band at 1710 cm^{-1},

attributed to the carboxyl group of aminomalonic acid, was shifted to about 1685 cm^{-1}. On the contrary,when no complex was formed, only superimposed absorption bands of aminomalonic acid were observed.

Differential Thermal Analysis and Thermogravimetric Analysis. The DTA–TGA curve of AM_1-β-AL_1 in air, using 87.4 mg of the sample at a heating rate of 1.4°C/min, is shown in Fig. 6, together with the corresponding curve of aminomalonic acid. These curves show that the beginning temperature of the decarboxylation of AM_1-β-AL_1 is slightly higher than that of aminomalonic acid, while the completion temperature of the former was about 5°C lower than that of the latter and that, consequently, the rate of decomposition of the former was larger than that of the latter. On the other hand, it is confirmed that, in the case of AM_1-β-AL_1, the endothermic process slightly precedes a decrease in weight, and the peak area is about 3 times that of aminomalonic acid. It is also found that the exothermic process proceeds in two steps. The peak area was about 3/2 times that of aminomalonic acid. To study the decarboxylation process of AM_1-β-AL_1, the samples were taken out rapidly at the a, b, c, and d points in the DTA curve shown in Fig. 6 and these samples were subjected to X-ray analysis. The results are shown in Fig. 7. Figure 7 shows that, at the a point, diffraction pattern is identical with that of AM_1-β-AL_1. This means that no change in AM_1-β-AL_1 occurs untill the decarboxylation begins. The diffraction patterns of the sample at the d point, where the decarboxylation is almost completed, were identical with those of γ-glycine and β-alanine. The sample rapidly taken out at the b point, where the decarboxylation proceeds about 15%, gives only a diffraction pattern identical with that of AM_1-β-AL_1. The sample at the c point, where the differencial thermal curve tends to a large second exothermic peak and where the decomposition fraction is about 70%, gives diffraction patterns of γ-glycine and β-alanine. These samples were allowed to stand in air in the sample holder for an X-ray diffractometer, and an X-ray analysis of the samples was carried out under the same conditions. The results are shown in Fig. 8. With the sample at the b point, the intensity of the diffraction pattern of AM_1-β-AL_1 increases and the diffraction peaks of γ-glycine and β-alanine appear. With the sample at the c point, the intensities of the diffraction peaks due to γ-glycine and β-alanine increase, but the increasing rate of intensity in β-alanine is larger than that in γ-glycine. Moreover, the diffraction peaks of AM_1-β-AL_1 appear, they can not be observed in the sample rapidly taken out. As it takes 7—10 min to transfer the sample from the DTA-TGA apparatus to the sample holder for X-ray analysis and to measure its diffraction pattern, the following decarboxylation process may be suggested. At first, AM_1-β-AL_1 may melt as a complex amorphous to X-ray analysis, and the amorphous complex may decarboxylate to amorphous glycine and amorphous β-alanine, which then soon crystallize to γ-glycine and β-alanine. The crystallization of amorphous glycine to γ-glycine may take place slightly earlier than that of β-alanine. Therefore, it can be considered that the endothermic peak corresponds to the heat required for the decarboxylation with melting, while the exothermic peak corresponds to the energy of crystallization to γ-glycine and β-alanine from their amorphous forms. The two-step change from the endothermic to the exothermic process can be interpreted in terms of a slight difference in crystallization velocity between the two compounds.

5) A. W. Coats and J. P. Redfern, *Nature*, **201**, 68 (1968).

Activated Energy. By applying the equation previously proposed by Coats and Redfern[5] for the determination of the activation energy of a solid state reaction accompanied by a weight decrease, the activation energies of the decarboxylation of aminomalonic acid and AM_1-G_1 were calculated as 69.4 kcal/mol and 20.3 kcal/mol respectively. The determination of the activation energy of the decarboxylation of AM_1-β-AL_1 from its thermogravimetric curve with a heating rate of 1°C/min (Fig. 9) was attempted using the same equation. In the decomposition range from 10 to 63%.

$$\log_{10}\{1-(1-\alpha)^{1-n}/T^2(1-n)\} \text{ or } \log_{10}\{-\log(1-\alpha)/T^2\}$$

was plotted against $1/T$, assuming $n=0$, 1/2, 2/3, or 1. The best linearity was found with $n=2/3$ (Fig. 10). From the slope, the activation energy was calculated as 119.2 kcal/mol. This very large value may be explained as follows, amorphous AM_1-β-AL_1, to which the complex has melted prior to its decomposition, is so active in the decarboxylation that the reaction proceeds very rapidly; consequently, the slope of the thermogravimetric curve may be so steep that a very large apparent activation energy can be obtained.

It was concluded from these experimental results that a solid complex of aminomalonic acid with β-alanine was formed, but unlike the complex of aminomalonic acid with glycine, thermal stabilization can be obtained in this complex.

The Diffusion of Gases at High Pressures. IV. The Diffusion of CTH_3 in the CH_4-CO_2 System

Shinji TAKAHASHI

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai

(Received June 24, 1971)

The diffusion coefficients of radioactive methane (CTH_3) in normal methane, in carbon dioxide, and in a mixture of normal methane with carbon dioxide (0.522 mol fraction of methane) were measured at the temperatures of 25, 50, and 75°C in the 15—250 atm pressure range. The measurements were made through a plug of porous bronze in the diffusion cell, using the radioactive tracer technique. The diffusion coefficient-density products, $D\rho$, for the CTH_3–normal methane system and the CTH_3– the binary mixture system increased slightly with an increase in the density in the lower-density region at 25 and 50°C, but they were nearly constant at 75°C. The $D\rho$ for the CTH_3–carbon dioxide system decreased with an increase in the density at each temperature. The $D\rho$-values at 1 atm, obtained by extrapolation, agreed fairly well with those reported in the literature. The density dependence of the $D\rho$ values at high densities could not be predicted by Enskog-Thorne's theory.

Although the diffusion coefficients of gases at high pressures have been reported by several investigators since 1950,[1] the relative scarcity of high-pressure diffusion data suggests a need for additional measurements in order to evaluate the various theoretical relations[2] and the generalized chart[3] available for the prediction of the transport properties of dense gases. In the present investigation, the diffusion coefficients of radioactive methane (CTH_3) in methane, in carbon dioxide, and in a mixture of normal methane with carbon dioxide (0.522 mole fraction of methane) were measured at the temperatures of 25, 50, and 75°C in the 15—250 atm pressure range, and the depencence on the pressure, the temperature, and the composition was studied.

Experimental

The apparatus and the experimental procedure were the same as those described previously.[4] The diffusion path in the cell was a porous bronze plug with a grain size of 60—70 μ. Radioactive methane, obtained from New England Nuclear Corp., was diluted with non-radioactive methane to a specific activity of about 20 μCi per m*l* at NTP. The purities of the carbon dioxide and non-radioactive methane used in this investigation were 99.9 and 99.6% respectively. The mixture of carbon dioxide with non-radioactive methane was prepared in a storage cylinder. The exact composition (0.522 mol fraction of methane) was determined by absorbing carbon dioxide from the sample into a potassium hydroxide solution. Under the conditions studied, the mixture is not in a liquid state.[5]

The proportionality betweeen the concentration of radioactive methane and the ionization current, essential for a quantitative treatment of the diffusion data, was confirmed experimentally for pure methane, carbon dioxide, and the mixture at a constant temperature and pressure. As examples, the results at 50°C are shown in Fig. 1.

Results and Discussion

The experimental results are given in Table 1. D is

the diffusion coefficient of radioactive methane in the CH_4–CO_2 system. The densities of the gases, ρ (mol/l), were calculated from the compressibility data given by Kvalnes and Gaddy for methane,[6] by Michels and Michels for carbon dioxide,[7] and by Reamer *et al.* for the mixture.[8]

The diffusion coefficient-density products, $D\rho$, are plotted against the density in Fig. 2. The open circles refer to the values obtained in the present experiment. Curves have been drawn through the experimental points for the three systems where the mole fractions of methane, x_3, are 1.000, 0.522, and 0.000. The D at $x_3=1.000$ is the diffusion coefficient of radioactive methane with normal methane, D_{13}, where the 1 and 3 subscripts denote radioactive methane and normal methane respectively. The $D_{13}\rho$ increases slightly with an increase in the density in the lower-density regions to 5 mol/l, and decreases slightly in the higher-density regions. Extrapolations of $D_{13}\rho$ *vs.* ρ curves to 1 atm provide a basis for comparison with published low-pressure experimental results. Applying the mass correction[9] to the self-diffusion coefficient of normal methane, D_{33}, reported by Winn,[10] the diffusion coefficient of radioactive methane with mormal methane, D_{13}, was obtained; the values of $D_{13}\rho$ thus calculated are denoted by darkened triangles in Fig. 2. As can be seen from Fig. 2, the values reported by Winn yield values which are in agreement with those extrapolated in this investigation. The D at $x_3=0.000$ is the diffusion coefficient of radioactive methane with carbon dioxide, D_{12}, where the 2 subscript denotes carbon dioxide. The $D_{12}\rho$ decreases with an increase in the density at each temperature. Applying the mass correction to the diffusion coefficient of normal methane with carbon dioxide, D_{23}, calculated by the empirical formula,[11] the diffusion coefficient of radioactive methane with carbon dioxide, D_{12}, at 1 atm was obtained; the values of $D_{12}\rho$ at 1 atm are denoted by darkened circles in Fig. 2. The empirical formula yields values which agree with those extrapolated. The $D\rho$ at $x_3=0.522$ increases slightly with an increase in the density in the lower-density regions to 5 mol/l, decreases in the higher-density regions at 25 and 50°C, and is nearly constant at 75°C. The diffusion coefficient of the trace of radioactive methane in the mixture, D, at 1 atm may be calculated using the following equation:

$$1/D=x_2/D_{12}+x_3/D_{13} \qquad (1)$$

where x_2 and x_3 are the mole fractions of carbon dioxide and non-radioactive methane respectively, and where $x_2+x_3\fallingdotseq1$. The calculated values of $D\rho$ at 1 atm are shown by darkened squares in Fig. 2. As Fig. 2 shows, Eq. (1) yields values which are about 7% lower than those extrapolated at 25 and 50°C, and 4% lower at 75°C.

The D_{23}(CH_4 trace) and the D_{23}(CO_2 trace) were obtained by applying the mass correction to the diffusion coefficient of the trace of radioactive methane with normal carbon dioxide measured in the present investigation, and to the diffusion coefficient of the trace of radioactive carbon dioxide with normal methane reported in the previous paper, respectively. They are shown by open circles and open triangles in Fig. 3. The extrapolation of the $D_{23}\rho$(CH_4 trace) *vs.* ρ curves to 1 atm yields values which agree with those obtained by the extrapolation of the D_{23}(CO_2 trace) *vs.* ρ curves to 1 atm. This means that the values of D_{23} in such

limiting cases as when $x_2\rightarrow0$ and $x_3\rightarrow0$ are identical at 1 atm. Similar results were reported by Walker and Westenberg.[13] for the CO_2—N_2 system. Although the $D_{23}\rho(CH_4$ trace) decreases with an increase in the density at each temperature, the $D_{23}\rho(CO_2$ trace) is nearly constant, and the difference between them become larger with an increase in the density. This means that the D_{23} is dependent on the composition at high densities.

According to Enskog-Thorne's theory, which is the only theoretical treatment offering any practical application, the binary diffusion coefficient is given by the following equation:

$$D_{ij}\rho=(D_{ij})^0\rho/\chi_{ij} \tag{2}$$

where $(D_{ij})^0$ is the binary diffusion coefficient calculated on the basis of the low-density kinetic theory as follows:

$$(D_{ij})^0=\frac{3}{16n\sigma_{ij}^2\,\Omega_{ij}^{(1,1)*}}\left(\frac{2kT}{\pi\mu}\right)^{\frac{1}{2}} \tag{3}$$

where n is the number density of the molecules (cm^{-3}); σ_{ij}, the collision diameter (cm); $\Omega_{ij}^{(1,1)*}$ the reduced

13) R. E. Walker and A. A. Westenberg, *J. Chem. Phys.*, **29**, 1139 (1958).

collision integral; k, the Boltzmann constant; T, the absolute temperature (°K), and μ, the reduced mass. χ_{ij} is a correction factor which is given for a two-component gas by the following series:

$$\chi_{ij}=1+0.2618n_i\sigma_i^3(8-3\sigma_i/\sigma_{ij}) +0.2618n_j\sigma_j^3(8-3\sigma_j/\sigma_{ij})+\cdots \quad (4)$$

where n_i and n_j are the number densities of the i and j species (cm^{-3}); σ_i and σ_j, the collision diameters of the i and j species between like molecules (cm), and σ_{ij} is that between unlike molecules, which may be obtained from the empirical combining law: $\sigma_{ij}=(\sigma_i+\sigma_j)/2$, and hence $\sigma_1=(\sigma_1+\sigma_j)/2\fallingdotseq(\sigma_3+\sigma_j)/2$, $(j=2,3)$. The collision diameters, $\sigma_2=3.996$ Å and $\sigma_3=3.882$ Å, were taken from Ref. 2. They are those determined from the viscosity measurement for the Lennard-Jones model. Since the 1 species is present only as a trace in this investigation, the second term on the right hand of Eq. (4) may be neglected. As the $(D_{1j})^0\rho$ quantity is constant at a constant temperature and is independent

of the density, the extrapolated values of the $D_{1j}\rho$ to 1 atm were used in place of the $(D_{1j})^0\rho$. As is shown in Fig. 2, the theoretical values of both the $D_{12}\rho$ and the $D_{13}\rho$ decrease with an imcrease in the density and are about 20—26% lower than those obtained in the present work at $\rho=5$ mol/l.

The diffusion coefficient of a trace amount of CTH_3 in methane, D_{13}, measured at high pressures using a

modified Loschmidt-type diffusion cell was reported by Jeffries and Drickamer.[15] As is shown in Fig. 2, their values of the $D_{13}\rho$ decrease monotonously with an increase in the density and much lower than those obtained in the present work.

15) Q. R. Jeffries and H. G. Drickamer, *J. Chem. Phys.*, **21**, 1358 (1953).

The self-diffusion coefficient of CH_4, as measured by the use of a pulsed NMR spectrometer, were reported by Trappeniers and Oosting[16] and Dawson *et al.*[17] The values of the $D_{13}\rho$ obtained by applying the mass correction to the results of Dawson *et al.* are shown by dashed lines in Fig. 2. These are 10% lower than those obtained in this investigation, but the shapes of the $D\rho$ *vs.* ρ curves are similar. It may be noted that the values obtained by the extrapolation of their curves to 1 atm agree well with those calculated by Eq. (3). The experimental values obtained by Trappeniers and Oosting agree very well with those calculated by Eq. (3); hence, the $D\rho$ is independent of the density.

The data may be cross-plotted to show the composition dependence of the diffusion coefficient at a constant density. If Eq. (5) derived from Eq. (1) is valid, the $1/D\rho$ *vs.* x_3 plots should be linear:

$$1/D\rho = x_2/D_{12}\rho + x_3/D_{13}\rho \qquad (5)$$

Fig. 4 shows that such cross-plots made at 2, 5, and 10 mol/l are concave lines and that Eq. (5) is not valid in this system.

The author wishes to express his deep gratitude to Professor Hiroji Iwasaki for his kind direction and encouragement throughout this work.

Catalytic Properties of BF_3-treated Aluminas. IV. The Effect of BF_3 Adsorption on the Acidic Properties of Aluminum Oxides

Kanjiro MATSUURA, Akira SUZUKI, and Mitsuomi ITOH
Department of Chemical Process Engineering, Hokkaido University, Sapporo
(Received October 19, 1971)

An account was given of the surface acidic properties of a series of BF_3-treated aluminum oxides, ranging in their precalcination temperature up to 1000°C. It was concluded that all aluminum oxides dehydrated over 300°C were converted to solid acids with new strong acid centers of $H_0 \leqq -8.2$ by adsorption with BF_3. This new acid centers would be certainly of the Brönsted type. Their catalytic activities in some carbonium ion type reactions are well correlated with the *n*-butylamine acidity in the presence of Hammett's indicators, and the maximum number of acid centers was observed in catalyst samples precalcined at 450 and 800°C respectively. The present study also suggests that the acid centers developed on the surface of aluminum oxides are somewhat different in nature depending upon their precalcination temperatures. Since there was a good correlation between the amount of the remaining hydroxyl groups and that of the absorbed BF_3, the surface hydroxyl groups, in addition to the aluminum atoms serving as the Lewis centers, which are not fully coordinated, were discussed as the most important factors in the formation of such acid centers.

It is well known that BF_3-treated acidic oxides are effective for catalysis in some hydrocarbon conversion reactions. Some studies of catalysts activated with BF_3 have been published in the literature;[1-5] however, little work has been done to clarify the effect of BF_3 adsorption on the nature of the acid centers responsible for catalytic activity. Recent results reported by Antipina and Vinokurora[5] have indicated that the treatment of aluminum oxide with HF or BF_3 does not greatly increase the strength of the acid centers on the surface, but is accompanied by the formation of a certain number of new, relatively weak centers. Since BF_3 is believed to react with the surface hydroxyl groups, it can be accepted that the activity and stability of activated aluminum oxide depend substantially upon the surface properties of the initial alumina.

Pure aluminum oxide has intrinsic acidic properties and thus has been widely employed as a catalyst or as a catalyst support. It is now well established that the acid center of pure alumina can generally be characterized as a Lewis type. On the other hand, there are very little consideration of the presence or absence of Brönsted acid centers on the surface. When aluminum hydroxide is calcined at various temperatures up to 1000°C, it may be expected that the alumina formed will have a great variety of acidity and activities corresponding to the respective surface properties. For example, Peri[6] has demonstrated that several acidic types of hydroxyl groups exist on the surface of dehydrated alumina; it is considered that such surface properties are strongly affected by BF_3 treatment.

Accordingly, we have attempted to clarify the nature of the acid centers developed by such a treatment, and to find whether these centers are of the Brönsted and/or the Lewis type. In this study, we selected a series of aluminum oxides ranging in precalcination temperature from 130°C to 1000°C as adsorbents and investigated the effect of BF_3 treatment on the acidic properties after modification.

Experimental

Materials. The alumina (A-) used in this work was obtained by the thermal decomposition of bayerite. The aluminum hydroxide was prepared by the hydrolysis of aluminum isopropoxide with water. The product was washed with distilled water, kept standing overnight at 130°C, and finally calcined at various temperatures for 3 hr a stream of dry nitrogen. The boron trifluoride was a commercial product of the Hashimoto Kasei Co. (Osaka), with a purity of 99.5%. All the chemicals, cumene, toluene, *o*-xylene, and benzene, were the reagent-grade commercial products. They were dried over metallic sodium and then distilled. The propylene was used after purification by distillation. The ethylmagnesium bromide used for the determination of the hydroxyl content was prepared by mixing ethyl bromide with a magnesium ribbon in di-*n*-butyl ether at 30°C. The Hammett's and arylmethanol indicators for the determination of the acidity distribution are

listed in Table 1, together with the pK_a and pK_r values.

Apparatus and Procedure. The adsorption of BF_3 was carried out at room temperature under atomospheric pressure by exposing the dehydrated aluminum oxides for 5 min or less; then immediate evacuation was done to remove any residual vapors. Differential thermal analysis was carried out under atomospheric pressure. The water loss of alumina with heating was determined gravimetrically on a silica spring balance, as has been reported elsewhere.[7] The X-ray data were obtained using nickel-filtered Cu-$K\alpha$ radiation, a Geiger-counter X-ray spectrometer of the Toshiba Electric Co. The specific surface area (BET) was measured with nitrogen as the adsorbate. The micropore volume was determined by a method proposed by Benesi.[8] The surface hydroxyl content was determined by the technique of Satoh *et al.*[9] The butylamine acidity was determined in the way described by Benesi.[10] All the catalyst sample, screened to 100—200 mesh particles, were evacuated by a high vacuum technique at 300°C for 3 hr before the measurement of their acidity. The catalytic activity for cumene cracking, *o*-xylene isomerization, and toluene disproportionation were studied using an all-glass, fixed-bed-flow reactor system. Each reactant mixture was fed in continuously by means of a gas-syringe drive. The reaction products were analyzed by glpc using a column packed with 5% silicon DC-550. Propylene polymerization was carried out in a closed apparatus, as has been described by Tamele.[11]

Results

Aluminum Oxides as Adsorbents. The characteristics of the various aluminum oxides used in this work are summarized in Table 2. Thermograms of a starting hydroxide are shown in Fig. 1. The main residual water is shown to have a sharp endothermic peak at around 350°C, which is believed to be characteristic of bayerite or gibbsite. The water loss of hydrous alumina at several dehydration temperatures is shown in Fig. 2. It is shown that a rapid decline in the water content occurred between 200 and 400°C, while above 600°C only a little loss of weight was detectable. These results are in good agreement with those of the endothermic heat change shown in Fig. 1.

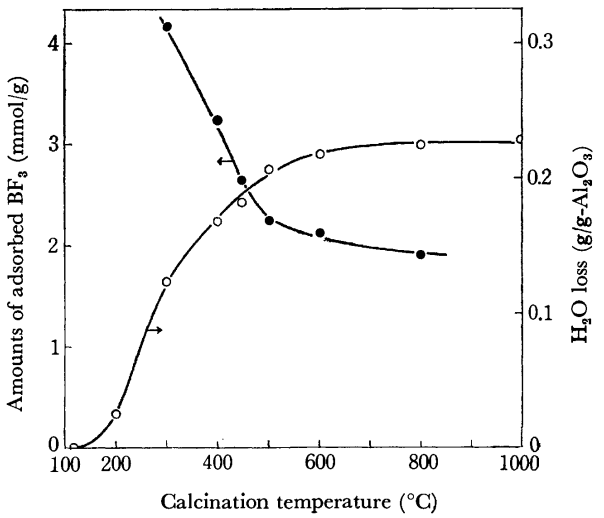

Fig. 2. Water loss with calcination temperature *vs.* amount of adsorbed BF_3 on aluminum oxides.

The specific surface area gradually decreases with the increase in calcination temperature. This diminution is appreciable after the elimination of the residual water shown in the endothermic peaks. The total pore volume of aluminum oxides increases as the heating temperature is raised, and they become simultaneous in pores of 18 to 77 Å. The maximum volume in the micropore is exhibited at around 500°C, indicating that the materials are obviously highly porous at this temperature.

The X-ray diffraction pattern of the original hydrate indicated a well-crystallized bayerite containing a trace of boehmite. As far as was determined by X-ray diffraction, no major phase transformations took place between 300° to 600°C, and the usual transformation to *theta* and *alpha* alumina was found above 600°C. It was indicated that when this material was heated at 400° to 500°C, it became a highly porous solid showing an X-ray pattern characteristic of relatively poorly crystallized *eta* alumina. This is possibly of great interest from the point of view of their catalytic action.

were determined by *n*-butylamine titration using Hammett's indicators. The concentrations and strengths of the surface acid centers are demonstrated in Table 3. It is shown that some aluminas had a certain number of acid centers (~0.56 meq/g at $H_0 \leq -8.2$). It was also observed that the acidity at any acid strength varied remarkably with the increase in the dehydration temperature, which had its maximum at 500°C. Since these dehydrated aluminum oxides have such different surface properties, the appearance of an interesting surface behavior both for acidity and activity possibly resulted from their modification with BF_3.

Surface Properties of Aluminum Oxides after BF_3 Adsorption. The characteristics of a series of BF_3-treated aluminum oxides are summarized in Table 4. The adsorption of BF_3 was studied on various aluminum oxides, ranging in precalcination temperature from 300 to 1000°C. It was found that the amount of BF_3 adsorbed on the adsorbents dehydrated below 500°C decreases markedly with the increase in preheating temperature. However, the difference in the amount was negligibly small above approximately 600°C. When the results in Table 2 are compared with those in Table 4, it is clear that there is a good correlation between the remaining hydroxyl content and the amount of adsorbed BF_3.

The acidity of the BF_3-treated aluminum oxides was also determined by butylamine titration using two types of indicators, Hammett's and arylmethanol indicators. The distribution of the acid centers at different strengths is shown in Table 5 and Fig. 3. The following conclusions were obtained:

Table 4. Surface properties of BF_3-treated aluminas

BA-1000	0.10	0.24	0.14	0.00	0.02	0.25	0.05	0.01

a) BF_3-treated aluminas had an appreciable number of acid centers at a strength of $H_0 \leq -8.2$ ($\sim$0.64 meq/g), but none or little acidity was observed in relatively weak centers ($H_0 > -3.0$). This does not coincide with the results of Antipina and Vinokurora.[5]

b) As the precalcination temperature is raised from 300 to 1000°C, there is a remarkable difference in overall acidity; namely, the number of strong acid centers at $H_0 \leq -8.2$ reaches a maximum in the catalysts dehydrated at about 400 and 800°C. The catalyst obtained at 600°C indicated a considerably low acid number as is shown in Fig. 3.

c) All of the aluminum oxides, after treatment with BF_3, convert some arylmethanol indicators to the corresponding acid forms. On the other hand, initial pure aluminas do not change any H_r indicators to the acid form. This is evidently due to the difference in the nature of the surface acid centers.

As will be shown in the later part of this paper, such differences in acid number among several aluminum oxides are related to the results on the catalytic activity of various carbonium ion type reactions. The results for acidities shown in Table 5 enable us to differentiate the H_0 from the H_r acidity. BA-300 to BA-500 in Table 5 have large number of acid centers in both indicators. BA-800 to BA-1000, on the other hand, have relatively small H_r acidities but, more overall acidity exists.

Catalytic Activity. The comparative catalytic activities for some acid-catalyzed reactions are examined. The results are shown in Table 6. It was generally concluded that all of the catalytic activities of BF_3-treated alumina were much higher than those of non-treated alumina; the latter indicated no activity for any conversion reactions examined under the present experimental conditions. The BF_3-treated samples of BA-450 and BA-800 indicated a maximum conversion for all reactions, and BA-600 showed a quite low conversion. This activity profile shows a good fit the acid-site distribution shown in Fig. 3. The activity for *o*-xylene isomerization in Table 6 is plotted against the number of relatively strong acid centers. The plots with $H_0 \leq -5.6$ lie on a comparatively good straight line, as is shown in Fig. 4. Therefore, it seems likely that the acid centers having a strength of $H_0 \leq -5.6$ are responsible for the reactions studied in this paper.

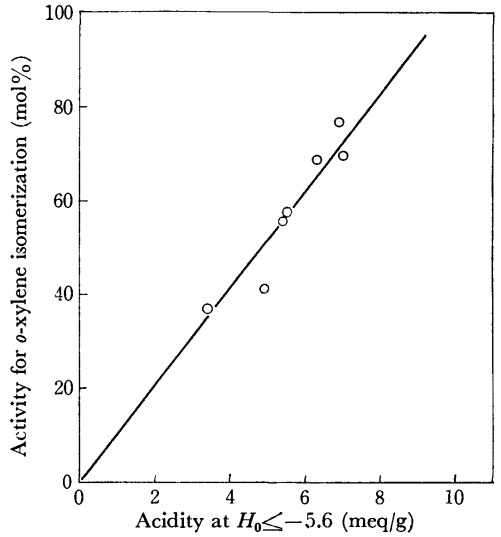

Fig. 4. Acidity at $H_0 \leq -5.6$ *vs.* activity for *o*-xylene isomerization at 350°C.

Discussion

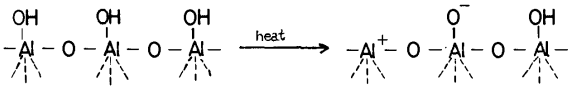
Mainly in view of the acidic behavior of aluminum oxides before and after BF_3-treatment, the difference in surface properties due to the variation of their dehydration temperatures was studied, and it was demonstrated that the surface acidity of the activated catalysts depended, at least in part, on the initial properties, such as the hydroxyl content and the crystallinity.

Table 6 shows the catalytic activities with some other solid acids. It was found that the BF_3-treated aluminas, especially those precalcinated at around 450 and 800°C, indicated nearly the same high activity as the silica-alumina catalyst. However, non-treated pure alumina showed no activity for any of the reactions in this work. The catalytic action of BF_3-treated aluminas is assumed to be due to the formation of new Brönsted centers. As may be seen in Tables 2 and 4, it has already been described that the concentration of the surface hydroxyl groups of aluminum oxides decreases gradually as the dehydration temperature is raised to 1000°C, and there is a proportional relationship between the hydroxyl content and the amount of BF_3 adsorbed. Since all of the BF_3-treated aluminum oxides converted the arylmethanol indicators to their respective acid forms, it has generally been suggested that the appearance of Brönsted acid centers in the case of alumina activated with BF_3 is associated with the hydroxyl groups of the initial alumina. Accordingly, it may be considered that the hydroxyl concentration has an effective influence upon the catalytic action after the treatment with BF_3. According to Rhee and Basila,[12] hydrogen-bonding interactions similar to those in the BF_3-aliphatic alcohol complexes[13] may occur on the surface

12) K. H. Rhee and M. R. Basila, *J. Catal.*, **10**, 243 (1968).
13) K. Nakamoto and M. Margoshes, *J. Phys. Chem.*, **77**, 6480 (1955).

of alumina. A similar interaction between adjacent surface hydroxyl groups, which is promoted by the BF_3 complex formation, seems to be strongly affected at higher concentrations. Thus, it is possible that the most effective sites for all reactions in the present work result from the coordination of BF_3 with the remaining hydroxyl group, which varies gradually in its concentration and acidic property with the heating temperature of the initial aluminum oxide.

On the other hand, other higher conversions were observed with the catalyst samples of BA-800 or BA-900, although relatively small hydroxyl contents were found at such higher precalcination temperatures (Table 2). Though either of the O atoms in the Al-O-Al, Al-O^- or surface OH group on the dehydrated aluminas was regarded as the adsorption site of BF_3, it was demonstrated that a greater part of the BF_3 adsorbed on the surface OH group to form Brönsted acid centers. However, it can also be assumed from the results shown in Table 5 that BF_3 generally coordinates with the O atoms in Al-O^- or Al-O-Al to strengthen the Lewis acidity on the surface, especially on the alumina dehydrated over 700°C. It is believed that Brönsted centers on alumina, if present at all, are of a very low acid strength. The Lewis acid centers of the dehydrated alumina can be best explained by not-fully-coordinated aluminum atoms, and their formation during calcination can be pictured by the model suggested by Hindin and Weller:[14]



As to the effect of the surface properties of alumina, such factors as the number of Lewis acid centers, besides the concentration and acidic behavior of each remaining surface hydroxyl group, must be causes of the difference in the catalytic activities with the aluminum oxides promoted by BF_3 complex formation, as is shown in Table 6.

As has been mentioned above, in the effective sites of a series of BF_3-treated aluminum oxides there are a considerable number of Brönsted centers and a small number of Lewis centers, and these acid centers are responsible for the acid-catalyzed reactions in this work. These catalytic activities correspond well to the *n*-butylamine acidity in the presence of a Hammett indicator rather than an arylmethanol indicator. Although some arylmethanol indicators are believed to be converted to their respective acid forms on Brönsted acid centers, as has been discussed by Hirschler,[15] it is an open question whether their butylamine titers are equal to the number of Brönsted centers; the Lewis center, if present, should also be taken into consideration, as should other adsorption sites of the amine. It is also demonstrated that the activity and product selectivity in the isomerization of 1-butene differ considerably depending upon their respective precalcination temperatures. This is largely due to the difference in the nature of active centers, as was described in a recent work.[16]

Ultrasonic Absorption in Solutions of Propionic Acid

Nobuhide TATSUMOTO, Takayuki SANO, Norihiko MATSUNAGA,
Eiso TOCHIGI, and Tatsuya YASUNAGA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received October 20, 1971)

The effect of a solvent on the ultrasonic relaxation of propionic acid has been studied. The relaxation frequency is affected a little in hydrophilic solvents, while in non-hydrophilic solvents it shifts to a higher-frequency side. The activation enthalpy in a reaction from open to cyclic dimers decreases with dilution in the non-hydrophilic solvents; the magnitude of the change in the hydrophilic solvents is less than in the non-hydrophilic solvents. This means that the open dimer is destabilized by non-hydrophilic solvents. The sequence of the magnitude of the solvent effect on the relaxation frequency is consistent not with that estimated from the magnitude of the dielectric constant of the solvent, but with that estimated from the magnitude of the non-hydrophilic strength of the solvent. The stability of an open dimer in a hydrophilic or polar solvent is attributed to the interaction of the free OH group on the open dimer with the solvent.

The present authors have previously reported that the mechanism of ultrasonic relaxation in solutions of propionic acid[1] and other carboxylic acids[2] is associated with the perturbation of the equilibrium between the cyclic and open dimers formed by intermolecular hydrogen bonding between carboxyl groups. It was reported there[1] that the relaxation frequency increased with the dilution for various solvents. A similar result has also been observed for acetic acid

1) N. Tatsumoto, *J. Chem. Phys.*, **47**, 4561 (1967).
2) T. Sano, N. Tatsumoto, T. Niwa, and T. Yasunaga, This Bulletin, in press.

by Piercy and Lamb.[3] One purpose of this paper is to study in more detail the effect of solvents on the relaxation in solutions of propionic acid. The solvents used are dioxane, methyl propionate, benzene, chlorobenzene, cyclohexane, and xylene.

Experimental

The measurements of ultrasonic absorption in various solutions were made over the frequency range from 2.5 to 95 MHz, at various temperatures from 15 to 35°C, by the pulse method. The apparatus and experimental techniques have been fully described in a previous paper.[1] The velocity of sound at 1.92 MHz was measured with a sing-around system produced by Cho Onpa Kogyo Kaisha (Tachikawa, Tokyo, Japan), model UVM-2-1, and that at 3.00 MHz, with an ultrasonic interferometer. The experimental procedures have also been described in previous papers.[4] The dielectric constant was measured with the bridge method at 200 kHz. The chemical shift of the acid proton of propionic acid in NMR was measured at 34°C in various solvents, where tetramethylsilane was used as the reference. The chemicals used were all guaranteed reagents and were used without further purification except in the case of propionic acid. Propionic acid was purified by fractional distillation under reduced pressure.

Results and Discussion

As is shown in Fig. 1, the ultrasonic absorption in solutions of propionic acid in various solvents can be represented by a single relaxation equation:

$$\alpha/f^2 = \frac{A}{1+(f/f_m)^2} + B \qquad (1)$$

where α is the ultrasonic absorption coefficient; f, the frequency of sound; f_m, the relaxation frequency, and

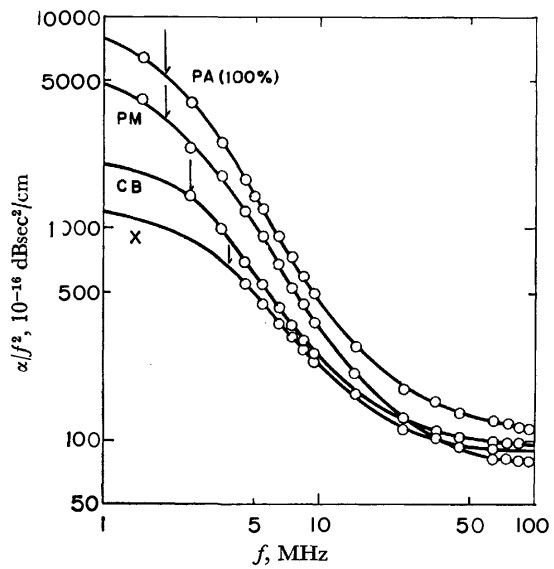

Fig. 1a. Ultrasonic absorption spectra in various solvents at 20°C: PA (100%), 100% propionic acid; PM, in methyl propionate; CB, 10M in chlorobenzene; X, 10M in xylene.

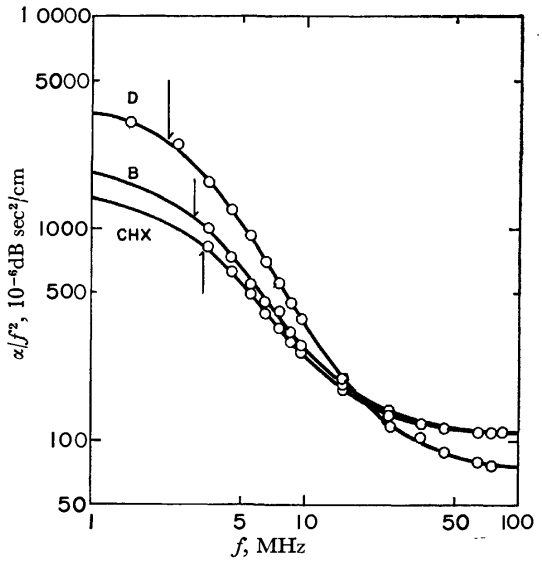

Fig. 1b. Ultrasonic absorption spectra at 20°C: D, 10M in dioxane; B, 10M in benzene; CHX, 10M in cyclohexane.

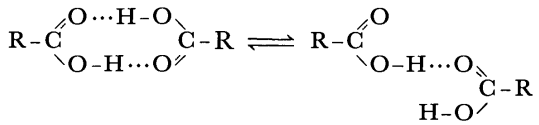
A, and B, the chemical and classical absorptions respectively. The values of f_m calculated from the experimental data are listed in the table. In Fig. 2, the relaxation frequencies are plotted against the concentrations. As can be seen in Fig. 2, the relaxation frequency, f_m, does not change with the concentration in methyl propionate, but it decreases in dioxane, chlorobenzene, benzene, cyclohexane, and xylene. The magnitude of its change with the concentration increases in the order noted. Since the relaxation frequency changes monotonously with the concentration, it is highly probable that the relaxation mechanism in those solutions is identical with that in liquid propionic acid itself. The relaxation mechanism may, therefore, be associated with an equilibrium:



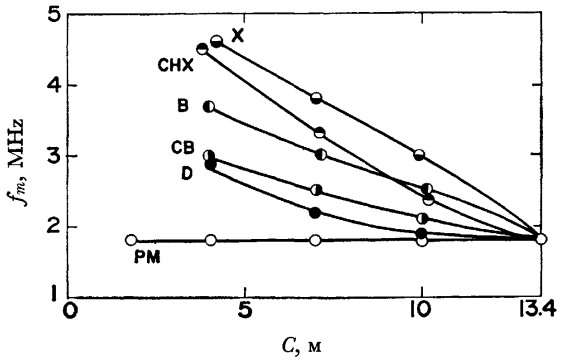


Fig. 2. Changes in relaxation frequencies at 20°C with concentration of propionic acid in various solvents:
○ PM, methyl propionate;
● D, dioxane;
◑ CB, chlorobenzene;
◐ B, benzene;
◓ CHX, cyclohexane;
◒ X, xylene.

The relaxation time, τ, in this reaction is represented by this equation:

$$\tau^{-1}=2\pi f_{inf}\ (C_V^{\infty}/C_V^0)=k_f+k_b\simeq 2\pi f_m \qquad (2)$$

where f_{inf} is the frequency of the inflection point in the curve of the dispersion of the sound velocity; C_V^0, the heat capacity at a constant volume and at zero frequency; C_V^{∞}, the heat capacity at an infinite frequency, and k_f and k_b, the forward and backward rate constants respectively.

When the reaction in this solution is principally one involving enthalpy rather than volume change, the temperature change in the heat capacity resulting from the chemical reaction at a constant pressure, C_p^r, is expressed as:

$$C_p^r=\frac{H^2}{RT^2}\cdot\frac{K}{(1+K)^2} \qquad (3)$$

$$K=k_f/k_b \qquad (4)$$

The equilibrium constants, K_1 and K_2, at the temperatures of T_1 and T_2 respectively are represented as:

$$K_1/K_2=exp\left\{\frac{H}{R}\left(\frac{1}{T_2}-\frac{1}{T_1}\right)\right\} \qquad (5)$$

where H is the enthalpy of reaction. Equations (3)—(5) are used to calculate H and K from the change in C_p^r with the temperature ascertained by using experimental data for the velocity of sound, density, thermal expansion coefficient, and heat capacity at a constant pressure and zero frequency, C_p^0. The C_p^0 values for the solutions at various concentrations are determined by the interpolation using those values found in the literature and our experimental data for the solute and solvents.[1,5] The reaction rate constants, k_f and k_b, are calculated by means of Eq. (2). As can be seen in the table, k_b is much greater than k_f, and the tendencies of the changes in k_b with the concentration are similar to those in f_m, as can be seen in Fig. 3. The enthalpy of activation is given by the temperature dependence of the rate constant:

$$k/T=C\exp(-H^*/RT)\exp(S^*/R) \qquad (6)$$

where C is a constant and where H^* and S^* are the enthalpy and the entropy of activation respectively. As can be seen in Figs. 2, 3, and 5, f_m and k_b increase with the concentration, while H_b^* decreases with it. This shows that H_b^* is one of the factors changing f_m and k_b. The magnitude of the change in f_m with the concentration stands in the order of the non-hydrophilic strength rather than in that of the dielectric constants of the solvents. This means that the open dimer is stabilized by the hydrophilic solvent; this increase in the stability is probably to be ascribed to the interaction of hydrophilic groups in the solvent with the free OH groups in the open dimer. In xylene, the change in f_m with the concentration is greater than that in other non-hydrophilic and non-polar solvents, benzene and cyclohexane. This seems to be attributable to the interaction of hydrophobic groups in propionic acid with two methyl groups in the benzene ring.

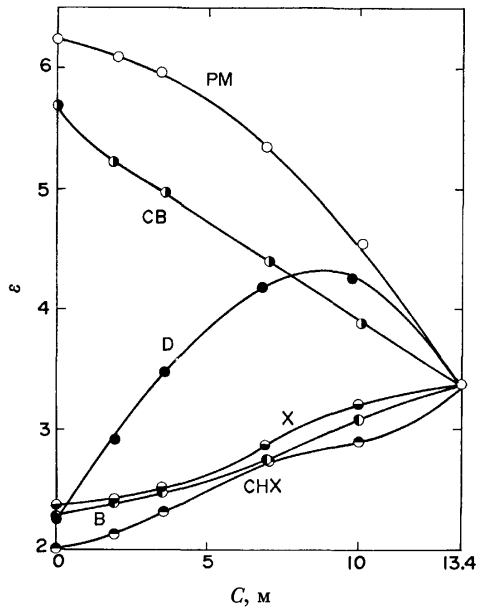

Fig. 7. Changes in dielectric constants at 20°C with concentration of propionic acid in various solvents:
○ PM, methyl propionate; ● D, dioxane; ◑ CB, chlorobenzene; ◐ B, benzene; ◓ CHX, cyclohexane; ◒ X, xylene.

Since the accuracy in H_f^* is rather poor, the change in it with the concentration will not be fully discussed here.

The energy and equilibrium constant of the reaction are listed in the table, while the changes in H and K with the concentration are shown in Figs.4 and 6. With dilution, the enthalpy of reaction, H, decreases in dioxane and methyl propionate and increases in the other solvents. From the changes in H and K with the concentration, it can be concluded that H can be regarded as a measure of the destabilization of the open dimer and K, as a measure of the stabilization. Figure 7 shows the changes in the dielectric constant with the concentration. As can be seen in the figure, they are concavo or complex curves, deviating little from the corresponding ideal straight line, for the benzene, cyclohexane, xylene, and chlorobenzene solutions, and clearly convex curves for the dioxane and methyl propionate solutions. The changes in the dielectric constants of hydrophilic solvents with the concentration, therefore, seem to be different from those of the other solvents. This is probably due to the fact that the open dimer, the dipole moment of which is greater than that of the cyclic dimer, is more abundant in the hydrophilic solvents than in the other solvents, as may be found from the changes in H and K with the concentration, as shown in Figs. 5 and 6. This conclusion is also confirmed by the NMR spectra. As can be seen in Fig. 8, the absorption of NMR shifts with dilution to the side of a higher magnetic field in the hydrophilic solvents and to the lower-side field in the non-hydrophilic solvents.

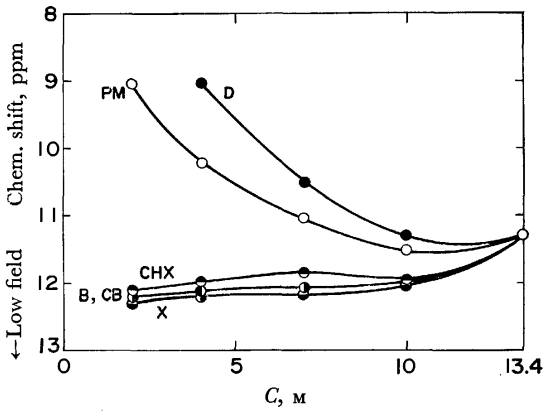

Fig. 8. Chemical shift of carboxylic acid proton in propionic acid in various solvents:
○ PM, methyl propionate; ● D, dioxane; ◑ CB, chlorobenzene; ◐ B, benzene; ◓ CHX, cyclohexane; ◒ X, xylene.

As was stated above, H increases with dilution in the non-hydrophilic solvent. This shows that the solvent effect on the open dimer decreases, until finally the value of H reaches that of the standard energy of the breakage of one hydrogen bond. The open dimer does not exist in an extremely dilute solution because of the decreases in H_b^* and K with dilution. In an extremely dilute solution, the equilibrium between the dimer and the monomer is similar to that in the gas state of propionic acid.[6] Further studies are in progress in a dilute solution of propionic acid; they will be reported in due course.

Ion-Solvent Interaction of Tetraalkylammonium Ions in Solvents of High Dielectric Constant. II. Conductance and Walden Product of Tetraalkylammonium Ions in *N*-Methylformamide and *N*-Methylpropionamide at Different Temperatures

Raj Deo SINGH and Ram GOPAL

Department of Chemistry, Lucknow University, Lucknow, India

(Received January 25, 1971)

Ion-solvent interaction of the tetraalkylammonium ions (R_4N^+) in *N*-methylformamide and *N*-methylpropionamide has been investigated from the electrical conductance point of view. It appears that the R_4N^+ ions act as net structure breakers in these solvents as in *N*-methylacetamide. The appreciable negative deviation of the experimental slope of the Λ *vs.* $\sqrt{c}$ curves from the theoretical slope suggests some kind of obstruction to the movement of the R_4N^+ ions, probably due to their unwieldy size or to some kind of cation-anion association, although the usual kind of association is ruled out in view of the high dielectric constant of these solvents. The cation-anion interaction may be the penetration of the cations by the anions which has been suggested as a possible reason for the negative slope in the apparent molal volume *vs.* $\sqrt{c}$ curves, obtained at higher concentrations, to which apparent molal volume measurements usually have to be confined on account of difficulties in accurate density measurements at low concentrations. The smaller alkali metal ions appear to be more solvated than the R_4N^+ ions, so much so that the λ_0^+-values of Na^+ and K^+ ions are lower than the corresponding values of the Me_4N^+ and Et_4N^+ ions.

Earlier studies[1,2] on the conductance of the tetraalkylammonium ions (R_4N^+) in *N*-methylacetamide (NMA) suggest that these ions are net structure breakers in this solvent. It seems desirable to extend the study to other similar solvents, such as *N*-methylformamide (NMF), *N*-methylpropionamide (NMP) which have high dielectric constant and strong hydrogen bonding. The study should give us a more general idea about the behaviour of these ions in highly polar nonaqueous solvents of high dielectric constant and strong hydrogen bonding. The study should give us a more general idea about the behaviour of these ions in highly polar nonaqueous solvents of high dielectric constant. The present communication deals with the results on the study of conductance of some R_4NI salts ($R=CH_3-$ to $R=C_7H_{15}-$) in NMF and NMP.

Experimental

R_4NI salts, obtained from M/S Distillation Products Industries, U.S.A., were purified by fractional crystallisation from suitable solvents or their mixtures.

Solvents (NMF and NMP) were purified by repeated drying over freshly ignited quicklime and vacuum distillation as for NMA. The conductivity of the samples of the solvents thus obtained was around 10^{-6} mho. Solvents were stored in dark amber-coloured bottles in a dry nitrogen box and were used, as far as possible, the day after distillation. While NMP appeared to be stable, NMF was found to be slightly unstable. Solvent correction was applied in determining the conductances of solutions. The rest of the experimental procedure and the degree of reliability of the apparatus were the same as those given in the previous communication on NMA[1].

Results and Discussion

The equivalent conductance Λ was plotted against Λ *vs.* $\sqrt{c}$ curves were found to be almost straight lines for all the R_4NI salts in NMF and NMP, within the concentration and temperature ranges studied. The Λ *vs.* $\sqrt{c}$ curves for different salts are given in Figs. 1 and 2 at one temperature only (25°C in NMF and 40°C in NMP); the curves at other temperatures are similar and hence have been omitted. Extrapolation of Λ *vs.* $\sqrt{c}$ curves to infinite dilution leads to Λ_0-values given in Tables 1 and 2. From these Λ_0-values, the ionic conductances, λ_0^+, of the R_4N^+ ions at different temperatures, were obtained, using the appropriate transport number data given in literature;[3,4] these λ_0^+-values are given in Tables 1 and 2.

The applicability of the Debye-Hückel-Onsager conductance equation to solutions under study was examined.

Hep_4NI	21.47	−13.5	−16.5	20

It is to be noted from Table 3 that there is a significant negative deviation from the theoretical slope S_T for the R_4NI salts in all the three solvents. The percentage deviation, in general, increases with the increase in the radius of the R_4N^+ ion. In view of the high dielectric constant of these solvents, incomplete dissociation of the salts in the usual sense is un-

thinkable, although Dawson and coworkers[8,9] have tried to explain their conductance results in NMA on this ground. Does this behaviour (appreciable negative deviation) indicate penetration of R_4N^+ ions by anions causing a sort of association,[10] or does it simply indicate that the solvent molecules offer a greater resistance to the movement of the R_4N^+ ions, than that caused by viscosity of the solvent medium, so that the movement of these ions is more sluggish than expected from theory? There is, apparently, no way to decide which factor is actually responsible. Since the larger the ion, the larger the deviation, one feels that the geometry and size of the ions have something to do with their sluggish movement; their tetrahedral, open structure and their large volume will favour their penetration by anions and will also cause obstruction in their movements. It should be mentioned that penetration has been ascribed as one of the factors responsible for the reported abnormal negative slope in the apparent molar volume *vs.* $\sqrt{c}$ curves of these salts in aqueous and nonaqueous solvents.[11,17] The conductance data of these salts at higher concentrations in a variety of solvents can be expected to throw further light on their behaviour.

The cationic Walden products of different R_4N^+ ions at different temperatures have been calculated from the appropriate λ_0^+-values (given in Tables 1 and 2) and viscosity data given earlier. From the Walden product data, thus obtained, $\lambda_0^+\eta_0$ *vs.* temperature curves have been drawn and are given in Figs. 3 and 4.

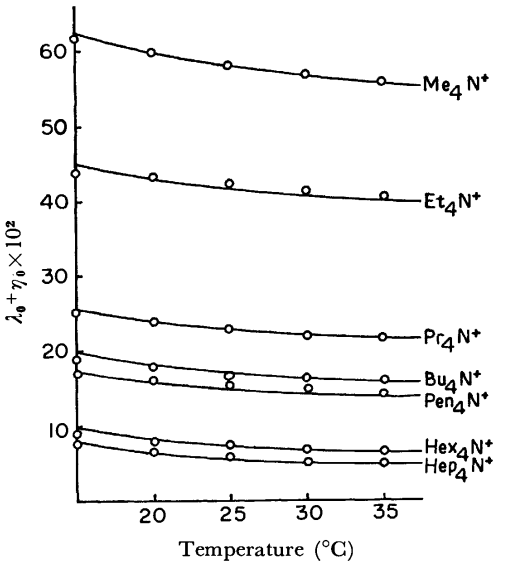

Fig. 3. Plot of $\lambda_0^+\eta_0$ *vs.* t°C in NMF.

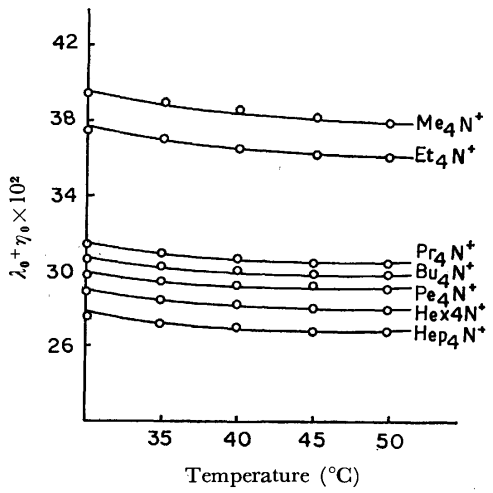

Fig. 4. Plot of $\lambda_0^+\eta_0$ *vs.* t°C in NMP.

It is obvious that the Walden product decreases with the rise in temperature in both solvents, as in NMA,[1] indicating a net structure breaking role of the R_4N^+ ions in these amides. It should be pointed out that in aqueous solutions, the dependence of Walden product on temperature indicates that Me_4N^+ ion (perhaps Et_4N^+ ion also) is a net structure breaker whereas the larger R_4N^+ ions are net structure promoters.[18]

A comparison of λ_0^+-values of R_4N^+ ions in the three solvents with those in water brings out some points of interest. Both Λ_0 and λ_0^+-values are comparatively lower in these solvents than the corresponding values in water, probably on account of the highly viscous nature of these solvents and, perhaps, due to a possible stronger ion-solvent interaction.[1,19,20] It may be noted that λ_0^+ of the smaller R_4N^+ ions are actually larger than those of the alkali metal ions, *e.g.*, in NMF at 25°, $\lambda_0(Me_4N^+)=35.45$ and $\lambda_0(Et_4N^+)=26.19$, whereas $\lambda_0(Na^+)=21.64$ and $\lambda_0(K^+)=22.20$ and in NMP at 30°, $\lambda_0(Me_4N^+)=8.66$ and $\lambda_0(Et_4N^+)=8.21$, whereas $\lambda_0(Na^+)=5.06$ and $\lambda_0(K^+)=5.36$, in spite of the much larger radii of the R_4N^+ ions. This obviously indicates a stronger solvation of alkali metal ions in NMF and NMP as compared to R_4N^+–NMF and R_4N^+–NMP interactions, as one would expect from the much higher electrical charge density on the smaller alkali metal ions. This also indicates a net structure breaking role of R_4N^+ ions and a possible structure promotion by the smaller alkali metal ions.

Faculty of Engineering, Tottori University, Koyama-cho, Tottori
(Received November 12, 1971)

The crystal structure of averufin has been determined by means of the X-ray diffraction method. The space group is $P2_1/a$, with $a=23.70$ Å, $b=7.24$ Å, $c=9.48$ Å, and $\beta=105.5°$. The structure was solved by the interpretation of the three-dimensional Patterson function and was refined by the least-squares method. The molecular structure is in agreement with that proposed by Roffey and Grandjean. In the crystal, the molecules are linked to form a molecular pair by a OH----O hydrogen bond across the center of symmetry.

Aspergillus versicolor (Vuillemin) Tiraboschi produces a number of xanthones and anthraquinones. The fact that all these metabolites are produced by the same mold leads to the postulate that some of them may be biogenetic precursors of the carsinogenic sterigmatocystin. In a previous paper, the crystal structure of *p*-bromobenzoate of sterigmatocystin was reported by Tanaka *et al.*[1]

Averufin was isolated as the metabolite of this mold by Pusey *et al.*,[2] and its chemical structure was proposed by Holker *et al.*[3] and Roffey and Sargent.[4]

The present paper will describe the crystal and molecular structure of averufin, as analyzed by means of the X-ray diffraction method, as one of a series of studies of the crystal structures of some metabolites from this mold. After this study was completed, it was discovered that the structure of averufin had been elucidated by Grandjean by means of NMR spectroscopy.[5] The molecular structure determined by us is in agreement with that proposed by Roffey and Sargent[4] and Grandjean.[5]

Experimental

The crystal grown from an acetone solution was in the form of a reddish, flat, rectangular plate elongated in the *a*-axis direction. The unit cell dimensions are shown in Table 1.

TABLE 1. CRYSTAL DATA OF AVERUFIN

Molecular formula;	$C_{20}H_{16}O_7$
	$M=368.328$
Monoclinic; space group	$P2_1/a$
	$a=23.704$Å
	$b=7.239$Å
	$c=9.483$Å
	$\beta=105.46°$
	$V=1568.3$Å^3
	d(obs)$=1.562$ g/cm^3
	d(cal)$=1.558$ g/cm^3
	$Z=4$

Mo-K_α radiation filtered by means of a zirconium foil was used to collect all the reflections in the $0<\sin\theta/\lambda<0.651$ range, within the (hkl) and $(hk\bar{l})$ octants. All the intensities were measured on a Rigaku Denki computer-controlled four-circle diffractometer (AFC-II). A scintillation counter with a pulse-height discriminator was used. Altogether, 2909 independent reflections were collected. A crystal of the approximate dimensions of $0.23\times0.22\times0.13$ mm^3 ($0.964<e^{-\mu r}<0.968$) was mounted with the *b*-axis parallel to the ϕ-axis of the diffractometer. The ω-2θ scan technique was employed, with a scan speed of 1°/min by ω, backgrounds were measured for 10 seconds at each start and end points of the scan range. The scan range for each reflection was calculated by means of the formula indicated by Alexander *et al.*[6]: ω scan range$=0.70°+0.40°\tan\theta$. Attenuators were automatically inserted when the maximum counting rate exceeded 5000 cps. The intensities were corrected only for Lorentz and polarization factors. Measurements of three reference reflections, (14 0 0), (0 0 8), and (0 4 0), were repeated every fifty reflections; for 62 repetitions of the measurements, $|F_0(14\ 0\ 0)|=144.26\pm0.33$, $|F_0(0\ 0\ 8)|=42.78\pm0.11$, and $|F_0(0\ 4\ 0)|=56.37\pm0.10$.

Determination of the Structure

The angular coordinates defining the orientation of the planar anthraquinone group in the molecule were readily established by means of the vector-set-seeking method;[7] the vector set of the anthraquinone skeleton was superposed on the three-dimensional Patterson function and rotated until the best fit was obtained. The location of this planar group in the unit cell was determined from the Patterson function, in which a large non-Harker peak is expected corresponding to the anthraquinone-anthraquinone vector from molecules related by a center of symmetry. Of several possible peaks, the one which satisfied a reasonable packing condition in the crystal and which gave the best match with the Patterson function was selected. This interpretation was proved to be correct. The 780 largest structure factors were calculated by the use of the atomic positions of the anthraquinone group only, and the *R* value defined by $R=\sum||F_o|-|F_c||/\sum|F_o|$ was 0.69. The Fourier synthesis phased by the anthraquinone group was computed. The peaks corresponding to some additional atoms were clearly visible, their peak-heights were approximately

half of those of the atoms of the anthraquinone group. The whole structure of the molecule except for the hydrogen atoms was revealed after three successive Fourier synthesis. At this stage, the R value was 0.46. The structure was refined by a diagonal-matrix least-squares procedure with the isotropic temperature factors, until the R value of 0.15 was reached. Further refinement was carried out by the least-squares of block-diagonal matrix approximations with anisotropic temperature factors, using all the reflections. The R value was thus reduced to 0.12. At this stage, the difference Fourier synthesis showed all the hydrogen atoms. The final refinement was made by including the positional parameters and the isotropic temperature factors of the hydrogen atoms, where upon the R value decreased to 0.083. The final atomic parameters are listed in Tables 2 and 3. The final electron density map is shown in Fig. 1. The difference electron density map, for which the contributions of the hydrogen atoms were excluded from the calculated structure factors, is shown in Fig. 2.

A list of the observed and calculated structure factors is available from the authors on request.

Most of the calculations were done on the TOSBAC-3400 by the use of the programs written by the authors. The block-diagonal least-squares refinement was performed on the HITAC 5020E of the university of Tokyo using a program written by T. Ashida, the weighting scheme in the calculation was $w=1.0$ for reflections with $|F_o|\geq 1.5$ and $w=0.5$ for the others. The atomic scattering factors were taken from Ref. 8.

Description of the Structure and Discussion

The bond lengths and bond angles are given in Table 4. The mean bond length of the carbon-carbon bonds in the benzenoid rings is 1.393 Å, which is the same as the length, 1.397 Å, formed in the benzene ring[9] within the limits of error. However, the lengths of C–C bonds adjacent to the quinonoid carbonyl bonds, C(4)–C(5), C(5)–C(6), C(11)–C(12), and C(12)–C(13), are considerably longer than those in the benzenoid rings. The lenghts of the C(12)–O(7) and C(5)–O(4) of the quinonoid carbonyl bonds are 1.219 Å and 1.252 Å respectively. The former agrees well with the C–O bond length in acetaldehyde (1.215)[9] and may be a normal double bond. The latter is longer than the former, the elongation of the latter bond may be due to the influence of the adjacent hydroxyl groups. The lengths of the C–O bonds attached to the anthraquinone skeleton, C(1)–O(1), C(3)–O(3), C(7)–O(5), and C(9)–O(6), are almost constant and have a mean of 1.351 Å. All are in agreement with the length of a single bond between an oxygen and an sp^2-hybridized carbon atom.

The dimensions of the quinonoid group in the averufin show features similar to those in other related molecules whose structures have been studied: *p*-benzoquinone,[10] anthraquinone,[11] 1,5-dihydroxyanthraquinone,[12] 1:2,5:6-dibenzanthraquinone,[13] and some derivatives of anthraquinone.[14]

There are no significant differences among the five bond lenghts of C(sp^3)–C(sp^3), and the mean value (1.515 Å) is shorter than that of a pure single C–C bond. The lengths of the C–O bonds involving C(sp^3) have a mean of 1.435 Å and agree with the C–O single bond distance.

The least-squares plane for the aromatic condensed ring including O(3) to O(7) can be represented by the equation:

$$Z=1.3981X+0.6983Y+3.2390$$

where $X=ax+cz\cos\beta$, $Y=by$, and $Z=cz\sin\beta$. The perpendicular displacements of the atoms from the plane are given in Table 5. As may be seen in Table 5, these atoms are coplanar.

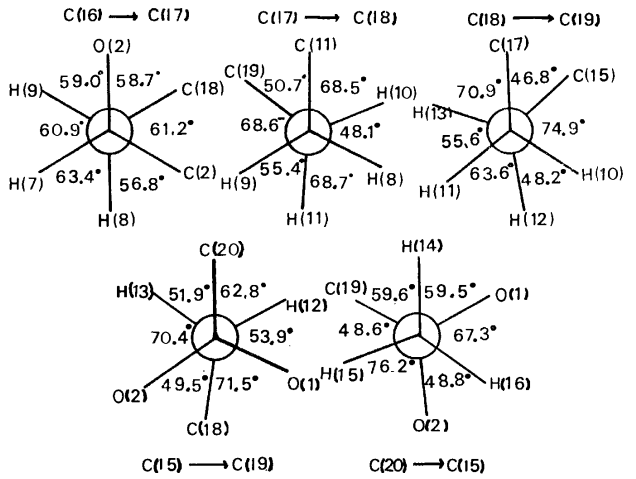

Fig. 4. Internal rotation angles.

The π-bond orders were obtained from a simple LCAO molecular orbital treatment (simple Hückel's method) for the π-electron system alone. The set of Coulomb and exchange integral values suggested by Pullman[15] were used. There are:

$$\alpha(\mathrm{C})=\alpha_0,\ \alpha(=\mathrm{O})=\alpha_0+1.2\beta_0,\ \alpha(-\mathrm{O}-)=\alpha_0+2.0\beta_0,$$
$$\beta(\mathrm{C}-\mathrm{C})=\beta_0,\ \beta(\mathrm{C}=\mathrm{O})=2.0\beta_0,\ \beta(\mathrm{C}-\mathrm{O})=0.9\beta_0$$

where α_0 is the Coulomb integral of the carbon atom in the benzene and whose β_0 is the exchange integral of the C–C bond in the benzene. The lengths of the C–C bonds were estimated from the existing bond order-bond length curve.[16] In the C–C bonds, the agreement between the calculated and observed bond lengths is within 0.02 Å. The lengths of the C–O bonds were not predicated in the present work, because the C–O bond order–bond length data generally have a much wider range of values than the corre sponding curve for the C–C bond. The results of the MO calculation are given in Fig. 3.

The conformation of the six-membered ring, C(16)–C(17)–C(18)–C(19)–C(15)–O(2), is a chair form. The internal rotation angles around the C(sp^3)–C(sp^3) bonds are illustrated in Fig. 4. They show a stable, staggered conformation. The average bond angle at the C(sp^3) is 109.8°, and that at the C(sp^2) is 119.9°. The C(15)–O(2)–C(16) angle in the six-membered ring of the chair form is 112.4°; this agrees well with the corresponding angles in sugars.[17] There are two

intramolecular hydrogen bonds of the OH···O type: O(3)···O(4)=2.56 Å and O(4)···O(5)=2.55 Å. The molecule has, therefore, the conformation which might be expected to have the lowest energy. A stereoscopic drawing of the molecule is given in Fig. 5.

The crystal structure projected along the *b*-axis is shown in Fig. 6. The closest intermolecular distances are listed in Table 6. The reference molecule at (x, y, z) is connected by the intermolecular hydrogen bond of OH···O of 2.79 Å with the molecule at ($-x$, $1-y$, $1-z$), thus forming a pair of molecules across the center of symmetry. Although the molecule itself has two asymmetric centers, the crystal of averufin is racemized by the molecules related by the centers of symmetry. The intermolecular approach distance between O(3) and O(3) in the "*b*-molecule" is 2.81 Å. Although this distance corresponds to the sum of the van der Waals radii, it is less than the intermolecular O···O distances found in common compounds and compares with the rather long intermolecular hydrogen bonds. Such a close distance has been found in 1,5-dihydroxyanthraquinone: according to Hall *et al.*,[12] this intermolecular interaction is due to the proton of the hydrogen atom in the hydroxyl group, which may participate in the interactions among the closest oxygen atoms. However, in averufin, it appears that the approach of these oxygen atoms may correspond to the van der Waals interaction, because the hydrogen atom attached to the O(3) atom may participate only in the formation of the intramolecular hydrogen bond.

The other intermolecular distances require no special comment; all correspond to the normal van der Waals interaction.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2096—2100(1972)

The Electrical Properties of Iodine Complexes of *N*-Methyl- and *N*-Ethyl-phenothiazines and Their Mixtures

Kazuo KAN* and Yoshio MATSUNAGA**

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received January 7, 1972)

The electrical resistivities and Seebeck coefficients of 2: 3 iodine complexes of *N*-methyl- and *N*-ethyl-phenothiazines were measured. The former complex exhibits a resistivity of 2.0 ohm cm and an activation energy for semiconduction of 0.20 eV at 20°C. Applying the equation of Johnson and Lark-Horowitz for the Seebeck coefficient of an intrinsic semiconductor, the ratio of the electron mobility to the hole mobility in the *N*-methyl-phenothiazine complex was found to be 2.08 and the electron mobility was estimated as 0.23 $cm^2/Vsec$. The resistivity of the *N*-ethylphenothiazine complex is 74 ohm cm, and the activation energy 0.15 eV at 20°C. In this complex, the hole appears to be more mobile by a factor of five than the electron. Lichtenecker's logarithmic rule is observed neither by the resistivity nor by the activation energy of the mixtures of these two complexes.

N-Methyl-phenothiazine has been found by one of the present authors to form a 2: 3 iodine complex exhibiting an electrical resistivity as low as 1.4 ohm cm at room temperature.[1] As this value is only about one-tenth of the resistivity shown by the iodine complex of the unsubstituted donor, it seemed that a further examination of the size effect of the alkyl group on the electrical properties would be interesting. A preliminary study of this problem indicated an increase in the resistivity upon the introduction of larger alkyl groups.[2] However, the comparison made in that study was merely qualitative because no complexes with a definite composition were isolated. Here, we wish to report a comparison of the resistivities and Seebeck coefficients of 2: 3 iodine complexes of *N*-methyl- and *N*-ethyl-phenothiazines in order to see how the introduction of a larger group modifies the properties.

According to Lichtenecker, a logarithmic rule ap-

plies for the resistivity value when two non-interacting materials are mechanically mixed.[3] The essential expression derived by him is:

$$\rho_m = \rho_1^{1-x}\rho_2^{x} \quad (1)$$

where ρ_m is the resistivity of the mixture; ρ_1 and ρ_2 are the resistivities of the respective components, and x is the volume fraction of the second component. If the materials are semiconductors, we obtain:

$$\rho_m = \rho_{01}^{1-x}\rho_{02}^{x} \exp\{[(1-x)E_1 + xE_2]/kT\} \quad (2)$$

where ρ_{01} and ρ_{02} are preexponential factors of the components and where E_1 and E_2 are the respective activation energies for semiconduction. Recently, Ulbert has studied the electrical properties of mechanical mixtures of two chemically-stable organic semiconductors, 4,4′-bis(dimethylamino)-diphenylamine iodide and the iodine complex of *N*,*N*′-bis(aminophenyl)-*p*-phenylenediamine.[4] The generalized logarithmic rule, Eq. (2), has been well observed not only by the resistivity but also by the activation energy of the mixtures. Therefore, we examined the properties of the mixtures to see whether or not the same rule applies to the present iodine complexes.

Experimental

Materials. The *N*-alkyl-phenothiazines were prepared by the reaction of the corresponding alkyl iodide on phenothiazine following the procedure given by Bernthsen.[5] The complexes were precipitated by mixing the components dissolved in ether. As was described in our earlier paper, the complexes dissociate into their components when dissolved in benzene, so the compositions were determined by iodometric titration.[1] For the examination of the (*N*-methyl- and *N*-ethyl-phenothiazines)-iodine, the weighed complexes were thoroughly mixed by grinding in an agate mortar. Samples with the following volume percents of the *N*-ethyl-phenothiazine complex were prepared: 13.5, 27.1, 44.7, 49.4, 58.2, and 72.6.

Measurements. The resistivities of compressed polycrystalline samples were measured by a potential probe method in the range from −90°C to room temperature. Below the lower limit, the contact between the pellet and the probe became too sluggish for any reliable measurements to be made. The pellet and its holder were accommodated in a thick copper cylinder and cooled with liquid nitrogen. When the temperature of the sample had been lowered enough, the whole was transferred into an empty Dewar and allowed to warm up slowly to room temperature. During this process, the temperature of the holder was recorded on the X axis of a Yokogawa X–Y recorder, Type 3078, and the potential drop between the probes and that in the standard resistance, on the Y_1 and Y_2 axes respectively.

The Seebeck voltage measurements were carried out on the same pellets as those employed for the resistivity measurements. In this mounting, the faces painted with colloidal graphite were clamped between copper electrodes. The temperatures on the upper and lower faces of the pellet were measured by means of copper-constantan thermocouples attached to the electrodes. The Seebeck coefficient observed with a dried colloidal graphite block was 1—3 μV/deg over the entire temperature range; therefore, no correction was made for the following data. The temperature difference between the two faces was not controlled except near room temperature; it ranged from 10 to 30°C. The limit of the measurable low temperature, the mean value of those temperatures at the two faces, was about −130°C. The measurements were made by recording the Seebeck voltage on the X axis and the thermocouple potentials on the Y_1 and Y_2 axes.

The densities of the complexes were determined from the pellets.

Results and Discussion

The complexes of *N*-methyl- and *N*-ethyl-phenothiazines consist of two molecules of thiazine and three of iodine. The former complex is black, and the latter dark green. They melt at 72° and 74.5°C respectively. In Fig. 1 the logarithm of the resistivity is plotted

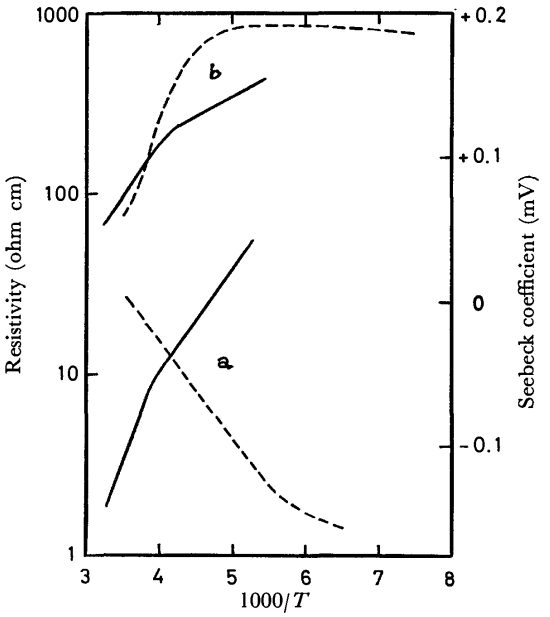

Fig. 1. Electrical resistivities (——) and Seebeck coefficients (----) of (a) *N*-methyl-phenothiazine-iodine and (b) *N*-ethylphenothiazine-iodine complexes.

against the reciprocal temperature. The plot gives two straight lines, with a break around −70°C in both cases. The activation energy for semiconduction, calculated on a basis of:

$$\rho = \rho_0 \exp(E/kT) \quad (3)$$

is 0.20 eV in the higher temperature region and 0.11 eV in the lower temperature region of the curve for the *N*-methyl-phenothiazine-iodine complex. In our earlier work, the activation energy was estimated as 0.14 eV by measurements over a rather narrow temperature range (from 0 to 40°C). This value must be compared with that of 0.20 eV obtained in the present work. The resistivity value at 20°C is 2.0 ohm cm; it is in reasonable agreement with the previously-reported one, 1.4 ohm cm. Similarly, 0.15 and 0.045 eV can be estimated for the *N*-ethyl-phenothiazine-iodine complex. The resistivities at 20°C and the activation energies at this temperature are summarized in Table

a) By extrapolation of the Seebeck coefficient curve in the higher temperature region.

1. The values for the phenothiazine-iodine complex, taken from our previous papers are included for the sake of comparison.[1,6] The results clearly indicate that the methyl substitution makes the arrangement of thiazine molecules in the iodine complex the optimum for electrical conduction. When the size of the group on the nitrogen atom is either smaller or larger, the overlapping of the thiazine molecules appears to decrease, resulting in an increase in the resistivity. Effects of such a size have been noted in several works on anion-radical salts derived from tetracyanoquinodimethane and also those derived from tetrahalo-*p*-diphenoquinones.[7-10] It is interesting to note that, contrary to the iodine complexes, the 2,3-dichloro-5,6-dicyano-*p*-benzoquinone complex of *N*-methyl-phenothiazine was found to have a resistivity about ten times higher than that of unsubstituted phenothiazine.[2,11] A compensating relation between the activation energy and the logarithm of resistivity has been frequently pointed out when a series of compounds, such as a series of derivatives of a given compound, is examined.[12-14] From this standpoint, the present complexes are rather anomalous. The most conducting *N*-methylphenothiazine complex is found to exhibit the highest activation energy for semiconduction.

The temperature dependence of the Seebeck coefficient, Q, is also presented in Fig. 1. First of all, the change in the sign by the kind of alkyl group must be noted; that is, the coefficient of the *N*-methyl-phenothiazine complex is negative except near and above room temperature, while that of the *N*-ethyl-phenothiazine complex is positive over the whole measurable range. A further observation of the alternation of the sign by the substituent is provided by the experiment on the phenothiazine-iodine complex, the Seebeck coefficient of which is positive (about 0.15 mV/deg in the vicinity of room temperature).[15] It must be added that the sign of the Seebeck coefficient in the phenothiazine-iodine system has been reported by Bhat and Rao to vary with the donor-acceptor ratio.[16] The following values, measured at 30°C, have been presented by them: +0.132 mV/deg at a composition of 1:3, −0.150 mV/deg at 1:1, and +0.300 mV/deg at 3:1. Unfortunately, none of the compositions mentioned here corresponds to the 2:3 stoichiometry reported by us and also by Gutmann and Keyzer.[1,6,17]

The higher-temperature region of the curve is practically straight and seems to fit in with the expression for the thermoelectric motive force of an intrinsic semiconductor:[18,19]

$$Q=-\frac{k}{e}\left[\frac{b-1}{b+1}\left(\frac{E_G}{2kT}+2\right)+\frac{3}{4}\ln\frac{m_e}{m_h}\right] \quad (4)$$

where E_G is the width of the forbidden band and where m_e and m_h are the effective masses of the electron and the hole respectively. In this equation, b denotes the ratio of the electron mobility, μ_e, to the hole mobility, μ_h; it is given by:

$$b=\frac{\mu_e}{\mu_h}=\left[\frac{E_G}{2}-\frac{\Delta Q}{\Delta(10^3/T)}\right]\left[\frac{E_G}{2}+\frac{\Delta Q}{\Delta(10^3/T)}\right]^{-1} \quad (5)$$

provided that Q is measured in mV. The application of these two equations implies that we should accept the band model as a basic work hypothesis. In the case of the *N*-methyl-phenothiazine complex, b is evaluated as 2.08, assuming that $E_G/2=0.20$ eV. As is shown in Fig. 1, the change of the sign is observed at $10^3/T=3.60$. Therefore, m_e/m_h can be estimated to be about 130 by means of Eq. (4). The values obtained for the *N*-ethyl-phenothiazine complex are listed in Table 1. The conductivity, σ, is given by:

$$\sigma=\frac{1}{\rho}=e(\mu_e+\mu_h)N\exp(-E/kT)=e\mu_e\left(\frac{b+1}{b}\right)N\exp(-E/kT) \quad (6)$$

where $N=2.53\times10^{22}$ *N*-methyl-phenothiazine molecules or 2.30×10^{22} *N*-ethyl-phenothiazine molecules per cm^3 of the complex. With the values given in Table 1, the electron mobility in the *N*-methyl-phenothiazine complex is estimated as 0.23 cm^2/Vsec. This value falls right on the borderline between the band and hopping conduction and is of the same order as the only known Hall mobility observed with iodine complexes.[20] On the other hand, the hole mobility in the *N*-ethyl-phenothiazine complex is estimated to be smaller by a factor of hundreds. The width of a forbidden band is expected to reflect the strength of the interactions amongst the molecular orbitals; this strength, in turn, depends upon the degree of overlap of the orbitals. When the overlap is poor, the band is narrow

and the carrier mobility is low. Consequently, both the small activation energy and the high resistivity observed in the *N*-ethyl-phenothiazine complex may be attributed to the poor overlapping of the thiazine molecules.

The slope of the Seebeck coefficient curve of the *N*-methylphenothiazine complex gradually becomes smaller in the temperature region which is markedly lower than the break observed in the resistivity curve. In the lower temperature region, the complex may be considered as an extrinsic semiconductor. The Seebeck coefficient may be expressed by:

$$Q=\pm\frac{k}{e}\left\{2+\ln\left[2\left(\frac{2\pi m^{*}kT}{h^{2}}\right)^{3/2}\right]-\ln c\right\} \quad (7)$$

where c is the concentration of the free electron or the hole, depending upon which is the major carrier and where m^{*} is the effective mass of the carrier. If kT is relatively small compared with the energy difference, ΔE, between an impurity level and the edge of the conduction or valence band, Q can be approximated by:

$$Q=\pm\frac{k}{e}\left[C+\frac{3}{2}\ln(kT)+\Delta E/2kT\right] \quad (8)$$

where C represents all the terms independent of the temperature. This expression is for a semiconductor with a partially-ionized impurity level. The (3/2) $\ln(kT)$ and $\Delta E/2kT$ terms vary in the opposite direction with respect to the temperature. As was pointed out by Hadek and Ulbert, a relatively good compensation between these two terms can be expected when the activation energy, $\Delta E/2$, is about 0.02 eV.[21] If we assume that the activation energy estimated by the resistivity measurement in the lower temperature region is valid even in the lower temperature region of the Seebeck coefficient curve, the change due to the former term can be expected to be overbalanced by that due to the latter, in accordance with the observations. However, the agreement is only qualitative. For example, the slope in the unit of $\Delta Q/\Delta(10^{3}/T)$ is calculated by Eq. (8) to be about 0.08 mV if $\Delta E/2=0.11$ eV. This value cannot be differentiated from the slope found in the higher temperature region. Unless the change in the activation energy occurs below the lower limit of the resistivity measurement, the observed slope is in serious disagreement with the calculated one. In the case of the *N*-ethyl-phenothiazine complex, the changes in the slope of the Seebeck coefficient curve are found around -15 and -50°C ($10^{3}/T=3.9$ and 4.5). None of them is located close to the break in the resistivity curve. The observed slope in the intermediate temperature region, 0.18 mV, is appreciably higher than that given by Eq. (8) with $\Delta E/2=0.045$ eV. Thus, it appears to be difficult to explain the Seebeck coefficient in the lower temperature region by the band model. This conclusion is not surprising if we consider the values of the carrier mobilities estimated above.

The resistivity-composition isotherms at $10^{3}/T=3.5$ and 4.5, where the component complexes may be supposed to behave as intrinsic and extrinsic semiconductors

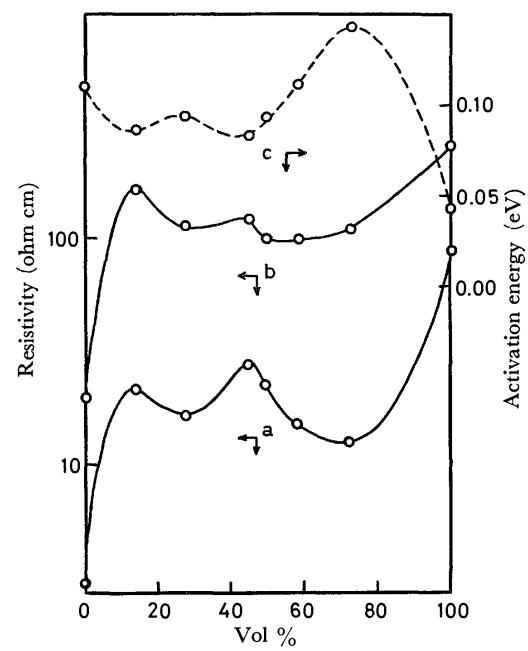

Fig. 2. Resistivities at (a) $10^{3}/T=3.5$ and (b) $10^{3}/T=4.5$ and (c) activation energies for semiconduction in the lower temperature region determined for the mixtures of iodine complexes of *N*-methyl- and *N*-ethyl-phenothiazines.

respectively, are presented in Fig. 2. Clearly, the present system does not obey Lichtenecker's logarithmic rule. The resistivity of the mixture at room temperature is much higher than that given by Eq. (1) when the volume percent of the *N*-ethyl-phenothiazine complex is less than 50%, and much lower when the percent is higher than 50%. In other words, the resistivity of the component complex is much more sensitive to the addition of a small amount of the other one than one would expect from Eq. (1). The resistivity exhibits a rather complicated temperature-dependence near room temperature; therefore, the relationship between the activation energy and the composition cannot be obtained.

When the temperature is lowered below -20°C ($10^{3}/T=4.0$), straight lines are obtained in the resistivity curve of all the mixtures. The isotherm at $10^{3}/T=4.5$ bears some resemblance to that observed in the higher temperature region. The deviation from Eq. (1) is small when the percent of the *N*-ethyl-phenothiazine complex is high; however, such a coincidence is accidental. As is plotted in Fig. 2, the activation energy does not obey Eq. (2), but depends, in a complicated way, on the composition. A marked maximum in the activation energy is found around 75% (see Curve *c* in Fig. 2); therefore, the resistivity-composition isotherm gives a large positive deviation from Eq. (1) in the entire composition if measured below -70°C ($10^{3}/T=5.0$). As a result, an increase in the resistivity of the *N*-ethyl-phenothiazine complex by the addition of a small amount of the *N*-methyl-phenothiazine complex is observed in such a temperature range. In addition, it must be noted that the shallow minimum around 30% in the resistivity-composition isotherm becomes less pronounced upon cooling. This change arises partially from the shift of the minimum at a

21) V. Hadek and K. Ulbert, *Coll. Czech. Chem. Commun.*, **32**, 1118 (1967).

higher content of the *N*-ethylphenothiazine complex to about 50%. The remarkable difference in the electrical properties between Ulbert's mixed system and ours must be attributed to the interaction of the two complexes in the latter system. As the room temperature is as high as 0.85 T_m, where T_m is the melting point given in °K, it is very likely that mixing results in the mutual, possibly partial, dissolution of the complexes.

Light-scattering Studies of the Interaction between Bovine Serum Albumin and Guanidine Hydrochloride in Aqueous Solutions[1)]

Masayuki NAKAGAKI and Yoh SANO
Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto

(Received January 25, 1972)

The denaturation of bovine serum albumin (BSA) by guanidine hydrochloride (GuHCl) was studied by means of the light-scattering method. The Zimm plots were curved so that apparently imaginary values of the radius of gyration were obtained, but the modified Zimm plots, drawn by applying the correction factor for the optical anisotropy of segments, gave reasonable values of the weight-average molecular weight, the radius of gyration, and the second virial coefficient. The correction factor was calculated by using the experimental values of the scattering ratio at 90° of the scattering angle. The analysis of the intrinsic viscosity showed that the BSA molecules were elongated. According to these results, it has been concluded that the BSA molecules are streched by the denaturation the more as the GuHCl concentration is higher, and that the denatured BSA molecules, at first, form dimers by the side-by-side aggregation of two molecules, but that the intermolecular bindings, too, are broken with the further addition of GuHCl. The length reached at 5M GuHCl was about 1/5 of the fully stretched length. This suggests the possibility that the denatured BSA molecules can keep their local natural conformations.

It has been well established that proteins form complexes with various kinds of molecules and ions. The interaction between bovine serum albumin and sulfamines has also been studied by many investigators, including one of the present authors.[2)] As a continuation of these studies, the present authors intend to discuss the denaturation of bovine serum albumin (BSA) by guanidine hydrochloride (GuHCl) on the basis of a physico-chemical interpretation of the results from light-scattering measurements.

Bovine serum albumin is one of the well-studied proteins; its molecular weight is said to be about 70000, and its isoelectric is 6.4. Guanidine hydrochloride is a typical denaturating agent extensively used for various proteins. The mechanism of the denaturation is considered to involve the breaking-down of the secondary intramolecular bonds, such as ionic bonds, hydrogen bonds and hydrophobic bonds, as a result of the selective combination of GuHCl on the proteins, the conformation of the latter being changed according to the complex formation. The mechanism of the denaturation, however, has not yet been made very clear, particularly in relatively low concentrations of the denaturating agent or in the earlier stages of the denaturation process.

In the present investigation, the denaturation of BSA by GuHCl in aqueous solutions has been studied, including the low concentration range of the latter. The experimental method mainly used was light-scattering measurements, which were undertaken with particular attention paid to the following two points: (1) the variation in the refractive index increment, $(\partial n/\partial c)$, due to the complex formation, and (2) the deformation of the so-called Zimm plots due to the optical anisotropy of segments of the macromolecules.

Experimental

Materials. The guanidine hydrochloride used was a guaranteed reagent supplied by Nakarai Chemicals, Ltd. A solution of 6M was prepared gravimetrically, and from it solutions of various concentrations were prepared volumetrically.

The bovine serum albumin used was Fraction V from Armour Co. Ltd. (No. G5717, D. 1029), the same as that used in the previous paper.[3)] The concentration of BSA was determined by measuring the optical density at 278 mμ by means of a Shimadzu photoelectric spectrometer QR-50 with quartz cells 1 cm thick.

Water was distilled, refined by ion-exchange resin, and distilled again with an all-glass still.

Scattered Light Intensity. The method of the light-scattering measurements was the same as in the previous paper.[3)] A Shimadzu electrophotometric light-scattering photometer, PG-21, was used at 436 mμ and at 25°C. The

reduced scattering intensity for unpolarized incident light, $R_u(\theta)$, was obtained and examined by the Zimm plot method, where θ is the scattering angle. The solutions and the solvent for the light-scattering measurements were made optically clear by ultrafiltration with Membrane Filter No. 15 from Sartorius Co., Ltd. It has been ascertained that the concentration of BSA does not change upon the ultrafiltration.

Scattering Ratio. The measurements were made by using the light-scattering photometer described above. The photometer was, for this experiment, equipped with a polarizer but not with an analyzer. The direction of the vibration of the electric vector of the light which passed through the polarizer was determined by using a reflecting glass plate set perpendicular to the plane of observation, for the intensity of the reflected light is greatest when the light vibrates perpendicularly to the plane of observation. The scattering ratio, $S(\theta)$, defined by the following equation:

$$S(\theta)=J_{//}(\theta)/J_{\perp}(\theta) \quad (1)$$

was determined, rotating the polarizer by 90°, where $J_{//}(\theta)$ and $J_{\perp}(\theta)$ are the Rayleigh ratios for incident beams vibrating, respectively, parallel to and perpendicular to the plane of observation, the latter being the plane containing the incident and scattered beams.

Refractive Index Increment. The measurements were made by means of a Shimadzu photoelectric differential refractometer, DR-3 type (Brice type) at 436 mμ and at 25°C, according to the method described in the previous paper.[3]

Two kinds of refractive index increment, ϕ_c and ϕ_μ, are defined as follows:

$$\phi_c=(\partial n/\partial c_2)_{T,P,c_3} \quad (2a)$$

$$\phi_\mu=(\partial n/\partial c_2)_{T,P,\mu_3} \quad (2b)$$

where n is the refractive index of the solution, T is the temperature, P is the pressure, and c_2 and c_3 are the concentrations in g/ml of BSA and GuHCl respectively. The ϕ_c quantity is measured by diluting a mixed solution of BSA and GuHCl with a GuHCl solution whose concentration is the same as in the mixed solution. The ϕ_μ quantity, on the other hand, is measured by diluting it with a GuHCl solution which has been in membrane equilibrium with the mixed solution.

In the latter case, the membrane equilibrium was achieved by using a size-18/32 cellotube (diameter, 1.5 cm) of the Visking Co. It was swollen in pure water, soaked in a 0.05M EDTA solution for 30 min treated with hot water of 90°C for 30 min, washed sufficiently with pure water, and then used for the membrane equilibrium. The cellotube containing a mixed solution of BSA (about 0.5%) and GuHCl was shaken for 3 days at 25°C in an "outer" solution which contained GuHCl of the same concentration as the "inner" solution, the volume of the former being twice the latter. The concentration of GuHCl was determined by two methods: (1) by the measurement of the refractive index of the solution by means of the differential refractometer mentioned above, and (2) by the Mohr method of titrating the chloride ion with an $AgNO_3$ solution. The results of these two methods agreed well with each other. The concentration of BSA was determined spectrophotometrically, and it was ascertained that no BSA was present in the outer solution after the equilibrium.

Intrinsic Viscosity. The viscosity of the BSA solution containing GuHCl was measured by means of an Ostwald Viscometer in a thermostat at 25°C. It took about 120 sec for pure water to flow down. The intrinsic viscosity, $[\eta]$, of BSA was calculated according to the Huggins equation:

$$\eta_{sp}/(100c_2)=[\eta]+k[\eta]^2\cdot(100c_2) \quad (3)$$

where η_{sp} is the specific viscosity of the solution calculated by considering the GuHCl solution as the solvent. Here, c_2 is the concentration of BSA in g/ml, and k is the Huggins constant.

Density. A picnometer (about 35 ml) was used a 25°C. The methods of the measurements and of the analysis of the results were the same as those described in the previous paper.[3]

Results

Viscosity and Density. The viscosity, η, of the BSA solution containing GuHCl has been measured at various BSA concentrations, c_2(g/ml), by diluting the original solution with the solvent that contains GuHCl at the same concentration, [GuHCl] (M), as in the original solution. The relation between the reduced viscosity, $10^{-2}\cdot\eta_{sp}/c_2$, and the concentration of BSA, $100c_2$, is shown in Fig. 1 for various GuHCl

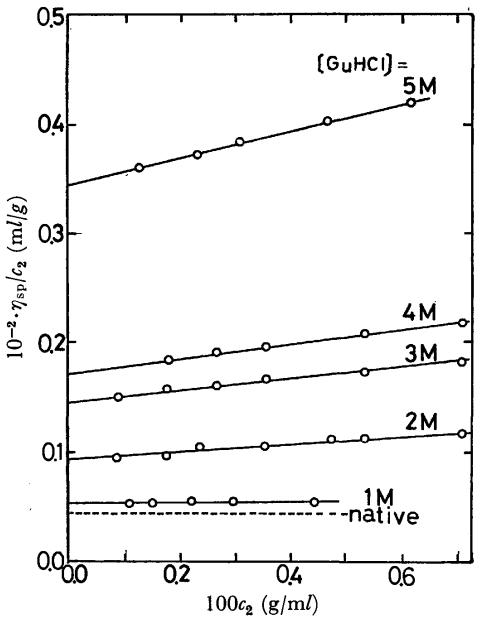

Fig. 1. Relations between the reduced viscosity and concentration of BSA for various GuHCl concentration.

concentrations. A linear relationship was seen for each case, with a good reproducibility. The dotted line in Fig. 1 is for native BSA, that is, for [GuHCl]=0. The intrinsic viscosity, $[\eta]$, the slope of the straight lines, $k[\eta]^2$, and the Huggins constant, k, obtained from these data according to Eq. (3) are shown in Table 1. The intrinsic viscosity of the denatured BSA increases

Table 1. Intrinsic viscosity and specific volume of denatured BSA

[GuHCl] (M)	$[\eta]$ (100 ml/g)	$k[\eta]^2$ (100 ml/g)^2	k	$\bar{v}_2$ (ml/g)
0	0.045	0	0	0.7265
1	0.054	0	0	—
2	0.093	0.033	3.4	—
3	0.145	0.054	2.1	0.7265
4	0.172	0.066	2.2	—
5	0.345	0.120	1.0	0.7265

with the GuHCl concentration, particularly in the range between 4M and 5M.

The partial specific volume of BSA, $\bar{v}_2$, in GuHCl solutions did not vary with the concentration of the latter; the average value was 0.7265 ml/g, as is shown in Table 1. This is in accord with the fact that the partial specific volume of BSA does not change upon the addition of urea, as has been reported in the literature.[4]

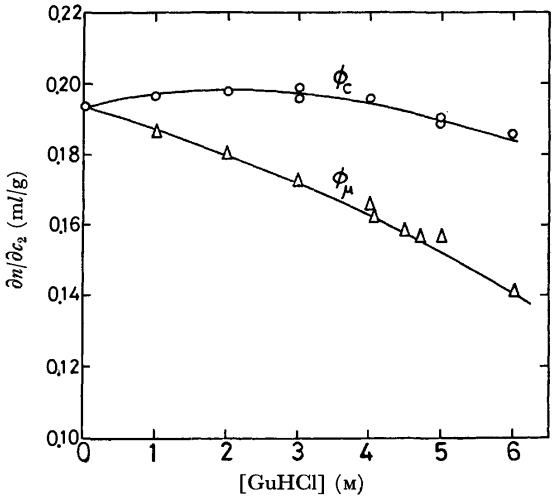

Fig. 2. Refractive index increments, ϕ_c(○) and ϕ_μ(△), of BSA in GuHCl solutions.

Refractive Index Increment. The refractive index of the solution, n, was found to be linear to the BSA concentration, c_2 (g/ml). Two kinds of refractive index increment, ϕ_c and ϕ_μ, as defined by Eqs. (2a) and (2b) respectively, were obtained at various GuHCl concentrations, [GuHCl] (M). The results are shown in Fig. 2. The concentration of GuHCl in the outer solution at the membrane equilibrium was the same as that in the inner solution, at least within the limits of accuracy of the chemical analysis, since the concentration used here was relatively high. In spite of this, the values of these two refractive index increaments, ϕ_c and ϕ_μ, were definitely different from each other, as is shown in Fig. 2. This means that GuHCl is bound to BSA, as will be quantitatively discussed later on.

Light Scattering. The reduced scattering intensity for unpolarized incident light, $R_u(\theta)$, was measured as a function of the scattering angle, θ, at various BSA concentrations, c_2(g/ml), using GuHCl solutions of the respective concentrations. [GuHCl] (M), as the solvents. According to the usual Zimm-plot method, the apparent values of the weight-average molecular weight, M*, the radius of gyration, R_g*, and the second virial coefficient, A_2, are expected to be obtained on the basis of the following well-known equation:

$$\frac{K'\phi_\mu^2 c_2}{R_u(\theta)}=\frac{1}{M^*}\left(1+\frac{16\pi^2}{3\lambda^2}R_g^{*2}\sin^2\frac{\theta}{2}\right)+2A_2c_2 \quad (4)$$

where:

$$K'=2\pi^2 n_1^2/N_0\lambda_0^4 \quad (5)$$

4) S. Katz and T. G. Ferris, *Biochemistry*, **5**, 3246 (1966).

It has been established[5] that ϕ_μ, instead of ϕ_c, must be used in Eq. (4) for multi-solute systems.

In the case of [GuHCl]=0, it has been reported[3] that the Zimm plot of native BSA in a 0.01M sodium chloride solution (pH=5.40) is in accord with Eq. (4), that the value of the molecular weight (M^* in Eq. (4)) is 71900, which is in good agreement with the value reported in the literature,[6] and that the value of the second virial coefficient, A_2, is nearly equal to zero. On the other hand, the Zimm plot of the BSA denatured by the addition of GuHCl could not completely be analyzed according to Eq. (4).

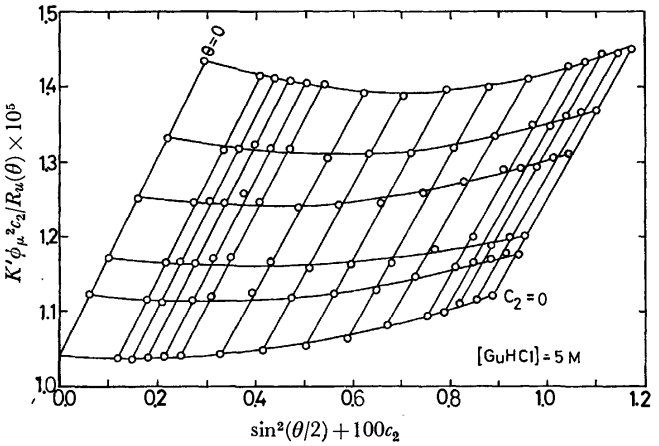

Fig. 3. Zimm plot of BSA at [GuHCl]=5M.

Table 2. Results of light scattering measurements

GuHCl (M)	$M^*\times10^{-4}$	$A_2\times10^4$ (mol·ml/g^2)	$M\times10^{-4}$	M/M_0	R_g (Å)
0	7.09	0	6.84	1.00	45
1	9.34	1.23	8.97	1.26	58
2	13.70	1.20	13.23	1.85	77
3	13.70	0.83	13.33	1.88	92
4	12.05	3.00	11.61	1.64	113
5	9.61	6.75	9.24	1.30	147

It can be seen from Fig. 3, which shows the case of [GuHCl]=5M as an example, that the plots obtained by the extrapolation to zero of θ are linear against c_2, and that the intersection and the inclination of the straight line give the apparent molecular weight, M^*, and the second virial coefficient, A_2, according to Eq. (4). The values of M^* and A_2 thus obtained are given in Table 2. However, the plots obtained by the extrapolation to zero of c_2 are not linear against $\sin^2(\theta/2)$, so Eq. (4) cannot be used to obtain the apparent value of R_g*. The initial slope (the slope at the limit of $\theta\to0$) cannot be used, either, because the slope is negative in the case of Fig. 3 and because R_g* cannot take an imaginary value. This anomalous behavior may be supposed to be due to the optical anisotropy of segments. The correction factor for this can be calculated, according to the theory presented previously,[7] by using the

value of the scattering ratio at $\theta=90°$.

Scattering Ratio. If the segments of a macromolecule are completely isotropic and are sufficiently small compared to the wavelength of light, the light scattered at $\theta=90°$ must be completely polarized and vibrating perpendicularly to the plane of observation, even when unpolarized light is used as the incident light. If the incident light is linearly polarized, the intensity of the scattered light at $\theta=90°$ must be zero when the incident light is vibrating parallel to the plane of observation, as long as the segments are isotropic and sufficiently small.

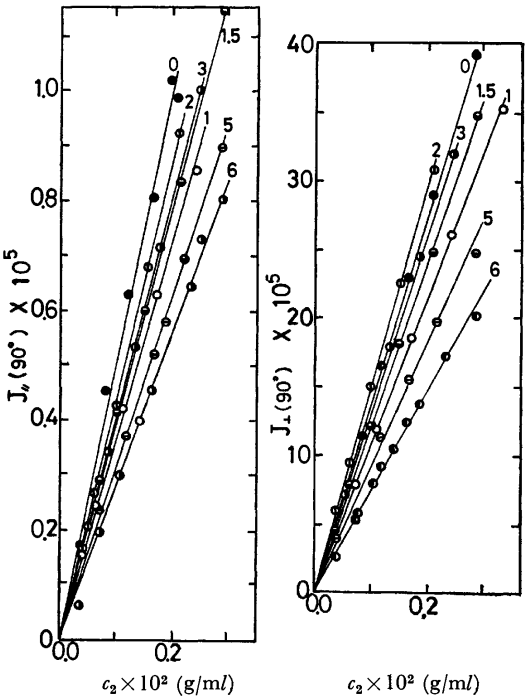

Fig. 4. The proportionality of the Rayleigh ratios, $J_\perp$ (90) and $J_{//}(90)$, to BSA concentration, at various GuHCl concentrations.

On the other hand, if the segments are optically anisotropic, the scattered light is depolarized even at $\theta=90°$, or the scattered light has some intensity even when the linearly-polarized incident light is vibrating parallel to the plane of observation. The Rayleigh ratio, that is, the scattered light intensity per unit of solid angle from a unit of the volume of the solution per unit of the intensity of the incident light, was measured at $\theta=90°$ for the incident light vibrating perpendicular to and parallel to the plane of observation; the results, $J_\perp$ (90°) and $J_{//}$ (90°) respectively, are shown in Fig. 4 as functions of the BSA concentration, c_2 (g/ml). The parameter values in Fig. 4 show the GuHCl concentration, [GuHCl] (M). In each case, the scattered light intensity is proportional to the BSA concentration.

The values of the scattering ratio at $\theta=90°$, Q, defined by the following equation:

$$Q=S(90°)=J_{//}(90°)/J_\perp(90°) \tag{6}$$

are given in Table 3 for various GuHCl concentrations. The scattering ratio is of the same numerical value as the depolarization ratio for unpolarized incident light, but the latter has an experimental disadvantage because perfectly unpolarized incident light is rather difficult to obtain. The scattering ratio is, therefore, used in the present paper. As is shown in Table 3, the scattering ratio is slightly dependent on the GuHCl concentration, although it is nearly independent of the BSA concentration.

Table 3. Scattering ratio and anisotropy of BSA segments

5	3.33	1.62	1.182

Discussion

Variation in the Refractive Index Increment due to the Complex Formation. In a ternary system, water (1)-protein (2)-low-molecular-weight substance (3), the analysis of the refractive index increment and, therefore, of the light-scattering data is simple if one can treat the aqueous solution of the third component as a solvent (1+3) and the ternary system as a solution of the protein (2) in the solvent (1+3). According to this conventional method, the refractive index increment, ϕ_c, defined by Eq. (2a) is measured by diluting the ternary system with a "solvent" (1+3) whose concentration is c_3 (g/ml).

If, however, a special interaction such as complex formation exists between the protein (2) and the third component (3), the "free" concentration or the chemical potential of the third component decreases with the complex formation. This results in a change in the composition of the solvent (1+3). In order to obtain the refractive index increment, ϕ_μ, defined by Eq. (2b), the solvent composition must be kept constant by diluting the ternary system with a solution which is in a membrane equilibrium with the ternary system.

Several theoretical papers discussing the relation between the ϕ_c and ϕ_μ are found in the literature.[5,8] In most cases reported so far, the difference between ϕ_c and ϕ_μ is small enough, particularly when the concentration of the third component is smaller than about 0.5M. If, however, the c_3 concentration is higher than this, or if the third component has a particularly strong affinity to the protein, the difference between these two quantities becomes important. In this case, the following equation is used at a constant temperature and pressure:

$$\left(\frac{\partial n}{\partial c_2}\right)_{\mu_3}=\left(\frac{\partial n}{\partial c_2}\right)_{c_3}+\left(\frac{\partial n}{\partial c_3}\right)_{c_2}\cdot\left(\frac{\partial c_3}{\partial c_2}\right)_{\mu_3} \tag{7}$$

Here, the quantity $(\partial n/\partial c_3)_{c_2}$ is the refractive index increment of the third component at a constant protein

8) R. H. Ewart, C. P. Roe, P. Debye, and J. R. McCartney, *J. Chem. Phys.*, **14**, 687 (1946); H. C. Brinkman and J. J. Hermans, *ibid.*, **17**, 574 (1949); J. Ooi, *J. Polymer Sci.*, **28**, 459 (1958); B. E. Read, *Trans. Faraday Soc.*, **56**, 382 (1960).

concentration, c_2. Since the value does not change very much, the value in water, ϕ_3, may be used for it as long as the protein concentration is not high. The quantity;

$$\delta' = \left(\frac{\partial c_3}{\partial c_2}\right)_{\mu_3} \tag{8}$$

is the amount of the third component bound to the protein (g/g), if c_2 and c_3 are expressed in g/m*l*. Therefore, Eq. (7) may be rewritten as follows:

$$\phi_\mu = \phi_c + \phi_3 \cdot \delta' \tag{9}$$

The apparent binding ratio, δ', can thus be calculated from the data shown in Fig. 2 and the experimental value for GuHCl: $\phi_3 = 0.1938$ m*l*/g. The value of δ' is negative, however, as is shown in Table 4, because ϕ_μ is smaller than ϕ_c. The negative value of the apparent binding ratio, δ', is due to the effect of the volume excluded by BSA molecules. The actual value of the binding ratio, δ (g/g), is obtained by means of:

$$\delta = \delta' + c_3\bar{v}_2 \tag{10}$$

Here, $\bar{v}_2$ is the specific volume of BSA, 0.7265 (m*l*/g), and is independent of the GuHCl concentration, c_3, as is shown in Table 1.

The molar binding ratio of GuHCl per amino-acid residue of BSA, δ_m (mol/mol), may be calculated on the basis of the average molecular weight per amino-acid residue, $\bar{M}_a = 112.8$, which is obtained by means of the data on amino-acid composition of BSA reported in the literature.[9] As may be seen in Table 4, the value of δ_m increases with the GuHCl concentration, but it is less than 1 even at concentrations as high as 6M GuHCl.

Optical Anisotropy of BSA Segments and of Benzene. It has already been discussed theoretically in a previous paper[7] that the angular variation in the scattered light intensity from macromolecules depends on the optical anisotropy of the segments, and that the degree of the anisotropy could be estimated by means of measurements using polarized incident light.

In the case of isotropic segments which can be treated as Rayleigh spheres, the Rayleigh ratio for unpolarized incident light, $J_u(\theta)$, is proportional to the $(1+\cos^2\theta)$ factor. According to this fact, the reduced scattering intensity, $R_u(\theta)$, used in Eq. (4) may be defined by the following equation:

$$R_u(\theta) = J_u(\theta)/(1+\cos^2\theta) \tag{11}$$

If the segments are Rayleigh scatterers, the value of $R_u(\theta)$ is independent of the scattering angle, θ, except the anglar dependency due to the interference factor which contains the term of the radius of gyration.

In the case of anisotropic segments, however, $R_u(\theta)$ is dependent on the scattering angle, θ. If the segments are considered to be Rayleigh-Gans scatterers, as in the previous paper,[7] the Rayleigh ratios are given as follows, since $R_u(90°) = J_u(90°)$:

$$\frac{J_{/\!/}(\theta)}{R_u(90°)} = \frac{2Q}{1+Q} + 2\left(\frac{1-Q}{1+Q}\right)\cos^2\theta \tag{12a}$$

$$\frac{J_\perp(\theta)}{R_u(90°)} = \frac{2}{1+Q} \tag{12b}$$

$$\frac{J_u(\theta)}{R_u(90°)} = 1 + \left(\frac{1-Q}{1+Q}\right)\cos^2\theta \tag{12c}$$

Before going further, these relations were examined experimentally by using benzene, a standard liquid commonly used to determine the cell constants of the light-scattering apparatus. The values of $R_u(90°)$ and Q for benzene are known from the literature[10] to be $R_u(90°) = 4.85 \times 10^{-5}$ and $Q = 0.41$, the latter being equal to the depolarization ratio, ρ_u. Eqs. (12a—c) for benzene are, therefore:

$$\left.\begin{aligned} J_{/\!/}(\theta) \times 10^5 &= 2.82 + 4.06\cos^2\theta \\ J_\perp(\theta) \times 10^5 &= 6.89 \\ J_u(\theta) \times 10^5 &= 4.85 + 2.03\cos^2\theta \end{aligned}\right\} \tag{13}$$

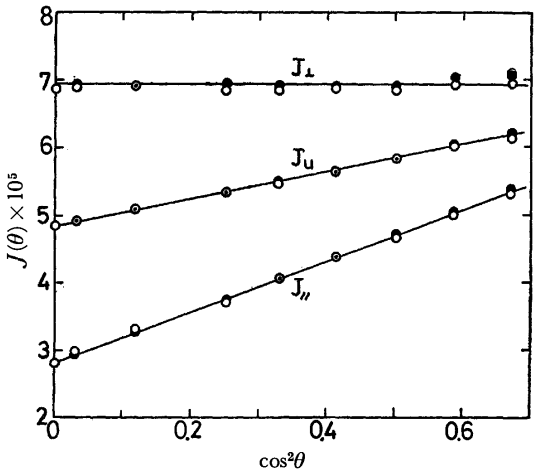

Fig. 5. The relation between the Rayleigh ratios, $J(\theta)$ and $\cos^2\theta$, for benzene. (○) $\theta < 90°$, (●) $\theta > 90°$.

The experimental values obtained for benzene purified by the method described in the previous paper[3] are shown in Fig. 5, with open circles for $\theta < 90°$ and closed circles for $\theta > 90°$, together with the straight lines drawn according to Eq. (13). The agreements between the experiment and the theory are satisfactory.

Since Eqs. (12a—c) have been justified experimentally, the treatment may be extended to explain the anomalous behaviour of the Zimm plots of BSA, an example of which has been shown in Fig. 3. For this purpose, the following equation, which can be derived easily from Eq. (12c), may be used:

$$P_u(\theta) = \frac{R_u(\theta)}{R_u(0)} = 1 + Q\frac{1-\cos^2\theta}{1+\cos^2\theta} \tag{14}$$

9) W. H. Stein and S. Moore, *J. Biol. Chem.*, **178**, 79 (1949).

10) C. L. Carr and B. H. Zimm, *J. Chem. Phys.*, **18**, 1616 (1950).

Before doing this, the Q-values of BSA given in Table 3 will be discussed further. The Q quantity is related to the excess-polarizability ratio, p_α, defined by:

$$p_\alpha = \alpha_a/\alpha_b \tag{15}$$

where α_a and α_b are the principal values of the excess polarizability (in excess of that of the solvent) of the segments parallel to and perpendicular to, respectively, the axis of the rotation of the spheroidal segments. The relation is given by the following equation:[11]

$$Q = \frac{(2/15)(p_\alpha-1)^2}{1+(2/3)(p_\alpha-1)+(1/15)(p_\alpha-1)^2} \tag{16}$$

It is obvious that $Q=0$ for optically-isotropic segments ($p_\alpha=1$). The p_α-values of BSA obtained by Eq. (16) are given in Table 3. It may be seen that the value of p_α changes only a little with the GuHCl concentration and shows its minimum point at about 2—3M of the latter. This is related to the side-by-side dimerization of BSA molecules, as will be discussed later on.

As for the magnitude of the p_α value, it has already been concluded in a previous paper[7] that the value should be within the following range, if the anisotropy is due to the anisometry, that is, the segments are considered to be non-spherical particles of an isotropic material. If the value of p_α is outside the range, the segments must have intrinsic anisotropy:

$$(m^2+1)/2 > p_\alpha > 1/m^2 \tag{17}$$

where m is the relative refractive index of the segments.

The value of m may be estimated according to the following equation:[7]

$$\phi_\mu = (m-1)n_1\bar{v}_2 \tag{18}$$

Here, $\bar{v}_2$ is the specific volume of BSA, as is given in Table 1, and n_1 is the refractive index of the solvent, that is, the GuHCl solution of the corresponding concentration. As is shown in Table 3, the value of m is about 1.2, which is the value usually obtained for various organic substances in water.

The range given by Eq. (17) for this m-value is:

$$1.21 > p_\alpha > 0.70 \tag{19}$$

The p_α value of BSA shown in Table 3 is definitely outside this range. The optical anisotropy of BSA may, therefore, be concluded to be intrinsic.

Modified Zimm Plot of Denatured BSA. For the macromolecules of anisotropic segments, it has already been stated[7] that the light-scattering equation must be modified by replacing M^* of Eq. (4) with $M\cdot P_u(\theta)/F$, where $P_u(\theta)$ is the function already given by Eq. (14), and where the factor, F, is given by the following equation:[12]

$$F = 1-(7/6)Q \tag{20}$$

Equation (4) can, therefore, be rewritten as follows, since $P_u(0)=1$:

$$[P_u(\theta)/F]\cdot[K'\phi_\mu^2 c_2/R_u(\theta)] = \frac{1}{M}\left(1+\frac{16\pi^2}{3\lambda^2}R_g^2\sin^2\frac{\theta}{2}\right)+2\frac{A_2}{F}c_2 \tag{21}$$

11) The quantity, p_α, defined here is the reciprocal of that used in Ref. 7. Equation (16) may be derived readily from Eqs. (21) and (29) of the same paper.

12) The equation $F=1+Q/2$, derived from Eqs. (29) and (37) of Ref. 7, is in error. This point will be discussed in a separate paper.

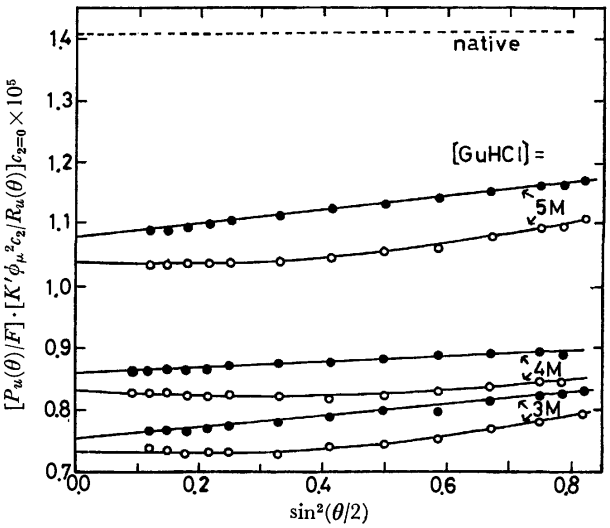

Fig. 6. Usual (open circles) and modified (closed circles) Zimm plots of BSA at $c_2\to 0$, for various GuHCl concentrations.

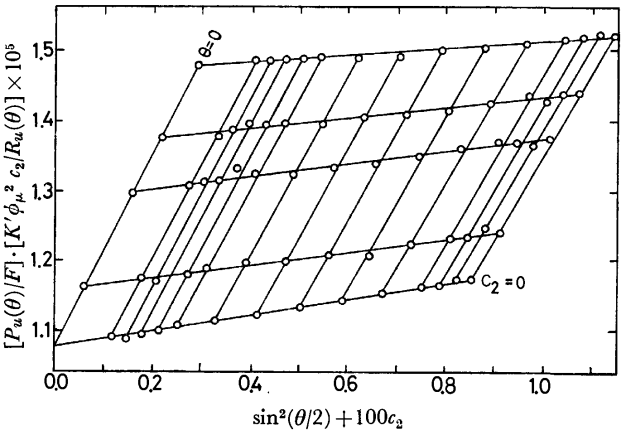

Fig. 7. Modified Zimm plot of BSA at [GuHCl]=5M.

The left side of Eq. (21) can be plotted on the ordinate to draw the modified Zimm plot, because $P_u(\theta)$ and F can be calculated by using the value of Q obtained experimentally, as is shown in Table 3.

It can be seen from Fig. 6 that the plots for $c_2\to 0$ are curved in the usual Zimm plots, as is shown by the open circles, but that the plots are on straight lines in the modified Zimm plots, as is shown by the closed circles. As an example, the modified Zimm plot of BSA in 5M GuHCl is given in Fig. 7; it is composed of straight lines only, in contradistinction to the usual Zimm plot of the same system shown in Fig. 3. It may, therefore, be concluded that the curved feature of the usual Zimm plot, and also the apparently imaginary value of the radius of gyration, R_g^*, are due to the optical anisotropy of BSA. The correct values of the molecular weight, M, and the radius of gyration, R_g, as obtained from the modified Zimm plot, are given in Table 2.

Molecular Weight of Denatured BSA. The weight-average molecular weight, M, of BSA, obtained from the modified Zimm plot, increases with the GuHCl concentration at first and then reaches a maximum point at about 3M GuHCl, as is shown in Table 2. The ratio (M/M_0) of the molecular weight to that of

native BSA is nearly equal to 2 at the maximum point. This means that dimers are formed by the intermolecular binding of two denatured BSA molecules. With a further increase in the GuHCl concentration, however, the intermolecular binding seems to be broken, because the molecular weight decreases to as low as $M/M_0=$ 1.30 at 5M GuHCl.

The following conclusions may, therefore, be drawn: (1) GuHCl, at first, breaks the intramolecular binding of BSA and changes the shape of the molecules, as will be discussed in the next section. (2) The broken bonds, which have been brought to the outer surface of the molecule by the change in the molecular shape, combine with those of another denatures BSA molecule to form a dimer. (3) These intermolecular bonds, too, are broken with a further increase in the GuHCl concentration.

Molecular Shape and Intrinsic Viscosity of Denatures BSA. As has been described above, the following three quantities, the intrinsic viscosity, $[\eta]$; the molecular volume, V_m (which is equal to $M\bar{v}_2/N_0$, where N_0 is the Avogadro number), and the radius of gyration, R_g, of BSA at various GuHCl concentrations have been determined. On the basis of these results, the shape and size of BSA molecules may be discussed if the molecular shape is approximated by a suitable model, as has already been shown in a previous paper[13] on chondroitin sulfate.

If the denatured BSA molecule is approximated by a random coil;[14]

$$[\eta]=6^{3/2}\Phi R_g^3/M \tag{22}$$

where $\Phi=2.87\times10^{21}$.

In the case of a cylindrical rod or a sheroid,

$$[\eta]=0.025\bar{v}_2\cdot\nu(p) \tag{23}$$

where $\nu(p)$ is the shape factor as a function of the axial ratio, p.

$$p=L/D=a/b \tag{24}$$

where L and D are the length and diameter respectively of the cylindrical rod, and where a and b are the radii of the sheroid in the direction parallel to and parpendicular to respectively, the axis of rotation. The shape factor is given by one of the following equations.[15]

$$\nu(p)=0.373+0.08p^2\left\{\frac{1}{3(\ln 2p-1.8)}+\frac{1}{(\ln 2p-0.8)}\right\} \tag{25a}$$

For a prolate sheroid ($p>1$),

$$\nu(p<15)=1+0.163(p-1)^{1.508} \tag{25b}$$

$$\nu(p>15)=0.64+0.08p^2\left\{\frac{1}{3(\ln 2p-1.5)}+\frac{1}{(\ln 2p-0.5)}\right\}$$

For a oblate spheroid ($p<1$),

$$\nu(p)=1+0.272\frac{1-p}{p}-0.251\left\{\frac{1-p}{1-0.075p}\right\} \tag{25c}$$

The value of $[\eta]$ may, therefore, be calculated if the value of the axial ratio, p, is known.

The molecular volume, V_m, is given by the equation:

$$V_m=\frac{\pi}{4}L^3/p^2=\frac{4}{3}\pi a^3/p^2 \tag{26}$$

The radius of gyration, R_g, is given as follows. For a cylindrical rod,

$$R_g^2=\frac{L^2}{12}(1+3/2p^2) \tag{27a}$$

For a sheroid,

$$R_g^2=\frac{a^2}{5}(1+2/p^2) \tag{27b}$$

According to these equations, the molecular dimensions, L and D or a and b, and the axial ratio, p, can be calculated.

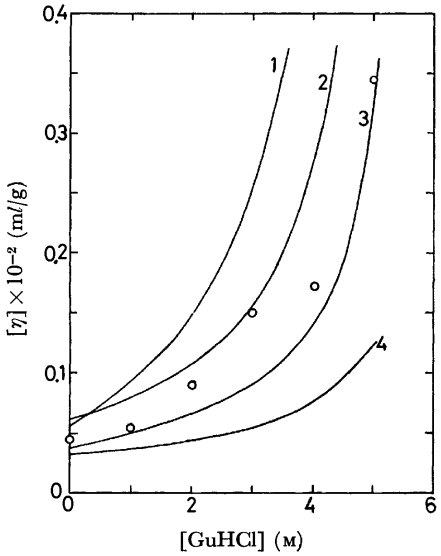

Fig. 8. Intrinsic viscosity of BSA in GuHCl solutions.
(1) Random coil, (2) cylindrical rod, (3) prolate spheroid and (4) oblate spheroid.

The value of the intrinsic viscosity, $[\eta]$, obtained experimentally and theoretically are compared in Fig. 8. The experimental values, already given in Table 1 and shown in Fig. 8 by open circles, are close to the theoretical curve of the prolate spheroid, except at a GuHCl concentration of about 3M, where the experimental plot is close to the theoretical curve of the cylindrical rod, probably because the dimer formation is the most complete at this GuHCl concentration. At any rate, the experimental plots are located between the theoretical curve of the prolate spheroid and that of the cylindrical rod. It may, therefore, be concluded that the denatured BSA molecules are shape in elongated.

TABLE 5. DIMENSIONS OF DENATURED BSA MOLECULES AS PROLATE SPHEROIDS

[GuHCl] (M)	a (Å)	b (Å)	p	b_1 (Å)	p_1
0	71.2	16.8	4.23	16.8	4.23
1	91.7	17.0	5.40	14.8	6.20
2	122.4	17.8	6.87	12.8	9.56
3	145.5	16.1	9.02	11.8	12.3
4	179.3	13.8	13.0	10.6	16.9
5	231.9	10.6	21.9	9.31	24.9

14) P. J. Flory, "The Principles of Polymer Chemistry," Cornell University Press (1953), p. 611.
15) R. Simha, *J. Phys. Chem.*, **44**, 25 (1940); *J. Chem. Phys.*, **13**, 188 (1945); W. Kuhn and H. Kuhn, *Helv. Chim. Acta*, **28**, 97 (1945); H. A. Scheraga, *J. Chem. Phys.*, **23**, 1526 (1955).

The dimensions and the axial ratio of BSA molecules as prolate spheroids are shown in Table 5. These values were calculated on the basis of the radius of gyration determined by the light-scattering measurements and on the basis of the molecular volume determined by the density measurements.

It may be mentioned here that the axial ratio, p, increases from 4.23 to 21.9 with the GuHCl concentration, in contradistinction to the excess-polarizability ratio, p_α, which scarcely changes with the GuHCl concentration, as shown in Table 3. This is because p_α expresses the optical anisotropy of each segment, while p expresses the anisometry of the molecule as a whole, and the molecule is composed of many segments.

According to Table 5, the length, $2a$, of BSA molecules increases monotonously with the GuHCl concentration, but the diameter, $2b$, has a maximum point at about 2M GuHCl. This maximum may be supposed to be due to the maximum of the dimerization of BSA at about this GuHCl concentration, suggesting that the dimerization is realized by a side-by-side combination of two denatured BSA molecules. If this is so, then the radius, b_1, and the corresponding axial ratio, p_1, of one BSA molecule in the aggregate may be calculated by means of the following equations:

$$b_1 = b/\sqrt{M/M_0}$$
$$p_1 = a/b_1 \tag{28}$$

As is shown also in Table 5, the value of b_1 monotonously decreases, and that of p_1 monotonously increases, with the GuHCl concentration. It may, therefore, be concluded that the denaturating agent, GuHCl, breaks the intramolecular bonds of BSA to make the molecular shape the longer as the GuHCl concentration is higher, and that two molecules of denatured BSA aggregate side-by-side to form a dimer.

The largest length of a BSA molecule observed here is $2a=464$ Å at 5M GuHCl. This is about 1/5 of the length of a fully-stretched BSA molecule, that is estimated to be about 2200 Å for BSA containing 602 amino-acid residues.[9] This is in contrast to sodium chondroitin sulfate C whose length is between 1/2 ($J=\infty$) and 2/3 ($J=0.01$M) of the fully-stretched length,[13] where J is the ionic strength. The relatively small stretching of the BSA molecule by denaturation suggests that denatured BSA molecules keep their natural local conformation even in a GuHCl solution as concentrated as 5M.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2107—2110(1972)

An Isothermal Displacement Calorimeter for Measuring Enthalpies of Mixing

Reiji TANAKA, Sachio MURAKAMI, and Ryoichi FUJISHIRO

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received January 21, 1972)

An isothermal displacement calorimeter of the Van Ness type has been constructed. The calorimeter was tested on three systems, benzene+cyclohexane, cyclohexane+*n*-hexane, and benzene+dichloromethane, at 25°C, and the performance of the calorimeter was discussed in connection with the literature values. The precision of the new calorimeter was within 0.5%; this was equal to, or better than, that of calorimeters of a similar type which have been constructed by several investigators.

After the pioneering work of Van Ness and his co-workers[1-3] in isothermal dilution calorimetry, several calorimeters based upon a similar principle have been constructed and relatively precise enthalpies of mixing have been measured for various kinds of binary systems.

We have great interest in the measurements of enthalpies of mixing for non-ideal solutions at a high dilution, and this type of calorimeter seems to be most suitable for our purpose. The calorimeter was designed with the following features. (a) It is capable of measuring both exothermic and endothermic heats of mixing without any external calibration.[3] (b) The wall inside the mixing vessel is kept free from any dampness from the bath water by employing a vessel of fixed dimensions, the type of calorimeter designed by Stockes and his co-workers.[4,5] (c) By adopting a flange-type lid for sealing the vessel, the calorimeter is simple and can easily be washed after a run. Furthermore, the use of a flange-type lid makes a precision bore tube unnecessary.

The principle and the operation of this type of calorimeter have been fully described by Van Ness and his co-workers, so only a brief outline describing some improvements in our instrument will be given in the next section.

Apparatus and Procedure

A schematic drowing of the apparatus is shown in

Fig. 1, accompanied by enlarged sections of the mixing vessel. The vessel, A, is a 130 m*l* Dewar flask which is silvered and which has a strip window. The upper face of the vessel is polished flat, and on it lid, B, is fitted with two O-rings, C, held by six bolts, to provide a tight seal. The lid contains six main parts: the stirrer, the feed tube to introduce the second component, the air vent to introduce the first component, the thermistor, the heater, and the cooling assembly.

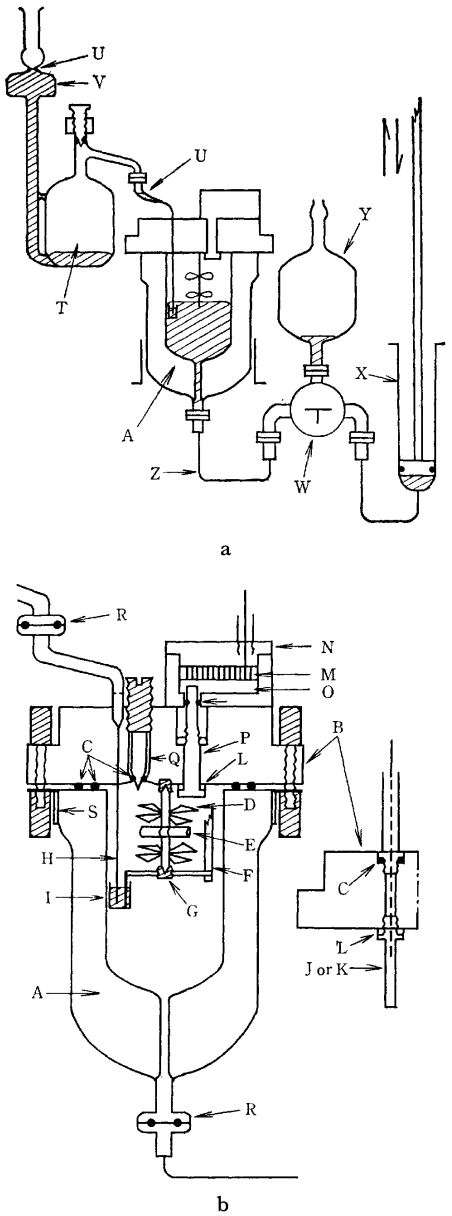

Fig. 1. Diagram of isothermal displacement calorimeter. A, silvered Dewar flask with strip window, capacity 130 ml; B, lid of Teflon impregnated with molybdenum disulphide and carbon; C, Viton O-ring; D, 4-blade propl lar (stainless steel), 19 mm diameter; E, magnet coated with Teflon attached to stirrer axle; F, stainless steel frame for stirrer; G, stainless teel screw to support stirrer; H, feed tube (needle of hypodermic syringe); I, mercury cup of stainless steel, capacity 1 m*l*; J, 37 KΩ thermistor in blass tube; K, 50Ω manganin wire heater in brass tube; L, Teflon washer; M, cooling module; N, stainless steel heat sink; O, copper cooling plate; P, copper cooling rod, 6 mm diameter; Q, air vent, sealed with bakelite screw and Teflon needle; R, glass or Teflon connector; S, brass collar, cemented to Dewar. T, feed bulb for second component, capacity 70 m*l*; U, meniscuss; V, mercury reservior, capacity 15 m*l*; W, three way tap, Teflon-glass; X, precision piston burette; Y, mercuty reservior; Z, stainless steel tube, 0.8 mm internal diameter.

The stirrer, D, is supported between the bottom of the lid and the stainless steel frame, F. It is rotated at 430 min^{-1}, activated by an external magnet by means of a constant-speed motor. The feed tube, H, is inserted through the lid into the cup, I, located on the stirrer frame. The cup is filled with mercury in order to separate the second component from the first.

The thermistor, J, about 37KΩ at 25°C, is used as the temperature-sensing element in the calorimeter vessel; it is mounted in a thin-walled brass tube containing a drop of oil in order to improve the thermal contact. The thermistor is balanced against a D.C. bridge, and its output signal is amplified and taken to a recorder. The thermistor is calibrated against the bath temperature each time before a run begins.

The wire heater, K, with a resistance of about 50Ω, consists of manganin wire wound on a small glass capillary and mounted in a thin-walled brass tube. The brass tube contains grease to make a good thermal contact and is sealed on the top with a small Teflon plug to prevent heat leakage from the top of the tube. The heater is connected in series with a 5V D.C. power supply, a rheostat, and a standard 1Ω resistance. A volt box, which contains two standard resistances of 30KΩ and 100Ω connected in series, is connected in parallel with the heater in order to reduce the potential drop across the heater by a factor of 301 for measurring the voltage of the heater. Before switching over to the calorimeter heater, the D.C. power supply is discharged into a dummy heater for 1 hr to stabilize the voltage output. The heater control switch turns the current from a dummy heater load to the heater and simultaneously activates an electronic timer. The heater power is calculated by measuring the voltages across the standard 1Ω resistance and reduced voltages across the 100Ω standard resistance in the volt box.

The cooling assembly consists of a 1500 mA cooling module (Cambion Thermoionic Corp. Model 3952-1), M, sandwiched between a stainless steel heat sink, N, and a copper cooling plate, O. The 6-mm-diameter copper rod, P, is connected to the copper plate, O, and penetrates through the lid into the mixing vessel. The thermal contact between the components is promoted by a thin film of silicon grease. The upper face of the stainless-steel heat sink is exposed to the water in a thermostatted bath.

The stabilized D.C. power supply, connected in series with a rheostat and with the cooling module, is used to activate the cooling module. The current through the cooling module is fed into a standard resistance in the by-passed circuit and the potential drop across the standard resistance is amplified by a D.C. amplifier in order to get the same sensitivity as the measurement of the heater power, and is monitored on a recorder.

After the calorimeter has been placed over 2 hr in a thermostatted bath controlled to within ±0.001°C, the temperature in the vessel is controlled by means of cooling module to the set temperature of the surroundings

within ± 0.0002°C. The stirring energy causes the steady temperature in the vessel to be higher than that of the thermostat by $\Delta T \approx 0.01$°C, so for the endothermic systems the current of the cooling module needs to compensate for only the energy dissipated by the stirrer. On the other hand, for the exothermic systems it needs to remove the energy supplied previously to the calorimeter heater. As soon as the temperature control is obtained, the run begins.

When the run is endothermic, the heater is switched on and the second component is introduced into the calorimeter vessel at such a rate that the contents of the vessel are kept at the set temperature within ± 0.003°C. At the end of each injection, the mercury level in the feed tube and in the mercury reservoir is restored before the final addition of energy is made. The equilibrium temperature is restored within 0.0002°C by the manipulation of the burette drive and heater switches.

When the run is exothermic, the heater is turned off so that the thermal energy of mixing is removed from the mixing vessel at a net rate equal to the rate of energy added previously by the heater before mixing. The other procedures in the exothermic run are the same as that in the endothermic run.

Test on Standard Systems

Materials. The systems used for testing the new calorimeter were benzene+cyclohexane, and cyclohexane+*n*-hexane at 25°C as endothermic systems and dichloromethane+benzene at 25°C as an exothermic system. The materials used in the cyclohexane+*n*-hexane system were Phillips Petroleum Company "Research Grade." The specified purity of the two hydrocarbon reagents has 99.98 mol per cent; these materials were used without further purification. The benzene was shaken with sulphuric acid about 10 hr and then washed with water. After drying over calcium chloride about 6 months, the benzene was distilled through a 1.5-meter column over P_2O_5 at a reflux rate of 80: 1. The boiling range was 79.9 to 80.2°C. The cyclohexane used in the cyclohexane+benzene system was shaken with a 10: 50 nitric acid+sulphuric acid mixture about 40 hr and then washed with water. After having been dried over calcium chloride about 6 months, the cyclohexane was distilled through the same column over P_2O_5 at a reflux rate of 80: 1. The boiling range was 80.5 to 80.7°C. The dichloromethane was a commercially-available "special-grade" reagent; it was distilled through the same column at a reflux rate of 80: 1. The boiling range was from 39.6 to 39.8°C. The distilled dichloromethane did not react with mercury. The chromatographic analysis of all the materials showed no impurities.

Results and Discussion. The benzene+carbon tetrachloride system has been used in evaluating the calorimeter performance. This system is suitable for testing the efficiency of stirring because of the large density difference between components, but the study of this system is not well established as a standard. Therefore, we adopted the cyclohexane+*n*-hexane

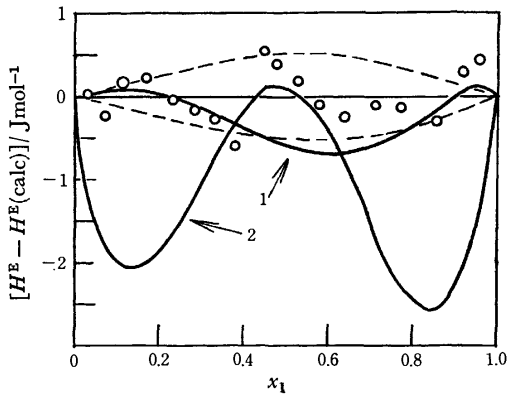

Fig. 4. Deviations of experimental and literature values of excess enthalpies for system benzene+dichloromethane at 25°C where x_1 is the mole fraction of benzene. ○, divations of our experimental points; 1, data of Murakami and Benson (7); 2, Otterstedt and Missen (11); dashed curves represent ±0.5 per cent deviations.

system, which had been suggested as a possible standard by McGlashan.[6]

All three systems used for testing our new calorimeter were measured at 25°C. The results are summarized in Table 1. The experimental points were fitted with the form[12]

$$H^E(\text{calc})/J\,\text{mol}^{-1}=x_1(1-x_1)\sum c_p(1-2x_1)^{p-1} \quad (1)$$

by the least-squares method, where x_1 is the mole fraction of the (1) component. The coefficients, c_p, adopted are listed in Table 2, along with the corresponding standard deviations. The values of the standard deviations were estimated by means of the following equation:

$$\sigma=[\sum\{H^E-H^E(\text{calc})\}^2/n]^{1/2} \quad (2)$$

where n is the number of observed points. The deviations of our experimental points from the smoothed function calculated from Eq. (2), $H^E-H^E_{\text{calc}}$, are shown in Figs. 2—4, together with those of other investigators, which are cited so that they can be compared with our results. Our results for the benzene+cyclohexane and cyclohexane+n-hexane systems are in close agreement with those of other investigators,[4,7-10] since the deviations of all sets fall almost entirely within about 0.5 per cent. However, it may be noted that our results appear to be slightly high at a low x_1 value and slightly low at a high x_1 value when compared with the results of other investigators.

At present, there is no suitable exothermic system for the test of a calorimeter. We used the benzene+dichloromethane system as an exothermic system, since the enthalpy of mixing for this system has been measured by several authors and since reliable data seem to have been obtained by using a similar type of calorimeter.[7] In the low-mole fraction of benzene, we observed an endothermic reaction which had too small a heat to be estimated. Our results agree well with those of Murakami and Benson,[7] but the results of Otterstedt and Missen[11] deviate fairly much at $x_1=0.15$ and 0.85 from ours.

The results obtained with our calorimeter seem to be internally consistent to better than 0.5 per cent, and the accuracy for the measurement of the enthalpy of mixing is believed to be equal to, or better than, that of the calorimeter described previously.

Results have been obtained by using this calorimeter for a number of systems containing polar materials; they will be reported in the near future.

This investigation was supported in part by a grant from the Ministry of Education. The authors wish to thank Dr. G. C. Benson, National Research Council of Canada, for his continuous interest during the design of the calorimeter.

The Reaction of Mono-, Di-, and Trisodium Orthophosphate in a Mixed Solution of Acetic Acid and Acetic Anhydride

Makoto WATANABE and Tetsushi SENDA

Department of Industrial Chemistry, Chubu Institute of Technology, Matsumoto-cho, Kasugai-shi, Aichi

(Received May 31, 1971)

Mono-, di-, or trisodium orthophosphate was heated at 100°C in an equivolume mixture of acetic acid and its anhydride. By X-ray diffractometry and paper chromatography, the products from these three sodium salts of orthophosphate were found to be sodium trimetaphosphate. At the end of the 30-hr reaction period, the purity of the trimetaphosphate was higher than 90%. The ease of formation of the trimetaphosphate ring under various conditions was shown, and the stability of the ring was discussed on the basis of the strain of the bonding angle.

Some condensed phosphates are synthesized by the dehydration of orthophosphate at a high temperature. Thilo and his co-workers made potassium trimetaphosphate by treating monopotassium dihydrogen orthophosphate with a mixture (1: 1) of acetic acid and its anhydride at 90°C.[1] Kasparek reported the dehydration of alkalimetal salts of dihydrogen orthophosphates with acetic anhydride.[2] In the present work, we succeeded in synthesizing trimetaphosphate not only from monosodium orthophosphate, but also from di- and trisodium orthophosphate, which had been treated in an equivolume mixture of acetic acid and its anhydride at 100°C. The reactivity of these three sodium salts of orthophosphate in the mixed solution was examined.

Experimental

Materials and Instruments. All the materials used were of a commercial grade. The water of crystallization of the orthophosphates was removed by heating them at 120°C in an air bath. The instruments used for the analysis of phosphates were a Toshiba X-ray diffractometer, ADG-102, and a Shimadzu photoelectric photometer, Spectronic-20.

Reaction of the Orthophosphates in a Mixture (1: 1) of Acetic Acid and Its Anhydride. After 50-m*l* portions of acetic acid and of acetic anhydride had been taken in a 300-m*l*, four-necked, round-bottom flask, 5 g of the orthophosphate was added to the solution and then the mixture was heated at 100°C with a mantle-heater, while being stirred and refluxed at the same time, for 5, 10, 15, 20, 25, or 30 hr. At first, these sodium salts of orthophosphates were completely dissolved in the mixed solution at 100°C, the solution gradually became turbid, with a white deposit. The quantity of the white deposit increased with the increase in the reaction time. The reaction mixture at each reaction time was cooled; the deposit was filtered off and then washed with ethyl alcohol. The compositions of the deposit and of the filtrate were estimated from the data obtained by X-ray diffractometry and paper chromatography.

X-ray Diffractometry. The samples were ground with an agate mortar until they could pass through a 150-mesh screen. Their X-ray diffraction patterns were taken by means of the powder method.

Paper Chromatography. About 1 g of the white deposit was dissolved in 50 m*l* of water, and then 3 μl of the solution or the filtrate obtained by the filtration of the reaction mixture were placed on a filter paper (Toyo No. 51A of 2 by 40 cm) and developed at room temperature for 20 hr by using an acidic and a basic solvent. The acidic solvent was prepared by mixing 73.5 m*l* of isopropyl alcohol, 5.0 g of trichloroacetic acid, 0.25 m*l* of concentrated aqueous ammonia, and 26.5 m*l* of water; it was used for the separation of ortho-, pyro-, tripoly-, and long-chain phosphates. The basic solvent was prepared by mixing 38.7 m*l* of isopropyl alcohol, 20.0 m*l* of isobutyl alcohol, 0.5 m*l* of concentrated aqueous ammonia, and 40.8 m*l* of water and was used for the separation of trimeta- and tetrametaphosphates. After the solutions of phosphate had been developed for 20 hr, the filter paper was dried at 75°C for more than 30 minutes in an air bath. The paper was sprayed with a perchloric acid-molybdate solution. After it had dried again, the paper was exposed to ultraviolet rays in order to reduce the molybdophosphates to blue complexes. Each band of the phosphates on the filter paper was identified by the same treatment as in the case of a reference solution of a known mixture of phosphates.

Colorimetric Determination of Phosphorus. The separated phosphates on the paper chromatograms were determined as follows. Filter paper containing each separated phosphates was cut at the demarcation line, and each part was immersed in 10 m*l* of a 0.1N aqueous solution of ammonia in a 50-m*l* Erlenmeyer flask for 1 hr. The resulting solution was transferred to a 25-m*l* volumetric flask, and then 10 m*l* of water and 2 m*l* of Lucena-Conde and Prat's reagent[3] were added. The flask was placed in boiling water for 1 hr, then cooled in a bath of cold water, and diluted to the mark with water. The absorbance of the solution was measured at 800 mμ. The compositions of the phosphates were calculated from the absorbance data.

Results and Discussion

The chemical compositions of the phosphates contained in the white deposit are shown in Tables 1, 2, and 3. The data indicate that the main product from these three sodium salts of orthophosphate is trimetaphosphate and that its purity increases with an increase in the reaction time and is higher than 90% at a reaction time of 30 hr. The compositions of the filtrate at the reaction time of 30 hr were as follows: for monosodium orthophosphate, 45.8% of orthophosphate, 16.7% of pyrophosphate, and 37.5% of an unknown substance; for disodium orthophosphate, 53.7% of orthophosphate, 19.2% of pyrophosphate, and 27.1% of an unknown substance; for trisodium orthophosphate,

86.8% of orthophosphate, and 13.2% of pyrophosphate, while the quantity of the unknown substance was so small that it could not be determined. The unknown substances contained in these filtrate, are all the same substance, which has an R_f value of 0.60 for the acidic solvent employed in this chromatography. The unknown substance may be an orthophosphate the hydrogen atoms of which are replaced by acetyl groups.

The X-ray diffraction patterns of the white deposits are given in Fig. 1. From the results, it is clear that the white deposits are sodium trimetaphosphate. The sodium trimetaphosphate was identified by comparing the X-ray patterns of the white deposits with those of the "A.S.T.M. Diffraction Data File." According to the above results, the following reactions were considered for the formation of trimetaphosphate:

$$3NaH_2PO_4 + 3(CH_3CO)_2O = (NaPO_3)_3 + 6CH_3COOH$$

$$\begin{pmatrix} 3Na_2HPO_4 + 3CH_3COOH = 3NaH_2PO_4 + 3CH_3COONa \\ 3NaH_2PO_4 + 3(CH_3CO)_2O = (NaPO_3)_3 + 6CH_3COOH \end{pmatrix}$$

$$\begin{pmatrix} 3Na_3PO_4 + 6CH_3COOH = 3NaH_2PO_4 + 6CH_3COONa \\ 3NaH_2PO_4 + 3(CH_3CO)_2O = (NaPO_3)_3 + 6CH_3COOH \end{pmatrix}$$

By using the above equations, the theoretical amounts of sodium trimetaphosphate to be obtained per 100 g of each orthophosphate were calculated. The theoretical values, the experimental values, and the yields of sodium trimetaphosphate are given in Table 4.

TABLE 4. THE YIELDS OF SODIUM TRIMETAPHOSPHATE

	NaH_2PO_4	Na_2HPO_4	Na_3PO_4
EV	80.6	67.1	57.5
CV	85.0	71.8	62.2
Yield	94.8	93.4	92.4

EV: Gram quantities of sodium trimetaphosphate obtained by the experiment per 100 g of each orthosphate.
CV: Gram quantities of sodium trimetaphosphate obtained by calculation per 100 g of each orthophosphate.
Yield: The yields (%) of sodium trimetaphosphate.

It is well known that sodium trimetaphosphate is usually made by heating monosodium orthophosphate to temperatures between 500 and 600°C. The sodium trimetaphosphate is formed very readily as a well-crystallized salt. It can also be prepared by cooling a sodium metaphosphate melt to the right temperature or by heating various mixtures of sodium phosphates exhibiting an over-all composition corresponding to the metaphosphate. It is very difficult, on the other hand, to prepare tetrametaphosphates by heating monomer phosphates; they are prepared by slowly adding phosphorus pentoxide to ice water. Anhydrous sodium tetrametaphosphate is irreversibly transormed to sodium trimetaphosphate at temperatures around 400°C; it cannot be restored by any known subsequent treatment of the sodium trimetaphosphate. Sodium salts of pyro- and tripolyphosphate are made by heating sodium phosphates which have a composition corresponding to these phosphates. It is difficult to prepare tetrapolyphosphates by heating phosphates, however, they are made by the alkaline hydrolysis of tetrametaphosphate. Usually, it is very difficult to prepare condensed phosphates, which are larger than tetra. Condensed phosphates hydrolyze to the uncondensed form in an aqueous solution. It is also well known that small

rings (mainly trimeta and a little tetrameta) are formed as the long chains are hydrolyzed. In view of the above facts, sodium trimetaphosphate may have a very stable structure and the trimetaring may be made readily. Phosphorus exhibits sp^3-bonding in the phosphates. The usual hybridization of the oxygen atom lies between p^2 and sp, so the bond angle of P–O–P lies between 90° and 180°. If the P–O–P angle is near the average value of 135° and if the O–P–O angle is 109°28′, the total bond angle of the trimetaring is very close to that of the six membered-ring, which is planar. The trimetaphosphate ion is considered to have a D_{3h} symmetry in an aqueous solution.[4]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2113—2120(1972)

The Syntheses of 3-(Carboxyalkyl)salicylaldehyde Derivatives and Their Copper Chelates[1)]

Tsuguo TANAKA

Department of Science and Technology, Saga University, Saga

(Received March 26, 1971)

In order to study the influence of the side-chain carboxylic acid groups on the formation of the metal chelates, 5-bromo-3-carboxymethyl-, 5-methyl-3-β-carboxyethyl-, and 5-chloro-3-β-carboxyethyl-salicylaldehyde (**2a, b c**) were synthesized. The green binuclear copper chelates of these aldehydes, di-μ-aquo-bis-(5-bromo-3-carboxymethylsalicylaldehyde)-, di-μ-aquo-bis-(5-methyl-3-β-carboxyethylsalicylaldehyde)-, and di-μ-aquo-bis-(5-chloro-3-β-carboxyethylsalicylaldehyde)-dicopper (**11a, b, c**) yielded the green binuclear bis-ethylenediimine chelates (**12a, b, c**), while bis-(5-bromo-3-carboxymethylsalicylaldehyde)-, bis-(5-methyl-3-β-carboxyethylsalicylaldehyde)-, and bis-(5-chloro-3-β-carboxyethylsalicylaldehyde)-ethylenediimine (**14a, b, c**) gave a brown (**13a**) and gray-purple (**13b, c**) mononuclear copper chelates. The reduction of **14a, b, c** with sodium borohydride yielded the hexadentate ligands *N,N'*-bis-(5-bromo-2-hydroxy-3-carboxymethylbenzyl)-, *N,N'*-bis-(5-methyl-2-hydroxy-3-β-carboxyethylbenzyl)-, and *N,N'*-bis-(5-chloro-2-hydroxy-3-β-carboxyethylbenzyl)-ethylenediamine (**15a, b, c**), which proved useful for the spectrophotometric determination of the copper (II) ion from solutions containing copper (II) and nickel (II) ions, and the iron (II) ion from solutions containing iron (II) and nickel (II) ions.

Since the isolation of purple penta-coordinate addition compounds of bis-salicylaldehyde-ethylenediiminecopper with the carboxylic acids and the phenols,[2)] many penta-coordinate copper chelates have been reported.[3)] In view of the role of carboxylic acid groups in the penta-coordination as well as in the formation of the ethylenediamine conjugates,[4)] the aldehydes **2a,b,c**, their ethylenediimine derivatives **14a,b,c**, and their copper chelates were synthesized for a study of the physical properties and chemical behaviors of the ligands as well as their chelates.

A binuclear structure of the copper chelate of **2a** was deduced from the analyses, IR spectrum and mass spectrum of the copper chelate. The mass spectrum[5)] of **11a** is illustrated in Fig. 2. Ions having values of *M/e* 474 ($-CO_2$, $-2Br$, $+2H$), 429 ($-2CO_2$, $-2Br$, $+H$) and others with values of *M/e* higher than 337 of the ion of monomeric form (**20**) were observed in the spectrum. The ions are considered to originate from the dimeric chelate **11a**. Four sets of twin peaks (240, 242), (228, 230), (200, 202), and (184, 186) represent those of the bromine containing fragments.

The carboxylate, the coordinated aldehyde and the phenoxide structures of **11a** were assigned on the basis of the 1580 and 1400 cm^{-1} IR peaks due to the antisymmetric and the symmetric vibration of the carboxylate ions,[6,4)] the 1611 cm^{-1} IR peak due to the shifted C=O stretching vibration of the aldehyde groups and the 1535 cm^{-1} absorption, respectively (Table 2 (B)).

Lower magnetic moments of binuclear copper chelates were summarized.[7)] The magnetic moments of the penta-coordinate copper chelates were normal.[8)] The

8) The measured magnetic moments of the penta-coordinate addition compounds were 1.74 Bohr magneton (at 256.2°K, $\Delta = -1°$) for the addition compound of bis-(5-methylsalicylaldehyde)-ethylenediimine-copper with propionic acid and 1.68 Bohr magneton (at 219°K, $\Delta = 0°$) for the addition compound of the same chelate with hydroquinone of the composition $(C_{18}H_{18}N_2O_2Cu)_2$-$C_6H_4(OH)_2$. The magnetic moments were measured by K. Hirakawa and his collaborators on their instrument. K. Hirakawa, K. Hirakawa, and S. Yoneyama, *Japan J. Appl. Phys.*, **2**, 816 (1963).

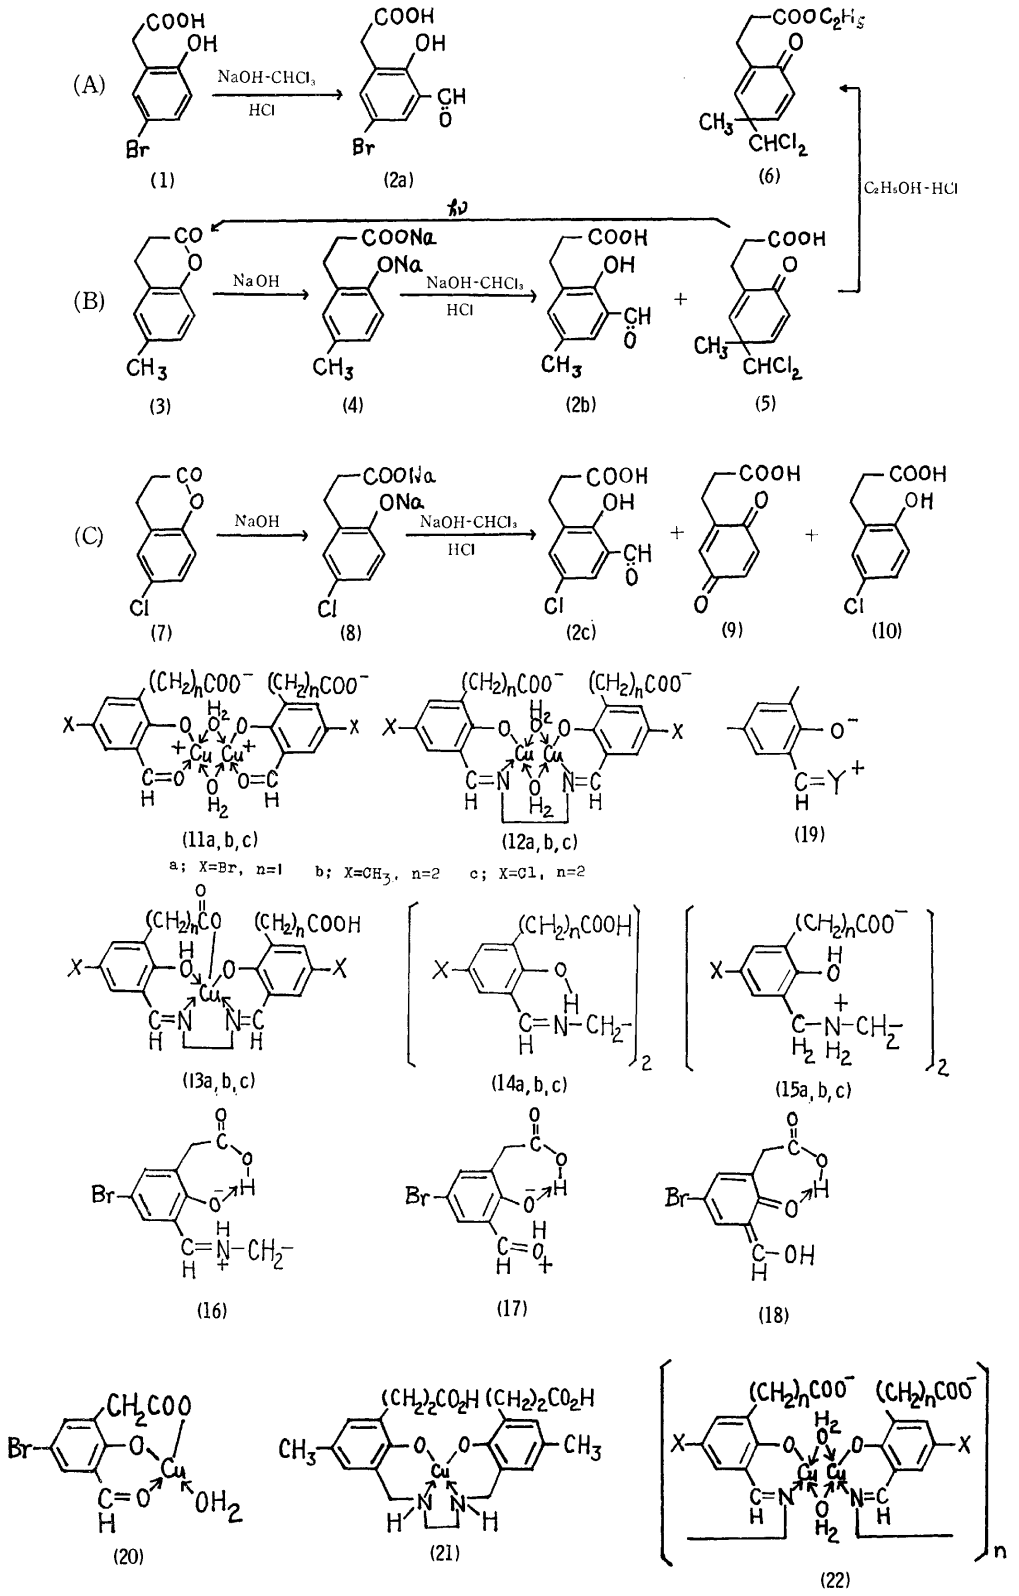

Fig. 1.

magnetic moments of **11a**,**b**,**c** were 1.90 Bohr magneton (273°K,$\Delta = -70°$), 1.77 Bohr magneton (272°K,$\Delta = -52°$), and 1.73 Bohr magneton (273°K,$\Delta = -77°$), respectively, and a deviation from the Curie-Weiss law was observed for **11c** at low temperatures (Fig. 3).

In the mass spectrum of **11b**, 345 (-2 $CH_2CH_2CO_2$, -2 CH_3, -2 CO, $+$H) and 317 were observed for M/e indicating a dimeric structure. The structure of **11c** was deduced from the similarity of results of its analysis, IR and UV spectra to those of **11a**,**b**.

The reaction of **11a**,**b**,**c** with ethylenediamine gave deep green ethylenediimine chelates which were considered to be either **12a**,**b**,**c** or the polymer **22a**,**b**,**c**. On the other hand, the Schiff base **14a**,**b**,**c** yielded

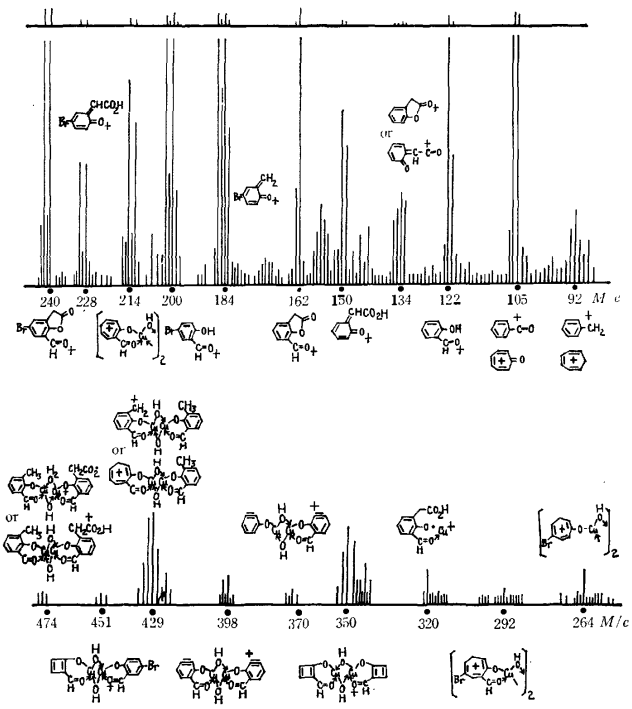

Fig. 2. Mass spectrum of **11a**. Ionizing voltage, 75 eV; ionizing current, 200 μA; sample temperature, 240°C; chamber temperature, 280°C. The formulae are possible ionic species.

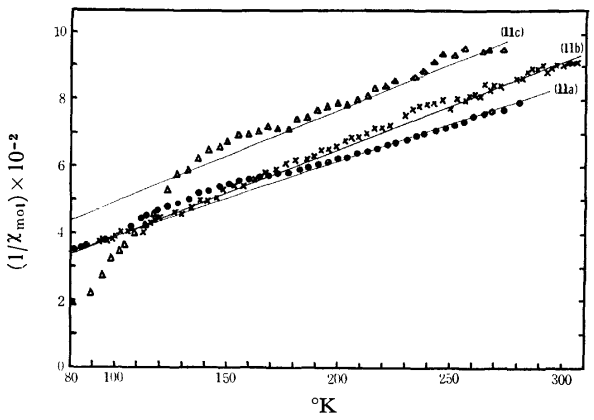

Fig. 3. Magnetic susceptibilities of **11a**, **b**, **c**.

mononuclear chelates **13a,b,c** respectively. The pentacoordinated structure of the mononuclear chelates is discussed with reference to absorption spectra.

The ligand **15a** formed a colorless stable chelate with Ni(II) ion in aqueous buffer solution of pH 10, and revealed the purple color of murexide on addition to a solution of nickel-murexide complex. Thus, the quantitative determination of nickel(II) ion was attained by chelatometric titration by use of M/100 aqueous solution of the disodium salt of **15a** and murexide in a buffer solution of pH 10.[9] Ligands **15b,c**, which, were colorless, formed no stable chelate with Ni(II), but formed green copper(II) and red iron(II) chelates in buffer solutions of pH 10 and pH 7, respectively. Spectrophotometric determinations were achieved for the copper(II) ion from the solutions containing Cu(II) and Ni(II) ions, and for the iron(II) ion from those containing Fe(II) and Ni(II)[10] as illustrated in Fig. 8. Of the Mg, Ca, Sr, Ba, Hg, Zn, Cd, Pb, Sn, Ni, Fe(II), Co(III) and Cu(II) ions, Co(III) (green), Cu(II) (green), and Fe(II) (red) ions formed colored chelates with **15a,b,c** in the aqueous solutions of pH 10 and 7.

Structure of the Abnormal Product of the Reimer-Tiemann Reaction[11]

Formation of dienone (**5**) as the main product of reaction B (Fig. 1), was deduced from the following experiments. 1. In the NMR spectrum of the product **Q** (see Experimental), a singlet CH_3 proton peak of 8.60 τ[12] and a singlet $HCCl_2$ proton peak of 4.40 τ were observed. 2. In the IR spectrum of **Q**, clear doublet dienone peaks of 1663 and 1640 cm^{-1} were observed together with the 1705 cm^{-1} peak of the carboxylic acid group. 3. In the mass spectrum, the ions with *M/e* values of 262, 244, 227, 216, 208,[13] 190, 180 and others with the value 262 corresponding to the molecular weight of **5** were observed. 4. Esterification of **Q** with ethanol and hydrogen chloride gave a fairly good yield of **6**. The semicarbazone of **6** was also obtained. 5. Distillation of **Q** after irradiation with sunlight for 20 hrs gave 69% of the lactone **3**,[14] while ditillation without irradiation resulted in polymerization into a resinous substance.

Structure of 6. Comparison of the UV absorption maxima of **6**, 202 mμ (log ε 3.58), 233 mμ (log ε 3.99), 267 mμ (shoulder, log ε 3.47), and 332 mμ (log ε 2.82) with those of its semicarbazone, 201 mμ (log ε 3.62), 251 mμ (log ε 3.84), and 301 mμ (log ε 4.25) suggested the cyclohexadienone structure of **6**, because on the formation of the semicarbazone, the 233 mμ absorption band of **6** disappeared and a 301 mμ band appeared as is usually the case with a dienone.[15] In the NMR spectrum of **6**, the singlet methyl protons

9) Buffer solution: H. A. Flaschka, EDTA titration, Pergamon, Oxford, 1964, p. 72. Titration: *ibid.*, p. 83. The results of titration were reported in the preliminary communication. It should be added that the reagent solution separated white precipitate when stored for more than four or five days.

13) Since the *M/e* value 208, corresponding to the molecular weight of **2b**, was observed in the mass spectrum of **Q**, part of it was treated with an aqueous alcoholic solution of potassium acetate and semicarbazide hydrochloride. Semicarbazone of mp 207°C was obtained in 8.83% yield. The yield of **2a** in the reaction B preliminary reported should be revised to 9.48%.

of 8.55 τ, the triplet methylene protons adjascent to the double bond (4H) of 7.5 τ (J=7.7 cps), a singlet $HCCl_2$ proton (1H) of 4.20 τ, a doublet vinyl proton (1H) of 3.72 τ (J_1=9.4 cps), a quartet vinyl proton (1H) of 3.17 τ (J_1=9.4 cps, J_2=2.6 cps), and a doublet vinyl proton (1H) of 3.32 τ (J_2=2.6 cps) were observed corresponding to **6**, as illustrated in Fig. 4. The 1735 cm^{-1} IR peak of the ester carbonyl group together with the clear doublet peaks 1663 and 1640 cm^{-1} of the dienone indicated the structure **6**. Of the mass spectrum (Fig. 5), the triplet sets of ions with M/e values such as 290, 292, 294, and 240, 242, 244 whose intensity ratio was approximately 1.0: 0.65: 0.15, seemed to be those of the dichloro fragments, while the doublet sets (254, 256), (181, 183), and (155, 157), whose intensity ratio was approximately 1.0: 0.4, seemed to be the monochloro fragments. Structures of **6** and **5** were confirmed by these physical measurements and chemical transformations.

Absorption Spectra

The O–H stretching IR peak of 3400 cm^{-1} of **2a** was considered from its similarity to those of hydroxyacids **1a** and **9** to be due to the hydrogen bond between the carboxyl and the hydroxyl groups and not to that between the hydroxyl and the aldehyde groups.

The UV spectra of **2a,b,c** in the ethanolic solutions as well as in the 0.5% aqueous sodium hydroxide solutions were nearly the same. However, in the hexane solutions in which acid exerts strong action, the 344 mμ n-π^* transition band[16] of **2a** disappeared while those of **2b,c** remained (Table 1).

a) Absorbance of their saturated solutions. sh. Shoulder.

The results suggest a dipolar ion such as **17**, with the following structure: — phenoxide and the protonated + carbonyl groups. A shoulder of 248 mμ ascribed to the phenoxide ion, was observed in the spectrum of **14a** but not in those of **14b,c** in the ethanolic solutions and the intensity of 347 mμ n-π^* band of the former decreased. A strong absorption peak of 1543 cm^{-1} was observed in the IR spectrum of the ligand **14a** but not in those of **14b,c**.

The absorption peak 1540 cm^{-1} of the salicylaldehyde Schiff base chelates was discussed and its assignment based on three different views. 1. the C=N stretching vibration.[17] 2. the C–O$^-$ stretching vibtation of the phenoxide ion endowed with a double bond character.[18] 3. the skeletal vibration of the aromatic ring loosened by ctoss resonance between the aromatic and the chelate ring.[19] It was recognized that the IR as well as the UV spectra of **14a** were closely related to those of the Schiff base chelates. It was thus considered that the proton shifted from the phenol oxygen atom toward the nitrogen atom to form a dipolar structure such as **19**. The structure **16** was introduced in place of **14a** on this basis.

In contrast to those of **11a,b,c**, and **12 a,b,c,** the IR absorption peaks of the carboxylic acid groups of **13a,b,c**, were observed between 1703 and 1710 cm^{-1} together with the shoulders appearing between 1725 and 1730 cm^{-1} as illustrated in Fig. 6 and in Table 2 (B). The shoulders were ascribed to the C=O stretching vibration

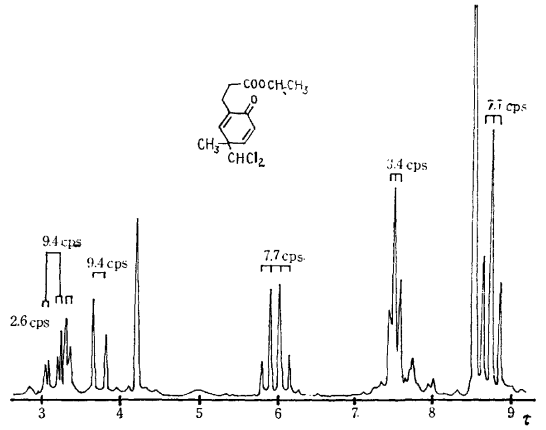

Fig. 4. NMR spectrum of **6** ($CDCl_3$).

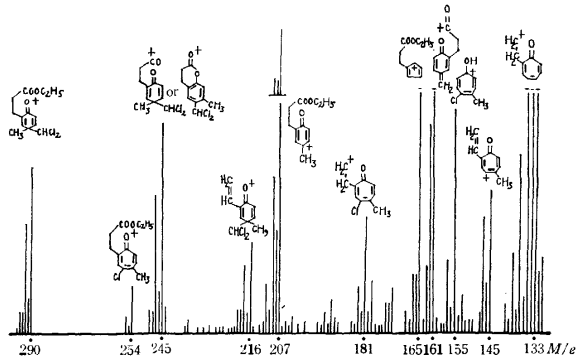

Fig. 5. Mass spectrum of **6**. Ionizing voltage, 75 eV; ionizing current, 200 μA; Sample temperature, 75°C; chamber temperature, 80°C. The formulae are possible ionic species.

of the COO–Cu/2 bond,[20] in analogy with those of the penta-coordinate addition compounds of bissalicylaldehyde-ethylenediimine-copper derivatives with propionic acid. The broad first bands of binuclear chelates **11a,b,c** and **12a,b,c** were observed between 690 and 750 mμ and between 624 and 700 mμ (blue shift), respectively, while the distinct first bands of **13a,b,c** were observed between 553 and 560 mμ as shown in Fig. 7 and Table 2 (A). The wave lengths of the absorption maxima of **13a,b,c** were nearly the same as those of the addition compounds of bis-salicylaldehyde-ethylene-diimine-copper derivatives with propionic acid. This indicates that one of the side chain carboxylic acid groups form the addition compound of the chelate itself to make the pentacoordinate structure such as **13a,b,c**.

The absorption peaks of 1610—1645 cm^{-1} due to the carboxylate ions of the ligands **15a,b,c** and the $-\overset{+}{N}H_2-$ peaks of 1550—1565 cm^{-1} indicate their dipolar structure.

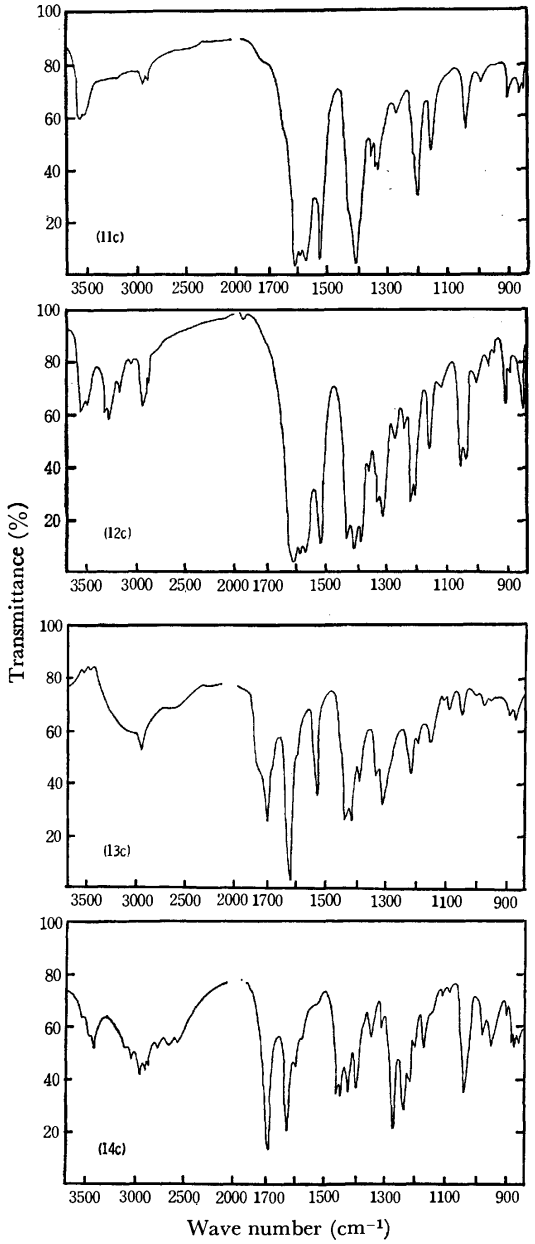

Fig. 6. Infrared spectra of **11c**, **12c**, **13c**, and **14c**. (KBr disc)

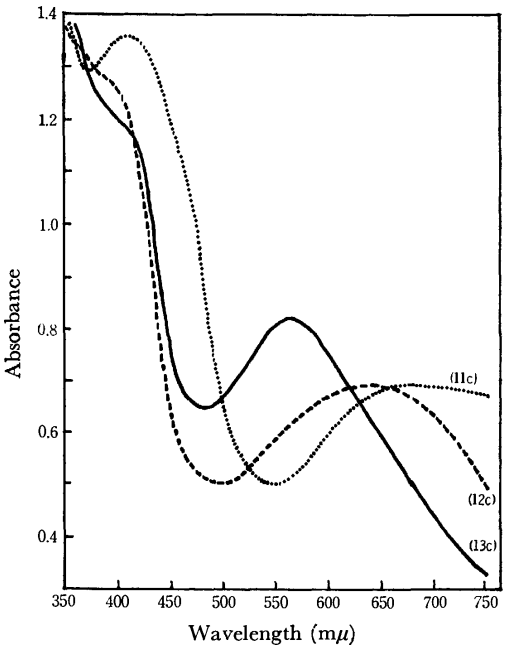

Fig. 7. Reflectance spectra of **11c**, **12c**, and **13c**.

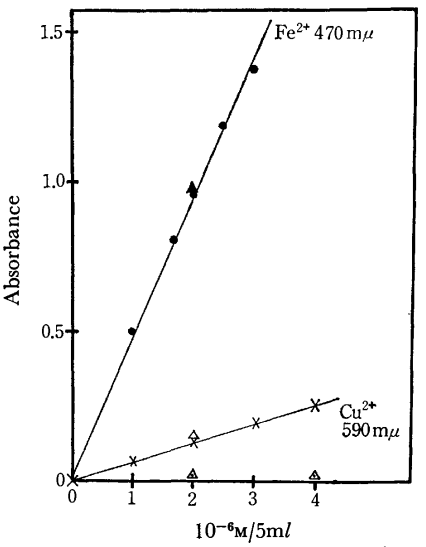

Fig. 8. Spectrophotometric determination of Cu(II) and Fe(II). Measurements were made of 5 m*l* of aqueous solutions containing 0.5 m*l* of 1/100 M solution of disodium salt of (15c), 0.1 m*l* of pH 10 and 7 buffer solutions respectively and; ×, moles of copper acetate; ●, moles of ferrous chloride; ◬, moles of nickel acetate; △, ▲, mixtures of each moles of Cu(II)-Ni (II) and Fe (II)-Ni (II) respectively. Cell depth 1 cm and pure water as reference.

20) Most of the copper carboxylates are of the symmetric carboxylate ion coordination type (ref. 5) and references are not available for the asymmetric copper carboxylate of this structure. Assignment of the structure, nevertheless, was based on the steric hindrance studies: T. Tanaka, *Nippon Kagaku Zasshi*, **79**, 942 (1958) and the IR spectra: T. Tanaka, *ibid.*, **81**, 1013 (1960).

Experimental

The melting points were uncorrected. The spectra were taken on a Hitachi EPS-3T ultraviolet and visible spectrophotometer, Hitachi EPI-G2 infrared spectrophotometer, Hitachi H-60 NMR spectrometer and Nihon-Densi JMS-O1S-G mass spectrometer. The infrared spectra were measured over 400—4000 cm^{-1} in Nujol mull and a potassium

bromide disk. The wave numbers of the observed absorption bands were calibrated with polystyrene. The samples for magnetic measurements were purified by washing twice with hot ethanol, three times with hot water and four times with 70% (v/v) aqueous ethanol in an amount from which **11a**, **b**, **c** could be recrystallized.

*5-Methyl-3-β-carboxyethylsalicylaldehyde (**2b**).* Forty grams of 6-methyldihydrocoumarin[21] was dissolved in an aqueous sodium hydroxide solution (110 g of sodium hydroxide in 650 m*l* of water) at 65—70°C. To the solution was added 90 g of chloroform for an hour at the same temperature under thorough stirring which was continued for 7 hr and a half. The reaction mixture was cooled, acidified with hydrochloric acid and extracted twice with ether. The combined ether solution was washed with water and extracted twice with a saturated aqueous solution of sodium bisulfite (30 g of sodium bisulfite was used). The ether layer (A) and the sodium bisulfite solution were separated. The combined sodium bisulfite solution was acidified with hydrochloric acid and extracted with ether (B). The ethereal extract (B) was washed with water, dried over sodium sulfate. A grease-like residue obtained after the evaporation of ether was extracted with hot petroleum ether. Crystals obtained from the petroleum ether solution were recrystallized from the same solvent. Pale yellow crystal, mp 93°C. Yield 332 mg.[22] In another run, extraction with an aqueous solution of 50 g of sodium bisulfite yielded 956 mg of the aldehyde.

*4-Methyl-4-dichloromethyl-2-β-carboxyethyl-cyclohexa-2,5-dien-1-one (**5**).* The ether layer (A) obtained as above was washed with water and dried over sodium sulfate. Evaporation of ether in a vacuum at room temperature yielded 31 g of residual dark red oil **Q**. Examination of the mass spectrum and thin layer chromatogram of **Q** indicated that it consisted of **5** (main fraction), **2b** (minor fraction) and a small amount of other compounds.

*Separation of **2b** in **Q** as Semicarbazone.* Three grams of semicarbazide hydrochloride and 3 g of potassium acetate were dissolved in 9 m*l* of water. To the solution was added 5.9 g of **Q** dissolved in 8 m*l* of ethanol. The semicarbazone of **2b** separated immediately after the addition was recrystallized from ethanol. Mp 207°C. Yield 1.1 g. This was identified by both the mixed melting point and a comparison of the IR spectra with those of the authentic sample.

Found: C, 53.40; H, 5.75; N, 15.39%. Calcd for $C_{12}H_{15}O_4N_3$: C, 54.33; H, 5.70; N, 15.84%.

*Conversion of **5** into 6-Methyldihydrocoumarin (**3**).* Thirty grams of **Q** dissolved in 100 m*l* of dioxane was irradiated with sunlight for twenty hours. The solution was dried over sodium sulfate and distilled. A distillate of bp 120—150°C/4 mmHg was obtained and solidified by the seeding. Recrystallization of the distillate from aqueous alcohol (alcohol 7: water 3) gave 12.68 g of 6-methyldihydrocoumarin. Distillation without any irradiation gave a resinous polymerizate.

*The Ethyl Ester **6**.* Fifteen grams of **Q** was dissolved in 100 m*l* of ethanol (in which 3 g of dry hydrogen chloride was contained), warmed in a water bath at 60°C for 3 hr and left to stand overnight. The solution was treated with 50 m*l* of benzene, washed with water, dried over sodium sulfate and distilled. Fraction I. bp —153°C/6 mmHg, 1.4 g; Fraction II. bp 135—155°C/5 mmHg, 1.8 g; Fraction III. bp 155—168°C/5 mmHg, 9.1 g. Redistillation of Fraction III gave slightly yellow colored distillate of bp 158—162°C/5 mmHg (tlc, R_f=0.58, silica gel; benzene 8: ethyl acetate 2) which was proved to be the ester **6** as discussed above. Fractions I and II contained a compound of R_f=0.72 as the major component and *6* as a minor component.

Found: C, 53.98; H, 5.53; Cl, 22.60%. Calcd for $C_{13}H_{16}O_3Cl_2$: C, 53.62; H, 5.54; Cl, 24.35%.

*The Semicarbazone of **6**.* To a solution of 600 mg of semicarbazide hydrochloride and 600 mg of potassium acetate in 1.8 m*l* of water was added 920 mg of ***6*** and a small amount of ethanol. The solution was left to stand for 4 days at room temperature. The crystals separated were recrystallized from ethanol. Mp 153°C. Yield 586 mg.

Found: C, 48.34; H, 5.49; N, 12.07; Cl, 20.21%. Calcd for $C_{14}H_{20}O_3N_3Cl_2$: C, 48.14; H, 5.77; N, 12.03; Cl, 20.29%.

*5-Chloro-3-β-carboxyethylsalicylaldehyde (**2c**) and 2-β-carboxyethyl-1,4-benzoquinone (**9**).* The same procedure as for the Reimer-Tiemann reaction by use of 30 g of 6-chlorodihydrocoumarin,[21] 72.6 g of sodium hydroxide in 220 m*l* of water and 62 g of chloroform followed by bisulfite extraction yielded a mixture of compounds. On recrystallization of the mixture from benzene, a compound with very small solubility 2-β-carboxyethyl-1,4-benzoquinone, mp 160°C, separated out. Yield 232 mg (after recrystallization from benzene). IR spectrum, 1703 cm^{-1} (COOH), 1650, 1586 cm^{-1} (quinonoid enone). NMR spectrum ($(CD_3)_2SO$), 1H (COOH) 0.25 τ; 3H (quinone ring) 1H doublet 3.06 τ (J_1=9 cps), 1H doublet 2.38 τ (J_2=2 cps), 1H quartet 2.41 τ (J_1=9 cps, J_2=2 cps).

Found: C, 60.64; H, 5.25%. Calcd for $C_9H_8O_3$: C, 60.00, H, 4.48%.

From the mother liquor of recrystallization, **2c** of mp 118°C was obtained. Yield 2.15 g (after recrystallization from benzene).[22]

As a non-carbonyl fraction (not removed by bisulfite extraction) 19.5 g of crystal was obtained which after recrystallization from benzene melted at 136°C and was identified to be **10** by melting point, analysis and the superimposable IR spectra.

*5-Bromo-2-hydroxyphenylacetic acid (**1**).* To a vigorously stirred mixture of 30.2 g of 2-hydroxyphenylacetic acid[23] in 200 m*l* of carbon disulfide cooled in an ice-salt bath, was added a solution of 32 g of bromine in 80 m*l* of carbon disulfide for two hours. Stirring was continued for 2 hr, and left to stand overnight at room temperature. The precipitate separated was filtered and recrystallized from benzene. Mp 151°C, yield 23.7 g.[22]

*5-Bromo-3-carboxymethylsalicylaldehyde (**2a**).* 1.60 g of **2a** was obtained by the same Reimer-Tiemann procedure, starting with 11.6 g of 5-bromo-2-hydroxyphenylacetic acid, 22 g of sodium hydroxide in 120 m*l* of water and 18 g of chloroform. Recrystallized from benzene. Pale yellow crystal. Mp 204°C.[22]

*Bis-(5-bromo-3-carboxymethylsalicylaldehyde)-ethylenediimine (**14a**).* To a solution of 1.036 g of **2a** in 50 m*l* of ethanol heated on a water bath was added a solution of 0.156 g of ethylenediamine in 10 m*l* of ethanol and the mixture was heated for 30 min on the water bath. The precipitate with a small solubility in ethanol separated immediately, and was filtered (1.1 g) and recrystallized from a large amount of ethanol. Yellow crystal. Mp 242°C.[22]

*Bis-(5-methyl-3-β-carboxyethylsalicylaldehyde)-ethylenediimine (**14b**).* To a hot solution of 51 mg of ethylenediamine in 4 m*l* of ethanol were added crystals of 312 mg of **2b** and the mixture was heated on a water bath for 30 min. On

cooling and scratching the wall of the flask with a glass rod, yellow crystals separated; readily soluble in ethanol and recrystallized from ethanol, mp 195°C, yield 276 mg.[22]

Bis-(5-chloro-3-β-carboxyethylsalicylaldehyde)-ethylenediimine (14c). Prepared in the same way as **14b**, from 457 mg of **2c** and 65 mg of ethylenediamine in 6 m*l* of ethanol. Yellow crystal. Mp 204°C. Yield 226 mg.[22]

N,N'-*bis-(5-chloro-2-hydroxy-3-β-carboxyethylbenzyl)-ethylenediamine (15c).* To a suspension of 150 mg of the Schiff base **14c** in 18 m*l* of absolute methanol heated to 48—50°C in an oil bath, was gradually added 100 mg of crystals of sodium borohydride after the frothing subsided.[24] When the addition was over, the temperature of the reaction mixture was gradually raised to 90°C, and then cooled and filtered. To the filtrate was added 15 m*l* of water and then a dilute aqueous acetic acid solution until turbidity appeared. In a few minutes white crystals separated out and which were filtered and dried. For further purification, the product was dissolved in 15 m*l* of a dilute aqueous sodium hydroxide solution (*ca.* 1/10 N), to which was added 18 m*l* of methanol and a dilute aqueous acetic acid solution until turbidity ensued. Crystals which separated out in a few minutes were filtered, washed with water and dried. Colorless crystals. Mp (dec.) 280—300°C, yield 128 mg.

Found: C, 53.55; H, 5.70; N, 5.19%. Calcd for $C_{22}H_{26}O_6N_2Cl_2$: C, 54.43; H, 5.40; N, 5.79%.

N,N'-*bis-(5-bromo-2-hydroxy-3-carboxymethylbenzyl)-ethylenediamine (15a).* Prepared in the same way as **15c**, starting with 437 mg of **14a** and 322 mg of sodium borohydride. Colorless crystal. Mp (dec.) 300°C, yield 287 mg.[22]

N,N'-*bis-(5-methyl-2-hydroxy-3-β-carboxyethylbenzyl)-ethylenediamine (15b).* Prepared in the same way as **15c**, starting with 700 mg of **14b** and 500 mg sodium borohydride in 56 m*l* of absolute methanol. Colorless crystal. Mp (dec.) 285°C, yield 559 mg.[22]

Di-μ-aquo-bis-(5-bromo-3-carboxymethylsalicylaldehyde)-dicopper (11a). To a hot solution of 518 mg (1/1000 mol) of **2a** in ethanol was added an aqueous solution of 399 mg (1/1000 mol) of copper acetate and the mixture was heated on a water bath for 20 min. The precipitate separated out immediately was filtered while hot and purified by washing several times with hot ethanol and water; bright green crystal, yield 587 mg. The yield and composition of the chelate were not altered even when twice as much aldehyde was used.

Found: C, 31.70; H, 1.58; Cu, 18.77%. Calcd for $C_{18}H_{14}O_{10}Br_2Cu_2$: C, 31.92; H, 2.08; Cu, 18.77%.

Di-μ-aquo-bis-(5-methyl-3-β-carboxyethylsalicylaldehyde)-dicopper (11b). Prepared in the same way as **11a**, starting with 412 mg of **2b** and 400 mg of copper acetate. Bright green powder. Yield 496 mg.

Found: C, 46.18; H, 4.57; Cu, 21.02%. Calcd for $C_{22}H_{24}O_{10}Cu_2$: C, 45.91; H, 4.20; Cu, 22.08%.

Di-μ-aquo-bis-(5-chloro-3-β-carboxyethylsalicylaldehyde)-dicopper (11c). Prepared in the same way as **11a**, starting with 115 mg of **2c** and 98 mg of copper acetate; bright green powder. Yield 140 mg.

Found: C, 38.51; H, 3.02; Cu, 21.01%. Calcd for $C_{20}H_{18}O_{10}Cl_2Cu_2$: C, 38.97; H, 2.94; Cu, 20.62%.

Di-μ-aquo-bis-(5-chloro-3-β-carboxyethylsalicylaldehyde)-ethylenediimine-dicopper (12c). To a suspension of 100 mg of **11c** in 5 m*l* ethanol was added a solution of 10 mg of ethylenediamine in 3 m*l* of water and the mixture was heated on a water bath for 20 min. Green crystals precipitated which were purified by washing repeatedly with ethanol and water. Yield 91 mg.

Found: C, 41.55; H, 3.64; N, 4.92; Cu, 20.53%. Calcd for $C_{22}H_{22}O_8N_2Cl_2Cu_2$: C, 41.26; H, 3.46; N, 4.37; Cu, 19.84%.

Di-μ-aquo-bis-(5-bromo-3-carboxymethylsalicylaldehyde)-ethylenediimine-dicopper (12a). Prepared by the reaction of 102 mg of **11a** and 10.2 mg of ethylenediamine; green powder, yield 89 mg.

Found: C, 33.63; H, 2.22; N, 4.85; Cu, 18.60%. Calcd for $C_{20}H_{18}O_8N_2Br_2Cu_2$: C, 34.25; H, 2.59; N, 4.01; Cu, 18.12%.

Di-μ-aquo-bis-(5-methyl-3-β-carboxyethylsalicylaldehyde)-ethylenediimine-dicopper (12b). Prepared by the reaction of 87 mg of **11b** in 3 m*l* of ethanol with 10 mg of ethylenediamine in 1 m*l* of water; green powder, yield 85 mg.

Found: C, 47.35; H, 5.13; N, 4.64; Cu, 20.38%. Calcd for $C_{24}H_{28}O_8N_2Cu_2$: C, 48.08; H, 4.70; N, 4.67; Cu, 21.20%.

Bis-(5-chloro-3-β-carboxyethylsalicylaldehyde)-ethylenediimine-copper (13c). To a hot solution of 240 mg of **14c** in 20 m*l* of ethanol was added a solution of 100 mg of copper acetate in 10 m*l* of water. The reaction mixture was heated on a water bath for 30 min and the precipitate was filtered hot. The gray purple product was recrystallized from a large amount of ethanol, yield 239 mg.

Found: C, 47.94; H, 3.73; N, 5.13; Cu, 12.03%. Calcd for $C_{22}H_{20}O_6N_2Cl_2Cu$: C, 48.67; H, 3.71; N, 5.16; Cu, 11.70%.

Bis-(5-methyl-3-β-carboxyethylsalicylaldehyde)-ethylenediimine-copper (13b). Prepared in the same way as **13c** by the reaction of 220 mg of **14b** in 20 m*l* of ethanol with 100 mg of copper acetate in 10 m*l* of water. Gray purple crystal, yield 208 mg.

Found: C, 56.10; H, 5.32; N, 5.59; Cu, 13.12%. Calcd for $C_{24}H_{26}O_6N_2Cu$: C, 57.42; H, 5.22; N, 5.58; Cu, 12.66%.

Bis-(5-bromo-3-carboxymethylsalicylaldehyde)-ethylenediimine-copper (13a). The reaction of 108 mg of **14a** and 40 mg of copper acetate yielded 103 mg of a brown copper chelate. The chelate could not be obtained in a pure state owing to the low solubility of **14a** and the copper chelate; purplish brown powder.

Found: C, 39.13; H, 3.02; N, 5.63; Cu, 9.50%. Calcd for $C_{20}H_{16}O_6N_2Br_2Cu$: C, 39.79; H, 2.67; N, 4.64; Cu, 10.53%.

N,N'-*bis-(5-methyl-2-hydroxy-3-β-carboxyethylbenzyl)-ethylenediamine-copper (21).* A solution of 40.8 mg of copper acetate in 3 m*l* of water was added to a solution of 89.38 mg of **15b** in 5.4 m*l* of 1/10 N aqueous sodium hydroxide (f= 0.744) at room temperature with stirring. Yellow green crystals separated immediately. After stirring for one and a half hour, the precipitate was filtered, washed thoroughly with water and ethanol and recrystalized from 70% aqueous ethanol. Green crystal, yield 88.08 mg.

Found: C, 51.88; H, 6.40; N, 5.01; Cu, 10.91%. Calcd for $C_{24}H_{30}O_6N_2Cu$–$3H_2O$: C, 51.46; H, 6.48; N, 5.01; Cu, 11.34%.

The author wishes to thank Dr. M. Nakanishi and Mr. T. Kuriyama, Yoshitomi Pharmaceutical Company, for the mass spectral measurements, Profs. M. Kikutani and T. Kuraishi and the staff of NMR center, Nagasaki University, for the NMR measurements, and Prof. K. Hirakawa, Tokyo University, Prof. K. Hirakawa and their co-workers, Kyushu University, for the magnetic measurements.

Kinetics of the Acid Hydrolysis of Carboxylatopentammineruthenium(III) Complexes

Akira OHYOSHI, Akinori JYO, and Noriaki SHIN

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kurokami-machi, Kumamoto

(Received April 23, 1971)

The kinetics of the hydrolysis of pentammineruthenium(III) complexes containing carboxylates and α-substituted acetates (glycolate and glycinate) have been studied. The experiments were carried out in a solution of $[H^+]=0.025$—0.1 M, at 40—70°C. For each complex, the rate law was found to be: rate$=[\text{complex}](k_{H_2O}+k_H[H^+])$. The k_{H_2O} and k_H values for the formato, acetato, propionato, isobutyrato, glycolato, and glycinato complexes are, respectively (at $\mu=0.10$, 59—61°C): k_{H_2O}, 5.37×10^{-5}, 11.8×10^{-5}, 14×10^{-5}, 13.7×10^{-5}, 5.7×10^{-5}, and 6.75×10^{-5} sec^{-1}; k_H, 3.3×10^{-3}, 2.3×10^{-3}, 2.5×10^{-3}, 1.7×10^{-3}, 0.75×10^{-3}, and 3.1×10^{-3} $M^{-1}sec^{-1}$. The mechanisms of acid hydrolysis are discussed for the two reaction paths.

Recently, the kinetic studies of the hydrolysis of halogenopentammineruthenium(III)[1,2] and related complexes[2] have been reported. The kinetics of aquation have also been studied with some carboxylatopentammine complexes $[M(NH_3)_5OOCR]^{2+}$ (where M= Co(III), Rh(III), and Ir(III)) by Basolo *et al.*,[3,4] Kuroda,[5,6] and Saito *et al.*[7,8] These metal ions have six *d*-electrons, but Ru(III) has five. Therefore, it is of interest to study the aquation of a similar type of Ru(III) complexes and to compare them with d^6-metal complexes. In this paper, we will report on the kinetics of the aquation of several alkyl-, hydroxyl-, or amino-substituted-carboxylatopentammineruthenium-(III) complexes.

Experimental

Reagents. All the chemicals used were of a reagent grade. Twice-distilled water was used in all the kinetic runs. The ionic strength and the acidity of the reaction solution were adjusted with *p*-toluenesulfonic acid and its sodium salt. The sodium salt was prepared by the neutralization of *p*-toluenesulfonic acid with sodium hydroxide.

Preparation of Complexes. *Chloropentammineruthenium(III) chloride* was prepared by the method of Allen *et al.*[9,10] from ruthenium trichloride and hydrazine hydrate.

Found: H, 5.08; N, 23.75%. Calcd for $[RuCl(NH_3)_5]Cl_2$: H, 5.19; N, 23.98%.

Aquopentammineruthenium perchlorate was prepared by the method of Endiccot and Taube.[11]

Found: H, 3.20; N, 13.74%. Calcd for $[Ru(H_2O)(NH_3)_5](ClO_4)_3$: H, 3.42; N, 13.94%.

Formatopentammineruthenium and other carboxylatopentammineruthenium perchlorates were prepared by the method of Stritar and Taube[12] from chloropentammineruthenium chloride, a carboxylate buffer solution, and a zinc amalgam.

Found: C, 3.00; H, 3.62; N, 16.39%. Calcd for $[Ru(NH_3)_5OOCH](ClO_4)_2$: C, 2.79; H, 3.75; N, 16.28%.

Found: C, 5.37; H, 3.86; N, 15.61%. Calcd for $[Ru(NH_3)_5OOCCH_3](ClO_4)_2$: C, 5.41; H, 4.08; N, 15.77%.

Found: C, 7.90; H, 4.29; N, 15.15%. Calcd for $[Ru(NH_3)_5OOCC_2H_5](ClO_4)_2$: C, 7.86; H, 4.41; N, 15.28%.

Found: C, 10.44; H, 4.32; N, 14.70%. Calcd for $[Ru(NH_3)_5OOCCH(CH_3)_2](ClO_4)_2$: C, 10.17; H, 4.70; N, 14.83%.

Found: C, 5.47; H, 3.75; N, 14.97%. Calcd for $[Ru(NH_3)_5OOCCH_2OH](ClO_4)_2$: C, 5.22; H, 3.94; N, 15.22%.

Found: C, 4.37; H, 3.80; N, 14.84%. Calcd for $[Ru(NH_3)_5OOCCH_2NH_3](ClO_4)_3$: C, 4.28; H, 3.60; N, 14.99%.

These complexes were also characterized by their electronic and IR spectra.

Kinetic Runs. The rates of the reactions were followed spectrophotometrically. It was found that the usual inorganic acids were unsuitable for the study of acid hydrolysis. In perchloric and nitric acid solutions, the aquation and decomposition of the complex occurred simultaneously. Several hours later, the appearance of the reaction mixture changed from a transparent pale yellow to a turbid dark brown. These phenomena are probably due to the oxidation of ruthenium(III) by acid anions. In hydrochloric and sulfuric acid, ligand replacements were spectrophotometrically identified. *p*-Toluenesulfonic acid is the best for studying the kinetics of aquation. Since *p*-toluenesulfonate has a strong $\pi\leftrightarrow\pi^*$ absorption below 280 mμ, the rates of hydrolysis were followed by measuring the changes in the absorbances of the respective complex ion in the wavelength region of 290—300 mμ.

All the kinetic experiments were performed in a stoppered quartz cell placed in a cell compartment of HITACHI 124 spectrophotometer. The reaction mixture in the cell was kept at a constant temperature, ±0.2°C, by circulating water from a thermostated bath. After thermal equilibrium has been achieved, a weighed amount of the complex (about 1 mg) was rapidly dissolved in an aqueous solution of a given ionic strength and acid concentration. The absorbances of the complexes in the reaction mixtures were measured at appropriate intervals.

Identification of the Reaction Product. Since aquopentammineruthenium(III), which has an absorption maximum at 268 mμ,[5] can not be directly detected, as was mentioned above, it was separated and identified. About six half-lives

later, the reaction mixture was passed through a column of ion-exchange resin (Dowex 50X-8, 100—200 mesh). The column was washed several times with water until no *p*-toluenesulfonate ion was detected in the washings, and then a 3M sodium perchlorate solution (pH 1.0 with perchloric acid) was passed through the column. The electronic spectrum of this eluate was measured and compared with that of the authentic aquopentammine complex.

Results

The electronic spectrum of the reaction product coincided with that of the aquopentammineruthenium(III) ion prepared from chloropentammineruthenium(III) and ammonia water (Fig. 1). The extent of the absorbance of the reaction product contributing to that of the reactant was smaller than 3% at one half-life of the reaction. The changes in the spectrum during the acid hydrolysis of the acetatopentammine complex are exemplified in Fig. 2. The acid hydrolysis reaction is an irreversible one, for the plot of log C_t *vs.* the reaction time is linear over a period of approximately one half-life, as is shown in Fig. 3, where C_t denotes the concentration of the complex at the reaction time, t. As is shown in Fig. 3, the slopes of the first-order plots are independent of the initial concentration of the reactant complex at the same hydrogen-ion concentration, ionic strength, and reaction temperature.

The pseudo first-order rate constants, k_{obs}, for the acid hydrolysis of carboxylatopentammines as a function of the hygrogen-ion concentration are listed in Table 1. The values of k_{obs} have a precision of $\pm 5\%$ or better. As is shown in Fig. 4, the plots of k_{obs} *vs.* the hydrogen-ion concentration are linear for the formatopentammine complex, and similar relationships were obtained for the other five complexes. From these results, it is possible to estimate an acid-independent rate constant, k_{H_2O}, and an acid-dependent rate constant k_H. The observed rate constant, k_{obs}, can be expressed by Eq. (1):

$$k_{obs} = k_{H_2O} + k_H[H^+] \quad (1)$$

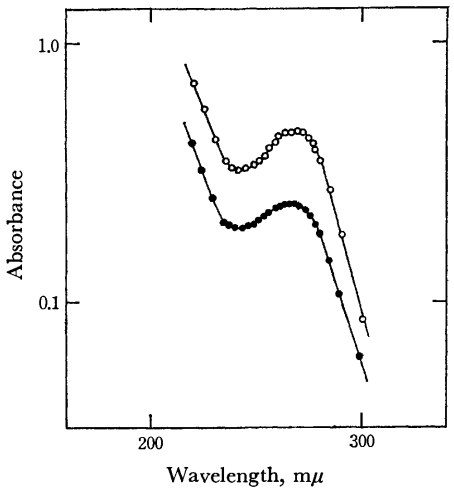

Fig. 1. Identification of the reaction product.
A: Spectrum of $[Ru(H_2O)(NH_3)_5]^{3+}$ prepared from $[RuCl(NH_3)_5]^{2+}$ in 0.1M $HClO_4$.
B: Spectrum of the reaction product eluted from cation exchange resin.
Reactant complex=$[Ru(NH_3)_5OOCH]^{2+}$

The calculated k_{H_2O} and k_H values are listed in Table 2, together with the pK_a values of the carboxylic acids.

The influence of the ionic strength on the rate of the hydrolysis was also investigated, the results are given in Table 3. The rates of hydrolysis increase with an increase in the ionic strength. This fact indicates that there is a positive kinetic salt effect.

The activation parameters for the reactions were evaluated from the kinetic data at 40—70°C and at an ionic strength of 0.1. The results are listed in Table 4.

Discussion

Equation (1) shows that the rate of hydrolysis of the complex is dependent on the hydrogen-ion concentration and that the two reaction paths are involved in the reaction mechanism of the hydrolysis. This can be expressed by Eq. (2) for one path and by Eqs. (3) and

(4) for the other path:

$$[(NH_3)_5Ru\text{-}O\overset{O}{\overset{\|}{C}}R]^{2+} + H_2O \xrightarrow{k_2} [(NH_3)_5RuOH_2]^{3+} + RCOO^- \quad (2)$$

$$[(NH_3)_5Ru\text{-}O\overset{O}{\overset{\|}{C}}R]^{2+} + H^+ \overset{K_3}{=} [(NH_3)_5Ru\text{-}O\overset{OH}{\overset{|}{C}}R]^{3+} \quad (3)$$

$$[(NH_3)_5Ru\text{-}O\overset{OH}{\overset{|}{C}}R]^{3+} + H_2O \xrightarrow{k_4} [(NH_3)_5RuOH_2]^{3+} + RCOO^- + H^+ \quad (4)$$

The rate constant of an uncatalysed path [Eq. (2)], k_2, corresponds to k_{H_2O}. Equations (3) and (4) indicate an acid-catalysed path, the rate constant, k_H, of which can be expressed by Eq. (5):

$$k_H = k_4K_3 \quad (5)$$

these relationships for the hydrolyses of similar complexes of Co(III), Rh(III), and Ir(III) have previously reported.[4-8] However, it should be noted that the values of k_{H_2O} and k_H for ruthenium(III) complexes are greater than those of the Co(III), Rh(III), and Ir(III) complexes. In view of the electrostatic attraction between the metal and the ligand ion, the aquation of the d^5-metal complex should proceed faster than that of the d^6-metal complex if the break of the metal-ligand bond is the rate-determining step.

As is shown in Table 2, the k_{H_2O} values in a solution of $\mu=0.1$ at 59—61°C decrease in the order of isobutyrato-, (≃propionato-), acetato-, glycinato-, glycolato-, and formatocomplex. This suggests that the rate becomes faster, the greater the size of the leaving group, and that the reactions proceed through a dissociation-type mechanism.

The rates of the aquation of some carboxylatopentammineruthenium(II) complexes have been reported by Stritar and Taube.[12] In the acid-independent path, the values of the rate constants are 1.28 sec^{-1} and <5 sec^{-1} for the formato- and acetatocomplexes at 25°C and an ionic strength of 0.1. The values for the corresponding ruthenium(III) complexes which are obtained from the present experiments and extrapolated to the same experimental conditions are 1×10^{-5} and 7×10^{-6} sec^{-1} respectively. The ratios of the rate constants of the Ru(II) complexes to those of the Ru(III) complexes are 10^5 and 10^6. The effect of the positive charge of the complex on the rate could be interpreted as follows. The separation of a negative charge in the form of the carboxylate ion is more difficult as the remaining charge on the complex increases. These facts may indicate that the bond break is important and that we are dealing with an S_N1 mechanism in the present reactions.

The rate constant of hydrolysis, k_{obs}, increases with the increase in the ionic strength of the acidic solution (Table 3). This indicates that both of the reactants have same kinds of charge. When $[H^+]=0.1$ M, we can assume k_{H_2O} to be much smaller than k_H; thus, k_{obs} is nearly equal to k_4K_3. As may be seen from Eqs. (3) and (4), a positive kinetic salt effect can be expected in Eq. (3), the equilibrium constant of which is K_3. Therefore, it can be concluded that K_3 is the more effective fraction in the acid-dependent path.

Basolo *et al.*[4] reported that the k_{H_2O} values of carboxylatopentamminecobalt(III) complexes tend to decrease with an increase in the pK_a values of the ligand acids. The results in Table 2 do not indicate that such a relation fits the ruthenium(III) complexes. On the contrary, the k_H values for the ruthenium(III) complexes decrease with the increase in the pK_a values. The pK_a values affect the equilibrium constant, K_3, of Eq. (3), and hence the k_H values. The k_H values of the glycolato- and glicinatocomplexes are smaller than those of the other complexes. Concerning the glicinatocomplex of cobalt(III), Saito *et al.*[8] described the small k_H value as being due to the difficulty with which the protonated species are formed. For the similar complex of ruthenium(III), the same effect seems to be exhibited. The influence of the substituting hydroxyl group in the glycolatocomplex is not very clear, but it may be considered that there are some interactions between the hydroxyl and the carboxylate groups such as those in the aminoacid complex.

With regard to the hydrolysis of acetatopentamminecobalt(III), Monacelli *et al.*[4] reported that the acid-independent path proceeds by means of metal-oxygen bond fission and that the acid-dependent path takes place through the breaking of the acyl-oxygen bond. Bunton and Llewllyn[13] found that the aquation of this complex proceeds by means of metal-oxygen bond cleavage on the basis of a tracer study with oxygen-18.

The k_{H_2O} values for Co(III)[4] and Ru(III) acetatopentammine are, respectively, $8.0\times10^{-1}sec^{-1}$ and $2.9\times10^{-4}sec^{-1}$ at 70°C and an ionic strength of 0.1. Thus, the ratio of the rate constants, k_{H_2O}, for these complexes is 1 : 36, while the ratio of k_H is 1 : 5 under the same experimental conditions.

These facts suggest that the influence of the central metal ion on the rate of aquation is larger for the acid-independent path than for the acid-dependent path. Therefore, it may be supposed that the bond fission occurs at a position farther from the central metal ion

13) C. A. Bunton and D. R. Llewellyn, *J. Chem. Soc.*, **1953**, 1692.

in the acid-dependent path than that in the acid-independent path. Thus, we believe that the acid-dependent path proceeds *via* acyl-oxygen bond fission and that the acid-independent reaction takes place through the breaking of the ruthenium-oxygen bond. These reaction mechanism are shown in Eq. (8) and (9):

$$[(NH_3)_5Ru\text{-}\overset{O}{\overset{\|}{O}}CR]^{2+} \longrightarrow [(NH_3)_5Ru\cdots\overset{O}{\overset{\|}{O}}CR]^{2+} \xrightarrow{H_2O} [(NH_3)_5RuOH_2]^{3+} + RCOO^- \quad (8)$$

$$[(NH_3)_5Ru\text{-}\overset{O}{\overset{\|}{O}}CR]^{2+} + H^+ \overset{K_3}{\rightleftharpoons} [(NH_3)_5Ru\text{-}\overset{OH}{\overset{|}{O}}CR]^{3+}$$

$$[(NH_3)_5Ru\text{-}\overset{OH}{\overset{|}{O}}CR]^{3+} \longrightarrow [(NH_3)_5Ru\text{-}O\cdots\overset{OH}{\overset{|}{C}}R]^{3+} \xrightarrow{H_2O} [(NH_3)_5RuOH_2]^{3+} + RCOO^- + H^+ \quad (9)$$

As another possibility, the attack of the water molecule on the carboxyl group may be considered; this would also lead to the acyl-oxygen bond cleavage.[13] We have, however, not yet obtained any experimental evidence to confirm this mechanism.

As is shown in Table 4, the activation energies for the acid-independent paths are generally larger than those for the acid-dependent paths. These values are independent of the substituting group in carboxylic acids except for the acid-dependent path of isobutyrato-complex. The activation energies for the k_{H_2O} values of d^5-(Ru^{III}) metal complexes are nearly the same as those of the d^6-(Co^{III}, Rh^{III}, and Ir^{III}) metal complexes. However, it was found that the activation energies for the k_H values of d^5-metal complexes are less than those of the d^6-metal complexes. The difference between the values of the formatocomplexes amounted to 6.2 kcal/mol.

The entropies of activation for k_H are more negative than those for k_{H_2O}. This suggests that the difference in the extent of hydration between the transition state and the ground state is larger in the acid-dependent path than in the acid-independent path. As is shown in Eqs. (8) and (9), there is an increase of +1 unit charge in the acid-dependent path, while no variation of the charge arises in the acid-independent path.

In the acid-dependent path, the entropy of activation, $\Delta S^{\ddagger}$, obtained may be expressed as follows:

$$\Delta S^{\ddagger} = \Delta S_{K_3} + \Delta S^{\ddagger}_{K_4}$$

where ΔS_{K_3} is the change of entropy for the process of protonation to the complex cation with the equilibrium constant K_3, and where $\Delta S^{\ddagger}_{K_4}$ is the entropy of activation with respect to the rate constant, K_4, described in Eq. (9). When reactions take place between two ions, an important contribution to the entropy of activation arises from the electrostatic force. For a reaction between two ions, A (Z_A charge) and B (Z_B charge), in a dilute aqueous solution, the entropy of activation is approximately $-10\ Z_AZ_B$ e.u./mol.[14] Considering that Z_AZ_B is +2 in the process of protonation, the value of −20 e.u./mol can be calculated for ΔS_{K_3}. This is comparatively close to the observed values of activation entropies, and they are nearly the same for the cases of the formato-, acetato-, and propionatocomplexes. Therefore, it may be considered that a large part of $\Delta S^{\ddagger}$ consists of ΔS_{K_3} in these cases. The values of the activation entropies for k_H are considerably different in the case of the isobutyrato- and glycinatocomplexes. This indicates that the extent of the contribution of ΔS_{K_3} to $\Delta S^{\ddagger}$ may not be the same as in the other cases.

Study of Hydration and Association of Ions in Solution. II.[1] Complete Resolution of Tris(ethylenediamine)Cobalt(III), Chromium(III), and Rhodium(III) Complexes by Means of Paper Electrophoresis

Hayami YONEDA* and Takao MIURA

Chemistry Department A, The Technical University of Denmark, Lyngby, Denmark
Department of Chemistry, Wakayama University, Masagocho, Wakayama, Japan

(Received August 21, 1971)

Complete resolution of racemic $[M\ en_3]^{3+}$ ($M=Co^{III}$, Cr^{III}, and Rh^{III}) by means of electrophoresis was achieved in a background solution of sodium *d*-tartrate and aluminum chloride. Electrophoretic data obtained under various conditions (various compositions, concentrations, and pH values of supporting electrolyte solutions) indicated that the separation of the enantiomers of $[M\ en_3]^{3+}$ complexes was accomplished not by the *d*-tartrate anion but by some aluminum *d*-tartrate complex anion.

Racemic mixtures of complex ions can be resolved by combining them with some optically-active counterions to form diastereoisomers which can be separated by the use of solubility differences. For example, $\Lambda(+)_{589}$-$[Co\ en_3]Cl\cdot d\text{-tart}\cdot H_2O$ is easily separated as crystals, while $\Delta(-)_{589}$-$[Co\ en_3]^{3+}$ remains in solution. This suggests that the tendency of the Λ and Δ forms of the $[Co\ en_3]^{3+}$ complex cation towards association with the *d*-tartrate anion is different. In fact, Ogino and Saito[2] showed that the association constant of the $\Lambda(+)_{589}$-$[Co\ en_3]^{3+}$-*d*-tartrate^{2-} system differs from that of the $\Delta(-)_{589}$-$[Co\ en_3]^{3+}$-*d*-tartrate^{2-} system by analyzing the increase in the optical density of the charge-transfer absorption band.

On the other hand, the studies[3] of the electrophoretic behavior of complex salts revealed that the mobility of the complex depends largely on the type and concentration of the supporting electrolyte. This can be attributed to the different degrees of association between the complex ion and the counterion in a supporting electrolyte solution.

This leads to a possible method for resolution of the racemate into optically-active enantiomers by electrophoresis. That is, when the Λ and Δ forms of the complex ion have quite large difference in association tendency to some optically-active counterion, the Λ and Δ cations should have different mobilities. Therefore, under suitable conditions, complete resolution can be expected. With this idea in mind, Mazzei and Lederer[4] attempted to resolve racemic complex salts by electrophoresis in a chiral supporting electrolyte solution. However, they did not succeed in resolution. We also attempted the electrophoretic resolution and tried to resolve the racemic $[Co\ en_3]^{3+}$ complex by running it in sodium *d*-tartrate solutions. This also proved to be unsuccessful. However, we achieved complete resolution just by adding aluminum chloride to the sodium *d*-tartrate background solution.[5] Further, we achieved resolution of the racemic $[Co\ en_3]^{3+}$ by means of thin-layer chromatography[6] using a solution of a similar composition to that used in electrophoretic resolution.

In order to obtain a deeper insight into the mechanism of resolution, we carried out electrophoresis in various background solutions having various compositions, concentrations, and pH values. We also tried three other trisethylenediamine complexes and obtained similar resolution in the cases of $[Cr\ en_3]^{3+}$ and $[Rh\ en_3]^{3+}$, but not in the case of $[Pt\ en_3]^{4+}$.

Experimental

A migration apparatus with multicompartment cells was used, so that ten samples could be run at the same time. A paper strip was dipped uniformly in the background solution, and then the excess of the solution was removed by hanging the strip. After that about 5 μl of a sample solution was placed on the paper (Toyoroshi No. 51A, 2×40 cm).

Samples were run for 2—3 hr under a potential gradient 250 V/34 cm, keeping the temperature of the migrating box at 25°C (The box is filled with carbon tetrachloride in which the strips are immersed). In the case of the $[Cr\ en_3]^{3+}$ complex, the whole apparatus was covered with black cloth to prevent the photodecomposition.

The spot of cobalt, rhodium, and platinum complexes was detected by spraying with sodium sulfide solution, while in the case of the chromium complex, it could be easily detected by the red color which was developed after by exposure to daylight.

Results and Discussion

Table 1 shows the mobilities of four kinds of trisethylenediamine complexes in background solutions of stepwise concentrations which contain only sodium *d*-tartrate as a supporting electrolyte. In this study, the mobility of a complex is defined as a migration distance relative to that of the $[Co\ en_3]^{3+}$ complex in 0.1 M NaCl solution. The data clearly indicate the effect of ionic association, because the mobility of these complexes goes down with the increase in the background tartrate concentration. However, the migrat-

0.06M	7.20	0.55	0.63	0.54	0.83
0.03M	7.10	0.73	0.80	0.76	0.98

ing racemic species appeared always in one spot, irrespective of the concentration of sodium *d*-tartrate. This means that the difference in the degree of ionic association between the *Λ*-complex-*d*-tartrate and the *Δ*-complex-*d*-tartrate combinations is too small to be observed in electrophoresis.

However, the addition of the aluminum salt caused a marvellous effect as reported in the earlier communication.[5] In this paper, the extended work is presented in Table 2. Here the mole ratio between Al^{3+} and *d*-tartrate was fixed at 2: 3, and the concentration of the tartrate was increased stepwise just as in Table 1.

To facilitate the understanding of general features, the data concerning the [Co en_3]$^{3+}$ complex are shown in Fig. 1. As is clearly seen in this figure, the addition of Al^{3+} causes the separation of two spots in a wide concentration range of the background solution (from 0.06M up to 0.36M *d*-tartrate).

Table 2. The mobilities of four kinds of racemic trisethylenediamine complexes in sodium *d*-tartrate–aluminum chloride mixed solutions. (250 V, 2.5 hr., 25°C)

Na_2*d*-tart / $AlCl_3$	pH	[Co en_3]$^{3+}$	[Cr en_3]$^{3+}$	[Rh en_3]$^{3+}$	[Pt en_3]$^{4+}$
0.72M / 0.48M	1.65	0.29	0.22	0.25	0.29
0.36M / 0.24M	2.00	0.14—0.31 / 0.45	0.11—0.29 / 0.39	0.09—0.23 / 0.40	0.45
0.18M / 0.12M	2.23	0.14—0.32 / 0.60	0.12—0.32 / 0.59	0.11—0.32 / 0.61	0.61
0.12M / 0.08M	2.50	0.11—0.32 / 0.63	0.15—0.28 / 0.61	0.18—0.38 / 0.63	0.64
0.09M / 0.06M	2.60	0.14—0.33 / 0.69	0.15—0.31 / 0.64	0.18—0.38 / 0.65	0.70
0.06M / 0.04M	2.71	0.16—0.35 / 0.69	0.12—0.35 / 0.68	0.41—0.62 / 0.68	0.85
0.03M / 0.02M	2.79	1.03	1.03	1.03	1.12

This can be regarded as resolution, because the *Λ* or *Δ* form of the complex showed only either one of these two spots in the background solution having the same composition (The *Λ* form corresponds to the spot of longer migration, the *Δ* form to that of shorter migration).

Here it must be noted that the background solutions are fairly acidic due to the presence of aluminum chloride. To see the effect of pH variation upon

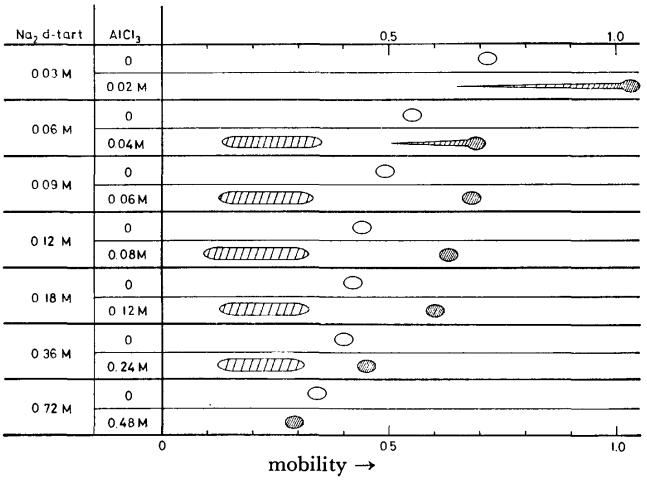

Fig. 1. Electrophoresis pattern of the racemic [Co en_3]$^{3+}$ complex in sodium *d*-tartrate solution with and without aluminum chloride.

resolution, a sample was migrated in several background solutions of different pH values which were prepared by adding a small amount of HCl or NaOH to the original solution containing 0.18M Na_2 *d*-tartrate and 0.12M $AlCl_3$. The result is shown in Fig. 2. It is easily understood that no resolution was achieved in the solution of pH 1. In such a solution, the tartrate is protonated and becomes a neutral molecule. However, it was a surprise to find that resolution was successful only within a limited acidic pH range of the solution. Even in a neutral background (pH 7), it was worth noting that resolution is incomplete.

If the resolution were due to the different degrees of association of the *d*-tartrate to the *Λ* and *Δ* forms of the complex cation, resolution should take place in neutral and alkaline solutions. However, this is not the case, which implies that the mechanism is more complicated than considered before.[6] In connection with this discussion, one thing must be pointed out. That is, the addition of aluminum chloride effects the migration of the *Λ* and *Δ* forms of the complex in opposite directions. As is seen in Fig. 1, the one component of the separated two spots in the presence of aluminum ions appears

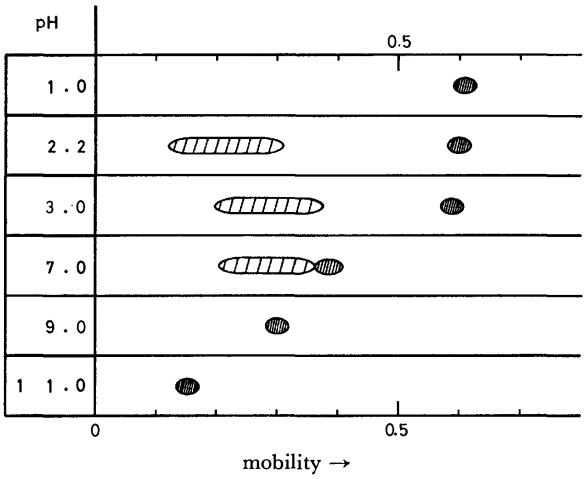

Fig. 2. Effect of pH upon the electrophoretic resolution of the racemic [Co en_3]$^{3+}$ complex.
(The background solution contains 0.18M Na_2*d*-tratrate and 0.12M $AlCl_3$ in all cases).

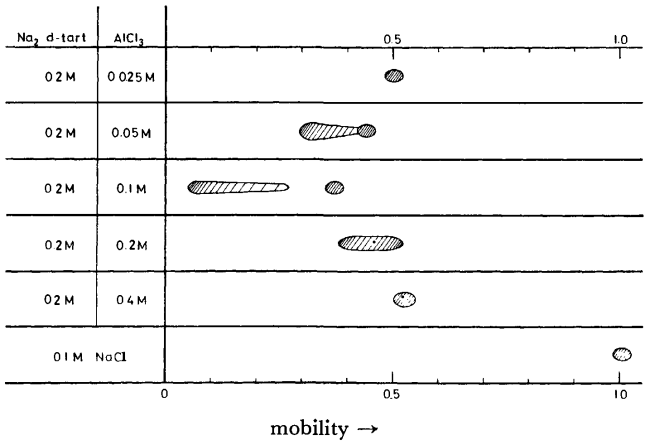

Fig. 3. Effect of the addition of aluminum chloride upon the electrophoretic resolution of the racemic $[Co\ en_3]^{3+}$ complex.

behind and the other component ahead of the original spot observed in the absence of aluminum ions. If the role of aluminum ions is simply dehydration of the complex ion, the split two spots should be both behind of the original spot due to increased ionic association. Therefore it is more reasonable to assume that the aluminum ion forms the *d*-tartrate complex anion which can select the Λ and Δ form of the $[Co\ en_3]^{3+}$ complex.

To find the favorable concentration of aluminum chloride for resolution, five supporting electrolyte solutions, each of which contains 0.2M sodium *d*-tartrate and various concentrations of aluminum chloride, were tested as shown in Fig. 3.

Thus it was revealed that the mole ratio between the aluminum ion and the tartrate for successful resolution was also confined to a certain limited range.

As shown in Table 2, the resolution of $[Cr\ en_3]^{3+}$ and $[Rh\ en_3]^{3+}$ was achieved in the same way as the resolution of $[Co\ en_3]^{3+}$. The small difference in their ionic weight did not cause any practical difference in migration distance. However, the quadrivalent $[Pt\ en_3]^{4+}$ ion could not be resolved in the same way. This is probably because the complex is more highly hydrated than the tervalent complex, and the situation of ionic association concerning this complex may be quite different from that in the case of tervalent complexes.

With regard to the mechanism of resolution, we can obtain information from the data obtained using the *meso*-tartrate and *l*-malate as a supporting electrolyte. Since the *meso*-tartrate is not optically-active, no resolution is expected even in the presence of aluminum ions. Nevertheless, it is worthwhile to see whether the spot appears near the longer migrating component or near the shorter migrating component in the case of the aluminum-*d*-tartrate system. Actually, the mobility in the aluminum-*meso*-tartrate system is almost the same as that of the longer migrating component in the corresponding aluminum-*d*-tartrate system (See Table 3). Although the *l*-malate is optically active, no resolution was achieved in the aluminum-*l*-malate system, and the mobility of the complex is even higher than those in the corresponding aluminum-*d*-tartrate and aluminum-*meso*-tartrate systems.

These findings can be interpreted in the following way. While the *d*- and *l*-tartrates are constructed with two *d* and two *l* moieties, respectively, the *meso*-tartrate consists of one *d* and one *l* moiety. Suppose two or three *d*-tartrate anions are coordinated to the aluminum ion to form a complex, they use their *d* moiety for coordination and leave the other *d* moiety free. When two or three optically active ligands are coordinated in the metal ion, the complex produced takes as a whole one type of enantiomeric form, say D or L. Thus if we represent the *d*-tartrate as *d-d*, we may represent the aluminum *d*-tartrate complex with D-*d-d*. Usually there is no L-*d-d*. On the other hand, the aluminum-*meso*-tartrate complex can exist in two enantiomeric forms D-*d-l* and L-*l-d*. Although there are four possible combinations between the aluminum-*meso*-tartrate complex (D-*d-l* and L-*l-d*) and the racemic $[Co\ en_3]^{3+}$ complex (*d* and *l*) ion, we obtained only one spot corresponding to the spot of longer migration distance in the case of the aluminum-*d*-tartrate (D-*d-d*) system.

Thus, it was revealed that among these three aluminum-tartrate systems D-*d-d*, D-*d-l*, and L-*l-d*, only D-*d-d* shows a strong interaction with the $\Delta(-)_{589}$-$[Co\ en_3]^{3+}$ complex. This interaction is therefore stereospecific.

In addition, the aluminum-*l*-malate system gives even longer migration than the component of longer migration in the D-*d-d* system. Therefore, it is presumed that cooperation of the OH and COO^- groups is necessary for such a stereospecific interaction.

Finally, we wish to go further to the discussion of the

probable structure of D-*d*-*d*. Since it attracts the complex cation, it must be an anion. Thus, we have two possible aluminum tartrate complex anions, $[Al(d\text{-tart})_3]^{3-}$ and $[Al(H_2O)_2(d\text{-tart})_2]^-$. The possibility of $[Al(d\text{-tart})_3]^{3-}$ can be excluded, because this should also give resolution in neutral and alkaline solution, contrary to the observations. Therefore, we may presume that the most probable D-*d*-*d* is $[Al(H_2O)_2(d\text{-tart})_2]^-$.

Our sincere appreciation is due to Professor Flemming Woldbye for his keen interest in and his stimulating discussion on this subject.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2129—2137(1972)

Metal Complexes Containing Six-Membered Chelate Rings. II. Preparation and Structure of 2,4-Pentanediamine Complexes of Cobalt(III)

Fujio MIZUKAMI, Haruko ITO, Junnosuke FUJITA, and Kazuo SAITO
Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received September 13, 1971)

New cobalt(III) complexes containing optically active (*RR* and *SS*) and *meso*(*RS*) 2,4-pentanediamine (2,4-ptn) have been synthesized. $[Co(RR\text{-}2,4\text{-ptn})_3]^{3+}$ gives two diastereoisomers, prismatic crystals with $(-)_{546}$ rotation and needle-like crystals with $(+)_{546}$ rotation. The former is produced much more than the latter. The conformations of the *RR*- (or *SS*-) and *RS*-2,4-pentanediamine chelate of the complexes were assigned to λ- (or δ-) twist and chair form, respectively, from comparison of their PMR spectra with those of the corresponding tetraacetato complexes. $[Co(RS\text{-}2,4\text{-ptn})_3]^{3+}$ seems to have *fac* structure with respect to the coordination of the amino groups adjacent to the *R*- and *S*-carbon atoms. The circular dichroism spectra of mono and *trans*-bis-(*RR*-2,4-ptn) complexes in the first band region are essentially the same as those of the corresponding *R*-propylenediamine complexes. The circular dichroism spectra of $(+)_{546}$- and $(-)_{546}$-$[Co(RR\text{-}2,4\text{-ptn})_3]^{3+}$ and $(-)_{546}$-$[Co(RS\text{-}2,4\text{-ptn})_3]^{3+}$ are very different from those of the triscobalt(III) complexes of *R*-propylenediamine and trimethylenediamine. Such differences have been discussed with reference to the stereochemistry of six-membered chelate complexes.

The stereospecificity of complex formation from metal ions and ligands has been elucidated mostly in terms of a specific conformation of the ligand and the repulsive interaction between non-bonded atoms of the coordinated ligands. Most of such studies, however, have been made on metal complexes containing five-membered chelates such as α-diamines or α-aminoacids. It is, therefore, of great interest to investigate whether a similar specificity is seen in metal complexes containing six-membered chelates. In the previous paper,[1] we reported that the formation of cobalt(III) complexes of *RR*- (or *SS*-) and *RS*-2,4-pentanediaminetetraacetate was stereospecific to give a sexadentate Δ-type (or Λ-type) and a quinquedentate complex, respectively. The tendency of the methyl groups on the carbon atoms to take equatorial orientation was thus demonstrated to be very strong in these puckered six-membered rings as well as in the five-membered rings. This paper deals with preparation and stereochemistry of cobalt(III) complexes containing six-membered β-diamines, optically active and *meso*-2,4-pentanediamine (2,4-ptn), which are expected to have a preferred, non-convertible conformation upon coordination.

Circular dichroism (CD) study provides useful information on the absolute configuration of metal complex and the conformation of chelated ligands. However, the work on metal complexes of β-diamines is limited to those of trimethylenediamine(tn),[2-6] in contrast to the extensive work on α-diamine complexes. Furthermore, these trimethylenediamine complexes are known to exhibit CD curves considerably different from those of the corresponding α-diamine complexes in the region of the first absorption band. Thus, the CD data reported in this paper on 2,4-pentanediamine complexes of cobalt(III) will give valuable information for elucidating the origin of optical activity of metal complexes as well as the conformation of six-membered chelate rings.

trans-[*Co(NO$_2$)$_2$(RR- or SS-ptn)$_2$]ClO$_4$*. An aqueous solution containing 11.5 g of $Na_3[Co(NO_2)_6]$[8] and 5.8 g of *RR*- or *SS*-2,4-pentanediamine in 40 m*l* of water was heated at 60—70°C for 5 hr, and filtered. To the filtrate was added a large excess of sodium perchlorate. Yellow flakes were precipitated, filtered off, washed with a small amount of cold water and dried over phosphorus pentoxide under reduced pressure.

Found: C, 26.55; H, 6.26; N, 18.58%. Calcd for $C_{10}H_{28}N_6O_8CoCl$: C, 26.41; H, 6.21; N, 18.48%.

trans-[*CoCl$_2$(RR- or SS-2,4-ptn)$_2$]ClO$_4$*. Twelve grams of *trans*-$[Co(NO_2)_2$(*RR*- or *SS*-ptn)$_2]ClO_4$ was dissolved in 100 m*l* of 6N hydrochloric acid by heating at 65—70°C for 10 hr with occasional stirring. To the resultant green solution was added 100 m*l* of 60% perchloric acid. Upon cooling at 5°C, green crystals were precipitated, filtered off, washed with a small amount of cold water and dried over phosphorus pentoxide under reduced pressure.

Found: C, 27.70; H, 6.56; N, 13.24%. Calcd for $C_{10}H_{28}N_4O_4CoCl_3$: C, 27.70; H, 6.51; N, 12.92%.

trans-[*CoCl$_2$(RS-2,4-ptn)$_2$]Cl*. This complex was prepared from cobalt(II) chloride-hexahydrate and *RS*-2,4-pentanediamine by air oxidation according to Dippel's method.[7]

Found: C, 32.16; H, 7.70; N, 14.97%. Calcd for $C_{10}H_{28}N_4CoCl_3$: C, 32.49; H, 7.64; N, 15.16%.

trans-[*CoBr$_2$(RR- or SS-2,4-ptn)$_2$]ClO$_4$*. To an aqueous solution of 1 g of *trans*-$[CoCl_2$(*RR*- or *SS*-2,4-ptn)$_2]ClO_4$ in 25 m*l* of water was added 1 g of silver perchlorate. The solution was stirred for 3 hr at room temperature, and then filtered to remove the silver chloride. The filtrate was treated with 10 m*l* of 47% hydrobromic acid and evaporated to about 8 m*l* in a vacuum desiccator over potassium hydroxide. Yellowish green crystals were filtered off, washed with cold ethanol and recrystallized from hot ethanol.

Found: C, 23.48; H, 5.56; N, 10.78%. Calcd for $C_{10}H_{28}N_4O_4Br_2CoCl$: C, 22.98; H, 5.40; N, 10.72%.

trans*(Br-Br)-[CoBr$_2$(NH$_3$)$_2$(RR- or SS-2,4-ptn)]Br·H$_2$O*. A suspension of $NH_4[Co(SO_3)_2(NH_3)_4]$[9] in 10% aqueous solution of *RR*- or *SS*-2,4-pentanediamine (1 : 1 mole ratio) was heated at 80°C for 2 hr with stirring and cooled to room temperature. To the dark brown solution was added a large amount of methanol. After a while, the solution was filtered. An oily product was precipitated by adding ether to the filtrate and separated from the supernatant. A yellow complex was obtained as powder by treating the oily product with an appropriate amount of ethanol, filtering off, washing with ethanol and air-drying. This complex which was believed to be crude $NH_4[Co(SO_3)_2(NH_3)_2$(*RR*- or *SS*-2,4-ptn)], was dissolved in a small amount of 47% hydrobromic acid and the solution was warmed at 35—40°C for 2 hr to give yellowish green crystals. After a while, the crystals were filtered off, washed with ethanol and recrystallized from methanol by adding ether.

Found: C, 12.86; H, 4.74; N, 12.47%. Calcd for $C_5H_{22}N_4OCoBr_3$: C, 13.26; H, 4.90; N, 12.37%.

[Co(NH$_3$)$_4$(RR- or SS-2,4-ptn)](ClO$_4$)$_3$. This complex was synthesized according to a similar method to that for the corresponding *R*-propylenediamine complex by Hawkins *et al.*[10]

Liquid ammonia was poured onto *trans*(Br-Br)-$[CoBr_2$-$(NH_3)_2$(*RR*- or *SS*-ptn)]Br·H_2O to give an orange solution. Orange powder which remained after the ammonia had evaporated, was dissolved in a minimum amount of hot water, and the solution was cooled to room temperature and filtered. To the filtrate was added an appropriate amount of 60% perchloric acid. Upon cooling at 0°C, orange crystals were precipitated and filtered off. The crystals were dissolved in a minimum amount of water and concentrated in a vacuum desiccator over sodium hydroxide. Deposited orange crystals were filtered off, washed with ethanol and air-dried.

Found: C, 11.11; H, 5.20; N, 15.72%. Calcd for $C_5H_{26}N_6O_{12}CoCl_3$: C, 11.38; H, 4.97; N, 15.93%.

[Co(NH$_3$)$_4$(RS-2,4-ptn)](ClO$_4$)$_3$·H$_2$O, [Co(NH$_3$)$_4$(tn)]Br·H$_2$O and [Co(NH$_3$)$_4$(d,l-1,3-btn)]Br$_3$.[11]

These complexes were prepared from $NH_4[Co(SO_3)_2(NH_3)_4]$ and *RS*-2,4-ptn, tn, or *d,l*-1,3-btn by a similar method to that for the corresponding *RR*- or *SS*-2,4-ptn complex described above. The complexes of tn and *d,l*-1,3-btn were obtained as bromide by use of 47% hydrobromic acid instead of 60% perchloric acid.

Found: C, 11.10; H, 5.01; N, 15.36%. Calcd for $C_5H_{28}N_6O_{13}CoCl_3$: C, 11.01; H, 5.17; N, 15.40%.

Found: C, 7.80; H, 4.86; N, 17.89%. Calcd for $C_3H_{24}N_6O_{13}Br_3Co$: C, 7.85; H, 5.27; N, 18.31%.

Found: C, 10.84; H, 5.44; N, 18.17%. Calcd for $C_4H_{24}N_6Br_3Co$: C, 10.56; H, 5.32; N, 18.47%.

(−)$_{546}$-[Co(RR-2,4-ptn)$_3$](ClO$_4$)$_3$·H$_2$O. An aqueous solution containing 1 g of *trans*-$[CoCl_2$(*RR*-2,4-ptn)$_2]ClO_4$, 0.5 g of *RR*-2,4-pentanediamine and 1 g of activated charcoal in 20 m*l* of water was warmed at 60°C. After about 2 hr, prismatic crystals began to appear. CD study showed that each of these single crystals was composed of about 90% $(-)_{546}$-isomer and 10% $(+)_{546}$-isomer of tris-diamine complex. Without separating these crystals, the reaction was still caused to proceed for 8—10 hr, and then the reaction mixture was cooled to room temperature. The precipitate containing activated charcoal was filtered off and washed with 60 m*l* of hot water (70°C). To the filtrate was added 34 m*l* of 60% perchloric acid. Upon cooling at 0°C for half an hour, first fraction of orange needle crystals was precipitated. They were filtered off, washed with a small amount of cold water, and recrystallized by evaporating the aqueous solution in a vacuum desiccator over potassium hydroxide. All the filtrates and washings were combined, concentrated to 30 m*l* at 50°C under reduced pressure and cooled to room temperature. The second fraction was obtained and recrystallized from water according to the method described above. The species remained in the final fraction on the above procedure seemed to be mostly bis-diamine complexes, since the filtrate changed its color to green on warming with hydrochloric acid and green dichloro complex was precipitated. Yield: Total 0.78 g.

Found: 26.35; H, 6.51; N, 12.07%. Calcd for $C_{15}H_{44}N_6O_{13}Cl_3Co$: C, 26.42; H, 6.50; N, 12.33%.

(+)$_{546}$-[Co(RR-2,4-ptn)$_3$]Cl$_3$·2H$_2$O. Two grams of *trans*-$[CoCl_2$(*RR*-2,4-ptn)$_2]ClO_4$ was converted into chloride by use of the anion exchanger Dowex 1-X4. This chloride was dissolved in 60 m*l* of 50% aqueous ethanol, and 0.5 g of *RR*-2,4-pentanediamine was added. The solution was warmed at 55—60°C for 8—10 hr. Deposited orange needle crystals were filtered off in hot, and recrystallized from water in a similar way as for $(-)_{546}$-isomer. Yield: 0.09 g.

Found: C, 35.74; H, 9.40; N, 16.61%. Calcd for $C_{15}H_{46}N_6Cl_3CoO_2$: C, 35.47; H, 9.13; N, 16.55%.

Orange prismatic crystals were obtained by evaporating

the filtrate to almost dryness in a vacuum desiccator. The crystals recrystallized from water in a similar way gave the chemical composition $[Co(RR\text{-}2,4\text{-ptn})_3]Cl_3 \cdot 2H_2O$. Yield: 0.48 g.

Found: C, 35.32; H, 9.34; N, 16.55%. Calcd for $C_{15}H_{46}N_6Cl_3CoO_2$: C, 35.47; H, 9.13; N, 16.55%.

However, the CD spectra of each of these single crystals in water coincided with that of a mixed sample consisting of 93% $(-)_{546}$-isomer and 7% $(+)_{546}$-isomer.

Racemic-*[Co(RS-2,4-ptn)$_3$](ClO$_4$)$_3 \cdot 3H_2O$.* An aqueous solution containing 5 g of *trans*-$[CoCl_2(RS\text{-}2,4\text{-ptn})_2]Cl$ and 2 g of *RS*-2,4-pentanediamine and 1.5 g of activated charcoal was warmed at 60°C for a day, and filtered. Orange crystals were precipitated by the addition of sodium perchlorate to the filtrate, filtered off and recrystallized by evaporating an aqueous solution in a desiccator over phosphorus pentoxide under reduced pressure. Yield: 5 g.

Found: C, 25.49; H, 6.34; N, 11.29%. Calcd for $C_{15}H_{48}N_6O_{15}CoCl_3$: C, 25.10; H, 6.34; N, 11.29%.

$(-)_{546}$-[Co(RS-2,4-ptn)$_3$](ClO$_4$)$_3 \cdot 3H_2O$. Five grams of *racemic*-$[Co(RS\text{-}2,4\text{-ptn})_3](ClO_4)_3 \cdot 3H_2O$ was converted into chloride by use of the anion exchanger Dowex 1-X4. To the aqueous chloride solution was added 4 g of silver tartrate with stirring. After half an hour, silver chloride was filtered off and the filtrate was concentrated to about 15 m*l* in a desiccator over phosphorus pentoxide under reduced pressure. Reddish orange powder (0.5 g) was obtained by filtration, and recrystallized by concentrating its aqueous solution in a similar way. This procedure was repeated to give a constant CD curve. Pure sample was dissolved in a small amount of water and sodium perchlorate was added. The perchlorate salt was recrystallized from water.

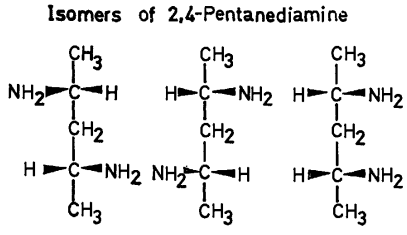
Found: C, 25.31; H, 6.30; N, 11.72%. Calcd for $C_{15}H_{48}N_6O_{15}CoCl_3$: C, 25.10; H, 6.74; N, 11.71%.

Measurements. Visible and ultraviolet absorption spectra were recorded with a Hitachi 124 recording spectrophotometer. The CD curves were recorded with a Model ORD/UV-5 spectrophotometer of Japan Spectroscopic Co. with its CD attachment. PMR spectra were obtained with a Varian T-60 spectrometer using HOD signal as an internal standard. The complexes prepared here were hardly soluble in deuterium oxide containing Na-TMS. All the measurements were made at room temperature.

Results and Discussion

Conformation of Chelate Rings and Geometrical Isomerism. As shown in Part I, four conformations, chair, boat, and a pair of twist (skew boat) forms are possible in β-diamine chelate rings. The boat form is generally unstable and not formed in octahedral complexes such as those of cobalt(III), because big steric hindrance is involved between apical ligands and the central methylene group of the equatorial ligand. Hence chair and a pair of twist forms are the more probable conformations. A pair of twist forms are mirror images to each other, and they are designated as δ and λ, as shown in Part I.

It is generally understood that substituting groups on carbon atoms in puckered chelate rings always tend to take equatorial positions. Therefore, *RR*-, *SS*-, and *RS*-2,4-pentanediamine are expected to give λ- and δ-twist and chair conformation, respectively in six-membered chelate rings (Figs. 1 and 2). Such conformations of 2,4-pentanediaminetetraacetato-(2,4-ptnta)cobalt(III) complexes in Part 1.



Ligand	Conformation		
	chair	δ-twist	λ-twist
R,R-2,4-ptn	a,e	a,a	e,e
S,S-2,4-ptn	a.e	e,e	a,a
R.S-2,4-ptn	a,a e,e	a,e	a,e

e:methyl equatorial a:methyl axial

Fig. 1. Isomers of 2,4-pentanediamine and their conformations in the chelate.

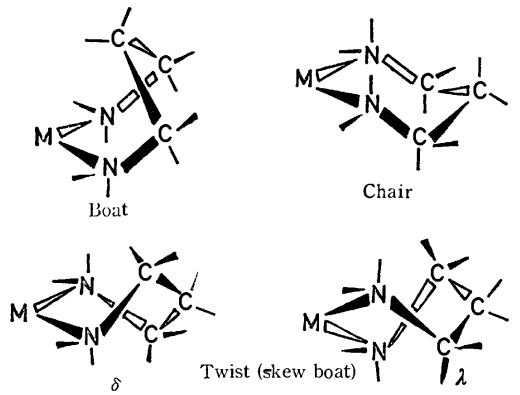


Fig. 2. Possible conformations of six-membered 1,3-diamine chelate.

The interconversion between δ- and λ-twist and between twist and chair form is not likely because of the steric hindrance among the chelate rings and the preference of equatorial orientation of the methyl groups. Appleton and Hall[12] studied the PMR spectra of a number of complexes of platinum(II) and palladium(II) with trimethylenediamine and its methyl-substituted derivatives including 2,4-pentanediamine. They suggested that the 2,4-pentanediamine chelates in these complexes might take stable conformations with equatorial orientation of the methyl groups.

As Fig. 3 shows, the PMR spectrum of $[Co(NH_3)_4(RR\text{-}2,4\text{-ptn})]^{3+}$ in deuterium oxide gives a sharp doublet of the methyl signal and a sharp triplet of the central methylene signal. The pattern of these multiplets is very similar to that of the diamine part of $[Co(RR\text{-}2,4\text{-ptnta})]^-$.[1] Since the diamine part of the tetraacetato complex should have fixed λ-twist form, the *RR*-2,4-pentanediamine chelate of the tetrammine complex should take λ-twist form, and the interconversion among conformers would not take place in an aqueous solution at room temperature. The PMR spectrum of $[Co(NH_3)_4(RS\text{-}2,4\text{-ptn})]^{3+}$ in deuterium oxide gives a sharp doublet and a broad triplet corre-

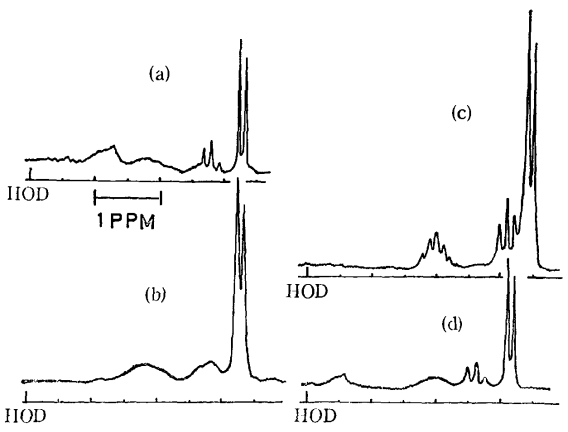

Fig. 3. PMR spectra of a) $[Co(NH_3)_4(RR\text{-}2,4\text{-ptn})]^{3+}$, b) $[Co(RR\text{-}2,4\text{-ptn})_3]^{3+}$, c) *trans*-$[Co(NO_2)_2(SS\text{-}2,4\text{-ptn})_2]^{+}$, d) $(-)_{546}$-$[Co(RR\text{-}2,4\text{-ptn})_3]^{3+}$ in D_2O. (Relative shifts in ppm from the HOD signal.)

sponding to the signals of the methyl and the central methylene protons, respectively. Such a signal of methyl protons indicates that the two methyl groups are equivalent in the chelate. Therefore, the conformation of the *RS*-2,4-pentanediamine of $[Co(NH_3)_4(RS\text{-}2,4\text{-ptn})]^{3+}$ was assigned to chair form with equatorial methyl groups.

The spectral pattern in a lower field region is complicated because of the overlapping of the signals of -CH, $-NH_2$, and -NHD, and depends sensitively on the other ligands. Hence it is not useful for discussing the conformation of 2,4-pentanediamine chelates.

Figure 3 shows also the PMR spectra of $[Co(NO_2)_2(SS\text{-}2,4\text{-ptn})_2]^{+}$ and $(-)_{546}$-$[Co(RR\text{-}2,4\text{-ptn})_3]^{3+}$. These spectra are also similar to that of $[Co(NH_3)_4(RR\text{-}2,4\text{-ptn})]^{3+}$ in the region of the methyl and the central methylene signals, indicating that the chelate rings have also twist form. Furthermore, each spectrum of these complexes seems to consist of the signals due to one kind of chelate ring. These facts suggest that the dinitro complex is in trans form and the tris complex has D_3 symmetry. The diastereoisomer, $(+)_{546}$-$[Co(RR\text{-}2,4\text{-ptn})_3]^{3+}$ gives the same PMR spectrum as that of $(-)_{546}$-$[Co(RR\text{-}2,4\text{-ptn})_3]^{3+}$ at 60 MHz. The *trans* structure of the dinitro complex may also be supported from comparison of *cis* and *trans* isomers of the corresponding trimethylenediamine complex, $[Co(NO_2)_2(tn)_2]^{+}$. Kawaguchi and Kawaguchi[6] obtained the *cis* isomer by treating the *trans* isomer with a warm aqueous nitrite solution, and found that the former gives the first absorption band at a lower wavelength than does the latter. When the present dinitro complex was treated similarly with an aqueous nitrite solution, the resultant solution gave the first absorption band at lower wavelength by 11 nm as compared with that of the original complex. The CD spectrum also changed substantially. An attempt to isolate the product was unsuccessful because of its high solubility in water.

As Fig. 3 shows, the PMR spectrum of $[Co(RS\text{-}2,4\text{-ptn})_3]^{3+}$ exhibits a broader methyl signal than that of $[Co(RR\text{-}2,4\text{-ptn})_3]^{3+}$. This complex can have two geometrical isomers with respect to *mer* and *fac* coordination of the amino groups adjacent to the *R*- and *S*-carbon atoms. However, studies with molecular models disclose that only the *fac* isomer is formed without big steric hindrance among the chelate rings. Therefore, the broad methyl signal may not be due to the presence of two geometrical isomers, but will be due to C_3 symmetry of the *fac* isomer. The two methyl groups on *R*- and *S*-carbon atom are in a different environment from each other in this complex.

The dichloro and dibromo complexes prepared here were assigned to *trans* (Cl-Cl, or Br-Br) structure from their characteristic green color.

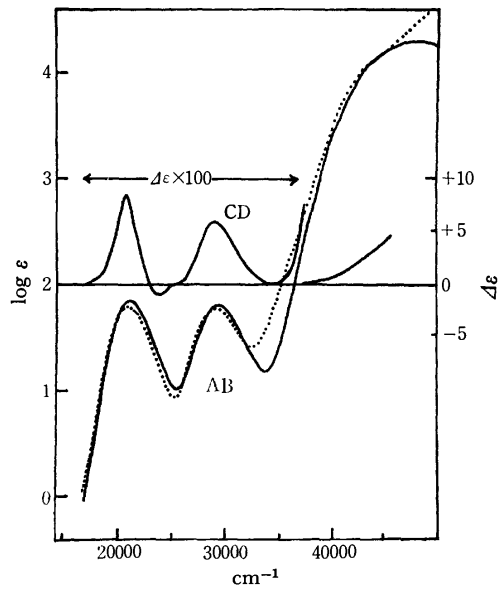

Fig. 4. Absorption (AB) and CD sepectra of (——) $[Co(NH_3)_4(RR\text{-}2,4\text{-ptn})]^{3+}$, (·····) $[Co(NH_3)_4(tn)]^{3+}$ in water.

Absorption Spectra. Table 1 and Fig. 4 compare the absorption spectra of four tetrammine-β-diamine cobalt(III) complexes. The absorption bands including the first, the second and the charge transfer band are shifted from longer to shorter wavelength with increase in the number of methyl group, *i.e.* in the order $[Co(NH_3)_4tn]^{3+}$, $[Co(NH_3)_4(1,3\text{-btn})]^{3+}$, and $[Co(NH_3)_4(2,4\text{-ptn})]^{3+}$. The absorption spectra of $[Co(NH_3)_4(RR\text{-}2,4\text{-ptn})]^{3+}$ and $[Co(NH_3)_4(RS\text{-}2,4\text{-ptn})]^{3+}$ are almost identical with each other, regardless of the different conformation of the chelate rings. A similar relationship also holds between *trans*-$[CoCl_2(RR\text{-}2,4\text{-ptn})_2]^{+}$ and *trans*-$[CoCl_2(RS\text{-}2,4\text{-ptn})_2]^{+}$ as shown in Fig. 5. On the other hand, the absorption bands of the four tris complexes are shifted to shorter wavelength in the sequence $[Co(RS\text{-}2,4\text{-ptn})_3]^{3+}$, $[Co(tn)_3]^{3+}$, $(+)_{546}$-$[Co(RR\text{-}2,4\text{-ptn})_3]^{3+}$, and $(-)_{546}$-$[Co(RR\text{-}2,4\text{-ptn})_3]^{3+}$, as shown in Fig. 6 and Table 1. Such a sequence is not in accord with that of tetrammine complexes given above. The differences in the absorption maxima of the first bands amount to 380 cm^{-1} between $[Co(RS\text{-}2,4\text{-ptn})_3]^{3+}$ and $(-)_{546}$-$[Co(RR\text{-}2,4\text{-ptn})_3]^{3+}$ and 220 cm^{-1} between $(+)_{546}$-$[Co(RR\text{-}2,4\text{-ptn})_3]^{3+}$ and $(-)_{546}$-$[Co(RR\text{-}2,4\text{-ptn})_3]^{3+}$. It is not possible to discuss these results in detail at present. However, they seem to be related to the steric interaction among chelate rings. Such an inter-

action may affect more or less the strength of coordination bonds, when a large and bulky ligand such as 2,4-pentanediamine forms a tris type complex. Molecular models indicate that the steric interaction among twist chelate rings in the tris complexes is much smaller than that among chair chelate rings, and that $\Delta(\lambda\lambda\lambda)$ form involves less congestion of ligand atoms than $\Lambda(\lambda\lambda\lambda)$ form. As shown later, the $(-)_{546}$- and $(+)_{546}$-isomer of $[Co(RR\text{-}2,4\text{-ptn})_3]^{3+}$ have $\Delta(\lambda\lambda\lambda)$ and $\Lambda(\lambda\lambda\lambda)$ absolute configuration, respectively. The diamine chelate rings in $[Co(tn)_3]^{3+}$ can take both twist and chair form in solution without involving big mutual interaction, although they have chair form in crystals.[13] The fact that the absorption bands of $[Co(tn)_3]^{3+}$ are at shorter wavelengths than those of $[Co(RS\text{-}2,4\text{-ptn})_3]^{3+}$ may be caused by conformational interconversion of the trimethylenediamine chelate rings in solution. Thus, it seems that the complexes involving less steric

interaction cause the absorption peaks to shift to shorter wavelength. It is worth noticing that such a shift has not been observed clearly for the complexes with five-membered chelates. For example, the absorption peaks of two diastereoisomers, $\Lambda(\lambda\lambda\lambda)(lel)$- and $\Lambda(\lambda\lambda\lambda)$-$(ob)$-[Co(*R*-pn)$_3$]$^{3+}$(*R*-pn=*R*-propylenediamine) are at almost identical wavelengths with each other.[14] The mono and *trans*-bis diamine complexes studied here should involve smaller steric interactions among ligands, and in fact give their absorption peaks at the wavelengths expected from the spectrochemical series.

14) K. Ogino, K. Murano, and J. Fujita, *Inorg. Nucl. Chem. Lett.*, **4**, 351 (1968).

Circular Dichroism and Absolute Configuration. So far as the methyl group on the carbon atoms tends to take equatorial orientation to the chelate ring, *RR*-2,4-pentanediamine and *R*-propylenediamine should give λ-twist and λ-gauche conformation, respectively. Since these two belong to the chirality λ, it seems interesting to compare the CD spectra of their cobalt(III) complexes with one another.

(1) Mono- and bis-2,4-Pentanediamine Cobalt(III) Complexes: As shown in Figs. 7 and 8, the CD pattern of *trans*-[$Co(NO_2)_2$(*RR*-2,4-ptn)$_2$]$^+$ is very similar to that

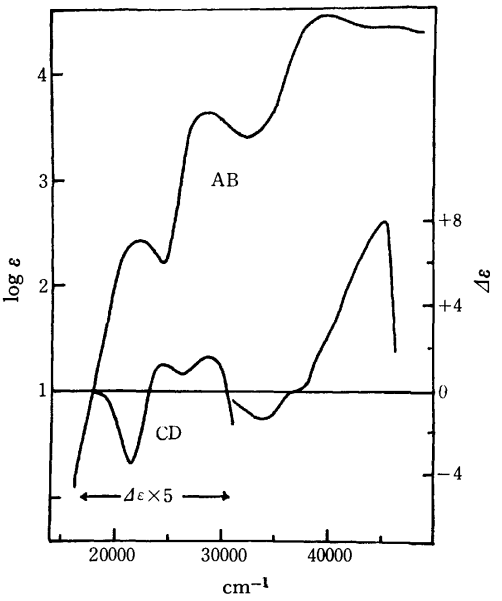

Fig. 7. Absorption (AB) and CD spectra of *trans*-[$Co(NO_2)_2$-(*RR*-2,4-ptn)$_2$]$^+$ in water.

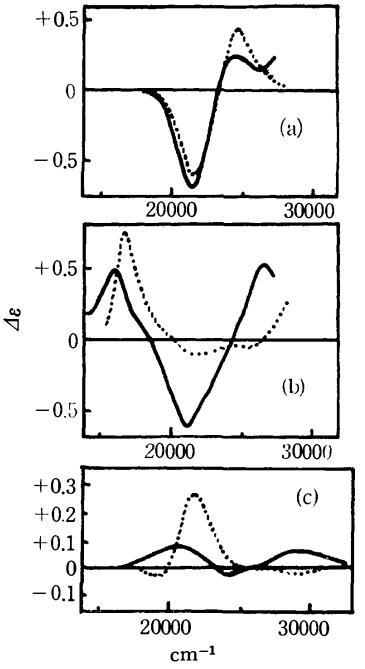

Fig. 8. Comparison of the CD spectra of *RR*-2,4-pentanediamine (——) and *R*-propylenediamine (·····) complexes. a) *trans*-dinitro complexes, b) *trans*-dichloro complexes, c) tetrammine complexes.

of *trans*-$[Co(NO_2)_2(R\text{-pn})_2]^+$.[15] The CD curve of *trans*-$[CoCl_2(RR\text{-2,4-ptn})_2]^+$ shown in Figs. 5 and 8 is also similar to that of *trans*-$[CoCl_2(R\text{-pn})_2]^+$[16] essentially, but the CD band with minus sign of the former in the Ib band region (A_2) is much stronger than that of the latter. The CD curves of the tetrammine complexes of *RR*-2,4-pentanediamine and *R*-propylenediamine are different from each other. In the first band region, the former gives a plus and a small minus peak at 20620 and 23530 cm^{-1}, respectively, whereas the latter a small minus and a plus peak at 19300 and 21580 cm^{-1}, respectively.[10] (Fig. 8)

Such a difference could be explained if the location for propylenediamine and 2,4-pentanediamine in the spectrochemical series were taken into consideration. The first absorption bands of $[Co(NH_3)_4(R\text{-pn})]^{3+}$, $[Co(NH_3)_6]^{3+}$ and $[Co(NH_3)_4(RR\text{-2,4-ptn})]^{3+}$ are at 21500,[10] 21100, and 20960 cm^{-1}, respectively. Thus, the order of these ligands in the spectrochemical series may be determined as *R*-pn>NH_3>*RR*-2,4-ptn. Since the complex, $[Co(NH_3)_4AA]^{3+}$ (AA=diamine) can be approximated as C_{2v} symmetry, the first absorption band would consist of two components, Ia(B_1) and Ib(A_2, B_2; accidentaly degenerate) as predicted by Yamatera's theory.[17] These components may be arranged in the order Ia and Ib, and Ib and Ia from longer to shorter wave length in $[Co(NH_3)_4(R\text{-pn})]^{3+}$ and $[Co(NH_3)_4(RR\text{-2,4-ptn})]^{3+}$, respectively, on the basis of the spectrochemical series of the ligands given above. Hence the CD patterns of the tetrammine complexes of *R*-propylenediamine and *RR*-2,4-pentanediamine are understood as due to such a different arrangement of the two components, Ia and Ib.

16) H. Ito, J. Fujita, and K. Saito, This Bulletin, **42**, 1286 (1969).
17) H. Yamatera, *ibid.*, **31**, 95 (1958).

The CD of $[Co(NH_3)_4(RR\text{-2,4-ptn})]^{3+}$ in the region of the second absorption band is entirely different from that of $[Co(NH_3)_4(R\text{-pn})]^{3+}$; the sign is reversed, and the magnitude is almost the same as in the region of the first absorption band. However, the reasons are unknown.

Figure 9 shows the absorption and CD spectra of *trans*(Br-Br)$[CoBr_2(NH_3)_2(SS\text{-2,4-ptn})]^+$ and *trans*-$[CoBr_2(SS\text{-2,4-ptn})_2]^+$ in a mixture of methanol and 47% hydrobromic acid (9: 1, v/v). The absorption spectra are essentially equal, and the CD curves have the same pattern. The dotted line in Fig. 9 shows the CD curve of the former complex with doubled $\Delta\varepsilon$ value. This curve coincides well with the CD curve of the latter complex. Thus the magnitude of CD due to the vicinal effect is proportional to the number of optically active ligand. The same relation was observed between *trans*(Cl-Cl)-$[CoCl_2(NH_3)_2(R\text{-pn})]^+$ and *trans*-$[CoCl_2(R\text{-pn})_2]^+$ by Hawkins *et al.*[10] It is, thus, suggested that the six-membered chelate rings in the two dibromo complexes have almost the same state in the given solution and there seems to be no substantial interaction between the chelate rings in the *trans*-bis-complex.

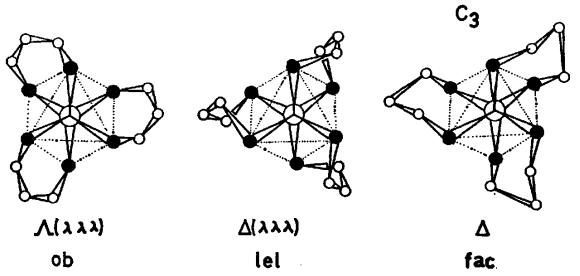

Fig. 10. Schematic structures of tris(1,3-diamine) complexes.

(2) Tris-RR-*2,4-pentanediamine Complexes*: Tris-*RR*-2,4-pentanediamine cobalt(III) complex gives two diastereoisomers, prismatic crystals with $(-)_{546}$ rotation and needle-like crystals with $(+)_{546}$ rotation. The CD and absorption spectra are shown in Fig. 6. We tentatively assigned that the former and the latter have *Δ* and *Λ* configuration, respectively, on the basis of the sign of CD bands in the region of the first absorption band.[18] Lately two of us, together with colaborators, examined the absolute configuration of $(+)_{546}$-isomer by X-ray diffraction method and found that it has *Λ* configuration and the three chelate rings have *λ*-twist conformation.[19] The line connecting two asymmetric carbon atoms of *RR*-2,4-pentanediamine chelate is oblique to the C_3 axis of the complex ion. Hence this isomer is written as *Λ*(*λλλ*)(*ob*). Thus, the other $(-)_{546}$-isomer should have unequivocally *Δ*(*λλλ*)(*lel*) form. (Fig. 10) Therefore, the empirical rule that the diastereoisomer with plus main CD sign in the region of the first absorption band has *Λ* configuration, seems to hold in the two diastereoisomers, $(+)_{546}$- and$(-)_{546}$-$[Co(RR\text{-2,4-ptn})_3]^{3+}$. However, the magnitudes of the CD are very different from each other, even if the vicinal

19) A. Kobayashi, F. Marumo, Y. Saito, J. Fujita, and F. Mizukami, *Inorg. Nucl. Chem. Lett.*, **7**, 777 (1971).

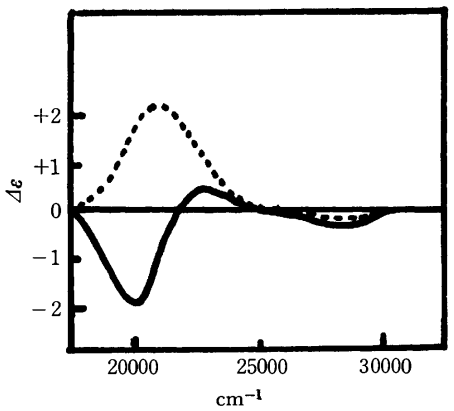

Fig. 11. CD spectra of (——) Δ ($\lambda\lambda\lambda$)(*lel*)-[Co(*R*-pn)$_3$]$^{3+}$, (·····) Λ($\lambda\lambda\lambda$)(*ob*)-[Co(*R*-pn)$_3$]$^{3+}$. (Ref. 13)

contribution of the *RR*-2,4-pentanediamine is taken into account.

In general, the optical activity of a metal complex is understood as a superposition of configurational and conformational (vicinal effect of optically active ligand) chirality. In other words, both chiralities contribute to the CD of a metal complex additively. The CD spectra of Δ($\lambda\lambda\lambda$)(*lel*)- and Λ($\lambda\lambda\lambda$)(*ob*)-[Co(*R*-pn)$_3$]$^{3+}$ shown in Fig. 11 was interpreted satisfactorily by such an additive law.[14,20] However, this law does not hold in the present two diastereoisomers as stated above. There should be some kinds of factors affecting the optical activity of these complexes. Although the factors are not clear at present, they seem to be characteristic of the six-membered tris-complexes, since the CD spectra of mono and *trans*-bis-(*RR*-2,4-ptn) complexes given before are rather normal as compared with those of the corresponding *R*-propylenediamine complexes.

It was stated previously that the Λ($\lambda\lambda\lambda$)(*ob*) isomer might involve larger steric interaction among chelate rings than the Δ($\lambda\lambda\lambda$)(*lel*) isomer, and such an interaction seemed to correlate with the frequency difference of absorption bands between the two diastereoisomers. The same interpretation may be useful for the CD spectra. The interaction among chelate rings may produce a somewhat different field from that expected from a superposition of configurational and conformational chirality. A large interaction of such kind may also induce delicate change in conformation or configuration of the complex. These factors may be reflected sensitively on the CD spectra, although the PMR spectra of the two diastereoisomers are almost identical with each other at 60 MHz. The CD of Λ($\lambda\lambda\lambda$)(*ob*) isomer which involves larger steric interaction seems to be exceptionally strong as compared with those of other tris-β-diamine complexes shown in Figs. 6 and 13. However, further studies on such anomalous CD will be needed.

Both $(+)_{546}$ and $(-)_{546}$ isomers of [Co(*RR*-2,4-ptn)$_3$]$^{3+}$ give plus CD bands in the charge transfer region. This fact may be attributed to the vicinal contribution of the optically active ligand, *RR*-2,4-pentanediamine.[14] Details on the CD in the charge transfer region will be discussed later.

The Δ($\lambda\lambda\lambda$)(*lel*) isomer may be more stable thermodynamically than the Λ($\lambda\lambda\lambda$)(*ob*) isomer because of smaller steric interaction. The yield of diastereoisomers is governed by various factors including kinetics and solubility, and does not necessarily reflect the relative stability of the isomers. However, it should be pointed out that the Δ($\lambda\lambda\lambda$)(*lel*) isomer was produced much more than the Λ($\lambda\lambda\lambda$)(*ob*) isomer as stated in the Experimental part.

As also stated in the Experimental part, [Co(*RR*-2,4-ptn)$_3$]$^{3+}$ gives large single crystals of pseudo-racemate with different moles of the two diastereoisomers. The CD spectrum of the single crystal dissolved in water indicates the composition, 93% Δ($\lambda\lambda\lambda$)(*lel*) and 7% Λ($\lambda\lambda\lambda$)(*ob*) (Fig. 12).

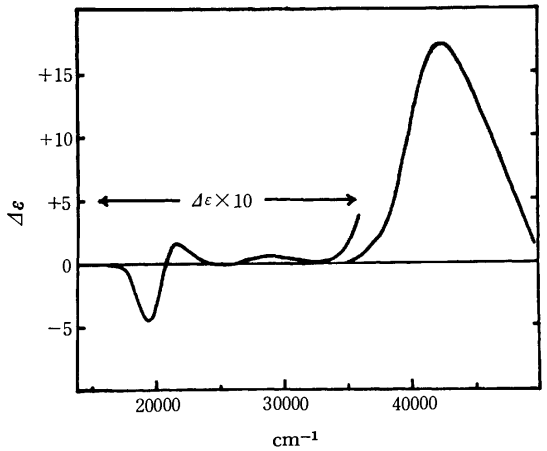

Fig. 12. CD spectra of pseudo-racemate, (Δ(93)+Λ(7))-[Co(*RR*-2,4-ptn)]$^{3+}$ in water.

*(3) Tris-*RS*-2,4-pentanediamine Complex*: Figure 6 shows the CD spectrum of $(-)_{546}$-[Co(*RS*-2,4-ptn)$_3$]$^{3+}$ in water. As stated before, [Co(*RS*-2,4-ptn)$_3$]$^{3+}$ can give two geometrical isomers. We assigned the $(-)_{546}$-isomer as *fac*, and the conformation of the chelated ligands as chair form, on the basis of the PMR spectrum. The absolute configuration of this isomer, however, can be assigned with difficulty from the CD spectrum. When the empirical rule that the main CD of Δ-isomer in the region of the first absorption band has minus sign, is applied, the $(-)_{546}$-isomer seems to have Δ configuration. This assignment seems to be in good harmony with the CD sign of $(+)_{546}$- and $(-)_{546}$-[Co(*RR*-2,4-ptn)$_3$]$^{3+}$ given before, but contradicts the fact that the major CD peak of Λ-$(-)_D$-[Co(tn)$_3$]$^{3+}$ has minus sign[3] (Fig. 13). The trimethylenediamine chelates in this complex have chair conformation in crystals.[12] Gollogly and Hawkins[4] reported that the major CD component (A_2) of Δ-$(+)_D$-[Co(tn)$_3$]$^{3+}$ was increased while the minor CD component (E) decreased in 0.05M-selenite or 0.05M-phosphate solution. The resultant CD pattern seems to be enantiomeric with that of $(-)_{546}$-[Co(*RS*-2,4-ptn)$_3$]$^{3+}$ as shown in Fig. 14. A similar CD change was also observed by Beddoe and Mason[3] with Λ-$(-)_D$-[Co(tn)$_3$]$^{3+}$ in 0.01M sodium selenite. Very recently Beddoe *et al.*[21] observed that

20) B. E. Douglas, *Inorg. Chem.*, **4**, 1813 (1965).

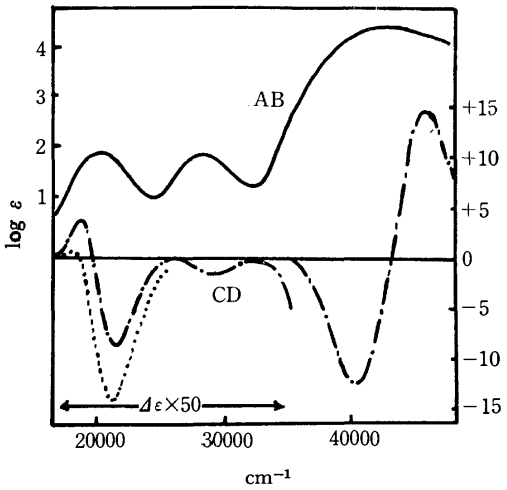

Fig. 13. Absorption (AB) and CD spectra of Λ-(−)$_D$-]Co(tn)$_3$]$^{3+}$. (——) AB in water, (-·-·) CD in water, (·····) CD in 0.01M sodium selenite. (Ref. 3)

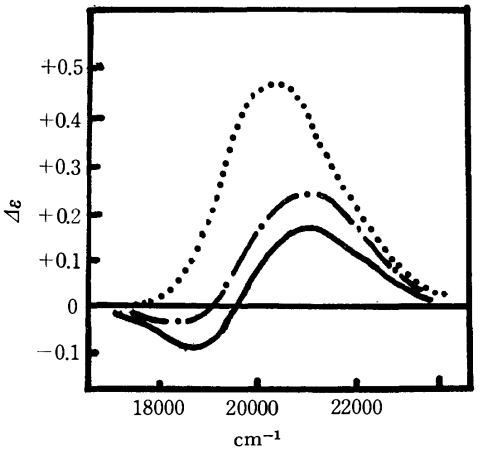

Fig. 14. CD spectra of Λ-(+)$_D$-[Co(tn)$_3$]$^{3+}$. (——) in water, (-·-·) in 0.01M-sulfate, (·····) in 0.05M-selenite. (Ref. 4)

the CD spectrum of Λ-(+)$_D$-[Co(tn)$_3$]$^{3+}$ in 0.05M oxy-anion solutions are almost identical with that in the solid state. They suggested that the [Co(tn)$_3$]$^{3+}$ in water exists in an equilibrium between a tris-chair and a tris-skew boat form, and that the CD change on the addition of oxy-anions can be attributed to the stabilization of the tris-chair form by ion-association. The solid-state CD spectrum of Λ-(+)$_D$-[Co(tn)$_3$]Br$_3$·H$_2$O (tris-chair form[13]) are almost enantiomeric with the solution CD spectrum of (−)$_{546}$-[Co(*RS*-2,4-ptn)$_3$]$^{3+}$ which is constrained to the tris-chair conformation by the equatorial preference of the methyl groups in the chelate rings. Thus, these experiments seem to support strongly that the (−)$_{546}$-[Co(*RS*-2,4-ptn)$_3$]$^{3+}$ has Λ configuration.

On the other hand, the CD pattern of (−)$_{546}$-[Co(*RS*-2,4-ptn)]$^{3+}$ in the charge transfer region is enantiomeric with that of Λ-(−)$_D$-[Co(tn)$_3$]$^{3+}$ as shown in Fig. 13. Previously, one of the authors[14] suggested that the sign of the CD bands of a tris(diamine)cobalt(III) complex in the charge transfer region seemed to depend on the absolute configuration of the complex; Λ-isomer gives a CD band with minus sign at longer wavelength side. The CD pattern of Λ-(−)$_D$-[Co(tn)$_3$]$^{3+}$ in the charge transfer region is in good accord with this rule. When this rule is applied, the (−)$_{546}$-[Co(*RS*-2,4-ptn)$_3$]$^{3+}$ seems to have Λ configuration.

These conflicting results discourage us to give any plausible assignment of the absolute configuration of this complex on the basis of the CD spectrum. Further studies including an X-ray analysis will be needed.

Synthesis and Properties of Metal Complexes with a New Multidentate Schiff Base Containing Ethereal Oxygen Atoms[1)]

Ichiro MURASE, Kuniko YAMANOUCHI,* and Shoichiro YAMADA*

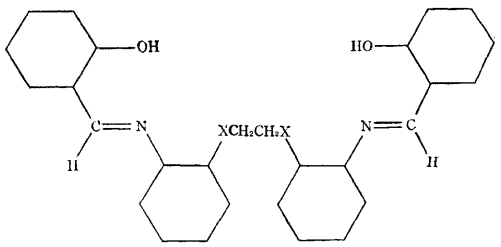
Laboratory of Chemistry, College of General Education, Kyushu University, Ropponmatsu, Fukuoka
**Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka*

(Received October 6, 1971)

A new multidentate Schiff base, 1,4-bis(*o*-salicylideneaminophenyl)-1,4-dioxabutane having six atoms which may be available for bonding with a metal ion was prepared. With this ligand several metal complexes have been synthesized. From their magnetic properties, electronic absorption spectra and X-ray powder diagrams, it has been concluded that the cobalt(II), nickel(II), and zinc(II) complexes are isomorphous, having a five-coordinated configuration, in which one of the ethereal oxygen atoms of the ligand is bound with the metal ion. The copper(II) complex with a similar composition has a different configuration.

It is well known that the ability of the ethereal oxygen atom to be coordinated with a transition metal ion is significantly lower than that of the alcoholic oxygen atom, and only a small number of complexes which involve the linkage between the ethereal oxygen atom and the metal ion have so far been reported.[2)] It is expected, however, that the oxygen atom, when incorporated into a multidentate ligand, may be bound with a metal ion more readily than that in a unidentate ligand.

In the present work, we have synthesized a new multidentate ligand (I), which contains six atoms capable of coordination with a metal ion and may function as a sexa-, a quinqui-, or a quadridentate ligand, depending upon the nature of the metal ion involved.



I: X=O (abbreviated as H_2L)
II: X=S (abbreviated as H_2Ls)

Furthermore, complexes of several transition metal ions with this ligand have been synthesized, and their stereochemistry has been investigated, in order to examine the effect of the metal ions upon the behaviour of the ligand.

Experimental

Materials. 1,4-Bis(*o*-salicylideneaminophenyl)-1,4-dioxabutane. A mixture of ethyleneglycol-bis(2-aminophenyl-ether)[3)] (0.0044 mol) and salicylaldehyde (0.016 mol) in 20 m*l* of ethanol was refluxed on a water bath for 2 hr. On cooling, the resulting crystals were collected and recrystallized from a large amount of ethanol; mp 178°C. The yield was almost quantitative. Yellow crystals. Found: C, 73.61; H, 5.33; N, 6.19%. Calcd for $C_{28}H_{24}N_2O_4$: C, 74.32; H, 5.35; N, 6.19%.

[*NiL*]: To a hot solution of the Schiff base H_2L (0.0022 mol) in 50 m*l* of dimethylformamide (DMF) was added nickel(II) acetate (0.0024 mol) in 50% DMF-water, and the mixture was heated on a water bath. The formation of the metal chelate was completed in 10 min. The crystals were filtered and washed with hot ethanol and dried over phosphoric oxide under vacuum at 110°C. Yellow-brown crystals. Found: C, 65.25; H, 4.38; N, 5.6%. Calcd for $C_{28}H_{22}N_2O_4Ni$: C, 66.04; H, 4.36; N, 5.50%.

[*CoL*]: The procedure was the same as described above, except that cobalt(II) acetate was used in place of nickel(II) acetate. Red-violet crystals. Found: C, 65.15; H, 4.31; N, 5.66%. Calcd for $C_{28}H_{22}N_2O_4Co$: C, 65.42; H, 4.32; N, 5.45%.

[*CuL*]: A mixture of the Schiff base (0.0022 mol) and copper(II) acetate (0.0024 mol) in 15 m*l* of DMF was heated on a water bath and the resulting solution was filtered. Methanol was added to the hot filtrate until the solution began to become turbid, and the solution was allowed to cool to room temperature. Brown plates were filtered and washed with hot methanol and dried over phosphoric oxide under vacuum at 110°C. Found: C, 64.66; H, 4.36; N, 5.49%. Calcd for $C_{28}H_{22}N_2O_4Cu$: C, 65.42; H, 4.32; N, 5.45%.

[*ZnL*]: The procedure was the same as described above, except that zinc(II) acetate was used instead of nickel(II) acetate. The product was recrystallized from chloroform to yield yellow-orange crystals. Found: C, 65.17; H, 4.38; N, 5.50%. Calcd for $C_{28}H_{22}N_2O_4Zn$: C, 65.19; H, 4.30; N, 5.43%. The zinc(II) complex is soluble in methanol, ethanol, and chloroform, but insoluble in acetone and benzene.

The other metal complexes, [CoL], [NiL], and [CuL], are almost insoluble in organic solvents, but they were found to be pure and crystalline without recrystallization.

Measurements. Electronic absorption spectra of the ligand and its metal complexes were determined with a Shimadzu MPS-50L spectrophotometer.

Powder diffraction diagrams were obtained with a Toshiba ADX-103 X-ray diffractometer.

Magnetic measurements were carried out by the Gouy method at room temperature.

Infrared spectra of the compounds were determined in the rock-salt region with a Hitachi EPU-2A infrared spectrophotometer using the potassium bromide disc method.

Results and Discussion

It was confirmed by the X-ray powder diagrams that the metal complexes prepared in the present work

1) Presented, in part, at the 24th Annual Meeting of the Chemical Society of Japan, Osaka, April 1971.

2) F. Dwyer, N. S. Gill, E. C. Gyarfasand, and F. Lions, *J. Amer. Chem. Soc.*, **75**, 1526 (1953); *ibid.*, **78**, 4905 (1956).

3) E. Wagner, *J. Prakt. Chem.*, [2] **27**, 201 (1883).

were not polymeric but crystalline.

The ligand, 1,4-bis(*o*-salicylideneaminophenyl)-1,4-dioxabutane, contains an N_2O_4 ligand set consisting of six atoms capable of combining with a metal ion. Judging from the low ability of the ethereal oxygen atom to be bound with a metal ion, however, coordination numbers lower than six may also be possible.

It is presumed that the cobalt(II) complex, [CoL], is not a six-coordinated one, since it is paramagnetic with a magnetic moment of 4.33 B.M. This value is considered to be in the range of magnitude so far observed for a tetrahedral or a five-coordinated cobalt(II) complex, but far below the moment for a six-coordinated one.[4,5] The electronic absorption spectrum of [CoL], as shown in Fig. 1, is quite different from those of octahedral cobalt(II) complexes and tetrahedral ones, but has the main characteristics of the spectrum for the five-coordinated cobalt(II) complex.[6] It is thus concluded that the cobalt(II) ion in [CoL] is five-coordinated, with one of the ethereal oxygen atom bound to the cobalt(II) ion. Any attempt to isolate the cobalt(III) complex with L as a ligand by oxidizing [CoL] has so far been unsuccessful. With 1,4-bis(*o*-salicylideneaminophenyl)-1,4-dithiabutanate (Ls), however, six-coordinated cobalt(III) complexes only were previously reported.[7] This result probably indicates that the ligand field produced by L may be weaker than that produced by Ls, showing significant difference between sulfur and oxygen as a coordinating atom.

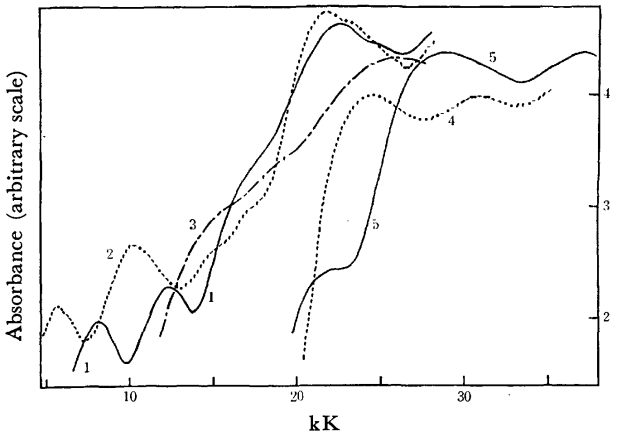


Fig. 1. Electronic absorption spectra of 1,4-bis(*o*-salicylideneaminophenyl)-1,4-dioxabutane (H_2L) and its metal complexes: 1, [CoL], solid; 2, [NiL], solid; 3, [CuL], solid; 4, [ZnL], in chloroform; 5, H_2L, in chloroform. The solid spectra are shown in aribitrary scale.

For the nickel(II) ion in [NiL], the planar four-coordination is excluded, since the nickel(II) complex is paramagnetic with a magnetic moment of 2.86 B.M. at room temperature. The moment observed is much smaller than those reported for tetrahedral nickel(II) complexes.[5] Moreover, the electronic absorption spectrum of [NiL], which is shown in Fig. 1, is similar to that of the typical five-coordinated nickel(II) complex, but is different from that of the octahedral complex.[6] It is concluded that the nickel(II) ion in [NiL] is five-coordinated.

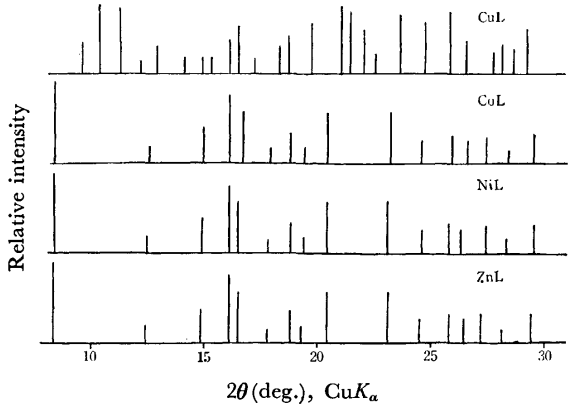

Fig. 2. X-Ray diffraction diagrams of [CuL], [CoL], [NiL], and [ZnL]

The X-ray powder diffraction diagram of [NiL], as shown in Fig. 2 is similar to that of [CoL], indicating that the cobalt(II) and the nickel(II) complexes have a similar configuration, namely the configuration containing the metal ion in five-coordination. Moreover, the infrared spectrum in the rock-salt region of [NiL] is also virtually identical with that of [CoL], in agreement with the conclusion derived above about their structure.

Since the zinc(II) complex, [ZnL], also shows an X-ray powder diagram and an infrared spectrum similar to those of [CoL] and [NiL], it is concluded that the three complexes [CoL], [NiL], and [ZnL] have a similar configuration, in which the metal ion assumes the five-coordination.

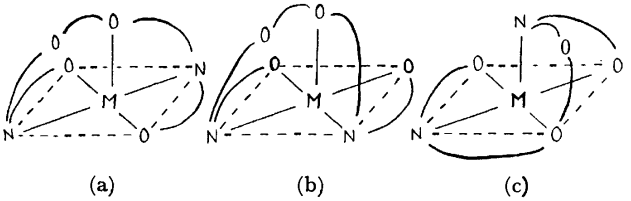

Fig. 3. Some possible configurations for the five-coordinated complexes of the [ML] type.

Some possible configurations for the five-coordinated complexes are shown in Fig. 3. The configuration (a) seems to be more favorable than the other configurations from the steric condition alone, but the definitive conclusion about the precise configuration must await the more detailed X-ray studies. It should be noted, in any case, that the ligand in these complexes is not sexadentate but quinquedentate, with only one of the two ethereal oxygen atoms bound to the metal ion.

The absorption spectrum of [ZnL], which is shown in Fig. 1, may be interpreted on the basis of previous results about *N*-substituted-salicylideneiminato-metal(II) complexes.[8] It is thus considered that the absorp-

tion bands at about 24.4 kK (log ε, 4.0) and 30.5 kK (log ε, 4.0) of [ZnL] are originated mainly from excitations involving both the metal ion and the ligand and π-π^* transitions within the ligand, respectively.

The X-ray diffraction diagram of [CuL] is different from those of the other three metal complexes. The infrared spectrum of [CuL] in the region from 1200 to 1275 cm^{-1}, where compounds having an ethereal structure similar to that in the ligand, L, is known to absorb,[9] is very different from that of [ZnL] but similar to that of HL.

The electronic absorption spectrum of [CuL] may be interpreted on the basis of the model having a four-coordinated configuration, scarcely distorted from a planar one. As shown in Fig. 1, [CuL] shows *d-d* absorption bands at frequencies nearly identical with, or even higher than, those of bis(*N*-aryl-salicyliden-iminato)copper(II) and related complexes;[10,11] their *d-d* bands in the lowest frequency region appear at about 15 kK.

From these data combined, a four-coordinated, essentially planar configuration seems to be likely for [CuL], but any definitive conclusion about its structure may not safely be drawn, except that [CuL] has a different configuration from that of [CoL], [NiL], or [ZnL].

The present authors are grateful to Professor Mitsue Koizumi and Dr. Satoru Ueda of Osaka University for the determination of the X-ray powder diffraction diagrams. Thanks are also due to the Ministry of Education for financial support.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2140—2143(1972)

Six-coordinate Chromium(III) Complexes with *N,N'*-Ethylene-bis(acetylacetoneiminate) as a Ligand[1]

Katsumoto YAMANOUCHI (Formerly IWASAKI) and Shoichiro YAMADA
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received January 13, 1972)

Numerous six-coordinate chromium(III) complexes with *N,N'*-ethylene-bis(acetylacetoneiminate) (abbreviated as Acen) have been synthesized. The complexes obtained are of the type $[Cr(Acen)X_2]Y$, where $X=H_2O$, NH_3, CH_3NH_2, n-$C_3H_7NH_2$, and n-$C_4H_9NH_2$ for Y=Cl and X=CN, NCS, and NO_2 for Y=K. The complex $[Cr(Acen)(H_2O)_2]Cl$ has been obtained by a reaction of anhydrous chromium(III) chloride with *N,N'*-ethylene-bis(acetylacetoneimine) in tetrahydrofuran. The other complexes have been derived from the diaquo-complex. Infrared spectra show that the nitrite ions in $[Cr(NO_2)_2(Acen)]^-$ and the thiocyanate ions in $[Cr(NCS)_2(Acen)]^-$ are bound with the chromium(III) ion through oxygen and nitrogen atoms, respectively. Electronic absorption bands of all these complexes, which arise from internal transitions within the ligand Acen, differ greatly from those of the free ligand, suggesting that the electronic states of the ligand in the complexes differ from those of the free ligand.

A number of papers have been published on metal complexes with Schiff bases.[2,3] However, not many chromium(III) complexes have so far been reported.[4-7] Chromium(III) complexes with Schiff bases obtained from salicylaldehyde derivatives and various amines have recently been synthesized.[4,5] As an extension of the previous study on six-coordinate chromium(III) complexes with *N,N'*-ethylenebis(salicylideneiminate) (abbreviated as Salen),[6] this paper deals with six-coordinate chromium(III) complexes with *N,N'*-ethylenebis(acetylacetoneiminate)[8] as a quadridentate ligand (I, abbreviated as Acen). These complexes have not been reported, although tris(*N*-arylacetylacetoneiminato)chromium(III) complexes have been known for some years.[7]

Experimental

Materials. Chromium(III) complexes with *N,N'*-ethylene-bis(acetylacetoneiminate) as a ligand are shown in Table 1, together with analytical data.

$[Cr(Acen)(H_2O)_2]Cl$. *N,N'*-ethylene-bis(acetylacetoneimine) (0.1 mol) and potassium ethoxide (0.2 mol) in ethanol

(50 m*l*) were added to 300 m*l* of tetrahydrofuran in a flask attached to a Soxhlet apparatus. Anhydrous chromium(III) chloride (0.1 mol) and zinc dust (1 g) were placed in the thimble of the apparatus, and the tetrahydrofuran solution was allowed to reflux for about 4 hr until the recycling liquid became colorless. The reaction mixture was allowed to cool down to room temperature. Potassium chloride which precipitated in the solution was filtered, and a reddish brown filtrate obtained was concentrated nearly to dryness on a rotary evaporator. The residue was dissolved again in ethanol (150 m*l*), and the resulting solution was filtered, diluted with 200 m*l* of benzene and concentrated to about 50 m*l*. The procedure with the residue was repeated several times. Brown crystals which separated out in the solution were collected by filtration and dried *in vacuo* for 24 hr.

$[Cr(Acen)(NH_3)_2]Cl \cdot 1.5H_2O$. $[Cr(Acen)(H_2O)_2]Cl$ (0.01 mol) was dissolved in a mixture of methanol (50 m*l*) and 30% aqueous ammonia (50 m*l*) at about 50°C. The resulting solution was heated at this temperature for 15 min, filtered and allowed to stand overnight. Reddish orange needle-like crystals which separated out in the solution were collected.

$[Cr(Acen)(RNH_2)_2]Cl \cdot nH_2O$. ($R=CH_3$, C_2H_5, n-C_3H_7, and n-C_4H_9; n=2, 1.5, 1, and 1, respectively). $[Cr(Acen)(H_2O)_2]Cl$ (0.01 mol) was added to a solution of an appropriate alkyl amine (0.2—0.3 mol) in methanol (20—30 m*l*) and the solution was stirred for 15 min at about 50°C. Diethyl ether or benzene was added to the solution until the solution became turbid. It was then allowed to stand overnight to give orange needle-like crystals.

$[Cr(Acen)(C_6H_5NH_2)_2]Cl \cdot 2H_2O$. Aniline (0.1 mol) and $[Cr(Acen)(H_2O)_2]Cl$ (0.01 mol) were added to acetone (50 m*l*), stirred at about 50°C for 15 min, then filtered and allowed to stand overnight. Yellow-brown crystals were collected.

$K[Cr(CN)_2(Acen)] \cdot 2H_2O$. An aqueous solution of potassium cyanide (0.04 mol) was added to a solution of $[Cr(Acen)(H_2O)_2]Cl$ (0.01 mol) in methanol (30 m*l*). The resulting solution was heated at about 50°C for 15 min and allowed to stand overnight to give reddish orange crystals.

The chromium(III) complexes described so far were pure enough without recrystallization. However, purification was carried out whenever necessary by recrystallization from methanol or ethanol. The complexes are soluble in methanol, ethanol, water, tetrahydrofuran and acetonitrile, but insoluble in diethyl ether and benzene.

$K[Cr(NCS)_2(Acen)] \cdot H_2O$. A suspension of $[Cr(Acen)(H_2O)_2]Cl$ (0.01 mol) and potassium thiocyanate (0.04 mol) in acetone (50 m*l*) was heated at about 50°C for 1 hr. The potassium chloride which separated out in the solution was removed by filtration. The filtrate was concentrated to yield the crude product of the desired complex which was recrystallized from acetone. Dark red crystals were obtained. The compound is soluble in acetone.

$K[Cr(ONO)_2(Acen)]$. A suspension of $[Cr(Acen)(H_2O)_2]Cl$ (0.01 mol) and potassium nitrite (0.045 mol) in methanol (50 m*l*) was heated under stirring at about 50°C for 1 hr, and the resulting potassium chloride was filtered. On concentrating the filtrate, the desired complex was obtained as yellowish brown crystals. Purification was carried out by filtration from methanol or ethanol.

All the complexes except for the dicyano-complex are gradually decomposed by water. The diisothiocyanato-complex undergoes decomposition even in methanol or ethanol.

Measurements. The electronic absorption spectra of the chromium(III) complexes were determined with a Shimadzu MPS-50L spectrophotometer. The infrared absorption spectra were measured in the region 600—4000 cm^{-1} with a Hitachi EPI-G31 infrared spectrophotometer using Nujol mull and potassium bromide disc methods.

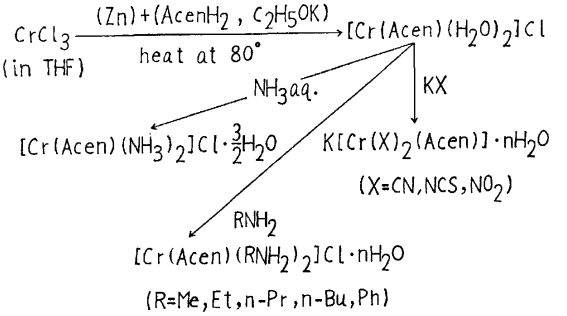

Fig. 1. Synthetic routes of the complexed of the type $[Cr(Acen)X_2]Y$

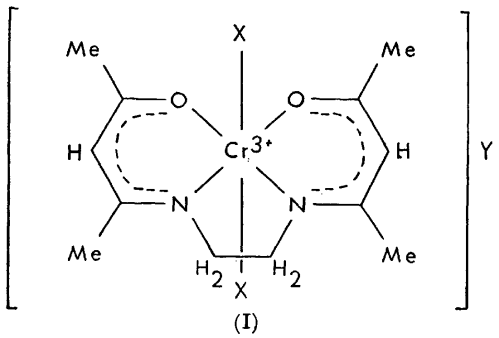
Results and Discussion

The synthetic routes of the chromium(III) complexes are summarized in Fig. 1. A method which involves reactions in ethyleneglycol at a higher temperature and which was successful for preparing $[Cr(Salen)(H_2O)_2]Cl$,[5,6] did not yield $[Cr(Acen)(H_2O)_2]Cl$, but gave instead tris(acetylacetoneiminato)chromium(III). The method for preparing $[Cr(Acen)(H_2O)_2]Cl$ proved to be more appropriate for the synthesis of $[Cr(Salen)(H_2O)_2]Cl$ than the previously one.

Since the quadridentate ligand Acen usually requires, but not necessarily a square-planar coordination, it most likely that the chromium(III) complexes prepared have a six-coordinate, *trans*-configuration.



(I)

The main infrared bands of $[Cr(ONO)_2(Acen)]^-$ and $[Cr(NCS)_2(Acen)]^-$ are shown in Table 2. From the table and with the aid of the criteria previously established,[9,10] it is concluded that the nitrite ions in $[Cr(ONO)_2(Acen)]^-$ are coordinated through their oxygen atoms to the chromium(III) ion. This is in agreement with the results for other chromium(III) complexes.[11]

TABLE 2. INFRARED ABSORPTION MAXIMA OF THIOCYANATO-ISOTHIOCYANATO AND NITRO-NITRITO ISOMERS

Nitro-nitrito isomers	ν_{as}	ν_s	δ	reference

In a similar way, we see that the thiocyanate ions are bound through their nitrogen atoms to the chromium(III) in $[Cr(NCS)_2(Acen)]^-$. It seems to be generally accepted that the ν (CS), which appears at about 690 to 860 cm^{-1}, is useful for the diagnostic purposes, the band being observed at 780 to 860 cm^{-1} for the M–NCS complex and at 690 to 730 cm^{-1} for the M–SCN complex.

The electronic absorption spectra of some of the chromium(III) complexes are shown in Fig. 2, the maxima of the bands being given in Table 3. It should be noted that, as far as the main peaks are concerned, the absorption spectra of the complexes are similar, regardless of the position of a ligand X in the spectrochemical series. As an example, the maxima of these bands for $[Cr(CN)_2(Acen)]^-$ are nearly the same as those for $[Cr(Acen)(H_2O)_2]^+$, in spite of the fact that the cyanide ion is far apart from H_2O in the spectrochemical series. Consequently, it is concluded that the bands at about 22—23, 27—28, and 36—37 kK observed for all the chromium(III) complexes may not be assigned to *d-d* bands. It is more likely that they correspond to internal transitions within the coordinated Acen and/or transitions, in which the ligand Acen is mainly involved. This situation seems to be similar to that with complexes of the type $[Cr(Salen)L_2]$.[6]

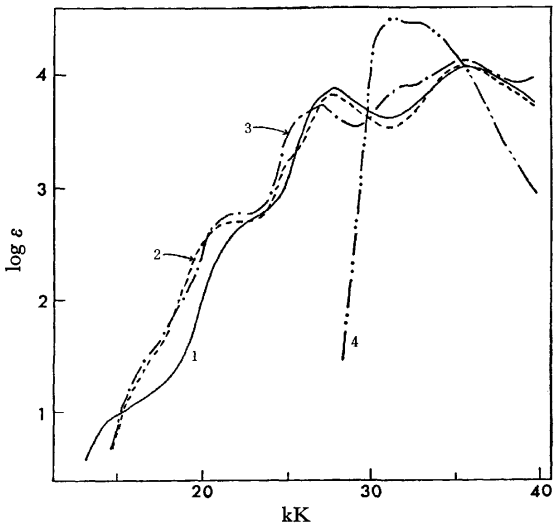

Fig. 2. Electronic absorption spectra of complexes of the type $[Cr(Acen)X_2]Y$ in solution: 1, X=H_2O, in methanol: 2, X=CN, in methanol; 3, X=NCS, in acetonitrile; 4, *N,N'*-ethylene-bis(acetylacetoneimine), in methanol

Their ligand field bands are probably hidden under more intense bands of other origins, except for some complexes which show a small shoulder in the lower frequency side of the absorption curves, possibly arising from *d-d* transitions.

The inflation at about 32 kK in the spectrum of $[Cr(NCS)_2(Acen)]^-$ indicates the presence of a band, which may be assigned to a "specific absorption band" due to the isothiocyanate group linked with the chromium(III) ion. A band of a similar nature has also been reported to appear in the neighbourhood of this frequency region for chromium(III) ammine complexes.[12] A specific absorption band due to the coordinated nitrite ion is known to be generally weaker and may be considered to be hidden under more

intense bands of other origins.

We see from Fig. 2 and Table 3 that the bands of $[Cr(Acen)X_2]$, due to internal transitions within the ligands, differ remarkably from those of the free ligand itself. This is also found to be the case with the corresponding cobalt(III) complexes,[13)] which show spectra with main features similar to those of the chromium(III) complexes. This indicates that the electronic state of the ligand in the chromium(III) complexes, as well as in the cobalt(III) complexes, differ from that in the free ligand. Comparison also shows that the spectra of tris(*N*-arylacetylacetoneiminato)chromium(III) complexes[7)] have features similar to those of complexes of the type $[Cr(Acen)X_2]Y$.

Since it is known that these free ligands exist in the form of β-ketoamines rather than β-ketoimines,[14)] the above result seems to show that their electronic state in the chromium(III) complexes differs considerably from that of the β-ketoamines.

The present authors are grateful to the Ministry of Education for financial support.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2143—2147(1972)

Syntheses of Formato-, Acetato-, Benzoato-, and Chlorosubstituted Acetatoruthenium Complexes, and Their Properties

Masao MUKAIDA, Terunosuke NOMURA, and Tatsujiro ISHIMORI*

Department of Chemistry, Sophia University, Chiyoda, Tokyo

**Department of Chemistry, Rikkyo (St. Paul's) University, Ikebukuro, Tokyo*

(Received October 29, 1971)

Complexes with the general formula of $[Ru_2(RCOO)_4X]$, where R=H, X=Cl, or Br; R=Me, X=Cl, Br, I, SCN, NO_3, or MeCOO; R=ph, X=Cl, or Br, were prepared. The magnetic properties, conductivities, polarographic behavior, and infrared spectra of these complexes were investigated. All the complexes show magnetic moments of 2.84—2.96 B.M., and their susceptibilities, at from about 300 to 100°K, can be fitted to the Curie-Weiss law with negative values of the Weiss constant (θ=−30—−60°K). These complexes seem to be isostructural. Monochloroacetato-, and trichloroacetatoruthenium complexes ($[Ru_2(CH_2ClCOO)_4Cl]\cdot 2H_2O$ and $[Ru(OH)(CCl_3COO)_2(H_2O)]$) were also prepared.

Carboxylatoruthenium complexes of the $[Ru_2(RCOO)_4Cl]$ (R=Me, Et, *n*-Pr) type have been prepared by the reaction of hydrated ruthenium trichloride with carboxylic acid-acid anhydride mixtures, and the complexes have been formulated as containing Ru(II) and Ru(III).[1] $[Ru_2(RCOO)_4Cl]$ (R=H, Me) complexes have also been obtained by the reaction of ruthenium(III and IV) chlorides with acetic or formic acid in a sealed tube.[2] An X-ray investigation of the analogue butyrato complex has recently been accomplished.[3] In this study, formato-, acetato-, and benzoatoruthenium complexes were

3) M. J. Bennett, K. G. Caulton, and F. A. Cotton, *Inorg. Chem.*, **8**, 1 (1969).

prepared and their properties were investigated. Monochloroacetato- and trichloroacetatoruthenium complexes, $[Ru_2(CH_2ClCOO)_4Cl]\cdot 2H_2O$ and $[Ru(OH)(CCl_3COO)_2(H_2O)]$, were also prepared.

Experimental

Syntheses. $[Ru_2(MeCOO)_4Cl]$ (Complex [1]). A ruthenium(III, IV)-hydrochloric acid solution (Ru, 250 mg) was evaporated to dryness on a water bath. The residue was dissolved in 12N acetic acid (30 m*l*) and then gently heated for about 100 min at 110°C in a sealed, stainless-steel (SUS 32) tube. The solution thus obtained was concentrated on a water bath to prepare crystals. The crude crystals were recrystallized from a 3N acetic acid solution. Brown crystals were thus obtained; they were filtered and washed several times with ethanol and ether, and then dried *in vacuo*, to yield about 300 mg. The complex is poorly soluble both in water and in methanol.

Found: Ru, 42.23; C, 20.3; H, 2.40; Cl, 7.17%. Calcd for $Ru_2(MeCOO)_4Cl$: Ru, 42.66; C, 20.27; H, 2.53; Cl, 7.49%.

$[Ru_2(MeCOO)_4Br]$ (Complex [2]), $[Ru_2(MeCOO)_4I]$ (Complex [3]), and $[Ru_2(MeCOO)_4SCN]$ (Complex [4]) were prepared by adding large amounts of sodium bromide, sodium iodide, and potassium thiocyanate respectively to an acetic acid solution of Complex [1]. Complex [2] is poorly soluble both in water and in methanol, and Complexes [3] and [4] are insoluble in these solvents.

Complex [2]. Found: Ru, 38.54; C, 18.7; H, 2.44; Br, 15.08%. Calcd for $Ru_2(MeCOO)_4Br$: Ru, 39.00; C, 18.54; H, 2.32; Br, 15.43%.

Complex [3]. Found: Ru, 35.34; C, 17.3; H, 2.05; I, 21.30%. Calcd for $Ru_2(MeCOO)_4I$: Ru, 35.76; C, 16.99; H, 2.12; I, 22.45%.

Complex [4]. Found: C, 21.86; H, 2.12; N, 2.82%. Calcd for $Ru_2(MeCOO)_4SCN$: C, 21.77; H, 2.44; N, 2.82%.

$[Ru_2(MeCOO)_4NO_3]$ (Complex [5]). An 1N acetic acid solution containing 500 mg of Complex [1] was passed through an anion exchange column of Dowex 1-X4 (30 m*l* of the NO_3^- form). To the effluent, a 200-mg portion of potassium nitrate was then added, and the solution was concentrated on a water bath. The brown crystals thus obtained were filtered, washed with water, methanol, and ether, and dried *in vacuo*, to yield about 350 mg. The complex is poorly soluble both in water and in methanol.

Found: C, 18.90; H, 2.48; N, 2.91%. Calcd for $Ru_2(MeCOO)_4NO_3$: C, 19.21; H, 2.42; N, 2.80%.

$[Ru_2(MeCOO)_4OCOMe]$ (Complex [6]). An 1N acetic acid solution containing 400 mg of Complex [1] was passed through an anion exchange column of Dowex 1-X4 (30 m*l* of the SO_4^{2-} form). The effluent was concentrated on a water bath. The brown crystals thus obtained were filtered, washed with water, methanol, and ether, and dried *in vacuo*, to yield about 200 mg. The complex is poorly soluble both in water and in methanol.

Found: C, 23.58; H, 3.62%. Calcd for $Ru_2(MeCOO)_4OCOMe$: C, 24.15; H, 3.04%.

$[Ru_2(HCOO)_4Cl]$ (Complex [7]). This complex was prepared by the same procedure as was Complex [1], but using formic acid, as was reported previously.[2]

$[Ru_2(HCOO)_4Br]$ (Complex [8]). The bromo-formato complex was prepared by adding a large amount of sodium bromide to a solution of Complex [7]. The complex is poorly soluble both in water and in methanol.

Found: Ru, 43.35; C, 10.5; Br, 16.82%. Calcd for $Ru_2(HCOO)_4Br$: Ru, 43.73; C, 10.39; Br, 17.30%.

$[Ru_2(phCOO)_4Cl]$ (Complex [9]). The chloro-formato complex [7] (100 mg) was dissolved in a mixture of methanol and water (30 m*l*+30 m*l*), and then a methanol solution of benzoic acid (100 mg/10 m*l*) was added to that solution. The mixture thus obtained was kept at room temperature for a week. The brown, crystalline material thus obtained was filtered, washed with water, methanol, and ether, and dried *in vacuo*, to yield about 150 mg. The complex is insoluble in most organic solvents and in water.

Found: Ru, 28.04; C, 46.4; H, 2.61; Cl, 4.90%. Calcd for $Ru_2(phCOO)_4Cl$: Ru, 27.98; C, 46.54; H, 2.77; Cl, 4.91%.

$[Ru_2(phCOO)_4Br]$ (Complex [10]). The bromo-benzoato complex was prepared in the same way as was the chloro-benzoato complex, using the bromo-formato complex [8] as the starting material. (Yield, about 150 mg). The complex is insoluble in most organic solvents and in water.

Found: Ru, 26.51; C, 43.9; H, 2.60; Br, 9.64%. Calcd for $Ru_2(phCOO)_4Br$: Ru, 26.36; C, 43.85; H, 2.61; Br, 10.43%.

$[Ru_2(CH_2ClCOO)_4Cl]\cdot 2H_2O$ (Complex [11]). To Complex [1] (200 mg) in a mixture of methanol (50 m*l*) and water (50 m*l*), a monochloroacetic acid solution (500 mg/10 m*l* H_2O) was added. The solution was then kept at room temperature for one or two weeks. The brown crystals thus obtained were filtered, washed with methanol, and ether, and dried *in vacuo*, to give 200 mg. Recrystallization was made from a 2M monochloroacetic acid solution. The complex is slightly soluble in methanol.

Found: Ru, 31.14; C, 15.52; H, 2.40; H_2O, 5.85%. Calcd for $Ru_2(CH_2ClCOO)_4Cl\cdot 2H_2O$: Ru, 31.20; C, 14.83; H, 1.85; H_2O, 5.55%.

$[Ru(OH)(CCl_3COO)_2(H_2O)]$ (Complex [12]). To a solution of Complex [1] (500 mg) in a mixture of methanol (100 m*l*) and water (100 m*l*), trichloroacetic acid (8 g) was added. The solution was then heated about 10 min. A flaky, brown crystalline material was thus obtained; and it was filtered, washed with water, and dried in a vacuum line (10^{-3} mmHg), to give 200 mg. The complex is soluble in most organic solvents.

Found: Ru, 22.02; C, 10.58; H, 0.61%. Calcd for $Ru(OH)(CCl_3COO)_2(H_2O)$: Ru, 21.87; C, 10.39; H, 0.87%.

Apparatus and Reagents. The molar conductivity was measured with a Metrohm Konduktoskope E365, the IR spectra, with Leitz 221, JASCO DS-301, and Hitachi EPI-L IR spectrometers, and the molecular weight, with a Mecrolab Osmometer 302. The magnetic susceptibility was measured by the Gouy method.

Ruthenium (III, IV) in a hydrochloric acid solution was prepared from a distillate of ruthenium(VIII) tetroxide passed into an alcoholic acid solution. All the other reagents used were of an analytical grade.

Results and Discussion

The complexes obtained are summarized in Table 1, along with the magnetic data, the conductivity data, the molecular weights, and the absorption maxima in their visible spectra.

The chloro-acetato complex [1] and chloro-formato complex [7] were prepared by the reaction of ruthenium(III and IV) chloride with acetic and formic acid respectively in a sealed tube. Complex [1] was confirmed by X-ray fluorometry to be free from contamination by the components of the sealed, stainless-steel

a) Corrections for diamagnetism were made and effective magnetic moments in Bohr magnetons, μ_{eff}, were calculated according to the formula, $\mu_{eff}=8T\chi_{corr}^{1/2}$, where χ_{corr} is the molar susceptibility corrected for diamagnetism and T is the absolute temperature.
b) The hydrated water was determined by the weight loss at 140°C.
c) in MeOH (30°C), 10^{-3} mol/*l*.
d) in MeOH. e) The values in Table are twice the observed ones for 1:1 electrolytes.

tube.[4] The chloro-benzoato complex [9] was obtained from a mixture of the chloro-formato complex [7] and benzoic acid. The other acetato complexes [2]—[6] were obtained from solutions of the chloro-acetato complex [1] in acetic acid containing an excess of the anions. A similar derivation can also be expected for the chloro-formato complex [7]. The conversion from the chloro-acetato complex [1] to the chloro-formato complex [7], and *vice versa*, are possible. The monochloroacetato and trichloro-acetato complexes, [11] and [12], $[Ru_2(CH_2ClCOO)_4Cl]\cdot 2H_2O$ and $[Ru(OH)(CCl_3COO)_2(H_2O)]$, were obtained as reaction products of Complex [1] and the corresponding monocarboxylic acid. In Fig. 1, these conversion procedures are shown schematically.

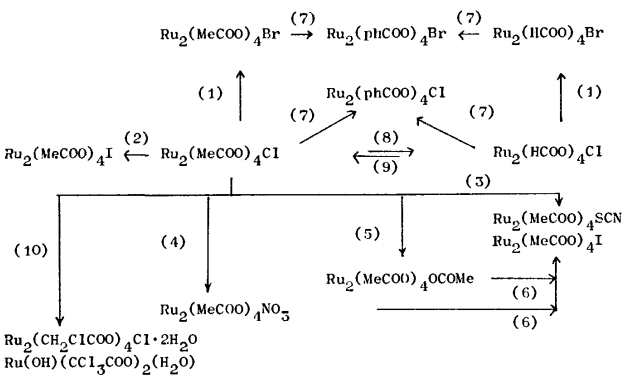

Fig. 1. Preparative conversion procedure of carboxylatoruthenium complexes.
1—3), 6): addition of the anions.
4,5): addition of the anions (after complex [1], chloroacetato complex, was passed through an anion exchanger column).
7): crystallized from a mixture solution of complex [1], $[Ru_2(MeCOO)_4Cl]$, or complex [7], $[Ru_2(HCOO)_4Cl]$, and benzoic acid.
8,9): interconversion of acetato and formato complexes.
10): crystallized from a mixture solution of complex [1], $[Ru_2(MeCOO)_4Cl]$, and monochloroacetic acid or trichloroacetic acid.

As has been described above, several monocarboxylatoruthenium complexes, $[Ru_2(RCOO)_4Cl]$ (R= Me, Et, *n*-Pr), have been reported.[1] An X-ray diffraction study of the analogous butyratoruthenium complex has indicated that the complex contains binuclear units consisting of two ruthenium atoms bridged by four *n*-butyrato groups, and that these binuclear units are linked by bridging chlorine atoms into infinite zigzag chains.[3] The complexes of the $[Ru_2(RCOO)_4X]$ type prepared in this study are thought to be analogous to those reported in Refs. 1 and 3.

Conductivities and Molecular Weight. The molar conductivities for Complexes [1], [5], [6], [7], and [11] are within 70 to 90 mho cm^{-1}, indicating that these complexes are 1:1-type electrolytes. The small conductivity for Complex [12] suggests that the complex is non-electrolyte. The chloride ion of Complex [1] in an acetic acid solution was adsorbed quantitatively by the NO_3^--form ion exchanger (Dowex 1-X4). These facts suggest that the formato and acetato complexes can dissociate into $Ru_2(RCOO)_4(solvent)^+$ and X^-, and that the cation formed is present without decomposition.

The molecular weights measured for Complexes [1], [2], [7], [11], and [12] support the formulae expected for these complexes.

Polarographic Measurement. The polarographic behavior of the $[Ru_2(OAc)_4]^+$ cation has very recently been described.[5] The acetato complex [1] gave two polarographic waves when acetic acid was used as the supporting electrolyte (Fig. 2). One of them is the oxidation wave of mercury in the presence of the chloride ion; this supports the idea that the complex

4) The authors wish to thank Mr. Tadao Ooizumi of the Rigaku Denki Co., Ltd., for this data.

in an aqueous solution dissociates to give the chloride ion. The other wave ($E_{1/2}=+0.06$ V *vs* S.C.E.) results from the reduction of the complex. The nitrato-acetato complex [5] also gave the same polarographic wave as that of Complex [1] except for the oxidation wave due to the chloride ion. The reversibilities of the second step were confirmed by the measurement of the A. C. polarogram. The log-plot analysis of the reduction wave gave linear relations, with a reciprocal slope following into 63 mV. These facts indicate that the electrode reduction of the complex solutions proceeds reversibly in the usual polarographic sense; the reduction is thought to be a one-electron one on the basis of the diffusion current.

Magnetic Property and Visible Absorption Spectra. As is shown in Table 1, Complexes [1]—[10] have effective magnetic moments of 2.84—2.96 B.M. at room temperature. The values are significantly higher than the spin-only moment for a binuclear ruthenium-(II, III) complex with a single unpaired electron. The temperature variation in the experimental atomic susceptibilities and effective magnetic moments of Complexes [1]—[3] and [7]—[10] were also examined. The data for Complexes [1], [7], and [9] are given in Table 2. The reciprocal susceptibilities varied linearly with the temperature and obeyed the Curie-Weiss law with θ over the range of −30——60°K. These results are similar to those obtained by Stephenson *et al.*[1] Bennett, Caulton, and Cotton have explained the effective magnetic moments of $[Ru_2(RCOO)_4Cl]$ complexes by saying that the paramagnetism indicates three unpaired electrons per pair of metal atoms. They also suggested that the two ruthenium atoms in the complexes exist in the same nonintegral oxidation state of +2.5.[3]

a) dehydrated complex.

The monochloroacetato complex [11], $[Ru_2(CH_2ClCOO)_4Cl]\cdot 2H_2O$, shows a magnetic moment close to that of the acetato complex, suggesting a similar dimeric structure. On the other hand, the magnetic moment of the trichloroacetato complex [12], $[Ru(OH)(CCl_3COO)_2(H_2O)]$, is reasonable compared with the values reported for Ru(III) complexes.[6]

The visible absorption spectra of the complexes of the $[Ru_2(RCOO)_4X]$ type in a methanolic solution were almost the same. Such data for analogous complexes have also been reported.[1] The band has been assigned to the $b_{2g}-a_{1g}$ and/or $b_{2g}-a_{2u}$ transitions using a molecular orbital diagram for an M_2X_8 species.[3] The absorption spectra of the trichloroacetato complex [12], $[Ru(OH)(CCl_3COO)_2(H_2O)]$, was quite different from those of other monocarboxylato complexes, indicating that Complex [12] is different from the other monocarboxylato complexes.

Infrared Spectra. The infrared spectra of the complexes were measured over the range of 4000—200 cm^{-1}. The general features of the spectra of the chloro-monocarboxylato complexes were very similar to those of the corresponding bromo- and iodo-monocarboxylato complexes. No absorption bands due to OH and H_2O groups were found in Complexes [1]—[10]. The infrared absorption bands in the carboxyl stretching frequency region are shown in Table 3, along with their tentative assignments.

The chloro-formato complex [7] displays two strong absorption bands at 1480 and 1336 cm^{-1} in the carboxyl-stretching frequency region. These bands can be assigned to the antisymmetric and the symmetric COO-stretching vibrations respectively. The separation ($\Delta=144$ cm^{-1}) between the two absorption bands may indicate the symmetrical coordination of the carboxyl groups.[7]

The chloro-acetato complex [1], however, shows a strong band with several shoulders near 1444 cm^{-1} in this region; the band is very different in shape from that in the chloro-formato complex. This carboxyl band has been explained by assuming an overlapping of the antisymmetric and symmetric COO-stretching vibrations of a bridged carboxyl group.[1] Since the antisymmetric COO-stretching frequency is known to be sensitive to the electronic environment of a carboxylato ion,[8] the observed different features in the carboxyl region between the formato and the acetato complexes are probably due to the difference in the character of the coordinating carboxyl bands.

The monochloroacetato complex [11], $[Ru_2(CH_2ClCOO)_4Cl]\cdot 2H_2O$, showed a carboxyl band similar to that of the acetato complex. On the other hand, the trichloroacetato complex [12], $[Ru(OH)(CCl_3COO)_2(H_2O)]$, exhibited two characteristic peaks in this region. These bands are thought to be due to the antisymmetric and symmetric stretching vibrations of the bidentate carboxyl groups respectively. The separation between the two absorption bands for the trichloroacetato complex [12], $[Ru(OH)(CCl_3COO)_2(H_2O)]$, is appreciably larger than those of known binuclear acetato metal complexes.[9] The increase in the separation may reflect the considerable influence of the halogens on the carboxyl vibrations of trichloroacetato groups.[10]

It is possible to distinguish the complex type between $[Ru_2(MeCOO)_4X]$ and $[Ru_2(MeCOO)_4]X$ on the basis of the infrared spectra of the nitrato-caetato complex [5]. Complex [5] shows N–O stretching bands of the nitrato group at 1388, 1288, and 809 cm^{-1}. The observation of three absorption bands indicates that the nitrato group in Complex [5] is present as a coordinate ligand, according to the Gatehouse *et al.* interpretation.[11]

With respect to the properties observed, a series of complexes of the $[Ru_2(RCOO)_4X]$ type were very similar. No remarkable substitution effect of R groups or X groups was observed. This might be understood on the basis of the structure for the butyrato complex.[3]

The trichloroacetato complex [12], $[Ru(OH)(CCl_3COO)_2(H_2O)]$, was thought to be monomeric. Since the ruthenium(III) complexes prefer a six-coordinated structure, the octahedral arrangement appears probable.

The authors wish to express their appreciation to Professor Gen P. Sato and Mr. Kunio Shimizu of Sophia University for their helpful discussions and for the measurement of the polarogram, and to Dr. Eiichi Miki of St. Paul's (Rikkyo) University for the measurement of the IR spectra. Thanks are also due to Mr. Norihiko Iida, Mr. Tsuguo Takaku, Mr. Kenji Ogisu, Mr. Masahiko Hayashi, Mr. Hiroshi Ogata, and Mr. Yujiro Saito for their technical assistance.

Cobalt(I) Tetraphenylporphin

Hiroshi KOBAYASHI, Tetsuo HARA, and Youkoh KAIZU

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 14, 1971)

Cobalt(I) tetraphenylporphin was prepared by reduction of tetraphenylporphinatocobalt(II) with sodium benzophenone ketyl in tetrahydrofuran (THF) and was purely isolated. The compound was identified as Na-[Co(I)TPP]·5THF (tetraphenylporphin is abbreviated to TPP). On the basis of electronic absorption spectrum, magnetic circular dichroism, magnetic susceptibility and NMR spectrum, the complex formed was concluded to be a complex of cobalt(I). Although some part of cobalt electron is migrated into the conjugated system of porphin, an electron furnished by the reducing reagent is mainly trapped by the central cobalt. The compound should be named sodium tetraphenylporphinatocobaltate(I).

When a metalloporphyrin is reduced, an electron given by the reducing reagent is trapped by either porphyrin π^* orbital or metal d orbital depending upon the electronic structure of the central metal. Metalloporphyrins with vacancies in $d\pi$ orbitals can capture electrons into the central metal ion, whereas metalloporphyrins with a d^8, d^9, or d^{10} dipositive metal cation accept electrons into the porphyrin conjugated system. By one-electron reduction, tetraphenylporphinatozinc(II), for example, traps an electron in the porphyrin conjugated system.[1] Thus it shows an electronic absorption spectrum of the mononegative ion of tetraphenylporphin and also an ESR signal with a g-value of almost free-spin.

If the lowest antibonding π molecular orbital of the coordinating conjugated systems is lower than the ligand field antibonding orbitals, z^2 and x^2-y^2, an electron from the reducing reagents will be trapped in the conjugated system. This gives rise to a mononegative ion of the coordinating ligand. The present authors have isolated a complex coordinated by bipyridine negative ion, $[Cr(0)(CO)_4(bipy^-)]^-$ (bipy denotes bipyridine), which was prepared by reduction of $[Cr(0)(CO)_4bipy]$.[2] Similarly $[Fe(bipy)_3]$ was a complex coordinated by bipyridine negative ions.[3] On the contrary, however, the isoelectronic $[Co(bipy)_3]^+$ was not a complex of bipyridine negative ions but a complex of Co(I) in the triplet ground state.[4] In this particular case, the lowest vacant π molecular orbital of the coordinating bipyridine must be higher than the ligand field antibonding orbitals. This arises from a rather high electron affinity of Co(II) ion. Co(I) in an octahedral ligand field should be in a triplet state with electronic configuration of $(d\pi)^6(z^2)(x^2-y^2)$, while in a planar environment it should be either in a singlet state of $(d\pi)^6(z^2)^2$ or in a triplet state of $(d\pi)^6(z^2)(x^2-y^2)$ depending upon an energy gap of z^2 and x^2-y^2 orbitals. Since z^2 and x^2-y^2 orbitals are the antibonding orbitals of the coordination binding, an electron occupation in these orbitals results in a dissociation of the coordination binding unless an electrostatic attraction between the metal ion and the ligands is present as in $[Co(bipy)_3]^+$. Although $[Co(bipy)_3]^+$ shows a trend to form $[Co(bipy)_2]^+$, it keeps two electrons with parallel spin in z^2 and x^2-y^2 orbitals, which are predominantly localized on the central metal, rather than in the lowest antibonding π molecular orbital of bipyridine. A planar cobalt(II) complex, tetraphenylporphinatocobalt(II), for example, traps an electron furnished upon reduction into a molecular orbital predominantly localized on cobalt ion. Since a gap of z^2 and x^2-y^2 orbitals in a strong planar ligand field of metalloporphyrin is appreciably large, the ground configuration of cobalt(I) at almost center of the planar ligand field turns out to be diamagnetic $(d\pi)^6(z^2)^2$. The formations of other planar diamagnetic cobalt(I) species have been established.[5]

Whitlock and Bower[6] first presumed the reduction product of tetraphenylporphinatocobalt(II) as the spin-paired cobalt(I) porphin on the basis of gram-equivalents of sodium amalgam to complete the reduction, NMR spectrum and Gouy balance experiments of the reduced species in tetrahydrofuran, and activity of catalyzing the sodium borohydride reduction of nitrobenzene.[7,8] Recently we succeeded in isolation of the cobalt(I) tetraphenylporphin. In this paper, we will present an identification of the porphin on the basis of electronic absorption spectrum, magnetic circular dichroism, magnetic susceptibility and NMR spectrum.

Experimental

Materials. $\alpha, \beta, \gamma, \delta$-Tetraphenylporphin (abbreviated to TPP) was synthesized from pyrrole and benzaldehyde by the method of Adler, *et al.*[9] Chromatographic purification was repeated on activated alumina columns using chloroform

as solvent and also eluent. Cobalt(II) complex, TPPCo(II), was prepared from the metal-free base and cobalt(II) acetate by the method of Rothemund and Menotti.[10] The complex was purified by sublimation at 250—300°C under reduced pressure. Lustrous violet crystals thus obtained was identified by elemental analysis.

Found: C, 78.8; H, 3.9; N, 8.4; Co, 8.6%. Calcd for $C_{44}H_{28}N_4Co$: C, 78.7; H, 4.2; N, 8.3; Co, 8.8%.

Cobalt(III) complex, TPPCo(III)Cl·Py·C_2H_5OH, where Py denotes pyridine, was prepared from TPPCo(II) in benzene being refluxed with a mixture of pyridine, ethanol, and hydrochloric acid by the method of Yamamoto and Tonomura.[11]

Found: C, 73.4; H, 4.3; N, 8.6%. Calcd for $C_{51}H_{39}N_5$-CoCl: C, 73.6; H, 4.7; N, 8.4%.

All other reagents and solvents were commercially available. Tetrahydrofuran (THF) used for solvent was purified by careful distillation over cuprous chloride and a trace of water was removed by adding $LiAlH_4$.

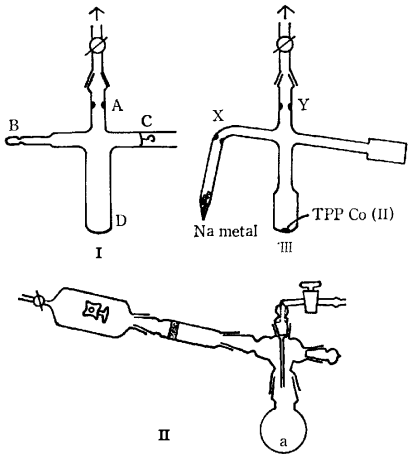

Fig. 1. Apparatus for reduction.
Benzophenone ketyl was prepared in I. The reduction of TPPCo (II) with benzophenone ketyl was carried out in II. The vessel III was used to measure absorption spectrum during the reduction process of TPPCo(II) with sodium metal in THF.

Preparation of Co(I) Complexes. Benzophenone (0.2 g) and sodium metal (0.2 g) were placed in D of the apparatus I shown in Fig. 1. The apparatus was connected to a vacuum system. After deaerated dry THF (20 m*l*) was transferred into D by distillation, the apparatus was sealed off at A and shaken for 2 hr. Thus sodium benzophenone ketyl was obtained with deep reddish violet color. TPPCo(II) (0.35 g) was placed at a under dry nitrogen in the apparatus II shown in Fig. 1. Being connected with a dry nitrogen atmosphere, the break-seal C of the apparatus I was broken, and then the tube B was cut at the top. In the nitrogen atmosphere sodium benzophenone ketyl was transferred from B onto TPPCo(II) in the apparatus II. After the mixture was stirred for 3 hr, solvent THF was removed by vacuum distillation into a trap cooled in liquid nitrogen. Then the residue was added with a mixture of deaerated dry ether (10 m*l*) and petroleum ether (10 m*l*) and then filtered. The product was dried *in vacuo*.

Found: Co, 5.4%. Calcd for $C_{64}H_{68}N_4O_5CoNa$ (Na[TPP-Co]·5THF): Co, 5.6%.

Reduction of TPPCo(II) with sodium metal in THF was also followed using the apparatus III shown in Fig. 1. After the apparatus was evacuated being connected with a vacuum system, sodium mirror was formed on the wall of the branch X and then the branch was sealed off at X. Deaerated dry THF was transferred by distillation into the container of TPPCo(II) and the apparatus was sealed off at Y. The solution was shaken being contacted with the mirror. The absorption spectrum of the solution was recorded after a period of the shaking.

Electronic Absorption Spectra and Magnetic Circular Dichroism. Measurements of the electronic absorption spectra of the air-sensitive compounds were described in a previous paper.[12] Spectra were taken on a Shimadzu automatic recording spectrophotometer Model MPS-50. Circular dichroism under an external magnetic field of 10,000 gauss was measured by a JASCO automatic recording spectropolarimeter Model ORD/UV-5 with CD attachment.[13]

Magnetic Susceptibility. Magnetic susceptibility of the complexes was measured by means of Gouy method. The measurements were carried out at room temperature. After it was calibrated for the diamagnetic term by the usual method,[14] magnetic moment of the complex was calculated.

Nuclear Magnetic Resonance. NMR spectra were recorded at room temperature on a 100 MHz Japan Electron Optics Laboratory spectrometer Model JNM 4H-100. Solvents were THF and pyridine. In the case of Co(III) complex, THF and $CDCl_3$ were used as solvent. Tetramethylsilane was used as an external reference.

Results and Discussion

Spectral change during the reduction process of TPPCo(II) with sodium metal in THF is shown in Fig. 2. The change takes place stepwise. During the first step of the reduction, remarkable isosbestic points are observed at 18.7, 19.2, 23.4, and 25.7 kK. Further reduction proceeds rather successively, therefore isosbestic points are shifted during the reaction. The complex, which has been isolated successfully in the present study, is first step product of the reduction. Absorption spectrum of the isolated complex (Fig. 3) is in good agreement with the one observed in the first step of the reduction shown in Fig. 2. The absorption maxima also coincide with those given by Whitlock and Bower.[6]

The reduced complex is extremely soluble in THF and pyridine. The spectra of the complex in benzene, THF and pyridine are actually the same in shape (Fig. 3). However the results indicate that there occurs no such axial coordination as to give a drastic change in the electronic structure, since the axial coordination by pyridine or THF may give rise to a change in the ligand field electronic structure as has been observed in Fe(II)tetraphenylporphin.[15]

TPPCo(III)X (Fig. 4). As is seen in Fig. 3, the absorption spectrum of reduced complex lacks the near-infrared bands at 11.3, 12.5, and 14.2 kK characteristic of the mononegative ion of tetraphenylporphin, which have been observed with a mononegative ion complex coordinated to Zn(II),[1,16,17] and therefore an electron furnished by the reducing reagent is much likely to localize on the central metal ion.

The first step product of the reduction was isolated in the solid state. The complex was identified by elemental analysis as Na[Co(I)TPP]·5THF. The crystal-containing THF was detected by NMR as described later. Measurements of the magnetic susceptibility reveal that the isolated first step product is diamagnetic in the solid state. Cobalt(II) ion in TPPCo(II) has an unpaired electron in the configuration $(d\pi)^6(z^2)$, whereas the observed value of the magnetic moment is larger than that expected for $S=1/2$ because of a mixing of the excited states by spin-orbit coupling perturbation.[18] Since there is no appreciable overlap between z^2 orbital and the lowest vacant π orbitals of porphin and thus there is no strong interaction between them, the ground state of the reduced complex must be triplet, $(d\pi)^6(z^2)(\pi^*)$, when an electron is trapped in one of the lowest vacant π orbitals of porphin, π^*. The observed diamagnetism of the complex prepared by one-electron reduction of TPPCo(II) should be interpreted in terms of the configuration $(d\pi)^6(z^2)^2$, where the central cobalt is

trapping an electron given by the reducing reagent. Whitlock and Bower have observed a diamagnetic behavior of the reduced complex present in THF solution.[6] However the fact that NMR spectrum of the complex in THF could be measured is regarded for first-order approximation as an evidence of diamagnetism of the complex in THF. As a matter of fact, opening the solution to air leads to immediate disappearance of the porphin signal and broadening of the solvent peaks.

TPP: tetraphenylporphin
Py: pyridine
THF: tetrahydrofuran

NMR spectrum of the complex was measured in THF and pyridine. In THF, a singlet was observed at 1.95 τ, a multiplet, at 2.10 τ and another multiplet, at 2.55 τ (Fig. 5). The singlet at 1.95 τ (band a in Table 1) is assigned to pyrrole ring protons. The multiplet at 2.10 τ (band b) is assigned to *o*-protons of phenyl groups and the one at 2.55 τ (band c), to *m*- and *p*-protons. The chemical shift values are summarized in Table 1. As is seen in the case of TPP-Co(III)Cl, the chemical shift of pyrrole protons are not influenced with the central metal ion which is less $d\pi$-donating and solvent effect of the NMR spectrum is not so appreciable. However NMR signal of the pyrrole ring protons in $[Co(I)TPP]^-$ is shifted toward higher field. This high-field shift is attributed to an increase of electron density at the pyrrole ring protons which arises from a back-donation of $d\pi$ electron to the lowest vacant π molecular orbitals of porphin.

NMR spectrum of a pyridine solution of the isolated solid sample is shown in Fig. 6. Multiplets were observed at 6.25 τ and 8.15 τ. These multiplets are very close to the ones observed with free THF. THF included in Na[Co(I)TPP]·5THF is set free in pyridine

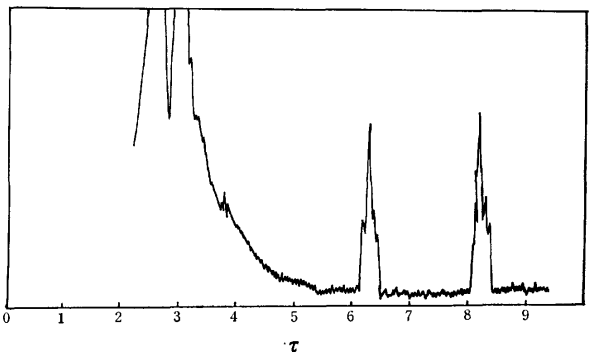

Fig. 6. NMR spectrum of Na[Co(I)TPP]·5THF in pyridine.

solution. The THF molecules are much likely to coordinate toward sodium ion in the crystal. Further studies are required concerning with the location of sodium ion in pyridine solution of the complex. However the THF molecules in the solution are present in considerably distant locations from the porphin moiety, since the THF multiplets are free from the ring current of porphin. This type of the crystal-containing THF has been found in various similar reduced metal phthalocyanines.[20]

Molecular orbital calculations on porphin yield two top filled orbitals a_{2u} and a_{1u}, and the lowest degenerate empty orbital pair e_g.[21-24] Thus the lowest excited states arise from the electronic configurations $(a_{2u})^2a_{1u}e_g$ and $(a_{1u})^2a_{2u}e_g$, whereas the ground state is $(a_{2u})^2(a_{1u})^2$. A circular box is described by a radial coordinate r and an angular coordinate θ. Orbitals are written $|\pm k)=f(r)\exp(\pm ik\theta)$, where k denotes orbital angular momentum.[25] Gouterman has pointed out that the top filled orbitals are accidentally degenerate and the orbital pair $(a_{2u}\pm ia_{1u})/\sqrt{2}$ can be identified with the degenerate pair of circular box orbitals $|\pm 4)=f(r)\exp(\pm 4i\theta)$, while the lowest empty e_g orbitals, $|\pm 5)=f(r)\exp(\pm 5i\theta)$.[26,26a]

In the ground state, the orbital pair which has z components of angular momentum $\lambda_z=\pm 4$ and angular momentum $\lambda=4$ are filled with four electrons; the configuration is denoted $(4)^4$ and has zero angular momentum $\lambda_z=0$. The first excited configurations arise by exciting a $\lambda=4$ electron to an orbital with $\lambda=5$, and are denoted $(4)^35$. This configuration gives rise to degenerate pairs of states with $\Lambda_z=\pm 1$ and with $\Lambda_z=\pm 9$. A selection rule allows a pair of transitions $\Delta\Lambda_z=\pm 1$. The allowed transition pair, $\Delta\Lambda_z=\pm 1$, is assigned to the intense Soret band of porphin

in the near-ultraviolet denoted B band, whereas the forbidden pair, $\Delta A_z = \pm 9$, the vibronically-allowed weak visible band denoted Q band.

The measurements of magnetic circular dichroism (MCD) will give an evidence of the orbital angular momentum in the excited state.[27] As a matter of fact, an A-type dispersion of MCD observed at each of the Q and B bands of TPPZn(II) reveals an orbital angular momentum arising in the respective excited state.[13] The lowest excited states of TPPCo(II) and TPPCo(III)X can be described by pure (π, π^*) excitations. As are shown in Figs. 7 and 8, MCD spectra of these complexes preserve such a characteristics as observed with TPPZn(II).

In the case of $[TPPCo(I)]^-$, back-donation of the cobalt $d\pi$ electron toward the porphin conjugated system should be appreciable in the ground state and the excited states, since an electron furnished by the reducing reagent is trapped in the cobalt z^2 orbital. Therefore the lowest excited states of $[TPPCo(I)]^-$ should be described in terms of a configuration-interaction admixture of the porphin (π, π^*) excitations and the "metal to porphin" charge-transfer excitations. Even so, as shown in Fig. 9, MCD spectrum of $[TPPCo(I)]^-$ still preserves a characteristics of the porphin Q and B bands and gives rise to A-type dispersions at 18.5, 20.0, and 23.5 kK corresponding to 0-0 and 0-1 components of Q band and B band, respectively, which are typically shown with TPPCo(III) and TPPCo(II) in Figs. 7 and 8. Two other bands were observed at 17.0 and 27.5 kK. No remarkable A-type MCD could be observed at the 17.0 kK weak band under a magnetic field of 10000 gauss. On the other hand, however, a reverse A-type dispersion was observed at 27.5 kK.

The molecular orbitals of $[TPPCo(I)]^-$ responsible to

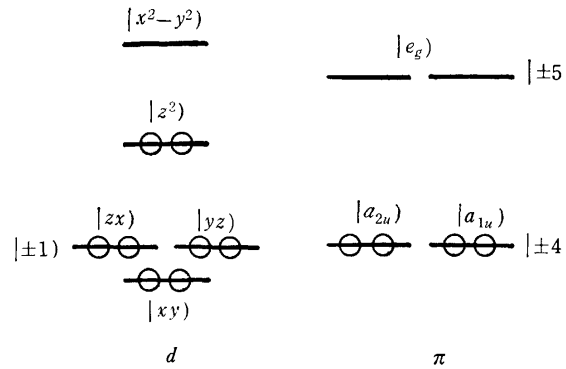

Fig. 10. The highest occupied and the lowest vacant molecular orbitals of $[TPPCo(I)]^-$.

the outer electronic configuration are schematically shown in Fig. 10. A degenerate $d\pi$ orbital pair, zx and yz, makes charge-transfer interactions with the porphin π molecular orbitals of e_g symmetry. The degenerate $d\pi$ orbital pair can be rewritten by $|\pm1)=(zx\pm iyz)/\sqrt{2}$, where ±1 denote z components of angular momentum $\lambda=1$. A one-electron term connecting the orbitals $|\pm1)$ and $|\pm5)$, $(\pm1|\hat{h}^{\text{eff}}|\pm5)\equiv\beta$, gives rise to a delocalization of the cobalt $d\pi$ electrons toward the lowest vacant porphin π orbital.

The electrons in the orbitals with $\lambda=1$, $\lambda=4$, or $\lambda=5$ (*i.e.*, the top eight electrons) are assumed to move in a one-electron effective potential set up by the nuclei and the remaining electrons. These electrons are assumed to interact with one another by two-electron term e^2/r_{ij}. There is no interaction between states with different Λ_z except the states which are connected with $(\pm1|\hat{h}^{\text{eff}}|\pm5)$. Wave functions are taken as Slater determinants which are eigenfunctions of total spin singlet.

E^0 is defined as the ground state energy, except for the electron interaction of the top eight electrons. I_1, I_4, and I_5 denote one-electron core energy of the orbitals with $\lambda=1$, $\lambda=4$, and $\lambda=5$. The Coulomb and exchange integrals over molecular orbitals are defined as

$$J_{ab}=e^2\int\frac{\phi_a^*(1)\phi_b^*(2)\phi_a(1)\phi_b(2)}{r_{12}}d\tau_1d\tau_2$$

$$K_{ab}=e^2\int\frac{\phi_a^*(1)\phi_b^*(2)\phi_b(1)\phi_a(2)}{r_{12}}d\tau_1d\tau_2$$

where 1 and 2 refer to the position of electrons 1 and 2, ϕ_a and ϕ_b, two molecular orbitals, and the star, complex conjugate. The numbers a and b refer of the λ_z value of the orbitals.

Table 2 shows the singlet states arising from the configurations $(1)^4(4)^4$, $(1)^3(4)^4(5)$, $(1)^4(4)^3(5)$, and $(1)^3(4)^3(5)^2$. Two singlets appear from a configuration of four electrons in four different orbitals. Slater determinants were then taken as follows:

$$|+5a\rangle\equiv[|1\bar{1}4\bar{4}-1-45-\bar{5}|-|1\bar{1}4\bar{4}-1-\bar{4}\bar{5}-5|+|1\bar{1}4\bar{4}-\bar{1}-\bar{4}5-5|-|1\bar{1}4\bar{4}-\bar{1}-45-\bar{5}|]/2,$$

$$+|1\bar{1}-4-\bar{4}-\bar{1}4\bar{5}-5|\}]/\sqrt{3},$$

where no bar implies spin α, a bar implies spin β and the molecular orbitals are denoted by their λ_z values. In the circular box model, $\phi_a^* \cdot \phi_a$ are identical for all the porphin molecular orbitals. It then follows that,

$$J_{44} = J_{45} = J_{55} = e^2 \int \frac{f^2(r_1) f^2(r_2)}{r_{12}} d\tau_1 d\tau_2 \equiv J$$

and

$$J_{14} = J_{15} = e^2 \int \frac{f_1^2(r_1) f^2(r_2)}{r_{12}} d\tau_1 d\tau_2 \equiv J'$$

For the K values, we set

$$K_{4-4} = K_{4-5} = K_{5-5} \equiv K$$
$$K_{45} \equiv K_1$$

as Gouterman assumed.[26] The orbitals $|\pm 1\rangle$ and $|\pm 5\rangle$ are overlapping. Therefore $(\pm 1|\hat{h}^{\text{eff}}|\pm 5)$ could be non-zero. However K_{15} and also K_{1-5} are assumed very small and are neglected. We define

$$\Delta_{CT} \equiv W_2 - W_0$$
$$\Delta \equiv W_1 - W_0.$$

For TPPZn(II), the Soret band $(\Delta + 2K_1)$ appears at 23700 cm^{-1} and the visible band $(\Delta + 2K)$, at 16900 cm^{-1}.[13] The phosphorescence of TPPCu(II) (Δ) occurs at 13300 cm^{-1}.[28] We then find

$$\Delta = 13300\ cm^{-1},\ K = 1800\ cm^{-1},\ K_1 = 5200\ cm^{-1},$$

for the tetraphenylporphins. The last column of Table 2 shows the values of the state energies in terms of Δ, Δ_{CT}, K_1, and K using the empirical values. For a variety of the values of Δ_{CT} and β, the transition energies of the cobalt(I) porphin were calculated. The singlet energy levels of the cobalt(I) porphin are shown in Fig. 11 as a function of β, assuming $\Delta_{CT} = 4000\ cm^{-1}$. The excited states of $[TPPCo(I)]^-$ can be reproduced for $\Delta_{CT} = 4000\ cm^{-1}$, $\beta = -4000\ cm^{-1}$. This β value is close to the value estimated from molecular orbital coefficient of the central nitrogens[23] and a similar resonance integral value as used by Hanazaki and Nagakura for a calculation of $[Fe(bipy)_3]^{2+}$ [29].

The calculation shows that the visible band of $[TPPCo(I)]^-$ arises mainly from $|\pm 9\rangle \leftarrow |0\rangle$ and the near-ultraviolet band, $|\pm 1\rangle \leftarrow |0\rangle$. A-type dispersions observed at 18.5, 20.0, and 23.5 kK reveal the orbital angular momentum expected for these porphin (π, π^*) excited states. The 17.0 kK weak band,

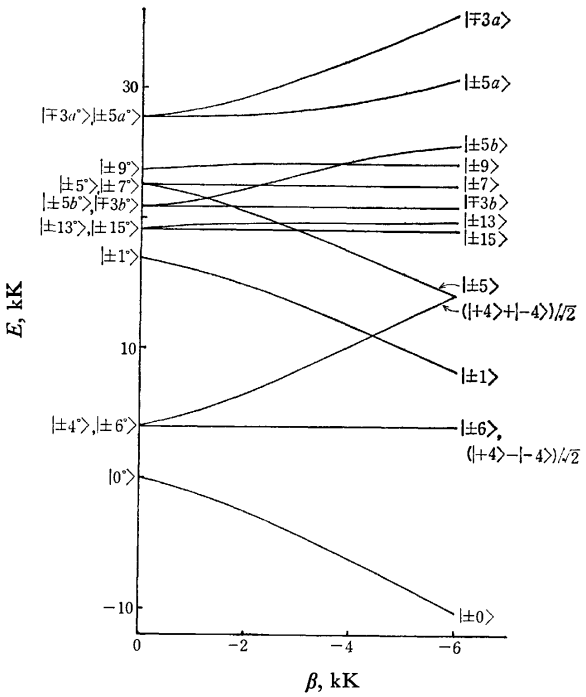

Fig. 11. The singlet energy levels of the cobalt(I) porphin as a function of β. (Δ_{CT} is assumed 4000 cm^{-1}).

however, is assigned to a "cobalt to porphin" charge-transfer transition, $(|+4\rangle + |-4\rangle)/\sqrt{2} \leftarrow |0\rangle$, which gives no orbital angular momentum in the excited state. In fact no remarkable A-type MCD could be observed at the 17.0 kK band. A reverse A-type dispersion observed at 27.5 kK may be assigned as arising from a transition mainly consisting of $|\mp 3b\rangle \leftarrow |0\rangle$. However spectral intensity of the transition $|\mp 3b\rangle \leftarrow |0\rangle$ is formally zero based on an assumption of the accidental degeneracy of a_{2u} and a_{1u} orbitals. From the same reason, the visible Q bands, $|\pm 9\rangle \leftarrow |0\rangle$, are formally prohibited. As shown in Figs. 7 and 8, intensity of the visible Q bands is appreciably high, although it is forbidden in character. Since the highest occupied a_{2u} and a_{1u} are not exactly degenerate, a term equal to half their energy difference,

$$(-4|\hat{p}|4) = 1/2[(a_{2u}|\hat{h}^{\text{eff}}|a_{2u}) - (a_{1u}|\hat{h}^{\text{eff}}|a_{1u})] \equiv \varepsilon,$$

connects two wave functions that differ by a single orbital, which is the one is $|+4\rangle$ and in the other $|-4\rangle$. This carries an spectral intensity from the allowed transition pair $|\pm 1\rangle \leftarrow |0\rangle$ to the forbidden transition apir $|\pm 9\rangle \leftarrow |0\rangle$. To reproduce the transition energies and the ratio of Q and B bands of TPPCo(II), we redetermined

$$\Delta = 14810\ cm^{-1},\ K = 2530\ cm^{-1},\ K_1 = 4600\ cm^{-1}$$
and $\varepsilon = \pm 1480\ cm^{-1}$.

As was pointed out by Gouterman on the empirical basis, the a_{1u} orbital is slightly higher than the a_{2u} orbital which is reverse to the ordering predicted by the conventional molecular orbital calculations.[26a]

From these parameters with $\Delta_{CT} = 4{,}000\ cm^{-1}$ and $\beta = -4{,}000\ cm^{-1}$, we can well reproduce the excited states of $[TPPCo(I)]^-$ as shown in Fig. 12. To get a better fit of the spectral intensity of Q and B bands,

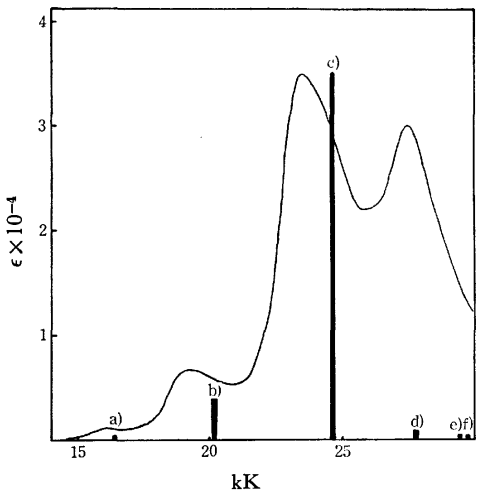

Fig. 12. Absorption spectrum of $[Co(I)TPP]^-$.
Curve: observed spectrum Vertical lines: calculated spectrum
a): $(|+4\rangle+|-4\rangle)/\sqrt{2} \leftarrow |0\rangle$, b): $|\pm 9\rangle \leftarrow |0\rangle$,
c): $|\pm 1\rangle \leftarrow |0\rangle$, d): $|\pm 13\rangle \leftarrow |0\rangle$, e): $|\mp 3b\rangle \leftarrow |0\rangle$,
f): $|\pm 15\rangle \leftarrow |0\rangle$

the parameters for $[TPPCo(I)]^-$ may be replaced by $\Delta = 14310\ cm^{-1}$ and $\varepsilon = \pm 2560\ cm^{-1}$. However the theory could not get an intensity of the band at 27.5 kK, although it could predict a reverse A-type dispersion. The (π, π^*) excited states of porphin in the ultraviolet region can not be well described without being mixed with higher energy configurations. In this context, a self-consistent molecular orbital calculation including cobalt electrons will be reported elsewhere. In a recent paper, Gouterman and his coworkers obtained $(\pm 4|\hat{\mu}_z|\pm 4) = \mp 2.27\ \beta$ and $(\pm 5|\hat{\mu}_z|\pm 5) = \mp 2.09\ \beta$ by a molecular orbital calculation.[30] If this is the case, some D_{4h} porphin should show a reverse A-type dispersion at the Soret band.[31] The circular box model predicts

$$(\pm 4|\hat{\mu}_z|\pm 4) = -\beta/\hbar(\pm 4|\hat{l}_z|\pm 4) = \mp 4\beta$$

and

$$(\pm 5|\hat{\mu}_z|\pm 5) = -\beta/\hbar(\pm 5|\hat{l}_z|\pm 5) = \mp 5\beta.$$

In a more exact treatment such as molecular orbital calculations based on a linear combination of atomic orbitals, these values are reduced. However magnetic circular dichroism of the cobalt porphin in the oxidation states, (I), (II), and (III), presented in this paper does not show any reverse A-type dispersion at B band. This indicates that $|(\pm 5|\hat{\mu}_z|\pm 5)| > |(\pm 4|\hat{\mu}_z|\pm 4)|$ even if it is treated with extensive configuration interactions.

Absorption spectrum and also magnetic circular dichroism spectrum of the cobalt(I) porphin were reproduced taking back-donation effect of the cobalt $d\pi$ electrons to porphin. To get the best fit, we assumed $\Delta_{CT} = 4000\ cm^{-1}$. However the experimental energy levels of $[TPPCo(I)]^-$ are qualitatively reproduced for $2000\ cm^{-1} < \Delta_{CT} < 8000\ cm^{-1}$. Such a positive charge-transfer energy, even if it is small, indicates an energy necessary to carry an electron from the cobalt to the porphin. Since an electron furnished by the reducing reagent is being trapped in d_{z^2} orbital of the central cobalt, a back-donation tendency of the cobalt $d\pi$ electrons to the porphin antibonding π orbital is sufficiently enhanced. The calculation predicts a transfer of the net charge 0.38 e from the cobalt $d\pi$ orbitals. Felton and Linschitz have made measurements of polarographic halfwave potentials on a number of TPP complexes in dimethyl sulfoxide.[32] A gap between the first and second waves is almost constant for various systems except Co(II). Halfwave potential of the first step reduction of TPPCo(II) is appreciably lower than those of the other complexes, whereas that of the second step is rather close to those of the others. The second step reduction is assigned to an electron trapping in the porphin conjugated system, while the first step is an electron trapping in the central cobalt ion which arises from a higher electron affinity of the cobalt(II) ion in a strong planar ligand field. On the contrary, however, TPP metal free base and the metal complexes of divalent ion such as Mg(II), Ni(II), Cu(II), or Zn(II) capture an electron into the porphin conjugated system during the first step reduction process. This trend has been reproduced by an extended Hückel molecular orbital calculation.[24]

We should like to express our appreciation to Dr. M. Uyemura of the Research Laboratory of Resources Utilization, Tokyo Institute of Technology, for numerical calculation. One of the authors (H. K.) should appreciate Professor S. Nagakura and Dr. I. Hanazaki and also Professor M. Gouterman for helpful discussions. This work was supported by a grant from the Ministry of Education.

31) Molecular constant A of the A-term magnetic circular dichroism at the porphin degenerate transition $|j\rangle \leftarrow |0\rangle$ is defined as follows,

$$A = 3\sum_j \langle j|\mu_z|j\rangle \cdot Im\{\langle 0|\hat{m}_x|j\rangle\langle j|\hat{m}_y|0\rangle\},$$

where $\hat{\mu}$ and $\hat{m}$ are the magnetic and electric dipole operators, respectively, $\langle j|\hat{\mu}_z|j\rangle = -\beta/\hbar\langle j|\hat{l}_z|j\rangle$. Magnetic circular dichroism spectrum shows a normal dispersion when $A/D<0$, where $D=3\sum_j\{|\langle 0|\hat{m}_x|j\rangle|^2+|\langle 0|\hat{m}_y|j\rangle|^2\}$. For $A/D>0$, the spectrum shows an anomalous dispersion. "A-type dispersion" in this paper denotes the normal dispersion ($A/D<0$), whereas "reverse A-type dispersion", the anomalous dispersion ($A/D>0$).

Electronic Absorption Spectra of Tris(2,2′-bipyridine)- and Tris(1,10-phenanthroline) Complexes of Vanadium(II) and Chromium(II)

Ichiro FUJITA, Takanori YAZAKI, Yasuo TORII,* and Hiroshi KOBAYASHI
Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo
(Received November 11, 1971)

Electronic absorption spectra of tris(2,2′-bipyridine) complexes of vanadium(II) and chromium(II) were measured. When methyl groups are introduced into the coordinating bipyridine, (d, d^*) transitions in the central metal, (π, π^*) transitions in the coordinating ligand, and "metal to ligand" charge-transfer transitions show their respective characteristic shifts. Thus the visible and near-infrared bands of tris(2,2′-bipyridine) complexes of vanadium(II) and chromium(II) are assigned to "metal to ligand" charge-transfer transitions as well as the visible bands of tris(2,2′-bipyridine)iron(II). A comparison between the corresponding bands of tris(2,2′-bipyridine) complexes and tris(1,10-phenathroline) complexes also verifies the assignment.

Transition metal complexes of 2,2′-bipyridine, 1,10-phenanthroline and their derivatives are one of the best studied group of metal complexes.[1] The complexes of a divalent cation of the first transition-metals such as manganese(II), cobalt(II), nickel(II), copper(II), or zinc(II) give rise to feeble colors in the solid state and in solutions.[2-6] Formation of the tris complexes of divalent iron, however, gives intense red coloration which permits an effective amplification of iron signal in the colorimetry.[7] The electronic absorption spectra of the divalent complexes have been established on the basis of considerable experimental and theoretical work. Strong absorption bands in the ultraviolet region are assigend to (π, π^*) transitions of the coordinating ligands.[2-6,8,9] The absorption bands of the coordinating ligand are slightly shifted in position and also changed in intensityf or a possible conformational change upon chelation and for inductive and/or mesomeric perturbation by the central metal ion. The feebly colored complexes of manganese(II), cobalt(II), nickel(II), or copper(II) show weak absorption bands arising from (d, d^*) transitions in the visible and near-infrared regions.[2-6] On the other hand, the deeply colored iron complexes show intense absorption bands in the visible region. The intense absorption bands are assigned to "metal to ligand" charge-transfer transitions. An electron in a molecular orbital primarily localized on a $d\pi$ orbital of the central iron is promoted to one of the antibonding π molecular orbitals distributed over the coordinating ligands.[9,10] Similar visible bands observed in the corresponding ruthenium(II) complexes were also assigned to "metal to ligand" charge-transfer transitions.[6,11]

Tris(bipyridine)- and tris(phenanthroline) complexes of divalent vanadium and chromium are known to be deeply colored. Some of their intense absorption bands were observed in the visible and near-infrared region.[12] The observed absorption bands were as intense as those of the iron(II) complexes. So far, however, assignment of the electronic absorption spectra of these complexes has never been established on the basis of sufficient experimental evidences. In this paper, we present the electronic absorption spectra of tris(2,2′-bipyridine), tris(4,4′-dimethyl-2,2′-bipyridine) and tris(5,5′-dimethyl-2,2′-bipyridine), and also tris(1,10-phenanthroline) complexes of vanadium(II) and chromium(II). On the basis of the observed evidences, the visible and near-infrared bands of the vanadium(II) and chromium(II) complexes will be assigned to "metal to ligand" charge-transfer transitions.

Experimental

Materials. By means of Sasse's method, 2,2′-bipyridine and its 4,4′-dimethyl- and 5,5′-dimethyl derivatives were prepared (Fig. 1).[13,14] Commercially available 1,10-phenanthroline of analytical reagent grade made by Tokyo Kasei Co., Ltd. was used without further purification. 2,2′-Bipyridine and its 4,4′-dimethyl- and 5,5′-dimethyl derivatives and 1,10-phenanthroline are abbreviated to bipy, 4dmbip, 5dmbip, and phen, respectively.

Tris(2,2′-bipyridine)vanadium(II), -chromium(II), -iron(II), and -nickel(II) perchlorates, and tris(1,10-phenanthroline)chromium(II), -iron(II), and -nickel(II) perchlorates were prepared by the methods given in the literature.[15-20]

Since vanadium(II) and chromium(II) ions are very sensitive to oxygen in the air, all the preparations were carried out in an oxygen-free dry nitrogen atmosphere. The

solvent used for the preparation should be thoroughly freed from oxygen.

Tris(4,4′-dimethyl-2,2′-bipyridine)vanadium(II) diperchlorate, $[V(4dmbip)_3](ClO_4)_2$. One gram of 4,4′-dimethyl-2,2′-bipyridine was dissolved in a mixture of 25 m*l* of methanol, 3 m*l* of 2N hydrochloric acid and 50 m*l* of water. To this solution was added 2 m*l* of 1M solution of vanadium(II) sulfate prepared by electrolytic reduction of oxovanadium(IV) sulfate.[22] When the complex was formed, the solution turned dark blue-green. It was stirred for several hours, and then mixed with a solution of 0.5 g of ammonium perchlorate in 20 m*l* of water. After standing for 3 hr, dark blue-green crystals were collected by filtration, washed twice with water and once with methanol, and dried over calcium chloride *in vacuo*.

Found: V, 6.1%. Calcd for $[V(4dmbip)_3](ClO_4)_2$: V, 6.35%.

Tris(5,5′-dimethyl-2,2′-bipyridine)vanadium(II) diperchlorate, $[V(5dmbip)_3](ClO_4)_2$. In a mixture of 25 m*l* of methanol and 20 m*l* of water, 2.7 g of 5,5′-dimethyl-2,2′-bipyridine was dissolved and then 6.0 m*l* of 1M solution of vanadium(II) sulfate was added. The solution turned dark blue-green. After it was stirred for several hours, a solution of 1.5 g of ammonium perchlorate in 15 m*l* of water was added to the colored solution. After standing for 24 hr, the dark blue-green precipitate was collected by filtration, washed with water and dried over calcium chloride *in vacuo*.

Found: V, 6.0%. Calcd for $[V(5dmbip)_3](ClO_4)_2$: V, 6.35%.

Tris(1,10-phenanthroline)vanadium(II) diperchlorate, $[V(phen)_3](ClO_4)_2$. 0.6 g of vanadium(II) sulfate hydrate was dissolved in 50 m*l* of water, and then 1.3 g of 1,10-phenanthroline previously dissolved in a small amount of methanol was added.[22] The solution turned dark blue. After it was stirred for several hours, the solution was added a mixture of 0.5 g sodium perchlorate hydrate and 0.3 m*l* of 70% perchloric acid in a small amount of water. The dark blue fine crystal thus formed was collected, washed several times with water and dried *in vacuo*.

Found: V, 6.4%. Calcd for $[V(phen)_3](ClO_4)_2$: V, 6.46%.

Tris(4,4′-dimethyl-2,2′-bipyridine) chromium(II) diperchlorate, $[Cr(4dmbip)_3](ClO_4)_2$. 0.5 g of chromium(II) acetate was dissolved in a mixture of 1.0 m*l* of 6N hydrochloric acid and 50 m*l* of water. To this was added 1.2 g of 4,4′-dimethyl-2,2′-bipyridine dissolved in a mixture of 0.1 m*l* of 6N hydrochloric acid and 100 m*l* of water. The dark brown solution was then thoroughly stirred, and to this was added 1 g of sodium perchlorate dissolved in a small amount of water. Black precipitate thus obtained was collected by filtration, washed several times with water and dried *in vacuo*.

Found: Cr, 6.3%. Calcd for $[Cr(4dmbip)_3](ClO_4)_2$: Cr, 6.47%.

Tris(5,5′-dimethyl-2,2′-bipyridine)chromium(II) diperchlorate, $[Cr(5dmbip)_3](ClO_4)_2$. The procedure was the same as that for tris(4,4′-dimethyl-2,2′-bipyridine)chromium(II) diperchlorate.

Found: Cr, 6.3%. Calcd for $[Cr(5dmbip)_3](ClO_4)_2$: Cr, 6.47%.

Measurements of Electronic Absorption Spectra. Electronic absorption spectra were taken on a Beckman spectrophotometer Model DU and a Shimadzu automatic recording spectrophotometer Model MPS-50. Quartz cuvettes of 1 and 10 mm optical path were used. Cylindrical cells of 100 mm path with quartz windows were used for measurements of weak (*d*, *d**) bands.

Since the vanadium(II) and chromium(II) complexes in the solid state are fairly stable against oxidation, the samples were weighed in the usual way in a dried atmosphere. The sample thus weighed was sealed in a vessel with a branch attached to an optical cuvette previously saturated with dry nitrogen. The vessel was connected through a ground joint to a vacuum line and evacuated. The procedure was carried out as quickly as possible.

Methanol was used as a solvent. The methanol was thoroughly degassed by successive freeze-thaw pumping cycles and transferred by distillation into the vessel. After the vessel was sealed off from the vacuum line, the sample was allowed to dissolve in methanol. Both procedure and apparatus were described in detail in a previous paper.[23]

Results and Discussion

Electronic absorption spectra of vanadium(II), chromium(II), iron(II), and nickel(II) complexes of 2,2′-bipyridine and its 4,4′-dimethyl- and 5,5′-dimethyl derivatives and of 1,10-phenanthroline are shown in Figs. 2—6.

Two intense absorption bands were observed in the ultraviolet region. They are assigned to (π, π^*) transitions within the molecular orbitals of the coordinating ligand. The lowest transitions of free bipyri-

dine which are assigned to (π, π^*) transitions are shifted by such a weak perturbation as methyl substitutions (Fig. 7). The lowest wave number band of the bipyridine is shifted to higher wave number in the order 5dmbip < bipy < 4dmbip. The ordering is preserved in the lowest (π, π^*) transition of the coordinating bipyridines. A conformational change of two pyridine rings in bipyridine on the chelate formation is expected to change the (π, π^*) transition. However, such an effect, at least to the lowest excited states, was estimated to be negligibly small by theoretical calculation. The lowest (π, π^*) transition of the bipyridines coordinating to Mn(II), Fe(II), Co(II), Ni(II), Cu(II), and Zn(II) was observed around 33000 cm^{-1}, whereas the corresponding band of free bipyridine was observed at 35000 cm^{-1}. This shift might be attributed to a spectral shift arising from an excitation coupling between three bipyridines in a tris complex. However, the exciton interaction predicts another direction of the spectral shift. The coordinat-

------: 5,5′-dimethyl-2,2′-bipyridine

ing bipyridine is polarized partially by an electrostatic interaction due to the residual positive charge on the central metal ion and partially by σ donation of the coordinating nitrogens. Such a polarization, however, gives rise to a slight red-shift. The lowest wave number band is shifted to lower wave number in the order Fe(II) $<$ Mn(II) $\sim$ Zn(II) $<$ Co(II) $\sim$ Ni(II) $<$ Cu(II). Although the observed shift is within several hundred wave numbers, it is almost parallel to the natural order of complex stability except for Fe(II).[24]

Since iron(II) in the diamagnetic state is highly π-donating, π electronic system of the bipyridine coordinating to the iron can not be described in terms of a simple electronic polarization as in the complexes of less π-donating metal ions such as Mn(II), Co(II), Ni(II), Cu(II), and Zn(II). The vanadium(II) and chromium(II) complexes show absorption bands corresponding to those of the coordinating bipyridine at almost the same position as in the iron(II) complexes. Since V(II), Cr(II) as well as Fe(II) are less π electron-attractive, the coordinating ligand should accept migration of π electron into the vacant molecular orbitals. The lowest excited states of the coordinating bipyridine in such a complex should be described in terms of a configuration admixture of "metal to ligand" charge-transfer excited states and coupled (π, π^*) excited states of three coordinating bipyridines.

When such a high π-donating power is attained as in V(II), Cr(II), or Fe(II), some "metal to ligand" charge-transfer excited states should be lower than (π, π^*) excited states. These charge-transfer transitions, however, should be very weak unless they can borrow their intensities from the allowed (π, π^*) transitions by a mixing due to the configuration interaction mentioned above. In fact, the vanadium(II) and chromium(II) complexes give rise to a series of superposing intense and diffuse absorption bands over the visible and near-infrared region (Figs. 2—3). These bands are assigned to charge-transfer transitions as well as those observed in the iron(II) complexes (Fig. 4). The fact that the charge-transfer transitions were observed indicates that mixing due to the configuration interaction takes place. The vanadium(II) complexes show a remarkable extra shoulder at 31600 cm^{-1} besides the corresponding band of the iron(II) complexes, while the chromium(II) complexes show a rather diffuse composite system of bands. In the case of the open-shell ions such as V(II) and Cr(II), not only singlet-singlet (π, π^*) excited states but also singlet-triplet (π, π^*) excited states can appreciably participate in the lowest excited states of the coordinating bipyridine.

As is shown in Fig. 2, the visible absorption spectrum of the vanadium(II) complexes indicates a characteristic of the allowed transition very similar both in shape and intensity to that of the iron(II) complexes except for the position which is shifted by about 4000 cm^{-1} to lower wave number. The visible absorption spectrum of the chromium complexes is rather complicated, but also shows a characteristic of the allowed transition as well (Fig. 3). The lowest wave number bands at *ca.* 20000 cm^{-1} of the iron(II) complexes are charge-transfer bands and are shifted to the higher wave number upon methyl substitutions in the order 4dmbip $<$ bipy $<$ 5dmbip. The ordering is the reverse of that observed in the lowest (π, π^*) transitions of the coordinating bipyridine. The band at 16000 cm^{-1} of the vanadium(II) complexes and that at 8500 cm^{-1} of the chromium(II) complexes show a similar spectral shift as observed in the charge-transfer band at 20000 cm^{-1} of the iron complexes. On the other hand, the band at 25000 cm^{-1} of the vanadium(II) complexes, that at 28000 cm^{-1} of the iron(II) complexes and that at 18000 cm^{-1} of the chromium(II) complexes are observed in the order 4dmbip $<$ 5dmbip $<$ bipy. This does not coincide with the ordering observed for either the lowest wave number charge-transfer transition or for the lowest (π, π^*) transition. The bands are assigned to charge-transfer transitions from a $d\pi$ orbital to a second antibonding π molecular orbital of the ligand. The band at 21500 cm^{-1} of the chromium complexes, however, contrary to the band at 18000 cm^{-1} shows a similar behavior upon methyl substitutions to that observed for the band at 8500 cm^{-1}. The molecular orbitals involved in both transitions are very similar.

Nickel(II) complexes give rise to two weak (d, d^*) bands of Laporte forbidden character in the visible region (Fig. 5). When the coordinating bipyridine is introduced methyl groups, "metal to ligand" charge-transfer bands in the vanadium(II), chromium(II), and iron(II) complexes are shifted, but not much the (d, d^*) transitions in the nickel(II) complexes. Energy of the first (d, d^*) transition, $^3T_2 \rightarrow {}^3A_2$, of an octahedral nickel(II) complex corresponds to the ligand-field splitting parameter, 10 Dq.[25] The fact that no shifts of the first band of the nickel(II) complexes were observed upon methyl substitutions indicates that σ donation of the ligand, hence the ligand-field splitting of the d orbitals, is not influenced by such a weak perturbation as introduced by methyl substitutions. This must be true in the (d, d^*) transitions of other metal ions.

The spectral shifts arising from dimethyl substitutions of tris(bipyridine) complexes are summarized in Fig. 8.

The coordinating phenanthroline gives rise to (π, π^*) transitions in the ultraviolet region. Absorption spectrum of the coordinating ligand preserves the band shape of free ligand and is slightly shifted to lower wave number in the order Fe(II) $<$ V(II) $<$ Cr(II) (Fig. 6).

The visible absorption bands of $[Fe(phen)_2]^{2+}$ are assigned to "metal to ligand" charge-transfer transitions as well as the visible bands of $[Fe(bipy)_3]^{2+}$.[26] The band at 16000 cm^{-1} of $[V(phen)_3]^{2+}$ corresponds to that at almost the same position as $[V(bipy)_3]^{2+}$. As was observed in $[Cr(bipy)_3]^{2+}$, the visible and near-infrared spectrum of $[Cr(phen)_3]^{2+}$ is much more complicated than those of $[V(phen)_3]^{2+}$ and $[Fe(phen)_3]^{2+}$. However, a similar spectral corre-

4: 4dmbip; b: bipy; 5: 5dmbip

spondence is observed between $[V(phen)_3]^{2+}$ and $[V(bipy)_3]^{2+}$, and also $[Cr(phen)_3]^{2+}$ and $[Cr(bipy)_3]^{2+}$. The absorption spectra of $[V(phen)_3]^{2+}$ and $[Cr(phen)_3]^{2+}$ in the visible and near-infrared region are assigned to "metal to ligand" charge-transfer transitions.

Transition energy of the lowest charge-transfer excitation should be proportional to a difference of the ionization potential of the metal $d\pi$ orbitals in complex and the electron affinity of the lowest vacant antibonding π orbitals in the coordinating ligand.

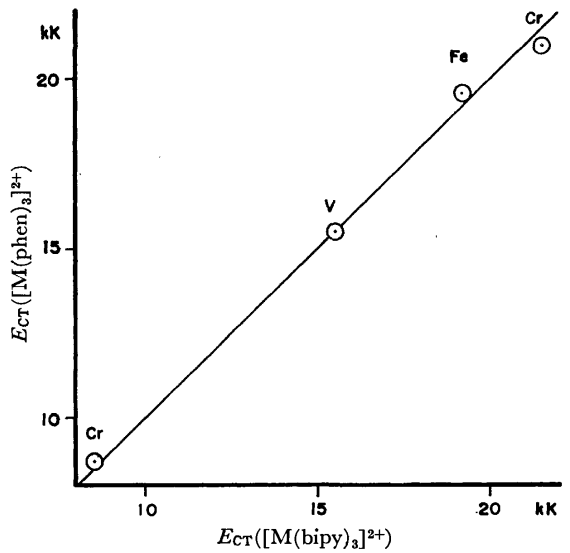

Fig. 9. Plots of the charge-transfer excitation energies of tris(1,10-phenanthroline) complexes, $E_{CT}([M(phen)_3]^{2+})$ *vs.* tris(2,2′-bipyridine) complexes, $E_{CT}([M(bipy)_3]^{2+})$.

Excitation energy of the charge-transfer band of tris(bipyridine) complexes, for example, varies primarily depending upon the $d\pi$ ionization potential of the central metals. Since the same argument holds for tris(phenanthroline) complexes as well, a linear relationship is expected between transition energies of the corresponding charge-transfer bands of tris(bipyridine) complexes and tris(phenanthroline) complexes. In fact, plots of the transition energies show an excellent linearity as seen in Fig. 9. This will very likely verify an assignment of "metal to ligand" charge-transfer transitions to the visible and near-infrared bands observed in the vanadium(II) and chromium(II) complexes.

Figure 9 reveals that the $d\pi$ ionization potential of the central metals is decreased in the order Cr < V < Fe. The ionization potential of M(II) in the ground state was experimentally estimated to be 29.31 eV for V(II), 30.95 eV for Cr(II) and 30.64 eV for Fe(II). When the ionization potential is estimated for the valence state, the values are obtained as follows: 29.5 eV for V(II)$(d\pi)^3$, 28.8 eV for Cr(II)$(d\pi)^4$, and 35.3 eV for Fe(II)$(d\pi)^6$.[27] The observed ordering of π-donating power of the central metals can be reproduced. However, a divalent cation in such a complex must be electroneutralized by σ-donation of the coordinating nitrogens and the values should be corrected for the electroneutrality. The ionization potentials were evaluated for the neutral species with the configuration $d^n s^2$,[28] where s^2 is assumed to be furnished by σ-donation of the coordinating nitrogens. The values thus obtained seem to be a rather realistic approximation and are, in fact, linear to the lowest charge-transfer transition energy of the respective complexes.

	$d\pi$ ionization potential	$E_{CT}([M(bipy)_3]^{2+})$	$E_{CT}([M(phen)_3]^{2+})$
$V(II)\sigma^2(d\pi)^3s^2$	11.27 eV	1.92 eV	1.93 eV
$Cr(II)\sigma^2(d\pi)^4s^2$	10.25 eV	1.05 eV	1.06 eV
$Fe(II)\sigma^2(d\pi)^6s^2$	12.61 eV	2.38 eV	2.43 eV

In the case of Cr(II), however, there are two types of the lowest $d\pi$ ionization as follows:

$$\text{I}\quad (d\pi_1)^2(d\pi_2)(d\pi_3) \longrightarrow (d\pi_1)(d\pi_2)(d\pi_3) + e$$

$$\text{II}\quad (d\pi_1)^2(d\pi_2)(d\pi_3) \longrightarrow (\overline{d\pi_1})(d\pi_2)(d\pi_3) + e$$

In the process I an electron with β spin pairing in a $d\pi$ orbital is detached, while in the process II an electron with α spin is transferred. The difference in the inter-electronic electrostatic repulsion energy between the processes I and II is given in terms of Racah's parameters and estimated at 13000—15000 cm^{-1} by the empirical values of the central metal ion. There must be two types of the charge-transfer transition from chromium(II) to the lowest antibonding π orbitals of the coordinating ligands. In fact, as was shown in

27) J. S. Griffith, "The Theory of Transition-Metal Ions," Cambridge University Press, (1961), p. 100.
28) C.E. Moore, "Atomic Energy Levels," Vol. 1 and 2, National Bureau of Standards, Washington (1949, 1952).

Fig. 8, $[Cr(bipy)_3]^{2+}$ gives rise to a charge-transfer band at 21500 cm^{-1}, which shows a similar dimethyl substitution effect to that of the lowest charge-transfer band at 8500 cm^{-1}. The energy difference is 13000 cm^{-1}. For the other ligands, the observed energy differences are 12850 cm^{-1} for 4dmbip, 12800 cm^{-1} for 5dmbip and 12400 cm^{-1} for phen. These values indicate a reduction of Racah's parameters in the complexes due to the delocalization of $d\pi$ electrons over the ligands.

Platinum(II)-Olefin Complexes Containing Amino Acids. III.[1] Optical Inversion and Substitution of Coordinated Olefins in Optically Active *trans(N)*-Chloro-L-prolinato-olefin-platinum(II) Complexes in Organic Solvents

Kazuo KONYA,[2] Junnosuke FUJITA, Hiroaki KIDO, and Kazuo SAITO

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received December 6, 1971)

Optical inversion of coordinated 2-methyl-2-butene and *trans*-2-butene in *trans(N)*-chloro-L-prolinato-olefin-platinum(II),[1] *trans(N)*-[PtCl(L-prol)(olefin)] (nitrogen of L-prolinate ion is *trans* to the olefin), *i.e.* the interconversion between diastereoisomers (Fig. 1), has been kinetically studied in acetone by measuring the decrease in the intensity of circular dichroism (CD) in near ultraviolet region. The rate was measurable only in the presence of olefin, and can be expressed by the relation, Rate=k[complex][olefin]. The E_a and the $\Delta S^{\neq}$ values for the two complexes are 7.8 ± 1.0 and 9.0 ± 1.0 kcal/mol, and -44 and -39 entropy unit, respectively. The coordinated *trans*-2-butene is replaced by other olefins, 2,3-dimethyl-2-butene, 2-methyl-2-butene, *trans*-2-butene (optical inversion), and styrene, under similar conditions to give the same rate formula. The second order rate constant increases in the given order. The inversion seems to take place *via* bimolecular mechanism with excessive olefin as nucleophile. The corresponding complexes containing styrene and its *para* derivatives give such an inversion much faster in the absence of excess of olefin. With change of *para* substituents, the rate increases in the order, methoxy<methyl<hydrogen<chloro<nitro. This seems to be related with their electrondrawing ability.

Kinetics of substitution of coordinated olefins in Zeise type complexes have been studied by several authors. Cramer found that the rate of exchange between free and coordinated ethylene is greater than 70 sec^{-1} at 75°C on the basis of nuclear magnetic resonance spectroscopy.[3] Paiaro and Panunzi examined the mutarotation of diastereoisomers of olefin complexes of platinum(II) and suggested that the exchange takes place through S_N2 Smechanism.[4] Joy and Orchin[5] and Shupack and Orchin[6] measured the equilibrium constants between some platinum(II) complexes of 1-dodecene and various substituted styrenes, and discussed the relative affinity of the olefins toward the platinum(II) ion. Recently, Venanzi and his co-workers studied the formation constants of Zeise type complexes systematically in aqueous solutions containing halo complexes of platinum(II) and various olefins.[7-10]

In previous papers we reported on the preparation and characterization of platinum(II)-olefin complexes containing amino acids,[11] and also on the preparation and circular dichroism (CD) of optically active *trans(N)*-chloro-L-prolinato-olefinplatinum(II), *trans(N)*-[PtCl(L-prol)(olefin)] (nitrogen of L-prolinate ion is *trans* to the olefin).[1] These optically active olefin-platinum(II) complexes seem particularly suitable for the kinetic study of the exchange reaction of coordinated olefins, by following the change in CD spectra, due to the asymmetric coordination of olefins to platinum(II). In this paper we report on the kinetics of optical inversion and substitution of coordinated olefins in such complexes.

The inversion reaction of coordinated olefins, shown in Fig. 1, is an interconversion between (a) and (b) and involves the cleavage of both the so-called σ- and

(a) (b)

Fig. 1. Enantiomeric coordination of an olefin ligand, *e.g.* *trans*-2-butene.

π-bond between the metal ion and the olefin.

The complexes of such olefins as 2-methyl-2-butene and *trans*-2-butene show no change in absorption and CD spectra in the absence of free olefin in organic solvents such as ethanol, chloroform, and acetone. When the same kind of olefin as in the complex is added, the CD spectrum changes with time and approaches a constant pattern, but the ultraviolet absorption spectrum remains unchanged. This fact indicates that only inversion reaction of the coordinated olefin takes place without involving any other reaction. When another kind of olefin is added to the solution, both ultraviolet absorption and CD spectrum change with time. The absorption pattern of the final solution suggests that an exchange of the coordinated olefin takes place with the added olefins. We have followed the change in peak height of CD spectra in near ultraviolet region of optically active $(+)^{\Delta\varepsilon}_{380}$-*trans*(*N*)-[PtCl(L-prol)(*trans*-2-butene)] and $(+)^{\Delta\varepsilon}_{380}$-*trans*(*N*)-[PtCl(L-prol)(2-methyl-2-butene)] on the addition of various olefins, and found that the rate depends on the kind of added olefin. The reaction mechanism has been discussed on the basis of the rate constants and other kinetic parameters.

The corresponding complexes containing styrene and its derivatives *trans*(*N*)-[PtCl(L-prol)(styrene)], on the other hand, show a significant change in ultraviolet absorption and CD spectrum in the absence of free olefin in organic solvents. The change is fast even at 0°C. The rate has been qualitatively examined at temperatures 0—15°C, and the influence of the substituting groups on styrene is discussed.

Results and Discussion

Optical Inversion of Coordinated Olefins in Optically Active $(+)^{\Delta\varepsilon}_{380}$-trans(N)-[*PtCl(L-prol)(2-methyl-2-butene)*] *and* $(+)^{\Delta\varepsilon}_{380}$-trans(N)-[*PtCl(L-prol)*(trans-*2-butene)*].

The inversion reaction of olefins in both complexes was studied in acetone. Decrease in the peak height of the CD spectrum was measured on addition of the same olefin as the ligand. No change in the absorption spectrum was observed. Only the inversion reaction of coordinated olefins seemed to take place in the solution. No stereoselective coordination of the olefins was observed, when 2-methyl-2-butene and *trans*-2-butene were added to the *trans*(*N*)-[PtCl(L-prol)-(ethylene)]. Thus, we can presume that neither stereoselective reaction would take place on the addition of these olefins to the solution of their complexes.

The change in CD peak height ($\Delta\varepsilon$) at 380 nm with time, when 2-methyl-2-butene (0.50M) is added to $(+)^{\Delta\varepsilon}_{380}$-*trans*(*N*)-[PtCl(L-prol)(2-methyl-2-butene)]

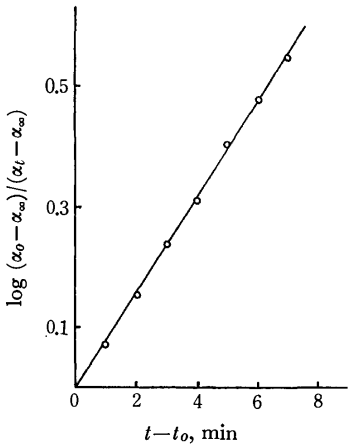

Fig. 2. CD change at 380 nm of *trans*(*N*)-[PtCl(L-prol)(2-methyl-2-butene)] with time in acetone. (23.6±0.3°C, complex (2×10^{-3}M), 2-methyl-2-butene (0.5M)).

(0.0020M) in acetone, is shown in Fig. 2. The rate of change in CD follows the first order rate law, and the apparent rate constant is given by

$$k_{obs}=\ln[(\alpha_0-\alpha_\infty)/(\alpha_t-\alpha_\infty)]/(t-t_0) \quad (1)$$

where α_o, α_t, and α_∞ denote the $\Delta\varepsilon$ values at time t_o, t, and infinite time, respectively. k_{obs} is related to the rate constant of inversion reaction, k_{inv}, by the relation $k_{obs}=2k_{inv}$. However, the k_{obs} values are used in the following discussion for a comparison with the rate constants of substitution reactions.

The relationship between k_{obs} and the amount of added 2-methyl-2-butene at three temperatures is shown in Fig. 3, the concentration of the complex being kept constant at 1.9×10^{-3}M. In a given con-

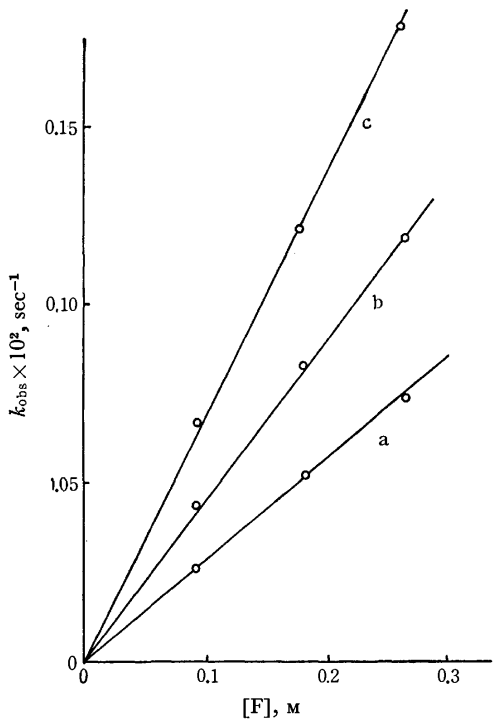

Fig. 3. Relationship between k_{obs} and the concentration of added 2-methyl-2-butene. (*trans*(*N*)-[PtCl(L-prol)(2-methyl-2-butene)] (1.90×10^{-3}M)). a, 3.7±0.3°C; b, 13.2±0.3°C; c, 21.6±0.3°C.

centration range, k_{obs} is proportional to the amount of added olefin. The lines showing the proportionality pass the origin. This coincides with the observation that the CD spectrum does not change in the absence of excessive olefin. Thus the apparent rate is given by

$$\text{Rate} = k_{obs}[\text{complex}] = k[\text{F}][\text{complex}] \quad (2)$$

where [F] is the concentration of added olefin.

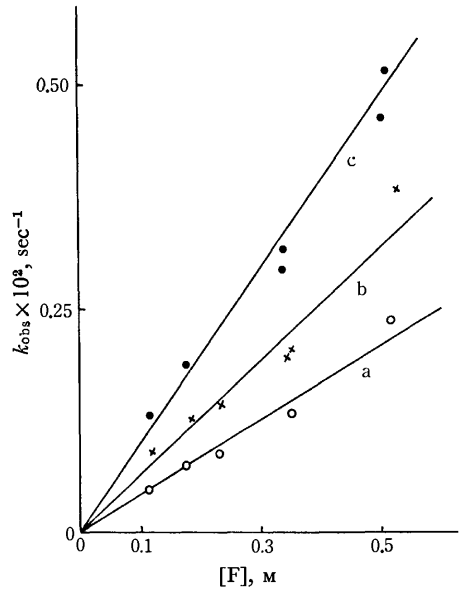

Fig. 4. Relationship between k_{obs} and the concentration of added *trans*-2-butene. (*trans*(*N*)-[PtCl(L-prol)(*trans*-2-butene)] (1.50×10^{-3}M)). a, 8.1±0.3°C; b, 17.0±0.3°C; c, 23.6±0.3°C.

The CD strength of the corresponding *trans*-2-butene complex also decreases in a similar way. In the relationship between k_{obs} and the amount of added *trans*-2-butene complex shown in Fig. 4, the fluctuation in individual plots is slightly greater than that in Fig. 3. This is due to the inaccuracies involved on the addition of the olefin to the sample solution, since *trans*-2-butene is a gas at room temperature (bp +0.88°C).

The Arrhenius plots of the results for the two complexes are given in Fig. 5, and the kinetic parameters summarized in Table 1.

In general, substitution reactions of square planar complexes obey the formula

$$\text{Rate} = -\text{d[substrate]}/\text{d}t = [\text{substrate}](k_1 + k_2[\text{Y}]) \quad (3)$$

where [Y] stands for the concentration of the nucleophile substituting for the ligand. The k_1 and k_2 term represent the solvent path and the reagent path, respectively. Both paths are believed to proceed *via*

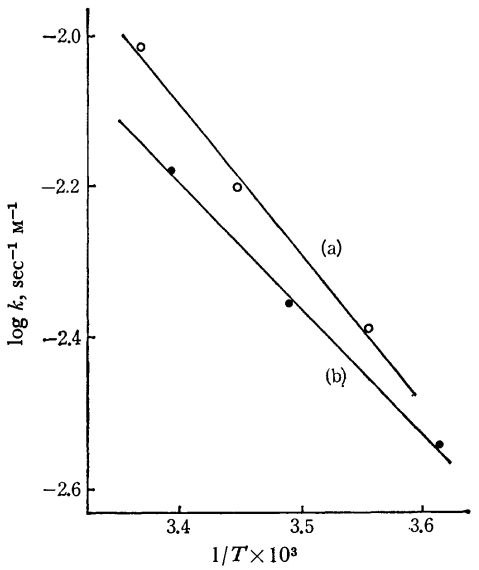

Fig. 5. Arrhenius plots for the interconversion reaction of *trans*-2-butene(a) and 2-methyl-2-butene(b) complex.

S_N2 reaction mechanism. Our rate formula (Eq. (2)) corresponds to Eq. 3 where k_1 is equal to zero.

The small E_a and the big absolute value of ΔS^* given in Table 1 indicate that the inversion of coordinated olefins would take place through S_N 2reaction mechanism. A probable intermediate state is shown in Fig. 6. Since proline has a large pyrolidine ring, the olefin could approach the complex only from one side of the complex plane. The very big negative values of ΔS^* seem to reflect this limited possibility in the formation of the intermediate state with coordination number five.

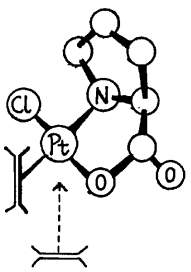

Fig. 6. Probable intermediate state.

Negligible contribution of the solvent path to the inversion reaction could be understood by considering the fact that acetone is a very weak nucleophile towards platinum(II).[12]

Substitution Reaction of Optically Active $(+)^{Ae}_{360}$-trans(N)-[*PtCl(L-prol)(*trans-*2-butene)*]. In order to examine the steric effect of the nucleophile, we have examined

Table 1. Activation parameters for the inversion reaction of olefins in *trans*(*N*)-[PtCl(L-prol)(2-methyl-2butene)] and *trans*(*N*)-[PtCl(L-prol)(*trans*-2-butene)] in acetone

Complex	T, °C	$k \times 10^3$(sec^{-1}M^{-1})	E_a,kcal/mol	ΔS^*, e.u.
trans(*N*)-[PtCl(L-prol)(2-methyl-2-butene)]	13.2	4.44±0.02	7.8	−44
trans(*N*)-[PtCl(L-prol)(*trans*-2-butene)]	17.0	6.3 ±0.1	9.0	−39

12) R. G. Pearson, H. B. Gray, and F. Basolo, *J. Amer. Chem. Soc.*, **82**, 787 (1960).

the replacement of coordinated *trans*-2-butene in $(+)^{\Delta\varepsilon}_{380}$-*trans*(*N*)-[PtCl(L-prol)(*trans*-2-butene)] by various olefins including styrene, 2-methyl-2-butene, and 2,3-dimethyl-2-butene. Although the reaction products were not isolated crystalline, change in absorption spectra indicated that substitution reaction took place as follows.

$$trans(N)\text{-}[PtCl(L\text{-}prol)(trans\text{-}2\text{-}butene)] + \text{olefin} \rightleftharpoons trans(N)\text{-}[PtCl(L\text{-}prol)(\text{olefin})] + trans\text{-}2\text{-}butene \quad (4)$$

The substitution reactions were best followed by measuring the change in CD, since it is much more marked than the change in absorption spectra on the substitution reaction.

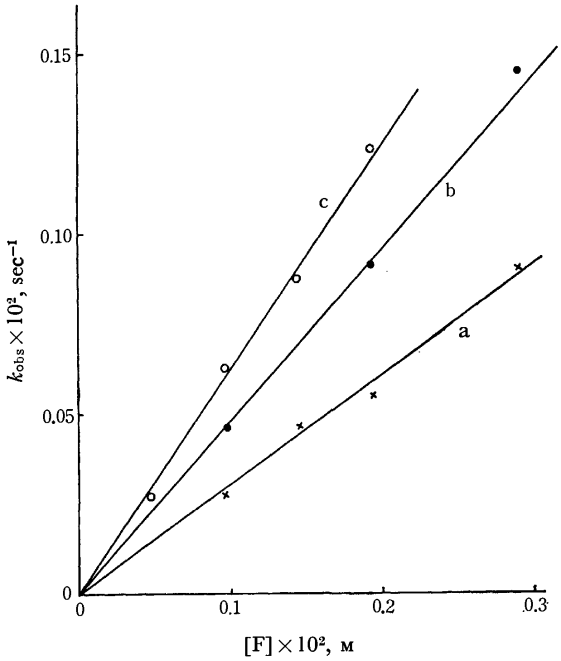

Fig. 7. Relationship between k_{obs} and the concentration of added styrene. (*trans*(*N*)-[PtCl(L-prol)(*trans*-2-butene)] (1.50×10^{-3}M)). a, 8.1±0.3°C; b, 17.0±0.3°C; c, 23.6±0.3°C.

All the reactions obeyed the second order rate expression with regard to both the concentration of the complex and that of added olefin (Eq. (2)). The relationship between the k_{obs} and the concentration of styrene at three temperatures is shown in Fig. 7. 2-Methyl-2-butene and 2,3-dimethyl-2-butene give similar diagrams on the substitution reaction. All the straight lines have zero intercepts. The rate constants and the activation parameters are given in Table 2.

The rate constants increase in the order 2,3-dimethyl-2-butene < 2-methyl-2-butene < *trans*-2-butene(optical inversion) < styrene.

We also see that the activation energies are almost equal to one another in the given substitution reactions, and the order of increase in the rate constant is the same as the order of decrease in $-\Delta S^*$ values. The order of increase in nucleophilicity of the olefins seems to be the reverse of that for the increase in the rate constant, since methyl is more electron pushing than phenyl, and the increase in number of methyl group will certainly result in the increase in electron density on the C=C bond of the olefins. Thus, a steric effect seems to be more responsible for determining the rate of the substitution reaction of such prolinato olefin complexes. A decrease in the number of substituting groups on the carbon atoms of C=C double bond would make it easier for the olefin to approach the complex as shown in Fig. 6.

Observation on the Change in CD of trans*(*N*)-*L*-Prolinatoplatinum(II) Complexes Containing Styrene and Its Derivatives.* The CD strength of the optically active complexes *trans*(*N*)-[PtCl(L-prol)(*p*-X-styrene)] (X=methoxy, methyl, chloro, nitro, and hydrogen) decreases with time in acetone, and becomes constant within 5 to 10 min at room temperature in the absence of excessive styrenes as shown in Fig. 8. The rate increases with the progress of reaction. The absorp-

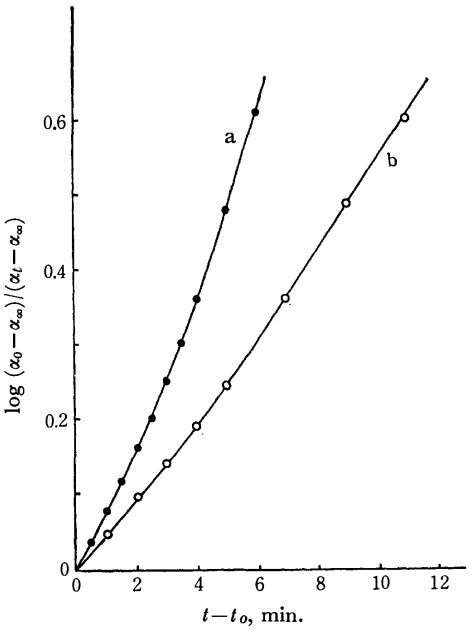

Fig. 8. CD change at 380 nm with time of *trans*(*N*)-[PtCl(L-prol)(styrene)] (1.326×10^{-3}M)(a) and *trans*(*N*)-[PtCl(L-prol)(*p*-methoxystyrene)] (1.455×10^{-3}M) (b) in acetone. (17.1±0.3°C).

Table 3. Results of microanalysis

	C(%) Found	C(%) Calcd	H(%) Found	H(%) Calcd	N(%) Found	N(%) Calcd
trans(*N*)-[PtCl(L-prol)(*p*-methoxystyrene)]	35.02	35.19	3.85	3.59	2.98	2.93
trans(*N*)-[PtCl(L-prol)(*p*-methylstyrene)]	35.96	36.41	3.92	3.71	2.95	3.03
trans(*N*)-[PtCl(L-prol)(*p*-chlorostyrene)]	32.67	32.37	3.22	2.93	2.81	2.90
trans(*N*)-[PtCl(L-prol)(*p*-ntrostyrene)]	31.56	31.68	3.07	2.87	5.51	5.68

tion spectra of these complexes change simultaneously and seem to approach a constant pattern in a few hours at room temperature. Thus the following solvolytic equilibrium might be involved.

$$\textit{trans}(N)\text{-[PtCl(L-prol)}(p\text{-X-styrene)}] + \text{solvent} \rightleftharpoons \textit{trans}(N)\text{-[PtCl(L-prol)(solvent)]} + p\text{-X-styrene} \quad (5)$$

The decrease in CD strength can be presumed to proceed *via* two routes, the solvent path and the reagent path, as in most square planar complexes. If the inversion reaction were accompanied by the solvolysis, the styrene liberated on solvolysis would operate as nucleophile and bring about an increase in the rate of CD change with the progress of reaction. Preliminary experiments showed that the CD strength of optically active styrene complexes decreased rapidly when a very small amount (*e.g.* 1% to the complex in molar ratio) of styrene was added to the complex solution.

The final pattern of the absorption spectrum should correspond to that of the equilibrated state of Eq. (5). However, the absorption spectrum of the product is unknown. Thus, we analyzed the initial part of the curves in Fig. 8 by use of Eq. (1), as in other olefin complexes in order to find the effect of substituents on styrene. The k_{obs} values increase almost linearly with the increase in the initial concentration of the complex, and are too great to enable kinetic treatment. It is seen, however, that the apparent rate constant k_{obs} increases in the sequence

p-methoxystyrene$<$*p*-methylstyrene$<$styrene$<$*p*-chlorostyrene$<$*p*-nitrostyrene

The order of such an increase is in accord with that of electrondrawing ability of the substituents on the *para* position. The stronger the attraction of electrons by substituent, the smaller the electron density on the C=C double bond in the side chain. The smaller electron density on the C=C double bond may result in a decrease in the σ-donating ability and an increase in the π-accepting ability of the olefin ligand.[5,6] The rate for the present reactions should have both non-zero k_1 and k_2 term (Eq. 3), although their values were not obtained separately. Thus the true mechanism of the reaction remains uncertain. However, the above sequence of the styrene derivatives suggests that the racemization is closely related to the strength of the metal-olefin σ-bond.

Experimental

Material. (+)-$^{\Delta\varepsilon}_{380}$*trans*(*N*)-[PtCl (L-prol) (2-methyl-2-butene)] and (+)$^{\Delta\varepsilon}_{380}$-*trans*(*N*)-[PtCl(L-prol)(*trans*-2-butene)] were prepared as described previously.[1] 2-Methyl-2-butene, *trans*-2-butene, styrene, and 2,3-dimethyl-2-butene are of extra-pure grade (Tokyo Kasei Co.) and used without further purification. Derivatives of styrene (*p*-methoxy, *p*-methyl, *p*-chloro, and *p*-nitrostyrene) were prepared by the method of Walling and Wolfstirn.[13] The complexes were synthesized as in the case of styrene.[1] Commercial acetone of spectro-grade was used as solvent without purification. The results of microanalysis are shown in Table 3.

Equipments. Circular dichroism was measured with a JASCO Model ORD/UV-5 Spectrometer with CD attachment and a cell jacket to keep the temperature constant within ±0.3°C (Komatsu-Yamato Coolnics). A Takara Thermister Type SPD-1D thermometer was calibrated with Toa's standard thermometer and the unit was placed inside the CD cell. Absorption spectra were recorded with a Hitachi 124 Spectrometer.

Procedure. Inversion reaction of coordinated olefins in (+)$^{\Delta\varepsilon}_{380}$-*trans*(*N*)-[PtCl(L-prol)(olefin)] (olefin = 2-methyl-2-butene, *trans*-2-butene). To a thermostated acetone solution of the complex ($\simeq 10^{-3}$M) was added a certain amount ($\simeq 10^{-1}$M) of olefin with a micro syringe. The solution was kept in the cell box of the spectrometer which had also been thermostated. The $\Delta\varepsilon$ value at 380 nm was continuously recorded.

The complexes of styrene and its derivatives were dissolved in acetone and the decrease in CD was measured at 380 nm, the temperature being controlled within ±0.3°C.

We are grateful to the Ministry of Education for a Grant-in-aid for our studies on optically active complexes.

Thermal Decomposition Reactions of Metal Oxalato Complexes in the Solid State. I. Thermographic Studies of Metal Oxalato Complexes

Kenzo NAGASE

Department of Chemistry, Tohoku University, Kawauchi, Sendai

(Received December 24, 1971)

The thermal decomposition reactions of metal oxalato complexes in the solid state were studied by the TG and DSC methods. The results from TG indicated that the thermal stability of the anhydrous complex decreases approximately with the increase in the electron affinity of the central metal ion. From DSC, the complexes can be divided into two groups, giving endothermic and exothermic peaks on the decomposition of their anhydrous complexes respectively. The two enthalpy changes, ΔH, corresponding to the dehydration and to the decomposition of the anhydrous complexes, are also presented.

Although the thermal properties of metal oxalates have been extensively studied, few studies have been made of metal oxalato-type complexes. Wendlandt and George[1] carried out the thermogravimetry (TG) of $K_3[Cr(ox)_3]3H_2O$, $K_3[Fe(ox)_3]3H_2O$, $K_3[Co(ox)_3]$-$3H_2O$, and $K_3[Rh(ox)_3]2.5H_2O$.

Tanaka and Nanjo[2] have followed the change in the valence state of the central metal ions on the thermal decomposition reactions of $K_3[Fe(ox)_3]$ and $K_3[Co(ox)_3]$; they have suggested that the decomposition of these complexes is initiated by the electron transfer from the coordianted oxalate ion to the central metal ion.

Information on the intermediates and kinetic data on the thermal decomposition reactions of $K_3[Mn(ox)_3]$-$3H_2O$,[3] $K_3[Fe(ox)_3]3H_2O$,[4-7] and $K_3[Co(ox)_3]$-$3H_2O$,[8,9] have been presented by several workers.

In this study, the TG and DSC curves of a number of metal oxalato complexes will be presented, and the relations between the thermal property of the complex and the nature of the central metal ion will be examined.

Experimental

TG and DSC. Thermogavimetric (TG) and Differential scanning calorimetric (DSC) curves were obtained with a Rigaku 2008 CS thermobalance equipped with a standard differential scanning calorimeter in a dynamic nitrogen atmosphere. About ten milligrams of a powdered sample in an aluminum crucible were used in each measurement. The heating rate was exactly linear with the time at about 4°C per min.

Materials. The complexes of Al(III),[10] V(III),[11] Cr(III),[12] Mn(III),[13] Fe(III),[14] Co(III),[15] Rh(III),[16] Cu(II),[17], Pd(II),[18] and Pt(II),[19] were prepared according to the litterature. The $K_2[Zn(ox)_2]2H_2O$ was prepared by boiling $Zn(OH)_2$ with a stoichiometric amount of aqueous $H_2C_2O_4 \cdot 2H_2O$ and $K_2C_2O_4 \cdot H_2O$ until the solution was neutral. The analytical results on the complexes were as follows: $K_3[Al(ox)_3]3H_2O$; C, found, 15.45, calcd, 15.85; H, found, 0.90, calcd, 1.30; $K_3[V(ox)_3]3H_2O$; C, found, 14.76, calcd, 14.79; H, found, 1.19, calcd, 1.23; $K_3[Cr(ox)_3]3H_2O$; C, found, 14.77, calcd, 14.78; H, found, 0.86, calcd, 1.23; $K_3[Fe(ox)_3]3H_2O$; C, found, 14.49, calcd, 14.65; H, found, 0.81, calcd, 1.22; $K_3[Co(ox)_3]3H_2O$; C, found, 14.41; calcd, 14.57; H, found, 1.21, calcd, 1.21; $K_3[Rh(ox)_3]4.5H_2O$; C, found, 12.43, calcd, 12.74; H, found, 1.25, calcd, 1.25; $K_2[Cu(ox)_2]2H_2O$; C, found, 13.48, calcd, 13.56; H, found, 0.93, calcd, 1.13; $K_2[Zn(ox)_2]2H_2O$; C, found, 13.39, calcd, 13.48; H, found, 0.83, calcd, 1.12; $K_2[Pd(ox)_2]3H_2O$; C, found, 11.54, calcd, 11.56; H, found, 1.43, calcd, 1.45; $K_2[Pt(ox)_2]2H_2O$; C, found, 9.55, calcd, 9.89; H, found, 0.66, calcd, 0.83.

Results and Discussion

TG Study. The thermogravimetric curves of the metal oxalato complexes obtained in this work are given in Figs. 1 and 2. The TG curves of Al(III), V(III), Cu(II), Zn(II), Pd(II), and Pt(II) complexes seem to be the first to appear. Although the TG curves of the remaining metals have been presented by several workers, these curves were reproduced under the experimental conditions employed in the present work. The temperature range and the percentage of mass loss are summarized in Table 1. Except for $K_3[Mn(ox)_3]3H_2O$, all the complexes evolved hydrated water at about 100°C to form the corresponding anhydrous complexes. The dehydration of K_3-$[Mn(ox)_3]3H_2O$ took place, along with the decomposition of the anhydrous complex. Except for

$K_2[Pt(ox)_2]2H_2O$	75—110	6.7	7.4 for $2H_2O$	207—223	18.7	18.1 for $2CO_2$

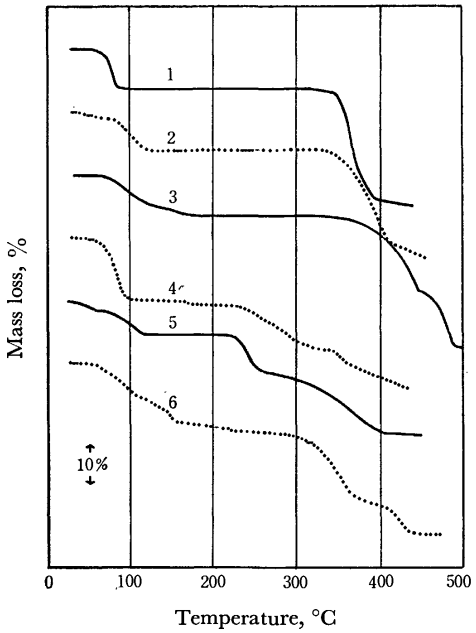

Fig 1. TG curves of (1) $K_3[Al(ox)_3]3H_2O$, (2) $K_3[V(ox)_3]$-$3H_2O$, (3) $K_3[Cr(ox)_3]3H_2O$, (4) $K_3[Mn(ox)_3]3H_2O$, (5) K_3-$[Fe(ox)_3]3H_2O$ and $K_3[Co(ox)_3]3H_2O$ in a nitrogen atmosphere.

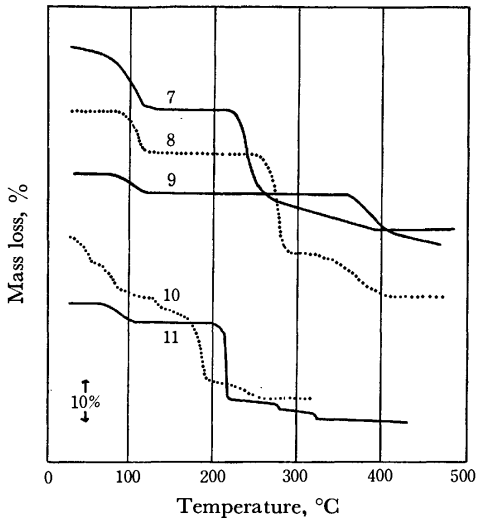

Fig. 2. TG curves of (7) $K_3[Rh(ox)_3]4.5H_2O$, (8) $K_2[Cu(ox)_2$-$]2H_2O$, (9) $K_2[Zn(ox)_2]2H_2O$, (10) $K_2[Pd(ox)_2]3H_2O$ and (11) $K_2[Pt(ox)_2]2H_2O$ in a nitrogen atmosphere.

$K_3[Rh(ox)_3]4.5H_2O$ and $K_2[Pd(ox)_2]3H_2O$, the observed values of mass loss corresponding to the dehydration were somewhat lower than the calculated values for the formula described. This difference may be due to the partial evolution of the hydrated water before measurement. In a previous paper,[1] it has been reported that the rhodium(III) complex evolved 2.5 mol of water in two steps; however, it evolved 4.5 mol of water in one step in the present work.

The order of the decomposition temperatures of the anhydrous complexes is as follows:

$K_3[Mn(ox)_3]<K_3[Co(ox)_3]<K_2[Pd(ox)_2]<$
$K_2[Pt(ox)_2]<K_3[Rh(ox)_3]<K_3[Fe(ox)_3]<$
$K_2[Cu(ox)_2]<K_3[Cr(ox)_3]<K_3[V(ox)_3]<$
$K_3[Al(ox)_3]<K_2[Zn(ox)_2]$

This order has no relation to the strength of the metal-oxygen bond as obtained by the infrared spectroscopic

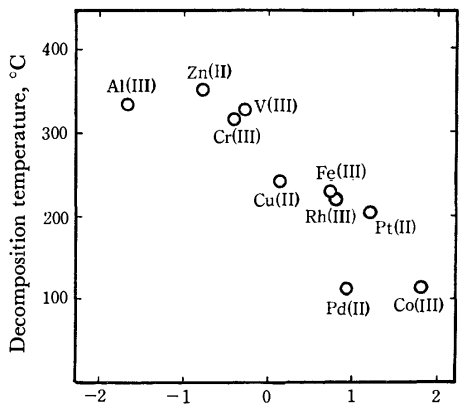

Fig. 3. Correlation of decomposition temperatures of metal oxalato complexes with oxidation-reduction potentials of central metal ions in aqueous solution. The redox potentials adopted correspond to the couples M(II)/M(III) for V, Cr, Fe, and Co, M(0)/M(III) for Al and Rh, and M(0)/M(II) for Cu, Zn, Pd, and Pt, respectively.

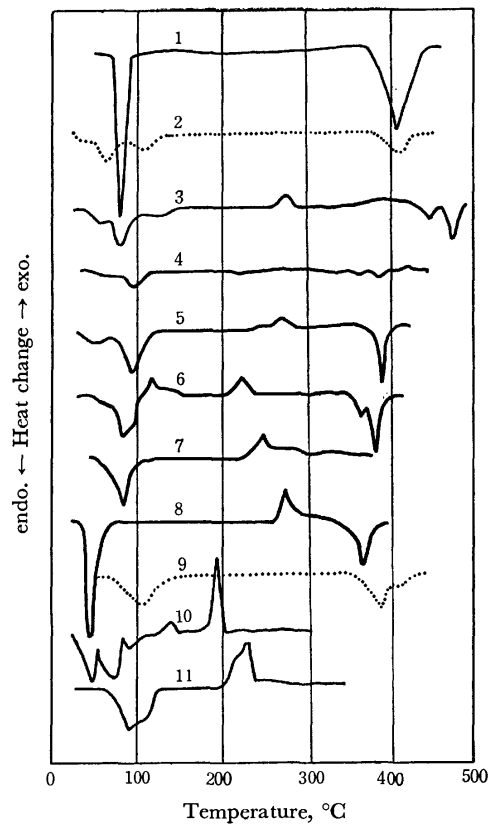

Fig. 4. DSC cruves of (1) $K_3[Al(ox)_3]3H_2O$, (2) $K_3[V(ox)_3]$-$3H_2O$, (3) $K_3[Cr(ox)_3]3H_2O$, (4) $K_3[Mn(ox)_3]3H_2O$, (5) $K_3[Fe(ox)_3]3H_2O$, (6) $K_3[Co(ox)_3]3H_2O$, (7) $K_3[Rh$-$(ox)_3]4.5H_2O$, (8) $K_2[Cu(ox)_2]2H_2O$, (9) $K_2[Zn(ox)_2]$-$2H_2O$, (10) $K_2[Pd(ox)_2]3H_2O$ and $K_2[Pt(ox)_2]2H_2O$ in a nitrogen atmosphere.

study.[20] In Fig. 3, the plots of the decomposition temperatures of the anhydrous complexes *versus* the oxidation-reduction potentials[21] of the central metal ions forming an aquo complex are given. These potentials are considered to measure the relative electron affinities of the central metal ions forming an oxalato complex, since Dq value of H_2O is near to that of $C_2O_4^{2-}$. The results in Fig. 3, therefore, indicate that the thermal stability of the anhydrous complex decreases approximately with the increase in the electron affinity of the central metal ion.

DSC Study. The differential calorimetric curves of the complexes obtained in the present work are given in Fig. 4. The values of the enthalpy change, ΔH, corresponding to the dehydration and to the decomposition of the anhydrous complexes are both summarized in Table 2.

Table 2. Enthalpy change of dehydration and decomposition of metal oxalato complexes

Complex	Dehydration (kcal/mol)	Decomposition of anhydrous complex (kcal/mol)
$K_3[Al(ox)_3]3H_2O$	13.9	15.3
$K_3[V(ox)_3]3H_2O$	8.2	4.1
$K_3[Cr(ox)_3]3H_2O$	9.7	−1.9
$K_3[Fe(ox)_3]3H_2O$	12.8	−2.4
$K_3[Co(ox)_3]3H_2O$	13.6	−2.5
$K_3[Rh(ox)_3]4.5H_2O$	12.4	−6.6
$K_2[Cu(ox)_2]2H_2O$	12.1	−3.4
$K_2[Zn(ox)_2]2H_2O$	9.3	2.8
$K_2[Pd(ox)_2]3HO$	9.3	−2.4
$K_2[Pt(ox)_2]2H_2O$	11.3	−6.5

In connection with the enthalpy change corresponding to the dehydration, it should be noticed that there is some difference between the amount of hydrated water from TG and the theoretical value for the formula described. The values calibrated, therefore, are given in Table 2. The values of ΔH corresponding to the dehydration are about 10 kcal/mol for all of the complexes.

From the values of ΔH corresponding to the decomposition of the anhydrous complexes, the anhydrous complexes can be divided into two groups: the complexes of Cr(III), Fe(III), Co(III), Rh(III), Cu(II), Pd(II), and Pt(II), all decomposing with a negative value of ΔH, belong to the first group, while the complexes of Al(III), V(III), and Zn(II), which decompose with a positive value, belong to the second group.

From the analyses of the gaseous products, this division for metal oxalato complexes seems to be suitable; *i.e.*, all the complexes in the first group except for $K_3[Cr(ox)_3]$ evolved only CO_2 upon their decomposition, suggesting an electron transfer from the coordinated oxalate ion to the central metal ion, while the complexes in the second group evolved both CO and CO_2, suggesting the formation of the metal oxide. The details of the gaseous and solid products will be reported later.

The DSC curve of the chromium(III) complex shows a small exothermic peak without any mass loss in the 265—290°C temperature range. This may be due to the transition of the anhydrous complex from the amorphous state (after water removal) to the crystalline state. The ΔH value of this transition was 1.4 kcal/mol. The details of the transition will be reported later.

The author wishes to thank Dr. N. Tanaka, Professor of Tohoku University, for his advice.

**Chemistry Department, Faculty of Engineering, Ibaraki University, Narisawa, Hitachi, Ibaraki*

(Received January 27, 1972)

In GEDTA solutions with pH's lower than 7.0_0, the nickel(II), zinc(II), and cadmium(II) ions were found to yield the one-step, two-step, and three-step polarographic waves respectively. The polarographic wave of the nickel(II) ion, the first step of the zinc(II) ion, and the first and second steps of the cadmium(II) ion showed a kinetic-controlled nature. In this study, the polarographic wave of the nickel(II) ion, the first step of the zinc(II) ion, and the second step of cadmium(II) ion were studied systematically. From an experimental examination of the nature of the kinetic currents of these complexes, the mechanisms for the above polarographic steps were determined as:

i) $NiHY^- \rightleftharpoons Ni^{2+} + HY^{3-}$ rate-determining step
$\downarrow\uparrow$ rapid
pH<5.70 NiY^{2-}
$Ni^{2+} + 2e^- + Hg = Ni(Hg)$
$NiY^{2-} \rightleftharpoons Ni^{2+} + Y^{4-}$ rate-determining step
$\downarrow\uparrow$ rapid
pH>5.70 $NiHY^-$
$Ni^{2+} + 2e^- + Hg = Ni(Hg)$

ii) $ZnHY^- + H^+ = Zn^{2+} + H_2Y^{2-}$ rate-determining step
$\downarrow\uparrow$ rapid
ZnY^{2-}
$Zn^{2+} + 2e^- + Hg = Zn(Hg)$

iii) $Cd(HY)_2^{4-}$
$\downarrow\uparrow$ rapid
$CdHY^- = CdHY^{-*}$ rate-determining step
$\downarrow\uparrow$ rapid
CdY^{2-}
$CdHY^{-*} + 2e^- + Hg = Cd(Hg) + HY^{3-}$

where $CdHY^{-*}$ is the electroactive cadmium(II)-GEDTA complex. By comparing the dissociation rate constant of the nickel(II)-GEDTA complex with that of the nickel(II)-aspartate complex, the detailed dissociation mechanism was determined. The rates and mechanisms of the dissociations of zinc(II) and cadmium(II)-GEDTA complexes were also discussed in detail.

In a previous paper,[1] we studied the polarographic behavior of the copper(II)-2,2′-ethylenedioxybis[ethyliminodi(acetate)] (GEDTA) complex systematically. In contrast with the copper(II)-ethylenediaminetetraacetate and *N*-(2-hydroxyethyl)-ethylenediamine-*N*,*N*′,*N*′-triacetate (EDTA-OH) complexes, it has been found to give two polarographic waves, both of which are diffusion-controlled in nature. From the GEDTA concentration dependence of the half-wave potential, it was concluded that the hexadentate GEDTA anion can form a complex with a 1:2 composition with the copper(II) ion. The GEDTA complex of the zinc(II) ion also gives the two-step polarographic wave in GEDTA solutions of pH's lower than 7.00. The second polarographic step of the zinc(II)-GEDTA complex was diffusion-controlled in nature. However, the first step showed a kinetic-controlled nature. The nickel(II) and cadmium(II) ions in GEDTA solutions were also found to give kinetic waves. In this paper, we will investigate the polarographic behaviors of nickel(II), zinc(II)-, and cadmium(II)-GEDTA complexes systematically, and will determine the rate constants and the electrode reaction mechanisms by analyzing the experimental data with the aid of theoretical relations derived previously.[2] The structure of the reaction intermediate and the reaction mechanism will also be discussed in detail on the basis of a comparison of the observed rate constant with that calculated from the reaction intermediate proposed.

Experimental

Reagents. The way of preparing the standard nickel(II) nitrate solution was given previously.[2] Standard zinc(II) and cadmium(II) solutions were prepared by dissolving known amounts of pure cadmium(II) and zinc(II) sulfates in redistilled water. GEDTA (2,2′-ethylenedioxybis[ethyliminodi(acetic acid)]) was recrystallized from its aqueous solution by adding pure ethanol and hydrochloric acid. All the other chemicals used were of an analytical-reagent grade and were used without further purification.

Apparatus and Experimental Procedures. All the DC current-voltage curves were measured by using a manual polarograph similar to that of Kolthoff and Lingane or a

2) M. Kodama, H. Nunokawa, and N. Oyama, *ibid.*, **44**, 2387 (1971).

Yanagimoto pen-recording polarograph, PA-102. The characteristic features of the dropping mercury electrode (DME) used in this study were given previously.[2] All the other apparatuses used and the experimental procedures were also described in that previous paper.[2] The ionic strength of the solution was adjusted to 0.30 by adding an appropriate amount of pure sodium perchlorate. To keep the solution's pH constant, a sodium acetate–acetic acid mixture or a potassium dihydrogen phosphate–disodium hydrogen phosphate mixture was used.

Results and Discussion

Polarographic Behavior of the Nickel(II) Ion in the GEDTA Solution. From the thermodynamic point of view,[3] all the nickel(II) ions in a 10.0 mM GEDTA solution with a pH higher than 5.0 are considered to exist as GEDTA complex. Even under these experimental conditions, the nickel(II)-GEDTA complex gives the polarographic step at the potentials where the nickel(II) aquo ions give a polarographic wave

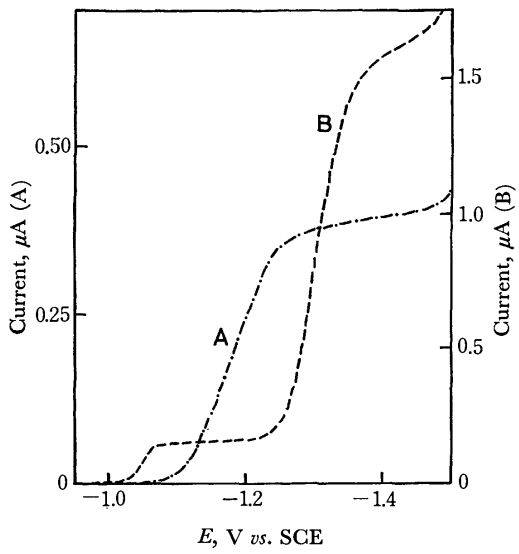

Fig. 1. Polarograms of metal(II)-GEDTA complexes.
A) Ni(II)-GEDTA system
The concentration of uncomplexed GEDTA=20.0 mM
The concentration of nickel(II) ion=1.00 mM
The total concentration of phosphate=0.12 M
pH=6.11, μ=0.30, 25°C
B) Zn(II)-GEDTA system
The concentration of uncomplexed GEDTA=10.0 mM
The concentration of zinc(II) ion=0.50$_0$ mM
The concentration of uncomplexed acetate ion=20.0 mM
pH=5.24, μ=0.30, 25°C

(Fig. 1). Although the results are not shown, its limiting current was almost independent of the effective pressure of the mercury column within the limits of experimental error. This fact clearly implies that the polarographic step of the nickel(II)-GEDTA complex is kinetic-controlled in nature. In order to maintain the solution's pH constant, an acetic acid–acetate buffer mixture (5.00<pH<5.70) or a potassium dihydrogen phosphate–disodium hydrogen phosphate mixture

3) A. Ringbom, "Complexation in Analytical Chemistry," John Wiley & Sons, New York (1963).

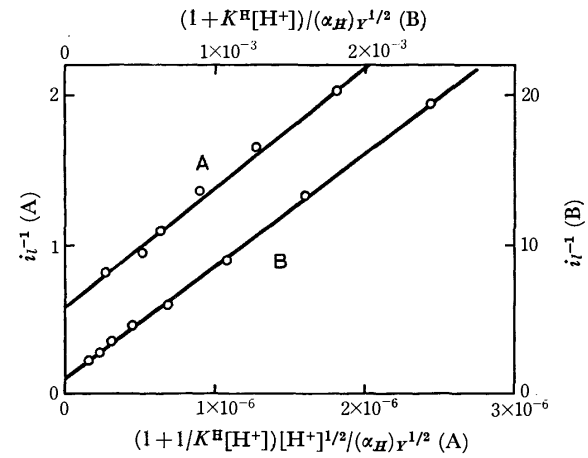

Fig. 2. The plot of i_l^{-1} against $(1+1/K^H[H^+])[H^+]^{1/2}/(\alpha_H)_Y^{1/2}$ or $(1+K^H[H^+])/(\alpha_H)_Y^{1/2}$.
The concentration of uncomplexed GEDTA=20.0 mM
The concentration of nickel(II) ion=1.00 mM
μ=0.30, 25°C
A) The plot of i_l^{-1} *vs.* $(1+1/K^H[H^+])[H^+]^{1/2}/(\alpha_H)_Y^{1/2}$ 5.00<pH<5.70, The total concentration of acetate=0.05M
B) The plot of i_l^{-1} *vs.* $(1+K^H[H^+])/(\alpha_H)_Y^{1/2}$ 5.70<pH<7.00, The total concentration of phospate=0.12M

(5.70<pH<7.00) was used in this study. However, these buffer mixtures had no effect on the wave-height and the half-wave potential of the reduction wave of the nickel(II)-GEDTA complex. In the pH range from 5.00 to 5.70, the plot of a reciprocal of the wave-height, i_l^{-1}, against the $(1+1/K^H\cdot[H^+])\cdot[H^+]^{1/2}/(\alpha_H)_Y^{1/2}$ or the $[Y]_f^{1/2}$ gave a straight line with an intercept nearly identical to the reciprocal of i_d (Fig. 2). Here, i_d is the limiting current when it is completely diffusion-controlled and is represented by the well-known Ilkoviç equation. K^H is the protonation constant of the nickel(II)-GEDTA complex (defined as $K^H=[NiHY^-]/[NiY^{2-}]\cdot[H^+]$); $(\alpha_H)_Y$, the (α_H) value of GEDTA, and $[Y]_f$, the concentration of uncomplexed GEDTA On the other hand, in solutions with pH

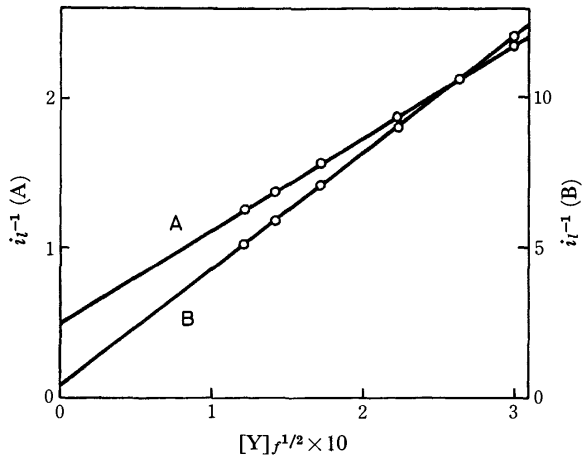

Fig. 3. The plot of i_l^{-1} against $[Y]_f^{1/2}$.
μ=0.30, 25°C
The concentration of nickel(II) ion=1.00 mM
A) pH=5.37
The total concentration of acetate=0.05M
B) pH=6.69
The total concentration of phosphate=0.12M

values from 5.70 to 7.00, the plot of i_l^{-1} *vs.* the $(1+K^{H}\cdot[H^+])/(\alpha_H)_Y^{1/2}$ or $[Y]_f^{1/2}$ gave a straight line (Fig. 3). As was discussed in connection with polarography of the nickel(II)-aspartate and glutamate complexes,[2] these facts evidently show that the reaction mechanism for the polarographic wave of the nickel(II)-GEDTA complex can be expressed as:

$5.00<pH<5.70$

$$NiHY^- \overset{(k_d)_{NIHY}}{\rightleftharpoons} Ni^{2+}+HY^{3-} \text{ r.d.s.}$$
$$\downarrow \text{ rapid}$$
$$NiY^{2-} \qquad \text{I}$$
$$Ni^{2+}+2e^-+Hg=Ni(Hg)$$

$5.70<pH<7.00$

$$NiY^{2-} \overset{(k_d)_{NIY}}{\rightleftharpoons} Ni^{2+}+Y^{4-} \text{ r.d.s.}$$
$$\downarrow \text{ rapid}$$
$$NiHY^- \qquad \text{II}$$
$$Ni^{2+}+2e^-+Hg\rightleftharpoons Ni(Hg)$$

where Y^{4-} denotes the completely-deprotonated GEDTA anion. In consideration of the chemical equilibria in solution, the following two equations can be derived for the above reaction mechanisms, I and II respectively:

$$\frac{1}{i_l}=\frac{K_{NIHY}^{1/2}\left(1+\dfrac{1}{K^{H}[H^+]}\right)\cdot[Y]_f^{1/2}}{2AF\cdot D^{1/2}(k_d)_{NIHY}^{1/2}\cdot(\alpha_H)_Y^{1/2}}+\frac{1}{i_d} \qquad (1)$$

$$\frac{1}{i_l}=\frac{K_{NIY}^{1/2}\,(1+K^{H}\cdot[H^+])\cdot[Y]_f^{1/2}}{2AF\cdot D^{1/2}\cdot(k_d)_{NIY}^{1/2}\cdot(\alpha_H)_Y^{1/2}}+\frac{1}{i_d} \qquad (2)$$

All the symbols used in Eqs. (1) and (2) have their usual meanings.[2]

Table 1. Rate constants (μ=0.30, 25°C)

Elementary reaction	Rate constant
$NiHY^-=Ni^{2+}+HY^{3-}$	9.3×10^{-4} sec^{-1}
$NiY^{2-}=Ni^{2+}+Y^{4-}$	$2.5_3\times10^{-3}$ sec^{-1}
$ZnHY^-+H^+=Zn^{2+}+H_2Y^{2-}$	14.9 M^{-1} sec^{-1}

From the slopes of the linear relations in Figs. 2. and 3, the $(k_d)_{NIHY}$ and $(k_d)_{NIY}$ values were determined; they are listed in Table 1 together with other numerical values. If the electrode reaction mechanisms for the polarographic step of the nickel(II)-GEDTA complex at pH's lower than 5.70 and that at pH's higher than 5.70 are given by I and II respectively, the half-wave potentials should be given by (3) and (4) respectively:

$$E_{1/2}=\text{constant}_1+\frac{0.0591}{4\alpha}\cdot\log\frac{[Y]_f[H^+]}{(\alpha_H)_Y} \qquad (3)$$

$$E_{1/2}=\text{constant}_2+\frac{0.0591}{4\alpha}\cdot\log\frac{[Y]_f}{(\alpha_H)_Y} \qquad (4)$$

These relations were examined by using some typical experimental data. Typical results obtained at pH's lower than 5.70 are shown in Tables 2 and 3. The agreement between the shift of the half-wave potential obtained experimentally, $(\Delta E_{1/2})_{ob}$, and that calculated with the aid of Eq. (3), using the α value of 0.50, can be regarded as satisfactory. In solutions of pH's higher than 7.00, the nickel(II)-GEDTA complex give no polarographic wave.

Polarographic Behavior of Zinc(II) Ions in a GEDTA Solution. Reported equilibrium constants for the formation of the zinc(II)-GEDTA complex[3] show that all the zinc(II) ions in the 10.0 mM GEDTA solutions with pH's higher than 4.60 invariably exist as GEDTA complex. As is illustrated by the polarogram in Fig. 1, in the pH range from 5.0 to 6.0, the zinc(II) ions in 10.0 mM GEDTA solutions yielded two polarographic steps. Under the present experimental conditions, the total wave-height was almost constant, but was exactly proportional to the square-root of the effective pressure on the DME and zinc(II) ion concentrations. However, the wave-height of the first reduction step was

almost independent of the effective mercury pressure, suggesting its kinetic nature (the results are not shown here). As in the case of the polarography of the nickel(II)-GEDTA complex, the nature of the first polarographic wave of the zinc(II)-GEDTA complex was investigated thoroughly. Provided that the other experimental conditions are kept constant, the plot of the reciprocal of the limiting current, i_l^{-1}, against $[Y]_f^{1/2}$ or $(1+1/K^H\cdot[H^+])/(\alpha_H)_Y^{1/2}$ invariably gives a linear relation (Fig. 4). Considering that the first wave is located at the potentials where the zinc(II)-aquo ions will give the reduction wave, it seems that the electrode-reaction mechanism for the first step of the zinc(II)-GEDTA complex can be depicted as:

$$\begin{array}{l} ZnY^{2-} \\ \quad \downarrow\uparrow \text{ rapid } (k_d)^H_{ZnHY} \\ ZnHY^- + H^+ \rightleftharpoons Zn^{2+} + H_2Y^{2-} \quad \text{r.d.s} \\ Zn^{2+} + 2e^- + Hg = Zn(Hg) \end{array} \qquad \text{III}$$

Although, in the polarographic study of the zinc(II)-GEDTA complex, an acetate buffer mixture was used to keep the solution pH constant, it has practically no effect on the polarographic behavior of the zinc(II)-GEDTA complex provided that the acetate ion concentration was lower than 0.025M. Therefore, all the kinetic measurements were carried out by using an acetate buffer mixture where the acetate-ion concentration was lower than 0.025M. If the above reaction mechanism is correct, the half-wave potential of the first wave should shift linearly to the negative potentials with an increase in the log $[Y]_f\cdot[H^+]^2/(\alpha_H)_Y$ value, giving the slope of $0.0591/4\alpha$ V. Although the experimental data are not shown here, the above linear relation could be examined successfully. From the slope of the linear relation between i_l^{-1} and $[Y]_f^{1/2}$ or $(1+1/K^H\cdot[H^+])/(\alpha_H)_Y^{1/2}$, the proton-assisted dissociation rate constant of $ZnHY^-$, $(k_d)^H_{ZnHY}$, was determined. The $(k_d)^H_{ZnHY}$ value obtained is also given in Table 1.

Polarographic Behavior of Cadmium(II) Ions in GEDTA Solutions. Previously,[4] the polarographic behavior of the cadmium(II)-GEDTA complex in acetate buffer solutions containing a large excess of calcium(II) ions, was studied by Fujisawa and Tanaka. In the presence of an excess of calcium(II) ions, the cadmium(II)-GEDTA complex gives two polarographic steps. By investigating the nature of the first reduction step systematically, they concluded that the first step can be ascribed to the reduction of the free cadmium(II) ion liberated by the dissociation of the normal cadmium-(II)-GEDTA complex at the electrode surface (Reaction mechanism IV).

$$\begin{array}{l} CdY^{2-} + jH^+ \rightleftharpoons Cd^{2+} + H_jY^{j-4} \\ Cd^{2+} + 2e^- + Hg \rightleftharpoons Cd(Hg) \end{array} \qquad \text{IV}$$

On the other hand, the cadmium(II) ions in GEDTA solutions not containing calcium(II) ions give three polarographic steps at pH's lower than 3.50. With an increase in the solution's pH, the first wave-height decreased, and it disappeared completely at pH's higher than 3.50. Thus, the cadmium(II)-GEDTA complex

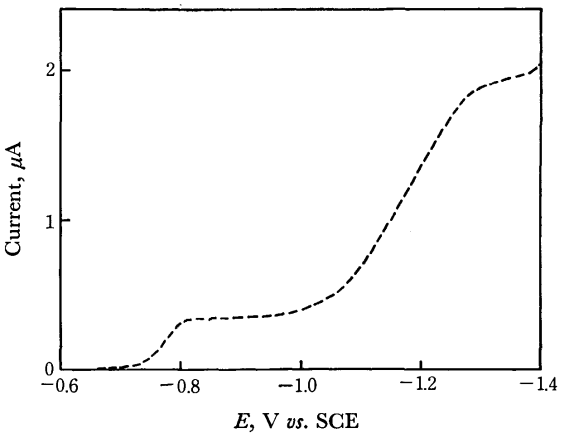

Fig. 5. Polarogram of cadmium(II)-GEDTA complex.
The concentration of cadmium(II) ion=1.00 mM
The concentration of uncomplexed GEDTA=14.0 mM
The total concentration of acetate=0.05 M
μ=0.30, 25°C, pH=4.00

in GEDTA solutions of pH's higher than 3.50 yields the two-step polarographic wave (Fig. 5). In view of the reduction potential of the first wave at pH's lower than 3.50, and in view of the effect of the GEDTA concentration on the limiting current, the first polarographic step of the cadmium(II)-GEDTA complex at pH's lower than 3.50 may be considered to correspond to the first polarographic wave reported by Fujisawa and Tanaka. In this investigation, we studied the polarographic behavior of the cadmium(II)-GEDTA complex in GEDTA solutions not containing calcium-(II) ions at pH's higher than 3.50. The positive polarographic step observed in solutions containing an excess of GEDTA salt showed the characteristic kinetic-controlled nature (its limiting current is independent of the effective mercury pressure on the DME). The limiting current was decreased remarkably by increasing the solution's pH. However, the GEDTA concentration had little effect on it. By rearranging Eq. (5_a) in Ref. 2, one can easily derive the following relation:

$$\frac{i_l}{i_d - i_l} = \text{constant}_3 \times \frac{t^{1/2} k_2^{1/2}}{K_{1a}^{-1} K_{2a}^{-1/2}} \qquad (5)$$

This relation is the same as that derived by Koryta[5] for the kinetic current. With the aid of this relation, we analyzed the experimental data. Provided that the other experimental conditions are kept constant, the plot of $(i_d-i_l)/i_l$ against the reciprocal of the hydrogen-ion concentration or the GEDTA concentration, $[Y]_f$, invariably gives a linear relation. The results are reproduced in Figs. 6 and 7.

Under the present experimental conditions, the total wave-height of the cadmium(II)-GEDTA complex was exactly proportional to the square-root of the effective mercury pressure on the DME. However, it decreased appreciably with an increase in the concentration of uncomplexed GEDTA. If this can be ascribed to the formation of the cadmium(II)-GEDTA complex with a 1:2 composition, one can determine the second successive formation constant by examining the effect

of the GEDTA concentration on the limiting current with the aid of the following well-known relation (6):

$$D_{ob}=\frac{D_1+D_2\cdot K'_2[Y]_f}{1+K'_2\cdot[Y]_f} \quad (6)$$

If the composition of a 1:2 ratio complex is given by $Cd(HY)_2^{4-}$, K'_2 in Eq. (6) should be given by $K_2^{HY}\cdot[H^+]/(1+K^{H-1}\cdot[H^+]^{-1})\cdot K_4\cdot(\alpha_H)_Y$. On the other hand, if the composition of the 1:2 ratio complex is given by CdY_2^{6-}, K_2 will be given by $K_2^Y/(1+K^H\cdot[H^+])\cdot(\alpha_H)_Y$. Here, $K_2^{HY}=[Cd(HY)_2^{4-}]/[CdHY^-]\cdot[HY^{3-}]$, $K_2^Y=[CdY_2^{6-}]/[CdY^{2-}][Y^{4-}]$, and K_4 is the fourth dissociation constant of GEDTA. By introducing the Ilkoviç equation into Eq. (6) and by rearranging the resulted equation, we can obtain the following relation:

$$(i_d)_{ob}^2=\frac{(i_d)_0^2-(i_d)_{ob}^2}{[Y]_f}\times\frac{1}{K_2}+(i_d)_l^2 \quad (7)$$

where $(i_d)_{ob}$ is the diffusion current of the cadmium(II)-

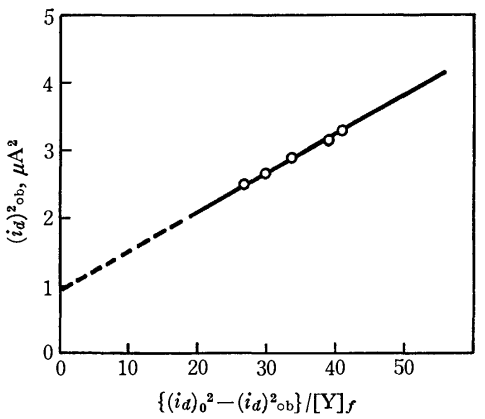

Fig. 8. The plot of $(i_d)^2_{ob}$ against $[(i_d)_0^2-(i_d)^2_{ob}]/[Y]_f$.
The concentration of cadmium(II) ion=1.00 mM
The total concentration of acetate=0.05M

GEDTA complex in a solution where 1:1 and 1:2 complexes coexist; $(i_d)_0$, the diffusion current in a solution where all the complex ions have the 1:1 composition, and $(i_d)_l$, the diffusion current in a solution where all the complex ions have the 1:2 composition. The above relation was examined by using some typical experimental data. A typical result is shown in Fig. 8. From the slope of the straight line in Fig. 8, the K_2^{HY} or K_2^Y value was determined to be $10^{6.34}$ or $10^{11.34}$. The latter value is too large to be understood, disproving the formation of CdY_2^{6-}. It was also found that the solution's pH and the concentration of free GEDTA had practically no effect on the half-wave potential. All the above findings evidently indicate that the electrode reaction mechanism for the second step of the cadmium(II)-GEDTA complex can be expressed as:

$$\begin{array}{l} CdY^{2-} \\ \quad\downarrow \text{ rapid} \\ CdHY^- \underset{K}{\overset{k_f}{\rightleftharpoons}} CdHY^{-*} \quad \text{r.d.s.} \\ \quad\downarrow \text{ rapid} \\ Cd(HY)_2^{4-} \end{array} \quad \text{V}$$

$$CdHY^{-*}+2e^-+Hg=Cd(Hg)+HY^{3-}$$

Here, $CdHY^{-*}$ means the electroactive protonated-cadmium(II)-GEDTA complex. For the above reaction mechanism, the (5) relation can be rewritten as:

$$\frac{i_l}{i_d-i_l}=\text{constant}_4\times\frac{t^{1/2}\cdot k_f^{1/2}}{\left(1+\frac{1}{K^H\cdot[H^+]}+\frac{K_2^{HY}\cdot K_3\cdot[H_2Y^{2-}]}{[H^+]}\right)} \quad (8)$$

where K_3 is the third dissociation constant of GEDTA and K, $[CdHY^{-*}]/[CdHY^-]$. We can mention here that, under the present experimental conditions, $[H_2Y^{2-}]$ is practically equal to the $[Y]_f$ value. Equation (8) evidently indicates that, from the slope of linear relations shown in Figs. 6 and 7, the k_f value can be estimated. However, the lack of data on the K value prevents us from calculating the k_f value from

the slope of linear relations shown in Figs. 6 and 7.

The formation constant of the protonated nickel(II)-GEDTA complex, $NiHY^-$, $K_{NiHY}=[NiHY^-]/[Ni^{2+}]\cdot[HY^{3-}]$, can be calculated to be $10^{7.94}$ ($\mu=0.30$) from the relation $K_{NiHY}=K_{NiY}\cdot K^H K_4$. This value is in good agreement with the formation constant of the 1 : 1 ratio nickel(II)-iminodiacetate complex. This agreement suggests that the tervalent GEDTA anion in the protonated nickel(II)-GEDTA complex is coordinated to the nickel(II) ion through an iminodiacetate chelate ring. Therefore, it is reasonable to believe that the protonated nickel(II)-GEDTA complex can be depicted by (A) in Fig. 9. If the structure proposed above is reasonable, the reaction intermediate in the dissociation reaction of $NiHY^-$ must be given by (B) in Fig. 9.

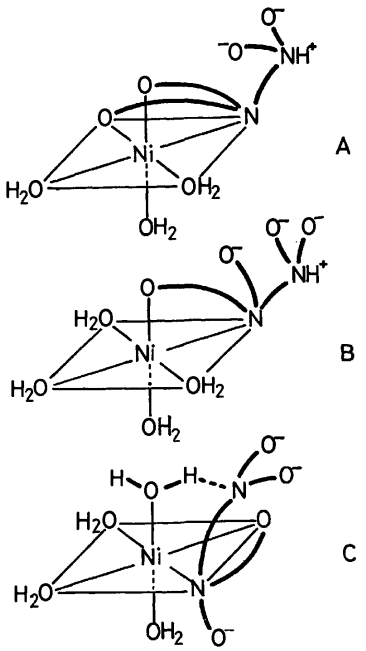

Fig. 9. Reaction intermediates.

As has been reported previously,[2] the nickel(II)-aspartate complex dissociates through the glycinate reaction intermediate, in which the leaving aspartate anion is bonded to the nickel(II) ion through a glycinate chelate ring. When the structure of the reaction intermediate in the dissociation of $NiHY^-$ is depicted by (B), and when the dissociations of aspartate and GEDTA anions from the glycinate reaction intermediates are rate-determining steps, the dissociation-rate-constant ratio between the aspartate and GEDTA systems should be given by $K_{NiHY}/K_{Ni(II)-Asp}\times 2=7.0$. Here, 2 is the statistical factor for the reaction intermediate (B). The observed ratio was 13.0. The agreement between the observed ratio and that calculated on the basis of the glycinate reaction intermediates can be regarded as satisfactory. Furthermore, the rate constant for the formation of the protonated nickel(II)-EDTA complex has been reported to be $10^{5.30}$ by Margerum and Zabin.[6] This corresponds to the dissociation constant of $2.4\times10^{-6}\,sec^{-1}$. The dissociation rate constant ratio between the protonated GEDTA and EDTA complexes, calculated by using the above rate constant, was found to be nearly equal to the ratio of the reciprocals of the K_{NiHY} value between the GEDTA and EDTA complexes of the nickel(II) ion. This suggests that the protonated nickel(II)-EDTA complex also dissociates through the reaction intermidiate in which the leaving tervalent EDTA anion is bonded to the nickel(II) ion through the glycinate chelate ring. The formation rate constant of the protonated nickel(II)-GEDTA complex, k_f, from Ni^{2+} and HY^{3-} was claculated to be $8.1\times10^4\,M^{-1}sec^{-1}$ from the relation $K_{NiHY}=k_f/k_d$. This value is slightly larger than the reported rate constant for the water loss from the aquated nickel(II) ion.[7] Considering that the association constant of the outer-sphere complex between the nickel(II) ion and the HY^{3-} anion is expected to be larger than unity from the Fuoss equation,[8] the k_f value thus estimated suggests that the rate-determining step in the formation of $NiHY^-$ is the water loss from the nickel(II)-aquo ion. As is shown in Table 1, the k_d value for the dissociation of the normal nickel(II)-GEDTA complex, NiY^{2-}, was $2.5_3\times10^{-3}\,sec^{-1}$. As has been discussed in the dissociation of $NiHY^-$ with reference to the dissociation of the nickel(II)-aspartate complex, if the normal complex, NiY^{2-}, also dissociates through the glycinate reaction intermediate, the dissociation-rate-constant ratio between the protonated and normal nickel(II)-GEDTA complexes should be approximately 1.4×10^2. Here, the electrostatic contribution to the stability of the reaction intermediate and the statistical factor are also taken into account. The observed ratio was 0.36. This is approximately 360 times smaller than that calculated on the basis of the simple glycinate reaction intermediate. The larger discrepancy between the observed and calculated ratios evidently implies that the stability of the reaction intermediate in the dissociation of NiY^{2-} is much greater than that of the simple glycinate reaction intermediate. Here, we can mention that the second protonation constant of the GEDTA anion ($pK_{a_3}=8.74$) is nearly identical to the protonation constants of $Ni(OH_2)_5(OH)^+$ ($\log K^{Ni-H}=9.0$).[9] This similarity in the two protonation constants strongly suggests the possibility of a hydrogen-bond formation between the water molecule coordinated to the nickel(II) ion and the free nitrogen donor atom of the GEDTA anion in the reaction intermediate. This internal hydrogen-bond formation within the reaction intermediate will effectively increase its stability and, thus, will give an enhanced rate constant. Therefore, it is reasonable to assume the following reaction intermediate (C) for the dissociation of NiY^{2-}. On the other hand, the tervalent GEDTA anion in the reaction intermediate of the dissociation of $NiHY^-$ has no such nitrogen donor atom available for the formation of a hydrogen bond with the coordinated water molecule. For this reason, the observed dissociation rate constant of $NiHY^-$ agrees well with

that calculated on the basis of a simple glycinate reaction intermediate.

The rate constant, $(k_d)^{H}_{ZnHY}$, for the proton-assisted dissociation of the protonated zinc(II)-GEDTA complex was determined to be 13.0 sec^{-1} from the slope of the linear relation between i_l^{-1} and $(1+1/K^{H}\cdot[H^+])/(\alpha_H)_Y^{1/2}$. By using the $(k_d)^{H}_{ZnHY}$ value thus determined, the rate constant for the formation of $ZnHY^-$ from Zn^{2+} and H_2Y^{2-}, $(k_f)_{ZnHY}$, was calculated to be 2.5$M^{-1}sec^{-1}$ with the aid of the relation $(k_f)_{ZnHY}=(k_d)_{ZnHY}\cdot K_{ZnY}\cdot K^{H}_{ZnY}\cdot K_3\cdot K_4$. The estimated $(k_f)_{ZnHY}$ value is very small as compared with the reported water exchange rate of the zinc(II) aquo complex, $k_{Zn}^{-H_2O}$, 5×10^7 sec^{-1}.[10] Genearlly, it is assumed that, in the formation of a metal complex in an aqueous solution, the metal ion and the ligand first diffuse together to form an outer-sphere complex, and that then a water molecule dissociates from the aquated metal ion and a donor group of the ligand coordinates with the metal ion. If the dissociation of the proton from the ligand is rapid enough, and if the water loss from the aquated metal ion is the rate-determining step, the formation-rate constant should be given by $K_{as}k_M^{-H_2O}$. Here, K_{as} means the association constant for the formation of an outer-sphere complex. Since the K_{as} value for the formation of the outer-sphere complex between Zn^{2+} and H_2Y^{2-} is considered to be larger than unity, if the formation of $ZnHY^-$ from Zn^{2+} and H_2Y^{2-} has a water-loss mechanism, the $(k_f)_{ZnHY}$ value should be larger than $5\times10^7M^{-1}sec^{-1}$. Sudmeier and Reilley have reported in their NMR study of the protonation of the GEDTA anion in an aqueous solution[11] that two nitrogen atoms of the divalent GEDTA anion, H_2Y^{2-}, are completely protonated. Although the small $(k_f)_{ZnHY}$ value obtained may be explained by assuming an alternative mechanism, it is also possible to interpret it by assuming that the reactive species in the complex formation of the divalent GEDTA anion with the zinc(II) ion is not the nitrogen-protonated GEDTA due to the blocking of the nitrogen atoms by the proton, but is the carboxylate-protonated H_2Y^{2-} isomer with a small equilibrium concentration, in which at least one of the two nitrogen atoms is deprotonated. Similar reactive species has been proposed for the reaction of the diprotonated EDTA anion with the nickel(II) ion.[12] As was suggested by Rabenstein,[10] the relative amount of the carboxylate-protonated H_2Y^{2-} species is calculated from the relative basicity of the nitrogen atom and that of the carboxylate oxygen group of GEDTA. Since the K_4 and K_1 values approximate the basicity of the nitrogen and carboxylate oxygen groups of the GEDTA anion, the relative amount of carboxylate-protonated species is approximated as 1×10^{-7}. This estimated value will explain satisfactorily the discrepancy between the observed $(k_f)_{ZnHY}$ value and the value calculated on the basis of the simple water-loss mechanism.

Equation (8) indicates that, at a constant pH, the slope and the intercept of the linear relation between the $(i_d-i_l)/i_l$ value and the concentration of uncomplexed GEDTA $[Y]_f$, should be $K_2^{HY}\cdot K_3/K^{1/2}\cdot t^{1/2}\cdot k_f^{1/2}\cdot[H^+]$ constant$_4$ and $1/K^{1/2}\cdot t^{1/2}\cdot k_f^{1/2}\cdot K^{H}_{CdY}\cdot[H^+]$ constant$_4$ respectively. By using the $1/K^{1/2}\cdot t^{1/2}\cdot k_f^{1/2}$ constant$_4$ value determined from the slope of the linear relation between the $(i_d-i_l)/i_l$ value and $1/[H^+]$, the slope and intercept were calculated as 9.6 and 4.0 respectively. The observed slope and intercept were 12.6 and 3.0. The agreement between the observed value and the calculated one can be regarded as satisfactory. This agreement also gives strong support to the reaction mechanism (V) proposed by the present authors. The formation constant of $CdHY^-$, K_{CdHY}, was estimated to be $10^{10.23}$ from the relation $K_{CdHY}(=[CdHY^-]/[Cd^{2+}][HY^{3-}])=K_{CdY}K^{H}_{CdY}K_4$. In sharp contrast to the finding observed in the nickel(II)-GEDTA system, this value is much greater than the first successive formation constant of the cadmium(II)-iminodiacetate ($10^{5.35}$) or -*N*-2-hydroxyethyliminodiacetate complex ($10^{7.21}$). This fact suggests that two iminodiacetate groups of the GEDTA anion are involved in the complex formation of $CdHY^-$. Therefore, it is reasonable to believe that the electroactive form, $CdHY^{-}$*, proposed in the dissociation reaction of the cadmium(II)-GEDTA complex is that resulting from the partial rupture of the cadmium(II)-GEDTA bonds in the $CdHY^-$. To describe the detailed structure of $CdHY^{-}$* precisely, further systematic investigations will be necessary.

Studies of Ethylenediamine-*N,N'*-diacetatocobalt(III) Complexes. III.[1] The Preparation and Identification of Ethylenediamine-*N,N'*-diacetatocobalt(III) Complexes with Ammonia, Pyridine, or Alkylamines as the Additional Ligand

Kashiro KURODA

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama, Ehime

(Received January 5, 1972)

A group of cobalt(III) complexes containing the tetradentate ethylenediamine-*N,N*-diacetate anion (EDDA) and ammonia, pyridine, or alkylamines have been derived from ethylenediamine-*N,N'*-diacetato(diaquo)cobalt-(III) perchlorate. Three different series among the complexes—(1) the aquo(amine) series, $[Co(EDDA)(H_2O)(am)]ClO_4$, (2) the *α-cis*-bis(amine) series, *α-cis*-$[Co(EDDA)(am)_2]ClO_4$, and (3) *β-cis*-$[Co(EDDA)(NH_3)_2]ClO_4$ as well as *β-cis*-$[Co(EDDA)(en)]ClO_4$, have been obtained, depending on the conditions of the reaction between the starting diaquo complex and the amines. Some properties of the complexes have been examined, and the geometrical configuration of each complex has been identified on the basis of the electronic absorption spectra and the proton NMR spectra. The coordination tendency of EDDA and the amines have also been discussed.

In contrast to the great many cobalt(III)-ammine and cobalt(III)-polyamine complexes which have been synthesized, the number of complexes in which monoamines coordinate to the metal ion is extremely small. Only a few types of complexes, such as $[Co(Cl)(amine)(en)_2]^{2+}$ and $[Co(amine)_2(en)_2]^{3+}$, have been prepared,[2] and in such complexes the amine is mostly a primary amine. The weaker tendency of the coordination of monoamines has been attributed to its basic character being larger than ammonia, although the character itself should promote the coordination. That is, in the substitution reaction of a starting complex, *e.g.*, $[Co(Cl)_2(en)_2]^+$, with an amine, a hydroxo-complex, *e.g.*, $[Co(Cl)(OH)(en)_2]^+$, is formed instead of the desired amine-complex (especially in the cases of the secondary and tertiary amines). Furthermore, cobalt-(III) complexes in general are relatively unstable in a basic solution and decomposition may occur during the substitution.

In the preceding report of this study,[3] it has been shown that ethylenediamine-*N,N'*-diacetato(diaquo)-cobalt(III) perchlorate, $[Co(EDDA)(H_2O)_2]ClO_4$, is a suitable starting complex for the preparation of various species of the Co(III)-EDDA series. Since EDDA is a strong chelating agent to the metal, and since the Co(III)-EDDA entity is stable enough in a basic solution, it has been considered to be worth examining the reaction between the diaquo-complex and various amines. Thus, the resulting complexes will be dealt with in this report. It will be shown that aquo(amine)-complexes or *α-cis* isomers of bis(amine)-complexes were obtained, depending on the reaction conditions, and that the *β-cis* isomer of the diammine complex was obtained by the reaction at 100°C. The *β-cis* diammine complex is the first example of a *β-cis* isomer in which two unidentates occupy the residual coordination sites of the Co(III)-EDDA complex.

Experimental

Materials, Analysis, Apparatus, and Measurements. Ethylenediamine-*N,N'*-diacetic acid (Dotite Reagents), alkylamines, and pyridine (Nakarai Chemicals), and all the other reagent-grade chemicals were used without further purification. The apparatus used and the procedures for the analysis and the measurements have been described in a preceding report.[3]

Preparations. *(1) Ethylenediamine-*N,N'*-diacetatoaquoamminecobalt(III) Perchlorate, $[Co(EDDA)(H_2O)(NH_3)]ClO_4$*: Into 5 m*l* of water, 0.5 g of ethylenediamine-*N,N'*-diacetato-(diaquo)cobalt(III) perchlorate[3] was dissolved, and then 1 m*l* of 6N ammonia was added. The mixture was stirred at 45°C until the first-formed blue precipitate disappeared, and then for a further 10 min. After one milliliter of 6N $HClO_4$ had been added, the mixture was cooled at 0°C. A violet precipitate thus formed was recrystallized from about 3 m*l* of warm water by the addition of a few drops of 6N $HClO_4$. Yield, 0.2 g.

Found: C, 19.22; H, 4.17; N, 11.11%. Calcd for $[Co(EDDA)(H_2O)(NH_3)]ClO_4 = CoC_6H_{15}O_9N_3Cl$ (367.59): C, 19.61; H, 4.11; N, 11.43%.

All the filtrates of the above procedure were combined and mixed with 1 m*l* of 6N ammonia and 0.1 g of active charcoal. Then the mixture was evaporated to dryness at ~45°C with the aid of an air stream. The residue was extracted with cold water and then with hot water. From the latter extract, bright reddish violet crystals appeared upon cooling. A few drops of 6N $HClO_4$ were added for complete precipitation. This is *α-cis*-$[Co(EDDA)(NH_3)_2]ClO_4 \cdot H_2O$. (A different procedure for the preparation of this complex has been described elsewhere.[3,4]) Yield, 0.2 g.

*(2) β-*cis*-Ethylenediamine-*N,N'*-diacetato(diammine)cobalt-(III) Perchlorate Monohydrate, β-*cis*-$[Co(EDDA)(NH_3)_2]ClO_4 \cdot H_2O$:*[5] One milliliter of 6N ammonia was added to a solution of the diaquo complex (0.5 g) in 3 m*l* of water. The blue solution, which contained a precipitate, was immersed in boiling water and then concentrated to nearly dryness with stirring. During this process, the precipitate soon disappeared and the solution turned red. After cooling, when the tarry product was stirred with a glass rod, crystals

5) This complex has been reported briefly in the following paper: K. Kuroda, *Chem. Lett.*, **1972**, 197.

deposited suddenly and the whole solidified. The product, after washing with methanol, was dissolved in 3 m*l* of warm (~50°C) water, and then the solution was filtered and cooled. A few drops of 6N $HClO_4$ were added for precipitation. Bright red crystals came out after a while. The product was washed with methanol and ether. Yield, 0.3 g.

Found: C, 18.75; H, 4.60; N, 14.67%. Calcd for $[Co(EDDA)(NH_3)_2]ClO_4 \cdot H_2O = CoC_6H_{18}O_9N_4Cl$ (384.62): C, 18.74; H, 4.72; N, 14.57%.

(3) Ethylenediamine-N,N'-*diacetatoaquopyridinecobalt(III) Perchlorate*, $[Co(EDDA)(H_2O)(py)]ClO_4$: In 10 m*l* of water, 0.2 g of the diaquo complex and 0.1 g of pyridine were dissolved, and then the mixture was evaporated at 45°C. During the evaporation red-violet crystals appeared. After the evaporation was complete, the residue was washed with methanol and then recrystallized from 10 m*l* of warm water with the addition of a few drops of 6N $HClO_4$. Yield, 0.2 g.

Found: C, 30.89; H, 3.91; N, 9.96%. Calcd for $[Co(EDDA)(H_2O)(py)]ClO_4 = CoC_{11}H_{17}O_9N_3Cl$ (429.66): C, 30.75; H, 3.99; N, 9.78%.

(4) α-cis-*Ethylenediamine*-N,N'-*diacetato(dipyridine)cobalt(III) Perchlorate Hemihydrate*, α-cis-$[Co(EDDA)(py)_2]ClO_4 \cdot 0.5H_2O$: In 10 m*l* of water, the diaquo complex (0.3 g), pyridine (0.3 g), and active charcoal (0.1 g) were mixed; the mixture was heated at ~50°C for 1 hr and then evaporated to ~2 m*l* with continuous stirring. The excess of pyridine was removed by mixing the product with ether several times. The resulting product, which contained crystals, was extracted with 15 m*l* of warm water, and a few drops of 6N $HClO_4$ were added to the extract. After standing for 1 hr, the red crystals were collected and washed with ethanol and ether. The product was recrystallized once more. Yield, 0.2 g.

Found: C, 38.30; H, 4.13; N, 11.33%. Calcd for $[Co(EDDA)(py)_2]ClO_4 \cdot 0.5H_2O = CoC_{16}H_{21}O_{8.5}N_4Cl$ (499.75): C, 38.45; H, 4.24; N, 11.21%.

(5) Ethylenediamine-N,N'-*diacetatoaquo(methylamine)cobalt(III) Perchlorate Monohydrate*, $[Co(EDDA)(H_2O)(mam)]ClO_4 \cdot H_2O$: To a solution of the diaquo complex (0.3 g) in 10 m*l* of water, 0.2 g of an aqueous solution of monomethylamine (30%) was added. The mixture turned from red-violet to blue, and then it gradually returned to red-violet. After the mixture had evaporated to dryness at 45°C, the residue was recrystallized from a small amount (~3 m*l*) of water with the addition of a few drops of 6N $HClO_4$. The product was washed with methanol and ether. Yield, 0.3 g.

Found: C, 20.93; H, 4.76; N, 10.80%. Calcd for $[Co(EDDA)(H_2O)(mam)]ClO_4 \cdot H_2O = CoC_7H_{19}O_{10}N_3Cl$ (399.63): C, 21.04; H, 4.79; N, 10.51%.

(6) α-cis-*Ethylenediamine*-N,N'-*diacetatobis(methylamine)cobalt(III) Perchlorate Monohydrate*, α-cis-$[Co(EDDA)(mam)_2]ClO_4 \cdot H_2O$: In 10 m*l* of water, 0.3 g of the diaquo complex, 1 g of aqueous methylamine (30%), and 0.1 g of charcoal were mixed, after which the mixture was evaporated to dryness at ~50°C. The residue was extracted with cold water (~3 m*l*), and then with warm (~60°C) water amounting about 30 m*l*. Bright violet-pink crystals appeared upon cooling. A few drops of 6N $HClO_4$ were added to complete the precipitation. The crystals were washed with methanol and ether. Yield, 0.3 g.

Found: C, 23.18; H, 5.15; N, 13.22%. Calcd for $[Co(EDDA)(mam)_2]ClO_4 \cdot H_2O = CoC_8H_{22}O_9N_4Cl$ (412.67): C, 23.28; H, 5.37; N, 13.58%.

(7) Ethylenediamine-N,N'-*diacetatoaquo(ethylamine)cobalt(III) Perchlorate Monohydrate*, $[Co(EDDA)(H_2O)(eam)]ClO_4 \cdot H_2O$: This complex was prepared in a manner analogous to that used for the aquo(methylamine)-complex (5), using an equivalent amount of ethylamine instead of methylamine. Violet crystals. Yield, 0.3 g.

Found: C, 22.60; H, 4.94; N, 9.91%. Calcd for $[Co(EDDA)(H_2O)(eam)]ClO_4 \cdot H_2O = CoC_8H_{21}O_{10}N_3Cl$ (413.66): C, 23.23; H, 5.11; N, 10.16%.

(8) α-cis-*Ethylenediamine*-N,N'-*diacetatobis(ethylamine)cobalt(III) Perchlorate*, α-cis-$[Co(EDDA)(eam)_2]ClO_4$: This complex was prepared in a way similar to that used for the bis(methylamine)-complex (6). Bright pink-violet crystals. Yield, 0.3 g.

Found: C, 27.65; H, 5.62; N, 13.25%. Calcd for $[Co(EDDA)(eam)_2]ClO_4 = CoC_{10}H_{24}O_8N_4Cl$ (422.71): C, 28.41; H, 5.72; N, 13.25%.

(9) Ethylenediamine-N,N'-*diacetatoaquo(*n*-propylamine)cobalt(III) Perchlorate Monohydrate*, $[Co(EDDA)(H_2O)(n\text{-}pam)]ClO_4 \cdot H_2O$: This complex was prepared in a way similar to that used for the aquo(methylamine)-complex (5). Since methanol dissolved the complex to some extent, ethanol was used for washing. Reddish-violet crystals. Yield, 0.3 g.

Found: C, 25.26; H, 5.39; N, 9.91%. Calcd for $[Co(EDDA)(H_2O)(n\text{-}pam)]ClO_4 \cdot H_2O = CoC_9H_{23}O_{10}N_3Cl$ (427.68): C, 25.28; H, 5.42; N, 9.83%.

(10) α-cis-*Ethylenediamine*-N,N'-*diacetatobis(*n*-propylamine)cobalt(III) Perchlorate*, α-cis-$[Co(EDDA)(n\text{-}pam)_2]ClO_4$: This complex was prepared in a way analogous to that used for the bis(methylamine)-complex (6). Pink-violet crystals. Yield, 0.3 g.

Found: C, 31.70; H, 6.15; N, 12.38%. Calcd for $[Co(EDDA)(n\text{-}pam)_2]ClO_4 = CoC_{12}H_{28}O_8N_4Cl$ (450.76): C, 31.98; H, 6.26; N, 12.43%.

(11) Ethylenediamine-N,N'-*diacetatoaquo(isopropylamine)cobalt(III) Perchlorate*, $[Co(EDDA)(H_2O)(i\text{-}pam)]ClO_4$: This complex was prepared from 0.5 g of the diaquo complex and 0.2 g of isopropylamine by a procedure similar to that used for the aquo(methylamine)-complex (5). The use of an exess of the amine made an unknown insoluble product, while in the preparations of the other aquo(amine)-complexes the quantity of amines was not so decisive as this case. Violet crystals. Yield, 0.2 g.

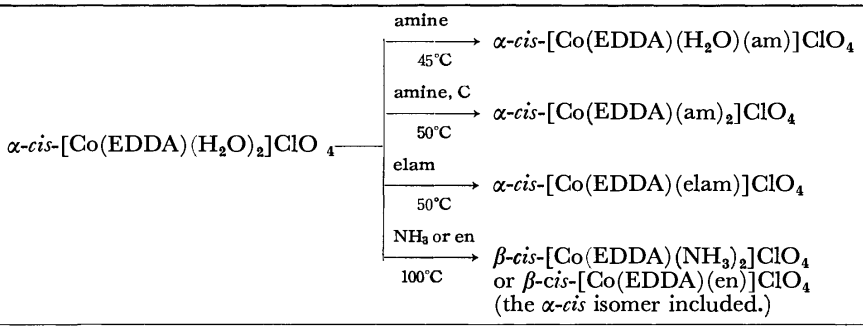
Found: C, 25.92; H, 5.06; N, 10.25%. Calcd for $[Co(EDDA)(H_2O)(i\text{-}pam)]ClO_4 = CoC_9H_{21}O_9N_3Cl$ (409.67): C, 26.39; H, 5.15; N, 10.26%.

(12) Ethylenediamine-N,N'-*diacetato(ethanolamine)cobalt(III) Perchlorate*, $[Co(EDDA)(elam)]ClO_4$: A mixture of the diaquo complex (0.5 g) and ethanolamine (0.2 g) in 10 m*l* of water was evaporated to nearly dryness at 50°C. The mixture turned from blue to a dark reddish-violet during the process. The tarry residue was dissolved in 4 m*l* of water; after filtration, 6N $HClO_4$ was added till the mixture became more reddish. Crystals appeared gradually when the wall of the vessel was rubbed. After about 5 hr, the violet crystals were recrystallized from a small amount of water by the addition of a few drops of 6N $HClO_4$. Yield, 0.4 g.

Found: C, 24.47; H, 4.32; N, 10.71%. Calcd for $[Co(EDDA)(elam)]ClO_4 = CoC_8H_{17}O_9N_3Cl$ (393.63): C, 24.41; H, 4.35; N, 10.68%.

(13) β-cis-*Ethylenediamine*-N,N'-*diacetato(ethylenediamine)cobalt(III) Perchlorate*, β-cis-$[Co(EDDA)(en)]ClO_4$: This complex was first prepared by Legg and Cooke.[4] They separated this isomer from the α-*cis* isomer by means of ion-exchange chromatography; this took a long time, and the yield was very low. The following procedure, which is similar to that used for the β-*cis* isomer of the diammine complex (2), is very simple and gives a higher yield. A vessel containing a mixture of the diaquo complex (0.5 g) and ethylenediamine hydrate (0.1 g) in 3 m*l* of water was immersed in boiling water, and the solution was concentrated to nearly dryness. The tarry evaporation product was extracted by 5 m*l* of

TABLE 1. PREPARATION SCHEME OF Co(III)-EDDA-AMINE COMPLEXES
(The water of crystallization is omitted.)



water, and the orange extract, after the addition of a few drops of 6N $HClO_4$, was placed in a refrigerator overnight. The deposit thus formed was recrystallized from 3 m*l* of water, and then washed with methanol and ether. Yield, 0.2 g. The less soluble red residue of the extraction consisted of the *α-cis* isomer. Upon recrystallization from 20 m*l* of warm water, it was purified easily. Yield of the *α-cis* isomer, 0.2 g.

Results and Discussion

Preparation Procedures. The general scheme of the preparations in this study is shown in Table 1. The diaquo complex, $[Co(EDDA)(H_2O)_2]ClO_4$, was used as the starting complex, and all of the complexes were derived by the substitution of the coordinated water with various amines under different conditions. The merit of this preparation procedure has been discussed previously.[3]

As has been described in the preceding section and the Table, the aquo(amine) complexes occurred at relatively low temperatures (~45°C) without charcoal, the *α-cis* isomers of the bis(amine) complexes at low temperatures with charcoal, and the *β-cis* isomers, although the only two species were isolated, at high temperatures (~100°C). It was presumed at the beginning of this study that the coordination mode of EDDA depended on the temperature and that the *α-cis* mode was more stable than the *β-cis* and *trans*; therefore, the occurrence of the *β-cis* isomers needed a heat of rearrangement and, hence, a higher temperature.[3] The preparations were attempted on these assumptions; they were verified to some extent by the isolation of the *β-cis* isomers of the diammine and the ethylenediamine complexes.

The preparation of the complexes containing a secondary amine or a tertiary amine was also attempted in a similar way. The red-violet color of the starting diaquo complex changed to blue and then returned to reddish, as in the cases of the preparation of the primary amine complexes. However, no desired complex has been isolated so far. Since the color change suggests the coordination of the amines in solution, attempts at isolation are still being continued.

Electronic Absorption Spectra. Table 2 and Figs. 1—4 show the electronic absorption spectra of the complexes studied. In the case of the bis(amine) complexes, the *α-cis* isomers are of the *trans(O)*-$[CoN_4O_2]$-type, whereas the *β-cis* and *trans* isomers belong to the *cis(O)*-$[CoN_4O_2]$-type. It has been well-established, both experimentally and theoretically, that the *trans(O)* isomers exhibit a largely split first band, while the *cis(O)* isomers show a more intense, nearly symmetrical first band.[6] As may be seen in Figs. 1 and 2, all the

bis(amine) complexes show a first band which is apparently composed of two components, and the spectra closely resemble those of such well-known complexes as *trans*-[Co$(CH_3CO_2)_2(NH_3)_4]^+$,[7] *trans*-[Co$(CH_3CO_2)_2$(en)$_2]^+$,[7] α-*cis*-[Co(EDDA)$(NH_3)_2]^+$, and α-*cis*-[Co(EDDA)(en)]$^+$.[3,4] Therefore, the configuration of the bis(amine) complexes is α-*cis*, without any question. Some trends are observable in the spectra of the isomers; the maxima of both the first and the second bands shift slightly to a lower wave number, and the intensities of the bands increase with the increase in the methylene number in the amines. It may be estimated that the ligand field strength of amines decreases with the enlargement of the amines, and that the enlargement decreases the symmetry of the complexes and, hence, makes the intensity larger.

The spectra of the aquo(amine) complexes are similar to one another. Again, with the increase in methylene in the amines, the maxima of the first and the second bands shift to a lower wave number and the absorption intensity increases, although a few cases of the reverse are included.

The spectrum of the β-*cis* isomer of the ethylenediamine complex has already been reported by Legg and Cooke.[4] The spectrum of the isomer which was prepared by the present procedure agreed with their spectrum except for slight differences in the ε values. The spectrum of the red isomer of the diammine complex closely resembles that of the β-*cis* ethylenediamine

7) K. Kuroda and P. S. Gentile, This Bulletin, **38**, 1368 (1965).

complex, as may be seen in Fig. 2. The ethylenediamine complex can exist only as the α-*cis* or the β-*cis* isomer; therefore, the similarity indicates that the configuration of the diammine complex is the β-*cis* and not the *trans*.

Infrared Spectra. The infrared spectra were supplementally used to confirm the structure of the complexes prepared. All of the complexes showed a strong fairly broad absorption around 1650 cm^{-1}, the CO-stretching region. The lack of absorption between 1700—1800 cm^{-1} indicates that the carboxyl groups of EDDA certainly coordinate to the central cobalt and are not present as free-acid.[8] Another strong absorption was observed around 1080 cm^{-1}, the absorption of the perchlorate ion. It is, thus, certain that the aquo(amine) complexes are cationic and not the hydroxo(amine) species. (This is natural, since the complexes were precipitated in an acid medium with perchloric acid.)

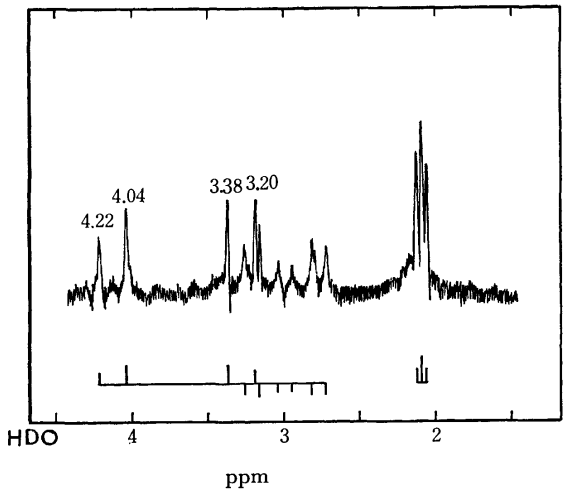

Fig. 5. PMR Spectrum of α-*cis*-$[Co(EDDA)(mam)_2]ClO_4$ in D_2O.

Proton Nuclear Magnetic Resonance Spectra. In the α-*cis* isomer of a bis(amine) complex, the two glycinate rings of EDDA are equivalent and only one AB quartet pattern due to the glycinate ring protons can be expected. In fact, such simple absorptions have been previously observed in several α-*cis* isomers of the Co(III)-EDDA system, *e.g.*, $[Co(EDDA)(NH_3)_2]^+$,[4] $[Co(EDDA)(H_2O)_2]^+$,[3] $[Co(EDDA)(ox)]^-$,[9] and $[Co(EDDA)(N_3)_2]^-$.[1] Figure 5 illustrates the PMR spectrum of α-*cis*-$[Co(EDDA)(mam)_2]ClO_4$ in D_2O as an example. As may be seen in the figure, the absorptions can be divided into three groups—one AB quartet due to the glycinates, a symmetrical absorption from the ethylene backborn protons, and a sharp triplet due to the methyl groups in the coordinated amines. The appearance of the triplet can be attributed to the spin-spin coupling with the amino protons which had not completely exchanged with deuterium at the time of the measurement. Thus, the assignment of the α-*cis* isomers is supported by the PMR spectra.

In the cases of the β-*cis* isomers, the two glycinates are not equivalent and a more complicated absorption pattern can be expected. Legg and Cooke[4] first measured the PMR spectrum of β-*cis*-$[Co(EDDA)(en)]^+$ and observed a single strong absorption due to the protons of glycinate coplanar with the ethylene ring. Legg and his co-workers[10] extended such an observation to the other β-*cis* isomers, such as those of $[Co(EDDA)(ox)]^-$ and $[Co(EDDA)(mal)]^-$; in order to explain the singlet absorption, they indicated that the two protons in the in-plane glycinate are located at magnetically very similar situations. Thus, the appearance of the strong singlet is a remarkable characteristic of the β-*cis* isomers. In Fig. 6, the PMR spectra of the α-*cis* and the β-*cis* isomers of the diammine complex are shown. In contrast to the relatively simple pattern of the α-*cis* isomer, the β-*cis* isomer exhibits an intense absorption as well as the AB quartet of the out-of-plane glycinate protons and the absorptions of the ethylene backborn protons with an unsymmetrical feature.

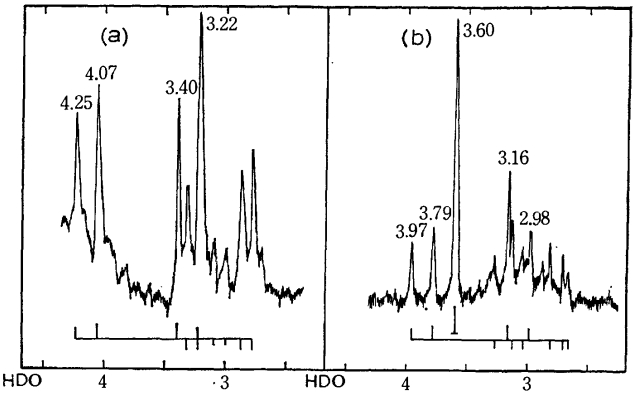

Fig. 6. PMR Spectra of $[Co(EDDA)(NH_3)_2]ClO_4$ in D_2O.
(a) α-*cis* isomer, (b) β-*cis* isomer

The aquo(amine) complexes are considered to have the α-*cis* configuration, since one of the coordinated water molecules of the starting α-*cis* diaquo complex was replaced at a relatively low temperature and since further substitution at that same temperature gave the α-*cis* bis(amine) complexes, as has been discussed above. Even in the α-*cis* configuration, however, the two glycinate rings are not equivalent in these complexes because of the coordination of the two different molecules as the additional ligands. Thus, as may be seen in Fig. 7, two sets of an AB quartet are observable; this is in accordance wih the expected configuration. From a comparison of the spectrum with those of the α-*cis* diammine and diaquo complexes, the quartet of the lower field can be assigned to the glycinate protons near the coordinated ammonia.

In all the AB quartets of the out-of-plane glycinate protons, the differences in the chemical shifts, δ_{AB}, are in the range of 0.80—0.87 ppm and the coupling constants, J_{AB}, are 18 Hz; these values are in good

accordance with those previously obtained in the other Co(III)-EDDA complexes.

Ethanolamine Complex. Ethanolamine may be a unidentate or a bidentate, and as a bidentate it may be a neutral (as NH_2–CH_2–CH_2–OH) or an uninegative (as NH_2–CH_2–CH_2–O^-) ligand.[11] Therefore, the coordination of the ligand in the ethanolamine complex (12) is worth considering. Although the complex was prepared by a procedure similar to those used for the aquo(amine) complexes, it is certain that the complex is not the aquo(ethanolamine) complex, because the calculated composition for the aquo(ethanolamine) complex disagrees more than the limits of experimental error with the analytical results. (For example, C is 23.34% for the aquo(ethanolamine) complex against the experimental value of 24.47%.) The coordination of ethanolamine as a bidentate is supported further by its absorption spectrum, which is considerably different from those of the aquo(amine) complexes, as may be seen in Figs. 3 and 4. That is, both the first and the second bands are broad and the intensities are considerably lower than those of the aquo(amine) complexes. These characteristics may indicate that the central cobalt ion is surrounded by a different field from that of the aquo(amine) complexes.

As is indicated in Fig. 4, however, the spectrum of the ethanolamine complex changed slightly upon the addition of perchloric acid, while there was no change in those of the aquo(amine) complexes. In the basic solution, both the aquo(amine) and the ethanolamine complexes, as well as the diaquo complex, exhibited different spectra from those in neutral water. These facts indicate that the hydroxy proton in the ethanolamine complex is more dissociative than that of the coordinated water, and that the complex exists partly in the form of $[Co(EDDA)(NH_2–CH_2–CH_2–O)]$ in water. This conclusion is consistent with the low pH value of the aqueous solution which contains nothing but the complex (3.94 in a 0.0025 molar solution).

Finally, the coordination of EDDA in this complex is considered to be of the *α-cis* mode. The complex was prepared from the *α-cis* diaquo complex at low temperatures (~50°C), as were the *α-cis*-aquo(amine) and *α-cis*-bis(amine) complexes; no sign of the rearrangement of the coordinated EDDA was observed during the reaction. The assignment is supported by the relatively low intensities of its absorption maxima. (The ε_1's of the *β-cis* isomers prepared so far are all over 150, possibly because of the highly unsymmetric structure of the isomers.) The PMR spectrum also showed no characteristic indicating that the complex had the *β-cis* configuration.

ESR of Hot Ions: Zn(I), Cd(I), and Hg(I) in γ-Irradiated Potassium Tetracyano Zincate(II), Cadmate(II), and Mercurate(II)

Jun-Ichi Isoya and Shizuo Fujiwara

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received July 6, 1971)

It is known that X-ray or γ-ray irradiation of inorganic complexes produces hot ions which have lower valence states than the original ones and yet are sited in the regular crystalline array of the undamaged mother complexes. ESR study reveals that the hot ions of paramagnetic Zn(I), Cd(I), and Hg(I) complexes are formed by γ-irradiation of $K_2[Zn(CN)_4]$, $K_2[Cd(CN)_4]$, and $K_2[Hg(CN)_4]$, respectively. Hyperfine structures of the ESR signals shows that the Zn(I) and Cd(I) complexes have C_{3v} symmetry instead of T_d symmetry of the original complex, and Hg(I) complex has a slightly distorted C_{3v} symmetry. In Zn(I) complex, one of the four symmetry axes along Zn(II)–CN bondings is stretched. This occurs evenly with respect to each axis, resulting in the formation of four sites of the electron spins. For Cd(I) complexes, four species are produced as an irradiation product, where each species has four sites which are axially symmetric with respect to any one of the four Cd(II)–CN bondings. In Hg(I) complex, there exist twenty-four sites and the symmetry axis of each site lies along a direction slightly deviated from the original Hg(II)–CN bonding. From the behavior of the decay of ESR signal intensity at liquid nitrogen temperature, it is concluded that the stability is in the order Hg(I)>Cd(I)>Zn(I).

X-ray or γ-ray irradiation of diamagnetic substances results in the production of ESR active paramagnetic centers. It has been found that the central metal ions are reduced to the lower valence state in the case of X-ray or γ-ray irradiated Co(III) or Pd(II) complexes.[1-5] These metastable paramagnetic centers have been referred to as hot ions[5] because they are hot (unstable) in the sense that the valence state differs from that of the original complex and yet they are sited in the host lattices of the original complex.

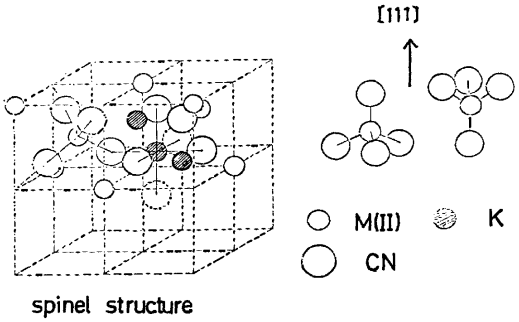

Fig. 1. Crystal structure of $K_2[Zn(CN)_4]$, $K_2[Cd(CN)_4]$, and $K_2[Hg(CN)_4]$.
$M(II)(CN)_4$ forms a regular tetrahedron with four M(II)-CN bondings aong [111], [1$\bar{1}\bar{1}$], [$\bar{1}$1$\bar{1}$], and [$\bar{1}\bar{1}$1].
The figure of spinel structure is quoted from E.W. Gorter *Philips Res. Repts.* **9**, 295, (1954).

Since Zn(II), Cd(II), and Hg(II) ions are formed of closed *d*-shell, the reduced ions Zn(I), Cd(I), and Hg(I) are expected to have an unpaired electron of large *s*-character. No report has so far been found with regard to the presence of stable complex of Zn(I). The only example reported is of $Cd_2[AlCl_4]_2$. However, as it is a diamagnetic diatomic ion,[6] no ESR signal is expected. The situation is the same with all stable Hg(I) salts such as Hg_2Cl_2. The existence of paramagnetic Zn(I) and Cd(I) ions was evidenced in the γ-ray irradiated frozen solutions of Zn(II) or Cd(II) salts.[7,8] ESR was observed with Cd(I) ion which was isolated in the matrix of rare gas.[9] All the systems referred to in literature are amorphous with respect to the host lattices, and not crystalline. We carried out ESR investigation with single crystals of Zn(II), Cd(II), and Hg(II) complexes. Formation of hot ions of paramagnetic Zn(I), Cd(I), and Hg(I) by γ-ray irradiation was evidenced. The total dose of γ-rays was made to not exceed the magnitude with which the host lattices are destroyed. It is expected that the metastable M(I) complexes are formed in the mother compounds, where M(I) refers to either one of Zn(I), Cd(I), or Hg(I). It will be shown that the crystal fields of the M(I) ions still keep the symmetry properties of the mother compounds fairly well. The location of the electron spins and the bonding nature of Zn(I), Cd(I), and Hg(I) ions are elucidated. It should be noted that the hot ions can be used for making possible ESR investigation of diamagnetic inorganic complexes which are normally ESR insensitive.

Experimental

Compounds investigated were potassium tetracyanozincate(II) $K_2[Zn(CN)_4]$, potassium tetracyanocadmate(II) $K_2[Cd(CN)_4]$, and potassium tetracyanomercurate(II) $K_2[Hg(CN)_4]$. Single crystals of $5\times10\times10$ mm^3 are easily obtained by slow evaporation of aqueous solution. They exihibit the faces of the octahedron (111), generally tabular in habit. Dickinson[10] confirmed that $K_2[Zn(CN)_4]$, $K_2[Cd(CN)_4]$, and $K_2[Hg(CN)_4]$ have a spinel structure with the tetrahedral

complex ion $[M(II)(CN)_4]^{2-}$. The direction of the four M(II)–CN bondings in the tetrahedral complex ion are parallel to the crystallographic axes [111], [1$\bar{1}\bar{1}$], [$\bar{1}$1$\bar{1}$], and [$\bar{1}\bar{1}$1]. The neutron diffraction study by Sequeira and Chidambaram[11] confirmed that $[Zn(CN)_4]^{2-}$ forms a regular tetrahedron.

The crystals and powder samples were exposed to γ-rays from a ^{60}Co source in a vacuum ($\sim$1 mmHg) or nitrogen atmosphere with a dose rate of 5×10^4 R/hr for 20 hr at 77°K. After irradiation, ESR spectra were recorded at 77°K by a JEOL 3BS X-band spectrometer and a JEOL SK-1 K-band spectrometer using 100 kHz field modulation. On irradiation, the color of the crystals turned reddish orange (Zn), yellow (Cd), and orange (Hg). When the crystals were taken out of the liquid nitrogen Dewar vessel into the air, the color diminished rapidly and the ESR signals of M(I) complexes disappeared. Single crystals were attached to a glass or Teflon rod, and irradiated by γ-rays in a liquid nitrogen Dewar vessel. After irradiation they were transferred immediately to another Dewar vessel for ESR measurements. Powders were sealed in one end of a quartz tube and subjected to irradiation. After irradiation, the tube was quickly turned upside down, the sample being transferred to the other end which had been protected from irradiation. ESR measurements were performed twice, first with the sample in the γ-ray irradiated end and then in the other non-irradiated end. In the first measurement, the doublet signal of H atom observed beside the signal of hot ions was used as the reference for the field sweep caliblation. The H atom is assumed to have been produced by irradiation in the quartz tube. Inversion of the sample tube was carried out as quickly as possible to make the decrease of the signal intensity negligible.

Results and Discussion

The spectra of γ-irradiated powder $K_2[Zn(CN)_4]$, $K_2[Cd(CN)_4]$, and $K_2[Hg(CN)_4]$ are shown in Figs. 2—5, where signals of radicals (central sharp line) and metal complexes can be seen. The latter was mainly examined. All the spectra show hyperfine structures of fairly large splitting constants, g value of about 2 and isotropic and small linewidth. The results can be interpreted in terms of the electronic configuration of $nd^{10}(n+1)s^1$ (n=3, 4, and 5 for Zn, Cd, and Hg, respectively). Thus the products of γ-irradiation are the cyano complex of Zn(I), Cd(I), and Hg(I). The location of the electron spin in the outer shell was investigated. Two locations are possible, spherical isotropic distribution in the outermost s shell and that confined in any one of the four metal-cyano bondings. The crystal structure of the mother compounds is of the spinel type. If the structure of tetrahedron symmetry of the mother compound is maintained and the electronic distribution is completely spherical in $[M(I)(CN)_4]^{3-}$, a simple spectrum of a single line or of hyperfine structure is expected. No angular de-

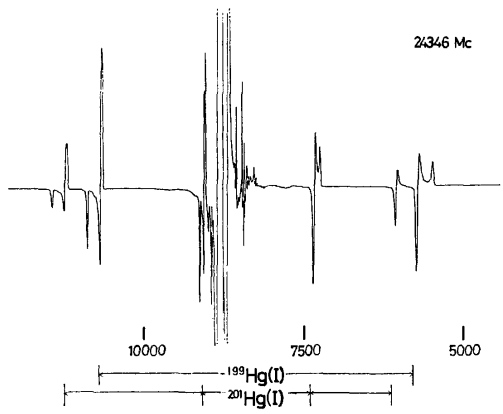

Fig. 5. The powder spectrum of γ-irradiated $K_2[Hg(CN)_4]$. (K-band, 100 kHz field modulation, at 77°K)
Full hyperfine structure can be observed at this frequency. The large hyperfine structure constants shift the apparent g-value far away from the position of $g=2$. The shoulder in the perpendicular line in the high field shows a slight deviation from axial symmetry.

pendence is expected with respect to the spectrum of single crystal samples. The results show angular dependence eliminating the spherical distribution of spins, and suggest that M(I) ions are in C_{3v} field. Namely, the electron spins in $[M(I)(CN)_4]^{3-}$ occupy the outermost s orbital but are confined in one of the four bondings. Detailed results will be given in the following.

(1) γ-Irradiated $K_2[Zn(CN)_4]$. The spectrum consists of a single strong line ($g=2$) and six satellite lines (the spectrum of this structure will be referred to as a set). The satellites are attributed to the isotope of ^{67}Zn ($I=5/2$) with a natural abundance of 4.11%. The intensity ratio of satellites to the central signal agrees with the abundance ratio of isotopes.

The single crystal shows a spectrum of four sets which suggests the coexistence of four sites for the distribution of electron spin. Angular variation cannot be seen distinctly with respect to the g value, but clearly with A values. Hence, the symmetry of Zn(I) complexes is fairly accurately determined by an examination of the angular dependence of hyperfine structure. An example of a γ-irradiated single crystal of $K_2[Zn(CN)_4]$ being rotated around [111] axis which is perpendicular to the static magnetic field is shown in Fig. 6. During the rotation, the crystallographic face [111] preserved the direction parallel to the magnetic field, in which one site is invariant and the relation of the remaining three sites displays threefold rotational

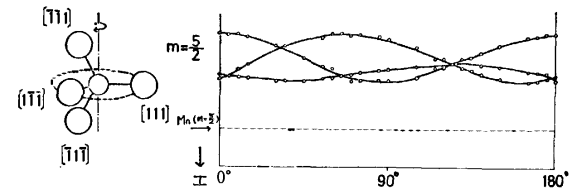

Fig. 7. Anglar dependence of hyperfine structure lines of γ-irradiated single crystal of $K_2[Zn(CN)_4]$ with $[0\bar{1}1]\perp H$. In this rotation, [111] and $[1\bar{1}\bar{1}]$ varies from 0° to 90° against H. The largest splitting occurs where one of these two axis is parallel to H. The samllest splitting occurs where H becomes perpendicular to Zn(II)-CN direction.

symmetry with respect to the [111] axis. The results of the rotation $[0\bar{1}1]$ axis perpendicular to the static field are given in Fig. 7. The crystal rotates with the [111] face parallel to the rotational axis. Two sites show the same variation with an interval of the tetrahedral angle and the other two are found to be equivalent. At the positions of the crystal where the static field bisects the tetrahedral angles, four sites of lines collapse into one.

It is to be noted that if g-tensor and A-tensor of Zn(I) are (within experimental error) axially symmetric along the Zn–CN bond of the original complex ion $[Zn(CN)_4]^{2-}$, the angular dependence of its ESR spectrum can be readily inferred. When one of the four Zn(II)–CN directions in the host crystal, [111], $[1\bar{1}\bar{1}]$,

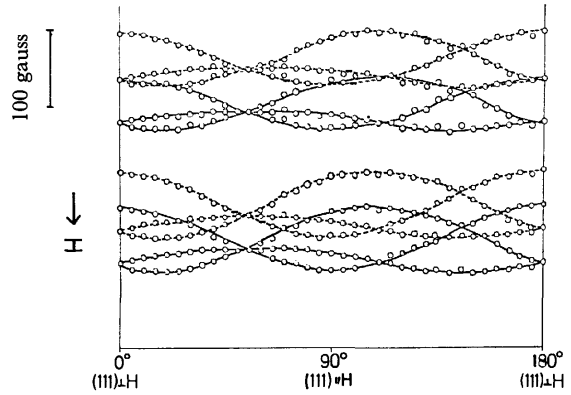

Fig. 9(a). Angluar dependence of hyperfine structure lines of γ-irradiated single crystal of $K_2[Cd(CN)_4]$ with rotation with $[0\bar{1}1]\perp H$ (the lines in the low field).

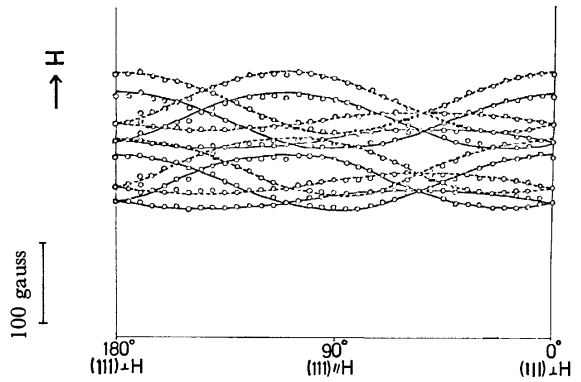

Fig. 9(b). Angular dependence of hyperfine structure lines of γ-irradiated single crystal of $K_2[Cd(CN)_4]$ with rotation with $[0\bar{1}1]\perp H$ (the lines in the higher field).

$[\bar{1}\bar{1}1]$, and $[\bar{1}1\bar{1}]$, is parallel to the static field, the corresponding site shows the largest splitting. The smallest splitting occurs when one of the axes is perpendicular to the static field. It is thus concluded that the paramagnetic Zn(I) complex is axially symmetric with respect to the symmetry axis along Zn(II)–CN bonding of the host lattice. Since each Zn(II)–CN bonding coincides with the threefold symmetry axis in the original complex $[Zn(CN)_4]^{2-}$, it is probable that the Zn(I) complex has C_{3v} symmetry instead of T_d symmetry. As the four Zn(II)–CN bondings are equivalent in the original complex $[Zn(CN)_4]^{2-}$, the location of the spin is assumed to be of equal probability with respect to all four bondings. Hence, in the Zn(I) complex produced by γ-ray irradiation, one of the Zn(II)–CN directions becomes the unique axis, and such a distortion is assumed to occur evenly with respect to the four bondings. Thus the symmetry is lowered from T_d to C_{3v}. The signal intensities indicate that four sites are produced in an equal quantity.

ESR parameters are calculated by the following spin Hamiltonian:

$$\mathcal{H}=\beta\mathbf{S}\cdot\mathbf{G}\cdot\mathbf{H}+\mathbf{S}\cdot\mathbf{A}\cdot\mathbf{I} \qquad (1)$$

In the case of $[Zn(I)(CN)_4]^{3-}$, the high field approximation is adopted satisfactorily. Under conditions where the g-tensor and A-tensor are axially symmetric about the same axis, the solution of the spin Hamiltonian has been given by Abragam and Bleany.[12]

$$h\nu=g\beta H+Km+\frac{B^2}{4g\beta H}\left(\frac{A^2+B^2}{K^2}\right)\{I(I+1)-m^2\}+\frac{1}{2g\beta H}\left(\frac{A^2-B^2}{K}\right)\left(\frac{g_{//}-g_\perp}{g^2}\right)\sin^2\theta\cos^2\theta m^2 \qquad (2)$$

$$K^2g^2=A^2g_{//}^2\cos^2\theta+B^2g_\perp^2\sin^2\theta \qquad (3)$$

($S=1/2$, $I=5/2$, quadrupole term is not taken into account.)

Using Eq. (2), we obtain for $[^{67}Zn(I)(CN)_4]^{3-}$:

$g_{//}=2.000\pm0.005$ $\quad g_\perp=1.999\pm0.005$
$A=131\pm1$ gauss $\quad B=110\pm1$ gauss

For $[Zn(I)(CN)_4]^{3-}$ of zinc isotopes with no nuclear spin we get:

$g_{//}=2.001\pm0.005$ $\quad g_\perp=1.999\pm0.005$

(2) γ-Irradiated $K_2[Cd(CN)_4]$. Of the stable isotopes of cadmium, two isotopes, ^{111}Cd ($I=1/2$, natural abundance 12.86%) and ^{113}Cd ($I=1/2$ natural abundance 12.34%), possess nuclear spins. In accordance with the constitution of isotopes, the ESR spectrum of the irradiated compound shows two sets of hyperfine lines. One set with larger splitting refers to that of ^{113}Cd which has a larger absolute value of magnetic moment. The signals of the isotopes of zero nuclear spin cannot clearly be distinguished from those of radicals.

We see from the spectrum of powdered sample (Fig. 3) that four different species of the Cd(I) complexes are produced for each isotope. These species are denoted by A, B, C, and D in decreasing order of magnitude of hyperfine splitting. Each species differs with regard to the value of hyperfine splitting, signal intensity, behavior of the decay at 77°K and linewidth.

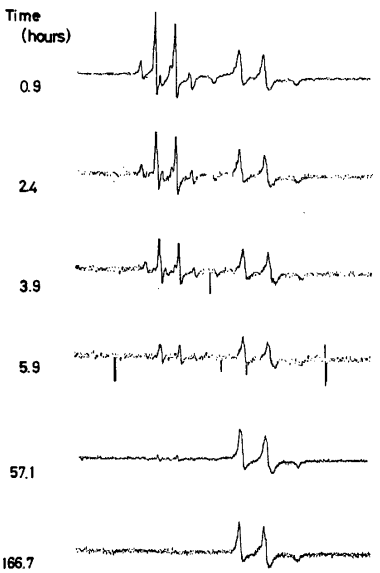

Fig. 10. Decay behaviour of Cd(I) complex (powder, non-degassed, at 77°K)
Intensities are almost normalized by Mn^{2+} signal present in the sample. Species A is sable at this temperature. Other species decay into nothing.

12) A. Abragam and B. Bleany, "Electron Paramagnetic Resonance of Transition Ions.," Clarendon Press, Oxford (1970), p. 173.

Immediately after irradiation, the signal intensity of each species is in the order C>A≫B~D. The intensity of B and D is very small. At 77°K, B, C, and D decay with the half-life of about 1/2 day. A which shows the largest hyperfine splitting is stable at this temperature in non-degassed sample. The decay behavior is shown in Fig. 10.

The number of sites and the symmetry of the Cd(I) complexes were determined by single crystal spectra. The results of experiments where γ-irradiated single crystal of $K_2[Cd(CN)_4]$ was rotated around the [111] axis and the [0$\bar{1}$1] axis perpendicular to the static magnetic field are given in Figs. 8 and 9, respectively. Measurements of the ESR spectra of B and D could not be carried out owing to the weakness of intensity. The angular dependence of these species is assumed to be similar to that of A and C in the whole range of rotation. This is confirmed by the fact that at the direction where the four sites of A and C merge in one, four sites of B and D also collapse in one. We thus assume that the number of sites and the angular variation of each species are the same except for the magnitude of the splitting. The same is assumed to hold for Zn(I) complex. Thus the hyperfine spectrum of Cd(I) consists of 2 (isotopes) $\times$4 (species) $\times$4 (sites). Each species has four sites axially symmetric with respect to the Cd(II)–CN direction in the host lattice, [111], [1$\bar{1}\bar{1}$], [$\bar{1}$1$\bar{1}$], and [$\bar{1}\bar{1}$1]. The paramagnetic Cd(I) complex is stretched along the symmetry axis (z-axis) which is parallel to any one of the four Cd(II)–CN directions in the host lattice. It was thought that the reduction of Cd(II) to Cd(I) might accompany the distortion of the mother complex, particularly that along the Cd(II)–CN bonding. As in the case of $K_2[Zn(CN)_4]$, γ-irradiation produced Zn(I) ion with C_{3v} symmetry. We assume that this holds with Cd(I), but in this case four species are produced. We take it for granted that the distortion occurs along Cd(II)–CN bonding with four different magnitudes in each Cd(II)–CN direction, resulting in the formation of the four species.

The parameters of ESR hyperfine spectrum are calculated for A and C by Eq. (1). For both isotopes ^{111}Cd(I) and ^{113}Cd(I), $S=1/2$ and $I=1/2$. In this case, the hyperfine splitting is too large for application of high field approximation. If the principal axes of the g- and A-tensors are taken to be parallel and the static magnetic field parallel to one of the principal axes, Eq. (1) can be exactly solved. With axial symmetry, the Hamiltonian becomes simpler. The method for $S=1/2$ and $I=1/2$ has been developed.[13]

The strongly allowed transitions under the experimental conditions are as follows. For the case of H parallel to the z-axis (symmetry axis), we have

$$\begin{aligned} h\nu &= \frac{1}{2}g_{//}\beta H_1 + \frac{1}{2}A + \frac{1}{2}[(g_{//}\beta H_1)^2 + B^2]^{1/2} \\ h\nu &= \frac{1}{2}g_{//}\beta H_2 - \frac{1}{2}A + \frac{1}{2}[(g_{//}\beta H_2)^2 + B^2]^{1/2} \end{aligned} \quad (4)$$

For the case of H perpendicular to the z-axis, we have

$$\begin{aligned} h\nu &= \frac{1}{2}\left[(g_{\perp}\beta H_1)^2 + \left(\frac{A-B}{2}\right)^2\right]^{1/2} + \frac{1}{2}B + \frac{1}{2}\left[(g_{\perp}\beta H_1)^2 + \left(\frac{A+B}{2}\right)^2\right]^{1/2} \\ h\nu &= \frac{1}{2}\left[(g_{\perp}\beta H_2)^2 + \left(\frac{A-B}{2}\right)^2\right]^{1/2} - \frac{1}{2}B + \frac{1}{2}\left[(g_{\perp}\beta H_2)^2 + \left(\frac{A+B}{2}\right)^2\right]^{1/2} \end{aligned} \quad (5)$$

Taking the difference in each two equations of Eqs. (4) and (5), the hyperfine splitting constants A and B are connected to the observed magnetic field values H_1 and H_2. The difference between the observed separation H_2-H_1 and the true hyperfine splitting constants A and B becomes smaller at higher microwave frequency. First, with the use of an approximate value of B for the observed separation in the K-band powder spectrum, Eq. (4) and the single crystal data with z-axis parallel to H give an approximate value of A. Due to the nearly isotropic nature of g-value, calculation is easy. With the use of the A value thus obtained and the observed value of the magnetic field for the single crystal spectrum with z-axis perpendicular to H as well as Eq. (5), a more appropriate value of B is obtained. This process is repeated until the values of A and B become consistent within experimental error. Next, $g_{//}$ and $g_{\perp}$ are calculated with the use of A and B thus obtained. The results are as follows.

Species A for ^{113}Cd (I)
$g_{//}=1.99\pm0.01$ $g_{\perp}=1.998\pm0.005$
$A=(1.58\pm0.01)\times10^3$ gauss
$B=(1.47\pm0.01)\times10^3$ gauss
for ^{111}Cd (I)
$g_{//}=1.99\pm0.01$ $g_{\perp}=1.998\pm0.005$
$A=(1.52\pm0.01)\times10^3$ gauss
$B=(1.40\pm0.01)\times10^3$ gauss
Species C for ^{113}Cd (I)
$g_{//}=2.00\pm0.01$ $g_{\perp}=1.986\pm0.005$
$A=(1.37\pm0.01)\times10^3$ gauss
$B=(1.23\pm0.02)\times10^3$ gauss
for ^{111}Cd (I)
$g_{//}=2.00\pm0.01$ $g_{\perp}=1.986\pm0.005$
$A=(1.31\pm0.01)\times10^3$ gauss
$B=(1.18\pm0.01)\times10^3$ gauss

(3) γ-Irradiated $K_2[Hg(CN)_4]$. The ESR spectrum of the γ-irradiated powder sample of $K_2[Hg(CN)_4]$ consists of the signals of the radicals and those of mercury isotopes of $I=0$, 1/2, and 3/2. The signal of $I=0$ spin mercury appears in the field very close to the free spin. Due to the very large magnitude of A, the hyperfine constant and the limited range of the field sweep of the ESR spectrometer used, all the components of the hyperfine lines have not been recorded at X-band frequency as seen in Fig. 4, but they are measurable at K-band frequency as shown in Fig. 5. The center of the hyperfine lines does not refer to the true g-value for Hg(I) because the quantization axis of the electron spin differs from the applied magnetic field.

The K-band spectrum of powder gives the whole hyperfine spectrum and allows calculation of all prin-

13) P. W. Atkins and M. C. R. Symons, "The Structure of Inorganic Radicals.," Elsevier Publishing Co., Amsterdam (1967), p. 236.

cipal values. With respect to the hyperfine spectrum of Hg(I), due to its large hyperfine splitting the difference in intensity of the hyperfine lines is distinctly observed. This is interpreted by the fact that the transition moment is a function of the magnetic field at which the signal appears. From the whole structure of the spectrum of the powdered sample and the number of isotopes it is concluded that the number of species of the hot ion of Hg(I) is one and the structure of its crystal field is slightly deviated from axial symmetry.

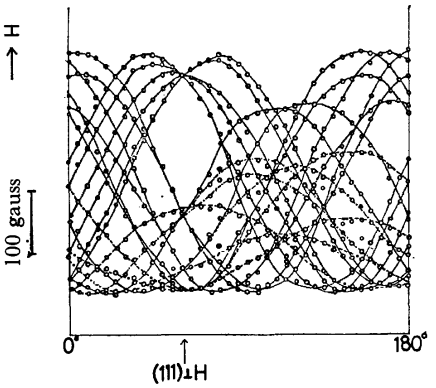

Fig. 11. Angular dependence of hyperfine structure line of γ-irradiated single crystal of $K_2[Hg(CN)_4]$ with the rotation with $[0\bar{1}1]\perp H$.
The second line of ^{199}Hg hyperfine structure is shown. (X-band)

The number of sites and the orientation of Hg(I) complex have been determined from X-band single crystal spectra. For examination of the spectrum, the lines of ^{199}Hg are chosen as an example. The result of the rotation of the γ-irradiated single crystal of $K_2[Hg(CN)_4]$ with the $[0\bar{1}1]$ axis perpendicular to the static magnetic field is shown in Fig. 11. When the [111] axis is parallel to the static magnetic field, the spectrum is the simplest consisting of four lines. The one in the highest field is assumed to refer to Hg(I) in the site of Hg(II)–CN along the [111] axis. With the variation of the angle, the line begins to be separated into six lines. The largest splitting does not occur at the angle where Hg(II)–CN of the host lattice is parallel to the magnetic field, but occurs at the angle about 20° deviated from the direction of Hg(II)–CN. At an interval of the tetrahedral angle, six lines similarly appear in the higher field which are assumed to refer to the sites corresponding to Hg(II)–CN along $[1\bar{1}\bar{1}]$. The other nine lines are assigned to those resulting from the sites corresponding to the remaining two Hg(II)–CN directions $[\bar{1}\bar{1}1]$ and $[\bar{1}1\bar{1}]$. With this rotation, $[\bar{1}\bar{1}1]$ and $[\bar{1}1\bar{1}]$ are equivalent, which makes the number of lines smaller than twelve (6×2).

From the results we reach the following conclusion. The reduction is accompanied by the distortion of the mother lattice of the complex to some extent. The symmetry of Hg(I) complex is not far from the axial symmetry of the diamagnetic compound with a structure slightly distorted from C_{3v}. The distortion occurs nearly parallel to the Hg(II)–CN bonding and the deviation is estimated to be about 20°. Six directions of the distortion are distributed around each Hg(II)–CN direction, probably with the distribution determined by the arrangement of the neighboring atoms. The number of sites is twenty-four (6×4). The Hg(I) complex is orientated to a direction slightly deviated from Hg(II)–CN bonding in the host lattice.

The parameters of ESR hyperfine spectrum are calculated from the K-band powder spectrum by Eq. (1). For the sake of simplification, approximation by means of the equation for the strong allowed transition under the conditions of axial symmetry was adopted. Equations for ^{199}Hg ($I=1/2$) are (4) and (5). The equations for $S=1/2$ and $I=3/2$ are found in literature[14] and quoted for ^{201}Hg ($I=3/2$):
For the symmetry axis parallel to H, we have

$$\begin{aligned}
h\nu &= \frac{1}{2}g_{//}\beta H_1 + A + \frac{1}{2}[(g_{//}\beta H_1 + A)^2 + 3B^2]^{1/2} \\
h\nu &= \frac{1}{2}[(g_{//}\beta H_2 + A)^2 + 3B^2]^{1/2} + \frac{1}{2}[(g_{//}\beta H_2)^2 + 4B^2]^{1/2} \\
h\nu &= \frac{1}{2}[(g_{//}\beta H_3 - A)^2 + 3B^2]^{1/2} + \frac{1}{2}[(g_{//}\beta H_3) + 4B^2]^{1/2} \\
h\nu &= \frac{1}{2}g_{//}\beta H_4 - A + \frac{1}{2}[(g_{//}\beta H_4 - A)^2 + 3B^2]^{1/2}
\end{aligned} \tag{6}$$

For the symmetry axis perpendicular to H, we have

$$\begin{aligned}
h\nu &= \frac{1}{2}g_{\perp}\beta H_1 + B + \frac{1}{2}\left[(g_{\perp}\beta H_1 + B)^2 + 3\left(\frac{A+B}{2}\right)^2\right]^{1/2} \\
h\nu &= \frac{1}{2}\left[(g_{\perp}\beta H_2 + B)^2 + 3\left(\frac{A+B}{2}\right)^2\right]^{1/2} + \\
&\qquad \frac{1}{2}\left[(g_{\perp}\beta H_2)^2 + 4\left(\frac{A+B}{2}\right)^2\right]^{1/2} \\
h\nu &= \frac{1}{2}\left[(g_{\perp}\beta H_3 - B)^2 + 3\left(\frac{A+B}{2}\right)^2\right]^{1/2} + \\
&\qquad \frac{1}{2}\left[(g_{\perp}\beta H_3)^2 + 4\left(\frac{A+B}{2}\right)^2\right]^{1/2} \\
h\nu &= \frac{1}{2}g_{\perp}\beta H_4 - B + \frac{1}{2}\left[(g_{\perp}\beta H_4 - B)^2 + 3\left(\frac{A+B}{2}\right)^2\right]^{1/2}
\end{aligned} \tag{7}$$

Calculations were repeated following the method adopted for Cd(I) from the observed separation of members. First, from the observed magnetic field values for z-direction and x-direction in the powder spectrum, principal values for z-direction and x-direction were calculated under the assumption of the axial symmetry. The principal values for y-direction were calculated next. The results are:

For ^{199}Hg ($I=1/2$)

$g_{zz}=1.97\pm0.05$	$A_{zz}=(5.02\pm0.05)\times10^3$ gauss
$g_{yy}=1.96\pm0.05$	$A_{yy}=(4.58\pm0.00)\times10^3$ gauss
$g_{xx}=1.96\pm0.05$	$A_{xx}=(4.56\pm0.05)\times10^3$ gauss

and for ^{201}Hg ($I=3/2$)

$g_{zz}=1.97\pm0.05$	$A_{zz}=(1.85\pm0.01)\times10^3$ gauss
$g_{yy}=1.96\pm0.05$	$A_{yy}=(1.68\pm0.02)\times10^3$ gauss
$g_{xx}=1.96\pm0.05$	$A_{xx}=(1.66\pm0.02)\times10^3$ gauss

(4) Comparison of the Results for M(I) Complexes. The analysis of ESR spectrum shows that hot ion of paramagnetic M(I) is produced by γ-ray irradiation of M(II) complex compounds, where M(I) ion is trapped in the host lattice of M(II) compound with a small distortion. The concentration of M(I) ion is

14) W. C. Lin and C. A. McDowell, *Mol. Phys.*, **7**, 223 (1964).

evaluated to be less than about 10^{-1} % by measurement of the intensity of the ESR signal of M(I).

When M(II) is reduced to M(I) by γ-rays, the symmetry of M(II) is also reduced from T_d to C_{3v}. In the case of cyanomercurate(I) in cyanomercurate(II), the symmetry is more distorted than C_{3v}. However, even in this case, the deviation from C_{3v} is small. The symmetry around M(I) is not C_∞ but C_{3v}. We assume the product to be assigned to $[M(I)(CN)_4]^{3-}$ and not to $[M(I)(CN)_3]^{2-}$, because we consider it difficult to eliminate one cyano radical from the sphere of complex.

Details of the characteristic difference of Zn(I), Cd(I), and Hg(I) are as follows. In Zn(I), one of the four Zn–CN bondings is stretched with equal probability of stretching for four bondings. Hence, the irradiation product Zn(I) is one species with four equivalent sites of electron. In the case of Cd(I), stretching similar to that in Zn(I) occurs along four Cd–CN bondings equivalently. However, in the former, four different kinds of stretching occur along one bonding, which results in possible 16 sites (4 species $\times$ 4 bondings) of electron, all with C_{3v} symmetry. In Hg(I), electron is not sited along any one of Hg(II)–CN bondings, but at a place slightly apart from the bonding. Six different sites are referred to for one Hg(II)–CN direction from the pattern of the spectra. The number of possible sites of the electron is 24.

The electronic structure of the product is also of interest. The values of $|\Psi(0)|^2$ and $\langle r^{-3}\rangle$ for the M(I) ions have not been determined qualitatively. We can evaluate the hyperfine splitting constants for $(n+1)s$ orbital electron with the use of the data of isoelectronic Cu, Ag, and Au atoms using Goudsmit's relation $z_i z_o^2 \propto |\Psi(0)|^2$ [15] and the value of the nuclear gyromagnetic ratio. In the case of Cd(I), the reported data of the Cd(I) ions isolated in argon matrix at 4.2°K is available.[9] It gives the isotropic hyperfine splitting constants, $A=(5137\pm1)$ gauss for ^{111}Cd(I) and $A=(5347\pm1)$ gauss for ^{113}Cd(I). In our experiment, Cd(I) complex has axial symmetry and the hyperfine splitting is divided into the isotropic and anisotropic parts. The ratio of the hyperfine splitting constants of the two nuclei ^{111}Cd and ^{113}Cd agrees with the ratio of the nuclear gyromagnetic ratio within experimental error. The isotropic parts of the observed hyperfine splitting constants leads to the spin population of $5s$ orbital of 0.24 for species C and 0.28 for species A. Taking the anisotropic part of the hyperfine splitting constant into consideration, the hybridization for the unpaired electron orbital is taken to be between sp^2 and sp^3. The same statement might hold for the electronic structure of Hg(I) complex from the estimated hyperfine splitting constants. This supports the assumed symmetry of C_{3v}. We assume further that the complexes of Cd(I) and Hg(I) do not differ so much from each other with respect to the electron densities. This agrees with the observed result after normalization by nuclear gyromagnetic ratio. In contrast to the case of Cd(I) and Hg(I), the observed hyperfine splitting of Zn(I) complex is considerably small, suggesting that the unpaired electron density on zinc nucleus is small and the electron is delocalized considerably to the ligand atoms.

The remarkable difference between the M(I) complexes lies in the stability of the oxidation number, (I). First, the sequence of the signal intensity under the same γ-ray dose is Hg(I)>Cd(I)>Zn(I). Second, Zn(I) and three species of Cd(I) decay at 77°K and species A of Cd(I) and Hg(I) are stable at this temperature. It should be noted that of the Cd(I) species those which decay at 77°K have smaller hyperfine splitting constant than the stable one.

We wish to thank Dr. Yoji Arata, Dr. Tokuko Watanabe, Mr. Michihiro Nakamura, and Dr. Yoshio Umezawa for valuable discussions. We are also indebted to Mr. Shingo Katsura of γ-ray irradiation station for his experimental assistance.

Note Added in Proof. We have recently noticed that M. C. R. Symons and J. K. Yardell have measured the ESR of Hg(I) (*J. Chem. Soc.*, *A*, **1971**, 761). However, they only report the production of Hg(I) in the γ-irradiated frozen solutions.

ESR Studies of the Copper(II) Complexes of Amino Acids

Hiroshi Yokoi, Mitsuru Sai, Taro Isobe, and Shigeru Ohsawa*

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai

**Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai*

(Received February 2, 1972)

The X-band and K-band ESR spectra of the *trans*-planar copper(II) complexes of amino acids, whose crystal structures are now known, were measured in a polycrystalline state at room temperature and in frozen aqueous-methanolic solutions at the temperature of liquid nitrogen. The polycrystalline samples showed a variety of ESR line shapes, most of which had three different principal g values; $g_1=2.04$—2.07, $g_2=2.08$—2.12, and $g_3=2.16$—2.29. On the other hand, all the ESR line shapes observed for the frozen solutions were quite similar, and they indicate a normal tetragonal copper(II)-ion environment. There was, moreover, a remarkable difference in the g values between the complexes in the two states. The correlation among the g values, the *d-d* band energies, the bonding parameters (a measure of the degree of covalency of the copper-ligand bondings), and the geometrical configurations of the coordinating atoms for the complexes in a crystal is discussed in some detail.

ESR studies of metal complexes present much useful information about coordination bonding.[1-11] It is very important to see how the ESR data correlate practically with various structural factors for the metal complexes with complicated structures. Recently, some works along this line have been reported; the optical absorption and ESR studies of various ammine and ethylenediamine complexes of copper(II) whose crystal structures are known were carried out in the form of single crystals or of polycrystals, and rhombic g tensors have been discussed in terms of a ground-state of the form: $\varphi=a|x^2-y^2\rangle-b|z^2\rangle$.[6,12-14]

The metal complexes of amino acids have structures likely to participate in hydrogen-bonding with their surroundings, and any of their crystal structures is unpredictably unique because of their characteristic hydrogen-bonding behavior.[15,16] The purpose of this paper is to present the ESR spectra of the copper(II) complexes of amino acids, whose crystal structures are known, in the form of polycrystals and in frozen aqueous-methanolic solutions, and to investigate the ESR and optical absorption data in connection with the structures. This kind of investigation seems to be fundamentally important for the structural estimation of various other metal complexes and the metal-binding sites of various metalloenzymes.[17]

Experimental

Materials. The samples employed here are listed in Table 1, together with their abbreviations. The amino acids used were all commercial products except for cyclopentane-1-amino-1-carboxylic acid, which was prepared and purified according to the method of Henze and Speer.[18] The copper(II) complexes of these amino acids were prepared by the usual method,[19,20] and were recrystallized from water. The results of the chemical analyses are also listed in Table 1.

Measurements. The X-band and K-band first-derivative ESR spectra were measured for the powdered samples at room temperature and for the frozen solutions at the temperature of liquid nitrogen with a Hitachi ESR spectrometer, Model MES-4001. The sample solutions were in concentrations of 10^{-3}—10^{-4}M of the complexes, with an equivolume mixture of water and methanol used as the solvent. The field was calibrated with an Oki magneto-field scope, Model WX-601, using the NMR signals of proton and lithium, and then with a benzene solution of vanadyl acetylacetonate. The visible absorption spectra were measured for the powdered samples at room temperature with a Cary model 14 spectrometer, using the so-called opal-glass method, where a suspension of finely-powdered samples in

liquid paraffin is dealt with;[21] several of the observed spectra are shown in Fig. 1.

Results and Discussion

Principal Values of g. The observed powder ESR spectra, which are shown in Figs. 2—5, were analyzed by the use of the approximation of Kneubühl;[22] the results are shown in Table 2.

The principal values of g for the copper(II) ion in a rhombic field, for which the ground-state may be written as in Eq. (1),

$$\varphi=\cos\delta(d_{x^2-y^2})-\sin\delta\,(d_{z^2}) \qquad (1)$$

can generally be given by the following expressions;[6,14,23,24]

$$g_x=2-\frac{2k_x^2\lambda}{\Delta E_{xz}}(\sqrt{3}\,\sin\delta-\cos\delta)^2$$
$$g_y=2-\frac{2k_y^2\lambda}{\Delta E_{yz}}(\sqrt{3}\,\sin\delta+\cos\delta)^2 \qquad (2)$$

TABLE 2. g VALUES AND VISIBLE ABSORPTIONS IN A POLYCRYSTALLINE STATE

Copper(II) complex	g_1	g_2	g_3	λ_{max} (nm)
[Cu(L-Ala)$_2$]	2.059	2.107	2.197	590
[Cu(DL-α-NH$_2$but)$_2$]	2.052	2.098	2.204	585
[Cu(DL-Met)$_2$]	2.053	2.100	2.190	580
[Cu(DL-Val)$_2$]	2.057	2.105	2.202	605
[Cu(DL-Ser)$_2$]	2.058	2.112	2.208	615
[Cu(Pen)$_2$]	2.053	2.089	2.160	490, 590[a]
[Cu(DL-Pro)$_2$]·2H$_2$O[b]	(2.065)[c]		(2.190)	605
[Cu(L-Pro)$_2$]·2H$_2$O	2.058	2.158[c]		610
[Cu(β-Ala)$_2$]·6H$_2$O	2.068	2.109	2.223	635
[Cu(β-NH$_2$but)$_2$]·2H$_2$O	2.044	2.090	2.280	655
Cu(L-Glu)·2H$_2$O	2.111[c]		2.250	720

a) These values were roughly estimated by a Gaussian analysis.
b) The g values were tentatively determied from the positions shown by arrows in Fig. 5.
c) The numbers written between the neighboring g columns express the same g values in both of the columns.

$$g_z = 2 - \frac{8k_z^2\lambda}{\Delta E_{xy}}(\cos\delta)^2$$

where k^2s are the orbital reduction factors, which are regarded as an approximate measure of the degree of covalency for the coordinate bonds of planar copper(II) complexes,[2,5,25] and where the other symbols have their usual meanings. In Eqs. (1) and (2), the normal tetragonal copper(II)-ion environment with which we have most often met means $\cos\delta=1$. It is clear from Eq. (2) that the inclusion of a small amount of a d_z^2 character in the ground-state is sufficient to account for the fairly large difference between the g_x and g_y values. On the assumption of a square-planar configuration to start with, none of the small distortions except for a rhombic or rectangular one is important in affecting the g values and the d-d band energies.[26] g_x, g_y, and g_z can now be assumed to correspond to g_1, g_2, and g_3 respectively in Table 2.

Before discussing the g values directly determined from the powder ESR spectra, it is necessary to check whether these g values reflect the local copper(II)-ion environment. If a large spin-exchange interaction is present between crystallographically non-equivalent molecules, the determined g values will not be equal to the principal g values of the local copper(II) ions. Hathaway *et al.* defined the value of $(g_{//}-2)/(g_{\perp}-2)$ as G and used this G value as a criterion for examining whether there is such a strong spin-exchange interaction in a crystal; when $G<4$, such a strong interaction is considered to be present.[5,12] Much reliance, however, can not always be placed on this criterion, since many planar copper(II) complexes have been known to have $G<4$ even in the magnetically-diluted state,[9,27] and since there is always a possibility that $G<4$ can be established for certain planar copper(II) complexes because of the unusual order of the d-orbital levels or of the bonding parameters.

The results of the X-ray analysis of all the copper(II) complexes of amino acids whose crystal structures are known are listed in Table 3. A spin-exchange interaction between crystallographically-equivalent molecules makes the ESR absorption line widths decrease, but does not change the g values; in such a case, the determined g values directly reflect the local copper(II)-ion environment. The three different g values clearly observed for [Cu(β-NH$_2$but)$_2$]·2H$_2$O are, accordingly, just its true principal g values, since this complex has one molecule per unit cell.[34] Similarly, all the other complexes in Table 3 except [Cu(DL-Pro)$_2$]·2H$_2$O and Cu(L-Glu)·2H$_2$O have three different g values in spite of their having two molecules per unit cell. Evidently the first four complexes in Table 3, which have no water molecules in the crystal, are significantly different in the relative configurations of the two crystallographically non-equivalent molecules in an unit cell. Nevertheless, these four complexes are quite similar in ESR line shape, as is shown in Figs. 2 and 3. This suggests that there may be no such strong spin-exchange interactions as has been mentioned above in most crystals of the copper(II) complexes of amino acids. This is also

a) The apical oxygen atoms belong to the groups shown in parentheses.
b) The square planar coordination of this complex is due to two oxygen atoms and a nitrogen atom of glutamates and one oxygen atom of a water molecule.

supported by other ESR experiments concerning the aggregation and dimerization of the complexes in frozen aqueous media.[36] Therefore, it may be concluded that almost all the g values determined here are correct as principal g values.

Correlation Between g *Values and Crystal Structures.* The *trans*-planar copper(II) complexes of amino acids are mainly dealt with in this work. The coordination about the copper atom is schematically represented in Fig. 6, where O_{A1} and O_{A2} are the double-bonded oxygen atoms of adjacent molecules for some complexes, or the oxygen atoms of water molecules for other complexes.

$[Cu(L\text{-}Ala)_2]$ showed a typical powder ESR spectrum, with relatively broad absorption lines and three different g values. Many other copper(II) complexes of amino acids, such as $[Cu(DL\text{-}\alpha\text{-}NH_2but)_2]$, $[Cu(DL\text{-}Met)_2]$, $[Cu(DL\text{-}Val)_2]$, $[Cu(DL\text{-}Ser)_2]$, and $[Cu(Pen)_2]$, showed similar powder ESR line shapes, as may be seen in Figs. 2 and 3. $[Cu(Pen)_2]$ is characterized by the smallest g_3 value. On the other hand, $[Cu(\beta\text{-}Ala)_2]\cdot 6H_2O$ and $[Cu(\beta\text{-}NH_2but)_2]\cdot 2H_2O$ showed comparatively sharp absorption lines, as Fig. 4 shows, and they had large g_3 values compared with all the other complexes. $Cu(L\text{-}Glu)\cdot 2H_2O$ also had large g values. It has been a generally-accepted rule that the g values decrease as the planar ligand field becomes stronger, or as the axial ligand field becomes weaker,[4,11,37] and that this behavior of the ligand field is accompanied by a blue-shift of the *d-d* absorption bands.[38] The above-mentioned characteristics of the g values for $[Cu(Pen)_2]$, *etc.* can be understood from their structures and observed visible absorptions according to this general rule. $[Cu(Pen)_2]$ has an especially large L_A value and relatively small L_N and L_O values, and its visible absorption appears at shorter wavelengths, as Tables 2 and 3 show. $[Cu(\beta\text{-}Ala)_2]\cdot 6H_2O$ and $[Cu(\beta\text{-}NH_2but)_2]\cdot 2H_2O$ have comparatively large L_N and L_O values and small L_A values, and their visible absorptions appear at longer wavelengths. $Cu(L\text{-}Glu)\cdot 2H_2O$, which showed a visible absorption at the longest wavelength, has an especially small L_A value.

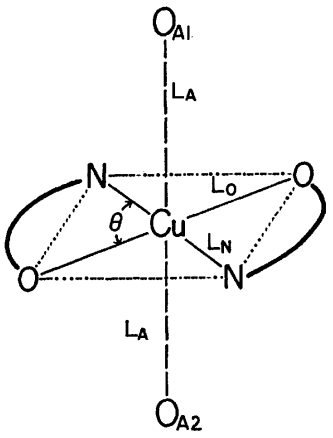

Fig. 6. The schematically represented structure of the *trans*-planar copper(II) complexes of amino acids.

It has generally been believed that the g_3 (or g_z) is oriented along the axis normal to the molecular plane and that the g_1 and g_2 (or g_x and g_y) axes lie on the plane;[34,39] moreover, in view of the crystal-field theory, it is a most probable assumption that the g_1 and g_2 axes are nearly oriented along the different respective coordinate bond directions. All the complexes employed here except three have three different principal values of g. This fact indicates that the copper(II) ions of these complexes are present in rhombically-distorted ligand fields. However, the differences between the g_1 and g_2 values were almost constant for

all of them, regardless of the fact that their values of L_N, L_O, L_A, and Θ vary over considerably wide ranges, as may be seen in Tables 2 and 3. It may, accordingly, be suggested that there are certain factors which lead to almost constant differences between the g_1 and g_2 values in their crystals. The data of the X-ray analysis listed in Table 3 indicate that L_O is somewhat smaller than L_N for most of the complexes. In spite of this fact, however, the Cu–N bonding is considered to be a little more covalent than the Cu–O bonding, since the overlap integrals for the bond lengths given in Table 3 can be calculated to be larger for the Cu–N bond than for the Cu–O bond using the table of overlap integrals (we can regard the overlap integral as a measure of the degree of covalency).[40] This small difference between the two bondings in the degree of covalency, accordingly, seems to be responsible for a rhombically-distorted field around the copper atom and, therefore, for a rhombic g tensor. (Just for information, the mixing parameter, δ, in Eq. (1) could be calculated to be about 5° on the rough assumption that $\Delta E_{xy}=\Delta E_{yz}$ and $k_x^2=k_y^2$ in Eq. (2)).

$[Cu(DL\text{-}Pro)_2]\cdot 2H_2O$ showed a complicated powder ESR line shape which was quite different from all the others, as is shown in Fig. 5; its g values also can naturally be expected to be different from the others. It can, however, be suggested from its powder ESR line shape that the powder sample of this complex may be contaminated by a significant amount of an impurity, which could not be removed by repeated recrystallizations from water. Since this sample in a frozen solution showed a typical ESR line shape due to a single complex species, as will be described below, the impurity may be considered as either a geometrical isomer of the *cis*-form or another hydrate. Interestingly, this complex has a characteristic structure of $L_N<L_O$ (contrary to the other complexes) and has the smallest θ value. The abnormal properties of the complex are also demonstrated by the powder ESR spectrum of its isomer, $[Cu(L\text{-}Pro)_2]\cdot 2H_2O$, whose crystal structure is yet unknown; the ESR line shape of $[Cu(L\text{-}Pro)_2]\cdot 2H_2O$ is a so-called reverse one ($g_{//}<g_{\perp}$, $\sin\delta=1$ in Eq. (1)), as is shown in Fig. 5. It is also an interesting fact that the ESR line shape of Cu(L-Glu)$\cdot 2H_2O$ showed a normal tetragonal copper(II)-ion environment, in spite of the fact that four different coordinating groups form a planar coordination about the copper atom.[35]

Visible Absorption and Bonding Parameters. Any of the complexes employed here in both the polycrystal state and an aqueous solution showed only a single broad band in the visible region. It has been a generally accepted rule for the copper(II) complexes that the visible absorptions shift to shorter wavelengths and the g values become smaller as the copper-ligand bondings in the molecular plane become more covalent.[4,11,37,38] The mean, g_0, of the g_1, g_2, and g_3 values was plotted against the energies at the visible absorption peak, ΔE_{max}, for all the complexes under discussion; it is shown in Fig. 7. It is clear from this figure that the g_0 value decreases uniformly as the value of ΔE_{max} increases.

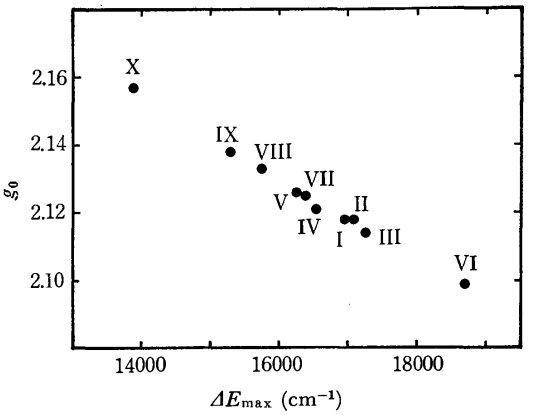

Fig. 7. A plot of g_0 against ΔE_{max} (the numbers are referred to in Table 4).

The following equation can be derived from Eq. (2):

$$k_0^2=-\frac{\Delta E_0}{4\lambda}(g_0-2)-\frac{\Delta E_0}{12\lambda}\{(e_{xz}-h_x)(g_x-2)+(e_{yz}-h_y)(g_y-2)+(e_{xy}-h_z)(g_z-2)\}+\frac{\Delta E_0}{12\lambda}\{e_{xz}h_x(g_x-2)+e_{yz}h_y(g_y-2)+e_{xy}h_z(g_z-2)\} \quad (3)$$

where $k_0^2=(1/3)(k_x^2+k_y^2+k_z^2)$ and $\Delta E_0=(1/3)(\Delta E_{xy}+\Delta E_{xz}+\Delta E_{yz})$, and where $k_s^2=k_0^2(1+h_s)$ for $s=x$, y, or z and $\Delta E_t=\Delta E_0(1+e_t)$ for $t=xy$, yz, or xz. The second and third terms on the right-hand side of Eq. (3) are much smaller than the first term. Roughly speaking, the value of (g_0-2) is inversely proportional to ΔE_0. The k_0^2 values can be regarded as a measure of the degree of covalency for the copper-ligand bondings. The approximate values of k_0^2 were calculated only from the first term, using the value of ΔE_{max} as an approximate value of ΔE_0. The k_0^2 values thus obtained, together with the values of (g_0-2) and $-4\lambda/\Delta E_{max}$, are listed in Table 4. It is shown by this table that the k_0^2 values can be arranged in the same order as that obtained in Fig. 7; the complexes become

more covalent in the copper-ligand bondings as they go to the right in Fig. 7.

It is interesting to see once more how the k_0^2 and ΔE_{max} values correlate with the actual geometry of the coordinating atoms. A plot of the values of k_0^2 and $-4\lambda/\Delta E_{max}$ and the bond lengths of L_E and L_A on the different axes is shown in Fig. 8, where $L_E=(1/2)(L_N+L_O)$, and where, for the complexes with two different L_A values, the smaller one was adopted. The meaning of this figure is as follows: as a complex has a smaller circle on this figure, the complex becomes more covalent in the coordinate bond, and there is a smaller L_E value and a larger L_A value. It is clearly shown in this figure that many circles become concentric, although there is one exception to this tendency, and the facts that the coordinate bond becomes more covalent as L_E value is smaller and the L_A value is larger may be established for this kind of complex in a crystal.

a) The ESR spectra were measured in aqueous–methanolic (1:1 volume ratio) solutions at 77°K, while the visible absorption spectra were measured in aqueous solution at room temperature.
b) The values were determined from the X-band ESR spectra.
c) The $g_\perp$ values were determined from the K-band ESR spectra (see Fig. 10).

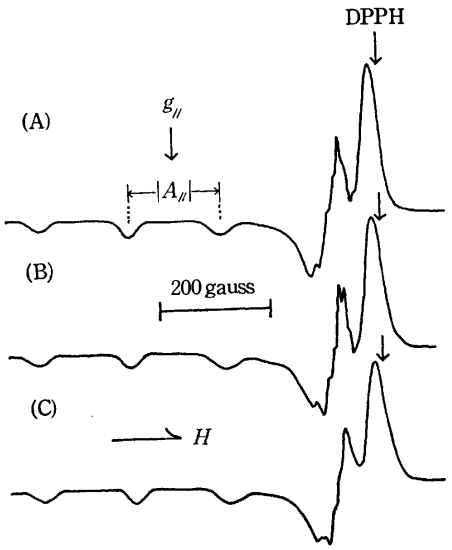

Fig. 9. X-band ESR spectra in frozen solution (at 77°K, Solvent: an equivolume mixture of water and methanol). (A):[Cu(L–Ala)$_2$], (B):[Cu(Pen)$_2$], (C):[Cu(L-Pro)$_2$]·2H$_2$O.

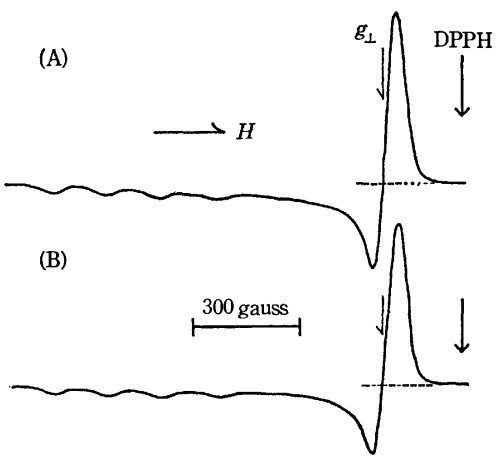

Fig. 10. K-band ESR spectra in frozen solution (at 77°K, Solvent: an equivolume mixture of water and methanol). (A):[Cu(L–Ala)$_2$], (B):[Cu(Pen)$_2$].

The Complexes in Frozen Solution. Several of the X-band and K-band ESR spectra of the complexes employed here in frozen aqueous-methanolic solutions at 77°K are shown in Figs. 9 and 10; the results are listed in Table 5. The magnetic parameters of the first seven complexes in this table were found to be almost equal to each other; $g_{//}=2.264\pm0.006$, $g_\perp=2.057\pm0.002$, and $|A_{//}|=(181\pm7)\times10^{-4}$ cm^{-1}. On the other hand, the last two complexes have somewhat larger g values and much smaller values of $|A_{//}|$ than the others.

It is characteristic of all the complexes in the solution that the observed ESR line shapes are quite similar to each other and indicate a normal elongated-tetragonal copper(II)-ion environment ($g_1\fallingdotseq g_2<g_3$), as is shown in Figs. 9 and 10; this tetragonality is clearly demonstrated, especially by the K-band ESR line shapes. This is a very interesting fact and is in contrast with the fact that the powder samples of the same com-

plexes showed a variety of ESR line shapes, with three different principal g values, as has been mentioned above. It seems, therefore, that it is a general property for the copper(II) complexes of amino acids in solution to keep the symmetry of the ligand field in a higher degree. Furthermore, this property is consistent with a previously-obtained result concerning the mixed-ligand complexes of copper(II), which also keep a high symmetry of ligand field in solution in spite of the asymmetrical coordination about the copper atom due to all the different coordinating groups.[41]

$[Cu(Pen)_2]$, whose crystals are purple, turns blue in an aqueous solution; the visible absorption spectrum of this complex shifts to a longer wavelength in the solution and resembles that of $[Cu(L\text{-}Ala)_2]$. $[Cu(Pen)_2]$ has the smallest g_3 value in a crystal, but its g_3 value becomes as large as that of $[Cu(L\text{-}Ala)_2]$ in a solution. These facts indicate that the water molecules can come close to the cupric ions in an aqueous solution for $[Cu(Pen)_2]$ as well as for $[Cu(L\text{-}Ala)_2]$, and that there is an accompanying strengthening of the axial-ligand field. Judging from the data on g and the visible absorptions, a tendency for the axial-ligand field to be strengthened in an aqueous solution can be seen in a greater or lesser degree for the anhydrous complexes. The properties of $[Cu(\beta\text{-}Ala)_2]\cdot 6H_2O$ and $[Cu(\beta\text{-}NH_2but)_2]\cdot 2H_2O$ were similar in a solution; their g values are larger than the others', and their visible absorptions appear at somewhat longer wavelengths. These two complexes, therefore, are less covalent in the coordinate bond than the others; this fact seems to be consistent with a general accepted theory that the complexes with six-membered chelate rings are less stable than those with five-membered ones.

All the facts mentioned above indicate that the copper(II) complexes of amino acids change their structures according to the molecular surroundings, and that their structures resemble each other in an aqueous solution, a normal tetragonal copper(II)-ion environment being kept.

CNDO/2 Calculations of Hydrogen Bonding; Phenol- and *p*-Nitrophenol-Ammonia Systems

Akio MATSUYAMA and Akira IMAMURA

Biophysics Division, National Cancer Center Research Institute, Tokyo 104

(Received July 24, 1971)

Detailed information on the double minimum potential curve for the proton of a hydrogen-bonded complex is especially useful for understanding the nature of hydrogen bonding and of great interest in connection with many biological problems. Baba, Matsuyama, and Kokubun showed[1] that in the *p*-nitrophenol–triethylamine system the second potential minimum which corresponds to an ion pair becomes stable upon excitation, while unstable in the ground state. On the other hand, recent development of the semi-empirical MO method which can treat all valence electrons has made it possible to calculate directly the potential energy curve of a rather complicated hydrogen-bonding system. Along this line, the CNDO/2 method[2,3] has been applied recently to some simple hydrogen-bonding systems[4] and guanine–cytosine base pair.[5] The main purpose of the present study was to see whether the CNDO/2 method can explain successfully the previous experimental results or not. Owing to the limited capacity of the computer used, ammonia was used as a proton acceptor instead of triethylamine throughout the calculations. However, this does not seem to have caused any essential effects.

Method of Calculation

The method of calculation was the same as described previously.[6] Molecular constants of phenolic compounds were taken from the results of X-ray diffraction analysis,[7] ammonia being assumed to be tetrahedral. Proton-donor and -acceptor molecules were arranged as shown in Fig. 1. In order to obtain the hydrogen-bonding energies and potential energy curves for the hydroxyl proton, the total energies of the hydrogen-bonded complexes were calculated at intervals of 0.1 or 0.2 Å of the O···N and O–H distances, respectively.

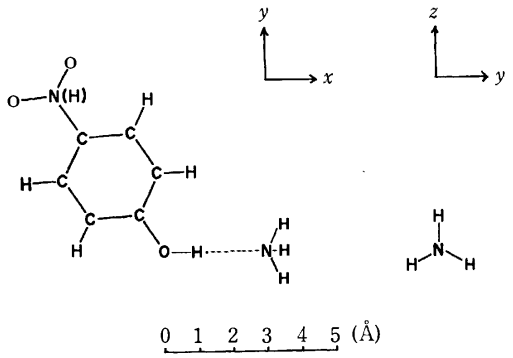

Fig. 1. Molecular arrangement of *p*-nitrophenol or phenol and ammonia.

Results and Discussion

First the total energies of the two hydrogen-bonded complexes, phenol–ammonia and *p*-nitrophenol–ammonia, were calculated as a function of the O···N distance. Distinct minima of the energies were obtained at 2.6 Å for both complexes. The hydrogen-bonding energies were found to be 10.2 and 11.1 kcal for phenol- and *p*-nitrophenol–ammonia complexes, respectively. These values seem to be slightly larger than those reported as the usual hydrogen-bonding energy.[8] However, the stronger proton-donating power of *p*-nitrophenol can be reasonably predicted by the present calculations.

Next, the potential energy curves for the hydroxyl proton in both the ground and excited states were calculated by varying the coordinate of the proton, keeping the O···N distance constant. The O···N distance of 3.0 Å was used instead of the calculated value (2.6 Å), since the latter seems to be short for the hydrogen-bonding distance related to a weak base such as ammonia.[8] The potential energy curves in the excited states were obtained using the ground state wave functions in the virtual orbital approximation. Although the CNDO/2 method is recognized as unreliable for the interpretation of electronic spectra, it should be noted that the energy concerned is not an absolute value but a relative one on varying the coordinate of the proton. Kroto and Santry[9] have shown that this virtual orbital approximation can predict successfully conformations of molecules in the excited state. These facts will permit us to adopt this procedure as a first approximation. The total energies in the ground and excited states are plotted against the coordinate of the proton in the phenol–ammonia system in Fig. 2. With regard to the excited states, only the lowest states of a (π,π^*) type are shown. In addition to potential minima at 1.0 Å, distinct shoulders

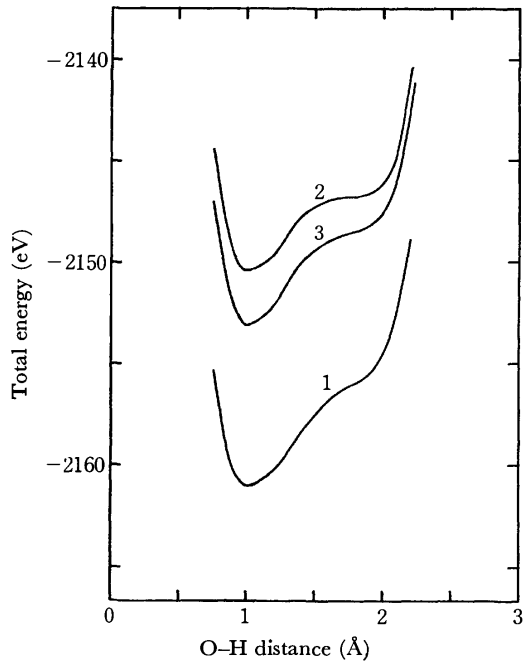

Fig. 2. Variations of the total energies in the ground and excited states of a phenol–ammonia complex as a function of the coordinate of the hydroxyl proton. 1; ground state, 2; the lowest singlet-excited state, 3; the lowest triplet-excited state.

or minima are found at 1.8 Å in all curves, which correspond to a proton-transferred species or an ion pair. The ion pair is unstable in both the ground and excited states, apparently due to the use of ammonia instead of more basic triethylamine as proton acceptor. It is evident, however, that the ion pair becomes less unstable upon excitation. Similar curves were obtained also for the *p*-nitrophenol–ammonia system. This finding is in qualitative agreement with the experimental evidence that the ion pair is more stable than the hydrogen-bonded complex in the singlet-excited state of *p*-nitrophenol–triethylamine system, but less stable in the ground state.[1)]

Table 1. The energy differences between the hydrogen-bonded complex and ion pair

State	Energy difference (eV)	
	Phenol–Ammonia	*p*-Nitrophenol–Ammonia
Ground state	5.082	4.686
Singlet-excited state	3.574	3.697
Triplet-excited state	4.001	4.417

The energy differences between the hydrogen-bonded complex and ion pair in the ground and excited states are summarized in Table 1. The values indicate the differences between the total energies at the O–H distances of 1.8 and 1.0 Å. In the ground state, the energy differences are 5.082 and 4.686 eV for phenol and *p*-nitrophenol complexes, respectively. Greater lowering of the second potential minimum in the *p*-nitrophenol system can be reasonably interpreted in terms of the stronger acidity of the molecule. In both systems the energy differences in the singlet-excited state are smaller than those in the triplet-excited state, *viz.*, the ion pair is more stable in the singlet state than in the triplet state. This is consistent with the fact that the acidity of a phenolic compound is in general weaker in the triplet-excited state than in the singlet-excited state.[10)]

In conclusion, it can be said that the present calculations could explain at least qualitatively the following experimental results: Existence of the second potential minimum, lowering of the minimum in the excited state, greater lowering in the singlet-excited state than in the triplet-excited state and a stronger proton-donating power of *p*-nitrophenol.

The authors wish to thank Dr. Chikayoshi Nagata of our Laboratory and Professor Hiroaki Baba of Hokkaido University for their helpful discussions and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2198—2199(1972)

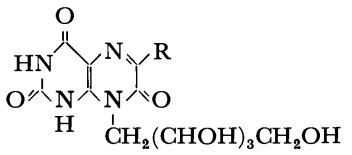
The Structure of a New Pteridine Compound Produced by *Pseudomonas ovalis*

Akira SUZUKI, Toshiaki MIYAGAWA, and Miki GOTO
Department of Chemistry, Gakushuin University, Toshima-ku, Tokyo

(Received September 28, 1971)

The following ribityllumazines were hitherto isolated from microorganisms: 6,7-dimethyl-8-(1-D-ribityl)-2,4-dioxohexahydropteridine (Masuda's G-compound),[1] 6-methyl-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine (Masuda's V-compound)(II),[2] 6-(3-indolyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine,[3] 6-(*p*-hydroxyphenyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine and 6-(2-carboxyethyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine (Putidolumazine)(III).[4,5]

This paper describes the isolation of D-*erythro*-neopterin and three ribityllumazine compounds from cultures of *Pseudomonas ovalis*. Two of them have been identified as compounds II and III, but the last compound (I) has not been isolated from natural sources. The structure of this compound was deduced to be 8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine from UV-spectra and chemical degradation. The compound was synthesized by condensation of 2,6-dihydroxy-5-amino-4-D-ribitylaminopyrimidine and glyoxylic acid, and its identity with the natural compound I was confirmed.



(I) R: -H (II) R: $-CH_3$
(III) R: $-CH_2CH_2COOH$

Experimental

Isolation of Compound I. *Pseudomonas ovalis* (IAM 1506) was cultivated for 10 days in six fermentation jars (total quantity: 60 liters) at 30°C with aeration. The medium for cultivation was as follows: sodium glutamate 200 g, glucose 50 g, $Na_2HPO_4 \cdot 12H_2O$ 56 g, KH_2PO_4 2.5 g, $MgSO_4 \cdot 7H_2O$ 1.0 g, $FeSO_4 \cdot 7H_2O$ 50 μg, $Ca(NO_3)_2 \cdot 4H_2O$ 14.4 mg and water 10 liters. The pH was adjusted to 7.6. After cells were removed by centrifuging at 13000 rpm, fluorescent compounds were adsorbed on charcoal (240 g), eluted with 50% ethanol–4% ammonia (1:1) solution and the concentrated eluate was subjected to chromatography as shown in Fig. 1.

Characterization of Compound I. The aqueous solution of this compound shows strong purple fluorescence. R_f-values and UV-spectra are given in Table 1 and Fig. 2.

Periodate Oxidation: One milliliter of aqueous solution of I (4.56×10^{-5}M) was treated with 2 m*l* of aqueous potassium metaperiodate solution (11.1×10^{-5}M, pH 3.5) at room temperature. At intervals the amount of undestroyed periodate was estimated from UV-absorption (222 mμ) by the method of Dixon and Lipkin.[6] The compound (M, 314) consumed 2.77 mol of periodate per mole.

$NaBH_4$ Reduction of the Periodate Oxidation Product: I (*ca.* 0.3 mg) was dissolved in 0.3 m*l* of water and 0.4 mg of potassium metaperiodate was added. After 1 hr, the oxidation product was purified by paper chromatography using 1-butanol–acetic acid–water (4:1:1) and 2-propanol–water

Synthesis of 8-(1-D-Ribityl)-2,4,7-trioxohexahydropteridine (I). 2,6-Dihydroxy-5-nitro-4-D-ribitylaminopyrimidine[8] (625 mg) in water (80 m*l*) was hydrogenated over a platinum oxide catalyst (300 mg). After the theoretical amount of hydrogen was taken up, the catalyst was removed by filtration. The solution was acidified with acetic acid (3 m*l*). Glyoxylic acid (400 mg) was added and the mixture was heated for 5 hr on a water bath. The solution was neutralized with aqueous ammonia and concentrated *in vacuo* to about 30 m*l* below 40°C. The product was purified by chromatography using a DEAE–cellulose column (5.5×32 cm; elution: 0.005N HCl) and a cellulose column (7.5×30 cm; elution: 2-propanol–1% ammonia (2: 1)). The eluate was concentrated to dryness *in vacuo* below 40°C. The residue was recrystallized from water, yield, 76 mg, mp 262—263°C (decomp.).

Found: C, 40.65; H, 4.52; N, 16.79%. Calcd for $C_{11}H_{14}O_7N_4 \cdot 1/2H_2O$: C, 40.86; H, 4.64; N, 17.33%.

The UV-absorption spectrum of the substance in 0.1N HCl was as follows: $\varepsilon_{mln}^{250m\mu}$ 3410, $\varepsilon_{max}^{278m\mu}$ 12800, $\varepsilon_{min}^{298m\mu}$ 5520, $\varepsilon_{max}^{332m\mu}$ 11800; in H_2O: $\varepsilon_{mln}^{243m\mu}$ 3930, $\varepsilon_{max}^{261m\mu}$ 5190, $\varepsilon_{mln}^{267m\mu}$ 4940, $\varepsilon_{max}^{287m\mu}$ 9680, $\varepsilon_{mln}^{305m\mu}$ 2860, $\varepsilon_{max}^{350m\mu}$ 13700.

Discussion

Four pteridines have been isolated from the culture of *Pseudomonas ovalis*. Three of them were characterized as D-*erythro*-neopterin, 6-methyl-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine (II) and 6-(2-carboxyethyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine (III).

The fourth compound (I) was a new pteridine. UV-spectra of this compound suggests that it is a 2,4,7 (1H,3H,8H) pteridinetrion with alkyl side chains at N-8 and C-6 position (Fig. 2). I is stable against Al–Hg reduction suggesting that it has –H or $-CH_2-$ bound to carbon-6.[9] It is stable against esterification, suggesting that it has no carboxyl group. One mole of compound I consumed 3 mol of KIO_4 and reduction of the product with $NaBH_4$ yielded a substance identical with 8-(2-hydroxyethyl)-2,4,7-trioxohexahydropteridine (IV);[7] this was identified by cochromatography with the synthetic material (Table 1). From these results the structure of 8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine (I) was postulated for I. The compound was synthesized by condensation of 2,6-dihydroxy-5-amino-4-D-ribitylaminopyrimidine and glyoxylic acid and its identity with the natural product was confirmed.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2200—2201 (1972)

A NMR Study of the Thioacetic Acid-Acetone Mixture

Toyokazu Horii, Shunichi Kawamura, and Jitsuo Tsurugi
Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka

(Received November 10, 1971)

It is well known that thiols add readily and reversibly to the carbonyl group of aldehydes and ketones to form hemimercaptals and hemimercaptols as intermediates to mercaptals and mercaptols respectively. Hemimercaptals and hemimercaptols have been isolated only for aldehydes and ketones which contain electron-withdrawing groups.[1] Although it was demonstrated that thioacetic acid adds to simple aldehydes to form vacuum-distillable hemimercaptals,[2] the isolation of hemimercaptol has never been reported.

In the present study, we measured the NMR spectra of mixtures of acetone and thioacetic acid (**1a**), α-chlorothioacetic acid (**1b**), or α-dichlorothioacetic acid (**1c**). These mixtures were considered to be in equilibrium, as is shown below:

$$RCOSH + CH_3COCH_3 \rightleftharpoons (CH_3)_2C(OH)SCOR \quad (1)$$

1a: R = CH_3 **2**a: R = CH_3
b: R = CH_2Cl b: R = CH_2Cl
c: R = $CHCl_2$ c: R = $CHCl_2$

Therefore, we can expect at the lower temperatures to detect the spectra of α-hydroxyisopropyl thioacetate (**2a**), α-chlorothioacetate (**2b**), and α-dichlorothioacetate (**2c**). We determined each equilibrium constant in a large excess of acetone-d_6. Such substituents as α-chloro- and α-dichlorothioacetate were chosen for the sake of the simplicity of the NMR spectra.

Experimental

Acetone was dried over anhydrous calcium sulfate and distilled. Thioacetic,[3] chlorothioacetic[4], and dichlorothioacetic acid[4] were prepared and purified by the method described in the literature. The NMR spectra were measured on a JNM 3H-60 spectrometer, with tetramethylsilane as the internal standard. The probe temperature was determined immediately after each spectral measurement, using a thermocouple in a sample tube containing 0.5 m*l* of acetone. The accuracy of the temperature thus obtained should be within 1°.

Measurements of Equilibrium Constants. The NMR spectra of thioacetic acid solutions (3—7%) in a large excess of acetone-d_6 were taken, and the areas of the resonances of the R-group protons of RCOSH (**1**) and $(CD_3)_2C(OH)SCOR$ (**2**) were measured at various temperatures. The equilibrium constants were determined from:

$$K = [\text{Area of } (CD_3)_2C(OH)SCO\underline{R}]/[\text{Area of } \underline{R}COSH]$$

In 6.8, 4.2, and 3.0% solutions of thioacetic acid, all the plots of $\log K$ against $1/T$ gave only a straight line, with a correlation coefficient of 0.993 (Fig. 2). Therefore, at concentrations below 7% the molar fraction of acetone can safely be anticipated to be 1. Each measurement was initiated about 10 min after the solution in an NMR tube and the NMR probe had been temperature-equilibrated.

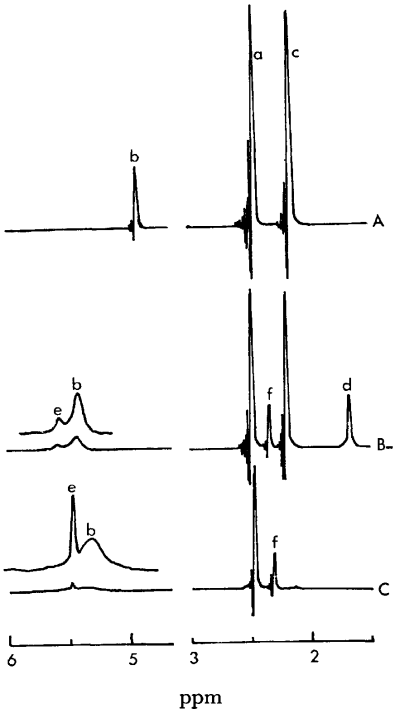

Fig. 1. The NMR spectra of thioacetic acid. A: 70 w/w% acetone solution at 25°C, B: at −56°C, C: 40 w/w% acetone-d_6 solution at −36°C.

$$\underset{a}{C\underline{H}_3}COS\underset{b}{\underline{H}} + (\underset{c}{C\underline{H}_3})_2CO \rightleftharpoons (\underset{d}{C\underline{H}_3})_2C(\underset{e}{O\underline{H}})SCO\underset{f}{C\underline{H}_3}$$

Results and Discussion

The NMR spectrum of the mixture of acetone and thioacetic acid at room temperature showned only resonances of acetone and thioacetic acid (Fig. 1A). However, in the spectrum at a low temperature, two additional peaks appeared reversibly at δ=1.7 (d) and δ=2.3 (f) (Fig. 1B). The intensities of these spectra increased as the temperature was lowered, and integral ratios of these peaks were always 2: 1. When acetone was replaced with acetone-d_6, only the peak of δ=2.3 remained (Fig. 1C). Therefore, these peaks (d and f) may be considered to be responsible for the methyl groups of the 1: 1 adduct of thioacetic acid and acetone, which was concluded to be hemimercaptol (**2a**). As another possible adduct of thioacetic acid and acetone,

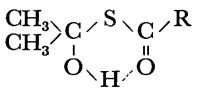
we may consider α-hydroxyisopropyl thionacetate $(CH_3)_2C(OH)OCSCH_3$, which is produced by the addition of tautomeric thionacetic acid to acetone. This possibility could not be excluded experimentally.[5] However, thioacetic acid reacted with aldehyde to produce hemimercaptal,[6] and also no example has been reported of thionesters being prepared from thioacetic acid.[7] Therefore, the authors prefer the first conclusion. In the spectrum of the lower field, the sharp former peak of the hydroxy proton (e) of **2a** can be interpreted as partly overlapped on the broad peak of the sulfhydryl proton (b) of thioacetic acid by comparing their strengths.

Mercaptol (**2a**) is expected to have the following intra-molecular hydrogen bond.[8] The most striking



characteristic of an intra-molecular hydrogen bond is the absence of any shift upon dilution with an inert solvent.[9] Therefore, we tried to obtain the spectra in a dilute solution of an inert solvent. However, in a large excess of carbon disulfide Eq. (1) lies so far to the left, even at a low temperature, and the concentration of **2a** is so small that the peak of the hydroxyl proton can not be detected. Therefore, the following experiment was carried out. A mixture of **1a** (20 mg) and acetone (0.5 m*l*) in an NMR tube was cooled slowly to −78°C. Fortunately, we found that, at such a low temperature, the rates of both the formation and decomposition of **2** in Eq. (1) become very slow. (See the bending of the straight line at lower temperatures in Fig. 2.) The NMR tube maintained at this temperature was attached to a vaccum line; in this way the acetone was almost evaporated, whereupon about 0.5 m*l* of carbon disulfide was added. The NMR spectrum of this solution was measured at −78°C. The spectrum indicated the presence of a large amount of hemimercaptol (**2a**) ([**2a**]/[acetone]=1.5). The peaks of the sulfhydryl and hydroxyl protons were detected separately at δ=4.72 and δ=5.38 respectively in such an inert solvent. The chemical shift of the latter peak did not move when the solvent was changed from acetone to carbon disulfide. This fact supports the above chelating structure.

The proton resonances of the methylene and methine groups in **2b** and **2c** appeared at δ=4.68 and at δ=6.84 respectively at −35°C; they were in a field lower by 0.22 and 0.14 ppm than those of the corresponding thioacetic acids, **1b** and **1c**. However, the peak of the hydroxyl proton seemed to be superposed on, and was indistinguishable from, that of the sulfhydryl proton.

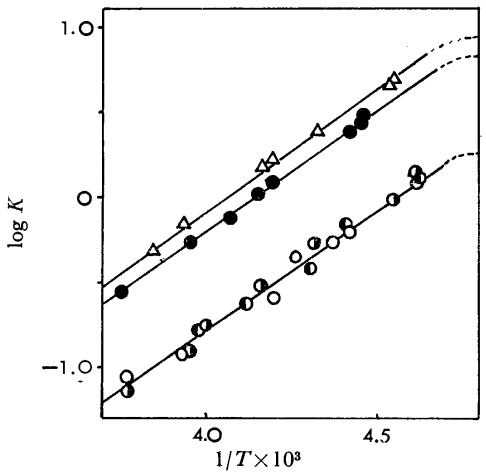


Fig. 2. Plots of log K *vs.* $1/T$ in acetone-d_6.
○: **2a** (3%), ◑: **2a** (4.2%), ◐: **2a** (6.8%), ●: **2b** (5.0 %), △: **2c** (6.8%).
Full lines were drawn by the method of least-squares and dashed lines indicated that experimental points were not on the full lines below *ca.* −60°C.

Table 1. Thermodynamic quantities for the formation of **2** in a large excess of acetone-d_6

Thioacetic acid	ΔH (kcal/mol)	ΔS (e.u.)	Correlation coefficient
CH_3COSH	−6.5±0.2	−30±1	0.993
$ClCH_2COSH$	−6.6±0.1	−27.4±0.6	0.999
$Cl_2CHCOSH$	−6.5±0.1	−26±0.5	0.999

The equilibrium constants were determined in the presence of a large excess of acetone-d_6 between −5 and −50°C. Figure 2 shows a plot of these data employed to determine the thermodynamic quantities (Table 1). The substitution of the electronegative group for the proton of thioacetic acid influences the entropy term more than enthalpy term in the equilibrium. Thus, the value of $-\Delta S$ in the formation of **2b** and **2c** is smaller than that of **2a**. These results can be explained by the view that the substitution of groups which weaken the six-membered chelation increases the degree of freedom of hemimercaptol.

5) In IR spectra, either C=O or C=S stretching absorption of the adduct could not be detected because of being concealed behind the very large absorptions of a large amount of acetone and thioacetic acid.

6) We prepared the adducts of thioacetic acid and aldehyde, RCHO (R: H, CH_3, and CH_3CH_2), described in Ref. 2, and in IR spectra detected the C=O stretching absorptions, respectively in 1680, 1670, and 1675 cm^{-1}.

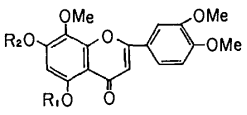
Synthetic Studies of the Flavone Derivatives. XXIV.[1] The Synthesis of 5-Hydroxy-7,8,3′,4′-tetramethoxyflavone, A Pigment from Bergamott Oil

Mitsuru NAKAYAMA, Shûichi HAYASHI, Kenji FUKUI, Tokunaru HORIE,* and Mitsuo MASUMURA*

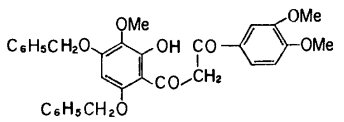
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima
**Department of Applied Chemistry, Faculty of Engineering, University of Tokushima, Tokushima*

(Received December 17, 1971)

In 1968, 5-hydroxy-7,8,3′,4′-tetramethoxyflavone (I) was isolated from Bergamott oil by Farid.[2] In previous papers,[3,4] the present authors reported the syntheses of 5,7-dihydroxy-8-methoxyflavone derivatives from 4,6-dibenzyloxy-2-hydroxy-3-methoxyacetophenone (II). The present paper will describe the synthesis of I in a manner similar to that previously described.[3,4]



I R_1=H, R_2=Me,
IV R_1=R_2=$C_6H_5CH_2$,
V R_1=R_2=H,
VI R_1=R_2=Ac,
VII R_1=H, R_2=Et,
VIII R_1=Ac, R_2=Me,



III

By the Baker-Venkataraman transformation, 4,6-dibenzyloxy-2-hydroxy-3-methoxy-ω-(3,4-dimethoxybenzoyl)acetophenone (III) was obtained from II and 3,4-dimethoxybenzoyl chloride *via* the corresponding ester. The cyclodehydration of III with sodium acetate afforded 5,7-dibenzyloxy-8,3′,4′-trimethoxyflavone (IV). The catalytic hydrogenolysis of IV gave 5,7-dihydroxy-8,3′,4′-trimethoxyflavone (V). The flavone (V) was easily converted into a diacetate (VI) and a monoethyl ether (VII). The partial methylation of V yielded the desired flavone, I, which was then easily converted into an acetate (VIII). The properties of the flavone, I, and of VIII were found to be almost the same as those recorded in the literature.[2]

Experimental[5]

4,6-Dibenzyloxy-2-hydroxy-3-methoxy-ω-(3,4-dimethoxybenzoyl)-acetophenone (III). A mixture of II[3] (510 mg) and 3,4-dimethoxybenzoyl chloride (700 mg) in anhydrous pyridine (5 m*l*) was heated at 120°C for 2 hr. The cooled reaction mixture was then poured into diluted hydrochloric acid. The mixture was extracted with ether, and the ether layer was washed with a sodium carbonate solution and then water. The solvent was removed, and the resulting semi-solid was dried in a desiccator.

A mixture of the above crude ester, powdered potassium hydroxide (1.5 g), and anhydrous pyridine (12 m*l*) was heated at 60°C for 4 hr with stirring. The reaction mixture was acidified with diluted hydrochloric acid, and then extracted with ether. The ether layer was allowed to stand overnight in a refrigerator. The separated crystals were recrystallized from ethyl acetate to give III; mp 169.5—170.5°C (yellow needles); yield, 457 mg (60%). It gave a green color with ferric chloride in ethanol.

Found: C, 70.84; H, 5.62%. Calcd for $C_{32}H_{30}O_8$: C, 70.83; H, 5.57%.

5,7-Dibenzyloxy-8,3′,4′-trimethoxyflavone (IV). A mixture of III (400 mg), sodium acetate (1 g), and acetic acid (10 m*l*) was heated at 140°C for 1 hr. The reaction mixture was diluted with water, and then extracted with ether. The product was recrystallized from ethyl acetate-methanol (1:1) to give IV; mp 157—158.5°C (colorless needles); yield, 350 mg (91%). UV: λ_{max}^{EtOH} nm (log ε); 249 (4.35), 273.5 (4.36), 343 (4.37). NMR:[5] ($CDCl_3$) 6.51_s (H-3); 6.62_s (H-6).

Found: C, 73.43; H, 5.41%. Calcd for $C_{32}H_{28}O_7$: C, 73.27; H, 5.38%.

5,7-Dihydroxy-8,3′,4′-trimethoxyflavone (V). A mixture of IV (300 mg) and palladium-charcoal (Pd: 10%; 90 mg) in a mixed solvent of ethyl acetate and methanol was shaken in an atmosphere of hydrogen for 4 hr. The product was recrystallized from ethyl acetate to give V; mp 217—218°C (yellow prisms); yield, 170 mg (86%). It gave a green color with ferric chloride in ethanol. UV: λ_{max} nm (log ε); (EtOH) 252.5_{sh} (4.20),[5] 278.5 (4.32), 336 (4.26); (EtOH–AcONa) 286.5 (4.46), 315 (4.24), 383 (4.05); (EtOH–$AlCl_3$) 286 (4.28), 349 (4.30), 400_{sh} (3.92). NMR: (DMSO) 3.79_s (3×MeO); 6.28_s (H-6); 6.95_s (H-3); 7.05_d (J=9) (H-5′); 7.46_{bs} (H-2′); 7.59_q (J=2.5, 9) (H-6′); 10.7_{bs}, 12.63_s (2×OH).

Found: C, 63.04; H, 4.52%. Calcd for $C_{18}H_{16}O_7$: C, 62.79; H, 4.68%.

Diacetate (VI): mp 163—164°C (colorless needles from aqueous methanol). UV: λ_{max}^{EtOH} nm (log ε); 247 (4.39), 262_{sh} (4.21), 341 (4.39). NMR: ($CDCl_3$) 6.59_s (H-3); 6.79_s (H-6).

Found: C, 61.84; H, 4.66%. Calcd for $C_{22}H_{20}O_9$: C, 61.68; H, 4.71%.

Monoethyl ether (VII): mp 184.5—185.5°C (yellow needles from ethanol). UV: λ_{max} nm (log ε); (EtOH) 256.5 (4.18), 292 (4.27), 359 (4.42); (EtOH–$AlCl_3$) 262.5 (4.17), 286.5 (4.31), 353 (4.30), 406 (4.09). NMR: ($CDCl_3$) 6.42_s (H-3); 6.60_s (H-6).

Found: C, 64.21; H, 5.40%. Calcd for $C_{20}H_{20}O_7$: C, 64.51; H, 5.41%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2203—2204(1972)

A Convenient Synthesis of Methyl Methylthiomethyl Sulfoxide

Katsuyuki OGURA and Gen-ichi TSUCHIHASHI

Sagami Chemical Research Center, Ohnuma, Sagamihara, Kanagawa 229

(Received December 27, 1971)

Recently we have developed a new method for synthesizing labile aldehydes by using methyl methylthiomethyl sulfoxide (**1**); the method is shown by the following scheme:[1]

$$RX + \underset{\textbf{1}}{CH_2(SOCH_3)(SCH_3)} \xrightarrow[THF]{NaH} RCH(SOCH_3)(SCH_3) \xrightarrow{H^+} RCHO + CH_3SSCH_3$$

The synthetic utility of this method seems to be widely recognized, and we have received many inquiries about the details of the method for the preparation of this new reagent (**1**). In this note we will describe a convenient way to synthesize **1** and the related compounds.

Although **1** can be obtained by the substitution reaction of chloromethyl methyl sulfoxide[2] with the methyl mercaptide anion, as has previously been reported by us,[3] this method does not appear to be suitable for the large-scale preparation of **1**, because chloromethyl methyl sulfoxide is relatively unstable. Therefore, we searched for a way to obtain **1** on a large scale and developed the improved method for the synthesis of **1** which will be described below.

Formaldehyde dimethyl mercaptal, which had easily been obtained by the acid-catalyzed condensation of formaldehyde with methyl mercaptan, was oxidized by one mole-equivalent of hydrogen peroxide in acetic acid to afford **1** in a 78% yield. In a similar manner, ethyl ethylthiomethyl sulfoxide (**2**), isopropyl isopropylthiomethyl sulfoxide (**3**), and phenyl phenylthiomethyl sulfoxide (**4**) were formed in yields of 83, 76, and 96% respectively. The oxidation with other oxidizing reagents did not give satisfactory results. For example, *m*-chloroperbenzoic acid and sodium metaperiodate converted formaldehyde diethyl mercaptal into **2** in yields of 56% and 9% respectively.

It should be noted that the oxidation of acetaldehyde

$$RSCH_2SR \xrightarrow[AcOH]{H_2O_2} RSOCH_2SR$$

1, R=Me
2, R=Et
3, R=*i*-Pr
4, R=Ph

dimethyl mercaptal with hydrogen peroxide in acetic acid gave a mixture of two diastereoisomeric methyl 1-methylthioethyl sulfoxides (**5**, 66% yield, in a ratio of 66: 34).[4]

$$\underset{}{CH_3CH(SCH_3)(SCH_3)} \xrightarrow[AcOH]{H_2O_2} \underset{\textbf{5}}{CH_3CH(SOCH_3)(SCH_3)}$$

Experimental

Oxidation of Formaldehyde Dimethyl Mercaptal. To a solution containing 25.09 g of formaldehyde dimethyl mercaptal in 50 m*l* of acetic acid, 26.5 m*l* of an aqueous solution of hydrogen peroxide (concentration: 30%) was added under cooling with ice, and then the resulting mixture was stirred for 30 min at room temperature. After 300 m*l* of methylene chloride had been added, the acetic acid was neutralized with 60 g of potassium carbonate. The mixture was filtered, and the filtrate was dried with anhydrous sodium sulfate. Upon the removal of the solvent, the residue was subjected to fractional distillation to yield 22.41 g of methyl methylthiomethyl sulfoxide (**1**) as a colorless liquid; bp 92—93°C/2.5 mmHg, IR (neat): 1040 cm^{-1}, NMR (in $CDCl_3$): δ 3.63 (s, 2H), 2.59 (s, 3H), and 2.32 (s, 3H).

Found: C, 28.97; H, 6.78%. Calcd for $C_3H_8OS_2$: C, 29.00; H, 6.49%.

The oxidation of this sulfoxide (**1**) with excess hydrogen peroxide in acetic acid yielded bis(methylsulfonyl)methane; mp 148—149°C (lit,[5] mp 145°C).

Oxidation of Formaldehyde Diethyl Mercaptal. (a) To a solution containing 2.486 g of formaldehyde diethyl mercaptal in 15 m*l* of acetic acid, 2.07 m*l* of an aqueous solution of hydrogen peroxide (concentration: 30%) was added while cooling with ice, and then the resulting mixture was stirred for 2 hr at room temperature. The same work-up as above and the fractional distillation of the leavings afforded 2.305 g of ethyl ethylthiomethyl sulfoxide (**2**) as a colorless liquid; bp 95—97°C/2.5 mmHg, IR: 1042 cm^{-1}, NMR (in $CDCl_3$): δ 1.32 (t, 3H, J=7.4 Hz), 1.36 (t, 3H, J=7.4 Hz), 2.5—3.3 (m, 4H), and 3.72 (s, 2H).

Found: C, 39.22; H, 8.00; S, 42.04%. Calcd for $C_5H_{12}OS_2$: C, 39.43; H, 7.94; S, 42.12%.

(b) To a solution containing 871 mg of formaldehyde diethyl mercaptal in 10 m*l* of methylene chloride, a 1.382-g portion of *m*-chloroperbenzoic acid (80% active) was added while the mixture was being cooled with ice. After continuous stirring for 1.5 hr, the mixture was neutralized with 500 mg of potassium carbonate and then subjected to filtration. The subsequent concentration of the filtrate under reduced pressure and the purification of the residue by column chromatography (Florisil, methylene chloride) gave 543 mg of ethyl ethylthiomethyl sulfoxide (**2**). (c) To a solution containing 2.652 g of formaldehyde diethyl mercaptal in 14 m*l* of water and 7 m*l* of methanol, a 4.11-g portion of sodium metaperiodate was added under cooling with ice. After 1 hr of stirring, the mixture was subjected to filtration, and then the filtrate was extracted with methylene chloride. The extract was dried with anhydrous sodium sulfate and concentrated under reduced pressure. The residue was separated by column chromatography (silica gel, methylene chloride, and ethyl acetate) to afford 260 mg of ethyl ethylthiomethyl sulfoxide (**2**).

Oxidation of Formaldehyde Diisopropyl Mercaptal. To a solution containing 4.324 g of formaldehyde diisoproply mercaptal in 15 m*l* of acetic acid, a 3.00-m*l* portion of an aqueous solution of hydrogen peroxide (concentration: 30%) was added while cooling with ice, and then the resulting mixture was stirred for 4.5 hr at room temperature. The same work-up as above, followed by the distillation of the residue under reduced pressure, gave 3.606 g of isopropyl isopropylthiomethyl sulfoxide (**3**) as colorless crystals; mp 39—40°C (bp 87—88°C/1 mmHg), IR: 1048 cm^{-1}, NMR (in $CDCl_3$): δ 1.28 (d, 3H, J=6.8 Hz), 1.32 (d, 3H, J=6.8 Hz), 1.34 (d, 6H, J=6.8 Hz), 2.7—3.6 (m, 2H), and 3.68 (s, 2H).

Found: C, 46.51; H, 9.00; S, 35.76%. Calcd for $C_7H_{16}OS_2$: C, 46.62; H, 8.92; S, 35.56%.

Oxidation of Formaldehyde Diphenyl Mercaptal. To a solution containing 1.538 g of formaldehyde diphenyl mercaptal in 5 m*l* of acetic acid, 0.75 m*l* of an aqueous solution of hydrogen peroxide (concentration: 30%) was added, and then the mixture was stirred for 1 hr at room temperature. After 100 m*l* of methylene chloride, 6 g of potassium carbonate, and a small amount of water had then been added, the resulting mixture was dried with anhydrous sodium sulfate and filtered. The filtrate was concentrated under reduced pressure, and the residue was separated by column chromatography (silica gel, methylene chloride) to afford 1.585 g of phenyl phenylthiomethyl sulfoxide (**4**) as a colorless liquid; IR: 1049 cm^{-1}, NMR (in CCl_4): δ 3.98 (d, 1H, J=13.5 Hz), 4.03 (d, 1H, J=13.5 Hz), and 7.1—7.8 (m, 10H).

Found: C, 62.78; H, 4.85; S, 25.87%. Calcd for $C_{13}H_{12}OS_2$: C, 62.87; H, 4.87; S, 25.82%.

Oxidation of Acetaldehyde Dimethyl Mercaptal. To a solution containing 4.72 g of acetaldehyde dimethyl mercaptal in 10 m*l* of acetic acid, 4.05 m*l* of an aqueous solution of hydrogen peroxide (concentration: 30%) was added, drop by drop, while the mixture was being cooled with ice. After the addition of methylene chloride, the mixture was neutralized with potassium carbonate and filtered. The filtrate was dried with anhydrous sodium sulfate, and, on distilling under reduced pressure, a 3.62-g portion of methyl 1-methylthioethyl sulfoxide (**5**, bp 84°C/2 mmHg) was obtained as a colorless liquid. This liquid was shown by its NMR analysis to consist of two diastereoisomers in a ratio of 66: 34. NMR (in $CDCl_3$): the major component; δ 1.62 (d, 3H, J=7.2 Hz), 2.23 (s, 3H), 2.69 (s, 3H), and 3.64 (q, 1H, J=7.2 Hz), the minor component; δ 1.57 (d, 3H, J=7.2 Hz), 2.31 (s, 3H), 2.55 (s, 3H), and 3.73 (q, 1H, J=7.2 Hz).

Found: C, 34.36; H, 7.44%. Calcd for $C_4H_{10}OS_2$: C, 34.75; H, 7.29%.

The ESR Spectrum of 2-Dimethylaminoazulene Anion Radical

Yusaku IKEGAMI, Hidetoshi WATANABE, and Shuichi SETO

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-2-chome, Sendai

(Received January 12, 1972)

ESR studies of the anion radicals of biazulenyls[1] and methoxyazulenes[2] were reported in previous papers. A similar study has been carried out on the anion radical of 2-dimethylaminoazulene obtained in a relatively stable form.

Experimental

2-Dimethylaminoazulene, mp 99°C,[3] was purified by recrystallization. The solvent *N,N*-dimethylformamide (DMF) and acetonitrile (AN) were distilled onto Molecular Sieve after being purified and degassed. Electrolytic reduction was carried out using DMF and AN as the solvent and tetra-*n*-propylammonium perchlorate as a supporting electrolyte.

The ESR spectra were measured at room temperature with a Hitachi X-band ESR spectrometer, Model 771. A JEOL spectrum computer, JEC-5, was used for spectral simulation.

Results and Discussion

The anion radical of 2-dimethylaminoazulene was prepared by the electrolytic technique which was found useful for the generation of radical ions, particularly of azulene anion radicals.[1,2,4] The electrochemical reduction of the compound in degassed AN gives the ESR spectrum shown in Fig. 1. A similar spectrum was also presented by the electrolysis in DMF.

Hyperfine structure of the spectrum was analyzed with six splitting constants listed in Table 1. The analysis was confirmed by a spectral simulation with the constants and a half-width of 200 milligauss. The assignments for the constants were given according to the type of splitting and by a comparison of the constants with the calculated spin densities.

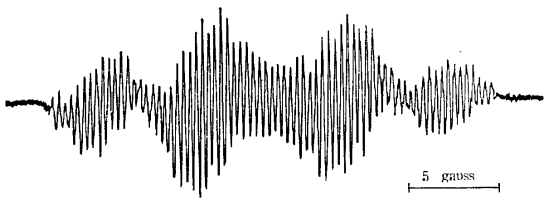

Fig. 1. ESR spectrum of 2-dimethylaminoazulene anion radical generated by the electrolytic reduction in acetonitrile (g=2.0017).

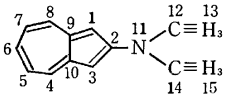
Table 1. Splitting constants (a_i) and spin densities for 2-dimethylaminoazulene anion radical

Position	a_i, gauss		Calcd spin density[a] ρ_i		$\lvert Q^H_{CH}\rvert$[b]
	in AN	in DMF	Hückel	McLachlan	
1,3	0.1	0.1	0.0000	−0.0402	2.5
2			0.1033	0.1060	
4,8	5.62	5.58	0.1937	0.2794	20.0
5,7	1.40	1.40	0.0132	−0.0670	20.9
6	8.01	7.94	0.2435	0.3653	21.8
9,10			0.1020	0.0946	
11 (N)	1.05	1.02	0.0310	−0.0032	
12,14	0.35	0.35	0.0000	−0.0006	
13,15			0.0022	−0.0003	

a) The following parameters were used for the calculation:



$\alpha_{11}=\alpha+1\beta$, $\alpha_{13}=\alpha_{15}=\alpha-0.5\beta$, $\beta_{9,10}=0.9\beta$, $\beta_{2,11}=\beta_{11,12}=\beta_{11,14}=0.8\beta$, $\beta_{12,13}=\beta_{14,15}=3\beta$, and $\lambda=1.2$.
All other bond length variations were neglected.

b) $\lvert Q^H_{CH}\rvert$ value in the relation of $a_i=Q^H_{CH}\rho_i$, in which the average a_i observed and the McLachlan spin density were used.

Calculations of unpaired spin densities (ρ_i) for the anion radical were carried out by means of the Hückel MO theory and the approximate configuration interaction treatment proposed by McLachlan.[5] The Coulomb and resonance integral parameters for the dimethylamino group were chosen by referring to a conjugation model for the methyl group.[6] The values are given in the footnote of Table 1. The calculated spin densities are shown in the table. The McLachlan procedure gives a much more satisfactory result than the Hückel MO calculation. The Q^H_{CH} values obtained by the McConnell relation are reasonable for the seven-membered ring and close to those for azulene anion radicals.[2,4] The low Q^H_{CH} value for the 1- and 3-positions arises mainly from the inaccuracies of both the spin density and the splitting constant for these positions. The splitting constant is less than the halfwidth of a spectral line. Such a calculation might be applied for the analogous anion radicals.

A Fluorescence Study of a Random Coil-to-α-Helix Transition of a 1-Dimethylaminonaphthalene-5-sulfonyl Poly-L-lysine Conjugate

Takayoshi Iio, Yoshihiro Iwashita, and Hideharu Watanabe
Department of Physics, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received February 7, 1972)

In this communication, we wish to report on our studies of a 1-demethylamino-naphthalene-5-sulfonyl poly-L-lysine (DNS-PLy) conjugate by the fluorescence method.

Poly-L-lysine is reversibly transformed in its conformation from a random coil to an α-helix at room temperature when the pH value of the solution is changed from 8 to 11.[1] We intended to obtain information on the state of the L-lysyl residue in each conformation. For this purpose, we bound a fluorescent molecule, DNS, to the ε-N atom of the lysyl residue and observed the polarization of the fluorescence under various conditions.

We found that the L-lysyl residue got some flexibility in the random coiled conformation, while the flexibility of the L-lysyl residue was almost completely suppressed in the α-helical conformation.

Experimental

PLy was obtained according to the usual *N*-carboxyanhydride method.[2] The molecular weight of PLy was determined to be 30000 by the Archibald method;[3] the degree of polymerization was 230.

DNS was coupled to the L-lysyl residue according to the method reported by Weber.[4] The molar ratio of the bound DNS to the L-lysyl residue was 1 : 48.5.

All the fluorescence measurements were performed in polymer concentrations ranging from 0.75×10^{-7} to 3.7×10^{-7} mol residue/*ml*. In these concentrations, the relative fluorescence intensity was proportional to the polymer concentration.

The fluorescence spectra and the relative fluorescence intensity were measured with a Hitachi Fluorescence Spectrometer, MPF-2A.

The polarization of the fluorescence was measured with an improved apparatus which had originally been made for light scattering experiments by Shimadzu Seisakujo, Kyoto. The apparatus was improved in the same manner as is shown in Fig. 5 of ref. 5. A monochromatic filter for excitation light with a maximum of transmittance at 350 mμ, and a cut off filter for emitted light which transformed light only above 420 mμ, were used in this experiment. The size of a fused quartz cell was $6.5\times1.0\times1.0$ cm. The value of polarization (P) was calculated according to Eq. (1);

$$p=\frac{I_v-I_h}{I_v+I_h} \tag{1}$$

where I_v and I_h are the fluorescence intensity of vertically polarized light and that of horizontally polarized light when the solution is excited with vertically polarized light.

The optical rotatory dispersion curves were measured with a JASCO ORD/UV 5 apparatus.

Results and Discussion

The conformational change in PLy with the pH value is shown in Fig. 1, curve a.

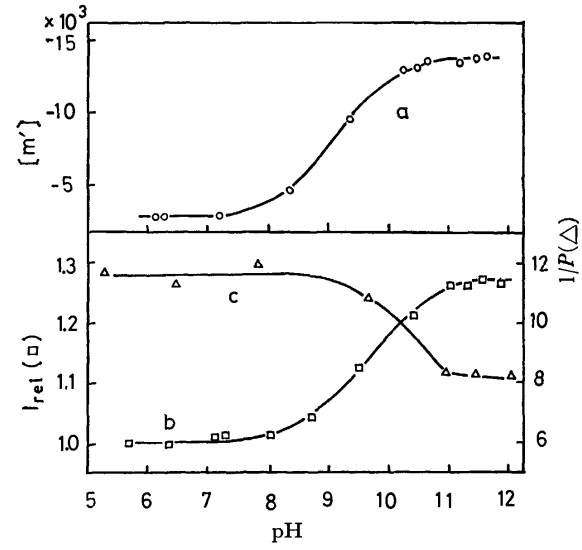

Fig. 1. pH Dependences of mean residue rotation [m'] at 233 mμ of PLy solution (curve a), relative fluorescence intensity (I_{rel}) of DNS-PLy conjugate (curve b), and of inverses value of polarization of the conjugate (curve c). These experiments were performed at room temperature (18—20°C)

DNS bound to PLy had a fluorescence maximum at 495 mμ when it was excited with a light of 350 mμ. The relative fluorescence intensity increased when the pH value of the solution was increased from 8 to 11, as shown in Fig. 1, curve b. In the following discussion, we will make use of the curve b for the purpose of estimating the lifetime of the DNS bound to α-helical PLy.

The inverse value of polarization indicates the degree of flexibility of the L-lysyl residue to which DNS is bound.[6] The pH dependence of this value is shown in curve c (Fig. 1). From an inspection of the curve

6) G. Weber, Adv. in Protein Chem. VIII, 415 (1953).

c, we can conclude that the flexibility of the L-lysyl residue decreased as the conformation of PLy changed from the random coil to the α-helix.

Further information can be obtained from the Perrin plots for the DNS-PLy conjugate. In Fig. 2, we show the effects of the temperature and the viscosity on the polarization of the fluorescence. The data allow the conclusion that Perrin's law of depolarization (Eq. (2)) is closely followed in the cases of both the random coiled and the α-helical PLy.

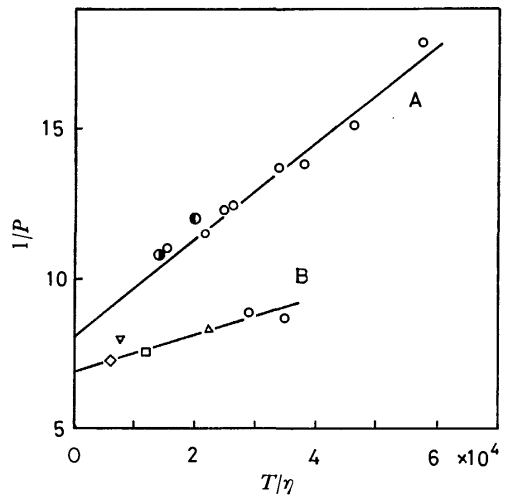

Fig. 2. Effects of temperature and viscosity on the polarization of the fluorescence of the conjugate. Plot A for random coiled conformation was obtained in pH 5.5—6.0 and plot B for α-helix was obtained in pH 11.3—11.9. Open circules were from aqueous solutions at various temperatures and the others were from conjugate-water-glycerine systems at 20°C; glycerine content were 15% (◐), 25% (◑), 10% (△), 30% (□), 40% (▽), and 50% (◇).

From the linear plots in Fig. 2, we can calculate the mean rotational relaxation time (ρ_h) of the DNS molecule bound to PLy according to Eq. (2);[6]

$$\left(\frac{1}{p}-\frac{1}{3}\right)=\left(\frac{1}{p_0}-\frac{1}{3}\right)\left(1+\frac{3\tau_0}{\rho_h}\right) \qquad (2)$$

where P_0 is an intrinsic polarization and where τ_0 is the lifetime of the excited state of the fluorescent molecule. The τ_0 value is proportional to the relative fluorescesce intensity.[7] In the neutral pH region, the τ_0 value has been reported as 1.2×10^{-8} sec,[4] so the τ_0 value in the high pH region (above 11.0) was estimated as 1.5×10^{-8} sec.

The ρ_h value was obtained as 5.6×10^{-8} sec at 20°C in the case of the random coil, and as 16.2×10^{-8} sec at 20°C in the case of the α-helix. The former value is equivalent to a rotational relaxation time of a sphere with a radius of 26 Å; this means that the DNS bound to the L-lysyl residue rotates with a few lysyl residues in the polypeptide chain. The latter value is approximately equal to a harmonic mean rotational relaxation time of an α-helical PLy molecule with a degree of polymerization of 230; that is, the flexibility of the L-lysyl residue is completely suppressed and the rotational motion of the DNS molecule coincide with that of one rigid α-helical PLy molecule.

These results are reasonable because the following situation may occur in the PLy molecule: in low-pH regions, where PLy takes the random coil, the main chain of PLy assumes a locally-extended form because of repulsive interaction between charged side chains, and both the main chain and the side chain get some flexibility. On the other hand, in the case of the α-helix, the main chain is regularly folded and the flexibility of the side chain may be completely suppressed.

Other evidence on this suppression of the flexibility of the L-lysyl residue in the α-helical conformation was obtained by a nuclear magnetic resonance study in D_2O solutions.[8]

As the temperature of an α-helical PLy solution (pH>11.0) is increased to 30°C or more, PLy is transformed in its conformation from the α-helix to the β-form.[9] An intermolecular β-form was also assumed in this case. The hydrophobic bonding between side chains is one of the main factors in stabilizing the β-form.[9] Therefore, we expected the $1/P$ value to decrease when PLy took the β-form. In fact, when the temperature of the PLy solution in pH 11.5 was raised to 34°C from 20°C, the $1/P$ value decreased to 6.0 from 8.7. The details of the fluorescence studies of the β-form will be published elsewhere.

The authors wish to thank to Dr. Sho Takahashi of the Institute for Chemical Research, Kyoto University, for his valuable discussions.

The Convenient Preparation of L-Aspartic Anhydride Hydrochloride and Hydrobromide

Yasuo ARIYOSHI, Tetsuo YAMATANI, Noboru UCHIYAMA, and Naotake SATO

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki, Kanagawa

(Received January 26, 1972)

L-Aspartic anhydride hydrochloride (I) and hydrobromide (II) are useful intermediates for the preparation of aspartyl peptides,[1] aspartic acid α-esters,[1] and polyaspartic acid.[2] II has been prepared thus far by the deprotection of carbobenzoxy-L-aspartic anhydride with hydrogen bromide in acetic acid[1] or by the direct dehydration of L-aspartic acid with an excess of thionyl chloride in chlorosulfonic acid or trifluoroacetic acid, followed by the removal of the strong acid used as the solvent and treatment with hydrogen bromide in acetic anhydride.[3] The strongly acidic solvent has played a role in protecting the amino group from undesirable reactions during the dehydration reaction. However, it seems that these methods are somewhat inconvenient because of the need to protect the amino group or the use of the strongly acidic solvent. Furthermore, the properties of I have not been reported in the literature.

We wish to report a more convenient method for preparing I and II. The synthesis was conducted as a heterogeneous reaction in a more convenient solvent, tetrahydrofuran, in which the dehydrating reagent is dissolved. The reaction proceeds smoothly according to the equation (Fig. 1). L-Aspartic acid was readily

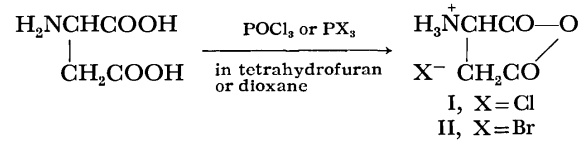

Fig. 1. L-Aspartic anhydride hydrochloride (I) and hydrobromide (II)

dehydrated with phosphorous oxychloride or phosphorous trichloride in tetrahydrofuran at room temperature to give, after filtration, an analytically pure I in a fairly good yield (Table 1). Because of the salt formation at the amino nitrogen, the further condensation of the product to polyaspartic acid does not occur under these conditions. In order to confirm its optical purity, the I obtained here was converted to L-aspartic acid and its optical rotation was measured. The value of the optical rotation of an aqueous solution

of hydrochloric acid in which a given amount of I had been dissolved agreed with that of an aqueous solution of hydrochloric acid containing the corresponding amount of L-aspartic acid (Table 1). These results show that no racemization occurred during the dehydration reaction. Attempts to measure the optical rotation of the anhydride itself in *N,N*-dimethylformamide, dimethyl sulfoxide, or pyridine did not give reproducible results. The anhydride hydrochloride decomposed slightly in such a solvent, even under anhydrous conditions.

When dioxane was used as the solvent for the dehydration reaction, the anhydride (I) contained half a mole of dioxane as the solvent of crystallization; this was confirmed by the elemental analysis and by the NMR spectrum of I (Fig. 1 and Table 1).

A similar treatment of L-aspartic acid with phosphorous tribromide in tetrahydrofuran gave pure L-aspartic anhydride hydrobromide (II) (Fig. 1 and Table 1). The anhydrides (I and II) decomposed slowly on exposure to atmospheric moisture, but they were found to be stable for more than two weeks when stored *in vacuo* over phosphorous pentoxide. Their use for peptide synthesis will be described elsewhere.

Experimental

All the melting points are uncorrected. The IR spectra were obtained in Nujol mull with a Jasco IR-S spectrometer. The optical rotations were measured in 6N hydrochloric acid or 6N hydrobromic acid with a visual polarimeter.

L-Aspartic Anhydride Hydrochloride (I). A typical run (No. 1 in Table 1) was as follows. To a stirred suspension of L-aspartic acid (13.3 g) in tetrahydrofuran (200 m*l*) was added phosphorous oxychloride (15.3 g) at 25°C over a period of 5 min. The mixture was stirred for 1.5 hr at the same temperature. After being stirred for an additional 4 hr at 5—10°C, the crystals thus formed were collected by filtration and washed with tetrahydrofuran. The anhydride hydrochloride so obtained was analytically pure without further purification. Purification by recrystallization is ineffective because the anhydride slightly decomposes in a solution, as has been described in connection with the attempted measurements of its optical rotation.

In the case of phosphorous trichloride (No. 2 in Table 1), the crystals obtained were accompanied with a disagreeable odor but the odor could be removed by adding acetic acid (20 m*l*) to the reaction mixture before filtration.

The results are summarized in Table 1.

L-Aspartic Anhydride Hydrobromide (II). This compound was prepared by the direct dehydration of L-aspartic acid with phosphorous tribromide in tetrahydrofuran according to the procedure described in connection with the preparation of I. The results are shown in Table 1.

As moisture may cause the anhydrides (I and II) to undergo decomposition, dried solvents should be empolyed in order to obtain satisfactory results in their preparation.

Préparations des Sels de Diiodobis(éthylènediamine)cobalt(III)

Masayoshi NAKAHARA et Motoko MITSUYA

Laboratoire de Chimie Minérale, Faculté des Sciences, Rikkio Université, Ikebukuro, Tokio

(Reçu, le 9, Mars 1972)

La littérature abonde en nombreux exemples rélatifs à la détermination des bandes d'absorption du transfert de charge entre les atomes d'halogènes et l'atome cobaltique ou l'atome chromique. Linhard et son collaborateur,[1] ont tout particulièrement effectués des études sur des complexes du cobalt(III) avec la pentammine et le bis(éthylènediamine). Cependant, il n'y a pas de résultat concernant les bandes d'absorption du complexe diiodobis(éthylènediamine)cobalt(III), ceci s'explique par le fait, qu'il est difficile d'obtenir le sel de diiodo-complexe approrié. Seul le triiodure de ce complexe, $[CoI_2(en)_2]I_3$, a été déjà préparé par G. Spacu et P. Spacu,[2] mais on ne peut pas mesurer les bandes d'absorption du champ des coordinats et du transfert de charge à cause de la présence des bandes d'absorption de I_3^-. Nous nous sommes intéressés aux bandes d'absorption du champ des coordinats et du transfert de charge du diiodocomplexe et nous avons comparés les valeurs observées avec les valeurs déterminées par Linhard et son collaborateur pour le difluoro-, dichloro- et dibromo-complexe.

Partie Expérimentale

Préparations. 1) L'iodure de carbonatobis(éthylènediamine)cobalt(III), $[CoCO_3(en)_2]I$, a été préparé selon le procédé de Werner.[3] L'acide iodhydrique utilisé a été purifié selon la méthode usuelle[4] et a été employé fraîchement distillé. 2) Iodure de diiodobis(éthylènediamine)cobalt(III), $[CoI_2(en)_2]I$. Environ 10 g de poudre de $[CoCO_3(en)_2]I$ sont ajoutés, petit à petit, à 15 m*l* d'acide iodhydrique concentré en isolant de l'air par une couche d'éther de pétrole. Le sel de complexe obtenu est un solide brun-rouge. On l'a purifié par recristallisation dans l'alcool méthylique et ensuite séche à l'air. Rendement 10 g.

Trouvé: Co, 10.34; I, 66.94; C, 8.40; H, 2.94; N, 9.73%. Calculé: Co, 10.53; I, 68.00; C, 8.58; H, 2.88; N, 10.01%.

Ce composé est soluble dans l'alcool méthylique, l'alcool éthylique, l'acétone et le dioxane en donnant une solution brun-rouge, par contre il est insoluble dans l'hexane et le

dichlorométhane. 3) Perchlorate de diiodobis(éthylènediamine)cobalt(III), $[CoI_2(en)_2]ClO_4$. A une solution d'iodure de diiodobis(éthylènediamine)cobalt(III) dans l'alcool méthylique on ajoute du perchlorate de sodium en solution dans l'alcool méthylique et en léger excés par rapport à l'iodure. On obtient un précipité brun-rouge. On filtre et lave à l'alcool méthylique, puis on séche à l'air.

Trouvé: Co, 11.00; I, 49.63; C, 9.25; H, 3.19; N, 10.81%. Calculé: Co, 11.07; I, 47.67; C, 9.02; H, 3.03; N, 10.52%.

La composé obtenu est une poudre brun-rouge, insoluble dans l'alcool méthylique et l'éther. 4) Nitrate de diiodobis(éthylènediamine)cobalt(III), $[CoI_2(en)_2]NO_3$. L'iodure de diiodobis(éthylènediamine)cobalt(III) a été dissous dans l'alcool méthylique; sur la solution ainsi obtenue on verse du nitrate d'ammonium en solution dans CH_3OH et en léger excés par rapport à l'iodure. On filtre et lave le précipité avec de l'alcool méthylique, puis on séche à l'air.

Trouvé: Co, 11.55; I, 50.94; C, 9.40; H, 3.15; N, 13.58%. Calculé: Co, 11.10; I, 51.28; C, 9.71; H, 3.25; N, 14.15%.

Poudre brun-rouge, insoluble dans l'alcool méthylique et l'éther.

Analyse. *1) Cobalt*: On a dosé le cobalt sous forme de sulfate par l'α-nitroso-β-naphthol. Le sulfate de cobalt est obtenu en fondant un mélange constitué par le complexe lui-même et l'hydrogénosulfate de potassium.

2) Iode: On aquotise le complexe en procédant à sa dissolution à chaud dans une solution de NH_3 diluée. On ajoute de l'acide sulfurique et on oxyde par le nitrite de sodium. On extrait l'iode par le tétrachlorure de carbone et on fait alors l'analyse colorimétrique.

Les Spectres d'Absorption. Nous avons enregistré les spectres d'absorption dans l'ultraviolet et dans le visible des différents complexes en solution dans l'alcool méthylique ou à l'état solide avec un spectrophotomètre du type HITACHI EPS2A et un appareil annexe pour mesurer la réflexion diffuse. Les cuves de quartz ont une épaisseur de 1 cm. Les échantillons solides que nous avons utilisés ont été, tout d'abord, pulvérisés et nous en avons déterminé le pourvoir réflecteur diffuse (R_d) en prenant la magnésie comme étalon. Les valeurs de $f(R_d)$ qui sont en rapport direct avec ε peuvent être calculées par l'expression de Kubelka-Munk pour obtenir la courbe $\log f(R_d)$.[5] Nous avons également déterminé les spectres d'absorption infrarouge avec un appareil JASCO (Japan Spectroscopic Co., Ltd) DS 402 G en adoptant la méthode Nujol-Mull.

Résultats et Discussion

Dans les spectres d'absorption visible du $[CoI_2(en)_2]I$ en solution dans l'alcool méthylique, les positions et les configurations des bandes du champ des coordinats coïncident presque parfaitement dans la région comprise entre 12000 cm^{-1} et 20000 cm^{-1} avec les spectres d'absorption à l'état solide des composés $[CoI_2(en)_2]I$, $[CoI_2(en)_2]ClO_4$ et $[CoI_2(en)_2]NO_3$. Nous avons donc réussi à observer en solution le spectre d'absorption du complexe sans décomposition. Dans la figure 1, nous avons representé pour la région comprise entre 12000 cm^{-1} et 22000 cm^{-1} les spectres d'absorption du complexe $[CoI_2(en)_2]^+$ en solution et également ceux des composés *trans*-$[CoX_2(en)_2]ClO_4$ (avec X=F, Cl, Br)[1] afin de pouvoir les comparer. Les données ainsi obtenues sont rassemblées dans le tableau 1.

En ce qui concerne les spectres d'absorption de

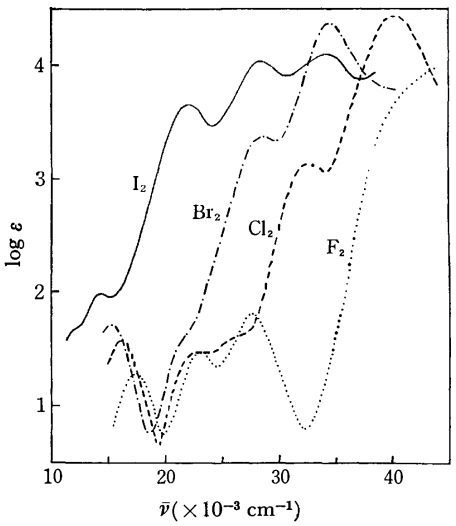

Fig. 1. Spectres d'absorption de $[CoX_2(en)_2]^+$ (X=F,Cl,Br,I)

TABLEAU 1. MAXIMA DES BANDES D'ABSORPTION (cm^{-1}) ET COEFFICIENT D'EXTINCTION MOLAIRE (log ε)

trans-$[CoX_2(en)_2]^+$	Ia	Ib	II	III	IV	V
X=F	17200	22620	27600			
	(1.35)	(1.49)	(1.67)			
X=Cl	16120	22490	25920	32500	40270	
	(1.61)	(1.46)	(1.49)	(3.12)	(4.43)	
X=Br	15210	21680		28100	34600	
	(1.73)	(1.49)		(3.35)	(4.34)	
X=I	14000			21700	28600	33900
	(2.01)			(3.68)	(4.02)	(4.17)

$[CoI_2(en)_2]^+$ nous avons trouvé une bande interdite par spin, une bande permise par spin et trois bandes de transfert de charges. Les bandes de champ de coordinat Ib et II ont été couvertes par les bandes de transfert de charges III et IV. Nous n'avons pas pu aboutir à un résultat précis du fait que la bande d'absorption III empiéte sur la bande d'absorption Ia; le maximum de la bande Ia s'est déplacé vers les plus fortes longueurs d'ondes et son coefficient d'éxtinction molaire augmente; ces résultats sont à comparer avec ceux obtenus dans les cas du dibromo, dichloro et difluoro-complexe. Le déplacement de la bande Ia vers les longueurs d'ondes élevées et l'augmentation de l'extinction molaire se font suivant l'ordre F, Cl, Br, I. Les positions du maximum de la bande d'absorption III, du dichloro, dibromo et diiodocomplexe sont déplacées vers les plus fortes longuers d'ondes; les coefficients d'extinctions molaires augment suivant l'ordre précédent. La bande d'absorption IV se déplace dans le même sens que les bandes précédents, mais par contre son coefficient d'extinction molaire évolue en sens inverse. Nous avons observé une bande d'absorption V uniquement dans le cas du diiodocomplexe.

Les spectres d'absorption du *cis*-$[CoX_2(en)_2]^+$ (où X=Cl, Br) mesurés par Linhard et son collaborateur[1] montrent que les bandes d'absorption correspondantes à III et IV sont très plates et tout à fait différentes avec des bandes III et IV observées dans le complexe *trans*-

5) P. Kubelka et F. Munk, *Z. Tech. Physik.*, **12**, 593 (1931).

Tableau 2. Maxima des bandes d'absorption infrarouge (cm^{-1}) de *trans*-$[CoX_2(en)_2]X$

X=Cl	585	555	513	473
X=Br	580, 575	554	507	470
X=I	570	544	497	460

$[CoX_2(en)_2]^+$ (où X=Cl, Br).

De ces faits nous avons conclu que les composés que nous avons préparés sont du type *trans*.

Nous avons étudié également le spectre d'absorption infrarouge dans la région comprise entre 4000 cm^{-1} et 400 cm^{-1}. Nous avons remarqué entre 4000 cm^{-1} et 600 cm^{-1} les diverses bandes d'absorption à haut coefficient d'extinction molaire qui correspondent aux bandes d'absorption de l'éthylènediamine dans le complexe *trans*-$[CoX_2(en)_2]X$ (où X=Cl, Br).[6] Nous avons trouvé les bandes d'absorption des liaisons Co–N et de la déformation de l'anneau du chélate entre 600 cm^{-1} et 400 cm^{-1} (le tableau 2). Les position des bandes ainsi que leur déplacement vers les longueurs d'ondes élevées sont en bon accord avec les résultats de Hughes et collaborateurs.[6]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2211—2212(1972)

The Prins Reaction of Styrene in the Presence of Cation-exchange Resin

Yasuhiko KURUSU

Department of Chemistry, Faculty of Science and Technology, Sophia University, 7 Kioicho, Chiyoda-ku, Tokyo

(Received August 24, 1971)

The application of ion-exchange resin to the Prins reaction has been investigated by several workers. The reactions of styrene, methyl styrene[1] and propyrene[2] were carried out with KU-2 cation-exchange resin, which gave the corresponding 1,3-dioxanes in good yields. However, in any case, no detailed study from the viewpoint of a solid acid catalyst has been reported on a Prins reaction in the presence of ion-exchange resin. Because the active site of a solid catalyst is the surface of the resin, the reactivity of the ion-exchange resin is largely dependent upon a crosslinkage which is determined by the content of divinylbenzene(DVB), and the crosslinkage makes a micropore in the state of swelling. The ion-exchange resin with a higher DVB content has smaller micropores. Besides the micropores, the ion-exchange resin polymerized with a macroreticular reagent has macropores. Thus, the reaction of styrene with formaldehyde in the presence of various types of ion-exchange resins was carried out, and the relation of the reactivity and the crosslinkage was investigated. The ion-exchange resins used were Diaion SK 1B, SK 104, the Diaion PK series, and Amberlite XE 284, all of which are strongly acidic cation-exchange resins and WK 10, and WK 11, which are weakly acidic cation-exchange resins.

When the SK series was used, the crosslinkage was dependent upon the yield of 4-phenyl-1,3-dioxane. The crosslinkage of SK 104 is 4%, and that of SK 1B is 8%. The crosslinkage in the PK series varies from 4%(PK 208) to 14%(PK 228). It is interesting that the yield of 4-phenyl-1,3-dioxane is highest with the crosslinkage of 10% among the other PK series. It may be found from this result that the size of the micropores is related to the reactivity. As the size of the pores of the resins becomes larger, the yield of 4-phenyl-1,3-dioxane increases. However, the micropore sizes of No. 8, 9, and 10 in Table 1 are so large that swelling occurs and it is difficult to separate the product because of its adsorption by resin. Also, the macropore has an important effect upon the yield; the porous type of 10% crosslinkage is most effective. However, the highly porous types (HPK, XE 284) prepared from higher contents of DVB are not so excellent as the PK series. The highly porous ion-exchange resin adsorbs the start-

ing materials and products, so filtration is troublesome. It may safely said that the highly porous ion-exchange resin is a good adsorbent, but is unsuitable for the catalyst of the Prins reaction. That is, XE 284 gave a considerable yield in 3 hr, but this resin was gradually wrecked by the reaction. Therefore, it is difficult to carry out the reaction further, and a repeated reaction with XE 284 is impossible.

In No. 2, 3, and 4 in Table 1, reactions with the same catalyst were repeated. The results show that this catalyst was sufficiently used without regeneration.

To examine the effect of the temperature, the reaction was carried out with PK 220 at 30°C. In the case of PK 220, the yield was 6.4%. When SK 1B and SK 104 were used as the catalysts, the same results were obtained. These results show that the reaction is dependent upon the temperature.

Swelling is a very important factor in a porous-type ion-exchange resin. Therefore the reactions were investigated in various solvents. As the solvents, dimethylsulfoxide, methylene chloride, dioxane, and methanol were used, and paraformaldehyde was employed instead of formalin. In dimethylsulfoxide, a small amount of 4-phenyl-1,3-dioxane was obtained. However, in the other solvent, 4-phenyl-1,3-dioxane was not obtained but an unidentified product was obtained besides recovered styrene. A further investigation of the reaction in nonaqueous solvents is now in progress.

When the reaction is carried out with ion-exchange resin as the solid acid catalyst insted of sulfulic acid, phospholic acid, acetic acid or Lewis acid, it is easy to separate the product and the catalyst, and styrene and formalin are made to flow from the top of the column, packed with resin, and 4-phenyl-1,3-dioxane is obtained at the bottom of the column. It is possible to recycle the unreacted material after the separation in order to raise the yield and the efficiency.

Experimental

The ion-exchange resin (100 m*l*) was immersed into 250 m*l* of 50% H_2SO_4 for 8 hr at room temperature, and then filtered and washed with water until the washings were found by litumus paper to be no longer acid.[3] The treated ion-exchange resin, 35 g of styrene, and 100 m*l* of formalin (37%) were mixed in a 300 m*l*, three-necked, round-bottom flask for a given time at an appropriate temperature. After the reaction, the mixture was poured into 300 m*l* of water and the resin was filtered off. The filtrate was extracted with ether. The ether solution was distilled, and the unreacted styrene was obtained at 42°C and 20 Torr. The product was distilled at 90—95°C and 3 Torr. This compound was identified as 4-phenyl-1,3-dioxane by comparison with the IR spectrum of an authentic sample. The results are shown in Table 1. In these reactions, the unreacted styrene was recovered quantitatively.

The SK series are the strongly acidic sulfonic-acid-type cation-exchange resins, and the WK series are the weakly acidic carboxylictype cation-exchange resins. The PK series are the porous ion-exchange resins, which are of the sulfonic-acid type. The HPK and XE 284 are highly porous ion-exchange resins.

The author wishes to thank Mr. Moriyama, Mitsubishi Chemical Industries, Ltd., for his supply of ion-exchange resins.

acrylate (a molar ratio 1 : 2) in pyridine at 110—120°C to afford a dicarboxylic acid ester IIa in a 66% yield with small amounts of Ia and IIIa.

Products Ia and IIa are normal Michel addition products. The cyclic product IIIa would be formed through the cyclization of Ia, since heating of Ia in pyridine afforded IIIa.

Product IIa was hydrolyzed by hydrochloric acid to give an aldehyde IV and hydrogenated with PtO_2 to form a saturated cyclic product V.

N-Propylidene-*t*-butylamine reacted in the same way to give IIb and Ib in 74 and 11% yields, respectively.

Experimental

The reaction products were identified by means of elemental analysis, molecular-weight measurement, and IR, NMR spectral measurements. The physical and analytical data of the products, which are all new compounds, are given in Table 1.

Reaction of N-*Propylideneisopropylamine*[1] *with Methyl Acrylate.* A mixture of 20 m*l* of pyridine, 9.9 g (0.1 mol) of *N*-Propylideneisopropylamine, 17.2 g (0.2 mol) of methyl acrylate, and a small amount of hydroquinone was heated at 110—120°C for 16 hr. The reaction mixture was fractionally distilled to afford 0.8 g (4%) of methyl 5-isopropylimino-4-methylvaleate (Ia), 17.9 g (66%) of dimethyl 4-(isopropylimino)methyl-4-methylheptanedioate (IIa) and 1.1 g (7%) of 1-isopropyl-3-methyl-6-oxopyperidine-2-ene (IIIa).

Hydrolysis of IIa. A mixture of 5.4 g (0.02 mol) of IIa and 10 m*l* of 1N HCl aqueous was refluxed for 30 min. The usual work-up of the resultant solution afforded 3.0 g (63%) of dimethyl 4-formyl-4-methylheptanedioate (IV).

Hydrogenation of II. A mixture of 26 g (0.1 mol) of IIa, 0.15 g of PtO_2 and 25 m*l* of absolute ethanol was stirred at a room temperature under a hydrogen pressure of 20 kg/cm^2 for 2 hr in a 100 m*l* autoclave to give 19.3 g (80%) of methyl 3-(1-isopropyl-3-methyl-6-*oxo*-3-piperidyl) propionate (V).

On the Catalytic Addition of Alcohols to 1,3-Butadiene with Rhodium Trichloride Hydrates

Hiroshi KAWAZURA and Toshio OHMORI

Research Laboratory, Japan Synthetic Rubber Co., Mochi-izaka, Ikuta, Kawasaki

(Received November 20, 1971)

Recently, it was disclosed by Dewhirst[1] that ethanol added to 1,3-dienes in the presence of $RhCl_3 \cdot 3H_2O$ to give allylic ethers, but the mechanism of formation of the ethers was left uncertain.

We wish to report some facts which may shed light on the mechanisms of this new addition reaction.

Table 1 summarizes the results of the addition reactions of various alcohols to 1,3-butadiene. The reaction proceeds at room temperature under nitrogen in the presence of catalytic amount of $RhCl_3 \cdot nH_2O$ (n=2 or 3) to give an addition product which is found to be a single component from glc analysis. The addition product of EtOH separated by preparative glc, a colorless liquid of bp 76°C, was confirmed to be 3-ethoxybut-1-ene by comparison of the IR and NMR spectra with those of an authentic sample.[2] Similarly, the addition products of the other alcohols were identified as 3-alkoxybut-1-ene.

$$CH_2{=}CH{-}CH{=}CH_2 + ROH \longrightarrow CH_3{-}\underset{\displaystyle OR}{\underset{|}{CH}}{-}CH{=}CH_2$$

The known binuclear rhodium complex (I)[3] was

isolated from the reaction mixture as brown crystals, and this was found to be able to catalyze the selective addition of *n*-PrOH to butadiene to give 3-*n*-propoxybut-1-ene. Therefore it is likely that I is an intermediate of the reaction, although other nascent π-allylic complex which might be convertible to I is not necessarily excluded.

The mononuclear rhodium complex (II)[3,4] which may be formed at lower temperature in the reaction mixture would not be a true intermediate, since the yield of 3-*n*-propoxybut-1-ene decreased drastically at lower temperature as shown in the Table 2.

Table 2. Temperature dependence of the addition reaction of *n*-PrOH to 1,3-butadiene[a]

Reaction Temp (°C)	Time (hr)	Yield of 3-*n*-propoxybut-1-ene (mmol)	% [b]
70	40	1.9	0.5
50	40	24.3	6.1
20	42	7.8	2.0
10	42	1.1	0.3

a) $RhCl_3 \cdot 3H_2O$ 1 mmol, *n*-PrOH 800 mmol, and 1,3-Butadiene 400 mmol.
b) On the basis of butadiene fed.

It should be noted that the Pd complex catalyzes dimerization of butadiene in alcohols[5,6] producing predominantly 1-alkoxy derivatives of butadiene dimer in contrast to the present rhodium catalyst.

The yields of the addition products seem to have linear correlations with intensities of the OH stretching vibrations of the alcohols which are considered to be a measure of ionization degree of the OH bonds.[7] This indicates a predominant contribution of the ionic nature of the alcohols to the addition reaction, while the steric influence of the alkyl group should not be overlooked since the butanol family shows somewhat different correlation.

Charge-Transfer Absorption in the Solid Aromatic Diamine Complexes with Picrates

Gunzi SAITO and Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received December 3, 1971)

Molecular complexes have received considerable attention for many years. Nonetheless, most of those described in the literature are derived from neutral donor and acceptor molecules; relatively little is known about complexes made from neutral molecules and salts. Recently, we reported on the vibrational and electronic spectra of Kofler's ternary complex, α-naphthylamine-pyridine-picric acid (1 : 1 : 1), and postulated that the interaction between the amine molecule and the picrate ion is of the charge-transfer type.[1] Our interest in the acceptor strength of the picrate ion has led to a further study of the molecular complexes with picrates. As it seemed highly desirable to have simple counter ions, we chose sodium, potassium, and ammonium picrates. Their electron-acceptor strengths are expected to be comparable with that of *s*-trinitrobenzene; therefore, strong electron-donors must be combined with the picrates if one is to observe the charge-transfer absorption separated from the spectrum of the yellow-colored component. Benzidine, *o*-tolidine, and *o*-dianisidine were thought to be best suited to our purpose. These donors have low enough ionization potentials and were extensively used in the related work to be described in forthcoming papers.

The picrates were prepared by the addition of an aqueous solution of an appropriate carbonate or nitrate to picric acid dissolved in alcohol. The diffuse reflection spectra were recorded on a Beckman DK 2A spectroreflectometer and were plotted using the Kubelka-Munk function, as has been described in a

1) Y. Matsunaga and G. Saito, This Bulletin, **45**, 963 (1972).

previous paper.[2] Our attempts to prepare the solid complexes with sodium picrate from a solution failed except in the case of *o*-dianisidine. With this combination, dark brown-colored crystals were obtained from hot acetone. As is shown in Fig. 1, comparison with the spectrum of sodium picrate clearly indicates the appearance of a weak low-energy absorption upon the complex formation. When an equimolecular mixture of *o*-dianisidine and sodium picrate was thoroughly ground and heated to the melting point of the diamine, the same spectrum could be observed with the product. Therefore, all the other combinations were examined by the latter technique. The spectra of the *o*-dianisidine complexes with potassium and ammonium picrates

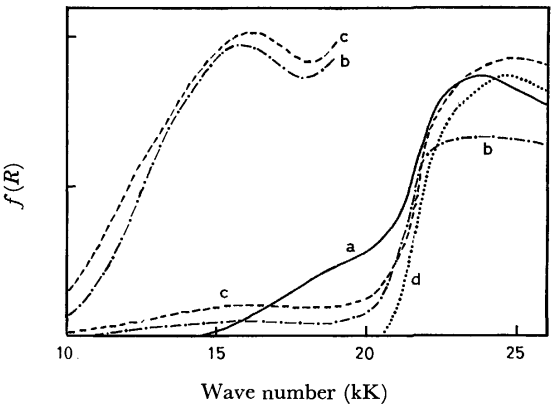

Fig. 1. Diffuse reflection spectra of the *o*-dianisidine complexes with (a) sodium picrate, (b) potassium picrate, (c) ammonium picrate, and (d) sodium picrate alone.

are also presented in Fig. 1. The strong absorptions around 24 kK common to all three complexes should be assigned to the picrate ion. In the complexes with potassium and ammonium picrates, the maxima of the low-energy absorptions are located at 15.8 and 16.1 kK respectively; see the spectra, the ordinates for which are expanded. The results with all the donors are summarized in Table 1. An examination of the data for each picrate shows a hypsochromic shift going from *o*-dianisidine→*o*-tolidine→benzidine. This shift is nearly parallel to that of the charge-transfer absorption observed in the *s*-trinitrobenzene complexes. These pieces of spectroscopic evidence lead to the conclusion that the weak absorptions are due to a charge-transfer interaction between the diamine and the picrate. The weakness of the charge-transfer absorptions was noted also in Kofler's ternary complex and in a related one;[1] it now appear to be characteristic of the complexes with picrates.

Table 1. The energies of the charge-transfer absorptions appeared in the solid diamine complexes with picrates (in kK)

Donor	Acceptor			
	Na picrate	K picrate	NH_4 picrate	*s*-Trinitrobenzene
None	24.8	23.7	24.2	—
Benzidine	*ca.* 20	16.6	17.0	19.0
o-Tolidine	*ca.* 19	15.8	16.7	17.6
o-Dianisidine	*ca.* 19	15.8	16.1	17.3[a]

a) The composition is known to be 1:2, see Ref. 3.

Although the charge-transfer absorption in the present solid complex is close to that in the corresponding *s*-trinitrobenzene complex, the location is somewhat affected by the kind of cation in the picrate. In Fig. 1, we see that the absorption maximum in the complex with sodium picrate appears at an energy higher by a few kK than that in the complex with potassium or ammonium picrate. This displacement may be, at least qualitatively, interpreted in terms of the polarization theory. The polarizing power of alkali ions is in the order of decreasing ionic radius: $K^+ > Na^+$. Consequently, the sodium ion in the crystal brings about an enhanced partial localization of the electron cloud of the picrate ion. Besides, the constancy of the absorption maximum in the three picrates implies that the lowest vacant orbital, with which the charge-transfer from the diamine is associated, becomes as unstable as the occupied orbital. Thus, the polarization of the picrate ion may account for the shift of the charge-transfer absorption toward the high-energy side. The ammonium ion is known to be a little larger when it rotates freely than the potassium ion. However, the present results suggest that the anion in the ammonium salt is slightly more polarized than that in the potassium salt.

Our finding is unique in the sense that the complex has an anion acting as an electron-acceptor. As early as 1910 Sudborough and Beard reported that potassium *o*-, *m*-, and *p*-aminobenzoates form deeply-colored molecular complexes with *s*-trinitrobenzene.[4] In addition, a black potassium α-anthranolate-*s*-trinitrobenzene complex with a 1:2 composition was isolated by Cadre and Sudborough.[5] More recently, several complexes containing the phenazinium ion and related ions were prepared.[6,7] Furthermore, there are some hydrocarbon complexes with tropylium bromide acting as an acceptor.[8] In the cases which have appeared so far in the literature, the complexes are of anionic donors and neutral acceptors or of neutral donors and cationic acceptors.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2216—2217(1972)

The Formation of Benzoyl Chlorides from 1,2-Dibenzoylhydrazines or Dibenzoyldiimides

Tsuneo IMAMOTO

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka

(Received December 13, 1971)

The reaction of acid hydrazide with chlorine was reported by Carpino.[1,2] He obtained acid chlorides in good yields from the corresponding hydrazides by successive treatments with hydrogen chloride and chlorine. Later, Kissinger and Ungnade showed that the prior conversion of acid hydrazide to the hydrochloride was not necessary.[3]

The pathway of the reaction was proposed by Carpino to be as in Scheme (1).[2] This mechanism appears to be

$$\text{R-CONHNH}_2 \xrightarrow{\text{HCl}} \text{R-CONH}\overset{+}{\text{N}}\text{H}_3\text{Cl}^- \xrightarrow{\text{Cl}_2} [\text{R-CO-N=N-Cl}] \xrightarrow{-\text{N}_2} \text{R-COCl} \qquad (1)$$

reasonable for his reaction conditions. However, in the cases of no concomitant addition of hydrogen chloride (Kissinger's conditions), the reaction seems to proceed not solely through the above pathway (1).

In order to clarify the reaction pathways, we first isolated the intermediates under Kissinger's conditions, using benzoylhydrazine as a representative acid hydrazide.

When benzoylhydrazine was treated with chlorine in nitromethane without prior conversion to the hydrochloride, large amounts of white precipitates appeared at the initial stage of the reaction. These precipitates completely disappeared upon the further introduction of chlorine to give benzoyl chloride in a good yield (78%). The precipitates were identified as a mixture of benzoylhydrazine hydrochloride and1,2-dibenzoylhydrazine (mol ratio: *ca.* 4: 1).

On the other hand, no 1,2-dibenzoylhydrazine was detected at any stage of the reaction under Carpino's conditions.

These results indicate that benzoylhydrazine hydrochloride and 1,2-dibenzoylhydrazine may both be precursors of benzoyl chloride under Kissinger's conditions. This was supported by the results of the reaction of pure 1,2-dibenzoylhydrazine with excess chlorine in nitromethane or dichloromethane; benzoyl chloride was obtained in yields of 76 and 82% in the respective solvents.

Further, several 1,2-bis(substituted benzoyl)hydrazines were allowed to react with chlorine. Table 1 shows the yields of the corresponding chlorides obtained. In the cases of *m*-chloro and *p*-chloro derivatives, the reaction rates were fairly slow, and the chlorides were scarcely obtained.

It is well known that 1,2-diaroylhydrazine is oxidized by halogen to afford diaroyldiimide.[4,5] This suggests that dibenzoyldiimide is also the precursor of benzoyl chloride. Thus, we treated dibenzoyldiimide with chlorine in the same solvents as in the cases of the preceding dibenzoylhydrazines. The reaction proceeded quite smoothly at room temperature. The yields of benzoyl chloride are also shown in Table 1, along with those of other chlorides.

Table 1. Yields of benzoyl chlorides

X	X-C_6H_4-CONH-NHCO-C_6H_4-X		X-C_6H_4-CON=NCO-C_6H_4-X	
Solvent	CH_3NO_2	CH_2Cl_2	CH_3NO_2	CH_2Cl_2
H	76%	82%[a]	79%	89%
p-CH_3O	87[c]	49[b]+44[c]	11[b]+81[c]	93[b]
p-CH_3	82	87[a]	86	91
o-CH_3	81	90	81	90
o-Cl	79	88	—	—

a) The reaction time was 10—30 hr at room temperature.
b) *p*-Anisoyl chloride.
c) 3-Chloro-4-methoxybenzoyl chloride.

These results lead to the conclusion that acid chloride is formed through both the pathways, (1) and (2), under Kissinger's conditions.[6]

$$2\ \text{R-CONHNH}_2 \xrightarrow{\text{Cl}_2} \text{R-CONHNHCO-R} \xrightarrow{\text{Cl}_2} \text{R-CO-N=N-CO-R} \xrightarrow{\text{Cl}_2} 2\ \text{R-COCl} \qquad (2)$$

Experimental

Isolation of Intermediates. Into a solution of 3.91 g of benzoylhydrazine in 120 m*l* of anhydrous nitromethane, dry chlorine gas was passed at about 0.5 m*l*/sec, while stirring was continued for 5 min. The white precipitates thus formed were collected, washed with nitromethane, and dried. This material (1.99 g) was then triturated with 40 m*l* of water; a subsequent filtration left a colorless powder I (0.43 g; mp 238—240°C). The filtrate was evaporated to afford colorless crystals, II (1.50 g, mp 192—194°C (decomp.)).

o-Cl	219—221	54.27	3.27	8.79	22.98
		(54.39)	(3.26)	(9.06)	(22.94)
m-Cl	272—274	54.47	3.20	9.23	23.22
		(54.39)	(3.26)	(9.06)	(22.94)

The substances (I and II) separated above were identified as 1,2-dibenzoylhydrazine and benzoylhydrazine hydrochloride respectively by comparing their infrared spectra with those of authentic samples.

1,2-Dibenzoylhydrazines. These were prepared by the usual method.[7] The melting points and analytical data for the new hydrazines are listed in Table 2.

Dibenzoyldiimides. The general procedures were as follows. 1,2-Dibenzoylhydrazine (0.20 mol) was saturated in dimethylformamide. Bromine (48 g, 0.30 mol) was added dropwise into this solution with vigorous stirring for 15 min. After the addition of bromine, stirring was continued for 2 hr, and then the reaction mixture was poured into *ca.* 3 *l* of ice water. The precipitated solid was collected, washed with water, and dried *in vacuo* at 50—60°C. The yield of the crude product was 87—94%. This crude diimide was recrystallized from *n*-hexane-benzene (2: 1).

The melting points and analytical data for bis(substituted benzoyl)diimides are shown in Table 3.

The Reaction of 1,2-Dibenzoylhydrazine with Chlorine. 1,2-Dibenzoylhydrazine (6—8 g) was suspended in 50 m*l* of nitromethane or dichloromethane. Chlorine gas was passed slowly into this suspension at room temperature until the dibenzoylhydrazine had been completely dissolved. This required 1—5 hr. The solvent was then removed by rotary evaporation, and the liquid was distilled under reduced pressure.

The benzoyl chlorides obtained were identified by comparing their infrared spectra with those of authentic samples.

The Reaction of Dibenzoyldiimides with Chlorine. Dibenzoyldiimides were treated with chlorine under the same conditions as in the cases of the preceding dibenzoylhydrazine. The reactions were completed within 30 min.

Halogen Migration of 2,2-Dihaloadamantane Induced by Aluminum Halides

Kwan Her YANG, Koichi KIMOTO, and Mituyosi KAWANISI

Department of Industrial Chemistry, Faculty of Engineering Kyoto University, Yoshida, Kyoto

(Received February 4, 1972)

We reported on the halogen migration in the reaction of organic dihalides with aluminum halide.[1] McKervey and coworkers have shown the formation of 1,3-dichloroadamantane (IVa) from 2,2-dichloroadamantane (Ia) when Ia was treated with aluminum chloride in carbon tetrachloride.[2] When the reaction of Ia was effected in nitromethane, they could identify a mixture of *trans*- and *cis*-1,4-dichloroadamantanes (Va) (VIa) from the reaction mixture. However, no experimental details were given. As an effective means for the synthesis of new haloadamantane,[3] we have reinvestigated the reaction in more detail under slightly different conditions.

When a solution of 2,2-dichloroadamantane[2] (Ia) was treated with anhydrous aluminum chloride at a low temperature, six compounds IIa—VIIa (conversion 100%) could be separated by a combination of column chromatography and preparative glc (Scheme 1; % ratio in brackets). Compounds IIa, IIIa, and IVa were identified by comparison with the corresponding authentic samples. The structure of stereoisomers (Va) and (VIa) were assigned to *trans*- and *cis*-1,4-dichloroadamantanes, respectively, mainly by spectroscopic

methods. The fragmentation patterns of mass spectra of Va and VIa were very similar. NMR spectrum of Va showed the existence of one proton due to CH–Cl at δ 4.26, and that of VIa at δ 4.19. When these shift values were compared with those of a mixture of Va and VIa derived from 1,4-dihydroxyadamantane[4] a very good coincidence was observed (Table 1). The

b) Observed values.
c) Values estimated from the mixture of 1,4-dichloroadamantanes.[4]

product (VIIa) was assigned to 1,4,4-trichloroadamantane, since VIIa was identical with the compound obtained by the reaction of 1-hydroxyadamantan-4-one[4] with a mixture of phosphorus trichloride and phosphorus pentachloride. 2,2-Dibromoadamantane (Ib)[5] being more reactive than Ia, its reaction with aluminum bromide was carried out at lower concentration and temperature. Six products (IIb—VIIb) were obtained (conversion 100%; % ratio in brackets in Scheme 1) and each was identified similarly, Vb, VIb, and VIIb being new compounds.

The reactions of VIa and IIIa were also investigated. A solution of VIa was treated with aluminum chloride

$$\text{VIa} \xrightarrow[CS_2]{AlCl_3} \text{IIa}(1.2) + \text{IIIa}(5.6) + \text{IVa}(18.5) + \text{Va}(74.4)$$

$$\text{IIIa} \xrightarrow[CS_2]{AlCl_3} \text{Adamantane}(21.9) + \text{IIa}(71.1) + \text{Va}(1.0) + \text{VIa}(5.4)$$

Scheme 2

at −15——20°C. The formation of IIa—Va was confirmed by glc method (conversion 38.3%) (Scheme 2). A similar reaction of IIIa was conducted at −35——40°C, and adamantane, IIa, Va, and VIa were produced (conversion 61.6%).

Experimental

All mp are uncorrected. IR spectra were obtained in nujol mull on a Shimadzu IR-27 spectrophotometer. MS spectra were taken using a Hitachi RMS-4 mass spectrometer. NMR spectra were obtained on a JEOL C-60H spectrometer in CCl_4 solution, TMS being chosen as an internal standard.

Authentic Samples. 1-Chloroadamantane (IIa),[6] 2-chloroadamantane (IIIa),[7] 1,3-dichloroadamantane (IVa),[8] 1-bromoadamantane (IIb),[6] 2-bromoadamantane (IIIb),[7] and 1,3-dibromoadamantane (IVb)[9] were prepared according to the reported methods.

Reaction of Ia with aluminum chloride. To a solution of Ia (3.83 g) in 80 m*l* of carbon disulfide, 4 g of aluminum chloride was added at −40°C. The solution was stirred at −35——40°C for 3.5 hr. It was then poured onto ice and extracted three times with ether. The extract was washed with dil. aqueous NaOH and dried ($CaCl_2$). Evaporation of the solvent yielded 3.7 g (96%) of a white solid which was separated into six compounds (IIa—VIIa) by silica gel column chromatography with *n*-hexane as an eluent followed by preparative glc (15% HVSG on chromosorb W AW, 3 m, 150°C, 40 m*l* N_2/min). Va: mp 131.5—133.5°C, MS: 204 (M^+), 159 (100%), 133, 91, NMR: δ 4.26 (1H, bs), 1.20—2.95 (13H, adamantyl), IR: 1347 (m), 1231 (m), 1102 (m), 1030 (s), 946 (m), 923 (m), 823 (s), 783 (m), 764 (s) cm^{-1}, Found: C, 58.50; H, 6.85%. Calcd for $C_{10}H_{14}Cl_2$: C, 58.55; H, 6.88%. Reaction of VIa with Aluminum Chloride. To a solution of VIa (62 mg) in 1 m*l* of carbon disulfide, 134 mg of aluminum chloride was added at −20°C. The mixture was stirred at −15——20°C for 3 hr. The usual work-up yielded 60 mg (96%) of a white solid which was analyzed by glc (column temp: 120°C).

Reaction of IIIa with Aluminum Chloride. To a solution of IIIa (51 mg) in 1 m*l* of carbon disulfide, 134 mg of aluminum chloride was added at −40°C. The mixture was stirred at −35——40°C for 3 hr. The usual work-up gave 49 mg (96%) of a white solid which was subjected to glc analysis (column temp: 120°C).

Preparation of a Mixture of Va and VIa. To 1,4-dihydroxyadamantane (100 mg; a mixture of *trans*- and *cis*-isomers),[4] 3 m*l* of PCl_3 and 2 g of PCl_5 were added. The mixture was stirred for 26 hr at 70°C. Hydrolysis followed by extraction (Et_2O) gave 155 mg (95%) of a mixture of Va and VIa, mp 146—149°C (lit.[4] mp 148—151°C).

Preparation of a Mixture of Vb and VIb. This was obtained in 98% yield with a mixture of PBr_3 and PBr_5 by a similar procedure to that mentioned above, mp 99—101°C.

Preparation of VIIa. The authentic sample was obtained in 88% yield by treating 1-hydroxyadamantan-4-one[4] (150 mg) with a mixture of PCl_3 (3 m*l*) and PCl_5 (2 g) and gave correct analysis, mp 151—153°C.

Preparation of VIIb. The authentic specimen was obtained in 88% yield with a mixture of PBr_3 and PBr_5 by a similar procedure to the mentioned above and gave correct analysis, mp 120.5—122.5°C.

The authors wish to thank Prof. Hitosi Nozaki for help and encouragement.

Chlorine-35 NQR of Hexachlorodisilazane and the Si-Cl Bond of $SiCl_3$-Groups

Keinosuke HAMADA and E. A. ROBINSON*

Faculty of Education, Nagasaki University, Nagasaki

**Department of Chemistry, University of Toronto, Toronto, Canada*

(Received February 14, 1972)

Chlorine-35 NQR of hexachlorodisiloxane ($Cl_3SiOSiCl_3$), hexachlorodisilazane ($Cl_3SiN(H)SiCl_3$), and hexachlorodisilane ($Cl_3SiSiCl_3$) are measured with a superregenerative spectrometer. All samples exhibit complex chlorine NQR spectra: the average frequencies for $Cl_3SiOSiCl_3$, $Cl_3SiN(H)SiCl_3$, and $Cl_3SiSiCl_3$ are 19.89, 19.66, and 19.29 MHz respectively. The very small difference among the averages of the NQR frequency values of the three compounds may be due to the difference in the ionic character of the Si–Cl bond, and it may be due to an increase in the double-bond character of the $F^{\ominus}\overset{|}{Si}{=}Cl^{\oplus}$ type that the NQR frequency of $FSiCl_3$ is less than that of $SiCl_4$.

Experimental

The hexachlorodisilane and hexachlorodisiloxane were obtained from commercial sources. The hexachlorodisilazane was synthesized as follows: an ammonia gas diluted with a nitrogen gas was passed through ether containing silicon tetrachloride at −75°C.[1,2] The product was purified by distillation. All the compounds were measured at −196°C with a superregenerative spectrometer, the details of which have been given elsewhere.[3]

Results and Discussion

The present authors asked Professor Whitehead[4] to measure the NQR of $Cl_3SiN(H)SiCl_3$. The frequencies he obtained were 19.723, 19.704, 19.699, 19.663, 19.635, and 19.551±0.001 MHz, the mean value being 19.66 MHz. The NQR frequencies of $Cl_3SiSiCl_3$ and $Cl_3SiOSiCl_3$ we measured were in good accordance with those reported in the literature;[5] the mean values are 19.29 MHz for $Cl_3SiSiCl_3$ and 19.89 MHz for $Cl_3SiOSiCl_3$.

The increasing nuclear quadrupole resonance frequencies in the sequence from $Cl_3SiSiCl_3$, $Cl_3SiN(H)SiCl_3$, $Cl_3SiOSiCl_3$ to $SiCl_4$[6] may reflect a decrease in the ionic character of the Si–Cl bond. This is consistent with the view that replacing a chlorine of $SiCl_4$ with the groups whose electronegativity decreases in the order $Cl > Cl_3SiO > Cl_3SiN(H) > Cl_3Si$ produces progressively less competition for silicon electrons and, hence, an increased ionic character in the Si–Cl bond.

When chlorine is replaced by fluorine, a still larger increase in the NQR frequency can be expected, since fluorine is much more electronegative than chlorine. However, the NQR frequency of $FSiCl_3$, 19.753 MHz[7]

is less than the average frequency of $SiCl_4$, 20.390 MHz.[6] It has been proposed,[8] in order to explain such an unexpected consequence, that there is an increase in the double-bond character due to the contributions of resonant structures of the $F^{\ominus}\overset{|}{\underset{|}{Si}}=Cl^{\oplus}$ type. Since a double-bond character is in the direction of decreasing NQR frequencies, this effect could explain the decrease in the NQR frequency when chlorine is replaced by fluorine. The increase in the double-bond character due to a fluorine substitution may be clarified by the shortening of the Si–Cl distance. That is, the Si–Cl distance of $SiCl_4$ is 2.01 Å, but that of $SiClF_3$ is only 1.99Å.[8]

The increase in the NQR frequencies in the sequence from CF_3Cl, CF_2Cl_2, $CFCl_3$ to CCl_4 has been reported,[6] but the NQR frequencies of $SiCl_mF_{4-m}$ have not been previously reported, except for that of $SiFCl_3$.[7] Therefore, it would be of interest to obtain the NQR frequencies of SiF_2Cl_2 and SiF_3Cl; thus far, however, attempted NQR measurements of them have been unsuccessful.[7]

The authors are indebted to Professor M. A. Whitehead and his collaborators of McGill University for their NQR measurements.

Reactions of Thiobenzophenones with Benzenediazonium-*o*-carboxylate, and Salicyloyl and *o*-Mercaptobenzoyl Chlorides as 1,4-Dipolar Reagents

Hirokazu TOKUNAGA, Takayuki KAWASHIMA, and Naoki INAMOTO

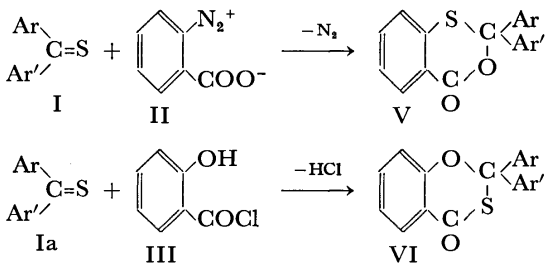
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received January 18, 1972)

Recently cycloaddition of *o*-carboxybenzenediazonium chloride to thiobenzophenone has been reported.[1] It has been known that salicyloyl chloride reacts with ketones as a 1,4-dipolar reagent.[2]

In order to obtain heterocycles containing sulfur atom by 1,4-cycloaddition, we carried out reactions of substituted thiobenzophenones (I) with benzenediazonium-*o*-carboxylate (II), and salicyloyl (III) and *o*-mercaptobenzoyl chlorides (IV).

Reactions of II and III with I gave 2,2-diarylbenzo[*d*][1,3]oxathian-6-one (V) and 2,2-diarylbenzo[*e*][1,3]oxathian-4-one (VI), respectively (see Table).



a: Ar=Ar′=Ph; b: Ar=Ph, Ar′=*p*-MeC_6H_4;
c: Ar=Ph, Ar′=*p*-ClC_6H_4; d: Ar=Ar′=*p*-MeC_6H_4;
e: Ar=Ar′=*p*-ClC_6H_4

The structures of V and VI were confirmed on the basis of the elemental analyses, and the MS and IR spectra.

Table. 2,2-Diaryl-benzoxathian-6- and 4-ones (V and VI)

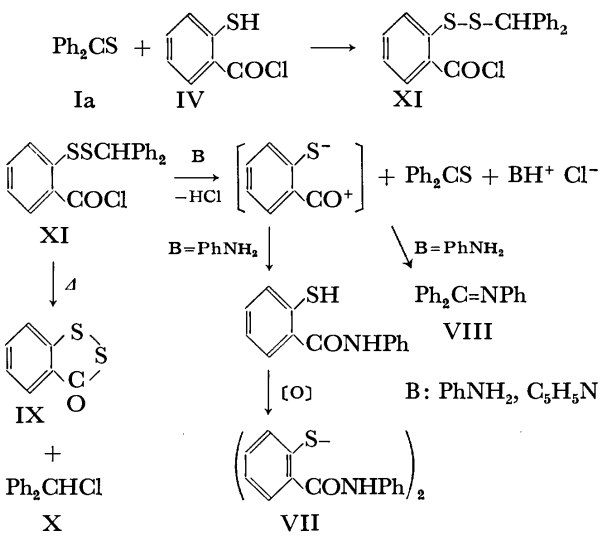
On the contrary, treatment of IV with Ia did not evolve hydrogen chloride, but gave oily products (A). Treatment of A with aniline gave bis[*o*-(phenylcarbamoyl)phenyl] disulfide (VII) (65%), diphenylmethyleneaniline (VIII) (40%) and aniline hydrochloride (99%). Similar treatment with pyridine gave Ia (70%) and pyridine hydrochloride (94%). On heating A afforded benzo[*d*][1,2]dithiolan-3-one (IX) (60%) and diphenylmethyl chloride (X) (80%). Moreover,

1) D. C. Dittmer and E. S. Whitman, *J. Org. Chem.*, **34**, 2004 (1969).

2) E. Ziegler and H. D. Hanus, *Monatsh. Chem.*, **95**, 1053 (1964).

A exhibited no absorptions due to thioester and SH groups in the IR spectrum. Therefore, A was assigned as the structure of *o*-(diphenylmethyldithio)benzoyl chloride (XI), although it was unsuccessful to obtain pure XI.

Benzophenone did not react with II and IV.



Experimental

Materials. Substituted thiobenzophenones were prepared by the method previously reported.[3] Benzenediazonium-*o*-carboxylate,[4] salicyloyl[5] (bp 57—58°C/0.5 mmHg) and *o*-mercaptobenzoyl chlorides[6] (bp 110—111°C/0.45 mmHg, mp 56—58°C) were prepared by the methods described in the literature.

Reactions with Benzenediazonium-o-carboxylate (II). A typical procedure is described for a reaction of *p,p'*-dimethylthiobenzophenone (Id).

To Id (3.3 g, 14.5 mmol) in dichloromethane (200 m*l*) was added II (5.4 g, 36 mmol), and the mixture was refluxed for 3 hr with stirring under nitrogen atmosphere. After removal of the solvent, the residual oil was chromatographed on silica gel. Elution with benzene gave 1.5 g (30%) of Vd, mp 101—102°C (from ethanol-petroleum ether). IR (KBr disk): 1727 cm^{-1} (-COO-); *m/e*: 346 (M^+, 11%), 136 ([M−Tol_2CO]$^+$, 100), 120 ([M−Tol_2CS]$^+$, 11), 108 ([M−Tol_2COCO]$^+$, 20), and 105 ($PhCO^+$, 6), where Tol represents *p*-MeC_6H_4.

Other results were summarized in Table.

Reactions with Salicyloyl Chloride (III). A typical procedure is described for a reaction of thiobenzophenone (Ia).

A mixture of Ia (8.7 g, 44 mmol) and III (7.0 g, 45 mmol) was heated for 6 hr at 100—120°C under nitrogen atmosphere, until evolution of hydrogen chloride ceased. The cooled solution was extracted with 1 *l* of petroleum ether. Removal of the solvent from the extract gave 11.2 g (80%) of VIa, mp 119.5—121°C (from petroleum ether). IR (KBr disk): 1660 cm^{-1} (-COS-); *m/e*: 318 (M^+, 62%), 258 ([M−COS]$^+$, 33), 198 (Ph_2CS^+, 100), 165 (($C_6H_4)_2CH^+$, 84.5), 121 ([M−Ph_2CS+H]$^+$, 67), and 77 (Ph^+, 61).

Other results were summarized in Table.

Reaction with o-Mercaptobenzoyl Chloride (IV). a) A mixture of Ia (5.55 g, 28 mmol) and IV (4.86 g, 28 mmol) in benzene (200 m*l*) was stirred for 10 hr at room temperature, until the blue color of the mixture disappeared. After removal of the solvent, the residual oil, which could not be purified, was heated for 3 hr at 180—190°C, and then distilled *in vacuo* (bp 112—116°C/0.2 mmHg). After cooling, 2.8 g (60%) of yellow crystals (IX) thus obtained were recrystallized from petroleum ether, mp 76—78°C (lit,[7] 77°C). After removal of IX, diphenylmethyl chloride (4.5 g, 80%) was detected in the distillate by gas chromatography.

b) To a similar reaction mixture from Ia (5.55 g, 28 mmol) and IV (4.86 g, 28 mmol) in benzene (200 m*l*) was added aniline (8.0 g, 86 mmol), and the mixture was stirred for 3 hr at room temperature. Hydrogen sulfide evolved and white precipitates appeared. The precipitates were washed with water and recrystallized from pyridine-petroleum ether to afford 4.2 g (65%) of disulfide (VII), mp 236—240°C (lit,[8] 243°C). Concentration of the filtrate and the above aqueous washings gave 2.9 g (40%) of VIII, mp 104—110°C (from petroleum ether) (lit,[9] 109°C) and aniline hydrochloride (3.6 g, 99%), respectively.

In the addition of pyridine instead of aniline, pyridine hydrochloride (1.5 g, 94%) and Ia (70%, by UV spectroscopy) were produced.

The Reactions of 4-Aminothiazolium Salts with Amines

Akiko CHINONE, Mineo MARUYAMA, and Masaki OHTA

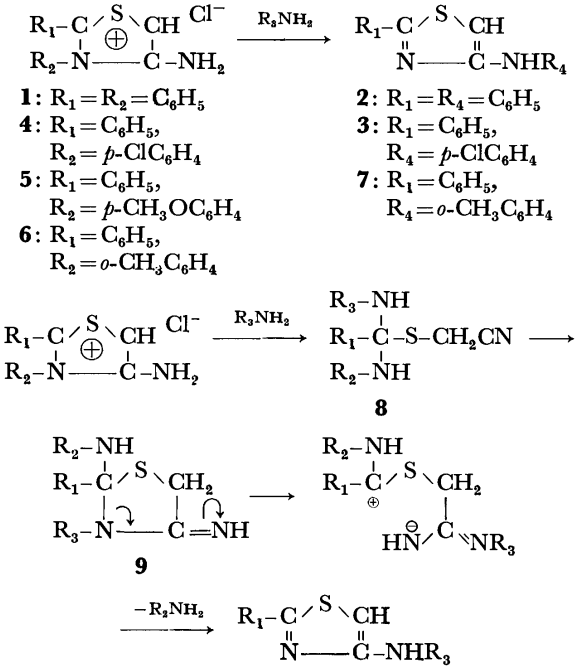
Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 25, 1972)

In our previous papaer,[1] we reported that 4-amino-2,3-diphenylthiazolium chloride (**1**) reacted to give 4-anilino-2-phenylthiazole (**2**) in the presence of aniline. In this report, we wish to describe the further detail of the reactions of 4-amino-2,3-diarylthiazolium chlorides with amines.

A benzene solution of **1** was heated with excess amount of *p*-chloroaniline at 50°C for 6 hr and neutralized with hydrochloric acid to give **2** and 4-*p*-chloroanilino-2-phenylthiazole (**3**). The structure of **3** was determined by elementary analysis and spectral data. The IR spectrum of **3** showed absorption peaks at 3330 cm^{-1} due to an NH stretching vibration and at 1530 cm^{-1} due to a thiazole ring. As in the UV spectrum of **2**, **3** showed characteristic absorption peaks at 278 mμ (ε 34000) and 360 mμ (ε 4600), which are suggestive of an aromatic heterocyclic system. In the NMR spectrum, **3** showed a peak at τ 3.64 which was attributed to 5-proton. When a toluene solution of **1** was heated with excess amount of *p*-chloroaniline at 100°C for 3 hr, **3** was obtained exclusively. In the presence of excess amount of aniline and *p*-chloroaniline (1 : 1) or aniline and *p*-anisidine (1 : 1) at room temperature, **1** afforded **2**. Expecting that the reaction of 4-amino-3-*p*-chlorophenylthiazolium chloride (**4**) with aniline may proceed *via* the same intermediate as that of the reaction of **1** with *p*-chloronailine, we examined the reaction of **4** with aniline. Treatment of **4** with aniline followed by neutralization with hydrochloric acid afforded **3** at room temperature. The products from the reaction of **4** with aniline were dependent on reaction temperature as in the case of the reaction of **1** with *p*-chloroaniline. The reaction of **4** with aniline was carried out at 50°C to give **2** and **3**, and at 100°C **2** was obtained exclusively. Treatment of **4** with *p*-chloroaniline at 50°C gave **3**, which was not obtained by treating *S*-cyanomethylisothiobenz-*p*-chloroanilide with *p*-chloroaniline in benzene at 50°C. The consideration that the substituent at 2-phenyl group may effect the course of the reaction led us to examine the reaction of 2-*p*-methoxy derivative **5** with amines. Compound **5** was treated with aniline at room temperature to give **2**, and treatment of **5** with *p*-chloroaniline, *p*-anisidine or *o*-toluidine afforded intractable oil. Treatment of 2-*o*-tolyl derivative **6** with aniline afforded **2**, and with *o*-toluidine, the corresponding thiazole **7** was obtained only as the picrate. Compound **6** was treated with *p*-chloroaniline at 50°C to give **3**. Compound **3** was not converted to **2** in the presence of amine at 100°C, and *vice versa*.

These results indicated that the reaction mechanism previously postulated,[1] in which amine used was not involved in a final product, required revision for the reaction of **5** and **6** even at room temperature. But we could not show the reasonable reaction mechanism and intermediate conclusively which was commonly involved. In the presence of equimolar amount of *p*-chloroaniline in toluene, DMSO or pyridine at 100°C, **1** afforded **2** instead of **3**. The reaction may probably proceed as shown below. It seems plausible that amine interchange occurs at the step **8**→**9** preferentially at 100°C, and consequently, the reaction may be controlled by the concentration of the amine.



1: $R_1=R_2=C_6H_5$

8

9

Experimental

The Reaction of 4 with Aniline. Compound **4** (0.6 g) was dissolved in 6 g of aniline and heated at 50°C for 6 hr. After cooling, the reaction mixture was neutralized with 10% hydrochloric acid under cooling with ice-water. Precipitates were collected by filtration and filtrate was treated as shown below. Precipitates were recrystallized from ethanol to give **2**; yield 0.4 g (80%). From the filtrate, **3** was precipitated out on standing for 3 days, which was recrystallized from ethanol to give needles with a mp of 104—105°C; yield 0.1 g (20%).

Found: C, 62.55; H, 3.95; N, 9.93; S, 11.19%. Calcd for $C_{15}H_{11}N_2SCl$: C, 62.83; H, 3.84; N, 9.81; S, 11.17%. IR: 3330, 1595, 1530, 820, 770, and 695 cm^{-1}. λ_{max}^{EtOH} mμ (ε) 278 (34000) and 360 (4600). NMR: τ ($CDCl_3$) 3.64 (1H) and 2.0—2.9 (10H).

The Reaction of 4 with p-*Chloroaniline.* A mixture of **4** (1 g), *p*-chloroaniline (10 g) and benzene (15 m*l*) was heated at 50°C for 14 hr. After cooling the reaction mixture was neutralized with 10% hydrochloric acid and extracted

1) S. Sato and M. Ohta, This Bulletin, **41**, 2801 (1968).

with ether. Ether layer was washed with water, dried over sodium sulfate and concentrated to give **3**, which was treated as shown above.

The Reaction of ***6*** *with* o-*Toluidine.* In 10 g of *o*-toluidine **6** (1 g) was heated at 50°C for 12 hr. The reaction mixture was treated as mentioned above to give **7**, which was converted to the picrate. The picrate was recrystallized from ethanol to give prisms with a mp of 105—106°C; yield 0.2 g (10%).

Found: C, 53.47; H, 3.36; N, 14.40; S, 6.51%. Calcd for $C_{22}H_{17}O_7N_5S$: C, 53.33; H, 3.46; N, 14.14; S, 6.47%. IR: 3350, 1600, 1570, and 1535 cm^{-1}.

Kinetics of the Autoxidation of Dialkyl Phenylphosphonites*

Yoshiro OGATA, Mitsuji YAMASHITA, and Toshinao UKAI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received April 17, 1972)

The kinetics and mechanism for the autoxidation of trialkylphosphine and trialkyl phosphite have been reported,[1,2] but little is known about the autoxidation of phosphonite and phosphinite. The present note reports our kinetic study on the radical-initiated autoxidation of dialkyl phenylphosphonite in *o*-dichlorobenzene to discuss the mechanism.

Results and Discussion

The autoxidation of dimethyl phenylphosphonite (I) at 60—80°C with 2,2′-azobisisobutyronitrile (AIBN) gave quantitatively dimethyl phenylphosphonate. The observed stoichiometry is shown in Table 1, and expressed as Eq. (1). No reaction of I with AIBN or *o*-dichlorobenzene was observed.

$$PhP(OR)_2 + \frac{1}{2}O_2 \longrightarrow PhP(O)(OR)_2 \qquad (1)$$

6.61	3.24	0.98

a) 5×10^{-6} mol of AIBN was used.
b) The ratio of consumed amount of atomic oxygen to phosphonite.

The autoxidation of dimethyl phenylphosphonite (I) in *o*-dichlorobenzene with AIBN at 60°C was followed by measuring the consumption of O_2 in the apparatus previously reported by us.[4] The effects of concentration of I, partial pressure of O_2 (p) and concentration of AIBN are shown in Table 2, which shows that the rate law of autoxidation of dimethyl phenylphosphonite (I) in *o*-dichlorobenzene is expressed as Eq. (2) up to 70—85% conversion.

Table 2. Autoxidation of dimethyl phenylphosphonite in *o*-dichlorobenzene at 60.0°C

Partial pressure of O_2 (mmHg)	$[PhP(OMe)_2]_0$[a] (10^{-2} M)	$[AIBN]_0$[a] (10^{-3} M)	$10^4 k_a$[b] (sec^{-1})

200	5.94	2.31	3.22
200	5.94	0.00	0.0
420	5.55	4.42	6.17
200	5.55	4.42	6.17
100	5.55	4.42	6.15

a) [ ]$_0$ means initial concentration.
b) Pseudo-first-order rate constant.

$$v = -\frac{d[O_2]}{dt} = k[PhP(OMe)_2][AIBN] \qquad (2)$$

The value of k was calculated to be $0.105 M^{-1}sec^{-1}$ at 60.0°C.

The autoxidation of dialkyl phenylphosphonite was found to involve radical intermediates, since no autoxidation occurs without AIBN. The zero-order dependence of rate on oxygen pressure (p) was observed. The same phenomenon has been observed in the autoxidation of tributyl phosphite.[1b] This suggests a mechanistic similarity of the autoxidation of phosphonite to that of phosphite. The first-order dependence on AIBN concentration suggests that the autoxidation may involve a unimolecular termination.[5] The autoxidation product of dialkyl phenylphosphonites was the corresponding phosphonates. These results suggest the following mechanism.

$$AIBN \xrightarrow{k_i} 2R'\cdot + N_2 \qquad (3)$$

$$R'\cdot + O_2 \xrightarrow{k_1} R'O_2\cdot \quad (4)$$

$$R'O_2\cdot + PhP(OR)_2 \xrightarrow{k_2} PhP(O)(OR)_2 + R'O\cdot \quad (5)$$

$$R'O\cdot + PhP(OR)_2 \xrightarrow{k_3} PhP(O)(OR)_2 + R'\cdot \quad (6)$$

$$R'O_2\cdot \xrightarrow{k_t} \text{inactive product} \quad (7a)$$

$$R'O\cdot \xrightarrow{k'_t} \text{inactive product} \quad (7b)$$

Here, R is Me, Et, and *i*-Pr, and R'· is $Me_2\dot{C}CN$. Even if O_2 may be produced from steps 7a and 7b, the amount of formed O_2 is negligible when the radical chain length is long enough. Thus the rate of absorption of O_2 is expressed as:

$$v = -d[O_2]/dt = k_i[R'\cdot][O_2] \quad (8)$$

If the termination occurs *via* step 7a alone, the application of steady state method assuming approximate constant concentrations of $R'O_2\cdot$, R'O·, and R'· as probable carriers leads to Eq. (9).

$$v = 2k_i[AIBN] + \frac{2k_ik_2}{k_t}[AIBN][PhP(OR)_2] \quad (9)$$

Since $k_t \ll k_2$, Eq. (9) is reduced to Eq. (10).

$$v = k[AIBN][PhP(OR)_2] \quad (10)$$

Here, $k = 2k_ik_2/k_t$

If the termination is effected by step 7b alone, the analogous derivation gives Eq. (11).

$$v = k'[AIBN][PhP(OR)_2] \quad (11)$$

Here, $k' = 2k_ik_3/k'_t$

In general, R'O· seems to be more reactive than $R'O_2\cdot$ with dialkyl phenylphosphonites.[6] Therefore, the unimolecular termination of $R'O_2\cdot$ is more probable than that of R'O·. The other termination mechanisms (*e.g.*, R'· → inactive product or simultaneous reactions of Eqs. (7a) and (7b)) lead rate equations conflicted with the observed rate law.

The effect of substituent R of $PhP(OR)_2$ on the autoxidation rate was estimated in *o*-dichlorobenzene at 60.0°C. The rate law for $PhP(OR)_2$ [R=Et (II) and R=*i*-Pr (III)] was the same as that of $PhP(OMe)_2$. The second-order rate constants (*k*) for R at 60.0°C were Me, 0.105; Et, 0.110; *i*-Pr, 0.112 $M^{-1}sec^{-1}$. The Taft plot for $PhP(OR)_2$ gives a ρ^* value of −0.058 (correlation coefficient, *r*, −0.95). Hence, the substituents in dialkyl phenylphosphonites affects the autoxidation rate much more than that of the radical intermediate.

The radical chain length (*CL*) was calculated to be 200—2000 by means of Eq. (12), using values of $a = 0.6$ and $k_i = 3.2 \times 10^{-6}$ sec^{-1}.[1b]

$$CL = (k_2[R'O_2\cdot] + k_3[R'O\cdot])[PhP(OR)_2]_0/2ak_i[AIBN]_0 = k_a[PhP(OR)_2]_0/2ak_i[AIBN]_0 \quad (12)$$

Here, *a* is the efficiency of initiation and k_i is the decomposition rate of radical initiator (AIBN), and k_a is an apparent first-order rate constant.[1b]

Experimental

Materials. Phenylphosphonous dichloride was prepared by the Friedel-Crafts reaction of benzene with PCl_3,[8] bp 101—104°C/17 mmHg (lit,[8] bp 68—70°C/1 mmHg), yield 68%. Dimethyl phenylphsophonite was prepared by the esterification of phenylphosphonous dichloride,[9] bp 101—102°C/23 mmHg (lit,[9] bp 98°C/17 mmHg), yield 30%. Diethyl and diisopropyl phenylphosphonites were also prepared by the similar procedure; bp and yield were 78—79°C/8 mmHg (lit,[10] bp 110—111°C/10—13 mmHg), 27% and 82—85°C/8 mmHg (lit,[11] bp 121—122°C/10 mmHg), 11%, respectively. Dimethyl phenylphosphonate was prepared by the Ullmann reaction of trimethyl phosphite with iodobenzene,[12] bp 122—125°C/7 mmHg (lit,[12] bp 115°C/0.9 mmHg), yield 35%. Diisopropyl phenylphosphonate was prepared by the esterification of phenylphosphonic dichloride, bp 116—117°C/3 mmHg (lit,[12] bp 94°C/0.1 mmHg), yield 33%. All phosphonates were identified by IR (a Perkin-Elmer Model 337 spectrophotometer) and NMR (a JNM-C-60HL spectrometer). Commercial solvents, AIBN, O_2, and N_2 were purified by ordinary methods and used.

Product Analysis. The autoxidation product of dialkyl phenylphosphonite was confirmed to be the corresponding phosphonate alone by means of glc (a Yanagimoto GCG 550F gas chromatograph with a flame ion detector) with 3% Apiezone Grease L on Cellite 545 using programming attachment.

Kinetic Procedure. The autoxidation apparatus has been reported previously.[4] A typical kinetic run was as follows: O_2 gas at 200 mmHg and N_2 gas at 350 mmHg were mixed in the apparatus and introduced into the reaction vessel at 60.0°C containing 6.54×10^{-2}M dimethyl phenylphosphonite in *o*-dichlorobenzene (10 ml), then 5.39×10^{-3}M AIBN in *o*-dichlorobenzene (1 ml) was added into it. The reaction was started with vigorous stirring. The partial pressure difference between the reaction mixture and the reference solution was measured at appropriate intervals of time. The observed pseudo-first-order rate constant was calculated by means of Eq. (13).

$$\log(a - 2x) = -\frac{2}{2.303}k_at + \log a \quad (13)$$

Here, *a* and *a*-2*x* are the concentrations of substrate at the start and at time *t*, respectively.

The authors are thankful to Dr. Y. Sawaki for his helpful suggestion and discussion, and also to Nissan Chemical Co., Ltd. for their kind supply of diethyl phenylphosphonate and phenylphosphonic dichloride.

Infrared Intensities of Crystalline NH_3 and ND_3

Masakatsu UYEMURA and Shiro MAEDA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology Meguro-ku, Tokyo

(Received November 11, 1971)

The infrared spectra of crystalline ammonia were investigated by Reding and Hornig,[1] by Anderson and Walmsley,[2] and by Wolf, Rollar, and Wolf[3] for films deposited on a cold window, and interpreted on the basis of the cubic structure of the space group T^4, as given by X-ray diffraction.[4] However, Mauer and McMurdie[5] have reported that the X-ray pattern of such a deposited film can not be solely attributed to the cubic structure; they have suggested the intermixing of one or two non-cubic phases. Staats and Morgan[6] observed rather remarkable changes in the infrared spectra when they annealed the film or deposited it at a higher temperature, but they came to no definite conclusion concerning the structure of the film. The spectral changes mentioned above are so spectacular that the investigation of its origin is of great interest in connection with the role of hydrogen bonding in this crystal. In the present paper, the absolute infrared intensities of crystalline NH_3 and ND_3 films will be reported, and then the intensity behavior in the course of annealing will be described.

Experimental

Commercial NH_3 gas of a reagent grade was used without purification. The ND_3 was obtained by the reaction of Mg_3N_2 with D_2O; it was distilled several times to remove all traces of water. In both samples, no evidence of the impurities was observed in the infrared spectra except for a small amount of H-species remaining in the ND_3 sample, whose deuterium concentration was determined from the intensity of a remaining NH_3 band to be 95—97%. The measurement of the absolute intensity was made using a conventional vacuum cell with a KRS-5 window for depositing the sample. Another metal cell equipped with a wire heater and an extra chamber sealed with Ge and KRS-5 windows was used in observing the spectral changes by annealing. The sample films were formed on the inside surface of the Ge window, and the chamber was filled with helium gas (20—30 Torr) to suppress the dissipation of the film.

Results

The spectral features of the films deposited at 77°K were, in general the same, as those reported by Reding and Hornig,[1] as is shown in Fig. 1 (i). In evaluating the intensity, the density was assumed to be equal to the cubic value (NH_3; 0.861 gr cm^{-3} at 77°K) calculated from the X-ray data.[7] The refractive index at the wavelength of 1 micron, where the interference

Average	1.22	1.42	0.26
	D/Å	D/rad	D/rad

c) Two possihle choices of relative sign in $\lvert\partial\mu/\partial Q_3\rvert$ and $\lvert\partial\mu/\partial Q_4\rvert$ are denoted by (+) and (−), where (−) combination gives better agreement in NH_3 and ND_3.

fringes were recorded for measuring the film thicknesses,[9] was estimated to be 1.47, on the basis of the data in the visible region. Linear Beer's law plots were obtained; the resulting intensities and dipole-moment derivatives are given in Tables 1 and 2. Since the two stretching absorptions were not well separated, the results were interpreted by assuming the vector addition of NH(ND) bond moment derivatives.[10] It is equivalent to assume that:[11]

$$\lvert\partial\mu_{(NH)}/\partial r\rvert = (3L_{11}^2)^{-1/2}\{(\partial\mu/\partial Q_1)^2+2(\partial\mu/\partial Q_3)^2\}^{1/2}.$$

The derivatives with respect to the bending coordinate, *i.e.*, $(\partial\mu/\partial S_2)$ and $(\partial\mu/\partial S_4)$, are given by the following equations:

$$\lvert\partial\mu/\partial S_2\rvert = L_{22}^{-1}\lvert\partial\mu/\partial Q_2\rvert \pm L_{12}^{-1}\lvert\partial\mu/\partial Q_1\rvert$$
$$\lvert\partial\mu/\partial S_4\rvert = L_{34}^{-1}\lvert\partial\mu/\partial Q_3\rvert \pm L_{44}^{-1}\lvert\partial\mu/\partial Q_4\rvert.$$

In these expressions the contributions from stretching modes are relatively small and $\lvert\partial\mu/\partial Q_1\rvert$ is estimaed to be by far smaller than $\lvert\partial\mu/\partial Q_3\rvert$, so that the $\lvert\partial\mu/\partial S\rvert$'s were evaluated by ignoring $\lvert\partial\mu/\partial Q_1\rvert$ and assuming that the stretching intensities are to be attributed solely to $\lvert\partial\mu/\partial Q_3\rvert$. In general, the observed intensity change from gas to crystal shows the characteristic features of hydrogen-bonded systems.

When the films were annealed up to about 180°K,[12] the spectra showed rather striking changes, as was also found by Staats and Morgan[6] mentioned above, although the present observations were not quite consistent with theirs. Figure 1 (ii) shows the spectra of NH_3 when the film deposited at 77°K[12] was annealed to 180°K[12] with the suppressive gas in the chamber, while (iii) shows the spectra when the film was annealed to a somewhat higher temperature than (ii) without suppressive gas.[13] Similar behavior was observed for ND_3 too. Although Staats and Morgan attributed the (iii) to the cubic phase, the preliminary results on the Raman spectra[14] seem to suggest that the (ii) is more likely to be cubic.

As the sample dissipation on annealing was considerable, no measurement of the absolute intensity was possible for (ii) and (iii). It may be pointed out, however, that the relative intensities in the various phases are appreciably different; the enhancement of the stretching band in the (iii) is particularly notable, suggesting still stronger hydrogen bonding in this phase than in the others.

Effect of Acetic acid on the Polarographic Behavior of Copper(II) Acetate in Acetonitrile

Eiki ITABASHI*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received November 18, 1971)

Dimeric copper(II) acetate in acetonitrile solution is reduced at the dropping mercury electrode and gives a two-step reduction wave. The reduction wave is distorted in dilute $LiClO_4$ and $NaClO_4$ solutions.[1] This distortion results from the interaction of alkali metal ions with acetate ions which are liberated from the monovalent copper species.

Acetic acid in acetonitrile solution keeps the liberated acetate ions from precipitating as an insoluble film of alkali metal acetates on the surface of the electrode. The present investigation deals with the polarographic behavior of copper(II) acetate in acetonitrile in the presence of acetic acid.

The experimental details were the same as previously described.[2,3]

Results and Discussion

The effect of acetic acid on the polarograms o copper(II) acetate in $NaClO_4$ solution is shown in Fig. 1. With small amounts of acetic acid present,

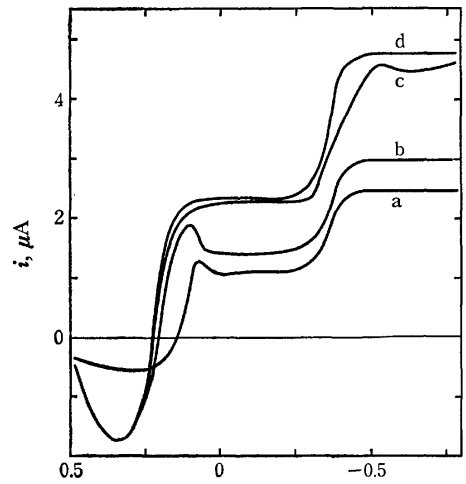

Fig. 1. Effect of the acetic acid concentration on the polarograms of 0.5 mM copper(II) acetate in 0.05M $NaClO_4$. [CH_3COOH]: (a), 0; (b), 0.032%; (c), 0.064%; (d), 0.096%.

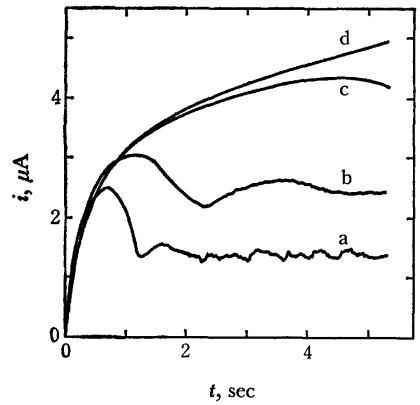

Fig. 2. Effect of the acetic acid concentration on the *i-t* curves for the reduction wave of 0.5 mM copper(II) acetate in 0.05M $NaClO_4$. The electrode potential is set up at −0.55 V *vs.* SCE. [CH_3COOH]: (a), 0; (b), 0.032%; (c), 0.064%; (d), 0.096%.

the limiting current of the wave was enhanced, and a peak current was observed in the anodic part. When the concentration of acetic acid exceeded 0.1% in volume, there was no apparent change in the shape of the developed wave. The zero current potential is a mixed potential where the cathodic current caused by the one-electron reduction of copper(II) acetate to monovalent copper species is equal to the anodic current caused by the oxidation of mercury to mercuric acetate. In the absence of acetic acid, the current-time (*i-t*) curves of individual drops at the constant potential exhibited remarkable irregularities at the whole potential region examined. Figure 2 presents the typical *i-t* curves in $NaClO_4$ solution in the presence and the absence of acetic acid. This irregularity is due to the formation of the insoluble film of sodium acetate on the surface of the electrode. On addition of small amounts of acetic acid, the irregularities of the *i-t* curves disappeared when the acetic acid concentration reached a critical value. The *i-t* curves for the reduction wave in 0.05M $NaClO_4$ solution containing 0.1% acetic acid had the characteristics of normal diffusion control. This result suggests that acetic acid keeps the liberated acetate ions from precipitating as an insoluble film of sodium acetate on the electrode surface. The solubility of sodium acetate in $NaClO_4$ acetonitrile solution was found to increase as the acetic acid concentration increased.

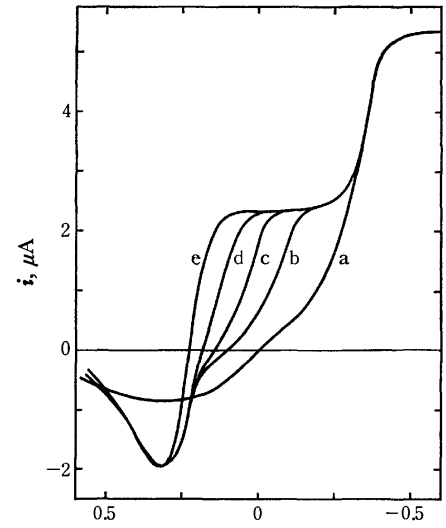

Fig. 3. Effect of the acetic acid concentration on the polarograms of 0.5 mM copper(II) acetate in 0.05M *n*-Bu_4NClO_4. [CH_3COOH]: (a), 0; (b), 0.032%; (c), 0.096%; (d), 0.24%; (e), 0.64%.

In the presence of acetic acid, the one-electron reduction wave of copper(II) acetate to monovalent copper species shifts towards more positive potentials. This is due to the shift of the potential of mercury dissolution and not to the involvement of any chemical reaction prior to the electron transfer of copper(II), because there was no apparent change on the absorption spectrum of copper(II) acetate in acetonitrile with and without acetic acid. A similar displacement of the one-electron reduction wave was also observed in tetra-*n*-buthylammonium perchlorate (*n*-Bu_4NClO_4) solution in the presence of acetic acid, as shown in Fig. 3. In *n*-Bu_4NClO_4 solution in the absence of acetic acid, no well-defined one-electron reduction wave was observed. The value of the limiting current at −0.65 V *vs.* SCE corresponds to a two-electron reduction, that is, Cu(II)→Cu(O). With acetic acid present, the one-electron reduction wave began to appear and shifted towards more positive potentials as the acetic acid concentration increased. The half-wave potentials of the anodic wave caused by the oxidation of mercury to mercuric acetate in 1.0 mM *n*-Bu_4NOAc and 0.05M *n*-Bu_4NClO_4 solutions in the presence and the absence of 0.64% acetic acid were found to be +0.24 V and −0.02 V *vs.* SCE, respectively. Therefore, the appearance of the one-electron reduction wave of Cu(II) to Cu(I) results from the displacement of the anodic wave caused by the oxidation of mercury to mercuric acetate.

The anodic part of the composite anodic-cathodic waves in the presence of acetic acid exhibits a peak

current rather than a limiting plateau. This peaking could be the result of the difference in the electron numbers involved in the anodic and cathodic prosesses. It was predicted by Vlček[4] that the anodic part of the composite wave exhibits a peak current when the electron number involved in the anodic process caused by the electrooxidation of the reduction products is larger than that in the cathodic process. The reaction mechanism of the composite anodic-cathodic waves of copper(II) acetate at the dropping mercury electrode may be written as follows.

$$1/2Cu_2(OAc)_4 + e \longrightarrow 1/2Cu_2(OAc)_4^{2-} \quad (1)$$

$$1/2Cu_2(OAc)_4^{2-} \xrightarrow{k} Cu(I) + 2OAc^- \quad (2)$$

$$2OAc^- + Hg \longrightarrow Hg(OAc)_2 + 2e \quad (3)$$

where the coordinated molecules were omitted for convenience, and k is the rate constant for the dissociation reaction of monovalent copper species. The peak current of the anodic part has the characteristics of kinetically control. The exponent of the i-t curves for the peak current of the anodic wave in 0.05M n-Bu_4NClO_4 solution containing acetic acid had a value of 0.52 ± 0.02. This value is well beyond the value of 0.17 expected for a diffusion controlled electrode mechanism. This could indicate that the rate of the reaction (2) is finite in order that the limiting current is attained.

The author would like to express his hearty thanks to Professor Shigero Ikeda.

A Chlorine NQR Study of *anti*-Perchloro-(3,4,7,8-tetramethylenetricyclo [4.2.0.0^{2,5}] octane), $C_{12}Cl_{12}$

Masao HASHIMOTO, Kenshô SAGISAWA, and Koichi MANO*

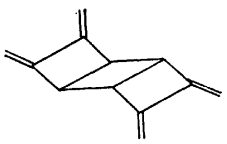
Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe

**Research Institute for Atomic Energy, Osaka City University, Sumiyoshi-ku, Osaka*

(Received March 1, 1972)

In our previous work, we investigated the correlations between the molecular structures and the NQR frequencies of perchloro-compounds, using seven perchloro-compounds for which the crystal or molecular structures have been well established.[1)]

In the present paper, in connection with the previous work, we wish to report on the NQR study of *anti*-perchloro-(3,4,7,8-tetramethylenetricyclo[4.2.0.0^{2,5}]-octane) (I), for which the crystal and molecular structures have been determined.[2)] The details of the experimental procedures have also been reported previously.[1,3)]



I

The NQR frequencies were measured at temperatures in the range from 77 to 360°K. The experimental results at 77°K are given in Table 1. The intensities of these resonance lines were rather weak, and the half-widths were about 6.0±0.5 KHz at 77°K. The temperature dependence of these lines is shown in Fig. 1. Two lines, ν_2 and ν_3, were found to disappear at about 273 and 225°K respectively (fade-out). Figure 1 shows that the resonance frequencies of the other four lines decrease monotonously with an increase in the temperature. This suggests that I undergoes no phase transition between 77°K and room temperature. Therefore, six crystallographically-nonequivalent chlorine atoms exist in the unit cell of the crystal of I at room temperature, although only four resonance lines were observable at room temperature. Furusaki, in his X-ray study of I at room temperature, assumed that the space group was $P\bar{1}$.[2)] Our NQR results are consistent with his assumption.

From a structural point of view, I is related to perchloro-(3,4-dimethylenecyclobutene) (II) and perchloro-(1,2-dimethylenecyclobutane) (III). Their

Table 1. The nuclear quadrupole resonance frequencies of ^{35}Cl of I and the relative intensities of the resonance lines at liquid nitrogen temperature

No.	Resonance frequency (MHz)	Relative intensity

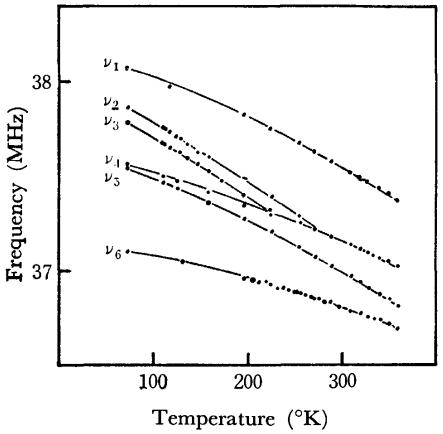

Fig. 1. Temperature dependence of the NQR frequencies of I.

NQR spectra, discussed in the previous paper, are of assistance in assigning the resonance lines of I.

II III

The NQR frequencies of ^{35}Cl in the dichloromethylene groups of II and III lie in a frequency region from about 37.8 to 38.1 MHz at 77°K.[1] Among the six lines of I, therefore, the five lines besides ν_6 are assignable to the chlorine atoms in the dichloromethylene groups on the basis of a comparison with the data for II and III.

The chlorine atoms corresponding to ν_2 and ν_3 may have large temperature factors, because the fade-out found for the two lines may be due to the reorientation of the chlorine atoms. In fact, according to the X-ray study of I,[2] two of the chlorine atoms, Cl(4) and Cl(5)

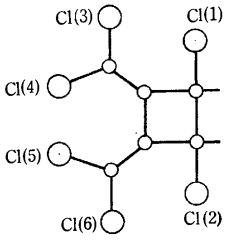

Fig. 2. One half of the molecule of I.

in Fig. 2, have unusually large temperature factors. Therefore, ν_2 and ν_3 are assignable to Cl(4) and Cl(5). For several other compounds, a correlation between the fade-out and the large temperature factor has also been found.[1,4]

Although the symmetry of I is C_i, the molecular geometry shows that Cl(1) is nearly equivalent to Cl(2).[2] Consequently, the characteristics of the torsional vibrations may be almost the same for these two chlorine atoms. This means that the temperature coefficient of the resonance frequency of Cl(1) is also similar to that of Cl(2).[5] For a similar reason, the temperature coefficients of the resonance frequencies of Cl(3) and Cl(6), and those of Cl(4) and Cl(5), may be almost the same. Figure 1 shows, on the basis of a comparison of the temperature dependence of the resonance frequency, that the six lines of I can be divided into three pairs of lines, ν_1 and ν_5, ν_2 and ν_3, and ν_4 and ν_6. As has been described above, the second pair, ν_2 and ν_3, are assignable to Cl(4) and Cl(5). The first pair, ν_1 and ν_5, may be assigned to Cl(3) and Cl(6), and the third, to Cl(1) and Cl(2).

Transition Metal Ions on Molecular Sieves. I. Complexes of Copper(II) on Y Molecular Sieves and Their Catalytic Activities

Isao MOCHIDA, Akio KATO, and Tetsuro SEIYAMA

Department of Applied Chemistry, Faculty of Engineering, Kyushu University, Fukuoka

(Received October 30, 1971)

An isolated metal ion attached to a molecular sieve would be expected to behave quite differently from a metal ion or atom in an ordinary metal oxide. In the latter case, the metal atoms are located that their interaction is possible, while on a molecular sieve the metal ions or atoms are more isolated and tend to behave as their homogeneous analogues even though they are located on a solid surface. Catalytic activities of transition metal ions bound to molecular sieves have been reported for the oxidation of propylene.[1,2]

Molecular sieve-bound metal ions have been extensively studied.[3] However, the interactions of a metal ion with polydentate chelating agents have scarcely been investigated in spite of the fact that such a system can be compared with that of an analogous homogeneous case. Burwell *et al.*[4] studied the exchange of complex metal ions with the hydroxide group of silica gel.

We have investigated the adsorption of bidentate chelating reagents such as ethylenediamine on isolated cupric ions by visible and infrared spectroscopy and also the heterogeneous catalytic activities of these compounds for the decomposition of hydrogen peroxide.

Experimental

Chemicals. Ethylenediamine(en) was obtained from Tokyo Kasei Co, ethanedithiol and dimethylglyoxime from Nakarai Chemicals Co. They were used without further purification.

The Cu(II)-form of the Y molecular sieves (Linde) was obtained by the exchange of sodium ion with aqueous cupprammonium ion. This treatment was followed by a thorough washing with deionized water and calcined at 400°C in the atmosphere. Details have been reported.[1] Cu(II)-Y, saturated with atmospheric water vapor, was found to contain 5.2% copper by weight.

Adsorption of Chelating Reagents. Cu(II)-Y was stirred for 2 days with aqueous diamine or ethanedithiol solution and washed with dry ethanol to yield the chelate-impregnated material. The dimethylglyoxime complex was similarly prepared using ethanol as a solvent.

Spectroscopic Analysis. Electronic spectra were obtained by the decalin mull method in a quartz cell on a Hitachi Type 124 Double Beam Spectrophotometer. The original Y sieve in decalin was used as a reference. Infrared spectra were measured in KBr on a IR-G double beam spectrophotometer of the Nippon Bunko Co.

Decomposition of Hydrogen Peroxide. The rates of decomposition of hydrogen peroxide were determined by the manometric measurement of oxygen evolved. After the reaction flask (containg 50 cc of aqueous NaOH solution of pH 11.8 and the catalyst) was immersed in a constant temperature bath for 2 hr, 1 cc of 30% aqueous hydrogen peroxide was added. After the reaction, the pH of the reaction media was found to be 9.8 for each catalyst.

Results and Discussion

Adsorption of Chelating Agents on Cu(II)-Y. Impregnation of Cu(II)-Y with ethylenediamine turned the sieve deep blue with heat evolution. The complex of the sieve Y-Cu(II)-en kept its color (visible absorption maximum, 660 mμ) in dry air, but turned purple (visible absorption maximum, 550 mμ) in contact with moisture. Similar values were reported for bisethylenediaminecopper(II) complexes.[4,5,6]

Y-Cu(II)-en had an infrared absorption band at 1048 cm^{-1} in addition to those at 1573, 1475, and 1318 cm^{-1} due to the adsorption of ethylenediamine on Cu(II)–Y. The absorption at 1048 cm^{-1} was overlapped by a strong band due to the molecular sieve, but was resolved by using a molecular sieve-containing KBr reference plate. Formation of chelates is indicated by the presence of this band which was assigned to the ring skeletal vibration by Powell and Sheppard.[7]

Ethanedithiol and dimethylglyoxime formed light green complexes on the sieve. These colors coincide with those of the corresponding sulfate complexes. In the case of ethenedithiol, the conformation of the coordinating ethanedithiol rings was determined by inspection of the infrared spectrum. This solid showed a weak absorption band at 1280 cm^{-1} (lit, 1275 cm^{-1})[8] which suggests that the rings are in a gauche form.

Thus, all the results indicate that cupric ions on molecular sieves have an affinity for chelating agents. The affinity suggests a new type of catalytically active sites which are expected to behave much like the usual coordination compound, but kept on the rigid surface.

Decomposition of Hydrogen Peroxide. Various copper compounds have been investigated as models for the

enzyme by testing their ability to decompose hydrogen peroxide in basic aqueous solution.[9] The catalytic activity of ethylenediaminecopper(II) complex for this reaction was reported.[10] Jacobson and Smith[11] reported on the catalytic activities of ammine and diamine complexes of metal ions on silica gel.

The catalytic activities of Cu(II)–Y, Y–Cu(II)-en, and Y–Cu(II)-dimethylglyoxime toward the decomposition of hydrogen peroxide were observed in aqueous sodium hydroxide. In this pH region, no measurable decomposition of hydrogen peroxide could be observed without catalyst in the sodium hydroxide solution. For Y–Cu(II)-en, the decomposition rate was proportional to the weight of the catalyst. It was found that one molecule of the complex on the surface decomposed more than four hundred molecules of hydrogen peroxide. The reaction seemed to proceed in the first order with 90% decomposition.

Y–Cu(II)-en had a five times larger catalytic activity than Cu(II)–Y at the same pH region as shown in Fig. 1. The fact that catalytic activity of the dimethylglyoximato-complex is significantly less than that of Y–Cu(II)-en (Fig. 1) shows that the catalysis strongly depends on the type of chelating ligand employed. Such catalytic activity enhanced by chelation is of interest as an example of a complex catalyst on the rigid surface.

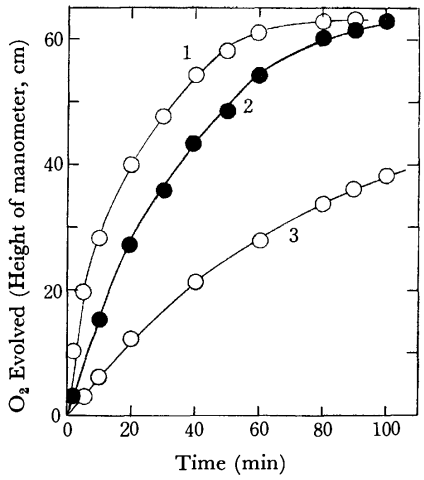

Fig. 1. Decomposition of hydrogen peroxide catalyzed by cupric ions on the molecular sieve at 26°C. The relative activities are calculated 4.6 (Y–Cu(II)-en), 1.0 (Cu(II)–Y), and 0.93 (Y–Cu(II)-dimethylglioxime).
1: Y–Cu(II)-en, 82 mg. 2: Cu(II)–Y, 132 mg.
3: Y–Cu(II)-dimethylglyoxime, 52.5 mg.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2231—2233(1972)

The Nature of Acid Sites on the Surface of Silica-alumina. III. The Mechanism of the Photo-ionization of Perylene and Anthracene Adsorbed on the Surface of Silica-alumina

Kazuto TAKIMOTO and Masaji MIURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received August 13, 1971)

The photo-ionization of various aromatic compounds has been extensively studied in solid matrices and solutions.[1-3] However, hardly no work on the dynamic behavior or the mechanism for the photo-ionization on solid surfaces has been done, although the identification and structure of the radicals generated on the surfaces by UV irradiation have been widely investigated.[4] The purpose of this work is to reveal the mechanism of the photo-ionization of polyacenes adsorbed on the surface of silica-alumina with Lewis-acid sites of various strengths.

Experimental

Anthracene, perylene, and 40% silica-alumina were used; they were the same as those used in our preceding work.[5] The polyacenes were adsorbed from their vapor phase on a silica-alumina surface pretreated at 500°C for 3 hr in a vacuum of 5×10^{-5} mmHg. The increase in the amount of the cation radical under irradiation of UV light was continuously measured by fixing the magnetic field at one of the peaks of the ESR spectrum. UV light was supplied from a 1-kW high-pressure mercury lamp or a 1-kW, point-source, superhigh-pressure mercury arc. The light intensity was controlled by means of nets of various meshes. The filters used were Toshiba UVD-25, UV-39, VY-42, and VY-46, while a Shimadzu-Bausch-Lomb Model 33-86-01 Mono-

chromator was also used. The ESR spectra and diffuse reflection spectra were obtained by using, respectively, the spectrometer and spectrophotometer described previously.[6]

Results and Discussion

When perylene was adsorbed on the surface of silica-alumina from the vapor phase, an ESR spectrum with nine well-resolved peaks was observed. On the other hand, the diffuse reflection spectrum showed the absorption maxima at 540, 600, and 700 mμ.[4,6] These spectra are due to the cation radical of perylene. The increment of the cation radical with the irradiation time is shown in Fig. 1. The initial rate of the radical formation was approximately proportional to the intensity of the exciting light which includes wavelengths longer than 320 mμ, as may be seen in Fig. 2. In the case of anthracene, the situation was the same. These phenomena suggest that the photo-ionization of these two polyacenes proceeds through a single-photonic process on the silica-alumina surface.

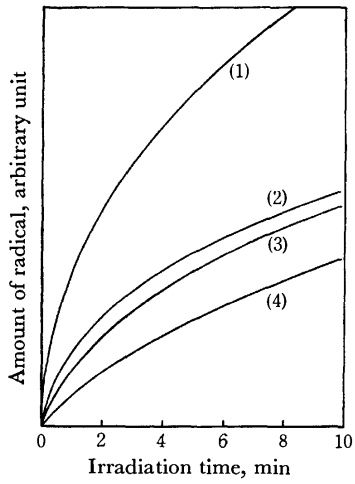

Fig. 1. Rates of the radical formation of perylene adsorbed on the 40% silica-alumina. Transmittancy of net (%): (1) 100, (2) 42.2, (3) 37.0, and (4) 14.0.

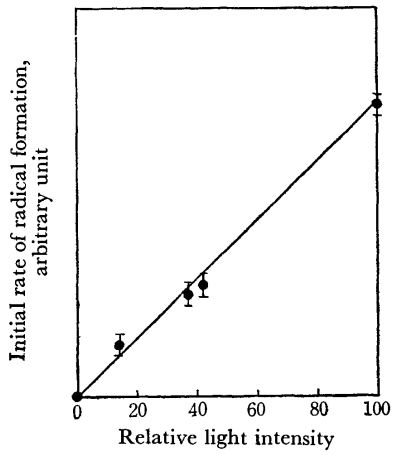

Fig. 2. Relation between the initial rate of the radical formation of perylene adsorbed on the silica-alumina and the intensity of exciting light.

6) K. Takimoto and M. Miura, This Bulletin, **44**, 1534 (1971).

Silica-alumina has Lewis-acid sites with various strengths; the strong acid sites exist in the range of $-3.0>H_0>-8.0$, while the weak ones exist in the range of $H_0>+3.0$.[5] The cation radical and the trapped electron are formed on the strong Lewis-acid sites even in the absence of UV irradiation and are stabilized on the surface.[6] A sort of charge-transfer complex with polyacene is formed on the weak Lewis-acid site even in the ground state.[6] Physically-adsorbed perylene which possesses absorption maxima at 410 and 430 mμ is present on much weaker Lewis-acid sites.[4,6]

The cation radicals of polyacenes were not formed in a sulfuric acid solution of 48 weight-percent, which corresponds to $H_0=-3.0$; the cation radicals are formed only in the range of $H_0<-3.0$ in the absence of UV irradiation. In addition, the amount of the cation radicals decreased markedly with an increase in the value of the ionization potential in the absence of UV light.[6] It may be considered, therefore, that the critical acid strength of the Lewis-acid sites required for the ionization of these polyacenes is situated in the range of $-3.0>H_0>-8.0$. The charge-transfer complexes and the physically-adsorbed polyacenes are presumably generated on the Lewis-acid site with an acid strength weaker than the critical value.

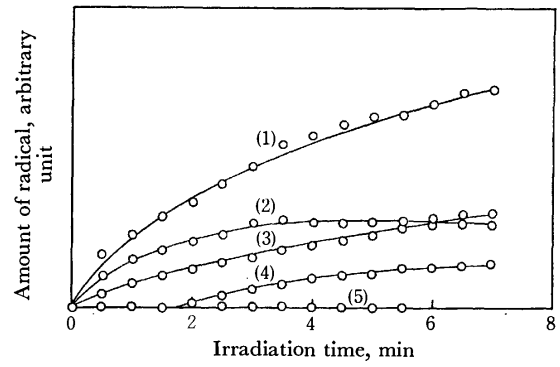

Fig. 3. Filter effect on the radical formation of perylene adsorbed on the silica-alumina: (1) full line, (2) UV-39, (3) UVD-25, (4) VY-42, and (5) VY-46.

The effect of the energy of the photon on the photo-ionization of the perylene adsorbed on the silica-alumina surface is shown in Fig. 3. The increment of the cation radical by using the VY-42 ($\lambda>420$ mμ) filter and a high-pressure mercury lamp was smaller than those caused by the use of the UV-39 ($\lambda>390$ mμ) and UVD-25 ($250<\lambda<400$ mμ) filters. When the VY-46 ($\lambda>460$ mμ) filter was employed during the irradiation of UV light from the same light source, no increase was observed. However, an increase was observed when the 1-kW, point-source, superhigh-pressure mercury lamp and the VY-46 filter were used. The VY-42 and VY-46 filters transmit the light of wavelengths longer than those absorbed by the physically-adsorbed perylene. The charge-transfer bands ($\lambda>480$ mμ) which are situated at wavelengths longer than those ($400<\lambda<450$ mμ) of the perylene physically adsorbed on much weaker Lewis-acid sites may exist even in the ground state, although they can not usually be observed because of the band-broadening

due to the broad distribution of the acid strength of the Lewis-acid sites on the silica-alumina surface.[6] These phenomena may indicate that the photo-ionization is caused by the absorption of photons with an energy corresponding to $h\nu_{CT}$. On the other hand, the light of wavelengths absorbed only by the physically-adsorbed perylene was separated by the use of a monochromator. An increase in the amount of the cation radical was also observed here, though it was appreciable only with difficulty because of the low transmittancy of the monochromator. The cation radical was formed on the surface even by exciting the physically-adsorbed perylene which may be present on much weaker Lewis-acid sites.

The photo-ionization of polyacenes can possibly occur through the following two processes.[1] In the case of the single-photonic process, the amount of the cation radical generated is proportional to the intensity of the exciting light, I, while in the case of the two-photonic process it is proportional to I^2. When a charge-transfer complex has been formed on the surface, the photo-ionization is accomplished through a single-photonic process. For the photo-ionization of these physically-adsorbed polyacenes, the following two processes may be considered: one through the triplet state as an intermediate (two-photonic process), and the other through the formation of a charge-transfer complex *via* a first excited singlet state of these polyacenes, resulting in the formation of the cation radical and the trapped electron (single-photonic process). The photo-ionization of these physically-adsorbed polyacenes probably takes place through the latter process, since the amount of the cation radical formed is approximately proportional to I.

On Inhibition of Polarographic Reduction of the Dioxalatocuprate(II) Ion by the One-Electron Reduction Product of Phenylmercury Hydroxide

Teisuke MURAYAMA and Akio TAKAYANAGI

Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu

(Received March 29, 1972)

Organomercury salts are reduced at a dropping mercury electrode in double one-electron steps. Benesch and Benesch observed that the first wave of phenylmercury hydroxide has severe irregularities on the diffusion current plateau.[1] They considered that this is due to the coating of the electrode caused by an insoluble product. They also showed that the polarographic reduction of Cd^{2+} and Pb^{2+} ions is inhibited in the range of potentials between the end of the first and the beginning of the second waves of phenylmercury hydroxide. We studied inhibition of the polarographic reduction of the dioxalatocuprate(II) ion in oxalate buffer solutions.

Experimental

The phenylmercury hydroxide was made from phenylmercury acetate (Shudzui, Tokyo) and sodium hydroxide,[2] and recrystallized from water: mp with decomposition 226—230°C (lit.[3] 226—233°C). The stock solution of phenylmercury hydroxide was prepared by dissolving a weighed amount.

The concentration of the copper sulfate was determined by means of complexometric titration.[4]

The oxalate buffer solution of pH 4.08 was prepared from guaranteed reagents.

The test solution was prepared by mixing stock solutions of phenylmercury hydroxide, oxalate buffer, copper sulfate, and sodium nitrate, and diluting it to the desired volume. Sodium nitrate was added to control the ionic strength of the test solution to 0.35. Five one-thousandths of 1% gelatin was also added as a maximun suppressor.

All solutions were prepared with redistilled water.

Test solutions were degassed with nitrogen and thermostated at 25.0 ± 0.1°C.

The dropping mercury electrode had the following characteristics (in 0.3M KNO_3 at zero applied potential *vs.* SCE). Rate of flow of mercury, 1.978 mg/sec; drop time, 4.13 sec. The cell and the salt bridge were described elsewhere.[5] Polarograms were recorded with a Yanagimoto PA-102 polarograph. Current-time curves were recorded by a Mini Writer-H (Watanabe Instruments Co.) in terms of a potential drop across a resistor inserted in series with the cell circuit.

Results and Discussion

Polarograms of the dioxalatocuprate(II) ion (I) are shown in Fig. 1. They are corrected for the current due to the reduction of phenylmercury hydroxide (II) and for the residual current. In the presence of II the single step reduction of I splits into two waves.

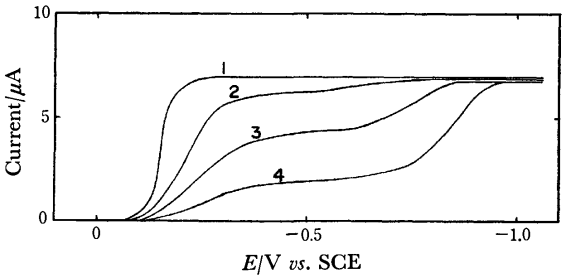

Fig. 1. Polarograms of I in the presence of II. Concentration of I, 0.934 mM. Concentration of II: 1, 0 mM; 2, 0.123 mM; 3, 0.198 mM; 4, 0.297 mM.

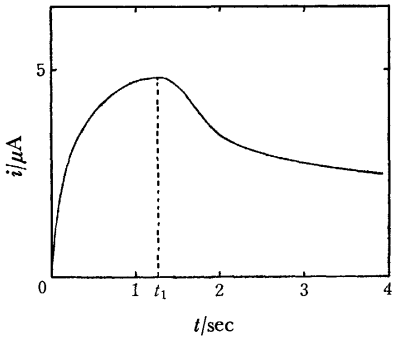

Fig. 2. Current-time curve for the reduction of I in the presence of II at a potential of −0.50 V *vs.* SCE. Concentration of I, 0.934 mM; concentration of II, 0.198 mM.

The potential of the second wave coincides with that of the second step of II, which shifts to negative potentials with increasing concentration of II. Current-time curves were recorded at a potential of −0.50 V *vs.* SCE, which lies in the limiting current region of the first wave of I. A current-time curve is shown in Fig. 2, where the current is corrected for that due to the reduction of II and the residual current. The current reaches a maximum at t_1 and then decreases. This is caused by the reduction product of II, adsorbed as soon as it was formed. If Q is the quantity of electricity consumed for the reduction of II until t_1, the quantity $Q/t_1^{2/3}$ is proportional to the fraction of the electrode surface covered by the reduction product of II. Figure 3 shows the relation between $Q/t_1^{2/3}$ and $\log t_1$. Since t_1 increases tenfold, it is surprising that there is a linear relationship between these two quantities.

This relationship may be explained as follows. The current which flows at the electrode surface is a function of the concentration gradient of I and the surface area of the electrode. At around t_1 the fraction θ of the electrode surface covered by the reduction product of II increases so rapidly that the concentration gradient decreases very slowly. Thus the change of the surface area gives rise to a larger effect on the current than the change of the concentration gradient does. Under these circumstances one may assume that the concentration gradient is constant at around t_1. Hence, the increase of θ is equal to the increase of the electrode surface divided by the total surface area of the electrode dq/q at t_1, where $di/dt=0$. Thus

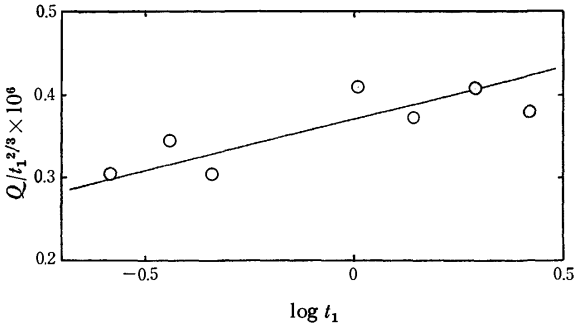

Fig. 3. Relation of $Q/t_1^{2/3}$ *vs.* $\log t_1$.

$$d\theta = \frac{dq}{q} \tag{1}$$

at t_1. Integrating Eq. (1), one has

$$\theta = \ln q + b \tag{2}$$

where b is a constant. The surface fraction θ is related to Q by the following equations.

$$\theta = \frac{\Gamma}{\Gamma_m} \tag{3}$$

$$\Gamma = \frac{Q/F}{q} \tag{4}$$

where Γ is the surface concentration of the reduction product of II at t_1, Γ_m the maximum surface concentration in a monolayer of the product, and F Faraday. By introducing Eqs. (3) and (4) and the relation $q=0.00852(mt_1)^{2/3}$ into Eq. (2), and rearranging, one obtains

$$Q/t_1^{2/3} = 0.0131F\Gamma_m m^{2/3}\log t_1 + b' \tag{5}$$

where m is the rate of flow of mercury in mg/sec, and b' a constant. Equation (5) shows that $Q/t_1^{2/3}$ is a linear function of $\log t_1$, in agreement with results given in Fig. 3.

From the slope of the straight line in Fig. 3 and Eq. (5), $1/\Gamma_m$ was calculated to be 291 Å^2/molecule. It seems to be too large compared with a value of 60 Å^2/molecule which was estimated from a molecular model. This is not the case, however. Inhibition occurs not only at the surface covered by adsorbed molecules, but also at narrow strips which encircle islets of adsorbed molecules with a width equal to the radius of the ion of I. In addition, hydration increases the apparent ionic size of I. If these facts are taken into consideration, $1/\Gamma_m$ might be several times as large as the area of cross section of the molecule. Thus Γ_m should be redefined as the minimum surface concentration to inhibit the electrode reaction completely.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2235—2236 (1972)

Preparation of Orthoesters Having Functional Group

Javad AZIZIAN*
Department of Chemistry, A.A.C. Jundi-Chapour University, Ahwaz, Iran
(Received March 1, 1971)

During the course of studies on the selective protection of hydroxyl group of nucleosides reported in our previous communication,[1] it became necessary to prepare orthoesters in which alcohol residue is substituted by functional group. Among various orthoesters, methyl and ethyl orthoformate are most commonly used in organic synthesis but their applications as a protecting reagent is rather limited.

Most of the orthoesters already known are those in which the alcohol residue is alkyl, aryl, aralkyl, or alkylene[2] and only a few orthoesters are prepared hitherto in which alcohol residue has a functional group. Hence the author attempted the synthesis of orthoesters having functional group in alcohol residue.

One of the most convenient and practical method of preparation of orthoesters is the ester interchange between methyl or ethyl orthoformate and alcohol and in this note the ester interchange between ethyl orthoformate or orthoacetate with alcohols having functional group are described. As substituted alcohols, ethylene chlorohydrin, 3-chloro-1-propanol, 1,3-dichloro-2-propanol, 2,2,2-trichloroethanol, 2-aminoethanol, 2-dimethylaminoethanol, and ethylene cyanohydrin were used.

The ester interchange reactions were carried out in the usual manner by heating the mixture of alcohol and ethyl orthoformate in the presence or absence of catalyst, ethanol being continuously removed through fractionating column. After nearly the theoretical amount of ethanol was removed, the residual reaction mixture was fractionated.

The interchange reaction proceeds partially or completely depending on the structure of substituted alcohol and the reaction conditions such as the molar ratio of the reactants. The orthoesters which were obtained in this study are listed in Table 1.

The ester interchange between ethyl orthoacetate and ethylene chlorohydrin was also attempted and 2-chloroethyl orthoacetate was obtained.

In our detailed examination on the reaction conditions of the ester interchange between ethyl orthoformate and ethylene chlorohydrin, it was found that the presence of catalyst such as zinc chloride, *p*-toluenesulfonic acid, or sulfosalicyclic acid reduced the reaction time but not affected the yield and increasing amount of catalyst decreased the yield due to the decomposition of ethyl orthoformate to form ethyl formate.

The reaction of ethyl orthoformate with 2-aminoethanol was failed to give interchanged orthoester. Thus, when 1 mol of orthoformate was heated with 4 mol of 2-aminoethanol in the presence of *p*-toluenesulfonic acid, 3 mol of ethanol distilled over, but on distilling the reaction mixture, 2 mol of 2-aminoethanol

was recovered and on further distillation caused decomposition and the distillate was found to be 2-aminoethanol.

Experimental

In all cases the ethyl orthoformate and the alcohols employed were redistilled before use. Unless otherwise stated, the experiments summarized in Table 1 were carried out according to the following procedure using the same apparatus. It is illustrated here with the preparation of 2-chloroethyl orthoformate. All boiling points are uncorrected.

2-Chloroethyl Orthoformate. In a 100 m*l* flask was added 30 g (0.2 mol) of ethyl orthoformate, 65 g (0.8 mol) of ethylene chlorohydrin and 0.1 g of anhydrous zinc chloride. In order to remove the ethanol as it was formed, a 25 cm column packed with glass helices was used and adjusted so that a maximum temperature of the condensing vapor was 79°C by controlling the heating of the flask. After 2—3 hr, nearly theoretical amount of ethanol (27 g) was removed. The residual reaction mixture was distilled under vacuum and the fraction boiling at 125—130°C/4 mmHg was collected.

Reaction of Ethylene Chlorohydrin with Ethyl Orthoacetate. The reaction was carried out using 32 g (0.2 mol) of ethyl orthoacetate and 65 g (0.8 mol) of ethylene chlorohydrin. After 3.5 hr, 27 g of ethanol was removed. The residual mixture was distilled under vacuum and 19.5 g of unreacted ethylene chlorohydrin and 30 g (56%) of 2-chloroethyl orthoacetate (bp 135°C/4 mmHg) was obtained.
Found: C, 36.98; H, 5.98; Cl, 38.92%. Calcd for $C_8H_{15}O_3Cl_3$: C, 36.15; H, 5.90; Cl, 40.10%.

The author wishes to express his hearty thanks to Professor Masaki Ohta for his encouragement.

Electron Spin Resonance of Manganese Ions on Magnesium Oxide

A. J. TENCH
Chemistry Division, A.E.R.E., Harwell, England

(Received June 8, 1971)

The study of surface properties of oxides using transition metal ions as a probe to investigate the environment of surface ions is potentially a very valuable technique; however, the interpretation of the results can present some difficulties since the location of the paramagetic ions observed is often not known. The reactivity of MgO doped with manganese[1] has been studied previously both by ESR and chemisorption; the results indicate that the Mn^{2+} ion is present in a variety of environments. A recent paper by Yamamura *et al.*[2] reports an ESR study of the behaviour of the Mn^{2+} ion on the surface of MgO. In this note, we wish to suggest an alternative interpretation of the data which indicates that not all the Mn^{2+} is on the surface.

In the latter paper,[2] it is assumed that Mn^{2+} ions initially adsorbed on the surface remain on the surface throughout the various treatments *in vacuo* and in oxygen *etc.*, even when the treatments are carried out at 1000°C. A variation in the A and D values (the hyperfine splitting and zero field splitting values of the Hamiltonian for Mn^{2+}) is attributed to changes of environment at the surface. We suggest that the observed changes in A and D could arise from a changing environment of the Mn^{2+} due to the onset of ionic diffusion processes above 500°C which allow the diffusion of some of the Mn^{2+} ions into substitutional sites in the bulk oxide, where the environment is more nearly octahedral and is characterised by lower D values. The existence of this ionic diffusion phenomena at 600°C has been well characterised,[1] and would be expected, since the ionic sizes of Mg^{2+} and Mn^{2+}, and Mn^{3+} are similar (0.65, 0.80, and 0.66 Å respectively[3]).

Up to 300°C, *in vacuo*, the MgO surface is covered with close to a monolayer of hydroxyl groups[4] and the environment of the manganese ions will not be characteristic of the oxide surface. Heating to 500—600°C reduces the OH^- coverage to less than 10% of a monolayer with the desorption of water. In the paper the authors do not indicate how the ESR spectral intensity was measured but the loss of Mn^{2+} intensity between 300—600°C could arise from the oxidation of Mn^{2+} ions to Mn^{3+} by the water vapour although this appears unlikely, and it seems more probable that Mn^{2+} ions on the bare surface experience a considerable crystal field effect giving rise to large D terms and an apparent loss in Mn^{2+} concentration. Heating the samples at higher temperatures permits the diffusion of manganese ions into the bulk where the environment is more nearly octahedral and the D values will be progressively smaller away from the surface thus giving an apparent increase in concentration of Mn^{2+}. The extremely broad spectrum shown in Fig. 1(b)[2] after treatment at 1000°C for 4 hr *in vacuo* can be interpreted by assuming the broad wings arise from surface Mn^{2+} ions which have a D value of >100 gauss whilst the sharper lines are more characteristic of ions incorporated into the bulk.

4) P. J. Anderson, R. F. Horlock, and J. F. Oliver, *Trans. Faraday Soc.*, **61**, 2754 (1965).

The influence of added gases on the Mn^{2+} spectrum can be explained in a similar manner. For example, previous work[1] has shown that Mn^{2+} ions on a surface can be oxidised very easily with oxygen at comparatively low temperatures and if all the Mn^{2+} was present on the surface as isolated ions, we would expect the intensity to drop to zero after treatment at 300°C. This apparently does not occur and the observed change in D values (Fig. 7)[2] can be explained by a progressive oxidation of the Mn^{2+} ions inwards from the surface and the remaining ions have progressively lower D values. At the same time, some line narrowing would occur due to the reduction in the Van Vleck dipole-dipole interaction[5] as the Mn^{2+} ions are converted to Mn^{3+}. The effect on the hyperfine A values is not so clear, but it seems likely that those Mn^{2+} ions remote from the surface will have an A value close to that reported for single crystals, whereas, those ions near the surface may have a slightly higher value, similar perhaps, to that observed in CaO where the ionic spacing is a little higher. However, this is not regarded as being very significant.

The results reported for Mn^{2+} on silica gel suggest that in this case the Mn^{2+} ion is not incorporated into the silica gel and remains on the surface. When the surrounding hydroxyl groups are removed by thermal treatment *in vacuo* no detailed ESR structure of the Mn^{2+} ion can be resolved and only a broad line is observed due to either the high D values from the surface field or the formation of aggregates of ions. This latter alternative certainly influences the susceptibility studies on MgO, which were carried out using a doping level of 3% manganese ion,[2] and makes any comparison with the ESR studies difficult. It is possible that ion pair formation (with very high D values[6]) also influences the results observed in the ESR study reported by Yamamura[2] where levels of 3000 ppm were used but it is regarded as very unlikely to occur in the earlier studies[1] where doping concentrations of <250 ppm were used.

We think that ESR studies of the Mn^{2+} can be used as a valuable probe of surface properties but the possible diffusion of the ion needs to be considered, and in addition, the concentration of the dopant must be kept low if the formation of ions pairs is to be ignored.

Remarks on the Crystallization and Dehydration of Copper Sulfate Pentahydrate

K. HEINZINGER and B. MAIWALD

Max - Planck - Institut für Chemie (Otto-Hahn-Institut), Mainz, Germany

(Received July 20, 1971)

Isotope effects have been used in studying crystallization and dehydration processes in hydrated crystals.[1-3] In drawing conclusions it has to be taken into consideration that there may exist different kinds of water molecules distinguished by their binding in the crystal. In copper sulfate pentahydrate there occur two kinds of bonding as shown by the neutron diffraction study of Bacon and Curry.[4] Four water molecules are bonded as ligands by a metal-oxygen bond and two hydrogen bonds and one water molecule by four hydrogen bonds. This grouping of the water molecules into two main classes is a general feature of hydrated crystals (see *e. g.* Hamilton and Ibers[5]). Another property of relevance for this discussion is, that the unit cell consists of two molecules $CuSO_4 \cdot 5H_2O$. To each of the copper ions four water molecules are coordinated. They form together with two sulfate oxygens two octahedra, slightly different in geometry.

The available hydrogen and oxygen isotope fractionation factors between the different kinds of water in the crystal, and between crystal water and the saturated solution which are relevant in respect to crystallization and dehydration processes are listed in Table 1. The reported oxygen isotope fractionation factors are still preliminary; exact numbers cannot be given yet but the direction of the enrichment alone is significant for this discussion.

Crystallization

In studying the crystallization process with the help of isotope effects, it would be an unjustified simplification to consider only the overall fractionation factor between saturated solution and total crystal water, α_{S-G}. In the case of the hydrogen isotopes, the two kinds of water in $CuSO_4 \cdot 5H_2O$ show different preferences for the isotopes.[3] This follows from the fact that the D/H ratios of four water molecules are equal in the limits of error while the D/H ratio of the fifth water molecule is bigger by 5.7%.

It has been shown that the enrichment of deuterium in the fifth molecule is not a result of a Rayleigh dis-

TABLE 1. HYDROGEN AND OXYGEN ISOTOPE FRACTIONATION FACTORS BETWEEN DIFFERENT KINDS OF WATER MOLECULES IN COPPER SULFATE PENTAHYDRATE AND BETWEEN CRYSTAL WATER AND THE SATURATED SOLUTION

α_{x-y}	α_{K_1-G}	α_{K_2-G}	α_{L-G}	α_{S-G}	Ref.
$(D/H)_x/(D/H)_y$	—	—	—	1.022	6
	0.988	0.988	1.045	1.023	3
$(T/H)_x/(T/H)_y$	—	—	—	1.044	1
$(^{18}O/^{16}O)_x/(^{18}O/^{16}O)_y$	α_{K_1-G} >	α_{K_2-G}	—	<1	7

K_1 refers to the first two moles of water per mol of $CuSO_4 \cdot 5H_2O$ liberated on dehydration, K_2 to the third and fourth and L to the fifth mol. G means total crystal water and S stands for saturated solution.

tillation. Therefore, the fractionation can only be caused by a difference in bonding. Then it can be concluded from the crystal structure together with α_{S-G} that in the water coordinated with the copper ion the light isotope is enriched, in the fifth water molecule bonded by four hydrogen bonds, the heavy isotope is enriched compared with the saturated solution, as can be seen from Table 1:

$$\alpha_{K_1-S} = \frac{\alpha_{K_1-G}}{\alpha_{S-G}} < 1, \quad \alpha_{L-S} = \frac{\alpha_{L-G}}{\alpha_{S-G}} > 1$$

This difference shows that the fractionation of the hydrogen isotopes is not a consequence of a diffusion isotope effect during crystallization, as has been suggested by Tanaka and Negita.[1] This conclusion is supported by the result of the oxygen isotope effect measurement: $\alpha_{S-G}<1$; for the overall enrichment of ^{18}O in the crystal water cannot be explained by the diffusion of the water molecules.

Therefore, it has to be concluded that during crystallization either the water on the surface of the crystal is in isotopic equilibrium with the water in the solution or that four water molecules are carried into the crystal with the cation and the fifth is taken from the bulk water. Both possibilities are reasonable, as it has been shown that in the solution a remarkable isotope fractionation between hydration water and bulk water exists. In the solution the hydration water of the cations is by a few percent enriched in the light hydrogen isotope and in ^{18}O compared with the bulk water (see *e.g.* Heinzinger and Weston,[8] and Taube[9]).

The similarity of the fractionation factors between hydration water and bulk water in the solution to those between the two kinds of water in $CuSO_4 \cdot 5H_2O$ can be understood by considering that the bonding of the hydration water in the solution is similar to the bonding of the four water molecules to the copper ion in the crystal, while the bonding of the water molecules in the bulk water of the solution is similar to the bonding of the fifth water molecule in the crystal. The vibrational spectra of concentrated solutions and hydrated crystals are similar (see *e.g.* Leung and Safford[10]).

Dehydration

From the hydrogen isotope effect measurements it has been concluded that the fifth water molecule bonded in the pentahydrate by four hydrogen bonds becomes quantitatively the water molecule of the monohydrate at dehydration temperatures below 50°C.[3] This conclusion is independent of a possible change of structure, because at these low temperatures the water molecules are not mixed up and the isotope ratios of the different kinds of water in the crystal are not changed during dehydration.

As there exists a slight difference in geometry between the two octahedra in the unit cell, it is not unreasonable to expect that at room temperature first one octahedron breaks up and looses its four waters and then the other, in agreement with the existence of a stable trihydrate. While the hydrogen isotope fractionation data do not allow a conclusion, because $\alpha_{K_1-G} = \alpha_{K_2-G}$ (Table 1), the oxygen isotope measurements support this assumption, for $\alpha_{K_1-G} > \alpha_{K_2-G}$. The enrichment of ^{18}O in the first water fraction relative to the second is necessarily a consequence of differences in the binding of the water molecules in the crystal. An isotope shift during dehydration could only be caused by some kind of a Rayleigh distillation, which would mean that the first fraction would have to be enriched in ^{16}O.

While it can be concluded from the oxygen isotope measurements that one octahedron breaks up after the other, the information from these measurements is still insufficient to decide which one of the two octahedra breaks up first. Analysis of vibrational spectra would be helpful for this decision.

Concluding this short discussion, it should be mentioned that the possibility to attribute the water molecules, collected on stepwise dehydration, to certain bonding situations in the crystal does not provide, by reversing the process, a possibility to produce a $CuSO_4 \cdot 5H_2O$ crystal with the water molecules of a given isotopic composition at given positions. The following simple experiment has been performed: $CuSO_4 \cdot 5H_2O$ was dehydrated to the monohydrate and then exposed to D_2O vapor. After the pentahydrate had formed again (checked by the amount of water taken up), dehydration in vacuum at room temperature was started. After 80% of the water was again collected, the isotopic composition was determined and it was found that deuterium and hydrogen were mixed up. This implies that the water of the monohydrate

Fractionation of Oxygen and Carbon Isotopes during Floatation of Calcite

T. SHARMA, A. K. BISWAS,* and N. V. PILLAI

Department of Chemistry, Indian Institute of Technology, Kanpur, India

** Department of Metallurgical Engineering, Indian Institute of Technology, Kanpur, India*

(Received September 17, 1971)

Fractionation of oxygen and carbon isotopes in systems containing CO_2, HCO_3^-, CO_3^{2-}, and H_2O has been investigated by many workers due to its importance in explaining the isotope variations in natural calcium carbonate deposits.[1-4] In addition to various factors like temperature, source deposition, and equilibrium conditions, the isotopic composition will be affected also by postdepositional exchanges and recrystallisation. If calcium carbonate from a particular site is transported by water to a different location through a process of floatation, the isotopic composition of calcium carbonate at the new site will depend on fractionations involved in the floatation process as well. In the present work oxygen and carbon isotopic compositions of calcium carbonate (calcite) obtained from floatation concentrates and tailings have been determined to see whether any isotopic fractionation occurs during the floatation of calcium carbonate.

Basic principles underlying floatation have been discussed by various authors.[5-7] During floatation, concentration of finely divided material occurs on the variations in their ability to keep themselves on a phase interface. Processess occuring in floatation are based on specific chemical and physical interactions between the various components involved in the system. Froth-floatation has been used to beneficiate the lime content of limestone as well as for removing it out as one of the gangue constituents of other ores. Role of oleic acid as a collector for calcite has been investigated by Lee[8] and Breewood and Miller.[9] Klassen and Kokrousov[6] have given the collecting properties of oleic acid and oleate ions under different conditions. Recently the role of sodium oleate on the floatation of calcite using different collector concentrations and different activators was investigated by Biswas and coworkers.[10,11] They have shown that the recovery of calcite increases with collector concentration, and by using carbon dioxide as the lifting agent instead of air. The nature of acids used to adjust the pH of the pulp before floatation was also found to affect the floatation yield considerably. In the present investigations, calcite from the floatation concentrates and tailings obtained in the presence of hydrochloric, benzoic, citric, and oxalic acids have been used for isotopic studies.

Experimental

Floatation. About 100 g of powdered calcite (−100+200 mesh ASTM) was mixed with about one litre of distilled water. The pH of the solution was adjusted to about 5.7 by the addition of hydrochloric, benzoic, citric, or oxalic acid. Calculated amount of sodium oleate was added so that the concentration was about $2.5—3\times10^{-6}$ mol/l in the solution. About 5 ml of 5% Dowfroth-250 was added and the pulp was conditioned for about 3 min at an impeller speed of 900 rpm. The pH after conditioning was 6.1 to 6.4. Air was introduced by opening the suction valve and and impeller speed was set to 2100 rpm. Froth was collected and the floatation was over within 3 min. Calcite was collected from the froth (floatation concentrate) and from the solution (tailing), washed, dried, and weighed. Calcite slurry bubbled with carbon dioxide and calcite slurry kept under distilled water also were sampled for isotopic analysis. the experiments were carried out at 27°C. Floatation concentrates and tailings used for isotopic analysis are listed in Table 1.

Isotope Analysis. Samples were decomposed using 100% phosphoric acid according to the procedure of McCrea[1] and the liberated carbon dioxide collected and the yield measured. The isotopic analysis of the carbon dioxide was done on a 6''-60°-RMS-19 double collecting isotope ratio mass spectrometer. The values were corrected as described by Craig.[12] The $^{18}O/^{16}O$ ratio of the carbonate was calculated using the isotope fractionation factor given by Sharma

a) Calculated from the following material balance calculation

$$\delta = \frac{\left[\begin{matrix}\%\text{ yield of}\\ \text{concentrate}\end{matrix}\right] \times \delta_{\text{concentrate}} + \left[\begin{matrix}\%\text{ yield}\\ \text{of tailing}\end{matrix}\right] \times \delta_{\text{tailing}}}{100}$$

and Clayton.[13] The isotopic ratios are reported in the delta terminology defined as:

$$\delta = \left[\frac{R_{\text{sample}}}{R_{\text{standard}}} - 1\right] \times 1000 \qquad (1)$$

where $R = {}^{18}O/{}^{16}O$ or $^{13}C/^{12}C$ ratio. The oxygen and carbon isotope values are reported with respect to SMOW (standard mean ocean water) and Chicago PDB carbonate standards respectively. The results of isotopic analyses are presented in Table 2.

Discussion

Factors that can affect the distribution of oxygen and carbon isotopic composition of calcite in the floatation concentrate and tailings are (1) various chemical equilibria involved when calcite dissolves in water, (2) isotope exchange reactions occurring in the solution, (3) solubility of calcium carbonate, (4) relative affiinity of various isotopic molecules towards collector anions, (5) pH of the floatation pulp, and (6) temperature. Isotopic fractionation will accompany the several reactions that take place in the system. The various reactions that occur when calcite is placed in water are the following:

$$CO_3^{2-}\ (\text{solid}) \rightleftarrows CO_3^{2-}\ (\text{aq}) \qquad (2)$$

$$CO_3^{2-} + H_2O \rightleftarrows HCO_3^- + OH^- \qquad (3)$$

$$HCO_3^- + H_2O \rightleftarrows H_2CO_3 + OH^- \qquad (4)$$

$$H_2CO_3 \rightleftarrows H_2O + CO_2 \qquad (5)$$

In a closed system at equilibrium each component will possess characteristic carbon and oxygen isotopic ratios.[3] This is the result of isotopic fractionation occurring between the various components and existence of several exchange reactions of the type:

$$H_2{}^{12}CO_3 + H^{13}CO_3^- \rightleftarrows H_2{}^{13}CO_3 + H^{12}CO^{3-} \qquad (6)$$

$$1/3\ C^{18}O_3^{2-} + H_2{}^{16}O \rightleftarrows 1/3\ C^{16}O_3^{2-} + H_2{}^{18}O \qquad (7)$$

Relative solubility of calcium carbonate in the solution in presence of different ionic species will change the isotopic composition of solid calcite in the floatation pulp and hence will affect the isotopic composition of calcite in the floatation conecntrate and tailing. Experimental investigations of calcium carbonate solubility have shown that solubility varies with temperature, pressure, added salts, pH, and the total amount of CO_2 in the solution.[14] An increased solubility of calcium carbonate will make the remaining calcite isotopically heavier. The affinity of the collector anions towards the various isotopic molecules will also affect the relative isotopic composition in the floatation concentrate and tailing.

The results in Table 2 show that except in the case when benzoic acid was used to adjust the pH, the floatation concentrate is found to be richer in the lighter isotope. This enrichment of lighter isotopes in the floatation concentrate may be due to the greater affinity of the collector anions towards the lighter isotopic molecules and consequent increase in the lighter calcite particles in the froth. Other factors like differences in the solubility of the light and heavy isotopes and partial dissolution of calcite when it is in contact with water will make the tailings enriched in heavy isotopes due to preferential dissolution of lighter isotopic molecules. Oxygen and carbon isotopic fractions between the solid and the dissolved species also might have caused the observed enrichment in the tailings.

Although we do observe differences in the ^{13}C and ^{18}O contents of the floatation concentrates and tailings, the differences are found to be very small, compared to the equilibrium fractionations in other systems. This is owing to nonattainment of isotopic equilibrium conditions due to short period of time. Since all

13) T. Sharma and R. N. Clayton, *Geochim. Cosmochim. Acta*, **29**, 1347 (1965).

14) R. M. Garrels and R. M. Dreyer, *Bull. Geol. Soc. Amer.*, **63**, 325 (1952).

the floatation experiments are over within ten minutes much fractionation cannot be expected. Moreover, since the relative amount of bicarbonate and carbonate ion concentration in the solution is much less compared to the total amount of calcite present in the system, change in isotopic composition due to isotopic exchange and solubility differences will be small. The total $\delta^{18}O$ and $\delta^{13}C$ values calculated from material balance of floatation concentrates and tailings are very close to that of calcite kept under distilled water.

Calcite slurry bubbled with CO_2 is found to be heavier than calcite kept under distilled water. When carbon dioxide is bubbled through the slurry, more calcium carbonate will dissolve to form calcium bicarbonate.

$$CaCO_3 + CO_2 + H_2O \rightleftarrows Ca(HCO_3)_2 \quad (8)$$

As explained earlier, the lighter $CaCO_3$ particles will undergo preferential dissolution making the remining calcite heavier. The observed enrichment in $\delta^{18}O$ and $\delta^{13}C$ are in agreement with this view.

The foregoing results show that there is isotopic fractionation during the floatation of calcium carbonate. The floatation experiments carried out here were in presence of floatation reagents and may be far from conditions under which floatation occurs in nature. Still, it might be one of the factors which determine the distribution of oxygen and carbon isotopes in natural calcium carbonate deposits.

Nouvelle Synthèse Totale de la Cétone Sabinique (*dl*)

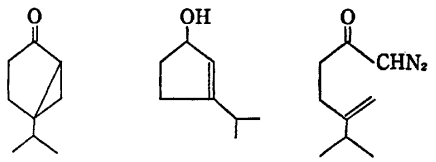
Christian ALEXANDRE et Francis ROUESSAC

Laboratoire de Synthèse Organique, Centre Universitaire du Mans, Route de Laval 72, Le Mans France

(Reçu le 5 Octobre, 1971)

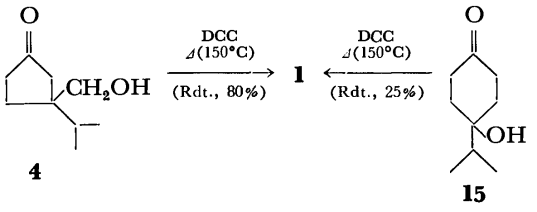
En dehors de l'oxydation du sabinene en cétone sabinique **1**,[1,2] on ne trouve en faisant l'examen de la littérature, que deux voies de synthèse totale conduisant à cette cétone.

Dans ces deux méthodes, les auteurs créent le cycle cyclopropanique soit par réaction de Simmons-Smith sur le cyclopenténol **2**[3] soit par addition intramoléculaire d'un α-cétocarbène sur une double liaison éthylénique[4] (Composé **3**).



1 **2** **3**

Nous décrivons ici une nouvelle synthèse de la cétone sabinique racémique dans laquelle l'α-cyclopropylcétone est créée par deshydratation intramoléculaire du γ-cétol **4**, en présence de dicyclohexylcarbodiimide (DCC), selon la méthode que nous avons développée au laboratoire.[5,6]



4 **1** **15**

L'acide isopropyl-1 cyclohexène-3 carboxylique **6**, obtenu (Rdt.: 80%) par réaction de Diels et Alder entre l'acide α-isopropylacrylique **5**[4] et le butadiene est transformé en ester méthylique **7** avec une solution éthérée de diazométhane (Rdt : 90%). Par oxydation permanganique **7** conduit à **8** (Rdt: 77%) qui est alors estérifié de façon classique (EtOH, Rdt : 75%) en triester **9**. Ce dernier est converti par une cyclisation de type Dieckmann en un mélange des deux cétoesters isomères **10** et **11** (Rdt : 62%) dont l'hydrolyse ménagée conduit dans l'un et l'autre cas au cétoester **12** (Rdt : 79%): Après le blocage préalable de la fonction cétone en dioxolanne **13** (Rdt.: 90%), la réduction de ce composé par $LiAlH_4$ donne l'alcool **14** (Rdt : 84%) puis l'alcool **4** par traitement acide aqueux (HCl) (Rdt : 92%).

4 réagit avec un équivalent de DCC pour donner un carbamidate dont le chauffage à 150°C pendant 2 heures suffit pour obtenir (Rdt : 80%) la cétone sabinique (*dl*) dont la pureté (CPV) est supérieure à 98%.

est seulement de 25%,[6] la réaction d'élimination étant beaucoup moins rapide dans ce cas, que pour le composé **4**.

Partie Experimentale

Acide Isopropyl-1 Cyclohexène-3 Carboxylique ***6***. 60 g d'acide isopropyl-2 acrylique,[4] 100 m*l* de butadiène et 1 g d'hydroquinone sont maintenus à 170°C pendant 20 hr. Après distillation, on obtient 73 g d'acide **6**. $Eb_{0,03}$: 98—100°C. F : 61°C. Rdt.=84%.

Isopropyl-1 cyclohexène-3 Carboxylate de Méthyle ***7***. Une solution éthérée de diazométhane est ajoutée à une solution de 50 g de **6** dans l'éther, le tout refroidi à 0°C. Aprés concentration, le résidu distillé donne 48 g de **7**. Eb_{12} : 86—87°C. Rdt,=90%.

Isopropyl-1 Oxo-3 Cyclopentanecarboxylate de Méthyle ***12***. Préparé selon le mode opératoire de Toki.[7] On ajoute par petites portions, 148 g de $KMnO_4$ a 57,5 g d'ester **7** dans 600 m*l* d'eau. Après filtration, concentration et extraction à l'ether, on obtient 60 g (77%) de diacide **8** que l'on estérifie directement en triester **9** (54 g) $Eb_{0.2}$: 125—127°C (Rdt.= 75%). **9** (54 g) est ajouté goutte a goutte à une suspension de 4,2 g de sodium dans 200 ml de benzene puis porté à reflux une nuit; apres isolation, on obtient 28 g du mélange **10** et **11**. $Eb_{0,07}$: 114—115°C. Rdt.=62%. Ce mélange traité 3 hr à reflux dans 250 m*l* d'H_2SO_4 à 8% donne 15 g d'ester **12**. Eb_{15} : 132—133°C. Rdt.=75%.

Isopropyl-7 Dioxa-1,4 Spiro[4.4]nonanecarboxylate-7 de Méthyle ***13***. Préparé selon la technique habituelle avec un rendement de 90%. Eb_{15} : 142—143°C.

Isopropyl-7 Hydroxyméthyl-7 Dioxia-1,4 Spiro[4,4]nonane ***14***. A partir de 13.5 g de cétone et 4 g de $LiAlH_4$ dans 300 m*l* d'éther, on isole 10 g d'alcool ***14***. $Eb_{0.01}$: 100—102°C. Rdt.=94%.

Hydroxyméthyl-3 Isopropyl-3 Cyclopentanone ***4***. **14** (9 g) est débloqué à 0°C par une solution d'HCl concentré dans l'acétone pendant 1/2 hr. On obtient 5,9 g de **4**. $Eb_{0,01}$: 93—94°C. Rdt.=92%.

Cetone Sabinique ***1***. Le carbamidate (4 g) (préparé en agitant 12 hr à température ambiante, 1,7 g de cétol **4**, 2,5 g de DCC et 50 mg de chlorure cuivreux), est chauffé à 150°C pendant 2 hr, la cetone sabinique étant distillée sous vide au fur et à mesure de sa formation. On obtient 1,25 g de cétone **1** (Rdt.=80%). Constantes en accord avec la littérature.[1,4]

8) Des analyses et des spectres IR et de RMN corrects ont été obtenus pour les composés nouveaux décrits dans cet article.

SHORT COMMUNICATIONS

Studies on Chrysanthemate Derivatives. II.[1] Pyrolysis of Pyrethrin-I

Yasuo NAKADA, Yasuo YURA, and Keisuke MURAYAMA
Central Research Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo

(Received May 8, 1972)

Five compounds were obtained by the pyrolysis of allethrin.[2] In this communication we wish to report a new product obtained by the pyrolysis of pyrethrin-I.

Pyrethrin-I, cinerin-I, and jasmolin-I were advantageously separated from the mixtures extracted from pyrethrum flowers,[3] using a special column chromatography on silica gel impregnated with silver nitrate. Pyrolysis of pyrethrin-I was carried out at 400°C as reported previously.[2] The reaction products were separated into an acidic and a neutral fraction by alkaline extraction.

The acidic fraction gave chrysanthemic acid (I) as the only product.

The neutral fraction consisted of pyrocin (II) and a new compound (III) separated by column chromatography on silica gel. Compound III revealed the following spectral data; *m/e* 160 (M^+) and 145 (M-15); IR, ν_{max} cm^{-1}: 1680 and 1640; UV, $\lambda_{max}^{EtOH}m\mu$ ($\log \varepsilon$): 230 (3.50) and 319 (3.64); NMR,[4] a doublet methyl at 9.39 (3H; J=7.1 Hz), a singlet methyl at 8.87 (3H), a multiplet proton on a tertiary carbon at 7.73 (1H), and five olefinic protons at 3.70—3.90 (m, 3H), 3.41 (ddd, 1H; J=1.0, 2.1, and 5.0 Hz), and 2.55 (dd, 1H; J=1.0 and 6.0 Hz). Heating compound III with concentrated hydrochloric acid afforded a white crystalline substance, mp 84—86°C, which was designated as 4,5-dimethyl-1-indanone(IV) on the basis of the following mass, IR, UV, and NMR spectral data and by comparison with those of the independent synthetic product prepared from *o*-xylene using the method of Hart and Teble;[5] *m/e* 160 (M^+), 145 (M-15), and 132 (M-28); IR, ν_{max} cm^{-1}: 1709 and 818 (1,2,3,4-tetrasubstituted phenyl); UV, $\lambda_{max}^{EtOH}m\mu$ ($\log \varepsilon$): 258 (4.19) and 292 (3.46); NMR,[6] two singlet methyls at 7.80 (3H) and 7.67 (3H), two multiplet methylenes at 7.48 (2H) and 7.09 (2H), and two aromatic protons centered at 2.95 (d, 1H; J=4.0 Hz) and 2.65 (d, 1H; J=4.0 Hz).

From these results compound III is presumed to be 4,5-dimethyl-bicyclo[4.3.0]nona-2,6,8-triene.

We propose that the reaction mechanisms for the pyrolysis of pyrethrin-I and for the acid catalyzed rearrangement of compound III to compound IV take place as shown in Scheme 1 and 2, respectively.

The Reaction of Trialkylboron and α-Lithiobenzyl-2-pyridyl or Phenylsulfide. A Convenient Method for the Preparation of Alkylbenzenes

Teruaki MUKAIYAMA, Shoji YAMAMOTO, and Manzo SHIONO

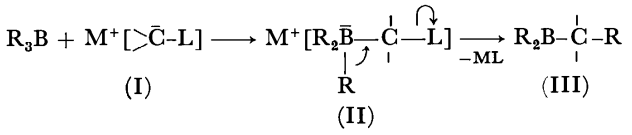
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 6, 1972)

Recently it was shown[1] that benzyl-2-pyridylsulfide is easily metalated at −75°C in tetrahydrofuran by *n*-butyllithium or phenyllithium to give α-lithiobenzyl-2-pyridylsulfide, which in turn successfully reacts with various carbonyl compounds and halides.

Now we wish to report a new synthetic method for the preparation of alkylbenzenes by the use of the α-lithio derivatives of sulfides and trialkylborons.

It is well known[2] that trialkylboron reacts with the carbanion (I) to form the quaternary salt (II), in which subsequently one alkyl group migrates to a carbon atom from a boron atom to produce a new trialkylboron (III) accompanied with the elimination of ML as shown in Scheme 1.



(I) (II) (III)

M: metal L: leaving group

Scheme 1

When the α-lithio derivative of benzyl-2-pyridylsufide or benzylphenylsulfide was treated at −75°C in tetrahydrofuran under argon atmosphere with tri-*n*-butylboron, the formation of the quaternary salt was observed. The salt was converted into two alkylbenzenes, *n*-amylbenzene and 1,2-diphenylhexane in 63% and 24% yields, respectively, after refluxing for 3 hr and alkaline hydrolysis. The products were identified on the basis of NMR spectra and gas chromatographical data.

In a similar way, various trialkylborons reacted with the α-lithio derivatives to give the corresponding alkylbenzenes. But tricyclohexyl and tricyclopentylboron failed to react with α-lithiobenzylphenylsulfide. The results are summarized in Table 1.

An undesirable by-product, diphenylethane derivative is considered to be formed by the further reaction of the new trialkylboron (III) and the α-lithio derivative.

Table 1. YIELDS OF TWO ALKYLBENZENES

R_3B	Isolated yield %			
			$PhCH_2SPh$	
	$PhCH_2R$	$PhCH_2$-CHPhR	$PhCH_2R$	$PhCH_2$-CHPhR
$(n\text{-}C_4H_9)_3B$	63	24	71	16
$(n\text{-}C_6H_{13})_3B$	70	23	75	20
$(n\text{-}C_8H_{17})_3B$	73	trace	61	12
	85	0	0	0
	83	0	0	0

In order to minimize the formation of the by-products, the reactions were tried in the presence of the additives which would facilitate the elimination of the mercapto group from the quaternary salt.

It was found that the addition of cuprous iodide at −75°C or dimethylsulfate at room temperature was effective for the prevention of the formation of the by-products in the reaction between trialkylboron and α-lithiobenzylphenylsulfide. In each case, the desired alkylbenzene was obtained in good yield without accompanying the formation of the by-product. The results are summarized in Table 2. The reaction is considered to proceed involving cuprous quaternary salt (IV) or sulfonium betaine (V) as shown in Scheme 2.

Table 2. YIELDS OF ALKYLBENZENES

The Bromine Nuclear Quadrupole Resonance of the Molecular Complex of Aluminum Tribromide with Benzene

Tsutomu OKUDA, Yoshihiro FURUKAWA, and Hisao NEGITA
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima
(Received January 26, 1972)

The bromine nuclear quadrupole resonance (NQR) and its Zeeman effect have been observed in the molecular complex of aluminum tribromide with benzene at room temperature. The resonance frequencies are 79.99, 90.10, and 91.18 MHz for ^{81}Br at 301°K. The asymmetry parameters of the field gradient are 28.9±1.1, 8.6±1.0, and 6.0±0.9% for the bromine atoms in the order of increasing resonance frequency. Aluminum tribromide forms the dimer in the complex crystal as well as in the pure state. The bond angle between a pair of terminal bromine atoms and the interbond angle at the bridging bromine atom are found to be 117.3±0.5° and 95.5±0.2° respectively; these values correspond to those of 122±2° and 87±2° obtained from the X-ray analysis. Furthermore, the charge-transfer from the benzene ring to the bromine atom is discussed on the basis of the NQR parameters.

It has been established that aluminum tribromide forms molecular complexes with many organic compounds, and they have been studied extensively by various methods. These complexes with organic compounds belong mostly to the type of $AlBr_3 \cdot D$,[1] where the aluminum atom coordinates the oxygen or nitrogen atom of the donor, D. There is also another type of complex, such as $Al_2Br_6 \cdot D$,[2] where the bromine atom may combine with the aromatic ring of a donor, D, such as benzene or toluene.

The NQR frequency depends on the electric-field gradient at the site of the resonant nucleus. As the bromine atom seems to be involved in the binding between the component molecules in the complex of $Al_2Br_6 \cdot D$, the Br NQR will clarify the extent and direction of the charge-transfer as well as the molecular structure of Al_2Br_6. In this respect, it will be interesting to examine the Br NQR of the $Al_2Br_6 \cdot C_6H_6$ complex and to observe the Zeeman effect on the NQR, using the single crystal of the complex.

Concerning aluminum tribromide itself, both the Al[3] and Br NQR frequencies[4] as well as the Br Zeeman effect[5] have been measured. The ^{81}Br NQR spectrum is composed of the singlet of 81.82 MHz and the doublet of 95.01 and 96.43 MHz at 77°K. The singlet was attributed to the bridging bromine atom, and the doublet, to the two different sites of the terminal bromine atoms in the dimer. NQR studies of the bromine atoms in some complexes of $AlBr_3 \cdot D$ have been reported,[6] but none on the complex of $Al_2Br_6 \cdot D$ are known to us.

According to the crystal structure of $Al_2Br_6 \cdot C_6H_6$ established by X-ray analysis,[7] the space group is C_i, with one species, $Al_2Br_6 \cdot C_6H_6$, in a unit cell of the dimensions of $a=6.85$ Å, $b=6.91$ Å, $c=9.00$ Å, $\alpha=104.6°$, $\beta=103.1°$, and $\gamma=90.0°$. The aluminum tribromide molecule in the complex was confirmed to form the dimer as in its pure crystal, and the centers of both the Al_2Br_6 and C_6H_6 components are centrosymmetric. Figure 1 shows the crystal structure projected along the b axis. The shortest distance between the layer of the bromine atoms and the plane of the benzene ring is 3.2 Å.

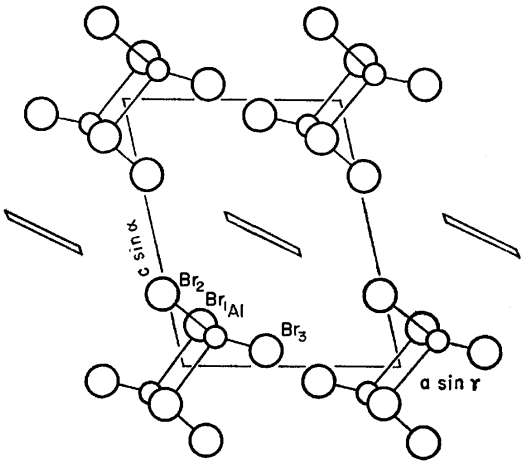

Fig. 1. Crystal structure of $Al_2Br_6 \cdot C_6H_6$ projected along b axis.

Experimental

Aluminum tribromide was prepared by dropping liquid bromine into aluminum metal and was purified by distillation several times. The purification of benzene and the synthesis of the complex were performed with reference to the literature.[7] The single crystal of the complex was obtained by lowering an ampoule of the saturated benzene solution of aluminum tribromide slowly through an electric furnace at about 40°C.

The NQR spectrometer employed was a superregenerative oscillator with frequency modulation, and the absorption lines were displayed on an oscilloscope. The resonance frequencies, ν, were measured with a standard frequency generator whose frequency was determined by means of a universal counter, TR-5578, of the Takeda Riken Industry

Co., Ltd. The Zeeman effect was measured by means of the zero-splitting cone method in the low-magnetic field. The magnetic field of about 300 gauss was supplied by a Helmholtz coil, and the patterns of the zero-splitting loci were observed at room temperature.

Results and Discussion

The observed NQR frequencies for the bromine atoms in the complex at 301°K are listed in Table 1.

TABLE 1. ^{81}Br NQR PARAMETERS OF $Al_2Br_6 \cdot C_6H_6$ AND Al_2Br_6 AT 301°K

Compound	ν (MHz)	e^2Qq (MHz)	η (%)	ρ
$Al_2Br_6 \cdot C_6H_6$	79.99	157.8	28.9±1.1	0.45
	90.10	180.0	8.6±1.0	0.67
	91.18	182.3	6.0±0.9	0.67
Al_2Br_6	79.85	158.1	24.8[a]	0.45
	92.36	184.6	7.3[a]	0.66
	93.47	186.6	10.6[a]	0.66

a) Ref. 5

The spectrum of each bromine isotope consists of three resonance lines; in the case of ^{81}Br, the singlet is about 10 MHz below the doublet in the 90 MHz region, and three lines have almost the same intensity. This feature of the spectrum and the asymmetry parameters calculated from the Zeeman effect are quite similar to those in pure aluminum tribromide and other trihalides of the IIIb group.[4,8] Therefore, the two resonance lines in the 90 MHz region may be ascribed to two kinds of terminal bromine atoms, and the remaining one, to the bridging bromine atom.

Bond Angle. The zero-splitting patterns observed are shown in Fig. 2, where Br_1, Br_2, and Br_3 are the directions of the z axes of the field gradient on the bromine atoms contributing to the resonance frequency, in order from the lower to the higher. The asymmetry parameter, η, and the quadrupole coupling constant, e^2Qq, may be determined from the following relation:[9]

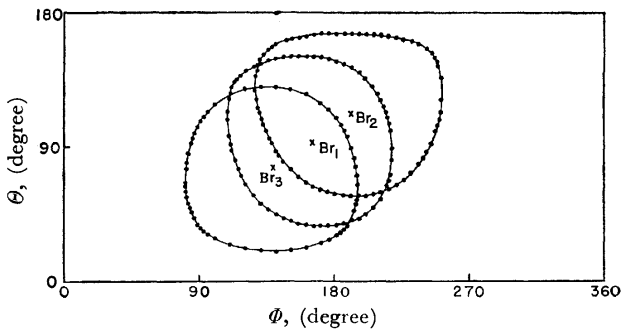

Fig. 2. Zero-splitting patterns of Zeeman lines of $Al_2Br_6 \cdot C_6H_6$. The axis of $\Theta=0$ is taken as the rotational axis of the sample tube. The plane of $\Phi=0$ is arbitrarily chosen.

$$\eta = 3(\sin^2\theta_{max} - \sin^2\theta_{min})/(\sin^2\theta_{max} + \sin^2\theta_{min}) \quad (1)$$

$$\nu = \tfrac{1}{2} e^2Qq(1+\eta^2/3)^{1/2} \quad (2)$$

where θ_{max} and θ_{min} are the maximum and minimum zero-splitting angles corresponding to the directions of the x and y axes of the field gradient respectively. The values of η and e^2Qq are listed in Table 1, along with those of pure aluminum tribromide. The z axes on the monovalent bromine atoms, Br_2 and Br_3, are usually parallel to the relevant bond directions. The bond angle, α, and the asymmetry parameter, η, at Br_1 are related by the following equation[3] under the coordinate system of the field gradients, as is shown in Fig. 3:

$$\eta = -3\cos\alpha. \quad (3)$$

The molecular shape of aluminum tribromide in the complex thus obtained is shown in Fig. 3; it is similar

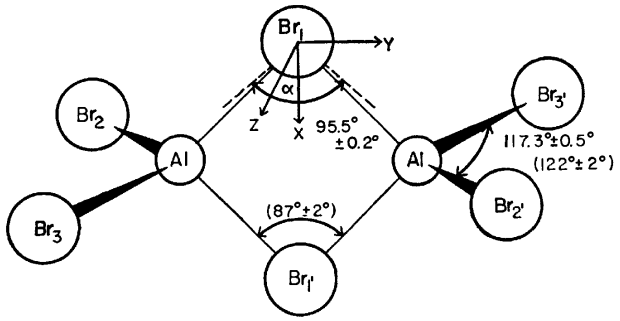

Fig. 3. The coordinate system of the principal field gradient on the bridging bromine atom and the molecular shape of Al_2Br_6 in $Al_2Br_6 \cdot C_6H_6$. Values in parenthsis are cited from the X-ray analysis.

to that in the pure state.[5] The agreement of the results of the NQR with those of the X-ray analysis is fairly good for the $\angle Br_2$–Al–Br_3 angle, but not good for the $\angle$Al–Br_1–Al angle. This discrepancy is probably caused by the bent bond, as is the case in pure Al_2Br_6[5] and Ga_2Cl_6.[10]

The z axis of Br_1 is parallel to the plane including the z axes of Br_2 and Br_3, as may be seen in Fig. 2. The angles which the z axis of Br_1 makes with those of Br_2 and Br_3 are 30.5° and 32.2° respectively.

Intramolecular and Intermolecular Bonds. The asymmetry parameter depends on the unbalance of the π-electrons of the atom and on the intermolecular interaction, as is seen in the case of solid iodine.[11] Fairly large values of η for the terminal bromine atoms are observed, so the intermolecular interaction can not be ignored in the solid state. In this complex, two kinds of intermolecular interaction are possible. One would be that between a given terminal bromine atom and the nearest bromine of the neighboring Al_2Br_6 molecule. There are short interatomic distances, 3.7Å and 3.9Å for $Br_3 \cdots Br''_3$ and $Br_2 \cdots Br'_1$ whereas the sum of the van der Waals radii of the

8) S. L. Segel and R. G. Barnes, *J. Chem. Phys.*, **25**, 578 (1956); R. G. Barnes, S. L. Segel, P. J. Bray, and P. A. Cassabella, *ibid.*, **26**, 1345 (1957).

10) G. E. Peterson and P. M. Bridenbaugh, *J. Chem. Phys.*, **51**, 238 (1969).

11) Ref. 9, p. 173.

bromine atoms is 3.90Å. The shorter distance for $Br_3\cdots Br''_3$ is evidently ascribable to the intermolecular bonding. The $\angle Al\text{–}Br_3\cdots Br''_3$ angle is about 140°, whereas the $\angle Al\text{-}Br_2\cdots Br'_1$ angle is 90°. Accordingly the η of Br_2 can be expected to be larger than that of Br_3. This is really the case.

The other intermolecular interaction may be seen between the bridging bromine atom and benzene. The interatomic distance for $Br_1\cdots C$ is 3.7Å, which is comparable to the sum of the van der Waals radii, 3.65Å. The interaction seems to be smaller than the $Br_3\cdots Br''_3$ bonding. All the other distances between bromine and carbon atoms are not less than 4Å.

The quadrupole coupling constant of the bromine atom depends primarily on its own bonding electron population. If the charge transfers from the benzene to the bromine atom, the e^2Qq value of the atom may be expected to decrease due to an increase in its electronic charge. As can be seen from Table 1, the e^2Qq values of the terminal bromine atoms are lower by about 4 MHz than those of pure aluminum tribromide. On the other hand, the shift of the e^2Qq of the bridging bromine atom is only 0.3 MHz. According to Townes and Dailey, the field gradient can be ascribed to $4p$ electrons of the bromine atom, and one may calculate the number of the electrons, ρ, which the bromine atom gains from its own molecule and neighboring ones. The equations used here are

$$\rho = 1 - Up/0.85 \tag{4}$$

for the terminal bromine atom, and

$$\rho = (1+2\,Up)/(1-2\,\varepsilon\,Up) \tag{5}$$

for the bridging bromine atom,[3] where Up is the number of unbalanced p electrons and where ε, which is estimated to be 0.25, is a known factor. These values of ρ are listed in Table 1. Those at the terminal Br_2 and Br_3 of the complex are increased by only 0.01, and that of the bridging Br_1 remains almost unchanged in comparison with those of pure aluminum tribromide. Therefore, taking account of the asymmetry parameters and the quadrupole coupling constants at the bromine atoms in the complex, it may be suggested that the charge transfer if any, takes place from the benzene to the terminal bromine atoms.

The Photo-induced Electron Transfer Reactions between Crystals of Aromatic Hydrocarbons and Quinones

Mitsuyuki SOMA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received December 6, 1971)

The photo-induced electron transfer reactions between crystals of aromatic hydrocarbons and several quinones were studied by measuring the increase of the photocurrent in the crystals due to the carrier injection from the ethanol electrode containing the quinones. The reaction rates were shown to be independent of sorts of quinones used when its concentration was sufficiently high. The excitation limited mechanism of the reaction was proposed to be consistent with this behavior and the observed concentration dependence of the reaction.

It has been reported previously[1,2] that the photo-induced electron transfer reaction occurs with high efficiency between a crystal of aromatic hydrocarbon and a π-electron acceptor dissolved in the liquid electrode contracted with the crystal. The rate of the electron transfer reaction is proportional to the saturation value of the photo-hole-current in the crystal which is attained by applying sufficiently high voltages.

In such cases as the photo-hole injection from tetrachloro-phthalonitrile into anthracene crystals, the saturation photocurrent depends linearly upon the concentration of added electron acceptor. On the other hand when *p*-benzoquinone is used as an acceptor, the saturation photocurrent begins to deviate from the linear dependence as the concentration increases and reaches a limiting value. This behavior was attributed tentatively to the electron transfer including *p*-benzoquinone adsorbed on the surface of the crystal.

It is reported in this paper that this feature is found generally in the photo-induced electron transfer reactions between the crystals of aromatic hydrocarbons and quinones with fairly high electron affinities, and the evidences which suggest another explanation for this behavior are presented

Experimental

The measuring procedures for the photocurrent in the crystals due to the photo-induced hole injection from the liquid ethanol electrode were the same as previously described[1] where the simplified type of Kallmann- and Popes' cell[3] was used. Thin platelets of single crystals of the aromatic hydrocarbons, anthracene, naphthacene, perylene, and *p*-terphenyl were prepared following the method previously reported.[2] All the quinones except *o*-chloranil were of com-

mercial source, purified by recrystallization and by sublimation if possible. *o*-Chloranil was synthesized according to Brook,[4] purified by recrystallization from carbon tetrachloride and by sublimation.

Results

Figure 1 shows changes in the saturation photo-hole-current in an anthracene single crystal with the

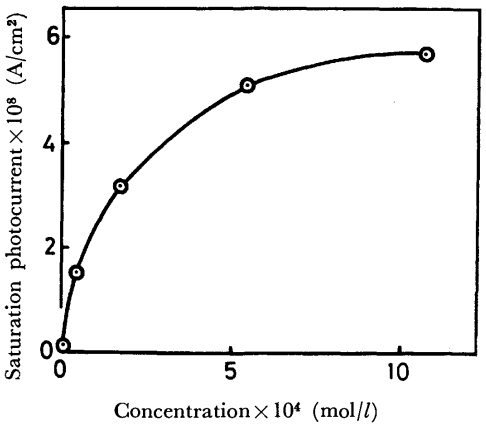

Fig. 1. Changes in the saturation photocurrent in anthracene crystal with the concentration of added *p*-chloranil.
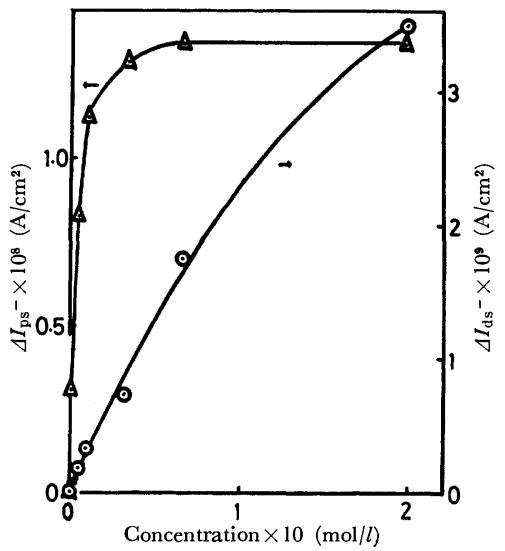
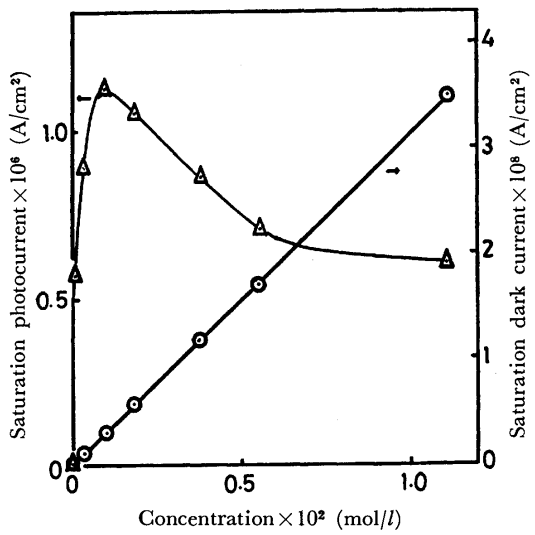
Electrode arrangement, water|crystal|ethanol+*p*-chloranil, water electrode illuminated by 4010 Å light, ethanol electrode biased positive.

concentration of *p*-chloranil added to the dark side (back face concerning to the direction of illumination) electrode. The crystal was excited by the light of wavelength at 4010 Å. As the back face electrode was positively biased, the observed photocurrent was attributed to the hole injection from the electrode, *i.e.* to the photo-induced electron transfer reaction between the excited anthracene crystal and *p*-chloranil. The saturation photocurrent reached to the certain limiting value as the concentration of *p*-chloranil increased. This behavior of concentration dependence of the photocurrent was already reported for the anthracene crystal/*p*-benzoquinone system,[1] and now, was found to be a general feature of the photo-induced electron transfer between excited aromatic hydrocarbons and various quinones. Figures 2a and 2b exemplify this behavior in the perylene crystal/*p*-benzoquinone, and the naphthacene crystal/*o*-chloranil systems. In these cases the crystals were illuminated at 5025 Å. Perylene and naphthacene have considerably lower ionization potentials than holes from the electrode to the crystal. The electron transfer reaction from the aromatic crystals to the quinones occurred without photo-excitation. In Figs. 2a and 2b, the concentration dependence of the dark injection was shown for comparison. They are quite different from those of the photo-injection. The dark currents were almost proportional to the concentration of the added electron acceptors in the concentration range studied.

This fact suggests that there might be specific



a) perylene crystal/*p*-benzoquinone system excited by 5020 Å



b) tetracene crystal/*o*-chloranil system excited by 5020 Å

Fig. 2. Changes in the saturation photo-(ΔI_{ps}^-) and dark (ΔI_{ps}^-) current in the aromatic hydrocarbons with the concentration of the added acceptors.

circumstances causing the appearance of the limiting values in the photocurrents but not in the dark current. To get more information about the phenomena, the photo-induced electron transfer reactions with various quinones as electron acceptor were compared. Two types of comparison were made.

The relative limiting values of the saturation photo-hole current in an anthracene crystal with four quinones as electron acceptor are shown in Table 1. In the last column are the reduction potentials of the quinones[5] which are the measure of their electron affinities in the polar organic solvents. The limiting values were attained at the lower concentrations of the acceptor, the larger the electron affinity (smaller the reduction potential) of the acceptor was. Although the electron affinity varies in fairly wide range

among the quinones used, the differences in the limiting values of the photocurrents were small. The limiting values of the photocurrents in the naphthacene crystal with p-chloranil and 2,6-dichloro-p-benzoquinone as acceptors were also roughly the same, while with p-benzoquinone it gave substantially smaller limiting value (one third or one fourth of the former). The latter might be attributed, at least partly, to the presence of another concentration effect which caused the photocurrent to decrease below the limiting value with further increasing the concentration as was the case in the naphthacene crystal/o-chloranil system shown in Fig. 2b.

The second comparison was made in the small concentration region where the photocurrent was almost proportional to the concentration of the electron acceptor. In Fig. 3, the relative saturation photocurrents normalized per unit concentration in anthracene and naphthacene crystals are plotted aginst the electron affinities of the various quinones.

Discussion

The saturation photocurrent I_{ps} attained by applying sufficiently high voltage can be related to the number of holes, n, injected per unit time by the following equation.

$$n = \frac{F}{q} I_{ps} \tag{1}$$

where F is Faraday constant and q is the charge of an electron. Accordingly, changes in the saturation photo-hole-current upon the addition of the electron acceptor are the direct measure of the rate of the electron transfer reactions between the excited crystal and the electron acceptor. The rate of the photo-induced electron transfer reaction was shown to have a different concentration dependence from that of the electron transfer reaction in the dark. It reached a limiting value.

In the case of the anthracene crystals the limiting value was almost independent of the acceptor as demonstrated in Table 1. The steady state for the concentration of the excited molecule M* in the lowest singlet excited state in the surface molecular layer of the crystal might be expressed as follows

$$p - \{k_f + k_d + k_e[A]\}[M^*] = 0, \tag{2}$$

where k_f is the fluorescence life time of M*, k_d nonradiative decay constant of M*, k_e rate constant of the electron transfer reaction between M* and the acceptor molecule A, [A] the concentration of the acceptor molecule, and p is the rate of the production of the excited molecule M* at the surface, including those produced by direct excitation and by excitation migration. The rate of electron transfer reaction, $R=k_e\cdot[A][M^*]$, therefore, using Eq. (2) is expressed by

$$R = \frac{k_e p[A]}{k_f + k_d + k_e[A]} \quad (3)$$

If the concentration of the acceptor is sufficiently high, so that $k_e[A] \gg k_f + k_d$, R reaches to the limiting value as was experimentally observed. In these cases, the rate is limited by the rate of the production of the excited molecules, p. Equation (3) can also be expressed in the following form

$$\frac{[A]}{R} = c_1 + c_2[A], \quad (4)$$

where c_1, c_2 are constants. This type of concentration dependence of R,*i.e.* concentration dependence of the saturation photo-hole-current was reported previously in the case of the anthracene crystal/*p*-quinone system[1] and now proved to be generally the case as exemplified by the anthracene/*p*-chloranil system (Fig. 1). It was attributed tentatively to the formation of the adsorbed layer of the acceptor molecule. However, the present with the acceptor-independent limiting value of the saturation photo-current is preference of the excitation limited mechanism.

The electron transfer reaction from excited anthracene crystal to organic electron acceptors were shown to be a very efficient process.[1,2] In fact, the limiting values of the saturation photocurrent in the anthracene and naphthacene crystal were at least several times as large as the photocurrent due to the photo-induced hole injection from the aqueous electrode, whereas the quantum efficiencies for the hole injection were reported to be 0.033 (at 3650Å)[6] and 0.075 (at 5050Å)[7] respectively.

The relative photo-currents in the smaller concentration region are the direct measure of the rate constant, k_e, of the electron transfer reaction between the excited aromatic molecule at the surface and the quinones, if the reaction is assumed to occur *via* direct collision of the excited molecule and the electron acceptors. In this case the rate constant may be expressed in the conventional equation.

$$k_e = Z \exp(-\Delta F^{\ddagger}/RT) \quad (5)$$

where Z is the collision number and $\Delta F^{\ddagger}$ is the free energy of activation. On the other hand, the standard free energy of the reaction ΔF° is expressed as follows

$$\Delta F^{\circ} = I_c - E_a - E_x \quad (6)$$

where I_c is the ionization potential of the crystal, E_a is electron affinity of the quinone including the solvation energy, and E_x is the energy supplied by light. For the same crystal only E_a is changed in Eq. (6) from one acceptor to another. The collision number Z in Eq. (5) can be reasonably assumed to be the same for all the quinones used. In such circumstances, Figs. 3a and 3b represent the relation between the rate constant or the free energy of activation and the changes in the standard free energy of reaction. The observed increase in the rate constant with the increasing electron affinity of the acceptor is in accordance with trend of the efficiency of acceptors in quenching the fluolescence of aromatic hydrocarbons in solution *via* the electron transfer reaction.[8]

The larger the reaction rate constant, the limiting value was attained at the lower concentration of the acceptor, which is again consistent with Eq. (3).

The author wishes to express his gratitude to Professor Kenzi Tamaru for his constant encouragements through the work.

Ternary Lamellar Compounds of Graphite with Aluminum Bromide and Bromine

Tadashi SASA, Yoichi TAKAHASHI, and Takashi MUKAIBO

Department of Nuclear Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received December 7, 1971)

Graphite was allowed to react with binary reactants of aluminum bromide and bromine. The formation of ternary lamellar compounds was observed. A change in the activity of the reactants in the system gave three compounds I, II, and III with different contents of aluminum bromide and bromine. Compound I, obtained as the reaction product of graphite with the solution of bromine saturated with aluminum bromide, has a composition of $C_9AlBr_3 \cdot Br_2$, and a lamellar structure of the first stage with I_c of 10.24 Å. Compound II, which has the lowest bromine content, has a composition of $C_{24}AlBr_3 \cdot Br_{0.3}$ and a lamellar structure of the second stage with I_c of 13.35 Å. Compound III, obtained at a bromine activity higher than that for compound I, has a non-stoichiometric composition of about $C_{5-6}Br(AlBr_3)_{0.2}$, and a structure of the second stage with I_c from 13.58 to 13.72 Å. The phase diagram of the ternary system was derived. Compounds I and III have higher bromine contents than C_8Br, which is the saturation compound of graphite-bromine system. This is supposed to be due to the stabilization of bromine by the coexistence of aluminum bromide.

There are a large number of chemical substances which react with graphite to form lamellar compounds. In some cases, two different chemical species are intercalated together in the graphite crystal. They are called ternary lamellar compounds. Halogens and alkali metals form a type such as $C_8Br_xCl_{1-x}$[1] or

1) G. Furdin, B. Bach, and A. Herold, *C. R. Acad. Sci. Paris, Ser. C*, **271**, 683 (1970).

$C_8Cs_xRb_{1-x}$.[2] These compounds are considered to be a solid solution of two kinds of binary lamellar compounds. Most ternary lamellar compounds known, such as $C_nCl(AlCl_3)_3$,[3] are defined to be compounds containing three components. It is peculiar that the mole ratio of the two reactants takes a fixed value in the ternary lamellar compound of this type. In many cases, the reactant does not react with graphite by itself and requires another component for the lamellar reaction to occur. Hennig[3] studied the lamellar compounds of this type extensively, especially on the ternary system of graphite–metal chloride–chlorine.[3,4] Alkali or alkaline-earth metals[5] are also known to form this type of graphite compound with ammonia. Other graphite compounds of the ternary system containing alkali metals have recently come to be known.[6,7] However, most of them are studied under limited conditions and what the phases with respect to the compositions and structures in each ternary system are not known.

The authors[8] reported that aluminum bromide ($AlBr_3$) forms a ternary compound of graphite in the presence of bromine. In the present study, the compositions and structures of the ternary lamellar compounds of graphite–$AlBr_3$–Br_2 were investigated in detail under the conditions of various activities of bromine and aluminum bromide.

Experimental

Materials. The following two types of graphite were used.

(1) Natural graphite with pitch-binder, heat-treated at 3000°C, $c_0=6.708\pm0.002$ Å.

(2) Pyrolytic graphite deposited at 1700°C and heat-treated at 3000°C, $c_0=6.712\pm0.002$ Å.

GR-grade bromine was distilled and passed through concentrated sulfuric acid before use. Aluminum bromide was prepared by the reaction between aluminum chips of high purity and bromine vapor and the following distillation to remove excess free bromine and aluminum.

Formation of the Ternary Compounds and X-ray Structural Analysis. The ternary compounds of graphite–$AlBr_3$–Br_2 were prepared by the direct reaction of graphite and a liquid mixture of $AlBr_3$ and Br_2. Pyrolytic graphite, about 0.5 mm in thickness, was placed in an evacuated glass bulb, which was connected by a constriction to another bulb containing the mixture of the reactants. In some cases bromine was doped directly to the graphite sample into the form of a residue compound. The graphite sample was exposed to the reactant liquid at 120°C for 24 hr. The whole system was then cooled gradually for 24 hr to attain equilibrium at room temperature (25°C). The excess reactant condensed on the surface of the sample was removed carefully by evaporation during the course of cooling.

The changes in weight and macroscopic thickness of the sample were measured after the reaction. The sample was taken out of the glass tube in an atmosphere of dry argon and mounted on a sample holder for X-ray diffraction. The front surface of the sample was then covered with a Teflon sheet 0.05 mm thick to prevent decomposition in the air. X-ray diffraction measurements were carried out by means of a G. M. counter with a strip-chart recorder.

Chemical Analyses of the Compounds. The sample of the ternary compound prepared from natural graphite was heated in vacuum at 500°C for the decomposition. The released $AlBr_3$ and Br_2 were collected separately, and their amounts were determined by both weight measurements and chemical analyses. After decomposition, a few per cent of the reactants was found to remain persistently in the graphite sample. The residue compound was burnt at 1200°C in a stream of air for the determination of Al in the form of Al_2O_3, from which the amounts of $AlBr_3$ and Br_2 contained in the compound were estimated. The total content of each reactant was determined as the sum of the amounts of released and residual reactants. The original weight of the graphite sample was used as the amount of carbon in the ternary compound.

The samples prepared from pyrolytic graphite were found to be inadequate for chemical analyses, as their decomposition was much more difficult than that of the samples prepared from natural graphite. It was confirmed that the samples prepared from the two different types of graphite had nearly the same contents of reactants under the same conditions of reaction.

Results

(1) Formation of Ternary Compounds. The change of composition of the ternary compound with the increase of activity of bromine with activity of $AlBr_3$ fixed at unity is shown in Fig. 1. As the solubility of $AlBr_3$ in Br_2 liquid is known to be about 40 mol% at 25°C,[9] the activity of $AlBr_3$ remains at unity until Br_2 content exceeds 60 mol% in the binary reactant.

We investigated the relation between the content of $AlBr_3$ and that of Br in the ternary compound over relatively low range in bromine content, where the

ratio of $AlBr_3$ to Br was found to be nearly three up to the bromine content of Br/C=0.14[8] (Fig. 1). Beyond this bromine content, the ratio of $AlBr_3$ to Br decreased so that a distinct break of the curve was observed. This break point (II, Fig. 1) corresponds to an approximate atomic composition of $C_{24}AlBr_3 \cdot Br_{0.3}$. Beyond point II, the composition changes along a line extending to point I. The compound corresponding to I was obtained when the sample was kept in equilibrium with the solution of bromine saturated with $AlBr_3$ at room temperature. The contents of the reactants in compound I were determined by chemical analysis to be $AlBr_3$/C=0.11±0.02 and Br/C=0.22± 0.02 in mole ratio, which lead to an approximate composition of $C_9AlBr_3 \cdot Br_2$.

(2) Compounds I and II. It is remarkable that compound I ($C_9AlBr_3 \cdot Br_2$) had a bromine content far higher than C_8Br, which is the saturation compound of the binary system of graphite–bromine. The formation of compound I was accompanied by a considerable dimensional change and a distinct color change of the graphite. The samples prepared from the pyrolytic graphite gave a thickness about three times as large as the original samples and a dark green color with metallic luster. Compound I was hygroscopic and unstable in the air, and easily released bromine vapor. It decomposed to compound II in a vacuum at room temperature.

Compound II had the same black color as that of the original pyrolytic graphite, and its macroscopic thickness was about twice as large as that of the original one. Although compound II was comparatively stable, a gradual decomposition was observed in moist air.

The results of X-ray study of compounds I and II prepared from pyrolytic graphite sample are shown in Tables 1 and 2. The lattice constant I_c indicates the distance from one reactant layer to the next along the direction of *c*-axis, neglecting the AB stacking of carbon layers or reactant layers. The results shown in Table 1, together with the observations of the macroscopic dimensional change of the sample along the direction of *c*-axis, lead to the conclusion that compound I has a structure of the first stage, where every layer spacing of graphite is intercalated by reactants and expands from 3.35 Å to 10.24 Å. It is concluded also, from the results shown in Table 2, that compound II has a structure of the second stage with an expansion of every other carbon layer spacing from 3.35 Å to 10.00 Å.

The X-ray study on the sample with an intermediate composition between the compounds I and II showed the coexistence of these two phases, no other intermediate phase being observed. The X-ray diffraction pattern of the sample with the reactant contents below that of compound II showed a mixture of patterns of original graphite and compound II.

(3) Intermediate Phase between Compound I and C_8Br. The reaction of graphite with the binary solution of $AlBr_3$ and Br_2 was carried out, in which the activity of $AlBr_3$ was changed from zero to unity. The change of the composition of the compound with the change of activity of $AlBr_3$ is shown in Fig. 2. The diversity of the results of chemical analyses might be attributed to the possible errors caused by the condensation of excess reactants or decomposition of the compounds during the course of removing excess reactants. The curve in Fig. 2, which extends from C_8Br to compound

I, shows a bend in its midst (III in Fig. 2). X-ray diffraction confirmed the existence of the third new phase around point III. The results of structural analysis of compound III (Table 3) and the macroscopic dimensional change of the sample lead to the conclusion that compound III has a structure of the second stage similar to compound II. Its composition was observed to change from $C_{6.2}Br(AlBr_3)_{0.2}$ to $C_{5.1}Br(AlBr_3)_{0.2}$, and its lattice constant I_c varied also from 13.72 to 13.58 Å. It is considered that compound III is non-stoichiometric. It was black like the original graphite or compound II, not being so stable in the air. Decomposition of compound III was observed in a vacuum to produce compound II finally. No new phase other than compound III was found in the composition range from C_8Br to compound I.

The composition, stage and spacing of carbon layers which contain a reactant layer between them are summarized in Table 4 for each compound together with the data for C_8Br.

Table 4. Ternary lamellar compounds of graphite with aluminum bromide and bromine

III	$C_{5-6}Br(AlBr_3)_{0.2}$	2	10.22 ~ 10.37
C-Br	C_8Br	2	7.03

Discussion

(1) Ternary System, Graphite–$AlBr_3$–Br_2. The phase diagram of the present ternary system at 25°C is derived from Figs. 1 and 2, and illustrated in Fig. 3. The region surrounded by the dashed curve represents the extent of the composition of the graphite lamellar compounds. Points I, II, and III in Fig. 3 correspond to compounds I, II, and III. The non-stoichiometric compound III is not represented by a single point, but has a certain range of composition. Along line O–A, the existence of several graphite bromine lamellar compounds having the structures of 5th stage to 2nd stage are known.[10] On line O–II, no phase other than compound II and original graphite was observed. Along line I–II, the coexistence of I and II with a varying ratio was observed. The situations are similar on lines I—III and A-III.

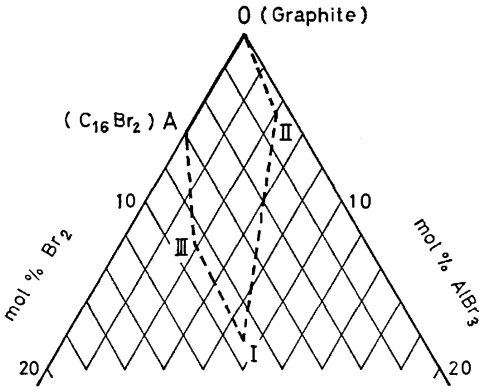

Fig. 3. Phase diagram of the ternary system of graphite $AlBr_3$–Br_2 (25°C).

(2) Formation and Stability of the Ternary Compounds. It is well-known[3,11] that aluminum chloride ($AlCl_3$) and chlorine form ternary lamellar compounds with graphite. Hennig[3] interpreted the role of the third component chlorine as follows. In the system, graphite–$AlCl_3$, $AlCl_3$ can not raise the charge-transfer with the carbon layers by itself, which is necessary for the formation of lamellar compounds with graphite. When chlorine is added to the system, it forms an ionic bonding with the carbon layers and stabilizes the neutral $AlCl_3$ molecules in the interstices of the carbon layers. The ratio of $AlCl_3$ to Cl in the compound was found to remain nearly three up to the saturation compound of the first stage.

The ternary compound in the present study, graphite–$AlBr_3$–Br_2, is very similar system to that of graphite–$AlCl_3$–Cl_2. $AlBr_3$ does not react with graphite by itself and requires bromine for the occurrence of lamellar reaction. The mole ratio of $AlBr_3$ to Br was also found to be nearly three up to the compound of the second stage (compound II). The situation is, however, different for the compound of the first stage. The atomic composition of the lamellar compound with $AlCl_3$–Cl_2 was reported to be approximately $C_9AlCl_3 \cdot Cl_{0.3}$,[3] whereas that with $AlBr_3$–Br_2 is $C_9AlBr_3 \cdot Br_2$. The ratio of $AlBr_3$ to Br does not remain three for the first stage, decreasing to nearly 1/2, which means that the mole ratio of $AlBr_3$ to Br_2 is unity. The difference in composition of both

compounds of the first stage may be attributed to the fact that chlorine is scarcely absorbed by graphite at room temperature by itself,[12] while bromine is easily absorbed in the same condition.

The bromine content of the first stage compound of graphite–$AlBr_3$–Br_2 is far higher than that of C_8Br. Figure 2 shows that the bromine content of the ternary compound increases with the increase of $AlBr_3$ content from the value corresponding to C_8Br to that of compound I *via* compound III. It is obvious that the coexistence of $AlBr_3$ molecules stabilizes the bromine molecules in the graphite crystal, in the same way as bromide stabilizes $AlBr_3$. $AlBr_3$ and Br_2 are considered to be complementary with each other in the lamellar reaction with graphite. It is also remarkable that although the activity of bromine in the system decreases when the composition changes from C_8Br to compound I, the bromine content in the lamellar compound increases due to the stabilizing effect of $AlBr_3$ on Br_2 molecules. It should be noted that in the case of the ternary compound, graphite–bromine–chlorine $C_8Br_xCl_{1-x}$,[1] the bromine content of the compound is known to decrease as the activity of bromine in the system decreases.

In the system, graphite–$AlCl_3$–Cl_2, the stabilization of chlorine by $AlCl_3$ is also observed. Although chlorine is hardly intercalated in graphite above room temperature, a considerable amount of chlorine is found to be intercalated in graphite in the presence of $AlCl_3$. The energy of stabilization by the coexistence of aluminum halide in both cases may be attributed to a kind of solvation energy between halogen molecules and aluminum halide molecules.

(3) Arrangements of Reactant Molecules in an Interstice of Graphite Layers. Table 4 shows that the carbon layer spacings containing reactant molecules have similar values in the three compounds in spite of different molecular compositions. It is considered that the skeleton of $AlBr_3$ determines the layer spacing in all the three cases, because Br_2 molecules are too small to maintain such a large layer spacing as 10 Å.

The arrangements of reactant molecules in an interstice of graphite layers are investigated in several graphite lamellar compounds,[13–15] and found to be analogous to that of pure reactant solid. The structural analysis was carried out on the assumption that the skeleton of $AlBr_3$ in an interstice of graphite layers is analogous to that of pure solid of $AlBr_3$. It is known that in the crystal of $AlBr_3$,[16] Br atoms form trigonal layer planes and Al atoms are distributed in the interstices of Br layers. The experimental value of the spacing of carbon layers of compound I, 10.24 Å, was found to coincide with the calculated value, if it is assumed that two Br layers of $AlBr_3$ are included in an interstice. The structure factors calculated based on the assumed stacking sequence of the reactant molecules gave qualitative agreement with the experimental values (Table 1). The quantitative agreements, however, were not satisfactory.

The composition of $C_9AlBr_3 \cdot Br_2$ and the interlayer spacing of 10.24 Å give a density of 4.4 g/cc for the reactants in the interstices of graphite layers. This is much higher than the density of solid $AlBr_3$, 3.01, or liquid Br_2, 3.10. The arrangements of the molecules in an interstice of graphite layers should be deformed considerably from those in pure reactant solids to give dense packings corresponding to 4.4 g/cc.

Conclusion

Aluminum bromide and bromine were found to form ternary lamellar compounds with graphite. Three phases of the ternary system were found to exist with the changes of activity of $AlBr_3$ and Br_2 in the system at 25°C. The first phase (compound I), which has the highest reactant contents among the three, has the approximate composition $C_9AlBr_3 \cdot Br_2$, and a lamellar structure of the first stage where every interstice of graphite layers is intercalated with reactants and expands from 3.35 Å to 10.24 Å. The second phase (compound II) formed at a lower activity of bromine than that for compound I, has the composition of $C_{24}AlBr_3 \cdot Br_{0.3}$, and the structure of second stage with I_c of 13.35 Å. The third phase (compound III) formed at the activity of bromine between compound I and C_8Br, has a non-stoichiometric composition of $C_{5-6}Br(AlBr_3)_{0.2}$, and a structure of the second stage similar to compound II. The bromine content of the ternary compounds was found to increase with the increase of $AlBr_3$ content from C_8Br to compound I through compound III. It is concluded that $AlBr_3$ and Br_2 stabilize with each other complementarily in graphite crystal.

The authors are grateful to Mr. M. Iwakura for his collaboration in the experimental work.

Dimerization of Ethylene Catalyzed by σ-Aryl Nickel Compound in the Presence of Trifluoro Boron Etherate

Ken-ichi MARUYA, Tsutomu MIZOROKI, and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo

(Received January 13, 1972)

It was found that σ-aryl nickel(II) complex catalyzes the dimerization of ethylene rapidly and selectively when trifluoro boron etherate is added. The rate of dimerization increases in order Br≪mesityl<naphthyl<*o*-tolyl. The aryl ligands remain in the nickel complexes during the course of dimerization, since vinyl naphthalene, butenyl-naphthalene, *etc.*, which are expected to be the reaction products of ethylene with the σ-aryl lingands, were not detected. The isotopic exchange between ethylene and deuteroethylene and the dimerization of deuteroethylene were studied to confirm the active species of this catalyst system. The isotopic exchange is faster than both the dimerization and isomerization of 1-butene formed. No increase in the atomic fraction of hydrogen of deuteroethylene was observed after treatment with the catalyst system. Thus it is concluded that the nickel hydride formed by the dissociative addition of ethylene is the active species of the catalyst system. The role of trifluoroboron etherate was also elucidated by a comparison of its effect on the rate of ethylene dimerization with that of sodium tetraphenyl borate.

Much interest has been shown in the use of transition metal catalysts for the dimerization of monoolefins and has extended recently to homogeneous catalysis. Of the catalysts, complex nickel catalysts are considered to greatest interest.

In solid catalyst systems such as $NiO–SiO_2$ and $NiCl_2$ for ethylene dimerization, the active species was proposed by one of the authors to consist of an exposed nickel ion possibly of low valence and an acid site of the catalyst; the former catalyzes the isotopic exchange of $C_2H_4–C_2D_4$, but has no activity for the dimerization in the absence of the acid site. In homogeneous catalysis, a wide range of nickel compounds are known to show excellent catalytic activity for olefin dimerization in an organic solvent, when they coexist with certain Lewis acids such as aluminium alkyl halide.[3-6] This indicates that the coexistence of the Lewis acid with the nickel compound is essential for olefin dimerization in heterogeneous as well as homogeneous catalysis. Several mechanisms for olefin dimerization have been proposed, but the real configuration of active species is still obscure.

In a previous paper it was reported that bis(triphenylphosphine)nickel(II) dihalide in organic solvent catalyzes the isotopic exchange of $C_2H_4–C_2D_4$ in the presence of molecular hydrogen, and that a nickel hydride formed by the heterolytic splitting of molecular hydrogen is responsible for the exchange.[7] However, no dimerization of ethylene was observed. From the characteristics of the catalyst for dimerization the nickel compound is expected to have catalytic activity for ethylene dimerization, in the presence of some Lewis acid. This was realized by using trifluoroboron etherate as the Lewis acid. Dimerization into butenes was observed. The catalytic activity, however, was considerably smaller than that of the catalyst system composed of nickel(II) halide compound and alkyl aluminium halide. In the coexistence of nickel(II) halide with alkyl aluminium halide, it has been proposed that a σ-alkyl nickel complex is formed by the substitution of a halide coordinated to nickel with an alkyl ligand of alkyl aluminium halide, and the σ-alkyl nickel complex thus formed promotes the dimerization of olefin not isolated probably because of its unstability.[4,5] This suggests the use of the well-known stable σ-aryl nickel(II) halide in place of bis(triphenylphosphine)nickel(II) dihalide as a component of the catalyst, leading to the result that both the activity and selectivity are effectively enhanced for ethylene dimerization.[8] This work was undertaken to investigate the active species of the catalyst system composed of bis(triphenylphosphine)σ-arylnickel(II) bromide and trifluoroboron etherate by examining the effect of the amounts of trifluoroboron etherate and σ-aryl ligand of the nickel compound on the catalytic activity for ethylene dimerization and also by using deuteroethylene.

Experimental

Materials. Bis(triphenylphosphine)nickel(II) dibromide (Found: C, 58.2%; H, 4.0%, Calcd C, 58.2%; H, 4.1%) was prepared according to the method of Venanzi.[9] Bis(triphenylphosphine)1-naphthylnickel(II) bromide (Found: C, 69.9%; H, 4.5%. Calcd: C, 69.9%; H, 4.7%), bis(triphenylphosphine)*o*-tolylnickel(II) bromide (Found: C, 67.9%; H, 4.6%. Calcd: C, 68.5%; H, 4.9%) and bis(triphenylphosphine)mesityl nickel(II) bromide (Found: C, 69.1%; H, 4.7%. Calcd: C, 69.1%; H, 5.3%) were prepared by almost the same method as that of Chatt and Shaw.[10] Organic solvents were dried with sodium, magnesium, or molecular sieve before they were distilled under dry nitrogen. Trifluoroboron etherate

obtained from commercial sources was also distilled under dry nitrogen and its benzene solution (10 vol %) was prepared. Moisture in ethylene was trapped by dry ice methanol. Deuteroethylene (C_2D_4 93.3%, C_2D_3H 6.7%) obtained from partial deuteration of deuteroacetylene was purified by means of a gas chromatographic column of silica gel. Deuteroacethylene was obtained from the reaction of heavy water with calcium carbied preevacuated at 800°C for 3 hr.

Procedure, All the experiments were carried out under nitrogen atmosphere. One of nickel compounds placed in a flask (50 or 100 ml) was dried in a vacuum at 50°C before organic solvents were added in order to dissolve the compound completely. The benzene solution of trifluoro boron etherate was then poured into the flask with stirring. Before ethylene was introduced into the flask at the reaction temperature, the nitrogen gas in the flask was evacuated with the solution cooled to liquid nitrogen temperature. The rate of ethylene absorption was measured with a mercury manometor or a gas burette. After the dimerization had been carried out for a given period of time with vigorous stirring, it was stopped by cooling the flask with liquid nitrogen. All volatile materials (butenes, ethylene, and solvent) were transferred to another flask by means of liquid nitrogen and the amounts of olefins were quantitatively determined by gas chromatography. Non-volatile materials were extracted with *n*-hexane, when necessary.

Isotopic exchange of C_2H_4–C_2D_4 and dimerization of C_2D_4 were also carried out according to the same procedure as described above, where a part of the butenes formed and the residual ethylene were separated from the solvent by gas chromatographic column and subjected to mass spectrometry with an ionization potential of 12 eV.

Results

Dimerization Catalyzed by Bis(triphenylphosphine)-Nickel(II) Dibromide and Trifluoroboron Etherate. When isotopic exchange of C_2H_4–C_2D_4 was catalyzed by bis(triphenylphosphine)nickel(II) dibromide in benzene solution in the presence of molecular hydrogen, no dimerization was observed.[7] In the presence of trifluoroboron etherate, however, a small amount of ethylene was dimerized into butenes even in the absence of hydrogen as shown in Table 1 (Run 1). The effect of the amount of trifluoroboron etherate on the rate of ethylene absorption was examined. The result is plotted against the mole ratio of trifluoroboron etherate to nickel compound ($BF_3 \cdot OEt_2/Ni(P\phi_3)_2Br_2$) in Fig. 1, where the rate was determined by the decrease in ethylene pressure during initial 10 min. It shows that the rate increases with the added amount of trifluoroboron etherate.

Dimerization Catalyzed by Bis(triphenylphosphine)σ-Arylnickel(II) Bromide–Trifluoroboron Etherate. Bis(triphenylphosphine)σ-arylnickel(II) bromide was used in place of the corresponding nickel(II) dibromide. Ethylene dimerization with this catalyst system selectively took place without any induction period at room temperature under atmospheric pressure. The result is also given in Fig. 1. It is seen that the rate of ethylene absorption is considerably faster than that by bis(triphenylphosphine)nickel(II) dibromide catalyst and that the rate increases in the order Br≪mesityl<1-naphthyl<*o*-tolyl. The products of these runs are shown in Table 1 (Run 2, 3, and 4). More than 97% of the consumed ethylene is converted into butenes accompanied only by a small

amount of hexene. Propylene seems to be less reactive than ethylene. When an equimolar amount of triphenylphosphine was added to the solution of bis(triphenylphosphine)-1-naphthylnickel(II) bromide ($BF_3 \cdot OEt_2$/1-$C_{10}H_7Ni(P\phi_3)_2Br$=1), the rate of ethylene absorption under the same reaction conditions as shown in Fig. 1 decreased to about one-seventh of that in the absence of triphenylphosphine. Acrylonitrile as well as butadiene strongly inhibited the ethylene dimerization, while a trace amount of hexadiene was detected on addition of butadiene.

Whether the olefin reacts with the aryl ligand of the nickel complex or not was examined by using a large amount of σ-arylnickel(II) compound. It can be expected that the reaction of olefin with the aryl ligands results in the formation of vinylnaphthalene, vinyltoluene, butenylnaphthalene *etc.* However, none of them was detected by gas chromatography and only a small amount of decomposed products of the complex such as naphthalene, 1,1'-dinaphthyl and triphenylphosphine were detected in the solution after dimerization, as is shown in Table 1 (Run 5, 6, 7, and 8). This means that the aryl ligand remains in the nickel complex during the course of dimerization.

Effect of Trifluoroboron Etherate. When bis(triphenylphosphine)nickel(II) dibromide was used as a catalyst, no activity for ethylene dimerization was observed in the absence of trifluoroboron etherate. However, it was found with bis(triphenylphosphine)σ-arylnickel(II) bromide that it slowly catalyzes ethylene dimerization even in the absence of trifluoroboron etherate. The rate of ethylene absorption was, for example, 1.8×10^{-2} (m*l* min^{-1}mmol-cat^{-1}) at 0°C under atmospheric pressure, when a methylene chloride solution (30 m*l*) of bis(triphenylphosphine)1-naphthylnickel(II) bromide (1 mmol) was used as a catalyst. Under the same conditions, the rate was surprisingly accelerated up to 44.9 [m*l* min^{-1}mmol-cat^{-1}] by the addition of trifluoroboron etherate (1 mmol), *viz*, the rate is increased to 2.6×10^3 times as much with one mole of trifluoroboron etherate and increases linearly with the mole ratio of trifluoroboron etherate to σ-arylnickel(II) complex as shown in Fig. 1.

We examined sodium tetraphenyl borate in place of trifluoroboron etherate to get information on the interaction between σ-arylnickel(II) compound and trifluoroboron etherate. Sodium tetraphenyl borate is known to take off anionic ligand from dihalide complexes of platinum(II) and nickel(II) giving cationic complexes as follows. $2M(P\phi_3)_2X_2+2NaB\phi_4 \rightarrow [M_2(P\phi_3)_4X_2][B\phi_4]_2+2NaX$ (M=Pd(II), Pt(II), Ni(II); X=Cl, Br).[11,13] Dried bis(triphenylphosphine)-1-naphthyl nickel(II) bromide (1 mmol) and sodium tetraphenyl borate (2 mmol) were dissolved in methylene chloride (50 m*l*) and the solution was kept at 0°C for 10 hr with stirring. It was filtered to separate the sodium bromide formed and the residual sodium tetraphenyl borate. Ethylene (40 cmHg) was introduced into the filtrate at 0°C and kept at the temperature for 2 hr with vigorous stirring. No dimerization was observed. The solution no longer showed any activity for dimerization in the presence of trifluoroboron etherate.

Isotopic Exchange of C_2H_4–C_2D_4 and Dimerization of C_2D_4. We examined the isotopic exchange of C_2H_4–C_2D_4 to investigate the active species of the catalyst system of σ-arylnickel compound-trifluoroboron etherate. The isotopic distribution (mol fraction) in the residual ethylene is given in Table 2.

Table 2. Isotopic exchange[a] of C_2H_4-C_2D_4

a) CH_2Cl_2 10 m*l*, Temp. 0°C.
b) 1-$C_{10}H_7NiBr(P\phi_3)_2$.
c) C_2H_4/C_2D_4=1.0 (isotopic distribution of reactant ethylene, d_0=50, $d_1=d_2$=0, d_3=4.0, d_4=46.0).
d) Isomer distribution; 1-C_4', 55.8%; *trans*-2-C_4', 29.9%; *cis*-2-C_4', 14.3%

In Run 2, 46.5% of the ethylene used is dimerized into butenes, where the isomer distribution is far from its equilibrium, whereas the isotopic distribution is in good agreement with the equilibrium distribution (d_0=6.7, d_1=25.9, d_2=37.5, d_3=24.0, d_4=5.9) in the residual ethylene as well as in the butenes formed. In Run 1 where the catalyst concentration was extremely small and Run 3 where no trifluoroboron etherate was added, only isotopic exchange and no butene was detected. This shows that the isotopic exchange between C_2H_4 and C_2D_4 is sufficiently faster than ethylene dimerization or butene isomerization and that one hydrogen atom undergoes exchange in one act. Thus there should be an active hydrogen atom which catalyzes the exchange reaction.

The source of active hydrogen was examined by means of dimerization using C_2D_4 (atomic fraction of hydrogen (f_H)=0.020). If the active hydrogen is supplied from the substances contained in the catalyst system except for ethylene, hydrogen would be taken up into butene and ethylene, leading to the result that f_H becomes higher than that of the starting ethylene. f_H's of olefins obtained under the various reaction conditions are shown in Table 3, where the amount of C_2D_4 used is approximately fixed. No appreciable increase of f_H is observed, independent of reaction time, the amount of catalyst and that of solvent. This means that no hydrogen is supplied from the solvent, diethylether, triphenylphosphine, or 1-naphthyl ligand present in the catalyst system.

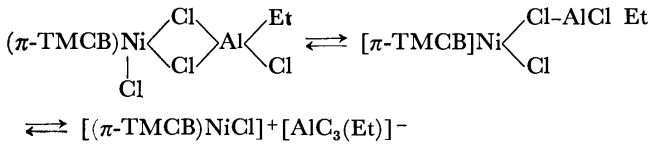
Discussion

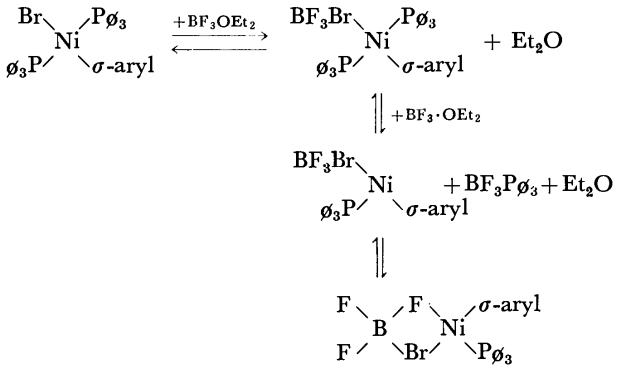
Effect of Trifluoroboron Etherate. It is known that boron trifluoride reacts with $PdCl_2(PR_3)_2$ or $PtCl_2(PR_3)_2$ (R=alkyl, aryl) in organic solvent to give an ionized species such as $[Pd_2Cl_2(P\phi_3)_4]2BF_4$[11-13)] or $[(Pt_2Cl_2(P\phi_3)_4]2BF_4$,[11-14)] respectively. The corresponding ionized species will be formed from nickel compounds and boron trifluoride. In the case of Ni(π-TMCB)Cl_2-$AlEtCl_2$ (TMCB=tetramethylcyclobutadiene) catalyst, for example, the following equilibrium is usually assumed during the course of olefin dimerization.[5)]



$\rightleftharpoons$ $[(\pi\text{-TMCB})NiCl]^+[AlC_3(Et)]^-$

Similar ionized intermediates have also been suggested for the other nickel halides-ethyl aluminium compounds systems.[3,6)] An ionized species, $[Ni(\sigma\text{-aryl})(P\phi_3)_2]^+$ might be formed in the present catalyst system. Thus $Ni(\sigma\text{-aryl})(P\phi_3)_2Br$ was treated with $NaB\phi_4$ for preparation of the species. However, no activity for ethylene dimerization was found even in the presence of trifluoroboron etherate. This indicates that such ionized species which has no halogen ligand is inactive for ethylene dimerization. It might be concluded that the active species should have at least one halogen ligand through which boron trifluoride can interact with nickel atom.

Boron trifluoride has so far been regarded as an acceptor for halide ion. However, it is more probable that it acts as an acceptor for phosphine ligand. It is known that a tertiary phosphine can coordinate to a Lewis acid to give salts such as $AlCl_3 \cdot P(Et)_3$ and $AlEtCl_2 \cdot P(Et)_3$[5)] and that the coordinated tertiary phosphine, such as triethylphosphine of $PdI_2 \cdot (PEt_3)_2$, can also be removed by a strong Lewis acid, boron trifluoride,[10)] as follows. $2[PdI_2(PEt_3)_2]+2BF_3 \rightarrow [Pd_2I_4(PEt_3)_2]+2BF_3 \cdot PEt_3$. Thus the addition of triphenylphosphine to the catalyst solution reduces the rate of dimerization, and the activity increases linearly with the mole ratio of $BF_3 \cdot OEt_2$ to σ-arylnickel compound as shown in Fig. 1. This suggests that the presence of trifluoroboron etherate is favorable for the dissociation of triphenylphosphine from bis(triphenylphosphine)σ-arylnickel(II) halide to give free coordination site on nickel available for the coordination of ethylene molecule. The role of trifluoroboron etherate can be summarized by the following scheme (Scheme 1).



Scheme 1.

Reaction Scheme. The dimerization of lower olefin by the catalyst composed of nickel(II) complex and alkylaluminum has been explained in terms of a nickel-hydride-complex formed by catalyst components.[4,5)] No alkyl aluminum compound, however, is involved in the present catalyst system. There are two points to be clarified; (a) whether a nickel hydride acts as an intermediate, and (b) what substance supplies hydrogen to nickel. The result of isotopic exchange of C_2H_4–C_2D_4 as shown in Table 2 indicates that a nickel hydride has to be taken into account as an intermediate in the course of ethylene dimerization. Neither cyclobutane intermediate accepted in olefin metathesis,[15)] nor carbonium ion observed in acid catalysis[7)] offers satisfactory explanation for one hydrogen atom being exchanged in one act of the exchange and its rate being exceedingly faster than the isomerization of butenes formed.

The equilibrium values of f_Hs of total olefins in the dimerization of C_2D_4 are calculated by assuming that hydrogen is supplied to nickel from one of the substances involved in the reaction mixture, *i.e.* methylene chloride, triphenylphosphine, diethylether, and 1-naphthyl. They are given in Table 4. It is shown that the f_H value should increase, at lowest to 0.07, if isotopic scrambling is accomplished between these substances. However, since f_H remains at the starting value 0.02 within experimental error as shown in Table 3, it is clear that hydrogen is supplied to nickel from ethylene molecule.

Two processes can be expected for the formation of nickel hydride from ethylene molecule, one is an inser-

Table 4. Calculated values[a] of f_Hs in olefin assuming the occurence of isotopic scrambling of C_2D_4

Substances supplying hydrogen	f_H
Solvent (CH_2Cl_2)	1
$P\phi_3$	0.40[b]
$(C_2H_5)_2O$	0.19[c]
1-naphthyl	0.07[d]
C_2D_4	0.02[e]

a) Calculated values, when (1-naphthyl)NiBr($P\phi_3$)$_2$ (0.20 mmol), $BF_3 \cdot OEt_2$ (0.8 mmol) and C_2D_4 (1 mmol) are used CH_2Cl_2 solvent.
b) With orthohydrogen atom of phenyl in $P\phi_3$ ligand.
c) With one hydrogen atom per one diethylether molecule.
d) With one hydrogen atom per one naphthyl ligand.
e) f_H of the C_2D_4 used.

tion process in which ethylene is inserted between nickel-carbon bond of 1-naphthyl nickel complex to give Ni–CH_2–CH_2–$C_{10}H_7$, followed by elimination of β-hydrogen to give Ni–H and 1-vinyl naphthalene. However, this seems to be unlikely, because neither vinylnaphthalene nor butenylnaphthalene was detected, and σ-aryl ligand was proved to remain in the nickel complex after ethylene dimerization. The other process is a dissociative addition of ethylene to give H–Ni–CH=CH_2. A similar addition was proposed by one of the authors (A.O.) for the mechanism of ethylene dimerization catalyzed by NiO–SiO_2 catalyst,[1] or by bis(benzonitrile) palladium(II) dichloride.[16]

The following course of reaction would account for the rapid hydrogen exchange of ethylene and its dimerization. The dissociative addition of ethylene takes place on the nickel complex shown in scheme 1, and another ethylene then attacks the nickel hydride to form a σ-ethyl-nickel complex reversibly, which is responsible for the rapid hydrogen exchange. 1-Butene may be formed from σ-ethyl-nickel complex by two processes. One is the coupling of ethyl and vinyl attached to the complex. The other is the insertion of another ethylene molecule into ethyl-nickel bond to form primary butyl-nickel complex followed by elimination of β-hydrogen to give 1-butene and nickel hydride. In the former, nickel hydride must be renewed or the next dimerization, while in the latter the hydride is always reproduced the vinyl being kept behind. Discrimination between these two processes is difficult at present.

The variation in activity among σ-aryl nickel compounds supports the view that the σ-aryl ligand is effectively involved in the catalytic species. A combination of steric and inductive factors seems to be responsible for the activity and selectivity for the dimerization. The exact function of the σ-aryl ligands, however, is obscure.

Magnetic Susceptibilities and Broad-Line PMR Spectra of Dichloro(pyridazine)copper(II) and Related Compounds

Shuji EMORI, Motomichi INOUE, and Masaji KUBO

Department of Chemistry, Nagoya University, Chikusa, Nagoya

(Received February 14, 1972)

The magnetic susceptibilities of CuX_2L (X: halide ion, L: 1,2,4-triazole, pyridazine, phthalazine, 4-amino-1,2,4-triazole) conform to the linear Ising model or Heisenberg model, indicating the presence of linear magnetic chains in the crystals. Fermi contact shift observed in the broad-line PMR spectrum indicates the diffusion of a positive hole from a copper atom to the molecule of heterocycles. The magnitude of the exchange integrals is related to the spin densities on the atoms of the heterocycles.

In the crystals of dichloro(1,2,4-triazole)copper(II), $CuCl_2$(tr), each copper atoms has a distorted octahedral coordination of four chlorine atoms and two nitrogen atoms.[1] The octahedra are joined with one another by sharing chlorine edges and are also linked by 1,2,4-triazole molecules, constituting an infinite linear chain as the structural unit. The magnetic susceptibility of the compound conforms to the linear Ising model.[2] From contact shifts in PMR spectrum, spin densities on atoms in 1,2,4-triazole have been evaluated.[3] From these, it was concluded that superexchange interaction operates between copper atoms through the heterocycle. From the same steric reason as for 1,2,4-triazole in $CuCl_2$(tr), a bidentate heterocyclic ligand having two neighboring nitrogen atoms (for example, pyridazine and phthalazine) is expected to coordinate to two copper atoms.[4] Therefore, in the crystals of CuX_2L type complexes (X: halide ion, L: bidentate nitrogen heterocycle), the magnetic unit is presumed to be an infinite linear chain, –Cu–L–Cu—, analogous to that in $CuCl_2$(tr). In this linear chain, superexchange

interaction can operate between copper atoms through the molecules of the heterocycles, its magnitude depending on the electronic state of bridging ligands.[5] Therefore, we have measured the magnetic susceptibilities of this type of complexes in order to estimate exchange integrals and also recorded broad-line PMR spectra to evaluate the spin densities on atoms in the heterocycles.

Experimental

$CuCl_2L$ was prepared by modifying the method of Hyde *et al.*[4] A solution of an appropriate nitrogen heterocycle in 1 N hydrochloric acid was added in slight excess to a solution of copper(II) chloride in 3 N hydrochloric acid. On standing, green powder crystals separated. They were recrystallized from 3 N hydrochloric acid. $CuBr_2L$ was prepared in the same manner as for $CuCl_2L$ using hydrobromic acid in place of hydrochloric acid. The results of chemical analysis are listed in Table 1.

pid: pyridazine, pht: phthalazine, tr: 1,2,4-triazole, atr: 4-amino-1,2,4-triazole.

Magnetic susceptibility was determined by means of magnetic balances described in our previous paper.[2] The molar susceptibilities were corrected for diamagnetic contributions (in 10^{-6} emu/mol) from copper ions (-11),[6] chloride ions (-26),[6] bromide ions (-36),[6] 1,2,4-triazole (-38),[7] pyridazine (-38), phthalazine (-75), and 4-amino-1,2,4-triazole (-46). The value for pyridazine was assumed to be equal to that of pyrazine.[7] The values for phthalazine and 4-amino-1,2,4-triazole were evaluated on the basis of those for pyridazine and 1,2,4-triazole, respectively, by use of the Pascal constants. The temperature-independent paramagnetism was assumed to be equal to 60×10^{-6} emu/mol.[8]

The PMR spectra of the powder crystals were recorded at 25°C by means of a Model JNS-B broad-line NMR spectrometer from JEOLCO operating at 29.7 MHz with an amplitude of magnetic field modulation equal to 1.0 Oe. Water was employed as an external standard.

Results

The susceptibilities corrected for diamagnetic contributions and the temperature-independent paramagnetism obey the Curie-Weiss law at high temperatures as shown in Fig. 1. The Weiss constants and g-values evaluated from the Curie constants are listed in Table 2. The susceptibilities in the low-temperature region are plotted against the temper-

ature in Figs. 2—6.

The observed PMR absorption derivative curves are shown in Figs. 7—10. Dibromo(1,2,4-triazole)-copper(II), $CuBr_2$(tr), dichloro(pyridazine)copper-(II), $CuCl_2$(pid), dibromo(pyridazine)copper(II), $CuBr_2$(pid), and dibromo(phthalazine)copper(II), $CuBr_2$(pht), show asymmetric curves, each of which can be decomposed into two simple derivative curves, one shifted to the low-field side and the other shifted to the high-field side. The shifts, $\Delta H/H$, are listed in Table 3. The curve of dichloro(phthalazine)copper-(II), $CuCl_2$(pht), is made up of a broad component

having a low-field shift, another broad component having a high-field shift, and a sharp component. The integrated intensity of the sharp component amounted to less than 0.1% of the total intensity and fluctuated among different preparations. Therefore,

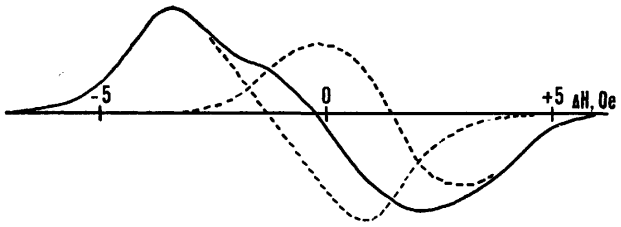

Fig. 7. PMR absorption derivative curve (full curve) of $CuBr_2$(tr) decomposed into two simple derivative curves (broken curves).

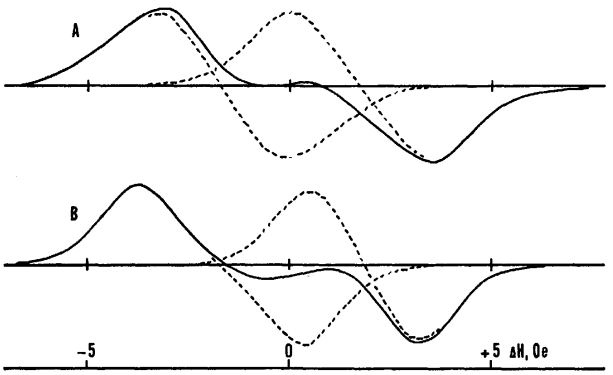

Fig. 8. PMR absorption derivative curves of $CuCl_2$(pid) (A) and $CuBr_2$(pid) (B). Each curve (full curve) is decomposed into two simple derivative curves (broken curves).

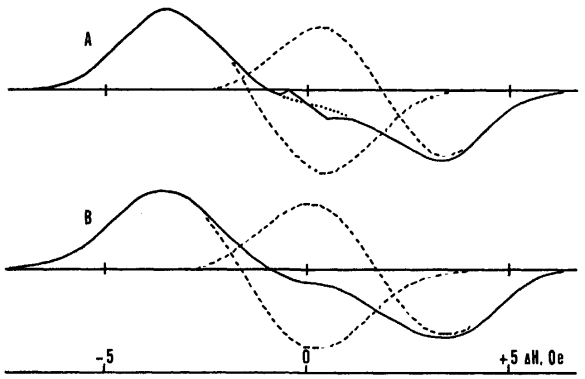

Fig. 9. PMR absorption derivative curves (full curves) of $CuCl_2$(pht) (A) and $CuBr_2$(pht) (B). The dotted curve in (A) shows the superposition of two derivative curves. A sharp unshifted component appears. The intrinsic absorption derivative curve of each compound is decomposed into two simple derivative curves(broken curves).

the unshifted curve is attributable to impurities or protons in randomly tumbling molecules. The dotted curve in Fig. 9A shows the superposition of the two broad curves and agrees with the observed curve except for a region near the unshifted component. The PMR absorption curves of dichloro(4-amino-1,2,4-triazole)copper(II), $CuCl_2$(atr), and dibromo-(4-amino-1,2,4-triazole)copper(II), $CuBr_2$(atr), also yield a sharp unshifted component, the integrated intensity of which is less than 1% and 0.5% of the total intensity, respectively. The intrinsic absorption curve of each of these compounds can be decomposed into two components.

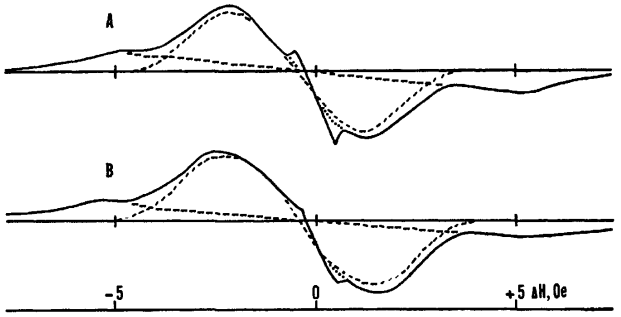

Fig. 10. PMR absorption derivative curves (full curves) of $CuCl_2$(atr) (A) and $CuBr_2$(atr) (B). Each of the dotted curves represent the superposition of two derivative curves (broken curves). In addition, a sharp component appears near the origin.

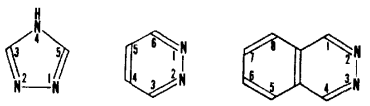
a) In ref. 3, a_i and ρ_i were evaluated assuming $g=2.00$. The values in this table are based on g_C. b) The absolute value could not be determined.



Discussion

The susceptibility *versus* temperature curve observed for $CuCl_2$(pid) exhibits a broad maximum at about 60°K and a paramagnetic behavior below about 20°K as shown in Fig. 2. $CuCl_2$(pht) and $CuCl_2$-(atr) shows a magnetic behavior resembling that of $CuCl_2$(pid) (Figs. 2 and 3). These magnetic properties are characteristic of linear antiferromagnets, typical examples of which are $CuCl_2$(tr),[2] potassium trifluorocuprate(II),[9] and 2,5-dihydroxy-*p*-benzoquinonatocopper(II).[10]

The susceptibility of $CuCl_2$(tr) has already been determined between 4.2 and 300°K (Fig. 3 in Ref. 2). With decreasing temperature, the susceptibility passes

through a maximum at about 11°K and increases sharply obeying the Curie-Weiss law below about 8°K. The behavior below 8°K is due either to the effect of magnetically isolated copper(II) ions existent in a small quantity or to interaction between linear chains. Susceptibility attributable to these effects was subtracted from the observed values. The resulting intrinsic susceptibility conforms to the parallel susceptibility, χ, of a linear Ising chain.[11]

$$\chi = \frac{Ng^2\beta^2}{4kT} \exp \frac{J}{kT} \quad (1)$$

Here apart from obvious notations, J denotes the exchange integral between the nearest neighbors in a chain. Therefore, the susceptibility of $CuCl_2$(tr) can be expressed by

$$\chi = \frac{Ng^2\beta^2}{4kT} \exp \frac{J}{kT} + \frac{C_{low}}{T-\theta_{low}} \quad (2)$$

where C_{low} and θ_{low} are the Curie constant and the Weiss constant in the low temperature region, respectively. From the susceptibility of $CuCl_2$(pid), C_{low} and θ_{low} cannot be determined accurately, because the temperature range of the paramagnetic effect is narrow. However, θ_{low} is estimated to be almost equal to 0°K (see Fig. 1). Therefore, the value of θ_{low} was assumed to be 0°K and g, J, and C_{low} were varied to get the best fit to the observed susceptibility especially near the temperature of the maximum susceptibility. The broken curve in Fig. 2 shows the result of calculation carried out with parameters listed in Table 2. Fisher[12] has pointed out that the perpendicular susceptibility given by

$$\chi = \frac{Ng^2\beta^2}{4|J|}\left[\tanh \frac{|J|}{2kT} + \frac{|J|}{2kT} \operatorname{sech}^2 \frac{|J|}{2kT}\right] \quad (3)$$

should be taken into account as well in the linear Ising model. However, all attempts to calculate curves involving both parallel and perpendicular components failed to reproduce the observed relative susceptibility as well as the absolute susceptibility. Bonner and Fisher[13] have calculated the susceptibility of a one-dimensional Heisenberg spin lattice. The observed susceptibility agrees well with the Bonner-Fisher curve corrected for the paramagnetic behavior in the low temperature region (see Fig. 2). For $CuCl_2$(pht) and $CuCl_2$(atr), the exchange integrals and the g-values were evaluated by the same procedure as employed for $CuCl_2$(pid) (see Table 2 and Figs. 2 and 3). The g-values are almost equal to those evaluated from the Curie constants and also to a value, 2.13±0.03, determined by ESR[4] (see Table 2). These support a presumption that –Cu–L–Cu— chains are formed in the crystals of the chlorine compounds. Hyde *et al.*[4] have carried out an ESR measurement on $CuCl_2$(pid) and suggested that the Heisenberg model rather than the Ising model is adequate because the value of $|D/J|$ is very small (D is the dipole-dipole interaction constant for spins in an axially symmetric crystal field). In fact, the observed susceptibility agrees with the theoretical curve for the Heisenberg model more closely than that for the Ising model.

The crystal of $CuBr_2$(tr) is expected to be isostructural with $CuCl_2$(tr). The susceptibility *versus* temperature curve can be reproduced by Eq. 2 in a manner similar to the case of $CuCl_2$(tr) (see Table 2 and Fig. 4). However, the Heisenberg model gives poor agreement with experimental data as in the case of $CuCl_2$(tr).[2]

The susceptibility *versus* temperature curve observed for $CuBr_2$(pid) exhibits two maxima at 12 and 55°K (see Fig. 5). The broad maximum at the higher temperature is undoubtedly due to a short-range magnetic interaction within a linear chain. Another maximum at the lower temperature is attributable to a three-dimensional long-range ordering existing below the temperature owing to interaction between chains.[14] The magnetic behavior of $CuBr_2$(pht) resembles that of $CuBr_2$(pid) as shown in Fig. 5. The susceptibilities of $CuBr_2$(pid) and $CuBr_2$(pht) at high temperature can be analyzed in the same way as for $CuCl_2$(pid). The g-values obtained from the Ising model are nearly equal to those evaluated from the Curie constants (see Table 2). On the other hand, the g-values based on the Heisenberg model are smaller than 2.00, whereas the g-value of a copper ion should be greater than 2.00 owing to spin-orbit interaction. This inconsistency indicates that the susceptibilities calculated with the Heisenberg model can hardly be fitted to the observed absolute susceptibilities despite an apparent qualitative agreement as in Fig. 5. Presumably this discrepancy is due to a strong magnetic interaction between chains suggested by the appearance of two maxima in the susceptibility *versus* temperature curves. The susceptibility of $CuBr_2$(atr) can be explained with difficulty by the Ising model as well as by the Heisenberg model (see Table 2 and Fig. 6) presumably because interaction exists between chains. A coupled-double-chain model[15,16] gives an approximation to the susceptibility of a crystal consisting of infinite chains, each of which is weakly coupled with neighboring chains. However, curves calculated with this model fail to agree with the observed susceptibility. Table 2 lists exchange integrals evaluated on the basis of the Heisenberg and Ising models for an isolated linear chain. The J/k values of the bromine compounds have some significance for the comparison of exchange interaction among the compounds. The effect of magnetic interaction between chains appears markedly in the bromine compounds, suggesting that the interaction takes place through bromine atoms.

An asymmetric PMR absorption curve observed for

$CuBr_2$(tr) bears a striking resemblance to that of $CuCl_2$(tr) (see Fig. 7). This supports a presumption that $CuBr_2$(tr) is isostructural with $CuCl_2$(tr) and that all 1,2,4-triazole molecules are equivalent in the crystals.[1] From the intensity ratio, 2 : 1, of the two components, the stronger one on the low-field side is assigned to protons, 3-CH and 5-CH, bonded to carbon at positions 3 and 5, while the curve shifted to the high-field side is attributable to a proton, 4-NH, bonded to nitrogen at position 4. Undoubtedly, the shifts are due to the isotropic contact hyperfine interaction field and are given by[5,17]

$$\frac{\Delta H}{H} = -a_i\left(\frac{\gamma_e}{\gamma_N}\right)\frac{\chi}{g\beta N} \tag{4}$$

where H is the NMR field, a_i is the contact interaction constant of a proton bonded to carbon or nitrogen at position i, γ_e is the magnetogyric ratio of an electron, and γ_N is that of a nucleus. The constants, a_i, listed in Table 3 were calculated from the observed shifts, $\Delta H/H$, the susceptibility at room temperature, and the g-value evaluated from the Curie constant. For an aromatic radical species, in which spin density localized on the pπ orbital of a carbon atom interacts with a proton bonded to the carbon atom, a_i is related to the spin density, ρ_i, on the adjacent carbon atom by the McConnell relation:[17,18]

$$a_i = Q_{CH}\rho_i \tag{5}$$

where Q_{CH} is a proportionality constant, the value of which has been determined empirically as -22.5 Oe. This relation is expected to hold for protons bonded to nitrogen as well.[19] However, few data are available for Q_{NH}. Barton and Fraenkel[20] have carried out an ESR experiments on dihydropyrazine cation radicals and found that $Q_{NH}=-33.7$ Oe by use of $Q_{CH}=-23.7$ Oe. The values of Q_{CH} and Q_{NH} may vary to a considerable extent among different bonding types.[19] Using Barton and Fraenkel's values, we evaluated spin densities, $\rho_{3,5}$ and ρ_4 as listed in Table 3. Negative and positive spin densities are distributed alternately on atoms in a triazole ring: $\rho_{3,5}<0$ and $\rho_4>0$. The alternation in sign of the spin density indicates that ρ_1 and ρ_2 are positive. Accordingly, it is concluded that the migration of an unpaired electron from copper creates a positive spin density on nitrogen atoms bonded to copper.

For $CuCl_2$(pid), a_i and ρ_i were evaluated in the same manner as for $CuBr_2$(tr) and are listed in Table 3. In the crystals of $CuCl_2$(pid), all pyridazine molecules are presumed to be equivalent, because the crystal consists of linear chains, –Cu–(pid)–Cu–, as units. Hence, there are two kinds of protons in equal amounts in agreement with the result of PMR absorption. Since a positive spin density is expected to exist on nitrogen atoms bonded to copper as in CuX_2(tr), carbon atoms at positions 3 and 6 bear a negative spin density (see Table 2). Therefore, the absorption curve on the low-field side is attributable to protons, 3-CH and 6-CH, whereas the curve shifted to the high-field side is assigned to 4,5-CH protons, indicating that ρ_4 and ρ_5 are positive. For pyridazine anion radicals, the interaction constants, a_i, have been determined as $|a_{3,6}|=0.16$ Oe and $|a_{4,5}|=6.45$ Oe by ESR measurements.[21] A molecular-orbital calculation on the radical has shown that $a_{3,6}$ is positive whereas $a_{4,5}$ is negative (therefore, $\rho_{3,6}<0$ and $\rho_{4,5}>0$)[22] in support of our assignment. The ratio, $|a_{3,6}/a_{4,5}|=1.0$, for $CuCl_2$(pid) is much greater than 0.025 for a pyridazine anion radical. An odd electron in the radical is attracted to nitrogen owing to the difference between the electronegativities of carbon and nitrogen. Accordingly negative spin densities are induced on carbon atoms bonded to nitrogen. On the other hand, in the copper(II) complex positive spins are mostly localized on nitrogen atoms bonded to copper, because unpaired electrons migrate from copper to the molecules of the heterocycle. In π-bond conjugation, negative spin density on an atom increases with increasing positive spin density on adjacent atoms. This is the reason why the ratio, $|a_{3,6}/a_{4,5}|$, is larger in the copper complex than in the radical.

The observed absorption curve of $CuCl_2$(pht) can be decomposed into two simple curves of intensity ratio equal to 2 : 1 (see Fig. 9). In $CuCl_2$(pht), ρ_1 and ρ_4 are expected to be negative for the same reason as in $CuCl_2$(pid). In addition, an assumption of alternation in sign of the spin density leads to a conclusion that $\rho_{5,8}<0$ and $\rho_{6,7}>0$. These conform to the intensity ratio and the shifts of the two components (see Table 3). Although $\rho_{1,4}$ and $\rho_{5,8}$ must differ from each other, the stronger curve on the low-field side is difficult to resolve owing almost complete overlap. Table 3 gives average values. A molecular-orbital calculation carried out on a phthalazine anion radical has indicated the absence of a negative spin density on any carbon atoms.[22] However, in $CuCl_2$-(pht), an unpaired electron migrating from copper gives rise to a strong polarization in the π-bond system of the heterocyclic ligand. Owing to this effect, negative spin densities are distributed on carbon atoms at positions, 1, 4, 5, and 8.

The intrinsic absorption curve of $CuCl_2$(atr) consists of a curve with a peak-to-peak width of 3.3 Oe and a broad curve with a width of 10 Oe (see Fig. 10). The narrower one can be assigned to protons, 3,5-CH, by comparing the curves with those of CuX_2(tr). Therefore, the broad curve is attributable to protons in N-NH_2. The shift, $\Delta H/H$, of the broad curve cannot be determined accurately because the curve is very broad and an absorption curve due to impurities is superposed on it. The shift, however, suggests that the nitrogen atom at position 4 carries a positive spin density, in conformity with the results of CuX_2(tr).

22) J. A. Pople and D. L. Beveridge, "Approximate Molecular Orbital Theory," McGraw Hill, New York, N. Y. (1970), p. 134.

For $CuBr_2$(pid), $CuBr_2$(pht), and $CuBr_2$(atr), the spin densities can be evaluated in a manner similar to that for the corresponding chlorine compounds (see Table 3).

The magnitude of the exchange integrals depends on the kind of heterocycles rather than halide ions (see Table 2). This indicates the predominance of superexchange interaction through the heterocycles. CuX_2(pid) and CuX_2(pht) carry larger spin densities on the atoms of the heterocycles than do CuX_2(tr) and CuX_2(atr). Large spin densities on the atoms of bridging ligands favor the migration of positive holes and, consequently, superexchange interaction between copper atoms. In conformity with this expectation, the exchange integrals of CuX_2(pid) and CuX_2(pht) are greater than those of CuX_2(tr) and CuX_2(atr).

Our grateful thanks are due to Dr. M. Iwasaki and Dr. B. Eda of the Government Industrial Research Institute, Nagoya, for giving us facilities to use a broad-line NMR spectrometer in the Institute.

The Second CMC of the Aqueous Solution of Sodium Dodecyl Sulfate. II. Viscosity and Density

Michiko KODAMA and Masaji MIURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received December 20, 1971)

Our viscosity and density studies of an aqueous solution of sodium dodecyl sulfate have revealed that the 2nd critical micelle concentration (CMC) exists in addition to the 1st CMC and that the 2nd CMC is greatly influenced by such additives as sodium chloride, dodecyl alcohol, and benzene; these results are in good agreement with those obtained from the conductivity measurements described in the previous paper. The reduced viscosity of the micelle ($\eta_{sp.m}/C_m$) *vs.* C_m curve showed a knick at the concentration corresponding to the 2nd CMC as obtained by Tyuzyo and his co-workers. The molar volume of the hydrated micelle was calculated by using the equation: $\eta_{r.m}=1+2.5\phi_m+14.1\phi_m^2$; it has been found to decrease at about the 2nd CMC, similarly to the partial specific volume ($\bar{v}$) of SDS obtained from the density measurement. This may be attributed to a change in the micelle structure at the 2nd CMC, caused by a variation in the type of aggregation and by a decrease in the counter-ion binding by the micelle.

In our previous paper (Part 1), the micelle structure of an aqueous solution of sodium dodecyl sulfate (SDS), mainly in the concentration region above the 1st critical micelle concentration (CMC), has been studied from the point of view of conductivity measurements.[1] It was revealed by the conductivity studies that a so-called 2nd CMC exists at about 65 mM in addition to the 1st CMC at 8.3 mM, and also that the 2nd CMC is greatly influenced by such additives as sodium chloride, dodecyl alcohol, and benzene.

In the present study, density and viscosity measurements were carried out in order to obtain some more information about the micelle structure of the aqueous solution of SDS. This study can be expected to afford a new clue for clarifying the micelle structure above the 2nd CMC.

Experimental

Materials. The SDS, sodium chloride, dodecyl alcohol, and benzene used in this study were the same as those described in our previous paper,[1] and the aqueous solutions of SDS, both in the absence and presence of the additives, were prepared in the same manner as in the above work.

Procedures. A capillary viscometer of the Ubbelohde type was designed and employed to minimize the effect of the surface tension. Since dust has a great influence upon the flow time, particular attention was given to protect the solution from contamination with dust; the entrances of the viscometer were equipped with glass-filters, the viscometer was carefully cleaned and rinsed with dust-free, distilled water and alcohol, and the solution was introduced into the viscometer through a glass-filter. The flow time was determined by repeating the measurements at least four times, using a stop-watch, in a water-thermostat of 25.000±0.005°C after the temperature equilibrium had been established. The flow time of pure water was 570.00 sec. The density was measured by using pycnometers of the improved Ostwald type,[2] with capacities of 9—10 ml.

Results and Discussion

Viscosity, No Additive. The relative viscosity (η_r) of the aqueous solution of SDS is plotted against the concentration of SDS in Fig. la. As may be seen from this figure, a break point appears at about 65 mM in addition to that at 8.3 mM; the latter corresponds to the 1st CMC, while the former, the so-called 2nd CMC, agrees fairly well with the results obtained by other methods.[1,3,4]

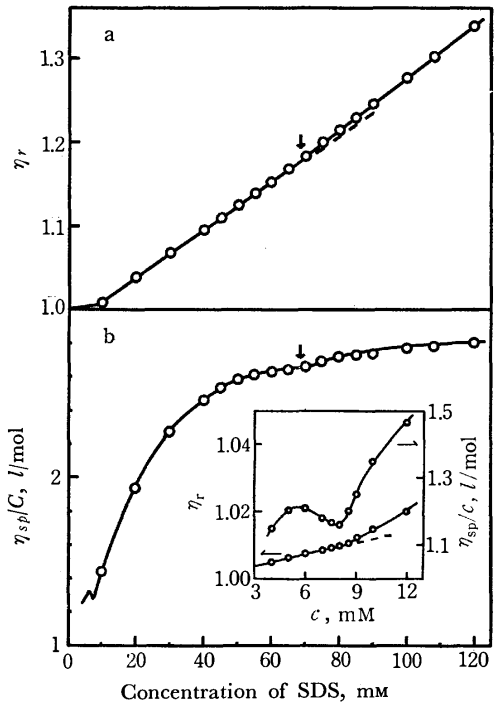

Fig. 1. Relative and reduced viscosities of SDS solution. The arrow in the figure indicates the 2nd CMC. a: Relative viscosity. b: Reduced viscosity. The viscosities in the neighborhood of the 1st CMC are shown under enlargement in Fig. 1b.

The reduced viscosity (η_{sp}/C) is also plotted against the concentration in Fig. 1b ; the results in the neighborhood of the 1st CMC are also shown in an enlarged form in Fig. 1b. As can be seen in Fig.1b, the reduced viscosity shows a minimum at the 1st CMC, as was found by Tyuzyo and his co-workers,[5,6] and then increases markedly above the 1st CMC. Tyuzyo and his co-workers did the following operations, presuming that above the 1st CMC the concentration of the detergent monomer in a solution which is in equilibrium with the micelle is almost constant:—

$$C_m = C - C_{cmc(I)}, \tag{1}$$

$$C_m^\circ = C_{cmc(II)} - C_{cmc(I)}, \tag{2}$$

$$\eta_{sp\cdot m}/C_m = (\eta_{r\cdot m} - 1)/C_m = (\eta_r/\eta_{r\cdot cmc(I)} - 1)/C_m, \tag{3}$$

$$[\eta_1]_m = \lim_{C_m \to 0}(\eta_{sp\cdot m}/C_m), \tag{4}$$

$$[\eta_2]_m = \lim_{C_m \to C_m^\circ}(\eta_{sp\cdot m}/C_m), \tag{5}$$

where C is the total concentration of SDS; C_m is the concentration of a micellar substance; $C_{cmc(I)}$ and $C_{cmc(II)}$ are the 1st and 2nd CMC's as obtained from viscosity measurements respectively; $\eta_{r\cdot cmc(I)}$ is the relative viscosity of the solution against water at the 1st CMC; $\eta_{r\cdot m}$ and $\eta_{sp\cdot m}/C_m$ are the relative and reduced viscosities of the micellar substance respectively, and $[\eta_1]_m$ and $[\eta_2]_m$ are the intrinsic viscosities of the micellar substance at the 1st and 2nd CMC's respectively.

The reduced viscosity of micellar SDS, as obtained from Eq. (3), is plotted against the concentration of micellar SDS in Fig. 2, where a knick corresponding to the 2nd CMC appears as in the experiments done

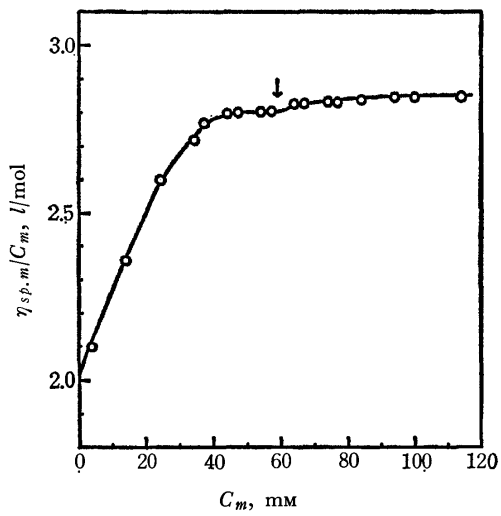

Fig. 2. Reduced viscosity of SDS micelle.

by Tyuzyo and his co-workers.[5,6] The values of $[\eta_1]_m$ and $[\eta_2]_m$ obtained from Fig. 2 by means of Eqs. (4) and (5) are, respectively, 2.0 and 2.8; those values agree fairly well with the reference values.[6]

The Guth and Simha equation,[7] which is a form of the Einstein equation extended for use with more concentrated solutions, was used in the present case:

$$\eta_r = 1 + 2.5\phi + 14.1\phi^2. \tag{6}$$

In this equation, ϕ is the volume fraction occupied by particles. It may be necessary to discount the detergent monomer, which play no role as a micellar substance, in the application of Eq. (6) to a micelle system. Therefore, on the assumption that the monomer concentration remains constant above the 1st CMC, the following equation can be obtained for the concentrated solutions containing the spherical micelles:

$$\eta_{r\cdot m} = 1 + 2.5\phi_m + 14.1\phi_m^2, \tag{7}$$

where ϕ_m is the volume fraction of hydrated micelles. The value of ϕ_m was calculated by the use of Eq.(7). The molar volume of the hydrated micelle (V_m) was obtained from this relation: $V_m = \phi_m/C_m$. The values of ϕ_m and V_m obtained in this manner are plotted against C_m in Figs. 3a and 3b respectively. It may be seen from these figures that ϕ_m increases linearly with C_m up to the 2nd CMC at about C=55 mM, while, in the range above the 2nd CMC, the curve bends toward the C_m axis, and that this phenomenon is reflected in the V_m *vs.* C_m curve—that is, V_m takes a nearly constant value up to the 2nd CMC and then decreases gradually. The values of V_m in the (I) and (II) parts in Fig. 3b are 0.91 *l*/mol and 0.80 *l*/mol respectively. These results may support the view that, in the concentration range between the 1st CMC and the 2nd CMC, the SDS micelle is spherical with a nearly constant volume ($V_{m(I)}$), while above the 2nd CMC it is deformed from the spherical shape to an asymmetric one, accompanied by a decrease in the

molar volume ($V_{m(II)}$)[8-12]

Effect of Sodium Chloride. The results of the viscosity measurements of the SDS solution containing 0.01 M sodium chloride are shown in Fig. 4, while those in the neighborhood of the 1st CMC are shown in the same figure in an enlarged form. The 2nd CMC as well as the 1st CMC is lowered and at the same time the slope of the curve above the 2nd CMC is raised, compared with the results shown in Fig. 1a; this is in agreement with the results obtained by the conductivity measurements. The reduced viscosity of micellar SDS containing 0.01 M sodium chloride is shown in Fig. 5. It may also be seen from this figure that the knick at the concentration corresponding to the 2nd CMC is more remarkable than that in the absence of sodium chloride. The values of $[\eta_1]_m$ and $[\eta_2]_m$ are, respectively, 1.4 and 2.0; each of those values is lower than the value in the absence of an additive. In the presence of sodium chloride, the decrease in the $[\eta_1]_m$ or $[\eta_2]_m$ value may be due to the electroviscus effect predicted for charged systems.[13-16]

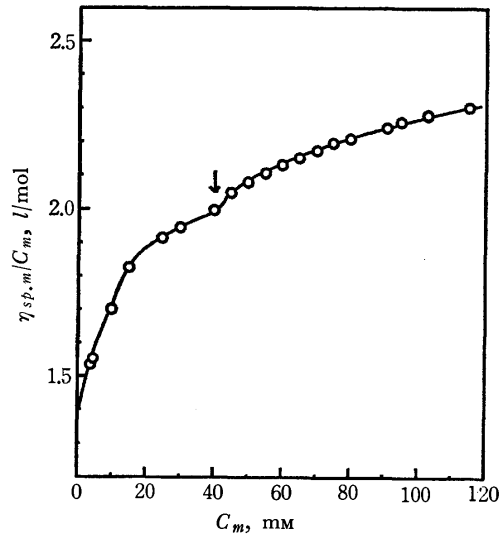

Fig. 5. Reduced viscosity of SDS micelle in the presence of 0.01 M NaCl.

Effect of Dodecyl Alcohol (DA). The results of the viscosity measurements of the SDS solution containing DA in a 1/10 molar ratio of DA to SDS are shown in Fig. 6, where the relative and reduced viscosities are plotted against the concentration of the SDS solution. It may be seen from this figure that no change appears at the concentration corresponding to the 2nd CMC. In this case, there may be no 2nd CMC. It can be concluded from the viscosity measurements, much as in the case of the conductivity measurements, that the presence of a proper amount of DA stabilizes the micelle in the region of low concentrations.

Effect of Benzene. The viscosity measurements of the SDS solution containing benzene in a molar

of 1/4 were also carried out. The results obtained were almost the same as those obtained in the absence of additives, represented in Fig. 1; benzene has no remarkable influence upon the 2nd CMC, a finding in agreement with the results obtained by the conductivity measurements.

Density. The partial specific volume of SDS ($\bar{v}$) is calculated on the basis of the following equation (8):[17,18]

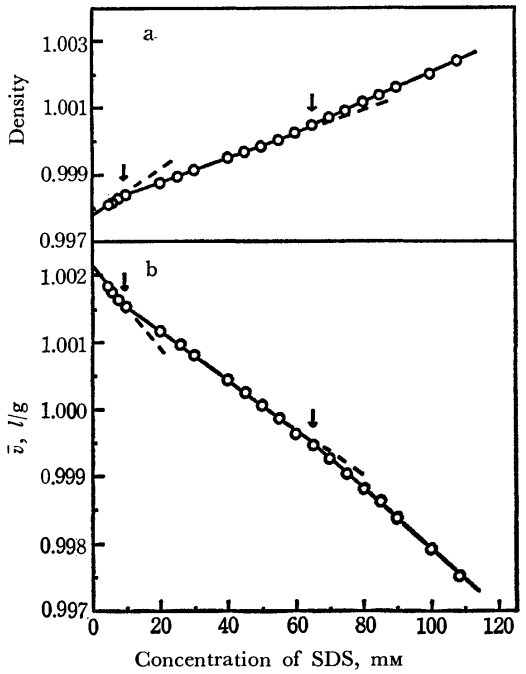

Fig. 7. a: Density of SDS solution. b: Specific volume of SDS solution.

17) H. Lal, *J. Colloid Sci.*, **8**, 414 (1953).
18) P. Mukerjee, *J. Phys. Chem.*, **66**, 1733 (1962).

$$\bar{v} = v + (1-x)\mathrm{d}v/\mathrm{d}x, \quad (8)$$

where v is the specific volume of the solution and x, the concentration of the solute per gram of the solution. The value of $\mathrm{d}v/\mathrm{d}x$ can be evaluated graphically from the v *vs.* x curve. The density and the specific volume of the aqueous solution of SDS in the absence of an additive are plotted against the concentration in Figs. 7a and 7b respectively. As may be seen from this figure, a break point exists at the 2nd CMC in addition to that at the 1st CMC. The partial specific volume of SDS is shown in Fig. 8;

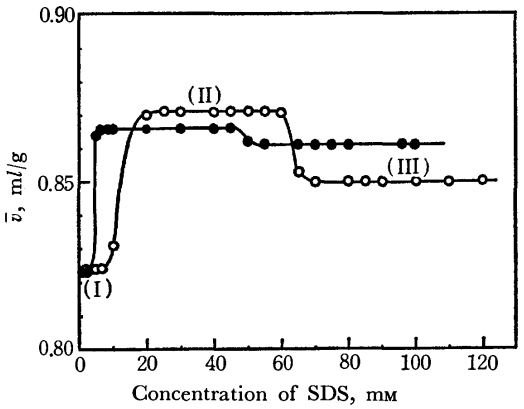

Fig. 8. Partial specific volume of SDS. ○: No additive, ●: 0.01 M NaCl.

after taking a practically constant value (I) in the concentration range below the 1st CMC, the partial specific volume increases rapidly at about the 1st CMC, remains constant (II) again over a wide concentration range up to the 2nd CMC, then decreases at about the 2nd CMC, and again remains constant (III) above the 2nd CMC. The values of v were estimated from the figure to be 0.871 ml/g and 0.851 ml/g in the (II) and (III) parts respectively. It may be noted that the behavior of the partial specific volume is quite similar to that of the hydrated molar volume obtained from the viscosity measurements shown in Fig. 3b. The partial specific volume and the hydrated molar volume both remain constant in the concentration range between the 1st CMC and the 2nd CMC. This may imply that the micelle structure — that is, the micelle size and shape — does not change in this concentration range.[19] The marked decreases in the partial specific volume and the hydrated volume at the 2nd CMC may be attributed to the change in the micelle structure; the SDS molecules, of which the micelle is composed, occupy a smaller space above the 2nd CMC than below the 2nd CMC as a result of a change in the type of aggregation.

Ekwall and his co-workers have observed, from their measurements of the viscosity[12] and density[19] of sodium caprylate solutions, that both the hydrated molar volume and the partial specific volume increased at about the 2nd CMC; they have concluded that these phenomena may be attributed to an increase

19) P. Ekwall, H. Eikrem, and L. Mandell, *Acta Chem. Scand.*, **17**, 111 (1963).

in the binding force between the micelle and the counter ion above the 2nd CMC. It is interesting to note that these two kinds of volumes of SDS decrease at the 2nd CMC, contrary to the results obtained by Ekwall and his co-workers. It was revealed from the conductivity measurements of the SDS solutions that the specific conductivity-concentration curve breaks upward at the 2nd CMC.[1] On the assumption that this conductivity behavior may be caused at least partly by an increase in the free counter ion (Na^+) as a result of a decrease in the counter-ion binding by the micelle, the decrease in the hydrated molar volume or the partial specific volume is explicable; the former may be ascribed to the dehydration of the SDS micelle resulting from a decreased counter-ion binding of the micelle, while the latter may be ascribed to a decrease in the volume of the SDS solution due to the interaction between the free counter ion and water, because the partial volume can be regarded as the sum of the volume of the ions themselves and that of the volume change of the solvent associated with the solvent-solute interaction.[18] The partial specific volume of SDS in the presence of 0.01 M sodium chloride is also represented in Fig. 8. The degree of decrease in the partial specific volume above the 2nd CMC is much smaller than that in the absence of sodium chloride. These problems will be discussed in detail later, with more experimental data.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2269—2273 (1972)

The Quenching of Hg(6^3P_1) Atoms by Molecular Hydrogen as Investigated by ESR Spectroscopy

James B. FARMER and Kazuo SHIMOKOSHI*

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia, Canada

(Received March 11, 1972)

The gas phase electron spin resonance technique has been applied to study the quenching efficiency of Hg(6^3P_1) mercury atoms by molecular hydrogen. The concentration of hydrogen atoms produced by the mercury photosensitized decomposition of molecular hydrogen in a flow apparatus was followed as a function of the partial pressure of hydrogen with argon, neon, and hydrogen as carrier gases. The kinetic equations derived from the reaction mechanism proposed was shown to be in agreement with the experimental observations. The total quenching rate k_H was evaluated from the experimental results.

The quenching of excited mercury atoms Hg (6^3P_1) was first observed by Cario and Franck[1] and since that time this process has been the subject of numerous detailed investigations. Several comprehensive reviews of the literature have appeared.[2,3] Most investigators have devoted their attention to studying the quenching of excited Hg($^3P_1$) mercury atoms by hydrogen,[1-9] or hydrocarbons,[2-4,10-13] though many detailed studies have been made of the quenching processes caused by other molecules.[7,12-14] Undoubtedly the reaction of this type which has been most extensively investigated is that of the mercury photosensitized decomposition of molecular hydrogen. These extensive studies have been carried on not only because of the intrinsic importance of the quenching process itself, but because the mercury photosensitized decomposition of molecular hydrogen has proven to be a clean source of hydrogen atoms of considerable importance in the study of hydrogenation processes.

The quenching of excited mercury Hg(6^3P_1) atoms has been measured by both physical and chemical methods. Thus Thomas and Gwinn[5] studied the quenching efficiency of molecular hydrogen by measuring the pressure changes in the reaction cell. Cvetanovic[2] developed a chemical method for the estimation of quenching efficiencies. This method is based on chemical analysis of the reactants. Generally mixtures of nitrous oxide and hydrocarbons were used to quench the excited Hg*(6^3P_1) atoms, and subsequent product analysis enabled relative values for the quenching efficiencies to be estimated. Both physical[12,13] and chemical methods[2,6,10] have been used to study the quenching of excited mercury Hg (6^3P_1) atoms by alkanes and related compounds. The

flash photolysis technique was first used by Callear and Norrish[4] to investigate mercury photosensitized reactions and in particular to study the role of $Hg(^3P_0)$ atoms. Callear and Williams[15,16] studied mixtures of mercury vapour and various gases when subjected to a single pulse of uv radiation. A microwave pulse method was developed by Callear and Hedges[7,8] and applied particularly to study the role of HgH as an intermediate in $Hg(6^3P_1)$ photosensitized reactions. More detailed studies of the formation of HgH in the mercury photosensitized decomposition of molecular hydrogen were reported by Callear and McGurk[9]. Many workers have studied the importance of complex formation as an intermediate in the quenching of excited mercury $Hg(6^3P_1)$ atoms by molecules other than hydrogen. Thus Homer and Lossing[18] as the result of studies using a mass spectrometric technique postulated the formation of a HgCO* complex with a life-time of about 3×10^{-5} sec to account for the results of their study of the reaction $Hg(6^3P_1)$ atoms with CO. This same system was studied extensively by Karl, Kruss, and Polanyi[19-21] who recorded the infrared emission of vibrationally excited carbon monoxide to its ground state. The results were also interpretated in terms of the formation of a HgCO* complex. Later, in an extensive physical and chemical study[22] of the Hg/CO system, by London, Vikis, and Le Roy, it was stated that the results failed to yield any substantial additional evidence for the existence of the HgCO* complex.

Recently electron spin resonance spectroscopy has been used to study atom concentrations in reacting systems. In the case of certain reactions it has proved possible to detect atomic hydrogen in the gas phase at concentrations as low as 10^{10}-10^{11} atom/cc, and to estimate the concentrations of such atomic species quantitatively.[23] This method has been applied to the study of the mercury photo-sensitized reaction between hydrogen and oxygen.[24] In this paper we describe a somewhat improved experimental method using electron spin resonance spectroscopy and a flow system to study in greater detail this photosensitized reaction.

Experimental

The pure cylinder hydrogen used in these experiments was further purified by passage through a catalytic deoxygenator unit (Deoxo), and through a cold trap held at liquid nitrogen temperature. The other gases used, namely argon and neon, were obtained from the Matheson Company and were stated to be better than 99.998% pure. Before use these were passed through a cold trap held at liquid nitrogen temperature.

Figure 1 shows a schematic diagram of the experimental arrangement. The gaseous mixtures containing hydrogen were introduced to the reaction vessel after passing through the thermostated mercury saturator. The vapour pressure of the mercury was varied by changing the temperature of the circulating water cooling the saturator. The temperature could readily be controlled to ±0.2°C. After passing the radiation zone the gases entered the ESR cavity operating in a TE_{102} mode. The partial pressure of the gases was determined by measuring the flow rate of each gas which was accurately controlled by needle valves at the inlet and outlet of the system. The capillary flow meters were carefully calibrated before use.

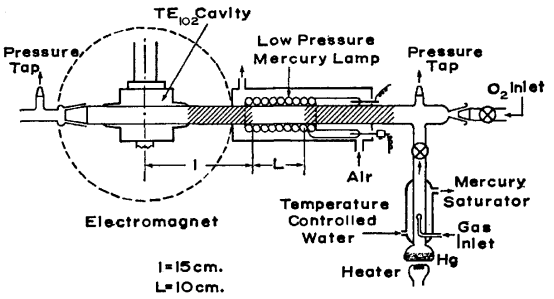

Fig. 1. Diagrammatic sketch of the experimental apparatus.

The irradiations were carried out using a Hanovia low pressure mercury vapour lamp which was spiral in form and having a diameter of 5 cm, and was 15 cm in length. The flow tube was 2 cm o.d. quartz coated on the inside with DuPont Teflon to reduce the rate of recombination of the hydrogen atoms at the surface. It is well known that without such wall coatings it is difficult to observe ESR signals due to H atoms because of high efficiency of the recombination due to wall collisions when uncoated quartz is used. A X-band homodyne ESR spectrometer using a modulating frequency of 100 kHz was used to determine the hydrogen atom concentrations. The H atom concentrations being

estimated by comparing the integrated intensities with lines in the ESR spectrum of molecular oxygen whose concentrations in the reaction zone was known. The integration was achieved by using two successive operational amplifiers which provided respectively, the first and second integrals of the original derivative spectrum. A plot of the integrated intensity of the atomic hydrogen ESR signal against the peak heights is shown in Fig. 2. These data were obtained at mean pressures of hydrogen of 0.3 to 2.2 torr in the flow system.

Results and Discussion

As will be clear from the above, our experimental technique yields values for the variation of the concentration of the hydrogen atoms as a function of pressure. These data can be used to develop a kinetic analysis of the processes which occur when excited Hg (6^3P_1) atoms are quenched by molecular hydrogen.

When ground state mercury atoms $Hg(6^1S_0)$ absorb radiation of wavelength 2537Å the following initial processes occur:

$$Hg(6^1S_0) + h\nu \xrightarrow{k_1} Hg(6^3P_1) \quad (1)$$

$$Hg(6^3P_1) \xrightarrow{k_2} Hg(6^1S_0) + h\nu \quad (2)$$

Collision of the excited $Hg(6^3P_1)$ atoms with molecular hydrogen leads to a number of processes, all of which are of importance in understanding the nature of the complex reactions involved in the overall quenching phenomena.

The first reaction leading to the production of hydrogen atoms which obviously occurs is

$$Hg(6^3P_1) + H_2 \xrightarrow{k_3} HgH + H \quad (3)$$

Indirect evidence for the formation of HgH was obtained by Thomas and Gwinn.[5] Various workers[6,10,25,26] have discussed the possibility of this process both in terms of studies of potential surfaces correlating the $Hg(6^3P_1)$ atom and molecular hydrogen energy states, and phase-space theory in which reactive scattering is assumed to occur when the relative energy of translation exceeds the hump in the effective interaction potential curve. The observation of the spectrum of HgH in flash spectroscopic studies of mixtures of mercury and H_2, D_2, by Callear and Hedges[7,8], and by Callear and McGurk[9] clearly established that reaction (3) does occur. We should perhaps mention that Callear and McGurk[9] have suggested that the interaction of $Hg(6^3P_1)$ atoms and molecular hydrogen is somewhat more complicated than has been indicated in Eq. (3). They suggested that the following sequence of reactions occur,

$$Hg(6^3P_1) + H_2 \longrightarrow HHgH^* \text{ (insertion)}$$

$$HHgH^* \longrightarrow HHgH \text{ (crossing)}$$

$$HHgH \longrightarrow HgH + H \text{ (dissociation)}$$

In the present studies, however, we are of the opinion that Eq. (3) is an adequate representation of the interaction. The HgH formed in reaction (3) was found[8] to decay in less than 200 μsec.

Various mechanisms have been suggested for the subsequent reactions of the HgH produced in reaction (3). It may for example simply dissociate rapidly as follows

$$HgH + M \longrightarrow Hg(6^1S_0) + H + M$$

since the bond dissociation energy of HgH is only 8.6 kcal mol^{-1}. Another possible reaction is, of course,

$$HgH + H \longrightarrow Hg(6^1S_0) + H_2$$

which was postulated by Thomas and Gwinn[5] and subsequently adopted by a number of workers.[6-9,22]

Apart from reaction (3) there are two other quenching processes which must be considered to be of some importance, namely

$$Hg(6^3P_1) + H_2 \xrightarrow{k_4} Hg(6^3P_0) + H_2 \quad (4)$$

$$Hg(6^3P_1) + H_2 \xrightarrow{k_5} Hg(6^1S_0) + H_2 \quad (5)$$

The role of spin-orbit relaxation (reaction (4)) in the quenching of excited mercury (6^3P_1) atoms has been studied in some detail[4,7-9,12-14,22] and it is clear that in the case of hydrogen reaction (4) is an important process. Corresponding processes must occur when a carrier gas is used in the experiments using hydrogen mixtures so we must, in these cases, also include the following processes

$$Hg(6^3P_1) + M \xrightarrow{k_6} Hg(6^3P_0) + M \quad (6)$$

$$Hg(6^3P_1) + M \xrightarrow{k_7} Hg(6^1S_0) + M \quad (7)$$

many authers[1-5,7-9,12-14,29,30,32,33] have considered the role of metastable $Hg(6^3P_0)$ atoms in mercury photosensitized reactions. Callear and Hedges[7,8] showed conclusively that both molecular hydrogen and deuterium, in the presence of large excess of nitrogen react with $Hg(6^3P_0)$ atoms in the manner analogous to reaction (3), namely:-

$$Hg(6^3P_0) + H_2 \longrightarrow HgH + H \quad (3^1H)$$

$$Hg(6^3P_0) + D_2 \longrightarrow HgD + D \quad (3^1D)$$

and that the yields of HgH (or HgD) were slightly higher from $Hg(6^3P_0)$ than from $Hg(6^3P_1)$ atoms. Earlier, however, Callear and Norrish[4] had shown that the cross-section for quenching of $Hg(6^3P_0)$ by molecular hydrogen is 0.08Å^2, whereas that for $Hg(^3P_1)$ and hydrogen is 6Å^2. More recently London *et al.*[22] and Callear and McGurk[17] have confirmed that the rate of deactivation or reaction of $Hg(6^3P_0)$ atoms by hydrogen is very small. For these reasons it is unlikely that reaction (3^1H) is of any major significance in our case. The only reactions of $Hg(6^3P_0)$ atoms with hydrogen which need be considered are therefore,

32) A. B. Callear and W. P. D. Pereira, *Trans. Faraday Soc.*, **59**, 2758 (1963).

$$Hg(6^3P_0) + H_2 \longrightarrow Hg(6^1S_0) + 2H \quad (8)$$

$$Hg(6^3P_0) + H_2 \longrightarrow Hg(6^1S_0) + H_2 \quad (9)$$

The corresponding reaction to (9) may also occur with a non-chemically reacting atom or molecule, *i.e.*,

$$Hg(6^3P_0) + M \xrightarrow{k_{10}} Hg(6^1S_0) + M \quad (10)$$

Because the life-time of the $Hg(6^3P_0)$ atoms is long, the radiative transition to the ground state

$$Hg(6^3P_0) \longrightarrow Hg(6^1S_0) + h\nu'$$

is also not likely to be of importance in our case.

The termination reactions involving hydrogen atoms are:—

$$H + H + H_2(M) \longrightarrow H_2 + H_2[M] \quad (11)$$

$$H \text{ (wall)} \longrightarrow \tfrac{1}{2}H_2 \quad (12)$$

Since the life-time of $Hg(6^3P_1)$ is quite short and the quenching processes k_3, k_4, and k_5 (and k_2) are fast, we can assume that a steady state concentration of $Hg(6^3P_1)$ and $Hg(6^3P_0)$ will quickly be established. Applying the normal steady state approximations we obtain the following equation for the rate of formation of hydrogen atoms:—

$$d[H]/dt = 2k_3[Hg(6^3P_1)]_{ss}[H_2] + 2k_8[Hg(6^3P_0)]_{ss}[H_2] - k_{12}[H] - k_{11}[H]^2[H_2] \quad (13)$$

As the total pressure in the flow tube was lower than 5 torr, and the concentration of hydrogen atoms was also so low, the termolecular recombination process (11) can be neglected, particularly as the transit time from the irradiation zone to the cavity is probably only 10^{-3} sec. Equation (13) therefore can be simplified to

$$d[H]/dt = A - k_{12}[H], \quad (14)$$

where

$$A = \frac{2I_0[H_2]}{k_2 + k_H[H_2] + k_M[M]}\left\{k_3 + k_8\frac{k_4[H_2] + k_6[M]}{k_H^\circ[H_2] + k_{10}[M]}\right\}. \quad (15)$$

In Eq. (15) we have written k_H for $k_3+k_4+k_5$, k_M for k_6+k_7, and k_H° for k_8+k_9.

Outside the illumination region the rate of formation of H atoms can be neglected so in those regions Eq.(14) has the form

$$d[H]/dt = -k_{12}[H]. \quad (16)$$

Under our experimental conditions when $[H_2] \gg [H]$, then the hydrogen atom concentration $[H]_c$ in the cavity given by the expression

$$[H]_c = \frac{A}{k_{12}}\{1 - \exp(-k_{12}L/v)\}\exp(-k_{12}l/v). \quad (17)$$

Where L is the length of the illumination zone, l the distance from the end of the illumination zone to the ESR cavity, and v is the linear flow velocity. The effect of the flow velocity on the hydrogen atom concentration in the cavity $[H]_c$ at constant pressure of hydrogen of 0.374 torr is shown in Fig. 3. If we assume that $k_{12}L/v$ and $k_{12}l/v$ are both $\ll 1$, then from Eq. (17) we obtain the result

$$[H]_c = \frac{AL}{v}\left(1 - \frac{k_{12}l}{v}\right)$$

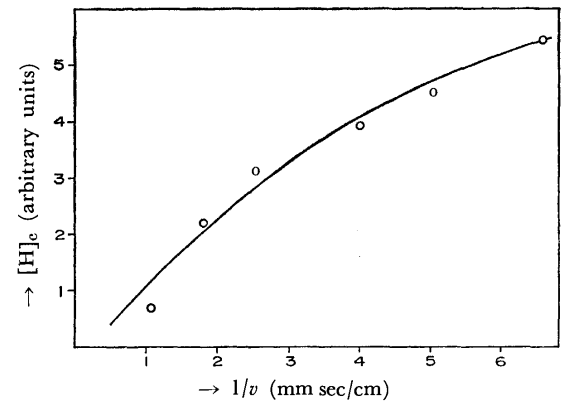

Fig. 3. Plot of hydrogen atom concentration $[H]_c$ as a function of $1/v$ at pressure of hydrogen of 0.374 torr.

which is in agreement with the experimental results as shown in Fig. 3.

From Eqs.(13)—(17) we can obtain the expression

$$\frac{B}{[H]_c} = \left(k_H + \frac{k_2}{[H_2]} + \frac{k_M[H]}{[H_2]}\right) \times \left\{\frac{k_H^\circ[H_2] + k_{10}[M]}{(k_3k_M^\circ + k_8k_4)[H_2] + (k_3k_{10} + k_8k_6)[M]}\right\}, \quad (18)$$

where $B=(2I/k_{12})\{1-\exp(-k_{12}L/v)\}\exp(-k_{12}l/v)$ which is constant under the conditions of our experiments where L, v, and I were kept constant. To evaluate $k_H=k_3+k_4+k_5$ we proceed as follows. Eq. (18) can be rewritten as

$$\frac{C}{[H]_c} = \left(k_H + \frac{k_2}{[H_2]}\right) \quad (19)$$

where $C=Bk_H^\circ/(k_3k_H^\circ+k_8k_4)$ if we neglect the quenching by inert gases used as carriers. A series of experiments were carried out using Ar, Ne, and H_2 as carrier gases at constant flow rate. Plots of the function $1/[H]_c$ obtained from the measurements of $[H]_c$, the hydrogen atom function in the cavity against $1/[H_2]$ are shown in Figs. 4, 5, and 6. Least squaring the data gave the values of k_H/k_2 at 20°C listed in Table 1. The ratio k_H/k_2 was evaluated because the method was thought not to be accurate enough to determine the parameters separately.

To evaluate k_H we need to have an estimate of k_2

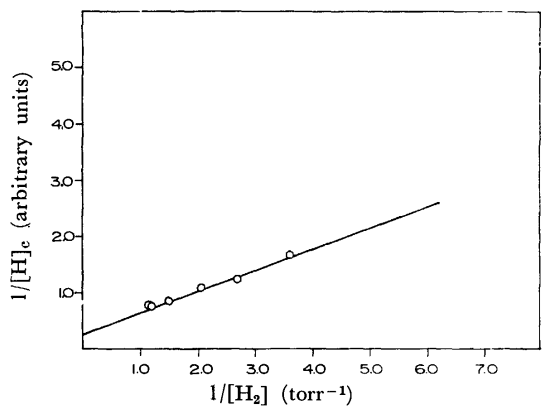

Fig. 4. Plot of $1/[H]_c$ against $1/[H_2]$ at total pressure of 1.0 torr with argon as the carrier gas.

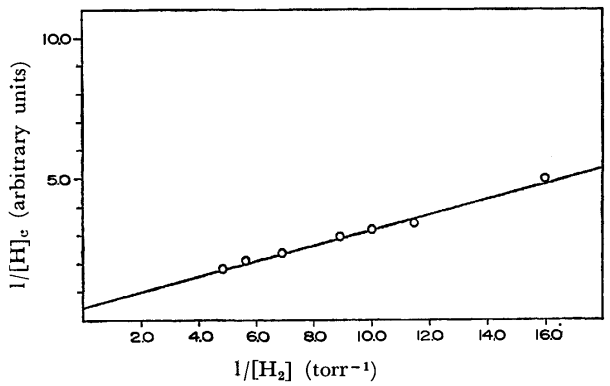

Fig. 5. Plot of $1/[H]_c$ against $1/[H_2]$ at total pressure of 2.0 torr with neon as the carrier gas.

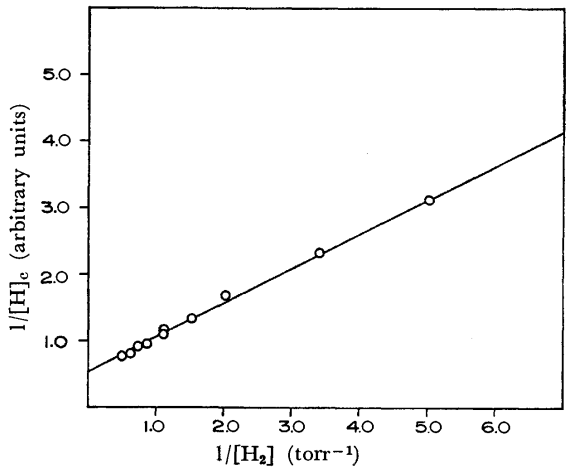

Fig. 6. Plot of $1/[H]_c$ against $1/[H_2]$ with hydrogen as carrier gas.

under the conditions of our experiments. The true lifetime of Hg(6^3P_1) atoms with respect to radiation has been reported by Garrett[27] as being 1.08×10^{-7} sec. This value may, however, need correction because of the possible imprisonment of the resonance radition, which has the effect of decreasing this value as the mercury vapour pressure is increased. For the range of mercury vapour pressure used in our experiments, we may make use of the expression (20) proposed by McAlduff and LeRoy[28]

$$k_2 = (1-q[\mathrm{Hg}])/\tau \qquad (20)$$

when q is a constant. As has been pointed out by many authors[29-31] radiation imprisonment effects depend on the geometry of the cell as well as the nature of the light source used. Under our experimantal conditions it was difficult to measure the concentration of the mercury atoms with high precision. This difficulty was, however, circumvented to an acceptable degree by the following method. The concentration in the reactor region was assumed to be linearly related to that in the saturator. If we assume there was little change in I_0 then by reducing the concentration of mercury atoms by one half, we carried out a determination of k_H/k_2 with the temperature of the reactor at 12°C at which point the vapour pressure of mercury is one half the value at 20°C. The value of the ratio $(k_H/k_2)_{20°}/(k_H/k_2)_{12°}$ was found to be 0.91, and substituting this value into Eg.(20) we obtain the result that $k_2=1.2/\tau$. This enables us to calculate k_H from the data in column 2 of Table 1. The resulting values of k_H are given in column 3 of Table 1. The only other data available for comparison is given in column 4 which are obtained by a chemical method.[1,22] The chemical method for determining the kinetic parameters is possibly subject to several inherent errors. The ESR method is more direct and may be more accurate. The agreement between the two sets of values is, however, satisfactory.

Table 1. Summary of the rate constants at 20°C

Carrier gas	k_H/k_2 (torr^{-1})	$10^{-10}\times k_H$ (l mol^{-1} sec^{-1}) this work	Literature values

The Crystal and Molecular Structure of Butein Monohydrate, Isolated from *Dahlia variabilis*

Norio SAITO*, Katsuhiko UENO,** and Yoshio SASADA

Laboratory of Chemistry for Natural Products, Tokyo, Institute of Technology, Ookayama, Meguro-ku, Tokyo, 159

(Received January 5, 1972)

The crystals of butein monohydrate isolated from *Dahlia variabilis* are monoclinic. The unit cell, with dimensions of $a=10.89$, $b=28.88$, $c=4.29$ Å, and $\beta=96.7°$, contains four molecules, and the space group is $P2_1/n$. An approximate structure was obtained by applying the symbolic addition procedure. The structural parameters were refined by the block-diagonal least-squares method, and the final R factor for 1063 observed reflexions was 0.171. In the molecule, the C(7)-C(8) double bond and the C(9)-O(3) carbonyl group take the *s-cis* conformation with respect to the C(8)-C(9) single bond. The A phenyl group and the exocyclic atoms (C(7)~O(3)) are nearly coplanar, and this plane makes a dihedral angle of 15.6° with that of the B phenyl group. The molecules build up a three-dimensional net through the hydrogen bonds. There is also an intramolecular hydrogen bond between O(3) and O(4).

From the experiment of feeding labelled acetate, phenylalanine, cinnamic acid, or shikimic acid to, for example, red cabbage, Neish *et al.*[1] have demonstrated conclusively that the C15-skeleton of flavonoids is biosynthesized through two separate pathways. One of the aromatic rings of flavonoids arises from the malonyl-CoA unit, whereas the other arises from the compounds in the prephenic-acid pathway. The C15-intermediate formed is then modified in various ways to give different types of flavonoid compounds. However, the problem has remained of whether the C15-intermediate is an activated flavanone or chalcone. Grisebach *et al.*[2] observed that ^{14}C-labelled chalcones are incorporated into flavonols, anthocyanins, and isoflavones, supporting the idea that chalcones are C15-intermediates of flavonoids. This is not conclusive, however, because the degree of the incorporation of chalcone is very low.

In order to carry out a study of flavonoids, it is necessary to have more detalied information on the structure of natural chalcones. Price[3] has reported that the chemical structure of butein from a yellow variety of species of dahlia is 3,4,2',4'-tetrahydroxychalcone (I). The present paper will deal with the X-ray structure determination of butein, isolated from the scarlet variety of the species of dahlia, as one of the major components of flavonoids.[4]

Experimental

Crystals were prepared by slow evaporation from a water-acetone mixture. They were yellow-orange needle crystals, showing a predominant (0 0 1) face. The crystal data obtained from the oscillation and Weissenberg photographs are summarized in Table 1. The reflexions were recorded, using Cu-K_α radiation, on equiinclination Weissenberg photographs for 0—3 layers around the c axis and for 0—2 layers around the b. The dimensions of the crystals used were $0.05\times0.03\times0.50$ mm. A total of 2217 independent reflexions were collected, of which 1154 were too weak to be measured, perhaps because of the small size of the crystals. Lorentz, polarization, and Phillips corrections were made as usual, but the absorption correction was omitted. The overall temperature factor obtained at this stage was 4.90 Å^2.

TABLE 1. CRYSTAL DATA OF BUTEIN MONOHYDRATE

Formula:	$C_{15}H_{12}O_5\cdot H_2O$
	M.W.=290.3; $F(0\ 0\ 0)=608$
Monoclinic,	$a=10.89$, $b=28.88$, $c=4.29$Å
	$\beta=96.7°$
Volume of the unit cell,	1393.9Å^3
Density (by flotation)	1.42 g·cm^{-3}
Density (calculated)	1.42 g·cm^{-3}
$Z=4$	
Absent spectra:	$h0l$ when $h+l$ is odd.
	$0k0$ when k is odd.
Space group is	$P2_1/n$

Structure Determination

The symbolic addition procedure[5] was applied for sign-determination. The starting set for applying the Σ_2 formula, in which three phases define the point of origin, is shown in Table 2. The SIGMA program was utilized to list the reflexion triplets with the associated probabilities. The signs of 161 reflexions out of 282 with $|E| \geq 1.5$ were determined, although 53 of them were later found to be incorrect. The E map computed with these signs (A+, B−) has shown the molecular skeleton clearly.

Table 2. Starting set of the symbolic addition procedure

h	k	l	$\|E\|$	Phase or symbol
−10	6	1	4.42	+
− 7	14	1	4.93	+
− 6	11	2	3.71	+
− 8	16	2	4.88	A
− 8	15	1	3.99	B

A structure factor calculation based on this approximate structure gave an R factor of 0.46. Six cycles of block-diagonal matrix least-squares refinement decreased the R to 0.36. The water of crystallization was located from a difference Fourier synthesis.

Four subsequent cycles of refinement reduced the R to 0.23. Anisotropic thermal factors were then introduced; the R dropped to 0.183 after three cycles. At this stage, hydrogen atoms were located by assuming a suitable geometry and were included in the least-squares refinement. The R factor was reduced to 0.171 after three cycles. The atomic scattering factors were taken from International Tables for X-ray

Table 3. Final atomic coordinates and temperature factors

The anisotropic temperature factors are expressed in the form of $\exp\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)\}$

Crystallography.[6] The final atomic coordinates and temperature factors are given in Table 3. The observed structure factors may be obtained on request to the authors. The computations were done on a HITAC 5020E computer with programs written by Tamaichi Ashida.

Discussion

Molecular Shape. The C(7)–C(8) double bond and the C(9)–O(3) carbonyl group are in the *s-cis* conformation with respect to the C(8)–C(9) bond. A similar conformation is observed in 4-methoxychalcone[7] and chalcone[8]. This cisoidal conformation is considered to be more stable than the transoidal conformation, because it does not suffer from repulsion between H(4) and H(6).

P(1), the plane of all atoms; *P*(2), the plane of the ring A; *P*(3), the plane of the exocyclic atoms; *P*(4), the plane of the ring B; *P*(5), the plane of the ring A and exocyclic atoms. The atom with asterisk is not included in the plane evaluation.

Dihedral angle between the planes *P*(2) and *P*(3) 3.7°
P(2) and *P*(4) 15.6°
P(5) and *P*(4) 15.8°

As is shown in Table 4, the two phenyl rings, A and B, are planar within 0.01 Å and 0.05 Å respectively. The C(4), C(7), C(8), C(9), C(10), and O(3) atoms are also on a plane, within deviations of 0.05Å. The A ring and the plane of the exocyclic atoms (C(4)~O(3)) are nearly coplanar (±0.05Å). On the other hand, this plane makes a dihedral angle of 15.8° with the plane of the B phenyl group, mainly because of the rotation around the C(4)–C(7) bond. This may be due to the interaction of H(5) and H(3). The dihedral angle between the A and B rings is 15.6°. Thus, the molecule can be expressed to be nearly planar as a whole.

Bond Lengths and Angles. Figure 1 shows the bond lengths and angles in butein monohydrate calculated from the coordinates in Table 3. The estimated standard deviations are 0.02-0.03Å for the lengths and 1.0-2.0° for the angles. The average bond length in the two benzene rings is 1.39Å. The C–C single bond lengths–C(4)–C(7), 1.44, C(8)–C(9), 1.43, and C(9)–C(10), 1.47Å—are rather shorter than those in 4-methoxy chalcone (1.47, 1.49, and 1.47Å) and in chalcone (1.50,1.48, and 1.46Å). On the other hand, the doble bonds, C(7)–C(8) (1.35Å) and O(3)–C(9) (1.27Å), are somewhat long; the corresponding bond lengths are 1.33 and 1.23Å in 4-methoxychalcone, and 1.32 and 1.20Å in chalcone. The average bond length of four C–O(hydroxy) bonds is 1.37Å, which is slightly shorter

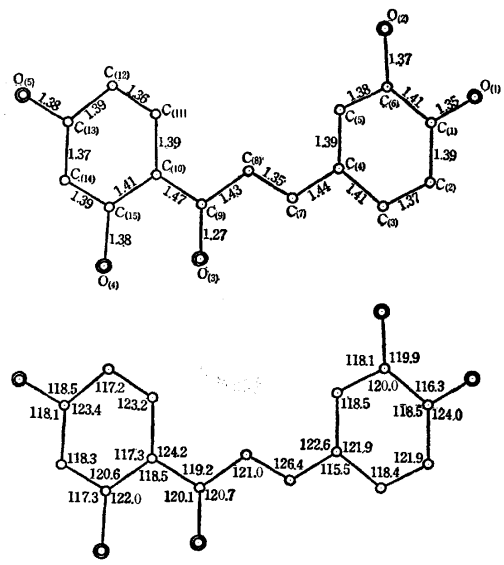

Fig. 1. Bond lengths (Å) and bond angles (°).
◎: O, ○: C

than the usual value. These bond lengths and the approximate planarity of the whole molecule mentioned above suggest that the π-electrons are delocalized, to some extent, throughout the whole molecule. The fluctuation in the C–C–C angles in two benzene rings is rather large. The C(4)–C(7)–C(8) angle is quite large (126.2°); similar values, 127.2° and 127.6°, are found in 4-methoxychalcone and chalcone respectively.

Hydrogen Bond. The O(4)–H hydroxyl group is hydrogen-bonded to the carbonyl oxygen atom, O(3), in the same molecule with the length of 2.49Å. Similar intramolecular hydrogen bonds are observed in obtusifolin (2.53Å),[9] salicylic acid (2.62Å),[10] 4-

Interconversion of Chalcone to Flavanone. As is well known, the chalcone-flavanone transformation is reversible, the equilibrium being shifted in favour of the flavanones.[13] Actually, chalcones can be converted to flavanones upon prolonged heating in an alcoholic acid or alkaline solution. From the structural characteristics revealed in the present study, the interconversion may be considered to occur through the following steps; the rotation of the A ring around the C(9)–C(10) single bond, accompanied by the breaking of the intramolecular hydrogen bond, the rotation of the A ring around the C(8)–C(9) single bond (the *s-trans* conformation (I)), and the cyclization of chalcone into flavanone (III).

The authors wish to thank Dr. Hirotaka Shimanouchi and Mr. Yuji Ohashi for their valuable discussions.

On the Emission Spectra of the Unimolecular Reaction of Methylamine by Electron Impact

Kiyoshi FUKUI, Iwao FUJITA, and Keiji KUWATA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received January 20, 1972)

The emission spectra of the following excited species produced from methylamine by electron impact (the energy of 150 eV) at a low pressure were observed: NH($A^3\Pi - X^3\Sigma$), CN($B^2\Sigma - X^2\Sigma$), CH($A^2\Delta - X^2\Pi$), and H(Balmer series). It was confirmed that the excited species are produced by a unimolecular reaction of methylamine. The replacement by deuterium decreases the production of the excited hydrogen atom from methylamine by about 40%, this supports the idea that the excited hydrogen atom is produced through a superexcited state of methylamine. It was also determined that the production of the excited hydrogen atom of the methyl group was less than that of the amino group by about 20%. This is in contrast to the findings on the mass spectrum of CD_3NH_2, where the peak of $CD_2NH_2^+$ was much higher than that of CD_3NH^+. The NH radical in the $A^3\Pi$ state was produced from methylamine and dimethylamine, while the NH radicals in the $A^3\Pi$ and the $c^1\Pi$ states were produced from ammonia.

The probability of the bond-scission of amines in a mass spectrometer has been studied by Hirota *et al.* In their study, it was pointed out that the skeletal bond-scission of the molecules proceeds through a superexcited state. On the other hand, the contribution of the superexcited state has been verified by a study of the isotope effect on the ionization yield.[2] In the present study, the possibility of superexcited state for the primary process of the bond-scission in a simple amine is examined.

The authors presumed that the contribution of the superexcited state can be verified by observing the Balmer-β line (the transition from $n=4$ to 2 of hydrogen) under electron impact. The excited hydrogen atom should be produced through a state with a higher energy than the ionization potential of methylamine (8.97 eV),[3] *i.e.*, a superexcited state, because the atom is in a higher energy state than 8.97 eV. In addition, the isotope effect on the dissociation of the C–H or the N–H bond in the molecule through such a superexcited state is studied.

Futhermore, the primary process of the ionization and dissociation of methylamine by electron impact will be discussed on the basis of the results on both the emission spectra and the mass spectra. The relative scission probavility of the C–H and N–H bond of methylamine as well as the isotope effect will be examined. It should be noticed that the electronic states of the NH radical produced from ammonia differ from those of hydrazine,[4] methylamine, and dimethylamine This problem will be discussed briefly in the present paper.

Experimental

Methylamine hydrochloride ($CH_3NH_2 \cdot HCl$, $CD_3NH_2 \cdot HCl$, or $CH_3ND_2 \cdot DCl$) was mixed with an excess of CaO which had been dried at 400°C in a vacuum to liberate the methylamine in the gas phase. Furthermore, the purification of methylamine by vacuum distillation was repeated at −90°C until it was about 99.9%, as determined by gas chromatography. In the present experiments, all the reagents used were of a guaranteed grade.

The $CH_3ND_2 \cdot DCl$ was prepared by the exchange of the amino hydrogen with heavy water. For the isotopic analysis of the deuterated methylamines, mass spectrometry was done by means of a Hitachi RMU-5 mass spectrometer. The CH_3ND_2 contained CH_3NDH of 34%, and the CD_3NH_2 contained CD_3NHD of 2% and CD_2HNH_2 of 2%. The mass spectrometry of CD_3NH_2 was done by means of the mass spectrometer in order to estimate the scission probabilities of the C–H bond and the N–H bond in $CD_3NH_2^+$ with the electron impact energy of 80 eV.

The principle of our apparatus for observing the emission spectra in the gas phase was the same as that used by Ogawa *et al.*[5] To observe the emission spectra, a Narumi RM-23 grating monochromator with an EMI-6256B photomultiplier was used. In the present study, the emission spectra from the fragments of methylamine were observed in the region from 300 nm to 500 nm. The dependence of the intensity of the Balmer-β line and the (0, 0) band of NH($A^3\Pi - X^3\Sigma$) on both the electron-beam current (target current) and the pressure in the collision chamber was examined. The pressure was measured by means of an ionization gauge connected to the chamber. The ratio of the intensity of the D_β line (the transition from $n=4$ to 2 of deuterium) to that of the H_β line (the transition from $n=4$ to 2 of hydrogen) was observed (the difference in the wave lengths was about 0.13 nm) by means of a Shimadzu GE-100 grating monochromator of a higher resolution equipped with a photomultiplier.

Results and Discussion

The emission spectrum of the fragments of methylamine in electron impact (energy of electron: 150 eV) is shown in Fig. 1, where the 336 nm and 337 nm bands were assigned to the (0,0) and (1,1) bands of NH($A^3\Pi - X^3\Sigma$) respectively. The sequence of (0,0), (1, 1), (2, 2), (3, 3), and (4, 4) bands of CN($B^2\Sigma -$

5) T. Ogawa, I. Fujita, M. Hatada, and K. Hirota, This Bulletin, **44**, 659 (1971).

$X^2\Sigma$) was found in the region from 388 nm to 385 nm, and the emissions at 431 nm and 432 nm were assigned to the (0, 0) and (2, 2) bands of CH($A^2\Delta - X^2\Pi$) respectively. Moreover the emissions at 397, 410, 434, and 486 nm were assigned to the ε, δ, γ, and β lines of the Balmer series respectively.

The intensity of emission from the excited hydrogen atom and the (0, 0) band of the triplet NH radical depends linearly on the target current, as is shown in Fig. 2, when the pressure in the collision chamber is 5×10^{-4} Torr. This result shows that the excited species are produced by a single collision of the parent molecule with an electron. As is shown in Fig. 3, the intensity of the emission seems to depend linearly on the pressure of the collision chamber when the energy of the electron impact is 150 eV. This result could indicate that the excited species are produced directly through the unimolecular dissociation of the original molecule.

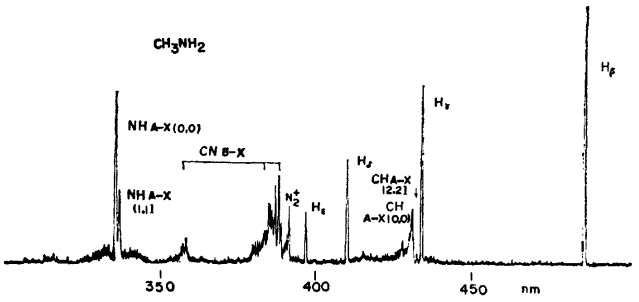

Fig. 1. Emission spectrum observed in electron impact of CH_3NH_2. The energy of electron impact is 150 eV. The pressure of the collision chamber is 3×10^{-4} Torr.

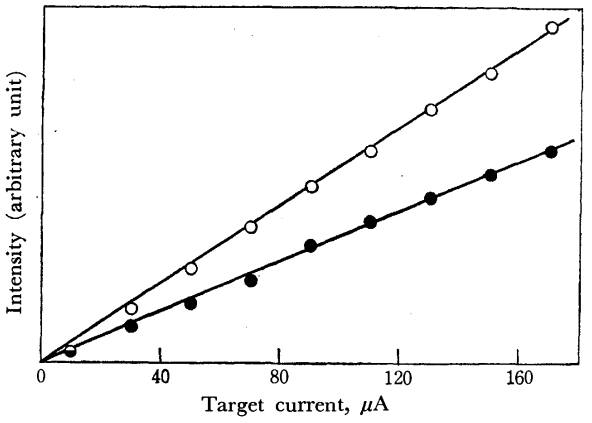

Fig. 2. Dependency of emission intensities on the target current. ○: Balmer-β line. ●: (0, 0) band of NH($A^3\Pi$-$X^3\Sigma$). The energy of electron impact is 150 eV. The pressure of the collision chamber is 5×10^{-4} Torr.

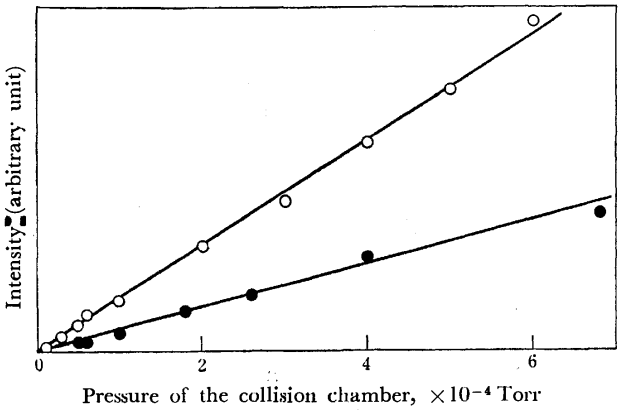

Fig. 3. Dependency of emission intensities on the pressure of the collision chamber. ○: Balmer-β line. ●: (0, 0) band of NH($A^3\Pi$-$X^3\Sigma$). The energy of electron impact is 150 eV. Target current is 100 μA for Balmer-β and 190 μA for NH.

Both results show that the excited species are produced in the primary processes of the decomposition of methylamine. It is also established in the case of NH_3 that the excited hydrogen atom and the triplet NH radical are produced through a unimolecular reaction. It is also presumed that other species, *e.g.*, CH($A^2\Delta$) and CN($B^2\Sigma$), are produced in a similar process.

Putting the pressure, the temperature in the collision chamber, and the radius of methylamine at 10^{-4} Torr, 300°K, and 5×10^{-8} cm[6] respectively, the collision time of an ideal gas for methylamine in the system is about 6×10^{-4} sec. Hence, the excited species emit the photon within a shorter peroid than the collision time under the given conditions.

As for the production of excited hydrogen atoms from methylamine, it may be presumed as a necessary condition that they are produced through a superexcited state of methylamine, because they have a higher energy than the ionization potential of methylamine (8.97 eV). Therefore, the following mechanism of bond-scission for methylamine under electron impact seems reasonable:

$$CH_3NH_2 \xrightarrow{e^-} CH_3NH_2^{**} \begin{cases} \xrightarrow{(1)} H^* + CH_3\dot{N}H \\ \xrightarrow{(2)} H^* + \dot{C}H_2NH_2 \end{cases}$$
$$CH_3NH_2^{**} \xrightarrow{(3)} CH_3NH_2^+ + e^-$$

In this mechanism, H* shows an excited hydrogen atom, and CH_3NH_2** shows a superexcited state of methylamine whose lifetime is known to be shorter than or in the same order as the period of one vibration. A dissociation process, (1) and/or (2), competes with the ionization process (3) from the superexcited state. If the mechanism is valid, substitution by the heavier isotope may decrease the probability of the (1) and (2) dissociations and may increase the probability of ionization (3). By the use of CD_3NH_2 and CH_3ND_2 the isotope effect on the dissociation, and also the ratio of the probability of dissociation (1) to that of (2) can be found.

Letting the observed intensity ratios of D_β to H_β be I_D/I_H for CD_3NH_2 and I_D'/I_H' for CH_3ND_2, the relations:

$$\frac{I_D}{I_H} = \frac{3\lambda\varepsilon_C}{2\varepsilon_N} \quad \text{and} \quad \frac{I'_D}{I'_H} = \frac{2\lambda\varepsilon_N}{3\varepsilon_C}$$

are obtained, where ε_N and ε_C represent the effects of the difference in the kind of bonding on the scission probability— *i.e.*, the N–H and C–H bonds of methylamine, respectively, and λ repersents the isotope

6) This value is a rough one.

effect on the bond-scission. As CH_3NH_2 contained CH_3NDH, and as CD_3NH_2 contained small amounts of CD_3NDH and CD_2HNH_2, in the above calculation corrections of I_D/I_H and I_D'/I_H' were made on the basis of the results of mass spectrometery. Putting the corrected values of 0.7 and 0.5 into I_D/I_H and I_D'/I_H' respectively, $\varepsilon_C/\varepsilon_N$ and λ were determined to be 0.8 and 0.6 respectively. From these results, the contribution of the (2) pathway to the production of the excited hydrogen atom is less than that of the (1) pathway by about 20% for each bond, and the isotope effect of deuteration on the dissociation process is shown to be a decrease of about 40%.

This isotope effect is consistent with the decrease in the (1) and (2) dissociations by the replacement by a heavier isotope, as is to be expected from the above mechanism including the superexcited state.

Contrary to the dissociation process of the neutral methylamine, the $CH_3NH^+/CH_3NH_2^+$ ratio of 0.2 was smaller than the ratio $CH_2NH_2^+/CH_3NH_2^+$ of 2.4 in the mass spectrum.

$$CH_3NH_2^+ \begin{cases} \nearrow CH_3NH^+ + H \\ \searrow CH_2NH_2^+ + H \end{cases}$$

However, we can not say which of bonds, the C–H bond or the N–H bond, in $CH_3NH_2^+$ dissociates more easily, because there are two possibilities: the scission of the C–H bond may occur more easily than the N–H bond, and the CH_3NH^+ may decompose further and so be little detected. It should be noticed that, in the decomposition of the positive ion, the hydrogen atom in the ground state is, in view of the energy, more favorable than that in the excited state. Thus, the hydrogen atom produced from $CH_3NH_2^+$ may contribute little to the emission.

The similar facts that the CH_3O^+/CH_3OH^+ and CH_2OH^+/CH_3OH^+ ratios were 0.2 and 1.6[7] respectively in mass spectrum (electron imapct energy: 80eV) should also be noticed. $\varepsilon_C/\varepsilon_O$ and λ had the same values of 0.8 in the case of CH_3OH[8].

Last, the production of the NH radical from methylamine may be discussed in relation to that from ammonia and dimethylamine. The emission spectra of the NH radical produced from methylamine and ammonia by electron impact are shown in Fig.4. Both the $c^1\Pi$ and $A^3\Pi$ state of the NH radical appeared in the emission spectrum of ammonia, while only the $A^3\Pi$ state of the NH radical appeared in those of methylamine and dimethylamine in the present study.

In a former study,[9] the NH radical in the $A^3\Pi$ state is not produced from ammonia by photon impact with energies up to about 11.87 eV (λ=105 nm), a value which is higher than the ionization potential of ammonia (10.15 eV).[10] Hence, if the $A^3\Pi$ state of the NH radical is supposed to be produced from ammonia in a triplet excited state, the ratio of the emission intensity of the $A^3\Pi$ state to that of the $c^1\Pi$ state should depend on the energy of the impact electron,

Fig. 4. The spectra of NH (the energy of electron impact: 150 eV). a) CH_3NH_2. b) NH_3. An arrow (↓) at 323 nm indicates R-head of (0, 0) band of NH($c^1\Pi$-$a^1\Delta$). Sharp bands at 336 and 337 nm are (0, 0) and (1, 1) bands of NH($A^3\Pi$-$X^3\Sigma$).

because the spin-forbidden transition is possible in the case of excitation by an electron impact with a lower energy. However, in the present study it did not depend on the impact energy in the region from 40 eV to 150 eV. Therefore, it can be supposed that the $A^3\Pi$ state of the NH radical is produced only through a superexcited state of ammonia with a higher energy than 11.87 eV.

The fact that the electronic state of the NH radical produced from methylamine and dimethylamine as well as hydrazine[4] differs from that produced from ammonia by electron impact can be explained by the spin conservation rule and redistribution of the excitation energy in the parent molecule. In addition, the type of the decomposition of the substituent group to ammonia probably determines the electronic state of the NH radical produced from the molecules.

In the present study, it can not be mentioned whether or not the NH($A^3\Pi$), CH($A^2\Delta$), and CN($B^2\Sigma$) radicals are produced through a superexcited state of methylamine, because the energy of these species does not exceed the ionization potential of methylamine and because the threshold energy which is needed to form the excited species is not known.

The authors would like to express their gratitude to Professors Shigero Ikeda and Yu Yokoyama for use of their Shimadzu GE-100 monochromator. The authors also wish to thank Dr Motoyoshi Hatada for his technical advice as constructing the collision chamber and Professor Kozo Hirota for his encouragement throughout this work.

The Normal Magneto-Optical Rotatory Dispersion and the Magnetic Moment of Benzene

Yoshiya TAKENOSHITA

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka

(Received February 21, 1972)

The magneto-optical rotatory dispersion in the absorptionless region has been investigated with liquid benzene, and the related magnetic moment has been discussed theoretically. It has been concluded that the main contribution to the magneto-optical rotatory dispersion consists of an A term through the $^1A_{1g}\rightarrow{}^1E_{1u}$ transition and that the contribution from σ-electrons is never negligible. The magnetic moment in the excited state, $^1E_{1u}$, of benzene has been obtained as $-1.72\,\beta$ (Bohr magneton), which is about 2 or 4 times greater than the value of $-1.0\,\beta$ calculated with the FEN-model or the value of $-0.396\,\beta$ calculated by the LCAO-MO method.

The anomalous magneto-optical rotatory dispersion (MORD) and the magnetic circular dichroism (MCD) of porphyrine and other organic compounds have been studied by Shashoua and others.[1-3] The MCD's of benzene, triphenylene and coronene have been studied by Stephens *et al.*,[4] and the magnetic moment has been discussed in detail with triphenylene and coronene. No discussion has been made with benzene, however, since they did not succeed in observing the MCD of benzene in the region below 2300 Å because of the limitations of these experiments.

However, it could be possible to discuss the magnetic properties of benzene in the excited states if the normal magneto-optical rotatory dispersion (or the normal Faraday effect in an absorptionless region) would be simple enough to analyze. In 1955, Garner *et al.*[5] observed the normal MORD of liquid benzene. However, they had no intention of studying the magnetic properties of benzene itself, but those of several solute compounds dissolved in benzene. Already, in the period between 1896 and 1906, Perkin had made an extensive study of the Faraday effects of various organic compounds for the Na-D line.[6] Although his excellent experimental data have never been examined from the viewpoint of modern molecular physics, π-electrons may be expected to make an important contribution to the magnetic properties of benzene. No direct information has been obtained so far concerning the magnetic properties of benzene in the excited states.

We will try here to analyze the normal MORD of benzene and estimate its magnetic moment. The estimated value will be compared with the theoretical one, which will also be developed in this paper.

Theoretical Results of MORD

The contribution of the $a\rightarrow j$ transition to the normal MORD of isotropic molecules in a longitudinal magnetic field, H, along the $+z$ axis may be expressed as follows:[2,7,8]

$$[\phi(a\rightarrow j)]_M = -\frac{24NH}{\hbar c}\left[\frac{2\nu_{ja}\nu^2}{h(\nu_{ja}^2-\nu^2)^2}A(a\rightarrow j) + \frac{\nu^2}{\nu_{ja}^2-\nu^2}\{B(a\rightarrow j)+C(a\rightarrow j)/kT\}\right], \quad (1)$$

where $[\phi]_M$ is a molar magnetic rotation defined for natural optical activity,[9] where N is the Avogadro number, and where $h\nu_{ja}=W_j-W_a$ is the energy difference between the a and j states.

Assuming a random orientation of rotating anisotropic molecules, one obtains the Faraday parameters, A, B, and C, as follows:

$$A(a\rightarrow j) = (2d_a)^{-1}\sum[(j|\boldsymbol{\mu}|j)-(a|\boldsymbol{\mu}|a)] \times \mathrm{Im}\{(a|\boldsymbol{m}|j)\times(j|\boldsymbol{m}|a)\}, \quad (2a)$$

$$B(a\rightarrow j) = (2d_a)^{-1}\sum \mathrm{Im}\{\sum_{k\neq a}(k|\boldsymbol{\mu}|a)\cdot(a|\boldsymbol{m}|j) \times (j|\boldsymbol{m}|k)/(W_k-W_a)+\sum_{k\neq j}(j|\boldsymbol{\mu}|k)\cdot(a|\boldsymbol{m}|j) \times (k|\boldsymbol{m}|a)/(W_j-W_k)\}, \quad (2b)$$

$$C(a\rightarrow j) = (2d_a)^{-1}\sum(a|\boldsymbol{\mu}|a)\cdot\mathrm{Im}\{(a|\boldsymbol{m}|j)\times(j|\boldsymbol{m}|a)\}, \quad (2c)$$

where d_a is the degeneracy of the ground state, a, (the summations are taken over all the transitions degenerate with $a\rightarrow j$), where $\boldsymbol{m}$ and $\boldsymbol{\mu}$ $(=(\beta/\hbar)\sum(\boldsymbol{l}_i+\boldsymbol{s}_i))$ are the electric and magnetic dipole operators respectively, and where β stands for a Bohr magneton. The A, B, and C terms of Eq. (1) arise, respectively, from the Zeeman splitting of $a\rightarrow j$, the mixing of a and j with other states, k, by means of the magnetic field, and the change in the populations of the component levels of the ground state, a, due to its Zeeman splitting. Hence, A is different from zero only when a or j is degenerate, and C is different from zero only when a is degenerate.

If an imaginary term, $\mathrm{Im}\{(a|\boldsymbol{m}|j)\times(j|\boldsymbol{m}|a)\}$, in Eqs. (2a) and (2c) can be defined with a real dipole strength, D, one obtained the following:

$$D(a\rightarrow j) = (d_a)^{-1}|(a|\boldsymbol{m}|j)|^2 = 2.126\times10^6(d_a)^{-1}f_{ja}/\omega_{ja} \text{ (square of the Debye unit)}, \quad (3)$$

9) Formerly, molar Verdet's constant $V_M(=-600[\phi]_M/H)$ was used as a technical term, but recently Stephens and coworkers have been using this term.

where f_{ja} is an oscillator strength[10] and where ω_{ja} is the energy difference between j and a in cm^{-1}. Accordingly, the magnetic moment of a diamagnetic organic molecules can be estimated as follows:

$$-\mu = 2A/D, \tag{4}$$

since $(a|\boldsymbol{\mu}|a)=0$, and since, then, $C=0$.

However, the normal MORD for an arbitary wave number in the absorptionless region is naturally expressed as the summation of $[\phi(a\rightarrow j)]_M$ over j. In a system with only one allowed electronic transition as benzene, the MORD in the absorptionless region is given as follows:

$$[\phi(\omega)]_M = -\frac{24NH}{c\hbar}\frac{2\omega^2}{c\hbar(\omega_{ja}^2-\omega^2)^2}A(a\rightarrow j) + \sum_{k\neq j}[\phi(a\rightarrow j)]_M, \tag{5}$$

where k consists of the excited states with π and/or σ excited electrons. As the first and second terms in Eq. (1) are proportional to ω^2, the last part in Eq. (5) can be regarded for $\omega_{ka}\gg\omega$ $(k>j)$ as:

$$\sum_{k>j}[\phi(a\rightarrow k)]_M = E\omega^2, \tag{6}$$

where E is constant and is expressed as $\sum_{k>j}2A(a\rightarrow j)/h\omega_{ka}{}^3$ and $\sum_{k>j}(B(a\rightarrow k)+C(a\rightarrow k)/\boldsymbol{k}T)/\omega_{ka}{}^2$. Then, one can estimate the values of the A term and the μ on the basis of an analysis of the normal MORD.

Magnetic Moment and Orbital Angular Momentum

The magnetic moment and electronic orbital angular momentum make discussed in 1966 by Stephens *et al.*[2] and in 1968 by Bishop and Dingle.[11] Now, the magnetic moment of benzene will be discussed. For convenience, we will take all the molecular orbital functions of benzene as real. The benzene is a regular hexagon molecule with a diamagnetic ground state, $^1A_{1g}$. The angular momentum vector operator can have only one non-zero component $(^1E_{1u}x|L_z|^1E_{1u}y)$ in excited states which involve two allowed electric dipole transitions, $(^1A_{1g}|m_x|^1E_{1u}x)$ and $(^1A_{1g}|m_y|^1E_{1u}y)$.[12] Therefore, the magnetic moment of the excited state, $^1E_{1u}$, may be defined by:

$$\mu = -(i\beta/\hbar)(^1E_{1u}x|L_z|^1E_{1u}y), \tag{7}$$

where z is the principal molecular axis; x and y, the mean basis functions transforming like the two coordinates, x and y respectively, and $\boldsymbol{L}(=\sum\boldsymbol{l}_i)$ is a total orbital angular momentum operator.

In the singly-excited configuration approximation of the MO theory, the $^1E_{1u}$ state $(e_{1g}{}^3, e_{2u})$ of benxene[13] is:

$$|^1E_{1u}x) = \frac{1}{2}[\{y\bar{y}x\bar{\xi}\}+\{y\bar{y}\xi\bar{x}\}+\{y\bar{\eta}x\bar{x}\}+\{\eta\bar{y}x\bar{x}\}],$$
$$|^1E_{1u}y) = \frac{1}{2}[\{y\bar{y}x\bar{\eta}\}+\{y\bar{y}\eta\bar{x}\}+\{y\bar{\xi}x\bar{x}\}+\{\xi\bar{y}x\bar{x}\}], \tag{8}$$

where x and y denote e_{1g}, ξ and η e_{2u} MO's, and where the braces symbolize anti-symmetrization. By substituting Eq. (8) into Eq. (7), one obtains:

$$\mu = -(i\beta/\hbar)[(\xi|l_z|\eta) - (x|l_z|y)]. \tag{9}$$

The calculation of the magnetic moments resolves itself into the problem of the estimation of the angular momentum of each electronic molecular orbital. An electronic angular momentum is generally equal to zero for non-linear molecules, but equal to a non-zero value, $\zeta_e\hbar$,[14] corresponding to a rotation around the molecular axis, for planar cyclic molecules, which are deemed intermediate between highly symmetric molecules and less symmetrical or asymmetrical ones. In the FEN model,[15] the wave functions of the degenerate states, $\psi_n{}^+$ and $\psi_n{}^-$ with quantum numbers, $\pm|n|$, are $a_{Bn}\cos(k_n, x)$ and $a_{Bn}\sin(k_n, y)$ respectively, where $a_{Bn}=\sqrt{2/L}$ for $n\geq 1$ or $1/\sqrt{2}$ for $n=0$, and where $k_n=2n\pi/L$. The x, y, ξ, and η in Eqs. (6) and (7) correspond to $n=1$, -1, 2, and -2 respectively. The matrix elements of l_z are equal to $(\psi_n{}^+|l_z|\psi_n{}^-)=-in\hbar$. In the LCAO-MO treatment, on the other hand, a new problem occurs when one operates l_z on each atomic orbital. If the atomic orbitals, χ_a, are expressed with $2p$-Slater AO's and if the molecular orbitals are taken as $\psi_k=\sum C_{ka}\chi_a$, the matrix elements of l_z are given as:

$$(\psi_2|l_z|\psi_1) = \sum_{a,b}C_{1a}C_{2b}(\chi_b|l_z|\chi_a). \tag{10}$$

If the origin of l_z is then transferred from the center of the molecular skeleton to the middle point, P, of a

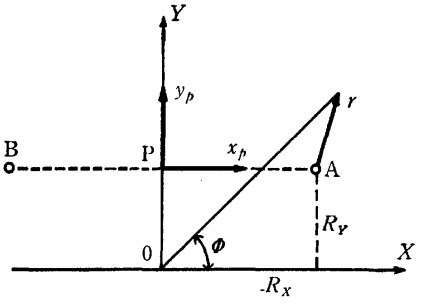

Fig. 1. A relation of an angular momentum operator with the coordinates.

bond between the A and B nuclei, as is shown in Fig. 1, one obtains:

$$l_z = l_z^p + i\hbar R_Y(\partial/\partial x_p). \tag{11}$$

Since $(\chi_b|l_z^p|\chi_a)=0$, one obtains:

$$(\chi_b|l_z|x_a) = i\hbar R_Y(\chi_b|\partial/\partial x_p|\chi_a). \tag{12}$$

The $R_Y\partial/\partial x_p$ operator corresponds to an infinitesimal rotation, $R_Y\delta\Phi$, and an effective component of l_z in

the multicenter field (see Appendix); therefore, it may express an electronic motion on a circle with a radius, R_Y, through the middle points between the A and B nuclei. For benzene, two circles are possible, since $R_Y=0$ on a connecting line through the point of origin.

If the coordinate system (x_p, y_p, z_p) is transformed to the elliptic coordinates (ξ, η, φ), one obtains:

$$R_Y\frac{\partial}{\partial x_p}|\chi_a) = \frac{1}{2}Z_{eff}R_Y\frac{\xi\eta-1}{\xi-\eta}|\chi_a), \quad (13)$$

and then:

$$(\chi_b|l_z|\chi_a) = \frac{\hbar}{i}\frac{p^2}{10}\frac{R_Y}{R_X}\exp(-p)\left(1+p+\frac{p^2}{3}\right), \quad (14)$$

where $p=Z_{eff}R_{ab}/2$ in atomic units.

Consequently, we can estimate and compare both the magnetic moments calculated experimentally from Eq. (6) and those calculated theoretically from Eqs. (9), (10), and (14) for some planar molecules. We shall discuss a normal MORD and a magnetic moment in the next section.

Results and Discussion

The normal MORD of liquid benzene, which is observed at 10°C with the same apparatus as was described in one of the present author's previous paper,[16] is shown in Fig. 2, which also gives the result estimated from the Verdet constant by Garner *et al.*[5] assuming a temperature of 20°C.

Assuming the contribution from only one electronic transition to the normal MORD and modifying Eqs. (1), (5), and (6), one can obtain:

$$\omega^2 = \omega_{ja}^2 - (A_0+B_0)^{1/2}\omega/[\phi]_M^{1/2}, \quad (15)$$

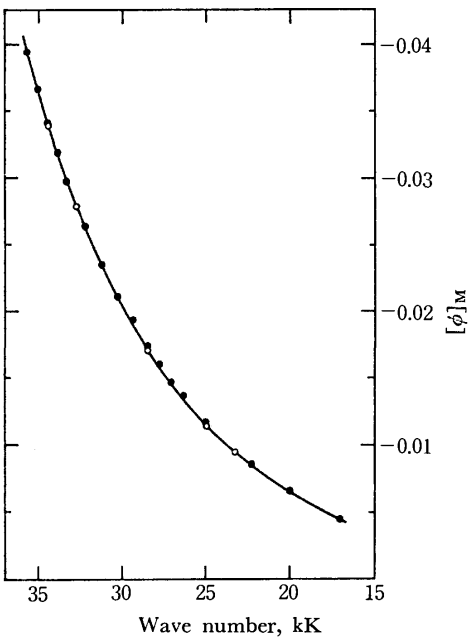

Fig. 2. The MORD (deg·l/m·mol·gauss) of benzene; dark circles are taken in this work and white ones show the data by Garner *et al.* (Ref. 5).

16) Y. Takenoshita and Y. Kanda, This Bulletin, **44**, 2293 (1971).

$$\omega^2 = \omega_{ja}^2 - A_0^{1/2}\omega/([\phi]_M - E\omega^2)^{1/2}, \quad (16)$$

where $A_0=21.346\times 2\omega_{ja}|A(a\rightarrow j)|$, where $B_0=21.346\times B(a\rightarrow j)(\omega_{ja}{}^2-\omega^2)+\sum_{k>j}[\phi(a\rightarrow k)]_M(\omega_{ja}{}^2-\omega^2)^2$, where ω is expressed in cm^{-1}, and where the factor 21.346 is the value of $(24N/c\hbar)$ when m stands for the Debye unit, and μ, the Bohr magneton.

From Eq. (15), it may be seen that the curve of $\omega/[\phi]_M^{1/2}$ *vs.* ω^2 is nearly a straight line; it is shown in Fig. 3(a). The deviation, increasing with a decrease in the ω^2 value from the straight line, shows that no terms except for $A(a\rightarrow j)$ are always completely negligible because of the behavior of B_0. A tangent, $A_0^{1/2}$, of the line becomes apparently greater, so the extrapolated resonance absorption, 59,500 cm^{-1}, may be assigned to the $^1A_{1g}\rightarrow{}^1E_{1u}$ transition (54,500 cm^{-1}).[17] It should, however, be stressed that the contributions of σ-electrons to the MORD are never negligible.

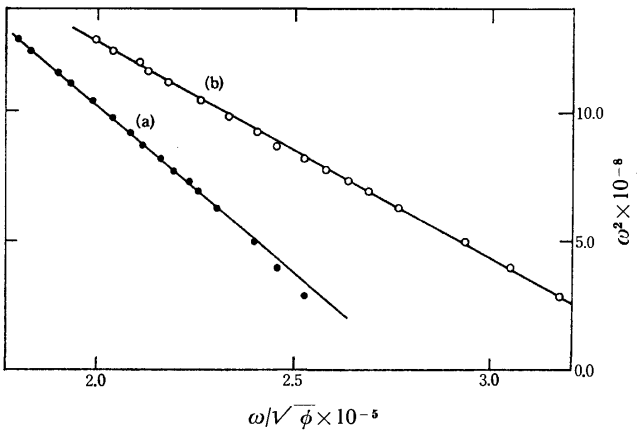

Fig. 3. Diagrams plotted (*a*) $\omega/([\phi]_M)^{1/2}$ and (*b*) $\omega/([\phi]_M - E\omega^2)^{1/2}$ *vs.* ω^2 for benzene.

According to the method of Perkin,[6] we can approximately estimate the ratio of the contribution by π and σ electrons. Perkin reported that, from the results of the Faraday effects of various organic compounds, the molecular rotation can be assumed to consist of rotations of constituent atoms. For example, the molecular rotation of the benzene skeleton, $[C_6H_6{}^{6+}]_M^D$, is proportional to the difference, $[C_6H_{12}]_M^D-6[H^+]^D=4.140$,[18] and the ratio of the contributions of the π and σ electrons is approximately equal to 7 : 4. Then, let us assume that the contributions of the electrons correspond to the E term in Eqs. (6) and (16). When $E=5.74\times10^{-12}$ for $E\omega_D^2=0.165\times10^{-2}$ (deg·l/m·mol·gauss), the curve of $\omega/([\phi]_M-E\omega^2)^{1/2}$ *vs.* ω^2 becomes almost straight, as is shown in Fig. 3(b). Since the straightness of the curve is very good, it is confirmed that the normal MORD of benzene has a large A term with one transition and that the other

17) H. B. Klevens and J. R. Platt, *J. Chem. Phys.*, **17**, 470 (1949).

18) $[C_6H_6]_M^D=11.284$, $[C_6H_{12}]_M^D=5.664$ and $[H]^D=0.254$. See Ref. 6. These values are defined with a dimensionless term, $V_M=[V]_M d_w/M_w r_w$, where r_w, d_w and M_w are the magnetic rotation per cm per gauss and the density and the molecular weight of water respectively. The MORD $[\phi]_M$ values are obtained through the multiplication of a factor, $-M_w r_w/600d_w=0.0003938$, to V_M.

TABLE 1. FARADAY PARAMETERS OF BENZENE

A_0 $\times 10^{-7}$	Res. abs. cm^{-1}	A $(d^2\beta)$[a]	D (d^2)[a]	Magnetic moment (β)[a]		
				Exp.	FEN	LCAO-MO
7.04	54280	30.4	35.3[b]	−1.72	−1.0	−0.396

a) d is expressed in Debye unit and β is a Bohr magneton.
b) Calculated from $f=0.94$ and $\omega=56{,}300\ cm^{-1}$ in Ref. 17.

terms are negligible in $([\phi]_M - E\omega^2)$. The extrapolated resonance absorption 54,280 cm^{-1}, is closer to 54,500 cm^{-1} than to the 59,500 cm^{-1} obtained by Eq. (15); therefore, the transition may be assigned to $^1A_{1g} \rightarrow {}^1E_{1u}$. The normal MORD of benzene, certainly, depends mainly on the π electronic structures. According to Stephens *et al.*,[4] this can naturally be predicted for coronene, which has a much greater value of the circular dichroism of the $^1A_{1g} \rightarrow {}^1E_{1u}$ transition than that of the $^1A_{1g} \rightarrow {}^1B_{2u}$ or $^1B_{1u}$ transition.

Therefore, the magnetic moment is given as -1.72β, with an f value of 0.94[19] (Table 1), and may be assigned to the excited degenerate state, $^1E_{1u}$. This observed moment is rather greater than the values of -1.0β for the FEN model or -0.396β for LCAO-MO when $r_{CC}=1.39$ Å, $Z_{eff}=3.25$, and the molecular orbitals without zero-differential overlap approximation[20] are used. This means that the observed magnitude of the A term is much greater than the theoretical values. Therefore, this probably means that the ratio, 7.144/11.284, of the contributions to the MORD by π-electrons used is too great, or that the observed A value consists of not only $A(^1A_{1g} \rightarrow {}^1E_{1u})$ but also of some terms for the other transitions. However, it is confirmed at last that there is a large A value. The existence of the large A value proves that the absorption band at 54,500 cm^{-1} has two symmetrical doublet transition moments, $(0|m_x|x)$ and $(0|m_y|y)$; this supports the conventional assignment of the β-band to $^1E_{1u}$.[4,12,21,22] It may be predicted that both the abnormal MORD and the MCD of the $^1A_{1g} \rightarrow {}^1E_{1u}$ transition of benzene may be assigned to the positive A type in Stephens' classification[2] or to the III type of Shashousa's[1].

It should be noted that the main component of the MORD is estimated experimentally in spite of difficulties in analyzing normal MORD. We shall not discuss further the magnetic properties of benzene, especially its magnetic moment, until the MCD or the abnormal MORD of benzene has been measured in its absorption regions. The normal MORD of benzene is never simple to analyze in its structure since a normal MORD depends on many transitions.

Finally, it should be noted that the MORD in the S-T absorptional region of benzene[23] has never been observed either with or without O_2-gases.

The author would like to thank Professor Yoshiya Kanda of his laboratory for his guidance, and Professor On Matsumura and Professor Yoshio Shibuya of the Department of Physics, Kyushu University, for providing him with the electric magnet.

Appendix

According to Bishop and Dingle, an electronic angular momentum operator[11] in the multicenter field of molecular orbitals has an effective component to atomic orbital, $|\chi_a)$ as follows:

$$\partial/\partial\phi\,|\chi_a) = -\frac{1}{2}Z_a \sin\theta_a(R_X \sin\varphi_a - R_Y \cos\varphi_a)\,|\chi_a), \tag{A.1}$$

where r_a, θ_a, and φ_a denote the polar coordinates at the nuclei A; the other notations are shown in Fig. 4. This

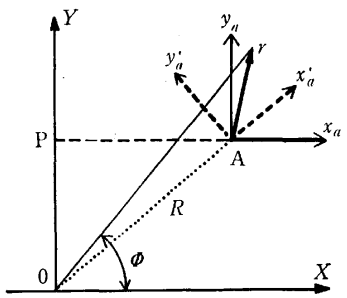

Fig. 4. A relation of the coordinates x_a and y_a by Bishop and Dingle with the x_a' and y_a' by Stephens *et al.*

can be easily proved to coincide with the operator reported by Stephens *et al.*[2] In Eq. (A. 1), as $\sin\theta_a \cos\varphi_a$ and $\sin\theta_a \sin\varphi_a$ can be put at x_a/r_a and y_a/r_a respectively, one obtaines:

$$\frac{\partial}{\partial\phi}|\chi_a) = -\frac{Z_a}{2r_a}(R_X y_a - R_Y x_a)\,|\chi_a) = R\frac{\partial}{\partial y_a'}|\chi_a). \tag{A.2}$$

If the atomic orbitals are expressed with Slater orbitals, which have no factor for φ in the confocal elliptic coordinate system, the integration of Eq. (A. 2) for φ agreeds with Eq. (13). In the multicenter field of molecular orbitals, therefore, the effective component of l_z may be obtained with Eq. (12).

The Vibrational Spectra of Water of Crystallization in Barium Chlorate Monohydrate, Calcium Sulfate Dihydrate and Copper Chloride Dihydrate Crystals

Kunio FUKUSHIMA and Tsutomu YANAGIDA

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka

(Received October 22, 1971)

Infrared spectra of water of crystallization and heavy water of crystallization were mesasured for $Ba(ClO_3)_2 \cdot H_2O$, $CaSO_4 \cdot 2H_2O$, $CuCl_2 \cdot 2H_2O$, $Ba(ClO_3)_2 \cdot D_2O$, $CaSO_4 \cdot 2D_2O$, and $CuCl_2 \cdot 2D_2O$, in which the divalent metal ion lies on the bisector line of H–O–H angle or D–O–D angle. From a comparison of the spectra, assignment of the infrared absorption bands was made for the rotational and the translational vibrations of the water of crystallization.

Water of crystallization is classified into several types by the mode of bonding with surrounding atoms and ions.[1] It was reported[2-4] that the optically active lattice vibration frequencies associated with water of crystallization change sensitively with the change of its state of bonding. In the present study, barium chlorate monohydrate. $Ba(ClO_3)_2 \cdot 2H_2O$, calcium sulfate dihydrate, $CaSO_4 \cdot 2H_2O$, copper chloride dihydrate, $CuCl_2 \cdot 2H_2O$ (type D in Chidambaram's classification[1]) were chosen as representatives of the crystals in which water of crystallization coordinates with a divalent metal ion on the bisector line of H–O–H angle,[5-7] and their bands due to water of crystallization were measured and assigned on the basis of the spectral change on deuteration.

Experimental

The sample were obtained by recrystallization of $Ba(ClO_3)_2 \cdot H_2O$ of guaranteed grade, Kanto Chemical Co., Inc., $CaSO_4 \cdot 2H_2O$ of guaranteed grade, Wako Pure Chemical Industries Ltd., and $CuCl_2 \cdot 2H_2O$ of guaranteed grade, Kanto Chemical Co., Inc. from their aqueous solutions. The deuterates of $Ba(ClO_3)_2 \cdot 2H_2O$ and $CaSO_4 \cdot 2H_2O$ were prepared as residues obtained by vacuum distillation of their heavy water solutions. The duterate of $CuCl_2 \cdot 2H_2O$ was obtained by exposure of $CuCl_2$ to D_2O vapor overnight in a small sealed bottle.

IR spectra in the region 4000—400 cm^{-1} were measured with the Nujol mulls of $Ba(ClO_3)_2 \cdot H_2O$, $CaSO_4 \cdot 2H_2O$, and their deuterates, and those of $CuCl_2 \cdot 2H_2O$ and its deuterate with the Nujol mulls placed between KBr plates covered with thin polyethylene sheets to avoid reaction of the samples with KBr plates. Far IR spectra (400—30 cm^{-1}) of $CaSO_4 \cdot 2H_2O$, $CuCl_2 \cdot 2H_2O$ and their deuterates were measured with their Nujol mulls placed between two polyethylene plates of 2 mm thickness, while those of $Ba(ClO_3)_2 \cdot H_2O$ and its deuterate were measured with a solid paraffin-sample mixture prepared by dispersing the sample powder into molten paraffin and solidifying the mixture cast on a polyethylene plate. The spectra are shown in Figs. 1—6.

Infrared spectra of $CaSO_4 \cdot 2H_2O$ above 300 cm^{-1} have been reported by many investigators.[8-10] The spectra of $CaSO_4 \cdot 2H_2O$ above 300 cm^{-1} in Figs. 3 and 4 are given mainly for the sake of comparison with those of its deuterate. A Hitachi EPI-G3 Infrared Spectrophotometer and a FIS-3 Far Infrared Spectrometer were used.

Discussion

The relative intensities of O—H stretching and H-O-H bending bands are much weaker than those of O-D stretching and D-O-D bending bands as shown in Figs. 1, 3, and 5. This indicates that the major component of each deuterate is $Ba(ClO_3)_2 \cdot D_2O$ $CaSO_4 \cdot 2D_2O$, or $CuCl_2 \cdot 2D_2O$.

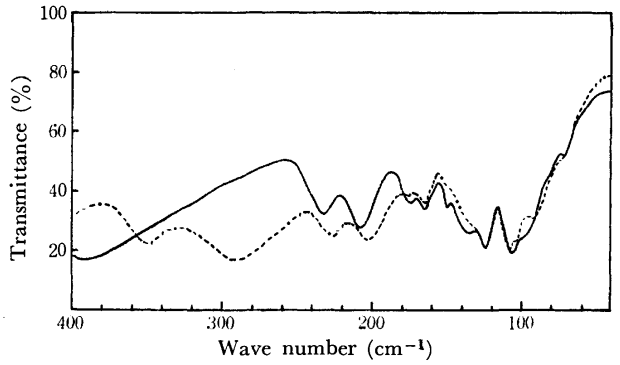

Fig. 2. Far infrared spectra of barium chlorate monohydrate dispersed into solid paraffin (solid line) and its deuterate dispersed into solid paraffin (broken line).

As shown in Fig. 6, the band of deuterated copper chloride dihydrate at 223 cm^{-1} corresponds to that of $CuCl_2 \cdot 2H_2O$ at 243 cm^{-1}. The asymmetrical band of $CuCl_2 \cdot 2H_2O$ at 298 cm^{-1} is interpreted to be composed of two overlapped bands at about 310 cm^{-1} and at 298 cm^{-1} from the fact that two bands appear at 295 cm^{-1} and 255 cm^{-1} for the deuterate and from a comparison of 310/255 value with the ν_H/ν_D values in Table 2. Similarly, the band of $CaSO_4 \cdot 2H_2O$ at 306 cm^{-1} corresponds to that of the deuterate at 259 cm^{-1}.

Comparing the spectra of the crystals with those of their deuterates, a correspondence can be set up between the observed frequencies of the former and of the latter as shown in Table 1. For $Ba(ClO_3)_2.2H_2O$,

TABLE 2. CALCULATED MOMENTS OF INERTIA OF H_2O AND D_2O MOLECULES IN $CaSO_4 \cdot 2H_2O$ AND $CuCl_2 \cdot 2H_2O$ AND THEIR DEUTERATES[a] (IN 10^{-40} g·cm²)

	I_A	I_B	I_C	$\sqrt{I_{A,D_2O}/I_{A,H_2O}}$	$\sqrt{I_{B,D_2O}/I_{B,H_2O}}$	$\sqrt{I_{C,D_2O}/I_{C,H_2O}}$
$CaSO_4 \cdot 2H_2O$	1.067	2.089	3.157	1.34	1.41	1.39
$CaSO_4 \cdot 2D_2O$	1.919	4.174	6.093			
$CuCl_2 \cdot 2H_2O$	0.922	1.970	2.892	1.34	1.41	1.39
$CuCl_2 \cdot 2D_2O$	1.658	3.936	5.594			

a) The moments of inertia in the table were calculated using the bond length and bond angle of water of crystallization.[5,6] The same bond length and bond angle as H_2O molecule in the crystals were assumed for D_2O molecule in the deuterate crystals.

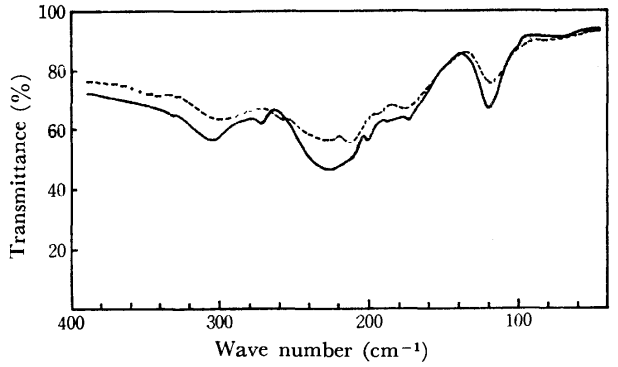

Fig. 4. Far infrared spectra of calcium sulfate dihydrate in Nujol mull (solid line) and its deuterate in Nujol mull (broken line).

Prask and Boutin observed[11] neutron scattering peak frequencies of 458 cm^{-1}, 390 cm^{-1}, 318 cm^{-1}, 238 cm^{-1}, 212 cm^{-1}, 149 cm^{-1}, 81 cm^{-1}, and 67 cm^{-1} as those due to water of crystallization. The observed IR band frquencies, which were found to shift on deuteration, correspond to the frequencies observed by Prask and Boutin except for the frequencies 318 cm^{-1}, 81 cm^{-1}, and 67 cm^{-1}. As shown in Table 1, the ν_H/ν_D values of 1.29 and 1.34 for the bands at 451 cm^{-1} and 390 cm^{-1}, respectively, lead to an assignment of the bands to the rotational vibrations of crystallization, while those of 1.03 and 1.02 for the bands at 233 cm^{-1} and 207 cm^{-1}, respectively, lead to an assignment of the bands to the translational vibartions of water of crystallization.

In the case of $CaSO_4 \cdot 2H_2O$ and $CuCl_2 \cdot 2H_2O$, the

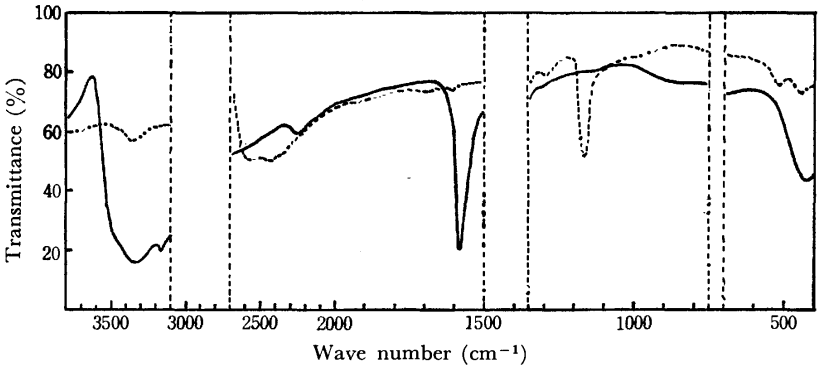

Fig. 5. Infrared spectra of copper chloride dihydrate in Nujol mull (solid line) and its deuterate in Nujol mull (broken line).

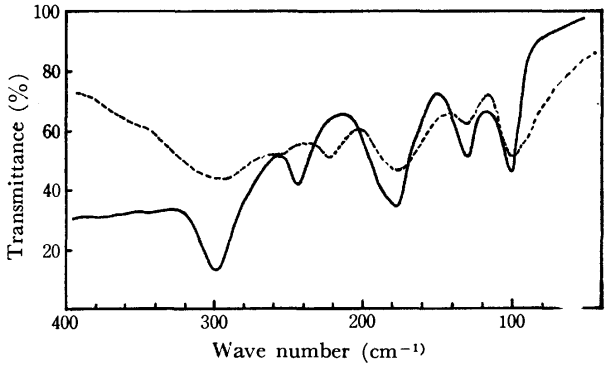

Fig. 6. Far infrared spectra of copper chloride dihydrate in Nujol mull (solid line) and its deuterate in Nujol mull (broken line).

bands at 576 cm^{-1} 460 cm^{-1}, and 430 cm^{-1}, are assigned to the rotational vibrations of water of crystallization on the basis of ν_H/ν_D values of 1.33, 1.33, and 1.36, respectively. The values are in accordance with the calculated values of $\sqrt{I_{A,D_2O}/I_{A,H_2O}}$ and $\sqrt{I_{C,D_2O}/I_{C,H_2O}}$ in Table 2. It is expected that ν_H/ν_D values of the translational vibrations of water of crystal lization in $CaSO_4 \cdot 2H_2O$ and $CuCl_2 \cdot 2H_2O$ crystals differ from those of $Ba(ClO_3)_2 \cdot H_2O$ crystal since the reduced masses of $Ca^{2+} \cdots OH_2$ and $Cu^{2+} \cdots OH_2$ systems differ from the mass of $Ba^{2+} \cdots OH_2$ system which is close to that of H_2O molecule. Thus, the bands at 271 cm^{-1} and 243 cm^{-1}, which have different ν_H/ν_D values higher than those of the bands at 233 cm^{-1} and 207 cm^{-1} of $Ba(ClO_3)_2 \cdot H_2O$ can be assigned to the translational vibrations of water of crystallization. The bands at 306 cm^{-1} and 310 cm^{-1} have very close ν_H/ν_D values. This indicates that these bands can be assigned to the rotational rather than the translational vibrations.

It has been reported that the spectra of the rotational vibrations of water of crystallization change remarkable with the change of bound state of water of crystallization.[2-4] Our results show that the spectra of water of crystallization having a coordinated divalent metal ion on the bisector line of H–O–H angle has a characteristic pattern, that is, the spectra consist of a broad band with medium intensity having two weaker bands on both sides, the characteristic spectra showing the difference corresponding to the different bound states of water of crystallization in the crystals. Interatomic distances in the crystals differ with the crystals. ($Ba(ClO_3)_2 \cdot H_2O$, $O_w \cdots Ba^{2+}$ 2.60 Å, $H_w \cdots O(ClO_3)$ 2.77 Å; $CuCl_2 \cdot 2H_2O$, $O_w \cdots Cu^{2+}$ 1.925 Å, $H_w \cdots Cl^-$ 2.258 Å; $CaSO_4 \cdot 2H_2O$, $O_w \cdots Ca^{2+}$ 2.34 Å and 2.35 Å, $H_w \cdots O(SO_4^{2-})$ 2.816 Å and 2.824 Å). These distances suggest that the water of crystallization of $CuCl_2 \cdot 2H_2O$ and $CaSO_4 \cdot 2H_2O$ is more strongly bound than that of $Ba(ClO_3)_2 \cdot H_2O$. This seems to cause the shift of frequencies of the weak band and the broad band having higher freuqncies than the other weak band.

The Molecular and Crystal Structures of Two Isomeric Dihydrofukinolidol Sulfites, $C_{15}H_{22}O_5S$

Akio FURUSAKI* and Tokunosuké WATANABÉ
Faculty of Science, Kwansei Gakuin University, Nishinomiya
(Received November 12, 1971)

The molecular and crystal structures of two isomeric dihydrofukinolidol sulfites, $C_{15}H_{22}O_5S$, have been studied by means of an X-ray analysis. The two sulfites, called S-1 and S-2, both crystallize in the orthorhombic space group $P2_12_12_1$, with four molecules in each unit cell. The cell dimensions are $a=12.544$, $b=14.457$, and $c=8.545$ Å for S-1, and $a=12.919$, $b=14.375$, and $c=8.496$ Å for S-2. The reflection intensities were measured visually from equi-inclination integrating Weissenberg photographs taken with Cu$K\alpha$ radiation. The structures were solved by the tangent formula procedure and refined by the block-diagonal-matrix least-squares method, the anisotropic thermal motions being assumed for all the atoms. The final R factor was 10.8% for S-1 and 11.2% for S-2. The absolute configurations of the molecules were determined by using the anomalous dispersion effects of the sulfur atoms for Cu$K\alpha$ radiation. It was found that the six-membered ring containing the sulfite group in S-1 takes the chair conformation, while the same ring in S-2 has the twist boat form. The exocyclic S–O bond in the two sulfites are both axially oriented, and the other corresponding parts of the two isomers are closely similar to each other.

Fukinolidol, $C_{15}H_{22}O_4$, is a hydrolysis product of the sesquiterpenoids, named fukinolide, fukinanolide, and S-fukinolide, which are isolated from the flower stalks of wild butterburs, *Petasites japonicus* Maxim. (Japanese name, "Fuki").[1] The molecular structure of the substance has already been studied by the X-ray method as well as by organic chemical means.[1,2] It has been found that the dihydro derivative of the substance is converted into two isomeric sulfites, $C_{15}H_{22}O_5S$, by the drop-by-drop addition of its pyridine at −35°——45°C over a two-hour period, followed by standing at room temperature for two hours.[3] The isomers, called hereafter S-1 and S-2, are similar in their UV and IR spectra, while they are considerably different in their NMR spectra and solubilities; S-2 is more soluble in polar solvents, such as methanol and chloroform. These facts suggest that the difference in the structure of the two isomers may arise solely from the configuration of the part containing the sulfur atom. Figure 1 shows the structural formula applicable to the two isomers. With respect to the sulfite group, this formula gives four different stereostructures shown in Fig. 2. The purpose of the present work is to determine which of the four structures S-1 and S-2 actually have.

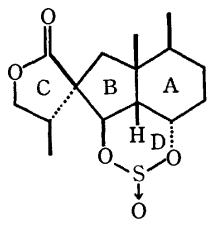

Fig. 1. The molecular structure of dihydrofukinolidol sulfites.

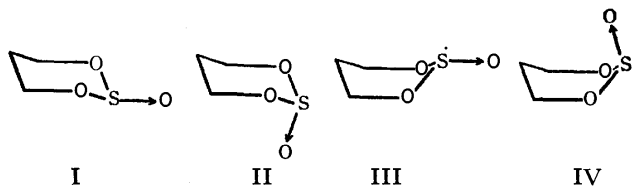

Fig. 2. The four possible stereostructures for the sulfite group.

Experimental

Single crystals of S-1 and S-2 were kindly supplied by Professor Keizo Naya of this university. The crystal data were derived from oscillation and Weissenberg photographs taken with CuK_α radiation; the results are summarized in Table 1. The reflection intensities were measured visually from equi-inclination integrating Weissenberg photographs taken with CuK_α radiation around the a and c axes. For the reflections whose α_1-α_2 doublets were completely split, 1.5 times α_1 spot intensities were used. The Lorentz-polarization and spot-size corrections were made, while the absorption effect was not taken into account, since the crystals used were sufficiently small. These data were then put on an

dure.[4] For the reflections whose E-values were larger than 1.20, the structure factors were calculated with sulfur atom positions obtained from sharpened Patterson functions and with the overall temperature factors previously described. Phase angles with $|F_c|$ values larger than $0.4\times|F_o|$ were selected for the starting set of phases necessary for the tangent formula calculation. This phase calculation was repeated under the condition that the corresponding phases were accepted only when the α-values and the numbers of the correlation terms were larger than 5.0 and 5 respectively. After three cycles of calculation, the accepted phases were increased from 202 to 375 for S-1, and from 204 to 385 for S-2. For both crystals, E-maps calculated with these phases showed clearly the positions of all the atoms except hydrogen.

The structures thus obtained were refined by the block-diagonal-matrix least-squares method, first with isotropic temperature factors and then with anisotropic thermal parameters. The following weighting scheme was introduced at this stage:

$$W = \exp(-AX^2-BY^2-CXY-DX-EY-F)$$
$$X = |F_o|,\ Y = \sin\theta/\lambda$$

The intensity data were made into groups with constant intervals along two coordinates, $|F_o|$ and $\sin\theta/\lambda$. The coefficients, A, B, C, D, E, and F, were determined by the least-squares method, so as to give as equal values of $\langle W\Delta|F_o|^2\rangle$ for all the reflection groups as possible. The coefficients thus obtained for S-1 and S-2 and the distributions of $\langle W\Delta|F_o|^2\rangle$ evaluated with these values are, respectively, given

The standard deviations are given in parentheses.

in Tables 2 and 3. After several cycles of the refinement using this weighting scheme, the R factor reached a value of 0.108 for S-1 and one of 0.112 for S-2. The final atomic parameters and their standard deviations are given in Tables 4 and 5. The tables of the observed and calculated structure factors are preserved by the Chemical Society of Japan.

The determination of the absolute configurations of the two sulfites was attempted by using the anomalous disperison effect of sulfur atoms for CuK_α radiation ($\Delta f_s''=0.6$). The comparison of the pairs of intensities, hkl and $h\bar{k}l$, was made on the Weissenberg photographs around the a axis already mentioned in the Experimental section. From the data shown in Tables 6 and 7, it can be concluded without any uncertain that the atomic parameters given in Tables 4 and 5, expressed in terms of a right-handed set of axes, correspond to the actual absolute configuration for either of the two sulfites. The absolute configurations of the two isomers thus obtained are both consistent with that of another derivative of fukinolidol.[2)]

The calculations necessary for the present work were carried out on a FACOM 270—20 computer in this university, using programs written in our laboratory.

Results and Discussion

Molecular Structures. The absolute configurations of the S-1 and S-2 molecules are, respectively, illustrated in Figs. 3(a) and 3(b) where each atom is represented as an ellipsoid, in conformity with the thermal parameters listed in Tables 4 and 5. From these figures, it is found that S-1 and S-2 correspond to II and IV respectively out of the four possible stereostructures given in Fig. 2. The bond distances and

angles calculated with the final parameters are given in Tables 8 and 9, together with their standard deviations. The correction for the thermal motions of the atoms has been made, on the assumption of the riding motion, by means of the Busing-Levy method.[5] If the standard deviations are taken into consideration, the corresponding values of the bond distances and angles in the S-1 and S-2 molecules are in good agreement with each other, in particular for parts remote from the sulfite group. In both S-1 and S-2 molecules, the D rings containing the sulfite group are *cis*-fused with the A ring and *trans*-fused with the B ring, while the A and B rings are joined to each other in the *cis* configuration. On the other hand, the D ring makes a spiro-union with the B ring, the spiro-atom being C(7).

It has been already reported that the six-membered ring of trimethylene sulfite (TSU), like that of 2,2′-dichlorotrimethylene sulfite (DCT), has the chair conformation with the exocyclic S–O bond pointing

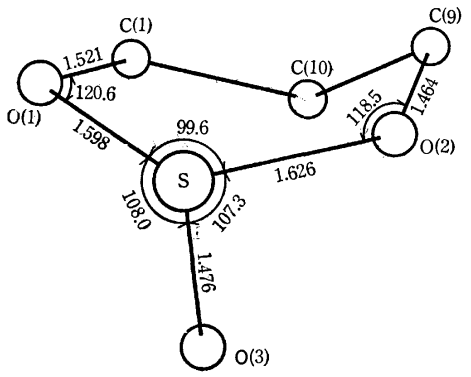
(a) S-1



(b) S-2

Fig. 4. The geometry of the sulfite group.

in the axial direction.[6,7] It is interesting to see that S-1 closely resembles the two simple sulfites mentioned above with respect to both the ring conformation and the S–O orientation. On the other hand, the D ring in S-2 has the twist boat form, although the exocyclic S–O bond is also axial. The geometries of the sulfite group in S-1 and S-2 are shown in Figs. 4(a) and 4(b) respectively. These bond distances and angles are nearly the same as those in TSU and DCT; the four sulfites are compared in Table 10. In this table, it may be seen that the average C–O distances in S-1 and S-2, 1.486 and 1.493 Å, are somewhat longer than those in TSU and DCT, 1.46 and 1.462 Å, and that the S–O(3) bond in S-2 is slightly lengthened as compared with those in other, similar compounds.

It is noteworthy that, in both S-1 and S-2, the C(1)-O(1) and C(9)-O(2) distances, especially the former (1.502 Å in S-1 and 1.521 Å in S-2) are significantly longer than the accepted values for C–O bonds in ethers and alcohols, 1.43—1.44 Å. An elongation of the C–O bond has already been found in TSU (1.49 and 1.42 Å) and DCT (1.471 and 1.453 Å), but the deviation from the normal value was taken as hardly significant.[7] The large deviation for the C(1)-O(1) bonds found in the two isomeric sulfites can, though, be taken as significant and can be explained as follows. We may suppose that the lone-pair electrons on the sulfur atom are delocalized. It follows that a portion of the electrons on the sulfur atom, distributed over the tetrahedral directions, will be displaced towards the anti-bonding σ-orbital of the C–O grouping. This picture will explain not only the elongation of the C–O bond, but also the fact that the endocyclic S–O bonds are somewhat shortened in comparison with the S–O single bond distance calculated by using Schomaker-Stevenson's method, 1.69 Å. If this view is accepted, and if we compare the lengths of the S–O and C–O bonds for the sulfite groups, it can be concluded that the outflow of the lone-pair electrons on the sulfur atom will be somewhat more in S-2 than in S-1. Consequently, the sulfur atom in S-2 will become more electronegative and will form a weaker dative bond, S→O(3).

It is of great interest to examine why the two dative bonds, S→O(3), in S-1 and S-2 are formed not in the equatorial orientation, but in the axial orientation. There are several conceivable reasons for this. First, the equatorial orientation of the lone-pair orbital on

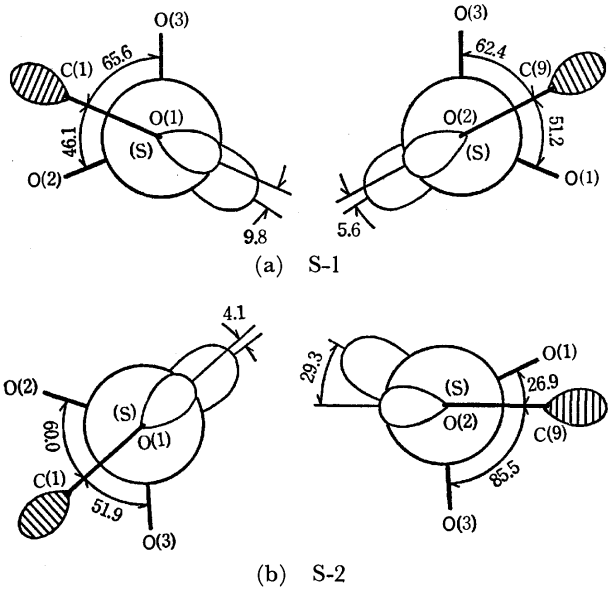

Fig. 5. The overlapping of the lone-pair orbital on S and the C–O anti-bonding orbitals.

the sulfur atom is more suitable for the overlapping with the anti-bonding σ-orbital of the C–O groups, as is shown in Fig. 5. Second, if the O(3) atom were equatorially bonded to the sulfur atom, this oxygen atom, carrying a considerable amount of negative charge, would be subjected to a stronger repulsion from the lone-pair electrons on the two oxygen atoms, O(1) and O(2), which, for the major part, would be localized in the sp^3 orbitals and extended axially and equatorially. Third, the attractive interaction between the negatively-charged oxygen atom, O(3), and the more or less positively-charged hydrogen atoms in the neighborhood of the oxygen would make the axial configuration of the S–O(3) bond stable. The distances from the O(3) atom to these hydrogen atoms are: 2.51 Å for H at C(9) and 2.61 Å for H at C(2) in S-1, and 2 54 Å for H at C(10) and 3.12 Å for H at C(1) in S-2 These values are calculated by assuming that the four bonds of the carbon atoms are in the tetrahedral direction and that the C–H distances are 1.08 Å.

It has already been mentioned that the D ring in S-1 takes the chair form. The dihedral angles around the endocyclic bonds in this ring and the internal valency angles are shown in Fig. 6(a). The average dihedral angle, ψ, and the average valency angle, θ, are calculated to be 54.9° and 111.2° respectively, while they are 59.2° and 109.8° in TSU and 59.6° and 109.7° in DCT. The values for the latter two substances are in good agreement with the normal values for cyclohexane, 60.0° and 109.5°. On the other hand, both of the ψ and θ values for S-1 deviate from the normal values in such a way that the ring becomes less puckered. The two C–O bonds make an angle of about 9° with each other, while the angle formed by the same bonds is found to be about 20° before the formation of the sulfite ring.[2] This shows that the sulfite ring is more or less strained. In fact, the valency angles at the O(1) and O(2) atoms differ from each other by no less than about 10°. Even

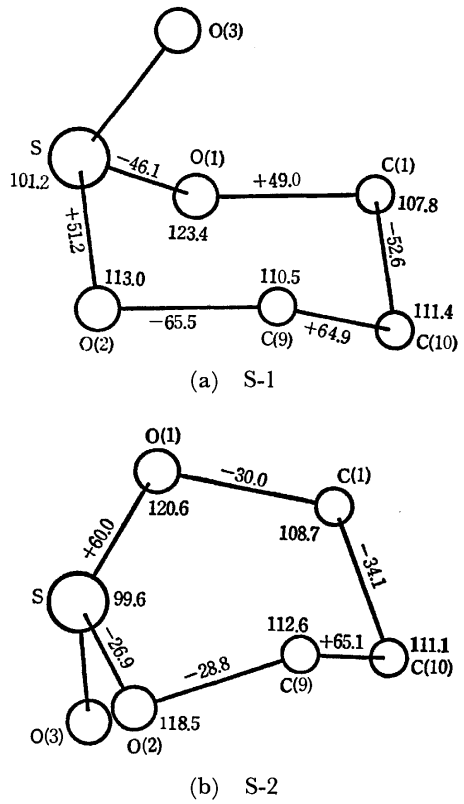

Fig. 6. The valency and torsional angles in D ring.

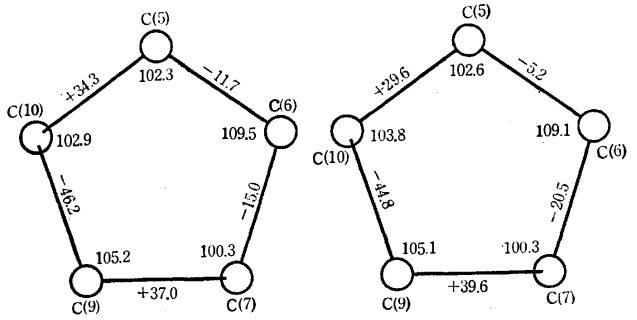
for such a deformed heterocyclic ring, Altona's relation, $\cos\psi = -\cos\theta/(1+\cos\theta)$, holds approximately; the calculated value is 55.5°, while the average of the observed dihedral angles is 54.9°.[7]

On the other hand, the twist boat form of the corresponding ring in S-2 is not only the most stable of the flexible forms, but is also suitable for the fusion with the bicyclononane system; the two C–O bond directions make an angle of about 25° with each other differing by only 5° from the angle found before the cyclization. Further, the valency angles at the O(1) and O(2) atoms, 120.6° and 118.5° respectively, are not so different from each other as those in S-1. From the symmetry of the torsional angles shown in Fig. 6(b), it may be seen that the heterocyclic ring in S-2 has roughly a two-fold rotation axis through the O(2) and C(1) atoms, though it is somewhat more flattened than the ideal twist boat form of cyclohexane, where the dihedral angels are 70°39′ or 33°10′.

The conformation of the B ring in S-1 differs from that in S-2; the former takes almost the half-chair form, while the latter has nearly the envelope form. The two ring conformations are illustrated in Fig. 7. In S-1, the C(9) and C(10) atoms deviate above and below from the plane containing the C(5), C(6), and C(7) atoms; the deviations are about 0.39 Å for the C(9) atom lying on the side opposite to the C(15) and about −0.30 Å for the C(10) atom. On the other hand, in S-2, the C(5), C(6), C(7), and C(10) atoms are nearly coplanar, and the C(9) atom deviates by about 0.63 Å toward the same side as the C(4) atom from the mean plane through the first four atoms. Though the five-membered rings in



(a) (b)

Fig. 7. The valency and torsional angles in B rings; (a) S-1, (b) S-2.

fukinolidol di-bromoacetate as well as in S-2 are found to be approximately of the envelope form, in the former the C(10) atom is considerably displaced from the mean plane through the other four atoms. Thus, the conformation of the five-membered ring varies not only with the fusion of a heterocyclic ring containing the sulfite group, but also with the conformation of the sulfite ring itself.

The conformations of the A rings in S-1 and S-2 are shown in Figs. 8(a) and 8(b) respectively. These two conformations are quite close to each other. This shows that, in the two sulfites, the conformation of the cyclohexane rings is less influenced than that of the cyclopentane rings by the fusion of the sulfite group. The same conclusion can also be drawn from an examination of the conformations around the C(1)-C(10), C(5)-C(10), and C(9)-C(10) bonds. These can be explained by the rigidness of the chair form of the cyclohexane ring. However, a closer examination shows that the A ring is, in fact, affected to some extent by the conformation of the D ring; for example, the difference between the dihedral angles for the C(1)–C(10) bond is found to be about 5.8°. The six-membered rings in the bicyclononane system of S-1 and S-2 are somewaht more flattened than the normal ring of cyclohexane. The averages of the

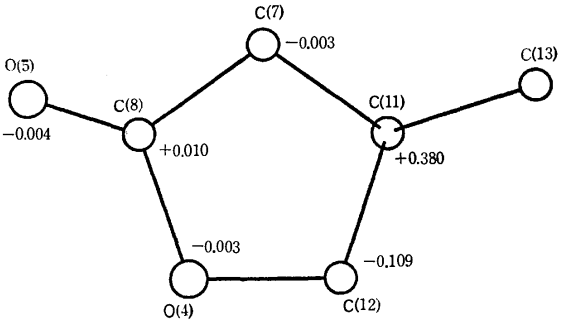
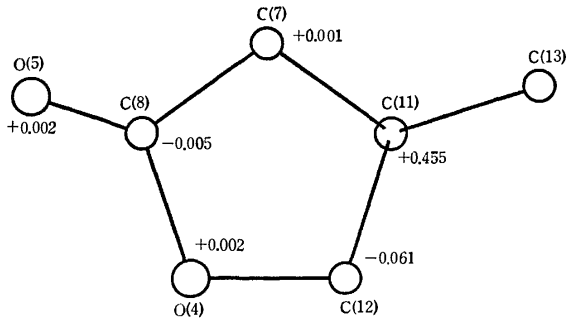
Fig. 8. The valency and torsional angles in A ring.



(a) S-1



(b) S-2

Fig. 9. The deviations of the atoms from the carbonyl plane.

internal valency angles, θ, are 112.8° for S-1 and 112.9° for S-2. The mean values of the dihedral angles, ψ, as calculated by Altona's equation, are 50.8° and 50.4° for S-1 and S-2 respectively, while the observed values are 49.6° and 47.8° respectively.

Out of the four rings present in the S-1 and S-2 molecules, the remaining one is a γ-lactone C ring, which makes a spiro-union with the B ring and takes the envelope form for both of the two isomers. The corresponding bond lengths, valency angles, and torsional angles for the lactone rings of the two molecules are in good agreement with each other within the present limits of experimental error. This may show that the lactone ring is located too far from the sulfite group to be influenced by the conformational

change of this group. The C(7), C(8), C(12), and O(4) atoms lie nearly on a plane, and the C(11) atom is displaced from the mean plane through the four atoms by about 0.47 Å for S-1 and 0.50 Å for S-2. The deviations of the atoms from the carbonyl plane are illustrated in Fig. 9.

Crystal Structures. The molecular arrangements viewed along the *a* and *c* axes are, respectively, shown in Figs. 10 and 11 for S-1 and in Figs. 12 and 13 for S-2. As may be seen in these figures, the two crystal structures are so similar to each other that they may be said to be isostructural. It is interesting to see that, notwithstanding the remarkable variation in the structure of the sulfite group, the molecular arrangments do not differ much from each other. The arrangement of the molecular centers is close to a face-centered lattice. The intermolecular contacts of a molecule with its nearest neighbors are listed in

Tables 11 and 12 for S-1 and S-2 respectively. In the S-1 crystal, there are several contacts somewhat closer than the usual van der Waals ones—for example, 3.25 Å for O(5)···C(12′) and 3.73 Å for S···C(1). From the comparison of the intermolecular distances, it may be said that S-1 has a closer molecular packing than S-2, corresponding to the higher density and the higher melting point.

In conclusion, the authors wish to express their thanks to Professor Keizo Naya and Dr. Ichiro Takagi** of this university, for providing them with the samples.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2299—2303 (1972)

Vapor Pressure of a Mixed System of Asphaltene and Organic Solvent

Shinji SAKANOUE and Mitsuo ENDO

Faculty of General Education, The Tokyo University of Agriculture and Technology, Saiwai-cho, Fuchu, Tokyo

(Received December, 1971)

The vapor pressure of a system in which it is assumed that the maltene component in petroleum asphalt has been replaced by an organic solvent, *i.e.*, a mixed system of an asphaltene component and an organic solvent, was measured over a wide range of composition. The experimental results were then analyzed on the assumption that such a system is a binary system and that the equation $\mu_1=\mu_1^\circ+\boldsymbol{R}T\ln(1-v_2)+(1-1/z)v_2+\chi_1 v_2^2$ which Flory and Huggins derived for the chemical potential of a solvent of a linear, high-polymer solution which is not relatively dilute is applicable; the volumetric ratio, z, of the asphaltene particle and solvent molecule and the value of the parameter, χ_1, of the interaction of the asphaltene and solvent molecules were obtained. The above results made it clear that mixed systems of asphaltene plus chloroform and carbon tetrachloride all form a homogeneous phase over the entire composition range, but in the case of a cyclohexane system, separation into 2 phases occurs in the mixed composition range of 3.0 vol%—40 vol% asphaltene and a dilute phase of 3.0 vol% asphaltene and a concentrated phase of 40.0 vol% coexist. It may be assumed from the above results that there is a possibility of the presence of a state in which separation into 2 phases is also present in the case of asphalt.

The petroleum asphalt is composed of three components, which are called "asphaltene", "asphaltic resin," and "asphaltic oil," and it is generally accepted that it has a colloidal structure in which the asphaltene molecules or the micelles which absorb or adsorp the asphaltic resin disperse in asphaltic oil. However, there has been no study confirming such a colloidal structure of asphalt experimentally.

Here, we measured the vapor pressures of mixtures asphaltene with various organic solvents and examined the dissolved states of the asphaltene in the systems, the sizes of the asphaltene molecules or particles, and the interaction between the asphaltene and the organic solvent molecule. It can be considered that this examination is the first step in elucidating the structure of asphalt, since the above-mentioned system can be regarded as one in which a maltene component which is the mixture of asphaltic oil and resin is replaced by an organic solvent.

Experimental

Materials. Straight asphalt manufactured by the Nippon Sekiyu Co., Ltd., was used as the sample from which the asphaltene component was separated. The values of the penetration degree[1] and the ring and ball softening point[2] of this asphalt were 73 and 49 respectively.

Cyclohexane, benzene, chloroform, and carbon tetrachloride which had been purified according to the common method were used as the solvents to dissolve the asphaltene.

Separation of Asphaltene from Asphalt. The straight asphalt described above was mixed with 3 volumes of *n*-hexane, shaken, and left to stand for a long time; then the supernatant solution of the mixture was removed by decantation. The insoluble component separated from the mixture was mixed again with 3 volumes of *n*-hexane; this mixture was shaken and filtered, and the residue was used as the sample of asphaltene in the experiments.

Method for the Measurement of the Vapor Pressure. A quartz spring, on which a small glass basket containing the

2) JIS K 2531.

sample was hung, was placed in a long glass tube which was connected to a mercury manometer and a mercury diffusion pump and placed in a liquid thermostat.

The glass tube was evacuated, and then it was closed by shutting a mercury cut; a solvent vapor was introduced into the tube, and after giving a suitable length of time for the temperature equilibration to be reached, the vapor pressure of the sample mixture was read on the mercury manometer to within 0.001 cm. This apparatus is drawn schematically in Fig. 1. The pressure inside of this vacuum line without a sample, as measured by a Macleod gauge, was 10^{-5} mmHg. The compositions by the volume fractions of the systems were determined by means of the weight of the sample mixture, which was measured by means of the quartz-spring balance, and the densities of the asphaltene and the solvent. The dried asphaltene powder did not show the vapor pressure; accordingly, the asphaltene was treated as a non-volatile material.

Results and Discussion

Many difficulties arose in the theoretical treatment of the experimental results, for the asphaltene is not a single compound, but a mixture of several kinds of compounds; further, our information about these compounds and the molecular forms is sparse. Consequently, we will discuss the experimental results on the basis of two assumptions. The first is that the mixture of the asphaltene and organic solvent is a binary system, and the second is that the equation for a chemical potential of the solvent of a relatively concentrated solution of linear high polymers;

$$\mu_1 = \mu_1^\circ + \boldsymbol{R}T\ln(1-v_2) + \left(1-\frac{1}{z}\right)v_2 + \chi_1 v_2^2 \qquad (1)$$

which was derived by Flory[3] and by Huggins[4], can be applied to the system of the asphaltene and an organic solvent. In the above equation, μ_1 and μ_1° are the chemical potentials of the solvent in the system and the pure solvent respectively; z, the ratio of the molar volume of the solute molecule to the solvent molecule; χ_1, the parameter of the interaction between a solute and solvent molecules; v_2, the volume fraction of the solute in the system; $\boldsymbol{R}$, the gas constant, and T, the absolute temperature of the system.

On the other hand, when the vapor is assumed to be an ideal gas, the activity, a_1, of a solvent in the solution of a non-volatile material is given by;

$$a_1 = \frac{p}{p_0} \qquad (2)$$

where p and p_0 are the vapor pressures of the solvent over, respectively, a solution and a pure solvent. When the vapor is assumed to be an imperfect gas, a_1 is represented by;

$$a_1 = \frac{p}{p_0}\exp\left[\frac{-B}{\boldsymbol{R}T}(p_0-p)\right] \qquad (3)$$

where B is the second virial coefficient of the vapor of a pure solvent at T°K. In Eq. (3), $\exp[(-B/\boldsymbol{R}T)(p_0-p)]$ is the factor for the gas-imperfection correction. The relative deviation from 1 of this value is estimated to be 1.5% at most, and about 0.5% in mean value, in relation to the data of this experiment. Here, however, we ignored these gas-imperfection corrections and used Eq. (2), because we could not find the accurate values of B for the vapors at every measuring temperature of every solvents. The chemical potential of the solvent in solution can, therefore, be represented by the following equation:

$$\mu_1 = \mu_1^\circ + \boldsymbol{R}T\ln\frac{p}{p_0} \qquad (4)$$

A comparison of Eq. (1) with (4) gives:

$$\ln a_1 = \ln\frac{p}{p_0} = \ln(1-v_2) + \left(1-\frac{1}{z}\right)v_2 + \chi_1 v_2^2$$

or

$$a_1 = \frac{p}{p_0} = (1-v_2)\exp\left[\left(1-\frac{1}{z}\right)v_2 + \chi_1 v_2^2\right] \qquad (5)$$

In general, the interaction parameter, χ_1, can be determined by using the observed a_1 and z values, which are evaluated by means of the molecular weight. However, as the molecular weight of asphaltene has not been found, it was necessary to determine the values of both z and χ_1 at the same time, Eq. (5) was, therefore, rewritten as follows:

$$Y = \frac{\ln\frac{p}{p_0} - \ln(1-v_2)}{v_2} = \left(1-\frac{1}{z}\right) + \chi_1 v_2 \qquad (6)$$

If neither the z value nor the χ_1 value depends on the volume fraction, the plots of Y *vs.* v_2 should be linear. The intercept and the slope of the straight line will, then, give the values of $(1-1/z)$ and χ_1 respectively.

The plots of Y *vs.* v_2 for the four kinds of systems are shown in Figs. 2—5. As can be seen in these figures, the relation of Y to v_2 was found to be linear; accordingly, the values of χ_1 and z could be determined simultaneously. The values thus obtained for each system are shown in Table 1.

The above results show that χ_1 does not depend on v_2. Furthermore, the plot points of Y *vs.* v_2 at the different equilibrium temperatures were found to be on the same straight line. It may be thought that χ_1 does not depend on the temperature, either. Ac-

cording to Flory,[3] χ_1 is a dimensionless quantity formally defined by:

$$\chi_1 = \frac{qx_{12}\Delta w_{12}}{kT} \tag{7}$$

where Δw_{12} is the exchange interaction energy per molecule; k, the Boltzmann constant, T, the absolute temperature; q, the coordination number about a lattice in solution and x_{12}, the number of segments in a solvent molecule. The mixing enthalpy change, ΔH_m, is represented by:

$$\Delta H_m = -kT^2\left(\frac{\partial \chi_1}{\partial T}\right)n_1 v_2 \tag{8}$$

Table 1. The volumetric ratio z of solute and solvent molecules, the interaction parameter χ_1 and the critical volume fraction and χ_1 value for phase separation

Solvent	Volumetric ratio	Interaction parameter	Critical values	
			Volume fraction	Interaction parameter
	z	χ_1	$(v_2)_c$	$(\chi_1)_c$
Cyclohexane	30.6	0.76	0.18	0.68
Benzene	13.1	0.77	0.27	0.78
Chloroform	34.3	0.41	0.17	0.67
Carbon tetrachloride	27.1	0.54	0.19	0.69

where n_1 is the mole number of the solvent in a solution. If the Δw_{12} does not depend on the temperature, it follows, by virture of Eq. (7), that χ_1 should be proportional to $1/T$. However, if χ_1 does not depend on the temperature, as here, it may be concluded from Eq. (8) that Δw_{12} should be proportional to T and that ΔH_m should become zero. These conclusions include the contradiction that such a solution is athermal; besides, the interaction parameter, χ_1, consists only of a configurational entropy change due to a solvent-solute interaction. Therefore, it is reasonable to assume that the variation in the value of χ_1 with the temperature is so slight in the temperature range of this experiment that the difference in the slope of the straight line for the different temperature could not be found.

Next, as the value of z is the ratio of the size of an asphaltene particle to that of a solvent molecule, if the molecular sizes of the solvents do not differ from one another, these values for the different systems should not differ from one another, either. The molecular sizes of benzene and the other solvents do not differ greatly; nevertheless, values of z for the asphaltene-benzene system are smaller than the others. This can probably be attributed to the fact that the values of z obtained from the intercepts of the straight lines in Figs. 2—5 are very sensitive to the length of the intercepts; we can not expect to obtain highly accurate values of z by this method. However, in order to know the order of magnitude of the molecular weight of asphaltene, we did attempt to estimate it roughly by multiplying the molecular weight of the solvent by z. For example, it was 2500 for the asphaltene-cyclohexane system and 1020 for the asphaltene-benzene system.

The lower the value of χ_1, the better the solvent. Consequently, as is shown in Table 1, chloroform is the best solvent among those used, while benzene and cyclohexane are relatively poor solvents.

The solid lines in Figs. 6—9 show the curves of the functions, which were obtained by substituting the values of χ_1 and z shown in Table 1 into Eq. (5). The observed values of activities, $a_1=p/p_0$, are also plotted

in these figures. Among these results, it is noteworthy that a phase separation occurs in the asphaltene-cyclohexane system, as is shown in Fig. 6, where the two different compositions of the separating phases are indicated by the symbols a and b.

The critical volume fraction and the critical interaction parameter of a phase separation are given by:

$$(v_2)_c = \frac{1}{(1+z)^{1/2}}$$

$$(\chi_1)_c = \frac{1}{2} + \frac{1}{z^{1/2}}$$

The values of $(v_2)_c$ for each system are also shown in Table 1, together with the actual values of χ_1. When $\chi_1 > (\chi_1)_c$, the phase separation occurs in a certain region of some mixture compositions. As is shown in Table 1, $\chi_1 > (\chi_1)_c$ only in the case of the asphaltene-cyclohexane system (that is, a phase separation should occur in this system), while all the other systems except the asphaltene-benzene system should be homogeneous over the range of composition. In the case of the asphaltene-benzene system, as the value of χ_1 is close to the value of $(\chi_1)_c$, and as the difference between the two values is in the range of experimental error of the values, we could not decide whether or not this system is homogeneous over the range of composition. In the case of the asphaltene-cyclohexane system, the compositions of the two separated phases were obtained by the following method. Corresponding to Eq. (1), the chemical potential of the solute is given by:

$$\mu_2 = \mu_2^\circ + \boldsymbol{R}T \ln v_2 - (z-1)(1-v_2) + \chi_1 z(1-v_2)^2 \quad (9)$$

where μ_2° is the chemical potential of the pure solute, while the relation between the volume fraction and the molar fraction of the solute is given by:

$$v_2 = \frac{zx_2}{1+(z-1)x_2} \quad (10)$$

From Eqs. (1), (9), and (10), the mean molar Gibbs energy of mixing in units of $\boldsymbol{R}T$ is represested by;

$$\frac{g-g^\circ}{RT} = (1-x_2)\ln\frac{(1-x_2)}{1+(z-1)x_2} + x_2\ln\frac{zx_2}{1+(z-1)x_2} + \frac{\chi_1 z(1-x_2)x_2}{1+(z-1)x_2}$$

when g and g° are the mean molar Gibbs free energies of the system after and before mixing respectively, and x_2 is the molar fraction of the solute. When a separation into two phases occurs, a double tangent with two contact points can be drawn to the curve of the plots of $(g-g^\circ)/RT$ *vs.* x_2, and the two contact points represent the two different compositions of the two phases.[7]

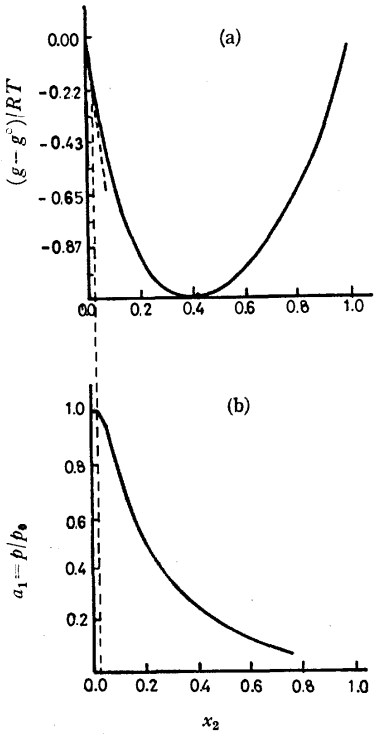

Fig. 10. Mean molar free energy of mixing asphaltene with cyclohexane, in units of RT, $(g-g^\circ)/RT$ *versus* the mole fraction of asphaltene x_2.

7) H. Tompa, "Polymer Solutions," Butterworths Scientific Publications, London (1956), Chap. 2.

The curves of these plots for the asphaltene-cyclohexane system are shown in Fig. 10(a), while the plots of $a_1=p/p_0$ *vs.* the molar fraction of the solute, x_2, are shown in Fig. 10 (b). A double tangent can be drawn to the curve in Fig. 10 (a), and it has become apparent that the composition of the dilute phase is 0.001 asphaltene relative to the molar fraction, or 3.0 vol%, while that of the concentrated phase is 0.021 relative to the molar fraction, or 40.0 vol%.

We attempted to confirm the presence of two separated phases in this system by using another method as well. That is, a mixture of asphaltene and cyclohexane (8.5% asphaltene by volume) was prepared; it was centrifuged, and then the concentration of the supernatant solution was determined. This concentration was 5.1% asphaltene by volume. This value is slightly different from that obtained from the contact point of the double tangent drawn to the curve in Fig. 10 (a), but it is evidence of the presence of a phase separation that the concentration of the supernatant solution is different from the composition of the total mixture.

As has been mentioned above, it has become apparent that separation into two phases occurs in a mixture of asphaltene with a saturated hydrocarbon such as cyclohexane; therefore, if the maltene component of asphalt, which is regarded as a solvent of asphaltene in a real asphalt, has an abundance of saturated hydrocarbon compounds, it can be guessed that the separation into the concentrated and dilute phases of asphaltene is possible at equilibrium in a real asphalt, too. Furthermore, in many cases the content of asphaltene in a straight asphalt is about 10—25% by weight; this agrees with the region of compositions in which a phase separation occurs in the asphaltene-cyclohexane system. If the fine drops of the concentrated phase of asphaltene disperse in its dilute phase, these states shall be relatively stable, because the difference in the specific weights of their phases is small and the viscosity of the dilute phase is considerably high. These states inside the asphalt can be described by saying that the asphaltene particles which adsorp a maltene component disperse in a maltene phase in which a slight quantity of asphaltene is dissolved.

Kinetic Study of the Formation and Decomposition of Amylose-iodine-iodide Complex

Akihiko YAMAGISHI, Taira IMAMURA, and Masatoshi FUJIMOTO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received January 5, 1972)

The complex formation reaction among amylose, iodine and iodide ion in aqueous solution was investigated with a stopped-flow apparatus. The forward reaction rate was found to be expressed as $v=k[\text{Amylose}]([I_3^-]-\theta)$ for $[I_3^-]>\theta$, where θ is a critical value determining the mechanism. For $[I_3^-]>\theta$, the rate was considered to be determined by the process between a free amylose unit and free I_3^-. For $[I_3^-]<\theta$, the rate-determining step is considered to be intramolecular conversion from an intermediate to a final product. The rate of the reaction between amylose units and I_3^- is close to that of a diffusion-controlled process (7×10^8 M^{-1} sec^{-1}). These conclusions are supported by the study of the decomposition reaction of complex, using $Na_2S_2O_3$ or $Ce(SO_4)_2$.

The blue complex of amylose and iodine has been the subject of many investigators since its discovery in the last century. Recently a few investigations proved that a kinetic study, using stopped-flow technique, is a powerful approach to look into the formation mechanism and the structure of the amylose-iodine complex.[1,2] Hiromi *et al.* pointed out in his excellent paper that there exists an intermediate form of a complex before the final stable product appears.[1] Since the intermediate complex has an absorption maximum at a shorter wavelength than that of a final product, it is thought to be a short poly-iodine-chain randomly distributed in the amylose helix. The intermediate complex rearranges intramolecularly to the stable product. The growth of the triiodide chain was undoubtedly confirmed by the shift of an absorption peak and also by the fact of the high order dependence (about five) of the formation rate on triiodide ion concentration. These observations are a definite proof to show that a kinetic approach is powerful to study this complicated phenomena. There are, however, several problems left unsettled. For example, the magnitude of the rate constant of the initial attack of triiodide ion on the amylose helix is yet to be determined. If this rate constant is obtained, it will help us to consider what is happening in the initial stage of the reaction. It is also important to discriminate the role of iodide ions from that of iodines. This will explain why iodide ion is necessary for the complex formation in aqueous solution.[3] Another problem is about the effect of temperature on the reaction, since temperature is known to have a large influence over the amount of the complex in equilibrium.[4]

We tried to settle these questions under the appropriate conditions of amylose, iodide ion and iodine amounts.

Experimental

Materials. Commercial corn amylose (Sigma) was recrystallized twice from *n*-butanol under nitrogen atmosphere. Fractional precipitation was made, using dimethylsulfoxide and ethanol as solvents according to Everett and Forster.[5] Precipitates were dried *in vacuo*. The molecular weights of five fractions were determined by viscosity measurements, following Potter and Hassid.[6] A fraction with MW 1.0×10^4 was used for kinetic studies.

All inorganic reagents were commercial reagent grade and used without further purification.

Solutions. About 5 mg of amylose was dissolved in 1 m*l* of 1 M KOH solution, and neutralized by 1 M $HClO_4$ solution. The solution was diluted to 100 m*l* and used as a stock solution. This solution was freshly prepared before use.

About 1 g of iodine was added into a 250 m*l* aqueous solution containing 1.4×10^{-6} M KIO_3 and 0.1 M $HClO_4$, where KIO_3 and $HClO_4$ were added in order to suppress the hydrolysis of iodine.[7] After this mixture was stirred at room temperature for about 10 hr, it was filtered through sintered glass. The concentration of iodine and triiodide ion were determined spectrophotometrically from the molar extinction coefficients given by Awtrey and Connick;[7] 746 at 460 mμ for iodine and 26400 at 352 mμ for triiodide ion. The typical value of iodine concentration in a stock solution was about 1×10^{-3} M, and the upper limit of triiodide ion concentration 2×10^{-7} M.

Number of Amylose Equivalents. The concentration of amylose equivalents present in a solution was calculated from the spectra of an amylose-iodine complex. In Fig. 1 is shown an optical density of the complex at 620 mμ under the condition of excess iodine over amylose. Seeing that the optical density increases linearly with the concentration of amylose and that it stays constant in the range from 10 to 25°C, it was concluded that amylose was complexed to its maximum capacity. Using the molar extinction coefficient for one bound-iodine in case of $(0.1-0.3)[I^-]/[I_2]$, given by Schneider *et al.*,[4] we obtained that 7.8 glucose units take up one iodine molecule. This is in good agreement with the generally accepted value.[4] Therefore, we used this relationship to calculate the number of amylose equivalents from the weight percentage of amylose.

Kinetic Measurements. The rate of formation reaction between amylose and iodine was measured by following the rise of optical density at 620 mμ in a Yanagimoto stopped-flow apparatus. Iodide ions were added in an iodine solution before mixing. The rate of decomposition reaction was

measured by mixing a solution containing amylose-iodine-iodide complexes with a solution containing decomposing reagents ($Ce(SO_4)_2$ or $Na_2S_2O_3$). The decrease of optical density was followed at 620 mμ. In both experiments, a 10 mm observation cell was used. Temperature was maintained within ±0.1°C.

Results and Discussion

(A) Dependence of Amount of Complex on the Concentration of Iodide Ions. It is known that the complex is not produced when no iodide ion is present in aqueous solution.[3] In order to obtain the dependence of the amount of the complex on the concentration of iodide ion, we mixed the solution of amylose with that of iodide ion and iodine in a stopped-flow apparatus, varying the concentration of iodide ion, $[I^-]$. The time course of the rise of the optical density is shown in Fig. 2 for several values of $[I_2]$ and $[I^-]$. As $[I_2]$ and $[I^-]$ decrease, it changes from an exponential curve to non-exponential one. Non-exponential curves consist of at least two relaxations. We call the first and the second relaxations the relaxation (I) and (II) respectively. In Fig. 3, the amount of the complex formed in the relaxation (I) is plotted against the initial value of $[I_2]$, where we assumed that in the exponential curves the product is formed only through the relaxation (I). In Fig. 4 the same result is also plotted against the initial concentration of triiodide ion, $[I_3^-]$, which was calculated from an equilibrium constant given by Awtrey and Connick.[7] The latter plot shows that the amount of complex seems to be determined uniquely by the initial $[I_3^-]$ in spite of various values of $[I^-]$ and $[I_2]$. Thus from the figure, 1.0×10^{-5} equivalents of amylose are all complexed when 6×10^{-7} M of $[I_3^-]$ is present. In other words one molecule of I_3^- is required for about 17 equivalents of amylose to form the complex by a single relaxation. Another conclusion is that the complex contains a smaller number of iodide ions in comparison with amylose equivalents, since nearly all amylose equivalents become complexed for sufficiently high $[I_2]$ under the condition of $[I^-]/[\text{Amylose Equivalent}]=0.125$ as shown in Fig. 3.

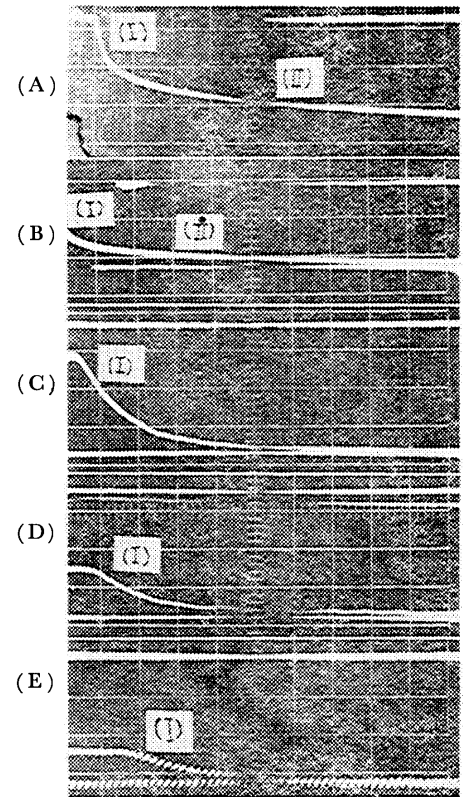

Fig. 2. The increase of the optical density at 620 mμ with time for various concentration of iodine and iodide ion at 25°C.
The initial values of $[I_2]$ and $[I^-]$ and the time scale are: (A) 5.5×10^{-5} M, 1.25×10^{-6} M, 5 sec/div., (B) 1.1×10^{-4} M, 1.25×10^{-6} M, 2 sec/div., (C) 1.6×10^{-4} M, 2.0×10^{-6} M, 50 msec/div., (D) 2.6×10^{-4} M, 3.0×10^{-6} M, 2 msec/div., (E) 2.6×10^{-4} M, 4.5×10^{-6} M, 1 msec/div. The vertical scale 0.1 ΔO.D./div. Amylose concentration 1.0×10^{-5} eq. The horizontal line above each signal shows the initial position of the optical density.

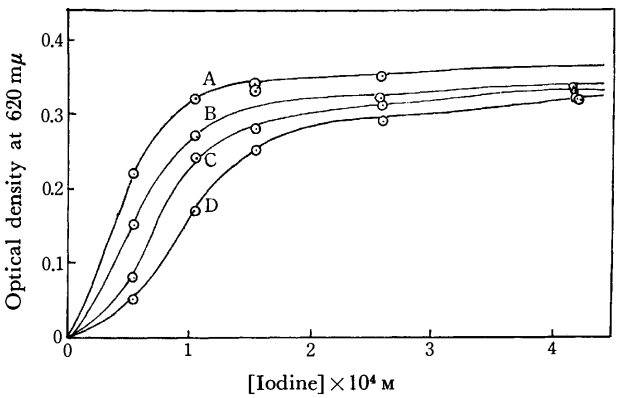

Fig. 3. The dependence of the optical density at 620 mμ on the iodine concentration for various values of iodide ion concentrations at 25°C.
$[I^-]$ is (A) 4.50×10^{-6} M, (B) 3.0×10^{-6} M, (C) 2.0×10^{-6} M, (D) 1.25×10^{-6} M. Amylose concentration 1.0×10^{-5} eq.

(B) Dependence of the Rate of Complex Formation on the Initial Concentration of Amylose. The rate of formation was measured, varying the initial number of amylose equivalents, [Am.]. The result is shown in

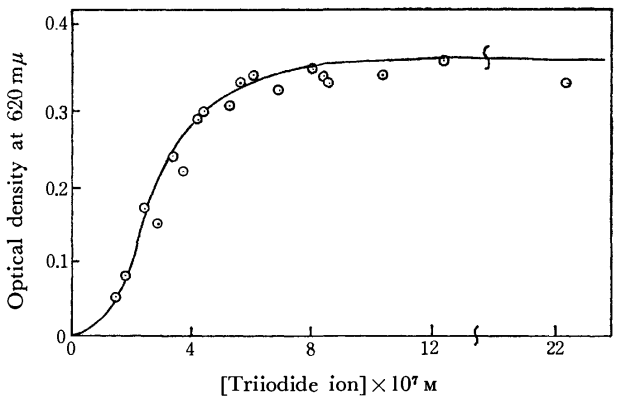

Fig. 4. The dependence of the optical density at 620 mμ on the triiodide ion concentration at 25°C.

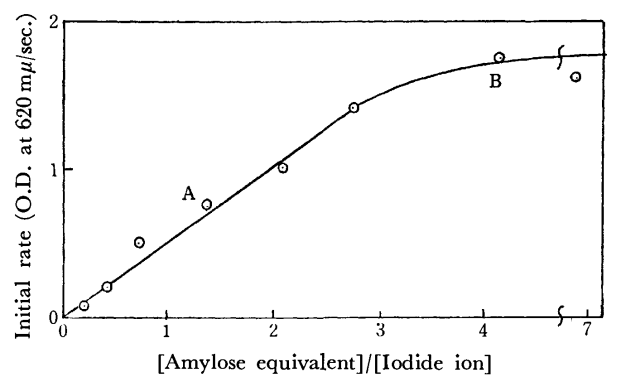

Fig. 5. The dependence of the initial rate of the complex formation on the ratio of the number of amylose equivalents to the iodide ion concentration at 10°C.
$[I_2]=2.6\times10^{-5}$ M, $[I^-]=5.0\times10^{-6}$ M. The region A denotes a linear portion, and the region B a staturated portion.

Fig. 5. As expected from the assumption that a certain unit of amylose polymer behaves independently in the course of formation reaction, the initial rate increases in proportion to [Am.] for small [Am.]. However, the rate becomes saturated to a constant value as [Am.] becomes comparable to $[I^-]$. In this region the time dependence of the rise of optical density becomes non-exponential, coinciding with the results in section (A). The result means that, although we called the initial stage of complex formation the relaxation (I) over all amylose range, the mechanism itself changes as the amylose amount passes through a critical value. Taking the results reported by Hiromi into account,[1] we concluded that, for small [Am.] (region A), the formation rate is determined by the reaction between a free amylose unit and free I^- or I_2 or its variants. On the other hand, for large [Am.] (region B), the rate is determined by the intramolecular process of an intermediate. The rise of optical density was followed in the wavelength range from 700 mμ to 300 mμ in order to find the spectra of a transient compound. However, no shift of the absorption peak was observed in both region A and B. Therefore, it is assumed that the process following the rate-determining step is too rapid to be observed, and that the transient compound has no absorption in the visible region.

(C) Dependence of the Rate of Complex Formation on the Concentration of Iodine and Iodide Ion. The rate of formation was measured for various values of $[I^-]$ and $[I_2]$. The results are shown in Fig. 6, in which the reciprocal of the half-life of the relaxation (I), $t_{1/2}$, is plotted against the initial $[I_3^-]$. The reason to choose $[I_3^-]$ as a parameter is that this plot is found to give a single curve in the wide range of $[I^-]$ and $[I_2]$. For small $[I_3^-]$, corresponding to region B in section (B), the rate is extremely slow and depends crucially on $[I_3^-]$. For large $[I_3^-]$, corresponding to region A, the rate increases linearly with $[I_3^-]$. Therefore, $t_{1/2}$ is expressed approximately as

$$t_{1/2}^{-1} = k([I_3^-]-\theta) \quad (1)$$

where θ is a value of the $[I_3^-]$ at the intercept obtained by extrapolating the linear portion of the curve. In section (B) it was suggested that in the region of $[I_3^-]<\theta$, the rate of complex formation is determined by the intramolecular process and that in the region of $[I_3^-]>\theta$, the rate is determined by the reaction between free amylose units and I^- or I_2 or its variants. From the relationship of Eq. (1), one of the possibilities for the rate-determining step is a reaction between an amylose unit and I_3^-,

$$Am + I_3^- \rightarrow Am\cdot I_3^-. \quad (2)$$

Since the complex $Am\cdot I_3^-$ is thought to have no absorption in the wavelength longer than 600 mμ,[8] reaction (2) may be followed by chain growth reaction. This later step which is too fast to be observed as stated in section (B) involves a reaction between an intermediate complex and I_2, *e.g.*

$$Am\cdot I_3^- + I_2 \rightarrow Am\cdot I_3^-\cdot I_2. \quad (3)$$

Thus the final product contains many I_2 molecule as concluded in section (A). In the region $[I_3^-]>\theta$, since $[I_2]$ and $[I^-]$ are in excess over amylose equivalents, they are assumed to be kept constant during the reaction. Supposing the equilibration $I^-+I_2 \rightleftarrows I_3^-$ is much faster than the formation rate,[9] $[I_3^-]$ is also kept constants. In reaction (2), therefore, the decrease of amylose units is expressed as below, neglecting a reverse reaction

$$d[Am.]/dt = -k[Am.][I_3^-],$$

where [Am.] represents the number of free amylose units, and k a second-order rate constant. From the slope of a linear portion in Fig. 6, k can be calculated as

$$k = 7\times10^8\ \text{M}^{-1}\text{sec}^{-1} \quad \text{at } 25°\text{C}.$$

This value is so large that it is close to the rate of a diffusion-controlled reaction.[10] Ono *et al.* concluded that amylose should be in helical form so as to form a complex with iodine.[11] Thus the above result means

8) H. Murakami, *J. Chem. Phys.*, **22**, 367 (1954).
9) O. E. Myers, *ibid.*, **28**, 1027 (1958).
10) Here we assume that a free amylose unit moves in liquid just as a free particle. However another extreme assumption that the unit is restricted to one position in medium will not affect the result very much. (*cf.* A. A. Frost and R. G. Pearson, "Kinetics and Mechanism," John Wiley and Sons, Inc., N. Y., 1961, p. 221).

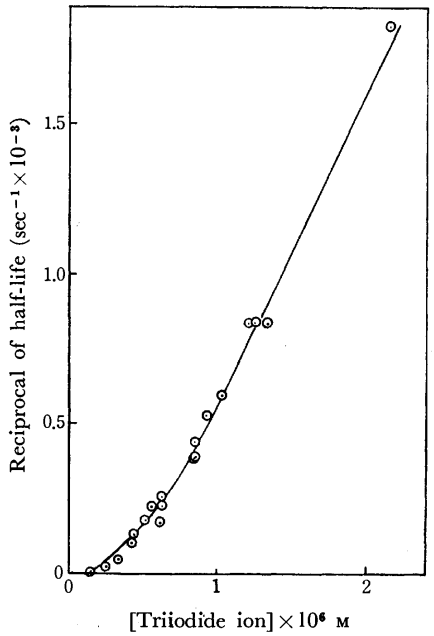

Fig. 6. The dependence of the rate of the complex formation on the triiodide ion concentration at 25°C.
This results are from the same experiments for Fig. 3.
$[I_2]=(1-4)\times10^{-4}$ M, $[I^-]=(1-5)\times10^{-6}$ M, and the amylose concentration 1.0×10^{-5} eq.

that the reaction between a triiodide ion and helical amylose is nearly a diffusion-controlled process.

The origin of the θ term in equation (2) is not clear. Apparently owing to this term, the dependence of the rate on $[I_3^-]$ is very crucial in the region of $[I_3^-]<\theta$. Also θ depends greatly upon temperature. Figure 7 shows the plot of the initial rate against $[I_3^-]$ at various temperatures. As temperature decreases, the linear portion becomes larger. Therefore in the region of $[I_3^-]<\theta$, the formation rate is greatly affected by $[I_3^-]$ and temperature. Under the present assumption of intramolecular process, it is suggested that the stability and the concentration of an intermediate depends very much on $[I_3^-]$ and temperature.

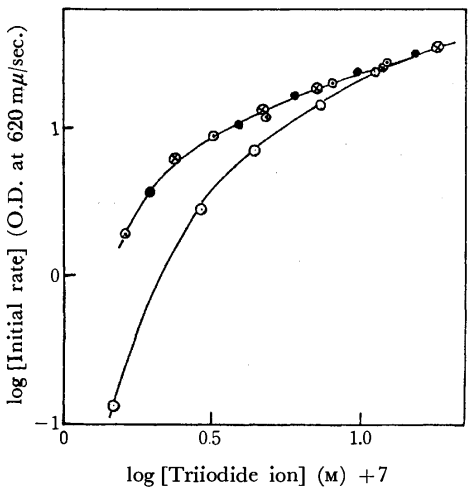

Fig. 7. The dependence of the initial rate of the complex formation on the triiodide ion concentration at various temperatures.
$[I_2]=5.4\times10^{-5}$ M, and amylose concentration 1.0×10^{-5} eq.
$[I^-]=(1.5-11)\times10^{-7}$ M. Temperature ○ 20°C, ⊙ 15°C, ● 10°C, ⊗ 5°C respectively.

(D) Decomposition of the Complex by Thiosulfate Ion and Cerium(IV). The amylose-iodine-iodide complex was found to decompose by adding sodium thiosulfate solution or cerium(IV) sulfate solution.

First the rate of decomposition was measured, using a $Na_2S_2O_3$ solution. At the sufficiently high concentration of $Na_2S_2O_3$, the decomposition occurs so rapidly within a dead time (about 1.5 msec). This is a surprising result, since this means that the decomposition rate is larger than that of formation. This is very unbelievable seeing that the formation constant is rather high.[4] One of the possible explanation is that the reversible equilibrium exists between the transient complex $Am\cdot I_3$ in Eq. (2) and the final products. They may be

$$Am\cdot I_3 + I_2 \rightleftharpoons Am\cdot I_3\cdot I_2. \quad (4)$$

By adding $Na_2S_2O_3$, I_2 is reduced to I^- and the above equilibrium moves toward the decomposition. The fact that the equilibrium (3) is very rapid coincides well with the direct appearance of a final product as stated in section (B).

Next the rate of decomposition was measured, using a $Ce(SO_4)_2$ solution. The rate was measurable this time even at 0.05 M Ce(IV). The example is shown in

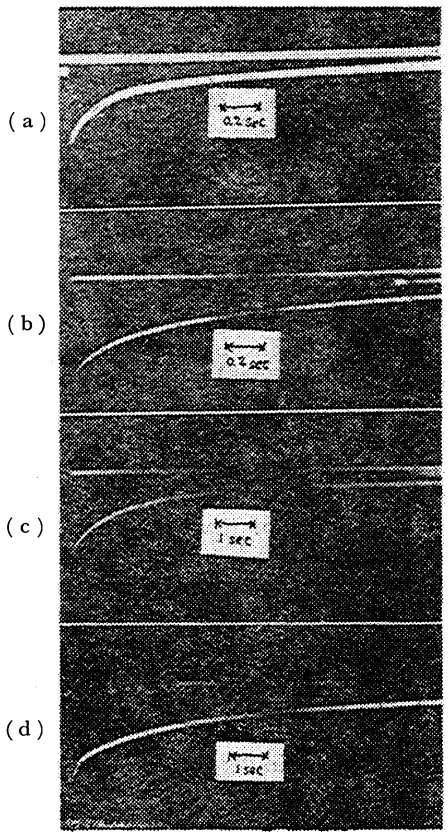

Fig. 8. The decrease of the optical density at 620 mμ with time at various temperatures, induced by the addition of $Ce(SO_4)_2$.
$[Ce(SO_4)_2]=2.8\times10^{-2}$ M, and [Complex] $=3.5\times10^{-6}$ eq.
Temperature and time scale: (a) 25°C, 0.2 sec/div., (b) 20°C, 0.2 sec/div., (c) 15°C, 1 sec/div., (d) 10°C, 1 sec/div., The vertical scale 0.05 ΔO.D./div.

Fig. 8. Since the decrease of the complex was found independent of $[Ce(SO_4)_2]$, we concluded that the decomposition occurs by the oxidation of free I^- by Ce(IV). The rate is considered to be determined by the reverse reaction of Eq. (2). The time dependence of decomposition is not exponential in spite that the formation is exponential in an appropriate condition. This means that triiodide ion is bound to amylose helix with various degrees of strength. In this sense, it is impossible to obtain the unique value for the equilibrium constant in this complexation reaction. Interestingly the reverse reaction is greatly temperature dependent as shown in Fig. 8. Therefore, the large temperature dependence of the stability of the amylose-iodine-iodide complex arises from the reverse reaction not from the forward reaction.

Summarizing these results, the forward, and the reverse reaction rate constants for the reaction,

$$Am + I_3^- \rightleftharpoons Am \cdot I_3^-,$$

are given as below.

Temperature	Forward	Reverse[a)]
25°C	7×10^8 M^{-1} sec^{-1}	4 sec^{-1}
20	same	2
15	same	0.5
10	same	0.3

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2308—2312 (1972)

Energy Transfer in the γ-Irradiated Benzene Solutions of Carbonyl Sulfide, Nitrous Oxide, and Carbon Dioxide

Shin SATO, Kiyoshi HOSOYA, Seishi SHISHIDO, and Shun-ichi HIROKAMI

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received January 21, 1972)

The γ-radiolysis of benzene solutions containing carbonyl sulfide, nitrous oxide, and carbon dioxide has been investigated at room temperature and at 0°C. Carbonyl sulfide was shown to be an effective electron scavenger and to give carbon monoxide as the product. By comparing the solute concentration dependences of $G(N_2)$ and $G(CO)$, it was concluded that the collision of secondary electrons with benzene does not efficiently produce the first excited singlet state, the G-value of which is less than 0.2 if it is produced at all. The concentration dependences of the $G(CO)$ and G(phenol) from the benzene solution of carbon dioxide also suggested that the superexcited state or the highly-excited state of benzene is too short-lived to transfer its energy to the solute.

When a benzene solution containing a small amount of a solute is irradiated by γ-rays, the solute molecules are subject to the attack of active species produced in the solvent and an "energy transfer from solvent to solute" occurs. Various mechanisms have been proposed for this energy transfer. The mechanisms may be classified into three categories. (1) The real energy transfer. The active species in this case are the first excited singlet ($^1B_{2u}$) and the lowest teiplet state ($^3B_{1u}$) of benzene. These states may be formed by the neutralization of benzene cations or by the direct excitation of secondary electrons. This type of energy transfer has been studied by many photochemists.[1,2] Our laboratory has also studied this type of energy transfer and shown that the benzene-photosensitized *cis-trans* isomerization of butene-2 in cyclohexane occurs through the triplet-triplet energy transfer when the concentration of the solute is less than 10^{-2} mol/l,[3] and that the benzene photo-sensitized decomposition of carbonyl sulfide through the singlet-singlet energy transfer.[4] (2) Ionic reactions. The active species in this case are electrons and benzene cations, whose reactions have been studied as an important subject of radiation chemistry. An example is the nitrogen formation from a γ-irradiated benzene solution of nitrous oxide.[5,6] It is believed that this reaction is initiated by the electron capture of nitrous oxide. As an example of the reaction of benzene cations, the formation of anisole in the γ-irradiated benzene-methanol mixture may be taken.[7] (3) The energy transfer from the superexcited state of benzene. This process has not been established by direct evidence, but its possibility has been discussed by theoretical radiation chemists.[8] Recently, Voltz quoted our data on the quenching effect of nitrous oxide on the scintillation from the *p*-terphenyl–benzene system as an example of this type of energy transfer.

The present paper will report the results of the γ-radiolysis of benzene solutions of carbonyl sulfide,

nitrous oxide, and carbon dioxide and will discuss the reaction mechanism for the formation of the products. The discussion will inevitably include the energy trasfer described above.

Experimental

Tokyo Kagaku Seiki Co. benzene (purest grade) was used as supplied. Further purification was not made.[6] The carbonyl sulfide (Merck Co.), nitrous oxide (Matheson Co.), and carbon dioxide (Takachiho Chemical Co.) were distilled bulb-to-bulb, and the head and tail fractions were rejected.

All the mixtures were sealed into small sampling tubes (about 3 m*l*) with a breakable seal attached. The subsequent procedure was the same as that reported in a previous paper.[6] Ostwald's solubility coefficients of carbonyl sulfide and nitrous oxide in benzene at room temperature are 12.5 and 3.8 respectively.

The samples were irradiated by ^{60}Co γ-rays at a dose rate of about 0.8×10^6 R/hr. In order to analyze the gases noncondensable at the temperature of liquid nitrogen, a Toepler pump with a gas buret and a cuprous oxide furnace attached was used. For the analysis of the products in the solution, we made use of a gas chromatograph, the column of which was 1-m dioctylphthalate at 130°C.

Results

COS–Benzene System. Table 1 shows the *G*-values of carbon monoxide and hydrogen as a function of the concentration of COS in benzene. The presence of the benzenethiol as one of the products could be detected by gas chromatography. However, the *G*-value at the COS concentration of 0.6 mol/*l* was as low as 0.12. No other products could be detected.

Since the dependence of $G(CO)$ on the concentration of COS was very similar to that of $G(N_2)$ on the concentration of N_2O, as reported in a previous paper,[6] the radiolysis at 0°C was carried out for the sake of comparison, for at that temperature any ratio of COS to benzene can be obtained. The result is shown in Fig.1, along with the $G(N_2)$ from the benzene solution of N_2O. Within the limit of experimental error, the two series of measurements coincide with each

other.

COS–N_2O–Benzene System. In order to study the competition of COS and N_2O as electron scavengers, benzene solutions containing the two solutes were γ-irradiated. Figures 2 and 3 show the results. Some of the results in Fig. 2 have already been reported.[9] In each figure, it is noticeable that the sum of $G(CO)$ and $G(N_2)$ at a certain concentration of $[COS]+[N_2O]$ is almost equal to the $G(CO)$ or $G(N_2)$ value obtained at the same concentration of COS or N_2O.

CO_2–Benzene System. In place of COS and N_2O, CO_2 was also used as a solute. Figure 4 shows the G-values of CO, phenol, and biphenyl as a function of the mole fraction of CO_2. The temperature was 0°C; no CO_2 mole fraction higher than 0.9 could be attained because of the fragility of the breakable seal attached to the reaction vessel.

Discussion

In the previous paper on the γ-radiolysis of the benzene solution of N_2O,[6] the reactions initiated by the electron capture of N_2O were described as follows:

$$e^- + N_2O \rightarrow N_2 + O^- \quad (1)$$

$$O^- + C_6H_6 \rightarrow C_6H_6O^- \quad (2)$$

$$C_6H_6O^- + N_2O \rightarrow N_2 + C_6H_6O_2^- \quad (3)$$

$$C_6H_6O_2^- + C_6H_6^+ \rightarrow C_6H_6O + C_6H_5OH \quad (4)$$

As was stated in the Results section, the behavior of COS as the solute in the γ-irradiated benzene solution was very similar to that of N_2O. Therefore, the reactions of COS may be written as follows:

$$e^- + COS \rightarrow CO + S^- \quad (5)$$

$$S^- + C_6H_6 \rightarrow C_6H_6S^- \quad (6)$$

$$C_6H_6S^- + COS \rightarrow CO + C_6H_6S_2^- \quad (7)$$

$$C_6H_6S_2^- + C_6H_6^+ \rightarrow 2\,C_6H_6 + S_2 \quad (8)$$

In Reaction (8), the formation of benzenethiol was not assumed, because the G-value of this compound was very small. The product, S_2, in this reaction probably polymerizes to S_8.[10] When the two solutes, N_2O and COS, are present together in a solution, the following two reactions must be taken into account for the formation of CO and N_2:

$$C_6H_6O^- + COS \rightarrow CO + C_6H_6OS^- \quad (9)$$

$$C_6H_6S^- + N_2O \rightarrow N_2 + C_6H_6SO^- \quad (10)$$

As is shown in Fig.2, when COS is added to the benzene solution containing N_2O, the $G(N_2)$ rapidly decreases with the increase in the COS concentration, while the sum of $G(N_2)$ and $G(CO)$ is almost equal to the $G(N_2)$ obtained at the N_2O concentration corresponding to $[COS]+[N_2O]$. The reverse situation is shown in Fig. 3, where N_2O is added to the COS–benzene solution. In this case, the decrease in $G(CO)$ with the concentration of added N_2O is not so rapid as the decrease in $G(N_2)$ on the addition of COS to the N_2O solution. These results may be explained as follows.

The electrons ejected in the solution are captured by N_2O or COS, the rate constants of which may be almost equal.

$$k_1 = k_5 \quad (I)$$

Otherwise, the curves for $G(N_2)+G(CO)$ in Fig. 2 and 3 should differ considerably from each other. On the other hand, the second steps of the formation of N_2 and CO are strongly dependent upon the rate constants; $k_3<k_9$ and $k_{10}<k_7$.

For the further analysis of these data, we may tentatively divide the G-values of noncondensable gases into two parts:

$$\begin{aligned} G(N_2) &= G_1(N_2) + G_2(N_2) \\ G(CO) &= G_1(CO) + G_2(CO) \end{aligned} \quad (II)$$

Here, G_1 denotes the G-value of the noncondensable gas resulting from Reaction (1) or (5), and G_2, that resulting from Reactions (3) and (10) or (7) and (9). Therefore, the following relation should hold:

$$\frac{G_1(N_2)}{G_1(CO)} = \frac{k_1[N_2O]}{k_5[COS]} = \frac{[N_2O]}{[COS]} \quad (III)$$

Since the solute concentration under present consideration is higher than 0.4 mol/l, the $C_6H_6O^-$ and and $C_6H_6S^-$ species may react further with the solutes before being neutralized. In other words, all the electrons captured by scavengers will produce two molecules of N_2 or CO:

$$G(N_2) + G(CO) = 2\{G_1(N_2) + G_1(CO)\} \quad (IV)$$

Then, if the $[N_2O]/[COS]$ ratio is known, we can calculate $G_2(N_2)$ and $G_2(CO)$.

On the other hand, if we can assume:

$$k_3/k_9 = k_{10}/k_7 = K \quad (V),$$

then we can easily derive the following equation:

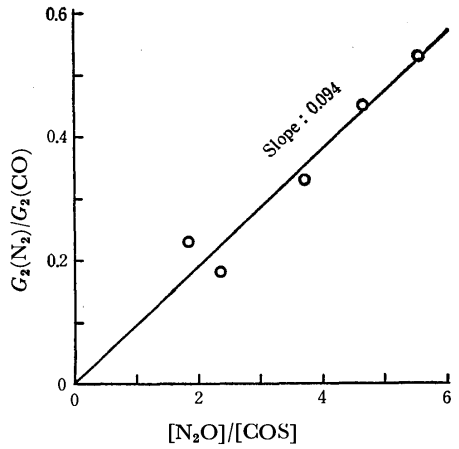

Fig. 5. $G_2(N_2)/G_2(CO)$ as a function of $[N_2O]/[COS]$ calculated from Fig. 2.

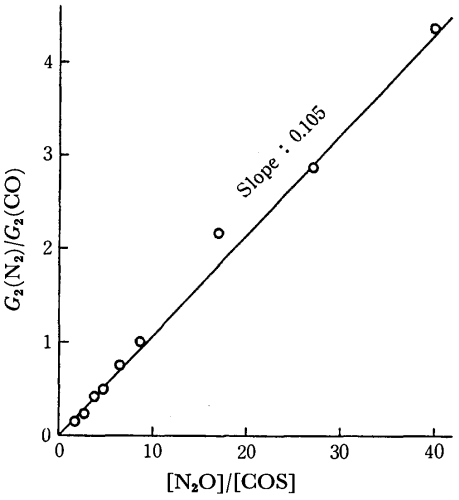

Fig. 6. $G_2(N_2)/G_2(CO)$ as a fuuction of $[N_2O]/[COS]$ calculated from Fig. 3.

$$\frac{G_2(N_2)}{G_2(CO)} = K\frac{[N_2O]}{[COS]} \qquad \text{(VI)}$$

Figure 5 was drawn from the data in Fig.2, and Fig.6, from those in Fig.3. Obviously, we could obtain the linear relationships expected from Eq. (VI) and a constant slope:

$$K = 0.10 \pm 0.005 \qquad \text{(VII)}$$

The agreement of these two slopes seems to support the reasoning presented above. We have tried to a more general relationship between the G-values of N_2 and CO, and the concentrations of N_2O and COS on the basis of the proposed reaction scheme, but no simple equations have so far been derived because of the inhomogeneous kinetics involved in the neutralization processes of ions in the system.

So far, we have stressed that the two curves of $G(N_2)+G(CO)$ in Figs. 2 and 3 are similar: however, a detailed comparison reveals that the two curves do not coincide with each other exactly especially, at the lower concentrations of the solutes. In the previous paper,[6] we showed that the $G(N_2)$ from the N_2O benzene solution is proportional to the square root of the N_2O concentration up to 2 mol/l:

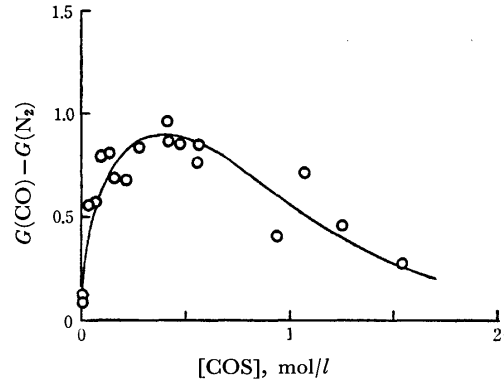

Fig. 7. The difference between $G(CO)$ and $G(N_2)$ as a function of the concentration of the solute.

$$G(N_2) = 3.78\sqrt{[N_2O]} \qquad \text{(VIII)}$$

By using this relation, the difference between $G(N_2)$ in Fig. 2 and $G(CO)$ in Fig. 3 was plotted as a function of the concentration of the solute. The results are shown in Fig.7. This difference may be partly due to the difference in the electron-scavenging efficiencies of N_2O and COS, but we believe that the main part result from the difference between the two compounds in sensitivity to the excited state of benzene. As has already been reported, N_2O and COS show quite different behaviors in the benzene-photosensitization; that is, the quantum yield of the formation of N_2 in the benzene-photosensitized decomposition of N_2O in cyclohexane is very small (<0.01 at 0.06 mol/l N_2O),[6] while COS is easily decomposed into CO and S by the benzene photo-sensitization ($\phi_{CO}=0.4$ at 0.06 mol/l COS).[4] Therefore, if the first excited singlet state of benzene ($^1B_{2u}$) is efficiently formed by the direct excitation of the secondary electrons in the radiolysis of the benzene solution, the $G(N_2)$ curve in Fig.2 should differ considerably from the $G(CO)$ curve in Fig. 3. In fact, the difference is small, as is shown in Fig. 7, and may be explained as follows. The electrons not scavenged by COS return to the parent benzene cations and produce the excited states of benzene, which can decompose COS. This process may be schematically described as follows:

$$e^- + C_6H_6^+ \rightarrow C_6H_6^*(^1B_{2u}) \qquad (11)$$

$$\searrow\ C_6H_6^{**}(^3B_{1u} \text{ or others}) \qquad (12)$$

$$C_6H_6^* + COS \rightarrow C_6H_6 + CO + S \qquad (13)$$

If this reasoning is correct, the following conclusion can be drawn—that the secondary electrons produced in the γ-radiolysis of benzene do not produce the first excited singlet state of benzene by direct collision. This statement, of course, does not mean that collisions of the secondary electrons with benzene give no electronically-excited states of benzene. Rather, the truth is probably that a large number of the electronically-excited states are produced, but their states are so high compared with the $^1B_{2u}$ state that the

conversion to the $^1B_{2u}$ state is not efficient.[11] Although the experimental error precludes an accurate estimation, the G-value of the $^1B_{2u}$-state benzene produced directly by the collision of secondary electrons cannot be higher than 0.2, if it is produced at all.

Fighure 4 shows the G-values of CO, phenol, and biphenyl from the benzene solution of CO_2. The yields of CO and phenol are almost linearly dependent upon the concentration of CO_2 at its lower concentrations. This suggests that CO and phenol are produced by the reactions of the active species formed from CO_2. It is known that oxygen atoms in the ground state do not efficiently produce phenol in the reaction with benzene. One possible mechanism for the formation of phenol, therefore is as follows:

$$C_6H_6 \rightsquigarrow C_6H_6^+ + e^-$$

$$CO_2 \rightsquigarrow CO + O$$

$$CO_2^+ + e^-$$

$$O + e^- \rightarrow O^-$$

$$O^- + C_6H_6 \rightarrow C_6H_6O^-$$

$$CO_2^+ + C_6H_6 \rightarrow CO_2 + C_6H_6^+$$

$$C_6H_6^+ + C_6H_6O^- \rightarrow C_6H_5OH + C_6H_6$$

This reaction scheme is very tentative, but it explains the linear dependence of G(CO) and G(phenol) on the CO_2 concentration.

Recently, much interest has been taken in the superexcited state produced in the radiolysis.[12] According to Voltz's estimation,[8] the energy transferred from the superexcited state or highly-excited state of aromatic compounds in the liquid phase is, very roughly, 20 eV. Moreover, he quoted our data regarding the quenching effect of N_2O in the scintillation from the p-terphenyl-benzene system as an example of the energy transfer from the superexcited state or the highly-excited state of benzene to the solute.[8] However, if the energy of 20 eV is transferred from the superexcited state of benzene to the solute, CO_2 should be decomposed as was N_2O if the solute used is CO_2 instead of N_2O. Figure 4 obviously shows that this is not likely. Therefore, it may safely be said that superexcited state or the highly-excited state of benzene is too short-lived to transfer its energy to the solute molecules.

The Orientation Overgrowth of Polycyclic Aromatic Quinones on the Cleavage Surface of Alkali Halide Single Crystals

Michio ASHIDA, Akihiko HAMADA, and Teizo WATANABE
Department of Industrial Chemistry, Faculty of Engineering, Kobe University, Nada-ku, Kobe

(Received November 15, 1971)

Vacuum-condensed films of polycyclic aromatic quinones (flavanthrone, indanthrone, and pyranthrone) were found to grow epitaxially on the cleavage faces of NaCl and KCl. Electron microscopy studies have shown that all the films on NaCl were composed of small, needle-like crystallites crossing orthogonally. The needle axis of the crystals coincides with the ⟨110⟩ directions of NaCl. When a cleavage surface of KCl was used as the substrate, vacuum-condensed films of flavanthrone and indanthrone were composed of dendroid crystals which assumed the standing *b*-axis orientation with an apparent C_{4v} symmetry. On the other hand, a pyranthrone film on KCl was composed of wedge-like crystals which assumed the standing *b*-axis orientation. The electron-diffraction pattern of the film revealed that the *b*-axis of each crystal tilts against the normal of the substrate face at an angle of 29° and takes a random orientation. When the films assume the standing *b*-axis orientation, the planar molecule in the crystal comes into parallel contact with the cleavage face of KCl. It may be presumed that the nitrogen atoms in both flavanthrone and indanthrone molecules are placed on potassium ions in the (001) plane of KCl.

The epitaxial crystallization of organic compounds on a cleavage face of alkali halides has been observed by many investigators. The orientation overgrowth of polyethylene,[1,2] *p*-aminobenzoic acid and sulfonicamide,[3] polyethylene and various other polymers,[4,5] poly γ-benzyl L-glutamate[6] and five oligopeptides[7] has been reported in little more than a decade. In these experiments, epitaxial deposits were formed on alkali halide surfaces from a supersaturated solution of the crystallizing substances.

In a previous paper, condensed polycyclic aromatic compounds were found to grow epitaxially when they

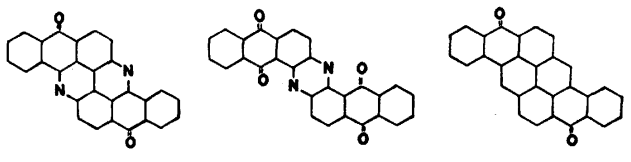
were condensed onto a cleavage face of a muscovite crystal *in vacuo*.[8] These molecules consist largely of flat benzene rings. In the crystals they are stacked together to form a column, in which the molecules are parallel to one another. The normal of the molecular plane is slightly tilted against the column axis. Thin films of copper-phthalocyanine, one of polycyclic aromatic compounds, when vacuum-sublimated on muscovite had two sorts of orientation according to the conditions of sublimation.[9,10] Similarly, phthalocyanine crystals deposited on a cleavage face of alkali halides took two types of orientation in compliance with the sort of substrate crystal.[11] These two orientations were called the parallel *b*-axis and the standing *b*-axis orientation, according to the direction of the *b*-axis of the crystal relative to the substrate face. In the crystal with the parallel *b*-axis orientation, the flat molecule stands obliquely on the substrate face and touches it at several points. On the contrary, in the case of the standing *b*-axis orientation the molecular planes are in contact parallel to the substrate face and the apparent symmetry of the oriented crystals is determined by the molecular symmetry. The basic orientation taken by a single molecule is determined by the molecular interaction between substrate atoms and adsorbed gas on the cleavage face. The molecules of polycyclic aromatic quinones have lower symmetry than that of phthalocyanine, and their way of packing in the crystal is remarkably similar to that of the latter. In order to establish that two such kinds of orientation occur also for other condensed polycyclic aromatic compounds, similar polycyclic aromatic quinones were vacuum-sublimated onto a cleavage face of alkali halides and the orientation overgrowth of these crystals was investigated by means of electron microscopy as well as by means of electron diffraction.

Experimental

The polycyclic aromatic quinones used in this work were flavanthrone ($C_{28}H_{12}O_2N_2$), indanthrone ($C_{28}H_{14}O_4N_2$), and pyranthrone ($C_{30}H_{14}O_2$); their constitutional formulas are shown in Fig. 1. These compounds were purified by repeated sublimation in a low-pressure stream of carbon dioxide at a temperature above 400°C and were examined by means of an X-ray diffractometer. The purified materials were sublimated from a tungsten basket onto a clean surface of alkali halide in a vacuum evaporator, as has been described in a previous paper.[10] Single crystals of rock salt and sylvine were used as the substrate. They were cleaved in air and immediately placed in the vacuum evaporator. The temperature of the substrate was kept in the range from 100 to 200°C.



Flavanthrone Indanthrone Pyranthrone

Fig. 1. Constitutional formulas of quinones.

The specimens used for electron microscopy were prepared by the wet-stripping method after they had been reinforced with evaporated carbon film. Thallium chloride prepared by deposition *in vacuo* was used as a standard calibration material for the spacing measurements.

Results

A) Epitaxial Growth on Rock Salt. When flavanthrone was sublimated onto a cleavage face of rock salt at 150°C, certain areas of the film showed the well-defined, sngle-directional orientation whose electron micrograph and electron-diffraction pattern are shown in Figs. 2(a) and (b) respectively. The film was composed of laminar crystal strips giving rise to a raft structure as a whole. The fiber diagram obtained from the film reveals that the meridian coincides with the needle axis of the crystal strips. The maximum lattice spacing along this direction turned out to be 3.81 Å, which is in good agreement with the unit cell length of the *b*-axis. The diffraction spots on the equator have an equidistance of 8.10Å, which

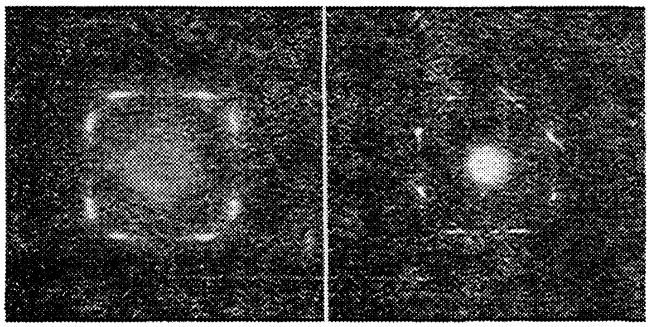
corresponds to 001 and its higher-order reflections. Thus, each crystal strip grows along the *b*-axis and its (001) plane lies parallel to the substrate face. The other areas of the flavanthrone film were composed of two groups of slender crystal strips crossing each other orthogonally, as is shown in Fig. 3 (a). Corresponding to such a configuration of the film, the diffraction pattern also had an orthogonal appearance, as Fig. 3(b) shows. This pattern is a superposition of two identical fiber diagrams, each of which is essentially the same as that of the single-directional orientation mentioned above. In order to establish the orientation of the deposited crystals relative to the substrate rock salt, well-developed crystals on the cleavage face were observed by means of an optical microscope. The needle axis of the deposited crystals was found to be parallel to the <110> direction of the substrate crystal.

When indanthrone was sublimated onto a cleavage face of rock salt, the film was built up of quite the same networks of laminar crystal strips crossing orthogonally as those of flavanthrone film. The electron-diffraction pattern in Fig. 4(a) also shows that the film assumes a double-directional orientation with strips crossing each other rectangularly. Each fiber spacing with a distance of 3.83 Å coincides with the unit length of the *b*-axis, and the series of the spots on the equator with a interplanar spacing of 15.4 Å corresponds to 200 and its higher-order reflections. The individual *b*-axis of the crystal was parallel to the <110> direction of rock salt.



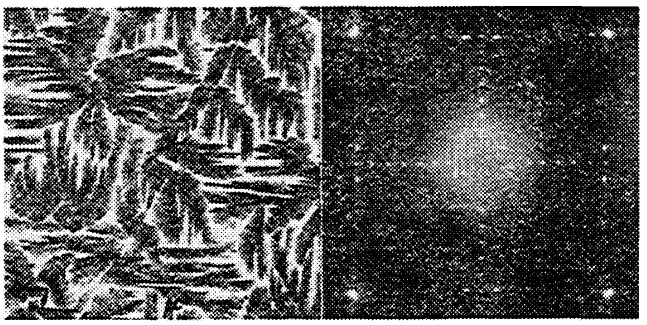
(a) (b)

Fig. 4. (a): Electron diffraction pattern of indanthrone film vacuum-condensed onto the (001) plane of NaCl at 150°C. (b): Electron diffraction pattern of pyranthrone film vacuum-condensed onto the (001) plane of NaCl at 200°C.

Pyranthrone films sublimated on rock salt took the same double-directional orientation as flavanthrone and indanthrone when the substrate was held to under 150°C. On the other hand, a triple-directional orientation was observed when the temperature of the substrate was raised to 200°C. An electron-diffraction pattern of the resulting film is a superposition of three identical fiber diagrams, as is shown in Fig. 4(b). The two dominant directions coincide with both the [110] and [1$\bar{1}$0] directions of rock salt, while the other faint direction runs parallel to the [100] direction of the substrate crystal. It should be noted that there are a few crystallites of pyranthrone growing along the [100] direction of the substrate rock salt as the temperature is raised to 200°C.

The characteristic behavior of the crystals deposited on rock salt is that their *b*-axes run parallel to the substrate face and that, consequently, they assume the parallel *b*-axis orientation.

B) Epitaxial Growth on Sylvine. When a cleavage face of sylvine was used as the substrate, vacuum-condensed films of polycyclic aromatic quinones showed quite a different orientation from those on the rock salt.



(a) (b)

Fig. 5. Electron micrograph (a) and electron diffraction pattern (b) of flavanthrone film vacuum-condensed onto the (001) plane of KCl. Crystals assume the standing *b*-axis orientation.

Flavanthrone crystals sublimated onto sylvine grow well-defined dendrites and form a discrete film, as is shown in Fig. 5(a). The electron-diffraction pattern of the film shown in Fig. 5(b) appears to overlap two single crystal patterns crossing orthogonally each other in spite of the reflections from many crystallites. This finding suggests that all the crystals deposited on sylvine take a well-defined orientation. Since the series of spots on the equator is equidistant corresponding to the interplanar spacing of 13.9 Å, they are clearly 200 and its higher-order reflections. On the contrary, the spacing of 1.75 Å, which is obtained from the distance between the first layer line and the equator, does not agree with any unit length of the crystallographic axes. The appearance of such layered lines should be ascribed to the position of the main zone axes of the deposited crystals, which are tilted against the substrate face and, consequently, against the electron beam. Because the equatorial spots have the indices of *h*00, all the spots within each layer line should have indices with the same *k* and *l* values. The spacing of the (014) plane is 1.78 Å. Thus, the spots on the layer lines above and below the equator correspond to *h*14 (or *h*1$\bar{4}$) and *h*$\bar{1}$4 (or *h*$\bar{1}$$\bar{4}$) respectively, and the *b*-axis of the crystal makes an angle of about 28° with the normal of the substrate face. The diffraction spots were indexed as is shown schematically in Fig. 6, in which the white circles represent the basic single crystal pattern. The total pattern is obtained by a superposition of this elementary pattern by the symmetry operation of C_{4v}, whose major axes are XX′ and YY′. By relating the orientation to the substrate crystal, the *a*-axis of flavanthrone was found to run along the <110> direction of sylvine.

In the case of indanthrone, the deposited film on

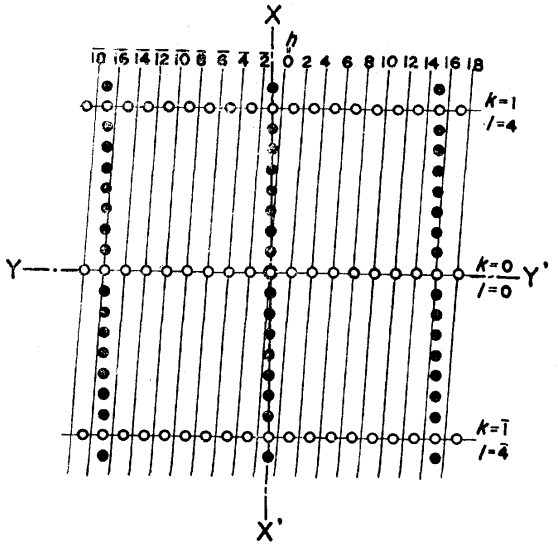


Fig. 6. The interpretation of the diffraction pattern shown in Fig. 5. White circles are the representation of the basic single pattern.

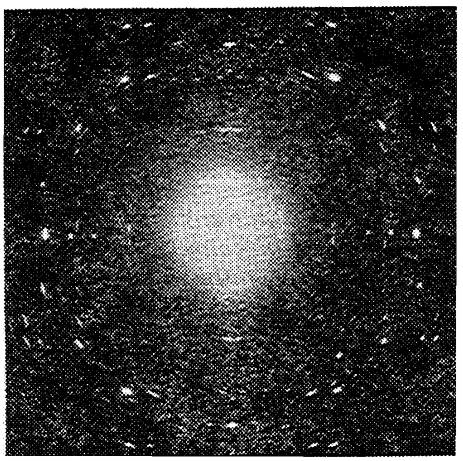

Fig. 7. Electron diffraction pattern of indanthrone film vacuum-condensed onto the (001) plane of KCl.

sylvine was composed of dendroid crystals similar to those of flavanthrone. The electron-diffraction pattern of the film shows a complicated pattern with the C_{4v} symmetry, as is represented in Fig. 7. Therefore, the film turned out to include eight groups of crystals, in each of which the crystals had the same orientation. Each elementary cross-grating pattern consits of three parallel regions. The unit length of the *b*-axis is more shorter than those of the *a*- and *c*-axes, so the reciprocal lattice plane with $k=1$ is located at a far distance compared with the other reciprocal lattice planes. Therefore, the spots in the region which includes the origin are the *h*0*l* reflections. They appear as at the intersection of the reciprocal lattice points as well as in their elongated intensity regions with the Ewald sphere. The other regions, which do not pass through the point of origin, correspond to the reciprocal lattice planes of $k=\pm1$. Thus, the total diffraction pattern is as is schematically reproduced in Fig. 8, in which the white circles indicate the basic single crystal pattern associated with one of two groups of crystals which have an apparent C_2 symmetry. Although the total pattern appears to be complicated, it can be illustrated by the systematic superposition of this elementary pattern with the major axes of C_{4v} symmetry, XX′ and YY′, which further coincide with the [110] and [1$\bar{1}$0] directions of sylvine respectively. From a consideration of the observed and calculated spacings as well as the intensities, the reciprocal lattice points, 804 and 91$\bar{2}$, were found to lie directly on the Ewald sphere. Consequently, the *a*-, *b*-, and *c*-axes of the crystal are inclined to the normal of the substrate face at angles of about 120°, 35°, and 76° respectively. As the AB line is the reciprocal *c** axis in the elementary pattern, the other lines, CD, EF, and GH, are similar *c** axes associated with individual crystal groups. Each reciprocal *c** axis was found to make an angle of about 5° with the nearest major axis of C_{4v} symmetry.

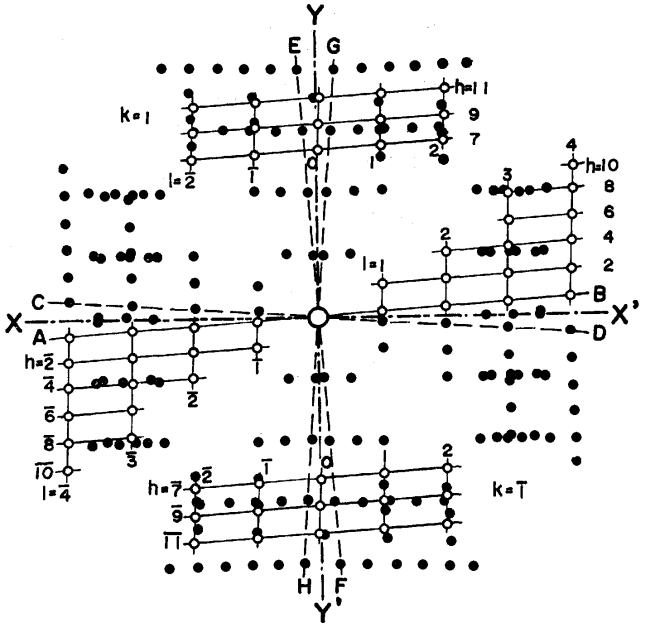

Fig. 8. The interpretation of the diffraction pattern shown in Fig. 7. White circles are the representation of the basic single crystal pattern.

Well-developed crystals of pyranthrone sublimated on sylvine had a definite wedge-like form, as is shown in Fig. 9(a). The electron-diffraction pattern of Fig. 9(b) represents an imperfect ring diagram, which indicates a random orientation. However, a selected area electron-diffraction pattern from one of the crystals, such as the one circled in Fig. 9(a), gave a single net pattern composed of three separate regions, as Fig. 9(c) shows. The diffraction spots were indexed as is schematically shown in Fig. 10. Considering the interplanar spacings and the intensities of the diffraction spots, it is found that the reciprocal lattice points, 105 and 10,1,$\bar{3}$, lie directly on the Ewald sphere. Consequently, the *b*-axis of the crystal tilts against the normal of the substrate surface at an angle of about 29°. If this single net pattern rotates around the point of origin, the resulting diagram coincides with the ring pattern of Fig. 9(b). Therefore, the random orientation seen in Fig. 9(b) arises from the differences in the tilting directions of the *b*-axes of the individual

crystallites, though the inclination angle of each *b*-axis to the normal of the substrate face is always a constant value of 29°.

Discussion

The crystal data of indanthrone, flavanthrone, and pyranthrone reported by Bailey,[12] Stadler,[13] and Maitland and Stadler[14] are summarized in Table 1. The molecules of polycyclic aromatic quinones are composed of many condensed benzene rings and form a flat plane, or a nearly flat one, as a whole. These flat molecules are closely packed together in a column, giving rise to a tilt against the column axis. The inclination angles of the molecular plane against the orthogonal *a*-, *b*-, or *c**-axis of each crystal are also shown in Table 1. When flavanthrone was sublimated on rock salt, the (001) face of the deposited crystal lay parallel to the substrate surface and its *b*-axis ran along either the [110] or [1$\bar{1}$0] axis of the substrate crystal. Since the planar molecules are not parallel to the (001) plane, they stand obliquely on the substrate surface so that they come in contact with the interface at several points. It is a problem which ion of sodium chloride attracts the deposited molecule and which atom of the flavanthrone molecule touches the substrate face. However, if a particular part in one molecule is located on the top of one Na^+ or Cl^- ion, it is likely that the same part of the adjacent molecule along the *b*-axis comes near to the top of the other like-charged ion and the crystal grows along the *b*-axis to form rod-like outward. In the cleavage face of rock salt, the distance between like-charged ions is 5.63 Å and 3.97 Å along the [100] and [110] axes respectively. Comparing these values with the length of the *b*-axis of the flavanthrone crystal, it seems reasonable that the preferential orientation of the deposits in the <110> directions occurs in the cleavage face of rock salt. The same characteristic behavior of other quinones, indanthrone, and pyranthrone was found in their epitaxial growth on rock salt. When the strips assume a cross-directional raft structure, the mutual orientation is uniquely defined and the needle axis of individual strips, essentially the *b*-axis, coincides with the <110> directions of rock salt. In the case of pyranthrone, in addition to these directions, a small number of crystallites oriented their *b*-axis parallel to the [100] direction of rock salt at high temperatures above 200°C. The different orientation observed in the pyranthrone film may be due to a weaker interaction between the deposit and substrate ions than those in the other quinones studied. If the energy of thermal vibration is not very high, the orientation in the <110> direction caused by this interaction will be favored. If the substrate temperature is raised and the energy of thermal vibration becomes high, the effect of the interaction will be reduced relatively and the alignment of the crystal will not be entirely specific in the <110> directions. Recently, Koutsky *et al.*[4,5] have reported that some polymers which crystallized epitaxially from a solution on alkali halide surfaces grew small, rod-like crystallites with an orientation in the <110> directions of the substrates. They also concluded that the polymer epitaxy was dependent on rows of like-charged ions in the

substrate surfaces.

On the contrary, when sylvine was used as the substrate, the deposited films showed quite a different orientation, one giving rise to various morphological features. In the case of the flavanthrone crystal on sylvine, its b-axis is inclined to the normal of the substrate face at an angle of 28° and the a-axis runs along the <110> directions of sylvine. Because the molecular plane of flavanthrone is inclined against the (010) plane at an angle of 26°, the standing b-axis orientation suggests that the planar molecule nearly comes in contact parallelly with the substrate face. In heterocyclic compounds the charge is distributed on nitrogen atoms with a high density.[15] Therefore, in the planar molecule facing the substrate, it seems reasonable to assume that the nitrogen atoms of the molecule come in contact with K^+ ions, as is schematically shown in Fig. 11. A projection of the above molecules facing parallel along the b-axis on a molecular plane shifts in either the b_p or b_p' direction, which coincides with the [110] direction of sylvine, depending upon the staggering of the overlapping molecule. This configuration results in two different crystals which are related by a two-fold rotation axis. As sylvine has a four-fold rotation axis perpendicular to its (001) plane, the same relative orientation between the deposited and substrate crystals is obtained by the rotation of 90° in the deposited molecule. This gives rise to two different crystals, the projection of whose b-axis coincides with the $[1\bar{1}0]$ direction of sylvine. Thus, the total film consists of four groups of oriented crystals and the electron-diffraction pattern from them gives two overlapping diagrams crossing orthogonally. However, when we compare the inclination angles of the crystal axes to molecular plane with the tilting angle of the oriented crystal, it is clear that the flat molecule does not lie strictly parallel to the substrate face. Presumably each molecule is initially adsorbed parallelly to the (001) plane of sylvine, but the intermolecular force among neighboring molecules pulls the lying molecule slightly up, so that a perfect three-dimensional configuration builds up within the crystal.

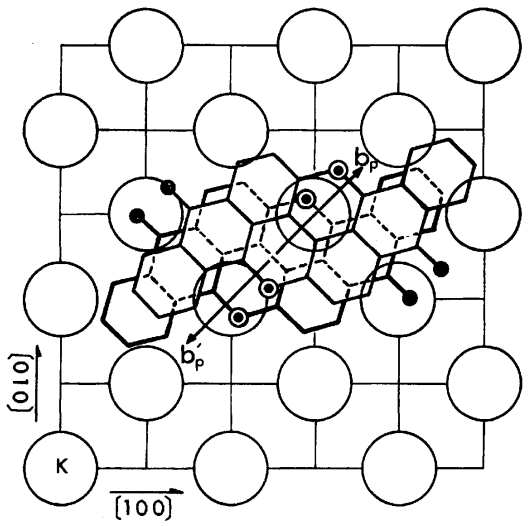

Fig. 11. The lattice structure of the (001) plane of KCl and the relative orientation of the deposited flavanthrone.
●: oxygen atom
⊙: nitrogen atom

The crystal of indanthrone sublimated on sylvine took the standing b-axis orientation, in which the a-, b-, and c-axes are inclined to the normal of the substrate face at angles of about 120°, 35°, and 76° respectively. When we compare these values with the inclination angles of the molecular plane against the crystal axes, it seems reasonable to conclude that the molecular plane comes into parallel contact with the substrate face. If the nitrogen atoms of the molecule are assumed to lie on K^+ ions, as is schematically shown in Fig. 12, a projection of the above molecule facing parallel along the b-axis on a molecular plane shifts in either the b_p or b_p' direction, which makes an angle of 30° with the $[1\bar{1}0]$ direction of sylvine. A projection of the c-axis on a molecular plane makes an angle of 125° with that of the b-axis, as is shown by the OA and OB lines concerned with b_p and b_p' and, consequently, makes an angle of 5° with the $[1\bar{1}0]$ direction of sylvine; this results in two different crystals related by the two-fold rotation axis. It should be noted that this angle coincides with that between the projection of the reciprocal c^*-axis of the indanthrone crystal and the [110] direction of sylvine as revealed by the electron-diffraction pattern. If a molecule is rotated about the XX′ axis by 180°, the molecule lies at the same position relative to the substrate ions. In this case, a projection

⊙: nitrogen atom

of the *b*-axis on the surface makes an angle of 30° with the [1$\bar{1}$0] direction of sylvine, as is shown by b_q and b_q', and the projection of the *c*-axis is as is represented by the CD line. Consequently, such a molecular orientation gives rise to four sets of crystals with an apparent C_{2v} symmetry, whose mirror plane is perpendicular to the [110] direction, as is represented by the XX′ line. Moreover, the same relative orientation between the deposited and substrate crystals is obtained by the rotation of 90° in the deposited molecule. The orientation of the resulting crystals has a symmetry of C_{2v} as a whole, whose mirror plane is perpendicular to the [1$\bar{1}$0] direction, as is represented by the YY′ line. Thus, the total film involves eight sets of oriented crystals and shows an apparent C_{4v} symmetry, as far as the orientation of individual crystallites is concerned.

In the pyranthrone film vacuum-sublimated on sylvine, the individual crystals assumed the standing *b*-axis orientation, in which the *b*-axis tilted against the substrate face with an angle of 29°. However, the ring pattern from the total film suggested that the individual tilting *b*-axis took a random direction independent of the alignment of ions in the cleavage face of sylvine. When the inclination of the molecular plane to the crystal axes is considered, it is clear that the molecular plane is parallel to the substrate face, but no strictly preferential location of the component atoms in the deposited molecule seems to occur in this case. Pyranthrone is closely related to flavanthrone, in which the two C-H groups are replaced by N atoms. Both flavanthrone and indanthrone belong to the same structure type with the $P2_1/a$ space group, and their molecular planes are tilted about the C–O bond as an axis. On the other hand, pyranthrone belongs to a different structure type which contains two independent molecules per asymmetric unit. Perhaps there is a difference in the intermolecular forces of pyranthrone and the other quinones studied.

The various orientations on the cleavage faces of alkali halides may be caused by the complex combination of mutual interaction between the deposited and substrate crystals and the intermolecular force within the crystal. The condensed polycyclic aromatic compounds include π electrons out of the molecular plane. These electrons may affect the way of molecular adsorption by interaction with the gas which is adsorbed on the substrate face in advance, as been described in previous papers.[10,16] Therefore, the mode of molecular adsorption, the parallel *b*-axis or the standing *b*-axis orientation, is perhaps primarily determined by the interaction between these π electrons and the substrate face. The position of the individual component atoms relative to the substrate ions is determined by the charge distribution in the molecule itself. The influence of adsorption gas on orientation overgrowth will be described in a future report. For organic crystals composed of large flat molecules, we may suppose that both the charge distribution and the configuration of the molecules themselves, as well as the total lattice dimensions of the deposited and substrate crystals, are important in determining epitaxial growth.

The authors wish to thank Professor Eiji Suito and Dr. Natsu Uyeda of the Institute for Chemical Research, Kyoto University, for their many helpful discussions during this work.

The Dehalogenation of Haloalkanes on SiO_2-supported Metals

Yasuhide ANJU, Isao MOCHIDA, Hiroko YAMAMOTO, Akio KATO, and Tetsuro SEIYAMA

Department of Applied Chemistry, Faculty of Engineering, Kyushu University, Fukuoka

(Received November 25, 1971)

The dehalogenations of haloethanes and halopropanes over metals (Cu, Ag, Au, Fe, Co, Ni, Pd, and Pt) supported by silica gel were studied by means of the microcatalytic pulse technique in order to elucidate the mechanism of dehalogenation. The dechlorination reactivities of *cis*- and *trans*-1,2-dichloroethylenes and the dechlorination products from *dl*- and *meso*-2,3-dichlorobutanes were observed from the viewpoint of stereoselectivity. The order of catalytic activities among the metals for the dehalogenation of haloethanes was: Pt>Cu≈Ni>Ag≈Co≈Pd>Fe≈Au. Dehalogenation proceeded exclusively in the 1,2-dihaloethanes. However, dehydorhalogenation took place in the 1,2-dihalopropanes to an appreciable extent when the product distributions of dehydrohalogenation were similar to those on solid acids. Both 1,1,2-trichloroethane and 1,2-dichloropropane were more reactive than 1,2-dichloroethane. 1,2-dichloroethylenes from 1,1,2,2-tetrachloroethane and 2-butenes from *dl*- and *meso*-2,3-dichlorobutanes were nearly in an equilibrium ratio of *cis*/*trans* forms. From a comparison of these results with those of the dehydrohalogenation on solid acids, it is concluded that the dehalogenation of haloalkanes on metals proceeds through a radical-step-by-step mechanism.

It has been reported that the dechlorination of chloroethanes on chromia proceeds through an E2-concerted mechanism.[1] The dechlorination on metal sulfates has interest in connection with the stereoselectivity and activity which depend on the kind of metal ion.[2] It may be expected that the dehalogenation takes place selectivity on metals because of the nonpolar nature of their surfaces.

In the liquid phase, the reactions of *vic*-dibromoalkanes with metals such as Mg and Zn were studied, and an E2-concerted mechanism or a carbanion mechanism has been proposed on the basis of the product distribution.[3] It is interesting to compare the gas-phase dehalogenation on metals with the liquid-phase reaction.

In the present study, the dehalogenation of haloethanes and halopropanes on metals (Cu, Ag, Au, Fe, Co, Ni, Pd, and Pt) was investigated in order to elucidate the characteristics of metals compared with compound catalysts with regard to halogen-metal interaction. The activities of metals and the reactivities of several chloroalkanes were analyzed on the basis of the δ_C and δ_R LFER approaches.[1,2,4]

Additional information was obtained from the dechlorinations of 1,2-dichloroethylenes and 2,3-dichlorobutanes on several metals.

Experimental

Reagents. The reagents used in this work were obtained from the Tokyo Kasei Co. They were of an E.P. grade and were used without further purification. The *dl*- and *meso*-2,3-dichlorobutanes were obtained by the resolution of their mixture by using a DIDP (2 m, 20°C) column.

Catalysts. The metal catalysts supported by silica gel were obtained by impregnating silica gel (Wako) with an aqueous solution of metal salt (Cu, Ag, Co, Ni : nitrate, Au, Pd, Pt : chloride, Fe : hydroxide); then they were dried at 120°C in the atmosphere. Each catalyst contained 0.4 mg-atom/g-silica gel. Before use, all of them except Fe, Co, and Ni (Fe, Co : 450°C, Ni : 400°C) were reduced at 300°C by the hydrogen in the reactor.

Procedures. The reaction rates and selectivities were measured by the microcatalytic gas chromatographic technique in the temperature range from 200 to 450°C. TCP was used in an analytical column (60 or 120°C, 2 m). Silicon SF (4 m, room temperature) was also used for the separation of the butenes. Hydrogen gas was used as the carrier. Hydrogenolysis was very small, even on Pt, Ni, and Pd, in the reaction of 1,2-dihaloethane. However, decompositions other than dechlorination took place to a considerable extent in the reactions of 1,1,2,2-tetrachloroethane and 1,1,2-trichloroethane on Pd and Pt, so helium gas was used in these cases. The activities decreased from pulse to pulse (the second pulse conversion was *ca.* 50% of the first), so the reaction rates were obtained from the first pulse. This deactivation by reaction products means that the reaction observed in the present study is the halogenation of metals by haloalkanes. The reaction rates (ml/g·min) were measured below a 20% conversion. The details of the experiments have been described in previous papers.[1,2,5]

Results

Dehalogenation Activities of Metal Supported by Silica Gel. As for 1,2-dihaloethanes, dehalogenation took place exclusively on the metals supported by silica gel, except for 1,2-dibromoethane on Fe, where dehydrobromination took place to a considerable extent. The catalytic activities of metals for 1,2-dichloroethane are shown in Fig.1 as a function of the reaction temperature. The results for 1,2-dibromoethane are shown in Fig.2. The activities of the meatls at 300°C were in the order of Pt>Cu≈Ni>Co≈Ag≈Pd>Fe≈Au in both dehalogenations. The reactivities of the two haloethanes are compared in Fig.3. The rates of debromination were larger than those of dechlorination. This difference was pronounced on Pt, Pd, and Fe. The apparent activation energies were smaller for debromination than for dechlorination, corresponding to the higher re-

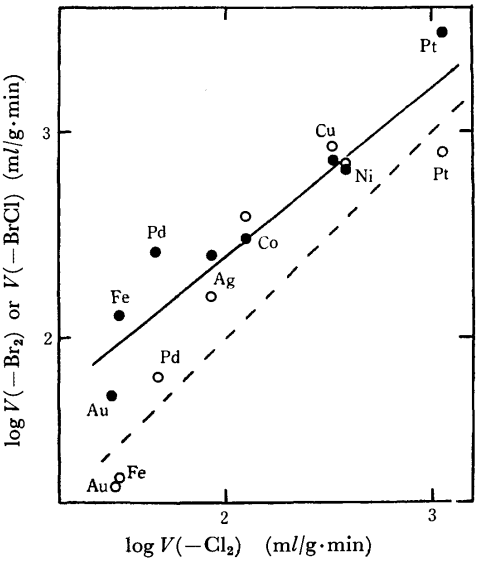

Fig. 3. Dehalogenation-reactivities of 1,2-dihaloethane at 300°C, abscissa; dechlorination of 1,2-dichloroethane, ordiate; debromination of 1,2-dibromoethane(●), and dechlorobromination of 1-bromo-2-chloroethane(○). Dotted line indicates the rate equal to dechlorination of 1,2-dichloroethane.

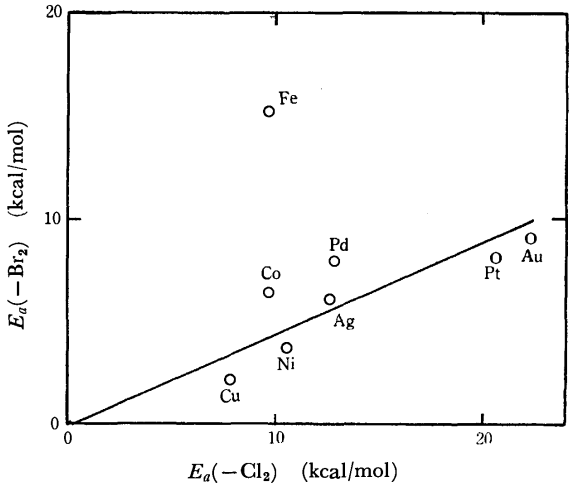

Fig. 4. Apparent activation energies of dehalogenation, abscissa; dechlorination of 1,2-dichloroethane, ordiate; debromination of 1,2-dibromoethane.

activity of the bromoethane. One can observe a correlation between the values of the apparent activation energies for the two dehalogenations. This correlation, together with the correlation of reactivities shown in Fig.3, indicates a similarity in the mechanisms between the two reactions.

On the other hand, the reactivity order among the three dihaloethanes, 1,2-dichloroethane, 1,2-dibromoethane and 1-bromo-2-chloroethane, varied according to the kind of metal as may be seen in Fig.3. The debromochlorination-reactivity of 1-bromo-2-chloroethane was near the debromination-reactivity of 1,2-dibromoethane on Cu, Ni, Co, and Ag, but was rather close to the dechlorination-reactivity on Pt, Pd, Au, and Fe. The first metal group shows a small activation energy, as may be seen in Fig.4. These results may reflect the difference between the two groups in the affinity of the metal to chlorine and bromine.

Substituent Effects on the Dechlorination Reactivity. The reactivities of three chloroethanes and 1,2-dichloropropane on some metals at 300°C are shown in Table1. The order of the reactivity was 1,1,2,2-tetrachloroethane > 1,1,2-trichloroethane > 1,2-dichloropropane > 1,2-dichloroethane. This order is different from that in dehydrohalogenation on solid acids, where 1,1,2-trichloroethane is much more reactive than 1,1,2,2-tetrachloroethane.[6] The above order is rather similar to that of dehydrochlorination on solid bases, but the reactivity differences among these reactants are not so large as in the dehydrochlorination on solid bases.[6]

a) Dehydrohalogenation did not proceed on Pd and Pt at all.
b) 2-chloropropylene was not detected at all except on Ni.
c) 2-bromopropane was detected on Fe, Co, Ni, but the mount was very small except Ni.
d, d') The ratio of allylchloride/1-chloropropylene and that of allylbromide/1-bromopropylene, respectively.
e, e') The ratio of *trans*-1-chloropropylene/*cis*-1-chloropropylene and that of *trans*-1-bromopropylene/*cis*-1-bromopropylene, respectively.
f) Silica alumina (13% Al_2O_3)
g) Alumina (calcined at 550°C)
h) Helium was used as a carrier gas.

The dehydrohalogenation of 1,2-dihalopropanes took place simultaneously with the dehalogenation to various extents, according to the kind of metal. The ratios of dehydrohalogenation/dehalogenation are shown in Table 2. The ratio is high on Fe and Co. The dehydrohalogenation-activities of metals were in the following order: Fe>Co>Cu, Ag, Ni, Au≫Pt, Pd. Allyl chloride, and 1-chloropropylenes, mainly *cis*-1-chloropropylene, were formed by the dehydrochlorinaiton of 1,2-dichloropropane. These product distributions are similar to those on solid acids.[7]

Stereoselectivity in Dechlorination. The products of dechlorination of 1,1,2,2-tetrachloroethane were *trans*- and *cis*-1,2-dichloroethylenes. 1,1-dichloroethylene was not detected. The ratios of *trans*-1,2/*cis*-1,2 obtained were near to the equilibrium value (0.654 at 300°[8]) on most metals except for Cu and Au, where the ratios were nearly unity. These selectivities were considered to be those for the primary product, since the rates of the isomerization of 1,2-dichloroethlyene were small compared with those of the dechlorination. It is interesting that the ferric and cupric sulfates on silica gel also gave, respectively, the equilibrium value and unity for this selectivity.

The *meso*- and *dl*-forms of 2,3-dichlorobutane have been used to investigate the stereospecificity in the eliminations: the dechlorination on zinc and magnesium metals in the liquid phase[3] and the dehydrochlorination on alkali- and alkali earth-metal salts.[9] In the present dechlorination on metals in the vapor

c) Hydrogen was used as a carrier gas.
d) Helium was used as a carrier gas. *i*-Butene was the main dechlorination product.

Table 4. The rates of *trans*- and *cis*-elimination ($-Cl_2$) of 1,2-dichloroethylenes at 300°C

Metal	Rate of *trans*-elim.[a] (ml/g·min)	Rate of *cis*-elim.[b] (ml/g·min)	Ratio $\left(\frac{\text{trans-elim.}}{\text{cis-elim.}}\right)$
Cu[c]	91	78	1.2
Pt[d]	15	52	0.3

a) $\begin{matrix}H\\Cl\end{matrix}\!\!>\!C\!=\!C\!<\!\!\begin{matrix}Cl\\H\end{matrix} \longrightarrow H\text{-}C\equiv C\text{-}H + Cl_2$
b) $\begin{matrix}H\\Cl\end{matrix}\!\!>\!C\!=\!C\!<\!\!\begin{matrix}H\\Cl\end{matrix} \longrightarrow H\text{-}C\equiv C\text{-}H + Cl_2$
c) Hydrogen was used as a carrier gas.
d) Helium was used as a carrier gas.

phase, both *meso*- and *dl*-2,3-dichlorobutanes produced *trans*- and *cis*-2-butenes to the same degree, as is shown in Table 3; this is in contrast to the dechlorination on zinc and magnesium metals in the liquid phase, where *meso*- and *dl*-forms gave *trans*- and *cis*-2-butenes respectively.[3] The rates of the isomerization of the 2-butenes were negligibly small on these metals under the same conditions. The lack of stereospecificity in the dechlorination of 2,3-dichlorobutanes indicated that the dechlorination took place through an intermediate in which the rotation of the C–C bonds was free. Therefore, a similar situation might occur in the dechlorination of 1,1,2,2-tetrachloroethane to 1,2-dichloroethylene.

Discussion

Mechanism of the Dehalogenation of Haloalkanes on Metal. In contrast to the selective occurence of dehydrohalogenation on solid acids and bases, the dehalogenation of haloethanes took place predominantly on the metals examined in the present study. Solid acids and bases have polar sites on their surface, whereas there are no such polar sites on matel surfaces. This difference between metals and solid acids or bases in the nature of the surface may be responsible for the variation in the elimination products. An ionic-step-by-step mechanism has been proposed for the dehydrohalogenation on solid acids,[2b] in this mechanism, the first step is the abstraction of a halogen atom as a halide ion. Judging from the nonstereospecific dechlorination of 2,3-dichlorobutanes, the dehalogenation of haloalkanes on metal may also occur by a step-by-step mechanism. The difference in elimination products, however, shows that the manner in the halogen abstraction is different between metals and solid acids. From the nonpolar nature of the metal surface, a non-ionic mechanism may be considered likely for the dehalogenation on matels. The small substituent effect on the dehalogenation reactivity on metals, compared with the dehydrohalogenation-reactivity on solid acids and bases, indicates a non-ionic intermediate in the dehalogenation on metals.[10]

A similar difference between metals and solid acids or bases was observed in the elimination reaction of 1,2-dichloroethylenes. On solid acids and bases, *cis*- and *trans*-1,2-dichloroethylenes underwent dehydrochlorination when the *cis*-form showed a much higher reactivity than the *trans*-form.[11] On the other hand, the dichloroethylenes underwent dechlorination on metals, as was observed on haloalkanes, and the reactivity difference of both isomers was not very large, as is shown in Table 4. The higher reactivity of *cis*-1,2-dichloroethylene is characteristic of an ionic medium, such as solid acids or bases and basic solutions. The comparable reactivity of the two isomers on metals, accordingly, shows that the dechlorination occurs through a non-ionic mechanism on metals.

From these comparisons between metals and solid acids or bases, it can be concluded that the dehalogenation of haloalkanes on metals proceeds though a radical-step-by-step mechanism.

The interaction between the halogen atom and a metal surface may result from the coordination of a lone pair of the halogen atom to the unoccupied orbitals. In the above mechanism, the first step of the dehalogenation of haloalkanes on metals is the abstraction of the halogen atoms by a metal surface. The fact that 1-bromo-2-chloroethane shows a close reactivity to 1,2-dibromoethane on Cu, Ni, Co, and Ag can be easily understood by the above radical-step-by-step mechanism, provided that the weaker C–Br bond is broken in the first step on both reactants. 1-bromo-2-chloroethane showed, on the other hand, a lower reactivity than 1,2-dibromoethane on Pt, Pd, and Au. This may be related to the large back-donating powers of these metals in M–Br coordination.[12]

The dehydrohalogenation which was observed with regard to 1,2-dihalopropane may proceed *via* an El carbonium ion mechanism, as is indicated by the product distribution being similar to that on the solid acids.[7] This mechanism can explain the high dehydrohalogenation reactivity of 1,2-dihalopropane from the electron-donating effect of the methyl group, as has been described previously.[2] High ratios of $-HX/-X_2$ were observed on Fe and Co, showing that these metals have a considerable ability to abstract the halogen atom as a halide ion besides a radical. The metals with a high value of dehydrohalogenation/

dehalogenation selectivity (Fe and Co) and the metals with a low ratio (Pt and Pd) also showed a high activity for acetaldehyde formation and ethylene formation respectively from ethylene chlorohydrin.[5] The former was considered to proceed through a carbonium-ion mechanism, and the latter, through a radical mechanism.[5]

Origin of the Fine Structure of the Electronic Spectra of Pyrazine in Benzene Crystals

Isamu SUZUKA and Mitsuo ITO

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai, Japan

(Received December 2, 1971)

The absorption, fluorescence, and phosphorescence spectra of pyrazine doped in benzene crystal have been observed at 4.2°K. It was found that the 0-0 band and the main vibronic bands are accompanied by the fine structures consisting of several very sharp bands and few broad bands. A detailed examination of the fine structures has suggested that the sharp bands arise from the differently oriented guest molecules in the host crystal, and the broad bands come from coupling of the host crystal phonon with the guest molecule.

Low temperature electronic spectra of aromatic compounds doped in host crystal often exhibit fine structure in $0\sim200\ cm^{-1}$ region near main vibronic band. As the fine structure is in most cases very different for the same guest spectra on different host crystals, a coupling of the host crystal phonons with the electronic state of the guest molecule has been suggested to be the cause of the fine structure. Many workers have attempted to explain the fine structure with the $k=0$ phonons. However, the attempt seems unsuccessful because of lack of definite correspondence with the Raman and IR active phonon frequencies. Recently, Zahlan[1] and Ostertag[2] *et al.* have suggested that the $k\neq0$ phonons also play an important role and the fine structure represents more or less the frequency distribution of phonon density of the host crystal. Hochstrasser and Small[3] have pointed out, on the other hand, that the fine structure is partly explained by existence of several differently oriented guest molecules in the host lattice.

In the present investigation, the absorption, fluorescence and phosphorescence spectra of pyrazine in benzene crystal have been observed at 4.2°K. It was found that the main vibronic bands of these spectra are accompanied by the fine structures consisting of several very sharp bands and a few broad bands. Comparison among the fine structures of the absorption, fluorescence and phosphorescence spectra and effects of changing the host crystal from benzene to benzene-d_6 on their features revealed possible causes of the fine structure.

Experimental

The absorption, fluorescence and phosphorescence spectra were measured photographically with a Shimadzu GE-100 grating spectrograph in the second and third orders, the linear reciprocal dispersions being 4.1 and 2.7Å/mm, respectively. Exposure time ranged from 1 min to 4 hours with slit width of 50 μ.

Wave numbers of the sharp and broad bands were determined within accuracies of 0.5 and 1.0 cm^{-1}, respectively. Photoelectric spectral measurements were also carried out by using a Narumi grating double monochromator having a linear reciprocal dispersion in the first order of 11 Å/mm and an EMI 9558 BQ photomultiplier. The optical arrangement for taking the spectra at low temperatures is essentially the same as that described by Mikami.[4] The emission spectra were excited by Hg line of 3130Å from a Ushio high pressure mercury lamp, which was isolated by a Shimadzu Baush & Lomb high intensity monochromator as well as a Corning CS-75 filter.

Pyrazine (Tokyo Kasei, GR grade) was sublimated several times in vacuum. Benzene (Wako, GR grade) was purified by the procedure recommended by Kanda *et al.*[5] Benzene-d_6 (E. Merck, spectro-grade) was vacuum distilled. Concentration of the sample solutions were 10^{-2}—10^{-4} mol/*l*. The solution was degassed several times and transferred to a quartz cell of 1 mm path length in vacuum. The sample inserted in a cryostat was slowly cooled until 77 °K by cooled nitrogen gas, then, immersed in liquid He.

Results and Discussion

The absorption, fluorescence, and phosphorescence spectra of pyrazine in benzene crystal at 4.2°K are shown in Fig.1. These spectra are all due to an n-π^* transition of pyrazine. The spectra were sharp in benzene crystal compared with those in other host

crystal such as cyclohexane.[6] The essential feature of the spectra did not change when temperatrue and concentration of the sample were varied in the ranges of 4.2°K—77°K and 10^{-2}—10^{-4} mol/l, respectively.

The fine structures of the 0-0 bands of the absorption, fluorescence and phosphorescence spectra in benzene are reproduecd in Fig.2.[7] It is seen that the 0-0 bands are composed of very sharp bands and broad bands. A good mirror image relationship is seen between the absorption and fluorescence. Table 1 gives the frequency differences of the individual main bands measured from the strongest band in each spectrum selected as reference. It is seen that a good correspondence exists among the three spectra, especially the broad bands. Such broad bands are often observed in the electronic spectra of aromatic molecules doped in host crystal as side bands of the main vibronic bands. They are usually interpreted as "lattice or phonon bands" of the host crystal without evidence. If this interpretation would be correct, the broad bands should shift as a whole relative to the reference band when the host crystal is changed from C_6H_6 to C_6D_6. It is seen from Table 1 that the frequency differences between the broad bands and the reference band decrease in changing the host crystal from C_6H_6 to C_6D_6. The ratio of the frequency differences between C_6H_6 and C_6D_6 hosts is in average 1.05. This is close to the ratio of the lattice vibrational frequencies of C_6H_6 and C_6D_6 crystals, which is about 1.11 and 1.04 for optical active rotational and translational phonon modes, respectively.[8] It is

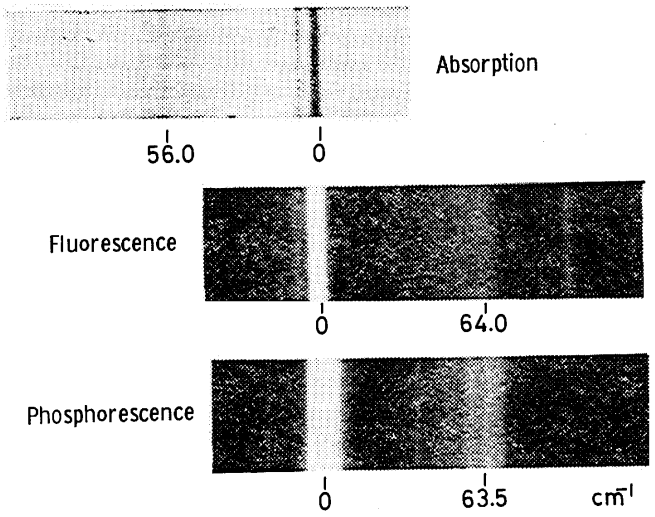

Fig. 2. Fine structures near the 0-0 bands of the absorption, fluorescence, and phosphorescence spectra of pyrazine in benzene crystal at 4.2°K.

6) I. Suzuka and M. Ito, unpublished data.

7) The 0-0 band of the fluorescence spectrum was not observed because of reabsorption. The fine structure shown in the figures and the tables of this paper is for 0-596 cm^{-1} band which was assumed to have same structure as that of the 0-0 band.

8) M. Ito and T. Shigeoka, *Spectrochim. Acta*, **22**, 1029 (1966).

suggested therefore that the broad bands arise from coupling with the host crystal phonons. Broadness of the bands is reasonable because all the phonons of various wave vectors k having quasi-continuous frequencies are able to contribute to intensity of the phonon bands.

Now, we shall consider the origin of the sharp bands. In Table 2 the frequencies of the sharp bands near the 0-0 bands of the absorption spectra of pyrazine in C_6H_6 and C_6D_6 are compared with the corresponding frequencies of the fluorescence spectra, the latter being estimated from the observed frequencies of the sharp bands near the 0—596 cm^{-1} vibronic bands of the fluoresence by adding a constant frequency of 596 cm^{-1} to them.

a) see the footnote in text.

Assuming the same structure for the 0-0 and 0-596 cm^{-1} bands, the fluorescence frequencies listed in Table 2 may be regarded as representing the sharp bands near the 0-0 bands of the fluorescence spectrum which would be observed in absence of reabsorption. It is seen from the table that the sharp bands of the absorption and fluorescence agree very well within 2 cm^{-1}. Furthermore, the relative intensities are parallel between the two spectra. Similar results were found also for the absorption and fluorescence spectra of pyrazine in cyclohexane crystal.[6] We may conclude therefore that the individual sharp bands represent common origins of the absorption and fluorescence spectra. Recently, Small[9] reported the mixed crystal spectrum of anthracene in terphenyl, in which he found three fluorescence bands coinciding in frequency with the absorption bands. He interpreted them as due to the guest molecules differently oriented in the host lattice. This interpretation seems to be applied to our present case. In Fig.3, the fine structures associated with several main vibronic bands of the phosphorescence spectrum of pyrazine in benzene crystal are compared. The spectral pattern of the sharp bands which occur mainly on higher frequency side of the most intense band in each vibronic band is considerably different for different vibronic bands. This may also be taken as an evidence supporting the above interpretation that the sharp bands arise from

9) G. J. Small, *J. Chem. Phys.*, **52**, 656 (1970).

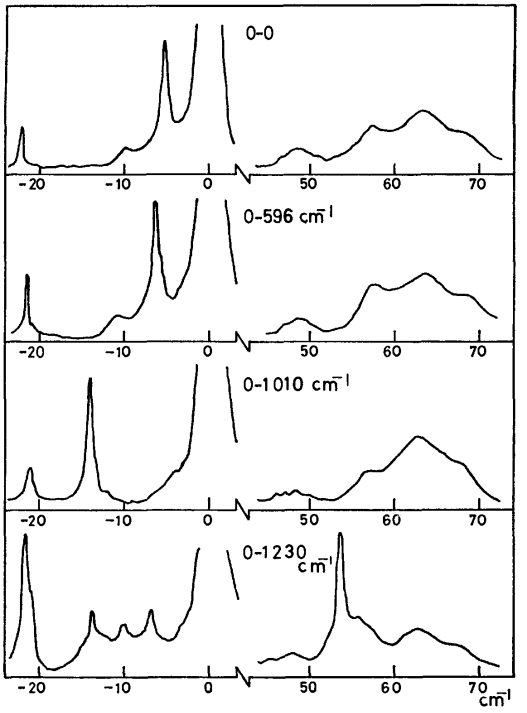

Fig. 3. Fine structures accompanied by several main vibronic bands of the phosphorescence spectrum of pyrazine in benzene crystal at 4.2°K.

different guest molecules situated in different circumstances in the host crystal. The molecules situated at different sites will have different frequencies of the molecular vibrations depending on degree of distortion of the guest molecules induced by crystal field of the host lattice. Since these guest molecules give rise to their own spectra having different 0-0 bands and different vibrational structures, different patterns of the fine structures are expected for different vibronic bands. The sharp bands associated with the main vibronic bands of the fluorescence spectrum also showed different spectral patterns similar to that of the phosphorescence spectrum.

In contrast to the sharp bands, the broad bands associated with the main vibronic bands of the phosphorescence spectrum, which occur mainly on lower frequency side of the strongest band in each vibronic band, are very similar in spectral feature to each other (Fig.3). As described before, when the host is replaced from benzene to benzene-d_6, these broad bands shift as a whole toward the strongest bands (hereafter, referred to as "reference band"), and this was taken as evidence supporting that the broad bands are host phonon bands. In this interpretation, we implicitly assumed that the broad bands are resulting from coupling of the host crystal phonons with the vibronic states of the guest molecule which gives the reference bands. The host crystal phonons will be able to couple also with other guest molecules which give the sharp bands other than the reference bands.

However, intensities of the phonon bands resulting from the sharp bands other than the reference bands will be much smaller than intensities of the phonon bands associated with the reference bands, because the

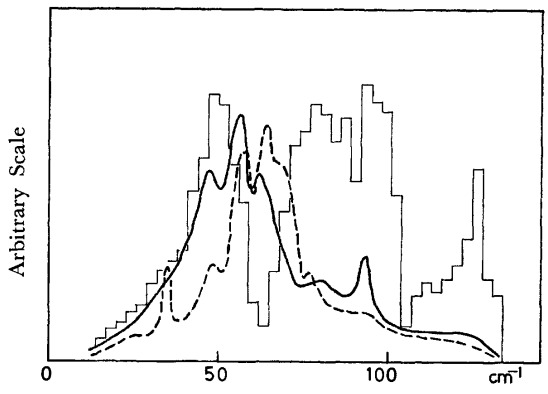

Fig. 4. Typical phonon bands of the absorption (—) and phosphorescence (----) of pyrazine in benzene at 4.2°K compared with the calculated D(ν) (—) of benzene at 135°K (taken from ref. (9)).

former are much weaker in intensity than the latter. Thus, the observed broad bands may be regarded as the phonon bands belonging mainly to the reference bands.

It may be worthwhile to mention here that the spectral pattern of the phonon bands seems not to depend on symmetry species of the molecular vibrations involved in the vibronic bands. For example, in the fluorescence spectrum we found two kinds of vibronic bands involving totally symmertric and nontotally symmetric molecular vibrations which give the same pattern of the phonon bands. This suggests that no specific selection rule is operative in coupling between the vibronic states of guest molecule and the phonons of host crystal. If it would be the case, the phonon bands should represent the density of states of the phonon, $D(\nu)$. Recently, Nakamura and Miyazawa[10] calculated $G(\nu)$ ($D(\nu)$ weighted with squared amplitude) of benzene crystal, which agrees well with that obtained from the neutron inelastic scattering experiment[11]. In Fig. 5, the $D(\nu)$ calculated by Nakamura and Miyazawa is compared with typical phonon structures of the phosphorescence and absorption spectra. According to Nakamura and Miyazawa, the peak near 50 cm^{-1} and the long tail in the region less than 50 cm^{-1} is mainly contributed from the acoustic phonons. The fact that greater part of intensity of the phonon bands is concentrated in the above frequency range suggests that the acoustic phonons of the host lattice play an important role in coupling of the electronic state of the guest molecule with the lattice vibrations of the host crystal.

The authors express their sincere thanks to Dr. N. Mikami for helpful discussions and advice throughout this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2326—2329 (1972)

On the Equivalence of Two Expressions for Potentiometric Titration of Polyelectrolytes

Hiroshi MAEDA

Department of Chemistry, Faculty of Science, Nagoya University, Nagoya

(Received December 3, 1971)

Two expressions for potentiometric titrations of polyelectrolytes are proved to be equivalent, being derived from a common basis. A thermodynamic interpretation of the term representing the non-ideality of polyelectrolyte solutions is also explicitly given.

It has been well known that potentiometric titrations of polyelectrolyte solutions can be described by the equation,[1-4]

$$\mathrm{pH} = \mathrm{p}K_0 + \log(\alpha/1-\alpha) + \Delta\mathrm{p}K \qquad (1)$$

Here K_0 and α denote the intrinsic dissociation constant of dissociable sites and the degree of ionization respectively. The last term in Eq.(1) represents the non-ideality of the solution and in ordinary cases arises solely from the electrostatic work accompanying ionization.

On the other hand, the following thermodynamic expression has been presented.[5]

$$(\partial\mu_p/\partial\mu_{\mathrm{H}})_{m_p,m_s} = \alpha x \qquad (2)$$

Here μ_p and μ_{H} denote the chemical potentials of polymer component and of hydrogen ions, and m_p and m_s the concentrations of ploymer and salt components. Futher x denotes the number of the dissociable sites on a polyion.

However, the equivalence of the two expressions, Eq.(1) and Eq.(2), has not been presented. The purpose of the present study is to derive the two expressions from a common basis and thus to show their equivalence.

Theory

For the sake of simplicity, let us take a poly (weak) acid neutralized to various degrees by alkali as a polyelectolyte. Let us consider a solution containing n_w, n_p, n_s, and n_a moles of water, polyacid, simple salt (uni-uni valent), and alkali. We take a fully protonated species as a polymer component here. Concentrations of solutes are expressed in m's. The counter ions from alkali and those from simple salt are assumed to be of the same species. Since we consider the changes at a constant temperature and pressure, these variables do not appear explicitly in the present formulation.

Let us denote the average number of charged sites on a polyion as i, that is $i=\alpha x$. At equilibrium, i should be determined from the condition of minimum free energy.

$$(\delta G/\delta i)_{n_w,\ m_p,\ m_s,\ m_a} = 0. \tag{3}$$

Here G denotes the Gibbs free energy of the solution. The equation is just the equation for potentiometric titrations. The expression, however, corresponds to an infinitesimal virtual change δi. If the corresponding free energy change can be evaluated, we can obtain Eq.(1). On the other hand we can derive Eq.(2), if we can express the free energy due to a virtual change in terms of some thermodynamic quantities corresponding to quasi-static changes.

We denote the free energy arising from the electrostatic interaction between charges as G^{el}. Self-energy of a polyion, the electrostatic interaction between charged sites on a polyion, is also included in G^{el}. The remaining part of G will be further divided into two parts, G^p and G^s, where G^p represents the contribution from polyions and G^s from all other species. The unitary part of G^p can be divided into three parts; $G_0{}^p$ which is independent of i, $G_1{}^p$ which contains the contributions from the standard free energy of charged and uncharged sites and from their ideal mixing entropy, and $G_2{}^p$ which involves any other contributions depending on i. The cratic part of G^p can be expressed in terms of the ideal term in m_p when neither association nor conformational change occurs. However, it is designated here as $G_3{}^p$ for the purpose of wider applicability.

Let us consider the changes which actually occur in the solution accompanying the virtual change under consideration. At equilibrium, G may be written in terms of species as follows, if we take into account a relation demonstrating the dissociation equilibrium of water, $\mu_w=\mu_H+\mu_{OH}$.

$$G = (n_w+n_a)\mu_w + n_p\mu_{p,i} + (n_a+n_s)\mu_+ + n_s\mu_- + (n_H-n_{OH})\mu_H. \tag{4}$$

Here $\mu_{p,i}$ denotes the chemical potential of a polyion having i charged sites, and μ_+ and μ_- those of counter ions and coions. The equation implies that the contribution from excess hydrogen ions n_H^{ex} rather than that from total hydrogen ions is necessary to be taken into account when we consider the contribution from hydrogen ion species to the change of G associating with some process. Here the excess hydrogen ions are defined as the remainder resulting from the subtraction of hydroxyl ions from hydrogen ions, $n_H^{ex}=n_H-n_{OH}$. From the condition of electroneutrality,

$$n_p\delta i = \delta n_a + \delta n_H^{ex}. \tag{5}$$

The virtual change under consideration thus leads to the increase of the excess hydrogen ions by $n_p\delta i$ moles, since the change occurs at constant n_a. The result should not be interpreted as demonstrating that the hydrogen ions produced by the virtual change do not interact with hydroxyl ions and thus do not participate in the dissociation equilibrium of water. In fact, part of hydrogen ions released may be consumed by means of the combination with hydroxyl ions. But as a result of this reaction, exactly the same amount of the latter is also consumed and thus the amount of excess hydrogen ions is not altered. Practically the same result can be obtained, if we notice that except the extremely narrow region near pH 7, either hydrogen or hydroxyl ions are present in great excess so that the difference between the amount of excess ions and that of total ions becomes quite insignificant.

Therefore, corresponding to the virtual change, the number of charged sites on each polyion increases by δi, and $n_p\delta i$ moles of hydrogen ions are released into a solution from these polyions.

Let us evaluate the free energy change G involved in Eq. (3). For the calculation of the free energy other than electrostatic part, we may calculate it in two independent processes. For the process corresponding to the increase of charged sites, the free energy change can be expressed by the change of chemical potentials, since the process does not involve any variation of the number of particles in the system. We may reasonably assume that the interionic interaction other than electrostatic one is negligible except that between polyions. The exception is made here to leave room for the possibility that association of polyions occurs by short range interactions such as hydrogen bonding. According to this assumption, the unitary part of G^s is clearly independent of i and the cratic part can be expressed in terms of the ideal term $\boldsymbol{R}T\ln m$. Therefore G^s remains unchanged under the process considered. As to the remaining part G^p, it can be written as $n_p(\mu_{p,i}-\mu_{p,i}^{el})$. Here $\mu_{p,i}^{el}$ represents the electrostatic part of the chemical potential of a polyion. Corresponding to an increase of $n_p\delta i$ moles of hydrogen ions, the free energy change becomes $n_p\delta i(\mu_H-\mu_H^{el})$. Thus the free energy change except the electrostatic one amounts to,

$$\delta(G-G^{el}) = n_p\delta(\mu_{p,\,i}-\mu_{p,i}^{el})+n_p(\mu_H-\mu_H^{el})\delta i. \tag{6}$$

For the calculation of the change of electrostatic free energy, we regard the process as such that n_p moles of polyions having i charged sites are removed from the solution and exactly the same amount of polyions having $i+\delta i$ charged sites as well as $n_p\delta i$ moles of hydrogen ions are introduced into the solution. Then the total change becomes.

$$\delta G^{el} = n_p\mu_H^{el}\delta i + n_p(\mu_{p,i+\delta i}^{el}-\mu_{p,i}^{el}) = n_p\mu_H^{el}\delta i + n_p\delta\mu_{p,i}^{el}. \tag{7}$$

Adding Eqs. (6) to (7), we obtain

$$(\delta G/\delta i)_{n_w,\, m_p,\, m_s,\, m_a} = n_p[(\delta\mu_{p,i}/\delta i)_{m_p,\, m_s,\, m_a} + \mu_H]. \quad (8)$$

From Eq. (3), the r.h.s. of Eq. (8) should be zero at equilibrium.

Potentiometric Equation. In order to evaluate the derivative on the r.h.s. of Eq. (8), we examine various constituent contributions to $\mu_{p,i}$. In analogy with the classification of G^p, $\mu_{p,i}$ is also divided in the corresponding manner.

$$\mu_{p,i} = \mu_p^0 + \mu_{p,i}^1 + \mu_{p,i}^2 + \mu_{p,i}^3 + \mu_{p,i}^{el}. \quad (9)$$

Since G_0^p is defined as being independent of i, μ_p^0 is also independent of i. As to $\mu_{p,i}^1$, the term can be explicitly written as follows.

$$\mu_{p,i}^1 = -(\boldsymbol{R}T \ln K_0 + \mu_H^0)i + \boldsymbol{R}T[i \ln(i/x) + (x-i)\ln(x-i)/x].$$

Hence,

$$\delta u_{p,i}^1 = \delta i(-\boldsymbol{R}T \ln K_0 - \mu_H^0) + \boldsymbol{R}T(\delta i) \ln(i/x-i). \quad (10)$$

Substituting Eq. (10) into Eq. (8) and rearranging it a little, we obtain

$$\mathrm{pH} = \mathrm{p}K_0 + \log(\alpha/1-\alpha) + (0.434/\boldsymbol{R}T) \times [\delta(\mu_{p,i}^2 + \mu_{p,i}^3 + \mu_{p,i}^{el})/\delta i]. \quad (11)$$

Thus we have derived a potentiometric equation. Comparing Eq. (11) with Eq. (1), we have

$$\Delta\mathrm{p}K = (0.434/\boldsymbol{R}T)[\delta(\mu_{p,i}^2 + \mu_{p,i}^3 + \mu_{p,i}^{el})/\delta i]. \quad (12)$$

It can be seen from Eq. (12) that the non-ideal term depends on the non-ideal part of the chemical potential of a *polyion* and not of a *polymer component*. This result has not been explicitly given, though essentially equivalent statements were implicitly presented.[3,4] It may be somewhat significant to give the result in an explicit form, since a confusing expression about the thermodynamic interpretation of the non-ideal term has been reported recently.[6]

For ordinary polyelectrolytes, where a transition between discrete conformations is absent and polymer concentration remains unchanged during ionization, the term $\delta\mu_{p,i}^3$ vanishes. In this case, involved in the term $\mu_{p,i}^2$ are such contributions that the deviation of the mixing entropy of charged and uncharged sites from that of ideal behavior or the free energy due to the expansion of polymer chains. However, these contributions have been considered to be small compared with those involved in the term $\mu_{p,i}^{el}$.[7] Hence in this case the non-ideal term reduces to

$$\Delta\mathrm{p}K = (0.434/\boldsymbol{R}T)(\delta u_{p,i}^{el}/\delta i). \quad (13)$$

If conformational transition depending on ionization occurs, including the association of polymers, then the effect may be involved in the terms $\mu_{p,i}^2$ and $\mu_{p,i}^3$. Thus $\Delta\mathrm{p}K$ should be expressed in a general form as Eq. (12).[8-10]

Thermodynamic Expression. Since we have derived an ordinary potentiometric equation in the preceding section, it becomes necessary to deduce a thermodynamic expression represented by Eq. (2) in terms of the same model consideration.

It should be noted that the change of the chemical potential of polyions associating with an infinitesimal change δi is independent of whether the change occurs as a virtual one or as a quasi-static one. The difference between these two changes resides in the respect whether the increase of charges on polyions is neutralized by hydrogen ions alone or by both counter ions and hydrogen ions. On account of this, the derivative involved in Eq. (8) can be replaced with one corresponding to quasi-static change.

$$(\delta\mu_{p,i}/\delta i)_{m_p,\, m_s,\, m_a} = (\partial\mu_{p,i}/\partial i)_{m_p, m_s}. \quad (14)$$

Thus from Eq. (8),

$$(\partial\mu_{p,i}/\partial i)_{m_p, m_s} + \mu_H = 0. \quad (15)$$

Changing a variable from i to μ_H, we obtain the equation,

$$(\partial\mu_{p,i}/\partial\mu_H)_{m_p,\, m_s}(\partial\mu_H/\partial i)_{m_p,\, m_s} + \mu_H = 0. \quad (16)$$

According to the definition employed in the present treatment, the chemical potential of a polymer component can be written in terms of the constituent species.

$$\mu_p = \mu_{p,i} + i\mu_H. \quad (17)$$

Differentiation of Eq. (17) with respect to μ_H yields,

$$(\partial\mu_p/\partial\mu_H)_{m_p,\, m_s} = (\partial\mu_{p,i}/\partial\mu_H)_{m_p,\, m_s} + i + \mu_H(\partial i/\partial\mu_H)_{m_p,\, m_s}. \quad (18)$$

After Eq. (16) is taken into account, Eq. (18) finally reduces to

$$(\partial\mu_p/\partial\mu_H)_{m_p,\, m_s} = i = \alpha x. \quad (2)$$

Thus we have presented the equivalence of the two expressions, Eq. (2) and Eq. (11), by deriving them from a common basis.

Discussion

A brief comment should be added about the implication of the equations and averages under the situation of conformational changes. For the sake of brevity, we consider a solution where two discrete conformations "a" and "b" are present in equilibrium. In this case, three parameters are necessary to describe the system, which are taken to be i_a, i_b, and i. Here i_a and i_b denote average degrees of ionization of the respective conformations. The fraction of polymers in the "a"-conformation, f_a, is given as $(i-i_b)/(i_a-i_b)$. Two parameters i_a and i_b as well as f_a can be generally considered to be solved as the functions of $[m]$ and i from the equations

$$(\delta G/\delta i_a)_{[m],\, i,\, i_b} = 0, \quad (19)$$

and

$$(\delta G/\delta i_b)_{[m],\, i,\, i_a} = 0. \quad (20)$$

Here $[m]$ represents a set of variables n_w, m_p, m_s, and m_a. Hence, a virtual change δi consists of corresponding changes in δi_a, δi_b, and δf_a, which are uniquely determined if δi is given. The equilibrium value of i will be given by Eq. (3) as before. However, the implication of the equation in this case is,

$$(\delta G/\delta i)_{[m]} = (\delta G/\delta i_a)_{[m],\, i,\, i_b}(\delta i_a/\delta i)_{[m]} + (\delta G/\delta i_b)_{[m],\, i,\, i_a}(\delta i_b/\delta i)_{[m]} + (\delta G/\delta i)_{[m],\, i_a,\, i_b} = 0. \quad (21)$$

6) G. Torrence, S. Amdur, and J. A. Marinsky, *J. Phys. Chem.*, **75**, 2144 (1971).
7) L. Kotin and M. Nagasawa, *J. Chem. Phys.*, **36**, 873 (1962).
8) B. H. Zimm and S. A. Rice, *Mol. Phys.*, **3**, 391 (1960).
9) M. Nagasawa and A. Holtzer, *J, Amer. Chem. Soc.*, **86**, 538 (1964).
10) M. Nagasawa and A. Holtzer, *ibid.*, **93**, 606 (1971).

Subsequent equations, except the expressions for $\mu^{1}_{p,i}$ and $\delta\mu^{1}_{p,i}$ (Eq. (10)), can be interpreted similarly, if we take into account the relations,

$$\mu_{p,\,i} = f_a\mu_{p,\,i_a} + (1-f_a)\mu_{p,\,i_b} \tag{22}$$

and

$$\mu_{p,\,a} = \mu_{p,i_a} + i_a\mu_{\mathrm{H}} = \mu_{p,i_b} + i_b\mu_{\mathrm{H}} = \mu_p \tag{23}$$

since the conformational equilibrium is attained. Expressions for $\mu^{1}_{p,i}$ and $\delta\mu^{1}_{p,i}$ should be regarded as the definitions of them in this case.

From the discussion presented above, most of the equations are proved to hold in the case of conformational changes. However, the implication of averaged quantities such as $\mu_{p,i}$ or i may differ in both situations. Fluctuations from averages are considered to be relatively small in ordinary polyelectrolyte solutions, whereas they become considerably large in solutions where discrete conformations are present in equilibrium.

Studies on Microcapsules. XIII. Effect of Span 85 and pH of Aqueous Phase on the Formation of Polyamide Microcapsules

Tomoharu OGAWA*, Kouichi TAKAMURA, Masumi KOISHI, and Tamotsu KONDO**

* *Research Laboratory, Pentel Co., Ltd., Soka, Saitama*

Faculty of Pharmaceutical Sciences, Science University of Tokyo, Shinjuku-ku, Tokyo

(Received December 10, 1971)

The effects of the pH of aqueous phase containing piperazine and the concentration of Span 85, a nonionic surfactant with chemical description of sorbitan trioleate (Atlas Power Co., U.S.A) on the formation of polyphthalamide microcapsules were systematically investigated by the interfacial polycondensation method in the organic phase containing *p*-phthaloyl dichloride. The presence of Span 85 facilitated the formation of microcapsules by increasing the transfer of undissociated diamine molecules into the organic phase in the pH range 9.0–12.0, outside of which Span 85 did not significantly contribute to the formation of microcapsules. An increase in the pH in this range gives rise to an increase in the number of undissociated diamine molecules, promoting the transfer of diamine.

It is known that the partition of diamines between water and a water-immiscible organic liquid is important for the formation of polymers by interfacial polycondensation reaction.[1] The same holds for the formation of microcapsules by the interfacial polycondensation method.[2-4]

On the other hand, the partition coefficients of diamines were found to be affected favorably in an organic phase in the presence of Span 85, a nonionic surfactant.[2] Diamine molecules should exist in an undissociated form so that they can be transferred into an organic phase. This indicates that the partition might be significantly reduced near a pH equal to the pK value of diamines. Actually, when $NaHCO_3$ was present instead of Na_2CO_3 the partition of diamines was unfavorably affected, and hardly any microcapsules were formed.[5]

Since the findings are still scanty, a systematic study is needed to understand the effects of the pH of aqueous phase and the Span 85 concentration in organic phase on the formation of microcapsules. Thus, the effects of the pH of aqueous phase containing piperazine, a diamine, and the Span 85 concentration in a chloroform-cyclohexane mixture containing *p*-phthaloyl dichloride on the formation of polyphthalamide microcapsules were systematically examined.

Experimental

Determinarion of Apparent Partition Coefficient of piperazine. The apparent partition coefficient of piperazine was determined at various pH in the same way as in the preparation of micrlcapsules.[2] Ten milliliters of 0.40 M piperazine (diethylenediamine) was added to 10 ml of 0.90 N Na_2CO_3–$NaHCO_3$ in a 500 m*l* round bottom flask surrounded by ice. The Na_2CO_3–$NaHCO_3$ mixture was used with varying the mixing ratio but keeping constant the total concentration at 0.90 N. One hundred milliliters of mixed organic solvent (cholroform-cyclohaxane, 1 : 3 vol), containing 0–7 vol% Span 85 was added to the solution as an emulsifying agent. The mixed solution was then mechanically emulsified with a Chemistirrer (Tokyo Rika Kikai Co., Tokyo, Model B-100) at 521 r. p. m. for 5 min to yield a water-in-oil emulsion.

Immediately after stirring was stopped the emulsion was centrifuged at 13000 g for 10 min to remove the aqueous phase from the organic phase. The concentration of piperazine in the organic phase was then determined by titration with HCl solution in an isopropanol-ethyleneglycol mixture (1 : 1 vol) using BTB-BCG mixed indicator.[6] The

partition coefficient of piperazine was calculated from its initial concentration in the aqueous phase and final concentration in the organic phase.

Determinarion of the percentage of Reacted Piperazine. The determination was carried out as follows. The mixture of the aqueous phase and the organic phase was mechanically emulsified under the same conditions as in the determination of apparent partition coefficient. One hunderd milliliters of 0.04 *M* *p*-phthaloyl dichloride solution in the mixed organic solvent was added to the emulsion obtained, and the resulting microcapsule suspension was centrifuged at 29000 g for 10 min after stirring was continued for 3 min. Centrifugation caused the breakdown of microcapsules and a clear aqueous phase was obtained.

A 5 m*l* portion of the aqueous phase was mixed with an equal volume of *p*-dimethylaminobenzaldehyde solution in methanol containing 30 vol% H_2SO_4. The amount of piperazine remaining unreacted was determined by measuring the absorption of colored complex at 425 mμ spectrophotometrically.[7] The percentage of reacted piperazine was calculated from its initial and final concentrations in the aqueous phase.

Measurement of Viscosity of Ploymer Solution. The measruement of viscosity of polymer solution was carried out in a way similar to that described previously.[4] Each microcapsule suspension prepared under various conditions was centrifuged to break down the microcapsules and the microcapsule membrane obtained was collected, washed, and dried under reduced pressure. The dried sample was dissolved in *m*-cresol. For each sample solution thus prepared, the relative viscosity was measured at 30 °C with a dilution type Ubbelohde viscometer. The reduced viscosity was then plotted against the polymer concentration and the intrinsic viscosity was graphically estimated by extrapolation to zero conecntration.

Determination of CMC of Span 85. The determination of critical micelle concentration of Span 85 was carried out by the method of Ross and Olivier.[8] 5m*l* of iodine solution (70 mg/*l*) in the mixed organic solvent was added to an equal volume of each Span 85 solution of various concentrations around its CMC in the same solvent. The transmittance of the solutions was then measured at a wavelength of 360 mμ using the mixed solvent as a reference. The CMC was graphically determined as the break point of transmittance *versus* concentration curve.

Results and Discussion

Apparent Partition Coefficient. The dependence of apparent partition coefficient of piperazine on the pH of aqueous phase at several Span 85 concentrations in the organic phase is shown in Fig. 1.

At any concentration of Span 85 in the organic phase, the apparent partition coefficient decreased first and then levelled off as the pH of aqueous phase increased, indicating that the transfer of piperazine from the aqueous to the organic phase initially inincreases but approaches a saturation value as the hydrogen ion concentration in the aqueous phase decreases.[9] This results from the fact that the pK values of piperazine are 5.57 and 9.81. Increases in the pH of aqueous phase will cause an increase in the number

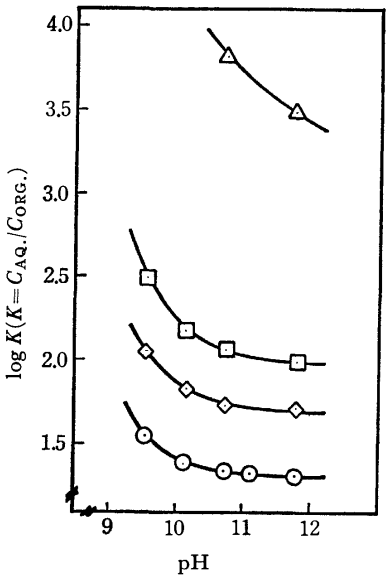

Fig. 1. The dependence of apparent partition coefficient of piperazine on the pH of aqueous phase at several Span 85 concentrations in the organic phase. Span 85 concentrations: (△) 0%, (□) 1%, (◇) 2%, and (○) 5%.

of unprotonated piperazine molecules and a transfer would be favored. The transfer would stop increasing when all the piperazine molecules in the aqueous phase take the unprotonated form above pH 10.0. This trend of a transfer of substances with pH-dependent dissociable groups in their molecules is frequently observed.[10–12]

It was reported that the transfer of piperazine or 1,6-hexamethylenediamine from aqueous Na_2CO_3 solution to a chloroform-cyclohexane mixture is facilitated by the presence of Span 85 in the organic solvent.[2] We see from Fig. 1 that the presence of Span 85 in the organic phase increases the transfer of piperazine irrespective of the pH of aqueous phase and the amount transferred increases as the Span 85 concentration increases. Although the exact role of Span 85 in facilitating the transfer of piperazine is not yet fully understood, a portion of piperazine transferred should exist in the solubilized form in Span 85 micelles since the concentrations of Span 85 we used lie beyond its CMC (9.3×10^{-2}%).

various pH and Span 85 concentrations is given in Table 1.

The percentage was greatly affected by both the pH of aqueous phase and the Span 85 concentration in organic phase. Since the interfacial polycondensation reaction occurs on the organic solvent side of the interface of water and organic solvent,[1] the percentage of reacted piperazine should be related to its apparent partition coefficient. The relation between the percentage and its apparent partition coefficient is illustrated in Fig. 2. The relation is linear for all the pH values and the slope of straight line increases with increasing pH. At a pH of about 12, the straight line becomes vertical, suggesting that the percentage is practically independent of the transferred amount of piperazine above this pH.

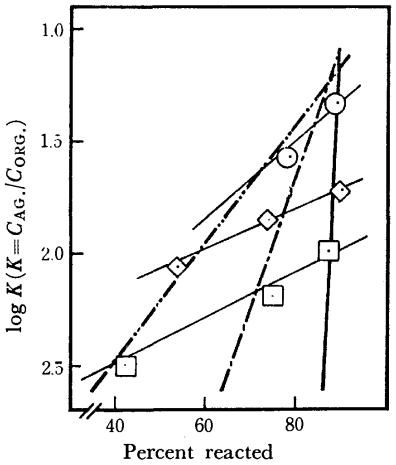

Fig. 2. The relation between the percent reacted of piperazine and its apparent partition coefficient. Span 85 concentrations: (□) 1%, (◇) 2%, and (○) 5%. pH of aqueous phase: (—··—) pH 9.54, (—·—) pH 10.13, and (—) pH 11.77.

We see also that the apparent partition coefficient increases, and consequently, the percentage decreases as the pH of aqueous phase lowers at any Span 85 cancentration in the organic phases. Since the apparent partition coefficient drastically rises below pH 9.0 irrespective of Span 85 concentration (Fig. 1), it would be inferred that the percentage greatly falls below this pH. In fact, polyphthalamide microcapsules were not formed appreciably below pH 9.0, however high the Span 85 concentration. This indicates a very low percentage. This would mean that the lower limit of pH for the formation of microcapsules making use of polycondensation reaction between a diamine and an acid dichloride lies around a value equal to the pK of the diamine used.

Intrinsic Viscosity of Polymers Constituting Microcapsules. The intrinsic viscosities of polymers constituting polyphthalamide microcapsules prepared under various conditions are given in Table 2.

A close relation is clearly observed between the intrinsic viscosity of polyphthalamide and the percentage by comparison with Table 1. A polymer with high intrinsic viscosity or high molecular weight is obtained at high percentage while a low intrinsic viscosity corresponds to a low percentage. Typical photomicrographs of microcapsules prepared under the conditions pH 9.54 of aqueous phase and 1 vol% of Span 85 in the organic phase, and pH 11.77 and 5 vol% of Span 85, are shown in Photos. 1 and 2, respectively.

Table 2. Intrinsic viscosity of polymers constituting microcapsules

pH / Span 85 (vol%)	9.54	10.31	11.77
1.0	0.20	0.31	0.56
2.0	—	0.35	0.43
5.0	0.53	—	0.55

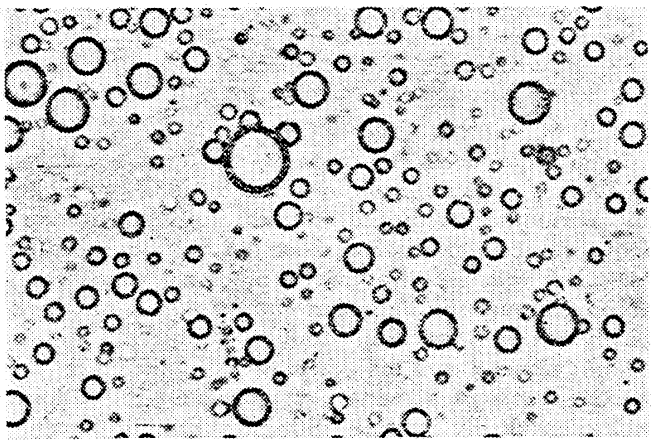

Photo. 1. Photomicrograph of polyphthalamide microcapsules prepared at pH 9.54 of aqueous phase and 1 vol% of Span 85 in the organic phase (×600).

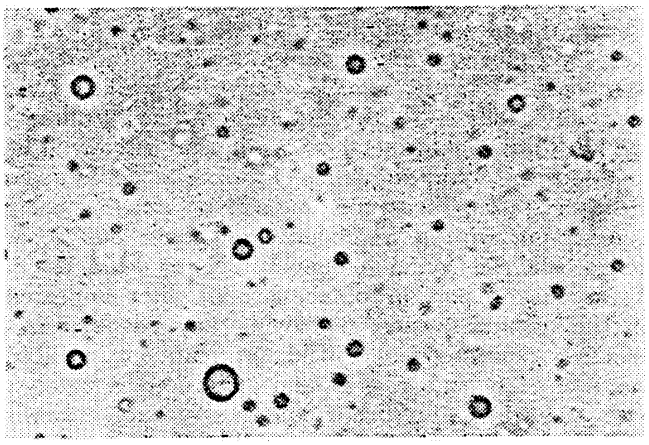

Photo. 2. Photomicrograph of polyphthalamide microcapsules prepared at pH 11.77 of aqueous phase and 5 vol% of Span 85 in the organic phase (×600).

Microcapsules were generally larger in size if they were prepared at low pH and Span 85 concentration as compared with those prepared at high pH and Span 85 concentration. Formation of large microcapsules was also reported[4] for the case in which the oil soluble reactant concentration in organic phase was reduced or the temperature at which polycondensation reaction takes place was lowered. It might be concluded that large microcapsules are formed by the mechanism discussed[4] whenever polymers with low intrinsic viscosity are produced.

The Formation of Metallic Silver in Silver-Form Zeolites

Kazuo TSUTSUMI and Hiroshi TAKAHASHI

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received December 23, 1971)

The formation of silver crystallites in silver-form zeolites was investigated, mainly by means of X-ray diffraction analysis. Silver ions were reduced to the zero-valent state; they aggregated to metals in three cases in this study—first, when silver-form zeolites were heated in a helium flow at above 600°C; secondly, when they were reduced by hydrogen, and lastly, when they were treated with the alkyl benzenes or alcohols above 300°C. The silver crystallites had sizes of 150—400, 150—200, and 200—300Å respectively when Ag(31.6%)-Na-$Y_{4.6}$ was re-reduced in the three cases mentioned above. If the silver ions are reduced, the zeolite becomes decationated-form, in which metallic silver is dispersed. The silver metals formed in the zeolite have peculiar interactions with oxygen.

Zeolite has been known to be useful as a catalyst in various organic reactions,[1] since it is so highly crystalline that theoretical studies of its activity and active site seem easier than those of many other catalysts. Furthermore, the activity is much higher than that of conventional silica-alumina catalysts, so it has been widely used as a practecal catalyst.

The present authors previously found that the cumene-cracking activities of transition metal-form zeolites gradually increase with each slug of cumene, eventually attaining maximum values.[2] The data of magnetic susceptibility indicate that paramagnetic nickel-form zeolite becomes ferromagnetic during the reaction as a result of the formation of metallic nickel. Thus, transition metal cations, such as Ni^{2+}, Fe^{3+}, Co^{2+}, Cd^{2+}, and Cr^{3+}, incorporated into the zeolite were reduced to the metals when these zeolites were used for catalysts in the cumene-cracking reaction.

The formation of metal in zeolite has already been reported by many authors. Lawson *et al.* studied nickel-crystallite formation in a Ni-Y zeolite using a reduction with a hydrogen flow above 300°C, as detected by electronmicroscope and X-ray diffraction.[3] A significant portion of these crystallites appeared on the outside surface, destroying any possible size-selective characteristics. Mild pretreatment reduced the rate of crystal growth and produced a catalyst with a slightly improved poison resistance. Lewis reported on the platinum crystallite formation in a Pt-Y zeolite.[4] The X-ray absorption edge data showed that all the platinum was reduced to a zero-valent state, and that, on the average, this platinum was smaller in size than that found in conventional reforming catalysts. Sixty percent of the reduced platinum was estimated to be 10Å size or less. Yates found that reducible metal cations such as Cd^{2+}, Mg^{2+}, and Zn^{2+} can be removed from zeolites by hydrogen treatment.[5] The reduced nickel and silver were held loosely in the zeolite lattice because of their low vapor pressures. The average nickel crystallite size was 240Å. In each case, no free metals were formed when the samples were heated in a vacuum. Rabo *et al.* investigated, by ESR, the oxidation state of nickel ions contained in Ni-Y which had been treated by either sodium vapor or by hydrogen; they found the formation of Ni^0 at 575°C.[6] Gioia has reported the reduction of Ni-X by hydrogen.[7]

Alloy fromation on zeolite Y was reported by Reman *et al.*[8] If two types of metal ions were present, for instance Ni^{2+} and Cu^{2+}, reduction by hydrogen, under favorable circumstances, led to the formation of crystals of alloys. Alloy formation was found to have a profound influence on the type of conversion of *n*-hexane.

In almost all the cases mentioned above, the reductions were performed by hydrogen.

In this paper, the formation of silver crystallites in Ag-form zeolites with reduction by hydrocarbons, mainly cumene, and other substances were investigated by X-ray diffraction analysis.

Experimental

The starting materials were synthetic sodium faujasite (Na-$Y_{4.6}$,$Na_2O \cdot Al_2O_3 \cdot 4.6SiO_2 \cdot nH_2O$) and synthetic mordenite (Na-M,$Na_2O \cdot Al_2O_3 \cdot 10SiO_2 \cdot nH_2O$).

The ion exchange of sodium ions for the silver ion was performed by stirring an aqueous suspension of the Na-form zeolite in the presence of a proper amount of silver nitrate. This treatment was done in the dark to prevent the silver ion being reduced. The degree of ion exchange was determined from chemical analysis.

Hydrocarbons were guaranteed-grade samples which had been dehydrated with a molecular sieve 4A before use.

For studying the catalytic activity, a pulse microreactor was used. The details were described in a previous paper.[9] The reactants (or the reducing agents), alkylbenzene, alcohol, or hydrogen, were injected by means of a syringe and were fed to the catalyst with a flow of dry helim, the flow rate of which was 60 cc/min. The products were trapped and analyzed by gas chromatography.

The electronmicrographs were taken by means of a Hitachi HU-11A-type electronmicroscope.

The X-ray powder diagrams were recorded by means of a X-ray diffractometer. The experimental conditions were as follows. Copper radiation was used; the scanning speed was 1° or 1/4° 2θ/min; the time constant was 2 sec; the receiving slit was 0.15 mm; the angular aperture was 1°. Silicon was used as the internal standard for the measurement of the crystallite size.

Results and Discussion

In Fig.1, the change in the cumene-cracking activities over Ag–Na–$Y_{4.6}$ with an increase in the Ag^+ exchange is shown in relation to the pulse number of the added cumene. The pretreatment was carried out at 450°C, and the reaction temperature was 350°C. As is clearly, the activities

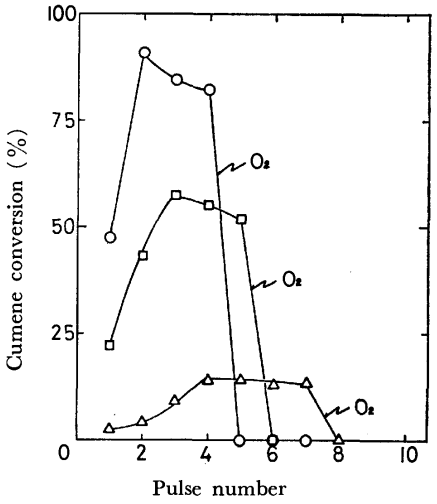

Fig. 1. Conversion of cumene over Ag-Na-$Y_{4.6}$ as a function of cumene pulse number and effect of oxygen addition.
—○— Ag(86.1%)-Na-$Y_{4.6}$
—□— Ag(31.6%)-Na-$Y_{4.6}$
—△— Ag(14.4%)-Na-$Y_{4.6}$

gradually increase with each slug of cumene until they attain a maximum value. The higher the extent of ion exchange or the reaction temperature, the greater the saturated activity. These tendencies are similar to those of transition metal-form zeolites such as Ni, Fe, Co, Cd, and Cr.[2] Therefore, the silver ion must be reduced to zero-valent silver, which aggregates to metal, during the reaction. At the same time, an active site, a decationated site, is newly formed. The activity was greatly decreased by the addition of oxgen at 450°C, and it could not be restored even if excess cumene was fed in. This behavior was surely connected with the formation of metallic silver.

Table 1 shows the cumene-cracking activity of Ag (31.6%)–Na–$Y_{4.6}$ at 350°C after various hydrocarbons, alcohols, and water were added at 450°C. The addition of hydrocarbons and alcohols clearly induces the activity increase; thus, the reduction of the silver ion by such reagents must occur in the zeolite. Water molecules, however, have no influence on the catalytic activity.

The X-ray diffraction diagrams of Ag(31.6%)–Na–$Y_{4.6}$ treated in various ways are illustrated in Fig.2. The B, C, E and F samples have a new prominent peak at about $2\theta = 37.5°$ and 44.0° which is not observed in the original. Since these peaks correspond to the (111) and (200) reflections of crystalline silver, it is confirmed that silver ions are reduced to Ag, which then aggregates to metal. Metallic silver can be formed even by heat treatment in a helium

Table 1. Effects of the additives on the cumene conversion rate on Ag(31.6%)-Na-$Y_{4.6}$[a]

Additives	Conversion rate (mol%)
Without addition	23.0
Toluene	46.0
Ethylbenzene	57.6
Cumene	60.7
t-Butylbenzene	56.9
p-Xylene	45.0
Mesitylene	34.1
Ethyl alcohol	22.1
i-Propyl alcohol	51.0
t-Butyl alcohol	54.2
Water	23.0

a) After 60 mg of Ag(31.6%)-Na-$Y_{4.6}$ was pretreated at 450°C and followed by addition of 5.7×10^{-5} mol of hydrocarbons, alcohol or water, the conversion rate of 5.7×10^{-5} mol cumene pulse was examined.

flow at above 600°C; no such formation was observed in the case of Ni-form zeolites. The conversion of cumene and the formation of silver metal did not occur during the reaction below 250°C when the catalyst had been pretreated at 450°C. The oxygen addition destroyed the structure of the zeolite, as is shown in F: this agrees with the decrease in catalytic activity. The water addition under similar conditions induced no destruction of the structure and no decrease in the catalytic activity of zeolite.

The electronmicrographs of Ag(31.6%)-Na-$Y_{4.6}$ under various conditions are shown in Fig.3. There was no metallic silver in the original sample; however, its formation can be clearly observed in the B, C, and D species. The particle-size distribution in B is comparably uniform. The crystallite size of B is measured as 363Å by X-ray diffraction analysis, so the particle consists of several crystallites. The particle sizes in C are widely distributed. As is shown in D, the oxygen addition makes the particle size larger.

Judging from the particle size of metallic sliver, silver atoms which are formed with the reduction of ions are mobile and grow to the metallic state on the external surface.

Crystallite sizes of (200) faces of silver metals formed in Ag–Na–$Y_{4.6}$ under various conditions are listed in Table 2. The change in the crystallite sizes of the silver metals formed in Ag(31.6%)–Na–$Y_{4.6}$ with the heat treatment tempteature in the He flow is illustrated in Fig. 4. No formation of silver metal

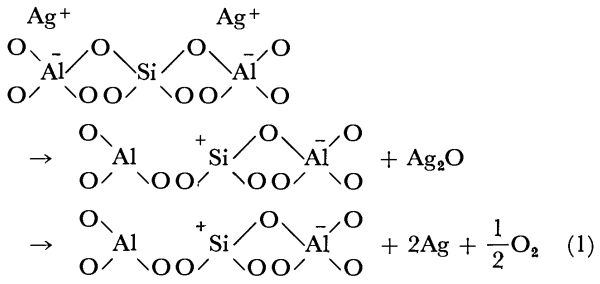
a) More than 1.4×10^{-3} mol-cumene was added to 200 mg of Ag-Na-$Y_{4.6}$.
b) One pulse of 1.4×10^{-4} mol-cumene was added to 200 mg of Ag-Na-$Y_{4.6}$.

is observed under a heat treatment at temperatures lower than 600°C. The higher the temperature, the larger the crystallite. The mechanism of metal formation under heat treatment is thought to be as follows:



Since Ag_2O could not be detected by X-ray diffraction analysis, Ag_2O probably exists in the transition state.

An increase in the degree of silver-exchange facilitates the formation of comparably large crystallites, as is shown in Fig.5. In view of the relation between the degree of exchange and the crystallite size, the number of crystallites formed seems to be nearly constant regardless of the degree of exchange. The number of cages necessary for the formation of one crystallite are 1.7, 1.9, 2.2, and 1.6×10^5 in the samples of Ag-Na-$Y_{4.6}$ where the degrees of exchange are 14.4, 22.3, 31.6, and 81.6% respectively.

The change in crystallite size with the pulse number

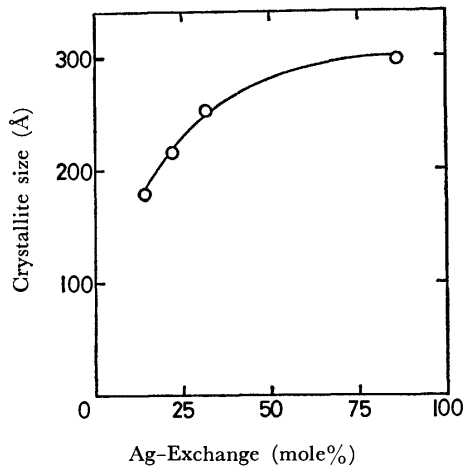


Fig. 5. Change of crystallite size of silver formed in Ag-Na-$Y_{4.6}$ with degree of Ag-exchange.

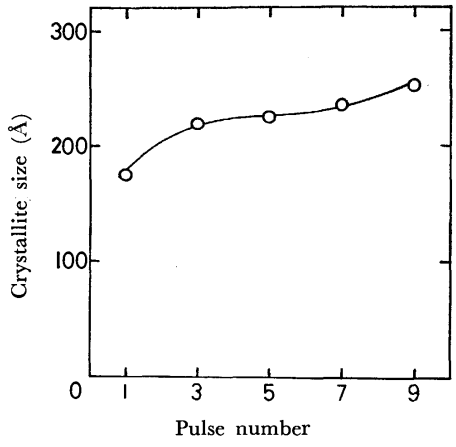

Fig. 6. Change of crystallite size of silver formed in Ag (31.6%)-Na-$Y_{4.6}$ with cumene pulse number.

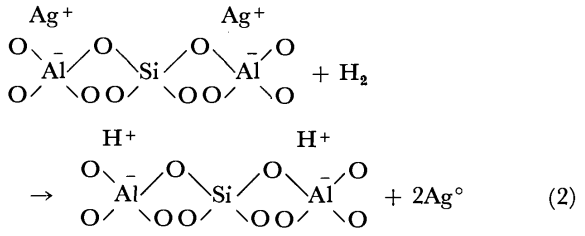
—□— pretreated in He at 750°C.

in Ag(31.6%)–Na–$Y_{4.6}$ is illustrated in Fig.6. The figure shows that the growth of the crystallite is related to the amount of cumene converted.

The dependence of the crystallite formation upon the reaction temperature in Ag(31.6%)–Na–$Y_{4.6}$ which has been pretreated at 450°C or 750°C is also shown in Table 2. When the zeolite is pretreated at 450°C, the crystallite size depends remarkably upon the reaction temperature; however, when it is pretreated at 750°C, the crystallite size formed in the reaction as 250°C is relatively large even though no cumene conversion occurred, and it merely changes at higher temperatures.

The crystallite size was increased to 261 or 320Å when oxgen was added to Ag(31.6%)–Na–$Y_{4.6}$ at 350 or 450°C after a cumene-cracking reaction at 350°C.

In Fig.7, the cumene conversion rates at 350°C are plotted against the pulse number over two Ag(31.6%)–Na–$Y_{4.6}$ samples; one was pretreated at 750°C, while the other was pretreated and then hydrogen was added at 450°C before the reaction. Although silver was formed in both samples, the activities differed greatly from each other. Since the transition from a Brønsted acid to a Lewis acid associated with the formation of metallic silver occurred upon the heat treatment at 750°C, the conversion of the first cumene pulse over the former was low. However, an increase in activity was observed upon the subsequent addition of cumene; this increase presumably resulted from the transition from a Lewis acid to a Brønsted acid by the cumene reacted. Over the zeolites which had been pretreated from 500 to 600°C, the conversions of the first cumene pulse were 15—20%; this reflected a few transitions from a Brønsted acid to a Lewis acid, and the saturated activities, 70—80%, resemble independently upon the pretreatment temperatrue. In the latter zeolite, Brønsted-acid sites were formed, accompanied by the formation of metallic silver, as in Equation (2):



(2)

Therefore, the reduction by cumene and the increase in activity no longer occurred. The crystallite size of the silver formed in this zeolite before the reaction was 176Å, much smaller than that of the silver formed in the earlier case. This fact suggests that the catalytic activity is not essentially influenced by the formation and the size of silver crystallite, but by the formation of the Brønsted acid site.

The radiation by ultraviolet rays did not facilitate reduction of silver ions in Ag–Na–$Y_{4.6}$ under various conditions—that is, at 35, 200°C in air or at 300°C in a vacuum.

In Fig.8, the conversion rates of cumene at 350°C over silver-exchanged mordenite-type zeolite pretreated at 450°C are shown. The silver formed in Ag (35.1%)–Na–Mord. by cumene addition at 350°C after pretreatment at 450°C has a relatively large crystallite size, though the pore diameter of mordenite is smaller than that of faujasite. The heat treatment at 750°C also induced the formation of large crystallites of silver. However, since the X-ray diffraction peak of the (200) face of silver is overlapped by the peak of mordenite, the measurement of the crystallite size by X-ray-diffraction analysis is difficult The conversion of cumene was decreased with each slug of cumene over Ag(35.0%)–H(64.7%)–Na-Mord. and only traces of silver formation were found. In Ag (68.6%)–H(26.8%)–Na–$Y_{4.6}$, no formation of silver was observed. In these cases, H-form sites contribute to the activity and cumene molecules interact more strongly with H^+ than with Ag^+. This behavior agrees with the finding of Richardson that the reducibility of supported nickel was small if the support had an increased acidity.[10]

Some work has been done on the reducibility of Ag(36.1%)–Ni(50.6%)–Na–$Y_{4.6}$ zeolite. The reduction of silver was preferred to that of nickel, and the

(Received December 10, 1971)

Continuous liquid-phase isomerization and disproportionation reactions over silica-alumina catalysts were carried out using *m*-xylene with varying concentration of water. The reactions were conducted at 290°C and 400°C under a pressure of 300 kg/cm². The results showed that the concentration of water required to attain a maximum activity for the isomerization was higher than that needed for the disproportionation reaction. The high-boiling by-products produced at 400°C comprized 2—5 per-cent of the weight of the total products, and the main component, polymethyldiphenylmethane, amounted to 70—80 per-cent of the by-products. The yield of polymethyldiphenylmethane was linearly correlated with that of toluene. This result appears to suggest that the disproportionation reaction and the polymethyldiphenylmethane formation proceed at a common active site and through the same intermediate.

In an earlier paper[1] the present authors reported that, in the liquid-phase isomerization of *m*-xylene, a silica-alumina catalyst revealed higher activity than in the vapor-phase reaction; moreover, even after 20 days no practical decline in the activity was observed. This superior ability of the catalyst in the liquid phase can be ascribed to the cleaning effects of the liquid reactant: in the liquid-phase reaction, the high-boiling by-product which, in the vapor-phase reaction, causes the activity to diminish due to its strong adsorptivity on the surface sites, is successively dissolved into the reactant; therefore, more surface sites are available for the isomerization.

As was shown in an earlier paper,[1] some components in the high-boiling by-product exhibit a temporary inhibiting effect, and these seem to be transformed into higher boiling compounds which exert a permanent poisoning effect on the catalytic activity. Hence, the decline in activity can not be avoided even in the liquid phase when the high-boiling by-product is produced to a great extent. On the basis of such considerations, it will be valuable, for the sake of the improvement of the catalyst life, to discover some means to reduce the yield of the high-boiling by-product.

The liquid-phase reaction can be characterized from another point of view—the yields of the high-boiling by-product can be measured rather quantitatively. Therefore, for the purpose of examining the possibility of reducing the high-boiling by-product or the disproportionation reaction products in the isomerization of *m*-xylene, the correlation between the yield of the high-boiling by-product and that of the disproportionation product, as well as the correlation between the yield of the isomerization product and that of the disproportionation product, will be studied in this paper. Practically, the correlations were studied over silica-alumina catalysts calcined at various temperatures by using *m*-xylene containing various amounts of water. It is well-known that a small amount of water influences the catalytic activity of silica-alumina.[2,3]

Experimental

The catalysts employed were two kinds of silica-alumina: one (I) was synthesized from aluminum isopropoxide and ethyl silicate,[4] while the other (II) was Nikki N633L. Both of these catalysts were calcined at 400°C or at 600°C for 20 hours. The equipment and the procedure for carrying out the continuous liquid-phase xylene isomerization under a high pressure were shown in previous papers.[1,5] In this study, all the experiments were carried out at a contact time (W/F) of 0.5 g-cat. h/g under a pressure of 300 kg/cm².

The reactant *m*-xylene (produced by Japan Gas Chemical Co. Inc.) was 99.6% pure and contained 100—130 ppm of water. Therefore, the concentration of water in the *m*-xylene was adjusted to the desired extent by drying with metallic sodium or calcium chloride and was determined by means of the Kaal-Fisher method.

The product was analyzed by gas chromatography. Two kinds of columns were used: one was 4 m in length, 1 mm in dia., and was packed with 5 per-cent Benton 34+DIDP

on diasolid L (100—200 mesh), while the other was 2 m in length, 3 mm in dia. and was packed with 20 per-cent silicone grease on celite 545.

The high-boiling by-product was separated by distilling the product at 100°C under a reduced pressure of 5 mmHg. Its composition was determined from the parent peaks of the mass spectra obtained by means of a Hitachi double-beam mass spectrometer.

Results and Discussion

Under the liquid-phase reaction conditions, the silica-alumina catalyst pretreated at a moderate temperature showed a considerably high activity for the isomerization reaction.[1,5] Accordingly, in order to detect the effects of water content on the activity, the reaction had to be carried out at a low temperature of 290°C where the equilibria among xylene isomers had not been established. On the other hand, at this temperature the rate of the production of the high-boiling compounds was very slow. Hence, in order to get information about the high-boiling by-product formation, the reaction was carried out at a higher temperature of 400°C, where measurable amounts of these compounds could be obtained.

3.1 Results at the Reaction Temperature of 290°C. The effects of water on both the isomerization and the disproportionation reaction were studied by using the II catalyst calcined at 600°C; the results are shown in Figs. 1-a, 2-a, and 3-a. In addition, it is known that the yield of toluene is approximately equal to that of trimethylbenzene at the reaction temperature of 290°C; hence, the yield of toluene can be considered as the disproportionation activity.[5] In these figures, the yield for neither the isomerization nor the disproportionation reaction in the first sample taken after 4 hours' reaction was obtained with a good reproducibility. As will be described below, however, this study aimed to follow only the manner of variation in the yields of the isomerization products and the disproportionation-reaction products with time. Thus, the lack of the reproducibility of the first yields of the products was not taken into account. The figures show that when the concentration of water in *m*-xylene was changed, the yields of the isomerization products varied with time in a different manner from those of the disproportionation. This fact suggests that different active sites may be available for the two reactions. This consideration was more clearly supported by the result shown in Fig. 1-b: when the reactant was changed from the *m*-xylene containing water below 5 ppm to the *m*-xylene containing 100—130 ppm, the yields of the isomerization products were recovered to about 50 per-cent of the initial ones, while the yield of the disproportionation product was decreased monotonously.

The variations in the activities for the isomerization and the disproportionation with the reaction time, as are shown in Figs. 1—3, appear to be attributable to the gradual adsorption of water in the reactant *m*-xylene in the cases of Figs. 2-a and 3-a, and to the deactivation due to the adsorption of undesirable high-boiling by-

products in the case of Fig. 1-a. Also, Figs. 3-b and 3-c show the effects of the adsorption and desorption of water on the activities. In Fig. 3-b, methyl alcohol was decomposed to water and methyl ether. These results show that there was an amount of water adequate for the maximum activity for the isomerization, but that the activity for the disproportionation increased with a decrease in the concentration of water in *m*-xylene.

Figure 4-a illustrates that the II catalyst calcined at 400°C showed practically no activity in the two reactions. However, the I catalyst calcined at the same temperature revealed a low but measurable activity, as is shown in Fig. 5. This difference between the two catalysts may be related to the content of water in the catalysts, since the results obtained by the use of TGA and DTA showed that the dehydration of the II catalyst took place at a higher temperature than that of the I catalyst.

3.2 The Results at a Reaction Temperature of 400°C.
3.2.1 The Results Using II Catalyst: The results obtained at a reaction temperature of 400°C are shown in Figs. 2-b, 4-b, 6-b, and 7. These results can be divided into three groups, depending on the yields of the isomerization products and the disproportionation reaction products. In the first group (Figs. 6-b and 7), the equilibria among xylene isomers were established; also, the disproportionation products were produced in high yields. It can be said such results were obtained for the cases where the catalysts calcined at 600°C were used and where the reaction systems involved

comparatively high concentrations of water; the reactant *m*-xylene contained a high concentration of water or 1000 ppm of methyl alcohol. On the other hand, the characteristic feature of the second group (Fig. 2-b) is that the yield of the disproportionation-reaction product was higher than that of the isomerization product in spite of the low conversion of *m*-xylene. In this group, the equilibria among xylene isomers were not established. This feature can be seen more clearly by comparing Fig. 2-b (obtained at a reaction temperature of 400°C) with Fig. 2-a (obtained at a reaction temperature of 290°C); the yields of the isomerization products at a reaction temperature of 290°C were more than those of the disproportionation, though the conversion of *m*-xylene was approximately equal to that at a reaction temperature of 400°C. The results of Fig. 2 were obtained using a catalyst calcined at 600°C and *m*-xylene containing a low concentration of water. The third was a group which showed a medium activity (Fig. 4-b). This was the case where a catalyst calcined at 400°C for 20 hours was used. It seems that the relatively lower activity than that of the first group may result from the insufficiency of the dehydration of the catalyst; the pretreatment of the II catalyst at 400°C for 20 hours was insufficient for the catalyst to reveal a high activity. The increasing activity up to the fourth day appears to correspond to the increase in the extension of the dehydration.

3.2.2 The Results with Using I Catalyst: According to the yields of the isomerization products and the disproportionation-reaction products, it may be said that the results shown in Figs. 5-b and 8-b belong to the first group and the second group respectively. The I catalyst calcined at 400°C revealed a high activity, as is shown in Fig. 5, where the reactant *m*-xylene contained 20—30 ppm of water. This result differs from that with using the II catalyst calcined at 400°C (Fig. 4-b). This discrepancy in activity may also be attributed to the greater ease of the dehydration of the I catalyst. The results shown in Fig. 8-b, where the catalyst was calcined at 600°C and where the reactant, *m*-xylene, contained 20—30 ppm of water, are the same

as those in Fig. 2-b.

3.3 High-boiling By-product. The product for 23 hours' operation (about 130 g) was distilled at a reduced pressure of 5 mmHg and at a temperature of 100°C; the residue thus obtained was regarded as comprising the high-boiling by-products. As is shown in Figs. 1—8, the yields of the high-boiling by-products were in the range of 2—5 per-cent and seemed to be correlated with the yields of toluene. However, as to the isomerization products, the correlation with the high-boiling by-products could not be examined because, in most of cases, the equilibria of the isomerization were established.

The decline in activity observed in most cases at the reaction temperature of 400°C might be attributed to the large yields of high-boiling by-products. Two per-cent of the weight of the by-products was sufficient to lower the catalyst activity.[1)]

The compositions of the high-boiling by-products were analyzed by means of a mass spectrometer under the conditions described in a previous paper.[1)] The mass spectra of the samples designated by A—H in Figs. 2—8 were observed; three representative spectra are shown in Fig. 9. It can be seen that all the spectra consist of three homologous series differing in mass number by 14, corresponding to the replacement of a hydrogen atom by a methyl group. The three series correspond to polymethylnaphthalene, polymethyldiphenylmethane, and polymethylanthracene. The compositions and the yields are shown in Table 1. This table shows that polymethyldiphenylmethanes amounted to 70—80 per-cent and were the main components of the high-boiling by-product at the reaction temperature of 400°C. In the case of the reaction at 290°C, tetramethyldiphenylmethane, the mass number of which is 224, was the main product, and the amount of anthracene was small.

3.4 The Active Sites for the Isomerization and the Disproportionation. The results presented in Section 3.2 show that, at a reaction temperature of 400°C, the high activity for the isomerization and the disproportionation reaction was obtained under the reaction conditions of the first group, where an adequate amount of water existed in the reaction systems. This suggests that an adequate concentration of water is required to attain a maximum activity not only for the isomerization but also for the disproportionation reaction. However, considering the finding at 290°C that the activity for the disproportionation increased with a decrease in the concentration of water the required concentration for the disproportionation appears to be lower than that for the isomerization.

In connection with the active sites available for the isomerization, it has been generally accepted that the reaction is catalyzed by a protonic acid.[6,7,8,9,10)] The present results related with the effect of water concentrations on the isomerization activity really coincide with this view. As for disproportionation or transalkylation, however, the active sites proposed by several authors are not entirely consistent. From the correspondency of the catalytic activity to the Brønsted acidity, Izumi and Shiba[11)] concluded that the disproportionation of toluene over an alumina-boria catalyst proceeds mainly on protonic-acid sites. Matsumoto *et al.*[8)] reached the same conclusion with regard to the active sites for the disproportionation of *o*-xylene over a calcium-exchanged NaX-zeolite catalyst. On the other hand, according to Csicsery,[9)] the ratio of the isomerization to the transalkylation of 1-methyl-2-ethylbenzene over a silica-alumina catalyst increased with an increase in the water content of the reactant. They suggested, therefore, that transalkylation is catalyzed predominantly by a Lewis acid or by a protonic acid and Lewis acid pair.

If we assume that the disproportionation occurs at the protonic acid site, the present results can be interpreted as indicating that the acid strength of the site available for the disproportionation should be stronger than that for the isomerization, because the increasing concentration of water in the reaction system would reduce the mean acid strength due to the adsorption of water, which has a basic property. On the other

hand, if we assume that the disproportionation reaction would be catalyzed by a Lewis acid, the role of water may be interpreted as promoting the desorption of undesirable products, polymethyldiphenylmethanes, due to the strong affinity of water with the acid sites. Up to an adequate content of water for the disproportionation, the produced polymethyldiphenylmethanes are desorbed successively without any formation of higher condensation products; thus, the effective sites could be prevented from permanent poisoning. A further increase in the water content, however, may result in a decrease in the effective active sites.

In conclusion, a full designation of the active sites available for the disproportionation seems to be beyond our reach at present; thus, further investigations must be made from a different point of view.

3.5 High-boiling By-products and Toluene. As is indicated in Fig. 10, the yield of polymethyldiphenylmethane, the main component of the high-boiling by-products, shows an approximately linear relation with that of toluene. This appears to suggest that the disproportionation reaction and the polymethyldiphenylmethane formation proceed at a common active site

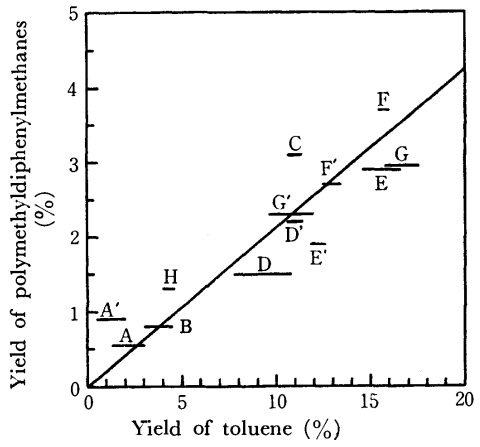

Fig. 10. Yield of polymethyldiphenylmethane *versus* that of toluene.
The letters indicate the samples shown in Table 1.
The width of the yield of toluene was caused by the fact that the deactivation occurred during 23 hr operation to obtain high-boiling by-products.

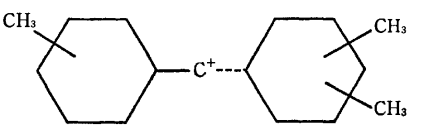

Fig. 11. A probable intermediate for the disproportionation reaction and the formation reaction of the polymethyldiphenylmethane.

and through the same intermediate. Therefore, it may be reasonable to think that the intermediate is similar to diphenylmethane, as is shown in Fig. 11. Lanewala[12] and Csicsery[13] proposed an intermediate similar to Fig. 11 for the transalkylation of alkylbenzenes over zeolite catalysts. Polymethyldiphenylmethanes seem to be produced by the release of a hydrogen molecule or methane from the intermediate.

As is shown in Fig. 9-c, tetramethyldiphenylmethane is the main component of the high-boiling by-product at the reaction temperature of 290°C. Considering the intermediate shown in Fig. 11, trimethyldiphenylmethane may be expected to be the main component at that reaction temperature, since the xylenes in the product amounted to more than 90 per-cent. This conflict can be resolved by considering the occurrence of a rapid exchange reaction between a reactant xylene and an aromatic ring of diphenylmethane.[14]

In addition, as is shown in Figs. 9-a and 9-b, the composition of the high-boiling by-product at 400°C was independent of the water concentration in *m*-xylene. In connection with the high-boiling by-products, another finding was that the product distribution of parent peaks of polymethylanthracene, which exert a stronger poisining effect on the catalyst activity than does diphenylmethane,[14] is similar to that of polymethyldiphenylmethane. This result leads us to think that polymethylanthracene would be formed dominantly from polymethyldiphenylmethane. However, poly-

methylanthracene or polymethylphenanthrene formation may occur through polymethylnaphthalene, since a small amount of polymethylnaphthalene was found in the products.

On the basis of the suggested mechanism concerning the formation of high-boiling by-products, it may be concluded that, under reaction conditions or a reaction system where the disproportionation products are required to be produced in high yields, a decline in the catalytic activity is unavoidable.

The Surface Properties of Rutile Prepared by the Hydrolysis of Titanium Tetrachloride. I. The Heat of Immersion in Water

Toru IWAKI, Masayoshi KOMURO, and Masaji MIURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received January 17, 1972)

The surface properties of rutile prepared by hydrolyzing titanium tetrachloride have been studied by measuring the heat of immersion in water as a function of the outgassing temperature. The heat of immersion showed an extremely large value at outgassing temperatures between 300 and 400°C. However, when the rutile was calcined at 800°C, it showed a heat-of-immersion curve similar to those hitherto reported. In order to examine the phenomenon found on uncalcined rutile, the amounts of water physically and chemically adsorbed on the surface were estimated by measuring the water-vapor adsorption. We found that hydroxyl groups were formed in bulk as well as on the surface by means of the chemisorption, resulting in the formation of a hydrous structure because of the low crystallinity of the sample at temperatures below 400°C.

It is well known that the surface hydroxyl groups on such metal oxides as SiO_2, TiO_2, and Al_2O_3 are removed by thermal treatment *in vacuo*, resulting in the formation of an activated oxide structure, $Me\langle^{O}_{O}\rangle Me$, as a result of the condensation of the adjacent hydroxyl groups. The activated site may be rehydrated easily by the adsorptiom of water or may be stabilized by calicing at an elevated temperature. From our examinations of the heat of immersion, the water content, and the features of the adsorption of water, it seems that the nature of the activated site depends also on the nature of the substrate oxide.[1] So far, a number of studies on the heat of immersion of titanium dioxide have been performed by many workers. As for rutile, some studies have been done on samples calcined at high temperatures,[2-4] but none on uncalcined samples.

In the present work, the surface properties of titanium dioxide pretreated at various temperatures from 100 to 800°C *in vacuo* were examined by measuring the heats of immersion in water for uncalcined-rutile samples as well as for calcined ones. The uncalcined samples gave a relation between the heat of immersion and the outgassing temperature different from the results hitherto reported on calcined samples;[1-4] that is, an extremely large maximum occurred at about 300°C. In order to investigate the phenomenon in detail, the adsorption of water was measured for those samples. As a result, it was revealed that the hydroxyl groups were formed in bulk as well as on the surface by means of the chemisorption of water.

Experimental

Material. Three kinds of rutile samples were prepared by the hydrolysis of titanium tetrachloride as follows. An aqueous solution of 1 M titanium chloride was heated at 90°C for 12 hr with vigorous stirring until the deposition of the precipitate had stopped. The precipitate was then washed with distilled water, purified further by means of electrodialysis in order to remove the chloride ions, and then dried at 100°C for two days in air (Sample I). By X-ray analysis this sample was proved to be a rutile modification. The second sample was prepared by calcining Sample I at 800°C for 1 hr in air; then it was exposed to saturated water vapor for a week at room temperature (Sample II). The third sample was obtained by heating Sample II again to 800°C and by then keeping it at that temperature for 1 hr in air. The resulting product was steeped in water and dried at room temperature (Sample III).

The measurements of the differential thermal analysis of Samples I and II were carried out at various temperatures, from 20 to 800°C, in air. A large endothermic peak appeared around 110°C on Sample I, but did not on Sample II. This peak is considered to be connected with the dehydration.

Prior to carrying out the following measurements, each sample was pretreated at various temperatures between 100 and 800°C for 3 hr in a vacuum of 10^{-5} Torr.

Surface Area. The surface areas of the samples were determined from the nitrogen adsorption at 77°K by the conventional B.E.T. method, assuming the area of a nitrogen molecule to be 16.2 Å^2.

Water Content. The water vapor desorbed from the sample by evacuating at a given temperature was condensed in a trap cooled by liquid nitrogen, evaporated in a given system, and then recondensed in a trap cooled by dry ice. The water content of the sample was determined by

measuring the amount of reevaporated water volumetrically, assuming the water content at 800°C to be zero.

Heat of Immersion. The heats of immersion of the samples in water were measured at 25°C by using a calorimeter equipped with an automatic recorder; the details have been described elsewhere.[5] In order to prevent the effect of organic contaminants, the sample was outgassed with a liquid nitrogen trap just before the sample.[6]

Water-vapor Adsorption. The adsorption of water vapor on the surface was measured at 25°C gravimetrically by using a Cahn RG electrobalance. After the first adsorption isotherm had been obtained on the sample, this sample was outgassed at 25°C for 24 hr in a vacuum of 10^{-5} Torr in order to remove all the physically-adsorbed water. Then the second adsorption isotherm was determined at 25°C. A series of the first and second adsorption isotherms of water vapor on Sample I outgassed at various temperatures was obtained.

Results and Discussion

Surface Area. The specific surface areas of the three samples are shown in Fig.1 as a function of the outgassing temperature. The surface area of Sample I decreases remarkably as the outgassing temperature rises from 200 to 800°C, whereas that of Sample II is almost constant. The surface area of Sample III was determined at only one temperature because it was considered to be independent of the outgassing temperature, as was the case of Sample II. The progressive decrease in the surface area of Sample I suggests that sintering occurs even at low temperatures such as 300°C. The particle size of Sample I, estimated by using the Scherrer equation from the half-value breadth of the X-ray diffraction line from the (110) plane, increased from 33 to 186 Å with a rise in the outgassing temperature from 100 to 800°C. The surface area was calculated by assuming the shape of the particle to be spherical in order to compare it with the results of nitrogen adsorption, S_N. The resulting values, which are shown in Fig. 1, have the same tendency with regard to the effect of the temperature as in the case of S_{N_2}. However, these values are considerably larger than the nitrogen area. This implies that Sample I does not take as characteristically porous a structure as a result of the removal of water molecules as does Al_2O_3.[7] Therefore, outgassing at higher temperatures may make the particle grow in size, resulting in a decrease in the surface area.

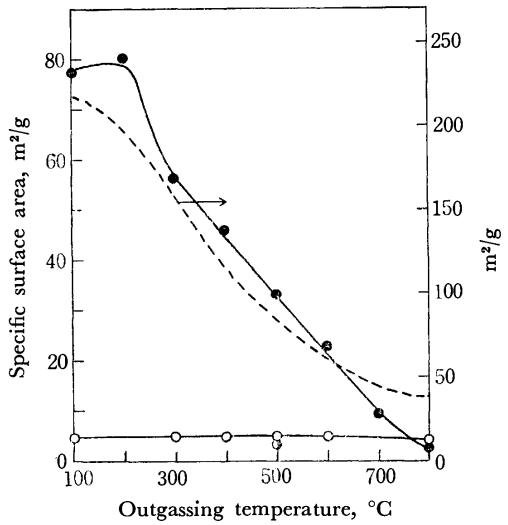

Fig. 1. Specific Surface area obtained from the adsorption of nitrogen as a function of the outgassing temperature; ●: Sample I, ○: Sample II, ◑: Sample III. Dotted line shows the specific surface area of the sample I estimated from the particle size.

Water Content. The water contents of Samples I and II are shown in Fig. 2, where the amounts of water are expressed by the number of hydroxly groups per unit of surface area, S_N. The fact that the amount of water in Sample I was much larger than that in Sample II was supported by the endothermic peak in the differential thermal analysis. The smaller surface area of Sample I at 100°C than at 200°C in Fig.1 may be due to the insufficient desorption of the water which may be present in the capillary, such as in the contacting zone among particles. The large water content may be one of the factors in the sintering at low temperatures.

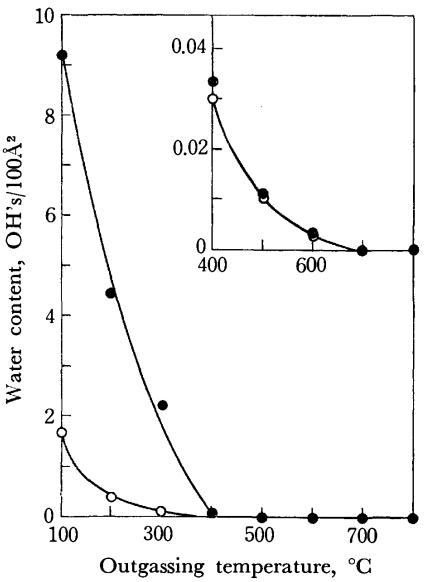

Fig. 2. Water content of rutile as a function of the outgassing temperature; ●: Sample I, ○: Sample II.

Heat of Immersion. Figure 3 shows the relation between the heats of immersion of the three samples in water and the outgassing temperature. Sample I revealed an extremely large heat-of-immersion value at temperatures between 300 and 400°C. The heat of immersion of Sample II was approximately constant above 400°C and did not reveal a maximum. Sample III, however, showed a maximum in its heat-of-immersion curve at a temperature between 400 and 500°C; this curve is similar to that reported by Morimoto *et al.*[3] From these results it is clear that

the heat of immersion depends remarkably on the initial calcination of the sample.

The appearance of a maxiumm in the heat-of-immersion curve has generally been explained as being caused by the stabilization of the surface oxo-structure during the treatment at high temperatures *in vacuo*. This explanation is applicable to the behavior of Sample III, since it was calcined at a high temperature and may have a well-defined surface oxo-structure. However, it seems strange that an extremely large maximum in the heat-of-immersion curve was found for the sample treated at a low temperature. In order to investigate this phenomenon in detail, the adsorption of water on the surface of Sample I was examined as follows.

Water Adsorption. Figures 4a and 4b show, respectively, the first and second adsorption isotherms of water vapor on the surface of Sample I outgassed at various temperatures between 100 and 800°C. The ordinate in the figure represents the amount of water adsorbed per unit of area, S_{N_2}. The second isotherm obtained lies below and nearly parallel to that of the first run. The difference between these two curves is regarded as the amount of the water adsorbed chemically on the surface as hydroxyl groups. The second isotherm indicates the water adsorbed physically on the hydroxyl groups formed on the surface.

Both the first and second isotherms of the sample outgassed at 300°C indicate the largest adsorbed amounts of all; this phenomenon is similar to that of the heat of immersion, where the maximum occurs at a temperature between 300 and 400°C. By applying the BET method to the second isotherm, the monolayer volume of the physically adsorbed water was calculated. The amount of the hydroxyl groups formed by the chemisorption was estimated from the difference in the initial weights of the two samples on which the first and second adsorption runs were performed. This amount is almost consistent with that obtained

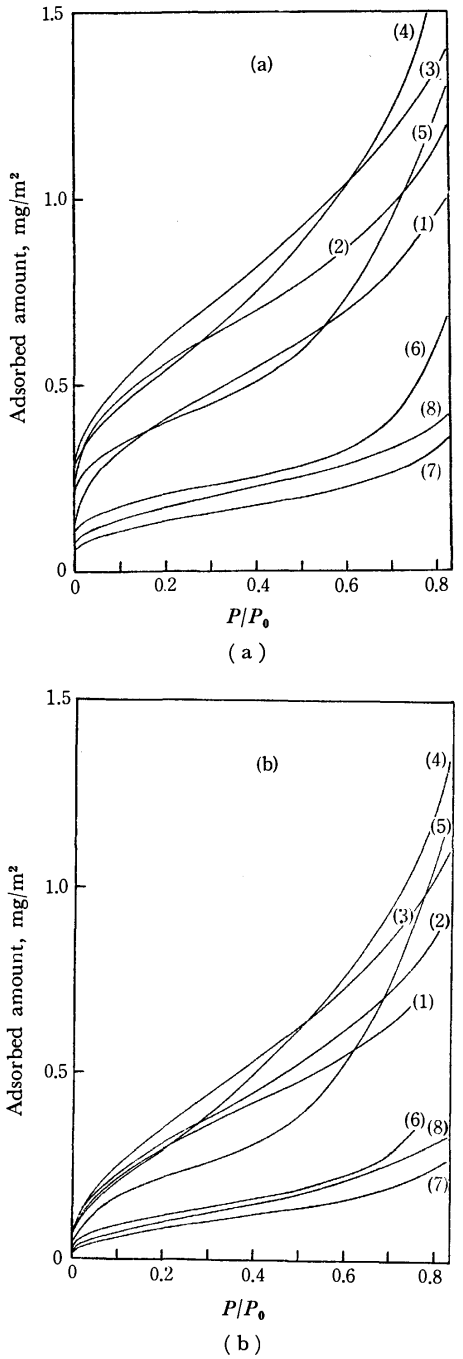

Fig. 4. Adsorption isotherms of water on rutile (Sample I) outgassed at various temperatures; (1) 100, (2) 200, (3) 300, (4) 400, (5) 500, (6), 600, (7) 700, (8) 800°C.
(a) First adsorption isotherms, (b) Second adsorption isotherms.

from the difference in the amounts of water adsorbed at a high pressure in the two isotherms. The number of the physically-adsorbed water molecules and that of the hydroxyl groups per unit of area obtained from the nitrogen adsorption are plotted in Fig.5 as functions of the outgassing temperature. In the figure there is also plotted the total number of hydroxyl groups per nitrogen area, which is the sum of the amount of the chemisorbed water and the water content. From this figure, it may be considered that the large heat of immersion at about 300°C is attributable

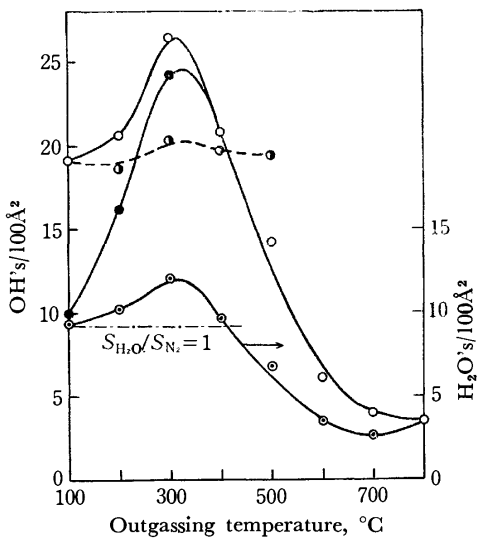

Fig. 5. Amounts of physically and chemically adsorbed water on the surface as a function of the outgassing temperature; ●: the number of hydroxyl groups formed by chemisorption per nitrogen area, ⊙: the number of physically adsorbed water per nitrogen area, ○ and ◑: total hydroxyl groups obtained by summing the chemically adsorbed water and water content per nitrogen area and water area respectively. Dotted line (—·—·—) shows that water area, S_{H_2O}, coincides with nitrogen area, S_{N_2}, at the amount of 9.3 H_2O's/100 Å².

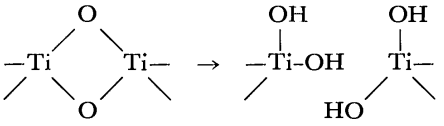
mainly to the chemisorbed water.

It should be noted that the total number of hydroxyl groups per unit of area at temperatures between 100 and 500°C is too large to be accommodated to the monolayer coverage because the number of the hydroxyl groups corresponding to the monolayer coverage is 12/100 Å², which is calculated by assuming the radius of the hydroxyl group to be 1.45 Å.[8] There is the possibility that the true surface area of the sample is not evaluated by the nitrogen adsorption. Therfore, the surface area, S_{H_2O}, was estimated from the monolayer volume of the physically-adsorbed water by assuming the cross-sectional area of the water molecule to be 10.8 Å². The ratio of the water area, S_{H_2O}, to the nitrogen area, S_{N_2}, is related to the amount of the physically-adsorbed water per nitrogen area, as is indicated in Fig. 5. The water area exceeds the nitrogen area in the outgassing temperature range from 100 to 400°C and shows a maximum at about 300°C. The total number of hydroxyl groups per unit of water area is also plotted in Fig. 5; the number at 300°C is about 20/100 Å².

The surface of Sample I, when evacuated at a low temperature, may have an ill-defined oxo-structure because of the low crystallinity of the surface. When water molecules adsorb on such a surface, the hydroxyl groups may be formed in bulk as well as on the surface, resulting in the formation of hydrous titanium dioxide in part as in the following scheme:



This reaction is irreversible; in other words, the unhydrated state produced by evacutaion does not return to the original unevacuated state, since the evacuation destroys the structure of the latter state. As the average number of titanium atoms exposed on the surface of rutile modification is 8/100 Å²,[9] it is calculated that about two or three hydroxyl groups combine with one titanium atom at temperatures below 400°C. This reaction may not occur on the stabilized surface oxo-groups, since the number of hydroxyl groups and also the heat of immersion decrease remarkably above 400°C. Above this temperature, the sample will form the more stable rutile structure in bulk and stabilized oxo-groups on the surface. As a consequence, the rehydration of the surface titanium atoms may be retarded, resulting in a decrease in the heat of immersion. The surface area of S_{H_2O} larger than S_{N_2} around 300°C may be responsible for the large number of hydroxyl groups on the surface, since water molecules adsorb physically on the hydroxyl groups.

Smaple I was tinged bluish gray when evacuated above 600°C. This color change has been considered to be caused by the removal of oxygen atoms from the surface.[10] Samples II and III also underwent a color change at high temperature, but it was slight compared with that of Sample I. The increase in the heat of immersion of Sample I above 600°C may be due to the contribution of the oxygen vacancy and the resulting distorted structure of the surface to the heat value.

Behavior of Positive Hole in a γ-Irradiated 3-Methylpentane Glass at 77°K

Masahiro IRIE, Hiroshi YOSHIDA, Koichiro HAYASHI, and Seizo OKAMURA*

Faculty of Engineering, Hokkaido University, Sapporo

**Research Reactor Institute, Kyoto University, Kumatori-cho, Osaka*

(Received July 13, 1971)

In order to elucidate the behavior of a positive hole in irradiated alkane glasses, the effect of solutes having ionization potential lower than that of a glass matrix molecule upon the decay of a trapped electron was examined in a 3-methylpentane glass at 77°K by means of electron spin resonance. The decay was found to be explained in terms of the superposition of two exponentially decaying processes, as in the absence of a solute. Although the fast process was not affected by a solute, the slow process was further slowed by the addition of a solute. The effect of a solute is described by the empirical relation, $k/k_0=1/(1+fN)$, where k and k_0 are the rate constants of the slow decay in the presence and in the absence of a solute, respectively. N is the mole fraction of a solute. The observed values of the slowing-down efficiency, f, increase in parallel with the decreasing values of ionization potential of solutes: 2-methyltetrahydrofuran, diethylether, methylvinylether, 2-methylpentene-1 and *n*-butylvinylether. The results are interpreted in terms of trapping of a positive hole by a solute molecule and positive hole tunneling from a hole trap to a trapped electron.

Several investigations have been reported on the trapping process of an electron and its reactions in saturated hydrocarbon glasses irradiated by ionizing radiations at 77°K.[1] Little consideration, however, has been given to the behavior of a positive hole in the glasses. Louwrier and Hamill reported the absorption spectra attributable to the positive hole trapped by higher alkane solutes, a radical cation of higher alkanes, in a 3-methylpentane glass at 77°K, the behavior of which suggested that the charge recombination process involved hole migration by fast resonant charge transfer in a neat glass and by slow electron tunneling in a doped glass.[2,3] The hole migration was elucidated also by an electron spin resonance (ESR) study of the radical cation of tetramethylethylene in a 3-methylpentane glass by Ichikawa and Ludwig.[4]

The present authors studied the behavior of a trapped electron in an irradiated 3-methylpentane glass at 77°K and found that its decay was expressed by the superposition of fast and slow exponential decays.[5] The slow decay was found to be dependent on the 2-methylpentene-1 added to the glass, which suggests that it is due to the migration of positive charge. On the other hand, the fast decay was thought to be due to the migration of an electron. Recently, they have observed the ESR spectra attributable to a trapped positive hole in irradiated 3-methylpentane and 3-methylhexane glasses at 77°K.[6] The spectra were replaced by that of a solute cation when vinylethers were added to the glasses.[7] These facts also imply that migration and trapping of the positive hole are involved in ionic processes in an irradiated 3-methylpentane glass.

In the present investigation, the effect of several solutes on the slow decay of a trapped electron in a 3-methylpentane glass is studied in order to elucidate the behavior of a positive hole in detail. The results obtained confirm the previous interpretation that the slow decay of a trapped electron is caused by the migration of the positive hole in the glass.

Experimental

3-Methylpentane, 2-methylpentene-1, and *n*-butylvinylether were purified by the same treatment as described previously.[7] Ethylether and 2-methyltetrahydrofuran were fractionally distilled three times over sodium and distilled *in vacuo* into a sodium–potassium mirrored vessel repeatedly until the mirror was no longer damaged. Methylvinylether was passed through a column of potassium hydroxide, dried with calcium hydride and distilled into a sodium-potassium mirrored vessel five times *in vacuo*.

The samples were distilled into ESR sample tubes of pure quartz and sealed under the pressure less than 10^{-4} mmHg. The amount of a solute was estimated from the volume and gas pressure.

Irradiation was carried out at 77°K in the dark to a dose of 5.2×10^{18} eV/g. ESR measurements were carried out with the aid of a conventional X-band spectrometer with 100 kHz magnetic field modulation and at the low microwave power of 0.3 milliwatts, at 77°K in the dark.

Ionization potentials were measured by means of a conventional mass spectrometer, by determining the threshold of appearance potentials with a linear extraporation method.

Results

The ESR signal of a neat 3-methylpentane glass irradiated at 77°K is composed of three spectra: a sextet spectrum due to a 3-methylpentyl radical, a broad unresolved spectrum due to a trapped positive hole (the cation radical of 3-methylpentane) and a sharp singlet spectrum due to a trapped electron, as reported previously.[5,6] The trapped electron decays rapidly at 77°K in the dark. The decay includes two exponentially decaying processes; the rate constants are 0.2 and 0.04 min^{-1} for the fast decay and the slow

one, respectively.[5]

Even if a small amount of a hole scavenger is added, the decay of the trapped electron is still caused by the two processes, as shown in Fig. 2 of Ref. 5. However, the rate constant of the slow decay decreases with the increasing concentration of the added solute. Fig. 1 shows the effect of an added solute, representatively of *n*-butylvinylether. The yield of a slowly decaying electron increases very slightly with the addition of a solute. These facts imply that a small amount of a solute (less than 10^{-1} mol%) provides few additional physical trapping sites for an electron but interrupts the charge neutralization process. It should be noted that the fast decay of a trapped electron is not affected by the addition of a small amount of a solute.

As to the dependence of the rate constant of the slow decay of a trapped electron upon the concentration of a solute, representative results are shown in Fig. 2. Changes in the rate constant follow the empirical relation,

$$k/k_0 = 1/(1+fN) \quad (1)$$

where k_0 and k are the rate constants in the absence and in the presence of a solute, respectively.

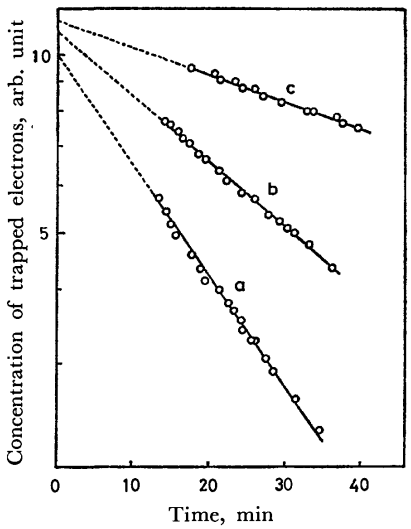

Fig. 1. Decay of trapped electrons in 3-methylpentane glass at 77°K in the presence and in the absence of *n*-butylvinylether. Radiation dose: 5.2×10^{18} eV/g. Concentration of *n*-butylvinylether: (a) 0, (b) 6.6×10^{-3} mol% and (c) 3.2×10^{-2} mol%.

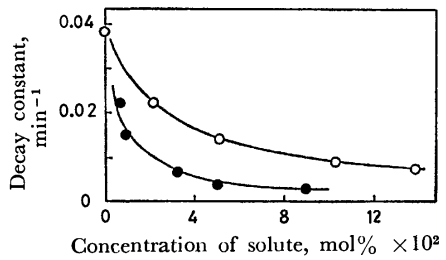

Fig. 2. Relation between the first order rate constant of the slow decay of trapped electrons at 77°K in 3-methylpentane glass irradiated to a dose of 5.2×10^{18} eV/g and the concentration of added solutes, (○) methylvinylether and (●) *n*-butylvinylether. Curves are derived from the relation (1). See text.

N and f are the mole fraction of a solute and the slowing-down efficiency proper to each solute, respectively.

The slowing-down efficiency of several solutes thus determined and their values of ionization potential are listed in Table 1. All the solutes have ionization potential lower than that of 3-methylpentane. The slowing down efficiency increases with the increasing difference of ionization potential between a solvent molecule and a solute. This is illustrated in Fig. 3.

Table 1. Relation between the slowing-down efficiency and the ionization potential of solutes added to the irradiated 3-methylpentane glass

Solute	Slowing-down efficiency f	Ionization potential (eV)	
		This work	Reported value[a]
n-Butylvinylether	1.4×10^4	8.44	——
2-Methylpentene-1	5.4×10^3	8.94	——
Methylvinylether	3.4×10^3	9.14	8.93
Diethylether	3.2×10^3	9.43	9.53
2-Methyltetrahydrofuran	2.7×10^3	——	9.54[b]
3-Methylpentane	——	10.20	10.08

a) See Ref. 8. b) Ionization potential of tetrahydrofuran.

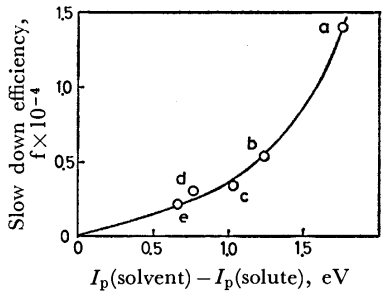

Fig. 3. Relation between the slowing-down efficiency and the difference of ionization potential between the glass matrix molecule and the added solutes, (a) *n*-butylvinylether, (b) 2-methylpentene-1, (c) methylvinylether, (d) diethylether, and (e) 2-methyltetrahydrofuran.

The ionization potential has not yet been reported for some of the solutes. Therefore, it was determined by the conventional mass spectrometric method, being shown in the third column of Table 1. Although the method seems unfortunately not to give the absolute values of significance, the difference between them may be enough significant to be related with the slowing-down efficiency. The ionization potential previously reported for some solutes is cited in the fourth column for comparison.

Discussion

The solutes examined have ionization potential lower than that of 3-methylpentane and negative electron affinity. Therefore, they are able to stabilize the positive hole in the glass forming a radical cation, whereas they do not capture electrons chemically. The results shown in Fig. 3 provide the evidence that the slow decay of a trapped electron is caused by the

migration of a positive hole to the immobile deeply trapped electron. If the decay resulted from the migration of an electron itself, the slowing-down efficiency might depend on the nature of a solute molecule such as dipole moment (dielectric constant) and electron affinity, rather than on ionization potential. However, this is not the case. For example, the slowing-down efficiency of 2-methylpentene-1 is found to be larger than that of methylvinylether, though the dipole moment of the former is evidently smaller than that of the latter.

The above argument leads also to the conclusion that the fast decay of a trapped electron is thought to be caused independently of a solute by the migration of an electron, as suggested previously.[5] This necessarily requires electron population in two kinds of traps, a shallow trap and a deep trap. The shallow trap is intrinsic to non-polar hydrocarbon glasses formed by preferably oriented C–H bond dipoles,[9] while the deep trap involves a solute molecule or an impurity molecule which can not be removed by the purification of 3-methylpentane.

What is to be considered is why the positive hole trapped by the solute still moves, bringing about the slow decay of a trapped electron. In order to account for the slow dark decay of a trapped hole in a 3-methylpentane glass containing a higher alkane solute, Louwrier and Hamill postulated hole migration involving electron tunneling from a solute molecule to a solute radical cation.[2,3] In their case where the concentration of a solute was rather high (~1 mol %), the tunneling occurred more readily with the increasing concentration of a solute. In the present experiment for low concentration of a solute (less than 10^{-1} mol %), the slow decay of a trapped electron may be interpreted in terms of hole tunneling from a trapped positive hole to the trapped electron, rather than that between solute molecules.

A rough estimation of the rate of tunneling can be made by assuming a one-dimensional potential barrier as shown in Fig. 4, where the region A is the potential well formed by a solute molecule which traps a positive hole. In the region C, there is a trapped electron which the hole tunnels to and recombines with. If one takes the potential in this region as zero, U_0 and V_0 are approximated by the values of ionization potential of solute and glass matrix molecules, respectively. If one assumes that the trapped positive hole has the same energy eigenvalue as that in the potential well of infinite height and length of a, the flow of probability at the region C is expressed by the following relation,

$$\lambda = \frac{2(E-U_0)\sqrt{2mE}}{maV_0} \exp\left(-2\hbar^{-1}l\sqrt{2m(V_0-E)}\right) \quad (2)$$

which is identical with the rate of charge neutralization.[10] The mass of a hole is taken to be the same as that of an electron, m. $E-U_0$ is the kinetic energy of a positive hole in the ground state, being estimated to be 0.1 eV. V_0-E can be approximated with the difference of ionization potential between glass matrix and solute molecules, ~1 eV. The widths of a well, and of a barrier l, are taken to be 5×10^{-8} (molecular dimension) and 4×10^{-7} cm (charge separation distance), respectively. These numerical estimates lead to $\lambda\sim10^{-4}$ sec^{-1}, which is consistent with the observed rate constant of the slow decay of a trapped electron in the presence of a solute.

The absolute value obtained above is somewhat arbitrary, because it is rather sensitive to the estimated values, especially those of V_0 and l. However, equation (2) accounts for the experimental results well at least qualitatively. If the ionization potential of a solute is lower and therefore V_0-E is larger, the trapped electron decays more slowly. Consequently, the slowing-down efficiency is expected to be larger. This agrees qualitatively to what was observed.

With the increasing concentration of a solute, the positive hole is more readily trapped, on the way back to the electron in a deep trap, by a solute molecule. This results in a trend that the average distance between a trapped positive hole and an electron (the average value of l in Eq. (2)) is lengthened by an increase of concentration, as far as the tunneling occurs between a solute molecule and a trapped electron. The above argument accounts for qualitatively the observed dependence of the rate constant of the slow decay of a trapped electron upon the concentration of a solute as shown in Fig. 2. The reason why the effect of a solute follows the empirical relation (1) still remains unknown, because of lack of knowledge on the distribution of distance l.

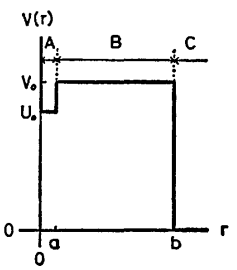

Fig. 4. A simplified one-dimensional trapping potential of positive hole. Region A is the potential well formed by a solute molecule which traps a positive hole. An electron is trapped in region C. V_0 and U_0 are ionization potential of solvent molecule and solute molecule, respectively.

10) According to the potential shown in Fig. 4, the wave function in the region C is easily obtained by a usual treatment, as

$$\Psi_C = \frac{k_1\cos k_1a - \kappa\sin k_1a}{\sqrt{2\pi a}\,(ik_3-\kappa)} \exp(-\kappa l) \exp\{ik_3(r-b)\},$$

where

$$k_1=\sqrt{\frac{2m}{\hbar^2}(E-U_0)},\ k_3=\sqrt{\frac{2m}{\hbar^2}E},\ i\kappa=\sqrt{\frac{2m}{\hbar^2}(E-V_0)},$$

and

$$l = b - a.$$

Using the approximation $k_1a=\pi$, the wave function is reduced to

$$\Psi_C = \frac{k_1}{\sqrt{2\pi a}\,(\kappa-ik_3)} \exp(-\kappa l) \exp\{ik_3(r-b)\}.$$

Therefore, the flow of probability is obtained as Eq. (2). See for example, G. Araki, "Quantum Chemistry," Baifukan, Tokyo, (1961), p. 505.

The Structural Transformation of Ferric Oxyhydroxides and Their Activity to Sulfur Dioxide

Tatsuo Ishikawa and Katsuya Inouye

Department of Chemistry, Faculty of Science, Chiba University, Chiba

(Received January 20, 1972)

α-, β-, and γ-FeOOH calcined at various temperatures up to 500°C have been examined by determining adsorption isotherms in order to relate the reactivity to SO_2 with the structural transformation. For each ferric oxyhydroxide, the amount of chemisorbed SO_2 per unit surface area (A_c), a measure of reactivity to SO_2, decreases with the progress of transformation into α-Fe_2O_3. At temperatures of calcination below 200°C the A_c value of β-FeOOH is larger than that of α-FeOOH or γ-FeOOH. It is shown by thermogravimetric analysis that the weight loss of β-FeOOH caused by heating is larger than the theoretical value corresponding to the dehydration of hydroxyl groups; $2FeOOH \rightarrow Fe_2O_3 + H_2O$. Changes in the X-ray diffraction patterns and Cl content of β-FeOOH with calcination indicate that β-FeOOH is transformed into α-Fe_2O_3 with elimination of inherently contained Cl at a higher temperature than other oxyhydroxides. The high reactivity to SO_2 and large weight loss of β-FeOOH caused by heating have been discussed with respect to the particular crystal structure of β-FeOOH containing Cl and molecular H_2O, in addition to hydroxyl groups.

It is known that SO_2 in the atmosphere and stack gases accelerates the corrosion of iron. Various oxides and oxyhydroxides of iron, composing the corrosion products of iron, play important roles in the corrosion process and consequently determine the physical and chemical properties of corroded metal surfaces. It seems significant to clarify the mechanism of the acceleration of corrosion by studying the interaction of SO_2 with those oxidized compounds.

Ferric oxyhydroxide is transformed into α-Fe_2O_3 by heating, through courses differing with environmental conditions and the crystal structures of ferric oxyhydroxides in question,[1] although the transformation mechanism has been proposed by several workers.[2,3,4]

The surface activity also changes during the course of transformation. Jurinak[5] reported from water adsorption measurement on α-FeOOH heated at various temperatures that the adsorbability decreases at the temperature range where the conversion occurs from α-FeOOH to α-Fe_2O_3. It is well-known that hydroxyl groups contained in ferric oxyhydroxide are eliminated as H_2O at approximately 300°C according to the reaction; $2FeOOH \rightarrow Fe_2O_3 + H_2O$. Okamoto, Furuichi and Sato[4] have reported that ferric oxyhydroxide releases the "bound" water at approximately 170°C and the "crystallization" water is evolved at approximately 300°C, the former appearing to affect the chemical reactivity of ferric oxyhydroxide.

If we assume that the reactivity of ferric oxyhydroxide to SO_2 mainly depends on hydroxyl groups in ferric oxyhydroxide, it would be interesting to see whether the reactivity changes with the removal of hydroxyl groups in the transformation into α-Fe_2O_3. In the preceding paper,[6] the authors reported on the SO_2 adsorption on ferric oxyhydroxides (α-, β- and γ-FeOOH) to show that each oxyhydroxide chemisorbs a considerable amount of SO_2; the amount of chemisorption is especially larger for β-FeOOH than other oxyhydroxides. Furthermore, by the kinetic treatment of the reaction between SO_2 and ferric oxyhydroxides, it was suggested that β-FeOOH is more reactive to SO_2 than other oxyhydroxides.

The purpose of the present investigation is to study the interaction of SO_2 with α-, β- and γ-FeOOH at various temperatures of calcination and to relate the reactivity to SO_2 with the structural transformation.

Experimental Procedures

Materials. α-FeOOH (α-1) was precipitated by the hydrolysis of 0.1 M ferric oxalate solution at 100°C for 45 minutes and at the initial pH of 6.6, regulated by adding 1 M $NaHCO_3$ solution. The precipitate produced was washed repeatedly and dried at 100°C.[7] More crystalline α-FeOOH (α-2) prepared similarly by the hydrolysis of ferric sulfate solution, the pH being adjusted at 13.6 with 0.1 M KOH solution, was stirred at 50°C for 30 hours. After filtering the suspension, the α-FeOOH precipitates obtained were washed until no sulfate ions were detected. They were then dried at 100°C for 5 hr.[8]

The hydrolysis of 1 liter of 0.1 M ferric chloride solution containing 100 g urea at 100°C for 15 hours gave crystalline β-FeOOH (β-1). The precipitates of β-FeOOH were washed with water and dried at 100°C for 2 hr.[9] Less crystalline β-FeOOH (β-2) was prepared by hydrolysing 0.1 M ferric chloride solution at 75°C for 6 hours. The precipitates were washed with 1 N ammonium chloride until no Fe ions were detected with thiocyanate solution. They were finally washed with methanol and with ether, and dried in an air oven at 100°C for 2 hours.[10].

Crystalline γ-FeOOH (γ-1) was prepared by the method

of Baudisch and Albrecht.[11] The ferrous hydroxide suspension, obtained by mixing 1 liter of ferrous chloride aqueous solution containing 40 g $FeCl_2 \cdot 4H_2O$ with 200 m*l* of 2 M hexamethylenetetramine solution, was treated with 27 m*l* of 1 M sodium nitrate, and then kept at 60°C for 45 minutes. γ-FeOOH (γ-1) was collected by filtering the suspension. Amorphous γ-FeOOH (γ-2) was prepared by adding 400 m*l* of 0.25 M potassium iodate to the mixture of 800 m*l* ferrous sulfate aqueous solution containing 56 g $FeSO_4 \cdot 7H_2O$ and 800 m*l* of sodium thiosulfate aqueous solution containing 90 g $Na_2S_2O_3 \cdot 5H_2O$, and then by stirring the resulting suspension at 45°C for 1 hr.[12] Preparation of γ-FeOOH samples was performed in a stream of nitrogen, and the resulting precipitates were thoroughly washed with water and dried at 60°C for 10 hr.

Methods. The amount of adsorbed SO_2 was determined gravimetrically at 30°C by means of a quartz spring balance with an accuracy of 0.20 mg. Before the adsorption measurement, approximately 200 mg of the sample was outgassed under 10^{-5} Torr, heated up to 110, 150, 200, 300, 400, and 500°C at a heating rate of 8°C/min and kept for 5 hours at each temperature under 10^{-5} Torr. Pure SO_2 dried with $CaCl_2$ was then introduced to the adsorption apparatus to measure the elongation of quartz spring by a cathetometer. The adsorption equilibrium was attained within 1 hr for each sample. Desorption was carried out immediately after the adsorption experiment. The desorption equilibrium was attained within 2 hours.

The BET surface area determination was made by a conventional volumetric nitrogen adsorption measurement. The pretreatment of the sample was similar to that in the SO_2 adsorption.

The X-ray diffraction patterns were obtained by the powder method with a diffractometer Geigerflex 2001 (Rigaku Denki Co. Ltd.) by use of Mn-filtered FeK_α (30 kV, 10 mA). The samples, calcined at 110, 150, 200, 300, 400 and 500°C under 10^{-5} Torr for 5 hours, were examined by means of X-ray diffraction.

Differential thermal analysis was carried out in air by Thermoflex 8001 S (Rigaku Denki Co. Ltd.) using α-Al_2O_3 as a reference sample. The enthalpy change in the structural transformation of the sample was measured by a differential scanning calorimeter DSC-1 (Perkin-Elmer Co.), at a heating rate of 8°C/min. The weight loss of the sample by heating was determined gravimetrically with a quartz balance, at a heating rate of 8°C/min.

The Volhald method was employed to determine the chlorine content of β-FeOOH. A solution of 100 mg of the sample in 30 m*l* concentrated nitric acid was diluted with water to 50 m*l* and an aliquot was titrated with 0.1 N $AgNO_3$ solution.

The iron content in the sample was determined by the following method; Fe^{3+} in hydrochloric acid solution, reduced to Fe^{2+} with $SnCl_2$, was titrated against a standard 0.05 N $K_2Cr_2O_7$ solution in the presence of sodium 4-diphenylammine sulfonate as an indicator.

Results

The thermogravimetric analysis (TGA) curves for α-FeOOH samples (α-1 and α-2) are given in Fig. 1. Both samples show rapid weight losses in the temperature range 200—300°C, but the weight loss of α-1 occurs in a temperature range lower than α-2. However, the total weight loss of each sample is consistently 12%, which is somewhat higher than the theoretical value (10%) corresponding to the change; $2FeOOH \rightarrow Fe_2O_3 + H_2O$. Similar curves were obtained for γ-FeOOH. The TGA curves of β-FeOOH in Fig. 2 differ from those of α-FeOOH in a gradual loss in the temperature range 100—450°C. The total weight loss is 20% for β-1 and 18% for β-2. The sublimed $FeCl_3$ was observed in the inner wall of the TGA apparatus during the course of heating around 400°C, where a stepwise drop of weight also took place for β-1 as shown in Fig. 2.

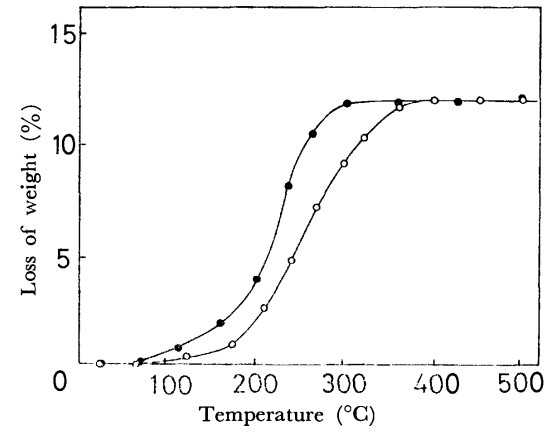

Fig. 1. TGA curves for α-1 and α-2: ●, α-1; ○, α-2.

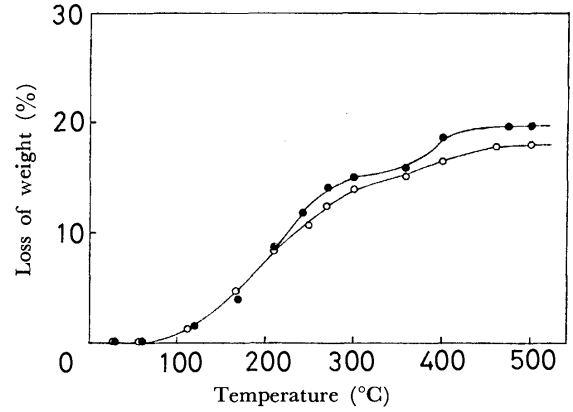

Fig. 2. TGA curves for β-1 and β-2: ●, β-1; ○, β-2.

The differential thermal analysis (DTA) curves of α-2, β-1 and γ-1 are given in Fig. 3. The curves of crystalline α-FeOOH (α-2) involves an endothermic peak at 110°C caused by the desorption of adsorbed water and an endothermic peak at 295°C by the dehydration of "crystallization" water.[13] For β-FeOOH, endothermic and exothermic peaks overlap each other at nearly 300°C. The endothermic peak of the sublimation of $FeCl_3$ appears at 400°C as found in the TGA curves. An endothermic peak at 170°C is probably caused by the elimination of molecular water embraced in β-FeOOH crystal. γ-FeOOH shows the exothermic peak at 430°C, which is considered to be due to the transformation of γ-Fe_2O_3 to α-Fe_2O_3.[13]

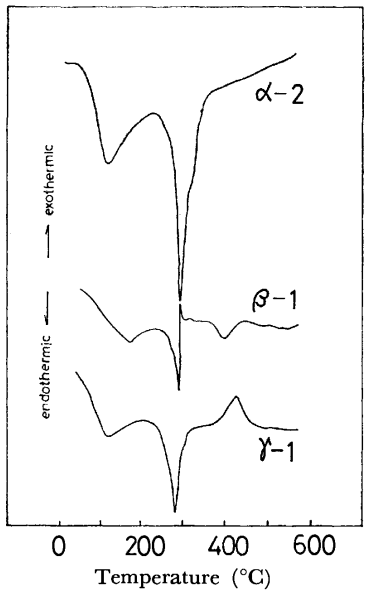

Fig. 3. DTA curves for α-2, β-1 and γ-1.

The endothermic peaks in the differential scanning calorimeter (DSC) curves in Fig. 4 correspond to dehydration. However, the samples used for DSC determinations kept in a desiccator for a long time adsorb less water than the samples used for DTA. No endothermic peaks caused by the desorption of physically adsorbed water are observed in DTA curves. The heat of dehydration obtained from the endothermic DSC peaks is 49, 75, 45 and 36 cal/g for α-1, α-2, γ-1 and γ-2, respectively. These results indicate that the more crystalline oxyhydroxide has a higher heat of dehydration than the less crystalline oxyhydroxide.

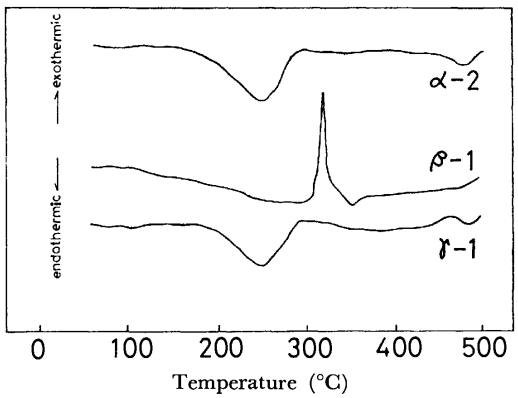

Fig. 4. DSC curves for α-2, β-1 and γ-1.

As demonstrated by the change of X-ray diffraction patterns in Fig. 5, α-2 is transformed into α-Fe_2O_3 at 200°C. The crystallinity of resulting α-Fe_2O_3 is seen to be gradually improved with further appearance of additional diffraction peaks of α-Fe_2O_3 at 400°C. On the other hand, β-1 (Fig. 6) changes to an amorphous mixture, composed of β-FeOOH and α-Fe_2O_3, in the temperature range 200—300°C. At 400°C, however, the amorphous mixture is suddenly transformed into the crystalline α-Fe_2O_3. γ-1 (Fig. 7) is transformed into amorphous γ-Fe_2O_3 at 200°C and is suddenly converted to crystalline α-Fe_2O_3 at 400°C. However, the TGA, DTA and DSC curves

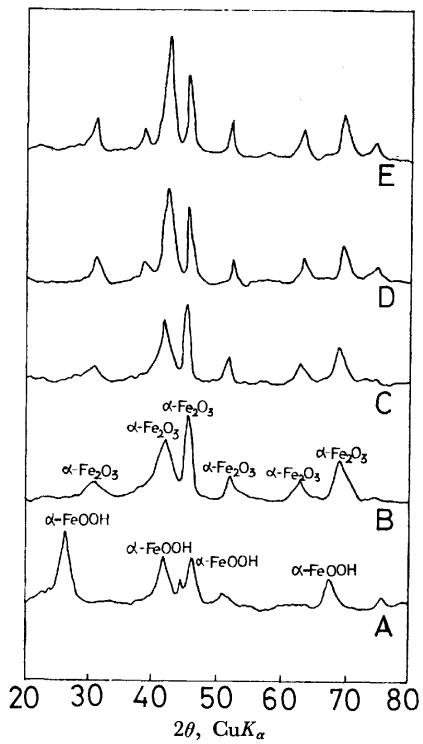

Fig. 5. X-ray diffraction patterns of α-2 at various temperatures of calcination: A, 150°C; B, 200°C; C, 300°C; D, 400°C; E, 500°C.

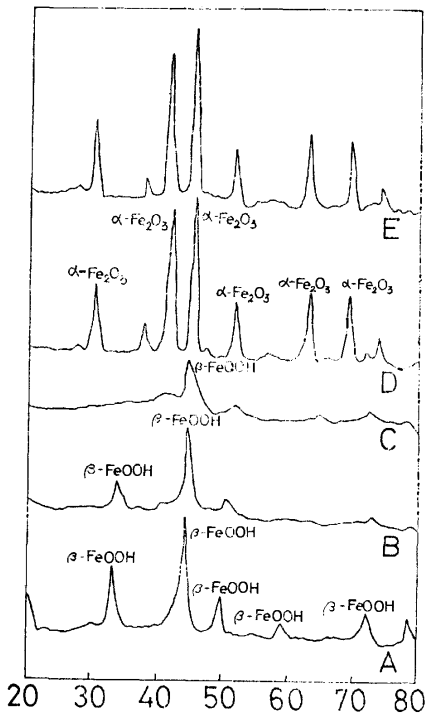

Fig. 6. X-ray diffraction patterns of β-1 at various temperatures of calcination: A, 150°C; B, 200°C; C, 300°C; D, 400°C; E, 500°C.

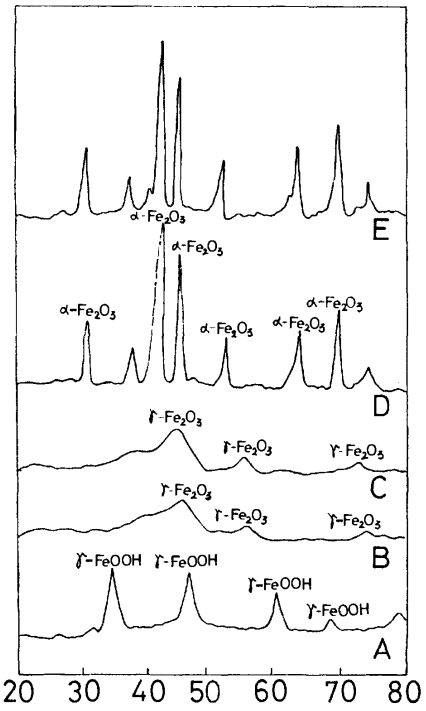

Fig. 7. X-ray diffraction patterns of γ-1 at various temperatures of calcination: A, 150°C; B, 200°C; C, 300°C; D, 400°C; E, 500°C.

shown in Figs. 1, 3 and 4 indicate that α-2 and γ-1 are transformed into α-Fe_2O_3 and γ-Fe_2O_3 at temperatures higher than the transformation temperatures obtained by X-ray diffraction. The discrepancy in transformation temperature is considered to be due to different heat treatments; the X-ray samples were outgassed for 5 hours at various temperatures under 10^{-5} Torr, whereas the DTA, TGA and DSC curves were obtained in air at a fixed rate of heating.

The variation of specific surface area with the temperature of calcination given in Fig. 8 shows a maximum between 200 and 300°C for each sample.

The SO_2 adsorption isotherm obtained at 30°C is of the BET-II type for each sample. Figure 9 shows the isotherm for α-2. The monolayer capacity of the

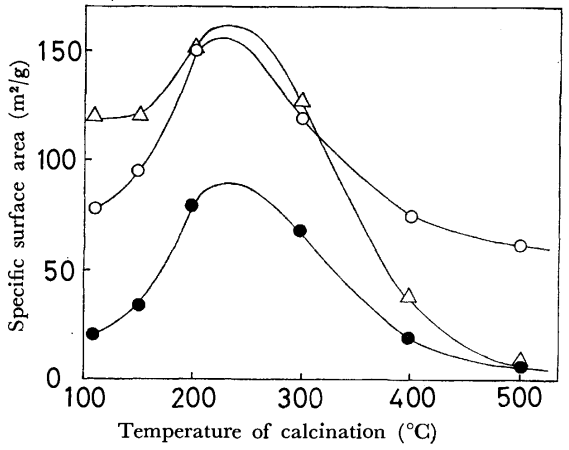

Fig. 8. Specific surface area plotted against temperature of calcination: ○, α-2; ●, β-1; △, γ-1.

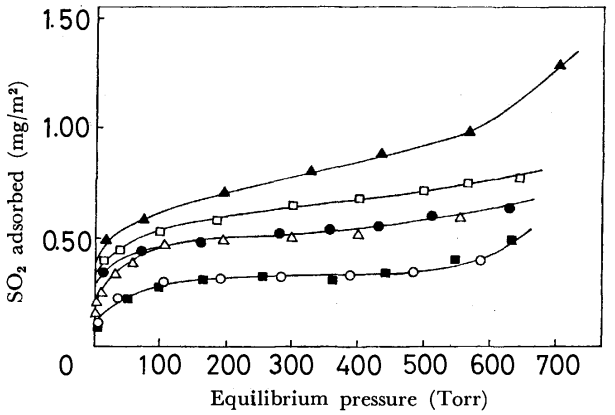

Fig. 9. Adsorption isotherms for α-2 at various outgassing temperatures: △, 110°C; ●, 150°C; □, 200°C; ▲, 300°C; ■, 400°C; ○, 500°C.

SO_2 adsorption per unit surface area (A_m), calculated by the BET method, is illustrated in Fig. 10 as a function of the outgassing temperature. Below 150°C, the A_m values are almost constant and no differences in A_m are observed between ferric oxyhydroxides examined. The adsorbed SO_2, remaining on the surface after desorption under 10^{-5} Torr at 30°C for 24 hr, is regarded as the chemisorbed SO_2.[6] The relationship between the amount of the chemisorbed SO_2 per unit surface area (A_c) and the temperature of calcination is given

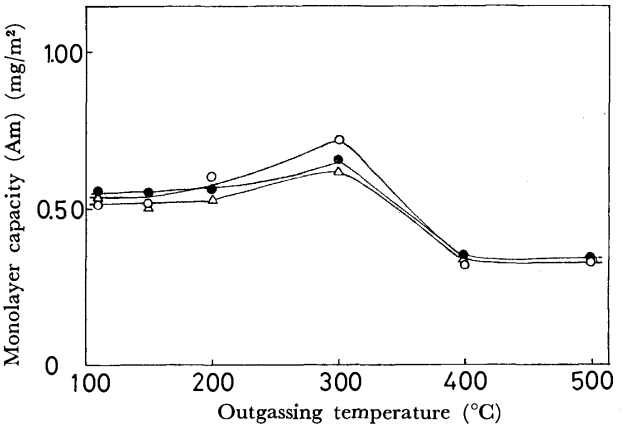

Fig. 10. Effect of outgassing temperatnre on monolayer capacity: ○, α-2; ●, β-1; △, γ-1.

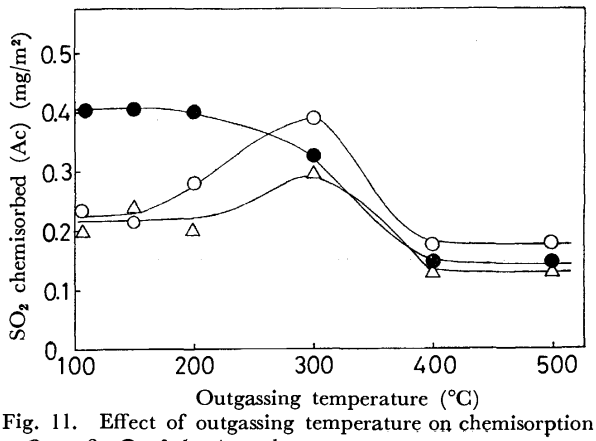

Fig. 11. Effect of outgassing temperature on chemisorption; ○, α-2; ●, β-1; △, γ-1.

in Fig. 11. The A_c value of β-FeOOH is larger than those of other ferric oxyhydroxides below 200°C. However, in the temperature range 200—400°C, the A_c of β-FeOOH drops with the formation of crystalline α-Fe_2O_3 and is nearly equal to the A_c of α-FeOOH and γ-FeOOH above 400°C.

The content of chlorine, which is characteristic of β-FeOOH, was found to be 4.6 wt% for β-1. As illustrated in Fig. 12, the chlorine content of β-FeOOH expressed in the atomic ratio (Cl/Fe) is constant below 200°C and decreases rapidly with increasing temperature in the range 200—400°C.

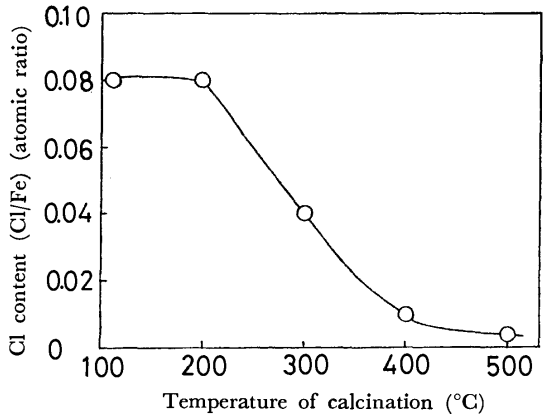

Fig. 12. Cl content in β-1 against temperature of calcination.

Discussion

The weight loss of α-FeOOH and γ-FeOOH by heating, which is larger than the stoichiometric value of water content, indicates that α-FeOOH and γ-FeOOH contain a small amount of "bound" water which is eliminated at a lower temperature range. As shown in Fig. 1, the crystalline sample (α-2) is dehydrated at a higher temperature than the less crystalline sample (α-1). A similar tendency was also observed for γ-FeOOH. Furthermore, the higher heat of dehydration calculated from the DSC curves was obtained for the crystalline sample. These results imply that the crystalline ferric oxyhydroxide is more difficult to be dehydrated as compared with the less crystalline ferric oxyhydroxide.

Dasgupta and Mackay[14,15] suggested that β-FeOOH has the hollandite ($BaMn_8O_{16}$) or α-MnO_2 structure with Cl and H_2O in the Ba^{2+} position. It is known that the Cl content in β-FeOOH varies with the extent of washing, since the Cl can be replaced by H_2O molecule.[3] In our experiments, the DTA curve for β-1 (Fig. 3) shows that H_2O is released from the crystal at approximately 170°C. Chlorine begins to be eliminated at 200°C as shown in Fig. 12, and DTA and TGA curves show that $FeCl_3$ is sublimed at 400°C. Thus the large total weight loss of β-FeOOH is obviously associated with the evolution of Cl_2 and H_2O in the crystal. It is therefore presumed that β-FeOOH contains two kinds of Cl; one which can be easily replaced by H_2O molecule, and the other which is strongly bound to Fe and removed as $FeCl_3$ by heating at 400°C. Figures 6 and 12 show the structural changes of β-FeOOH to α-Fe_2O_3, with elimination of Cl as $FeCl_3$ at approximately 400°C. From our results, the strongly bound Cl seems to stabilize the crystal structure of β-FeOOH with regard to transformation into α-Fe_2O_3. Thus the higher temperature is observed for the transformation of β-FeOOH into α-Fe_2O_3.

The relations between the specific surface area and temperature of calcination (Fig. 8) indicate that each ferric oxyhydroxide becomes amorphous and porous during the course of dehydration. After showing the maximum, the surface area decreases with the rise in temperature owing to crystallization and sintering.

The almost constant value of A_m below 150°C shown in Fig. 10 is referred to the fact that X-ray diffraction patterns are identical up to 150°C. It may be further assumed that the decrease of A_m with transformation is due to the disappearance of hydroxyl groups. On the other hand, the maximum monolayer capacity observed for each sample at 300°C seems to be due to the maximum chemisorption at 300°C as shown in Fig. 11. The maxima of chemisorption observed for α-2 and γ-1 appear to be caused by the higher surface activity in the temperature range, in which the samples undergo transformation into crystalline α-Fe_2O_3 and their crystals are distorted. As illustrated in Fig. 11, β-FeOOH chemisorbs a larger amount of SO_2 than other oxyhydroxides below 200°C. It is considered from the extraordinarily high activity of β-FeOOH to SO_2 that the vacancies formed by the removal of the molecular water by outgassing may be the chemisorption sites for SO_2. The number of such sites decreases with the destruction of the β-FeOOH structure with heating.

These results indicate that the reactivity to SO_2 decreases with the transformation from ferric oxyhydroxide into α-Fe_2O_3, and β-FeOOH in particular has a higher reactivity to SO_2 than other ferric oxyhydroxides at the temperature of calcination below 200°C. The characteristic behavior of β-FeOOH in the transformation process to α-Fe_2O_3 and the higher reactivity to SO_2 would be due to the crystal structure containing molecular water and chlorine which do not exist in other ferric oxyhydroxides.

The authors wish to thank Professor H. Kambe of Tokyo University for the DSC measurements.

(Received January 22, 1972)

The reduced partition function ratios (r.p.f.r.) of α, β-quartz and calcite were calculated for oxygen isotopic substitution, using the force fields. Optical vibrations are represented by factor group mode ($k=0$) and acoustic contributions were approximated by the Debye mode of vibration. The theoretical calculation predicts that the r.p.f.r. of quartz could have a discrete gap of about 0.8‰ at the α-β-transition temperature (573°C), the r.p.f.r. of α-quartz being larger in magnitude and in temperature-dependency. This implies that the isotopic fractionation factors between quartz and other materials such as water, could be significantly affected by the transition. A comparison of the calculated r.p.f.r. of quartz and calcite with the experimental fractionation factors between these minerals and water yields a fairly consistent value of the r.p.f.r. of water, supporting the force field models used for calculations. The comparison also revealed that the r.p.f.r. of water in the temperature interval 300—800°C and under a hydrostatic pressure of 2 Kb should deviate from those of ideal water vapor at the same temperatures by as much as 1‰ due to the non-ideality of the compressed water fluid.

Distribution of oxygen isotopes in nature is largely controlled by the equilibrium partitioning of the isotopes among coexisting phases. Detailed knowledge on the isotopic fractionation factors between major rock-forming minerals and water is essential in order to understand the isotopic ratios of the various substances in nature. The isotopic fractionation factors have been experimentally determined for a wide range of temperature for systems such as quartz-water, feldspar-water and calicte-water (*e.g.*, O'Neil and Clayton[1], O'Neil and Taylor[2]). On the other hand, the theoretical calculation of the isotopic fractionation factors has been developed by Urey[3], Bigeleisen and Mayer[4], and Bigeleisen[5]. However, application of the theory to condenced materials has been rather limited because of the complicated nature of the calculation. The fractionation factors between calite and water were first studied by McCrea[6], but his model was two simple to explain the experimental results. More refined calculations on the system were made by Bottinga[7] and O'Neil *et al.*[8] and the agreement between the experimental and theoretical values was greatly improved. The present authors calculated the reduced partition function ratios of α-quartz, β-quartz and calcite, using the force fields reported by Shiro[9,10] and Yamaguchi.[11] The present paper will describe the calculation in some detail and the results will be compared with the experimental fractionation factors obtained by other investigators. The effect of the non-ideality of water vapor at high temperatures and pressures on the isotopic fractination factors between water and these minerals will also be discussed.

Calculation of the Reduced Partition Function Ratios of α-, β-Quartz and Calcite. For the isotopic exchange reactions

$$1/2\ Si^{16}O_2 + H_2{}^{18}O = 1/2\ Si^{18}O_2 + H_2{}^{16}O, \quad (1)$$

$$1/3\ CaC^{16}O_3 + H_2{}^{18}O = 1/3\ CaC^{18}O_3 + H_2{}^{16}O, \quad (2)$$

the fractionation factors, α_{q-w} and α_{c-w}, are defined as follows.

$$\alpha_{q-w} = (^{18}O/^{16}O)_{quartz}/(^{18}O/^{16}O)_{water}, \quad (3)$$

and

$$\alpha_{c-w} = (^{18}O/^{16}O)_{calcite}/(^{18}O/^{16}O)_{water}, \quad (4)$$

These fractionation factors can be calculated from the relations

$$\alpha_{q-w} = f_q{}^{1/2}/f_w, \quad (5)$$

and

$$\alpha_{c-w} = f_c{}^{1/3}/f_w, \quad (6)$$

where f represents the reduced partition function ratios (r.p.f.r.) of the subscript substance.

The r.p.f.r. is generally defined by[4]

$$f = (Q^*/Q)_{qm}/(Q^*/Q)_{cl}, \quad (7)$$

where the numerator is the quantum mechanical partition function ratio and the denominator is the classical partition function ratio. The asterisk represents the heavy isotopic species. The partition function ratios of a crystalline solid are related to vibrational frequencies as follows.

$$(Q^*/Q)_{qm} = \prod_i \frac{e^{-u_i^*/2}(1-e^{-u_i})}{e^{-u_i/2}(1-e^{-u_i^*})}, \quad (8)$$

and

$$(Q^*/Q)_{cl} = \prod_i \frac{u_i}{u_i^*} = \left(\frac{m^*}{m}\right)^{3n/2}, \quad (9)$$

where $u_i = h\nu_i/kT$, ν_i=vibrational frequencies, h=Planck's constant, k=Boltzman constant, m=mass of light isotope, m^*=mass of heavy isotope, n=number of atoms involved in the substitution, and T=absolute temperature.

The r.p.f.r. of quartz and calcite were calculated

under the following assumptions: (1) all vibrations are harmonic oscillations, (2) crystal vibrations can be divided into optical and acoustic modes, and (3) the vibrational phases of all unit cells in the optical mode are the same, or $k=0$. The r.p.r.f. due to the optical mode are the same, or $k=0$. The r.p.f.r. due to the mode of vibration, f_{opt}, is then obtained by

$$\ln f_{opt} = \sum_{i=1}^{3N-3} \{[u_0(i)-u_0^*(i)]/2 + \ln[1-e^{-u_0(i)}]/[1-e^{-u_0^*(i)}] - \ln[u_0(i)/u_0^*(i)]\}, \quad (10)$$

where N=number of atoms in a unit cell, $u_0=h\nu_0/kT$ and ν_0=optically active vibration frequency (k=0).

The r.p.f.r. due to the acoustic vibrations can be calculated from the following equation if the Debye approximation of the acoustic vibration is valid.[12]

$$\ln f_{acoust} = \frac{3}{40}(\Theta^2-\Theta^{*2})/T^2, \quad (11)$$

$$= \sum_{j=1}^{3} \frac{h^2}{40k^2T^2}[\nu_a^2(j)-\nu_a^{*2}(j)], \quad (11)'$$

where Θ and ν_a represent the Debye temperature and acoustic (Debye) frequencies. Since acoustic vibration is a periodic translation of all atoms in a unit cell, acoustic frequency of the heavy isotopic crystal is assumed to be

$$\nu_a^*/\nu_a = \Theta^*/\Theta = (M/M^*)^{1/2} \quad (12)$$

where M denotes the mass of unit cell.

The observed values of ν_0 (i) of α-quartz were taken from Scott and Porto[13] and Saksena[14] and are given in Table 1. Since β-quartz belongs to factor group D_3, the vibrations of B_1- and B_2-symmertry groups are infrared- and Raman-inactive and only the frequencies of vibrations belonging to A_1, A_2, E_1, and E_2 have been measured[15] (Table 1). The missing frequencies were estimated as follows. Inspection of the observed frequencies of α- and β- quartz indicates that the latter are, on the average, 0.990 of the corresponding frequencies of the former in the region above 600 cm^{-1} and 0.924 below 600 cm^{-1}. This implies that the vibrations of lower frequencies are more strongly affected by the transition than those of higher frequencies. Assuming that the frequency ratios are the same for the B_1 and B_2 vibrations, the "observed frequencies" of the missing vibrations were estimated by multiplying the corresponding freuqencies of α-quartz by the ratios mentioned above (Table 1). The optical frequencies of α- and β- ^{18}O-quartzs were calculated by using the force fields obtained by Shiro[9] and Yamaguchi.[11] The calculated frequencies ν_{cal}^* were then converted into the "observed values" ν_0^*, assuming the following relationship.

$$\nu_0^*/\nu_0 = \nu_{cal}^*/\nu_{cal} \quad (13)$$

The acoustic frequencies of calcite can be calculated by means of the Giulotto-Loinger model[7,16], since carbonate ions are relativaly independent of each other in calcite crystals. However, the structure of quartz is too complicated to apply thier method. Thus,

the Debye temperature obtained by specific heat measurement of α-quartz[14] was used to calculate the acoustic portion of the r.p.f.r. of both α- and β-quartz (Table 1). Contribution of the acoustic vibrations to the total reduced partition function ratios is less than 0.5% and the assumption made above will not seriously affect the results.

The observed optical frequencies of calcite were taken from Ramdas results.[17] The optically inactive frequencies of A_{1u}- and A_{2g}-symmetry groups were calculated by Shiro.[10] The "observed frequencies" of ^{18}O-calcite were obtained as described above by using the force field given by Shiro.[10] The Debye temperatures of ^{16}O-calcite were taken from the calculation of Giulotto and Loinger.[16] The values are given in Table 2.

Results

The r.p.f.r. of α-, β-quartz and calcite are given in Table 3. The r.p.f.r. of calcite were obtained by using the same frequencies of the free carbonate ion and the lattice vibrations as used by Bottinga.[7] Our "Bottinga's values" are approximately 1.5‰ larger than his at all temperatures. The reason for this is not clear at present. The values quoted as "Bottinga's values" are those we re-calculated using the vibrational frequencies presented by Bottinga[7], and the value of 3/2 $\ln(m^*/m) = 3/2 \ln \frac{17.999167}{15.99491} = 0.17708$.

Discussion

The oxygen isotopic fractionation factors between calcite and water have been experimentally studied by McCrea[6] and Epstein *et al.*[8] at higher temperatures. The observed fractionation factors were found to be well approximated by an equation of the form $10^3 \ln \alpha_{c-w} = a/T^2 + b$, for a wide range of temperature, although the deviation from the linear equation becomes large at temperatures above 800°C. The experimental fractionation factors employed in this paper for calcite-water system is that given by O'Neil *et al.*[8]:

$$10^3 \ln \alpha_{c-w} = 2.78 \times 10^6/T^2 - 3.39 \qquad (14)$$

The experimental range of temperature was 0—500°C for equation (14). The calculation was extended to 800°C for the purpose of comparison with the fractionation factors between quartz and water. A slightly different equation, $10^3 \ln \alpha_{c-w} = 2.71 \times 10^6/T^2 - 1.84$, was also given by the same authors[1] for a temperature rage 0–750°C. The former equation gives a value about 0.6‰ higher at room temeprature and about 1.5‰ higher at 1000°C than that given by the latter equation.

The experimental fractionation factors in the system quartz-water have been subjected to significant revision since the first experimental work of O'Neil and Clayton.[1] The value of $\ln \alpha_{q-w}$ =used in the following discussion was taken from Fig.1 of Epstein and Taylor[19] and approximated by the least square fit equation[20],

$$10^3 \ln \alpha_{q-w} = 3.57 \times 10^6/T^2 - 2.71 \qquad (15)$$

The applicable temperature range of equation (15) would be 300–800°C. However, the equation gives about 2‰ larger fractionation factors in the temperature range 500–800°C than those reported by O'Neil and Clayton.[1] These discrepancies are apparently due to experimental difficulty in determination of the fractionation factors, suggesting that a comparison of theory and experimental rseults can not be free from uncertainty arising not only from the theory, but also from the experimental estimation of the fractionation factors.

The difference between the calculated r.p.f.r. of quartz and the observed values of $\ln \alpha_{q-w}$ is shown in Table 4. Similar values for calcite-water system are also shown. The differences (denoted as $f_{1w(q)}$ and $f_{1w(c)}$), should be equal to the r.p.f.r. of water and can be compared to the r.p.f.r. of water obtained independently by other methods.

The r.p.f.r. of liquid water may be obtained from the theoretically calculated r.p.f.r. of gaseous water and the observed isotopic vapor pressure ratios of water by means of the relationship

$$\ln f_{1w} = \ln f_{vw} + \ln \alpha_{1w-vw}, \qquad (16)$$

where subscripts 1w and vw stand for liquid and vapor water, respectively. The latest values of $\ln f_{vw}$ (Table 4) were claculated by Bottinga[7] who took into account the anharmonicity of the vibrations of water molecules. The values of $\ln \alpha_{1w-vw}$ have been mesaured by several

authors in a temperature range below 100°C.[21-24] Unfortunately, agreement between the values reported by these authors was rather poor, the maximum discrepancy being as much as 1‰. Values were obtained from the least square fit equation of the form $\ln p/p^* = a/T+b$ to the data given by Uvarov *et al.*[23] Theoretical verification of the equation was given by Bigeleisen.[5] We selected the data of Uvarov *et al.*[23] because only their measurements were extended to temperatures above 100°C, but in the least square fit calculation, the three highest temperature points were excluded for the reason that their data show a significantly different temperature dependency as compared to the lower temperature data. O'Neil and Adami[25] computed the values of $\ln f_{1w}$ from the observed isotopic fractionation factor between carbon dioxide and water and the calculated reduced partition function ratios of carbon dioxide. Their results are represented by the least square fit equation, $10^3 \ln f_{1w} = 29.14 \times 10^3/T - 26.54$ as shown in Table 4. The values of $\ln \alpha_{1w-vw}$ reported by Uvarov *et al.*[23] are essentially the lowest among those reported by other investigators, while the values of O'Neil and Adami[25] would rather represent a highest estimation of this kind. Hence, the two sets of data could define a possible range of values of $\ln f_{1w}$. We see from Table 4 that in spite of many uncertainties involved in the experimental and theoretical estimations, the values of $\ln f_{1w(c)}$ and $\ln f_{1w(q)}$ at a temperature range below 600°C are fairy close to each other, especially those of $\ln f_{1w(c)}$ being within a possible range of the values presented above.

Above the α-β transition point of quartz (573°C) the values of $\ln f_{1w(q)}$ deviate significantly from those of $\ln f_{1w(c)}$, because the r.p.f.r. of β-quartz is about 0.8‰ smaller at the transition point. The temperature dependency is also smaller than for α-quartz. This is a reflection of the fact that β-quartz is characterized by a less dense crystal structure than α-quartz: the unit cell of the former being appeoximately 0.1Å

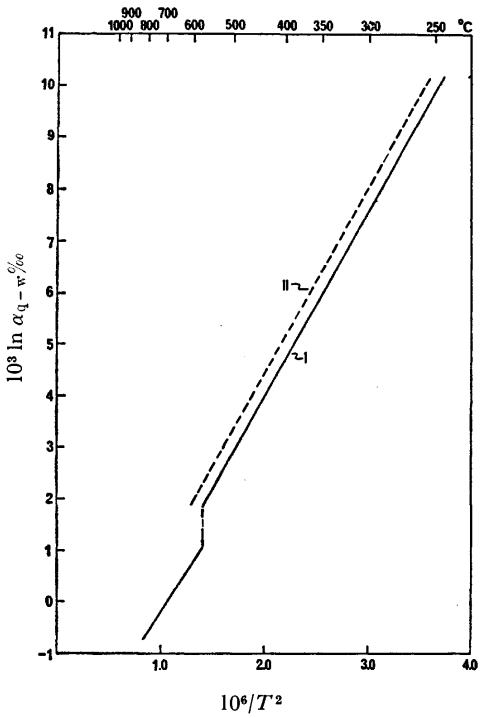

Fig. 1. Isotopic fractionation factors between quartz and water.

longer than the latter in both the a and c axes.[26] Yamaguchi[11] also demonstrated that the strecthing force constant of Si-O bond in β-quartz is about 0.2 mdyn/Å smaller than that in α-quartz on normal coordinate treatment. The "theoretical" values of $\ln \alpha_{q-w}$, calculated by the relationship $\ln \alpha_{q-w} = 1/2 \ln f_q - \ln f_{iw(c)}$, are plotted against $10^6/T^2$ in Fig. 1. The experimental values represented by equation (15) are also shown for comparison (dotted line). It is seen that the α-β transition of quartz should have a significant effect on the isotopic fractionation factors between quartz and water, although the experimental results so far obtained do not support the prediction. The calculated discontinuity at the transition point may be made smaller by adjusting the vibrational frequencies of α-quartz, while the uncertainty in the experimental determinations of the fractionation factor may also be large. Thus we feel that an exact comparison between theory and experiments is rather difficult at present.

The experimental data of quartz-water and calcite-water system at higher temperatures were determined under a hydrostatic pressure of 2 Kbar.[1] The values of $f_{iw(q)}$ and $f_{iw(c)}$ in Table 4 are, therefore, those of supercritical water at 2 Kbar. A good agreement between $f_{iw(q)}$ and $f_{iw(c)}$ below the α-β transition temperature of quartz allows us to say with some confidence that the difference between $f_{iw(c)}$ and the r.p.f.r. of gaseous water calculated by Bottinga above the critical temperature of water is ascribed to the non-ideality of water fluid under the experimental conditions. The non-ideality in the r.p.f.r. is about 1‰ at temperatures around 600°C and then decreases rapidly above 700°C. It should be noted that the compressed supercritical water fluid is "isotopically lighter" than the freely expanded water vapor at the same temperature. The cross-over point of the liquid-vapor water system lies somewhere around 150–200°C.[23] Above this temperature the heavy water ($H_2{}^{18}O$) possesses a higher vapor pressure than that of $H_2{}^{16}O$. The cross-over phenomena are qualitatively ascribed to the difference between $H_2{}^{16}O$ and $H_2{}^{18}O$ of the zero-point energy change by condensation of water.[5] The non-ideality in the r.p.f.r. of the compressed supercritical water fluid would also be due to the same effect, although a quantitative explanation is not possible at the present time.

Table 3 indicates that "Bottinga's values" of the r.p.f.r. of calcite ($1/3 \ln f_c$) are about 3% larger than our values. In our model, the carbonate ions in calcite crystals are not independent of each other, while in Bottinga's model, they vibrate freely without interaction.[7] As a result of mutual interaction of carbonate ions in our model, the ν_3 vibration at 1467 cm^{-1} a free carbonate ion[27] splits into two broad lines at 1434 and 1484 cm^{-1}. In general, the vibration of higher frequency makes more contribution to the r.p.f.r., hence the neglect of this unsymmetric splitting in Bottinga's model could be a cause of the discrepancy mentioned above.

The authors would like to express thier thanks to Professor T. Miyazawa, Osaka University, for his critical reading of the manuscript and helpful discussion. One of the authors(Y.S.) is indepted to the Sakkokai Foundation for financial help.

Added in Proof: The experimental equation of high temperature liquid-vapor fractionation factor for $H_2{}^{16}O$-$H_2{}^{18}O$ by Y. Bottinga and H. Craig (*Amer. Geophys. Union Trans.* **49**, 356 (1968)) is $\ln \alpha_{1w-vw} = -7.174 + 4.716 \times 10^3/T - 0.058 \times 10^6/T^2$. Due to their values, our obtained values $\ln \alpha_{q-w}$ become 6.3‰, 11.1‰, and 21.1‰, at 300°C, 200°C, and 100°C, respectively. The values are *ca.* 2‰ smaller than the Talor's results.[20]

Steady-Light Irradiation and Flash Photolysis Studies of [2.2]Metacyclophane-Iodine Systems. Mechanistic Implications of Transannular Dehydrogenation Reaction

Shigenari HAYASHI and Takeo SATO*

Department of Chemistry, Nihon University, Sakurajosui, Setagaya-ku, Tokyo

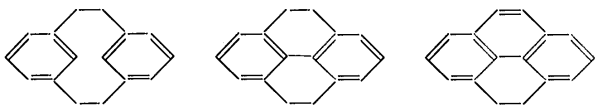
**Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo*

(Received January 25, 1972)

Irradiation of cyclohexane solutions of [2.2]metacyclophane in the presence of iodine is shown to yield 4,5,-9,10-tetrahydropyrene as the initial product. In order to clarify the mechanism of the cyclodehydrogenation reaction, steady-light irradiation, and flash photolysis experiments have been carried out. The rate of formation of 4,5,9,10-tetrahydropyrene is followed by UV spectra measurements using a characteristic band maximum at 292 nm. The rate of appearance of 4,5,9,10-tetrahydropyrene is found to be proportional to the absorption of light. The reaction is a one photon process. The reaction rate is almost constant when the concentration of iodine is less than 7×10^{-4} mol/*l*, but decreases gradually with higher concentrations. A long-lived species, whether radical or excited triplet, can not be detected by flash techniques. It is most likely that the first step involves the excited singlet. Involvement of CT-complex is proposed.

Due to the proximity of two benzene rings, [2.2]-metacyclophane (MCP) shows transannular interaction which causes spectral anomalies and results in transannular reactions to give pyrene derivatives.[2] Spectral studies of the charge transfer complexes involving TCNE and other electron acceptors were reported.[3]

Sato *et al.* reported on a photochemical transannular reaction of MCP induced by iodine.[4] Examination of the photoreaction using a high-pressure mercury lamp gave the following results:[5] a) Irradiation of degassed MCP-I_2-cyclohexane solutions results in a spectral change indicative of the formation of 4,5,9,10-tetrahydropyrene (4HP), which can be isolated in a fair yield. b) When photolysis is continued, further dehydrogenation occurs to give 4,5-dihydropyrene (2HP) and pyrene. c) No appreciable reaction occurs when the solution is photolyzed in air in the absence of iodine. d) Besides an oxidant, iodine appears to play a special role in the photoreaction. e) A light source with 253.7 nm line is the most effective one.



MCP 4HP 2HP

A mechanistic study of the transannular reaction is especially attractive in comparison with the related photocyclization reactions such as the formation of phenanthrene from *cis*-stilbene,[6] photolytic cleavage of [2.2]paracyclophane,[7] and photoequilibrium in certain metacyclophane compounds.[8]

In order to reveal the initial stage of the reaction, to account for acceleration of the reaction with iodine and to provide mechanistic implications, this paper records spectral studies under steady-light conditions and flash photolysis experiments.

Experimental

Materials and Procedures. [2.2]Metacyclophane (MCP)[9,10] was purified by combining recrystallization and column chromatography. 4,5,9,10-Tetrahydropyrene (4HP) and 4,5-dihydropyrene (2HP) were recrystallized three times from ethanol and sublimed. Cyclohexane (Wako Junyaku G.R. grade) was purified by the ordinary method. Purity was confirmed by UV spectrum and gas chromatography. Apparatus similar to that reported[11] was used for the steady-light illumination. The light source is a Ushio U12-1E low pressure mercury lamp operating at 100 V, supplied through a voltage stabilizer. The reaction temperature was 30°C. The sample solutions were degassed 7—8 times by the freeze-pump-thaw method *in vacuo* (the degassed solution). Aerated solutions were also used. At various time intervals, the sample cell was taken out and the absorption spectra were measured with a Hitachi EPU-2A spectrophotometer or a Shimadzu RM autorecording spectrophotometer. The effect of wavelength on the quantum yields was studied by choosing monochromatic light selected from a Toshiba SHL-100UV mercury lamp with a suitable

combination of Hoya or Toshiba glass filters, an aqueous solution of nickel sulfate (100 g/300 m*l*, 1 cm) and an interference filter. The quantity of light absorption was measured by a potassium ferrioxalate actinometer,[12] or a calibrated Kipp & Zonen thermopile and a Shimadzu K-2 potentiometer.

Main xenon flash lamp (96J, duration time of 15 μ sec) of the flash photolysis apparatus was followed by a second flash after 50 μsec and the transmitted light, after being passed through a Nalumi RM spectrography/monochromator, was led to a dry-plate. Alternatively, transmitted light was received by a Hamamatu photomultiplier and observed with the aid of an Iwasaki oscilloscope.

Results and Discussion

Steady Light Experiments. General Features of the Photooxidation: A spectral change occurs when a degassed MCP-I_2-cyclohexane solution is irradiated using 253.7 nm light as shown in Fig. 2. When irradiation is continued new maxima appear at 260, 268, 280, 292, 320, and 334 nm, which are ascribed to 4HP (see Fig. 1). The structure of 4HP was confirmed by IR and NMR spectra, and by direct comparison with the authentic material. The formation of 4HP is almost quantitative.

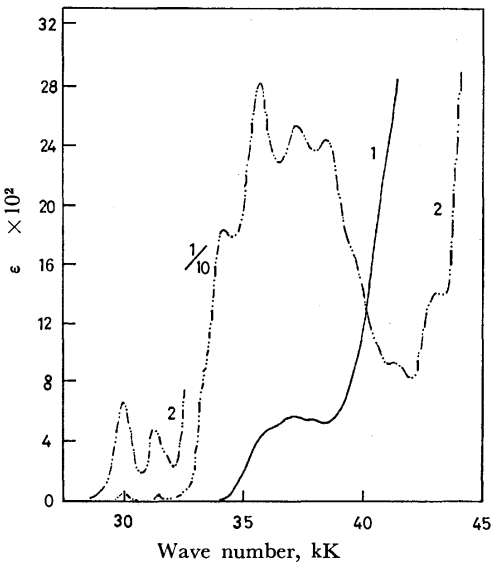

Fig. 1. Absorption spectra in cyclohexane.
(1): [2.2]Metacyclophane,
(2): 4, 5, 9, 10-Tetrahydropyrene.

On further irradiation, 4HP is converted in to 2HP and eventually to pyrene.[5] The reaction occurs successively. The secondary dehydrogenation steps are, however, much slower than the formation of 4HP from MCP and can be neglected. No thermal reactions occur with dilute solution. The transannular bonding is possible only under photolytic conditions.

An absorption maximum due to iodine, occurring at 525 nm diminished during the course of irradiation (Fig. 2). Conversion of iodine to hydrogen iodine could be inferred, but attempts to characterize it failed.

light is 253.7 nm line. Excitation of iodine absorption in the visible region using a 500 W tungsten lamp was not effective. The experiments described hereafter were carried out with a low pressure lamp. The reaction rate was determined by UV spectra following absorbance changes at 292 nm with appropriate time intervals.[13]

Effect of Light Intensity: A satisfactory linear correlation was obtained from plots absorbance *vs.* *t* at the initial stage. We see from Fig. 3 that the rate of appearance of 4HP (evaluated from the initial slope of the run for reaction) is proportional to light intensity. The main reaction is a one photon process.

Effect of Initial Iodine Concentration on the Rate: Since absorbing species at 253.7 nm are MCP, 4HP, and iodine, the light absorption can be expressed as follows.

$$I_{abs} = (I_0/d)(1-\exp(-2.303\mathrm{d}D_t)) \times 10^3$$
$$D_t = \varepsilon_{MCP}C_{MCP} + \varepsilon_I C_I + \varepsilon_{4HP}C_{4HP} \quad (1)$$

In the present studies, however, the conversion of MCP does not exceed 15%. For treatment of the initial stage of the reactions the term due to 4HP can be neglected.

$$I_{abs} = (I_0/d)(1-\exp(-2.303\mathrm{d}(\varepsilon_{MCP}C_{MCP}+\varepsilon_I C_I))) \times 10^3$$
$$= 2.303I_0(\varepsilon_{MCP}C_{MCP}+\varepsilon_I C_I) \times 10^3 \quad (2)$$

where C_{MCP}, C_I, C_{4HP}, ε_{MCP}, ε_I, and ε_{4HP} represent concentration and molar absorptivity of MCP, iodine, and 4HP, I_0 and d are light intensity and sample path length, respectively. Molar absorptivity of 4HP is more than ten times that of MCP and iodine, and would cause inner filter effects but only at a later stage. Assuming that only MCP takes part in reaction and that the rate of disappearance is proportional to light absorption, the following formula is obtained.

$$-\frac{\mathrm{d}C_{MCP}}{\mathrm{d}t} = \frac{\mathrm{d}C_{4HP}}{\mathrm{d}t} = kI_{abs}\frac{\varepsilon_{MCP}C_{MCP}}{\varepsilon_{MCP}C_{MCP}+\varepsilon_I C_I}$$
$$C_{4HP} = 2303kI_o\varepsilon_{MCP}C_{MCP}t = k_{4HP}t \quad (3)$$

Eq. (3) indicates that the formation of 4HP is proportional to the reaction time. This was satisfied experimentally (Fig. 4-a).

The reaction rate changes with iodine concentration[5]. For the sake of quantitative study, reaction mixtures with various iodine concentration were subjected to photolytic reaction. A good linear relationship was observed between C_{4HP} and reaction time (t) for several sets of mixtures (Fig. 4-a), although at very low iodine concentration some discrepancies were found except for the initial stage of the reaction. The rate of formation of 4HP(k_{4HP}) can be calculated from the slope.

At 253.7 nm iodine behaves also as an absorbing species and its decay being observed. Cleavage of iodine to radicals $I_2 \rightarrow 2I\cdot$ occurs, making it an attacking species. The relation between iodine concentration and rate of 4HP formation is shown in Fig. 5. When iodine concentration exceeds 7×10^{-4} mol/*l*, the reaction rate decreases gradually, possibly due to an innerfilter

13) At 292 nm, $\varepsilon_3 \gg \varepsilon_1$, ε_2, $\varepsilon_1+\varepsilon_2$, where ε_1, ε_2, and ε_3 are molar absorptivities for MCP, I_2, and 4HP, respectively. Therefore, absorbance increase in this region is assumed to be due to 4HP.

effect of iodine. This indicates that the following scheme is not the sole path.

$$\left.\begin{aligned} &I_2 \xrightarrow{h\nu} I_2^* \rightarrow 2I\cdot \\ &MCP + 2I\cdot \rightarrow 4HP + 2HI \end{aligned}\right\} \quad (4)$$

The fact that the dehydrogenation reaction proceeds with a significant rate even at very low iodine concentration ($<7\times10^{-4}$ mol/l) suggests two possibilities involving either a CT-complex between MCP and iodine or a rather long-lived intermediate subjected to iodine attack. For the latter case MCP can be excited to a triplet state, which may undergo electron and proton transfer reactions

$$\left.\begin{aligned} &MCP^* + I_2 \rightarrow MCP^+ + I_2^- \\ &MCP^+ + I_2^- \rightarrow 4HP + 2HI \end{aligned}\right\} \quad (5)$$

From flash photolysis experiments, however, such species could not be detected.

The rate of disappearance of iodine (k_I) determined at 525 nm also depends on the initial iodine concentration, as for k_{4HP}. Decrease of MCP leads to 4HP formation. The rate is in a complimentary relation

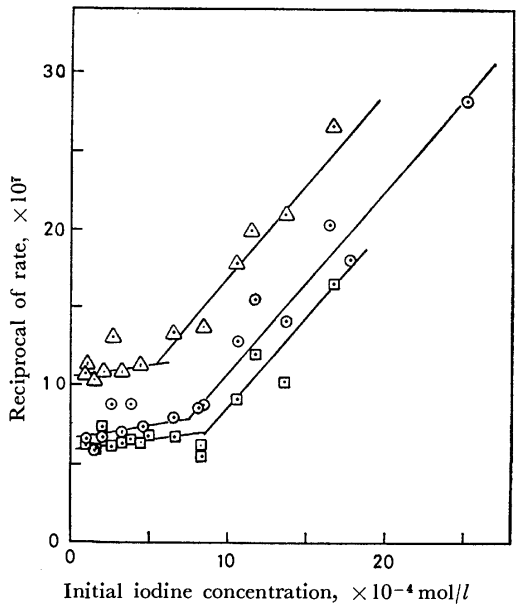

Fig. 5. Reaction rates (k_{4HP}, k_{MCP}, k_I) *vs.* initial iodine concentration plot.

(Fig. 4-b, Fig. 5).

Spectral changes observed by illuminating an aerated MCP-I_2-cyclohexane system are shown in Fig. 6. Recently, Sorimachi, Shizuka, and Morita[14] reported that the photolytic reaction of MCP to 4HP occurred in the absence of iodine. Photodehydrogenation with oxygen is, however, much slower than with iodine. Even slower rate of reaction was observable with degassed cyclohexane solutions (Fig. 7). Although the ability of hydrogen abstraction in *cis*-stilbene-phenanthrene reactions is considered to be in the order $I\cdot > O_2 > I_2$,[6] it does not hold in the present case. This suggests that an essentially different mechanism is involved in the photolytic reaction of MCP. Irradiation of *cis*-stilbene gives 4*a*,4*b*-dihydrophenanthrene in a reversible process, which in the dark reaction is oxidized by an added oxidant. On the other hand MCP is subjected to irreversible oxidation on irradiation. Even with the lack of unsaturation connecting two aromatic moieties, MCP undergoes photodehydrogenation by virtue of favorable molecular geometry, proximity of coupling positions and great strain energy.

14) H. Shizuka, K. Sorimachi, and T. Morita, Abstracts of Papers, the 24 th Annual Meeting of the Chemical Society of Japan, Osaka, April, 1971.

Apparent activation energy of the reaction is 5.5 kcal/mol which can be compared with 5.0 kcal/mol found for stilbene.

The Effect of MCP Initial Concentration. Experiments carried out with MCP concentrations show that the rate of 4HP formation is proportional to MCP concentration. The relation between MCP concentration and k_0 which can be calculated from k_{4HP} assuming $k_{4HP}/C_{MCP}=k_0$, is shown in Fig. 8. The values represent approximate quantum yields. For [MCP]$\geqq 5\times10^{-4}$ mol/l, k_0 is almost constant. No such linear correlation exists with more dilute solutions.

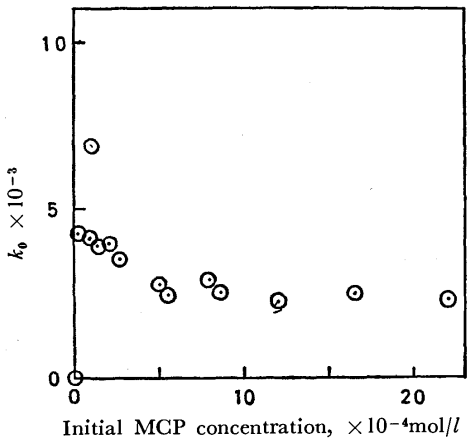

Fig. 8. k_0 *vs.* MCP concentration plot.
[I_2]: 3.3×10^{-4}mol/l

Flash Technique Experiments. Although the overall process of the I_2-induced dehydrogenation of MCP can be written as $MCP+I_2 \xrightarrow{h\nu} 4HP+2HI$, it is necessary to know whether it is such a simple reaction or a multistep reaction going through some intermediates. Muszkat and Fisher[15] presented a free radical mechanism involving radical species such as PH·, formed by hydrogen abstraction from dihydrophenanthrene PH_2, and HO_2· in the *cis*-stilbene-phenanthrene reaction. In order to solve the problems flash photolysis experiments were carried out for degassed cyclohexane solutions of MCP-I_2, MCP and I_2.

No absorption spectra suggesting the presence of an intermediate was observed. If an intermediate with a lifetime longer than 5×10^{-5} sec had been involved, the corresponding absorption could have been observed. For several wavelength regions, the diminishing absorption after main flash was followed by oscilloscope observation. Although absorption due to the product was observed, no diminishing absorption characteristic of an intermediate was detected.

Formation of Molecular Complex. The results of flash photolysis eliminate the possibility that the reaction proceed through a long-lived intermediate such as triplet species. As an alternative, we can postulate an intermediacy of the CT complex between MCP and iodine. The UV spectrum of a mixture of MCP ($\sim10^{-2}$ mol/l) and iodine ($\sim10^{-3}$ mol/l) in cyclohexane showed the presence of a band maximum at 334 nm which was absent in the individual spectra (Fig. 9). The band position is in agreement with the expected maximum[16] 336 nm, calculated from the ionization potential of MCP, 8.41 eV.[3]

15) K. A. Muszkat and E. Fisher, *J. Chem. Soc., B*, **1967**, 662.

16) Briegleb[18] presents the relation between the ionization potential (I_D) of the electron donor and the transition energy($h\nu_{CT}$) of CT-band as follows.

$$h\nu_{CT} = I_D - C_1 + \frac{C_2}{I_D - C_1}$$

Since $C_1=5.20$ eV, $C_2=1.5$ eV in iodine, calculation gives $h\nu_{CT}$ using $I_D=8.41$ eV.

TABLE 2. PHYSICAL PROPERTIES FOR THE MCP-I_2 COMPLEX (20.2°C)

Hydrocarbon	$\lambda_{CT.\ max.}$ nm	ε_{max}	K l/mol	$-\Delta H$ kcal/mol	$-\Delta S$ cal/mol/deg	$-\Delta G$ kcal/mol
MCP	334	1050	16.7	1.83	3.9	0.69
m-Xylene[18]	318	12500	—	—	—	—

The equilibrium constant K and the molar absorptivity ε of the complex calculated from the Rose-Drago equation[17] are in agreement with experimental values. This suggests the possibility that the photocyclodehydrogenation of MCP proceed by complexing with iodine.

As compared with the *m*-xylene-I_2 complex, the MCP complex absorbs at a longer wavelength region with intensity of about one-tenth. The difference is caused by a transannular electronic interaction which delocalize electron density in a charged structure, and also by bent benzene structure.[2] The equilibrium constant is larger than that of *m*-xylene, which is about 3 l/mol, but smaller than that of the MCP-TCNE complex.

Experiments with p-*Benzoquinone and Others.* *p*-Benzoquinone (BQ) and benzophenone (BP)[19] were also found to be effective as an oxidant.

The spectral change indicating the formation of 4HP upon irradiation with MCP–BQ–cyclohexane solutions is shown in Fig. 10. The reaction is rather complex since both MCP and BQ absorb at 253.7 nm. The formation of 4HP appears to be slower compared with iodine.

With BP as an oxidant, 4HP was formed when both MCP and BP were excited although no reaction occurred when BP alone was excited.[19] Abstraction of aryl hydrogens with BP and BQ is interesting when we consider the fact that they are usually photo-reduced only with good hydrogen donors.

On the other hand, irradiation of MCP-TCNE complex gave no indication of 4HP formation. Electon affinity[20] increases in the order O_2(0.7—0.9 eV) < iodine(1.7—1.8 eV) < BQ(2.0 eV) < TCNE-(2.89 eV). A stronger complex can be formed in this order. No relation exists between reactivity and this order.

General Discussion

Photolysis reaction of MCP differs in many ways with respect to the cyclization reaction of *cis*-stilbene, in which oxidation of the dihydrophenenthrene intermediate is accomplished both with oxygen and iodine in the dark reaction. It also differs from the photolysis reaction of [2.2]paracyclophane case since no ring cleavage product could be obtained. In the presence of iodine the rate of formation of 4HP is rapid as compared with other oxidants. This suggests that iodine plays a special role in the photocyclization. Mechanistic considerations, however, reveal that the action of iodine is not simple and appears to involve complicated processes.

From the results of flash photolysis study and the fact that photodehydrogenation was not scavenged by oxygen, one could eliminate the possibility of involvement of MCP triplet (Eq. (5)).

If the reaction comprises uncomplexed MCP in the excited singlet state as given by

$$\left.\begin{aligned} &\text{MCP} \xrightarrow{h\nu} \text{MCP*} \\ &\text{MCP*} + I_2 \rightarrow \text{4HP} + \text{2HI} \end{aligned}\right\} \quad (6)$$

one can expect the dependence of iodine concentration on the rate of formation of 4HP. The results given in Fig. 5, however, clearly indicate that the formation of 4HP is not affected by iodine concentration, if $[I_2] <$ *ca.* 7×10^{-4} mol/l. On the same basis, one can deny that iodine radical is involved in Eq. (4).

We propose the following scheme involving a molecular complex for the initial stage of the photolysis

$$\text{MCP} + I_2 \rightleftarrows (\text{MCP}\cdots I_2) \quad \text{(complex formation)} \quad (7)$$

$$(\text{MCP}\cdots I_2) \xrightarrow{h\nu} (\text{MCP*}\cdots I_2) \quad (8)$$

$$(\text{MCP*}\cdots I_2) \rightarrow (\text{MCP}\cdots I_2) \text{ or } \text{MCP} + I_2 \quad (9)$$

$$(\text{MCP*}\cdots I_2) \rightarrow \text{4HP} + \text{2HI} \quad (10)$$

where MCP* denotes excited state of MCP. It is highly probable that the excited singlet MCP is reactive. This formulation fits nicely the experimental results.

No intermediate compound corresponding to 4*a*,4*b*-dihydrophenanthrene formulated in *cis*-stilbene cyclization can be postulated in the MCP case, since two benzene rings are not in conjugation. The fact that no long-lived species can be detected by flash photolysis and oxygen has little effect on the reaction suggests the absence of any free-radical intermediate such as the one lacking one hydrogen atom from MCP.

Whether step(10) is such a simple process or consists of multi-step reactions is not known. However, it might be attractive to assume electron transfer processes followed by dehydroiodination:

$$\left.\begin{aligned} &(\text{MCP*}\cdots I_2) \rightarrow (\text{MCP}^+\cdot I_2^-) \\ &(\text{MCP}^+\cdot I_2^-) \rightarrow \text{4HP} + \text{2HP} \end{aligned}\right\} \quad (11)$$

The importance of such electron transfer processes and charge-transfer resonance configuration (CT configuration) might be suggested as follows: a) Photolysis of [2.2]paracyclophane in methanol with

17) N. J. Rose and R. S. Drago, *J. Amer. Chem. Soc.*, **81**, 6138, 6141 (1959).

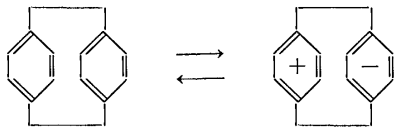
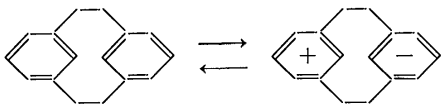
253.7 nm light can best be explained by assuming a CT configuration.[7] b) With [2.2]paracyclophane, the contribution of CT configuration caused by transannular interaction can be seen even with molecules in the neutral ground state. With the anion radical the contribution can be assumed to be about 50%. Energy of the CT configuration was considered to be several eV.[21] c) A similar interaction was observed with MCP and a delocalized configuration helps to form CT-complex. d) On contact with potassium film, MCP is shown to form 4HP anion radical instead of MCP anion radical. Martin and Gerson[22] interpreted the result by assuming initial formation



Ground configuration CT configuration
Neutral [2.2]Paracyclophane[21]



Ground configuration CT configuration
Neutral MCP

of MCP anion radical which undergoes transannular dehydragenation reaction. Kowata, Hoshino, and Koizumi,[23] on the other hand, presented evidence that 4HP is formed first on the surface of the metal, and is then reduced to 4HP anion radical. Regardless of the mode of formation, hydrogen abstraction $C_{8,16}$ occurs very rapidly. The facile oxidation can be explained in terms of the large strain energy, calculated by Boyd *et al.*[24] to be *ca.* 13 kcal/mol. The role of iodine is dual; it helps to increase delocalized configuration and acts as a hydrogen abstractor.

One of the authors (S. H.) wishes to thank Professor Masao Koizumi, Tohoku University, for many helpful discussions and suggestions during this work. Flash photolysis was carried out in the Institute of Physical and Chemical Research. The author (S. H.) is also grateful to Dr. Akira Kira for use of the flash apparatus and valuable discussions.

Appendix

The rate of disappearance of MCP is followed by calculating absorbance change of MCP, D^{272}_{MCP}, at 272 nm. After appropriate time intervals, the observed absorbance at 272 nm, D^{272}, can be expressed as follows.

$$D^{272} = D^{272}_{MCP} + D^{272}_{I} + D^{272}_{4HP}$$

where D^{272}_{I} and D^{272}_{4HP} are the absorbances due to iodine alone, and 4HP at 272 nm, respectively. Thus D^{272}_{MCP} is calculated as follows.

$$D^{272}_{MCP} = D^{272} - \frac{\varepsilon^{272}_{4HP}}{\varepsilon^{292}_{4HP}} D^{292}_{4HP} - \frac{\varepsilon^{272}_{I}}{\varepsilon^{520}_{I}} D^{520}_{I}$$

where D^{292}_{4HP} and D^{520}_{I} are the observed absorbances at 292 nm and 520 nm, respectively. The reaction rate of MCP, k_{MCP} is evaluated from the initial slopes (Fig. 4-c).

Studies of Built-up Films by Means of the Polarized Infrared ATR Spectrum. III. Elaidic Acid Films[1]

Tohru TAKENAKA and Kazuko NOGAMI

Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received January 31, 1972)

Attenuated total reflection studies with polarized infrared radiation have been made of multilayers of elaidic acid built up on a germanium plate by the Blodgett technique. It is concluded that the built-up films prepared from the tap-water substrate are made of calcium elaidate monohydrate. From the intensity changes in the regularly-spaced peaks (progression bands) in the region from 1350 to 1180 cm^{-1}, the planarity of the chain segment between the carboxylate group and the double bond is found to be dependent upon the surface pressure applied in the process of monolayer transfer onto the germanium plate. Studies of the anisotropy of the absorption index in the films show that the molecules assume a uniaxial orientation with respect to the axis normal to the germanium-sample interface (the *z*-axis), with an angle from 30° to 33° (in average) between the *z*-axis and the molecular axes. Furthermore, from the changes in the reflectivity with the number of layers, the film thickness per layer is estimated to be *ca.* 21.9 Å, a value which is in good agreement with the half-value of the long spacing, 44.16 Å, of the films as determined by X-ray diffraction studies. This apparently indicates that the films appear as the Y type.

In previous papers[2,3] of this series, attenuated total reflection (ATR) studies[4-6] have been made of multilayers of stearic acid and mixed multilayers of stearic acid and barium stearate built up on a germanium plate by the Blodgett technique.[7] It has been found that they are made of microcrystallites in the monoclinic or triclinic form, and that the hydrocarbon chains of stearic acid assume a uniaxial orientation on the axis normal to the germanium-sample interface, whereas the hydrocarbon chains of barium stearate give rise to a specific orientation in the interface with respect to the polishing direction of the germanium plate in its cleaning procedure. The film thickness per layer has been estimated to be 23.8 Å for the stearic acid films and 24.3 Å for the mixed films of stearic aicd and barium stearate; both values are in good agreement with the value previously reported.[7,8]

Since elaidic acid has the double bond in the *trans* form at the center of the C_{18} hydrocarbon chain, it is worth studying the multilayers of elaidic acid by the same method and discussing the effect of the double bond on the structure of the films as well as on their molecular orientation. Thus, in the present work, the polarized infrared ATR method was extended to studies of the multilayers of elaidic acid built up on the germanium plate by the Blodgett technique.[7] Unfortunately, attempts to compare the results of this study with those of oleic acid, which is the *cis* isomer, were unsuccessful, for the transfer of the oleic acid monolayer onto the germanium plate was incomplete and reproducible results could not be obtained, although Alexander[9] has prepared "excellent" multilayers of oleic acid (much less readily than the *trans* form) from the Cambridge tap-water substrate.

Theoretical

A full discussion of the theory used in this study has been given in the previous paper,[2] and so it will not be repeated here.

Experimental

The elaidic acid was a material of the highest purity (99%); it was purchased from the Sigma Chemical Co., and was used without further purification. It melted at 44.0°C, the melting point being in good agreement with the value in the literature.[10]

The multilayers of elaidic acid were formed by transferring the monolayer spread on a substrate (from a 0.04% solution in benzene) onto a germanium trapezoidal ATR plate, 50 mm long, 18 mm high, and 2 mm thick, by the Blodgett technique.[7] As Alexander[9] has pointed out, the best substrate was found to be ordinary tap water, filtered before use. Its pH was *ca.* 7.7, and it contained approximately 5×10^{-5} mol of calcium bicarbonate per liter of water. A synthetic substrate of the same pH and calcium concentration was comparatively poor for multilayer building, but the reason for this marked difference has not been investigated. The plate was slowly dipped in the water and then withdrawn, with its large faces (50 mm long × 18 mm high) vertical through the monolayer, at the fixed rate of 5 mm/min maintained with the use of a motor and reduction gear. Rapeseed oil (spreading pressure: 10.5 dyn/cm) or triolein (15 dyn/cm) was employed as the piston oil, with reference to the surface pressure-area isotherm of the elaidic acid monolayer reported by Marsden and Rideal.[10]

The germanium plate was cleaned by the same procedure as that reported in the previous paper.[2] The main step was the repolishing of the plate on a plane ground pitch plate covered with a silk cloth by the use of a polishing material (Linde) and a detergent solution. The plate was then thoroughly rinsed with water. This was followed by ultrasonic cleaning in alcohol and in chloroform.

The polarized infrared ATR spectra of the multilayers were recorded by a Perkin-Elmer model 521 grating spectrophotometer equipped with a multiple ATR attachment as well as a wire grid polarizer.[2] The ATR attachment has been designed so that the radiation can be reflected between the germanium-plate faces 25 times at the average angle of incidence of 45°. The semiangle of the radiation cone incident upon the ATR plate is *ca.* 3°. The error due to this beam convergence was estimated to be relatively small and was ignored in this study. The X-ray diffraction patterns of the multilayers were obtained with the aid of a Rigaku Denki X-ray diffractometer through the reflection method using the copper-K_α line.

All the experiments were carried out in a room of a constant temperature (20±0.2°C) and a constant humidity (45±2%).

Results and Discussion

The Polarized ATR and Transmission Spectra. In Fig.1 the infrared absorption specturm of elaidic acid obtained by the KBr pellet technique is reproduced for reference. Figures 2A and 2B represent the polarized ATR spectra of the 3-layer and 31-layer films, respectively, of elaidic acid prepared by the use of rapeseed oil as the piston oil. The solid line refers to the orientation of the electric vector parallel to the plane of incidence ($R_\parallel$), while the broken line refers to the electric vector perpendicular to it ($R_\perp$). Unfortunately, the latter line could not be recorded in the region lower than *ca.* 850 cm^{-1}, since the intensity of this particular polarized radiation was largely reduced in this region by various causes, such as the polarization characteristics of the grating in the monochromator and the absorption by the germanium plate. The transmission spectrum of the 31-layer films is also given (by the dotted line) in Fig. 2B. Apparently, the peaks are much stronger in the ATR spectra than in the transmission specturm.

It should be noticed that the C=O stretching band observed at 1710 cm^{-1} in the specturm of elaidic acid itself (Fig. 1) disappears in Fig. 2A and 2B, and that a pair of new peaks appears at 1550 and 1522 cm^{-1} in the spectra of the 3-layer film (Fig. 2A). With an increase in the number of layers, another pair of peaks appears at 1573 and 1537 cm^{-1}; these peaks are enhanced, while the intensities of the 1550 and 1522 cm^{-1} peaks are kept unchanged (Fig. 2B). Since the pair of bands at 1572 and 1536 cm^{-1} observed in the spectra of calcium salts (monohydrates) of long-chain fatty acids has been assigned to the antisymmetrical stretching vibration of the carboxlyate group,[11-13] the pair of peaks at 1573 and 1537 cm^{-1} observed in this

study (Fig. 2B) can confidently be attributed to the same vibration of calcium elaidate monohydrate. In other words, the multilayers of elaidic acid are prepared in the form of calcium salt (monohydrate) from the tap-water substrate. The disappearance of the peaks of elaidic acid itself at *ca.* 3100 cm^{-1} (the OH stretching vibration) and at 870 cm^{-1} (the OH out-of-plane deformation vibration) in Fig. 2B can also be interpreted in the same way. The first pair, at 1550 and 1522 cm^{-1}, observed in the spectra of the very thin-layer films (Fig. 2A) may be ascribed to calcium salts interacting with the germanium surface. Corresponding to the pair of peaks assigned to the antisymmetrical stretching vibration of the carboxlate group, the two peaks at 1432 and 1398 cm^{-1} can be attributed to the symmetrical strecthing vibration of the same group in calcium elaidate monohydrate.

Another marked difference in the spectra between the elaidic acid crystal and films is seen in the region from 1350 to 1180 cm^{-1}. In the spectrum of the elaidic acid crystal (Fig.1), regularly-spaced peaks of a medium intensity are found in this region, but only traces are observed in the spectra of the elaidic acid films (Fig. 2B). This is different from the cases of the multilayers of stearic acid[2] and of barium stearate,[3] for which the progression bands have been observed in the ATR spectra as in the spectra of their crystals. According to Susi,[14] the bond progression of the elaidic acid crystal is to be ascribed to the coupled wagging and/or twisting vibrations of the methylene groups in the chain segment between the carboxyl group and the double bond,[15] and it appears only when the segment is in the planar *trans*-zigzag configuration. The above-mentioned finding, therefore, suggests that the first chain segment of elaidic acid is scarcely in the planar configuration in the films prepared with rapeseed oil (spreading pressure: 10.5 dyn/cm).

When, however, the multilayers of elaidic acid are formed with triolein (spreading pressure: 15 dyn/cm), the weak progression bands appear as shown in Fig. 3. The positions of the bands are identical with those of the progression bands in the crystal spectrum (Fig. 1). The high parallel polarization of the progression bands can be interpreted in terms of an orientation of the planar chain segment toward the *z*-axis (Fig. 4), because the transition moments of the wagging and/or twisting modes of the methylene groups lie along the chain axes.[2,3] The other parts of the spectra are the same as those in Fig. 2B. It is apparent from these facts that the planarity of the chain segment is largely dependent upon the surface pressure applied in the process of monolayer transfer onto the germainum plate. The presumption that the multilayers prepared at higher surface pressures will give rise to stronger progression bands could not be ascertained, because of the collapse of the monolayer at such a surface pressure. The poor planarity of the chain segment of elaidic acid in the films may arise from the expanded structure of its monolayer which is seen in the surface pressure–area isotherm.[10]

The intense peak at 963 cm^{-1} is assigned to the CH out-of-plane deformation vibration of the *trans*-vinylene group, and the peak at *ca.* 720 cm^{-1}, to the rocking vibration of the methylene groups.[16] The other major peaks will be dicussed below.

The Molecular Orientation. The orientation of the elaidic acid molecules in the films was discussed by calculating three components of their absorption indices[5,17] (κ_x, κ_y, and κ_z) from Eqs. [5] and [8] in Ref. 2. Three axes, *x*, *y*, and *z*, of the germanium plate are shown in Fig. 4. The plane of incidence is the *yz*-plane. The dipping direction of the plate during the course of the film transfer and the polishing direction of the plate in its cleaning procedure are parallel to the *x*- and *y*-axes, respectively. The reflectivities ($R_\parallel$ and $R_\perp$) were obtained from the polarized ATR spectra. Some typical results are shown in Fig. 2 for the 3-layer and 31-layer films. The coefficients, *A*, *B*, and *C*, of Eq. [5] in the previous paper[2] were evaluated from Eq. [6] as $A=18.0$, $B=15.2$, and $C=20.7$ using the above-mentioned number of reflections ($q=25$) and the angle of incidence ($\theta_1=45°$), on the assumption that the refractive indices of the germanium plate (n_1) and the elaidic acid films (n_2) were 4.00 and 1.46,[18] respectively, at room temperature.

Table 1. Molecular orientation in the elaidic acid films

	Wave number (cm^{-1})	$\kappa_x(=\kappa_y)$	κ_z	D_{xz}	F	α
31 layers	2920	0.071	0.022	3.26	−0.301	31°
	2850	0.044	0.012	3.83	−0.327	29°
163 layers	2920	0.123	0.041	3.01	−0.286	32°
	2850	0.080	0.028	2.89	−0.279	33°

The polarized transmission measurements were also carried out for the thicker films with more than 31 layers, because they are sufficient for the detection of the absorption bands in the 2900-cm^{-1} region. For all the films examined, no difference was found between the transmission spectra obtained by the use of polarized radiations with the electric vectors parallel to the x- and y-axes, as in the case of the stearic acid films.[2] This apparently indicates that $\kappa_x=\kappa_y$, suggesting that the molecules in the films give rise to a random orientation on the z-axis, in other words, to a uniaxial orientation with respect to the z-axis, irrespective either of the dipping direction or of the polishing direction during the film preparation. From these discussions, we obtain, for example, the values of $\kappa_x(=\kappa_y)$ and κ_z shown in Table 1 for the peaks at 2920 and 2850 cm^{-1} (the antisymmetrical and symmetrical stretching vibrations of the methylene groups, respectively) of the 31-layer and 163-layer films.

In the case of the uniaxial orientation, the orientation of the molecules is evaluated by the orientation function, F,[19] calculated from:

$$F = \frac{1-D_{xz}}{1+2D_{xz}} \tag{1}$$

with:

$$D_{xz} = \kappa_x/\kappa_z. \tag{2}$$

Here, F defines the degree of the orientation of the transition moments with respect to the z-axis, as has been described in the previous paper.[2] The values of D_{xz} and F are given in Table 1 for 31-layer and 163-layer films. As a model of uniaxial orientation, if we assume that the molecular axis is uniformly oriented with an angle of α around the z-axis and that, further, the transition moment of the peak is uniformly oriented with an angle of β around the molecular axis, F can be expressed by the following equation:[13]

$$F = \frac{1}{2}(3\overline{\cos^2\alpha}-1)\cdot\frac{1}{2}(3\cos^2\beta-1), \tag{3}$$

where $\overline{\cos^2\alpha}$ denotes the average value of $\cos^2\alpha$. Since it is well known that the antisymmetrical and symmetrical stretching modes of the methylene guoups do not mix with the other modes, and that both their transition moments are perpendicular to the molecular axis ($\beta=90°$), while they are normal to each other, the values of α can be obtained for the 31-layer and 163-layer films as is shown in the last column of Table 1. The results are in agreement with the corresponding values of stearic acid,[2] suggesting that the inclination of the molecular axes in the elaidic acid films is nearly the same, on the average, as that in the stearic acid films.[2] In other words, the effect of the double bond in the *trans* form on the molecular orientation can virtually be ignored.

Film Thickness per Layer. In Fig.5, the reflectivity, $R_\perp$, is plotted against the number of layers, m, for five major peaks at 2920, 2850, 1537, 1465, and 1398 cm^{-1}. In the process of calculating the reflectivity, the effect of the absorption of radiation by the sample films on both sides of the germanium trapezoidal plate upon the polarized ATR spectra was corrected by the method described in the previous paper.[2] For each peak, $R_\perp$ decreases first with the increase of m and attains a constant value at a certain number of layers, m_c (indicated by an arrow in Fig. 5), which is characteristic of the peak. The larger $R_\perp$ values for the 1537 cm^{-1} peak at the small m values are interpreted as resulting from the peak shift in the very thin films as a result of the interaction between the carboxylate group and the germanium surface described previously.

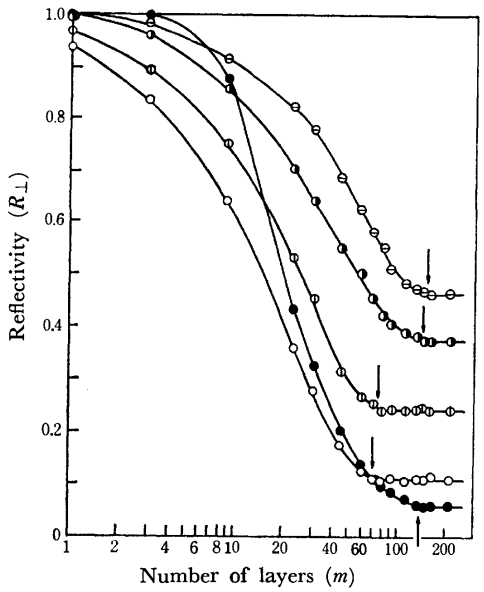

Fig. 5. Reflectivity $R_\perp$ as a function of the number of layers m:
—○—: 2920 cm^{-1}, —◑—: 2850 cm^{-1}, —●—: 1537 cm^{-1},
—◑—: 1465 cm^{-1}, —⊖—: 1398 cm^{-1}.

Since, from the discussions in the previous paper,[2] m_c is thought to be the number of layers which gives the penetration depth,[4] d, of the radiation (into the sample films) expressed by Eq. [1] of the previous paper,[2] we can obtain the film thickness per layer, d_0, by dividing d by m_c. The results are summarized

19) R. Zbinden, "Infrared Spectroscopy of High Polymers," Academic Press, New York (1964), Chap. V.

Table 2. Film thickness per layer of the elaidic acid films

Wave number (cm^{-1})	Assignment	d (Å)	m_c	d_0 (Å)
2920	CH_2 antisym. stretching	1560	70	22.3
2850	CH_2 sym. stretching	1600	75	21.3
1537	COO^- antisym. stretching	2960	135	21.9
1465	CH_2 scissoring	3110	140	22.2
1398	COO^- sym. stretching	3260	150	21.7
			Mean	21.9 Å

in Table 2 for all the peaks examined, together with their assignments.

The X-ray diffraction pattern of the 163-layer films is shown in Fig.6. An analysis of the main peaks in Fig.6 gives the value of 44.16 Å as the long spacing of the films. The fact that half of this value, 22.08 Å, is in good agreement with the mean value of d_0, 21.9 Å, suggests that the elaidic acid films appear as the Y type,[7] as Alexander[9] has pointed out.

In the case of stearic acid, the long spacing of the film has been found to be equal to that of the crystal.[3] In the case of elaidic acid, however, the above-mentioned value of the long spacing of the film is apparently shorter than that of the crystal, 48.9 Å.[20] This may correspond to the finding that the chain segment of elaidic acid is not in a clear planar configuration in the films.

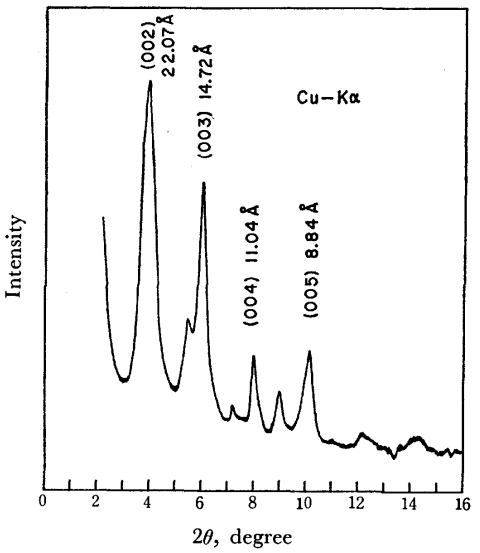

Fig. 6. X-Ray diffraction pattern of the 163-layer film of elaidic acid.

Vibrational Spectra of Propionamide and Its C- and N-Deuterated Compounds

Yoshihiro KURODA, Yutaka SAITO, Katsunosuke MACHIDA, and Toyozo UNO

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto

(Received February 3, 1972)

The infrared and Raman spectra of $CH_3CH_2CONH_2$, $CH_3CD_2CONH_2$ and their *N*-deuterated compounds in the solid state have been measured. The normal coordinate analysis has been made by assuming the molecular symmetry of C_s. A Urey-Bradley force field was used for the in-plane vibrations and a valence force field for the out-of-plane vibrations of the amide group. The ethyl group was treated by a Urey-Bradley type force field as well as a valence type force field. The assignments of the fundamental frequencies have been made by referring to the infrared and Raman intensities, isotopic frequency shift and the calculated frequencies by using the force constants which were taken from *n*-paraffins and acetamide. The agreement between the observed and the calculated frequencies in the initial calculation was good for the CH_3 and the amide group vibrations but was not good enough for some vibrations involving the α-carbon atom. Only the force constants related to these vibrations were refined by the least squares method in order to obtain the best fit. The calculated frequencies in this way fit to the observed satisfactorily.

Recently, we reported the infrared spectra of *n*-fatty acid amides, $CH_3(CH_2)_nCONH_2$ (n=1—16), and discussed the effect of the end amide group on the band progression frequencies arising from vibrations of the alkyl chain.[1] By assuming the invariance of the force field of the chain part, the shifts of band progressions on going from *n*-paraffins to amides were elucidated satisfactorily to arise from the change in the fashion of the vibrational coupling between the alkyl chain and the end groups. The force constants related to the α-methylene group are expected, however, to differ more or less from those of the *n*-paraffins, reflecting the change in the electronic structure induced by the polar end group. The present work has been undertaken to see if such difference in the force con-

1) K. Machida, S. Kojima and T. Uno, *Spectrochim. Acta*, **28**, 235 (1972).

stants between amides and *n*-paraffins can be estimated from the vibrational analysis of propionamide.

Besides our previous work,[1] the infrared and Raman spectra of propionamide have been reported by several investigators,[2-6] but there have remained many fundamental frequencies yet unassigned. In order to discuss the vibrational spectra of propionamide more precisely and to examine the transferability of force constants, we synthesized $CH_3CD_2CONH_2$ and $CH_3CD_2COND_2$, and measured the infrared and Raman spectra of these compounds together with those of usual species, $CH_3CH_2CONH_2$ and $CH_3CH_2COND_2$. The infrared spectrum of the 50 per cent *N*-deuterated sample of propionamide was also recorded for comparison. The normal coordinate analysis based on the GF matrix method[7] has been made by using the force constants transferred from acetamide[8-9] and *n*-paraffins.[10] By comparing the observed spectra with the result of the initial calculation, reasonable assignments have been given to all the fundamental frequencies of four isotopic species of propionamide. The agreement between the observed and the initially calculated frequencies was not good enough for some vibrations of the joint part of the ethyl and amide groups, but an appreciable improvement of frequency fits was attained soon by the least squares refinement of the related force constants.

Experimental

Materials. Methylmalonic acid was prepared by the saponification of commercially available diethyl methylmalonate,[11] and was submitted to the exchange reaction with D_2O in a sealed tube twice. After the removal of the excess D_2O, methylmalonic-d_1-acid-d_2 was thermally decomposed at 140—150°C and the product was distilled at the same time.[12] Thus obtained propionic-α,α-d_2 acid-*d* (CH_3CD_2COOD) was purified by distillation under reduced pressure. The deuterium content at the α-position of this acid was estimated to be about 92 per cent by the NMR spectrum. Propionyl-α,α-d_2 chloride (CH_3CD_2COCl) was prepared from propionic-α,α-d_2 acid-*d* and benzoyl chloride,[13] and was converted into propion-α,α-d_2 amide ($CH_3CD_2CONH_2$) by the reaction with NH_3 gas in ether at about -15°C. Similarly, propionamide ($CH_3CH_2CONH_2$) was synthesized from commercially available propionyl chloride. The amides were purified by the recrystallization from benzene. The NH_2 compounds were converted into the corresponding ND_2 compounds by the exchange reaction with

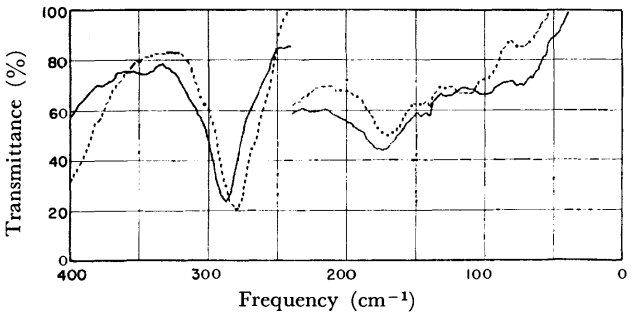

Fig. 4. Infrared spectra of $CH_3CD_2CONH_2$ (——) and $CH_3CD_2COND_2$ (----) in the region between 400 and 33 cm^{-1}.

D_2O. The partially *N*-deuterated samples were prepared by using mixtures of H_2O and D_2O.

Measurement. The infrared spectra were recorded on a Perkin-Elmer Model 521 grating spectrophotometer (4000—250 cm^{-1}, Figs. 1 and 2) and on a Hitachi FIS-3 grating spectrophotometer (400—33 cm^{-1}, Figs. 3 and 4). The samples were measured as mulls with Nujol or hexachlorobutadiene. The wave number was calibrated by the standard absorptions of polystyrene, indene and ammonia. The Raman spectra were measured for the crystalline samples obtained from the melt sealed in a capillary tube on a SPEX RAMALOG laser Raman spectrophotometer (Figs. 5 and 6). The exciting line (4880 Å) was generated by an argon ion laser at an approximate output power of 200 mW. The observed frequencies are listed in Table 1 together with the relative intensities and assignments.

Normal Coordinate Analysis

The molecular symmetry of propionamide adopted in the present calculation is that of the point group C_s with the C_α-C_β bond at the *trans* position of the C–N bond (hereafter, the alkyl carbon atoms are specified by greek subscripts if necessary). Although the structure determination by the X-ray analysis has not yet been made for propionamide, the assumption of the C_s structure may be justified from the crystallographic data for a number of long chain *n*-fatty acid amides.[14-17] It has been shown that the cell di-

a) Force constants Nos. 1—12 and Nos. 21—39 in units of mdyn/Å.
Force constants Nos. 13—20 and Nos. 40—48 in units of mdyn·Å/(rad)²
b) ( ): initial value
c) The force constants Nos. 1–20 are the same as those in the Calculation A.
d) The force constants of ethyl group were taken from Calculation V in Ref. 10: Stretching constants in units of mdyn/Å. Stretch-bend interaction constants in units of mdyn/rad. Bending constants in units of mdyn·Å/(rad)².

model, the 30 fundamental vibrations of propionamide are classified into 19 in-plane (a′) and 11 out-of-plane (a″) modes. The internal coordinates and the internal symmetry coordinates are shown in Fig. 7 and Table 3, respectively. In order to avoid missassignments due to any inadequacy of force constants, the calculation was carried out in two ways, in which the CH_3-CH_2-group was treated by a modified Urey-Bradley force field (Calculation A) and by a general valence force field (Calculation B). In both Calculations A and B, the amide group was treated by a simple Urey-Bradley force field for the a′ vibrations and a valence force field for the a″ vibrations. In the initial calculations, the force constants of the amide group were transferred from our earlier results for acetamide.[8-9] and those of the ethyl group from Schachtschneider and Snyder's work on *n*-paraffins; see Table 4.[10] Calculations A and B by the transferred force constants gave essentially the same results as each other, reproducing well the observed fundamental frequencies of $CH_3CH_2CONH_2$ and $CH_3CH_2COND_2$ for the vibrations of the CH_3 and the $CONH_2$ ($COND_2$) groups. The initial calculation failed, however, to give satisfactory fits for the C_α–C stretching, the CH_2 bending and the C_β–C_α–C deformation frequencies. By taking account of these results together with the observed infrared and Raman intensities and isotopic frequency shifts, vibrational assignments have been made for the remaining fundamentals of four isotopic species of propionamide.

Vibrational Assignment

There is no question on the assignment of the NH_2 asymmetric and symmetric stretching frequencies (*ca.* 3350 and 3190 cm^{-1}) and their ND_2 counterparts (2530 and 2370 cm^{-1}). They were observed as strong bands in both the infrared and Raman spectra. For the NH_2 and ND_2 symmetric stretching vibrations, we observed an apparent difference by about 20 cm^{-1}

between the infrared and the Raman frequencies. This difference is attributable to the intermolecular interaction by hydrogen bonds in the crystalline state, where the infrared active and the Raman active vibrations may belong to different symmetry species of the factor group. In Figs. 1 and 2, the band at 3310 cm^{-1} and the shoulder at 3200 cm^{-1} are assigned to the NH stretching vibrations of the NHD compounds. In order to distinguish between the bands due to the NHD compounds and those of the ND_2 compounds clearly, the infrared spectra of 50 per cent *N*-deuterated samples were measured and the normal coordinate analysis was also made for the *trans* and the *cis* isomers of CH_3CH_2-CONHD. The observed and the calculated frequencies, the relative intensities and the assignments are summarized in Table 5. The assignments of the CH_3 and CH_2 stretching vibrations are easily made by comparing the infrared and Raman spectra of the CH_2 compounds with those of the CD_2 compounds. Following Nolin and Jones,[20] the strong Raman band at 2940 cm^{-1} observed for each isotope of propionamide may be assigned to the first overtone of the CH_3 asymmetric deformation vibration at about 1460 cm^{-1}, enhanced by the resonance with the CH_3 symmetric stretching vibration. The CD_2 asymmetric and symmetric stretching frequencies were observed, respectively, at about 2180 and 2120 cm^{-1} for $CH_3CD_2CONH_2$ and $CH_3CD_2COND_2$. They are not immediately obvious in the infrared, but are definitely found as sharp strong bands in the Raman spectra.

In the region between 1800 and 1550 cm^{-1}, the infrared spectra of $CH_3CH_2CONH_2$ and CH_3CD_2-$CONH_2$ show two strong and broad bands centered at about 1665 and 1625 cm^{-1} which almost overlap with each other, but the Raman spectra of these compounds show two clearly separated bands at about 1674 and 1590 cm^{-1} (see Figs. 5 and 6). These bands arise certainly from the C=O stretching and the NH_2 bending vibrations. According to the normal coordinate analysis, both S_1 (C=O stretching) and S_2 (NH_2 bending) are important in the potential energy distribution for each of these fundamentals. The infrared band at 1418 cm^{-1} of $CH_3CH_2CONH_2$ shifts to 1425 cm^{-1} on the *N*-deuteration (see Fig. 1). This band is assigned to two fundamentals, *viz.*, the CH_2 bending and the C–N stretching vibrations, the high frequency shift on the *N*-deuteration being associated only with the latter. A distinct evidence for the contribution of the C–N stretching vibration to this band is that CH_3CD_2-$CONH_2$ shows the corresponding band at 1409 cm^{-1}, which shifts also to a high frequency on the *N*-deuteration (Fig. 2). The assignment of the α-CH_2 bending frequency has been established for a number of *n*-acyl compounds.[21]

The infrared band of $CH_3CH_2CONH_2$ observed at 1296 cm^{-1} was assigned previously to the CH_2 wagging mode. The N-deuteration causes an upward shift of this band by about 22 cm^{-1}, in accordance with the removal of the NH_2 bending frequency from its high-frequency side. The corresponding Raman band at 1300 cm^{-1} is very weak, but it is easily assigned to the CH_2 wagging mode since it shifts to a higher frequency on the N-deuteration similar to that of the infrared counterpart. In the Raman spectrum CH_3-CH_2CONH_2 shows a weak band at 1260 cm^{-1} which does not shift on the *N*-deuteration and is assignable to the CH_2 twisting vibration. The corresponding infrared band was not observed. In the region between 1300 and 1200 cm^{-1}, neither the infrared nor the Raman spectrum of $CH_3CD_2CONH_2$ shows noticeable bands, but a weak Raman band is observed at 1224 cm^{-1} for $CH_3CD_2COND_2$. According to the normal coordinate analysis, this band is assigned to the ND_2 bending vibration, which gives rise to the medium infrared band at 1165 cm^{-1} and the weak Raman band at 1180 cm^{-1} for $CH_3CH_2COND_2$.

In the infrared spectrum between 1200 and 900 cm^{-1} (see Fig. 1), $CH_3CH_2CONH_2$ shows three bands at 1142, 1068, and 1004 cm^{-1}, the first arising from the NH_2 rocking vibration. Its Raman counterpart appears at 1148 cm^{-1} very strongly. The 1068 cm^{-1} band was assigned previously to the C_α–C_β stretching vibration. The normal coordinate analysis in this work indicates that the C_α–C_β stretching and the a′ CH_3 rocking vibrations couple strongly with each other, and give rise to the two bands at 1068 and 1004 cm^{-1}. On the *N*-deuteration the 1068 cm^{-1} band shifts to 1078 cm^{-1} but the 1004 cm^{-1} band remains unshifted. The very strong Raman band at 945 cm^{-1} of $CH_3CH_2COND_2$ is easily assigned to the ND_2 rocking vibration by taking account of the isotope shift and its characteristic intensity. The infrared and Raman spectra of the CD_2 compounds in this region are much more complicated than those of the CH_2 compounds. As shown in Fig. 6, the Raman bands corresponding to the infrared bands at 1136 cm^{-1} of $CH_3CD_2CONH_2$ and at 956 cm^{-1} of $CH_3CD_2COND_2$ are very strong and are easily assigned to the NH_2 and ND_2 rocking vibrations, respectively. The assignments of the other bands have been made by referring to the calculated

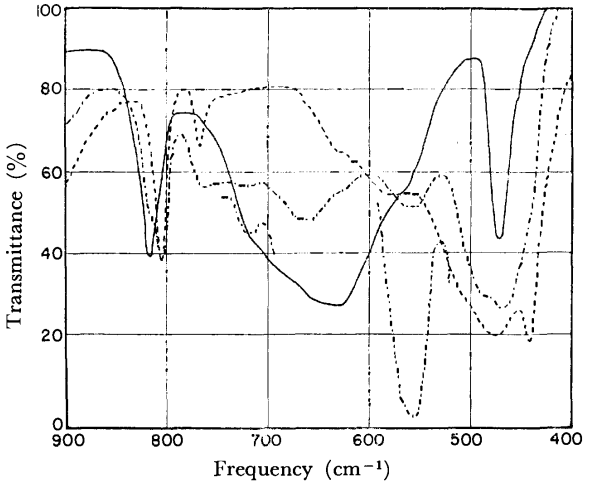

Fig. 8. Infrared spectra of $CH_3CH_2CONH_2$ (——), CH_3-CH_2CONHD (·—·) and $CH_3CH_2COND_2$ (----) in the region between 900 and 400 cm^{-1}.

frequencies. According to the normal coordinate analysis, the coupling among the CH_3 rocking, C_α–C_β stretching, $NH_2(ND_2)$ rocking and the CD_2 bending vibrations seems to be considerable.

Three fundamental frequencies are expected for $CH_3CH_2CONH_2$ in the region between 900 and 700 cm^{-1}, *viz.*, the C–C_α stretching, the CH_2 rocking and the NH_2 torsional frequencies, but the infrared spectrum of this compound shows only one medium absorption band at 821 cm^{-1}. We assigned this band to a composite absorption contributed by the above three modes. On the *N*-deuteration, this band is replaced by a medium band at 808 cm^{-1} due certainly to the CH_2 rocking vibration, and a weak band assignable to the C–C_α stretching vibration appears at 765 cm^{-1}. The contribution of the NH_2 torsional

vibration to the 821 cm^{-1} band of $CH_3CH_2CONH_2$ is suggested from the fact that the infrared spectrum of the 50 per cent *N*-deuterated sample of propionamide shows two weak bands at 767 and 721 cm^{-1} (Fig. 8). These bands may be assigned to the NH out-of-plane deformation vibrations of the NHD compounds.[9] The initially calculated C–C_α stretching frequencies of $CH_3CH_2CONH_2$ and $CH_3CH_2COND_2$ were about 50 cm^{-1} higher than the observed values, but the assignment of these fundamentals was substantiated by the appearance of strong Raman bands at 820 and 769 cm^{-1} for $CH_3CH_2CONH_2$ and $CH_3CH_2COND_2$,

respectively. In the infrared spectrum of $CH_3CD_2CONH_2$, a medium band assignable to the C–C_α stretching and the NH_2 torsional vibrations is observed at 803 cm^{-1}. The corresponding Raman band at 807 cm^{-1} is again very strong and is replaced by a medium band at 750 cm^{-1} on the *N*-deuteration. Besides these bands, $CH_3CD_2CONH_2$ shows a weak band at 850 cm^{-1} which hardly shifts on the *N*-deuteration and is assignable to the CD_2 wagging vibration.

The NH_2 and ND_2 wagging and the skeletal deformation frequencies are expected in the region between 700 and 250 cm^{-1}. For the infrared spectrum of $CH_3CH_2CONH_2$, we assigned previously the very strong and broad band centered near 640 cm^{-1} to the NH_2 wagging vibration, the shoulder band at 570 cm^{-1} to the C=O a'' deformation vibration and the band at 472 cm^{-1} to the C=O a' deformation vibration.[1] The asymmetrical contour of the first of these bands indicates, however, the presence of an implicit absorption with the maximum near 680 cm^{-1}. Furthermore, the 50 per cent *N*-deuterated sample of propionamide shows a weak infrared band at 660 cm^{-1}, which is not observed in the spectrum of $CH_3CH_2COND_2$ (see Fig. 8). If this band is due to a fundamental vibration of *trans* or *cis* CH_3CH_2CONHD, the NH_2 wagging frequency of $CH_3CH_2CONH_2$ should be higher than 660 cm^{-1} in order that the isotopic shifts fulfil the Rayleigh condition.[22] Accordingly we assigned the implicit absorption near 680 cm^{-1} of $CH_3CH_2CONH_2$ to the NH_2 wagging vibration. The strong absorption giving rise to the peak near 640 cm^{-1} was then attributed to the C=O a' deformation vibration by referring to the normal coordinate analysis, which led also to the revised assignment of the band at 472 cm^{-1} to the C_α–C–N deformation vibration. In the Raman spectrum of $CH_3CH_2CONH_2$, there is no noticeable band assignable to the NH_2 wagging vibration, but two weak bands arising from the C=O a' and a'' deformation vibrations are observed at 630 and 570 cm^{-1}, respectively. The shifts of these bands on the C_α- and *N*-deuterations were found to agree well with the initial calculation, and the assignments of the infrared and Raman bands of the CD_2 compounds in this region were made without much difficulty by referring to the calcu-

lated frequencies. For the C–C_α–C_β deformation frequency of $CH_3CH_2CONH_2$, the initially calculated values are about 40 cm^{-1} lower than the observed frequency of the infrared band (292 cm^{-1}), but we are quite confident on the assignment of this fundamental from the previous analysis of the band progression of *n*-fatty acid amides as well as the intensity of the Raman counterpart.

In the region below 200 cm^{-1}, $CH_3CH_2CONH_2$ and its *N*- and C_α-deuterated compounds show several infrared bands assignable to the torsional vibrations about the C–C_α–C_β skeleton, but unambiguous assignments of these fundamentals are difficult since the bands due to lattice vibrations may overlap with them. According to the normal coordinate analysis, the C_α–C_β and C–C_α torsional vibrations of the CH_2 compounds are thought to contribute to the bands at about 170 and 70 cm^{-1}, respectively. No appreciable shifts of these bands were observed on the C_α-deuteration.

Refinement of Force Constants

There are two factors which may affect the shifts of the CH_2 group frequescies on going from propane to propionamide, *viz.*, the change in the fashion of mechanical couplings with the rest of molecules and the change in the force constants within the CH_2 group. How these two factors participate in the observed shifts may be estimated from a comparison of the experimental results with the initially calculated frequencies, since the force constants for the CH_3CH_2-group used in the initial calculation have been known to reproduce the observed frequencies of *n*-paraffins very well.[10] Table 6 shows the observed and the calculated values of the CH_2 group frequencies of propane and propionamide; the results for the C–C_α–C_β deformation frequency are also listed. From the failure of the calculation to reproduce the observed difference in the CH_2 bending frequency between propane and propionamide, it is seen that the observed shift stems from the change of the force constants related to this frequency. Contrarily, the agreement between the calculated and the observed shifts of the CH_2 rocking frequency suggests that the nature of the shift is essentially mechanical. The calculated shift of the C–C_α–C_β deformation frequency is too large and the mechanical effect on this shift should be cancelled partly by the change in appropriate force constants. For the

CH_2 wagging frequency, Calculation B gave a much better result than Calculation A, but both the calculations failed to give sufficient shift of this frequency on the *N*-deuteration of propionamide.

Taking account of these results as well as the discrepancies in the C–C_α stretching frequencies, we tried to improve the force field of propionamide by the least squares refinement of the deformation constants related to the valence angles around the C_α atom and the C–C_α, C=O, and C–N stretching constants. In addition to the adjustment of the last two constants, the introduction of an interaction constant $f_{4,9}$ was found necessary to suppress the influence of the C–C_α stretching constant on the C=O and the C–N stretching frequencies. Another interaction constant, $f_{2,14}$ was introduced to amplify the calculated shift of the CH_2 wagging frequency on the *N*-deuteration. The other force constants were fixed to the transferred values. In the course of the refinement in Calculation A, the C–C_α stretching constant, $K(CC_\alpha)$, became smaller than the fixed C_α–C_β stretching constant, $K(C_\alpha C_\beta)$. This result is physically unacceptable, since the bond order of the C–C bond adjoining a double bond is expected to be higher than that of an isolated C–C bond. Accordingly, we fixed $K(CC_\alpha)$ to the mean value of those of acetamide (3.187)[8] and *n*-paraffins (2.229)[10], and refined the remaining constants until they converged. A similar diminishing of the C–C_α stretching constant, $K_R^I(CC_\alpha)$, occurred also in Calculation B. In this case the diagonal *F* matrix element for the C–C_α stretching coordinate is contributed not only from $K_R^I(CC_\alpha)$ but also from the Urey-Bradley type repulsion constants of the amide group, $F(C_\alpha CO)$ and $F(C_\alpha CN)$, and it is difficult to correlate the force constants to the bond order directly. Accordingly, the refinement was carried through with no restriction on $K_R^I(CC_\alpha)$.

The final sets of force constants are given in Table 4, and the results obtained from these constants are summarized together with the observed frequencies in Tables 7—10. The discrepancies between the observed and the calculated values of the C–C_α stretching frequencies in Calculation A are larger than those in Calculation B, because of fixing $K(CC_\alpha)$ to a value which perhaps is not optimum. In other respects, the results of Calculations A and B are not much different

from each other, the fits between the observed and the calculated frequencies being fairly good.

The authors wish to express their thanks to Prof. K. Nakamoto of Marquette University for the use of laser Raman spectrophotometer and Prof. T. Takenaka of Kyoto University for the use of Perkin-Elmer 521 and Hitachi FIS-3 grating infrared spectrophotometers. Thanks are due to Dr. T. Shingu of Kyoto University for the NMR measurement. Throughout this work, FACOM 230-60 computer of Kyoto University Computer Center was used.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2383—2385(1972)

On the Mechanism of H-Atom Formation by Reaction of Electrons in Frozen Acidic Solutions at 77°K[1]

Shin-ichi OHNO, Teikichi SASAKI, and Mitsuru KOIKE
Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken

(Received November 13, 1971)

A model for the reaction of radiation-produced electrons in frozen acidic solutions is presented to explain anomalies. It does not assume the inertness of the hydrogen ion as an electron scavenger in the solid phase but involves a process in which an H-atom, the product of the ($e^- + H^+$) reaction, is transferred to an adjacent water molecule through an H-bonded network until it finds a suitable site where it can be trapped or a species with which to react. Results from ESR-measurements on photolysed frozen solutions of ferrocyanide ions in the presence of nitrate ions and 2-propanol as well as the data on H/D isotope effects were used as evidence supporting the model.

It is generally believed that radiation-produced electrons are converted into hydrogen atoms on reacting with the hydrogen ion in both liquid[2] and gas phases.[3]

$$e^- + H_3O^+ \longrightarrow H_3O \longrightarrow H + H_2O \qquad (1)$$

However, the above mechanism does not seem to hold in the solid phase, because of three anomalies: (1) The yield of H-atoms in ice is not as high as might be expected from the experimental results in the liquid phase.[4] (2) In a solvent consisting of D_2O and H_2O where both H- and D-atoms are produced, the product ratio H/D in the solid phase is quite different from that in gas or liquid phase.[5] (3) Paramagnetic relaxation experiments on γ-irradiated frozen aqueous systems have shown that the trapped H-atoms are distributed uniformly in the irradiated sample,[6] while the trapped electrons are non-uniformly distributed.

Some authors assume that the electron does not react with the hydrogen ion at 77°K,[4,7] but the trapped H-atoms found in irradiated acidic ice result from the reactions of the electron either with undissociated acids or with water molecules in the hydration layer of the added solute.[4,7] However, many other solutes, inorganic and organic, react with the electron as effectively in the solid as in the liquid phase.[4,8,9] The hydrogen ion would be the only exception for which no reason was given.[8]

The purpose of this paper is to present a model for the reaction of electrons in acidic ice which would reasonably explain the anomalies, not assuming the exceptional inertness of the hydrogen ion as an electron scavenger.

Experimental and Results

Electrons were generated from ferrocyanide ions by photolysis at 254 nm. The merit of this method over the radiolysis method is that other reactive species (*e.g.* OH, H, H_2O^+, or H_2O_2) are not produced, thus eliminating the complex reaction sequences. Details of the experimental procedures were the same as described.[5] ESR spectra of UV-irradiated frozen solutions (at 77°K) of 10^{-2}M potassium ferrocyanide containing various concentrations of sodium nitrate and 2-propanol are shown in Fig. 1. In the liquid phase, the electron (e_{aq}^-) reacts rapidly with both H_3O^+ and NO_3^- (rate constants$\approx 10^{10}$M^{-1}s^{-1}) but not with 2-propanol,[10] while the H-atom reacts with both NO_3^- and 2-propanol (rate constants$\approx 10^7$M^{-1}s^{-1}) but only slowly with H_3O^+.[10] Thus, one might expect that, in a frozen solution containing 10^{-3}M NO_3^- and 10^{-1}M 2-propanol, the electron reacts only with NO_3^- to

(b): 1N H_2SO_4	0.01	0.01
(c): 1N H_2SO_4	0.001	0.1
(d): 1N H_2SO_4	0	0.2

Lines (×) refer to the signals due to the NO_2 radical.

give NO_2 radical. This was found to be the case with an alkaline medium (Fig. 1, a), but not with an acidic medium (Fig. 1, c) where the signals due to the NO_2 radicals are largely replaced by one due to the 2-propanol radical.[11] This suggests that the electron is converted into an H-atom on going from an alkaline to an acidic medium.

One of us (S. O.) observed[5] the product ratio H/D arising from the reaction between the electron and the hydrogen ion in a solvent composed of light and heavy water (the atom ratio in the solvent $(H/D)_{water}=1$) in the liquid phase as a function of temperature (2—40°C) and also in the solid phase at 77°K. Since it is known that H-atoms are fractionated over D-atoms in the hydronium ion, the observed isotope effect (S_{all}) will comprise two consecutive isotope effects; the equilibrium isotope effect (K) in the formation of hydronium ion from water and the kinetic isotope effect (S_{ion}) in the formation of hydrogen atom from the hydronium ion.

$$S_{all} = K \times S_{ion} \qquad (2)$$

11) ESR signals ascribed to NO_2 and 2-propanol radicals are identical with those reported by Chachaty and Hayon.[12]

Figure 1, a, shows the presence also of O^- radical ion. They can be formed as follows:

$$e^- + NO_3^- \longrightarrow NO_3^{2-}$$
$$\begin{cases} NO_3^{2-} + H_2O \longrightarrow NO_2 + 2OH^- \\ NO_3^{2-} \longrightarrow NO_2^- + O^- \end{cases}$$

The value of the equilibrium isotope effect at various temperatures can be calculated with data by Heinzinger and Weston.[13] The observed overall isotope effects together with the kinetic isotope effects thus calculated for the liquid phase system are plotted in Fig. 2 against the reciprocal of absolute temperature. The value obtained at 85°C by Meyerstein[14] and the gas phase datum at 140°C reported by Johnson and Simic[3] are also given.

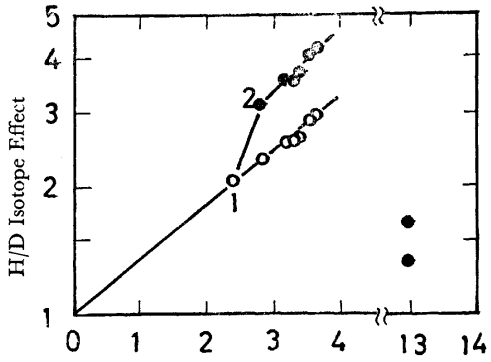

Fig. 2. Temperature dependence of the isotope effects on H/D atom production.
Point (1) refers to the gas phase datum obtained by Johnson and Simic at 140°C (Ref. 3). Point (2) is that due to Meyerstein (Ref. 14). The other values of S_{ion} (●) are from Ref. 5. For S_{all} (○), see text.

Discussion

The straight line (in Fig. 2) throughout the liquid and gas phase regions which is obtained when $\log(S_{ion})$ is plotted against $1/T$ indicates that the same reaction mechanism holds in both phases and that the relative rates of O–H and O–D bond breakages k_H/k_D can be given by

$$\frac{k_H}{k_D} = \exp\left(\frac{E_D - E_H}{RT}\right) \qquad (3)$$

where E_H and E_D are the activation energy of O–H and O–D breakages, respectively. The slope of the straight line in Fig. 2 gives $E_D - E_H = 0.6$ kcal/mol. A value of this order of magnitude might be appropriate for the difference in zero-point energy between O–H and O–D bonds in the intermediate complex such as H_2DO.

On the other hand, the observed isotope effect in the solid phase is strikingly low ($S_{all} \approx 1.5$), suggesting that the H-atom trapping process in the solid differs a great deal from liquid phase reactions.

13) K. Heinzinger and R. E. Weston, *J. Phys. Chem.*, **68**, 744 (1964).
14) D. Meyerstein, Ph. D. Thesis, Hebrew Univ. 1965, quoted by M. Anbar and D. Meyerstein, in Ref. 4, p. 109,

The results shown in Fig. 1 indicate that photodetached electrons from ferrocyanide ions are converted into H-atoms in sulfuric acid ice. Fletcher and Freeman observed that the trapped H-atom yields, $G(H_t)$, found in γ-irradiated sulfuric acid glasses can be reduced from 1.3 to 0.24 by the presence of 10^{-3} mol fraction of ethanol.[15] This demonstrates that the precursor of H_t in the acid glass which can react with ethanol might be an H-atom rather than an electron. Recent observations that the presence of sulfuric acid in frozen aqueous solutions of a number of organic compounds enhances the yield of the radiation-produced organic radical[16] also suggest the conversion of the electron into an H-atom in acidic ice.

Concerning H-atom trapping in irradiated ice, the following facts are well-known. H-atoms are not stabilized in pure water at 77°K, though they are stable near 4°K.[4] At 77°K, only aqueous systems containing ions of a certain type such as ClO_4^-, SO_4^{2-}, or PO_4^{3-} can stabilize H-atoms.[17] Acids such as HF, CCl_3COOH, H_2SO_3 do not give stabilized H-atoms when irradiated at 77°K.[17] This would indicate that at 77°K H-atoms can migrate through the water structure until they reach a trapping site which can stabilize an H-atom. The structure of this particular trap in the ice cannot be precisely visualized as yet, but it is probably associated with an oxyanion. According to Ultee and Kepford,[17] the site involves a hydrated MO_4^--type ion, which in aqueous solution should provide a tight three-dimensional lattice, destroying the open structure of ice rather than providing a specific site.

We feel that reaction (1) takes place irrespective of the phase, *i.e.*, even in the solid phase. An H-atom, the product of reaction (1) in the solid phase, will be transferred through the hydrogen-bonded network of the ice and be trapped stably at the site which can stabilize the H_t.

$$H_m\cdots O(H)-H \longrightarrow H-O(H)\cdots H_m \qquad (4)$$

Here, a moving H-atom is designated by H_m. An H-atom transfer of this type can be caused by the thermal vibration of the lattice at 77°K, but not at 4°K. The process may be so slow that in the liquid phase the H-atom would predominantly diffuse about in the usual sense to be scavenged by the solute added. Such a transfer would prevail only in the solid phase where all the atoms can be assumed to be immobilized.

Our model would explain the three anomalies associated with the solid phase. Assuming that the observed H_t is caused by reaction (1) alone, not including an H-atom transfer, an H/D isotope effect as large as 50 would be expected at 77°K if Eq. (3) holds. In fact, a value of about 1.5 was obtained. The value of H_t/D_t by the present model would be a consequence of the H/D atom ratio eventually present in the trapping site. The isotope effect of this kind does not arise from competing reactions and will not make the value of H/D largely differ from unity. It is thus not surprising that a marked difference in the magnitude of the isotope effect is found between the solid and the liquid phases.

One may expect that, in an acidic ice, competition occurs between the solute(S) and the trapping site(T) for the moving H-atom through the H-bonded chain-(H_m):

$$e^- + H_3O^+ \longrightarrow H_m \begin{cases} + T \longrightarrow H_t \\ + S \longrightarrow [SH] \end{cases} \qquad (5)$$

[SH] would decompose to give more stable species in the matrix. If as an example NO_3^- and 2-propanol are taken for S, the decomposition would be:

$$[NO_3H^-] \longrightarrow NO_2 + OH^- \text{ or } NO_2^- + OH \qquad (6)$$

$$[(CH_3)_2CHOH_2] \longrightarrow (CH_3)_2COH + H_2 \qquad (7)$$

Reaction (7) is a possible process producing the alcohol radical by an attack of a diffusing H-atom.[18] If we assume that the order of magnitude for the concentration of T in an acidic glass to be 10^{-2}M, any solute which is involved in the H-bonded chain and which can scavenge H_m could reduce the yield of H_t, even though its concentration is small compared to that of the acid. This is why the hydrogen ion does not apparently react with the electron in frozen matrices.

The wider distribution from the point of energy deposit of the trapped H-atoms than that of the trapped electrons may also be understood.

It is of interest to note that the mobile energy in 5.3M H_2SO_4 glass, assumed by Dainton and Gopinathan,[21] which can liberate Cl^- ion from chloracetic acid (with a G-value of about 2), and which is incapable of reacting with nitrous oxide is possibly the mobile H-atom through hydrogen bonds.

The Primary Photochemical Process of 4-Nitropyridine *N*-Oxide II. Decay Kinetics of the Photochemical Intermediates[1]

Norisuke HATA, Isao ONO, and Tamio TSUCHIYA

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo

(Received February 4, 1972)

In order to clarify the primary photochemical process of 4-nitropyridine *N*-oxide in solution, kinetic flash spectrophotometric studies were carried out under various conditions. The flash excitation of 4-nitropyridine *N*-oxide in alcoholic solution resulted in three transient species in the spectral region between 360 nm and 580 nm; one of them was a weak absorption at about 530 nm (transient species A and A'), and the other, a stronger one around 380 nm (transient species B). The experiments on the decay kinetics of these transients revealed that the photochemical reaction of 4-nitropyridine *N*-oxide in an alcoholic solution proceeded through these intermediate species originating from the excited singlet state; Process I (the photochemical formation of 4-hydroxypyridine *N*-oxide nitrate) involved the bimolecular interaction between an intermediate A' and unexcited molecule, while Process II (the photochemical formation of 4-hydroxylaminopyridine *N*-oxide) was initiated by a hydrogen-atom abstraction from a solvent molecule by an intermediate B which was produced from another intermediate A. The two intermediates A and A' were reasonably assumed to be formed concurrently from the excited singlet state of 4-nitropyridine *N*-oxide.

4-Nitropyridine *N*-oxide changes upon irradiation of 313 nm light in ethanol to give 4-hydroxypyridine *N*-oxide nitrate (Process I) or 4-hydroxylaminopyridine *N*-oxide (Process II), depending on the reaction conditions.[2-5] As has been described in a previous paper,[5] the observation of the transient absorption in the region between 360 nm and 580 nm and the measurements of the quantum yields under various conditions led to the conclusions that Processes I and II both proceed *via* some intermediate species originating from the excited singlet state of 4-nitropyridine *N*-oxide; Process I being due to a bimolecular interaction between an intermediate and an unexcited molecule, and Process II involving a hydrogen abstraction of an intermediate from an alcoholic solvent.

The purpose of the present investigation is to clarify whether or not the transient species observed in a flash photolysis of 4-nitropyridine *N*-oxide are actually responsible for Processes I and II, and then to obtain some information on the primary process.

Experimental

Materials. The 4-nitropyridine *N*-oxide used in this experiment was synthesized by nitrating the pyridine *N*-oxide according to the method given in the literature,[6] and the product was purified by recrystallization from acetone several times. The solvents used for the flash experiments were reagent-grade methanol, ethanol, isopropanol, and glycerol, all of which were used without further purification.

Flash Spectrophotometric Experiment. A sample solution contained in a quartz reaction cell (8 cm in length and 2 cm in diameter) was deaerated by flushing the cell with nitrogen. A quartz flash photolysis lamp (10 cm in length and 2 cm in diameter) filled with xenon gas was operated at 11 kV and 2 μF, dissipating an energy of 120 J; the duration of the flash was 10 μsec. The absorption spectra of transient species and their decays were determined with a xenon lamp (Toshiba 500 W) or a tungsten lamp (60 W), a plane grating spectrograph (Shimadzu GE-100), a photomultiplier tube (RCA 1P28), and a synchroscope (Toshiba 3054).

Results and Discussion

Figures 1 and 2 show the absorption spectra of the transient species produced by a flash excitation of 4-nitropyridine *N*-oxide in deaerated ethanol or glycerol at room temperature; the spectrum was plotted immediately after the flash and also at some specified time interval following the flash. As can be seen from the figures, two absorption systems were observed in the region between 360 nm and 580 nm; one of them was a weak absorption at about 530 nm, and the other, stronger one around 380 nm. Both absorptions were reduced to some extent in their intensity

(a): at 530 nm, (b) at 380 nm

in an oxygen-saturated solution, but they were not quenched completely. In addition, it may be inferred from these figures that the decay of the 530-nm species was followed by the formation of the 380-nm species. Figure 3 presents some typical pictures of oscilloscope traces taken at 530 nm and 380 nm after flash illumination of a 3.0×10^{-5} M solution of 4-nitropyridine *N*-oxide in deaerated ethanol. It is clear that an appreciable time was required for the appearance of the 380-nm species, while the formation of the 530-nm species was instantaneous-within the time of the flash. Quite similar results were also obtained in a methanol or an isopropanol solution. These observations indicate that the transient absorption which appeared around 530 nm was due to species different from those of the 380 nm absorption.

Next, kinetic examinations of the transients produced by flash illumination in deaerated solutions such as methanol, ethanol, isopropanol, and glycerol were carried out by measuring photoelectrically the time dependence of the absorption intensity (D) at 530 nm and 380 nm under various conditions.

Figure 4(a) shows the results when the first-order rate law was applied for the decay of the transients at 530 nm, while the second-order rate plots are shown

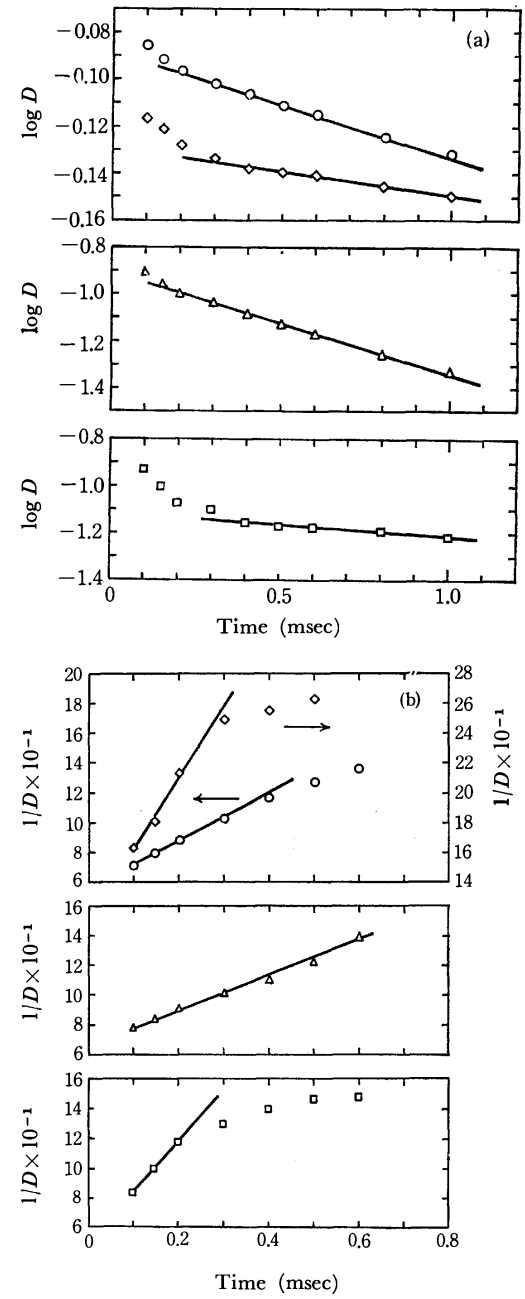

Fig. 4. First- and second-order rate plots for the decay of the transient absorption at 530 nm in various solvents at room temperature.
-◇-: in methanol, -○-: in ethanol, -△-: in isopropanol, -□-: in glycerol.
(a) first-order rate plots, (b) second-order rate plots.

in Fig.4(b). There, the second-order rate plot in Fig. 4(b) seems to require some considerations, because the slope at the first (initial) stage of decay is greater than that at the second stage in the cases of methanol, ethanol, and glycerol solution.

Generally, when any transient species, say X, is able to decay according to both the first- and second-order processes, the decay rate is expressed as follows:

$$-\mathrm{d}[\mathrm{X}]/\mathrm{d}t = k_1[\mathrm{X}] + k_2[\mathrm{X}]^2 \quad (1)$$

where k_1 and k_2 represent, respectively, the first- and second-order rate constants. The slope of the first-order rate plot is given by Eq. (2). Thus, the slope at the first stage of decay must be greater than that at the second stage.

$$-\mathrm{d}(\ln[\mathrm{X}])/\mathrm{d}t = k_1 + k_2[\mathrm{X}] \quad (2)$$

Equation (3) gives a slope of the second-order rate plot, indicating that the slope at the second stage of decay can be expected to be greater than that of the first stage.

$$\mathrm{d}(1/[\mathrm{X}])/\mathrm{d}t = k_1/[\mathrm{X}] + k_2 \quad (3)$$

These general relations were applied to the present experimental results. Tentatively, let us suppose that the transient absorption around 530 nm is due to a single species which decays according to both the first- and second-order rate laws. On this assumption, the first-order rate plot in Fig.4(a) is consistent with Eq.(2), whereas the second-order rate plot in Fig.4(b) is in conflict with Eq.(3). For this reason, it seems most reasonable to conclude that the 530 nm absorption should be ascribed to two transient species which decay with different first-order rate constants. Therefore, the faster species is referred to as the intermediate A (rate constant, k_A) and the slower one as the intermediate A′ (rate constant, $k_{A'}$). The values of these rate constants, as evaluated from the decay curve in Fig. 4(a), are given in Table 1.

TABLE 1. RATE CONSTANTS OF THE INTERMEDIATE SPECIES A, A′, AND B IN VARIOUS SOLVENTS AT ROOM TEMPERATURE

Solvent	k_A(sec^{-1}) $\times 10^{-4}$	$k_{A'}$(sec^{-1}) $\times 10^{-2}$	k_B(sec^{-1}) $\times 10^{-1}$	k_B^f(sec^{-1}) $\times 10^{-4}$
Methanol	2.4	2.3	0.17	5.0
Ethanol	0.90	9.2	1.2	1.5
Isopropanol	0.48	9.2	3.1	0.82
Glycerol	1.0	2.0	0.25	1.1

Figures 5 and 6 show the first- and second-order rate plots for the transient absorption around 380 nm. There, a single straight-line relation was obtained by plotting log D against the time in an isopropanol or glycerol solution, while in a methanol or ethanol solution the decay curve followed, at the first stage of decay, the second-order rate law and, at the second stage, the first-order kinetics. Moreover, in the case of a methanol or ethanol solution, the first- and second-order rate plots were fairly consistent with Eqs.(2) and (3). From these results, it may be concluded that the transient absorption around 380 nm is due to a single species which decays according to the first-order kinetics, but that there is a small contribution from the second-order process in the case of a methanol

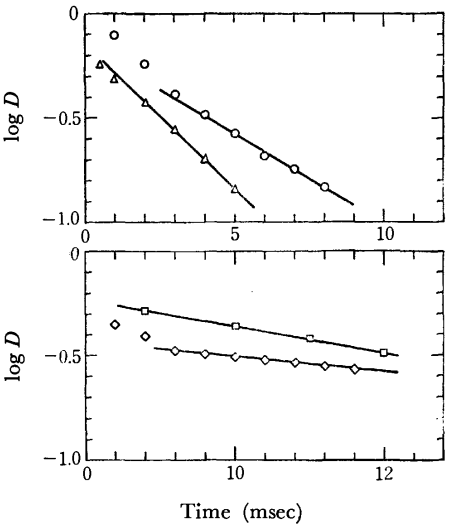

Fig. 5. First-order rate plots for the decay of the transient absorption at 380 nm in various solvents at room temperature.
-◇-: in methanol, -○-: in ethanol, -△-: in isopropanol, -□-: in glycerol.

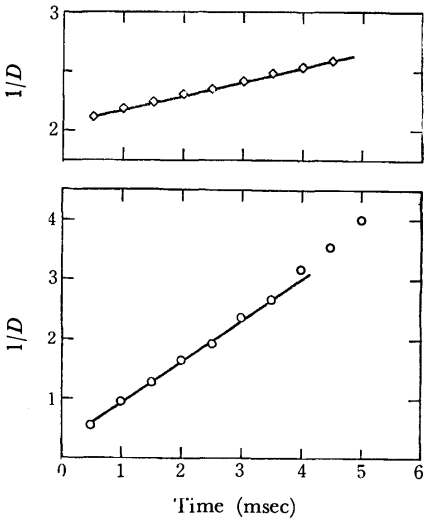

Fig. 6. Second-order rate plots for the decay of the transient absorption at 380 nm in methanol (-◇-) and in ethanol (-○-).

or ethanol solution. Therefore, the transient species is referred to as the intermediate B, and the first-order rate constants, k_B, estimated from the straight-line portion of the curve in Fig. 5 are given in Table 1.

The rate constant of the formation of the intermediate B, k_B^f, was evaluated from the rise in the transient absorption at 380 nm (Fig.3). The values thus obtained of k_B^f in various solutions are listed in Table 1. In Table 1 the decay rate of the intermediate A may be found to agree closely with that of the formation of the intermediate B. This suggests that the species B is produced directly from the intermediate A.

Although the decay rate of the intermediate B increased when the solvent was changed from methanol to ethanol and then to isopropanol, such a solvent dependency of the decay rate was not found in the case of the intermediate A or A′ (Table 1). The data imply that the intermediate B is probably responsible

for Process II, which involves a hydrogen-atom abstraction from the solvent alcohol, as has been reported previously.[5] Generally, when any transient species can abstract a hydrogen atom from a hydrogen donor, its decay rate may be expected to increase in proportion to the concentration of the hydrogen donor. In order to confirm which intermediate, A, A′, or B, is involved in the hydrogen-atom abstraction from the solvent alcohol, therefore, the decay rates of these species were determined as a function of the concentration of isopropanol added as a hydrogen donor in a methanol solution; the results are shown in Fig.7. The decay

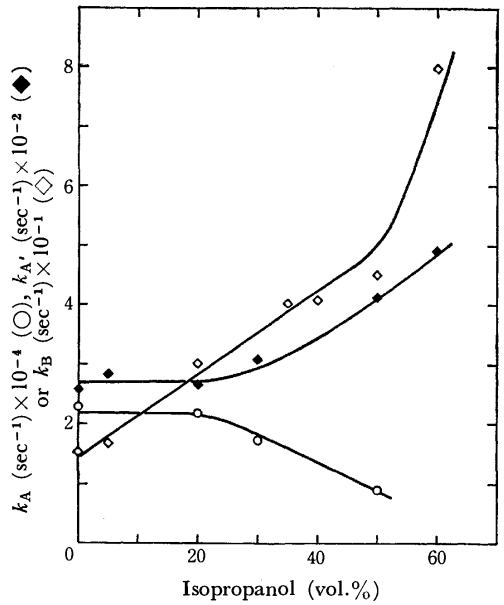

Fig. 7. Effect of an addition of isopropanol on the first-order decay rates of the intermediate species A, A′, and B in methanol.
-○-: intermediate species A, -◆-: intermediate species A′, -◇-: intermediate species B.

rate of the intermediate B increased proportionately with the amounts of isopropanol added, while the decay of the intermediate A or A′ was independent of the addition of isopropanol up to about 20 vol.%. Consequently, it appears plausible that the intermediate B is responsible for Process II. When the amounts of isopropanol added exceeded *ca* 40% in volume, however, the decay rates of these species showed a great change and approached the value in the case of the isopropanol solution.

In a previous paper,[5] on the basis of the concentration and temperature dependences of the quantum yield of the 4-nitropyridine *N*-oxide disappearance, Process I has been inferred to proceed *via* a transient complex formed from the interaction of an intermediate, say Y, originating from the excited singlet state (S_1) with an unexcited molecule (S_0), as described in the following sequence:

	Rate
$Y \rightarrow S_0$ (or chemical change)	$k_Y^a[Y]$
$S_0 + Y \rightarrow (S_0Y)$	$k_Y^b[S_0][Y]$
$(S_0Y) + S_0 \rightarrow Y + S_0 + S_0$	$k_Y^c[(S_0Y)][S_0]$
$(S_0Y) \rightarrow$ Process I	

If these steps are actually involved in Process I, and if one of the three transients, A, A′, and B, observed here corresponds to the intermediate Y described above, then its decay rate (k_Y) may be expected to vary with an increased concentration of 4-nitropyridine *N*-oxide following Eq.(4).

$$k_Y = k_Y^a + k_Y^b[S_0] - k_Y^c[(S_0Y)][S_0]/[Y] \quad (4)$$

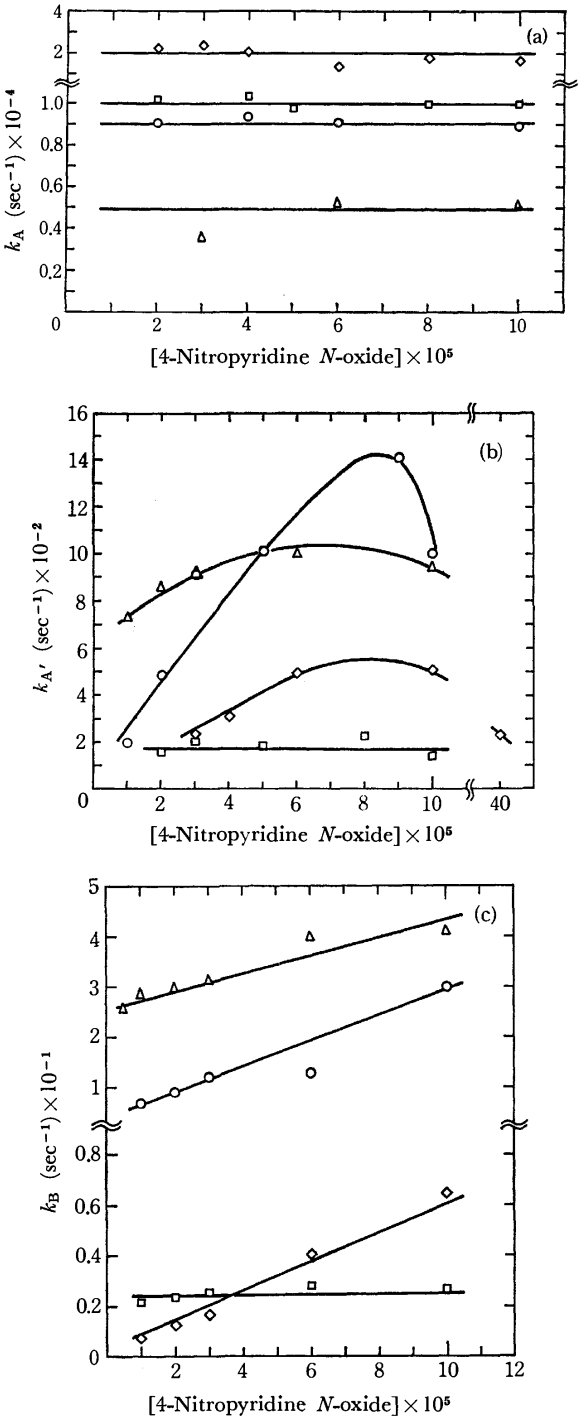

Fig. 8. First-order decay rates of the intermediate species A, A′, and B *versus* initial concentration of 4-nitropyridine *N*-oxide.
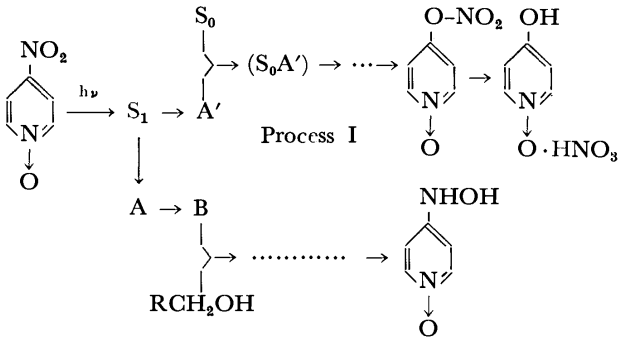
-◇-: in methanol, -○-: in ethanol, -△-: in isopropanol, -□-: in glycerol.
(a) intermediate species A, (b) intermediate species A′, (c) intermediate species B.

For this reason, the effect of the initial concentration of 4-nitropyridine *N*-oxide on the decay rates of the intermediates, A, A′, and B, was examined in deaerated ethanol. With an increase in the concentration of 4-nitropyridine *N*-oxide, as Fig. 8 shows, the decay rate of the intermediate A′ increased until it approached a steady value, and then decreased; such a concentration-dependence of the decay rate is consistent with Eq.(4). On the other hand, the decay rate of the intermediate B increased linearly with an increase in the concentration of 4-nitropyridine *N*-oxide, while that of the intermediate A remained unchanged, in the range of concentrations used in this experiment. These resluts support the idea that the intermediate A′ is responsible for Process I, and that this process proceeds through the formation of a transient complex (S_0A').

From the experimental results presented above, the following scheme seems to be reasonable for the primary photochemical process of 4-nitropyridine *N*-oxide in an alcoholic solution;[7] a partial modification is made of a scheme proposed in a previous paper.[5] The 4-nitropyridine *N*-oxide excited into the S_1 state by absorbing the ultraviolet light (>300 nm) is converted into the intermediate A (530nm), followed by transformation to the intermediate B (380 nm),



which then abstracts a hydrogen atom from an alcoholic solvent to lead to Process II. Here, it seems to be of particular interest that 4-nitropyridine *N*-oxide is photochemically reduced *via* some intermediates originating from the excited singlet state, since the photochemical reduction of aromatic nitro compound generally proceeds through the lowest triplet state.[8] As will be reported in a later paper,[9] however, it has become apparent from the studies of the biacetyl sensitization that the photoreduction of 4-nitropyridine *N*-oxide is also capable of proceeding *via* the lowest triplet state. The intermediate A′ (530 nm), which is also considered to result from the S_1 state, would interact with the ground state molecule, S_0, to give a transient complex (S_0A'), through which Process I proceeds. The end product of Process I, the 4-hydroxypyridine *N*-oxide nitrate, has been demonstrated to result from a hydrolysis of the nitric acid ester of 4-hydroxypyridine *N*-oxide generated during the photoreactions.[3] Accordingly, certain reactions taking place within the transient complex (S_0A') appear to lead to the formation of this nitric acid ester, although the mechanism is entirely ambiguous at present. The 4-hydroxylaminopyridine *N*-oxide formed by Process II may be converted photochemically to 4-nitropyridine *N*-oxide under an oxygen atmosphere.[10] Hence, the ultraviolet irradiation of the 4-nitropyridine *N*-oxide in an atmosphere of oxygen is expected to give 4-hydroxypyridine *N*-oxide nitrate as the major product; in fact, its yield has been reported to be 60–65% in an ethanol solution.[3] On the contrary, the 4-hydroxylaminopyridine *N*-oxide is expected to be the main product under a nitrogen atmosphere, particularly in the case of a concentrated solution of 4-nitropyridine *N*-oxide, because most of the transient complex (S_0A') is quenched by collision with an unexcited *N*-oxide molecule; Process II thus becomes more likely. The experiments performed under such conditions support this idea.[2,5]

Meanwhile, as has been suggested by Kaneko *et al.*[3,4] the Nef-type mechanism is also anticipated to be responsible to some extent for the formation of 4-hydroxypyridine *N*-oxide nitrate; especially, the photoreaction of 3,5-dimethyl 4-nitropyridine *N*-oxide has been considered to be due to this mechanism.[4] It seems, therefore, that further studies are necessary in order to elucidate the mechanism of Process I.

As to the structure of the intermediates, A, A′, and B, involved in Process I or II, we could not draw any conclusions from only the present experimental results. As judged from the facts that 4-nitropyridine *N*-oxide undergoes a photochemical change in a moiety of the nitro group, but not of the N→O group, however, it may be assumed that the nitro group in each of these intermediates is considerably different from a normal one in structure. In addition, the fact that the absorption spectrum of the intermediate A (530 nm) exists in the same region as that of the intermediate A′ suggests that their electronic structures are quite similar to each other. On the other hand, the absorption band of the intermediate B (380 nm) is located rather close to that of 4-nitropyridine *N*-oxide (330 nm), which probably means

7) Considered from the fact that the transient absorptions are always observed regardless of the presence or absence of oxygen in solution, the intermediate species A, A′, and B are assumed to originate from the excited singlet state (S_1) but not the lowest triplet state.

10) The photochemical conversion of 4-hydroxylaminopyridine *N*-oxide to 4-nitropyridine *N*-oxide in ethanol under an oxygen atmosphere has been reported by Kaneko *et al.*[3]

that the nitro group of the intermediate B structurally a little resembles that of unexcited 4-nitropyridine *N*-oxide. In order to clarify the structure of the intermediates, A, A′, and B, it seems to be important to elucidate in detail the reaction mechanism for both Processes I and II; along this line further studies are now in progress.

In conclusion, the authors wish to express their hearty thanks to Professor Ikuzo Tanaka of Tokyo Institute of Technology for his encouragement and Professor Shiro Matsumoto of this university for his permission to use a flash-photolysis apparatus.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2391—2397 (1972)

Studies of the Properties of the Basic Sites on the Silica-alumina Surface through the Reaction of the Basic Sites with Copper(II) Complexes Containing 2,2′-Bipyridine

Kazuto TAKIMOTO

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received February 14, 1972)

The substitution reactions of complexes with basic sites on the surfaces of silica-alumina and alumina and the properties of the basic sites were studied through the adsorption of the complexes onto the surfaces. The hydroxyl groups with basic strengths of two kinds, $H_0 > 9.3$ and $7.2 < H_0 < 9.3$, exist on the silica-alumina surface pretreated at 300°C. They are present in a cluster state. The basic strength becomes higher as the outgassing temperature becomes lower. The complexes predominantly interact with the O^{2-} ions on the surface pretreated at a relatively high temperature, resulting in new chemical species. The basic strength of the O^{2-} ions is lower than that of the hydroxyl groups on the surface pretreated at a lower temperature. The hydroxyl groups on the alumina surface outgassed at 300°C are distributed, on the whole, homogeneously in comparison with those of the silica-alumina surface, and their basic strength is $H_0 > 9.3$. The nature of the basic sites on the alumina surface tends to vary with the outgassing temperature, similarly to those on the silica-alumina surface. These analyses were performed on the basis of the ESR spectra for complexes in basic solutions.

The acidic properties of the silica-alumina surface have been extensively studied by various techniques[1-4] because the catalytic action of silica-alumina is closely correlated with its acidic properties.[5,6] The nature and the structure of the acidic sites and such reactions as isomerization and polymerization on the surface have been reviewed by Tanabe and Takeshita.[7]

On the other hand, Krylov *et al.* have found, by the phenol-vapor adsorption method, that the basic sites are present on the surface of silica-alumina.[8] It is of great interest from the viewpoint of acid-base bifunctional catalysis that the basic sites as well as the acidic sites exist on the surface. The basic properties of the silica-alumina surface have been investigated by several means,[8,9] but the nature and structure of the basic sites have scarcely been revealed. However, the basic properties of alumina[10] as well as those of calcium oxide [11] and magnesium oxide[12] have been fairly well elucidated in comparison with those of silica-alumina. It has been reported that weakly basic sites are present on the surface of silica gel on the basis of the measurement of the amounts of phenol vapor retained on this surface at various elevated temperatures.[8] Peri[13] and Yamadaya[14] have proposed a mechanism of the formation of the basic sites which include hydroxyl groups and/or negatively-charged oxygen ions, O^{2-}.

We found, from our ESR measurements, that the coordinated water molecules in the copper(II) complexes with 2,2′-bipyridine were replaced by one or two hydroxyl ions in aqueous solutions at pH values higher than 8.[15] Such a phenomenon was also observed in basic methanol solutions. Thus, these complexes were adsorbed as so-called indicators in order to elucidate the basic properties of the hydroxyl groups on the surfaces of silica-alumina and alumina. The ESR spectra for the complexes adsorbed on the surfaces were quite similar to those in the basic solutions; the hydroxyl groups contribute to the formation of the chemical species on the surfaces. However, in

addition to these hydroxyl groups, it is also necessary to take negatively-charged oxygen ions into consideration as basic sites when the samples are treated at relatively high temperatures; α sites which contain a negatively-charged oxygen ion in close proximity to an exposed aluminum ion are formed by the condensation of Al-OH groups in the course of the dehydration of the surface.[16] These sites are acid-base rather than Lewis-acid sites. This method can differentiate to some extent which of the basic sites is mainly bound to these complexes, as will be discussed later. In this paper, the substitution reaction of the complexes with the basic sites on the surfaces of silica-alumina and alumina, and the properties of the basic sites, as estimated from an analysis of the chemical species which are generated by these reactions, will be reported.

Experimental

Materials. The cupric sulfate, methanol, and 2,2′-bipyridine, all obtained from the Wako Pure Chemical Co., were of a guaranteed reagent grade and were used without further purification. The indicators,[17] bromothymol blue ($pK_a=7.2$), and phenolphthalein ($pK_a=9.3$) from the Yoneyama Co., were also of a guaranteed reagent grade. The copper(II) complexes with 2,2′-bipyridine, the 1 : 1 complex (or $[Cu(bip)(H_2O)_4]SO_4$) and the 1 : 2 complex (or $[Cu(bip)_2(H_2O)_2]SO_4$), were synthesized in methanol and were recrystallized repeatedly from methanol. The alumina, 50% silica-alumina, and silica gel were the same as those used in our preceding work.[18]

Procedures. These complexes were adsorbed from water-free methanol solutions onto surfaces which had previously been treated at 100, 300, 500, and 800°C for 3 hr. After the methanol had been eliminated, the ESR spectra were measured at 77°K. These experiments were carried out in a dark room because these complexes are photosensitive.

Apparatus. The ESR spectra were obtained by using a spectrometer described elsewhere.[19] The chemical species were determined from the ESR spectra of the 1st and 2nd derivatives.

Results and Discussion

Chemical Species in the Solutions. The ESR spectra in methanol solutions were measured in order to be compared with those obtained on the surfaces. The ESR spectrum for the 1:1 complex is shown in Fig. 1. The spin Hamiltonian can be described as:

$$\mathscr{H} = \beta[g_{//}H_zS_z+g_\perp(H_xS_x+H_yS_y)] + A_{//}S_zI_z + A_\perp(S_xI_x+S_yI_y)$$

where β is the electron Bohr magneton, where $g_{//}$ and $g_\perp$ are the components of the axial g tensor, and where $A_{//}$ and $A_\perp$ are the components of the copper nuclear hyperfine (hf) interaction. This spectrum is axially symmetrical. Four peaks were observed in the lower

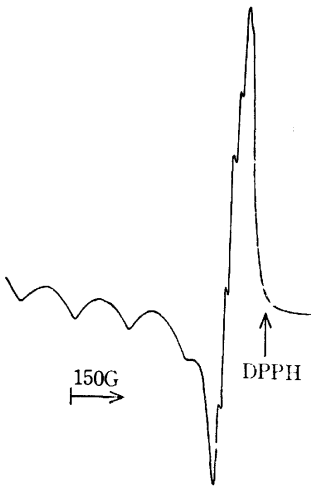

Fig. 1. ESR spectrum for the 1 : 1 complex in methanol at 77°K.

magnetic field. These are ascribed to the parallel component of the hf interaction due to the nuclear spin of copper, $I=3/2$. The superhyperfine (shf) structure was observed in the perpendicular component in the higher magnetic field. When the 1:1 complex is prepared in methanol, the following chemical equilibrium may be established:

$$Cu^{2+} + bip + 4H_2O \rightleftarrows \underset{I}{[Cu(bip)(H_2O)_4]^{2+}} \quad (1)$$

Only the I species was observed, probably because the equilibrium lies almost completely to the right. According to the Jahn-Teller effect, the long or distortion axis is frozen in different orientations at low temperatures. The stable state is the one in which the distorted z axis is perpendicular to the plane containing ligands. Thus, two nitrogen atoms in a bipyridine molecule predominantly coordinate with the copper ion in the xy plane.[20,21]

The ESR parameters for the 1:1 complex are plotted against the concentration of sodium hydroxide in a methanol solution in Fig. 2. With an increase in the basic concentration, three sets of $g_{//}$ and $A_{//}$ values were observed. The reactions of this complex with the hydroxyl ion may be represented as:[22]

$$\underset{I}{[Cu(bip)(H_2O)_4]^{2+}} + OH^- \rightleftarrows \underset{II}{[Cu(OH)(bip)(H_2O)_3]^{1+}} + H_2O \quad (2)$$

$$2\underset{II}{[Cu(OH)(bip)(H_2O)_3]^{1+}} \rightleftarrows \underset{II'}{[(H_2O)_2(bip)Cu\langle^{OH}_{OH}\rangle Cu(bip)(H_2O)_2]^{2+}} + 2H_2O \quad (3)$$

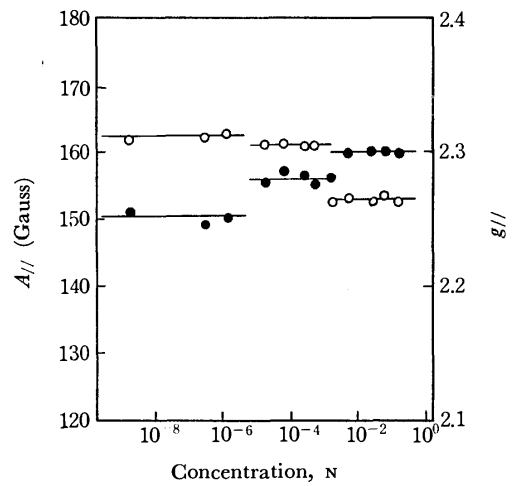

Fig. 2. Variations of the ESR parameters for the 1 : 1 complex with the concentration of sodium hydroxide in methanol solution.
●: $A_{//}$; ○: $g_{//}$

$$\frac{1}{2}[(H_2O)_2(bip)Cu\langle^{OH}_{OH}\rangle Cu(bip)(H_2O)_2]^{2+} + OH^-$$
II′
$$\rightleftarrows [Cu(OH)_2(bip)(H_2O)_2]^0 \quad (4)$$
III
$$[Cu(OH)(bip)(H_2O)_3]^{1+} + OH^-$$
II
$$\rightleftarrows [Cu(OH)_2(bip)(H_2O)_2]^0 + H_2O \quad (5)$$
III

It is well known that the value of $g_{//}$ decreases, and that of $A_{//}$ increases, with an increase in the ability of eletron donation of a ligand, which can be represented by pK_a;[23] the covalency of the bonding of the copper ion with the ligand increases. The covalency depends mainly upon the value of $g_{//}$, as has been reported by Maki and McGarvey[24] and by Kivelson and Neiman.[25] When the ligand is replaced by a more basic one, the values of $g_{//}$ and $A_{//}$ change with the number of the latter ligands.[26] Thus, the species with the highest value of $g_{//}$ (2.313) corresponds to I. On the other hand, the species with the middle and lowest values of $g_{//}$ (2.306 and 2.263) correspond to II and III respectively. However, the dimer species II′ could not be observed in the methanol solution; the coupling constant of the hf interaction was not one-half of that of the II species, and furthermore the signal due to the $\Delta M_s = \pm 2$ transitions could not be detected in a much lower field, *ca.* 1600 gauss. On the contrary, the formation of the dimer species was confirmed in a basic aqueous solution by Ryland[22] and by Harris.[27]

When the 1:2 complex is prepared in methanol, the chemical equilibrium may be established as follows:

$$[Cu(bip)(H_2O)_4]^{2+} + bip$$
I
$$\rightleftarrows [Cu(bip)_2(H_2O)_2]^{2+} 2H_2O \quad (6)$$
IV

The IV species was overwhelmingly observed, probably because the equilibrium lies almost to the right. Figure 3 shows the ESR parameters for the 1:2 complex, also with the basic concentration of the methanol solution. The following chemical equilibria for the 1:2 complex in the basic methanol solution are considered to be established by taking those in the basic aqueous solutions into account:[28]

$$[Cu(bip)_2(H_2O)_2]^{2+} + OH^-$$
IV
$$\rightleftarrows [Cu(OH)(bip)(H_2O)_3]^{1+} + bip \quad (7)$$
II
$$2[Cu(OH)(bip)(H_2O)_3]^{1+}$$
II
$$\rightleftarrows [(H_2O)_2(bip)Cu\langle^{OH}_{OH}\rangle Cu(bip)(H_2O)_2^{2+} + 2H_2O$$
II′ (8)
$$[Cu(OH)(bip)(H_2O)_3]^{1+} + OH^-$$
II
$$\rightleftarrows [Cu(OH)_2(bip)(H_2O)_2)]^0 + H_2O \quad (9)$$
III
$$\frac{1}{2}[(H_2O)_2(bip)Cu\langle^{OH}_{OH}\rangle Cu(bip)(H_2O)_2]^{2+} + OH^-$$
II′
$$\rightleftarrows [Cu(OH)_2(bip)(H_2O)_2]^0 \quad (10)$$
III

Two sets of ESR parameters were observed, as can be seen in Fig. 3. The species with the higher value

of $g_{//}$ corresponds to IV. The II species in Eq. (7) could not be observed, although that in Eq. (2) could be detected. This may indicate that the equilibrium of Eq. (7) lies almost completely to the left. On the contrary, the II species in Eq. (7) could be observed in the aqueous solution. The dimer species II′ could not be observed either, as in the case of the 1:1 complex.

When the 1:2 complex was dissolved in 40% ethanol-60% water and measured at 77°K, two chemical species were observed by Noack and his co-worker.[21] One is a *trans* isomer which is the same as the IV species observed in methanol at 77°K. The other species, with a much lower value of $g_{//}$ and a smaller value of $A_{//}$, is the *cis* isomer (Species V). Two bipyridine molecules coordinate with the copper ion, on the *xy* and *xz* or *yz* planes respectively. The *cis* isomer is predominant at room temperature.

The ESR spectra were also measured in the basic aqueous solution, since the chemical species in the aqueous solution had been determined by means of the absorption-spectra and conductometric-titration methods.[22,28] The $g_{//}$ value in a methanol solution was almost the same as that in an aqueous solution, while the $A_{//}$ value varied somewhat; the chemical species of the former are the same as the latter. However, the perpendicular component of the ESR spectra obtained in the methanol solution was a single line, while that in the aqueous solution was split. This may be ascribed to the effect of the linewidth. The over-all spectra obtained on the surface are rather similar to those in methanol solutions

Chemical Species on the Surfaces. Since the acitve sites on the surface are largely influenced by water molecules, an adsorbate is usually adsorbed on the surface from a solution of a nonpolar solvent. In this study, however, these complexes were adsorbed on the surface from water-free methanol solutions because they scarcely dissolved at all in any nonpolar solvent. The complex and methanol competitively react with surface hydroxyl groups, so that an ester may be formed by the reaction of methanol with the hydroxyl groups. If the 1:1 complex is present on the esterified surface, the values of $g_{//}$ and $A_{//}$ may be similar to those of the I species, since the electron-donation ability of the $-OCH_3$ group is much lower than that of the hydroxyl group. Such a species, however, could not be observed on the surfaces. Thus, the basic hydroxyl group on the surfaces may be considered to react with the complexes in preference to methanol. The comparison of the ESR parameters in the solutions with those obtained on the surfaces is reasonable, since the axial symmetry of the latter is also approximately maintained.

The properties of the basic sites on the surfaces, the distribution and the strengths of the basic sites, were determined in the following way. The qualitative distribution of the basic sites was estimated from the distance between the neighboring ligands replaced by two hydroxyl ions or hydroxyl groups, which can be calculated from the data of the X-ray analysis of the 1:2 complex;[29,30] the complex is a measure for determining the distribution of the basic sites. It is presumed that the distance is about 3 Å. The distance between the neighboring ligands of the 1:1 complex may be slightly different from that of the 1:2 complex.[21] On the other hand, the strengths of the basic sites on the surfaces were deduced from the pK_a value corresponding to the pH value of the aqueous solution, in which the complexes begin to react with hydroxyl ions. For the 1:1 complex, the coordinated water molecule begins to be replaced by the hydroxyl ion at pH≒8. The color of bromothymol blue ($pK_a=7.2$) begins to change from yellow to green at pH≒ 8. Thus, the basic strength of the aqueous solution at pH≒8 appreximately corresponds to $H_0=7.2$.[31] The basic strength of the aqueous solution at pH≒ 9.6 corresponds to $H_0=9.3$, since the color of phenolphthalein ($pK_a=9.3$) begins to change at pH≒9.7. The coordinated water molecule in the 1:2 complex begins to be replaced by the hydroxyl ion at pH≒9.6; it resists the substitution reaction more than the 1:1 complex. This tendency becomes larger with an increase in the number of the bipyridine molecule coordinated to the copper ion.[28] Thus,

the formation of the II or III species by the adsorption of the 1:1 and 1:2 complexes suggests that basic sites with at least $H_0>7.2$ and $H_0>9.3$ exist on the surfaces.

Figure 4 shows the parallel component of the ESR spectrum for the 1:1 complex adsorbed on the surface of 50% silica-alumina treated at 300°C for 3 hr. By comparison with the values of $g_{//}$ and $A_{//}$ in the solutions, only one species formed on this surface was determined to be III. The chemical species which are possibly generated by the interaction between the complexes and the surfaces are represented in Fig. 5. The III species can be illustrated by (a) in the figure. The basic strength of the hydroxyl groups participating in the formation of the (a) type is at least $H_0>7.2$. The distance between the neighboring hydroxyl groups on the surface is estimated to be about 3 Å.[29,30] Thus, the (a) type is generated on only two contacted hydroxyl groups. The maximum number of hydroxyl groups which can be present on the surface is calculated to be 11 OH's per 100 Å. On the other hand, Morimoto *et al.*[32] have reported that the number of hydroxyl groups on the 50% silica-alumina surface pretreated at 300°C is 3.5 OH's per 100 Å. These facts may indicate that the hydroxyl groups exist in a cluster rather than homogeneously.

Figure 6 shows the parallel components of the ESR spectrum for the 1:2 complex adsorbed on the surface of 50% silica-alumina which had previously treated at 300°C for 3 hr. This spectrum indicates that another type exists in addition to the (a) type. The spectrum with the values of $g_{//}=2.224$ and $A_{//}=138$ gauss is the *cis* isomer, represented as the (c) type; only the hydroxyl groups of $H_0>9.3$ can expel one bipyridine molecule from the 1:2 complex, while those of $7.2<H_0<9.3$ can not, as can be understood from the substitution reaction in the basic aqueous solution. The (b) type could not be observed, either. Certainly, then, basic sites with basic strengths of two kinds are present on the 50% silica-alumina.

Figure 7 shows the parallel components of the ESR

spectrum for the 1:1 complex adsorbed on the surface of alumina pretreated at 300°C for 3 hr. Three chemical species were observed. The species with the lowest value of $g_{//}$ (2.265) corresponds to the (a) type, while that of the middle value of $g_{//}$ (2.306) is assigned to the (b) type by comparison with those in the solutions. In additon to these two species, a third species ($g_{//}=2.340$) exists. Its structure is still uncertain. It is necessary for the formation of the (a) type that the distance between the neighboring basic hydroxyl groups of $H_0>7.2$ is at least 3 Å, as has been described previously. Furthermore, the presence of the (b) type suggests that the distance between the neighboring hydroxyl groups of $H_0>7.2$ is larger than 3 Å. That is, the basic hydroxyl groups may, as a whole, be distributed homogeneously without forming a cluster, unlike the case of 50% silica-alumina. When the 1:2 complex was adsorbed on the alumina surface, the ESR spectrum was exactly the same as that for the 1:1 complex. Three types are present on this surface, while the (c) type could not be observed. This suggests that the basic hydroxyl groups of $H_0>9.3$ predominate over those of $7.2<H_9<9.3$.

The ESR parameters on the surface of 50% silica-alumina are plotted against the outgassing temperature in Fig. 8. When the 1:2 complex was adsorbed on a surface pretreated at 100°C for 3 hr, the (c) type could hardly be detected. This probably reflects the lack of basic hydroxyl groups of $7.2<H_0<9.3$. The basic strength of the hydroxyl groups became higher as the outgassing temperature was lowered; the value of $g_{//}$ increased and that of $A_{//}$ decreased with a rise in the outgassing temperature from 100 to 300°C. O'Reilley *et al.* have indicated, from their NMR studies, that the majority of protons are present as Si-OH groups on the surface.[33] Basila has reported that the isolated Si-OH groups on the silica-alumina surface increase as the outgassing temperature is raised.[34] The appearance of the stronger hydroxyl groups, with a decrease in the outgassing temperature seems, therefore, to be due to the weakly-bonded hydroxyl group attached to the aluminum atom. This me-

chanism is similar to that for the alumina surface, as will be described later. When the surface is pretreated at a relatively high temperature, it is considered that the negatively-charged oxygen ions play an important role in the substitution reaction. It has been reported that α sites which contain a negatively-charged oxygen ion in close proximity to an exposed aluminum atom are present on the surface pretreated between 300 and 500°C at a concentration of less than 10^{13} sites/cm^2.[16] Above this outgassing temperature, the O^{2-} ions are closely connected with the formation of the chemical species of the (d)-(g) types.

The 1:2 complex was adsorbed on the surface pretreated at a much higher temperature, 800°C, in order to investigate whether or not the O^{2-} ions reacted with the complex. Two chemical species were observed on this surface. However, they were different from the two types, (a) and (c), generated on the surface pretreated at 300°C. The value of $g_{//}$ for one species was somewhat higher than that of the (a) type. The other was slightly different from that of the (c) type. The absorption band at 3745 cm^{-1} which is due to an isolated Si-OH group appears on the surface pretreated at 500°C and is quite similar to that on the the silica gel surface.[34] Linear relationships have been found between the electronegativities of elements bonded to the hydroxyl groups and the vibrational frequencies of the hydroxyl groups;[35] the charge density of the hydroxyl groups becomes larger and the wave number shifts upward as the electronegativities of the elements decrease. The wave number of the Si-OH group on the surface of silica-alumina is approximately the same as that on silica gel. Thus, the hydroxyl groups on the silica-alumina surface pretreated at higher temperatures are not basic, since the silica gel sufrace is not basic, as will be discussed later. The (e) and (g) types, therefore, seem to be present on the surface pretreated at 800°C. Judging from the $g_{//}$ value, the basic strength of the O^{2-} ions formed at relatively high temperatures is rather weaker than that of the hydroxyl groups retained on the surface pretreated at a lower temperature. The values of $g_{//}$ for the complex adsorbed on the surface pretreated at 400–800°C were approximately constant. This may indicate that the O^{2-} ions predominantly react as basic sites on the surface, while the hydroxyl groups mainly react as basic sites on the surface pretreated below 300°C.

In order to compare them with those of the silica-alumina surface, the ESR spectra were also measured on the calcium oxide surface since the basic properties of the latter surface have been fairly well established. The basic strength of the hydroxyl groups on the surface of calcium hydroxide is quite different from that of the O^{2-} ions on the surface of calcium oxide. When the 1:2 complex was adsorbed on the surface of calcuim hydroxide pretreated at 100°C for 3 hr, the (a) type was observed. On the other hand, when the 1:2 complex was adsorbed on the surface of calcium oxide pretreated at 600°C for 3 hr, the observed species was quite different from the (a) type. The O^{2-} ions are responsible for the formation of this species, since scarcely no hydroxyl groups exist on this surface.[36] The parallel components of the ESR spectrum consist of four peaks. This spectrum is rather similar to that of cupric sulfate in methanol. All the bipyridine molecules in the 1:2 complex, therefore, seem to be expelled through the reaction with the surface. However, no such phenomenon was observed in the basic solutions These facts suggest that the basic strength of the O^{2-} ions is much higher than that of hydroxyl ions or hydroxyl groups. This is aslo in good agreement with the fact that the basic strength of the O^{2-} ions on the surface of calcium oxide is quite great, as determined by the phenol-vapor adsorption method.[8,12]

The ESR parameters for the surface of alumina are plotted against the outgassing temperature in Fig. 9. When the complexes were adsorbed on the surface of alumina pretreated at 100°C, the (a) and (b) types were observed. The value of $g_{//}$ for the (a) type was low in comparison with that on the alumina surface pretreated at 300°C. This supports the mechanism of the formation of the basic sites proposed by Yamadaya *et al.*; [14] they attributed the basic property of alumina to weakly-adsorbed hydroxyl groups rather than to strongly-adsorbed ones. The 1:2 complex was adsorbed on the surface of alumina pretreated at 800°C in order to determine whether the complex reacts with the hydroxyl groups or with O^{2-} ions. Two chemical species were observed. The $g_{//}$ values for these two species ($g_{//}$=2.270 and 2.316) were somewhat higher than those of the (a) and (b) types respectively. The α sites which contain negatively-charged oxygen ions begin to appear at about 400°C.[24] Thus, the O^{2-} ions are considered to be responsible for the formation of three chemical species, the (d), (e), and (f) types. The surface of alumina pretreated at 800°C has well-defined absorption maxima at 3700, 3733,

●: $g_{//}$, ○: $A_{//}$ for the 1:2 complex

3744, 3780, and 3800 cm^{-1}.[13] These correspond to the isolated hydroxyl groups. Peri has reported that the basic strength of the hydroxyl group becomes higher as the number of negatively-charged oxygen ions surrounding its hydroxyl group increases;[13] some of these isolated hydroxyl groups can act as basic sites. The species with the value of $g_{//}$ (2.270) may be ascribed to the (d) or (e) type, and that with the value of $g_{//}$ (2.316) may correspond to the (b) or (f) type. On the whole, the basic strengths of both the hydroxyl groups and O^{2-} ions on this surface are lower than those of hydroxyl groups on the surface pretreated at a very low temperature, as can be seen in Fig. 9. The value of $g_{//}$ increased to 400°C and thereafter was approximately constant. This may indicate that the strengths of the basic sites on the surface of alumina pretreated below 400°C mainly depend on the hydroxyl groups, while those of sites on the surface evacuated above this temperature predominantly depend upon the the hydroxyl groups and/or the O^{2-} ions.

When the 1:1 complex was adsorbed on the surface of silica gel pretreated at 300°C for 3 hr, only one species was observed. The shf structure at the higher magnetic field coincided in position with that observed in the acidic methanol solution. The hydroxyl groups on the surface of silica gel, therefore, seem to be acidic rather than basic, though it has been reported, on the basis of the phenol-vapor adsorption method,[8] that those on the surface are weakly basic.

Conclusion. Hydroxyl groups with basic strengths of two kinds, $H_0>9.3$ and $7.2<H_0<9.3$, are present on the 50% silica-alumina surface pretreated at 300°C for 3 hr. They exist in a cluster state on the surface. The negatively-charged oxygen ions play an important role as basic sites on the silica-alumina surfaces pretreated at relatively high temperatures. The basic strengths of the hydroxyl groups become higher as the outgassing temperature is lowered. This seems to be due to the weakly-bonded Al-OH groups on the silica-alumina surface. The hydroxyl groups of $H_0>9.3$ are present on the alumina surface pretreated at 300°C, and they are distributed, as a whole, homogeneously in comparison with those on the silica-alumina surface. The basic strengths of the hydroxyl groups get higher as the outgassing temperature is lowered. This seems to be ascribable to the weakly-bonded hydroxyl groups rather than to the strongly-bonded ones. The negatively-charged oxygen ions and/or the hydroxyl groups act as basic sites on the alumina surface pretreated above 400°C. The hydroxyl groups on the silica gel surface are acidic rather than basic.

The author wishes to express his hearty thanks to Professor Masaji Miura for his continuous encouragement and guidance throughout this work.

Calorimetric and Magnetic Studies of Crystalline and Glassy Bis[*N*-(3-methoxysalicylidene)isopropylamine]nickel(II)[1]

Naoto Arai, Michio Sorai, and Syûzô Seki

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received March 1, 1972)

Thermal and magnetic properties of Ni(3-CH_3O-SAL·*iso*-C_3H_7)$_2$ were investigated by measuring thermograms, infrared and electronic spectra, heats of solution, magneitc susceptibilities, and heat capacities around glass transition temperature. In addition to the known paramagnetic crystalline phase III and the diamagnetic crystalline phase IV, two new crystalline phases (I and II) were discovered. Phase I was found to be paramagnetic, its molecular geometry being of a tetrahedral four-coordinated form like that of phase III, while phase II, similar to phase IV, is diamagnetic and has a square-planar four-coordinated form. Although the order of thermodynamic stability of these four crystalline phases was not determined, they were isolated stably at room temperature. The supercooled liquid and glassy states of this compound were realized for the first time by quenching the sample in the molten state. Unusual magnetic behaviors of these two states were satisfactorily accounted for by assuming an equilibrium between the diamagnetic and the paramagnetic species. In the supercooled liquid state, the paramagnetic species was partially converted into the diamagnetic one with decreasing temperature. Below the glass transition temperature T_g, however, this conversion process was prevented and the magnetic susceptibility obeyed apparently Curie's law with a 26% paramagnetic content. The heat capacity measurement revealed a typical glass transition phenomenon at 297.5 K and the heat capacity jump at T_g was determined to be 172 $JK^{-1}mol^{-1}$. Detailed discussions were given for the relationship between molecular geometry and its associated magnetic property and also for the phase relationship between various phases.

Extensive studies have been carried out on the magnetic properties of the Schiff base metal complexes. An interesting problem in this field might be the elucidation of the relationship between the geometry of molecules and their associated magnetic properties. Bis(*N*-R-X-salicylidene)nickel(II) is a typical example. The molecular formula of this compound is illustrated in Fig.1 and abbreviated as Ni(X-SAL·R)$_2$

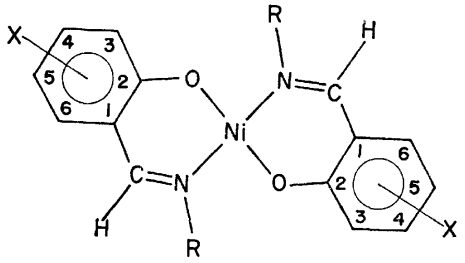

Fig. 1. Molecular formula of Ni(X-SAL·R)$_2$.

hereafter. By varying the substituent groups X and/or R, this coordination compound can possess the following four molecular forms; (i) square planar four-coordinated form, (ii) tetrahedral four-coordinated one, (iii) binuclear five-coordinated one, and (iv) polymeric octahedral six-coordinated chain form.[2-4]

In the solutions in inert solvents, Ni(X-SAL·R)$_2$ exists as an equilibrium mixture consisting of two or more species of the four forms. The magnetic properties of these solutions depend on both temperature and concentration. This phenomenon is well known as "solution paramagnetism."

In a solid state, however, a given Ni(X-SAL·R)$_2$ can possess only one form. Rare exceptions are the cases of Ni(H-SAL·CH_3)$_2$,[5,6] Ni(5-Cl-SAL·CH_3)$_2$,[7] and Ni(5-Br-SAL·CH_3)$_2$,[7] where the additional paramagnetic forms have been obtained by heating the stable diamagnetic form in a solid state.

Recently Yamada *et al.*[8] reported the new finding of a pair of isomers for crystalline Ni(3-CH_3O-SAL·*p*-Cl-C_6H_4)$_2$ and Ni(3-CH_3O-SAL·*p*-Br-C_6H_4)$_2$, where the binuclear five-coordinated as well as the polymeric six-coordinated forms have been stably isolated as a crystalline state. A similar isolation has been also reported for the present material by the same authors.[9] In this case brown and green crystals were obtained from methanol and ethylether solutions, respectively. The electronic spectra and magnetic susceptibility measurements at room temperature revealed that the brown crystal shows paramagnetism and its central Ni^{2+} ion is coordinated tetrahedrally, while the green crystal is diamagnetic with a square-planar form. These authors also reported transformation of the green form into the brown one at 430—431 K followed by melting at 460—461 K.

The main purpose of the present work is to investigate the relationship between molecular geometry and magnetism in Ni(3-CH_3O-SAL·*iso*-C_3H_7)$_2$ and also to elucidate the relative thermodynamic stability among different crystalline forms by means of precise heat of solution and magnetic susceptibility measurements as well as spectroscopic methods. In addition to the green and the brown forms mentioned above, we found two other new crystalline phases which exist stably at room temperature. We also found that both the supercooled liquid and the glassy states can

be realized by quenching the molten state. The brown and green forms will be designated as crystalline phases III and IV, respectively, and the two new forms as crystalline phases I and II, respectively, following the order of magnitude of heat of solution of each phase (see Fig.5).

For the sake of comparison, the magnetic structure of Ni(H-SAL·$CH_3)_2$ crystal was also investigated by measuring the infrared and electronic spectra as well as the thermograms.

Experimental

Material. *(A) Ni(3-CH_3O-SAL·iso-$C_3H_7)_2$*: Of the four isomers of the present complex, crystalline phases III and IV were prepared by following the method of Takeuchi and Yamada[9] and phases I and II were obtained from III or IV on heating in the solid state. Preparation of each crystalline phase, the supercooled liquid and the glassy state was carried out as follows:

(i) Crystalline phase III. The crude material was recrystallized from methanol solution to give brown prism crystals. *(ii) Crystalline phase IV.* Evaporation of a solvent from a green ethylether solution of the brown crystal yielded a green prism crystal which was purified by recrystallization from the same solvent. *(iii) Crystalline phase I.* Heating the crystalline phase III up to 443—448 K for *ca.* 15 minutes or phase IV up to 403—438 K for *ca.* 30 minutes under the atmosphere of helium gas converted the respective phases into a brown colored phase I, which was easily supercooled down to room temperature. *(iv) Crystalline phase II.* By keeping the supercooled liquid of the present complex at 343—363 K for *ca.* 30 minutes, crystallization took place to give a green solid phase II, which was also supercooled easily to room temperature. *(v) Supercooled liquid and glassy states.* These phases were obtained by quenching the molten substance at a cooling rate greater than 10 K min^{-1}. Results of chemical and elementary analyses of each crystalline phases are given in Table 1.

Table 1. Elementary and chemical analyses of Ni(3-CH_3O-SAL·*iso*-$C_3H_7)_2$ and Ni(H-SAL·$CH_3)_2$

		C(%)	H(%)	N(%)	Ni(%)
	Ni(3-CH_3O-SAL·*iso*-$C_3H_7)_2$

Found	Phase I	59.49	6.28	6.32	—
	Phase II	59.67	6.39	6.29	—
	Phase III	59.75	6.47	6.34	13.16
	Phase IV	59.70	6.37	6.32	—
	Ni(H-SAL·$CH_3)_2$				
Calcd		58.77	4.93	8.57	17.95
Found	Phase I	58.61	4.94	8.56	17.83
	Phase II	58.73	4.95	8.56	17.82

(B) Ni(H-SAL·$CH_3)_2$: Diamagnetic green form (phase II) and paramagnetic buff-colored form (phase I) were prepared according to the methods by Klemm and Raddatz[10] and others.[5,6] The results of elementary and chemical analyses of both forms are also shown in Table 1.

Thermal Analysis. Prior to precise calorimetric investigation, thermal analysis was made by using a differential scanning calorimeter (Perkin-Elmer, DSC-1B) at 173—473 K. The scanning rate was 10 K min^{-1}.

Infrared Absorption Spectra. The infrared spectra of Ni(3-CH_3O-SAL·*iso*-$C_3H_7)_2$ and Ni(H-SAL·$CH_3)_2$ were recorded on a Grating-type Infrared Spectrophotometer Model DS-402G (Japan Spectroscopic Co., Ltd.) in the range 4000—400 cm^{-1} at room temperature and 120 K. The far-infrared spectra of both compounds were also obtained by a Spectrophotometer No.FIS-001 (Hitachi Ltd.) in the range 500—80 cm^{-1} at the same temperatures. The Nujol mull method was employed for preparation of the samples.

Electronic Spectra. In order to get more insight into the coordination schemes in each phase of Ni(3-CH_3O-SAL·*iso*-$C_3H_7)_2$ we measured the electronic spectra. For the sake of comparison the electronic spectra of Ni(H-SAL·$CH_3)_2$ were also measured. The electronic reflection spectra of both compounds in solid state were recorded on a spectrophotometer model EPU-2A (Hitachi Ltd.) in the range 23,000—10,000 cm^{-1} at room temperature.

Heat of Solution. The heat of solution of Ni(3-CH_3O-SAL·*iso*-$C_3H_7)_2$ into chloroform was measured by using a LKB-8700 Precision Calorimetry System at 18—30°C. The calorimeter was standardized on an international scale in our laboratory by measuring the heat of solution of tris(methylhydroxy)aminomethane into 0.1 N HCl solution. The amount of sample used in each measurement varied from 90 to 620 mg but the amount of solvent was always about 100 cm^3.

Heat Capacity. The heat capacities of phase II and the glassy state of Ni(3-CH_3O-SAL·*iso*-$C_3H_7)_2$ at 230—343 K were measured by using an adiabatic calorimeter.[11] The amount of specimen was 24.3532 g(=0.0549502 moles). A small quantity of helium gas was sealed into the calorimeter cell along with the sample to aid in the heat transfer. The experimental errors were within ±0.3% in all cases.

The glassy state was prepared by quenching the molten substance in the calorimeter cell to dry-ice temperature. In this case the cooling rate was estimated to be about −100 K min^{-1}. After quick setting of the calorimeter cell to the cryostat, the temperature of the cell was maintained at 273 K during the course of evacuation of the equipment. This procedure prevented the transformation of the supercooled liquid into phase II.

The sample of phase II was prepared by complete transformation of the supercooled liquid into this phase by keeping the sample at 339.4 K (just above the crystallization temperature) for *ca.* 12 hr.

Magnetic Susceptibility. The magnetic susceptibilities of Ni(3-CH_3O-SAL·*iso*-$C_3H_7)_2$ were measured at the field-strength of 7.65 kG by use of the Faraday method in the temperature region 120—530 K. The amount of specimen employed was 400—500 mg.

Phase Relationships

Thermal analysis is one of the most effective methods for determining phase relations. Run 1 in Fig.2 shows the DSC curve of the brown paramagnetic phase III of Ni(3-CH_3O-SAL·*iso*-$C_3H_7)_2$. In heating direction the DSC curve showed an endothermic peak with a small subsequent exothermic effect at 433—443 K. Phase III was transformed into a new high-temperature phase. This phase (mp 460 K) was easily supercooled down to 173 K (see Run 2). The thermal behavior of the green phase IV is shown in Run 3. Phase IV was transformed into a high-temperature phase at 383 K, which was also supercooled down to 173 K and

melted at 460 K (see Run 4). The thermal behavior of the molten substance of phase IV was exactly the same as that of phase III. By cooling the molten substance at the rate -10 K min^{-1} the liquid state was quenched to the lowest temperature investigated. Run 5 shows the heating curve of the quenched substance, which exhibited a thermal anomaly similar to that in a glass transition at *ca.* 298 K. The anomaly was confirmed to be a real glass transition through the enthalpy relaxation effects observed by auxiliary experiments. On further heating an exothermic peak due to crystallization was observed at *ca.* 333 K where the supercooled liquid state was irreversibly transformed into another crystalline phase, which we designate crystalline phase II. The phase showed rather complicated thermal behaviors at 423—453 K and melted at 460 K. It should be noticed that both high-temperature phases obtained by heating phases III and IV were recognized as the same crystalline phase, which we designate crystalline phase I. The colors of phases I and II were brown and green, respectively.

Infrared absorption spectra can provide useful information on molecular structure. Although quantitative assignments have not been made, noticeable differences in absorption peaks were observed among each crystalline phases. In the case of Ni(3-CH_3O-SAL·*iso*-$C_3H_7)_2$, the infrared spectrum of phase I was, on the whole, similar to that of phase III. However, extra absorption peaks characteristic of phase I were observed especially in the range 800—700 cm^{-1} and at 1045 cm^{-1}. The spectra of phases II and IV, on the other hand, resembled each other except for a slight differences in the range 400—350 cm^{-1}. The spectra of phases I and III were, however, quite unlike those of II and IV. The four spectra might be grouped into two classes, one consisting of the spectra of phases I and III, and the other the spectra of phases II and IV. One of the most characteristic peaks which can be distinguished from

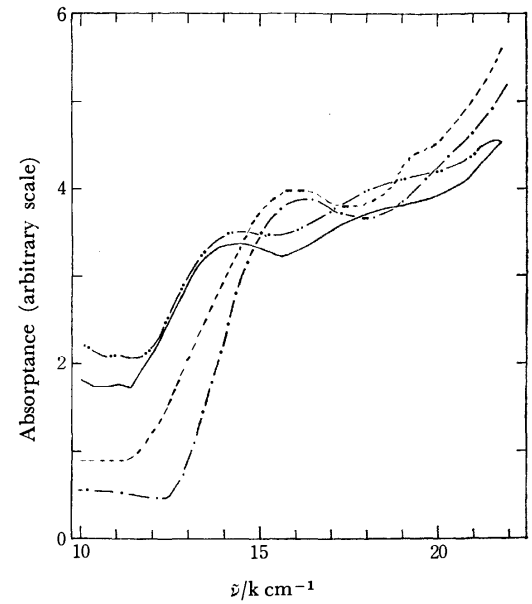

Fig. 3. The electronic spectra at room temperature; ——, phase I; ----, phase II; —·—, phase III; —·—, phase IV.

each class is the C=N stretching vibration near 1600 cm^{-1}. The single peak due to the C=N stretching in the first class was found to split into a doublet in the case of the second class; *i. e.*, 1607 cm^{-1} (strong) for phase I; 1607 cm^{-1} (strong) for phase III; 1602 (shoulder) and 1615 cm^{-1} (strong) for phase II; 1603 (moderate) and 1622 cm^{-1} (strong) for phase IV. Another characteristic band probably due to one of the metal-ligand coordinate bonds appeared in the far-infrared region; 304 cm^{-1} (phase I), 346 cm^{-1} (phase II), 301 cm^{-1} (phase III), and 347 cm^{-1} (phase IV).

In general, infrared spectra reflect the difference in molecular structure as well as the local symmetry in which a relevant absorption mode will be excited. Appreciable differences observed between the two classes indicate that remarkable differences exist in the molecular structure and the local symmetry. There is, however, little distinction between phases I and III and also between II and IV.

Similar situations were also observed in the electronic spectra of the four crystalline phases. The electronic spectra of Ni(3-CH_3O-SAL·*iso*-$C_3H_7)_2$ at room temperature are shown in Fig.3. The absorption maxima due to the crystal-field bands appeared at 11100 (weak), 14330 (strong), and 17830 cm^{-1} (broad) for phase I and at 11050 (weak), 14500 (strong), and 18300 cm^{-1} (broad) for phase III. These spectra have the closest resemblance to those of the other Schiff base nickel complexes with tetrahedral configuration. On the other hand, phases II and IV showed the crystal-field band at 16000 cm^{-1} and at 16200 cm^{-1}, respectively. These features are similar to the spectrum of the square planar phase II in Ni(H-SAL·$CH_3)_2$. It is therefore safely concluded that the coordination scheme in phases I and III of Ni(3-CH_3O-SAL·*iso*-$C_3H_7)_2$ is tetrahedral and in phases II and IV square planar.

Heat of Solution

If the precise heat capacity data from sufficiently

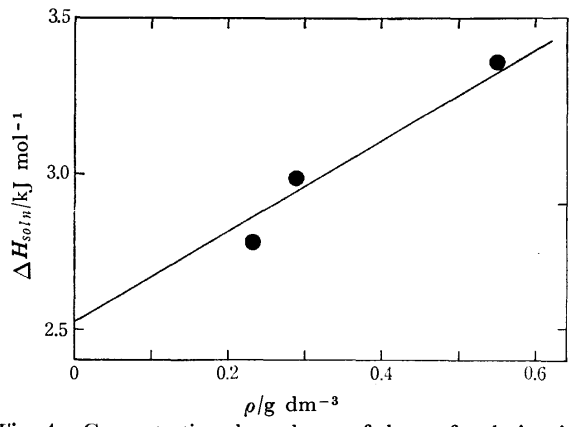

Fig. 4. Concentration dependence of heat of solution into chloroform at 24°C.

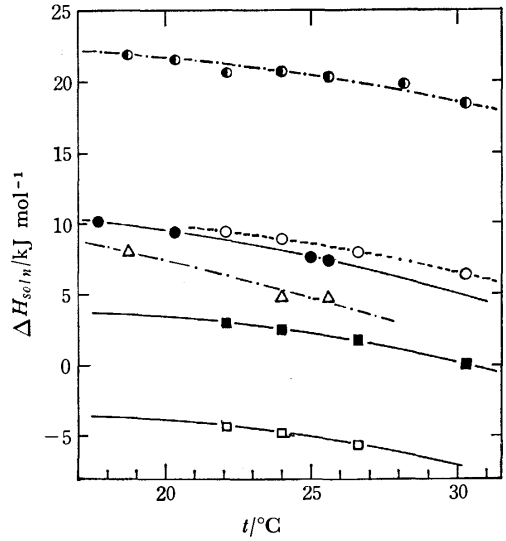

Fig. 5. Temperature dependence of the heat of solution; ○, phase I obtained from phase III; ●, phase I obtained from phase IV; △, phase II; ■, phase III; □, phase IV; and ◐, supercooled liquid state.

low temperatures are combined with the data of heat of solution, the difference in standard Gibbs energy between the phases might be obtained. The values enable us to determine the order of thermodynamic stability among various crystalline phases which remain "stable" at room temperature. We have measured the heat of solution of four crystalline phases and the supercooled liquid state of Ni(3-CH_3O-SAL·*iso*-$C_3H_7)_2$ at 18–30 °C. In order to confirm a possible concentration dependence on the heat of solution in advance, the data for the brown phase III was measured at 24°C by varying the amount of specimen. As is shown in Fig.4, an approximately linear dependence exists in the concentration region investigated. In determining the heat of solution, the following two assumptions were made; (i) the final state of the solution is identical in all cases and (ii) the correction to the infinitely diluted state of any sample is regarded as the same as the result given in Fig.4. The heats of solution thus obtained for each phase and the supercooled liquid state are plotted in Fig.5 as a function of temperature. The experimental error was estimated to be within ±0.62%. The ordinate ΔH_{soln} corresponds to the enthalpy difference between the infinitely diluted solution and solid phase.

We have regarded two high-temperature phases obtained by heating both phases III and IV as the identical phase (phase I), based on the results of infrared spectra. It was found, however, that there exists a slight but significant discrepancy in the heat of solution between the two kinds of samples of phase I prepared from phases III and IV (Fig.5). The discrepancies are beyond experimental error. This could be accounted for by close examination of each transition behavior revealed by the DSC curves. As shown in Fig.2, phase IV is transformed into phase I at 383 K accompanied by an endothermic peak, while phase III is transformed into phase I at a higher temperature *via* a metastable phase. The endothermic peak at 433 K corresponds to the transition from phase III to a metastable phase and the subsequent exothermic peak corresponds to that of metastable phase to phase I. In this two-step transition a sintering phenomenon was observed directly in the sample glass tube. The temperature range for phase I obtained from phase III is quite narrow compared with that formed from phase IV. Thus, severe control of temperature and complete transformation are necessary for the preparation of pure and stable phase I from phase III. The differences in the heat of solution of phase I can be attributed to the incomplete transformation from a metastable phase to phase I.

On the other hand, the heat of solution data for a supercooled liquid state and for phase II is not so accurate compared with those for phases I, III, and IV for the following reasons. The heat capacity measurement revealed that partial crystallization occurred in the supercooled liquid region even at temperatures far below the exothermic peak in the DSC curve. Thus the supercooled liquid samples used for the measurement of heat of solution seem to involve a certain amount of phase II arising from a partial crystallization at these temperatures, while the samples of phase II can involve partially the supercooled liquid state since the crystallization was too sluggish to attain completion.

It should be pointed out that there is a fundamental difference between thermal and various spectroscopic investigations. Only a slight difference was observed between phases I and III, and also between phases II and IV both in the infrared as well as in the electronic spectra. We have thus grouped these four phases into two classes; one consisting of phases I and III with the tetrahedral molecular form and the other of phases II and IV with the square-planar molecular form. The heat of solution, however, revealed large differences between phases I and III, and also between phases II and IV. These results imply that thermal investigations such as the measurement of heat of solution are more useful than spectroscopic analysis in the study of intermolecular interaction in relation to molecular arrangement or phase problem in the solid state.

Heat Capacity around Glass Transition Temperature

In order to obtain more quantitative insight into the glass transition phenomenon, the heat capacities

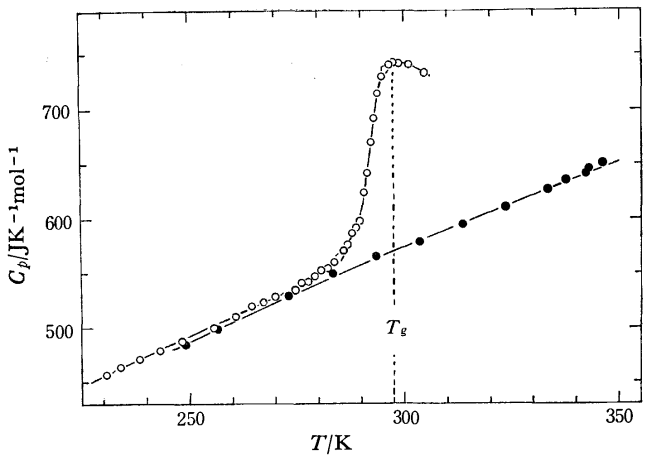

Fig. 6. Heat capacity around T_g; ○, glassy state and ●, phase II.

291.527	642.05	343.002	646.12

of the glassy state and phase II were measured at 230—343 K. The results are plotted in Fig .6 and listed in Table 2. A typical glass transition was observed at 297.5 K. The ratio of the glass transition temperature T_g to the melting point amounted to 0.648. This value falls within the range 0.50—0.67, which is favorable to a number of glass-forming materials. The heat capacity jump ΔC_p at T_g was 172 JK^{-1}mol^{-1} and the ratio of ΔC_p to the heat capacity of phase II at this temperature was found to be 0.309. The exothermic effect due to crystallization was observed just above T_g and the heat capacity in the narrow supercooled liquid region decreased with increasing temperature, even after correction of a temperature drift in the computation of the heat capacities. We were not able to measure the heat capacity of the supercooled liquid state above 305 K because the great evolution of heat due to the crystallization effect disturbed the measurements. Due to this gradual heat evolution effect even above T_g, we were not able to estimate the heat of crystallization directly from the heat capacity data. We can, however, evaluate this heat effect from the difference of heats of solutions for phase II and supercooled liquid state which amounts to *ca.* 15.7 kJ mol^{-1}.

Magnetic Properties

Extensive studies have been carried out on the magnetic susceptibility measurements of the Schiff base metal complexes. However, almost all the data are restricted to those obtained at room temperature. More quantitative information on the magnetic properties could be provided by varying the temperature.

We measured the magnetic susceptibility of the various phases of Ni(3-CH_3O-SAL·*iso*-$C_3H_7)_2$ over a wide temperature range of 120—530 K. The molar susceptibilities χ_m are plotted in Figs. 7—10. To make clear their correspondence to thermal behaviors, the results of DSC curves are also given. Although the general aspect of magnetic susceptibility coincided with the results of thermal data, slight mismatches in some anomalous parts were observed because of the different scanning rate of temperature, *i.e.*, 4—6 K min^{-1} in the magnetic measurement and 10 K min^{-1} in the thermal analysis, and also because of the uncertainty involved in temperature measurement for

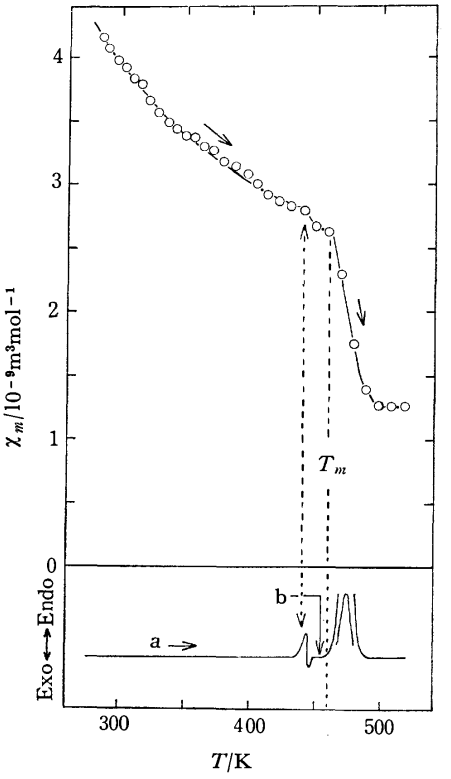

Fig. 7. Magnetic susceptibility χ_m *versus* temperature for phase III; (a) phase III and (b) phase I. In this and in Figs. 8—10, the DSC curves are also shown for comparison.

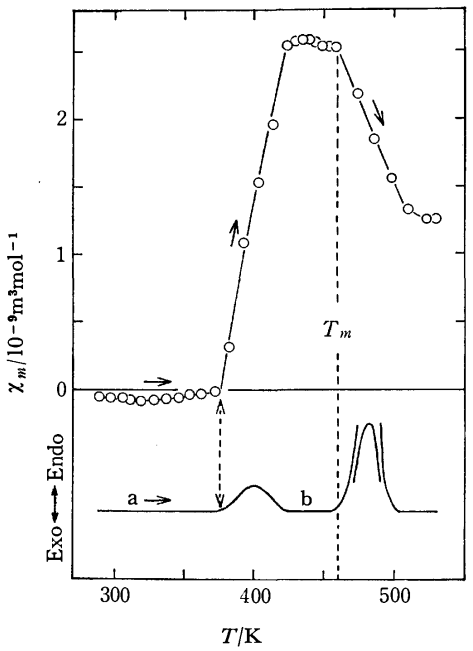

Fig. 8. χ_m *versus* T for phase IV; (a) phase IV and (b) phase I.

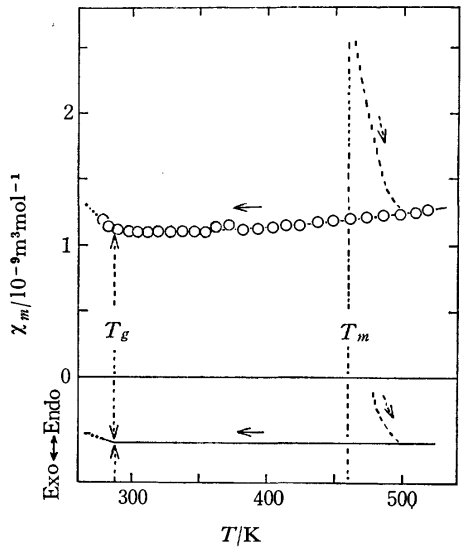

Fig. 9. χ_m *versus* T for supercooled liquid state.

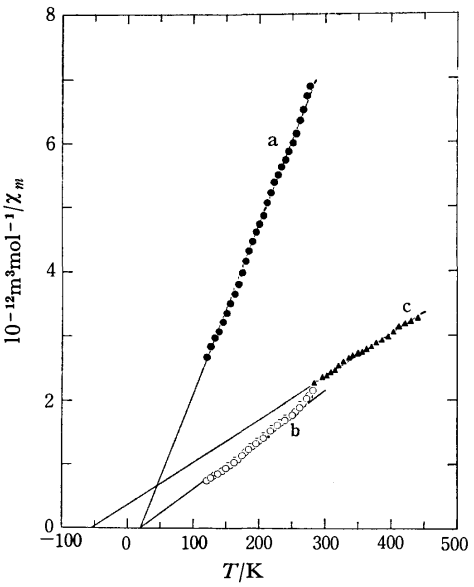

Fig. 11. $1/\chi_m$ *versus* T relationship; (a) glassy state, (b) paramagnetic species in glassy state, and (c) phase III.

magnetic data. In the figures the melting points of each sample obtained from the magnetic study are fitted to those from the thermal study.

χ_m of phase III decreases with increasing temperature according to the characteristic behavior of paramagnetic substances (Fig. 7). Although a slight fall in χ_m occurred at the transition point corresponding to phase III→I, the magnetic property of the new phase I was found to be paramagnetic similar to phase III. At melting point T_m, the value of χ_m decreased abruptly by one half, but in the liquid state χ_m was nearly independent of the temperature.

In the heating curve of χ_m for phase IV (Fig. 8), the value of χ_m increases sharply at the transition point and the diamagnetic phase IV is transformed into a paramagnetic phase I. The melting behavior is quite the same as that shown in Fig. 7.

In the cooling curve of χ_m for the molten substance (Fig.9), the liquid and the supercooled liquid states show paramagnetism but the magnetic behavior is peculiar. Upon cooling to the glass transition point T_g, the values of χ_m decrease but are almost independent of temperature. Below T_g, however, χ_m seems to obey roughly the Curie law.

In the heating curve of χ_m for the glassy state (Fig.10), magnetic susceptibility up to T_g, shows an ordinary paramagnetism except in the vicinity of T_g. Above T_g, the behavior of χ_m is characteristic of the supercooled liquid state. The value χ_m, however, decreases suddenly at crystallization temperature and shows diamagnetism in the new phase II. On further heating, the diamagnetic phase II is transformed into a paramagnetic phase *via* complicated steps of transition and finally melts at 460 K.

The effective Bohr magneton number μ_{eff} of phases I, III, and the glassy state is given in Table 3. It

Table 3. Effective Bohr magneton number of Ni(3-CH_3O-SAL·*iso*-$C_3H_7)_2$ $\mu_{eff}=2.83\sqrt{\chi_a(T-\theta)}$

T/K	μ_{eff}/μ_B		T/K	μ_{eff}/μ_B		T/K	μ_{eff}/μ_B	
	Phase I			Apparent μ_{eff} of glassy state			μ_{eff} of paramagnetic species	
	$\theta=0$			$\theta=0$	$\theta=+21$		in glassy state	
437	3.15		133	1.89	1.74		$\theta=0$	$\theta=+21$

			169	1.88	1.74	151	3.58	3.25
	Phase III		185	1.85	1.74	169	3.54	3.25
	$\theta=0$	$\theta=-54$	201	1.84	1.74	185	3.46	3.25
297	3.17	3.46	218	1.82	1.74	201	3.42	3.25
331	3.17	3.46	234	1.82	1.74	218	3.37	3.25
342	3.18	3.46	251	1.83	1.74	234	3.36	3.25
363	3.21	3.46	267	1.81	1.74	251	3.35	3.25
387	3.24	3.46	282	1.78	1.74	267	3.30	3.25
412	3.24	3.46				282	3.23	3.25

has been calculated on the basis of both the Curie law, $\mu_{eff}=2.83\sqrt{\chi_a T}$, and the Curie-Weiss law, $\mu_{eff}=2.83\sqrt{\chi_a(T-\theta)}$, the atomic magnetic susceptibility χ_a being determined by correcting the underlying diamagnetism of all constituent atoms (-267×10^{-12} m^3mol^{-1}). The Weiss constants of phase III and of the glassy state were determined from Fig.11 to be -54 K and $+21$ K, respectively. It was impossible to estimate the Weiss constant of phase I because of the limited temperature region. The signs of the constant imply that the intermolecular interactions in the glassy state and in phase III have a ferromagnetic and antiferromagnetic nature, respectively. The values of the Weiss constants for both cases, however, seem to be extraordinarily large in view of the fact that the Weiss constant is proportional to the interaction between magnetic ions in molecular field theory. In the glassy state, the packing of molecules may be somewhat loose as compared with a crystalline phase and the regular superexchange paths established in a crystalline phase may be disturbed randomly in the glassy state. Therefore, a small value for the Weiss constant is expected for the glassy state. The interpretation for the large Weiss constant obtained by the present experiment will be a further problem. The Weiss constant for phase III, $\theta=-54$ K, indicates the existence of a heat capacity anomaly or a magnetic phase transition at a temperature of several tens degree-Kelvin. However, such a heat capacity anomaly was not found down to 13 K. Further discussions concerning the magnetic interaction will not be given, since a small uncertainty in temperature and a large extrapolation from the high temperature will lead to errors.

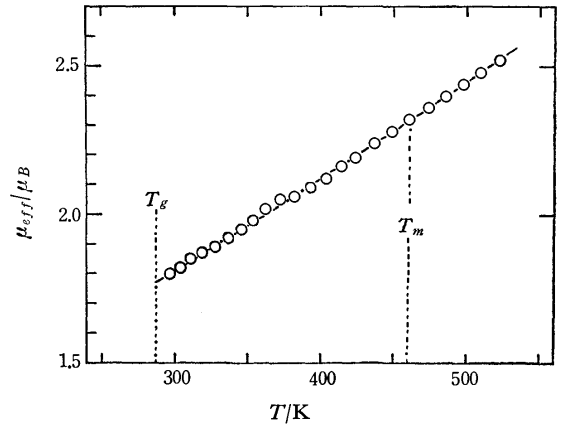

Fig. 12. Effective Bohr magneton number of supercooled liquid against temperature.

The effective Bohr magneton number of the supercooled liquid state is shown in Fig.12 as a function of temperature. An explanation of the magnetic susceptibilities of the molten nickel(II) complexes based on the existing equilibrium between the diamagnetic and the paramagnetic species has already been given.[12] We have applied a similar discussion to the present supercooled liquid and the glassy states of Ni(3-CH_3O-SAL·*iso*-$C_3H_7)_2$. In the supercooled liquid state, an equilibrium between two species seems to be established since the magnetic susceptibility shows a curious behavior and does not obey the Curie law. It is assumed here that a certain equilibrium may be reached between the paramagnetic tetrahedral molecule of phase III and the diamagnetic planar molecule of phase II and/or phase IV. The molar fraction of the paramagnetic species x in the supercooled liquid state is related to the effective Bohr magneton number of phase III and that of the supercooled liquid state as follows.

$x=\chi_a$(supercooled liquid state)/χ_a(phase III)
$=[\mu_{eff}$(supercooled liquid state)$]^2/[\mu_{eff}$(phase III)$]^2$.

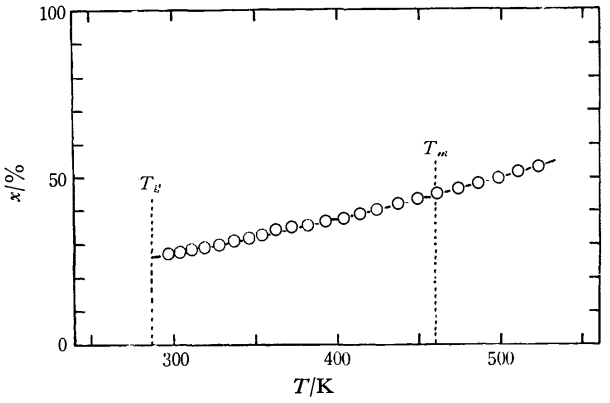

Fig. 13. Temperature dependence of the paramagnetic content in the liquid and the supercooled liquid states.

12) L. Sacconi, R. Cini, and F. Maggio, *J. Inorg. Nuclear Chem.*, **8**, 489 (1958).

The temperature dependence of x is shown in Fig.13. Upon cooling down to T_g, the paramagnetic species are partially converted into a diamagnetic one according to the following equilibrium relationship.

$$\underset{(1-x)}{\text{diamagnetic species}} \rightleftarrows \underset{(x)}{\text{paramagnetic species.}}$$

The equilibrium constant K_p was determined from the relation

$$K_p = [\text{paramagnetic species}]/[\text{diamagnetic species}] = x/(1-x).$$

The thermodynamic quantities ΔG, ΔH, and ΔS associted with this equilibrium can be calculated from the plot of $\ln K_p$ against $1/T$ as shown in Fig.14. The numerical values are listed in Table 4. As was expected the free energy difference between the two species is rather small. This may be one reason why two crystalline forms can be obtained stably from different solvents. The free energy data also show that at lower temperatures the diamagnetic planar form is more stable than the paramagnetic tetrahedral one, but at higher temperatures such as 510 K, the order of stability is reversed. Both ΔH and ΔS are considerably small compared with those of other solutions of Schiff base metal complexes.[4] Steric effects of the substituent groups and solvent effect will be responsible for this difference.

In the glassy state, however, the conversion of the paramagnetic species into the diamagnetic one seems to be frozen because of a long relaxation time required. The content of the paramagnetic species in the glassy state was estimated from Fig.13 to be about 26%. The magnetic susceptibility of the glassy state obeys the Curie law in keeping the paramagnetic content at 26%. This behavior seems to be consistent with the thermodynamic nonequilibrium condition in the glassy state. By using the paramagnetic content of *ca.* 26% the experimental susceptibility data in the glassy state was reduced to the molar paramagnetic susceptibility. In this case the Weiss constant also becomes +21 K (Fig. 11).

As is shown in Fig.10, the magnetic susceptibility around the glass transition temperature varies continuously with temperature with no jump. This is in contrast to other phase transition regions. In the temperature range from about 232 K to T_g, an approximately linear relationship holds between the magnetic susceptibility and temperature for the glassy state. This may be partially due to the enthalpy relaxation effect, which is generally observed just below the glass transition point. In other words, in setting the sample at this temperature region for a long time, its magnetic susceptibility decreases gradually to the extrapolated value from the supercooled liquid state.

Table 4. Thermodynamic quantities for diamagnetic ⇄ paramagnetic equilibrium in the supercooled liquid state of Ni(3-CH_3O-SAL·*iso*-$C_3H_7)_2$

Conclusion

Thermal and magnetic properties of Ni(3-CH_3O-SAL·*iso*-$C_3H_7)_2$ were investigated by means of various methods. In addition to the known crystalline phases III and IV, two new crystalline phases I and II and the existence of the supercooled liquid and the glassy states were found. The molecular structure and its associated magnetic properties in phases I and II were determined to be of paramagnetic tetrahedral form and diamagnetic square-planar one, respectively. The infrared and electronic spectra elucidated that the molecular configuration in phase I resembles that in phase III and that the molecular form in phase II is similar to that in phase IV. However, remarkable differences were observed in the heat of solution data between phases I and III, and between phases II and IV. These facts imply that the spectroscopic methods reflect the local symmetry in a molecule, or that information on short-range effects can be obtained from the spectroscopic methods. The calorimetric methods reveal the intermolecular or the long-rang effects in a condensed system.

The unusual magnetic behavior observed in the supercooled liquid state was well accounted for by assuming that an equilibrium between the paramagnetic and the diamagnetic species is established. In decreasing temperature the paramagnetic species was partially converted into the diamagnetic one. But further cooling below glass transition temperature prevented the conversion between two species because of a much longer relaxation time. In the glassy state the para-

magnetic content was found to be about 26% and its magnetic susceptibility obeyed the Curie-Weiss law.

From the viewpoint of statistical mechanics the paramagnetic glass will provide an interesting problem. The present glassy state may be regarded as a random-system in which the paramagnetic species are distributed randomly. The question, whether any phase transition will occur or not in such a random-system, remains unsolved. To obtain more insight into this problem it will be necessary to measure exactly the magnetic susceptibility of the glassy state down to a further low temperature region.

The magentic measurements of the paramagnetic phases I and III at lower temperature will also provide the detailed knowledges about the Weiss constants and the nature of the intermolecular interactions.

The authors would like to express their sincere thanks to Professor Y. Shimura and Dr. S. Kaizaki who kindly permitted use of the spectrophotometer to obtain the electronic spectra, and to Professor A. Tazaki and Mr. G. Kaji, Faculty of Engineering Science, for the use of the apparatus for magnetic susceptibility measurements.

The Crystal Structure of μ-Oxo-bis{pentamminechromium(III)} Chloride Monohydrate, $[(NH_3)_5Cr\text{-}O\text{-}Cr(NH_3)_5]Cl_4 \cdot H_2O$[1]

Akio URUSHIYAMA

Department of Chemistry, Faculty of Science, Rikkyo University, Nishi-Ikebukuro, Toshima-ku, Tokyo

(Received March 13, 1972)

The crystal structure of μ-oxo-bis{pentamminechromium(III)} chloride (basic rhodochromic chloride) monohydrate, $[(NH_3)_5Cr\text{-}O\text{-}Cr(NH_3)_5]Cl_4 \cdot H_2O$, has been determined from the three-dimensional X-ray data. The crystals are orthorhombic. The cell dimensions are: $a=11.94\pm0.01$, $b=11.71\pm0.01$, and $c=13.40\pm0.02$ Å. The space group is *Pbca*, with four formula units in a unit cell. The structure was refined by the least-squares method, with anisotropic temperature factors, to $R=0.14$. A bridging oxygen atom of the basic rhodochromic complex ion is situated on the inversion center. Therefore, the complex has a center of symmetry and, accordingly, a linear Cr–O–Cr system. The N–Cr–O angles are nearly 90° or 180°, and the Cr–N bond distances are in the range from 2.09 to 2.14 Å (average 2.11 Å). The complex ion has approximately a D_{4h} symmetry. The Cr–O distance is 1.80 Å, which is quite short compared with that found in the other Cr(III) complexes. The linear Cr–O–Cr system and its short bond distance suggest the presence of an extensive π-bonding in this system. The single-crystal polarized absorption spectra in the visible and ultraviolet regions were also measured. It was found that the characteristic sharp absorption bands of the basic rhodochromic complex ion are all polarized along the four-fold rotation axis of the complex.

Since the rhodochromic (μ-hydroxo-bis{pentamminechromium(III)} ion: rhodochromic ion, μ-oxo-bis{pentamminechromium(III)} ion: basic rhodochromic ion) and erythrochromic (μ-hydroxo-aquotetramminechromium(III) pentamminechromium(III) ion: erythrochromic ion, μ-hydroxo-hydroxo-tetramminechromium(III) pentamminechromium(III) ion: basic erythrochromic ion) series of compounds were first prepared by Jørgensen[2] in 1882, their correct constitutions and their interesting transformation relationships have been discussed in several studies.[3,4] Wilmarth *et al.*,[5] in 1955, on the basis of their careful analyses, determination of pK values, and cleavage-reaction studies of these compounds, proposed the following formulae and relationships for these binuclear complexes of chromium(III):

$$[(NH_3)_5Cr\text{-}OH\text{-}Cr(NH_3)_5]^{5+} \underset{H^+}{\overset{OH^-}{\rightleftharpoons}} [(NH_3)_5Cr\text{-}O\text{-}Cr(NH_3)_5]^{4+}$$

rhodochromic ion — basic rhodochromic ion

$$[(NH_3)_5Cr\text{-}OH\text{-}Cr(H_2O)(NH_3)_4]^{5+} \underset{OH^-}{\overset{H^+}{\rightleftharpoons}} [(NH_3)_5Cr\text{-}OH\text{-}Cr(OH)(NH_3)_4]^{4+}$$

erythrochromic ion — basic erythrochromic ion.

1) A short communication including the present X-ray work has been reported: a) A. Urushiyama, T. Nomura, and M. Nakahara, This Bulletin, **43**, 3971 (1970). Subsequently, correspondence on the structures of the binuclear complexes of chromium(III), including the basic rhodochromic complex ion, has appeared: b) M. Yevitz and J. A. Stanko, *J. Amer. Chem. Soc.*, **93**, 1512 (1971). The results obtained by these arthors were essentially consistent with our X-ray studies. The polarized absorption spectra of the basic rhodochromic salt have also been reported in a short communication: c) A. Urushiyama, M. Nakahara, and Y. Kondo, This Bulletin, **44**, 2290 (1971).

2) S. M. Jørgensen, *J. Prakt. Chem.*, **25**, 231 (1882).

3) A. Werner, "Neuere Anschauungen auf dem Gebiete der anorganischen Chemie," 5 Aufl. (1923), p. 273.

4) K. A. Jensen, *Z. Anorg. Chem.*, **232**, 257 (1937).

5) W. K. Wilmarth, H. Graff, and S. T. Gustin, *J. Amer. Chem. Soc.*, **78**, 2683 (1956).

Subsequently, a variety of the μ-hydroxo-acidotetramminechromium(III)pentamminechromium(III) (acidoerythrochromic) complexes, $[(NH_3)_5Cr\text{-}OH\text{-}CrX(NH_3)_4]^{4+}$ ($X=F^-$, Cl^-, Br^-, I^-, NCS^-, and NO_2^-),[6,7] have been synthesized from the erythrochromic complex, and $[(NH_3)_5Cr\text{-}OH\text{-}Cr(NH_3)_4enH]^{6+}$ [8] from the thiocyanato-erythrochromic complex (en= ethylenediamine).

In these binuclear complexes of chromium(III), the chracteristic "blue" basic rhodochromic salts have been reported to have very different properties from the other compounds in the series. That is, the remarkably reduced magnetic susceptibilities of these salts and their variation with the temperature have been investigated by several workers.[9-12] Schwarzenbach and Magyar[13] investigated the hydrolysis reaction of the rhodo- and erythrochromic series of complexes in an aqueous solution, and reported that the basic rhodochromic complex ion in a basic aqueous solution is transformed very rapidly into the red basic etythrochromic complex with a half-lifetime of 44 sec at 25°C. The visible and ultraviolet absorption spectra of the basic rhodochromic salts show one broad band in the 16600 cm^{-1} region and several unfamiliar sharp bands in the near-ultraviolet region[9,14-16] which have never been found in the spectra of the ordinary chromium(III) complexes.

These unusual properties of the basic rhodochromic complex have been ascribed to the fact that the Cr–O–Cr system of the basic rhodochromic complex may be linear and, hence, may contain an extensive π-bond character, while the other red binuclear complexes in these series may have the bent Cr–OH–Cr bridging system.[1a]

Therefore, it is important to know the structural features of the basic rhodochromic complex, *i.e.*, the Cr–O–Cr angle, the Cr–O and Cr–N bond distances, *etc.* In the present work, in order to determine the structure of the basic rhodochromic complex, the relatively stable crystal of the basic rhodochromic chloride monohydrate, $[(NH_3)_5Cr\text{-}O\text{-}Cr(NH_3)_5]Cl_4\cdot H_2O$, was subjected to three-dimensional X-ray analysis. The single-crystal polarized absorption spectra of the basic rhodochromic perchlorate monohydrate, $[(NH_3)_5Cr\text{-}O\text{-}Cr(NH_3)_5](ClO_4)_4\cdot H_2O$, were also measured and found to be related to the orientation of the complex.

Experimental

X-ray Studies. Crystals of basic rhodochromic chloride monohydrate, $[(NH_3)_5Cr\text{-}O\text{-}Cr(NH_3)_5]Cl_4\cdot H_2O$, were prepared by Jørgensen's method.[2] When 7g of the rhodochromic chloride monohydrate, $[(NH_3)_5Cr\text{-}OH\text{-}Cr(NH_3)_5]Cl_5\cdot H_2O$, were dissolved in 50 m*l* of an ice-cold 2 N NH_3 aqueous solution, almost black crystals of basic rhodochormic chloride monohydrate were soon produced. Because the hydrolysis reaction of the complex takes place immediately in an aqueous solution, the crystallization has to be hastened, and so it is difficult to obtain large crystals. However, a few crystals with dimensions as large as about $0.15\times0.15\times0.10$ mm were found upon a carefull examination under a microscope of the crystals produced. The crystals exhibited some dichroism (blue—greenish blue)and were unstable to even ordinary levels of humidity, turning to red after a few days in the atmosphere of the laboratory. Therefore, the crystals were sealed in a Lindemann glass capillary and mounted on a goniometer. The changes in their color could not be observed for at least a week under these conditions. The oscillation and Weissenberg photographs indicated the crystals are orthorhombic, with unit cell dimensions of $a=11.94\pm0.01$, $b=11.71\pm0.01$, and $c=13.40\pm0.02$ Å, and that the Laue symmetry is mmm. The systematic absences—$0kl$ for $k=2n+1$, $h0l$ for $l=2n+1$, and $hk0$ for $h=2n+1$—are compatible with the *Pbca* space group. The density of the crystals observed by the flotation method was 1.58 g cm^{-3}, and the calculated one was 1.59 g cm^{-3} for $z=4$. The schematic drawing of the crystal related to its crystallographic axes is shown in Fig.1. For the intensity data collection, multiple-film equi-inclination Weissenberg photographs were taken around the *a* axis from zero through the 7th layer and around the *c* axis from zero through the 5th layer, changing the crystals, whose approximate dimensions were $0.15\times0.15\times0.10$ mm, for each layer. Ni-filtered CuK_α radiation was used. The intensities were estimated visually with a standard film strip; 811 independent reflections were thus obtained. Lorentz and polarization corrections were applied.

Spectroscopic Studies. For the measurement of the visible and ultraviolet absorption spectra of single crystals of a microscopic size, an apparatus was used constructed of a Hitachi EPS-3T spectrophotometer and a Nippon Kogaku POH polarizing microscope, together with two Olympus M090 reflecting-type objectives (×90). The microscope part of the apparatus was sealed in a stainless steel box and was evacuated to 10^{-3} mmHg for the studies at low temperatures. A thin plate of a single-crystal of the basic rhodochromic perchlorate monohydrate, prepared by Linhard's method[6] and of the approximate dimensions of 0.5×0.6 mm, was

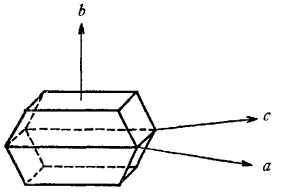

Fig. 1. Schematic drawing of a single crystal of $[(NH_3)_5Cr\text{-}O\text{-}Cr(NH_3)_5]Cl_4\cdot H_2O$ with reference to its crystallographic axes.

mounted on a fused quartz slide. This slide was placed on a copper stage and cooled to near the temperature of liquid nitrogen, and the absorption spectra were measured through the crystal on the aperture of the copper stage. By using a small amount of grease on the slide, the crystal was fixed with its faces upright; its thickness was estimated with a micrometer eyepiece to be about 2μ. A thermocouple indicated that the crystal was cooled to 90°K in the low-temperature studies.

Structure Determination

As there are four formula units, $[(NH_3)_5Cr\text{–}O\text{–}Cr(NH_3)_5]Cl_4\cdot H_2O$, in a unit cell, the space group symmetry (*Pbca*) requires the bridging oxygen atom of the complex to lie on a special position with inversion symmetry. Therefore, the binuclear basic rhodochromic complex should have a center of symmetry, and the Cr–O–Cr group should be strictly linear. The position of the chromium atom was deduced from a three-dimensional Patterson map. The chloride ions and the nitrogen atoms were easily located by a series of three-dimensional Fourier syntheses. After these atomic positions were refined by several cycles of block-diagonal-matrix least-squares refinement, the discrepancy factor, R, defined as $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$ was reduced to 0.21. At this stage, a difference Fourier synthesis was calculated to search for the position of the water molecule of crystallization, whose presence was also confirmed by infrared spectroscopy. A relatively low electron density peak was found at the general position of $x=0.04$, $y=0.44$, and $z=0.06$. Thus, the oxygen atom of the water molecule with a multiplicity of 0.5 was placed at this position, and after several cycles of the block-diagonal-matrix least-squares refinement with isotropic temperature factors, R was reduced to 0.15. Finally, a refinement using the anisotropic temperature factors for all atoms led to $R=0.14$ (0.11 for non-zero reflections). In the final least-squares refinement, the weights were assumed to be $w=1$ for $F_o\geq 3.6$ and $w=0.5$ for $F_o<3.6$. The final atomic coordinates and the temperature factors are given in Table 2, and their standard deviations are in Table 3. The observed and calculated structure factors are listed in Table 1. The atomic scattering factors used in the calculations were taken from the International Tables for X-ray Crystallography.[17] All the computations were done on a HITAC 5020E computer at the Computer Center of the University of Tokyo, using the library program system UNICS.

Results and Discussion

Crystal Structure. A perspective drawing of the basic rhodochromic ion is shown in Fig. 2. The bond distances and angles, with their standard deviations, are listed in Tables 4 and 5. The basic rhodochromic ion has the center of symmetry as already described;

Table 2. Final atomic coordinates and temperature factors

Anisotropic temperature factors are expressed in the form $\exp\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)\}$

therefore, the Cr–O–Cr oxygen bridging system is linear. Each N_1–Cr–N_2, N_2–Cr–N_3, N_3–Cr–N_4, and N_4–Cr–N_1 angle is nearly 90°, and the N_5–Cr–O angle is approximately 180°, as is shown in Table 5, the complex roughly has a four-fold rotation axis passing through a sequence of the N_5–Cr–O–Cr'–N'_5 atoms. Hence, the basic rhodochromic complex ion must have an approximately D_{4h} symmetry. Hewkin and Griffith[18] have reported, in their infrared spectroscopic studies of the binuclear transition metal complexes, that the basic rhodochromic complex chloride shows the absorption band assigned to the asymmetric stretching vibration of the Cr–O–Cr group at almost the same position as in the similar oxo-bridged binuclear complexes, $K_4[Cl_5Ru\text{-}O\text{-}RuCl_5]$[19] and $K_4[Cl_5Re\text{-}O\text{-}ReCl_5]$,[20] both of which have been confirmed to be of the D_{4h} symmetry by the X-ray method (Table 6). They also suggested that, in the case of the linearly oxygen-bridged transition metal binuclear complexes, the asymmetric stretching vibrations of the bridge atoms are almost independent of the mass of the metal atoms involved, assuming that the Cr–O–Cr group in the basic rhodochromic complex is linear. The results of the present X-ray work are consistent with these findings.

TABLE 6. INFRA-RED ABSORPTION DATA[a]

Complex	M-O-M asym. str.	M-O-M sym. str.
$K_4[Cl_5Ru\text{-}O\text{-}RuCl_5]\cdot H_2O$	866 cm^{-1}	226 cm^{-1}

$[(NH_3)_5Cr\text{-}O\text{-}Cr(NH_3)_5]Cl\cdot H_2O$	873	215

a) Date from ref. 18.

The Cr–O distance is 1.80 Å, which is quite short compared with the values found in the rhodochromic complex ion, $[(NH_3)_5Cr\text{-}OH\text{-}Cr(NH_3)_5]^{5+}$, (Cr–O 2.00 Å);[1a] it is comparable to that in $K_4[Cl_5Ru\text{-}O\text{-}RuCl_5]$ (Ru–O 1.80 Å) and in $K_4[Cl_5Re\text{-}O\text{-}ReCl_5]$ (Re–O 1.86 Å). Dunitz and Orgel[21], to explain the diamagnetic properties of $[Cl_5Ru\text{-}O\text{-}RuCl_5]^{4+}$, elucidated its electronic structure by means of a molecular orbital model, which allowed the unpaired electrons of ruthenium(IV) to couple through the bridging oxygen. The linear Cr–O–Cr system and its short bond distance certainly suggest the presence of an extensive π-bonding in this system, as in the ruthenium complex. The remarkably reduced magnetic susceptibilities and the unusual electronic spectra of the basic rhodochromic complex are certainly due to this π-bonding.

The basic aqueous solutions of the acido-erythrochromic complex salts show a characteristic blue color, although it fades out rapidly. The absorption spectra of these blue solutions,[13] similar to those of the basic rhodochromic complex ion, are characterized by one broad band in the visible region and several sharp bands in the near-ultraviolet region, indicating that these blue chemical species also contain the linear Cr–O–Cr system.

Several other binuclear transition metal complexes have been known to have a linear M–O–M group, as confirmed by the X-ray method. They are listed in Table 7, along with their M–O distances and M–O–M angles. All of them show the distinctive feature of the short M–O distance, strongly indicating the presence of the π-bonding character in these systems.

Some Cr–N bond distances of the basic rhodochro-

mic complex ion had been expected to be significantly longer than others, since a transformation reaction from the basic rhodochromic complex to the red basic erythrochromic complex takes place very rapidly in an aqueous solution, substituting an OH^- group for one of the ammonia molecules. Indeed, the $Cr\text{–}N_5$ distance (2.14 Å) was observed to be somewhat longer than the others. However, its difference from the other Cr–N distances (average value 2.10 Å) did not exceed three times the estimated standard deviation.

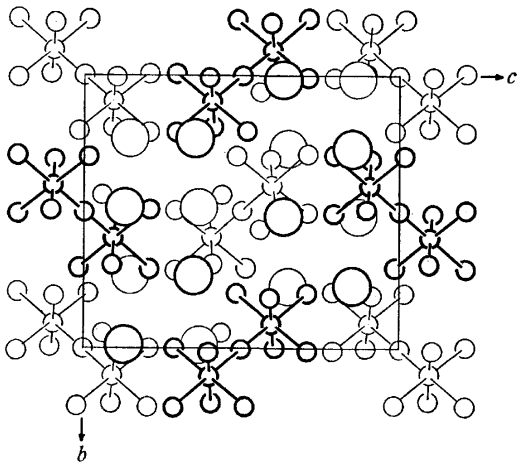

Fig. 3. Crystal structure viewed along the *a* axis.

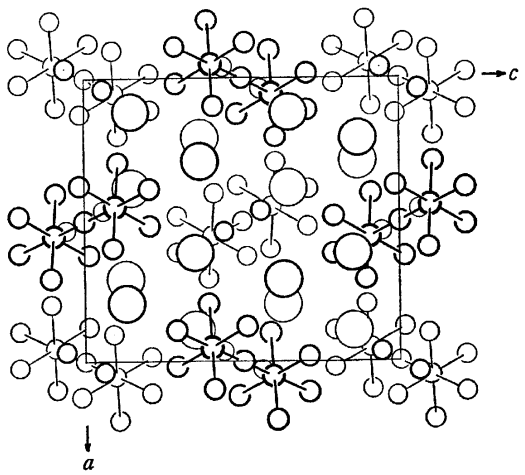

Fig. 4. Crystal structure viewed along the *b* axis.

The crystal structures viewed along the *a* and *b* axes are shown in Figs. 3 and 4 respectively. The complexes are arranged as shown in Fig. 4 by bold lines or fine lines, retaining the bridging oxygen atoms on the same planes, which are alternately piled up back to back, sliding along the *b* axis with a half unit for each layer. The chloride ions are packed into channels elongated along the *b* axis between these piles. The water of crystallization is located in the space surrounded by the six complex ions. The shortest $Cl^{-}\cdots N(NH_3)$ approach appears at a distance of 3.32 Å.

Visible and Ultraviolet Absorption Spectra. The visible and ultraviolet absorption spectra of the basic rhodochromic complex salts, which cannot be measured easily in an aqueous solution because of their rapid hydrolysis, have been studied by several methods, *e.g.*, the extrapolation of the aqueous solution spectrum,[14] the diffuse reflectance method,[9,15] the rapid-flow method,[13] and the microspectroscopic technique.[16,29]

As has already been stated, it has been found in these spectroscopic studies that the basic rhodochromic complex ion shows some unfamiliar sharp absorption bands in the near-ultraviolet region. Furthermore, Kondo[16] has pointed out that these sharp bands are strongly polarized, and recently Dubicki *et al.*[15] have found that some of these sharp bands disappear at the temperature of liquid nitrogen.

The crystal structure of the basic rhodochromic chloride monohydrate has been determined in the present X-ray studies; hence, it has become possible to relate the single-crystal polarized absorption spectra

of the complex salt to the orientation of the dimeric unit. Unfortunately, single-crystals of basic rhodochromic chloride monohydrate, although they exhibit a dichroism (blue through light polarized parallel to the *a* axis, greenish-blue through light polarized parallel to the *c* axis), are unsuitable for study by means of the microspectroscopic technique because of their shape (Fig. 1). However, a similar dichroism can be observed more distinctly in thin plates of the crystals of the perchlorate, and they *are* suitable for microspectroscopic study. As the color of the chloride crystal has already been related to the orientation of the complex. it seems reasonable to say that the absorption parallel to the four-fold rotation axis of the complex contributes greatly to the polarized absorption spectrum along the extinction direction of the perchlorate crystal that shows greenish-blue with polarized light having a parallel electric vector.

The single-crystal polarized absorption spectra of the basic rhodochromic perchlorate monohydrate along two extinction directions are shown in Fig. 5.

The absorption spectra at room temperature consist of two broad bands in the 16600 and 22000 cm^{-1} regions, of three strong sharp bands at 25350, 26630, and 29830 cm^{-1}, and of at least four weak sharp bands at 14320, 23920, 28010, and 28320 cm^{-1}. These sharp bands were found to be all polarized along the four-fold rotation axis of the complex, while the broad band in the 16600 cm^{-1} region seems to be slightly reduced in intensity along the four-fold rotation axis. When the crystal was cooled to about 90°K, a new band was revealed at 32400 cm^{-1}; it was found also to be polarized along the four-fold rotation axis. The intensity of the strong sharp band at 26630 cm^{-1} was considerably sensitive to the temperature, as has already been pointed out by Dubicki *et al.* It had almost disappeared in the 90°K spectrum, implying that this band originated from the thermally-excitable electronic level above the ground state.

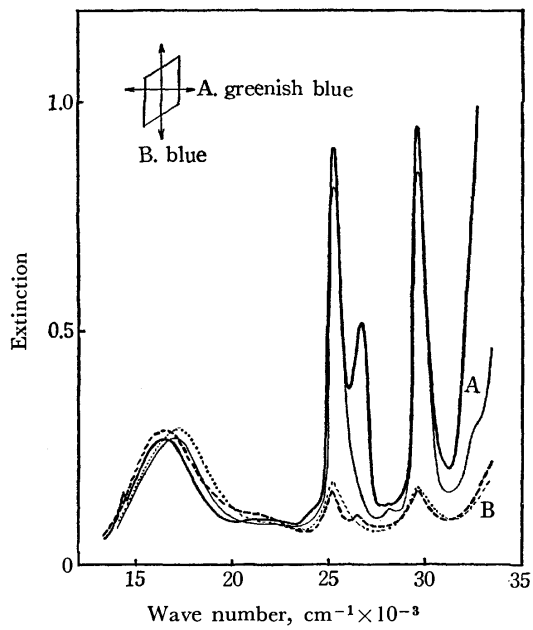

Fig. 5. Polarized absorption spectra of the basic rhodochromic perchlorate, $[(NH_3)_5Cr\text{-}O\text{-}Cr(NH_3)_5](ClO_4)_4 \cdot H_2O$. —— and ----: at room temperature, —— and ·····: at 90°K

The electronic spectra of the basic rhodochromic complex are very difficult to characteriz. Furthermore, no other polynuclear transition metal complexes have been found to show sharp absorption bands similar to those of the basic rhodochromic complex. If the electronic structure of the basic rhodochromic complex can be described in terms of the molecular orbital model,[15,21] the ordering of the molecular orbitals of the binuclear complex of D_{4h} symmetry can be expected to be;

$$e_u,\ (b_{2g},\ b_{1u},\ e_g),\ e_u^*.$$

These orbitals should be filled with ten electrons in the case of the basic rhodochromic complex. That the relative energies of the non-bonding b_{2g}, b_{1w}, and e_g orbitals are not known makes the problem very complicated. Recently, Schmidtke[30] has described the electronic structure of the basic rhodochromic complex in further detail, assuming the complex to have a D_{4h} or D_{4d} symmetry; he has pointed out that the d_z^2 orbitals of the metals should be coupled with the oxygen p_z orbital in either symmetry case to produce a higher-energy anti-bonding a_{2u} orbital than these molecular orbitals. He assigned the sharp band at 25350 cm^{-1} to the electronic transition from the metal-localized b_{2g} or b_{1u} orbital to the delocalized a_{2u}^* orbital with some vibrational structures, and the band at 29830 cm^{-1} to that from the metal-localized e_g orbital to the delocalized a_{2u}^* orbital.

However, that the intensity of the band at 26630 cm^{-1} is considerably sensitive to the temperature compared with that of the band at 25350 cm^{-1} leads to some confusion. If the same excited state is concerned, the "hot" band should appear on the lower-wavenumber side of the band from the ground state. Thus, as Dubicki has suggested, it seems that some selection rule, perhaps the spin one,[31] has a strong influence upon the appearance of the absorption spectra in this region. These electronic transitions are possibly coupled with some vibrational modes of the complex. The results of the present polarized spectroscopy indicate that each direct product of the representations of the (vibronic) wavefunctions of the ground state and the excited state concerned with these sharp bands should contain not E_u but A_{2u}. Only such conditions can lead to the *z* polarization of the absorption bands of the complex in the D_{4h} symmetry.

The author wishes to express his thanks to Professor Yukio Kondo, Professor Masayoshi Nakahara, and Dr. Teruo Nomura of Rikkyo University for their helpful discussions and encouragement throughout the course of this work.

Vibrational Spectra of *trans-trans* Diacetamide and Its C- and N-Deuterated Compounds

Yoshihiro KURODA, Yutaka SAITO, Katsunosuke MACHIDA, and Toyozo UNO
Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto,
(Received March 24, 1972)

The infrared spectra of $CH_3CONHCOCH_3$, $CD_3CONHCOCH_3$, $CD_3CONHCOCD_3$, and their N-deuterated compounds have been recorded for the unstable crystalline modification in which the molecules are in the *trans-trans* conformation (form B). The Raman spectra of $CH_3CONHCOCH_3$ in the form B crystal and in the complex with KI have also been recorded. Vibrational assignments have been given by referring to the characteristic group frequencies of related compounds, the infrared dichroic measurement for $CH_3CONHCOCH_3$ and the isotopic frequency shifts. The normal coordinates analysis has been made by assuning the planar *trans-trans* conformation of the –CONHCO– (–CONDCO–) group. The calculated frequencies fit to the observed satisfactorily.

The rotational isomerism of the imide (–CONHCO–) group has been found for diacetamide, the first member of the homologous series of aliphatic acyclic imides.[1,2] In the usually occuring crystalline modification, form A, and in the concentrated solutions in non-polar solvents, diacetamide takes the *trans-cis* conformation, in which one of the C=O bonds is at the *trans* position and the other at the *cis* position with respect to the central NH bond. The more symmetric *trans-trans* conformation is taken, on the other hand, by molecules in another crystalline modification, form B, which is unstable at room temperature. Previously, the in-plane normal frequencies of *trans-trans* diacetamide and the corresponding *N*-deuterated derivatives were calculated on a simplified model in which the methyl groups were taken as point masses.[3] However, more detailed investigations for both the *trans-trans* and the *trans-cis* conformations are necessary to discuss how the force constants of the –CONHCO– group are affected by the change of molecular environments on the interconversion of the conformation. In succession to the recently reported vibrational analysis of *trans-cis* diacetamide,[4,5] the present paper deals with the infrared and Raman spectra of *trans-trans* diacetamide and the infrared spectra of its C- and N-deuterated derivatives. Most of the fundamental frequencies have been assigned and the normal coordinate calculation has been made by assuming a Urey-Bradley force field supplemented by the general valence force constants for C–C and C–N torsions and the C=O and N–H out-of-plane deformations. The force constants have been refined by the least squares method to give the best agreement between the observed and the calculated frequencies. The C=O and C–N stretching force constants of the *trans-trans* and *trans-cis* molecules reflect well the difference in the type of hydrogen bonds between the form A and form B crystals.

Experimental

The preparation and N-deuteration of $CH_3CONHCOCH_3$ and $CD_3CONHCOCD_3$ were described in our preceding paper.[4] In the present work, $CD_3CONHCOCH_3$ was also synthesized from CH_3COND_2 and CD_3COCl by the same method that was used to synthesize $CD_3CONHCOCD_3$.[4] The NMR spectrum of the obtained specimen revealed that it contained a small amount of the CHD_2 and CH_2D species. However, this specimen exhibited no indication of infrared absorptions due to such isotopic impurities, and the infrared spectra of $CD_3CONHCOCH_3$ and $CD_3CONDCOCH_3$ were used as references for the interpretation of the vibrational spectra of diacetamide. The recrystallization from water, which is the previously described method to prepare the form B crystal,[1] resulted mostly in the formation of the form A crystal for the material used in this work. Instead, the slow crystallization from the melt in a sealed glass tube was found to lead effectively to the formation of the form B crystal. For Nujol mulls of the samples prepared as described above, the infrared spectra were measured on a Koken DS-301 infrared spectrophotometer (4000—700 cm^{-1}), on a Perkin-Elmer Model-521 grating spectrophotometer (900–250 cm^{-1}) and on a Hitachi FIS-3 grating spectrophotometer (400—33 cm^{-1}). In the region where the absorptions of Nujol appear, hexachlorobutadiene was used as the mulling medium for $CH_3CONHCOCH_3$ and $CH_3CONDCOCH_3$,

but hexachlorobutadiene could not be used for the C-deuterated compounds since the transition to the form A crystal took place very quickly in this medium. It was found previously that diacetamide mixed with NaBr, NaI, and KI shows similar infrared spectra to the form B crystal.[6] Recently, Roux *et al.* have confirmed by the X-ray analysis that diacetamide takes the *trans-trans* conformation on forming the complex with NaBr and KI.[7] Since the form B crystal of the C-deuterated compounds were found to be very unstable even in Nujol mulls, infrared spectra of the complex with KI were used to check the absorptions due to the *trans-cis* molecules. Occasionally, the form B crystal was obtained by the slow crystallization form the melt inserted between two KBr plates. One of these solid films of CH_3-

$CONHCOCH_3$ was found to contain a small portion of the oriented crystal by the inspection under a polarization microscope. The infrared dichroic measurement for this sample has been made on a Perkin-Elmer Model-521 grating spectrophotometer with a wire-grid polarizer in the region between 1100 and 350 cm^{-1} (Fig. 1). All the wave numbers were calibrated by the standard absorptions of polystyrene, indene, ammonia, and 1, 2, 4-trichlorobenzene. The Raman spectrum of the form B crystal of $CH_3CONHCOCH_3$ obtained from the melt sealed in a capillary tube was recorded on a JEOL JRS-O1A laser Raman spectrophotometer. The exciting line (4880Å) was generated by an argon-ion laser at an approximate output power of 250 mW. The Raman spectrum of a mixed pellet of $CH_3CONHCOCH_3$ and KI was measured on a JRS-U1 laser Raman spectrophotometer with the excitation source of a 400 mW argon-ion laser (4880Å). The observed infrared and Raman frequencies are listed in Table 1.

Vibrational Assignment

On the assumption of the *trans-trans* planar conformation, the C-undeuterated and the fully C-deuterated diacetamides belong to the point group C_{2v}, and should contain 30 infrared active fundamental transitions, $12(a_1)+11(b_2)+7(b_1)$, while the remaining $6(a_2)$ normol modes are infrared inactive. All of the fundamental transitions of the half C-deuterated diacetamides, which have the C_s symmetry, should be infrared active. There is no Raman inactive transition for both the C_{2v} and the C_s molecules. The X-ray analysis by Roux and Boeyens[7] has revealed that the –CONHCO– group of diacetamide in the diactamide-KI (2 : 1) complex is only slightly distorted from the *trans-trans* planar conformation. Since the infrared spectrum of this complex and that of the form B crystal of diacetamide are almost identical with each other, it is reasonable to assume that diacetamide molecules in the form B crystal have essentially the same conformation as those in the KI complex.

The characteristic infrared absorptions of the *trans*-CONHCO-group observed in the region above 1150 cm^{-1} are the NH stretching doublet at 3260 and 3180 cm^{-1}, the imide I (a_1 C=O stretching) band at 1730 cm^{-1} and the imide II and III bands.[2] The last two bands arise from the coupled vibrations of the NH in-plane bending and CN stretching. All these bands were observed similarly for the C-deuterated compounds, and were used to check the formation of the form B crystal throughout this work. The diminishing of the imide II and III bands and the appearance of the imide II′ band (CN stretching) on the N-deuteration are clearly recognized for the fully C-deuterated compounds, for which no interference by the CH_3 absorptions is expected in the region between 1450 and 1350 cm^{-1} (see Fig. 2).

The assignment of infrared absorptions of *trans-trans* $CH_3CONHCOCH_3$ below 1150 cm^{-1} were much facilitated by the dichroism observed for the thick oriented specimen of the form B crystal described in the experimental section. By analogy with the X-ray analysis of dipropionamide, which takes the *trans-trans* conformation in the crystlline state,[8] *trans-trans* diacetamide is thought to form chain polymers by means of the bifurcated hydrogen bond, retaining the two-fold axis in the direction of chains along which the crystal grows. We may accordingly expect that the direction of crystal growth is parallel to the transition moment of a_1 vibrations but is perpendicular to those of b_1 and b_2 vibrations. The medium band at 1030 cm^{-1} of $CH_3CONHCOCH_3$ was assigned previously to the a_1, b_1, and b_2 CH_3 rocking vibrations.[3] In accord with this assignment, the dichroic measurement disclosed three components, one of which was observed at 1030 cm^{-1} for the parallel polarization of the incident radiation, while the others, a peak at 1027 cm^{-1} and a shoulder at 1070 cm^{-1}, for the perpendicular polarization. Since the initial calculation in the normal coordinate analysis gave the b_1 CH_3 rocking frequency about 50 cm^{-1} higher than the b_2 frequency, we assigned the shoulder near 1070 cm^{-1} and the peak at 1027 cm^{-1} to the b_1 and b_2 CH_3 rocking vibrations, respectively. On the N-deuteration, the intensity of the 1030 cm^{-1} band is reduced appreciably, and two weak bands

8) T. Uechi, T. Watanabé, and K. Osaki, *Sci. Rep.* (*Osaka Univ.*) **15**, 1 (1966)

appear nearly at 1094 and 947 cm^{-1}. This spectral change has been ascribed to the coupling between the b_2 CH_3 rocking and the ND in-plane deformation vibrations.[3] The b_1 CH_3 rocking absorption of $CH_3CONDCOCH_3$ could not be identified (Fig. 3).

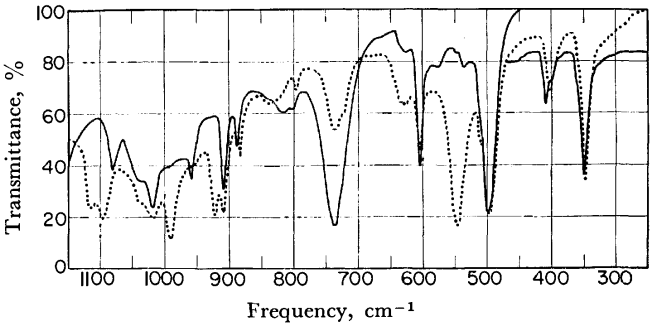

Fig. 4. Infrared spectra of $CD_3CONHCOCH_3$ (solid line) and $CD_3CONDCOCH_3$ (dotted line) in the region between 1150 and 250 cm^{-1}.

From analogy with the cases of CD_3CONH_2 and *trans-cis* $CD_3CONHCOCD_3$,[4,9] the infrared bands at 1087 and 1030 cm^{-1} of *trans-trans* $CD_3CONHCOCD_3$ are assigned to the CD_3 symmetric (a_1 and b_2) and asymmetric (a_1, b_1, and b_2) deformation vibrations, respectively. The *N*-deuteration gives rise to two additional bands at 1120 and 1011 cm^{-1}, which indicate that one of the b_2 CD_3 deformation vibrations couples with the ND in-plane deformation vibration. The half C-deuterated compound, $CD_3CONHCOCH_3$ shows two weak bands at 1079 and 1018 cm^{-1} and a shoulder band at 1038 cm^{-1} (see Fig. 4). According to the normal coordinated analysis, there is no appreciable coupling between the CH_3 and the CD_3 group vibrations, and the band at 1079 cm^{-1} and the shoulder at 1038 cm^{-1} are assigned respectively to the a' CD_3 symmetric and asymmetric deformation vibrations, while the band at 1018 cm^{-1} is assigned to both the a' CH_3 rocking and the a'' CD_3 asymmetric deformation vibrations. On the N-deuteration, the half *C*-deuterated compound shows a spectral change between 1150 and 950 cm^{-1} which is similar to that observed for the fully C-deuterated compound. The occurence of the coupling between the ND in-plane deformation vibration and the CH_3 or CD_3 deformation vibrations of $CH_3CONDCOCH_3$, $CD_3CONDCOCH_3$, and $CD_3CONDCOCD_3$ was confirmed by the normal coordinates analysis, and the assignments of the infrared absorptions of the N-deuterated compounds in this region were given reasonably by referring to the calculated frequencies.

Diaceamide has two C–C stretching vibrations, the intrinsic frequency of which is estimated to be near 900 cm^{-1} from analogy with acetamide[9] and *N*-methylacetamide.[10] So we assigned first the parallel and perpendicular components of the band at 920 cm^{-1} of $CH_3CONHCOCH_3$ to the a_1 and b_2 C–C strecthing vibrations, respectively. According to the mormal coordinates analysis, however, the a_1 mode responsible for this band is rather complex, consistimg of the CN stretching, the CH_3 rocking and the C–N–C deformation vibrations. The calculated a_1 and b_2 frequencies are very close to each other just as are observed. On the N-deuteration, the band at 920 cm^{-1} is replaced by a weak band at 900 cm^{-1}, which may be assigned to analogous vibrations. The infrared spectrum of $CD_3CONHCOCD_3$ between 1000 and 700 cm^{-1} is much more complicated than that of $CH_3CONHCOCH_3$, since the CD_3 rocking frequencies occur in this region. There are five bands in all, among which the bands at 972 and 868 cm^{-1} shift to 955 and 842 cm^{-1}, respectively, while those at 909 and 819 cm^{-1} shift hardly on the N-deuteration. By referring to the calculated frequencies, we assigned the 972 cm^{-1} band to the complicated a_1 vibration corresponding to that related to the 920 cm^{-1} band of $CH_3CONHCOCH_3$, and the 868 cm^{-1} band to the b_2 C–C stretching vibration. The N-deuteration insensitive bands at 909 and 819 cm^{-1} were assigned to the b_1 and b_2 CD_3 rocking vibrations, respectively. The remaining a_1 CD_3 rocking frequency was calculated to be 756 cm^{-1}. The corresponding absorption seems to be overlapped by the broad band at 734 cm^{-1} due to the NH out-of-plane deformation (imide V) vibration. For $CH_3CONHCOCH_3$, this imide V band shows the perpendicular dichroism just as expected for the b_1 species.

In the region between 700 and 300 cm^{-1}, *trans-trans* diacetamide is expected to have five infrared active fundamentals due to the a_1, b_1, and b_2 C=O deformations and the a_1 and b_2 C–C–N deformations, but the form B crystal of $CH_3CONHCOCH_3$ shows only four bands at 626, 526, 418, and 368 cm^{-1} for the unpolarized radiation. Previously, the band at 626 cm^{-1} was assigned to the a_1 and b_1 C=O deformation vibrations, based on the appearance of an additional band at 640 cm^{-1} on the N-deuteration.[1] The band at 640 cm^{-1} observed previously for the form B crystal of $CH_3CONDCOCH_3$ is missing, however, in the newly recorded spectra in this work, and is considered to be due to the contaminated *trans-cis* compound. Instead, the Raman spectra of the form B crystal and the KI-complex of $CH_3CONHCOCH_3$ recorded

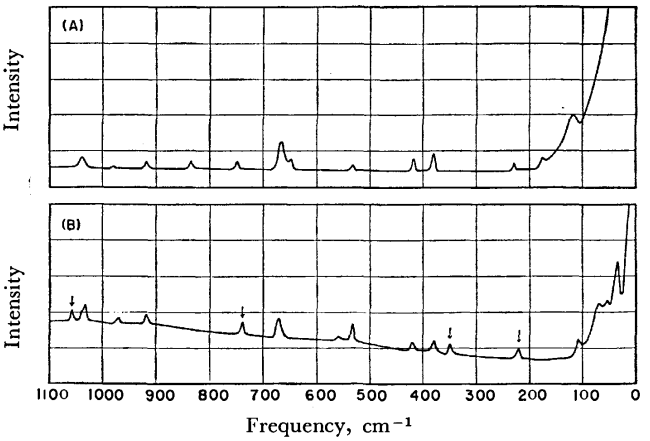

Fig. 5. (A) Raman spectrum of $CH_3CONHCOCH_3$-KI complex in the region between 1100 and 0 cm^{-1}. (B) Raman spectrum of $CH_3CONHCOCH_3$ in the region between 1100 and 0 cm^{-1}. (↓): Ar^+

10) J. Jakes and B Schneider, *Collect. Czech. Chem. Commun.* **33**, 643 (1968).

in this work (Fig. 5) exhibited a very strong band near 673 cm^{-1} hardly assignable to non-totally symmetric fundamentals. Correspondingly, the infrared dichroic measurement revealed the presence of a weak band at 661 cm^{-1} appearing only for the parallel polarization of the incident radiation(Fig.1). The difference of 12 cm^{-1} between the Raman and infrared frequencies may be ascribed to a factor group splitting. Based on this result, the assignment of the a_1 C=O deformation (imide IV) frequency in the infrared spectrum should be revised from 626 cm^{-1} to 661 cm^{-1}. According to the normal coordinates analysis, the contribution of the C-C stretching vibration to this fundamental is also large, explaining well the prominent intensity of the Raman band at 673 cm^{-1}.

The infrared bands at 626, 526, and 418 cm^{-1} show the perpendicular dichroism and are assigned to the b_1 C=O deformation (imide VI), b_2 C=O deformation (imide IV) and the b_2 C–C–N deformation vibrations, respectively. The assignments of the bands at 526 and 418 cm^{-1} to b_2 fundamentals are supported by the appearance of a weak infrared band at 945 cm^{-1}, which shows the parallel dichroism and is assignable to the combination tone, 526+418. The remaining infrared band at 368 cm^{-1} shows the parallel dichroism and is assigned undoubtedly to the a_1 C–C–N deformation vibration. In the Raman spectra, three bands are observed near 530, 420, and 380 cm^{-1} corresponding to the infrared bands at 526, 418, and 368 cm^{-1}, but no Raman counterpart is observed for the infrared band at 626 cm^{-1}. This result is reasonable since out-of-plane fundamentals are usually weak in Raman spectra. It is difficult to explain why the infrared band at 626 cm^{-1} does not shift on the N-deuteration, whereas the normal coordinates analysis predicts a high-frequency shift of 10 cm^{-1} for the b_1 C=O deformation vibration. For the $CH_3CONHCOCH_3$-KI complex, the corresponding infrared band at 621 cm^{-1} shifts to 626 cm^{-1} on the N-deuteration, reflecting a small interaction between the ND and the C=O deformation vibrations in the b_1 species. The assignments of the infrared bands due to the skeletal deformation vibrations of the C- and N-deuterated diacetamide were made by referring to the result for $CH_3CONHCOCH_3$ and taking account of the isotope shifts. The infrared band due to the a_1 imide IV vibration of the C- and the N-deuterated compounds could not be identified probably because of its extreme weakness. In the infrared spectrum of the form B crystal of $CD_3CONHCOCD_3$ in Fig. 6, the bands at 587 and 523 cm^{-1} are due to the *trans-cis* molecules formed by the partial transition from the form B to the form A crystal. Similarly, the bands of *trans-cis* $CD_3CONDCOCD_3$ appear at 620, 587, and 521 cm^{-1} in Fig. 6.

In analogy with the case of *trans-cis* diacetamide, the infrared bands due to the C–N and the C–C torsional and C–N–C deformation vibrations are expected in the region below 300 cm^{-1}. We assigned the broad band centered at about 250 cm^{-1} and the very weak band at 160 cm^{-1} of the form B crystal of $CH_3CONHCOCH_3$ to the b_1 C–N torsional and the a_1 C–N–C deformation vibrations, respectively (Fig. 7). In consistent with the calculated isotope effect, the former band undergoes a low-frequency shift by about 10 cm^{-1}, while the latter remains unshifted on the *N*-deuteration. In the Raman spectrum of $CH_3CONHCOCH_3$-KI complex, the corresponding bands were observed at 227 and 177 cm^{-1}. For both $CH_3CONHCOCH_3$ and $CH_3CONDCOCH_3$, the infrared absorption due to the b_1 C–C torsional vibration is thought to overlap with a lattice absorption, giving rise to the peak at 95 cm^{-1}, since the form B crystal of CD_3COND-

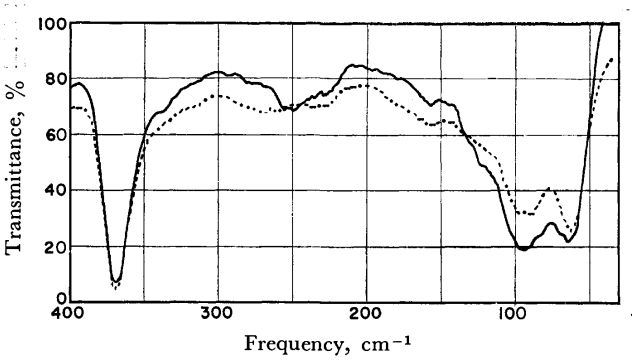

Fig. 7. Infrared spectra of $CH_3CONHCOCH_3$ (solid line) and $CH_3CONDCOCH_3$ (dotted line) in the region between 400 and 33 cm^{-1}.

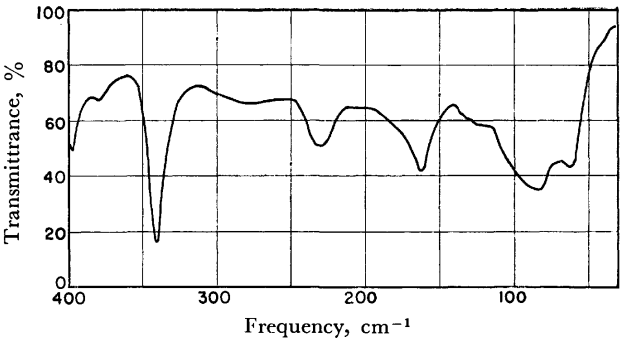

Fig. 8. Infrared spectrum of $CD_3CONDCOCD_3$ in the region between 400 and 33 cm^{-1}.

$COCD_3$ shows the corresponding peak at 80 cm^{-1} (Fig. 8). No isotope shift is observed for the infrared band at 65 cm^{-1} of the form B crystal. This band is missing in the spectra of the form A crystal, and is assigned undoubtedly to lattice vibrations. The infrared band due to the C–N torsional and the C–N–C deformation vibrations of the C-deuterated diacetamides in the *trans-trans* conformation could not be detected because of the interference of the bands due to the *trans-cis* molecules.

Normal Coordinates Analysis

In order to check the internal consistency of the present assignments of the fundamental frequencies of various isotopic molecules and to obtain a reliable set of force constants, the normal coordinates treatment has been made for *trans-trans* diacetamide and its C- and N-deuterated compounds. The internal symmetry coordinates were written down in the same way as the case of *trans-cis* diacetamide,[4,5] since we included the half C-deuterated molecules having the C_s symmetry in the calculation. The meanings of the symmetry coordinates are listed in Table 2. The secular equations were set up according to the GF matrix method.[11] We used a Urey-Bradley force field for the in-plane vibrations and the out-of-plane vibrations concerning the methyl groups and a valence force field for the remaining out-of-plane vibrations. The starting set of the Urey-Bradley force constants was the same as that used in the calculation for *trans-cis* diacetamide.[4] The diagonal valence force constants were transferred from acetamide[12] and *trans-cis* diacetamide,[5] while the off diagonal valence force constants were assumed to be zero first. The isotope shifts predicted by the initial calculation were useful to pick up some of the empirically unassignable fundamentals of the N- and the C-deuterated compounds. The force constants for the in-plane vibrations were refined in an analogous way to the case of *trans-cis* diacetamide,[4] until an overall

convergence of force constants was attained. On the refinement of the out-of-plane force constants, the Urey-Bradley force constants for the methyl groups were fixed to the converged values in the in-plane calculation, and the valence force constants were adjusted by referring to the Jacobian matrix and repeating the least squares method by parts. The final values of force constants are given in Table 3, and the calculated frequencies are listed in Tables 4—9 together with the dominant terms in the potential energy distribution and the assignments. The reliability of the presently obtained force constants may be ascertained from the agreement between the observed and the calculated frequencies. The potential energy distributions in Tables 4—9 show that the coupling among the skeletal deformation vibrations is considerable. For the C-deuterated compounds, the CD_3 rocking vibrations also participate in this coupling, explaining well the fact that the C-deuteration gives rise to much larger shifts of the skeletal deformation frequencies than the N-deuteration. In Table 10, the stretching force constants obtained in the present work are compared with those of the *trans-cis* diacetamide reported before (Calculation II in Ref. 4). In the form A crystal, only the *cis*-CONH- group of *trans-cis* diacetamide is involved in the hydrogen bonds, and accordingly K(CO)(*trans*) is larger than K(CO)(*cis*) and K(CN)(*trans*) is smaller than K(CN)(*cis*). The presently obtained values of K(CO) and K(CN) of *trans-trans* diacetamide fall between the values of the corresponding *trans-* and *cis-*constants of *trans-cis* diacetamide. This result is reasonable since the C=O and the C–N bonds involved in the bifurcated hydrogen bonds of the form B crystal are expected to have intermediate bond orders between the unassociated and the normally hydrogen-bonded cases.

A Molecular Orbital Calculation of Chemically Interacting Systems. Addition of Singlet Methylene to Ethylene

Hiroshi FUJIMOTO, Shinichi YAMABE, and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received March 31, 1972)

A semi-empirical self-consistent-field molecular orbital calculation of the addition of singlet methylene to ethylene was carried out on the basis of an isolated molecule approximation. The calculation was made with respect to two modes of approaches of methylene to ethylene which were proposed by Hoffmann. A calculation of the electron populations by use of the configuration interaction wave function showed that singlet methylene added to ethylene double bond in an electrophilic fashion with a quasi-synchronous formation of two σ bonds to yield cyclopropane. The present calculation revealed the important roles of the interaction between the highest occupied molecular orbital of ethylene and the lowest unoccupied molecular orbital of methylene and of the interaction between the highest occupied molecular orbital of methylene and the lowest unoccupied molecular orbital of ethylene, in interpreting the formation of new σ bonds between ethylene and methylene and the disappearance of the π bond of ethylene.

Molecular orbital (MO) theory has achieved a fair success in interpreting the orientation and stereoselection in various sorts of chemical reactions.[1,2] In dealing with chemical reactions by MO methods, there exist two kinds of approaches. One is to apply MO methods, regarding the whole system composed of two reacting species as if it were one molecule, while the other intends to express the energy and the electron populations of a reacting system by use of the MO's which are obtained with respect to the two reactants in their isolated states. Although the application of the latter approach is usually limited to the cases of weak interaction, it is capable of providing us with some basic information on the nature of chemical reactions. Murrell and his collaborators extended the theory of long range force to the interaction with small orbital overlap and divided the interaction energy into several terms.[3] Their theory has been applied to some weak interactions, such as hydrogen bonding and molecular complexes.[4,5] In one of our previous papers, we have discussed the interaction energy between two reacting systems, by partitioning it into the Coulomb, exchange, delocalization, and polarization terms and have pointed out the importance of the delocalization interaction in promoting reactions.[6] An investigation of the delocalization energy has led us to a supposition that the interaction between the highest occupied (HO) MO of one reactant and the lowest unoccupied (LU) MO of the other reactant is almost solely responsible for the determination of the favorable paths of a majority of chemical reactions.[7] The concept of the HOMO-LUMO interaction now seems to be a well established and powerful means to disclose the detailed mechanisms of chemical reactions.[8-10] It is interesting to examine how such particular orbital interaction explains bond formation, bond loosening and charge-transfer, since these are characteristics of chemical reactions.

In this paper, we show the results of calculation on the addition of singlet methylene to ethylene. This reaction was studied by Hoffmann mainly from an energetic viewpoint, using the extended Hückel MO method.[11] Therefore, it will be a test of our configuration interaction (CI) approach to chemical reactions to compare our result with that of Hoffmann.

Interaction between Two Systems

In order to calculate the electron distribution of chemically interacting system of two molecules, by use of the MO's obtained for each of them in an isolated state, we proceed in the following way; (1) we make a self-consistent-field (SCF) calculation on each of the two reactants separately and determine the MO's, (2) we construct the Slater determinantal wave functions for the combined system which represent the original and charge-transferred electron configurations, using the MO's obtained in (1), and (3) then we calculate the wave function for the lowest energy state of the interacting system by solving the secular equation by the usual CI procedure of the electron configurations given in (2), with respect to a given nuclear framework of the system composed of the two reactants.[12]

The wave function of the interacting system is ap-

proximately given by;

$$\Psi = C_0\Psi_0 + \sum_i^{occ}\sum_l^{uno} C_{i\to l}\Psi_{i\to l} + \sum_k^{occ}\sum_j^{uno} C_{k\to j}\Psi_{k\to j} \quad (1)$$

where Ψ_0 is the original electron configuration with the adiabatic interaction, $\Psi_{i\to l}$ is the charge-transferred state in which an electron in the ith occupied MO of one reactant is shifted into the lth unoccupied MO of another, and $\Psi_{k\to j}$ is the charge-transferred state in the converse fashion. The symbols $\sum^{occ}$ and $\sum^{uno}$ imply the summation over all the occupied and unoccupied MO's respectively. The local-excited states are less important than the charge-transferred states and can be neglected in a first approximation.[12]

Calculation on Isolated Reactants

The MO's of ethylene and methylene were calculated by a semi-empirical all valence-electrons SCF MO method as before.[13] The nuclear configurations of these species were chosen as the same as those adopted by Hoffmann.[11] The calculated MO energy levels of ethylene and methylene are shown in Fig. 1. The

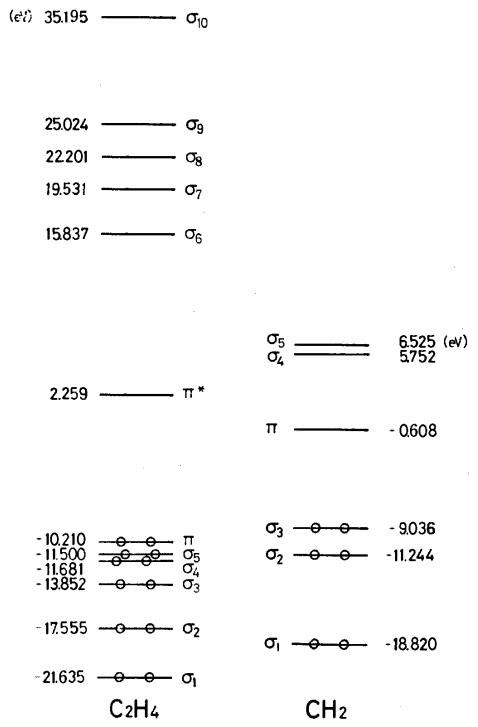

Fig. 1. MO energy levels of ethylene and methylene.

calculated ionization potential of ethylene is 10.2 eV, which is 0.2~0.4 eV smaller than the observed values.[14] The HOMO of methylene is a lone-pair like orbital and the LUMO is a purely p atomic orbital (AO) of the carbon atom. We tentatively term the MO's as shown in Fig. 1.

Electron Populations

Hoffmann proposed two modes of approaches of methylene to ethylene.[11] Those are schematically illustrated in Fig. 2 in order to define the variables and

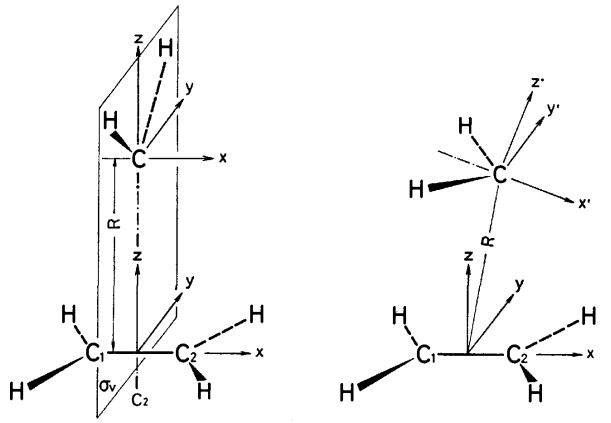

Fig. 2. A schematic representation of assumed reaction models.

coordinates. In Model I, methylene approaches ethylene on the C_2 principal axis, directing the lone-pair orbital toward ethylene. In Model II, the carbon atom of methylene locates away from the bisecting axis of the ethylene C–C bond. We follow the paths suggested by Hoffmann.[11] In this context, we distinguish each model only by specifying the value of R in Fig. 2. It is convenient to choose different Cartesian coordinate systems for methylene and for ethylene in Model II as shown in Fig. 2. The integrals which are necessary for the calculation of the matrix elements of the secular equation were estimated in the same way as in our previous calculation.[13]

Table 1 gives the coefficients of the CI wave function, C_0, $C_{i\to l}$'s and $C_{k\to j}$'s in Eq. (1), for the lowest root of the secular equation, with respect to Models Ia (R=3.0 Å), IIa (R=3.0 Å), and IIb (R=2.85 Å). By comparing Models Ia and IIa, it is clear that the mixing in of charge-transferred electron configurations is much more effective in the latter than in the former. In Models IIa and IIb, the most dominant term except Ψ_0 is the charge-transferred electron configuration from the HOMO of ethylene to the LUMO of methylene, and the next dominant is the one from the HOMO of methylene to the LUMO of ethylene. Comparison of these two models elucidates that the mixings of the charge-transferred electron configuration from the HOMO of ethylene to the LUMO of methylene and of the one from the HOMO of methylene to the LUMO of ethylene become more and more dominant over other charge-transferred electron configurations with the progress of the reaction.

The electron densities of the combined system of ethylene and methylene are given by

$$\rho(1) = M\int \Psi^*(1,2,\cdots,M)\Psi(1,2,\cdots,M)d\xi_1 d\tau_2\cdots d\tau_M \quad (2)$$

where M is the total number of electrons of the system

i and j denote the MO's of ethylene and k and l stand for those of methylene.

composed of ethylene and methylene (=18). By calculating the terms appearing in Eq. (2) separately, we can disclose the origin of the formation of the intermolecular σ bonds between ethylene and methylene and of the disappearance of the π bond of ethylene. This is an advantage of the present CI method over the usual variational approaches to chemically interacting systems. In order to visualize this circumstance, we show the results of calculation on Models Ib and IIc in which R is 2.7 Å. Figure 3 shows the electron densities of Model IIc in the x–z cross section at $y=0$. Figure 3 (a) indicates the simple sum of the electron densities of ethylene and methylene without interaction and Fig. 3 (b) shows the electron densities of the state of adiabatic interaction, ρ_0. It is noted that the electron densities in the intermolecular region between ethylene and methylene in the Ψ_0 state decrease in comparison with $\rho_{CH_2}+\rho_{CH_2CH_2}$, due to the electron exchange interaction in that state. This is essential to the interaction between two closed shell systems.[12,15] Figure 4 demonstrates ρ. By comparing Figs. 3 and 4, it is clear that the mixing of charge-transferred electron configurations into Ψ_0 is of importance in interpreting the chemical bond formation

between ethylene and methylene, as well as the weakening of the π bond of ethylene. Figure 5 shows the electron densites in Ψ' state, in which only the charge-transfer interaction from the HOMO of ethylene into the LUMO of methylene and that from the HOMO of methylene into the LUMO of ethylene are taken into consideration. Comparison of Figs. 4 and 5 indicates that the changes in the electron densities due to the mixing in of charge-transferred electron configurations are almost covered by only introducing the HOMO-LUMO interactions. This signifies the mobility of π electrons in case of chemical reactions and suggests the pertinency of the π electrons approximation in discussing the chemical reactivity of conjugated molecules.[1,2] In this calculation, the nuclear configuration of ethylene was kept unchanged. As ethylene loses its planarity with the progress of the reaction, the $\sigma-\pi$ interaction takes place.[16] The σ part and the π part of ethylene will also mix through the orbital overlap interaction with the MO's of methylene.

Figure 6 shows the electron densities of Model Ib. The left of the vertical line presents the simple sum of the electron densities of ethylene and methylene and the right gives the electron densities of the interacting state, ρ. We can see that the bond formation between ethylene and methylene is not effective, indicating the disadvantage of such an approach of methylene to ethylene as Model I. This conclusion is consistent with the results of the extended Hückel MO calculation by Hoffmann.[11]

Figure 7 shows the changes in atomic populations and in atomic bond populations of ethylene and methylene due to the interaction with respect to Models Ia and IIa. We can see that ethylene becomes positively charged, while methylene gets negatively charged in Model II. This agrees with the experimental observations that singlet methylenes add to olefinic double bonds in an electrophilic fashion.[17] Both of the atomic bond populations between the carbon of methylene and the carbons 1 and 2 of ethylene are positive, demonstrating a synchronous character of

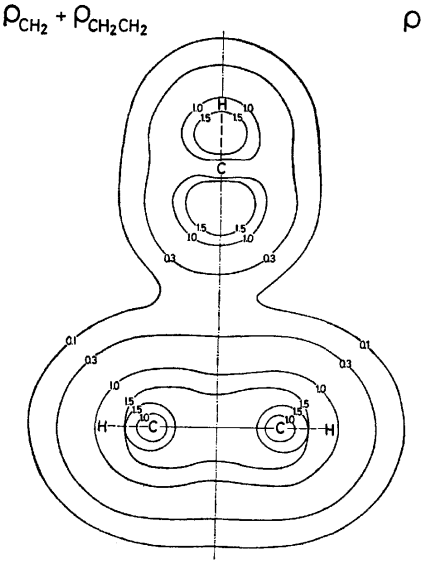

Fig. 6. Electron densities of Model I in the $x-z$ cross section at $y=0$.

this reaction.

Here let us investigate the mode of charge-transfer in some details. As has been mentioned above, there exist two modes of charge-transfer, *i.e.*, from ethylene to methylene and the converse. Tables 2 and 3 give the changes in AO populations of ethylene and of methylene, due to the charge-transfer from ethylene to methylene and from methylene to ethylene, with respect to Model IIa. The values in the second column in Table 2 indicate the changes in the electron populations of the AO's of ethylene by the charge-transfer from ethylene to methylene, and those in the third column are the changes in the AO populations due to the charge-transfer from methylene to ethylene. Table 3 can be similarly understood. The negative values in the columns of accepted electrons in Tables 2 and 3 may appear strange at first sight. This is

caused by the negative intermolecular overlap population of the AO t (t belongs to the molecule A), which is not recovered by the increase in intramolecular populations of that AO, in case of the electron delocalization from the molecule B to the molecule A.[12] We can recognize that the apparent changes in AO populations are only overall results of mutual electron donating and electron accepting interactions. This may be a characteristic feature of chemical interaction between two electronically neutral systems. The AO bond populations between the AO's of ethylene and the AO's of methylene are given in Table 4 with respect to Model IIa. The results indicate that the most contributing term to the bond formation is the combination of the $p\pi$ orbitals of ethylene and the vacant p orbital of methylene. Table 5 shows the changes in the AO bond populations of the C–C bond of ethylene. We can see that the weakening of the π bond is conspicuous, although the σ bond remains almost unchanged. Tables 4 and 5 may be helpful to understand how the double bond of ethylene is converted into the single bonds with methylene in the course of the addition of singlet methylene to ethylene.

Conclusion

We have made an approximate MO calculation on the addition of singlet methylene to ethylene by an isolated molecule CI method. The electron populations of the system, composed of ethylene and methylene, have been calculated by use of the SCF MO's of the two species. The results of the present calculation have proved the important role of the HOMO-LUMO interactions in determining the favorable path of the addition of singlet methylene to ethylene. The analysis of the electron populations

has demonstrated an interesting feature of chemical interactions between two electronically neutral systems that stronger electron donating and electron accepting interactions take place than simply expected from the apparent changes in electron populations. The present calculation suggests that the CI approach to chemically reacting systems is promising for a better understanding of the mechanisms of chemical reactions.

It is a pleasure to express our gratitude to the Data Processing Center, Kyoto University for its generous permission to use the FACOM 230-60 computer.

Dipole Moment Functions of CO and HCl

Isao SUZUKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo

(Received April 11, 1972)

A general formalism is presented for the least-squares determination of dipole moment functions of diatomic molecules in which the radial part wave functions obtained as numerical solutions of vibration and vibration-rotation Hamiltonian matrix are used. Although this approach is purely numerical, the advantage of using orthonormal basis and perturbed wave functions is retained. Attempts have been made on the determination of the cubic dipole moment functions for the CO and HCl molecules. All the available data of dipole as well as transition moments and the Herman-Wallis factors for these molecules are considered in the refinement process. The following cubic dipole moment functions are obtained (in Debye): $M(\Delta r)=0.1243-3.0722(\Delta r)+0.1909(\Delta r)^2+2.1856(\Delta r)^3$ for CO and $M(\Delta r)=1.093+0.949(\Delta r)+0.034(\Delta r)^2-0.78(\Delta r)^3$ for HCl.

Dipole moment of a diatomic molecule in a given electronic state solely depend on its internuclear distance and can be expressed as $M(r)$. It is customary to expand $M(r)$ in a power series around the equilibrium distance r_e,

$$M(r)=\sum_{k=0} M_k(r-r_e)^k=\sum_{k=0} M_k(\Delta r)^k \qquad (1)$$

Equation (1) may be rewritten by using dimensionless normal coordinate $q=(\omega_e/2B_e)^{1/2}(\Delta r/r_e)$

$$M(q)=\sum_{k=0} p_k q^k, \qquad (2)$$

where $p_k=M_k r_e \gamma^{1/2}$ and $\gamma=(2B_e/\omega_e)$. The diagonal matrix element

$$\mu_{vJ}=\langle v, J|M(q)|v, J\rangle \qquad (3)$$

represents the dipole moment of a vibration-rotation state (v,J), where $|v,J>$ is the wave function for the radial part Schrödinger equation, while the intensity of a vibration-rotation line $(v,J\rightarrow v',J')$ is proportional to the square of matrix element

$$R_{vJ}^{v'J'}=\langle v' J'|M(q)|v, J\rangle. \qquad (4)$$

The total intensity of a vibrational transition $(v\rightarrow v')$ is related with the rotationless matrix element

$$R_v^{v'}=\langle v'|M(q)|v\rangle, \qquad (5)$$

where $|v>=|v,0>$. Similarly, Eq. (3) is reduced to

$$\mu_v=\langle v|M(q)|v\rangle. \qquad (6)$$

Therefore, the coefficients p_k in Eq. (2) can be determined from the measured infrared intensities or dipole moments, provided that accurate wave functions are known for the vibration-rotation states involved. In a previous paper,[1] a method was given in which the vibration or vibration-rotation levels of a diatomic molecule are related with the harmonic and anharmonic force constants by solving the vibrational Hamiltonian numerically. It was emphasized that a set of orthonormal wave functions is readily obtained as linear combinations of the harmonic oscillator basis functions through numerical diagonalization,[2]

$$|v\rangle=\sum_{n=0} a_{vn}|n\rangle \text{ and } \sum_{n=0} a_{vn}a_{v'n}=\delta_{vv'} \qquad (7)$$

As described in I, the coefficients a_{vn}'s for the low lying vibrational states have been determined very accurately from the hexic and octic potential functions respective for the CO and HCl molecules. These results are combined with the recent measurements of infrared line intensities and of dipole moments to determine the dipole moment functions for these molecules. An effort has been made to collect and evaluate as many relevant data as possible.

Determination of Dipole Moment Function

A number of attempts have been made to determine the dipole moment functions of diatomic molecules. The previous works have been summarized by Young and Eachus,[3] who calculated the dipole moment matrix elements for the CO molecule by a purely numerical method, in which the radial part Schrödinger equation is solved by a computer program. The resultant wave functions were used to compute $R_v^{v'}$ and $R_{vJ}^{v'J'}$. Recently, Toth, Hunt, and Plyler[4] have calculated the same matrix elements by

1) I. Suzuki, This Bulletin, **44**, 3277 (1971); Hereafter referred to as I.

2) The indices n and m are used to indicate the harmonic oscillator wave functions $\varphi_n^0(q)$ and $\varphi_m^0(q)$, and v and v' refer to the true (perturbed) vibrational states. Symbols and notations used in this paper are given in I.

3) L. A. Young and W. J. Eachus, *J. Chem. Phys.*, **44**, 4195 (1966).

4) R. A. Toth, R. H. Hunt, and E. K. Plyler, *J. Mol. Spectrosc.*, **32**, 74, 85 (1969).

an analytical method with the cubic dipole moment function and the quintic potential function, the second-order perturbation method being used. These authors have extended their calculation to the HCl molecule, the third-order perturbation theory was used in this case.[5] More recently, Kaiser[6] has analyzed the molecular beam electric resonance spectra of HCl and and DCl, and obtained very precise values of dipole moments for a few vibration-rotation states. He has used the 'wave function approximation' to compute the coefficients M_0—M_4 from the RKR potential.

Our present approach is to use the coefficients a_{vn}'s ($v \leq 4$) for CO and HCl which have been determined precisely by the numerical diagonalization of the vibrational Hamiltonian matrix. Although this method is purely numerical as the RKR approach, we can take full advantage of the orthonormal property of the basis and the perturbed wave functions. This seems to be very useful for practical purpose. It will be shown later that the radial part wave function for the vibration-rotation state (v,J) is also expressed as

$$|v, J> = \sum_{n=0} b_{vn}{}^J |n>. \tag{8}$$

Equations (3)—(6) may be written by using Eqs. (7) and (8),

$$\mu_{vJ} = \sum_{k=0} p_k \sum_{n=0} \sum_{m=0} b_{vn}{}^J b_{vm}{}^J \langle m|q^k|n\rangle, \tag{9}$$

$$R_{vJ}{}^{v'J'} = \sum_{k=0} p_k \sum_{n=0} \sum_{m=0} b_{vn}{}^J b_{v'm}{}^{J'} \langle m|q^k|n\rangle, \tag{10}$$

$$\mu_v = \sum_{k=0} p_k \sum_{n=0} \sum_{m=0} a_{vn} a_{vm} \langle m|q^k|n\rangle, \tag{11}$$

$$R_v{}^{v'} = \sum_{k=0} p_k \sum_{n=0} \sum_{m=0} a_{vn} a_{v'm} \langle m|q^k|n\rangle, \tag{12}$$

The matrix element $<m|q^k|n>$ is well-known (see, for example, Table A-1 in I), and its value can be generated in a computer by a subroutine OPERQ ($k \leq 8$). The coefficients a_{vn} and $b_{vn}{}^J$ are evaluated through numerical diagonalization, it is much simpler to use Eqs. (9)—(12) for the evaluation of the dipole and transition moments. This is the method we have used throughout this study.

Herman-Wallis Factors $C_v{}^{v'}$ and $D_v{}^{v'}$. It was first recognized by Herman and Wallis[7] that the vibration-rotation transition moment, $R_{vJ}{}^{v'J'}$ is related with the rotationless transition moment $R_v{}^{v'}$ as

$$\begin{aligned} |R_{vJ}{}^{v'J'}|^2 &= |R_v{}^{v'}(m)|^2 = |R_v{}^{v'}|^2 F_v{}^{v'} \\ &= R_v{}^{v'}|^2 (1 + C_v{}^{v'} m + D_v{}^{v'} m^2 + \cdots), \end{aligned} \tag{13}$$

where $m = -J$ for P-branch and $m = J+1$ for R-branch. In the present study, the Herman-Wallis factors are used as input data, instead of using numerous vibration-rotation transition moments.

Numerical Computations. The numerical computations have been carried out on a HITAC 5020E computer of the Computer Centre in the University of Tokyo, double precision arithmetic (64 bits) being used.

Input Data. For the determination of the dipole moment function, *i.e.* the coefficients M_k's, we

have tried to use all the available data on the dipole and transition moments, those on the isotopic species being included.[8] The data used in the present study for the CO and HCl molecules are listed respectively in Tables 1 and 2. The relative weights of these data are estimated from the quoted values of error limits and are also included in Tables 1 and 2.

Potential Functions. Throughout the present study, the results with the hexic potential function for CO (Set 9) and the octic potential function for HCl (Set 10) given in I are used. The coefficients a_{vn}'s were obtained numerically from the above potentials, and the matrix elements of the form

$$\langle v|q^k|v'\rangle = \sum_{n=0} \sum_{m=0} a_{vn}a_{v'm}\langle n|q^k|m\rangle \qquad (14)$$

are computed. Numerical values of the relevant matrix elements are listed in Tables 3 and 4 respective for CO and HCl, the values of force constants are reproduced at the bottom of each table.

Evaluation of Coefficient $b_{vn}{}^J$. In order to calculate $R_{vJ}{}^{v'J'}$ and μ_{vJ},$b_{vn}{}^J$ in Eq. (8) must be known. This may be done by two different ways. Since the wave function $|v>=|v,0>$ is known, the perturbation method may be applied;

$$|v,J> = |v> + \sum_{v'\neq v}{}' H_{vv'}{}^{(1)}|v'>/(E_v{}^o - E_{v'}{}^o) \qquad (15)$$

where

$$H_{vv'}{}^{(1)} = \langle v'|H_{ROT}|v\rangle = B_eJ(J+1)\times \sum_{k=1} R_k \sum_{n,m=0} a_{vn}a_{v'm}\langle m|q^k|n\rangle, \qquad (16)$$

from which $b_{vn}{}^J$ is obtained after appropriate normalization.[9] Another method to obtain the coefficients $b_{vn}{}^J$ is the direct diagonalization of each vibration-rotation submatrix. The coefficients are directly obtained by solving the J-submatrices.[10] The above methods have been applied to evaluate the coefficients $b_{vn}{}^J$ for the CO and HCl molecules. The coefficients $b_{0n}{}^J$ and $b_{1n}{}^J$ calculated for the J=0, 10, 20, and 30 levels of the HCl molecule are listed in Table 5. Apparently, the perturbation technique breaks down about J=10. The coefficients obtained by the direct numerical diagonalization method are used in the present investigation. No significant discrepancies

8) The treatment for the isotopic species was described in I.

9) See Eq. (4) in I. The term with k=0 vanishes from orthogonality.

10) The entire vibration-rotation Hamiltonian matrix is factored into a number of submatrices characterized with the quantum number J, since no cross terms occur in H_{ROT} with regard to J.

have been found for the coefficients of the CO molecule, and the both methods yield almost identical results up to $J=30$.

Results and Discussion

It was reported by Toth *et al.*[4] that their analytical method for the CO molecule gave the identical results with those calculated by the numerical method of Young and Eachus.[3] We have also checked our method by feeding the M_k values given by Young and and Eachus, and obtained the identical results for the transition moments R_0^1, R_0^2, and R_0^3. The M_k values given by Toth *et al.*[6] for the HCl molecule have also been tested. Again we can reproduce their calculated results with the exceptions of C_0^3 and D_0^3. This is, however, somewhat expected, since we included higher order force constants in our potential, and as we reported in I, this effects is prominent in the wave function related with the $v=3$ level : $|3,J>$.

The least-squares adjustment for the coefficients p_0—p_3 has been done for the CO and HCl molecules by using the experimental data in Tables 1 and 2, the results being included in the same tables.[11] Table 1 shows that the four parameter dipole moment function can fit the ten experimental data of CO with an exception of D_0^3, to which the contributions of the neglected higher terms in the dipole moment function are large. In the last column of Table 1, indicated as calcd(2), are listed the calculated values when the p_3 term is omitted from the dipole moment function. This is done to demonstrate the effect of the p_3 term, and it is easily seen that the p_3 term contributes significantly to the moments related with the $v=3$ level. The converged values of p_0 through p_3 are not very much different from those obtained previously. However, one comment must be made on the value of p_0.

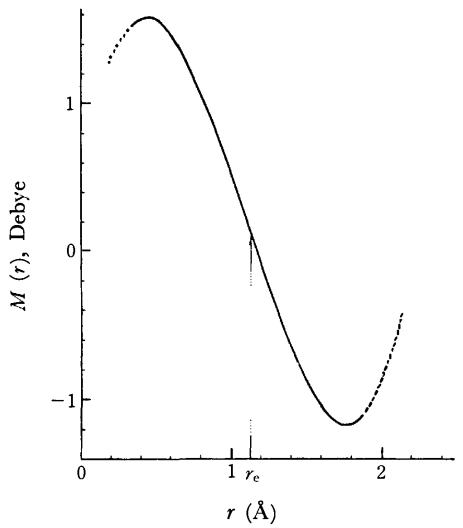

Fig. 1. The cubic dipole moment function of CO.
$M(\Delta r)=0.1243-3.0722(\Delta r)+0.1909(\Delta r)^2+2.1856(\Delta r)^3$
$M(q)=0.1243-0.1465\,q+0.000434\,q^2+0.000237\,q^3$

11) The value p_0 is taken as positive in the present calculation, since only the relative signs among the coefficients $p_k(M_k)$ have physical significance.

The previous calculations were made on the assumption of $p_0=\mu_0$, the dipole moment of the ground vibrational state. As seen from Eq. (9) and Tables 3 and 4, this assumption is obviously incorrect, the higher coefficients also contribute to μ_0. Consideration of this fact makes the value of p_0 about 10% higher than given previously, since p_1 has an opposite sign in CO. The dipole moment function around its equilibrium distance r_e is plotted in Fig. 1.

In the case of HCl and DCl, we have also used the cubic dipole moment function with four parameters to fit the eighteen independent data listed in Table 2. The agreement between the calculated and experimental data is much improved as compared with those previously done. As expected, the discrepancies are rather large for the values of C_0^3 and D_0^v's to which, again, the larger contributions from the neglected higher terms are expected. The converged values of p_k are converted to coefficients M_k and are listed in Table 6 along with those obtained by previous work-

Table 6. The coefficients of dipole moment function, M_k, of HCl determined by several investigators

	Present		Kaiser (Ref. 6)		THP (Ref. 5)
	(a)	(b)	HCl	DCl	
M_0(D)	1.093	1.094	1.093_3	1.092_2	1.095
M_1(D/A)	0.949	0.939	0.925	0.935	0.905
M_2(D/A^2)	0.034	−0.087	0.08	0.07	−0.066
M_3(D/A^3)	−0.78	−0.55	−0.64	−0.63	−0.73
M_4(D/A^4)	—	—	−0.39	−0.32	—

ers. There is a discrepancy in the previous works as to the sign of M_2; Toth *et al.*[5] gave the value of −0.066 D/A^2 to M_2, whereas Kaiser[6] gave 0.08 and 0.07 D/A^2 respectively for HCl and DCl. As we started the least squares procedure with $M_0=1.095$ D, $M_1=1.0$D/A, $M_2=M_3=0$, we have obtained a converged set, Set(a), given in the first column of Table 6. However, if we started from the values given in Ref. 5, we obtain the second converged set, Set(b), in the second column. The calculated dipole and transition moments as well as the Herman-Wallis factors are given respectively in Columns 3 and 4 in Table 2. Overall fit of the calculated results with the experiment is better in Set (a), which seems to be a natural choice. In order to draw firmer conclusion, however, more experimental data are necessary, because most disagreements between the calcd(b) and experimental values occur in the constants to which the higher terms in the dipole moment function which are neglected in the present study may well contribute significantly. The present calculation is performed within the framework of the Born-Oppenheimer approximation, although the deviations from the Born-Oppenheimer behavior are detected in Kaiser's precise measurement of dipole moments for HCl and DCl, this effect is too small for the separate determination of dipole moment functions of both species. In addition, more complex treatment is necessary for the potential functions.[12] The present

calculation gives the somewhat averaged results for p_k's.

Finally, the dipole moment function for HCl, Set (a), is plotted against the internuclear distance in Fig. 2. Figure 3 is also the plot of the same function close to the equilibrium distance in an enlarged scale. The positions of the average internuclear distances in the $v=0$, 1, and 2 levels: $\langle\bar{r}\rangle_0$, $\langle\bar{r}\rangle_1$, and $\langle\bar{r}\rangle_2$, and the dipole moments of μ_0, μ_1, and μ_2 are indicated by arrows. Since in the linear dipole moment function,

Photochemical Reactions of *p*-Benzoquinone Complexes with Aromatic Molecules

Satoshi ARIMITSU* and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received April 14, 1972)

Electronic absorption spectra and ESR spectra have been measured for the photolyzed charge transfer complexes between *p*-benzoquinone and aromatic donors in low temperature matrices. When the *p*-benzoquinone complex with toluene or *p*-xylene was irradiated at 77°K, an electronic absorption spectrum attributable to the semiquinone radical was obtained together with that of the benzyl-type radical. The spectral shape and position of the former are somewhat different from those of the semiquinone radicals obtained by the photolysis of *p*-benzoquinone or hydroquinone. These differences indicate the presence of interaction between semiquinone and benzyl-type radicals. The ESR spectra obtained from these systems show that these radicals form pairs in the triplet ($S=1$) state. It is concluded that the radical pairs are produced as a result of intermolecular hydrogen atom transfer from the aromatic donor molecule to *p*-benzoquinone in the excited states of the CT complexes formed between them. The irradiations of various *p*-benzoquinone complexes were carried out in the wavelength regions corresponding to the lowest CT absorption bands at 77°K, and the reactivities were discussed in relation to the electronic structures and geometrical configurations of the CT complexes in the excited states. From the analysis of ESR spectra, the fine structure constant was evaluated for each of the radical pairs, from which the average distance between interacting unpaired electrons was calculated.

Studies on the chemical behaviors of charge transfer (CT) complexes have presented some informations for understanding the reaction paths in which CT complex are involved.[1] In view of the electronic nature of the CT interaction, it is understood that the complexes in the states are generally the precursors of ionic reactions. It was found by Leonhardt and Weller that flash illumination of a solution of peryline and *N,N*-dimethylaniline in a polar solvent leads to the formation of perylene anion.[2] Thereafter, it has been shown for

aromatic donor-acceptor systems that the formation of ionic species *via* the CT complexes in the excited states is a general phenomenon.[3] Recently, the ionic dissociation processes of excited CT complexes were studied by the nano-second laser photolysis.[4]

We have found that the photoreduction of benzophenone proceeds easily in low temperature rigid matrices containing aniline derivatives, leading to the formation of radical-pair between ketyl and aromatic amine radicals in the triplet state.[5] Since the photoreduction of benzophenone does not take place apprecibly in ordinary organic matrices at 77° K, we have proposed that the formation of electron donor-acceptor complexes of benzophenone with aromatic amines enhances the photoreduction of benzophenone. In order to obtain further information on the roles of CT interactions in such chemical reactions, we have made a detailed study on the photochemistry of *p*-benzoquinone complexes in low temperature rigid matrices.

It is well known that *p*-benzoquinone forms stable CT complexes with various aromatic compounds.[6] Photoreductions of *p*-benzoquinone and its derivatives yield the semiquinone radicals in the hydrogen-donating solvents.[7] In the present paper, we have examined the photo-chemical reactivity of *p*-benzoquinone complexed with various electron donors. The electronic absorption and emission spectra of these complexes and the ESR spectra of the photolysis products have also been studied.

Experimental

Materials. Both *p*-benzoquinone (BQ) and hydroquinone were purified by repeated recrystallization from ethanol and sublimation in vacuum. Toluene, *p*-xylene, mesitylene, *p*-methylanisole, α-methylnaphthalene, and *N,N*-dimethyl-*p*-toluidine were purified by fractional distillation under ordinary or reduced pressure. β-Methylnaphthalene and *p*-toluidine were purified by vacuum sublimation. The organic solvents used in the present work, 2-methyltetrahydrofuran (2-MTHF), ether, ethanol, and isopentane, were purified by the methods described in our previous papers.[5,8]

Apparatus. Photolysis was carried out with a 500-W super high pressure mercury lamp combined with various Toshiba glass filters in order to select the excitation wavelengths corresponding to the first CT absorption band of BQ complexes. All samples examined in this work were degassed by the usual freeze-pump-thaw technique. All experiments were performed at the temperature of liquid nitrogen. The instruments used for the measurements of emission and absorption spectra in the ultraviolet and visible region, and the ESR spectra are the same as described in our earlier paper.

Results

Electronic Absorption and Emission Spectra of BQ Complexes. The electronic spectrum of BQ shows an (n,π^*) band in the visible region and the lowest (π,π^*) band in the near ultraviolet region.[9] Apart from these bands, the electron donor-acceptor interactions between BQ and aromatic donors cause CT absorption bands. Both the maxima and the onset positions for the CT bands observed in 2-MTHF matrix at 77° K are summarized in Table 1, showing clearly that they shift to lower frequencies with decreasing ionization potentials of donor molecules.

The emission spectra of BQ complexes with toluene, mesitylene, and *p*-methylanisole are shown in Fig. 1. In the low temperature rigid matrix containing only BQ, a weak emission was found visually by high intensity excitation, but the emission was so weak that no spectrum could be recorded. As is seen in Fig.1, the

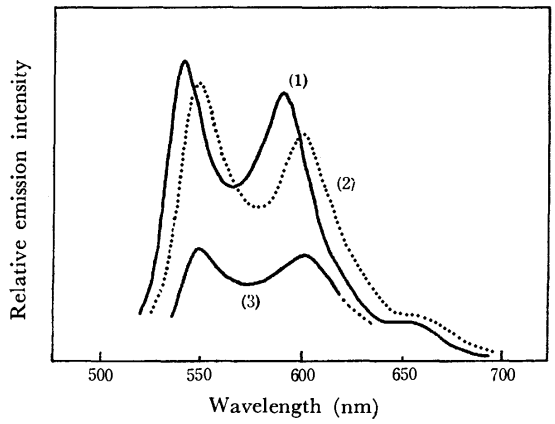

Fig. 1. Emission spectra of BQ complexes with aromatic donors in 2-MTHF at 77°K: 1) toluene; 2) mesitylene; 3) *p*-methylanisole.

emission maximum shifts slightly to longer wavelength as the ionization potential of donor molecules decreases. The phosphorescence spectra of BQ and its complexes with toluene and mesitylene were measured at low temperature by Briegleb *et al.*[10] The results obtained in the present work agree well with theirs. Since the shapes and band positions of the emission spectra obtained for the CT complexes are very much similar to those of BQ, the phosphorescent states of these complexes are most probably the modified locally excited $^3(n,\pi^*)$ state of BQ. Similar phosphorescence spectra have been observed for the BQ complexes with *p*-xylene, α-methylnaphthalene, and β-methylnaphthalene. In the case of CT complexes with *p*-toluidine and *N,N*-dimethyl-*p*-toluidine, no emission could be observed.

Absorption Spectra of BQ Complexes Irradiated at 77°K. Electronic absorption spectrum obtained after the photolysis of BQ in an ethanol rigid matrix is shown by curve a in Fig.2. A similar spectrum was observed after the photolysis of hydroquinone in ethanol.[11] Therefore, it is unambiguously concluded that these absorptions are ascribed to the semiquinone radical, in agreement with the assignment of previous authors.[12] When hydroquinone in a mixed (1:1) solvent of toluene and ethanol was photolyzed at 77° K, the absorption spectrum of semiquinone radical as shown by curve b in Fig.2 was obtained. The spectrum is a little broader than that in pure ethanol at 77°K. When BQ-toluene complex was irradiated in the wavelength region corresponding to the CT absorption band at 77° K, a spectrum shown by curve c in Fig.2 was obtained, by subtracting the absorption before irradiation. It seems reasonable to attribute the visible absorption to the semiquinone radical and the near ultraviolet absorption to the benzyl radical.

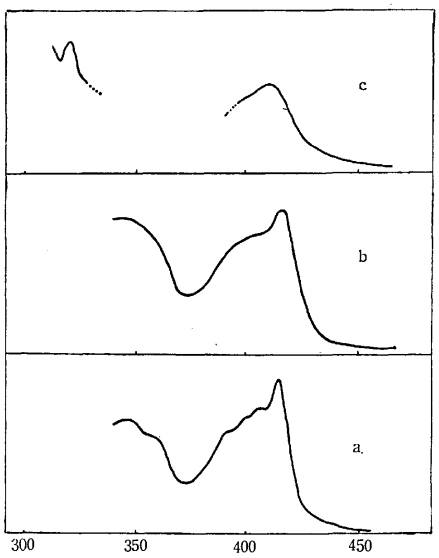

Fig. 2. Electronic absorption spectra of semiquinone radicals obtained after the photolysis of BQ and hydroquinone in low temperature rigid matrices: a, BQ in ethanol at 77°K; b, hydroquinone in toluene and ethanol (1 : 1) at 77°K; c, BQ in toluene and ethanol (1 : 1) at 77°K.

BQ–*p*-xylene complex shows a CT absorption maximum at 360 nm in an EPA (5 parts ether, 5 parts isopentane, 2 parts ethanol) rigid matrix. When it was subjected to irradiation in the range from 350 to 400 nm at 77° K, the absorption of semiquinone radical appeared gradually. At the same time, the CT absorption faded and the absorption attributable *p*-methylbenzyl radical also appeared. No spectral change was detected by the illumination of *p*-xylene in an EPA solution at the same wavelength region at 77° K.

ESR Spectra of BQ Complexes Irradiated at 77°K. A typical ESR spectrum obtained after the photolysis of the CT complex of BQ and *p*-methylanisole is shown in Fig.3. The spectrum consists of a weak band at a low magnetic field and stronger bands showing large splittings centered at a magneitc field twice as large as that for the weak one. In our previous study on the photochemistry of benzophenone in aromatic amine solutions, we found that the ESR spectra obtained after the irradiation of benzophenone–aromatic amine systems can be attributed to the radical pair in the triplet state ($S=1$).[5] The ESR spectrum shown in Fig. 3, together with those obtained from other BQ complexes, agrees well with them, and unambigously indicates that similar radical pairs are produced.

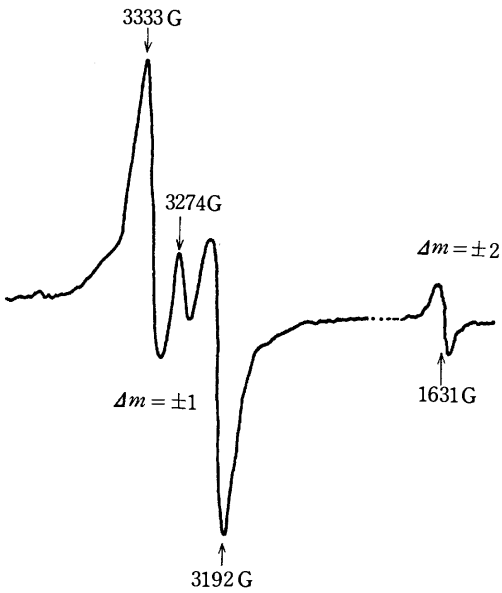

Fig. 3. An ESR spectrum of BQ-*p*-methylanisole complex in 2-MTHF irradiated at 77°K. ($\nu=9147$ MHz.)

When BQ was irradiated at 77° K, the ESR spectrum obtained shows only the absorption signals due to free radicals at the $g=2$ region, attributable to the semiquinone and solvent radicals. From these experimental results, it is established that the absorption spectra are due to radical pairs produced by the intermolecular hydrogen transfer from donors to BQ. Photolysis of the BQ complexes with toluene, *p*-xylene, mesitylene, and α-methylnaphthalene also showed similar ESR spectra. In the case of BQ–β-methylnaphthalene, it has been suggested by the ESR measurement that the hydrogen transfer reaction does not take place appreciably, only radical absorption appearing at the $g=2$ region. In BQ–*p*-toluidine and BQ–*N*,*N*-dimethyl-*p*-toluidine systems, no ESR signal could be found by excitation of the lowest CT absorption band, indicating no photochemical reaction. From the electronic absorption measurements, it was also established that

the absorption intensity of the CT bands of these systems did not change detectably throughout the irradiation.

We can evaluate the fine structure constants (D) from the spin-spin splittings of the $\Delta m = \pm 1$ transitions of the ESR spectra obtained. The fine structure constants obtained from the separation corresponding to D are listed in Table 1, together with the average distance (R) between two unpaired electrons, calculated from these constants by using a point-charge-density approximation.[13]

Discussion

It can be seen in Table 1 that the frequencies of the charge-transfer bands arising from the interaction between the aromatic donor and BQ shift to the longer wavelength with decreasing ionization potentials of the donor molecules. As to the photochemical behaviors, the CT complexes of BQ can be classified into two groups. The complexes with toluene, *p*-xylene, mesitylene, α-methylnaphthalene, and *p*-methylanisole belong to group A and those with *p*-toluidine and *N,N*-dimethyl-*p*-toluidine to group B. The photoreduction of BQ takes place in group A, but not in group B. In group A, the CT state is higher than the lowest triplet state in each system, characterized as the locally excited $^3(n,\pi^*)$ state of BQ, as indicated by the measurements of emission spectra. The lowest excited singlet states of BQ complexes in group A have mainly the nature of either the CT state or the locally excited $^1(n,\pi^*)$ state of BQ. In group B, on the other hand, the lowest triplet state is not the $^3(n,\pi^*)$ state of BQ but mostly of the CT nature, as suggested by the emission spectral measurements, and the lowest excited singlet state is also the CT state. Therefore, it can safely be concluded that the distinction between photochemical behaviors of group A and B can be explained on the basis of the different electronic structures in the lowest triplet states of these complexes. Consequently, it is concluded that the hydrogen trasnfer reaction of BQ complexes occurs in the lowest triplet states of the CT complexes characterized by the (n,π^*) state of BQ.

Another possible alternative for the photochemical reaction mechanism for the BQ complexes is the initial electron transfer from the donor molecule to BQ, followed by the proton transfer. This seems unlikely, however, because such a reaction should be favorable in the cases of stronger CT complexes such as BQ–*p*-toluidine and BQ–*N,N*-dimethyl-*p*-toluidine systems, contrary to our experimental results.

As shown in Table 1, the fine structure constants of radical pairs are different from complex to complex. It can be concluded from these results that the intermolecular hydrogen transfer occurs from the donors, not from the solvent, to BQ in the low temperature matrices, leading to the formation of the radical pair in the triplet spin state, because, if the hydrogen transfer reaction were to occur from the solvent molecule to BQ, the fine structure constant should be the same in all cases.

It is interesting to note that the photochemical reaction of these complexes is affected critically by the position of the methyl-group in the donor molecules. For example, the CT complex of BQ–α-methylnaphthalene excited in the wavelength region of the CT absorption band shows an ESR spectrum arising from the triplet radical pair, but the spectrum attributable to the semiquinone and solvent radicals were obtained from the photolysis of BQ–β-methylnaphthalene system. Therefore, no hydrogen atom transfer reaction from the donor to BQ is shown to take place in the latter system. The distinction in the photochemical reaction between the above two complexes is not explained by the electronic natures of the lowest excited triplet states, since they have both the locally excited $^3(n,\pi^*)$ levels of BQ as the lowest triplet level as suggested by the emission measurements. Thus it seems more reasonable to conclude that the distinction is caused by the different geometric conditions between the two complexes, leading probably to the changes of $CH_3\cdots O$ distance, there are some theoretical arguments on the geometrical configuations of molecular complexes in the excited states.[14] The present results and those of the similar studies might provide bases for

the elucidation of the geometries of CT complexes in the excited states as well as in the ground states.

In conclusion, it has been established in the present work that the photochemical hydrogen abstraction reaction of BQ in the complexes with aromatic donors occurs in low temperature rigid matrices, only in cases where the lowest triplet state is mainly of the $^3(n,\pi^*)$ character of BQ. In cases where the donor is so strong that the ^{3}CT state is lower than the $^3(n,\pi^*)$ state of BQ, no hydrogen abstraction takes place. These results indicate that the reactions proceed from such states as those in which the oxygen atom has an unpaired electron in its non-bonding atomic orbital. These results also clearly indicate that the initial electron transfer followed by proton tunnelling is not the route for the hydrogen abstraction reaction irrespective of the strengths of the donor-acceptor interactions.

Self-Diffusion Coefficients and Interdiffusion Coefficient in Acetone-Benzene System

Yoshinobu KAMEI and Yasumichi OISHI

Department of Nuclear Engineering, Faculty of Engineering, Kyushu University, Fukuoka, Japan

(Received May 1, 1972)

Self-diffusion coefficients of acetone and benzene have been determined in the whole composition range of the binary system at 25°C by a capillary-cell method using the ^{14}C-marked tracer. The results were in a good agreement with those determined by the NMR spin-echo method by McCall and Douglass. The products of the respective self-diffusion coefficients and the viscosity of this system showed a relatively constant compositional dependence. Bearman's relation was shown to hold between the self-diffusion coefficients and the partial molar volumes for the system. The validity of Darken's equation was confirmed for the self-diffusion coefficients and the interdiffusion coefficient of the system.

The relationship between the self-diffusion coefficients of the components and the interdiffusion coefficient for a binary system has been described by Darken[1] and by Hartley and Crank[2] as Eq. (1):

$$D_{12} = (N_1 D_2^* + N_2 D_1^*)\ (\mathrm{d} \ln a_1 / \mathrm{d} \ln N_1) \qquad (1)$$

where D_{12} is the interdiffusion coefficient, D^* the self-diffusion coefficient, N the mole fraction, a the activity, and the subscript i refers to component i. In the present work, the self-diffusion coefficients of both components were determined for the whole composition range of the acetone–benzene system to test the validity of Eq. (1) for this system by comparing the interdiffusion coefficient experimentally determined and that theoretically calculated with Eq. (1).

Experimental

The capillary-cell method was used for determining self-diffudion coefficients. The employed apparatus and technique have been described elsewhere.[3] All the determinations were made at 25±0.02°C. The acetone and benzene used were of spectrum analysis reagent grade. The radioactivity of the tracer in the sample solution in the capillary was adjusted so as to be about 0.06 μCi/cc with ^{14}C-labelled $(CH_3)_2CO$ or C_6H_6. The radioactivity of the tracer was determined in a toluene solution of 2,5-diphenyloxazole with a liquid scintillation counter.

Results

Figure 1 shows the self-diffusion coefficients of acetone, $D^*((CH_3)_2CO)$ and benzene, $D^*(C_6H_6)$ determined at 25°C as a function of mole fraction of acetone.

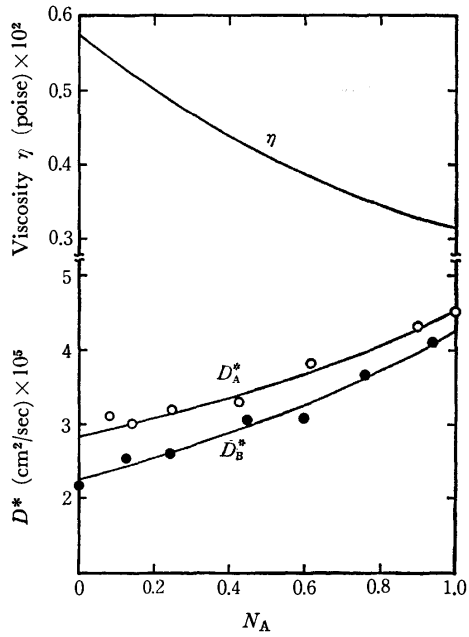

Fig. 1. Self-diffusion coefficients and viscosity for acetone-benzene system as a function of mole fraction of acetone at 25°C. D_A^* and D_B^* are self-diffusion coefficients of acetone and benzene. η is viscosity.

All are the averaged values of more than three determinations. The self-diffusion coefficients of pure acetone[4] and benzene[5-9] were taken from the literatures. Both self-diffusion coefficients show similar and relatively linear compositional dependence.

Discussion

(1) *Comparison of the Results with Those by NMR Spin-Echo Method.* Self-diffudion coefficients of both components for the acetone–benzene system have been determined by McCall and Douglass using the NMR spin-echo method.[10] They confirmed the accuracy of their method by comparing their results with Mills data determined by a diaphragm-cell method for the benzene–cyclohexane system.[11] For the acetone–chloroform system, the results by McCall *et al.* and those by Hardt *et al.* by a capillary-cell method[12] are in a good agreement only for the self-diffusion coefficients of acetone, but show a large discrepancy of about 18% for chloroform. For the acetone–benzene system, however, our results by the capillary-cell method are in good agreement with McCall and Douglass's results by the NMR spin-echo method for both components.

(2) *Products of Self-Diffusion Coefficient and Viscosity.* The compositional dependence of both self-diffusion coefficients and that of the viscosity, η[13] are in reverse trends as seen in Fig. 1. Figure 2 shows the products of the viscosity and the respective self-diffusion coefficients as a function of composition where $\eta \cdot D^*((CH_3)_2CO)$ and $\eta \cdot D^*(C_6H_6)$ remain constant for the whole composition range of the system. The similar results have been showed previously for the carbon tetrachloride–cyclohexane[3] and acetone–water[4] systems.

(3) *Bearman's Relation.* The relationship between the self-diffusion coefficients and the partial molar volumes for a binary regular solution has been described by Bearman[14] as Eq. (2):

$$D_1^*/D_2^* = \bar{V}_2/\bar{V}_1 \qquad (2)$$

where $\bar{V}_1$ and $\bar{V}_2$ are the partial molar volumes of components 1 and 2, respectively. $D^*((CH_3)_2CO)/D^*(C_6H_6)$ is shown as a function of compositon in Fig. 2. $\bar{V}(C_6H_6)/\bar{V}((CH_3)_2CO)$ ranges within 1.19 to 1.24 for the whole composition range of the system and in a good agreement with $D^*((CH_3)_2CO)/D^*(C_6H_6)$ shown in Fig.2. This means that Bearman's relation holds for this system.

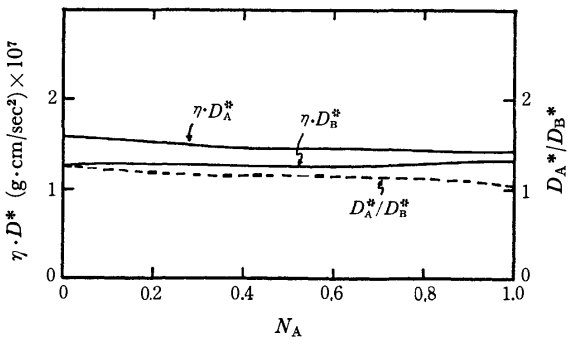

Fig. 2. Compositional dependence of $\eta \cdot D_A^*$, $\eta \cdot D_B^*$, and D_A^*/D_B^*.

(4) *Darken's Equation.* The theoretical interdiffusion coefficient calculated by Eq. (1) is compared with those determined experimentally by Anderson, Hall, and Babb[15] and by Cullinan and Toor[16] in Fig.3 as a function of mole fraction of acetone. The ther-

modynamic factor for the system necessary for the calculation was estimated from the excess free energy calculated from equilibrium vapour pressure at 45°C determined by Brown and Smith[17] and shown in Fig.4. The theoretical and experimental interdiffusion coefficients are in a good agreement within ±6%. This confirms the validity of Darken's equation for the acetone–benzene system. A similar comparison of the theoretical and experimental interdiffusion coefficients has been made by McCall and Douglass.[10] Their results, however, showed a fairly large discrepancy between the experimental and theoretical values as shown together in Fig.3. As described already, the self-diffusion coefficients of the respective components determined by them are close to our determinations. The cause of their discrepancy is in their thermodynamic factors, shown in Fig.4, which they estimated from the vapour-liquid equilibrium at boiling points for varied compositions.[18]

The authors thank M. Kurokawa for his assistance in experimental works.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2439—2444 (1972)

Temperature Dependence of Corona-charging Properties on TiO_2-Polymer Dispersion Layers

Takeaki IIDA, Toyokazu NONAKA, and Hiroshi NOZAKI

Institute of Industiral Science, University of Tokyo, Roppongi, Minato-ku, Tokyo, 106

(Received September 3, 1971)

The corona-charging properties of TiO_2-polymer dispersion layers were determined in the dark at temperatures 0°—35°C by the turn-table method. Dispersion layers of TiO_2 (rutile) and polyvinyl acetate, coated on an aluminum foil to about 15 μ thickness, were used. The results showed the rising rate of the surface potential has a maximum at around 20°C. The saturation potential decreases slightly with a rise in temperature. The decay potentials were represented by the plot log V *vs.* $\sqrt{t}$. The relation between log V and $\sqrt{t}$ is linear in certain range of the surface potential, and the gradient increases in proportion to the rise in temperature. This is discussed with the use of an equivalent-circuit model.

Studies have been made on the corona-charging properties of electrophotographic sensors with respect to change with the contents of the photoconductor,[1] sensitization of the corona-charging,[2] and effects of the relative humidity.[3] The results were summarized by Schaffert,[4] Yoshida,[5] and Ionue.[6]

Amick's model for the corona-charging mechanism,[7] and Inoue's empirical equation for the dark decay[8] are often used to explain the behaviors of the corona-charging properties.

Inoue's equation is convenient for representing the experimental results of surface potential decay. The surface potential $V(t)$ at decay period is approximated by the following equation in a certain range of surface potential.

$$V(t) = V_0 e^{-\alpha\sqrt{t}} \quad (1)$$

where V_0 is the initial potential, α is the decay constant, and t is the time from the instant at which corona discharge is turned off. Taking the logarithm of (1), we get

$$\log V(t) = \log V_0 - 0.43\,\alpha\sqrt{t} \quad (2)$$

This means that the decay curve is linear when the log V is plotted against $\sqrt{t}$. According to Inoue's experiments, the gradient depends on such factors as the initial potentials, binder to photocondutcor weight-ratio and amounts of additives.

In this study the corona-charging properties of the sensors were found to depend a great deal on temperature. The results obtained will be of use not only for studying the mechanism of the corona-charging but also for controlling the surface potentials in commercial machines operating at various temperatures.

Experimental

Titanium dioxide of the rutile type was prepared by the hydrolysis of titanium tetrachloride distilled several times, and ignited at 500°C for 2 hrs. The average diameter of the power was about 0.5μ, and the specific surface area as determined by BET was 1.57m²/g. Polyvinyl acetate (PVAc) of the average polymerization degree of 1400 was used as a binder.

Preparation of the dispersion layers was as follows. The ratio of binder to titanium dioxide in weight was chosen to

be 100/0, 90/10, 70/30, 50/50, 20/80. The materials were mixed in a ball-mill crasher for 10 hr, using ethyl acetate as a solvent. The mixture was coated on an aluminium foil with a film coater, and the samples were dried at 110°C for 2 hr. The thickness of the layers was around 15 μ.

The layers cut out in the size of 12 cm × 7 cm were fixed on an aluminiun plate and kept in a chamber where the relative humidity was kept at 30%—35% for 48hr or more.

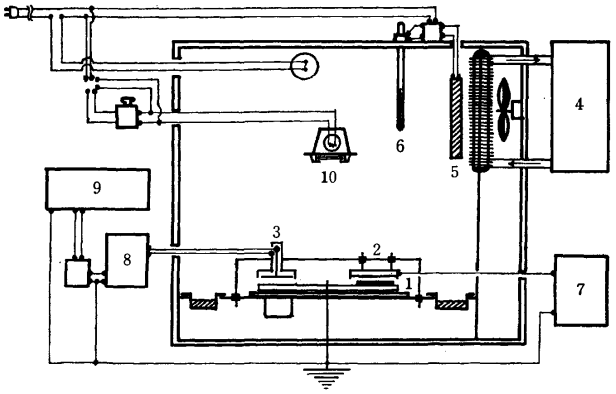

Fig. 1. A schematic illustration of the experimental equipment.
(1) dispersion layer, (2) corona discharger, (3) detecter, (4) refrigerator, (5) cooling fin, (6) relay thermometer, (7) high voltage battery, (8) surface potential meter, (9) recorder, (10) infrared light.

Measurement of the surface potentials at low temperatures was carried out in a chamber where the air was cooled by a cooler to which a cooling medium was circulated from a refrigerator, as shown in Fig. 1. Measurement at high temperatures was carried out with a heater regulated by a relay thermometer. The temperature was raised from 0°C to 35°C by each 5°C. To avoid air leakage from outside, all operations were performed with a pair of rubber gloves attached to the chamber wall.

When the chamber was insulated from the outside, the humidity inside decreased with the rise in temperature. A small amount of humid air was then introduced to the chamber to keep the relative humidity constant at 35%.

The negative corona discharge was carried out by applying −5kV on three steel wands, 0.1mm in diameter, fixed 5mm the turn-table. The corona current was controlled at around 5×10^{-6}A. The turn-table was rotated at 78 rpm. Measurements of the surface potential on the layers were carried out with a surface potential meter of a chopper type.

A typical surface potential change against time is shown in Fig. 2. The slow potential-rise during the initial few seconds is attributed to the charging period of space charges in the layer.[7] After this period, the potential rises almost in proportion to the time from the point M to N in Fig.2, and is saturated to a certain surface potential. The rising rate of the corona potential was determined from the gradient of the line MN. The corona discharge was carried out for one minute, after that the potential gradually decreased to zero. The initial potential V_0 is defined to be the potential at one minute after the turn-off of the corona discharge.

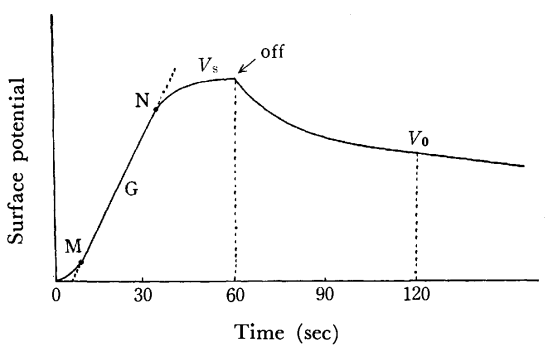

Fig. 2. The typical curve of the surface potential change against the time.

To eliminate the fatigue effect of the corona charging on the layer, an infrared light (200 W) was adjusted to the smaple for 10 minutes at 33°C and the sample was kept in the dark at room temperature for 48 hr between each measurements.

Measurements of the electrical resistivity and the electrocapacity of the dispersion layer were carried out by changing the temperature. A silver electrode (5 × 5 cm²) was evaporated in a vacuum on the layer. The specimen was fixed in a dark chamber in which temperature and relative humidity were controlled. A stainless-steel plate was placed on the sample surface with contact pressure 10.0g/cm². The electrical resistivity was directly measured with a 610-B Keithley electrometer. The electrostatic capacity was measured with a Wheatstone brige applying an alternative current of 1kHz.

Results

The rising rate of the corona potential G (volt/sec) is plotted against the temperature in Fig. 3. From the results it can be said that G for 0–30% TiO_2-contents increases with a rise in temperature, through its maximum at around 20°C, and suddenly decreases from 25 to 35°C. For 10% and 30% TiO_2-contents, G at 35°C is lower than that at 0°C. However, for 50% and 80% TiO_2-contents, G decreases gradually from 5 to 10°C, becoming almost constant from 10 to 35°C.

The temperature dependence of the asturation potential V_s is shown in Fig.4. The saturation potentials for 0–30% TiO_2-contents are almost constant at 0°–

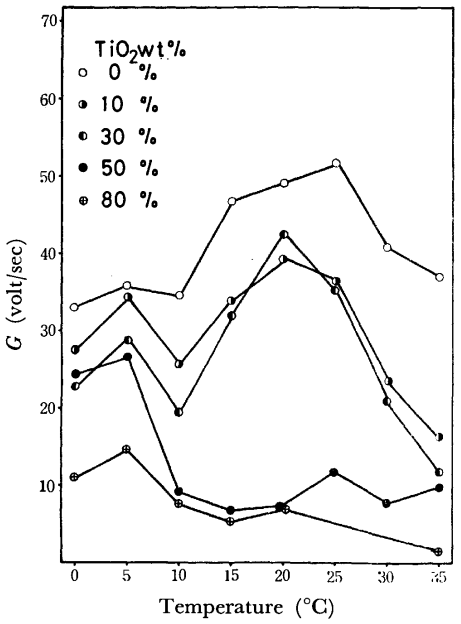

Fig. 3. The rising rate of the surface potential, G (volt/sec), were plotted against the temperature.

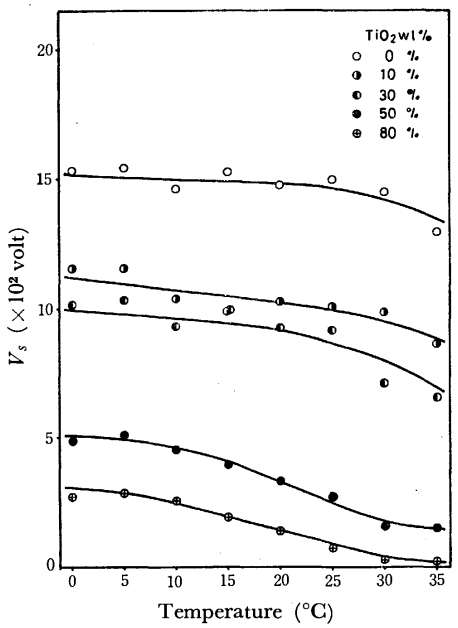

Fig. 4. The temperature dependence of the saturation potential.

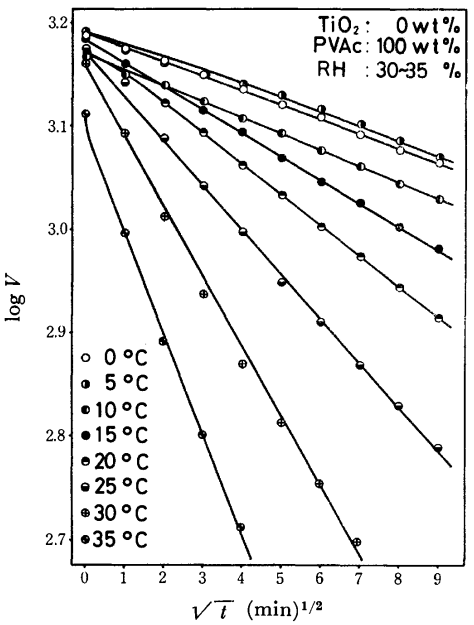

Fig. 6. The logarithm of the dark decay potential on the polyvinyl acetate layer is plotted against the square root of the time at various temperatures.

25°C, decreasing slightly at 25°–35°C. The saturation potentials for 50–80% TiO_2-contents decrease gradually with the rise in temperatures.

The temperature dependence of velocity of the dark-decay is shown in Fig.5. The velocity defined by $(V_s-V_o)/V_s$ increases considerably with the rise in temperature. This tendency is greater for the high percentage of TiO_2-contents.

The dark-decay of the surface potential at various temperatures for long duration was studied by changing the titanium-dioxide contents. The results are represented by the relation between log V and $\sqrt{t}$ in Figs. 6—10.

A good linear relation is given on the polyvinyl acetate layer for a long duration of the decay (Fig.6). However, the linearity between log V and $\sqrt{t}$ at higher TiO_2-contents does not hold at the initial steps (Figs. 7–8). The decay velocities for 50–80% TiO_2-contents are so rapid that the linearity holds for a short range of the decay period (Figs. 9–10). It can be said that the potential decay increases with the rise in temperature. The temperature dependence of the gradients of the linear lines in the plots between log V and $\sqrt{t}$, *viz.*, the decay constant α, is shown in Fig. 11. The decay

constant increases in proportion to the rise in temperature, and with the increase in the percentage of TiO_2-contents.

The temperature dependence of the air-gap conductivity between the corona and the turn-table at corona-discharging which corresponds to the corona current at the applied voltage of -5kVi sre presented by a dotted line in Fig.12. The solid line represents the resistance of the air gap calculated from the values of the corona current. It can be said that the corona current gradually increases with the rise in temperature.

The resistivity of the layer at various TiO_2-contents is shown as a function of the temperature in Fig.13. The layer of 0% of TiO_2-contents has the highest resistivity, and the resistivity decreases with the increase in TiO_2-contents. In general the resistivity of the layer greatly decreases with the rise in temperature.

The capacitance (per one square centimeter) of the layer at various TiO_2-contents is shown as a funtion of the temperature in Fig.14. The layer of 80% of TiO_2-contents has the highest capacitance, and the capacitance of the layer slightly increases with the rise in temperature.

Discussion

The corona-charging properties of titanium-dioxide dispersion layers were studied by changing the temperature from 0 to 35°C. To interpret the temperature dependence with the use of an equivalent-circuit model shown in Fig.15, the corona current, the resistance of the layer, and the capacitance of the layer were mesaured by changing the temperature. It is reasonable that the corona current (Fig.12) increases with the increase in temperature, since not only the electron emission from the corona electrodes but also the mean free-path of corona ions increase with the rise in temperature. It is also reasonable that the resistivity of the layer decreases with the rise in temperature, since the free electrons in the layer increases with the rise

in temperature as shown in Fig.14. Würstlin[10] reported that the dielectric constant of polyvinly acetate increases with a rise from 25°C to 80°C. On the other hand, the dielectric constant of TiO_2-ceramics (rutile) decreases with a rise from 25 to 70°C.[11] In the case of the dispersion layer, the capacitance of the layer increases with a rise in temperature (Fig.14). It can thus be said that the temperature dependence of the capacitance is dominantly governed by the dependence of the dielectric constant of polyvinyl acetate.

In the equivalent-circuit given in Fig.15, when the switch is turned on and a voltage E is applied to the circuit, the change in potential between I and J is given by the equation

$$V = \frac{ER}{R_0+R}\left[1-\exp\left\{-\frac{1}{C}\left(\frac{1}{R_0}+\frac{1}{R}\right)t\right\}\right]. \quad (3)$$

Differentiating V with time, the rising rate of the surface potential is obtained:

$$G = \frac{dV}{dt} = \frac{E}{R_0C}\left[\exp\left\{-\frac{1}{C}\left(\frac{1}{R_0}+\frac{1}{R}\right)t\right\}\right]. \quad (4)$$

9) T. Iida and H. Nozaki, This Bulletin, **42**, 2820 (1969).

10) F. Würstlin, *Kolloid-Z.*, **134**, 143 (1953),

11) L. J. Berberich and M. E. Bell, *J. Appl. Phys.*, **11**, 681 (1940).

Since G is a function of three independent variables of R_0, R, and C, we can not satisfactorily explain the temperature dependence of G only by means of the partial differentiation of G with R_0, R, or C. We thus calculated G directly with the use of the observed values of R_0, R, and C. The rising rate of the surface potential calculated by Eq. (4), in which time was taken at ten seconds, with the use of the data, R_0, R, and C in Figs.12—14, is shown in Fig.16. It can be said that G for 0% TiO_2-contents has a maximum at around 25°C, and the maximum shifts to lower temperature range with the increase in TiO_2-contents. Consequently, G for 80% TiO_2-contents has a maxiumm at around 10°C. The agreement between the calculated values and the observed values (Fig.3) is fairly good.

The saturation potential is given by $ER/(R_0+R)$ from Eq. (3). Figure 4 shows that V_s depends on the temperature of the layer. V_s was calculated with the use of the data R_0 and R in Figs. 12—13 as a function of temperature. In this case the agreement between the calculated values and the observed values (Fig. 4) is also fairly good.

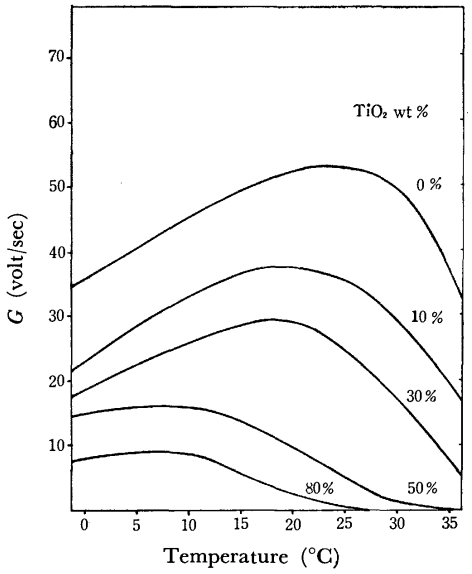

Fig. 16. The rising rate of the surface potential calculated by the equation (4) with the use of the data, R_0, R, and C in Figs. 12—14.

In the case of the discharging process, when the switch is turned off, the discharging current flows only through the resistance of the layer. Therefore, the speed of the dark decay depends greatly on the resistance of the layer. Figure 5 shows that the velocity of the dark decay depends greatly on the temperature of the layer, since R of the layer decreases with a rise in temperature (Fig.13)

The results in Figs.6—10 show that the logarithm of the decay potential decreases in proportion to the square root of the time at a certain range of the decay period. It is not possible to derive directly such a relation with the use of the simple qeuivalent-circuit shown in Fig. 15. Inoue[8] and Papazian[12] proposed a more complex empirical equation in which the summation of the exponential terms of $V_i \exp(-t_i/R_iC_i)$ is considered, where V_i, R_i, and C_i are the potential, resistance and capacitance at the time t_i, respectively. However, it is rather difficult to calculate the potential decay with the use of V_i, R_i, and C_i, since R_i and C_i are not easily measured in actual cases.

We should point out that the decay constant α increases in proportion to the temperature rise from 0° to 35°C. It is not possible to derive such a relation with the use of the simple equivalent-circuit model shown in Fig.15. A more complex model will be needed.

The authors wish to thank Mr. T. Watabe, Mr. H. Ishii, and Mr. T. Takayama for their experimental assistance in this work.

Photochemical Reaction of 9-Chloroacridine in Aerated and Deaerated Ethanol. II. Studies by Means of a Flash Technique

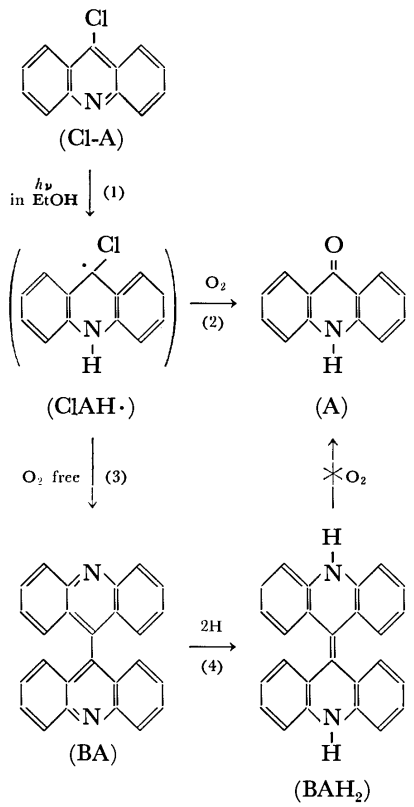
Katsumi NAKAMARU, Shigeya NIIZUMA, and Masao KOIZUMI

Dapartment of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai

(Received September 3, 1971)

Studies were made on the transient species produced when the aerated and deaerated ethanol solutions of 9-Cl-acridine (9-Cl-A) are flashed. In the deaerated solution, triplet state of 9-Cl-A and a long-lived radical species of unknown structure were detected. It was established that the latter is produced by a reatcion in the singlet excited state of 9-Cl-A (and possibly in the higher triplet ($T_{n-\pi}$*)) and that it produces biacridyl by a bimolecular reaction. In the aerated solution, another radical species of a long life of which structure is still unknown, was detected. It was established that this radical species reacts bimolecularly and produces acridone.

In a previous paper,[1] we have established that irradiation of 9-Cl-acridine in ethanol by 365 nm, produces acridone (A) in the aerated solution, while in the absence of oxygen, mainly biacridan (BAH_2) is produced *via* biacrydyl (BA). The proposed scheme is as follows.



The identification of BA and BAH_2 was established in the previous paper, and there is no doubt on the occurence of process (4). But it is quite unknown how processes (1) and (3) occur, or in other words, whether the splitting of HCl preceeds or follows the dimerization reaction. Still less unknown is the detailed mechanism of the production of acridone. The only information obtained experimentally is that the presence of reductive medium and of oxygen is necessary for the reaction to occur.

In order to elucidate the detailed mechanism of these reactions, we have performed flash photolysis studies for both the aerated and deaerated solutions. For the aerated solution, a certain transient intermediate was detected which produces acridone by a bimolecular reaction. In the deaerated solution, two transient species, long-lived and short-lived were detected and it was established that the long-lived species produces biacridyl bimolecularly. Although we did not succeed in identifying the transient species, the present results are consistent with the conclusion given in the previous paper and are helpful for elucidating the mechanisms of the reactions.

Experimental

Materials. All the materials were purified as described in the previous paper.

Apparatus and Procedures. The apparatus for the flash photolysis is an usual one employed in our laboratory.

Results and Discussion

Deaerated Solution. Two kinds of transient intermediates, short-lived M_1, and long-lived M_2, were detected. It was established that the photoproduct is biacridyl by measuring its spectrum after flashing the sample several times. Although the absorption spectra of M_1 and M_2 overlap with each other to some extent, they can be distinguished rather easily because of their great difference in their lifetimes.

Figure 1 gives the plot of $1/D$ (D, optical density at 460 nm) against time. As will be verified below, the later stage obeys the second order, while the earlier stage deviates greatly from the second order plot. The order of reaction in an early stage was examined by the following procedures; 1) extrapolation of the later linear portion, 2) substraction of the D-value on the extrapolated line (D_{ext}) from D at various time points and 3) plotting of $\log(D-D_{ext})$ or $1/(D-D_{ext})$ against time. As shown in Fig. 1b the $\log(D-D_{ext})$ *vs.* t plot gives a straight line irrespective of the wavelengths. Hence one can conclude that the decay in the early stage obeys the first order. To check the reliability of this procedure and to obtain the correct spectral shape, we plot $(D-D_{ext})$ at various wavelengths against $(D-D_{ext})_{440}$. As shown in Fig. 2 all of them give good linear plots, and the spectral shape could thus be determined accurately. This is given in Fig. 3. All the transient spectra reported below were obtained or checked by the similar

a: decay of M_2 (long-lived intermediate)
b: decay of M_1 (short-lived intermediate)

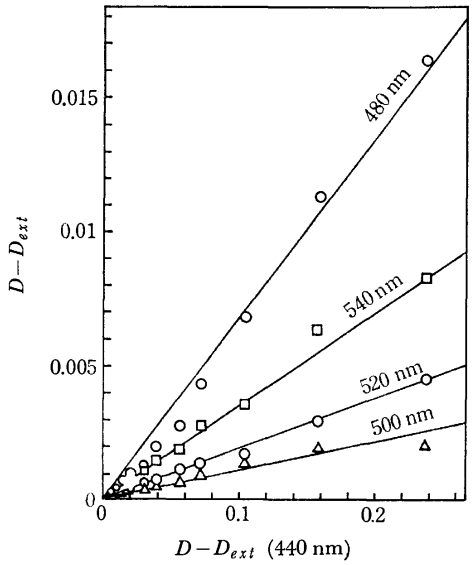

Fig. 2. Plot of $D-D_{ext}$ (at various wavelengths) *vs.* $D-D_{ext}$ (at 440 nm). Degassed solution of 9-Cl-A in ethanol (1×10^{-4} M).

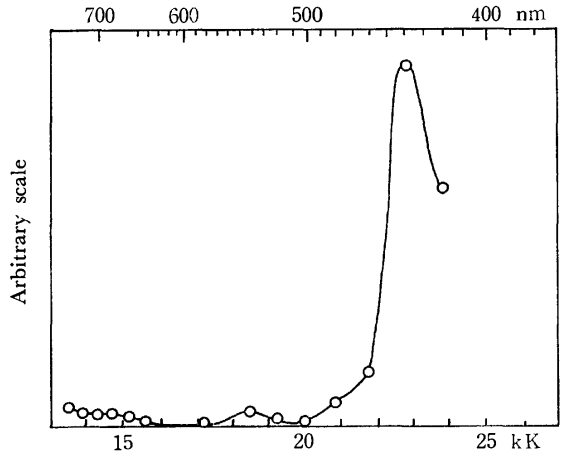

Fig. 3. Spectrum of short-lived intermediate, M_1 obtained in the degassed solution of 9-Cl-A (1×10^{-4} M).

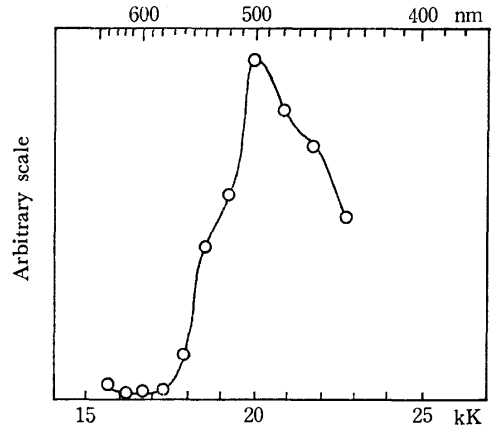

Fig. 4. Spectrum of long-lived intermediate, M_2 obtained in the degassed solution of 9-Cl-A (1×10^{-4} M).

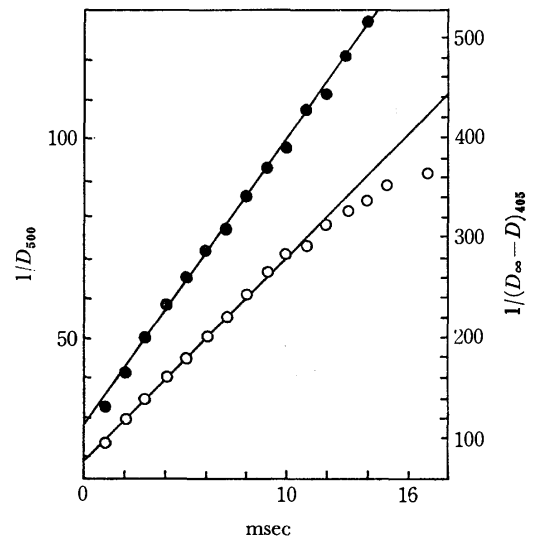

Fig. 5. Second-order plot for the decay of M_2 (at 500 nm) and for the build-up of BA (at 405 nm). Degassed solution of 9-Cl-A in ethanol (1×10^{-4} M).
○: $1/D_{500}$, ●: $1/(D_\infty-D)_{405}$

method as described above. The success of the above procedure implies that there is no interrelation between M_1 and M_2. M_1 may safely be identified as the triplet state on the basis of its lifetime (rate constant, 7.4×10^3 sec^{-1}) and a somewhat similar spectral shape as that of acridine triplet. Hence it is likely that M_2 is produced by a reaction in the singlet excited state of 9-Cl-A(and possibly in the high triplet (n-π^*)).

Figure 4 gives the spectral shape of M_2 as obtained by the similar method as described above. Figure 5 gives the decay of M_2 and the build-up of BA plotted according to the second order rate formula. The former was measured at 500 nm while the latter at 405 nm. The inclinations of the plots which give $k/\varepsilon d$ are for the former 1.8×10^4 sec^{-1} and for the latter 2.8×10^4 sec^{-1}. Figure 6 gives the relation between the decrease of M_2 and the increase of BA, as measured by the change in the optical densities respectively at 500 nm and at 405 nm. It is seen that the plot of D_{500} *vs.* $(D_\infty-D)_{405}$ gives a good straight line passing through the origin. We can conclude from Figs. 5 and 6 that BA is produced from M_2 accord-

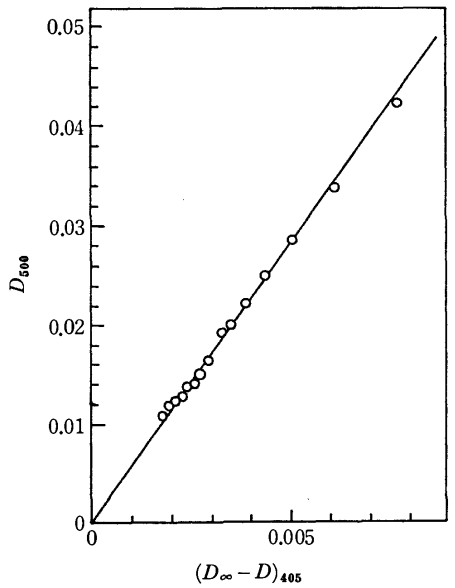

Fig. 6. Relation between the quantity of the intermediate M_2 and that of BA in the degassed solution of 9-Cl-A in ethanol (1×10^{-4} M).

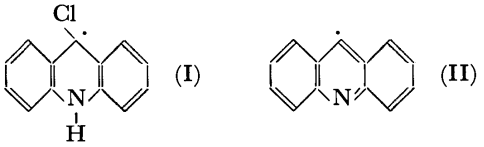
ing to a bimolecular reaction. As to the identification of M_2, there are two possibilities. One is a half-reduced 9-Cl-acridine (I). In this case splitting of hydrogen



chloride occurs during or after dimerization. Another possible structure is (II). This is produced when the splitting of HCl from (I) preceeds dimerization. Discrimination of the two will be possible if we undertake the similar experiments using other 9-halogenated acridines.

The Aerated Ethanol Solution. Only one transient species with a rather long lifetime was detected. The product after flashing was identified as acridone by measuring the UV spectrum. A transient species has a spectral shape as given in Fig. 7. Since it is common that no T-T absorption is observed in the aerated solution, this transient species is attributed to some kind of radical species. Comparing Fig. 7 with Fig. 4, we can conclude that this radical species is different from M_2. We call it M_3 for the sake of convenience.

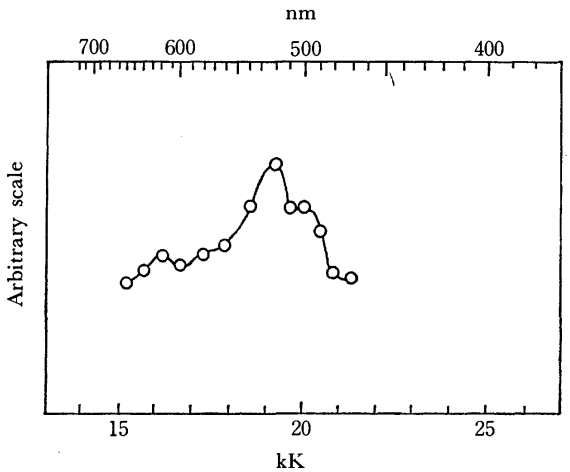


Fig. 7. Spectrum of intermediate M_3 obtained in the aerated solution of 9-Cl-A in ethanol (1×10^{-4} M).

In Fig. 8 the decay of M_3 measured at 520 nm and the build-up of acridone as measured at 400 nm are plotted as a second order process. Since at 400 nm, the spectra of M_3 and acridone overlap to some extent, $(D_\infty - D)_{400}$ was plotted against time. It is evident that the decay of M_3 and the build-up of acridone run parallel. This was confirmed further by Fig. 9 where $(D_\infty - D)_{400}$ and D_{520} at corresponding time points are plotted. The plot is a good straight line. We can conclude therefore, that acridone is produced from some unknown radical species M_3 bimolecularly.

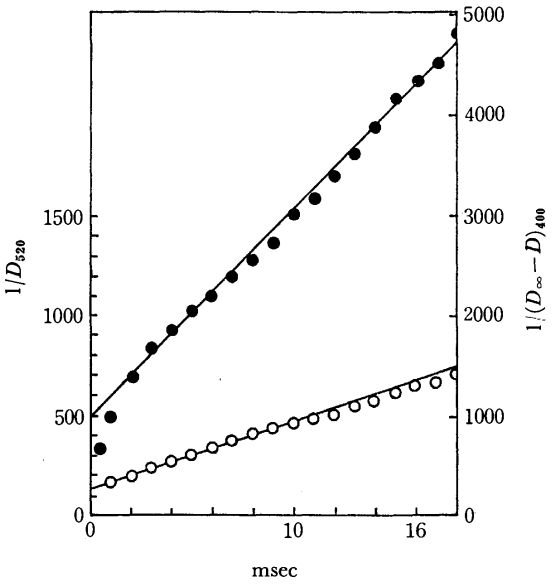

Fig. 8. Second-order plot for the decay of M_3 (at 520 nm) and for the build-up of acridone (at 400 nm). Aerated solution of 9-Cl-A in ethanol (1×10^{-4} M).

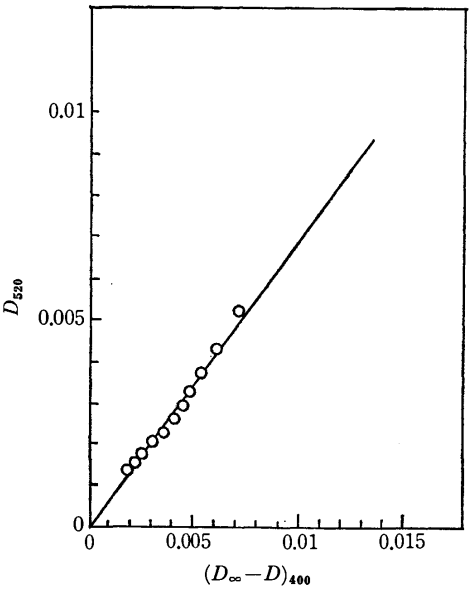

Fig. 9. Relation between the quantity of the intermediate M_3 and that of acridone in the aerated solution of 9-Cl-A in ethanol (1×10^{-4} M).

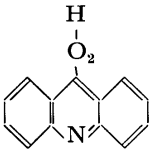
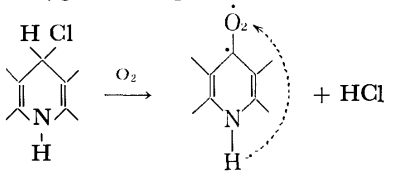
The identification of M_3 will become easier when M_2 is identified and so was not attempted at the present stage. Only provisional discussions will be given below. Judging from the fact that M_3 gives rise to acridone bimolecularly and that oxygen is involved in the reaction, it seems very probable that HO_2 group is attached to acridine structure in some way. If one assumes M_2 has a structure (II) and further assumes that (II) is formed even in the presence of exygen, then it is conceivable that (II) reacts with oxygen, and the resulting peroxiradical deprives hydrogen atom from ethanol producing the following hydroper-



oxide. This will produce acridone bimolecularly. On the other hand, if M_2 has structure (I), it is expected to be oxidized back to 9-Cl-acridine from analogy to acridine, rather than attacked by oxygen at 9-position. Another possibility is primary production of 9-Cl-acridan *via* molecular mechanism and the attack of oxygen at 9-position. But this is also im-



probable because acridan type product was not detected in the steady light reaction of 9-Cl-acridine.[1]

The identification of M_2 and M_3 is most desirable to establish the mechanism of the general photoreaction of 9-Cl-acridine. Furthermore it will be interesting to investigate the transient radical species of photoreaction of BA at various acidities in view of great difference of stability in $BAH_2^{+}\cdot$ and $BAH\cdot$ reported in a previous paper.[2] These studies will be made in near future.

Fluorinated Ligands. I. Chelating Behavior of 1-Amino-3,3,3-trifluoro-2-propanol with Copper(II) Ion and Preparation of Copper(II)-, Cobalt(III)-, and Nickel(II) Complexes*

Isao YOSHIDA and Hiroshi KOBAYASHI

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka, 812

(Received October 5, 1972)

In the reaction of 1-amino-3,3,3-trifluoro-2-propanol (LOH) with cupric ion in aqueous solutions two kinds of complex species were found to be formed: One was a complex ion of $[Cu(LO)(H_2O)_2]^{+1}$, which was of major abundance in the solutions where mole ratio of the ligand to the metal ion was less than 3, and the other was an inner complex of $[Cu(LO)_2]$ predominating in the solutions which contained a large excess of the ligand or a small amount of alkali. The structures of the species in the solution phases were assigned by the spectral data. Chelate compounds of inner complex type, $[Cu(LO)_2(H_2O)]$, $[Co(LO)_3]$, and $[Ni(LO)_2]$, were synthesized from the present ligand and corresponding metal ion. These are insensitive to moisture in the air. Structures of the chelates are discussed on the basis of spectroscopic observations.

In connection with studies on coordinating behaviors of hydroxyl group of aminoalcohols and of their *N*-alkylated derivatives, various preparative and spectral studies have been carried out. In the early preparative studies by Hieber and Levy[1] and by Brintzinger and Hase,[2] the isolated products were complex salts containing the neutral ligands accompanied by counter anions. Complex formation with copper(II) in aqueous solution was studied by means of the spectroscopic method by Ojima and Sone,[3] who concluded that a tetraaminocopper(II) complex, $[Cu(amine)_4]^{+2}$, was formed in the region of lower concentration of the ligand, which behaved therein as a monodentate ligand, and that an increase in the ligand concentration or an addition of a strong base afforded a 1:2 (Cu: ligand) inner complex chelate. These complexes, however, could not be isolated as a stable form from such solutions. Yoneda and Kida[4] also isolated a neutral trisethanolaminecoblat(III), $[Co(NH_2CH_2CH_2O)_3]$, from a strongly alkaline aqueous solution. Subsequently Kida[5] obtained copper(II) chelates of inner complex type, $[Cu(NH_2CH_2CH_2O)_2(H_2O)]$ and $[Cu(NH_2CH(C_6H_5)CH(C_6H_5)O)_2]$, from anhydrous alkaline ethanol solutions. In every case, the isolated metal chelates of inner complex type were unstable and readily affected by moisture.

In this paper, we discuss the chelating behavior of

1-amino-3,3,3-trifluoro-2-propanol [$CF_3CH(OH)CH_2NH_2$; LOH] with copper ion in aqueous phases and the structures of copper(II)-, cobalt(III)-, and nickel(II) chelates of the present ligand in solid phase, in comparison with some other ethanolamine type ligands.

Experimental

Apparatus. All melting points measured were uncorrected. Visible absoprtion and reflectance spectra were measured with a Hitachi ESP-2 and a Hitachi EPU-2 spectrophotometers, respectively. The IR spectra were recorded with a JASCO DS-403G spectrophotometer. Molecular weights were determined on a Vapor Pressure Osmometer (Mechrolab Inc.) with 2-methyloxine as a standard substance for the copper complex in absolute ethanol, and *p*-bromonitrobenzene for the nickel complex in absolute methanol. Copper(II) acetate monohydrate (an extrapure grade from the Wako Pure Chemicals Co., Ltd.) was used without further purification for the reaction equilibrium study in aqueous media.

Synthesis of 1-amino-3,3,3-trifluoro-2-propanol. The aminofluoropropanol hydrochloride was prepared according to Jones.[6] Into a solution of the hydrochloride in as a small amount of water as possible, was added a saturated aqueous sodium bicarbonate up to pH 8. The freed aminopropanol was extracted with ethylether. The ethereal solution was dried and concentrated slowly on a water bath to give precipitates, which were recrystallized from ethylether, melting at 97—98°C.

Found: C, 27.77; H, 46.6; N, 8.22; Cu, 10.82%. Calcd for $C_3H_6ONF_3$: C, 27.95; H, 4.65; N, 10.82%.

Synthesis of Bis(1-amino-3,3,3-trifluoro-2-propanolato)copper(II) Monohydrate. One gram of copper acetate monohydrate was dissolved into 50 m*l* of water containing 1.3 g of the ligand, and then 0.2 M aqueous sodium hydroxide was added slowly up to pH being 8. The solution was kept at about 40°C for 12 hr on a water bath. The resulting mixture, when cooled to 0°C, gave a red-violet crystalline precipitate, which was recrystallized from an ethyl acetate-ethanol mixture, to give red-purple needles decomposing at 199—200°C.

Found: C, 21.44; H, 3.60; N, 8.22; Cu, 18.81%; mol wt, 324. Calcd for $C_6H_{12}O_3N_2F_6Cu$: C, 21.38; H, 3.56; N, 8.30; Cu, 18.81%; mol wt, 337.5.

Synthesis of tris(1-amino-3,3,3-trifluoro-2-propanolato)cobalt(III). One and three tenth gram of cobaltous perchlorate was added into 20 m*l* of ethanol containing 0.32 g of the ligand and then 0.2 M aqueous sodium hydroxide was added slowly into the mixture until its pH became 9. The solution was maintained at about 50°C on a water bath for about 24 hr. A pink powdery precipitate, which was obtained from the resulting mixture when cooled to 0°C, was washed with ethanol, and then dried *in vacuo*, decomposing at 240°C. The product was insoluble in donating solvents such as ethanol and water, whereas being soluble in inert organic solvents such as benzene.

Found: C, 24.52; H, 3.45; N, 9.99; Co, 13.63%. Calcd for $C_9H_{15}O_3N_3F_9Co$: C, 24.38; H, 3.39; N, 9.48; Co, 13.29%.

Synthesis of bis(1-amino-3,3,3-triffuoro-2-propanolato)nickel(II). A saturated ethanol solution of 0.45 g of nickel(II) perchlorate was added into a saturated ethanol solution of 0.32 g of the ligand. Light-blue crystals which precipitated immediately, were collected by filtration and recrystallized from ethanol, to give light-blue plates decomposing at 170—173°C. The complex was insoluble in an inert organic solvent such as benzene, while being soluble in a donating solvent such as methanol.

Found: C, 22.62; H, 3.48; N, 8,87% mol wt (in methanol), 312. Calcd for $C_6H_{10}O_2N_2F_6Ni$: C, 22.81; H, 3.18; N, 8.88; mol wt, 314.89.

Paper Electrophoresis. Paper electrophoresis of the copper complex was performed in a solvent immersion method on a filter paper strip soaked in a 0.1 M sodium chloride electrolyte. Potential applied between both ends (14 cm distant) was 640 V (45.7 V/cm) and current 3 mA. A copper spot of the fluoro-ligand complex did not migrate when the potential was applied for 5 min, while those of bis(ethylenediamine)copper(II) perchlorate and of copper(II) perchlorate travelled 20 mm respectively toward the negative electrode in 5 min under the same operation conditions. Diphenyl-carbazone was used as a chromogenic indicator for copper ion.

Results and discussion

Spectrophotometric Studies on the Chelating Behavior of the Ligand (LOH) with Copper(II) Ion. Figure 1 shows absorption spectra of aqueous solutions containing copper(II) ion and various amouts of the ligand (LOH). When the mole ratio of copper ion to the ligand in the solution is less than 1:2 (Cu:LOH), copper(II) ion precipitates in a form of hydroxide. A 1:3 (Cu:LOH) mixture gives a clear solution showing an absorption peak at 14500 cm^{-1}. An increase in the ligand concentration causes a blue shift of the absorption peak up to 16600 cm^{-1} until the mole ratio becomes as much as 1:6. Further increase in the ligand concentration does not produce any more shift in the absorption band. The 1:6 or 1:8 solution shows the absorption curve superimposable to that of the red-violet copper chelate in aqueous solution phases which is shown in Fig. 3. Figure 2 indicates that an addition of an equimole of aqueous sodium hydroxide to the 1:1 (Cu:LOH) mixture results in dis-

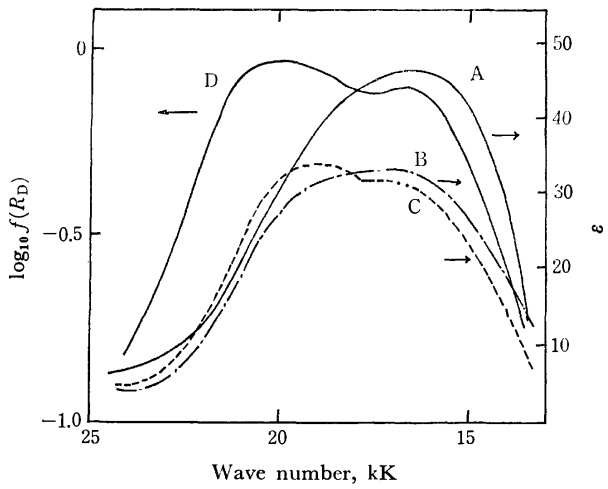

Fig. 3. The absorption spectra in water (A), methanol (B) and ethanol (C), and the reflectance spectrum (D) of $Cu(LO)_2(H_2O)$.

solution of the precipitates of copper hydroxide, giving a clear blue solution, an absorption peak of which is at 14500 cm^{-1} in good agreement with that of the 1 : 3 mixture in Fig. 1. Dissolution of the solid copper chelate, $Cu(LO)_2(H_2O)$, in an equimole of aqueous copper acetate also gives a blue solution showing the absorption curve B in Fig. 2, absorption maximum of which is also in good agreement with the above 1 : 3 mixture in Fig. 1. This value of the absorption peak corresponds to that of a 1:1 copper chelate of ethylenediamine at 15200 cm^{-1} [7] or that of *N*-hydroxyethylethylenediamine at 14500 cm^{-1},[8] and is most likely to be ascribed to the formation of a 1 : 1 ($Cu:LO^{-1}$) chelate in the aqueous solutions. An ddition of alkali into the 1 : 2 (Cu : LOH) mixture in which precipitates of copper hydroxide are formed, affords a clear red-violet solution, which shows an absorption peak at 16600 cm^{-1}, as illustrated by Curve E in Fig. 2, in agreement with that of the 1 : 6 mixture in Fig. 1. Further addition of alkali or the ligand does not produce any shift of the absorption band.

In a region of the mole ratio higher than 1 : 6, the 1 : 2 inner complex is formed. An excess of the ligand is likely to play a role of an agent deprotonating from the hydroxyl group upon the chelate formation. Presence of the 1 : 2 inner complex is also indicated by the results of high voltage paper electrophoresis, which show that the copper chelate is of zero charge in aqueous media. In contrast with isopropanolamine which produced a 1:2 chelate in a region of the mole ratio higher than 1 : 10,[3] the present ligand readily forms the neutral 1 : 2 chelate under much milder conditions.

Complexing behavior of the present fluoro-ligand, therefore, seems to be quite different from that of an ordinary ethanolamine type ligand. The latter causes precipitation of copper hydroxide in a 1:3 (Cu:ligand) aqueous mixture and gives a tetraammine type complex in a range of mole ratio slightly higher than 1 : 4, forming no 1 : 1 chelate.[3] The trifluoromethyl group affects the donating power of the adjacent hydroxyl group presumably by its strong electron-withdrawing effect, favoring the dissociation of proton from hydroxyl oxygen. Consequently chelate formation with copper ion is more easily attained.

Spectral Studies on the Chelate Compounds of Copper(II)-, Cobalt(III)-, and Nickel(II) ions. IR spectral results on the ligand and its metal chelates are summarized in Table 1, including assignments of the bands according to Brannon.[9] The free ligand shows a broad band diffused between 3200 and 2400 cm^{-1} due to a strongly hydrogenbonded hydroxyl group, and a sharp doublet at 3330 and 3280 cm^{-1} related to a primary amino group involved in the hydrogen bonding. The hydrochloride of the ligand shows also a broad strong band centered at 3220 cm^{-1} due to a hydroxyl group, N–H stretching bands due to the ammonium group being probably hidden under the hydroxyl absortion.

Copper Complex, $Cu(LO)_2(H_2O)$. IR spectrum of the copper chelate shows a prominent absorption band spread over from 3260 to 3100 cm^{-1} due to lattice water in agreement with the result of elemental analysis, N–H absorptions again being hidden under the strong water band. The absorption peak due to ν(C–F) is observed at 1123 cm^{-1}. Figure 3 shows the visible reflectance and absorption spectra of the chelate in some donating solvents respectively. The reflectance spectrum exhibits an absorption peak and a shoulder at 20200 and about 16600 cm^{-1} respectively, indicating a square planar structure with respect to the central metal ion in the chelate molecule.[10,11]

$Co(LO)_3$		3300 m	3220 m	1616 m	1165 s	1120	1100 s
$Ni(LO)_2$		3400 w	3376 w	1600 m	c)	c)	c)

a) In Nujol mulls. Frequencies are given in $K(cm^{-1})$. Intensity designations: w, weak; m, medium; s, strong; br, broad; sh, shoulder.
b) Obscured by hydroxyl bands.
c) Unable to be assigned due to much complicated spectrum in these region.

On the other hand, the paper electorphoresis of the chelate indicates that the complex is present as a zerocharged, neutral complex in aqueous media. Combined with the result of molecular weight determination, these observations indicate consistently the copper chelate to be an inner complex type, excluding a possibility of an ion-pair type complex such as $[Cu(LO)(LOH)]^+[OH]^-$.

Absorption spectrum in water shows at 16400 cm^{-1} a broad peak, which is at much lower wave-number with a narrower half-band width than those of the corresponding band observed in the solid reflectance spectrum. These spectral evidences indicate an existence of axial ligation of the solvent molecules on the planar tetracoordinate copper chelate to form the penta- or hexacoordinations.[12,13)]

While the spectral characteristics in methanol and in ethanol in the region between 15000 and 21000 cm^{-1} are rather resemblant to those observed in the reflectance spectrum, and the effect of axial ligation of the solvent molecules in such alcohol solutions is, therefore, considered to be in a small extent, though comparisons of the absorption intensities suggesting the slightly stronger effect of methanol than that of ethanol.

Cobalt complex, $Co(LO)_3$. A strong IR absorption band at 3220 cm^{-1} due to ν(O–H) of the present aminofluoropropanol hydrochloride disappears in the spectrum of the cobalt chelate, while the absorption peak due to ν(C–F) remains at 1120 cm^{-1}. Curve A in Fig. 4 shows the spectrum of the chelate in a benzene solution. Two absorption maxima at 25200 and 18200 cm^{-1} indicate an octahedral hexacoordination structure in respect to the central cobalt(III) ion.[14)] The solubility of the chelate in inert organic solvents also supports to be of an inner complex type.

Nickel Complex, $Ni(LO)_2$. Curve B in Fig. 4 shows the reflectance spectrum of the nickel chelate. General feature of three absorption peaks at 27000, 16200, and 9700 cm^{-1} indicates[15)] an octahedral coordination structure of the chelate in respect to the central metal ion, whereas the analytical data indicate the mole ratio of 1:2 for nickel ion to the ligand and the IR spectrum shows no absorption band due to hydroxyl group or water. The nickel chelate is, therefore, considered to be of a polymeric structure at least in a solid phase. On the other hand, the chelate takes a monomeric form in a donating solvent such as methanol. The absorption spectrum in the solvent, as shown in the curve C of Fig. 4, indicates an octahedral coordination structure regarding the central metal ion. Therefore solid polymeric chelate complex cleaves to give a monomeric form by donating of two molecules of methanol upon dissolution.

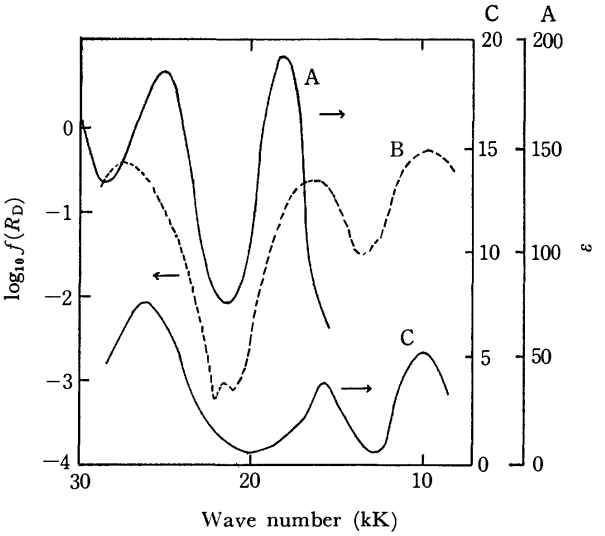

Fig. 4. The absorption spectrum of $Co(LO)_3$ in benzene (A), and the reflectance (B), and absorption (C) spectra of $Ni(LO)_2$

The metal chelates of the present ligand were isolated as stable forms without any precautions, forming a striking contrast to those of monoethanolamine which were highly sensitive to moisture.

Schiff Bases Derived from Heptane-2,4,6-trione and Ethylenediamine, and Its Copper(II) and Oxovanadium(IV) Chelates*

Tairoku YANO, Tetsuaki USHIJIMA, Masaomi SASAKI, Hiroshi KOBAYASHI, and Keihei UENO

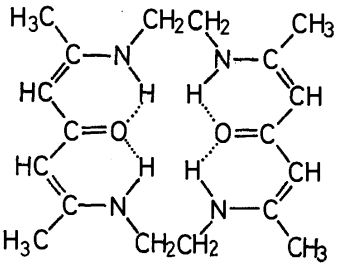
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka, 812

(Received October 6, 1971)

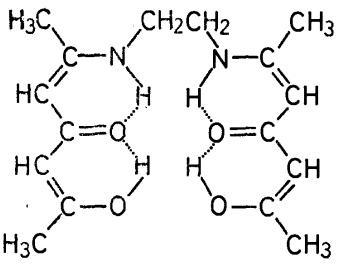
The copper(II) and oxovanadium(IV) complexes of a new Schiff base derived from heptane-2,4,6-trione and ethylenediamine were prepared. Of a macrocyclic two-to-two and an open jaw-shaped two-to-one (trione to diamine) condensation product, only the latter gave mononuclear copper(II) and oxovanadium(IV) complexes. The coordinating sites to the metal ion in each complex are discussed referring to the spectroscopic results.

In the course of an investigation of the chelate complexes of heptane-2,4,6-trione with various metal ions,[1,2] we have been interested in the Schiff base derived from the trione and diamines, in an analogous manner to the Schiff bases of pentane-2,4-dione and diamines.[3] In the case of heptane-2,4,6-trione and ethylenediamine, however, two kinds of the Schiff bases can be formed. One is DAADEN (5,9,14,18-tetramethyl-1,4,10,13-tetraazacyclooctadeca-5,8,14,17-tetraene-7,16-dione) (structure I) which is a two-to-two condensation product of the trione and the diamine. The other is DAAEN (6,11-dimethyl-7,10-diazahexadeca-6,10-diene-2,4,13,15-tetraone) (structure II) which is a two-to-one condensation product. As seen from their structures, both can behave either as a sexadentate or as a quadridentate ligand, and macrocyclic DAADEN may be less flexible upon complex formation than open jaw-shaped DAAEN. Thus, it is of great interest to investigate the chelating behavior of these multidentate ligands.

This paper is to report on the synthesis of a new macrocyclic Schiff base ligand, DAADEN, as well as the syntheses and structural studies on the mononuclear open jaw-shaped DAAEN chelates of copper(II) and oxovanadium(IV) ions.



Structure I



Structure II

Experimental

Synthesis of the Ligand. DAADEN. To 60 ml of a methanolic solution containing 10.0 g (0.07 mol) of heptane-2,4,6-trione, was added 10 ml of methanolic solution of 4.6 g (0.074 mol) of 98% ethylenediamine, and the mixture was warmed at 30—40°C for a few minutes. Resulting precipetate was collected by filtration, and recrystallized from a methanol-chloroform mixture to give pale yellow needles. Yield was 10.7 g; mp 215—216°C. NMR($CDCl_3$): 1.88 ppm (12H), 3.23—3.40 ppm(8H), 4.77 ppm(4H), 10.70—11.50 ppm(4H). IR: 1625 cm^{-1} $\nu_{C=O}$(hydrogen bonded); 1580 and 1520 cm^{-1}, $\nu_{C=C}$ and $\nu_{C=N}$.

Found: C, 64.76; H, 8.53; N, 16,69%. Calcd for $C_{18}H_{28}N_4O_2$: C, 65.03; H, 8.49; N, 16.85%.

Syntheses of the Metal Chelates. Copper(II)-DAAEN Chelates: Into 250 ml of a chloroform solution containing 3.32 g (0.01 mol) of DAADEN, was added with stirring 100 ml of an aqueous solution of 2.0 g (0.01 mol) of cupric acetate monohydrate, and the mixture was stirred for 30 min at 18°C until a green precipitate appeared in an aqueous layer and a chloroform layer became dark violet. The green precipitate in the aqueous layer was collected by filtration, recrystallized from pyridine and dried under reduced pressure to yield green powder (1.48 g, 36.3%) which was found to be bis(heptane-2,4,6-trionato)dicopper(II), by elemental analysis and infrared spectral comparison with an authentic sample.[2]

The dark violet chloroform layer was evaporated under reduced pressure to remove the solvent, and the residual oil was dissolved again into a small amount of chlorofrom. The chloroform solution was eluted on a column of activated alumina (50 g) with the same solvent. After the solvent was distilled off from the eluate, the residual solid was recrystallized from a *n*-hexane-chloroform mixture, to yield red-violet crystalline powder, Complex A, (0.94 g, 25.5%). IR: 1720 and 1705 cm^{-1}, $\nu_{C=O}$(free); 1590 and 1520 cm^{-1}, $\nu_{C=O}$, $\nu_{C=C}$ and provably $\nu_{C=N}$.[4]

Found: C, 52.66; H, 6.20; N, 7.39%. Calcd for $C_{16}H_{22}N_2O_4Cu$: C, 52.00; H, 5.95; N, 7.30%.

Oxovanadium(IV)-DAAEN Chelate. Into a solution of 2.84 g (0.02 mol) of heptane-2,4,6-trione in 70 ml of methanol, were added a solution of 0.6 g (0.01 ml) of 98%

ethylenediamine in 20 ml of methanol and 1.01 g (0.01 mol) of finely powdered oxovanadium hydroxide. The mixture was refluxed under a nitrogen atmosphere for 1.5 hr. The resulting green precipitate and unreacted oxovanadium hydroxide were collected by filtering the reaction mixture, and the solid mixture was treated with chloroform to dissolve the chelate. After evaporating the solvent from the chloroform solution, the green residue was recrystallized from pyridine to yield brown needles (2.07 g). When this product was dried at 64°C under 10^{-3}—10^{-4} mmHg, green needles, VO-DAAEN, (1.7 g, 49.5%) were obtained. IR: 3220 cm^{-1}, ν_{N-H}(hydrogen bonded); 1627 cm^{-1}, $\nu_{C=O}$(coordinated); 1595, 1555, and 1538 cm^{-1}, $\nu_{C=O}$, $\nu_{C=C}$, and $\nu_{C=N}$ of chelate ring; 980 cm^{-1}, $\nu_{V=O}$.

Found: C, 52.11;H, 6.05; N, 7.51%. Calcd for $C_{16}H_{22}N_2O_5V$: C, 51.49; H, 5.94; N, 7.51%.

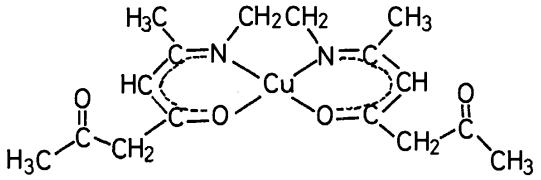
Apparatus and Measurement. IR spectra were measured with JASCO DS-301 and DS-403G spectrophotometers. The NMR spectra were recorded on a Varian A-60 instrument using TMS as an internal reference. Thermogravimetric analysis on the pyridine adduct of the oxovanadium chelate was conducted with a Shimadzu automatic recording thermobalance. The furnace temperature was raised at a rate of 3°C per minute under a nitrogen atmosphere and the weight loss was recorded automatically up to 367°C.

Results and Discussion

Quadridentate ligands derived from 1,2- or 1,3-diamines and β-dicarbonyl compounds have been investigated extensively, and their coordinating structure has been well established to be *N,N,O,O*,-tetracoordinate square planar. In this connection, our first attempt was to synthesize a macrocyclic sexadentateligand (DAADEN) which was a two-to-two condensation product of ethylenediamine and heptane-2,4,6-trione. The condensation reaction took place very easily in methanol, yielding an expected compound. The infrared absorption spectrum of the product does not show any band due to ν_{N-H} of free amino group, indicating that both amino groups on ethylenediamine are involved with the condensation reaction. On the other hand, the reaction of heptane-2,4,6-trione and methylamine gave 1,2,6-trimethylpyridone in a high yield,[5] and the above fact suggests the inactivity of the carbonyl group at 4-position of the trione against the condensation with amines. It is very likely, therefore, that the condensation of heptane-2,4,6-trione with diamines also takes place on the both terminal carbonyl groups of the trione, but not on the central one. These presumptions, combined with the empirical formula from the elemental analysis, indicate the structure I for DAADEN.

Our second attempt was to synthesize an open jaw-shaped sexadentate ligand (DAAEN) which was a two-to-one (trione to diamine) condensation product. However, our trials under various reaction conditions have not been successful yet. On the other hand, this particular ligand was found to be only obtainable in a form of metal chelate as described below.

Copper Chelates. Contrary to our expectation, the reaction of DAADEN with cupric ion gave no macrocyclic copper(II) chelate, but bis(heptane-2,4,6-trionato)dicopper(II) and the complex A (Cu-DAAEN). The fact that the chelate of the parent trione is obtained in a considerable yield even under such mild reaction conditions is indicative of the relative easiness of hydrolysis of DAADEN. The ligand itself is, however, fairly stable in an aqueous solution, and therefore copper(II) ion may catalyze to accelerate such hydrolysis reaction.



Structure III

As to the complex A, the infrared spectrum shows a coordinated carbonyl band at 1590 cm^{-1} and two peaks related to uncoordinated carbonyl groups at 1720 and 1705 cm^{-1}, the presence of the latter band indicating that not all of the carbonyl groups are engaged in coordination with copper ion. The result of elemental analysis also suggests the one-to-one mononuclear DAAEN chelate. Electronic spectrum of the complex A in chloroform is shown in Fig.1 along with those of the model compounds of similar coordination structures; bis(acetylacetonato)copper(II) ($Cu(acac)_2$) and bis(acetylacetone)ethylenediiminato-copper(II) (Cu-ACEN), in the same solvent. It is well known that the absorption maxima and intensity of *d-d* transition band are sensitive to the number and symmetry of donor atoms around the central metal ion, and to the ligand field strength. Thus, the close similarity of the absorption spectrum of the complex A to that of bis(acetylacetone)ethylenediiminato-copper(II), strongly suggests the N_2O_2-tetracoordinate planar structure III for the complex A. Analytical

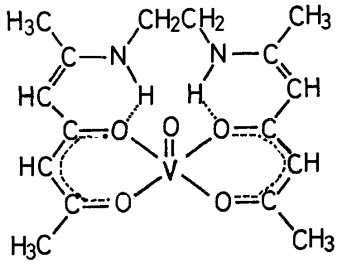
result and infrared spectra are also consistent with this structure.

It is interesting to note that DAAEN could not be formed without the presence of copper ion and could be isolated only in a form of the metal chelate, though in a low yield. Copper(II) ion in this case may stabilize the Schiff base ligand against hydrolysis in a similar manner as in the case of bis(acetylacetone)ethylenediiminatocopper(II). This behavior of DAAEN forms a striking contrast to the macrocyclic DAADEN, of which we have been unsuccessful in obtaining the copper(II) chelate.



Structure IV

Oxovanadium(IV) Chelate. The reaction of DAADEN with oxovanadium(IV) salts in aqueous media did not give any product of definite composition. However, the reaction of heptane-2,4,6-trione and ethylenediamine with oxovanadium(IV) hydroxide under a nitrogen atmosphere yielded the metal chelate of DAAEN presumably *via* a template reaction.

The result of elemental analysis suggests the one-to-one oxovanadium(IV) chelate of DAAEN. Infrared spectrum is characterized with absorption bands due to an imino group, a coordinated carbonyl group and a V=O bond at 3220,1628, and 980 cm^{-1} respectively. The bands assignable to uncoordinated carbonyl groups are not observed.

Electronic spectrum of the VO-DAAEN chelate in chloroform is shown in Fig. 2 along with those of bis(acetylacetonato)oxovanadium(IV) ($VO(acac)_2$) and bis(acetylacetone)ethylenediiminatooxovanadium(IV) (VO-ACEN) in the same solvent. In contrast to the copper chelate, close similarity of thes pectra is noticed between the DAAEN- and the acetylacetonato-chelate, suggesting that an O_5-pentacoordinate square pyramidal structure IV is preferable to an N_2O_3 type coordination for the VO-DAAEN chelate. The structure IV is consistent with the infrared spectral

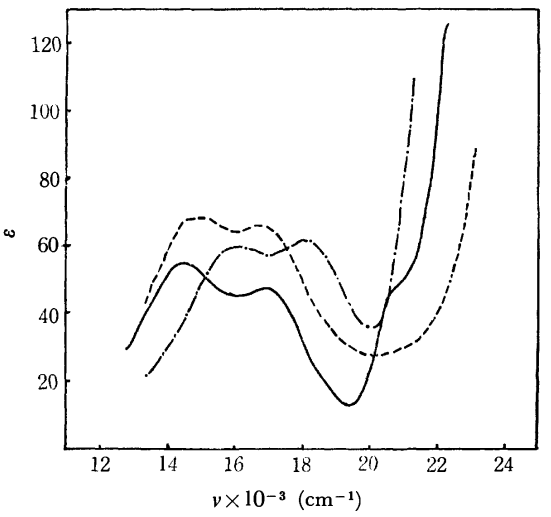


Fig. 2. Electronic absorption spectra in chloroform.
—— VO-DAAEN, —·— VO-ACEN,
--- $VO(acac)_2$.

evidence that no frec carbonyl group is left in the chelate.

The reversible addition of one mole of pyridine to one mole of the chelate also indirectly supports the square pyramidal structure. When the green VO-DAAEN chelate is recrystallized from pyridine, a brown DAAEN-VO-Py, which is presumably an octahedral coordination sturcture, is obtained. Thermogravimetric analysis on the pyridine adduct showed a sudden weight decrease corresponding to the loss of one mole of pyridine per mole of the adduct at a temperature between 199 and 201°C. The substance remaining after the thermal analysis was identical with the green VO-DAAEN.

The reason why the coordination site of DAAEN differs depending upon the kind of metal ions can be explained by the soft and hard acid and base concept.[6] If one reminds that oxovanadium(IV) ion is a harder acid than copper(II) ion, and that oxygen is a harder base than nitrogen, then it is reasonable that oxovanadium(IV) ion prefers an O_4 type coordination, while copper(II) ion prefers an N_2O_2 coordination.

The authors are grateful to Messrs. Hiroshi Yamachika and Shûzo Kano for their laboratory work during the early stage of this work. They also thank the Ministry of Education for a financial support.

Polarographic Behavior of Nickel(II) in Propionitrile and Benzonitrile in the Presence of Thiocyanate Ions

Eiki ITABASHI*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka.

(Received November 24, 1971)

The effect of the cation of the supporting electrolyte on the electrode reaction of nickel(II) in propionitrile and benzonitrile solutions containing thiocyanate ion was investigated by DC polarography and *i-t* curve analysis. In the absence of thiocyanate ion, a propionitrile solution of nickel(II) gives a single irreversible wave in $LiClO_4$ and $NaClO_4$ supporting electrolytes and a double wave in Et_4NClO_4 and n-Bu_4NClO_4, and a benzonitrile solution of nickel(II) gives a double wave in alkali metal and quaternary ammonium perchlorates. Nickel(II) in these nitrile solvents in the presence of thiocyanate ion exhibits a catalytic pre-wave in alkali metal perchlorates and a catalytic maximum wave in quaternary ammonium perchlorates. The double wave of nickel(II) in the absence of thiocyanate ion is due to the inhibition of the charge transfer process by the relatively weak adsorption of quaternary ammonium cations and not to the presence of two electroactive species. A mechanism which involves the cyclic regeneration of adsorbed thiocyanate ion for the catalytic pre-wave and the catalytic reduction of thiocyanate ion with the electroreduced metallic nickel for the maximum wave has been presented.

The adsorption effect of the foreign substance on the electrode reaction in non-aqueous media has received less considerable attention, although that in aqueous media is well known. This could be the result of a weak adsorption of substance from non-aqueous solvents. Specific adsorption of quaternary ammonium cations from acetonitrile solution seems to be considerably weaker than from aqueous solution.

The electrode reaction of nickel(II) at the dropping mercury electrode in acetonitrile has previously been reported to be inhibited by the adsorption of quaternary ammonium cations[1] and to be accelerated by the adsorption of halide ions[2] as well as thiocyanate ions.[3] An acetonitrile solution of nickel(II) in the presence of thiocyanate ion exhibits two kinds of catalytic polarographic current.

Nickel(II) in $LiClO_4$ and $NaClO_4$ supporting electrolytes gives a catalytic pre-wave which arises at less negative potentials than that for the usual nickel(II) reduction wave, and in $(C_2H_5)_4NClO_4$ (Et_4NClO_4) and $(n\text{-}C_4H_9)_4NClO_4$ (n-Bu_4NClO_4) electrolytes a catalytic maximum wave over a wide range of potentials at which the usual nickel(II) reduction wave reaches its limiting plateau. It was proposed in a previous paper[3] that the electrode reaction mechanism for the maximum wave of nickel(II) was due to the catalytic reduction of thiocyanate ion with the electroreduced metallic nickel, and not to the catalytic hydrogen evolution.

In order to investigate the adsorption effect of quaternary ammonium cations on the electrode reaction of nickel(II) and the properties of the catalytic polarographic current of nickel(II) in the presence of thiocyanate and quaternary ammonium ions in non-aqueous solvents, some experiments were carried out in propionitrile and benzonitrile solvents. The present paper describes the experimental results on the above-mentioned systems.

Experimental

Purified propionitrile[4] and benzonitrile[5] were obtained by the procedures given in the literatures. All the other chemicals were prepared by the procedures described previously.[1,3] The total water content of the polarographic solution containing nickel(II) perchlorate and supporting electrolyte was found to be 10—20 mM by Karl Fisher titration. All solutions were *deaerated* with nitrogen gas.

Direct current (D. C.) polarograms and current-time (*i-t*) curves of individual drops at constant potential were obtained with the potentiostat previously described[2] and made from operational amplifiers. In the following section and in the figures, "current" means them aximum current observed just before the fall of a mercury drop. The potential of the DME was measured against a saturated calomel electrode (SCE). The cell equipment for the polarographic measurements was the same as previously reported.[1] The dropping mercury electrode (DME) had an m value of 1.44_6 mg/sec and a drop time of 5.01 sec in a *deaerated* 0.1 M lithium perchlorate acetonitrile solution at −0.70 V *vs.* SCE and 60 cm mercury height. All measurements were made at 25.0±0.1°C.

Results

Propionitrile System. Larson and Iwamoto[4] have reported that a propionitrile solution of nickel(II) in 0.1 M Et_4NClO_4 supporting electrolyte gave an irregular reduction wave. The reduction wave of nickel(II) in propionitrile solution is influenced by the nature of the cation of the supporting electrolyte. The resultant polarograms are shown in Fig. 1. Nickel(II) gives an irreversible wave in $LiClO_4$ electrolyte and a double wave in Et_4NClO_4 and n-Bu_4NClO_4 electrolytes. A similar single reduction wave was also observed in 0.1 M $NaClO_4$ solution. Nickel(II) in alkali metal perchlorate solutions containing LiSCN gives a pre-wave, where it is reduced with greater reversibility. Figure 2 shows the effect of the thiocyanate concentration on the reduction waves of nickel(II) in $LiClO_4$ solution. The pre-wave increases in height

and becomes a more appreciable portion of the total limiting current of nickel(II) species as the thiocyanate concentration increases. There was no further essential change in the shape of the reduction wave when the thiocyanate concentration exceeded 0.5 mM. The effect of the thiocyanate concentration on the reduction waves of nickel(II) in n-Bu_4NClO_4 solution is shown in Fig. 3. Nickel(II) in n-Bu_4NClO_4 solution in the presence of small amounts of LiSCN exhibits a maximum wave over a wide range of potentials rather than a limiting plateau. The maximum wave increases in height with increase in concentration of LiSCN up to about 0.5 mM. Table 1 presents the exponents of the i-t curves for the reduction waves of nickel(II) in n-Bu_4NClO_4 solution containing various concentrations of LiSCN. The first step of the double wave of nickel(II) in the absence of LiSCN has a mixed diffusion-kinetic character, and the second step has the characteristics of normal diffusion control. In the presence of LiSCN, the exponents of the i-t curves for the maximum wave at the whole potential region examined are very close to the value of 0.67 expected for a kinetic-controlled electrode mechanism. The exponents of the i-t curves for the limiting current observed at the most negative potentials at which

the maximum wave disappeared were found to be close to the value of 0.17 expected for a diffusion-controlled mechanism, whereas the limiting current of the pre-wave observed at potentials less negative than −0.5 V *vs.* SCE had a mixed diffusion-kinetic character.

Benzonitrile System. The reduction wave of nickel(II) in benzonitrile has been investigated by Larson and Iwamoto,[5] who reported that nickel(II) gave a two-step reduction wave, and the second step was accompanied by a peak-type of maximum. Figure 4 shows the typical reduction waves of nickel(II) in benzonitrile containing various supporting electrolytes.

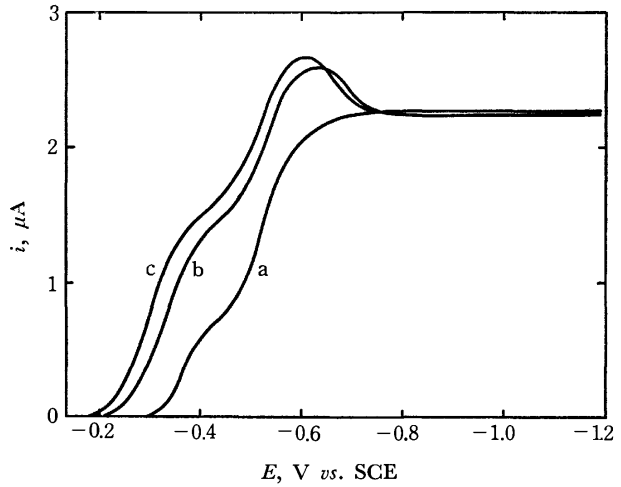

Fig. 4. Effect of electrolyte on the polarograms of 0.5 mM nickel(II) in benzonitrile. (a), 0.1 M $LiClO_4$; (b), 0.1 M Et_4NClO_4; (c), 0.1 M n-Bu_4NClO_4.

In any case, a two-step reduction wave was observed. The second step in quaternary ammonium percholrate solutions exhibits a round maximum at around −0.6 V *vs.* SCE. The limiting current of the first step was found to have a mixed diffusion-kinetic character from the results of the *i-t* curve measurements. In order to investigate the form of the electrocapillary curve, drop time measurements were made for benzonitrile solution. Drop time *vs.* potential curve exhibited a plateau in the potential region between −0.1 V and −0.7 V *vs.* SCE in 0.1 M $LiClO_4$ electrolyte solution, and irregularities which appeared as increase or decrease of drop time in the potential region between −0.2 V and −0.7 V *vs.* SCE in 0.1 M n-Bu_4NClO_4. Similar irregularities of drop time were also observed in benzonitrile solutions containing Et_4NClO_4, $C_6H_5N(CH_3)_3ClO_4$, and $C_6H_5CH_2N(CH_3)_3ClO_4$. The fact that drop time *vs.* potential curves in benzonitrile solution exhibits a slight irregularity has also been reported by Larson and Iwamoto.[5]

With small amounts of LiSCN present, the first step in $LiClO_4$ solution increased in height with increase in concentration of LiSCN. When the concentration of LiSCN exceeded 0.5 mM, the second step merged with the first step to give a single wave with the half-wave potential corresponding to the first step of the double wave. Figure 5 shows the effect of the thiocyanate concentration on the reduction waves of nickel(II) in 0.1 M n-Bu_4NClO_4 solution. In the presence of LiSCN, two maxima are observed in the potential region between −0.5 V and −1.5 V *vs.* SCE. The heights of the double maxima increase with increase in concentration of LiSCN up to about 1.0 mM. The limiting current observed at the most negative potentials at which the maximum wave disappeared was also enhanced by the presence of LiSCN. A similar enhancement of the limiting current at the most negative potentials was observed in benzonitrile solution containing the other quaternary ammonium perchlorates as supporting electrolyte. The resultant reduction waves are shown in Fig. 6. The increment of the limiting current caused by the addition of LiSCN was

found to be proportional to the concentration of LiSCN. Table 2 presents the exponents of the *i-t* curves for the reduction wave of nickel(II) in 0.1 M n-Bu_4NClO_4 solution in the presence of LiSCN. When the thiocyanate concentration exceeds 0.1 mM, the double maxima have the characteristics of kinetic control. While the exponents of the *i-t* curves of the limiting plateau observed at the most negative potentials are very close to the value of 0.17 expected for a diffusion controlled electrode mechanism.

Discussion

The double wave of nickel(II) in propionitrile and benzonitrile solutions containing quaternary ammonium cations could be explained by considering the adsorption of cations.

The kinetic property of the first step of the doublet is the result of the relatively weak adsorption of quaternary ammonium cations from nitrile solvents. The weakly surface active substance at consideravely higher concentrations causes the limiting current to decrease and also the drop life dependence of the instantaneous current to change[6,7] from $t^{1/6}$ to $t^{2/3}$. The appearance of the double wave in benzonitrile solution containing $LiClO_4$ is attributable to the adsorption of benzonitrile molecules on the mercury surface. Drop time *vs.* potential curve for benzonitrile solution containing 0.1 M $LiClO_4$ exhibited a plateau having no apparent change of drop time over a wide range of potentials at which the double wave of nickel(II) appeared. This finding could indicate the specific adsorption of benzonitrile molecules on the mercury surface. Benzonitrile differs from acetonitrile and propionitrile; it has delocalized electrons in the phenyl ring which are capable of interacting with mercury electrode.

The reaction mechanism of the pre-wave and the maximum wave for the nickel(II)-thiocyanate systems in propionitrile and benzonitrile can be written as the following sequence.[4]

$$Ni(NCS)^+ \overset{K}{\rightleftharpoons} Ni(II) + NCS^- \quad (1)$$

$$NCS^-_{bulk} \rightleftharpoons NCS^-_{ads} \quad (2)$$

$$R_4N^+_{bulk} \rightleftharpoons R_4N^+_{ads} \quad (3)$$

$$Ni(II) + NCS^-_{ads} \overset{k_1}{\longrightarrow} Ni(NCS)^+_{ads} \quad (4)$$

$$Ni(NCS)^+_{ads} + 2\,e \xrightarrow[fast]{} Ni(0)metal + NCS^-_{ads} \quad (5)$$

$$Ni(0)metal + NCS^-_{ads} \overset{k_2}{\longrightarrow} Ni(II) + CN^- + S^{2-} \quad (6)$$

where R_4N^+ refers to quaternary ammonium cation, K is the effective formation constant of the nickel(II)-thiocyanate complex in the bulk of the solution. k_1 and k_2 are the rate constants of reactions (4) and (6). The reactions (2) and (3) represent the adsorption equilibria of NCS^- and R_4N^+ ions, respectively. The cyclic regeneration of the adsorbed thiocyanate ion in the sequence of reactions (4) and (5) accounts for the catalytic enhancement of the pre-wave, and the cyclic regeneration of electroactive nickel(II) in the sequence of reactions (5) and (6) accounts for the catalytic process of maximum wave. The reaction mechanism of the maximum wave might be explained by considering the direct reduction of the adsorbed thiocyanate ion at the surface of electrodeposited nickel as the working electrode instead of reaction(6).

If the maximum wave is caused by the direct reduction thiocyanate ion at the deposited nickel, the height of the maximum wave would be close to the value of the diffusion controlled current to be expected. It is reasonable to postulate that the catalytic enhancement of the limiting current is due to the chemical reduction of thiocyanate ion with the deposited metallic nickel, and not to the direct reduction of thiocyanate ion at the deposited nickel.

The peaking of the catalytic current of the nickel(II)-thiocyanate system in the presence of quaternary ammonium cations could be the result of a slight polarographic maximum or it could indicate that the electrode reaction mechanism involves some adsorbed species. It is well known that the catalytic hydrogen waves of some organic sulfur-containing compounds and amines exhibit peaks which have been attributed to a mechanism involving adsorbed species.

Although this study has not provided any conclusive evidence as to the exact role of quaternary ammonium cations involved in the mechanism of the catalytic maximum wave, the fact that the catalytic maximum wave is observed in quaternary ammonium solutions and not in alkali metal solutions suggests that the nature of the electrodeposited metallic nickel is strongly dependent on the electrolyte present in the solution. If the reduction of nickel(II) proceeds at the part of the electrode covered with quaternary ammonium cations the amalgamation of the electrodeposited metallic nickel would be inhibited and the deposit remains on the surface of mercury electrode. The amalgamation of the electrodeposited iron-group metals in aqueous solutions is inhibited by the adsorption of several surface active substances.[8-10]

If the deposited metallic nickel in nitrile solvents in the presence of quaternary ammonium cations is an active species, it could react with thiocyanate ion. At the most negative potentials, the catalytic maximum wave disappears as a result of decreasing adsorption of quaternary ammonium cations and hence of decreasing concentration of the active metallic nickel. No appearance of the catalytic maximum wave of nickel(II) in alkali metal solutions is caused by the quick amalgamation of metallic nickel.

The limiting current observed at the most negative potentials in benzonitrile solution containing quaternary ammonium cations is enhanced by the presence of LiSCN. The total limiting current has the characteristics of normal diffusion control, and the increment of the limiting current caused by the addition of LiSCN is proportional to the concentration of LiSCN. The diffusion-current constant, I_D, for the increment

of the limiting current was found to be nearly equal to the value expected for the one-electron reduction of various alkali metal ions in benzonitrile. When experiments were carried out using the benzonitrile solution containing 0.5 mM $(n\text{-}Bu_4N)_2Ni(NCS)_4$ and 0.1 M $n\text{-}Bu_4NClO_4$, the height of the limiting current at the most negative potentials at which the catalytic maximum wave disappeared was found to be equal to the magnitude of the diffusion current of nickel(II). Therefore, it is reasonable to postulate that the enhancement of the limiting current at the most negative potentials in benzonitrile solution containing quaternary ammonium cations is due to the discharge of lithium ions. The half-wave potentials of lithium ions in benzonitrile solutions containing 0.1 M $n\text{-}Bu_4NClO_4$ and 0.1 M $C_6H_5N(CH_3)_3ClO_4$ were found to be -1.80 V and -1.82 V *vs.* SCE, respectively. In the potential region where the specific adsorption of quaternary ammonium cations is absent, the electrodeposited metallic nickel is unstable and quickly amalgamates and reacts further with mercury to give the stable nickel amalgam. If a slight amount of deposited stable nickel still remains on the mercury surface in the potenital region where the catalytic maximum wave disappears in benzonitrile solution, this deposited nickel aids in reducing the overvoltage of lithium ions.

The reduction potential of sodium ions was also displaced towards less negative potentials in benzonitrile solution containing nickel(II), quaternary ammonium cations and NaSCN.

However, no apparent displacement of the reduction potentials of alkali metal ions was observed in acetonitrile and propionitrile solvents. This could be the result of the delocalized electrons in the phenyl ring of benzonitrile molecule facilitating electron transfer in the bridge mechanism of the electrode process.

The auther wishes to thank Professor Shigero Ikeda for his encouragement throughout this study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2459—2464 (1972)

An NMR Study of Metal Complexes Containing Acetylacetone and Related Compounds. III. The Preparation and Determination of the Configurations of Cobalt(III) Complexes Containing *N,N'*-Ethylenebis(acetylacetonimine) and *N,N'*-Ethylenebis(salicylideneimine)

**Department of Chemistry, Ibaraki Technical College, Fukayatsu, Nakane, Katsuta, Ibaraki*

(Received December 14, 1971)

A series of *cis-β*-form cobalt(III) complexes containing *N,N'*-ethylenebis(acetylacetonimine) dianion (baen) or *N,N'*-ethylenebis(salicylideneimine) dianion (salen) were prepared—*cis-β*-[Co(X)(Y)] and *cis-β*-[Co(X)(Z)]ClO_4 (where X=baen or salen, Y=anions of acetylacetone, benzoylacetone, 8-hydroxyquinoline, and Z=ethylenediamine, 1,10-dipyridyl, 1,10-phenanthroline). The synthetic methods and characterization data are given. Also prepared were a series of *trans*-form cobalt(III)-bean complexes—*trans*-[Co(X)$(A)_2$]ClO_4 and *trans*-K[Co(X)$(NO_2)_2$] where X=baen, and A=ammonia, methylamine, pyridine, aniline). The isolation of only *cis-β*-form complexes in reactions between [Co(X)$(H_2O)_2$] and the bidentate ligands contrasts with the isolation of only *trans*-form ones in those between [Co(X)$(H_2O)_2$] and the monodentate ligands. This result was explained in terms of the relative stabilities of the three configurations of the coordinated baen and salen. On the basis of the configurational analysis, the relative stabilities of the three configurations were determined to be *trans*-planar form > *cis-β* form > *cis-α* form.

Cobalt(II) and Cobalt(III) complexes containing *N,N'*-ethylenebis(acetylacetonimine) dianion (baen) or *N,N'*-ethylenebis(salicylideneimine) dianion (salen) have been known for some time.[1-15] All the reported

complexes have a planar configuration except for the complexes described in Reference 1). In a previous paper,[16] we reported the preparation and the halogenation reaction of the [Co(baen)(acac)] complex, and we mentioned that we could obtain only a *cis*-β-form complex, not a *cis*-α one. In this paper, we will report the preparation and the determination of the structures of two series of *cis*-β and *trans-planar*-forms cobalt(III)-baen, -salen complexes, and will describe the reason for isolating only *cis*-β-form complexes in the reactions of $[Co(X)(H_2O)_2]$ (where X=baen or salen) and the bidentate ligands.

Experimental

Preparation of Complexes. *1)* trans-N,N'-*ethylenebis(acetylacetoniminato)diamminecobalt(III) perchlorate Dihydrate*, trans-$[Co(baen)(NH_3)_2]ClO_4\cdot 2H_2O$ *(I)*: Five milliliters of 18 N ammonia were added to *trans-N,N'*-ethylenebis(acetylacetoniminato)diaquocobalt(II)[1] (3.2 g, 0.01 mol) in 200 m*l* of methanol, and then, to the resultant solution, a hydrogen peroxide solution was added. When sodium perchlorate monohydrate (5 g) in methanol was added to the above solution, yellowish-brown crystals were separated out. They were subsequently recrystallized from methanol. Yield, about 90%.

2) trans-N,N'-*ethylenebis(acetylacetoniminato)dimethylaminecobalt(III) perchlorate Dihydrate*, trans-$[Co(baen)(CH_3NH_2)_2]ClO_4\cdot 2H_2O$ *(II)*: This complex was prepared by using the method employed for the preparation of Complex I. Brown crystals were obtained in about a 90% yield.

3) trans-N,N'-*ethylenebis(acetylacetoniminato)dipyridinecobalt(III) perchlorate*, trans-$[Co(baen)(py)_2]ClO_4$ *(III)*: This complex was also prepared by using the method employed for the preparation of Complex I. Brown crystals were obtained in about a 90% yield.

4) trans-N,N-*ethylenebis(acetylacetoniminato)dianilinecobalt(III) perchlorate*, trans-$[Co(bean)(aniline)_2]ClO_4$ *(IV)*: This complex was also prepared by the method used for Complex I. Brown crystals were obtained in about an 80% yield.

5) Sodium trans-*dinitro*-N,N'-*ethylenebis(acetylacetoniminato)cobalt(III)*, trans-$Na[Co(baen)(NO_2)_2]$ *(V)*: *N,N'*-ethylenebis(acetylacetoniminato)diaquocobalt(II) (6.3 g, 0.02 mol) was dissolved in 200 m*l* of methanol, and then sodium nitrite (4 g, 0.06 mol) in 50 m*l* of water was added to this solution. The resulting solution was heated on a water bath and was concentrated to about 150 m*l* by evaporating the solvent. When the solution was cooled to 0°C, brown crystals were separated out. They were recrystallized from methanol. Yield, about 70%. From the IR spectrum, the coordination of the nitro groups was confirmed.

6) trans-*nitro*-N,N'-*ethylenebis(acetylacetoniminato)aquocobalt(III)*, trans-$[Co(baen)(NO_2)(H_2O)]$ *(VI)*: Complex V was dissolved in water, and the solution was heated on a water bath for one hour. When the resulting solution was cooled to 0°C, dark green crystals were separated out. They were subsequently recrystallized from methanol. Yield, about 30%. From the IR spectrum, the coordination of the nitro group was confirmed.

7) trans-*nitro*-N,N'-*ethylenebis(acetylacetoniminato)pyridinecobalt(III)*, trans-$[Co(baen)(NO_2)(py)]$ *(VII)*: Complex VI was dissolved in methanol, and then an equimolar amount of pyridine was added to the solution. When the resultant solution was slowly concentrated at room temperature, reddish-brown crystals were separated out. They were washed with methanol. Yield, about 60%.

8) cis-β-N,N'-*ethylenebis(acetylacetoniminato)acetylacetonatocobalt(III)*, cis-β-$[Co(baen)(acac)]$ *(VIII)*: This complex was prepared by means of the known method given in Ref.16). Green crystals were obtained in about an 80% yield.

9) cis-β-N,N'-*ethylenebis(acetylacetoniminato)benzoylacetonatocobalt(III)*, cis-β-$[Co(baen)(bzac)]$ *(IX)*: Benzoylacetone (1.8 g, 0.011 mol) in 100 m*l* of methanol neutralized by potassium hydroxide (0.6 g, 0.011 mol) was added to a methanol (200 m*l*) solution of *N,N'*-ethylenebis(acetylacetonimonato)-diaquocobalt(II) (3.2 g, 0.01 mol). After air had been sucked through the solution for two hours, it was concentrated to about 100 m*l* by evaporating the solvent under reduced pressure. When the solution was then allowed to stand for two or three days, green crystals were separated out. They were recrystallized from methanol. Yield, about 70%.

10) cis-β-N,N'-*ethylenebis(acetylacetoniminato)-8-oxyquinolinatocobalt(III)*, cis-β-$[Co(baen)(oxin)]$ *(X)*: This complex was prepared by the method employed for the preparation of Complex IX, but using 8-hydroxyquinoline in place of benzoylacetone. Green crystals were obtained in a 40% yield.

11) cis-β-N,N'-*ethylenebis(acetylacetoniminato)ethylenediaminecobalt(III) Perchlorate Dihydrate*, cis-β-$[Co(baen)(en)]ClO_4\cdot 2H_2O$ *(XI)*. An equimolar amount of ethylenediamine was added to a methanol solution of *N,N'*-ethylenebis(acetylacetoniminato)diaquocobalt(II). Then, to the resultant solution hydrogen peroxide solution was added. When sodium perchlorate monohydrate in methanol was added to the above solution, brown power was separated out. This was washed thoroughly with methanol. Yield, about 90%.

12) cis-β-N,N'-*ethylenebis(acetylacetoniminato)-1,10-dipyridylcobalt(III) Perchlorate*, cis-β-$[Co(baen)(dip)]ClO_4$ *(XII)*: This complex was prepared by using the method employed for complex XI. Recrystallized from methanol, green crystals were obtained in about an 80% yield.

13) cis-β-N,N'-*ethylenebis(acetylacetoniminato)-1,10-phenanthrolinecobalt(III) Perchlorate*, cis-β-$[Co(baen)(phen)]ClO_4$ *(XIII)*: This complex was prepared by the method employed for the preparation of Complex XII. Green crystals were obtained in about an 80% yield.

14) cis-β-N,N'-*ethylenebis(salicylideneiminato)acetylacetonatocobalt(III)*, cis-β-$[Co(salen)(acac)]$ *(XIV)*: *N,N'*-ethylenebis(salicylideneiminato)cobalt(II)[2] (1.5 g) was dissolved in 200 m*l* of methanol, and potassium acetylacetonate was added to the solution. The resulting solution was heated on a water bath for fifteen minutes. When the resulting solution was concentrated to about 50 m*l*, yellowish-green crystals were separated out. They were subsequently recrystallized from methanol. Yield, about 90%.

15) cis-β-N,N'-*ethylenebis(salicylideneiminato)benzoylacetonatocobalt(III)*, cis-β-$[Co(salen)(bzac)]$ *(XV)*: This complex was prepared by using the method employed for Complex XIV. Yellowish-green crystals were obtained in about a 90% yield.

16) cis-β-N,N'-*ethylenebis(salicylideneiminato)ethylenediaminecobalt(III) Perchlorate Dihydrate*, cis-β-$[Co(salen)(en)]ClO_4\cdot 2H_2O$ *(XVI)*: This complex was prepared by using the method used for Complex XI. A brown powder was obtained in an 80% yield.

17) cis-β-N,N'-*ethylenebis(salicylideneiminato)-1,10-dipyridylcobalt(III) Perchlorate*, cis-β-$[Co(salen)(dip)]ClO_4$ *(XVII)*: This complex was prepared by using the method employed for the preparation of Complex XII. Green crystals were obtained in about an 80% yield.

18) cis-β-N,N'-*ethylenebis(salicylideneiminato)-1,10-phenanthrolinecobalt(III) Perchlorate*, cis-β-$[Co(salen)(phen)]ClO_4$ *(XVIII)*. This complex was prepared by using the method employed for Complex XIII. Green crystals were obtained in about

an 80% yield.

The elemental analyses data of all the complexes are summarized in Table 1.

Measurements. The NMR spectra of the complexes were recorded with a Hitachi R-20 spectrometer (60 MHz) at 35°C, using D_2O, $CDCl_3$, or deuterated dimethylsulfoxide as the solvent. In all the NMR measurements, TMS or NaTMS was used as the internal reference.

Results anb Discussion

NMR Spectra of Complexes I, II, III, IV, V, VI, and VII. The NMR spectra of the *trans* complexes are summarized in Table 2, together with those of *trans*-form Co(III)-salen complexes. Some typical NMR spectra of *trans*-form complexes are shown in Fig. 1.

Complexes I, II, III, IV, V, VI, and VII, all of which involve unidentate ligands, show NMR spectra having one C=CH and two CH_3 signals with relative intensities of 1 : 3 : 3. Generally, three geometrical isomers, *trans-planar*, *cis-*α, and *cis-*β, are possible for these complexes.[1] Complexes VI and VII, in which two unidentate ligands are present, show the typical NMR spectral pattern corresponding to the *trans* isomer. Therefore, these complexes, VI and VII, can be assigned a *trans*-form structure. Considering that the well-known oxygen carriers, Co(II)-baen complexes,[3,8–10,14] also have a *trans*-form structure, all the complexes, I, II, III, IV, V, VI, and VII, can be concluded to have *trans-planar* structures.

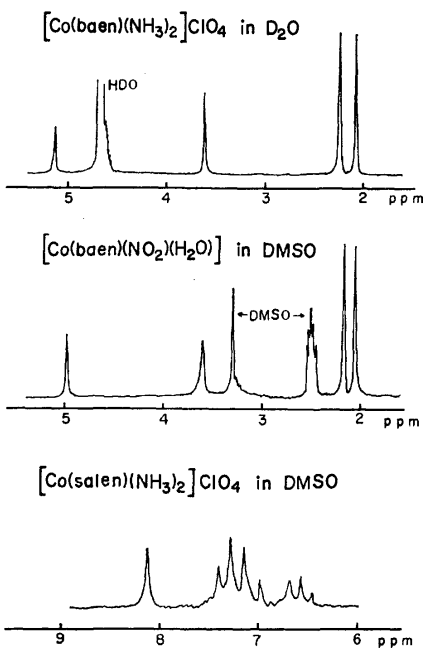

Fig. 1. Typical NMR spectra of *trans* form Co(III)-baen, -salen complexes.

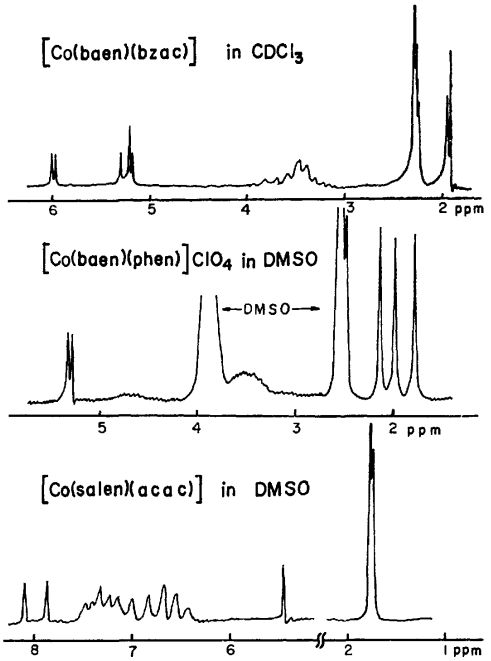

Fig. 2. Typical NMR spectra of *cis-β* form Co(III)-baen, -salen complexes.

The Co(III)-salen complexes containing ammonia or methylamine, which were prepared by using the well-known method described in Ref. 5), show NMR spectra with one CH=N signal; it is confirmed form study of their NMR spectra that these Co(III)-salen complexes take the *trans-planar* structure.

NMR Spectra of Complexes VIII, IX, X, XI, XII, and XIII. The data of the NMR spectra of *cis-β*-form Co(III)-bean, -salen complexes are listed in Tables 3 and 4, while some typical NMR spectra of these complexes are also shown in Fig. 2.

The baen complexes VIII, X, XI, XII, and XIII, show NMR spectra with two C=CH and four CH_3 signals for baen (the relative intensities of their peaks are 1 : 1 : 3 : 3 : 3 : 3). Since these spectral patterns correspond to the structure of the *cis-β*-form, as has been mentioned in a previous paper,[16] Complexes VIII, X, XI, XII, and XIII are assigned *cis-β*-form structures. On the other hand, Complex IX shows three C=CH signals with relative intensities of 1 : 2 : 1 for baen, two C=CH signals with relative intensities of 1 : 1 for bzac, and six CH_3 signals with relative intensities of 9 : 6 : 3 : 3 : 3 : 6 for baen and bzac. Although all the signals are not clearly resolved in this NMR spectrum, it can easily be understood that Complex IX does not contain only one species of the three

possible geometrical isomers—*cis-α*, *cis-β*$_1$, and *cis-β*$_2$, but that it is either a 1 : 1 mixture of two *cis-β* isomers or a 1 : 1 mixture of *cis-α* and one of the two *cis-β* isomers. However, as the NMR spectra expected for the two cases are thought to be nearly identical with each other, we can not distinguish whether the observed NMR spectrum corresponds to the former case or to the latter one. Since Complexes VIII, X, XI, XII, and XIII take only the *cis-β*-form structure, as has been mentioned above, and since all the above Co(III)-baen complexes are synthesized by using nearly the same reaction conditions, Complex IX is also thought to have the *cis-β*-form structure. Thus, Complex IX can be assummed to be a 1 : 1 mixture of two *cis-β* isomers.

Despite the fact that Complex IX contains two *cis-β*-form isomers in a relative ratio of 1:1, Complex X contains only one *cis-β*-form isomer, though two *cis-β* isomers are also possible in this case. As will be mentioned later, this can be mainly ascribed to the steric nature of these complexes.

NMR Spectra of Complexes XIV, XV, XVI, XVII, and XVIII. Complexes XIV and XV show two CH=N signals and one C=CH signal. Therefore, we can safely assign the *cis-β* structure to these complexes. However, in the cases of Complexes XVII and XVIII, the CH=N signal overlaps with the signals of the coordinated dipyridyl or phenanthroline. Therefore, it is difficult to determine the structure of these complexes from the NMR spectra only. Also it is difficult to determine the structure of Complex XVI because of its low solubility in a solvent. However, since the baen complexes containing bidentate ligands have *cis-β*-form structures, and since the salen complexes of acac and bzac have also *cis-β*-form structures, we can assign a *cis-β*-form structure to Complexes XVI, XVII, and XVIII, too. The reason for isolating only one *cis-β*-form isomer in Complex XV can be ascribed to the steric interaction of this complex, which will be discussed later.

The Preference of the trans-*Planar Structure in [Co(baen)(A)$_2$]ClO$_4$ and the Preference of a* cis-*β Structure in [Co(baen)(Y)]ClO$_4$.* In the reaction between *trans*-[Co(baen)(H_2O)$_2$] and the monodentate ligands, we can obtain only the *trans*-planer-form complexes in high yields. On the other hand, in the reaction between *trans*-[Co(baen)(H_2O)$_2$] and the bidentate ligands, we can obtain only *cis-β*-form complexes in high yields. In both cases, as we used the *trans*-[Co(baen)(H_2O)$_2$] as the starting material, it is thought possible that the configuration of the reaction products depends strongly on the reaction mechanism. In order to confirm this point, we prepared the complexes starting from the coblat(II) ion. The complex which was prepared by mixing the cobalt(II) ion, ammonia, and baen (in this order) gives the same NMR spectrum as that of Complex I. The complex which was prepared by mixing the cobalt(II) ion, phenanthroline, and baen (in this order) gives a NMR spectrum corresponding to the *cis-β*-form structure. From these observations, it can be concluded that the formation of the *trans*-form complex in the case of the unidentate ligands and the formation of only the *cis-β*-form complex in the case of the bidentate ligands do not depend on only the reaction mechanism.

Relative Stability of the Configuration. It has been established that baenH_2 takes the ketamine structure in solution.[17] On the other hand, although two resonance structures, ketamine and ketimine, are possible, the coordinated baen is thought to take the ketimine structure exclusively.[4] In the cases of the coordinated salen, it is clear that the salen takes the ketimine structure, because free salenH_2 takes the ketimine structure and the resonance from ketimine to ketamine structures in salen complexes is almost impossible because of the phenyl group.[3,18] Therefore, it can be thought that the C=N bonds of the coordinated baen and salen have mainly a double-bond character; therefore, their nitrogen atoms take the electronic configuration of the sp^2 hybridization. From the above structual restrictions, and the fact that the O—⟩ N=⟩ group of baen and salen is planar in nature, it is expected that the coordinated baen and salen will prefer the planar to all other configurations, corresponding to the *trans*-planar structure of octahedral complexes. The reason why only *trans*-form complexes isolated in the reaction between *trans*-[Co(baen)-(H_2O)$_2$] and the unidentate ligands is thought to be mainly based on the above facts.

In the cases of the baen and salen complexes which contain a bidentate ligand, baen and salen can not take a *trans*-planar configuration, but only a *cis-α* or *cis-β* form. When baen and salen take a *cia-α*

cis-α *cis-β*

Fig. 3. The geometrical structures of *cis-α* and *cis-β* forms Co(III)-baen, -salen backbones.

or *cis-β*-form, it can be concluded form the molecular model test that the chelate rings A, B and B in Fig. 3 are distorted from the plane of $Co\langle^{O}_{N}$ by about 30°. This distortion will cause the decrease in the π-bond-formation ability of baen and salen with the cobalt(III) ion as compared with that in the *trans*-planar complexes. From this point of view, it is concluded that the relative stabilities among three configurations are as follows: planar>*cis-β*>*cis-α*.

In the cases of the *cis-β*-form complexes, some steric interaction between the coordinated baen, salen, and the bidentate ligands is observed in their molecular model tests. Since the chelate ring B is distorted from the plane of $Co\langle^{O}_{N}$ by about 30°, as is shown in Fig. 3, when the sterically bulky groups such as benzoylacetone and 8-oxyquinoline are coordinated to the cobalt(III)-baen, salen backbone, some steric interaction between the bulky groups and the methyl, phenyl groups of the distorted $^{O-}_{N=}\rangle$ group occurs. This steric hindrance is thought to be much larger in salen than in baen, and much larger in 8-oxyquinoline than in benzoylacetone. This steric hindrance is thought to be the main reason why only one *cis-β*-form isomer is siolated in the cases of Complexes X and XV.

The authors wish to express their deep thanks to Dr. M. Kodama of Ibaraki University for his encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2464—2468 (1972)

Mixed Solvent Deuterium Isotope Effects on the Hydrolysis of UO_2^{2+} and Be^{2+} Ions

Masunobu MAEDA,[1] Toshihiko AMAYA*, Hitoshi OHTAKI, and Hidetake KAKIHANA*

Department of Electrochemistry, Faculty of Engineering, Tokyo Institute of Technology, O-okayama, Meguro, Tokyo

**Research Laboratory of Nuclear Reactor, Tokyo Institute of Technology, O-okayama, Meguro, Tokyo*

(Received February 8, 1972)

Stability constants of the hydrolysis species of UO_2^{2+} ion were determined in pure light water and 80% heavy water containing 3M $NaClO_4$ as an ionic medium at 25°C, and the results were compared with those in pure heavy water. The decrease of the stability constants in hydrolysis reactions of UO_2^{2+} ion, as well as of Be^{2+} ion, was discussed in terms of the equilibrium theory of the solvent deuterium isotope effects, which is based on the assumptions that activity coefficients of chemical species in isotopic exchange equilibria remain unchanged with the change in the deuterium atom fraction in the solvent, that the solvated hydrogen ion possesses three equivalent lyons, and that the isotopic equilibria are subject to the rule of the simple geometric mean. Satisfactory agreements were found between the observed and calculated values for the relative stability constants of the hydrolysis species of UO_2^{2+} and Be^{2+} in water of various hydrogen isotopic compositions.

In the preceding papers,[2-5] we have studied on the hydrolysis reactions of Be^{2+}, UO_2^{2+}, Cu^{2+}, and Y^{3+} ions in pure heavy water and have found that the compositions of complexes formed by hydrolysis in heavy water are the same as those in light water, and that the stability constants of the complexes in heavy water are smaller than those in light water. In the study of the hydrolysis of Be^{2+} ion in mixtures of light and heavy water, it has been found that the stability constants decrease monotonously with the increase in the deuterium atom fraction.[6]

In the present paper are included results on the hydrolysis of UO_2^{2+} ion in 80%(deuterium atom fraction) heavy water as well as in light water, and a quantitative interpretation is attempted for the variation of the stability constants for hydrolysis species of UO_2^{2+} and Be^{2+} ions in H_2O-D_2O mixtures in terms of the equilibrium theory of solvent deuterium isotope effects, which have so far been applied to acid-base equilibria in light and heavy water by a number of investigators.[7]

Results

Values of Z, average number of lyonium ion split off per metal ion by hydrolysis, and log l at each series of B, the total concentration of the metal ion, are shown graphically in Figs. 1 and 2, respectively. A generalized least squares method was applied to determine the most probable values of stability constants of the minimum number of hydrolysis species which would suffice to account for the experimental data. Values of stability constants were so chosen that the error square sum ($\Sigma(Z_{calc}-Z)^2$) becomes minimum, where Z_{calc} denotes calculated values of Z with a particular set of the constants, $\beta_{p,q}$. Among some combinations of complexes, the assumptions of formation of (2, 2), (4, 3) and (5, 3) complexes, the (4, 3) complex being a minor component, gave the most satisfactory agreement between experimental and calculated values of Z in both systems of 80% heavy water and light water. These complexes have also been found in heavy water.[3] The final values of stability constants of the complexes are listed in Table 1, together with those in pure heavy water.

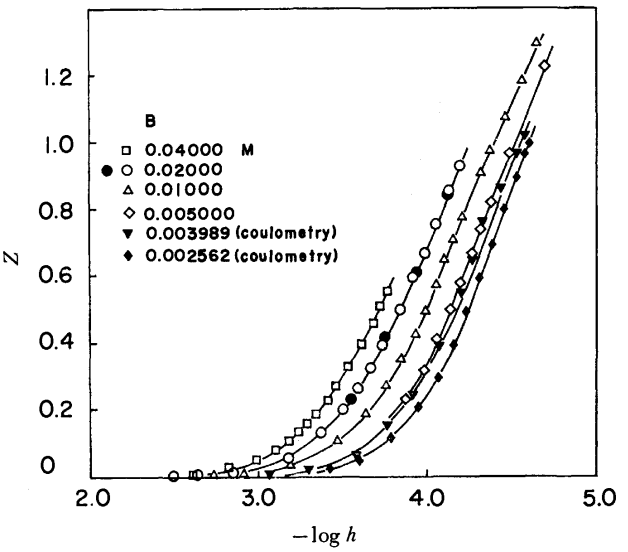

Fig. 1. Average number, Z, of OH bound per UO_2^{2+}, as a function of log h for the system of light water. Drawn curves were calculated with the stability constants given in Table 1. Open symbols denote the forward titrations and filled symbols the back titrations.

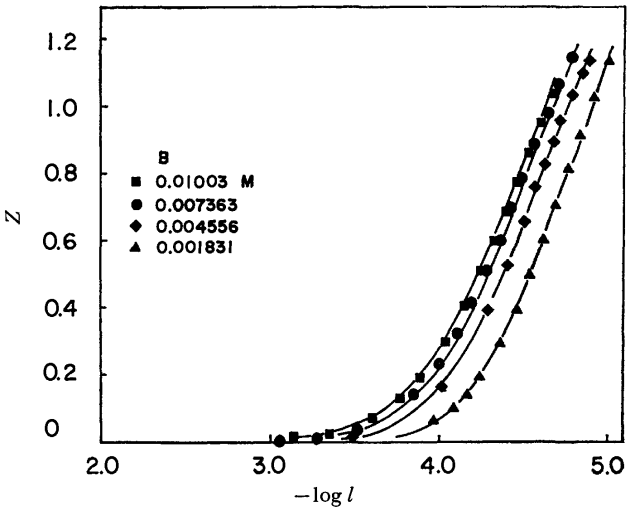

Fig. 2. Average number, Z, of OL bound per UO_2^{2+}, as a function of log l for the system of 80% heavy water. Drawn curves were calculated with the stability constants given in Table 1.

Table 1. Stability constants of uranyl hydroxo complexes in light and heavy water and 80% heavy water

	Light water[a]	80% Heavy water[a]	Heavy water[a]
$-\log \beta_{2,2}$	6.17±0.02	6.61±0.03	6.80±0.02
$-\log \beta_{4,3}$	$12.92\pm0.1_5$	$14.28\pm0.2_0$	$14.00\pm0.1_5$
$-\log \beta_{5,3}$	17.04±0.03	18.16±0.04	18.63±0.02

a) The uncertainties of the constants were estimated as 3σ.

The present results for the light water system were compared with those obtained by Sillén *et al.*[15] in the same ionic medium(3 M $NaClO_4$). Values for $\beta_{p,q}$ they obtained were $-\log \beta_{1,1}\simeq6.10$, $-\log \beta_{2,2}=6.04\pm0.02$, $-\log \beta_{4,3}\simeq13.21$ and $-\log \beta_{5,3}=16.53\pm0.02$. For the (4, 3) complex almost the same stability constant was found in the present study. For the (2, 2) and (5, 3) complexes, on the other hand, the smaller stability constants were obtained in this work than those of their work. No (1, 1) complex found by Sillén *et al.* was detected.

Discussion

As has been seen from results in systems of Be^{2+},[2,6] Cu^{2+},[4] and Y^{3+},[5] the compositions of complexes formed by hydrolysis in heavy water are the same as those in light water, while the stability constants of the complexes are smaller in heavy water than in light water. Essentially the same results were found in the system of uranyl ions.

The first attempt of interpretation of the solvent deuterium isotope effect was made by Gross and his co-workers[8] for acid catalyzed reactions, and the Gross' treatment has been applied to acid dissociation equilibria of water itself[9] and some acids such as am-

9) P. Salomaa, L. L. Schaleger, and F. A. Long, *J. Amer. Chem. Soc.*, **86**, 1 (1964).

monium ion[10] and phosphoric acid,[9] as well as to reaction kinetics.[11]

Since hydrolysis reactions are regarded as acid dissociation reactions of aquated metal ions, essentially similar treatments as Gross' may be used for analysis of hydrolysis schemes of metal ions in H_2O-D_2O mixtures. In the equilibrium theory first proposed by Gross,[8] the following assumptions are made; (1) Activity coefficients of chemical species do not change through the exchange of protons in a molecule with deuterons, (2) a solvated hydrogen ion possesses three lyons, and (3) isotopic disproportionation equilibria are subject to the rule of the simple geometric mean. Under these assumptions and with knowledge of values of stability constants of hydrolysis species in light and heavy water, variations of stability constants of hydrolysis species of UO_2^{2+} and Be^{2+} ions with the deuterium atom fraction in the solvent were discussed.

(1) Solvent Deuterium Isotope Effects on the Hydrolysis of UO_2^{2+}. On the basis of the above assumptions, prevailing equilibria among the various solvent species, protons, and deuterons along with their equilibrium constants are written as follows.

$$H_2O + D_2O = 2HDO \ ; \ 4 \tag{1}$$

$$2H_3O^+ + D_3O^+ = 3H_2DO^+ \ ; \ 27 \tag{2}$$

$$H_3O^+ + 2D_3O^+ = 3HD_2O^+ \ ; \ 27 \tag{3}$$

$$1/3H_3O^+ + 1/2D_2O = 1/3D_3O^+ + 1/2H_2O \ ; \ \psi \tag{4}$$

From Eq.(1), the concentrations of waters in a solvent mixture of a deuterium atom fraction n become

$$[H_2O] = (1-n)^2 \tag{5}$$

$$[HDO] = 2n(1-n) \tag{6}$$

$$[D_2O] = n^2 \tag{7}$$

The total concentration of lyonium ions, $\sum[L_3O^+]$ is expressed by Eq. (8) in terms of $[H_3O^+]$, n and ψ by means of Eqs. (1)—(7).

$$\sum[L_3O^+] = [H_3O^+] + [H_2DO^+] + [HD_2O^+] + [D_3O^+] = [H_3O^+](1-n+n\psi)^3(1-n)^{-3} \tag{8}$$

Let us consider a solution of the (2, 2) complex in a mixed H_2O-D_2O solvent. There are three different types of complexes, $(UO_2)_2(OH)_2^{2+}$, $(UO_2)_2(OH)(OD)^{2+}$ and $(UO_2)_2(OD)_2^{2+}$. The following two deuterium fractionation factors are defined;

$$(UO_2)_2(OH)_2^{2+} + D_2O = (UO_2)_2(OD)_2^{2+} + H_2O \ ; \ \Phi_{20}$$

$$(UO_2)_2(OH)_2^{2+} + 1/2D_2O = (UO_2)_2(OH)(OD)^{2+} + 1/2H_2O \ ; \ \Phi_{21}$$

and they are given as

$$\Phi_{20} = \{[(UO_2)_2(OD)_2^{2+}]/[(UO_2)_2(OH)_2^{2+}]\} \times \{(1-n)/n\}^2 = (\beta^D_{2,2}/\beta^H_{2,2})\psi^{-6} \tag{9}$$

$$\Phi_{21} = \{[(UO_2)_2(OH)(OD)^{2+}]/[(UO_2)_2(OH)_2^{2+}]\} \times \{(1-n)/n\} = K(\beta^D_{2,2}/\beta^H_{2,2})\psi^{-3} \tag{10}$$

Here, K is the isotopic disproportionation factor for the reaction,

$$1/2(UO_2)_2(OH)_2^{2+} + 1/2(UO_2)_2(OD)_2^{2+} = (UO_2)_2(OH)(OD)^{2+} \ ; \ K \tag{11}$$

From Eqs. (8)—(10), the total concentration of the (2, 2) complexes is given as follows.

$$\sum[(UO_2)_2(OL)_2^{2+}] = [(UO_2)_2(OH)_2^{2+}] \times \{1 + \Phi_{20}(n/(1-n))^2 + \Phi_{21}(n/(1-n))\} \tag{12}$$

The equilibrium constant, $\beta_{2,2}$ in a mixed solvent, which is accessible to experimental measurement is made up of the total concentrations of the various isotopic species involved.

$$\beta^n_{2,2} = \{\sum[(UO_2)_2(OL)_2^{2+}] \cdot \sum[L_3O^+]^2\} / \{[UO_2^{2+}]^2 \sum[L_2O]^4\} \tag{13}$$

Introducing the expressions for the total concentration of the (2, 2) complexes (Eq. (12)) and of lyonium ions (Eq.(8)) into Eq. (13), we obtain

$$\beta^n_{2,2} = [\{[(UO_2)_2(OH)_2^{2+}][H_3O^+]^2\}/\{[UO_2^{2+}]^2(1-n)^6\}] \times \{1 + \Phi_{20}(n/(1-n))^2 + \Phi_{21}(n/(1-n))\}(1-n+n\psi)^6 \tag{14}$$

If we assume that the equilibrium constant of the reaction $2UO_2^{2+} + 4H_2O = (UO_2)_2(OH)_2^{2+} + 2H_3O^+$ in a mixed solvent with a deuterium atom fraction n is equal to that of the same reaction in pure light water, the following equation is readily obtained.

$$\beta^n_{2,2}/\beta^H_{2,2} = (1-n+n\psi)^6 \times \{(1-n)^2 + \Phi_{20}n^2 + \Phi_{21}n(1-n)\} \tag{15}$$

The application of the rule of the geometric mean to the equilibrium(11) leads to K=2.[12] As the values for $\beta^H_{2,2}$ and $\beta^D_{2,2}$ have been obtained experimentally and the value for ψ has been reported to be 0.69,[13] the relative stability constant, $\beta_{2,2}/\beta_{2,2}$ can be calculated using Eqs.(9) and (10).

The relative stability constant, $\log(\beta^n_{2,2}/\beta^H_{2,2})$ at $n=0.8$ thus calculated is shown in Table 2. The agreement between the experimental and calculated values is satisfactory.

TABLE 2 CALCULATED AND OBSERVED RELATIVE STABILITY CONSTANTS, $\log(\beta^n_{p,q}/\beta^H_{p,q})$ AT $n=0.8$

Complex	$\log(\beta^n_{p,q}/\beta^H_{p,q})$	
	Calcd	Obsd
$(UO_2)_2(OL)_2^{2+}$	−0.46	−0.44
$(UO_2)_3(OL)_5^+$	−1.17	−1.12

In general, Eq. (15) can be written, for the (p,q) complex, as follows;

$$\beta^n_{p,q}/\beta^H_{p,q} = (1-n+n\psi)^{3p} \cdot \{\sum_m \Phi_{pm} n^{(p-m)}(1-n)^m\} \tag{16}$$

and Φ_{pm} is given as

$$\Phi_{pm} = K_m(\beta^D_{p,q}/\beta^H_{p,q})^{(p-m)/p} \cdot \psi^{-3(p-m)} \tag{17}$$

where K_m denotes the equilibrium constant of the following isotopic disproportionation reaction (charges are omitted);

10) P. Salomaa, L. L. Schaleger, and F. A. Long, *J. Phys. Chem.*, **68**, 416 (1964).

11) C. G. Swain and E. R. Thornton, *J. Amer. Chem. Soc.*, **83**, 3890 (1961).

12) J. Bigeleisen, *J. Chem. Phys.*, **23**, 2264 (1955).

$$\frac{m}{p}M_q(OH)_n + \frac{p-m}{p}M_q(OD)_p = M_q(OH)_m(OD)_{p-m} \; ; \; K_m \quad (18)$$

Φ_{pp}, K_0, and K_p are defined as 1.

Variation of the stability constant of the $(UO_2)_3(OL)_5^+$ complex, $\log(\beta^n{}_{5,3}/\beta^H{}_{5,3})$, can be calculated from Eq. (16); in this case $K_1=5$, $K_2=10$, $K_3=10$, and $K_4=5$ are given under the assumption of the geometric mean.[12]

The calculated results at $n=0.8$ are represented in Table 2.

For the $(UO_2)_3(OL)_4^{2+}$ complex, the formation of which is quite small, uncertainties of the stability constants are so large that the discussion of the variation of the stability constant with the solvent composition can hardly be made.

(2) Solvent Deuterium Isotope Effects on the Hydrolysis of Be^{2+}. In the previous studies for the hydrolysis of Be^{2+} ion in light water,[2,14] heavy water,[2] and their mixtures,[6] we found that the main product of the reaction is $Be_3(OL)_3^{3+}$ in all systems examined and the stability constant of the species decreases with the increase of the deuterium atom fraction in the solvent. The continued variation of the relative stability constant of the (3, 3) species with the change in the deuterium atom fraction in the solvent has been determined experimentally as follows.[6] If only the (3, 3) species is present in appreciable amounts in mixed H_2O-D_2O solvents, the following equation can be derived:

$$1/2\log Z - 3/2\log(1-Z) = 1/2\log 3 + 1/2\log\beta_{3,3} + \log B - 3/2\log l \quad (19)$$

Differentiation of Eq.(19) with respect to the deuterium atom fraction at constant B and Z values gives the equation:

$$\partial\log\beta_{3,3} = 3\,\partial\log l \quad (20)$$

The variation of the stability constant can be determined according to Eq.(20) if the change in l with the deuterium atom fraction is measured. In order to determine the variation of l with the deuterium atom fraction, the change in emf, ΔE, with the solvent composition was measured at constant B (0.02 and 0.04 M) and Z values ($Z\simeq0.5$, where the (3, 3) species has been found to be predominant), and the change in E_0, that is ΔE_0, with the deuterium atom fraction was also measured by the similar titration procedure without beryllium ions. From the values for ΔE and ΔE_0 at any given solvent composition the change in l, $\Delta\log l$, could be evaluated by the equation $\Delta\log l=(\Delta E-\Delta E_0)/59.15$. The observed changes in $\beta_{3,3}$ with varying deuterium atom fraction from 0 to 0.8 are shown in Fig. 3.

Calculation of the relative stability constant of the $Be_3(OL)_3^{3+}$ complex in water of different hydrogen isotopic compositions was carried out by substituting the relation $K_1=K_2=3$[12] into Eq.(16). The results are compared with the experimental ones in Fig. 3. We see that the agreement is satisfactory.

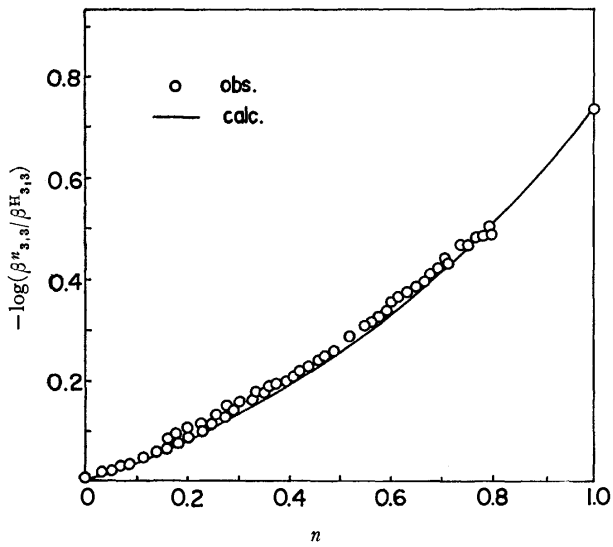

Fig. 3. Observed and calculated values of $-\log(\beta^n{}_{3,3}/\beta^H{}_{3,3})$ for the (3, 3) complex of Be^{2+} in H_2O-D_2O mixtures.

Conclusion

1) Stability constants of hydrolysis species of UO_2^{2+} ion were determined in light and 80% heavy water containing 3 M $NaClO_4$ as an ionic medium at 25°C. The results are tabulated in Table 1.

2) Relative stability constants of hydrolysis species of UO_2^{2+} and Be^{2+} ions in various H_2O-D_2O mixtures were estimated by application of the equilibrium theory of solvent deuterium isotope effects. Satisfactory agreements were found between the observed and calculated values.

Experimental

Reagents. Reagents used were, unless otherwise stated, prepared and analyzed as have been described in Refs. 2 and 3.

Uranyl percholrate solution was prepared and analyzed with the same procedures as those described in Ref. 15. *Uranyl perchlorate in* 80% *heavy water* was prepared by the repeated evaporation of uranyl perchlorate solution under an infrared lamp, while adding 80% heavy water.

NaOL solution in 80% *heavy water* was prepared by electrolysis of sodium perchlorate in 80% heavy water.

Apparatus. *A Wilhelm type half-cell*[17] was used for emf measurements, and a modified one for constant-current coulometry.

Glass electrodes of Beckman No. 40498 were used in combination with *a Radiometer PHM-4C pH-meter (Copenhagen).*

A coulometric analyzer(Leeds & Northrup Co., Philadelphia) was used as a constant current power source.

Procedures. Hydrolysis of uranyl ions in 80% heavy water and in light water was investigated by measurements of the total concentration of free lyonium ion using a glass electrode. Sodium perchlorate was used as an ionic medium in order to keep the total concentration of perchlorate ion to be 3 M. The total concentration of uranyl ion was kept constant in each series of experiments.

The lyonium ion concentration was measured by means

of the cell;

$$\text{GE}|\text{Test Solution}|\text{Ref} \qquad \text{(A)}$$

where GE denotes a glass electrode and Ref, the reference half cell containing 2.99 M $NaClO_4$—0.01 M $AgClO_4$ solution and a silver-silver chloride electrode. The liquid junction between the reference half cell and the test solution was constructed with 3 M $NaClO_4$ in 80% heavy water or in light water.

For the system of light water, both coulometric and ordinary titrations were employed. Since no difference has been observed between the results by these two methods, a coulometric titration was used for the system of 80% heavy water.

The emf of the cell(A) is given, at 25°C, as follows:[18]

$$E = E_0 + 59.15 \log l + E_j \qquad (21)$$

E_j, a liquid junction potential was negligible under the present experimental condition.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2468—2472 (1972)

Some Metal Complexes Containing Ethyl Acetoacetate or Ethyl Malonate as a Neutral Ligand

Hideyoshi MORITA,* Yukio NAKAMURA, and Shinichi KAWAGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received February 23, 1972)

The following metal complexes containing ethyl acetoacetate (etacH) or ethyl malonate (etmalH) as a neutral ligand have been prepared: $CoCl_2L$, $CoBr_2L$, $ZnCl_2L$ (L=etacH or etmalH), and $MnBr_2$(etmalH). These compounds are all hygroscopic and unstable, releasing the ester ligand below 100°C *in vacuo* or in donor solvents. The infrared spectra show that the ratio of keto and enol tautomers in etacH complexes is similar to that for the free ligand. The ν(C=O) band attributable to the enol tautomer of etmalH is observed in the complexes, though not in the free ligand. The electronic spectra measured in Nujol suggest that the cobalt(II) complexes are tetrahedral. The structure of $MnBr_2$(etmalH) is not yet certain.

Acetylacetone is one of the most versatile ligand; it usually coordinates to the metal atom as a bidentate anion,[1] although in some cases it serves as a unidentate anion, forming a metal-carbon bond[2] or an ether type metal-oxygen[3] linkage. In a previous paper we reported on several metal complexes containing acetylacetone as a neutral ligand.[4]

The neat liquid of acetylacetone (acacH) is a mixture of keto and enol tautomers; the equilibrium content of the latter was determined by the NMR method to be 81.4% at 25°C.[5] However, in the above metal complexes of neutral acetylacetone, such an equilibrium composition is not maintained; rather, one of the two tautomers is incorporated exclusively. Thus, $MnBr_2(acacH)_2$ involves enolic molecules as unidentate ligands,[6] but $NiBr_2(acacH)_2$,[7] $ZnCl_2$-(acacH), CoX_2(acacH), and CrX_2(acac)(acacH) (X=Cl, Br) all contain the keto tautomer as a bidentate ligand.[4] Similarly, $UO_2(acac)_2(acacH)$ has been reported to have an enol molecule,[8] and] [Ni-$(acacH)_3](ClO_4)_2$ and other related Ni(II) complexes, the keto tautomer.[9] Proton magnetic resonance studies of $[Mg(acacH)_2(H_2O)_2](ClO_4)_2$ in CD_3NO_2 have also revealed that the keto tautomer is the dominant species bonded to the magnesium ions in solution.[10]

As an extension of the previous work, we have tried to synthesize several metal complexes containing ethyl acetoacetate or ethyl malonate as a neutral ligand. In contrast with acetylacetone, the keto tautomer is the major component in these esters; the enol content has been reported to be about 8% in ethyl acetoacetate[11] and seems to be negligible in ethyl malonate. Thus, it was expected that metal complexes of these ester molecules involve the keto tautomer exclusively.

Experimental

Materials. The anhydrous metal halides were prepared by the following methods. About 50 ml of freshly-distilled thionyl chloride was added to 25 g of cobalt(II) chloride hexahydrate, and the mixture was refluxed for about 2 hr. After the vacuum distillation of the excess thionyl chloride, the residual anhydrous cobalt(II) chloride was dried for three days in a vacuum desiccator containing po-

tassium hydroxide.[12] Anal. Found: Co, 45.59; Cl, 54.32%. Commercial zinc(II) chloride was also dried by a similar method to yield an anhydrous compound.[12] Anal. Found: Zn, 47.14; Cl, 52.42%. The anhydrous cobalt(II) bromide was obtained by the dehydration of the commercial hexahydrate by heating at 130°C for 10 hr and by evacuating at the same temperature for 2 hr. Anal. Found: Co, 27.12; Br, 72.61%. The anhydrous manganese(II) bromide was prepared according to Watt and Manhas[13] by a reaction between manganese(II) carbonate and hydrobromic acid. Anal. Found: Mn, 25.48; Br, 74.23%.

Ethyl acetoacetate and ethyl malonate were distilled under reduced pressure, and the distillates, collected at 83—86°C and 99—102°C respectively, were used in this study. Mercury(II) tetraisothiocyanatocobaltate(II) was prepared according to Figgis and Nyholm.[14] Anal. Found: C, 9.73; N, 11.43%. Calcd for $HgCo(NCS)_4$: C, 9.77; N, 11.39%.

Syntheses and Analyses of the Ester Complexes. About a 40-m*l* portion of ethyl acetoacetate or ethyl malonate was added to about 1 g of an anhydrous metal halide, and the mixture was stirred for about 48 hr. The precipitate was filtered, washed with petroleum ether, and dried *in vacuo*. The complexes thus prepared are all hygroscopic; special care was taken to exclude atmospheric moisture in the preparation and filtration procedures.[4]

The cobalt and manganese in these complexes were determined gravimetrically as sulfates, and zinc, as ammonium phosphate. The halide contents were also measured gravimetrically as silver salts. The results of the elemental analysis of these compounds are tabulated in Table 1, together with some properties.

Measurements. No solvent is available in which these complexes are dissolved without decomposition. A solid specimen was ground with Nujol and placed between two plates of opal glass, and its transmission spectrum was measured[15] with a Hitachi-Perkin Elmer 139 spectrophotometer. The infrared spectra were measured in Nujol by means of Hitachi EPI-2 (700—4000 cm^{-1}) and EPI-L (200—700 cm^{-1}) infrared spectrophotometers.

A thermo-spring balance (C-282) of Hamada Denki Seisaku-sho, Ltd., was used for the thermogravimetric analysis of the ethyl malonate complexes; the temperature of a sample was raised at a rate of 20°/hr. The decomposition residue was dissolved in water and analyzed.

The magnetic susceptibility was determined at room temperature by the Gouy method with an automatically-recording magnetic balance of Shimadzu Seisakusho, Ltd. Mercury(II) tetraisothiocyanatocobaltate(II) was used as the reference.

Results

Infrared Spectra. In Table 2 are summarized the infrared absorption spectra of metal complexes of ethyl acetoacetate (etacH) and ethyl malonate (etmalH) in the regions of the carbonyl, metal-oxygen, and metal-halogen stretching vibrations. The carbonyl stretching frequencies of the free ligands were assigned by reference to the literature;[16] they are included in the table. In the infrared spectrum of the free ligand etacH, the ν(C=O) band for the keto tautomer is very strong and that for the enol tautomer is weak, reflecting the equilibrium composition of the two tautomers. The ν(C=O) band for the enol tautomer is hardly detectable in the spectrum of etmalH.

The infrared spectra of acetylacetone complexes showed the carbonyl stretching absorption solely due to either the keto or the enol tautomer, revealing that either one of the tautomers was incorporated exclusively in each complex.[4] On the contrary, carbonyl stretching bands attributable to both tautomers are observed in each of the present ester complexes (Table 2), indicating that each compound is a mixture of complex molecules containing the keto tautomer as a ligand and those having the enol tautomer. Although the carbonyl stretching region of these complexes is very broad and exact estimation is difficult, the rough intensity ratio of the carbonyl bands of the two tautomers in each ethyl acetoacetate complex is near to that for the free ligand. This observation suggests that the formation constants of keto and enol complexes are similar in these cases. Since the carbonyl stretching band of the enol tautomer of free ethyl malonate can hardly be identified, it is not certain whether the bands observed at 1618—1658 cm^{-1} for the metal complexes are assignable to the coordinated enol tautomer. If this is indeed the case, though, it must be concluded that the complex formation constant of the enol tautomer is much larger than that

of the keto tautomer in the case of ethyl malonate.

Distinct absorption bands appearing in the 377—397 cm^{-1} region were attributed to the metal-oxygen stretching vibrations in the complexes of the keto tautomers. On the other hand, the ν(M–O) bands of the enol tautomers are obscure because of their minor abundances; they will not be assigned here.

The metal-halogen stretching absorptions were assigned according to the literature;[17,18] they are listed in Table 2. These exist in the range of frequencies attributable to the non-bridging metal-halogen stretching vibration in tetrahedral complexes of the MX_2L_2 type, where L respresents a unidentate ligand.

Electronic Spectra and Magnetic Data. The absorption spectra of $CoCl_2$(etacH) and $CoCl_2$(etmalH) in Nujol (Fig. 1) exhibit three maxima, at 600, 675, and 717 nm, and at 598, 680, and 722 nm, respectively. These spectra unequivocally indicate that those are tetrahedral complexes,[19] although their magnetic moments are a little higher than the values usually observed for tetrahedral cobalt(II) complexes.[19]

The observed magnetic moment (5.51 B. M.) of $MnBr_2$(etmalH) certifies that this is a high-spin complex, but we can not distinguish whether it is tetrahedral or octahedral. The absorption spectrum can not be observed by the opal glass method due to the low absorption intensity. However, the pale pink color might reflect an octahedral structure, since manganeses(II) usually has a green-yellow color in tetrahedral environments.[20]

Thermogravimetric Data. The negative shifts of the carbonyl stretching frequencies of etacH and etmalH caused by ligation to metal atoms are minute, suggesting the weakness of these bonds. This is also revealed by the thermogravimetric data of etmalH complexes depicted in Fig. 2 and summarized in Table 3. The zinc complex is most unstable and begins to decompose at 40°C. The weight loss coincides

with the calculated content of the ligand in each complex, while the composition of the residue coincides with that of the metal halide.

Although the final decomposition residue is thus the metal halide, a plateau-like portion is observed in each decomposition curve, suggesting the presence of some metastable intermediate. The composition corresponds to $CoCl_2$: etmalH=6 : 1, $MnBr_2$: etmalH =5 : 1, and $ZnCl_2$: etmalH=5 : 3. Allan *et al.*[21] studied the thermal decomposition of adducts of cobalt(II) chloride and manganese(II) bromide with pyridine and its methyl derivatives; they found $CoCl_2$·2/3 py and $MnBr_2$·2/3 (Me-py) as intermediates. Much more effort will be needed to characterize the decomposition intermediates in the present case.

Discussion

In a previous paper acetylacetone complexes were synthesized by three alternative methods:[4] (1) the direct addition of acetylacetone to anhydrous metal halides, (2) the reaction of the usual acetylacetonate chelate with dry hydrogen bromide in dichloromethane containing free acetylacetone, and (3) the reaction of trichlorotris(tetrahydrofurn)chromium(III) with acetylacetone. The ester complexes were prepared by the first method. In order to succeed in getting solid complexes by this method, the metal halide should have an appropriate solubility in the free ligand. Anhydrous nickel(II) chloride is insoluble in etacH and etmalH, and does not give either complex. On the other hand, the solubility of manganeses(II) bromide in etacH is too high and the isolation of a solid complex was unsuccessful.

The thermodynamic stabilities of ester complexes are relatively low, but those listed in Table 1 were stable enough to be analyzed and characterized. Anhydrous manganese(II) chloride reacted with both etacH and etmalH, giving solid products, but their decomposition pressures were so large that they easily decomposed to the starting materials without affording any complexes of a definite composition. On the contrary, the cobalt(II) bromide complex with etacH held the ligand in excess of the 1 : 1 composition. As is shown in Table 1, even after prolonged evacuation at 50°C the analytical data showed some contamination with the free ligand. The function of the slight excess of etacH in this complex is not at all clear.

As to the structures of these ester complexes, any conclusive discussion is impossible, since no adequate solvent is available for the molecular-weight determination and since no suitable crystal has yet been obtained for the X-ray analysis. The infrared spectra indicate that both the keto and the enol tautomers are incorporated in these ester complexes, while the electronic spectra of solid specimens of cobalt(II) chloride complexes in Nujol suggest the tetrahedral structure for these complexes. The ketonic complex may be presumed to be monomeric, two halogen atoms and two carbonyl oxygen atoms of the keto tautomer surrounding the metal atom tetrahedrally. It is not certain whether the structure of the minor enolic complex is reflected in the absorption spectra. If this is indeed the case, and if the enolic complex also assumes a tetrahedral structure, some polymeric structure containing the Co-Br chain must be formed, since the enol tautomer of etacH or etmalH does not seem to act as a bidentate.

The octahedral structure might be assigned to $MnBr_2$(etmalH) on the basis of its pale pink color. This structure may be realized if the keto tautomer of the ester occupies two adjacent coordination sites and if the $MnBr_2$ unit constructs an infinite spiral chain. On the other hand, two enolic molecules of acetylacetone are used in $MnBr_2(acacH)_2$ to complete the octahedral structure around each manganese atom in the infinite linear $MnBr_2$ chain.[6] Such a difference in the tautomeric form of the ligand molecule incorporated might be the reason why acetylacetone forms the 2 : 1 complex with $MnBr_2$, while ethyl malonate froms the 1 : 1 complex. Recently Kemula and Iwamoto[22] investigated the complex formation equilibria in a solution of $SnCl_4$ and various esters. Ethyl acetate, ethyl glutarate, and ethyl adipate act as monodentate ligands and form 1 : 1 and 2 : 1 complexes with $SnCl_4$, depending on the ratio of the ester to $SnCl_4$, but ethyl oxalate and ethyl malonate serve as chelating agents and form only 1 : 1 complexes.

The relative bonding strengths of acacH, etacH, and etmalH to metal might be worth noting. The metal-oxygen stretching frequencies for zinc complexes nearly coincide ($ZnCl_2(acacH)$[4] 230, 210; $ZnCl_2$-(etacH) 233, 218; $ZnCl_2$(etmalH) 230, 218 cm^{-1}), but some difference is noticed for cobalt(II) complexes

22) A. Kemula and R. T. Iwamoto, *J. Phys. Chem.*, **72**, 1334 (1968).

($CoCl_2$(acacH)[4] 264, 248; $CoCl_2$(etacH) 250, 242; $CoCl_2$(etmalH) 243, 232 cm^{-1}). The latter results might reflect the relative bonding strengths of these ligands in the order of acacH > etacH > etmalH. The amounts of the nagative shift in the carbonyl stretching frequencies of these complexes from those of free ligands are so small that they do not permit the differentiation of their bonding strengths.

The magnetic measurements were carried out at Kyoto University, and the authors are indebted to Dr. H. Kobayashi for providing facilities for them. Acknowledgement is made to Mr. J. Gohda for the elemental analysis, and also to the Ministry of Education for its financial support.

Isotopic Exchange Kinetics between Trisacetylacetonatocobalt(III) and Acetylacetone-^{14}C in Organic Solvents

Kazuo SAITO and Mizue MURAKAMI

Chemistry Department, Faculty of Science, Tohoku University, Sendai

(Received February 26, 1972)

The isotopic exchange proceeds faster than the decomposition of the complex at more than 80°C and below 120°C. McKay plot gives a linear diagram at the initial stage of isotopic exchange. The rate is expressed by $R=[\text{complex}](k_1+k_2[\text{acacH}])$, where acacH stands for free acetylacetone. The Arrhenius activation energy decreases in the order anisole (25 kcal per mole), chlorobenzene (21), and toluene (18) and is subject to acid catalysis with a strong acid as trichloroacetic. Comparison of the data with those of racemization of this complex, and isomerization and inversion of tris(benzoylacetonato)cobalt(III) suggested that k_1 represents dissociation mechanism through a five coordinate intermediate containing a unidentate acetylacetonate anion, and the k_2 an association mechanism involving association of free acacH with the intermediate.

In order to extend our studies of isotopic exchange kinetics of β-diketonato complexes,[1,2] exchange reaction between tris(acetylacetonato)cobalt(III) [Co(acac)$_3$] and acetylacetone (acacH) labelled with ^{14}C has been examined in organic solvents. This complex was claimed to be substitution inert on a qualitative experiment,[3] and to undergo decomposition at higher temperatures.[4] We have found that this complex decomposes to bis(acetylacetonato)-cobalt(II) at more than 130°C in gaseous state within several minutes. On the other hand, in organic solvents the cobalt(III) complex gave brown precipitate on prolonged heating at more than 70°C (*e.g.* after 30 hr at 90°C). Infrared absorption spectrum of the precipitate in KBr pellet disclosed that it consists mainly of polymeric acetylacetonatocobalt(III) complex and does not contain cobalt(II) complex. The visible and ultraviolet absorption spectrum of the remaining reaction mixture suggested that [Co(acac)$_2$] is appreciable, when the reaction mixture was heated so long as to give the precipitate.

McKay plot[5] in toluene and anisole at 80 to 97°C (Fig. 1) gave a straight line at the initial stage of the exchange reaction, where the absorption spectrum remained unchanged. With progress of the reaction, however, the apparent rate gradually decreased accompanied by change in absorption spectrum and eventually with formation of the brown precipitate. The apparent rate of exchange (R) was reproducible in the initial stage at 85 to 100°C and seemed to suit for kinetic studies.

near to unity in both solvents and the rate is expressed by Eq. (1).

$$R = k_0[\text{complex}] \quad (1)$$

Figure 3 gives the relationship between R and the concentration of the free ligand in anisole and toluene. The diagram indicates that the k_0 consists of two terms, one of which is independent of and the other dependent on the concentration of acacH. (Eq. 2)

$$R = [\text{complex}](k_1 + k_2[\text{acacH}]) \quad (2)$$

The k_1 and the k_2 are known from the intercept and the gradient of the lines, respectively, and listed in Table 1. The Arrhenius activation energy is known from the data in Table 1 and listed together. Because of the big error involved in the determination of k_1 and k_2 values by extrapolation, only overall E_a values are significant. The influence of acid and base on the

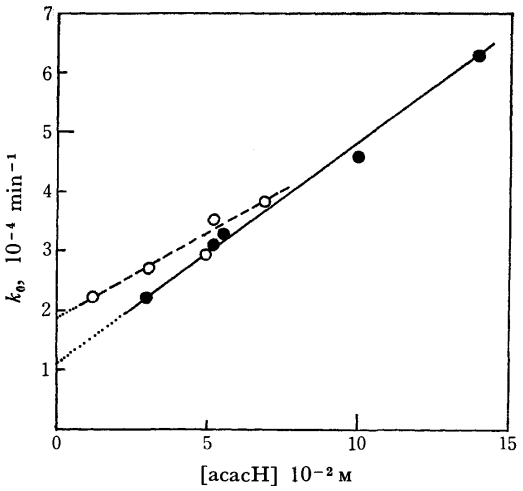

Fig. 3. Relationship between k_0 and the initial concentration of free acetylacetone-^{14}C.
90°C, —●— in toluene, --○-- in anisole.

exchange rate in toluene and anisole is shown in Table 2. Addition of the bivalent cobalt(II) complex [Co(acac)$_2$] did not affect the rate. Toluene was almost saturated with water, and its content was changed within a limited range (0.008 to 0.019 M) in the given temperature region. However, no significant change in R values was observed. The water content remained practically unchanged (within ±0.001 M) during kinetic runs.

Discussion

As the McKay plot indidates, isotopic exchange reaction predominates at the early stage of reaction without being involved by the irreversible decomposition. It appears as if the linear range on the McKay plot is larger at a higher temperature. It is presumably because the temperature coefficients of the rates of isotopic exchange and the decomposition differ from each other.

[complex]=[acacH]=0.05 M, 90°C.

The k_1 Path. The first term of Eq. (2) seems to represent a mechanism in which the break of metal-ligand bond is the rate-determining step. This path can be interpreted in two ways. In one of them, break of the first metal-oxygen bond at one of the chelate rings is the rate-determining step, and the remaining metal-oxygen bond breaks fast. The second way is to consider that the first bond breaks and forms rapidly so that an intermediate state involving unidentate acetylacetonate can survive for a significant lapse of time, and the break of the remaining bond is the rate-determining step.

Girgis and Fay[6] studied the kinetics of ligand interchange between tris(benzoylacetonato)cobalt(III) [Co(bzac)$_3$] with the same complex labelled with ^{2}H in chlorobenzene at 96.1°C, and compared the rate and activation parameters with those of the inversion and isomerization of this complex (Table 1). The ligand interchange proceeds slower by one order or two, and they proposed a predominating intermediate involving axial trigonal bipyramidal structure with a unidentate ligand. Their k_0 value for ligand interchange was obtained in the absence of excessive ligand, and can be compared with our k_1 values. Although the experimental conditions are different, our k_1 values are larger than theirs by *ca.* two orders. This fact would be due to the smaller basicity of acetylacetonate than benzoylacetonate.

Fay, Girgis, and Klabunde measured the rate of racemization of partly resolved [Co(acac)$_3$] in chlorobenzene at 78 to 108°C.[4] The results are included in Table 1. Although their experimental condition is not exactly equal to ours, the isotopic exchange rate is smaller than the rate of racemization by one order.

In order to account for the mechanisms of isotopic exchange and racemization in consonance, we tend to consider an intermediate involving a unidentate ligand. Fig. 4 gives a probable scheme for the mechanism of the present isotopic exchange. One of the cobalt(III)-oxygen bonds in one of the three ligands can break and restore rapidly. The vacant coordination site could be occupied either by the solvent molecule or free acetylacetone. The latter case will be discussed later. The intermediate can also rearrange to give trigonal bipyramidal structure. Whenever the remaining bond of the unidentate ligand

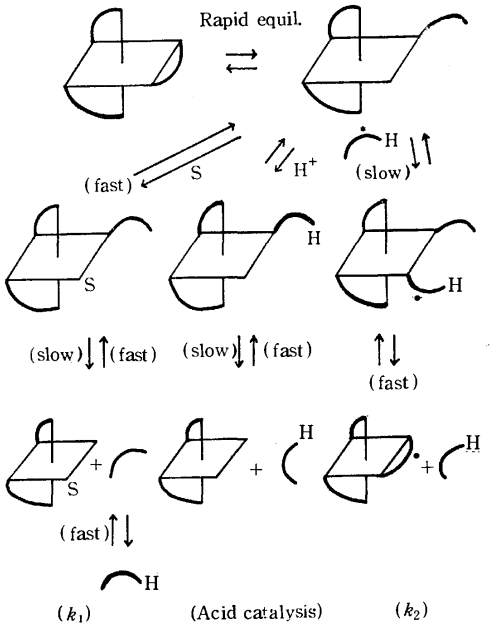

Fig. 4. Probable mechanism for the isotopic exchange. S, solvent molecule; the arc-form represents acac$^-$.

breaks spontaneously, the ligand would be liberated and the labelled free acetylacetone would combine with cobalt(III) rapidly to give a first order rate term corresponding to k_1. Contribution of this term would depend on how easily the free end of unidentate ligand recombines with cobalt(III). A polar solvent such as anisole would occupy the vacant site more easily than less polar solvents (*e.g.* toluene) do, and retard the recombination to increase the contribution of k_1. This is what was experimentally found.

An alternative explanation could be encountered by considering the role of water in the solvent. However, water content did not affect the rate, although the examined range of concentration was rather small, and its participation could be excluded.

The acid catalysis could be understood by considering the protonation at the free end of unidentate ligand, which increases the difficulty with which the free end recombines with cobalt(III) to restore the original complex. Only a strong acid such as trichloroacetic acid seems to be eligible of bringing about such an effect. Contribution of free acetylacetone (p$K\simeq6$) as acid catalyst is ruled out, because a stronger acid, *m*-toluic acid (pK=4.27) is not useful as acid catalyst.

6) A. Y. Girgis and R. C. Fay, *J. Amer. Chem. Soc.*, **92**, 7061 (1970).

If an acetylacetonate ligand were liberated whenever its first bond with cobalt(III) was broken, this would result in simultaneous racemization and isotopic exchange. Hence the fact that racemization is faster than isotopic exchange (Table 1) should be interpreted by an intra-molecular twist mechanism without liberation of the ligand. The activation enthalpy of the racemization is close to those of inversion and isomerization of $[Co(bzac)_3]$, and there seems to be no reason to exclude such a twist mechanism for the racemization of $[Co(acac)_3]$.

The k_2 Term. The second term of Eq. (2) is also interpreted in two ways. One is to reckon a rate-determining nucleophilic attack of acetylacetone upon the intermediate containing a unidentate acetylacetonate. The other is to consider a preliminary equilibrium between free acetylacetone and the intermediate, and regard the break of remaining cobalt(III)-oxygen bond of the original ligand as rate-determining step. In this case the k_2 term is written as $k_2'K_2$[acacH], where K_2 and k_2' stand for the apparent association constant and the rate of bond break in the adduct, respectively.

Such an interaction was first proposed by Graziano and Harris,[7] and later modified by Llewellyn, O'Connor and Odell[8] for the isotopic exchange of trioxalatochromate(III) with oxalic acid-^{14}C. Neither of them, however, distinguished these two mechanisms. It is generally understood that a dissociative mechanism gives higher E_a values than an associative mechanism does. The E_a values in Table 1 decreases in the sequence, anisole, chlorobenzene, and toluene. Because of experimental difficulty E_a values for the k_1 and the k_2 path were not obtained separately. Anisole, with the biggest contribution of the k_1 term, gives the biggest E_a, whilst toluene with the smallest contribution of k_1 gives the smallest E_a. Chlorobenzene will have less affinity toward cobalt(III) than anisole despite of its bigger dipole moment.

This fact seems to be in favor of the first mechanism reckoning rather associative nature of the k_2 term. Dielectric constants of organic compounds decrease with rise of temperature, and the rather ionic interaction involved in the preliminary equilibrium between free acetylacetone and the intermediate will be facilitated at a higher temperature. This would give rise to increase in K_2 values with rise of temperature and the the dissociative $k_2'K_2$ values might bring about bigger temperature coefficient for the k_2 term. Such a tendency does not seem to suit for interpretation of the experimental results, and we tend to reckon the rather associative interpretation more appropriate, although nothing decisive can be stated at the present stage.

Experimental

Materials. The labelled compound, acetylacetone-^{14}C was prepared as reported before.[1] The specific activity was 0.02 mCi per mg. Tris(acetylacetonato)cobalt(III) was synthesized from cobalt(II) carbonate, commercial acetylacetone, and hydrogen peroxide, and recrystallized from hot benzene by addition of petroleum ether and cooling.[8] When the recrystallized $[Co(acac)_3]$ was sublimed at 3 mmHg at 120°C, the product gave the same kinetic result. Hence the product was regarded sufficiently pure. Impure complex can give erroneous results.

Toluene was shaken with concentrated sulfuric acid, washed with water and sodium hydroxide solution, dried with calcium chloride and then with metallic sodium and distilled. Anisole was washed with sodium hydroxide solution and water, dried with calcium chloride and then with sodium and distilled. Chlorobenzene was washed with 1% sodium carbonate solution and water, dried with calcium chloride and distilled. The water contents of these solvents were *ca.* 0.012, 0.035, and 0.0046 M, respectively, on Karl Fischer titration in a mixture of pyridine and propyleneglycol. *m*-Toluic and trichloroacetic acid were sublimed *in vacuo*, and pyridine was distilled by the usual method.

Measurement. A known amount of labelled acetylacetone was added to the thermostated complex solution ($\simeq 10^{-2}$ M, 10 or 15 ml) to produce $\simeq 10^{-2}$ M solution and kept in a thermostat. Aliquots ($\simeq 2$ ml each) were taken out of the solution at appropriate intervals, added to cold petroleum ether (*ca.* 20 ml), and set aside in a cold Dewar vessel. Green needles appeared within 3 hr. The mother liquor was decanted, the precipitate washed with petroleum ether and dried at 80°C. A portion (3 to 7 mg) was dissolved in anisole containing 0.4% *p*-terphenyl and 0.01% POPOP (30 ml) to prepare liquid scintillator and the counting rate measured by use of the photomultiplier pulse due to β rays.[1] The quenching effect of the colored solution was corrected by use of a calibration curve. (*e.g.* the apparent counting rate decreases to 72% in the liquid scintillator containing 3 mg of $[Co(acac)_3]$ per 30 ml.) Acids and bases were added to the original complex solution in advance.

The authors wish to thank Nishina Memorial Foundation for the Grant-in-aid.

Synthesis of Tengerite Type Rare Earth Carbonates[1]

Hisanobu WAKITA* and Kozo NAGASHIMA

Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, Bunkyo-ku, Tokyo, 112

(Received March 28, 1972)

Rare earth carbonates which give the same X-ray powder diffraction pattern as tengerite were prepared by heating aqueous solutions containing rare earth chlorides and ammonium trichloroacetate. Y, Er, Ho, and Gd gavee xactly the same X-ray powder pattern as tengerite, while Nd and Sm were similar to tengerite but with a few additional diffractions. X-ray powder data of the tengerite type rare earth carbonate were indexed and cell parameters of $a_0=9.20\pm0.02$ Å, $b_0=11.32\pm0.03$ Å, and $c_0=7.59\pm0.01$ Å for $Y_2(CO_3)_3\cdot nH_2O$ ($n=2$—3), with 4 moles of formula units per cell and orthorhombic symmetry were established. Linear correlations were demonstrated between refractive indices or cell parameters of the synthesized carbonates and their respective rare earth element atomic numbers.

The compositions and structures of rare earth carbonates have been the subject of numerous recent studies.[2] Some of the results reported in these studies are inconsistent. Most mineralogists consider the existence in nature of only three normal carbonates: lanthanite $La_2(CO_3)_3\cdot 8H_2O$,[3] calkinsite $(La,Ce)_2(CO_3)_3\cdot 4H_2O$,[4] and tengerite $Y_2(CO_3)_3\cdot nH_2O$ ($n=2$—3),[5] and several double carbonates such as burbankite $Na_2(Ca, Sr, Ba, Ce, La)_4(CO_3)_5$,[4] and sahamalite $(Ce, La, Nd)_2(Mg, Fe)(CO_3)_4$.[6]

Shinn and Eick[7] studied the structure of lanthanite and indicated that it contains 4 formula units in an orthorhombic unit cell of space group Pccn, with lattice parameters of $a_0=8.984\pm0.004$, $b_0=9.580\pm0.004$, and $c_0=17.00\pm0.01$ Å ($\rho_{obsd}=2.72\pm0.02$ g cm^{-3}; $\rho_{calcd}=2.732$ g cm^{-3}). Pecora and Kerr[4] examined calkinsite X-ray crystalographically and determined the following cell parameters; $a_0=9.57\pm0.02$, $b_0=12.65\pm0.08$, $c_0=8.94\pm0.02$ Å, space group $P2_122_1$ or D_2,[4] 4 formula units per cell. Among these rare earth carbonates, rather little has been known of the characteristics of tengerite, a very rare hydrous yttrium carbonate mineral, despite its early discovery at Ytterby, Sweden.

Regarding the composition of tengerite, Iimori[8] suggested the formula of a hydrous basic double carbonate of yttrium and calcium, $Y_3Ca(OH)_3(CO_3)_4\cdot 3H_2O$-(?) based on the analysis of the material from Suishoyama, Iisaka, Fukushima, Japan. On the other hand, the material from Baringer Hill, Texas, USA, was described as a hydrous double carbonate of yttrium and beryllium.[9]

To study the composition, a hydrated yttrium carbonate was synthesized by precipitation from a homogeneous aqueous solution containing yttrium chloride and ammonium trichloroacetate and digestion of the precipitate in the mother liquor for an extended period. The X-ray diffraction pattern of the precipitated carbonate agreed with that of tengerites from Suishoyama[10] and from Iveland, Norway (ASTM-16-698). The similarity between the sample from Suishoyama and the synthesized carbonate was also confirmed by DTA, TGA, and IR absorption data.[5] The analysis of the synthesized carbonate established the following molecular ratio; $Y_2O_3=1.00$: $CO_2=3.01$: $H_2O=2.35$ (average). This ratio is close to the normal carbonate of yttrium.

Experimental and Results

Preparation of the Tengerite Type Rare Earth Carbonates. Rare earth carbonates may be conveniently prepared by precipitation from homogeneous solution by hydrolysis of the trichloroacetates of rare earth elements.[11]

$$2M(C_2Cl_3O_2)_3 + (x+3)H_2O \rightarrow M_2(CO_3)_3\cdot xH_2O + 3CO_2 + 6CHCl_3$$

Rare earth carbonates thus obtained are usually coarse and easily filtered. However, the precipitates generally appear amorphous when examined by X-ray powder diffractometry. (This is probably the explanation for the many different results reported for the compositions of artificially prepared rare earth carbonates.) Crystalline precipitates of excellent quality were obtained by heating the solutions containing the precipitates for several days. As will be described in the following section, the crystalline yttrium carbonate prepared by this procedure has the tengerite structure.

The procedure applied throughout the study is as follows: Four g of trichloroacetic acid were added

to 250 m*l* of aqueous solution containing 6 mM yttrium chloride. The pH of the solution was adjusted between 4 and 5 with dilute ammonium hydroxide, then the solution was heated on a steam bath for two days.

Figure 1 shows a typical micrograph of yttrium carbonate prepared by this procedure.

Fig. 1. Hydrated yttrium carbonate.

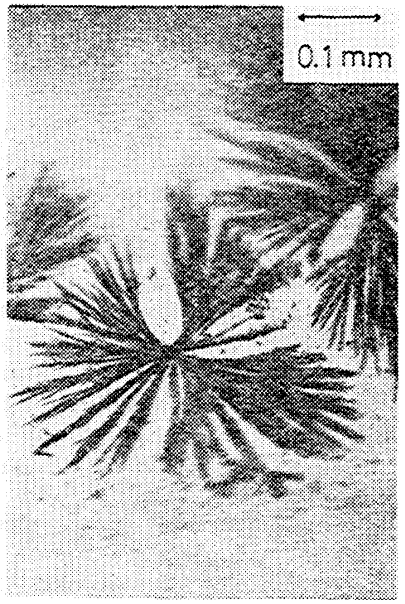

Fig. 2. Hydrated yttrium carbonate (prepared in a sealed tube).

Figure 2 is also a micrograph of yttrium carbonate prepared by maintaining the solution (YCl_3+CCl_3-COOH+NH_4OH, pH=4—5) in a sealed glass ampoule for about one week at 70°C. Carbonates of the other rare earth elements were synthesized by applying the same procedure. Most of the specimens were in the form of radial aggregates of fine fibers as seen in Fig. 1. Carbonates samples other than yttrium exhibited admixed larger amorphous particles in addition to the crystalline particles.

X-Ray Powder Diffraction and Optical Properties. The X-ray powder diffraction data for the synthesized yttrium carbonate are tabulated in Table 1, in which those for tengerite from Iveland, Norway (ASTM 16-698(1966)) are also represented for comparison.

The X-ray powder data of the synthesized sample are virtually identical with those of natural tengerite.

I: Iveland, Norway (ASTM). Fe/Mn rad.=1.9373 Å.
II: Synthesized hydrated yttrium carbonate, Cu/Ni rad.=1.5418 Å.

Under the microscope the synthesized sample shows a straight extinction and positive axial character. The refractive indices of the synthesized yttrium carbonate are

$\gamma=1.624\pm0.002$, $\alpha=1.612\pm0.001$ and $\gamma-\alpha=0.012\pm0.003$

Those of natural tengerite from Suishoyama, Japan measured by Kato[10] are

$\gamma=1.642$, $\alpha=1.622$, and $\gamma-\alpha=0.020$

The small difference between the two materials may be due to the compositional difference. The other optical properties could not be measured accurately, because the synthesized sample is too finely grained. The above data lead the assignment of tetragonal or orthorhombic (or hexagonal) symmetry to the carbonate.

The indexing to the X-ray powder data for tengerite was accomplished through the application of Battelle indexing charts,[12] since a literature survey, did not reveal an index to the X-ray powder data for tengerite.

In Table 1 the probable indices are given, and good agreement is shown between the observed and calculated Q values when an orthorhombic cell with $a_0=9.20\pm0.02$, $b_0=11.32\pm0.03$, $c_0=7.59\pm0.01$ Å was assumed. Applying these cell parameters and measured density (3.3—3.1 g cm^{-3}), the number of the formula units in a cell was calculated as 4. The results of electron diffraction studies were used to determine the crystal system and cell parameters.

12) J. C. Bell and A. E. Austin, "Battelle Indexing Charts for Diffraction Patterns of Tetragonal, Hexagonal and Orthorhombic Crystals," Battelle Memorial Institute, Columbus 1, Ohio, U.S.A.

Chemical Analysis of Rare Earth Carbonates. The results of the chemical analyses of air dried carbonates are given in Table 2. Table 2 also shows that the molar ratios, $R_2O_3 : CO_2$ ($: H_2O$) are not whole numbers except in the case of yttrium carbonate which corresponds to $Y_2(CO_3)_3 \cdot nH_2O$ ($n=2$—3, a part of H_2O may be zeolitic). This apparent anomaly may be attributed to the admixed amorphous particles and to the instability of the carbonates. Concerning the instability of rare earth carbonates, Shinn and Eick[7] mentioned two bonding positions of carbonate ions in the lanthanite structure, one coordinates as a unidentate ligand and one as a bidentate ligand. Water molecules behave similarly; one coordinates to a metal ion and one does not, therefore some of the carbonate ions and water molecules may be expected to be rather easily lost from the structure.

Table 2. Chemical analyses of synthesized rare earth carbonate

	M_2O_3 : CO_2 : H_2O (molar ratio)		
$Y_2(CO_3)_3 \cdot nH_2O$	1.00	3.01	2.35

La-	1.00	2.97	8.04

a) Amorphous by X-ray examination.
b) Prepared in a sealed tube.

Proton magnetic resonance of the synthesized hydrated lanthanum carbonate (lanthanite type) and hydrated yttrium carbonate (tengerite type) were run at room temperature using a broad-line NMR spectrometer. A spectrum composed of a broad and a sharp absorption indicating two bonding positions for water molecules, was obtained for the lanthanum compound, while a signal with one sharp absorption was obtained for the yttrium compound.

X-Ray Powder Diffraction of Some Rare Earth Carbonates. By the procedure described in the prior section, hydrated carbonates were obtained from lanthanum, neodymium, samarium, gadolinium, dysprosium, holmium, erbium and ytterbium. The X-ray powder diffraction patterns and the powder data of these carbonates are shown in Fig. 3 and Table 3 respectively. Figure 3 indicates the X-ray powder patterns of gadolinium, dysprosium, and holmium carbonates are almost identical with that of yttrium carbonate. The increase in d values with increasing ionic radii of the metals is well recognized (Table 3).

As for neodymium and samarium compounds, although several additional diffractions, for example at 5.529(Nd) and 5.481Å(Sm), were observed, the arrangements and intensities of most of the diffractions are almost the same as those of yttrium carbonate. The lanthanum compound given an X-ray powder pattern quite different from that of yttrium carbonate

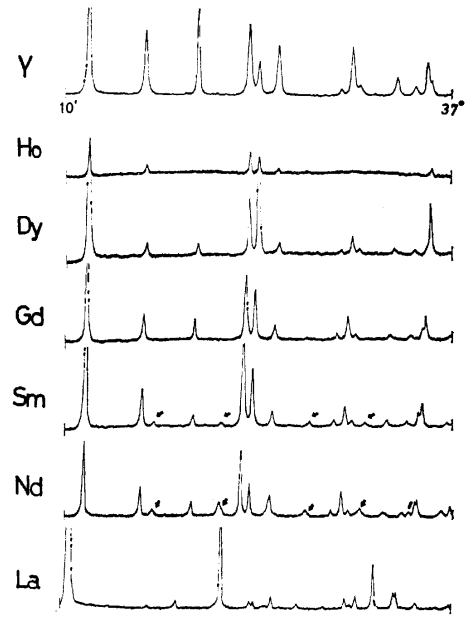

Fig. 3. X-ray powder diffraction patterns of hydrated rare earth carbonates.
Arrows indicate peaks not observed in the diffractions of tengerite

and similar to that of lanthanite.[3] The pattern and powder data for ytterbium and scandium compounds are not listed in the figure and table, because only an amorphous phase for ytterbium and a hydroxide for scandium were obtained by the present procedure. These results may indicate the fact that La^{3+} is too large and Yb^{3+} and Sc^{3+} are too small for the tengerite structure.

In Table 3, in addition to the powder data, cell parameters a_0, b_0, c_0 and refractive indices γ and α of

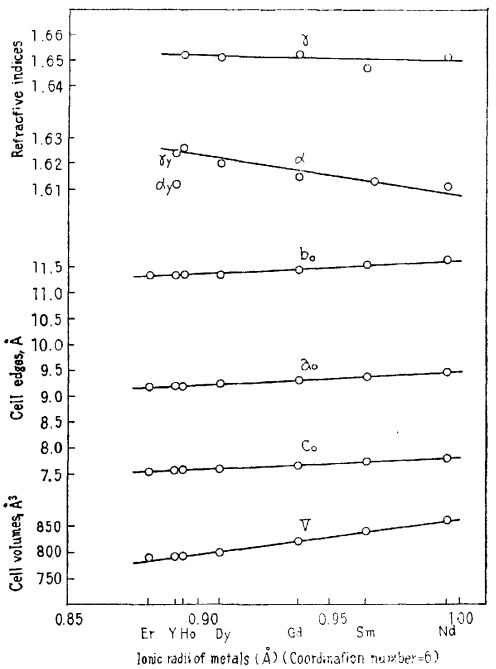

Fig. 4. Lattice parameters, refractive indices *vs.* ionic radii of rare earth metals.

a) Except for yttrium compound, calculated from 001, 020, and 200.
b) Additional diffractions. In calculation of a_0, b_0, c_0, these diffractions were neglected.

the compounds are listed. The values of a_0, b_0, and c_0 for samarium and neodymium compounds were calculated by applying the indices of tengerite to most of the diffractions and neglecting the weak diffractions to which indices of tengerite could be given.

Relations between Lattice Parameters and Refractive Indices of Rare Earth Carbonates and the Ionic Radii of Rare Earth Elements. In Fig. 4, cell parameters a_0, b_0, and c_0 and refractive indices γ and α, of the synthesized carbonates are plotted *versus* ionic radii of rare earth metals.[13] It is observed in Fig. 4 that cell parameters a_0, b_0, and c_0 and unit cell volumes of tengerite type rare earth carbonates increase linearly with increasing ionic radii of the metals, while refractive indices, (which closely follow the densities) decrease with increasing ionic radii of the metals.

Binuclear Metal Complexes. IV.[1] The Preparation and Properties of Binuclear Copper(II) Complexes of Schiff Bases Derived from 2,6-Diformyl-4-methylphenol and Glycine or Alanine[2]

Hisashi OKAWA, Sigeo KIDA, Yoneichiro MUTO,* and Tadashi TOKII*

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

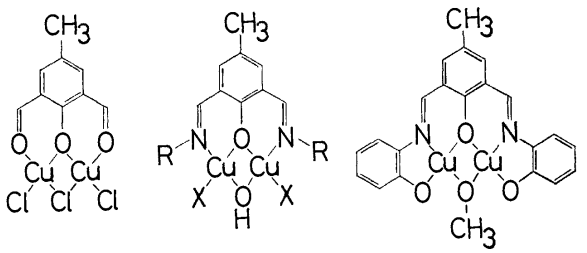
**Department of Chemistry, Saga University, Saga*

(Received April 10, 1972)

A new series of binuclear copper(II) complexes with different bridging groups, Fsal(=gly)$_2$Cu$_2$X (X=OH, Cl, Br) and Fsal(=ala)$_2$Cu$_2$X (X=Cl), were synthesized, Fsal(=gly)$_2$ and Fsal(=ala)$_2$ being the Schiff bases prepared by condensation of 2,6-diformyl-4-methylphenol with glycine and alanine, respectively. The copper(II) ions are bridged by the phenolic oxygen in the organic moiety and also the X. The properties of the complexes were studied by IR spectra, visible spectra, and magnetic susceptibility measurements at various temperatures. From the cryomagnetic data it was concluded that the effect of the bridging group X upon magnetic exchange interaction decreases in the order: OH>Cl~Br.

It is known that 1,3,5-triketones[3-5] and diethyl cyclopentanone-2,5-diglyoxylate[6,7] form binuclear copper(II) complexes composed of two ligands and two copper(II) ions. Although 2,6-diformyl-4-methylphenol is similar to the ligands in structure, its complex-forming behavior is markedly different. The ligand and copper(II) chloride form a binuclear complex, dichloro-μ-chloro-μ-2,6-diformyl-4-methylphenolatodicopper(II)[8] (Fig. 1, (a)), in which the ratio of copper to the ligand is 2 : 1. Thus the use of 2,6-diformyl-4-methylphenol makes it possible to prepare binuclear copper(II) complexes bridged with two different groups, i.e., the phenolic oxygen (the first bridging group) and a monoatomic or polyatomic anion such as chloride, bromide, hydroxide, or methanolate ion (the second bridging group). Okawa prepared dihalogeno-μ-hydroxo-μ-2,6-bis-(*N*-alkyliminomethyl)-4-methylphenolatodicopper(II)[8] (Fig. 1, (b)), by the reaction of 2,6-diformyl-4-methylphenol, an alkyl amine and copper(II) chloride or copper(II) bromide. A binuclear copper(II) complex of the Schiff base with *o*-aminophenol, in which a methanolate ion acts as the second bridging group, was also prepared[9] (Fig. 1, (c)).

It is clear that the second bridging group is variable depending upon the nature of the four coordinating atoms other than the bridging atoms. It appears that there is a certain relation between the coordinating and bridging atoms closely associated with

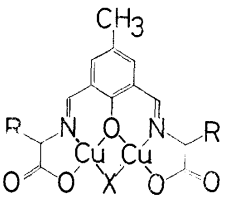


R=alkyl
X=Cl or Br

(a) (b) (c)

Fig. 1.

the stability of the binuclear copper(II) complex. In order to find the relation, we attempted to synthesize binuclear copper(II) complexes of the Schiff bases derived from 2,6-diformyl-4-methylphenol and α-amino acids. We obtained a series of Fsal(=gly)$_2$-Cu$_2$X (X=OH, Cl or Br) and Fsal(=ala)$_2$Cu$_2$X (X=Cl), where Fsal(=gly)$_2$ and Fsal(=ala)$_2$ indicate the Schiff bases with glycine and alanine, respectively, and the X is the second bridging group(Fig. 2).



R=H: Fsal(=gly)$_2$Cu$_2$X (X=OH, Cl or Br)
R=CH$_3$: Fsal(=ala)$_2$Cu$_2$X (X=Cl)

Fig. 2. Structure of complexes.

These complexes are the first series of planar binuclear copper(II) complexes bridged with two different groups.

The magnetic exchange between a pair of copper(II) ions has also been studied. In Fsal(=gly)$_2$Cu$_2$X only the second bridging group, X, varies. Thus the complexes are very suitable for a study of the effects of the bridging groups upon the spin-spin coupling interaction.

Experimental

Syntheses. The synthesis of 2,6-diformyl-4-methylphenol has been described previously.[1]

Fsal(=gly)$_2$Cu$_2$Cl. An aqueous solution of glycine (300.3 mg) was added to a solution of 2,6-diformyl-4-methylphenol (330 mg) and copper(II) chloride dihydrate (681 mg) in ethanol (75 m*l*). The clear solution was heated at 70°C for ten minutes and left standing overnight. The separated green needles were collected and washed with ethanol.

Found: C, 35.42; H, 2.67; N, 6.11; Cl, 7.82%; mol wt, 430 (methanol). Calcd for $C_{13}H_{11}N_2O_5ClCu_2$: C, 35.67; H, 2.53; N, 6.40; Cl, 8.10%; mol wt, 437.78.

Fsal(=gly)$_2$Cu$_2$Br. An aqueous solution of glycine (300.3 mg) was added to a dark solution of 2,6-diformyl-4-methyl-phenol (330 mg) and anhydrous copper(II) bromide (893.5 mg) in ethanol (100 m*l*). The resulting green solution was heated on a water-bath and then cooled to give green needles, which were collected and washed with ethanol.

Found: C, 32.74; H, 2.41; N, 5.51; Br, 16.71%. Calcd for $C_{13}H_{11}N_2O_5BrCu_2$: C, 32.38; H, 2.30; N, 5.81; Br, 16.57%.

Fsal(=gly)$_2$Cu$_2$(OH)·H$_2$O: An aqueous solution of glycine (300.3 mg) was added to an ethanolic solution of 2,6-diformyl-4-methylphenol (330 mg) and copper(II) acetate monohydrate (800 mg) or copper(II) sulfate pentahydrate (1 g). A yellowish green by-product was separated by decantation and the remaining blue product was collected and thoroughly washed with ethanol. Contamination by the yellow by-product was avoided by employing anhydrous copper(II) fluoride as the source of metal ions.

Found: C, 35.88; H, 3.25; N, 6.33%. Calcd for $C_{13}H_{12}N_2O_6Cu_2\cdot H_2O$: C, 35.70; H, 3.23; N, 6.41%.

The water of crystallization could be removed by heating at 110°C/2 mmHg for 8 hours.

Fsal(=ala)$_2$Cu$_2$Cl. This complex was obtained by treating 2,6-diformyl-4-methylphenol (330 mg), *dl*-alanine (360 mg) and copper(II) chloride dihydrate (681 mg) in ethanol. The green solution was concentrated to 30 m*l*, and 20 m*l* of acetone was added. After the reaction mixture was left standing overnight, the separated deep green needles were collected and washed with cold ethanol.

Found: C, 38.88; H, 3.72; N, 5.76; Cl, 7.70%. Calcd for $C_{15}H_{15}N_2O_5ClCu_2$: C, 38.68; H, 3.25; N, 6.01; Cl, 7.61%.

Measurements. Magnetic susceptibilities were determined in the range from liquid nitrogen temperature to room temperature by the Gouy method with a magnetic field strength of about 7000 Oersted. The apparatus was similar in design to the one described by Figgis and Nyholm;[10] an electromagnet (Nihon-Komitsu Model 350) and a vacuum semimicro balance with a reading accuracy of ±0.02 mg (Chyo Balance Co.). Temperature control was carried out by an electrically regulated system with an accuracy of ±0.2°K at 150°K. Temperature measurements were carried out by means of a copper-constantan thermocouple. The effective magnetic moment μ_{eff} was calculated from the expression

$$\mu_{eff}=2.83\sqrt{(\chi_A-N\alpha)T}\ ,$$

where χ_A is the atomic susceptibility corrected by use of Pascal's constants[11,12] for diamagnetism and $N\alpha$ is the temperature independent paramagnetism associated with copper(II) ions.

The infrared spectra of the complexes were measured with a Hitachi EPI-S2 spectrophotometer in the region 4000—650 cm^{-1} on a KBr disk. In some cases the hexachlorobutadiene mull method was used for the measurements in the region 4000—2000 cm^{-1}. The reflectance spectra and solution spectra of the complexes in water, methanol, and pyridine were measured with a Hitachi EPS-3T spectrophotometer in the near-infrared and visible regions.

Results and Discussion

The complexes Fsal(=gly)$_2$Cu$_2$Cl and Fsal(=gly)$_2$-Cu$_2$Br were obtained quantitatively but the yield of Fsal(=gly)$_2$Cu$_2$(OH)·H$_2$O was low. Only Fsal-(=ala)$_2$Cu$_2$Cl was isolated from Fsal(=ala)$_2$ in a very low yield. The syntheses of binuclear copper(II) complexes of the Schiff bases with other α-amino acids such as valine, leucine, isoleucine, and phenylalanine were unsuccessful. A deep green solution was formed when 2,6-diformyl-4-methylphenol, an amino acid and a copper(II) salt were mixed in

ethanol, but only 2,6-diformyl-4-methylphenol was recovered from the concentrated reaction mixture. The marked differences in isolating the complexes are difficult to explain at present. The molecular weight determination for Fsal(=gly)$_2$Cu$_2$Cl supports the binuclear structure shown in Fig. 2.

The IR spectra of Fsal(=gly)$_2$Cu$_2$X (X=OH, Cl and Br) and Fsal(=ala)$_2$Cu$_2$Cl are very similar to each other (Table 1), suggesting similar structures of the complexes. The spectra in the region 1700—1400 cm^{-1} resemble those of the copper(II) complex of the Schiff base derived from salicylaldehyde and glycine.[13] The complicated bands at 1650—1630 cm^{-1} may be assigned to the C=O and C=N stretching vibrations, while the bands at 1600 and 1455 cm^{-1} have been assigned to the aromatic skeletal vibration.[14,15] Okawa and Kida[9] pointed out that the new band around 1555 cm^{-1} can be attributed to a skeletal vibration of the aromatic ring. The band appears on the low-frequency side of 1550 cm^{-1} in the mononuclear copper(II) complexes of the Schiff bases derived from salicylaldehyde, and on the high-frequency side of 1550 cm^{-1} in the complexes where a phenolic oxygen acts as a bridge.[16] The present complexes are therefore expected to have a binuclear structure bridged with a phenolic oxygen. The very strong band at 1380—1350 cm^{-1} might be assigned to the C–O vibration.[14,15,17] Ueno and Martell[18] assigned the strong band near 1085 cm^{-1} to the C–O stretching vibration. We found that the corresponding band in dichloro-μ-hydroxo-μ-2,6-bis(*N*-alkyliminomethyl)-4-methylphenolatodicopper(II)[7] depends markedly upon the alkyl group (CH_3, 1030; C_2H_5, 1040; *iso*-C_3H_7, 1065; *tert*-C_4H_9, 1080 cm^{-1}). Consequently this band can be assigned to the C–N stretching vibration. In anhydrous Fsal(=gly)$_2$Cu$_2$(OH) the O–H vibration was found at 3370 cm^{-1}.

The ligand field bands of the complexes are given in Table 2. The reflectance spectrum of Fsal(=gly)$_2$Cu$_2$(OH)·H$_2$O showed the ligand field band at 650 mμ, which is higher in energy than those of other complexes. The complexes except for Fsal(=gly)$_2$Cu$_2$(OH)·H$_2$O are likely to keep their binuclear structures in polar solvents such as water, methanol, and pyridine, since they can be recrystallized from these solvents and their visible spectra in them are similar. On the other hand, Fsal(=gly)$_2$Cu$_2$(OH)·H$_2$O is hardly soluble in most solvents though it is soluble in pyridine. However, it is clear that the complex decomposes in pyridine since the green prisms isolated from the concentrated solution were found to be bis(glycinato)copper(II) by IR spectrum. The thermal decomposition temperatures for Fsal(=gly)$_2$Cu$_2$Cl, Fsal(=gly)$_2$Cu$_2$Br and Fsal(=gly)$_2$Cu$_2$(OH)·H$_2$O are 220—225°, 223—225°, and 217—220°C, respectively. Though the difference in the decomposition temperature of the complexes is small, the results indicate that in the series of complexes Fsal(=gly)$_2$Cu$_2$X (X=OH, Cl, and Br) the relative stability increases with X=Cl~Br>OH, in spite of the lower bridging ability of the halide atoms.[19] This is in contrast to that found for the series of binuclear copper(II) complexes of the Schiff bases derived from 2,6-diformyl-4-methylphenol and N,N-dialkylethylenediamines.[20] The remarkable stability of the present complexes may be explained by the fact that the organic moieties are suitable for forming binuclear complexes and consequently strongly combine two copper(II) ions.

The χ_A and μ_{eff} values at various temperatures are given in Table 3. It was found that Fsal(=gly)$_2$Cu$_2$(OH)·H$_2$O is antiferromagnetic. The experimental data could be explained in terms of the Bleaney-Bowers equation[21]

$$\chi_A=\frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp(-2J/kT)\right]^{-1}+N\alpha \quad ,$$

where $-2J$ is the energy separation between the singlet and triplet states, k the Boltzmann constant, N the Avogadro number, β the Bohr magneton and g the Lande g-factor (Fig. 3). The $-2J$, g and $N\alpha$ values were obtained by the best fit of susceptibility data to the Bleaney-Bowers equation. The results are given in Table 3.

Fsal(=gly)$_2$Cu$_2$Cl, Fsal(=gly)$_2$Cu$_2$Br and Fsal(=ala)$_2$Cu$_2$Cl obey the Curie-Weiss law (Fig. 4). Approximate values of the Weiss constant θ were obtained by extrapolating the curves $1/(\chi_A-N\alpha)$ *vs.* T assuming 60×10^{-6} cgs. emu for $N\alpha$.[22] Since all

these complexes possess negative Weiss constants, it is evident that there is antiferromagnetic exchange interaction between the copper(II) ions in the complexes. In most oxygen-bridged copper(II) complexes,[23-26] the Cu-O bond lengths and the Cu-O-Cu bond angles are in the ranges 1.8—2.0 Å and 100—115°, respectively. If the Cu-O bond length and the Cu-O-Cu bond angle in the present complexes are assumed to be 1.9 Å and 110° respectively, then the copper-copper interatomic distance is about 3.4 Å. Since this interatomic distance is much greater than

the 2.56 Å of metallic copper, a direct exchange interaction between copper(II) ions is not likely to occur. Thus the superexchange through the bridging groups is most important in the magnetic interaction in the complexes.

The powder X-ray diffraction spectra of Fsal(=gly)$_2$Cu$_2$Cl and Fsal(=gly)$_2$Cu$_2$Br are quite similar to each other, but differ from that of Fsal(=gly)$_2$Cu$_2$(OH)·H$_2$O. This implies that the crystal structures of Fsal(=gly)$_2$Cu$_2$Cl and Fsal(=gly)$_2$Cu$_2$Br are very similar to each other but differ from the structure of Fsal(=gly)$_2$Cu$_2$(OH)·H$_2$O. Nevertheless, in the present discussion we regard the molecular structures of all these complexes as practically the same, since the 5–6–6–5 condensed ring system makes a rigid skeleton for each of the complexes. This is supported by the consideration on the series of tetranuclear copper(II) complexes[27-31] of the type Cu$_4$OX$_6$L$_4$ (X is chloride or bromide atom and L is a unidentate ligand), in which the bond angles and bond lengths in one bridge are fixed and another bridging group is replaceable.

We assume that the spin-spin coupling through the phenolic oxygen is the same in all complexes. Consequently, the difference in magnetic behavior of the complexes reflects the effect of the second bridging groups upon the spin exchange interaction. From the data given in Table 3 the effect is found to be in the order: OH>Cl~Br. As it is known that most binuclear copper(II) complexes with phenolic oxygen bridges show demagnetisation,[16] it is remarkable that Fsal(=gly)$_2$Cu$_2$Cl, Fsal(=gly)$_2$Cu$_2$Br, and Fsal(=ala)$_2$Cu$_2$Cl have relatively large magnetic moments close to the spin-only value of 1.73 B.M. This might be due to the out-of-plane distortion of the Cu-O-Cu plane of the complexes.

From the Weiss constants of the complexes it can be assumed that the chloride bridge is more effective than the bromide bridge in spin coupling. It is usually found that the spin exchange interaction in binuclear complexes bridged with bromide ions is greater than that in the corresponding complexes bridged with chloride ions. For example, anhydrous copper(II) bromide has a lower magnetic moment (1.31 B.M.) than anhydrous copper(II) chloride (1.75 B.M.).[32] In the binuclear copper(II) complexes[14] of the Schiff bases derived from 2,6-diformyl-4-methylphenol and *N*,*N*-dialkylethylenediamines, the complexes bridged with a bromide ion exhibit a greater antiferromagnetic interaction than the complexes bridged with a chloride ion. Lever *et al.*[33] prepared some tetrahedral binuclear cobalt(II) complexes of a phthalazine derivative containing one halide bridge. From cryomagnetic measurements they found that the bromide-bridged complex shows a larger $-2J$ value than the corresponding chloride-bridged complex. However, the difference of effect between chloride and bromide bridging groups is usually small, and insofar as our complexes are concerned, it is reasonable to say that the chloride and bromide bridges exert a comparable effect on the spin exchange interaction.

Magnetic Circular Dichroism of Nickel(II) and Copper(II) Complexes with 1,4,8,11-Tetraazacyclotetradecane Derivatives

Hiroshi KOBAYASHI and Bohdan KORYBUT-DASZKIEWICZ*

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 10, 1972)

The magnetic circular dichroism (MCD) spectra of nickel(II) and copper(II) complexes with 1,4,8,11-tetraazacyclotetradecane derivatives were measured. An anomalous MCD dispersion was observed in a (*d*, *d**) band at 22000 cm^{-1} for the copper(II) complexes and at 22000—23000 cm^{-1} for the nickel(II) complexes. In the ultraviolet region, the nickel(II) complexes show a normal MCD dispersion in the 35500 cm^{-1} band which appears only for the ligands with >C=N- double bonds, while the copper(II) complexes show an anomalous dispersion in the 39000 cm^{-1} band which appears even if the ligand lacks >C=N- double bonds. The 35500 cm^{-1} band of the nickel(II) complexes is assigned to a "metal to ligand" charge-transfer transition $1e_g \rightarrow \pi^*$ and the 39000 cm^{-1} band of the copper(II) complexes to a "ligand to metal" charge-transfer transition $1e_u \rightarrow 2b_{1g}$. In the nickel(II) complex of a ligand with two isolated and two conjugated double bonds shows a normal MCD dispersion in the 25000 cm^{-1} band. The absorption band is assigned to a "metal to ligand conjugated double bonds" charge-transfer transition rather than a (*d*, *d**) transition.

Macrocyclic coordination compounds formed by condensation of metal-amine complexes with aliphatic carbonyl compounds are of great interest.[1] Recent magnetic circular dichroism (MCD) measurements have furnished various information on the electronic characteristics of the low energy electronic excitations of planar complexes.[2-5] So far, however, the MCD spectra were only briefly discussed with respect to the planar complexes with macrocyclic ligands.[6] In the present work, nickel(II) and copper(II) complexes with different tetraazacyclotetradecane derivatives in various steps of oxidation as well as in different conformations were chosen for the MCD measurements in order to get more general information on the low energy electronic excitations.

Fig. 1. Structures of the complexes studied.

Experimental

Materials. Preparation of the complexes was described elsewhere.[7-9] Samples obtained from the original preparative works were used without further purification. The names, notations, preparation, and structures of the complexes used in the present work are summarized in Table 1 and Fig. 1. Two isomeric 5,12-dimethyl-1,4,8,11-tetraazacyclotetradecanes [denoted by IA (mp 110°C) and IB (mp 145°C)] were complexed with copper(II) perchlorate (Table 1). The free ligand 5,7,12,14-tetramethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene was obtained by the condensation of ethylenediamine monohydroperchlorate with methyl propenyl ketone in water-methanol solution and complexed with nickel(II) acetate. Three isomers IVANiα, IVANiβ, and IVBNi (Table 1) were separated by fractional recrystallization. The complexes IVANiα and IVANiβ are an interconvertible pair, while the complex IVBNi is a nonconvertible isomer.

Measurements. The measurement technique of magnetic circular dichroism was given previously.[10] All measurements were carried out with a JASCO ORD/UV-5 spectropolarimeter with its CD attachment and an electromagnet. The magnetic field was set at 10000 Gauss. The visible and ultraviolet absorption spectra were taken on a Shimadzu automatic recording spectrophotometer Model MPS-50 and the infrared spectra of Nujol mull were recorded with a Hitachi spectrophotometer Model EPI-G3.

The organic solvents used were nitromethane and pyridine. In the case of aqueous solution, an acidic solution (0.05 N $HClO_4$) was used in order to prevent a possible isomerization of the complexes.

Results and Discussion

Magnetic circular dichroism (MCD) and absorption spectra are shown in Figs. 2—6. An apparent single absorption band was observed at about 20000 cm^{-1} (ε=100) for the copper(II) complexes and at 22000—23000 cm^{-1} (ε=80) for the nickel(II) complexes except the complex VINi. The single weak band is composed of an envelope with several overlapping (d, d^*) bands. The diamagnetic ground states of the nickel complexes were established by magnetic susceptibility measurements. They are all diamagnetic in the solid state as in nitromethane solution.[1,7,9] Both the nickel(II) and copper(II) complexes show an asymmetric anomalous MCD dispersion in the (d, d^*) band. The asymmetric shape of the MCD spectra in the visible region should be interpreted as a superposition of B term extremes of the excitations $d_{z^2}\rightarrow d_{x^2-y^2}$ and $d_{xy}\rightarrow d_{x^2-y^2}$ and an A term dispersion of a degenerate excitation $d_{zx}, d_{yz}\rightarrow d_{x^2-y^2}$ in term of Ste-

phens' theory of MCD.[11-13] Such a superposition of (d, d^*) bands can also be confirmed by the measurements of optical rotatory dispersion (ORD) or circular dichroism (CD) of the optically active isomers of the complex IVBNi. The CD curve extremes, in fact, were not coincident with the observed absorption maximum. Similar phenomena have been observed.[14,15] An MCD dispersion observed in the (d, d^*) bands of the nickel(II) and copper(II) complexes evidently reveals the location of a degenerate excitation $d_{zx}, d_{yz} \rightarrow d_{x^2-y^2}$.

When the solvent was changed, a red-shift and intensity enhancement of the absorption band of the copper(II) complexes were observed in the ordering nitromethane<water<pyridine. The solvent effect is shown in Fig. 7. In the case of the nickel(II) complexes, however, no such red-shift and intensity enhancement were observed. In pyridine solution a remarkable splitting and intensity reduction were found in the visible band of the nickel(II) complexes IVANiα, IVANiβ, and IVBNi and an appreciable enhancement of the absorption intensity was observed in near-ultraviolet region. As evidenced by magnetic

susceptibility and NMR measurements, these complexes in pyridine solution exist partially in a paramagnetic state. An axial coordination of pyridine sufficiently reduces an energy gap between the diamagnetic and triplet ground states, thus giving rise to a thermal equilibrium between the states. The MCD minima at 18000—19000 cm^{-1} are assigned to the second (d, d^*) transition $^3A_2 \rightarrow a^3T_1$ in the paramagnetic octahedral nickel(II) complexes. Enhancement of absorption intensity in near-ultraviolet is also interpreted as arising from the third (d, d^*) transition $^3A_2 \rightarrow b^3T_1$ of the paramagnetic species. This is in good agreement with the recent observations by Harding *et al.* on paramagnetic trisethylenediamine nickel(II) and tris-2,2′-bipyridine nickel(II) complexes.[16] The complex IANi shows this type of spectral behavior even in aqueous solution as shown in Fig. 3, whereas in pyridine, alcohol and nitromethane it shows a single absorption band at 22000 cm^{-1} characteristic of the diamagnetic square-planar nickel complexes. In organic solvents, the counter perchlorate ion tends to disturb the coordination of solvent donors. Furthermore a steric hindrance against axial coordination arising from a conformation of two methyl groups in one side of the macrocyclic ligand of the complex IANi should be noted. On the contrary, a similar complex prepared by reduction of 2,4,4,10,12,12-hexamethyl-1,5,9,13-tetraazacyclohexadeca-1,9-dienenickel(II) perchlorate shows a coexistence of the triplet and singlet ground states in such donor solvents as dimethylsulfoxide, dimethylformamide and methyl cyanide, whereas in aqueous solution it gives rise to only a single absorption band at 22500 cm^{-1} of the diamagnetic species.[17]

16) M. J. Harding, S. F. Mason, D. J. Robbins, and A. J. Thomson, *J. Chem. Soc., A*, **1971**, 3058.

In the ultraviolet region the nickel(II) complex with isolated >C=N- double bonds shows an absorption band of intermediate intensity (ε=5000) at 35500 cm^{-1}, which increases with the number of isolated double bonds. The other bands appear around 44000 cm^{-1} and 47500 cm^{-1} (ε=12000). The copper(II) complexes, even if the ligand lacks the >C=N- double bonds, show an absorption band around 39000 cm^{-1} (ε=5000—10000) with a similar shape as observed in the nickel(II) complexes. The nickel(II) complexes of the ligands with no >C=N- double bands show no absorption band up to the 44000 cm^{-1} band. Non-existence of the >C=N- double bonds in the complexes IACu, IBCu and IANi was confirmed by IR spectrum. The A term dispersion of MCD is observed in the ultraviolet region as shown in Figs. 2, 4, and 5. However, the A term dispersion in ultraviolet region of the nickel(II) complexes has a sign opposite to that of the A term dispersion in visible region observed for both nickel(II) and copper(II) complexes and also to that of the A term dispersion in ultraviolet region of the copper(II) complexes.

The ultraviolet band at 39000 cm^{-1} of the copper(II) complexes observed even when the ligand lacks >C=N- double bonds is assigned to a degenerate charge-transfer transition from a degenerate molecular orbital pair σ_x and σ_y, predominantly localized on nitrogen lone-pair orbitals, a vacant copper(II) antibonding orbital x^2-y^2. In the case of the nickel(II) complexes, the ultraviolet band at 35500 cm^{-1} is assigned to a degenerate charge-transfer transition from a degenerate non-bonding $d\pi$ orbital pair zx and yz to the lowest antibonding molecular orbital π^*. When the number of isolated >C=N- double bonds in the ligand is increased, the ultraviolet charge-transfer band makes no shift but the intensity is enhanced. However, a complex of the ligand with two isolated double bonds and two conjugated ones gives rise to an intense absorption band around 25000 cm^{-1} (ε= 1400) with a shoulder on the lower wave number side around 24100 cm^{-1} as shown in Fig. 6. The sign of term dispersion in the 25000 cm^{-1} band is opposite to that in (d, d^*) bands, which are usually observed in the same region, and the same as the sign observed at the 35500 cm^{-1} band of the nickel(II) complexes with isolated double bonds. The shoulder at 24100 cm^{-1} might be due to a (d, d^*) transition. The absorption band at 25000 cm^{-1} should be assigned to a degenerate charge-transfer transition from a degenerate non-bonding $d\pi$ orbital pair to the antibonding molecular orbital π^* predominantly delocalized over the conjugated double bonds.

A schematic molecular orbital diagram of the diamagnetic d^8 planar complex is given in Fig. 8. There are three spin-allowed (d, d^*) transitions corresponding to the one-electron transitions $1b_{2g} \rightarrow 2b_{1g}$ ($^1A_{1g} \rightarrow {}^1A_{2g}$), $2a_{1g} \rightarrow 2b_{1g}$ ($^1A_{1g} \rightarrow {}^1B_{1g}$), and $1e_g \rightarrow 2b_{1g}$ ($^1A_{1g} \rightarrow {}^1E_g$). An A term dispersion is anticipated for the (d, d^*) transition $1e_g \rightarrow 2b_{1g}$ ($^1A_{1g} \rightarrow {}^1E_g$). Because of

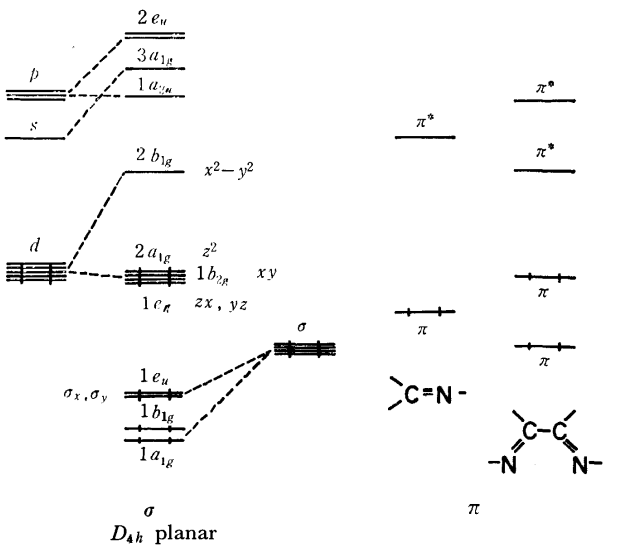

Fig. 8. Molecular orbital diagrams (schematic).

the Laporte forbidden character, the transition should borrow a spectral intensity by vibronic coupling from the allowed charge-transfer transition $1e_u \rightarrow 2b_{1g}$ ($^1A_{1g} \rightarrow {}^1E_u$ x, y polarized), $1e_g \rightarrow 1a_{2u}$ ($^1A_{1g} \rightarrow {}^1E_u$ x, y polarized) and/or $1e_g \rightarrow 1e_u$ ($^1A_{1g} \rightarrow {}^1A_{2u}$ z polarized). Since the transition $1e_g \rightarrow 1e_u$ is z polarized, it can not participate in the MCD observed in (d, d^*) band. As shown in the Appendix, A/D of the transition $1e_u \rightarrow 2b_{1g}$ is negative, while A/D of the transition $1e_g \rightarrow 1a_{2u}$ is positive. Since the MCD dispersion observed in (d, d^*) band is an anomalous one, the allowed transition granting spectral intensity to the (d, d^*) transition is a charge-transfer transition with negative A/D, namely $1e_u \rightarrow 2b_{1g}$. The same theory can also be applied to the (d, d^*) transition of the copper(II) complexes. Molecular vibrations which can mix the Laporte forbidden transition $1e_g \rightarrow 2b_{1g}$ with the allowed transition $1e_u \rightarrow 2b_{1g}$ are out of plane deformation vibrations ν_3 (a_{2u}) and ν_5 (b_{2u}) rather than any other stretching vibrations. These vibrations give rise to a temporary overlapping between zx, yz and nitrogen lone-pair orbitals and thus a non-zero off-diagonal term $(1e_g|\hat{h}'|1e_u)$.

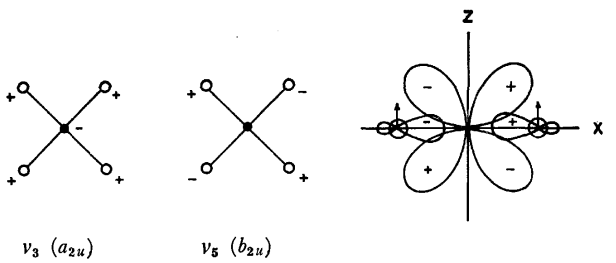

Fig. 9. Out of plane deformation vibrations which mix a Laporte forbidden transition $1e_g \rightarrow 2b_{1g}$ with the allowed transition $1e_u \rightarrow 2b_{1g}$.

The copper(II) complexes, even when the ligand lacks >C=N- double bonds, show an ultraviolet band of intermediate intensity at 39000 cm^{-1} and an anomalous MCD dispersion in the band. Thus the band is assigned to a symmetry allowed transition with a character of charge-transfer from the degenerate molecular orbital pair $1e_u$ to the vacant copper(II) antibonding orbital $2b_{1g}$. The transition $1e_u \rightarrow 2b_{1g}$ gives negative A/D and thus an anomalous MCD dispersion. In the case of the nickel(II) complexes, however, the ultraviolet band of intermediate intensity at 35500 cm^{-1}, is observed only when the ligand has isolated >C=N- double bonds and shows a normal MCD dispersion. The band is assigned to a "metal to ligand" charge-transfer transition from the degenerate nickel(II) $d\pi$ orbitals zx, yz to a vacant antibonding molecular orbital of exciton-coupling >C=N- double bonds π^*. The charge-transfer transition should borrow spectral intensity from a strongly allowed coupling (π, π^*) transition in the isolated >C=N- double bonds or the Laporte allowed transition $1e_g \rightarrow 1a_{2u}$.

(a) (b)

Fig. 10. Normal and anomalous dispersions.
(a) normal dispersion
(b) anomalous dispersion

An exciton coupling between isolated π systems in the coordinating ligand is possible and thus the resultant allowed (π, π^*) oscillator can be a planar oscillator in the case of the complexes VANi and VINi, whereas it gives only a linear oscillator in the case of the complexes with two *trans* >C=N- double bonds such as IVANiα, IVANiβ, and IVBNi. Thus the allowed (π, π^*) transitions in the double bond systems in the coordinating ligand could grant an MCD dispersion intensity to the "metal to ligand" charge-transfer transition only in the cases of the complexes VANi and VINi. In such a planar molecular environment, the allowed degenerate excitation $1e_g \rightarrow 1a_{2u}$ principally localized on the central metal ion is a planar oscillator rather energetically low. Since the molecular orbital $1a_{2u}$ can conjugate with two *trans* >C=N- double bonds in the complexes IVANiα, IVANiβ and IVBNi, the transition $1e_g \rightarrow 1a_{2u}$ can grant a spectral intensity and also an MCD dispersion intensity to the charge-transfer transition $1e_g \rightarrow \pi^*$. Although the possibility of spectral intensity borrowing in the "metal to ligand" charge-transfer transition from the allowed (π, π^*) transitions can not be eliminated, some spectral intensity should surely be stolen from the intrametal allowed transition $1e_g \rightarrow 1a_{2u}$. As shown in the Appendix, the excitation $1e_g \rightarrow 1a_{2u}$ gives rise to a normal MCD dispersion. In fact, the "metal to ligand" charge-transfer transition in the nickel complexes IVANiα, IVANiβ, IANi, and VINi constantly shows a normal MCD dispersion which indicates a borrowing of spectral intensity from the planar oscillator $1e_g \rightarrow 1a_{2u}$.

(B. K-D.) wishes to express his gratitude to the Japanese Government for a UNESCO fellowship and also to the Polish Academy of Sciences which made his stay in this country possible. This work was also supported by a grant from the Ministry of Education.

Appendix

A degenerate transition from the ground state $|o\rangle$ to a degenerate excited state pair $|\pm j\rangle$ is accompanied by an A term dispersion of MCD. The molecular constant A in the transition $|o\rangle \rightarrow |\pm j\rangle$ is defined as follows:[11-13]

$$A = 6\langle +j|\mu_z|+j\rangle \mathrm{Im}\{\langle o|\hat{m}_x|+j\rangle\langle +j|\hat{m}_y|o\rangle\}$$

where $\hat{\mu}$ and $\hat{m}$ are magnetic and electric dipole operators, respectively, and

$$\langle \pm j|\hat{\mu}_z|\pm j\rangle = -\beta/\hbar\langle \pm j|\hat{l}_z|\pm j\rangle .$$

MCD spectrum shows a normal dispersion when $A/D>0$, where

$$D = 6\{|\langle o|\hat{m}_x|+j\rangle|^2+|\langle o|\hat{m}_y|+j\rangle|^2\} .$$

It shows an anomalous dispersion when $A/D<0$.

The state wave functions $|o\rangle$ and $|\pm j\rangle$ are given in terms of a degenerate molecular orbital pair $|\pm j)$ and a non-degenerate molecular orbital $|a)$ as follows:

$$\begin{array}{ll} |o\rangle & |+j)|\overline{+j})|-j)|\overline{-j}) \\ |+j\rangle & |+j)|\overline{+j})[|-j)|\overline{a}) - |\overline{-j})|a)]/\sqrt{2} \\ |-j\rangle & |-j)|\overline{-j})[|+j)|\overline{a}) - |\overline{+j})|a)]/\sqrt{2} \end{array}$$

where no bar implies spin α, a bar implies spin β and

$$(\pm j|\hat{\mu}_z|\pm j) = -\beta/\hbar(\pm j|\hat{l}_z|\pm j) = \mp j'\beta.$$

Since

$$\langle \pm j|\hat{\mu}_z|\pm j\rangle = (\pm j|\hat{\mu}_z|\pm j) = \mp j'\beta,$$

it follows that

$$A = 6(-j'\beta)\mathrm{Im}\{2(-j|\hat{m}_x|a)(a|\hat{m}_y|-j)\}$$

and

$$D = 6\{2|(-j|\hat{m}_x|a)|^2+2|(-j|\hat{m}_y|a)|^2\}.$$

The degenerate transition $1e_g \rightarrow 1a_{2u}$, for example, is rewritten $|\pm j) \rightarrow |a)$, in terms of $|\pm j) = \{|xz) \pm i|yz)\}/\sqrt{2}$ and $|a) = |z)$. Since

$$(-j|\hat{m}_x|a) = \frac{1}{\sqrt{2}}(zx+iyz|\hat{m}_x|z) = \frac{1}{\sqrt{2}}(zx|\hat{m}_x|z) \equiv \frac{1}{\sqrt{2}}m$$

and

$$(a|\hat{m}_y|-j) = \frac{1}{\sqrt{2}}(z|\hat{m}_y|zx-iyz) = -\frac{i}{\sqrt{2}}(z|\hat{m}_y|yz) \equiv -\frac{i}{\sqrt{2}}m$$

it follows that

$$A/D = (1/2)j'\beta.$$

This gives a normal dispersion. For the degenerate transition $1e_u \rightarrow 2b_{1g}$ given in terms of $|\pm j) = \{|\sigma_x) \pm i|\sigma_y)\}/\sqrt{2}$ and $|a) = |x^2-y^2)$, we have

$$(-j|\hat{m}_x|a) = \frac{1}{\sqrt{2}}(\sigma_x+i\sigma_y|\hat{m}_x|x^2-y^2) = \frac{1}{\sqrt{2}}(\sigma_x|\hat{m}_x|x^2-y^2) \equiv \frac{1}{\sqrt{2}}m'$$

$$(a|\hat{m}_y|-j) = \frac{1}{\sqrt{2}}(x^2-y^2|\hat{m}_y|\sigma_x-i\sigma_y) = \frac{-i}{\sqrt{2}}(x^2-y^2|\hat{m}_y|\sigma_y) \equiv \frac{i}{\sqrt{2}}m'$$

and thus $A/D = -(1/2)j'\beta$. The gives an anomalous dispersion.

Preparation and Circular Dichroism Spectra of Bis(amino-acidato)ethylenediaminecobalt(III) Complexes

Nobuko MATSUOKA, Jinsai HIDAKA, and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received April 26, 1972)

Cis(O) and *trans(O)* complexes of bis(L-serinato)ethylenediaminecobalt(III) ion have been prepared and completely separated into six possible isomers by ion-exchange column chromatography. These isomers have been assigned to *Λ-trans(O)*, *Λ-trans(O)*, *Λ-C_2-cis(O)*, *Λ-C_1-cis(O)*, *Λ-C_1-cis(O)* and *Λ-C_2-cis(O)* in the elution order, on the basis of their absorption and circular dichroism spectra. *Trans(O)*- and *C_1-cis(O)*-bis(glycinato)ethylene-diaminecobalt(III) complexes have been resolved into their optically active isomers, and *trans(O)*-bis(L-alaninato)-ethylenediaminecobalt(III) ion has been prepared and separated into two configurationally active isomers. The absorption and circular dichroism data of six isomers of $[Co(L\text{-ser})_2en]^+$, two isomers of $[Co(L\text{-ala})_2en]^+$ and two isomers of $[Co(gly)_2en]^+$ have been discussed in being compared with those of the corresponding isomers of oxalatobis(L-serinato)cobaltate(III) complex.

Recently a number of reports[1-8] have been presented for the stereochemistry of cobalt(III) complexes with α-aminoacidato ligand and these studies have mainly been developed on the basis of their absorption and circular dichroism (CD) spectra. In a previous paper,[7] we reported the spectral and stereochemical properties of six isomers of oxalatobis(L-serinato)cobaltate(III) complex, with which are compared those of the corresponding isomers of oxalatobis(glycinato)cobaltate(III) complex. It is interesting to compare the results for such $[Co(O)_4(N)_2]$ type complexes with those for $[Co(O)_2(N)_4]$ type complexes. The present work is concerned with the absorption and CD spectra of six isomers of bis(L-serinato)-ethylenediaminecobalt(III) complex and optical isomers of *trans(O)*- and *C_1-cis(O)*-bis(glycinato)-ethylenediaminecobalt(III) complexes, all of which belong to a general type, $[Co(O)_2(N)_4]$. This may be the first study reported for the CD of bis(amino-acidato)ethylenediaminecobalt(III) type complexes.

Experimental

1) Resolution of Bis(glycinato)ethylenediaminecobalt(III) Iodide. By using an aqueous solution of sodium perchlorate as an eluting agent, we obtained three kinds of racemic perchlorates, *trans(O)*, *C_1-cis(O)* and *C_2-cis(O)*, of this complex, more easily than by using the potassium bromide solution as in a previous paper.[9] A large excess of sodium iodide was added to the concentrated solution of each the perchlorate; then the corresponding racemic iodides deposited. When the crystallization was not easy, they were obtained by adding an appropriate amount of ethanol to the solution. The red crystals were filtered off, washed with ethanol-water mixture and ethanol, and dried in air.

$(+)_{589}$-trans(O)-[Co(gly)$_2$en]I·H_2O. An aqueous suspension of 2.0 g (0.0048 mol) of racemic *trans(O)* iodide[10] was stirred well with 0.8 g (0.0048 mol) of silver acetate. The resulted yellow precipitate of silver iodide was removed. To the filtrate, 1.0 g (0.0024 mol) of $(-)_{546}$-K[Co(edta)]·$2H_2O$ was added, and a small amount of insoluble material formed was filtered out. From this solution the reddish violet diastereomer was obtained by concentrating it in a vacuum desiccator, and was recrystallized from aqueous solution by adding acetone. Pure crystals were filtered, washed with acetone-water mixture and acetone, and dried in air. Then the diastereomer was converted to iodide by dissolving it in a small amount of water and by adding an excess of sodium iodide. The red crystals deposited were filtered, washed with ethanol and dried in air.

$(+)_{589}$-C_1-cis(O)-[Co(gly)$_2$en]I·$2H_2O$. Racemic *C_1-cis(O)* iodide (2.6 g, 0.006 mol) and silver acetate (1.2 g, 0.007 mol) were stirred well in 20 m*l* of water. After the silver iodide formed was removed, a saturated solution of 1.0 g (0.003 mol) of potassium antimony(III) L-tartrate 1½-hydrate was added to the filtrate. The red crystals of diastereomer deposited when the solution was evaporating in a vacuum desiccator. If a colorless compound was formed before deposition of the diastereomer, it was removed. The red crystals were filtered, washed with ethanol-water mixture and ethanol, and dried in air. To a concentrated solution of the diastereomer a large excess of sodium iodide was dissolved and the solution was cooled in an ice-bath. The optically active iodide was recrystallized from water by adding ethanol. The red crystals were filtered, washed with ethanol-water mixture and dried in air.

2) Preparation and Separation of Two Isomers of trans(O)-*Bis(L-alaninato)ethylenediaminecobalt(III) Perchlorate.* To a solution of 12.0 g (0.05 mol) of cobalt(II) chloride hexahydrate in 40 m*l* of water, a mixed solution of 9.0 g (0.10 mol) of L-alanine and 3.0 g (0.05 mol) of ethylenediamine in 50 m*l* of water was added. The resulting solution was oxidized by mechanical stirring with 10 g of lead dioxide at 70°C for about 20 min, and cooled to room temperature. After removing a bulky insoluble material, a large amount of acetone was added to the filtrate. The supernatant was decanted out and the residual dark-red oil was dissolved in a small amount of water. Insoluble material was filtered out and the filtrate was poured into a column (30 mm × 900 mm) containing strong anion-exchange resin (Dowex 50 W × 8, 200~400 mesh, hydrogen form). The neutral

species was swept out with water. By eluting with 0.1 N $NaClO_4$ solution, the adsorbed bands were gradually separated to a violet, two kinds of dark-red, and a broad red bands in this order. From the measurements of the visible absorption spectra of eluants, it was confirmed that the species in the violet band was *mer*-$[Co(O)_3(N)_3]^+$ type by-product, and that complexes in the dark red bands were two kinds of isomers of *trans(O)*-$[Co(L\text{-ala})_2en]^+$, and that one in the red band was a mixture of isomers of C_1- and C_2-*cis(O)*-$[Co(L\text{-ala})_2en]^+$. As for the *trans* isomers it was also shown that the earlier eluted species was $(-)_{589}$-isomer and the later eluted $(+)_{589}$-isomer, by measurements of their ORD. The eluates of the two *trans(O)* isomers were independently concentrated in a vacuum evaporator, and the obtained crystals were filtered, washed with ethanol-water mixture and ethanol, and dried in air.

3) Preparation and Separation of Six Isomers of Bis(L-serinato)ethylenediaminecobalt(III) Complexes. A solution containing 12.0 g (0.05 mol) of cobalt(II) chloride hexahydrate in 30 m*l* of water was mixed with a solution of 3.0 g (0.05 mol) of ethylenediamine and 10.5 g (0.10 mol) of L-serine in 40 m*l* of water. The resulting brown solution was mechanically stirred with 20 g of lead dioxide at 70°C for about 30 min; then the solution became violet-red. The solution was cooled to room temperature and kept in a refrigerator overnight. After the bulky insoluble material precipitated was filtered out, ethanol-ether mixture was added to the filtrate, until an oily substance settled and the supernatant became colorless. The supernatant was decanted out and dark red oil was dissolved in a small amount of water. If an insoluble compound was formed, it was filtered out. The resulting solution was poured into a column (30 mm × 150 mm) containing strong cation exchange resin (Dowex 50W × 8, 200~400 mesh, hydrogen form), and the violet and pink neutral species, which were *mer*- and *fac*-$[Co(L\text{-ser})_3]$ respectively, were swept out with water. By elution with $NaClO_4$ aqueous solution (0.02 N in the first stage, then 0.05, 0.1, 0.2, and 0.5 N in the later stage of elution, successively) at a rate of 3 m*l*/min, the adsorbed bands were gradually separated into several violet and blue violet bands, two dark red bands, and four red bands in this order. Of the last four red bands the first and the fourth bands were of faint color as compared with the other two. It was confirmed from the measurements of absorption spectra and ORD that there were some by-products in the violet and blue violet bands. There were $(+)_{589}$-*trans(O)*- and $(-)_{589}$-*trans(O)*-$[Co(L\text{-ser})_2en]^+$ isomers in the two dark red bands in the elution order, and $(+)_{589}$-C_2-*cis(O)*-, $(-)_{589}$-C_1-*cis(O)*, $(+)_{589}$-C_1-*cis(O)*- and $(-)_{589}$-C_2-*cis(O)*-$[Co(L\text{-ser})_2en]^+$ isomers in the four red bands in the elution order. In top region of the column, brownish red bands of some higher charged complexes stayed. Each eluate of six isomers was concentrated to less than 50 m*l* in a vacuum evaporator at 30°C, and the perchlorate or iodide was crystallized from the concentrated solution as follows.

$(+)_{589}$-trans(O)-$[Co(L\text{-ser})_2en]ClO_4$. To the concentrated eluate containing this isomer, about two times volume of ethanol was added. Red needles deposited. This was recrystallized from water by adding ethanol. Yield: 0.5 g.

$(-)_{589}$-trans(O)-$[Co(L\text{-ser})_2en]I$. This isomer did not deposit by adding ethanol to the concentrated eluate. So that an appropriate amount of ether was added to the mixture of the eluate and ethanol. Then an oily substance was separated, and it was dissolved in a methanol-water mixture. To solution ether was added once more. If the substance formed was oily again, this treatment was repeated until crystals began to appear. Thus a crude perchlorate was obtained. By adding an excess of sodium iodide (solid) and an appropriate amount of ethanol to an aqueous solution of the crude perchlorate, the red crystals of iodide were deposited. The pure crystals were filtered, washed with ethanol-water mixture and ethanol, and dried in air. Yield: 0.6 g.
