One of the most significant differences in the ground state geometries of **1a—c** is revealed by the interatomic distances C_4C_6 (=C_2C_8). They are 2.158, 2.327 and 2.527 Å, for **1a**, **1b**, and **1c**, respectively; the order of bond indices is **1a**>**1b**>**1c**. Since the distances should eventually be reduced to *ca.* 1.51 Å to form a carbon-carbon single bond of the cyclopropane ring in the course of the Cope rearrangement, it is interesting that from the present calculation the ground state of **1a** is already forced towards the geometry of the transition state **2a**, while **1b** is less, and **1c** is least perturbed in the direction of the respective transition states.

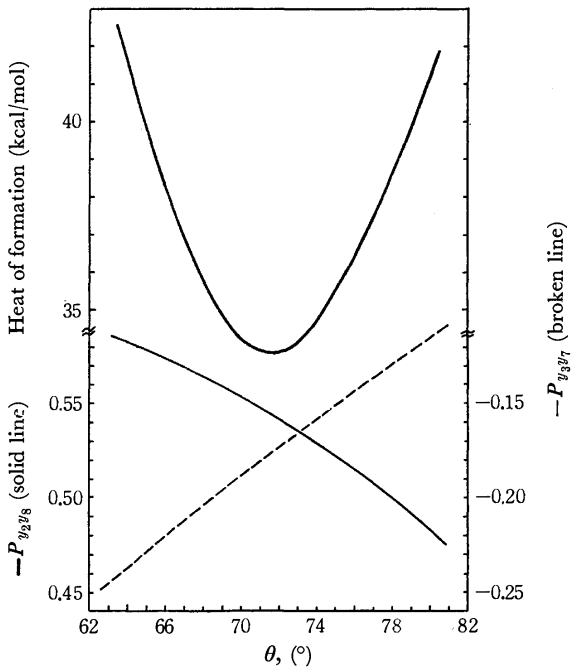

Fig. 2. Heat of formation and bond orders, $P_{y_2y_8}$ (between the $2p_y$ orbitals of C_2 and C_8, the y axis being in the direction $\overrightarrow{C_2C_8}$) and $P_{y_3y_7}$, *vs.* θ_1 for **2b**.

Results for Transition State Geometry

The optimized geometries of **2a—c** are collected in Table 2. It is noted that, contrary to the ground state geometry in which the angle between the wings of the divinylmethane moiety ($C_4C_5C_6$) is in the order **1a**< **1b**<**1c**, θ_1 defined as the dihedral angle between the two allylic planes is almost constant at 72° throughout the transition states **2a—c**. Their C_2C_8 (=C_4C_6) distances differ by not more than 1%. The result suggests that the energy of the transition states **2a—c** basically does not differ. The mode in which the total molecular energy depends on the dihedral angle θ_1 is illustrated in Fig. 2 It is apparent that the potential energy curve is considerably steep on both sides of the equilibrium geometry. A bond population analysis reveals that the energy minimum is reached as a result of an intricate balance between the bonding interaction of both termini of the biallylic systems which stabilizes the transition state to a greater extent as θ_1 decreases and the anti-bonding interaction of the *p*-orbitals on C_3 and C_7 which destabilizes the internal energy. To the latter has to be added the strain energy produced in the angle $C_2C_1C_8$ and $C_4C_5C_6$ as θ_1 decreases. A similar argument based on the simple Hückel approximations has been proposed by Fukui and Fujimoto for preference to the chair-like conforma-

11) E. Goldish, *J. Chem. Educ.*, **36**, 408 (1959).

tion of the transition state for the Cope rearrangement,[12] while Woodward and Hoffmann explained the effect in terms of the orbital symmetry.[13] This orbital repulsion effect first suggested by Doering and Roth[14] also explains why the carbon atoms 3 and 7 tend to be out of the planes defined by $C_1C_2C_4C_5$ and $C_5C_6C_8C_1$, respectively, in the equilibrium geometries of **2**. The average deviation of 6° seems enough to bring the distance between C_3 and C_7 apart without suffering from loss of total conjugative stabilization energy in each allylic group and from strain produced in the ring systems.

Table 3. Heats of formation and strain energies of the homotropilidenes **1a—c** calculated by the MINDO methods

	Heats of formation (kcal/mol)			Strain energies (kcal/mol)
	MINDO/2	MINDO/1	Franklin's group additivity	
1a	27.1	53.0	33.3	19.7
1b	15.5	37.2	28.4	8.8
1c	38.4	52.8	52.3	0.5

Results for Heat of Formation and Charge Distribution of the Ground States 1a—c

Heats of formation corresponding to the equilibrium geometries optimized by the MINDO/2 method and given in Table 1 are listed in Table 3. Border *et al.* reported a value of 42.0 kcal/mol by applying the MINDO/2 method to the observed geometry of bullvalene.[15] The energy minimization along the line outlined in the previous section resulted in heat of formation of 38.4 kcal /mol for bullvalene with the normal 1.51 Å for the C–C bond length of the cyclopropane ring.

In the third column of Table 3 are given heats of formation calculated by the MINDO/1 version on the geometries of the same bond angles determined by the MINDO/2 method. Bond lengths are, however, shifted from the optimized ones to the standard values originally proposed by Baird and Dewar.[6] The MINDO/1 method is considered to give better results as far as heat of formation is concerned.[6,7]

By applying Franklin's group additivity method,[16] heats of formation were estimated for the ideal strain-free molecules corresponding to **1a—d**. The difference between the molecular energies obtained by the MINDO/1 method and those computed by Franklin's method can be regarded to give good estimate for the strain energy of these hydrocarbons.

The charge distributions and resultant dipole moments for the homotropilidenes **1a—c** calculated by the two MINDO methods are summarized in Table 4.

Results for Heat of Formation and Charge Distribution of the Transition States 2a—c

The optimized heats of formation of the biallylic structures **2a—c** representing to the transition states for the Cope rearrangement are listed in Table 5. For the MINDO/1 predictions of the transition state energies, ambiguity remains in the choice of the C_2C_3 bond length. Although it should not be far from 1.40 Å optimized by the MINDO/2 version, we do not know which length will give most accurate heats of formation by the MINDO/1 parametrization.[6] In Fig. 3 is illustrated how heats of formation predicted by the MINDO/1 method depend

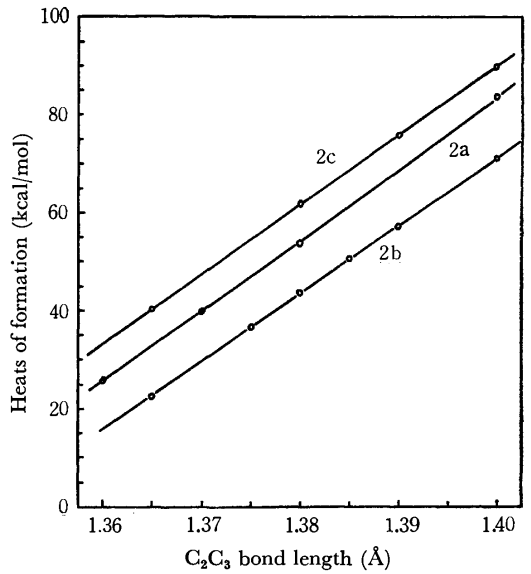

Fig. 3. Dependence of heats of formation by the MINDO/1 method on the C_2C_3 bond length in **2a**—**2c**.

on the C_2C_3 bond length. Although the curves show neither minima nor maxima in the region in question, it is noted that the difference in heats of formation between **2a**—**c** is independent of the choice of the C_2C_3 bond lengths. The numerical values of heat of formation arbitrarily obtained at the intercept of the curves in Fig. 3 at $C_2C_3=1.38$ Å are listed in the third column of Table 5.

Franklin's group additivity method is now employed to calculate the heats of formation of X part of **2a**—**c**,

Table 5. Heats of formation of the transition states **2a**—**c** for the Cope rearrangement

	MINDO/2	Heats of formation (kcal/mol)	
		MINDO/1 ($C_2C_3=1.38$ Å)	Biallyl moiety
2a	45.4	53.6	53.6
2b	33.8	43.9	48.8
2c	64.8	61.9	42.9

they are 0, −4.9, and 19.0 kcal/mol, respectively. By subtracting the latter from the heats of formation predicted by the MINDO/1 method, the partial molecular energies due to the biallylic portion of **2a**—**c** are estimated.

In view of the similar distances between the two allylic moieties in **2a**—**c** as listed in Table 2, we assume that the stability derived from resonance coupling between the two allylic portions does not differ much in **2a**—**c**. A slight difference in stability which is in the order **2a**<**2b**<**2c** in the last column of Table 5 can be attributed to varieties in the strain energy due to the deformation of the "sp^2" hybridized carbon atoms, C_2, C_3, and C_4 in the transition states.

The electron densities and the resultant dipole moments for the transition states **2a**—**c** calculated by the two versions of the MINDO methods are summarized in Table 6.

Discussion on the Origin of Different Activation Energy for Values the Cope Rearrangement

We now arrive at the theoretical activation energy for the Cope rearrangement of the bridged homotropilidenes by comparing the heats of formation of the ground states **1a**—**c** with those of the transition states **2a**—**c**. The results are shown in Table 7. Note that the MINDO/1 method reproduces almost quantitatively the activation energies for the rearrangement. A satisfactory agreement is not unexpected since it is generally accepted that special effort is made during parametrization of the MINDO/1 approximation towards the reproduction of heats of formation.[6] The results of the MINDO/2 approximation are on the contrary less quantitative, and the deviation might be due to underestimation of the strain energy of the cyclopropane ring; the calculated heat of formation of cyclopropane is 3.8 in marked contrast to the observed 12.7 kcal/mol.[6,7] Thus the heats of formation of **1a**—**c** are underestimated relative to **2a**—**c** which have no such strain, with the consequent elevation in the calculated activation energies by the MINDO/2 method.

Satisfactory reproduction of the activation energies

Table 7. Activation energy for the Cope rearrangement

	Activation energy (kcal/mol)		
	MINDO/1	MINDO/2	obsd
Semibullvalene (**1a**)	0.6	18.3	<5[3]
Barbaralane (**1b**)	6.7	18.3	8.76[2,17]
Bullvalene (**1c**)	9.1	25.4	11.8[18]

by the present SCF MO calculations is surprising in view of the fact that the experimental data are obtained in the condensed phase while the calculation is applied to the isolated molecules in a vacuum. Success can partly be ascribed to special situation where there is no significant deviation of electric charge from even distribution in **1a**—**c** as well as in **2a**—**c** (Tables 4 and 5).

From the NMR spectral behavior of **1a**, it could be postulated that semibullvalene might have the mesovalent structure **2a**.[3] However, this can be easily ruled out by the normal UV spectrum of **1a**.[3] It is supported on theoretical ground that semibullvalene has no such novel bonding but only facile Cope rearrangement. Recently, Anet obtained the value of 6.4 kcal/mol as the activation energy for the Cope rearrangement of the octamethyl derivative of **1a**.[19] The effect of methyl substitution in enhancing or retarding valence isomerization is not uncommon. Complete thermal conversion from cyclooctatetraene to semibullvalene can be achieved only when they are fully methylated,[20] while the interconversion is less efficient in the tetramethyl derivatives.[21] No effort has so far been successful in the parent semibullvalene. In the present case, the effect of the methyl substitution can be rationalized by considering a greater planarity of the five membered ring of C_1 through C_5 in the transition state than in the ground state; the eclipsing methyl groups are sterically more demanding than the more or less staggered orientation.

With respect to the origin of different acitvation energies for the Cope rearrangement of these bridged homotropilidenes,[22] we note from Table 3 and 5 that the strain energies in the ground state are sharply in the order **1a**>**1b**>**1c**, while those of the transition state are moderately in the order **2a**>**2b**>**2c**. Thus it is concluded that one of the possible factors contributing to the different activation energies stems from the strain energies of the ground state of these hydrocarbons. We see from Table 1 and 2 that the bond between carbons 4 and 6 ($=C_2C_8$) in the transition states is conventionally represented by the dotted line, and the bond index is easily expected to be one half; the calculated values by the MINDO/2 methods are 0.46, 0.45, and 0.45 for **2a**, **2b**, and **2c**, respectively. The corresponding values in the ground states, **1a**, **1b**, and **1c**, are 0.06, 0.03, and 0.01, respectively. Although no strict proportionality holds *a priori* between bond indices and bond formation, we can say as a first approximation that the Cope rearrangement has already taken place *ca.* 13% ($=0.06/0.46\times100$) in **1a** to the forward direction of the reaction coordinate. The effect is less pronounced in **1b**, and almost negligible in **1c**.[22]

The Photochemical Reaction of α-Diketones

Kazuhiro MARUYAMA,* Keiichi ONO, and Jiro OSUGI

**Department of Chemistry, College of Liberal Arts and Science, Kyoto University, Kyoto*
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto

(Received July 5, 1971)

The relative photochemical reactivity of α-diketones, in particular, 9,10-phenanthraquinone, 1,2-naphthoquinone, acenaphthoquinone, benzil, 4,4′-dimethylbenzil, 2,4,6-trimethylbenzil, 2,5,2′,5′-tetramethylbenzil, 2,3,5,6-tetramethylbenzil, 2,4,6,2′,4′,6′-hexamethylbenzil, phenylglyoxal, 2,5-dimethylphenylglyoxal, and 2,4,6-trimethylphenylglyoxal was investigated in hydrogen donating solvents. Type of the product and relative reactivity differ widely according to the structure of α-diketones. Whereas 9,10-phenanthraquinone gives 1,4-adduct (V) in a hydrogen donating solvent (THF), 2,5,2′,5′-tetramethylbenzil gives 2-hydroxy-2-(2′,5′-dimethylphenyl)indanone (VII) *via* intramolecular hydrogen abstraction in nearly quantitative yield. No photochemical reaction of 2,4,6-trimethylbenzil or 2,3,5,6-tetramethylbenzil could be observed in the same solvent even under a long irradiation.

The photochemical reaction of α-diketones has been studied under various reaction conditions since Klinger.[1] Vapor phase photolysis of biacetyl or hexafluorobiacetyl yields products formed by cleavage of the carbon-carbon bond between two carbonyl groups. However, when *o*-quinones are irradiated in solution in the presence of a hydrogen donor, the resulting products can almost invariably be rationalized taking consideration the mechanistic pathway involving the initial hydrogen abstraction by photo-excited *o*-quinone *via* $n\rightarrow\pi^*$ excitation. As an example, camphorquinone[2] in methanol and 2-propanol gives products derived from initial hydrogen abstraction from the solvent, and 9,10-phenanthraquinone yields 1,2-adduct or 1,4-adduct corresponding to the structure of the sovent when it is irradiated in solution.[3] On the contrary, benzil in cyclohexane gives benzaldehyde formed by cleavage of the carbon-carbon bond between the two carbonyl groups. The present study was undertaken with the aim of elucidating the relationship between reactivity and the structure of α-diketones. 9,10-Phenanthraquinone, 1,2-naphthoquinone, acenaphthoquinone, benzil, methyl substituted benzils and methyl substituted glyoxals have been studied.

Results and Discussion

Reaction Products. Irradiation of 1,2-naphthoquinone in 2-propanol in the absence of oxygen led to an unstable white product identified to be naphthalene-1,2-diol (I). Similarly irradiation of acenaphthoquinone in tetrahydrofuran(THF) in the absence of oxygen give a white product (II) formed by photo-addition. However, in the presence of oxygen, acenaphthoquinone in THF gave naphthalene-1,8-dicarboxylic acid anhydride (III), when it was irradiated. Presumably the first step for the production of this anhydride may be hydrogen abstraction from the solvent resulting in the formation of semiquinone radical, which may react with oxygen to give III according to Scheme 2. Rubin and Zwitkowits reported on the photochemical reaction of phenanthraquinone in some hydrogen donating solvents.[3] They stated that phenanthraquinone reacted with solvents produced 1,2-adduct or 1,4-adduct in the absence of oxygen. Irradiation of phenanthraquinone in mesitylene and in THF gave the corresponding 1,2-adduct (IV) and 1,4-adduct (V), respectively. Relative hydrogen abstraction rate of photo-excited phenanthraquinone in several hydrogen donating solvents have been reported.[4] Recently the reactions have been extensively reinvestigated and their radical nature was confirmed using CIDNP technique.[5] The *o*-quinones unexceptionally abstract hydrogen from the solvent in the first stage of the reaction. The photochemical behavior of benzil, however, differs from that of the *o*-quinones and the principal products in cyclohexane are benzoic acid, benzaldehyde, phenyl cyclohexyl ketone and benzoin.[6]

We have studied in detail the photochemical reaction of benzil and its methyl substituted derivatives, *viz.* 2,5,2′,5′-tetramethylbenzil, 2,4,6-trimethylbenzil, 2,3,5,6-tetramethylbenzil, 2,4,6-trimethylphenylglyoxal, 2,4,6,2′,4′,6′-hexamethylbenzil, and 4,4′-dimethylbenzil. The reaction products are shown in Scheme 1. Irradiation of benzil in THF (in the absence of oxygen) gave a mixture of products containing benzaldehyde, a small amount of benzoin and unidentified products. 2,5,2′,5′-Tetramethylbenzil gave a white product (VII) 2-hydroxy-2-(2′,5′-dimethylphenyl)indanone, *via* intramolecular hydrogen abstraction accompanying 2,5-dimethylbenzaldehyde (VI) when it was irradiated in THF in the absence of oxygen (Scheme 3). In benzene, carbon tetrachloride, or cumene no 2,5-dimethylbenzaldehyde was obtained but product (VII) was exclusively obtained in a nearly quantitative yield. Both 2,4,6,2′,4′,6′-hexamethylbenzil and 2,4,6-trimethylphenylglyoxal dissolved in THF gave 2,4,6-trimethylbenzoic acid as the main product when they were irradiated. Possibly, this acid is formed by the autoxidation of the

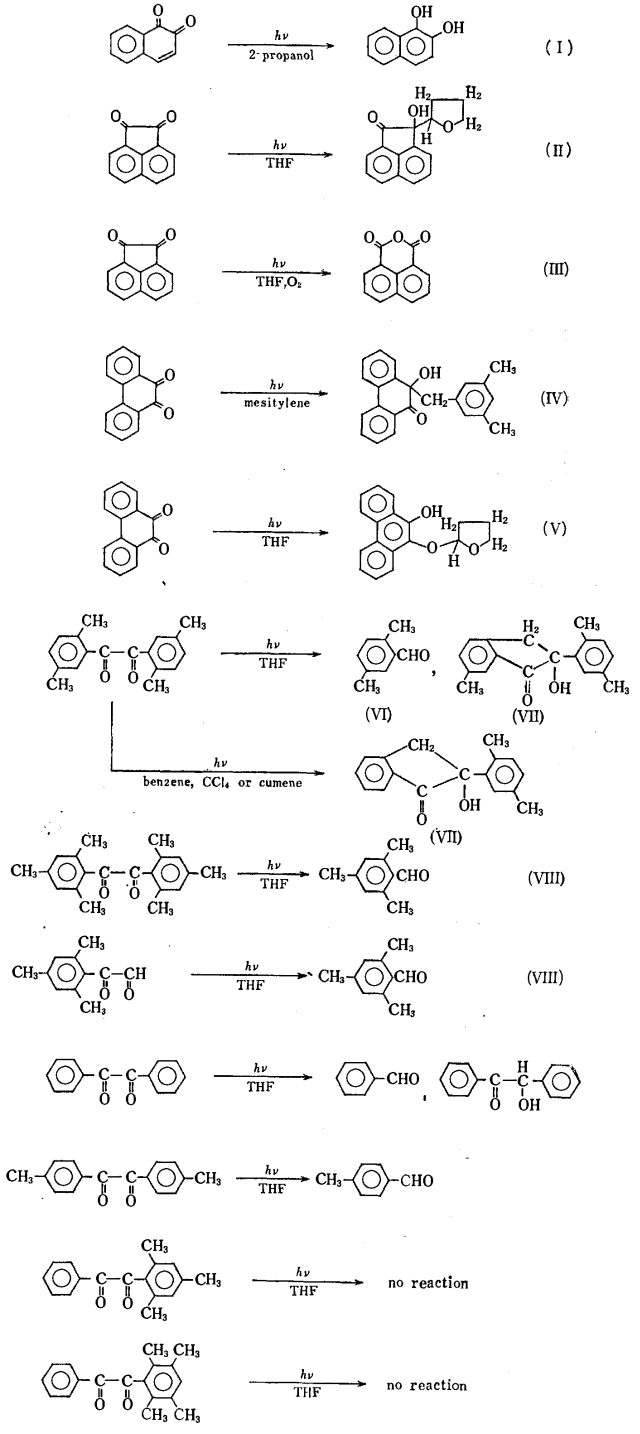
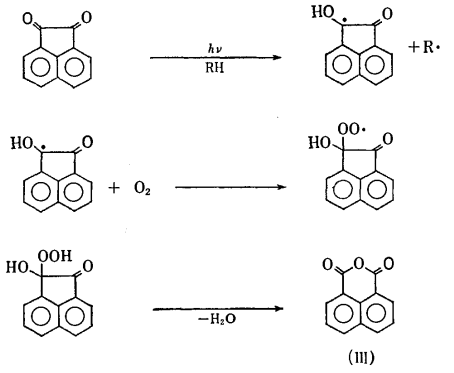
resulting 2,4,6-trimethylbenzaldehyde in the course of separating procedures.[7] However, both 2,4,6-trimethylbenzil and 2,3,5,6-tetramethylbenzil were extremely photo-stable and did not change after being irradiated for over a week.

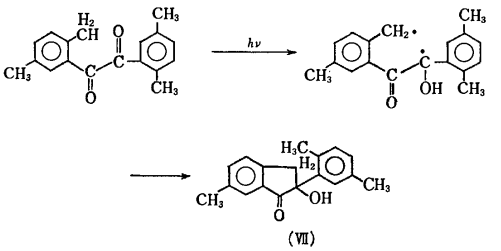
Determination of Quantum Yields. The quantum yields for the disappearance of α-diketones are shown in Table 1. It has been reported that the quantum yield for the photo-reduction of camphorquinone is very low.[2] On the other hand, the quantum yield of 1,2-naphthoquinone or 9,10-phenanthraquinone was nearly unity. These reactions are characteristic in that the photo-reduction with the solvent acts as a hydrogen donor. The reaction mechanism can be described by the following equations, where Q^s and Q^t are excited singlet and triplet states, respectively and AH the hydrogen donor.



Scheme 1.



Scheme 2.



Scheme 3.

TABLE 1. QUANTUM YIELDS OF THE DISAPPEARANCE OF α-DIKETONES IN THF (EXCITING LIGHT: 3640 Å, TEMPERATURE: 25°C)

α-Diketone	Quantum yield	Condition
1,2-Naphthoquinone	1.00	Degassed
9,10-Phenanthraquinone	0.86	Degassed

Benzil	0.85	In the air
2,5,2′,5′-Tetramethylbenzil	1.30	In the air
2,4,6-Trimethylbenzil	<0.02	In the air

Light intensity was determined by a potassium ferrioxalate actinometer.

$$Q^s \longrightarrow Q^t \quad (1)$$

$$Q^t \xrightarrow{k_d} Q \quad (2)$$

$$Q^t + AH \xrightarrow{k_r} QH + A \quad (3)$$

$$QH + A \longrightarrow QHA \quad (4)$$

$$A + A \longrightarrow A_2 \quad (5)$$

If the quantum yield for intersystem crossing is unity, the quantum yield for the disappearance of *o*-quinone is given by

$$\Phi = \frac{k_r[AH]}{k_r[AH]+k_d} \quad (6)$$

7) Methyl substituted benzaldehyde can be oxidised rapidly in the air.

The quantum yield for intersystem crossing of camphorquinone is known to be nearly unity[2] and the life time of its triplet state is similar to those of the other *o*-quinones.[8] Therefore, the difference in the quantum yield of 1,2-naphthoquinone or 9,10-phenanthraquinone and camphorquinone seems to be caused by the difference in the nature of the triplet state. The radical oxygen atom of 1,2-naphthoquinone or 9,10-phenanthraquinone in the photo-excited $n\rightarrow\pi^*$ triplet state should be more electrophilic than that of camphorquinone, for in the former the excited electron to π-orbital may be delocalized entirely on the rest of the molecule.[4] Thus, the $n\rightarrow\pi^*$ triplet state of the 1,2-naphthoquinone or 9,10-phenanthraquinone could be a better hydrogen abstractor.

8) A. Kuboyama and S. Yabe, This Bulletin, **40**, 2475 (1967).

Thus, we can conclude reasonably that 2,5,2′,5′-tetramethylbenzil or 4,4′-dimethylbenzil has twisted

Photochemical Behavior of Benzil Derivatives. The photochemical behavior of benzil derivatives is more complicated than that of *o*-quinones. Both photo-decomposition and photo-reduction take place at the same time, and in some cases phto-decomposition become the main reaction. Moreover, 2,4,6-trimethylated or 2,3,5,6-tetramethylated benzil derivatives are extremely photo-stable even in THF. We inspected the structural features using UV and PMR techniques and tried to discuss the relationship between the structure and the photochemical behavior of benzil derivatives. The wave lengths of maximum absorption of $n\rightarrow\pi^*$ transition are shown in Table 2 and the chemial shifts of methyl protons of the derivatives in Table 3. Leonard and Blout[9] concluded from the measurement of absorption spectra that non-substituted benzil had a skew structure as shown in Fig. 1 and 2,4,6,2′,4′,6′-hexamethylbenzil had a *trans* planar structure as shown in Fig. 2.

form around the carbon-carbon bond of the two carbonyl groups like that of non-substituted benzil. As shown in Table 3 τ-values of *meta* or *para* methyl protons (to carbonyl group) remain almost unchanged, but those of *ortho* methyl protons vary in the range $\tau=$ 7.24—7.87. The differences seem to depend on the magnetic anisotropy of carbonyl group. The plane of the two carbonyl double bond and that of the mesityl ring of 2,4,6,2′,4′,6′-hexamethylbenzil would be perpendicular (Fig. 2), but in 2,5,2′,5′-tetramethylbenzil the plane of the dimethylphenyl and the adjacent carbonyl might be nearly co-planar (Fig. 1). Thus, the *ortho* methyl protons of the former might be affected most effectively by the magnetic shielding effect of the carbonyl group. On the other hand, that of the latter is under the influence of the magnetic deshielding effect.

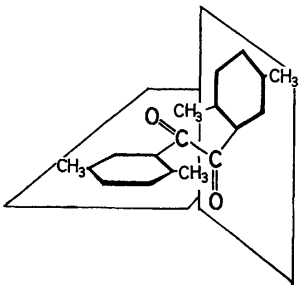

Fig. 1. Skew structure of benzil derivatives.

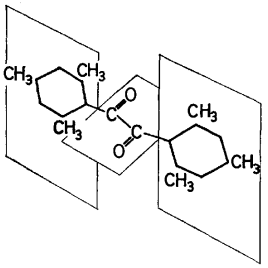

Fig. 2. Trans planar structure of benzil derivatives.

Whereas benzil, 2,5,2′,5′-tetramethylbenzil and 4,4′-dimethylbenzil dissolved in THF react fast in the absence of oxygen, 2,4,6-trimethylbenzil or 2,3,5,6-tetramethylbenzil dissolved in THF remains almost unreacted after a long irradiation over a week. 2,4,6,2′,4′,6′-Hexamethylbenzil reacts slowly. The quantum yields for the photo-reaction of methylated benzils in the presence of oxygen are given in Table 1. We see that 2,4,6-trimethylbenzil or 2,3,5,6-tetramethylbenzil is very unreactive compared with benzil or 2,5,2′,5′-tetramethylbenzil in the presence of oxygen as well as in the absence of oxygen.

Comparing the relative intensity of the phosphorescence of these benzils qualitatively, benzil or 2,5,2′,5′-tetramethylbenzil shows intense phosphorescence in contrast to 2,4,6-trimethylbenzil, 2,3,5,6-tetramethylbenzil, or 2,4,6,2′,4′,6′-hexamethylbenzil, which shows extremely weak phosphorescence. The lifetime of triplet state of benzil and 2,5,2′,5′-tetramethylbenzil in MMA plastic[10] are 0.20 msec and 0.65 msec, respectively, at room temperature, but in the case of 2,4,6-trimethylbenzil, 2,3,5,6-tetramethylbenzil, or 2,4,6,-2′,4′,6′-hexamethylbenzil no T–T, absorption of these benzils could be observed.

Thus, we might consider that the quantum yield for the intersystem crossing of 2,4,6-trimethylbenzil and 2,3,5,6-tetramethylbenzil are strikingly small. These benzil derivatives should be strongly photo-resistive.[11] However, there may be the other possibilities which are remained to be clarified in future. We next examined the solvent effects on the photochemical reactions. The reaction rate of non-substituted benzil showed a remarkable solvent effect. In non-polar solvents such as benzene, toluene, or *n*-hexane, benzil, 4,4′-dimethylbenzil, and 2,4,6,2′,4′,6′-hexamethylbenzil were less reactive than in polar solvents such as THF, *N,N*-dimethylformamide, ether, or methanol, whereas 2,5,-2′,5′-tetramethylbenzil was equally reactive in the polar or non-polar solvents. Qualitative comparison of the relative reactivity of these benzils is given in Table 4.

TABLE 4. RELATIVE REACTIVITY OF α-DIKETONES IN SEVERAL SOLVENTS (LIGHT SOURCE: 400W HIGH PRESSURE Hg LAMP, ROOM TEMPERATURE)

α-Diketones	Qualitative rates in several solvents
Benzil	THF, methanol, DMF, ether $\gg$ benzene, toluene, *n*-hexane
4,4′-Tetramethylbenzil	methanol $\gg$ benzene, *n*-hexane
2,4,6,2′,4′,6′-Tetramethylbenzil	THF $\gg$ benzene
2,5,2′,5′-Tetramethylbenzil	THF, methanol, benzene, toluene, *n*-hexane (reacts fast in all solvents)
2,4,6-Trimethylbenzil	THF, methanol, benzene (does not react in all solvents)

These phenomena seem to be ascribed to the cage effect of solvent for the carbonyl-carbonyl bond scission. However, 2,5,2′,5′-tetramethylbenzil is reactive in non-polar as well as polar solvents. The carbonyl group and the *ortho* methyl proton of this benzil derivative should be positioned very close and nearly overlapping. Consequently VII might be produced *via* intramolecular hydrogen abstraction fairly easily even in the non-polar solvents. On the other hand, 2,4,6-trimethylbenzil and 2,3,5,6-tetramethylbenzil are unreactive in the polar or non-polar solvents. The cause of the low quantum yield for the intersystem crossing of these benzil derivatives remains to be explained. However, it does not seem incidental that these photochemically unreactive benzil derivatives are antisymmetric and the mean value of the dihedral angle between the two carbonyl groups are in the range 90—180°.

Experimental

Materials. 1,2-Naphthoquinone (mp 121—122°C), acenaphthoquinone (decomp. 242°C), and 9,10-phenathraquinone (mp 204°C) were prepared by the oxidation of 2-amino-1-naphthol, of acenaphthene, and of phenanthrene with suitable oxidizing agents. 2,5,2′,5′-Tetramethylbenzil (mp 113—114°C), 2,4,6,2′,4′,6′-hexamethylbenzil (mp 120—121°C), 2,4,6-trimethylbenzil (mp 135°C) and 2,3,5,6-tetramethylbenzil (mp 62—63°C) were prepared by the air-oxidation of the corresponding benzoins[12] produced by the condensation of the corresponding glyoxals with suitable methylated benzenes.[13] Benzil (mp 94—95°C) and 4,4′-dimethylbenzil (mp 104—105°C) were prepared by the oxidation of the corresponding benzoins produced by the benzoin condensation of benzaldehyde and *p*-tolualdehyde.

Irradiation of α-Diketones. A typical photo-reaction was performed as follows. A known amount of α-diketone

10) methyl metacrylate

11) 2,4,6,2′,4′,6′-Hexamethylbenzil reacts very slowly.

12) "Organic Syntheses," Coll. Vol. II, p. 509 (1948); "Organic Reaction," Vol. 4, p. 269.

13) "Organic Syntheses," Coll. Vol. I, p. 87 (1948).

(usually 1/100—1/1000 mol) dissolved (or suspended) in a solvent (20—100 m*l*) was irradiated in an ordinary glass tube through 5 cm thick of water layer from a light source (400W high-pressure Hg-lamp). Change of the substrate was followed spectroscopically. A reaction vessel fitted with a cell for spectroscopic measurement was used for the experiments under degassed conditions.

Analyses of Photochemical Products. 1,2-Dihydroxynaphthalene(I): After the characteristic orange color of 1,2-naphthoquinone dissolved in 2-propanol faded to pale yellow, 2-propanol was evaporated under reduced pressure. The resulting dark orange colored solid was extracted with *n*-hexane. Removal of *n*-hexane left unstable white crystal which changes easily to the corresponding quinhydrone in the air, mp 59—60°C, IR: ν_{OH}=3340—3360 cm^{-1}.

1-Hydroxy-1-α-tetrahydrofuranyl-8-oxoacenaphthene(II): 1,8-Acenaphthoquinone dissolved in THF was irradiated in the absence of oxygen. After two days irradiation the solvent was removed under reduced pressure, and the resulting reddish oil was extracted with petrol ether, and then colorless crystal was obtained, mp 217—223°C (decomp), (yield 80%). Elemental analysis: $C_{16}H_{14}O_3$; Found, C: 75.61%, H: 5.53%; Calculated, C: 75.57%, H: 5.56%.

1,8-Dinaphthoic acid anhydride(III): After the orange yellow color of acenaphthoquinone faded to pale yellow, removal of THF as solvent left a pale yellow solid which was recrystallized from ether. Colorless crystal, mp 273—276°C, $\nu_{C=O}$; 1730, 1770 cm^{-1}. Elemental analysis; Found, C: 72.79%, H: 3.07%, Calculated, $C_{12}H_6O_3$, C: 72.75%, H: 3.13%.

9-Hydroxy-9-(3',5'-dimethylbenzyl)-10-oxo-9,10-dihydrophenanthrene(IV): After 9,10-phenanthraquinone suspended in mesitylene was irradiated for two days, the unreacted mesitylene was removed under reduced pressure. The resulting viscous oil was rinsed with petrol benzene several times, and then yellow crystals were crystallized out, mp 125—126°C, ν_{OH}: 3470 cm^{-1}, $\nu_{C=O}$: 1690 cm^{-1}, $\tau_{m\text{-}CH_3}$: 7.83, $\tau_{\text{-}CH_2\text{-}}$: 7.15, τ_{OH}: 6.20, (yield: 75%). Elemental analysis; Found, C: 82.20%, H: 6.21%, Calculated, $C_{23}H_{17}O_2$, C: 84.93%, H: 5.26%.

9-(10-Hydroxy)phenanthrenyl α-tetrahydrofuranyl ether (V): *i.e.*, 1,4-adduct of 9,10-phenanthraquinone with THF; after 9,10-phenanthraquinone dissolved in THF was irradiated until it became colorless, removal of unreacted THF left crystals which were recrystallized from petrol ether, mp 110—112°C, ν_{OH}: 3250 cm^{-1}, (yield: 80%). Elemental analysis; Found, C: 81.90%, H: 4.48%, Calculated, $C_{18}H_{16}O_3$; C: 81.79%, H: 4.57%.

2-Hydroxy-2-(2',5'-dimethylphenyl)indanone (VII): After 2,5,-2',5'-tetramethylbenzil dissolved in THF (or a suitable solvent) was irradiated for three days under degassed conditions, removal of THF under reduced pressure left heavy viscous oil, which was rinsed with petrol benzene several times. All of the oil then solidified, recrystallized from petrol benzene-benzene, pale yellow crystal, mp 153°C, ν_{OH}: 3390 cm^{-1}, $\nu_{C=O}$: 1705 cm^{-1}, τ_{CH_3}: 7.80, 7.77, 7.55, τ_{OH}: 7.25, $\tau_{\text{-}CH_2\text{-}}$: 6.63, (nearly quantitative yield). Elemental analysis; Found; C: 81.24%, H: 6.75%, Calculated, $C_{18}H_{18}O_2$, C: 81.19%, H: 6.81%. From the mother liquor *2,5-dimethylbenzaldehyde* was isolated after it was treated with aqueous sodium bicarbonate and identified as semicarbazone, mp 217°C. After acidification of the bicarbonate solution a small amount of 2,5-dimethylbenzoic acid was separated, mp 132°C.

2,4,6-Trimethylbenzaldehyde and 2,4,6-trimethylbenzoic acid: After the solution of 2,4,6,2',4',6'-hexamethylbenzil in THF was irradiated for a week, the solution was concentrated and diluted with ether, and then treated with aqueous sodium bicarbonate. From the ethereal solution 2,4,6-trimethylbenzaldehyde was isolated and identified as semicarbazone, mp 184—187°C. After acidification of the sodium bicarbonate extract a fair amount of 2,4,6-trimethylbenzoic acid was isolated, recrystallized from ligroin, mp 153°C, $\nu_{C=O}$: 1690 cm^{-1}, τ_{CH_3}: 7.70, 7.58, τ_{CO_2H}: −2.10.

Benzaldehyde: After benzil dissolved in THF was irradiated under degassed conditions for three days, THF was removed under reduced pressure. The residue dissolved in ether was treated with aqueous sodium bicarbonate and concentrated to a small volume. It was treated with 2,4-dinitrophenylhydrazine hydrochloride solution and then reddish colored crystals were separated, mp 237°C. From a part of the ethereal solution, benzoin was isolated identified by the mp 137°C.

p-*Tolualdehyde*: After the usual treatment of irradiated solution of 4,4'-dimethylbenzil in THF *p*-tolualdehyde was identified to be its 2,4-dinitrophenylhydrazone, mp 232—232°C.

Determination of Quantum Yields and Lifetime of Triplet State. A known amount of an α-diketone was dissolved in THF and irradiated with 400 W high-pressure Hg-lamp through a UV-cut filter (Toshiba VY-42) under the conditions indicated in Table 1. The light intensity was determined with a potassium ferrioxalate actinometer. The lifetime of triplet state of benzil derivatives was determined as follows. Benzil derivatives dissolved in MMA plastic were irradiated by flash method, and the decay of phosphorescence was followed oscillographically. T–T' absorption was also observed spectroscopically through the further activation of triplet state thus attained with a tungsten-lamp.

The Photochemical Reduction of Nitrobenzene and Its Reduction Intermediates. XI. The Photochemical Reduction of Azobenzene in Isopropyl Alcohol[1]

Shizunobu HASHIMOTO and Koji KANO

Department of Applied Chemistry, Doshisha University, Kamikyo-ku, Kyoto

(Received July 9, 1971)

The photochemical reduction of azobenzene in isopropyl alcohol has been investigated. The n-π^* transition of azobenzene caused only the *cis-trans* photoisomerization, while the π-π^* transition caused both photoisomerization and photoreduction. The reduction product was hydrazobenzene. The photoreduction was accelerated by a small amount of oxygen and was quenched by 1,3-pentadiene. The photoreduction was sensitized by fluorene and the aromatic carbonyl compounds (benzophenone, benzaldehyde, and acetophenone). These results suggest that the π,π^* excited triplet state (T_2) of azobenzene abstracts a hydrogen atom.

Previous investigations of azobenzene photochemistry have dealt almost exclusively with the photoisomerization,[2] and so little is known about the photoreduction of the aromatic azo compounds. Irick *et al.*[3] have reported that the photolysis of 4-diethylamino-4′-nitroazobenzen in hydrogen-donative alcohols, such as methanol, ethanol, and isopropyl alcohol (IPA), gives the corresponding hydrazo compound with a low quantum yield (Φ=*ca.* 10^{-4}). On the other hand, we have reported in a previous paper[4] that azobenzene is photoreduced in an IPA or acidic IPA solution to afford hydrazobenzene upon irradiation with a high-pressure mercury lamp. However, the photoreduction mechanisms of azobenzene have been uncertain until recently.

Consequently, this study was undertaken in order to clarify the photoreduction mechansims of azobenzene in IPA.

Experimental

Materials. Azobenzene[5] and *para*-substituted azobenzenes[6] were prepared according to the procedures described in the literature. Reagent-grade IPA was distilled prior to use. 1,3-Pentadiene commercially obtained was further purified by distillation (bp 42—45°C). The other materials, commercially obtained, were recrystallized or distilled as required.

Apparatus and Procedures. In most experiments, an immersion-type Taika 130-W high-pressure mercury lamp was used. We took much a care to remove the oxygen in the reaction system, because the hydrazobenzene produced is photooxidized to give azobenzene.[7] That is, the photolysis was carried out in an atmosphere of nitrogen, freed of oxygen by having been passed through a xylene solution of metal ketyl.

Analytical Procedures. The progressive spectral change in azobenzene photochemistry were measured by means of UV spectroscopy (a Hitachi 124 spectrophotometer was used). The primary amines were determined by means of paper chromatography and/or thin-layer chromatography.[8]

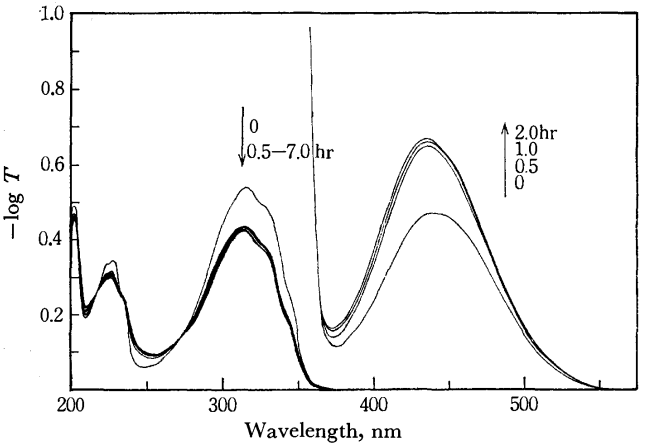

Fig. 1. The progressive spectral change of the photoreaction of azobenzene. For UV spectra measurement, 0.5 m*l* of the photolyzed solution was exactly diluted to 20 m*l* with IPA. The photolyzed solution was directly used as the sample for visible spectra measurement.

Results

Photochemical Reaction of Azobenzene. Figure 1 shows the progressive spectral change during the course of the photolysis of a 1×10^{-2} mol/*l* solution of *trans*-azobenzene in IPA on irradiation with an immersion-type 130-W high-pressure mercury lamp under a nitrogen atomosphere at room temperature. After irradiation, the *trans-cis* photoisomerization proceeded rapidly.[9-11] The formation of *cis*-azobenzene was determined by means of spectroscopy; that is, after the irradiation, the absorption maximum of *trans*-azobenzene at 440 nm in IPA shifted to 435 nm because of the n,π^* excitation of *cis*-azobenzene.[10] *cis*-Azoben-

zene was also detected by means of thin-layer chromatography. As Fig. 1 shows, the absorption spectra did not change during irradiation after 0.5 hr; this suggests that *cis*- and *trans*-azobenzenes might coexist at equilibrium. Under these conditions, the photoreduction of azobenzene did not proceed; therefore, the initial concentration of *trans*-azobenzene was lowered.

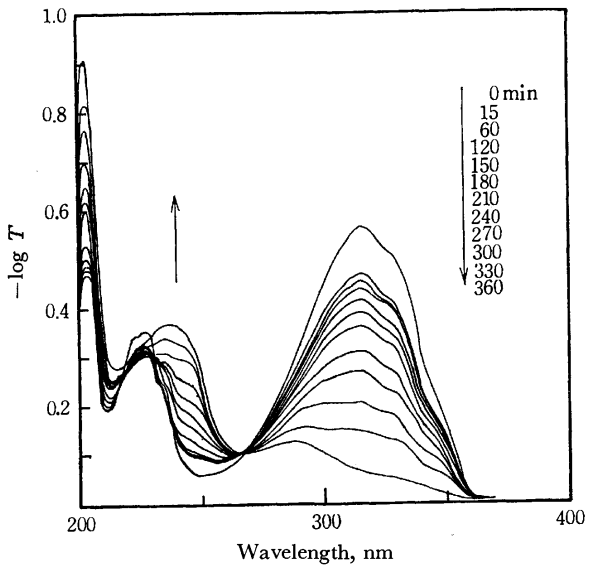

Fig. 2. The progressive spectral change of the photoreduction of azobenzene in IPA.

Figure 2 shows the progressive spectral change during the photolysis of a 5×10^{-4} mol/*l* solution of *trans*-azobenzene in IPA on irradiation under the conditions described above. In this photolysis, the phtoisomerization of azobenzene proceeded in the primary step; then the absorption spectrum of *trans*-azobenzene ($\lambda_{max}=$ 316 nm) decreased progressively in intensity, and a new absorption band with its maximum at *ca.* 242 nm appeared. The new absorption suggested the generation of hydrazobenzene ($\lambda_{max}^{IPA}=242$ nm) as a photoreduction product. When HCl was added to the samples collected after 2 hr, the products of the benzidine rearrangement of hydrazobenzene (benzidine, diphenyline, and aniline)[12] were detected by means of paper chromatography and/or by thin-layer chromatography. This finding supported the idea that a photoproduct of azobenzene was hydrazobenzene.

Effect of Oxygen. The photolysis described above was carried out under an atomosphere of nitrogen which had been freed of oxygen by passage through a xylene solution of metal ketyl; in this case, only the photoisomerization of azobenzene proceeded in an IPA solution when the initial concentration of azobenzene was high (1×10^{-3} mol/*l*). By the way, nitrogen gas commercially obtained contains a small amount of oxygen (*ca.* 1 vol%). Therefore, we studied the effect of oxygen on the photochemistry of azobenzene upon irradiation under an atomosphere of nitrogen containing a small amount of oxygen. The procedures of photolysis were the same to those described above. The initial concentration of *trans*-azobenzene was 1×10^{-3} mol/*l*.

In this reaction, *ca.* 40% of azobenzene was photoreduced to hydrazobenzene after the solution had been irradiated for 8 hr. It was found from this experiment that the rate of the photoreduction of azobenzene was accelerated by a small amount of oxygen.

Meanwhile, when the photolysis was carried out in an air-saturated IPA solution, the photoreduction of azobenzene did not proceed. In this case, it seemed that the photooxidation of hydrazobenzene to azobenzene[7] might proceed or that the triplet state of azobenzene might be quenched by oxygen.

Effect of the Triplet Quencher. The quenching effect on the photoreduction of azobenzene in IPA was investigated by using 1,3-pentadiene as a triplet quencher.

A nitrogen gas was passed into a 5×10^{-4} mol/*l* solution of *trans*-azobenzene in IPA containing 0.4 vol% of 1,3-pentadiene for 1 hr at 0°C. After this procedure, the solution was irradiated with an immersion-type 130W high-pressure mercury lamp at *ca.* 15°C. After 5 hr, the photolyzed solution was analyzed by means of UV spectroscopy. Consequently, it was found that the photoreduction was completly quenched by 1,3-pentadiene and that only the photoisomerization proceeded. In the absence of 1,3-pentadiene, about 13% of the azobenzene was photoreduced to hydrazobenzene upon irradiation under the same conditions. On the basis of the data, it seems reasonable to conclude that the hydrogen abstraction of photoexcited azobenzene proceeds from its triplet state.

The Wavelength Dependence of the Photoreduction of Azobenzene. In the UV spectrum of *trans*-azobenzene in IPA, the n,π^* and π,π^* absorption maxima were observed at 440 ($\varepsilon_{max}=470$) and 316 nm ($\varepsilon_{max}=$

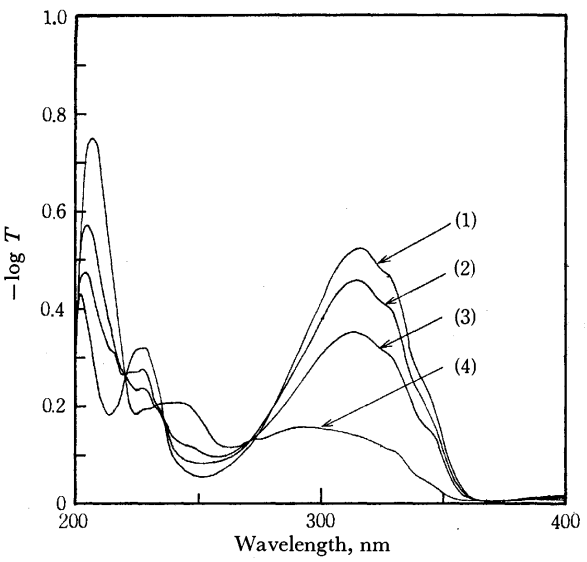

Fig. 3. Wavelength dependence of the photoreduction of azobenzene.
(1): Before irradiation
(2): Irradiation of >420 nm light for 2 hr
(3): Irradiation of a 366 nm light for 1 hr
(4): Irradiation of a 366 nm light for 2 hr

12) H. J. Shine, "Mechanisms of Molecular Migrations," Vol. 1, ed. by B. S. Thyagarajan, Interscience Publishers, New York, N. Y. (1969), p. 191.

2.2×10^4) respectively. Therefore, the reactivity toward the photoreduction of n,π^* and π,π^* excited azobenzene was investigated by using suitable filters.

A 5×10^{-5} mol/l solution of *trans*-azobenzene in a quartz cell (5 cm in diameter and 2 cm in width) was irradiated at wavelengths longer than 420 nm (Toshiba V-Y42 filter) and/or a 366-nm light (Toshiba UV-D2 filter) isolated from a 130W high-pressure mercury lamp under a nitrogen atmosphere at room temperature. The photolyzed solutions were analyzed by means of UV spectroscopy and paper chromatography.

The UV spectra of the photolyzed solutions are shown in Fig. 3. When the solution was irradiated at wavelengths longer than 420 nm, only the *cis-trans* photoisomerization proceeded. However, upon irradiation with a 366-nm light, the azobenzene was photoreduced to hydrazobenzene.

In view of the above facts, it was found that the π,π^* excited triplet of azobenzene abstracted hydrogen atoms.

Photosensitized Reduction of Azobenzene. A 5×10^{-4} mol/l solution of *trans*-azobenzene in IPA containing a photosensitizer (1×10^{-3} mol/l) was irradiated with an immersion-type 130W high-pressure mercury lamp under a nitrogen atmosphere at room temperature. The results obtained are summarized in Table 1.

Table 1. Photosensitized reduction of azobenzene

Sensitizer	E_T[a] kcal/mol	Φ_{ST}[b]	Sensitization	Quenching	Time required for 100% conversion, hr
—	—	—	—	—	6.0
Benzene	85	0.24	—	—	6.0
Benzoic acid	78	—	—	+	—[c]
Benzonitrile	77	—	—	+	—[c]
Acetophenone	74	0.99	+	—	1.5
Benzaldehyde	72	—	+	—	1.25
Diphenylamine	72	0.38	—		—

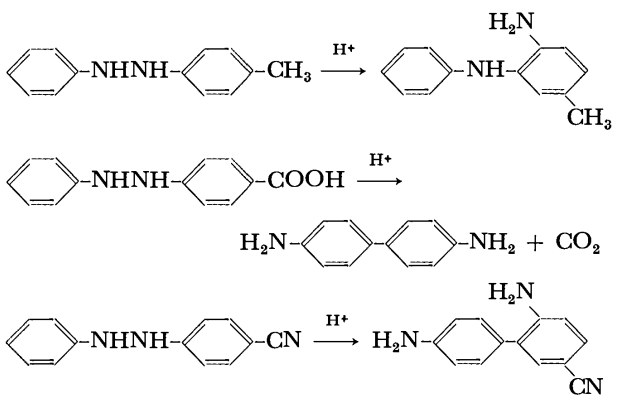
Benzophenone	69	1.00	+	—	1.0
Fluorene	68	0.31	+	—	3.5
Biphenyl	65	—	—	—	6.5
Phenanthrene	62	—	—	—	6.0
Michlar's ketone	62	1.01	—		—
Naphthalene	61	0.39	—	—	6.0

a) N. J. Turro, "Molecular Photochemistry," W. A. Benjamin, Inc., New York, N. Y. (1965), p. 132.
b) Ref. a) p. 131.
c) In these cases, the photoreduction is completely quenched.

As is shown in Table 1, the photoreduction of azobenzene was sensitized by fluorene and the aromatic carbonyl compounds (except Michlar's ketone). By the way, thiophene, benzonitrile, and benzoic acid quenched the photoexcited azobenzene.

Substituent Effect on the Photoreduction of Azobenzene. A 5×10^{-4} mol/l solution of 4-methylazobenzene, 4-phenylazobenzonitrile, and 4-phenylazobenzoic acid in IPA was irradiated under the conditions described in the case of azobenzene photochemistry. The results are shown in Table 2.

In the absorption spectra of photolyzed solutions, new absorption bands were observed in the 435—443 nm range; these bands seem to be due to the *cis*-isomers of the azobenzenes in view of the similarity of the visible spectra to that of *cis*-azobenzene. The absorption spectra of photolyzed solutions did not change between 0.5 and 2 hr after irradiation; therefore, the π,π^* absorption at *ca.* 320 nm of the *trans*-azobenzenes consecutively decreased in intensity and new absorption bands which were due to the hydrazobenzenes appeared. The preparation of the hydrazobenzenes was also determined by means of the paper chromatography of the primary amines, which were generated by the acid-catalyzed rearrangement of the hydrazobenzenes[12] as follows:



The time required for the complete disappearance of the 4-H, 4-CH_3, 4-COOH, and 4-CN derivatives were 6, 12, 9, and 7 hr respectively. Therefore, it seems that increasing the electronegativity of the substituents tends to increase the apparent rates of photoreduction.

Discussion

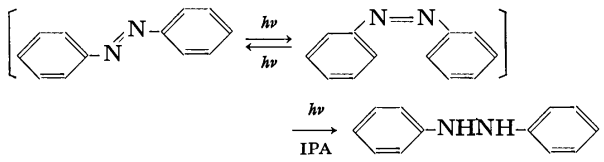
Photoreduction Mechanisms of Azobenzene. *trans*-Azobenzene reacted photochemically by way of two

Table 2. Photochemical reduction of 4-substituted azobenzenes

Azobenzenes	n,π^*, nm (ε)	π,π^*, nm (ε, 10^4)	λ_{max} of *cis*-isomers, nm	Time required for 100% conversion, hr	λ_{max} of the products, nm
H	440 (470)	316 (2.2)	435	6	242
CH_3	440 (620)	322 (2.4)	435	12	243
COOH	448 (300)	322 (2.6)	438	9	292
CN	450 (600)	322 (2.5)	443	7	*ca.* 270

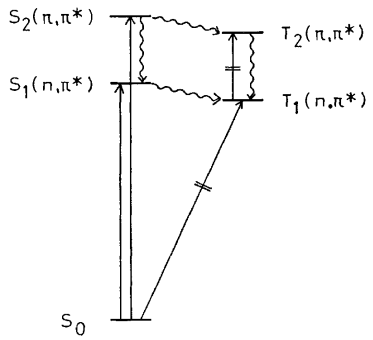
In all cases, UV spectra were measured in IPA.

processes, the photoisomerization and the photoreduction.



Azobenzene was relatively unreactive toward photoreduction under a nitrogen atmosphere; only the photoisomerization proceeded in a solution with a high concentration (1×10^{-3} mol/l). On the other hand, when a small amount of oxygen existed in the reaction system, the photoreduction was accelerated. It is well-known that oxygen quenches photoexcited species. It might also be mentioned that oxygen also induces the $S^* \rightarrow T$ transition. Before the beginning of the experiments, we inferred that oxygen might quench the triplet state of azobenzene or might oxidize the hydrazobenzene produced to azobenzene; therefore, the photoreduction might be depressed by oxygen. Nevertheless, the fact that the rate of the photoreduction of azobenzene was accelerated by a small amount of oxygen suggests that oxygen induces the $S^* \rightarrow T$ transition. Actually, the excited species of the photoreduction of azobenzene was determined to be the triplet state by the experiment of energy transfer using 1,3-pentadiene.

We also studied the wavelength dependence of the photoreduction of azobenzene. It was found that the $n \rightarrow \pi^*$ transition induced only the photoisomerization, while the $\pi \rightarrow \pi^*$ transition caused the photoreduction. These findings differ from those described for the photoreductions of the benzophenone[13] and/or nitrobenzenes,[1] which are caused by the $n \rightarrow \pi^*$ transition. This wavelength dependence on the azobenzene photochemistry is very interesting; however, we have not obtained sufficient experimental data to interpret the photochemical behavior of azobenzene. We may interpret the mechanisms of azobenzene photochemistry on the basis of the state diagram, as is shown as follows. That is, azobenzene is excited to the S_2 (π,π^*) state by the $\pi \rightarrow \pi^*$ transition. The S_2 state is converted to the $S_1(n,\pi^*)$ state by the internal conversion. The *cis-trans* photoisomerization of azobenzene may mainly be caused by the S_1 state, because the $n \rightarrow \pi^*$ transition causes only photoisomerization in neat IPA or IPA containing 1,3-pentadiene and/or oxygen. By the way, if the S_2 state converts to the $T_2(\pi, \pi^*)$ state by the spin-orbital interaction, this excited species may be able to abstract a hydrogen atom. It seems that the $T_1(n,\pi^*)$ state is not a species of the hydrogen-abstraction reaction, because this state may also be obtained by the intersystem crossing process, $S_1(n,\pi^*) \rightarrow T_1(n,\pi^*)$. The $S_0 \rightarrow T_1$ or $T_1 \rightarrow T_2$ transition has not occurred under our reaction conditions.



Photosensitized Reduction of Azobenzene. The photoreduction of azobenzene in IPA was sensitized by fluorene (E_T=68 kcal/mol) and by the aromatic carbonyl compounds (benzophenone, benzaldehyde, and acetophenone) except Michler's ketone. If the hydrogen-abstraction reaction of azobenzene proceeds from its π, π^* triplet (T_2), the triplet energy of fluorene may transfer to azobenzene, and then azobenzene may be excited to the T_2 state. Therefore, the energy of the T_2 state of azobenzene may be less than 68 kcal/mol. It seems that the photosensitization by the carbonyl compounds can be interpreted by two mechanisms. One of them is the triplet energy-transfer mechanism, and the other is the hydrogen-transfer mechanism. It is well-known that benzophenone, benzaldehyde, and acetophenone abstract a hydrogen atom from hydrogen donative solvents to generate their ketyl radicals:[14]

$$C_6H_5COR^* + R'H \longrightarrow C_6H_5\dot{C}(OH)R + \dot{R}'$$

Analogously with the IPA ketyl radical,[15] these ketyl radicals may be able to reduce azobenzene in the ground state:

$$C_6H_5\dot{C}(OH)R + C_6H_5N{=}NC_6H_5 \longrightarrow C_6H_5COR + C_6H_5NH\dot{N}C_6H_5$$

Reactions Leading to 1,2-Dibenzoylethanes: The Dehalogenation of Phenacyl Bromide and the Photolysis of Methyl Phenacyl Sulfoxide

Hitosi NOZAKI, Tamio SHIRAFUJI, Kiyosi KUNO, and Yasusi YAMAMOTO

Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto

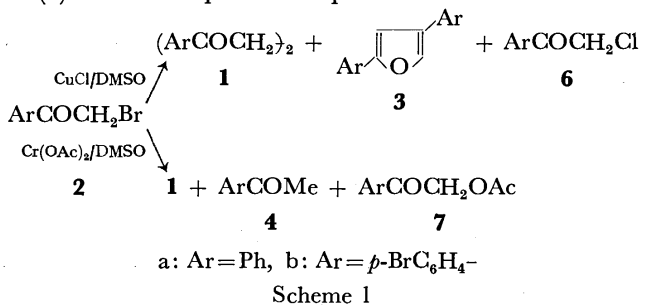
(Received July 12, 1971)

The dehalogenation of phenacyl bromide by means of lower-oxidation-state metallic ions complexed by DMSO gives 1,2-dibenzoylethane. The by-products are 2,4-diphenylfuran and phenacyl chloride in the presence of Cu(I) chloride, whereas acetophenone and ω-acetoxyacetophenone are produced in the reaction with Cr(II) acetate. Treatment with $K_3Co(CN)_5$/DMSO gives 1,2-dibenzoylethane and acetophenone. The second title reaction consists of the photolysis of methyl phenacyl sulfoxides, the isolated by-products being acetophenones and methyl methanethiolsulfonate. The product distribution is strongly affected by the pH of the reaction mixture and also by the benzene-ring substituents.

Few reactions are known with respect to the formation of 1,2-dibenzoylethane (**1**) *via* the dehalogenation of phenacyl halides (**2**) or the recombination of phenacyl radicals. The treatment of phenacyl bromide (**2a**) with nickel carbonyl gives 1,2-dibenzoylethane (**1a**) in THF, whereas 2,4-diphenylfuran (**3a**) is the sole product in the DMF solvent.[1] The photolysis of dimethylphenacylsulfonium bromide in an aqueous solution gives **1a** besides **2a** and acetophenone (**4a**).[2] We now wish to record two independent reactions producing **1a**: the dehalogenation of phenacyl bromide with lower-oxidation-state metal salts dissolved in DMSO and the photolysis of methyl phenacyl sulfoxide (**5a**).[3]

Dehalogenation of Phenacyl Halide. Complexed metal salts of the lower oxidation state effectively dehalogenate organic halides.[4,5] In continuation of previous studies along this line,[6] we have now examined the reaction of phenacyl bromide with Cu(I) chloride, Cr(II) acetate, and $K_3Co(CN)_5$, all dissolved in DMSO: we thus obtained **1a** in varying yields, along with by-products, as is shown in Scheme 1 and Table 1.

The formation of 2,4-diarylfurans (**3a**, **3b**) in the Cu(I) reaction is parallel to previous observations made



Scheme 1

Table 1. Reaction of $ArCOCH_2Br$ with CuCl, $Cr(OAc)_2$, or $K_3Co(CN)_5$ in DMSO[a]

Components	Reaction time (hr)	Products yield (%)[b] 1	3	4	6	7
2a+CuCl	18.5	13	14		39	
2b+CuCl	38.5	11	13		43	
2a+$Cr(OAc)_2$	12.5	28		—		43
2b+$Cr(OAc)_2$	23	16		32		18
2a+$K_3Co(CN)_5$	24	7		50		
2b+$K_3Co(CN)_5$	17	25		40		

a) Each reaction was carried out at room temperature (CuCl and $Cr(OAc)_2$) and 80—90°C ($K_3Co(CN)_5$) in N_2 atmosphere with 1M DMSO solution or of the salt with Br/metal ratio of 1:2.5.

b) The isolation yields were based on **2**. The recovery was not considered.

of the reactions of α-haloketones with nickel(0) tetracarbonyl,[1] metallic magnesium,[7] or zinc.[8] Analogously with these reactions, we may account for the route to **3a**, and **3b** as in Scheme 2, where the intermediacy of Cu(I) enolate is postulated.[7,8] The Wurtz-type condensation of this enolate with **2** (Route A) or, alternatively, the recombination of phenacyl radicals gives **1**, whereas aldol condensation, followed by dehydro-

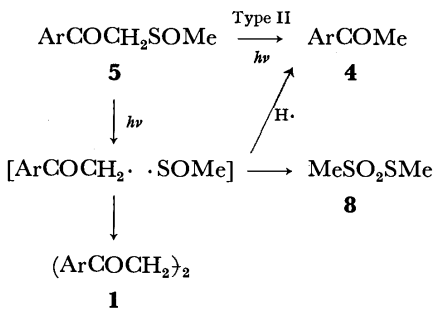
a) Irradiation was performed on 0.1 M solutions with an external 200W high pressure mercury lamp through a Pyrex filter at room temperature under nitrogen atmosphere.
b) Irradiation under oxygen atmosphere.
c) A trace of concentrated H_2SO_4 was added to adjust the pH of the media at 5—6 on a test paper.
d) A trace of 10% NaOH (EtOH) was added to adjust the pH of the media at 8—9.
e) EtOH:H_2O=2:1 (volume ratio). A by product, *p*-$ClC_6H_4COCH_2SO_2Me$ (18%) was obtained.
f) A by product, *p*-Me_2N-$C_6H_4COCH_2OH$ (20%) was obtained.

bromination (Route B), produces the furans **3**. Schematically, the possibility of Route C cannot be excluded. The anhydrous Cr(II) acetate/DMSO system is apparently less selective than the previously-recorded Cr(II) sulfate/aqueous DMF system,[4c] which produces **4** almost quantitatively. The complete absence of aldol condensation in the Cr(II) reaction may be ascribed to the higher covalency of the chromium-phenacyl bond than that of copper enolate. The ligand-ligand reaction leading to **7** prevails in this case.

Few organic reactions have been recorded to occur under the participation of $K_3Co(CN)_5$.[9-12] The reaction with **2** is mainly reduction to **4** in DMSO. Smaller yields of **1** were obtained.

Photolysis of Phenacyl Sulfoxides (5). The irradiation of β-keto sulfones[13] or β-keto sulfides[14] ($RCOCH_2$-X-CH_2R', X=SO_2 or S) gives $RCOCH_3$ ketones. The reaction of the sulfides is supposed to proceed *via* the Norrish type-II route, whereas that of sulfones has been claimed to involve the homolysis of the C-S bond, followed by hydrogen abstraction by the $RCOCH_2\cdot$ radicals.

The photochemistry of the β-keto sulfoxides[15,16] now readily available has apparently not been described. We will report the formation of **1** and **4** in the photolysis of phenacyl sulfoxides, **5**, mainly in ethanol (Scheme 3), as well as the effects of the pH values of the reacting media and those of aromatic substituents. The results are summarized in Table 2.



Scheme 3

At the initial stage of this investigation we experienced difficulties in securing reproducible experimental data. Soon it was found that the product distribution is quite sensitive to the pH of the reaction media. Table 2 contains the effect of added acids and bases. Slightly basic conditions favor the yields of dibenzoylethanes, **1**, whereas acetophenones, **4**, are mainly produced under acidic conditions. This effect may be ascribed to the amphoteric character of the phenacyl sulfoxide, that is, to the methylene acidity and the SO

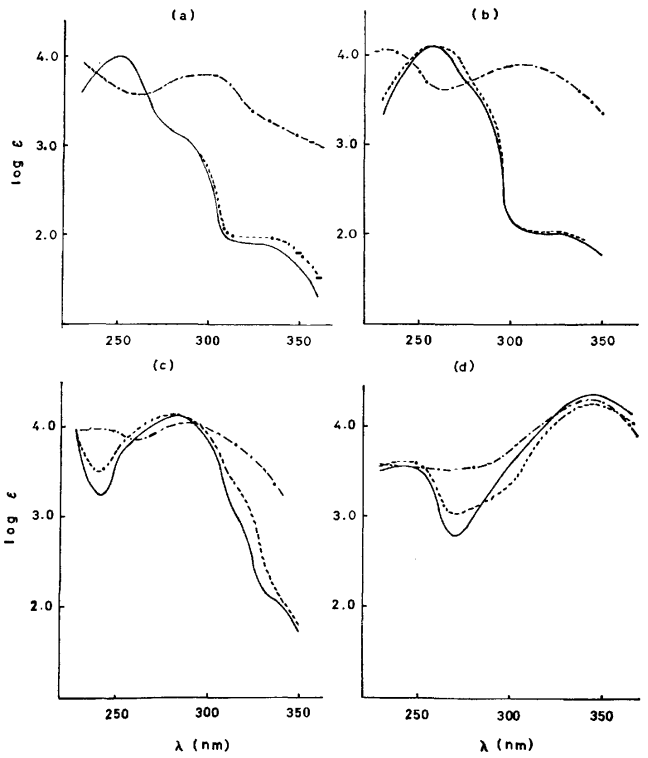

Fig. 1. UV spectra of β-keto sulfoxides in ethanol (——), ethanol-H_2SO_4(------), and ethanol-NaOH (-·-·-).
(a) $PhCOCH_2SOMe$ (**5a**); (b) p-$ClC_6H_4COCH_2SOMe$ (**5c**); (c) p-$MeOC_6H_4COCH_2SOMe$ (**5e**); (d) p-$Me_2NC_6H_4COCH_2SOMe$ (**5f**).

oxygen basicity (*vide infra*). Aromatic substituents also influenced the product distribution; the *p*-dimethylamino group strongly increased the yield of **1**, while *p*-methoxy and *p*-halogen substituents favored **4**. In *t*-butyl alcohol or benzene, **5a** gave **1a** mainly.

The UV absorptions of the reacting mixtures are given in Fig. 1. The bathochromic and hyperchromic shift of longer wavelength (n-π^*) absorptions was observed under basic conditions, the presence of a trace of acid did not change the spectra appreciably. The spectra of the *p*-dimethylamino derivative, **5f**, showed little dependence on the pH and remarkably resembled ot the spectra of **5a**, **5c**, and **5e** under basic conditions. The relationship between the product distribution and the spectral change has not yet been clearly explained. The photolysis appears to involve initial homolysis of the phenacyl-SO bond. The $ArCOCH_2\cdot$ radicals then dimerize to **1** or, alternatively, abstract hydrogen from the solvent to give **4**. Presumably, smaller photoquanta under basic conditions give less energetic $ArCOCH_2\cdot$ radicals, which easily dimerize. The absence of the removable solvent hydrogen also favors the formation of **1**. The counter radicals, ·SOMe, dimerize to give methyl methanethiolsulfonate (**8**), which has been isolated as is shown in Table 2.

Experimental

All the mps are uncorrected. The microanalyses were performed at the Elemental Analyses Center of Kyoto University and by Mrs. K. Fujimoto of this Department. The NMR spectra were taken on a 60 MHz instrument (JEOL C-60H spectrometer) in deuteriochloroform or carbon tetrachloride with tetramethylsilane as the internal standard. The UV spectra were obtained on a Shimadzu MPS-50L spectrometer.

Unless otherwise stated, irradiation was effected externally by means of a 200-W high pressure mercury lamp under a nitrogen atmosphere at room temperature.

Commercial Cu(I) chloride was used without purification. Cr(II) acetate and $K_3Co(CN)_5$ were prepared according to the methods shown in the literature.[12,17] The β-keto sulfoxides were synthesized by the Corey method.[15] The NMR, IR, and microanalyses of novel ones are given below.

Methyl p-*chlorophenacyl sulfoxide (5c)* showed a mp of 128°C. IR (Nujol): 1670 cm^{-1} ($\nu_{C=O}$), 1030 cm^{-1} (ν_{SO}). NMR ($CDCl_3$): δ 2.80 (s, 3H, Me), 4.40 (s, 2H, $-CH_2-$), and 7.35—8.15 (two d, 4H, aromatic protons).

Found: C, 50.2; H, 4.2%. Calcd for $C_9H_9ClO_2S$: C, 49.9; H, 4.2%.

Methyl p-N,N-*dimethylaminophenacyl sulfoxide (5f)* showed a mp of 144—145°C. IR (Nujol): 1600 cm^{-1} ($\nu_{C=O}$), 1020 cm^{-1} (ν_{SO}). NMR ($CDCl_3$): δ 2.74 (s, 3H, -SOMe), 3.10 3.10 (s, 6H, Me_2N), 4.02—4.63 (two d, 2H, $-CH_2-$), and 6.59—7.93 (two d, 4H, aromatic protons).

Found: C, 58.6; H, 6.6%. Calcd for $C_{11}H_{15}NO_2S$: C, 58.6; H, 6.7%.

Reaction of Phenacyl Bromide (2a) with Cu(I) Chloride. In a N_2 atmosphere, Cu(I) chloride (1.5 g, 15 mmol) was dissolved in freshly-distilled DMSO (30 m*l*) (over CaH_2). To this, a solution of **2a** (1.2 g, 6.0 mmol) in DMSO (10 m*l*) was added. The reaction mixture was stirred for 18.5 hr at room temperature, treated with water and extracted with ether. The extract was then washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. Chromatography on a silica-gel column gave 1,2-dibenzoylethane (**1a**) (0.09 g, 13%), 2,4-diphenylfuran (**3a**) (0.09 g, 14%), and phenacyl chloride (**6a**) (0.36 g, 39%). The **1a** product showed a mp of 148—150°C (lit.[1] 145°C) and was identical with an authentic sample. IR (Nujol): 1675 cm^{-1} ($\nu_{C=O}$). NMR ($CDCl_3$): δ 3.47 (s, 4H, $-CH_2-$) and 7.35—8.40 (m, 10H, aromatic protons). The **3a** product showed a mp of 111°C (lit.[18] 111°C). IR (Nujol): 1538 and 910 cm^{-1} (furan ring). NMR (CCl_4): δ 6.82 (s, 1H, proton of the furan ring at the C-3 position) and 7.15—7.65 (m, 11H, protons of the benzene ring and furan ring at the C-5 position). The **6a** product showd a mp of 57—58°C (lit.[19] 58°C), and its structure was supported by NMR and IR.

Reaction of p-*Bromophenacyl Bromide (2b) with Cu(I) Chloride.* A solution of Cu(I) chloride (0.89 g, 9.0 mmol) in DMSO (30 m*l*) was prepared under N_2. To this, a solution of **2b** (0.99 g, 3.6 mmol) in DMSO (10 m*l*) was added and the mixture was stirred at room temperature for 38.5 hr. Chromatography on a silica-gel column gave **1b** (0.08 g, 11%), **3b** (0.09 g, 13%), and **6b** (0.36 g, 43%). The **1b** product showed a mp of 180°C (lit.[1] 180—181°C). IR (Nujol): 1670 cm^{-1} ($\nu_{C=O}$). NMR ($CDCl_3$): δ 3.43 (s, 4H, $-CH_2-$) and 7.54—7.98 (m, 8H, protons of the aromatic ring). The **3b** product showed a mp of 160°C. IR (Nujol): 1539 and 912 cm^{-1} (furan ring). NMR ($CDCl_3$): δ 6.90 (s, 1H, proton of the furan ring at the C-3 position) and

7.40—7.73 (m, 9H, protons of the aromatic ring and the furan ring at the C-5 position). The **6b** product showed a mp of 116—118°C (from ethanol) (lit.[20] 117—118°C).

Reaction of 2a with Cr(II) Acetate. Under N_2, Cr(II) acetate (1.5 g, 8.8 mmol) was dissolved in DMSO (50 m*l*) so to give *ca.* 0.18 M solution. To this, a solution of **2a** (0.70 g, 3.5 mmol) in DMSO (10 m*l*) was added and the mixture was stirred at room temperature for 12.5 hr. Chromatography on a silica-gel column gave **1a** (0.12 g, 28%), ω-acetoxyacetophenone (**7a**) (0.27 g, 43%). The **7a** product showed a mp of 47—49°C (lit.[21] 49°C); its structure was supported by the IR and NMR.

Reaction of 2b with Cr(II) Acetate. The **2a** halide (2.23 g, 8.0 mmol) in DMSO (10 m*l*) was treated with a solution of Cr(II) acetate (3.40 g, 20 mmol) in DMSO (100 m*l*) at room temperature for 23 hr to afford **1b** (0.25 g 16%), **4b** (0.51 g, 32%), and **7b** (0.37 g, 18%). The **7b** product showed a mp of 84—85°C (lit.[22] 85°C).

Reaction of 2a with $K_3Co(CN)_5$. A solution of the cyanocobalt(II) complex was prepared under N_2 from potassium cyanide (9.75 g, 150 mmol) and Co(II) chloride (3.25 g, 25 mmol) in DMSO (50 m*l*). To this, a solution of **2a** (2.0 g, 10 mmol) in DMSO (5 m*l*) was added, and the mixture was stirred at 80—90°C for 24 hr. A subsequent work-up gave **1a** (0.08 g, 7%) and **4a** (0.60 g, 50%).

Reaction of 2b with $K_3Co(CN)_5$. To a solution of the cobalt complex prepared from potassium cyanide (4.88 g, 75 mmol) and Co(II) chloride (1.63 g, 13 mmol) in DMSO (50 m*l*), a solution of **2b** (1.39 g, 5.0 mmol) in DMSO (10 m*l*) was added, after which the mixture was stirred at 80—90°C for 17 hr. A subsequent work-up gave **1b** (0.25 g, 25%) and **4b** (0.40 g, 40%).

Photolysis of Methyl Phenacyl Sulfoxide (5a). Sulfoxide **5a** (0.182 g, 1 mmol) was dissolved in ethanol (10 m*l*) and degassed under vacuum at −70°C on a dry-ice bath. This was then irradiated by means of high-pressure mercury lamp for 5 hr. After the irradiation, the ethanol was removed *in vacuo* and the residue was chromatographed on a silica-gel column. 1,2-Dibenzoylethane (**1a**) (0.045 g, 38%), acetophenone (**4a**) (0.06 g, 49%), and methyl methanethiolsulfonate (**8**) (0.005 g, 8%) were obtained. The **8** product was identical with an authentic sample.

The photolyses of **5b—5g** were carried out under similar conditions. The results are summarized in Table 2. All the acetophenone derivatives were identical with authentic samples. The **1c**, **1d**, and **1e** products showed mps of 151°C (lit.[23] 151°C), 158—159°C (lit.[24] 159°C) and 154—155°C (lit.[25] 154°C) respectively, their structures were supported by IR and NMR. The **1f** product did not melt below 220°C. IR (Nujol): 1595 cm^{-1} ($\nu_{C=O}$). NMR ($CDCl_3$): δ 3.03 (s, 12H, Me_2N), 3.33 (s, 4H, $-CH_2CH_2-$), and 6.45—8.10 (two d, 8H, aromatic protons). Microanlyses were carried out without purification, as **1f** is difficult to purify in conventional ways.

Found: C, 73.2; H, 7.5; N, 8.4%. Calcd for $C_{20}H_{24}N_2O_2$: C, 74.0; H, 7.5; N, 8.6%.

A by-product, ω-hydroxy-*p*-*N*,*N*-dimethylaminoacetophenone, showed a mp of 155°C. NMR ($CDCl_3$): δ 3.10 (s, 6H, $-NMe_2$), 4.74 (s, 2H, $-CH_2-$), 7.35 (s, 1H, OH) and 6.55—7.97 (two d, 4H, aromatic protons). MS: 179 (M^+).

Found: C, 67.3; H, 7.2; N, 7.6%. Calcd for $C_{10}H_{13}NO_2$: C, 67.0; H, 7.3; N, 7.8%.

Photolysis of 5a in the Presence of Sulfuric Acid. The sulfoxide, **5a** (0.182 g, 1 mmol), was dissolved in ethanol (10 m*l*). A solution of sulfuric acid in ethanol was then added, drop by drop, so to give a solution of pH 5—6 (pH test paper). This solution was degassed and then irradiated under N_2 for 5 hr. The products were isolated and identified as has been described above. The photoreactions of **5c** and **5e** was carried out under similar conditions. The results are summarized in Table 2.

Photolysis of 5a in the Presence of Sodium Hydroxide. The sulfoxide, **5a** (0.182 g, 1 mmol), was dissolved in ethanol (10 m*l*). A solution of sodium hydroxide in ethanol was then added, drop by drop, so to give a solution of pH 8—9. This solution was irradiated under N_2 for 5 hr and the products were confirmed as has been described above. The results are summarized in Table 2.

The authors are grateful to Professor K. Sisido for his generous help. Financial support from the Ministry of Education, Japanese Government, and from the Toray Science Foundation is acknowledged with pleasure.

Thallium(III) Chloride Tetrahydrate as a Lewis Acid Catalyst for Aromatic Alkylation and Acylation[1]

Sakae UEMURA, Kazuhiro SOHMA, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received July 12, 1971)

From a study of aromatic alkylation and acylation using $TlCl_3 \cdot 4H_2O$ catalyst, it was revealed that this metal chloride was a milder Lewis acid catalyst than $AlCl_3$ and $FeCl_3$ and was similar in activity to $ZnCl_2$. Although the yields of the products were generally low, the characteristics of this catalyst were observed in the formation of β,β'-dimethylstyrene and benzoylacetone upon the respective methallylation and acetylation of benzene and in the fact that the hydrated chloride was more effective than the anhydrous one. In a sharp contrast to aromatic bromination, $Tl(OAc)_3$ showed little activity in these reactions.

Although many metal halides have been studied as Lewis acid catalysts for aromatic alkylation and acylation, Tl(III) salts seem to have received little attention so far[2]; only one report on the benzylation, benzoylation, and acetylation of benzene using the anhydrous $TlCl_3$ catalyst has been found in the literature.[3] Recently, Taylor and McKillop showed that the acetylation of anisole could be catalyzed by $Tl(OAc)_3$.[4] On the other hand, the use of Tl(III) salts, such as $Tl(OAc)_3$ and $TlBr_3 \cdot 4H_2O$, has been reported to be very effective in aromatic bromination[5,6], and their role has been considerably clarified.[6]

Our study of the Tl(III) salt-catalyzed aromatic alkylation and acylation has been started in the hope of finding some specific use for the catalyst in these reactions, as in the case of the Tl(III) salt-catalyzed aromatic bromination. Unfortunately, no distinctive feature was found from a synthetic point of view. Considering the yields of the products of butylation, allylation, haloalkylation, and acylation, however, it is clear that the activity of $TlCl_3 \cdot 4H_2O$ is qualitatively comparable to that of $ZnCl_2$ and inferior to that of $FeCl_3$ or $AlCl_3$. Here, it seems to be characteristic that the hydrated Tl(III) salt shows a moderate activity, in contrast to the fact that other active metal halide catalysts are used mostly in the anhydrous state. This report will deal with these observations.

Results and Discussion

The reactions were generally carried out by adding the alkylating or acylating agents to aromatic compounds (in excess as solvents) containing $TlCl_3 \cdot 4H_2O$ at various temperatures and by stirring the resulting mixtures for appropriate periods. Although an $AlCl_3$- or $FeCl_3$-catalyzed Friedel-Crafts alkylation and acylation generally proceeds at a low temperature, it was necessary to heat the reaction mixture in most of these $TlCl_3 \cdot 4H_2O$ catalyzed reactions. Some typical results are summarized in Table 1.

Butylation and Benzylation. It has been reported[7] that, in the presence of $AlCl_3$, *n*- and *t*-butyl chlorides reacted with benzene at 0°C to give *s*- and *t*-butylbenzenes in 50 and 60% yields respectively, and that the reaction of *t*-butyl chloride with benzene gave an 80% yeild of *t*-butylbenzene at 25°C in the presence of the $FeCl_3$ catalyst. In the presence of the $TlCl_3 \cdot 4H_2O$ catalyst, the *s*- and *t*-butyl halides reacted with aromatic compounds to give *s*- and *t*-butylated compounds (I) respectively in 22—39% yields at 60—76°C. The lower the reaction temperature was, the lower the yields of I became. *n*-Butyl chloride or bromide afforded only a small amount of *s*-butylbenzene (*ca.* a 2% yield at 76°C for 10 hr) without any trace of *n*-butylbenzene which was expected to be formed by the attack of the strongly polarized but undissociated alkyl halide molecule. *t*-Butyl alcohol could not be used as an alkylating agent at 70°C because of its rapid oxidation by $TlCl_3 \cdot 4H_2O$; this is in sharp contrast to the reactions with other acidic catalysts (*e.g.*, H_2SO_4, HF, $AlCl_3$, $FeCl_3$, and BF_3), in which *t*-butylbenzene was obtained in high yields from benzene.[7] In the benzylation of toluene with benzyl bromide or acetate, $TlBr_3 \cdot 4H_2O$ showed an activity similar to that of $TlCl_3 \cdot 4H_2O$ as a Lewis acid catalyst. Although $Tl(OAc)_3$ was a very effective catalyst in aromatic bromination, the *s*-butylation of benzene using this catalyst was almost entirely unsuccessful because of the conversion of $Tl(OAc)_3$ to inactive Tl_2O_3.

Allylation and Haloalkylation. It has been reported[8,9] that the reaction of allyl halide and aromatic compounds gives 1-aryl-2-halopropane or 1,2-diarylpropane in the presence of mild Lews acid catalysts, such as $ZnCl_2$, or with strong catalysts, such as $AlCl_3$, respectively, and that both of the products are derived from allylated compounds. Although $TlCl_3 \cdot 4H_2O$ has been shown by the aromatic butylation described above to be a milder Lewis acid catalyst than $AlCl_3$ or $FeCl_3$, it is not known to what kind of metal salts the activity

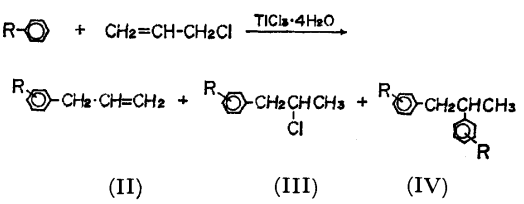
of $TlCl_3 \cdot 4H_2O$ is comparable. If $TlCl_3 \cdot 4H_2O$ is a milder catalyst than $ZnCl_2$, we could expect the allylated aromatic compounds to be isolated using this catalyst. In this connection, several aromatic compounds were treated at 55—70°C for 0.3—4 hr with allyl chloride or bromide in the presence of this catalyst. 1-Aryl-2-halopropanes (III) were generally isolated as the main products, along with small or trace amounts of monoallylated compounds (II) and diarylpropanes (IV) (Eq. 1).



(II) (III) (IV)

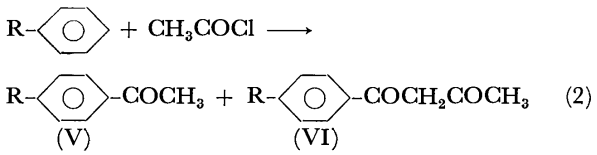
This means that the catalytic activity of $TlCl_3 \cdot 4H_2O$ is qualitatively similar to that of $ZnCl_2$ and milder than that of $AlCl_3$ in aromatic allylation. The formation of II was observed only under milder conditions (a short reaction time or a low reaction temperature), though the yields were very poor. The yields of III, which was probably formed by the hydrochlorination of II, decreased in the following order of aromatics, as would be expected; toluene>benzene>halobenzenes. The allylation of halobenzenes with this catalyst at 65—70°C for 1.5—2 hr gave only 9—18% yields of III, while with the $FeCl_3$ catalyst somewhat higher yields (24—53%) were recorded, even at lower reaction temperatures (—21——16°C).[10] Compound IV was probably produced by aromatic alkylation with III. An isomer of IV, 1,1-diarylpropane, was also formed, and the amount of which was larger than that of IV. The presence of such an isomer indicates that the hydrogen transfer has occurred in the intermediary cation ($ArCH_2\overset{+}{C}HCH_3$) derived from III on prolonged heating, as in the case of the *n*-butylation of benzene described above. The use of a solvent led to a significant decrease in the reaction rate; *e.g.*, with benzene and allyl chloride, no reaction occurred at 50°C after 4 hr in carbon disulfide, and only 6% of the III was obtained at 65°C after 4 hr in chloroform. Allyl bromide reacted more easily with benzene than allyl chloride, but a mixture of 2-bromo- and 2-chloro-1-phenylpropanes (in 4: 1 ratio) was obtained in a 43% yield, together with diphenylpropanes (14% yield), when the reaction was at 55°C for 0.3 hr. The allylation with allyl alcohol, which was easily achieved by other Lewis acid catalysts, was unsuccessful when we used $TlCl_3 \cdot 4H_2O$, which has a strong oxidizing property. The reaction with *trans*-crotyl chloride showed a behavior similar to that of the reaction with allyl chloride. With methallyl chloride, however, β,β'-dimethylstyrene was obtained in a 9% yield without any trace of such compounds as III and IV when the reaction was at 75°C for 5 hr. This compound, which is probably formed by the isomerization of the methallylated compound, has not been reported to be formed by a Friedel-Crafts reaction using any Lewis acid catalyst; rather its formation seems to be one of the characteristics of the $TlCl_3 \cdot 4H_2O$ catalyst.

The attacking species in this reaction seem to be rather reactive, because the k_T/k_B ratio in the formation of II and III by the competitive reaction of toluene and

10) T. M. Patrick, Jr., E. T. McBee, and H. B. Hass, *J. Amer. Chem. Soc.*, **68**, 1009 (1946).

benzene with allyl chloride (at 50°C for 0.3 hr) is revealed to be 2.6; this value is comparable with the value (3.2) obtained in the $AlCl_3$-catalyzed benzylation in nitromethane.[11] Further, it is interesting to note that the favorable attack at the *p*-position of toluene by allylic species (the *o*/*p* ratio is 0.15 in III) contrasts strikingly with that at the *o*-position by benzylic species (where the *o*/*p* ratio is 1.38), as is shown in Table 1.

Acylation. Although Kashtanov has obtained a 12% yield of acetophenone from the acetylation of benzene using anhydrous $TlCl_3$,[3] a recent description of Taylor and McKillop of the selective para acetylation of anisole by the $Tl(OAc)_3$ catalyst[4] encouraged us to reinvestigate the acylation using $TlCl_3 \cdot 4H_2O$. In the presence of $TlCl_3 \cdot 4H_2O$, the reactions of acetyl or propionyl chloride with benzene, toluene, and anisole were examined; the *para*-monoacylated compounds (V) were isolated as the main products, although the yields were low. It seems that the low yield is not be accounted for by the hydrolysis of acyl chloride with the water of the hydrated catalyst, because the reaction with anhydrous $TlCl_3$ gave a smaller amount of the product. In a contrast to Kashtanov's report, the acetylation of benzene and toluene at 56°C gave benzoylacetone and *p*-methylbenzoylacetone (VI) respectively, together with V (Eq. 2). When acetophenone



(2)

was heated with $TlCl_3 \cdot 4H_2O$ at 56°C for 5 hr, α-methylchalcone, the Claisen condensation product of acetophenone, was obtained in a 10% yield, as in the $AlCl_3$-catalyzed reaction[12] (in this case, an 11.5% yield was reported); however, the presence of excess (*e.g.*, 5 equiv.) acetyl chloride changed the product to benzoylacetone (9% yield) under the same reaction conditions. Although it has been reported that the methyl group of acetophenone was acetylated with acetic anhydride using the $FeCl_3$ or $ZnCl_2$ catalyst to give benzoylacetone,[12] there have been no reports about acetylation with acetyl chloride. This $TlCl_3 \cdot 4H_2O$-catalyzed acetylation of acetophenone and this formation of VI seem to be characteristic of this catalyst. Acetic anhydride could not be used as the acetylating agent of aromatic compounds with the $TlCl_3 \cdot 4H_2O$ catalyst.

Recently, Taylor and McKillop reported,[4] without any detailed description of the experimental conditions, that, in the CCl_4 solvent, anisole was acetylated by acetyl chloride to give *p*-acetylanisole in an 80% yield when the $Tl(OAc)_3$ catalyst was used. When a similar reaction was carried out with anisole as the solvent and with the $TlCl_3 \cdot 4H_2O$ catalyst, only a 28% yield of the acetylated product was obtained at 25°C after 0.3 hr. For comparison, the reaction of anisole (0.1 mol) and acetyl chloride (0.05 mol) using the $Tl(OAc)_3$ (0.05 mol) catalyst was carried out in CCl_4 (80 ml) at 20°C for 3 hr, but only a 15% yield of *p*-acetylanisole was thus obtained. The reason for the discrepancy with Taylor's result is obscure.

Experimental

Materials. All the organic starting materials were used after distillation. The $TlCl_3 \cdot 4H_2O$ (mp 35—37°C, lit.[13] 37°C; the purity (as determined by iodometry) was more than 96%) and $TlBr_3 \cdot 4H_2O$ (mp 40—42°C, lit.[13] 40°C; purity, 97%) catalysts were of commercial origin. The $Tl(OAc)_3$ was prepared by heating Tl_2O_3 in aceitc acid.[14] Anhydrous $TlCl_3$,[15] which is very hygroscopic, was prepared by dissolving $TlCl_3 \cdot 4H_2O$ into thionyl chloride at room temperature, evaporating the hydrogen chloride, sulfur dioxide, and excess thionyl chloride to dryness on a water bath, and drying under a vacuum for 6 hr (purity, 96.6%). The *n*-, *s*-, and *t*-butylbenzenes, allylbenzene, diphenylmethane, acetophenone, *p*-methylacetophenone, and benzoylacetone were commercial products and were used as the authentic samples for glc analysis. The 1-phenyl-2-chloropropane and 1,2-diphenylpropane were prepared from a benzene-allyl chloride-$FeCl_3$ system at −10—−20°C for 1 hr; the yields were 41% and 14% (1,2-isomer/1,1-isomer= 1.5 by NMR) respectivey. The 1-halophenyl-2-chloropropanes were prepared by the reported method[10] using the corresponding halobenzene, allyl chloride, and $FeCl_3$ catalyst.

Experimental Procedure. The reaction of benzene with allyl chloride in the presence of $TlCl_3 \cdot 4H_2O$ is shown below as a typical example. Allyl chloride (15.2 g, 0.2 mol) was stirred into a suspension of molten $TlCl_3 \cdot 4H_2O$ (9.6 g, 0.025 mol) and benzene (78 g, 1 mol) at 60°C. The color of the reaction mixture changed from pale yellow to orange and finally to deep purple, while the reaction temperature rose to 70°C. After 4 hr, the black precipitates were filtered off, and the filtrate was washed with water and a saturated aqueous $NaHCO_3$ solution and dried over Na_2SO_4. Glc analysis showed that it consisted of almost pure III, 1-phenyl-2-chloropropane (37% yield), and trace amounts of II and IV. III was isolated in a pure state by vacuum distillation; bp 90—93°C/19 mmHg, 9.9 g (64.2 mmol). NMR τ 8.52 (d. J=6.5 Hz, 3H), 6.99 (m. 2H), 5.79 (m. 1H), 2.76 (m. 5H).

Identification of the Products. *Allyltoluene* (II, R=CH_3) was obtained as a mixture with 1-tolyl-2-chloropropane (III, R=CH_3) at bp 50—65°C/7 mmHg (the ratio of II/III=2). The NMR of a mixture of *o*- and *p*-isomers of III τ 7.68 (s. 3H), 6.25—6.05 (m. 2H), 5.30—4.75 (m. 2H), 4.30—3.90 (m. 1H), 3.0—2.75 (m. 5H).

1-Tolyl-2-chloropropane (III, R=CH_3) was obtained as a mixture of *o*- and *p*-isomers at bp 79—82°C/5 mmHg. Found: C, 71.39; H, 7.81%. Calcd for $C_{10}H_{13}Cl$: C, 71.21; H, 7.77%. NMR τ 8.53 (d. J=7.5 Hz, 3H, *o*-isomer), 8.50 (d. J=7.5 Hz, 3H, *p*-isomer).

2-Bromo-1-phenylpropane: Bp 85—89°C/5 mmHg. NMR τ 8.35 (d. J=6.4 Hz, 3H), 6.95—6.78 (m. 2H), 6.0—5.5 (m. 1H), 2.9—2.7 (m. 5H).

Ditolylpropane (IV, R=CH_3) was obtained as a mixture of 1,1- and 1,2-ditolylpropanes at bp 132—135°C/3 mmHg. Found: C, 89.70; H, 8.94%. Calcd for $C_{17}H_{20}$: C, 91.01; H, 8.99%. NMR τ 9.12 (t. J=8 Hz, 3H, 1,1-ditolylpro-

pane), 8.78 (d. J=8 Hz, 3H, 1,2-isomer).

β,β'-Dimethylstyrene: Bp 85—86°C/25 mmHg. NMR τ 8.18—8.05 (m, 6H) 3.8—3.65 (m, 1H), 2.8—2.65 (m, 5H).

p-*Anisylacetophenone* (*V*, $R=CH_3O$): Bp 113—122°C/6 mmHg. NMR τ 7.48 (s, 3H), 6.17 (s, 3H), 3.1 (d, J=9.5 Hz, 2H), 2.05 (d, J=9.5 Hz, 2H).

α-Methylchalcone, $C_6H_5C(CH_3)=CHCOC_6H_5$: Bp 160—163° C/2 mmHg (lit.[16] bp 225°C/22 mmHg), IR (liq. film) 1670 (s, $\nu_{C=O}$), 1610 (s, $\nu_{C=C}$) cm^{-1}.

Benzoylacetone: Bp. 115°C/5 mmHg (lit.[12] bp 103—105° C/1.8 mmHg), mp 59°C (lit.[18] 60—61°C). Found: C, 74.03; H, 6.42%. Calcd for $C_{10}H_{10}O_2$: C, 74.05; H, 6.22%.

Spectral Measurements. The IR spectra were measured on Hitachi EPI-2 and EPS-3T spectrometers. The NMR spectra were determined on a Varian A-60 spectrometer, using TMS as the internal standard in $CDCl_3$. Glc analysis was carried out on Shimadzu 5APTF apparatus, using PEG 6000 (25%)-Chromosorb-W 3-m and Apz-L (30%)-Celite 3-m columns, and on a Hitachi F-6 apparatus, using Apz-L 1-m columns.

Studies of Peptide Antibiotics. XXVII. Synthesis of an Analog of Gramicidin S Containing a Glycine Residue in Place of a Proline[1]

Shuji MATSUURA, Michinori WAKI, and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received July 14, 1971)

[Gly^5]-Gramicidin S in which one L-proline residue at 5-position in gramicidin S is replaced with glycine was synthesized and tested for antibacterial properties. The cyclic decapeptide obtained was as active as natural gramicidin S. It was suggested that the mode of antibacterial activity of [Gly^5]-gramicidin S and its conformation are similar to those of GS.

In the studies of synthetic analogs of biologically active peptides, several hybrid analogs which contain two peptide portions suggested from different natural peptides have been synthesized. As such an analog, oxypressin containing the cyclic hexapeptide portion of vasopressin and the linear tripeptide portion of oxytocin was synthesized. The hybrid peptide exhibited unique biological activities compared with the parent hormones.[2] From the results it occurred to us to prepare a gramicidin S analog which contain two peptide portions and to investigate its antibacterial properties.

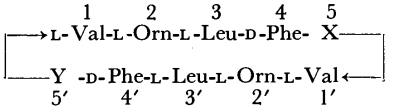

Fig. 1. Structure of GS (X, Y=L-Pro), [Gly^5]-GS (X=Gly, Y=L-Pro) and [Gly$^{5,5'}$]-GS (X, Y=Gly).

In order to understand the relationship between the chemical structure and antibacterial activity of gramicidin S (GS) (Fig. 1), various analogs of GS in which two amino acid residues are substituted with two other amino acids have been synthesized. An analog, [Gly$^{5,5'}$]-GS, was synthesized in this laboratory originally[3] and also in other laboratories,[4] and its strong antibacterial activity has been observed. However, a GS analog in which one amino acid residue is replaced with other amino acid has not yet been synthesized.

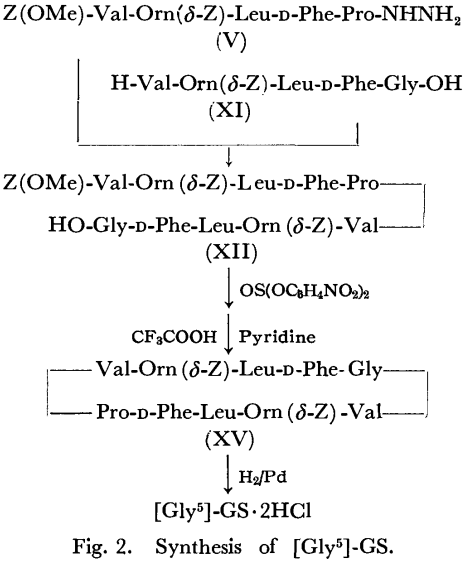

Fig. 2. Synthesis of [Gly^5]-GS.

1) Presented at the 23rd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1970.

2) R. A. Boissonnas, S. Guttmann, P.-A. Jaquenoud, and J.-P. Waller, *Helv. Chim. Acta*, **39**, 1421 (1957); J. Rudinger, J. Honzl, and M. Zaoral, *Collection Czech. Chem. Commun.*, **21**, 770 (1956); P.G. Katsoyannis, *J. Amer. Chem. Soc.*, **79**, 109 (1957).

3) H. Aoyagi, T. Kato, M. Ohno, M. Kondo, M. Waki, S. Makisumi, and N. Izumiya, This Bulletin, **38**, 2139 (1965).

4) J. Halstrom and H. Klostermeyer, *Ann.* **715**, 208 (1968); A. A. Kiryushkin, Y. A. Ovchinnikov, I. V. Kozhevnikova, and M. M. Shemyakin, "Peptides," North-Holland Pub. Co., Amsterdam (1967), p. 100.

It thus seemd of interest to prepare [Gly^5]-GS (Fig. 1) which is composed of two peptide portions, -Val-Orn-Leu-D-Phe-Pro- from GS and -Val-Orn-Leu-D-Phe-Gly- from [Gly$^{5,5'}$]-GS. This paper describes the synthesis, antibacterial properties and optical rotatory dispersion (ORD) measurement of [Gly^5]-GS.

Figure 2 indicates the route for the synthesis of [Gly^5]-GS.[5] Condensation of the azide derived from Z(OMe)-pentapeptide hydrazide (V) with a neutral pentapeptide (XI) gave an acyldecapeptide acid (XII). Pentapeptide (XI) obtained previously from Z(OMe)-pentapeptide acid[3] was prepared alternately from Boc-pentapeptide acid (X) by the action of formic acid. Z(OMe)-decapeptide acid (XII) was converted into an acyldecapeptide nitrophenyl ester (XIII), and its Z(OMe) group was removed with trifluoroacetic acid. Decapeptide trifluoroacetate (XIV) thus obtained was treated with pyridine for the cyclization reaction. The reaction mixture yielded a pure Z-substituted cyclic decapeptide (XV) which was hydrogenated to afford [Gly^5]-GS as a crystalline dihydrochloride.

TABLE 1. ANTIBACTERIAL ACTIVITY OF THE COMPOUNDS
(Minimum inhibitory concentration, μg/ml)

Compound	*Echerichia coli*	*Staphylococcus aureus*	*Bacillus subtilis*
	(Bouillon agar medium, pH 7.0)		
GS	20	2	2
[Gly^5]-GS	20	5	5
[Gly$^{5,5'}$]-GS	20	5	5
Mixture of GS and [Gly$^{5,5'}$]-GS[a]	20	2—5	2—5
	(Synthetic medium, pH 7.0)		
GS	20	5	5
[Gly^5]-GS	20	5	5
[Gly$^{5,5'}$]-GS	20	5	2—5
Mixture of GS and [Gly$^{5,5'}$]-GS[a]	20	5	5

a) A mixture was prepared with 1:1 weight ratio of GS and [Gly$^{5,5'}$]-GS.

The antibacterial activities of [Gly^5]-GS and several reference compounds toward microorganisms were tested (see Table 1). Three compounds, [Gly^5]-GS, GS and [Gly$^{5,5'}$]-GS, exhibited approximately the same activities for all the microorganisms tested. Erlanger and Goode observed that some linear decapeptides, *e.g.* H-(Val-Lys-Leu-D-Phe-Pro)$_2$-OH, revealed synergistic activity with GS against *E. coli*. They noted that the mode of antibacterial action of such linear peptides might differ from that of GS.[6] As shown in Table 1, a mixture of GS and [Gly$^{5,5'}$]-GS possessed activity in the same degree with each compound GS, [Gly$^{5,5'}$]-GS and [Gly^5]-GS; no synergistic activity of [Gly$^{5,5'}$]-GS on GS was observed. We thus assumed that the mode of action of [Gly$^{5,5'}$]-GS, and then [Gly^5]-GS, is similar to that of GS. This assumption is favored by comparison of ORD curves (Fig. 3) of the compounds referred to above with that of [β-Ala$^{5,5'}$]-GS which possessed no antibacterial activity.[7] The three compounds, [Gly^5]-GS, GS, and [Gly$^{5,5'}$]-GS, afforded a similar shape with a trough at approximately 232 mμ, while [β-Ala$^{5,5'}$]-GS afforded a shape of simple dispersion curve with no trough. The results of ORD measurements suggest that [Gly^5]-GS possesses a conformation similar to that of GS.

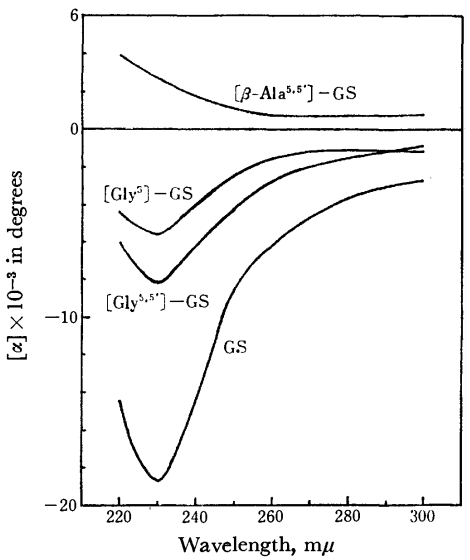

Fig. 3. ORD curves of the four compounds in ethanol. The curve of [β-Ala$^{5,5'}$]-GS is talen from a pre^{v}ious paper.[7]

Experimental

Thin layer chromatography was carried out on Merck silica gel G with the following solvent systems: R_f^1, *n*-butanol-acetic acid-pyridine-water (4:1:1:2, *v/v*); R_f^2, chloroform-methanol (5:1, *v/v*).

H-D-Phe-OEt·TsOH (I). This was prepared according to the procedure for the L isomer.[8] Yield, 88%; mp 153—154°C; $[\alpha]_D^{20}$ −20.0° (*c* 1, ethanol) (Found: C, 59.18; H, 6.48; N, 3.83%). Reported values for the L isomer;[8] mp 153°C, $[\alpha]_D$ +15.5° (DMF).

Z-Leu-D-Phe-OEt (II). This was prepared from Z-Leu-OH·DCHA (21.8 g) and I (17.8 g) with DCC (10 g) in the same way as for Z-Leu-D-Phe-OBzl.[9] Yield, 18.0 g (84%); mp 106—107°C; $[\alpha]_D^{15}$ −7.8° (*c* 1, methanol); R_f^1 0.98, R_f^2 0.76.

Found: C, 67.89; H, 7.34; N, 6.46%. Calcd for $C_{25}H_{32}O_5N_2$: C, 68.16; H, 7.32; N, 6.36%.

Z-Leu-D-Phe-NHNH$_2$ (III). This was prepared from II (17.2 g) and hydrazine hydrate (38 ml) in the same way as for the same product from Z-Leu-D-Phe-OBzl and hydrazine.[9] Yield, 15.8 g (95%); mp 163°C. No depression

5) Abbreviations: Z, benzyloxycarbonyl; Z(OMe), *p*-methoxybenzyloxycarbonyl; Boc, *t*-butyloxycarbonyl; ONp, *p*-nitrophenoxy; DCC, dicyclohexylcarbodiimide; DCHA, dicyclohexylamine; TEA, triethylamine; TsOH, *p*-toluenesulfonic acid; DMF, dimethylformamide. Amino acid symbols except D-Phe and Gly denote the L-configuration.

of melting point was observed on a mixture of III with the product[9] prepared before. III was used for the preparation of Z-Leu-D-Phe-Pro-OEt[9] and Z(OMe)-Val-Orn(δ-Z)-Leu-D-Phe-Pro-OEt (IV)[10] as described in literature.[9,10]

Z(OMe)-Val-Orn(δ-Z)-Leu-D-Phe-Pro-NHNH$_2$ (V). A solution of IV (7.65 g, 8.4 mmol) and hydrazine hydrate (8.3 ml, 167 mmol) in DMF (15 ml) was allowed to stand at room temperature for 7 days. The reaction mixture was poured into water (1000 ml), and the crystals formed were collected by filtration; yield, 7.01 g (93%); mp 131—132°C; $[\alpha]_D^{15}$ −32.8° (*c* 0.5, DMF); R_f^1 0.64.

Found: C, 61.77; H, 7.23; N, 12.13%. Calcd for $C_{47}H_{64}O_{10}N_8 \cdot H_2O$: C, 61.42; H, 7.24; N, 12.19%.

Z(OMe)-D-Phe-Gly-OBzl (VI). This was obtained from Z(OMe)-D-Phe-OH·DCHA[11] (15.32 g) and H-Gly-OBzl·TsOH (10.11 g) with DCC (6.18 g) in the same way as for Z(OMe)-Trp-D-Phe-OBzl.[9] Yield, 11.72 g (82%); mp 115—116°C; $[\alpha]_D^{20}$ +14.2° (*c* 1, ethanol); R_f^1 0.95.

Found: C, 68.12; H, 6.19; N, 5.98%. Calcd for $C_{27}H_{28}O_6N_2$: C, 68.05; H, 5.92; N, 5.88%.

Z-Leu-D-Phe-Gly-OBzl (VII). To a mixture of VI (16.2 g, 34 mmol) and anisole (10 ml) was added 2 N hydrogen chloride in dioxane (240 ml). After 3 hr at room temperature, the solution was evaporated to dryness (yield of a syrup, 11.9 g; R_f^1 0.75). The syrup (H-D-Phe-Gly-OBzl·HCl) was condensed with Z-Leu-OH·DCHA (15.2 g, 34 mmol) and DCC (7.02 g) in chloroform (150 ml) as in the case of Z-Leu-D-Phe-OBzl.[9] Yield, 13.1 g (69%); mp 106—107°C; $[\alpha]_D^{20}$ +13.8° (*c* 1, methanol); R_f^1 0.95.

Found: C, 68.36; H, 6.73; N, 7.62%. Calcd for $C_{32}H_{37}O_6N_3$: C, 68.67; H, 6.66; N, 7.51%.

Z-Leu-D-Phe-Gly-OH (VIII). To a solution of Z-Leu-D-Phe-Gly-OEt[3] (7.0 g, 14.1 mmol) in methanol (70 ml) was added N sodium hydroxide (16.9 ml). The solution was left for 2 hr at room temperature, and N hydrochloric acid (17 ml) was added. The solution was evaporated and the resulting crystals were recrystallized from ethyl acetate-petroleum ether; yield, 5.43 g (82%); mp 116—117°C; $[\alpha]_D^{20}$ +9.3° (*c* 1, methanol); R_f^1 0.75.

Found: C, 62.87; H, 6.96; N, 8.85%. Calcd for $C_{25}H_{31}O_6N_3 \cdot 1/2H_2O$: C, 62.74; H, 6.74; N, 8.78%.

H-Leu-D-Phe-Gly-OH (IX). *(a) From VII*: A solution of VII (13.1 g, 23.4 mmol) in a mixture of acetic acid (70 ml), methanol (35 ml) and water (12 ml) was hydrogenated in the presence of palladium black. The filtrate was evaporated and the resulting crystals were collected with the aid of a mixture of ethanol and acetone; yield, 5.89 g (75%); mp 231—232°C (decomp.); $[\alpha]_D^{20}$ +32.5° (*c* 0.5, acetic acid); R_f^1 0.67.

Found: C, 60.83; H, 7.69; N, 12.30%. Calcd for $C_{17}H_{25}O_4N_3$: C, 60.88; H, 7.51; N, 12.53%.

(b) From VIII. VIII (4.69 g, 10 mmol) was hydrogenated as described above; yield, 2.58 g (77%); mp 230—232°C (decomp.); $[\alpha]_D^{20}$ +32.2° (*c* 0.5, acetic acid).

Boc-Val-Orn(δ-Z)-Leu-D-Phe-Gly-OH (X). Boc-Val-Orn(δ-Z)-NHNH$_2$ (9.69 g, 20.2 mmol)[12] was dissolved in DMF (200 ml) and 2N hydrogen chloride in dioxane (20.2 ml). To the solution at −30°C was added isoamyl nitrite (3.11 ml, 22.2 mmol). After some 10 min, disappearance of the hydrazide was recognized by the detection method of Ertel and Horner.[13] To the reaction mixture was added TEA (3.11 ml, 22.2 mmol). After 5 min at 0°C, a suspension of IX (6.77 g, 20.2 mmol) in DMF (450 ml) and dimethyl sulfoxide (50 ml) containing dicyclohexylamine (4.02 ml, 20.2 mmol) was added to the mixture. After 3 days at 4°C, the reaction mixture was evaporated to approximately 200 ml. To this was added 0.01 M citric acid (5000 ml). The resulting solid was collected and recrystallized from methanol-ether; yield, 12.02 g, (76%); mp 182—183°C; $[\alpha]_D^{25}$ +3.8° (*c* 1, DMF); R_f^1 0.82.

Found: C, 59.52; H, 7.60; N, 10.51%. Calcd for $C_{40}H_{58}O_{10}N_6 \cdot 1/2H_2O$: C, 59.31; H, 7.59; N, 10.38%.

H-Val-Orn(δ-Z)-Leu-D-Phe-Gly-OH (XI). A solution of X (3.9 g, 5 mmol) in 98% formic acid (80 ml)[14] was allowed to stand for 3 hr at room temperature. The solution was evaporated, and a mixture of TEA (20 ml) and methanol (100 ml) was added. The solution was evaporated and the resulting crystals were collected by filtration with the aid of water; yield, 2.59 g (76%); mp 192—193°C; $[\alpha]_D^{25}$ −4.3° (*c* 0.2, acetic acid); R_f^1 0.80, R_f^2 0.55 (Found as monohydrate: C, 59.86; H, 7.44; N, 12.20%). The same compound (XI) was prepared from Z(OMe)-Val-Orn(δ-Z)-Leu-D-Phe-Gly-OH with the action of trifluoroacetic acid;[3] mp 191—192°; $[\alpha]_D^{25}$ −4.2° (acetic acid).

Z(OMe)-Val-Orn(δ-Z)-Leu-D-Phe-Pro-Val-Orn(δ-Z)-Leu-D-Phe-Gly-OH (XII). V (292 mg, 0.32 mmol) was treated with isoamyl nitrite (0.049 ml, 0.352 mmol) as in the case of X. To the azide solution was added a solution of XI (240 mg, 0.352 mmol) in DMF (4 ml) containing TEA (0.049 ml, 0.352 mmol). After being stirred for 5 days at 4°C, the reaction mixture was added to 0.02 M citric acid (250 ml). The resulting solid was collected and recrystallized from methanol-petroleum ether; yield, 343 mg (69%); mp 128—129°C; $[\alpha]_D^{20}$ −21.0° (*c* 0.5, DMF); R_f^1, 0.98, R_f^2 0.62.

Found: C, 61.39; H, 7.16; N, 10.62%. Calcd for $C_{82}H_{110}O_{18}N_{12} \cdot 3H_2O$: C, 61.32; H, 7.28; N, 10.47%.

cyclo-*(Val-Orn(δ-Z)-Leu-D-Phe-Pro-Val-Orn(δ-Z)-Leu-D-Phe-Gly) (XV).* XII (280 mg, 0.18 mmol) was converted into the corresponding *p*-nitrophenyl ester (XIII) (344 mg) with di-*p*-nitrophenyl sulfite (583 mg, 1.8 mmol). After XIII (340 mg) was converted into a decapeptide nitrophenyl ester trifluoroacetate (XIV), XIV was subjected to the cyclization reaction with pyridine.[3] Yield, 76 mg (31% from XII); mp 156—157°C; $[\alpha]_D^{20}$ −93.5° (*c* 0.25, acetic acid).

Found: C, 62.00; H, 7.36; N, 11.43%; mol wt,[15] 1380. Calcd for $C_{73}H_{100}O_{14}N_{12} \cdot 2H_2O$: C, 61.97; H, 7.48; N, 11.67%; mol wt, 1405.

cyclo-*(Val-Orn-Leu-D-Phe-Pro-Val-Orn-Leu-D-Phe-Gly) Dihydrochloride ([Gly^5]-GS·2HCl).* A solution of XV (36mg, 0.026 mmol) in 0.01 N methanolic hydrogen chloride (5.7 ml) was hydrogenated and the filtrate was evaporated. The resulting crystals were recrystallized from methanol-ether-petroleum ether; yield of an air-dried product, 31.8 mg (94%); mp 205—207°C (decomp.); $[\alpha]_D^{20}$ −88.9° (*c* 0.25, ethanol); R_f^1 0.77, R_f^2 0.02. Paper electrophoresis and carboxymethylcellulose column chromatography of this product[7] revealed a single spot or peak, which was at the same position as that by natural GS. Amino acid ratio in acid hydrolysate; Pro 1.08, Gly 0.98, Val 2.11, Leu 2.10, Phe 1.98, Orn 2.05.

Found: C, 52.88; H, 7.91; N, 12.63%. Calcd for $C_{57}H_{88}O_{10}N_{12} \cdot 2HCl \cdot 7H_2O$: C, 52.64; H, 8.06; N, 12.92%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 866—870(1972)

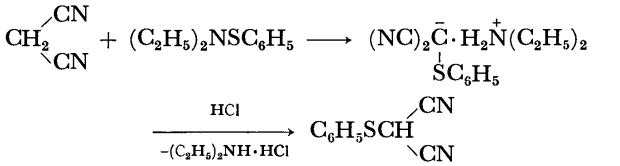
Sulfenylation of Active Methylene Compounds with Sulfenamides

Takanobu KUMAMOTO, Susumu KOBAYASHI, and Teruaki MUKAIYAMA
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo
(Received July 21, 1971)

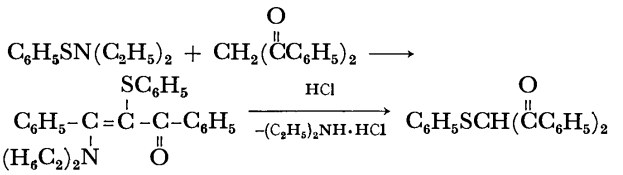
Equimolar reactions of sulfenamides derived from secondary alkylamines with active methylene compounds afforded mono-sulfenylated compounds in good yields. The reactions of 2 mol of sulfenamides derived from imides with 1 mol of active methylene compounds in the presence of a base gave di-sulfenylated compounds. It was found that α-mono-sulfenylated ketones were prepared by the reactions of enamines with sulfenamides derived from imides. α-*gem*-Di-sulfenylated ketones were prepared by the reactions of α-mono-sulfenylated ketones with sulfenamides derived from imides in the presence of a base. The preparation and reactions of *N*-phenylthiobenzamidine hydrochloride were also examined.

In a previous communication,[1] sulfenylation of active methylene compounds by the use of sulfenamides was reported. The reactions are described more in detail with new results in this paper.

It was found that the equimolar reaction of *N,N*-diethylbenzenesulfenamide with malononitrile in methylene chloride at room temperature for 5 hr resulted in the formation of the dimethylammonium salt of phenylthiomalononitrile in 55% yield. By acid hydrolysis of the salt, phenylthiomalononitrile was obtained in quantitative yield.



In the case of the reaction of *N,N*-diethylbenzenesulfenamide with dibenzoylmethane, α-phenylthio-β-*N,N*-diethylaminochalcone was obtained in 66% yield instead of the salt. The enamine was converted into phenylthiodibenzoylmethane in quantitative yield by acid hydrolysis.



The reactions of *N,N*-diethylbenzenesulfenamide with acetylacetone, ethyl acetoacetate or ethyl malonate under similar conditions without isolation of the intermediates, enamines or salts, afforded corresponding mono-sulfenylated products in good yields (Table 1).

The reactions of *N*-phenylthiopyrrolidine with active methylene compounds were examined. Treatment of *N*-phenylthiopyrrolidine with ethyl acetoacetate at room temperature, followed by acid hydrolysis gave ethyl acetyl(phenylthio)acetate in 60% yield. Similarly, ethyl phenylthiomalonate was obtained in 52% yield by the reaction of *N*-phenylthiopyrrolidine with ethyl malonate. The yields of the mono-sulfenylated products by the above mentioned reactions are higher than those of the reactions of active methylene compounds with *N,N*-diethylbenzenesulfenamide. The results suggest that the reactivity of the sulfenamides depends on the basicity of the amino component of the sulfenamides.

In order to clarify the effects of the amino component of the sulfenamide on this type of sulfenylation, the reactions of ethyl malonate with various sulfenamides such as *N*-phenylthioaniline, *N*-phenylthiopiperidine or *N*-phenylthiobenzamidine[2] were examined (Table 2). The results show that neither *N*-phenylthioaniline, derived from a weak base, nor *N*-phenylthiobenzamidine derived from a strong base, affords a sulfenylated compound. *N,N*-diethylbenzenesulfenamide, *N*-phenylthiopyrrolidine or *N*-phenylthiopiperidine is suitable for mono-sulfenylation of active methylene compounds.

On the other hand, it was found that di-sulfenylated products were obtained by the reactions of *N*-phenylthiosuccinimide with active methylene compounds in the presence of a base. For example, when 2 mol of *N*-phenylthiosuccinimide, 1 mol of dibenzoylmethane and 2 mol of triethylamine were stirred overnight in methylene chloride at room temperature, bis(phenylthio)dibenzoylmethane was obtained in 50% yield.

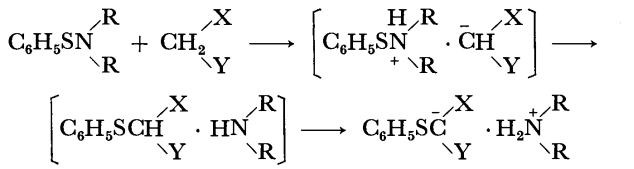
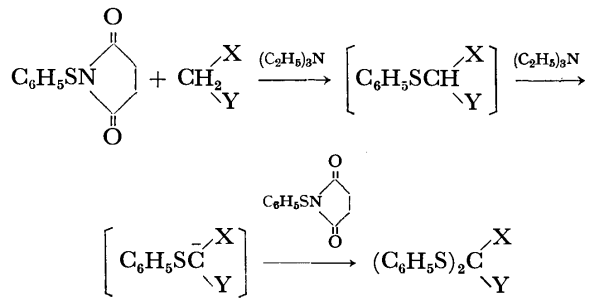
In a similar way, the reactions of *N*-phenylthiosuccinimide with acetylacetone, malononitrile, ethyl acetoacetate or ethyl malonate afforded the corresponding di-sulfenylated products in good yields (Table 3).

The results can be explained as follows. Sulfenylation of active methylene compounds with the sulfenamide derived from the secondary alkylamines would proceed through the activation of sulfur-nitrogen bond by the protonation to the nitrogen atom, followed by the reaction on the sulfur atom with active methylene compounds to give mono-sulfenylated products. These would be converted rapidly to enamines or salts by the subsequent reactions with the secondary alkylamines formed at the same time. Since enamines or salts can not participate in the activation of the sulfenamides, di-sulfenylated products would not be produced in these reactions.



In the case of sulfenylation by the use of sulfenamides derived from imides, the sulfenamide can react with active methylene compounds in basic media to produce sulfenylated products owing to a labile elimination of stable imide anions from the sulfenamides. Thus, the initially formed triethylammonium salts of mono-sulfenylated products further react with sulfenamides to give di-sulfenylated products.



Sulfenylation of the α-carbon of ketones by the use of the above mentioned sulfenamides was next tried in order to establish a convenient method for the preparation of α-mono or α-*gem*-di-sulfenylated ketones considered to be valuable as synthetic intermediates. When *N,N*-diethylbenzenesulfenamide was allowed to react with cyclohexanone in methylene chloride, no sulfenylated product was obtained and only starting materials

Table 3. Reactions of *N*-phenylthiosuccinimide with active methylene compounds

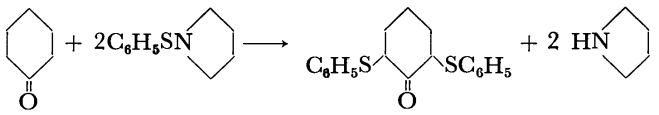
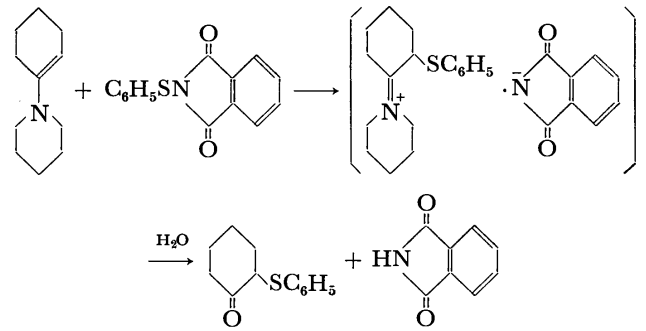
a) This compound was isolated as its 2,4-dinitrophenyl hydrazone.

were recovered quantitatively. However, the reaction of 2 moles of *N*-phenylthiopyrrolidine and 1 mol of cyclohexanone in methylene chloride at room temperature for 20 hr, followed by acid hydrolysis gave 2,6-bis(phenylthio)cyclohexanone in 67% yield.

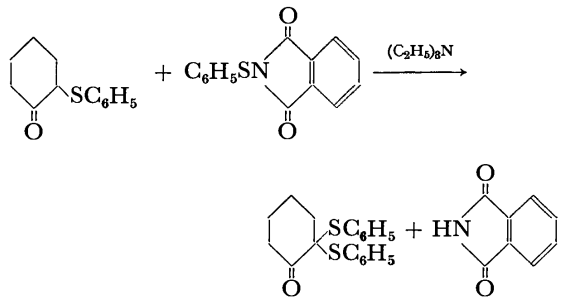


A convenient method for the preparation of α-mono-sulfenylated ketones was established by the reactions of *N*-phenylthiophthalimide with enamines. For example, the reaction of 1-piperidinocyclohexene with *N*-phenylthiophthalimide in tetrahydrofuran at room temperature for 4 hr, followed by acid hydrolysis, afforded 2-phenylthiocyclohexanone and phthalimide in 74% and quantitative yields, respectively.



Similarly, α-mono-sulfenylated ketones were obtained in good yields by the reactions of *N*-phenylthiophthalimide with 4-methyl-1-piperidinocyclohexene, β-piperidinostyrene, or 1-piperidino-1-butene (Table 4).

It was found that the α-*gem*-di-sulfenylated ketones were obtained by the reactions of mono-sulfenylated ketones with *N*-phenylthiophthalimide in the presence of a base. When 2-phenylthiocyclohexanone was stirred with *N*-phenylthiophthalimide and triethylamine in methylene chloride, 2,2-bis(phenylthio)cyclohexanone was obtained in 55% yield.



It was found that *N*-phenylthiobenzamidine hydrochloride could be isolated as a white stable solid by the reaction of *N*-phenylthiobenzamidine with hydrochloric acid in benzene. No report has been found on the isolation of hydrochloride of the sulfenamide because of the facile cleavage of the sulfur-nitrogen bond by the action of hydrochloric acid to afford sulfenyl chloride and amine hydrochloride.

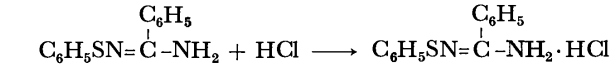


Table 4. Reactions of enamines with *N*-phenylthiophthalimide

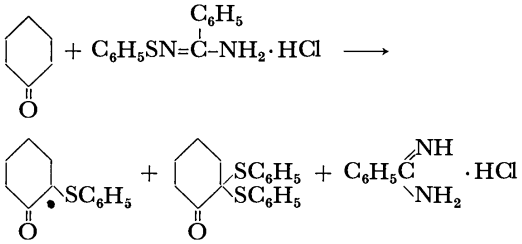
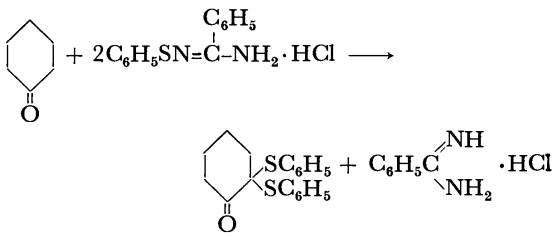
Enamine	α-Mono-sulfenylated ketone	
	Yield (%)	Bp °C/mmHg
	74	122—124/2
	75	127—131/2
	65	135—138/2
	50	98—100/2

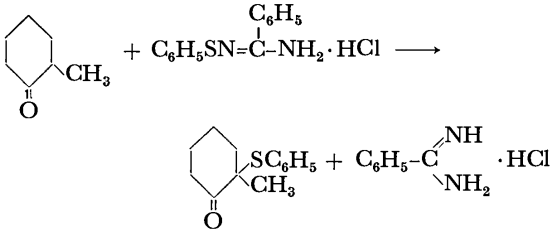
It was found that *N*-phenylthiobenzamidine hydrochloride reacted with ketones to afford α-mono-sulfenylated ketones in fairly good yields. For example, the equimolar reaction of *N*-phenylthiobenzamidine hydrochloride with cyclohexanone in dimethyl sulfoxide at room temperature resulted in the formation of 2-phenylthiocyclohexanone and 2,2-bis(phenylthio)cyclohexanone in 40% and 15% yields, respectively.



In the case of the reaction of 2 moles of *N*-phenylthiobenzamidine hydrochloride with 1 mol of cyclohexanone in dimethyl sulfoxide at room temperature, 2,2-bis(phenylthio)cyclohexanone was obtained in 70% yield.



Sulfenylation of unsymmetric ketones by the use of the above mentioned hydrochloride was examined. When 2-methylcyclohexanone was allowed to react with *N*-phenylthiobenzamidine hydrochloride in dimethyl sulfoxide at room temperature, 2-methyl-2-phenylthiocyclohexanone was exclusively obtained in 57% yield.



2-Methyl-2-phenylthiocyclopentanone, 2-methyl-2-phenylthio-3-butanone or 3-phenylthio-2-butanone was obtained by the reaction of *N*-phenylthiobenzamidine hydrochloride with 2-methylcyclopentanone, 2-methyl-

Table 5. Reactions of *N*-phenylthiobenzamidine hydrochloride with ketones

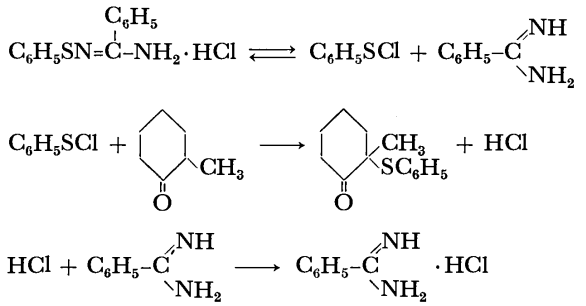
3-butanone or 2-butanone, respectively (Table 5). The results show that sulfenylation of unsymmetric-ketones by the use of *N*-phenylthiobenzamidine hydrochloride occurs on the α-carbon of ketones bearing the larger number of alkyl groups.

The reactions could be interpreted as follows.



At first, an active intermediate, benzenesulfenyl chloride, is generated from *N*-phenylthiobenzamidine hydrochloride in dimethyl sulfoxide along with benzamidine. The chloride in turn reacts with ketones to afford α-sulfenylated ketones and hydrogen chloride. The benzamidine acts as a hydrogen chloride scavenger. The presence of benzenesulfenyl chloride can be supposed from the following. (1) Sulfenylation of unsymmetric-ketone with the use of *o*-nitrobenzenesulfenyl chloride occurs on the α-carbon of ketone bearing larger number of alkyl groups.[3] (2) The reaction of cyclohexene with *N*-phenylthiobenzamidine hydrochloride in dimethyl sulfoxide affords 2-chlorocyclohexyl phenyl sulfide. The same compound was also obtained by the reaction of cyclohexene with benzenesulfenyl chloride in methylene chloride.[4]

It should be noted that the reactions of active methylene compounds with sulfenamides derived from secondary amines afforded mono-sulfenylated compounds. The reactions of active methylene compounds with sulfenamides derived from imides gave di-sulfenylated compounds.

Mono-sulfenylated ketones are prepared by the reactions of enamines with sulfenamides derived from imide or the reactions of *N*-phenylthiobenzamidine hydrochloride with ketones. *gem*-Di-sulfenylated ketones are prepared by the reactions of α-mono-sulfenylated ketones with sulfenamides derived from imides in the presence of a base.

Experimental

Reaction of N,N-*Diethylbenzenesulfenamide with Malononitrile.* A mixture of *N,N*-diethylbenzenesulfenamide (1.81 g, 0.01 mol) and malononitrile (0.66 g, 0.01 mol) was stirred in methylene chloride (30 m*l*) at room temperature for 5 hr. Removal of the solvent under reduced pressure gave white crystals. Recrystallization from benzene afforded diethylammonium salt of phenylthiomalononitrile 1.36 g 55% mp 85—87°C. Found: C, 62.84; H, 6.87; N, 17.14; S, 12.99%. Calcd for $C_{13}H_{17}N_3S$: C, 63.14; H, 6.93; N, 16.99; S, 12.94%. The salt was stirred in a mixture of 10% hydrochloric acid (30 m*l*) and benzene (30 m*l*) at room temperature. After stirring for 1 hr, the benzene layer was separated. Removal of the solvent gave phenylthiomalononitrile. It was recrystallized from isopropyl alcohol. (0.93 g, guantitative) mp 84—87°C. Found: C, 62.37; H, 3.37; S, 18.67%. Calcd for $C_9H_6N_2S$: C, 62.07; H, 3.47; S, 18.37%.

The reaction of *N,N*-diethylbenzenesulfenamide with dibenzoylmethane was carried out by a similar procedure. In the case of the reaction of *N,N*-diethylbenzenesulfenamide with acetylacetone, ethyl acetoacetate or ethyl malonate, the reaction was carried out without isolation of the intermediates, salts or enamines (Table 1).

4) N. Kharasch, "Organic Sulfur Compounds" Pergamon Press, New York, Vol. I, Chapter 32.

Reaction of N-*Phenylthiosuccinimide with Dibenzoylmethane in the Presence of Triethylamine.* A mixture of *N*-Phenylthiosuccinimide (2.09 g, 0.01 mol), dibenzoylmethane (1.14 g, 0.005 mol) and triethylamine (1.11 g, 0.011 mol) was stirred in methylene chloride (40 m*l*) at room temperature. After stirring was continued overnight, the solvent was removed under reduced pressure. Fifty m*l* of water was added to the residue and the resulting oil was extracted with benzene. Removal of the solvent gave a white solid. It was recrystallized from ethanol to give bis(phenylthio)dibenzoylmethane. 1.08 g (50%). Mp 184.5—185.5°C. Found: C, 73.41; H, 4.87; S, 14.39%. Calcd for $C_{27}H_{20}O_2S_2$: C, 73.63; H, 4.58; S, 14.53%.

By a similar procedure, 3,3-bis(phenylthio)-2,3-pentanedione, bis(phenylthio)malononitrile, ethyl α,α'-bis(phenylthio) acetoacetate and ethyl bis(phenylthio)malonate were obtained by the reactions of *N*-phenylthiosuccinimide with acetylacetone, malononitrile, ethyl acetoacetate and ethyl malonate, respectively, in the presence of triethylamine (Table 3).

Reaction of N-*Phenylthiopyrrolidine with Cyclohexanone.* A mixture of *N*-phenylthiopyrrolidine (3.67 g, 0.02 mol) and cyclohexanone (1.00 g, 0.01 mol) was stirred in methylene chloride at room temperature for 20 hr. Removal of the solvent gave an oily residue. Into the residue, a mixture of 10% hydrochloric aicd (30 m*l*) and benzene (30 m*l*) was added under stirring. After stirring for 1 hr, the benzene layer was separated from the mixture and dried with sodium sulfate. The solvent was removed under reduced pressure to give an oily product. It was chromatographed on silica gel. 2,6-Bis(phenylthio)cyclohexanone was obtained from the eluate with a mixture of benzene and petroleum ether (1: 1) 1.96 g, 67%, and was confirmed by conversion into 2,4-dinitrophenylhydrazone. Mp 197—198°C. Found: C, 58.05; H, 4.51; N, 11.50; S, 13.15%. Calcd for $C_{24}H_{22}N_4O_4S_2$: C, 58.30; H, 4.48; N, 11.33; S, 12.95%.

Reaction of 1-Piperidinocyclohexene with N-*Phenylthiophthalimide.* To a suspension of *N*-phenylthiophthalimide (2.55 g, 0.01 mol) in tetrahydrofuran (20 m*l*), a solution of 1-piperidinocyclohexene (1.67 g, 0.01 mol) in tetrahydrofuran (10 m*l*) was added dropwise. With the addition, the precipitate of *N*-phenylthiophthalimide disappeared. After stirring for 4 hr at room temperature, the solvent was removed under reduced pressure. The resulting white solid was added to 10% hydrochloric acid (20 m*l*) under stirring. After stirring for 1 hr, the reaction mixture was extracted with benzene. Removal of the solvent gave an oily residue. Purification of the residue by silica gel column chromatography gave 2-phenylthiocyclohexanone. It was further purified by distillation under reduced pressure. 122—124°C/2 mmHg. 1.52 g (74%). The structure of the compound was confirmed by a direct comparison of its IR spectra with those of the authentic sample.[5]

Similarly, 4-methyl-2-phenylthiocyclohexanone, phenyl(phenylthio)acetaldehyde and 2-phenylthiobutyraldehyde were obtained by the reactions of 4-methyl-1-piperidinocyclohexene, β-piperidinostyrene and 1-piperidinobutene with *N*-phenylthiophthalimide (Table 4).

Reaction of 2-Phenylthiocyclohexanone with N-*Phenylthiophthalimide in the presence of Triethylamine.* A mixture of 2-phenylthiocyclohexanone (41.2 g, 0.2 mol), *N*-phenylthiophthalimide (51 g, 0.2 mol) and triethylamine (22 g, 0.22 mol) was refluxed in methylene chloride (300 m*l*) for 4 hr. The resulting precipitate, phthalimide, was filtered off and filtrate was evaporated under reduced pressure. One hundred m*l* of benzene was added to the residue and the resulting phthalimide was filtered again. Removal of the solvent under reduced pressure gave crystalline solids. Recrystallization from ethanol afforded 2,2-bis(phenylthio)cyclohexanone 36.09 g, 55%, mp 120—122°C. Found: C, 68.77; H, 5.97; S, 20.32%. Calcd for $C_{18}H_{18}OS_2$: C, 68.78; H, 5.77; S, 20.36%.

Preparation of N-*Phenylthiobenzamidine Hydrochloride.* To a solution of *N*-phenylthiobenzamidine (2.28 g, 0.01 mol) in benzene, 6N hydrochloric acid (2 m*l*) was added dropwise. After stirring for 30 min, a white precipitate, *N*-phenylthiobenzamidine hydrochloride, was deposited. The precipitate was filtered under reduced pressure and dried in a desiccator without further purification. 2.30 g, (87%), mp 120—121°C (decomp.). Found: C, 59.28; H, 4.69; N, 10.31; S, 12.12%. Calcd for $C_{13}H_{13}N_2SCl$: C, 58.98; H, 4.91; N, 10.59; S, 12.10%.

Reaction of N-*Phenylthiobenzamidine Hydrochloride with Equimolar Amounts of Cyclohexanone.* A mixture of *N*-phenylthiobenzamidine hydrochloride (1.32 g, 0.005 mol) and cyclohexanone (0.49 g, 0.005 mol) was stirred in dimethyl sulfoxide (20 m*l*) at room temperature for 6 hr. The mixture was added into 300 m*l* of water and the resulting oil was extracted with benzene. The benzene layer was evaporated under reduced pressure to give an oily residue. The residue was chromatographed on silica gel. 2-Phenylthiocyclohexanone (0.41 g, 40%) and 2,2-bis(phenylthio)cyclohexanone (0.12 g, 15%) were obtained from the eluate with a mixture of benzene and petroleum ether (1: 1).

By a similar procedure, 2-methyl-2-phenylthiocyclohexanone, 2-methyl-2-phenylthiocyclopentanone, 2-methyl-2-phenylthio-3-butanone, and 3-phenylthio-2-butanone were obtained from the reaction of *N*-phenylthiobenzamidine hydrochloride with 2-methylcyclohexanone, 2-methylcyclopentanone, 3-methyl-2-butanone and 2-butanone.

Reaction of 2 mol of N-*Phenylthiobenzamidine Hydrochloride with 1 Mol of Cyclohexanone.* A mixture of *N*-phenylthiobenzamidine hydrochloride (1.32 g, 0.005 mol) and cyclohexanone (0.25 g, 0.0025 mol) was stirred in dimethyl sulfoxide (20 m*l*) at room temperature for 6 hr. The mixture was added to 300 m*l* of water and the resulting oil was extracted with benzene. The solvent was removed under reduced pressure and residue was purified by silica gel column chromatography. From the eluate with a mixture of benzene and petroleum ether (1: 1), 2,2-bis(phenylthio)cyclohexanone was obtained, 0.55 g (70%) mp 122—123°C.

The Apparent Molar Volumes of Tetraalkylammonium Halides in Liquid Sulfur Dioxide

Kohei UOSAKI, Yasuhiko KONDO, and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received July 30, 1971)

The apparent molar volumes, Φv, of tetraalkylammonium halides, R_4NX (R=Me, Et, *n*-Pr, and *n*-Bu; X=Br^- and I^-), have been determined in liquid sulfur dioxide at several concentrations, and from these values the apparent molar volumes at an infinite dilution, Φv°, have been obtained for these salts at 25°C. The results indicate that, for all the salts, the Φv *vs.* $\sqrt{c}$ curves are almost straight over the concentration ranges studied. The slopes of the plots have large positive values for all the salts in this solvent. In order to study the ion-solvent interaction, the apparent molar volumes of the individual ions at an infinite dilution have been determined from those values by Conway's method. While the Φv° values of tetraalkylammonium ions are similar to those in other solvents, the Φv° values of bromide and of iodide ions in this solvent are quite small compared with those in other solvents. The results can be explained in terms of a strong anion-solvent interaction in liquid sulfur dioxide resulting from the formation of a charge-transfer complex of the halide ion with sulfur dioxide.

The study of the ion-solvent interaction is not only very interesting in itself, but also very instructive in making clear the role of a solvent in the process of Finkelstein, **Sn Ar**, and other ionic reactions in solution.[1]

On the other hand, liquid sulfur dioxide has been well known to be a peculiar solvent, for in spite of its low dielectric constant, it dissolves inorganic salts well and has a high ionizing power, and a reaction containing carbonium ion as an intermediate can proceed at an extraordinary fast rate in this solvent.[2] These facts have been explained as being due to a strong anion-solvent interaction in liquid sulfur dioxide,[2] but on the nature of the ion-solvent interaction in the solvent only a few, widely varying studies have been reported, including the studies of electrolytic conductance by Lichtin[3] and a short article on electrostriction volume measurements.[4] Therefore it is very important to investigate the ion-solvent interaction in liquid sulfur dioxide.

Though there are many ways to study ion-solvent interactions, in the present article the authors will discuss it from the view point of the apparent molar volumes of tetraalkylammonium halides, R_4NX (R=Me, Et, *n*-Pr, and *n*-Bu; X=Br^- and I^-) at an infinite dilution, Φ°_V.

The measurements were also performed in acetonitrile and in methanol, and the values obtained were compared with those in the references.

Experimental

Materials. The liquid sulfur dioxide was dried over phosphorus pentoxide for at least one day, distilled twice, and degassed before use. The acetonitrile was refluxed over calcium hydride, distilled, and then repeatedly distilled from phosphorus pentoxide and from calcium hydride.[5] The methanol was treated with magnesium ribbon and distilled.[6] The tetramethylammonium bromide and iodide were obtained from Wako Pure Chemicals and were recrystallized three times each from an ethanol-water mixture and water. The other tetraalkylammonium halides were synthesized from the corresponding trialkylamine and alkyl halide in various solvents at the reflux temperature, and were recrystallized from various solvents. These solvents are summarized in Table 1.

All the salts were dried *in vacuo* at 65°C for one day before use.

Procedure. The densities of an electrolyte solution of liquid sulfur dioxide were measured in a sealed pressure vessel by means of glass float, which was calibrated to a standard state of pure water using mixed solutions of sulfuric acid and water. The values of the density of pure liquid sulfur dioxide (d_0=1.3719 at 25°C) obtained by the present study argeed well with the value (d_0=1.3718) which was obtained by the extrapolation to 25°C of the value quoted

from the International Critical Tables,[7] within the limits of experimental error.

The densities of solutions of acetonitrile and methanol were determined by using a pycnometer with a 50-m*l* capacity.

All the solutions were prepared by weight.

Results and Discussion

The experimental values of the densities of these salt solutions of liquid sulfur dioxide are given in Fig. 1.

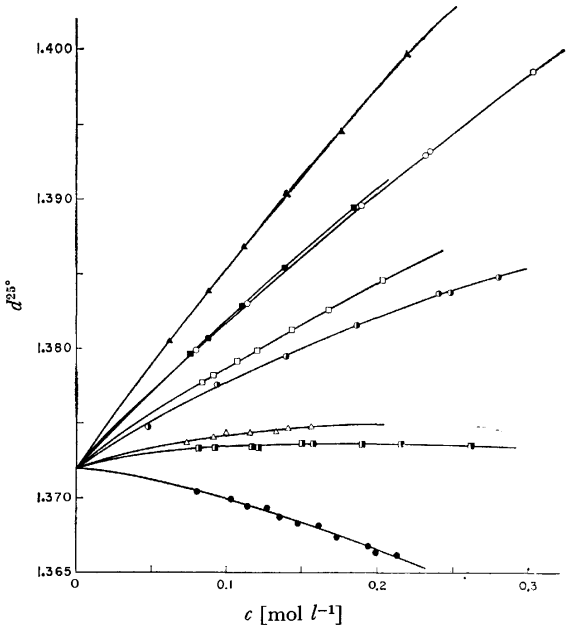

Fig. 1. Densities of liq. SO_2 solutions of tetraalkylammonium halides at 25°C.

The apparent molar volumes, Φv, were calculated from the density data by the equation:[8]

$$\Phi v = (M/d_0) - 1000(d-d_0)/cd_0 \qquad (1)$$

where d_0, M, d, and c are the density of the pure solvent, the molecular weight of the salt, the density of the solution, and the concentration of the solutes respectively.

In Figs. 2, 3, and 4, the apparent molar volumes, Φv, are plotted against the square root of the concentration of the salt, $\sqrt{c}$. In all cases, the plots of Φv *vs.* $\sqrt{c}$ gave nearly straight lines. Then, the apparent molar volumes of the salts at an infinite dilution, Φv°, and the slope, Sv, were obtained on the basis of Eq. (2)[8] by a least-squares method:

$$\Phi v = \Phi v^\circ + Svc^{1/2} \qquad (2)$$

These values are summarized in Tables 2 and 3.

By the Debye-Hückel limitting law, the values of Sv can be calculated from the expression:[10]

$$Sv = Kw^{3/2} \qquad (3)$$

n-Bu_4NI	36.3	−4.8	6.9

unit: ml mol$^{-3/2}$ $l^{1/2}$

where:

$$w = (1/2)\sum_i \nu_i Z_i^2$$

$$K = 2N^2e^3(2\pi/1000RT)^{1/2}D^{-3/2}\,(\mathrm{d}\ln D/\mathrm{d}p - \beta/3)$$

where N, D, β are Avogadro's number, the dielectric constant, and the compressibility of the solvent respectively, and where the other terms have their usual meanings.

Since the concentration ranges used in this investigation are comparatively high, the values of S_V in Table 3 can not reasonably be expected to provide a basis for testing the applicability of the Debye-Hückel limitting law to the solvent system. Also, it is not possible to calculate the theoretical values of S_V from Eq. (3), since the required values of the pressure dependence of the dielectric constant and of the compressibility of the solvent are not available for liquid sulfur dioxide. Though it may be seen that, for all salts studied, the S_V values in this solvent are positive and are quite large compared with those in other solvents, the theoretical implication of the observed difference could not be explored, partly for the reason mentioned above.

In order to make clear the nature of the ion-solvent interaction, it is necessary to assign the absolute ionic partial molal volumes. Conway and his collaborators developed a method by which the Φv values of tetraalkylammonium halides can be divided into the Φv° values of the cation and of the anion in water.[11,12]

Among several methods developed for assigning the absolute ionic partial molar volumes,[13] the most convenient way for the present study seemed to be to follow the one developed by Conway and his collaborators,[11,12] since only a limitted number of the

required data are available for the present solvent system.

In the present experiment, the apparent molar volumes of ions in liquid sulfur dioxide, acetonitrile, and methanol were determined on the basis of their method.

According to his procedure, the Φv° values of tetraalkylammonium halides were plotted against the molecular weight of the cation: these plots are shown in Figs. 5 and 6. For the series of tetraalkylammonium bromides and of iodides, straight lines were obtained, as is shown in part in Figs. 5 and 6 for all the solvent systems.

In Fig. 5, the extrapolation of the straight line to a zero-cation molecular weight should directly lead to the apparent molar volumes of the bromide ion at an infinite dilution in the respective solvent,[12] while in Fig. 6, such an extrapolation should correspondingly lead to the Φv° of the iodide ion.[12] Averaging the two series of measurements, the Φv° values of tetraalkylammonium ions, $\Phi v^\circ_{R_4N^+}$, can be calculated by means of Eq. (4):

$$\Phi v^\circ_{R_4N^+} = (1/2)\{(\Phi v^\circ_{R_4NBr} - \Phi v^\circ_{Br^-}) + (\Phi v^\circ_{R_4NI} - \Phi v^\circ_{I^-})\} \quad (4)$$

where $\Phi v^\circ_{R_4NX}$ and $\Phi v^\circ_{X^-}$ are the apparent molar volumes of tetraalkylammonium halide and of halide anion at an infinite dilution.

These apparent molal volumes of ions at an infinite dilution, Φv°_i, and the slopes of the plots of Figs. 5 and 6, b, which were obtained by the least-squares methods on the basis of the equation, are shown in Table 4:

$$\Phi v^\circ_{R_4NX} = \Phi v^\circ_{X^-} + b \text{ (M. W. of cation)} \quad (5)$$

Two or three interesting feature are to be seen in Table 4.

One of these is that the slope of the plot, b, takes a nearly constant value throughout the various solvents with the exception of water. This leads to an insensitive change in the ionic molal volume of the cation, $\Phi v^\circ_{R_4N^+}$, over these solvents. This result is not unexpected provided that the cation-solvent interaction is of an uniform nature throughout these solvents. The smaller values of the slope, b, and of the ionic molal volumes of cations in water may be ascribed to the hydrophobic interaction between the tetraalkylammonium ion and water molecules.

In contrast to the constancy of these slopes, the values of the intercept, which according to Conway's proposal, correspond to the inonic molar volumes of the anions, scatter with a change in the solvent over much wider ranges than would be expected from the experimental uncertainties.

On the basis of the characteristic values of the intercept, the solvents or the nature of the solvent-anion interaction are likely to be classifiable into three or four groups, *i.e.*, large negative (liq. SO_2), small positive (acetonitrile, methanol, *N,N*-dimethyl formamide), moderate positive (*N*-methyl acetoamide, formamide), and large positive (water).

For the case of amides, the observed transition of the $\Phi v^\circ_{I^-}$ from *N,N*-dimethyl formamide to formamide, that is to say, the tendency of the $\Phi v^\circ_{I^-}$ values to approach that of water, with an increase in the number of amino hydrogens, is consistent with the variation in the absolute ionic entropies accompanying the same solvent change.[16] Therefore, some of the solvent characteristics would seem to be specifically reflected in both thermodynamic variables. This might be the "structuredness" of the solvents.[16]

At any rate, water and liquid sulfur dioxide constitute two extreme causes. These results suggest that anion-solvent interaction is markedly strong in this solvent in comparison with that in other solvents. It is well known that sulfur dioxide forms charge-transfer complexes with halide anions in water,[17] methanol,[17] and acetonitrile.[18]

As a result of the formation of a charge-transfer complex of halide anions with sulfur dioxide, the absorption maxima were observed at 341 nm in water at 20°C[17] and at 355 nm in methanol at 22.6°C.[17] The absorption maximum was also observed at 383 nm in liquid sulfur dioxide at 20°C.[19]

Considering these facts, the strong anion-solvent interaction in liquid sulfur dioxide can be explained by the formation of a charge-transfer complex of halide anions with sulfur dioxide.

Linear Conjugated Systems Bearing Aromatic Terminal Groups. VII. Syntheses and Electronic Spectra of 1,1′- and 2,2′-Dipyrenylpoly-ynes

Kazuhiro NAKASUJI, Shuzo AKIYAMA, and Masazumi NAKAGAWA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka
(Received August 6, 1971)

1,1′- and 2,2′-Dipyrenylpoly-ynes (I_n and II_n, $n=1$—6) have been synthesized. It was found that the bathochromic shift of the longest-wavelength absorption maxima (λ_L) according to the increase in the number of acetylenic bond (n) can be well expressed by the following formulas:

I_n: $\lambda_L = 3.7n^{1.7} + 430$ (nm in toluene)
II_n: $\lambda_L = 12.6n^{1.4} + 327$ (nm in toluene)

New linear relationships between the longest-wavelength absorption maxima (λ_L) and the xth power of the number of acetylenic bond (n)[$\lambda_L \propto n^x$] observed in various kinds of diarylpoly-ynes have been reported in previous papers.[1-9] Since the value of x is dependent on the nature of terminal groups and the position of linking of polyacetylene chain, we were interested in the behavior of pyrene as the terminal groups of poly-yne system. The present paper deals with the syntheses and electronic spectral properties of 1,1′- and 2,2′-dipyrenylpoly-ynes (I_n and II_n, $n=1$—6).

Syntheses. The syntheses of monoacetylenes (I_1

I_n II_n

and II_1) by means of an intramolecular Wittig reaction have been reported.[8] As illustrated in Scheme 1, the reaction sequence used in the syntheses of I_n and II_n is a general method which has been successfully adapted for the preparation of various kinds of diarylpoly-ynes.[6,8,9] 2,2′-Dipyrenylhexaacetylene (II_6) was found to be an unstable, scarcely soluble substance, and gave an unsatisfactory elemental analysis. However, the compound gave a satisfactory electronic spectrum for the present purpose.

Some physical properties of 1,1′- and 2,2′-dipyrenylpoly-ynes (I_n and II_n) are summarized in Tables 1 and 2.

TABLE 1. PHYSICAL PROPERTIES OF 1,1′-DIPYRENYLPOLY-YNES (I_n)

n	Color of crystals	Melting point (°C)	$\nu_{C\equiv C}$(cm^{-1})
1	yellow	266	—
2	yellow	(297—298)	2125
3	yellow	(*ca.* 300)	2185
4	orange yellow	(*ca.* 260)	2190
5	orange	(*ca.* 215)	2175
6	red	(*ca.* 200)	2145

Figures in parentheses indicate decomposition points.

TABLE 2. PHYSICAL PROPERTIES OF 2,2′-DIPYRENYLPOLY-YNES (II_n)

n	Color of crystals	Melting point (°C)	$\nu_{C\equiv C}$(cm^{-1})
1	pale yellow	>330	—
2	light yellow	>330	—
3	yellow	(*ca.* 260—270)	2190
4	yellow	(*ca.* 180)	2195
5	orange yellow	(*ca.* 140)	2185
6	orange		

Figures in parentheses indicate decomposition points.

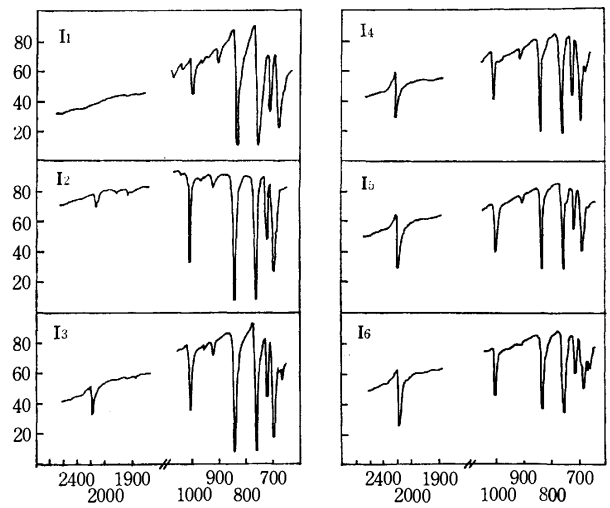

Fig. 1. IR spectra of 1,1′-dipyrenylpoly-ynes (I_n).

The IR spectra of I_n are shown in Fig. 1 as representative of dipyrenylpoly-ynes. The most intense peak in $\nu_{C\equiv C}$ band showed appreciable intensification with increasing number of n. The highest wave number of $\nu_{C\equiv C}$ was observed in the spectra of the tetraacetylenes (I_4 and II_4). The same trend has been observed in the other series of diarylpoly-ynes.[3,4,6,8,9]

Electronic Spectra. The absorption curves and numerical data of the electronic spectra of I_n and II_n are shown in Figs. 2 and 3, and Tables 3 and 4, respectively. In the electronic spectrum of pyrene, there is a low intensity band in the 350—370 nm region (^1L_b) and a strong band in the 290—340 nm region (^1L_a). Both bands exhibit considerable fine structure. The longest-wavelength bands in I_n and II_n seem to arise from the interaction of ^1L_a band of pyrene with polyacetylenic chromophore. The difference in wave-

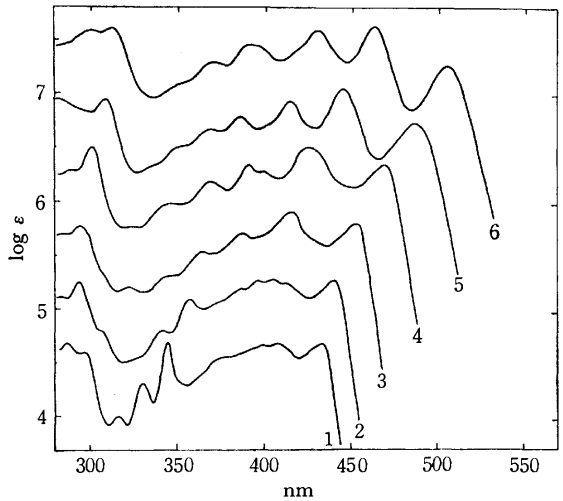

Fig. 2. Absorption curves of 1,1′-dipyrenylpoly-ynes (I_n). With the exception of the monoacetylene at the bottom, the curves are shifted upward along the ordinate by 0.5 log ε unit increments from the curve immediately below (in toluene).

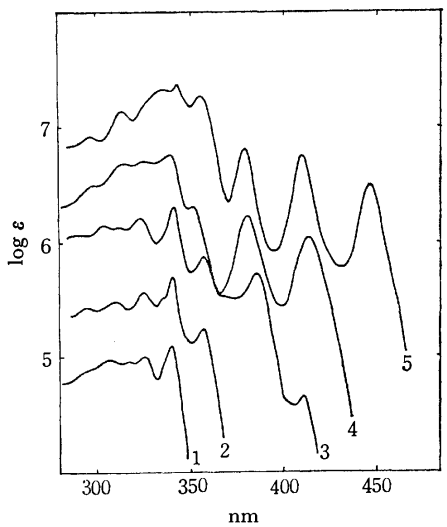

Fig. 3. Absorption curves of 2,2′-dipyrenylpoly-ynes (II_n). With the exception of the monoacetylene at the bottom, the curves are shifted upward along the ordinate by 0.5 log ε unit increments from the curve immediately below (in toluene).

6[b]				355	379	404	437	478

a) Accurate ε-values could not be obtained owing to poor solubility.
b) On account of the purity of II_6, only the locations of the long-wavelength bands are shown.

Table 5. Difference of wavelength of λ_L between I_n and II_n

n	1	2	3	4	5	6
I_n	434	442	454	470	487	502
II_n	340	358	387	415	447	478
$\Delta\lambda$	94	84	67	55	40	29

length of the longest-wavelength absorption maxima (λ_L) between I_n and II_n is shown in Table 5. The marked difference ($\Delta\lambda$) between I_n and II_n was found to be the largest ever observed, *i.e.*, the difference between 1,1′- and 2,2′-dinaphthylacetylenes is 23 nm,[6] and that between 2,2′- and 3,3′-, and between 3,3′- and 9,9′-diphenanthrylacetylenes 11.5 and 16.5 nm,[8] respectively. Since the transition associated with ^1L_a band of pyrene is considered to be polarized in the direction of the long axis,[10] the remarkable hypsochromic shift of λ_L of II_n as compared with that of I_n indicates that we do not get what we expect intuitively for dipyrenylpoly-ynes. A similar phenomenon has been observed in phenanthrene derivatives and explained in terms of configuration interaction.[11] Thus, it seems to be pertinent to ascribe the hypsochromism of II_n to configuration interaction.

The absorption band associated with ^1L_b band of pyrene could not be observed in the spectra of I_n. However, II_1, II_2, and II_3 showed low intensity bands at long-wavelength region. The same phenomena were observed in the lower member of 2,2′-dinaphthylpoly-ynes[6] and in that of 2,2′-difluorenylpoly-ynes.[12]

As has been observed in various series of diarylpoly-ynes, increase in the length of poly-yne chain results in a progessive enhancement of the vibrational fine structure. Thus the spectra of higher members of I_n and II_n exhibit a characteristic feature of polyacetylene chromophore. The spacing, *i.e.*, the difference of wavelength between the longest-wavelength sub-band and the next longest-wavelength sub-band, was found to be 1800—2150 cm^{-1} in the case of $n=3$—6 (*cf.* Table 6). The spacing can be considered to correspond to the stretching vibration of acetylenic linkage at excited state. The unusual value of spacing of the diacetylenes (I_2 and II_2) can be attributed to the superposition of vibration of acetylene bond with that inherent to the terminal groups. The same unusual spacing has been observed in the electronic spectra of dianthrylpoly-ynes.[5] The correlation of spacing and $\nu_{C\equiv C}$ with the electronic spectral behavior of diarylpoly-

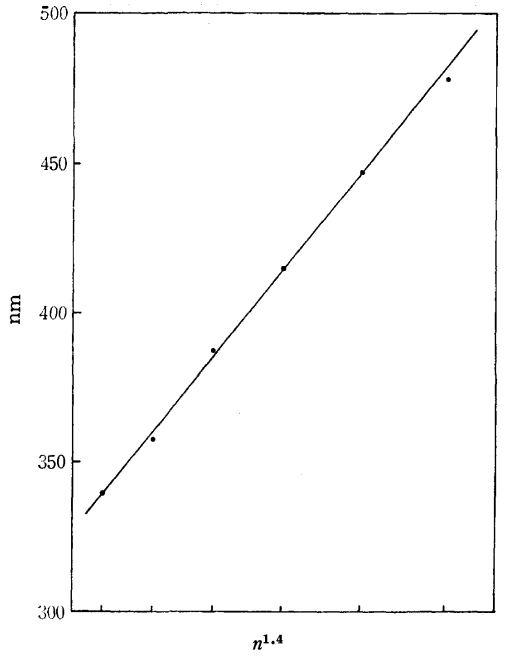

Fig. 5. Plot of λ_L *versus* $n^{1.4}$ for 2,2′-dipyrenylpoly-ynes (II_n).

ynes was discussed elsewhere.[13]

The plots of λ_L of I_n against $n^{1.7}$ and those of II_n *versus* $n^{1.4}$ gave good straight lines as illustrated in Figs. 4 and 5. The linear relationships can be expressed by the following empirical formulas. Agreement of calculated values with observed data was found to be excellent (*cf.* Table 7).

$$I_n: \lambda_L = 3.7n^{1.7} + 430 \quad \text{(nm in toluene)}$$

$$II_n: \lambda_L = 12.6n^{1.4} + 327 \quad \text{(nm in toluene)}$$

TABLE 7. OBSERVED AND CALCULATED λ_L (nm)

	n	1	2	3	4	5	6
I_n	Obs.	434	442	454	470	487	507
	Calcd	434	442	454	469	487	508
	Δ	0	0	0	1	0	−1
II_n	Obs.	340	358	387	415	447	478
	Calcd	340	360	386	415	447	482
	Δ	0	−2	1	0	0	−4

In the above-mentioned dipyrenyl series, the difference in position of linking of polyacetylenic chain exerts a prominent effect on the location of λ_L. This tendency seems to be reflected in the marked difference of the value of x between 1,1′-series (I_n, $x=1.7$) and 2,2′-series (II_n, $x=1.4$).

Experimental

All melting points are uncorrected. The electronic spectra were measured on a Hitachi EPS-3T Spectrophotometer. The IR spectra were obtained on a Hitachi EPI-2 Spectrophotometer by KBr-disk method. Evaporation of solvent or concentration of solution was carried out under reduced pressure.

13) M. Nakagawa, S. Akiyama, K. Nakasuji, and K. Nishimoto, *Tetrahedron*, **27**, 5401 (1971).

1-Ethynylpyrene (V). *Chlorination of 1-Acetylpyrene (IV)*: 1-Acetylpyrene (IV, mp 89°C, 4.88 g, 0.02 mol) prepared by the reported method[14] was mixed with phosphorus pentachloride (4.58 g, 0.022 mol) in benzene (20 m*l*). After the mixture had been refluxed for 1 hr, volatile materials were removed under reduced pressure. The residue was placed in an evacuated desiccator containing potassium hydroxide, thus yielding greenish yellow crystals. This material was used in the subsequent reaction without purification.

Dehydrochlorination. To a stirred suspension of sodium amide [from sodium, 1.80 g (0.08 g-atom)] in liquid ammonia (100 m*l*) was added a solution of the crude chloride in tetrahydrofuran (10 m*l*) over a period of 20 min. After stirring for 3 hr, ammonia was allowed to evaporate. Ether (200 m*l*) was added to the residue and a saturated ammonium chloride solution was added under cooling on an ice-salt bath. The organic layer was washed with water and dried. The residue obtained by evaporation of the solvent was dissolved in benzene (30 m*l*), and the solution was passed through a short column of alumina (15 g). Concentration of the filtrate yielded the ethynyl derivative (V) as pale yellow needles (3.92 g, 87%, mp 112—114°C). Percolation of crude V in petroleum benzine through a column of alumina gave pure V as colorless needles, mp 113—114°C. 1-Ethynylpyrene (V) gave orange cuprous and yellow silver acetylides.

Found: C, 95.45; H, 4.44%. Calcd for $C_{18}H_{10}$: C, 95.54; H, 4.46%. IR: 3310 (≡CH), 2090 (C≡C), 1027 (C–O) cm^{-1}. UV: $\lambda_{max}^{n\text{-hexane}}$ (log ε): 218 (4.10), 236 (4.59), 246.5 (4.78), 261 (4.09), 270.5 (4.47), 281.5 (4.76), 311.5 (3.74), 324 (4.19), 338.5 (4.57), 356.5 (4.80), 373.5 (3.04), 381.5 (3.23) nm.

2-Acetylpyrene (IV′). Acid chloride prepared from 2-carboxypyrene[15] (24.6 g, 0.1 mol) and thionyl chloride (16 m*l*) was dissolved in hot tetrahydrofuran (200 m*l*). The hot solution was added to an ice-cooled solution of diethyl magnesiomalonate [from magnesium, 2.4 g (0.1 g-atom), diethyl malonate, 16.0 g (0.1 mol), anhydrous ethanol, 10.1 g (0.2 mol) and anhydrous toluene (100 m*l*). The excess of ethanol had been removed by an azeotropic distillation with toluene] in toluene. After the addition had been completed, the mixture was stirred for 3 hr at 80°C. 4N Sulfuric acid (40 m*l*) was then added to the reaction mixture. The organic layer was washed with water and dried. The crude ketomalonate obtained by evaporating the solvent was mixed with acetic acid (80 m*l*) and concentrated sulfuric acid (0.5 m*l*). After the mixture had been refluxed for 2.5 hr, 4N sulfuric acid (40 m*l*) was added to the mixture and the reflux was continued for further 2 hr. The reaction mixture was put to stand overnight. The crude crystals deposited were collected by filtration and washed with water and then dissolved in ethyl acetate. After treatment with active charcoal, the solvent was removed to give yellow crystals (16.2 g, 66%). The crude material was recrystallized twice from ethyl acetate to give pure IV′, pale yellow leaflets, mp 145—147°C.

Found: C, 88.27; H, 4.87%. Calcd for $C_{18}H_{12}O$: C, 88.50; H, 4.95%.

2-Hydroxymethylpyrene. Reduction of 2-carbethoxypyrene[15] by means of lithium aluminum hydride afforded 2-hydroxymethylpyrene in a good yield. Recrystallization from ethanol gave pure material as colorless needles, mp 168—169°C.

Found: C, 87.61; H, 5.17%. Calcd for $C_{17}H_{12}O$: C,

14) W. E. Bachmann and M. Carmack, *J. Amer. Chem. Soc.*, **63**, 2494 (1941).

15) H. Vollmann, H. Becker, M. Correll, and H. Streek, *Ann.*, **531**, 1 (1937).

87.90; H, 5.21%.

2-Formylpyrene (III'). A solution of 2-hydroxymethylpyrene (8.68 g, 0.04 mol) in pyridine (60 m*l*) was added to a mixture of chromium trioxide (12.4 g, 0.124 mol) in pyridine (140 m*l*) under ice-cooling. After shaking for 30 min, the cooling bath was removed and the mixture was kept at room temperature for 1 hr. The reaction mixture was then poured into water (1 *l*) and extracted with ether (1.8 *l*). The extract was washed several times successively with 10% hydrochloric acid, a saturated solution of sodium carbonate and water. The residue obtained by evaporating the solvent was recrystallized from ethyl acetate to yield III' (6.2 g, 68%). This material was recrystallized 3 times from the same solvent to give pure III', yellow rods, mp 153—154°C.

Found: C, 88.63; H, 4.36%. Calcd for $C_{17}H_{10}O$: C, 88.67; H, 4.38%.

2-Ethynylpyrene (V'). A mixture of 2-acetylpyrene (IV', 15.9 g, 0.065 mol), phosphorus pentachloride (14.0 g, 0.067 mol) and benzene (200 m*l*) was refluxed for 2 hr, and the volatile materials were removed under reduced pressure. The residue which had been kept in an evacuated desiccator over potassium hydroxide was dissolved in tetrahydrofuran (100 m*l*). The solution was added to a suspension of sodium amide [from sodium, 9.2 g (0.4 g-atom)] in liquid ammonia (500 m*l*) at −70°C. After stirring for 3 hr, the ammonia was allowed to evaporate. A saturated solution of ammonium chloride was added to the residue at −30°C. The aqueous layer was extracted with ether and combined with the organic layer and dried. The residue obtained by evaporating the solvent was dissolved in hot ligroin containing a small amount of benzene. The filtrate obtained by passing the hot solution through a column of alumina (30 g) was concentrated to yield V' as colorless needles, 11.0 g (75%). Recrystallization twice from ethanol gave pure specimen, mp 125—127°C.

Found: C, 95.53; H, 4.41%. Calcd for $C_{18}H_{10}$: C, 95.54; H, 4.46%.

1,1'-Dipyrenyldiacetylene (I_2). Cupric acetate monohydrate (5.0 g) was added to a stirred solution of 1-ethynylpyrene (V, 0.510 g, 2.3 mmol) in pyridine (20 m*l*). The mixture was stirred for 3 hr at 55°C. The insoluble material deposited on cooling the reaction mixture was collected by filtration and washed successively with methanol and water to yield tiny yellow cubes, 0.504 g (98%), mp 297—298°C (dec.). The crude material was dissolved in hot toluene and passed through a short column of alumina. The crystals obtained from the filtrate were recrystallized from toluene, yielding pure I_2, yellow cubes, mp 298°C (dec.).

Found: C, 95.93; H, 4.07%. Calcd for $C_{36}H_{18}$: C, 95.97; H, 4.03%.

2,2'-Dipyrenyldiacetylene (II_2). According to the procedure used in the synthesis of I_2, 2-ethynylpyrene (V') gave II_2, pale yellow needles (from toluene) in a 96% yield. The crystals showed no melting point, but began to decompose at 330°C.

Found: C, 95.91; H, 3.97%. Calcd for $C_{36}H_{18}$: C, 95.97; H, 4.03%.

1-(1-Pyrenyl)-2-propyn-1-ol (VII). A solution of 1-formylpyrene[16] (III, 6.90 g, 0.03 mol) in tetrahydrofuran (60 m*l*) was added to an ice-cooled solution of ethynylmagnesium bromide [from ethyl bromide, 8.20 g (0.075 mol), magnesium, 1.80 g (0.075 g atom) and an excess of acetylene] in the same solvent (85 m*l*). After the mixture had been stirred overnight at room temperature, a saturated solution of ammonium chloride was added to the reaction mixture. The organic layer was dried and the crystals obtained by evaporating the solvent were dissolved in acetone. The insoluble material was removed by filtration. The crystals (6.95 g, 91%, mp 145—150°C) obtained from the filtrate were redissolved in acetone and passed through a short column of alumina. The filtrate was concentrated, and the crystals deposited were recrystallized from ethanol - benzene, yielding pure VII as colorless rods, mp 159—160°C.

Found: C, 88.90; H, 4.67%. Calcd for $C_{19}H_{12}O$: C, 89.04; H, 4.72%. IR: 3600—3100 (OH), 3300 (≡CH), 2100 (C≡C) cm^{-1}.

1-(2-Pyrenyl)-2-propyn-1-ol (VII'). According to the procedure used for VII, 2-formylpyrene (III') gave crude VII' in a 96% yield. The crude material was recrystallized 3 times from carbon tetrachloride - ethanol to give pure VII as colorless needles, mp 132—135°C.

Found: C, 89.06; H, 4.71%. Calcd for $C_{19}H_{12}O$: C, 89.04; H, 4.72%. IR: 3350—3200 (OH), 3250 (≡CH), 1035 (C–O) cm^{-1}.

1,6-Di-(1-pyrenyl)-2,4-hexadiyn-2,6-diol (VIII). A mixture of ethynylcarbinol (VII, 3.98 g, 0.0156 mol), acetone (50 m*l*), methanol (50 m*l*), ammonium chloride (0.30 g), and cuprous chloride (0.40 g) was vigorously stirred at room temperature under a slight excess pressure of oxygen for 48 hr. The crystalline material deposited was collected by filtration and washed with methanol containing hydrochloric acid. The light brown crystals thus obtained (2.02 g, 51%, decomposed at *ca.* 220°C) were dissolved in tetrahydrofuran and passed 4 times through a thin layer of alumina. Concentration of the filtrate gave pure VIII as fine colorless needles. The crystals turned pink at *ca.* 160°C and decomposed at *ca.* 225—260°C.

Found: C, 88.96; H, 4.42%. Calcd for $C_{38}H_{22}O_2$: C, 89.39; H, 4.34%. IR: 3400—3100 (OH), 2250 (C≡C), 1015 (C–O) cm^{-1}.

1,6-Di-(2-pyrenyl)-2,4-hexadiyn-1,6-diol (VIII'). According to the procedure for VIII, the oxidative coupling of ethynylcarbinol (VII') afforded a crude VIII' in a 47% yield which decomposed at *ca.* 245°C. Owing to its poor solubility, the crude material was subjected to the following reaction without purification.

1,1'-Dipyrenyltriacetylene (I_3). Preparation of Dichloride (IX). A mixture of thionyl chloride (0.144 g, 1.2 mmol), pyridine (0.096 g, 1.2 mmol) and tetrahydrofuran (5 m*l*) was added over a period of 30 min to a solution of diacetylenic glycol (VIII, 0.244 g, 0.4 mmol) in tetrahydrofuran (15 m*l*) at −10°C. When the addition had been completed, the mixture was shaken for 10 min at the same temperature and immediately used for the following reaction.

Dehydrochlorination. To a stirred suspension of sodium amide [from sodium, 0.14 g (6 mg-atom)] in liquid ammonia (90 m*l*) maintained at −60°C was added a solution of dichloride (IX). After 30 min, ammonium chloride (1 g) was added and the ammonia was allowed to evaporate. After the organic solvent had been removed, a small amount of water was added to the residue. The insoluble material was collected by filtration, washed with a small amount of methanol and benzene. The solid thus obtained was dissolved in boiling toluene and the hot solution was percolated through a short column of alumina. Concentration of the filtrate afforded fine yellow needles, 0.080 g (42%) which decomposed at *ca.* 295°C. The crystals were redissolved in boiling toluene and passed through a thin layer of alumina, yielding pure I_3 as yellow needles which decomposed at *ca.* 300°C.

Found: C, 96.18; H, 3.85%. Calcd for $C_{38}H_{18}$: C, 96.18; H, 3.82%.

2,2'-Dipyrenyltriacetylene (II_3). The procedure used in the preparation of I_3 was followed. Chlorination of crude

16) A. Rieche, H. Gross, and E. Höft, *Chem. Ber.*, **93**, 88 (1960).

VIII′ followed by dehydrochlorination gave crude II_3 in a 27% yield. Purification of this material gave II_3 as yellow needles (decomp. 260—270°C).

Found: C, 95.93; H, 3.81%. Calcd for $C_{38}H_{18}$: C, 96.18; H, 3.82%.

1-(1-Pyrenyl)-2-butyn-1,4-diol (X). A solution of 1-formylpyrene (II, 6.00 g, 0.026 mol) in tetrahydrofuran (60 m*l*) was added dropwise to an ice-cooled solution of the Grignard derivative of propargyl alcohol [from magnesium, 3.74 g (0.156 g-atom), ethyl bromide, 17 g (0.156 mol), and propargyl alcohol, 4.37 g (0.078 mol)]. The mixture was stirred overnight and then a saturated solution of ammonium chloride was added. The dried organic layer was concentrated. The residue was triturated with benzene and washed with the same solvent, thus yielding pale yellow crystalline powder, 7.20 g (97%), mp 141—145°C. Recrystallization of the crystals from ethanol and from ethanol - benzene afforded pure X as colorless needles, mp 150—151°C.

Found: C, 83.56; H, 4.95%. Calcd for $C_{20}H_{14}O_2$: C, 83.90; H, 4.93%. IR: 3600—3100 (OH), 1055, 1012 (C–O) cm^{-1}.

1-(2-Pyrenyl)-2-butyn-1,4-diol (X′). According to the procedure for X, 2-formylpyrene (III′) gave crude X′ in 82% yield. Recrystallization three times of this material from ethanol yielded pure X′, colorless leaflets, mp 183—185°C.

Found: C, 83.90; H, 4.86%. Calcd for $C_{20}H_{14}O_2$: C, 83.90; H, 4.93%. IR: 3350—3200 (OH), 1000, 1007 (C–O) cm^{-1}.

1-Butadiynylpyrene (XII). Preparation of the Dichloride (XI). A solution of thionyl chloride (4.65 g, 0.039 mol) in tetrahydrofuran (10 m*l*) was added over a period of 1 hr to a mixture of acetylene glycol (X, 4.30 g, 0.015 mol), pyridine (3.08 g, 0.039 mol), and tetrahydrofuran (10 m*l*) kept at −10°C. The temperature of the reaction mixture was gradually raised to room temperature and stirring was continued for 1 hr and then for 1 hr at 30°C. Cracked ice was then added to the reaction mixture. The organic layer was separated and the aqueous layer was extracted with benzene (100 m*l*). The combined organic layer was dried, and concentrated to *ca.* 5 m*l*. The solution of dichloride (XI) thus prepared was used in the subsequent reaction.

Dehydrochlorination. The solution of XI was added over a period of 20 min to a stirred suspension of sodium amide [from sodium, 2.5 g (0.11 g-atom)] in liquid ammonia (100 m*l*) at a temperature of −70°C. After 3 hr ammonium chloride (7 g) was added to the reaction mixture and the ammonia was allowed to evaporate. After the organic solvent had been removed, the residue was extracted with petroleum ether (bp 60—80°C, total 450 m*l*). The extract was passed through a thin layer of alumina (12 g). Concentration of the filtrate afforded extremely unstable XII as fine needles, 1.33 g (36%), mp *ca.* 105°C (dec.). XII gave orange yellow, silver and orange cuprous acetylides.

UV: $\lambda_{max}^{petroleum\ ether}$ 377 nm.

1,1′-Dipyrenyltetraacetylene (I_4). A mixture of 1-butadiynylpyrene (XII, 0.050 g, 0.2 mmol), cupric acetate monohydrate (0.50 g), pyridine (3 m*l*) and methanol (0.5 m*l*) was stirred at room temperature for 12 hr. The insoluble material was collected by filtration and washed successively with water, a small amount of methanol and benzene, yielding fine yellow needles, 0.038 g (76%), which decomposed at *ca.* 255°C. This material was dissolved in hot toluene and percolated through a thin layer of alumina. Concentration of the filtrate gave pure I_4 as fine orange yellow needles, which decomposed at *ca.* 260°C.

Found: C, 96.06; H, 3.64%. Calcd for $C_{40}H_{18}$: C, 96.36; H, 3.64%.

2-Butadiynylpyrene (XII′). Preparation of the Dichloride (XI′). A solution of thionyl chloride (2.33 g, 19.5 mmol) in tetrahydrofuran (10 m*l*) was added to a stirred mixture of the acetylene glycol (X′, 2.15 g, 7.5 mmol), pyridine (1.54 g, 19.5 mmol), and tetrahydrofuran (40 m*l*) under cooling on an ice-salt bath. The temperature of the reaction mixture was allowed to rise gradually to room temperature, and stirring was continued at 30°C for 1 hr. Cracked ice was added to the reaction mixture under external cooling with ice-water. The organic layer was washed successively with water and sodium hydroxide solution, and dried. The concentrated solution of XI′ (*ca.* 10 m*l*) was subjected to the following reaction.

Dehydrochlorination. To a stirred suspension of sodium amide [from sodium, 1.3 g (0.055 g-atom)] in liquid ammonia (50 m*l*) was added the solution of XI′ at −70°C, and stirring was continued for 3 hr. After ammonium chloride (4 g) had been added tothe reaction mixture, ammonia was allowed to evaporate and the organic solvent was removed. The residue was extracted with petroleum benzine (1 *l*). The extract was concentrated to *ca.* 500 m*l* and passed through a short column of alumina, yielding colorless filtrate. It was impossible to isolate diacetylene (XII′) in solid state owing to the unstable nature of the compound. The petroleum benzine solution of XII′ was thus used in the subsequent reaction.

UV: $\lambda_{max}^{benzine}$ 336, 321, 306, 300, 288 nm.

2,2′-Dipyrenyltetraacetylene (II_4). To a stirred solution of cupric acetate monohydrate (4.0 g) in pyridine (20 m*l*) was added a small portion of the solution of diacetylene (XII′), and petroleum benzine was removed under reduced pressure at room temperature. A second portion of the solution was then added, benzine being again removed *in vacuo*. The entire benzine solution was added, portion by portion to the oxidizing reagent, repeating the above procedure. After addition of the solution and removal of the benzine had been completed, additional pyridine (20 m*l*) and methanol (5 m*l*) were added to the solution, and the mixture was stirred overnight at room temperature. After the solvent had been removed, water was added to the residue and the insoluble material was collected by filtration, washed thoroughly with water and then ethanol and benzene. The yellow crystals thus obtained [140 mg, 15% based on the glycol (X′)] were dissolved in hot toluene. The filtrate obtained by percolating the hot solution through a short column of alumina was put to stand to deposit pure II_4 as fine yellow needles. II_4 decomposed at *ca.* 180°C accompanying decoloration.

Found: C, 96.51; H, 3.62%. Calcd for $C_{40}H_{18}$: C, 96.36; H, 3.64%.

3-(1-Pyrenyl)-prop-2-ynal (VI). A solution of 1-ethynylpyrene (V, 10.08 g, 0.045 mol) in tetrahydrofuran (50 m*l*) was added under stirring over a period of 20 min to an ice-cooled solution of isopropylmagnesium bromide [from magnesium, 2.16 g (0.09 g-atom) and isopropyl bromide, 12.18 g (0.099 mol)] in tetrahydrofuran (60 m*l*). The mixture had been refluxed for 1 hr, and then chilled on an ice-salt bath. Dimethylformamide (16 m*l*) was added in one portion to the chilled mixture and stirred for 20 min. Stirring was continued for further 4 hr at room temperature. The reaction mixture was then poured into vigorously stirred 5% sulfuric acid (600 m*l*) and stirred overnight. The mixture was extracted with benzene (1 *l*) and the extract was washed successively with water and a solution of sodium hydrogen carbonate. The organic layer was shaken with a saturated solution of sodium hydrogen sulfite. The adduct deposited was washed with ether, tetrahydrofuran and ether, succes-

sively, and decomposed with a saturated solution of sodium hydrogen carbonate. The crude propynal (VI) thus obtained was extracted with hot benzene (100 m*l*) using a Soxhlet extractor. Orange cubes, 9.19 g (81%), mp 145—147°C, obtained from the extract were recrystallized several times from benzene - cyclohexane. Aldehyde (VI) showed dimorphism, *viz.*, rapid cooling of the benzene - cyclohexane solution gave orange needles, mp 141—142°C. On the other hand, orange cubes, mp 148—149°C were obtained on slow cooling of the solution.

Low mp isomer. Found: C, 89.27; H, 4.01%. High mp isomer. Found: C, 89.63; H, 3.99%. Calcd for $C_{19}H_{10}O$: C, 89.74; H, 3.96%. IR: 2840, 2735 (CHO), 2170 (C≡C), 1645 (C=O) cm^{-1}. Both isomers exhibited almost the same IR spectra, a slight difference being observed in the region 1200—650 cm^{-1}.

3-(2-Pyrenyl)-prop-2-ynal (VI'). To an ice-cooled and stirred solution of isopropylmagnesium bromide [from magnesium, 0.72 g (0.03 g-atom) and isopropyl bromide, 4.06 g (0.033 mol)] in tetrahydrofuran (20 m*l*) was added over a period of 15 min a solution of 2-ethynylpyrene (V', 3.36 g, 0.015 mol) in tetrahydrofuran (20 m*l*). The mixture was stirred for 30 min at room temperature and then refluxed for 30 min. The mixture was then chilled on an ice-salt bath. After dimethylformamide (6 m*l*) had been added in one portion, the temperature of the reaction mixture was gradually raised to room temperature. Stirring was continued for 3 hr and then for 1 hr at 30°C. The reaction mixture was poured into vigorously agitated 5% sulfuric acid (200 m*l*) and stirring was continued overnight. The mixture was extracted with benzene (330 m*l*) and the extract was washed successively, with water, a saturated solution of sodium hydrogen carbonate and water, and dried. The crystalline residue obtained by evaporating the solvent was recrystallized from benzene to afford yellow crystals, 3.1 g (81%). The crystals dissolved in ethanol were treated with active charcoal and recrystallized 3 times from benzene - cyclohexane to yield pure VI' as yellow cubes, mp 160—161°C.

Found: C, 89.60; H, 4.12%. Calcd for $C_{19}H_{10}O$: C, 89.74; H, 3.96%. IR: 2180 (C≡C), 1660 (C=O) cm^{-1}.

1-(1-Pyrenyl)-1,4-pentadiyn-3-ol (XVI). A solution of 1-pyrenylpropynal (VI, 5.09 g, 0.02 mol) in tetrahydrofuran (150 m*l*) was added over a period of 20 min into an ice-cooled and stirred solution of ethynylmagnesium bromide [from magnesium, 1.15 g (0.048 g-atom), ethyl bromide, 5.78 g (0.053 mol) and an excess of acetylene]. The cooling bath was removed after 3 hr, and stirring was continued overnight at room temperature. A saturated ammonium chloride solution was added to the reaction mixture under cooling with ice-salt bath. The organic layer was separated and the aqueous layer was extracted with benzene (100 m*l*). The combined organic layer was dried. A light brown oily material obtained by evaporation of the solvent was mixed with hot benzene (20 m*l*), thus yielding fine light brown needles, 4.07 g (73%), mp 114—119°C. The crystals were recrystallized 4 times from methanol-benzene to yield pure XVI as pale yellow needles, mp 122—123°C. XVI gave yellow cuprous acetylide.

Found: C, 89.69; H, 4.30%. Calcd for $C_{21}H_{12}O$: C, 89.98; H, 4.32%. IR: 3400—3100 (OH), 3295 (≡CH), 2220, 2110 (C≡C), 1010 (C–O) cm^{-1}.

1-(2-Pyrenyl)-1,4-pentadiyn-3-ol (XVI'). Crude crystals of XVI' obtained according to the procedure for the synthesis of XVI were dissolved in benzene - ethanol and treated with active charcoal, yielding light yellow crystals in a 73% yield. The material was recrystallized 3 times from ethanol to give pure XVI' as colorless plates, mp 175—178°C.

Found: C, 89.98; H, 4.35%. Calcd for $C_{21}H_{12}O$: C, 89.98; H, 4.32%. IR: 3500—3400 (OH), 3295 (≡CH), 1180 (C–O) cm^{-1}.

1,1'-Dipyrenylpentaacetylene (I_5). Oxidative Coupling of XVI. A mixture of pentadiynol (XVI, 2.10 g, 7.5 mmol), cuprous chloride (0.20 g), ammonium chloride (0.18 g) and methanol (50 m*l*) was vigorously stirred under a slight excess of oxygen pressure at room temperature for 48 hr. The residue obtained by evaporating the solvent was dissolved in acetone (50 m*l*) and the insoluble material was removed by filtration. The acetone solution was passed through a short column of alumina, and the filtrate was concentrated. The residue solidified on addition of a small amount of benzene. The solid was washed with a small amount of methanol to yield crude XVII as light brown unstable crystalline powder, 1.01 g (58%). The IR spectrum of this material indicates the absence of ethynyl group. The crude material was subjected to the subsequent reaction without purification because of its instability.

Chlorination of XVII. A solution of thionyl chloride (0.18 g, 1.5 mmol) and pyridine (0.12 g, 1.5 mmol) in tetrahydrofuran (5 m*l*) was added over a period of 15 min to a solution of the crude tetraacetylene glycol (XVI, 0.279 g, 0.5 mmol) in the same solvent (15 m*l*) at a temperature of −30°C. After shaking for 10 min, the reaction mixture was used immediately in the following reaction without isolation of XVIII.

Dehydrochlorination of XVIII. The reaction mixture containing XVIII was added to a suspension of sodium amide [from sodium, 0.20 g (8.7 mg-atom)] in liquid ammonia (70 m*l*) at −70°C. After the mixture had been stirred for 30 min, ammonium chloride (1.0 g) was added and the ammonia was allowed to evaporate. The organic solvent in the residue was removed. A small amount of water was added to the residue and the insoluble material was collected and washed successively with water, a small amount of acetone and benzene. A deep brown solid thus obtained was extracted with hot toluene (total 500 m*l*) and the hot extract was passed through a short column of alumina (15 g). I_5 (0.089 g, 34%) was obtained as fine orange needles on putting the orange yellow filtrate to stand. I_5 decomposed at *ca.* 215°C.

Found: C, 96.11; H, 3.55%. Calcd for $C_{42}H_{18}$: C, 96.53; H, 3.47%.

2,2'-Dipyrenylpentaacetylene (II_5). A mixture of diynol (XVI', 1.05 g, 3.75 mmol), cuprous chloride (0.40 g), ammonium chloride (0.36 g), concentrated hydrochloric acid (1 drop) and methanol (80 m*l*) was vigorously stirred in an atmosphere of oxygen under slightly elevated pressure for 48 hr at room temperature. The precipitate collected by filtration was washed with methanol to give brown crystals. The crystals were dissolved in tetrahydrofuran and filtered. Concentration of the filtrate gave crude XVII' as brown crystals, 500 mg (48%). Crude XVII' was converted into dichloride (XVIII') and then dehydrochlorinated to yield II_5 according to the method used in the preparation of I_5. Pentaacetylene (II_5) was obtained as orange yellow needles (13% based on XVII') which decomposed at *ca.* 140°C.

Found: C, 96.43; H, 3.37%. Calcd for $C_{42}H_{18}$: C, 96.53; H, 3.47%.

1-(1-Pyrenyl)-2,5-hexadiyn-1,4-diol (XIII). A solution of 1-formylpyrene (III, 6.68 g, 0.029 mol) in tetrahydrofuran (60 m*l*) was added to a stirred solution of the Grignard derivative of 1,4-pentadiyn-3-ol [from 3.08 g of the alcohol] in tetrahydrofuran (15 m*l*) under cooling on an ice-salt bath. The temperature of the reaction mixture was gradually raised

to room temperature, stirring was continued overnight and a saturated solution of ammonium chloride was then added. The aqueous layer was extracted with benzene (100 m*l*). The combined organic layer was dried and concentrated to give an oily material. The crystals formed by trituration with benzene were washed with a small amount of benzene and dissolved in acetone (50 m*l*). The acetone solution was passed through a short column of alumina (15 g) and the filtrate was concentrated. The oily residue was mixed with hot benzene (25 m*l*) to deposit fine light brown crystals, 6.55 g (73%), mp 115—125°C. Recrystallization of the crystals from ethyl acetate - benzene afforded pure XIII as pale yellow needles which decomposed at *ca.* 145—155°C.

Found: C, 84.88; H, 4.61%. Calcd for $C_{22}H_{14}O_2$: C, 85.14; H, 4.55%. IR: 3600—3100 (OH), 3290 (≡CH), 2110 (C≡C), 1027 (C–O) cm^{-1}.

1-Pyrenyltriacetylene (XV). Chlorination of XIII. To a solution of slightly crude XIII (0.310 g, 1 mmol) in tetrahydrofuran (5 m*l*) maintained at −30°C was added over a period of 15 min a solution of thionyl chloride (0.36 g, 3 mmol) and pyridine (0.24 g, 3 mmol) in the same solvent (5 m*l*). After the addition had been completed, the mixture was stirred for 2 hr at room temperature. Crushed ice was added to the reaction mixture and extraction was carried out with benzene (100 m*l*). The extract was washed successively with water and sodium hydrogen carbonate solution, and dried. The reddish brown oily material obtained by evaporation of the solvent was subjected to the following reaction.

Dehydrochlorination. A solution of crude dichloride (XIV) in tetrahydrofuran (5 m*l*) was added over a period of 10 min to a suspension of sodium amide [from sodium, 0.14 g (6 mg-atom)] in liquid ammonia (50 m*l*) at −70°C. After the mixture had been stirred for 30 min, ammonium chloride (0.7 g) was added and the ammonia was allowed to evaporate. The residue, after the organic solvent had been removed, was extracted with petroleum ether (bp 60—80°C, total 150 m*l*). The extract was passed through a thin layer of alumina (2 g) and the filtrate was used in the subsequent reaction. Extremely unstable yellow crystals (XV) were obtained by concentration of a small portion of the filtrate. The filtrate exhibiting UV maximum at 396 nm gave orange red cuprous acetylide.

1,1'-Dipyrenylhexaacetylene (I_6). The petroleum ether solution of XV was added to a mixture of cupric acetate monohydrate (1.5 g), methanol (5 m*l*), and pyridine (10 m*l*). Petroleum ether was removed under reduced pressure and additional pyridine (5 m*l*) was then added. The mixture was stirred for 2 hr at room temperature. The insoluble material was filtered, washed with water, a small amount of methanol and benzene to yield dark red fine crystals, 0.089 g (33% based on XIII). The crystals were digested with hot toluene (total 400 m*l*) and the extract was passed through a short column of alumina (10 g). On leaving the filtrate to stand, hexaacetylene (I_6) deposited as tiny red crystals which decomposed at *ca.* 200°C.

Found: C, 96.18; H, 3.24%. Calcd for $C_{44}H_{18}$: C, 96.68; H, 3.32%.

1-(2-Pyrenyl)-1,4-hexadiyn-3,6-diol (XIX'). To an ice-cooled and stirred solution of the Grignard derivative of propargyl alcohol [from propargyl alcohol, 1.86 g (0.033 mol)] in tetrahydrofuran (35 m*l*) was added a solution of the propiolaldehyde (VI', 2.80 g, 0.017 mol) in tetrahydrofuran (30 m*l*). After the reaction mixture had been stirred overnight, a saturated solution of ammonium chloride was added. The aqueous layer was extracted with tetrahydrofuran and combined with the organic layer and dried. The combined organic layer was concentrated to yield light brown crystals, 2.9 g (85%). The crystals were recrystallized 3 times from ethanol to give pure XIX' as tiny light brown leaflets, mp 200—203°C (dec.).

Found: C, 85.12; H, 4.58%. Calcd for $C_{22}H_{14}O_2$: C, 85.14; H, 4.55%. IR: 3350—3100 (OH), 2240 (C≡C), 1020, 1040 (C–O) cm^{-1}.

2-Pyrenyltriacetylene (XV'). Chlorination of XIX'. A solution of thionyl chloride (720 mg, 6 mmol) in tetrahydrofuran (10 m*l*) was added to a solution of XIX' (620 mg, 2 mmol) and pyridine (480 mg, 6 mmol) in the same solvent (20 m*l*) at −30°C. The mixture was stirred for 30 min at room temperature and then for 40 min at 30°C. The mixture was chilled again on an ice-salt bath and crushed ice was added. The organic layer was washed with a solution of sodium hydrogen carbonate and dried. The residue obtained by evaporation of the solvent was redissolved in tetrahydrofuran (15 m*l*). The solution of XX' thus prepared was subjected to the following dehydrochlorination.

Dehydrochlorination of XX'. The solution of XX' was added to a suspension of sodium amide [from sodium, 1.3 g (0.055 mg-atom)] in liquid ammonia (100 m*l*) at −70°C. After the mixture had been stirred for 1 hr, ammonium chloride (5 g) was added and ammonia was allowed to evaporate. The residue obtained by evaporation of the organic solvent was extracted with petroleum ether (bp 60—80°C, total 500 m*l*). The extract was percolated through a thin layer of alumina (10 g) and the filtrate was used in the following oxidative coupling without isolation of triacetylene (XV').

2,2'-Dipyrenylhexaacetylene (II_6). The petroleum ether solution of XV' was mixed with a mixture of cupric acetate monohydrate (2 g) and pyridine (20 m*l*) and the petroleum ether was removed under reduced pressure. Pyridine (5 m*l*) and methanol (5 m*l*) were added to the residue and the resulting mixture was stirred for 2 hr at room temperature. The insoluble material was collected by filtration, washed successively with water, methanol and benzene. The yellowish brown solid thus obtained was digested with toluene and the hot extract was passed through a short column of alumina. The filtrate was allowed to cool to room temperature, yielding II_6 as tiny brownish orange yellow crystals. II_6 was found to be rather unstable and gave an unsatisfactory elemental analysis.

Found: C, 94.91; H, 3.90%. Calcd for $C_{44}H_{18}$: C, 96.68; H, 3.32%.

Linear Conjugated Systems Bearing Aromatic Terminal Groups. VIII. Syntheses and Electronic Spectra of Bis(4-biphenylyl)- and 2,2′-Difluorenylpoly-ynes

Kazuhiro NAKASUJI, Shuzo AKIYAMA, and Masazumi NAKAGAWA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka
(Received August 6, 1971)

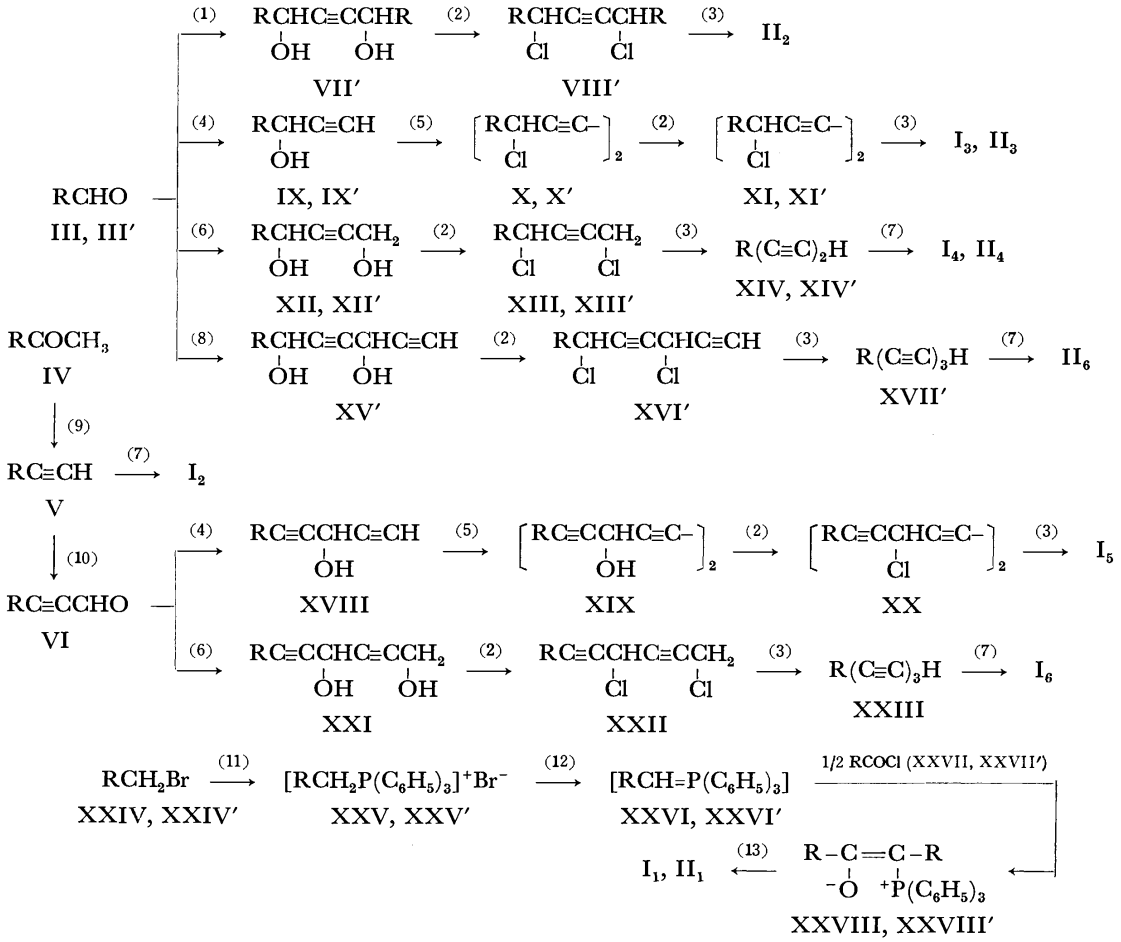
In order to get further information on the effect of terminal groups on the spectral regularity of diarylpoly-ynes, we carried out the syntheses of bis(4-biphenylyl)poly-ynes (I_n, $n=1$—6) and 2,2′-difluorenylpoly-ynes (II_n, $n=1$—4 and 6). The bathochromic shift of the longest-wavelength absorption maxima (λ_L) along with the increase in n was found to be expressed by the following empirical formulas:

I_n: $\lambda_L = 24.0n^{1.1} + 304$ (nm in tetrahydrofuran)

II_n: $\lambda_L = 9.0n^{1.5} + 350$ (nm in tetrahydrofuran)

The spectral behavior of bis(4-biphenylyl)poly-ynes (I_n) strongly supported the relationship $\lambda_L \propto n$ in diphenylpoly-ynes.

The syntheses and electronic spectral behavior of various diarylpoly-ynes [Ar(C≡C)$_n$Ar] bearing condensed aromatic nuclei as terminal groups have been reported.[1] It was found that the bathochromic shift of the longest-wavelength absorption maxima (λ_L) can



Scheme 1. Syntheses of I_n and II_n

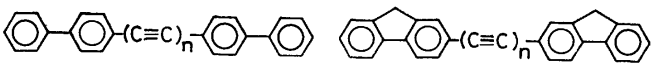
be expressed by the empirical formula

$$\lambda_L = An^x + B.$$

The value of x was found to depend on the nature of terminal group as well as on the position of linking of acetylenic chain. In view of the gradual change of the value of x, it was desirable to synthesize diarylpoly-ynes bearing non-condensed aromatic terminal groups to get further information on the effect of terminal groups on the electronic spectra of diarylpoly-ynes. In this paper, we will describe the syntheses and electronic spectral regularity of bis(4-biphenylyl)poly-ynes (I_n, n=1—6) and 2,2'-difluorenylpoly-ynes (II_n, n=1—4 and 6).



I_n II_n

Syntheses. The reaction sequence used in the syntheses of I_n and II_n are shown in Scheme 1.

The formyl- (III, III') and the propargylaldehyde derivatives (VI) are used as starting materials. In 4-biphenylyl series, the tri- and tetraacetylenes (I_3 and I_4) were obtained from formyl derivative (III), and propargylaldehyde (VI) was used in the preparation of penta- and hexaacetylenes (I_5 and I_6). 2,2'-Difluorenyl-poly-ynes (II_n, n=1—4 and 6) were prepared from 2-formylfluorene (III'). Dehydrochlorination of intermediate chloro-compounds by means of sodium amide in liquid ammonia successfully applied to biphenylyl series resulted in the formation of decomposition products in fluorenyl series, presumably owing to the presence of acidic methylene group. The elimination reactions of fluorenyl series were achieved by means of sodium or potassium ethoxide in ethanol. An attempt to prepare 2,2'-difluorenylpentaacetylene (II_5) according to the following reaction sequence gave fruitless results in the final step: RCHO→RCH(OH)(C≡C)$_2$H→RCH(OH)(C≡C)$_4$(HO)CHR→RCHCl(C≡C)$_4$ClCHR→R(C≡C)$_5$R.

Monoacetylenes (I_1 and II_1) were prepared by the intramolecular Wittig reaction,[2] *i.e.*, by thermolysis of betaines (XXVIII and XXVIII').

The physical properties of I_n and II_n are given in Tables 1 and 2.

The IR spectra of I_n and II_n exhibit the same characteristics observed in the other diarylpoly-ynes, *viz.*, the highest wave number of stretching vibration of acetylenic bond ($\nu_{C\equiv C}$) was observed in the cases of I_4 and II_3 and as illustrated in Fig. 1 the absorption intensity of $\nu_{C\equiv C}$ increased with the increase of n.

Electronic Spectra. The absorption curves and spectral data of I_n and II_n are summarized in Figs. 2 and 3, and Tables 3 and 4.

The marked difference in location of absorption maximum between biphenyl and fluorene has been

Table 1. Physical properties of I_n

n	Color of crystals	Mp (°C)	$\nu_{C\equiv C}$
1	colorless	253—254	—
2	colorless	232—233	2140

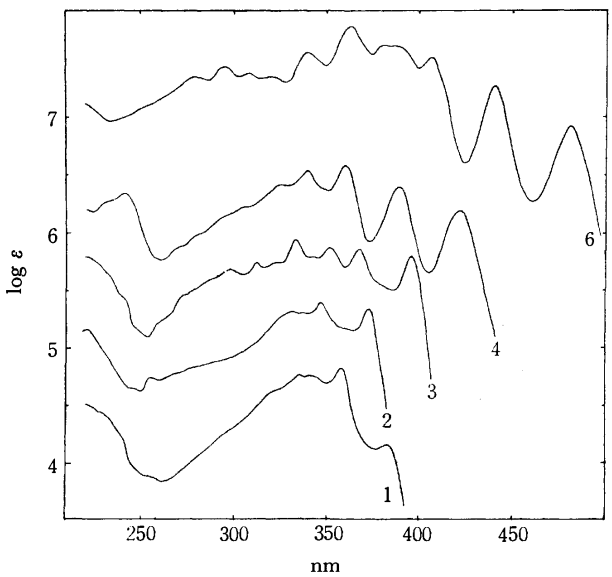

Fig. 3. The absorption cruves of 2,2′-difluorenylpoly-ynes (II_n). The cruves, with the exception of monoacetylene at the bottom, have been displaced upward on the ordinate axis by 0.5 log ε unit increments from the curve immediately below (in tetrahydrofuran.)

attributed to the strained planar structure of the latter.[3] The same characteristic difference was observed between I_n and II_n. Bis(4-biphenylyl)acetylene (I_1) displays a broad and structureless band in the long-wavelength region, while 2,2′-difluorenylacetylene (II_1) exhibits a band with vibrational structure, and an absorption maximum which might be related to ^1L_b band of fluorene can be observed in the longest-wavelength region. However, the members of biphenylyl series higher than diacetylene (I_2—I_6) exhibit vibrational fine structure. As with other diarylpoly-ynes, the fine structure in the spectra of I_n and II_n becomes progressively distinct with the increase of length of the acetylenic chain.

As shown in Table 5, the spacing between the longest-wavelength vibrational sub-band and the next longest-wavelength sub-band was found to be 1900—200 cm^{-1}. Detailed discussion on the spacing and $\nu_{C\equiv C}$ of diarylpoly-ynes is presented elsewhere.[4]

Table 5. Spacing of vibrational fine structure of I_n and II_n

n	2	3	4	5	6
I_n	1950	2120	2030	1980	1940
II_n	2080	1990	2010	—	1890

The plots of the longest-wavelength absorption maxima (λ_L) of I_n and II_n against $n^{1.1}$ and $n^{1.5}$ gave straight lines, as illustrated in Figs. 4 and 5. The linear relationships can be expressed by the following empirical formulas:

I_n: $\lambda_L = 24.0n^{1.1} + 304$ (nm in tetrahydrofuran)

II_n: $\lambda_L = 9.0n^{1.5} + 350$ (nm in tetrahydrofuran)

4) M. Nakagawa, S. Akiyama, K. Nakasuji, and K. Nishimoto, *Tetrahedron*, **27**, 5401 (1971).

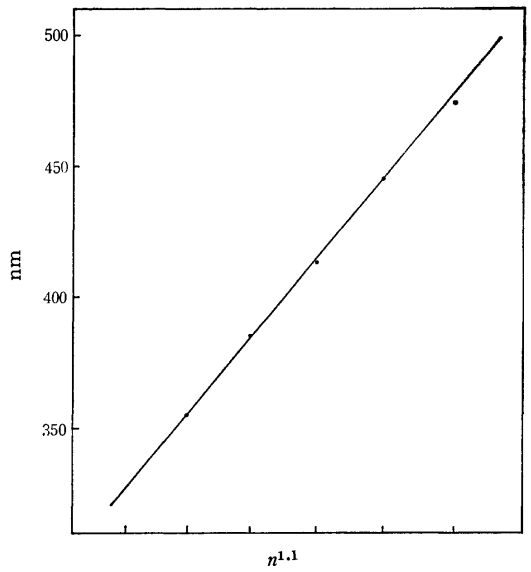

Fig. 4. Plot of λ_L against $n^{1.1}$ for bis(4-biphenylyl)poly-ynes (I_n).

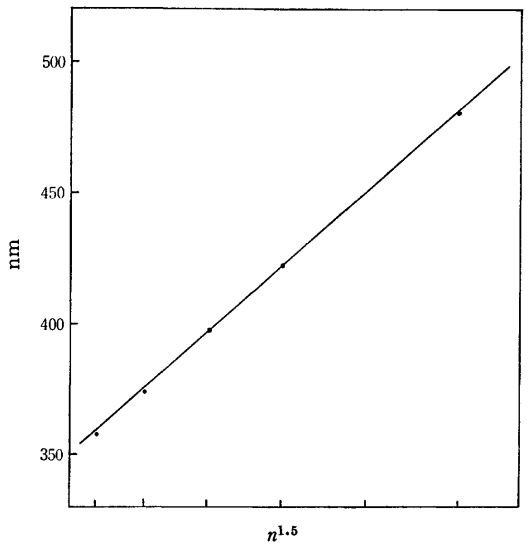

Fig. 5. Plot of λ_L against $n^{1.5}$ for 2,2'-difluorenylpoly-ynes (II_n).

TABLE 6. OBSERVED AND CALCULATED λ_L OF I_n AND II_n

n		1	2	3	4	5	6
I_n	Obsd	—	355	385	413	445	474
	Calcd	328	355	384	414	445	476
	λ		0	1	−1	0	−2
II_n	Obsd	358	374	397	422	—	481
	Calcd	359	375	397	422	451	482
	λ	−1	−1	0	0		−1

As is shown in Table 6, the agreement between observed and calculated values was found to be satisfactory.

It is to be noted that the linear relationship of 1,1'-dinaphthylpoly-ynes[5] could be expressed by the same empirical formula which is valid for 2,2'-difluorenylpoly-ynes (II_n).

We pointed out[6] that the spectral shift of diphenylpoly-ynes should be expressed by the relation $\lambda_L \propto n^{1.0}$ instead of the widely accepted $\lambda_L^2 \propto n$.[7] The spectral behavior of bis(4-biphenylyl)poly-ynes (I_n) seems to afford an additional strong support for the relation $\lambda_L \propto n^{1.0}$ in diphenylpoly-ynes.

A general view of the spectral behavior of various kinds of diarylpoly-ynes and a HMO explanation based on a modified bond-alternation approximation for the novel linear relationship are given elsewhere.[4]

Experimental

All the melting points are uncorrected. The electronic and IR (KBr-disk method) spectra were obtained on Hitachi EPS-3T and EPI-2 spectrophotometers, respectively. Evaporation of solvent or concentration of solution was carried out under reduced pressure throughout this work.

Bis(4-biphenylyl)diacetylene (I_2). Diacetylene (I_2) was prepared by modifying the reported method. Oxidative coupling of 4-ethynylbiphenyl (V)[8,9] by means of the Eglinton method gave I_2 in a 90% yield as colorless needles, mp 232—233°C (lit, mp 232°C,[8] mp 235—236°C[9]).

1-(4-Biphenylyl)-2-propyn-1-ol (IX). A solution of 4-formylbiphenyl[10] (III, 7.3 g, 0.04 mol) in tetrahydrofuran (50 m*l*) was added over a period of 15 min to a stirred solution of lithium acetylide [from lithium, 0.83 g, 0.12 g-atom] in liquid ammonia (200 m*l*) at −60°C. The reaction mixture was stirred for 1 hr at this temperature, then for 17.5 hr at −50——55°C and finally for 3 hr at the boiling point of ammonia. Ammonium chloride (4 g) was added to the reaction mixture at −70°C, and the ammonia was allowed to evaporate. The residue was mixed with a saturated solution of ammonium chloride, and the aqueous layer was extracted with ether. The extract was combined with organic layer and dried. The residue obtained by evaporation of the solvent was crystallized from benzene - cyclohexane to yield brown crystals, 6.7 g (80%). Recrystallization of the crude crystals three times from the same solvent gave pure IX as colorless tiny crystals, mp 114—116°C.

Found: C, 86.31; H, 5.83%. Calcd for $C_{15}H_{12}O$: C, 86.51; H, 5.81%. IR: 3400—3300 (OH), 3290 (≡CH), 2090 (C≡C), 1015 (C–O) cm^{-1}.

1,6-Bis(4-biphenylyl)-2,4-hexadiyn-1,6-diol (X). A mixture of ethynylcarbinol (IX, 3.1 g, 0.015 mol), cuprous chloride (0.3 g, 3 mmol), ammonium chloride (0.23 g, 4.2 mmol) and methanol containing 1 drop of concentrated hydrochloric acid (20 m*l*) was vigorously stirred for 2 hr at room temperature under a slight excess of oxygen pressure. Five drops of concentrated hydrochloric acid was then added to the reaction mixture, and stirring was continued for further 2 hr. Inorganic materials were removed by filtration and washed with methanol. The residue obtained by evaporation of the combined organic layer was dissolved in ether

containing tetrahydrofuran and washed with 2N hydrochloric acid. The crude material obtained after washing, drying and evaporation was crystallized from benzene - ethanol, giving crude X, 2.1 g (66%). Recrystallization of the crude X three times from the same solvent yielded pure X as light brown plates, mp 215—217°C.

Found: C, 86.73; H, 5.40%. Calcd for $C_{30}H_{22}O_2$: C, 86.93; H, 5.35%. IR: 3450—3350 (OH), 1005 (C–O) cm^{-1}.

Bis(4-biphenylyl)triacetylene (I_3). Preparation of Dichloride (XI). A solution of thionyl chloride (0.72 g, 6 mmol) in tetrahydrofuran (5 m*l*) was added to a stirred solution of the glycol (X, 0.83 g, 2 mmol) and pyridine (0.48 g, 6 mmol) in tetrahydrofuran (10 m*l*) under cooling on an ice-salt bath. Stirring was continued for 1 hr at the same temperature. The reaction mixture was subjected to the subsequent reaction without isolation of XI.

Dehydrochlorination of XI. The solution of XI was added to a stirred suspension of sodium amide [from sodium, 0.4 g, 0.018 g-atom] in liquid ammonia (50 m*l*) at −70°C. After the mixture had been stirred for 2 hr, ammonium chloride (3 g) was added and the ammonia was allowed to evaporate. The residue was mixed with water and the insoluble material was washed with a small amount of ethanol and benzene. The brown crystals thus obtained were dissolved in benzene, and the solution was percolated through a thin layer of alumina (6 g). The filtrate was concentrated to yield yellow crystals, 190 mg (25%). The product was recrystallized twice from benzene to give pure I_3 as pale yellow tiny crystals which decomposed at *ca.* 250°C.

Found: C, 94.74; H, 4.83%. Calcd for $C_{30}H_{18}$: C, 95.21; H, 4.79%.

1-(4-Biphenylyl)-2-butyn-1,4-diol (XII). To an ice-cooled solution of the Grignard derivative of propargyl alcohol [from magnesium, 4.6 g (0.192 g-atom)], ethyl bromide, 25 g (0.23 mol) and propargyl alcohol, 5.4 g (0.096 mol)] in tetrahydrofuran (120 m*l*), was added under stirring a solution of 4-formylbiphenyl[10] (III, 10 g, 0.055 mol) in the same solvent (30 m*l*). The stirred mixture was allowed to warm to room temperature and stirring was continued overnight. 4N Sulfuric acid was then added to the reaction mixture and the organic layer was separated. The aqueous layer was extracted with benzene. The combined organic layer was washed successively with saturated solutions of sodium chloride, sodium hydrogen carbonate and water, and dried. The brown crystals obtained by evaporation of the solvent were dissolved in ethanol and treated with active charcoal and evaporated under reduced pressure. The crude crystals were recrystallized from benzene - ethanol, yielding brown crystals, 9.4 g (72%). The product was recrystallized 3 times from the same solvent to afford pure XII as colorless needles, mp 133—134°C.

Found: C, 80.85; H, 6.04%. Calcd for $C_{16}H_{14}O_2$: C, 80.64; H, 5.92%. IR: 3300—3200 (OH), 1015 (C–O) cm^{-1}.

4-Butadiynylbiphenyl (XIV). Preparation of Dichloride (XIII). A solution of thionyl chloride (14 g, 0.114 mol) in tetrahydrofuran (20 m*l*) was added over a period of 30 min to an ice-cooled mixture of butynediol (XII, 8.8 g, 0.037 mol), pyridine (9.0 g, 0.114 mol) and tetrahydrofuran (80 m*l*) and the reaction mixture was stirred for 1 hr. After the mixture had been stirred for further 40 min at 40°C, crushed ice was added to the mixture under ice-cooling. The aqueous layer was extracted with ether and combined with the organic layer, and washed with water and sodium hydrogen carbonate solution. It was dried and evaporated. Crude XIII thus prepared was used immediately in the following reaction.

Dehydrochlorination of XIII. A solution of the crude XIII in a mixture of tetrahydrofuran (15 m*l*) and ether (5 m*l*) was added in a stirred suspension of sodium amide [from sodium, 6 g (0.26 g-atom)] in liquid ammonia (450 m*l*) at −70°C and the mixture was stirred for a further 2 hr. Ammonium chloride (20 g) was then added and the ammonia was allowed to evaporate. The residue obtained by evaporation of the organic solvent was repeatedly digested with petroleum benzine (total 600 m*l*). The benzine solution was concentrated to *ca.* 200 m*l* and passed through a column of alumina (10 g). Diacetylene (XIV) was obtained as colorless needles, 1.9 g (26%) on concentration of the filtrate. The product was recrystallized from petroleum benzine to give pure XIV, colorless needles, mp 105°C (dec.). XIV was found to be unstable and turned to black insoluble material on standing.

Found: C, 94.57; H, 4.87%. Calcd for $C_{16}H_{10}$: C, 95.02; H, 4.98%. UV: $\lambda_{max}^{n\text{-hexane}}$ (log ε) 302* (4.52), 292 (4.56), 245 (3.99) nm. The asterisk indicates shoulder.

Bis(4-biphenylyl)tetraacetylene (I_4). A solution of 4-butadiynylbiphenyl (XIV, 0.8 g, 4 mmol) in petroleum benzine (20 m*l*) was added to a mixture of cupric acetate monohydrate (4 g) and pyridine (20 m*l*) and the mixture was stirred for 2 hr at room temperature. After benzine had been removed under reduced pressure, stirring was continued for a further 3 hr at 50°C. The reaction mixture was chilled on an ice-salt bath. The solid deposited was filtered and washed with a small amount of methanol and water, successively. The yellowish brown crystals, 620 mg (77%) thus obtained were dissolved in benzene and treated with active charcoal. Recrystallization twice from the same solvent afforded pure I_4 as yellow rods which decomposed at *ca.* 240°C.

Found: C, 95.90; H, 4.48%. Calcd for $C_{32}H_{18}$: C, 95.49; H, 4.51%.

3-(4-Biphenylyl)-prop-2-ynal (VI). To an ice-cooled and stirred solution of ethynylmagnesium bromide [from magnesium, 2.92 g (0.12 g-atom), ethyl bromide, 15.8 g (0.15 mol) and an excess of acetylene] in tetrahydrofuran (70 m*l*) was added over a period of 20 min a solution of 4-ethynylbiphenyl[8,9] (V, 17.8 g, 0.1 mol) in the same solvent (40 m*l*). After 1 hr, the mixture was refluxed for 30 min and then cooled on an ice-salt bath. A solution of dimethylformamide (23 m*l*) in tetrahydrofuran (40 m*l*) was added in one portion to the chilled mixture. The reaction mixture was left to reach room temperature. After stirring for 6 hr, the reaction mixture was poured into cold 5% sulfuric acid (700 m*l*) under vigorous agitation, after which the stirring was continued overnight. The mixture was then extracted with benzene. The extract was washed successively with water and sodium hydrogen carbonate solution and dried. The crude yellow crystals obtained by evaporation of the solvent were recrystallized from benzene - petroleum ether to give colorless needles, 12.3 g (60%), mp 75—78°C. This substance was recrystallized 3 times from benzene - cyclohexane to give pure VI as colorless needles, mp 76—78°C.

Found: C, 87.54; H, 4.89%. Calcd for $C_{15}H_{10}O$: C, 87.35; H, 4.89%. IR: 2180 (C≡C), 1652 (C=O) cm^{-1}.

1-(4-Biphenylyl)-1,4-pentadiyn-3-ol (XVIII). A solution of the aldehyde (VI, 7.22 g, 0.035 mol) in tetrahydrofuran (50 m*l*) was added to an ice-cooled solution of ethynylmagnesium bromide [from magnesium, 2.13 g (0.088 g-atom), ethyl bromide, 11.43 g (0.105 mol) and an excess of acetylene] in tetrahydrofuran (100 m*l*), after which the mixture was stirred for 1 hr at the same temperature. The cooling bath was then removed and stirring continued overnight at room temperature. The reaction mixture was chilled again on an ice-salt bath and a saturated solution of ammonium chloride was added, extracted with benzene. The extract

was dried and evaporated, resulting in crude crystals. The crude material was dissolved in ethanol and treated with charcoal. The crystals obtained from the filtrate were recrystallized from benzene - petroleum benzine to give slightly crude XVIII, 5.6 g (69%), mp 100—103°C. Recrystallization of this substance twice from the same solvent gave pure XVIII, mp 107—109°C.

Found: C, 87.85; H, 5.19%. Calcd for $C_{17}H_{12}O$: C, 87.90; H, 5.21%. IR: 3320—3180 (OH, ≡CH), 2220, 2105 (C≡C) cm^{-1}.

1,10-Bis(4-biphenylyl)-1,4,6,9-decatetrayn-3,8-diol (XIX). A mixture of diacetylene alcohol (XVIII, 4.64 g, 0.02 mol), cuprous chloride (0.40 g, 0.004 mol), ammonium chloride (0.30 g, 0.0056 mol), methanol (30 m*l*) and a drop of concentrated hydrochloric acid was vigorously stirred overnight at room temperature under a slight excess pressure of oxygen. The inorganic materials deposited were removed by filtration. The filtrate was evaporated and the residue was dissolved in ether, washed successively with 2N hydrochloric acid, water, sodium hydrogen carbonate solution and water, and dried. The crystals obtained by evaporation of the solvent were dissolved in ethanol and treated with active charcoal. Slightly impure XIX, 2.8 g (56%), thus prepared, was used in the subsequent reaction without further purification.

Bis(4-biphenylyl)pentaacetylene (I_5). Preparation of the Dichloride (XX). A solution of thionyl chloride (0.54 g, 4.5 mmol) and pyridine (0.36 g, 4.5 mmol) in ether (5 m*l*) was added over a period of 20 min to a stirred solution of the glycol (XIX, 0.69 g, 1.5 mmol) in tetrahydrofuran (10 m*l*) at −58°C and the mixture was stirred for a further 30 min at the same temperature. The reaction mixture was used immediately in the following reaction without isolation of XX.

Dehydrochlorination of XX. The reaction mixture containing XX was added into a stirred suspension of sodium amide [from sodium, 0.6 g (0.26 g atom)] in liquid ammonia (60 m*l*) maintained at −70°C. After stirring for an additional 1 hr at the same temperature, ammonium chloride (3 g) was added and the ammonia was allowed to evaporate. The residue obtained by evaporating the organic solvent was mixed with water. The insoluble material was filtered, washed with ethanol and a small amount of benzene. The deep brown solid thus obtained was dissolved in benzene and the solution was percolated through a short column of alumina (10 g). Yellowish crystals, 345 mg (54%) obtained by evaporation of the filtrate were recrystallized twice from benzene to yield pure I_5 as yellow needles. I_5 decomposed at *ca.* 200°C.

Found: C, 96.03; H, 4.42%. Calcd for $C_{34}H_{18}$: C, 95.75; H, 4.25%.

1-(4-Biphenylyl)-1,4-hexadiyn-3,6-diol (XXI). A solution of biphenylylpropynal (VI, 8.24 g, 0.04 mol) in tetrahydrofuran (20 m*l*) was added to a stirred solution of the Grignard derivative of propargyl alcohol [from magnesium, 2.88 g (0.12 g-atom), ethyl bromide, 15.7 g (0.144 mol) and propargyl alcohol, 3.66 g (0.06 mol)] in tetrahydrofuran (75 m*l*) under cooling on an ice-salt bath, after which the cooling bath was removed and the mixture was stirred overnight at room temperature. To the ice-cooled reaction mixture was added a saturated solution of ammonium chloride and the organic layer was separated. The aqueous layer was extracted with ether. The combined organic layer was washed with sodium chloride solution and dried. The light yellow crystals, 9.0 g (85%) obtained by the evaporation of the solvent were recrystallized twice from benzene to give pure XXI as colorless needles, mp 115—117°C.

Found: C, 82.40; H, 5.51%. Calcd for $C_{18}H_{14}O_2$: C, 82.42; H, 5.38%. IR: 3300—3200 (OH), 2220 (C≡C), 1020 (C–O) cm^{-1}.

1-(4-Biphenylyl)-1,3,5-hexatriyne (XXIII). Preparation of the Dichloride (XXII). To a stirred solution of glycol (XXI) 2.36 g, 9 mmol) in tetrahydrofuran (15 m*l*) maintained at −40°C, was added over a period of 30 min a solution of thionyl chloride (3.12 g, 27 mmol) and pyridine (2.13 g, 27 mmol) in ether (7 m*l*). The mixture was stirred for a further 30 min at the same temperature and then for 1 hr at room temperature. The reaction mixture containing XII was subjected immediately to the following reaction.

4-Biphenylyltriacetylene (XXIII). The solution containing XII was added to a suspension of sodium amide [from sodium, 2.0 g (0.09 g-atom)] in liquid ammonia (150 m*l*) at −70°C. After the mixture had been stirred for 1 hr at the same temperature, ammonium chloride (7 g) was added and ammonia was allowed to evaporate. The residue obtained by removing the organic solvent was digested with petroleum benzine (total 800 m*l*) and the extract was concentrated to *ca.* 200 m*l*. The extract was passed through a short column of alumina (15 g). The filtrate containing extremely unstable XXIII was used in the following reaction.

UV: $\lambda_{max}^{benzine}$ 338, 317, 300 nm.

Bis(4-biphenylyl)hexaacetylene (I_6). The benzine solution of XXIII was evaporated *in vacuo* under continuous addition of ethanol. The ethanol solution of XXIII thus prepared was mixed with a solution of cupric acetate monohydrate (15 g) in pyridine (100 m*l*), and ethanol was removed under reduced pressure. After the reaction mixture had been stirred for 2 hr at 50°C, pyridine was evaporated. The residue was mixed with benzene, and benzene was evaporated to remove the remaining pyridine. The resulting deep brown crystalline mass was dissolved in benzene and percolated through a thin layer of alumina (10 g). Concentration of the filtrate afforded yellowish brown crystals, 180 mg (9%). The procedure of percolation of the benzene solution was rapidly repeated 2 times to give pure I_6, orange yellow needles, which decomposed at *ca.* 160°C.

Found: C, 95.68; H, 4.50%. Calcd for $C_{36}H_{18}$: C, 95.97; H, 4.03%.

1,4-Bis(2-fluorenyl)-2-butyn-1,4-diol (VII'). A solution of 2-formylfluorene[11] (III', 5.4 g, 0.028 mol) in tetrahydrofuran (30 m*l*) was added to an ice-cooled solution of acetylenedimagnesium bromide [from magnesium, 1.9 g (0.08 g-atom), ethyl bromide, 10.7 g (0.096 mol)] in benzene - tetrahydrofuran (1 : 1, 100 m*l*). The reaction mixture was stirred overnight at room temperature, and was then chilled on an ice-salt bath. A saturated solution of ammonium chloride was added to the chilled reaction mixture and the organic layer was separated. The aqueous layer was extracted with ether. The combined organic layer was dried, and evaporated, thus yielding a solid contaminated with a reddish brown oily material. Recrystallization of this material from benzene - ethanol yielded light brown crystalline powder, 3.5 g (60%). The crude material was recrystallized twice from tetrahydrofuran to yield pure VII' as light yellow leaflets, mp 236—238°C.

Found: C, 86.58; H, 5.33%. Calcd for $C_{30}H_{22}O_2$: C, 86.93; H, 5.32%. IR: 3350—3250 (OH), 1005, 980 (C–O) cm^{-1}.

2,2'-Difluorenyldiacetylene (II_2). Preparation of the Dichloride (VIII'). A solution of thionyl chloride (360 mg, 3 mmol) in tetrahydrofuran (5 m*l*) was added to a stirred solution of glycol (VII', 310 mg, 0.75 mmol) and pyridine (240 mg, 3 mmol) in tetrahydrofuran (5 m*l*) under cooling on an ice-salt bath. After the mixture had been stirred for 1 hr at the same temperature and for 2 hr at room temperature,

11) R. Rieche, H. Gross, and E. Hoft, *Chem. Ber.*, **93**, 88 (1960).

crushed ice was added to the reaction mixture under cooling with ice-water. The mixture was extracted with benzene. The extract was washed with water and a solution of sodium hydrogen carbonate and dried. The residue obtained by evaporation of the solvent was used in the following reaction without further purification.

Dehydrochlorination of VIII'. A solution of the crude VIII' in tetrahydrofuran (60 m*l*) and ethanol (20 m*l*) was added dropwise into an ice-cooled solution of potassium ethoxide [from potassium, 0.15 g (3.8 mg-atom)] in ethanol (10 m*l*). After the reaction mixture had been stirred for 2 hr at room temperature, the solvent was evaporated. The residue was extracted with benzene and the extract was passed through a short column of alumina (15 g). The yellow filtrate was evaporated to yield yellowish brown crystals, 180 mg. This material was recrystallized from benzene to yield yellow crystals, 120 mg (42%). The crystals were redissolved in benzene and percolated through a thin layer of alumina (5 g). The crystals obtained from the filtrate were recrystallized twice from benzene to yield pure II_2 as pale yellow needles, mp 280—282°C (dec.). [lit[8] mp 278°C (dec.)].

Found: C, 95.08; H, 4.80%. Calcd for $C_{30}H_{18}$: C, 95.21; H, 4.79%.

1-(2-Fluorenyl)-2-propyn-1-ol (IX'). To an ice-cooled solution of ethynylmagnesium bromide [from magnesium, 1.80 g (0.075 g-atom), ethyl bromide, 8.20 g (0.075 mol) and an excess of acetylene] in tetrahydrofuran (150 m*l*) was added a solution of 2-formylfluorene (III', 5.82 g, 0.03 mol) in tetrahydrofuran (30 m*l*). The reaction mixture was left to reach room temperature and stirring was continued overnight. The mixture was then chilled on an ice-salt bath and a saturated solution of ammonium chloride was added. The organic layer was dried, and evaporated to give crude brown crystals. After recrystallization from benzene, the crystals were dissolved in ethanol and treated with charcoal, giving brown crystals, 5.3 g (80%). A solution of the crystals in ethyl acetate was passed through a thin layer of alumina (10 g). A slightly crude material obtained from the filtrate was recrystallized 3 times from petroleum benzine-benzene to yield pure IX' as pale yellow needles, mp 147—149°C.

Found: C, 87.37; H, 5.50%. Calcd for $C_{16}H_{12}O$: C, 87.24; H, 5.49%. IR: 3450—3300 (OH), 3260 (≡CH), 2120 (C≡C), 1010 (C–O) cm^{-1}.

1,6-Bis(2-fluorenyl)-2,4-hexadiyn-1,6-diol (X'). A mixture of ethynylcarbinol (IX', 2.1 g, 10 mmol), cuprous chloride (200 mg, 3.0 mmol), ammonium chloride (150 mg, 2.8 mmol) and methanol (15 m*l*) containing 1 drop of concentrated hydrochloric acid was vigorously stirred overnight at room temperature under a slight excess of oxygen pressure. The reaction mixture was worked up according to the procedure used in the preparation of X, affording crystals, 1.36 g (63%). The crystals were recrystallized 3 times from benzene - ethanol to give colorless needles, mp 210—212°C (dec.).

Found: C, 87.80; H, 5.11%. Calcd for $C_{32}H_{22}O_2$: C, 87.64; H, 5.06%. IR: 3500—3200 (OH), 1000, 965 (C–O) cm^{-1}.

2,2'-Difluorenyltriacetylene (II_3). Preparation of the Dichloride (XI'). A solution of thionyl chloride (240 mg, 2.0 mmol) in tetrahydrofuran (10 m*l*) was added to a stirred solution of the glycol (X', 220 mg, 0.5 mmol) and pyridine (160 mg, 2.0 mmol) in tetrahydrofuran (10 m*l*) under cooling on an ice-salt bath. The mixture was stirred for 30 min at the same temperature and for 2 hr at room temperature. The reaction mixture was chilled on an ice-salt bath and mixed with crushed ice, then extracted with ether. The extract was washed successively with water and a dilute solution of sodium hydroxide and dried. The brown crystals obtained by evaporating the solvent were dissolved in tetrahydrofuran (30 m*l*) and used in the subsequent reaction.

Dehydrochlorination of XI'. To a stirred and ice-cooled solution of sodium ethoxide [from sodium, 70 mg (3 mmol)] in ethanol (10 m*l*), was added the solution of crude XI' in tetrahydrofuran. After the mixture had been stirred for 2 hr at room temperature, the solvent was removed and the residue was extracted with benzene. The extract was concentrated to *ca.* 80 m*l* and percolated through a short column of alumina (15 g). The brown solid obtained by evaporation of the filtrate was crystallized from benzene, yielding crude crystals, 120 mg (60%). The crude substance was dissolved in benzene and passed through a thin layer of alumina. The crystals obtained by evaporation of the filtrate were redissolved in the same solvent and passed again through a short alumina column. Pure II_3 was obtained from the filtrate as yellowish brown fine crystals, which decomposed at *ca.* 250°C.

Found: C, 95.34; H, 4.47%. Calcd for $C_{32}H_{18}$: C, 95.49; H, 4.51%.

1-(2-Fluorenyl)-2-butyn-1,4-diol (XII'). The crude product obtained by the reaction of 2-formylfluorene[11] (III', 6.4 g, 0.033 mol) in tetrahydrofuran (20 m*l*) with the Grignard derivative of propargyl alcohol [from magnesium, 2.8 g (0.115 g-atom), ethyl bromide, 15 g (0.138 mol) and propargyl alcohol, 3.2 g (0.058 mol)] in the same solvent (75 m*l*) according to the procedure used for XII was recrystallized from benzene - ethanol to give light brown crystals, 6.4 g (82%). Recrystallization of this material 3 times from benzene containing a small amount of ethanol afforded pure XII' as colorless plates, mp 133—135°C.

Found: C, 81.78; H, 5.54%. Calcd for $C_{17}H_{14}O_2$: C, 81.58; H, 5.64%. IR: 3300—3100 (OH), 1105, 1000, 995 (C–O) cm^{-1}.

2-Butadiynylfluorene (XIV'). Preparation of Dichloride (XIII'). A solution of thionyl chloride (3.6 g, 0.03 mol) in tetrahydrofuran (20 m*l*) was added to a solution of butynediol (XII', 2.2 g, 0.01 mol) and pyridine (2.4 g, 0.03 mol) in tetrahydrofuran (50 m*l*) under cooling on an ice-salt bath. The reaction mixture was stirred for 30 min at the same temperature, for 1 hr at room temperature and for 1 hr at 40°C. The reaction mixture was concentrated to *ca.* 30 m*l* and used in the following reaction.

Dehydrochlorination of XIII'. The solution of XII' was added to a stirred solution of sodium ethoxide [from sodium, 2.1 g (0.09 g-atom)] in ethanol (80 m*l*) under cooling on an ice-salt bath. After the mixture had been stirred for 30 min at the same temperature and for 1 hr at room temperature, a saturated solution of ammonium chloride was added to the reaction mixture under ice-cooling. The aqueous layer was extracted with benzene. The combined organic layer was dried and evaporated. The residue was digested with petroleum benzine and the extract was passed through a thin layer of alumina (30 g). The resulting colorless filtrate was concentrated to *ca.* 200 m*l* and subjected to the subsequent reaction without isolation of XIV'.

UV: $\lambda_{max}^{benzine}$ 324, 315, 303 nm.

2,2'-Difluorenyltetraacetylene (II_4). The oxidative coupling used in the synthesis of I_4 was applied to the benzine solution of XIV' yielding crude II_4, 190 mg (9%). The crude material was recrystallized twice from benzene using active charcoal to yield pure II_4 as orange yellow rods which decomposed at *ca.* 210°C.

Found: C, 95.67; H, 4.32%. Calcd for $C_{34}H_{18}$: C, 95.75; H, 4.25%.

1-(2-Fluorenyl)-2,5-hexadiyn-1,4-diol (XV'). A solution of 1,4-pentadiyn-3-ol (3.08 g, 0.039 mol) in tetrahydrofuran (65 ml) was added over a period of 20 min to a solution of ethylmagnesium bromide [from magnesium, 2.05 g (0.086 g-atom) and ethyl bromide, 10.4 g (0.095 mol)] in the same solvent (55 ml) under an atmosphere of nitrogen at 25°C. Stirring was continued for 30 min at the same temperature. A solution of 2-formylfluorene (III', 5.82 g, 0.03 mol) in tetrahydrofuran (60 ml) was then added dropwise to the ice-cooled solution of the Grignard derivative of pentadiyneol. The reaction mixture was left to reach room temperature and stirring was continued overnight. After the reaction mixture had been stirred for 20 min at 40°C, a saturated solution of ammonium chloride was introduced to the mixture under cooling on an ice-salt bath. The organic layer was separated and the aqueous layer was extracted with benzene. The combined orgaic layer was washed, dried and evaporated. The resulting dark reddish brown oily material was mixed with a small amount of hot benzene to give crude crystals, 4.0 g (48%), mp *ca.* 120—140°C. The crude material was recrystallized twice from benzene to yield XV' as light brown crystals, mp 153—173°C.

Found: C, 93.16; H, 5.11%. Calcd for $C_{19}H_{14}O_2$: C, 83.20; H, 5.15%. IR: 3300—3250 (OH), 3260 (≡CH), 2120 (C≡C), 1025, 1010 (C-O) cm^{-1}.

1-(2-Fluorenyl)-1,3,5-hexatriyne (XVII'). Preparation of Dichloride (XVI'). A solution of thionyl chloride (720 mg, 6 mmol) in tetrahydrofuran (8 ml) was added to a stirred solution of glycol (XV', 550 mg, 2 mmol) and pyridine (480 mg, 6 mmol) in tetrahydrofuran (10 ml) under cooling on an ice-salt bath. The reaction mixture was stirred for 1 hr at the same temperature and for 1 hr at 30°C. The reaction mixture was used in the following reaction without isolation of XVI'.

Dehydrochlorination of XVI'. The reaction mixture containing XVI' was added dropwise to a stirred solution of potassium ethoxide [from potassium, 1.2 g (30 mg-atom)] in ethanol (40 ml) under cooling with an ice-salt mixture. After the mixture had been stirred for 30 min at the same temperature and then for 30 min at 30°C, a saturated solution of ammonium chloride (5 ml) was added to the ice-cooled reaction mixture and the volatile material was removed *in vacuo*. The residue was extracted with petroleum benzine, and the extract was concentrated to *ca.* 100 ml. Percolation of the concentrated extract through a short column of alumina (20 g) gave a light yellow filtrate. The filtrate was used in the following reaction without isolation of triacetylene (XVII').

UV: $\lambda_{max}^{benzine}$ 354, 325 nm.

2,2'-Difluorenylhexaacetylene (II_6). To a solution of cupric acetate monohydrate (2 g) in pyridine (10 ml) was added, portion by portion, the benzine solution of the triacetylene (XVII') under reduced pressure. After addition of the solution and removal of benzine had been completed, the pyridine solution was stirred for 30 min at 35°C and then at room temperature overnight. The reaction mixture was concentrated, and benzene was added to the residue. The solvent was again evaporated to remove pyridine completely. The residue was triturated with cold benzene (10 ml) and the insoluble material was collected by filtration and washed thoroughly with water. The brown solid thus obtained was dissolved in hot benzene and the hot solution was passed through a short column of alumina (5 g). The resulting orange yellow filtrate gave orange yellow crystals, 70 mg (7%) on concentration. The crystals obtained by the recrystallization of this substance from benzene were redissolved in benzene and percolated through a short column of alumina. The crystals obtained from the filtrate were recrystallized again from benzene, yielding pure II_6 as orange yellow leaflets which decomposed at *ca.* 250°C.

Found: C, 95.75; H, 3.81%. Calcd for $C_{38}H_{18}$: C, 96.18; H, 3.82%.

4-Biphenylylmethyl-triphenylphosphonium Bromide (XXV). A solution of 4-bromomethylbiphenyl[12] (XXIV, 3.9 g, 0.016 mol) and triphenylphosphine (5.8 g, 0.022 mol) in benzene (40 ml) was refluxed overnight. The solid deposited was collected by filtration and washed with benzene, yielding colorless crystalline powder, 7.4 g (92%). Recrystallization of this material from ethanol gave colorless leaflets, mp 283—287°C.

Found: C, 73.08; H, 5.21; Br, 15.69%. Calcd for $C_{31}H_{26}BrP$: C, 73.10; H, 5.14; Br, 15.69%.

Preparation of the Betaine (XXVIII). To a suspension of the phosphonium bromide (XXV, 1.12 g, 2.2 mmol) in toluene (25 ml) was added an ethereal solution of phenyllithium (0.765N, 3.0 ml) under an atmosphere of nitrogen. Instanteneous deep red coloration took place. After the mixture had been stirred for 30 min at 60°C, a solution of acid chloride (XXVII) [from 4-biphenylcarboxylic acid,[13] 0.20 g (1 mmol) and thionyl chloride, 180 mg (1.5 mmol)] in toluene (20 ml) was added to the solution of phosphorane and stirred overnight. The insoluble material was collected by filtration and digested with boiling toluene (total 200 ml). The extract was concentrated and the residue dissolved in benzene - cyclohexane (1: 1, 5 ml). The crystals deposited, 510 mg (84%), were recrystallized from the same solvent to give pure XXVIII as light yellow rod which decomposed at 215—218°C (foaming was observed at *ca.* 200°C).

Found: C, 87.06; H, 5.53%. Calcd for $C_{44}H_{33}OP$: C, 86.83; H, 5.46%.

Bis(4-biphenylyl)acetylene (I_1). Betaine (XXVIII, 63 mg, 0.103 mmol) was gradually heated to 210°C under reduced pressure (20 mmHg) and kept at this temperature for 15 min. Foaming was observed at *ca.* 190°C. After cooling, the product was extracted with benzene. Evaporation of the solvent gave crude crystals, 32 mg (94%). The crude material was dissolved in benzene and passed through a thin layer of alumina. The crystals obtained by evaporating the filtrate were recrystallized from benzene to yield pure I_1 as colorless leaflets, mp 253—254°C (lit, mp 243—244°C[14]).

Found: C, 94.68; H, 5.44%. Calcd for $C_{26}H_{18}$: C, 94.51; H, 5.49%.

2-Fluorenylmethyltriphenylphosphonium Bromide (XXV'). According to the same procedure as that for XXV, 2-bromomethylfluorene[15] (XXIV', 3.5 g, 0.0134 mol) was converted into phosphonium bromide (XXV', 6.0 g, 87%). The phosphonium bromide (XXV') was recrystallized twice from ethanol - acetone (1:1). The crystals were dried at *ca.* 115°C for 48 hr under reduced pressure to give pure XXV', mp 252—256°C.

Found: C, 73.31; H, 4.99; Br, 15.57%. Calcd for $C_{32}H_{26}BrP$: C, 73.72; H, 5.03; Br, 15.32%.

Preparation of Betaine (XXVIII'). The same procedure as that used for XXVIII was employed. The reaction of phosphonium bromide (XXV', 2.34 g) and acid chloride [from 2-fluorenylcarboxylic acid[16] (0.42 g)] gave the betaine

(XXVIII') in a yield of 87% (1.10 g). The material was recrystallized twice from benzene-cyclohexane to give pure XXVIII' as pale yellow cubes, mp 268—270°C.

Found: C, 87.29; H, 5.45%. Calcd for $C_{46}H_{33}OP$: C, 87.33; H, 5.26%.

2,2'-Difluorenylacetylene (II_1). Pyrolysis of betaine (XXVIII', 192 mg, 0.303 mmol) was performed at 230°C under reduced pressure (*ca.* 20 mmHg). Foaming was observed at *ca.* 220°C. The product was extracted with benzene. The extract was concentrated and passed through a short column of alumina. The crystals, 82 mg (77%) obtained by evaporating the filtrate were recrystallized from benzene affording pure II_1 as colorless rods which decomposed at *ca.* 295°C.

Found: C, 94.50; H, 5.17%. Calcd for $C_{28}H_{18}$: C, 94.88; H, 5.12%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 891—894(1972)

Molecular Orbital Treatment of *Para* Orientation in the Diels-Alder Reactions of 2-Substituted Butadienes with Methyl Acrylate[1]

Takashi INUKAI,[2] Hideo SATO, and Takeshi KOJIMA

The Central Research Laboratories, Chisso Corporation, Kamariya, Kanazawa-ku, Yokohama

(Received August 12, 1971)

The intermolecular orbital method was applied to the orientation phenomena in the Diels-Alder reactions of 2-R-butadienes (R=Me, Ph, Cl, and CN) with methyl acrylate assuming the parallel biplanar transition state geometries. Although qualitatively correct predictions of *para* orientation (major isomer) were obtained with the calculated overlap energies, it is suggested that the non-bonding interactions are overestimated. The simple perturbational molecular orbital method, which takes only the interactions at the terminal positions into account, was also unsatisfactory. However, frontier orbital interactions provided qualitatively correct prediction of the major isomeric product in every case.

The general *ortho/para* orientation in the Diels-Alder reactions between unsymmetrical dienes and dienophiles is questionable with regard to its rationalization in terms of organic electronic theory.[3,4] The experimental vindication of the orientation rule was ill-founded.[3] We recently determined the kinetically controlled isomer ratios of the adducts from 1-Me-, 2-Me-, 2-Ph-, 2-Cl-, 2-CN-, and 2-CF_3-butadienes with methyl acrylate.[5] We are satisfied that the enigmatic orientation rule was qualitatively correct and this led us to seek an explanation.

Since the multicenter mechanism of the Diels-Alder reactions is generally accepted, we have to take into account a number of electronic interactions contributing to the energies of the transition states in order to make a reasonable prediction of the orientation. The relative importance of these contributing factors may not be estimated by the qualitative argument of organic electronic theory. Thus the present problem requires an estimate of various contributing factors by computation.

Feuer *et al.*[4] used a perturbational molecular orbital method (PMO) with considerable success, but their dienes were limited to methyl and phenyl substituted butadienes. For explaining the *ortho/para* orientation by electron-releasing substituents alone, the electronic theory is sufficient.[6] But the real difficulty with this theory lies in rationalizing the same *ortho/para* orientation also by the substituents of opposite polarity. Therefore, in order to know whether the PMO treatment gives a satisfactory solution of the problem or not, the cases with electron-releasing substituents and electron-withdrawing substituents must be studied by application of the PMO method. In this article we describe the results of some attempts of explanation of the orientation phenomena[7] in the Diels-Alder reactions of methyl acrylate with 2-substituted butadienes using the intermolecular orbital (IMO)[8] and the PMO methods.

Method

In the first part of the study the interaction energies $\Delta E_{\text{overlap}}$ of multicenter [4+2] transition states were calculated by the IMO method with the formula,[9]

$$\Delta E_{\text{overlap}} = -\sum_{rr'}(q_r+q_{r'})\gamma_{rr'}S_{rr'} - 2\sum_{j}^{\text{occ}}\sum_{k'}^{\text{vac}}\left(\sum_{rr'}C_{jr}C_{k'r'}\gamma_{rr'}\right)^2/(E_{k'}-E_j) - 2\sum_{k}^{\text{vac}}\sum_{j'}^{\text{occ}}\left(\sum_{rr'}C_{kr}C_{j'r'}\gamma_{rr'}\right)^2/(E_k-E_{j'}) \quad (1)$$

1) Presented in part at the IUPAC Symposium "Cycloaddition Reactions," Munich, Germany, September 9, 1970.

6) For example, J. S. Meek, B. T. Poon, R. T. Merrow, and S. J. Cristol, *J. Amer. Chem. Soc.*, **74**, 2669 (1952).

7) The term *orientation* in this article is used to mean the choice of the major isomeric product.

8) J. Salem, *J. Amer. Chem. Soc.*, **90**, 543 (1968).

9) See Reference 8 for the definition of various symbols.

The first summation denotes the repulsion between π-electron shells of a diene and dienophile. The second summation (hereafter called term 2) denotes the stabilization due to delocalization of π-electrons of a diene to the vacant orbitals of a dienophile, and the third summation (term 3) that due to delocalization of π-electrons of a dienophile to the vacant orbitals of a diene. The unprimed and primed suffixes refer to a diene and dienophile, respectively. The wave functions and energy values for the isolated reactants were calculated by the simple Hückel method. The Hückel parameters used are listed in Table 1. Further parametrization employed is

$$\gamma_{rr'}/S_{rr'} = 3\beta \text{ (for all } r \text{ and } r')^{8)}$$

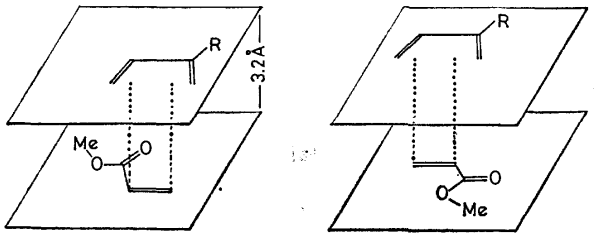
where β is the standard resonance integral of benzene.

TABLE 1. HÜCKEL PARAMETERS USED[a)]

Coulomb parameter, $h(X)$		Resonance parameter, $k_{x-x'}$	
h(Ċ)	0	C—C	S/S_0
h(Ȯ)	1.5	C—O, carbonyl	0.85
h(Ö)	2.0	C—O, ether	0.6
h(Ṅ)	0.5	O—Me	0.3
h(C̈l)	2.0	C—N, nitrile	1.19
h(M̈e)	2.0[b)]	C—Cl	0.37
		C—Me	0.7[b)]

a) $\alpha_x = \alpha_c + h(X)\beta$; $\beta_{x-x'} = k_{x-x'}\beta$.
b) The heteroatom model of methyl group.

The geometries of the reactant molecules were assumed to be planar and constructed from the probable bond angles and lengths.[10)] The transition state model were constructed by putting the reactants in parallel planes at 3.2 Å distance;[11,12)] there are eight transition state geometries corresponding to possibilities of *para* and *meta* orientation, *endo* and *exo* stereochemistry, and cisoid and transoid conformation of C=C–C=O moiety of methyl acrylate—only two of these are illustrated in Fig. 1.



A B

Fig. 1. Transition State Models. A, *para*, *endo*, cisoid; B, *meta*, *exo*, transoid.

The required overlap integrals $S_{rr'}$ were calculated by

$$S_{rr'} = S_{rr'}(\sigma\sigma)\cos^2\theta_{rr'} - S_{rr'}(\pi\pi)\sin^2\theta_{rr'} \quad (2)$$

where $\theta_{rr'}$ is the angle between the interatomic line and the normal on the molecular plane (Fig. 2). $S_{rr'}(\sigma\sigma)$ and $S_{rr'}(\pi\pi)$ are known through the extensive tables by Mulliken *et al.*[13,14)]

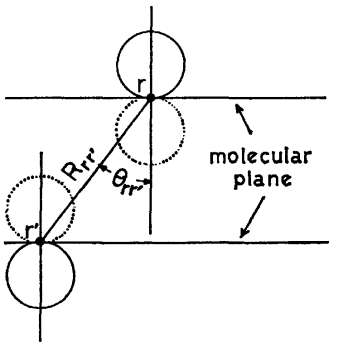


Fig. 2.

Calculation of $\Delta E_{\text{overlap}}$ was performed using a computer program which reads seqular determinants for a pair of isolated reactant molecules and the appropriate overlap matrix ($(S_{rr'})$) for each transition state geometry, and gives the desired energy terms of Eq. 1.

In the second half of the study the same simplest PMO method as that used by previous workers was used.[4)] Thus the perturbational energies, E_p, for the four-center transition states were calculated considering only the terminal interactions, *i.e.*, those between the two pairs of atoms at which σ-bonds will close (Eq. 3).[15)] The Hückel parameters used are those listed in Table 1.

$$E_p = 2[\sum_m^{occ}\sum_n^{vac} - \sum_m^{vac}\sum_n^{occ}](a_{mr}b_{ns} + a_{mu}b_{nv})^2\gamma^2/(E_m - E_n) \quad (3)$$

Results and Discussion

The results by the IMO method for *endo* addition of the cisoid methyl acrylate are shown in Table 2. The main features of interest are:

1) $\Delta E_{\text{overlap}}$ gives correct predictions of *para* orientation by all the substituents.

2) The delocalization energy, namely term 2 plus term 3 of eq 1, indicates *meta* orientation by Ph and CN groups and practically null selectivity in the cases of Me and Cl. It is the repulsion term that makes $\Delta E_{\text{overlap}}$ turn out to be *para* directing.

3) The calculations of the delocalization energy taking only the frontier orbitals into account lead to correct orientation in all cases.

10) Butadiene skeleton [A. Almenningen *et al.*, *Acta Chim. Scand.*, **12**, 1221 (1958)] was assumed to be maintained in all the 2-substituted butadienes. Bond lengths between $C_{(2)}$ (butadiene) and substituent atoms are: $C_{(2)}$—C_{methyl}, 1.50 Å; $C_{(2)}$—C_{phenyl}, 1.46 Å $C_{(2)}$—Cl, 1.70 Å; $C_{(2)}$—C_{cyano}, 1.44 Å, $R_{C\equiv N}$, 1.16 Å. Based on the three-dimensional structure of methyl acrylate [T. Ukaji, This Bulletin, **32**, 1275 (1959)], the following flat structure was assumed: $C_{(1)}=C_{(2)}$, 1.36 Å; $C_{(2)}$—$C_{(3)}$, 1.44 Å; $C_{(3)}$—$O_{(4)}$, 1.36 Å; $O_{(4)}$—$C_{(5)methyl}$, 1.46 Å; $C_{(3)}=O_{(6)}$, 1.22 Å; $\angle C_{(1)}C_{(2)}C_{(3)}$, 120°; $\angle C_{(2)}C_{(3)}O_{(4)}$, 125°; $\angle C_{(2)}C_{(3)}O_{(6)}$, 120°; $\angle C_{(3)}O_{(4)}C_{(5)}$, 115°.

11) W. C. Herndon and L. H. Hall, *Theor. Chim. Acta*, **7**, 4 (1967).

12) P. Markov and P. N. Skancke, *Acta. Chim. Scand.*, **23**, 1295 (1969).

13) R. S. Mulliken, C. A. Rieke, D. Orloff, and H. Orloff, *J. Chem. Phys.*, **17**, 1248 (1949).

14) Those unavailable in the tables were calculated using the appropriate master formula (Reference 13) with the aid of the numerical values of $A_k(p)$, $B_k(pt)$ integrals given by Kotani *et al.* [M. Kotani, A. Amemiya, E. Ishiguro, and T. Kimura, "Tables of Molecular Integrals," Maruzen Co., Ltd, Tokyo (1963)].

15) See Reference 4 for the definition of various symbols.

Table 2. Interaction energies (in units of β) by IMO method for reactions of 2-substituted butadienes with cisoid methyl acrylate by *endo* mechanism

Substituent		Repulsion	Delocalization	$\Delta E_{overlap}$	$\Delta E_{frontier}$ [a]

	meta	−0.0212	0.0151	−0.0061	0.0110 (0.0090)

a) See Table 2, footnote a.

4) These statements are qualitatively valid also when the transoid conformation of methyl acrylate is assumed.

Similar results for *exo* addition of the cisoid methyl acrylate are listed in Table 3. In this case both the $\Delta E_{overlap}$ and delocalization energy predict preferred formation of *meta* isomer for Ph and CN, in disagreement with experimental facts.[5] The discrepancies are reasonable since the *exo* geometry is evidently improbable in view of the general *endo* rule of the Diels-Alder reactions.[3,16] Similar results are obtained for the transoid methyl acrylate *endo* addition.

16) J. G. Martin and R. K. Hill, *Chem. Rev.*, **61**, 537 (1961).

The above apparent success with $\Delta E_{overlap}$ for *endo* is only superficial, however, as is evident if we compare the results of *endo* (Table 2) and *exo* (Table 3) mechanism. Thus the $\Delta E_{overlap}$ values for the *endo* mechanism are greater (higher $\Delta H^{\neq}$) than the corresponding values for the *exo* mechanism: this erroneous prediction of general predilection for the *exo* addition comes from the excessively large repulsion energy calculated for the *endo* transition state model as shown by exact figures (Tables 2 and 3).

Inclusion of the classical Coulomb potential ΔE_{polar} given by Eq. 4[17] does not give improved results. According to the results (Table 4), 2-Ph- and 2-CN-

$$\Delta E_{polar} = \sum_{r}\sum_{r'} \Delta q_r \Delta q_{r'} / R_{rr'}$$

$$\Delta E = \Delta E_{overlap} + \Delta E_{polar} \quad (4)$$

butadienes should react by the *exo* mechanism in disagreement with Alder's *endo* rule.

Appropriateness of the value of the interplanar distance (3.2 Å) assumed in the present study is questionable. Furthermore, the assumption of a parallel biplanar transition state is debatable although it has usually been made.[11,12,18] Since it is known experimentally that the *endo* mechanism only slightly exceeds the *exo* generally in the Diels-Alder reactions of acyclic dienes,[19] the non-bonding interactions might not be strong enough to pull the reactants close together into

Table 4. Comparison of ΔE^{a} (Eq. 4) for *endo* and *exo* addition of cisoid methyl acrylate

a near parallel *endo* geometry, making a more open geometry likelier.[20] Our present calculation, therefore, might have overestimated the non-bonding interactions. To make matters worse, the calculated orientation is influenced by the delicate balance of counteracting factors.

An alternative approach is to neglect the non-bonding interactions altogether and see whether qualitatively

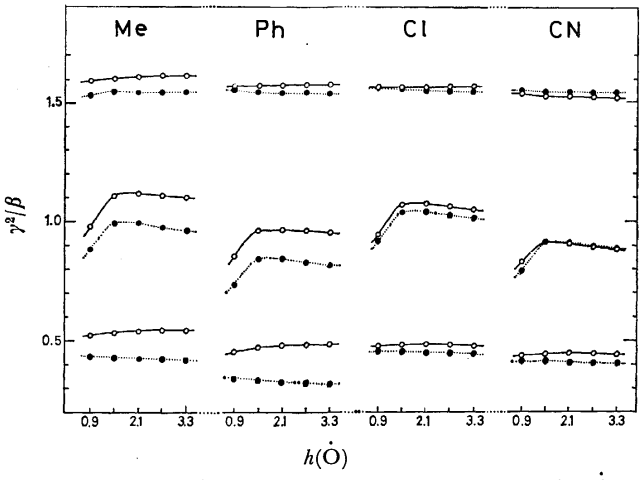

Fig. 3. Perturbation Energy Terms as Functions of $h(\dot{O})$. Upper Curves, Ep; Middle Curves, $E_{frontier}$; Bottom Curves, Highest Occupied MO (Diene)—Lowest Vacant MO (Dienophile). —○— *Para*, ···●··· *Meta*.

20) *Endo* dimerization of cyclopentadiene could be explained by considering only the interactions at the terminal positions when an interplanar angle of 60° was assumed for the *endo* transition state: W. C. Herndon and L. H. Hall, *Tetrahedron Lett.*, **1967**, 3095.

correct predictions can be obtained.[4] The perturbation energies E_p by the PMO method are shown in Table 5. The preferred orientation is predicted correctly in Me, Ph, and Cl cases, but not in the CN case. Thus the claim for successful rationalization of the orientation rule resulted from the hasty conclusion arising from incomplete analysis of the problem.[4]

The frontier orbital interactions, however, agree with the experimental orientation in all the cases, and the delocalization energy corresponding to the highest occupied MO(diene)→lowest vacant MO(dienophile) plays a decisive role in conducing to correct predictions.

Variation of the Coulomb parameter h(Ȯ) of the dienophile from 0.9 to 3.3, far beyond the reasonable range for methyl acrylate itself, did not alter the orientations in terms of both the E_p and $E_{frontier}$ as shown in Fig. 3. This is in line with the fact that the *ortho/para* orientation rule holds over a wide range of dienophile polarity.[3,5,19,21]

It may be appropriate to emphasize the importance of the frontier orbitals in determining reactivity.[22] Their role was undervalued[4] because of the fact that $E_{frontier}$ constitutes only a moderate fraction of total E_p. This reasoning is not convincing, because the most easily perturbed highest occupied MO will play a greater role, in the real transition state, than that allotted to it by the perturbational calculation as Fukui and Fujimoto discussed in general terms.[23] Therefore, unless one treats the transition state more realistically, including the hybridization change *etc.* of the reactants, the full term calculation may turn out to be less accurate, in spite of its formal preciseness, than the frontier orbital method. In fact attention to the frontier orbital interactions alone rather than the full term value was found to be a more judicious choice at least for predictive purposes. Furthermore, the diene→dienophile delocalization part of $E_{frontier}$ plays a decisive role in giving right predictions (Table 5 and Table 2).

The Palladium-catalyzed Ferrocenylation of Olefins

Akira KASAHARA, Taeko IZUMI, Genji SAITO, Minoru YODONO, Ryu-ichi SAITO, and Yoshiaki GOTO

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa-shi, Yamagata

(Received September 6, 1971)

Ferrocenylpalladium chloride, prepared *in situ* from chloromercuriferrocene and lithium chloropalladite, reacts readily with various olefins to produce alkenylferrocene derivatives. Enol esters and allylic alcohols also react to form (2-oxoalkyl)- and (3-oxoalkyl)-ferrocene derivatives. The synthesis of 1,1′-dialkenylferrocene derivatives from 1,1′-bis(chloromercuri)ferrocene, olefins and palladium salt is also reported. The reaction may proceed by means of a catalytic amount of the metal salt and by the aid of cupric chloride; it provides an extremely convenient method for the synthesis of a wide variety of ferrocene derivatives.

The reactions of olefins in the presence of transition metal compounds have been studied by many workers.[1] Recently, Heck[2] reported that the arylation of unsaturated compounds with Group VIII metal-aryl complexes has proved to be a generally applicable reaction. Several new useful synthetic organic reactions are based upon this arylation: olefinic arylation,[2a,g] aromatic haloethylation,[2c] aromatic allylation,[2e] and the synthesis of aldehydes or ketones with an aryl substituent on the α- or β- position by the arylation of allylic alcohols or enol esters.[2b,d] For example, "phenylpalladium chloride," prepared from phenylmercuric chloride and a palladium salt *in site*, reacts with ethylene to form styrene, hydrogen chloride, and palladium metal:

$$C_6H_5HgCl + PdCl_2 \rightleftarrows [C_6H_5PdCl] + HgCl_2$$

$$[C_6H_5PdCl] + CH_2{=}CH_2 \longrightarrow C_6H_5CH{=}CH_2 + HCl + Pd$$

We have now found that, when Heck's reaction is carried out with ferrocenylpalladium salt prepared *in situ* from chloromercuriferrocene and a palladium salt the ferrocenyl group is introduced into the olefinic system.

Results and Discussion

In the presence of palladium salt, chloromercuriferrocene (**1**) was allowed to react with various olefins in polar solvents, such as methanol, ethanol, acetone, acetic acid, and acetonitrile. As with Heck's olefin arylation, the substitution reaction on the double bond has been observed to lead to the formation of 1-alkenylferrocenes, accompanied by a small amount of biferrocenyl (**2**). Moreover, 1,1′-bis(chloromercuri)ferrocene (**3**) reacts with olefins and palladium catalyst to form 1,1′-di(1-alkenyl)ferrocenes (**4**), accompanied by a small amount of bi-1,1′-ferrocenylene (**5**). The reactions carried out are summarized in Table 1. The properties of the products are given in Table 2.

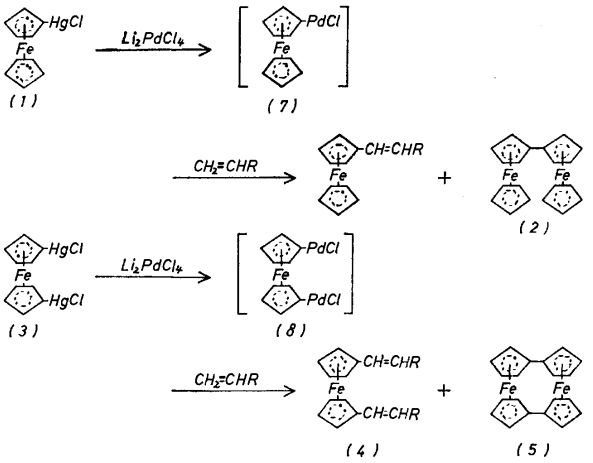

Fig. 1.

Furthermore, it was found that the reactions are generally initiated by a catalytic amount of palladium salt when cupric chloride is added to the reaction system. The latter has been to reoxidize the reduced palladium to the reactive Pd(II) form. Examples of catalytic ferrocenylation are given in Table 3.

The ferrocenylation of simple olefins, such as ethylene, styrene, and ethyl acrylate, resulted in the formation of vinylferrocene, styrylferrocene, and ethyl 3-ferrocenylacrylate respectively in moderate yields, accompanied by a small amount of **2**. In the olefinic palladium salt (**6**) from arylmercuric chloride and palladium salt, followed by the addition of **6** to the olefinic double bond and then the elimination of the hydride ion with palladium.

$$ArHgCl + PdCl_2 \rightleftarrows \underset{(6)}{[ArPdCl]} + HgCl_2$$

$$[ArPdCl] + CH_2{=}CH{-}R \longrightarrow \left[\begin{array}{l} \quad PdCl \\ Ar{-}CH_2{-}\overset{|}{C}H{-}R \end{array}\right] \longrightarrow Ar{-}CH{=}CH{-}R + Pd + HCl$$

a) Yields are based upon the ferrocenylating agent used.

In the reactions of olefins with **1** and palladium salt, a δ-bonded ferrocenylpalladium compound (**7**) will function as the ferrocenylation agent, just as arylpalladium salt (**6**) in Heck's arylation reaction. The formation of **2** probably results from a coupling reaction of **7** or from a reaction of **7** with **1**. Similarly, the reactions of olefins with **3** and palladium salt may involve the formation of 1,1'-bis(chloropalladium)ferrocene (**8**) and the mechanism of the formation of **5** as a by-product involves a coupling reaction of **8** or a reaction of **8** with **3**.

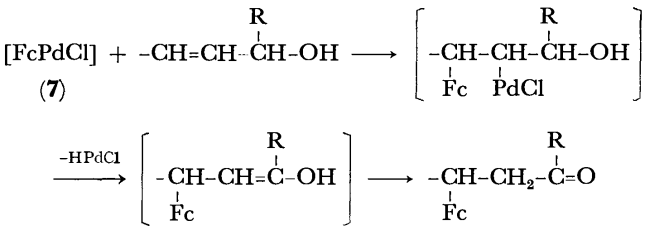
$$\underset{(\mathbf{1})}{FcHgCl} + PdCl_2 \rightleftharpoons \underset{(\mathbf{7})}{[FcPdCl]} + HgCl$$

$$2\underset{(\mathbf{7})}{[FcPdCl]} \longrightarrow \underset{(\mathbf{2})}{Fc\text{-}Fc} + PdCl_2 + Pd$$

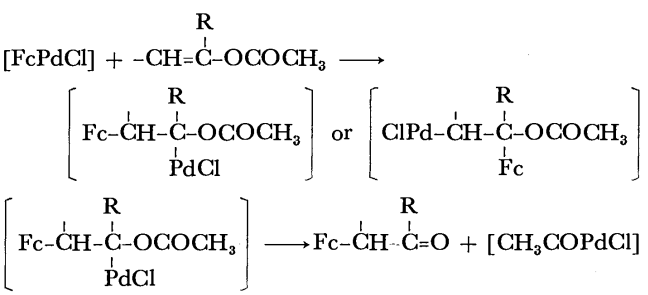
$$\underset{(\mathbf{7})}{[FcPdCl]} + \underset{(\mathbf{1})}{FcHgCl} \longrightarrow \underset{(\mathbf{2})}{Fc\text{-}Fc} + HgCl_2 + Pd$$

The ferrocenylation of allylic alcohols led to the formation aldehydes or ketones with a ferrocenyl substituent at the β-position. For example, 2-methyl-2-propenol, 5-phenyl-2-cyclohexenol, and 5,5-dimethyl-2-cyclohexenol reacted with **1** in the presence of palladium salt to produce 2-methyl-3-ferrocenylpropionaldehyde, 3-ferrocenyl-5-phenylcyclohexanone, and 3-ferrocenyl-5,

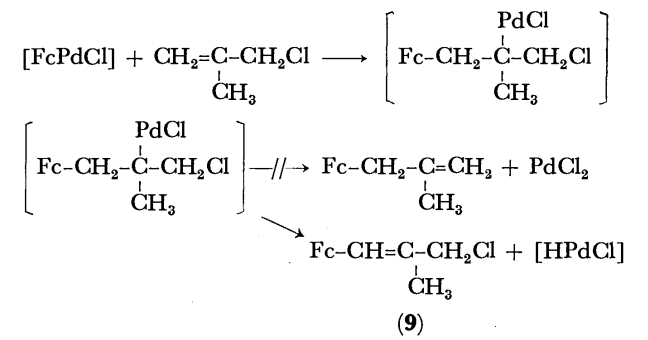
5-dimethylcyclohexanone respectively. These result suggest that the mechanism of the ferrocenylation of allylic alcohol involves the addition of **7** to the allylic double bond, and then hydride elimination from the hydroxylsubstituted carbon:



In addition, isopropenyl acetate and acetophenone enol acetate reacted with **1** and palladium salt to yield α-ferrocenylacetone and α-ferrocenylacetophenone respectively. These results suggest that the mechanism of the ferrocenylation of the enol ester involves an addition-elimination sequence; the addition of the ferrocenyl group preferentially occurs on the less substituted carbon atom, followed by the elimination of palladium with an acyl group to produce a carbonyl compound:



Heck[2c] reported that the reaction of arylpalladium salts with allylic halides produces the allylated aromatic compounds. For example, phenylpalladium salts react with allyl chloride and 2-methylallyl chloride to produce allylbenzene and (2-methylallyl)benzene respectively. He also suggested that this allylation reaction involves the addition of the arylpalladium chloride to the allylic double bond and the elimination of palladium chloride rather than of palladium hydride chloride. However, the reaction of **1** with 2-methylallyl chloride led to the formation of 3-chloro-1-ferrocenyl-2-methylpropene (**9**). This result suggests that the mechanism of the formation of **9** involves the elimination of palladium with a neighboring hydrogen rather than with chlorine.



(**9**)

Experimental

Analysis and Materials. All the melting points are uncorrected. The IR spectra were measured on KBr disks with a Hitachi EPI-S2 spectrometer, and the NMR spectra were obtained by means of a Hitachi H-60 spectrometer in $CDCl_3$, using tetramethylsilane as the internal standard.

Chloromercuriferrocene (**1**) and 1,1′-bis(chloromercuri) ferrocene (**3**) were prepared according to the method described by Fish and Rosenblum.[3] 3-Buten-2-ol,[4] phenyl vinyl ketone,[5] and acetophenone enol acetate[6] were synthesized according to known procedures. 5-Phenyl-2-cyclohexenol and 5,5-dimethyl-2-cyclohexenol were synthesized by the lithium-auminum-hydride reduction of 5-phenyl-2-cyclohexenone and 5,5-dimethyl-2-cyclohexenone respectively. The other olefins were of a commercial grade and were purified before use.

General Procedure for the Ferrocenylation of Olefins. Lithium chloropalladite solutions were prepared by stirring 0.84 g (20 mmol) of anhydrous lithium chloride and 1.77 g (10 mmol) of anhydrous palladium chloride overnight at room temperature in 100 m*l* of the respective solvent expect in the case of acetonitrile, where 10 mmol instead of 20 mmol of lithium chloride was used. To this lithium chloropalladite solution, except in the reaction with ethylene, a mixture of 4.20 g (10 mmol) of **1** and four times as much olefin was added, after which the mixture was stirred at room temperature for 12 hr. In the case of the reaction with ethylene, ethylene was bubbled into the reaction mixture under atmospheric pressure. The products were isolated by filtration to remove any precipitated palladium and by distillation under reduced pressure to remove the solvent. The residue was dissolved in benzene; chromatograph on alnmina afforded yellow crystals (mp 228—229°C, 2.12% yields) which were identified as biferrocenyl (**2**)[7] by a comparison of the IR spectra and by a mixed-melting-point determination. Further elution with benzene and recrystallization from methanol, ethanol, or benzene-cyclohexane afforded the respective ferrocenylation product. The structures of the products were confirmed by a mixed-melting-point determinations with an authentic sample and by observation of the IR and NMR spectra. The results are summarized in Table 1, while the analytical results and the properties of the products are listed in Table 2.

In the reactions with **3**, 3.28 g (5 mmol) of **3** and four times olefin as much were added to a lithium chloropalladite solution prepared from 0.84 g of lithium chloride and 1.77 g of palladium chloride; the reactions were then carried out in the manner described above. The crude product was dissolved in benzene and chromatographed on alumina. First, elution with benzene afforded deep yellow crystals (mp 370°C), which were identical as bi-1,1′-ferrocenylene (**5**)[8] by a comparison of the IR and NMR spectra with those of an authentic sample. Further elution with benzene or chloroform afforded 1,1′-divinylferrocene derivatives (**4**). The structures of the products were confirmed by a mixed-melting-point determination with an authentic sample and by observation of the IR and NMR spectra. The results and the

Spectroscopic Studies on the Tautomers of Heptane-2,4,6-trione and Its Methylated Homologues[1]

Fumio SAGARA, Hiroshi KOBAYASHI, and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received September 6, 1971)

3,5-Dimethylheptane-2,4,6-trione and 3-methylheptane-2,4,6-trione are synthesized by methylationheptane of-2,4,6-trione *via* alkali metal enolates or an enamine intermediate of the mother compound. In keto-enol tautomerism, the latter two compounds take triketo-, monoenol-, and bisenol forms, while the first one exists in triketo- and monoenol forms, being unable to take a bisenol form. NMR spectra of the tautomers are assigned by combining with IR data. *Keto-enol* ratio in a range of solution phases at various temperatures are estimated by NMR method and effect of the branched methyl groups upon the keto-enol tautomerism is discussed.

A β,δ-tricarbonyl compound is a higher analogue of a β-dicarbonyl compound, and can take triketo-, monoenol- or bisenol forms in its tautomeric equilibrium. Accordingly, the tricarbonyl compound can behave as a bidentate- or terdentate ligand to form a metal chelate complex.

In the course of studies on chelating behavior of some β,δ-tricarbonyl compounds,[2] we were interested in their keto-enol tautomerism in relation to positions of the coordinating sites in the respective ligand molecules, especially in unsymmetric ones.

Tautomerism of compounds of this kind in aqueous media[3] have been studied extensively and recently NMR studies in a range of organic solvents were also reported.[4]

In this paper, we present synthesis and spectroscopic studies on keto-enol tautomerism of three triones; heptane-2,4,6-trione(H_2daa),[5] 3-methylheptane-2,4,6-trione (H_2mmd) and 3,5-dimethylheptane-2,4,6-trione (H_2dmd) in various phases by means of IR and NMR methods.

Results and Discussion

(1) Tautomeric Structures in Crystalline Phases. IR spectrum of H_2daa in a crystalline phase is somewhat different from those of crystalline H_2mmd and H_2dmd despite close similarity in their tricarbonyl skeletons. A band diffused over 3400 to 2200 cm^{-1}, combined together with a broad absorption at 1650 cm^{-1}, indicated the presence of a *cis*-β-ketoenol system with strong intramolecular hydrogen-bonding in crystalline H_2daa, while H_2mmd and H_2dmd exhibit an additional strong peak at 3400 cm^{-1}, which was apparently ascribable to intermolecularly hydrogen-bonded enolic hydroxyl groups in such a condensed phase. Presence of free keto groups is unlikely in the crystalline phases of the three tricarbonyl compounds, since such a keto group, if being present, would display an additional sharp ab-

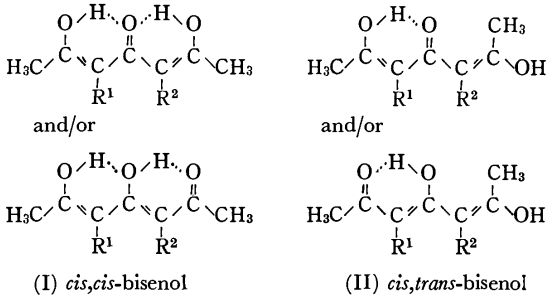

Fig. 1. Possible bisenol structures of the triketones in crystalline phases.

5) Abbreviation, H_2daa, comes from *dia*cetyl*a*cetone, and prefixed H_2 shows that the trione contains two dissociable enol protons upon metal-chelate formation, according to usage in coordination chemistry. H_2mmd and H_2dmd correspondingly symbolize the *mono*methyl- and *di*methyl-*d*aa, both prefixed also with H_2 meaning two dissociable protons. Though the prefix, H_2, is no use as far as the present paper is concerned, we feel it more convenient to use consistent symbols with subsequent reports on various metal chelates of the ligands.

sorption near 1710 cm^{-1} as observed in oily H_2mmd or in molten H_2daa.

Above observations in IR absorptions lead reasonably to a presumption that a *cis,cis*-bisenol form with cyclic intramolecular hydrogen-bondings is a major component among the H_2daa tautomers, while a *cis,-trans*-bisenol form is predominant regarding H_2mmd and H_2dmd in their crystalline phases as shown in Fig. 1. The present spectral evidences, however, do not distinguish which two of the three carbonyl groups enolize in the bisenols of crystalline phases, two possible forms in respect to enol positions being equally probable, and neither suggest the detailed stereochemistry of the *cis,trans*-bisenol, which is remained to be elucidated. In any case, the introduction of additional methyl groups at the interposition between carbonyl groups does not favor the formation of *cis, cis*-bisenol tautomer with cyclic intramolecular hydrogen-bondings.

Table 1. NMR spectra of H_2daa (c=1.0M) at 38°C

Assignment	Chemical shifts δ(ppm) in solvent			
	Methanol	$CDCl_3$	CCl_4	Benzene
Bisenol CH_3	1.97	1.97	1.94	1.63
C=C–H	—	5.12	5.02	4.88
Monoenol				
CH_3 (enol side)	2.05	2.07	2.04	1.63
CH_3 (keto side)	2.19	2.23	2.19	1.82
CH_2	—	3.38	3.27	2.97
C=C–H	—	5.53	5.45	5.15
Triketo CH_3	—	2.23	2.19	1.73
CH_2	—	3.67	3.57	3.20
Enol OH		14.10[a]	14.20[a]	14.53
Bisenol fraction (mol %)	18[b]	21	54	57

a) A diffused enol proton signal at room temperature is splitted into two signals at 14.05 and 15.13 ppm at −41°C in $CDCl_3$, and 13.83 amd 15.00 ppm at −21°C in CCl_4, respectively. The sharp peak at a higher field being assigned to that of bisenol and the broad one at a lower field to that of monoenol.

b) Value determined from the respective methyl signal intensities.

(2) Tautomeric Structures in Solution Phases. (2-a) Tautomerism of H_2daa: Table 1 summarizes the NMR spectra of H_2daa in various solvents, including the assignments of signals and bisenol content in solution phases. The assignments are virtually in agreement with those reported by the previous workers[4] except the assignment of the enolic hydroxyl protons. Since the intramolecular hydrogen-bonding in the monoenol would be stronger than those in the bisenol in which two enol protons are chelated to the common central carbonyl oxygen, enol protons in the *cis,cis*-bisenol are conceivably much more shielded than that of the monoenol, and correspondingly the former signal would appear in a higher field than the latter one. Although the conclusion being different from the assignment, by Marcus *et al.*,[4b] this reasoning is confirmed by comparisons of relative intensities of enol protons of the tautomers in H_2daa, and in H_2mmd of variable temperature NMR measurements, which are described below,

Table 2. *Keto-enol* ratio of H_2daa at various temperatures (c=1.0M)

Temp. (°C)	Monoenol (%)	Bisenol (%)	Triketo (%)
	in $CDCl_3$		
48	74	17	9
36	73	21	6
5	68	27	5
−41	68	25	5
	in CCl_4		
56	54	43	3
36	45	54	2
5	36	62	2

especially at lower temperatures. Presence of a monoenol form in the solution phases is consistently indicated in IR spectra which show a sharp intense peak at 1720 cm^{-1}.

Table 2 shows the temperature dependence of keto-enol equilibrium of H_2daa in solution phases, indicating that a higher temperature favors the monoenol form among the tautomeric isomers. This tendency is consistent with the fact that both molten H_2daa and H_2mmd at an elevated temperature reveal a free carbonyl band at 1720 cm^{-1}. Fraction of the triketo form, though being minor, also increases with the elevation of temperature.

On the other hand, as shown in Table 1, bisenol content of H_2daa increases with decrease in polarity of the solvent used. This tendency, being in good agreement with those observed in related pentane-2,4-diones, indicates highly polar character of keto form than an enol form with intramolecular hydrogen-bonding.[6]

(dipivaloylmethane)		benzyl-	16.7[a]

a) Private communication from Prof. Y. Murakami.

The NMR signal of a monoenol proton of H_2dmd appears as a sharp peak at a lower field by 1 ppm as compared with that of H_2daa. Comparisons of chemical shifts of enol protons in some β-dicarbonyl compounds as shown in Table 5, indicate that introduction of an alkyl group to the central carbon causes a deshielding effect upon an enolic hydroxyl signal by about 1 ppm and gives a narrower peak, whereas substitution on side carbons, except with *t*-butyl group does not very much affect the chemical shift, remaining as a broad signal. The deshielding effect observed here is conceivably due to increased hydrogen-bonding of the enol proton which becomes closer to the β-carbonyl oxygen by steric repulsion between methyl groups on the both sides and the alkyl group on the central carbon. Enol proton chemical shift of dipivaloylmethane at an exceptionally lower field may be also explained in a similar manner by steric repulsion between the central hydrogen and bulky *t*-butyl groups on the both sides.

These observations on the enol protons lead that two hydroxyl signals observed at 16.00 and 15.10 ppm in H_2mmd can be assigned to two kinds of enol protons, one carrying an additional methyl group and the other not methylated respectively. Correspondingly the hydroxyl signals at 14.85 and 14.25 ppm of the bisenol form of H_2mmd are also assigned to the two kinds of enol protons in a similar manner.

Measurements on H_2dmd in 100 MHz in deuteriochloroform[7] shows the overlapped doublets centered at 1.33 ppm consisting of three doublets separated by about 0.01 ppm. By deuteration of H_2dmd, the doublet signals of the branched methyl protons coalesce respectively into three broad peaks and signals at a lower field than 2.3 ppm disappear. Combined with the

7) Measured with a JNM-PS-100 by courtesy of Mr. A. Kito in the Government Industrial Research Institute, Osaka, to whom the authors are very grateful.

decoupling data, the above results indicate that the missing signals upon deuteration are undoubtedly due to active protons such as an enolic hydroxyl and methine group interposed between two carbonyls and the coalesced signals are those of the methyl groups on the 3- and 5-carbons of H_2dmd. Also the overlapped doublet signals assigned to three kinds of methyl groups, suggest the presence of two diastereomeric triketo forms, one being a *meso*- and another a racemic form, and a monoenol form at the central oxygen, which is not found among monoenol forms of H_2daa and H_2mmd.

Signals assignable to a bisenol form of H_2dmd can not be found in the NMR spectra either in deuteriochloroform nor in carbon tetrachloride. As reported by Kobachinik *et al.*,[6] the methyl group interposed between two carbonyl groups in a β-diketone does not prevent the formation of a *cis*-enol with cyclic intramolecular hydrogen-bonding. Absence of a *cis,cis*-bisenol form in H_2dmd would be, therefore, conceivably due to steric repulsion between two methyl groups on the 3- and 5-carbons of H_2dmd. A study with molecular model shows that the coplanar *cis,cis*-bisenol form is accompanied by a strong steric hindrance due to the overlapping of the two methyl groups as illustrated in Fig. 4.

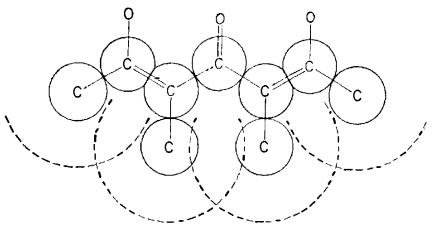

Fig. 4. Coplanar *cis, cis*-bisenol form of H_2dmd, broken semi-circles showing van der Waals radii of the methyl groups.

(2-c) Tautomerism of H_2mmd: H_2mmd in a carbon tetrachloride solution exhibits a widely diffused IR band over the range of 3600 to 2200 cm^{-1}, a sharp absorption at 1720 cm^{-1} and a broad, more intense band from 1650 to 1550 cm^{-1}. In a deuteriochloroform solution the carbonyl band at 1720 cm^{-1} increases in its intensity.

Combined with NMR data, these results indicate that H_2mmd in a solution phase takes in a major portion a *cis*-monoenol as well as a *cis,cis*-bisenol with intramolecular hydrogen-bonding, and that decrease in solvent polarity seemingly favor the *cis,cis*-bisenol form in agreement with a case of H_2daa.

As shown in Table 6, temperature causes substantial effect on the tautomeric composition of H_2mmd in a carbon tetrachloride solution, whereas causing little effect in deuteriochloroform, the keto-enol contents being virtually invariable within the experimental error in so far as a temperature range used (from 55 to 0°C).

Table 6. *Keto-enol* ratio of H_2mmd at various temperatures in mol % (c=0.8M)

Temp. (°C)	Monoenol (A)	Monoenol (B)	Bisenol	Triketo
		in CCl_4		
59	77	8	13	2
36	30	25	46	0
6	13	30	58	0
		in $CDCl_3$		
36	76	9	12	3

(2-d) Tautomerism of H_2dmd: IR spectrum of H_2dmd in deuteriochloroform reveals a prominent hydroxyl band and a free carbonyl band at 3400 and 1720 cm^{-1} respectively, the former absorption indicating evidently the presence of a substantial concentration of a *trans*-enol form. In carbon tetrachloride, the free carbonyl band is splitted into three peaks at 1730, 1715 and 1700 cm^{-1}, which indicate the presence of some configurational isomers in respect to the carbonyl groups.

Consistent with IR data on the hydroxyl group, NMR spectra exhibit a broad signal ascribable to the *trans*-enol proton at 5.90 ppm in deuteriochloroform at −46°C, shifting to a higher field with elevation of temperature as a more sharpened peak, at 3.35 ppm at 46°C. In carbon tetrachloride, the signal appears as a much more diffused band centered at 4.65 and 3.78 ppm at 36 and 55°C respectively.

Table 7. *Keto-enol* ratio of H_2dmd at various temperatures in mol % (c=0.5M)

Temp. (°C)	Side monoenol	Central monoenol	Triketo
		in $CDCl_3$	
50	33	48	19
36	40	45	16
0	51	41	8
		in CCl_4	
56	35	54	11
36	54	30	16

Table 7 shows the temperature dependence of the tautomer content. The presence of a considerable fraction of the triketo form shows a striking contrast to H_2daa and H_2mmd. However, the effect of temperature here seems not so simple as in the other tricarbonyl compounds.

Comparisons of the total enol content of H_2daa, H_2mmd, and H_2dmd suggest that enolizability decreases in the above order and the interposed methyl group seems to hinder enolization. However, the effect of the interposed methyl group seems to be somewhat complicated by combination of both electronic and steric effects. On the other hand, solvents also influence the tautomeric equilibrium in agreement with those observed in β-dicarbonyl compounds, polar solvents favoring the abundance of a keto form and less polar solvents an enol form.

Experimental

Materials. Heptane-2,4,6-trione was prepared according to Bethel and Maitland.[8] Mp 41.0—41.5°C (lit. mp 49°C). Found: C, 58.99; H, 7.27%.

8) J. R. Bethel and P. Maitland, *J. Chem. Soc.*, **1962**, 3751.

3-Methylheptane-2,4,6-trione: (a) Heptane-2,4,6-trione (10.0 g, 0.0703 mol) was dissolved in ethanolic potassium ethoxide which was prepared from absolute ethanol (30 m*l*) and potassium metal (4.10 g, 0.105 mol). After an addition of methyl iodide (80.0 g, 0.563 mol), the solution was kept at 40—50°C for 20 min. The resulting mixture was evaporated under reduced pressure, giving a slurry, which was filtered to remove potassium iodide. A viscous filtrate was dissolved in chloroform (100 m*l*) and treated with an aqueous cupric acetate (14.0 g of the monohydrate in 300 m*l* of water). The resulting blue chloroform solution containing copper complexes was separated by filtration from precipitates, which was mainly the 2:2 (metal ion: ligand) copper complex of H_2daa, being insoluble in chloroform. The filtrate was evaporated to give blue solid, which was dissolved in an aqueous methanol solution of cupric acetate (7.2 g of the monohydrate in 760 m*l* of 10% aq. methanol). The solution, when heated at 50—55°C for 6 hr, gave green precipitates, which, being a 2:2 copper complex of H_2mmd, were collected by filtration and dissolved in 1N hydrochloric acid. Chloroform extract from the above acid solution was evaporated, giving an oil boiling at 45—49°C/5×10^{-3} mmHg. Yield was 3.84 g (35%). Found: C, 61.32; H, 7.92%. Calcd for $C_8H_{12}O_3$: C, 61.52; H, 7.74%. The oil crystallized either spontaneously, but very slowly at room temperature, or from a petroleum ether solution on cooling, to give colorless granular crystals melting at 56.0—56.6°C.

The same compound could be obtained by using sodium or lithium metal in place of potassium in a similar manner as above, but in poorer yields.

In the last methanolic filtrate, there remained the 1:2 complex of H_2dmd, being readily soluble in methanol and not convertible into a form of 2:2 complex.

(b) A mixture of pyrrolidine (10.0 g, 0.141 mol), heptane-2,4,6-trione (20.0 g, 0.141 mol) and ethyl acetate (100 m*l*) was left standing overnight at room temperature. The resulting yellow crystals, which were collected and dried under reduced pressure, were heated with dried methyl iodide (68.4 g, 0.481 mol) under reflux for 24 hr. The resulting solution was evaporated off, giving a semisolid mass which was heated together with water (100 m*l*) at boiling point. The aqueous mixture was extracted with chloroform (50 m*l*). The chloroform extract was shaken with aqueous cupric acetate thoroughly, and a separated chloroform layer was evaporated, giving blue crystalline residue, which was purified by eluting from a silica gel (WAKOGEL Q-23) column with acetonitrile, to give the 1:2 complex of H_2mmd (2.64 g, 20.2%). The free ligand was obtained as described in procedure (a).

The position to which a methyl group was introduced, was confirmed by acid-catalyzed intramolecular condensation of H_2mmd into 2,3,6-trimethyl-γ-pyrone as well as by the following NMR studies on this trione.

3,5-Dimethylheptane-2,4,6-trione: H_2daa (10.0 g, 0.0703 mol) was treated in a similar manner as above, using absolute ethanol (160 m*l*), potassium (8.10 g, 0.210 mol) and methyl iodide (94 g, 0.68 mol). The reaction took 2 hr at 55°C to afford 1.53 g of the 2:2 complex of H_2mmd and 5.8 g of the 1:2 complex of H_2dmd. Decomposition of the H_2dmd complex with 1N hydrochloric acid followed by extraction with chloroform and subsequent evaporation gave colorless oil, which was solidified when treated with petroleum benzine. Recrystallization from a benzene-petroleum benzine (1:1) mixture afforded fibrous needles melting at 81.5—82.5°C. Yield was 2.30 g (19.2%). Bp 105—110°C/4 mmHg. Found: C, 63.23; H, 8.54%. Calcd for $C_9H_{14}O_3$: C, 63.51; H, 8.29%. The methylated positions on the heptanetrione were confirmed by derivation of H_2dmd into 2,3,5,6-tetramethyl-γ-pyrone as well as the NMR studies on this trione.

2,3,6-Trimethyl-γ-pyrone from H_2mmd. A chloroform solution of H_2mmd was heated together with a catalytic amount of 0.1N hydrochloric acid for 5 hr. The resulting solution was evaporated to dryness and solid residue was sublimed. Mp 82.0—84.0°C, yield being 84%. Found: C, 69.58; H, 7.37%. Calcd for $C_8H_{10}O_2$: C, 69.55; H, 7.30%. NMR (1.0M in $CHCl_3$): Four singlets at 1.93 (3H), 2.30 (3H), 2.35 (3H), and 6.64 ppm (1H). IR (Nujol mull): $\nu_{C=O}$ 1675 cm^{-1}.

The structure of the product was characterized by spectral comparisons with 2,6-dimethyl-γ-pyrone[9] (Mp 135.5—137°C. Found: C, 67.47; H, 6.51%. NMR (1.0M in $CHCl_3$): Two singlets at 2.25 (6H) and 6.00 ppm (2H). IR (Nujol mull): $\nu_{C=O}$ 1675 cm^{-1}) and 2,3,5,6-tetramethyl-γ-pyrone[10] (Mp 91.0—92.0°C. Found: C, 70.46; H, 8.06%. NMR (1.0M in $CHCl_3$): Two singlets at 1.92 (6H) and 2.23 ppm (6H). IR (Nujol mull): $\nu_{C=O}$ 1660 cm^{-1}) which were obtained from H_2daa and H_2dmd respectively in a similar manner described above.

Deuteration of H_2dmd. H_2dmd (86 mg) was dissolved in a mixture of methanol-d_4 (328 mg) and heavy water (183 mg). Exchange reaction was traced by NMR measurements immediately after an addition of a drop of pyridine. The reaction was completed in 2 hr at 35°C. The resulting solution was evaporated to dryness under high vacuum (10^{-4} mmHg) at room temperature, to give colorless solid melting at 85—87°C. Treatment with methanol and successive drying afforded the original H_2dmd, which was identified by the infrared spectral comparison.

The β-dicarbonyl compounds quoted in Table 5 were either commercially available or synthesized in our laboratory unless otherwise described.

IR spectra were measured on a JASCO 403-G in both KBr disc and Nujol mull phases for crystalline samples. Of solution phases, the concentrations of samples were prepared so as to be equal to those of NMR samples respectively. NMR spectra were recorded on a Varian A-60 instrument. All chemical shifts from tetramethylsilane were calibrated by use of chloroform proton chemical shift to be 7.27 ppm, both used as internal references. Contents of tautomeric isomers were determined by the least squares calculation from the respective peak areas unless otherwise stated.

The authors are grateful to Messrs. Akira Kito and Isao Yoshida who were engaged in the syntheses of some of the 3-alkyl- and 1,5-dialkylpentane-2,4-diones. The authors also wish to thank the Ministry of Education for a financial support.

The Crystal Structure of 1-Ethyl-5-bromouracil. I. The Crystal Structure of the Form I Crystal of 1-Ethyl-5-bromouracil

Hiroshi MIZUNO, Takaji FUJIWARA, and Ken-ichi TOMITA

Faculty of Pharmaceutical Sciences, Osaka University, Toneyama, Toyonaka, Osaka

(Received September 8, 1971)

1-Ethyl-5-bromouracil, $C_6H_7N_2O_2Br$, is crystallized in two forms. Crystals of the form I are monoclinic with four molecules in a unit cell of dimensions; $a=7.89$, $b=12.01$, $c=9.71$ Å, $\beta=121.0°$, space group $P2_1/c$. Three-dimensional intensity data were collected by diffractometer with Mo-$K\alpha$ radiation. The structure was determined by heavy atom method and refined by the block-diagonal least-squares method. The final R-value was 0.052 for all observed reflections. The molecules are joined together in pairs around a center of symmetry with two N–H···O hydrogen bonds connecting N(3) to carbonyl oxygen O(4), and stacked with the base plane tilted each other.

5-Bromouracil, one of base analogue mutagens, can be incorporated into DNA in place of the normal thymine base. Such an incorporation probably reflects the structural similarity of 5-bromouracil and thymine; the van der Waals radius of bromine atom (1.95 Å) is close to that of methyl group (2.01 Å). In fact, the crystal structure of 1-methyl-5-bromouracil has been found to be isomorphous with that of 1-methylthymine[1] by X-ray study in this laboratory.[2] Once incorporated into DNA, however, the substituted bromine atom may cause to perturb an electron distribution on the pyrimidine ring, since bromine atom has the greater electronegativity than the methyl group. Therefore, this substitution of DNA affects on important biological properties; the increase of the sensitivity to ultraviolet irradiation[3] and the significantly higher melting temperature as compared with that of normal DNA.[4]

The structure analysis of 1-ethyl-5-bromouracil is of great interest in order to examine the influence of bromine atom on the molecular arrangement and the hydrogen bonding. In an earlier report, we described our finding of two forms of 1-ethyl-5-bromouracil, in which the main structural difference between two forms is on the mode of hydrogen bond.[5] In this paper, we describe the precise crystal structure analysis of the form I of 1-ethyl-5-bromouracil.

Experimental

1-Ethyl-5-bromouracil was kindly supplied by Professor A. Rich, M.I.T., U.S.A. and colorless plate-like crystal were obtained by slow evaporation of dimethyl sulfoxide solution. Rotation and Weissenberg photographs around the elongated axis showed the crystals to be monoclinic. The systematic absences for $h0l$ with $l=2n+1$ and for $0k0$ with

$k=2n+1$, indicate the space group to be $P2_1/c$. From measuring the 2θ setting angles for 14 reflections on the diffractometer with Mo-$K\alpha$ radiation, the unit cell dimensions were determined to be $a=7.89$, $b=12.01$, $c=9.71$ Å, and $\beta=121.0°$. The density measured by the flotation method, with a mixture of benzene and ethylene bromide, was 1.84 gcm^{-3}, whereas the calculated density on the assumption of four molecules in the unit cell is 1.84 gcm^{-3}. Three-dimensional intensity data were collected on a full automatic four-circle diffractometer (Rigaku Denki Co. Ltd.) with Zr-filtered Mo-$K\alpha$ radiation. For the intensity measurement, a plate-like crystal with approximate dimensions of $0.12\times0.20\times0.40$ mm was used and the c-axis was mounted as coincident to the ϕ axis of the goniostat. A total of 2244 independent reflections accessible in $\sin\theta/\lambda$ less than 0.65 were scanned by the ω-2θ technique at a scan speed of 4° per minute through the scan range from $\{2\theta(\alpha_1)-0.65°\}$ to $\{2\theta(\alpha_2)+0.65°\}$ for all reflections, in which a value of 0.65° was determined by measuring the scan range for a sufficiently strong and low order reflection. Background counts of five seconds duration were taken at both sides of each peak. In order to correct the intensities for coincidence loss, the counting rate was kept less than 10000 counts per second with an automatic attenuator mechanism. During the data collection, the intensities for three standard reflections (080), (006), and (800) were measured periodically to check the stability of the electronics and the damage on crystal lattice. After 1187 of all reflections, which have the net intensity exceeded three times of its estimated standard deviations, were recorded and corrected for the usual Lorentz and polarization effects, these data were converted to the absolute scale by means of the usual averaging process.

Structure Determination and Refinement

A three-dimensional Patterson function was calculated, and this easily revealed bromine atom position. Since y paprameter of bromine atom is nearly 1/4, however, the first Fourier synthesis phased on the bromine atom position brought about the pseudo mirror plane at $y=1/4$. To avoid such a trouble, the useful two-dimensional (0 1 0) Fourier synthesis was carried out, and all the non-hydrogen atoms except the terminal ethyl carbon could be assigned. Subsequent Fourier synthesis phased on these positions showed the complete structure including the terminal ethyl carbon.

Three-dimensional refinement was then carried out by block-diagonal least-squares method with unit weight factors for all reflections. The positional parameters of all the non-hydrogen atoms and anisotropic thermal parameters of the bromine atom were initially refined to drop R-index ($\Sigma||F_o|-|F_c||/\Sigma|F_o|$) to 0.08. At this stage, a difference Fourier map clearly revealed the positions of all the hydrogen atoms. Finally, all positional parameters, together with anisotropic temperature factors for the non-hydrogen atoms and isotropic temperature factors for the hydrogen atoms, were refined, and the R-index decreased to 0.052 for all observed reflections.

Final atomic coordinates and thermal parameters together with the corresponding standard deviations are given in Table 1. The observed and calculated structure factors are listed in Table 2.

Results and Discussion

The intramolecular bond lengths and angles are shown in Fig. 1. Within the experimental errors, these values except hydrogen atoms are in good agreement with the values found in other uracil derivatives; 1-methyluracil[6] and 1-methylthymine.[1] The only remarkable deviations were found in the C(2)-N(3) bond length, which is about 0.02 Å longer than those of the above-mentioned derivatives, and in the N(3)-C(4)-C(5) angle which is significantly less here (113.3°) than in 1-methyluracil (116°)[6] and 1-methylthymine (116.1°)[1]. A similar value of this angle is also found in the form II (112.7°) of 1-ethyl-5-bromouracil.[7] Such a smaller angle is commonly found in crystal structures of 5-halogenated uridines; 5-fluoro-2′-deoxy-β-uridine (112.6°)[8], 5-chlorouridine (113.7°),[9] 5-bromo-2′-deoxyuridine (112.4°) and 5-bromouridine (112.8°).[10] Therefore, it seems likely this angle is certainly affected by halogen substitution at C(5).

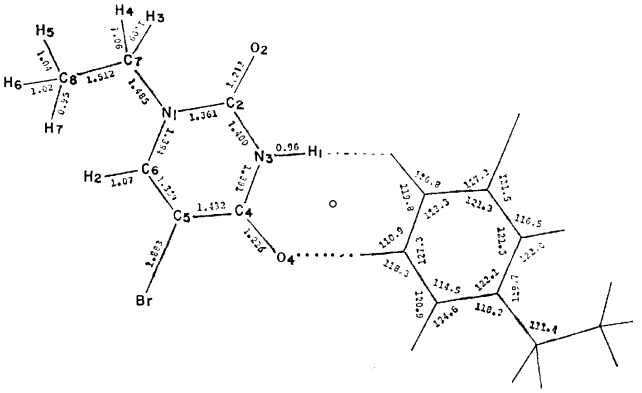

Fig. 1. Bond lengths and bond angles of 1-ethyl-5-bromouracil. The standard deviations are 0.008 Å in bond lengths and 0.6° in bond angles between non-hydrogen atoms.

The best plane through the six ring atoms, as calculated by the least-squares method, is defined by the equation. The distances from the non-hydrogen atoms to

$$-0.89763x + 0.32294y + 0.29995z + 1.30399 = 0.$$

Table 3. Deviations of atoms from the least-squares plane through the six ring atoms

this plane are listed in Table 3. Both exocyclic oxygen atoms O(2) and O(4) are significantly displaced on the same side of the plane. The substituent carbon atom C(7) is also markedly displaced by 0.068 Å from this plane. Such deviations from the base are frequently observed in crystal structures of purine and pyrimidine derivatives.

The arrangement of the molecules in the crystal is shown in Figs. 2 and 3. The basic molecular unit in this crystal is a dimer formed by two molecules which are joined together in pairs around a center of symmetry, with two N–H···O hydrogen bonds connecting the N(3) atom with the carbonyl oxygen O(4) at a distance of 2.85 Å. It is of particular interest that hydrogen bonded pairing system of the form I is quite different from that of the form II, in which N(3)–H and the carbonyl oxygen O(2) in place of O(4) are used for the hydrogen bond formation.[5,7]

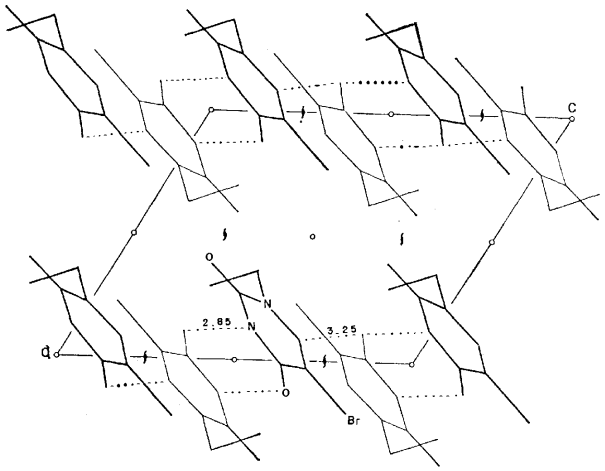

Fig. 2. The crystal structure viewed down the *b* axis.

Figures 2 and 3 show the stacking mode of the adjacent pyrimidine rings related by the *c*-glide plane, forming an infinite stack along the direction of the *c*-axis. This stacking is characterized by the following two points; one is the characteristic arrangement of the adjacent pyrimidine rings tilting to one another with the dihedral angle of 38.° The other is very little overlap of the bases and, therefore, main contact is due to the interactions between the bromine substituent and the adjacent pyrimidine ring as shown in Fig. 3. The distance from the bromine atom to this plane is 3.5 Å. Such a bromine-base contact is frequently found in crystal structures of halogenated purines and pyrimidines.[11]

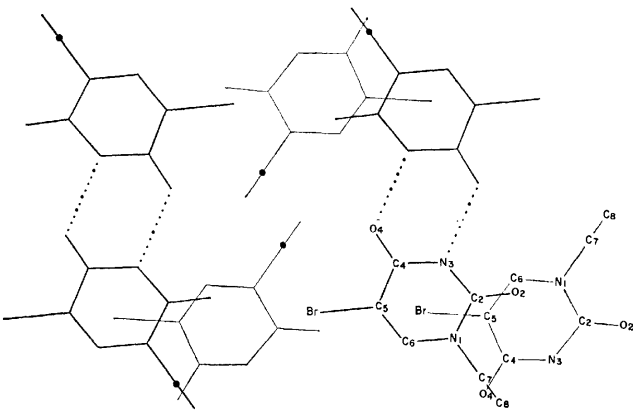

Fig. 3. The stacking of molecules viewed perpendicular to the plane (101).

The closest C···O intermolecular distance in the crystal is found between C(6) and the carbonyl oxygen O(4) of the adjacent molecule, and this distance is 3.25 Å, with the H···O distance 2.24 Å and the C–H–O angle 157.8°, which seems to be a weak hydrogen bond. A similar C–H···O contact has been reported in pyrimidine nucleotides; uridine residue of β-adenosine-2′-β-uridine-5′-phosphoric acid (3.18 Å),[12] calcium thymidine-5′-phosphate (3.42 Å)[13] and barium uridine-5′-phosphate (3.17 Å)[14], and in uracil derivatives; 1-methylthymine (3.11 Å)[1] and uracil (3.19 and 3.28 Å).[15] These values agree quite well with those suggested by Sutor as to the existence of C–H···O hydrogen bond in the solid state.[16]

The Crystal Structure of 1-Ethyl-5-bromouracil. II. The Crystal Structure of the Form II Crystal of 1-Ethyl-5-bromouracil

Tomitake TSUKIHARA,[1] Tamaichi ASHIDA, and Masao KAKUDO
Institute for Protein Research, Osaka University, Osaka

(Received September 8, 1971)

Two crystalline forms of 1-ethyl-5-bromouracil were found. The crystal structure of the form II has been determined. The dimension of the tetragonal unit cell are $a=b=17.13$ Å, $c=5.36$ Å, and $Z=8$. The space group is $P4_2/n$. The final R is 0.064. The hydrogen bond scheme in this crystal, N(3)–H(3)···O(2), is the first finding in alkylated pyrimidine dimers. The carbon atom binding to the nitrogen atom of the pyrimidine ring deviates significantly from the pyrimidine ring plane.

Two crystalline forms of 1-ethyl-5-bromouracil were recently found. The study of these structures showed the presence of different modes of hydrogen bond.[2] The detail of the structure of the form I is presented in the preceeding paper.[3]

The present paper deals with details of the crystal structure of the form II, in which a new hydrogen-bonding type in the alkylated pyrimidine dimers has been found.

TABLE 1. CRYSTAL DATA

$C_6H_7BrN_2O_2$	M.W.=219.05
Tetragonal	$P4_2/n$
$a=b=17.13$ Å	$c=5.36$ Å
$D_{cal}=1.85$ g/cm^3	
$D_{obs}=1.84$ g/cm^3 (by flotation)	

Experimental

Two types of crystals were grown from a dimethyl sulfoxide solution at room temperature. From I crystal is a colorless plate-like crystal and the form II is a transparent needle. Preliminary Weissenberg and Precession photographs established that the form II was tetragonal with the c axis along the needle axis. The systematic extinction of $(00l)$ for l odd and $(hk0)$ for $h+k$ odd restricted the space group to $P4_2/n$. The crystal data are listed in Table 1.

A nickel filtered Cu-$K\alpha$ radiation was used to collect intensity data for all the reflections in the range $0<\sin\theta/\lambda<0.55$ Å^{-1} in octant (hkl) and $(\bar{h}k0)$. All the intensities were measured on a Rigaku Denki computer-controlled four-circle diffractometer (AFC-II). A scintillation counter was used with a pulse-height discriminator. A crystal of approximate dimension, 0.02 mm×0.02 mm×0.10 mm ($0.14<\mu r<0.16$), was mounted with the c axis parallel to the ϕ-axis of the diffractometer. The ω-2θ scan technique was employed with a scan speed of 2°/min by ω, and backgrounds were measured for 6.00 sec at each start and end points of the scan range. A scan range of ω for each reflection was calculated by the formula;[4] scan range$=1.00°+0.15°\times\tan\theta$. Attenuators were automatically inserted when the maximum count rate exceeded 8000 cps. The intensities were corrected only for Lorentz and polarization factors.

Measurements of two reference reflections, (400) and (200), were repeated at every fifty reflections. For 35 time repetition of the measurements, $|F_o(400)|=149.50\pm0.57$ and $|F_o(002)|=93.14\pm0.56$. The standard deviation of $|F_o(hk0)|$ were assigned on the basis of the following equation

$$\sigma^2(|F_o|) = \langle((|F_o(hk0)| - |F_o(\bar{k}h0)|)/2)^2\rangle_{av} \quad (1)$$

where $\langle\ \rangle_{av}$ represents the average of 10 reflections of similar magnitude of F_o. The standard deviations of $|F_o(hkl)|$ were substituted for $\sigma(|F_o(hk0)|)$ of similar $|F_o|$. An index of experimental accuracy

$$\sum_{h,k}(|F_o(hk0)| - |F_o(\bar{k}h0)|)/\sum_{h,k}(|F_o(hk0)| + |F_o(\bar{k}h0)|) \quad (2)$$

is 0.0119, where the summation is over all reflections, of which $|F_o|$ are greater than 10.0. Figure 1 shows the distribution of $\sigma(|F_o(hk0)|)$ *versus* $|F_o|$.

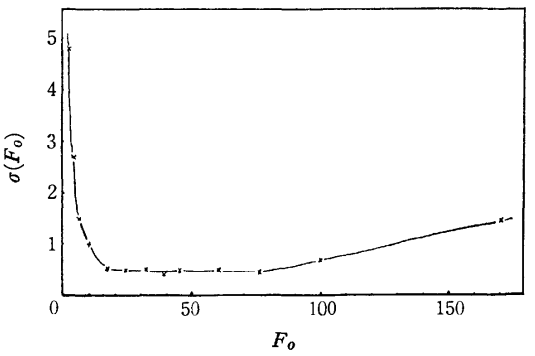

Fig. 1. The standard deviations of $|F_o(hk0)|$. Each symbol (x) represents the average of 10 reflections of similar $|F_o|$.

Structure Determination and Refinement

The position of the bromine atom was found from the three dimentional Patterson function. A Fourier synthesis was computed on the basis of the position of bromine atom. Eight extra atoms except ethyl group showed up on the first map. The definite location of the ethyl group could not be found on the electron density map. The peak which corresponds to the carbon atom C(7) binding to N(1) is too much elongated along the direction perpendicular to the pyrimidine ring plane.

Structure refinements were carried out by the block diagonal least-squares method. The function, $\sum w(|F_o|-|F_c|)^2$, was minimized for the least-squares refinements. The atomic scattering factors were taken from "Inter-

national Table for X-ray Crystallography (1962)." To take into account of the anomalous scattering by bromine atom, $\Delta f'(-0.95)$ and $\Delta f''$ (1.40) were included in the calculations. The weighting scheme employed was

$w = 0.0$ ($|F_o|<10.0$ or attenuated reflection)
$w = \sigma^{-1}(|F_o|)$ (others).

Five cycles of least-squares refinement of positional parameters and anisotropic thermal parameters for the nine atoms except ethyl group resulted an a value of R of 0.1394. An (F_o—F_c) synthesis then revealed the two possible site of the ethyl group (Fig. 2).

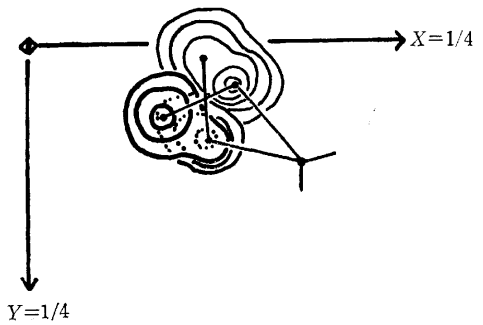

Fig. 2. The composite difference electron density map, for which the contribution of the hydrogen atoms and ethyl group carbon atoms were excluded from the calculated structure factors. Contours are drown at interval of 0.5 e/Å^3, starting at 0.5 e/Å^3.

After three cycles of least-squares refinements of the positional parameters, the anisotropic thermal parameters for the nine atoms except ethyl group and the isotropic thermal parameters for the four atoms of the two sites of the ethyl group, the R value decreased to 0.068. The ethyl group was supposed as equally distributed to the two sites, that is, the occupancies of the both sites are 0.5. In the course of the refinement,

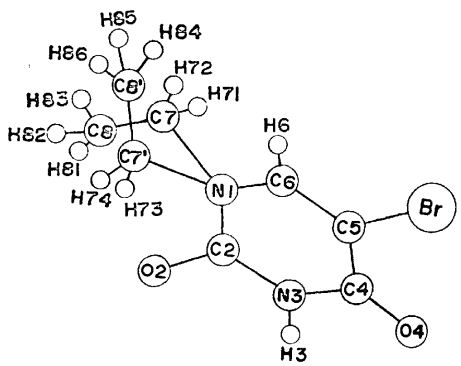

Fig. 3. Structural formula of 1-ethyl-5-bromouracil.

the temperature factor of an atom of the ethyl group compensated for particular choice of the occupancy of the same atom. Accurate occupancies of two ethyl group sites could not be determined, partly because only about 60% of reflections within the limiting sphere of Cu-$K\alpha$ radiation was used in the determination. For several sets of occupancies of two ethyl group sites, similar refinements were tried. These calculations suggested that two ethyl group sites should be multiplied by 0.60—0.45 and 0.45—0.60 respectively. The (F_o—F_c) synthesis at this stage revealed two hydrogen atoms bound to the pyrimidine ring.

The final refinement included all atoms except for the hydrogen atoms of the ethyl group. The final R is 0.064.*

Molecular Structure

Tables 4 and 5 give the bond distances in the pyrimidine ring of this crystal and some other crystals respectively. Comparison with these crystals shows that structure of the pyrimidine ring are in good agreement with each others. The molecule except ethyl group is nearly planar (Table 6), bromine atom being displaced from the plane by 0.04 Å. The carbon atom C(7) and C(7′) deviate significantly from the plane by 0.53 Å and 0.57 Å, respectively. This displacement suggests an increase of p-character in the bond orbitals of C(7)–N(1) and C(7′)–N(1). Triethylpyrazine[5] and bromodihydroacromycine[6] have a similar structure. In form I, the carbon atom C(7) does not displace from the pyrimidine ring plane. In form II, if the carbon atom C(7) is placed on the plane, the distance between the carbon atom C(8) and the oxygen atom O(2) or O(4) of the neighboring molecule is shorter than 3.2 Å.

Molecular Packing

There are four intermolecular contact regions. Bromine atoms pack closely around a 4_2-axis. Hydrogen bonds, N–H···O, are formed around a center of symmetry. Disordered ethyl groups surround a $\bar{4}$-axis. The hydrogen atom H(6) and the oxygen atom O(4) contact closely with each other. One of the interesting

k	$1.0-y$	$0.5+x$	$-0.5+z$

aspects of this crystal structure is the packing of bromine atoms. Two non-equivalent distances between bromine atoms are 4.22 Å and 4.01 Å respectively (Table 7). This closest packing region elongates along the needle axis.

The hydrogen bond scheme in this crystal, N(3)–H(3)···O(2), is the first finding in the alkylated pyrimidine dimers. While the hydrogen bond scheme in form I, N(3)–H(3)···O(4), is usually found in the self-dimer of uracil and thymine derivatives, for example, uracil,[10,11] 1-methyluracil,[12] 5-ethyl-6-methyl uracil[13] and 1-methylthymine.[14] It seems that a change of electron distribution in pyrimidine ring by a substitution of a bromine atom or van der Waals interaction between closest packed bromine atoms perturbs the construction of the hydrogen bond scheme. Table 7 gives a list of all the intermolecular contacts between the disordered carbon atoms of the ethyl group. The distances of C(8)–C(8d)[15] and C(8)–C(8'c)[15] are shorter than usual, but a similar intermolecular contact between methyl groups in a crystal of octamethyltetraamidodiphosphono-2,3-butadiene-1,3.[16] The distance between H(6) and O(4), 2.27 Å, is fairly short, and the angle C(6)–H(6)–O(4) is 178.0°. In a thymine or uracil molecule, C(6) has a fairly positive charge.[17] Thus C(6)–H(6)···O(4) may be a hydrogen bond. Similar hydrogen bonds were reported in form I crystal and some other crystals, barium uridine-5′-phosphate,[18] β-adenosine-2′-β-uridine-5′-phosphoric acid[19] and calcium thymine phosphate.[20]

The Syntheses of 1,3-Oxathiolan-5-one Derivatives

Sadayoshi SATSUMABAYASHI, Shuichi IRIOKA, Hiroshi KUDO,
Kozo TSUJIMOTO, and Shinichi MOTOKI
Department of Chemistry, Science University of Tokyo, Kagurazaka 1-3, Shinjuku-ku, Tokyo
(Received September 17, 1971)

The condensations of aldehydes with thioglycollic acid or α-mercaptopropionic acid were carried out; 2-substituted- or 2,4-disubstituted-1,3-oxathiolan-5-ones were thus obtained. The intermediate of the reaction was isolated only when phenylglyoxal and thioglycollic aicd were used.

We can expect to obtain the 1,3-oxathiolan-5-one derivative by the reaction of α-mercapto acid with aldehyde. However, this heterocyclic system has rarely appeared in the literature except for the 2-trihalomethyl-[1,2] and 2,4,4-triaryl-derivatives.[3-5] In this paper, the syntheses of several 1,3-oxathiolan-5-one derivatives (III) and related compounds will be described.

Acetaldehyde (Ia), propionaldehyde (Ib), and butyraldehyde (Ic) were used as the aliphatic aldehydes and were allowed to react with thioglycollic acid (IIa). The reactions were first carried out in refluxing benzene with an azeotropic removal of the water eliminated in the reaction (Method A). The products thus obtained are presented in Table 1. The results of elementary analyses and the NMR spectra were well in accord with the expected structures. When acetic anhydride was used as the dehydrating agent at 60°C, the product, III, was contaminated with diacetoxyalkane and the separation of the two compounds was almost impossible.

$$\underset{\text{(I)}}{RCHO} + \underset{\text{(IIa)}}{HSCH_2COOH} \longrightarrow \underset{\text{(III)}}{RCH\begin{cases} S-CH_2 \\ | \\ O-CO \end{cases}}$$

The III compounds were also obtained by stirring I and IIa at room temperature without any solvent or dehydrating agent, followed by direct distillation (Method B). As may be seen in Table 1, the yields of the products were here somewhat higher than those given by Method A.

The condensation of IIa with benzaldehyde (Id), *p*-nitrobenzaldehyde (Ie), or *p*-tolualdehyde (If) by Method B was unsuccessful. That is, the bisthioglycollic acid derivative (IV), a condensation product of one mole of I and two of IIa, was thus formed in a nearly quantitative yield. When Method A was adopted, large quantities of the starting materials were recovered, while III was obtained in only about a 15% yield. Therefore, *p*-toluenesulfonic acid was used as the catalyst and the reaction was carried out in refluxing benzene (Method C). Both III and IV were formed in about 30% yields (Table 2).

$$I + IIa \longrightarrow III + \underset{\text{(IV)}}{RCH\begin{cases} SCH_2COOH \\ SCH_2COOH \end{cases}}$$

Since Compound V was considered as an intermediate in the reaction, the isolation of V was attempted.

In all cases involving the above aldehyde, however, this attempt failed. However, phenylglyoxal (Ig) reacted readily with IIa to give (1-hydroxyphenacyl)-thioacetic acid (V, R=C_6H_5CO), which was then converted to IIIg by means of dehydration with acetic anhydride at room temperature:

$RCH(SCH_2COOH)(OH)$ (V)

The reaction of aliphatic aldehyde with α-mercapto-propionic acid (IIb) was also examined (Method B); the corresponding 4-methyl-1,3-oxathiolan-5-one derivatives (VI) were thus obtained (Table 3).

The above reaction was then applied to the synthesis of the 1,3-oxathian-6-one derivative (VIII) from β-mercaptopropionic acid (IIc) and aldehyde. The hetero-ring VIII has not been reported in the literature. Although VIII was not obtained by the reaction of IIc with Ia—f, it *was* obtained when Ig or chloral (Ih) was used as the aldehyde. In both cases, the intermediates (VII) were isolated in high yields.

$RCHO + HSCH_2CH_2COOH \longrightarrow$

(I) (IIc)

$RCH(OH)-SCH_2CH_2COOH \longrightarrow RCH(S-CH_2)(O-CO)CH_2$

(VII) (VIII)

Experimental

Method A. Into a solution of 0.2 mol of aldehyde (I) and 100 m*l* of benzene, 0.1 mol of thioglycollic acid (IIa)

was added, and then the mixture was stirred for 2 hr at room temperature. The mixture was then refluxed for about 5 hr, the water formed in the reaction being removed continuously by azeotropic distillation. The reaction mixture was washed with a 10% sodium carbonate aqueous solution. Distillation gave the products shown in Table 1.

Method B. Into 0.1 mol of I, 0.1 mol of IIa was added slowly and stirred for 7 hr at room temperature. When the mixture was then distilled, a fraction boiling at 60—110°C/5 mmHg was collected. The distillate was washed with a sodium carbonate solution and then redistilled.

The reaction of α-mercaptopropionic acid (IIb) with aldehyde was carried out in the same manner. The results are shown in Table 3.

Method C. A mixture of 0.2 mol of I, 0.1 mol of IIa, about 0.1 g of *p*-toluenesulfonic acid, and 100 m*l* of benzene was refluxed for about 10 hr, cooled, and washed with a sodium carbonate solution. The benzene was then removed, and the residue was recrystallized from *n*-hexane to give III.

By the acidification of the alkaline solution with hydrochloric acid, IV was precipitated. As IV consists entirely of known compounds,[6] they were confirmed, by studying their melting points and neutralization equivalents to be benzylidenebisthioglycollic acid (IVd) (mp 124°C), *p*-nitrobenzylidenebisthioglycollic acid (IVe) (mp 160—161°C), and *p*-methylbenzylidenebisthioglycollic acid (IVf) (mp 123—125°C). The results are summarized in Table 2.

(1-Hydroxyphenacyl)thioacetic acid (V). To a solution of 0.1 mol of phenylglyoxal (Ig) in 50 m*l* of benzene, 0.1 mol of IIa was added, after with the mixture was stirred for 2 hr at room temperature. The product thus precipitated was collected by filtration and recrystallized from toluene to give V; yield, 81.0%; mp 121°C. Found: C, 52.86; H, 4.31; S, 14.28%; mol wt (neutralization equivalent), 230.4. Calcd for $C_{10}H_{10}O_4S$: C, 53.10; H, 4.46; S, 14.15%; mol wt, 226.2.

2-Benzoyl-1,3-oxathiolan-5-one (IIIg). A solution of 0.05 mol of V, 0.15 mol of acetic anhydride, and 200 m*l* of benzene was stirred at room temperature until the white solid disappeared. When the benzene was then removed under reduced pressure, the residue was poured into a 10% sodium carbonate solution. The product thus precipitated was collected by filtration and recrystallized from ligroin; yield, 58.3%; mp 93—94°C. Found: C, 57.83; H, 3.84; S, 15.33%. Calcd for $C_{10}H_8O_3S$: C, 57.69; H, 3.87; S, 15.37%.

3-(1-Hydroxyphenacyl)thiopropionic Acid (VIIa) and 3-(1-Hydroxy-2,2,2-trichloroethyl)thiopropionic Acid (VIIb). As in the preparation of V, 19.8 g (or 21.4 g) of VIIa (or VIIb) were obtained from 0.1 mol of phenylglyoxal (Ig) (or chloral (Ih)) and 0.1 mol of β-mercaptopropionic acid (IIc). VIIa: yield, 82.5%; mp 107—108°C (recrystallized from toluene). Found: C, 55.23; H, 5.01; S, 13.26%; mol wt (neutralization equivalent), 225.7. Calcd for $C_{11}H_{12}O_4S$: C, 55.00; H, 5.04; S, 13.32%; mol wt, 240.2. VIIb: yield, 84.5%; mp 82—83°C (from ligroin). Found: C, 23.65; H, 2.91; S, 12.88; Cl, 42.08%; mol wt, 245.7. Calcd for $C_5H_7O_3SCl_3$: C, 23.69; H, 2.78; S, 12.65; Cl, 41.95%; mol wt, 253.5.

2-Benzoyl-1,3-oxathian-6-one (VIIIa) and 2-Trichloromethyl-1,3-oxathian-6-one (VIIIb). As in the preparation of IIIg, VIIIa (or VIIIb) was obtained from VIIa (or VIIb). VIIIa: yield, 59.6%; mp 86—87°C (from ligroin). Found: C, 59.27; H, 4.55; S, 14.21%. Calcd for $C_{11}H_{10}O_3S$: 59.46; H, 4.54; S, 14.40%. VIIIb: yield, 48.5%; mp 69—70°C (from hexane). Found: C, 25.58; H, 2.36; S, 13.71; Cl, 44.88%. Calcd for $C_5H_5O_2SCl_3$: C, 25.50; H, 2.14; S, 13.61; Cl, 45.16%.

The authors wish to thank Professor Yojiro Tsuzuki for his helpful advice and encouragement.

Asymmetric Reactions. VII. Stereoselectivities in Phenyllithium and Grignard Reactions with Tetrahydrofurfural Derivatives

Juji YOSHIMURA, Yoshiaki OHGO, Katsumi AJISAKA,[1a] and Yaeko KONDA[1b]

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received October 5, 1971)

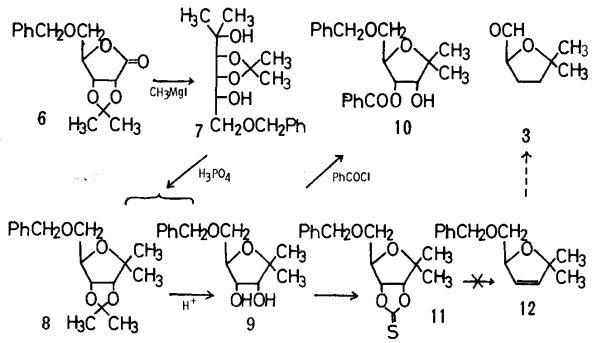
Stereoselectivities in the phenyllithium and phenylmagnesium bromide reactions with tetrahydrofurfural (**1**), its diacetate (**2**) and 5,5-dimethyl-(*S*)-tetrahydrofurfural (**3**) were examined, in order to clarify the cause of anomalous stereoselectivity of Grignard reactions with *N*-substituted 2,3-*O*-isopropylidene-D-glyceraldimine and the carbonyl analogue(giving *erythro* product predominantly). The presumption that the anomalous stereoselectivity might be caused by coordination ability of magnesium to C_3-oxygen, together with C_1-oxygen or C_1-nitrogen, and C_2-oxygen, was solidified from the present results that no stereoselectivity difference was observed between both reactions with substrates having no C_3-oxygen. Detailed discussion on the stereoselectivity differences between substrates was also made.

The authors have previously reported on the stereoselectivity difference between Grignard and phenyllithium reactions with 2,3-*O*-isopropylidene-D-glyceraldimines, and related compounds, and the difference was explained by assuming that the presence or absence of a coordinative interaction between C_3-oxygen and metal atoms in Grignard or phenyllithium reaction, respectively.[2-4]

In this paper, the presumption was solidified by comparison of the stereoselectivities of tetrahydrofurfural (**1**), its diacetate (**2**), and 5,5-dimethyl-(*S*)-tetrahydrofurfural (**3**) with the previous results.

Results

Synthesis of 5,5-Dimethyl-(S)-tetrahydrofurfural. At first, the synthesis was attempted by process shown in Scheme 1, starting from 2,3-*O*-isopropylidene-5-*O*-benzyl-D-ribonolactone (**6**).[5] Methylation of **6** by methylmagnesium iodide gave the corresponding dimethylated product (**7**) in a good yield. The ring-closure of **7** was attained by heating with anhydrous orthophosphoric acid to give 1,1-dimethyl-1,4-anhydro-2,3-*O*-isopropylidene-D-ribitol (**8**) and its deacetonated derivative (**9**) which was benzoylated for identification to give a monobenzoate with mp 94—96°C. Among two possible structures, it was shown to be 3-*O*-benzoate (**10**) by NMR spectrum (Fig. 1). The doublet at 7.55 τ (J=6.3 Hz) and the triplet at 5.93 τ were assigned to the hydroxyl proton and C_2-proton, respectively, because they changed to a singlet and a doublet (J=6.3 Hz) by addition of a few drop of trifluoroacetic acid. Consequently, other proton signals were easily determined from the coupling constants. Treatment of **9** with thiocarbonylimidazole gave the corresponding



Scheme 1.

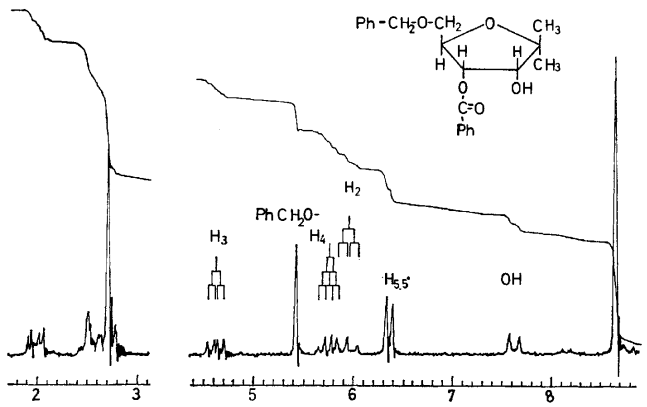


Fig. 1. NMR spectrum of **10** in $CDCl_3$ (τ).

2,3-*O*-thiocarbonate (**11**), however, several trials for elimination of thiocarbonic acid from **11** by refluxing with trimethylphosphite[6] in order to obtain the corresponding unsaturated compound (**12**) gave unsuccessful results.

The successful synthesis of **3** was accomplished by another process shown in Scheme 2, starting from 2,3-*O*-isopropylidene-D-glyceraldehyde. It was converted to ethyl 4,5-*O*-isopropylidene-(4*S*), 5-dihydroxypentenoate-2 (**13**) by Wittig reaction,[7] which was then hydrogenated to the corresponding saturated ester (**14**).

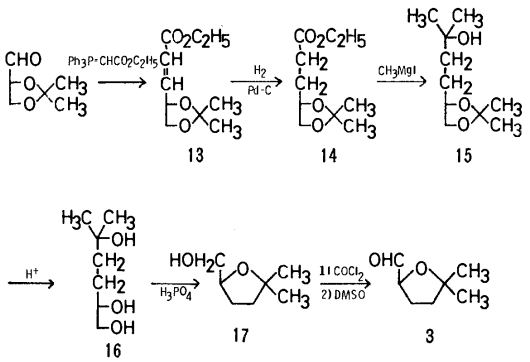
7) H. J. Bestmann and O. Kratzer, *Chem. Ber.*, **95**, 1894 (1962).

Treatment of **14** with an excess amount of methylmagnesium iodide gave 1,2-*O*-isopropylidene-5-methyl-1,(2*S*),5-trihydroxy-*n*-hexane (**15**) which was deacetonated with Amberlite IR-120 to **16**. Treatment of **16** with 85% phosphoric acid[8] gave an anhydride with bp 74—75.5°C/15 mmHg. Both five and six-membered ring structures are possible for the anhydride, however, it was confirmed to be 5,5-dimethyl-(*S*)-tetrahydrofurfuryl alcohol (**17**) by the facts that the chemical shifts of CH_2OH and H_2, and splitting patterns of signals in NMR spectra (Fig. 2) are closely similar to those of tetrahydrofurfuryl alcohol,[9] and that the oxidation of it gave an aldehyde. The oxidation product of 5-*O*-chloroformyl derivative of **17** by dimethyl sulfoxide showed an characteristic absorption of aldehyde at 1715 cm^{-1} in IR spectrum, and a signal of it at 0.4 τ (d, J=1.8 Hz) in the NMR spectrum. The elemental analysis of its 2,4-dinitrophenylhydrazone derivative agreed with theoreticals.



Scheme 2.

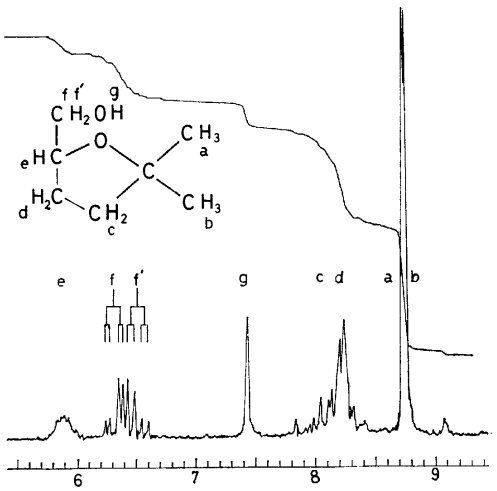


Fig. 2. NMR spectrum of **17** in $CDCl_3$.

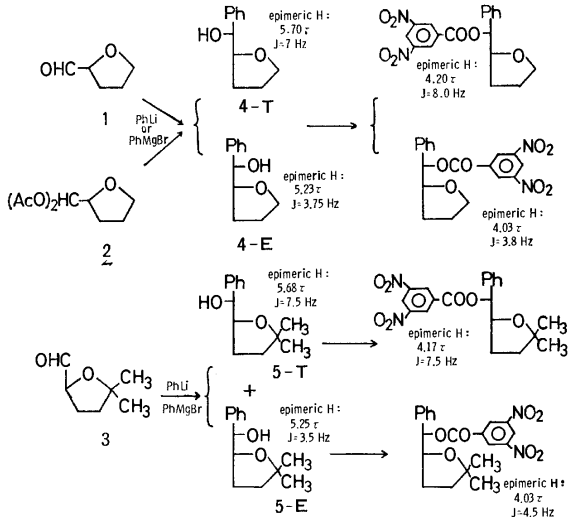
Stereoselectivities in the Phenyllithium and Grignard Reactions with Substrates 1, 2, and 3. Substrates **1** and **2** prepared by the method of Scheibler *et al.*,[10] or **3** were treated with an excess amount of phenyllithium or phenylmagnesium bromide by the procedure mentioned in a previous paper.[4] In the case of **1** and **2**, the reaction product was distilled at 80—99°C/0.3 mmHg or purified by column chromatography on silica gel C-100 column, respectively, whose analytical values agreed with those calculated for 2-(hydroxybenyl)tetrahydrofuran (**4**). Although *threo* and *erythro* isomers in **4** could not be isolated, the ratio of them was estimated by glpc and NMR techniques.



Scheme 3.

Table 1. Diastereomer ratios produced by the reactions of tetrahydrofurfural derivatives with phenyllithium or phenylmagnesium bromide

Substrate	PhLi Product threo : erthro (%)		PhMgBr Product threo : erythro (%)		
1	72.5[a]	27.5[b]	70[a]	30[b]	A
	72.7[a]	27.3[b]	70.5[a]	29.5[b]	B
2	66[a]	34[b]	66[a]	34[b]	C
3	57[c]	43[d]	57.4[c]	42.6[d]	
	(58	42)	(58.7	41.3)	
			58.9[c]	41.1[d]	
			(62	38)	

The diastereomeric ratios except for those in parentheses were estimated by glpc with 20% PEG-6000-Chromosorb AW column, and those in parentheses were estimated from NMR peak areas of epimeric H_1-signals.

A: Fraction 2 of distillates with bp 85—99°C/0.28—0.3 mmHg (PhLi reaction) or with bp 80—99°C/0.28—0.3 mmHg (PhMgBr reaction).

B: Fraction 2′ with bp 99°C/0.3 mmHg which was interceptedly taken. Analytical values of these fractions agreed with those of expected products (see experimental part).

C: The results shwon are of crude products, and the sample purified by silica gel C-100 column chromatography gave analytical values agreed with those of the expected product (see experimental part.)

a) Faster fraction with retention time 633 sec on glpc.

b) Slower fraction with retention time 689 sec on glpc.

c) Faster fraction with retention time 528 sec on glpc.

d) Slower fraction with retention time 556 sec on glpc.

8) J. Colonge and G. Clerc, *Bull. Soc. Chim. Fr.*, **835** (1955).

9) The NMR spectrum of tetrahydrofurfuryl alcohol was taken for comparison with that of 5,5-dimethyl-(S)-tetrahydrofurfuryl alcohol: 5.92 τ (m, H_2); 6.28 τ (q, $J_{HH'}$=12 Hz, J_{HH_2}=4Hz——CH of hydroxymethyl); 6.475 τ (q, $J_{HH'}$=12Hz; $J_{H'H_2}$=6Hz——CH′ of hydroxymethyl).

Table 2. Comparison of stereoselectivities in organometallic reactions with several aldehydes and aldimine

	Substrate						
	HC=O	$HC(OAc)_2$	HC=O 	HC=O 		$HC=NCH_2Ph$ 	HC=O 	B	B	B	A[a]	B[b]	A	A
T/E(PhLi)	3.5	1.94	1.33	1.7	1.8	1.7	1.66
T/E(PhMgBr)	2.8	1.94	1.35	0.9	1.1	0.28	1.56
R_{Li}/R_{Mg}	1.25	1.0	0.99	1.8	1.6	6.0	1.06

A: By optical rotation.
B: By gas-liquid partition chromatography using 20% PEG-6000-Chromosorb AW.
a) This Bulletin, **42**, 2957 (1969).
b) Stereoselectivities were reexamined by glpc analysis; NMR analysis gave the same results; signals of the proton attached to carbinol carbon in *erythro* and *threo* isomer appear at 5.2τ (d, J=5 Hz) and 5.5τ (d, J=8 Hz) respectively. The ratio was given by the intergrals of peak areas.
T/E(PhLi): The ratio of *threo* to *erythro* in the PhLi reaction. T/E(PhMgBr): The same ratio in the PhMgBr reaction.
R_{Li}/R_{Mg}: The ratio of T/E(PhLi) to T/E(PhMgBr).

The glpc showed two peaks, of which the amount of faster fraction was larger than that of slower in both the products in organometallic reactions. The NMR spectrum showed two sets of doublet at 5.23 τ (J=3.8 Hz) and 5.70 τ (J=7 Hz), due to epimeric hydrogen attached to carbinol carbon. 3,5-Dinitrobenzoate of **4**, which could not also be isolated, showed the corresponding signals in lower field; at 4.03 τ (J=3.8 Hz) and 4.2 τ (J=8 Hz). It is known that the *erythro* isomers in analogous compounds give a smaller coupling constant than that of *threo* isomers,[4,11-13] and therefore, both the doublets mentioned are assigned to that of *erythro* and *threo* isomers, respectively. These results were presented in Scheme 3 with one presentative structural formula.

In the case of **3**, the product was distilled at 158—160°C/21 mmHg, which showed analytical values consisted with that of 2-(hydroxybenzyl)-5,5-dimethyltetrahydrofuren (**5**). The glpc and NMR analyses of the diastereomeric mixture and the corresponding 3,5-dinitrobenzoate showed the similar results to those in the cases of substrates **1** and **2**, and moreover, two diastereomers of **5** were successfully separated by column chromatography on silica gel C-100 column. Consequently, the relative configurations of the major and the minor products were concluded to be *threo* and *erythro*, respectively.

The diastereomeric ratios in **4** and **5** measured by methods mentioned above were summarized in Tables 1 and 2. These results indicate that there are no substantial differences in stereoselectivities between phenyllithium and phenylmagnesium bromide reactions with **1**, **2**, or **3**. This fact gave a positive support to our previous assumption that Grignard reagents have a coordinative interaction with C_3-oxygen of substrates, but phenyllithium cannot have such an interaction in the transition state of the reaction.

Discussion

For comparison, stereoselectivities of organometallic reactions with *N*-substituted 2,3-*O*-isopropylidene-D-glyceraldimine, its carbonyl analogue and related aldehydes were summarized in Table 2. R_{Li}/R_{Mg} is regarded as an indicator of stereoselectivity difference between phenyllithium and phenylmagnesium bromide reactions. As already pointed out,[4] stereoselectivity difference between phenyllithium and Grignard reactions is brought about when C_3-*O* (or C_β-*O*) of a substrate is sterically fixed at a certain position. The stereoselectivity of phenyllithium reaction should be explained by Cram's model.[14] On the other hand, anomalous stereoselecitvity of the Grignard reactions with aldehydes and aldimines having 2,3-dioxolane ring was explained by assuming that dimeric Grignard species (or two monomeric species) could coordinate to C_3-*O* together with C_2-*O* and imino nitrogen or carbonyl oxygen.[2-4] The validity of the assumption was solidified by the present results that there was no substantial difference in stereoselectivity between phenyllithium and phenylmagnesium bromide reactions with substrate **1**, **2**, and **3** in which C_3-*O* of 2,3-*O*-isopropylidene-D-glyceraldehyde was substituted with methylene group.

However, there still exist questions why there is not so large difference in stereoselectivity between Grignard and phenyllithium reactions with 2,3-*O*-isopropylidene-D-glyceraldehyde[4] as those in the case of *N*-substituted 2,3-*O*-isopropylidene-D-glyceraldimines which are nitrogen analogues of the former and why the reaction with tetrahydrofurfural has higher stereoselectivity than that with 5,5-dimethyltetrahydrofurfural. This can be explained mainly in terms of dual directionality of lone pair orbitals of carbonyl oxygen as follows. As seen from comparison of stereoselectivities with substrate **1** and **3**, stereoselectivity is influenced by existence of methyl on C_5; the methyl group decreases stereoselectivity in either phenyllithium or Grignard reaction. This seems to be concerned with increased difficulty of

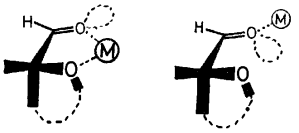
bridged coordination between carbonyl and ring oxygen. Lone pair electron orbitals of carbonyl oxygen extend to two directions (C_2-*O* side and aldehydic *H* side) to which organometallics can coordinate. In the case of 2,3-*O*-isopropylidene-D-glyceraldehyde or 5,5-dimethyltetrahydrofurfural, metal may not necessarily make coordinative bridge between carbonyl oxygen and C_2-*O*, because of steric hindrance of methyl group. Both chelated and non-chelated coordination states, **A**



(A) (B)

and **B**, may exist in the transition states. Consequently, reaction may occur from both states and proportion of these two states will depend on the balance of the energy saved by the chelation and repulsion by methyl groups. Increase of non-chelated coordination state in the equillibrium is considered to cause lower stereoselectivity and also smaller difference in stereoselectivity between Grignard and phenyllithium reactions.

It can also be understood that both phenyllithium and Grignard reactions with tetrahydrofurfural have higher stereoselectivity than those with its 5,5-dimethyl derivative, because the substrate has no methyl group and therefore the chelated coordination state would be favored in the equillibrium; rigidity of the bridged coordination and proximity of asymmetry to the reaction center may afford higher stereoselectivity.

On the other hand, imino compounds have alkyl substituent on the nitrogen and the alkyl may be oriented to the sterically less-hindered hydrogen side so that the lone pair electron orbital is oriented to the C_2-*O* side and then dimeric organomagnesium compound may be compelled to form a bridged coordination between C=N, C_2-*O* and C_3-*O*, in spite of the repulsion by isopropylidene group. This allows to explain the unique reversal of stereoselectivity with change from phenyllithium to phenylmagnesium bromide reaction.

Experimental

The NMR spectra were taken with a JNM-4H-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.) at 100 MHz in a deuteriochloroform or carbon tetrachloride solution, using tetramethylsilane as an internal standard. The IR spectra were recorded with a Hitachi Model EPI-G2 grating IR spectrophotometer. The optical rotations were measured with a Carl-Zeiss Photoelectric Precision Polarimeter (0.005°). The gas-liquid partition chromatographic analyses were performed with a Hitachi Model K-53 gas chromatograph using a column packed with 20%PEG-6000-Chromosorb AW (1 m column in the case of **4**; 2 m column in the case of **5**).

Reaction of Tetrahydrofurfural with Phenylmagnesium Bromide. To an ice-cooled solution of phenylmagnesium bromide prepared from magnesium (1.2 g) and bromobenzene (4.85 m*l*) in ether (50 m*l*) was added an ethereal solution of tetrahydrofurfural (2.1 g) with stirring. The reaction mixture was refluxed with stirring for 1.5 hr, and then poured into ice-water saturated with ammonium chloride. The ether layer was separated and the water layer was extracted with ether. The combined ether layer was washed, successively with *N*-NaOH, water, *N*-H_2SO_4 and water, and dried over anhydrous sodium sulfate, and concentrated to a syrup (3.2 g). The syrup was fractionally distilled;

Fr. 1 50—60°C/0.3 mmHg 0.8 g.
2 80—99°C/0.3 mmHg 2.2 g.
2′ 99°C/0.3 mmHg 0.2 g.

The fraction 2′ was one which was taken interceptedly only at the boiling point of 99°C/0.3 mmHg. The analytical values agreed with 2-(hydroxybenzyl)tetrahydrofuran.

Found: C, 74.49; H, 8.11%. Calcd for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92%.

These fraction were analysed on glpc using 20% PEG-6000-Chromosorb AW (detector: FID, carrier gas: nitrogen with 0.67 kg/cm², oven temperature: 200°C). The results are shown in Table 1.

NMR: 8.1—8.7 τ (multiplet; H_3 and H_4 in tetrahydrofuryl group (THF group)), 6—6.45 τ (multiplet; H_2 and H_5 in THF group), 5.77 τ (singlet; OH), 5.7 τ (doublet, J=7 Hz; epimeric proton-*threo*), 5.23 τ (doublet, J=3.8 Hz; epimeric proton-*erythro*).

To a solution of Fr. 2 (0.3 g) and 3,5-dinitrobenzoyl chloride (0.5 g) in benzene (20 m*l*) was added 1.5 m*l* of pyridine, and the reaction mixture was poured into water after standing overnight and extracted with chloroform. The organic layer was washed successively with sodium carbonate solution, water, dil-HCl solution and water, and then was concentrated *in vacuo* to dryness. The NMR spectrum of the resulting diastereomeric mixture of 3,5-dinitrobenzoate showed two sets of doublet due to epimeric proton at 4.03 τ (J=3.8 Hz) and 4.2 τ (J=8 Hz).

Reaction of Tetrahydrofurfural (1) with Phenyllithium. The reaction was carried out with the same procedure as in the case of the Grignard reaction. The syrup obtained was fractionally distilled;

Fr. 1 50—85°C/0.28—0.3 mmHg
2 85—99°C/0.28—0.3 mmHg 3 g
2′ 99°C/0.3 mmHg 0.4 g

Yield (2+2′): 3.4 g (91%).

Anal. of fraction 2′. Found: C, 74.41; H, 7.67%. Calcd for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92%.

The products were analysed on glpc under the same condition as in the case of Grignard reaction (Table 1).

Reaction of Tetrahydrofurfural Diacetate (2) with Organometallic Reagents. The reactions were carried out of tetrahydrofurfural diacetate (10 g) with phenyllithium prepared from lithium (4.52 g) and bromobenzene (34.4 m*l*) or phenylmagnesium bromide prepared from magnesium (12 g) and bromobenzene (48.5 m*l*) in ether. Thereafter, the reaction mixture was treated as usual method (described above). The reaction products were tried to purify by distillation, but the aimed products were not separated from diphenyl methyl carbinol. The products were purified by column chromatography using silica gel C-100. The adsorbed products mixtures were successively eluted by *n*-hexane, *n*-hexane-benzene, benzene, and benzene-acetone. Each fraction was analysed by glpc. The acetone-benzene fraction contained the addition products; 2-(hydroxybenzyl)tetrahdrofuran. Found: C, 74.10; H, 8.05%. Calcd for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92%.

Reaction of 5,5-Dimethyl-(S)-tetrahydrofurfural with Phenylmagnesium Bromide or Phenyllithium. A solution of 5,5-dimethyl-(*S*)-tetrahydrofurfural (3.2 g) in 10 m*l* of ether was added with stirring at 0—5°C to an ethereal solution of phenylmagnesium bromide prepared from magnesium (1.8 g) and bromobenzene (11.8 g), and the reaction mixture was

refluxed for 2 hr, and then decomposed with 1N-HCl solution. The products were extracted with ether. The ether layer was concentrated *in vacuo* to a syrup. The syrup was distilled at 158—160°C/21 mmHg. Yield: 2.0 g (39%); $[\alpha]_D$+2.85° (*c* 2, ethanol). Found: C, 75.47; H, 9.06%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%.

A solution of 5,5-dimethyl-(*S*)-tetrahydrofurfural (3.3 g) was reacted with phenyllithium prepared from 1.1g of lithium and 12.5 g of bromobenzene in ether, and the reaction mixture was treated in the same procedure as in the Grignard reaction; bp 155—160°C/20 mmHg, yield: 2.5 g (48%); $[\alpha]_D$+2.54° (*c* 1.5, ethanol). Found: C, 75.63; H, 9.10%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%.

NMR spectrum of the diastereomeric mixture: 2.77 τ (Ph), 5.25 τ (doublet, J=3.5 Hz; epimeric proton-*erythro*), 5.68 τ (doublet, J=7.5 Hz; epimeric proton-*threo*), 5.8—6.2 τ (multiplet; H_2 in THF group), 6.85 τ (OH), 8.35—8.5 τ (multiplet; H_3 and H_4 in THF group).

The products were analysed on glpc using 20% PEG-6000-Chromosorb AW (Table 1).

The two diastereomers were separated with column chromatography using silica gel C-100 column and *n*-hexane-benzene (10: 1) as the eluting solvent: faster fraction contained *erythro* isomer and slower fraction contained *threo* isomer. The *erythro* isomer has $[\alpha]_D^{24}$ −3.3° (*c* 0.45, ethanol). NMR spectrum: 2.76 τ (Ph), 5.25 τ (doublet, J=3.5 Hz; epimeric proton), 5.8—6.0 τ (multiplet; H_2 in THF group), 7.58 τ (OH), 8.2—8.5 τ (multiplet; H_3 and H_4 in THF group), 8.73 and 8.78 τ (methyl).

Threo isomer has $[\alpha]_D^{24}$+6.7° (*c* 1.3, ethanol). NMR: 2.76 τ (Ph), 5.68 τ (doublet, J=7.5 Hz; epimeric proton), 5.95—6.2 τ (multiplet, H_2 in THF group), 7.7 τ (OH), 8.2—8.5 τ (multiplet; H_3 and H_4 in THF group), 8.73 and 8.78 τ (methyl).

*1,1-Dimethyl-2,3-O-isopropylidene-D-ribitol (**7**).* 5-*O*-Benzyl-2,3-*O*-isopropylidene-D-ribonolactone (116.4 g) was reacted with 6 molar equivalent of methylmagnesium iodide in ether at 0—5°C. The reaction mixture was left standing overnight and poured into 3 *l* of ice-water. The water layer was extracted twice with 1 litre of ether which was washed with water. The combined ether layer was dried over anhydrous sodium sulfate, concentrated to give a syrup which was distilled at bp 162°C/0.005 mmHg. Yield: 100 g (88%). Found: C, 65.42; H, 8.30%. Calcd for $C_{17}H_{26}O_5$: C, 65.78; H, 8.44%.

*1,4-Anhydro-5-O-benzyl-1,1-dimethyl-D-ribitol (**9**).* 50.4 g (0.16 mol) of 1,1-dimethyl-2,3-*O*-isopropylidene-5-*O*-benzyl-D-ribitol was treated with anhydrous orthophosphoric acid (0.12 mol) with stirring at 100°C for 50 min. The reaction mixture was extracted with 600 m*l* of ether, and the ether layer was washed with water, sodium bicarbonate solution and water, successively. The ether layer was concentrated to give a syrup (36 g). The syrup was fractionally distilled:

Fr. 1 119°C/0.007 mmHg 18.8 g.
2 149°C/0.007 mmHg 10.7 g.

Fr. 1 was dissolved in petroleum ether and extracted with a small amount of water. The evaporation of the petroleum layer gave 1,4-anhydro-1,1-dimethyl-2,3-*O*-isopropylidene-5-*O*-benzyl-D-ribitol (14.8 g) which was hydrolysed with 70% acetic acid (50 m*l*) under reflux for 4 hr, and the reaction mixture was extracted with ether. The ether layer was washed with sodium bicarbonate and water, concentrated to give a syrup (12.8 g) which was distilled at 149°C/0.007 mmHg. Found: C, 66.34; H, 8.16%. Calcd for $C_{14}H_{20}O_4$: C, 66.64; H, 7.99%.

*1,4-Anhydro-1,1-dimethyl-3-O-benzoyl-5-O-benzyl-D-ribitol (**10**).* The above distillate (1.2 g) with bp 149°C/0.007 mmHg was treated with benzoyl chloride (1.4 g) and pyridine (1 m*l*) in chloroform at room temperature. The reaction mixture was poured into ice-water and extracted with chloroform. The organic layer was washed with water and concentrated *in vacuo* to give crystals of mp 94—96°C. The product has absorption bands at 3400 cm^{-1} and 1735 cm^{-1} which correspond to OH and ester carbonyl absorptions, respectively. The structure was confirmed by NMR spectrum (Fig. 1).

*1,4-Anhydro-1,1-dimethyl-2,3-O-thiocarbonyl-5-O-benzyl-D-ribitol (**11**).* To a solution of 15.32 g of **9** in acetone (225 m*l*) was added thiocarbonyldiimidazole (16.3 g) and the solution was refluxed for 1 hr under nitrogen atmosphere. The reaction mixture was concentrated to give a syrup containing crystals which was extracted with ether (300 m*l*). The extract was washed with 400 m*l* of water. The water layer was extracted twice with 200 m*l* of ether. The combined ether solution was dried over anhydrous sodium sulfate. The ether layer was filtered and concentrated under reduced pressure to give a syrup (18 g). The syrup was distilled at bp 145—150°C/0.03 mmHg, yield 11.8 g. Found: C, 61.00; H, 6.68%. Calcd for $C_{15}H_{18}O_4S$: C, 61.22; H, 6.12%.

Elimination of thiocarbonyl group of **11**. 11.1 g of **11** was dissolved in 75 m*l* of trimethyl phosphite and refluxed under nitrogen atmosphere for 3 days. To the reaction mixture was added 6N-NaOH solution under powerful stirring till pH 10, and stirring was continued for 2 hr. The mixture was extracted twice with methylene chloride (200 m*l*), washed with water, and concentrated *in vacuo* to give a syrup. The syrup had no absorption in the region of stretching vibration of olefins.

*Ethyl-4,5-O-isopropylidene-(4S),5-dihydroxypentenoate-2 (**13**).* A solution of carboethoxymethylenetriphenylphosphonium bromide (400 g) in 700 m*l* of abs. ethanol was added with cooling and stirring into sodium alcoholate solution prepared from sodium (23 g) and 500 m*l* of abs. ethanol. To the solution was added 118 g of a freshly distilled 2,3-*O*-isopropylidene-D-glyceraldehyde with cooling and stirring. The reaction mixture was stirred for 48 hr at room temperature, and then concentrated. The resulting sodium bromide and triphenylphosphine oxide were filtered off, and the remainder was distilled at 115—117°C/12 mmHg; $[\alpha]_D^{21}$+83.4° (*c* 0.34, ethanol); yield 112 g (60%). Found: C, 60.59; H, 8.12%. Calcd for $C_{10}H_{16}O_4$: C, 59.98; H, 8.05%.

*Ethyl-4,5-O-isopropylidene-(4S),5-dihydroxypentanoate (**14**).* A solution of **13** (14.4 g) in ethanol (50 m*l*) was shaken with hydrogen in the presence of Pd-C (3 g) for 1 hr during which the substrate absorbed 1.75 *l* of hydrogen at room temperature. The catalyst was removed by filtration and the filtrate was concentrated to a syrup which was distilled at 119—120°C/25 mmHg; yield, 14 g (97%); $[\alpha]_D^{21}$ −5° (*c* 0.42, ethanol). Found: C, 59.85; H, 9.02%. Calcd for $C_{10}H_{18}O_4$: C, 59.41; H, 8.91%.

*1,2-O-isopropylidene-5-methyl-1,(2S),5-trihydroxy-n-hexane (**15**).* To a cooled ethereal solution of methylmagnesium iodide prepared from 400 g of methyl iodide and 70 g of magnesium was added dropwise **14** (70 g) with stirring. The mixture was refluxed for 30 min, poured into ice-water containing ammonium chloride, and the resulting solution was extracted with ether. The ether layer was concentrated to a syrup which was distilled at 108—110°C/9 mmHg; yield, 52 g (82%); $[\alpha]_D^{21}$ −2.2° (*c* 0.50, ethanol). Found: C, 63.86; H, 10.80%. Calcd for $C_{10}H_{20}O_3$; C, 63.79; H, 10.71%.

*5-Methyl-1,(2S),5-trihydroxy-n-hexane (**16**).* A solution of **15** (9.4 g) in water (80 m*l*) and ethanol (20 m*l*) was stirred in the presence of Amberlite IR-120[H] (16 g) at room temperature for 2 hr. The solution filtered was treated with activated carbon and concentrated to give a syrup which was distilled at 110—113°C/0.005 mmHg; yield, 6 g (81%);

$[\alpha]_D^{21}-12.5°$ (*c* 1.0, ethanol). Found: C, 56.16; H, 11.14%. Calcd for $C_7H_{16}O_3$: C, 56.73; H, 10.88%.

5,5-Dimethyl-(S)-tetrahydrofurfuryl Alcohol (17). **16** (25.2 g) was heated with 85% orthophosphoric acid with stirring for 40 min. After cooling the reaction mixture was poured into water, and the resulting solution was extracted with ethyl acetate. The ethyl acetate layer was washed with sodium bicarbonate solution and water, and concentrated to a syrup which was distilled at 74—75.5°C/15 mmHg; yield, 15.7 g (71%); $[\alpha]_D^{18}+13.6°$ (*c* 0.6, ethanol). Found: C, 64.29; H, 11.00%. Calcd for $C_7H_{14}O_2$: C, 64.58; H, 10.84%.

5,5-Dimethyl-(S)-tetrahydrofurfural (3). To a cooled ether solution containing phosgen (3.3 g) was added 4 g of **17** under cooling and the solution was left standing for 2 hr at room temperature. The reaction mixture was concentrated to remove ether and phosgen, and the resulting syrup was distilled at 84—85°C/11 mmHg to give the chloroformate quantitatively. To a solution of 5.6 g of the chloroformate in benzene (10 m*l*) was added 5 g of dimethyl sulfoxide and the reaction mixture was stirred with cooling until carbon dioxide evolution ceased. To this solution 16 m*l* of triethylamine was added and the resulting precipitate of triethylamine hydrochloride was removed by filtration. The mixture was purified through Magnesol-Celite (1:3) column to give 5,5-dimethyl-(*S*)-tetrahydrofurfural. Aldehydic proton signal was observed at 0.4 τ (doublet, $J=1.8$ Hz) in the NMR spectrum.

The reaction of the aldehyde with 2,4-dinitrophenylhydrazin gave an yellow precipitate; mp 119°C. Found: C, 51.26; H, 5.07; N, 18.78%. Calcd for $C_{13}H_{16}N_4O_5$: C, 50.64; H, 5.23; N, 18.18%.

The Catalytic Decomposition of Nitrous Oxide on Titanium Dioxide; Anatase and Rutile

Yoshito ONISHI

Department of Chemistry, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto

(Received July 18, 1970)

Many investigations have been published on the catalytic reactions on various metallic oxides,[1] but few deal with the correlation between the catalytic activity and crystal form. From the studies on the catalytic oxidation of carbon monoxide on anatase and rutile, it was confirmed that the catalytic action of titanium dioxide differed with its crystal form.[2,3] In order to examine whether the same result is obtained in other reactions, the catalytic decomposition of nitrous oxide on titanium dioxide was carried out.

The catalytic decomposition of nitrous oxide on various metallic oxides[4] have been studied by many investigators, but there are few on titanium dioxide.

Experimental

The catalysts[2] used were anatase (A) of a guaranteed grade obtained from the East Merck Company, and rutile (R) and an anatase-rutile mixture (AR). The latter two were obtained by heating A at 1150°C for 3 hr and at 1050°C for 1 hr, respectively. Polymorphic forms of the three samples were confirmed by means of the X-ray diffraction method. The specific surface areas of the samples A, R, and AR estimated by the B.E.T. method using nitrogen as the adsorbate were 10.3 m^2/g, 1.0 m^2g, and 3.8 m^2/g, respectively. Nitrous oxide, oxygen, and nitrogen supplied from commercial cylinders were purified by vacuum distillation with liquid nitrogen, or by passing through a liquid nitrogen cooled trap.

The apparatus described in the preceding paper[2] was used. All precautions were taken to keep the samples from contamination. Traps were cooled with dry ice during the run to prevent grease and mercury vapors from the sample. Greaseless stop cocks were used between the traps and the sample tube. Prior to the measurements, the catalyst was pretreated in circulating oxygen of about 70 mmHg for 3 hr at 600°C for the cleaning of its surface.

It was ascertained by the analysis of the decomposition products that there are no side reactions to the main reaction, $N_2O \rightarrow N_2 + 1/2O_2$. The rate of the decomposition was determined by measuring the total pressure. It was confirmed that the gas phase decomposition of nitrous oxide was negligible under the experimental conditions.

Results and Discussion

The decomposition rates of nitrous oxide on three samples were measured under pressures 10^{-3}—80 mmHg at 600—800°C. The rates were proportional to P_{N_2O}. A typical result measured on anatase at 700°C is shown in Fig. 1. The decomposition rates did not change even

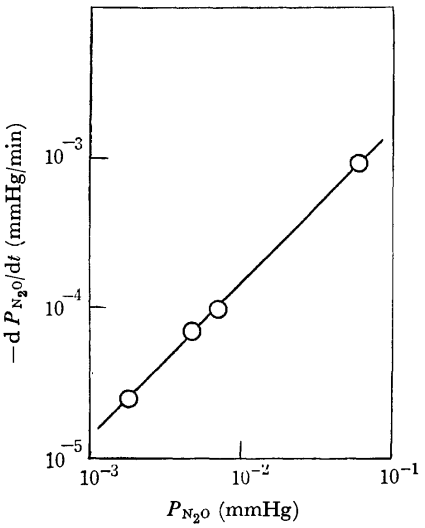

Fig. 1. Effect of N_2O pressure on the decomposition rate.

when oxygen or nitrogen was intentionally introduced into the reaction system. The decomposition rate is thus represented by

$$-d(N_2O)/dt = k_{N_2O} \cdot P_{N_2O} \quad (1)$$

where k_{N_2O} is a constant. The Arrhenius plots of the k_{N_2O} values are given in Fig. 2. The k_{N_2O} value of rutile is much larger than that of anatase at the same temperature, as in the case of oxidation of carbon monoxide. The activation energies of anatase and rutile are 42.3 and 31.0 kcal/mol, respectively. The difference between these values, about 10 kcal/mol, is comparable to the difference in the activation energies of the oxidation of carbon monoxide and that of the thermal desorption of surface oxygen atoms from the catalysts in two crystal forms.[2]

On the catalytic oxidation of carbon monoxide on titanium dioxide,[2] the rate constants k were characteristic for both anatase and rutile, and the k values of the sample AR consisting of particles in both anatase and rutile forms were calculated by assuming that the

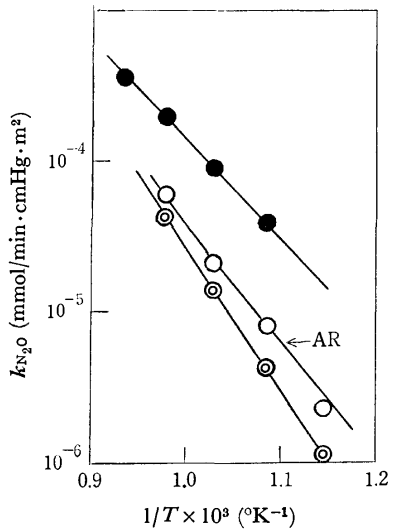

Fig. 2. Effect of temperature on the decomposition rate constant of nitrous oxide.
◎: A, ●: R, ○: AR

catalytic activity of an anatase-type surface and that of a rutile-type surface in AR were equal to those of pure anatase and rutile, respectively. The calculated values agreed well with the experimental values taken at different temperatures. The surface area ratio of the sample AR was estimated to be: anatase/rutile=86.8/13.2. Thus, if we assume that the rate constant k_{N_2O} is characteristic of the crystal form and the surface area ratio of two crystalline surfaces of the sample AR does not change, the rate constants k_{N_2O} of AR can be calculated by using the k_{N_2O} values of samples A and R. The calculated line of k_{N_2O} of the sample AR is shown by curve-AR in Fig. 2 with the experimental values shown by marks ○. The calculated line is in good agreement with the measured values.

It is found from the results that the catalytic action of titanium dioxide for the decomposition of nitrous oxide differs with its crystal form.

The author wishes to thank Prof. Takuya Hamamura, Kyoto Technical University, and Prof. Kumasaburo Kodera, Kyoto University, for their advice and discussions.

ESR Spectrum of Bromopyridines Irradiated with Ultraviolet Light. Confirmation of Pyridyl Radical Formation in Irradiated Pyridine and Their Formation Mechanism

Kozo Tsuji and Toshifumi Seiki
Central Research Laboratory, Sumitomo Chemical Co., Ltd. Takatsuki, Osaka

(Received January 21, 1971)

When pyridine was irradiated with electron beams or γ rays, there was observed the three line ESR spectrum with a coupling constant of about 30 gauss at -196°C.[1-5] Although this spectrum was attributed initially to pyridine cation radicals,[1-3] Symons *et al.*[4,5] attributed the spectrum to 2-pyridyl radicals mainly on the basis of observation of a large coupling constant of ^{13}C. The intensity of the ^{13}C signal, however, was not mentioned. The present investigation was carried out in order to confirm this assignment and to discuss about their formation mechanism.

It is well known that carbon-halogen bonds are easily broken homolitically by ultraviolet irradiation. Therefore it is expected that photolysis of halogenated pyridines will produce corresponding pyridyl radicals. Three isomers of bromopyridines were photolized and ESR spectra were recorded.

Experimental

Commercial 2- and 3-bromopyridines were used without further purification. 4-Bromopyridine was received as a hydrochloride and was used as it was. These samples were photolized in an ESR cavity by ultraviolet light from a Xenon short arc lamp (Ushio Electric Inc. UXL-500D) at -196°C. ESR measurements were carried out at -196°C with an X-band ESR spectrometer with 100 Kc field modulation. (Japan Electron Optics Lab. Co., Model JES, 3BS-X)[6]

Results and Discussion

After 2-bromopyridine was photolized at -196°C for 60 min, an ESR spectrum shown in Fig. 1a was observed, which is a three-line spectrum with a coupling constant of about 30 gauss. This spectrum is almost identical with that observed for pyridine irradiated with ionizing radiation.[1-5]

On the other hand 3- and 4-bromopyridines irradiated with ultraviolet light gave apparent singlet spectra with total line widths of about 66 and 60 gauss, respectively, as shown in Figs. 1b and c.

The fact that the triplet spectrum was obtained from only 2-bromopyridine leads to the conclusion that this hyperfine structure is caused by interaction of unpaired

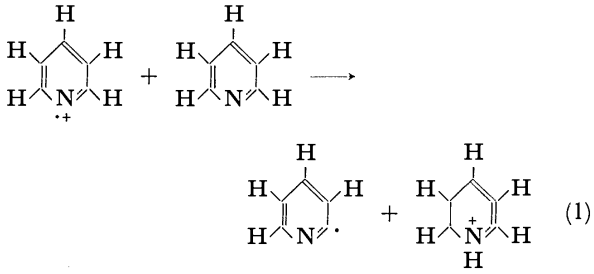
electrons with a nitrogen nucleus, and that the free radicals responsible for the ESR spectrum are 2-pyridyl radicals as expected, although the apparent intensity ratio of the triplet spectrum is not exactly 1 : 1 : 1, probably because of superposition of the spectrum due to the second radicals (II) described in the previous paper.[7] The line widths of the singlet spectra observed for 3- and 4-bromopyridines seem to be reasonable for corresponding pyridyl radicals since a close value is expected for the phenyl radicals[8,9] when the worse resolution of the spectrum is assumed. Therefore it is clear that the 2 pyridyl radical shows the three-line spectrum with a coupling constant of about 30 gauss. Consequently assignment of the ESR spectrum of pyridine irradiated with ionizing radiation at −196°C mainly to the 2-pyridyl radicals is thought to be reasonable.

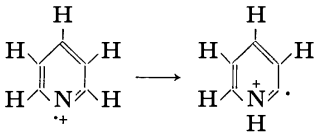
This pyridyl radical produced in pyridine irradiated with ionizing radiation, however, does not seem to be produced by direct hydrogen atom abstraction from the position-2. The primary process of radiation is ionization of electrons in the nonbonding orbital of the nitrogen nucleus.[1] Cation radicals thus formed could be precursors of the 2-pyridyl radicals, that is consistent with the fact that pyridine hydrochloride[10] and the pyridine complexes with metal salts[7] did not give the pyridyl radicals after γ-irradiation, where lone pair electrons of the nitrogen nucleus are no longer available for ionization. This is also supported by the fact that ultraviolet photolysis of the pyridine-iodine complex with the light corresponding to the charge transfer band of the complex gave the same spectrum even though the intensity is small, since photoexcitation of the complex will produce primarily pyridine cation radicals through the excited state.[2]

Symons *et al.*[5] suggested the 2-pyridyl radicals can be formed by the loss of a proton as follows:



(1)

There is, however, another possibility to produce 2-pyridyl radicals (although they are of protonated form) from pyridine cation radicals, that is, isomerization of pyridine cation radicals.



(2)

The protonated pyridyl radical has an extra proton on a nitrogen atom. Although the splitting due to this proton may be expected, the value will be too small to give the splitting in the similar way to the ring proton on position 3.[5] If this is correct, the protonated form can give the similar spectrum to that of unprotonated pyridyl radicals.

These two possible structures of free radicals (protonated- and unprotonated-forms) are quite similar to those of free radicals in irradiated 2-methyltetrahydrofuran.[11]

The protonated form is isoelectric with phenyl radical. Phenyl radicals produced by irradiation seem to be unstable even at −196°C since the ESR spectrum due to phenyl radicals was hardly observed at −196°C in benzene irradiated with ionizing radiation, although their formation is expected as donors of hydrogen atoms to form cyclohexadienyl radicals.[12] The situation is the same for protonated pyridyl radicals in irradiated pyridinium ions.[10] Therefore protonated form might be less stable than unprotonated one. The same conclusion could be drawn by comparison of resonance energies of pyridine (43 kcal/mol) and benzene (40 kcal/mol). Therefore according to this stability consideration, the reaction (1) might be predominant for the mechanism of pyridyl radical formation.

The authors wish to express their gratitude to Drs. S. Kodama, T. Nishikida, A. Segawa, and Y. Kubota for their kind guidance and encouragement. Thanks are also due to Dr. T. Takeshita for his helpful discussion.

1,2,3-Benzotriazole Complexes of Palladium(II)

Yoshihisa WATANABE, Take-aki MITSUDO, Masato TANAKA, Kazuo YAMAMOTO, and Yoshinobu TAKEGAMI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received February 19, 1971)

1,2,3-Benzotriazoles are known to decompose thermally and photochemically to give biradicals, with an accompanying evolution of nitrogen.[1] We attempted to prepare 1,2,3-benzotriazole complexes of transition metals[2] and to compare the complexes with free compounds. This note will describe how the reaction of 1*H*-, 1-benzyl-, and 1-vinyl-1,2,3-benzotriazoles with dichlorobis(benzonitrile)palladium(II) and di-π-allyl-μ,μ'-dichlorodipalladium(II) gives benzotriazole complexes of palladium(II). The pyrolysis and the photolysis of these complexes will bediscussed later.

1*H*-1,2,3-Benzotriazole readily reacts with dichlorobis(benzonitrile)palladium(II) in benzene at room temperature to give a yellow complex of the $PdCl_2$(1*H*-1,2,3-benzotriazole)$_2$ type almost quantitatively. The infrared spectrum of this complex has a very strong band at 3200 cm^{-1}, indicating that the >N–H group remains in the complex and that some of the nitrogen atoms in the benzotriazole act as donors. 1-Benzyl- and 1-vinyl-1,2,3-benzotriazoles react similarly with dichlorobis(benzonitrile)palladium(II) to give complexes of the $PdCl_2$(benzotriazole)$_2$ type. These complexes are also formed from palladium(II) chloride and the benzotriazoles in ethanol, but those reactions proceed very slowly.

The benzotriazoles react with di-π-allyl-μ,μ'-dichlorodipalladium(II) in benzene at room temperature to give white or yellow complexes of the (π-allyl)PdCl(benzotriazole) type. The PMR spectra of these complexes indicate that the allyl group gives a signal of the A_2B_2X type in $CDCl_3$ and of the AX_4 type in dimethyl sulfoxide (DMSO-d_6), and that the chemical shifts and the coupling constants of protons of methylene and the vinyl group are similar to those of the free corresponding benzotriazoles. In DMSO-d_6, the PMR spectra of the allyl groups depend on the temperature (20—70°C). Over 40°C all four terminal protons are equivalent (AX_4, τ 6.2 ppm doublet, 4.2 ppm quintet); this is best described in terms of a rapid dynamic equilibrium between the two possible σ-bonded forms.[3] However, at 20°C, the signal at the higher field appears as a broad singlet, suggesting that the dynamic equilibrium may be affected by the temperature. The fact that the PMR signals of the 1-methylene and 1-vinyl group in the 1-benzyl- and 1-vinyl-benzotriazoles are not affected by the complex formation strongly suggests that the nitrogen atom at the 2 or 3-position of the benzotriazoles acts as the donor in the complexes.

Experimental[4]

All the reactions were carried out in an argon atmosphere. The products, benzotriazole complexes of Pd(II), were stable in air in the solid state.

Dichlorobis(1H-1,2,3-benzotriazole)palladium(II). Into 380 mg of dichloro bis(benzonitrile)palladium(II) in 10 m*l* of benzene, we stirred 240 mg of 1*H*-1,2,3-benzotriazole at room temperature. A yellow substance (340 mg) precipitated out in a few minutes; this was filtered off and washed several times with benzene; mp>290°C; insoluble in benzene, ethanol, water, chloroform, and acetone, but slightly soluble in DMSO and *N,N*-dimethylformamide(DMF).

Found: C, 35.10; H, 2.55; N, 19.95; Cl, 16.80; Pd, 24.80%. Calcd for $C_{12}H_{10}N_6Cl_2Pd$: C, 34.68; H, 2.43; N, 20.23; Cl, 17.06; Pd, 25.60%.

IR (KBr): 3200 (very strong, broad), 1620(m), 1605(m), 1505(m), 1455(m), 1425(w), 1405(m), 1305(m), 1235(s), 1125(m), 1050(s), 915(m), 780(s), 760(m), 740(s) cm^{-1}. (s=strong, m=medium, w=weak intensity)

Dichlorobis(1-benzyl-1,2,3-benzotriazole)palladium(II). 1-Benzyl-1,2,3-benzotriazole[5] (105 mg) in 5 m*l* of benzene was similarly treated with dichlorobis(benzonitrile)palladium(II) (96 mg) for 5 min to give a pale yellow precipitate (120 mg); mp 250°C decomp.; insoluble in benzene, ethanol, chloroform, and acetone, but slightly soluble in DMSO and DMF.

Found: C, 51.58; H, 4.00; N, 13.61%. Calcd for $C_{26}H_{22}N_6Cl_2Pd$: C, 52.41; H, 3.72; N, 14.11%.

IR (KBr): 3080(m), 3050(m), 3000(w), 2940(m), 1615(m), 1595(m), 1495(m), 1480(m), 1455(m), 1330(w), 1310(m), 1300(w), 1245(s), 1165(m), 1140(m), 770(m), 745(s) cm^{-1}.

PMR (60 MHz, in DMSO-d_6); τ 1.8—2.6(multiplet, 4H), 2.65(singlet, 5H), 3.95(singlet, 2H).

Dichlorobis(1-vinyl-1,2,3-benzotriazole)palladium(II). 1-Vinyl-1,2,3-benzotriazole[6] (150 mg) was similarly treated with dichlorobis(benzonitrile)palladium(II) (190 mg) in 5 m*l* of benzene to give a pale yellow precipitate (180 mg); mp 265°C decomp.; insoluble in benzene, ethanol, chloroform, and acetone, but slightly soluble in DMSO and DMF.

Found: C, 41.86; H, 3.11; Pd, 23.31%. Calcd for $C_{16}H_{14}N_6Cl_2Pd$: C, 41.09; H, 3.02; Pd, 22.75%.

The Synthesis of Nucleoside and Nucleotide Analogs

Tooru SEITA, Kiyoshi YAMAUCHI, Masayoshi KINOSHITA, and Minoru IMOTO*

Department of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka

**Department of Applied Chemistry, Kansai University, Suita, Osaka*

(Received April 26, 1971)

During the course of our studies of the preparation of polymers containg nucleic acid bases,[1] we attempted to synthesize nucleoside and nucleotide analogs, replacing the sugar part of the nucleoside or the nucleotide with an aliphatic diol. In the present study, the preparation of nucleoside and nucleotide analogs, such as Ia, IIa, Ia-p, and IIa-p, was investigated. These nucleotide analogs may be useful for the study of the physicochemical properties of nucleic acids when the polymers of these nucleotide analogs are prepared. Moreover, these compounds might be of biological and chemotherapeutical interest because of their structual similarity to Cordycepin, Aristeromycin,[2] etc.

Adenine (I) was chosen as the base part of the nucleoside model. When the sodium salt of I, prepared without isolating from I and sodium hydride, was allowed to react with glycerol α-monochlorohydrin, 3- and 9-(2′,3′-dihydroxypropyl)adenines (Ia and Ib) were obtained. These products were easily separated by fractional crystallization. Both compounds were chromatographically pure. The structures of Ia and Ib were determined by studing their ultraviolet spectra.[3]

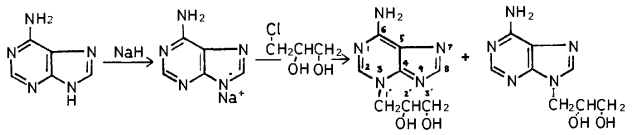
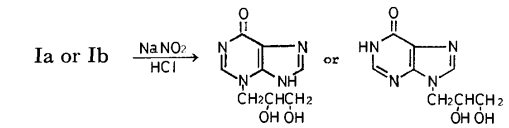
a) Solvent systems used were: water satulated with *n*-butanol - concd. NH_4OH (15:10) for Ia, Ib, IIa, IIb, and ethanol - conc. NH_4OH - water (15:10:1) for Ia—p, Ib—p, IIa—p, and IIb—p.

In this experiment, 7-(2',3'-Dihydroxypropyl)adenine was not obtained.



I Ia Ib

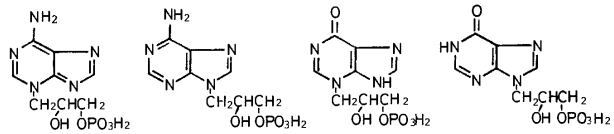
When compounds Ia and Ib were treated with concentrated hydrochloric acid and sodium nitrite, the corresponding hypoxanthine derivatives (IIa and IIb) were produced in 70 and 75% yields respectively.



IIa IIb

These compounds were purified by recrystallization. The UV and IR spectra supported the structures.[4]

The phosphorylation of the above compounds was carried out using phosphorus oxychloride in trimethyl phosphate by a modification of the procedure of Yoshikawa, Kato, and Takenishi.[5] By this method, compounds Ia, Ib, IIa, and IIb were phosphorylated to give the corresponding nucleotide analogs, Ia-p, Ib-p, IIa-p, and IIb-p, in 52, 39, 36, and 42% yields respectively. The phosphates were identified by paper chromatography and by elemental analysis. In these experiments, the 2'-phosphates were not obtained since the 2'-position of hydroxyl groups on the nucleoside analogs are sterically hindered.



Ia-p Ib-p IIa-p IIb-p

Pharmacological studies and a study of the polymerization reaction of these phosphates are now under way.

Experimental

The melting points are uncorrected. The infrared spectra (IR) were run on a JASCO Model IR-G Spectrometer. The ultraviolet spectra (UV) were measured by a Hitachi Recording Spectrometer Model EPS-3T. Paper chromatography was carried out by the ascending technique using Toyo Roshi No. 50 paper. The results of the elemental analysis, the UV data, the R_f, and the mp of the reported compounds are listed in Table 1.

3-(2',3'-Dihydroxypropyl)adenine (Ia) and 9-(2',3'-Dihydroxypropyl)adenine (Ib). A mixture of adenine (0.67 g, 5 mmol) and sodium hydride (0.25 g, 50%, 5.2 mmol) in anhydrous *N,N*-dimethylformamide (200 m*l*) was stirred at room temperature for 1 hr to give a milky solution of the sodium salt of adenine. To this solution glycerol α-monochlorohydrin (0.55 g, 5.5 mmol) was added, and the mixture was heated at 80—85°C with stirring for 24 hr. The sodium chloride thus precipitated in the cooled reaction mixture was filtered out, and the filtrate was concentrated as much as possible. The resulting solid was filtered and recrystallized from water to afford Ia (0.22 g (21%)) as colorless plates.

The mother liquid was concentrated to dryness. A yellow solid thus obtained was crystallized from ethanol. Recrystallization from water gave 0.47 g (45%) of Ib as colorless needles.

IR of Ia (KBr): 3350(s), 3200(s), 2980(s), 1960(s), 1628(s),

4) J. H. Lister and G. M. Timmis, *J. Chem. Soc.*, **1960**, 327.

5) This method is known to be useful for the selective phosphorylation of the 5'-hydroxyl group of nucleoside (M. Yoshikawa, T. Kato, and T. Tadenishi, *Tetrahedron Lett.*, **1967**, 5065); the selective phosphorylation of nicotinamide nucleoside and riboflavin has also been reported by this method. In the case of riboflavin, as intermediate, 4', 5'-cyclic riboflavin phosphate was isolated; it was exclusively hydrolized to riboflavin 5'-phosphate. Propanediol-1,2-cyclic phosphate and glycerol-1,2-cyclic phosphate produced the corresponding 1-phosphates almost quantitatively under acidic conditions. From these results, it seems that the reaction of diols with phosphorus oxychloride proceed through an intermediate, five-membered cyclic phosphate, which is selectively hydrolyzed into primary phosphates. Bull* (Tokyo), **5**, 127 (1957); E. Baer, ans M. Kates, *J. Biol. Chem.*, **175**, 79 (1948).

1560(w), 1415(m), 1225(w), 1180(w), 1010(m), 890(w), and 710(w) cm^{-1}.

IR of Ib (KBr): 3300(s), 3150(s), 2950(w), 1650(s), 1600(s), 1480(m), 1416(w), 1330(m), 1295(m), 1105(m), 1020(m), 900(m), and 730(s) cm^{-1}.

3-(2',3'-Dihydroxypropyl)hypoxanthine (IIa). Into a solution of Ia (1.0 g, 4.8 mmol) in concentrated hydrochloric acid (20 m*l*), sodium nitrite (1.2 g, 17.1 mmol) in water (40 m*l*) was slowly with vigorously stirring over a 1-hr period. The temperature was maintained at 0°C. After having been stirred at room temperature for an additional 6 hr, the reaction mixture was neutralized with sodium bicarbonate and evaporated to dryness under reduced pressure. The residue was crystallized from water to give IIa (0.7 g (70%)) as colorless plates.

IR (KBr): 3000(s), 2900(s), 2850(m), 1630(s), 1595(m), 1545(s), 1430(s), 1380(w), 1200(m), 1120(m), 1010(m), 940(w), and 790(w) cm^{-1}.

9-(2',3'-Dihydroxypropyl)hypoxanthine (IIb). Compound Ib(1.0 g, 4.8 mmol) was treated with sodium nitrite (1.2 g, 17.1 mmol) in a manner similar to that mentioned above. The reaction mixture was neutrallized with concentrated ammonium hydroxide and concentrated. Crude IIb was crystallized from ethanol. Recrystallization from water afforded IIb (0.75 g (75%)) as colorless needle crystals.

IR (KBr): 3200(s), 2900(s), 1690(s), 1620(w), 1590(m), 1550(m), 1520(m), 1420(m), 1380(w), 1227(s), 1120(s), 1060(m), 1015(m), 870(w), and 770(m) cm^{-1}.

3-(2',3'-Dihydroxypropyl)adenine 3'-Phosphate (Ia-p). Compound Ia (0.5 g, 2.4 mmol) was dissolved in trimethyl phosphate (5 m*l*) and cooled to 0°C. To this solution phosphorus oxychloride (0.4 g, 2.6 mmol) was added slowly over 6-hr period. Water was then added, and the mixture was stirred for 20—30 more min. A white precipitate was then filtered out and crystallized from water. The phosphate, Ia-p (0.36 g (52%)), was obtained as colorless needle crystals.

IR (KBr): 3100(m), 3000(s), 1680(m), 1630(s), 1410(m), 1200(s), 1100(s), 1060(s), 970(s), and 770(w) cm^{-1}.

9-(2',3'-Dihydroxypropyl)adenine 3'-Phosphate (Ib-p). Compound Ib (0.5 g, 2.4 mmol) was treated with phosphorus oxychloride (0.4 g, 2.6 mmol) in trimethyl phosphate (4 m*l*) in a manner similar to that described above. Water added to the reaction mixture and it was stirred for an additional hour. After the reaction mixture had then been concentrated under reduced pressure at below 50°C, the residue was treated with ethanol (20 m*l*). The white precipitate was crystallized from water to give Ib-p (0.26 g (39%)) as colorless needles.

IR (KBr): 3200(s), 3050(s), 1690(s), 1610(m), 1415(m), 1220(m), 1120(s), 990(s), 930(s), and 760(m) cm^{-1}.

3-(2',3'-Dihydroxypropyl)hypoxanthine 3'-Phosphate (IIa-p). Compound IIa (0.5 g, 2.4 mmol) was treated with phosphorus oxychloride (0.4 g, 2.6 mmol) in trimethyl phosphate (5 m*l*) as has been described above. Water the then added to the reaction mixture, and it was stirred for an additional hour. After the evaporation of water below 50°C, a mixture of 20 m*l* of ethanol and 10 m*l* of ether was added. The white precipitate was crystallized from water to give IIa-p (0.25 g (36%)) as colorless crystals.

IR (KBr): 3250(m), 3100(m), 1680(s), 1550(m), 1230(m), 1110(s), 770(w), and 610(w) cm^{-1}.

9-(2',3'-Dihydroxypropyl)hypoxanthine 3'-Phosphate (IIb-p). IIb-p was prepared in the way described in the case of IIa-p; IIb (0.5 g, 2.4 mmol) was treated with phosphorus oxychloride (0.4 g, 2.6 mmol) and trimethyl phosphate (5 m*l*). IIb-p (0.29 g (42%)) was obtained and crystallized from a mixture of ethanol and water (8: 2).

IR (KBr): 3400(m), 3150(s), 1700(s), 1570(m), 1530(w), 1370(s), 1210(s), 1100(s), 990(m), and 910(m) cm^{-1}.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 928—930(1972)

The Mass Spectra of 3-Aryl-5-methyl-1,2,3-oxathiazolidine-2-oxides

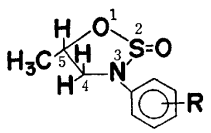
Tomihiro NISHIYAMA, Yasuyoshi FUJIMOTO, and Fukiko YAMADA
Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka

(Received June 2, 1971)

In continuation of our previous reports concerning the formation of 3-aryl-1,2,3-oxathiazolidine-2-oxides[1] and their mass spectra,[2] this report will deal with the fragmentation schemes of 3-aryl-5-methyl-1,2,3-oxathiazolidine-2-oxides.

We have prepared 3-phenyl-5-methyl-1,2,3-oxathiazolidine-2-oxide (I), 3-tolyl-5-methyl-1,2,3-oxathiazolidine-2-oxides (II), and 3-chlorophenyl-1,2,3-oxathiazolidine-2-oxides (III) by the reported method.[3]

The mass spectral data of the compounds are shown in Table 1, while the major fragmentation paths are shown in Scheme 1. The abundances of the molecular



I, R=H
IIa, R=*o*-CH_3
IIb, R=*m*-CH_3
IIc, R=*p*-CH_3
IIIa, R=*o*-Cl
IIIb, R=*m*-Cl
IIIc, R=*p*-Cl

ions of the compounds are quite low. This behavior can be ascribed to the easy cleavage of the oxathiazolidine ring; supporting evidence for this postulate is available from the large peaks (100% abundance) at *m/e* 104, 118, and 138, corresponding to the R-C_6H_4-NCH cation, in the spectra. These peaks occur because of the loss of the SO_2 group from the molecular ion, followed by the loss of both the $CH_2=CH_2$ group and the hydrogen radical (Path 1 in Scheme 1). These fragment ions lose the HCN group to give phenyl cations with *m/e* values of 77, 91, and 111 respectively.

The oxathiazolidines, I, II, and III, exist in the *cis*

111	C_6H_4Cl	36	39	53	51

and *trans* configurations between the S=O group and the methyl group in the 5-position, and it is possible to assign the substituent geometry of the isomeric pairs by means of NMR spectroscopy.[3] In the mass spectral data shown in Table 1, the *cis* and *trans* isomers of IIIa show a similar fragmentation pattern. It can be assumed that the fragmentation patterns of the other compounds are the same in the *cis* and *trans* configurations. Thus, the fragmentation pattern for each compound will be discussed by means of the data obtained in the case of either the *cis* or *trans* isomer.

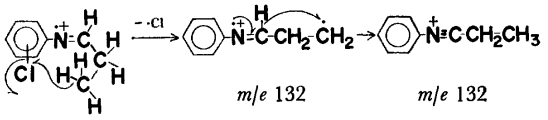
A significant difference in the mass spectral pattern on the position in the ring-substituted group in the III compounds can be observed at *m/e* 132, which is of 55% abundance for the *ortho* isomer, 15% for the *meta*, and 18% for the *para*. On the other hand, in the compounds of II, the abundance of the peak at *m/e* 132 is 10% for the *ortho* isomer, 15% for the *meta*, and 14% for the *para*. This ion at *m/e* 132, corresponding to $C_6H_5NC_3H_5$, can be produced by the loss of the SO_2 group from the molecular ion, followed by the loss of the ring substituent, methyl, or chloro group (Path 2 in Scheme 1). The above findings suggest that the abnudance of IIIa at *m/e* 132 may be caused by the substituent at the *ortho*-position.

In constrast to the present behavior, the above fragment ion was not observed in the spectra of either 3-phenyl-1,2,3-oxathiazolidine-2-oxide or 3-*p*-tolyl-1,2,3-oxathiazolidine-2-oxide bearing no 5-methyl group.

In the compounds of II, peaks at *m/e* 104 and 105, corresponding to the $C_6H_4NCH_2$ and $C_6H_5NCH_2$ cations respectively, were observed. On the contrary to this fact, these peaks were so small as to be negligible in the spectra of III. These differences can be explained by the following fragmentation mechanisms. It is thought that, in the compounds of II, the fragment ion at *m/e* 132 eliminates the $CH_2=CH_2$ group to give the ion at *m/e* 104, and that then a proton adducts to the benzene ring to give the ion at *m/e* 105, as follows:

m/e 132 *m/e* 104 *m/e* 105

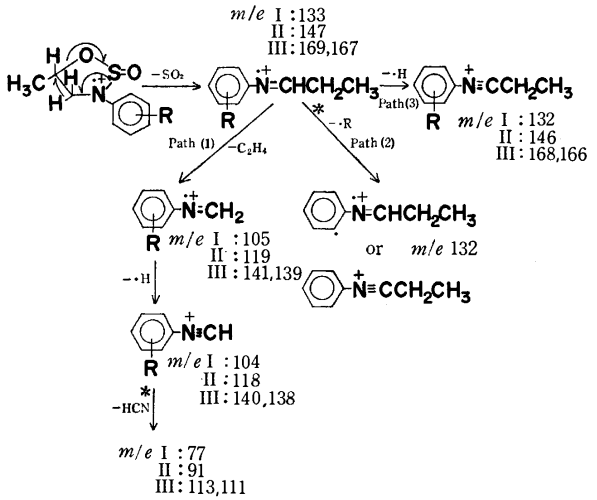
On the other hand, in the compounds of III, we supposed that the ion at *m/e* 132 can be formed by the elimination of the chloro substituent, followed by the migration of the hydrogen radical from the 5-methyl group to the position on the benzene ring, as follows:



m/e 132 *m/e* 132

m/e 169, 167

As has been described above, there are three principal paths of the fragmentation of the ion corresponding to R-C_6H_4N=$CHCH_2CH_3$ as a result of the loss of the SO_2 group from the molecular ion:



Scheme 1. The major fragmentation pathways of oxathiazolidines, I, II, and III.

* Asterisks denote the processes for which metastable transitions were observed.

(1) the elimination of the $CH_2=CH_2$ group
(2) the loss of the ring substituent (radical)
(3) the loss of the hydrogen radical.

Experimental

The mass spectra were obtained with a Japan Electron Optics Co., Ltd., JMS-O1SG Mattauch-Herzog double-focusing mass spectrometer. In the photographic-plate measurements, a sample was introduced with a marker (PFK), under normal operating conditions (accelerating voltage, 6.4 kV). Accurate masses were determined by the previously-reported method.[2)]

The Occurrence of Yangonin, 4-Methoxy-6-(*p*-methoxystyryl)-2-pyrone, in *Ranunculaceae*

Tamotsu SHIBATA,[1] Tsuyoshi SHIBUYA, and Kozo DOI
Department of Chemistry, Faculty of Science, Hirosaki University, Hirosaki

(Received June 21, 1971)

Since the isolation of protoanemonin from the essential oil,[2] little is known about the constituents of *Ranunculus quelpaertensis* Nakai (Kitsunenobotan in Japanese), belonging to *Ranunculaceae*. Recently we have reinvestigated the extractive of stems and leaves of the plant, and have isolated and characterized the following substances as the constituents: fumaric, palmitic, and stearic acids from the acidic fraction, and a long-chain saturated hydrocarbons mixture containing C_{23}—C_{31}, stigmasterol, β-sitosterol, hexacontanol, unidentified C_{27}-alcohol, and yangonin,[3] 4-methoxy-6-(*p*-methoxystyryl)-2-pyrone, from the neutral fraction. As far as we know, yangonin had been isolated only from the root of *Piper methysticum* Forst.[3] (*Piperaceae*), and it is of interest from the stand of chemotaxonomy to occur also in *Ranunculaceae*. The details of the work will be described in the following section.

Experimental

All melting points are uncorrected. The IR spectra were determined as KBr pellets on a Hitachi model EPI-S spectrophotometer. The mass spectra[4] were taken on a Hitachi model RMU-7 mass spectrometer at 70 eV. Gas-liquid chromatographic analyses (glc) were made at 180—220°C, using a Yanagimoto model GCG-5DH apparatus with a hydrogen flame ionization detector (3 mm × 1.5 m column, 10% SE-30/Chromosorb W).

Extraction and Fractionation. Dried stems and leaves (4.2 kg) of the plant were ground and extracted with hot methanol, and the extract were evaporated *in vacuo* to give dark green residue, which was extracted again with ether. The ether solution was then fractionated into the hydrogen carbonate-soluble, carbonate-soluble, and neutral fractions. The former two fractions were extracted respectively with ether after acidifications.

The Hydrogen Carbonate-soluble Fraction. The ether extract was evaporated *in vacuo* to give crystalline residue, from which was isolated fumaric acid, colorless needles (80 mg), mp and mixed mp 284°C (sealed tube), after vacuum sublimation followed by recrystallization from ethanol.

The Carbonate-soluble Fraction. After evaporation of the solvent *in vacuo* followed by crystallization from ethanol, the ether extract afforded a mixture (120 mg) of palmitic and stearic acids, identification of which was made with glc of their methyl esters.

The Neutral Fraction. The *n*-hexane solution of the neutral fraction (22 g) was chromatographed through a column packed with alumina (200 g), an effluent (1200 m*l*) from the same solvent was collected, and the remain was recovered with methanol (1900 m*l*). The former effluent was evaporated *in vacuo* to give colorless crystals (10 g), mp 57—64°C, identified as a mixture of long-chain saturated hydrocarbons containing C_{23}—C_{31}, consisting of mainly C_{27} and C_{29}, from the comparison of glc with standard sample of hydrocarbons.[5] The fraction recovered with methanol, after evaporation *in vacuo*, deposited colorless leaflets (1.6 g), mp 146—148°C, from ethanol. The IR spectrum shows maxima at 970 and 959 cm^{-1}, and the mass spectrum two molecular ion peaks at *m/e* 414 and *m/e* 412. From the comparison of glc, this was proved to be a mixture of stigmasterol and β-sitosterol (2: 1).[6]

The fraction removed from the above sterols was chromatographed through a column packed with alumina (300 g) and developed with a mixed solvent of benzene and ether. An effluent from the system (benzene–ether (99 : 1)) afforded colorless crystals (10 mg) by recrystallization from methanol, mp 68.5—69.5°C, ν_{max}: 3250, 1053, 720, and 710 cm^{-1}. The mass spectrum indicates base peak at *m/e* 31 ($CH_2=O^+H$) and two molecular ion peaks at *m/e* 392.403 (Calcd for $C_{27}H_{52}O$: 392.402) and *m/e* 382.418 (Calcd for $C_{26}H_{54}O$: 382.417), indicative of a mixture of alcohols containing at least hexacontanol.

An effluent from the system (benzene–ether (97: 3)) gave pale yellow prisms by recrystallization from ethanol, mp 152—

4) We are indebted to Mr. H. Sato, Hitachi Seisakusho, for measurements of the spectra.

5) We are very grateful to Dr. T. Kamano, Taisho Seiyaku Co., for generous gift of the standard sample of hydrocarbons.

6) The authors wish to thank Prof. T. Takemoto, Tohoku University, for carrying out of this analysis.

153°C. Its mass spectrum shows peaks at *m/e* 258 (M^+) and *m/e* 230.092 (M^+–CO) (Calcd for $C_{14}H_{14}O_3$: 230.094), establishing its molecular formula, $C_{15}H_{14}O_4$. The IR spectrum indicates the presence of 2-pyrone ring (1720, 1624, and 1556 cm^{-1}), 1,4-disubstituted phenyl with conjugation (1602, 1575, 1512, 1176, 1110, 1025, 1000, and 827 cm^{-1}), and an extra *trans*-disubstituted ethylene (960 cm^{-1}). The spectral pattern resembles closely that of naturally occurring yangonin. In fact, this constituent showed no depression of mixed melting point with authentic sample.[7] The other mass spectral peaks at *m/e* 215(M^+–CO–CH_3), 202(M^+–2×CO), 187(M^+–2×CO–CH_3), 159(M^+–3×CO–CH_3), 144(M^+–3×CO–2×CH_3), are also compatible to the structure of yangonin.

An effluent from the system (benzene–ether (1:1)) afforded further a mixture of stigmasterol and β-sitosterol.

7) We are very grateful to Dr. R. Hänsel, Freie Universität, Berlin, for generous gift of natural yangonin.

The Effect of the Shield Voltage on Appearance Potential Measurements Using a Mass Spectrometer

Susumu TAJIMA, Yukio SHIMIZU,* and Toshikazu TSUCHIYA

Government Chemical Industrial Research Institute, Tokyo, Honmachi, Shibuya-ku, Tokyo

**National Research Institute for Pollution and Resources, Kotobukicho, Kawaguchi-shi, Saitama*

(Received July 7, 1971)

In the usual type of mass spectrometer, a small negative voltage is applied to the filament shield as an aid in confining the largest portion of the filament's emission to the region of the electron slit. In measuring the appearance potential (AP) with the mass spectrometer, the obtained values were found to be affected by the shield voltage. To the authors' knowledge, however the effect of the shield voltage on the AP has not yet been discussed, though it is well known that the measured AP is affected by the repeller voltage[1,2] and/or the source magnetic field.[3] In the present note, the cause of the effect of the shield voltage on the AP will be discussed and a procedure to eliminate the effect will be reported.

Experimental

A CEC 21-103C mass spectrometer was used in measuring the AP. The ionization efficiency (IE) curves were treated by the E.D.D. technique[4] after the data had been smoothed by the least-squares method using a computer. The constant, b, used in the E.D.D. calculation was 0.67. Krypton was used as the calibrating gas for the electron energy scale. The ionization potential (IP) of krypton was taken as 14.00 eV. The sample, benzene, and krypton were introduced into the ion source at the same time. The repeller voltage was kept at a constant value[1,2] for all the measurements. The electron trap current was 10 μA; the temperature of the ion source was 250°C.

The IP value of benzene was measured by using two electric circuits, 1) a standard electric circuit, and 2) a modified electric circuit. In the standard circuit of the CEC 21-103C mass spectrometer, the electron accelerating voltage (V_e) and the shield voltage are supplied from the same circuit by changing the value of the resistor, R, in the circuit, as is shown in Fig. 1. Under usual experimental conditions, the shield voltage changes in proportion to V_e, since the value of the resistor between the filament and the shield electrodes is kept constant ($r \simeq 500$ ohm). In the modified circuit, the voltage, V_e, was supplied from a separate circuit and was set with a 10-turn potentiometer (Sakae Tsushin Kōgyō Co., Ltd.), as is shown in Fig. 2, while the shield voltage was set by the same resistor, R, as in the standard circuit. By this circuit, the shield voltage can be set at any value, independent of the V_e.

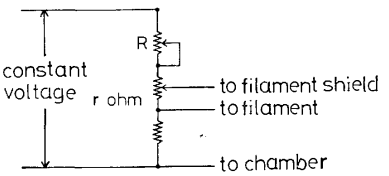

Fig. 1. Diagram of the standard electric circuit for the electron accelerating voltage and the shield voltage of a CEC 21-103C mass spectrometer.

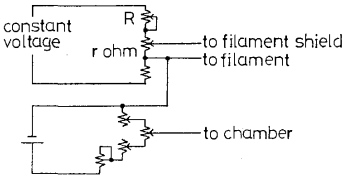

Fig. 2. Diagram of she modified electric circuit for the electron accelerating voltage and the shield voltage.

Results and Discussion

The two IP values of benzene determined in the present study are, in Table 1, compared with those obtained by various other methods.[5-8] As may be seen

Table I. Ionization potential of benzene obtained by using (a) standard electric circuit, and (b) modified electric circuit

	eV
Photoelectron Spectroscopy[5]	9.24
Spectroscopy[6]	9.24_8
Photoionization[7]	9.24_1
Electron Impact (RPD)[8]	9.21
This work[a]	9.52±0.1
This work[b]	9.20±0.1

in the table, the IP value obtained by using the modified circuit agrees reasonably well with the literature values, while that obtained by using the standard circuit is considerably higher. A little higher AP values were obtained for various ions from disubstituted benzenes,[9] too, when the standard circuit was used.

Table 2. Ionization potentials of krypton measured under various shield voltages

Shield voltage (mV)	Ionization potential (eV) (uncorrected)
$1.0\times r$	13.40±0.1
$1.5\times r$	13.30±0.1
$2.0\times r$	13.05±0.1

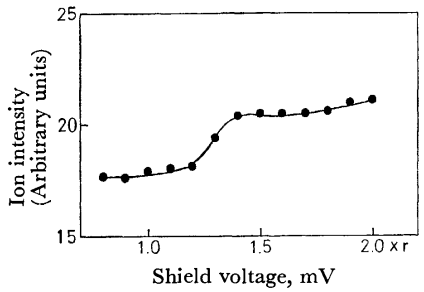

Fig. 3. Variation of the ion intensity of krypton (*m/e* 84) with the shield voltage at the electron accelerating voltage of 15.0 eV (uncorrected), and at ion accelerating voltage of about 1000 V.

To clarify the cause of these results, the IP of krypton was measured at three shield voltages corresponding to current flows of 1.0, 1.5, and 2.0 mA through the resistor ($r\simeq 500$ ohm). The values thus obtained are shown in Table 2. The variation in the krypton-ion (*m/e* 84) intensities with the shield voltage obtained at the electron accelerating voltage of 15.0 eV is shown in Fig. 3. From Figure 3 and Table 2, it may be seen that the ion intensity at a constant electron accelerating voltage increases with an increase in the shield voltage, and that the observed IP for krypton decreases with an increase in the shield voltage. Hence, if the IE curves of the two compounds are measured at different shield voltages, the difference between the two apparent IP's observed will be different from the difference between the true IP's for the two compounds, since different shield voltages exert different influences on the ion intensities of the two compounds. When the IP of benzene is measured by using the standard electric circuit of the CEC 21–103C mass spectrometer and when krypton is used as the calibrating gas for the electron energy scale, different shield voltage are used in each case—*i.e.*, for benzene, about $0.9\times r$ (mV), and for krypton, about $1.4\times r$ (mV). If the factors of the effects due to the shield voltage on the observed IP's of benzene and krypton are taken as $A(C_6H_6)$ and $A(Kr)$ respectively, in this case the following relation can be expected by referring to Table 2, since the shield voltage in the case of benzene is lower than that in the case of krypton:

$$A(C_6H_6) < A(Kr) \quad (1)$$

If the instrumental factors due to the contact potential, *etc.*, are taken as X, then the apparent IP's of benzene, $IP(C_6H_6)$, and of krypton, IP(Kr), are given by the following equations respectively:

$$IP(C_6H_6) = \text{true } IP(C_6H_6) + X - A(C_6H_6) \quad (2)$$

$$IP(Kr) = \text{true } IP(Kr) + X - A(Kr) \quad (3)$$

Since benzene and krypton are introduced into the ion source simultaneously, X is the same for both equations. By subtracting Eq. (2) from Eq. (3), we obtain:

$$IP(Kr) - IP(C_6H_6) = \text{true } IP(Kr) - \text{true } IP(C_6H_6) - A(Kr) + A(C_6H_6) \quad (4)$$

From Eq. (4), it may be seen that the difference detween the apparent IP's is smaller than that between the true IP's, because $A(C_6H_6) < A(Kr)$ in this case. Accordingly, to calibrate the electron energy scale, let the apparent IP of krypton, IP(Kr), be equal to 14.00 eV; then the IP value of benzene obtained will be somewhat higher than the true IP value. This may be the reason why a high IP value, as is shown in Table 1, was obtained when the IP was estimated without taking the effect of the shield voltage into account. On the other hand, the IP value obtained at a constant shield voltage for both benzene and krypton is in good agreement with those of the other workers. At least a part of the reason why a little higher AP values than those accepted were obtained previously[9] for some disubstituted benzenes may be understood in terms of the same explanation. The effect of the shield voltage on the AP may be due mainly to the fact that the electrons from the filament are somewhat accelerated by the shield voltage.

When a CEC 21-103C mass spectrometer is used to measure the AP, a compound which has almost the same ionization potential as that of the sample should be used as the calibration compound for the electron energy scale; otherwise, the shield voltage should be kept at a constant value for measuring the IE curves for both the sample and the calibration compound.

The authous wish to thank Akio Hashizume of this Institute for his valuable discussions.

Asymmetric Reactions. VI. Asymmetric Hydrogenation of Atropate Catalyzed by Cyanocobalt-Optically Active Diamine Complex[1]

Yoshiaki OHGO, Kazuhiko KOBAYASHI, Seiji TAKEUCHI, and Juji YOSHIMURA
Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received July 20, 1971)

In a previous paper,[2] the authors have reported that the asymmetric hydrogenation of atropate by pentacyanocobaltate - optically active α-amino acid system gives only slightly optically active hydratropic acid.

This paper presents the asymmetric hydrogenation catalyzed by a cyanocobalt complex coordinated with optically active *R*(−)-1,2-propanediamine or *S*(+)-*N*,*N*′-dimethyl-1,2-propanediamine.

Results and Discussion

Piringer *et al.*[3] have reported that μ-ethylenediamine-bis[tetracyanocobaltate(II)] has an ability to activate molecular hydrogen.

At first, the catalytic activity of (1,2-propanediamine)-cyanocobalt(II) complex for the reduction of α,β-unsaturated carboxylic acids, using racemic 1,2-propanediamine, was examined under the atmospheric pressure of hydrogen at room temperature. The results (Table 1) show that reactive α,β-unsaturated carboxylic acids,[2,4] itaconic acid and atropic acid, are catalytically reduced to give the corresponding saturated acids almost quantitatively. Subsequently, catalytic asymmetric hydrogenation of atropate using *R*(−)-1,2-propanediamine as a ligand was attempted and gave *S*(+)-hydratropic acid of $[\alpha]_D$ +0.8—+0.9° which corresponds to about 1% optical yield (Table 2). The optical rotation of the product purified by distillation rose to $[\alpha]_D$ +1.1°. No optical activity was, of course, observed in the hydratropic acid recovered after the treatment of the racemic hydratropic acid under the same conditions. From these facts, it is obvious that the catalytic asymmetric hydrogenation gave a little bit higher stereoselectivity than that in the previously studied system.[2]

It was expected that the coordination of *N*-substituted 1,2-propanediamine to metal would cause more selective asymmetric coordination of the substrate, because the former coordination should induce asymmetry on the nitrogen atom[5] which is placed nearer to the reaction center than asymmetric C_2 carbon. For this purpose, *N*,*N*′-dimethyl-1,2-propanediamine[6] was resolved through L(+)-tartrate salt to give (+)-isomer of $[\alpha]_D$ +53.9° (benzene) in pure state. The configuration was inferred to be *S*(+) from the specific rotation of analogous compound (*R*(−)-*N*[1]-phenyl-*N*[2]-methyl-1,2-propanediamine, $[\alpha]_D$ −29.5°).[7]

The hydrogenation of atropate catalyzed by (*S*(+)-*N*,*N*′-dimethyl-1,2-propanediamine)cyanocobalt(II)

complex was carried out under the same conditions as above. As expected, it was shown that somewhat greater steric control was affected, *i.e.*, the reduction gave hydratropic acid of $[\alpha]_D+5.73°$ (optical yield, 7%). In consequence, *S*(+)-hydratropic acid was predominantly produced either by use of *R*(−)-1,2-propanediamine or *S*(+)-*N*,*N*′-dimethyl-1,2-propanediamine, despite that these ligands have opposite configurations at C_2 to each other. This discrepancy in appearance may be interpreted as follows, though the asymmetric yields are rather low.

The complex used here showed an absorption spectrum [260 nm (ε, 670); 278 nm (ε, 560); 354 nm (ε, 155); 995 nm (ε, 7.3)] which is closely akin to the spectrum of μ-ethylenediamine-bis(tetracyanocobaltate-(II)) reported by Piringer *et al.*[3] and there is no substantial absorption due to complexes[9,10] produced by disproportionation of the (propanediamine)cyanocobalt complex. These facts indicate that the complex contained in the solution may be such a mixed ligand system as obtained by Piringer *et al.*[3] On the other hand, hydrogenation catalyzed by pentacyanocobaltate-(II) has been reported to proceed with *trans* addition.[8] If this is the case for diamine coordinated cyanocobalt complex described here, coordination models like A and B (Fig. 1) are considered as the transition states of the hydrogenations catalyzed by (*R*(−)-1,2-propanediamine)cyanocobalt(II) and (*S*(+)-*N*,*N*′-dimethyl-1,2-propanediamine)cyanocobalt(II) complexes, respectively. The alkylcobalt complexes are, then formed by hydride addition to the methylene carbon of olefin, and followed by attack of another hydride complex with inversion to give the same *S*(+)-hydratropic acid. However, there are many sites ineffective to asymmetric control. This may be the main cause of resulting in low optical yield.

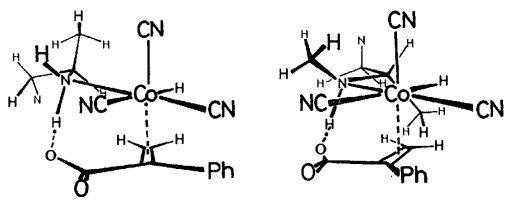

Fig. 1.

It is considered from the results that rigid conformational fixation and proximity of asymmetric groups to the reaction center result in higher optical yield, and that they concurrently prevent, however, coordination of the substrate and therefore the total yield is lowered. This will be an important problem to be overcome in order to design an excellent, homogeneous metal complex catalyst for asymmetric hydrogenation.

10) The electronic spectrum of $Co(Ph)_3Cl_2$ (prepared under the same condition as the catalyst did): 354 nm (ε, 11.8); 483 nm (ε, 12.0); 1020 nm (ε, 3.4).

Experimental

Reduction of Some α,β-Unsaturated Acids Catalyzed by (1,2-Propanediamine)cyanocobalt(II). To a solution of $CoCl_2\cdot 6H_2O$ (1 g, 0.0042 mol) in 10 m*l* of water was slowly added a solution of potassium cyanide (1.12 g, 0.017 mol) in water (10 m*l*) with stirring under nitrogen atmosphere to give brown precipitates. The precipitates were dissolved by addition of a solution of 1,2-propanediamine (0.62 g, 0.008 mol) in water (60 m*l*) which had been deoxygenated by bubbling nitrogen gas. To the resulting orange-colored homogeneous solution was added an aqueous solution prepared from 0.6 g (0.004 mol) of atropic acid and sodium hydroxide (0.004 mol). The flask was purged with hydrogen gas and then the reaction mixture was stirred under the atmospheric pressure of hydrogen at room temperature. The solution absorbed the theoretical amount of hydrogen within 2—3 days. The reaction mixture was concentrated and extracted with ether after acidification with conc. hydrochloric acid. The ether layer was washed with water, and concentrated to give a syrup (0.58 g). The product was characterized as hydratropic acid by IR and NMR spectra. Itaconic and tiglic acids were hydrogenated by the same procedure and the results are shown in Table 1.

Asymmetric Reduction by Use of Cyanocobalt Complex Coordinated with Optically Active Diamines (R(−)-1,2-Propanediamine or S(+)-N,N′-Dimethyl-1,2-propanediamine). The asymmetric reduction was carried out by the same procedure as described above, except for using optically active diamines instead of racemic diamine. In the case of the reaction with *R*(−)-1,2-propanediamine the crude product showed only one spot on tlc (silica gel) (R_f, 0.5, ethanol-benzene, 3:1; R_f, 0.65, methanol-water, 3:1). Optical rotation of these crude product was $[\alpha]_D+0.815$—$+0.905$ (see Table 2), and the product was distilled at 90—91°C/0.03 mmHg; $[\alpha]_D+1.1°$ (*c* 10.6, ethanol). The specific rotation corresponds to optical yield of 1.2% [optically pure *S*(+)-hydratropic acid, $[\alpha]_D^{20}$ +81.1° (*c* 3.1, ethanol)]. In the case of the reaction with *S*(+)-*N*,*N*′-dimethyl-1,2-propanediamine, the product was distilled at 83°C/0.0075 mmHg. The NMR spectrum of the distillate showed that the sample was a mixture of 84.1% of hydratropic acid and 15.9% of atropic acid. The optical rotation, $[\alpha]_D+5.73°$ (*c* 6.1, ethanol), corresponds to optical yield of 7%.

S(+)-N,N′-Dimethyl-1,2-propanediamine. Racemic compound was synthesized by reaction of 1,2-dibromopropane and methylamine according to William's method except for using a mixed solvent of benzene and methanol. A mixture of 1,2-dibromopropane (100 g), methylamine (350 m*l*), benzene (200 m*l*) and methanol (200 m*l*) was shaken in an autoclave at 95—105°C for 5 hours, and left standing overnight at room temperature. To the reaction mixture which was transferred to Erlenmeyer flask was added an excess amount of conc. HCl. The solution was concentrated under diminished pressure to give a solid. The solid was dissolved in a small amount of water, covered with benzene (2000 m*l*) and an excess of sodium hydroxide pellets was added to this solution. During this procedure, excess methylamine was evaporated and *N*,*N*′-dimethyl-1,2-propanediamine was transferred to benzene layer which was decanted to another vessel. Water layer was extracted with benzene several times. The combined extracts were distilled through a fractionating column. Bp 127—128°C; yield: 15 g (30%). A part of this sample was benzoylated to give crystals of mp 86—88°C whose analytical values were agreed with those of *N*,*N*′-dimethyl-*N*,*N*′-dibenzoylpropanediamine. Found: C, 73.76; H, 7.06; N, 9.07%. Calcd for $C_{19}H_{22}N_2O_2$: C, 73.52; H,

7.14; N, 9.03%.

Resolution of *N,N'*-dimethyl-1,2-propanediamine was accomplished by fractional crystallization of its L(+)-tartrate. Racemic *N,N'*-dimethyl-1,2-propanediamine (81 g) was dissolved into a solution of L(+)-tartaric acid (226.8 g) in 153 m*l* of water. The mixture was left standing in a refrigerator. The resulting crystals were separated by filtration. The procedures were repeated, and a part of the crystals obtained in some stage of crystallization was used in order to measure specific rotation; an aqueous solution of the crystals was made alkaline and extracted with benzene. The benzene layer was dried by adding sodium hydroxide pellets. The optical rotation of the dried benzene solution was measured, and the concentration was determined by acid titration. Thus obtained specific rotation in each stage of recrystallization was as follows.

Times of recrystallization	1	4	6	8	12
$[\alpha]_{578}$ of benzene solution (°)	+47.3	+51.25	+52.1	+52.6	+53.9

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 935—936(1972)

OH Bending Vibrations and Hydrogen Bond in Crystalline *p*-Hydroxybenzaldehyde

Ariyuki AIHARA and Yoshinori SHIROTA*

Department of Materials Science, Denki-Tsushin University, Kojima-cho, Chofu, Tokyo

(Received July 29, 1971)

The energy of hydrogen bond formed in the crystalline state of *p*-hydroxybenzaldehyde was estimated to be 7.3 kcal/mol from the heat of sublimation.[1] However, it has not yet been determined whether the molecules form a hydrogen bond of the type OH···OH or OH···O=C in the crystal.

Recently we carried out IR measurement in relation to our study on dielectric behavior and three-dimensional X-ray crystal structure analysis of this substance. This note reports on the bending vibrations of OH bond and their temperature variation in the crystalline state of *p*-hydroxybezaldehyde with reference to estimating the strength of hydrogen bond spectroscopically.

p-Hydoxybenzaldehyde was purified by vacuum sublimation and used as a KBr disc for the IR measurement. An IR spectrometer of JASCO IR-S type covering a frequency range 650—4000 cm^{-1} was used. Spectra obtained at several temperatures are shown in Fig. 1.

We note a characteristic feature of a broad band at 712 cm^{-1} (15°C) which shifts towards low frequency side with an increasing breadth with the rise of temperature. Similarly a band at 1240 cm^{-1} shifts slightly in the same direction with a tendency of broadening. On the other hand, the temperature variation of a strong and very broad band at 3180 cm^{-1}, which can be identified to be the OH stretching vibration (hydrogen-bonded), is not clear because of the poor resolving power of the instrument in this frequency region. From the characteristic behavior of these bands, it is almost certain that the 712 cm^{-1} band can be ascribed to the out-of-plane bending vibration of the OH bond intermolecularly hydrogen-bonded to neighboring molecules, and that the 1240 cm^{-1} band is due to the in-plane OH bending vibration under the influence of hydrogen bonding.[2-5]

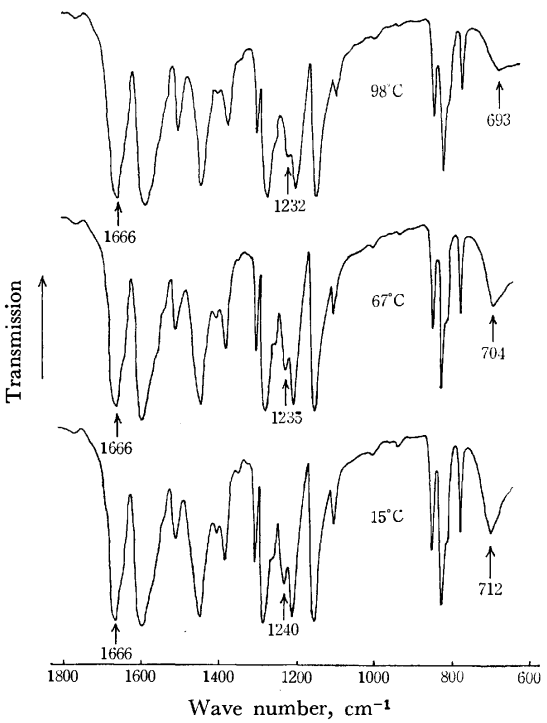

Fig. 1. IR spectra of *p*-hydroxybenzaldehyde (KBr disc) at three temperatures; spectra in the frequeney range, 600—1800 cm^{-1}, are shown.

So far several authors have reported on IR as well

as far-IR absorption of *p*-hydroxybenzaldehyde in solution and solid states,[5-8] but none have mentioned the OH bending vibration except for Bellamy[5a] who identified a band at 1160 cm^{-1} as δ_{OH} (in-plane bending vibration).

It is worthy of mention that the frequency of stretching vibration of C=O group 1666 cm^{-1} remains almost the same all through the temperature variation. This suggests that the carbonyl group is not involved in hydrogen bond formation in the crystalline state and the hydrogen bond in the crystal is very likely of the type, OH···OH···OH···.

A similar suggestion has been made by Fukushima[8] from far-infrared measurement.[9]

In order to estimate the energy of hydrogen bond from the frequency shift of OH vibration on hydrogen bonding, an empirical equation proposed recently by Purcell and Drago[10] has been used: $-\Delta H(\pm 0.5$ kcal/mol$)=0.016\times\Delta\nu_{OH}+0.63$, where ΔH is the energy of the hydrogen bond and $\Delta\nu_{OH}$ the frequency shift in cm^{-1}. Since the equation was derived originally for the anharmonic stretching vibration of a bond involved in hydrogen bonding, estimation of ΔH was made first with the frequency shift of OH stretching vibration observed in this experiment. Taking 3594 cm^{-1} observed in CCl_4 solution[11] as the free OH stretching vibration, $\Delta\nu_{OH}=3594-3180=414$ cm^{-1} leads to ΔH value of 7.25 kcal/mol which is in good agreement with the value 7.3 kcal/mol obtained thermochemically.[1]

A tentative calculation of the energy of the hydrogen bond has been made with the use of the frequency shift of the out-of-plane bending vibration 412 cm^{-1}, the difference between $\gamma_{OH}=712$ cm^{-1} observed in this measurement and $\gamma_{OH}=300$ cm^{-1} assigned to the free OH libration in phenol molecules.[12,13] The result obtained is almost the same as mentioned above, *viz.*, 7.23 kcal/mol. It is reasonable to infer that the anharmonicity of OH libration is reduced to a greater extent due to hydrogen bonding, making the Purcell and Drago equation applicable to the bending vibration in this case.

In the crystalline state of *p*-hydroxybenzaldehyde, the decrease of energy of the hydrogen bond with the rise of temperature can be estimated by following the above procedure as shown in Table 1.

Table 1. Temperature variation of OH bending vibration and the energy of hydrogen bond in crystalline *p*-hydroxybenzaldehyde estimated with the use of the Purcell and Drago equation

Temp. °C	15	50	67	88	98
γ_{OH} cm^{-1}	712	710	704	697	693
ΔH kcal/mol	7.22	7.19	7.10	6.98	6.91
δ_{OH} cm^{-1}	1240	1238	1235	1233	1232
ΔH kcal/mol	1.85	1.62	1.57	1.54	1.53

The decrease in ΔH as seen in the table might be correlated with the increase of O···O distance with the rise of temperature. The OH in-plane bending vibration would be unsuitable to be correlated with the strength of hydrogen bond[5b]: much smaller values of ΔH were obtained from $\Delta\delta_{OH}$ (Table 1) assuming 1176 cm^{-1} observed with phenol vapor[14] to be the free OH bending frequency.

A hindered rotator model with a potential

$$V = (V_0/2)(1-\cos n\theta)$$

can be applied also to calculate the energy of hydrogen bond, if we assume that V_0 is composed of two parts, *i.e.*, an attractive potential due to hydrogen bonding and a repulsive one which is intrinsic to a molecule free from hydrogen bonding. In the above equation, θ is an angle of rotation and n is the number of equilibrium positions the rotator will occupy during the rotation through 360°. Since the frequency of libration in the potential well can be expressed as

$$\nu = (n/2\pi)(V_0/2I)^{1/2}$$

where I is the moment of inertia of the rotator, we get V_0 by substituting the observed value of out-of-plane bending vibration $\gamma_{OH}=712$ cm^{-1} into the equation with appropriate values of I and n. Putting $n=2$, and assuming that the dimension of OH group in *p*-hydroxybenzaldehyde is the same as that of phenol molecule with $I=1.23\times10^{-40}$ gcm^2 (ref. 14), we obtain $V_0=15.96$ kcal/mol. Therefore, subtracting the hindering potential for the OH rotation in a phenol molecule 3.48 kcal/mol[13] from the V_0 value, we get 12.48 kcal/mol as the energy of hydrogen bond in *p*-hydroxybenzaldehyde crystal. The value is somewhat larger than those estimated with the use of the frequency shift on hydrogen bonding 7.22 kcal/mol, probably because the above equation is applicable only in the vicinity of the potential minimum. Or, we might presume that the hindering potential of the OH group in a free molecule of *p*-hydroxybenzaldehyde should be larger than that of a phenol mloecule, due to the reinforced effect of conjugation of the C–O bond with the benzene ring in the presence of an aldehydic substituent at the *para* position.

Lamellar Reactions of Graphite with Aluminum Halides

Tadashi SASA, Yoichi TAKAHASHI, and Takashi MUKAIBO

Department of Nuclear Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received July 30, 1971)

Graphite reacts with a large number of substances under suitable conditions to form lamellar compounds. Many kinds of metal chlorides are included. Few studies have been performed on the reaction of graphite with other metal halides such as bromides or iodides. The reactivity of aluminum chloride with graphite has been investigated in detail.[1,2] It was found that aluminum chloride does not react with graphite, by itself, and that the presence of another component such as chlorine, bromine or iodine is necessary for the lamellar reaction to occur. Croft[3] reported the reaction of aluminum bromide and graphite in his early systematic studies. It is doubtful, however, whether excess free bromine was thoroughly eliminated during the course of the reaction. The authors have extended the studies to investigate the reactivity of graphite with aluminum bromide and aluminum iodide.

1. Graphite-$AlBr_3$

High purity artificial graphite (heat-treated at 2400°C or 3000°C) was used for the samples. Aluminum bromide prepared by the reaction between aluminum and bromine of high purity was distilled before the reaction, and excess bromine was carefully removed. The graphite specimen was suspended by a quartz spring balance (sensitivity 20 mm/g) in an evacuated and sealed glass tube, and kept in contact with aluminum bromide vapor of saturation pressure at temperatures 100—250°C for 40 hours. No measurable gain in the weight of the graphite was observed. The electrical conductivity and X-ray diffraction measurement of the sample also showed no measurable change. It is concluded aluminum bromide alone does not react with graphite.

A small amount of gaseous bromine was added in aluminum bromide vapor at 150°C. Graphite is thought to absorb scarcely any bromine at such a high temperature.[4,5] Under these conditions, however, it started to absorb the reactants immediately. When bromine was also added to the graphite in the form of a lamellar compound and residue compound beforehand, absorption of the reactant was also observed. The optimum reaction temperature was 150°C, and the reaction terminated in 24 hours. The observed gain in the weight of the graphite by far exceeded the amounts of existing free bromine, and the existence of aluminum bromide in the graphite was actually confirmed by the decomposition of the reaction products.

It is to be noticed that release of a considerable amount of free bromine was observed at the first stage of the reaction of graphite-bromine residue compound and aluminum bromide. It is known that residue compound of artificial graphite is very stable and scarcely undergoes decomposition by heat treatment below 1000°C.[6,7] However, it was observed that some parts of bromine were released at 70°C and at the same time the reaction with aluminum bromide was initiated. As the reaction proceeded, most of the released bromine was absorbed again by the graphite. For checking the possibility of decomposition of aluminum bromide vapor, the reaction of graphite-bromine residue compound with aluminum chloride was carried out. The release of free bromine was also observed in this case. The released bromine should be attributed to the residual bromine contained in the graphite.

A quantitative investigation of aluminum bromide absorption in relation to the amount of coexisting bromine was carried out. Controlled amount of bromine was doped in graphite in the form of a residue compound or lamellar compound, and the graphite sample was allowed to react with aluminum bromide vapor. The reaction products were weighed for the determina-

tion of aluminum bromide uptake. Some samples were decomposed in a vacuum at 500°C, and the released bromine and aluminum bromide were collected separately and analyzed chemically. The relation of aluminum bromide contents and bromine contents of the ternary lamellar compounds is shown in Fig. 1. Aluminum bromide contents depend entirely on the amount of coexisting bromine, and the ratio $AlBr_3$ to Br is found to be nearly three. The result coincides with that of Hennig[2] on $AlCl_3$-Cl, or $AlCl_3$-Br. The atomic composition of the ternary compound was $C_{24}AlBr_3$-$Br_{0.3}$ for the highest reactant contents investigated.

X-ray diffraction study of the reaction products of the highest reactant contents showed the formation of a 'second stage structure' compound, where every other layer spacing of graphite is invaded by the reactants and expands from 3.35 Å to 10.0 Å.

2. Graphite-AlI_3

It was found that aluminum iodide also does not react alone with graphite at temperatures up to 250°C.

When bromine was doped in graphite as the residue compound, the absorption of aluminum iodide took place. However, aluminum iodide reacts easily with bromine to form aluminum bromide and free iodine. No further quantitative studies were carried out.

Free iodine was added to graphite-aluminum iodide system to start the reaction. The intercalation of reactants in graphite was not observed in several careful runs. Thus we conclude that the aluminum iodide and iodine system does not react with graphite.

The authors are grateful to Messrs. N. Arai and K. Matsuoka for their collaboration in a part of the study.

Hydrogen Transfer Reaction between Alcohols and Acetone

Hiroo NIIYAMA and Etsuro ECHIGOYA

Department of Chemical Engineering, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo

(Received August 2, 1971)

It was found in the previous paper[1] that hydrogen transfer reaction between alcohol and aldehyde was involved in the butadiene formation from ethanol over SiO_2·MgO. This fact was pointed out by Quattlebaum *et al.*[2] but the mechanism postulated by them was highly improbable. They found purified SiO_2 was most active, while Jones *et al.*[3] reported it was inactive. Basic oxides such as CaO[4] and MgO[5] were also reported as active catalysts.

In this study, various kinds of SiO_2·MgO having different composition and also different acidity and basicity, were used in order to make clear the roles of acidic and basic sites.

Experimental

Catalysts. SiO_2, MgO, and SiO_2·MgO having different MgO contents were prepared by the method described before.[1]

Acidity and Basicity Measurements. Adsorbed amount of pyridine at 200°C and boron trifluoride at 300°C was measured by the gravimetric method described before.[1]

Reaction. A coventional flow type reactor was used. Alcohol and acetone were introduced with hydrogen as a gaseous mixture into a catalyst bed.

Results and Discussion

The reaction took place between any alcohol and ketone or aldehyde. In this study, ethanol, 1-propanol, 2-butanol, and acetone were chosen as reactants. This reaction was confirmed to be an intermolecular hydrogen transfer, because (1) the same activity was observed when helium was used as carrier gas instead of hydrogen, and (2) the hydrogenation of acetone or dehydrogenation of these alcohols did not take place under this reaction condition.

Reactivity of ethanol, 1-propanol, and 2-butanol as hydrogen donors were compared. The sequence of reactivity was, 2-butanol (1.02)$\gg$1-propanol (7.2×10^{-4})$>$ethanol (4.7×10^{-4}) herein, the values in the bracket are the reaction rates in mol/g-cat·hr at 200°C over SiO_2·MgO (85 mol% MgO) catalyst.

It was shown in the previous paper[6] that release of the proton from hydroxy group was the rate determining step in the dehydrogenation of alcohols over basic sites, which gives the sequence of reactivity as follows, 2-butanol$\ll$1-propanol$<$ethanol. The reactivity sequence of alcohols in the hydrogen transfer reaction was quite different from that in the dehydrogenation reaction.

Acid-base properties and the activities of the catalysts were shown in Figs. 1 and 2. The catalytic activity in

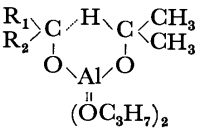
the ethanol-acetone system was well correlated with basicity. On the other hand, the profile of the activity against MgO content in the 2-butanol-acetone system was quite different from that of acidity or basicity. It is similar to that of butadiene formation from ethanol.[1] From this profile, it is expected that acidic sites also play important roles in the latter case.[7]

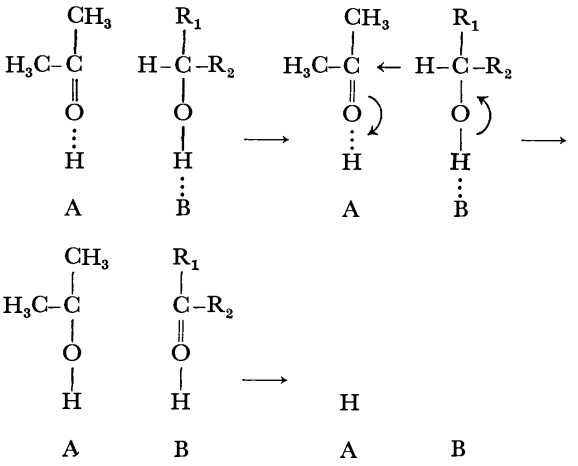
7) Acidic and basic sites are cooperative in the butadiene formation reaction.

Reaction Mechanisms. The reduction of ketone or aldehyde by aluminum isopropoxide is known as Meerwein-Ponndorf reduction. Williams *et al.*[8] and Jackman *et al.*[9] postulated that the reaction proceeded through the following cyclic intermediate. Hydride ion



Intermediate postulated by Williams *et al.*[8]

originally attached to the carbinol carbon transferred to ketone to make another alcolate. This mechanisms will be applied in our case.



That is, electrophilicity of carbonyl carbon increases by the adsorption on acidic sites (HA) and neucleophilicity of carbinol carbon also increases by the adsorption on basic sites (B). The reactivity of alcohols is expected to depend on the number of aliphatic group attached to the carbinol carbon. Since ethanol has no secondary carbon, it has very small neucleophilicity. Then, the activation of ethanol caused by basic sites is the most important process and so the correlation between activity and basicity is established. On the other hand, 2-butanol is rich in neucleophilicity. Then the difficulty of activation of 2-butanol becomes comparable with that of acetone. Accordingly, no simple correlation with acidity or basicity was obtained, but the catalyst which had adequate acidity and basicity showed high activity.

Activation Parameters of the Electrode Reaction of *trans*-1,2-Cyclohexanediaminetetraacetatochromate(III) Complex

Nobuyuki TANAKA, Takeshi TOMITA, and Akifumi YAMADA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai

(Received August 6, 1971)

In previous paper,[1] it was reported that in a solution of pH 4.6 the electrode reaction of *trans*-1,2-cyclohexanediaminetetraacetatochromate(II, III) complexes (Cr(II, III)-CyDTA) proceeds as

$$[Cr(III)\text{-}CyDTA]^- + e \rightleftarrows [Cr(II)\text{-}CyDTA]^{2-} \quad (1)$$

A mainly theoretical comparison between the kinetic parameters of the electrode reaction and those of the corresponding homogeneous reaction has been made by Marcus.[2] Although the value of the heat of activation of the electrode reaction is apparent and not absolute, as discussed by Vlček[3] and Tamamushi,[4] the activation parameters corrected for the electrical double layer seem to be useful for a comparison of the electron-transfer reaction at the electrode with those in the solution. The present communication presents the activation parameters of the reaction given by Eq. (1) which were obtained from potentiostatic measurements at various temperatures.

Experimental

Sample solutions of Cr(III)-CyDTA with the supporting electrolyte containing 0.4M sodium chloride, 0.1M sodium acetate buffer and 2×10^{-6}M polyoxyethylene lauryl ether (LEO) were prepared in the same way as previously reported.[1]

For the measurements at 0°C, the temperature was kept constant with an ice-bath, and at 10, 15, 25, and 35°C, controlled by a thermostat. Other apparatus for the measurement were those described previously.[1]

Results and Discussion

The polarograms of Cr(III)-CyDTA complex were measured at several temperatures and the results are given in Table 1. The slopes of log-plots of these polarograms showed that the electrode reaction of the Cr(II, III)-CyDTA system is diffusion-controlled at every temperature. A slope obtained from the Arrhenius plot of diffusion coefficients gave a reasonable value of the activation energy for diffusion. The kinetic parameters determined at various temperatures are given in Table 2.

Table 1. Characteristics of polarographic reduction of 1mM Cr(III)-CyDTA at various temperatures, measured in the supporting electrolyte solutions of pH 4.6 containing 0.4M NaCl, 0.1M acetate buffer and 2×10^{-6}M LEO

Temp. °C	i_d μA	$E_{1/2}$ V *vs.* SCE	Slope of log-plot mV	$D_O\times10^6$ $cm^2\cdot sec^{-1}$
10	−2.42	−1.190	55	3.4
15	−2.60	−1.192	58	4.2
25	−3.00	−1.200	62	5.5
35	−3.47	−1.204	62	7.4

Table 2. Measured kinetic parameters of Cr(III)-CyDTA at various temperatures, obtained in the supporting electrolyte solutions of pH 4.6 containing 0.4M NaCl, 0.1M acetate buffer and 2×10^{-6}M LEO

Temp. °C	$(E_0)_{ms}$ V *vs.* SCE	$(k_s)_{ms}$ $cm\cdot sec^{-1}$	$(\alpha_c)_{ms}$	$(\alpha_a)_{ms}$
0	−1.187	0.0045	0.36	0.78
10	−1.195	0.0011	0.38	0.60
15	−1.189	0.0093	0.39	0.57
20	−1.194	0.018	0.36	0.61
25	−1.198	0.029	0.33	0.67
35	−1.204	0.051	0.33	0.68

The logarithmic values of the standard rate constant, $\log(k_s)_{ms}$, were plotted against $1/T$ in Fig. 1. The measured heat of activation, $(\Delta H_s^*)_{ms}$, and the measured pre-exponential factor, A_{ms}, were obtained from the plot.

In Fig. 2, ϕ_2 potentials, *i.e.*, potentials at the outer Helmholtz plane (OHP), are plotted against the electrode potential E at 15, 25, and 35°C. At more negative potentials than *ca.* −1.18 V *vs.* SCE, ϕ_2 potentials at those temperatures virtually coincide with each other.

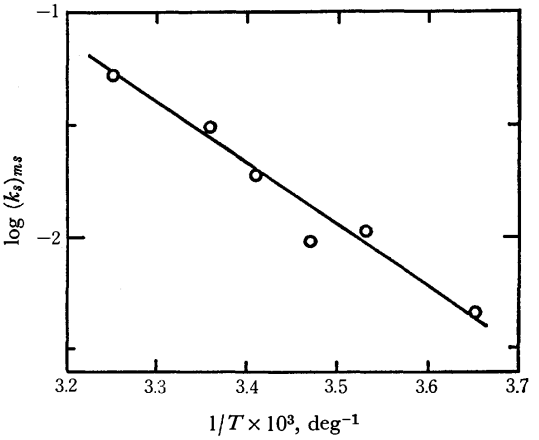

Fig. 1. The Arrhenius plot of $(k_s)_{ms}$ of Cr(III)-CyDTA obtained in the supporing electrolyte solutions of pH 4.6 containing 0.4 M NaCl, 0.1 M acetate buffer and 2×10^{-6} M LEO. The values obtained are: $(\Delta H_s^*)_{ms}=12$ kcal $mole^{-1}$ and $A_{ms}=10^{7.3}$ cm sec^{-1}.

4) R. Tamamushi, *Rev. Polarog. (Kyoto)*, **10**, 1 (1962).

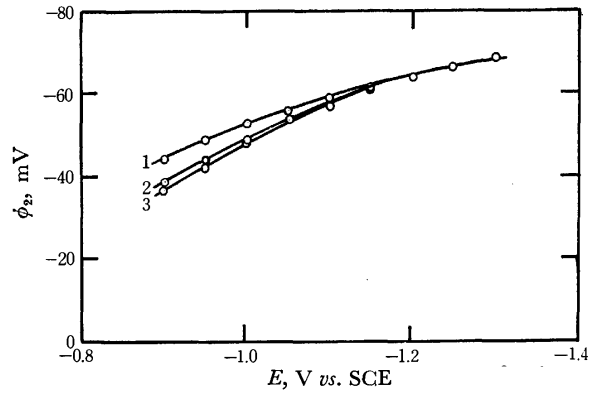

Fig. 2. ϕ_2 potential as a function of the electrode potential E at (1) 15°C, (2) 25°C, and (3) 35°C in a solution of pH 4.6 containing 0.4 M NaCl, 0.1 M acetate buffer and 2×10^{-6} M LEO. ϕ_2 values were estimated from the Gouy-Chapman theory.

TABLE 3. CORRECTED KINETIC PARAMETERS OF Cr(III)-CyDTA AT VARIOUS TEMPERATURES, OBTAINED IN THE SUPPORTING ELECTROLYTE SOLUTIONS OF pH 4.6 CONTAINING 0.4M NaCl, 0.1M ACETATE BUFFER AND 2×10^{-6}M LEO

Temp. °C	$(E_0)_{corr}$ V *vs.* SCE	$(k_s)_{corr}$ cm·sec^{-1}	$(\alpha_c)_{corr}$	$(\alpha_a)_{corr}$
0	−1.186	0.17	0.42	0.72
10	−1.194	0.46	0.49	0.54
15	−1.191	0.37	0.46	0.53
20	−1.195	0.65	0.44	0.55
25	−1.198	0.93	0.40	0.57
35	−1.204	1.5	0.39	0.59

The Frumkin correction can then be applied to the kinetic parameters using these ϕ_2 potentials, assuming that the electron-transfer reaction plane (ERP) is the same as the closest approach of supporting electrolyte (OHP), and none of the chemical species present in the solution is adsorbed on the electrode. The parameters corrected in this way are given in Table 3. The corrected activation parameters are: $(\Delta H_s^*)_{corr}=$ 10 kcal mol^{-1} and $A_{corr}=10^{7.5}$ cm sec^{-1} (Fig.3). There is a great difference between $(k_s)_{ms}$ and $(k_s)_{corr}$, as was reported previously.[1] On the other hand, $(\Delta H_s^*)_{ms}$ is not so much influenced by the correction for the effect of double layer, which was already expected by Joshi *et al.*,[5] when ϕ_2 potential is only slightly dependent on the temperature.

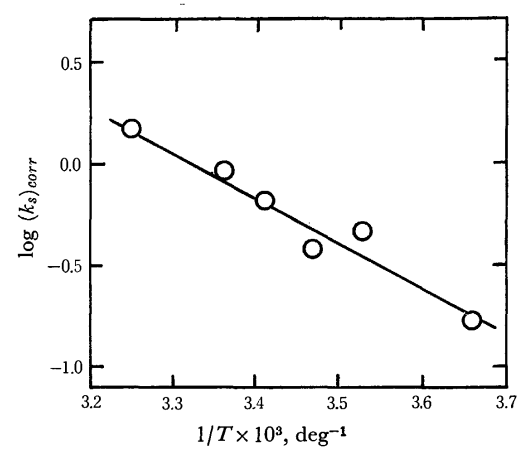

Fig. 3. The Arrhenius plot of $(k_s)_{corr}$ of Cr(III)-CyDTA obtained in the supporting electrolyte solutions of pH 4.6 containing 0.4 M NaCl, 0.1 M acetate buffer and 2×10^{-6} M LEO. The values obtained are: $(\Delta H_s^*)_{corr}=10$ kcal mole^{-1} and $A_{corr}=10^{7.5}$ cm sec^{-1}.

In conclusion, the contribution of the double layer effect to the heat of activation for Cr(II, III)-CyDTA system is relatively small although it can not be neglected.

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki, Kanagawa

(Received August 10, 1971)

Although aspartyl peptides can be conveniently prepared by the coupling of *N*-protected aspartic anhydrides with amino acids or amino acid esters, followed by deprotection, this method usually gives a mixture of α- and β-aspartyl peptides.[1-3] Furthermore, the separation of the isomers is generally so difficult and so complicated that only a few methods have been reported; in them techniques of fractional extraction and column chromatography were used.[2,3] Some aromatic acids have been used as specific precipitating reagents for amino acids.[4,5] However, no specific precipitating reagent for the α- and β-aspartyl peptides has been reported in the literature.

α-L-Aspartyl-L-phenylalanine methyl ester (α-APM), which has a sweet taste very similar to that of sucrose, has been found as a new sweetening agent.[6] When α-APM was prepared by the condensation of such *N*-protected L-aspartic anhydrides as benzyloxycarbonyl-L-aspartic anhydride with methyl L-phenylalaninate and by subsequent deprotection, the corresponding β-derivative, β-APM, was also produced as a by-product. α-APM must be sufficiently purified from β-APM, since β-APM has a weakly bitter taste. Purification by recrystallization from water is ineffective because α- and β-APM have almost equal solubilities, and because α-APM is easily changed to the diketopiperazine derivative by heating.

In the course of studies of the sweet peptide, it was

Table 1. Separation of α- and β-APM with various precipitating reagents

Reagent	APM	Grams of α- and β-APM in 100 ml of aqueous solution: Initial solution	Mother liquor
[a] 3,5-Dinitrobenzoic acid	α-APM	1.00	0.10
	β-APM	1.00	0.97
[b] β-Phenylpropionic acid	α-APM	1.00	0.26
	β-APM	1.00	0.91
[a] Cinnamic acid	α-APM	1.00	0.20
	β-APM	1.00	0.92
[b] *p*-Hydroxybenzoic acid	α-APM	1.00	0.30
	β-APM	1.00	1.00
[b] Gentisic acid	α-APM	1.00	0.16
	β-APM	1.00	1.00
[b] β-Resorcylic acid	α-APM	1.00	0.01
	β-APM	1.00	0.96
[b] 5-Chlorosalicylic acid	α-APM	1.00	0.10
	β-APM	1.00	1.00
[a] 2,5-Dichlorophenol	α-APM	1.00	0.06
	β-APM	1.00	1.00
[b] β-Naphthoic acid	α-APM	1.00	0.28
	β-APM	1.00	1.00
[b] β-Naphthoxyacetic acid	α-APM	1.00	0.27
	β-APM	1.00	0.99

To α-APM in the initial solution, 1.2[a] or 2.4[b] molecular equivalents of the reagents were used.

Table 3. Separation of α- and β-APM with various reagents on preparative scale

Mixture: α-APM g	Mixture: β-APM g	Reagent	Water g	Water ml	Recovery: α-APM g (%)	Recovery: β-APM g (%)

found that α-APM forms sparingly soluble compounds in water with 3,5-dinitrobenzoic acid, β-phenylpropionic acid, cinnamic acid, *p*-hydroxybenzoic acid, gentisic acid, β-resorcylic acid, 5-chlorosalicylic acid, 2,5-dichlorophenol, β-naphthoic acid, and β-naphthoxyacetic acid. β-APM, on the contrary, did not form such compounds with these reagents. This characteristic was successfully used for the separation of the two isomers of APM. When a mixture of α- and β-APM was placed in contact with these reagents in water, α-APM was selectively precipitated with the reagents, while β-APM remained almost quantitatively in the mother liquor (Table 1).

The separation of the isomers on a preparative scale was achieved with 3,5-dinitrobenzoic acid, cinnamic acid, gentisic acid, and β-resorcylic acid. The elementary analyses showed that the precipitates consist of α-APM and the reagent in a 1:1 molar ratio, except for the precipitate with β-resorcylic acid, which consists of α-APM and β-resorcylic acid in a 1:2 molar ratio (Table 2).

The precipitates and the mother liquors were separately acidified with hydrochloric acid. After removing the liberated reagents by extraction with ether, the acidic solutions were adjusted to the isoelectric point of APM with sodium bicarbonate. The α- and β-APM thus crystallized out were recovered by filtration in fairly high yields (Table 3).

Experimental

The melting points are uncorrected.

α- and β-APM. α- and β-APM were prepared by the method described by Mazur *et al.*[6] α-APM: mp 235—236°C (dec.); $[\alpha]_D^{25}+32.0°$ (*c* 1, acetic acid); $[\alpha]_D^{24}\pm0°$ (*c* 1, water). lit, mp 246—247°C (sintered at 190°C); $[\alpha]_D$ 0° (water).[6] lit, mp 246—247°C; $[\alpha]_D-2.3°$ (*c* 1, N HCl).[7] β-APM: mp 198—199°C (dec.); $[\alpha]_D^{28}+42.5°$ (*c* 1, acetic acid); $[\alpha]_D^{24}+4.0°$ (*c* 1, water). lit, mp 196—197°C; $[\alpha]_D+4°$ (water).[6]

Determination of α- and β-APM. Paper electrophoresis was carried out in aqueous acetic acid of pH 2.77 at 40 V/cm for 1.5 hr; the paper was stained with a cadmium-ninhydrin reagent.[8] The two spots corresponding to α- and β-APM were individually cut off and eluted with methanol, and the absorbances of the eluates were measured at 510 mμ.

Crystalline Compounds of α-APM with the Various Reagents (I, II, III, and IV in Table 2). α-APM Compound with 3,5-Dinitrobenzoic Acid (I): To a stirred solution of 2.0 g of α-APM in 200 m*l* of water, 1.7 g of 3,5-dinitrobenzoic acid was added at room temperature. The solution was kept in a refrigerator overnight. The crystals thus formed as needles were collected by filtration; yield, 3.2 g (89%).

α-APM compound with cinnamic acid (II) was obtained from a mixture of 1.0 g of α-APM and 1.0 g of cinnamic acid in 100 m*l* of 50% aqueous ethanol; yield, 0.9 g (60%).

α-APM compounds with gentisic acid (III) and with β-resorcylic acid (IV) were obtained form a mixture of 1.0 g of α-APM and 0.5 g of gentisic acid or β-resorcylic acid in 100 m*l* of water; yield of III, 0.8 g (50%); yield of IV, 0.5 g (28%). For anal. and mp, see Table 2.

Separation of α- and β-APM with the Various Precipitating Reagents. A typical run was as follows (Table 3): To 500 m*l* of an aqueous solution containing 5.0 g of α-APM and 5.0 g of β-APM, 3.0 g of cinnamic acid was added with stirring at room temperature. The mixture was stirred for 5 hr at room temperature and then kept in a refrigerator overnight. The precipitate was collected by filtration and suspended in 500 m*l* of water. The mixture was adjusted to pH 2.0 with hydrochloric acid. The cinnamic acid thus liberated was removed by extraction with ether. The aqueous solution was adjusted to pH 5.0 with sodium bicarbonate and evaporated *in vacuo* to dryness. The residual crystals were recrystallized from 100 m*l* of water; yield, 3.2 g (64%); mp 235—236°C (dec.); $[\alpha]_D^{26}+32.0°$ (*c* 1, acetic acid). Found: C, 55.50; H, 6.21; N, 9.35%. Cacld for $C_{14}H_{18}O_5N_2\cdot 1/2\ H_2O$: C, 55.44; H, 6.31; N, 9.24%. The compound was confirmed by paper electrophoresis to be free from the β-isomer.

The mother liquor, excluding the α-isomer, was treated as above to give β-APM; yield, 3.2 g (64%); mp 198—199°C (dec.); $[\alpha]_D^{26}+43.0°$ (*c* 1, acetic acid). (Found: N, 9.30%). The compound was confirmed by paper electrophoresis to be pure β-APM.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 944—945(1972)

Reaction of Norbornene with Butadiene Catalyzed by Low-valent Cobalt, Giving *trans*-1-(*exo*-Norbornyl)-1,3-butadiene

Hideo SATO and Takashi INUKAI

The Central Research Laboratories, Chisso Corporation, Kamariya, Kanazawa-ku, Yokohama

(Received August 16, 1971)

Transition metal-catalyzed reactions between olefins and butadiene generally occur through hydrogen transfer from the olefins to butadiene to give substituted 1,4-hexadienes[1] according to

$$CH_2{=}CHR + CH_2{=}CH{-}CH{=}CH_2 \longrightarrow \begin{cases} CH_2{=}CR{-}CH_2{-}CH{=}CH{-}CH_3 \\ RCH{=}CH{-}CH_2{-}CH{=}CH{-}CH_3 \end{cases} \quad (1)$$

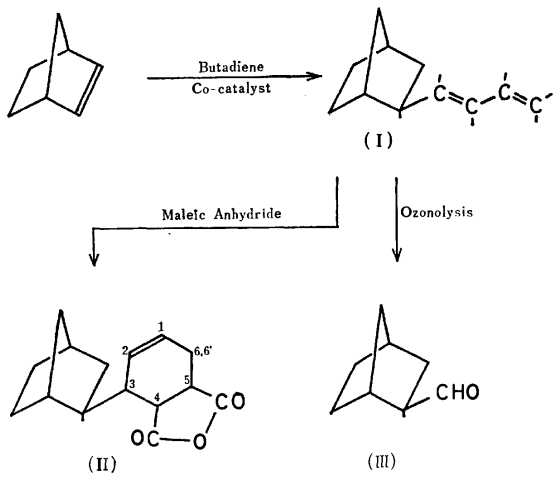
(R = H, alkyl, COOEt)

We recently reported,[2] however, that norbornadiene reacts with butadiene in the presence of cobalt catalysts of low valency, involving hydrogen transfer converse to that above, to give 5-butadienylnorborn-2-ene. This seems to be the first example of butadienylation of an internal carbon-carbon double bond. A similar butadienylation of terminal double bonds has been documented but is incomplete[3] and somewhat dubious,[4] except when the olefin is ethylene.[5]

We wish to report here another example of butadienylation, the reaction of norbornene with butadiene by low valent cobalt catalyst giving *trans*-1-(*exo*-norbornyl)-butadiene (I) with high stereochemical selectivity.

Results

Norbornene and butadiene were heated in a stainless steel reactor at 20—40°C for several hours under nitrogen in the presence of the catalysts prepared from $Co(acac)_3$ and Et_3Al. The reaction gave 30—40% yield of a mixture of 1:1 adducts (codimers), which was found by glpc analysis to consist of a main component (80—95%) and four minor ones. Practically no homodimers or oligomers were formed as by-products. The main product was separated by preparative glpc and its structure was determined as (I) from the following observations (Chart 1).



Chart

It has MW 148 (mass spectrum). The UV spectrum shows a typical s-*trans* 1,3-diene absorption, λ_{max} 230 nm, ε_{max} 28100, in cyclohexane, and the IR spectrum (liquid film) shows the $\nu_{C=C}$ at 1603 and 1650 cm^{-1}, δ_{C-H} of vinyl group at 892 and 1000 cm^{-1}, and δ_{C-H} of internal *trans* hydrogens at 949 cm^{-1}. That the butadiene moiety is *trans* substituted at its 1-position is proved by the facile reaction with maleic anhydride to give a Diels-Alder adduct whose NMR and IR spectra are consistent with the assigned structure of 3-norbornylcyclohexene-4,5-dicarboxylic anhydride (II). The butadienyl group is specifically located at the *exo* position of norbornane because *exo*-2-formylnorbornane (III) free from the *endo* isomer is obtained on ozonolysis of the main product. Consequently we conclude that it is *trans*-1-(*exo*-norbornyl)-1,3-butadiene (I).

Temperature around 40°C was found optimum for preparation of (I): at higher temperatures the selectivity for (I) tends to decrease presumably owing to the concomitant Diels-Alder reactions and the conversion decreases sharply. The molar ratio of Et_3Al:

Table 1. Reactions of norbornene with butadiene using several cobalt catalyst systems[a]

Catalyst components (mmol)		Conversion[b] (%)	Selectivity[c] (%)
$Co(acac)_3$ (0.5)	Et_3Al (1.5)	36	84.5
$Co(acac)_3$ (0.5)	Et_3Al[d] (1.5)	36	90
$Co(acac)_3$ (0.5)	Et_3Al[e] (1.5)	34	80
$CoCl_2$ (0.5)	Et_3Al (1.5)	20	80
$Co(acac)_3$ (0.5)	*i*-Bu_3Al (2.0)	32	82
$Co(acac)_3$ (0.5)	$Et_2(OEt)Al$ (2.0)	32	82

a) Reaction at 40°C, 4 hr; norbornene 43 mmol, butadiene 50 mmol, and *ca.* 2 *ml* of benzene.
b) Conversion of norbornene as determined from unreacted norbornene (glpc).
c) Percentage of (I) in the codimer fraction.
d) Plus ethylenediamine (1 mmol).
e) Plus ethanolamine (1 mmol).

2) A. Takahashi and T. Inukai, *Chem. Commun.*, **1970**, 1473. See also A. Carbonaro, F. Cambisi, and G. Dall'Asta, *J. Org. Chem.*, **36**, 1443 (1971).
3) D. Wittenberg, *Angew. Chem.*, **75**, 1124 (1963); H. Müller, D. Wittenberg, H. Seibt, and E. Scharf, *ibid.*, **77**, 318 (1965). Butadienylation of several terminal olefins and acrylates was claimed without evidence to prove the structures of the reaction products.
4) Different structures have been given: A. Misono, Y. Uchida, T. Sato, and K. Uchida, This Bulletin, **40**, 1889 (1967); H. Singer, W. Umbach, and M. Dohr, *Synthesis*, **1971**, 265.
5) T. Saito, Y. Uchida, and A. Misono, This Bulletin, **38**, 1397 (1965).

$Co(acac)_3$ can be varied from 1 to 6 without remarkable effect on selectivity and conversion. The molar ratio of norbornene to butadiene showed only minor effect on yield of (I) within the range 0.5—1.5. Excessive imbalance of the reactant ratio proved undesirable. The results with various catalyst combinations are summarized in Table 1.

Other internal double bond compounds such as cyclopentene, cyclohexene, cyclooctene, *endo*-dicyclopentadiene and *cis*-butene gave little if any codimers with butadiene under similar reaction conditions. Thus butadienylation at an internal double bond seems to be specifically limited to norbornene and norbornadiene.[2]

The reaction provides a convenient route to *exo* norbornane derivatives which are difficult to prepare in stereochemically pure state. As an example, *exo*-2-formylnorbornane prepared by the method given by Alder and Stein[6] was found to be contaminated with the *endo* isomer which could not be completely removed. Pure *exo* (I) and (III) are evidently versatile starting materials for various *exo* substituted norbornanes.

Experimental[7]

Materials. Norbornene (Aldrich Co.) solution in benzene was dehydrated and deaerated by distillation under nitrogen. Butadiene was dried by passing through a $CaCl_2$ column and deaerated by distillation in vacuum. Desiccated $Co(acac)_3$ (EP grade) was used. Alkylaluminums were purified by vacuum distillation of commercial products.

trans-*1-(*exo-*Norbornyl)-butadiene (I).* In a typical example, butadiene (0.2 mol), norbornene (0.2 mol), $Co(acac)_3$ (2 mmol), Et_3Al (6 mmol), and 2 m*l* of benzene were put into a 100 m*l* stainless steel autoclave under nitrogen and heated to 40°C for 4 hr. The catalysts were killed with acetone (2 m*l*) and the mixture was subjected to steam-distillation with a trace of hydroquinone. The oily product was dried with anhydrous sodium sulfate and distilled to give 10.3 g of a codimer fraction, bp 72.5°C at 9 mmHg. The product was 96% pure (I) by glpc (Silicone DC-550). It was purified by glpc using a Silicone DC-550 preparative column.

Found: C, 89.0; H, 11.1%. Calcd for $C_{11}H_{16}$: C, 89.12; H, 10.88%.

Diels-Alder Adduct (II). A solution of 3.01 g of (I) and 1.96 g of maleic anhydride in 25 m*l* of benzene was warmed to 45°C for 5 hr and was let to stand overnight at room temperature. The solvent was removed under reduced pressure, and the residue with mp 95—120°C, was recrystallized repeatedly from benzene-hexane solvent (1:2 by volume) to attain mp 148—149°C.

Found: C, 73.3; H, 7.5%. Calcd for $C_{15}H_{18}O_3$: C, 73.15; H, 7.33%.

NMR (in $CDCl_3$): τ 4.02 (2H; $H_{(1)}$ and $H_{(2)}$, apparent doublet, J *ca.* 4 Hz); τ 6.60 (2H; $H_{(4)}$ and $H_{(5)}$, multiplet); τ 7.28 (1H; $H_{(3)}$, a pair of triplets); τ 7.6—9.2 (13H; $H_{(6)}$, $H_{(6')}$, and norbornyl protons, overlapped multiplets).

*2-*exo-*Formylnorbornane (III).* Ozonized oxygen was bubbled through a solution of 0.034 mol of (I) in methanol (100 m*l*) at −70°C, excess ozone was purged with stream of nitrogen, and triphenylphosphine (0.12 mol) in ether (100 m*l*) was added dropwise to the ozonide solution during a period of 40 min. The dry ice-acetone bath was removed to let the reaction mixture stand overnight at room temperature. (III) was codistilled with the solvent under reduced pressure into a cold trap (−70°C) and redistilled, bp 66—68°C at 12 mmHg; yield 2.5 g (59% of theory). By comparison of its glpc peak (Golay column R-45, polypropylene glycol, Hitachi) with those of the *exo*- and *endo*-2-formylnorbornane mixture obtained by the method of Alder and Stein starting from cyclopentadiene and acrolein,[6] it was found that the product was pure *exo* III free from *endo*.

Semicarbazone, mp 173—174°C (lit,[6] mp 178°C), showed IR and NMR spectra which are superposable with those of the authentic *exo* semicarbazone.

6) K. Alder and G. Stein, *Ann. Chem.*, **525**, 247 (1936).

7) All melting points are uncorrected. IR and UV spectra were determined with Nihon Bunko Model 402G and Hitachi Model EPS-III spectrophotometers, respectively. NMR spectra were taken with a Varian A-60A spectrometer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 946—947(1972)

Cycloaddition of Spiro[2.4]hepta-4,6-diene to Tropone

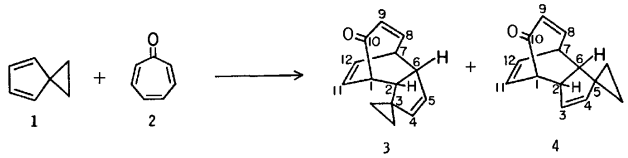
Hiroshi TANIDA, Toshisada YANO, and Masako UEYAMA*

Shionogi Research Laboratory, Shionogi and Co., Ltd., Fukushima-ku, Osaka

(Received August 16, 1971)

Cycloaddition of cyclopentadiene to tropone leading to *exo*-tricyclo[4.4.1.1^{2,5}]dodeca-3,7,9-trien-11-one was reported by Cookson *et al.*[1] and by Itō *et al.*[2] as the first example of a thermal [6+4] cycloaddition which had been predicted by Hoffmann and Woodward.[3] Whereas in [4+2] cycloaddition dimethylfulvene reacts with dienophile in the same way as cyclopentadiene does,[4] in [6+4] cycloaddition the fulvene was reported to react with tropone as a 6π electron addend due to participation of the exocyclic double bond, the final product being a 2: 1 adduct of tropone and the fulvene.[5] From our interest in the alteration of the reaction pattern we carried out cycloaddition of spiro[2.4]hepta-4,6-diene (**1**) to tropone (**2**). Since cyclopentadiene, dimethylfulvene, and **1** all react in a uniform way in the [4+2] cycloaddition, it would be of interest to know the behavior of **1** in the addition reaction with tropone and, particularly, to determine whether or not the cyclopropane ring in **1** takes part displaying its masked unsaturation character.

When a mixture of an equimolar amount of **1** and **2** was heated at 110°C for 6 days in a tube sealed under nitrogen, two major products in a 79: 16 percent ratio were indicated by vpc, together with two minor products in a total 5%. The vpc peak ratio of the two major products was constant through the reaction period, indicating that they are kinetically-controlled. The 79 and 16% products (**3** and **4**) were isolated by a preparative gas chromatograph (2 m×15 mm) and shown to be both 1: 1 adducts by elementary analyses and molecular weight determinations (osmometry and mass spectroscopy). Catalytic reduction of the adducts over PtO_2 in ethanol resulted in an uptake of 3 mol of hydrogen and in acetic acid that of 4 mol of hydrogen indicating the presence of three double bonds and one



1 2 3 4

cyclopropane ring. The UV and IR properties indicate the presence of an $\alpha\beta$-unsaturated carbonyl group for both the adducts, and consequently, the absence of a [6+4] cycloaddition type product as observed in the reaction of cyclopentadiene.

Conformatory evidence for the indicated structures **3** and **4** was obtained from the 100 MHz PMR spectra, in which the signal assignments were performed by double resonance technique. The NMR parameters (first-order analyses) are summarized in Table 1. It was concluded that the orientation of the cyclopentene moieties in both the adducts was *endo* by the relatively small vicinal $J_{1,2}$ and $J_{6,7}$ and by the presence of long-range $^4J_{2,11}$ and $^4J_{6,12}$ due to the "W" arrangements of

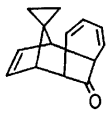
related protons. The values of $J_{1,2}$ and $J_{6,7}$ are of nearly the same magnitude as the corresponding coupling constants reported for the major [4+2] adduct of cyclopentadiene with 2-chlorotropone, 1-chlorotricyclo-[5.3.2.$0^{2,6(exo)}$]dodeca-3,8,11-trien-10-one.[6] Relative configuration (*anti* or *syn*) of the cyclopropane ring and the carbonyl group in **3** and **4** was determined by the following observations: the presence of spin-couplings between H_6 (or H_2) and the olefinic protons in **3** (or in **4**) (determinable by double resonance experiments); the relatively higher-field positions of H_1 and H_2 signals in **3** and those of H_6 and H_7 in **4** arising from the long-range anisotropy effect of the cyclopropane ring; and the presence of long-range couplings between H_1 and H_5 in **3** ($^5J_{1,5}$) and H_3 and H_7 in **4** ($^5J_{3,7}$) located in the zigzag paths.



5

Thus it is found that, with tropone, cyclopentadiene reacts as a 4π electron addend, dimethylfulvene as a 6π addend, and the present **1** as a 2π addend. In comparison to the reaction conditions reported for cyclopentadiene and dimethylfulvene,[1,2,5] the occurrence of reaction of **1** seems to require the severest conditions. A molecular model suggests that the [6+4] cycloadduct from **1** and **2** (**5**), if formed, would have severe steric compression around the cyclopropane ring and the butadiene bridge, so that this cycloaddition process would be strongly retarded and the cyclopentadiene moiety in **1** compelled to react as a 2π addend toward the 4π electron system in **2**, despite the higher activation energy required.

Experimental

Melting points were taken in capillary tubes and are corrected. Infrared spectra were determined with a Nippon Bunko IR-S spectrometer, ultraviolet spectra with a Hitachi EPS-3T spectrometer, and NMR spectra with a Varian A-60A and HA-100. VPC analysis was carried out on a Hitachi gas chromatograph K-53 equipped with a hydrogen flame ionization detector, using a 1 m×3 mm glass column packed with 5% XE 60 on Chromosorb W.

Reaction of 1 with 2. Diene **1** was prepared by the reported method.[7] A mixture of 1.5 g of **1** and 1.6 g of **2** was placed in a tube, sealed under nitrogen, and heated at 110°C for 6 days. VPC analysis of the reaction mixture revealed two major products (**3** and **4**) in a 79: 16 percent ratio, with two minor products in a total 5%. Isolation of **3** and **4** was carried out by a Yanagimoto gas chromatograph GCG-3 equipped with 2 m×15 mm glass column packed with 5% XE 60 on Chromosorb W. With a column temperature 180°C and helium carrier gas 300 ml/min, the retention times were 25 min for **3** and 31 min for **4**. Recrystalliaztion of the **3** fraction thus isolated from *n*-pentane gave colorless crystals, mp 66—66.5°; mass spectrum (70 eV) *m/e* 198 (parent peak); molecular weight by osmometry 192; UV λ_{max} (95% EtOH): 225 mμ (shoulder, ε 7000), 265 (1800); IR ($CHCl_3$): 1660 cm^{-1} (CO). Found: C, 84.76; H, 7.17%. Calcd for $C_{14}H_{14}O$: C, 84.81; H, 7.12%. Recrystallization of the **4** fraction from *n*-pentane gave colorless crystals, mp 96.3—97.0°C; mass spectrum (70 eV) *m/e* 198 (parent peak); UV λ_{max} (95% EtOH): 230 mμ (shoulder, ε 5370), 260 (2000); IR ($CHCl_3$): 1656 cm^{-1} (CO). Found: C, 85.10; H, 7.14%. Calcd for $C_{14}H_{14}O$: C, 84.81; H, 7.12%. NMR data for **3** and **4** are summarized in Table 1.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 947—949(1972)

The Kinetics of the Electron-transfer Reactions between Several Chloropentakis(alkylamine)cobalt(III) Complexes and Iron(II)

Kousaburo OHASHI

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received August 17, 1971)

In previous papers, the effect of the *cis*-ligand to the bridging chloride ion on the reactivity of *cis*-$Co(en)_2ACl^{2+}$ [1] (A=alkylamine and aminoalcohol) and the effect of amino acid[2] as the nonbridging ligand on the reactivity of *trans*(O,Cl)-Co(dien)(am)Cl^+ (am=amino acid, dien=diethylenetriamine) and *trans*(*N*)-$Co(am)_2(ox)^-$ (ox=oxalic acid) in the iron(II) reductions of these complexes have been reported.

It was demonstrated that the reactivity of *cis*-$Co(en)_2ACl^{2+}$ decreased slightly with an increase in the size of alkylamine and that the specific reduction rate for the β-alanine cobalt(III) complex was considerably larger than that for the other amino acid cobalt(III) complexes investigated.

Buckingham *et al.*[3] found that the base and acid hydrolyses of a series of chloropentakis(alkylamine)-cobalt(III) complexes were very much accelerated by the steric interaction of the alkylamines. The reactivities of these complexes are increased with increases

Table 1. The rate constants, the activation parameters for iron(II) reductions at 25±0.1°C and absorption maximum of cobalt(III) complexes

Complex	Rate constant[a] $M^{-1}\cdot sec^{-1}$	$\Delta H^{\neq}$ kcal/mol	$\Delta S^{\neq}$ eu	nm λ_{max}[b]	nm λ_{max}[c]
$Co(NH_3)_5Cl^{2+}$	7.30×10^{-3}	16.9	−10.4	525	362
trans-$Co(NH_3)_4(CH_3NH_2)Cl^{2+}$	1.26×10^{-2}	16.3	−11.0	535	364
$Co(CH_3NH_2)_5Cl^{2+}$	4.72×10^{-2}	14.8	−13.7	550	380
$Co(n\text{-}C_3H_7NH_2)_5Cl^{2+}$	9.14×10^{-2}	13.4	−16.4	550	383
$Co(i\text{-}C_4H_9NH_2)_5Cl^{2+}$	1.63×10^{-1}	—	—	550	382

a) $[H_2SO_4]=0.050M$, $\sum[SO_4^{2-}]=0.50M$
b) wavelength for the first absorption maximum
c) wavelength for the second absorption maximum

in the size of the alkylamine.

It is interesting to investigate the effect of the coordinated ligands on the reactivity of chloropentakis(alkylamine)cobalt(III) complexes with iron(II). Therefore, the present author wishes to report the results observed in the electron-transfer reactions of several chloropentakis(alkylamine)cobalt(III) complexes.

Experimental

Preparation of Complexes. $[Co(CH_3NH_2)_5Cl]Cl_2$,[4] $[Co(n\text{-}C_3H_7NH_2)_5Cl]Cl_2\cdot HCl$,[3] and $[Co(i\text{-}C_4H_9NH_2)_5Cl]Cl_2\cdot HCl$[3] were prepared by the methods described in the references cited. The *trans*-$[Co(NH_3)_4(CH_3NH_2)Cl]Cl_2$ was prepared by a manner similar to that for the preparation of *trans*-$[Co(^{15}NH_3)(NH_3)_4Cl](ClO_4)_2$.[5]

The wavelengths of the first and second absorption maxima for these complexes are listed in Table 1, along with the rate constants.

Materials. The preparation of a stock solution of iron(II) sulfate and the determination of iron(II), the sulfate ion, and the hydrogen ion were carried out by a method similar to that described in a previous paper.[6] All the other chemicals were of a guaranteed reagent grade. The concentration of sulfuric acid and the total concentration of the sulfate ion of the reaction mixture were adjusted to 0.05M and 0.50M respectively by the addition of sulfuric acid and sodium sulfate solutions.

Measurement of the Reaction Rate. The reactions were followed spectrophotometrically under pseudo-first-order conditions in which the iron(II) concentration was in a large excess to that of the Co(III) complex. The absorbance at the wavelengths corresponding to the first absorption maxima for the complexes were all recorded automatically except for the case of $Co(i\text{-}C_4H_9NH_2)_5Cl^{2+}$. Since the aquation of the $Co(i\text{-}C_4H_9NH_2)_5Cl^{2+}$ proceeded in some extent during the dissolution, the reduction rates were measured at 537 nm, which is the isosbestic point for this complex and $Co(i\text{-}C_4H_9NH_2)_5OH_2^{3+}$. The rate of the aquation of this complex during electron-transfer reaction was negligible small in comparison with that of the reduction during the initial period.

The activation parameters for all the complexes except for $Co(i\text{-}C_4H_9NH_2)_5Cl^{2+}$ were obtained from the log k *vs.* $1/T$ plot, using a linear least-squares method.

Results and Discussion

In the cases of $Co(NH_3)_5Cl^{2+}$, *trans*-$Co(NH_3)_4(CH_3NH_2)Cl^{2+}$, and $Co(CH_3NH_2)_5Cl^{2+}$, the plots of log (A_t-A_∞) *vs.* time were linear for at least two half-lives, but for the $Co(n\text{-}C_3H_7NH_2)_5Cl^{2+}$ and $Co(i\text{-}C_4H_9NH_2)_5Cl^{2+}$, the reaction obeyed a pseudo-first-order sequence for a 60% reaction.

The rates for these reductions are first-order dependences on the Co(III) and Fe(II) concentrations respectively.

In spite of the lability of iron(III) complexes, it has been found, by a direct observation of the transient species $FeCl^{2+}$, that the reactions of cobalt(III) complexes, such as $Co(NH_3)_4OH_2Cl^{2+}$,[7] $Co(HEDTA)Cl^-$,[7] and $Co(OH_2)_5Cl^{2+}$,[8] with iron(II) proceed *via* the chloride-bridged activated states. Therefore, it seems reasonable to assume a similar mechanism for the present reactions. The most important factors in determining the rates of the inner-sphere electron-transfer reactions of cobalt(III) complexes may be: (1) the ligand field strength of the *trans*-ligand which is located at the *trans*-position to the bridging ligand, and (2) the energy for stretching the *trans*-ligand away from the cobalt(III) center. The greater reactivity for *trans*-$Co(NH_3)_4(CH_3NH_2)Cl^{2+}$ than $Co(NH_3)_5Cl^{2+}$ may be ascribed to the weak ligand-field strength for the *trans*-ligand (methylamine) in the former compared with that for the *trans*-ligand (ammonia) in the latter (Table 1).

The rate constants shown in Table 1 indicate that the reactivity of the cobalt(III) complexes of the CoA_5Cl^{2+} type, where A is alkylamine, increases slightly with the size of the alkylamine ligand.

In a previous work,[1] it was suggested that the reactivity of *cis*-$Co(en)_2ACl^{2+}$ in the reduction by iron(II) decreased slightly with an increase in the size of the alkylamine from methylamine to butylamine. The specific rates for CoA_5Cl^{2+} with iron(II) are increased, however, with an increase in the size of alkylamine. The ligand-field strengths of alkylamines are of almost the same degree. Consequently, the small increase in the reactivity of CoA_5Cl^{2+} may be caused by the steric interaction[3] between the coordinated alkylamines. This steric interaction would reduce the reorganization

energy for the reduction. No detailed explanation of such a steric effect can be made from the results thus far obtained.

The rates of the base and acid hydrolyses of chloropentakis(alkylamine)cobalt(III) complexes are very much increased with the size of alkylamine. For example, the relative reactivities for the base and acid hydrolyses of $Co(i\text{-}C_4H_9NH_2)_5Cl^{2+}$ are, respectively about 6×10^5 and 10^2 times greater than those of $Co(NH_3)_5Cl^{2+}$.

In the Fe(II) reduction reactions of chloropentakis(alkylamine)cobalt(III) complexes, the effect of the size of alkylamine is very small compared with that in the base and acid hydrolyses reactions. This indicates that the steric effect of the nonbridging ligand in the Fe(II) reduction is not very important.

The authour wishes to express his thanks to Professor K. Yamamoto and Professor Y. Kurimura for their helpful discussions, to Mr. T. Suzuki for his assistance in this work, and to Professor E. Tsuchida for his microanalysis of the Co(III) complexes.

Rotational Isomerism in Epihalogenohydrin

Michiro HAYASHI, Kazuki HAMO, Keiichi OHNO, and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received August 19, 1971)

Thirty years ago, Ballaus and Wagner[1] studied the Raman spectra of epihalogenohydrin in the liquid state and discussed the molecular forms of these substances. Recently, several new investigations have been reported on the molecular forms of these substances.

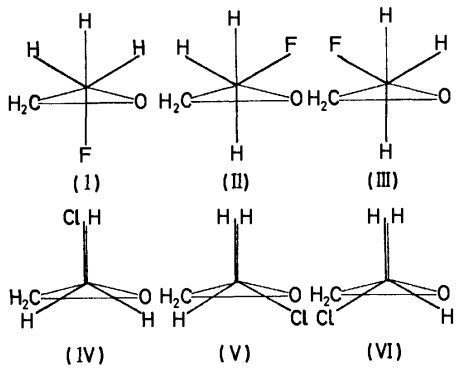

Fig. 1. Molecular forms of epihalogenohydrin.

For epifluorohydrin, the NMR study[2] and the microwave spectroscopy[3] have indicated that the most stable molecular form is the form I in Fig. 1, in which the fluorine atom occupies the *cis* position to the epoxide ring. For epichlorohydrin, however, the electron diffraction[4] has indicated that the preferred form is the form IV, in which the chlorine atom occupies the *trans* position to the epoxide ring.

Not only are the results of these investigations quite different, but the co-existence of the different isomers has never been proved explicitly. We have, therefore, investigated the vibrational spectra of epichlorohydrin, epibromohydrin, and epiiodohydrin in relation to the rotational isomerism, paying special attention to the problem of whether or not the isomers co-exist in the liquid state.

Experimental

Commercial propylene oxide, epichlorohydrin, and epibromohydrin were used without purification since the gas chromatograph showed no remarkable impurities. The epiiodohydrin was prepared from epichlorohydrin by an exchange reaction with KI in acetone.[1]

The infrared spectra were recorded in the region from 4000 to 200 cm^{-1} with a Perkin-Elmer 621 spectrophotometer in both the liquid and crystalline states. The solvent effects of the spectra were also examined using cyclohexane, acetone, and acetonitrile as solvents.

Results and Discussion

As is shown in Fig. 2, some of the spectra vanish in the crystalline state for epihalogenohydrin, while no remarkable change is seen for propylene oxide. The assignments of the observed spectra can be partially made if the spectra of epihalogenohydrin are compared with those of ethylene oxide[5] and propylene oxide.[6,7] Several strong infrared spectra found in the region below 750 cm^{-1} for these substances are regarded as originating from the CH_3 and CH_2X groups.

For propylene oxide, the observed strong bands at 370 and 415 cm^{-1} are assigned to two CCC deformation modes since the CH_3 torsional mode is known to be below 200 cm^{-1}.[7]

For epihalogenohydrin, three skeletal deformation modes may be expected in the region below 500 cm^{-1} for unique molecular form. As Ballaus and Wagner[1] have already pointed out, these skeletal deformations are found at the frequencies close to those of isobutyl

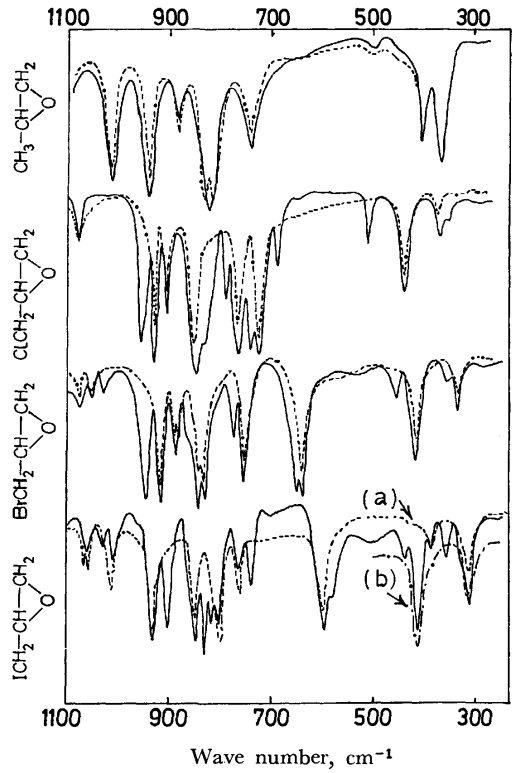

Fig. 2. The infrared spectra of propylene oxide and epihalogenohydrin:—in the liquid state, ----in the crystalline state; (a) in the most stable state, (b) in the metastable state.

halides. From a comparison with the observed spectra of isobutyl halides, the three skeletal deformation modes of epihalogenohydrin can be regarded as falling into two groups, one corresponding to two skeletal deformations of propylene oxide in the region over 300 cm^{-1}, and the other corresponding to the CCX deformation in the region below 300 cm^{-1}.

There are four infrared bands for epichlorohydrin and epibromohydrin and five for epiiodohydrin in this region in the liquid state, while two of them persist in the crystalline state. As is shown in Fig. 2, the frequency *vs.* intensity patterns of the infrared spectra observed around 400, 750, and 900 cm^{-1} show us that the isomers of epichlorohydrin and epibromohydrin in the crystalline state are probably similar to each other, but are different from that of epiiodohydrin. During the repetition of the crystallization procedure, a spectral pattern similar to those for epichlorohydrin and epibromohydrin was also obtained once in the region below 450 cm^{-1} for epiiodohydrin, as is shown in Fig. 2. However, the pattern was changed into an usual one by annealing the sample before recording the spectra around 750 and 900 cm^{-1}.

Although attempts at the reproduction of this special crystalline state have been unsuccessful thus far, these facts suggest that there exist two different crystalline states for epiiodohydrin and that the molecular form is similar to those of epichlorohydrin and epibromohydrin in the metastable crystalline state and is different in the most stable crystalline state.

The solvent effects of the infrared spectra were examined for the skeletal deformations around 400 cm^{-1} and for the C–X stretching modes in the region from 750 to 550 cm^{-1}, which can be easily assigned from the assignments for the similar molecules.[8,9]

For epichlorohydrin and epibromohydrin, the spectra vanishing in the crystalline state become stronger in the cyclohexane solution, while for epiiodohydrin, the spectra persisting in the most stable crystalline state become stronger.

From these results, it can be said that the form in the crystalline state is probably the more polar form for epichlorohydrin and epibromohydrin and the less polar form for epiiodohydrin, in relation to the other forms found only in the liquid state.

As is shown in Fig. 1, there are four other possible molecular forms besides the forms I and IV. Estimation from the bond moments indicates that the magnitudes of the dipole moments for the six different forms decrease in the order of V>I≒II>IV≒VI>III. However, we cannot conclude from these results alone which molecular forms in Fig. 1 correspond to the more polar form and the less polar form described above, though the co-existence of at least two different isomers in the liquid state is proved for these molecules.

The Carbonylation of 1,1′-Bis(chloromercuri)ferrocene with Palladium Salt: A Synthesis of [1.1]Ferrocenophane-1,12-dione

Akira KASAHARA, Taeko IZUMI, and Satoshi OHNISHI

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa-shi, Yamagata

(Received August 23, 1971)

It has recently been found that palladium or palladium chloride can be used as a catalyst for the carbonylation reaction of various compounds:[1] olefins,[2] dienes,[3] acetylene,[4] allyl halides,[5] and amines.[6,7] Furthermore, Henry[7] has reported that arylpalladium salts, prepared *in situ* from arylmercuric salts and palladium compounds, react with carbon monoxide to form arenecarboxylic acids or their derivatives; Heck[8] has also described that diaryl ketones could be formed in moderate yields from arylmercuric salts and carbon monoxide with a palladium-salt catalyst. In this paper, we wish to report that the reaction of 1,1′-bis(chloromercuri)ferrocene (**1**) and carbon monoxide in the presence of a palladium salt results in the formation of [1.1]ferrocenophane-1,12-dione (**2**) and ferrocenedicarboxylic acid derivatives (**3**), plus a small amount of bi-1,1′-ferrocenylene (**4**), while the diferrocenyl ketone (**6**) and methyl ferrocenecarboxylate (**7**) are also produced by the carbonylation reaction of chloromercuriferrocene (**5**) in methanol with a palladium-salt catalyst.

Experimental

Measurements. All the melting points are uncorrected. The NMR spectra were determined in $CDCl_3$ at 60 MHz with a Hitachi H-60 NMR spectrometer, using TMS as the internal reference. A Hitachi EPI-S2 infrared spectrometer was used for the measurements of the infrared absorption spectra. The molecular weight was determined in benzene or in chloroform, using a Hitachi 115 vapor-pressure osmometer.

Materials. 1,1′-Bis(chloromercuri)ferrocene (**1**) and chloromercuriferrocene (**5**) were prepared according to the method described by Fish and Rosenblum.[9]

Carbonylation of 1,1′-Bis(chloromercuri)ferrocene (1). The lithium palladium chloride solution was prepared by stirring 1.68 g (40 mmol) of anhydrous lithium chloride with 3.54 g (20 mmol) of anhydrous palladium chloride overnight at room temperature in 200 m*l* of methanol. Into this lithium chloropalladite solution, **1** (6.56 g, 10 mmol) was then carbonylated at 70°C under a carbon monoxide pressure (50 atm) for 6 hr with shaking; a pressure drop was thus observed. The products were isolated by filtering to remove a precipitated palladium and by distilling under reduced pressure to remove the solvent. The residue was dissolved in benzene and chromatographed on neutral alumina. The first elution with benzene and recrystallization from benzene afforded orange crystals (0.15 g, 8% yields); they were identified as bi-1,1′-ferrocenylene (**4**) by a comparison of the IR spectrum with that of an authentic sample and by a mixed-melting-point determination.[10] Mp 370°C. IR spectrum (KBr): 3090, 1101, 998 cm^{-1}. Found: C, 65.41; H, 4.46%; mol wt (in $CHCl_3$) 363. Calcd for $C_{20}H_{16}Fe_2$: C, 65.54; H, 4.39%; mol wt 368.

The second elution with benzene and recrystallization gave dimethyl 1,1′-ferrocenedicarboxylate[11] (**3**) (1.12 g, 36.8%); this was identified by a comparison of the IR and NMR spectra, and by a mixed-melting-point determination, with an authentic sample. Mp 114—115°C. IR spectrum (KBr): 1704 cm^{-1} (ester). NMR spectrum (ppm): 3.78 ($COOCH_3$, singlet), 4.35 (ring protons, triplet), 4.77 (ring protons, triplet).

Further elution with chloroform and recrystallization from chloroform afforded yellow orange crystals (1.19 g, 29%); they were identified as [1.1]ferrocenophane-1,12-dione[12] (**2**). Mp 350°C. IR spectrum (KBr): 1615, 1104, 998 cm^{-1}. NMR spectrum (ppm): 4.40 (ring protons, triplet); 4.80 (ring protons, triplet). Found: C, 62.17; H, 3.72%; mol wt (in $CHCl_3$) 419. Calcd for $C_{22}H_{16}O_2Fe_2$: C, 62.28; H, 3.80%; mol wt 424.2.

Carbonylation of Chloromercuriferrocene (5). In a lithium chloropalladite solution (prepared from 0.84 g of lithium chloride and 1.77 g of palladium chloride in 100 m*l* of methanol), **5** was carbonylated at 50°C under carbon monoxide (50 atm) for 3 hr with shaking. The isolation of the product in the same manner as was used for **1** gave biferrocenyl[13] (**8**) (mp 236—238°C, 0.21 g, 11.2%), methyl ferrocenecarboxylate[14] (**7**) (mp 70—71°C, 0.78 g, 32.3%), and diferrocenyl ketone[15] (**6**) (mp 205—206°C, 0.54 g, 31.5%). These products were identified by a comparison of the IR and NMR spectra, and by a mixed-melting-point determination, with an authentic sample.

Results and Discussion

The carbonylation of **1** was carried out at 70°C under a carbon monoxide pressure of 50 atm in the presence

of lithium chloropalladite in methanol; the main products were **2** and **3**, plus a small amount of **4**. Under the same conditions, the carbonylation of **5** in methanol resulted in the formation of **6**, **7**, and **8**. Heck[8] reported that arylmercuric chlorides react with palladium salts in the absence of carbon monoxide to form biaryls in good yields. We also observed that the reaction of **1** with palladium salts led to the formation of **4** in good yields.[16] The addition of carbon monoxide to the reaction mixture results in the formation of **2** and **3** at the expense of **4**. In the carbonylation of arylmercuric salts, the use of rhodium catalysts for the diaryl ketone has been reported. However, in the carbonylation of **1**, the use of rhodium trichloride as a catalyst did not bring about better results in the formation of **2** compared with the use of the palladium catalyst.

16) T. Izumi, G. Saito, and A. Kasahara, unpublished work.

The mechanism of the formation of **2** from **1**, as Heck pointed out in his carbonylation study,[8] probably involves the reaction of an acyl-palladium compound with a ferrocenylene palladium compound or a ferrocenylene mercuric compound. **3** and **4** are probably formed by side reactions.

Thiocyanoacetate. III. The Synthesis of 2-Hydrazono-4-thiazolidinone Derivatives[1)]

Satoshi KAMBE and Toshio HAYASHI*

Oyama Technical College, Oyama-shi, Tochigi

**The Institute of Physical and Chemical Research, Wako-shi, Saitama*

(Received August 23, 1971)

Although a number of papers[2-6)] have been published concerning the syntheses of 2-hydrazono-4-thiazolidinone derivatives, no syntheses using ethyl thiocyanoacetate (**1**) as the starting material have been reported. We wish now to report a convenient synthesis of 2-arylidenehydrazono-4-thiazolidinones from **1**, arylideneazines (**2**), and hydrazine hydrate (**3**).

The reaction was performed by refluxing a mixture of **1**, **2**, and **3** (molar ratio 2: 1: 1) in ethanol containing a small amount of acetic acid. For example, the reaction of **1** with **2a** and **3** afforded a pale yellow solid melting at 254—5°C, which was identified as 2-benzylidenehydrazono-4-thiazolidinone (**4a**). The structure of **4a** was inferred from the results of elementary analysis and of spectral studies. The IR spectrum of **4a** revealed the presence of NH (3025 cm^{-1}), C=O (1713 cm^{-1}), and C=N (1645 cm^{-1}) bands. The NMR spectrum showed the NH proton signal at δ 12.1, the CH_2 at 3.9, the =CH at 8.4, and the C_6H_5 at 7.5 ppm. For the structual confirmation of **4a**, an authentic sample was prepared by the treatment of ethyl chloroacetate with benzaldehyde thiosemicarbazone according to the method in the literature.[5)] These products were proved to be identical by a mixed-melting-point determination and by IR and NMR spectral studies. On the other hand, the reaction of **1** with **2a** and **3** (molar ratio 1: 1: 1) in acetic acid gave a product which was identified as 5- benzylidene-2-benzylidenehydrazono-4-thiazolidinone (**5a**). The NMR spectrum of **5a** lacked the CH_2 proton signal and showed the =CH proton as a doublet (δ 8.4 and 8.5 ppm). **5a** was hydrolyzed by hydrochloric acid to

give 5-benzylidene-2,4-thiazolinedione, whose IR spectrum showed a carbonyl stretching band as a doublet (1670 and 1740 cm^{-1}). A similar conversion has been reported in the case of 2-isopropylidenehydrazone-4-thiazolidinone.[2] Furthermore, **5a** was also obtained by the reaction of **1** with benzaldehyde acethylhydrazone in acetic acid. However, when **2 g** was employed as the azine reactant, the reaction did not lead to the formation of the corresponding product (**5 g**), but to **4 g**.

A plausible reaction sequence is illustrated in Scheme 1. Presumably, the reaction proceeds through the intermediary of the hydrazone (**6**), which subsequently condenses with **1** to give **4**. The product, **5**, may be formed by the further condensation of **4** with aromatic aldehyde.

Experimental[7]

2-Arylidenehydrazono-4-thiazolidinones (4). General Procedure. A mixture of **1** (0.02 mol), **2** (0.01 mol), and **3** (0.01 mol) in ethanol (10 m*l*) containing acetic acid (1 m*l*) was refluxed for a suitable period. Crystalline precipitates were formed during the reaction; these were collected on the filter and washed with ethanol. Recrystallization from acetic acid gave **4**. The results are summarized in Table 1.

5-Arylidene-2-arylidenehydrazone-4-thiazolidinones (5). General Procedure. To a mixture of **2** (0.01 mol) and **3** (0.01 mol) in acetic acid (10 m*l*), we added **1** (0.01 mol), and then the mixture was refluxed for a suitable period. The resulting precipitates were filtered and washed with ethanol. Recrystallization from dimethyl sulfoxide gave **5**. The results are summarized in Table 2.

7) All the melting points are uncorrected. The IR spectra were measured with a Shimadzu IR-27G spectrophotometer in Nujol mulls. The NMR spectra were determined in trifluoroacetic acid with a Nihondenshi JNM-C-60 high-resolution NMR spectrometer (60 MHz), using tetramethylsilane as the internal standard. The chemical shifts of the protons are presented in terms of δ values.

5-Benzylidene-2-benzylidenehydrazono-4-thiazolidinone (5a) from 1 and Benzaldehyde Acetylhydrazone. A mixture of **1** (0.01 mol) and benzaldehyde acetylhydrazone (0.02 mol) in acetic acid (10 m*l*) was refluxed for 14 hr. The resulting precipitate was collected on a filter, washed with ethanol, and recrystallized from dimethyl sulfoxide. Yield, 14%.

The Hydrolysis of 5a. To a solution containing concentrated hydrochloric acid (10 m*l*) and ethanol (10 m*l*), we added **5a** (0.01 mol), and then the mixture was heated for 15 hr. After being cooled, the reaction mixture was poured onto cracked ice. The crystalline matter thus formed was collected, washed with water, and air-dried. Recrystallization from acetic acid gave 5-benzylidene-2,4-thiazolidinones; mp 239—40°C; yield, 26%. IR (cm^{-1}): 3150 (NH), 1740 and 1690 (C=O), 1610 (C=C). NMR (δ): 7.50 (C_6H_5), 8.10 (=CH), 9.55 (NH).

Found: C, 58.65; H, 3.56; N, 6.75; S, 15.54%. Calcd for $C_{10}H_7O_2NS$: C, 58.54; H, 3.44; N, 6.83; S, 15.82%.

The authors wish to express their thanks to Dr. Hiroshi Midorikawa and Dr. Heinosuke Yasuda for their helpful discussions and encouragement throughout the course of this work. Thanks are also due to Dr. Akio Sakurai for his helpful advice in many respects.

Molecular Vibrations and Force Fields of Alkyl Sulfides. III. Infrared Spectra of Methyl Ethyl Sulfide

Masaru OHSAKU, Yuji SHIRO,* and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

**Shinonome Branch School, Faculty of Education, Hiroshima University, Shinonome-3-chome, Hiroshima*

(Received August 26, 1971)

The vibrational spectra of methyl ethyl sulfide have been extensively examined by several authors.[1-6] The rotational isomerism, C_s (T) and C_1 (G), has also been discussed.[2-5] Lately, Scott *et al.*[6] carried out a normal coordinate treatment using the valence force field. In the previous papers, however, the assignments of the observed bands were not consistent with each other, and in the C–H stretching, CH_3 degenerate deformation, CH_2 bending, and CH_3 rocking regions, the spectra were not well-resolved. In order to obtain the complete infrared data, we have newly recorded the infrared spectra of methyl ethyl sulfide in the gaseous, liquid, and solid states; on the basis of our results, we have then revised a few of the previous assignments. The vibrational data thus obtained will be used in a normal coordinate treatment of methyl ethyl sulfide.

Results and Discussion

The infrared data obtained and the consequent assignments of methyl ethyl sulfide are summarized in Table 1. The C–H stretching, CH_3 degenerate deformation, CH_2 bending, and CH_3 rocking regions are well-resolved in the unannealed or the annealed spectra. In the C–H stretching region, 3000—2800 cm^{-1}, we observed six and ten bands in the liquid and solid states respectively. Among these bands, the overtone bands of the CH_3 degenerate deformation vibrations may be confused. They are hardly distinguishable from each other. In the region around 1300 cm^{-1} two weak bands remain in the annealed spectra (1319 and 1305 cm^{-1}). The band at 1319 cm^{-1} may be assigned to the fundamental with reference to the data of dimethyl sulfide.[7] Scott *et al.*[2] assigned the band at 1305 cm^{-1} to the CH_2 wagging band. We consider this band to be too high to identify as the CH_2 wagging fundamental. The band at 1305 cm^{-1} may be due to the overtone or to the sum-combination. In the CH_2 wagging and twisting regions, some bands disappeared in the solid state. These bands may be

due to the less stable conformation. Methyl ethyl sulfide has four CH_3 rocking vibrational freedoms for each conformation. In the 990—940 cm^{-1} region, we observed five and three bands in the liquid and solid states respectively. These bands may be due to the CH_3 rocking fundamentals. Scott *et al.*[2] and Hayashi *et al.*[4] identified one band of this region as the C–C stretching vibration. For the CH_2 rocking vibrations, two bands were obtained in the liquid state and one band remained in the solid state. The C–S stretching vibration has two vibrational freedoms for each conformation. In the liquid state, three bands are observed. Among them, two bands remain in the annealed spectra. If two conformations may coexist in the liquid state, one band may overlap with the other one. In the skeletal deformation region, 400—200 cm^{-1}, three bands for each conformation may be expected. In the liquid state, we observed five bands. Two bands remain in the solid state.

Experimental

The methyl ethyl sulfide was commercially obtained (Tokyo Kasei Co., Tokyo) and distilled; bp 66.5—67°C/760 mmHg. The gaseous spectra (4000—600 cm^{-1}) were recorded at room temperature. The liquid spectra were recorded at room temperature in the 600—200 cm^{-1} region and at low temperatures, slightly above its mp in the 4000—600 cm^{-1} region. The solution spectra (1400—600 cm^{-1}) were obtained in CS_2. The solid state spectra (4000—200 cm^{-1}) were recorded near the temperature of liquid nitrogen. The instrument used for recording was a Perkin-Elmer Model 621 Spectrophotometer.

(Received August 26, 1971)

Many papers on the vibrations of diethyl sulfide have appeared.[1-5] Scott *et al.*[2] postulated three conformations: C_{2v} (TT), C_1 (TG), and C_2 (GG). Hayashi[3] carried out a normal coordinate analysis for skeletal vibrations using a Urey-Bradley type potential and assigned the obtained spectra assuming C_{2v}, C_1, and C_2 conformations. Lately, Scott *et al.*[5] carried out a normal coordinate treatment using a valence force-type potential; they suggested that the C_{2v} and C_1 conformations are stable and that the C_2 conformation must have a high energy. In the previous papers, however, the assignments of the observed bands were not con-

sistent with each other; moreover, the conformational analyses of this compound have not agreed with each other. In this paper, in order to complete the infrared data, we report anew on the infrared spectra of diethyl sulfide recorded in the gaseous, liquid, and solid states. We will treat the normal coordinates of this molecule and will report its full assignments in the succeeding paper.

Results and Discussion

The infrared data of diethyl sulfide obtained are summarized in Table 1. The existence of the rotational isomers may be confirmed by the spectra in the CH_2 rocking, C–S stretching, and skeletal deformation regions. For the CH_2 rocking region, 800—760 cm^{-1}, we observed five bands in the liquid state and only one band in the annealed film. Diethyl sulfide has two vibrational freedoms of the CH_2 rocking vibrations for each conformation. However, one band of the CH_2 rocking belonging to the A_2 species of the C_{2v} (TT) conformation is infrared-inactive. Therefore, five bands in the liquid spectra would arise from three conformations (TT, TG, and GG); we can not deny the existence of the C_2 conformation at present. The spectra of this region suggest that the stable form in the solid state is the C_{2v} conformation. In the 750—600 cm^{-1} region, C–S stretching vibrations are to be expected. Diethyl sulfide has two vibrational freedoms of the C–S stretching for each conformation. If the three conformations of C_{2v}, C_1, and C_2 coexisted in the liquid state, six bands would arise. In this region we observed five bands in the liquid state and one band in the solid state. Therefore, the stable conformation (TT) represents only one C–S stretching band in the solid state. The other four bands must arise from the other two conformations. Scott *et al.*[2] assigned the band at 688 cm^{-1} (liquid) to the accidentally-degenerate C–S stretching vibration of the C_{2v} conformation. Since this means, however, that the interaction between the two C–S bonds is zero, the assignment is not acceptable. The band at 692 cm^{-1} in the solid state is not overlapped. It is a weak band. Therefore, the dipole change due to the vibration may be small. Another C–S stretching band would be too weak to be observed, since, in the case of dimethyl sulfide,[6] one C–S stretching band is very weak in comparison with the other band. In

6) M. Ohsaku, Y. Shiro, and H. Murata, This Bulletin, **45**, 113 (1972).

the skeletal deformation region, 450—200 cm^{-1}, fifteen bands are to be expected for three conformations, and five bands, including two C–C torsions, for one conformation. Twelve bands are observed in the liquid spectra. Although all of the observed bands are not always considered to be fundamentals, the three bands remaining in the annealed spectra may be due to the skeletal deformation vibrations of the C_{2v} conformation. Therefore, there remain nine bands in this region. Most of these nine bands may correspond to the other two conformations. From the spectra of this region, therefore, we can not deny the existence of the C_2 conformation.

Experimental

The diethyl sulfide was commercially obtained (Tokyo Kasei Co., Tokyo) and distilled; bp 92°C/760 mmHg. The gaseous spectra (4000—600 cm^{-1}) were recorded at room temperature. The liquid spectra were recorded at room temperature in the 600—200 cm^{-1} region and at low temperatures, slightly above its mp in the 4000—600 cm^{-1} region. The solution spectra (1400—600 cm^{-1}) were obtained in CS_2. The solidstate spectra (4000—200 cm^{-1}) were recorded near the temperature of liquid nitrogen. The instrument used for recording was a Perkin-Elmer Model 621 Spectrophotometer.

Orientation Patterns in Nematic Liquid Crystal

Mitsunori SUKIGARA, Osamu NAGASAKI,* and Kenichi HONDA
Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received September 4, 1971)

It has been reported by Williams[1] that a periodic optical texture can be observed in certain nematic liquid crystals when an electric field is applied to transparent sandwich cells. There are two different versions of the molecular orientation for the field-induced domain in a sandwich cell. Meyer stressed the piezoelectric effects which cause the alternating regions of splay and bending as seen in Fig. 2-b in his paper.[2] On the other hand, Helfrich predicted a periodic distortion, which was illustrated in Fig. 2 of his report,[3] produced by a space charge electric field on the basis on his theory.[4]

We tried to observe patterns in nematic *N*-*p*'-anisilidene-*p*-*n*-butylaniline in the direction perpendicular to the electric field using a sandwich cell shown in Fig. 1. Observations were made in transmitted light under a polarizing microscope. The walls of the cell were rubbed with a cotton swab before placing the sample.

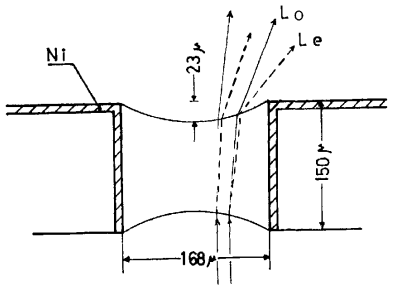

Fig. 1. Schematics of cell configuration and the shape of the sample. The electrodes were made with vacuum sublimated nickel on glass. The shape of the sample was determined with an interference microscope and a contact angle measurement apparatus. L_o and L_e mean the ordinary and extraordinary lights, respectively.

In the fieldless state the projection of the unique axis was aligned perpendicular to the wall near the electrode surface. It was gradually inclined with going away

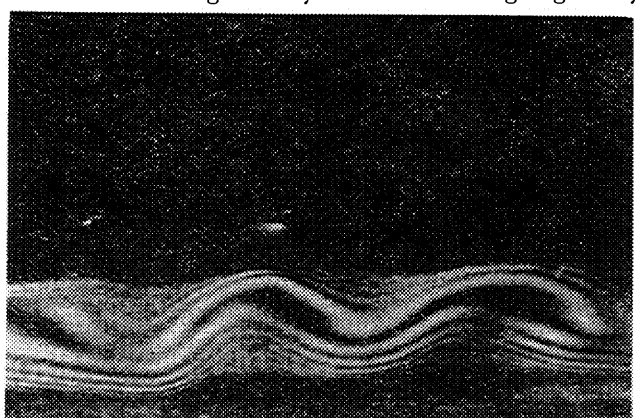

Fig. 2. Wave-like orientation pattern in *N*-p'-anisilidene-*p*-*n*-butylaniline at 25°C observed with crossed Nicols. Applied voltage was 5 V, the upper electrode being anode.

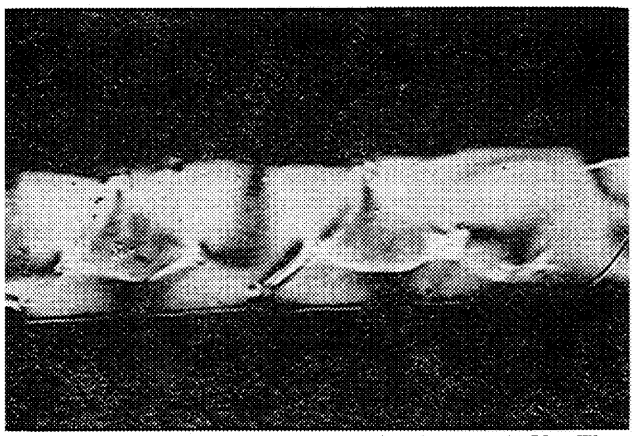

Fig. 3. Novel pattern in the nematic phase at 11 V. The cell was placed between the two parallel Nicols.

from the wall and finally aligned parallel to the wall. A white turbid part was seen at the center of the cell. The gradual change of the orientation could be seen by observing transmitted light which had been linearly polarized with a polarizer. When the direction of the electric vector of the incident light was rotated from perpendicular to parallel to the wall, a dark band moved from the wall to the center of the cell.

When an electric field ($\geqq$4.5 V) was applied, a wave-like orientation pattern appeared in the white turbid band. A typical pattern observed at 5 V is shown in Fig. 2. The pit in the pattern became deeper and reached the wall with the increase of the applied voltage up to 10 V. When the applied voltage exceeds 12 V, many lines were observed to move to and from the electrodes. This phenomenon corresponds to the dynamic scattering mode.[5] Several novel textures appeared between 10—12 V. An example is given in Fig. 3. The wave-like pattern observed in this experiment is much similar to one predicted by Helfrich.[3] Measurements of electric field distributions in the aligned nematic phase will give much information for the mechanism of the pattern formation.

Cyclic Disulfides. The Reaction of 1,2-Dithiaacenaphthene with Carbenoids

Seizo TAMAGAKI and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received September 4, 1971)

The chemistry of five-membered disulfides has drawn considerable interest mainly because of their characteristic properties in biological reactions and their special role in metabolic sequences.[1] Recently, the electronic features of the five-membered cyclic disulfides have been made clear on the basis of semi-empirical molecular orbital calculations, and the implications on the chemical reactivity have been discussed.[2] At the dihedral angle of 0° around the S–S bond the π-p orbitals of the lone-pairs on the two sulfur atoms are arranged parallel to each other, resulting in a larger splitting of the lone-pair energy levels than in disulfides containing non-parallel-allied lone pairs. Accordingly, electron pairs at the higher level may be expected to display a greater reactivity toward the electrophilic reagents than the less-splitting lone-pairs of the sulfur atom in open-chain disulfides.

The reaction of diaryl disulfide with the methylene formed by the photolysis of diazomethane has been investigated by German chemists and found to proceed in the following manner.[3,4]

$$\mathrm{Ar\text{-}S\text{-}S\text{-}Ar + CH_2N_2} \xrightarrow{h\nu} \mathrm{Ar\text{-}S\text{-}CH_2\text{-}S\text{-}Ar}^{3)}$$

$$\mathrm{Ph\text{-}S\text{-}S\text{-}Ph + Ph_2CN_2} \xrightarrow{h\nu} \mathrm{Ph\text{-}S\text{-}CPh_2\text{-}S\text{-}Ph}^{4)}$$

The similar insertion reaction of five-membered cyclic disulfide is interesting; we carried out the reaction of 1,2-dithiaacenaphthene with bis(arenesulfonyl)diazomethane or with diphenyldiazomethane in the presence of a catalytic amount of copper acetylacetonate.

Experimental

Reaction of 1,2-Dithiaacenaphthene with Bis(toluenesulfonyl)-diazomethane. A mixture of 1,2-dithiaacenaphthene (190 mg) and bis(toluenesulfonyl)diazomethane (350 mg) was refluxed for 15 min in the presence of 15 mg of copper acetylacetonate. After cooling, the solvent was evaporated to afford crystals, which were then recrystallized from benzene (450 mg: 88%) to give, finally, colorless crystals of (A): mp 148—148.5°C. Found: C, 58.36; H, 3.95%. Calcd for $C_{14}H_{14}S_2O_4$: C, 58.60; H, 3.91%.

Decomposition of (A). Compound (A) (140 mg) was decomposed in a test tube at 150°C. Then, the reaction mixture was extracted with hot *n*-hexane. After the evaporation of the solvent, the crystals (60 mg) were sublimated under reduced pressure to afford a carbonyl compound (B): mp 132—133°C. Found: C, 60.64; H, 2.85%. Cacld for $C_{11}H_{16}S_2O$: C, 60.50; H, 2.75%.

Reaction of 1,2-Dithiaacenaphthene with Diphenyldiazomethane. In a similar fashion, the reaction of 350 mg of diphenyldiazomethane with 1,2-dithiaacenaphthene (200 mg) gave 350 mg (91%) of crystals upon recrystallization from benzene-hexane; mp 180—181°C. Found: C, 77.65; H, 4.45%. Calcd for $C_{23}H_{16}S_2$: C, 77.52; H, 4.49%.

Results and Discussion

Diphenyl disulfide was allowed to react with an equimolar amount of bis(toluenesulfonyl)diazomethane in the presence of a catalytic amount of copper acetylacetonate to afford crystals melting at 169—170°C. This structure is at present yet unidentified. However, it is apparent that the reaction mixture did not contain disulfide linkage. Besides, from the reaction mixture no product was isolated which corresponds to the insertion product.

Contrary to the above reaction, the copper salt-

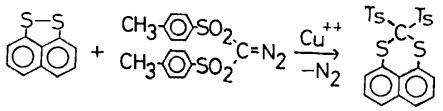
4) A. Schönberg and T. Stalpp, *ibid.*, **63**, 3102 (1930).

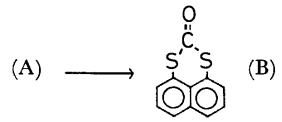
catalyzed reaction of 1,2-dithiaacenaphthene with bis-(toluenesulfonyl)diazomethane took place smoothly and was completed within 5 min in refluxing benzene; then the reaction gave crystals (A) with a decomposition temperature of 148—148.5°C. On the basis of the IR and NMR spectra, the compound obtained is considered to be an insertion adduct formed from bis-(toluenesulfonyl)diazomethane and 1,2-dithiaacenaphthene as is shown below.



(A)

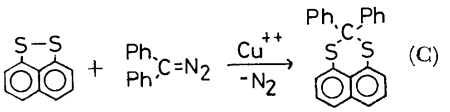
The IR spectrum showed bands at 1355 and 1175 cm^{-1} corresponding to the stretching frequencies of the sulfonyl group, while the NMR spectrum of the compound fully confirmed the (A) structure. The signals due to two methyl groups appear at δ 2.51 as singlet, and those of 14 aromatic hydrogens as a multiplet centered at δ 7.58.

The pyrolysis of (A) at its decomposition temperature gave carbonyl compound (B). The structure of the resulting compound was confirmed by IR, NMR, MS, and elemental analysis. The IR spectrum showed a strong band at 1610 cm^{-1} corresponding to that of the carbonyl groups. The mass spectrum showed a peak at *m/e* 218 as the molecular peak, followed by an

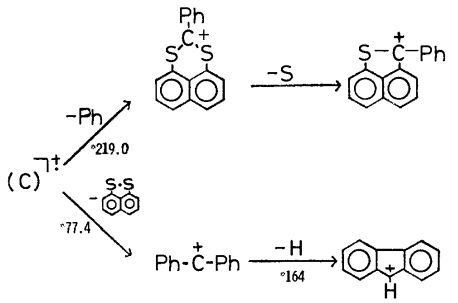


intense peak of *m/e* 190 and with a metastable peak appearing at *m/e* 165.0 due to decarboxylation.

Similarly, upon heating of a benzene solution of an equimolar mixture of 1,2-dithiaacenaphthene and diphenyldiazomethane in the presence of copper salts, a reaction took place promptly and the diphenylmethylene insertion product (C) was obtained as the sole product nearly quantitatively:



The structure of (C) was confirmed similarly on the basis of IR, MS, and elemental analysis. The mass spectrum showed a peak at *m/e* 356 as calculated from the expected structure (C):



(* indicates the metastable peak)

Unlike 1,2-dithiaacenaphthene, diphenyl disulfide did not give any similar product, as had been anticipated.

All these observations suggest that the reactions of carbenoids are essentially electrophilic. Thus, the effect of lone-pair lone-pair repulsion is evidently demonstrated by the above experiments; that is, the fact that the carbenoids react with 1,2-dithiaacenaphthene readily and not with diphenyl disulfide implies that the five-membered disulfide is much more reactive toward the electrophilic reagents than are the ordinary disulfides.

The formation of the metal carbenoid on the copper salts of acetylacetonate may be followed by the nucleophilic attack of 1,2-dithiaacenaphthene on the carbenoid carbon atom, resulting in the formation of ylide.[5] The mechanism of the carbenoid reaction may be represented as is shown below:

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 962—963(1972)

The MCD Spectrum of the Tropylium Cation

Akio TAJIRI and Masahiro HATANO

The Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai

(Received September 7, 1971)

One of the most interesting monocyclic odd-membered non-benzenoid aromatic hydrocarbons, the cycloheptatrienyl (tropylium) cation, $C_7H_7^+$, which has been shown to have a strong aromatic character due to the delocalization of the six π-electrons, was synthesized as early as 1954 by von Doering and Knox.[1]

Because of the intriguing chemical and physical properties of this cation, several authors[2-4] have attempted to calculate its electronic structures, especially its transition energies, on the basis of the π-electron molecular orbital theory. The N→V spectrum was theoretically studied by Murrell and Longuet-Higgins[2] using the SCF-MO theory. They predicted two transitions, an allowed transition at 6.36 eV ($^1A_1'\rightarrow{}^1E_1'$) and a forbidden transition at 4.33 eV ($^1A_1'\rightarrow{}^1E_3'$). The absorption band at 4.51 eV observed by von Doering and Knox was assigned to the latter transition.

The results of PPP-type calculations by Heilbronner and Murrell[4] of various odd-membered non-alternant hydrocarbons, including $C_7H_7^+$, using perimeter models were reported, along with their experimental data. The agreement between the theory and the experiment was quite good, and their results supported the above assignment of the absorption band of the tropylium cation.

TABLE 1. TRANSITION ENERGIES (eV) OF TROPYLIUM CATION

Symmetry	M-LH[2]	J[3]	H-M[4]	This Work[a]	Obsd[b]
$A_1'\rightarrow E_3'$	4.33	3.6	4.52	4.6(forb.)	4.54(ε=4350)
$A_1'\rightarrow E_1'$	6.36	5.7	5.83	6.3(0.32)	5.73(41000)

a) The values in the parentheses are the calculated oscillator strengths.

b) H. J. Dauben, Jr., F. A. Gadecki, K. M. Harmon, and D. L. Pearson, *J. Amer. Chem. Soc.*, **79**, 4557 (1957).

We also calculated the transition energies of $C_7H_7^+$ by use of a modified version of the CNDO/2 method parametrized by Tajiri *et al.*,[5] assuming the carbon skeleton to be heptagonal (D_{7h}) and also assuming each bond length to be 1.40 Å. The calculated transition energies are listed in Table 1, along with the observed values. The values predicted within the framework of the CNDO/2 method are in quite good agreement with the experimental data. The results of the previous authors are also included in the table for the sake of comparison.

On the other hand, recently, with the availability of very sensitive photoelectric spectropolarimeters, interest in optical activity measurements in the magnetic field through absorption bands (Magnetic Circular Dichroism: MCD) has been revived. Many authors[6-9] have used the MCD technique in order to extract information on the ground- and excited-states of ions and molecules. According to the theoretical consideration of Schatz and McCafferry,[10] when either the ground- or excited-state of a compound is degenerate, the Faraday A term is observed. The degeneracy of the ground-state causes the Faraday C term. In addition to these two terms, the B term originates from the mixing of the wavefunctions of the ground- and excited-states with some other states. Therefore, the molar ellipticity $[\theta]_M$(in deg·gauss^{-1}·cm^2·mol^{-1}) may be expressed as:

$$[\theta]_M = -21.348\{f_1A+f_2(B+C/kT)\}$$

where f_1 and f_2 are the functions of the frequency, ν, of the incident light (in general, a damped oscillator model is assumed).

Here let us turn again to the discussion of the electronic state of the tropylium cation. We should observe the A term for each band of the cation in question if we believe the predictions of previous authors, who assigned the $^1A_1'\rightarrow{}^1E_1'$ transition to the shorter wavelength absorption, and $^1A_1'\rightarrow{}^1E_3'$ to the longer. Therefore, we tried to measure the UV and MCD spectra of the tropylium cation in order to confirm the above assignment. The purification of the crude BF_4 salt was achieved by adding ether to its acetonitrile solution

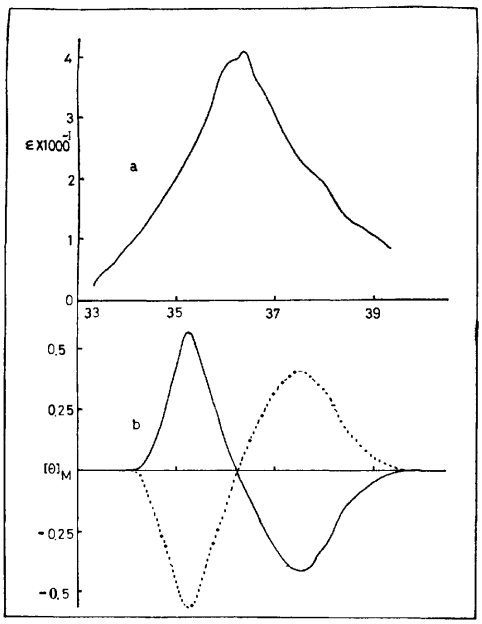

Fig. 2. (a) Molar extinction coefficient of tropylium cation in N/10 HCl solution at room temperature (300°K). (b) Molar ellipticity per unit magnetic field of tropylium cation in N/10 HCl solution at room temperature (300°K). The dotted line is obtained when the current in the magnet is reversed.

until white crystals formed. The concentration of this salt in the N/10 HCl solution was found to be 2.01×10^{-4} mol/*l*. For the measurement of the MCD spectrum, we employed a JASCO ORD/UV-5 recording spectropolarimeter provided with a CD measuring attachment and a 10 KG electric magnet.

Figure 1 shows the π-molecular orbitals and a schematic diagram of the two excited states caused by the lowest electronic transition from the degenerate HOMO to the degenerate LVMO. In Fig. 2 the UV and MCD spectra are shown. Unfortunately, however, because of the difficulties of the MCD measurement in the shorter-wavelength region, we were obliged to limit our measurement to the wavelength region longer than 230 nm.

A clear Faraday A term is shown in Fig. 2; its inflection point coincides with the absorption maximum (4.5 eV) within the limits of experimental error. This, in turn, shows that the lowest excited state of the tropylium cation, corresponding to the longest-wavelength absorption band, which is forbidden by the symmetry but which is partially allowed by the vibrational process, belongs to the $^1E_3'$ irreducible representation of the D_{7h} point group. Furthermore, the ground-state is totally symmetric and non-degenerate because of the lack of the Faraday C term, which should have an extreme in the MCD spectrum near the absorption maximum.

Actually the Faraday A term should be discussed in terms of an A/D which gives the parameters of theoretical interest and, in turn, the magnetic moment of the excited-state, where D is the dipole strength of the particular spectral line. From the observed MCD and UV spectra for this cation, we obtained the A/D value, which was estimated to be $-1.40\ \beta$ by use of the method of Briat *et al.*[6] At the same time, $[B+C/kT]/D$ was found to be negligibly small.

We conclude that the MCD measurements help in the direct assignment of an absorption band and, accordingly, provide us with information on the nature of the ground- and excited-states of ions and molecules.

We awfully acknowledge the generosity of Professor Y. Kitahara and Dr. M. Oda of Tohoku University for providing the sample. We are also grateful to Professor H. Kobayashi of the Tokyo Institute of Technology for giving us an opportunity to measure the MCD spectra.

(Received September 20, 1971)

The interaction between an aromatic amine and picric acid generally results in the formation of a yellow-colored 1 : 1 salt by means of proton-transfer. By adding pyridine to a mixture of α-naphthylamine and picric acid, Kofler isolated a red-colored complex, the composition of which happened to be α-naphthylamine-pyridine-picric acid (1 : 1 : 1).[2] To explain the deep color of this mixed picrate, he assumed that the pyridine molecule is bound to the hydroxy group of picric acid, while the aromatic amine interacts with the nitro groups of the acid. So far, however, no spectroscopic study of this ternary molecular complex has been reported.

As is shown in Fig. 1, the vibrational spectrum of the 1 : 1 salt derived from α-naphthylamine and picric acid, examined as a Nujol mineral oil mull, has sharp bands at 3075 and 3200 cm^{-1} and broader ones in the

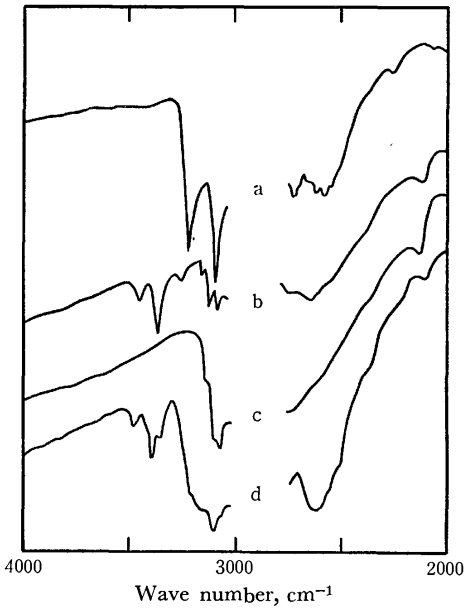

Fig. 1. Vibrational spectra; (a) α-naphthylamine-picric acid (1:1), (b) α-naphthylamine-pyridine-picric acid (1:1:1), (c) pyridine-picric acid (1:1), (d) α-naphthylamine-picric acid (2:1).

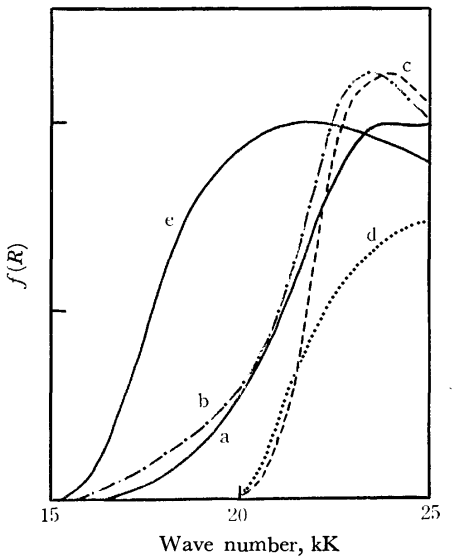

Fig. 2. Diffuse reflection spectra; (a) α-naphthylamine-pyridine-picric acid (1:1:1), (b) α-naphthylamine-picric acid (2:1), (c) α-naphthylamine-picric acid (1:1), (d) pyridine-picric acid (1:1), (e) α-naphthylamine-*s*-trinitrobenzene (1:1).

region from 2500 to 2800 cm^{-1}. This pattern is typical of picrates of primary amines. The first one is assigned to the picrate ion, and the second, to a NH_3^+ stretching frequency.[3] In the spectrum of the ternary complex, bands due to the amine appear at 3250, 3350, and 3450 cm^{-1} instead of at the above-mentioned locations. Although the spectrum in Fig. 1 presents no conclusive evidence for the protonation of pyridine, the pattern in the region below 1700 cm^{-1} includes that of the yellow-colored pyridinium picrate. Thus, the examination of the vibrational spectrum leads to the conclusion that the complex consists of pyridinium picrate and α-naphthylamine. This conclusion is in accordance with the fact that the pK_a value of pyridine is higher than that of the amine, *i.e.*, 5.22 *vs.* 3.92.[4] Kofler also reported the preparation of an orange-colored α-naphthylamine-picric acid (2:1) complex, "semipicrate" in his nomenclature. As may be expected, its vibrational spectrum indicates the presence of both NH_2 and NH_3^+ groups in this complex (see Curve d in Fig. 1).

Both the ternary molecular complex and the 2:1 complex are deeply colored. The diffuse reflection spectra given in Fig 2 clearly show that a broad weak absorption, the maximum of which is located around 20 kK, appears upon the incorporation of pyridine or additional α-naphthylamine into the 1:1 salt. The new absorption must be due to a charge-transfer interaction. The electron donor is undoubtedly α-naphthylamine. As the locations of the absorption maximum are nearly identical, the acceptor component is possibly a common species, namely, the picrate ion. A comparison with the spectrum of the *s*-trinitrobenzene complex suggests that the picrate ion is as strong as trinitrobenzene as an acceptor. The strength of picric acid is comparable with that of *s*-trinitrobenzene; therefore, it may be argued that the acceptor-strength is not much affected by the ionization. Further evidence to support this conclusion will be presented in a subsequent paper.[5] On the basis of this spectroscopic study, one may conclude that, in Kofler's ternary complex, a proton is transferred from picric acid to pyridine and that the interaction between α-naphthylamine and the picrate ion is of the charge-transfer type. It must be added that the explanation suggested by Kofler, of course in the terminology at that time, is in essential agreement with the present conclusion.

SHORT COMMUNICATIONS

Small Ring Compounds. I. Anodic Oxidation of 2,3-Dicarbethoxy-cyclopropanecarboxylic Acid

Ichiro MINATO, Tateo TAKASUKA, Koji KIMURA, Tsutomu SAKAKIBARA, and Yoshinobu ODAIRA

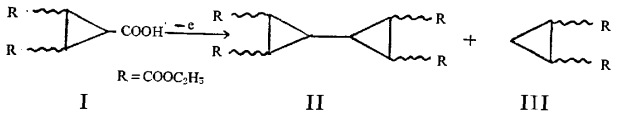
Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita-shi, Osaka

(Received November 18, 1971)

Highly strained small ring radicals have recently attracted special interest, and cyclopropyl radicals have been generated by several methods.[1] However, the yields are low and variable, and it would not be feasible to utilize the generated cyclopropyl radicals in various synthetic processes. In the anodic oxidation of cyclopropanecarboxylic acids, a common problem is the facile formation of a cationic intermediate, such as cyclopropyl cation or cyclopropanecarboxonium ion, by the additional one-electron oxidation of a generated cyclopropyl radical.[2] Cyclopropyl cations usually undergo concerted ring opening to afford many rearranged products.

We wish to report on attempts to generate an unrearranged cyclopropyl radical of high efficiency by anodic oxidation. For this purpose, 2,3-dicarbethoxy-cyclopropanecarboxylic acid (I), consisting of *trans,cis*- and *trans,trans*-isomers in the ratio 3: 2, was selected as the starting material. Compound I (0.02 mol) was electrolyzed in methanol (80 m*l*) containing sodium methoxide (0.02 mol) at 20—30°C for 6 hr: Anode, a platinum plate (1.5×20 cm); cathode, mercury-pool (surface area: *ca.* 13 cm^2); distance between the electrodes, *ca.* 1.0 cm; electrolytic cell, beaker-type vessel (150 m*l*) without diaphragm; initial current, 1.5 A (final value, 0.5 A); cell voltage, 60 V (final value 100 V).

2,2',3,3'-Tetracarbethoxy-bicyclopropyl (II) and 1,2-dicarbethoxy-cyclopropane (III) were obtained in 13 and 62.5% yields, along with small quantities of 1,2-dicarbethoxy-3-hydroxymethyl-cyclopropane (IV) and 1,2-dicarbethoxy-3-carbomethoxy-cyclopropane (V). All the products except III were identified by spectroscopic methods and gas chromatographic technique. Compound II can exist in eleven forms, it being confirmed by VPC (DEGSP, 230°C) and their mass spectra that at least nine out of the eleven were formed. Only the major component, mp 155—157°C, was isolated by VPC in *ca.* 30% yield, and determined to be *trans, trans,trans,trans*-isomer. It is significant that no ring opening products were found. Anodic oxidation with platinum anode and cathode (1.5×2.0 cm on each), mounted parallel to each other and 0.3 cm apart, resulted in similar products and their distributions.



I II III

It should be emphasized that a cyclopropyl radical is consistently generated in *ca.* 70% yield on the electrode. No concerted ring opening occurred through a cationic intermediate. In order to obtain further information on the stability of the radical, the thermal decomposition and photolysis of *t*-butyl-perester of I in benzene have been studied. The radical was also generated almost quantitatively and II and III were obtained in somewhat different yields together with considerable amounts of 3-*t*-butoxyl- and 3-phenyl-1,2-dicarbethoxy-cyclopropanes. Both the present electrolytic conditions employed and the electronic effect of two carbethoxy groups on the increase of the ionization potential of a cyclopropyl radical might be of importance.

The Photochemical Reaction of *p*-Benzoquinone in Water

Shizunobu HASHIMOTO, Koji KANO, and Hiroshi OKAMOTO
Department of Applied Chemistry, Doshisha University, Kamikyo-ku, Kyoto
(Received October 27, 1971)

Although the photochemical oxidation of alcohols by quinones has been extensively studied, few investigations of the photolysis of quinones in aqueous solutions have been done until recently. Broadbent[1] has reported that photoexcited 9,10-anthraquinonesulfonates decompose water to generate the ·OH radical. Hughes and Uaboonkul[2] have reported that photoexcited 9,10-phenanthrenequinone abstracts a hydrogen atom from water to generate a semiquinone radical, which then reacts with triphenylphosphine to produce a dipolar form of 2,2,2-triphenyl-1,3,2-dioxaphospholene. In this communication, we wish to report some preliminary results on the photochemistry of *p*-benzoquinone in water.

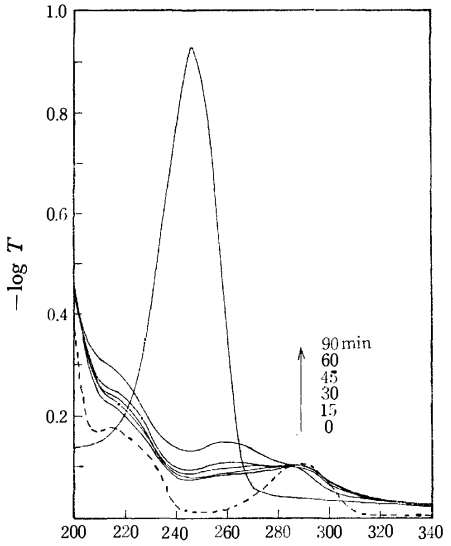

Fig. 1. The UV-spectral change of the photoreaction of *p*-benzoquinone in water. For UV-spectra measurement, 0.8 m*l* of the photolyzed solution was exactly diluted to 20 m*l* with water. The dotted line is the spectrum of the authentic sample of hydroquinone (4×10^{-5}M).

Figure 1 shows the UV-spectral change during the course of the photolysis of a 1×10^{-3}M solution of *p*-benzoquinone in water on irradiation with an immersion-type 130-W high-pressure mercury lamp in a stream of nitrogen. Upon irradiation, the reaction solution became dark orange; this seemed to be due to the formation of quinhydrone. The absorption spectrum of the final photoproduct was the same as that of hydroquinone. Paper chromatography also suggested the formation of hydroquinone (a Toyo filter paper No. 50 was used. Solvent: absolute ethanol; color-producing reagents: ferric chloride and potassium ferricyanide; R_f value of hydroquinone: 0.87).

A solution of *p*-benzoquinone (32.4 mg, 3×10^{-3} mol) in water (300 m*l*) was irradiated with an immersion-type 130-W high-pressure mercury lamp for 30 min at room temperature in a stream of nitrogen. The photolyzed solution was then extracted with ether. The residue obtained upon the removal of the ether was purified by alumina-column chromatography with absolute ethanol and then recrystallized from benzene. Colorless needles of hydroquinone were thus obtained; mp 172—173°C; 12.3 mg (37.2%). In this reaction, we could not detect hydrogen peroxide, which might be produced by the coupling of ·OH radicals.

In the UV spectrum of *p*-benzoquinone in water, the n,π^* and π,π^* absorption maxima were observed at 425 nm ($\varepsilon_{max}=20$) and 246 nm ($\varepsilon_{max}=2.2\times10^4$) respectively. Meanwhile, Kuboyama[3] has reported that the absorption band of *p*-benzoquinone at 539 nm ($\varepsilon_{max}=0.2$) in *n*-heptane can be attributed to the $T_1\leftarrow S_0$ transition (n,π^*). Therefore, we examined the wavelength dependence of the *p*-benzoquinone photochemistry in water. Anaerobic aqueous solutions of *p*-benzoquinone were irradiated with 313 nm (a combination filter of a Toshiba UV-D25 filter, an aqueous nickel sulfate solution, and carbon tetrachloride), 436 nm (a combination filter of a Toshiba V-Y42 filter and a Toshiba V-V42 filter), and >550 nm (a Toshiba V-O56 filter) light respectively. In all cases, *p*-benzoquinone was photolyzed to produce hydroquinone. Since the shoulder of the n,π^* band of *p*-benzoquinone is not observed at wavelengths beyond 550 nm, the n,π^* triplet of *p*-benzoquinone generated by the $T_1\leftarrow S_0$ transition must participate in this photoreaction.

Table 1. Quantum yields for the disappearance of *p*-benzoquinone in water at 313 nm

p-Benzoquinone, M×10³	Quantum yield
9.85	5.2
4.78	6.0
1.00	5.1
0.45	5.8

We determined the quantum yields for the disappearance of *p*-benzoquinone in the anaerobic aqueous solutions at 313 nm. The results are shown in Table 1. The quantum yields were independent of the initial concentrations of *p*-benzoquinone. This finding suggests that a bimolecular deactivation of photoexcited *p*-benzoquinone does not occur, and that photoexcited *p*-benzoquinone does not abstract a hydrogen atom from the quinone ring. Therefore, it seems that water is the hydrogen donor in this reaction. By the way, the quantum yields were greater than unity in all cases. This indicates a chain reaction. The mechanisms of the chain reaction are now under investigation.

A Convenient Synthesis of Symmetrical and Unsymmetrical Biphenyls by the Oxidation of *N*-Aryl-*N'*-(tri-*n*-butylstannyl)hydrazines

Hiroshi ISHIKAWA and Teruaki MUKAIYAMA[1]
The Noguchi Institute, 1-8, Kaga 1-Chome, Itabashi-ku, Tokyo
(Received November 19, 1971)

Unsymmetrical biaryls are customarily prepared by the Gomberg reaction and its modification,[2] or by arylation with free radicals generated by the decomposition of aroyl peroxides.[2] However, yields of symmetrical biaryls as well as a mixture of isomeric unsymmetrical biaryls are usually below 50%. An alternate procedure is the photolysis of aromatic iodides in benzene solution, giving biaryls in 40—80% yields.[3] Recently, Taylor and his co-workers have reported the photolysis of arylthallium ditrifluoroacetates in benzene giving unsymmetrical biaryls in 80—90% yields.[4]

In this communication we report a new aromatic phenylation reaction which involves an oxidative decomposition of readily accessible *N*-aryl-*N'*-(tri-*n*-butylstannyl)hydrazines, prepared by transamination reaction from diethylaminotri-*n*-butylstannane and arylhydrazine in aromatic solvent. The transamination reaction proceeded usually above 90% as estimated from the amount of diethylamine evolved.

$$Bu_3SnNEt_2 + PhNHNH_2 \longrightarrow Bu_3SnNHNHPh + Et_2NH$$
(I)

When I in benzene was oxidized with mercuric oxide at room temperature, a vigorous evolution of nitrogen took place quantitatively. Biphenyl was obtained in a 35% yield along with a 65% yield of diphenylmercury. Oxidation proceeds quantitatively. Of various metal oxides examined, silver oxide, manganese dioxide, and potassium permanganate proved to be also effective for oxidation. They liberated above 90% of the theoretical volume of nitrogen. Chromium trioxide and cuprous oxide liberated only a small amount of nitrogen under the same conditions. Oxidation of I with diethyl azodicarboxylate or mercury acetamide gave rise to the evolution of nitrogen in a nearly quantitative yield. Although the above reactions proceeded at room temperature, nitrogen was liberated quantitatively. The yield of biphenyl was usually below 30%. When the reaction of I (prepared from 15 mmol of diethylaminotri-*n*-butylstannane and an equimolar amount of phenylhydrazine) with chloranil (20 mmol) was carried out in benzene (300 m*l*) at room temperature, the yield of biphenyl increased to 93%. In an attempt to extend this type of phenylation reaction, similar oxidation of I with chloranil in anisole and pyridine were tried. The results are summarized in the following Table. It is noteworthy that, in pyridine, the oxidative decomposition of I proceeded even at −35°C giving a mixture of phenylpyridines in high yield along with nitrogen. Each mixture of isomeric phenylpyridines and methoxybiphenyls obtained was identical in composition with those observed on other free-radical phenylation of pyridine[5] and anisole.[6] The results suggest that the oxidation of I produced phenyl radicals, which in turn attacked the solvent to form biaryls. The reaction can be represented as follows. Similarly, when *N*-*p*-tolyl-*N'*-(tri-*n*-butylstannyl)hydrazine prepared from diethylaminotri-*n*-butylstannane and *p*-tolyl-hydrazine by transamination reaction was oxidized with chloranil in benzene, *p*-methylbiphenyl was formed in high yield. The yields and isomer distributions are given in the following Table.[4]

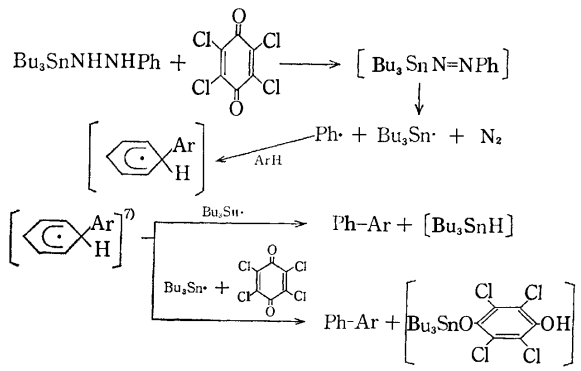

TABLE THE OXIDATION OF *N*-ARYL-*N'*-(TRI-*n*-BUTYLSTANNYL)HYDRAZINES WITH CHLORANIL IN AROMATIC SOLVENTS

Ar	Solvent	Reaction temperature	Yield of biaryls[a] (%)
Phenyl	Benzene	Room temp.	93
	Anisole	−15°——10°	89[c]
	Pyridine	−35°	*ca.* 90[b]
p-Tolyl	Benzene	Room temp.	85[d]

a) Purity of products was determined by glc. The identity of products was established by chromatographic comparison with authentic samples. b) Composition: 64.1% *o*-methoxybiphenyl, 22.5% *m*-methoxybiphenyl, 13.4% *p*-methoxybiphenyls. c) Composition: 59% α-phenylpyridine, 41% β-phenylpyridine. d) Composition: 93.3% *p*-methylbiphenyl, 6.2% *p,p'*-dimethyl-biphenyl, 0.5% biphenyl.

7) As shown in the equation, two pathways are conceivable for the hydrogen abstraction form intermediate, arylcyclohexadienyl radical. Since the reaction mixture was treated with aqueous potassium hydroxide in order to remove tetrachlorohydroquinone, tributyltin hydride and tributyltin 4-hydroxyl-2,3-5,6-tetrachlorophenoxide might be hydrolyzed to tributyltin hydroxide which was isolated as major tin-containing component.

The Gas Chromatographic Separation of Germanium Chlorobromides

Yoshihiro MAKIDE and Nobufusa SAITO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo
The Institute of Physical and Chemical Research, Wako-shi, Saitama

(Received December 16, 1971)

The formation of mixed halides of germanium in a mixture of germanium tetrachloride and germanium tetrabromide was observed by Delwaulle using Raman spectrometry.[1] However, the attempted mutual separation of these halides by distillation was reported to be unsuccessful.[2] In our recent study of the gas chromatographic behavior of inorganic halides, however, we have found that the mixed halides of germanium can indeed be separated by gas chromatography.

A gas chromatograph equipped with a thermal conductivity detector with platinum filaments was built in our laboratory. The path for the gas flow was made of glass and Teflon to avoid the contact of halides with metal. Kel-F Wax was used as the stationary liquid phase of the partition column. $GeCl_4$ and $GeBr_4$, prepared separately from the elements, were mixed and allowed to stand for a few days so that the halogen interchange equilibrium among the halides could be reached. The mass spectrum of their mixture was then measured by means of a double-focusing mass spectrometer. A mixture of these mixed halides with ^{82}Br-labeled arsenic tribromide was analyzed by means of a radio gas chromatograph. The separated halides were passed through a heated Teflon tube coil, and their activities were measured continuously by means of an NaI scintillation detector placed under the coil.

The formation of mixed halides ($GeCl_3Br$, $GeCl_2Br_2$, and $GeClBr_3$) in the mixture of $GeCl_4$ and $GeBr_4$ was confirmed by mass stectrometry.

The gas chromatogram of the $GeCl_4$–$GeBr_4$ mixture (Fig. 1) shows five peaks. The identification of the three intermediate peaks as mixed halides was confirmed by the following experimental results: (1) as Fig. 2

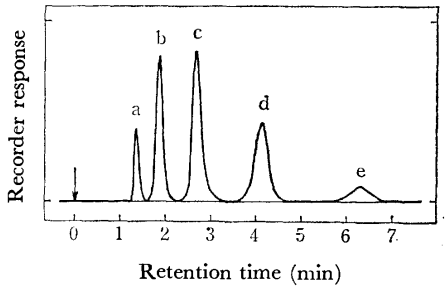

Fig. 1. Gas chromatogram of a mixture of $GeCl_4$ and $GeBr_4$.
Separation column: 200 cm×4 mm i.d., borosilicate glass, filled with 10% Kel-F Wax on silanized Chromosorb W (80—100 mesh). Column temperature: 100°C. Carrier gas: He, 30 ml/min.
a: $GeCl_4$; b: $GeCl_3Br$; c: $GeCl_2Br_2$; d: $GeClBr_3$; e: $GeBr_4$.

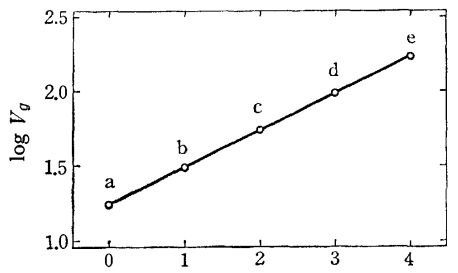

Fig. 2. Log specific retention volume *vs.* number of bromine atoms in a molecule for germanium halides.
a: $GeCl_4$; b: $GeCl_3Br$; c: $GeCl_2Br_2$; d: $GeClBr_3$; e: $GeBr_4$.

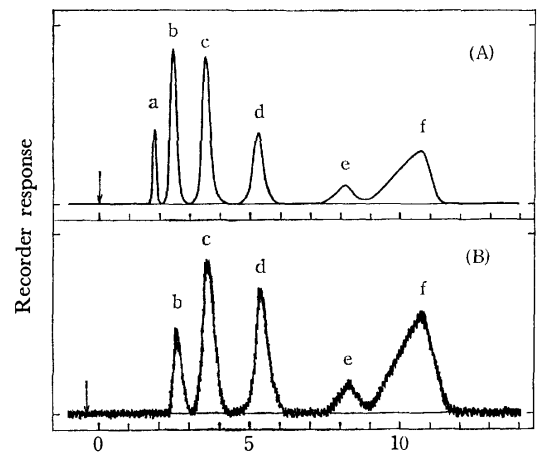

Fig. 3. Gas chromatogram (A) and radio chromatogram (B) of a mixture of $GeCl_4$, $GeBr_4$, and $As^{82}Br_3$.
Column and operating conditions: the same as in Fig. 1, with the exception of the flow rate (He): 20 ml/min. Radiation detector: 3″×3″ NaI(Tl).
a: $GeCl_4$; b: $GeCl_3Br$; c: $GeCl_2Br_2$; d: $GeClBr_3$; e: $GeBr_4$; f: $AsBr_3$.

shows, the logarithm of the specific retention volume has an approximately linear relationship with the number of bromine atoms in a molecule, as in the case of $CCl_{4-n}Br_n$ and $SiCl_{4-n}Br_n$;[3] and (2) the radio gas chromatogram of the mixture with $As^{82}Br_3$ shows that the germanium mixed halides were labeled with ^{82}Br by isotopic exchange (as shown in Fig. 3). Their specific activities were proportional to the number of bromine atoms in the molecule.

Further studies of the gas chromatographic behavior of inorganic halides are in progress and will be published shortly.

Far Infrared Spectra and Internal-Rotation Potential of Ethyl Methyl Ether

Teizo KITAGAWA, Keiichi OHNO,* Hiromu SUGETA, and Tatsuo MIYAZAWA

Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka

(Received April 14, 1971)

Far infrared spectra (700～40 cm^{-1}) of ethyl methyl ether and deuterated species ($CH_3CH_2OCD_3$, $CD_3CH_2OCH_3$, $CH_3CD_2OCH_3$, and $CD_3CD_2OCH_3$) were measured in the crystalline, liquid and gaseous states and carbon tetrachloride solution. A low temperature cell was constructed for measuring far infrared absorption of highly volatile samples in the liquid and crystalline states. Far infrared bands due to skeletal bending vibrations of the trans and gauche isomers and lattice vibrations were assigned. From analyses of isotope effects on infrared frequencies, internal-rotation vibrations of the CH_3-CH_2, CH_2-O, and O-CH_3 bonds of the trans isomer of ethyl methyl ether were found at 248, 115, and 202 cm^{-1}, respectively, in the gaseous state. Normal vibrations were treated with the local-symmetry force field and force constants were adjusted by the method of least squares. By the use of Mathieu equation, the threefold potential barriers of the methyl groups of the trans isomer were estimated as $V_3(CH_3\text{-}C)=3.3\pm0.1$ and $V_3(O\text{-}CH_3)=2.5\pm0.1$ kcal/mol.

Studies of the internal-rotation about the CH_2-O bond of the C-CH_2-O-C group are important for treating chain conformations of polyethers including polyethylene glycol[1] $[-CH_2\text{-}CH_2\text{-}O-]_p$. The molecule of ethyl methyl ether CH_3-CH_2-O-CH_3 serves as an appropriate model for studying the internal rotation about CH_2-O bonds.

Analyses of the infrared and Raman spectra[2-5] of ethyl methyl ether suggested that the trans and gauche isomers coexist in the gaseous state and liquid state while the trans isomer remains in the crystalline state. The coexistence of rotational isomers was confirmed by the measurement of the temperature effect on the infrared spectra[6]. Furthermore, from the relative intensity of the infrared bands at ～375 cm^{-1} and ～280 cm^{-1}, the energy difference between the gauche and trans isomers was estimated as 1.5 kcal/mol in the gaseous and liquid states[6]. The electron diffraction of gaseous molecules of ethyl methyl ether was analysed[7] and the predominant isomer was confirmed to be trans and also the weak peaks due to the gauche isomer were recognized in the radial distribution. The molecular structure of the trans isomer was determined precisely by the analyses of the microwave spectra[8]. Recently, the infrared and Raman spectra (3000～500 cm^{-1}) of eight isotopic species of ethyl methyl ether were measured and, from the relative intensity of the infrared bands at 1015 cm^{-1} and 980 cm^{-1}, the energy difference between the gauche and trans isomers was estimated as 1.35 kcal/mol[9].

Vibrational frequencies of internal-rotation modes are important for studying internal-rotation potential. Accordingly, for establishing vibrational assignments of the internal-rotation frequencies of ethyl methyl ether $[CH_3CH_2OCH_3(d_0)]$ and deuterated species $[CH_3CD_2OCH_3(d_2)$, $CD_3CH_2OCH_3(d_3)$, $CH_3CH_2OCD_3$ (d_3') and $CD_3CD_2OCH_3(d_5)]$, the far infrared spectra of the gaseous, liquid and crystalline states were measured in the present study. A low-temperature cell was constructed for measuring far infrared spectra of liquid and crystalline phases of highly volatile samples since the boiling point (6°C) of ethyl methyl ether was lower than room temperature.

Experimental

Ethyl methyl ether and deuterated species were synthesized with Williamson's method. Starting material of ethyl alcohol was prepared, in advance, by the reduction of acetyl chloride with lithium aluminum hydride (or deuteride)[10]. Samples of ethyl methyl ether and deuterated species were purified by repeated distillation from dry ice temperature to liquid nitrogen temperature in vacuum. The samples were dried over phosphorous pentoxide just before spectroscopic measurements and were transferred into absorption cells through vacuum line.

Infrared spectra in the 700～200 cm^{-1} region were recorded on a Hitachi EPI-L Infrared Spectrophotometer. Cesium iodide crystal plates of 3 mm thickness were used as windows of absorption cells. For the 400～50 cm^{-1} region, a Hitachi FIS-3 Far Infrared Spectrophotometer was used with absorption cells of polyethylene windows.

Low Temperature Cell. Figure 1 shows the low-temperature cell constructed in the present study for far infrared measrements. The cryostat consists of Parts A and B. Part A is the outer jacket and is held, with a fringe (1), on the cover of the sample compartment of the spectrophotometer. The fringe is fastened onto the cover (2) with an O-ring and screws, and polyethylene sheets of 1 mm thickness are used as optical windows (3). Part B is the inner jacket and is fastened to Part A with an O-ring and screws. The liquid nitrogen reservoir (4) is as large as 1.8 *l*. The copper block (5) is provided with a channel so that liquid nitrogen is led to the bottom part of the block. However, a small temperature difference is found between the copper block (5) and the sample (6) so that a copper constantan thermo-

couple is embedded into the window (polyethylene or silicon) of the sample cell. Thermocouple wires are connected outside through hermetic seals (7). The cryostat is evacuated better than 10^{-5} mmHg.

Double-Chopping Operation. In the far infrared region, the emission from the optical wedge in the reference beam of a double-beam spectrophotometer is not negligible as compared with the emission from the far infrared source. When the temperature of the sample in the sample beam is kept low, the emission difference between the wedge and the sample is also compensated by the wedge itself and the transmittance recorded on the chart is appreciably lower than the true transmittance. Accordingly, in the present study, the double-chopping mode (0.9 cps) of FIS-3 was used for absorption measurements of the liquid and crystalline phases at low temperatures and the systematic error due to the wedge emission was eliminated.

Solid Spectra. For absorption measurements of deposited solid, a silicon disk [(6) in Fig. 1] is held on the copper block (5). A glass jet opening is connected to a metal tube (8) so that the sample gas may be introduced from outside onto the silicon disk. Sample gas of ethyl methyl ether was deposited on the silicon disk at 77°K and was then annealed at temperatures as high as 150°K. Far infrared spectra of the solid phase at 77°K are shown in Fig. 2, where transmittance curves of deposited unannealed sample are shown with broken lines and curves of annealed sample are shown with solid lines.

Liquid Spectra. For absorption measurements of condensed liquid, a vacuum tight polyethylene cell (0.2 mm thick) was constructed by welding polyethylene sheets and tubes (entrance and exit). The cell is held on the copper block (5) of the cryostat (Fig. 1) and the entrance and exit are connected to the metal tubes (8). The sample of ethyl methyl ether is introduced through a metal tube and entrance polyethylene tube, and is liquified inside the polyethylene cell kept at low temperature.

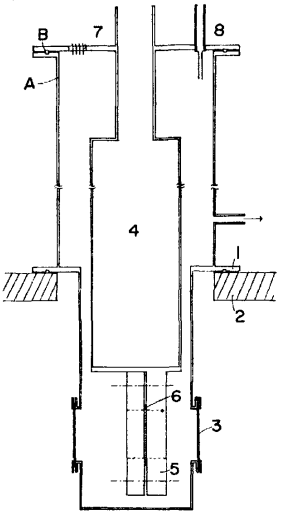

Fig. 1. Cryostat for far infrared absorption measurements.

Far infrared spectra of the liquid phase at ~170°K are shown in Fig. 3. The weak band at 78 cm^{-1} is due to polyethylene sheets of the liquid cell. Since low frequency modes are appreciably influenced by intermolecular interactions, observed peak frequencies of liquid spectra (Fig. 3) are appreciably lower than corresponding peak frequencies of the solid spectra (Fig. 2).

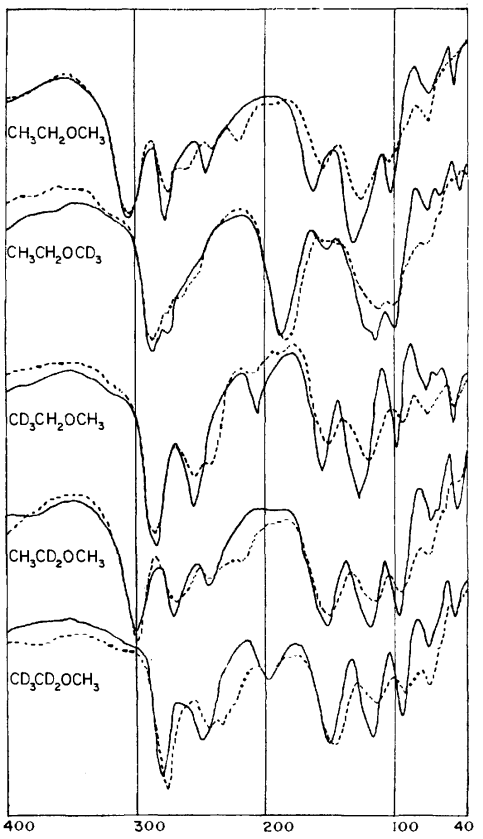

Fig. 2. Far infrared spectra of the solid phase (77°K) of ethyl methyl ether; broken line: deposited unannealed film, and solid line: annealed crystalline film.

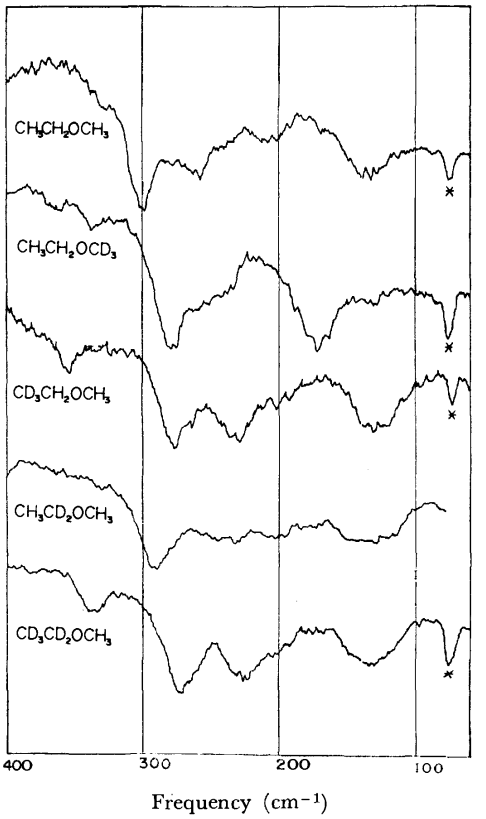

Fig. 3. Far infrared spectra of the liquid phase (~170°K) of ethyl methyl ether. The cell thickness is 0.2 mm. The band marked with * is due to polyethylene sheets.

Gas Spectra. Far infrared spectra of the gas phase (500 mmHg at room temperature) were measured with a 14 cm gas cell. Gas spectra (Fig. 4) are more complex than liquid and solid spectra, because of rotational structures and of overlapping hot bands.

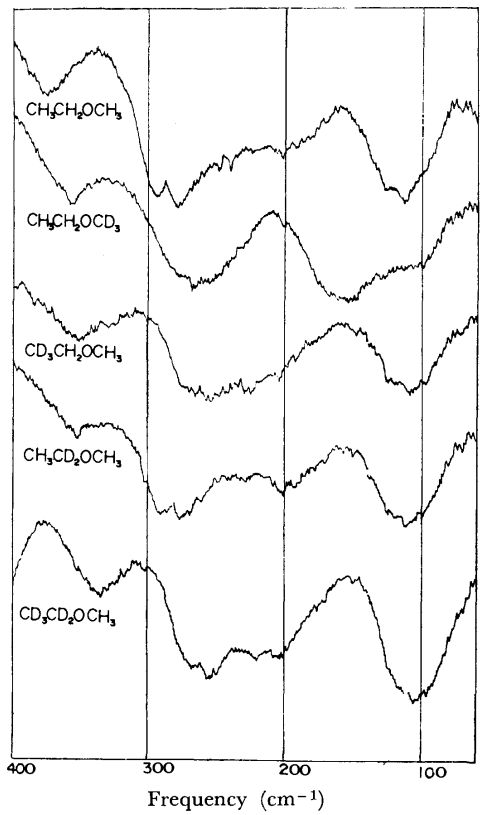

Fig. 4. Far infrared spectra of the gas phase (500 mmHg at room temperatrure) of ethyl methyl ether. The path length is 4 cm.

Solution Spectra. Infrared spectra (500~250 cm^{-1}) of ethyl methyl ether in carbon-tetrachloride solution were measured with a sealed KRS-5 cell (0.2 mm thick). Far infrared spectra of $CH_3CH_2OCH_3$ and $CH_3CH_2OCD_3$ in carbon-tetrachloride solution were measured with a sealed polyethylene cell (0.5 mm thick). Frequencies observed in solution are listed in Table 1, together with the frequencies observed for the solid, liquid, and gas phases.

Normal Vibration Treatments

The normal vibrations of the five isotopic species (d_0, d_3, d_3', d_2, and d_5) of ethyl methyl ether were treated with Wilson's ***GF*** matrix method[11]. In constructing inverse-kinetic energy matrices (***G***), the bond lengths of r(C-C)=1.530 Å, r(C-O)=1.420 Å, and r(C-H)=1.093 Å, tetrahedral bond angles, and the internal-rotation angles of 180°(trans) and 60°(gauche) were used. For the C-H stretching and deformation modes of the CH_3-C, C-CH_2-O, and O-CH_3 groups, local-symmetry coordinates (σ)[12] were used, together with the C-C and O-C stretching, C-O-C bending (ϕ), and internal-rotation coordinates (t).[13]

The potential energy matrices (***F***) were constructed on the basis of a generalized potential function, namely, the local-symmetry force field[12]. The initial set of potential constants of the CH_3-C, C-CH_2-O, and O-CH_3 groups were transferred from ethane[14], polyethylene glycol[15] and dimethyl ether[16], respectively, and were adjusted by the method of least squares[17] with reference to the infrared frequencies observed for the trans and gauche isomers of the five isotopic species (except for internal-rotation frequencies of the gauche isomer)[18]. After six cycles of adjustments, a converged set of potential constants was obtained. However, in the high frequency region (3000~600 cm^{-1}), a unique set of vibrational assignments of the five isotopic species were not yet established. On the other hand, in the low frequency region (<600 cm^{-1}), vibrational assignments were made satisfactorily, and a reliable set of potential constants was obtained for low-frequency modes; $f[\sigma(\text{C-C-O})]=0.925$, $f[\phi(\text{C-O-C})]=1.373$, $f[\sigma(\text{C-C-O})\cdot\phi(\text{C-O-C})]=0.167$, $f[t(CH_3\text{-}CH_2)]=0.0939$, $f[t(CH_2\text{-O})]=0.0769$, $f[t(\text{O-}CH_3)]=0.0682$ mdyn Å/rad², where three force constants were set as $f[r(\text{C-C})\cdot\sigma(\text{C-C-O})]=0.017$, $f[r(\text{C-O})\cdot\delta(\text{C-C-O})]=0.455$ and $f[r(\text{O-C})\cdot\phi(\text{C-O-C})]=0.259$ mdyn/rad.[15] Calculated frequencies lower than 600 cm^{-1} are listed in Table 1.

Lattice Vibrations

Far infrared spectra of the crystal, liquid and vapor phases of $CH_3CH_2OCH_3$ are shown in Fig. 5. In the lowest frequency region, the crystal bands at 52, 67, and 102 cm^{-1} disappear on melting and accordingly are assigned to lattice vibrations. On the other hand, the vapor band at 115 cm^{-1} corresponds to the liquid band at 132 cm^{-1} and to the crystal band at 166 cm^{-1}, since low-frequency internal-rotation vibrations are known to shift appreciably to higher frequency on phase-changes gas→liquid→crystal. Accordingly, the crystal band at 132 cm^{-1} is assigned to a lattice vibration, possibly coupled with internal-rotation modes. Observed frequencies of lattice vibrations of ethyl methyl ether (ν_0) and deuterated species (ν) and their ratios (ν_0/ν) are listed in Table 2.

In the crystal of ethyl methyl ether, the molecule does not have the center of symmetry, and, in principle, translatory and rotatory lattice modes are not separated from each other. However, for 'purely' translatory or rotatory vibrations, frequencies of isotopic molecules would be inversely proportional to the square root of the molecular mass or principal moments of inertia[8],

$CD_3CH_2OCH_3$	1.03	1.09	1.06	1.06
$CH_3CD_2OCH_3$	1.02	1.12	1.01	1.01
$CD_3CD_2OCH_3$	1.04	1.19	1.07	1.07

a) Ref. 8.

respectively. As shown in Table 3, frequency ratios of the translatory vibrations of ethyl methyl ether and deuterated species are as small as 1.02~1.04, whereas frequency ratios (1.01~1.19) of rotatory vibrations vary with deuterated species and rotation-axes. For the lattice vibration of $CH_3CH_2OCH_3$ (132 cm^{-1}), observed frequency ratios are as high as 1.07~1.14 (Table 2) and accordingly this highest-frequency lattice vibration is primarily due to a rotatory mode, possibly about the axis of the smallest moment of inertia (I_a).

Skeletal Deformation Vibrations

For the trans isomer of ethyl methyl ether CH_3-CH_2-O-CH_3, C-C-O and C-O-C bending vibrations are expected in the region below 600 cm^{-1}. In fact, infrared bands were observed at 472 and 310 cm^{-1} for the crystal phase. Since the mass of the oxygen atom is not much different from the mass of the methylene group, the C–C–O and C–O–C bending modes are hybridized, giving rise to the in-phase (ϕ_s) and out-of-phase (ϕ_a) bending modes. From normal vibration treatments, the bands at 472 and 310 cm^{-1} are assigned to ϕ_s and ϕ_a, respectively (Table 1). Skeletal bending vibrations of the trans isomer (point group C_s) belong to the A′ species and accordingly are expected to give rise to A, B, or AB hybrid bands in vapor spectra. In fact, the band of ethyl methyl ether at 287 cm^{-1} and corresponding bands of deuterated species are observed as B-type (Fig. 4).

The infrared band of liquid ethyl methyl ether at 378 cm^{-1} and corresponding bands of deuterated species disappear on crystallization, and accordingly are assigned to the gauche isomer (ϕ_s mode, Table 1). From normal vibration treatments[4,7], the other skeletal bending vibration (ϕ_a) of the gauche isomer of $CH_3CH_2OCH_3$ is expected at ~510 cm^{-1} but a corresponding band is not observed there. On the other hand, from the temperature dependence of the infrared intensities of the vapor bands at 465, 374, and 287 cm^{-1}, it was suggested[6] that the infrared band due to the ϕ_a vibration of the gauche isomer is overlapped by the band of the trans isomer at 465 cm^{-1}, although the intensity of the composite band is largely due to the gauche isomer. Corresponding bands are also observed for deuterated species (Table 1). It may be remarked that the potential term of $f[\sigma(\text{C-C-O})\cdot\phi(\text{C-O-C})]$ was necessary in least-square adjustments of potential constants with reference to skeletal-bending frequencies of the gauche isomer as well as of the trans isomer.

Internal Rotation Vibrations

For the trans isomer of ethyl methyl ether CH_3-CH_2-O-CH_3, the internal-rotation vibrations (CH_3-CH_2, CH_2-O, and O-CH_3) are all infrared-active. In fact, infrared bands are observed at 280, 249, and 166 cm^{-1} for the crystal phase (Fig. 6). The infrared band at 280 cm^{-1} is shifted appreciably to 205 cm^{-1} on deuteration of the CH_3-C group and is assigned to the internal-rotation vibration about the

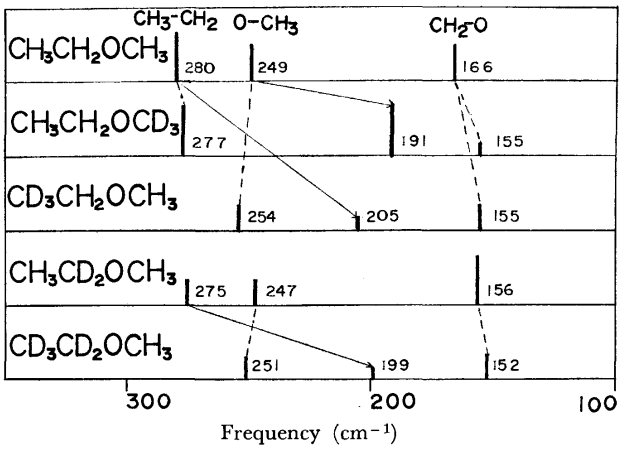

Fig. 6. Isotope shifts of internal-rotation frequencies of the crystal phase.

CH_3-CH_2 bond. On the other hand, the infrared band of $CH_3CH_2OCH_3$ at 249 cm^{-1} is shifted to 191 cm^{-1} on deuteration of the O-CH_3 group and is assigned to the internal-rotation vibration about the O-CH_3 bond. The low-frequency band at 166 cm^{-1} is shifted little on deuteration of the CH_3-C or O-CH_3 group and is assigned to the internal-rotation vibration about the CH_2-O bond. Similar deuteration effects are observed for the infrared bands of CH_3-CD_2OCH_3 at 275, 247, and 156 cm^{-1} (Fig. 6). Thus, the vibrational assignments of the internal-rotation vibrations of the CH_3-CH_2 and O-CH_3 groups are established in the present study. Previous vibrational assignments[4,7] need be revised accordingly.

In the vapor phase, the internal-rotation vibrations of the trans isomer of $CH_3CH_2OCH_3$ give rise to sharp peaks (C-type) at 248, 202, and 115 cm^{-1}, just as expected for the transition moments parallel to the axis of the largest moment of inertia (I_c).

Internal-rotation frequencies of the gauche isomer are calculated to be lower than corresponding frequencies of the trans isomer (Table 1). Frequency differences between the trans and gauche isomers are due to the vibrational coupling between the internal-rotation modes and skeletal bending modes; such coupling is possible for the gauche isomer but not for the trans isomer.

Barrier Height for Internal Rotation of Methyl Group

For the trans isomer of ethyl methyl ether, three internal rotation modes belong to the same species (A″) and hybridization of those modes are expected. Accordingly, potential energy distributions[19] were calculated for internal-rotation vibrations as shown in Table 4. Hybridization of the internal-rotation modes of the CH_3-C and O-CH_3 groups is not negligible although these groups are separated by the central C-O bond. Accordingly, in estimating the barrier height of methyl groups, hybridization. of the two modes need be taken into account.

Table 4. Frequencies and potential energy distributions calculated for internal-rotation vibrations

Species	Freq. (cm^{-1})	Distribution (%)		
		CH_3-CH_2	CH_2-O	O-CH_3
$CH_3CH_2OCH_3$	252	70	0	20
	201	19	1	78
	113	0	95	1
$CH_3CH_2OCD_3$	247	91	0	7
	156	6	3	89
	105	0	93	4
$CD_3CH_2OCH_3$	224	25	1	74
	171	72	1	24
	109	0	95	1
$CH_3CD_2OCH_3$	245	82	0	17
	200	16	1	80
	110	0	96	2
$CD_3CD_2OCH_3$	217	20	1	78
	169	78	0	19
	106	0	95	2

In the present study, threefold potential barriers were estimated first with the harmonic approximation, $V_3(CH_3\text{-}C)=3.00$ and $V_3(O\text{-}CH_3)=2.18$ kcal/mol, from the force constants of $f[t(CH_3\text{-}CH_2)]=0.0939$ and $f[t(O\text{-}CH_3)]=0.0682$ mdyn Å/rad^2. Threefold potential barriers were also estimated as shown in Tables 5 and 6 (third column), with the single-top harmonic approximation, directly from infrared frequencies observed in the vapor phase (Table 1). The structural parameters[20] $F(CH_3\text{-}C)$ and $F(O\text{-}CH_3)$ were calculated (Tables 5 and 6, second column) from the same molecular parameters as used in normal vibration treatments [essentially the same F values were also obtained by the use of the molecular parameters determined by microwave analyses[8]]. Then, with reference to the V_3 values estimated from force constants, the corrections for the single-top approximation were calculated as shown in Tables 5 and 6 (fourth column).

In the second step, the anharmonicity of the three fold potential function was taken into account. Thus, Mathieu equation for the single-top case was used and the V_3 values were calculated (Tables 5 and 6, fifth column) from infrared frequencies of the vapor phase. Finally, the corrections for the single-top approximation were made, yielding corrected V_3 values as shown in the sixth column of Tables 5 and 6. It may be remarked that final V_3 values calculated for the five isotopic molecules agree closely with one another, giving mean values of

$$V_3(CH_3\text{-}C) = 3.3 \pm 0.1 \text{ kcal/mol}$$

$$V_3(O\text{-}CH_3) = 2.5 \pm 0.1 \text{ kcal/mol}$$

Table 5. Structure parameters (F) and threefold potential barrier (V_3) of CH_3-C group

Species	F(cm^{-1})	V_3(kcal/mol)			
		Single-top harmonic	Corrected for single-top	Single-top Mathieu	Corrected barrier
$CH_3CH_2OCH_3$	6.18	3.16	−0.16	3.54	3.38
$CH_3CH_2OCD_3$	6.03	3.06	−0.06	3.42	3.36
$CD_3CH_2OCH_3$	3.54	2.75	+0.25	3.01	3.26
$CH_3CD_2OCH_3$	5.99	3.06	−0.06	3.42	3.36
$CD_3CD_2OCH_3$	3.35	2.74	+0.26	2.99	3.25

Table 6. Structure parameters (F) and threefold potential barrier (V_3) of O-CH_3 group

Species	F(cm^{-1})	V_3(kcal/mol)			
		Single-top harmonic	Corrected for single-top	Single-top Mathieu	Corrected barrier
$CH_3CH_2OCH_3$	6.18	2.10	+0.08	2.41	2.49
$CH_3CH_2OCD_3$	3.54	2.15	+0.03	2.38	2.41
$CD_3CH_2OCH_3$	6.03	2.79	−0.61	3.15	2.54
$CH_3CD_2OCH_3$	5.99	2.17	+0.01	2.49	2.50
$CD_3CD_2OCH_3$	5.89	2.61	−0.43	2.96	2.53

It is interesting to note that the threefold potential barrier of the CH_3-C group of ethyl methyl ether agrees closely with the corresponding barrier of propane[21], $V_3(CH_3\text{-}C)=3.325\pm0.020$ kcal/mol. Furthermore, the potential barrier of the O-CH_3 group of ethyl methyl ether agrees closely with the barrier of dimethyl ether recently determined from microwave analyses[22], $V_3(O\text{-}CH_3)=2.56$—2.60 kcal/mol.

The aerosols obtained by spraying an aqueous Na_2SO_4 solution of concentrations ranging from 0.1 to 10% by weight were dried by a furnace at 200 to 800°C and were then subjected to stirred aging at room temperature in an atmosphere of 90% relative humidity or less; the variations in both mass concentration and particle size were then measured with the lapse of time.

By employing the results thus obtained and by making some assumptions, the density of the particle in dried aerosols was calculated to be several tenths of one gram per cc, which is smaller by a factor of 3 to 4.5 than the bulk density of solid Na_2SO_4; further, the amount of water which the dried particle might hold if kept in a humidified atmosphere was estimated, with the finding that the density of a particle would decrease with increase in its water content; for example, the density of the particle with composition of $Na_2SO_4 \cdot 10H_2O$ would be 0.32 g/cc, smaller by a factor of 4 to 5 than the bulk density. In addition, the influence of water vapor on the stability of the dried aerosols was studied; it was found that the higher the humidity, the greater the rate of coagulation.

The production of the aerosols of hygroscopic salts and their properties in the presence of water vapor have been investigated by aerosol researchers, especially for the last two decades, from the viewpoint of meterological studies; in recent times, the spray-drying process has come into more frequent use by chemical engineers. The present paper will deal with the dehydration of aqueous Na_2SO_4 solution aerosols, the effect of the water vapor on the coagula-

tion rate of the dried aerosols, and, further, the determination of the density of the dried particle.

A number of experiments have been performed in an attempt to determine the influence of such additions as water or some organic vapors upon the stability of aerosols, but the results have shown conflicting trends. For instance, Samokhvalov and Kozhukhova[2] describe that, for anmonium chloride aerosols, water or octyl alcohol vapor acts as a stabilizer, in contrast to the coagulation-promoting effect of water and butyric acid vapor observed by Smirnov and Solnseva.[3]

Concerning the density of an aerosol particle, it is usually assumed to be the same as that in bulk. This is valid for a homogeneous solid particle, but it might lead to erroneous results for an aggregate of solid particles formed by coagulation. It has been shown by Patterson and R. Whytlaw-Gray.[4] that the particles of cadmium, zinc, and magnesium oxides possess a loose or chain-like structure, so that it would be wrong to apply to them the normal bulk density in deducing their size from the rate of settling. After examining dried, microcrystallized particles of several inorganic salts, Duffie[5] has concluded that they are of density far less than normal. For the determination of the density of an aerosol particle, the ultramicroscope method might be used, but it has the disadvantages that reliable value of the settling velocity must be obtained by means of a large number of measurements and that the particles coarser than submicron-sized range can be managed only with difficulty unless a photographic device[6] is utilized; in the present paper, a different method has been adopted to determine the densities.

Experimental

Materials. The Na_2SO_4 used was of extra pure grade, and the H_2SO_4 of chemically pure grade.

Apparatus and Procedure. The mist generated by means of an atomizer of the glass-bead type[7] under a pressure of 2 kg/cm^2 was passed through an electric furnace and charged for 10 minutes into a plastic chamber of a volume of about 0.8 m^3 (1 m in height and 1.02 m in diameter), the inside of which had been kept saturated with water vapor by putting an aqueous H_2SO_4 solution on the bottom and by agitating the atmosphere over it. The aerosol in the chamber was continuously agitated during and after charging by constant-rate stirring (50 rev/min). The time of aging after charging was reckoned from the moment the charging stopped. The concentration of the dispersing solution was varied from 0.1 to 10% by weight, the temperature of the furnace, from 200° to 800°C, and the relative humidity, from 0 to 90%. The temperature in the chamber was held somewhere near 25°C throughout all the experiments. The humidity and the temperature were measured before and after each run by means of an electrical-type hygrometer and a glass set on the walls of the chamber. Table 1 shows the experimental conditions in condensed form.

Analyses of Mass Concentration and Particle Size. The technique of collecting the samples for the analyses has been described previously[9]; the concentration was determined through electrical-conductivity measurements of the solution obtained by dissolving into distilled water the Na_2SO_4 deposit in an electrical precipitator. As for the size, the dried aerosol that came out of the furnace to be aged in the chamber was introduced into a thermal precipitator, where the particles were gathered on electron-microscope collodion-mesh grids; the particles were viewed at a magnification of 2300X, 3000X, or 5000X and were found to be either isolated and rounded ones or chain-like aggregates. As the size of the former, the number-averaged diameter was taken, and while as that of the latter, the number average of the volume-equivalent diameters was taken.

Results and Discussion

Time Variations of Mass Concentration and Particle Size. From the experiment, it was found that the relative mass concentration decreases with the time and, further, that it decreases as the concentra-

tion of the dispersing solution or the relative humidity of the chamber increases. Here, the relative mass concentration is defined as the ratio of the concentration (m_t) at time (t) to the initial one (m_0), determined by the extrapolation of m_t. It should be added that no influence of the temperature of the furnace upon the concentration change was found in so far an aqueous 10% solution was examined, the points corresponding to Runs E_{10}, E_{15}, and E_{23} overlapping one another.

◐ E_{33} ◓ E_{28} ◒ E_{26} ● E_{24} ○ E_{23} ⊖ E_{22} ⊕ E_{21}
◑ E_{20}

If the reciprocal of the relative mass concentration is plotted against the time, a linear relation is found for the early stage of the run (Fig. 1), suggesting that the time variation in the mass concentration is a second-order reaction.[9]

Figure 2 depicts the change in the particle size with the time under different conditions of the relative humidity in the chamber and of the concentration of the dispersing solution. From the figure, it is obvious that the particle size increases with the time and becomes larger with the increase in both humidity and concentration.

Estimate of the Density of Particle. The settling velocity of a particle of a monodisperse aerosol confined in a chamber under agitation may be expressed as follows[10]:

$$-dn_t/dt = n_t \cdot V_t/H \tag{1}$$

n_t: number concentration at time t
V_t: Stokes' velocity of settling at time t of a particle
H: height of chamber

The integration of Eq. (1) between time t to $t+\Delta t$ yields:

$$-\int_t^{t+\Delta t} dn_t/n_t = 1/H \cdot \int_t^{t+\Delta t} V_t \, dt \tag{2}$$

or

$$\ln n_{t+\Delta t}/n_t = -V_t/H \cdot \Delta t \tag{3}$$

V_t being assumed to be constant for a short interval of time, Δt. On substituting the relations:

$$n_{t+\Delta t} = 6\, m_{t+\Delta t}/\pi D_{t+\Delta t}{}^3 \rho_{t+\Delta t} \tag{4}$$

$$n = 6\, m_t/\pi D_t{}^3 \rho_t \tag{5}$$

m: mass concentration
D: diameter of particle
ρ: density of particle

it follows that:

$$-\ln [m_{t+\Delta t}/m_t \cdot (D_t/D_{t+\Delta t})^3] = V_t \cdot \Delta t/H - \ln [\rho_{t+\Delta t}/\rho_t] \tag{6}$$

Provided that the $\rho_{t+\Delta t}$ term is equal to ρ_t for the short interval Δt, the plot of the left-hand side of Eq. (6) against Δt passes through the point of origin, and the slope at the origin given the settling velocity at time, t, with the height of chamber H=100 cm. In Fig. 3, an example (Run E_{28}) is shown; the slope of the line gets steeper as the time becomes longer. For the other experiment runs, similar results are obtained. The values of the velocities thus found are represented in Fig. 4.

By equating the effective weight of particle at time, t, to the Stokes' drag, we obtain:

$$\pi/6 \cdot D^3(\rho - \rho')g = 3\,\pi\eta VD \tag{7}$$[11]

where D is the diameter of the particle; ρ and V, its density and settling velocity; η and ρ, the viscosity and density of the medium (air), and g, the gravitational acceleration. By neglecting ρ' in comparison with ρ, we obtain:

10) D. Sinclair, "Handbook on Aerosols," Chap. 5, U. S. A. Atomic Energy Commission, Washington D. C. (1950).
11) The subscript t is omitted for simplicity.

◑ E_{33} ◓ E_{28} ◒ E_{26} ● E_{24} ○ E_{23} ⊖ E_{22} ⊕ E_{21}

$$\rho = 18\,\eta V/gD^2 \qquad (8)$$

From Eq. (8), the value of ρ at time t can be estimated if D and V at time t are known. The values obtained are given in Fig. 5; the points for Runs E_{10} and E_{15} are not shown, since they coincide with those of Run E_{23}. It may be seen in Fig. 5 that the density of the particle decreases with the time of aging and, further, with the increase in the humidity.

Effect of Humidity on the Coagulation Rate. The number concentration (n_t) at the time, t, is obtained by substituting m_t, D_t, and ρ_t (Fig. 5) into Eq. (5);

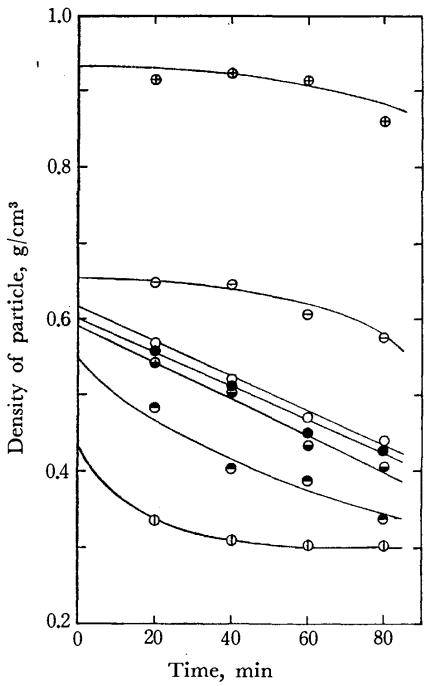

Fig. 5. Time-dependence of the density of air-borne Na_2SO_4 particles.
⊕ E_{21} ⊖ E_{22} ○ E_{23} ● E_{24} ◒ E_{26} ◓ E_{28} ◑ E_{33}

the concentration at zero time (n_0) is determined by extrapolation to zero time of the plot of n_t against t. Figure 6 represents the plot of the relative number concentration (n_t/n_0) against the time; from the figure, it may be seen that the influence of water vapor is roughly linear with the humidity. The half-decay period in terms of number concentration and the particle size at that time are shown in Table 2; from the table, it may be seen that, as the humidity is increased, the half-decay period gets shorter, the particle size larger, and the particle density smaller. According to Duffie *et al.*[5], spray-dried Na_2SO_4 particles are hollow and crystallized, and they show holes with edges rounded inward and have thin, compact shells with radius/thickness ratios of the order of 10. The

S_9[16]	20	164	74.5	0.67	0.74

formation of hollow particles due to the evaporation rate of water exceeding the diffusion rate of salt back into the inside, thereby creating internal voids after dryness is reached. In view of this fact, it might well be said that the Na_2SO_4 particles now under investigation are also so solidly-built that the particle size does not decrease in the presence of humidity. On the other hand, it was found by Andreasen *et al.*[12] that the particles smaller than 10 μ act as binders between colliding particles; further, Neumann[13] found that moisture leads to an increased stichness of the particles, particularly for hygroscopic ones.

Since the decrease in the relative mass concentration with the time follows the law of the second-order reaction rate (Fig. 1), whose mechanism will be discussed in a later paper, the decrease in the number concentration might be caused mainly by coagulation; some of the aggregates so formed fall to the bottom of chamber, vanishing from the system.

Comparison of the Density Found with Other Published Results. Crosby and Marshall,[14] after carrying out a series of experiment runs on spray-drying, at temperatures between 162° and 285°C, of aqueous Na_2SO_4 solutions with concentrations ranging from 10 to 20 wt%, concluded that, under all the conditions of temperature and concentration studied, the density of the particle increases as the size decreases, the variation being as great as fourfold; this explains, in part, why spraydried commercial products with small particles frequently exhibit higher densities than the corresponding products composed of large particles.

Table 3 presents comparison between the results obtained by the present authors and those obtained by Crosby and Marshall. It is apparent that two sets of figures are different from each other because of the difference in the experimental conditions, but that they are of the same order of magnitude. Concerning the variation in the density gets smaller with the time. This might be due to the formation of loose or chain-like aggregates by coagulation; the situation has been confirmed by the electron-microscope observation referred to above.

Determination of the Water Content of a Dried Particle. Let us suppose that droplets produced by atomization have passed through a furnace to be dried particles, without encountering mutual collision.

Since the solid content of a droplet will remain unaltered, there holds a mass-balance relation between the diameter (D_l) of a droplet produced by atomization and the diameter (d_s) of a particle formed by the dehydration of the droplet:

$$1/6\cdot\pi D_l^3\rho_l[1/(1+W_l)] = 1/6\cdot\pi d_s^3\rho_s[1/(1+W_s)] \quad (9)$$

ρ_l: density of liquid droplet
ρ_s: density of dried particle
W_l: water content of liquid droplet (grams of water per gram of Na_2SO_4)
W_s: water content of dried particle (grams of water per gram of Na_2SO_4)

Solving for the ratio of particle to droplet diameter, we obtain:

$$d_s/D_l = [\rho_l(1+W_s)/\rho_s(1+W_l)]^{1/3} \quad (10)$$

By the use of Eq. (10), the percentage of the water content of a dried particle or the number of H_2O molecules (X) associated with a Na_2SO_4 molecule can be estimated for Runs E_{24}, E_{26}, E_{28}, and E_{33}, all

of which were carried out in a humidified atmosphere. The results are depicted in Fig. 7. The procedure is as follows. On assuming that the value of D_l ($7.3_2\,\mu$) found with Run E_{23} (Table 3) is the same for these four runs, and, that dried particles leaving the furnace are hydrated in the humidified atmosphere to come to equilibrium with water vapor during charging, the W_s values are, first, calculated from Eq. (10) by substituting 7.3 for D_l, the values of d_s and ρ_s, being determined by extrapolation to zero time (Figs. 2 and 5). We know 1.089 for ρ_l and 9 for W_l: then, the W_s so found is converted into X. It may be seen in the figure that the particle density varies from 0.62 for an anhydrate particle to 0.32 for a decahydrate particles. These values are less than the normal densities, the ratio of normal density to that thus estimated being 4.4 for the former particle and 4.5 for the latter one. Futhermore, on the basis of the fact[5] that hollow particles with a radius/thickness ratio of 10 are formed, the density of the shell can be calculated; the results are 2.3 for an anhydrate particle and 1.2 for a decahydrate one, values close to the normal densities of 2.7 and 1.4.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 980—983 (1972)

Hydrogen Exchange Reactions between Olefins or an Olefin and Molecular Hydrogen over Alumina Studied by Microwave Spectroscopy

Yuzo SAKURAI, Takaharu ONISHI, and Kenzi TAMARU

Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 29, 1971)

The exchange reaction between propylene and deuterium was studied over alumina. The rate of the reaction was expressed by $V_{ex}=k[P_{D_2}]^{0.5}[P_{Pro}]^{0.0}$. In the initial stages of the reaction the *cis*- and *trans*-1-d_1 species of propylene were the only products of the exchange reaction, but the concentration of the 3-d_1 species increased continuously as the reaction progressed. The activation energy for the exchange reaction was about 8.2 kcal/mol.

Propylene-*cis*-d_1 was reacted over alumina, and the variation in the deuterium distribution of the propylene was followed by microwave spectroscopy. Isotope scrambling and "double-bond migration" occurred to considerable extents, while *cis-trans* equilibration between the two C_1 hydrogen positions proceeded even faster. In the reaction of propylene-3-d_1, the isotope mixing and "double-bond migration" were considerably slower than those of the *cis*-1-d_1 species. *Cis*- and *trans*-1-d_1 species were formed in equal amounts. The possible mechanism of these reactions is discussed on the basis of the results obtained.

n-Butene isomerization, especially double-bond migration, in the presence of perdeuteriopropylene over alumina was studied in a previous paper[1] in order to obtain further information about the reaction mechanism. It was concluded that the isomerization of *n*-butene, or at least the double-bond migration, occurs on some protonic sites formed on the catalyst by the adsorption of olefin molecules, and that extensive deuterium exchange during the isomerization proceeds independently of the isomerization.

In this report the exchange reaction between propylene and molecular deuterium was carried out over alumina to derive more information about the mechanism of the deuterium scrambling among terminal olefins, and to elucidate the nature of the catalytic action of the alumina.

Experimental

γ-Alumina employed in this study was obtained from Degussa Co., and was pretreated in the following manner. Dry oxygen was circulated over the catalyst at 600°C for two hours, and the catalyst was then cooled to 500°C, the oxygen was replaced by dry hydrogen, and the catalyst kept at this temperature for one hour. The system was then evacuated for two hours at 600°C. Usually 9 g of alumina was employed as the catalyst.

Propylene was obtained from Takachiho Shoji Co., and purified by repeated distillation *in vacuo*. The deuterium (Showa Denko Co.) had a quoted purity of 99.5 D%, and was used without further purification.

Methylacetylene from Takachiho Shoji Co. was treated several times with weakly alkaline deuterium oxide to re-

1) Y. Sakurai, T. Onishi, and K. Tamaru, submitted for publication in *Trans. Faraday Soc.*

place its acetylenic hydrogen with deuterium. Methylacetylene-1-d_1 thus obtained was selectively hydrogenated to propylene-*cis*-1-d_1 by a process similar to that developed by Rabinovitch and Looney.[2] Three samples of propylene-*cis*-1-d_1 were obtained and employed for the reaction. The deuterium contents were determined by mass spectrometry, and were found to be around 90% in all three cases. Microwave spectroscopic analysis of the samples revealed that they consisted of only the *cis*-1-d_1 and *trans*-1-d_1 species.

The 3-d_1 species of propylene was synthesized by reacting allyl chloride and deuterium oxide over zinc powder in an acetic anhydride medium. The deuterium content of the propylene-3-d_1 thus obtained was about 83%. According to the microwave spectroscopic analysis, the propylene-3-d_1 consisted solely of the 3-d_1 species without any trace of the other monodeuterated species.

A conventional closed circulating system with a total volume of about 300 cm^3 was employed for the reaction. A mixture of propylene and deuterium was circulated over the alumina catalyst which was kept at a constant temperature (−21—60°C).

Analysis of the isotopic composition of the deuterium was carried out by gas chromatography using a $MnCl_2$-alumina column at liquid nitrogen temperature. The mass spectra of the propylene were recorded with an ionization, and the appropriate corrections were applied.

Microwave spectra of propylene and its mono-deuterated species were observed by Lide and Christensen,[4] and used for the quantitative determination of the deuterium contents at each hydrogen position of propylene-d_1 by Hirota and Morino.[5] Measurements were carried out at dry ice temperature with a conventional Stark modulation spectrometer. The $1_{01}-0_{00}$ transition was employed for the analysis, and the intensities of the neighboring peaks were compared. When the appropriate corrections were applied to the results,[5] the corrected intensity ratio was taken to show the relative abundance of the two species concerned.[6]

Results

Exchange Reaction between Propylene and Deuterium. The initial rate of the hydrogen exchange between propylene and deuterium was studied at propylene pressures between 11 and 44 cmHg, the partial pressure of deuterium being kept constant at 44 cmHg. The results are shown in Fig. 1. The initial rate of the hydrogen exchange was also studied at a constant pressure of propylene (22 cmHg), with a varying partial pressure of deuterium and the results are given in Fig. 2. The results of Figs. 1 and 2 show that proportional to square root of the deuterium pressure. This can be interpreted by postulating that the propylene is strongly adsorbed on the surface of alumina, and the deuterium molecules dissociate on the surface, to take part in the exchange reaction with the adsorbed propylene.

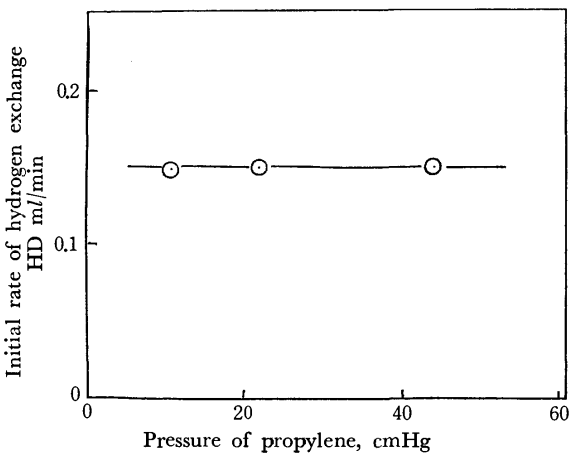

Fig. 1. Hydrogen exchange between propylene and deuterium over alumina. Dependence of the rate on partial pressure of propylene. P_{D_2}=44 cmHg.

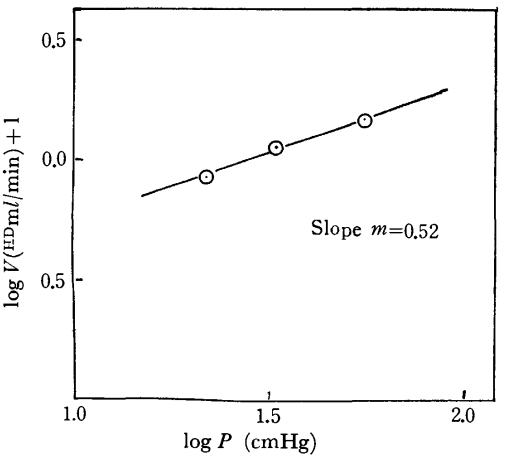

Fig. 2. Hydrogen exchange between propylene and deuterium over alumina. Dependence of the rate on partial pressure of deuterium. $P(C_3H_6)$=22 cmHg.

The hydrogen exchange between and equimolar mixture of propylene and deuterium was studied at temperatures between 0 and 60°C, and the Arrhenius plot of the exchange rate gave an activation energy of 8.2 kcal/mol. Recently deuterium exchange with hydrogen atoms in some olefins such as 1-butene, *cis*-2-butene and isobutene over alumina has been reported by Hightower and Hall.[7] They found an activation energy for the exchange reaction with D_2 of 5∼6 kcal/mol, which is slightly smaller than the value of 8.2 kcal/mol obtained here for the reaction between propylene and deuterium.

As the reaction progressed, hydrogenation of the propylene was found to occur to a small extent, but its rate was always almost one order of magnitude smaller than that of the exchange reaction. Therefore, the hydrogenation of propylene may be neglected under these conditions, and the subsequent discussions will be entirely concerned with the exchange

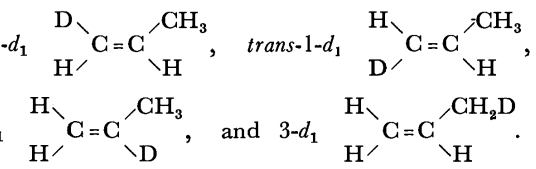
reaction.

A mixture of propylene and deuterium (3 : 5) was reacted over alumina at three different temperatures (0, 24, and 56°C), and the resultant mono-deuterated propylene species were analyzed by microwave spectroscopy. Four mono-deuterated species are distinguishable either by their chemical properties or by microwave spectroscopy;



The fractions of the four mono-deuterated species were plotted against the number of deuterium atoms which entered the propylene by the exchange reaction. The results are shown in Fig. 3. The total concentrations of the mono-deuterated species were always normalized to 100%. The notable features of the results in Fig. 3 are: i) The amount of the 2-d species formed in the reaction was negligible. A small amount of 2-d_1 species was observed after prolonged reactions, but its concentration was at most 4—5% of the total mono-deuterated propylene. ii) The *cis*-1-d_1 and *trans*-1-d_1 species were formed in approximately equal amounts throughout the course of the reaction. iii) The fraction of the 3-d_1 species increased continuously as the reaction proceeded, but its contribution was almost zero in the very initial stages of the reaction. In other words, *cis*-1-d_1 and *trans*-1-d_1 propylene were the only mono-deuterated species produced in the early stages of the exchange reaction. iv) At high conversion levels the deuterium in the propylene was equally distributed among the five hydrogen positions at C_1 and C_3. v) Reaction at the three different temperatures gave rise to similar deuterium distributions, which meant that the activation energy for the deuterium shift to form the 3-d_1 species ("double-bond migration") was nearly equal to that of the exchange reaction, 8.2 kcal/mol.

Hydrogen Exchange Reactions between Deuterated Olefins. When propylene-*cis*-1-d_1 was circulated over alumina at 30°C, isotope scrambling resulting in $C_3H_4D_2$ and $C_3H_3D_3$ occurred rapidly as shown in Fig. 4. Microwave spectroscopic analysis of the mono-deuterated propylene revealed that the deuterium which had initially been mainly at the C_1 *cis* position moved rapidly to the other positions on the C_1 and C_3 atoms, and attained an equilibrium distribution within one hour (Fig. 5). As Fig. 4 shows, the relative concentrations of the four isotopic propylene species, *i.e.*, C_3H_6, C_3H_5D, $C_3H_4D_2$, and $C_3H_3D_3$, which were detected in the course of the reaction, became constant after a reaction time of about one hour. These results suggest that the shift of the deuterium to yield the 3-d_1 species ("double-bond migration") is an intermolecular process.

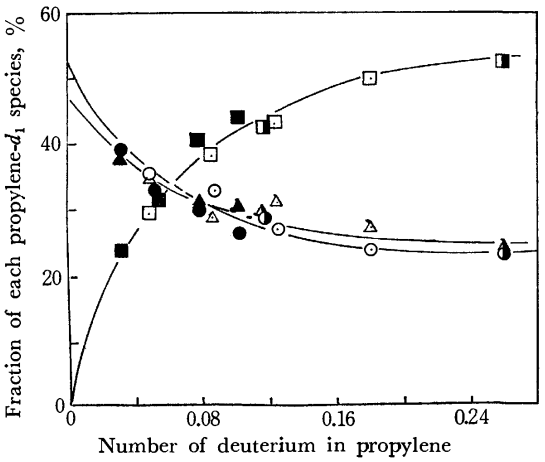


Fig. 3. Temperature dependence of deuterium distribution in propylene.
●▲■: 0°C, ○△□: 24°C, ◑◭◨: 56°C.

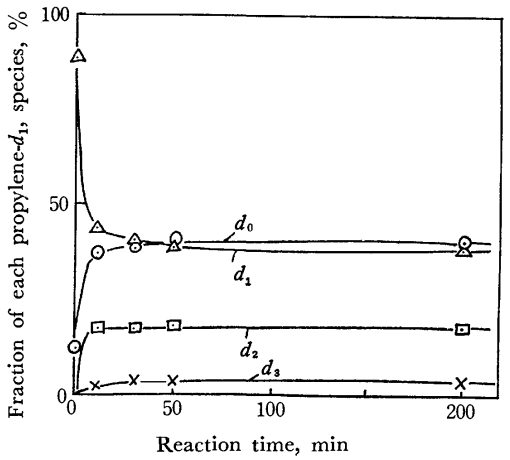

Fig. 4. Isotope mixing among the propylene, the change in deuterium content in propylene over alumina at 30°C.
○: C_3H_6, △: C_3H_5D, □: $C_3H_4D_2$, ×: $C_3H_3D_3$

□: 3-d_1, ○: *cis*-1-d_1, △: *trans*-1-d_1, ×: 2-d_1

When the reaction temperature was lowered, it was clearly demonstrated that *cis-trans* equilibration between the two hydrogen positions at C_1 atom occurred much more rapidly than "double-bond migration" to yield the 3-d_1 species. The activation energy for the *cis-trans* equilibration is lower than the "double-bond migration." The results are given in Fig. 6. Fig. 6 is for reaction at −21°C using sample B of the propylene-*cis*-1-d_1. The rate of isotope mixing to form $C_3H_4D_2$ and $C_3H_3D_3$ was considerably reduced at these temperatures.

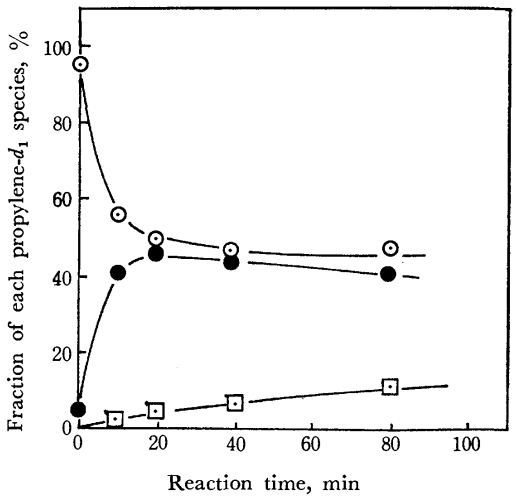

Fig. 6. The change in deuterated position of propylene-d_1 over alumina at −21°C.
○: *cis*-1-d_1, ●: *trans*-1-d_1, □: 3-d_1

When the 3-d_1 species of propylene was circulated over alumina at 0°C. under the similar conditions, *cis*-1-d_1 and *trans*-1-d_1 species formed in exactly equal amounts as shown in Fig. 7. The rate of the formation of the 1-d_1 species, however, was considerably slower than the rate of formation of the 3-d_1 species from *cis*-1-d_1 propylene.

Discussion

Three kinds of the reactions were involved in the experiments described above. The first is the exchange reaction between propylene and deuterium molecule. The second is isotope mixing among the propylene isomers, and the third is *cis-trans* equilibration of the deuterium in the two hydrogen positions on the C_1 atom.

The first reaction can be considered to proceed *via* the interaction of adsorbed propylene and a deuterium atom formed by dissociation of deuterium on the surface. This view is supported by the observed rate equation for the exchange, $V_{ex} = k[P_{D_2}]^{0.5}[P_{Pro}]^{0.0}$. The adsorption of propylene over alumina appears to be dissociative at C_1 position, because the deuterium exchange occurred selectively in the hydrogen positions at C_1 atom. If an associative mechanism is involved, where deuterium adds to the adsorbed propylene to form an isopropyl (or propyl) intermediate, then substantial amounts of the 3-d_1 (or 2-d_1) species should appear even in the initial stages of the reaction. This was not found in the experiments. Thus, propylene can be assumed to adsorb on alumina dissociatively rather than associatively.

The second reaction may correspond to the double-bond migration of *n*-butene over alumina described previously.[1] Isotope mixing among the propylene isomers as shown in Fig. 4 and "double-bond migration" in the mono-deuterated species as shown in Fig. 5 occurred at a comparable rate and both reactions get to final distribution in half an hour at 30°C. At lower temperatures such as −21°C the rates of both reactions were considerably slower. This suggests the hydrogen dissociation at C_3 and its association at C_1 position. Isotope mixing thus accompanies "double-bond migration."

The third reaction, the *cis-trans* equilibration of deuterium in the two hydrogen positions on the C_1 atom occurred very rapidly even at temperatures as low as −21°C. At −21°C the isotope mixing and "double-bond migration" slowed down remarkably. This suggests that the *cis-trans* equilibration reaction which may correspond to the *cis-trans* isomerization of 2-butene proceeds intramolecularly and is probably independent of the above two reaction. Hightower and Hall[8] studied that reaction of a mixture of butene and perdeuterio-butene over alumina, and concluded that *cis-trans* isomerization occurred by an intramolecular rearrangement.

The authors would like to express their gratitude to Professor Y. Morino and Dr. S. Saito of the Sagami Chemical Research Center for the measurement of microwave spectroscopy. The authors are also thankful for the assistance of Dr. A. C. Herd in preparing this manuscript.

The Trapping Efficiency for Electrons in Polar Glasses at 77°K

Takeshi SAWAI, Yoshiharu SHINOZAKI, and Gisuke MESHITSUKA

Tokyo Metropolitan Isotope Research Center, 2—11—1, Fukazawa, Setagaya-ku, Tokyo

(Received August 9, 1971)

The trapped electron yields in alcohols and methanol-water mixtures at 77°K as a function of the electron scavenger concentration have been measured. The reciprocal of the trapped electron yield increased linearly with the concentrations of phenol, acetone, and acrylamide. The relative trapping efficiency for electrons was found to increase with an increase in the dielectric constant of the matrix at room temperature. The relative travelling distance of electrons in these matrices was also estimated.

Extensive studies have been made of the formation of the trapped electrons in irradiated glasses of polar or non-polar substances.[1] The presence of electron scavengers,[1d,2,3] such as acrylamide, nitrate ions, nitrite ions, monochloroacetate, and acetone, decreases the yield of the trapped electrons, and these scavenging experiments showed that the mobile electron was the precursor of the trapped electron. Electrons produced by γ-irradiation or photoionization are trapped efficiently in polar glassy states at 77°K, and the absorption spectra of the trapped electrons are characterized by a very broad band in the visible or near-infrared spectral region.

Ekstrom and Willard[4] measured the optical absorption and ESR spectrum of the trapped electrons in γ-irradiated organic glasses covering a range in polarity, from 3-methylpentane to glycerol. They showed that the absorption maximum was shifted towards shorter wavelengths with an increase in the polarity of the matrix molecules, and the ESR line width increased. These results were explained by using a model in which the electrons are trapped in pre-existing cavities in the matrix.

Recent experiments, such as the pulse radiolysis of polar glasses at 77°K[5] and studies of water-ethylene glycol glass irradiated at 4°K,[6] have suggested that the mobile electrons were trapped in deeper traps at 77°K than at 4°K, indicating an orientational relaxation of the molecules at 77°K, and that the electrons trapped in the deeper traps had an absorption similar to that of the trapped electron irradiated with ^{60}Co γ-rays at 77°K. If the polarity of the solvent correlates with the formation processes of the trapped electrons, one can expect that the travelling distance of electrons prior to trapping in other words, the trapping efficiency of the matrix molecules for the mobile electrons, will depend on the polarity. The present investigation will show that the trapping efficiency depends on the polarity of the matrix molecules. The experiments were performed using glasses of alcohols and methanol-water mixtures containing phenol, acetone, or acrylamide at 77°K.

Experimental

The alcohols (isopropanol, ethanol, and methanol) were purified by distilling them twice after they had been refluxed for 24 hr with 2,4-dinitrophenyl hydrazine-sulfuric acid. The water was triply distilled. The solutions were purged with bubbling nitrogen prior to ^{60}Co γ-ray irradiation at 77°K. Methanol (5 mol% H_2O) and ethanol (5 mol% H_2O) formed clear glasses, and the other solutions were glassy with a few small cracks. Pyrex cells (~2 mm thick) were mainly used for the irradiation and for the optical measurements of trapped electrons. Metal cells (~3 mm thick) with high-purity silica windows were used for the measurement of the optical absorption below 400 nm in phenol solutions. The absorption spectra were measured at 77°K with a Cary Model 14R spectrophotometer. The optical densities of the trapped electrons (OD(e_t^-)) in various matrices were obtained by subtracting the OD after bleaching by light transmitting at $\lambda > 540$ nm (using a Toshiba V-054 glass filter) from the OD after γ-irradiation. Since the Pyrex cell absorbs from the visible to the UV region after γ-irradiation at 77°K, and since the intensity decreases upon optical bleaching, a correction was made for the OD (e_t^-). Irradiation was carried out at 77°K using a 5K Ci ^{60}Co source at a dose rate of 4×10^{19} eV/g hr, as determined by ferrous sulfate dosimetry.

Results and Discussion

The absorption spectra of the trapped electrons were observed in alcohols and methanol-water mixtures.[9] The results are summarized in Table 1. The presence of an electron scavenger decreases the trapped electron yield, but the position of the absorption maximum is not affected. Figure 1 shows the trapped electron yield *vs.* the irradiation dose at

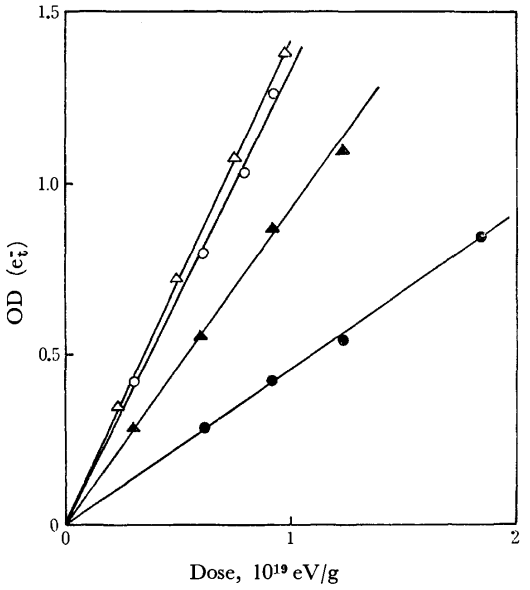

Fig. 1. Trapped electron yield as a function of dose in ethanol and methanol-water at 77°K.
○: ethanol, △: 40% methanol-60% water
●: 1.2 mol% phenol in ethanol
▲: 1.0 mol% phenol in 40% methanol-60% water

77°K obtained from 1.2 mol% phenol in ethanol and 1.0 mol% phenol in a 40% methanol - 60% H_2O mixture, and from the same solutions without any solute. The trapped electron yield is linear in dose in all the systems; the yields from systems without a solute seem to be almost the same, but the effect of phenol on the yield is quite different in different mixtures. This seems to be the effect of the electron-trapping efficiency of the matrices, which is correlated with the polarity. In the presence of phenol, the absorption maximum which is attributed to the C_6H_6OH radical appears at 345 nm in addition to the trapped electron band. It has been shown that phenol scavenges an electron to form the C_6H_6OH radical.[7] The radical yield increases with an increase in the concentration of phenol, and the radiation dose, $OD(C_6H_6OH)$ is larger in methanol than in the 40% methanol - 60% H_2O mixture at the same phenol concentration. The spectra of irradiated phenol in methanol and in 40% methanol - 60% H_2O at 77°K are shown in Fig. 2. Figure 2 suggests that the trapping efficiency by the matrix for the mobile electron is much smaller in methanol than in

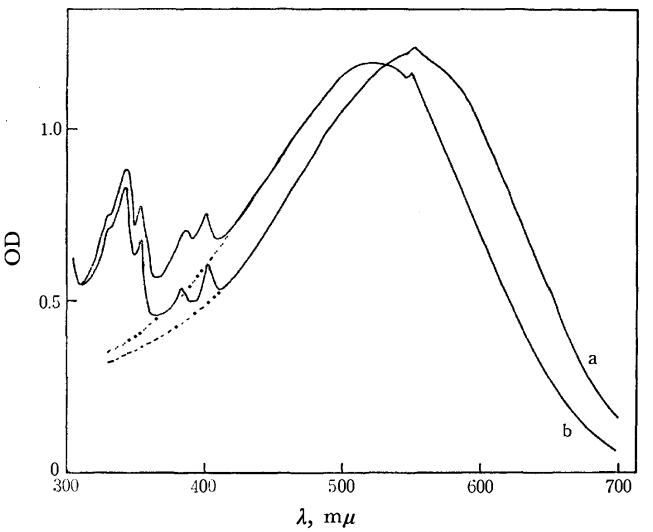

Fig. 2. Spectrum of irradiated phenol in methanol and in 40% methanol-60% water at 77°K.
a : 1.6 mol% phenol in 40% methanol-60% water
b : 0.8 mol% phenol in methanol
Dose: 1×10^{19} eV/g

the methanol-water mixture, since the $OD(C_6H_6OH)$ and $OD(e_t^-)$ in methanol are almost equal to those in the latter matrix, even though the phenol concentration is quite different. The trapping efficiency seems to correlate with the dielectric constant of the matrices; that is, the matrix with higher dielectric constant has the higher trapping efficiency.

It has been considered that the trapped electrons are produced by the reaction of mobile electrons with trapping sites in the solid state, and that the depth of the trapping sites is correlated with the dielectric constant of the matrix. The mechanisms for electron trapping are not very clear, but mobile electrons (e_m^-) may either recombine with positive holes to form excited molecules or react with traps (T) or scavengers (S) as is described in the following scheme:

$$M \rightsquigarrow M^+ + e_m^- \quad (1)$$

$$e_m^- + M^+ \rightarrow M^* \quad (2)$$

$$e_m^- + T \rightarrow e_t^- \quad (3)$$

$$e_m^- + S \rightarrow S^- \quad (4)$$

The linearity of the e_t^- yield with the dose, however, shows that reaction (2) can be neglected. From these simple competition reactions, it follows that:

$$G(e_t^-) = G_0(e_t^-)k_3[T]/(k_3[T]+k_4[S]) \quad (I)$$

where $G(e_t^-)$ and $G_0(e_t^-)$ are the trapped electron yields with and without a solute respectively. Since $G(e_t^-)$ can be replaced by the optical density:

$$1/OD(e_t^-) = 1/OD_0(e_t^-)(1+k_4[S]/k_3[T]) \quad (II)$$

The plot of $1/OD(e_t^-)$ *vs.* [S] at a constant dose should be linear for each matrix. $1/OD(e_t^-)$ plotted as a function of the concentrations of phenol, acetone, and acrylamide in isopropanol, ethanol, methanol, and methanol-water mixtures at 77°K is shown in Figs. 3, 4, and 5. $1/OD(e_t^-)$ is a linear function of

the solute concentration in all cases. The fact that $1/OD(e_t^-)$ in Fig. 3 is linear with the concentration of phenol to 2 mol% suggests that the trapping sites for e_m^- are unlikely to be destroyed even at a relatively high concentrations of the solute. From the slopes Figs. 3, 4, and 5, the relative trapping efficiencies

*: Dielectric constant at room temperature RTE: Relative trapping efficiency
S: Solute concentration required to reduce OD to 1/2 OD_0, mol%.

$(K_3[T]/k_4)$ in different matrices can be obtained. These results, which are normalized to the methanol matrix, are summarized in Table 2. The relative values of k_3 [T] as a function of the static dielectric constant (D_s) of the matrix at room temperature are plotted in Fig. 6. The trapping efficiency increases with the increase in D_s in the matrices. The intercepts in Figs. 3, 4, and 5 give $1/G_0(e_t^-)\varepsilon$, since OD is related to $G\varepsilon$; these figures show that the $G_0(e_t^-)\varepsilon$ values are almost the same in alcohols and in methanol-water mixtures except for the case of isopropanol.

The relative trapping efficiencies in various matrices should correlate with the travelling distance for mobile electrons prior to trapping. Dyne and Miller[8] and Seddon and Smith[2] have calculated the travelling distance on the bases of experiments with biphenyl in organic glass and acrylamide in alkaline glass respectively. Adopting the mathematical procedure described by Dyne and Miller[8] the root mean-square distance which electrons move prior to trapping, $(\bar{r}^2)^{1/2}$, can be estimated from the concentration of the solutes required to reduce the electron yield to one half its initial value. These concentrations ([S]) in various matrices are listed in Table 2. The relative travelling distances for mobile electrons in alcohols and methanol-water mixtures at 77°K are plotted in Fig. 6. In contrast with the relative trapping efficiency, the distance decreases with the increase in the dielectric constant at room temperature. However, further investigation seems to be necessary, especially concerning the temperature dependence of D_s and various phenomena occuring in the glassy state irradiated at 77°K, in order to correlate these facts with the phenomena in various matrices at 77°K.

The authors are indebted to Professor William H. Hamill for reading and discussing the manuscript.

Energy Transfer Concerning the Lowest Triplet State of Tetracyanobenzene with Methyl-Substituted Benzenes

Takayoshi KOBAYASHI and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo

(Received September 3, 1971)

The quantum-yield ratios of phosphorescence to fluorescence and the phosphorescence lifetimes were measured for the charge-transfer complexes of tetracyanobenzene with methyl-substituted benzenes. By combining the observed results with the fluorescence quantum yields and lifetimes reported previously, the upper and lower limits of the rate constants for the intersystem crossing and for the radiative and non-radiative energy-transfer processes from the lowest triplet state to the ground state were obtained with the complexes. The intersystem-crossing rate constant of tetracyanobenzene was found to be decreased by the complex formation. This tendency was explained by the mixing of the charge-transfer configuration with the appropriate singlet and triplet states of the component molecules. The phosphorescence radiative rate constant was found to be determined by the contribution of the higher excited singlet configurations of each complex to the phosphorescent state. The temperature dependence of the phosphorescence-quenching rate constant was determined, and the activation energy of the process was interpreted as being due to intramolecular out-of-plane bending vibrations.

The phosphorescences of charge-transfer (abbreviated hereafter to CT) complexes have been studied by several authors,[1-7] the trinitrobenzene, tetrahalophthalic anhydride, and tetracyanobenzene (abbreviated hereafter to TCNB) complexes with several donors having been taken as examples. The excited triplet states of some CT complexes may be expected to have the characters of a locally-excited (abbreviated hereafter to LE) triplet of acceptor, an LE triplet of donor, and a CT triplet, which can be represented by $^3(DA^*)$, $^3(D^*A)$, and $^3(D^+A^-)$, respectively. In actuality, phosphorescence spectra from these three types of triplet states have been observed.[1,4-7] In this connection, the TCNB complexes are especially remarkable, because the CT phosphorescence was first observed with the complex with hexamethylbenzene (abbreviated hereafter to HMB) and the above-mentioned three types of phosphorescence were all observed by changing donors.[6,7]

The natures of the lowest triplet states of CT complexes have also been studied by the ESR measurement.[8-10] Hayashi *et al.*[8,9] first succeeded in finding

the ESR signal of the lowest triplet states of CT complexes and in clarifying their nature by analyzing the observed fine structure constants.

From the above-mentioned phosphorescence and ESR studies, the natures of the phosphorescent states of CT complexes have been clarified unambiguously and understood systematically. The dynamical aspects of the phosphorescence of CT complexes, however, are still open to question, although Christdouleas and McGlynn studied the phosphorescence lifetimes and quantum yields for the naphthalene complexes with several acceptors.[5]

Under these circumstances, we have undertaken to study energy-transfer processes concerning the triplet states of several TCNB complexes with methyl-substituted benzenes, by obtaining the rate constants for the intersystem crossing and also for the phosphorescence emitting and quenching processes.

Experimental

The preparation and purification of materials, and also the measurements of the absorption and fluorescence spectra were described in a previous paper.[11] Sample solutions used for the measurements of phosphorescence lifetimes and quantum yields were degassed by the freeze-thaw technique. The phosphorescence lifetimes were determined by analyzing exponential decay curves measured by an oscilloscope. The phosphorescence quantum yields were determined by measuring quantum-yield ratios of phosphorescence to fluorescence, the quantum yields of which were obtained in the previous paper.[11]

During the measurement of the phosphorescence lifetime, the sample was kept in a Dewar vessel into which cold nitrogen gas was allowed to flow, in order to keep it at a temperature between ~100°K and ~280°K.

Results and Discussion

Phosphorescence Quantum Yield. The quantum-yield ratio of phosphorescence to fluorescence was measured by two different methods.

In method I, a fluorescence spectrum was obtained by subtracting the phosphorescence from a total emission spectrum, as is shown in Fig. 1. Thus, we obtained the quantum-yield ratio of the phosphorescence to the fluorescence. For the systems containing TCNB–durene and TCNB–HMB in methyl methacrylate (hereafter abbreviated to MMA), however, the total emission has only one peak: therefore, the separation into the two parts is rather optional and may cause a large error. For these cases, method II was used.

In method II, we measured the intensities of the total emission and phosphorescence by rotating two sectors in-phase and out-of-phase, respectively, as is shown in Fig. 2, keeping the sample in the same position and fixing the voltage of a photomultiplier and the sensitivity of a recorder. The total emission intensity was reduced by a neutral density filter to an intensity appropriate to be measured. The quantum-yield ratio of phosphorescence to fluorescence was evaluated from the observed intensities of total emission, $I_{\mathrm{Tot}}^{\mathrm{in}}$, and phosphorescence, $I_{\mathrm{P}}^{\mathrm{out}}$, with the aid of Eq. (1) derived from Eqs. (A-9)—(A-13) in the Appendix.

$$\frac{\Phi_{\mathrm{P}}}{\Phi_{\mathrm{F}}} \cong \frac{T_1+T_2}{T_1} \frac{I_{\mathrm{P}}^{\mathrm{out}}}{I_{\mathrm{Tot}}^{\mathrm{in}}-I_{\mathrm{P}}^{\mathrm{out}}} \qquad (1)$$

where T_1 and T_2 are the duration times of the "on" and "off" states of the sector.

The quantum-yield ratios obtained by methods I and II are given in Table 1. We adopted the values obtained by method II for the TCNB complexes with durene and HMB and the average values of methods I and II for the other TCNB complexes.

d) Fluorescence quantum yields were obtained in Ref. (11).

yields are given in Table 1. In this table, k_3, k_4, and k_5 are the rate constants for the intersystem crossing, phosphorescence, and phosphorescence-quenching processes, respectively, and k_2 is the rate constant for the fluorescence-quenching process other than the intersystem crossing.

The quantum yields, Φ_F and Φ_P, and also the lifetimes τ_F and τ_P, are obtained with the aid of the rate constants:

$$\Phi_F = \frac{k_1}{k_1+k_2+k_3}, \quad \Phi_P = \frac{k_3}{k_1+k_2+k_3}\frac{k_4}{k_4+k_5} \tag{2}$$

$$\tau_F = \frac{1}{k_1+k_2+k_3}, \quad \tau_P = \frac{1}{k_4+k_5} \tag{3}$$

where k_1 is the fluorescence radiation decay constant. From Eqs. (2) and (3) we obtain the following relationships:

$$k_1 = \frac{\Phi_P}{\tau_F} \tag{4}$$

$$0 \leqq k_2 \leqq \frac{1}{\tau_F}(1-\Phi_F-\Phi_P) \tag{5}$$

$$\frac{\Phi_P}{\tau_F} \leqq k_3 \leqq \frac{1}{\tau_F}(1-\Phi_F) \tag{6}$$

$$\frac{1}{\tau_P}\frac{\Phi_P}{1-\Phi_F} \leqq k_4 \leqq \frac{1}{\tau_P} \tag{7}$$

$$0 \leqq k_5 \leqq \frac{1}{\tau_P}\frac{1-\Phi_F-\Phi_P}{1-\Phi_F}. \tag{8}$$

By the aid of Eqs. (4)—(8), the upper and lower limited values of k_2, k_3, k_4, and k_5 can be represented as follows:

$$k_2(\min) = k_5(\min) = 0 \tag{9}$$

$$k_2(\max) = \frac{1}{\tau_F}(1-\Phi_F-\Phi_P) \tag{10}$$

$$k_3(\min) = \frac{\Phi_P}{\tau_F} \tag{11}$$

$$k_3(\max) = \frac{1}{\tau_F}(1-\Phi_F) \tag{12}$$

$$k_4(\min) = \frac{1}{\tau_P}\frac{\Phi_P}{1-\Phi_F} \tag{13}$$

$$k_4(\max) = \frac{1}{\tau_P} \tag{14}$$

$$k_5(\max) = \frac{1}{\tau_P}\frac{1-\Phi_F-\Phi_P}{1-\Phi_F} \tag{15}$$

The limited values actually evaluated by Eqs. (10)—(15) are tabulated in Table 1.

Intersystem-Crossing Rate Constant, k_3. In discussing the rate constants for intersystem crossing given in Table 1, we divide the systems under consideration into two groups, groups A and B. Group A contains the TCNB–benzene, TCNB–toluene, TCNB–*m*-xylene, TCNB–*p*-xylene, and TCNB–mesitylene systems, and group B, the TCNB–durene–MMA and TCNB–HMB–MMA systems.

First, let us consider the TCNB–benzene and TCNB–toluene systems belonging to group A. In both systems, the sums of the fluorescence and phosphorescence quantum yields are nearly equal to unity as may easily be seen in Table 1; therefore, the fluorescence quenching is mainly due to the intersystem crossing.

The fact that TCNB is nonfluorescent means that, when the internal conversion may be disregarded,[12] its intersystem-crossing rate constant is much larger than its fluorescence radiation decay constant which is evaluated from the intensity of the absorption spectrum to be 2.0×10^7 sec^{-1}. Therefore, the intersystem-crossing rate constants, k_3's, for the systems of group A are smaller than that of the acceptor molecule itself. On the other hand, Christdouleas and McGlynn showed that k_3 of naphthalene was increased by the complex formation with trinitrobenzene and tetrahalophthalic anhydrides.[5] The intersystem-crossing rate constant of naphthalene can be estimated to be smaller than 5.8×10^6 sec^{-1} from the lifetime (103 nsec) and quantum yield (~0.4) in the literature.[13,14]

12) The rate constant of internal conversion from the first singlet state to the ground state was found to be very small for several compounds (T. Medinger and F. Wilkinson. *Trans. Faraday Soc.*, **61**, 620 (1965)).
13) T. V. Ivanova, P. I. Kudrysahov, and B. Ya. Sevshinikov, *Dokl. Akad. Nauk. SSSR*, **138**, 572 (1961).
14) E. H. Gilmore, G. E. Gibson, and D. S. McClure, *J. Chem. Phys.*, **23**, 399 (1965).

The great difference in the intersystem-crossing rate constant between TCNB and naphthalene may be the reason why the TCNB complexes of group A and the naphthalene complexes with trinitrobenzene and tetrahalophthalic anhydrides show reverse tendencies with regard to the effect of complex formation on the intersystem-crossing rate constant. The CT complex formation may bring about the mixing of the CT configuration with the appropriate excited singlet and triplet states of component molecules. This mixing may decrease the great rate constant of TCNB and increase the small rate constant of naphthalene.

For complexes of group B, the $\Phi_F+\Phi_P$ values are considerably smaller than those for the complexes of group A, as is seen in Table 1. This increases the difference between k_3(min) and k_3(max), and makes it difficult to estimate the real values of k_3 for the complexes of group B. In order to remove this difficulty, we discuss the two limiting cases: namely, case 1 where the true k_2, k_3, k_4, and k_5 values are, respectively, close to k_2(min), k_3(max), k_4(min), and k_5(max); case 2, where they are, respectively, close to k_2(max), k_3(min), k_4(max), and k_5(min). As is clearly seen in Table 1, in case 1 k_3 has no correlation with the ionization potentials of the donors, while in case 2 there is a correlation between them. In view of the fact that the ionization potential of the donor may be expected to be related with the contribution of CT configurations to the lowest triplet state[9] and therefore related also with k_3, case 2 is more probable than case 1.

Consideration of k_4. On the assumption that there is only one singlet state $|S_p>$, which makes a major contribution to the perturbation of the lowest triplet state, $|T_i>$, the rate constant, k_4, and the transition moment, $\vec{M}$, for the phosphorescence are written as follows:

$$k_4 \simeq \frac{64\pi^4\nu_P^3}{3hc^3}|\vec{M}|^2 \tag{16}$$

$$\vec{M} = -\frac{<S_p|H_{SO}|T_1>}{E(S_p)-E(T_1)}<S_p|\vec{er}|S_0> \tag{17}$$

where ν_P is the frequency of the phosphorescence maximum, $E(S_p)$ and $E(T_1)$ are the energies of $|S_p>$ and $|T_1>$ states, H_{SO} is the spin orbit interaction hamiltonian, and $\boldsymbol{h}$, $\boldsymbol{c}$, and $\boldsymbol{e}$ are universal constants. Here, $|S_0>$, $|S_p>$, and $|T_1>$ are expanded into the ground, CT, and LE configurations;

$$|S_0> \cong |G> \tag{18a}$$

$$|S_p> \cong c_1^p|{}^1LE^p> + c_2^p|{}^1CT^p> \tag{18b}$$

$$|T_1> \cong c_3|{}^3LE> + c_4|{}^3CT> \tag{18c}$$

where $|G>$ is the ground configuration, $|{}^1LE^p>$ and $|{}^1CT^p>$ are the singlet LE and CT configurations, respectively which make major contributions to the expansion of $|S_p>$, $|{}^3LE>$, and $|{}^3CT>$ are the lowest triplet LE (within the acceptor) and lowest triplet CT configurations, respectively, and c_1^p, c_2^p, c_3, and c_4 are their coefficients in the expansion. By inserting Eqs. (18a—c) into Eq. (17), we can obtain:

$$\vec{M} \cong K\vec{M}(\text{G-LE}) + L\vec{M}(\text{G-CT}). \tag{19}$$

Here, K, L, $\vec{M}$(G–LE), and $\vec{M}$(G–CT) are defined as follows:

$$K = c_1^pN \tag{20a}$$

$$L = c_2^pN \tag{20b}$$

$$N = \{c_1^pc_4<{}^1LE^p|H_{SO}|{}^3CT> + c_2^pc_3<{}^1CT^p|H_{SO}|{}^3LE> + c_1^pc_3<{}^1LE^p|H_{SO}|{}^3LE> + c_2^pc_4<{}^1CT^p|H_{SO}|{}^3CT>\} \times \{E(S_p)-E(T_1)\}^{-1} \tag{20c}$$

$$\vec{M}(\text{G-CT}) = <{}^1CT^p|\vec{er}|G> \tag{20d}$$

$$\vec{M}(\text{G-LE}) = <{}^1LE^p|\vec{er}|G>. \tag{20e}$$

In the case where $|S_p>$ is the lowest excited singlet state, $|S_1>$, which mainly consists of the lowest singlet LE (within the acceptor) configuration, $|{}^1LE>$, and the lowest singlet CT configuration, $|{}^1CT>$,[15] k_4 is given by the following equation from Eqs. (16)—(20):

$$k_4 \propto \frac{\nu_p^3|(c_1^1c_4+c_2^1c_3)|^2\{|c_1^1\vec{M}(\text{G-LE})/\boldsymbol{e}|^2+|c_2^1\vec{M}(\text{G-CT})/\boldsymbol{e}|^2\}}{\{E(S_1)-E(T_1)\}^2} \equiv \frac{A}{\{E(S_1)-E(T_1)\}^2} \tag{21}$$

where c_1^1 and c_2^1 are the coefficients of $|{}^1LE>$ and $|{}^1CT>$ in the expansion of $|S_1>$.

By the use of the values of $|\vec{M}(\text{G-CT})/\boldsymbol{e}|=0.1$ Å and $|\vec{M}(\text{G-LE})/\boldsymbol{e}|=0.3$ Å, and of $|c_1^1|^2$, $|c_2^1|^2$, $|c_3|^2$, and $|c_4|^2$ given in Refs. (9) and (11), we can evaluate the right-hand side of Eq. (21). The relative values of A and $A/\{E(S_1)-E(T_1)\}^2$ are listed in Table 2, the corresponding values of the TCNB–benzene system being taken as the standards. The relative values of $A/\{E(S_1)-E(T_1)\}^2$ are much larger than those of k_4(max) except for the toluene complex.[16] On the other hand, the relative values of A coincide considerably well with those of k_4(max). This means that the discrepancy in the relative values between $A/\{E(S_1)-E(T_1)\}^2$ and k_4(max) is due to the too large change in the $\{E(S_1)-E(T_1)\}^2$ term in Eq. (21) from one complex to another. This difficulty can

15) Amano *et al.* measured the polarization of phosphorescence spectra for several TCNB complexes, and obtained the preliminary results of a ratio $\left|\frac{K\vec{M}(\text{G-LE})}{L\vec{M}(\text{G-CT})}\right| = \left|\frac{c_1^p\vec{M}(\text{G-LE})}{c_2^p\vec{M}(\text{G-CT})}\right|$ to be 2.4, 2.1, 1.4, 1.3, and 1.2 for the complexes with HMB, durene, mesitylene, *p*-xylene, and benzene, respectively. The results shows that the ratio increases with the decrease in the ionization potential of the donor. This means that the $|S_p>$ state has the decreasing $\left|\frac{c_1^p}{c_2^p}\right|$ value with the increasing ionization potential of donor. The lowest excited singlet state satisfied this condition.[11]

16) The relative value of $A/\{E(S_1)-E(T_1)\}^2$ for the TCNB-durene complex is larger than that for the TCNB-HMB complex. This is due to the fact that the energy separation $E(S_1)-E(T_1)$ is smaller for the former complex than for the latter. This tendency is found in solvents other than MMA; namely, the $(E(S_1)-E(T_1))$ are 1000 and 1300 cm^{-1} for the TCNB-durene complex in ethanol and a 1 : 1 mixed solvent of ethyl ether and isopentane, while the corresponding values for the TCNB-HMB complex are 1600 and 1700 cm^{-1}, respectively.

Table 2. The relative values of A, $\frac{A}{\{E(S_1)-E(T_1)\}^2}$, and k_4(max), and the $\{E(S_1)-E(T_1)\}^2$ values

Donor	A	$\frac{A}{\{E(S_1)-E(T_1)\}^2}$	k_4(max)	$\{E(S_1)-E(T_1)\}^2$ (10^6 cm^{-2})
Benzene	≡1.00	≡1.00	≡1.00	16.81
Toluene	1.29	1.99	1.27	10.89
m-Xylene	1.77	6.73	1.30	4.41
p-Xylene	1.85	7.04	1.21	4.41
Mesitylene	1.77	6.13	1.30	4.84
Durene	2.23	46.3	1.79	0.81
HMB	2.30	11.9	4.00	3.24

easily be removed by considering that the $|S_p>$ state is not $|S_1>$ but a higher excited singlet state, the energies of which, $E(S_p)$, is high, and that $\{E(S_p)-E(T_1)\}^2$ changes to a considerably smaller extent than $\{E(S_1)-E(T_1)\}^2$ from the benzene complex to the HMB complex.

Temperature Dependence of k_5. In a preceding paper,[11] we found that k_1 is temperature-independent in a rigid medium (polymethyl methacrylate) in the range from 300°K to 77°K. From the same reason, the phosphorescence radiative rate constant, k_4, can safely be assumed to be temperature-independent in polymethyl methacrylate in a similar temperature range.

Let us express the temperature dependence of k_5 in the following way:[17]

$$k_5 = k_5^0\left[1+B\exp\left(\frac{-\Delta E}{kT}\right)\right]. \tag{22}$$

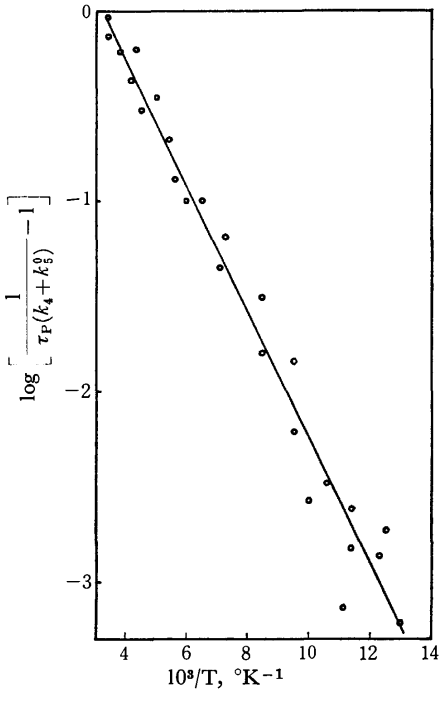

Fig. 3. Plot of $\log\left[\frac{1}{\tau_P(k_4+k_5^0)}-1\right]$ *versus* $1/T$ for the system including TCNB-durene in polymethyl methacrylate.

17) P. F. Jones and S. Siegel, *Chem. Phys. Lett.*, **2**, 486 (1968); *J. Chem. Phys.*, **50**, 1134 (1969).

The temperature dependence of the phosphorescence lifetime is given by the following equations:

$$\tau_P^{-1} = (k_4+k_5^0) + Bk_5^0\exp\left(-\frac{\Delta E}{kT}\right) \tag{23}$$

$$\frac{1}{\tau_P(k_4+k_5^0)} - 1 = \frac{Bk_5^0}{k_4+k_5^0}\exp\left(-\frac{\Delta E}{kT}\right) \tag{24}$$

From the extraporation of the $\tau_P^{-1}-1/T$ plot for the TCNB–durene complex in polymethyl methacrylate to a low-temperature region, we evaluated $1/(k_4+k_5^0)$ to be 1.70 sec. By the use of this value, we plotted $\log\left[\frac{1}{\tau_P(k_4+k_5^0)}-1\right]$ against $1/T$ for the same system. The results shown in Fig. 3 give a straight line as expected from Eq. (24), and ΔE is evaluated to be 535±30 cm^{-1}. From this value, it is revealed that the low-frequency intramolecular vibrations (probably out-of-plane bending modes) are responsible for the temperature dependence of k_5 for the temperature range studied. This is consistent with the conclusion presented by Jones and Siegel[17] after their measurement of the phosphorescence lifetimes of naphthalene-h_8, naphthalene-d_8, phenanthrene-h_{10}, and phenanthrene-d_{10}.

We should like to express our deep gratitude to Dr. Takako Amano, Department of Chemistry, Kyushyu University, for her kindness in offering her experimental results to us before publication.

Appendix

The integrated emission intensity over the observation time region from 0 to T is given by the following equation:

$$I = a\int_0^T D(t)\int_{-\infty}^{t} L(t')E(t-t')\mathrm{d}t'\mathrm{d}t, \tag{A-1}$$

where $L(t')$ is the exciting light intensity at time t', $D(t)$ is the ratio of detected photon number to the one emitted from the sample at time t, $E(t-t')$ is a decay function for the emission, and a is a proportionality coefficient. The integrated emission intensities are given by Eq. (A-2) for the two cases having the excitation and detection sectors "in-phase" and "out-of-phase":

$$I^\alpha = a\int_0^T D^\alpha(t)\int_{-\infty}^{t} L(t')E(t-t')\mathrm{d}t'\mathrm{d}t \tag{A-2}$$

where α indicates "in" or "out" and D, L, and E are as follows:

$$D^{in}(t) = \begin{cases} D_0 & n(T_1+T_2) \leqq t \leqq n(T_1+T_2)+T_1 \\ 0 & n(T_1+T_2)+T_1 \leqq t \leqq (n+1)(T_1+T_2) \end{cases} \tag{A-3}$$

$$D^{out}(t) = \begin{cases} D_0 & T_1+T_3+n(T_1+T_2) \leqq t \leqq 2T_1 \\ & \quad +T_3+n(T_1+T_2) \\ 0 & 2T_1+T_3+n(T_1+T_2) \leqq t \leqq T_1 \\ & \quad +T_3+(n+1)(T_1+T_2) \end{cases} \tag{A-4}$$

$$L(t) = \begin{cases} L_0 & n(T_1+T_2) \leqq t \leqq n(T_1+T_2)+T_1 \\ 0 & n(T_1+T_2)+T_1 \leqq t \leqq (n+1)(T_1+T_2) \end{cases} \tag{A-5}$$

$$E(t) = \frac{\Phi}{\tau}\mathrm{e}^{-t/\tau} \tag{A-6}$$

where n is an integer, L_0 is the number of photons absorbed by a sample when the excitation sector is "on" D_0 is the ratio of the number of photons detected to that emitted by the sample when the observation sector is "on", and τ and Φ are the lifetime and quantum yield, respectively. T_3 is a half of the difference between T_2 and T_1. By putting (A-3), (A-4), (A-5), and (A-6) into (A-2), and by integrating over one period, T_1+T_2, I^{in}, and I^{out} are obtained:

$$I^{\text{in}} = aL_0D_0\Phi\left[\tau(1-e^{-T_1/\tau})(e^{T_1/\tau}-1)\frac{e^{-((T_1+T_2)/\tau)}}{1-e^{-((T_1+T_2)/\tau)}} + T_1 + \tau(e^{-T_1/\tau}-1)\right] \quad \text{(A-7)}$$

$$I^{\text{out}} = aL_0D_0\Phi\left[\tau(e^{-T_3/\tau}-e^{-((T_1+T_3)/\tau)})(e^{T_1/\tau}-1) \times \frac{e^{-((T_1+T_2)/\tau)}}{1-e^{-((T_1+T_2)/\tau)}}\right]. \quad \text{(A-8)}$$

By taking τ and Φ to be τ_F and Φ_F, or τ_P and Φ_P, the integrated intensities of the fluorescence or phosphorescence in-phase and out-of-phase over one period T_1+T_2 can be given as follows:

$$I_F^{\text{in}} \cong aL_0D_0\Phi_F T_1 \quad \text{(A-9)}$$

$$I_F^{\text{out}} \cong 0 \quad \text{(A-10)}$$

$$I_P^{\text{in}} \cong I_P^{\text{out}} \cong aL_0D_0\Phi_P\frac{T_1^2}{T_1+T_2} \quad \text{(A-11)}$$

The intensities of the total emissions, $I_{\text{Tot}}^{\text{in}}$ and $I_{\text{Tot}}^{\text{out}}$, are also given as follows:

$$I_{\text{Tot}}^{\text{in}} \equiv I_F^{\text{in}} + I_P^{\text{in}} \cong I_F^{\text{in}} + I_P^{\text{out}} \quad \text{(A-12)}$$

$$I_{\text{Tot}}^{\text{out}} \equiv I_F^{\text{out}} + I_P^{\text{out}} \cong I_P^{\text{out}}. \quad \text{(A-13)}$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 992—996 (1972)

Polarized Absorption Spectrum of the Second S → T Transition of Phenazine Crystals

Naohiko MIKAMI and Mitsuo ITO

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received September 8, 1971)

Polarized absorption spectrum of the second S→T transition of phenazine single crystal was measured at 4.2°K. The transition moments of the individual vibronic bands were determined uniquely from their polarization characteristics. The 0—0 band at 20470 cm^{-1} was found to be polarized along the N-N axis of the molecule and assigned as $^3B_{3u}\leftarrow{}^1A_g$ (n-π^*) transition. The vibronic bands other than the 0—0 band was found to be exclusively polarized along the long axis of the molecule, and they were assigned as the vibronic bands induced by a nontotally symmetric vibration in the $^3B_{3u}$ state. The possible routes of vibronic spin orbit coupling mechanism are discussed on the basis of the observed results.

Recently, high resolution photo-excitation technique becomes popular for detection of extremely weak singlet-triplet absorption spectrum of aromatic molecules. This indirect method[1] has real advantages for the crystals which have delayed fluorescence produced by triplet-triplet annihilation,[2] or in such a case that the excitation energy of triplet state of host crystal transfers well to phosphorescent molecules doped in the crystal.[3,4] In other cases, however, the direct observation of singlet-triplet absorption spectrum always gives unambiguous results. The polarization characteristic of singlet-triplet transition of aromatic molecules is important not only in assignment of the triplet state but also in elucidation of the spin orbit coupling mechanism of the molecules. Especially if the polarization characteristic of individual vibronic bands is determined, it provides reliable information on the mechanism of so called vibronic spin orbit interaction. Many works along this line were performed mainly by measurements of polarization degrees of the phosphorescence spectra.[5] In the absorption studies, however, only a few works have been reported.

The lowest singlet-triplet absorption spectrum of phenazine crystal was first observed by Clarke and Hochstrasser[6] at about 6400 Å and it was assigned by them as $^3B_{1u}\leftarrow{}^1A_g$ (π-π^*) transition on the basis of Zeeman splitting pattern of the factor group components.[7] This assignment for the lowest triplet state is reasonable because of good correspondence to the assignment for anthracene.[8,9] Later, Hochstrasser and Mazzacco[10] reported another weak abosption system in the region of 4800 Å and assigned it to be due to a second singlet–triplet transition. their spectrum was too obscure to ensure detail analysis.

In the present work, the polarized measurements of the 4800 Å absorption were carried out for the single crystal at 4.2°K, and the assignments and the possible routes of vibronic spin orbit coupling mechanism are discussed on the basis of the observed results.

Experimental

The single crystal of phenazine was grown in a high vacuum Pyrex tube by conventional Bridgman method after sample purification by chromatographic extraction followed by extensive zone refinning. The crystal was cleaved along the *bc*-plane, and cut down perpendicular to it. Thickness of the crystal used for spectral measurements was 5 to 30 mm. The polarized absorption spectra were taken on the *bc*-plane with the light polarized along the *b*-axis and with light perpendicular to it. The *b*-axis of the crystal was identified by X-ray diffraction method.

We were also able to obtain another crystal which exposes the *ac*-plane. Polarizing microscopic observation of this crystal through the *b*-axis showed that the angles between the *c*-axis and the directions of the minimum and maximum refractive indices α, γ, were about 50° and 40°, respectively, in agreement with the crystallographic data cited in the literature.[11]

The crystals used were so large that it was difficult to cool them to 4.2°K without cracking. Therefore, we constructed a cryostat having a specially designed thermal exchange tube. With this cryostat, the crystal was cooled very slowly to liquid helium temperature. After many failures, we succeeded in obtaining very clear crystals having no cracking at 4.2°K, and they were subject to the spectral measurements.

The absorption spectra were photographed on Kodak 103a-O plates with a Shimadzu GE-100 grating spectrograph having reciprocal linear dispersion of 8.4 Å/mm in the first order. Continuum from a 500 W xenon arc lamp and/or a tungsten iodine lamp was condensed on the crystal after passing through a water filter of 100 mm path length and a Toshiba UV-39 glass filter. The light passed through the crystal was focussed on a slit of the spectrograph. A Glan-Foucault prism was placed in front of the slit for polarization measurements.

To serve in vibrational analysis of the spectrum, we observed also the Raman spectrum of the crystal. The Raman spectrum was measured with a Narumi double monochromator combining with a He-Ne gas laser. The single crystal cube whose edges are parallel to *a*,*b* axes was used for plarization measurements at room temperature. The depolarization degrees of the Raman lines were also measured for molten phenazine with a high temperature liquid cell.

Results and Discussion

The absorption spectra of the first and the second singlet-triplet transitions are reproduced in Fig. 1. The first singlet-triplet absorption spectrum obtained in this work is the same as that reported by Clarke and Hochstrasser.[6] The half band widths of this absorption region were about 0.5 cm^{-1}. Davydov splittings were observed for the 0—0 band at 15447.5 cm^{-1} and the 0+1328 cm^{-1} vibronic band. The observed frequencies of fundamental vibrations in the first triplet excited state are 415, 452, 599, 740, 1044, and 1384 cm^{-1}.

The second singlet-triplet absorption consists of many bands whose half widths are about 3 cm^{-1}.

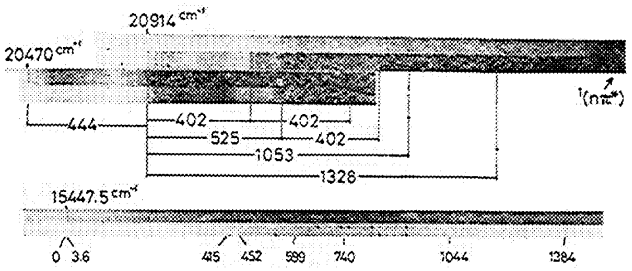

Fig. 1. Absorption spectra of phenazine crystal at 4.2°K. The upper is the second S→T absorption spectrum at about 4885 Å, and the lower is the first S→T transition at 6470 Å.

11) R. G. Wood and G. Williams, *Phil. Mag.*, **31**, 115 (1941).

Davydov splitting was not observed. The longest wavelength band at 20470 cm^{-1}, which was considered as a 0—0 band of this absorption system, was weak compared with the bands at higher frequencies than 20914 cm^{-1}. Frequencies of the main bands and their tentative vibrational analysis are shown in Table 1. Five fundamental frequencies, 402, 525, 606, 1053, and 1328 cm^{-1} were found which start from the band at 20914 cm.$^{-1}$ Of these frequencies, 402 and 525 cm^{-1} belong to totally symmetric vibrations in the excited state, since they form short progressions. The other frequencies 606, 1053, and 1328 cm^{-1} are also probably due to totally symmetric vibrations. On the other hand, no prominent progression starting from the 20470 cm^{-1} band was observed. The frequency difference between this band and the 20914 cm^{-1} band is 444 cm^{-1}. It is probably due to a fundamental frequency in the excited state, but it is not repeated anywhere except the above difference. This fact and the weak intensity of the 20470 cm^{-1} band suggest that the 20914 cm^{-1} band and the higher ferquency bands followed to it are attributed to "*forbidden bands*" induced by a nontotally symmetric vibration.[12] If this interpretation would be correct, 444 cm^{-1} should be a nontotally symmetric vibration in the excited state and the strong intensity of the 20914 cm^{-1} band is explained as the results of intensity borrowing from higher excited states through this perturbing vibration. This situation is very similar to that of the (n-π^*) singlet-singlet absorption spectrum of this crystal at about 4200 Å where a vibronic band perturbed by a b_{1g} vibration occurs[13].

In order to determine the directions of the transition moments of the individual vibronic bands, we observed polarized absorption spectrum. Phenazine forms a monoclinic crystal of space group $P2_{1/a}$ having two molecules in a unit cell, as shown in Fig. 2.[14] It is seen from Fig. 2 that projection of the long axis of the molecules on ac-plane is nearly parallel to the [201] direction shown by **L** in the figure. This direction is easily identified from the direction of the largest refractive index on the ac-plane and the angle made between it and the cleavage plane. It is also seen from the figure that projection of the molecular normal axis on the ac-plane is also almost parallel to **L** because the molecular short axis is nearly parallel to the ac-plane. Thus, polarization measurements were made on the ac-plane with incident light polarized parallel to **L** and with light polarized perpendicular to it. A part of the observed spectrum for a crystal of 28 mm thickness is reproduced in Fig. 3. The weak 0—0 band at 20470 cm^{-1} (which is not shown in the figure) and the band at 21208 cm^{-1} appear dominantly in the $\mathbf{L}_\perp$ component. Then, the transition moments of these bands are parallel to the short axis of the molecule. On the other hand, all the bands above 20914 cm^{-1} except the band at 21208 cm^{-1} is exclusively polarized in the $\mathbf{L}_{//}$ direction. Therefore, we may conclude that their transition moments are parallel to the long or normal axis of the molecule. In order to distinguish between the two possiblities for the latter, we measured the polarized spectrum on the bc crystal plane. The observed intensity ratio $\frac{I(b)}{I(c)}$ was 3 for all the bands exclusively polarized along the **L** direction. The calculated ratios for the long and normal axis transition moments should be 2.7 and 18, respectively, in oriented gas approximation. Therefore, we may conclude that the transition moments of the 20914 cm^{-1} band and its relatives are parallel to the long axis of the molecule.

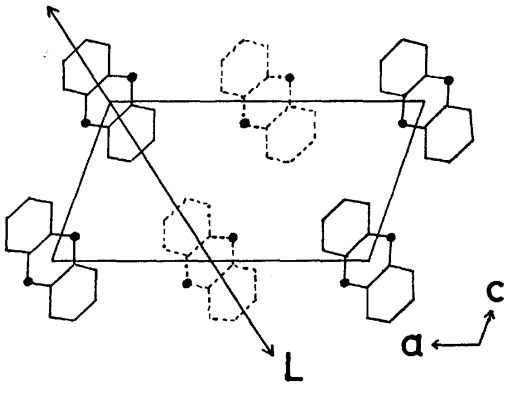

Fig. 2. Projection of the molecules onto the ac plane of the crystal. The molecules which are translationally inequivalent in a unit cell are indicated by the broken line. The direction **L** indicates the [201] in the crystal.

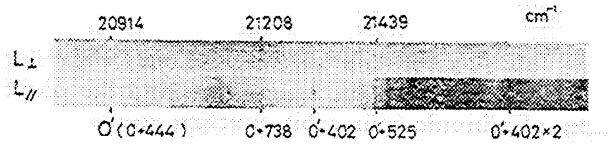

Fig. 3. Polarized absorption spectrum of the second S→T transition of phenazine single crystal at 4.2°K. The 0—0 band at 20470 cm^{-1} is not shown but its polarization characteristices is same as that of the band 0+738 at 21208 cm^{-1}.

Now, we proceed to assignment of the 0—0 band at 20470 cm^{-1} of the second triplet state which is polarized along the short axis (z) of the molecule. $^3B_{1u}$, $^3B_{2u}$, and $^3B_{3u}$ states are considered as candidates. All g-states are excluded because of appearance of the 0—0 band. In Table 2 are listed possible perturbing singlet states coupled with the triplet state by usual spin orbit interaction. It is found from this table that the triplet states which can couple with the $^1B_{1u}$ state of the short axis (z) transition moment must be $^3B_{3u}$ (n-π^*) or B_{2u} (π-π^*). Within the limit of LCAO MO consideration for the one electron spin orbit matrix elements, $^3B_{2u}$ (π-π^*) state can never couple with any short axis polarized singlet state, since operation of the operator l_x on an atomic orbital p_x from which the molecular orbitals are constructed always gives zero eigenvalue[15]. Hence, we have a unique

assignment of $^3B_{3u}$ $(n\,\pi^*)$ for this triplet state. This assignment is supported from the theoretical predictions of the location of the $(n\,\pi^*)$ triplet state[16] and from the smaller energy separation between the singlet and triplet $(n\,\pi^*)$ states of this molecule than that of pyrazine.

TABLE 2. SPIN ORBIT COUPLING SELECTION RULE FOR THE TRIPLET STATE

Γ(T)		$\Gamma(l_\xi)$		Γ(S)
$^3B_{3u}(n\pi^*)$	<	$B_{1g}(l_z)$	—	$^1B_{2u}(y)$
		$B_{2g}(l_y)$	—	$^1B_{1u}(z)$
$^3B_{2u}(\pi\pi^*)$	<	$B_{1g}(l_z)$	—	$^1B_{3u}(x)$
		$B_{3g}(l_x)$	—	$^1B_{1u}(z)$
$^3B_{1u}(\pi\pi^*)$	<	$B_{2g}(l_y)$	—	$^1B_{3u}(x)$
		$B_{3g}(l_x)$	—	$^1B_{2u}(y)$

Γ(T), $\Gamma(l_\xi)$, and Γ(s) indicate irreducible representations of triplet state, angular momentum operator and singlet state of the molecule having D_{2h} symmetry, respectively.

As mentioned before, the band at 20914 cm^{-1} has its transition moment parallel to the long axis (y) of the molecule. If it would be an electronic band origin of another triplet state, it should have the symmetry of $^3B_{3u}$ $(n\,\pi^*)$ or $^3B_{1u}$ $(\pi\,\pi^*)$ as is seen from Table 2. However, $^3B_{1u}$ $(\pi\,\pi^*)$ can not couple with any $^1B_{2u}$ states within the limit of LCAO MO approximation, while $^3B_{3u}$ $(n\,\pi^*)$ can couple only with $^1B_{2u}$ $(n\,\sigma^*)$. Such $(n\,\sigma^*)$ singlet state lies in general in far ultraviolet region and the corresponding absorption is not so intense. Therefore, contribution from the $^1B_{2u}$ $(n\,\sigma^*)$ seems not to be important. From these reasons, we exclude the possibility that the 20914 cm^{-1} band is a band origin of another triplet state. As already suggested before we interprete the band at 20914 cm^{-1} as a vibronic band induced by a nontotally symmetric vibration of the frequency 444 cm^{-1} in the excited state. In the Raman spectral measurement, we observed seven bands in the frequency range from 400 to 750 cm^{-1}. Of them, the Raman bands at 414, 582, 610, and 734 cm^{-1} are readily assigned as due to totally symmetric vibrations from their depolarization degrees observed for the molten sample. Furthermore, the experiment on the polarized Raman spectrum of the single crystal of phenazine indicated that the Raman spectrum of the single crystal of phenazine indicated that the Raman band at 494 cm^{-1} belongs to b_{1g} species and the bands at 449 and 512 cm^{-1} to b_{3g}. It is then very probable that the excited state vibration of 444 cm^{-1} is b_{3g} which corresponds to 449 cm^{-1} in the ground state.[17]

Now, we shall discuss the origin of the 20914 cm^{-1} on the vibronic-spin-orbit interaction scheme.[18] The Hamiltonian containing spin orbit coupling[19] is written to first order in nuclear displacement by

$$\mathbf{H} = \mathbf{H}_o^\circ + \mathbf{H}^\circ_{so} + \sum_a \left\{\left(\frac{\partial \mathbf{H}_o}{\partial \mathbf{Q}_a}\right)^0 + \left(\frac{\partial \mathbf{H}_{so}}{\partial \mathbf{Q}_a}\right)^0\right\}\mathbf{Q}_a$$

where, $\mathbf{H}_o$ is unperturbed term, $\mathbf{H}_{so}$ spin orbit coupling operator and $\mathbf{Q}_a$ indicates normal coordinate, the superscript zero referring to the equilibrium nuclear configurations. The vibronic wave function of the triplet state with which we are concerned is thus written in second order perturbation theory by

$$\begin{aligned}{}^T\theta = {}^T\theta_o &+ \sum_S \frac{\langle S|\mathbf{H}^\circ_{so}|T\rangle}{E_{ST}}{}^S\theta_o + \sum_S \frac{\langle S|\mathbf{H}'_{so}|T\rangle}{E_{ST}}{}^S\theta_o \\ &+ \sum_S \sum_{S'} \frac{\langle S|\mathbf{H}'_o|S'\rangle}{E_{SS'}} \frac{\langle S'|\mathbf{H}^\circ_{so}|T\rangle}{E_{S'T}}{}^S\theta_o \\ &+ \sum_S \sum_{T'} \frac{\langle S|\mathbf{H}^\circ_{so}|T'\rangle}{E_{ST'}} \frac{\langle T'|\mathbf{H}_o'|T\rangle}{E_{TT'}}{}^S\theta_o\end{aligned}$$

where $\mathbf{H}'_o$ and $\mathbf{H}'_{so}$ represent $\left(\frac{\partial \mathbf{H}_o}{\partial \mathbf{Q}_a}\right)^0\mathbf{Q}_a$ and $\left(\frac{\partial \mathbf{H}_{so}}{\partial \mathbf{Q}_a}\right)^0\mathbf{Q}_a$ respectively. S′ and T′ indicate intermediate states. The second term indicates the usual spin orbit coupling for pure electronic state. The third term represents "the direct spin vibronic coupling." The fourth term is called "vibronic coupling in the singlet manifold with spin orbit coupling" and the last term is called "spin orbit coupling with vibronic coupling in the triplet manifold."

As is already described, the vibrationless triplet state is $^3B_{3u}$ $(n\,\pi^*)$ which couple with a $^1B_{1u}$ state through spin-orbit interaction, while the states corresponding to the vibronic band at 20914 cm^{-1} and its relatives must be perturbed by $^1B_{2u}$ state on the same interaction scheme. The selection rule for the spin-orbit coupling with vibronic coupling in the singlet manifold (the fourth term of the above equation) is same as that of the usual spin orbit coupling. Hence, the coupling by this mechanism between the $^3B_{3u}$ $(n\,\pi^*)$ state and the intermediate singlet state $^1B_{2u}$ are almost forbidden from the reason mentioned previously. On the other hand, the last term of the above equation, for which selection rule is shown in Table 3, will be non-zero when the intermediate triplet state is ^3A_u because it interacts vibronically with the $^3B_{3u}$, $^3B_{2u}$, or $^3B_{1u}$ by vibrations of b_{3g}, b_{2g}, or b_{1g} species, respectively and also it interacts with $^1B_{2u}$ by the spin-robit coupling. Since the perturbing vibration to the $^3B_{3u}$ $(n\,\pi^*)$ electronic state is the

TABLE 3. SELECTION RULE FOR VIBRONIC SPIN ORBIT COUPLING WITH THE $^1B_{2u}(y)$ SINGLET STATE

16) L. Goodman and R. W. Harrell, *J. Chem. Phys.*, **30**, 1131 (1959).

17) In the previous paper,[13] we correlated the vibration of 413 cm^{-1} of the excited $(n\,\pi^*)$ singlet state with the ground state vibration of 449 cm^{-1}. However, polarized Raman spectrum reveals that the 449 cm^{-1} must be a b_{3g} vibration and the 494 cm^{-1} belongs to b_{1g} vibration. Then, we revise that the 413 (b_{1g}) vibration of the singlet $(n\,\pi^*)$ state corresponds to the 494 cm^{-1} in the ground state.

18) T. Pavlopoulos and M. A. El-Sayed, *J. Chem. Phys.*, **41**, 1082 (1964).

19) A. C. Albrecht, *ibid.*, **38**, 354 (1963).

b_{3g} vibration of 444 cm^{-1}, the "*forbidden band*" at 20914 cm^{-1} and its relatives borrow their intensities from ^3A_u intermediate state which interacts with $^1B_{2u}$ ($\pi\ \pi^*$) state by spin orbit coupling. Hence, the following scheme is considered as the most possible coupling route,

$$^3B_{3u}(n\pi^*)\frac{Vib}{b_{3g}}{}^3A_u(n\pi^*)\frac{SO}{l_y}{}^1B_{2u}(\pi\pi^*)$$

Group theoretically, the coupling route by the third term of the equation is not excluded, but it gives the same result as that given above.

The MO calculation[20] indicates that the symmetry of the highest occupied π obrital (π_7) of phenazine molecule is b_{2g} and the lowest and the second lowest vacant orbitals (π_8^* and π_9^*) are of b_{3u} and a_u, respectively. The two nonbonding orbitals resulting from the two nitrogen atoms are of $a_g(n_+)$ and $b_{1u}(n_-)$. The first singlet-singlet transition at about 2.9 eV is mainly described as $n_+\rightarrow\pi_8^*$, while the second singlet-singlet transition at 3.2 eV is due predominantly to $\pi_7\rightarrow\pi_8^*$. Roughly speaking, the n_+ orbital is slightly higher in energy than the π_7 orbital. Then, the A_u excited state ($n_+\rightarrow\pi_9^*$), which is forbidden optically, may have almost same excitation energy as that of the $^1B_{2u}$ ($\pi_7\rightarrow\pi_9^*$) state observed at about 5 eV. The singlet–triplet separation of ($n\rightarrow\pi^*$) transition is generally not so large that the ^3A_u ($n_+\rightarrow\pi_9^*$) state state will locate near the $^1B_{2u}$ ($\pi_7\rightarrow\pi_9^*$) state. Therefore, strong spin-orbit coupling between them is expected. The fact that the intensity of the 0—0 band is much weaker than the vibronic bands may be explained from absence of the short axis polarized singlet state in vicinity of this spectral region. This is in accord with the result obtained from the polarized absorption spectrum of ($n\ \pi^*$) singlet state of this crystal.[13]

Vibrational Analysis of Electronic Transition Bands of Coronene

Koichi OHNO, Takashi KAJIWARA, and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received September 10, 1971)

The fluorescence and absorption spectra of coronene dissolved in organic solvents were measured at room temperature. Their vibrational structures were analyzed by reference to the Raman lines of crystalline coronene measured by means of a He-Ne gas laser, and the observed transition energies were compared with the calculated ones. It was suggested that the p-band of the absorption spectrum of coronene (23000—27000 cm^{-1}) is composed of more than one electronic transition, in contrast with the case of benzene. The fluorescence and phosphorescence spectra of coronene in *n*-octane were also measured at 77°K, and their vibrational structures were successfully analyzed with some perturbing vibrations and a few totally-symmetric ones.

The absorption and emission spectra of the first singlet-singlet transition band of coronene in solution show distinct vibrational structures. Further, a good mirror-image correspondence between the intensities and positions of the vibrational peaks of the fluorescence spectra and those of the α-band of the absorption spectra, both in solution and in vapor, was found. Therefore, it is possible to attempt the vibrational anaysis of the bands; such analysis has been carried out by Sidman,[1] Shpolskii,[2] and Mentzel and Zimmermann.[3] However, their results are somewhat tentative and insufficient because of the lack of Raman spectra and infrared absorption spectra of the hydrocarbon.

In order to analyze the vibronic structure, it is necessary to know the frequencies and symmetries of the intramolecular vibrations, which can be introduced from the observation of the Raman spectra. However, no complete measurement of the Raman spectra of coronene has yet been reported. Only one line has been found by Mentzel and Zimmermann;[3] its frequency is 1363 cm^{-1} in a CS_2 solution and 1346 cm^{-1} in a tetrahydrofuran (THF) solution. No other lines could be detected because of the poor solubility of coronene in the solvents. In this work, however, by means of a He-Ne gas laser as a light source, weak but refined Raman spectra of crystalline coronene could be obtained.

The first singlet-singlet transition band of coronene (23000—27000 cm^{-1}), with $\log \varepsilon = 2.5$[4] in the absorption spectrum, has been interpreted as a weakly-allowed electronic transition one, as was indicated by Brocklehurst and Bowen.[5] This concept is the same as for benzene, for both hydrocarbons, benzene and coronene, have a D_{6h} symmetry. For benzene, the lowest one-electron transition is orbitally fourfold-degenerate in the Hückel MO calculation. The degeneracy is removed by electron-electron interactions; then, one degenerate E_{1u} state and two nonde-

4) ε is the extinction coefficient.

generate states, B_{1u} and B_{2u}, are given.

The absorption and fluorescence spectra of benzene vapor have been vibrationally analyzed.[6] The emission spectrum of benzene arises from one quantum addition of an e_{2g} vibration of 606 cm^{-1} to the symmetry-forbidden 0—0 band. The main progression is obtained by several further quanta addition of an a_{1g} vibration of 923 cm^{-1}. In coronene, as was reported by Brocklehurst and Bowen,[5] the vibrational structures of the fluorescence spectrum in heptane at −180°C are largely composed of several series of three bands. There are three remarkable series with interpeak distances of approximately 1360 cm^{-1}. This relation is common in the fluorescence spectrum and also in the α-band of the absorption spectrum, so it is possible to analyze the first singlet-singlet transition bands of coronene with some e_{2g} and a few a_{1g} vibrations, as in the case of benzene.

In this paper, the first singlet-singlet transition bands of coronene will be vibrationally analyzed by reference to the Raman lines of the crystalline sample. The above transition bands and the p- and β-bands of the absorption spectrum will also be analyzed using the transition energies calculated by means of the molecular obtital theory.[7-9] Further, the vibrational structures of the fluorescence and phosphorescence spectra of coronene in glassy *n*-octane (77°K) will be discussed.

Experimental and Results

1.1. Raman Spectra of Crystalline Coronene. In order to analyze the vibronic structures of the electronic spectra of coronene, the Raman lines of crystalline coronene were measured by means of a laser Raman spectrometer with a He-Ne gas laser (Japan Electron Optics Laboratory Co.) attached. The He-Ne gas laser (15803 cm^{-1}) was operated at an output of 40 mW. The applied sample was crystalline powder of high-purity coronene.[10] A single crystal was not employed because the crystal form was of a needle-type, so the polarized Raman spectrum could not be measured.

Although a weak emission spectrum was overlapped on the Raman spectrum, several Raman lines were identified at room temperature and at the temperature of liquid nitrogen (listed in Table 1).

Because a coronene molecule has a D_{6h} symmetry, the e_{2g}, e_{1g}, and a_{1g} vibrations should be Raman-active. Among them, a_{1g} vibrations are generally most intensive; therefore, it can be expected that most of the strong Raman lines obtained in the intramolecular vibration range belong to a_{1g} except for one line of 369 cm^{-1},[12] since, in the lower-frequency region, in general there is no totally symmetric vibration in a large aromatic hydrocarbon such as coronene.

Table 1. Raman lines of the crystalline coronene

	RT		77°K	
Lattice vivration range		40 cm^{-1}		43 cm^{-1}
		57		52
		87		77
				90
Intra-molecular vibration range	S	369 cm^{-1}	M	369 cm^{-1}
	W	435	M	435
	VS	482	VS	487
	W	830	M	571
	VS	1354	W	828
	VS	1371	S	840
	W	1584	VS	1354
	W	1631	VS	1369
			W	1584
			W	1625
			W	1633

Among the observed lines, 1354 and 1371 cm^{-1} are the most intensive lines in the intramolecular vibration range; they may correspond to 1363 cm^{-1} measured in the CS_2 solution by Mentzel and Zimmermann. The complete assignments of the Raman lines have not yet been made because of overlapping with weak emission spectra and because of the difficulty of polarized-Raman-spectra measurements.

In the lattice vibration range, there is a drastic change in the structure of the Raman lines between room temperature and the temperature of liquid nitrogen (Fig. 1). There-

fore, it seems that the phase transition takes place within the temperature range; the measurement of the heat capacity will now be undertaken.

1.2. Absorption Spectra of Gaseous Coronene. For understanding the optical properties of the coronene molecule, the absorption spectra of gaseous coronene are useful.[13] This seven-membered aromatic hydrocarbon, coronene, is very stable even at high temperatures of about 500°C, so that it was possible to obtain vapour phase enough to measure the absorption spectra. Purified coronene (46 mg) was enclosed in a cylindrical cell 3 cm in diameter and 30 cm in length *in vacuo*. The cell was placed in an electric furnace and heated to a constant temperature of 400°C in order to observe the α-band and to 250°C to observe the p-band. A tungsten lamp was used as the light source for the optical-absorption measurement. The most appropriate period of exposure was 20 min for the α-band observation and 10 min for the p-band observation, while the slit width of the spectrograph, a Spex Model 1700 III, was 100 μ. The relative intensities of the absorption peaks of the observed α-band are shown in Fig. 2.

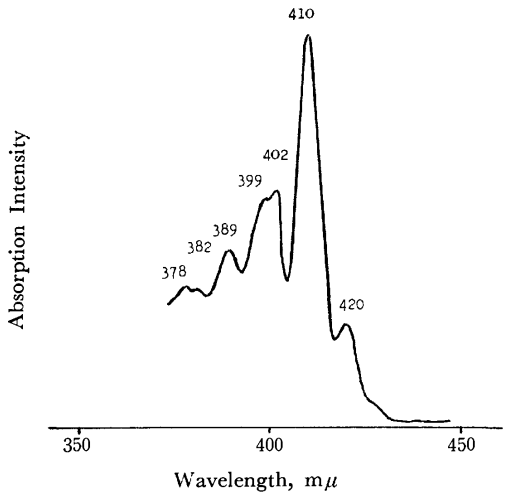

Fig. 2 The absorption spectrum of gaseous coronene.

As is shown in Table 2, the vibrational structure of the α-band of gaseous coronene is very similar to that of the benzene solution of coronene at room temperature reported by Clar,[14] while the p-band of the gaseous state is blue-shifted by a lack of solvent perturbation in comparison with that in solution. The fact that the α-band is hardly affected at all by the solvent supports the assignment of the band to an electronic transition from the $^1A_{1g}$ state to the $^1B_{2u}$ state which is symmetry-forbidden. The absence of the absorption peak at about 4270 Å in the gaseous phase, in contrast with its appearance in the benzene solution, suggests that the peak corresponds to that of the symmetry-forbidden transition.

1.3. Absorption and Emission Spectra of Coronene in Solution. The absorption and fluorescence spectra of coronene in solution were measured at room temperature. Fig. 3 and 4 show the absorption and emission spectra of coronene in THF. The peaks are named, as is shown in the figures,

according to the repeating structures and the mirror-image correspondence.

The vibrational structures of the fluorescence spectra of coronene in solution are composed of three (A_1, B, and C) or four series (A_1, A_2, B, and C), with a common interpeak distance, as in the case of the α-band of the absorption spectra of coronene. Clearly, there is a good mirror-image correspondence between the fluorescence spectra and the α-band of the absorption spectra. The mirror position at about 4270 Å (O-peak) coincides with the O-O position of the first singlet-singlet transition predicted by the absorption spectrum of gaseous coronene.

1.4. Fluorescence and Phosphorescence Spectra of Coronene in n-*Octane at 77°K.* As is well known, the quasi-linear spectra in *n*-paraffin at low temperatures give rather fine vibronic structures.[2,5] Therefore, the fluorescence and the phosphorescence spectra of high-purity coronene in *n*-octane were measured at 77°K in order to analyze the vibronic structures of the $^1A_{1g}$-$^1B_{2u}$ transition band and also the $^1A_{1g}$-$^3B_{1u}$ transition one. The resolving power of the spectra observed by means of a Spex 1700 III spectrograph are satisfactory (Fig. 5); for example, the line-widths at 4320 Å and at 4440 Å are about 4 Å (21 cm^{-1}). It is noted that the envelope of this fluorescence spectrum shows a very similar pattern (A_1, A_2, B, C, and their repetition) to that of the fluorescence bands in THF at room temperature. However, there exist some multiplicities. According to a recent report by Pfister,[15] the splittings are caused by many possible environments of a solute molecule dissolved in *n*-paraffin crystal. Although the number of possible sites depends, in general, upon the method of crystallization, in any of our measurements there were two possible sites for the case of coronene in *n*-octane; there exist two fluorescence origins, 23529 cm^{-1} and 23495 cm^{-1}, but only one phosphorescence origin is observed, at 19399 cm^{-1}. However, if the other phosphorescence origin is assumed to be 19411 cm^{-1}, the vibronic bands can be divided into two series with similar vibronic patterns; one series starts from 19399 cm^{-1}, and the other, from 19411 cm^{-1}.

Vibrational Analysis of the Spectra in THF

2.1. First singlet-singlet Transition Bands. The α-band of the absorption spectrum shows a good mirror-image correspondence to the fluorescence spectrum. The O-peak (4264 Å in Fig. 3 or 4265 Å in Fig. 4) is in the mirror position. As has already been suggested, the O-peak corresponds to the 0—0 position of the transition between the lowest $^1A_{1g}$ state and the lowest $^1B_{2u}$ state, which is a symmetry-forbidden transition and which is allowed with a one-quantum addition of an e_{2g} vibration. The main progressions are obtained by the further addition of several quanta of a_{1g} vibrations.

Therefore, it is possible to analyze the vibronic structure of the first singlet-singlet transition with several e_{2g} vibrations and a few a_{1g} vibrations. The results of the analysis of the α-band and the fluorescence spectrum of coronene in THF are shown in Table 3. The vibrational structure of the α-band (or the fluorescence spectrum) is composed of four series (A_1, A_2, B, and C), with a common interpeak distance of about 1340—1370 cm^{-1}. The adding frequency ν_0 (a_{1g}), reveals the existence of the totally

symmetric vibration of 1371 or 1354 cm^{-1} found in the Raman spectrum of crystalline coronene by means of a He-Ne gas laser. This frequency also appears in both the p- and β-bands. ν_1, ν_2, ν_3, and ν_4 in Table 3 are perturbing vibrations belonging to e_{2g}. Among them, ν_1 (375 cm^{-1}) corresponds to the Raman line (369 cm^{-1}), which may be one of the non-totally symmetric Raman active vibrations, e_{2g} or e_{1g}, so that it is possible to predict that the Raman line (369 cm^{-1}) is an e_{2g} vibration.

Two peaks (A_1^{-1} and B^{-1} of Fig. 3—1) apperaing on the longer-wavelength side of the α-band, and also the two peaks, A_1^{-1} and B^{-1} of Fig. 4, on the shorter-wavelength side of the fluorescence spectrum, have almost identical frequency differences form the O-peak which correspond well to the frequencies of the perturbing vibrations, ν_1 and ν_3. As has already been indicated by Brocklehurst and Bowen,[5] these bands seem to be the hot bands of the lowest singlet-singlet transition, for these bands could not be observed at the temperature of liquid nitrogen in either the absorption or in the fluorescence spectra. Although the agreements in the vibrational analysis between the hot-band florescence and the α-band are not adequate, these discrepancies can easily be understood by considering the reabsorption process.

Sidman[1] has assigned 990 cm^{-1} (corresponding to ν_3 in our assignment) to ν_1 (370 cm^{-1}, e_{2g})+ν (620

cm^{-1}, a_{1g}) but the absence of the 620 cm^{-1} line in the Raman spectrum suggests that his assignment is not correct.

2.2. p-Band. In the p-band of the absorption spectrum, the values of log ε range from 3 to 4.8 (Fig. 3—2). The intensity of the *D*-peak at 3547 Å is much weaker than that of any other peak in the p-band, while it is much stronger than the peaks in the α-band. Therefore, this peak seems to belong to another electronic transition.

Taking the *E*-peak (Fig. 3—2) at 3459 Å (28910 cm^{-1}) as the 0—0 position, we can obtain exactly the same frequencies (Table 4) as in the vibrational analysis of the α-band. In the p-band, the vibration of 530 cm^{-1} is the most effective perturbing vibration, and the additional frequency is 1365 cm^{-1}.

The two peaks (I and J of Fig. 3—2) in the shorter-wavelength region of the p-band have an interpeak distance of 445 cm^{-1}, which corresponds to the frequency of 1420—975 cm^{-1}, but the interpeak distance between G and I is 1550 cm^{-1}, which has not yet appeared elsewhere. If I and J are the repeating structure of G and H with a one-quantum addition of a totally symmetric vibration of 1550 cm^{-1}, the repetition of the most intense peak, F, must appear at the 530+1550 cm^{-1} position. Furthermore, although H is much weaker than G, J has an intensity almost comparable to that of I. Therefore, it is unreasonable to assign I and J to the repetition of G and H. It is, then, preferable to assume the existence of another electronic transition.[16] (Table 4)

16) This will be considered in Sec. 3.

2.3. β-Band. The β-band is clearly composed of an allowed transition, with log ε=5.4 at the most intensive absorption peak, which is assigned to the $^1A_{1g}$-$^1E_{1g}$ transition, as in the case of benzene. As is shown in Table 5, the vibrational structure of the β-band also reveals the totally symmetric vibration of 1370 cm^{-1} which appears in the β-band, the p-band, and the Raman spectrum.

3. Comparison of Transition Energies between Calculated and Observed Values

The molecular orbitals of coronene and their energies were first calculated by Moffitt and Coulson[17] by means of the simple LCAO-MO method. According to their calculations, the highest occupied MO belongs to e_{2u} and the lowest vacant MO belongs to e_{1g}, so that the lowest one-electron transition is orbitally fourfold degenerate, as in the case of benzene. The electron-electron interaction removes the fourfold

degeneracy to give one degenerate E_{1u} state and two nondegenerate states, B_{1u} and B_{2u}.

The transition energies calculated by Ham and Ruedenberg[7] and those reported by Hummel and Ruedenberg[8] reproduce the experimental absorption spectra somewhat better than the conventional Pariser-Parr SCF-MO calculation, as is shown in Fig. 6.[19] The agreement with the experimental results has been considered plausible. By many authors, it has been assumed that the first weak band at 23400 cm^{-1} might correspond to the 2600 Å band of benzene ($^1B_{2u}$); the band in the 29000 cm^{-1} region, to the 2000 Å band of benzene ($^1B_{1u}$), and the most intensive band, at 33000 cm^{-1}, to the 1800 Å band of benzene ($^1E_{1u}$). However, these correspondences may not always be appropriate, because, in the case of coronene, a much larger number of electronic configurations must be considered in the CI calculation than in the case of benzene.

Recently, a more improved calculation has been presented by Gutfreund and Little.[9] In their calculation, the correlation effects of the π-electrons were considered carefully, and it was shown that the Coulomb interaction between π-electrons in a conjugated molecule is screened by the presence of other π-electrons and that, therefore, the bare Coulomb potential must be replaced by the appropriate effective interaction potential. The obtained transition energies for the low-lying singlet states of polycyclic hydrocarbons, such as coronene, tetracene, and pyrene, agreed plausibly with the absorption spectra experimentally obtained. In the case of coronene, the ambiguous p-band can be explained clearly by their calculation. According to their calculation, it seems that the conventional assignments are not appropriate; thus, it is preferable to conclude that the α-band of coronene corresponds to the two forbidden transitions; the p-band, to the three forbid-

19) The conventional Pariser-Parr MO calculation gives much larger transition energies.

den transitions, and the β-band, to the one allowed transition.

In the present work, we calculated the transition energies of coronene by the SCF-MO CI method, with effective electron repulsion integrals as in the Gutfreund and Little calculation. The calculated transition energies and oscialltor strengths are listed in Table 6. These results show that there are three states between $^1B_{1u}$ and $^1E_{1u}$, as in the results of Gutfreund and Little.[9] We found that the three states (31751, 32171, and 32501 cm^{-1}) belong to $^1A_{1g}$, so that the transitions between these states and the ground states ($^1A_{1g}$) are forbidden and vibronically allowed by e_{1u} vibrations. Although the e_{1u} vibrations are infrared-active, the infrared spectrum of coronene has not been measured; therefore, we cannot discuss further the vibronic structures of the p-band. In order to analyze the observed p-band, it would be desirable to determine the vibronic states by a calculation including the vibronic interactions among the three A_{1g} states, the lowest $^1B_{1u}$ state, and the $^1E_{1u}$ state. Thus, we should prefer to suggest that the p-band is composed of more than one electronic transition.

4. Vibrational Analysis of Emission Spectra in *n*-Octane

The observed fluorescence and phosphorescence spectra of coronene in *n*-octane at 77°K were analyzed with reference to the results of the preliminary analysis reported in the Experimental and Results sections and with reference to the observed Raman lines. The assignments are shown in Table 7, while the obtained fundamentals are listed in Table 8. The fundamentals obtained from the phosphorescence spectrum agree well with those from the fluorescence one; most of the obtained Raman lines are also found in the fundamentals derived from the fluorescence spectrum. The adding a_{1g} frequencies found in the fluorescence spectra are 1347 cm^{-1} and 1366 cm^{-1} in Series I, and 1349 cm^{-1} and 1368 cm^{-1} in Series II. These frequencies coincide well with the most intensive Raman lines, 1354 cm^{-1} and 1369 cm^{-1}. The most effective perturbing fundamentals are 367, 1001, 1407, and 1443 cm^{-1} in the fluorescence spectrum and 367, 484, 1154, 1224, 1407, 1439, and 1633 cm^{-1} in the phosphorescence one. As was mentiaed in Sec. *2.1*, almost all of these should be e_{2g} vibrations; however, 484 cm^{-1}, corresponding to the intensive Raman line, 487 cm^{-1}, may be an a_{1g} vibration, since the 964 cm^{-1} observed in the phosphorescence spectrum approximately equals $484 \times 2 = 968$ cm^{-1}.

The authors wish to thank Professor Mitsuo Ito, Tohoku University, and Dr. Toru Yokoyama, Japan Optics Laboratory Co., for their kind cooperation in making the Raman-spectrum measurements. The authors are also indebted to Professor Satoshi Iwahima, Meisei University, for preparing the high-purity coronene used for the spectroscopical measurements.

Polarized Absorption Spectra of TCNNQ-Aromatic Hydrocarbon Molecular Complexes

Yasumasa J. I'HAYA, Toru YUNOKI,* and Noboru SUZUKI

Department of Materials Science, The University of Electro-Communications, Chofu, Tokyo

(Received September, 11, 1971)

Polarized absorption spectra of TCNNQ and TCNNQ-anthracene, pyrene, phenanthrene (Group 1), 1,2-benzanthracene, chrysene and triphenylene (Group 2) molecular complexes were measured in the frequency range of 13.5—42 kK at room temperature and 80°K. The mole ratio of donor to acceptor was found to be 2 : 1 for Group 1 complexes and 1 : 1 for Group 2 complexes. Two broad bands observed in each spectrum of these complexes were assigned to be the first and the second charge-transfer (CT) bands. The CT bands were enhanced in intensity and displaced to the red at 80°K. The first CT bands were confirmed to be associated with the charge transfer from the highest occupied molecular orbital (HOMO) of donor to the lowest vacant molecular orbital (LVMO) of acceptor. The charge transfer mechanism for the second CT bands may be divided into two classes; for Group 1 complexes it is mainly due to the second LVMO of acceptor, while for Group 2 complexes, in addition to this, there is a possibility of the charge transfer from the second HOMO of donor to the LVMO of acceptor.

TCNNQ (11,11,12,12-tetracyano-1,4-naphthaquinodimethane) is a new cyanocarbon acceptor with the electron affinity 1.49 eV and is known to form sufficiently strong charge-transfer π-complexes with aromatic hydrocarbons.[2] In a previous paper,[2] we have presented a preliminary survey on the polarized absorption spectra of the molecular complexes which involve TCNNQ as an acceptor and anthracene, pyrene, phenanthrene, 1,2-benzanthracene, chrysene

and triphenylene as donors. We have shown that the second charge-transfer (CT) bands of these complexes are mainly associated with a charge transfer from the highest occupied molecular orbital of donor to the *second* lowest vacant molecular orbital of acceptor.

In the present communication, we shall report the details of the polarized absorption spectra of TCNNQ and these TCNNQ molecular complexes observed at room temperature and liquid nitrogen temperature. To the authors' knowledge, there has been published no spectral datum of CT bands of a molecular complex observed at such a low temperature. We shall show that CT bands enhance their spectral intensities and disclose their vibrational structures at liquid nitrogen temperature. Using the low-temperature data, we re-examine the relationships between charge-transfer transition energies and highest occupied molecular orbital energies of donors.

Experimental

TCNNQ was synthesized by Chatterjee's method,[1] and purified by repetitive recrystallization from methanol and methylene chloride, followed by vacuum sublimation. Anthrancene, pyrene, phenanthrene, 1,2-benzanthracene, chrystene and triphenylene used as electron donors were of reagent grade from commercial sources and they were purified by recrystallization and sublimation. The molecular complex single crystals of microscopic size were prepared from the purified TCNNQ and donors by simultaneous sublimation onto a heated glass plate.

The absorption spectra of TCNNQ and its molecular complexes in solution were measured in methylene chloride by a JASCO ORD/UV-5 spectrophotometer. The mole ratio of donor to acceptor in each molecular complex was determined spectroscopically.

The polarized absorption spectra were measured with a specially designed microspectrophotometer. A 500 W high pressure xenon-arc lamp (Ushio Electric Co.) was used as a light source, which was operated with a 20A stabilized power supply. The light was passed through a grating monochrometer (Hitachi model 139), polarized by a Rochon prism, and focused onto a sample crystal mounted on a sample holder. The sample crystals, selected from among a number of sublimation flakes, were mounted between quartz objective slides which edges were sealed by Araldite cement in order to avoid sublimation of samples. The sample holder and two objectives of reflection type (Olympus Optical Co.) were set in a cryostat which had two cryogen containers. The section of the cryostat is shown in Fig. 1. Sample temperatures were measured with a copper-constantan thermocouple while spectra were being taken. An R-136 photomultiplier tube (Hamamatsu Television Co.) was used as the detector.

The directions of crystal axes were examined by the observation under a polarizing microscope. The crystal thickness was roughly estimated from birefringence and retardation using the polarizing microscope. The crystal spectra were observed from the direction normal to the developed face of a crystal for two polarizations, parallel and perpendicular to the crystal elongated axis which we hereafter call the *l*-axis. To each molecular complex, the spectral measurements were carried out for several crystals of different thicknesses. The position of each absorption maximum was found to be not dependent upon crystal thickness.

Results

1. Crystal and Solution Spectra of TCNNQ. The TCNNQ crystal is orthorhombic, space group *Pbca* with cell dimensions of $a=13.210$ Å, $b=7.209$ Å, and $c=26.629$ Å, eight molecules being contained in the unit cell. Fig. 2, the projection along the *a*-axis, shows that the TCNNQ molecule is non-polar in the crystal.[3] We have observed the *b*-axis and *c*-axis polarized spectra as well as the *a*- and *b*- polarized spectra, since we found the presence of two different crystal habits. They are shown in Figs. 3 and 4 together with the solution spectrum.

The solution spectrum in methylene chloride consists of two main bands, each having a few vibrational structures which maxima are estimated to be located at 25.3 kK ($\varepsilon=33{,}000$) and 34.7 kK ($\varepsilon=6{,}900$). Higher frequency bands have been observed at 45.2 kK and 48.1 kK.[4]

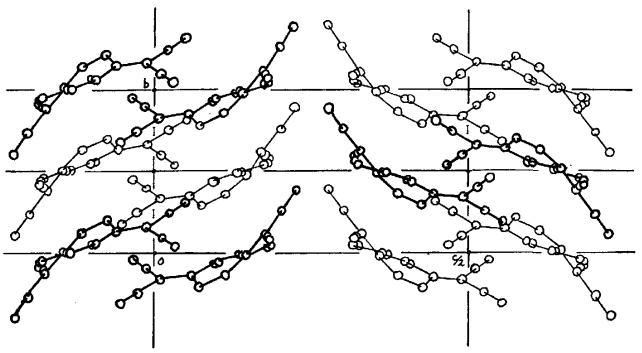

Fig. 2. Projection of the crystal structure of TCNNQ along the *a*-axis on the *bc* plane.

3) F. Iwasaki, private communication.
4) N. Suzuki and Y. J. I'Haya, *Tetrahedron*, **26**, 5379. (1970).

The *a*-axis polarized spectrum in Fig. 3 has two absorption bands; one at 33.8 kK is rather narrow and the other in the 22—27 kK region is quite broad. The *b*-axis polarized spectrum in the same figure has one narrow band at 31.2 kK with an weak shoulder at 25.6 kK.

In the *bc*-face spectra (Fig. 4), the *b*-axis polarized spectrum has a peak at 30.9 kK and a weak shoulder at 26.0 kK, while the *c*-axis polarized spectrum has two peaks at 22.9 kK and 33.6 kK and a shoulder at 25.1 kK.

(—·—·— solution spectrum in methylene chloride)

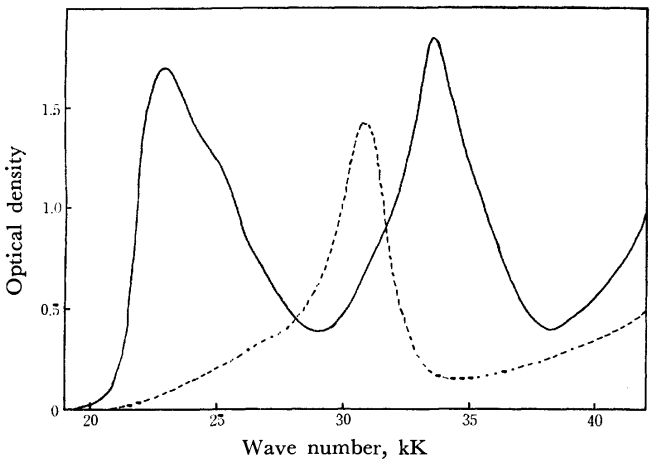

Fig. 4. Polarized absorption spectra of TCNNQ crystal observed from the *a*-axis at room temperature.

At liquid nitrogen temperature, we have not found any significant change in the overall spectrum of each polarization.

2. Composition and Solution Spectra of Molecular Complexes. The mole ratio of donor to acceptor was found to be 2 : 1 for anthracene-, pyrene-, and phenanthrene-TCNNQ complexes, while that for 1,2-benzanthracene-, chrysene-, and triphenylene-TCNNQ complexes was 1 : 1. The former is called Group 1 complexes and the latter Group 2 complexes in the following.

Measurement of the CT bands in a solution spectrum of each molecular complex was very difficult, because TCNNQ itself absorbed strongly in the longer wavelength side. The first CT bands were observed for all the complexes but second CT bands were not clearly observed in solution. The wave numbers of the first CT band maxima observed in solution are listed in the second column of Table 1.

3. Crystal Spectra of Molecular Complexes. Two broad bands were observed in each polarized absorption spectrum of all the molecular complexes studied, as shown in Figs. 5—10. These two bands (14—23 kK) are not local excitation bands but can be assigned to be the first and second CT bands, since the lowest transition of TCNNQ has an absorption maximum at 25 kK and those of electron donors appear at much shorter wavelength region. The wave numbers of these CT band maxima are listed in Table 1.

(a) Anthracene-TCNNQ (2 : 1) Complex: The first CT band appears at 14.3 kK in the room-temperature spectrum and is polarized in the *l*-axis, while the second CT band at 20.8 kK and polarized in a direction perpendicular to *l*. The polarization ratio, $I(//l)/I(\perp l)$, at each band maximum is 2.6 for the first CT band and 0.36 for the second CT band. When the crystal temperature is down to 80°K, the first CT band is displaced to the red by 600 cm^{1} and the second CT band remains unshifted, both bands being remarkably enhanced in intensity. Furthermore, it is seen that the first CT band discloses a vibrational structure at 80°K. The broad band in the 25—30 kK region is a local exci tation band associated mainly with the 25.9 kK transition of TCNNQ and partly with the 26.3 kK transition of anthracene.

Table 1. Wave numbers of absorption peaks in solution and crystal charge-transfer (CT) spectra of aromatic hydrocarbon-TCNNQ complexes (kK)

Donor molecule	Solution[a]	Crystal			
		Room temp.		Liq. N_2 temp.	
	CT	1 st CT	2 nd CT	1 st CT	2 nd CT
Anthracene	14.8	14.3	20.8	13.7	20.8
Pyrene	15.3	14.6	21.9	14.3	20.8
Phenanthrene	20.8	17.6	22.9	16.6	21.2
1,2-Benzanthracene	15.4	15.6	19.2	14.2	19.2
Chrysene	16.7	16.1	19.5	15.5	18.3
Triphenylene	21.7	18.5	21.6	18.1	21.3

a) Solvent: CH_2Cl_2. Only one CT band was observed in solution.

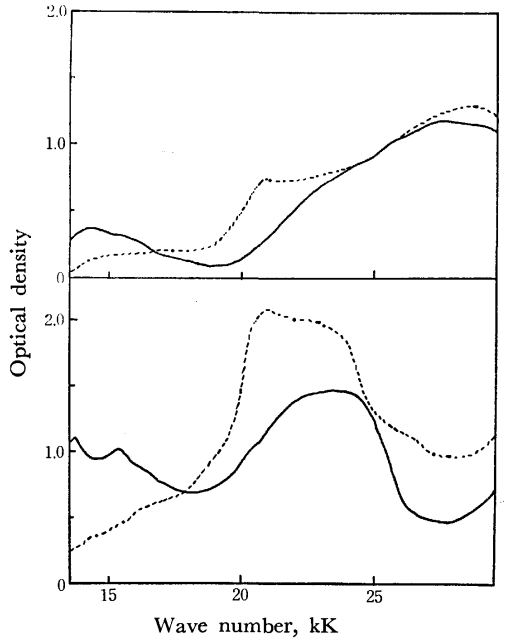

Fig. 5. Polarized absorption spectra of anthracene-TCNNQ complex at room temperature (above) and 80°K (below). Solid line: $//l$ spectrum; Broken line: $\perp l$ spectrum.

(b) Pyrene-TCNNQ (2 : 1) Complex: The 14.6 kK and 21.9 kK absorption bands are assigned to be the first and the second CT bands, respectively, since they are enhanced in intensity at low temperature. The polarization ratio is 3.6 for the first CT band and is 0.46 for the second CT band. The longest wavelength absorption spectrum of TCNNQ and other local excitation bands are to appear around at 25 kK and/or in the frequency region higher than 25 kK. At 80°K, the first and the second CT bands are displaced by 300 cm^{-1} and 1,100 cm^{-1}, respectively, to the red compared with those taken at room temperature. Here again the low temperature spectrum has clear vibrational structure.

(c) Phenanthrene-TCNNQ (2 : 1) Complex: The polarized spectra of this complex resemble those of the anthracene- and pyrene-TCNNQ complexes described above. The first CT band located at 17.6 kK is polarized parallel to the l-axis and the second CT band at 22.9 kK perpendicular to l. The observed polarization ratios are 2.4 for the former and 0.43 for the latter. At 80°K, vibrational structures become clearer in both bands, while their longest wavelength peaks corresponding probably to 0,0 transitions are shifted

to the red. The sharp absorption bands appearing around at 28.5 kK are due to phenanthrene.

(d) 1,2-Benzanthracene-TCNNQ (1 : 1) Complex: The spectrum of the complex is quite different from those three described above. The first and the second CT bands appear at 15.6 kK and 19.2 kK, respectively, both being polarized along the *l*-axis. At 80°K, the vibrational structure of the first CT band becomes clear-cut and the lowest frequency peak, probably a 0,0 band, is displaced by 1,400 cm^{-1} to the red. There has not frequently been observed an intermolecular CT spectrum that shows such a clear vibrational structure. On the other side, the lowest frequency peak of the second CT band appears as a shoulder of the corresponding band in the low-temperature spectrum, no spectral shift being observed.

Moreover, we have observed another absorption band which is polarized perpendicular to the *l*-axis and the absorption peak of which is located at 22.1 kK. The band is enhanced in intensity and displaced to the red by 500 cm^{-1} at 80°K. The band can not be attributed to any local excitation and is tentatively assigned to be the third CT band. The polarization ratio for this band is 0.61, while those for the first and the second CT bands are 5.2 and 3.9, respectively. Around at 25 kK, there appear the local excitation bands of 1,2-benzanthracene and TCNNQ.

(e) Chrysene-TCNNQ (1 : 1) Complex: The spectrum of the complex is rather broad in both polarization directions, parallel and perpendicular to the *l*-axis. The absorption shoulder at 16.1 kK can be assigned as the first CT band. The *l*-polarized spectrum has a peak at 19.5 kK which may be regarded as the second CT band. The polarization ratios are 2.2 and 1.2, respectively, for the first and the second CT bands. These broad bands become somewhat narrow at low temperature. The 16.1 kK shoulder is still not resolved well and shifted to 15.5 kK, while the 19.5 kK peak

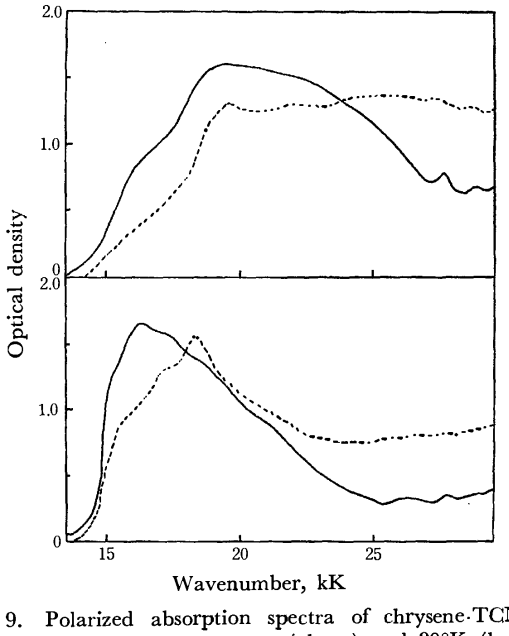

Fig. 9. Polarized absorption spectra of chrysene-TCNNQ complex at room temperature (above) and 80°K (below). Solid line: //*l* spectrum; Brolen line: ⊥*l* spectrum.

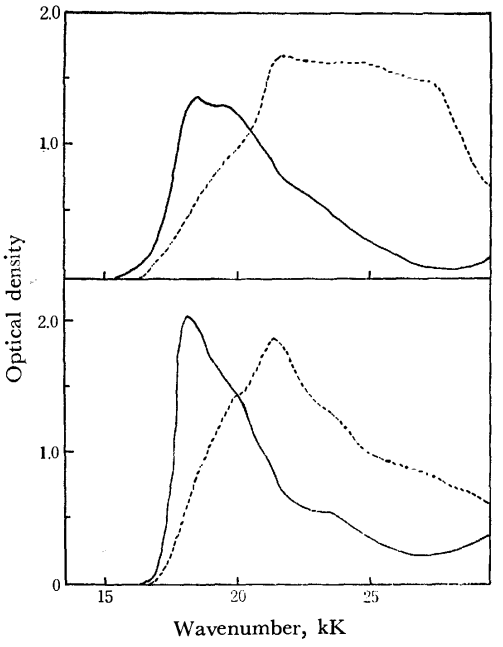

Fig. 10. Polarized absorption spectra of triphenylene-TCNNQ complex at room temperature (above) and 80°K (below). Solid line: //*l* spectrum; Broken line: ⊥*l* spectrum.

appears more clearly at 18.3 kK. The absorption band appearing around at 27 kK is evidently due to the local excitation associated with the *p*-band of chrysene (27.2 kK).

(f) Triphenylene-TCNNQ (1 : 1) Complex: The first CT band is found at 18.5 kK with an *l*-axis polarization and the second CT band at 21.6 kK with a polarization perpendicular to *l*. The broad absorption band in the 23—28 kK region is due to the local excitation associated with the TCNNQ transition and the 28.6 kK transition of triphenylene. At 80°K, both bands become considerably sharp, enhance their intensities, and shift to the red by 900 cm^{-1} and 300 cm^{-1}, respectively. The polarization ratios are 2.2 and 0.46, respectively, for the first and the second CT bands.

Discussion

Our previous calculation of the electronic spectrum of TCNNQ, assuming the molecule to be planar, has shown that in solution the 25.3 kK absorption band corresponds to the lowest B_2 transition polarized along the molecular longer axis and the weak 34.7 kK band to the next to the lowest A_1 transition polarized along the molecular short axis.[4] In the crystalline state, the bands are markedly intensified and broadened compared with the solution spectrum. The fact that the molecular structure of TCNNQ is non-planar in crystal puzzles us how to explain the observed crystal spectra and their polarization. Though a theoretical estimate of optically allowed exciton levels has to be carried out on the basis of the actual molecular structure, we may attribute the 33.8 kK (*a*-polarized) and 31.2 kK (*b*-polarized) bands in Fig. 3 to the two components of the 34.7 kK A_1 transition. The A_1 transition may be split and intensified through an interaction with

the strong B_2 transition. Similarly, the 33.6 kK (*c*-polarized) and 30.9 kK (*b*-polarized) bands appearing in the *bc*-face spectra (Fig. 4) may be attributed to the components of the same 34.7 kK transition. The broad bands in the 22—27 kK region in both the *ab*- and *bc*-face spectra are ascribed to the 25.3 kK B_2 transition of the free molecule.

Unlike the TCNQ- and TCNE-polycyclic aromatic hydrocarbon complexes, there exist two kinds of composition for the TCNNQ complexes as mentioned before, that is those of the mole ratios of donor to acceptor 2 : 1 and 1 : 1. Though the molecular sizes of Group 1 hydrocarbons are certainly smaller than those of Group 2 hydrocarbons, the difference in molecular size is not great enough to explain the existence of the two forms. A similar situation was found in some *p*-benzoquinone complexes.[5] This is probably due to the non-planar structure of the TCNNQ molecule, above and below which conditions for charge transfer interaction may be different.

As shown before, the TCNNQ molecular complexes studied exhibit two broad absorption bands, with the exception of the 1,2-benzanthracene-TCNNQ complex which shows three bands, in the spectral region where no local excitation band is expected to appear. We have assigned them to be the first and the second CT bands. In Group 1 complexes, the first CT bands are clearly polarized along the crystal elongated *l*-axes and the second CT bands are perpendicular to them. The two CT bands of Group 2 complexes, however, have both polarization components, except for the triphenylene-TCNNQ complex which exhibits polarization ratios of the first and the second CT bands quite similar to Group 1 complexes.

5) T. Amano, H. Kuroda, and H. Akamatu, This Bulletin, **42**, 671 (1969).

The wave numbers of the absorption maxima of the first and the second CT bands, $h\nu_{CT1}$ and $h\nu_{CT2}$, are plotted in Fig. 11 against the highest occupied molecular orbital (HOMO) energies of the corresponding polycyclic aromatic donors. The values of these HOMO energies are taken from the results of the Hückel molecular orbital calculations (the overlap integrals neglected)[7] and appear as χ_i on the ordinate of Fig. 11. Actual *i*th orbital energy is $\alpha+\chi_i\beta$ where α is the Coulomb integral for carbon and β is the carbon-carbon resonance integral. For the first CT bands, a straight line can be drawn (line I) as usual cases, so that these bands are most probably associated with the charge transfer from the HOMO of donor to the lowest vacant molecular orbital (LVMO) of acceptor. We have found that the energies of the first CT states of these complexes can be well expressed in terms of the ionization potentials, I_p, of the donor molecules as (in eV)

$$h\nu_{CT1} = 0.69\, I_p - 3.29.$$

The 25 kK band of TCNNQ, assigned to be the B_2 transition polarized along the molecular longer axis, appears as a local excitation band polarized perpendicular to the *l*-axis which coincides with the polarization direction of the first CT bands in all Group 1 complexes. The donor molecules and TCNNQ are therefore supposed to be alternately stacked along the *l*-axis in Group 1 complex crystals.

A plot of $h\nu_{CT2}$ *versus* the HOMO energy of donor products two linear relationships, Line II for Group 1 complexes and Line III for Group 2 complexes. The charge transfer mechanism for the second CT bands of these complexes may, therefore, be divided into two classes depending upon the mole ratio of donor to acceptor. A current explanation for the origin of a second CT band is that the band is mainly associated with a charge transfer from the second HOMO of a donor molecule to the LVMO of an acceptor molecule.[7] If we assume such a charge transfer mechanism for Group 1 complexes, the magnitude of $h\nu_{CT2}$ turns out to be in the order anthracene—pyrene—phenanthrene, which is entirely in the reverse order compared with the present observation.

We tentatively conclude, therefore, that the second CT bands of Group 1 complexes may be associated mainly with the charge transfer from the HOMO of donor to the *second* LVMO of acceptor. A similar explanation was given by Iwata, Tanaka, and Nagakura for the 1,2,4,5-tetracyanobenzene-aromatic donor complexes.[8] As they pointed out, Line II should be drawn parallel with Line I in Fig. 11, if a simple relationship is assumed for both first and second CT

$$h\nu_{CT} = I_p - E_A - C$$

bands. Here E_A is the electron affinity for the lowest and/or the second lowest vacant orbital of acceptor and C the sum of several terms including electrostatic

7) H. Kuroda, I. Ikemoto, and H. Akamatu, This Bulletin, **39**, 1842 (1966) and subsequent papers.

interaction energy, which may be supposed to be approximately constant for a given acceptor. The reason why this is not the case is just uncertain.

On the other side, a plot $h\nu_{CT2}$ of Group 2 complexes against the second HOMO energy of donor (the squares drawn in Fig. 11) suggests that there is a roughly linear relationship between them. Thus in this case, we can not exclude the possibility of a charge transfer from the second HOMO of donor. Our tentative conclusion is that the second CT bands of Group 2 complexes may be due to a mixed charge transfer mechanism, one from the HOMO of donor to the second LVMO of acceptor and the other from the second HOMO of donor to the LVMO of acceptor.

As mentioned before, the second CT band in each crystal spectrum is polarized in the direction almost perpendicular to the polarization direction of the corresponding first CT band. This fact suggests that the donor molecule and TCNNQ are alternately and slantly stacked along the *l*-axis so that charge transfer can occur in two directions, almost parallel and perpendicular to the *l*-axis.

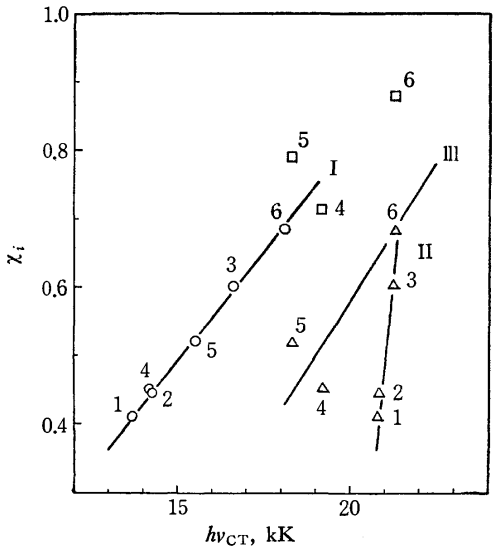

Fig. 12. Charge-transfer transition energies (80°K) *vs.* the Hückel molecular oribtal energy coefficients, χ_i, of the polycyclic aromatic donors. Symbols are the same as in Fig. 11.

The data taken at 80°K are plotted in Fig. 12 in exactly the same manner of Fig. 11. It is seen that the linear relationship for the first CT bands holds more precisely than in the room-temperature data. Line I of Fig. 12 is in parallel with Line I of Fig. 11 and is displaced to the red by 700 cm^{-1} compared with the latter. Line II strongly suggests that the second CT bands of Group 1 complexes are due to the charge transfer from the HOMO of donor to the second LVMO of acceptor, but the situation that its slope is so steep is again puzzling. Plots of $h\nu_{CT2}$ of Group 2 complexes against the HOMO energy of donor (triangles in Fig. 12) and the second HOMO energy of donor (squares in Fig. 12) both deviate considerably from linearity. Rather the datum for the triphenylene-TCNNQ complex seems to join with those for Group 1 complexes, namely Line II. Originally the crystal spectra of the triphenylene-TCNNQ complex taken at room temperature and at 80°K resemble those of Group 1 complexes in regard to their polarizations.

Thus the low-temperature data clearly support our conclusion on the charge transfer mechanism of these complexes obtained from the room-temperature data. On the other side, we can not say anything in detail about the polarization and intensity of these CT bands since the crystal structures of these complexes have not been analysed. Specifically, it is hard to understand that the intensity of each CT spectrum is as large as that of the strong TCNNQ local excitation. A series of studies along such requests is being planned, together with a theoretical estimate of optically allowed exciton levels of the TCNNQ crystal.

This work was supported in part by a grant of Ministry of Education.

Light-scattering Studies of the Interaction of Sodium Chondroitin Sulfate C with Bovine Serum Albumin[1)]

Masayuki NAKAGAKI and Yoh SANO

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto

(Received September 29, 1971)

Angular light-scattering investigations were carried out in 0.01 M sodium chloride solutions at 25°C for various mixed solutions of bovine serum albumin (BSA) and chondroitin sulfate (Chs). The experimental values of molecular weight and of the molecular dimensions showed an entirely different tendency from the calculated values, and we may assume that there is no interaction between them. It has, therefore, been concluded that Chs interacts with BSA strongly and that a complex is formed between them. For the soluble complex thus formed, the number of the bound BSA molecules with one Chs molecule was expressed by a Langmuir-type equation as a function of the amount of excess BSA existing free in the solution. When the latter was sufficiently large, the number of bound BSA molecules per Chs molecule approached 20.6.

A Zimm plot of the complex was drawn, and the molecular weight, the radius of gyration, and the second virial coefficient of the complex were determined. It has been concluded from these results that the complex molecule has a long-like shape; the length was about 30% longer, but the diameter was about 6 times thicker, than the Chs molecule at the maximum binding of BSA.

Chondroitin sulfate, one of natural acid mucopolysaccharides composes the primary part of the cartilage, together with collagen-like protein, and is present in the skin or in other connective tissues as mucoproteins, playing important physiological functions. Since the acid mucopolysaccharides are anionic polyelectrolytes, their protein complexes are bound primarily by polar linkages. The interaction between chondroitin sulfate and bovine serum albumin has been studied by quite a few workers.[2-11)] It seems, however, that is studies reported thus far have been little connected with the complexes themselves. Soluble complexes formed between chemically-different macromolecular species have recently come under investigation, but the angular light scattering of solutions containing the soluble complexes[12-14)] has not yet been studied very extensively. In the present paper, the interaction between bovine serum albumin and chondroitin sulfate will be discussed on the basis of the experimental results obtained by the light-scattering technique and the binding coefficient, *i.e.*, the binding ratio of protein to chondroitin sulfate; the molecular shape and size of the soluble complex will also be reported.

Experimental

Materials and Solvents. The sodium chondroitin sulfate (hereafter called Chs) used in this work was of the C type; it was extracted so carefully that it contained no electrolyte except, sometimes, sodium chloride. This sample is the same as that investigated by Nakagaki and Ikeda[15)] by the light-scattering technique in various ionic strengths. For the purpose of the experiments, a stock solution of about 1% was prepared, kept in a refrigerator at 4°C, and used after dilution if necessary. The stock solution was made up a fresh and kept for less than three days because of the denaturation of the sample. Bovine serum albumin (hereafter called BSA) was that made by Armour Co., Ltd., (Fraction V, No. G5717, D. 1029). Much as in the case of Chs, a stock solution of about 1% was prepared and diluted if necessary. The reduced scattering intensity of this sample did not change when it was left as long as 30 hr at 25°C. The water used here was distilled, refined by the use of ion-exchange resin, and distilled again with an all-glass still. Concentrations were corrected for the water content in the sample. The water content necessary for this correction was determined by drying in a vacuum over P_2O_5 at 60°C for two days.

Refractive Index Increment. The refractive index increment (dn/dc) was measured by means of a Shimadzu electrophotometric differential refractometer at 25°C. Measurements were carried out using unpolarized light from a mercury arc (100 V, 85 W), with a spectrum filter whose wavelength was 4360 Å. The instrument constant was obtained by using a standard solution of potassium chloride, whose concentration was 0.01483 g/ml; the value of (dn/dc) of 0.1344 was taken from the literature.[16)] The potassium chloride used was a reagent-grade commercial product dried in a vacuum at about 200°C for more than six hours. The refractive index increments obtained were 0.1535 for Chs and 0.1935 for BSA. The value for Chs agreed with that reported by Nakagaki and Ikeda[15)] for the same sample. The value for BSA agreed well with

those of the references.[13,17,18] For mixed solutions of Chs and BSA, the value of the refractive increment obtained by direct determination for each mixture was used for the calculation of the apparent molecular weight.

Light-scattering measurements. The apparatus used in this investigation was a Shimadzu electrophotometric light-scattering photometer, PG-21 type. All the measurements were performed with unpolarized light with a wavelength of 4360 Å in a vacuum and at 25°C, the temperature being kept constant by circulating thermostatted water. The apparatus constant was calibrated on the basis of the value, $R_{90°}=48.5\times10^{-6}$, for the reduced scattering intensity of dust-free benzene at a 90° angle. The benzene was a commercial product of a reagent grade. It was dried with Drynap (an alloy of sodium metal and lead; weight ratio, 1 : 10; specific gravity, 6.4; mp, 368°C),[20-22] distilled twice by means of an all-glass still, and filtered directly into the cylindrical glass cell for light-scattering measurements through a Cella Filter (Mitter, Sartorius Co., Ltd.). The correction of the illuminated volume was done by using a fluorescein solution which had been optically clarified with Membrane Filter No. 15 (Sartorius Co., Ltd.) under pressure. The solutions and the solvent for the light-scattering measurements were optically clarified as well with the same mebrance filter.

All the light-scattering measurements were done over the range of scattering angles between 35°—135° for solutions of BSA, Chs, and their mixtures in various mixing ratios, γ, (gBSA/gChs), in a 0.01 M sodium chloride solutions as a solvent.

$$\gamma = c_{BSA}/c_{Chs} \tag{1}$$

where c_{BSA} and c_{Chs} are concentrations (g/ml) of BSA and Chs respectively. After the solutions had been made up by the dilution of stock solutions, these solutions were kept at 4°C in the refrigerator until the light-scattering experiments were carried out the next day. Dust-free solution were obtained in the way described above. In order to avoid errors due to the temperature difference and due to the existence of tiny bubbles, the scattering intensities were read about an hour after setting.

Density measurements. All the measurements were done with a picnometer of about 35 ml at 25°C. The water was used directly after distillation.

Results

Light Scattering. The results of the light-scattering measurements were analyzed according to the well-known equation:

$$\frac{Kc}{R_\theta} = \frac{K'\phi^2 c}{R_\theta} = \frac{1}{M}\left\{1+\left(\frac{16\pi^2 n_0^2}{3\lambda_0^2}\right)R_g^2\sin^2\left(\frac{\theta}{2}\right)\right\} + 2A_2c \tag{2}$$

where R_θ is the reduced scattering intensity of the solution in an excess over the solvent at the scattering angle, $\theta°$, c is the weight concentration of the polymer, (g/ml), M is the weight-average molecular weight of the polymer, and K' is the optical constant given by the following equation:

$$K = K'\phi^2, \quad K' = 2\pi^2 n_0^2/\lambda_0^4 N_A, \quad \phi = dn/dc \tag{3}$$

where ϕ is the refractive index increment of the solution, λ_0 is the wavelength in a vacuum (the value used in this experiment being 4360 Å), n_0 is the refractive index of the solvent, N_A is Avogadro's number, R_g^2 is the mean square radius of gyration, and A_2 is the second virial coefficient of the system.

In order to obtain the values of the weight-average molecular weight, M, the mean square radius of gyration, R_g^2, and the second virial coefficient, A_2, according to Eq. (2), the experimental data were plotted according to the so-called Zimm plot method, taking Kc/R_θ and $\sin^2(\theta/2)+100c$ on the ordinate and the abscissa respectively.

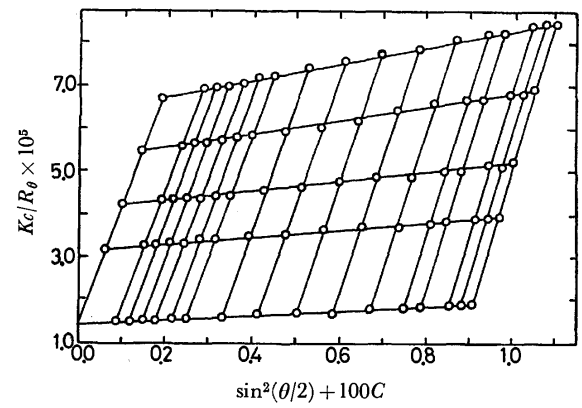

Fig. 1. Zimm plot for sodium chondroitin sulfate C (Chs) in 0.01 M NaCl at 25°C, pH 5.56.

Figure 1 shows the Zimm plot of Chs in 0.01 M sodium chloride (pH=5.56). The apparent weight-average molecular weight thus obtained was 70900. The values of the apparent mean square radius of gyration and the apparent second virial coefficient, as well as the molecular weight, agreed well with those obtained independently by Nakagaki and Ikeda[15] for the same sample. Figure 2 shows the Zimm plot of BSA in 0.01 M sodium chloride (pH=5.00). The molecular weight obtained from this was 71900; this value was in good agreement with the value found in the lite-

rature.[23] In the case of the mixed solutions of BSA and Chs, the scattering intensity was measured and the data were tentatively analyzed, at first, according to Eq. (2) by assuming them to be solutions of one solute whose weight concentration was equal to the sum of the two components. The apparent values of the molecular weight, the radius of gyration, and the second virial coefficient thus obtained were further examined theoretically as two-solute systems. All the experiments were carried out at concentrations between 3.5×10^{-3} and 5×10^{-4} g/m*l* in the total of the two solutes. Within this concentration range, the light-scattering data could be extrapolated without any difficulty.

Figure 3 (a), (b), and (c) are examples of the Zimm plot for the mixing ratios of $\gamma=12.9$, 24.4, and 101 respectively. As is shown in Fig. 3, the Zimm plot changed its shape and became narrower with an increase in the mixing ratio, γ. The Zimm plot at low γ-values was similar to that of Chs, while the Zimm plot at γ-values higher than 35.2 was similar to that of BSA.

23) J. T. Edsall, H. Edelhoch, R. Lontie, and P. R. Morrison, *J. Amer. Chem. Soc.*, **72**, 464 (1950).

The apparent values of the weight-average molecular weight, the second virial coefficient, and the radius of gyration, M_{app}, R_{gapp}, and A_{2app} respectively, obtained from these Zimm plots according to Eq. (2) are plotted against the mixing ratio, γ, in Fig. 4 for the region of rather low mixing ratios. The dotted curves are the calculated ones, which will be explained later.

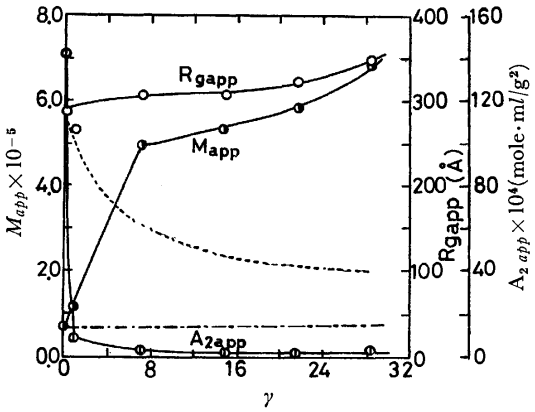

Fig. 4. Apparent molecular weight, M_{app}(◑), apparent radius of gyration, R_{gapp}(○), and apparent second virial coefficient, $A_{2\,app}$(ⓘ), obtained from BSA-Chs mixture of various mixing ratio, γ (gBSA/gChs)
◑,ⓘ,○: experimental values
– – – – theoretical curve of molecular weight for Chs-BSA system caluclated by equation (10)
------- theoretical curve of radius of gyration for Chs-BSA system calculated by equation (11)

It may be seen from this figure that the apparent molecular weight increases appreciably with the mixing ratios. It can further be seen from Fig. 4 that the apparent second virial coefficient decreases remarkably with the increase in the mixing ratio. In the region of the higher mixing ratios, that is, in the region of the higher BSA content, the apparent molecular weight has its maximum, as is shown in Fig. 5, where the mole fraction of BSA, X_{BSA}, is on the abscissa in place of the mixing ratio, γ. The mole fraction of BSA in the total solute, X_{BSA}, is related to by Eq. (4):

$$X_{BSA}=\frac{\gamma M_{Chs}}{M_{BSA}+\gamma M_{Chs}} \tag{4}$$

where M_{BSA} and M_{Chs} are the weight-average molecular weights for BSA and Chs respectively.

Density. The measurements of the density for the mixed solutions were carried out with a picnometer at 25°C. The values of the partial specific volume, V_{app}, of the mixed solute were calculated, they are plotted against the mole fraction of BSA in Fig. 6. It can be seen that the apparent partial specific volume increases linearly with the mole fraction of BSA. The value of the partial specific volume of Chs was 0.4448 m*l*/g. This value agrees well with the value obtained independently by Nakagaki and Ikeda.[15]

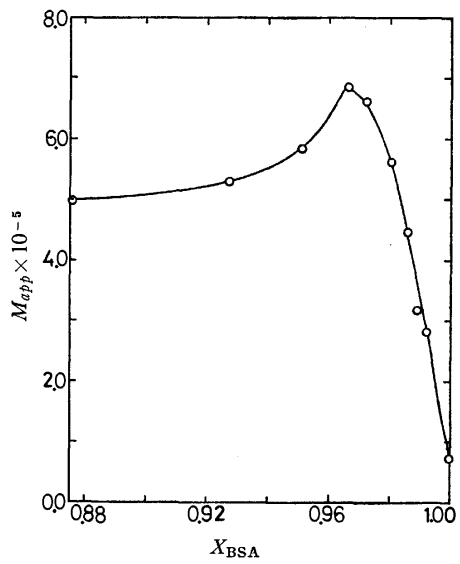

Fig. 5. Apparent molecular weight, M_{app}, plotted against mole fraction of BSA, X_{BSA}.

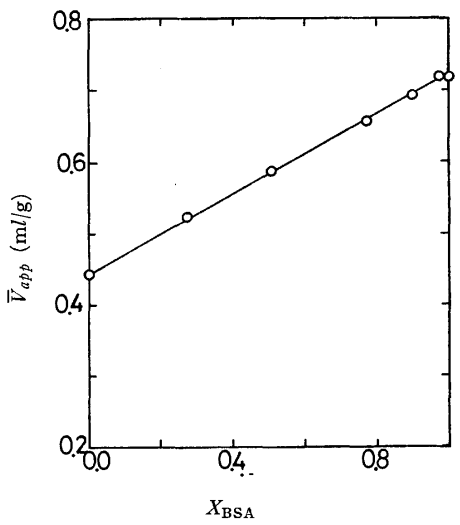

Fig. 6. Apparent partial specific volume, $\bar{V}_{app}$, (ml/g), plotted against mole fraction of BSA, X_{BSA}.

On the other hand, the partial specific volume of the native BSA was 0.7165 ml/g. This value agrees reasonably well with those values listed in the literature.[24-26]

Discussion

Binding of BSA on Chs Molecules. For the light scattering of a solution containing z macromolecular components, the following equation has been derived by Zimm,[27] by Stockmayer,[28,29] and by Blum and Morales[30,31] according to the theory of the fluctuation of the chemical potentials;

$$\frac{R_\theta}{K'c_t} = \sum_{i=1}^{i=z} M_i P_i(\theta) w_i \phi_i^2 - 2c_t \sum_{i=1}^{i=z} \sum_{j=1}^{j=z} A_2^{(ij)} M_i M_j P_i(\theta) P_j(\theta) w_i w_j \phi_i \phi_j \quad (5)$$

where R_θ is the reduced scattering intensity of the solution containing z macromolecular components and where $P_i(\theta)$ is the interference factor of the i-th macromolecular component and is approximately given by the following equation:

$$P_i(\theta) = 1 - \frac{16\pi^2 n_0^2}{3\lambda_0^2} Rg_i^2 \sin^2\left(\frac{\theta}{2}\right) \quad (6)$$

$A_2^{(ij)}$ is the second virial coefficient describing the interaction between the i-th and j-th components, w_i is the weight fraction of the i-th component in the total solute, and c_t is the total weight concentration (g/ml) for the mixed solution. Here,

$$c_t = \sum_{i=1}^{i=z} c_t \quad (7)$$

and

$$w_i = c_i/c_t \quad (8)$$

where c_t is the weight concentration of the ith macromolecular component.

Since the second term of Eq. (5) is smaller than the first term, Eq. (5) can be written as follows by using Eq. (6), in which the second term is again assumed to be smaller than the first:

$$\frac{K'c_t}{R_\theta} = \frac{1}{\sum_{i=1}^{i=z} M_i w_i \phi_i^2} \left\{ 1 + \frac{16\pi^2 n_0^2}{3\lambda_0^2} \left(\frac{\sum_{i=1}^{i=z} M_i w_i \phi_i^2 Rg_i^2}{\sum_{i=1}^{i=z} M_i w_i \phi_i^2} \right) \times \sin^2\left(\frac{\theta}{2}\right) \right\} + 2c_t \frac{\sum_{i=1}^{i=z} \sum_{j=1}^{j=z} A_2^{(ij)} M_i M_j P_i(\theta) P_j(\theta) w_i w_j \phi_i \phi_j}{\left(\sum_{i=1}^{i=z} M_i P_i(\theta) w_i \phi_i^2 \right)} \quad (9)$$

By comparing Eq. (9) with Eq. (2), the following equations can be obtained for a mixed solution of two macromolecular solutes described by the subscripts 1 and 2:

$$M_{app} = (M_1 w_1 \phi_1^2 + M_2 w_2 \phi_2^2)/\phi^2 \quad (10)$$

$$R_{gapp}^2 = (R_{g1}^2 M_1 w_1 \phi_1^2 + R_{g2}^2 M_2 w_2 \phi_2^2)/M_{app}\phi^2 \quad (11)$$

Here, M and R_g in Eq. (2) are replaced by M_{app} and R_{gapp} respectively. The results calculated according to these equations, assuming no interaction between Chs and BSA, that is, by setting 1=Chs and 2=BSA, are shown in Fig. 4 by dotted curves. It may be seen that the experimental values show an entirely different tendency from the calculated curves. This means that the chondroitin sulfate molecules interact with the BSA molecules strongly and that a complex is formed between them.

From Figs. 4 and 5, it can be seen that, with an increase in the mixing ratio, the apparent molecular weight and the apparent radius of gyration increase, while the apparent second virial coefficient decreases remarkably. These results suggest the formation of a complex between BSA and Chs by the following chemical equation:

$$(\text{Chs}) + \delta_m(\text{BSA}) \rightarrow (\text{Chs})\cdot(\text{BSA})_{\delta m}$$

If the affinity between Chs and BSA is strong, the complex is formed to as great an extent as one of these components is mostly used up. In this instance, the concentration of the component is negligibly small, so that the system can be considered to be a solution of two macromolecular solutes for which Eqs. (10) and (11) are applicable. By using these equations, the possibility that either Chs and BSA remains in excess after the complex formation has been examined. To explain the experimental data satisfactorily, it has been concluded that a part of the BSA is left free in the solution and that many BSA molecules are bound on one Chs molecule ($\delta_m > 1$). Equations (10) and (11) can be used, in this case also, by setting 1=complex (to be designated by the subscript m) and 2=free BSA (to be designated by the superscript f). The following equation:

$$M_{app} = [w_{\text{Chs}}M_{\text{Chs}}(\phi_{\text{Chs}} + \phi_{\text{BSA}}\delta)^2 + (w_{\text{BSA}} - w_{\text{Chs}}\delta)M_{\text{BSA}}\phi_{\text{BSA}}{}^2]/\phi^2 \quad (12)$$

can be deriven from Eq. (10) by using the following obvious relations:

$$M_m = M_{\text{Chs}}(1+\delta) = M_{\text{Chs}} + \delta_m M_{\text{BSA}} \quad (13a)$$

$$w_m = w_{\text{Chs}}(1+\delta) \quad (13b)$$

$$w_{\text{BSA}}{}^f = w_{\text{BSA}} - \delta w_{\text{Chs}} \quad (13c)$$

$$\delta = \delta_m M_{\text{BSA}}/M_{\text{Chs}} \quad (13d)$$

together with the Geiduschek-Doty equation:[12]

$$\phi_m = (\phi_{\text{Chs}} + \delta\phi_{\text{BSA}})/(1+\delta) \quad (14)$$

The weight-binding coefficient, δ, can be obtained according to Eq. (12) by using the experimental values of M_{app} and of all other quantities. As a result, it has been concluded that the value of δ increases with the mixing ratio, γ. The molar binding coefficient, δ_m, thus obtained is shown in Fig. 7 as a function of the molar ratio of free BSA, $\gamma_m{}^f$, relative to the molar concentration of Chs.

$$\gamma_m{}^f = (M_{\text{Chs}}/M_{\text{BSA}})\gamma - \delta_m \quad (15)$$

An equation of the same form as Langmuir's adsorption isotherm is often used to describe the amount of binding of a low-molecular-weight substance to macromolecules as a function of the equilibrium concestration of the latter.[32] A similar equation can be expected to be used as well in the case of complex formation between two macromolecular substances. In our case, the number of molecules, δ_m, of BSA bound on one molecule of Chs may be given by the following equation:

$$\delta_m = \delta_m{}^\infty \frac{k\,\gamma_m{}^f}{1 + k\,\gamma_m{}^f} \quad (16)$$

where the constant, k, indicates the strength of adsorption and where $\delta_m{}^\infty$ is the saturated molar binding coefficient.

On the basis of the linear relationship between $\gamma_m{}^f/\delta_m$ *vs.* $\gamma_m{}^f$, which is expected from Eq. (16) and which is shown in Fig. 7 by a dotted line, the parameter values, $\delta_m{}^\infty = 20.6$ and $k = 0.255$, were obtained. The solid curve in Fig. 7 shows the values calculated from Eq. (16) by using these parameter values. From this, it can be seen that the agreement between experimental and calculated values is good and that the maximum number of BSA molecules to be bound to a Chs molecule is about 21.

Since a Chs molecule consists of 145 disaccharide units, according to the observed value of its molecular weight, it may be concluded that, at saturation, one BSA molecule is bound to about seven disaccharide residues.

Zimm Plot of the Complex Molecules. Since it has been concluded in the preceding section that a complex and excess (free) BSA exist in the mixed solution of Chs and BSA, the next step is to obtain the reduced scattering intensity of the complex, $R_{\theta m}$, by subtracting the contribution of free BSA from the total reduced scattering intensity, and to attempt to draw a Zimm plot of the complex. The reduced scattering intensity of the complex may be calculated from the experimental data by the following equation, because the second virial coefficient of BSA is almost zero, as is shown in Fig. 2:

$$R_{\theta m} = R_\theta - K' c_{\text{BSA}}{}^f M_{\text{BSA}} \phi_{\text{BSA}}{}^2 P_{\text{BSA}}(\theta) \quad (17)$$

The Zimm plot may be analyzed according to the following equation, which has the same form as Eq. (2):

$$\frac{K'\phi_m{}^2 c_m}{R_{\theta m}} = \frac{1}{M_m}\left\{1 + \left(\frac{16\pi^2 n_0{}^2}{3\lambda_0{}^2}\right) R_{g_m}{}^2 \sin^2\left(\frac{\theta}{2}\right)\right\} + 2A_{2m}c_m \quad (18)$$

Here, ϕ_m has been given by Eq. (14). Finally, it

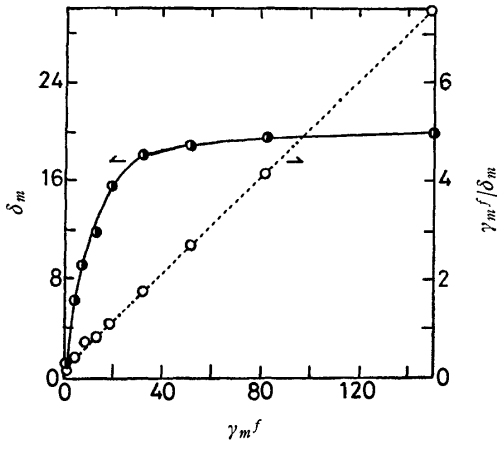

Fig. 7. Molar binding coefficient, δ_m, plotted against molar ratio of free BSA, $\gamma_m{}^f$ (BSA/Chs). The broken line is Langmuir plot of equation 16, where $\gamma_m{}^f/\delta_m$ is plotted against $\gamma_m{}^f$.

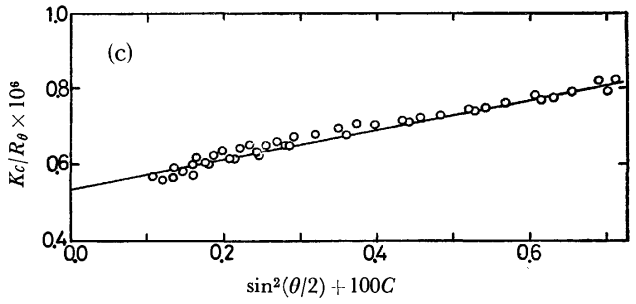

Fig. 8(c)

Fig. 8. Zimm plots for BSA-Chs complex molecule calculated from Fig. 3. Curves (a), (b), and (c) correspond to curves (a), (b) and (c) in Fig. 3.

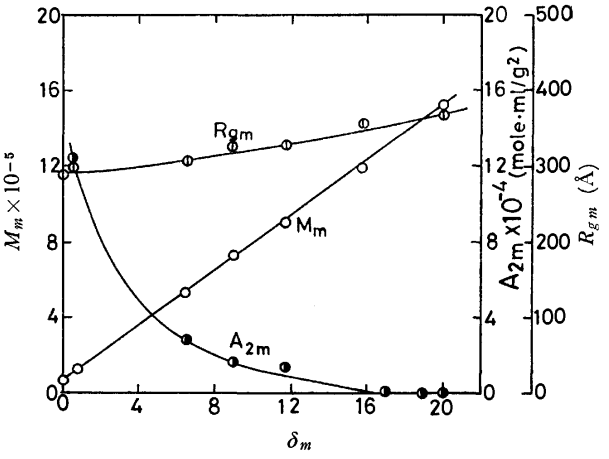

Fig. 9. Molecular weight, M_m(○), radius of gyration, R_{gm} (◫) and second virial coefficient, A_{2m}(◑) for BSA-Chs complex molecule against molar binding coeffient, δ_m, in 0.01 M NaCl at 25°C.

should be mentioned that the A_{2m} term in Eq. (18) is not the second virial coefficient of the complex itself, but contains the contribution due to the interaction between the complex and the free BSA.

Examples of the results are shown in Fig. 8, which corresponds to Fig. 3. The molecular weight, M_m; the radius of gyration, R_{gm}, and the second virial coefficient, A_{2m}, for the complex are plotted against the molar binding coefficient, δ_m, in Fig. 8. It can be seen that M_m increases remarkably and linearly with δ_m but that R_{gm} increases only slightly, while A_{2m} decreases rapidly and approaches the value of BSA alone ($A_{2BSA}=0$).

It is natural that the molecular weight of the complex, M_m, increases linearly with δ_m, as is to be expected from Eq. (13a). The molecular weight of the bound BSA, calculated from the inclination of the straight line of Fig. 9, is 72000, which is in good agreement with the molecular weight of native BSA, M=71900, already cited.

On the other hand, R_{gm} value for the complex is almost equal to R_{gapp} for the mixed solutes, as is clear from a comparison between Figs. 4 and 9, because R_g obtained from the light-scattering measurements is z-average and the radius of gyration of the free BSA is very small. Moreover, the length of the complex molecules seems to be nearly equal to that of Chs itself, because the value of R_g does not increase very much with δ_m. Finally, the second virial coefficient for the complex decreases rapidly with δ_m. This indicates that the electric charges of the Chs are shielded by the binding of BSA molecules. Therefore, it can be concluded that the complex molecule has as its core the chondroitin sulfate molecule, with its surface covered with BSA molecules.

Shape and Size of the Complex Molecule. The shape and size of the complex molecule will be discussed. The chondroitin sulfate is an unbranched linear anionic polyelectrolyte and is stretched extensively by the electrostatic repulsive force if the polyions have a low ionic strength. It is, however, known that the polyions gradually contract with the increase in the ionic strength because of the formation of ionic pairs or because of electrostatic shielding effect of the ionic atmosphere. Nakagaki and Ikeda[15] found, from their viscosity and the light-scattering investigations, that the polyion of chondroitin sulfate is a long rod-like shape which is, at an infinite ionic strength, about 800 Å in long and about 10 Å in diameter. The shape of the complex molecule may be assumed to be almost the same as that of chondroitin sulfate, because the radius of gyration does not change very much. Therefore, the complex molecule is assumed to be a rod-like molecule.

The radius of gyration, R_{gm}, and the volume, V_m, of a rod-like molecule are expressed as follows:

$$R_{gm}^2 = L_m^2/12 + D_m^2/8 \quad (19)$$

$$V_m = \pi(D_m/2)^2 L_m \quad (20)$$

According to these equations, the diameter, D_m, and the length, L_m, of the complex can be calculated, ignoring the solvation, from the value of the radius of gyration and the value of the partial specific volume of the complex.

The partial specific volume of the complex, $\overline{V}_m$, is calculated from Eq. (21), which is based on an additivity rule, as is generally assumed:

$$\overline{V}_{app} = \overline{V}_m w_m + \overline{V}_{BSA} w_{BSA}{}^f \quad (21)$$

Further, the value of the molecular volume of the complex, $M_m\overline{V}_m/N_A$, can be calculated from the data already shown in Fig. 6 according to Eq. (22). The results are plotted against the molar binding coefficient, δ_m, in Fig. 10. This figure shows that the volume of the Chs molecule does not change with the binding of BSA and also that the volume of a bound BSA is 0.862×10^5 (Å^3/molecule), which is 0.7212 m*l*/g in the partial specific volume. The partial specific volume of the native BSA, on the other hand, is 0.7165 m*l*/g. There is a reasonably good agreement between these values and those listed in the literature.[24-26] As has been mentioned above, the length and the diameter of the complex molecule can, therefore, be calculated, according to Eqs. (19) and (20), from the experimental values of $\overline{V}_m$ and

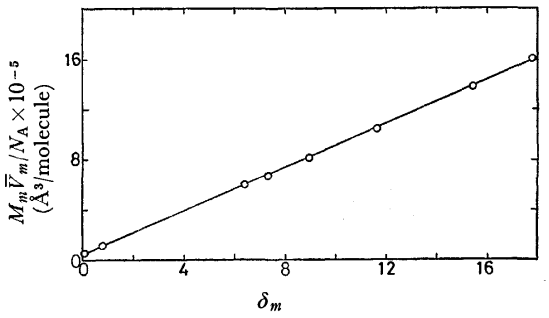

Fig. 10. Partial molar volume per complex molecule, $M_m\overline{V}_m/N_A$, (Å^3/molecule) plotted against molar binding coefficient, δ_m.

R_{gm} if the density in the complex molecule is assumed to be homogeneous. The results obtained are shown in Table 1. It may be seen that the length increases about 20 percent as compared with the Chs molecule, while the diameter increases about five times, upon the binding of BSA.

In contradistinction to the assumption of a homogenous density in complex molecules, if the molecule has a structure in which the core of the Chs molecule with a density of ρ_{Chs} is surrounded by BSA molecules with a density ρ_{BSA}, and if the complex molecule as a whole is assumed to be a rigid prolate spheroid with major axis a and minor axis b, the radius of gyration of the complex will be given by:

$$R_{gm}^2 = \frac{\left(\frac{a^2+2b^2}{5}\right)\rho_{BSA}\left(\frac{4}{3}\pi ab^2\right)+(\rho_{Chs}-\rho_{BSA})\frac{\pi}{4}D_{Chs}^2L_{Chs}\left(\frac{L_{Chs}^2}{12}+\frac{D_{Chs}^2}{8}\right)}{\rho_{BSA}\left(\frac{4}{3}\pi ab^2\right)+(\rho_{Chs}-\rho_{BSA})\frac{\pi}{4}D_{Chs}^2L_{Chs}} \quad (22)$$

$$V_m = \frac{4}{3}\pi ab^2 \quad (23)$$

According to Eqs. (22) and (23), the length of the two axes, $2a$ and $2b$, can be calculated from the experimental values of the radius of gyration and the partial specific volume by assuming that the Chs core has the same length, L_{Chs}, and the same diameter, D_{Chs}, as free Chs molecules. The results thus obtained are shown in Table 1.

If the complex molecule is assumed to be a rigid rod which has a Chs core, much like the structure of the prolate spheroid considered above, the length, L', and the diameter, D', of the complex molecule can be calculated in the same way:

$$R_{gm}^2 = \frac{\left(\frac{L'^2}{12}+\frac{D'^2}{8}\right)\rho_{BSA}\left(\frac{\pi}{4}D'^2L'\right)+(\rho_{Chs}-\rho_{BSA})\frac{\pi}{4}D_{Chs}^2L_{Chs}\left(\frac{L_{Chs}^2}{12}+\frac{D_{Chs}^2}{8}\right)}{\rho_{BSA}\left(\frac{\pi}{4}D'^2L'\right)+(\rho_{Chs}-\rho_{BSA})\frac{\pi}{4}D_{Chs}^2L_{Chs}} \quad (24)$$

Table 1. Molecular dimensions of the complex molecule between chondroitin sulfate C and bovine serum albumin at various molar binding coefficient

δ_m	0	0.707	6.404	8.895	11.628	15.455	20.360
	(rigid rod-like molecule of a uniform density)						
L_m	998	1039	1068	1130	1126	1227	1278
D_m	8.0	12.2	27.1	32.0	36.7	36.7	46.1
	(a prolate ellipsoid of revolution which is considered for a different density between Chs and BSA)						
$2a$		959.2	978.2	1036	1032	1125	1162
$2b$		15.0	18.6	38.6	44.0	48.2	55.2
	(rod-like molecule which is considered for a different density between Chs and BSA)						
L'		1180	1096	1152	1143	1241	1279
D'		11.0	26.3	29.9	34.1	37.5	42.9

These results are also shown in Table 1.

The results shown in Table 1 are in fairly good agreement with each other, irrespective of the model. It seems, at any rate, that the complex molecule has a long, deformed shape. In these models, the prolate spheroid is the most suitable to explain the results of viscosity measurements, as will be published elsewhere.

The authors are indebted to Dr. Kiyoshi Ikeda and Mr. Kenichi Sugimori for their helpful advice on this work.

(Received October 5, 1971)

The π–π^* electronic absorption spectra of 1-amino-, 1,4-diamino-, and 1,4,5,8-tetraaminoanthraquinones were investigated by means of the polarized absorption spectra using stretched PVA sheets and theoretical calculations. Each of these compounds has four absorption bands in the near-ultraviolet region (210—340 nm) and one in the visible region. The bands of the aminoanthraquinones which appear in the visible region can be assigned to the intramolecular charge-transfer transitions associated with the charge migration from the amino group to the carbonyl groups.

In a previous paper,[1] the polarized absorption spectra of sodium anthraquinonesulfonates were measured in stretched PVA sheets, and the polarization directions of the bands of anthraquinone and its sulfonates were discussed. It has been found that anthraquinone has four π–π^* absorption bands above 220 nm. The positions and the polarization directions of the bands are as follows; 324 nm (x-polarization), 272 nm (y-), 252 nm (x-), and about 249 nm (y-), where the y- and x-axes are, respectively, parallel and perpendicular to the C=O bond axis of the molecule.

It has been established that the substituted anthraquinones with electron-donating groups, such as hydroxyl or amino groups, have bands in the visible region.[2,3] For instance, Kuboyama and Wada[2] have measured the absorption spectra of several hydroxyanthraquinones; the visible band of each hydroxyanthraquinone corresponded to the 324 nm band of anthraquinone. Labhart[3] has measured the polarized absorption spectra of several aminoanthraquinones under an external electric field and has determined the polarization direction of each band. According to his results, the visible band at 564 nm of 1,4-diaminoanthraquinone is polarized along the x-axis of the molecule.

In the present paper, the electronic absorption spectra of 1-aminoanthraquinone, 1,4-diaminoanthraquinone, and 1,4,5,8-tetraaminoanthraquinone were studied by means of the polarized absorption spectra using stretched PVA sheets and of theoretical calculations.

Method of Calculation

The method of the calculation was the same as that in our previous works,[4–6] that is, the Pariser-Parr-Pople method[7–9] with a variable β approximation. The resonance integrals, β_{rs}'s, were adjusted at every iteration of the SCF calculations by means of the following equations:

$$\beta_{CC} = -1.84 - 0.51p_{CC}$$
$$\beta_{CN} = -2.02 - 0.53p_{CN}$$
$$\beta_{CO} = -2.20 - 0.56p_{CO}$$

where p_{rs} is a bond order between the r and s atoms. The valence-state ionization potentials, $I_p(r)$'s, and the electron affinities, $E_a(r)$'s, for carbon, nitrogen, and oxygen atoms were taken as:

$$I_p(C) = 11.42\ \text{eV}, \quad E_a(C) = 0.58\ \text{eV}$$
$$I_p(N) = 25.00\ \text{eV}, \quad E_a(N) = 10.0\ \text{eV}$$
$$I_p(O) = 17.32\ \text{eV}, \quad E_a(O) = 2.65\ \text{eV}.$$

The geometries of anthraquinone and its derivatives are shown in Fig. 1, in which the interatomic distances in the anthraquinone skeleton are taken from the results of the X-ray analysis by Sen[10]; all the valence angles are assumed to be 120°.

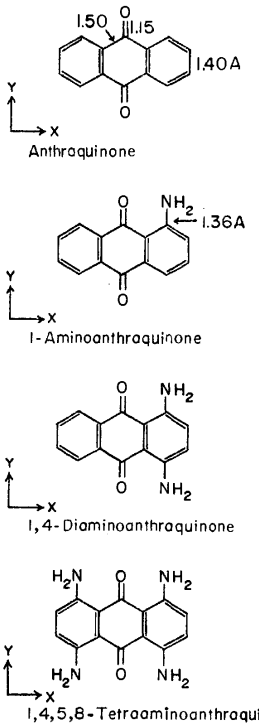

Fig. 1. The geometries of the molecules.

Experimental

Materials. All the anthraquinone derivatives used here were offered by Dr. Kou Naiki of the Tokyo Institute of Technology. The PVA (polyvinyl alcohol) powder used for the preparation of the sheets was obtained commercially (Nippon Gosei Co., Ltd., NM-14) and was used without further purification.

Measurements of the Polarized Absorption Spectra. The polarized absorption spectra using stretched PVA sheets were measured by the method already described.[1]

Notations. $D_{\parallel}$ and $D_{\perp}$: absorbances measured with the incident light polarized, respectively, parallel and perpendicular to the stretched direction of the PVA sheet. *Rd*: ratio between $D_{\parallel}$ and $D_{\perp}$, $D_{\parallel}/D_{\perp}$. R_s: degree of stretching of the sheet. θ: orientation angle, which indicates the angle between a transition moment and the orientation axis of a molecule.

Results and Discussion

The absorption spectra of 1-amino-, 1,4-diamino-, and 1,4,5,8-tetraaminoanthraquinone are shown in Fig. 2, in which the spectrum of anthraquinone is also shown for the sake of comparison. As has been described in a previous paper,[1] anthraquinone has four absorption bands, at 324 nm, 272 nm, 252 nm, and about 230 nm, which are polarized along the *x*-, *y*-, *x*-, and *y*-axes respectively, where the *x*- and *y*-axes are respectively perpendicular and parallel to the C=O bond axis of the molecule. In the case of the aminoanthraquinones studied here, there are four absorption bands in the near-ultraviolet region and one in the visible region. The former four bands may correspond to those of anthraquinone described above.

Figure 3 shows the polarized absorption spectra of 1-aminoanthraquinone in the stretched PVA sheets.

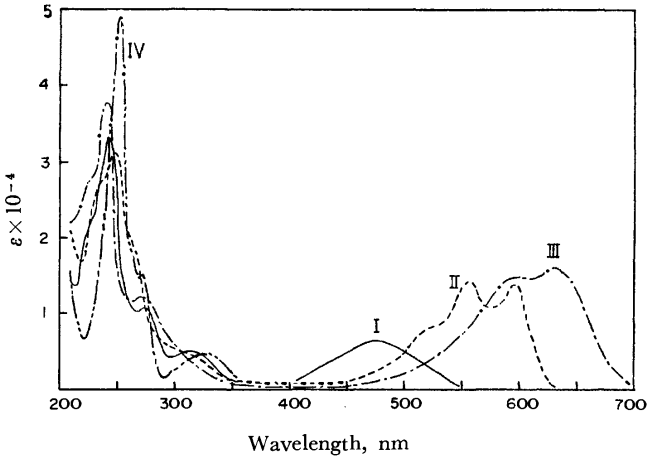

Fig. 2. The absorption spectra of 1-aminoanthraquinone (I), 1,4-diaminoanthraquinone (II), 1,4,5,8-tetraaminoanthraquinone (III), and anthraquinone (IV) in ethanol.

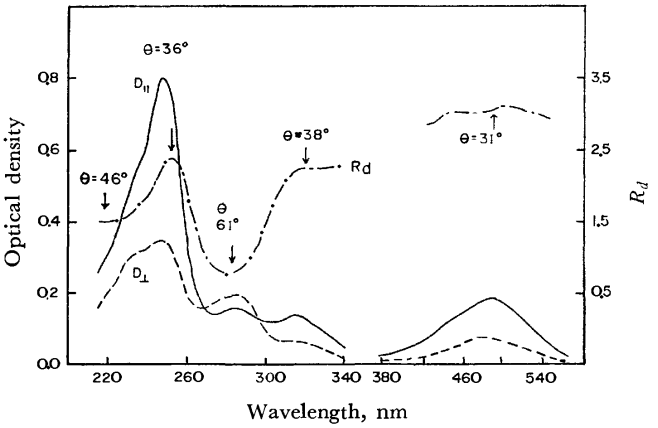

Fig. 3. The polarized absorption spectra of 1-aminoanthraquinone. (R_s=5.8)

From the behavior of the R_d curve, it is clear that the absorption spectrum of this compound consists of five bands in the observed wavelength region. They appear at 490 nm, 315 nm, 282 nm, 248 nm, and 235 nm; the orientation angles of these bands are 31°, 38°, 61°, 36°, and 46° respectively. As has been predicted above, the latter four bands can correspond to those of anthraquinone, because the behavior of the R_d curve in the region of 210—340 nm (Fig. 3) is very similar to that of anthraquinone.[1] A band corresponding to the 490 nm band of 1-aminoanthraquinone is not observed in the case of anthraquinone. The polarization direction of the 490 nm band seems to be almost parallel to those of the 315 nm and 248 nm bands.

These experimental results are compared with the theoretical ones in Table 1. From the comparison of the observed positions of the bands, the relative intensities, and the orientation angles with the theoretical results, the observed bands at 490 nm, 315 nm, 282 nm, 248 nm, and 235 nm can assigned to the calculated transitions, I, II, IV, VII, and VIII respectively. From the polarized absorption spectra obtained using stretched PVA sheets, we can not determine the precise polarization direction of each band unless the orien-

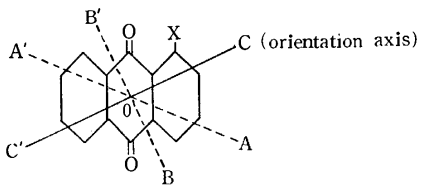
	Relative polarization	
	Obsd	Calcd
the 314 nm band	7°	1°
the 282 nm band	92°	97°
the 248 nm band	5°	8°
the 235 nm band	77°	88°

tation axis of the molecule is known. However, the relative polarization directions between two bands may be given by the sum or remaider of the two orientation angles.[11] Thus, the relative polarization directions in relation to the polarization direction of the 490 nm band are found to be as is shown in Table 2. These results are in good agreement with those of the theoretical calculations.

Figure 4 shows the polarized absorption spectrum of 1,4-diaminoanthraquinone. It is clear that this molecule has five absorption bands, at 600 nm, 320 nm, 280 nm, 255 nm, and 235 nm, and that their orientation angles are 34°, 52°, 58°, 41°, and 51° respectively. Since this molecule seems to belong to the C_{2v} point group, each π–π^* electronic transition should

11) If the directions of the transition moments of two bands of a molecule are represented by $\overrightarrow{AA'}$ and $\overrightarrow{BB'}$, the relative polarization direction between the two bands is expressed by $\angle AOB'$ or $\angle AOB$. The former angle ($\angle AOB'$) is given by the sum of two orientation angles ($\angle AOC + \angle COB'$), whereas the latter angle ($\angle AOB$) is given by the difference between the two orientation angles ($\angle BOC - \angle AOC$), where $\overrightarrow{CC'}$ represents the orientation axis of the molecule.



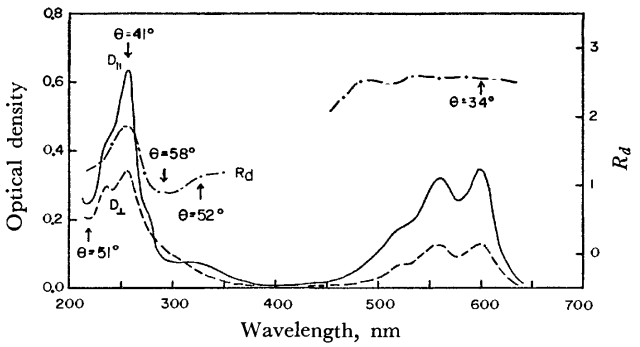


Fig. 4. The polarized absorption spectra of 1,4-diaminoanthraquinone. (R_s=5.1)

be polarized along the x- or y-axis of the molecule. As in the case of the anthraquinonesulfonates described in a previous paper, the x-axis of this molecule is preferentially oriented in the stretched direction of the PVA sheet; this implies that the R_d values of the x-axis polarized bands are larger than those of the y-axis polarized ones. Therefore, it is found that the 600 nm, 320 nm, and 255 nm bands are polarized along the x-axis, and the 280 nm and 235 nm bands, along the y-axis. The 600 nm band may consists of a single electronic band, since this band is isolated from the other bands; the R_d values of this band are almost constant. The sum of the orientation angles of the 600 nm and the 280 nm bands is nearly a right angle (92°), so the 280 nm band may be regarded as being almost pure, whereas the 320 nm and 255 nm bands are overlapped with other ones respectively, because the orientation angles of these bands are smaller than that of the 600 nm band.

These experimental results are compared with the calculated results in Table 3. The observed 600 nm, 320 nm, 280 nm, 255 nm, and 235 nm bands can be assigned to, respectively, the calculated transitions I, III, V, IX, and XI.

The polarized absorption spectrum of 1,4,5,8-tetra-

aminoanthraquinone is shown in Fig. 5. From the features of the absorption and R_d curves, in this case also, the absorption bands corresponding with those of the above compounds are found at 645 nm (x-axis polarized), 325 nm (x), 275 nm (y), 245 nm (x), and 230 nm (y).

The calculated results are tabulated in Table 4. The observed 645 nm (x), 325 nm (x), 275 nm (y), 245 nm (x), and 230 nm (y) bands are assigned to, resectively, the calculated transitions I, VII, VIII, XII, and X.

As has been described above, the electronic spectra of aminoanthraquinones consist of four bands in the near-ultraviolet region and one in the visible region; the former four bands correspond well to those of anthraquinone.

Table 5 shows the first excited state wave functions,

Ψ's, of 1-amino-, 1,4-diamino-, and 1,4,5,8-tetraaminoanthraquinone. The Ψ_1 of 1-aminoanthraquinone can be approximately represented by $\phi_{9,10}$; that of 1,4-diaminoanthraquinone, by $\phi_{10,11}$, and that of 1,4,5,8-tetraaminoanthraquinone, by $\phi_{12,13}$. The coefficients of the wave functions associated with these configurations are shown pictorially in Fig. 6. From this figure, it may be concluded that the transitions, I, of these compounds are to be assigned to the intramolecular charge-transfer transitions from the amino groups to the carbonyl groups.

Symmetry Rule for Predicting Bond Distortions in Conjugated Hydrocarbons

Takeshi NAKAJIMA, Azumao TOYOTA, and Sadao FUJII

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received October 5, 1971)

A symmetry rule for predicting molecular shapes which is based on the second-order Jahn-Teller effect has been applied to the predictions of bond distortions in a number of nonalternant hydrocarbons in their ground and electronically excited states. In spite of the very crude approximation that only the lowest-lying excited state plays a dominant role in determining the energetically most favorable nuclear displacement, a fairly clear-cut criterion for molecular-symmetry reduction was obtained. The actual types of the most soft bond distortions, determined by examining the two-center components of transition densities, are in good agreement with the results of variable bond-length SCF MO calculations and available experimental results. The problem of symmetry reductions possible in large cyclic polyenes $C_{4n+2}H_{4n+2}$ is briefly discussed.

A symmetry rule for predicting molecular structures has recently been developed by Pearson,[1-3] Salem,[4] and Bartell.[5] The rule is based on the second-order or pseudo Jahn-Teller effect, and follows the earlier work by Bader.[6,7] The symmetries of the ground state and the lowest excited state(s) determine which kind of nuclear motion occurs most easily in the ground state of a molecule. The rule has proved remarkably successful in predicting the stable molecular shapes of inorganic and small organic molecules. Symmetry rules have also been used to predict the course of chemical reactions by Bader,[7] Salem and Wright,[8] and Pearson.[9]

In this paper we consider the application of the symmetry rule to the prediction of the geometrical structures of conjugated π-electron systems. We deal, in particular, with the problem of molecular-symmetry reduction and double-bond fixation in the nonalternant hydrocarbons.[10]

On the basis of the second-order perturbation theory, Binsch *et al.*[11-15] have recently developed a general theory of double-bond fixation in conjugated systems. The symmetry rule is based also on the second-order perturbation theory, but it provides a more intelligible way of predicting the double-bond fixations and of understanding the origin of bond distortions in conjugated systems.

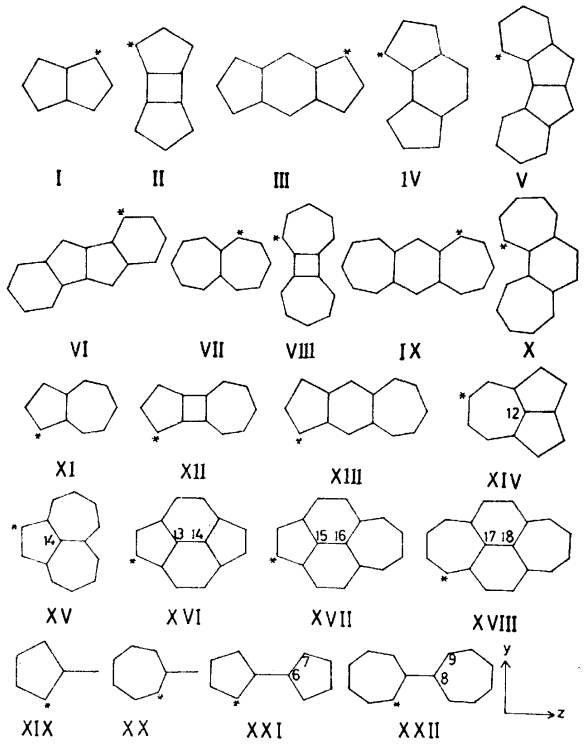

Fig. 1. Numbering of atoms and choice of axes in nonalternant hydrocarbons. Carbon atoms are numbered consecutively, starting with the starred atom and proceeding clockwise along the periphery. For VI the z axis is taken to be perpendicular to the molecular plane.

Theoretical

We start by assuming for a conjugated molecule a fully-symmetrical nuclear arrangement as the unperturbed nuclear configuration. The unperturbed electronic wavefunctions ϕ_0, ϕ_1, $\cdots$, ϕ_n, $\cdots$ and the corresponding eigenvalues E_0, E_1 $\cdots$, E_n, $\cdots$ are assumed to be known. We now distort the nuclei from the initial symmetrical arrangement by means of the ith normal coordinate of nuclear motion Q_i. With the use of the second-order perturbation theory, the energy of the ground state after deformation may be written as

$$E(Q_i) = E_0 + \left\langle \phi_0 \left| \frac{\partial H}{\partial Q_i} \right| \phi_0 \right\rangle Q_i$$

$$+\frac{1}{2}\left\{\left\langle\psi_0\left|\frac{\partial^2 H}{\partial Q_i^2}\right|\psi_0\right\rangle - 2\sum_n{}'\frac{\left|\left\langle\psi_n\left|\frac{\partial H}{\partial Q_i}\right|\psi_0\right\rangle\right|^2}{E_n-E_0}\right\}Q_i^2 \quad (1)$$

If the initial ground-state wavefunction ψ_0 is nondegenerate, as is the case with the nonalternant hydrocarbons deal with in this paper (since the fully-symmetrical nuclear arrangements of these molecules belong to point-group D_{2h}, C_{2h}, or C_{2v}), then the second term in Eq. (1) is nonzero only for the totally symmetric nuclear displacements.

Let us assume that the total energy of a conjugated molecule can be written as the sum of the π-electron energy and the σ-core energy, the latter being approximated by a quadratic function of the bond-distance variation

$$E_\sigma = \sum_{\mu<\nu}\frac{k}{2}(\Delta r_{\mu\nu})^2 \quad (2)$$

where k is the force constant for an sp^2 hybridized C–C σ-bond.

It is easily shown[11,12] that by equating the second term in Eq. (1) to zero, the usual linear relationship between bond order and bond length for conjugated hydrocarbons can be derived. It follows that in conjugated hydrocarbons all the symmetrical bond distortions will occur until the first-order energy equilibrium is reached. That is, bond lengths will change to the first-order equilibrium values through the bond-order - bond-length relationship, but still keep the original molecular symmetry.

Assuming that the first-order changes have taken place, we have

$$E(Q_i) = E_0 + \frac{1}{2}\left\{k+\left\langle\psi_0\left|\frac{\partial^2 H_\pi}{\partial Q_i^2}\right|\psi_0\right\rangle - 2\sum_n{}'\frac{\left|\left\langle\psi_n\left|\frac{\partial H_\pi}{\partial Q_i}\right|\psi_0\right\rangle\right|^2}{E_n-E_0}\right\}Q_i^2 \quad (3)$$

If we assume that the change in the π-electron energy on variation of a particular bond length can be considered to arise from a one-electron perturbation which can be incorporated in the core resonance integral $\beta(r)$, the second term in the braces in Eq. (3) can be written as[11,14]

$$\left\langle\psi_0\left|\frac{\partial^2 H_\pi}{\partial Q_i^2}\right|\psi_0\right\rangle = 2\sum_{\mu<\nu}p_{\mu\nu}\beta_{\mu\nu}''\left(\frac{\partial r_{\mu\nu}}{\partial Q_i}\right)^2 \quad (4)$$

where p is the bond order and β'' is the second derivative of $\beta(r)$ with respect to r. We may safely neglect this term since for the reduced bond-distance interval in question the curvature of the $\beta(r)$ curve should be very small.

According to Eq. (3), the force constant for the normal vibration Q_i can be identified with the term in the braces and can be negative if a given matrix element $\langle\psi_0|\partial H_\pi/\partial Q_i|\psi_n\rangle$ is nonvanishing and the associated energy gap E_n-E_0 is sufficiently small. If the force constant is negative, the energy should be lowered by the nuclear deformation Q_i, and a pseudo-Jahn-Teller distortion from the symmetrical nuclear arrangement would occur spontaneously.

In order to estimate the probable value of the force constant, we now make a rather drastic approximation that the infinite sum over excited states in Eq. (3) is replaced by one or two dominant terms corresponding to the lowest one or two excited states. Pearson[2,3] has shown that this approximation is justified in a large variety of small molecules and complex ions. Our approach is then simply to examine whether a given molecule in a symmetrical nuclear configuration has reasonably low lowest excited state(s) and, if so, whether any of the integrals $\langle\psi_0|\partial H_\pi/\partial Q_i|\psi_n\rangle$ are nonvanishing. Since Q_i and $\partial H_\pi/\partial Q_i$ have the same symmetry and the ground state is, in general, totally symmetric, the integral is nonzero only when ψ_n and Q_i have the same symmetry. The symmetry of the lowest excited state(s) now determines which kind of nuclear displacement occurs energetically most easily.

Although the symmetry of the most soft normal nuclear displacement can thus be determined, its actual type cannot always be uniquely determined, because there are, in general, several types of bond distortion belonging to the same symmetry. In order to determine which distortion is energetically most favorable, it is useful to interpret the third term in the braces of Eq. (3) as the "relaxability" of the molecule along the coordinate Q_i, and express the matrix element $\langle\psi_0|\partial H_\pi/\partial Q_i|\psi_n\rangle$ in terms of the transition density ρ_{0n} between the ground and excited states by[4]

$$\left\langle\psi_0\left|\frac{\partial H_\pi}{\partial Q_i}\right|\psi_n\right\rangle = \int\rho_{0n}\frac{\partial v}{\partial Q_i}\,d\tau \quad (5)$$

where v is the one-electron nuclear-electron potential operator. For a one-electron transition between molecular orbitals ϕ_i and ϕ_j, ρ_{0n} is given by $\sqrt{2}\,\phi_i\phi_j$.[10] A given state may contribute much to the molecular relaxability towards mode Q_i, if ρ_{0n} is large near nuclei which contribute much to Q_i, but little to the relaxability if ρ_{0n} is small near such nuclei. We may thus predict the most favorable type of bond distortion by examining the distribution of transition densities over the molecular skeleton.

Eigenvalues and wavefunctions for the fully-symmetrical nuclear arrangements are calculated using the self-consistent configuration-interaction formalism of Pariser-Parr-Pople MO method, in conjunction with the variable bond-length technique in which bond lengths and, consequently, the resonance and Coulomb repulsion integrals are allowed to vary with bond orders at each iteration until self-consistency is reached.[16]

Since it is based on the second-order perturbation theory, the symmetry rule only gives the type of the most favorable bond distortion. In order to obtain information about the actual magnitudes of distortions or the equilibrium bond lengths at which the

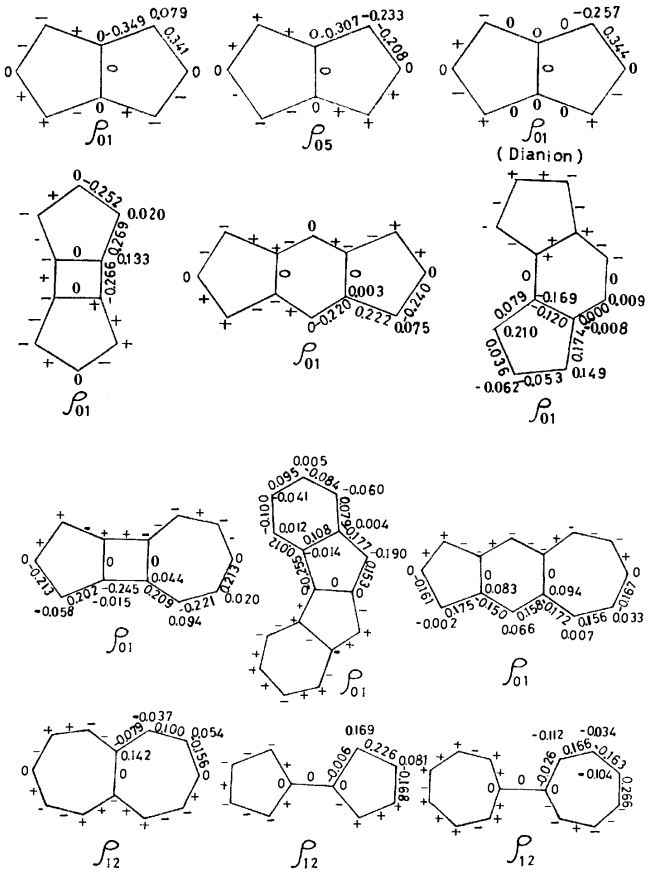

Fig. 2. One-center and two-center components of the transition densities.

nuclei of the real molecule will settle, we use the SCF MO method mentioned above, taking into account, as the starting geometries, all the possible distinct structures in which bond lengths are distorted so that the set of displacement vectors may form a basis for each irreducible representation of the full symmetry group of a molecule.[17,18] In pentalene (I, Fig. 1), for example, there are 3, 2, 2, and 2 distinct bond distortions belonging to respectively a_g, b_{2g}, b_{2u}, and b_{1u} irreducible representations of the point group D_{2h}. When self-consistency is achieved at two different geometries, one having a full symmetry and the other a lower symmetry, the latter should, in principle, be energetically favored as compared with the former. In such a case, we define the stabilization energy as the difference in total energy between the two geometries. The value of the force constant k adopted for use in calculating the σ-core energy is 714 kcal mol^{-1} Å^{-2}.[19]

Results and Discussion

The symmetries and energies (measured from the ground state) of the lowest excited states for the fully-symmetrical nuclear arrangements of the nonalternant hydrocarbons (Fig. 1) and some of their dianions are listed in Table 1. In Fig. 2 are shown the one-center and two-center components of the transition densities for some selected molecules.

The second excited states being, in most cases, well separated from the lowest excited states in these molecules, the symmetries of the most soft nuclear displacements may be given by those of the lowest excited states. In pentalene (I), for example, the most soft nuclear displacement is predicted to be of b_{3g} symmetry. In this molecule there are two distinct types of in-plane vibration both belonging to b_{3g} irreducible representation. In Fig. 2 are shown one-center and two-center components of ρ_{01} for pentalene, together with those of ρ_{05} associated with the fifth excited state which lies at 6.14 eV above the ground state and belongs also to B_{3g} representation. It will be seen from these data that the lowest excited state contributes much to the relaxability of the molecule towards the bond-alternation type of distortion, while the next B_{3g} excited state contributes mainly to that towards the other type of bond distortion. The data in Fig. 2 show that in most of the molecules examined, with the exception of molecules IV and V, the bond alternation in the peripheral carbon skeleton is the energetically soft most bond distortion in the ground state. Such will be the case with the seven-membered analogues of I, II,

and III (molecules VII, VIII and IX, respectively).

The molecular symmetry groups and the bond distances for the energetically most stable nuclear arrangements of the nonalternant hydrocarbons obtained by the variable bond-length SCF MO method are presented in Tables 2, and 3, Inspecting the data in Tables 1, 2 and 3. one may draw a fairly clear-cut criterion for the molecular symmetry reduction in nonalternant hydrocarbons that if the lowest excitation energy is smaller than about 1.2 eV, the force constant for a certain antisymmetric in-plane vibration should be negative and the molecule would be distorted into a less symmetrical nuclear configuration. In Fig. 3 the stabilization energies ΔE_s which favor a lower-symmetry nuclear arrangement are plotted against the lowest excitation energies E_1-E_0 as calculated by assuming the fully-symmetrical nuclear arrangements. It is seen that there exists a good correlation between E_1-E_0 and ΔE_s; the smaller the former, the larger the latter.

The molecular symmetry groups for the most stable nuclear configuration as obtained by using the SCF method are in complete agreement with those brought about by the most soft bond distortions predicted from the symmetry rule. Moreover, in molecules I, II, III, VII, VIII, IX, XII, and XIII which suffer a symmetry reduction, the bond-length distributions obtained by using the SCF method indicate that they exhibit a more or less marked bond-length alternation in the molecular periphery, as is expected from the distributions of transition densities. It is of interest to note in this connection that a fairly strong bond alternation is predicted even in molecules II, VIII, and XIII, the perimeters of which are composed of $4n+2$ carbon atoms.

Of particular notice is dibenzopentalene (V). The transition density ρ_{01} of this molecule (Fig. 2) indicates

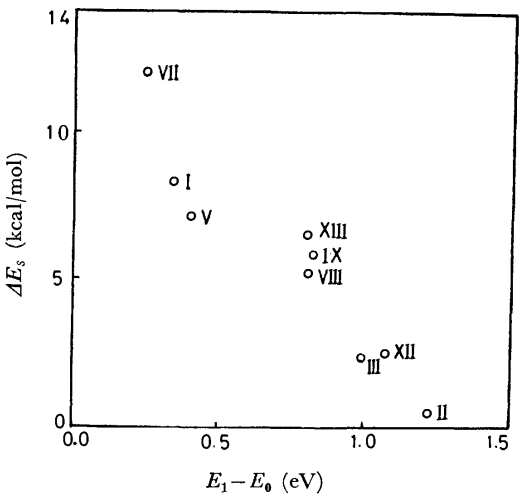

Fig. 3. Correlation of ΔE_s with E_1-E_0.

that strong double-bond fixations are localized in the pentalene segment, but there exists only a slight degree of double-bond fixation in each of the benzene rings. On the other hand, the results of SCF calculations show that in one of the benzene rings of this molecule, bond lengths are smoothed out as in benzene, whereas in the other ring there exists a strong double-bond fixation in the same degree as in the pentalene segment. In the case of V, the symmetry rule is thus insufficient in predicting the actual type of the most favorable bond distortion. In the isomeric dibenzopentalene (VI) which suffers only a first-order bond fixation, the two benzene rings are equivalent and in both the benzene rings bond lengths are almost equalized. Strong double-bond fixations are localized in the butadiene-like skeleton of the pentalene segment. It is therefore expected that the molecule undergoes addition reactions in this region. This is in accordance with experimental facts.[20,21]

Of the cata-condensed nonalternant hydrocarbons examined, pentalene (I) and heptalene (VII) which have been the objects of many theoretical investigations[13,15,19,22-27] are predicted to possess a marked tendency to the second-order double-bond fixation. In both molecules there exists a strong bond-length alternation in the molecular periphery. Available experimental information[28-30] agrees with this in indicating that the π-electrons in these molecules are strongly localized in "double" bonds, rather than uniformly delocalized over the entire molecule.

s-Indacene (III), recently prepared by Hafner *et al.*[31], is predicted to assume a skew structure with a moderate double-bond fixation. The results obtained by using different theoretical methods[13,15,32] agree with this. The theoretical predictions are in good agreement with the available experimental information.

Other molecules worth mentioning are peri-condensed nonalternant hydrocarbons XIV—XVIII; all these molecules are predicted not to suffer second-order bond distortions. As for XIV and XV, it is noted that bond lengths of the peripheral bonds belonging to the 5-membered ring of XV are all predicted to be 1.4 Å. In both molecules there is a pronounced double-bond fixation in the remaining region of the periphery. Derivatives of XIV and XV have been prepared by Hafner and Schneider[33,34] and the predicted distributions of bond lengths are in good agreement with the X-ray data (Table 2).[35-37] In molecules XIV—XVIII, it is predicted that bond lengths of the naphthalene core are almost the same as those in the free naphthalene molecule and there are marked double-bond fixations in the other region of the periphery.[38] The most stable nuclear arrangement in XVI corresponds to the aromatic model proposed by Lo and Whitehead.[39] Molecules XVI and XVIII have been synthesized by Trost and Bright[40] and Boekelheide and Vick,[41] respectively. The present results are in good qualitative agreement with the available experimental facts.

The lowest excitation energies calculated assuming the full molecular-symmetry for dianions of I, III IV, and VII are all larger than the critical value (1.2 eV). This indicates that no symmetry reduction should occur in the ground states of these dianions, the prediction being in agreement with the results of SCF calculations. In I, III, and VII, addition of two more electrons to the neutral molecule to form the dianion results in a complete disappearance of the unsymmetrical bond distortion, and in the dianions the bond lengths of the peripheral C–C bonds are nearly equalized. Dianions of I,[42,43] II,[44] and IV[45,46] have been prepared and are known to be stable species.

In this connection the molecular symmetries of anion and cation radicals of fulvalenes should be mentioned. If the full molecular symmetry (D_{2h}) is assumed, the ground states of the cation radical of pentafulvalene (XXI) and the anion radical of heptafulvalene (XXII) are predicted to be of $^2B_{1g}$ symmetry. The lowest excited states of these radicals are of ^2A_u symmetry and are predicted to be very close to the ground states; in the framework of one-electron approximation the two states are degenerate. In these radicals, therefore, the ground state interacts strongly with the first

TABLE 4. BOND LENGTHS OF CATION AND ANION RADICALS OF FULVALENES

Radical	Bond	Bond length (Å)	Radical	Bond	Bond length (Å)
XXI$^+$(C_{2v})	1—2	1.416	XXII$^+$(D_{2h})	1—2	1.379
	1—5	1.441		1—7	1.427
	2—3	1.396		2—3	1.426
	5—6	1.388		3—4	1.380
	6—10	1.461		7—8	1.422
	8—9	1.477			
	9—10	1.353	XXII$^-$(C_{2v})	1—2	1.400
				1—7	1.437
XXI$^-$(D_{2h})	1—2	1.378		2—3	1.399
	1—5	1.429		3—4	1.422
	2—3	1.428		7—8	1.396
	5—6	1.421		8—14	1.449
				11—12	1.354
				12—13	1.426
				13—14	1.360

excited state through the nuclear displacement of $b_{1u}(z)$ symmetry, with the result that the initial molecular symmetry (D_{2h}) should be reduced to C_{2v} (Table 4).

On the other hand, in the anion radical of XXI and the cation radical of XXII, the energy gaps between the first excited state (which is doubly degenerate in the one-electron approximation) and the ground state are reasonably large (1.4 and 1.7 eV, respectively) and these radicals would not suffer symmetry reduction.

The above predictions are in agreement with the results obtained by using the open-shell SCF method in conjunction with the variable bond-length technique.[47,48]

The cation and anion radicals of XXII have been prepared and their ESR spectra have been investigated by Sevilla *et al.*[49] The analysis of the hyperfine spectra of these radicals has revealed that the cation radical should have D_{2h} symmetry, whereas the molecular symmetry of the anion radical should be lower than D_{2h}.

Finally we consider the application of the symmetry rule to the prediction of the geometrical structures of the excited states of conjugated hydrocarbons. On the basis of the same approximation as used in predicting the ground-state geometrical structures, the force constant for the ith normal nuclear-displacement in the nth excited state may be written as

$$f_n^i = k - 2\sum_m{}' \frac{\left|\left\langle \psi_n \left| \frac{\partial H_\pi}{\partial Q_i} \right| \psi_m \right\rangle\right|^2}{E_m - E_n} \qquad (6)$$

In order to seek the most soft nuclear displacement in the excited state, the approximation is again made of replacing the sum in Eq. (6) by one or two terms correpsonding to the higher one or two excited states. Now, the transition density ρ_{nm} between the nth excited state corresponding to the orbital jump $\phi_i \rightarrow \phi_k$ and the mth one corresponding to $\phi_j \rightarrow \phi_l$ is $\phi_k\phi_l$ if $i=j$, and $-\phi_i\phi_j$ if $k=l$. Therefore, the value of the matrix element $|\langle\psi_n|\partial H_\pi/\partial Q_i|\psi_m\rangle|^2$ in Eq. (6) should be about one half of that of $|\langle\psi_0|\partial H_\pi/\partial Q_i|\psi_n\rangle|^2$ in Eq. (3) in so far as the transition densities are assumed not to vary significantly according to the molecular orbitals concerned. Thus, if the energy gap $E_m - E_n$ is smaller than about one half the critical value obtained above, that is, about 0.6 eV, the force constant in the excited state is expected to be negative.

In Table 1 are presented the energies of the second excited states (measured from the first excited states) as obtained by minimizing the ground-state energy assuming the full molecular symmetry. Use of these eigenvalues and corresponding wavefunctions in Eq. (6) is approximative. The energy values and corresponding wavefunctions to be used in Eq. (6) should, in principle, be those corresponding to the first-order equilibrium nuclear arrangement of the nth excited state, as given by minimizing its energy and keeping the molecular symmetry highest.

Inspection of Table 1 reveals that all those molecules which suffer a molecular-symmetry reduction in the ground state have $E_2 - E_1$ values considerably larger than the critical value and are predicted to possess a fully-symmetrical nuclear arrangement in their first excited state.

TABLE 5. BOND LENGTHS OF FIRST SINGLET EXCITED STATES OF VII, XXI AND XXII

Molecule	Bond	Bond length (Å)	Molecule	Bond	Bond length (Å)
VII (D_{2h})	1—2	1.402	XXII (C_{2v})	1—2	1.399
	1—12	1.412		1—7	1.436
	2—3	1.405		2—3	1.404
	6—12	1.463		3—4	1.421
				7—8	1.406
XXI (C_{2v})	1—2	1.422		8—14	1.442
	1—5	1.435		11—12	1.362
	2—3	1.394		12—13	1.448
	5—6	1.409		13—14	1.365
	6—10	1.442			
	8—9	1.444			
	9—10	1.366			

In the case of heptalene (VII), we have calculated the bond-length distribution in the first excited state using the same SCF procedure as that used for the ground state, except for the use of a different value 3.3 Å^{-1} (1.7 Å^{-1} for the ground state) for the exponent in the exponential expression of the resonance integral.[50] The results are presented in Table 5; all the possible starting bond distortions produce a unique set of bond

lengths belonging to the point group D_{2h} and the bond lengths of the peripheral bonds are nearly equalized, which supports the prediction given by the symmetry rule. The marked difference in the geometrical structure between the ground state and the lowest excited state in heptalene gives the main reason for the appearance of a long absorption tail throughout the visible region in its absorption spectrum.[28]

On the other hand, there are cases where a molecule has an E_1-E_0 value reasonably higher than the critical value, but the separation between the second and first excited states is relatively small. The E_2-E_1 value for I^{2-} is of the same order of magnitude as the critical value, and those for the peri-condensed hydrocarbon, XVII, the fulvalenes, XXI and XXII, and the dianions, IV^{2-} and VII^{2-}, are significantly smaller than the critical value for the first excited state. For XXI and XXII, the results of SCF calculations presented in Table 5 agree with the predictions given by the symmetry rule in indicating that on exciting to the first excited state, the molecular symmetries are reduced to C_{2v} from D_{2h}. This provides a probable explanation for the fact that the longest wave-length absorption bands of these molecules are relatively broad.[51]

Azulene (XI) has an E_2-E_1 value reasonably larger than the critical value and no symmetry reduction is expected on excitation to the first excited state. A recent analysis of the vibrational structures of the longest wavelength absorption band indicates that azulene retains C_{2v} symmetry in the first excited state.[52]

Conclusion

In predicting the geometrical structures with respect to the C–C bond distances of nonalternant hydrocarbons on the basis of the pseudo Jahn-Teller theorem, we have assumed that only the lowest excited state plays a dominant role in determining the most soft nuclear displacement. In spite of this very crude approximation, the predicted types of the energetically most favorable bond distortions and molecular-symmetry reductions are in good agreement with the results of the variable bond-length SCF MO calculations and available experimental facts.

The criterion for the symmetry reduction obtained above, that if the lowest excitation energy predicted assuming the full molecular-symmetry for a nonalternant hydrocarbon is smaller than *ca.* 1.2 eV, the molecule should be distorted into a less symmetrical nuclear configuration, is applicable to the conjugated hydrocarbons in general. It is interesting to mention, in this connection, the symmetry reductions possible in large cyclic polyenes $C_{4n+2}H_{4n+2}$.[10] The lowest excitation energies calculated assuming the full molecular-symmetry (D_{6h}) for $C_{18}H_{18}$ and $C_{30}H_{30}$, both known to date,[53] have been reported to be about 1.6[54-56] and 0.95 eV,[55] respectively. It is thus expected that $C_{30}H_{30}$ should suffer a symmetry reduction, and that contrary to the previous assumption,[10,55] there exists no symmetry reduction ($D_{6h}\rightarrow D_{3h}$) in the ground state of $C_{18}H_{18}$. Actually, as for $C_{18}H_{18}$, the lowest excitation energy (1.6 eV) predicted assuming D_{6h} symmetry is in good agreement with the position of the longest wave-length absorption band ($^1B_{2u}$) recently discovered by Blattmann *et al.*[54] The symmetry reduction in $C_{4n+2}H_{4n+2}$ is thus predicted to occur at $n\sim5$, which is in agreement with the result obtained by Binsch and Heilbronner using a more sophisticated theoretical procedure.[12]

ESR Studies of the Conformational Interconversion of the 9,10-Dihydrophenanthrene Radical Anion and Its Related Compounds

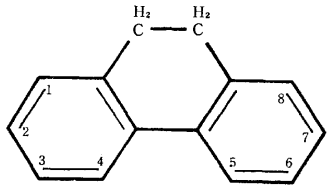
Masamoto IWAIZUMI, Takashi MATSUZAKI, and Taro ISOBE

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira 2—1—1, Sendai

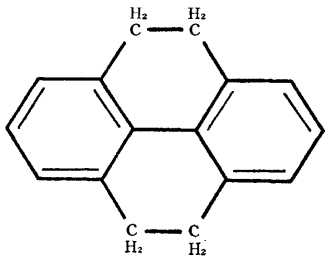
(Received October 6, 1971)

The ESR spectra of the 9,10-dihydrophenanthrene radical anion change drastically with the temperature, and at temperatures around −30°C the spectra show a marked line-width alternation effect. These temperature-dependent ESR spectra and the line-width alternation effect have been interpreted in terms of the conformational interconversion of the 9,10-dihydrophenanthrene radical anion molecule. From an analysis of the spectra, the activation energy of the inversion has been estimated to be 6.3±0.6 kcal/mol. It has also been estimated, from the ratio of the axial and equatorial proton splittings, that the dihedral angle of the axial protons is about 11°. These data are compared with those of the 4,5,9,10-tetrahydropyrene radical anion. The ESR of the 4,5-dihydropyrene radical anion is also presented.

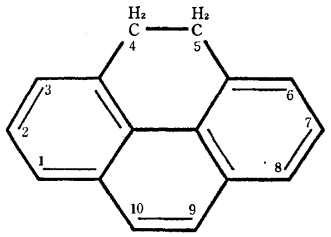
The conformational interconversion of several bridged biphenyls has been investigated by means of NMR[1,2] and ESR,[3] and also by the observation of the racemization of optically-active biphenyls.[4-7] The inversional motion of the neutral molecule of 9,10-dihydrophenanthrene (I) has been studied by the NMR[1] and the optical methods.[6] However, the techniques of NMR or optical measurements were not effective in obtaining information about the inversion process of the 9,10-dihydrophenanthrene molecule, because the inversion process was too fast to be treated by the NMR or optical measurements. In a previous paper,[3] we observed a line-width alternation effect in the ESR of the radical anion of 4,5,9,10-tetrahydropyrene (II) and explained it in terms of the inversional motion of the molecule. The ESR technique is sometimes quite effective in the study of fast rate processes; it makes possible the measurements of much faster rate processes than in the case of the NMR and optical methods.



[I]



[II]



[III]

In this paper, we wish to report on the inversion process of the radical anion of 9,10-dihydrophenanthrene as studied by the ESR method. We observed a line-width alternation effect in the ESR similar to that of the 4,5,9,10-tetrahydropyrene radical anion. This line-width alternation effect can be explained as arising from the rapid modulation of the methylene proton hyperfine splitting constants due to exchange between an axial and equatorial state by means of the inversional motion of the molecule. The data obtained for this inversion process and the structure of the molecule are compared with those of the 4,5,9,10-tetrahydropyrene radical anion. In connection with these compounds, the 9,10-dihydropyrene radical anion has also been studied by the ESR method.

Experimental

The 9,10-dihydrophenanthrene and 4,5-dihydropyrene were obtained commercially. The 9,10-dihydrophenanthrene was purified by recrystallization from ethyl alcohol (mp 34—35°C), and the 4,5-dihydropyrene, by column chromatography (mp 130—131°C). The radical anions were prepared by alkali metal reduction in ethereal solvents by the previously-established technique.[8] ESR measurements were carried out by means of a Hitachi X-band ESR spectrometer. Variable temperature experiments were performed using a gas-flow temperature control method previously described.[3] The temperature of the samples was monitored by means of a copper-constantan thermocouple which was fixed just below the sample tube.

Results and Discussion

Line-width Alternation Effect in the ESR spectra of the 9,10-Dihydrophenanthrene Radical Anion and the Inversional Motion of the Molecule. As Fig. 1 shows, the hyperfine structure of the ESR spectra of the 9,10-dihydrophenanthrene radical anion changes markedly with the temperature. This change in the hyperfine structure with the temperature comes mainly from the change in the hyperfine components due to the methylene protons. The spectrum at low temperatures (Fig. 1a, 4) can be analyzed in terms of the difference in the splitting constant for the axial and the equatorial methylene protons, and the four sets of triplet splittings due to the four sets of two equivalent ring protons. A typical set of splittings due to the methylene protons are shown with arrows in Fig. 1. As the temperature increases, this methylene proton hyperfine splitting changes extensively; at temperatures around −27°C (Fig. 1a, 1) it becomes a three-line pattern with an intensity ratio of about 1 : 4.2 : 1 and with line separation of $(a_{eq}+a_{ax})$, where the a_{eq} and a_{ax} are the splitting constants of the equatorial and axial protons obtained at low temperatures. This hyperfine pattern is a typical line-width alternation phenomenon, and the intensity ratio coincides well with the one expected, 1 : 4 : 1, from the theory of the line-width-alternation effect[9] for an extremely broadened case.

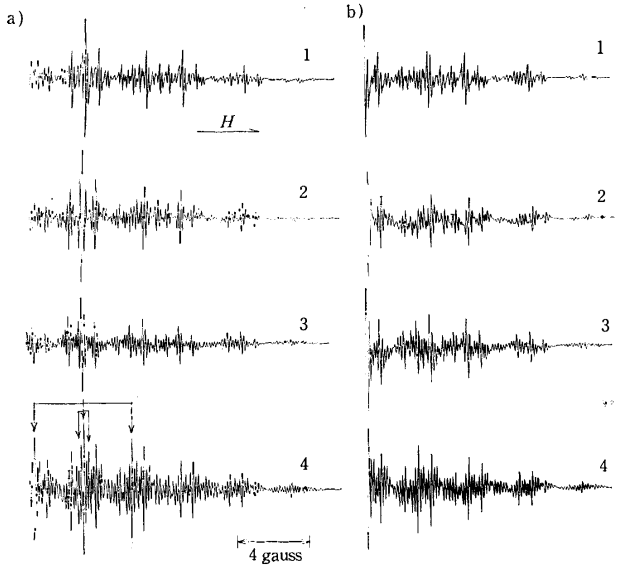

Fig. 1. ESR spectra of the 9,10-dihydrophenanthrene radical anion in tetrahydrofuran with lithium ion as a counter ion.
(a) Spectra observed 1) at −27°C, 2) at −71°C, 3) at −81°C, and 4) at −102°C.
(b) Computer simulation; 1) $\tau=1.4\times10^{-7}$ sec 2) $\tau=2.0\times10^{-6}$ sec, 3) $\tau=5.0\times10^{-6}$ sec 4) $\tau=4.0\times10^{-5}$ sec.

As has been reported in the previous paper,[3] the line-width alternation effect observed here can be attributed to the inversional motion of the 9,10-dihydrophenanthrene anion molecule. At low temperatures, the rate of the inversional motion is slow and the axial and equatorial splitting constants can be separately observed. On the other hand, at high temperatures the inversional motion becomes rapid and it becomes impossible to distinguish the axial and the equatorial protons by rapid exchange between the two states.

This rate process has, therefore, been analyzed by using a modification for the two-jump model of Bloch's equation.[10] The computer-simulated ESR spectra obtained on the basis of this model are compared with the observed spectra in Fig. 1. Although the ring proton hyperfine splitting constants change slightly with the temperature, the neglect of such slight changes in the splitting constants does not result in serious errors in the evaluation of the life-time of the conformation, τ. Therefore, the changes in the hyperfine splitting constants with the temperature were ignored and the hyperfine splitting constants obtained at −102°C were used throughout the ESR

Table 1. Hyperfine splitting constants and spin densities for the 9,10-dihydrophenanthrene radical anion[a] (in gauss)

Position	1,8	2,7	3,6	4,5	CH_2 Axial	CH_2 Equatorial
Hyperfine splitting constants at −102°C[b]	0.161	5.363	0.708	3.359	2.674	0.289
Spin densities[c]	−0.0064	0.2041	−0.0262	0.1154	—	—

a) The radical was prepared with lithium in tetrahydrofuran.
b) Absolute values.
c) The values were obtained by the McLachlan's calculation (*Mol. Phys.*, **3**, 233 (1960)) using the following parameters and $\lambda=1$.

$\delta_{\alpha_1}=-0.1\beta$ $\quad\delta_{\alpha_2}=\delta_{\alpha_3}=-0.1\beta$ $\quad\delta_{\alpha_4}=-0.5\beta$
$\beta_{12}=\beta_{23}=0.7\beta$ $\quad\beta_{24}=2.5\beta$

simulation. In Table 1 the hyperfine splitting constants obtained at −102°C are listed. The assignment of the observed splitting constants to the respective proton positions was made on the basis of the calculated spin distribution.

By applying the estimated τ values to the following relation:

$$k = 1/\tau = k_0 \exp(-E_a/RT) \quad (1),$$

the activation energy, E_a, of the inversional motion can be evaluated. Here, k is the rate constant of the inversion, and k_0 is the frequency factor. Figure 2 shows the plot of $\log_{10} 1/\tau$ against $1/T$. E_a and k_0 were calculated to be 6.3±0.6 kcal/mol and $3.5\pm2.9\times10^{12}$ sec^{-1} respectively from the figure.

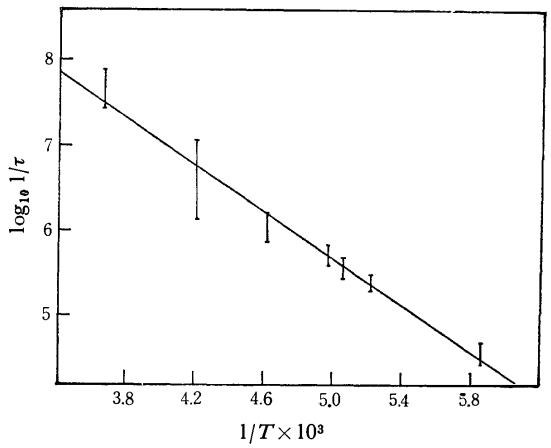

Fig. 2. Plot of $\log_{10} 1/\tau$ against $1/T\times10^3$ for the 9,10-dihydrophenanthrene radical anion.

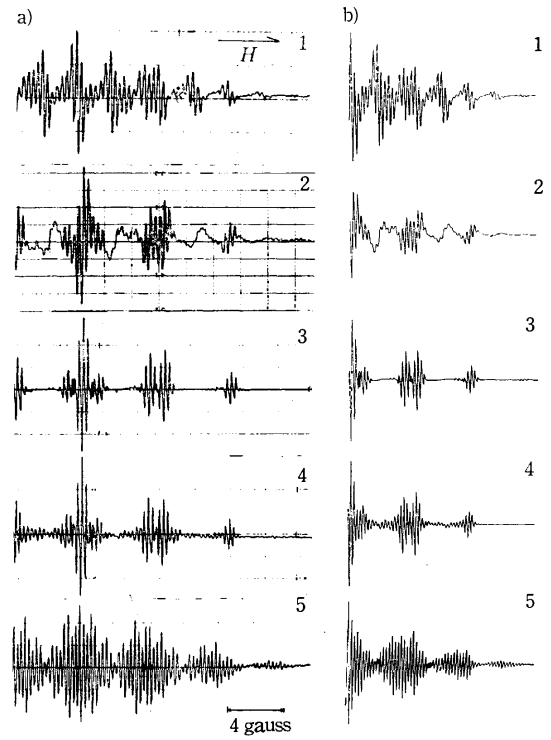

Fig. 3. Comparison of the computer simulated ESR spectra with the observed ones of the 4,5,9,10-tetrahydropyrene radical anion in 1,2-dimethoxyethane with potassium ion as a counter ion.
(a) Spectra observed 1) at +63°C, 2) at +23°C, 3) at −35°C, 4) at −58°C, and 5) at −81°C.
(b) Computer simulation; 1) $\tau=1.2\times10^{-9}$ sec, 2) $\tau=1.2\times10^{-8}$ sec, 3) $\tau=7.0\times10^{-8}$ sec, 4) $\tau=1.6\times10^{-6}$ sec, 5) $\tau=9.0\times10^{-6}$ sec.
The observed spectra are taken from Ref. 3.

For a comparison of the activation energy with that of the inversion of the 4,5,9,10-tetrahydropyrene radical anion, the inversion process of the 4,5,9,10-tetrahydropyrene radical anion previously reported was reexamined through a computer simulation of the spectra. The calculated spectra are compared with the observed ones in Fig. 3. From the plot of $\log_{10} 1/\tau$ against $1/T$ (Fig. 4), the activation energy of the inversion of the molecule was obtained as 8.7± 0.6 kcal/mol, and k_0, as $4.4\pm2.8\times10^{14}$ sec^{-1}.[11] That is, the increase in the activation energy of the inversion from the singly-bridged form to the doubly-bridged form is 2.4 kcal/mol. Milsow estimated, by a simple theoretical consideration, an activation energy of 7—8 kcal/mol for the 4,5,9,10-tetrahydropyrene and one of 4 kcal/mol for the 9,10-dihydrophenanthrene molecules.[6] These predictions are in agreement with our experimental results, although his calculation was made for neutral molecules and gave a larger difference in the activation energies between the two compounds.

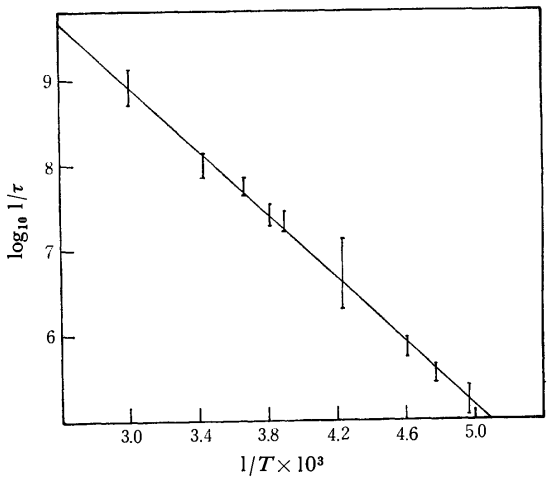

Fig. 4. Plot of $\log_{10} 1/\tau$ against $1/T\times10^3$ for the 4,5,9,10-tetrahydropyrene radical anion.

The Conformation of the 9,10-Dihydrophenanthrene Anion Molecule. β proton hyperfine splitting constants have a pronounced orientation dependence, which is given by the well-known formula:[12]

$$a_\beta = (B_0 + B_2 \cos^2\theta)\rho_t. \quad (2)$$

Here, ρ_t represents the spin density at the trigonal carbon(i), θ is the dihedral angle between the C–H$_\beta$

11) In a previous paper[3] the activation energy was estimated without attempting a computer simulation of the whole hyperfine pattern of the spectra, but by observing the behavior of the pair of lines with spin states (1,0) and (0,1) or (−1,0) and (0,−1). Here, the numbers in the parentheses correspond to the quantum numbers for the total angular momenta of the axial and equatorial protons respectively. In this work adopting the computer simulation of the whole hyperfine pattern of the spectra, it was found that the estimated activation energy in the previous paper contains a large error. The value reported previously must, therefore, be revised.

12) C. Heller and H. M. McConnell, *J. Chem. Phys.*, **32**, 1535 (1960).

bond and the $2p_z$ orbital on the ith carbon, and B_0 and B_2 are constants. In the 9,10-dihydrophenanthrene molecule, if the molecular structure is planar, the two protons in the methylene groups must be equivalent stereochemically and must have the same splitting constants. On the other hand, if the two aromatic rings twist about the bond joining the rings, the hyperfine splittings of the two methylene protons will become different, and the larger the amount of the twist becomes, the larger will the ratio of the axial and the equatorial proton splitting constants be. The observed ratio of the axial and the equatorial proton splittings in the 9,10-dihydrophenanthrene radical anion was 9.25. For the case of the 4,5,9,10-tetrahydropyrene radical anion, this ratio was 4.82. Furthermore, by assuming that $B_0=0$, the dihedral angle for the axial proton of the 9,10-dihydrophenanthrene radical anion is calculated to be 11°. This value is larger than the value, 3°, for the 4,5,9,10-tetrahydropyrene radical anion previously reported. These results indicate that the twist angle between the two benzene rings would be larger in the 9,10-dihydrophenanthrene radical anion than in the case of the 4,5,9,10-tetrahydropyrene radical anion, which is in agreement with the conclusion obtained from the studies by means of the NMR and UV spectra.[6]

ESR of the 4,5-Dihydropyrene Radical Anion. In the case of the 4,5-dihydropyrene radical anion(III), the two methylene protons will probably be in different states stereochemically, *i.e.*, in the axial and equatorial states, as in the cases of the 9,10-dihydrophenanthrene or 4,5,9,10-tetrahydropyrene radical anion, although the distortion of the molecule from a planar structure is small because of the presence of the 9—10 π bond. We examined the ESR spectra of the 4,5-dihydropyrene radical anion in the hope of getting information on the structure of the molecule and the inversional motion.

The observed spectra are shown in Figs. 5 and 6. The spectrum in Fig. 5 is analyzed in terms of four sets of triplet splittings, which can reasonably be assigned to the hyperfine interaction with the ring protons on the basis of a comparison with the spin-density distribution estimated by the MO calculation (Table 2). When the anion is prepared by reduction with potassium in 1,2-dimethoxyethane, the hyperfine splitting due to the methylene protons is not resolved. On the other hand, when the radical is prepared by reduction with potassium in 2-methyltetrahydrofuran, the radical shows a spectrum with further splittings due to the interaction with the methylene protons and a potassium ion associated with the radical anion (Fig. 6). The appearance of the methylene proton

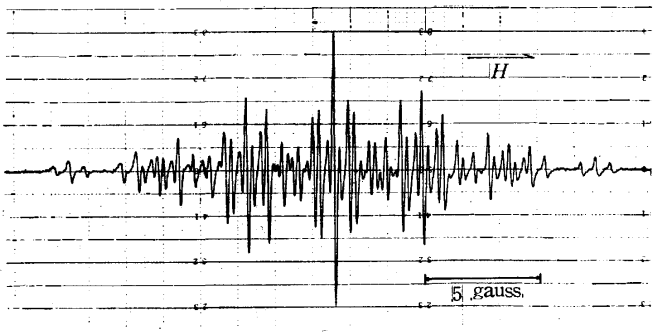

Fig. 5. ESR spectrum of the 4,5-dihydropyrene radical anion in 1,2-dimethoxyethane with potassium ion at 20°C.

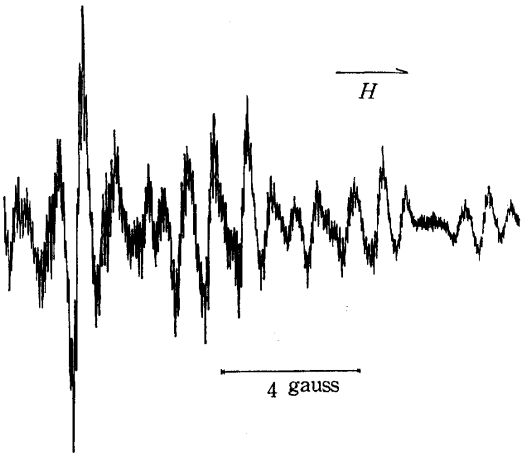

Fig. 6. ESR spectrum of the 4,5-dihydropyrene radical anion in 2-methyltetrahydrofuran with potassium ion at 20°C.

splitting is attributed to the redistribution of the odd electron in the molecule by the cationic field of the associated potassium ion. Unfortunately, the spectra could not be analyzed unequivocally because of the low S/N ratio, the complicated hyperfine pattern, and imperfect resolution. In the spectrum obtained at 20°C, however, the additional hyperfine splittings due to the methylene protons and the associated potassium seem to consist of eight lines. If it is assumed that the four methylene protons show quintet splitting with a binomial intensity ratio, and that potassium show a splitting with a splitting constant of half of the four methylene protons, an eight-line pattern with roughly the same intensity ratio as the observed one can be expected for the methylene proton and the potassium hyperfine splittings. According to this analysis, the two types of methylene protons, axial and equatorial, will be in an averaged state as a result of the fast inversional motion. The inversion rate will

then be faster than approximately 10^8 Hz. The NMR spectrum of the neutral molecule of 9,10-dihydropyrene shows a single line for the methylene protons, with a δ value of 3.22. This means that the inversional motion of the neutral molecule is apparently a fast process on the NMR time scale. More reliable information on the methylene protons in ESR is desirable for the analysis of the inversion process of the 9,10-dihydropyrene anion.

The numerical calculations were carried out on the NEAC 2200 Model 700 computer at the Computer Center, Tohoku University.

The Reactions between a Rhenium Filament and Nitric Oxide at High Temperatures and Low Pressures

Teijiro TAMURA

Department of Chemistry, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto

(Received October 22, 1971)

The rates of the reaction of rhenium with nitric oxide under a filament temperature of (1300—1800)°K and a nitric oxide pressure of ($3\times10^{-5}-1\times10^{-3}$)Torr have been measured by a static method. The rate of the reaction increases with an increase in the temperature, and the apparent activation energy is 24 kcal/mol. The rate of the reaction is proportional to the nitric oxide pressure and independent of the nitrogen pressure. The apparent compositions of the rhenium oxide produced in the reaction have been determined from the weight change in the rhenium filament and from the amount of nitric oxide consumed in the temperature range of (1300—2100)°K. The ReO_3 and Re_2O_7 were formed at lower temperatures and at higher temperatures respectively. The Re_2O_7 was presumed to be formed by the oxidation of the ReO_3 deposited on the vessel wall with atomic oxygen evolved in a high-temperature range.

At high temperatures, some metals react with oxidizing gases to form very highly volatile metal oxides. Therefore, the reactions proceed on surfaces practically free from the accumulation of the oxide layers. Adsorption, surface reaction, and desorption are included in these processes, and kinetic studies of such systems are expected to present useful information about the gas-solid interactions. These metals can be heated resistively to a considerably high temperature and can readily provide a clean metal surface when heated at a high temperature in a vacuum. Moreover, if the reactions are carried out at very low pressures, the following advantages may be expected; the diffusion rate of gas coming to and leaving from the surface is so large that it does not limit the overall rate of the process.

Rhenium possesses some advantageous properties;[1,2] that is, many refractory transition metals can form stable carbides and nitrides, while rhenium can not,[3] and it has a high resistance to the "water cycle"[4] at high temperatures. It is of interest to investigate the interaction of nitric oxide with rhenium, since nitric oxide is an odd molecule (possessing an odd number of electrons).

Many studies of the reactions of oxygen with tungsten[5-8] and rhenium[9-11] have been reported. However, although the reaction of tungsten with nitric oxide at very low pressures has been studied by Anderson[12], no reaction of rhenium with nitric oxide has been studied.

In the present investigation, the reaction rates of the rhenium filament with nitric oxide have been measured at pressure from 3×10^{-5} Torr to 1×10^{-3} Torr and in the temperature range from 1300°K to 1800°K by a static method. The apparent compositions of the rhenium oxide have also been determined from the amount of nitric oxide consumed and from the amount of rhenium lost in the temperature range from 1300°K to 2100°K.

Apparatus

The apparatus is shown in Fig. 1. For the measurement of the rate of the reaction, a reaction vessel of 5.2 *l* (including

a Pirani gauge) was used. It consisted of a spherical bulb 20 cm in diameter and side tubes 3.5 cm in diameter and 15 cm long. Along the axis of each side tube, a rhenium filament, 0.152 mm in diameter and 130 mm long, was mounted, being stretched by a tungsten spring and connected to lead wires by spot welding. The lead wires were coated with glass in order to exclude any reactions that consume nitric oxide on the lead-wire surface.

For the determination of the oxide composition, the apparatus was similar to that used for the measurement of the reaction rate except that it had a reaction vessel of 98 *l*, and rhenium filaments, each 75 mm long, were mounted in it. They were clamped at both ends with platinum strips which were welded to the glass-coated lead wire so that they could be easily disconnected from the wires for weighing.

Particular care was taken to keep the filaments free from grease and mercury-vapor contamination; liquid nitrogen traps and greaseless stopcocks were used. Nitric oxide in a reservoir was supplied to the reaction vessel by a gas pipet through a capillary tube so placed as to decrease the flow rate of the gas. The pressure in the reaction vessel was measured by a Pirani gauge which was calibrated against a McLeod manometer and which had a sensitivity of 7.2×10^{-5} Torr/mV for nitrogen and nitric oxide.

The rhenium filament was heated electrically by means of a controllable DC power supply, and its temperature was measured with a micro optical pyrometer. The rhenium filament was analyzed spectroscopically (Found: Si : 0.08%, Ti : 0.001%). It was cleaned by dipping it in a boiling 40% caustic potash solution for five minutes and then wiping it off aqua-dag with filter paper; this procedure was repeated several times.

The nitric oxide and nitrogen were prepared by the methods described in the previous paper[13].

Procedure

All the apparatus was evacuated by a mercury-diffusion pump; for degassing the reaction vessel was heated at 360°C for ten hours in an electric furnace, and the filaments were heated to about 2100°K in oxygen of 1×10^{-5} Torr in order to remove any possible carbonaceous surface contamination. This heating was done until the evolution of the inactive gases from the filaments had become negligibly small.

Before each experiment, a filament was flashed at 2200 °K for 2 min in a high vacuum. Then the nitric oxide was introduced into the reaction vessel. When the nitric oxide pressure attained the desired value, the reaction vessel was separated from the evacuating system by means of the greaseless cock. The filament was then heated to the experimental temperature. As the reaction proceeded, the pressure in the vessel decreased; it was measured from time to time after the filament had been switched off and cooled down at room temperature, because the Pirani gauge could not follow the rapid change in pressure.

In the case of the determination of the composition of the rhenium oxide, each filament was weighed with a micro balance before it was mounted in the vessel. The processes of degassing the apparatus and of introducing nitric oxide into the vessel were similar to those described above. Then the filament was heated at the experimental temperature until all the nitric oxide had been consumed. Separate filaments were thus heated at the temperatures between 1300°K and 2100°K. The filaments were then taken out from the reaction vessel, removed from the lead wires, and weighed again with the micro balance in order to determine the loss of the rhenium filament.

Results and Discussion

The Rate of the Reaction. The rate of the reaction between the rhenium filament and nitric oxide was measured at temperatures from 1300°K to 1800°K and at pressures from 3×10^{-5} Torr to 1×10^{-3} Torr.

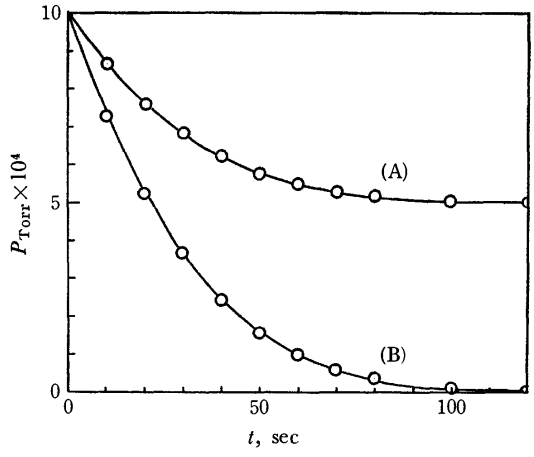

Fig. 2. Pressure *vs.* heating time of the filament.
Filament temperature, 1400°K.
(A) Total pressure of nitric oxide and nitrogen.
(B) Partial pressure of nitric oxide.

A typical plot of the pressure, as measured by the Pirani gauge, against the heating time of the filament is shown by curve A in Fig. 2. Since nitrogen is formed by the reaction, the pressure indicated by curve A is the total of the pressure of nitric oxide still remaining and that of the nitrogen produced. We assume that the overall process is represented by:

$$x\mathrm{NO} + \mathrm{Re} \rightarrow (1/2)x\mathrm{N_2} + \mathrm{ReO}_x,$$

and that nitrogen and a volatile rhenium oxide (it evaporates and sticks to the vessel wall) are produced, the intermediate steps being ignored; for every molecule of nitric oxide consumed, there is a net decrease of half molecules in the gaseous phase. It is thus possible, from measurements of the total pressure, P, at various times, to determine the partial pressure, P_{NO}, of the nitric oxide still remaining, as follows:

13) T. Tamura, This Bulletin, **44**, 590 (1971).

$$P_0 - P = (1/2)(P_0 - P_{NO})$$
$$P_{NO} = 2P - P_0$$

where P_0 is the initial pressure of nitric oxide. The plot of P_{NO} against the heating time is given by curve B in Fig. 2.

From the rate of consumption thus obtained, the amount of nitric oxide which reacts with the rhenium filament, D_{NO} mol/sec, can be calculated. The relation between the rate of reaction and the nitric oxide pressures at various temperatures is shown in Fig. 3.

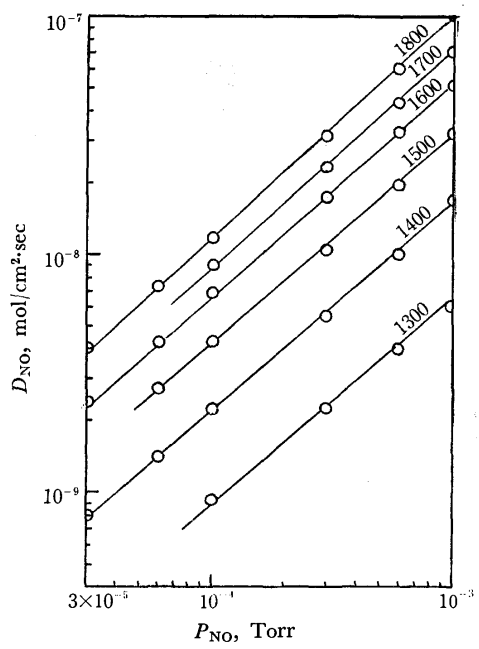

Fig. 3. Effect of nitric oxide pressure on the rate of reaction.

Under these experimental conditions, that is, when the total pressure in the reaction vessel is so low and the surface area of the filament is so small, it is assumed that the temperature of the nitric oxide molecules striking the filament is equal to that of the wall of the reaction vessel and that the pressure is uniform throughout the vessel. Therefore, the number of mols of nitric oxide that strike the filament per second can be calculated from the kinetic theory of gases as follows:

$$P_{NO}S/\sqrt{2\pi MRT}$$

where P_{NO} is the nitric oxide pressure in dyn/cm²; S, the surface area of the filament in cm²; M, the molecular weight of nitric oxide; $\boldsymbol{R}$, the gas constant, and T, the temperature of the reaction vessel. Consequently, the probability, $\boldsymbol{k}$, that a nitric oxide molecule which strikes the filament will disappear from the gaseous phase by some reaction processes can be calculated from the following equation:

$$D_{NO} = \boldsymbol{k}P_{NO}S/\sqrt{2\pi MRT},$$

$\boldsymbol{k}$ is the reaction probability. The reaction probabilities for various temperatures and pressures are given in Table 1. A plot of $\log D_{NO}$ *vs.* $1/T$ is given in Fig. 4. The apparent activation energy is about 24 kcal/mol. The effect of the nitrogen pressure on the rate of the consumption of nitric oxide was also investigated; the filament was heated at a constant temperature with various amounts of nitrogen added to the nitric oxide at first. As a result, the rate of consumption was found to be independent of the nitrogen pressure. This coincides with the fact that the nitrogen desorbs from the surface below 1300°K in the flash-desorption experiments.[13,14] If the filament temperature is kept constant, the rate of consumption is simply given as a function of the nitric oxide pressure alone:

$$D_{NO} = K \cdot P_{NO}^{n}$$
or: $$\log D_{NO} = \log K + n \log P_{NO}$$

Table 1. Reaction probabilities at various temperatures at nitric oxide pressures of 6×10^{-4} torr and 1×10^{-4} torr

Filament temp. °K	$\boldsymbol{k}$ (6×10^{-4} Torr)	$\boldsymbol{k}$ (1×10^{-4} Torr)
1300	0.011	0.015
1350	0.0168	0.024

1550	0.070	0.094
1600	0.0875	0.11
1650	0.101	0.123
1700	0.115	0.141
1770	0.143	0.163
1800	0.161	0.190

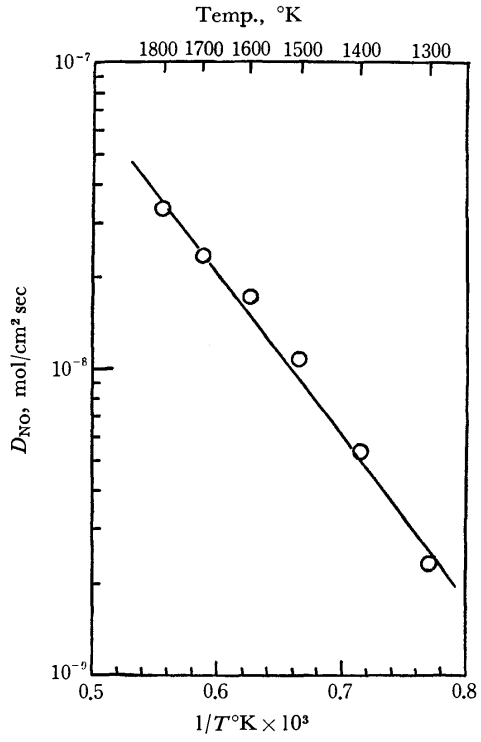

Fig. 4. Effect of filament temperature on the rate of reaction at 3×10^{-4} Torr of nitric oxide pressure.

14) T. Tamura, This Bulletin, **44**, 2116 (1971).

where K and n are constants. As can be seen from Fig. 3, the rate of consumption can be considered to be proportional to the nitric oxide pressure. If this reaction occurs with the direct impact of nitric oxide molecules from the gaseous phase to the rhenium surface, the rate of the reaction should depend on the higher-power of the pressure.

The pressure dependence of the rate of this reaction may be explained as follows. The flash-desorption experiments[13,14] have shown that nitric oxide molecules are dissociated to atomic species at high temperatures under the present experimental conditions, and that nitrogen atoms recombine and evaporate as nitrogen molecules, while oxygen atoms remain on the rhenium surface at a considerably high temperature as an adsorbed oxygen layer. Moreover, in the experiment of thermionic electron emission,[15] it was found that the surface condition for the Re-NO reaction was the same as that for the Re-O_2 reaction, the amounts of species other than oxygen atoms were extremely small on the surface, and that the surface was completely covered with oxygen atoms, whose concentration was independent of the nitric oxide pressure.

Since no rhenium oxides other than ReO_3 evaporate in the temperature range of this experiment,[16] we consider that ReO_3 is formed with oxygen atoms in an oxygen layer and incoming nitric oxide molecules. Therefore, the following steps of the reaction may be described:

$$NO_{(g)} \xrightarrow{k_1} N_{(a)} + O_{(a)} \quad (1)$$

$$N_{(a)} + N_{(a)} \xrightarrow{k_2} N_{2(g)} \quad (2)$$

$$NO_{(g)} + 2O_{(a)} + Re \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} ReO_{3(a)} + N_{(a)} \quad (3)$$

$$ReO_{3(a)} \xrightarrow{k_4} ReO_{3(g)} \quad (4)$$

In the step 1, although nitric oxide adsorbs on the rhenium surface as molecules at room temperature, it is decomposed immediately to atomic oxygen and nitrogen at elevated temperatures.[13] No nitric oxide was detected in the desorption from a mixed nitrogen-oxygen layer.[14] Moreover, in another experiment, when the rhenium filament was heated in a mixed gas of nitrogen and oxygen, nitric oxide was not detected by means of an omegatron mass spectrometer. Hence, the backward reaction of step 1 does not occur. In the step 2, hardly any nitrogen exists on the rhenium surface above 1300°K, as has been described above; k_2 in the step 2 is, therefore, very large and the rate of the backward reaction is negligibly small. In the step 3, the recombination and evaporation processes of the adsorbed nitrogen atom are the same as in the step 2; by supposing $k_3 \gg k_{-3}$ and $k_4 \gg k_3$ in such a high temperature range, the step 3 may be regarded as the rate-determining step, and nitric oxide may be regarded as consuming three molecules in one reaction.

15) will be published.

The rate equation may be written as follows:

$$-d[NO]/dt = D_{NO} = 3k_3P_{NO}.$$

The rate of the reaction between nitric oxide and rhenium is proportional to the nitric oxide pressure.

The Determination of the Composition of Rhenium Oxide. The apparent compositions of rhenium oxides were determined in the temperature range from 1300°K to 2100°K; these results are shown in Table 2, while the O/Re ratios are plotted against the temperature in Fig. 5.

TABLE 2. COMPOSITION OF RHENIUM OXIDE

Filament temp. °K	Consumed NO mol×10⁶	Loss of Re mol×10⁶	Oxide ReO_x value x
1300	7.94	2.62	3.03
1400	14.25	4.89	2.92
1500	7.817	2.56	3.05
1600	7.515	2.57	2.93
1700	15.0	4.76	3.15
1800	16.02	4.98	3.22
1900	11.6	3.23	3.48
2000	7.02	2.00	3.50
2100	9.03	2.51	3.59

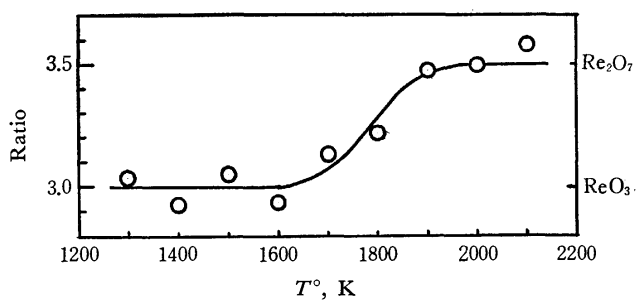

Fig. 5. The ratio, O/Re.

From these results, the ratio is seen to be close to 3.0 below 1700°K and then to increase to a steady value of close to 3.5 above 1900°K. These ratios of 3.0 and 3.5 correspond to the admitted oxides of rhenium trioxide, ReO_3, and rhenium heptoxide, Re_2O_7, respectively. Any ratio that lies between 3.0 and 3.5 may correspond to a mixture of the two oxides. The color of the rhenium oxide deposited on the wall of the reaction vessel depends upon the filament temperature. It is dark blue below 1600°K and colorless above 1900°K, while at intermediate temperatures its color is pale blue. Therefore, from these facts, it is considered that the ReO_3 on the wall is dark blue, that the Re_2O_7 is colorless, and that the pale blue deposit observed in the reactions at intermediate temperatures is composed of these two oxides. Although the apparent composition of Re_2O_7 is obtained at higher temperatures, the formation of Re_2O_7 on the rhenium surface and its evaporation from it at such high temperatures are thermodynamically unfavorable because the heat of the formation of Re_2O_7 is larger than that of ReO_3, and because the ReO_3 is found at lower temperatures. In another

experiment using the omegatron mass spectrometer, when the filament temperature was raised above 1800 °K in nitric oxide, a considerable amount of atomic oxygen was observed. Therefore, we consider that only the ReO_3 evaporates and deposits on the vessel wall, even above 1800°K, and that the ReO_3 on the wall is oxidized succesitively to Re_2O_7 with the atomic oxygen that is evolved in this high-temperature range.

The author wishes to express his deep thanks to Professor Takuya Hamamura of this Institute and to Professor Kumasaburo Kodera and Dr. Masaru Onchi of Kyoto University for their kind discussions and encouragement, and to Dr. Minoru Ozasa of the Matsushita Electronics Corporation, who made the spectroscopic analysis of rhenium.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1038—1044 (1972)

Effects of Chain Molecules on the Temperature of the Maximum Density of Water

Masao SAKURAI, Tsuyoshi KOMATSU, and Tsurutaro NAKAGAWA
Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo
(Received November 4, 1971)

The shifts in the temperature of the maximum density of water produced by the addition of small amounts of oligomers of polyethylene glycol and polyethylenimine and other related compounds were determined by dilatometry. These effects were interpreted in terms of the change in the structure of water around the various solute molecules in connection with their chain length. It was found that, as the chain length increases, the extent of the modification of the water structure by the chain molecules decreases because of the hydrophobic contact between ethylene groups. The apparent specific expansibility of the solute in the neighbourhood of 4°C was also evaluated as a function of the concentration.

The nature and role of water structure in aqueous polymer solutions have been subjects of great interest and controversy for a long time.[1] For example, recently Klotz[2] has discussed in detail the hydrophobic interactions between water and the alkyl groups of polymers; then, from the results of their near-infrared spectra measurements in H_2O/D_2O mixture, Worley and Klotz concluded that polyvinylpyrrolidone fits into the group of hydrogen-bonded structure makers.[3] On the contrary, Goldfarb and Rodriguez[4] have suggested, from their thermodynamic data, that the hydrated sheath around polyvinylpyrrolidone in water is not "ice-like," but is to be classified as part of the classical scheme of solute hydration.

An alternative approach to the problem of polymer-water interaction may be to examine the effect of chain length on certain properties of aqueous solutions of oligomers. From this point of view, the solubilities of hydrocarbons in oligomeric polyethylenimine solutions have been determined by Okubo and Ise.[5] Their solubility data indicate that the hydrophobicity of the oligomers increases with an increase in the molecular weight. More recently, the volumetric properties of aqueous solutions of the oligomers of polyethylene glycol and polypropylene glycol have been investigated by Sandell and Goring.[6] The apparent specific expansibility, which they have regarded as a measure of the structural effect of a solute,[7] increases with an increase in the chain length; that is, the extent of the hydrophobic hydration is reduced as the chain length increases. This has been interpreted in terms of the increasing hydrophobic contact between ethylene groups.

Since the hydrogen-bonded structure of water is greatly sensitive to the temperature, it seemed that it would be useful to examine the temperature dependence of some thermodynamic properties in order to specify the structural phenomena of aqueous polymer solutions.

In the present paper, we will report some results concerning the effects of the addition of chain molecules on the temperature of the maximum density (TMD) of water. The phenomenon of the TMD of water at 3.98°C has been regarded as coming from the balance of the increase in volume resulting from the thermal expansion and the decrease in volume resulting from the breakdown of the hydrogen-bonded low-density water structure.[1,8,9] Although, in general, the presence of various kinds of solutes depresses the TMD from 3.98°C, it is also well known that some alcohols elevate the TMD in very dilute

solutions.[10-13] This observation implies that these alcohol molecules stabilize the hydrogen-bonded intermolecular structure of water. Wada and Umeda[13] and Franks and Watson[14] have shown that the depression in the TMD produced by the addition of small amounts of many organic compounds is less than that to be expected when ideal mixing takes place, and that, as a rule, this effect is more pronounced when the number of carbon atoms within the solute molecules increases. Thus, the solutes which show a tendency to raise the TMD may be assumed to stabilize the structure of water.

The purpose of this work is to make an attempt to clarify the interactions between polymers and water on the basis of the measurements of the TMD and in connection with the concept of the structural change of water.

Experimental

Procedure. Bicapillary-type dilatometers with a capacity of about 80 m*l* and with capillary tubes 0.7 mm in diameter were used to measure the temperature dependence of the volumes of the aqueous solutions. Measurements were made with a cathetometer at approximately 0.3~0.5°C intervals in the range ±2°C from the TMD. The temperature of the thermostat bath was maintained with a precision of ±0.002°C, and the temperatures corresponding to the measured volumes were read on a Beckmann thermometer. In order to correct the thermal expansion of the dilatometer itself, the shift in the TMD, $\Delta\theta$, produced by the addition of a solute was determined graphically, according to the method of Wada and Umeda,[13] by comparing the meniscus height-temperature curve of the solution with that of pure water. By using this method, the maximum error in estimating $\Delta\theta$ was ±0.02°C. It has been found that the values of $\Delta\theta$ obtained preliminarily with regard to the solutions of both sodium chloride and ethylene glycol are in good agreement with the literature values.[13,15]

The densities of the pure solutes were determined at 5, 15, 25, 35, and 45°C using Ostwald-type pycnometers with a volume of about 20 m*l*.

Materials. The polyethylene glycol (PEG) was furnished by the Sanyo Kasei Co. The PEG-200 and PEG-400 (the average molecular weights are 200 and 400 respectively) were dried under reduced pressure and were used without further purification. The PEG-20000 was recrystallized from methyl ethyl ketone and was dried at room temperature under a vacuum. The polyethylenimine (PEI) was purified by passing its dilute solution through columns containing cation and anion exchange resins in the hydrogen and hydroxide forms respectively. Its molecular weight was estimated viscometrically to be about 2000. The ethylene glycol (EG) was a chromatographically pure reagent, and the ethylenediamine (ED) and triethylamine (TEA) were guaranteed reagents. These materials were dried over molecular sieve and were used without further purification. The diethylene glycol (DEG), triethylene glycol (TEG), ethylene glycol dimethyl ether (EGDME), diethylene glycol dimethyl ether (DEGDME), triethylene glycol dimethyl ether (TEGDME), diethylenetriamine (DT), triethylenetetramine (TT), and tetraethylenepentamine (TP) were fractionally distilled. The water used to prepare the solutions was distilled and then purified by passing it through a column of cation-anion exchange resin mixtures.

Results and Discussion

The specific volumes of the pure solutes at various temperatures are given in Table 1. From these data, the specific expansibilities, $\partial v_2/\partial T$, at 4°C can be

evaluated by the least-square method; the values are given in the last column of Table 1. The specific volumes of high polymers in the liquid state are not known, so the $\partial v_2/\partial T$ values of PEG-20000 and PEI were estimated roughly by extrapolating the corresponding values of the respective oligomers to an infinite molecular weight, as is illustrated in Fig. 1.

The shifts, $\Delta\theta$, in the TMD produced by the addition of various solutes are summarized in Table 2. The concentration is expressed in terms of the weight fraction in order to facilitate the comparison of the behavior of polymers with that of low-molecular-weight analogues.

The quantitative analysis of $\Delta\theta$ in terms of the water-structural concept has been proposed by Wada and

Umeda[13] and has been extended by Franks and Watson.[14] The specific volume, v, of a solution is expressed by:

$$v = (1-w)v_1 + wv_2 + \Delta v_w^M \quad (1)$$

where v_1 and v_2 are the specific volumes of water and a pure solute respectively, and where Δv_w^M is the excess volume of mixing referred to a mixture of the solute weight fraction, w. The temperature dependence of v_1 in the vicinity of the TMD can be given by a parabolic function:[13]

$$v_1 = v_1^*[1+\alpha_1(T-3.98)^2] \quad (2)$$

where v_1^* is the specific volume of water at 3.98°C and where α_1 is the coefficient relating to the thermal expansion. By inserting Eq. (2) into Eq. (1), and differentiating with respect to temperature, and then from the condition: $\partial v/\partial T=0$ at the TMD, one obtains the following relation:

$$\Delta\theta = (T-3.98) = -\frac{w\partial v_2/\partial T}{2(1-w)v_1^*\alpha_1} - \frac{\partial \Delta v_w^M/\partial T}{2(1-w)v_1^*\alpha_1} \quad (3)$$

The first term, denoted by $\Delta\theta_{id}$, on the right-hand side of Eq. (3) indicates that, for ideal solutions, $\Delta\theta$ is always negative and is proportional to the concentration as long as for very dilute solutions. The second term, denoted by $\Delta\theta_{str}$, is referred to the temperature dependence of the excess volume and may be attributed to the change in water structure caused by adding various solutes.

The values of $\Delta\theta_{str}$ have been evaluated for various solutes.[13,14] In general, it appears that the values of $\Delta\theta_{str}$ are large and positive for such solutes as monofunctional alcohols and amines, whereas more hydrophilic solutes such as ethylene glycol and dioxane produce negative $\Delta\theta_{str}$ values. In other words, the sign and magnitude of $\Delta\theta_{str}$ depend mainly on the hydrophilic-hydrophobic balance within the respective solute molecules, or are due to some kinds of water-structure modifications.

There have been various discussions with respect to the structure of water in a pure liquid state and in aqueous solutions. At present, however, no satisfactorily reasonable interpretation and models have been proposed.[1,8,9,16,17] In the present analysis, the so-called two-state model was adopted as a basis for discussion; it is assumed that water is an equilibrium mixture of bulky hydrogen-bonded species and dense unbonded species, and also that the introduction of a small quantity of non-polar molecules or groups into aqueous solutions shifts the equilibrium between the two species from dense species to bulky species.

The effect of a solute on TMD may be interpreted in terms of the difference in the specific expansibility of the pure solute and the apparent specific expansibility of the solute in water. The specific volume of a solution is also expressed using the apparent specific volume, ϕ_2, of a solute as follows:

$$v = (1-w)v_1 + w\phi_2 \quad (4)$$

Then, we obtain the following equation instead of Eq. (3):

$$\Delta\theta = -\frac{w}{2(1-w)v_1^*\alpha_1}\frac{\partial\phi_2}{\partial T} \quad (5)$$

Combining Eqs. (3) and (5) yields;

$$\frac{\partial \Delta v_w^M}{\partial T} = w\left(\frac{\partial\phi_2}{\partial T} - \frac{\partial v_2}{\partial T}\right) \quad (6)$$

Since the hydrogen-bonded structure of water is broken down rapidly with a rise in the temperature, and since, accordingly, the amounts of unbonded water mole-

cules with a higher density are increased, the increase in the apparent specific volume of a hydrophobic solute in aqueous solution caused by the increase in temperature might to some extent be canceled out in comparison with a case where no special hydrophobic interaction, the so-called "hydrophobic hydration," takes place. Therefore, when the solute is a structure-stabilizing one, the value of $\partial\phi_2/\partial T$ is smaller than that of $\partial v_2/\partial T$; namely, a positive $\Delta\theta_{str}$ value can be derived from Eq. (6).

In Table 2 and in Figs. 2 and 3, the values of $\Delta\theta_{str}$ obtained are shown as a function of the weight fraction.[18] From the results shown in Fig. 2, it is clear that, for a series of PEG oligomers, the $\Delta\theta_{str}$ values are all negative over the entire concentration range studied and that they change according to their chain lengths in the following order:

DEG>TEG>PEG-200>EG>PEG-400>PEG-20000

Unfortunately, little is yet known about the influence of such a polar substance on the structure of water, but the fact that negative $\Delta\theta_{str}$ values are obtained may indicate that these solutes disrupt the intermolecular structure of water because of the formation of strong hydrogen bonds between solutes and water. It seems that the increase in temperature produces such larger ϕ_2 values as a result of the disruption of the solute-water hydrogen-bonding, which itself results in the volume contraction around the hydroxyl groups. If this is true, the $\Delta\theta_{str}$ value should become negative according to Eq. (6).

As regards the hydrophilic-hydrophobic balance within a solute molecule, molecules of longer chain length should become more hydrophobic than lower-molecular-weight analogues in this series, because of the relative decrease in the contribution from the hydrophilic terminal hydroxyl groups. The above sequence observed for PEG oligomers is, however, just the opposite of what might be expected from this idea, except for the case of EG. As will be discussed in detail later, we propose another scheme of interpretation, *i.e.*, a concept of hydrophobic contact between ethylene groups.

Figure 3 shows the $\Delta\theta_{str}$ values for the PEI oligomers and TEA. The latter is expected to behave as a typical hydrophobic solute in water. In fact, TEA produces a strikingly large positive $\Delta\theta_{str}$, which is comparable in magnitude to those produced by monohydric alcohols[13] or dialkylamines.[14] It is observed with PEI oligomers that the $\Delta\theta_{str}$ changes according to their chain lengths in the following order:

DT>ED>TT>TP>PEI

which is quite similar to the sequence for the PEG oligomers. However, in contrast to the PEG oligomers, the values of $\Delta\theta_{str}$ are slightly positive except for the case of PEI. This difference suggests that the hydrogen bond between water and the hydroxyl group of the PEG oligomers is stronger than that between water and the amino group of the PEI oligomers. This may be accounted for on the basis that the more electronegative oxygen atom is generally able to form a stronger hydrogen bond than is the less electronegative nitrogen atom.

It could, however, be emphasized that too much significance should not be found in the difference in $\Delta\theta_{str}$ because of the choice of the standard state.[19,20] In the present analysis, the pure liquid state of the solute was used as the standard state in order to calculate $\partial v_2/\partial T$ and $\Delta\theta_{str}$. For the purpose of a more accurate discussion of the solute-water interaction, one should use the hypothetical value of $\partial v_2/\partial T$ in an infinitely dilute aqueous solution (in other words, under the condition that no solute-solute interaction takes place) instead of in the pure liquid state. Especially when liquids exhibits significant intermolecular interactions, the adoption of the pure liquid state as the standard has its disadvantages. We should not ignore this situation in comparing the behavior of the oligomers of the PEG with that of the PEI, since the former possesses a much greater ability of solute-solute hydrogen-bonding than the latter; this is suggested by their high viscosities and the characteristic variation in their specific expansibilities with the increase in the chain length for the PEG oligomers, as is shown in Fig. 1. This may also be closely related to the fact that the $\Delta\theta_{str}$ values of various alcohols and amines do not always increase in a regular manner with the number of carbon atoms within the solute molecules. It may, at any rate, be permissible to consider that the difference in $\Delta\theta_{str}$ indicates at least a relative difference in the solute-water interaction so far as the chain-length dependence of $\Delta\theta_{str}$ for the oligomers of the homologous series is concerned, as we have done in this study.

As is shown in Fig. 2, for the series of glycol dimethyl ethers the $\Delta\theta_{str}$ values are all positive, decreasing more rapidly in magnitude with the increase in chain length than for the series of the PEG and PEI oligomers. The positive $\Delta\theta_{str}$ value suggests a comparatively stronger hydrophobic hydration caused by the terminal methyl groups. This is confirmed by the results of the limiting partial molar volumes of various glycols in aqueous solutions by Nakanishi *et al.*,[21] who stated that such glycol molecules as 1,2-ethanediol and 1,3-propanediol mix "substitutionally" with water, whereas, when one of the hydroxyl groups is not located at the end of the molecule (*e.g.*, 1,2-propanediol or 1,3-butanediol), the "interstitial" contribution due to a possible cavity occupation by a methyl group increases.

As has been described above, ED and EG give rise

18) In order to calculate $\Delta\theta_{str}$ as a first approximation, the value of $\partial v_2/\partial T$ at 4°C is always employed in the present analysis, since it can be considered that there is no effect of the variation of $\partial v_2/\partial T$ in a small range of temperature (the maximum value of $\Delta\theta$ obtained in this experiment is −1.63°C). Also, the use of $\partial v_2/\partial T$ which are estimated roughly by a extrapolation method for the high polymers is believed not to result in a large error in calculating $\Delta\theta_{str}$, or at least this has no influence upon the present discussion relating to the chain length dependence.

19) F. Franks and H. T. Smith, *Trans. Faraday Soc.*, **64**, 2962 (1968).

to unordinary values of $\Delta\theta_{str}$, and EGDME produces a particularly large positive $\Delta\theta_{str}$ value. This observation suggests that, in the case of these small molecules with only one ethylene group, the nature of the terminal group may be one of the decisive factors in the interactions between the solute and the water molecules.

Thus, the results on the $\Delta\theta_{str}$ values of these oligomer solutions prove that the hydrophobic interaction of a chain molecule with water decreases as the chain length increases, provided that the interaction is not affected remarkably by the terminal group. It is plausible to consider that the effect of the chain length on the hydrophobicity is due to the conformational change of a chain molecule. Recently, Neal and Goring[7] measured the temperature dependence of the apparent specific volume, *i.e.*, the apparent specific expansibility, $\partial\phi_2/\partial T$, for various aqueous solutions; they proposed that this quantity might be a useful measure of the effect of a nonelectrolyte on the structure of water. Subsequently, they could show the increase in $\partial\phi_2/\partial T$ with an increase in the chain length for both oligomers of polyethylene glycol and polypropylene glycol.[6] That is to say, the hydrophobic character of a chain molecule decreases with an increase in the chain length. More recently, the partial molar volumes of the series of glycol dimethyl ethers in aqueous solutions have been measured at various temperatures by Nakajima *et al.*[22] According to their analysis, the partial molar volume of the ($-CH_2CH_2O-$) group can be calculated from the differences in the partial molar volumes between DEGDME and EGDME and also between TEGDME and DEGDME. The value obtained from TEGDME is greater than those obtained from DEGDME and EGDME. This fact suggests that the extent of the hydrophobic hydration of these chain molecules in aqueous solutions decreases with an increase in the chain length, if one accepts the hypothesis that such a hydration occurs with an overall economy of space. These results agree very well with the results of our TMD measurements. The most reasonable interpretation of this effect may be that, with an increase in the chain length, the hydrophobic contact between ($-CH_2CH_2-$) groups takes place more easily and that, consequently, the relative decrease in hydrophobic interaction is observed because of the reduction of the ($-CH_2CH_2-$) area which is accessible to water, as was proposed by Sandell and Goring.[6]

By using Eq. (5), the values of $\partial\phi_2/\partial T$ in the neighbourhood of 4°C at various concentrations can be calculated from the TMD data, which are summarized in the last column of Table 2. The maximum error in $\partial\phi_2/\partial T$ was estimated on the basis of the accuracy in determining TMD: ±0.02°C. Some results are shown in Figs. 4 and 5, in which the values for several alcohols calculated from the TMD data by Wada and Umeda[13] are also included. Of course, the values of $\partial\phi_2/\partial T$ at various concentrations cannot be evaluated at a constant temperature by this method; moreover, the accuracy of $\partial\phi_2/\partial T$ is not satisfactory because of the very low concentrations. The data shown in Figs. 4 and 5, however, may be good enough for us to discuss some qualitative tendency of these values in connection with the hydrophobic character of the solutes. The fact that the $\partial\phi_2/\partial T$ values of all the PEG oligomers increase with an increase in the chain length, except for EG, accords qualitatively with the results which were directly measured by Sandell and Goring. For the PEI oligomers, on the other hand, this is not the case. The variation in $\partial v_2/\partial T$ with the chain length is exceedingly larger for the PEI

oligomers than for the PEG oligomers, as is shown in Fig. 1; therefore, the variation in the $\partial\phi_2/\partial T$ values with the chain length seems to be largely due to the difference in $\partial v_2/\partial T$ values, though there exists a problem in the choice of the standard state, as has been mentioned above. In such a case it may be inadequate to use the quantity $\partial\phi_2/\partial T$ as a measure of the effect of a solute molecule on the structure of water.[23]

Figures 4 and 5 show the characteristic tendencies of $\partial\phi_2/\partial T$ for various solutes. The solutes which produce small positive or negative $\Delta\theta_{str}$ values, such as the chain molecules used in this experiment, give rise to a slight concentration dependence of $\partial\phi_2/\partial T$, whereas those which produce large positive $\Delta\theta_{str}$ values, such as TEA and many monohydric alcohols, bring about a striking concentration dependence of $\partial\phi_2/\partial T$. The latter have been regarded as hydrogen-bonded-structure makers and will give rise to a larger hydrophobic hydration than the former.

It is well known that the apparent specific volume of a hydrophobic substance in an aqueous solution decreases with its concentration so long as the concentration is low. This behavior has been interpreted in terms of "mutual salting-in"[25] or "mutual co-operative stabilization."[26] According to Franks and Smith,[26] the non-polar solutes form complete or partial clathrate cage systems, resulting in a contraction in the net volume. When two solute molecules approach each other at a suitable distance, such cage systems are stabilized co-operatively and, consequently, ϕ_2 decreases with a rise in the concentration. Therefore, the slope of the ϕ_2-concentration curve becomes more negative as the temperature is lowered or as the sizes of the non-polar groups of the solute molecules become larger. This phenomenon is the same as with the larger concentration dependence of $\partial\phi_2/\partial T$ of the strongly hydrophobic solutes. Thus, the concentration dependence of $\partial\phi_2/\partial T$ may also be regarded as a useful measure of the structural effect of a solute molecule from the viewpoint of solute-solute interaction.

One could find from Eq. (5) that a positive $\Delta\theta$ is equivalent to the negative expansibility. As has been mentioned in the introduction, this anomalous behavior should be considered as an evidence for the stabilization of the water structure surrounding the non-polar groups of a solute molecule. In fact, the negative expansibility has been observed directly with *tert*-butyl alcohol and *sec*-butyl alcohol in very dilute aqueous solutions.[19] As is shown in Fig. 5, it is evident that this phenomenon should also be observed in the very dilute aqueous solutions of many monohydric alcohols and possibly TEA.

Finally, it should be pointed out that our conclusion concerning chain molecule-water interaction is quite similar to that of Sandell and Goring,[6] but it may conflict with the explanation by Okubo and Ise of their solubility results.[5] The solubilities of naphthalene and biphenyl in aqueous solutions of PEI and its oligomers (ED, DT, TT, TP) increase with increases in their chain length. From these results they have concluded that the so-called "iceberg" formation of water molecules may be facilitated by an increasing degree of polymerization. It is difficult to solve the problem of these conflicting results. It can, however, be proposed that the solubility behavior of a non-polar co-solute in aqueous solutions of the chain molecules may be of a rather complicated nature as a result, for instance, of the conformational change of the solute molecules themselves. A more systematic investigation regarding the solubility behavior of nonelectrolytes in aqueous polymer solutions, and especially its temperature dependence, remains a subject for future study.

The authors wish to thank Mr. Toshio Nakajima for his helpful discussion. The present work has been supported in part by a Grant for Scientific Research from the Ministry of Education.

23) According to the data of Sandell and Goring,[6] the values of $\partial v_2/\partial T$ for PEG oligomers are independent of the chain lengths; in such a case $\Delta\theta_{str}$ must be in parallel with $\partial\phi_2/\partial T$. Our own data obtained by pycnometry, however, indicate that $\partial v_2/\partial T$ are clearly dependent on the chain lengths, as shown in Fig. 1. That is to say, it is not always advantageous to discuss any solute-water interaction in terms of $\partial\phi_2/\partial T$ or $\Delta\theta$ (not $\Delta\theta_{str}$). For example, it should be misleading to conclude from the measurements of $\Delta\theta$ alone that the quaternary alkylammonium halides, which are regarded as typical structure stabilizing solutes at room temperature, disrupt the hydrogen-bonded structure of water at low temperatures.[24]

Interaction of 1,2-Dichloroethane with Benzene and other Aromatic Hydrocarbons

Akio MORITA, Hiroaki TAKAHASHI, and Keniti HIGASI

School of Science and Engineering, Waseda University, Shinjuku, Tokyo

(Received August 21, 1971)

Experiments to confirm Kubo's conclusion on the complex formation of 1,2-dichloroethane with benzene were carried out following his procedure. Dielectric measurements were carried out with inert solvents hexane and cyclohexane. The interactions between 1,2-dichloroethane and each of the compounds toluene and *p*-xylene were also studied with inert solvents hexane, cyclohexane, and carbon tetrachloride. The results are discussed in relation to complex formation.

It was found that the dipole moment of 1,2-dichloroethane, when measured in benzene solution, is unaccountably high.[1] It was also found that the Raman lines of the same molecule in the same solvent show abnormal behavior.[2] Later investigation led to the conclusion that the gauche isomers of this molecule gain an extra stability in benzene. However, no satisfactory explanation has been offered since for the nature of the extra energy.[3] From ultrasonic and thermodynamic studies it was concluded that there is some interaction between 1,2-dichloroethane and an aromatic hydrocarbon but no evidenc for complex formation between these molecules was obtained.[4]

The complex formation between 1,2-dichloroethane and benzene has been suggested by many workers.[5] First experimental proof was given by Kubo[6] from the dielectric measurements of mixtures of the two molecules in the medium of carbon tetrachloride. He examined a general case of complex formation:

$$CH_2Cl\text{-}CH_2Cl + nC_6H_6 \rightleftarrows CH_2Cl\text{-}CH_2Cl\cdot nC_6H_6$$

and showed that the number n should be 1 and not 2. He gave the equilibrium constant $K_c=32$ ml/mol and the excess polarization for the solute $\Delta P=97.6$ cm^3 at 20°C. From his ΔP value the dipole moment of the 1 : 1 complex was estimated[7] to be almost equal to the value 2.55 D[8] of the gauche isomer. Thus, we might conclude that the gauche isomer is stabilized in benzene solution through the complex formation, because such formation will certainly result in stronger intensities of the Raman lines of the gauche isomer and give rise to a high dipole moment in benzene solution.

The present paper deals with dielectric measurements on the basis of complex formation; it is in fact an extention of Kubo's work. Three inert solvents were employed, *viz.*, hexane, cyclohexane, and carbon tetrachloride. Benzene, toluene (with polarity), and *p*-xylene (with no polarity) were also chosen as aromatic molecules for the interaction with 1,2-dichloroethane.

Experimental

Dielectric constants of dilute solutions of 1,2-dichloroethane were measured at 25°C with the use of a heterodyne apparatus at 1 MHz. Solvents are mixtures of aromatic and inert solvents. Dielectric constants ε and densities d of dilute solutions can be expressed by linear functions of concentration of the solute (wt. fraction $w<0.05$).

$$\begin{aligned} \varepsilon &= \varepsilon_m + aw \\ d &= d_m + bw \end{aligned} \qquad (1)$$

where ε_m, d_m are the dielectric constant and the density, respectively, of the mixture solvent and a, b are the so-called "slopes". With the use of these "slopes" we can obtain the apparent specific polarization ${}_\infty p^*$ of 1,2-dichloroethane (at zero concentration of the solute) in the mixture of two solvents with a given concentration of aromatic molecules.

$${}_\infty p^* = \frac{\varepsilon_m-1}{\varepsilon_m+2}\cdot\frac{1}{d_m}\left[\frac{3a}{(\varepsilon_m-1)(\varepsilon_m+2)}+\frac{d_m-b}{d_m}\right] \qquad (2)$$

The apparent polarization ${}_\infty p^*$ is a hypothetical polarization calculated on the assumption of no complex formation. It differs from the specific polarization ${}_\infty p$ obtained in the medium of inert solvent alone. The difference ${}_\infty p^*-{}_\infty p = \Delta p$ is, therefore, a measure of the interaction between the solute and the aromatic solvent. Multiplying Δp by the molecular weight M of 1,2-dichloroethane, we obtain the corresponding molecular polarization ΔP_{obs}. This polarization term has been obtained for the system of 1,2-dichloroethane, aromatic and inert solvents.

$$\Delta P_{obs} = M\,\Delta p = M({}_\infty p^* - {}_\infty p) \qquad (3)$$

The relationship between ΔP_{obs} and the concentration of aromatic solvent under the light of Kubo's equation[6] and the Benesi-Hildebrand[9] equation for complex formation were examined.

For the equilibrium of 1 : 1 complex formation

$$CH_2Cl\text{-}CH_2Cl + \text{Arom} \rightleftarrows \text{Complex}$$

we have the relation

$$K_c = \frac{\alpha}{(1-\alpha)c_B} \qquad (4)$$

where α is the fraction of dichloroethane combined with aromatic solvent and c_B the concentration of the aromatic solvent in equilibrium which is taken as equal to its initial concentration.

The following relation is assumed for fraction.

$$\alpha = \frac{\Delta P_{obs}}{\Delta P} \qquad (5)$$

and

$$\Delta P = P(\mathrm{AB}) - P(\mathrm{A}) - P(\mathrm{B}) \quad (6)$$

where $P(\mathrm{AB})$, $P(\mathrm{A})$, and $P(\mathrm{B})$ are the molecular polarizations of the complex, dichloroethane and aromatic solvent, respectively.

Introducing Eq.(5) into Eq.(4), we get Kubo's formula[6]

$$\frac{\Delta P_{\mathrm{obs}}}{c_{\mathrm{B}}} = K_c(\Delta P - \Delta P_{\mathrm{obs}}) \quad (7)$$

In a similar way Benesi-Hilderband's equation[9] can be derived as

$$\frac{1}{\Delta P_{\mathrm{obs}}} = \frac{1}{K_c \Delta P}\cdot\frac{1}{c_{\mathrm{B}}} + \frac{1}{\Delta P} \quad (8)$$

The following modification of Eq.(8) can be used as well.[10]

$$\frac{c_{\mathrm{B}}}{\Delta P_{\mathrm{obs}}} = \frac{c_{\mathrm{B}}}{\Delta P} + \frac{1}{K_c \Delta P} \quad (9)$$

Plots of $\Delta P_{\mathrm{obs}}/c_{\mathrm{B}}$ against ΔP_{obs} will confirm the validity of Eq. (7); plots of $1/\Delta P_{\mathrm{obs}}$ against $1/c_{\mathrm{B}}$ and those of $c_{\mathrm{B}}/\Delta P_{\mathrm{obs}}$ against c_{B} are related to Eqs.(8) and (9), respectively. If the plots all satisfy the straight-line relationship and provide the consistent values of K and ΔP, we could conclude that 1 : 1 complex is formed between 1,2-dichloroethane and the aromatic solvent. K_c and ΔP are obtained from these plots.

In addition we can estimate the dipole moment μ_{AB} of the complex AB in Debye units from ΔP.

$$P_0(\mathrm{AB}) = \Delta P + P_0(\mathrm{A}) + P_0(\mathrm{B}) \quad (10)$$

$$\mu_{\mathrm{AB}} = 0.0128\sqrt{P_0(\mathrm{AB})T} \quad (11)$$

where $P_0(\mathrm{AB})$, $P_0(\mathrm{A})$, and $P_0(\mathrm{B})$ are the orientation polarizations of the complex, 1,2-dichloroethane, and aromatic solvent, respectively; and $P_0(\mathrm{A}) = P(\mathrm{A}) - P_E(\mathrm{A}) - P_A(\mathrm{A}) = P(\mathrm{A}) - 23.9\ \mathrm{cm}^3$;[8] and $P_0(\mathrm{B}) = 0$ for benzene and p-xylene and $P_0(\mathrm{B}) = 3.8\ \mathrm{cm}^3$ for toluene.[2,11]

Materials. Both 1,2-dichloroethane of special grade (Wako) and carbon tetrachloride were kept over calcium chloride for a week before distillation. Benzene, toluene, p-xylene, hexane, and cyclohexane were stored over sodium wire and distilled.

Results and Discussion

Results of the dielectric measurements are summarized in Tables 1, 2, and 3. The concentration of the aromatic hydrocarbon c_{B} in the system of three components is shown in the first column in the units of mol/m*l*. The dielectric constant ε_m and the densities d_{m} refer to the mixture solvent (with a given c_{B}). Two slopes a and b are obtained from several solutions with the same c_{B} and with the concentration of the solute w=0.01—0.05. With the use of ε_{m}, d_{m}, a, and b, the apparent specific polarization ${}_\infty p^*$ is calculated from which ΔP_{obs} is easily obtained (*cf.* Eqs. (2) and (3)).

The quantity $\Delta P_{\mathrm{obs}}/c_{\mathrm{B}}$ will be a linear function of ΔP_{obs} if Eq. (7) for the complex formation is satisfied in the system under examination. Plots of $\Delta P_{\mathrm{obs}}/c_{\mathrm{B}}$ are made against ΔP_{obs} for nine systems of 1,2-dichloroethane, aromatic, and inert solvents (see Figs. 1, 2, and 3). Deviations from the linear relation are within experimental error. We see that 1,2-dichloroethane forms 1 : 1 complex with an aromatic molecule, benzene, toluene, and p-xylene.

Other plots using the relations given by Benesi-Hildebrand equation (8) and Eq. (9) are repeated for all the systems. No appreciable deviation from the

linearity was observed.

Two unknown quantities K_c and ΔP for each system can be determined by the least square method from the data with the use of any of Eqs.(7), (8), and (9). In Table 4 the equilibrium constant and the excess polarization ΔP thus obtained are recorded. Values calculated by Eq. (9) are omitted since they are very similar. All the K_c and ΔP values thus obtained are consistent with each other.

For the system of 1,2-dichloroethane, benzene, and carbon tetrachloride equilibrium constant K_c is found to be 30.0 ml/mol and the excess polarization ΔP= 90.0 cm³ at 25°C from Eq. (7). The values are in agreement with Kubo's K_c=32 ml/mol and ΔP= 97.6 cm³ at 20°C.[6]

We see from Figs. 1—3 that toluene has steeper inclinations. The different behavior of toluene may perhaps be due to the existence of polarity while both benzene and *p*-xylene lack it. The same trend is found in Benesi-Hildebrand's plots.

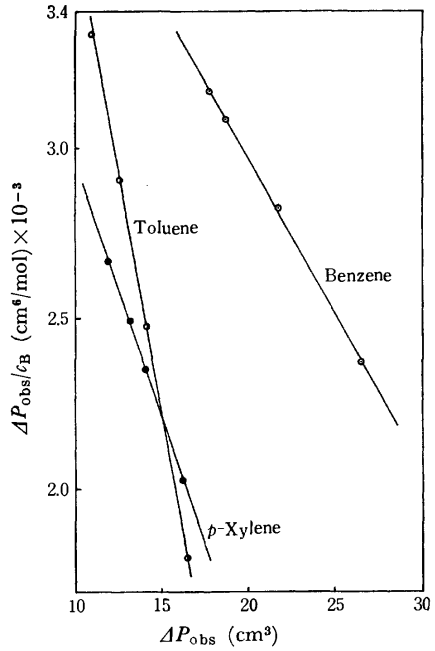

Fig. 1. Interaction of 1,2-dichloroethane with benzene, toluene, and *p*-xylene, in the inert medium of hexane.
⊙: Benzene, ○: Toluene, •: *p*-Xylene

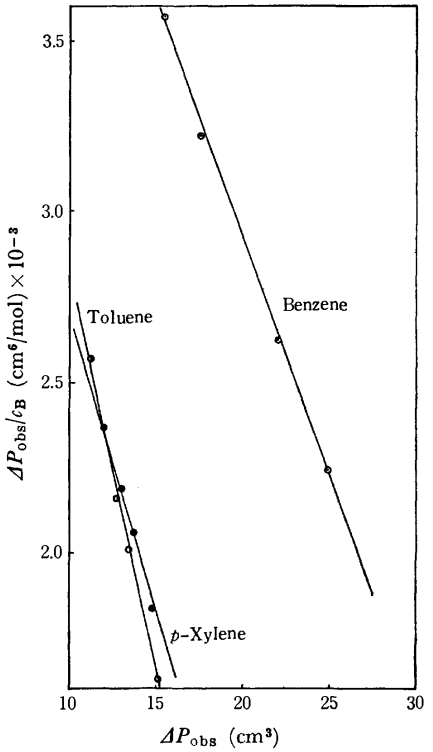

Fig. 2. Interaction as in Fig. 1, in the inert medium of cyclohexane.

From Table 4 we see that K_c in carbon tetrachloride is comparatively high with toluene and low with both benzene and *p*-xylene. Carbon tetrachloride may not be a perfectly inert solvent, some interaction with a solute often being suspected when this solvent is employed.[12,13] However, we have no means to decide the most ideal inert solvent among these non-polar solvents.

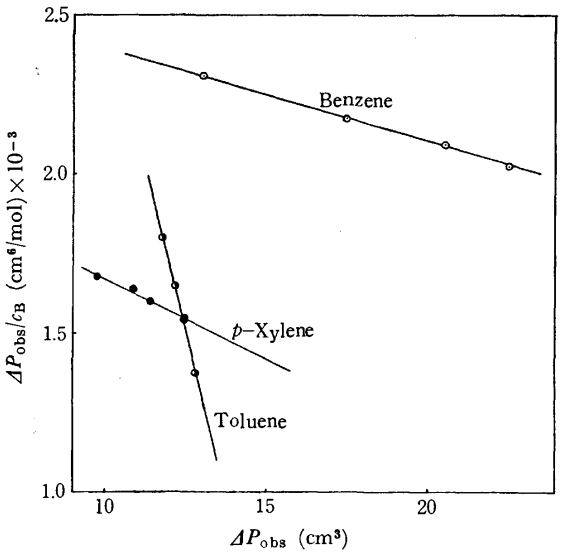

Fig. 3. Interaction as in Fig. 1, in the inert medium of carbon tetrachloride.

Table 4. K_c and ΔP obtained by Eqs. (7) and (8)

Inert solvent	Hexane	Cyclo-hexane	Carbon tetrachloride	
Intraction with Benzene				
K_c	90.7	139	30.0	(7)
(ml/mol)	90.4	140	30.6	(8)
ΔP	52.9	41.0	90.0	(7)
(cm^3)	52.9	40.8	88.5	(8)
Interaction with Toluene				
K_c	272	240	480	(7)
(ml/mol)	271	242	476	(8)
ΔP	23.4	21.9	15.6	(7)
(cm^3)	23.5	21.8	15.8	(8)
Interaction with *p*-Xylene				
K_c	155	196	51.0	(7)
(ml/mol)	154	200	53.1	(8)
ΔP	29.5	24.2	42.5	(7)
(cm^3)	29.6	24.0	41.5	(8)

The equilibrium constant K_c (Table 4) increases in the order

benzene < *p*-xylene < toluene

while the excess polarization varies in the order

toluene < *p*-xylene < benzene.

The trend is of interest since it will explain the apparently contradicting behavior of the relaxation times and the dipole moments obtained in benzene and *p*-xylene.[7]

The average relaxation time τ_0 and the Cole-Cole distribution parameter α of 1,2-dichloroethane increase from 3.69 psec and 0.13 in benzene to 4.53 psec and 0.19 in *p*-xylene. The increase seems parallel to the increase in the equilibrium constant. The ampler the complex, the greater the values of K_c and

12) T. Shibuya and Y. I'Haya, This Bulletin, **37**, 896 (1964).
13) K. Chitoku and K. Higasi, *ibid.*, **39**, 2160 (1966).

also of τ_0, since the average relaxation time becomes greater when the contribution from the complex with larger size is more important. The same contribution will give rise to an increase in α.

The dipole moment of 1,2-dichloroethane is found to be 1.63 D in *p*-xylene which is much less than the value 1.80 D in benzene.[7] This apparent decrease seems to be parallel to the decrease of ΔP from benzene to *p*-xylene. It reveals that the dipole moment of the complex with *p*-xylene becomes smaller compared with the moment of the complex with benzene.

In Table 5 the dipole moments of 1 : 1 complexes between 1,2-dichloroethane and aromatic solvents calculated from ΔP (Kubo's method) are recorded.

Table 5. Dipole moment of 1,2-dichloroethane-aromatic hydrocarbon complexes obtained by Eq. (11)

Aromatic Hydrocarbon	Inert solvent		
	Hexane	Cyclohexane	CCl_4
Benzene	2.11D	1.99D	2.54D
Toluene	1.79	1.79	1.74
p-Xylene	1.82	1.77	2.04

The dipole moment of the complex with benzene obtained in carbon tetrachloride is 2.54D, which is almost the same as the moment 2.55D presumed by Mizushima[8] as the moment of the gauche isomer. The equilibrium constant K_c=30.0 ml/mol (Kubo's method) gives α=0.25 in benzene at 25°C (*viz.*, c_B=$11.18\cdot10^{-3}$ mol/ml).

From the ratio of the intensities of the Raman lines I(gauche)/I trans), we can estimate the number of the gauche isomers in benzene and hexane at room temperature.[2] The mole fraction x_g of the gauche isomers increases from 0.16 (hexane) to 0.39 (benzene). On the other hand we find the increase in x_g is about 0.21 from dipole moment measurements, *viz.*, x_g in hexane 0.276, in carbon tetrachloride 0.289 and in benzene 0.491.[7]

It should be noted that the fraction of the complex 0.25 can be considered equal to the apparent increase 0.21—0.23 in x_g of the gauche isomers when transferred to benzene from a non-aromatic solvent.

This would imply that the extraordinary increase in numbers of the gauche isomers in benzene which is the so-called benzene effect is due to the formation of a complex which has the gauche conformation in the part of 1,2-dichloroethane. In the system of 1,2-dichloroethane - benzene - carbon tetrachloride the above statement appears to be valid since the complex has the same polarity as the gauche isomer. However, the situation is more complicated in other systems. The same problem will be discussed more in detail.[14]

From the dielectric measurements based on Kubo's procedure we get a similar evidence for complex formation between 1,2-dichloroethane and an aromatic hydrocarbon, *viz.*, benzene, toluene, or *p*-xylene, and we find that the so-called "benzene effect" might be related to the complex formation. It should be pointed out that both the equilibrium constant and the polarity of the complex are affected by the choice of inert solvents, hexane, cyclohexane, and carbon tetrachloride.

Radiolysis of Mixtures of Hydrocarbons and Ammonia. I. Formation of Ethylamine from a Mixture of Ethylene and Ammonia

Okihiro TOKUNAGA, Kumao HAMANOUE, Jiro OKAMOTO, and Akibumi DANNO

Japan Atomic Energy Research Institute, Tokai Research Establishment, Tokai-mura, Naka-gun, Ibaraki-ken

(Received August 18, 1971)

The γ-radiolysis of a gaseous mixture of ethylene and ammonia has been investigated over the whole range of composition. The products of decomposition were primarily hydrogen, ethane, *n*-butane, ethylamine, and acetylene. It was observed that the yields of ethane, *n*-butane, and ethylamine increased with the increasing concentration of ammonia, and that the *G*-values of these products at 98 mol% ammonia were 0.52, 2.12, and 0.89, respectively. Addition of oxygen or nitric oxide as radical scavengers tended to reduce the yields remarkably. The *G*-value of ethyl radical was calculated from the *G*-values of ethane, *n*-butane, and ethylamine, and the limiting value of $G(C_2H_5\cdot)$ was determined by extrapolation to 100 mol% ammonia. The value thus obtained agrees with the initial *G*-value of hydrogen radical, *i.e.*, $G_H=7.0\pm0.6$, which was obtained by Eyre and Smithies in the study of the γ-radiolysis of ammonia gas[1]. From these results, it was concluded that thermal hydrogen radicals produced by the γ-radiolysis react quickly with ethylene, giving ethane, *n*-butane, and ethylamine from ethyl radicals.

The radiolysis of olefins has been studied by many investigators. The primary process of hydrogen formation was investigated in detail by Hatano *et al.* on the simple olefins (ethylene, propylene, butene-1 and butene-2) under the action of γ-ray radiation.[2-7] They concluded that almost all the hydrogens produced were non-scavengeable and that they were produced by the decomposition of the so-called "super-excited state" which had been proposed by Platzman.[8-10]

It is well-known that thermal hydrogen radicals react quickly with olefins to form alkyl radicals *viz.*, the olefins are good radical scavengers.

It is obvious that hydrogen radical formed in the radiolysis of ammonia finally leads to hydrogen molecule or ammonia molecule. Eyre and Smithies reported that the initial *G*-value of hydrogen radical in the radiolysis of ammonia was as large as 7.0 ± 0.6.[1]

It is expected, therefore, that the concentration of ethyl radical may increase in the radiolysis of a mixture of ammonia and ethylene in which ammonia gives a a large *G*-value of hydrogen radical and ethylene is good radical acceptor. Thus the yields of the products produced by the reaction of ethyl radical might increase.

We have studied the γ-radiolysis of a gaseous mixture of ethylene and ammonia and will report on the mechanism of formation of ethane, *n*-butane, and ethylamine.

Experimental

Materials. Ethylene gas of high purity (over 99.8%) from the Takachiho Trading Co. was purified more than five times by bulb-to-bulb distillation, and only the middle fraction of the purified ethylene was used as the reactant. Purity was determined to be over 99.96% by gas chromatography. Ammonia of high purity (over 99.99%) from the Matheson Co. was dehydrated by metallic sodium and distilled by the bulb-to-bulb distillation method as in the case of ethylene, only the middle fraction of the purified ammonia being used as reactant. Purity of the ammonia was determined to be over 99.9% by gas chromatography. Oxygen and nitric oxide from the Takachiho Trading Co. were used without further purification.

Irradiation. A mixture of ethylene and ammonia was led into a 30 m*l* Pyrex glass ampoule fitted with a break-off seal at constant pressure (2 atm, 2.4×10^{-3} mol). Irradiation was carried out at room temperature by Co-60 γ-rays at the exposure-dose rate of 1.9×10^5 r/hr. In the run of hydrogen analysis, the experiment was carried out at 4 atm using a 3.1 m*l* Pyrex glass ampoule (5.0×10^{-4} mol of the mixture).

Analysis. *Ethylamine*: The irradiated sample was frozen at -196°C and dissolved in 1.0 m*l* benzene. 0.1 m*l* of the solution was then injected into a gas chromatograph (Yanagimoto, 3DH) equipped with a flame ionization detector by means of a micro-syringe. A column (2 m$\times$ 3 mm) with 10% KOH and 10% tetraethylene pentamine on 80/100 mesh Porapak Q was connected directly to a column with 10% KOH and 10% Lubrol MO on 80/100 mesh Porapak Q and used at 70°C. The carrier gas was nitrogen. Ethylamine was identified by the following. The retention time of the peak was consistent with that of a standard ethylamine and the peak disappeared when the sample was passed through sulfuric acid.

Hydrocarbons: The analysis was carried out with a gas chromatograph (Yanagimoto, G8) equipped with a flame ionization detector. A column (2 m$\times$4 mm) filled with silica gel was used, with nitrogen as a carrier gas. Measurement was carried out by the temperature promotion method in the range 50—150°C at a rate of 4°C/min.

Hydrogen: Non-condensable gases at -196°C were collected by a Toepler-pump and analyzed by a gas chromatograph (Yanagimoto, GC220) equipped with a thermal conductivity detector. A column (5 m$\times$5 mm) with Molecular Sieve 5A was used at room temperature with argon as a carrier gas.

Hydrazine: The irradiated sample was frozen at -196°C and dissolved in 2 m*l* water. The dissolved sample was analyzed by the method reported by Watt and Chrisp.[11]

Results

The products in the γ-radiolysis of ammonia were hydrogen, nitrogen, and hydrazine. Hydrogen and hydrazine were determined. In the case of ethylene radiolysis, hydrogen, methane, ethane, acetylene, propane, *n*-butane, *n*-pentane, and *n*-hexane were identified. These products were analyzed quantitatively except for *n*-pentane and *n*-hexane. In the γ-radiolysis of a mixture of ammonia and ethylene, formation of ethylamine was confirmed in addition to the above products.

In the radiolysis of pure ammonia, the *G*-value of hydrazine was very small, *i.e.*, $G(N_2H_4)=0.01$. In the case of the mixture of ammonia and ethylene, $G(N_2H_4)$ was not more than 0.01.

Dependence of the *G*-value of hydrogen $G(H_2)$ on the composition of the mixture is shown in Fig. 1. In the case of pure ethylene, $G(H_2)$ is 1.26 ± 0.03 both at 2 atm and 4 atm. This is consistent with the values reported.[6,12] Thus, there is no pressure effect in our experimental condition.

The dependence of the yield of ethylamine on dose at 90 mol% ammonia is shown in Fig. 2. The yield of ethylamine increases linearly with the increasing dose. From the slope of the straight line, the $G(C_2H_5NH_2)$ is calculated to be 0.73.

The depencence of the yield of ethylamine on the composition of the mixture is shown in Fig. 3. The yield of ethylamine increases with the increasing concentration of ammonia and the maximum yield 3.7×10^{-7} mol or $G(C_2H_5NH_2)=0.89$ is obtained at 98 mol% ammonia. In the case of pure ammonia, a small of ethylamine 0.25×10^{-7} mol was also obtained. This seems to be due to the elution of ethylamine by ammonia which was absorbed on the columns of the gas chromatograph.

Oxygen and nitric oxide are often used as radical scavengers in radiation chemistry. Table 1 shows the variations of the yields of ethylamine and *n*-butane by the addition of these scavengers. Both products were reduced completely by the addition of more than 0.15 mol% oxygen or by the addition of more than 0.6 mol% nitric oxide. It can be concluded that ethylamine and *n*-butane are formed through the radical processes.

Figure 4 shows the dependence of the yields of hydrocarbon products (methane, ethane, acetylene, and n-butane) on the composition of the mixture. The yields of n-butane and ethane increased with the increasing concentration of ammonia, and were reduced by addition of nitric oxide. On the other hand, the yield of acetylene, one of the main products, was not only independent of the concentration of ammonia but also was unaffected by the addition of nitric oxide. This fact shows that acetylene was formed through the ionic decomposition or the unimolecular decomposition process of an excited ethylene molecule.

The yield of methane was very small, and the data were not accurate. However, it can be qualitatively concluded that no effect of the addition of ammonia are observed as in the case of acetylene.

Discussion

The radiolysis of ammonia has been studied in detail by many investigators. Willis *et al.* found by electron beams that $G(H_2)$ was constant, *i.e.*, $G(H_2)=3.58\pm0.08$, in the pressure range 1—2.25 atm.[13] Recently we have obtained $G(H_2)$ to be 3.14 ± 0.11 in the pressure range 2—4 atm in the γ-radiolysis of ammonia.[14]

As shown in Fig. 1, it is obvious that $G(H_2)$ is reduced rapidly by the addition of a small amount of ethylene and then increases linearly with the increasing concentration of ethylene. It is well-known that olefins are effective scavengers of thermal hydrogen radicals, and that almost all the hydrogen formed in the radiolysis of olefins is non-scavengeable. Consequently, the value obtained by extrapolating the straight line (A) in Fig. 1 to 100 mol% ammonia corresponds to the G-value of the so-called non-scavengeable hydrogen or hot hydrogen, which might be produced in the radiolysis of pure ammonia, *i.e.*, $G_{hot}(H_2)$[15]$=0.68$. The value is in good agreement with our results in the radiolysis of a mixture of ammonia and propylene or 1,3-butadiene,[14] and with the result of Eyre and Smithies.[1]

It can be deduced that the difference between $G(H_2)$ which is the value of hydrogen produced in the radiolysis of pure ammonia and $G_{hot}(H_2)$, *viz.*, $G(H_2)-G_{hot}(H_2)=2.46$ corresponds to the G-value of hydrogen formed from the thermal hydrogen radicals.

In Fig. 1 is given the relationship between the G-values of products which seem to be formed from thermal hydrogen radicals, and the composition of the mixture. The value obtained by extrapolating curve B to 100 mol% ammonia is 3.2. The value corresponds to 6.4 which is the G-value (G_H) of hydrogen radicals. This agrees approximately with the initial G-value of hydrogen radical $G_H=7.0\pm0.6$ obtained by Eyre and Smithies[1] and $G_H=7.2\pm0.5$ by Johnson and Simic in the radiolysis of pure ammonia.[16]

As shown in Table 1, the yields of n-butane and ethylamine are reduced by the addition of oxygen or nitric oxide. The yields of products except acetylene are reduced by the addition of nitric oxide (Fig. 4).

It can be deduced that ethane, n-butane, and ethylamine are formed by the following radical processes:

$$H\cdot + C_2H_4 \rightarrow C_2H_5\cdot \quad (1)$$

$$C_2H_5\cdot + C_2H_5\cdot \rightarrow n\text{-}C_4H_{10} \quad (2)$$

$$\rightarrow C_2H_4 + C_2H_6 \quad (3)$$

$$NH_2\cdot + C_2H_5\cdot \rightarrow C_2H_5NH_2 \quad (4)$$

The relation between ethane/n-butane and the composition of the mixture is shown in Table 2. It is obvious that the ratio is independent of the composition, and the constant value is found to be 0.30 ± 0.06. This value is about twice 0.14 which is the ratio of the rate

constant of the disproportionation reaction of ethyl radicals to that of the combination reaction.[17] This suggests that some processes other than reaction (3) might participate in the formation of ethane. Smith *et al.*[18] and Rabinovich *et al.*[19] reported that reaction(5) as well as reaction(3) takes part in the formation of ethane:

$$H\cdot + C_2H_5\cdot \rightarrow C_2H_6 \qquad (5)$$

For the formation of ethylamine, the following reaction as well as reaction(4) might participate.

$$C_2H_5\cdot + NH_3 \rightarrow C_2H_5NH_2 + H\cdot \qquad (6)$$

However, from the bond energies of ammonia and of ethylamine[20], we can calculate the heat of reaction of (6) to be -2.4 kcal/mol, that is, the reaction is endothermic. Consequently, reaction(4) is considered to be more favorable than reaction(6).

Schurath *et al.* have investigated the photolysis of a mixture of ethylene and ammonia, and reported that the following reaction competes with reaction(4) and that the ratio of k_7 to k_4 is about 0.4:[21]

$$C_2H_5\cdot + NH_2\cdot \rightarrow C_2H_4 + NH_3 \qquad (7)$$

Thus, in our reaction system we have to take the contribution of reaction(7) into consideration.

It is obvious that the higher the yields of ethyl radical, the higher the concentration of ammonia. That is to say, the quantity of hydrogen radicals scavenged by ethylene increases with the increasing concentration of ammonia. On the other hand, it is reasonable to consider that the yield of amino radical increases with increasing concentration of ammonia. Consequently, the composition which gives the maximum yield of ethylamine lies so far to the high concentration of ammonia.

Table 3. *G*-Values of products and ethyl radical

Products	*G*-value	$G(C_2H_5\cdot)$ consumed
CH_4	0.01	
C_2H_6	0.52	(3)[a] 0.60
		(5) 0.22
C_2H_2	1.73	
$n\text{-}C_4H_{10}$	2.12	(2) 4.24
$C_2H_5NH_2$	0.89	(4) 0.89
		(7) 0.27
	Total	6.22

2 mol% C_2H_4, dose; 1.0×10^7 rad
a) Number in parentheses indicates reaction number.

Table 3 shows the *G*-values of products at 2 mol% ethylene. From them we can calculate the *G*-value of each ethyl radical consumed by reactions(2), (3), (4), (5), and (7). The values thus obtained are also given in Table 3. The total *G*-value of ethyl radical consumed is seen to be 6.22 which corresponds to the *G*-value of hydrogen radical consumed by the same processes. On the other hand, the *G*-value of thermal hydrogen radical in the radiolysis of pure ammonia is 6.4 to 7.0. In the radiolysis of pure ammonia, the difference between $G(H_2)=3.14$ and $G_{hot}(H_2)=0.68$ is 2.46. Thus, the apparent *G*-value of thermal hydrogen radical is 4.92. Consequently, the value 6.22 is reasonable and $G(C_2H_5\cdot)$ is considered to be nearly equal to G_H.

In the radiolysis of ethylene, ethyl radicals formed might be consumed not only by reactions(2), (3), and (5), but also by reaction(8).

$$C_2H_5\cdot + C_2H_4 \rightarrow C_4H_9\cdot \qquad (8)$$

Reaction(8) might give hydrocarbons of more than C_4. As shown in Table 3, the $G(C_2H_5\cdot)$ consumed by reactions(2), (3), (4), (5), and (7) is 6.22. k_2, k_3, and k_8 are the order of 10^{11}, 10^{11}, and 10^4 (l/mol sec), respectively.[14] Thus, the concentration of ethyl radical in the steady state can be estimated by the following equation using these values.

$$\frac{G(C_2H_5\cdot)\times I}{100} \simeq (k_2+k_3)[C_2H_5\cdot], \qquad (9)$$

where I is dose-rate in eV/ml sec. The value thus obtained is 0.7×10^{-9} mol/ml. Using these values, the ratio of the reaction rate of reaction(8) to that of reactions (2) plus (3) is as follows.

$$\frac{v_8}{v_2+v_3} = \frac{10^4[C_2H_4][C_2H_5\cdot]}{10^{11}[C_2H_5\cdot]^2} = 2.3\times10^{-4} \qquad (10)$$

Consequently, $v_8 \ll (v_2+v_3)$ and the quantity of ethyl radical consumed by reaction(8) may be negligible. It can be concluded that the thermal hydrogen radicals (scavengeable hydrogen radicals), formed in the radiolysis of a mixture of ethylene and ammonia, react mainly with ethylene and the resulting ethyl radical leads to ethane, *n*-butane, and ethylamine.

The *G*-value of thermal hydrogen radical in the radiolysis of pure ammonia is 6.4 to 7.0. This value must be equal to the *G*-value of amino radical. Con-

Magnetic Properties of Copper(II) Complexes of 6-Aminopurine and 6-Hydroxypurine

Toshiro ASAKAWA, Motomichi INOUE, Ken-ichi HARA, and Masaji KUBO
Department of Chemistry, Nagoya University, Chikusa, Nagoya
(Received December 6, 1971)

The magnetic susceptibilities of bis(6-aminopurinato)copper(II) trihydrate, dichlorobis(6-aminopurine) copper(II) sesquihydrate, and dichlorobis(6-hydroxypurine)copper(II) monohydrate obey the Bleaney-Bowers equation for binuclear clusters in conformity with the results of X-ray crystal analysis. The exchange integrals within binuclear clusters were evaluated as $J/k = -156$ to -208°K. Superexchange interaction rather than the interaction of direct nature operates predominantly between copper atoms through the $p\pi$ orbitals of the heterocycles. The J/k values of the compounds are nearly equal to the value, -204°K, of copper(II) acetate monohydrate, although the Cu–Cu distance in the former is greater than that in the latter. The magnetic susceptibilities of dibromobis(6-aminopurine)copper(II) dihydrate, dibromobis(6-hydroxypurine)copper(II) dihydrate, dichloro(6-aminopurine)copper(II), dichloro(6-hydroxypurine)copper(II) monohydrate, and dibromo(6-hydroxypurine)copper(II) hemihydrate indicate the presence of paired copper atoms in the crystals.

Copper(II) acetate monohydrate presents a typical example of binuclear structure,[1] its magnetic susceptibility conforming to the simple triplet-singlet formula.[2,3] For the magnetic interaction within a binuclear cluster, two types of mechanism have been proposed, *i.e.*, direct exchange interaction through a δ-bond ($d_{x^2-y^2}-d_{x^2-y^2}$) and superexchange interaction through four Cu–O–C–O–Cu linkages.[3-6] Some experimental results suggest the predominance of the latter mechanism.[4-6] However, no conclusive evidence has been proposed as yet. A recent X-ray crystal analysis has shown that the crystals of bis(6-aminopurinato)copper(II) tetrahydrate, $Cu(ap)_2 \cdot 4H_2O$, contain binuclear clusters closely resembling those of copper(II) acetate monohydrate as shown in Fig. 1.[7] However, the detailed structure of the compounds reveals two significant differences that the Cu–Cu separation, 2.949 Å, in $Cu(ap)_2 \cdot 4H_2O$ is much greater than 2.64 Å in copper(II) acetate monohydrate and that 6-aminopurinato ligands involve a strong π-bond conjugation as compared with acetate groups. The crystals of dichlorobis(6-aminopurine)copper(II) trihydrate, $CuCl_2(apH)_2 \cdot 3H_2O$, and dichlorobis(6-hydroxypurine)copper(II) trihydrate, $CuCl_2(hpH)_2 \cdot 3H_2O$ also have binuclear clusters analogous to those of $Cu(ap)_2 \cdot 4H_2O$.[8,9] The neutral molecules of the heterocycles in the first two compounds have a stronger aromatic character than that of anionic heterocycles in the last compound. The present investigation has been undertaken in order to obtain some information about the mechanism of magnetic interaction between copper atoms in the binuclear clusters of the copper(II) complexes having the nitrogen heterocycles and of copper(II) acetate monohydrate. In addition, we have determined the susceptibilities of some $CuBr_2L_2$ and CuX_2L type complexes (X: halide ions, L: 6-aminopurine or 6-hydroxypurine) to discuss magnetic interaction in relation to crystal structure.

Preparation of Materials

Bis(6-aminopurinato)copper(II) tetrahydrate, $Cu(ap)_2 \cdot 4H_2O$, was prepared by a method described by Weiss and Venner[10] and recrystallized from a 10% ethanol - water mixture.[7] When the crystals were dried over phosphorus pentoxide or silica gel in a desiccator, $Cu(ap)_2 \cdot 3H_2O$ was obtained.[10] The results of chemical analysis are listed in Table 1. Dichlorobis(6-aminopurine)copper(II) sesquihydrate, $CuCl_2(apH)_2 \cdot 1.5H_2O$, dichlorobis(6-hydroxypurine)copper(II) monohydrate, $CuCl_2(hpH)_2 \cdot H_2O$, dichloro(6-aminopurine)copper(II), $CuCl_2(apH)$, and dichloro(6-hydroxypurine)copper(II) monohydrate, $CuCl_2(hpH) \cdot H_2O$, were prepared by methods reported in the literature.[10,11] X-ray crystal analysis has been

carried out on $Cu(ap)_2 \cdot 4H_2O$, $CuCl_2(apH)_2 \cdot 3H_2O$, and $CuCl_2(hpH)_2 \cdot 3H_2O$. However, the crystals of these complexes gradually lost water of crystallization in air. On standing over silica gel in a desiccator, the crystals yielded $Cu(ap)_2 \cdot 3H_2O$, $CuCl_2(apH)_2 \cdot 1.5H_2O$, and $CuCl_2(hpH)_2 \cdot H_2O$, which were no longer dehydrated in vacuum as well as in air. Therefore, these hydrates were used for magnetic measurements. Dibromobis(6-aminopurine)copper(II) dihydrate, $CuBr_2(apH)_2 \cdot 2H_2O$, and dibromobis(6-hydroxypurine)-copper(II) dihydrate, $CuBr_2(apH)_2 \cdot 2H_2O$, and dibromobis(6-hydroxypurine)copper(II) dihydrate, $CuBr_2(hpH)_2 \cdot 2H_2O$, were prepared by adding a dilute aqueous solution of copper(II) bromide (1 mol) to aqueous solutions of appropriate ligands (2 mol) acidified with a minimum quantity of hydrobromic acid. Dibromo(6-hydroxypurine)copper(II) hemihydrate, $CuBr_2(hpH) \cdot 0.5\ H_2O$, was prepared in the same way as for $CuCl_2(hpH) \cdot H_2O$ using hydrobromic acid in place of hydrochloric acid. We tried to prepare $CuBr_2(apH)$ by a method similar to that for $CuBr_2(hpH) \cdot 0.5H_2O$, but failed to obtain pure samples.

Magnetic Measurements and Results

Magnetic susceptibilities were determined using magnetic balances described in a previous paper.[12] The molar susceptibilities were corrected for diamagnetic contributions (in 10^{-6} emu/mole) from copper(II) ions (−11), chloride ions (−26), bromide ions (−36), water (−13), 6-aminopurine (−62), and 6-hydroxypurine (−59).[13,14] The last value is based

on the observed values of 6-aminopurine (adenine) and 2-amino-6-hydroxypurine (guanine).[14] The temperature-independent paramagnetism was assumed to be equal to 60×10^{-6} emu/mol.[3] The corrected susceptibilities are plotted against the temperature in Figs. 2—5.

Discussion

The magnetic susceptibility of $Cu(ap)_2\cdot3H_2O$ conforms to the theoretical susceptibility, χ, of binuclear

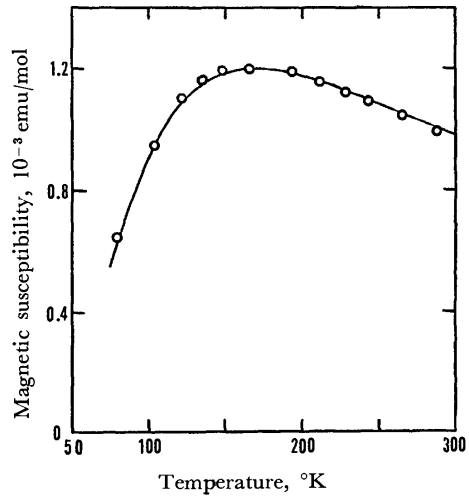

Fig. 5. Magnetic susceptibility of dibromo(6-aminopurine)-copper(II) hemihydrate. The solid curve represents the triplet-singlet formula.

clusters[2] (see Fig. 2).

$$\chi=\frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp\left(-\frac{2J}{kT}\right)\right]^{-1} \quad (1)$$

Here apart from obvious notations, J is the exchange integral between copper atoms within a cluster. The exchange integral and the g-value are evaluated as $J/k=-156$°K and $g=2.07$. The magnetic susceptibility of $Cu(ap)_2\cdot4H_2O$, on which X-ray crystal analysis had been carried out, could not be determined in a reproducible manner because the crystals gradually lost water of crystallization even in air. By use of Eq. 1, the exchange integral, J/k, was roughly estimated to be about -170°K from the susceptibility *versus* temperature curve. Goodgame and Price[15] have measured the susceptibility of $Cu(ap)_2\cdot4H_2O$ and evaluated the parameters as $J/k=-151$°K and $g=2.06$. The exchange integral and the g-value of $Cu(ap)_2\cdot3H_2O$ are almost equal to those of $Cu(ap)_2\cdot4H_2O$, indicating that the binuclear clusters are retained on dehydration without any significant change in bonding arrangement. The disagreement between the J/k values of $Cu(ap)_2\cdot4H_2O$ is due probably to fluctuation in composition. In fact, the magnetic moment of $Cu(ap)_2\cdot4H_2O$ gradually increased with time at room temperature. The J/k value of $Cu(ap)_2\cdot3H_2O$ is more reliable than that of the tetrahydrate because the former crystals were no longer dehydrated in vacuum as well as in air. Therefore, the following discussion is based on the data of $Cu(ap)_2\cdot3H_2O$ and an assumption that the crystals of the trihydrate contain binuclear clusters having the same bonding arrangement as in those of the tetrahydrate.

Dubicki and Martin[5] have pointed out that the δ-bond in the crystals of copper(II) acetate monohydrate is virtually nonbonding and that the configuration of the binuclear clusters is maintained by four bridging acetate groups. This has been supported by the following experimental results. The Cu–Cu

15) D. M. L. Goodgame and K. A. Price, *Nature*, **220**, 783 (1968).

bond length, 2.657 Å, in the crystals of copper(II) formate monourea is nearly equal to 2.64 Å in copper(II) acetate monohydrate,[6] although the former compound shows a magnetic moment, 1.08 B.M. (17°C), much lower than that of the latter, 1.40 B.M. (21.2 °C).[16] Because the Cu–Cu separation, 2.949 Å, in $Cu(ap)_2 \cdot 4H_2O$ is much greater than that in copper(II) acetate monohydrate, δ-bonds are presumed to be very weak in the former compound. Therefore, magnetic interaction is supposed to take place between copper atoms through Cu–ap–Cu linkages.

The crystals of $CuCl_2(apH)_2 \cdot 3H_2O$[8] and $CuCl_2(hpH)_2 \cdot 3H_2O$[9] have binuclear clusters bearing a striking resemblance to those of $Cu(ap)_2 \cdot 4H_2O$: neutral molecules of the heterocycles coordinate to two copper atoms in place of 6-aminopurinato groups and one of the two chloride ions in the chemical formula occupies the same position about a copper atom as does a water molecule coordinating weakly to a copper atom (see Fig. 6). $CuCl_2(apH)_2 \cdot 1.5H_2O$ and $CuCl_2(hpH)_2 \cdot H_2O$ show magnetic properties characteristic of binuclear clusters (see Fig. 3 and Table 2), indicating the retention of the binuclear structure on dehydration. The exchange integrals of $CuCl_2(apH)_2 \cdot 1.5H_2O$ and $CuCl_2(hpH)_2 \cdot H_2O$ are larger than that of $Cu(ap)_2 \cdot 3H_2O$ (see Table 2), although Cu–Cu distance, 3.066 and 3.024 Å, in the former are slightly greater than 2.949 Å in the latter. When paired copper atoms are separated from each other by three diamagnetic atoms (for example, Cu–N–C–N–Cu links), the π-path can give rise to a strong antiferromagnetic interaction between copper atoms,[17] whereas if the contribution from the σ-path is predominant, unpaired electrons of copper atoms are coupled ferromagnetically.[17] In the clusters of $CuCl_2(apH)_2 \cdot 1.5H_2O$ and $CuCl_2(hpH)_2 \cdot H_2O$, nitrogen atoms bonded to copper atoms have $p\pi$ orbitals, because neutral molecules of 6-aminopurine or 6-hydroxypurine coordinate to copper atoms as shown in Fig. 6. Hence, positive holes of copper atoms can migrate through the π-bond system of Cu–N–C–N–Cu links, giving rise to antiferromagnetic interaction in agreement with the sign of the exchange integrals. In the crystals of $Cu(ap)_2 \cdot 3H_2O$, 6-aminopurinato groups coordinate to copper atoms by nitrogen atoms having a negative formal charge (see Fig. 6). This hinders the migration of positive holes through the π-bond system and weakens antiferromagnetic interaction between copper atoms. Owing to this effect, the magnetic interaction is presumed to operate more strongly in $CuCl_2(apH)_2 \cdot 1.5H_2O$ and $CuCl_2(hpH)_2 \cdot H_2O$ than in $Cu(ap)_2 \cdot 3H_2O$ in accordance with the experimental results (see Table 2).

$Cu(CH_3COO)_2 \cdot H_2O$[a]	1.40[b]	204	2.13

a) Ref. 3, b) at 21.2°C.

The magnetic susceptibility *versus* temperature curves of $CuBr_2(apH)_2 \cdot 2H_2O$ and $CuBr_2(hpH)_2 \cdot H_2O$ conform to Eq. 1 (see Figs. 2 and 3), indicating the presence of binuclear clusters analogous to those in the crystals of the corresponding chlorides. The values of exchange integrals are almost equal to one another as listed in Table 2, indicating that the substitution of chlorine with bromine gives no appreciable effect on magnetic interaction.

The magnitude of superexchange interaction depends to a great extent on the electronic structure of bridging ligands. When superexchange interaction takes place through three diamagnetic atoms, a path through π-orbitals can give rise to a strong antiferromagnetic interaction.[17] Therefore, one would suspect that magnetic interaction operates more strongly in the complexes of 6-aminopurine and 6-hydroxypurine than in copper(II) acetate monohydrate, because the heterocycles are expected to facilitate the migration of positive holes more strongly than do acetate groups. Contrary to this expectation, the exchange integral of copper(II) acetate monohydrate is almost equal to those of $CuX_2(apH)_2 \cdot nH_2O$ and $CuX_2(hpH)_2 \cdot nH_2O$ type complexes and is evidently larger than that of $Cu(ap)_2 \cdot 3H_2O$ (see Table 2). These facts suggest that the effect of direct exchange interaction is not entirely negligible in the binuclear clusters of copper(II) acetate monohydrate despite the predominance of superexchange interaction.

The susceptibilities of $CuCl_2(apH)$, $CuCl_2(hpH) \cdot H_2O$, and $CuBr_2(hpH) \cdot 0.5H_2O$ also can be fitted well to the curves of Eq. 1 (see Figs. 4 and 5). Presumably, paired copper atoms are bridged by the heterocycles in the crystals.

The Chemical Structures of Glasses of the $NaPO_3$-Sb_2O_3 and $NaPO_3$-Sb_2O_5 Systems

Makoto WATANABE and Mineo KATO

Department of Industrial Chemistry, Chubu Institute of Technology, Matsumoto-cho, Kasugai-shi, Aichi

(Received May 12, 1971)

Glassy substances of the $NaPO_3$-Sb_2O_3 and $NaPO_3$-Sb_2O_5 systems with P/Sb ratios in the range from 5.0 to 300 were prepared by heating $NaPO_3$ and Sb_2O_3, or Sb_2O_5 at 1000°C, and by then quenching the melts of the mixtures. The condensed phosphates were separated by paper-chromatographic analysis and determined colorimetrically, and the average degree of polymerization of the phosphates was measured by the pH-titration method. From these results, it has been found that the degree of polymerization of the phosphates increased with the increase in the P/Sb ratio. When the glassy samples of both the systems were treated with water, antimony trioxide was deposited. The results show that, in the glassy samples of both the systems, the valency of antimony is three, assuming that the glasses have the P–O–P, P–O^-, P–O–Sb, and Sb–O^- linkages, a theoretical treatment of the degree of polymerization of condensed phosphates has been made and compared with the experimental data. It has been concluded that the glasses of both the systems with P/Sb ratios larger than 5.0 have P–O–P, P–O^-, and P–O–Sb linkages.

Condensed phosphates containing oxoacid anions of some elements other than phosphorus have been prepared by several investigators.[1-4] In a previous paper,[5] the chemical compositions and structures of glasses of the $NaPO_3$-Sb_2O_3-Na_2O system were reported. It has been revealed in these papers that, in structures of condensed phosphates containing oxoacid anions of an element, X, other than phosphorus, there are P–O–X linkages. In the present work, glassy substances of the $NaPO_3$-Sb_2O_3 and $NaPO_3$-Sb_2O_5 systems were prepared in order to obtain some information on the chemical compositions and the structural framework of the systems. As for the glasses of the $NaPO_3$-Sb_2O_3 system, it has been presupposed that its structural framework is the same as that of the glasses of the $NaPO_3$-Sb_2O_3-Na_2O system, this has been confirmed by the measurement of the degree of polymerization and by a theoretical treatment of that of the condensed phosphates. The theoretical treatment of the degree of polymerization of the condensed phosphates revealed that the glasses of these two systems have P–O–Sb linkages. The compositions of the condensed phosphates have been determined by the paper-chromatographic analysis of their aqueous solutions.

Experimental

Materials. Monosodium dihydrogen orthophosphate dihydrate was heated in a platinum crucible at 1000°C for 3 hr and then converted to a glass of sodium metaphosphate by cooling a melt in a crucible. The average chain length of the glass thus obtained was about 100. The antiomony trioxide and pentoxide were commercial reagents.

Classy substances. A mixture of sodium metaphosphate and antimony trioxide, or pentoxide was melted in a platinum crucible at 1000°C for 2 hr and then quenched by placing the crucible in ice water. By this procedure, glasses of the $NaPO_3$-Sb_2O_3 and $NaPO_3$-Sb_2O_5 systems with P/Sb ratios of 5.0 to 300 were prepared. All the glasses thus obtained were transparent and colorless.

Paper Chromatography. The phosphate species in the solution of the glassy substances were separated by paper chromatography and then determined colorimetrically. Except for the acidic solvent, the procedure was the same as that described in a previous paper.[5] In this experiment, the acidic solvent was made by mixing 26.5 m*l* of water, 0.25 m*l* of concentrated aqueous ammonia, 5 g of trichloroacetic acid, and 73.5 m*l* of isopropyl alcohol. It was used for the separation of ortho-, di-, tri-, tetra-, and long-chain phosphates.

The Measurement of the Average Chain Length of Polyphosphates. The average degree of the polymerization of phosphate species in the glassy samples was also measured by the method described in the previous paper.[5]

X-ray Diffractometry. The samples were ground with an agate mortar until they could pass through a 150-mesh screen. Their X-ray diffraction patterns were taken with nickel-filtered CuKα radiation, by using a Toshiba X-ray diffractometer, ADG-102.

Results and Discussion

The samples with P/Sb ratios larger than 5.0 were completely transparent and opaque. The data of X-ray diffractometry of these samples indicated that they were amorphous. The chemical compositions of the phosphate species contained in the glassy substances were estimated by paper-chromatographic analysis. The data of the paper chromatography for the $NaPO_3$-Sb_2O_3 system with P/Sb ratios of 5.0 to 300 are given in Table 1, while those for the $NaPO_3$-Sb_2O_5 system with P/Sb ratios of 5.0 to 300 are given in Table 2. It is found that the ortho-, pyro-, and tripolyphosphate contents of both the systems decrease with the increase in the P/Sb ratio from 5.0 to 300. The quantities of trimeta- and tetrametaphosphate are less than several percent throughout the range of P/Sb ratios from 5.0 to 300. The quantities of high polyphosphate increase with the increase in the P/Sb ratio.

When the glassy samples of the $NaPO_3$-Sb_2O_3 and $NaPO_3$-Sb_2O_5 systems were treated with a 0.03 N sodium hydroxide solution, a white substance was deposited. A study of the X-ray diffraction patterns

of the deposit showed it to be antimony trioxide. This indicates that the antimony pentoxide contained in the samples of the $NaPO_3$-Sb_2O_5 system is reduced to antimony trioxide. The careful treatment of weight change of this system supports the reduction. Therefore, the valency of antimony in the glassy samples of both the systems is three.

The average chain length of the polyphosphates contained in the samples of both the systems was measured. The results of the paper chromatography of these glasses show that the quantities of orthophosphate and of ring phosphates are not very large, therefore, the effect of their presence on the calculation of the average chain length of polyphosphates is disregarded in the following discussion. It is well known that the average chain length, $\bar{n}$, of polyphosphates in a sodium phosphate glass is given by the $Na/P=(\bar{n}+2)/\bar{n}$ equation, where Na/P is the atomic ratio of both the elements. If antimony trioxide or pentoxide does not react with phosphate glass to form P–O–Sb linkages in the melted state, the average chain length of phosphates in the glassy samples does not change when the P/Sb ratio is changed. The straight line,

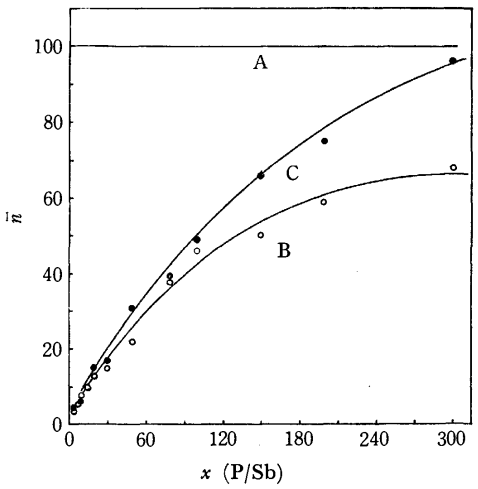

Fig. 1. Variation of average chain length of polyphosphates.
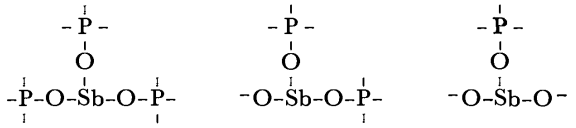
A: Pure sodium metaphosphate
B: Experimental values of the $NaPO_3$-Sb_2O_3 system
C: Experimental values of the $NaPO_3$-Sb_2O_5 system

A, in Fig. 1 exhibits this relation. Curves B and C in Fig. 1 indicate the relation between the measured average chain length of polyphosphates and the P/Sb ratio, x, of the $NaPO_3$-Sb_2O_3 and $NaPO_3$-Sb_2O_5 systems respectively. The great discrepancy between the straight line, A, and the curves B and C, and the results of paper chromatography indicate that the phosphate glass reacts with antimony trioxide or pentoxide at a high temperature to form P–O–Sb linkages.



From the finding that, when the glassy samples of both the systems are treated with a 0.03 N sodium hydroxide solution, antimony trioxide is deposited, it may be concluded that there are three possible types of structures containing P–O–Sb and Sb–O^- linkages. The average chain length, $\bar{n}$, of the polyphosphates produced by the hydrolytic scission of P–O–Sb linkages in the glassy samples of both the systems is given by Eq. (1):

$$(\bar{n}+2)/\bar{n} = (x+y-z)/x \qquad (1)$$

where x, y, and z are the numbers of phosphorus atoms, P–O–Sb linkages, and Sb–O^- linkages per atom of antimony respectively. For Structure A, B, or C, y is 3, 2, or 1, and z is 0, 1, or 2, respectively. The average chain length of polyphosphates derived from the $NaPO_3$-Sb_2O_3 and $NaPO_3$-Sb_2O_5 systems with various P/Sb ratios, x, was calculated by inserting these values into Eq. (1). The calculated values of $\bar{n}$ are given in Tables 3 and 4. The underlined values are the average chain length nearest to the measured one. As is shown by Column I of Table 3 or 4, even the calculated values of the average chain length based on Structure A are considerably larger than the measured values when x is larger than 30 or 80 respectively. Other factors that shorten the chain length of the polyphosphates present in the phosphate-antimonate

glasses are the existence of a branching point and impurities. If all these factors are represented by the factor, f, Eq. (1) is modified into Eq. (2):

$$(\bar{n}+2)/\bar{n} = (x+y-z+fx)/x \qquad (2)$$

where f is given with respect to an atom of phosphorus. The f factor is arbitrarily set at 0.02 for the $NaPO_3$-Sb_2O_3 system and at 0.01 for the $NaPO_3$-Sb_2O_5 system. The value of f of $NaPO_3$-Sb_2O_3 system is identical with that of the $NaPO_3$-Sb_2O_3-Na_2O system. The average chain lengths shown in Column II of Tables 3 and 4 are obtained by inserting these values into Eq. (2). The average chain length of pure sodium metaphosphate is usually in the range from 80 to 200, depending on the conditions of preparation. The f factor of the pure sodium phosphate glass is given by $(\bar{n}+2)/\bar{n}=(1+f)/1$; it ranges from 0.025 to 0.01. Therefore, the f factor of 0.02 for the $NaPO_3$-Sb_2O_3 system and that of 0.01 for the $NaPO_3$-Sb_2O_5 system seem to be reasonable. As is shown in Column II of Tables 3 and 4, the average chain lengths, as calculated on the basis of Structure A, are very close to the experimental values throughout the range of P/Sb ratios from 5.0 to 300. In view of the above discussion, it may reasonably be concluded that the structural framework of the glasses of the $NaPO_3$-Sb_2O_3 and $NaPO_3$-Sb_2O_5 systems with P/Sb ratios in the range from 5.0 to 300 was composed of Structure A, and that Structures B and C were not involved in the structural framework.

Preparation and Properties of Iron(II) Complexes with Tetraoxime Analogues[1]

Joseph BACKES, Isao MASUDA, and Koichiro SHINRA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka

(Recdived June 16, 1971)

Three polymeric iron(II)-tetraoxime chelates of the formula $CH_3C(NOH)C(NOH)$-R-$C(NOH)C(NOH)$-CH_3, where R: C_6H_4-O-C_6H_4, C_6H_4-C_6H_4, and 2,6-pyridyl, are characterized and compared with monomeric α-dioxime analogues. Analytical data indicate that in the solid state these Fe-N_4 type chelates do not coordinate an axial base. Axial substitution takes place only upon dissolution into pyridine or similar basic solvents. The resemblance between the substituted polymer chelates and the monomeric dimethylglyoxime compounds, as far as their electronic spectra are concerned, is discussed. While the solid state polymers are all paramagnetic with moments 2.0—2.5 B.M., ESR data show that in solution a conversion into a diamagnetic species takes place. A strong absorption band due to the O–N stretching vibration appears at about 1650 cm^{-1} upon complexing of the nitrogen atoms. The paramagnetism and the reflectance spectra of the solid state samples are related to their structure.

Many works have been presented dealing with the formation and properties of metal chelate polymers.[2] In these works the low solubility of the compounds often rendered a more accurate research impossible. Better understanding of the effect of polymerization on the central metal ion is expected from a further investigation of these chelate compounds.

Tetraoxime coordination polymers with nickel(II) and with cobalt(II), nickel(II), and copper(II) have been reported by Jones *et al.*[3] and Murahashi and Kubota,[4] respectively.

The present work involves an investigation of iron(II) complexes with ligands of the formula $CH_3C(NOH)C(NOH)$-R-$C(NOH)C(NOH)CH_3$, where R stands for C_6H_4-O-C_6H_4, C_6H_4-C_6H_4, and 2,6-pyridyl.

A close look at a molecular model reveals that the two α-dioxime groups within one ligand unit are not parallel to each other, which renders a binuclear structure with a ligand to iron molar ratio of 1 : 1 impossible.

The properties and structure of these chelates are compared with those of the monomeric iron(II)-α-dioximes.

Experimental

Preparation of the tetraoxime ligands. 4,4′-Bis(α,β-dioxopropyl)diphenyl-tetraoxime and 4,4′-bis(α,β-dioxopropyl)diphenylether-(1,1)-tetraoxime were prepared according to the methods described by Jones *et al.*[3] The products obtained showed the following characterstics:

4,4′-Bis(α,β-dioxopropyl)diphenyl-tetraoxime. White crystals; soluble in DMSO, hot DMF and hot pyridine; insoluble in methanol, ethanol, ethyl ether, petroleum ether, *etc.*; mp 358—359°C.

Found: C, 61.41; H, 5.07; N, 15.67%.

4,4′-Bis(α,β-dioxopropyl)diphenylether-(1,1)-tetraoxime. White crystals; soluble in DMSO, hot DMF and hot pyridine; insoluble in methanol, ethanol, ethyl ether, petroleum ether, *etc.*; mp 270—271°C.

Found: C, 58.28; H, 4.98; N, 15.22%.

2,6-Bis(α,β-dioxopropyl)pyridine-tetraoxime. The pyridine ligand was newly prepared according to the following method.

Pyridine-2,6-dicarboxylic acid chloride. This compound was obtained by heating a mixture of 25 g (0.15 mol) pyridine-2,6-dicarboxylic acid and 53.5 g (0.45 mol) of freshly distilled thionylchloride on a water bath for 1 hr. The excess thionylchloride was removed by azeotropic distillation with benzene. The product was not further purified, and immediately dissolved in 50 m*l* dry benzene for the next step.

N,N,N′,N′-*Tetraethylpyridine-(2,6)-diamide.* The compound was synthesized by the Schotten-baumann reaction in dry benzene using 51.2 g (0.7 mol) freshly distilled benzene to yield colorless crystals, soluble in all common solvents, yield 78%, mp 73—75°C.

Found: C, 65.25; H, 8.65; N, 15.30%. Calcd for $C_{15}H_{23}N_3O_2$: C, 65.95; H, 8.35; N, 15.15%.

2,6-Dipropionylpyridine. This compound was obtained by the reaction of *N,N,N′,N′*-tetraethyl-pyridine-(2,6)-diamide with ethylmagnesium bromide in anhydrous ether. Due to the low solubility of the diamide in ether, the Grignard reagent was added slowly to a suspension of the former in the solvent. The compound, after extraction with a benzene-ether mixture (1 : 1), was purified by consecutive column chromatography to yield colorless crystals, soluble in all common organic solvents, yield 33%, mp 64—65°C.

Found: C, 68.94; H, 6.86; N, 7.32%. Calcd for $C_{11}H_{13}O_2N$: C, 69.09; H, 6.85; N, 7.33%.

2,6-Bis(α,β-dioxopropyl)pyridine-2,2′-dioxime. The dioxime compound was obtained from 2.1 g (0.011 mol) of 2,6-dipropionyl-pyridine and 2.2 g (0.022 mol) freshly distilled *n*-butylnitrite in anhydrous benzene, dry hydrogen chloride being bubbled through the reaction mixture. The precipitate was filtered and thoroughly washed with water and benzene. Recrystallization from aqueous alcohol yields colorless crystals, yield 69%, mp 212—213°C.

Found: C, 52.70; H, 4.56; N, 16.80%. Calcd for $C_{11}H_{11}O_4N_3$: C, 52.99; H, 4,45; N, 16.85%.

2,6-Bis(α,β-dioxopropyl)pyridine-tetraoxime. An aqueous-methanolic solution of 1.5 g (0.006 mol) dioxime and 0.84 g (0.012 mol) hydroxylamine-hydrochloride was refluxed for 13 hr, until no more precipitation took place. The precipitate was collected, filtered, washed with cold methanol and dried in a vacuum. Recrystallization from aqueous alcohol yielded colorless crystals, soluble in hot alcohol,

DMSO, DMF, and pyridine, yield 56%, mp 241—242°C. Found: C, 47.19; H, 5.15; N, 24.43%. Calcd for $C_{11}H_{13}O_4N_5$: C, 47.31; H, 4.69; N, 25.08%.

Preparation of the complexes. One millimole of an iron(II) salt (Mohr's salt) was dissolved under nitrogen in 5 m*l* of water; to this solution was added at 50°C a solution of 0.5 mmol tetraoxime ligand dissolved in 10 m*l* hot DMF and 3 m*l* pyridine. An intensely red colored precipitate was immediately formed. The reaction mixture was kept at 50°C until the precipitation was completed (about 8 hr). The product was then filtered, washed with hot water, hot DMF and dried. The red powders obtained were insoluble in all common solvents, except pyridine and other organic bases. They were slightly soluble but unstable in DMF and DMSO. The analytical data are shown in Table 1.

Preparation carried out in pyridine yielded products identical to those obtained by the above standard procedure.

Apparatus and Procedures. Infrared spectra were measured by the KBr disk method using a Shimadzu IR-27C spectrophotometer in the 4000—650 cm^{-1} region. The polystyrene spectrum was used for calibration.

Magnetic moments in the solid state were determined by the Gouy method using freshly distilled water and $CuSO_4\cdot 5H_2O$ as reference substances. The molar susceptibilities were corrected using Pascal's constants for the diamagnetism of the component atoms.

Reflectance spectra of the finely ground samples were obtained with a Hitachi Spectrophotometer EPS-3, equipped with a reflectance attachment. Magnesium oxide was used as the standard of light reflectance. Electronic absorption spectra were determined with the same spectrophotometer.

The thermogravimetric analyses (TGA) were carried out using a Rigakudenki automatic recording thermobalance under atmospheric pressure. A sample of about 80 mg was held in a nitrogen stream and heated at a rate of 5°C/min.

ESR spectra were measured in the solid state at room temperature and in pyridine solution at room temperature as well as at the temperature of liquid nitrogen with a Japan Electron Optics Laboratory ESR spectrometer, Model JES-ME-2X, using 100 kHz field modulation. A blank test was run before each measurement using an evacuated sample tube. The magnetic field was calibrated with the EPR marker manganese(II) in magnesium(II) oxide.

Results and Discussion

The analytical data of the complexes, shown in Table 1, are in fair agreement with those calculated for a ligand to iron ratio of 1 : 1, indicating that one mole of ferrous ion coordinates with two α-dioxime groups.

The thermogravimetric curves of the metal chelates (*cf.* Fig. 1) show that a thermal decomposition takes

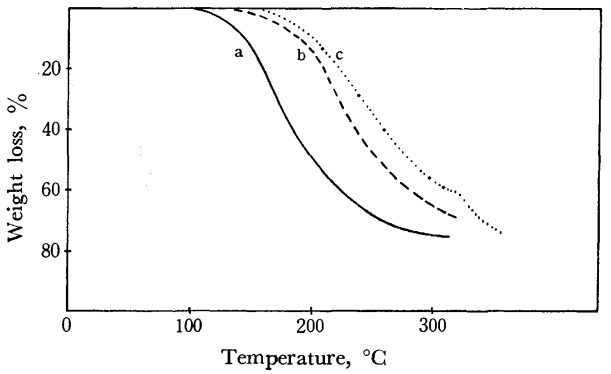

Fig. 1. Thermogravimetric curves of the iron(II)-tetraoximes in nitrogen atmosphere.
a : $(C_6H_4$-O-$C_6H_4)TOH_2\cdot$Fe
b : $(C_6H_4$-$C_6H_4)TOH_2\cdot$Fe
c : (2,6-pyridyl)$TOH_2\cdot$Fe

place according to the same pattern as for the three complexes. They give further evidence that no axial base is actually coordinated.[5)]

The present ferrous tetraoxime complexes are soluble in organic bases such as pyridine, aniline, *etc.* The electronic absorption spectra in pyridine solution show two intense bands at about 18 and 25 kK. This spectral feature is also found in pyridine-substituted iron(II)-dimethylglyoxime complexes, where two absorption maxima appear in the 17.5—19.6 and the 25.0—25.6 kK regions. The one at longer wavelength is attributed to the Fe→oxime charge transfer, the one at shorter wavelength to the Fe→pyridine charge transfer.[6)]

Though the three polymer chelates have all been found to be paramagnetic in the solid state (*cf.* Table 1), the above absorption pattern is consistent with a diamagnetic species.[6)] Spin-pairing is thus thought to take place upon substituting an axial base.

Support for this conversion was found in the ESR spectra of the compounds. For the solid state samples a clear signal without hyperfine structure was detected in the 3000 Gauss region. This signal completely disappeared in a pyridine solution.

Upon dissolving the chelates in organic bases such as piperidine or aniline which do not allow any axial

π-delocalization, the absorption band at higher energy, as for the dimethylglyoxime complexes, is no longer found. The band at lower energy, attributed to the Fe→oxime charge transfer, shifts considerably to longer wavelength with the increase of the basicity of the axial substituent (*cf.* Table 2).

In the case of the ferrous dimethylglyoxime complexes, substitution on the axially coordinated pyridine ligand was found to cause strong shifts of the charge transfer bands to longer or to shorter wavelength, depending on whether the donor properties (*cf.* aminopyridine, methylpyridine) or the acceptor properties (*cf.* cyanopyridine) of the pyridine were increased.[6] As can be seen from Table 2, this effect is considerably weaker in the tetraoxime complexes.

A plot of the absorption intensity of the complexes *vs.* the composition of a mixed pyridine-chloroform solvent (Fig. 4) indicates that the axial pyridine forms a very weak bond, which is consistent with the small effect of the pyridine substituents.

It is worth noticing that both the lower and the higher energy bands are shifted to longer wavelength in the pyridine-substituted tetraoxime complexes

		27.5 (3.79)	

(25.0 and 18.5 kK respectively), as compared to the pyridine-substituted dimethylglyoxime complexes (26.0 and 19.6 kK), which can be related to a stronger Fe→oxime bonding in the former.

Comparision of the infrared spectra of the ligands and the iron(II)-complexes reveals a divergent behavior from similar dimethylglyoxime compounds. Figure 3 shows that the complexing of the nitrogen atoms of the oxime compound leads to the appearence of a strong absorption band at about 1650 cm^{-1}.

For the diphenylether- and the diphenyl-tetraoxime ligands, an absorption band attributable to the C=N stretching vibration can hardly be assigned due to the low intensity absorptions in the characteristic 1650 cm^{-1} region. In the pyridine tetraoxime ligand, a sharp but low intensity band appears at 1620 cm^{-1}, which is tentatively assigned to the C=N stretching mode of the free oxime group. For the three complexes, coordination with Fe(II) leads to a strong, broad absorption band at about 1650 cm^{-1}. A similar effect has been found in 1,2-diimine compounds upon chelating with iron(II).[7]

A second noticeable feature of the infrared spectra is that in both the pure ligands and the complexes the OH stretching vibrations at 3250 cm^{-1} can be detected, which in the iron complexes can be assigned to terminal oxime groups within the polymer. The strong intensity of this absorption band within the complexes suggests that the polymer chain is not much extended.

The structure of the ferrous tetraoxime polymer chelates in solvents involving organic bases has so far been found to bear a close resemblance to the axially substituted, octahedral Fe(II)-dimethylglyoxime analogues. While the latter are very unstable in the absence of an axial base,[6] the former could be isolated in the solid state, even from a pyridine solution with no pyridine coordinated.

7) D. H. Busch and J. C. Bailar, Jr., *J. Amer. Chem. Soc.*, **78**, 1137 (1956).

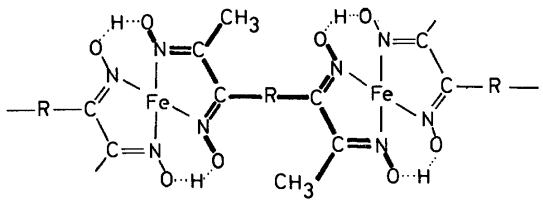

Fig. 5. Schematic representation of the tetraoxime-iron(II) complexes.

However, the reflectance spectra show the presence of a band in the 25 kK region, along with the Fe→ oxime charge transfer band at about 18 kK.

It is clear from a molecular model that, due to the sp^2 bonding between R and the oxime group, the R–C–C angle is equivalent to 120°, which excludes the formation of a monomeric binuclear complex (Fig. 5).

The absorption at shorter wavelength seems to result from an axial interaction of the central ferrous ion with another chelate molecule in the upper and lower-layers of the polymer network forming a pseudo-octahedral structure in the solid state.

Insufficient solubility and infusibility did not allow any accurate molecular weight determination.

Some paramagnetic ferrous chelates with small magnetic moments have been reported.[8] Among the explanations offered were impurities from residual ferrous or ferric ions, a thermal mixture of the low spin and the high spin form[9] or a planar arrangement with a large ligand field splitting.[10]

The present polymer chelates have been found to form a strong bonding in the Fe–N_4 plane, whereas the bonding toward the axial substituents is very weak. This seems to be a major factor determining the small magnetic moment.

Derivatographic Studies on Transition Metal Complexes. VII.[1] Thermal *cis, trans*-to-*trans, cis* Isomerization of $[CoCl_2(NH_3)_2en]Br \cdot H_2O$ in Solid Phase[2]

Ryokichi TSUCHIYA, Masatatsu SUZUKI, and Eishin KYUNO

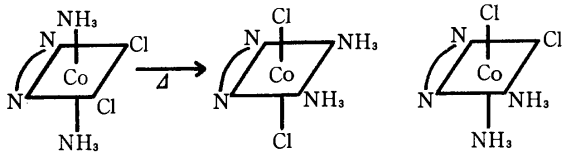
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received June 26, 1971)

The *cis, trans*-to-*trans, cis* isomerization as well as dehydration of $[CoCl_2(NH_3)_2en]Br \cdot H_2O$ were investigated by using derivatographic, isothermal, and sealed tube methods. Isomerization in a solid phase proceeded regardless of whether its state was monohydrate or anhydride. Two distinct processes were found for isomerization, one being accompanied by the liberation of water of crystallization and the other taking place after complete liberation of water of crystallization. Both reactions were of the first order. The thermochemical functions were obtained to be $\Delta H = (12 \pm 2)$ kcal/mol, $E^* = (28 \pm 3)$ kcal/mol and $\Delta S^* = (-10 \pm 4)$ e.u. for dehydration. The values $E^* = (28 \pm 3)$ kcal/mol and $S^* (-4 \pm 2)$ e. u. were estimated for isomerization in the first process, and $E^* = (28 \pm 3)$ kcal/mol and $\Delta S^* = (-12 \pm 3)$ e.u. for that in the second process. As a possible reaction mechanism for isomerization, an "aquation-anation mechanism" was introduced for the first process and an "intramolecular mechanism" for the second.

It is known that, owing to the small energy change in isomerization, some cis-complexes turn into the corresponding trans-complexes[3] and other trans-complexes are converted into the cis-complexes[4-7] in a solid phase. A striking feature particularly of isomerization in a solid phase is that the reactions are sensitively affected by the kind of counter ionic species contained, in contrast to the reactions in aqueous solution. As an example, the variation of the counter ion X in *cis, trans*-$[CoCl_2(NH_3)_2en]X$ type gives rise to a different reaction upon heating in a solid phase. In the case of X=Cl, no isomerization could be observed, whereas in the case of $X=ClO_4$, isomerization into the corresponding *trans, cis*-form[3] took place and in the case of X=SCN, the *cis, trans*-complex was converted into *cis, cis*-$[CoCl(NCS)(NH_3)_2en]Cl$.[1]

It is of interest to investigate the cause of isomerization path-ways differing with the kind of counter ionic species. For studying the problem, we attompted to observe the isomerization of *cis, trans*-$[CoCl_2(NH_3)_2en]Br \cdot H_2O$ and its anhydride as one of the series of studies on *cis, trans*-$[CoCl_2(NH_3)_2en]X$ type complexes. Three geometrical isomers of $[CoCl_2(NH_3)_2en]^+$ are schematically drawn in Fig. 1, together with their colors. When the monohydrate and anhydride of the corresponding bromide are heated in a solid phase, a distinct color change from blue to green is observed. This thermal isomerization step is shown by an arrow in Fig. 1. This paper deals with the measurement of rate and the estimation of the kinetics of isomerization as well as dehydration in the complex bromide.



cis, trans-form (blue) — *trans, cis*-form (green) — *cis, cis*-form (violet)

Fig. 1. Geometrical isomers of $[CoCl_2(NH_3)_2en]^+$.

Experimental

Preparation of Complexes. The complex, *cis,trans*-$[CoCl_2(NH_3)_2en]Br \cdot H_2O$ was prepared by the method of Bailar and Pepard.[8] The corresponding bromide was obtained by saturating the solution of the chloride with ammonium bromide at room temperature and by standing it in a refrigerator for a while. Purification was achieved by recrystallization from water. Blue crystals deposited out were filtered, washed with a small amount of cold water, ethanol and ether, and air-dried.

Found: C, 7.46; H, 5.00 N, 17.29%. Calcd for *cis,trans*-$[CoCl_2(NH_3)_2en]Br \cdot H_2O$: C, 7.46; H, 4.95; N, 17.39%.

The complex *trans,cis*-$[CoCl_2(NH_3)_2en]Cl$ was also prepared by the method of Bailar and Pepard for the corresponding *cis,trans*-complex.

Derivatographic Measurement. The apparatus and techniques for derivatography used were the same as described previously.[9]

Isothermal Measurement. A Shimadzu TM-1A Thermano balance and Abderhalden apparatus were used for the isothermal measurment. The measurement and analytical method were also the same as given previously.[9] In order to determine the ratio of the two isomers in the sample in each heating step, the visible and UV absorption spectra of the complexes were measured with a Hitachi R-3 Spectrophotometer. The electronic spectra of the complexes in DMF-water mixture (4 : 1), *cis, trans*-$[CoCl_2(NH_3)_2en]Br \cdot H_2O$, *trans,cis*-$[CoCl_2(NH_3)_2en]Br$ and the reaction product obtained by heating the former are given in Fig. 2. Since *cis,trans*- and *trans,cis*-complexes exhibit the absorption coefficients 110 and 34 at 598 nm ($\nu = 50.17 \times 10^{13}$ sec^{-1}) and 92 and 41 at 625 nm ($\nu = 48.00 \times 10^{13}$ sec^{-1}), respectively,

the ratios *cis*, *trans*/*trans*, *cis* of two isomers in each product were determined spectrophotometrically by means of the following equations,

$$\left.\begin{aligned} 110X + 34Y &= D_{598} \\ 92X + 41Y &= D_{625} \end{aligned}\right\} \quad (1)$$

where X and Y are the concentrations (mol l^{-1}) of *cis*, *trans*-complex and *trans*, *cis*-complex, respecitvely, and D_{598} and D_{625} are the observed absorbancies at 598 nm and 625 nm, respectively, with 1.0 cm cell.

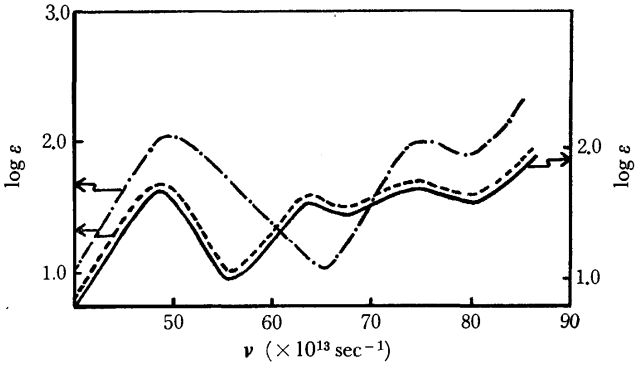

Fig. 2. Electronic spectra of *cis*, *trans*-$[CoCl_2(NH_3)_2en]Br \cdot H_2O$ (———), *trans*, *cis*-$[CoCl_2(NH_3)_2en]Br$ (——), and the product obtained by heating the former (----).

IR Spectral Measurement. The IR and Far IR spectra were measured by a nujol-mull method using JASCO Model IR-E and IR-F Spectrophotometers both in NaCl and in CsBr regions.

Results and Discussion

Structural Assignment. IR spectra of the complexes are shown in Fig. 3. In order to determine the geometric configuration in the thermal reaction product of *cis*, *trans*-$[CoCl_2(NH_3)_2en]Br \cdot H_2O$, δ_{NH_2} bands appearing in 1250—1350 cm^{-1},[1,10] ν_{Co-N} bands in 450—550 cm^{-1},[12] and ν_{Co-Cl} bands in 300—360 cm^{-1},[11] should be carefully studied.

The three wave number regions where the absorption peaks appear differ to some extent in *cis*, *trans*-$[CoCl_2(NH_3)en]Br \cdot H_2O$ and *trans*, *cis*-$[CoCl_2(NH_3)en]Br$ as seen in Fig. 3. On the other hand, the absorption peaks for δ_{NH_2}, ν_{Co-N} and ν_{Co-Cl} in the thermal reaction product were found to be in fair agreement with those in *trans*, *cis*-$[CoCl_2(NH_3)_2en]Br$.

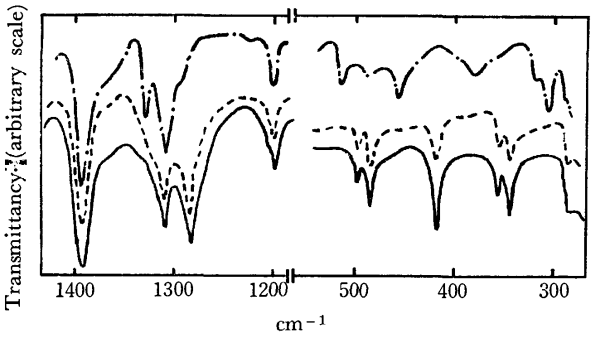

Fig. 3. IR spectra of *cis*, *trans*-$[CoCl_2(NH_3)_2en]Br \cdot H_2O$ (———), *trans*, *cis*-$[CoCl_2(NH_3)_2en]Br$, (——), and the product obtained by heating the former (----).

If the thermal exchange between chloride ion coordinating to the central metal ion and bromide ion in the outer coordination sphere occurs in the isomerization process, the bands in 300—360 cm^{-1} for the reaction rpoduct should differ from those for *trans*, *cis*-$[CoCl_2(NH_3)_2en]Br$. A similar exchange has been found in the isomerization, *cis*, *trans*-$[CoCl_2(NH_3)_2en]SCN \cdot H_2O \longrightarrow$ *cis*, *cis*-$[CoCl(NCS)(NH_3)_2en]Cl$.[1] However, no such exchange could be observed in *cis*, *trans*-$[CoCl_2(NH_3)_2en]Br \cdot H_2O$.

Thus, it is concluded that the thermal reaction product of *cis*, *trans*-$[CoCl_2(NH_3)_2en]Br \cdot H_2O$ is *trans*, *cis*-$[CoCl_2(NH_3)_2en]Br$.

Derivatography. The derivatogram for *cis*, *trans*-$[CoCl_2(NH_3)_2ne]Br \cdot H_2O$, is shown in Fig. 4, where the heating rate applied is 1°/min. The TG curve indicates that dehydration begins at about 90°C and is complete at 125°C and no further loss of weight is detectable until about 150°C. The DTA curve exhibits two overlapped, broad endothermic peaks: the first endothermic peak is centered at 100°C corresponding to genuine dehydration, and is followed by the second, somewhat less intense peak at 120—125°C, corresponding to the dehydration accompanied by the partial isomerization. Other endothermic and exothermic peaks appear at 150—170°C suggesting further decomposition from the TG curve. The DTG curve exhibits similar peaks to those in the DTA curve.

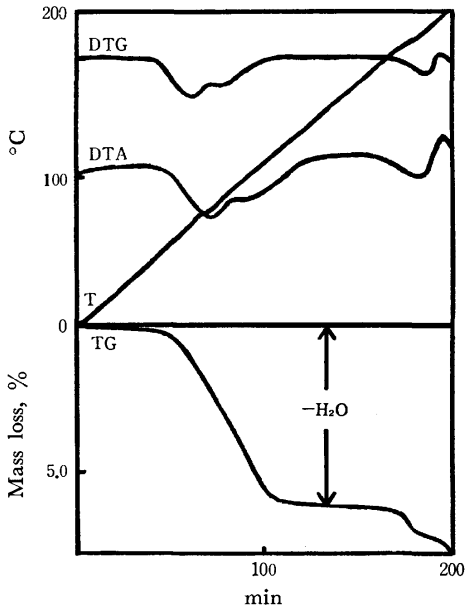

Fig. 4. Derivatogram for *cis*, *trans*-$[CoCl_2(NH_3)_2en]Br \cdot H_2O$.

The enthalpy change ΔH in the genuine dehydration was estimated to be (12±2) kcal/mol by means of analysis of the first endothermic peak.[9] The value is comparable to the enthalpy change in the dehydration from the general hydrate.

Rate Law for Dehydration and Isomerization. From the measurement of the weight change with a thermobalance at several isothermal temperatures in the region 100—140°C, the relationship between mass loss and time was obtained. By measurement of the absorption of the samples picked up at desired time intervals upon heating and application of equations (1), the conversion ratios of *cis, trans* type complexes to *trans, cis* type complexes were calculated. The results are summarized in Table 1.

Table 1. The rate constant of dehydration k_d, first step isomerization k_1* and second step isomerization k_1**, and thermochemical functions

°C	k_d (sec^{-1})	k_1* (sec^{-1})	k_1** (sec^{-1})
100	$(1.9\pm0.3)\times10^{-4}$	$(1.1\pm0.4)\times10^{-4}$	$(1.1\pm0.3)\times10^{-6}$
110.8	$(4.6\pm0.4)\times10^{-4}$	$(4.1\pm0.4)\times10^{-4}$	$(2.8\pm0.3)\times10^{-4}$
121.8	$(1.2\pm0.3)\times10^{-3}$	$(1.2\pm0.4)\times10^{-3}$	$(9.1\pm0.3)\times10^{-5}$
138.3	$(6.5\pm0.3)\times10^{-3}$	$(7.1\pm0.5)\times10^{-3}$	$(3.3\pm0.3)\times10^{-4}$

$\Delta H = (12\pm2)$kcal/mol
$E^* = (28\pm3)$ kcal/mol $E^* = (28\pm3)$kcal/mol $E^* = (28\pm3)$ kcal/mol
$\Delta S^* = (-10\pm3)$ e.u. $\Delta S^* = (-4\pm2)$ e.u. $\Delta S^* = (-12\pm3)$ e.u.

Let *a* denote the initial amount of *cis, trans*-complex monohydrate (in case of dehydration) or of its anhydride (in case of isomerization), *x* denote the amount of anhydride (dehydration) or *trans, cis*-complex (isomerization) produced, and let the values of log $a/(a-x)$ be plotted against time (Fig. 5.). The results

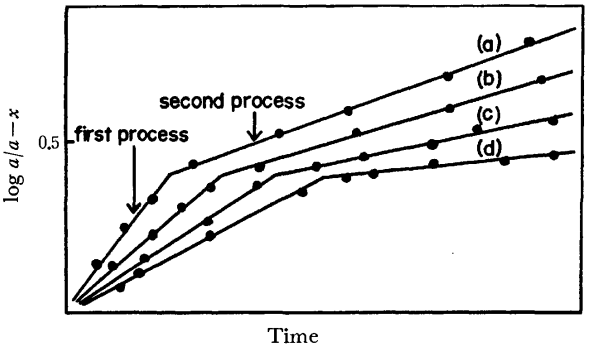

Fig. 5. Plots of log $a/(a-x)$ *vs.* time for isomerization. (a) 138.3°C, (b) 121.8°C, (c) 110.8°C, (d) 100°C Time scales are different in each run.

give two crossed straight lines at each temperature, indicating that the reactions proceed in the first order.

The appearance of a knick point in each plot suggests the presence of the two steps in isomerization. The first step of isomerization was followed by the dehydration from the complex and *cis, trans*/*trans, cis* ratios in the product at all temperatures were found to be 40 : 60 at the end of dehydration. The second step of isomerization proceeded in the absence of water.

Rate constants calculated are listed in Table 1, which includes the thermochemical functions estimated from the temperature-dependence of rate constant: the activation energies were obtained from the inclination of the plottings, and the entropies of activation were calculated by means of absolute rate theory.

The thermal reaction schemes are shown in Fig. 6. It is known that the isomerization accompanying dehydration in solid phase was interpreted in terms of the "aquation-anation mechanism," while the isomerization in anhydrous state was explained with the aid of the intramolecular mechanism[12,13]. In the thermal decomposition of *trans*-$[CoCl_2pn_2](H_5O_2)Cl_2$, the above concepts concerning the reaction mechanism were also applied.[5]

It is known that the activation energies in the dehydration and in the isomerization accompanying dehydration are 25—45 kcal/mol[1,5]. A comparison of the above activation energies with that given in Table 1 suggests that the isomerization of *cis, trans*-$[CoCl_2(NH_3)_2en]Br \cdot H_2O$ in solid phase proceeds through "aquation-anation mechanism" in the same way as in aqueous solution.

In order to confirm the presumption, the same thermal isomerization as above was tried in a sealed tube, since isomerization in a sealed tube is expected to be faster than that in an open system. In the anhydrous complex, no further change in reaction rate was found between the sealed tube and the open system. However, the rate of the first step isomerization accompanying dehydration was found to be considerably affected by the vapor pressure from water contained in the complex. This is probably due to the fact that, in the case of anhydride, a small amount of water coexisting with the sample can act only at the surface of solid, while in the hydrated crystals

water molecules can easily react with the complex in a sealed tube.

The "aquation-anation" path-way in the isomerization of the *cis, trans*-complex monohydrate to the *trans,cis*-complex monohydrate,

$$\textit{cis, trans}\text{-}[CoCl_2(NH_3)_2en]Br\cdot H_2O \searrow \rightarrow \textit{trans, cis}\text{-}[CoCl_2(NH_3)_2en]Br + H_2O$$

is presumed to consist of the following two steps:

$$\textit{cis, trans}\text{-}[CoCl_2(NH_3)_2en]Br + H_2O \searrow \rightarrow \textit{trans, cis}\text{-}[CoCl(H_2O)(NH_3)_2en]BrCl \quad \text{(i)}$$
(or *cis, trans*-)

$$\textit{trans, cis}\text{-}[CoCl(H_2O)(NH_3)_2en]BrCl \text{ (or } \textit{cis, trans}\text{-)} \searrow \rightarrow \textit{trans, cis}\text{-}[CoCl_2(NH_3)_2en]Br + H_2O \quad \text{(ii)}$$

Process (ii) may be considered to be the rate determining step since the isomerization was found to proceed according to the first rate law.

On the other hand, it was found that the complex chloride, *cis, trans*-$[CoCl_2(NH_3)_2en]Cl\cdot H_2O$, does not isomerize in the open system but isomerizes in the sealed tube, which gives similar conditions to those in aqueous solution. It may be due to the fact that the water of crystallization has little role in the isomerization of the chloride in the open system.

Since *cis, trans/trans, cis* ratios in the sample obtained immediately after the complete liberation of water of crystallization from *cis, trans*-$[CoCl_2(NH_3)_2en]Br\cdot H_2O$ are independent of the degree of isothermal temperature, a certain amount of water might have no contribution to the isomerization.

The activation energy for the first isomerization, $E^*=(28\pm3)$ kcal/mol, coincides with that for the dehydration. This suggests that the aquation process (i) is very fast, being followed by the slower anation (ii). Thus the consideration that process (ii) may be the rate determining step is supported and the "aquation-anation mechanism" would be accepted in the isomerization of *cis, trans*-$[CoCl_2(NH_3)_2en]Br\cdot H_2O$.

For the isomerization of anhydrous complex, either of the intramolecular mechanisms, "chain-opening-closing" or "twisting" mechanism, may be considered. If the former is predominant in the isomerization of anhydrous complex, the activation energy would be relatively large owing to the requirement of the bond-breaking energies. The activation energy actually obtained in the second isomerization $E^*=(28\pm3)$ kcal/mol was, however, considerably smaller than that expected. Thus, "chain-opening-closing" mechanism can be ruled out. On the other hand, "aquation-anation mechanism" also can not be accepted even if the activation energy is eventually equal to that in the first isomerization, since the second isomerization occurs in the absence of water.

Thus, we might conclude that the second isomerization of anhydrous complex *cis, trans*-$[CoCl_2(NH_3)_2en]Br$ proceeds with the aid of "twisting mechanism," because it does not require much activation energy.

With the values of the activation energy E^* and the entropy of activation ΔS^*, those of free energy of activation ΔG^* were calculated to be 30 kcal/mol and 33 kcal/mol, for the first and second isomerizations respectively. It is obivous from these values that the anhydrous complex is more difficult to isomerize than the hydrate complex.

Formation of Uranium Sesquicarbide by the Partial Decarburization of Uranium Dicarbide Using Magnesium Oxide

Hiroaki TAGAWA

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki

(Received August 2, 1971)

Formation of U_2C_3 by the reaction of UC_2 with MgO has been studied by means of chemical and X-ray analyses at temperatures 1450—1700°C *in vacuo*. The reaction was found to proceed generating CO and Mg vapor and to produce U_2C_3. The decarburization is represented by

$$2UC_2 + MgO \rightarrow U_2C_3 + CO + Mg.$$

UO_2 and UC were formed as the intermediate compounds. The amount of UO_2 was nearly equal to that formed by the reaction: $UC_2+4MgO=UO_2+2CO+4Mg$. The lattice parameter of U_2C_3 was 8.0890 Å. The lattice parameters of UC_2 and UC varied with the reaction time. The main reaction sequence was suggested to be:

$$1/4UC_2 + MgO = 1/4UO_2 + 1/2CO + Mg$$

$$7/4UC_2 + 1/4UO_2 = U_2C_3 + 1/2CO.$$

The experimental results were in good agreement with those obtained by thermochemical calculation.

In the system uranium-carbon, there are three compounds, monocarbide, sesquicarbide, and dicarbide. Monocarbide UC is NaCl-type face-centered cubic,[1,2] with a lattice parameter of 4.9605 Å. Sesquicarbide U_2C_3 is known to be body-centered cubic (space group I43d) by X-ray[3] as well as neutron diffraction studies[4]. The best parameter seems to be 8.0898 Å[5,6]. Dicarbide UC_2 has two modifications. α-UC_2 is CaC_2-type body-centered tetragonal.[1,2,4,7,8,9] The compound exhibits a non stoichiometric range of composition, $UC_{1.85}$—$UC_{1.96}$. Various lattice parameters are found in literature. They lie in the ranges a_0=3.515—3.526 Å, c_0=5.98—6.00 Å. It was shown that the values of carbon-saturated UC_2 obtained in equilibrium state are a_0=3.5256 Å and c_0=6.000 Å[6,10]. Above 1765°C the tetragonal structure is transformed into the cubic structure[8,11], which is considered to be of the NaCl-type with a C_2 group as in the case of CaC_2 and KCN.

Although uranium sesquicarbide is stable below 1780°C[12], it is not formed easily by the carburization of uranium metal or by the carbothermic reaction of uranium dioxide. In both reactions, the carbide phase of the composition C/U=1.5 is always found to be a mixture of monocarbide and dicarbide. No sesquicarbide is obtained directly. It was reported that sesquicarbide is formed by adding mechanical stress onto a mixture of monocarbide and dicarbide,[13] or by heating and cooling it repeatedly at about the temperature of decomposition of U_2C_3.[14] It was also reported that U_2C_3 is formed by heating a mixture of UC and UC_2 at 1500—1600°C,[15] or by the reaction of pure UC and graphite *in vacuo*.[16,17] The formation of sesquicarbide is apparently inhibited by the presence of dissolved oxygen in the matrix.[17,18] Self-purification is reported when the carbide of composition $UC_{1.5}$ is annealed at 1500°C in a vacuum of 10^{-5} mmHg, producing U_2C_3.[15,17]

However, it was found that uranium sesquicarbide is easily produced by the reaction of dicarbide with uranium dioxide:[19]

$$7UC_2 + UO_2 = 4U_2C_3 + 2CO.$$

In this reaction, U_2C_3 is formed not only by the direct reaction of UC_2 and UO_2, but also by the reaction of UC, which appears as an intermediate with some quantity of oxygen, with UC_2, which dissolves oxygen from UO_2 : $U(C,O)+U(C_2,O)\rightarrow U_2C_3+CO$.
Oxygen has an important role in the formation of sesquicarbide. Thus, if a suitable metal oxide is used instead of uranium dioxide, the oxygen will act to give the product U_2C_3.

The reaction of uranium dicarbide with magnesium oxide as a metal oxide was examined by means of X-ray and chemical analyses. Magnesium oxide was chosen because the vapor pressure of magnesium pro-

duced is very large at high temperatures, and magnesium does not form carbide under the experimental conditions, uranium sesquicarbide thus being expected as the product.

Experimental

Materials. Uranium dicarbide was prepared by the carburization of uranium metal. The procedure was the same as that reported.[6] Uranium hydride and spectroscopically pure graphite powder were mixed at a mole ratio 1 : 2, and cold-pressed to cylindrical pellets. The resulting pellets were heated in a graphite crucible at 400°C to decompose the hydride, and then at 1700°C for 3 hr *in vacuo*. Composition of the dicarbide produced: uranium, 90.767 wt%; total carbon, 8.870 wt% (C/U=1.937), with no free carbon. The lattice parameters were $a_0=3.5252$ Å and $c_0=5.999$ Å. Chemically pure magnesium oxide was ignited at 900°C in the air before use.

Procedure. The UC_2 and MgO powders under 200 mesh were mixed together at the ratio 13 : 1 by weight, and cold-compacted at 3 ton/cm² into cylindrical pellets, 7 mm in diameter and 7 mm in height. The pellets were heated in a graphite crucible *in vacuo* at 1450—1700°C for 0.5 to 7 hr. The reaction was carried out in a tantalum resistance furnace, evacuated to 1×10^{-5} mmHg or below. The temperature of crucible was measured with a two-color eye pyrometer, calibrated by the melting point of platinum.

Chemical and X-ray analyses. Chemical analysis of amounts of total carbon and uranium was carried out by means of combustion technique.[6] The amount of magnesium oxide unreacted was determined by the photometric method with 8-hydroxyquinoline.[20] The method involves TBP extraction to separate uranium, precipitation of magnesium as 8-hydroxyquinolate, and photometric measurement of combined 8-hydroxyquinoline in hydrochloric acid medium.

X-ray measurements were carried out with a diffractometer, the operation conditions being the same as reported.[10] The lattice parameters were calculated from diffraction lines between 165° and 70° of twice the Bragg angle, by the $\cos^2\theta$ extrapolation method. The standard deviations were within 0.0004 Å for UC, U_2C_3, a_0 of UC_2 and UO_2, and within 0.002 Å for c_0 of UC_2. The amounts of three uranium carbides in the product were determined by comparison of relative intensities. The (311) or (222) reflection for UC, the (521) reflection for U_2C_3 and the (211+202) reflection for UC, the (521) reflection for U_2C_3 and the (211+202) reflections for UC_2 were used. No reflection was found for magnesium oxide. The amount of uranium dioxide as an intermediate was determined by comparison of the reflection (111) for UO_2 with the (111) reflection for UC and (101) for UC_2. The results were compared with those of chemical analysis.

Results

Reaction of UC_2 with MgO. The reaction of a pelletized mixture of uranium dicarbide and magnesium oxide at temperatures 1450—1700°C *in vacuo* was found to proceed generating carbon monoxide and magnesium vapor, which condensed at a cold zone in the furnace. At 1500°C the weight change in the pellets before and after the reaction was 8.27, 8.60, 9.21, and 9.30 wt% corresponding to the heating time 0.5, 1, 2, and 7 hr, respectively. It was shown that most of the weight loss took place within 0.5 hr. The reaction at 1700°C terminated after heating about 1 hr. The results of chemical analysis for the products heated at 1500°C are given in Fig. 1. The change in the carbide composition by X-ray analysis obtained by the summation of the composition of the three carbides, is also given. The difference in the data obtained by X-ray and chemical analyses was taken as the amount of uranium dioxide. This was in good agreement with that obtained directly by X-ray analysis. Magnesium oxide unreacted was detected only in the products obtained by 0.5 hr heating and at 1500°C or below; the amount was 0.95 wt% at 1450°C and 0.09 wt% at 1500°C. Figure 2 shows the change in the phases UC_2, U_2C_3, UC, and UO_2 in the products with the reaction time at 1500°C. The amount of UO_2 showed a maximum in 0.5 hr of heating at all the temperatures. We see that UO_2 (10 mol%) was found in the product by heating for 0.5 hr. The amount was nearly the same as that formed by the reaction: $UC_2+4MgO=UO_2+2CO+4Mg$, *i.e.*, 12.5 mol%. On visual inspection of the cross section of the pellets heated for 0.5 hr, uranium dioxide was found to be scattered throughout the area. Uranium monocarbide was also formd as an intermediate; the amount of UC showed a maximum at all the reaction temperatures for 0.5—1 hr of heating time. The quantity of uranium sesquicarbide increased monotonically with the reaction time, UC_2 being rapidly consumed.

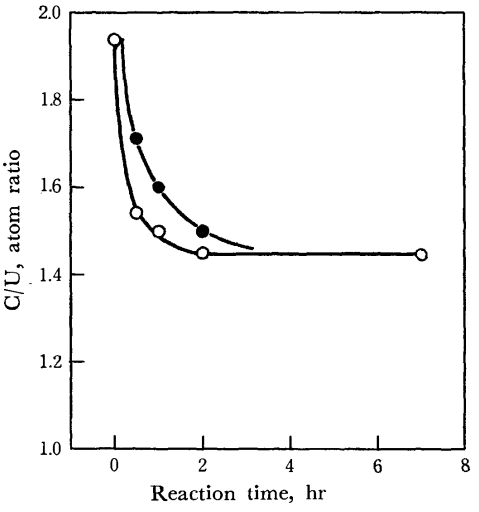

Fig. 1. Variation of the C/U atom ratios of the product at 1500°C by chemical and X-ray analyses with reaction time.
○: chemical analysis
●: X-ray analysis. The difference between X-ray and chemical analysis is taken as UO_2.

Change in the Lattice Parameters. The lattice parameters of the three uranium carbides were found to vary with the reaction time. The results for the products heated at 1500°C are given in Table 1. The lattice parameter of UC at 0.5 hr is slightly smaller

20) H. B. Evans and H. Hashitani, *Anal. Chem.*, **36**, 2032 (1964).

Table 1. The variation of the lattice parameters of uranium carbides and dioxide with the reaction time in the product heated at 1500°C

Time	UC	U_2C_3	UC_2		UO_2
			a_0	c_0	
(hr)	(Å)	(Å)	(Å)	(Å)	(Å)
0.5	4.9598	8.0900	3.5198	5.996	5.4715
1	4.9604	8.0897	3.5238	5.998	—
2	4.9606	8.0895	—	—	—
7	4.9604	8.0888	—	—	—

than that at 1 hr or longer heating times, which is the same as that of stoichiometric UC with a small quantity of oxygen[12]. The value at 0.5 hr at 1450°C was 4.9611 Å, and that for longer heating times was about 4.9605 Å. At 1600° and 1700°C, the UC lattice parameter took the nearly constant value 4.9605 Å. When oxygen is dissolved into UC, the lattice parameter has been shown to deviate from 4.9605 Å[21-24]. The change in the lattice parameter observed indicates that oxygen is dissolved in UC to form a $UC_{1-x}O_x$ phase. It is possible to determine the amount of dissolved oxygen from the change in lattice parameter. In the present work, the amount of oxygen dissolved in the UC phase does not seem to be very large. For example, the parameter 4.9611 Å for UC in the product heated at 1450°C for 0.5 hr corresponds to 2000 ppm of dissolved oxygen, according to Magnier et al.[21] By further heating, UC is converted into U_2C_3 by the reaction with UC_2. The oxygen dissolved would have been removed as CO.

The lattice parameter of U_2C_3 varied between 8.0900 and 8.0885 Å. The values at 7 hr at 1450—1700°C were 8.0890±0.0003 Å.

The lattice parameter of UC_2 varied considerably with the reaction temperature and time. The starting UC_2 phase disappeared within 2 hr in the products heated at temperatures higher than 1500°C. It was found that the lattice parameters varied with the reaction time in the same manner as that reported previously,[19] *viz.*, the parameters, a_0 and c_0, showed minimum values at about 0.5 hr. The change in the UC_2 lattice parameter with time indicates that oxygen is transferred into the carbide phase from MgO and/or UO_2 and then removed gradually.

Discussion

It was reported that the formation of uranium sesquicarbide is inhibited in the presence of dissolved oxygen[17,18]. However, the reaction of UC_2 with UO_2 was found to yield U_2C_3, even when the carbide phase coexisted with unreacted UO_2 and/or dissolved oxygen.[19] We found that partial decarburization of UC_2 with MgO produced U_2C_3 when magnesium oxide was used instead of uranium dioxide. The characteristic in this reaction is the formation of UO_2 as an intermediate. Figure 2 shows that the content of UO_2 in the product heated at 0.5 hr at 1500°C is 10 mol%, and that of UC_2 60 mol%. It is suggested that the reaction of UC_2 with MgO is predominant as compared with the other reactions and the formation of UO_2 by the reaction is complete within 0.5 hr, since the content of UO_2 is 12.5 mol% at a maximum. Uranium monocarbide was also formed as an intermediate dissolving a small amount of oxygen. From the results in Figs. 1 and 2, it is deduced that the reaction of UC_2 with MgO proceeds in three steps:

(1) MgO is consumed by UC_2 to form UO_2 : $UC_2 + 4MgO \rightarrow UO_2 + 2CO + 4Mg$, and UC_2 dissolves oxygen;

(2) U_2C_3 is produced by the reaction of UC_2 with UO_2 formed: $7UC_2 + UO_2 \rightarrow 4U_2C_3 + 2CO$, and at the same time UC is also formed by the paralled reaction: $3UC_2 + UO_2 \rightarrow 4UC + 2CO$; and

(3) UC_2 with dissolved oxygen reacts with UC : $U(C,O) + U(C_2,O) \rightarrow U_2C_3 + CO$.

Figures 1 and 2 show that step (1) terminates within 0.5 hr, step (2) takes place at reaction times between 0.5 and 2 hr or a little longer, and step (3) after 2 hr. The main reaction sequence is given by

$$1/4UC_2 + MgO = 1/4UO_2 + 1/2CO + Mg$$
$$7/4UC_2 + 1/4UO_2 = U_2C_3 + 1/2CO$$

$$2UC_2 + MgO = U_2C_3 + CO + Mg$$

The formation of U_2C_3 should be examined from a thermochemical standpoint. For the various reactions of UC_2-MgO system accompanied by the release of CO and Mg, the following reactions are probable:

$$2UC_2 + MgO = U_2C_3 + CO + Mg \quad (1)$$
$$UC_2 + MgO = UC + CO + Mg \quad (2)$$

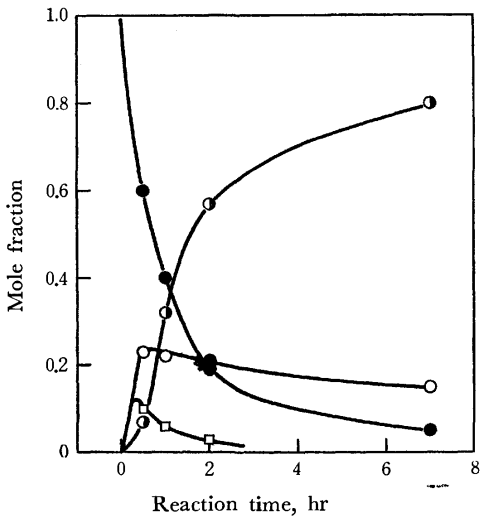

Fig. 2. Variation of mole fractions of UC_2, U_2C_3, UC, and UO_2 in the product at 1500°C with reaction time.
●: UC_2; ◑: U_2C_3; ○: UC; □: UO_2.

TABLE 2. STANDARD FREE ENERGIES OF FORMATION

Reaction	ΔG°(cal)	Validity Range (°K)	Reference
$U(l)+C(s)=UC(s)$	$-26160+0.4T$	1400—2100	25
$2U(l)+3C(s)=U_2C_3(s)$	$-48500-2.4T$	1400—2000	25
$U(l)+1.93C(s)=UC_{1.93}(s)$	$-21433-2.89T$	1400—2100	25
$U(l)+O_2(g)=UO_2(s)$	$-269700+97.0T-15.4T\log T$	1400—2000	26
$Mg(g)+1/2O_2(g)=MgO(s)$	$-181600+75.7T-7.37T\log T$	1380—2500	27
$C(s)+1/2O_2(g)=CO(g)$	$-26700-20.95T$	298—2500	27

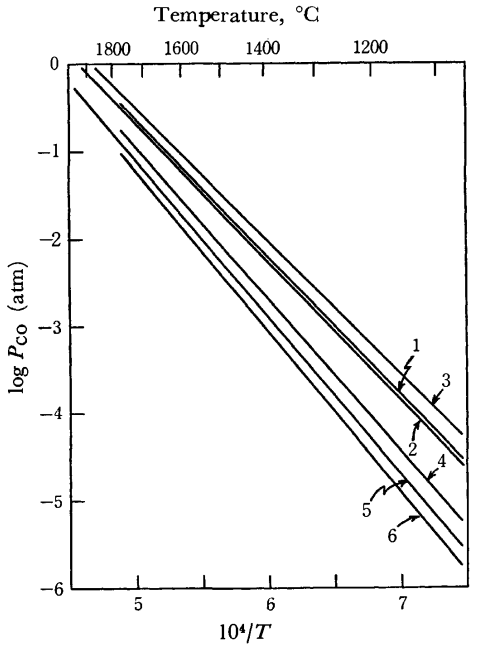

Fig. 3. Calculated equilibrium CO pressures in atm as a function of temperature.
1: $2UC_2+MgO=U_2C_3+CO+Mg$
2: $UC_2+MgO=UC+CO+Mg$
3: $UC_2+4MgO=UO_2+2CO+4Mg$
4: $7UC_2+UO_2=4U_2C_3+2CO$
5: $3UC_2+UO_2=4UC+2CO$
6: $3U_2C_3+UO_2=7UC+2CO$

$$UC_2 + 4MgO = UO_2 + 2CO + 4Mg \quad (3)$$

UO_2 is formed by the reaction of UC_2 and MgO. Consequently, it is necessary to consider the reactions of UC_2-UO_2 system:

$$7UC_2 + UO_2 = 4U_2C_3 + 2CO \quad (4)$$

$$3UC_2 + UO_2 = 4UC + 2CO \quad (5)$$

$$3U_2C_3 + UO_2 = 7UC + 2CO \quad (6)$$

The equilibrium CO pressures for the equations were calculated with use of the standard free energies of formation for UC,[25] U_2C_3,[25] UC_2,[25] UO_2,[26] MgO[27] and CO[27] listed in Table 2. The calculated values are given in Fig. 3. The figure shows that the CO pressure of reaction (3) is the highest at all temperatures. Thus, in the earlier stage of the reaction of UC_2 with MgO, the formation of uranium dioxide quite possibly takes place before that of uranium sesquicarbide. Once UO_2 is produced, U_2C_3 rather than UC is formed preferentially in the reaction of UC_2 with UO_2. The experimental results are in good agreement with those obtained by thermochemical calculation.

The author wishes to express his appreciation to Mr. K. Fujii for his help in the experiment, to Dr. H. Hashitani and Mr. T. Adachi for analyzing magnesium in the carbide samples and to Dr. Y. Sasaki for his continued support in this work.

Kinetic Studies of the Electron-Transfer Reaction in Iron(II) and Iron(III) Systems. V. The Reaction in Mixed Solvents of Methanol and Water[1)]

Goro WADA and Akiko ENDO

Department of Chemistry, Nara Women's University, Nara

(Received August 9, 1971)

The electron-transfer reaction between Fe(II) and Fe(III) species in mixed solvents of methanol and water was investigated by the use of Fe-59 as the radioactive tracer. The hydrolysis constant of Fe^{3+}, K_H, in the mixed solvent decreases gradually as the mole faction of methanol, x_M, increases. At very high acidities, ionic association between Fe^{3+} and ClO_4^- ions occurs, thus forming an ion-pair in the mixed solvent. The apparent rate constant, k_{app}, of the electron-transfer reaction is a function with respect to x_M; k_{app} does not vary much in the concentration range $x_M \leqq 0.3$, but it decreases as x_M grows higher than 0.3. k_{app} is also dependent upon $[H^+]$ and in a linear relationship with $[H^+]^{-1}$. Thus, the two reaction paths, Fe^{2+}-Fe^{3+} (k_0) and Fe^{2+}-$FeOH^{2+}$ (k_H), are deduced to be prevailing. Both rate constants, k_0 and k_H, decrease with an increase in x_M. The constancy of k_{app} at $0 \leqq x_M \leqq 0.3$ is a result of compensation between the increasing K_H value and the decreasing k_0 and k_H values. By taking into account the values of $\Delta H_H^{\neq} = 7.6$ kcal/mol and $\Delta S_H^{\neq} = -19.1$ e.u. at $x_M = 0.2$, both of which do not differ greatly from those in pure water, the reaction is concluded to proceed through the hydrogen-atom-transfer mechanism in the mixed solvent, the inhibiting effect of methanol being due to the reduction of the hydrogen bondings between water molecules.

The electron-transfer reaction between the hydrated species of iron(II) and iron(III) in aqueous media, $Fe^{2+}{}_{aq} + {}^*Fe^{3+}{}_{aq} \rightarrow Fe^{3+}{}_{aq} + {}^*Fe^{2+}{}_{aq}$, was early deduced by several authors[2-4)] to proceed *via* the hydrogen-atom-transfer mechanism. This mechanism was supported by the finding that the rate of the reaction decreased upon the addition of some substances in the reaction systems, such substances as nitromethane,[5)] 2-propanol,[6)] and other alcohols.[7)] These added substances were supposed to act as breakers of chains of the hydrogen bondings between water molecules, through which the hydrogen-atom-transfer would have occurred. When dimethyl sulfoxide[1)] is added to the reaction system, it is strongly associated with water molecules and, hence, lowers the water activity to a considerable extent, thus, suppressing the reaction rate. On the other hand, both mono- and dimethyl acetamides[8)] rather accelerate the reaction, in which cases their partial coordination to iron(III) ion enables the reaction to proceed faster than in the absence of the acetamides without altering the reaction mechanism.

In the present investigation, a quantitative determination of the reaction rate was performed in the mixed solvents of methanol and water in order to find out how the molecules of methanol participate in the electron-transfer process both as solvent and as ligand, and how they affect the reaction mechanism through hydrogen-atom-transfer.

Experimental

Commercial methanol of a guaranteed reagent grade was distilled and used. The preparation of the other chemical materials used and the procedure of the kinetic measurements have been described previously.[9,10)] The temperature and the ionic strength of the reaction systems were kept at 25°C and $\mu = 0.5$ M respectively, unless otherwise noted.

Determination of the Hydrolysis Constant, K_H, of Fe^{3+} in Methanol-water Mixed Solvents. The hydrolysis constant, $K_H = [FeOH^{2+}][H^+]/[Fe^{3+}]$, in mixed solvents of methanol and water at various mole fractions of methanol, x_M, was determined at a total concentration of iron(III) of 2×10^{-4} M and at a concentration of perchloric acid of 10^{-3}—10^{-2} M by spectrophotometry at wavelengths of 330, 340, and 350 nm. A Hitachi-Perkin-Elmer UV-VIS spectrophotometer, Model 139, with a thermostated cell compartment was used for the optical density determination. In this compartment was used for the optical density determination. In this connection, the optical densities of the solutions of iron(III) at high acidities up to 4 M were determined in order to show the probable occurrence of ionic association between the iron(III) ion and the perchlorate ion with an increase in the mole fraction of methanol, that is, with a decrease in the dielectric constant of the medium.

Since the values of pK for the second-step hydrolysis of the iron(III) ion in aqueous solutions, $FeOH^{2+} \rightleftarrows Fe(OH)_2^+ + H^+$, were found to be as small as 4.70[11)] and 4.59[12)] at 25°C, the contribution of the presence of $Fe(OH)_2^+$ in the reaction system could be ignored, the pK value in the mixed solvents not being determined.

Results and Discussion

Hydrolysis Constant of the Fe^{3+} Ion, K_H, in Mixed Solvents. Considering the balance relations:

$$A = \varepsilon_0[Fe^{2+}] + \varepsilon_H[FeOH^{2+}] \quad (1)$$

$$[HClO_4] = [H^+] - [FeOH^{2+}] \quad (2)$$

$$[Fe(III)] = [Fe^{3+}] + [FeOH^{2+}] \quad (3)$$

an equation is established as follows:

$$\frac{1}{A_H} = \frac{1}{\varepsilon_H[Fe(III)]} + \frac{[H^+]}{\varepsilon_H K_H[Fe(III)]} \quad (4)$$

in which [Fe(III)] and [$HClO_4$] are the total concentrations of iron(III) and perchloric acid, and ε_0 and ε_H, the molar extinction coefficients of Fe^{3+}_{aq} and $FeOH^{2+}$, respectively. A stands for the observed optical density of an aqueous solution containing iron(III) perchlorate, perchloric acid, and methanol, and A_H, for the calculated optical density of a solution simply containing $FeOH^{2+}$, which is equal to $\varepsilon_H[FeOH^{2+}]$. Eq. (4) suggests a linear relationship between A_H^{-1} and [H^+]. Since A_H and [H^+] are not known at first, A and [$HClO_4$] are respectively used instead as a first approximation; they give a rough straight line. The intercept and slope of the approximate straight line give a rough value of K_H, which also gives an approximate value of [$FeOH^{2+}$]. By using this value, more precise A_H and [H^+] values are obtained. By repeating the procedure of this successive approximation, the final relation between A_H^{-1} and [H^+] is reached. A typical relation is plotted in Fig. 1. The values of K_H at various mole fractions of methanol, x_M, at μ=0.5 M and 25°C observed at the wavelengths of 330, 340, and 350 nm are listed in Table 1; the table indicates a clear trend for K_H to increase monotonously as x_M increases because of the lowering of the dielectric constant of the mixed solvent.[13] The observed values of K_H are almost reasonably compared with those appearing in the literature, 1.59×10^{-3} M at x_M=0[14] and 1.70×10^{-2} M at x_M=0.52.[15]

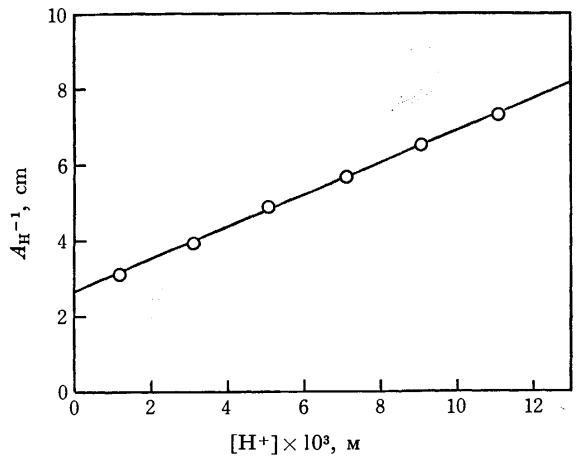

Fig. 1. Linear relation of A_H^{-1} with respect to [H^+] at 330 nm, μ=0.50 M, and 25°C.
[Fe(III)]=2×10^{-4} M, x_M=0.20.

TABLE 1. HYDROLYSIS CONSTANTS K_H AND DIELECTRIC CONSTANTS AT VARIOUS MOLE FRACTIONS OF METHANOL x_M AT μ=0.50 M AND 25°C

x_M	$K_H \times 10^3$ M	Dielectric constant
0	2.2	82.6
0.04	2.4	80.0
0.08	3.0	76.4
0.12	3.3	73.1
0.20	6.2	67.6
0.25	8.7	64.1
0.31	9.4	59.9

The dependence of K_H upon the temperature is shown in Table 2, at x_M=0.20. By plotting log K_H against T^{-1}, the enthalpy of the hydrolysis of Fe^{3+}_{aq} is obtained as ΔH_H=11.6 kcal/mol at x_M=0.20, which, for reference, is compared to a value of 13.7 kcal/mol for the enthalpy associated with the ionization process of the water molecule in the liquid state, $H_2O \rightarrow H^+ + OH^-$.

Ionic Association Between Fe^{3+} and ClO_4^- Ions. The determination of K_H values was carried out at concentrations of perchloric acid of 10^{-3}–10^{-2} M. As the acid concentration is raised within this concentration range, the apparent molar extinction coefficient of the iron(III) solution at 330 nm, ε (which is equal to A/[Fe(III)]), decreases because ε_0 is smaller than ε_H. However, when the acid concentration is raised higher than 10^{-2} M up to as high as 4 M, ε begins rather to increase through a broad minimum in the mixed solvents of methanol and water, although this is not the case in pure water, where the line is horizontal. The observations over the whole concentration range at various x_M's are depicted in Fig. 2. The higher the mole fraction of methanol, the steeper the slope of the curve in the concentrated acid media. The phenomena can reasonably be understood by the possible occurrence of the ionic association between Fe^{3+} and ClO_4^-,[16] as follows.

When an ion-pair between Fe^{3+} and ClO^{4-} is represented by $Fe{\cdot}ClO_4^{2+}$, the total optical density of the solution is expressed in the following form, the ionic association being taken into account:

$$A = \varepsilon[Fe(III)]$$
$$= \varepsilon_0[Fe^{3+}] + \varepsilon_H[FeOH^{2+}] + \varepsilon_a[Fe{\cdot}ClO_4^{2+}] \quad (5)$$

$$[Fe(III)] = [Fe^{3+}] + [FeOH^{2+}] + [Fe{\cdot}ClO_4^{2+}] \quad (6)$$

where ε_a is the molar extinction coefficient of the ion-pair.

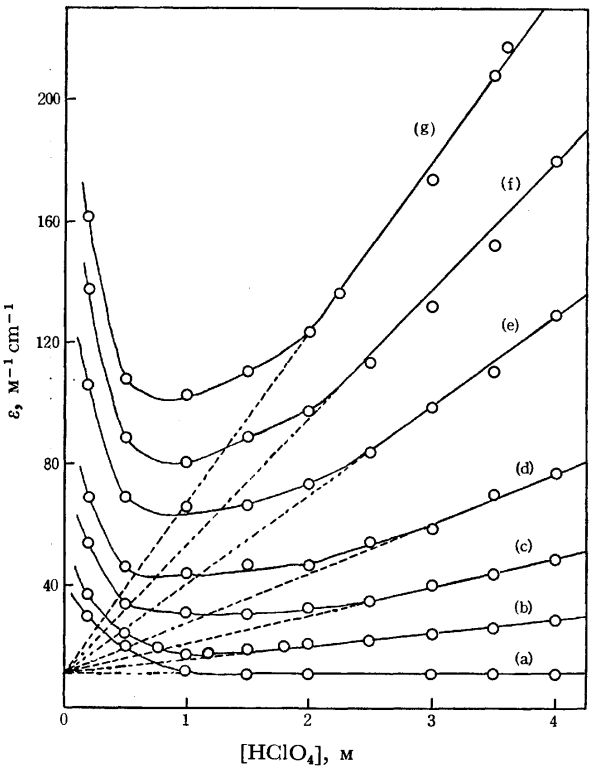

Fig. 2. Apparent molar extinction coefficient of Fe(III) in mixed solvents of methanol and water at 330 nm and 25°C. [Fe(III)]=2×10^{-3} M
a): x_M=0, b): x_M=0.04, c): x_M=0.08, d): x_M=0.12, e): x_M=0.20, f): x_M=0.25, g): x_M=0.31.

Since the formation constant of the ion-pair is defined as $K_a=[Fe\cdot ClO_4^{2+}]/[Fe^{3+}][ClO_4^-]$, ε is given as follows:

$$\varepsilon=\frac{\varepsilon_0+\varepsilon_H K_H/[H^+]+\varepsilon_a K_a[ClO_4^-]}{1+K_H/[H^+]+K_a[ClO_4^-]} \quad (7)$$

Considering that perchloric acid is a strong acid and that, therefore, it dissociates completely in aqueous media, $[H^+]$ is approximately equal to $[ClO_4^-]$ in the present circumstances. Therefore, Eq. (7) may be rewritten in this form:

$$\varepsilon=\frac{\varepsilon_0+\varepsilon_H K_H/[H^+]+\varepsilon_a K_a[H^+]}{1+K_H/[H^+]+K_a[H^+]} \quad (8)$$

When the acidity of the solution is very low as a limiting case, ε will be shown to involve a term in reciprocal proportion to $[H^+]$:

$$\varepsilon\approx\varepsilon_0+\varepsilon_H K_H/[H^+] \quad (9)$$

When the acidity of the solution is very high, as another limiting case, ε will vary under the control of a term proportional to $[H^+]$:

$$\varepsilon\approx\varepsilon_0+\varepsilon_a K_a[H^+] \quad (10)$$

At the intermediate of the two extreme cases, there must occur a minimum nearly at the acid concentration of $[H^+]=(\varepsilon_H K_H/\varepsilon_a K_a)^{1/2}$, actually occurring at $[H^+]\sim1$ M, which indicates that $\varepsilon_H K_H\sim\varepsilon_a K_a$ at each x_M.

Figure 2 also indicates that the slope of the line, $\varepsilon_a K_a$, grows larger as x_M becomes higher, although it is not known whether this is due to the increase in

Table 3. Apparent second-order rate constants at various mole fractions of methanol x_M at μ=0.50 M and 25°C

ε_a, to that in K_a, or to both. Another interesting indication is that all of the straight lines expressed by Eq. (10) converge on the same point on the axis, giving a common value of $\varepsilon_0=11\ \text{M}^{-1}\text{cm}^{-1}$ regardless of the concentration of methanol. Therefore, the Fe^{3+} ion might not be coordinated at all with methanol below $x_M=0.3$ at least, or might exhibit a constant value for ε_0, regardless of whether or not it is partially coordinated with methanol. At any rate, the value of K_a is not known at this time.

Rate of Electron-Transfer Reaction. Since the electron-transfer reaction between iron(II) and iron(III) has been recognized to be of the first order with respect to both [Fe(II)] and [Fe(III)],[1,7,8] the apparent second-order rate constant, k_{app}, can be calculated by the following equation:

$$k_{app}=\frac{0.693}{([Fe(II)]+[Fe(III)])t_{1/2}} \qquad (11)$$

The experimental results obtained at various mole fractions of methanol, mainly at $[HClO_4]=0.05$ and 0.20 M at $\mu=0.50$ M, and 25°C are shown in Table 3. A survey of k_{app} depending upon x_M is made in Fig. 3. k_{app} seems to be almost constant at $x_M<0.3$, over which point it begins to diminish abruptly. This trend can be noticed more clearly at a lower acid concentration.

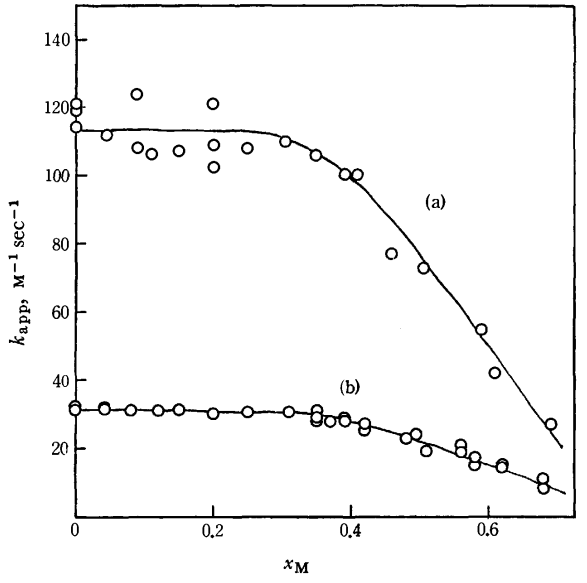

Fig. 3. Plot of k_{app} *vs.* x_M at $\mu=0.50$ M and 25°C.
a) $[H^+]=0.05$ M, b) $[H^+]=0.20$ M

The dependence of k_{app} upon the acidity of the solution at a constant mole fraction of methanol, at $x_M=0.2$ for instance, which belongs to the plateau portion in Fig. 3, was observed; it is shown in Fig.4. The plot of k_{app} *vs.* the reciprocal $[H^+]$ indicates that there may be a linear relationship between them, passing the vicinity of the origin of the coordinates.

Reaction Mechanism. When the facts revealed in Figs. 3 and 4 are taken into account, the following two paths of the electron-transfer reaction can most convincingly be considered to actually occur:

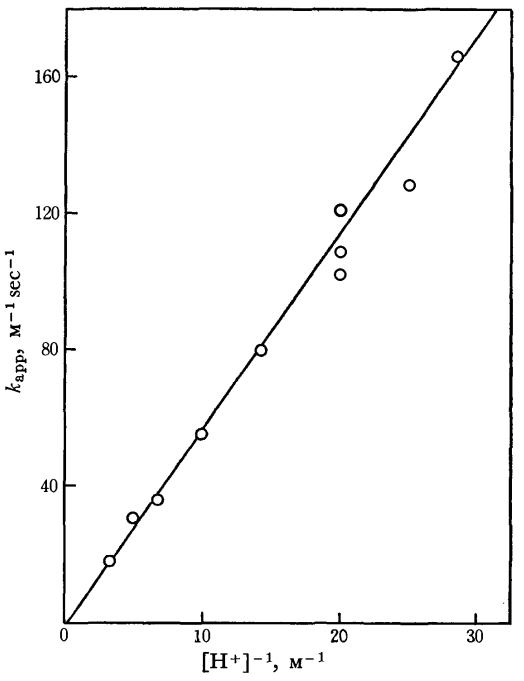

Fig. 4. Plot of k_{app} *vs.* $[H^+]^{-1}$ at $x_M=0.20$, $\mu=0.50$ M and 25°C.

$$Fe^{2+}+{}^*Fe^{3+}\rightarrow Fe^{3+}+{}^*Fe^{2+} \qquad (k_0) \qquad (12)$$

$$Fe^{2+}+{}^*FeOH^{2+}\rightarrow FeOH^{2+}+{}^*Fe^{2+} \qquad (k_H) \qquad (13)$$

By the usual means of calculation, the apparent rate constant, k_{app}, is given as follows, where k_0 and k_H are the rate constants for the (12) and (13) reaction paths respectively:

$$k_{app}=\frac{k_0+k_HK_H/[H^+]}{1+K_H/[H^+]} \qquad (14)$$

If the denominator on the right-hand side of Eq. (14) is regarded approximately as unity, k_{app} must show a linear trend, as has been seen in Fig. 4. When the denominator is precisely computed and multiplied by k_{app}, a more regular straight line than that in Fig. 4 is obtained between $k_{app}(1+K_H/[H^+])$ and $[H^+]^{-1}$, which is again reproduced in Fig. 5. The straight line in the figure passes near the point of origin, pointing out that k_0 is almost zero at $x_M=0.20$. By the use of the K_H values in Table 1, the k_0 and k_H values at different x_M's are similarly obtained from the intercepts and slopes of the respective straight lines; they are collected in Table 4.

The values of k_0 in Table 4 are very approximate, but it can be safely said that k_0 is almost zero at mole fractions of methanol over 0.2. The values of k_H in the table, on the other hand, more regularly decrease with an increase in x_M. The range of x_M values adopted in the table, $x_M=0-0.3$, corresponds to that exhibiting the plateau portion of the curve in Fig. 3.

It can be concluded, therefore, that although both k_0 and k_H decrease as x_M increases, k_{app} holds an approximate constancy, because the increase in K_H cancels the decrease in k_0 and k_H to make k_{app} almost unchanged, by chance. Table 4 also lists the prod-

ucts of k_H and K_H; they suggest the apparent constancy of k_{app} within the whole range of x_M values far observed.

Activation Parameters for Reaction. The values of k_H at x_M=0.20 were obtained at different temperatures in the same way as at 25°C; the correlation of log (k_H/T) against T^{-1} is drawn in Fig. 6, from which the activation enthalpy, $\Delta H_H^{\neq}$=7.6 kcal/mol, and the activation entropy, $\Delta S_H^{\neq}$=−19.1 e.u., are calculated. A comparison with the activation parameters in pure water is made in Table 5.

The activation enthalpy and entropy for the electron-transfer reaction between Fe^{2+} and $FeOH^{2+}$ do not greatly differ from each other in pure water and in methanol-water mixtures. This fact indicates that the hydrogen-atom-transfer mechanism[2-4] may still be active even in methanolic media. The effect of methanol on the rate of the reaction is the partial destruction and breaking of the hydrogen bondings in the chains between water molecules by substituting

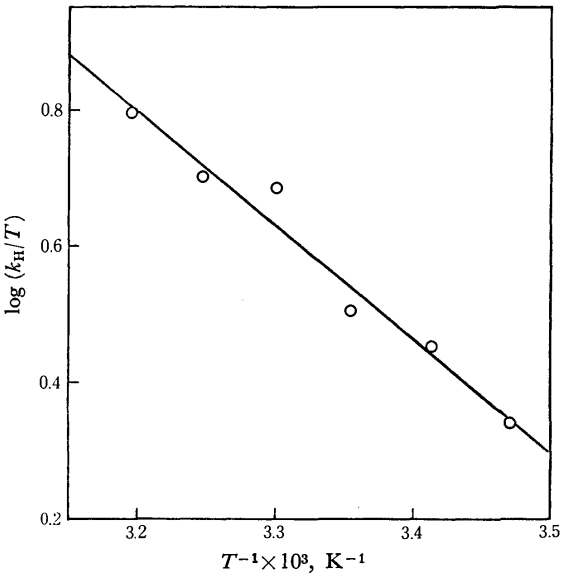

Fig. 6. Plot of log (k_H/T) *vs.* T^{-1} at x_M=0.2 and μ=0.50 M.

the methanol molecules for water in the bulk solvent.

In the case of a mixed solvent of DMSO and water,[1] the effect of DMSO is so great that it forms a molecular associate with water, thus lowering the activity of water. In the present case of methanol, its effect on the rate constant is not so markedly clear as to influence it explicitly, as a result of compensation for the growth of K_H.

According to the conductivity measurements,[19] Walden's ionic radius and the activation energy for the ionic migration for simple ions are nearly unchanged when the mole fraction of methanol is varied in methanol and water mixtures within the range of its mole fractions of 0—0.3. This suggests no possible occurrence of mixed solvation of methanol around the central ions in this mole fraction range. We have described above the constant molar extinction coefficient of the Fe^{3+} ion, ε_0=11 $M^{-1}cm^{-1}$, in the same mole fraction range of methanol. We attributed this either to the constancy of light absorption by the ions, regardless of the composition of their coordination sphere, or to the constancy of the composition sphere, or to the constancy of the composition of the coordination sphere itself, regardless of the surrounding medium. Now we can obviously decide that the latter is the case. In this concentration range, Fe^{3+}

may be preferentially solvated only with water molecules. The decrease in the rate of the electron-transfer reaction is, therefore, brought about, not by the reaction species themselves, but by the decrease in the ease of the hydrogen-atom-transfer along the chains of hydrogen bondings between the reacting species, by the insertion of methanol molecules in place of water ones, although the composition of the coordination sphere does not alter upon the addition of methanol.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1078—1080 (1972)

Preparation and Properties of *N,N*-Dialkylethylenediamine *N*-Oxide Complexes of Nickel(II), Copper(II), and Cobalt(III)

Sigeo KIDA and Takayuki ONIKI

*Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka**

(Received August 23, 1971)

The complexes of Ni(II), Cu(II), and Co(III) with *N,N*-Dialkylethylenediamine (alkyl=CH_3, C_2H_5, and C_3H_7) have been prepared. It was revealed that these ligands coordinate to metal ions as bidentate ligands with amino and tertiary amine oxide groups. Two forms have been obtained for the 1 : 2 nickel(II) complexes, the hydrated green form with $\mu_{eff}=3.3$ and the anhydrous red or reddish brown form with zero or very low magnetic moment. They are easily convertible into each other. Formation of square planar diamagnetic Ni(II) complexes with ionic-type ligand was interpreted in terms of the steric effect of the alkyl groups.

Only a few studies have been made on the metal complexes of tertiary amine oxide[1,2] compared with those of complexes of pyridine *N*-oxide and its derivatives.[3,4] It was reported that trimethylamine oxide forms tetrahedral complexes with cobalt(II), zinc(II), and cadmium(II) in alcoholic solution,[2] but octahedral or square planar complexes were not known.

We have attempted to prepare stable metal chelates involving a tertiary amine oxide as a coordinating group, using *N,N*-dialkylethylenediamine *N*-oxide as a neutral ligand. We succeeded in the preparation of new complexes of Cu(II), Ni(II), and Co(III) of tertiary amine oxide. It is to be noted that diamagnetic square planar nickel(II) complexes were readily obtained by using a ligand of the 2N2O-type which may be expected to form rather ionic bond with a metal ion.

Experimental

Preparation. N,N-*Dimethylethylenediamine* N-*Oxide (abbreviated as dimen-O)*: To 15 g of *N,N*-dimethylethylenediamine diluted with the same amount of water was added dropwise 220 m*l* of 3% hydrogen peroxide. After standing for 24 hours at room temperature, the solution was evaporated at 65°C under reduced pressure and a sirup of *N*-oxide was obtained. This was used for the preparation of complexes without further purification.

N,N-*Diethylethylenediamine* N-*Oxide (abbreviated as dieen-O)* and N,N-*Dipropylethylenediamine* N-*Oxide (abbreviated as dipen-O)*: The above two compounds were prepared by a method similar to that for dimen-O.

Bis-N,N-*(dimethylethylenediamine* N-*oxide)*nickel(II) *Perchlorate 1.5 hydrate (=[Ni(dimen-O)$_2$](ClO$_4$)$_2$·1.5H$_2$O)*: To a solution of 1.2 g of the ligand in 50 m*l* of 95% ethanol was added 2.0 g of nickel(II) perchlorate hexahydrate dissolved in 50 m*l* of 95% ethanol. Green crystals were immediately formed. They were collected on a glass filter and washed with ethanol.

Found: C, 19.61; H, 5.51; N, 11.52%. Calcd for [Ni(dimen-O$_2$)](ClO$_4$)$_2$·1.5H$_2$O: C, 19.49; H, 5.51; N, 11.36%. $\mu_{eff}=3.3$ B.M.

*Bis-(*N,N-*dimethylethylenediamine* N-*oxide)nickel(II) Perchlorate (=[Ni(dimen-O)$_2$](ClO$_4$)$_2$)*: The compound was prepared by recrystallization of the green hydrated form from ethanol as red crystals. It is also obtained by heating the hydrated complex over phosphoric anhydride at 80°C.

Found: C, 20.50; H, 5.24; N, 11.83. Calcd for [Ni(dimen-O)$_2$](ClO$_4$)$_2$: C, 20.62; H, 5.19; N, 12.02%. $\mu_{eff}=0.6$ B.M.

Bis-(N,N-diethylethylenediamine N-*oxide)nickel(II) Perchlorate (=[Ni(dieen-O)$_2$](ClO$_4$)$_2$*: To a solution of 1.5 g of the ligand in 40 m*l* of 99% ethanol was added 2.0 g of nickel(II) perchlorate hexahydrate dissolved in 40 m*l* of 99% ethanol. The resulting deep green solution was cooled in a refrigerator for 24 hr. Reddish brown crystals were formed. Recrystallization was carried out from ethanol.

Found: C, 27.50; H, 6.35; N, 10.51. Calcd for [Ni(dieen-O)$_2$](ClO$_4$)$_2$: C, 27.61; H, 6.18; N, 10.73%. Diamagnetic.

When the reddish brown crystals are kept in the humid atmosphere for one day, they gradually change into pale blue powder containing 2 mol of water for one nickel atom. This is readily reconverted into the reddish brown anhydride by heating at 100°C or keeping it in a desiccator over phosphoric anhydride.

Found: H_2O, 6.51. Calcd for [Ni(dieen-O)$_2$](ClO$_4$)$_2$·2H$_2$O: H_2O, 6.46%. $\mu_{eff}=3.3$ B.M.

*Bis-(*N,N-*di*-n-*propylethylenediamine* N-*oxide)nickel(II) Perchlorate (=[Ni(dipen-O)$_2$](ClO$_4$)$_2$)*: To a solution of 1.9 g of the *N*-oxide in 20 m*l* of 99% ethanol was added 1.5 g

* A part of the work was carried out in the Department of Chemistry, Wakayama University, Wakayama.

of nickel(II) perchlorate hexahydrate dissolved in 20 m*l* of 99% ethanol. Twenty m*l* of dioxane was added to this solution which was then cooled for 48 hr in a refrigerator. Reddish brown crystals were formed. Recrystallization was carried out from a mixed solvent of ethanol and dioxane.

Found: C, 33.20; H, 7.02; N, 9.65. Calcd for $[Ni(dipen\text{-}O)_2](ClO_4)_2$: C, 33.23; H, 6.92; N, 9.60%. diamagnetic.

The hydrated form of this compound was obtained as pale blue powder by the same procedure as for the ethyl homologue. However, the content of water was found to be much higher, *i.e.*, 6 mol of water for one nickel atom.

Found: H_2O, 15.15. Calcd for $[Ni(dipen\text{-}O)_2(ClO_4)_2\cdot 6H_2O$: H_2O, 15.74%. $\mu_{eff}=3.3$ B.M.

*Bis-(*N,N-*dimethylethylenediamine N-oxide)copper(II) Perchlorate (=[Cu(dimen-O)$_2$](ClO$_4$)$_2$*: The complex was prepared by the same method as that for $[Ni(dimen\text{-}O)_2](ClO_4)_2\cdot$ except for using copper(II) perchlorate $1.5H_2O$, instead of nickel(II) perchlorate.

Found: C, 20.58; H, 5.19; N, 11.91. Calcd for $[Cu(dimen\text{-}O)_2](ClO_4)_2$: C, 20.41; H, 5.14; N, 11.90%. $\mu_{eff}=1.74$ B.M.

*Bis-(*N,N-*diethylethylenediamine* N-*oxide)copper(II) Perchlorate (=[Cu(dieen-O)$_2$](ClO$_4$)$_2$*: The complex was prepared by a similar method to that for the above complex.

Found: C, 27.18; H, 5.94; N, 10.68. Calcd for $[Cu(dieen\text{-}O)_2](ClO_4)_2$: C, 27.36; H, 6.12; N, 10.63%. $\mu_{eff}=1.78$ B.M.

*Tris-(*N,N-*dimethylethylenediamine* N-*oxide)nickel(II) Perchlorate (=[Ni(dimen-O$_3$)](ClO$_4$)$_2$*: To a solution of 2.0 g of the ligand in 50 ml of 95% ethanol was added 2.0 g of nickel(II) perchlorate hexahydrate dissolved in 50 m*l* of 95% ethanol. Light blue crystals were formed. They were collected on a glass filter, washed with ethanol and dried *in vacuo* over phosphoric anhydride.

Found: C, 25.00; H, 6.13; N, 14.67. Calcd for $[Ni(dimen\text{-}O)_3](ClO_4)_2$: C, 25.28; H, 6.37; N, 14.74%. $\mu_{eff}=3.2$ B.M.

*Tris-(*N,N-*diethylethylenediamine* N-*oxide)nickel(II) Perchlorate (=[Ni(dieen-O)$_3$](ClO$_4$)$_2$*: Light blue crystals were obtained by a similar method to that for the above complex.

Found: C, 32.38; H, 7.55; N, 12.49. Calcd for $[Ni(dieen\text{-}O)_3](ClO_4)_2$: C, 33.05; H, 7.40; N, 12.84%. $\mu_{eff}=3.0$ B.M.

*Tris-(*N,N-*dimethylethylenediamine N-oxide)cobalt(III) Perchlorate (=[Co(dimen-O)$_3$](ClO$_4$)$_3$*: To an aqueous solution of 3.2 g of the N-oxide in 20 m*l* water were added 2.5 g of $[CoCl(NH_3)_5]Cl_2$ and 1 g of active carbon. The mixture was heated on a water-bath for 3 hr and filtered. To this filtrate were added 50 m*l* of acetone and 60 m*l* of ethanol saturated with sodium perchlorate. Deep blue violet crystals were immediately formed. Recrystallization was carried out from ethanol.

Found: C, 21.24; H, 5.46; N, 12.34. Calcd for $[Co(dimen\text{-}O)_3](ClO_4)_3$: C, 21.52; H, 5.42; N, 12.55%. diamagnetic.

Optical resolution of the complex was undertaken with the use of optically active trioxalato cobaltate(III) ion, but it was unsuccessful.

Reflectance Spectra. The powder reflectance spectra were measured with a Shimadzu Multipurpose Spectrophotometer Model MPS-50L.

Magnetic susceptibility. Magnetic susceptibilities were measured by Guy's method at room temperature.

Results and Discussion

Cobalt(III) Complexes. An aqueous solution of tris (N,N-dimethylethylenediamine N-oxied)cobalt(III) ion (abbreviated as $[Co(dimen\text{-}O)_3]^{3+}$) is fairly stable at room temperature, and gives an absorption spectrum similar in contour to those of *fac*-tris-(alaninato) cobalt(III) and of *fac*-tris-(β-alaninato)cobalt(III),[5] but the absorption peaks show a considerable red-shift (~1.7 kK) relative to those of the amino acid complexes as seen in Table 1. This seems to indicate that tertiary amine oxide is located at a lower position in the spectrochemical series than carboxylic acid.

Table 1. Absorption peaks of some Co(III) complexes of 3N-3O coordination in aqueous solution

	I kK(ε)	II kK(ε)
$Co(dimen\text{-}O)_3^{3+}$	17.62 (120)	24.93 (124)
fac-$Co(\beta\text{-ala})_3$	19.01 (141)	27.03 (61)
fac-$Co(ala)_3$	19.23 (186)	26.74 (160)
mer-$Co(\beta\text{-ala})_3$	17.55 (100) 20.49 (64)	27.03 (84)

Copper(II) Complexes. We see from Table 2 that the *d-d* bands of $[Cu(dimen\text{-}O)_2](ClO_4)_2$ and $[Cu(dieen\text{-}O)_2](ClO_4)_2$ (in solid state) are located in a much shorter wave-length region compared with those of the usual Cu-2N-2O type complexes such as $[Cugly_2]$. This is undoubtedly due to the steric effect of alkyl groups attached to nitrogen atoms, which may hinder the coordination to the axial position of the complex.[6]

Table 2. Peaks of reflectance spectra of some copper(II) complexes

complexes	ν_{max} (kK)

dieen=$(C_2H_5)_2NCH_2CH_2NH_2$

Nickel Complexes. The 1 : 3 complexes, $[Ni(dimen\text{-}O)_3](ClO_4)_2$ and $[Ni(dieen\text{-}O)_3](ClO_4)_2$, are undoubtedly hexacoordinated species, judging from their reflectance spectra (Table 3) and the bidentate nature of the ligands. Whereas, in the 1 : 2 complexes, however, there are two types, green hydrate ones and red or brown anhydrous ones. The former are readily converted into the latter when they are heated above 80°C or kept in a desiccator over phosphoric anhydride. The anhydrous complexes are

β-ala$=NH_2CH_2CH_2COO^-$, dipen$=(C_3H_7)_2NCH_2CH_2NH$

gradually hydrated in the atmosphere to form green complexes. Thus, the conversion of both forms is reversible. The reflectance spectra and the magnetic moments of the former clearly indicate that they are hexa-coordinated ones. Since the latter give the reflectance spectra which show one or two bands in the visible region and no absorption in the near infrared region (800 mμ~1200 mμ), it is evident that they are planar tetra-coordinated complexes. Formation of planar nickel(II) complexes with the ligands expected to form rather ionic bonds with a metal ion should be due to the steric effect of the alkyl groups of the ligand which may hinder coordinating groups from entering the fifth and sixth coordination positions of the tetragonal nickel(II) complex. Measurements of magnetic susceptibility showed that Ni $[dimen\text{-}O)_2](ClO_4)_2$ shows a feeble paramagnetism which could not be eliminated in spite of efforts to purify the complex. Repeated recrystallization and careful dehydration of the sample brought about no magnetic moment smaller than 0.6 B.M. (at room temperature). However, measurements of magnetic susceptibility over the temperature range (300°~77°K) showed that this complex obeys Curie's law.

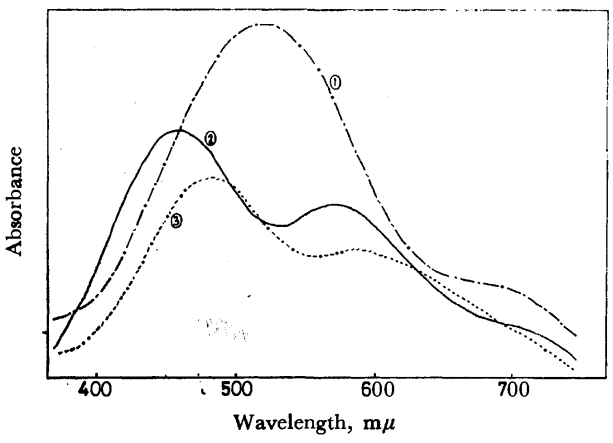

Fig. 1. Refrectance Spectra of ①—— $[Ni(dimen\text{-}O)_2](ClO_4)_2$, ②—— $[Ni(dieen\text{-}O)_2](ClO_4)_2$, and ③---- $[Ni(dipen\text{-}O)_2](ClO_4)_2$.

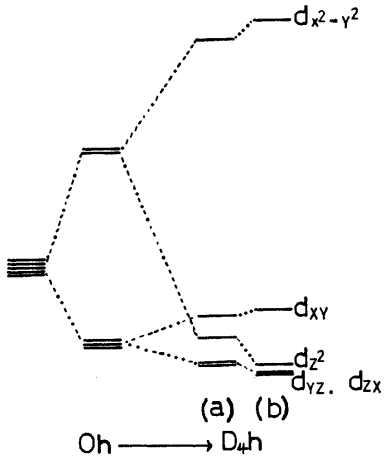

Fig. 2. Assumed energy level splittings of *d*-orbitals for (a) $[Ni(dimen\text{-}O)_2](ClO_4)_2$ and (b) $[Ni(dipen\text{-}O)_2](ClO_4)_2$.

Thus we can conclude that the small paramagnetism is due not to the thermal population of low-lying triplet state as might be anticipated from the energy-level diagram of Maki,[7] but to paramagnetic impurity, probably of the hydrated species. This is consistent with the fact that $[Ni(dimen\text{-}O)_2](ClO_4)_2$ is most easily hydrated among those planar complexes.

It is remarkable that the reflectance spectrum of $[Ni(dimen\text{-}O)_2](ClO_4)_2$ shows one broad band in the visible region, whereas $[Ni(dieen\text{-}O_2](ClO_4)_2$ and $[Ni(dipen\text{-}O)_2](ClO_4)_2$ show two bands in the visible region (Fig. 1). This is explainable in terms of the energy-level diagram[8] given in Fig. 2, granted that the methyl derivatives are less planar than the ethyl and propyl derivatives, i.e., perturbation along the tetragonal axis is somewhat larger in the methyl derivatives.

The authors wish to express their sincere thanks to Prof. Y. Muto, Saga University, for cryomagnetic measurements. They also thank Miss E. Yamagami for her help in the experiment.

Infrared Intensities of Crystalline HCN and DCN

Masakatsu UYEMURA and Shiro MAEDA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received September 3, 1971)

The absolute infrared intensities of crystalline HCN and DCN were measured at the temperature of liquid N_2. In comparison with the gaseous values, both stretching fundamentals (ν_1, ν_3) exhibited a striking increase in the integrated absorption, while the bending (ν_2) was almost unchanged. From the observed intensity change, the change in the dipole-moment derivatives with respect to the molecular internal coordinates was calculated to be $\partial \Delta \boldsymbol{M}/\partial r_{C\equiv N}=1.43$ D/Å and $\partial \Delta \boldsymbol{M}/\partial r_{C-H}=2.01$ D/Å, those values were chosen from two alternative possibilities as the more probable set. The significance of these values, however, is somewhat peculiar to the optically-active crystalline vibrations, so they were then resolved into derivatives with respect to purely intramolecular and intermolecular coordinates: $[\partial \Delta \boldsymbol{M}/\partial r_{C-H}]=0.58$ D/Å and $[\partial \Delta \boldsymbol{M}/\partial r_{H\cdots N}]=-1.43$ D/Å. The general intensity features were reasonably interpreted by considering the contribution of a charge-transfer structure to the H–N hydrogen bonding.

The study of the infrared intensity in condensed phases is supposed to be a potential source of information about the nature of interactions between molecules. It is quite common knowledge that the formation of a hydrogen bond, X–H···Y, gives rise to a striking increase in the integrated absorption of the X–H stretching vibration, as well as to a large frequency shift and a broadening of the band. This intensity behavior has thus far been qualitatively interpreted as being mainly due to the vibronic contribution of the charge-transfer effect.[1-3] In the present investigation, a somewhat detailed study of the intensity was attempted so as to obtain a closer understanding of the electronic features in the hydrogen-bonding interactions. Then, crystalline hydrogen cyanide was chosen as a particularly favorable system for an analytical study of the intensity change, because, besides its simple molecular structure, it forms strictly linear hydrogen-bonded chains, as has been shown by Dulmage and Lipscomb's X-ray data.[4]

Actually, the crystal has two modifications bounded at 170°K, that is, the high-temperature tetragonal phase described by the space group C_{4v}^{9}-*I4mm* and the low-temperature orthorhombic phase described by C_{2v}^{20}-*Imm*. In either phase, HCN (DCN) molecules are linked in a straight chain with a C–H···N distance of 3.18 Å, and such chains are assembled parallel with each other (Fig. 1). So far as the hydrogen bonding is concerned, the difference between these two phases seems to be of little significance; therefore the low-temperature phase crystal, which is experimentally more tractable, has been dealt with exclusively in the present work.

The infrared spectrum of crystalline (low-temperature-phase) HCN has been obtained by Hoffmann and Hornig,[5] and the Raman spectra of HCN and DCN crystals were investigated by Pézolet and Savoie[6]

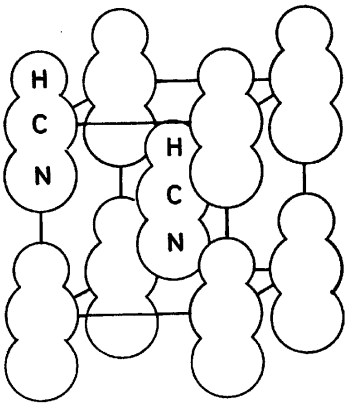

Fig. 1. Crystal structure of hydrogen cyanide (low temperature phase).

recently. In general these observations accord with the above crystal structure and indicate the formation of fairly strong hydrogen bonds. Pézolet and Savoie also observed high-frequency shoulders for each band in their spectra; they ascribed them to longitudinal vibrations, which will be discussed later in relation to the infrared intensities. Now, Hoffmann and Hornig[5] observed a remarkable change in the relative intensities from gaseous to crystalline HCN, and afterwards the absolute intensity was determined exactly for gaseous HCN and DCN by Hyde and Hornig.[7] In comparing the gaseous and crystalline relative intensities described above, it is noticeable that a striking change, certainly an intensification, has occurred not only in the usual C–H stretching vibration, ν_3, but also in the C≡N stretching, ν_1. A possible cause of the latter may be looked for in an increased mixing of the C–H stretching coordinate into the normal coordinate, Q_1, whose effect is further enhanced by the magnified value of the dipole-moment derivative, $\partial \mu/\partial r_{C-H}$. However, a brief consideration suggests that the $\partial \mu/\partial r_{CN}$ may also be influenced by the hydrogen bonding in the crystal. The intensity change in the acceptor-group vibration has been established for some carboxylic acid dimers by Wenograd and Spurr,[8] but

the change in hydrogen cyanide is far more conspicuous and may be adequate for the attainment of an unambiguous interpretation.

Experimental

HCN and DCN were obtained by adding aqueous H_2SO_4 or D_2SO_4 to potassium cyanide. The evolved gas was dried over calcium chloride and magnesium perchlorate, and was purified by repeated distillation within a vacuum line. The infrared spectra did not show any indication of impurities except for a minor amount of HCN mixed in the DCN sample, whose deuterium concentration was estimated at 85% from the intensity of the HCN bands.

The infrared spectra of the low-temperature-phase crystals were recorded on a Perkin-Elmer model 125 spectrophotometer. Thin solid films of the samples were obtained by spraying the gas onto a window cooled with liquid nitrogen in a conventional vacuum cell. The thickness of the deposited films was measured by monitoring the interference fringes at a fixed wavelength of one micron during the formation of films on a KRS-5 window.[9] The density at 77°K was calculated based on the X-ray data,[4] and the refractive index for the wavelength of one micron was obtained by extrapolating Anderson *et al.*'s[9a] dispersion data and by adjusting it for 77°K using Lorentz-Lorenz formula. The rate of film growth was about 3 to 4 microns per hour. The slit width was so chosen that it was always less than one-third of the half-width of the measured band.

The experimental quantity,

$$B' = \int_{\text{band}} \ln (T_0/T) \mathrm{d}\nu$$

where T/T_0 is the observed transmittance, was calculated by the use of Lagrange's polynomial of the third order fitted to four successive points among 13 to 20 experimental points. The integrations were carried out over such frequency ranges as cover more than 12 times the half-windth.

Results and Discussion

The Beer's law plots for the fundamental bands are illustrated in Figs. 2 and 3, where n is the concentration in mol/cm^3 and where l is the thickness in cm. The integrated absorption coefficient,

$$A = \int \alpha \mathrm{d}\nu$$

was obtained from the limiting slope of the curves, it is given in Table 1, and compared with the gaseous value by Hyde and Hornig.[7] If the Lorentz curve is assumed for the band shape, the errors caused by the finite slit width and the finite integration range are estimated to be about 3% and 6% at most,[10] but the composite error in the experiment may be roughly estimated at 20% at the maximum, considering other sources of error, such as in drawing the base-line and in the film-thickness determination. It may be seen that both stretching absorptions are intensified very much, whereas the bending intensity is almost unchanged, despite its considerable shift in frequency.

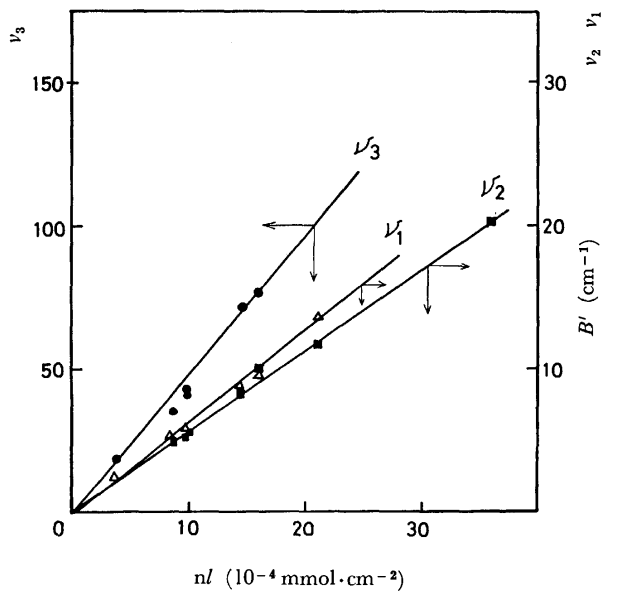

Fig. 2. The Beer's law plots of fundamental bands of crystalline HCN.

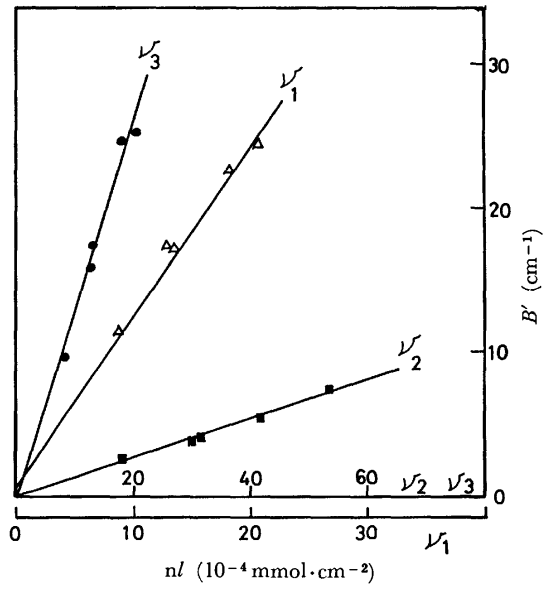

Fig. 3. The Beer's law plots of fundamental bands of crystalline DCN.

In Table 1 are also included the relative intensity values predicted by Pézolet and Savoie[6] based on their Raman observation, as well as those measured by Hoffmann and Horig.[5] The correspondence between the predicted values and the present observations is surprisingly good, supporting the conclusion of Pezolet and Savoie about the longitudinal and transverse frequencies.[11] The observed intensity, A, is related to the dipole-moment derivative by:

$$A_i = (N\pi/3c^2)\,|\partial \boldsymbol{M}/\partial q_i|^2, \qquad (1)$$

where $\boldsymbol{M}$ is the dipole moment of the crystal and where q_i is a molecular vibrational coordinate which partici-

pates in an optically-active ($k=0$) normal coordinate, Q_i, of the crystal. In the oriented gas model, q_i is equivalent to the corresponding molecular normal coordinate; this, however, may be unsatisfactory in the present system of strong interactions.

Since the unit cell contains only a single molecules,[4] Q_i is given by the normalized total sum of q_i:

$$Q_i = n\sum_j (q_i)_j, \tag{2}$$

where n is a normalization constants and where $\sum_j$ implies a summation over all the molecules in the crystal. q_i may be expressed in terms of molecular internal coordinates as:

$$q_i = \sum_k L_{ki}^{-1} r_k, \tag{3}$$

so that the dipole-moment derivative with respect to r_k is given by:

$$\frac{\partial M}{\partial r_i} = \sum_j L_{ji}^{-1}\frac{\partial M}{\partial q_j}. \tag{4}$$

Now, let us consider the quantity

$$\Delta M = M - \sum_i \mu_i. \tag{5}$$

which represents the contribution from the intermolecular interaction, where μ_i is the dipole-moment of an isolated molecule, i, and, $\sum_i \mu_i$ is equivalent to the M for the oriented gas model. Eq. (4) is also valid for ΔM; that is,

$$\frac{\partial \Delta M}{\partial r_i} = \sum_j L_{ji}^{-1}\frac{\partial \Delta M}{\partial q_j}, \tag{6}$$

(Bending vibration, ν_2)

As may be seen in Table 1, the gaseous and solid intensities of ν_2 coincide well within the limits of experimental error for both HCN and DCN. This may suggest that the charge distribution in a molecule was changed little as a result of hydrogen bonding. However, this mode of vibration necessarily involves a compensating rotation (or a libration in solids) of the molecule, so that the observed intensity includes the contribution from the accompanying rotation of the molecular dipole moment. It has been shown[12] from the gaseous data that the physically unambiguous

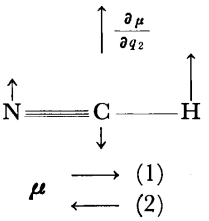

Fig. 4. Relative polarity of μ and $\partial\mu/\partial q_2$ in hydrogen cyanide.

quantity, P_R,[13] which is obtained by subtracting such a rotational contribution from the observed $\partial\mu/\partial q$, is in closer agreement between HCN and DCN, resulting in an average value of 1.08 D/rad, with the polarity shown in Fig. 4. As the molecular dipole moment in solids is not known (although it could be estimated from the intensity of a librational mode), the corresponding quantity in solids can not now be determined. The values tentatively given in Table 2 were calculated assuming that the dipole moment was equal to the gaseous value, 3.00 D.[14] At all events, such a close agreement between gaseous and solid data suggests no remarkable change in the dipole moment due to the hydrogen bonding in this case.

(Stretching vibrations ν_1 and ν_3)

If the stretching coordinates of the C≡N and C–H (C–D) bonds are expressed by r_1 and r_2, Eq. (4) for these parallel modes may be solved to give $\partial M/\partial r_1$ and $\partial M/\partial r_2$ from the observed $\partial M/\partial q$. The L^{-1} matrix was obtained on the basis of the force constants, which were chosen so as to minimize the standard deviation of the frequency for both HCN and DCN. For the sake of consistency, the L^{-1} was also calculated for

the gas by the same procedure, Hyde and Hornig[7] adopted a somewhat different criterion in determining their force constants. In Table 4 are given the force constants thus obtained. The dipole moment derivatives $\partial M/\partial r$'s, are summarized in Table 2 and there compared with the corresponding gaseous quantity, $\partial\mu/\partial r$, where the proper choice of a relative sign for $\partial M/\partial q_1$ and $\partial M/\partial q_3$ is definitely (++).

It is remarkable that $\partial M/\partial r_1$ and $\partial M/\partial r_2$ have the same direction of polarity in the solid, while they are opposite in the gas. There may be two possibilities in accounting for the additional contribution, $\partial \Delta M/\partial r$. According to the choice of opposite or equal signs for $\partial M/\partial r_1$ (solid) and $\partial\mu/\partial r_1$ (gas), either (i) or (ii) in Table 3 is obtained.

Now, if an additional coordinate, r_3, is introduced to give the N···H stretching, the condition:

$$r_1 + r_2 + r_3 = 0 \tag{7}$$

is always realized for the optically-active modes in the crystal. Therefore, the dipole-moment derivatives dealt with thus far, which conform with this condition, of course, may be given by the expressions:

$$\frac{\partial \Delta M}{\partial r_1} = \left[\frac{\partial \Delta M}{\partial r_1}\right] - \left[\frac{\partial \Delta M}{\partial r_3}\right]$$
$$\frac{\partial \Delta M}{\partial r_2} = \left[\frac{\partial \Delta M}{\partial r_2}\right] - \left[\frac{\partial \Delta M}{\partial r_3}\right] \tag{8}$$

where the bracketed derivatives imply that they have no connection with Eq. (7). In other words, the dipole-moment derivatives as given from Eq. (6) include inevitably a part which is properly attributable to a wholly intermolecular displacement, $[\partial \Delta M/\partial r_3]$.

As the C–N bonding electrons are supposed to be little involved in the hydrogen bonding, the $[\partial \Delta M/\partial r_1]$ in Eq. (8) may well be neglected in the following. Then, according to (i) or (ii) in Table 3,

$$\text{(i)} \qquad \text{(ii)}$$
$$-[\partial \Delta M/\partial r_3] \approx \partial \Delta M/\partial r_1 = 1.43 \text{ or } 0.63 \text{ D/Å}$$
$$[\partial \Delta M/\partial r_2] = \partial \Delta M/\partial r_2 + [\partial \Delta M/\partial r_3] \approx 0.58 \text{ or } 3.52 \text{ D/Å}$$

where the positive value of the derivatives indicates that the moment is increased in the direction of $\bar{N}\equiv C-\overset{+}{H}$ for the stretching of the bond.

As is commonly recognized, the hydrogen-bond formation may be described properly in terms of electrostatic and charge-transfer interactions. That is, an appropriate wave function for the C–H···N system may be:[15]

$$\Psi = c_1\psi_1 + c_2\psi_2 + c_3\psi_3 \tag{9}$$

where ψ_i represents these structures;

$$\begin{aligned} &\psi_1; \quad \mathrm{C{-}H \quad N} \quad \text{(I)} \\ &\psi_2; \quad \mathrm{C^-\ H^+ \quad N} \quad \text{(II)} \\ &\psi_3; \quad \mathrm{C^-\ H{-\!-\!-}N^+} \quad \text{(III)}. \end{aligned} \tag{10}$$

Although the contribution of ψ_2 may possibly be of greater importance in stabilizing the system, the vibrational change of the dipole moment is mainly ascribable to ψ_3. This is because not only does the structure III have a much greater inherent moment than II, but also the weight of III in the Ψ is expected from theoretical consideration to be more susceptible to the vibrational displacement than that of II. This latter point is supported by the results of Coulson and Danielsson's[15] semi-empirical calculation of the O–H··· O system. Therefore, the (i) set above corresponds to the case in which the approach of the H—N distance is far more effective in causing the charge transfer than the C–H stretching, and the (ii) set, *vice versa*.

Now, in order to obtain an approximate idea, the additional moment due to the contribution from the structure III may be given by:

$$\Delta M = c_3^2 Re, \tag{11}$$

15) C. A. Coulson and U. Danielsson, *Ark. Fys.*, **8**, 239, 245 (1954).

where the intrinsic moment of the structure III is roughly equalized to the C–H···N distance, R, multiplied by the electronic charge, e. Then,

$$[\partial \Delta \boldsymbol{M}/\partial r] = e(c_3^2 + 2c_3 R[\partial c_3/\partial r]), \quad (12)$$

where r may be either r_2 or r_3 and where the brackets imply the same as before. The size of c_3^2 has been estimated at a few per cent even in the O–H···O case, so ec_3^2 may be by far smaller than any possible $[\partial \Delta \boldsymbol{M}/\partial r]$ value given before. Therefore, the relationship:

$$\frac{[\partial \Delta \boldsymbol{M}/\partial r_2]}{[\partial \Delta \boldsymbol{M}/\partial r_3]} \simeq \frac{[\partial c_3/\partial r_2]}{[\partial c_3/\partial r_3]} \quad (13)$$

may be approximately valid in the present case.

The value of this ratio can not be estimated empirically. However, it can be shown that Coulson and Danielsson's findings on the O–H···O system[15] quated above give this ratio a negative value definitely less than unity in size. This fact suggests that the set (i) in Table 3 is preferable.

Finally, let us mention the polarity of the dipole-moment derivatives. Strictly speaking, the sign of those derivatives is significant only in a relative sense, as is obvious from Eq. (1). However, it is fairly conclusive from the above discussions that $[\partial \Delta \boldsymbol{M}/\partial r_3]$ has the polarity of $H^+\cdots N^-$ for $r_3>0$, and that then, $[\partial \Delta \boldsymbol{M}/\partial r_2]$ is the reverse. Therefore, the set (i) adopted above implies the following polarities of individual derivatives for $r_1, r_2>0$:

$$\partial \boldsymbol{M}/\partial r_1 \text{ (solid)} = 1.03 \quad (\cdots \dot{\overset{-}{N}}C\text{-}H\cdots)$$

$$\partial \boldsymbol{M}/\partial r_2 \text{ (solid)} = 3.08 \quad (\cdots N\overset{-}{C}\text{-}\dot{\overset{+}{H}}\cdots)$$

$$\partial \mu/\partial r_1 \text{ (gas)} = 0.40 \quad (N^+ \equiv C^-)$$

$$\partial \mu/\partial r_2 \text{ (gas)} = 1.07 \quad (C^- \text{-} H^+)$$

Critical Considerations

There may be some argument because the above interpretation ignored the possible influences on the intensities other than hydrogen bonding. In fact, there have been found several cases without hydrogen bonding which showed many-fold changes in intensity from a gas to a solid.[16] It may be noticed, however, that the absolute magnitude of such a change was generally much smaller than the present observations, althought it resulted in a remarkable change in ratio for the bands of a small intrinsic intensity. On the other hand, the field effect is of different category and may give some error in the numerical results, because Polo-Wilson's equation[17] employed in Table 1 may not be very satisfactory.[18]

It has been implicitly assumed so far that the sample films were composed of randomly-oriented polycrystals. There may be little doubt about the crystalline nature of the samples, because the observed spectra showed an excellent correspondence to the Raman spectra,[6] for which the samples were crystallized much more carefully. On the other hand, Hoffmann and Hornig observed an apparent change in the relative intensities of the splitted ν_2 components depending on the depositing condition; they attributed this change to the formations of oriented crystals.

In the present work, the features of the ν_2 bands were similar to those of the more scattering films of Hoffmann and Hornig which were looked on as less oriented, and were almost unchanged for various film thicknesses and different window materials. Accordingly, the orientation effect does not seem to be very significant even if it does occur. The close proximity of the gaseous and solid ν_2 intensities may possibly support the above inference.

Supposing the orientation effect to be considerable, the most probable case is one with molecular axes parallel to a window surface, because the parallel bands were observed to have a reasonably great intensity; also Hoffmann and Hornig observed only a single component of ν_2 in their more oriented films. When this is the case, the observed intensity, A, should be multiplied by 1.33 for ν_2 and by 0.67 for ν_1 and ν_3 before applying Eq. (1). Even in this case, however, the essential matter in the discussions so far may be little disturbed, because the stretching and bending vibrations were dealt with quite separately.

Stereochemical Studies of Metal Chelates. VII.[1] The Preparation, Stereochemistry, and Circular Dichloism of Dinitrocobalt(III) Complexes with (3*S*, 8*S*)-Dimethyltriethylenetetramine and Related Tetramines

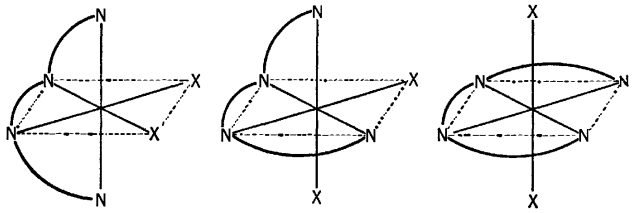
Masahiko SABURI, Tsutomu SAWAI, and Sadao YOSHIKAWA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received September 10, 1971)

Dinitrocobalt(III) complexes with (3*S*,8*S*)-dimethyltriethylenetetramine((3*S*,8*S*)-dimetrien) and related ligands were prepared and separated into the geometrical isomers. The *cis*-α and *cis*-β isomers of the (3*S*,8*S*)-dimetrien complex gave rise to the Λ and Δ isomers respectively. A similar stereospecificity could be observed for the other dissymmetric ligands employed in this study. The circular dichroism (CD) spectra of the *cis*-β isomers showed three kinds of patterns, which were related to the structural features of the complexes.

There are three topological ways for coordinating triethylenetetramine (trien) to a cobalt(III) ion, *cis*-α, *cis*-β, and *trans*, as is shown in Fig. 1. The actual stereochemistry of the trien complex is, however, more complicated because of the asymmetric feature of the secondary amino groups coordinated. Taking into account this source of asymmetry, the possible isomers of the trien complex are those shown in Fig. 2, where one of the enantiomeric pair is represented for each dissymmetric isomer. Only the *meso trans* isomer is intrinsically optically-inactive. In Fig. 2, the absolute configurations of the coordinated secondary amino groups and those of the central metal ion are denoted by *R* or *S*,[2] and by Λ or Δ,[3] respectively.



cis-α *cis*-β *trans*

Fig. 1. Topological isomers of trien complex. *cis*-α, *cis*-β, and *trans*.

Although only one enantiomeric pair is probable for the *cis*-α isomer (Λ-α(*RR*) and Δ-α(*SS*)), two kinds of diastereoisomers can be expected for the *cis*-β and *trans* isomers, because of the difference in the combination of the absolute configurations of the coordinated secondary N atoms. These configurations are the same for one of the β isomers (Λ-β(*SS*) and Δ-β(*RR*)) and the dissymmetric *trans* isomer (*trans*(*SS*) and (*RR*)), whereas they are antimeric for the other β isomer (Δ-β(*RS*) and Λ-β(*SR*)) and the *meso trans* form.

The conformations of the three chelate rings are closely related to the stereochemistry of the trien complex. The conformation of each chelate ring is represented by δ or λ,[5] as is shown in Fig. 2. The conformations of both of the outer chelate rings are the same in the *cis*-α form, as has been proved in a recent X-ray diffraction study.[6] On the other hand, they are antimeric in the usual *cis*-β isomers,[7–9] where

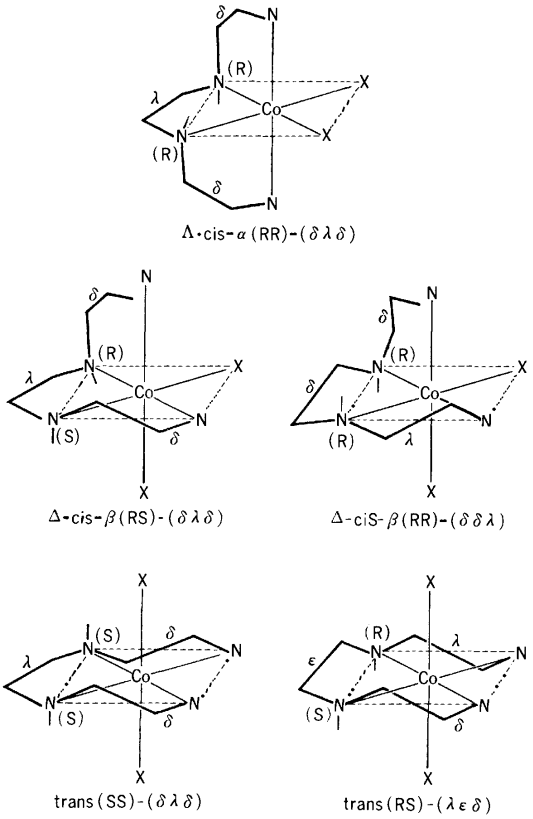


Fig. 2. Probable isomers of octahedral trien complexes. Λ-*cis*-α(*RR*)($\delta\lambda\delta$), Λ-*cis*-β(*RS*)($\delta\lambda\delta$), Δ-*cis*-β(*RS*)($\delta\lambda\delta$), *trans*-(*SS*)($\delta\lambda\delta$), *meso-trans*(*RS*)($\delta\varepsilon\lambda$).

1) Part VI. M. Saburi and S. Yoshikawa, This Bulletin, **45**, 806 (1972).

2) The asymmetric configuration is described as *R* or *S* according to the sequence rule of R. S. Cahn, C. K. Ingold, and V. Prelog, *Angew. Chem. Intern. Ed. Emgl.*, **5**, 385 (1966).

3) The absolute configuration about a central metal ion is described as Λ or Δ according to the tentative rule of *Inorg. Chem.*, **9**, 1 (1970).

4) The order of two kinds of sec-N atoms in the *cis*-β isomers follows the order proposed by D. A. Buckingham, P. A. Marzilli, and A. M. Sargeson, *Inorg. Chem.*, **6**, 1032 (1967).

5) The conformation of diamine chelate ring is represented as δ or λ. See ref. (3).

6) M. Dwyer and I. E. Maxwell, *Inorg. Chem.*, **9**, 1459 (1970).

7) H. C. Freeman and I. E. Maxwell, *ibid.*, **8**, 1293 (1969).

8) H. C. Freeman and I. E. Maxwell, *ibid.*, **9**, 649 (1970).

9) H. C. Freeman, L. G. Marzilli, and I. E. Maxwell, *ibid.*, **9**, 2408 (1970).

the coordinated asymmetric secondary N atoms of trien take the same configurations (see *Λ-cis-β(SS)* in Fig. 2).

However, a detailed examination of the Dreiding stereomodels shows[10] that these chelate rings probably take the same conformations in the *Λ-β(RS)* and its enantiomer. It appears, therefore, that the *cis-β* isomer of such a steric form (*Λ-β(RS)* and/or *Λ-β(SR)*) can be obtained by the use of trien analogues modified in such a way that the outer-side chelate rings are restricted to the same conformation by some steric effect(s) of the substituents.

For (3*S*,8*S*)-dimethyltriethylenetetramine ((3*S*,8*S*)-dimetrien) and (2*S*,9*S*)-dimethyltriethylenetetramine ((2*S*,9*S*)-dimetrien), the absolute configurations of the asymmetric carbon centers of both side arms have the same *S* configuration. The structures and abbreviations for these tetramines, along with the other ligands employed in the present study, are summarized in Table 1. Both the side chelate rings are fixed in the same (*δ*) conformation for these ligands, ((3*S*,8*S*)- and (2*S*,9*S*)-dimetrien); therefore, diacidocobalt(III) complexes with these tetramines give rise to the *Λ-cis-β(RS)* isomer (in which both the outer chelate rings have the *δ* conformation).

Recently, the *Λ-cis-β* isomers of dichlorocobalt(III) complexes with (3*S*,8*S*)-[1] and (2*S*,9*S*)-dimetrien[11] were isolated. The structures of these isomers could be determined to be the *Λ-cis-β(RS)* form on the basis of their circular dichroism (CD) spectra. It was shown that the CD curve of the *Λ-β(RS)* forms are different from those of the *Λ-β(RR)* forms (or *Λ-β(SS)*) in the case of dichloro complexes.

It is interesting to investigate the difference(s) in the CD spectra between the *Λ-β(RR)* and *Λ-β(RS)* forms (or their antipodes) for cobalt(III) complexes other than the dichloro complex. In order to examine this problem, we prepared and separated the isomers of dinitrocobalt(III) complexes coordinated with (3*S*,8*S*)-dimetrien, (2*S*,9*S*)-dimetrien, and related trien derivatives. The CD spectra of these complexes will be measured and discussed in the present paper.

Table 1. Abbreviation and structure of ligands

Experimental

(3S,8S)-Dimethyltriethylenetetramine Tetrahydrochloride (3S,8S)-dimetrien·4HCl). The method of preparing this ligang has been described previously.[1]

Λ-cis-*α-Dinitro ((3S,8S)-dimethyltriethylenetetramine)cobalt-(III) Perchlorate(Λ*-cis-*α-[Co((3S,8S)-dimetrien)(NO$_2$)$_2$]ClO$_4$).* To a solution of (3*S*,8*S*)-dimetrien·4HCl (2.55 g) and LiOH·H$_2$O (0.94 g) in 30 m*l* of water, CoCl$_2$·6H$_2$O (1.80 g) and NaNO$_2$ (1.10 g) were added successively; then the solution was aerated with carbon dioxide-free air for 10 hr at room temperature. The resultant solution was gradually evaporated on a water bath at 50°C until the volume was reduced to about 10 m*l*; it was then filtered, and 20 m*l* of ethanol were added. The white precipitates were removed quickly, 10 more m*l* of ethanol were added, and the mixture was kept in an ice bath for 1 hr. After the white precipitates has been removed once more, the filtrate was allowed to stand in an ice bath for 3 hr. The yellow precipitates which thus separated were filtered off and washed with a small volume of ethanol. The filtrate and washings were united and cooled in a refrigerator overnight. A further crop of yellow precipitates was then collected and washed with ethanol. The filtrate and washings were stored in order to separate the *cis-β* isomer.

The crude, hygroscopic yellow precipitates were dissolved in a small volume of warm water and then filtered. The pure perchlorate salt could be obtained by adding excess solid LiClO$_4$·3H$_2$O to the filtrate. It was recrystallized from warm water. Found: C, 22.65; H, 5.23; N, 19.62%. Calcd for [Co(C$_8$H$_{22}$N$_4$)(NO$_2$)$_2$]ClO$_4$: C, 22.62; H, 5.22; N, 19.79%.

Λ-cis-*β-Dinitro((3S,8S)-dimethyltriethylenetetramine)cobalt(III) Perchlorate (Λ*-cis-*β-[Co((3S,8S)-dimetrien)(NO$_2$)$_2$]ClO$_4$).* To the combined filtrate and washings from the separation of the *Λ-cis-α* isomer, we added an excess amount of solid LiClO$_4$·3H$_2$O; the yellow-brown crystals which thus separated were collected and washed with ethanol and ether. The product thus obtained was contaminated with the *Λ-cis-α* isomer, and so it was fractionally recrystallized from a warm aqueous solution. After removing the less soluble *Λ-cis-α* isomer, the *Λ-cis-β* isomer could be obtained as yellowish-brown crystals. It was recrystallized from warm water. Found: C, 22.86; H, 5.23; N, 19.31%. Calcd for [Co(C$_8$H$_{22}$N$_4$)(NO$_2$)$_2$]ClO$_4$: C, 22.62, H, 5.22; N, 19.79%.

(2S,9S)-Dimethyltriethylenetetramine Tetrahydrochloride (2S,-9S)-dimetrien·4HCl). This ligand was prepared by the method of Asperger and Liu.[11]

Λ-cis-*α-Dinitro((2S,9S)-dimethyltriethylenetetramine)cobalt(III) Chloride (Λ*-cis-*α-[Co((2S,9S)-dimetrien)(NO$_2$)$_2$]Cl).* The method of preparing this complex has been previosuly described.[1]

Λ-cis-*β-Dinitro((2S,9S)-dimethyltriethylenetetramine)cobalt(III) Perchlorate (Λ*-cis-*β-[Co((2S,9S)-dimetrien)(NO$_2$)$_2$ClO$_4$).* To a solution of *Λ-β*[Co(2*S*,9*S*)-dimetrien)CO$_3$]$^+$ prepared *in situ.* as has been described previously[1] (1.5×10^{-3} mol

10) M. Goto, M. Saburi, and S. Yoshikawa, *ibid.*, **8**, 358 (1969).
11) R. G. Asperger and C. F. Liu, *ibid.*, **4**, 1395 (1965).

scale), we added 5 N $HClO_4$ to pH 1, and then the solution was warmed at 80°C for 2 min. 5 N $HClO_4$ was further added in order to adjust the pH of the solution to 1, after which solid $NaNO_2$ (0.8 g) was added and dissolved. After the mixture had stood at room temperature for 15 min, an excess of solid $LiClO_4 \cdot 3H_2O$ was added to the brown solution. The yellow-brown crystals which separated out immediately were collected after standing 1 hr in an ice bath and washed with a small volume of cold water, ethanol, and ether. The product was slightly contaminated with the *Δ-cis-α*-isomer, and so it was fractionally recrystallized from a warm aqueous solution. The fractions showing a negative Cotton effect in the first absorption band region (~450 mμ) were combined and recrystallized repeatedly from warm water until they showed a constant CD curve. Found: C, 22.55; H, 5.38; N, 19.37%. Calcd for $[Co(C_8H_{22}N_4)(NO_2)_2]ClO_4$: C, 22.62; H, 5.22; N, 19.79%.

(R)-(−)$_D$- and (S)-(+)$_D$-*Propylenediamine.* These substances were obtained by resolving commercially-available racemic propylenediamine according to the method of Dwyer *et al.*[12]

N,N'-*Bis(carbobenzoxy*-(S)-*alanyl)*-(R)-*propylenediamine.* 17.8 g (0.075 mol) of carbobenzoxy-(*S*)-alanine hydrazide, obtained by a usual method,[13] was dissolved in a mixture of acetic acid (90 m*l*), 5 N HCl (38 m*l*), and water (375 m*l*). The solution was cooled to below −5°C in an ice-salt bath, and then a cold aqueous solution of $NaNO_2$ (5.5 g, 0.08 mol) was added in one portion. The carbobenzoxy-(*S*)-alanyl azide thus formed was extracted with 500 m*l* of cold ether. The ether layer was separated, washed with water (100 m*l*) a 3% sodium bicarbonate solution (100 m*l*), and water (100 m*l*) successively, and then dried briefly over anhydrous sodium sulfate. Sodium sulfate was removed and to the ether solution we added 2.22 g (0.03 mol) of (*R*)-(−)$_D$-propylenediamine; the mixture was subsequently stirred for 24 hr in an ice bath and then for 12 hr at room temperature. The resultant white precipitates were filtered off and washed with ether. For elemental analysis, small portion of the product was recrystallized from hot ethanol. mp 199.4—200.0°C (corr.). Found: C, 61.14; H, 6.25; N, 12.19%. Calcd for $C_{25}H_{32}N_4O_6$: C, 61.97; H, 6.66; N, 11.56%.

N,N'-*Bis(*(S)-*alanyl)*-(R)-*propylenediamine Diacetate.* 4.85 g (0.01 mol) of *N,N'*-bis(carbobenzoxy-(*S*)-alanyl)-(*R*)-propylenediamine was hydrogenated for 4 hr in 100 ml of methanol containing 1.5 g of acetic acid and 1 g of paradium black, using a Parr low-pressure apparatus. After the removal of the catalyst, the solution was concentrated to dryness under reduced pressure, giving white prceipitates of *N,N'*-bis((*S*)-alanyl)-(*R*)-propylenediamine diacetate. For the subsequent reaction, the product was used without further purification.

(2S,5R,9S)-*Trimethyltriethylenetetramine Tetrahydrochloride* ((5R)-*Me$_3$trien·4HCl*). 9.48 g (0.282 mol) of *N,N'*-bis((*S*)-alanyl)-(*R*)-propylenediamine diacetate was added to a suspension of 7.6 g of lithium aluminum hydride in 200 m*l* of anhydrous tetrahydrofuran. The mixture was stirred and heated under reflux for 24 hr. After the mixture had then been cooled to room temperature, 14.4 m*l* of water diluted with 50 m*l* of tetrahydrofuran was added, drop by drop; the resultant slurry was filtered off and washed with a small volume of tetrahydrofuran. The residue was extracted with boiling tetrahydrofuran (200 m*l*) under reflux (2 hr) and then filtered again. After repeating the extraction once more, the combined filterates and extracts were concentrated under reduced pressure, leaving an oily residue. This residue was dissolved in ethanol (100 m*l*), and exess dry HCl gas was bubbled through, yielding white precipitates. These were filtered off and recrystallized from 5 N HCl and ethanol. Found: C, 31.98; H, 8.41; N, 16.38%. Calcd for $C_9H_{24}N_4 \cdot 4HCl$: C, 32.35; H, 8.45; N, 16.77%.

Δ-cis-*α*-*Dinitro* ((2S,5R,9S)-*trimethyltriethylenetetramine) cobalt-(III) Chloride* (*Δ*-cis-*α*-[*Co*((5R)-*Me$_3$trien*)(NO_2)$_2$]*Cl*). To a solution of 1.02 g of (5*R*)-Me$_3$ trien·4HCl and 0.36 g of $LiOH \cdot H_2O$ in 25 m*l* of water $CoCl_2 \cdot 6H_2O$ (0.64 g) and $NaNO_2$ (0.42 g) were added and dissolved successively; the resultant solution was aerated for 6 hr at room temperature. The yellow precipitates which were thus separated were collected and washed with cold water and ethanol. A second crop could be obtained by concentrating the filtrate on a water bath (50°). The crude products were recrystallized from water and ethanol. Found: C, 29.03; H, 6.33; N, 22.14%. Calcd for $[Co(C_9H_{24}N_4)(NO_2)_2]Cl$: C, 28.85; H, 6.46; N, 22.43%.

Δ-cis-*β*-*Dinitro* ((2S,5R,9S)-*trimethyltriethylenetetramine)cobalt-(III) Perchlorate* (*Δ*-cis-*β*-[*Co*((5R)-*Me$_3$trien*)(NO_2)$_2$]*ClO$_4$*). To the filtrate from the isolation of the *Δ-cis-α* isomer as above, a large excess of solid $LiClO_4 \cdot 3H_2O$ was added. After the mixture had stood overnight, yellow-brown precipitates were collected, washed with water and ethanol, and dried *in vacuo*. They were then recrystallized from warm water. Found: C, 23.31; H, 5.80; N, 18.01%. Calcd for $[Co(C_9H_{24}N_4)(NO_2)_2]ClO_4 \cdot H_2O$: C, 23.67; H. 5.74; N, 18.40%.

N,N'-*Bis(carbobenzoxy*-(S)-*alanyl)*-(S)-*propylenediamine.* This compound was prepared by a procedure similar to that used for *N,N'*-bis(carbobenzoxy-(*S*)-alanyl)-(*R*)-propylenediamine, but using (*S*)-(+)$_D$-propylenediamine instead of (*R*)-(−)$_D$-propylenediamine. For the elemental analysis, a small portion of the product was recrystallized from ethanol. mp 233.5—234.5°C (corr.). Found: C, 61.92; H, 6.76; N, 12.14%. Calcd for $C_{25}H_{32}N_4O_6$: C, 61.97; H, 6.66; N, 11.56%.

N,N'-*Bis(*(S)-*alanyl)*-(S)-*propylenediamine Diacetate.* *N,N'*-Bis(carbobenzoxy-(*S*)-anlayl)-(*S*)-propylenediamine was hydrogenated in the same way as the corresponding (*R*)-propylenediamine derivative. The product was used in the following reaction without further purification.

(2S,5S,9S)-*Trimethyltriethylenetetramine* ((5S)-*Me$_3$trien*). *N,N'*-Bis((*S*)-alanyl)-(*S*)-propylenediamine diacetate (10.1 g, 0.03 mol) was treated with lithium aluminum hydride (9.1 g) in anhydrous tetrahydrofuran (200 m*l*) in a manner similar to that used in preparing (5*R*)-Me$_3$trien. The oily residue thus obtained was dried over KOH pellets and distilled under reduced pressure. bp 108—109°C (2 mmHg). Since the hydrochloride of this tetramine was hygroscopic, it was converted to the picrate salt for analysis. Found: C, 35.00; H, 3.73; N, 19.45%. Calcd for $C_9H_{24}N_4 \cdot 4C_6H_3N_3O_7 \cdot 2H_2O$: C, 34.75; H, 3.53; N, 19.65%.

Δ-cis-*β*-*Dinitro*((2S,5S,9S)-*trimethyltriethylenetetramine)cobalt-(III) Iodide Monohydrate* (*Δ*-cis-*β*-[*Co*((5S)-*Me$_3$trien*)(NO_2)$_2$]-*I·H$_2$O*). To a solution of (5*S*)-Me$_3$trien (0.565 g) in 20 m*l* of water containing 3 m*l* of 1 N HCl, we added $CoCl_2 \cdot 6H_2O$ (0.714 g) and $NaNO_2$ (0.435 g); the resultant solution was aerated with carbon dioxide-free air for 10 hr at room temperature. The solution was concentrated on a water bath to about 5 m*l*, and then 10 m*l* of ethanol were added. The white precipitates which thus separated (NaCl) were removed by filtration, and more ethanol was added. After removing the white precipitates if necessary, 5.64 g

of $LiI \cdot 3H_2O$ were added. When the mixture was left standing at room temperature, slightly hygroscopic yellow precipitates began to separate; they were collected and recrystallized from methanol and ethanol. A further crop was obtained from the filtrate by adding ethanol and isopropanol. Found: C, 22.41; H, 5.35; N, 16.78%. Calcd for $[Co(C_9H_{24}N_4)(NO_2)_2]I \cdot H_2O$: C, 22.33; H, 5.41; N, 17.36%.

Measurements. The visible absorption spectra were measured with a Shimadzu MPS-50L spectrophotometer. The circular dichroism spectra were measured with a JASCO J-10 automatic spectropolarimeter.

Results and Discussion

The dinitrocobalt(III) complexes coordinated with (3*S*,8*S*)-dimetrien, (2*S*,9*S*)-dimetrien, and other tetramines were prepared by the usual air-oxidation procedures. The isomers were separated by fractional crystallization. In a previous study,[1] the stereospecificity incorporated with the (3*S*,8*S*)- and (2*S*,9*S*)-dimetrien was clarified for the dichlorocobalt(III) complexes; it was revealed that only the *Λ* and *Δ* isomers could be isolated for the *cis*-*α* and *cis*-*β* isomers respectively. Thus, in the case of dinitro complexes, the *cis*-*α* and *cis*-*β* isomers with these tetramines would also take, stereospecifically, the *Λ* and *Δ* absolute configurations respectively. Hence, the structures of the fractionally-separated products were examined by measuring the CD and ORD curves.

The chloride salts of the dinitrocobalt(III) complexes of (3*S*,8*S*)-dimetrien were highly soluble in an aqueous solution. The first and second fractions obtained by adding ethanol showed ORD curves similar to that of the *Λ*-*cis*-*α*-$[Co(trien)(NO_2)_2]^+$ ion[14]

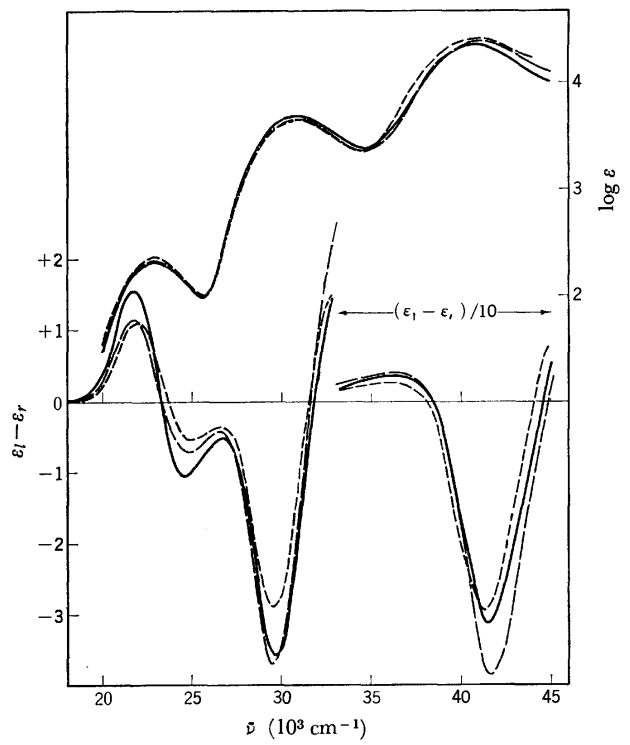

Fig. 3. Electronic absorption and CD spectra of the *Λ*-*cis*-*α* isomers. (3*S*,8*S*)-dimetrien (——), (2*S*,9*S*)-dimetrien (- - -) and 5(*R*)-Me_3trien (— — —).

and were regarded as consisting of the *Λ*-*cis*-*α* isomer of $[Co((3S,8S)\text{-dimetrien})(NO_2)_2]Cl$. However, these fractions were slightly hygroscopic and were considered to involve other isomer(s) as well. Thus, the chloride salt was converted into the perchlorate salt, the solubility of which was relatively low in water. The pure perchlorate salt of this isomer shows the absorption and CD spectra given in Fig. 3. The spectral data are summarized in Table 2.

On the basis of the similarity in the CD spectra between the present complex and the *Λ*-*cis*-*α* isomer of the trien complex,[14] the former was identified as

14) A. M. Sargeson and G. H. Searle, *Inorg. Chem.*, **4**, 45 (1965).

Λ-cis-α(RR)[15]-[Co((3*S*,8*S*)-dimetrien)$(NO_2)_2$]ClO_4. An X-ray analysis of this complex[16] revealed that the complex ion takes the *Λ-cis-α* structure illustrated in Fig. 4.

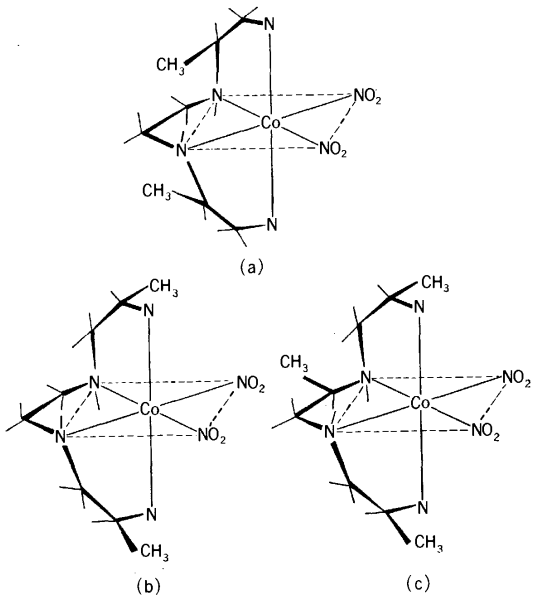

Fig. 4. Probable structures of the *Λ-cis-α* isomers. (a) (3*S*,8*S*)-dimetrien, (b) (2*S*,9*S*)-dimetrien, and (c) (5*R*)-Me_3trien.

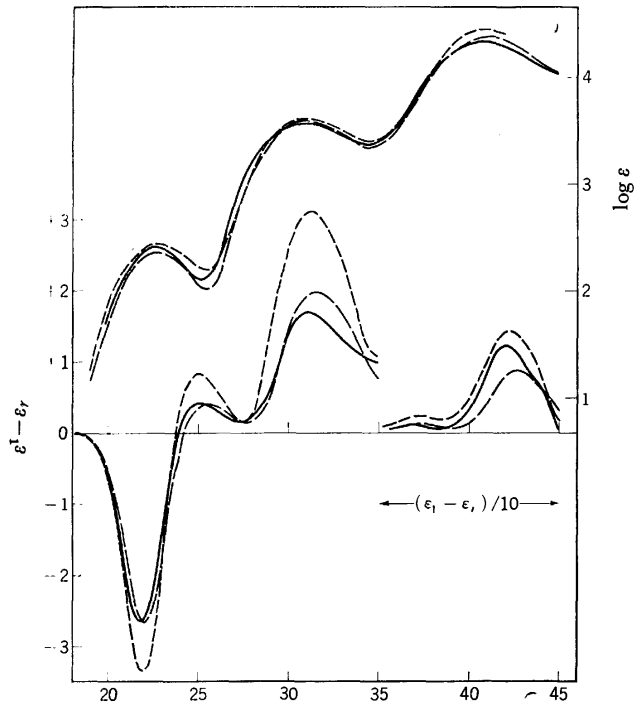

Fig. 5. Electronic absorption and CD spectra of the *Λ-cis-β(RS)* isomers. (3*S*,8*S*)-dimetrien (——), (2*S*,9*S*)-dimetrien (- - -) and (5*R*)-Me_3trien (— — —).

The second isomer of [Co((3*S*,8*S*)-dimetrien)$(NO_2)_2$]-ClO_4 could be obtained from the mother liquor by adding excess $LiClO_4$. The exact structure of the present isomer has been determined by a X-ray crystallographic study,[17] which showed that the complex ion takes the *Λ-cis-β(RS)* geometry, as is illustrated in Fig. 5. The electronic absorption and the CD spectra for this complex are shown in Fig. 6. A detailed comparison of the CD of the *Λ-β(RS)* geometry with that for the diastereoisomeric *β* geometry (*Λ-β-(SS)* and *Λ-β(RR)*) will be presented later.

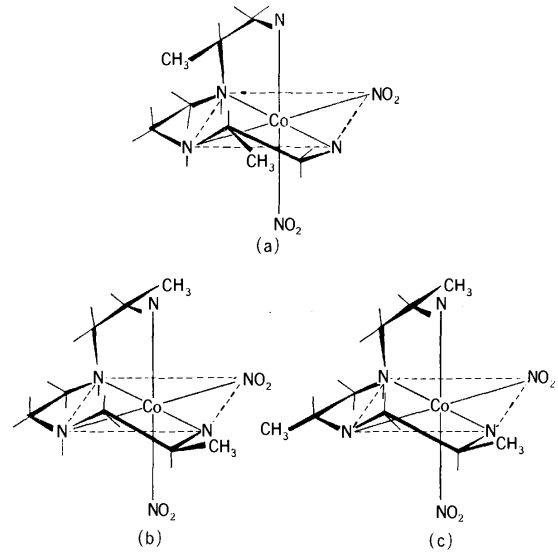

Fig. 6. Probable structures of the *Λ-cis-β(RS)* isomers; (a) (3*S*,8*S*)-dimetrien, (b) (2*S*,9*S*)-dimetrien, and (c) (5*R*)-Me_3trien.

The third isomer of [Co((3*S*,8*S*)-dimetrien)$(NO_2)_2$]-ClO_4, identified as the *trans* form, was eventually isolated from the filtrate of the separation of the *cis-β* isomer. However, the *trans* isomer can be prepared more easily by the reaction of the *trans*-[Co((3*S*,8*S*)-dimetrien)Cl_2]ClO_4 with $NaNO_2$ in hot methanol. The absorption and CD spectra of this isomer have been reported previously.[18]

The *Λ-cis-α* isomer of the dinitrocobalt(III) complex coordinated with (2*S*,9*S*)-dimetrien was readily obtained from an aerated solution as the chloride form because of its low solubility. The absorption and CD spectra of this complex are given in Fig. 3; they are similar to those of the corresponding (3*S*,8*S*)-dimetrien complex. This means that the present complex also has the *Λ-cis-α(RR)* geometry shown in Fig. 4, where the substituted methyl groups are situated in equatorial positions.

On the other hand, it was difficult to obtain the *Λ-cis-β* isomer of the (2*S*,9*S*)-dimetrien complex from the mother liquor of the *Λ-cis-α* isomer. Hence, the

15) The *RS* representation of the absolute configuration of the asymmetric secondary N atoms is complicated in substituted triens by the presence of methyl groups. For example, (3*S*,8*S*)-dimetrien and trien complexes have the opposite configurations in the *Λ-α* form; (*SS*) for the former and (*RR*) for the latter. In this paper the absolute configuration of the coordinated secondary N centers is represented by *R* and *S*, neglecting the substituted methyl groups.

Δ-β isomer was prepared by the reaction of $NaNO_2$ with *Δ-cis-β*-[Co((2*S*,9*S*)-dimetrien)$(H_2O)_2$]$^{3+}$ ion, which is prepared *in situ* through the carbonato complex. The carbonato complex, prepared *in situ* by the reaction of the *Δ-cis-α*-[Co((2*S*,9*S*)-dimetrien)Cl_2]$^+$ ion with excess Li_2CO_3, was found to show a dominant negative Cotton effect in the first absorption band region, suggesting that the resultant carbonato complex takes the *Δ* configuration predominantly.

The dinitro complex obtained above showed a negative CD band in the first absorption band region. The absorption and CD spectra of this complex are shown in Fig. 5. The CD spectrum markedly resembles that of the *Δ-cis-β*(*RS*) isomer of the (3*S*,8*S*)-dimetrien complex. Therefore, the *cis-β* siomer of the (2*S*,9*S*)-dimetrien complex can be said to adopt preferentially the *Δ-β*(*RS*) geometry, as is shown in Fig 6.

We supposed that a (2*S*,9*S*)-dimetrien analogue with a methyl group introduced into the central ethylenediamine linkage would give rise to the *Δ-cis-β*-(*RS*) isomer more preferentially than the original (2*S*,9*S*)-dimetrien. This was based on the observation[10] that trien derivatives with any equatorially-oriented substituent(s) at the central chelate ring yield, stereoselectively, *cis-β* isomers, though they have the *Δ-β*(*SS*) and/or *Δ-β*(*RR*) geometry. Therefore, it is necessary that the methyl group introduced into the (2*S*,9*S*)-dimetrien skeleton take the equatorial orientation with respect to the central diammine linkage. (2*S*,5*R*,9*S*)-Triemethyltriethylenetetramine ((5*R*)-Me_3trien) satisfies the above requirement. For this tetramine, the central chelate ring would be fixed in the *λ* conformation because of the steric effect of the methyl group, which has the *R* absolute configuration.

By the use of the (5*R*)-Me_3trien, the *Δ-cis-α* and *Δ-cis-β* isomers of dinitrocobalt(III) complex were isolated. The former was obtained as the chloride form by concentrating the aerated solution, while the latter was also obtained as the perchlorate salt by adding $LiClO_4$ to the mother liquor. The absorption and CD spectra of these complexes are shown in Figs. 3 and 5 respectively.

The CD spectra of the *Δ-cis-α* and *Δ-cis-β* isomers are clearly similar to those of the (3*S*,8*S*)- and (2*S*,9*S*)-dimetrien complexes, though the intensity of each CD band of the present cis-*β* isomer is slightly higher than those of the others. This means that the *cis-α* and *cis-β* isomers of the (5*R*)-Me_3trien complex have the *Δ-cis-α*(*RR*) and *Δ-cis-β*(*RS*) geometries respectively. The probable structures of these isomers are also shown in Figs. 4 and 6.

The steric effects incorporated with the equatorial methyl group introduced into the central diamine linkage were clearly observed for the (5*R*)-Me_3trien, since the *cis-β* isomer could be isolated from the mother liquor more readily than in the case of the (2*S*,9*S*)-dimetrien complex; morevoer, it was recognized that the yield of the *cis-β* isomer is larger than that of the *cis-α* isomer. However, the presence of the *cis-α* isomer suggests that the steric effect of the equatorial methyl group in the central chelate ring, which provides preferentially the *cis-β* isomer, is not so sufficient in the case of (5*R*)-Me_3trien as in the previous case.[10]

(2*S*,5*S*,9*S*)-Trimethyltriethylenetetramine ((5*S*)-Me_3-trien) is an epimer of (5*R*)-Me_3trien, and the asymmetric carbon atom at the central chelate ring has the *S* configuration. In this ligand the absolute configurations of all the asymmetric carbon centers are *S*; therefore, all three chelate rings should take the *δ* conformations if the methyl groups tend to take the equatorial orientations. However, it is impossible for complexes of trien derivatives to take a structure in which all three chelate rings have the same configuration at the same time, as is shown in Fig. 2.

It seems likely for the coordination of (5*S*)-Me_3-trien that one of the chelate rings takes the *λ* conformation and that the methyl group comes to lie in the axial orientation in this chelate with the *λ* conformation. Otherwise, a new very strained form may be brought about, in which at least one of the chelate rings no longer has the gauche conformation.

Only one isomer has been isolated for the dinitrocobalt(III) complex coordinated with (5*S*)-Me_3trien. The electronic absorption and CD spectrum of this complex are shown in Fig. 7. The CD curve is obviously different from that of the *Δ-cis-α* (or its enantiomer); it rather resembles those of the *Δ-cis-β*(*RS*) isomers. This suggests that the present complex has a *cis-β* geometry and the *Δ* absolute configuration.

The (5*S*)-Me_3trien complex may belong to either of two diastereoisomeric forms (*Δ-β*(*RR*) and *Δ-β*(*RS*)), though some deformations from the ordinary structures may be involved. The structure of this complex is difficult to identify in detail by only examining the

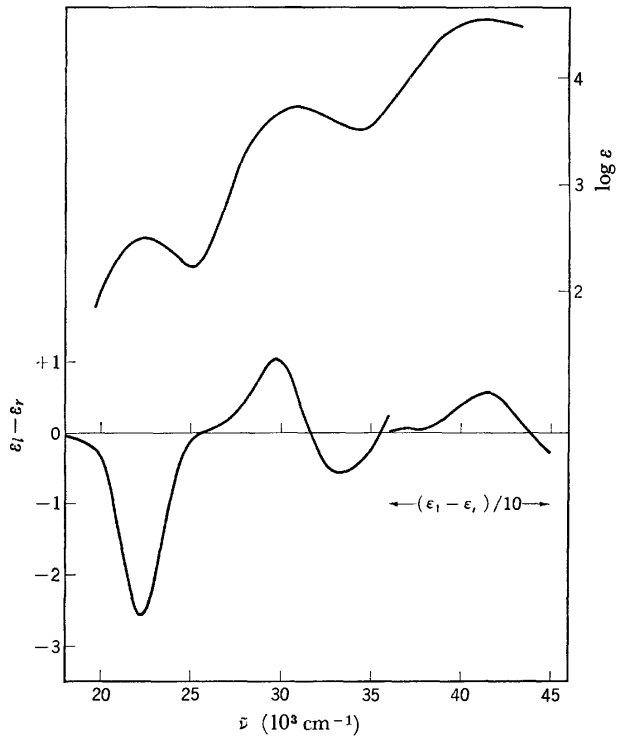

Fig. 7. Electronic absorption and CD spectra of the (5*S*)-Me_3trien complex.

CD spectrum, as will be described later. However, the influence of the difference in the absolute configuration of the methyl group introduced into the central diamine linkage was demonstrated in the different behavior between (5*R*)- and (5*S*)-Me_3trien as (2*S*,9*S*)-dimetrien analogues.

It has been indicated[19,20] that, in a *cis*-bis(diamine) complex, such as the *cis*-$Co(en)_2X_2^{n+}$ ion, with C_2 symmetry, the octahedral $A_{1g}\rightarrow T_{1g}$ transition breaks down into one component with A symmetry and two components with B symmetry. The three transitions have been distinguished, by means of their symmetry and trigonal (D_3) parentages, as $A(E_a)$, $B(E_a)$, and $B(A_2)$ transition.[19] The CD curve of the $(-)_D$-$[Co(en)_2(NO_2)_2]^+$ ion, which has the *Λ*-absolute configuration, shows a dominant positive band and a minor negative band at 21700 and 25000 cm^{-1} respectively. The former band was assigned to the $(A(E_a)+B(E_a))$ transitions, and the latter, to the $B(A_2)$ transition.[19]

The CD spectra of the *Λ-cis-α* isomers shown in Fig. 3 have a dominat positive band and a minor negative band at about 21800 and 25000 cm^{-1} respectively; they are markedly similar to those of $(-)_D$-*cis*-$[Co(en)_2(NO_2)_2]^+$ ion. Therefore, the CD bands at 21800 and 25000 cm^{-1} for the *Λ-cis-α* isomers can be assigned to the $(A(E_a)+B(E_a))$ transitions and the $B(A_2)$ transition respectively. This is reasonable, since both of the bis(en) and the α-trien complexes are related by a common two-fold rotation axis (C_2), as is shown in Fig. 8.

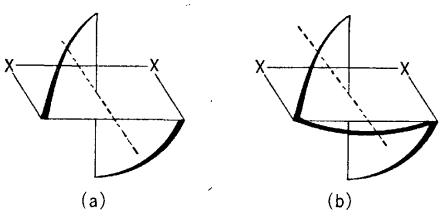

Fig. 8. The common two-fold rotation axis for *cis*-bis(en) and *cis*-α-trien complexes.

The CD spectra of the *Λ-cis-β(RS)* isomers show a dominant negative band and a minor positive band at about 22000 cm^{-1} and 25000 cm^{-1}, respectively. The positions of the band maxima of the major and the minor CD peaks correspond closely between the *Λ-cis-α* and *Λ-cis-β(RS)* isomers. This suggests that the *cis-β* isomer, which no longer has any symmetry elements, can be approximated by the same C_2 symmetry as the *cis-α* isomer. On this supposition, we assign the dominant negative band and the minor positive CD band of the *Λ-β(RS)* isomers to the $(A(E_a)+B(E_a))$ and the $B(A_2)$ transitions respectively.

The CD spectra of the *Λ-cis-β(SS)* isomers are given in Fig. 9. The exact structure of the dinitrocobalt(III) complex with (5*S*)-methyltriethylenetetramine ((5*S*)-metrien), which is enantiomeric to the (5*R*)-

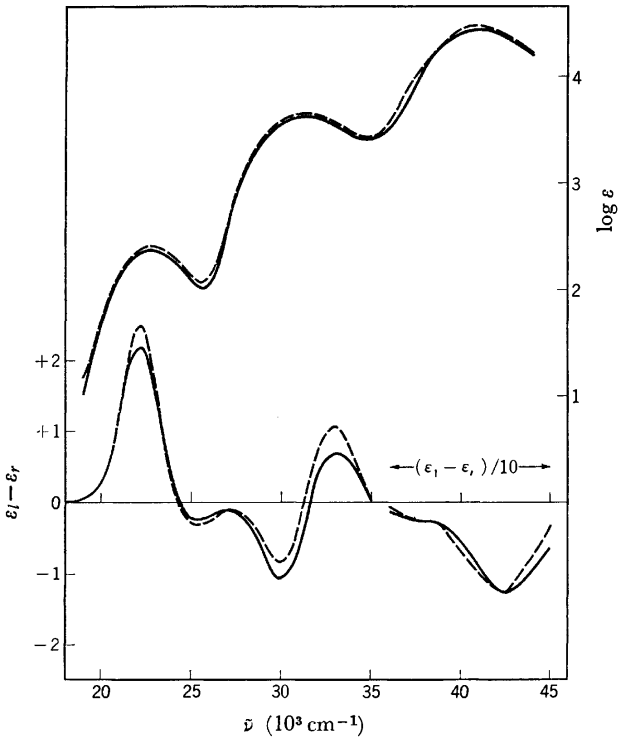

Fig. 9. Electronic absorption and CD spectra of the *Λ-cis-β(SS)* isomers. trien (——) and (5*R*)-metrien (- - -).

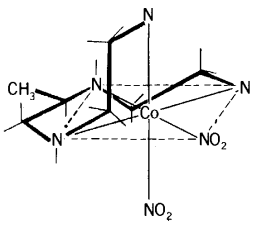

Fig. 10. Probable structure of the *Λ-cis-β(SS)*-[Co(5*R*)-metrien)$(NO_2)_2]^+$ ion.

metrien used in this study, has been determined by a recent X-ray analysis study,[21] which has revealed that the complex ion takes the *Λ-cis-β(RR)* geometry, as expected. Thus, the (5*R*)-metrien complex should have the *Λ-cis-β(SS)* configuration, which is illustrated in Fig. 10. The CD curves in Fig. 9 have a major positive band and a minor negative band at about 22100 cm^{-1} and 25300 cm^{-1} respectively. The patterns of the CD curve of the present isomers are rather similar to those of the *Λ-β(RS)* isomers. Therefore, the two CD bands can be assigned in the same way as for the *Λ-β(RS)* isomers. This is in contrast to the cases of the dichloro complexes, where a notable shift is observed between these geometries in the CD maxima in the first absorption band region.

However, there is a notable difference in the CD curves of the *Λ-β(RS)* and of the *Λ-β(SS)* isomers in the NO_2 specific absorption band region (26000—35000 cm^{-1}). The *Λ-β(SS)* isomers show two CD peaks with opposite signs in this region, a negative

band at the lower-wavenumer side (near 30000 cm^{-1}) and a positive band at the higher-wavenumber side (near 33000 cm^{-1}), whereas the *Δ-β(RS)* isomers show only one positive band, near 31000 cm^{-1}, in this region. Since the bands of nitro-cobalt(III) complexes in this region consist not only of the ligand field transition (T_{2g} in the O_h symmetry), but also of the charge transfer transitions (between Co^{3+} and NO_2^-), it was impossible to assign the CD band in this region. However, the observed difference in the CD curves must be attributed to the differences in the structures of the diastereoisomeric complexes, that is, to the configuration of the secondary N centers and the conformations of the three chelate rings.

The CD curve of the (5*S*)-Me_3trien complex shows two CD bands with opposite signs in the specific absorption band region, a positive band at about 30000 cm^{-1} and a negative band at about 33000 cm^{-1}. This appears to indicate that the (5*S*)-Me_3trien has the *Δ-cis-β(RR)* geometry. At present, this complex is considered to have the *Δ-cis-β-(RS)* geometry; this assignment is based on a study of trien derivatives with an axially-oriented methyl group in the central diamine linkage.[22] The new type of *Δ-cis-β(RS)* isomer, which shows two CD bands with opposite signs in the specific absorption band region, has a fairly distorted structure because of the axial methyl group. It is noticiable that the (5*S*)-Me_3trien complex and its homologs show only one CD band in the first absorption band region, as is indicated in Fig. 7.

Thus, it is revealed that the CD curves of *cis-β* dinitrocobalt(III) complexes with trien derivatives can be classified into the following series; (1) the *λ-β(SS)* and *Δ-β(RR)* isomers have two CD bands in the first absorption band region and two CD bands in the specific absorption band region; (2) the *Δ-β(RS)* isomers have two CD bands in the first absorption band region and one CD band in the specific absorption band region, and (3) the distorted *Δ-β(RS)* isomers have one CD band in the first absorption band region and two CD bands in the specific absorption band region. The detailed structure for the distorted *Δ-β(RS)* isomer will be discussed in a subsequent paper.[22]

Behavior of Alkali Metals in the Hydrogen Flame Ionization Detector for Ultra-Micro Analysis of Alkali and Alkaline Earth Metals

Masaaki YAMADA, Shigetaka SUZUKI, and Shun ARAKI

Department of Industrial Chemistry, Faculty of Engineering, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received September 13, 1971)

Behavior of alkali metals in the small hydrogen flame for ultra-micro analysis of alkali and alkaline earth metals were investigated. Distribution of free neutral atoms and formation of alkali hydroxides were studied by the photometric method, distribution of charged particles was determined by the Langmuir probe method, and confirmation of whether negative-charged particles are mostly electrons or negative ions by the sheath method. It was found that only lithium formed hydroxide in the flame, ionization chiefly occurred in the part 0—5 mm above the jet, and that most of negative-charged particles are not electrons but negative ions.

A new method for ultra-micro analysis of alkali and alkaline earth metals was developed by the authors,[1-3] a hydrogen flame ionization detector being used as a sensor. The detector, in which the electric current caused by ionization of the metal in flame is measured, has high sensitivity (*e.g.*, 10^{-14} mol in Rb and Cs).

Since the ionization method is based on the ionization of alkali and alkaline earth metals, it is important to investigate the behavior of the metals in flame. Physical investigations[4-10] have been carried out on ionization mechanisms or kinetics of alkali and alkaline earth metals in flame. Positive ion and electron concentrations were measured by the Langmuir probe method[4] and high-frequency method,[5-10] respectively. The former has been used for determining positive ion concentration in hydrocarbon flames.[11-14]

Most flames were pre-mixed flames whose temperature distributions were attained only in vertical direction, and were much larger (burner mouth several centimeters in diameter) than the diffusion flame used in this experiment. Metallic elements were added to the inner flame as fine sprays of dilute aqueous solution.

Behavior of alkali metals in a small diffusion flame were studied when alkali chlorides were added to the outer flame as vapor. Distribution of free neutral atoms and charged particles, and mobility of charged particles were determined by the flame photometric method, Langmuir probe method, and sheath method,[15] respectively. The results are discussed.

Experimental

The hydrogen flame ionization detector was the same type as that used previously.[3] The inner diameters of the evaporating and ionizing jets were 0.6 and 1 mm, respectively. The flow rates of hydrogen and oxygen for the ionizing flame (the upper flame) were 240 and 25 ml/min, respectively, and for the vaporating flame 120 and 85 ml/min, respectively. Alkali metals were continuously supplied to the ionizing flame by the evaporation of chlorides of alkali metals. A spiral of platinum wire (0.2 mm in diameter), coated with fused alkali chlorides, was placed near the evaporating flame. A small D.C. voltage was applied to both terminals of the wire and evaporation of these metals could be accurately controlled by regulation of electric current.

The temperature was measured at various points of the ionizing flame with a fine Pt-Pt/Rh 13% thermocouple 0.1 mm in diameter.

The flame photometric method was applied to determine the distribution of free neutral atoms in the flame. A diffraction grating was used as a monochrometer and a photomultiplier tube (Hamamatsu T.V. R213) as a sensor. The spectrum intensities of lithium and sodium resonance lines in emission were measured at several points through a pipe 2 mm in inner diameter.

Distribution of charged particles in the flame was determined by the Langmuir probe method. A fine probe (Pt/Rh 13% wire 0.1 mm in diameter, (1) in Fig. 1) was inserted into the flame and a potential was applied to the probe against the ionizing jet. When the potential was varied, the

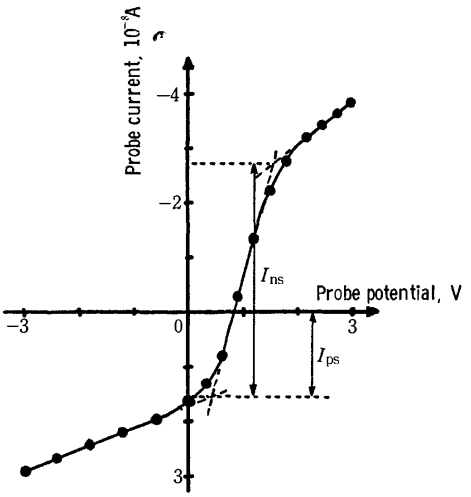

Fig. 2. Current-potential characteristic of Langmuir probe.

current-potential curve as shown in Fig. 2 was obtained. I_{ps} and I_{ns} are saturation currents due to only positive ions and only negative particles, respectively. The probe wire, together with its cooling tube, was mounted on the movable carriage of a cathetometer, the telescope being removed. The saturation current was measured at various points in each half of the flame. Measurements were carried out in a horizontal direction by inserting the probe in every one millimeter, and the saturation current in one position was determined by subtracting the values of two adjacent measurements.

Mobility of ions in the flame was observed by the sheath method to confirm whether the negative particles were chiefly electrons or negative ions. The diagram of the circuit used was the same as that of Kinbara.[15] A platinum wire 0.3 mm in diameter was used as an electrode. A potential difference was applied between the wire electrode and the ionizing jet. In order to observe the potential of the ionized gas, a probe of Pt/Rh 13% wire 0.1 mm in diameter was

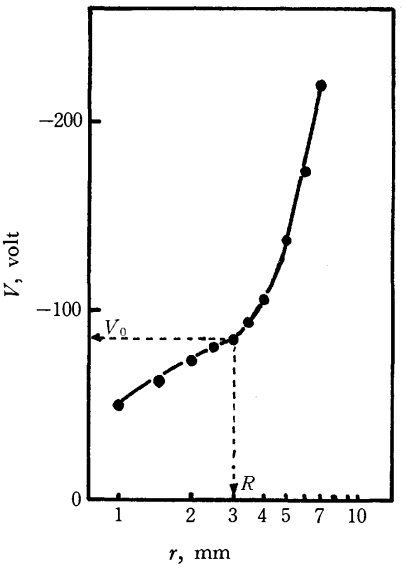

Fig. 3. Potential distribution around positively charged wire electrode.
Height of wire electrode from jet: 8 mm; r_0: 0.3 mm; l: 6 mm; Potential of jet: −600 V; i: 8×10^{-8} A

used. The probe was covered with a thin silica tube (0.4 mm in diameter) except for 6 mm at the end. The probe, together with its silica tube holder, was mounted on the movable carriage of a cathetometer. The uncovered part of the probe was carefully adjusted to be just beneath and parallel to the wire electrode. The potential was observed by the potentiometer. By adjusting the potential V of the probe with respect to the wire electrode under investigation, the probe current could be reduced to zero, at which point the probe would be at the same potential as the adjacent gas. Keeping the probe current at zero, the observed potentials of the probe were plotted as a function of ln r. A curve was obtained as given in Fig. 3. r is the distance between the center of the wire electrode and the probe. The mobility k_- for negative particles around the positive wire electrode is given by the equation.[15]

$$k_- = \frac{i[R^2 \ln(R/r_0) - 1/2(R^2 - r_0^2)]^2}{1.1 \times 10^{-12} l V_0^2 (R^2 - r_0^2)} \quad (\mathrm{cm \cdot sec^{-1}/V \cdot cm^{-1}}), \tag{1}$$

where i is the total current(A) through the flame, V_0 the potential difference (volt) in the sheath, $R - r_0$ the sheath thickness (cm), r_0 the radius (cm) of the wire electrode, and l the length(cm) of the wire electrode in the flame. V_0 and R were determined from Fig. 3 and k_- was calculated by Eq.(1).

It is necessary that the potential distribution is concentric with the wire electrode and uniform along its axis. Thus, measurements were carried out at 8—12 mm above the jet, where the ion distribution was relatively more homogeneous than other parts of the flame.

Results and Discussion

The temperature distribution of the ionizing flame is given in Fig. 4, and the distribution of free sodium atoms in vertical direction in Fig. 5. Determination was carried out as follows. If spectrum intensities in any two points of the flame are I_1 and I_2, the ratio of the numbers of free atoms N_2/N_1 would be as follows.

$$\frac{N_2}{N_1} = \frac{I_2 V_1}{I_1 V_2} e^{E/k(1/T_2 - 1/T_1)}, \tag{2}$$

where k is the Boltzmann constant, E the energy of excitation (2.10 eV for sodium resonance lines), V the volume of observed flame, and T the mean temperature of observed flame. The ordinate of Fig. 5 is given by Eq. (2), where N_1 is the number of free neutral atoms in the region 0—2 mm above the jet and N_2 the number in the region under investigation.

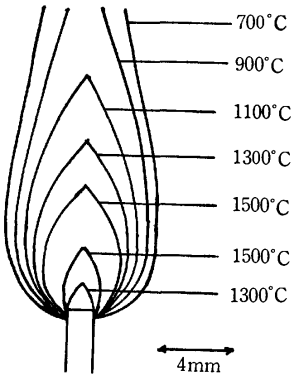

Fig. 4. Temperature distribution of ionizing flame.

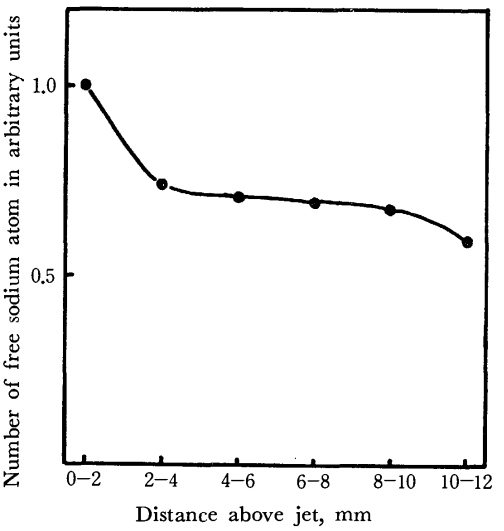

Fig. 5. Vertical distribution of free sodium atom.

The volume of inner flame 0—4 mm above the jet was subtracted from volume V, since it was considered that sodium atoms are not present in this part, or even if they were, the temperature of this part was too low to excite sodium atoms.

We see from Fig. 5 that free sodium atoms are mainly distributed in the lower and outer parts of the flame. In the upper part, the distribution was uniform due to the diffusion of sodium atoms.

Figure 6 shows the observed intensities of the sodium and lithium resonance lines in the emission 3—5 mm above the jet, plotted (logarithmic scale) against the reciprocal temperature. If these metals were present as free atoms, then Fig. 6 should show a straight line with slope $(-E/k)$, where E is 2.10 and 1.85 eV for sodium and lithium resonance lines, respectively.

Any systematic deviation from this line would mean that a significant part of the metals was present other than as free neutral atoms, in an amount depending on

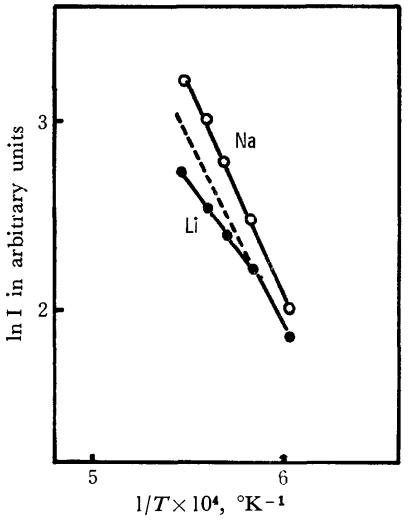

Fig. 6. Plot of ln (intensities of lithium and sodium in resonance lines) against $1/T$.
Emission intensity 3—5 mm above jet was measured. The dotted line corresponds to the theoretical slope, with the assumption that no compounds or ions are formed.

temperature. The plot for sodium showed a straight line, and E agreed with the energy of resonance lines. Hence, most of the sodium is present as free atoms in this region. On the other hand, the plot for lithium deviated from the theoretical straight line with the rise in temperature. Since lithium is more difficult to ionize than sodium, the decrease of free atoms by ionization dose not cause the deviation. A reasonable source of deviation would be formation of a molecular compound. Jensen and Padley[16] considered that gaseous hydroxide was formed as

$$A + H_2O \rightleftarrows AOH + H,$$

where A is alkali metals, and they determined dissociation energies of alkali hydroxides. From their results, LiOH is a most stable compound; the stability decreases in the order CsOH, RbOH, KOH, and NaOH.

If a metal and its position in the flame are given, spectrum intensity I is proportional to the number of free atoms N. If the number of free atoms and spectrum intensity decreased to N' and I' as a result of hydroxide formation:

$$\frac{[LiOH]}{[Li]} = \frac{N-N'}{N'} = \frac{I-I'}{I'}. \quad (3)$$

From the deviation in Fig. 6 and Eq. (3), it was found that [LiOH]/[Li] was 0.1—0.3 at 1500—1550°C. In the case of cesium, spectrum intensity could not be measured owing to lack of sensitivity. However, it was found from Fig. 7 that the hydroxide would be formed at 1700°C or above. Fig. 7 shows a relationship of dissociation energies of alkali hydroxides and formation temperatures of sodium, potassium, and rubidium hydroxides, determined by Jensen and Padley.[16] Only a small amount of lithium hydroxide appeared to formed. This is because the flame temperature was relatively low and alkali elements were not added as fine sprays of dilute aqueous solution.

Distributions of charged particles in the flame by the Langmuir probe method are shown in Figs. 8, 9,

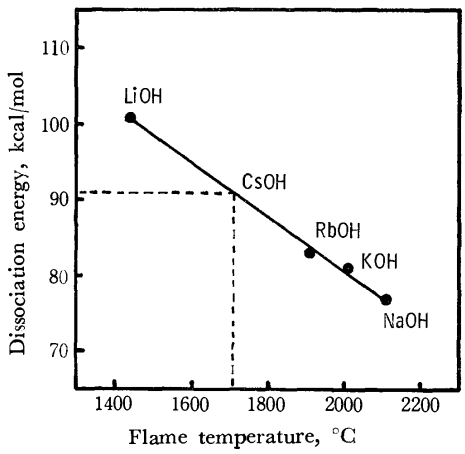

Fig. 7. Plot of dissociation energy against formation temperature of alkali hydroxides.
Temperature for the formation of LiOH was determined.

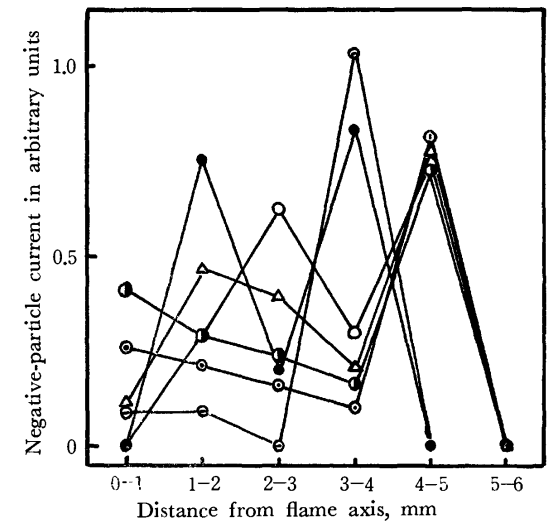

Fig. 9. Horizontal distribution of negative particles in adding sodium chloride in flame.
Distance above jet (mm): as Fig. 8.

and 10. The ordinates of these figures are represented by I_{ps} or I_{ns} in Fig. 2. It seemed reasonable that the positive-ion distributions have maxima in the parts of higher temperature, since alkali metals A are ionized by collisional process with flame gas molecules X, *viz.*,

$$A + X \rightleftarrows A^+ + e + X$$

and the ionization of the alkali metals is near thermal equilibrium. However, the negative-particle distributions also have larger maxima in the outer part of the flame. We see from Fig. 10 that ionization chiefly occurred in the part 0—5 mm above the jet and the negative-particle current was only about twice as large as the positive-ion current.

If negative particles were only free electrons, the negative-particle current should be much larger than the positive-ion current because of the larger mobility of free electrons. In such a small flame, however, it is possible that the higher diffusion rate of electrons allow them to diffuse out of the flame, causing a small

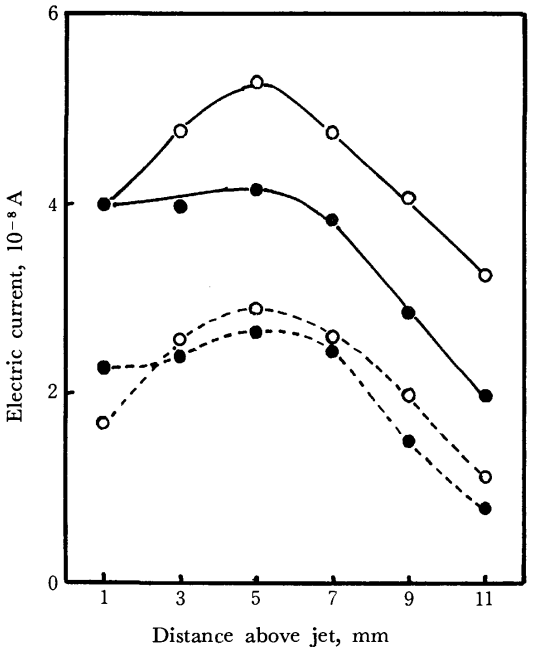

Fig. 10. Vertical distribution of positive ion and negative particles.
●: Sodium; ○: Rubidium
----: Positive ion; ——: Negative particles

negative-particle current. It appears that most negative particles are negative ions of small mobility formed by attachment of free electrons to electronegative gases such as hydroxyl radical, atomic oxygen and chlorine. However, it was not possible to distinguish electrons from negative ions by the probe method. To do this, negative-particle mobility should be measured.

Thus, the positive-ion and negative-particle mobilities were measured by the sheath method when sodium chloride was added to the flame. The plot for negative-particle mobility is shown in Fig. 3. From Eq. (1) and Fig. 3, k_- was calculated to be 9 $cm \cdot sec^{-1}/V \cdot cm^{-1}$, and k_+ to be 0.4 $cm \cdot sec^{-1}/V \cdot cm^{-1}$. If the negative particles were free electrons, the mobility would be of an order of about 10^3. If they were negative ions, it would be the same order as that of the positive-ion mobility. It thus seems reasonable that most of the negative particles were negative ions and a few electrons increased the mean negative-particle mobility. The negative-particle distributions in Figs. 9 and 10 showed maxima in the outer part of ionization zone. It was considered that electrons diffused to the outer surface of the flame, and negative ions were formed by attachment of electrons to the electronegative gases during the course of diffusion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1097—1100 (1972)

The Synthesis and Properties of *trans*-$[CrCl_2(NH_3)_4]Cl \cdot H_2O$

Kenzo NAGASE and Nobuyuki TANAKA*

Department of Chemistry, Tohoku University, Kawauchi, Sendai

**Department of Chemistry, Faculty of Science, Tohoku University Katahira, Sendai*

(Received October 2, 1971)

A simple method for the synthesis of *trans*-dichlorotetraamminechromium(III) chloride monohydrate was developed, and the configuration of the complex obtained was confirmed by measurements of the infrared and visible absorption spectra. It was found that the *cis-trans* isomerization took place in the solid state upon the thermal treatment of the complex at 200°C. The enthalpy change for the reaction was calculated to be 1.2 kcal·mol^{-1} by an analysis of the DSC curve.

Recently, several reports concerning the syntheses and properties of a *trans* type of tetraamminechromium(III) complex have been presented. Glerup and Schaffer[1] have reported the synthesis of a number of *trans*-diacidotetraamminechromium(III) complexes by the reaction of difluorotetrapyridinechromium(III) iodide with liquid ammonia in an autoclave. Hoppenjans and his co-workers[2] also obtained these complexes by a method based on the acid cleavage of the complex ion, $[(NH_3)_5Cr(OH)Cr(NH_3)_4Cl]^{4+}$. They[3] also investigated the stoichiometry and kinetics of the aquation reaction of *trans*-$[CrCl_2(NH_3)_4]^+$ in an acid solution. Brown *et al.*[4] measured the infrared absorption spectra of *trans*-$[CrCl_2(NH_3)_4]ClO_4$ in the frequency region of 200—600 cm^{-1}.

These syntheses, however, are somewhat complicated, and only a few studies have been made of the properties of these complexes. In the present study, a simple method for the synthesis of *trans*-$[CrCl_2(NH_3)_4]Cl \cdot H_2O$ was developed, and the infrared (400—4000 cm^{-1}) and visible absorption spectra of the complex were measured. Moreover, the thermal reactions of the complex in the solid state were examined.

Experimental

Material. Three complexes, $[Cr(NH_3)_6]Cl_3$,[5] *cis*-$[CrCl(H_2O)(NH_3)_4]Cl_2$[6], and *trans*-$[CoCl_2(NH_3)_4]Cl \cdot H_2O$,[7]

were prepared according to the literature, *cis*-$[CrCl_2(NH_3)_4]Cl$ was obtained by heating *cis*-$[CrCl(H_2O)(NH_3)_4]Cl_2$ at 120°C for 3 hr in a vacuum.

Measurements. A Hitachi EPI-2G infrared spectrophotometer was used for the measurement of the infrared absorption spectra. The electronic spectra in solutions were measured by means of a Hitachi EPS-3 spectrophotometer. The diffuse reflectance spectra in the solid state were measured by means of a Hitachi EPS-3 spectrophotometer equipped with a standard integrating sphere attachment. The thermogravimetric(TGA) and differential scanning calorimetric(DCS) curves were obtained with a Rigakudenki 2008 CS thermobalance equipped with a standard differential scanning calorimeter in a dynamic nitrogen atmosphere. A ten-milligram sample in a aluminum crucible was used in each measurement. The furnace-heating rate was about 5°C min^{-1}.

Synthesis of trans-$[CrCl_2(NH_3)_4]Cl \cdot H_2O$. The starting material $[Cr(NH_3)_6]Cl_3$ (5 g) in powder was heated at 230°C in air until the color was converted to green. The product was washed thoroughly with cold water until the washings was colorless. The residue was non-electrolyte, its formula was represented as $[CrCl_3(NH_3)_3]$ on the base of the analytical data.

To the fine powder of $[CrCl_3(NH_3)_3]$ (3 g) in a 100 m*l*-stoppered flask, a 20-m*l* portion of 28% ammonia water was added. The mixture was then maintained at about 25°C for 5 days. *trans*-$[CrCl_2(NH_3)_4]Cl \cdot H_2O$ was formed as green crystals, those crystals were filtered off and washed with a small amount of cold water and then with ethanol, and air dried (yield *ca.* 1.5 g).

The complex thus obtained was purified by recrystallization from water at about 20°C. The crude material was dissolved in a minimum amount of water and filtered off. The green filtrate, in a desiccator with concd. HCl, was kept over night in a refrigerator, the green crystals which thus appeared were filtered off, washed with ethanol, and air dried.

Analysis. Found: Cr, 21.5; H, 5.95; N, 22.81; Cl, 42.9; H_2O, 7.4%. Calcd. for $[CrCl_2(NH_3)_4]Cl \cdot H_2O$: Cr, 21.27; H, 5.77; N, 22.92; Cl, 43.49; H_2O, 7.36%. The water content was determined from the TGA curve.

Results and Discussion

The infrared spectra of the complex and its related complexes are shown in Fig. 1. The M–N stretching band, which provides direct information about the coordination bond, appears in a lower-frequency region. The complex obtained gives the corresponding band at 469 cm^{-1} as a single peak, *trans*-$[CoCl_2(NH_3)_4]Cl \cdot H_2O$ also gives a single peak at 501 cm^{-1}, whereas *cis*-$[CrCl_2(NH)_3]_4Cl$ gives three peaks, at 437, 462, and 475 cm^{-1}.

The electronic spectra of the complex and its analogue are shown in Fig. 2. In the region of the *d-d* transition, the spectrum of the complex has absorption maxima at 17000, 21100, and 25100 cm^{-1}, its pattern very similar to that of *trans*-$[CrCl_2(en)_2]^+$, the spectrum of which has been measured by Carner and Esparza.[8]

The analytical data and the infrared and visible absorption spectra confirm that the complex obtained in this study has a *trans*-configuration and that its

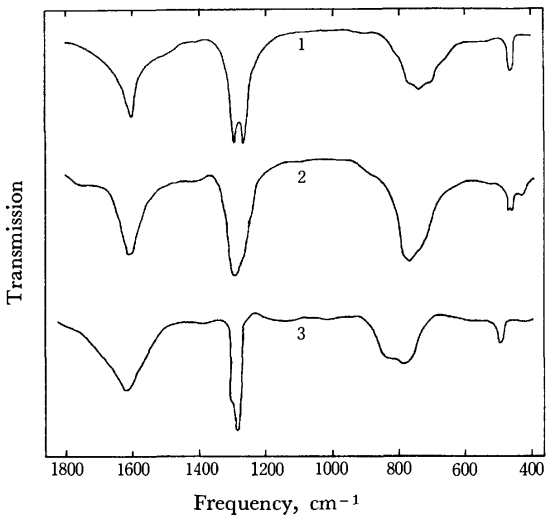

Fig. 1. Infrared spectra of (1) *trans*-$[CrCl_2(NH_3)_4]Cl \cdot H_2O$, (2) *cis*-$[CrCl_2(NH_3)_4]Cl$, and (3) *trans*-$[CoCl_2(NH_3)_4]Cl \cdot H_2O$.

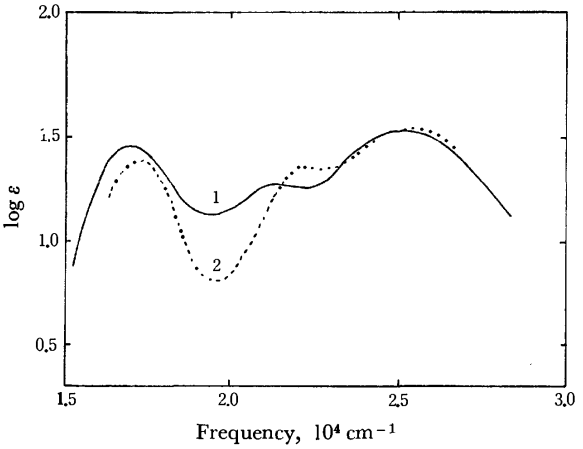

Fig. 2. Visible absorption spectra of (1) *trans*-$[CrCl_2(NH_3)_4]^+$ and (2) *trans*-$[CrCl_2(en)_2]^+$.

formula may be represented as *trans*-$[CrCl_2(NH_3)_4]Cl \cdot H_2O$.

The TGA and DSC curves of *trans*-$[CrCl_2(NH_3)_4]Cl \cdot H_2O$ are shown in Fig. 3. From the TGA curve, it can be seen that the decomposition in the solid state takes place in three steps. The first step, which begins at 65°C and which is completed at 110°C (weight loss, 7.4%), is attributed to the evolution of one mole of hydrated water. The second one, which begins at 210°C and which is completed at 260°C (weight loss, 6.8%), is due to the evolution of one mole of ammonia. The nature of the third step, which begins at 260°C, is not yet clear.

On the DSC curve of *trans*-$[CrCl_2(NH_3)_4]Cl \cdot H_2O$, an endothermic peak for each weight loss was observed, but the peak for the second step splits into two. The shoulder peak may be due to the *cis-trans* isomerization.

In order to confirm the *cis-trans* isomerization, the diffuse reflectance spectra of the samples were measured before and after heating the complex. These spectra are shown in Fig. 4. The spectrum of the dehydrated complex which was obtained by heating

8) C. S. Carner and M. Esparza, *J. Inorg. Nucl. Chem.*, **29**, 2377 (1967).

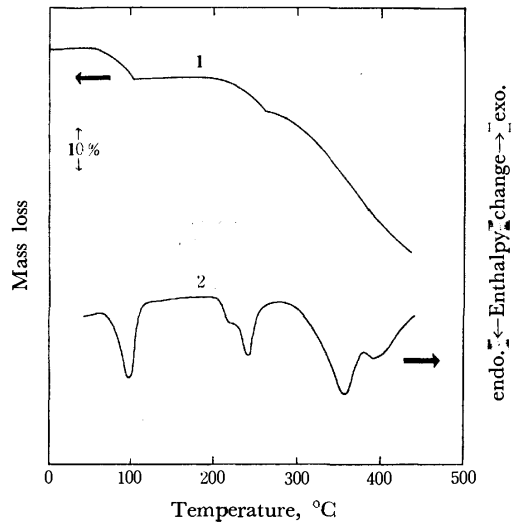

Fig. 3. TGA (1) and DSC (2) curves of *trans*-$[CrCl_2(NH_3)_4]Cl \cdot H_2O$ in a dynamic nitrogen atmosphere.

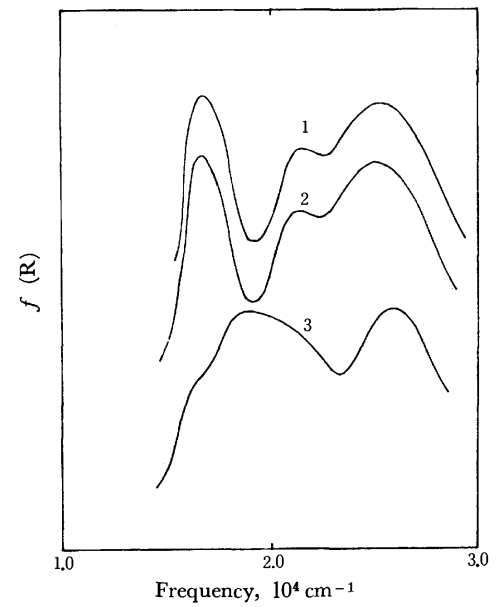

Fig. 4. Reflectance spectra of (1) *trans*-$[CrCl_2(NH_3)_4]Cl \cdot H_2O$, (2) *trans*-$[CrCl_2(NH_3)_4]Cl$, and (3) the sample obtained after heating *trans*-$[CrCl_2(NH_3)_4]Cl$ at 200°C for 24 hr in a sealed capillary tube.

trans-$[CrCl_2(NH_3)_4]Cl \cdot H_2O$ at 110°C for 3 hr in a vacuum is almost identical with that of the hydrated complex, from which it is clear that the *cis-trans* isomerization did not occur in the first step. When the dehydrated complex was heated at 220°C in a sealed capillary tube which was used for the purpose of suppressing the evolution of ammonia, the *cis-trans* isomerization occurred. The spectrum which is given by curve 3 in Fig. 4 suggests that the product was a mixture of the *cis* and *trans* isomers.

The enthalpy change, ΔH, for the isomerization reaction was calculated by means of an analysis of the DSC curve of *trans*-$[CrCl_2(NH_3)_4]Cl$. Since the isomerization was followed by the evolution of ammonia, as may be seen in Fig. 3, the peak area for the isomerization was estimated by drawing a curve which corresponded to the evolution of ammonia. The value of ΔH obtained for the isomerization (*trans*→*cis*) was 1.2 kcal·mol^{-1}. This value seems reasonable in view of the values reported in previous studies[9-11] for other isomerization reactions.

In order to confirm the existence of the reverse reaction, *cis*→*trans*, the *cis* isomer was heated under the same conditions as those employed for the *trans* isomer. The TGA and DSC curves of *cis*-$[CrCl(H_2O)(NH_3)_4]Cl_2$ are given in Fig. 5. From the TGA curves, it can be seen that the decomposition in the temperature

range from 25 to 500°C took place in three steps. In the temperature region from 142 to 200°C, the complex lost coordinated water to form *cis*-$[CrCl_2(NH_3)_4]$-Cl while at temperatures higher than 200°C the evolution of ammonia took place. Since the horizontal mass level was not observed between the evolution of water and the evolution of ammonia, pure *cis*-$[CrCl_2(NH_3)_4]Cl$ could not be obtained by heating *cis*-$[CrCl(H_2O)(NH_3)_4]Cl_2$ under the conditions employed for the measurement of the TGA curve. Therefore, the pure *cis*-$[CrCl_2(NH_3)_4]Cl$ used for the measurement was obtained by heating *cis*-$[CrCl(H_2O)(NH_3)_4]$-Cl at 120°C for 3 hr in a vacuum.

The *cis*-$[CrCl_2(NH_3)_4]Cl$ thus obtained was heated at 200°C for 24 hr in a sealed capillary tube. The reflectance spectrum of the product is given in Fig. 6, along with that of the *cis* isomer. The shoulder peak at 17000 cm^{-1} suggests that the products contained *trans* isomer. In fact, the *trans* isomer was separated from the product by the following procedure.

To the product (1 g) 20 m*l* of water was added, and then the mixture was filtered. The residue on a filter is a mixture of the *cis* isomer and a minute amount of $[CrCl_3(NH_3)_3]$ which was formed by the evolutoin of ammonia. The green filtrate was left over-night in a desiccator with concd. HCl, and then kept standing over night in a refrigerator. The green crystals formed were separated and washed with ethanol. The physical data of the product were identical with those of *trans*-$[CrCl_2(NH_3)_4]Cl \cdot H_2O$.

On the DSC curve, an endothermic peak for each mass loss was observed, but in the case of the *cis* isomer there was no peak corresponding to the *cis-trans* isomerization. From this result, it may be supposed that, when the *cis* isomer is heated in a dynamic nitrogen atmosphere the evolution of ammonia took place at a lower temperature than did the isomerization.

The equilibrium constant for the *cis-trans* isomerization reaction could not be obtained, since the side reaction, *cis*- or *trans*-$[CrCl_2(NH_3)_4]Cl \rightarrow [CrCl_3(NH_3)_3]+NH_3$, took place under the conditions employed in this study.

The authors wish to express their hearty thanks to Masahiro Sakurai for his measurements of the TGA and DSC curves. They also wish to thank the Ministry of Education for the financial support granted this research.

Thermochromisms of Some β-Diketone Chelate Copmlexes of Copper(II) in Pure Pyridine[1]

Hiroshi Yokoi, Mitsuru Sai, and Taro Isobe

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai

(Received December 3, 1971)

Two types of thermochromisms have been found for several β-diketone chelate complexes of copper(II) in pure pyridine or γ-picoline. One is observed for such complexes as bis(acetylacetonato)copper(II). In this case, the visible absorption spectra at various temperatures have well-defined isosbestic points; there are two different complex species, L and H, at equilibrium in the solvent, where L and H represent the low-temperature and high-temperature species respectively; they are different in the interaction between the complex and pyridine or γ-picoline molecules. The other is observed for such complexes as bis(salicylaldehydato)copper(II), where the spectral intensity increases remarkably with a rise in the temperature. The equilibrium for bis(acetylacetonato)copper(II) was studied over the temperature range of 0—60°C, and the results were used to derive the approximate thermodynamic parameters, $\Delta H = 4.0 \pm 1.0$ kcal/mol and $\Delta S = 13 \pm 4$ e.u., for the L→H change. The most probable structures for L and H were suggested from a spectrophotometrical point of view.

The thermochromism exhibited by many metal complexes in solution is associated with an equilibrium between the different configurations which the complexes can adopt in the solution at various temperatures.[2-6] It is interesting to us that some kinds of metal complexes change their structural configurations easily according to environmental conditions. Some of the configurations may be chemically labile. Investigations of the thermochromism are, therefore, important in understanding chemical reactions.

The purpose of this paper is to report the new experimental finding that the β-diketone chelate complexes of copper(II) in pure pyridine or γ-picoline exhibit two different types of thermochromisms and

to estimate the possible mechanisms for these thermochromisms. This experimental finding indicates that there are different interactions between the complex and pyridine or γ-picoline molecules.

Experimental

Materials. The β-diketone chelate complexes of copper(II) employed here are $Cu(acac)_2$, $Cu(dpm)_2$, $Cu(bzac)_2$, $Cu(sal)_2$, and $Cu(etacest)_2$, where acac, dpm, bzac, sal, and etacest are the anions of acetylacetone, dipivaloylmethane, benzoylacetone, salicylaldehyde, and ethyl acetoacetate respectively. They were prepared and purified by the same general method.[7] All the ligand agents were obtained commercially. G.R.-grade pyridine and γ-picoline were dried over potassium hydroxide and were fractionally distilled.

Spectroscopy. The visible absorption spectra for the complexes in pyridine and γ-picoline were measured over the temperature range of 0—60°C with a Cary model 14 spectrophotometer, using 1-cm quartz cells. Color changes occured reversibly with a change in the temperature for all the sample solutions.

Results and Discussion

The visible absorption spectra at various temperatures for $Cu(acac)_2$ and $Cu(bzac)_2$ in pyridine are shown in Figs. 1 and 2 respectively. The same temperature dependences of the spectra were also observed for $Cu(dpm)_2$ in pyridine and for $Cu(acac)_2$ in γ-picoline. It is characteristic of these three complexes in pyridine and γ-picoline that the visible absorption spectra at various temperatures have well-defined isosbestic points. On the other hand, the spectra of $Cu(sal)_2$ in pyridine at various temperatures are shown in Fig. 3; almost the same temperature dependences of the spectra were observed for $Cu(etacest)_2$ in pyridine and $Cu(sal)_2$ in γ-picoline. It is characteristic of the latter two complexes in pyridine and γ-picoline that the spectral lines observed at various temperatures do not intersect with one another and that only the spectral intensities increase remarkably with a rise in the temperature. The five complexes employed here, accordingly, group themselves in two classes, the former three complexes (Class A) and the latter two complexes (Class B), according to these temperature dependences of the visible absorption. This classification is also consistent with the one based upon the stability of the complexes,[8,9] the composition of the adducts of the complexes with pyridine,[10] and the solvent effect of the positions of the absorption maximum, as are listed in Table 1.

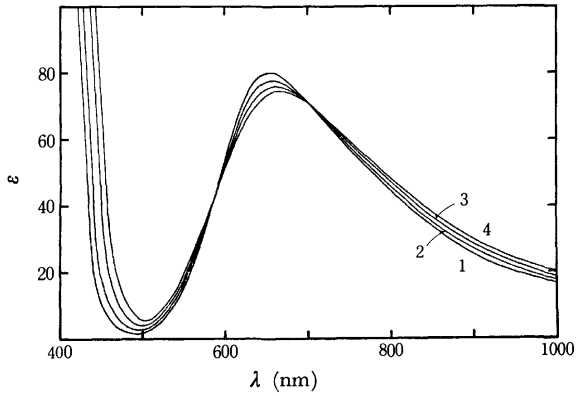

Fig. 1. Visible absorption spectra of $Cu(acac)_2$ in pyridine. (1): 0°C, (2): 20°C, (3): 40°C, (4): 60°C.

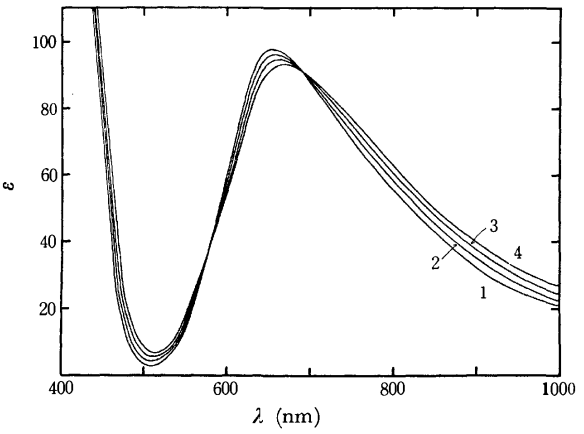

Fig. 2. Visible absorption spectra of $Cu(bzac)_2$ in pyridine. (1): 0°C, (2): 20°C, (3): 40°C, (4): 60°C.

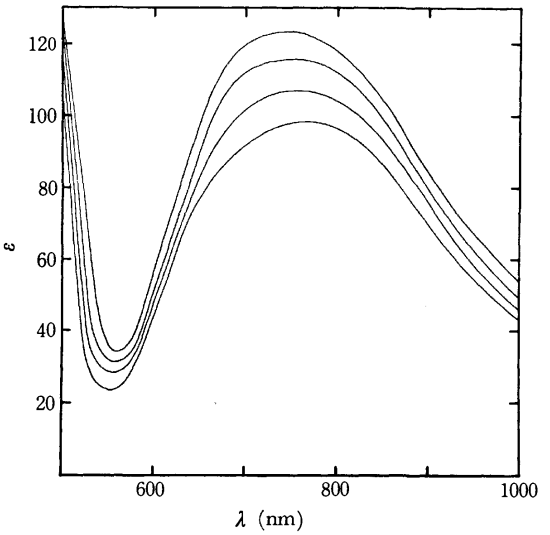

Fig. 3. Visible absorption spectra of $Cu(sal)_2$ in pyridine. (1): 0°C (the lowest line), (2): 20°C, (3): 40°C, (4): 60°C.

Such isosbestic points as are shown in Figs. 1 and 2 indicate that the complexes of Class A are present as two different complex species at equilibrium, even in a pure solvent of pyridine or γ-picoline. The two complex species will hereafter be called the low-temperature species, L, and the high-temperature species,

H.

$$L \rightleftharpoons H \qquad (1)$$

The equilibrium constant, K, for this equilibrium may be obtained from the following equation:

$$K = \frac{[H]}{[L]} = \frac{x}{c^0 - x} = \frac{D - D_L}{D_H - D} \qquad (2)$$

where c^0 represents an initially-given concentration, where D is the measured optical density at any suitable wavelength, and where D_L and D_H are the optical densities at the same wavelength which would be found for the pure L and H species respectively at the concentration of c^0. Unfortunately, neither D_L nor D_H could be determined directly here, but an attempt has been made to estimate them for $Cu(acac)_2$, using the following method.

The measured spectra in the neighborhood of the two isosbestic points are shown in Fig. 4, where the bold line represents the peak position for the measured spectra and the one estimated by extrapolation for the spectra at temperatures besides 0—60°C. Accordingly, if we properly estimate the two temperatures at which the L and H species are present in solution in their pure forms, the spectral peak positions at the temperatures will be determined by the bold line. Since the spectral lines of D_L and D_H pass through the two isosbestic points and the peak positions estimated for them, we can draw smooth curves like the measured spectral lines through the three points; the curves are regarded as assumed spectral lines of D_L and D_H and are shown by dotted lines in Fig. 4. The equilibrium constant at any temperature can then be determined at any suitable wavelength within the range of 585—700 nm by using Eq. (2). The results are listed in Table 2. It is expected, from a consideration of the absorption-line shapes, that the true temperatures at which the L and H species are present in solution in their pure forms do no deviate extremely from the assumed ones listed in Table 2. Although the values of ΔH and and ΔS for the equilibrium were finally determined to be 4.0±1 kcal/mol and 13±4 e.u. respectively, such large errors were introduced for extra safety because of some uncertainty in the values of D_L and D_H.

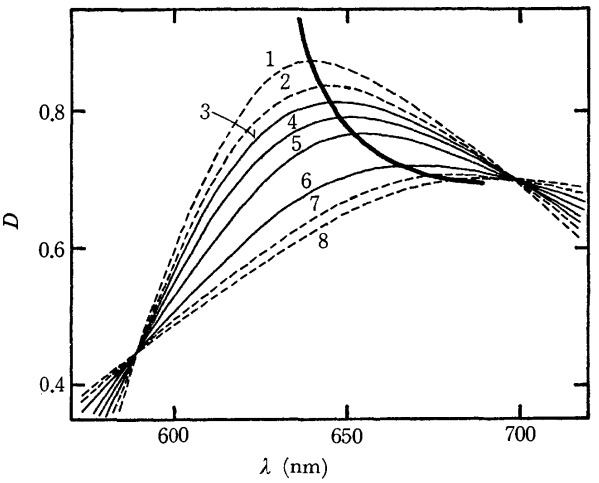

Fig. 4. The measured and estimated spectra in the neighborhood of isosbestic points for $Cu(acac)_2$ in pyridine (——: the measured spectra, ----: the estimated spectra, the bold line shows the spectral peak position).
(1): −60°C, (2): −40°C, (3): 0°C, (4): 20°C, (5): 40°C, (6): 60°C, (7): 110°C, (8): 130°C.

The temperature affects the intensity of an electronic transition induced by a vibrational mode, n, according to $\coth(h\nu_n/2kT)$ in the simplest theory.[11,12] The oscillator strength at t°C will hereafter be expressed as f_t. Assuming that $\nu_n = 150$—$300\ cm^{-1}$, we can calculate the (f_{60}/f_0) ratio to be 1.15—1.19 according to the coth rule mentioned above for the copper(II) complexes in pure forms. The spectral data of the β-diketone chelate complexes of copper(II) in pyridine and γ-picoline are listed in Table 3.

$Cu(etaccst)_2$	Py	730; 67	730; 77	1.63	1.99	1.22

a) Py: pyridine, γ-Pic: γ-picoline. b) Corrected values at 20°C (the observed f value at t°C was multiplied by the ratio of the density of pyridine at 20°C to the density of pyridine at t°C). c) These systems exhibited broad absorption peaks. d) f_t represents the oscillator strength at t°C.

There is a clear difference in the observed ratio (f_{60}/f_0) between the complexes of Class A and Class B, as may be seen in Table 3. The ratios observed for the complexes of Class B are larger than those calculated theoretically according to the coth rule; furthermore, the spectral intensities of the complexes increased remarkably without any crossings of spectral lines with a rise in the temperature, as has been mentioned above. It seems, therefore, probable that a change in structure accompanying a change in spectral intensity takes place continuously according to the temperature for the complexes of Class B in pyridine or γ-picoline.

On the other hand, the observed ratio (f_{60}/f_0) for the complexes of Class A is much smaller than for the complexes of Class B, as may be seen in Table 3. The ratio (f_H/f_L) for $Cu(acac)_2$ in pyridine at any temperature was evaluated to be about 1.1, using the following values: $K_{60°C}=3.3$, $K_{0°C}=1.2$, $f_0=1.76$, $f_{60}=1.95$, and $(f_{60,H}/f_{0,H})=(f_{60,L}/f_{0,L})=1.17$. These results indicate that the spectral intensity of L is almost equal to that of H, and that, therefore, there is almost no difference in the symmetry of the copper-ion environment between L and H.[13] The fact that, for the planar copper(II) complexes, the visible absorption bands shift to longer wavelengths as the axial coordination bondings strengthen, or as the planar coordination bondings weaken, has been confirmed both theoretically and experimentally.[14,15] This gives a basis for the interpretation of the experimental fact that the absorption maximum for H appears at a somewhat longer wavelength than that for L, as is shown in Table 3. It has been reported that the copper atom is penta-coordinated to the four oxygen atoms in the β-diketone and to the nitrogen atom of the pyridine molecule for $Cu(acac)_2$ in pyridine at any temperature.[16,17] Many X-ray diffraction studies have shown that, when the planar metal complexes form some penta-coordinated 1 : 1 adducts,

the metal ion is displaced from the plane in the direction of the fifth coordinating atom.[18] On the basis of all these facts concerning the structures of $Cu(acac)_2$ in pyridine, the most probable structures of L and H were estimated to be those shown in Fig. 5, where both structures are of an approximate C_{2v} symmetry in the copper-ion environment. It may be said that the displacement of the copper atom from the plane of the four oxygen atoms is somewhat larger for H than for L. If we assume that the pyridine molecule in H rotates freely, as is shown by an arrow in Fig. 5, the entropy change can be calculated to be 14.8 e.u. Interestingly, this value is almost equal to the observed entropy change for L→H. The possibility that the pyridine molecule in H may rotate freely can be fully expected, since the difference in structure between L and H seems to be too small to give rise to such a large entropy change because of the environmental difference between them, and since it is considered, from a structural point of view, that the pyridine molecule rotates more easily in H than in L.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1104—1110 (1972)

Activation of Iron-Alkyl Bonds in Dialkylbis (dipyridyl) iron(II) by Interaction with Olefins

Takakazu YAMAMOTO, Akio YAMAMOTO, and Sakuji IKEDA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro, Tokyo

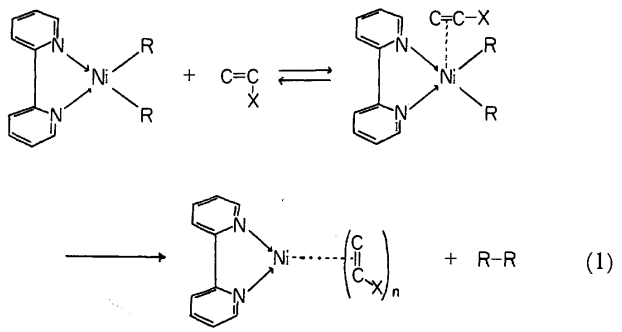
(Received May 19, 1971)

The reactions of dialkylbis(dipyridyl)iron(II) **1** with various substituted olefins were studied. Tetracyanoethylene, maleic anhydride, and acrylamide gave olefin-coordinated π-complexes on reactions with **1**, whereas other vinyl monomers with relatively large *e*-values were polymerized by the alkyl-iron complex. Kinetic study of the reactions of **1** with olefins by a spectroscopic method revealed that the reaction rate can be expressed by

$$-\frac{d[FeR_2(dipy)_2]}{dt} = \frac{[olefin][FeR_2(dipy)_2]}{A+B[olefin]+C[dipy]}.$$

On the basis of kinetic results and from comparison with the reactions of dialkyl(dipyridyl)nickel with olefins, a mechanism involving partial dissociation of the dipyridyl ligand from **1**, followed by a coordination of the olefin and activation of a Fe-alkyl bond was proposed.

Transition metal-alkyl complexes are generally considered to be the active species in various catalytic reactions involving olefins such as polymerization with Ziegler type catalysts, hydroformylation, hydrogenation, isomerization, and oligomerization[1]. Instability of the transition metal-alkyl bond usually makes isolation of the alkyl complexes difficult, thus hindering a detailed study of the interaction of olefins with the alkyl complexes, a crucial step in catalyses. From Ziegler type catalyst systems we have isolated transition metal-alkyl complexes, the metal alkyl bonds of which are stabilized by the presence of a ligand dipyridyl[2]. These alkyl complexes are very stable and prove to be particularly suitable for studying the mechanism of activation of the metal-carbon bond by coordination of olefins[3),4]. In some cases the reactions of some olefins with the alkyl complexes lead to polymerization[5] while in other cases a scission of the metal-alkyl bonds yielding metal-olefin π-complexes resulted[3]. We previously studied the reactions of dialkyldipyridylnickel with various olefins in detail[3] and found that the essential feature of the reactions of the nickel complex can be expressed by the following scheme.



(1)

The rate of the reaction is given by the equation

TABLE 1. REACTION OF $FeEt_2(dipy)_2$ WITH OLEFINS

Olefin	*e*-value[7]	Results	Shifts of IR bands
Tetracyanoethlene (TCNE)		Dark brown solid ($Fe(dipy)_2(TCNE)_2$)	$\nu_{C\equiv N}$ 2220 → 2110 cm^{-1}
Maleic anhydride (MAH)	2.25	Red solid ($Fe(dipy)(MAH)_4$)	$\nu_{C=O}$ 1780 → 1780～1730 cm^{-1}
Acrylamide (AcAm)	1.30	Reddish brown solid ($Fe(AcAm)_2$?)	ν_{N-H} 3370 → 3280 cm^{-1} $\nu_{C=O}$ 1670 → 1660 cm^{-1}
Acrylonitrile (AN)	1.20	Polymerization took place.	
Methacrylonitrile (MAN)	0.81	Polymerization took place.	
Acrolein (AC)	0.73	Polymerization took place.	
Methyl vinyl ketone (MVK)	0.69	Polymerization took place.	
Methyl acrylate (MA)	0.60	Polymerization took place.	
Methyl methacrylate (MMA)	0.40	Polymerization took place.	
Vinyl chloride (VCl)	0.20	Dark red solid	
Vinyl acetate (VAc)	−0.22	Reddish purple solid ($Fe(dipy)(Vac)_2$)	$\nu_{C=O}$ 1800～1730 → 1600～1560
2-Vinylpyridine (2-Vi-Py)	−0.50	Polymerization took place.	
Styrene (St)	−0.80	No apparent change was observed.	
Isobutyl vinyl ether (IBVE)	−1.77	No apparent change was observed.	
Ethylene (E)		No apparent change was observed.	

$$r = -\frac{d[NiR_2(dipy)]}{dt} = k_{Ni}[NiR_2(dipy)][olefin] \quad (2)$$

In contrast to the alkyl-nickel complex which does not initiate vinyl polymerization in the absence of oxygen, dialkylbis(dipyridyl)iron(II) (**1**) initiates the polymerization of some vinyl compounds and gives iron-olefin π-complexes. In this paper we report the results of preparative and spectroscopic studies of the reactions of $FeR_2(dipy)_2$ **1** with various olefins. The propagation mechanism in the polymerization of methyl methacrylate was discussed in a previous paper.[6]

Results and Discussion

Alkyl-iron complex **1** is fairly stable in the solid state but decomposes slowly in solution at room temperature. The methyl and ethyl complexes begin to decompose at about 95°C and the propyl complex at about 80°C when heated in the absence of solvent. Pyrolysis of the methyl complex released mainly methane, the ethyl complex ethane (65%) and ethylene (35%) and the propyl complex propane (60%) and propylene (40%). The compositions of the evolved gases differ from those of the pyrolysis products of $NiR_2(dipy)$ which gave ethane from the methyl complex, butane from the ethyl complex and propane and propylene from the propyl complex. The rates of pyrolysis of the solid alkyl-iron complexes[3] are proportional to the amounts of remaining **1**. The activation energy for the pyrolysis of $Fe(CH_3)_2(dipy)_2$ was estimated to be 23 kcal/mol, $Fe(C_2H_5)_2(dipy)_2$ 47—54 kcal/mol and $Fe(n\text{-}C_3H_7)_2(dipy)_2$ 16 kcal/mol. The variation of gaseous decopmosition products and of activation energies of the pyrolysis of the three alkyl-iron complexes suggest that the mechanism of pyrolysis in solid state is not simple.

The results of the reactions of **1** with various olefins are summarized in Table 1. Olefins are arranged in the decreasing order of Alfrey-Price's *e*-value which is considered to reflect the electronegativity of the olefin.[7] Except for the top three olefins, the olefins with large *e*-values were polymerized by **1**. The α,β-disubstituted olefins such as tetracyanoethylene (TCNE) and maleic anhydride (MAH) gave complexes containing a part of the dipyridyl ligands. The ethyl groups were absent in these complexes as proved by IR spectroscopy and methanolysis. Acrylamide has exceptionally high reactivity toward the iron complex and displaces both of the dipyridyl ligands. A similar behavior was observed in other cobalt-dipyridyl[8a] or phosphine complexes[8b]. In the case of vinyl chloride, C–Cl bond was cleaved and a complex of an approximate composition $Fe(dipy)_2Cl_2$ was obtained. With vinyl acetate (VAc) the iron complex gave a reddish purple solid with composition $Fe(dipy)(VAc)_2$ with extraordinarily low $\nu_{C=O}$ bands as compared with those of the free vinyl acetate. The vinyl acetate may be coordinated with iron through both double bond and the carbonyl group as in the case of nickel-vinyl acetate complex[3]. In most cases where olefin-coordinated iron complexes were obtained, purification of the complexes was difficult and the solid complexes appear to be mixtures of $Fe(dipy)_x(olefin)_y$ with different x and y values depending on the relative coordinating abilities of the dipyridyl and the olefin.

With olefins of large negative *e*-values no apparent reaction was observed, although spectral study revealed slow decomposition of **1** in some cases. Among olefins 2-vinylpyridine is exceptional in yielding a high polymer initiated by the alkyl-iron complex. As

8) a) A. Yamamoto, T. Yamamoto, and S. Ikeda, unpublished result; b) A. Yamamoto, Y. Kubo, and S. Ikeda, unpublished result.

in the case of vinyl acetate 2-vinylpyridine may coordinate to iron through both the double dond and the nitrogen of the pyridine ring, thus causing greater enhancement of the reactivity of the alkyl-iron bond.

Kinetics of Decomposition of $FeR_2(dipy)_2$ in Solution. On reactions of $FeR_2(dipy)_2$ with olefins, the deep blue color of the initial solutions turns brown or reddish brown both in polymerization and dealkylation reactions. The color change is considered to reflect the decomposition of the original complex, and the decomposition reaction was followed spectroscopically. As an example of the spectral study, the change of the electronic spectrum of $Fe(C_2H_5)_2(dipy)_2$ in solvents on addition of acrylonitrile is given in Fig. 1. The iron complex **1** decomposes very slowly in tetrahydrofuran even in the absence of olefin (*vide infra*), but the rate of decomposition is strikingly accelerated by the addition of olefins and the decomposition rate in the absence of olefins can be regarded negligible as compared with that in the presence of olefins.

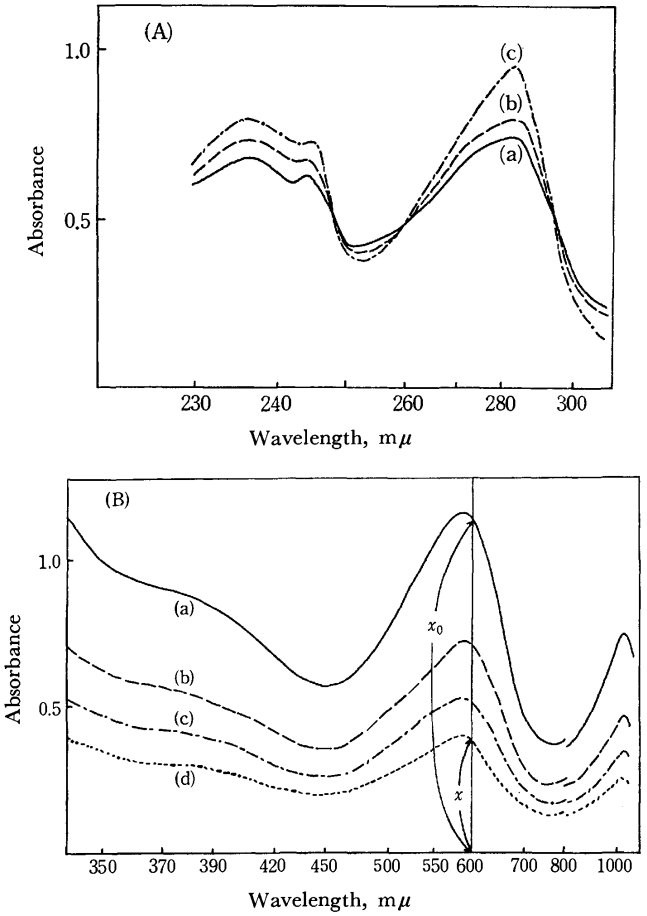

Fig. 1. Change of the ultraviolet (A) and visible spectra (B) of $Fe(C_2H_5)_2(dipy)_2$ by addition of acrylonitrile; (A) in diethyl ether at 24.3°C, [acrylonitrile] $= 1.5 \times 10^{-3}$ M, (a) 0 min, (b) 2.5 min, (c) 18 min,; (B) in tetrahydrofuran at 23.4°C, [acrylonitrile] $= 1.0 \times 10^{-3}$ M, (a) 0 min, (b) 3 min, (c) 6 min, (d) 9 min.

We assigned the two couples of absorption band of $Fe(C_2H_5)_2(dipy)_2$ **1** in UV (237, 282 mμ) and visible rgeions (590, 1010 mμ) to $\pi \rightarrow \pi^*$ excitation bands ($\varepsilon = 2 \times 10^4$) and $d \rightarrow \pi^*$ charge-transfer bands ($\varepsilon = 3 \times 10^3$)[3]. Since the final solution does not absorb

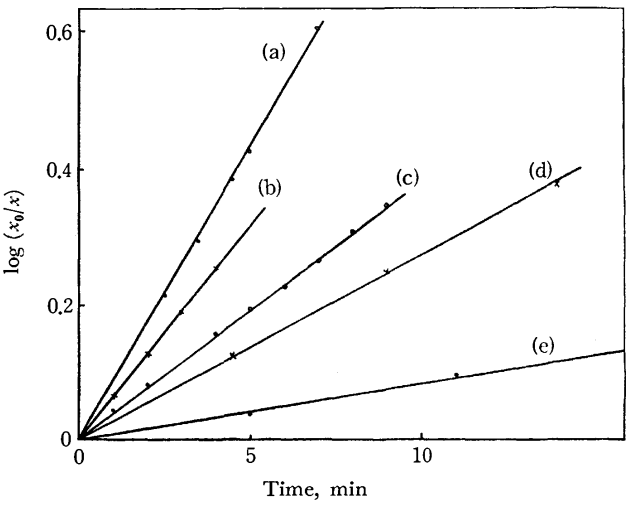

Fig. 2. Plots of log (x_0/x) (*cf.* Fig. 1) against time. (a): methyl acrylate (MA), 0.43 M, 22°C; (b): acrylonitrile (AN), 1.7×10^{-3} M, 22°C; (c): methyl vinyl ketone (MVK), 4.6×10^{-3} M, 23°C; (d): methacrylonitrile (MAN), 5.0×10^{-3} M, 23°C; (e): methyl methacrylate (MMA), 0.21 M. 24°C. solvent = tetrahydrofuran.

at 600 mμ after the reaction, we measured the rate of decomposition of **1** by observing the decrease of the absorbance at 600 mμ. The plots of log (x_0/x) values in Fig. 1 against time give linear relationships for various olefins (Fig. 2). The pseudo-first-order rate constants k were calculated from the slopes of the lines.

Rate of decomposition =

$$-\frac{d[Fe(C_2H_5)_2(dipy)_2]}{dt} = k[Fe(C_2H_5)_2(dipy)_2] \qquad (3)$$

Figure 3 indicates the variation of k with the concentrations of olefins. The k values change with the olefin concentration at low concentrations of olefin but level off at higher concentrations and approach a limiting value independent of the olefins. In the case of isobutyl vinyl ether (IBVE) k does not reach the limiting value even in bulk because of a very weak interaction of isobutyl vinyl ether with the iron com-

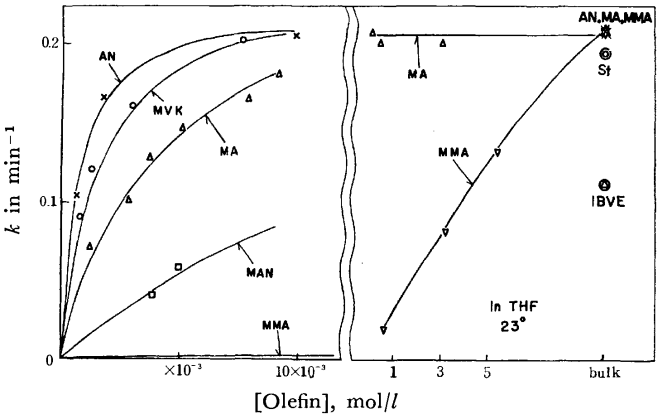

Fig. 3. Pseudo-first-order rate constant k *versus* concentration of olefin at 23°C; solvent = tetrahydrofuran. AN = acrylonitrile, MVK = methyl vinyl ketone, MA = methyl acrylate, MAN = methacrylonitrile, MMA = methyl methacrylate, St = styrene, and IBVE = isobutyl vinyl ether.

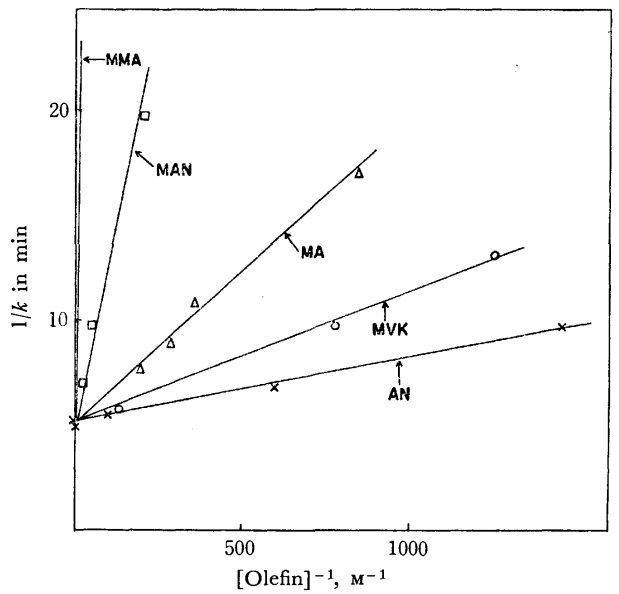

Fig. 4. The reciprocal plot for the data shown in Fig. 3.

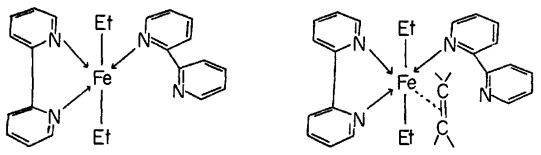
plex. The pattern as shown in Fig. 3 suggests an S_N1 mechanism. A similar pattern has been observed in the reaction of methyl manganese pentacarbonyl with nucleophiles.[9] The reciprocal plots of k against olefin concentrations give linear relationships as shown in Fig. 4. The results can be explained by assuming the following three-stage mechanism.

$$\underset{\mathbf{1}}{Fe(C_2H_5)_2(dipy)_2} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \underset{\mathbf{2}}{Fe(C_2H_5)_2(dipy)(dipy)^*} \quad (4)$$

$$\mathbf{2} + \text{olefin} \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} \underset{\mathbf{3}}{Fe(C_2H_5)_2(olefin)(dipy)(dipy)^*} \quad (5)$$

$$\mathbf{3} \xrightarrow{k_3} \text{decomposition products} \quad (6)$$

Since the initial complex $Fe(C_2H_5)_2(dipy)_2$ is coordinatively saturated and the kinetic results suggest an S_N1 mechanism, it is reasonable to assume a partial dissociation of dipyridyl ligands from **1** to make a coordination site available for the incoming olefin molecule. $Fe(C_2H_5)_2(dipy)(dipy)^*$ represents a partially dissociated species which may have a structure as shown below[10,11].



2 **3**

The complex may be either five-coordinated or have a solvent molecule in the sixth coordination position.

For complex **3** we assume an iron complex with an olefin coordinated through the double bond in analogy with that we observed in $Ni(C_2H_5)_2(dipy)(olefin)$.[3] The steady state approximation for the concentrations of **2** and **3** yields the rate equation:

$$\text{Rate} = -\frac{d[Fe(C_2H_5)_2(dipy)_2]}{dt} = k_3[\mathbf{3}]$$

$$= \frac{k_1k_2k_3[\text{olefin}][Fe(C_2H_5)_2(dipy)_2]}{k_{-1}(k_{-2}+k_3)+k_2k_3[\text{olefin}]} \quad (7)$$

The observed pseudo-first-order rate constant k is given by

$$k = \frac{k_1k_2k_3[\text{olefin}]}{k_{-1}(k_{-2}+k_3)+k_2k_3[\text{olefin}]} \quad (8)$$

$$\frac{1}{k} = \frac{1}{k_1} + \frac{k_{-1}(k_{-2}+k_3)}{k_1k_2k_3[\text{olefin}]} \quad (9)$$

The linear relationships between $1/k$ and $1/[\text{olefin}]$ and convergence of plots for different olefins into a single intercept as shown in Fig. 4 are in line with Eq. (9). Intercept $1/k_1$ is a function only of **1** and not of olefin. If we assume the partial dissociation of complex **1** into **2**, the frequency of dissociation can be estimated to be about 0.2/min. If we assume $k_{-2} \gg k_3$, as we observed in the decomposition of the olefin coordinated $Ni(C_2H_5)_2(dipy)$,[3] the reciprocal of the slope becomes $(k_1k_2k_3/k_{-1}k_{-2})$. Since the values k_1 and k_{-1} are functions only of the iron complexes **1** and **2** and not of olefin, the value $k_1k_2k_3/k_{-1}k_{-2}$ is proportional to the relative reactivity of olefin.

Concerning activation of Ni–R bonds by coordination of olefins we observed that electronegative olefins activate the Ni–R bonds more strongly than less electronegative olefins and that the rate constants (k_{Ni}) for decomposition of $NiR_2(dipy)$ are larger in reactions of $NiR_2(dipy)$ with more electronegative olefins. If we assume a similar mechanism of activation for the Fe–Et bond as in Eqs. (5) and (6), we can expect a parallel relation between the k_{Ni} value for the ethyl-nickel complex and the $k_1k_2k_3/k_{-1}k_{-2}$

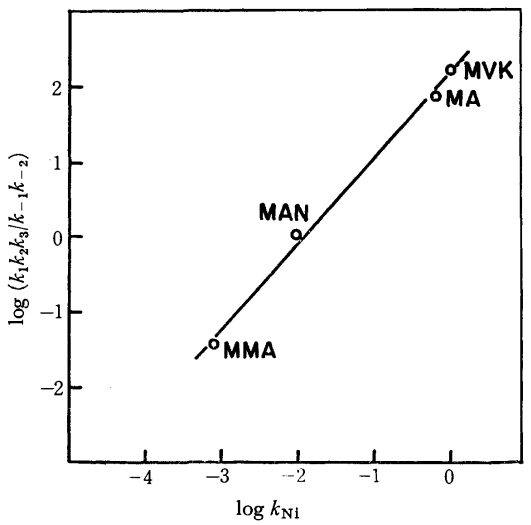


Fig. 5. Plot of log $(k_1k_2k_3/k_{-1}k_{-2})$ obtained from the reciprocal slopes of the lines in Fig. 4 against log k_{Ni} where k_{Ni} is a rate constant for the decomposition of $NiEt_2(dipy)$.[3]

9) B. J. Mawby, F. Basolo, and R. G. Pearson, *J. Amer. Chem. Soc.*, **86**, 3994 (1964).

10) A similar species was assumed in an acid-catalyzed replacement of a dipyridyl ligand from $Fe(dipy)_3^{2+}$, F. Basolo, J. C. Hayes, and H. M. Neuman, *J. Amer. Chem. Soc.*, **75**, 5102 (1953).

11) This is a partial revision of our mechanism[5,6] in which complete dissociation of one dipyridyl ligand was postulated.

value for the ethyl-iron complex. Figure 5 clearly demonstrates that a similar factor operates both in the activation of the nickel–ethyl and iron–ethyl bonds.

1 is stable in the solid state, but slowly decomposes in solution with evolution of ethane and ethylene even in the absence of olefins. The composition of the dark violet decomposition product obtained approximately agreed with the structure $Fe(dipy)_2$.[2b] The ethyl-iron bonds and hydrogen-iron bond, which might be formed through a hydrogen extraction from the ethyl group by iron, were not detected in the decomposition product. The decomposition rate depends on the nature of the solvent as shown in Fig. 6. The decomposition rate was higher in a solvent of greater coordinating ability. Decomposition was not detectable in diethyl ether and *n*-hexane.

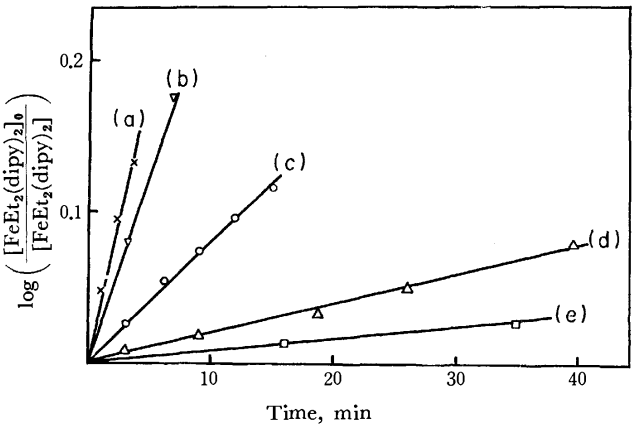

Fig. 6. Decomposition of $Fe(C_2H_5)_2(dipy)_2$ in solvents. (a): acetonitrile, 24.6°C; (b): dimethylformamide (DMF), 24.6°C; (c): Acetone, 23.5°C; (d): DMF, 22.4°C, containing dipyridyl (0.0137 M); (e): tetrahydrofuran, 25.6°C.

We observed a blue shift of the charge-transfer bands of $Ni(C_2H_5)_2(dipy)$ in solvents of strong coordinating ability, and explained this shift as the lowering of the energy of the *d*-orbitals of nickel through the coordination of solvent[3]. We have further postulated that an electron excitation from a σ_{Ni-C} orbital to a vacant *d*-orbital of nickel is a necessary step for the activation of the Ni–C bond. In the case of $Ni(C_2H_5)_2(dipy)$, however, the lowering of the *d*-level by coordination of the solvent was not sufficient to induce scission of the very stable Ni–C bond, whereas olefins with electronegative substituents caused the scission. If we assume that a similar factor operates in determining the activation of the iron-carbon as in nickel-carbon bond and take a smaller activation energy for the pyrolysis of $Fe(C_2H_5)_2(dipy)_2$ (about 50 kcal/mol) compared with the one for the corresponding ethyl-nickel complex (68 kcal/mol) into account, the easier scission of the Fe–Et bond in strongly coordinating solvents can be explained by the lowering of the energy of the vacant *d*-orbital of the iron complex. The decomposition rates of **1** in solvents are proportional to the concentration of **1** (Fig. 6). The decreasing order of the first-order rate constants was in line with that of the magnitude of the blue shifts of

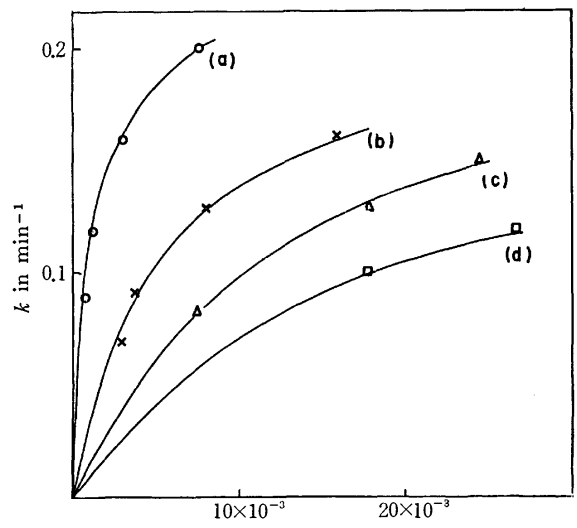

Fig. 7. Effect of the concentration of dipyridyl added on the pseudo-first-order rate constant k for the decomposition of $FeEt_2(dipy)_2$ in tetrahydrofuran at 23°C. (a): [dipy]= 0 mol/*l*, (b): 1.4×10^{-3} mol/*l*, (c): 2.31×10^{-3} mol/*l*, (d): 3.88×10^{-3} mol/*l*.

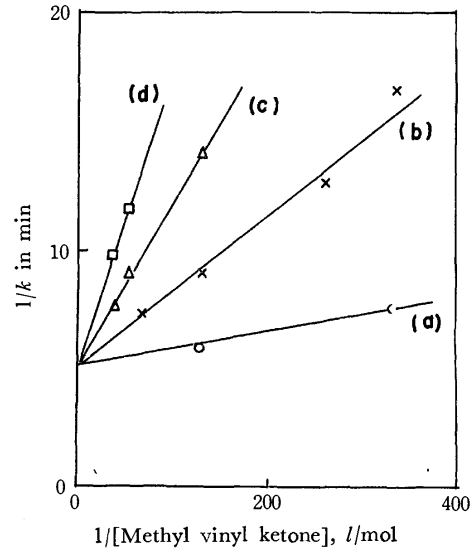

Fig. 8. The reciprocal plot for the data shown in Fig. 7.

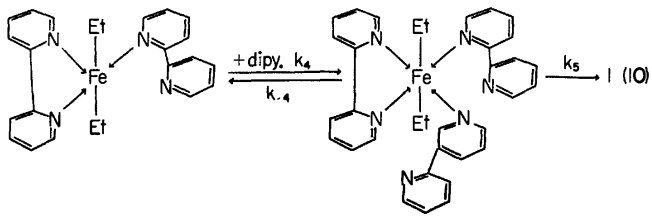
$Ni(C_2H_5)_2(dipy)$ caused by coordination of solvents: acetonitrile>dimethylformamide>acetone>tetrahydrofuran>ether, *n*-hexane.

Addition of dipyridyl to the reaction systems hinders the decomposition of $Fe(C_2H_5)_2(dipy)_2$ in the absence of olefin (Fig. 6, curve (d)) as well as in the presence of olefins (Fig. 7). The decomposition rates are still proportional to concentrations of $Fe(C_2H_5)_2(dipy)_2$. Figure 8 shows $1/k$ *versus* 1/[olefin] plots for the data shown in Fig. 7. Since the intercept is common to all lines in Fig. 8, the effect of dipyridyl can be explained in terms of a competitive coordination of dipyridyl with olefin and solvent to **2** to form a complex **4** which may be in equilibrium with **2**. Complex **4** may be converted directly into **1** through the process given below:



2 4

Using the steady-state approximation for concentrations of the intermediate complexes **2**, **3** and **4**, we get the rate equation:

$$\text{Rate} = -\frac{d[FeEt_2(dipy)_2]}{dt} = k_3[\mathbf{3}]$$

$$= \frac{k_1k_2k_3[\text{olefin}][FeEt_2(dipy)_2]}{k_{-1}(k_{-2}+k_3)+k_2k_3[\text{olefin}]+\dfrac{k_4k_5(k_{-2}+k_3)[\text{dipy}]}{k_{-4}+k_5}} \quad (11)$$

When k_{-2} is much greater than k_3, the observed pseudo-first-order rate constant k is given by:

$$k = \frac{k_1k_2k_3[\text{olefin}]}{k_{-1}k_{-2}+k_2k_3[\text{olefin}]+\bar{k}[\text{dipy}]} \quad (12)$$

where $\bar{k}=k_{-2}k_4k_5/(k_{-4}+k_5)$. The plots of $1/k$ against $1/[\text{olefin}]$ with varying concentrations of dipyridyl added (Fig. 8) substantiate the validity of Eq. (12). The intercept of the lines is $1/k_1$ and the slopes are $(k_{-1}k_2+\bar{k}[\text{dipy}])/k_1k_2k_3$. The effect of variation of the added dipyridyl concentration on the slopes in Fig. 8 is shown in Fig. 9. The linear relationship confirms Eq. (12).

The intercepts of the lines in Fig. 9 represent $k_{-1}k_{-2}/k_1k_2k_3$ values in the absence of added dipyridyl and the slopes $\bar{k}/k_1k_2k_3$. The results are in line with the postulated mechanism expressed by Eqs. (4), (5), (6), and (10), where spontaneous partial dissociation of dipyridyl forming **2** and the succeeding competitive coordination of olefin, solvent, and dipyridyl to **2** are assumed.

When a very polar solvent was employed in place of tetrahydrofuran and extra dipyridyl was not added to the solution, $Fe(C_2H_5)_2(dipy)_2$ decomposed at an appreciable rate even in the absence of olefin. Accordingly we could not obtain the *k versus* [olefin] relationship as shown in Fig. 3 in the polar solvent with no dipyridyl in the solution. When extra dipyridyl was added to the solution, the decomposition of $Fe(C_2H_5)_2(dipy)_2$ caused by the interaction of the polar solvent was hindered and the normal *k versus* [olefin] pattern was obtained.

With $Fe(CH_3)_2(dipy)_2$ and $Fe(n\text{-}C_3H_7)_2(dipy)_2$, similar kinetic patterns as in Fig. 3 have been obtained. The liniting k_1 values with the series of $FeR_2(dipy)_2$ were 0.27 min^{-1} for the propyl, 0.21 for the ethyl, and 0.013 for the methyl complexes. We previously found a linear relation between the inductive effect of the alkyl groups and the highest occupied energy level of $NiR_2(dipy)_2$, and discussed the influence of the alkyl groups on the reactivity of the complexes.[3] We see a similar linear relation between the rate constant k_1 and σ^* value proposed by Taft[12] in Fig. 10. The decrease in the partial dissociation rate of one dipyridyl ligand influenced by the decrease of the inductive effects of the alkyl groups is understandable if the decreasing stability of amine complexes with decreasing electronegativity of a transition metal[13] is taken into account.

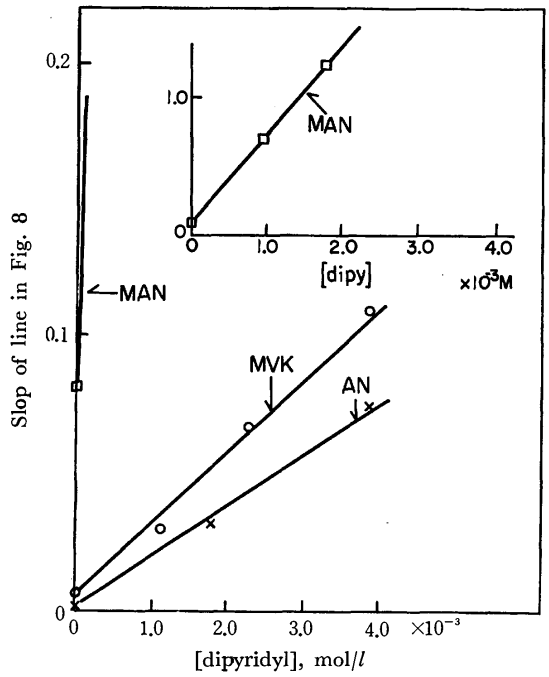


Fig. 9. Plot of the slopes of lines in Fig. 8 against the dipyridyl concentration, (○) for methyl vinyl ketone; analogous plots for methacrylonitrile (□) and acrylonitrile (×).

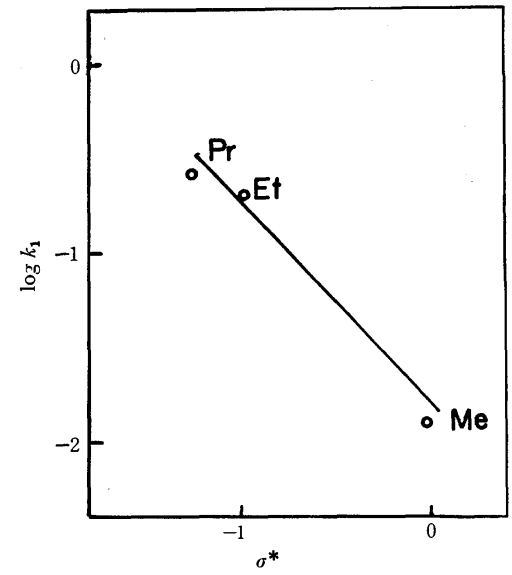

Fig. 10. Relation between the rate constant k_1 and σ^*.

Experimental

I. Materials and General Procedures. $Fe(C_2H_5)_2(dipy)_2$ was prepared by the method reported previously.[2] $Fe(CH_3)_2(dipy)_2$ and $Fe(C_3H_7)_2(dipy)_2$ were prepared in an analogous way. Found: C, 65.8; H, 5.73; N, 13.8%. Calcd for $C_{22}H_{22}N_4Fe$: C, 66.3; H, 5.57; N, 14.1%. Found: C, 67.8; H, 6.65; N, 12.2%. Calcd for $C_{26}H_{30}N_4Fe$: C, 68.8; H, 6.61; N, 12.3%. Olefins and solvents were purified and stored, and general procedures and techniques were almost the same as previously reported.[3] Because of the lack of suitable procedures for purification, some complexes can not be claimed very pure. However, structures which are consistent with the analytical data are given.

II. Reactions of $Fe(C_2H_5)_2(dipy)_2$ with Olefin and Isolations of Olefin-Coordinated Iron Complexes. *1. Tetracyanoethylene (TCNE)*: Ether (10 m*l*) was distilled in a vacuum into a reaction vessel containing 1.58 g of $Fe(C_2H_5)_2(dipy)_2$ (3.7 mmol) and 1.52 g of tetracyanoethylene (12 mmol). The mixture was allowed to react at room temperature for a day. The composition of the gas evolved was ethane, ethylene, and butane in a molar ratio of 1 : 1 : 0.1. The dark brown precipitate was filtered, washed many times with ether, and dired in a vacuum. The dark brown solid was insoluble in almost all organic solvents. The yield of the solid was almost quantitative. Found: C, 59.3; H, 2.16; N, 25.4%. Calcd for $Fe(dipy)_2(TCNE)_2$: C, 61.4; H, 2.56; N, 26.9%.

2. Maleic anhydride (MAH): A mixture of 0.60 g (1.4 mmol) of $Fe(C_2H_5)_2(dipy)_2$ and 4.2 g (43 mmol) of maleic anhydride in 10 m*l* of ether was allowed to react at room temperature for 20 hr. The gas evolved consisted of ethane, ethylene, and butane in a molar ratio of 0.1 : 1 : 1. The red solid was filtered, washed many times with ether and dried in a vacuum. The yield was almost quantitative. Found: C, 51.1; H, 2.52; N, 3.97%. Calcd for $Fe(dipy)(MAH)_4$: C, 51.5; H, 2.64; N, 4.61%.

3. Acrylamide (AcAm): A mixture of 0.38 g (0.89 mmol) of $Fe(C_2H_5)_2(dipy)_2$ and 2.0 g (28 mmol) of acrylamide in 40 m*l* of ether was allowed to react at room temperature for a day. The deep blue color of $Fe(C_2H_5)_2(dipy)_2$ turned reddish brown in 2 or 3 hr. The gas evolved consisted of ethane and ethylene in a molar ratio of 1 : 1. The reddish brown precipitate was filtered, washed, and dried under vacuum. The IR spectrum of the complex gave no peak characteristic of dipyridyl complexes. Found: C, 37.0; H, 4.12; N, 12.8%. Calcd for $Fe(AcAm)_2$: C, 36.4; H, 5.05; N, 14.1%.

4. Polymerization of Acrylonitrile (AN), Methacrylonitrile (MAN), Acrolein (AC), Methyl Vinyl Ketone (MVK), Methyl Acrylate (MA), Methyl Methacrylate (MMA), and 2-Vinylpridine (2-Vi-Py): These olefins were polymerized with $Fe(C_2H_5)_2(dipy)_2$. Temperatures when polymerization started were $-30°C$ for acrylonitrile, $-20°C$ to $-10°C$ for methacrylonitrile, acrolein, 2-vinylpyridine and methyl vinyl ketone, 20°C for methyl acrylate and methyl methacrylate. The compositions of the gases evolved were ethane and ethylene in ratios of 1 : 1~2.5.

5. Vinyl Chloride (VCl): Dry vinyl chloride was introduced into tetrahydrofuran solution (30 m*l*) containing 0.50 g (1.2 mmol) of $Fe(C_2H_5)_2(dipy)_2$. The deep blue color of $Fe(C_2H_5)_2(dipy)_2$ turned dark red in a day at room temperature. The dark red precipitate was filtered, washed with benzene, and dried in a vacuum. Found: C, 50.5; H, 3.63; N, 10.9; Cl, 21.7%. Calcd for $Fe(dipy)_2Cl_2$: C, 55.5; H, 3.66; N, 12.8; Cl, 16.7%. Calcd for $Fe(dipy)Cl_3$: C, 37.4; H, 2.49; N, 8.72; Cl,33.2%. As judged from analytical data, the solid is considered to be a mixture of $Fe(dipy)_2Cl_2$ and $Fe(dipy)Cl_3$ in a molar ratio of about 3 : 1.

6. Vinyl acetate (VAc): Vinyl acetate (5.5 m*l*, 59 mmol) was distilled *in vacuo* into a flask containing 0.91 g (2.1 mmol) of $Fe(C_2H_5)_2(dipy)_2$. The mixture was allowed to react for 3 days at room temperature. The reddish purple solid was filtered and recrystallized from acetone. The gas evolved consisted of ethane and ethylene in a molar ratio of 1 : 3. Found: C, 58.5; H, 5.04; N, 8.23%. Calcd for $Fe(dipy)(VAc)_2$: C, 56.2; H, 5.21; N, 7.31%.

7. Styrene (St), Isobutyl vinyl ether (IBVE), and Ethylene (E): No apparent change took place. Polymer was not obtained when $Fe(C_2H_5)_2(dipy)_2$ was treated with St, IBVE, or E for a few days at room temperature.

III. Spectral Measurements. The infrared spectra were obtained with a Shimadzu model IR 27C or Hitachi Model EPI-G3. Visible and ultraviolet spectra were recorded on a Shimadzu SV-50A spectrometer. When necessary, the temperature was controlled within 0.5°C by circulating water of a constant temperature around the cuvette.

IV. Analysis. The microanalysis of carbon, hydrogen, and nitrogen was performed by Mr. T. Saito of our laboratory with a Yanagimoto CHN Autocorder Type MT-2. Considerable difficulties were encountered in the microanalysis of unstable complexes.

The Mechanism of Vinyl Polymerization by Dialkylbis(dipyridyl)iron(II)

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro, Tokyo

(Received May 19, 1971)

Kinetics of polymerization of vinyl compounds (acrylonitrile, methacrylonitrile, acrolein, methyl vinyl ketone, methyl acrylate, alkyl methacrylates, and 2-vinylpyridine) with dialkylbis(dipyridyl)iron(II), $FeR_2(dipy)_2$ **1** (R= CH_3, C_2H_5, n-C_3H_7), was studied. By comparison with previous kinetic results in which the decomposition of **1** was followed spectroscopically, a polymerization mechanism including a slow initiation process followed by rapid propagation and unimolecular termination processes was proposed. The effects of the concentration of monomer, the addition of dipyridyl and the coordinating ability of solvent on the molecular weight of the polymer were explained by competitive coordination to the iron complex having a growing polymer chain. Results of copolymerization experiments were explained in terms of competitive coordination and insertion reactions between the monomers involved. A linear relationship was found between $\log(1/r_1)$ values and the logarithms of stability constants of nickel–olefin π-complexes with methacrylonitrile as the reference (M_1). From the formation of C_2H_5D in the polymerization of β-*cis*-d_1-methyl methacrylate with $Fe(C_2H_5)_2(dipy)_2$ a unimolecular termination process involving abstraction of β-hydrogens of the growing chain by the alkyl group or the iron complex was proposed.

Although great efforts have been made to unravel the mechanism of coordination polymerization by Ziegler type catalysts, the inherent complexity and instability of the mixed catalyst systems prepared *in situ* have hindered the drawing of a clear-cut conclusion on the kinetic results.[1]. Recently kinetic studies have been carried out successfully on the polymerization mechanisms of vinyl monomers[2] and butadiene[3] using isolated π-allyl-transition metal complexes. We have been studying the properties of isolated alkyl-nickel, cobalt, and iron complexes[4] which are thermally stable and appropriate for studies[5] on catalytic reactions of unsaturated conpounds. Our attention was focused on the activation mechanism of alkyl-iron bonds by interaction of dialkylbis(dipyridyl)-iron(II) with various olefins.[6] In this paper we deal mostly with the propagation and termination mechanisms. Vinyl polymerization by alkyl-iron and cobalt complexes has been communicated briefly.[7] NMR studies on the propagation mechanism have also been reported.[8]

Results and Discussion

Kinetics of Polymerization. The results of polymerization of various monomers with $FeR_2(dipy)_2$ are summarized in Table 1 where R=CH_3, C_2H_5, and n-C_3H_7. The monomers are arranged in decreasing order of Afrey-Price "*e*-value"[9]. The Table indicates a general trend, except for 2-vinylpyridine[6], for monomers with higher *e*-values to polymerize readily, monomers with medium *e*-values to polymerize slowly, and the polymerization of monomers with low or negative *e*-values to proceed either slowly or not take place. These monomers are not polymerized with dipyridyl alone; dipyridyl-iron complexes without R–Fe bonds such as $Fe(dipy)_2$[4], $Fe(dipy)_3$[4] and $Fe(dipy)(vinyl\ acetate)_2$[6] do not initiate polymerization. Methacrylic esters present an interesting intermediate case. Methyl methacrylate (*e*-value= 0.40) can be polymerized by $FeR_2(dipy)_2$ (R=CH_3, C_2H_5, C_3H_7), whereas less electronegative ethyl methacrylate (*e*-value=0.17) can be polymerized by $Fe(n\text{-}C_3H_7)_2(dipy)_2$ but not by the methyl and ethyl homologs (a negligible amount of polymer was obtained with $Fe(CH_3)_2(dipy)_2$). The results clearly indicate the important role of the alkyl-iron bond in the initiation process. In accordance with observation on the activation of alkyl-nickel bonds by interaction with olefins[5], the propyl-iron bond seems to be more easily activated than methyl- and ethyl-iron bonds. Once the polymerization is initiated by activation of the alkyl-iron bond through interaction with a monomer having a more electronegative substituent, a monomer with a less electronegative substituent can be taken into the copolymer; thus, ethyl methacrylate and methacrylonitrile were copolymerized with $Fe(C_2H_5)_2(dipy)_2$, but not ethyl methacrylate.

Figure 1 shows a typical time-conversion curve of the polymerization of acrylonitrile with $Fe(C_2H_5)_2$-$(dipy)_2$ and the dependence of molecular weight of the polymer on conversion. The polymerization was carried out in the presence of extra dipyridyl added in order to control the polymerization rate. Since the polymerization yield is low, the concentration of acrylo-

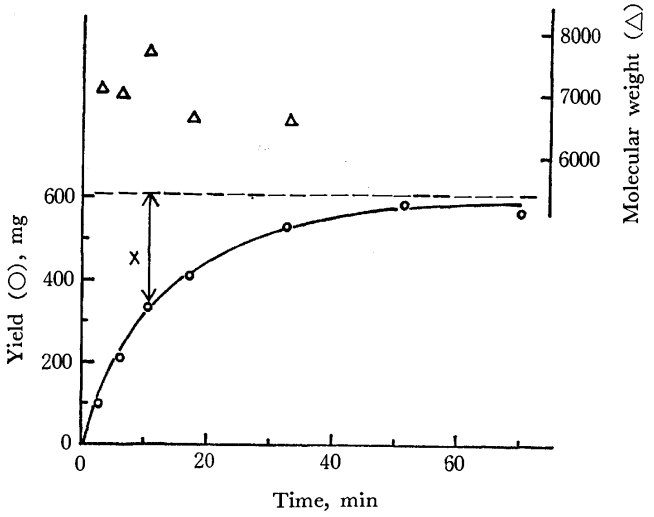

Fig. 1. Polymerization of acrylonitrile with $Fe(C_2H_5)_2(dipy)_2$ at 27.5°C; yield (○) *versus* time and molecular weight (△) of the polymer *versus* time. Acrylonitrile= 12.6 m*l*; dimethylformamide = 51 m*l*; $Fe(C_2H_5)_2(dipy)_2$= 0.19 g; dipyridyl = 1.24 g.

nitrile can be regarded to be constant during the polymerization. Figure 1 indicates that the molecular weight of the polymer is virtually independent of time. As our spectroscopic study revealed[6], the concentration of $Fe(C_2H_5)_2(dipy)_2$ decreases with time in the presence of an olefin. The decrease of the concentration of the ethyl-iron complex should be responsible for the decrease of the polymerization rate. In fact the polymerization stops when the deep blue color of $Fe(C_2H_5)_2(dipy)_2$ disappears. Since the molecular weights of the polymers obtained at different conversions remain virtually constant, the yield of the polymer can be regarded as proportional to the number of polymer chains. The number of polymer chains produced from a single ethyl-iron complex (initiator efficiency) is shown in Table 2. The initiator efficiency increases with the increase of the monomer concentration approaching unity. The polymer yield is thus considered to be proportional to the ethyl-iron complex decomposed at a certain monomer concentration. If we plot the logarithms of the value x (Fig. 1) *versus* time a linear relationship is observed (Fig. 2) indicating the validity of the following equation.

$$-\frac{dx}{dt} = \bar{k}x \qquad (1)$$

The value x can be regarded to correspond to the remaining concentration of the ethyl-iron complex. The change of the slope $\bar{k}$ (Fig. 2) against the acrylonitrile concentration is plotted in Fig. 3. The value $\bar{k}$ increases with the increase of the acrylonitrile concentration approaching a limiting value of 0.2 min^{-1} in the presence of a small amount of dipyridyl added. Addition of a large amount of dipyridyl suppresses

a) [Monomer] = concentration of the monomer; AN = acrylonitrile; MMA = methacrylate. Solvent: dimethylformamide for acrylonitrile and tetrahydrofuran for methyl methacrylate.
b) [dipy] = concentration of added dipyridyl.
c) The number of polymer chains produced from a single ethyl-iron complex (initiator efficiency).
d) Since the molecular weights of the polymers in these cases were very low, only approximate values could be obtained by viscometry.

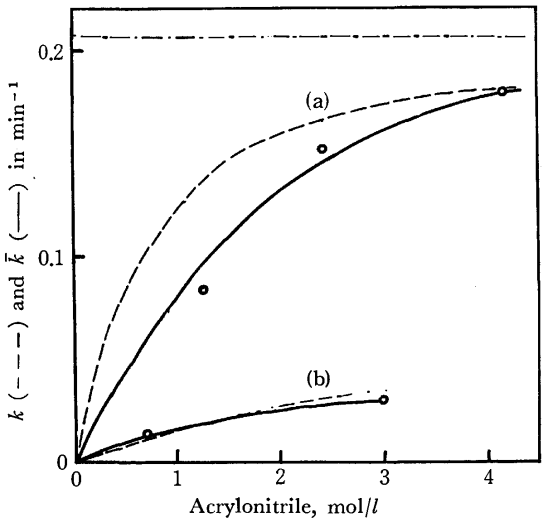

Fig. 3. Pseudo-first-order rate constants, k and $\bar{k}$, against the concentration of acrylonitrile at 23°C. (a), Concentration of dipyridyl was 7.2×10^{-3} mol/l; (b), Concentration of dipyridyl was about 0.14 mol/l. For k and $\bar{k}$ see the text. Solvent: dimethylformamide

the polymerization rate as shown by (b) in Fig. 3. We see a striking resemblance between this and the decomposition pattern of $Fe(C_2H_5)_2(dipy)_2$.[6] In Fig. 3 are also shown the change of pseudo-first-order rate constants k for decomposition of $Fe(C_2H_5)_2(dipy)_2$ with the concentrations of monomers (*cf.* Fig. 3 of the preceding paper[6]). The agreement between the rate constants indicates that the rate of polymerization of acrylonitrile by $Fe(C_2H_5)_2(dipy)_2$ is proportional to the decomposition rate of the ethyl-iron complex. This result implies that the initiation is the rate-determining step followed by rapid propagation and termination processes. The molecular weight of the polymer is independent of the initiator concentration[7] but is affected by the monomer concentration, the

Table 3. Effects of solvent on the molecular weight of poly(methyl methacrylate) at 30°C. Catalyst = $Fe(C_2H_5)_2(dipy)_2$. [dipy] = 0 $[Fe(C_2H_5)_2(dipy)_2] = 23\sim28$ mmol/l

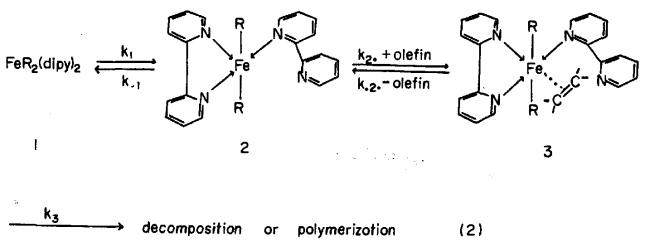
coordinating ability of the solvent employed and the concentration of dipyridyl added. Table 3 shows the effect of solvent on the molecular weight of poly(methyl methacrylate). Employment of a strongly coordinating solvent decreases the molecular weight of the polymer obtained. Table 2 shows that the molecular weight of the polymer increases with monomer concentration but decreases with the increase of dipyridyl concentration. These results suggest the competitive coordination of the monomer, dipyridyl and solvent toward an iron complex with a growing polymer chain.

Dealing with the kinetics of decomposition of $FeR_2(dipy)_2$ we assumed the following activation mechanism of the metal-alkyl bond:[6]



If the above mechanism is valid, an inhibiting effect

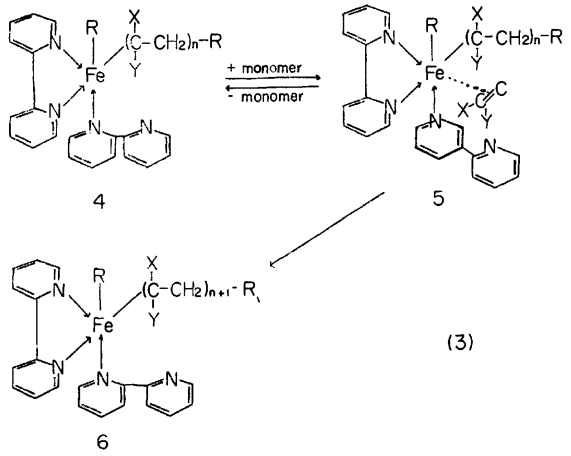
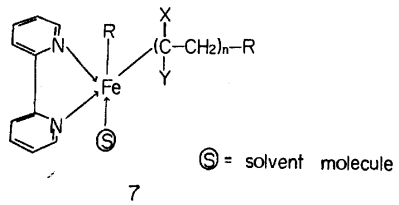
a) THF: tetrahydrofuran; DMF: dimethylformamide.

of dipyridyl for polymerization is expected. Table 4 substantiates this expectation showing that the polymerization of methyl methacrylate was completely inhibited and that of acrylonitrile severely retarded by the addition of dipyridyl.

If the polymerization proceeds through an insertion mechanism[7], the coordinated monomer is inserted between one of the two iron-alkyl bonds in complex **3** generating a growing species **4** ($n=1$) as shown below.



Propagation processes might proceed further by coordination and insertion reactions of monomer molecules as shown in Eq. (3). The partially dissociated dipyridyl ligand may remain attached to iron as in **4**, **5**, and **6**, but the possibility that one dipyridyl is completely displaced as shown below can not be excluded.



We observed the effects of solvents and alkyl groups on the stereoregularity of methyl methacrylate polymer and the presence of a penultimate effect on the polymer configurations[8]. Penultimate effects in solvents of low coordinating abilities were explained by assuming a species in which a coordination site is occupied by the substituent of the penultimate unit displacing the solvent molecule in **7**. The role of the singly bonded dipyridyl ligand in **4** may be similar at that of a solvent in **7**. If the explanation is reasonable we can anticipate that the proportion of acetone-insoluble stereoblock polymers produced by a propagation process involving a penultimate effect[8] will decrease by the addition of dipyridyl. Table 5 supports this view.

TABLE 5. EFFECT OF DIPYRIDYL ON THE FORMATION OF ACETONE-INSOLUBLE POLY(METHYL METHACRYLATE)

Dipyridyl added (g)	$Fe(C_2H_5)_2(dipy)_2$ (g)	Acetone-insoluble fraction (%)
0	0.50	10.7
0	0.81	7.56
0.30	0.67	2.90
0.30	0.68	5.06
0.50	1.45	2.18

Methyl methacrylate = 10 ml, Benzene = 20 ml, Temperature = 30°C, Time = 2 days.

For an explanation of the difference in stereochemical configuration of poly(methyl methacrylate) obtained with $Fe(CH_3)_2(dipy)_2$ and $Fe(C_2H_5)_2(dipy)_2$, we previously assumed a difference in steric effects between the methyl and ethyl groups bonded to iron. However, an inductive effect of the alkyl group may also be involved. The higher rate constant (k_1) for the breakage of one Fe–N bond of dipyridyl from $Fe(C_2H_5)_2(dipy)_2$ than for the methyl homolog has been explained by the inductive effect of the alkyl group in the preceding paper[6]. If a similar situation holds in the complete dissociation of one dipyridyl ligand from **4** giving **7**, the formation of an acetone-insoluble poly(methyl methacrylate) will be favored for the ethyl-iron complex than for the methyl complex in agreement with the experimental result that the acetone-insoluble stereoblock polymer was obtained with the ethyl complex but not with the methyl homolog.[8]

Copolymerization. We observed previously that acrylonitrile unit is introduced into a polymer chain preferentially to methyl methacrylate which has a less coordinating ability toward the iron complex[7]. We deal herewith with more quantitative aspect of copolymerization. From copolymerization experiments

TABLE 6. MONOMER REACTIVITY RATIOS IN COPOLYMERIZATIONS OF VINYL MONOMERS WITH $Fe(C_2H_5)_2(dipy)_2$.

M_1	M_2	r_1	r_2	$r_1 \times r_2$

Acrylonitrile	Methyl methacrylate	25±5	0.09±0.04	2.6 ±1.6

of vinyl monomers with $Fe(C_2H_5)_2(dipy)_2$, monomer reactivity ratios were obtained by using Fineman-Ross' method[10]. The values are summarized in Table 6.

The results can be explained by assuming the competitive coordination to the iron complex and the ensuing insertion reactions between metal-carbon bonds.

$$\begin{aligned}
&\text{Fe-m}_1\text{-}\sim + \text{M}_1 \underset{k_{11}^{(-1)}}{\overset{k_{11}^{(1)}}{\rightleftharpoons}} \text{Fe-m}_1\text{-}\sim \overset{k_{11}^{(2)}}{\longrightarrow} \text{Fe-m}_1\text{-m}_1\text{-}\sim \\

&\qquad\qquad\qquad\quad \vdots \\
&\qquad\qquad\qquad\quad \text{M}_1 \\
&\text{Fe-m}_2\text{-}\sim + \text{M}_2 \underset{k_{22}^{(-1)}}{\overset{k_{22}^{(1)}}{\rightleftharpoons}} \text{Fe-m}_2\text{-}\sim \overset{k_{22}^{(2)}}{\longrightarrow} \text{Fe-m}_2\text{-m}_2\text{-}\sim \\
&\qquad\qquad\qquad\quad \vdots \\
&\qquad\qquad\qquad\quad \text{M}_2
\end{aligned} \tag{4}$$

$$k_{11} = \frac{k_{11}^{(1)}k_{11}^{(2)}}{k_{11}^{(-1)}},\quad k_{12} = \frac{k_{12}^{(1)}k_{12}^{(2)}}{k_{12}^{(-1)}},\quad k_{21} = \frac{k_{21}^{(1)}k_{21}^{(2)}}{k_{21}^{(-1)}},\quad k_{22} = \frac{k_{22}^{(1)}k_{22}^{(2)}}{k_{22}^{(-1)}} \tag{5}$$

$$r_1 = \frac{k_{11}}{k_{12}},\quad r_2 = \frac{k_{22}}{k_{21}} \tag{6}$$

In these equations dipyridyl ligands and the other alkyl group are omitted for the sake of simplification. M_1 and M_2 are coordinating monomers and m_1 and m_2 represent monomer units taken into the polymer chains. We found a linear relationship between log k_{Ni}, the logarithms of rate constants for the scission of Ni–R bonds of $NiR_2(dipy)$, and log K, the logarithms of stability constants of Ni(dipy)(olefin)[5]. We have also found a linear relationship between the log k_{Ni} value for Ni–R scission and log $(k_1k_2k_3/k_{-1}k_{-2})$ which represent the relative reactivities of olefins for the decomposition of $FeR_2(dipy)_2$ (*cf.* Eq. (2),[9] and Fig. 5 of the preceding paper[6]). From these two relationships, a linear relationship between log K and log $(k_1k_2k_3/k_{-1}k_{-2})$ can be derived; $\log(k_1k_2k_3/k_{-1}k_{-2}) = 2.4\log K - 4.3$. Therefore, it is reasonable to assume a linear relationship between log K and the logarithms of rate constants, k_{ij}, for insertion of a monomer (j) into the iron-carbon bond of the preceding monomer unit (i) already introduced into the polymer chain. These assumptions lead to the following relationships.

$$\begin{aligned}
\log k_{11} - \log k_{12} &= a_1(\log K_1 - \log K_2) \\
\log k_{21} - \log k_{22} &= a_2(\log K_1 - \log K_2)
\end{aligned} \tag{7}$$

where a_1 and a_2 are constants depending on the nature of the Fe–m_1 and Fe–m_2 bonds into which the coordinated monomer is to be inserted. From these equations $1/r_1$ and $r_1 \cdot r_2$ can be expressed as follows.

$$\log 1/r_1 = a_1(\log K_2 - \log K_1) \tag{8}$$

$$\log (r_1 \cdot r_2) = (a_1 - a_2)(\log K_1 - \log K_2) \tag{9}$$

10) M. Fineman and S. Ross, *J. Polymer Sci.*, **5**, 259 (1950).

Figure 4 shows the plot of log $1/r_1$ *versus* (log K_2—log K_1), where M_1 is methacrylonitrile chosen as the reference. The roughly linear relationship supports Eq. (8) and demonstrates a unique characteristic of the coordination polymerization. It can be seen from a comparison of r_1 values in Table 6 that the relative reactivity of methacrylonitrile is 0.17 of that of acrylonitrile and 4.2 times of that of methyl methacrylate. If we assume the validity of the proposed coordination mechanism the relative reactivity of acrylonitrile to methyl methacrylate is expected to be 25 in good agreement with the experimental value of 25±5.

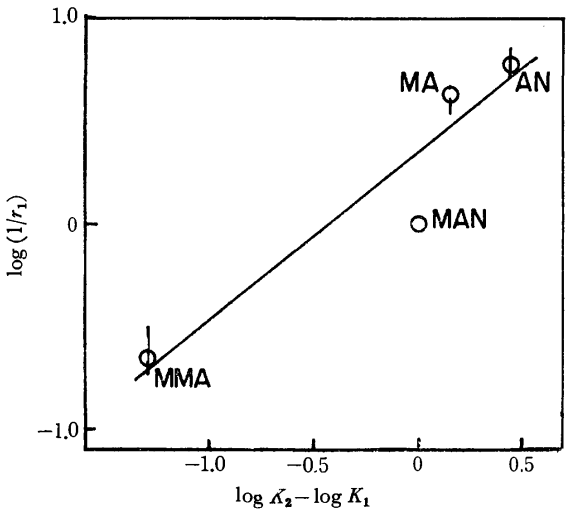

Fig. 4. Copolymerization of methacrylonitrile with olefins. M_1=methacrylonitrile as a reference. K represents the stability constant of the nickel–olefin π complex.[5]

Natta *et al.*[11] observed that $r_1 \cdot r_2$ values are very close to unity in the copolymerization of styrene derivatives with mixed catalysts prepared from aluminum alkyls and titanium halides and that log r_2 values are inversely proportional to the Hammett constants of the substituents. In our system log r_2 or log $1/r_1$ values increase with the increase of the Hammett constants of the substituent and hence with the increase of the log K values, but the $r_1 \cdot r_2$ values show significant deviations from unity. If a_1 should be equal to a_2 (Eq. (9)), $r_1 \cdot r_2$ should be unity. The observed deviations in our system suggest the considerable effects of the ultimate units in the growing polymer chains.

Termination Mechanism. The fact that molecular weights of poly(acrylonitrile) and poly(methyl methacrylate) are independent of the catalyst concentration suggests that the termination reaction is unimolecular as shown by

$$R_t = k_t[\text{Fe*}] \tag{10}$$

where [Fe*] represents the concentration of growing polymer chains attached to the iron complex such as **4** or **7**. In the proposed coordination mechanism the rate of propagation can be expressed by

$$R_p = k_p[\text{Fe*}][\text{M}] \tag{11}$$

11) G. Natta, F. Danusso, and D. Sianesi, *Makromol. Chem.*, **30**, 238 (1959); F. Danusso, *Chem. Ind.* (Milan), **44**, 611 (1962).

Thus from a comparison of Eqs. (10) and (11) the molecular weight of the polymer is expected to be proportional to the monomer concentration. The linear relationship between the molecular weight of poly(acrylonitrile) and the concentration of the monomer in Fig. 5 supports the above assumptions. The fact that the addition of dipyridyl (Fig. 5) and the employment of solvents with greater coordinating abilities caused the decrease of molecular weight suggests that coordination of a solvent and dipyridyl instead of a monomer destabilizes the bond between iron and the growing polymer chain to induce the unimolecular termination process. Further insight into the termination mechsnism was obtained by employing a deuterated monomer and analyzing the gas evolved in the termination process.[12]

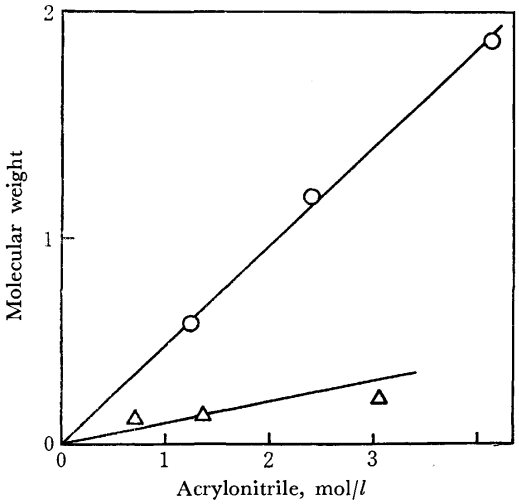

Fig. 5. Effect of the concentration of acrylonitrile and dipyridyl on the molecular weight of poly(acrylonitrile), (○) [dipy]≒7.2×10^{-3}, (△) [dipy]≒0.14 mol/*l*.

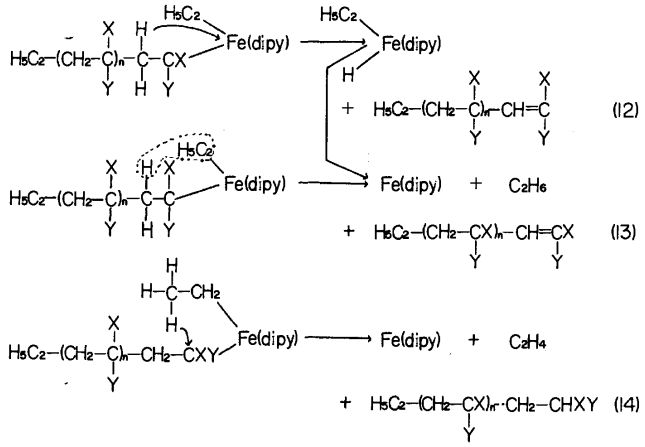
In the polymerization of *cis*-β-d_1-methyl methacrylate (78% isotopic purity) with $Fe(C_2H_5)_2(dipy)_2$, the evolution of ethane and ethylene was observed to take place in a molar ratio 1 : 2.5. Analysis of the ethane by mass spectroscopy indicated that it contained 32% of C_2H_5D and 68% of C_2H_6 (average of two experiments). The possibility of direct hydrogen abstraction of the methyl methacrylate monomer by the ethyl groups of $FeEt_2(dipy)_2$ can be excluded since the content of C_2H_5D in ethane evolved in the thermal decomposition of $FeEt_2(dipy)_2$ in benzene-d_6 at room temperature and at 80°C did not exceed the natural abundance of C_2H_5D. The NMR spectrum of the recovered deuterated monomer after the polymerization was identical with that of the deuterated monomer used for the experiment. Thus the source of ethane-d_1 is considered to be the ethyl group of $FeEt_2(dipy)_2$ and the β-hydrogens of the growing poly(methyl methacrylate-d_1) chain.

In a previous paper[8] we concluded that one of the alkyl groups of $FeR_2(dipy)_2$ remains attached to iron during the propagation process. The fact that the initiator efficiency (*n* in Table 2) does not exceed unity (except for one case where the accuracy of the molecular weight determination is not very great) also supports the conclusion. If we assume that ethane-d_1 was formed through an abstraction of β-hydrogens in the ultimate unit of the growing polymer chain attached to iron by the remaining ethyl-group, the theoretical content of C_2H_5D is 39%, which agrees with the experimental value. An experiment carried out with a 1 : 1 mixture of the normal methyl methacrylate and methyl methacrylate-d_1 showed a corresponding decrease in the amount of C_2H_5D in the evolved gas in comparison to C_2H_6.

Thus we believe that the termination involving the formation of ethane and ethylene takes place through one of the following courses:



where X=CH_3, Y=$COOCH_3$ for methyl methacrylate.

The coordinated solvent molecule or dipyridyl ligand as in **7** and **4** are omitted for the sake of simplification. From the available data it has not been determined yet whether the elimination (Eq. (12)) leaving the alkyl-iron hydride takes place first followed by an intramolecular elinination of RH, or the alkyl group abstracts the β-hydrogen directly as in Eq. (13). In a similar type of polymerization of methyl methacrylate by tris(allyl)chromium, Ballard *et al.*[2] proposed a termination mechanism in which the addition of an allyl group to the carbonyl group of the ultimate monomer unit was involved. The type of termination seems to be unlikely in our system.

Experimental

Materials. Dialkylbis(dipyridyl)iron(II) was prepared as previously described[4,6]. Methyl *cis*-β-d_1-methacrylate was prepared from methyl acetylene, deuterium chloride, nickel tetracarbonyl and methanol-d_1 by the method of Jones[13] and was purified by distillation 4-times, NMR: τ3.93 *β-cis* proton, (a complex peak with a relative area 0.22); τ4.47 *β-trans* proton (a quartet with a relative area 1); τ6.27 ester methyl proton (a singlet with a relative area 2.9); τ8.07 α-methyl proton (a doublett with a relative area 2.9). The deuterated monomer had 78% isotopic purity based on NMR. Monomers and solvents were purified

and stored as previously reported[6].

Polymerization. Polymerization was mostly carried out in a sealed ampoule in which the catalysts, olefin and solvent were transferred in an atmosphere of nitrogen or by trap-to-trap distillation *in vacuo*. After the set time of polymerization, the ampoule was opened and the content poured into acidic methanol. The precipitate was filtered, washed with methanol and dried. The kinetic study on acrylonitrile was carried out in a Schlenk type flask around which thermostatted water was circulated or in a dilatometer immersed in a thermostatted water bath. Acrylonitrile, catalyst, dipyridyl, and dimethylformamide were transferred in an atmosphere of nitrogen. The time-dependent yield was measured by pipetting out each fraction of the solution from the Schlenk type flask at set time or by reading the decrease of the volume of solution in the dilatometer. The density of poly(acrylonitrile) in the solution was measured by comparing the final decrease of volume with the weight of the recovered polymer. The density at 25°C was 1.05 g/m*l*. Poly(methyl methacrylate) was extracted in a Soxhlet extractor with acetone for 1 week and separated into acetone-soluble and acetone-insoluble fractions.

Compositions of the Copolymers. Compositions of the copolymers were calculated from microanalyses of carbon, hydrogen and nitrogen performed by Mr. T. Saito with a Yanagimoto CHN Autocorder Type MT-2.

Molecular Weight. The molecular weights of polymer were measured by viscometry by using the following equations: for poly(methyl methacrylate)[14], $[\eta]=3.80\times10^{-5}M_w^{0.79}$; for poly(acrylonitrile)[15], $[\eta]=1.66\times10^{-4}M_w^{0.81}$; for poly(methacrylonitrile)[16], $[\eta]=9.55\times10^{-4}M_w^{0.56}$.

Mass Analysis. The gas evolved in the polymerization of methyl β-*cis*-d_1-methacrylate was analyzed with a Hitachi type RMU-5B Mass Spectrometer by Mr. H. Sakurai.

The Photochemical Degradation of Diphenyl Sulfone-1-^{14}C

Mamoru NAKAI,* Naomichi FURUKAWA, and Shigeru OAE,

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

and Takeshige NAKABAYASHI

Department of Chemistry, Radiation Center of Osaka Prefecture, Sakai, Osaka

(Received May 26, 1971)

The photolysis of diphenyl sulfone-1-^{14}C upon irradiation with 2537 Å light in benzene gave biphenyl-1-^{14}C and benzenesulfinic acid-^{14}C. The yields of both compounds were estimated by means of an isotope dilution method. The ^{14}C activity of the sulfone recovered was equal to that of the sulfone employed, while that of biphenyl formed was found to have nearly one half of the ^{14}C activity. These results reveal that the phenylation reaction by phenyl radical formed by the photolytic cleavage of the C–S bond of the sulfone is an intermolecular reaction in which benzenesulfonyl radical appears to abstract hydrogen from the intermediate cyclohexadienyl radical rather than attacking benzene. The ^{14}C distribution indicates that the ^{14}C activity at 1-position was found to remain at the same position of biphenyl after photolysis of the sulfone. Thus, the photolysis of diaryl sulfones in benzene followed by the oxidation of biphenyl derivatives obtained would be a convenient method for the degradation of diaryl sulfones.

Degradation of ^{14}C-labeled diphenyl sulfone was previously carried out by way of initial alkaline fusion of the sulfone, followed by the subsequent cleavage of the phenol obtained, but the method was tedious. We sought to find a simple and more convenient degradative method of sulfone or sulfide, especially in our studies on the mechanisms of the reactions of diphenyl sulfone and related compounds with either sulfur[1] or diaryl disulfide[2], possible migration of phenyl group in the treatment of diphenyl sulfide with aluminum chloride[3] and also the alkali fusion of these compounds.[4] Recently, Kharasch and Khodair[5] reported that the photolysis of diaryl sulfone, sulfoxide, and sulfide in benzene produces aryl radicals which give the corresponding biphenyl in good yield. They proposed the following intermolecular mechanism since the photolysis of bis-*p*-tolyl sulfone in benzene gave only 4-methylbiphenyl and no 4,4′-dimethylbiphenyl.

Thus, the photolysis of diphenyl sulfone seems to be a convenient method for the degradation of diphenyl sulfone if there is no skeletal rearrangement. In order to confirm the absence of skeletal rearrangement during the reaction so that the method can be used for the degradation of diphenyl sulfone and sulfide conveniently, the photolysis of diphenyl sulfone-1-^{14}C was carried out, followed by the degradation of the biphenyl-*x*-^{14}C formed.

This paper describes a detailed account and implications of experimental observations.

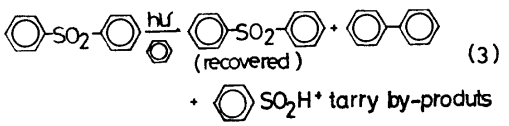
Results and Discussion

The synthesis of diphenyl sulfone-1-^{14}C has been described.[6] The rather low yield (27%) of biphenyl formation is due to the low efficiency of irradiation and our efforts to minimize any further reaction. Biphenyl formed by photolysis was diluted with an aliquot of inactive biphenyl and then oxidized with CrO_3 in acetic acid at 70—75°C (Eq. (2)). The

activity of benzoic acid thus obtained was compared with that of biphenyl. The percentage rearrangement of the activity at 1-position of the sulfone was calculated. The result reveals that more than 99% ^{14}C activity remained in the original position. Thus, the photolysis of diphenyl sulfone is shown to be a convenient method for the degradation to determine the ^{14}C activity at 1-position of diphenyl sulfone, sulfoxide and sulfide.

In order to shed further light on the mechanism of the photolysis of diaryl sulfone in benzene a more detailed analysis of products was performed by using the ^{14}C-labeled diphenyl sulfone.

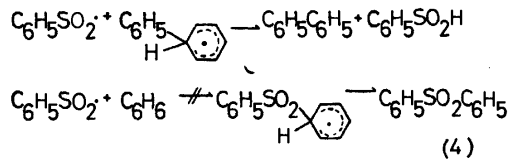
A benzene solution of diphenyl sulfone-1-^{14}C (0.0224 M) was irradiated with 2537 Å light at room temperature for 20 hr. After the reaction, unchanged diphenyl sulfone was recovered while biphenyl formed was isolated and subjected to ^{14}C activity measurement. Determination of the yield of a possible product, benzenesulfinic acid, was carried out by means of isotope dilution. (Eq. (3)). The result of



(3)

the photolysis is shown in Table 1.

The following conclusion may be drawn from the data in Table 1. Firstly, the activity of diphenyl sulfone recovered is equal to that of the starting material. Benzenesulfinic acid appears to be formed by the hydrogen atom abstraction from the intermediate cyclohexadienyl radical with benzenesulfonyl radicals produced by the initial C–S bond cleavage of the sulfone, while there is no addition of benzenesulfinyl radical to benzene to reproduce diphenyl sulfone as shown by Eq. (4). If the sulfonyl radical attacks the solvent benzene, the ^{14}C activity of the recovered sulfone would be less than that of the starting sulfone. Secondly, the fact that the activity of biphenyl formed is nearly one half of that of diphenyl sulfone used reveals that phenyl radical produced reacts with benzene to yield biphenyl, *viz.*, the process is an intermolecular free radical arylation reaction of benzene. That the ^{14}C activity of biphenyl (47%) is slightly less than the theoretical value might be due to the isotope effect during the initial C–S bond cleavage of the sulfone-^{14}C.



(4)

Thus, the photolysis of diphenyl sulfone in benzene is considered to proceed through the mechanistic route proposed earlier by Kharasch and Khodair as shown by the following equation. Consequently, the photolysis of diphenyl sulfone is found to be a simple

TABLE 1. PHOTOLYSIS OF DIPHENYL SULFONE-1-^{14}C

	Diphenyl sulfone (Starting material)	Diphenyl sulfone (Recovered)	Biphenyl	Benzenesulfinic acid
Activity (dpm/mmol)	8.26×10^5	8.31×10^5 (100.6%)	3.88×10^5 (47.0%)	1.02×10^4 [a]
Yield	Conversion: 58.7%	(41.3%) [d]	71.0% [b]	6.8% [c]

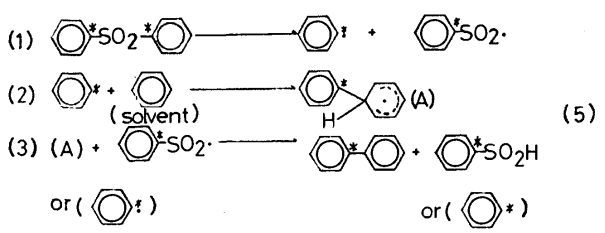
and convenient method of degradation of ^{14}C labeled diphenyl sulfone.



Experimental

Preparation of Diphenyl Sulfone-1-^{14}C. Diphenyl sulfone-1-^{14}C was synthesized through 9 steps starting from barium carbonate-^{14}C. The synthetic method has been given.[6]

The Photolysis of Diphenyl Sulfone-1-^{14}C. The photolysis of sulfone (1.223 g) was carried out in 250 m*l* of benzene at room temperature for 15 hr by the irradiation of 2537 Å light of a low-pressure cold cathode mercury lamp. The reaction mixture turned brown and then become tarry material which coated the lamp reducing the efficiency of prolonged irradiation. The benzene solution was divided into two parts. Three fifths of the contents of the flask was used for the measurement of the activity of diphenyl sulfone recovered and biphenyl formed *in situ* and the rest was subjected to the determination of the yields of the compounds listed in Table 2 by means of an isotope dilution method. The benzene solution was washed with 5% alkali solution to remove the acidic components including benzenesulfinic acid. After evaporation of benzene, both biphenyl and diphenyl sulfone were isolated and separated by means of silica gel column chromatography. Benzenesulfinic acid was extracted with ether from the aqueous layer after acidified with hydrochloric acid. Crude biphenyl thus obtained was purified by recrystallization from water-alcohol and then by sublimation twice. Diphenyl sulfone and benzenesulfinic acid isolated were purified by recrystallization twice from benzene-*n*-hexane and ether-*n*-hexane, respectively. Diphenyl sulfone, biphenyl, and benzenesulfinic acid thus obtained were subjected to the counting of ^{14}C activity.

Oxidation of Biphenyl. An aliquot amount of biphenyl (0.4 g) was dissolved in 5 m*l* of acetic acid, and to this solution was added a solution of 5 g of anhydrous chromic acid in 2 m*l* of water and 5 m*l* of acetic acid dropwise with stirring at 70—75°C. Carbon dioxide evolved during the oxidation. After the oxidation was completed, the content of the flask was stirred for 30 min at 70—75°C. The reactant was then poured into 40 m*l* of water and the whole mixture was extracted with ether. The ether layer was washed with water three times to remove acetic acid and then re-extracted with 5% alkali solution. The alkali solution was reacidified and the benzoic acid precipitated was purified by sublimation. The yield was about 20%. Both benzoic acid and biphenyl were subjected to the counting of ^{14}C activity. The specific activities of both biphenyl-*x*-^{14}C and benzoic acid-^{14}C were found to be the same. Thus no ^{14}C rearrangement occurred during photolysis and oxidation. The benzoic acid obtained was degraded according to the known method[7] and was found to have ^{14}C activity at its 1 position.

Measurement of the ^{14}C Activities. Activities of all the compounds were counted with a liquid scintillation counter (TEN) in toluene solution using POPOP as a scintillator.

We wish to thank Dr. M. Hamada of the Radiation Center of Osaka Prefecture for his advice and for affording facilities for the measurements.

Nitrate as an Oxidant in the Reaction of Silver(I) Salts with Grignard Reagents

Masuhiko TAMURA* and Jay K. KOCHI

Department of Chemistry, Indiana University, Bloomington, Indiana 47401, *U.S.A.*

(Received July 19, 1971)

The reaction between various Grignard reagents and silver(I) salts in the presence of nitrogen-containing oxidants such as lithium nitrate, nitrogen dioxide, and methyl nitrate has been examined in tetrahydrofuran solutions. Coupling dimer is formed in high yields almost independently of the structure of the Grignard reagent. From the stoichiometry, it is concluded that these oxidants oxidize two equivalents of metallic silver formed *in situ* to silver(I) species under proper reaction conditions. Other transition metal halides are also oxidized by these oxidants in a similar manner. Soluble forms of reduced silver complexes formed in the reaction of silver(I) nitrate and Grignard reagent are also described.

The reactions of various transition metal salts and Grignard reagents in which alkane, alkene, and coupling dimer are obtained as products have been studied for some time.[1] Silver(I) salts are generally reduced to the metallic state in the presence of excess Grignard reagent, and the stoichiometry[2] of the reaction is generally represented by Eq. (2).

$$2\,RMgY + 2\,AgX \rightarrow [RH, R(-H), R\text{-}R] + 2\,MgXY + 2\,Ag \quad (1)$$

$$Q(R) = \frac{R(-H) + RH + 2\,R\text{-}R}{AgX} = 1.0 \quad (2)$$

The distribution of products is dependent on the Grignard reagent as well as the reaction conditions. The mechanism of the formation of coupling dimer has also been proposed.[3]

$$2\,R\text{-}Ag \rightarrow R\text{-}R + 2\,Ag \quad (3)$$

In most studies for this reaction, diethyl ether has been a medium of choice.[4]

We have examined the mechanism of the Kharasch reaction catalyzed by various transition metal salts and the reactions of transition metal halides with Grignard reagents, especially in tetrahydrofuran (THF) solution.[5] During these studies we found that nitrate is capable of acting as an oxidant in the *catalytic* reaction of silver(I) salt and Grignard reagent in THF.

In this paper we describe the reaction of silver(I) salt and Grignard reagent in the presence of nitrogen-containing oxidants such as lithium nitrate, nitrogen dioxide, and methyl nitrate in THF solutions. We also describe the soluble silver complex formed in the reaction of silver(I) nitrate and Grignard reagent in THF.

Results and Discussion

Reactions of Silver(I) Salts and Grignard Reagents. When a silver(I) salt was mixed with ethylmagnesium bromide in THF, *n*-butane was formed quantitatively together with a metallic silver precipitate as shown in Table 1.

$$2\,EtMgBr + 2\,AgX \rightarrow C_4H_{10} + 2\,Ag + 2\,MgBrX \quad (4)$$

TABLE 1. REACTION OF SILVER(I) SALTS AND ETHYLMAGNESIUM BROMIDE IN TETRAHYDROFURAN[a]

AgX	Q(Et)	Distribution of product (%)			Alkali[c] (mmol)
		C_2H_4	C_2H_6	*n*-C_4H_{10} [b]

b) Percentage of *n*-C_4H_{10} was doubled.
c) Analysis after the reaction was completed.
d) Not determined.

A black precipitate was also formed immediately when silver(I) nitrate reacted with *excess* ethylmagnesium bromide. With this silver(I) salt, however, a part of the black precipitate gradually redissolved, accompanied by the formation of additional *n*-butane as shown in Fig. 1. Moreover, the value of Q(Et) in Eq. (2) was 3.6 in the case of silver(I) nitrate, which suggests that the nitrate acted as an oxidant during the reaction. The reactions of silver(I) nitrate and various organometallic compounds were also carried out in THF in order to see the general tendency of this unique behavior of nitrate. The results are summarized in Table 2 which shows clearly that Q(R) became greater than the usual stoichiometric requirements of 1.0, independently of the Grignard reagent. The coupling dimer was still the main product except

for secondary and tertiary alkyl Grignard reagents in which the formation of alkane and alkene predominated. Q(R) remained 1.0 when diethylzinc and triethylaluminum were employed, but no reaction took place between silver(I) nitrate and tetraethyllead or tetraethyltin.

Methyl, ethyl, n-propyl, isopropyl, and t-butylmagsium bromides, ethylmagnesium chloride, diethylmagnesium, and ethyllithium all produced a black-brown solution (*vide infra*) in varying yields after the reactions were complete. On the other hand, phenyl, benzyl, and allylmagnesium bromides, diethylzinc and triethylaluminum did not afford brown solutions. Only a black precipitate and a colorless solution remained after the reaction was complete. These observations suggest that the formation of a black-brown solution is related to the reactivity of organometallic compound since benzyl and allylmagnesium bromides are more reactive, and phenylmagnesium bromide is less reactive than other alkyl Grignard reagents.[6]

The reaction of silver(I) nitrate and ethylmagnesium bromide was also greatly affected by the reaction temperature and the molar ratio of ethylmagnesium bromide to silver(I) nitrate as shown in Table 3. Thus, the value of Q(Et) and the yield of coupling dimer became larger at lower temperatures. The higher yields of soluble silver complex were obtained at lower temperatures and molar ratios of ethylmagnesium bromide to silver(I) nitrate of 5—7. The lower value of Q(Et) and the higher yield of ethane at higher temperature may be ascribed to the reaction of nitrate with ethylmagnesium bromide and the aggregation of metallic silver formed *in situ* (see Experimental, Table 6). Q(Et) also became greater than 1.0 when the reaction of silver(I) nitrate and ethylmagnesium bromide was carried out in diethyl ether, dioxane, and diglyme as indicated in Table 4. However, no soluble silver complex was formed in these solvents.

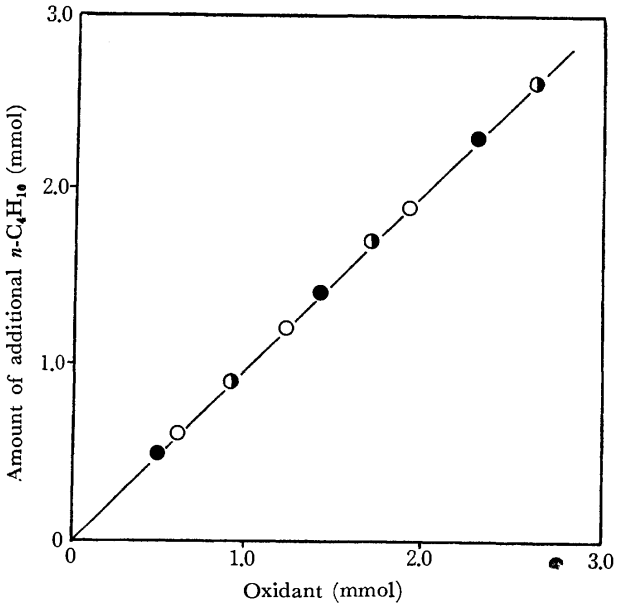

Fig. 2. Increase in the amount of *n*-butane from the reaction of silver(I) perchlorate and ethylmagnesium bromide in the presence of an oxidant in tetrahydrofuran at 2°C for 60 min. THF: 21 m*l*, $AgClO_4$: 1.0 mmol, EtMgBr: 8.7 mmol
●: Methyl nitrate, ○: Nitrogen dioxide, ◑: Lithium nitrate

to determine the role of nitrate as an oxidant, the reaction of silver(I) perchlorate and ethylmagnesium bromide in THF solutions was examined in the presence of other oxidants. When methyl nitrate, lithium nitrate, or nitrogen dioxide was added in the reaction, greater than stoichiometric amounts of coupling dimer was also formed as shown in Fig. 2. Furthermore, additional coupling dimer was formed when lithium nitrate was added to the black suspension resulting from the reaction of silver(I) bromide and excess ethylmagnesium bromide in THF. It is clearly indicated from the slope of the plot in Fig. 2 that these oxidants oxidize two equivalents of metallic silver.[7]

$$AgClO_4 + EtMgBr \rightarrow 1/2\ C_4H_{10} + MgBrClO_4 + Ag \quad (5)$$

$$2\ Ag \xrightarrow{Oxidant} 2\ Ag(I) \xrightarrow{EtMgBr} C_4H_{10} + 2\ Ag \quad (6)$$

Similar results were obtained when silver(I) bromide replaced silver(I) perchlorate. Lithium nitrate and nitrogen dioxide also produced a black-brown solution, but methyl nitrate only afforded a black precipitate and a colorless solution. Sodium nitrite, nitric oxide, isoamyl nitrite, nitroethane and nitrobenzene, on the other hand, showed no evidence of enhancing the value of Q(R) beyond 1.0. The behavior shown by nitrate is, therefore, quite different from the result reported for the reaction of organocuprate with nitrobenzene.[9]

The reaction between nitrate salts and Grignard reagents has not been published. It is known, how-

7) One of nitrogen oxides (nitrogen dioxide *etc.*) formed *in situ* may be the essential oxidant. Oxidation of metallic silver with nitrogen dioxide may involve electron transfer since a small amount of nitric oxide was detected in gas phase during the reaction of silver(I) nitrate with ethylmagnesium bromide.[8]

ever, that various products are formed in the reactions of nitrogen dioxide, nitroalkanes, and organic nitrates with Grignard reagents.[10] These reactions presumably involve addition of the Grignard reagent to the nitrogen–oxygen bond. Similar reactions are probably involved with nitrates since diethylhydroxylamine was obtained in the reaction of lithium nitrate and ethylmagnesium bromide in THF after hydrolysis (see Table 6).

Reactions of Transition Metal Halides and Ethylmagnesium Bromide in the Presence of Lithium Nitrate. The role of lithium nitrate as an oxidant was also examined in the reactions of other transition metal halides and ethylmagnesium bromide in THF solution. The results summarized in Table 5 show that lithium nitrate can act as an oxidant in varying degrees of efficiency.

$$MX_n \xrightarrow{\text{excess EtMgBr}} \text{Products} + M \quad (7)$$

$$M \xrightarrow{\text{Oxidant}} M^{+m} \xrightarrow{\text{EtMgBr}} \text{Products} + M \quad (8)$$

The higher efficiency was observed with manganous, ferric, ferrous, cobaltous, and nickelous halides since the values of $\Delta Et/LiNO_3$ were larger with these compounds.

Interestingly, the addition of lithium nitrate also afforded soluble metal species from manganous and cuprous(cupric) chlorides.

$$MX_n \xrightarrow{\text{excess EtMgBr}} \text{Products} + M \text{ (Black precipitate)} \quad (9)$$

$$MX_n \xrightarrow{LiNO_3\text{-excess EtMgBr}} \text{Products} + \text{Soluble M species (M; Ag, Cu, and Mn)} \quad (10)$$

10) M. S. Kharasch and O. Reinmuth, "Grignard Reagents of Nonmetallic Substances" Prentice-Hall Co., New York, N. Y. (1954).

The effect of lithium nitrate on the formation of reduced metal species was not clear with other transition metal halides since soluble species were also formed from these transition metals in its absence.

The formation of coupling dimer from other transition metal halides was also facilitated by lithium nitrate. Its effect could not be examined directly since most ethyl transition metal complexes are labile.

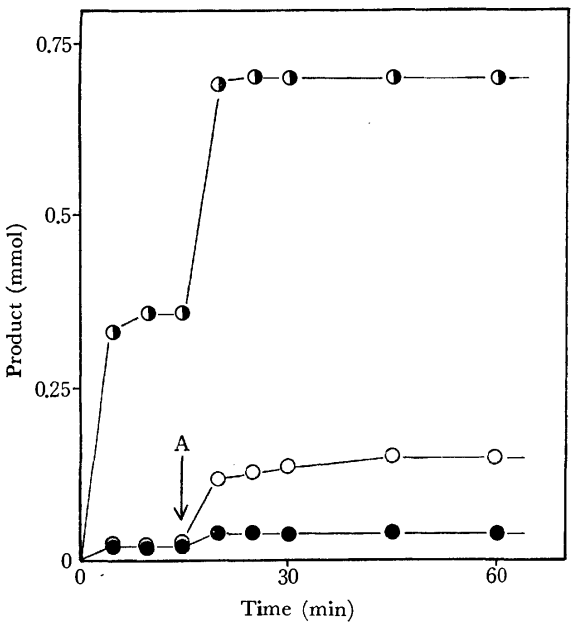

Fig. 3. Rate of formation of products in the reaction of cupric chloride and ethylmagnesium bromide in the presence of nitrogen dioxide.
In 21 ml THF solution containing 1.0 mmol $CuCl_2$ and 1.68 mmol EtMgBr at 2°C
◑: $n\text{-}C_4H_{10}$, ○: C_2H_6, ●: C_2H_4
Nitrogen dioxide (0.80 mmol) was added at point A.

Ethylcopper and ethylmanganese complexes, however, are relatively stable thermally in THF solutions.[5] The rate of the reaction between ethylcopper and nitrogen dioxide is illustrated in Fig. 3 which shows that the coupling dimer was formed immediately in high yield.

$$2\ \mathrm{EtCu} \xrightarrow{\mathrm{NO_2}} \mathrm{Et\text{-}Et} + 2\ \mathrm{Cu\ species} \qquad (11)$$

Ethane and ethylene, on the other hand, were the principal products in the absence of nitrogen dioxide as indicated in Table 5. The oxidation of organocuprates with molecular oxygen to form coupling dimer has been reported in an analogous situation.[9] We also find that the oxidation of ethylcopper species in THF with molecular oxygen affords *n*-butane in excellent yields. Oxidation of a mixture of ethylcopper and *n*-propylmagnesium bromide with nitrogen dioxide in THF yielded a mixture of three coupling dimers (*n*-butane, *n*-pentane, and *n*-hexane) in high yield.

$$\mathrm{EtCu} + n\text{-PrMgBr} \rightleftarrows n\text{-PrCu} + \mathrm{EtMgBr} \qquad (12)$$

$$\mathrm{EtCu} + n\text{-PrCu} \xrightarrow{\mathrm{NO_2}} \mathrm{C_4H_{10}} + \mathrm{C_5H_{12}} + \mathrm{C_6H_{14}} + \mathrm{Cu\ species} \qquad (13)$$

Nitrogen dioxide also oxidized methyl and ethylmanganese species in THF solutions. Coupling dimer was obtained quantitatively from methylmanganese species, and equimolar amounts of ethane and ethylene were formed from ethylmanganese species.[5]

These observations suggest that lithium nitrate increases the yield of coupling dimer by direct oxidation of the alkyl transition metal complex formed *in situ*.

Soluble Form of Reduced Silver Complex. A soluble silver complex was formed, as mentioned above, in the reaction of silver(I) nitrate with Grignard reagent, diethylmagnesium or ethyllithium and in the reaction of silver(I) perchlorate with ethylmagnesium bromide in the presence of lithium nitrate or nitrogen dioxide in THF. It was not formed in the reaction of silver (I) nitrate with phenyl, allyl, benzylmagnesium bromide, diethylzinc, or triethylaluminum or in the reaction of silver(I) perchlorate with ethylmagnesium bromide in the presence of methyl nitrate. The reaction temperature and the molar ratio of ethylmagnesium bromide to silver(I) nitrate also greatly influenced the yield of soluble silver complex (Table 3).

The soluble silver complex designated as (A) showed a sharp λ_{max}, at 415 nm after dilution of the reaction mixture with THF, and the absorption was independent of the organometallic compound (Table 2). When an excess of Grignard reagent was added to the silver complex(A), the λ_{max} was shifted to 400 nm to form a new species(B) as shown in Fig. 4.

The chemical behaviors of the soluble complex(A) obtained from the reaction of silver(I) nitrate with diethylmagnesium are summarized in Fig. 5. The solution did not contain ethyl–metal groups since no ethane was evolved on acidic hydrolysis. Metallic silver was recovered quantitatively as a black precipitate when the solution was hydrolyzed with dilute sulfuric acid. Silver(I) species were absent since no silver(I) chloride was detected after extraction with concentrated ammonium solution followed by neutralization with hydrochloric acid. The soluble silver complex did not appear to react with excess triphenylphosphine and diethylzinc (no change in the visible spectra). The addition of benzyl and allyl bromides to the silver complex(A) afforded dibenzyl and diallyl, respectively, and silver(I) bromide in stoichiometric amounts. Oxidation of the soluble silver complex(A) with oxygen afforded silver(I) species only partially. When an equal amount of diglyme was added to the solution of complex(A), a black-brown precipitate was formed immediately. This precipitate was soluble in fresh THF and the resulting solution showed the same λ_{max} at 415 nm. The black-brown precipitate was washed with a 1 : 1 mixture of diglyme–THF under helium several times until no magnesium compound was detected in the washings. The solid, however, still contained magnesium compound in amounts corresponding to the ratio of silver/magnesium=1.1. The infrared spectra of the purified brown solid, which was dried *in vacuo* at room temperature, showed no characteristic absorptions. Both solutions of the complexes absorbing at 415 and 400 nm also showed no signal when the electron spin resonance spectra were examined.

We infer from these observations that both complexes (A) and (B) are composed of zerovalent silver. No zerovalent silver complexes have been cited.[11]

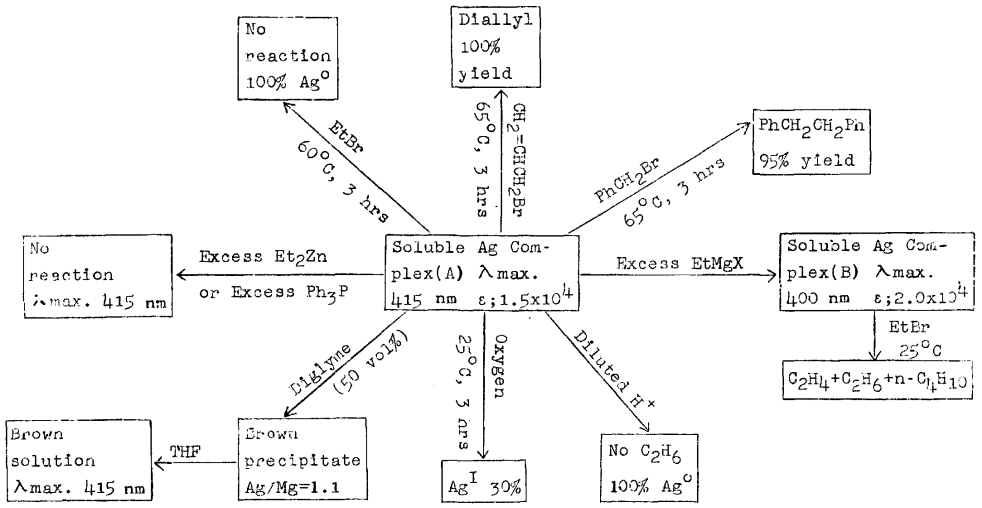

Fig. 5. Properties of the soluble silver complex obtained in the reaction of silver (I) nitrate and diethylmagnesium in tetrahydrofuran.

However, the formation of zerovalent cobalt and iron complexes coordinated with Grignard reagent have been reported under similar conditions.[12] Complex (B) absorbing at 400 nm may be a silver complex coordinated with Grignard reagent and is represented as the complex which shows enhanced catalytic activity in the Kharasch reaction.[5] The structure of complex(A) absorbing at 415 nm is not clear, but we assume that it is a zerovalent silver complex coordinated with one of the nitrogen-containing magnesium compounds formed in the reaction (see Experimental). Complex(B) absorbing at 400 nm was more stable than complex(A) absorbing at 415 nm and could be stored for prolonged periods in a refrigerator.

The lower yields of complex A) obtained at higher temperatures and at higher molar ratios of ethylmagnesium bromide to silver(I) nitrate may be attributed to the aggregation of the silver species presumed to be the catalyst in the Kharasch reaction.[5] The relationship between the organometallic compound and nitrogen-containing oxidant on the yield of complex (A) may also be related to the aggregation of silver.

Experimental

All reactions in this paper were carried out under an inert atmosphere.

Materials. A billet of triply sublimed magnesium was obtained from Dow Chemical Co. Anhydrous nickelous chloride was prepared from the reaction of its hexahydrate and thionyl chloride. Anhydrous ferrous chloride was prepared by disproportionation of iron and anhydrous ferric chloride in THF.[13] Anhydrous manganous chloride was prepared from its tetrahydrate by treating at 150°C for 50 hr *in vacuo*. Anhydrous ferric chloride, palladous chloride, cobaltous bromide, cuprous chloride, cuppric chloride, silver(I) bromide, acetate, nitrate, nitrite and perchlorate, lithium nitrate, nitrogen dioxide, nitric oxide, isoamyl nitrite, and triphenylphosphine were of commercial grade and used without further purification. Nitrobenzene, nitroethane, and all organic bromides were purified by distillation before use. Methyl nitratew as prepared from methyl alcohol and nitric acid.[14]

Organometallic Compounds. All Grignard reagents were prepared as usual except for the use of 1.5 times excess metallic magnesium and low temperature (5~25°C). After filtration under nitrogen, all solutions of the Grignard reagents (0.5~2.0 M) were almost colorless except for vinylmagnesium bromide. The concentration of each Grignard reagent was determined by back titration with base and by the measurement of the amount of hydrocarbon liberated after acidic hydrolysis. Diethylmagnesium was prepared by precipitation of magnesium bromide from the Grignard reagent with dioxane followed by replacement of ether with THF. Ethyllithium (benzene solution, purchased from Lithium Corporation of America, Inc.) and triethylaluminum (supplied from Du Pont Co.) were of commercial grade. Diethylzinc was prepared from the reaction of zinc–copper couple with a mixture of ethyl bromide and ethyl iodide.[15] Tetraethyllead[16] and tetraethyltin[17] were prepared from the Grignard reagent in ether solution.

Solvents. THF was purified by refluxing over lithium aluminum hydride for 2 days, fractionating under nitrogen and stored under helium. Diethyl ether, dioxane, and diglyme were purified in a similar manner.

Analysis of Organic Product. Organic products were analyzed by gas chromatography using the internal standard method as previously reported.[5]

Analyses of Silver and Magnesium. Silver(0) was analyzed by titration[18] with a standard solution of potassium thiocyanate after extraction of silver(I) species with concentrated ammonium solution, filtration and oxidation with

e) Not determined.

nitric acid. Silver(I) species was analyzed gravimetrically after precipitation as silver(I) bromide. Magnesium was determined by EDTA titration.[17]

Reaction of Silver(I) Nitrate and Ethylmagnesium Bromide in Tetrahydrofuran (Typical example). To a 250 m*l* round bottomed flask equipped with a magnetic stirring bar and sealed with a rubber serum cap was added 0.17 g silver(I) nitrate. The nitrogen atmosphere was replaced with helium and 17 m*l* of THF was added with a syringe. After the flask was immersed in a dry ice–acetone bath, 25 ml of methane and 25 m*l* of isobutane (both markers) were added with syringes. The flask was then transferred to an ice–water bath. After 5 min agitation, 4.0 m*l* of ethylmagnesium bromide (7.3 mmol) was added to the solution with stirring. The color of the solution became black (suspension) immediately and then gradually changed to a black-brown solution. A small portion of the gas phase was removed with a hypodermic syringe and analyzed by gas chromatography at intervals of time. After the reaction was complete (60 min), a small portion of the reaction mixture was transferred to a deaerated test tube sealed with a serum cap. The mixture was centrifuged for 5 min and 0.10 m*l* of the black-brown supernatant solution was transferred to UV cell sealed with a rubber septum and containing 20 m*l* of THF. Visible spectrum was measured in the range 300~600 nm (λ_{max} 415 nm, Absorbance; 0.82). λ_{max} shifted to 400 nm (Absorbance; 1.35) when 1.0 m*l* of ethylmagnesium bromide solution (1.8 M) was added to the solution in UV cell. All subsequent reactions were also carried out in a similar manner.

Reaction of Nitrogen-Containing Oxidants with Grignard Reagents in Tetrahydrofuran. The reactions of nitrogen-containing oxidants with Grignard reagents were examined in THF solutions. The results are summarized in Table 6 which shows that the corresponding alkane was formed in varying yield. The reaction of lithium nitrate and methylmagnesium bromide did not proceed smoothly at 23°C but it occurred at 62°C to form predominantly methane. The reaction of sodium nitrite and ethylmagnesium bromide was also negligible. After the reaction was complete, the amount of alkali was greater than that of ethylmagnesium bromide charged.

The rate of formation of ethane in the reaction of lithium nitrate and ethylmagnesium bromide was also examined in THF solution. The amounts of ethane were determined at 5-min intervals and plotted against time. From the slope of the resulting line, the rate of formation of ethane was calculated (initial rate). A systematic variation of the concentration of each component led to the following empirical equation.

$$\frac{dC_2H_6}{dt} = k[LiNO_3]^{1.0}[EtMgBr]^{1.2}$$

The apparent activation energy of this reaction was 17.0 kcal/mol and the apparent second order rate constant was approximately 10^{-3} l mol^{-1}–sec^{-1} at 2.0°C. These results suggest that the following reactions occurred in the reaction between lithium nitrate and ethylmagnesium bromide.[10]

$$LiONO_2 + EtMgBr \xrightarrow{slow} LiOMgBr + EtNO_2$$

$$EtNO_2 + EtMgBr \xrightarrow{fast} C_2H_6 + CH_3CH{=}N\begin{matrix}\nearrow OMgBr\\ \searrow O\end{matrix}$$

$$EtNO_2 + EtMgBr \rightarrow Et_2N\begin{matrix}\nearrow OMgBr\\ \searrow O\end{matrix}$$

$$Et_2N\begin{matrix}\nearrow OMgBr\\ \searrow O\end{matrix} + EtMgBr \rightarrow Et_2NOMgBr + EtOMgBr$$

$$LiOMgBr + H_2O \rightarrow LiOH + MgBrOH \text{ } etc.$$

Diethylhydroxylamine was the main product isolated after acidic hydrolysis from the reaction between lithium nitrate and ethylmagnesium bromide as well as that between silver(I) nitrate and ethylmagnesium bromide. However, these reactions can not be directly related to the oxidant since neither nitroethane or diethylhydroxylamine acted as an oxidant during the reaction of silver(I) perchlorate and ethylmagnesium bromide. It is possible that one of the nitrogen oxides (nitrogen dioxide *etc.*) is the essential oxidant. The formation of nitrogen oxides in the reaction of lithium nitrate and ethylmagnesium bromide may involve electron transfer since nitrogen oxides are formed during the oxidation of metallic palladium with lithium nitrate in acetic acid.[8]

Reaction of Silver(I) Nitrate and n-Butylmagnesium Bromide in the Presence of Lithium Nitrate. Silver(I) nitrate (2.5 mmol), lithium nitrate (20 mmol), and 50 m*l* THF were added to a 500 m*l* round bottomed flask which was previously flushed with nitrogen and sealed with a rubber serum cap. A solution of 1.0 M n-butylmagnesium bromide (100 m*l*) was added and the mixture was stirred for 3 hr

at 10°C. The reaction mixture was worked up in the usual manner after addition of dilute sulfuric acid and extraction with petroleum ether. Distillation afforded 1.85 g (72% based on total nitrate group) of *n*-octane.

We wish to thank the National Science Foundation for generous financial support, the Du Pont Company for the THF and the Dow Chemical Company for the billet of magnesium used in this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1127—1132 (1972)

The Reaction Mechanism of 2-Dimethoxymethyl-3-methoxypropionitrile with Acetamidine. I. A Revised Structure of the Intermediate[1]

Takenori NISHINO, Masumi KIYOKAWA, Yoshiyuki MIICHI, and Kanji TOKUYAMA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received July 29, 1971)

The reaction of 2-dimethoxymethyl-3-methoxypropionitrile (**1**) with acetamidine yields 2,7-dimethyl-5,6-dihydropyrimido[4,5-*d*]pyrimidine (**6**) *via* an intermediate, λ_{max}^{MeOH} 262 mμ. This intermediate has been identified as 2-acetamidinomethylene-3-methoxypropionitrile (**5**) without being isolated. However, this assignment seems to be somewhat inconsistent with the stabilities of an acetal group in basic media and with the UV spectra of compounds with structures similar to **5**. The reaction of **1** with sodium methoxide gave a dimeric compound (**8**). This result suggests the formation of **2**-dimethoxymethylacrylonitrile (**2**) in the initial stage of the reaction of **1** with acetamidine. The reaction of acrylonitrlie with acetamidine yielded 2-methyl-4-amino-5,6-dihydropyrimidine (**23**), whose UV spectrum in methanol showed its absorption maximum at 270 mμ in neutral media and at 258 mμ in basic media. Therefore, the structure of the intermediate may be concluded to be 2-methyl-4-amino-5-dimethoxymethyl-5,6-dihydropyrimidine (**27**) instead of **5**, and the reaction may be concluded to proceed *via* the pathway of **1**→**2**→**27**→**6**.

Interesting and rather complicated results have been reported by Takamizawa and his co-workers dealing with the syntheses of some pyrimidines from derivatives of 2-formyl-3-methoxypropionitrile with acetamidine.[2] Two types of pyrimidines are obtainable by the reactions: 2-methyl-4-amino-5-methoxymethylpyrimidine (**7**) can be obtained directly by the reaction of 2-methoxymethylene-3-methoxypropionitrile (**3**), while 2,7-dimethyl-5,6-dihydropyrimido[4,5-*d*]pyrimidine (**6**) can be obtained from 2-dimethoxymethyl-3-methoxypropionitrile(**1**) or 2-dimethoxymethylacrylonitrile (**2**) *via* a complex pathway, which is proposed to be as shown in Chart 1.[2] An intermediate can be detected spectrophotometrically, λ_{max}^{MeOH} 262 mμ or λ_{max}^{EtOH} 275 mμ, without being successfully isolated. When heated with another mole of acetamidine, this intermediate is converted into **6**. This intermediate has been identified as 2-acetamidinomethylene-3-methoxypropionitrile (**5**).

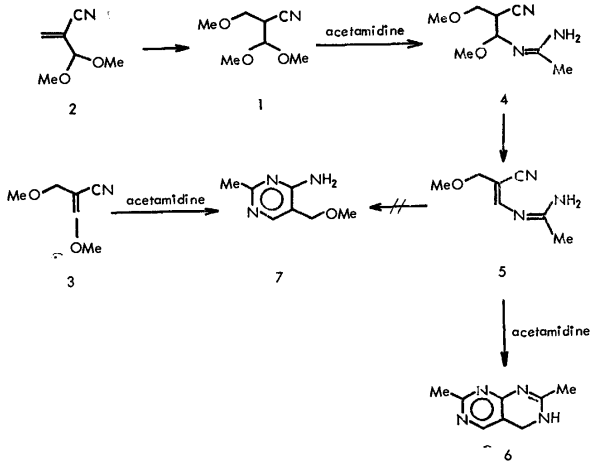

Chart 1

As acetamidine is a strong base (pK_a 12.4),[3] the reactions proceed under basic conditions. The reaction of **3**→**7** is quite natural, judging from the literatures.[4,5] On the other hand, the formation of **6** from **1** or **2** is very unusual and interesting. However, further investigation is thought to be required before we can reach any final conclusion on the reaction mechanism, since the step of **1**→**4**→**5** seems to be inconflict with the stabilities of an acetal group in basic media.[6]

A further question has been raised on the basis of the comparison of the UV spectra of compounds with structures similar to **5**. The absorption maximum of ethyl acetamidinomethylenecyanoacetate[7] appears at 330 mμ in ethanol, and that of 2-aminomethylene-3-ethoxypropionitrile appears at 270 mμ in methanol.[2] From these data the absorption maximum of **5** is expected to appear at a wavelength longer than 270 mμ.

7) T. Matsukawa, *Yakugaku Zasshi.* **62**, 417 (1942),

Consequently, the establishment of unequivocal structure of the intermediate is desired. For this purpose, studies of the behavior of **1** toward bases were attempted.

The treatment of **1** with sodium methoxide at 40°C for 2 hr gave a viscous oil (**8**). The analytical data and the integration of the NMR spectrum showed it to be a dimeric substance, $C_{12}H_{18}N_2O_4$, which was thought to be obtained from the dimerization of **1** by the elimination of one mol of methanol. The UV spectrum in ethanol showed the absorption maximum at 232 mμ suggesting the presence of a partial structure of MeO–C=C–CN.[8] The IR spectrum showed characteristic absorption bands due to non-conjugate and conjugate nitriles, double bond, and acetal and methoxy groups. Therefore, **8** was determined to be 2-dimethoxymethyl-2-methoxymethyl-4-methoxymethyleneglutaronitrile and to be, as will be described below, a mixture of *trans* and *cis* isomers.[9]

Figure 1 shows the NMR spectrum of **8** in carbon tetrachloride. With the 4-methoxymethylene group, the signal due to the methine proton appeared as two singlets at 2.98 τ (⅔H, a) and 3.18 τ (⅓H, b), while the signal due to the methyl group also appeared as two singlets, at 6.10 τ (2H, a) and 6.08 τ (1H, b). The signal due to the methylene proton at the 3-position appeared as an AB-type quartet at 7.43 τ and 7.55 τ (J 14 Hz, ⅔H, a), and as a singlet at 7.57 τ (⅔H, b). These data clearly supported the idea that **8** was a mixture of two isomers whose ratio was about 2 : 1.

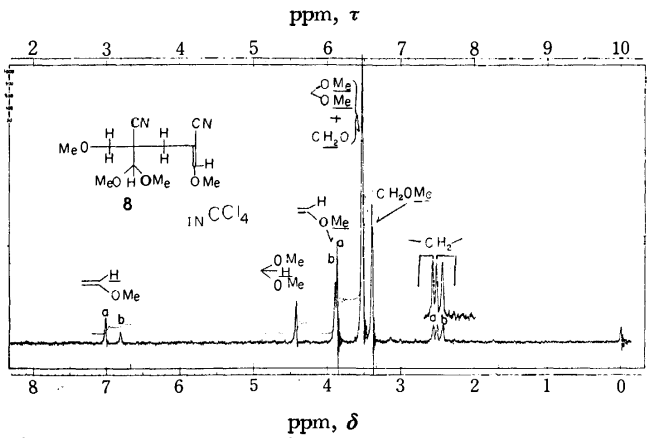

Fig. 1. NMR spectrum of **8** (a mixture of *cis* and *trans* isomers) in carbon tetrachloride at 60 MHz.

The assignment of the other signals was also consistent with the proposed structure. The methyl signal of the 2-methoxymethyl group was observed as a three-proton singlet at 6.60 τ and the two methyls of the acetal group, as a six-proton singlet at 6.45 τ, which overlapped with the two-proton singlet due to the methylene proton of the 2-methoxymethyl group. The methine proton of the acetal group was observed as an one-proton singlet at 5.60 τ.

8) A. Takamizawa, K. Hirai, and S. Sumimoto, *Chem. Pharm. Bull.* (Tokyo), **14**, 238 (1966).

9) "*Cis*" means that the methoxy group of the 4-methoxymethylene moiety is located on the same side of the nitrile group, while "*trans*" means that it is found on the opposite side.

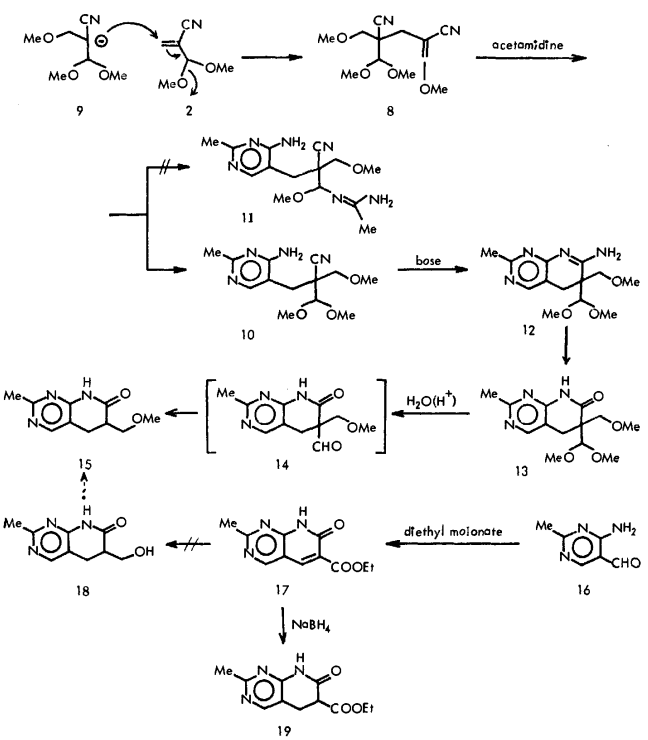

Chart 2

A reasonable pathway for the formation of **8** has been proposed; it is shown in Chart 2. Under basic conditions, an equilibrium of **1**⇌carbanion (**9**)⇌**2** can give **8**. Although the formation of **3** from **9** was also expected, the addition product of **9** to **3** was scarecely detected. Therefore, the initial step of the reaction of **1** under basic conditions must be the predominant formation of **2**. Consequently, in the reaction of **1** with acetamidine, the Michael-type addition of acetamidine to **2** initially formed may be expected as the second step. The disagreement for the initial step of the reaction of **1** with acetamidine between this conclusion (**1**→**2**→Michael-type addition compound→**6**) and the mechanism proposed by Takamizawa *et al.* (**2**→**1**→**5**→**6**)[2] has prompted us to study the reaction of **8** with acetamidine.

If the reaction of **1** with acetamidine proceeded only by the Michael-type addition of acetamidine to a double bond, **8** would be converted into a pyrimidine (**10**), in which the acetal group of **8** remained unchanged. On the other hand, if the reaction of **1** could proceed by the direct substitution of the acetal part, **8** could be converted into another pyrimidine (**11**), which has no acetal group. When **8** was treated with acetamidine in 1,2-dimethoxyethane (DME) at a reflux temperature, a compound, $C_{13}H_{20}N_4O_3$, was obtained which was proved to be 2-methyl-4-amino-5-(2′-cyano-2′-dimethoxymethyl-3′-methoxy)propylpyrimidine (**10**) by physical and chemical methods, as will be reported in detail below.

The UV spectrum showed the characteristic bands due to 4-aminopyrimidines[10,11] and the IR spectrum

10) A. Takamizawa, *Yakugaku Zasshi*, **74**, 748 (1954).

11) D. J. Brown, "The Pyrimidines," Interscience, New York (1962), p. 447.

showed the bands due to non-conjugate nitrile and acetal groups. The NMR spectrum also suggested the presence of pyrimidine ring and an acetal group. Therefore, the structure of **10** was established.

The structure of **10** was further confirmed by the following reactions. The heating of **10** in pyridine containing sodium hydroxide afforded **12**. The IR spectrum showed the absence of a nitrile group and the UV spectrum in ethanol showed the absorption maxima at 221 and 301 mμ, which were shifted to 281 and 322 mμ in acidic media. As these spectral data suggested the presence of a bicyclic structure, **12** was concluded to be 2-methyl-6-dimethoxymethyl-6-methoxymethyl-7-amino-5,6-dihydropyrido[2,3-*d*]pyrimidine.

The hydrolysis of **12** with acetic acid gave **13**, $C_{13}H_{19}N_3O_4$, which was identified as 2-methyl-6-dimethoxymethyl-6-methoxymethyl-7-oxo-8*H*-5,6-dihydropyrido[2,3-*d*]pyrimidine (**13**) from its IR spectrum, which showed the bands due to amidocarbonyl, acetal, and methoxymethyl groups. The UV spectrum in ethanol showing absorption maxima at 242 and 275 mμ which were shifted to 280 mμ in acidic media and to 280 and 301 mμ in alkaline media, also supported the structure. Hydrolysis of **12** under strongly acidic conditions gave **15**, $C_{10}H_{13}N_3O_2$. The IR and NMR spectra showed the absence of an acetal group, and the behavior in the UV spectrum was quite similar to that of **13**. Therefore, the structure of **15** is probably 2-methyl-6-methoxymethyl-7-oxo-8*H*-5,6-dihydropyrido[2,3-*d*]pyrimidine, which can be derived *via* a formyl compound (**14**). To obtain further evidence for the above-described structures, the synthesis of **15** was attempted by means of the scheme outlined in Chart 2 (**16**→**17**→**18**→**15**). 2-Methyl-6-carbethoxy-7-oxo-8*H*-pyrido[2,3-*d*]pyrimidine (**17**) was prepared by the reaction of 2-methyl-4-amino-5-formylpyrimidine (**16**)[12] with diethyl malonate, using piperidine as the catalyst. The IR spectrum, which showed the characteristic band due to the amidocarbonyl group, and the NMR spectrum, which showed signals of the ethoxy group, the methyl group, the pyrimidine-ring proton, and the pyridone-ring proton, confirmed the structure. The behavior in the UV spectrum also supported the structure.

The reduction of **17** with lithium aluminum hydride to **18** was unsuccessful because of the formation of many unexpected products. However, another reduced product (**19**) was obtained by using sodium borohydride as a reducing reagent. The IR spectrum showed two carbonyl bands, and the NMR spectrum exhibited signals due to the ethyl group, the pyrimidine-ring proton, the methyl group on the pyrimidine-ring, and the $-CH_2-CH-$ moiety appearing as an ABX pattern.

These data suggested that **19** was 2-methyl-6-carbethoxy-7-oxo-8*H*-5,6-dihydropyrido[2,3-*d*]pyrimidine. Although the attempt to prepare the expected compound, **18**, for the synthesis of **15** through a different scheme was unsuccessful, the behavior of **19** in the UV spectrum was quite similar to that of **15**. Therefore, the structures of the **13** and **15** and, consequently, the structure of **10** were confirmed. The formation of **10** from only the reaction of **8** with acetamidine suggested that the acetal group of **1** was inert for the substitution with acetamidine under basic conditions and that the Michael-type addition of acetamidine to double bonds was preferable.

As has been described above, under basic conditions, **1** would be predominantly converted into **2** in the initial stage and the Michael-type addition of acetamidine to a double bond would more easily occur as compared with the case of the low reactivity of an acetal group. Therefore, the intermediate, detected spectrophotometrically, is derived from the reaction of **2** with acetamidine, not directly from the reaction of **1**.

Pietra has reported a reaction of acrylonitrile with benzamidine which yields 2-phenyl-4-amino-5,6-dihydropyrimidine (**21**).[13] As no detailed data were presented, however, we reinvestigated this reaction under milder conditions. In the initial stage of the reaction, a new compound (**20**) was isolated; it was then easily converted into **21** on heating. The compound **20** showed the ba nddue to a non-conjugate nitrile group in the IR spectrum and the signal due to an ethylene group appearing as an A_2B_2 pattern in the NMR spectrum (chloroform-*d*). Therefore, **20** was determined to be 3-benzamidinopropionitrile, and this reaction was concluded to proceed through the Michael-type addition of benzamidine to acrylonitrile, followed by cyclization. Consequently, the most likely structure of the intermediate, λ_{max}^{MeOH} 262 mμ, is 2-methyl-4-amino-5-dimethoxymethyl-5,6-dihydropyrimidine (**27**), which is formed by the cyclization of 2-dimethoxymethyl-3-acetamidinopropionitrile (**26**), the addition product of acetamidine to **2**. To obtain further rational evidence of this idea, the synthesis of a model compound, 2-methyl-4-amino-5,6-dihydropyrimidine (**23**), was attempted. The treatment of acetamidine with acrylonitrile afforded a syrup, which was then converted into crystals at room temperature. The crystals, $C_5H_9N_3$, showed no band due to a nitrile group in the IR spectrum. Therefore, it was identified as 2-methyl-4-amino-5,6-dihydropyrimidine (**23**). The purification of the intermediate syrup was unsuccessful, but its IR spectrum, showing the band due to a non-conjugate nitrile group, suggested that it was 3-acetamidinopropionitrile (**22**).

The structure of **23** was also supported by the NMR spectrum in dimethyl sulfoxide-d_6 (Fig. 2), which showed a broad signal due to an amino group at 5.20 τ, a narrow triplet due to the methyl group at the 2-position at 8.18 τ, and signals due to H_5 (7.99 τ) and H_6 (6.78 τ) appearing as an A_2B_2 pattern. The triplet of the methyl group and the broad signal of H_6 must be caused by homoallyl coupling between them (J 1Hz). The value of the coupling constant was consistent with those of the coupling constants of **28** (J

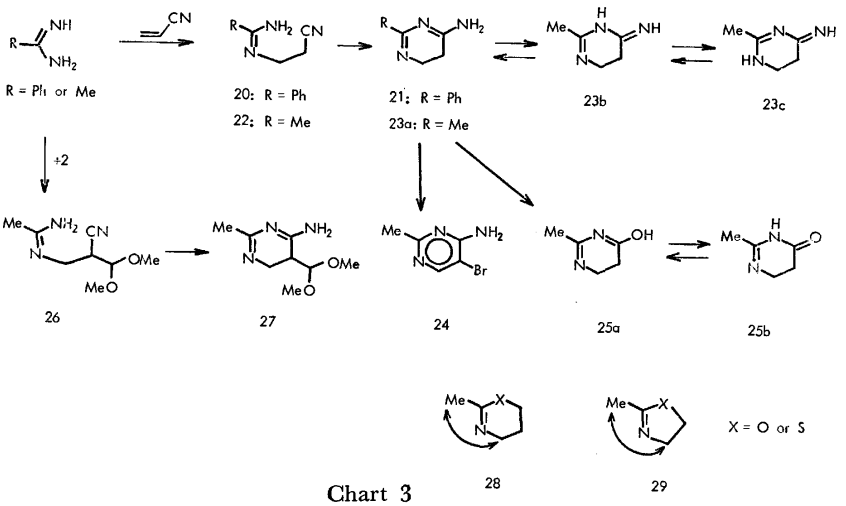

Chart 3

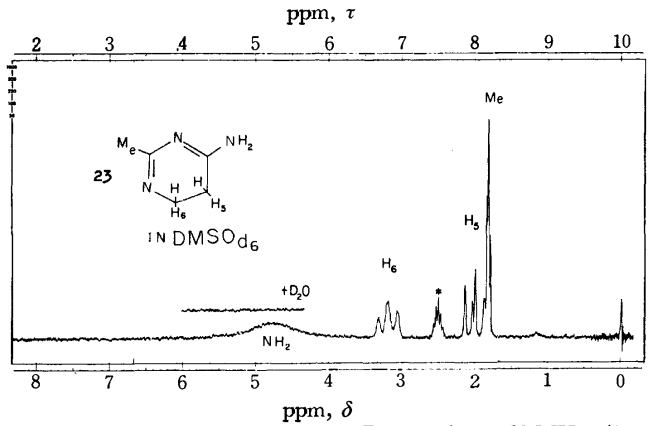

Fig. 2. NMR spectrum of **23** in DMSO-d_6 at 60 MHz (* DMSO-d_5).

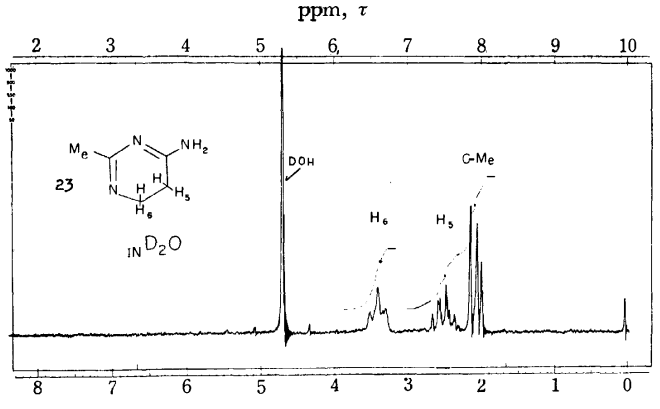

Fig. 3. NMR spectrum of **23** in deuterium oxide at 60 MHz.

1.5 Hz),[14] and **29** (J 1.38—1.65 Hz).[15] The methyl signal of **23** appeared as one triplet in dimethyl sulfoxide-d_6, but as three broad methyl singlets in deuterium oxide (Fig. 3). The spectrum seemed to suggest the existence of three kinds of tautomers, such as **23a**, **23b**, and **23c**.

The structure of **23** was unequivocally established by the following reactions. The bromination of **23** with bromine in acetic acid, followed by dehydrobromination with triethylamine, gave 2-methyl-4-amino-5-bromopyrimidine (**24**).[16] The addition of hydrochloric acid to a methanol solution of **23** immediately gave colorless crystals (**25**), whose molecular formula agreed with that of the hydrolized product of **23**. The NMR spectrum of **25** in methanol-d_4 showed a narrow triplet due to the methyl group, and signals due to H_5 and H_6 appeared as an A_2B_2 pattern. Therefore, **25** was determined to be 2-methyl-4-hydoxy-5,6-dihydropyrimidine (isolated as the HCl salt). As the IR spectrum of **25** showed the band due to an amidocarbonyl group, it seemed to have preferably the **25b** structure in a crystalline state rather than the **25a** structure. Easy hydrolysis of 4-amino group of **23** supported the presence of the partial structure of amidine, and the structure of **23**.[17]

The behavior of **23** in the UV spectrum was very important. The spectrum in methanol showed its absorption maximum at 270 mμ (ε 8,100); it was shifted to 275 mμ in acidic media and to 258 mμ in basic media. The values of the absorption maxima, 270 mμ and 258 mμ, were close to that of 262 mμ of the intermediate previously observed under basic conditions because of the presence of acetamidine. Therefore, the idea that **27** is the intermediate instead of **5** was supported.

In conclusion, for the reaction of **1** with acetamidine we would like to propose the following pathway **1**→**2**→**26**→**27** (the intermediate, λ_{max}^{MeOH} 262 mμ) → **6**, which accounts for the observed results. The mechanism of the step of **27**→**6** is also interesting; studies of it will be presented separately.

Experimental

All the melting points were recorded on a Kofler block and have not been corrected. The NMR spectra were taken with a Varian A-60-A spectrometer, using tetramethylsilane as the internal reference, and the chemical shifts were expressed in τ value (s: singlet, d; doublet, t: triplet, q:

quartet, m: multiplet). The molecular weights were determined by means of a vapor-pressure osmometer in chloroform unless otherwise stated. The solvents used were removed under reduced pressure.

*Reaction of 2-Dimethoxymethyl-3-methoxypropionitrile (**1**) with Sodium Methoxide.* A mixture of sodium methoxide (2.5 g) and **1** (50 g) was stirred at 40°C, while the methanol produced during the reaction period was eliminated under reduced pressure. After 2 hr, the mixture was dissolved in benzene (600 m*l*); the benzene solution was washed with water, 1 N hydrochloric acid, saturated sodium bicarbonate, and water, dried, and then the solvent was removed. The distillation of the residue (40 g) gave 2-dimethoxymethyl-2-methoxymethyl-4-methoxymethyleneglutaronitrile (**8**) (22.3 g, bp 177—183°C/2 mmHg). $UV_{m\mu}^{EtOH}$ 232 (ε 11100) $IR_{cm^{-1}}^{film}$ 2250, 2240 (CN), 1640 (C=C), 1080, 1150 (C–O–C, acetal). Found: C, 56.74; H, 7.33; N, 10.98%; mol wt, 260 (benzene). Calcd for $C_{12}H_{18}N_2O_4$: C, 56.68; H, 7.14; N, 11.02%; mol wt, 254.28.

*Reaction of 2-Dimethoxymethyl-2-methoxymethyl-4-methoxymethyleneglutaronitrile (**8**) with Acetamidine.* Acetamidine hydrochloride (2.6 g) was neutralized by methanolic sodium methoxide prepared from sodium (554 mg), and then the methanol was removed. To the residue, DME (100 m*l*) and **8** (2.2 g) were added, after which the mixture was refluxed for 2 hr. The solvent was evaporated to dryness and then extracted with ether (50 m*l*). From the ether layer, **8** (748 mg) was recovered. The recrystallization of the ether-insoluble residue from ethyl acetate gave 2-methyl-4-amino-5-(2'-cyano-2'-dimethoxymethyl-3'-methoxy)propylpyrimidine (**10**) (needles; 985 mg). Mp 139—140°C. $UV_{m\mu}^{MeOH}$ 235 (ε 6900), 278 (ε 3400); (+HCl) 252 $IR_{cm^{-1}}^{KBr}$ 2240 (CN), 1100, 1070 (acetal). NMR ($CDCl_3$) 1.93^s (1H, H_6), 5.63^s (1H, C<u>H</u>$(OMe)_2$), 7.53^s (3H, 2-Me), 6.43^s (6H, $CH(O\underline{Me})_2$), 6.59^s (3H, $CH_2O\underline{Me}$), 7.13^q (2H, $\underline{CH_2}OMe$). Found: C, 55.70; H, 7.10; N, 20.21%, mol wt, 279. Calcd for $C_{13}H_{20}N_4O_3$: C, 55.70; H, 7.19; N, 19.99%; mol wt, 280.32.

*2-Methyl-6-dimethoxymethyl-6-methoxymethyl-7-amino-5,6-dihydropyrido[2,3-d]pytimidine (**12**).* To a solution of 2-methyl-4-amino-5-(2'-cyano-2'-dimethoxymethyl-3'-methoxy)propylpyrimidine (**10**; 300 mg) in pyridine (1.5 g), a 48% sodium hydroxide solution (1 g) was added; the solution was then heated at 100°C for 20 min. After the removal of the pyridine, the residue was extracted with chloroform (200 m*l*), and then the chloroform was removed. The recrystallization of the residue from acetonitrile gave **12** (needles; 44 mg). Mp 195—196°C. $UV_{m\mu}^{EtOH}$ 221 (ε 13200), 301 (ε 14200); (+HCl) 281, 322. Found: C, 55.85; H, 7.18; N, 19.86%; mol wt, 285. Calcd for $C_{13}H_{20}N_4O_3$: C, 55.70; H, 7.19; N, 19.99%; mol wt, 280.32.

*2-Methyl-6-dimethoxymethyl-7-oxo-8H-5,6-dihydropyrido[2,3-d]pyrimidine (**13**).* A solution of 2-methyl-6-dimethoxymethyl-6-methoxymethyl-7-amino-5,6-dihydropyrido[2,3-*d*]pyrimidine (**12**; 0.5 g) in 10% acetic acid (10 m*l*) was heated at 100°C for 0.5 hr. The solution was concentrated and neutralized with a saturated sodium carbonate solution, and then the solvent was evaporated to dryness. The residue was extracted with ethyl acetate. From the extract, crude crystals of **13** were obtained (400 mg; mp 118—120°C). Recrystallization from ether gave pure plates of **13** (mp 125–125.3°C). $UV_{m\mu}^{EtOH}$ 242 (ε 5600), 275 (ε 10700); (+HCl) 280; (+NaOH) 280,301. $IR_{cm^{-1}}^{KBr}$ 1700 (CONH), 1065, 1100, 1120 (C–O–C, acetal). NMR ($CDCl_3$) 1.73^s (1H, H_4), 5.25^s (1H, C<u>H</u>$(OMe)_2$), 6.48^s (6H, $CH(O\underline{Me})_2$), 6.28^d, 6.33^d (2H, $\underline{CH_2}OMe$, J 9 Hz), 6.73^s (3H, $CH_2O\underline{Me}$), 6.82^m, 7.03^m (2H, H_5), 7.35^s (3H, 2-Me). Found: C, 55.52; H, 6.77; N, 15.07%, mol wt, 285. Calcd for $C_{13}H_{19}N_3O_4$: C, 55.52; H, 6.76; N, 14.95%, mol wt, 281.31.

*2-Methyl-6-methoxymethyl-7-oxo-8H-5,6-dihydropyrido[2,3-d]pyrimidine (**15**).* A solution of 2-methyl-6-dimethoxymethyl-6-methoxymethyl-7-amino-5,6-dihydropyrido[2,3-*d*]pyrimidine (**12**; 1 g) in 1 N hydrochloric acid (7 g) was heated at 100°C for 50 min. The solution was neutralized with a saturated sodium bicarbonate solution and then concentrated to 2 m*l*. After the extraction of this solution with chloroform (20 m*l*), the chloroform was evaporated to give a powder (723 mg). Recrystallization from methanol gave **15** (175 mg). Mp 185—186°C (columns). NMR ($CDCl_3$) 1.63^s (1H, H_4), 6.25^m (2H, $-CH_2O-$), 6.61^s (3H, OMe), 7.05^m (2H, H_5), 7.05^m (1H, H_6), 7.33^s (3H, 2-Me). Found: C, 58.11; H, 6.43; N, 20.37%. Calcd for $C_{10}H_{13}N_3O_2$: C, 57.96; H, 6.32; N, 20.28%.

*2-Methyl-6-carbethoxy-7-oxo-8H-pyrido[2,3-d]pyrimidine (**17**).* A mixture of 2-methyl-4-amino-5-formylpyrimidine[12] (**16**; 1.35 g), diethyl malonate (1.6 g), benzoic acid (45 mg), piperidine (100 mg) and benzene (18 m*l*) was refluxed for 2 hr, during which time the water produced was removed by azeotropic distillation with benzene. Then, more piperdine (110 mg) was added to the solution, and it was refluxed for an additional 4 hr. After cooling, the crystals which appeared were separated from the solution by filtration. The crystallization of the crystals from ethanol–methanol gave **17** (1.36 g). Mp 230—231.5°C (needles). $UV_{m\mu}^{EtOH}$ 265 (ε 3400), 274 (ε 3100), 324 (ε 9300), (+HCl) 265, 275, 320; (+NaOH) 256, 275, 353. $IR_{cm^{-1}}^{KBr}$ 1690 (CONH). NMR ($CDCl_3$) 5.29^q (2H), 8.58^t (3H)(OC_2H_5), 7.17^s (2-Me), 1.53^s (1H, H_4), 1.05^s (1H, H_5). Found: C, 56.39; H, 4.69; N, 17.79%; mol wt, 249. Calcd for $C_{11}H_{11}N_2O_3$: C, 56.65; H, 4.75; N, 18.02%; mol wt, 233.32.

*Reduction of 2-Methyl-6-carbethoxy-7-oxo-8H-pyrido[2,3-d]pyrimidine (**17**) with Sodium Borohydride.* To a solution of **17** (1.08 g) in ethanol (84 m*l*), sodium borohydride (470 mg) was added at 0°C. After the solution has been stirred for 1 hr at 0°C, the solution was adjusted to pH 4 with hydrochloric acid and then evaporated to dryness under reduced pressure. The residue was extracted with acetone (80 m*l*), and then the solvent was removed. The residue (powder 1.169 g) was purified by silica gel column chromatography [Wakogel Q-23 (30 g) was used]. The desired 2-methyl-6-carbethoxy-7-oxo-8*H*-5,6-dihydro[2,3-*d*]pyrimidine (**19**) was eluted with a mixture of chloroform and ethanol (8 : 1 v/v, 250 m*l*) after initial elution with chloroform (150 m*l*). The recrystallization of the eluted compound from ethanol gave **19** (333 mg). Mp 200—200.5°C. $UV_{m\mu}^{EtOH}$ 240 (ε 8200), 271 (ε 14100); (+HCl) 277; (+NaOH) 298. $IR_{cm^{-1}}^{KBr}$ 1740, 1690 (C=O). NMR ($CDCl_3$) 5.78^q (2H), 8.75^t (3H) (OC_2H_5), 1.63^s (1H, H_4), 7.35^s (3H, 2-Me), 6.78^m (2H, $-\underline{CH_2}-CH$), 6.32^m (1H, $-CH_2-C\underline{H}-$). Found: C, 56.21; H, 5.65; N, 17.71%; mol wt, 249. Calcd for $C_{11}H_{13}N_3O_3$: C, 56.16; H, 5.77; N, 17.86%, mol wt, 235.24.

Reaction of Acrylonitrile with Benzamidine. Benzamidine (4.5 g) was dissolved completely in acrylonitrile (2 g) at −30°C and then left at room temperature. After 1 hr, crystals of 3-benzamidinopropionitrile (**20**) appeared. $IR_{cm^{-1}}^{Film}$ 2280 (CN). NMR ($CDCl_3$) 6.48^m (2H, H_3), 7.27^m (2H, H_2). The crystals were heated for 20 min on a boiling water-bath and then recrystallized from chloroform-benzene. Colorless plates of 2-phenyl-4-amino-5,6-dihydropyrimidine (**21**) (mp 178—180°C)[13] were thus obtained (3.1 g).

Reaction of Acrylonitrile with Acetamidine. A solution of acetamidine hydrochloride (11.8 g) in methanol (30 m*l*) was neutralized with methanolic sodium methoxide pre-

pared from sodium (2.56 g) and methanol (50 ml). The solution was filtered, and then the filtrate was evaporated to dryness. To the residue, acrylonitrile (4 g) was added at 10—20°C, after which the solution was allowed to stand at room temperature for 1 day. The reaction mixture was then solidified. Recrystallization from ethanol–ether (3/8 v/v) gave crude crystals of 2-methyl-4-amino-5,6-dihydropyrimidine (**23**). The further recrystallization of **23** from ethanol gave a pure sample (cubics, 1.45 g). Mp 188—192°C. Found: C, 53.85; H, 8.39; N, 37.82%; mol wt, 125 (ethanol). Calcd for $C_5H_9N_3$: C, 54.03; H, 8.16; N, 37.81%; mol wt, 111.15.

*Dehydrogenation of 2-Methyl-4-amino-5,6-dihydropyrimidine (**23**).* Into a solution of **23** (222 mg) in acetic acid (6 ml) in portions was stirred below 15°C. After the solution had been stirred for 40 min, precipitates were collected by filtration and washed with ethanol. A mixture of precipitates, triethylamine (300 mg), and ethanol (3 g) was refluxed for 3 min, evaporated to dryness, and extracted with benzene, and the benzene was removed. The recrystallization of the residue from water gave 2-methyl-4-maino-5-bromopyrimidine (**24**) (80 mg), mp 138—140°C.[16]

*Hydrolysis of 2-Methyl-4-amino-5,6-dihydropyrimidine (**23**).* To a solution of **23** (111 mg) in methanol, 21% methanolic hydrochloric acid (w/w 0.4 g) was added. Crystals of hydrochloric acid salt of **23** thus appeared. Water (25 mg) was added to the solution, and the solution was stirred at room temperature. After 1 hr, the crystals dissappeared and columnar crystals were newly precipitated. Recrystallization of the columnar crystals from methanol gave 2-methyl-4-hydroxy-5,6-dihydropyrimidine hydrochloride (**25**) (40 mg). Mp>250°C. $UV_{m\mu}^{MeOH}$ 227 (ε 7,570); (+NaOH) 208. $IR_{cm^{-1}}^{KBr}$ 1740 (CONH). NMR (CD_3OD) 7.60^s (3H, 2-Me), 7.15^m (2H, H_5), 6.15^m (2H, H_6). Found: C, 40.41; H, 6.10; N, 18.86%. Calcd for $C_5H_9N_2OCl$: C, 40.36; H, 6.14; N, 19.06%.

The authors wish to express their deep gratitude to Professor Toshihiko Okamoto, University of Tokyo, and to Dr. Ken'ichi Takeda, Director of this Laboratory, for their encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1132—1136 (1972)

Study on Oxidation of Chalcones with Lead Tetraacetate and Manganic Acetate

Kazu KUROSAWA and Junko HIGUCHI

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto

(Received July 31, 1971)

2′-Hydroxychalcones were oxidized with lead tetraacetate and manganic acetate to give *trans*- and *cis*-aurones, together with substituted benzoic acids and cinnamic acid. In the oxidation, 2′-benzyloxy-4,4′-dimethoxychalcone gave 2-acetoxy-1-(2′-benzyloxy-4′-methoxy)phenyl-3-(4′-methoxy)phenylpropane-1,3-dione and *erythro*-2,3-diacetoxy-1-(2′-benzyloxy-4′-methoxy)phenyl-3-(4′-methoxy)phenylpropan-1-one. Structures of the products were elucidated spectrometrically and confirmed by syntheses.

Several papers[1-4] have been published on the oxidation of various organic compounds with manganic acetate. In a previous communication,[5] it was reported that 2′-hydroxychalcones (Ia–i) were oxidized with manganic acetate to give aurones (IIa–i). In some cases,[3,4] however, it was shown that under certain conditions the reagent has a strong similarity to lead tetraacetate.[6] We therefore carried out the oxidation of Ia–i with lead tetraacetate and also examined the oxidation with manganic acetate more in detail. We wish to report both results in this paper.

When 2′-hydroxychalcones (Ia–c) were oxidized with either manganic acetate or lead tetraacetate in acetic acid, several compounds were isolated (Table 1). From mother liquors of the main products aurones (IIb and IIc), compounds IIIb and IIIc, respectively, were separated by successive thin layer chromatography and were found to be isomers of IIb and IIc from the following evidences. IR spectra of IIIb and IIIc showed absorptions at 1676—1679 cm^{-1} which are slightly lower than those of IIa, IIb, and IIc (1700 cm^{-1}) (Table 2). In 60 MHz NMR spectra of IIa, IIb, IIc, IIIb, and IIIc (Table 3), the difference was shown in a signal corresponding to $H_{2'}$ and $H_{6'}$/ or $H_{6'}$. The signals of $H_{2'}$ and $H_{6'}$ of IIIb and $H_{6'}$ of IIIc appeared at δ8.29 and 8.77, respectively, rather lower field shifts as compared with those of IIb (δ 8.06) and IIc (δ 8.12). The cause of the shifts could be ascribed to the anisotropic effect of a carbonyl group. Thus, the NMR spectra indicated that IIa, IIb, and IIc have a *trans*-configuration with respect to the carbonyl and the phenyl groups, and IIIb and IIIc have a *cis*-configuration. Their UV spectra showed a characteristic absorption pattern, *viz.*, the *trans*-isomer (IIa–c) has an absorption maximum at a longer wavelength (376—392 nm) and the *cis*-isomer at a shorter wavelength (350—352 nm) (Table 2).

Three acidic compounds were isolated and they were found to be a 2-hydroxybenzoic acid (IV), a

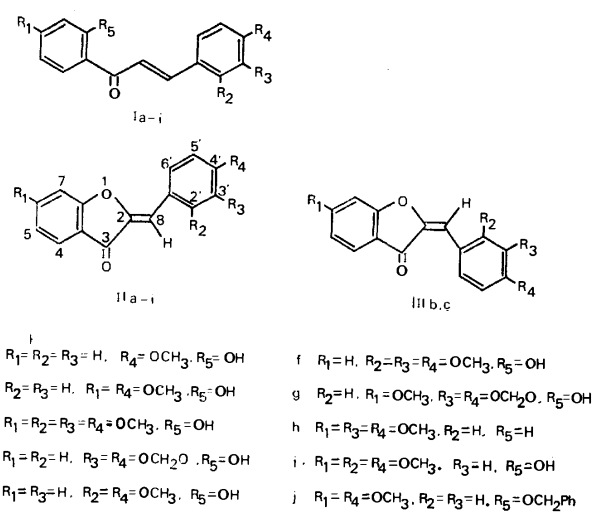

Fig. 1.

benzoic acid (V) and a cinnamic acid (VI). They were identified with authentic samples by their IR spectra.

It was reported recently[10] that the reaction of of chalcones with thallium acetate gave a product in which a skeletal rearrangement took place. This prompted us to investigate the oxidation of 2'-benzyloxy-4,4'-dimethoxychalcone (Ij)[11] with lead tetraacetate and manganic acetate. With both reagents, identical products IVj, V, VII, VIII, and IX were obtained (Table 1).

Product (VIII), $C_{26}H_{24}O_7$ (analysis and mass spectrum), mp 155—156°C, was isolated from chloroform extract of the reaction mixture by preparative tlc and recrystallization. The IR spectrum of VIII (ν_{max} 1750, 1250, and 1675 cm^{-1}) suggested the presence of an acetoxyl group and an aroyl group. The NMR spectrum (100 MHz) of VIII indicated the presence of a *p*-methoxybenzoyl group {δ 6.68(d, 2H), δ 7.61 (d, 2H) (AA'BB' system, $J_{AB}=J_{A'B'}=9$ Hz), and δ 3.64 (s, 3H)}, a 2-benzyloxy-4-methoxybenzoyl group δ 7.09 (broad s, 5H), δ 4.70 (d, 1H) and δ 4.82 (d, 1H) (AB system, $J=12.0$ Hz), δ 6.26 (d, 1H), δ 6.46 (dd, 1H) and δ 7.92(d, 1H)(ABX system, $J_{AB}=2$ Hz, $J_{AX}=0$ and $J_{BX}=9$ Hz), and δ 3.73(s, 3H)}, and an acetoxyl group {δ 2.08(s, 3H)}. This spectroscopic evidence indicated that product (VIII) is 2-acetoxy-1-(2'-benzyloxy-4'-methoxy)phenyl-3-(4'-methoxy)phenylpropane-1,3-dione.

Product (IX), $C_{28}H_{28}O_8$ (analytical and mass spectrum), mp 164—166°C, was isolated also from the chloroform extract. The IR spectrum of IX indicated the presence of an acetoxyl and a benzoyl groups (1745 and 1250, and 1675 cm^{-1}, respectively). The NMR spectrum (100 MHz) of IX indicated the presence of a *p*-methoxyphenyl group {δ 6.80(d, 2H), δ 6.58 (d, 2H) (AA'BB' system, $J_{AB}=J_{A'B'}=9$ Hz) δ 3.68(s, 3H)}, a 2-benzyloxy-4-methoxybenzoyl group {δ 7.3—7.6(m, 5H), δ 5.18(s, 2H), δ 6.52(d, 1H), δ 6.50(dd, 1H) and δ 7.76(d, 1H)(ABX system, $J_{AB}=2.5$, $J_{AX}=0$, and $J_{BX}=9.4$ Hz), δ 3.78(s, 3H)}, two acetoxyl groups {δ 1.92(s, 3H) and δ 2.02(s, 3H)}, and a CH=CH unit{δ 6.28 (d, 1H), and δ 6.36(d, 1H)(AB system, $J=3.0$ Hz)}. All the spectroscopic evidence showed that the product (IX) has a structure of 2,3-diacetoxy-1-(2'-benzoyloxy-4'-methoxy)phenyl-3-(4'-methoxy)phenylpropan-1-one (IX).

The third product isolated from the chloroform extract was found to be anisaldehyde (VII), being identified with an authentic sample by IR spectra.

The fourth product, mp 184°C, was isolated by sodium bicarbonate extraction of the chloroform extract and was proved to be anisic acid (V). This was confirmed on the mixed melting point test with an authentic sample.

The fifth product, mp 100—101°C, was found to be 2-benzyloxy-4-methoxybenzoic acid(IVj) by its NMR spectrum(60 MHz) {δ 7.53(s, 5H), δ 5.32 s, 2H), δ 3.88(s, 3H), δ 6.65(d, 1H), δ 6.70(dd, 1H) and δ 8.22 (d, 1H) (ABX system, $J_{AB}=2$, $J_{AX}=0$, and $J_{BX}=8.5$ Hz), and δ 12.0(s, 1H)}.

The structures of VIII and IX were finally confirmed by syntheses.

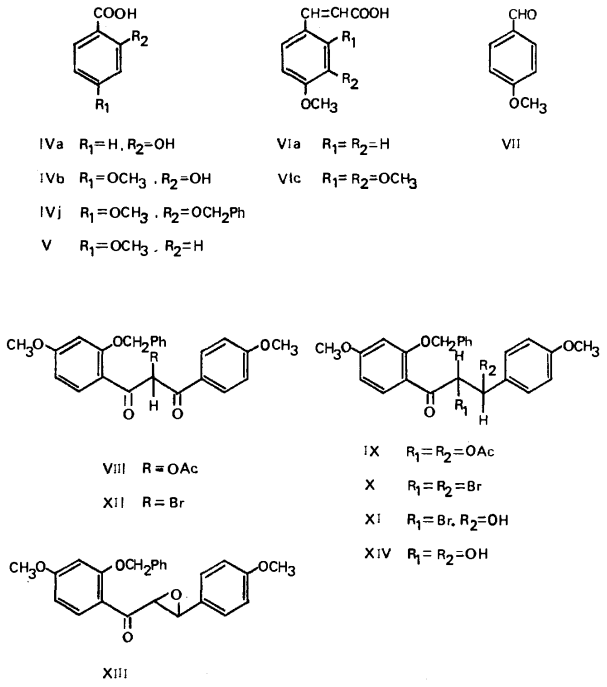

Fig. 2.

A chalcone dibromide (X), mp 163—165°C, obtained from Ij, was treated with wet acetone.[12] This yielded a bromohydrin (XI), mp 129—130°C. XI was oxidized with chromic acid to a diketone (XII), mp 80—82°C. XII was then heated with sodium acetate in acetic acid to give an acetate. The acetate has a melting point and IR spectrum identical with those of VIII.

12) M. G. Marathey, *J. Org. Chem.*, **20**, 563 (1955).

IX was synthesized as follows. The chalcone epoxide (XIII), mp 93°C, was treated with aqueous acetic acid and the resulting glycol (XIV), mp 134—135°C, was acetylated with acetic anhydride in pyridine. This acetate was found to be identical with product (IX). It is also shown by this synthesis that IX has an *erythro* diacetoxy configuration as a *trans*-chalcone epoxide is hydrolysed to a glycol by S_N2 mechanism and this makes a *trans* addition to a *trans* double bond.

Thus, the reaction of manganic acetate and lead tetraacetate with chalcone proceeded in a similar way to each other, but differed from the reaction of thallium acetate.[10] Rearranged products have not been isolated. It was also shown that the reaction takes place differently from those of a substituted styrene and a compound having an isolated double bond, which gave a lactone[3,4,6] and a 1,2-diacetate,[13] respectively. It can be said that the carbonyl group must have a significant influence in the oxidation of the chalcone. This was illustrated by the formation of the diketone (VIII), which seemed to be the first example. It seems unlikely that product (IX) is an intermediate in the formation of VIII as the former is not reactive with manganic acetate.

Table 4. Analysis of new compounds

Experimental

All NMR spectra were recorded for deuteriochloroform solutions with a JEOL JNM-MH-100 and a JNM-MH-60 spectrometers with tetramethylsilane as an internal standard; IR spectra were recorded for chloroform solution with a JASCO DS 403G grating spectrometer; UV spectra were obtained for methanol solutions with a Hitachi EPS-3T spectrophotometer. Preparative and analytical tlc were carried out with a Wakogel BlO. Melting points were determined with a Yanagimoto micro melting point apparatus and uncorrected.

Lead tetraacetate and manganic acetate were prepared according to references.[14,15]

Reaction of Lead Tetraacetate with Chalcones (Ia—i). Chalcone (1 mmol), dissolved in acetic acid (15 ml) was heated with lead tetraacetate (1.5 mmol) at 100°C for 30 min. After removal of the acetic acid *in vacuo*, the resulting solid was treated with 2 N sulfuric acid (10 ml) and then extracted with chloroform (20 ml). The chloroform layer was separated from the aqueous solution and then evaporated. The residue was dissolved in a small amount of chloroform and separated on tlc (10 g×5) with chloroform as an eluent. The crude aurone was recrystallized from ethanol.

Reactions of Lead Tetraacetate and Manganic Acetate with Chalcones (Ia—c) in a Large Scale. Chalcone (20 mmol) was oxidized as above with lead tetraacetate (30 mmol) or manganic acetate (60 mmol) and the products were separated on alumina (Wako, 100 g) with chloroform as an eluent. *cis*-Aurone was separated from a *trans*-aurone by repeated tlc and recrystallization from ethanol. Sodium bicarbonate extraction of the chloroform solution yielded a mixture of carboxylic acids (IV, V and VI), which were separated by fractional recrystallization from water.

Reaction of Manganic Acetate with 2'-Benzyloxy-4,4'-dimethoxychalcone (Ij).[11] Ij (2 mmol) was dissolved in acetic acid (20 ml) containing acetic anhydride (1 ml) and then heated with manganic acetate (8 mmol) at 100°C for 8 hr. After removal of the acetic acid, the resulting mixture was hydrolyzed with 2 N sulfuric acid and then extracted with chloroform. The chloroform layer was washed with aqueous sodium bicarbonate. The chloroform being removed, the resulting liquid was chromatographed on preparative tlc (35 g×5) effected with chloroform. From a band running just below Ij, product (VIII) was obtained and recrystallized from ethanol to give colorless plates, mp 155—156°C. From a slow running band, product (IX) was separated after recrystallization from ethanol as colorless needles, mp 164—166°C. From a band just above Ij, colorless liquid was isolated and identified as anisaldehyde (VII) on comparison of its IR spectrum with that of an authentic sample. Upon acidification of the sodium bicarbonate extract, two acids, IVj and V were obtained after recrystallization from water.

Reaction of Lead Tetraacetate with Ij. Ij (2 mmol) was oxidized with lead tetraacetate (4 mmol) in acetic acid (20 ml) at 100°C for 7.5 hr. Working up in a manner as described above, products (IVj, V, VII, VIII, and IX) were isolated.

1-(2'-Benzyloxy-4'-methoxy)phenyl-2,3-dibromo-3-(4'-methoxy)-phenylpropan-1-one (X). Ij (3.74 g) in carbon disulfide (50 ml) was treated with bromine (1.6 g) at 0°C for 15 min. The precipitates were collected and recrystallized from benzene to give microcrystals, mp 163—165°C (3.54 g, 67%).

1-(2'-Benzyloxy-4'-methoxy)phenyl-2-bromo-3-hydroxy-3-(4'-methoxy)phenylpropan-1-one (XI). X (3.00 g) was treated with 60% aqueous acetone (30 ml) under reflux for 15 min. After removal of the acetone, the aqueous solution was extracted with benzene. Benzene was removed and the resulting liquid was allowed to crystallize from a small amount of benzene. Recrystallization of the crude product from the same solvent yielded colorless cubes, mp 129—130°C, (1.22 g, 46%).

1-(2'-Benzyloxy-4'-methoxy)phenyl-2-bromo-3-(4'-methoxy)-phenylpropane-1,3-dione (XII). To XI (412 mg) in acetic acid (10 ml), was added chromic acid (246 mg) in acetic acid (25 ml) at room temperature and the mixture was warmed on a steam bath for 2.5 min. The reaction mix-

ture was treated with 2 N sulfuric acid (100 ml) and then extracted with chloroform. After removal of the chloroform, the resulting liquid was allowed to crystallize from benzene. Recrystallization of the crude product from benzene gave colorless microcrystals, mp 80—82°C, (199 mg, 54%).

2-Acetoxy-1-(2'-benzyloxy-4'-methoxy)phenyl-3-(4'-methoxy)phenylpropane-1,3-dione (VIII). XII (112 mg) was treated with a mixture of anhydrous sodium acetate (500 mg) and acetic acid (2 ml) under reflux for 7.5 hr. The reaction mixture was treated with 2 N sulfuric acid and then extracted with chloroform. The chloroform layer was concentrated and separated on silica gel (10 g×3) with chloroform as an eluent. From appropriate band, a crude material was separated and recrystallized from ethanol to give colourless plates, mp 154—155°C, (30 mg, 28%).

2'-Benzyloxy-4,4'-dimethoxychalcone Epoxide (XIII). To a mixture of the chalcone(Ij) (1 g), acetone (20 ml) and methanol (10 ml), and 2 N sodium hydroxide (2.0 ml) was added 30% hydrogen peroxide (2.5 ml) at 50°C during a period of 50 min. The reaction mixture was poured into ice water and extracted with chloroform. After removal of the chloroform, the resulting liquid was allowed to crystallize from ethanol. This yielded colorless microcrystals, mp 93°C, (49%).

1-(2'-Benzyloxy-4'-methoxy)phenyl-2,3-dihydroxy-3-(4'-methoxy)-phenylpropan-1-one (XIV). XIII (248 mg) was dissolved into a mixture of acetone (25 ml) and 10% acetic acid (25 ml) and kept at room temperature for 16 hr. The mixture was diluted with water and the precipitates were collected. Recrystallization of the crude product from ethanol gave colorless needles, mp 134—135°C, (117 mg, 45%).

2,3-Diacetoxy-1-(2'-benzyloxy-4'-methoxy)phenyl-3-(4'-methoxy)-phenylpropan-1-one (IX). XIV (117 mg) was treated with a mixture of acetic anhydride (0.5 ml) and pyridine (1 ml) at 0°C for 18 hr. The reaction mixture was poured into ice water and the precipitates were collected. Recrystallization of the precipitates from ethanol gave colorless needles, mp 164—166°C, (52 mg, (37%).

The authors wish to thank Professor Shin-ichi Sasaki and Mr. Hidetsugu Abe, Miyagi University of Education, for measuring NMR spectra. The authors also deeply thank the staff of JEOL Co. Ltd. for recording 100 MHz NMR and mass spectra.

Synthesis and Conformation of Cyclopropane Intermediates in the Total Synthesis of Illudin M and S

Takeshi MATSUMOTO, Haruhisa SHIRAHAMA, Akitami ICHIHARA, Hyonsobb SHIN, Shohei KAGAWA, Toshiaki HISAMITSU, Toshihiro KAMADA, and Fujio SAKAN

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received August 6, 1971)

Several promising cyclopropane intermediates in the total synthesis of illudin M and S have been prepared. Survey of NMR of these compounds showed the conformation **17** to be unfavourable.

Preliminary reports were given on the total synthesis of illudin M and S[1,2]. Cyclopropyl ketone derivatives of general formula **1**, where X represents hydrogen or any groups activating methylene group, were desirable for the Michael reaction (Scheme 1) which was expected for combined cyclopropane and cyclopentane moieties to give useful intermediates **3** for illudins. This paper describes the synthesis of several cyclopropane derivatives **6**, **9**, **12**, **13**, **14**, and **15** of this type and their preferred conformation.[3] Ethyl 2,2-ethano-3-ketobutyrate (**4**), bp 90—102°C/20 mmHg, was prepared by the alkylation of acetoacetic ester with ethylene bromide in 24% yield and the carbonyl group of compound **4** was masked with ethylene glycol in the usual manner to give ketal **5**, bp 127—137°C/20 mmHg, in 68% yield. Ketal **5** was converted into 1-methanesulfinyl-3,3-ethano-4,4-ethylenedioxy-2-pentanone (**9**), mp 41—43°C in 91% yield by treatment with methylsulfinyl carbanion according to Corey's general procedure.[5] The Pummerer reaction of **9** by heating with acetic anhydride at reflux temperature for 3 hr afforded acetoxysulfide **12**, mp 44—46°C, in 79% yield. On treatment with amalgamated aluminum in aqueous ethanol at room temperature, the methylthio group of **12** and

2) T. Matsumoto, H. Shirahama, A. Ichihara, H. Shin, S. Kagawa, F. Sakan, and K. Miyano, *Tetrahedron Lett.*, **1971** 2049.

3) Our purpose was finally achieved[4] by the Michael reaction of β-ketosulfoxide **9** (**1**, X=$SOCH_3$) with cyclopentenone **2**. Attempted Michael reactions of cyclopropyl ketones **6**, **12**, **13**, **14**, and **15** with **2** were unsuccessful.

4) T. Matsumoto, H. Shirahama, A. Ichihara, H. Shin, S, Kagawa, N. Ito, T. Hisamitsu, T. Kamada, F. Sakan, K. Saito, S. Nishida, and S. Matsumoto, *Tetrahedron Lett.*, **1968**, 1925.

5) E. J. Corey and M. Chaykovsky, *J. Amer. Chem. Soc.*, **87**, 1345 (1965).

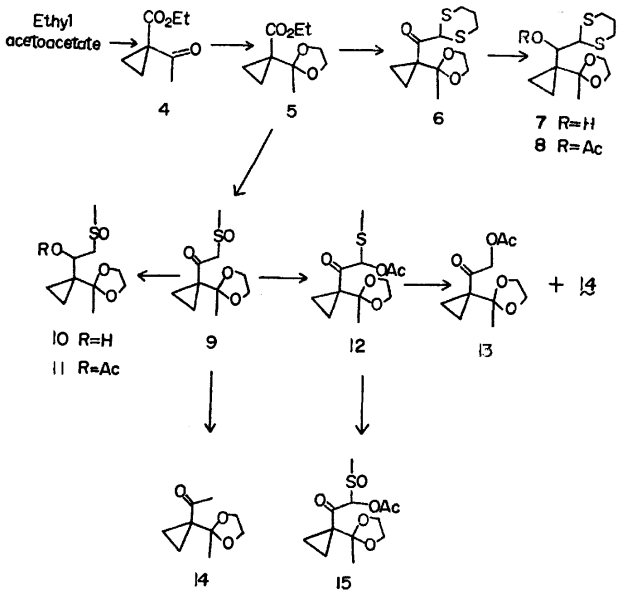

Fig. 1.

part of the acetoxy group were removed to give acetoxymethyl ketone **13**, bp 89—92°C/1 mmHg (30%) and methyl ketone **14**, bp 45—50°C/1 mmHg (25%). The latter was directly obtained by the treatment of **9** with the same reagent in aqueous tetrahydrofuran. Sulfide **12** was converted into sulfoxide **15** by oxidation with hydrogen peroxide in acetic acid (26%).

1,1-Trimethylenedithio-3,3-ethano-4,4-ethylenedioxy-2-pentanone (**6**), mp 59—60°C, was obtained by the action of an anion of 1,3-dithiane on the ester **5** according to Corey's method[6] in 45% yield.

We would like to add a note on the conformation of the cyclopropyl methyl ketone ethylene ketals. The long range shielding effect of the cyclopropane ring is well known[7,8] from which the instability of the conformation **16** of cyclopropyl methyl ketones has been

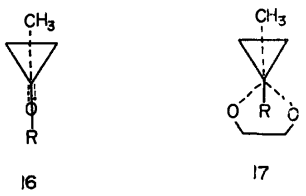

Fig. 2. Unstable conformations of cyclopropyl methyl ketones and their ketals.

deduced[7]. By comparison of chemical shifts of methyl group on the dioxolane rings with those of the compounds with *gem*-dimethyl group in the place of cyclopropane ring, information on the conformation of the above cyclopropyl methyl ketone ethylene ketals might be obtained. Three of such *gem*-dimethyl compounds (**21**, **18**, **22**) were prepared for another purpose[9] and some more pairs of cyclopropyl ketone ketals and the corresponding *gem*-dimethyl compounds were available. Cyclopropyl ketones **6** and **9** were reduced with sodium borohydride to give hydroxydithiane derivative **7** and hydroxysulfoxide **10**, mp 120—122°C, respectively. Both alcohol **7** and **10** were converted into acetates **8** and **11** in the usual manner. The *gem*-dimethyl compounds corresponding to **10** and **11**, 1-methanesulfinyl-3,3-dimethyl-4,4-ethylenedioxy-2-pentanol (**19**) and its acetate **20**, were prepared from dimethylmethanesulfinylpentanone **18** in the same manner as in the preparation of **10** and **11**.

As shown in Table 1, the methyl signals of the cyclopropyl compounds invariably appeared at a lower field than those of the *gem*-dimethyl compounds, showing that conformation **17** of the cyclopropyl compounds is not preferable. The fact that conformation **17** in which the methyl group situated just above the cyclopropane ring is unfavorable can be explained by the repulsion between cyclopropane ring and eclipsed methyl group. Instability of the so called transoid cyclopropyl methyl ketones **16** might be due, at least in part, to the same effect.

Table 1. Chemical shifts (τ) of methyl groups on the dioxolane rings

Compounds

Experimental

NMR spectra were taken on JEOL Co. Model 3H60 and Hitachi Model H60 spectrometers.

*Ethyl 2,2-Ethano-3-ketobutyrate (**4**).* An ethanolic solution prepared from 46 g of sodium and 900 ml of ethanol was added dropwise over a period of 6 hr with stirring, to a mixture of 130 mg of ethyl acetoacetate and 188 g of ethylene bromide. The temperature was maintained so that the the mixture was just refluxed. After addition was completed, the reaction mixture was further refluxed for 14 hr with stirring and concentrated under reduced pressure at temperatures below 50°C until most of the ethanol was removed. The residue was extracted with benzene several times and the combined extracts were washed with a saturated salt solution and dried. After evaporation of the solvent, the crude product was distilled to yield 39.1 g of an oil boiling at 85—90°C/25 mmHg. The distillate was dissolved in benzene and washed with 10% aqueous potassium hydroxide solution several times and then with a saturated salt solution and dried. Evaporation of the solvent gave 37.4 g (24%) of desired cyclopropane derivative: IR (neat) 3050, 1725, 1685 cm^{-1}.

*Ethyl 2,2-Ethano-3,3-ethylenedioxybutyrate (**5**).* A mixture of 115 g of **4**, 134 g of ethylene glycol, 300 mg of *p*-toluenesulfonic acid and 370 m*l* of benzene was refluxed for 46 hr. The water formed was removed by azeotropic distillation with a Dean-Stark separator. After cooling down to room temperature the reaction mixture was washed with a saturated sodium bicarbonate solution and then with water and dried. Evaporation of the solvent gave crude product which, on distillation, gave 100 g (68%) of the desired ketal; bp 127—137°C/20 mmHg; IR (neat) 1725 cm^{-1}; NMR $\tau(CCl_4)$ 9.00 (4H, m, cyclopropane), 8.73 (3H, t, $J=7$ Hz, CH_3CH_2O), 8.44 (3H, s, CH_3CO), 6.16 (4H, s, OCH_2CH_2O), 5.96 (2H, q, $J=7$ Hz, OCH_2CH_3).

Found: C, 59.98; H, 8.06%. Calcd for $C_{10}H_{16}O_4$: C, 59.98; H, 8.05%.

*1-Methanesulfinyl-3,3-ethano-4-ethylenedioxy-2-pentanone (**9**).* A portion of ether (210 m*l*) and 42.2 g of ester **5** were added dropwise over a period of 1 hr to a dimethyl sulfoxide solution of methanesulfinyl carbanion, prepared from 140 m*l* of dimethyl sulfoxide and 12.9 g of sodium hydride (50% mineral oil dispersion), under ice-water cooling and mechanical stirring in the atmosphere of nitrogen. The ice-water bath was removed and stirring was continued for additional 1.5 hr at room temperature and the reaction mixture was then poured into about 1 *l* of water washed three times with benzene, neutralized with diluted acetic acid to a pH of 5—6 (pH paper), and extracted five times with chloroform. The combined extracts were washed with a saturated salt solution until the washings were no longer acidic, dried over sodium sulfate and evaporated to yield 44.5 g (91%) of keto sulfoxide **10** as a pale yellow crystalline solid. A sample was recrystallized from ethyl acetate for analysis: mp 41—43°C; IR (Nujol) 1680, 1045 cm^{-1}; NMR $\tau(CDCl_3)$ 8.87 (4H, bs, cyclopropane), 8.53 (3H, s, CH_3), 7.32 (3H, s, CH_3SO), 6.07 (4H, s, OCH_2CH_2O), 5.99 and 5.73 (2H, ABq, $J=15$ Hz, CH_2SO).

Found: C, 51,65; H, 6.86%. Calcd for $C_{10}H_{16}O_4S$: C, 51.70; H, 6.94%.

*1-Methanesulfenyl-1-acetoxy-3,3-ethano-4,4-ethylenedioxy-2-pentanone (**12**).* A solution of 4.0 g of sulfoxide **9** in 40 g of acetic anhydride was gently refluxed for 3 hr. Most of the acetic anhydride was evaporated under reduced pressure and the residue was dissolved in chloroform, washed with a saturated sodium bicarbonate solution and a saturated salt solution and dried. Removal of the solvent gave an oil which was chromatographed on silica gel to give 3.8 g (79%) of crystalline product; mp 44—46°C; IR (Nujol) 1740, 1690, 1240, 1040 cm^{-1}; NMR $\tau(CCl_4)$ 8.7—9.4 (4H, m, cyclopropane), 8.45, (3H, s, CH_3), 8.12 (3H, s, CH_3S), 7.92 (3H, s, AcO), 5.9—6.3 (4H, m, OCH_2CH_2O), 3.62 (1H, s, SCHO).

Found: C, 52.74; H, 6.79%. Calcd for $C_{12}H_{18}O_5S$: C, 52.55; H, 6.62%.

*1-Acetoxy-3,3-ethano-4,4-ethylenedioxy-2-pentanone (**13**).* Aluminum amalgam freshly prepared from 2.4 g of aluminum foil was added with stirring to a solution of 2 g of the Pummerer reaction product in 120 m*l* of 10% aqueous ethanol. The mixture was stirred for 2 hr at room temperature, then filtered and the residue was washed with ethanol. The combined filtrate was concentrated under reduced pressure at a temperature below 50°C till the most of ethanol was removed. The residue was dissolved in ether and the solution was washed with water and dried over anhydrous sodium sulfate. Evaporation of the ether gave 1.2 g of the crude products which was subjected to preparative vpc (column: Apiezon Grease (1 m), at 175°C, carrier gas: He 120 m*l*/min) to give *ca.* 300 mg (25%) of methyl ketone **14** and 460 mg (30%) of the desired product: bp 89—92°C/1 mmHg; IR (neat) 1750, 1710, 1230, 1045 cm^{-1}; NMR $\tau(CCl_4)$ 8.9—9.2 (4H, m, cyclopropane), 8.51 (3H, s, CH_3), 7.90 (3H, s, AcO), 6.60 (4H, s, OCH_2CH_2O), 5.12 (2H, s, CH_2OAc).

Found: C, 57.89; H, 7.12%. Calcd for $C_{11}H_{16}O_5$: C, 57.88; H, 7.07%.

*3,3-Ethano-4,4-ethylenedioxy-2-pentanone (**14**.)* Amalgamated aluminum freshly prepared from 2.7 g of aluminum foil was added with stirring to a solution of 2.32 g of the sulfoxide **9** in 150 m*l* of 10% aqueous tetrahydrofuran. The mixture was stirred for 1 hr in an ice-water bath, then filtered and the filtered solid was washed with tetrahydrofuran. The filtrate was concentrated till most of the tetrahydrofuran was removed. The residue was dissolved in ether, washed with water and dried over anhydrous sodium sulfate. Removal of the solvent gave 1.28 g of desired ketone: bp 45—46°C/1 mmHg; IR (neat) 1688, 1045 cm^{-1}; NMR $\tau(CCl_4)$ 8.91 (4H, s, cyclopropane), 8.44 (3H, s, CH_3), 7.79 (3H, s, CH_3CO), 6.08 (4H, s, OCH_2CH_2O).

*1-Methanesulfinyl-1-acetoxy-3,3-ethano-4,4-ethylenedioxy-2-pentanone (**15**).* Hydrogen peroxide (30% solution, 500 mg, 2 equivalent) was added to a solution of 450 mg of the Pummerer reaction product **12** in 5 m*l* of acetic acid. The solution was kept at a temperature below 10°C for 20 hr, neutralized with saturated sodium carbonate solution and extracted with benzene several times. The combined extracts were dried over anhydrous magnesium sulfate and the solvent was removed to give an oil. The oil was purified by silica gel chromatography to yield 122 mg (26%) of the sulfoxide; IR (neat) 1745, 1690 cm^{-1}; NMR $\tau(CDCl_3)$ 9.5—8.0 (4H, m, cyclopropane), 8.36 (3H, s, CH_3), 7.7 (3H, s, AcO), 7.46 (3H, s, CH_3SO), 6.3—5.7 (4H, m, OCH_2CH_2O), 3.05 (1H, s, $OSHC<^{OAc}_{CO}$).

*1,1-Trimethylenedithio-3,3-ethano-4,4-ethylenedioxy-2-pentanone (**6**).* A solution of 7 g of *n*-butyl bromide in 10 m*l* of ether was added dropwise to 0.8 g of lithium metal covered with 20 m*l* of ether at −30——40°C and stirred for 1.5 hr at 0—10°C. To the resulting solution was added dropwise 4.3 g of 1,3-dithiane in 70 m*l* of tetrahydrofuran at −30——40°C and stirred. To the solution thus prepared was added dropwise 7 g of ester **5** in 10 m*l* of tetrahydrofuran

at −60——70°C with stirring. The reaction mixture was allowed to stand at the same temperature range for 3 days and then poured into water. The solution was acidified with dilute hydrochloric acid and extracted with *n*-hexane. The extract was washed with a saturated salt solution and dried over anhydrous sodium sulfate. After evaporation of the solvent, the residue was distilled to give 4.2 g (45%) of **6**: bp 146°C/2 mmHg which was soon crystallized, mp 59—60°C; IR (nujol) 3030, 1675, 1040 cm^{-1}; NMR τ($CDCl_3$) 8.90 (4H, bs, cyclopropane), 8.49 (3H, s, CH_3), 6.3—8.3 (6H, m, $S(CH_2)_3S$), 6.09 (4H, s, OCH_2CH_2O), 5.18 (1H, s, $COCH\langle^{S}_{S}$).

Found: C, 52.43; H, 6.86%. Calcd for $C_{12}H_{18}O_3S_2$: C, 52.52; H, 6.61%.

*1,1-Trimethylenedithio-3,3-ethano-4,4-ethylenedioxy-2-pentanol (**7**).* To a solution of ketone **6**[9] in dry ether was added a solution of excess lithium aluminum hydride in dry ether and stirred overnight at room temperature. The mixture was cooled in an ice bath and excess reagent was decomposed with a small amount of water. The mixture was extracted several times with ether. The extract was dried and concentrated to give a paste: IR (neat) 3400, 1040 cm^{-1}; NMR τ(CCl_4) 9.40 (4H, s, cyclopropane), 8.57 (3H, s, CH_3), 6.38 (1H, d, J=7 Hz, CHOH), 6.19 4H, s, OCH_2CH_2O), 5.66 (1H, d, J=7 Hz, SCHS); *m/e*: 276 (M^+).

*Acetate **8**.* A sample of alcohol **7** was acetylated with acetic anhydride and pyridine in the usual manner to give acetate **8** as a crystalline mass: mp 77—78°C; IR (Nujol) 1730, 1240, 1050 cm^{-1}; NMR τ(CCl_4) 8.4—9.7 (4H, m, cyclopropane), 8.55 (3H, s, CH_3), 7.90 (3H, s, AcO), 6.7—8.2 (6H, m, $S(CH_2)_2S$), 6.10 (4H, bs, OCH_2CH_2O), 5.77 (1H, d, J=10 Hz, SCHS), 5.09 (1H, d, J=10 Hz, AcOCH).

Found: C, 52.67; H, 7.01%. Calcd for $C_{14}H_{22}O_8$: C, 52.82; H, 6.97%.

*1-Methanesulfinyl-3,3-ethano-4,4-ethylenedioxy-2-pentanol (**10**).* To a solution of 1.97 g of **9** in 10 m*l* of ethanol was added a solution of 80 mg of sodium borohydride in 2 m*l* of ethanol. The mixture was allowed to stand overnight at room temperature with stirring. After removal of most of the ethanol under reduced pressure, the residue was dissolved in water and extracted with chloroform. The aqueous phase was concentrated under reduced pressure and extracted with chloroform. The combined extracts were dried over sodium sulfate and the solvent was removed to give 1.7 g (84%) of colorless paste which crystallized gradually. A sample of the product was recrystallized from ethyl acetate: mp 120—122°C; IR (Nujol) 3200, 1045, 1025, 995 cm^{-1}; NMR τ($CDCl_3$) 9.1—9.5 (4H, m, cyclopropane), 8.55 (3H, s, CH_3), 8.03 (1H, s, OH), 7.33 (3H, s, CH_3SO), 7.07 (2H, d, J=6 Hz, $SOCH_2$), 6.06 (4H, s, OCH_2CH_2O), 5.77 (1H, t, J=6 Hz, OCH).

Found: C, 51.33; H, 7.67%. Calcd for $C_{10}H_{18}O_4S$: C, 51.27; H, 7.75%.

*Acetate **11**.* A sample of above alcohol **10** was acetylated with acetic anhydride and pyridine in the usual manner to give acetate **11**: IR (neat) 1745, 1240, 1045 cm^{-1}; NMR τ (CCl_4) 9.1—9.5 (4H, m, cyclopropane), 8.55 (3H, s, CH_3), 7.95 (3H, s, AcO), 7.45 (3H, s, CH_3SO), 6.88 (2H, d, J=6 Hz, CH_2SO), 6.10 (4H, s, OCH_2CH_2O), 4.98 (1H, t, J=6 Hz, CHOAc); *m/e*: 276 (M^+).

*1-Methanesulfinyl-3,3-dimethyl-4,4-ethylenedioxy-2-pentanol (**19**).* To a solution of 249 mg of 1-methanesulfinyl-3,3-dimethyl-4,4-ethylenedioxy-2-pentanone (**18**) in 10 m*l* of water was added a solution of 15 m*l* of sodium borohydride in 1 m*l* of water. The mixture was stirred in an ice bath for 3 hr and left in a refrigerator overnight. The mixture was extracted several times with chloroform and the extract was dried and evaporated to give 202 mg (81%) of a crystalline mass which was recrystallized from ethyl acetate: mp 140—144°C; IR (neat) 3200, 1030, 1005 cm^{-1}; NMR τ ($CDCl_3$) 9.05 (3H, s, CH_3), 8.98 (3H, s, CH_3), 8,70 (3H, s, CH_3), 7.26 (3H, s, CH_3SO), 6.8—7.5 (2H, m, CH_2SO), 6.06 (4H, s, OCH_2CH_2O), 5.80 (1H, d, J=8 Hz, OCH).

*Acetate **20**.* A sample of alcohol **19** was acetylated with acetic anhydride and pyridine in the usual manner to give acetate **20**: IR (neat) 1740, 1235, 1035 cm^{-1}; NMR τ ($CDCl_3$) 9.00 (6H, s, 2×CH_3), 8.66 (3H, s, CH_3), 7.90 (3H, s, AcO), 7.39 (3H, s, CH_3SO), 6.3—7.3 (2H, m, CH_2SO), 6.06 (4H, s, OCH_2CH_2O), 4.40 (1H, d, J=10 Hz, of *d*, J=2.5 Hz, OCH).

Synthesis of 5,5-Dimethyl-4-acetoxy-2-cyclopentenone and 5-Methyl-*t*-5-acetoxymethyl-*r*-4-acetoxy-2-cyclopentenone Intermediates for Illudin M and S

Takeshi MATSUMOTO, Haruhisa SHIRAHAMA, Akitami ICHIHARA, Hyonsobb SHIN, Shohei KAGAWA, Fujio SAKAN, Shuji NISHIDA, Sojiro MATSUMOTO, Kenichi SAITO, and Hisanobu HASHIMOTO

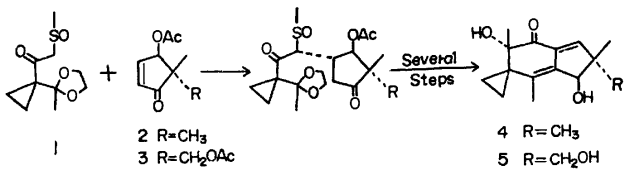
(Received August 6, 1971)

5,5-Dimethyl-4-acetoxy-2-cyclopentenone and 5-methyl-*t*-5-acetoxymethyl-*r*-4-acetoxy-2-cyclopentenone, intermediates for illudin M and S respectively, have been synthesized from ethyl adipate.

In an earlier communication[1] we reported a total synthesis of *dl*-illudin M[2] (**4**) through the Michael reaction between **1** and the cyclopentenone **2**. A total synthesis of illudin S[2,3] (**5**) has also been presented[4] by an analogous route employing **3a** (Scheme 1). In this paper we should like to describe synthesis of these cyclopentenone intermediates **2**[5] and **3a**.



Scheme 1.

At first attempts were made to derive the cyclopentenone **2** from 2,2-dimethylcyclopentanone[6] (**20**). However, **20** had been obtained as a mixture with some other methylated cyclopentanones by methylation of either cyclopentanone or methylcyclopentanone. Thus another route for **20** was desirable.

2-Methyl-2-carbethoxycyclopentanone[7] **6** was reduced by lithium aluminum hydride to give a semicrystalline 2-methyl-2-hydroxymethylcyclopentanol (**18**) in 80% yield, bp 148—153°C/4 mmHg, which was converted into a monotosylate **19** quantitatively. Treatment of one mol of **19** with 1.5 mol of lithium aluminum hydride afforded in 64% yield 2,2-dimethylcyclopentanol[7] (**17**) which furnished on Jones oxidation the desired ketone **20**, bp 139°C, in 70% yield. Alcohol **17** was also prepared by a modified Eschenmoser's method[7] through **8**→**9**→**15**→**16**. Attempted transformation of 2-methyl-2-tosyloxymethylcyclopentanone ethylene ketal (**14**) to **20** with lithium aluminum hydride was unsuccessful, *O*-tosyl bond being cleaved to regenerate **8**. The steric hindrance probably changed the vulnerable point of the tosyloxy group.[8] Bromination of **20** with bromine followed by dehydrobromination with lithium chloride in dimethylformamide gave, in 60% yield (two steps), 5,5-dimethyl-2-cyclopentenone (**22**), bp 150—154°C, which was again brominated with *N*-bromosuccinimide. Subsequent treatment with silver acetate in acetic acid gave 5,5-dimethyl-4-acetoxy-2-cyclopentenone (**2**), bp 92—94°C/10 mmHg, as an oil in 43% yield (from **22**).

The above method for the preparation of acetoxycyclopentenone **2** is advantageous in that diacetoxycyclopentenone **3**, the

intermediate for illudin S, can be prepared through common compounds. However, for the synthesis of illudin M, a simpler method for **2** was desirable. Readily accessible 5,5-dimethyl-2,4-dicarbethoxycyclopentanone **24**[9] was converted by boiling with dilute perchloride acid into 5,5-dimethyl-4-carboxycyclopentanone (**25**), mp 107°C, in 60% yield. Bromination of **25** with bromine afforded, in quantitative yield, 5,5-dimethyl-4-carboxy-2-bromocyclopentanone (**26**), mp 152—154°C, which was converted into **22** by treatment with lithium chloride in dimethylformamide in 43% yield with simultaneous decarboxylation.

The second five membered intermediate 5-methyl-*t*-5-acetoxymethyl-*r*-4-acetoxy-2-cyclopentenone (**3a**) was prepared in a similar way through bromination-dehydrobromination from 2-methyl-2-hydroxymethylcyclopentanone (**10**), bp 83.5°C/4 mmHg, which was obtained through the steps **6**→**7**→**8**[6]→**9**→**10** or **8**→**15**[6]→**10**. Cyclopentenone **12** was then converted into diacetoxycyclopentenone **3**, bp 134—160°C/20 mmHg, (70%), by the same method as employed in the preparation of acetoxycyclopentenone **2** from **22**. Compound **3** thus obtained was a mixture of two configurational isomers with respect to 4-acetoxy and 5-acetoxymethyl groups. The isomers were separated by preparative gas chromatography (3 m DEGS column) to give **3a** and **3b**. Isomer **3b**, which has a shorter retention time, exhibited in its NMR spectrum AB quartet peaks due to the acetoxymethyl group attached to a chiral center at τ 6.23 and 5.77 (J= 12 Hz). The other isomer **3a** showed a smaller difference of chemical shift between the diastereotopic methylene protons (ABq, τ 5.99 and 5.89, J=11 Hz). The larger magnitude of nonequivalence suggested that **3b** might have *cis* arrangement of the acetoxymethyl group to the acetoxy group on cyclopentanone, since in **12** the corresponding methylene protons showed a singlet at τ 6.07.

For the confirmation of stereochemistry, **3b** was converted into diol **18** to observe intramolecular H-bond between the two hydroxyl groups. Treatment of **3b** with sodium borohydride gave a single saturated alcohol **27**[10] which was oxidized with Jones reagent to give rise to 2-methyl-2-acetoxymethyl-3-acetoxycyclopentanone (**28**). Reduction of **3b** with sodium borohydride proceeded stereospecifically[11] and the the attack of the reagent took place from the less hindered site to give an alcohol **27**. The OAc/CH_2-OAc *cis* structure of alcohol **27** was deduced because the monoacetate of **27** exhibited in the NMR spectrum a sharp singlet due to methylene protons of acetoxylmethyl group suggesting the presence of the plane of symmetry in the triacetate (monoacetate of **27**). Pentanone **28** was converted into thioketal **29** which was desulfurized with Raney nickel to give diacetate **30**. On the other hand, an isomeric mixture of diol **18** obtained from **6** by reduction with lithium aluminum hydride was separated by chromatography to yield two stereoisomeric diols with the weight ratio of *ca.* 1 : 4. On observation on the IR spectrum of each isomer in highly diluted solution, the major diol **18a** exhibited absorption bands due to hydroxyl group at 3648 and 3590 cm^{-1} ($\Delta\nu$OH=58 cm^{-1}) and the minor one **18b** at 3645 and 3570 cm^{-1} ($\Delta\nu$OH=75 cm^{-1}). Thus the latter should have *cis* configuration with respect to hydroxyl and hydroxymethyl groups. Comparison of the diacetylated *trans* and *cis* diols (**18a** and **b**) with the diol diacetate **30** derived from isomer **3b** revealed that **3b** actually had *cis* configuration.

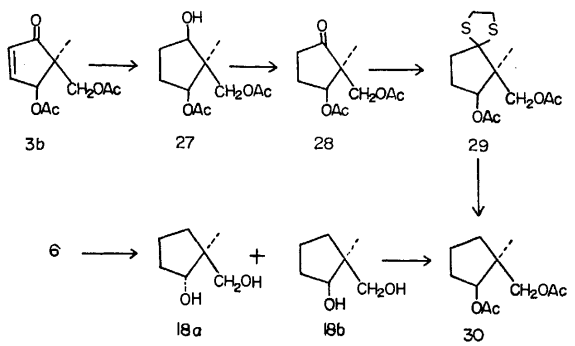

Fig. 2.

Experimental

*2-Methyl-2-hydroxymethylcyclopentanol (**18**).* To an ice cooled solution of 32 g of lithium aluminum hydride in 1.5 *l* of dry ether was added dropwise a solution of 127 g of 2-methyl-2-carbethoxycyclopentanone (**6**) in 100 m*l* of dry ether over a period of 2 hr with mechanical stirring. The resulting mixture was allowed to stand at room temperature and then refluxed for 5 hr. After the reaction was completed water was added dropwise to the ice cooled reaction mixture to decompose the excess of the reagent. The ethereal solution was washed with saturated salt solution, dried over anhydrous sodium sulfate and distilled to give 78 g (80%) of diol **18**: bp 148—153°C/4 mm; IR (neat) 3330, 1030 cm^{-1}.

Found: C, 64.70; H, 10.70%. Calcd for $C_7H_{14}O_2$: C, 64.58; H, 10.84%.

Chromatographic separation of *cis* and *trans* diols was achieved on a column of silica gel employing a mixture of benzene and ethyl acetate (3 : 2) as a solvent. Crude diol (450 mg) gave 121 mg of *trans* isomer **18a** (later eluted): IR (CCl_4, 0.005 M) 3648, 3590 cm^{-1}; NMR τ ($CDCl_3$) 9.00 (3H, s, CH_3), 6.71 (2H, s, OH), 6.52 (2H, s, CH_2O), 6.10 (1H, m, CHO) and 34 mg of *cis* isomer **18b** (earlier eluted): IR (CCl_4, 0.005 M) 3645, 3570 cm^{-1}; NMR τ ($CDCl_3$) 9.00 (3H, s, CH_3), 6.93 (2H, s, OH), 6.40 and 6.27 (2H, ABq, J=11 Hz, CH_2O), 6.04 (1H, m, CHO).

*2-Methyl-2-tosyloxymethylcyclopentanol (**19**).* To a solution of 260 g of diol **18** in 1 *l* of dry benzene were added 208 g of pyridine and 500 g of *p*-toluenesulfonyl chloride. After standing overnight at room temperature pyridine hydrochloride formed was removed by filtration. The benzene solution was washed six times with 6 N hydrochloric acid under ice cooling, three times with aqueous sodium carbonate solution, once with saturated salt solution and then dried over anhydrous sodium sulfate. Removal of the solvent left 567 g (quantitative) of tosylate **19**. An analytical sam-

9) G. Stork and F. H. Clarke, Jr., *J. Amer. Chem. Soc.*, **83**, 3114 (1961).

10) In general, the reduction of 2-cyclopentenone with complex hydrides gives saturated alcohol. See H. C. Brown and H. W. Hess, *J. Org. Chem.*, **34**, 2206 (1969).

ple was prepared by chromatography on silica gel: IR (neat) 3500, 3400, 1600, 1360, 1180 cm^{-1}.

Found: C, 58.85; H, 6.91%. Calcd for $C_{14}H_{20}O_4S$: C, 59.13; H, 7.09%.

*2,2-Dimethylcyclopentanol (**17**).* *A) By Reduction of **19**:* To an ice cooled solution of 57 g of lithium aluminum hydride in 1.8 *l* of dry ether was added dropwise 284 g of of tosylate **19** over a period of 2 hr with mechanical stirring. The resulting solution was allowed to stand at room temperature and then refluxed for 19 hr. After the reaction was completed the excess reagent was decomposed by water under ice cooling. The ethereal solution was washed, dried and distilled to afford 73 g (64%) of dimethylcyclopentanol **17**: bp 59.5—62°C/10 mmHg (lit,[7] 100°C/110 mmHg); IR (neat) 3370, 1380, 1360 cm^{-1}.

*B) By Reduction of **16**:* Tosylate **16** (19.2 g) was reduced by lithium aluminum hydride in dry ether in the same manner as above to yield 5.2 g (71%) of the alcohol **17**.

*2,2-Dimethylcyclopentanone (**20**):* To a solution of 57 g of cyclopentanol **17** in 130 m*l* of acetone was added dropwise the Jones reagent (prepared from 44 g of chromic anhydride in 130 m*l* of water and 38.2 m*l* of concentrated sulfuric acid) over a period of 2 hr with stirring by a mechanical stirrer under ice cooling. The resulting mixture was allowed to be warmed up to room temperature for 1 hr. The reaction mixture was then poured into 1 *l* of water and extracted with ether and the ethereal extract was washed with sodium carbonate solution and saturated salt solution, dried and distilled. 39 g (70%) of fragrant oil **20**, was obtained: bp 139°C; IR (neat) 1740, 1410, 1380, 1360 cm^{-1}.

Found: C, 74.98; H, 10.66%. Calcd for $C_7H_{12}O$: C, 74.95; H, 10.78%.

*5,5-Dimethyl-2-cyclopentenone (**22**).* *A) Preparation from Dimethylcyclopentanone **20**.* To a solution of 11.2 g of **20** in 250 m*l* of chloroform was added dropwise a solution of 16 g of bromine in 100 m*l* of the same solvent with stirring over a period of 5 hr. The reaction mixture was washed with aqueous sodium bicarbonate, then with saturated salt solution and dried. After removal of the solvent the residual bromoketone was dissolved in 130 m*l* of dimethylformamide and 11.4 g of lithium chloride was added. The solution was heated to reflux for 4 hr. The reaction mixture was poured into a large quantity of water and extracted several times with ether. The combined extracts were washed with sodium bicarbonate solution and saturated salt solution, dried and distilled to give 6.6 g (60%) of dimethylcyclopentanone **22**: bp 150—154°C; IR (neat) 3040, 1710, 1590, 1380, 1360, 810 cm^{-1}; NMR τ (CCl_4) 8.97 (6H, s, $2\times CH_3$) 7.53 (2H, t, J=2 Hz, CH_2), 4.02 (1H, d (J=6 Hz) of t (J=2 Hz) =CHCO), 2.53 (1H, d (J=6 Hz) of t (J=3 Hz), =CH–). Dinitrophenylhydrazone: mp 172—173°C.

Found: C, 53.77; H, 5.10; N, 19.49. Calcd for $C_{13}H_{14}N_4O_4$: C, 53.78; H, 4.86; N, 19.30%.

*B) Preparation from Bromoacid **26**:* A solution of 30 g of bromoacid **26** and 32 g of lithium chloride in 300 m*l* of dimethylformamide was refluxed for 1.5 hr. After cooling the reaction mixture was poured on 1 *l* of ice water and extracted three times with ether. The combined extracts were washed with saturated salt solution and dried. The solvent was removed and the residual oil was distilled, 6.1 g (43%).

*5,5-Dimethyl-4-acetoxy-2-cyclopentenone (**2**).* A solution of 2.2 g of cyclopentanone **22**, 5 g of *N*-bromosuccinimide and 80 mg of benzoyl peroxide in 70 m*l* of CCl_4 was heated to reflux for 2 hr. After reaction was completed the precipitated succinimide was removed by filtration. The filtrate was washed with sodium hydrosulfite, sodium bicarbonate and saturated salt solution, dried and evaporated to leave bromoketone **23** as an oil which was used in the next step without further purification. A sample of **23** was chromatographed (silica gel, benzene) for measuring spectra: IR (neat) 1720, 1585, 835 cm^{-1}; NMR τ (CCl_4) 8.80 (3H, s, CH_3), 8.76 (3H, s, CH_3), 5.02 (1H, d (J=3 Hz) of d (J=1.5 Hz), BrCH–), 3.78 (1H, d (J=6 Hz) of d (J=1.5 Hz), =CHCO), 2.42 (1H, d (J=6 Hz), of d (J=3 Hz), =CH–).

To a solution of crude bromoketone **23** (14 g) from four batches in 80 m*l* of acetic acid which was dried over phosphorus pentoxide, 18.5 g of silver acetate was added. The resulting mixture was heated at 110—115°C for 14 hr with stirring to precipitate silver bromide. The reaction mixture was then diluted with chloroform and filtered. The filtrate was neutralized with aqueous sodium carbonate solution, washed with saturated salt solution and dried. After removal of the solvent the residue was distilled to give 5.7 g of acetoxycyclopentanone **2** (42.5% from **22**): bp 92—94°C/10 mmHg; IR (neat) 3050, 1740, 1725, 1600, 1235 cm^{-1}; NMR τ (CCl_4) 9.05 (3H, s, CH_3), 8.83 (3H, s, CH_3), 7.93 (3H, s, AcO), 4.52 (1H, d (J=3 Hz) of d (J=1 Hz), AcOCH), 3.78 (1H, d (J=6 Hz) of d (J=1 Hz), =CHCO), 2.65 (1H, d (J=6 Hz) of d (J=3 Hz) =CH–).

Found: C, 64.51; H, 7.16%. Calcd for $C_9H_{12}O_3$: 64.27, H, 7.19%.

*5,5-Dimethyl-2,4-dicarbomethoxycyclopentanone (**24**).* This compound was prepared according to the method of Stork and Clarke[9] Two hundred and twenty grams of diester were obtained from 384 g of ethyl 2,3-dicyano-3-methylbutyrate (42% over 4 steps): bp 170—176°C/20 mmHg.

*5,5-Dimethyl-4-carboxycyclopentanone (**25**):* A mixture of 220 g of diester 24 and 1260 m*l* of 20% perchloric acid was refluxed for 7 hr until a homogeneous solution was obtained. The resulting solution was extracted with chloroform. The extract was washed with saturated salt solution and dried over anhydrous sodium sulfate and the solvent was distilled off. The crystalline residue was washed with hexane, 90 g (60%). A sample of product was recrystallized for analysis: mp 107°C; IR (Nujol) 1740, 1710 cm^{-1}; NMR ($CDCl_3$) 8.97 (3H, s, CH_3), 8.75 (3H, s, CH_3), 6.9—8.6 (5H, m, CH_2CH_2CH), −0.13 (1H, bs, CO_2H).

Found: C, 61.69; H, 7.88%. Calcd for $C_8H_{12}O_3$: C, 61.52; H, 7.75%.

*5,5-Dimethyl-4-carboxy-2-bromocyclopentanone (**26**).* The keto acid **25** (20 g) was dissolved in 200 m*l* of chloroform and 206 g of bromine was added with stirring under ice-cooling over a period of 1 hr. The chloroform solution was washed with water and dried over anhydrous sodium sulfate. Removal of the solvent left crude crystalline bromide (30 g). A small sample was recrystallized for analysis; mp 152—154°C; IR (Nujol) 1740, 1720 cm^{-1}.

Found: C, 40.65; H, 4.65%. Calcd for $C_8H_{11}O_3Br$: C, 40.53; H, 4.68%.

*2-Methyl-2-tosyloxymethylcyclopentanone Ethylene Ketal (**14**).* A solution of 29.2 g of 2-methyl-2-hydroxymethylcyclopentanone ethylene ketal (**8**)[7], 32.9 g of tosyl chloride and 30 g of pyridine in 180 m*l* of benzene was allowed to stand overnight in a refrigerator. The reaction mixture was poured into water and extracted with benzene. The extract was washed with aqueous sodium bicarbonate and saturated salt solution and dried. Evaporation of the solvent left 55 g (quantitative) of crude tosylate **14**. A sample of crude tosylate was recrystallized from carbon tetrachloride; mp 80°C, IR (Nujol) 1360, 1180 cm^{-1}.

Found: C, 59.03; H, 6.70%. Calcd for $C_{16}H_{22}O_5S$: C, 58.88; H, 6.80%.

Reduction of Tosylate ***14*** *with Lithium Aluminum Hydride.* To an ice-cooled solution of 750 mg of lithium aluminum hydride in 20 m*l* of dry ether was added dropwise with stirring a solution of 2.5 g of the tosylate **14** in 16 m*l* of dry ether. After refluxing for 7 hr the original tosylate was recovered. The recovered tosylate was dissolved in 25 m*l* of tetrahydrofuran and refiuxed with 750 mg of lithium aluminum hydride for 24 hr. The product obtained was the original alcohol **8** instead of dimethylcyclopentanone ethylene ketal.

*2-Methyl-2-tosyloxymethylcyclopentanone (****16****). A) By Tosylation of the Ketoalcohol* ***15***: The keto alcohol (141 g) was quantitatively converted by treatment with 209 g of tosylchloride and 87 g of pyridine in 500 m*l* of benzene to 310 g of tosylate **16**. A sample of the tosylate was recrystallized from carbon tetrachloride, mp 65—67°C; IR (Nujol) 1750, 1600, 1350, 1160 cm^{-1}.

B) By Deketalization of Tosylate ***14***: A solution of 2.5 g of ketal **14** and a pinch of *p*-toluenesulfonic acid in 100 m*l* of acetone was refluxed for 3 hr. The reaction mixture was concentrated under reduced pressure to remove most of acetone, and the residue was taken with ether. The ethereal phase was then washed with aqueous sodium bicarbonate solution and saturated salt solution and dried. Evaporation of ether left 1.6 g (74%) of tosylate **16**.

*2-Methyl-2-acetoxymethylcyclopentanone (****10****). A)* To a solution of 48 g of 2-methyl-2-hydroxymethylcyclopentanone ethylene ketal (**8**)[7] and 63 mg of *p*-toluenesulfonic acid in 480 m*l* of dry acetone was refluxed for 4.5 hr. After the reaction mixture was concentrated under reduced pressure at room temperature to remove most of acetone, benzene was added to the residue and the solution was washed with aqueous sodium bicarbonate solution and saturated salt solution and dried. The solvent was evaporated and the residue was distilled to give 26 g (73%) of ketone **15**, bp 93—98°C/6 mmHg, (lit,[6] 103—108°C/12 mmHg). Treatment of 10 g of the above alcohol with acetic anhydride and pyridine by the usual method gave 11.7 g (89%) of acetate **10**: bp 91—93°C/3 mmHg; IR (Neat) 1760, 1230 cm^{-1}.

Found: C, 63.32; H, 8.11%. Calcd for $C_9H_{14}O_3$; C, 63.53; H, 8.23%.

B): Ketal **8** (101 g) was acetylated by the usual method and treated with a pinch of *p*-toluenesulfonic acid in acetone to yield 80.2 g (80%) of acetoxy ketone **10**: bp 125—128°C/25 mmHg.

*5-Methyl-5-acetoxymethyl-2-bromocyclopentanone (****11****).* To a solution of 11 g of the acetoxy ketone **10** in 72 m*l* of chloroform was added dropwise a solution of 3.35 m*l* of bromine in 48 m*l* of the same solvent with stirring. The resulting mixture was washed with sodium bicarbonate solution and saturated salt solution and dried. The solvent was evaporated and the residue was distilled at 110—118°C/7 mmHg to give 145 g (90%) of bromoketone **11**. Formation of two configurational isomers might be expected. However, separation and examination of the ratio were not attempted. A sample of the bromo compound was redistilled and analyzed: IR (neat) 1750, 1735 cm^{-1}.

Found: C, 43.16; H, 5.27%. Calcd for $C_9H_{13}O_3Br$: C, 43.33; H, 5.22%.

*5-Methyl-5-acetoxymethyl-2-cyclopentenone (****12****).* A solution of 13 g of bromo compound **11** and 8.8 g of lithium chloride in 350 m*l* of dimethylformamide was heated at 150—160°C for 4 hr. The reaction mixture was then poured into ice-water and extracted several times with benzene. The combined extracts were washed successively with sodium bicarbonate and saturated salt solution, dried and distilled to yield 5.9 g (66%) of cyclopentenone; bp 94—100°C/4 mmHg, IR (neat) 1745, 1710, 1590, 1240 cm^{-1}; NMR τ (CCl_4) 8.91 (3H, s, CH_3), 8.07 (3H, s CH_3), 7.62 and 7.30 (2H, ABq, (J=19 Hz, each peak is split into J=2.5 Hz), CH_2) 6.07 (2H, s, CH_2OAc), 3.93 (1H, d (J=6 Hz) of t (J=2 Hz), =CHCO), 2.37 (1H, d (J=6 Hz) of t (J=2.5 Hz), =CH–).

Found: C, 64.23; H, 7.33%. Calcd for $C_9H_{12}O_3$: C, 64.28; H, 7.14%.

*5-Methyl-*t*-5-acetoxymethyl-*r*-4-acetoxy-2-cyclopentenone (****3****).* The compound (44.5 g 70%) was prepared from 52.2 g of cyclopentenone **12** by the same treatment as in the conversion of **22** into **2**. Bp 134—160°C/20 mmHg. A sample of ketone **3** was subjected to preparative vpc. A column of DEGS (3 m) was used at 170°C employing helium as a carrier gas (100 m*l*/min). The *cis* isomer **3b** appeared at 52 min (retention time) and the *trans* isomer **3a** at 62 min with a weight ratio of *ca.* 1 : 2.5. *cis*-5-Acetoxymethyl-4-acetoxy isomer (**3b**): IR (neat) 1745, 1725, 1595 and 1235 cm^{-1}; NMR τ (CCl_4) 8.80 (3H, s, CH_3), 8.05 (3H, s, AcO), 7.95 (3H, s, AcO), 6.23 and 5.77 (2H, ABq, J=2 Hz), HCOAc), 3.70 (1H, d (J=2 Hz) of d (J=6 Hz), =CHCO), 2.57 (1H, d (J=6 Hz) of d (J=3 Hz), -CH=). *trans*-5-Acetoxymethyl-4-acetoxy isomer (**3a**): IR (neat) 1745, 1725, 1595 and 1235 cm^{-1}; NMR τ (CCl_4) 9.05 (3H, s, CH_3), 8.05 (3H, s, AcO), 7.89 (3H, s, AcO), 5.99 and 5.89 (2H, ABq, J=11 Hz), 4.22 (1H, d (J=3 Hz) of d (J=2 Hz), HCOAc), 3.73 (1H, d (J=6 Hz) of d (J=3 Hz), –CH=), 2.56 (1H, d (J=6 Hz) of d (J=3 Hz), –CH=).

*2-Methyl-*c*-2-acetoxymethyl-*c*-3-acetoxy-*r*-1-cyclopentanol (****27****).* A sample (940 mg) of cyclopentenone **3b** was dissolved in 25 m*l* of ethanol. The solution was cooled in an ice bath and 315 mg of sodium borohydride was added with stirring. After stirring for 40 min, a small amount of acetic acid was added and the reaction mixture was poured into water and extracted with ethyl acetate. The extract was washed with saturated salt solution and dried. Removal of the solvent left 904 mg of reduced product: IR (neat) 3450, 1740, 1725, 1040 cm^{-1}.

Found: C, 57.18; H, 7.86%. Calcd for $C_{11}H_{18}O_5$: C, 57.38; H, 7.88%.

Treatment of 60 mg of alcohol with acetic anhydride and pyridine by the usual method gave 49 mg of pure triacetate; IR (neat) 1745, 1238, 1038 cm^{-1}; NMR τ (CCl_4) 8.90 (3H, s, CH_3), 8.00 (9H, s, 3×AcO), 5.99 (2H, s, CH_2OAc), 5.10 (2H, m, 2×HCOAc).

*2-Methyl-*r*-2-acetoxymethyl-*c*-3-acetoxycylcopentanone (****28****).* To a solution of 904 mg of alcohol derived from **3a** in 45 m*l* of acetone 0.7 m*l* of Jones reagent was added dropwise over a period of 80 min with ice cooling. After standing at room temperature for 20 min a small amount of ethanol was added and the precipitate was filtered off. The solvent was evaporated and the residue was extracted with ether. The extract was washed with saturated salt solution, sodium bicarbonate solution and then saturated salt solution and dried. Evaporation of the solvent left ketone which was chromatographed on silica gel to give 515 mg of ketone **28**: IR (neat) 1750, 1240, 1050, cm^{-1}; NMR τ(CCl_4) 8.88 (3H, s, CH_3), 8.03 (3H, s, AcO), 8.00 (3H, s, AcO), 5.94 (2H, d (appearance) J=2.4 Hz CH_2OAc), 4.87 (1H, m, HCOAc); *m/e*; 228 (M^+).

*2-Methyl-*r*-2-acetoxymethyl-*c*-3-acetoxycyclopentanone Ethylene Thioketal (****29****).* To a solution of 200 mg of ketone **28** in 2.7 m*l* of acetic acid, 840 mg of ethanedithiol and then 1.1 m*l* of boron trifluoride etherate were added and stirrred. The reaction mixture was allowed to stand at room temperature for 24 hr and poured into almost the same quantity of

water and extracted with ether. The extract was washed with sodium carbonate solution and with saturated salt solution and dried. After evaporation of the solvent, the residual oil was purified by chromatography to give 134 mg of thioketal; IR (neat) 1750 1250, 1045 cm^{-1}; NMR τ (CCl_4) 8.79 (3H, s, CH_3), 8.02, (3H, s, AcO), 7.91 (3H, s, AcO), 6.79 (4H, s, SCH_2CH_2S), 5.45 and 6.14 (4H, ABq, J=11 Hz CH_2OAc), 5.10 (1H, m, HCOAc).

r-*1*-*Acetoxy*-*2*-*methyl*-c-*2*-*acetoxymethylcyclopentane* (***30***). To solution of 130 mg of thioketal **29** in 40 m*l* of ethanol, 2.5 g of Raney nickel W-2 was added. The reaction mixture was stirred at 85°C to make the solvent reflux for 24 hr. The Raney nickel used was removed through a short column of aluminum oxide and the solvent was evaporated. The residue was dissolved in ether and filtered to remove solid mass and washed with saturated salt solution and dried. After removal of the solvent the residual oil was chromatographed to yield 91 mg of diacetate **30**; IR (neat) 1750, 1245, 1050 cm^{-1}.

Found: C, 61.86; H, 8.18%. Calcd for $C_{11}H_{18}O_4$: C, 61.66; H, 8.47%.

Synthesis of 5,5-Dimethyl-4-acetoxy-2-cyclopentenone, an Intermediate in the Total Synthesis of Illudin M, through Sulfur Compounds. A Novel Intramolecular Migration of Ethylenedioxy Group

Takeshi MATSUMOTO, Haruhisa SHIRAHAMA, Akitami ICHIHARA, Hyonsobb SHIN, and Shohei KAGAWA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received August 6, 1971)

5,5-Dimethyl-4-acetoxy-2-cyclopentenone, an intermediate in the total synthesis of illudin M, has been prepared from 1-methylsulfinyl-3,3-dimethyl-4,4-ethylenedioxy-2-pentanone as well as from 1,1-trimethylenedithio-3,3-dimethyl-4,4-ethylenedioxy-2-pentanone. An example of new intramolecular transketalization has been described.

A report was given on a total synthesis[1] of *dl*-illudin M. The synthesis was started from the Michael addition of a sulfoxide **1** to a cyclopentenone **2**. In the early stage[2] of this work, it was thought to be of interest to convert a sulfoxide **5** or a dithiane **10**, both similar in structure to **1**, into the cyclopentenone **2**.[3] If the conversion were possible, it would mean that illudin M can be synthesized from two structurally similar seven-carbon units.

The present paper describes the synthesis of the cyclopentenone **2** along this line.[4,5] At first, the carbonyl group of ethyl dimethylacetoacetate (**3**)[6] was masked with ethylene glycol in the usual manner (52% yield), and the ketal ester was treated with methylsulfinyl carbanion according to Corey's method[7]

to give a β-ketosulfoxide **5**, mp 53—56°C, in 91% yield. It has been shown that in general β-ketosulfoxides gave α-ketoacetals on treatment with iodine in methanol.[8] Compound **5** was accordingly treated under these conditions to afford a mixture of an epimeric pair of tetrahydrofuranones **6** in moderate yield and minor products. By chromatography on silica gel the mixture was separated into four fractions. The first fraction obtained in a small amount as an oil was found to be a mixture of an epimeric pair of 2,3,3-trimethyl-2-methoxy-5-methylthiotetrahydro-4-furanone, on the basis of the NMR spectrum. The second and third fractions contained the main products of the reaction. NMR spectra indicated that each product was one of the epimeric pair of 2,3,3-trimethyl-2,5-dimethoxytetrahydro-4-furanone (**6**). The last fraction was a mixture of epimers of **6** and unidentified substances. Reduction followed by acetylation of each epimer of **6** afforded a single, but not identical, product: diastereoisomeric 2,3,3-trimethyl-2,5-dimethoxy-4-acetoxytetrahydrofuran (**8**), respectively. Both isomers of **8** gave the same compound, 2-acetoxy-3,3-dimethyl-4-ketopentanal (**9**, bis DNP mp 201—202°C) in moderate yield, on being dissolved in a mixture of 1 N hydrochloric acid and tetrahydrofuran (1/1). For the preparation of the final product, cyclopentenone **2**, the series of reactions (**5**→**9**) can be performed without purification of the intermediates. A crude product containing **9** was obtained in 47.5% yield from **5**. Vpc analysis revealed that one third of the product was the desired aldehyde **9**. The crude aldehyde **9** was cyclized to afford 5,5-dimethyl-4-acetoxy-2-cyclopentenone (**2**)[3] in 21% yield based on the crude product, on treatment with sodium hydride in a large amount of benzene under refluxing.

Pure aldehyde **9** was also obtained through a 1,3-dithiane derivative as follows. The addition reaction of an anion of 1,3-dithiane[9] to dimethylacetoacetic ester afforded 1,1-trimethylenedithio-3,3-dimethyl-4,4-ethylenedioxy-2-pentanone (**10**), mp 89—90°C. Reduction and acetylation of the dithiane **10** gave 1,1-trimethylenedithio-2-acetoxy-3,3-dimethyl-4,4-ethylenedioxypentane (**12**) which was treated with mercuric chloride and cadmium carbonate in aqueous acetone in order to remove the trimethylenedithio group.[10]

18 R=CH_2OAc

Fig. 3.

The compound obtained lacked sulfur atom, but it was not the expected aldehyde and instead a ketone. The NMR spectrum showed signals for a *gem*-dimethyl group as singlets at τ 8.96 and 8.76, two acetyl groups as singlets at τ 7.89 and 7.81, an ethylenedioxy group as a rather sharp (W1/2=6Hz) multiplet at τ 6.31 and two methine groups as an AB quartet at τ 5.06 and 4.82 (J=7 Hz). Ethylenedioxy group was undoubtedly transferred to the γ-carbonyl group on the basis of the NMR spectrum and the structure of the product was expressed as 1,1-ethylenedioxy-2-acetoxy-3,3-dimethylpentanone (**13**). The reaction may be rationalized by a transition state containing as eight membered ring (Fig. 2). Similar rearrangements of ethylenedioxy group have been observed in our synthetic studies on illudin M[1] and S.[11,12] Methyl ketone **13** was readily converted into aldehyde **9** by a similar treatment to that for the deacetalization of **8**.

Experimental

Ethyl 2,2-dimethyl-3-ethylenedioxybutyrate (4). Ethyl 2,2-dimethyl-3-ketobutyrate (**3**)[6] was dissolved in 300 m*l* of benzene containing 27 g of ethylene glycol and 200 mg of *p*-toluenesulfonic acid. The mixture was heated at the reflux temperature of benzene. The water formed was removed by azeotropic distillation with a Dean-Stark separator and heating was continued until 4 m*l* of water was removed. The reaction mixture was washed three times with aqueous sodium carbonate and three times with water and dried. The solvent was removed and the residue was distilled to yield 27.2 g (52%) of **4**: bp 110°C/17 mmHg; IR (neat) 1730 cm^{-1} (CO); NMR τ ($CDCl_3$) 8.71 (3H, t, J=7 Hz, $CH_2\underline{CH_3}$), 8.80 (6H, s, 2×CH_3), 8.68 (3H, s, CH_3), 6.10 (4H, s, OCH_2CH_2O), 5.88 (2H, q, J=7 Hz, $\underline{CH_2}CH_3$).

1-Methylsulfinyl-3,3-dimethyl-4,4-ethylenedioxy-2-pentanone (5). The compound was prepared by the general method for preparation of β-ketosulfoxides according to Corey and Chaykovsky.[7] Ester **4** (27.2 g) was added dropwise to a dimethyl sulfoxide solution of methylsulfinyl carbanion prepared from 140 m*l* of dimethyl sulfoxide and 12.9 g of sodium hydride (50% mineral oil dispersion) under ice-water cooling and mechanical stirring in the atmosphere of nitrogen. The ice-water bath was removed, stirring was continued for 2 hr at room temperature and the reaction mixture was

12) In the course of studies on total synthesis of illudins,[1,11] reactions such as **14**→**17** and **16**→**18** (Fig. 3) were found. Warming compounds **14** and **16** in ethanol was enough to cause the transfer of the ethylenedioxy group but the rearrangement (**15**→**18**) did not occur under the same conditions.

then poured into 500 m*l* of water, wshed three times with benzenee, neutralized with dilute acetic acid to pH of 5—6 (pH paper), and extracted three times with chloroform. The combined extracts were washed three times with a saturated salt solution and dried over anhydrous sodium sulfate, and evaporated to yield 28.7 g (91%) of the ketosulfoxide **5** as a yellow crystalline solid. A small sample was recrystallized from carbon tetrachloride for analysis: mp 53—56°C; IR (nujol) 1700 cm^{-1}; NMR τ ($CDCl_3$) 8.77 (3H, s, $CH_3C\langle^{O}_{O}$), 8.75 (6H, s, CH_3CCH_3), 7.27 (3H, s, $SOCH_3$), 5.99 (4H, s, OCH_2CH_2O), 5.99 and 5.57 (2H, ABq, J=16 Hz, $SOCH_2CO$).

Found: C, 51.15; H, 7.65%. Calcd for $C_{10}H_{18}O_4S$: C, 51.27; H, 7.75%.

*2,3,3-Trimethyl-2,5-dimethoxytetrahydro-4-furanone (**6**).* Keto sulfoxide **3** (6.3 g) was dissolved in 120 m*l* of methanol containing 3.44 g of iodine. The solution was refluxed for 4 hr, and then allowed to cool. Most of the methanol was removed at room temperature on a rotary evaporator under reduced pressure. The dark residual oil was taken up in chloroform and washed twice with saturated sodium thiosulfate solution. The light yellow chloroform solution was dried with anhydrous sodium sulfate and the solvent was removed under reduced pressure. The residual oil was chromatographed on silica gel with benzene as a solvent and separated into four fractions.

The first fraction was 81 mg of an oil: IR (neat) 1765 cm^{-1}; NMR τ ($CDCl_3$) 8.90 (6H, s, CH_3CCH_3), 8.58 (3H, s, CH_3), 7.72 and 7.70 (3H, twin s, SCH_3), The qualitative analysis for sulfur was positive and the oil was converted into **6** by treatment with iodine in methanol. Thus, the oil should be a mixture of an epimeric pair of 2,3,3-tri methyl-2-methoxy-5-methylthiotetrahydro-4-furanone. The second fraction (877 mg): IR (neat) 1780 cm^{-1}; NMR ($CDCl_3$) 8.91, 8.86 and 8.57 (each 3H, s, 3×CH_3), 6.67 and 6.42 (each 3H, s, 2×OCH_3), 5.36 (1H, s, OCHO). The third fraction (1.338 g): IR 1780 cm^{-1}; NMR τ ($CDCl_3$) 8.90 (6H, s, CH_3CCH_3), 8.60 (3H, s, CH_3), 6.68 and 6.42 (each 3H, s, 2×OCH_3), 5.04 (1H, s, -OCHO-). From these spectral data, it was deduced that each of the second and the third fractions contained an epimer of **6**. The fourth fraction (694 mg) was a mixture of **6** and unidentified substances.

*2,3,3-Trimethyl-2,5-dimethoxy-4-acetoxytetrahydrofuran (**8**).* Each epimer of furanone **6** was separately reduced with sodium borohydride and then acetylated with acetic anhydride and pyridine. The earlier eluted furanone **6** (877 mg) gave 609 mg of a single epimer of **8**: IR (neat) 1750, 1240 cm^{-1}; NMR τ (CCl_4) 9.00 (6H, s, CH_3CCH_3), 8.78 (3H, s, CH_3), 7.95 (3H, s, OAc), 6.80 and 6.68 (each 3H, s, OCH_3), 5.29 and 5.11 (2H, ABq, J=6 Hz, $AcOCHCH\langle^{O}_{O}$). The later eluted furanone **6** (40 mg) gave 23 mg of another epimer of **8**: IR (neat) 1740, 1240 cm^{-1}; NMR τ (CCl_4) 9.04, 8.98 and 8.82 (each 3H, s, CH_3), 7.92 (3H, s, OAc), 6.78 and 6.55 (each 3H, s, OCH_3), 5.24 and 5.01 (2H, ABq, J=6 Hz, $AcOCHCH\langle^{O}_{O}$).

*2-Acetoxy-3,3-dimethyl-4-ketopentanal (**9**).* Each epimer of **8** was separately converted into aldehyde **9**. A sample of acetoxyfuran was dissolved in about 20 times its volume of a mixture of 1 N hydrochloric acid and tetrahydrofuran and allowed to stand for 3 hr at room temperature. The reaction mixture was extracted with chloroform three times. The combined extracts were washed with water twice, dried and evaporated to leave aldehyde **9**. IR (neat) 1740, 1705, 1230 cm^{-1}; NMR τ (CCl_4), 8.75 (6H, s, CH_3CCH_3), 7.86 (6H, s, OAc and $COCH_3$), 5.06 (1H, s, AcOCH), 0.50 (1H, s, CHO). Bisdinitrophenylhydrazone: mp 201—202°C.

Found: C, 46.21; H, 4.20; N, 20.19%. Calcd for $C_{21}H_{22}N_8O_{10}$: C, 46.15; H, 4.06; N, 20.50%.

Crude aldehyde **9** can be prepared from sulfoxide **5** without purification throughout the process as follows. Treatment of 8.2 g of the sulfoxide **5** gave 4.5 g of a crude epimeric mixture of acetoxyfuran **8**, 2.4 g which was hydrolysed to give 1.65 g of a crude product. Gas chromatographic analysis revealed that one third of the product was the desired aldehyde **9**.

*5,5-Dimethyl-4-acetoxy-2-cyclopentenone (**2**).* The above crude product (800 mg) containing aldehyde **9** was refluxed under stirring with 300 mg of sodium hydride in 400 m*l* of benzene for 9 hr. The reaction mixture was filtered and the solvent was removed. The resulting oil was fractionated by preparative gas chromatography on DEGS column (3m, at 270°C, He: 100 m*l*/min, reteniton time: 10 min) to give 150 mg of the cyclopentenone. The IR spectrum was identical with that of the authentic sample.[2]

*1,1-Trimethylenedithio-3,3-dimethyl-4,4-ethylenedioxy-2-pentanone (**10**).* A solution of 11.7 g of *n*-butyl bromide in 15 m*l* of ether was added dropwise to 1.4 g of lithium covered with 35 m*l* of ether −30——40°C and the mixture was stirred for 1.5 hr at 0—10°C. The resulting solution was added dropwise to a stirred solution of 3 g of 1,3-dithian in 50 m*l* of tetrahydrofuran at −30——40°C. To the solution prepared above was added dropwise 5 g of ethyl dimethylacetoacetate ethylene ketal (**4**) at −20——30°C with stirring. The reaction mixture was allowed to stand at the same temperature range for 40 hr and then poured into water. The solution was acidified with dilute hydrochloric acid and extracted with ethyl acetate. The extract was washed with a saturated salt solution and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was distilled to give 2 g (29.3%) of **10**, bp 152—152.5°C/4 mmHg, which crystallized soon and was recrystallized from isopropyl ether: mp 89—90°C; IR (nujol) 1690 cm^{-1}; NMR τ (CCl_4) 8.74 (9H, s, 3×CH_3), 8.0—7.4 and 6.8—6.2 (4H and 2H, m, $S(CH_2)_3S$), 6.01 (4H, s, OCH_2CH_2O), 5.30 (1H, s, SCHS).

Found: C, 52.07; H, 7.05%. Calcd for $C_{12}H_{20}O_3S_2$: C, 52.16; H, 7.30%.

*1,1-Trimethylenedithio-3,3-dimethyl-4,4-ethylenedioxy-2-pentanol (**11**).* Ketone **10** (1.375 g) was dissolved in anhydrous ether and 50 mg of lithium aluminum hydride was added. After standing overnight, another 50 mg of lithium aluminum hydride was added and the reaction mixture was refluxed for 6 hr, poured on ice-water and the product was extracted with ether. The extract was dried and the solvent was removed to leave 1.24 g (90%) of **11**. Crystalline mass was recrystallized from isopropyl ether and analyzed, mp 68—69°C: IR (neat) 3450 cm^{-1}; NMR τ (CCl_4) 8.97, 8.87 and 8.71 (each 3H, s, CH_3), 8.5—6.5 (6H, m, $S(CH_2)_3S$), 6.02 (4H, s, OCH_2CH_2O), 6.10 (1H, d, J=3 Hz, HOCH), 5.80 (1H, d, J=3 Hz, SCHS).

Found: C, 51.81; H, 7.86%. Calcd for $C_{12}H_{22}O_3S_2$: C, 51.79; H, 7.97%.

Alcohol **11** was acetylated with acetic anhydride and pyridine in the usual manner to give acetate **12**: IR (neat) 1745, 1235 cm^{-1}: NMR τ (CCl_4) 8.98, 8.90 and 8.70 (each 3H, s, CH_3), 7.89 (3H, s, OAc), 6.03 (4H, s, OCH_2CH_2O), 5.32 (1H, d, J=2 Hz, SCHS), 4.85 (1H, d, J=2 Hz, AcOCH).

*1,1-Ethylenedioxy-2-acetoxy-3,3-dimethylpentanone (**13**).*

Acetate **12** (127 mg) was dissolved in 10 m*l* of acetone and 630 mg of mercuric chloride, 917 mg of cadmium carbonate and 90 mg of water were added and the whole solution was stirred for 6 hr at room temperature. The acetone was removed and the residue was extracted with chloroform. After evaporation of the solvent, the extracted mass was chromatographed on silica gel column employing a mixture of ethyl acetate and benzene (1 : 9) as a solvent to give 28 mg (31%) of **13**: IR (neat) 1750, 1710, 1230 cm^{-1}; NMR τ (CCl_4) 8.96 and 8.76 (each 3H, s, CH_3) 7.89 and 7.86 (each 3H, s, OAc and $COCH_3$), 6.13 (4H, m, W1/2= 6 Hz, OCH_2CH_2O), 5.06 and 4.82 (2H, ABq, J=7 Hz, $AcOCHCH\langle^{O}_{O}\rangle$).

Hydrolysis of ***13***. To a solution of 17 mg of ketoacetal **13** in 1 m*l* of tetrahydrofuran was added five drops of 6 N hydrochloric acid and the solution was left to stand overnight at room temperature. After addition of 1 m*l* of water, the solution was kept for a few minutes under reduced pressure to remove most of the tetrahydrofuran and the residue was extracted with chloroform three times. The combined extracts were washed with a saturated salt solution, dried and evaporated to leave 9 mg of an oil whose IR spectrum was identical with that of the aldehyde obtained from **8**.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1147—1152 (1972)

The Stereochemistry of Nucleophilic Addition. IV.[1] The Condensation of 2,2,6-Trimethylcyclohexanone with *t*-Butyl Acetate in the Presence of Lithium Amide

Takashi MATSUMOTO, Gojo SAKATA, Yakudo TACHIBANA, and Kenji FUKUI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received August 23, 1971)

The stereochemistry of the condensations of 2,2,6-trimethylcyclohexanone with *t*-butyl acetate in the presence of lithium amide, with ethyl bromoacetate in the presence of zinc (Reformatsky reaction), and with ethylmagnesium iodide (Grignard reaction) was studied. The configurations of the products in these reactions were assigned on the basis of their chromatographic behavior, and on the basis of spectroscopic and chemical studies of them. From the present experiments it is evident that all of these nucleophilic addition reactions proceed in a similar fashion. Further, the treatment of *t*-butyl 1-hydroxy-2,2,*t*-6-trimethyl-*r*-1-cyclohexaneacetate (IIa) with potassium hydrogensulfate or with dilute sulfuric acid gave (±)-*cis*-tetrahydroactinidiolide (IX), which was isolated from the essential oil of cigar tobacco leaves by Kaneko and Hoshino, while the treatment of IIa with isopropenyl acetate in the presence of *p*-toluenesulfonic acid gave a mixture of IX and its *trans*-isomer (X).

In previous papers,[1-3] the present authors have reported on the stereochemistry of the Reformatsky reaction with carbonyl compounds possessing an asymmetic α-carbon atom. A similar aldol-type condensation of *t*-butyl acetate with carbonyl compounds in the presense of lithium amide has been reported by Hauser *et al.*[4,5] However, since this reaction has not been studied stereochemically, it is of interest to study the stereochemistry of the aldol-type condensation with carbonyl compounds possessing an asymmetric α-carbon atom, and to compare it with that of the Reformatsky and Grignard reactions. The present paper will describe the stereochemistry of these nucleophilic addition reactions with 2,2,6-trimethylcyclohexanone (I). The condensation of I with *t*-butyl acetate in ether in the presence of lithium amide gave a mixture of epimeric *t*-butyl 1-hydroxy-2,2,6-trimethyl-1-cyclohexaneacetates (IIa and IIb) in a 76% yield, accompanied by a small amount of dehydrated esters (3% yield, IIIa and IIIb). The separation of these esters was successively carried out by means of column chromatography on silica gel to give, in the order of elution, the oily IIIa, IIIb, IIa, and IIb esters in a 3 : 1 : 78 : 18 ratio. The structures of IIIa and IIIb were assigned on the basis of their spectral data, as will be shown in the Experimental section. The alkaline hydrolyses of IIa and IIb gave the corresponding crystalline β-hydroxy acids, IVa (mp 118.5—119.5°C) and IVb (mp 143.5—144°C) respectively. Sakan *et al.*[6], during the course of their synthetic work on dihydroactinidiolide, reported on the synthesis of ethyl 1-hydroxy-2,2,6-trimethyl-1-cyclohexaneacetate (V) by the Reformatsky reaction of I with ethyl bromoacetate, but the composition of the epimeric alcohols expected was not recorded. Therefore, the stereochemistry of this reaction was also studied in order to compare it with that of the above aldol-type condensation. A mixture of the epimeric β-hydroxy esters obtained (62% yield) by the Reformatsky reaction was also separated by means of column chromatography on silica gel into two oily ethyl esters

(Va and Vb) in a 76 : 24 ratio. These major (Va) and minor (Vb) esters were hydrolyzed with sodium hydroxide in methanol to give the corresponding acids (mp 117—119°C and mp 143—144°C), which were identified as IVa and IVb respectively. This finding means that the two reactions proceed on similar stereochemical courses. The NMR spectra of IIa, IIb, Va, and Vb are summarized in Tables 1 and 2. As is shown in these tables, the methylene protons alpha to the ester group in the major alcohols (IIa and Va) are observed as well-defined AB-type quartets in $CDCl_3$, while those in the minor alcohols (IIb and Vb) are observed as singlets. The pyridine-induced solvent shifts (Δ values[7]) of these methylene protons in IIa (−0.17 ppm) and Va (−0.13 ppm) are slightly larger than those in the corresponding epimers (IIb: −0.13 ppm and Vb: −0.08 ppm), although the differences (II: 0.04 ppm and V: 0.05 ppm) of these Δ values between the epimeric alcohols are smaller than those (0.10—0.14 ppm) in the cases of 2-monoalkylcyclohexylacetate derivatives which have been reported in previous papers[1,2] The above NMR spectral data suggest that the orientations of the $-CH_2CO_2R$ groups in the major (IIa and Va) and minor (IIb and Vb) alcohols are equatorial and axial respectively. These assignments are also supported by their IR spectra, because IIa and Va show the characteristic hydroxyl absorption bands, at 983 and 985 cm^{-1}, respectively, which suggest the presence of axial hydroxyl groups; on the other hand, in the cases of IIb and Vb their spectra (IIb: 1060 cm^{-1} and Vb: 1060 cm^{-1}) suggest the presence of equatorial hydroxyl groups. Recently, Demarco *et al.*[8] reported on the pyridine-induced solvent shift of a methyl group vicinally situated to a hydroxyl group; the extent of the deshielding is dependent upon the magnitude of the dihedral angle, θ,[9] subtended between the methyl and hydroxyl groups. As may be seen from Tables 1 and 2, the pyridine-induced solvent shifts[10] of the methyl groups at the 2 and 6 positions are observed to be in good accordance with the results of Demarco *et al.* That is, in the major alcohols (IIa and Va) one of three methyl groups is only slightly shifted in pyridine-d_5 (0.01—0.03 ppm), whereas the two other methyl groups experience strong deshielding effects (0.14—0.19 ppm). These pyridine-induced solvent shifts strongly suggest the presence of an axial hydroxyl, an axial methyl, and two equatorial methyl groups in IIa and Va. On the other hand, in the minor alcohols (IIb and Vb) all of the three methyl groups situated on the cyclohexane ring are shifted (0.10—0.13 ppm) in pyridine-d_5; this suggests the presence of an equatorial hydroxyl, an axial methyl, and two equatorial methyl groups.

Subsequently, the stereochemistry of the Grignard reaction of I with ethylmagnesium iodide in ether was also studied in order to compare it with that of the above aldol-type condensation and that of the Reformatsky reactions. The crude product obtained was then purified by means of column chromatography to give the epimeric alcohols (VIa and VIb) in a 58 : 42 ratio, accompanied by two by-products (VIIa and VIIb) in a 34 : 66 ratio.[11] The structures of VIIa (mp 62.5—63.5°C) and VIIb (mp 49—50°C) were confirmed by direct comparisons with the authentic 2,2,*c*-6- and 2,2,*t*-6-trimethyl-*r*-1-cyclohexanols[12] which had been prepared by the reduction of I with $LiAlH_4$ in ether, followed by the separation of a mixture of the epimers (30 : 70 ratio[11]) by means of column chromatography. The NMR spectra of VIIa and VIIb are summarized in Table 3; the preferred conformations of these alcohols may be assigned as

7) $\Delta_{ppm}=\delta$ in $CDCl_3-\delta$ in pyridine-d_5.

8) P. V. Demarco, E. Farkas, D. Doddrell, B. L. Mylari, and E. Wenkert, *J. Amer. Chem. Soc.*, **90**, 5480 (1968).

9) As θ decreases in magnitude, the Δ values increase; that is, when θ is 180°, 85°, and 60°, the reported Δ values are −0.03, −0.13, and −0.20— −0.27 ppm respectively.

10) The values observed in this series were somewhat smaller than those of Demarco *et al.*[8] See also Ref. 2.

11) Since VIIa and VIIb were easily sublimed during the evaporation of the solvent, the ratio was obtained by a NMR spectral analysis of the crude product.

follows. The magnitude of the coupling constant between the protons at the 1 and 6 positions suggests that the orientations of these vicinal protons in VIIa and VIIb are equatorial-axial[13] and diaxial respectively. The pyridine-induced solvent shifts of the methyl groups also suggest that the orientations of the hydroxyl groups in VIIa and VIIb are axial and equatorial respectively. Subsequently, the correlation of the β-hydroxy esters (II and V) with the alcohols (VIa and VIb) was also carried out in the following manner. The reduction of IIa and Va with $LiAlH_4$ in ether gave the same VIIIa diol (mp 46—46.5°C). On the other hand, the VIIIb diol (mp 51.5—52.5°C) was also obtained by the similar reduction of IIb or Vb. The VIIIa and VIIIb diols were subjected to tosylation with *p*-toluenesulfonyl chloride in pyridine; the reduction of the resulting tosylates with $LiAlH_4$ in tetrahydrofuran gave 1-ethyl-2,2,*c*-6-trimethyl-*r*-1-cyclohexanol and its *t*-6-isomer, which were shown to be identical with VIa and VIb respectively by comparisons of their IR and NMR spectra.

From the present study, it is evident that all of the aldol-type condensation and the Reformatsky reaction and the Grignard reaction with I proceed in a similar fashion. Furthermore, it is well known[2,14] that isomers with equatorial hydroxyl groups can be expected to be adsorbed more strongly on chromatography and that, therefore, they can be expected to be more difficult to elute than the isomers with more hindered axial hydroxyls. In this study, the isomers (IIa, Va, VIa, and VIIa) were eluted first in each instance on column chromatography. This behavior also supports the presence of the axial hydroxyl groups in these alcohols.

Finally, the tre2tment of IIa with potassium hydrogensulfate at 210—226°C or with dilute sulfuric acid under refluxing afforded a γ-lactone (mp 79.5—80.5°C). From the physical and spectral data which are shown in the Experimental section, the structure of the above lactone was deduced to be (±)-*cis*-tetrahydroactinidiolide (IX). The preparation of the optically-active or inactive IX by different methods had already been reported by Sakan *et al.*[6] and by other workers.[15-19] On the other hand, the treatment of IIa in toluene with isopropenyl acetate in the presence of *p*-toluenesulfonic acid gave a mixture of γ-lactones; the components were successfully separated by means of column chromatography on silica gel to give IX and a *trans*-γ-lactone (X), mp 71.5—74.5°C. The NMR spectrum of X in $CDCl_3$ showed signals at δ 0.92, 0.95, and 1.32 ppm due to three methyl groups. In contrast with the *cis*-lactone (IX), the lactone X was easily hydrolyzed with methanolic sodium hydroxide to give the corresponding γ-hydroxy acid (XI), mp 105—107°C; the preparation of this substance by a different method had also been reported by Ohloff and Schade.[15]

Experimental

All the melting and boiling points are uncorrected. The NMR spectra were taken on a Hitachi Model R-20 NMR spectrometer (60 MHz), using tetramethylsilane as the internal standard. Their chemical shifts are presented in terms of δ values; s: singlet; bs: broad singlet; d: doublet; t: triplet; q: quartet. The column chromatography was performed on Merck silica gel (0.08 mm).

The Condensation of 2,2,6-Trimethylcyclohexanone (I) with t-Butyl Acetate. A solution of *t*-butyl acetate (49.5 g: 0.426 mol) in dry ether (45 m*l*) was stirred, drop by drop over a 15-min period, into a lithium amide solution which had been freshly prepared from lithium (2.96 g: 0.423 mol) and liquid ammonia (*ca.* 150 m*l*), with cooling in a dry ice–acetone bath. After the ammonia had evaporated, the residual syrup was diluted with dry ether (60 m*l*). To this solution there was then added, drop by drop, a solution of I[20] (15 g: 0.017 mol) in dry ether (30 m*l*) at room temperature over a 20-min period. The mixture was refluxed for 60 min, cooled, decomposed with dilute hydrochloric acid (3 N: 30 m*l*), and then extracted with ether. The extract was successively washed with aqueous sodium hydrogencarbonate (10%) and water, and then dried over sodium sulfate. After the removal of the solvent, the residue was distilled under a vacuum to give an oil (28.5 g); bp 123—148°C/14 mmHg. A part (4.00 g) of the above distilled oil was chromatographed on silica gel (200 g), using benzene as the eluent. The first fraction gave an oil (IIIa; 73 mg) which showed no hydroxyl absorption band in its IR spectrum. IR in $CHCl_3$: 1696 (C=O), 1622 cm^{-1} (C=C). NMR

12) G. Barraud, R. Cornubert, and A. M. Lemoine-Tressont, *Bull. Soc. Chim. Fr.*, **1957**, 1499. These authors had prepared VIIa (mp 61—62°C) and VIIb (mp 54°C) from I by catalytic hydrogenation in the presence of platinum and by reduction with sodium in ethanol respectively.

13) The possibility of its being diequatorial is rejected on the basis of the result of the pyridine-induced solvent shift of the methyl group at the 6 position.

in $CDCl_3$: 1.10 and 1.16 (each 3H and s, 2-CH_3), 1.24 (3H, d, J=7 Hz, -$CHCH_3$), 1.47 (9H, s, -$C(CH_3)_3$), 5.65 (1H, s, -C=$CHCO_2Bu^t$). UV: λ_{max}^{EtOH} 223 nm (ε=11900).

Found: C, 75.59; H, 11.02%. Calcd for $C_{15}H_{26}O_2$: C, 75.58; H, 11.00%.

The hydrolysis of IIIa in ethanol with aqueous sodium hydroxide gave the corresponding acid as colorless crystals; mp 101—102°C (from ether containing petroleum ether). IR in $CHCl_3$: 1680 (CO_2H), 1620 cm^{-1} (C=C).

Found: C, 72.53; H, 10.12%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.96%.

The second fraction gave an oil (IIIb: 35 mg) which also showed no hydroxyl absorption band in its IR spectrum and no absorption maximum in the 210—250 nm region of its UV spectrum. IR in $CHCl_3$: 1725 cm^{-1} (C=O). NMR in CCl_4: 0.96 (6H, s, 2-CH_3), 1.42 (9H, s, -$C(CH_3)_3$), 1.57 or 1.46 (3H, s, -C=CCH_3), 2.88 (2H, s, -$CH_2CO_2Bu^t$).

Found: C, 75.46; H, 11.14%. Calcd for $C_{15}H_{26}O_2$: C, 75.58; H, 11.00%.

The third fraction gave IIa as an oil (2.364 g). IR in $CHCl_3$: 3450 (OH), 1702 cm^{-1} (C=O).

Found: C, 70.11; H, 10.89%. Calcd for $C_{15}H_{28}O_3$: C, 70.27; H, 11.01%.

Further elution was carried out with benzene containing 3% ether; the fourth fraction gave IIb as an oil (0.550 g). IR in $CHCl_3$: 3440 (OH), 1702 cm^{-1} (C=O).

Found: C, 70.39; H, 11.01%. Calcd for $C_{15}H_{28}O_3$: C, 70.27; H, 11.01%.

The Reformatsky Reaction of I with Ethyl Bromoacetate. A solution of ethyl bromoacetate (16.0 g: 0.092 mol) in dry benzene (15 m*l*) was stirred; drop by drop at 85—88°C, into a mixture of I (6.50 g: 0.046 mol), purified zinc powder[21] (6.40 g: 0.092 mol), and dry benzene (2.0 m*l*). After the addition was complete, the mixture was refluxed for 30 min and then treated in the usual manner. The crude product was distilled under a vacuum to give an oil; bp 137—138°C/10 mmHg; yield, 7.0 g. A part (1.520 g) of the above oil was chromatographed on silica gel (100 g), using benzene as the eluent. The first fraction gave a dehydrated ester (10 mg). The second fraction gave Va as an oil (1.006 g).

Found: C, 68.52; H, 10.65%. Calcd for $C_{13}H_{24}O_3$: C, 68.38; H, 10.59%.

The third fraction gave Vb as an oil (0.333 g).

Found: C, 68.46; H, 10.43%. Calcd for $C_{13}H_{24}O_3$: C, 68.38; H, 10.59%.

*1-Hydroxy-2,2,*t*-6-trimethyl-*r*-1-cyclohexaneacetic Acid (IVa) and Its* c*-6-Isomer (IVb).* *a*) The hydrolysis of Va (1.00 g) in methanol with aqueous sodium hydroxide for 2 hr gave IVa as colorless crystals; mp 118.5—119.5°C; yield, 0.570 g. NMR in $CDCl_3$: 0.90 (3H, d, J=5 Hz -$CHCH_3$), 0.98 (6H, s, 2-CH_3), 2.47 and 2.67 (2H, each d and J=16 Hz, -CH_2CO_2H).

Found: C, 65.89; H, 10.09%. Calcd for $C_{11}H_{20}O_3$: C, 65.97; H, 10.07%.

Similarly, IIa was also hydrolyzed with aqueous sodium hydroxide for 5 hr to give IVa; mp 118.5—119.5°C.

b) The Vb ester (295 mg) was treated by a method similar to that used for IVa. The product (260 mg) was recrystallized from ether containing petroleum ether to give IVb as colorless crystals; mp 143.5—144°C; yield, 150 mg. NMR in $CDCl_3$: 0.96 (3H, d, J=6.5 Hz, -$CHCH_3$), 0.98 and 1.06 (each 3H and s, 2-CCH_3), 2.65 (2H, s, -CH_2CO_2H).

Found: C, 66.16; H, 10.01%. Calcd for $C_{11}H_{20}O_3$: C, 65.97; H, 10.07%.

Similarly, IIb was hydrolyzed to give IVb; mp 143.5—144°C.

Reduction of I with $LiAlH_4$. A solution of I (1.25 g) in dry ether (10 m*l*) was stirred, drop by drop over 20 min and at room temperature, into a suspension of $LiAlH_4$ (500 mg) in dry ether (10 m*l*). The mixture was refluxed for 3 hr, cooled, poured into a mixture of ice and dilute hydrochloric acid (10%: 25 m*l*), and then extracted with ether. The extract was washed with a saturated sodium chloride solution, dried over sodium sulfate, and then evaporated under a vacuum to give an oil (1.20 g) which showed no carbonyl absorption band in its IR spectrum. The NMR spectrum of the crude oil showed the presence of epimeric alcohols in a 30 : 70 ratio. The crude oil was chromatographed on silica gel (90 g), using benzene as the eluent. The first fraction gave VIIa[22] (327 mg), which was recrystallized from ether containing petroleum ether to give colorless crystals; mp 62.5—63.5°C (lit,[12] mp 61—62°C): Found: C, 75.91; H, 12.73%.

The second fraction gave VIIb[22] (502 mg) as colorless crystals, mp 49—50°C (lit,[12] mp 54°C): Found: C, 75.84; H, 12.80%. A mixed fusion with VIIa showed *ca.* 25°C.

The Grignard Reaction of I with Ethylmagnesium Iodide. A solution of I (1.400 g) in dry ether (5.0 m*l*) was added, drop by drop over 15 min at room temperature, to the Grignard reagent which had been prepared from magnesium (360 mg) and ethyl iodide (2.600 g) in dry ether (7.0 m*l*). The mixture was refluxed for 4 hr, allowed to stand overnight at room temperature, and then worked up in a usual manner to give a crude product which showed the presence of VIIa and VIIb in a 34 : 66 ratio upon NMR spectrum analysis. The crude product was purified by means of column chromatography on silica gel (150 g). Elution was carried out with benzene to give four fractions. The first fraction gave VIa (401 mg) as an oil.

Found: C, 77.51; H, 13.11%. Calcd for $C_{11}H_{22}O$: C, 77.58; H, 13.02%.

The second fraction gave VIb (290 mg) as an oil.

Found: C, 77.63; H, 13.09%. Calcd for $C_{11}H_{22}O$; C, 77.58; H, 13.02%.

The third fraction gave colorless crystals (139 mg.[22] mp 62.5—63.5°C),which were shown to be identical with authentic VIIa by a mixed-melting-point determination and by a comparison of their spectra.

The fourth fraction gave colorless crystals (236 mg:[22] mp 49—50°C) which were also shown to be identical with authentic VIIb by a comparison of their IR spectra.

Reduction of IIa, IIb, Va, and Vb with $LiAlH_4$. *a) From IIa and Va:* A solution of IIa (1.550 g) in dry ether (20 m*l*) was reduced with $LiAlH_4$ (500 mg). The crude product (1.402 g) was purified by means of column chromatography on silica gel (70 g), using benzene containing 20% ether as the eluent. The first fraction gave the recovered IIa (673 mg). The second fraction gave a diol (VIIIa: 737 mg), which was then recrystallized from ether containing petroleum ether to give colorless crystals; mp 46—46.5°C.

Found: C, 71.08; H, 12.10%. Calcd for $C_{11}H_{22}O_2$:

21) R. L. Shriner, "Organic Reactions," Coll. Vol. I, p. 16 (1942).

22) A part of the substance was lost by sublimation during the removal of the benzene.

C, 70.92; H, 11.90%.

Similarly, the ethyl ester (Va: 1.500 g) was also reduced with $LiAlH_4$ (500 mg) to give VIIIa (889 mg: mp 46—46.5°C).

b) *From IIb and Vb*: The esters (IIb and Vb) were also both reduced with $LiAlH_4$ to give VIIIb; mp 51.5—52.5°C. A mixed-melting-point determination with VIIIa showed 32—34°C.

Found: C, 71.14; H, 12.01%. Calcd for $C_{11}H_{22}O_2$: C, 70.92; H, 11.90%.

1-Ethyl-2,2,c-6-(VIa) and 1-Ethyl-2,2,t-6-trimethyl-r-1-cyclohexanol (VIb). *a*) A solution of VIIIa (400 mg), *p*-toluenesulfonyl chloride (440 mg), and dry pyridine (3.0 m*l*) was allowed to stand at room temperature for 60 hr. After a usual work-up, the crude product (420 mg) was dissolved in dry tetrahydrofuran (11.0 m*l*) and then reduced with $LiAlH_4$ (300 mg) for 3.5 hr under refluxing. The product was chromatographed on silica gel (40 g), using benzene containing 10% ether as the eluent. The first fraction gave an oil (126 mg) which was shown to be identical with VIa by a comparison of their IR spectra. The second fraction gave the recovered VIIIa (230 mg).

b) The diol VIIIb (573 mg) was treated by a method similar to that described in *a*) to give an oil (163 mg) which was identical with VIb. The starting VIIIb (253 mg) was also recovered.

2-Hydroxy-2,6,6-trimethyl-1-cyclohexaneacetic Acid γ-Lactones (IX and X). *a*) A mixture of IIa (3.40 g) and fused potassium hydrogensulfate (3.0 g) was heated at 210—226°C for 30 min in an oil bath. After cooling and the subsequent addition of water, the mixture was extracted with ether; the extract was washed with water, dried over sodium sulfate, and then evaporated. The crude product (2.04 g) was chromatographed on silica gel (200 g), using benzene containing 10% ether as the eluent, to give a *cis*-γ-lactone (IX: 1.66 g) ((±)-tetrahydroactinidiolide), which was then recrystallized from ether containing petroleum ether to give colorless crystals; mp 79.5—80.5°C (lit,[17] mp 77—79°C); Found: C, 72.25; H, 10.05%. The IR and NMR spectra of IX were in good accrodance with those in the literature.[6,16-18]

A mixture of the above *cis*-lactone (IX: 1.10 g) and aqueous sodium hydroxide (5%: 20 m*l*) was stirred and heated on a steam bath for 1 hr. The clear solution, after cooling, was acidified with dilute sulfuric acid to give the starting IX (0.95 g).

b) A mixture of IIa (429 mg) and dilute sulfuric acid 30%: 8.0 m*l*) was refluxed for 3 hr. After a usual work-up, the crude product (297 mg) was chromatographed on silica gel (25 g), using benzene containing 3% ether as the eluent, to give the *cis*-lactone (IX: 256 mg).

c) A mixture of IIa (635 mg), isopropenyl acetate (1.0 m*l*), and *p*-toluenesulfonic acid (40 mg) in dry toluene (12 m*l*) was refluxed for 3 hr, and then, after cooling, solid sodium hydrogencarbonate (140 mg) was added. The mixture was stirred at room temperature for 10 min and filtered; the filtrate was then evaporated under a vacuum to give a crude product which was chromatographed on silica gel (60 g). Elution was carried out with benzene containing 3% ether. The first fraction gave a *trans*-γ-lactone (X: 70 mg) which was recrystallized from ether containing petroleum ether to give colorless crystals; mp 71—74.5°C (softened at 66°C). A mixed-melting-point determination with the *cis*-γ-lactone (IX: mp 79.5—80.5°C) showed 50—55°C; it softened at room temperature.

Found: C, 72.63; H, 10.22%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.96%.

The second fraction gave the *cis*-γ-lactone (IX: 33 mg), the identity of which was established by an IR spectral comparison.

Hydrolysis of trans-γ-Lactone (X) with Alkali. A solution of X (50 mg) and aqueous sodium hydroxide (5%; 1.0 m*l*) in methanol (5.0 m*l*) was refluxed for 1 hr. After a usual work-up, the crude product was recrystallized from ether containing petroleum ether to give an acid (XI) as colorless crystals; mp 105—107°C (lit,[15] mp 113—115.5°C); Found: C, 66.16; H, 10.31%; yield, 40 mg. NMR in $CDCl_3$: 0.81 and 0.94 (each 3H and s, $-\dot{C}(C\underline{H}_3)_2$), 1.19 (3H, s, $-\dot{C}(OH)C\underline{H}_3$), *ca.* 6.0 (2H, bs, $-CO_2\underline{H}$ and $-O\underline{H}$).

Carbon-13 Magnetic Resonance Chemical Shifts in Alkylbiphenyls[1)]

Hideo HASEGAWA,* Mamoru IMANARI,** and Kazuhiko ISHIZU***

(Received September 9, 1971)

Carbon-13 NMR spectra were observed for the seventeen alkyl biphenyls. For the *meta*- and *para*-alkyl derivatives, the observed ring carbon-13 chemical shifts could be adequately understood in terms of the Karplus-Pople's formula by taking into account the hyperconjugative effect of the substituents. The observed chemical shifts of aliphatic carbon were in good agreement with the values of the corresponding alkylated benzenes within the limits of experimental error. For the *ortho*-derivatives, the conformation of substituents in the hindered biphenyls was particularly discussed in relation to the observed alkyl carbon-13 chemical shifts. In the cases of 2,2′-dimethylbiphenyl and 2,2′,6,6′-tetramethylbiphenyl, the chemical shifts of methyl carbons at the *ortho*-position revealed a high field shift of about 1 ppm, but that of 2,4,6-trimethylbiphenyl indicated only 0.4 ppm. The different shifts of the *ortho*-methyl carbons in the two cases suggested a spece interaction between the two methyl groups. This interaction may arise an orbital overlap between the methyl groups, which were considered to approach one another to take the *cis*-conformation.

Interest in the molecular structures of numerous biphenyl derivatives has often been focused on their stereochemistry. In particular, the substituents at the *ortho*-positions may cause a large steric effect; hence, two phenyls in *ortho*-substituted biphenyl derivatives are incapable of taking a planar structure in a solution. Regarding the conformation of the phenyl groups in the *ortho*-alkylated biphenyl, Suzuki[2)] has already proposed a correlation between the rotation angle of the two planar phenyl groups and the wavelength of the ultraviolet obsorption maxima. Furthermore, Mislow *et al.*[3)] and Ōki *et al.*[4)] have also reported that a similar relationship holds between the twisted angle of biphenyls and the NMR chemical shifts of the alkyl protons at the *ortho*-position. In this case, the chemical shifts of the alkyl protons were reasonably explained in terms of an increased diamagnetic shielding effected by the ring current of the rotating phenyl groups. In the case of NMR studies of aromatic protons, however, the assignment of their chemical shifts becomes more or less difficult because of the superimposed structures caused by the various spin-spin couplings of the ring protons. In this work, the carbon-13 NMR measurement of both ring and the alkyl carbon-13 were carried out for the seventeen alkylbiphenyls, and the hyperconjugative and steric effects due to the higher alkyl groups were investigated.

The observed ring carbon-13 chemical shifts are discussed in terms of the Karplus-Pople's formula, taking into account the hyperconjugative effect of the substituents. Finally, the conformation of the hindered biphenyls is considered in relation to the observed alkyl carbon-13 chemical shifts.

Experimental

Each alkylated biphenyl was synthesized and identified in the manner reported in previous papers.[5-7)] Samples containing carbon-13 in its natural abundance, 1.1%, were dissolved in tetrahydrofuran (THF). The carbon-13 magnetic resonance spectra were recorded using a JNM-4H-100 type NMR spectrometer at 25 MHz. A JNM-IS-100 proton decoupler was used in order to enchance the carbon-13 signal due to the nuclear Overhauser effect and to remove the splitting due to the spin-spin coupling between carbon-13 and proton spins.[8)] Benzene was used as the external primary reference for the ring carbon-13 chemical shifts in biphenyl, and the shift of the β-carbon of THF was taken as the internal secondary reference. For the aliphatic carbon-13 chemical shifts of the alkyl group, cyclohexane was used as the primary reference.

Results and Disusssion

Chemical Shifts of Aromatic Ring Carbon Para- *or* Meta-*Alkylated Biphenyls.* The aromatic carbon-13 NMR spectrum of 4,4′-diethylbiphenyl is shown in Fig. 1. The observed spectrum consists of four lines; their integrated intensity ratios are about 1 : 1 : 2 : 2, which easily distinguishes $\Delta\sigma_1$ and $\Delta\sigma_4$ from $\Delta\sigma_2$ and $\Delta\sigma_3$.[9)]

The chemical shift of each aromatic carbon-13 is calculated according to the additivity rule[10)] based on the experimental values of both biphenyl and ethylbenzene, and the observed $\Delta\sigma_i$ value is assigned to each ring carbon, with reference to the results of the

Fig. 1. The aromatic carbon-13 NMR spectrum of 4,4'-diethylbiphenyl. (Solvent: THF).

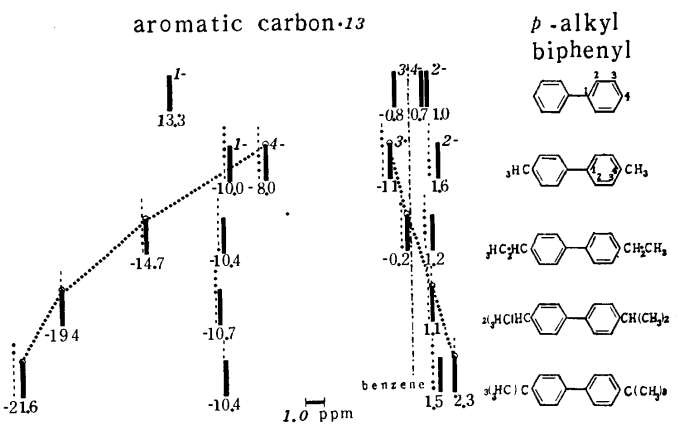

Fig. 2. The observed values and the calculated results of the aromatic carbon-13 chemical shifts for the *para*-alkylated biphenyls.[11] (Solvent: THF).

additivity calculations.

The observed and the calculated values of the aromatic carbon-13 chemical shifts for the *para*- and *meta*-alkylated biphenyls are summarized in Figs. 2 and 3. A satisfactory agreement can be seen between the observed values of the carbon-13 chemical shifts and those predicted by the additivity calculations.

In all cases, the hyperconjugative effect gives rise to a drastic lower-field shift for the ring carbon atoms ($\Delta\sigma_4$ and $\Delta\sigma_3$) bonded to the alkyl groups in the order of $CH_3<CH_3CH_2<CH(CH_3)_2<C(CH_3)_3$. At the same time, an alternative higher-field shift of the next neighboring carbon atoms of the alkyl groups can be observed; that is, in the case of 4,4'-dialkylbiphenyl, the ring carbons at the *meta*-position reveal a chemical shift in the directions opposite to the chemical shift of the *para*-positions.

This is probably due to the *ortho-para* conjugation

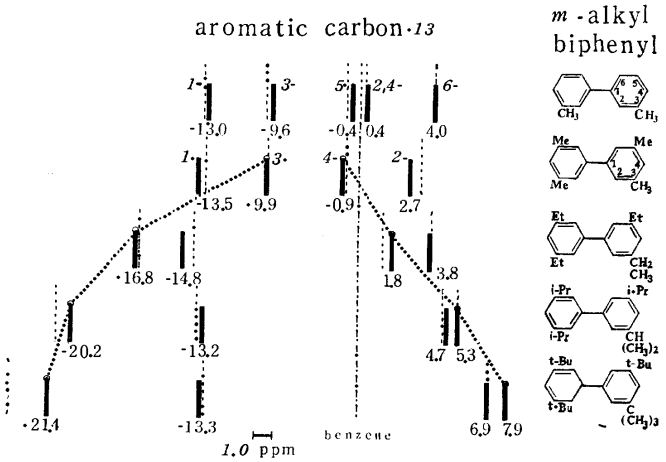

Fig. 3. The observed values and the calculated results of the aromatic carbon-13 chemical shifts for the *meta*-alkylated biphenyls.[11] (Solvent: THF).

or to the inductive effect of the alkyl groups. The large value of the chemical shift at the *para*-position in the *meta*-alkylated biphenyl is a result of this effect being enhanced by the neighboring two alkyl groups.

HMO Calculation of Carbon-13 Chemical Shifts in Aromatic Ring Carbon. In order to put the present experimental results on a more rigorous theoretical base, the aromatic carbon-13 chemical shifts ($\Delta\sigma_i$) were calculated using the Karplus and Pople's equation[12] expressed as follows; $\Delta\sigma_{i\,\mathrm{PPM}}=(86.7+46.0\lambda_H)(\rho-1)+46.0(F-0.399)$, where both the π-electron density (ρ) and the free valence (F) were calculated by the HMO method, and where the contribution due to the λ_H (polarity parameter of the C–H bond) is disregarded. For the treatment of the methyl group in the HMO calculation, we used two different models, the inductive (I) and the hyperconjugative models (II).

In the inductive model, any conjugative effect of the methyl group is disregarded, and the carbon to which the methyl group is attached is made somewhat more electropositive. The values of the Coulomb integral of these carbons, α_{CH_3} is estimated to be $\alpha_{CH_3}=\alpha-0.2\beta$.

The hyperconjugation model has been proposed by Coulson and Crawford[13]; in it a linear combination of the hydrogen 1*s* orbitals is taken to give the pseudo π-orbital conjugating with the ring system. The parameters used in the HMO calculation of the methyl group ($>C_1-C_2\equiv H_3$) are;

$$\alpha_2=\alpha-0.1\beta,\quad \alpha_{H_3}=\alpha-0.5\beta$$
$$\beta_{C_1-C_2}=0.7\beta,\quad \beta_{C_2\equiv H_3}=2.5\beta.$$

The results of 4,4'-dimethylbiphenyl, 3,3'-dimethylbiphenyl, and 3,3',5,5'-tetramethylbiphenyl are given in Table 1. It may be seen that the hyperconjugative model gives a more or less satisfactory prediction of the aromatic carbon-13 chemical shift, except for the *para*-position of the 3,3',5,5'-tetramethylbiphenyl, although the tendency of the observed chemical shift

11) Bold lines indicate the observed chemical shifts of the aromatic carbons and dotted lines correspond to the values of the chemical shifts calculated on the basis of the assumption of additivity rule. The chemical shifts are indicated such that positive ppm is to high field (to the right hand in each figure) of the shift from that of the carbon atoms of benzene (0 ppm) as an reference.

4	−0.9	−0.7	+6.0	+2.3

can also be qualitatively understood using the inductive model. It is interesting to see how the tendency of the observed ring carbon-13 chemical shift can be understood in terms of the HMO calculation for higher alkylated biphenyls.

For the sake of simplicity, we carried out the HMO calculation taking the Coulomb integral of the aromatic carbon, α_R, bonded to the higher alkyl group (R), $\alpha_R=\alpha-\delta\beta$.

The relation between the calculated carbon-13 chemical shift and the value of δ is plotted in Fig. 4 and Fig. 5.

In the case of the *para*-derivatives (Fig. 4), the theoretical value of the aromatic carbon-13 chemical shift of the *para*-position ($\Delta\sigma_4$) shows an increased lower-field shift with an increment of δ, while, conversely, a higher-field shift is predicted for the *meta*-position. The tendency of the observed ring carbon-13 chemical shift resulting from the higher alkyl substitution is also well explained for *meta*-derivatives (Fig. 5) in terms of the inductive parameter, which increases in the order of methyl, ethyl, isopropyl, and *t*-butyl groups.

These calculations thus support the idea that the hyperconjugative effect not only gives drastic lower-field shifts for the ring carbon atoms bonded to the

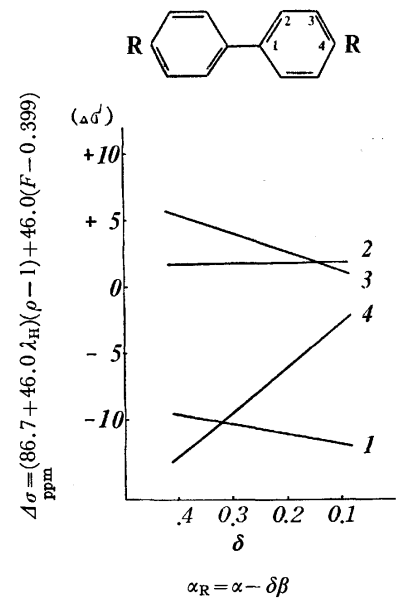

Fig. 4. The relation between the HMO carbon-13 chemical shift and the value of δ in 4,4'-dialkylated biphenyls.

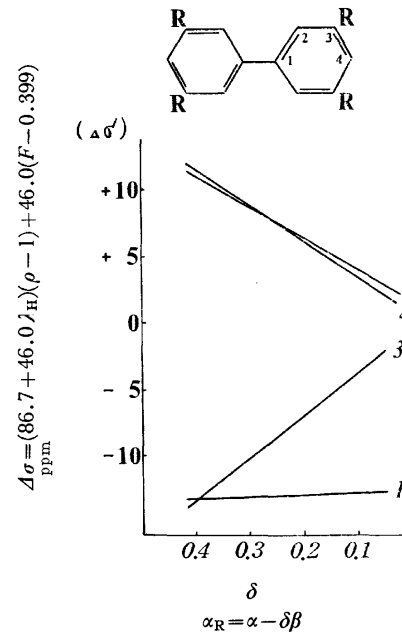

Fig. 5. The relation between the HMO carbon-13 chemical shift and the value of δ in 3,3',5,5'-tetraalkylated biphenyls.

alkyl groups, but also results in an auxiliary alternative shift on the next-nearest ring carbon atoms.

Ortho-*alkylated Biphenyls*. The observed chemical shifts of the ring carbons in several *ortho*-substituted biphenyls are given in Table 2. The analysis of the spectra of *ortho*-derivatives is much more difficult than *para*- or *meta*-derivatives, because we cannot make a quantitative assignment using the additivity rule such as was done for the *para*- and *meta*-derivatives. The HMO calculations of the aromatic carbon-13 chemical shift were carried out for the 2,2',6,6'-tetramethylbiphenyl, where the Coulomb integrals of the *ortho*-ring carbon atoms were taken as $\alpha-0.2\beta$ and were the resonance integral of the 1–1' bond was estimated to be

4	+0.8	+0.7	+0.7	+0.5	+0.2	−0.1

There are large discrepancies between the observed values and those calculated; however, this will probably means that the contribution of the σ orbital should be taken into account.

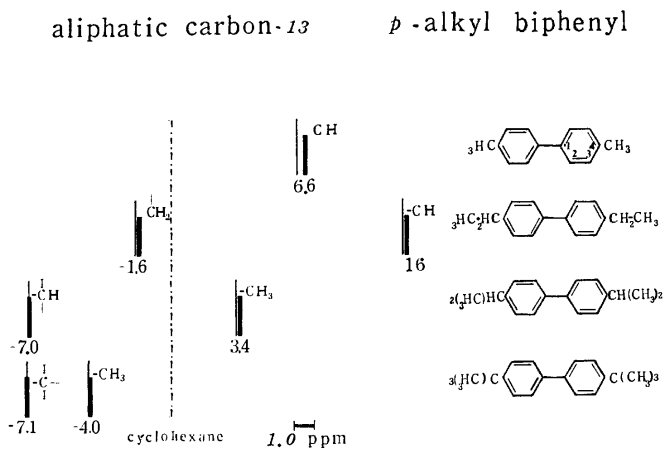

Fig. 6. The observed values of aliphatic carbon-13 chemical shifts for the *para*-alkylated biphenyls.[14] (Solvent: THF)

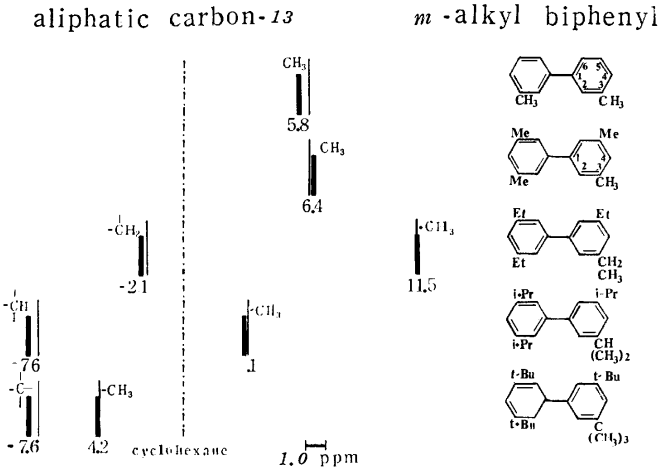

Fig. 7. The observed values of aliphatic carbon-13 chemical shifts for the *meta*-alkylated biphenyls.[14] (Solvent: THF)

$\beta\cos\theta$ as a function of the twisting angle (θ) of the two phenyl rings. The results are shown in Table 3. The calculations of the chemical shifts by the foregoing inductive model, however, could not be related to the observed values in the same manner as the *meta*- and *para*-alkylated biphenyls were. Therefore, these assignments are only qualitative.

Chemical Shifts of Aliphatic Carbon. The chemical shifts of aliphatic carbon-13 atoms for *para*-, *meta*-, or *ortho*-alkylated biphenyls are presented in Figs. 6—9. In the cases of *para*- or *meta*-alkylated biphenyls, the observed chemical shifts of the aliphatic carbon agree with the values of the corresponding alkylated benzenes within the limits of experimental error. In the case of *ortho*-alkylated biphenyls, such as 2,2'-dimethylbiphenyl (II) and 2,2',6,6'-tetramethylbiphenyl (III)

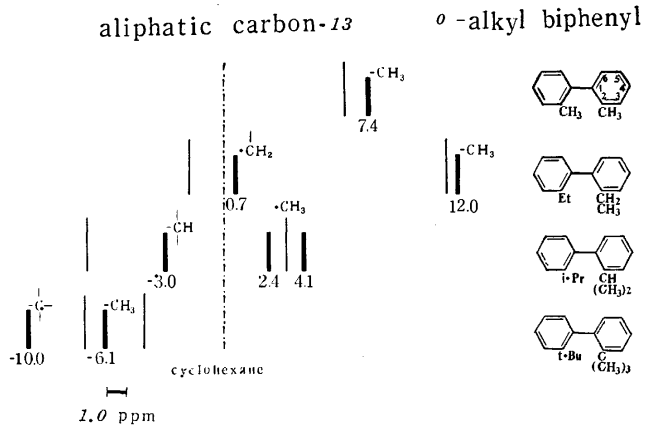

Fig. 8. The observed values of aliphatic carbon-13 chemical shifts for the *ortho*-alkylated biphenyls.[13] (Solvent: THF).

14) The bold lines indicate the observed chemical shifts and the narrow lines indicate those of aliphatic carbons in alkylated benzene. The chemical shifts were indicated in units of positive ppm to high field (to the right hand in each figure) taking the shift of the carbon atoms of cyclohexane (0 ppm) as a reference.

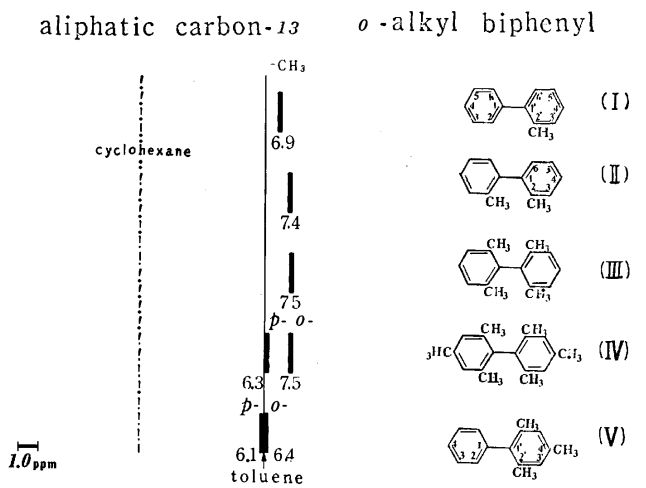

Fig. 9. The observed values of aliphatic carbon-13 chemical shifts for the *ortho*-methyl biphenyls. (Solvent: THF).

in Fig. 9, however, the chemical shifts of the methyl carbons shows a field shift higher by about 1 ppm than that of the corresponding toluene.

A similar higher-field shift is noted in the methyl protons, as is shown in Fig. 10; that is, the proton chemical shifts in the *ortho*-methyl groups also increase by about 0.4 ppm, thus exceeding the value for the methyl protons of toluene. These facts have already been understood in terms of the effect of the ring current[15] induced by the rotating biphenyl group[3,4]. It should be noticed, however, that a similar explanation is not always valid in all cases of the present investigation; a definite difference in the chemical shifts of carbon-13 NMR at the *ortho*-methyl groups is explicitly observed between the 2,4,6-tri-

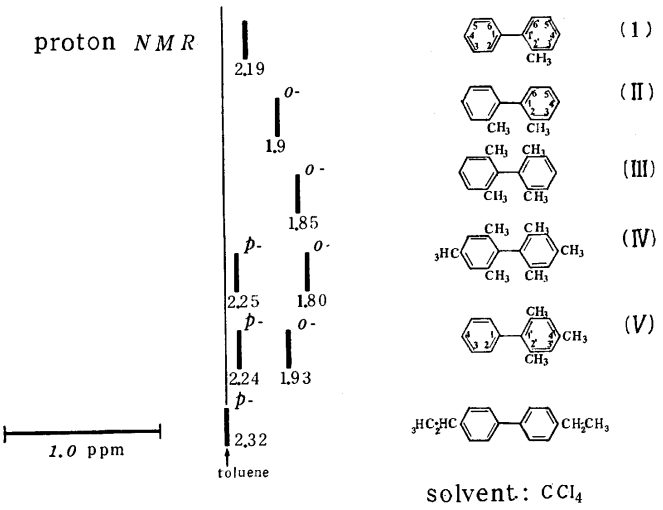

Fig. 10. The observed values of aliphatic proton chemical shifts for the *ortho*-methyl biphenyls. (Solvent: CCl_4).

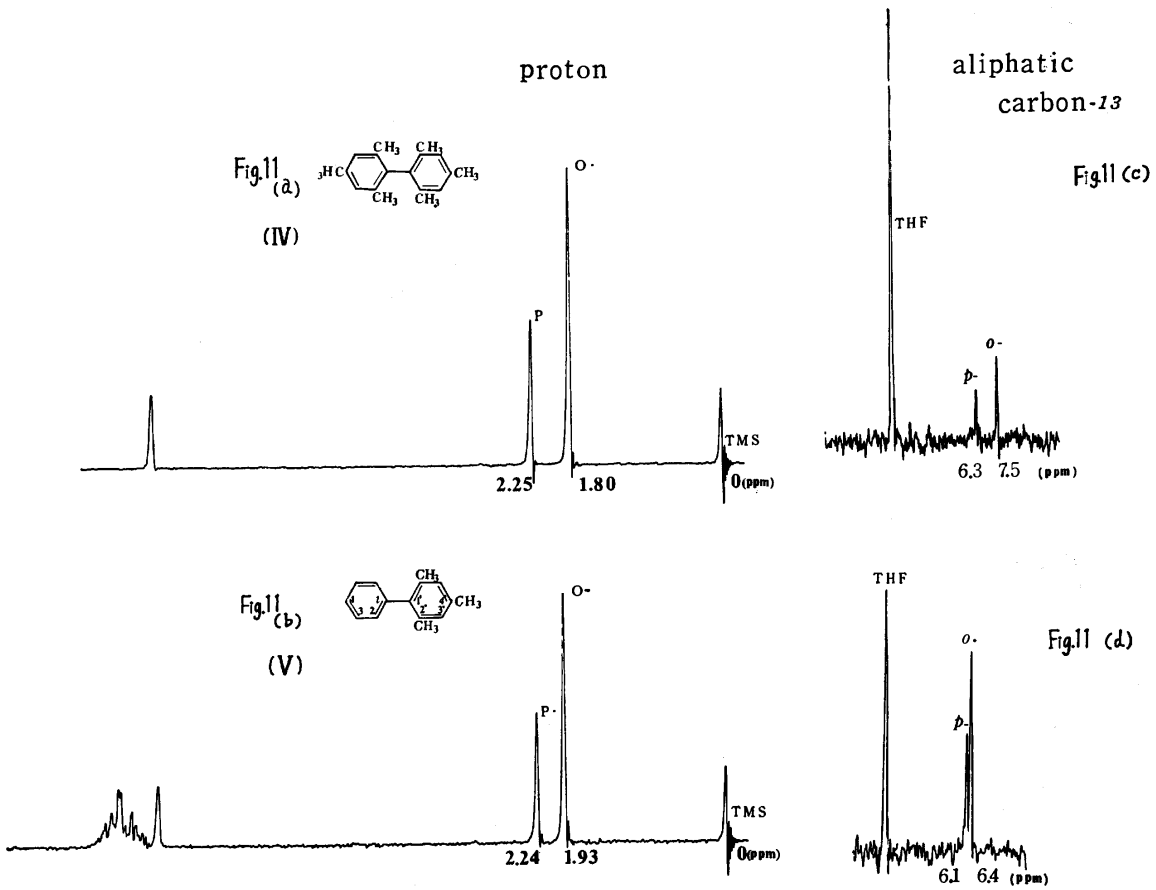

Fig. 11. The proton and carbon-13 NMR spectrum of 2,2′,4,4′,6,6′-hexamethylbiphenyl (IV) and 2,4,6-trimethylbiphenyl (V).

15) C. E. Johnson, Jr., and F. A. Bovey, *J. Chem. Phys.*, **29**, 1012 (1958).

methylbiphenyl (V) and the 2,2′,4,4′,6,6′-hexamethylbiphenyl (IV), as is shown in Figs. 11-c and d. The results of these anomalous carbon-13 chemical shifts cannot be explained only on the basis of the ring-current model, since the effect of the ring current can be expected to be nearly the same in both cases.

On the basis of the present results, one may speculate that the difference in the chemical shifts of the *ortho*-methyl groups is responsible for that in the short-range interaction across the neighboring 2,2′-dimethyl groups. If this is the case, the interaction may arise from an orbital overlap between the methyl groups, which will approach one another to take the *cis*-conformation, because, in the case of V, one cannot expect such interactions. On the other hand, for IV two pairs of *ortho*-methyl groups can be accessible through a rotation around the central C–C bond of the biphenyl ring. From this point of view, the chemical shifts of the aliphatic carbon-13 of the other 2,2′-substituted derivatives cited in Fig. 8 may be reasonably understood by assuming a space interaction between the two alkyl groups. The present results for carbon-13 NMR lead to the assumption that the 2,2′-alkyl biphenyls are likely to take the *cis*-conformation rather than the *trans*-form, as was previously proposed by Suzuki.[2] If the two methyl groups in the molecular structure of II have the *trans*-conformation, the chemical shifts for the methyl groups will have values near the chemical shift which V indicates.

We are grateful to Miss Keiko Suzuki for her HMO calculations.

Olefin Disproportionation by Rhenium, Tungsten, and Molybdenum Based Catalysts. Effect of the Addition of Oxygen

Yasuzo UCHIDA, Masanobu HIDAI, and Takashi TATSUMI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received September 11, 1971)

$ReCl_5$ was activated with Et_3Al and oxygen to give a catalyst effective for the disproportionation of α-olefins as well as internal olefins. The catalyst species was deactivated by excess oxygen. The catalyst system consisting of either WCl_6 or $MoCl_5$ and Et_3Al exhibited disproportionation activity in a short range of Al/M (M=W or Mo) molar ratio. The activity decreased with the increase in the Al/M ratio, but was restored by the introduction of oxygen.

A number of Ziegler-Natta type catalysts have been reported to be effective for olefin disproportionation. These catalysts were derived from WCl_6–$EtAlCl_2$,[1,2] WCl_6–$EtAlCl_2$–EtOH,[1),2)] WCl_6–*n*-BuLi,[3)] and nitrosyl complexes $L_2Cl_2(NO)_2M$ (M=Mo or W; L=Ph_3P, C_5H_5N, Ph_3PO, *etc.*)-alkylaluminum halides.[4,5)] We wish to report a disproportionation catalyst consisting of $ReCl_5$, Et_3Al, and oxygen, which effected the disproportionation of α-olefins as well as internal olefins. The catalyst system of WCl_6 and Et_3Al, reported to convert 2-pentene into unknown oligomers,[3)] exhibited disproportionation in a short range of Al/W molar ratio. Though disproportionation activity decreased with the increase in the ratio, it was restored by the introduction of oxygen. $MoCl_5$ behaved like WCl_6 upon treatment with Et_3Al and oxygen. Catalysts consisting of rhenium oxide on alumina are notable for their disproportionation activity at relatively low temperatures.[6,7)] Ziegler-Natta type catalysts containing rhenium compounds do not seem to have been reported in detail, although a patent[8)] has been claimed.

Experimental

Materials and Procedures. All the reactions were carried out with a Schlenk-type tube under nitrogen. The reaction mixtures were stirred at room temperature and atmospheric pressure. Analysis by gas-liquid partition chromatography(glpc) was performed on a Shimadzu Model GC-3AH chromatograph, using a 3 m stainless-steel tube column packed with Silicone SE 30 fluid on 60—80 mesh Diasolid M.

Chlorobenzene and benzene were dried and distilled under a nitrogen stream. Organoaluminum compounds were used after dilution to about 8 wt%. All the transition metal chlorides were commercially obtained. WCl_6 was used after removal of more volatile contaminants, $WOCl_4$ and WO_2Cl_2, by sublimation under a nitrogen stream at about 180°C. Molybdenum(III) acetylacetonate was prepared by the method of Larson and Moore.[9)] Commercial olefins were used after degassing in a vacuum. When olefins purified by distillation in the presence of WCl_6 were

used, the catalytic activity was higher than that with unpurified olefins.

Reaction of 2-Pentene with $ReCl_5$–Et_3Al–O_2. $ReCl_5$ (0.1 mmol) and 2 m*l* of chlorobenzene were treated with 0.4 mmol of Et_3Al (chlorobenzene solution) at *ca.* −30°C. The reduction was carried out for 30 min at ambient temperature and then 9.3 mmol (0.65 g) of 2-pentene purified by adding WCl_6 was injected by a syringe. The reaction mixture was degassed and a calculated amount of oxygen was introduced. Reaction times given in the tables were estimated from the time of introduction of oxygen. After 30 min, the reaction vessel was filled with nitrogen. Glpc analysis was carried out at 75°C and 20 cc/min of helium flow rate employing a chlorobenzene standard, and indicated the presnece of 2-butene, 3-hexene, and unreacted 2-pentene in the reaction mixture. All peaks in the chromatograms were identified by comparison of their retention times with those of authentic samples. The olefin yield in the tables is mol% of each olefin to the staritng olefin.

Reaction of 1-Pentene with $ReCl_5$–Et_3Al–O_2. The catalyst was prepared as described above except that oxygen was introduced 16 hr after the addition of Et_3Al. Glpc analysis showed the presence of olefins ranging from C_2 to C_8. The analytical conditions were the same as described above. Mass spectral data confirmed identification.

Reaction of 2-Pentene or 1-Pentene with WCl_6–Et_3Al (–O_2). A mixture of 0.1 mmol of WCl_6, 2 m*l* of chlorobenzene, and either 9.3 mmol of 2-pentene or 9.1 mmol of 1-pentene was treated with Et_3Al at *ca.* −30°C. Oxygen was subsequently introduced in some cases.

Reaction of 2-Pentene or 1-Pentene with $MoCl_5$–Et_3Al (–O_2). The catalyst was prepared as described above except that $MoCl_5$ was used in place of WCl_6.

Results and Discussion

Catalyst from $ReCl_5$. Treatment of $ReCl_5$ with Et_3Al in chlorobenzene gave a reddish brown solution, to which 2-pentene and oxygen were added. During the reaction a black precipitate was gradually deposited. Glpc analysis after 2 hr indicated the presence of 2-butene, 3-hexene, and unreacted 2-pentene; no additional products other than ethylene were detected. In order to determine the optimum O_2/Re ratio and to obtain information on the stoichiometry of the catalyst-formation reaction, a series of runs was made increasing the amount of added oxygen while the concentrations of $ReCl_5$ and Et_3Al were kept constant. At Al/Re=4, good results were obtained at O_2/Re=6—10. The Al/Re molar ratio was varied without adding oxygen. No disproportionation took place. The products after 20 hr consisted 25% of 2-butene, 50% of 2-pentene, and 25% of 3-hexene, indicating that a thermodynamic equilibrium was reached in each experiment. The data are collected in Table 1. At O_2/Re≧3.5, the catalytic activity disappeared after 20 hr. It seems that at such large O_2/Re molar ratios, the disproportionation catalyst species was destroyed by excess oxygen.

When α-olefins were used as substrates, two competing processes occurred, namely disproportionation and double-bond migration. As shown in Table 2, 1-pentene gave a mixture of olefins ranging from C_2 to C_8. Only double-bond migration occurred before

a) 1-Pentene/Re=60.
b) Ethylene and propylene were also detected.

the addition of oxygen. In this catalyst system the disproportionation of internal olefins proceeded at a fairly higher rate than the disproportionation and double-bond migration of α-olefins. Glpc analyses after 72 hr showed that at Al/Re=4, good results for disproportionation were obtained at O_2/Re=*ca.* 2.5. At Al/Re=4 and O_2/Re=2.6, the catalyst system was still active in the disproportionation of additional 1-pentene after 72 hr. This indicates that at a small O_2/Re ratio, the catalyst was probably long-lived. Thus 1-pentene was continually disproportionated little by little and 2-pentene which resulted from the slow double-bond migration of 1-pentene was rapidly disproportionated. But at a large O_2/Re ratio, the disproportionation catalyst was deactivated by excess oxygen present in the system before 2-pentene was gradually formed and the slow disproportionation of 1-pentene proceeded to a considerable extent. According to analyses after 72 hr, good results were obtained at relatively small O_2/Re ratios. At Al/Re=7, the optimum ratio was larger than that at Al/Re=4. At Al/Re=1 and O_2/Re=1, alkylation products were exclusively formed. The first three experiments in Table 2 indicate that in the early stage of the reaction, the high conversion of 1-pentene was attained at relatively large O_2/Re molar ratios. It seems that this was due to the slow catalyst-formation at small molar ratios. The result that large ratios are preferred (Table 1) could be similarly elucidated.

Glpc analyses of the 2-pentene reaction solutions after 96 hr showed the presence of small amounts of C_7 olefins (1—2%), which can be attributed to double-bond migration followed by disproportionation. This catalyst in combination with 1-hexene afforded a mixture of olefins ranging from C_2 to C_{10}. 2-Hexene gave a mixture of olefins ranging from C_4 to C_8 (Table 3). The formation of each olefin, as described in Tables 2 and 3, requires the interaction of a combination of α- and internal olefins.

In these catalyst systems olefins should be added after the reduction of $ReCl_5$ by Et_3Al, since $ReCl_5$ tself can promote the moderate alkylation of aromatic compounds and the oligomerization of olefins.[10] Aromatic compounds were suitable as solvent. Olefins were not disproportionated with tetrahydrofuran as a solvent. When three moles of PPh_3 per mole of $ReCl_5$ were present in the system before oxygen was introduced, the system showed no disproportionation activity. $ReCl_3$ showed none upon treatment with Et_3Al and oxygen.

TABLE 3. $ReCl_5$-Et_3Al-O_2 CATALYST WITH 1-HEXENE OR 2-HEXENE[a]

a) Olefin/Re=50.
b) Ethylene, propylene, and butene were present. However, they were not estimated.

Catalyst from WCl_6. Wang and Menapace[3] reported that with a WCl_6–Et_3Al catalyst system, 100% conversion into unknown oligomers was obtained. The catalyst system WCl_6 and Et_3Al, however, exhibited disproportionation activity for 2-pentene in a short range of Al/W molar ratio. The optimum ratio was *ca.* 0.5. Though the catalyst activity decreased with the increase in the ratio, it was restored by the introduction of oxygen into the system. At Al/W=2.6, good results were obtained at O_2/W=1.2—1.7. Traces of oligomerization and Friedel-Crafts alkylation products were observed in the reaction mixture.[11] Glpc analyses after 96 hr indicated the presence of C_7 olefins.

In the reaction of α-olefins by the catalyst system of WCl_6–Et_3Al, unknown oligomerizasion took place considerably accompanied by disproportionation and double-bond migration. Although both oligomerization and disproportionation activities disappeared with the increase in the Al/W ratio and the double-bond migration activity was not much influenced, introduction of oxygen into this system recovered only the disproportionation activity. Addition of PPh_3 to WCl_6–Et_3Al system also suppressed the oligomerization activity and effected disproportionation and double-bond migration. The results are given in Table 4. The disproportionation activity of the catalyst WCl_6–Et_3Al–O_2 was dependent on the mixing order of the catalyst components. Preparation of the active catalyst was favored by the presence of olefin when WCl_6 was treated with Et_3Al and then oxygen.

Catalyst from Molybdenum Compounds. The catalyst system of $MoCl_5$ and Et_3Al also exhibited catalytic activity for olefin disproportionation in a narrow range of Al/Mo ratio. This system appeared to be less active than the tungsten system. The disproportion activity was reduced by the increase in the Al/Mo ratio but restored by the introduction of oxygen into the system. In the reaction of α-olefins with $MoCl_5$–Et_3Al, oligomerization occurred accompanied by disproportionation and double-bond migration. The results are summarized in Table 5.

Molybdenum(III) acetylacetonate also exhibited disproportionation activity for 1-pentene upon treatment with Et_3Al and oxygen. At Al/Mo=7 and O_2/Mo=2, the system exhibited a slight activity. At Al/Mo=4, only double-bond migration and dimerization were observed with a change of O_2/Mo.

As a reducing agent, other organoaluminum compounds were also investigated. Several systems were found to form disproportionation catalysts. Pertinent data are given in Table 6.

	2.6	0	2	0	98	0		
	2.6	1.2	2	22	56	22		
	2.6	4.5	2	14	73	13		
1-Pentene	0.7	0	2	2.6	21	3.0	1.1	0.1
	2.6	0	12	0.9	96	0.6	3.0	0.0
	2.6	2.3[d]	2	11	59	11	5.3	3.5
	1.2	1.0[e]	44	19	26	20	11	4.4

a) 2-Pentene/W=93, 1-pentene/W=91.
b) In this reaction 2-pentene purified by adding WCl_6 was used. 2-Pentene/W=270.
c) When the reactant was 1-pentene, ethylene and propylene were also present. Although chlorophenylpentane was detected, the amount of alkylation products was so small that we could employ chlorobenzene as an internal standard in the glpc analysis.
d) Oxygen was added 12 hr after the reduction by Et_3Al.
e) PPh_3 was used in place of O_2. 1-Pentene was purified by adding WCl_6.

Table 5. $MoCl_5$-$Et_3Al(-O_2)$ catalyst[a]

Reactant	Al/Mo Molar ratio	O_2/Mo Molar ratio	Reaction time, hr	Olefin yield,[b] mol% C_4	C_5	C_6	C_7	C_8

$MoCl_5$	6	4	22	3.8	75	3.5
$ReCl_5$	7	5	24	1.0	80	1.0

a) 2-Pentene/M=93.
b) Traces of phenylpentane were also detected.

The Reaction Intermediate. Wang and Menapace[3] described the disproportionation of 2-pentene by a catalyst system of WCl_6 and *n*-BuLi. They reported that a conversion of 50% and a selectivity of 100% were obtained at Li/W=2, results not being good with other ratios. Thus they suggested a W-(IV) catalytic intermediate. Hughes[12] proposed a zero-valent molybdenum compound as the active species in the $L_2Cl_2(NO)_2Mo$–R_xAlCl_{3-x} catalyst.

In our catalyst systems starting metal chlorides, which demonstrate moderate Friedel-Crafts alkylation activity,[10,11] can be reduced to various oxidation states according to an added amount of Et_3Al. At Al/W=*ca.* 0.6, WCl_6 can be reduced to an appropriate oxidation state and exhibits disproportionation activity. Subsequently added oxygen can re-oxidize the low-valent complex and realize a favorable oxidation state for disproportionation. If oxygen was present in excess, the activity species would be further oxidized and destroyed. When three moles of PPh_3 per mole of $ReCl_5$ were present in the system before the introduction of oxygen, PPh_3 could stabilize the low-valent metal species and prevent it from re-oxidation. However, it is difficult to assume the precise oxidation state of the active species.

Studies on Hydroxy Amino Acids. IV.[1] Syntheses of Several Peptides Containing Aziridinecarboxylic Acid Derived from the Corresponding Hydroxy Amino Acid Derivatives

Yasuo NAKAGAWA,* Takashi TSUNO, Kiichiro NAKAJIMA, Michio IWAI, Haruki KAWAI, and Kenji OKAWA

Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received September 13, 1971)

The β-elimination reaction of the *O*-tosyl β-hydroxy amino acid peptide derivative was thoroughly investigated. The *N*-tosyl-L-serylglycine ester and the *N*-tosyl-L-threonylglycine ester gave the *N*-tosyl-L-aziridinecarbonylglycine ester and the *N*-tosyl-3-methyl-L-aziridinecarbonylglycine ester as the resulting products respectively by the elimination reaction. On the other hand, the *N*-carbobenzoxyglycyl-L-serylglycine ester was not converted into the aziridine peptide derivative; only the dehydroalanine peptide was obtained. However, the *N*-tosyl-L-phenylalanyl-L-threonylglycine ester and the *N*-carbobenzoxyglycyl-L-threonylglycine ester were converted into the corresponding aziridine peptide, and the *N*-tosyl-L-phenylalanyl-3-methyl-L-aziridinecarbonylglycine ester and the *N*-carbobenzoxyglycyl-3-methyl-L-aziridinecarbonylglycine ester were obtained respectively. It was concluded that the peptides containing threonine were easily converted into the aziridine peptides and not the serine peptides by the β-elimination reaction.

The typical β-elimination reactions of the *N*-acylated hydroxy amino acid esters, such as serine or threonine derivatives, usually gave dehydroalanine derivatives as the resulting products. For example, the *N*-carbobenzoxy-*O*-tosyl-L-serine ethyl ester (IIe) was converted into the *N*-carbobenzoxydehydroalanine ester (IIIe) by the elimination reaction described by Photaki.[2] The above result was also supported by the present investigation; that here is, the *N*-carbobenzoxyglycyl-*O*-tosyl-L-serine ethyl ester (IIf) and the *N*-carbobenzoxyglycyl-*O*-tosyl-L-threonine ethyl ester (IIk) were also converted into the corresponding *N*-carbobenzoxyglycyldehydroamino acid ester derivatives (IIIf, IIIk).

In the case of the *N*-alkylated serine ester, however, the aziridine ring is formed by the elimination reaction, even though the carboxyl group is replaced by the ester group. For example, the *N*-trityl-L-aziridinecarboxylic acid methyl ester (IVa) was obtained from the *N*-trityl-*O*-mesyl-L-serine methyl ester (IIa), as has been described by Smrt.[3]

On the other hand, as has been described in a previous paper[4], an aziridinecarboxylic acid derivative, *N*-tosyl-3-methyl-aziridinecarboxylic acid anilide(IVi), was obtained instead of the dehydroalanine derivative from the *N,O*-ditosyl-L-threonine anilide(IIi). We will use "Azyline" as the name of aziridinecarboxylic acid and "Azy" as an abbreviation of azyline.

In the present investigation, we have systematically tried to clarify the structural influences of the substituent group on the formation of the aziridine ring by the elimination reaction of the hydroxy amino acid peptide derivatives, as is shown in Table 1. As the first experiments, the substituent effects of the ester and amide groups of *N*-tosylated hydroxy amino acid in the elimination reaction were investigated. It was found that, the *N,O*-ditosyl-L-serine ethyl ester (IIb) was converted into the *N*-tosyldehydroalanine ester (IIIb), while the aziridine derivative was not obtained at all. On the other hand, *N,O*-ditosyl-L-serylglycine esters (IIc, IId), in which carboxyl groups of serine were protected by the amide group, gave only aziridine peptides derivatives (IVc, IVd).

In the case of the threonine derivatives, however, the *N,O*-ditosyl-L-threonine ethyl ester (IIh) was converted into both the *N*-tosyl-3-methyl-L-azylylglycine ester (IVh) and the *N*-tosyl-α-amino-crotonic acid ester (IIIh).

On the other hand, in the case of the amide derivative of threonine, the *N*-tosyl-3-methyl-L-azylylglycine ethyl ester (IVj) was obtained from the *N,O*-ditosyl-L-threonylglycine ethyl ester (IIj), as had been expected on the basis of the results of a previous investigation.

l	CH_3	-Gly-OBzl	Z-Gly-	—	80
m	CH_3	-Gly-OEt	Tos-L-Phe-	—	60

a) Elimination reactions were carried out in tetrahydrofuran solution in the presence of triethylamine, but some of the cases, benzene-methanol or acetonitrile was used as the solvent and *N*-ethylpiperidine was used as the base.
b) *N*-Tri-*O*-Mesyl-L-serine methyl ester is used as the starting material in literature.[3]
c) This value shows the yield of the free acid in literature.[4]
d) This result was published in the previous paper.[4]

As the next experiments, the substituent effects of the *N*-acyl masking group of the hydroxy amino acid amide derivatives were investigated. It was found that the *N*-carbobenzoxyglycyl-*O*-tosyl-L-serylglycine ethyl ester (IIg) was converted into the corresponding *N*-carbobenzoxyglycyldehydroalanylglycine ethyl ester (IIIg), but no aziridine derivatives were obtained. However, the *N*-carbobenzoxyglycyl-*O*-tosyl-L-threonylglycine benzyl ester (IIl) and the *N*-tosyl-L-phenylalanyl-L-threonylglycine ethyl ester (IIm) were converted into the *N*-carbobenzoxyglycyl-3-methyl-L-azylylglycine benzyl ester (IVl) and *N*-tosyl-L-phenylalanyl-3-methyl-L-azylylglycine ethyl ester (IVm). These were the first synthetic peptides in which aziridinecarboxylic acid was placed at the middle position in the peptide linkage.

On the basis of the above experiments, it was concluded that threonine peptides and their derivatives (R_1=–CH_3) are relatively more easily converted into the corresponding aziridine derivatives than the serine peptides derivatives (R_1=–H). The replacement of the ester group (R_2) of the hydroxy amino acid by an amide group, such as the anilide or glycine ester, increased the tendency of the ring formation. The aminoacyl group (R_3) did not promote the tendency of the ring formation; only aziridine peptides derivatives were synthesized in the case of threonine peptipdes (R_1=–CH_3).

It is a matter of course that the aziridine derivatives preserved their optical activity throughout the β-elimination reaction, unlike the dehydroamino acid derivatives, which did not show any optical activity at all. The X-ray crystallographic analysis of the compound, *N*-tosyl-L-azylylglycine, also supported the above results; that is, the original configuration on the α-carbon atom was retained during the elimination procedure. (Fig. 1). The results of the X-ray crystallographic analysis will be published in This Bulletin soon.

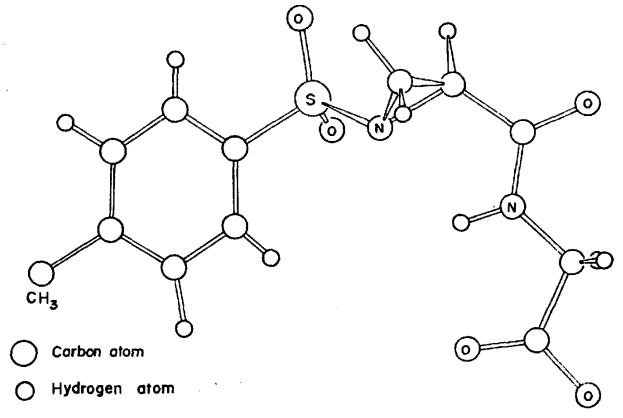

Fig. 1. The molecular structure of *N*-tosyl-L-azylylglycine as determined by X-ray analysis.

The *O*-tosylations of hydroxy amino acid derivatives were carried out in a dry pyridine solution with freshly-prepared *p*-toluenesulfonyl chloride at −5—−10°C. The *O*-tosylated products (II) thus obtained were gradually decomposed, especially in the solution, and were stored in a refrigerator.

The optimum conditions for a good yield of the aziridine derivative were also investigated by using the *N,O*-ditosyl-L-serylglycine ethyl ester (IIc). The results are summarized in Table 2.

The most satisfactory results were obtained when the solution of *N,O*-ditosyl derivatives in tetrahydrofuran was treated with 1.0—1.2 equivalent amounts of triethylamine at the refluxing temperature for a short time. Consequently, in the present investigation, tetrahydrofuran and triethylamine were mainly used as the solvent and the base respectively.

TABLE 2. THE REACTION CONDITION AND THE YIELD OF *N*-TOSYL-L-AZYLYLGLYCINE ETHYL ESTER (IVc)

Solvents[a]	Concentration of IIc (g/m*l*)	Bases[b]	Eq. amt. of bases	Reaction temp. (°C)	Reaction time	Yield (%)

a) THF: tetrahydrofuran, DMSO: dimethyl sulfoxide. b) EP: *N*-ethylpiperidine, DEA: diethylamine, TEA: triethylamine.

Experimental

All the melting points are uncorrected. The NMR spectra were obtained with a Hitachi R-20B High Resolution NMR spectrometer, while the chemical shifts are given from TMS as the internal reference.

N-*Tosyl-*L*-serine Ethyl Ester (Ib).* Ib was prepared from *N*-tosyl-L-serine[5] (20.0 g, 77 mmol) by the method of Stevens[6] in a 92% (20.4 g) yield; mp 103—104°C. $[\alpha]_D^{23}$ −8.2° (*c* 2.2, EtOH).

Found: C, 49.98; H, 5.96; N, 5.06; S, 11.45%. Calcd for $C_{12}H_{15}O_5N_5$: C, 50.16; H, 5.96; N, 4.88; S, 11.16%.

N-*Tosyl-*L*-serylglycine Ethyl Ester (Ic).* Into a solution of *N*-tosyl-L-serine hydrazide[5] (27.4 g, 0.10 mol) in acetic acid (11 m*l*) and N hydrochloric acid (200 m*l*), we added 3N sodium nitrite (50 m*l*), drop by drop, under cooling at −5——10°C. After the solution had been stirred for 10 min, the product was extracted with ice-cold ethyl acetate (200 m*l*); the organic layer was neutralized with ice-cold saturated aqueous sodium bicarbonate and immediately cooled under −5°C. A solution of glycine ethyl ester hydrochloride[7] (41.9 g, 0.30 mol) and triethylamine (41.8 m*l*, 0.30 mol) in ethyl acetate (50 m*l*) was then added, drop by drop, to the azide solution. The stirring was continued for 4 hr at −5°C. After the reaction mixture had then been allowed to stand overnight in a refrigerator, the mixture was washed with N hydrochloric acid, N sodium bicarbonate, and water, and was dried over anhydrous sodium sulfate. The solution was concentrated under reduced pressure. The Ic produced was collected and recrystallized from ethyl acetate. The crystals were obtained in an 85% yield (29.3 g); mp 108—109°C. $[\alpha]_D^{23}$ −24.3° (*c* 2.0, EtOH).

Found: C, 48.74; H, 5.75; N, 8.19; S, 9.16%. Calcd for $C_{14}H_{20}O_6N_2S$: C, 48.82; H, 5.85; N, 8.14; S, 9.31%.

N-*Tosyl-*L*-serylglycine Methyl Ester (Id).* Id was prepared from *N*-tosyl-L-serine hydrazide[5] (27.4 g, 0.10 mol) and the glycine methyl ester (from hydrochloride[8] (37.8 g, 0.30 mol)) by the above azide procedure in an 84% (28.9 g) yield; mp 107—108°C. $[\alpha]_D^{23}$ −20.7° (*c* 2.0, EtOH).

Found: C, 47.07; H, 5.51; N, 8.45; S, 9.93%. Calcd for $C_{13}H_{18}O_6N_2S$: C, 47.26; H, 5.49; N, 8.48; S, 9.71%.

N-*Carbobenzoxyglycyl-*L*-serine Ethyl Ester (If).* *N*-Carbobenzoxyglycine hydrazide[9] (22.3 g, 0.10 mol) was coupled with the L-serine ethyl ester (from hydrochloride[10] (17.0 g, 0.10 mol)) in ethyl acetate by the above azide procedure. Recrystallization from hot ethyl acetate gave a pure material (24.8 g (76.4%)); mp 112.5°C. $[\alpha]_D^{23}$ +17.0° (*c* 2.1, dioxane).

Found: C, 55.36; H, 6.16; N, 8.59%. Calcd for $C_{15}H_{20}O_6N_2$: C, 55.55; H, 6.21; N, 8.64%.

N-*Tosyl-*L*-threonine Ethyl Ester (Ih).* Ih was prepared from *N*-tosyl-L-threonine[11] (109 g, 0.4 mol) by the method of Brenner[12] in a 98% (118 g) yield; mp 106°C. $[\alpha]_D^{23}$ −4.4° (*c* 2.0, MeOH).

Found: C, 52.05; H, 6.55; N, 4.92; S, 10.52%. Calcd for $C_{13}H_{19}O_5NS$: C, 51.81; H, 6.35; N, 4.65; S, 10.64%.

N-*Tosyl-*L*-threonylglycine Ethyl Ester (Ij).* *N*-Tosyl-L-threonine hydrazide[12] (14.41 g, 50 mmol) was coupled with the glycine ethyl ester (from hydrochloride[7] (20.9 g, 150 mmol)) by the above azide procedure in an 84% (15.0 g) yield. Recrystallization from ethyl acetate-*n*-hexane gave a pure material; mp 116—116.5°C. $[\alpha]_D^{23}$ −23.2° (*c* 2.0, MeOH).

Found: C, 50.02; H, 5.86; N, 7.91; S, 9.05%. Calcd for $C_{15}H_{22}O_6N_2S$: C, 50.26; H, 6.19; N, 7.82; S, 8.95%.

N-*Carbobenzoxyglycyl-*L*-threonine Hydrazide.* The *N*-carbobenzoxyglycyl-L-threonine ethyl ester[13] (30 g, 88 mmol) was dissolved in 80% hydrazine hydrate (37.3 g, 0.62 mol) in absolute methanol (40 m*l*). After the reaction mixture had been allowed to stand overnight in a refrigerator, a crude precipitate was collected and recrystallized from hot methanol. The yield was 27.9 g (97.5%); mp 172—173°C.

N-*Carbobenzoxyglycyl-*L*-threonylglycine Benzyl Ester (Il).* *N*-Carbobenzoxyglycyl-L-threonine hydrazide (27.4 g, 84 mmol) was coupled with the glycine benzyl ester (from tosylate[14] (26.4 g, 0.168 mol)) by the above azide procedure. Recrystallization from hot methanol gave a pure material;

27.8 g (72%); mp 156—157°C. $[\alpha]_D^{23}$ −15.7° (*c* 2.0, dioxane).

Found: C, 60.35; H, 6.03; N, 9.34%. Calcd for $C_{23}H_{27}O_7N_3$: C, 60.38; H, 5.95; N, 9.19%.

N-*Tosyl-*L*-phenylalanyl-*L*-threonine Hydrazide.* The *N*-tosyl-L-phenylalanyl-L-threonine ethyl ester was prepared from *N*-tosyl-L-phenylalanine[15] and L-threonine ethyl ester hydrochloride[16] by the succinimide-ester method,[17] and was directly used for the next step without purification. The crude acyl peptide ester (15.9 g, 35 mmol) was treated with 80% hydrazine hydrate (43 m*l*) in methanol (20 m*l*) at room temperature for 44 hr. The crystals which appeared were collected and recrystallized from hot methanol in a 75% yield (from the ester) (11.4 g); mp 193°C.

Found: C, 55.48; H, 6.10; N, 12.62; S, 7.40%. Calcd for $C_{20}H_{26}O_5N_4S$: C, 55.28; H, 6.03; N, 12.89; S, 7.38%.

N-*Tosyl-*L*-phenylalnyl-*L*-threonylglycine Ethyl Ester (Im).* *N*-Tosyl-L-phenylalanyl-L-threonine hydrazide (11.3 g, 26 mmol) was coupled with the glycine ethyl ester (from hydrochloride[7]) (10.5 g, 75 mmol) by the above azide procedure. The yield of the crude product was 63.5% (8.4 g). Recrystallization from hot ethyl acetate–*n*-hexane gave a pure material; mp 162—163°C. $[\alpha]_D^{23}$ −65.3° (*c* 1.0, EtOH).

Found: C, 57.20; H, 6.20; N, 8.44; S, 6.53%. Calcd for $C_{23}H_{31}O_7N_3S$: C, 57.01; H, 6.18; N, 8.31; S, 6.34%.

O-*Tosylation of Hydroxy Amino Acid Derivatives.*

N,O-*Ditosyl-*L*-serine Ethyl Ester (IIb).* *p*-Toluenesulfonyl chloride (28.6 g, 105 mmol) in dry pyridine (45 m*l*) was stirred, drop by drop, into a solution of Ib (21.5 g, 75 mmol) in pyridine (150 m*l*) at −10°C over a 30-min period. The mixture was stirred for 1 hr at 0°C and then for an additional several hours at room temperature. The reaction mixture was poured into crushed ice (500 g) and allowed to stand overnight in a refrigerator. The precipitated products were dissolved in ethyl acetate, washed with water, and dried over anhydrous sodium sulfate. After the solution had been evaporated under reduced pressure, IIh was obtained as white crystals. Recrystallization from ethyl acetate-*n*-hexane gave pure crystals in a 52% (17 g) yield; mp 117—118°C. $[\alpha]_D^{23}$ +21.7° (*c* 1.0, MeOH).

Found: C, 51.64; H, 5.26; N, 3.04; S, 14.18%. Calcd for $C_{19}H_{23}O_7NS_2$: C, 51.68; H, 5.25; N, 3.17; S, 14.53%.

N,O-*Ditosyl-*L*-serylglycine Ethyl Ester (IIc).* IIc was prepared from Ic (10.3 g, 30 mmol) and *p*-toluenesulfonyl chloride (11.4 g, 50 mmol) in a dry pyridine (30 m*l*) solution by the above tosylation procedure. The crude product was obtained in a 92% (13.8 g) yield. The crude materials were recrystallized from ether-ethyl acetate; mp 107—108°C. $[\alpha]_D^{23}$ −2.7° (*c* 2.2, EtOH).

Found: C, 50.51; H, 5.15; N, 5.68; S, 12.76%. Calcd for $C_{21}H_{26}O_8N_2S_2$: C, 50.59; H, 5.26; N, 5.62; S, 12.86%.

N,O-*Ditosyl-*L*-serylglycine Methyl Ester (IId).* IId was prepared from Id (10.3 g, 30 mmol) and *p*-toluenesulfonyl chloride (11.4 g, 50 mmol) in a dry pyridine solution (30 m*l*) by the above tosylation procedure in an 85% (12.7 g) yield; mp 114—115°C. $[\alpha]_D^{23}$ −4.8° (*c* 2.0, $CHCl_3$).

Found: C, 49.58; H, 4.97; N, 5.61; S, 13.24%. Calcd for $C_{20}H_{24}O_8N_2S_2$: C, 49.58; H, 4.99; N, 5.78; S, 13.23%.

N-*Carbobenzoxyglycyl-*O*-tosyl-*L*-serine Ethyl Ester (IIf).* IIf was prepared from If (3.2 g, 10 mmol) and *p*-toluenesulfonyl chloride (3.8 g, 20 mmol) in dry pyridine (10 m*l*) by the above tosylation procedure in a 71.3% (3.5 g) yield. Recrystallization from ethyl acetate-ether gave a pure material; mp 109°—110°C. $[\alpha]_D^{23}$ +22.5° (*c* 2.0, dioxane).

Found: C, 54.97; H, 5.40; N, 5.79; S, 6.58%. Calcd for $C_{22}H_{26}O_8N_2S$: C, 55.22; H, 5.48; N, 1.85; S, 6.70%.

N,O-*Ditosyl-*L*-threonine Ethyl Ester (IIh).* IIh was prepared from Ih (15.1 g, 50 mmol) and *p*-toluenesulfonyl chloride (19.1 g, 100 mmol) in dry pyridine (45 m*l*) by the above tosylation procedure. Recrystallization from ethyl acetate–*n*-hexane gave a pure material in a 71% (16.1 g) yield; mp 118—119°C. $[\alpha]_D^{23}$ +20.3° (*c* 2.0. MeOH).

Found: C, 52.62; H, 5.41; N, 3.01; S, 14.20%. Calcd for $C_{20}H_{25}O_7NS_2$: C, 52.73; H, 5.53; N, 3.08; S, 14.08%.

N,O-*Ditosyl-*L*-threonylglycine Ethyl Ester (IIj).* IIj was prepared from Ij (17.9 g, 50 mmol) and *p*-toluenesulfonyl chloride (19.0 g, 100 mmol) in dry pyridine (30 m*l*) by the aobve tosylation procedure. Recrystallization from ethyl acetate–petroleum ether gave a pure material in an 85% (22.2 g) yield; mp 122—122.5°C. $[\alpha]_D^{23}$ +18.1° (*c* 2.0, MeOH).

Found: C, 51.36; H, 5.45; N, 5.31; S, 12.26%. Calcd for $C_{22}H_{28}O_8N_2S_2$: C, 51.55; H, 5.51; N, 5.47; S, 12.51%.

N-*Carbobenzoxyglycyl-*O*-tosyl-*L*-threonine Ethyl Ester (IIk).* IIk was prepared from the *N*-carbobenzoxyglycyl-L-threonine ethyl ester[13] (3.4 g, 10 mmol) and *p*-toluenesulfonyl chloride (3.8 g, 20 mmol) in dry pyridine (10 m*l*) by the above tosylation procedure. When the crude products were recrystallized from ether, fine crystals were obtained in a 71.4% (3.5 g) yield; mp 79—80°C. $[\alpha]_D^{23}$ +21.3° (*c* 1.0, EtOH).

Found: C, 55.93; H, 5.74; N, 5.70; S, 6.43%. Calcd for $C_{23}H_{28}O_8N_2S$: C, 56.08; H, 5.73; N, 5.69; S, 6.51%.

N-*Carbobenzoxyglycyl-*O*-tosyl-*L*-threonylglycine Benzyl Ester (IIl).* IIl was prepared from Il (4.6 g, 10 mmol) and *p*-toluenesulfonyl chloride (3.8 g, 20 mmol) in dry pyridine (25 m*l*) by the above tosylation procedure. Recrystallization from ethyl acetate-ether gave a pure material in a 77.6% (4.8 g) yield; mp 115—116°C. $[\alpha]_D^{23}$ −11.8° (*c* 1.0, THF).

Found: C, 58.83; H, 5.41; N, 6.78; S, 4.95%. Calcd for $C_{30}H_{34}O_9N_3S$: C, 58.83; H, 5.59; N, 6.86; S, 5.23%.

N-*Tosyl-*L*-phenylalanyl-*O*-tosyl-*L*-threonylglycine Ethyl Ester (IIm).* IIm was obtained from Im (7.8 g, 15.5 mmol) and *p*-toluenesulfonyl chloride (5.9 g, 31 mmol) in dry pyridine (24 m*l*) by the above tosylation procedure. Recrystallization from ethanol–ether gave a pure material in a 52% (5.3 g) yield; mp 121.3—122.5°C. $[\alpha]_D^{23}$ +7.9° (*c* 1.0, THF).

Found: C, 56.44; H, 5.69; N, 6.33; S, 9.47%. Calcd for $C_{31}H_{37}O_9N_3S_2$: C, 56.43; H, 5.65; N, 6.37; S, 9.72%.

β-Eliminations of O*-tosylated Hydroxy Amino Acid Derivatives.*

N-*Tosyldehydroalanine Ethyl Ester (IIIb).* A solution of IIb (2.2 g, 5 mmol) in tetrahydrofuran (18 m*l*) and triethylamine (0.7 m*l*, 5 mmol) was stirred for 9 hr at 35°C and then for 18 hr at room temperature. The reaction mixture was evaporated under reduced pressure, and the residue was dissolved in benzene; this benzene solution was washed with water three times, dried over anhydrous sodium sulfate, and concentrated under reduced pressure. The residual oily material was crystallized by scratching and then recrystallized from ether–petroleum ether; a pure material was obtained in a 90% (1.2 g) yield; mp 73—75.5°C.

Found: C, 52.69; H, 5.44; N, 5.40; S, 12.12%. Calcd for $C_{12}H_{15}O_4NS$: C, 53.51; H, 5.61; N, 5.20; S, 11.91%. NMR (DMSO-d_6): δ 5.33 ppm (1H(s) CH_2=), 5.52 ppm (1H(s) CH_2=).

N-*Tosyl-*L*-azylylglycine Ethyl Ester (IVc).* A solution of IIc (5.0 g, 10 mmol) and triethylamine (1.4 m*l*, 10 mmol) in tetrahydrofuran (30 m*l*) was refluxed for 30 min. After the removal of the solvent, water was added to the residue.

The reddish-brown mass was then dissolved in chloroform. The solution was washed with water, dried over anhydrous sodium sulfate, and concentrated under reduced pressure. The residue was recrystallized from chloroform-ether in an 80.6% (2.6 g) yield; mp 147—148°C. $[\alpha]_D^{23}$ −59.1° (*c* 2.3, dioxane).

Found: C, 51.76; H, 5.74; N, 8.58; S, 9.82%. Calcd for $C_{14}H_{18}O_5N_2S$: C, 51.52; H, 5.56; N, 8.58; S, 9.84%. NMR ($CDCl_3$): δ 2.43 ppm (1H(d), J_{trans}=4.2 Hz Azy; -CH_2-, 2.77 ppm (1H(d), J_{cis}=7.7 Hz Azy; -CH_2-), 3.32 ppm (1H(q), J_{trans}=4.2 Hz, J_{cis}=7.7 Hz Azy; α-proton).

N-Tosyl-L-azylylglycine Methyl Ester (IVd). IVd was obtained from IId (4.8 g, 10 mmol) and triethylamine (1.4 m*l*, 10 mmol) in tetrahydrofuran (40 m*l*) by the above elimination reaction procedure (IVc). Recrystallization from chloroform–ether gave a pure material in an 80% (2.6 g) yield; mp 116—117°C. $[\alpha]_D^{23}$ −55.7° (*c* 2.0, dioxane).

Found: C, 49.95; H, 5.23; N, 8.76; S, 10.49%. Calcd for $C_{13}H_{16}O_5N_2S$: C, 49.99; H, 5.16; N, 8.97; S, 10.27%.

N-Carbobenzoxyglycyldehydroalanine Ethyl Ester (IIIf). IIIf was prepared from IIf (2.4 g, 5 mmol) and triethylamine (1.4 m*l*, 10 mmol) in tetrahydrofuran (20 m*l*) by the above elimination reaction procedure (IVc). Recrystallization from ethyl acetate-ether gave a pure material in a 95% (1.5 g) yield; mp 81—81.5°C.

Found: C, 58.93; H, 5.96; N, 9.15%. Calcd for $C_{15}H_{18}O_5N_2$: C, 58.82; H, 5.92; N, 9.15%.

NMR ($CDCl_3$): δ 5.87 ppm (1H(d), J_{gem}=1.2 Hz, CH_2=), 6.53 ppm (1H(s), CH_2=).

N-Carbobenzoxyglycyldehydroalanylglycine Ethyl Ester (IIIg). A solution of the *N*-carbobenzoxyglycyl-*O*-tosyl-L-seryl-glycine ethyl ester[18] (5.4 g, 10 mmol) and *N*-ethylpiperidine (1.1 g, 10 mmol) in acetonitrile was incubated at 37°C for 24 hr. The solvent was then removed under reduced pressure, and the residue was dissolved in ethyl acetate. The solution was washed with water, dried over anhydrous sodium sulfate, and concentrated under reduced pressure. The resulting product was crystallized from ethyl acetate–ether. IIIg was thus obtained in a 67% (2.4 g) yield; mp 130—132°C.

Found: C, 56.07; H, 5.87; N, 11.53%. Calcd for $C_{17}H_{21}O_6N_3$: C, 56.19; H, 5.83; N, 11.56%.

NMR (DMSO-d_6): δ 5.58 ppm (1H(*q*), J=0.7, J=1.1 Hz, CH_2=), 6.25 ppm (1H(d), J=0.7 Hz, CH_2=).

N-Tosyl-α-amino-crotonic Acid Ethyl Ester (IIIh). *N-Tosyl-3-methyl-L-azyline Ethyl Ester (IVh).* Into a solution of IIh (9.1 g, 20 mmol) in benzene-methanol (50 : 1 v/v, 51 m*l*), we added *N*-ethylpiperidine (2.76 m*l*, 20 mmol). The solution was refluxed for 8.5 hr and then allowed to stand overnight. The reaction mixture was washed with water three times, dried over anhydrous sodium sulfate, and concentrated under reduced pressure; when the crystals thus produced were filtered off, IIIh (1.23 g) was obtained. The mother solution was chromatographed on silica gel (150 g) with benzene-chloroform (1 : 1 v/v) to yield the reaction products, IIIh and IVh respectively. The R_f values of IIIh and IVh were 0.24 (0.42 g) and 0.46 (3.62 g) respectively. The collected crystals of IIIh amounted to 1.65 g (29%); they were recrystallized from ethyl acetate–*n*-hexane; mp 93—94°C.

Found: C, 55.37; H, 6.00; N, 4.89; S, 11.23%. Calcd for $C_{13}H_{17}O_4NS$: C, 55.10; H, 6.05; N, 4.94; S, 11.32%.

NMR ($CDCl_3$): δ 2.02 ppm (3H(d), J=7.2 Hz, CH_3-CH=), 6.93 ppm (1H(q), J=7.2 Hz, CH_3-CH=). IVh was obtained in a 64% (3.62 g) yield; mp 56—56.5°C. $[\alpha]_D^{23}$ −40.2° (*c* 2.0, MeOH).

Found: C, 55.12; H, 6.01; N, 4.88; S, 11.52%. Calcd for $C_{13}H_{17}O_4NS$: C, 55.10; H, 6.05; N, 4.94; S, 11.32%.

NMR ($CDCl_3$): δ 1.31 ppm (3H(d), J=5.5 Hz Azy; CH_3-CH-), 3.13 ppm (1H(q), J=5.5, J_{cis}=7.5 Hz Azy; CH_3-CH-), 3.36 ppm (1H(d), J=7.5 Hz Azy; α-proton).

N-Tosyl-3-methyl-L-azylylglycine Ethyl Ester (IVj). The solution of triethylamine (2.8 m*l*, 20 mmol) and IIj (10.3 g, 20 mmol) in tetrahydrofuran was incubated at 50°C for 25 hr. The solvent was removed under reduced pressure, and the residue was dissolved in ethyl acetate. The solution was washed with water and dried over anhydrous sodium sulfate. After the evaporation of the solvent under reduced pressure, an oily product (IVj) was obtained in a 96% (7.0 g) yield. All efforts at crystallization failed.

N-Tosyl-3-methyl-L-azylylglycine. A solution of IVj (7.0 g) in acetonitrile (15 m*l*) and water (15 m*l*) was treated with N sodium hydroxide (22 m*l*) at 5°C for 1 hr and then allowed to stand at room temperature for 4 hr. After the acetonitrile had been removed under reduced pressure, the reaction mixture was acidified with 1 M citric acid (22 m*l*). The crystals which appeared were collected (6.0 g, 96%) and recrystallized from ethyl acetate–*n*-hexane (5.6 g); mp 138—139°C. $[\alpha]_D^{23}$ −52.3° (*c* 2.1, MeOH).

Found: C, 50.20; H, 4.97; N, 8.78; S, 10.29%. Calcd for $C_{13}H_{16}O_5N_2S$: C, 49.99; H, 5.16; N, 8.97; S, 10.26%.

NMR ($CDCl_3$): δ 1.23 ppm (3H(d), J=5.5 Hz Azy; CH_3-CH-), 3.02 ppm (1H(q), J=5.5, J_{cis}=7.5 Hz Azy; CH_3-CH-), 3.40 ppm (1H(d), J_{cis}=7.5 Hz Azy; α-proton).

N-Carbobenzoxyglycyl-α-amino-crotonic Acid Ethyl Ester (IIIk). A solution of IIk (3.5 g, 7.1 mmol) in tetrahydrofuran (15 m*l*) was treated with triethylamine (1.0 m*l*, 7.1 mmol) at 60°C for 4 hr, after which the solution was allowed to stand at room temperature for 15.5 hr. The solvent was then removed under reduced pressure; oily products were obtained and crystallized by the addition of *n*-hexane. IIIk was obtained in an 87.5% (2.1 g) yield; mp 86—88°C.

Found: C, 58.50; H, 6.33; N, 8.37%. Calcd for $C_{16}H_{20}O_5N_2 \cdot 1/2\,H_2O$: C, 58.35; H, 6.43; N, 8.50%.

NMR ($CDCl_3$): δ 1.73 ppm (3H(d), J=6.8 Hz, CH_3-CH=), 6.79 ppm (1H(q), J=6.8 Hz, CH_3-CH=).

N-Carbobenzoxyglycyl-3-methyl-L-azylylglycine Benzyl Ester (IVl). A solution of IIIl (610 mg, 1 mmol) and triethylamine (0.28 m*l*, 2 mmol) in absolute tetrahydrofuran (10 m*l*) was refluxed for 20.5 hr. The solvent was then removed under reduced pressure, and the residue was dissolved in ethyl acetate. The solution was washed with water, dried over anhydrous sodium sulfate, and concentrated under reduced pressure. The residual oil was crystallized by the addition of isopropyl ether. Recrystallization from acetone–isopropyl ether gave pure material in an 80% (350 mg) yield; mp 114—116°C. $[\alpha]_D^{23}$ −35.7° (*c* 1.0, THF).

Found: C, 62.66; H, 5.71; N, 9.68%. Calcd for $C_{23}H_{25}O_6N_3$: C, 62.86; H, 5.73; N, 9.56%.

NMR (DMSO-d_6): δ 1.01 ppm (3H(d), J=6.3 Hz Azy; CH_3-CH-), 4.49 ppm (1H(m), Azy; CH_3-CH-), 4.80 ppm (1H(d), J_{cis}=11.9 Hz Azy; α-proton).

N-Tosyl-L-phenylalanyl-3-methyl-L-azylylglycine Ethyl Ester (IVm). A solution of IIIm (1.30 g, 2 mmol) and triethylamine (0.28 m*l*, 2 mmol) in tetrahydrofuran (8 m*l*) was incubated at 40—50°C for 53 hr. The solvent was then removed under reduced pressure, and the residue was dissolved in ethyl acetate. The solution was washed with water, dried over anhydrous sodium sulfate, and concentrated under reduced pressure. The residual oily material

18) I. Photaki and V. Bardakos, *ibid.*, **87** 3489 (1965).

was chromatographed on silica gel (140 g) with chloroform–ethyl acetate (1 : 1 v/v) to yield a pure product. IVm was obtained as crystals from ethyl acetate–*n*-hexane in a 60% (0.59 g) yield; mp 118—121.5°C. $[\alpha]_D^{23}$ −52.0° (*c* 1.0, MeOH).

Found: C, 58.85; H, 5.84; N, 8.57; S, 6.86%. Calcd for $C_{24}H_{29}O_6N_3S$: C, 59.12; H, 6.00; N, 8.62; S, 6.58%.

NMR ($CDCl_3$): δ 1.16 ppm (3H(d), J=6.0 Hz Azy; CH_3–CH–), 4.20 ppm (1H(m) Azy; CH_3–CH–), 4.32 ppm (1H(d), J_{cis}=10.2 Hz Azy; α-proton).

The authors wish to express their deep thanks to the staff of the Fujisawa Pharmaceutical Co., Ltd., for their elemental microanalyses, and to Dr. Tokunosuke Watanabe, Professor of Kwansei Gakuin University, for his X-ray crystallographic analysis.

Stereochemical Studies and Synthetic Applications of Bis-β-keto Sulfoxides

Yasusi YAMAMOTO and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Yosida, Sakyo-ku, Kyoto

(Received September 23, 1971)

Bis-β-keto sulfoxides of the $MeSOCH_2CO(CH_2)_nCOCH_2SOMe$ ($n=7$, 8, or 10) type are prepared. The *dl* and *meso* isomers are isolated, and the stereochemistry of bis-β-keto sulfoxides ($n=8$) is established by means of the asymmetric synthesis of the resolvable isomer from an optically-active ester, (−)-menthyl-O-$CO(CH_2)_8$-CO-O-(−)-menthyl, and methylsulfinylcarbanion. It is concluded that the higher-melting one is the meso isomer and that the lower-melting one is racemic. The condensation of bis-β-keto sulfoxides, $MeSOCH_2CO(CH_2)_8COCH_2SOMe$, and allyl bromide in the presence of a base and the subsequent desulfurization give the olefinic ketone, $(CH_2=CHCH_2CH_2CO(CH_2)_4)_2$. Optically active sulfoxide, $MeSOCH_2COPh$, is obtained from (−)-menthyl benzoate and methylsulfinylcarbanion.

Sulfoxides (R_1R_2SO) are chiral and are configurationally stable enough under ordinary conditions to be resolvable into enatiomeric forms.[1] Hence, bis-β-keto sulfoxide, $MeSOCH_2CO$-X-$COCH_2SOMe$,[2] may be expected to exist in *dl* and *meso* forms. Though Corey and his co-workers have obtained bis-β-keto sulfoxide from dimethyl azelate and methylsulfinylcarbanion ($DMSO^-$), they have described nothing about the separation of diastereomers.[2a] The present paper will report that the bis-β-keto sulfoxides are separable into two isomers, whose stereochemistry is established by means of asymmetric synthesis.

Dimethyl sebacate was treated with a carbanion solution obtained from sodium hydride and dimethyl sulfoxide (DMSO) at room temperature. A subsequent work-up gave bis-β-keto sulfoxide I ($X=(CH_2)_8$) in a 55% yield. The recrystallization of I from chloroform gave crystals which melted at 145.5—147°C (Ia), whereas the treatment of the mother liquor with ether, followed by purification, gave crystals melting at 131—132°C (Ib). As a mixture of Ia and Ib showed a mp of 125—142°C, the two are different from each other. The IR spectra are shown in Fig. 1, in which the points of clear difference are enlarged.

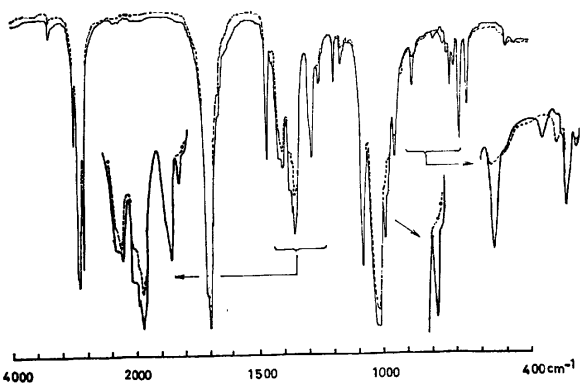

Fig. 1. IR spectra of bis-β-keto sulfoxides, Ia (——) and Ib (----) (KBr).

The higher homolog, II ($X=(CH_2)_{10}$), was similarly prepared (76%) and separated into isomers melting at 145—147°C (IIa) and at 125—127°C (IIb). A mixed-melting-point depression and IR differences were observed as in I. Bis-β-keto sulfoxides (III, $X=(CH_2)_7$) (19%) obtained from dimethyl azelate were also separated into two isomers, melting at 138—140°C and at 116—118°C (IIIb).

The independent reduction of each isomer (Ia or Ib) by means of an aluminum amalgam[2a,3,4] in aqous THF gave the same, single diketone, dode-

cane-2,11-dione. Both sulfoxides, IIa and IIb, similarly yielded a single diketone, tetradecane-2,13-dione.

On the basis of these results, it may be concluded that the separated bis-β-keto sulfoxides, Ia and Ib or IIa and IIb, are diastereoisomers.

The Ia-Ib pair of diastereomers showed no percetible difference in NMR spectra (Fig. 2) even in the presence of shift reagents such as tris(dipivalomethanato)Eu(III) ($Eu(DPM)_3$).[5]

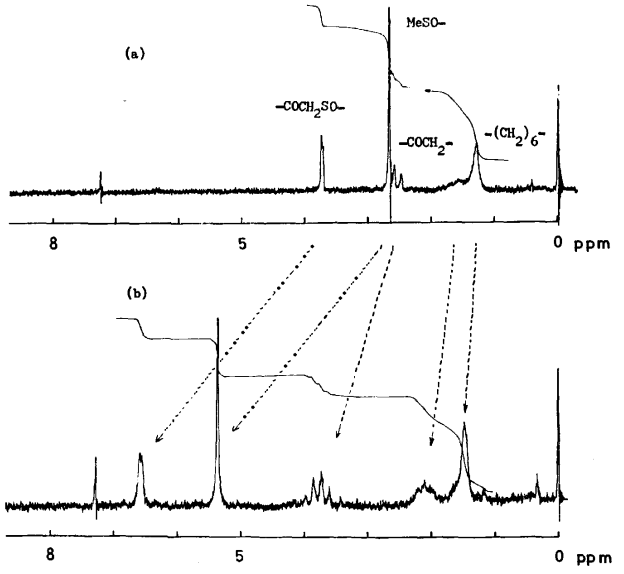

Fig. 2. NMR spectra of (a) sulfoxide Ia and (b) Ia (32 mg, 0.1 mmol) in $CDCl_3$ (0.75 m*l*) containing $Eu(DPM)_3$ (48 mg, 0.068 mmol),

The stereochemical assignment was finally established by means of an asymmetric synthesis of the resolvable isomers. Di-(−)-menthyl sebacate (IV), prepared from sebacoyl chloride and (−)-methnol, was treated with lithium methylsulfinylcarbanion in THF - hexane.[6] The resulting products were separated into two isomers by the method described above.

The sulfoxide melting at 141—143°C was optically inactive, $[\alpha]_D$ 0.0° (*c* 3.98, $CHCl_3$), whereas the other one, melting at 120—122°C, showed a specific rotation of $[\alpha]_D$ +1.22° (*c* 6.08, $CHCl_3$). Obviously, the higher-melting Ia is the *meso* isomer, while the lower-melting Ib is the *dl* isomer. Incidentally, the reaction of (−)-menthyl benzoate (V)[7] gave optically active methyl phenacyl sulfoxide (VI) $[\alpha]_D$ −1.68° (*c* 8.00, $CHCl_3$), of an unknown optical purity.

The condensation of I with allyl bromide in the presence of sodium hydride yielded an intractable oil. The subsequent desulfurization of this oil by means of an aluminum amalgam gave olefinic ketone ($CH_2=CHCH_2CH_2CO(CH_2)_4-)_2$ (21%). The bis-β-keto sulfoxides, such as I and II, are apparently useful in preparing long, straight chain compounds.

Experimental

All the mps are uncorrected. The microanalyses were performed by Mrs. K. Fujimoto of this department. The NMR spectra were obtained on a 60 MHz instrument (JEOL C-60H spectrometer) in deuteriochloroform, with tetramethylsilane as the internal standard. The mass spectra were taken on a Hitachi RMU-6L spectrometer.

The Reaction of Dimethyl Sebacate with DMSO⁻. A carbanion solution was obtained from sodium hydride (4.8 g, 0.20 mol) and DMSO (80 m*l*) under N_2. This was diluted with THF (50 m*l*), and then a solution of dimethyl sebacate (11.5 g, 0.05 mol) in THF (30 m*l*) was added, drop by drop in the course of 30 min under stirring and cooling in an ice bath. The ice bath was then removed, and stirring was continued at room temperature for 3 hr. The reaction mixture was then poured into water, acidified with diluted hydrochloric acid to a pH of about 5—6 (pH paper), and extracted with chloroform. The subsequent evaporation of chloroform *in vacuo* yielded I (8.95 g, 55%). The recrystallization of this product from chloroform gave the sulfoxide Ia (1.31 g, 8%); mp 145.5—147°C. The treatment of the mother liquor with ether and recrystallization from chloroform - ether (trace) gave the sulfoxide Ib (0.15 g, 1%); mp 131—132°C.

The Reaction of Dimethyl Dodecanedioate with DMSO⁻. The treatment of the ester (12.9 g, 0.05 mol) with a carbanion prepared from sodium hydride (4.8 g, 0.20 mol) and DMSO (80 m*l*) in THF (80 m*l*) at room temperature for 4 hr gave bis-β-keto sulfoxide II (13.3 g, 76%). This sulfoxide was separated into two isomers, IIa (1.24 g, 7%), mp 145—147°C, and IIb (0.68 g, 4%), mp 125—127°C.

Dimethyl azelate gave bis-β-keto sulfoxides (III) (19%), which were also separated into two isomers, IIIa (1%), mp 138—140°C, and IIIb (2%), mp 116—118°C. A mixed-melting-point depression and IR differences were observed as in I and II.

The Reduction of Ia with an Aluminum Amalgam. Bis-β-keto sulfoxide Ia (1.61 g, 0.005 mol) was dissolved in THF (40 m*l*) and water (30 m*l*), and then $HgCl_2$-pretreated aluminum foil (2.7 g) was stirred into the solution at room temperature. Stirring was continued at 60—70°C for 5 hr, during which time an additional amount of a mixed solvent (THF : water = 1 : 1) was added in order to overcome the difficulty in stirring due to the formation of aluminum hydroxide. The reaction mixture was then filtered with suction, and the residual solids were washed with chloroform. The combined organic solutions were washed with water and dried (Na_2SO_4). Upon the evaporation of the solvent, we obtained dodecane-2,11-dione (0.89 g, 90%), mp 68—69°C(lit,[8] 68—68.5°C). IR (Nujol): 1705 cm^{-1} (C=O). MS: 198 (M^+). NMR ($CDCl_3$): δ 1.00—1.90 (m, 12H, $-(CH_2)_6-$), 2.13 (s, 6H, COMe) and 2.42 (t (*J*=7 Hz), 4 H, $-CH_2CO$).

The sulfoxide Ib yielded the same diketone (97%).

The reduction of II under conditions similar to those used for I gave tetradecane-2,13-dione (90%), mp 72.5—74.5°C (lit,[9] 76—77°C). IR (Nujol): 1705 cm^{-1} (C=O). MS: 226 (M^+). NMR ($CDCl_3$): δ 1.00—1.90 (m, 16 H, $-(CH_2)_8-$), 2.14 (s, 6 H, -COMe), and 2.43 (t(J=7 Hz), 4 H, $-CH_2CO-$).

The Reaction of Di-(−)-menthyl Sebacate (IV) with Lithium Methylsulfinylcarbanion. Lithium methylsulfinylcarbanion was prepared by adding a hexane solution of *n*-butyllithium (1.50 N, 107 m*l*, 0.16 mol) to a stirred mixture of DMSO (12.8 g, 0.16 mol) in THF (70 m*l*) under ice cooling. The lithium salt separated as fine white precipitates. To this suspension, a solution of the ester IV (9.40 g, 0.02 mol) in THF (20 m*l*) was added at −30°C over a period of 30 min, after which the reaction mixture was stirred at −30——15°C for 2 hr. A work-up followed by the separation of the isomers gave sulfoxides Ia and Ib. The sulfoxide Ia, mp 141—143°C, showed $[\alpha]_D$ 0.0° (*c* 3.98, $CHCl_3$), and Ib, mp 120—122°C, showed $[\alpha]_D$ +1.22° (*c* 6.08, $CHCl_3$).

The Reaction of (−)-Methyl Benzoate (V) with Lithium Methylsulfinylcarbonion. The treatment of (−)-menthyl benzoate (2.7 g, 0.01 mol) with lithium methylsulfinylcarbanion prepared from a hexane solution of *n*-butyllithium (1.15 N, 35 m*l*, 0.04 mol) and DMSO (3.2 g, 0.04 mol) in THF (20 m*l*) gave methyl phenacyl sulfoxide VI (0.74 g, 41%). The sulfoxide VI showed a mp of 85—88°C (lit,[2a] 86—86.5°C); $[\alpha]_D$ −1.68° (*c* 8.00, $CHCl_3$).

The Condensation of I and Allyl Bromide in the Presence of Sodium Hydride. The treatment of I (3.23 g, 0.01 mol) with sodium hydride (0.48 g, 0.02 mol) in DMSO (15 m*l*) at 40°C for 1 hr gave a brown solution. To this, allyl bromide (2.42 g, 0.02 mol) in DMSO (15 m*l*) was added, after which the reaction mixture was stirred at 60°C for 3 hr. A work-up gave an intractable oil. This oil was dissolved in THF (40 m*l*) and water (30 m*l*), and this solution was treated with Hg_2Cl_2-pretreated aluminum foil (5.4 g) at 60—70°C for 3 hr. Subsequent distillation and chromatography on a Silicagel column gave octadeca-1,17-diene-5,14-dione (0.59 g, 21%), mp 68—71°C. IR (Nujol): 1710 cm^{-1} (C=O) and 1640, 995 and 915 cm^{-1} ($-CH=CH_2$). NMR ($CDCl_3$): δ 0.80—1.85 (m, 12 H, $-(CH_2)_6-$), 1.85—2.80 (m, 12 H, $-CHCH_2CH_2COCH_2-$), 4.80—5.25 (m, 4 H CH_2-) 1.85—2.80 (m, 12 H, $=CHC\underline{H}_2C\underline{H}_2COC\underline{H}_2-$), 4.80—5.25 (m, 4H, $CH_2=$) and 5.50—6.20 (m, 2 H, =CH-).

Found: C, 77.9; H, 10.8%. Calcd for $C_{18}H_{30}O_2$: C, 77.7; H, 10.9%.

Photochemical Reactions of Aromatic Compounds. IX.[1] Photochemical Reactions of Dimethylaniline with Halobenzenes[2]

Chyongjin Pac, Takafumi Tosa, and Hiroshi Sakurai

The Institute of Scientific and Industrial Research, Osaka University, Suita-shi, Osaka

(Received September 23, 1971)

Irradiation of methanolic solutions of DMA containing halobenzenes (chlorobenzene, bromobenzene and iodobenzene) and triethylamine (TEA) gave TEA hydrohalides in quantitative yields along with benzene (II), diphenyl, *N*-methylaniline, *o*- and *p*-dimethylaminodiphenyls (IV and V). From the properties of the products and spectroscopic and kinetic data, it was suggested that the reactions took place by way of electron transfer from DMA to halobenzenes. The electron transfer reactions were classified into a short range type (chlorobenzene and bromobenzene) and a long range type (iodobenzene) on the basis of the product ratio (IV+V)/II and the proportion of benzene-d_1 in the benzene fraction obtained from the photoreactions of DMA-d_6 with halobenzenes. From the kinetic and fluorescence data, an exciplex mechanism was suggested for the photoreactions with chlorobenzene and bromobenzene, and a direct electron transfer mechanism in the case of iodobenzene.

Photochemical bimolecular electron transfer reactions (ETR) are of physicochemical interest and have been investigated in connection with decay of exciplexes.[3–5] Except for ETR of triplet aromatic ketones with amines,[1,6] however, mechanistic details have not been fully investigated, although various photo-induced ETR have been published.[7–10]

we published ETR from excited singlet dimethylaniline (DMA) to ground state anilinium salts.[12] The suggested mechanism was speculative, since spectroscopic investigation was limited on account of insolubility of anilinium salts in non-polar and less polar solvents. In an attempt to obtain more information on photochemical ETR mechanism, halobenzenes (chlorobenzene, bromobenzene and iodobenzene) were used as electron acceptors instead of anilinium salts, since they are soluble in most organic solvents.

In the present paper, we report the product distribution, spectroscopic and kinetic results. Qualitative discussion is given on the ETR distance depending on halobenzenes.

Results

Product Distribution. Irradiation of a methanolic solution of DMA containing a halobenzene in the presence of triethylamine (TEA),[13] by means of a Pyrex filter with a high pressure mercury arc, gave TEA hydrohalide in a quantitative yield along with benzene, diphenyl, *N*-methylaniline, *o*- and *p*-dimethylaminodiphenyls (Table 1).

$$\mathrm{DMA} + \mathrm{PhX} \xrightarrow[\mathrm{TEA}]{h\nu} \underset{\mathrm{I}}{\mathrm{TEA{\cdot}HX}} + \underset{\mathrm{II}}{\mathrm{PhH}} + \underset{\mathrm{III}}{\mathrm{Ph\text{-}Ph}} + \underset{\mathrm{IV}}{o\text{-}\mathrm{Ph\text{-}C_6H_4N(CH_3)_2}} + \underset{\mathbf{V}}{p\text{-}\mathrm{Ph\text{-}C_6H_4N(CH_3)_2}} + \mathrm{PhNHCH_3}$$

The structures of the products were confirmed by direct comparison of the physical and spectroscopic (NMR, UV, and IR) data with those of the corresponding authentic samples.

TABLE 1. PRODUCT DISTRIBUTION IN PHOTOCHEMICAL REACTIONS OF DMA WITH HALOBENZENES IN THE PRESENCE OF TEA[a]

PhX	Yields (mmol)					Conversion[b] (%)
	I	II	III	IV	V	
X=Cl	12.6	4.4	trace	5.3	0.7	35
X=Br	12.8	5.8	trace	4.0	0.5	50
X=I	12.0	11.3	trace	1.1	0.4	85

a) Irradiation of methanolic solutions (30 m*l*) containing 4 g DMA, 4 g halobenzenes and 5 m*l* TEA in a Pyrex tube with a high pressure mercury arc at room temperature.

b) Consumption of halobenzenes determined by vpc analyses.

Chlorobenzene and bromobenzene were stable in the absence of DMA and gave only a trace of benzene by irradiation for a long time. Iodobenzene was photolyzed to some extent, decomposition being considerably enhanced in the presence of DMA.

Control experiments showed that I, II, IV, and V increased linearly with irradiation time. Diphenyl could not be detected. However, all the products were stable under the reaction conditions and are considered to be primary products. The products ratios (IV+V)/II and IV/V were determined at 10—15% conversion and found to be dependent on halobenzenes used (Table 2).

TABLE 2. PRODUCT RATIOS (IV+V)/II AND IV/V[a]

	PhX		
	X=Cl	X=Br	X=I
(IV+V)/II	1.8±0.17	1.1±0.1	0.24±0.07
IV/V	3.8±0.7	3.5±0.5	2.2 ±0.2

a) Irradiation of methanolic solutions (5 m*l*) containing 1.0 M DMA, 0.1 M TEA and 0.1 M halobenzenes at 313 nm. Mean values for every three runs.

It should be noted that the products except TEA hydrohalides were the same as those obtained from the photochemical reactions of DMA with trimethylphenylammonium halides.

Sensitized Decomposition of Halobenzenes by Carbonyl Compounds. Enhanced decomposition of halobenzenes by DMA could be interpreted as being caused by electronic energy transfer from an excited DMA to halobenzenes leading to decomposition of halobenzenes into phenyl radical and halogen atoms. If so, selected sensitizers would result in sensitized decomposition of halobenzenes. Sensitization with carbonyl compounds was thus carried out in order to confirm the possibility of triplet excitation transfer.

The 0–0 transition of DMA phosphorescence at 77°K was reported to lie at 26650 cm^{-1} (76.2 kcal/mol).[14] If triplet excitation transfer from DMA to halobenzenes take place, acetone (E_T 80 kcal/mol),[15] acetophenone (E_T 74 kcal/mol in non-polar solvents and 76.3 kcal/mol in polar solvents)[16] and propiophenone (E_T 75 kcal/mol in non-polar solvents)[16] can sensitize the decomposition of halobenzenes.

However, propiophenone- and acetophenone-sensitized decomposition did not occur for chlorobenzene and bromobenzene, and was not clear in the case of iodobenzene. Acetone was effective for decomposition of bromobenzene and iodobenzene, but entirely ineffective for chlorobenzene (Table 3). The results for chlorobenzene are understandable, since the lowest triplet state lies at 82 kcal/mol above the ground state.[17] Thus, the triplet energies of

13) In the absence of TEA, the photoreactions were complicated on account of the formation of DMA hydrohalides, since DMA was photochemically reactive with DMA hydrohalides.[12] For example, the photolysis of a methanolic solution containing DMA and bromobenzene gave crystal violet and bis(*p*-dimethylaminophenyl)methane along with II—V, while the photolysis in the presence of TEA gave a clean solution without the formation of the above two products.

c) See Ref. 15.

bromobenzene and iodobenzene can be estimated to be in the range 77—80 kcal/mol.

The triplet excitation transfer mechanism can be eliminated for DMA-induced decomposition of chlorobenzene and bromobenzene, and is considered to be also unfavorable in the case of iodobenzene.

Fluorescence Spectra of DMA in the Presence of Halobenzenes. A cyclohexane solution of DMA showed a structureless fluorescence spectrum with a maximum at 334 nm. On addition of chlorobenzene and bromobenzene into a cyclohexane solution of DMA, however, the fluorescence was quenched with bathochromic shift of the spectra. When chlorobenzene and bromobenzene were used as solvents, very weak and red-shifted new emissions appeared with respective maxima at 373 and 412 nm along with total quenching of DMA fluorescence (Fig. 1).[26] Appearance of new

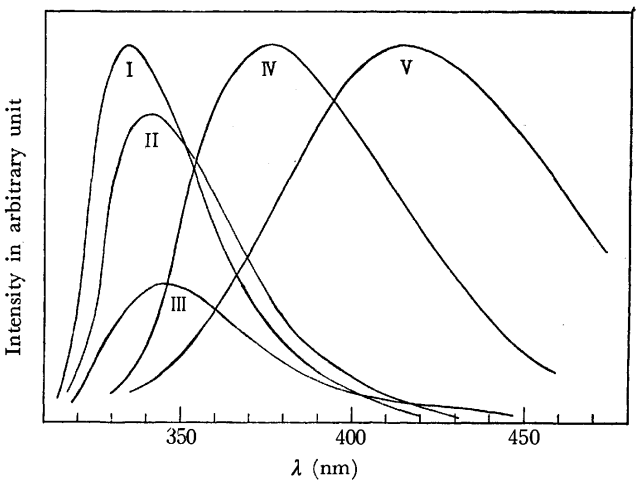

Fig. 1. The fluorescence spectra of DMA solutions in cyclohexane (curve I), in cyclohexane in the presence of 1 M PhCl (II), in cyclohexane in the presence of 0.1 M PhBr (III), in chlorobenzene (IV) and in bromobenzene (V). The spectra I—III were recorded with the same sensitivity, but the spectra IV and V with much higher sensitivities.

Table 4. Fluorescence maxima of aromatic amines in chlorobenzene and bromobenzene[a)]

emissions was general for chlorobenzene and bromobenzene solutions of aromatic amines. New very weak emission maxima for aniline, *N,N*-dimethyl-*p*-anisidine, *N,N*-dimethyl-*p*- and -*m*-toluidines are given in Table 4.

In contrast, fluorescence quenching with iodobenzene was not accompanied with any bathochromic shift of the spectrum or new emissions even in non-polar solvents. Moreover, solvent-dependency of quenching constant $k_r\tau$ also differed in the two groups of halobenzenes. In the case of iodobenzene, $k_r\tau$ was dependent on solvent viscosity rather than solvent polarity (Table 5). On the other hand, fluorescence quenching with chlorobenzene was more effective in a polar solvent than in a non-polar solvent; the half-value concentration was 0.2 M in methanol, about 10 times lower than that in benzene (*ca.* 2 M).[18]

Table 5. Solvent dependency of fluorescence quenching with iodobenzene[a)]

Solvents	η at 20°C (cpoise)	Rel. $1/\eta$	Rel. k_r
n-Hexane	0.32	2.0	1.5
Acetonitrile	0.59	1.1	1.2
Benzene	0.65	1.0	1.0
Methanol	0.611	1.06	0.98

a) Fluorescence quenching for the solutions containing 0.1 M DMA and 10^{-3}—5×10^{-2} M iodobenzene.

For methanolic solutions, however, fluorescence quenching with any halobenzene was accompanied with no change of shape of the spectra, bathochromic shift or appearance of new emissions.

Kinetic Results. Quantum yields for the formation of halide anions at 313 nm at room temperature were determined by potassium ferrioxalate actinometry.[19] Quantitative analyses for chloride and bromide anions were titrimetrically carried out by a

18) Since the shape of the fluorescence spectra in the presence of chlorobenzene were changed, the half-value concentration could not be explicitly determined.
19) C. G. Hatchard and C. A. Parker, *Proc. Roy. Soc.* (London), **A235**, 518 (1956).

modified Vorhard's method[20] and for iodide anion by Jamieson's method.[21] The conversion was maintained below 10% for all the kinetic runs. Reciprocals of the quantum yields changed linearly with reciprocals of concentrations of halobenzenes (Fig. 2).

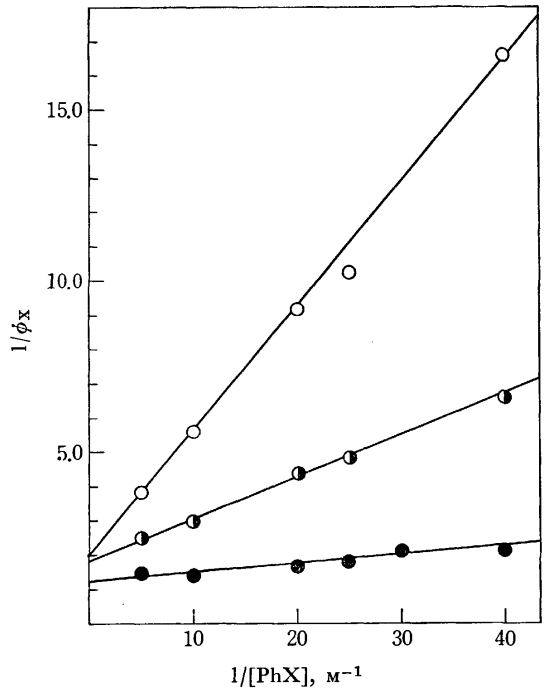

Fig. 2. The plots of reciprocals of quantum yields *vs.* reciprocals of concentrations of PhCl (-○-), PhBr (-◑-) and PhI (-●-).

Since fluorescence quenching for methanolic solutions was accompanied with no change of shape of the spectra, relative intensities of the fluorescence maximum at 352 nm in the absence and presence of halobenzenes (F_0/F) were plotted with concentrations of halobenzenes. Linear Stern-Volmer plots were obtained (Fig. 3). Table 6 lists the fluorescence quenching constants ($k_r\tau$, the slopes of the plots in Fig. 3), the rate ratios k_r/k_d ($=k_r\tau$, the intercept-to-slope ratios of the straight lines in Fig. 2) and k_n/k_e (the intercepts).

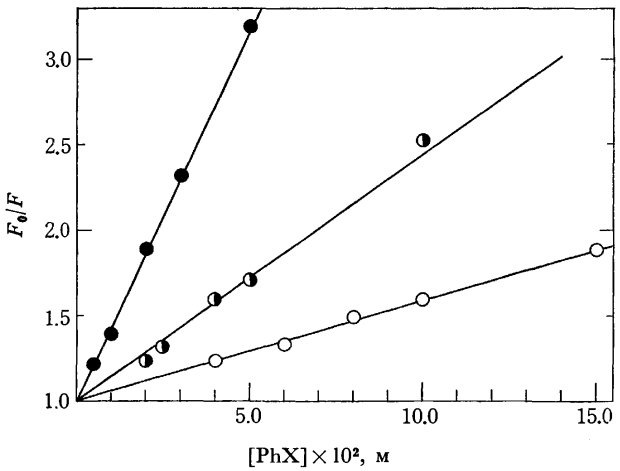

Fig. 3. The Stern-Volmer plots for the quenching of DMA fluorescence with chlorobenzene (-○-), bromobenzene (-◐-) and iodobenzene (-●-).

c) The slopes of Stern-Volmer plots for the solutions containing 0.1 M DMA and 10^{-3}–0.15 M halobenzenes which were not affected appreciably by the presence of 0.1 M TEA.

Discussion

The products obtained from the photochemical reactions can be interpreted by ETR mechanism; electron transfer from excited DMA to ground state halobenzenes led to DMA radical cation and halobenzene radical anions. Since halobenzenes are dis-

Scheme 1.

sociative in electron capture in vapor phase,[22a] it can be expected that the radical anions, if formed, are simultaneously decomposed into phenyl radical and halide anions in liquid phase. Phenyl radical abstracts hydrogen atom from solvent molecules, TEA, DMA radical cation and neutral DMA to give benzene, while the dimethylaminodiphenyls (IV and V) are formed by addition of phenyl radical to DMA and DMA radical cation. Thus the mechanism in Scheme 1 is suggested, from which rate equation (14) and the Stern-Volmer expression (15) for fluorescence quenching are derived.

Let F_0, F, and ϕ_X denote the fluorescence intensities in the absence and in the presence of halobenzenes and the quantum yields for the formation of halide anions, respectively in the rate equations. As is shown in Table 6, the rate ratios k_r/k_d are in good agreement with the quenching constants $k_r\tau$ within experimental errors for respective halobenzenes. Since k_d equals $1/\tau$, the agreement strongly supports the view that the photochemical reactions occur in the lowest excited singlet state of DMA (^{1}DMA).

It is noteworthy that the product ratios (IV+V)/II and IV/V change with halobenzenes. The photochemical reaction with iodobenzene leads to a remarkably low ratio of (IV+V)/II, *i.e.* dominant formation of benzene. In contrast, the dimethylaminodiphenyls are formed 1.8 times greater than benzene in the reaction with chlorobenzene. In the case of bromobenzene, the formation of the dimethylaminodiphenyls competes with that of benzene and the ratio (IV+V)/II is similar to the case of chlorobenzene rather than to the case of iodobenzene.

The results cannot be interpreted by means of a single mechanism, and suggest a competitive reaction mechanism. By assuming that ETR distance is dependent on halobenzenes, it can be predicted that the fraction of the radical pair (DMA radical cation and phenyl radical) in solvent cage increases with the decrease of distance and thus cage reaction plays a more important role in competition with free radical reaction. The product distribution is therefore expected to change with halobenzenes.

Since free phenyl radical is well known to abstract hydrogen from molecules having labile hydrogen atoms, free radical reaction affords benzene as an exclusive product. The photochemical reaction with iodobenzene is considered to fit the case. On the other hand, cage reaction may occur essentially between phenyl radical and DMA radical cation; bond formation of the radical pair giving IV and V may be competitive with hydrogen transfer from DMA radical cation to phenyl radical giving benzene. In the case of chlorobenzene and bromobenzene, therefore, the results suggest that the cage reaction plays important or dominant roles.

In order to clarify the above assumption and obtain information on ETR distances, the photochemical reactions were carried out with *N,N*-di(trideuteriomethyl)aniline (DMA-d_6) instead of DMA-h_{11}, and the contents of benzene-d_1 in benzene fraction of the products were estimated by vpc-mass spectrometry. Deuterium purity of DMA-d_6 was confirmed to be over 98% by NMR.

When the ETR distance is short, the cage reaction is dominant. When ETR takes place in a sufficiently long distance, the fraction of free phenyl radical will increase. The cage reaction might afford largely benzene-d_1 by deuterium transfer from DMA-d_6 radical cation to phenyl radical while free phenyl radical might abstract hydrogen atom from solvent molecules for the most part. Thus, it is reasonable to predict that the proportion of benzene-d_1 reflects a measure for the ETR distance.[22b]

$$(\overset{+\cdot}{\mathrm{PhN}}(\mathrm{CD_3})\mathrm{CD_3} + \cdot\mathrm{Ph})_{\mathrm{cage}} \rightarrow \mathrm{PhN}(\mathrm{CD_3})\mathrm{CD_2}^+ + \mathrm{PhD}$$

$$\mathrm{Ph}\cdot + \text{Hydrogen donor} \rightarrow \text{largely PhH}$$

Table 7 shows the proportions of benzene-d_1 obtained from the photochemical reactions of DMA-d_6 with halobenzenes which increase in the order: iodobenzene, bromobenzene, and chlorobenzene. In the case of iodobenzene, however, it should be noted that the proportion of benzene-d_1 is remarkably low in comparison with the other two cases, in analogy with the ratio (IV+V)/II. The low proportion of benzene-d_1 might be evidence of the free radical nature of the phenyl radical generated by electron transfer to iodobenzene and suggests that ETR occurs in a long range type[23] between ^{1}DMA and iodobenzene. On the other hand, a high proportion of benzene-d_1 is obtained from the photochemical reaction with chlorobenzene. This indicates that the cage reaction is dominant in the formation of benzene and suggests that ^{1}DMA donates the electron to chlorobenzene in close contact, *i.e.* in a short range type.[23] Since the proportion of benzene-d_1 obtained from the reaction with bromobenzene is nearer the case of chlorobenzene than iodobenzene, it can be suggested that the ETR distance for bromobenzene is in somewhat shorter range, but longer than the distance for chlorobenzene.

The results are in good parallelism with electron affinities of halobenzenes. The electron affinity of iodobenzene is the highest (0.5_7 eV) in the three halobenzenes,[24] while the electron affinities of chloro-

22) a) J. A. Stockdale and G. S. Hurst, *J. Chem. Phys.*, **41**, 255 (1964); W. E. Wetworth, R. S. Becker, and R. Tung, *J. Phys. Chem.*, **71**, 1652 (1967). b) This suggests only a qualitative measure, since the proportion of benzene-d_1 cannot represent the fraction of the cage reaction; the phenyl radical in the solvent cage might abstract the hydrogen atom of the wall of the solvent cage even in small proportions, while free phenyl radical might also abstract the deuterium atom from DMA-d_6.

23) T. Okada, H. Oohari, and N. Mataga, This Bulletin, **43**, 2750 (1970).

24) G. Briegleb, *Angew. Chem.*, **76**, 326 (1964).

benzene and bromobenzene are identical (0.4 eV)[24] or similar.[25] It is resonable to expect that ETR takes place in a long range type for iodobenzene with a high electron affinity,[23] while the acceptors having similar electron affinities may abstract electron from a donor in similar distances.

As regards quenching behavior to DMA fluorescence, halobenzenes are classified into two groups, one involving chlorobenzene and bromobenzene, and the other iodobenzene. It is of interest to note that the same classification of halobenzenes is made from both fluorescence data and product distribution.

With chlorobenzene and bromobenzene, exciplex formation in non-polar solvents is evident from the following observations; 1) appearance of new emissions,[2-4] 2) endothermic and dynamic property of the fluorescence quenching[26] and 3) solvent dependency of the fluorescence quenching on solvent polarity.[27] Moreover, the charge-transfer character of the emission entities is supported by the fact that the new emission maxima are shifted to longer wavelength with the decrease of ionization potentials of the aromatic amines (Table 4).[28] It might be suggested that the fluorescence quenching with chlorobenzene and bromobenzene is ascribed to the formation of the exciplexes between ^{1}DMA and the ground state halobenzenes, at least in non-polar solvents.

On the other hand, the exciplex formation with iodobenzene is negative. Therefore, the fluorescence quenching with iodobenzene is governed by a different mechanism from an exciplex one even in non-polar solvents. If a complex were assumed, it would have a configuration differing from the exciplexes discussed above and might be totally non-emissive as in the case of pyrene-tetracyanoethylene.[23] In polar solvents, in particular, no exciplex mechanism can be suggested, since exciplexes even if formed in non-polar solvents are non-existent[3] or quite shorter-lived[4] in polar solvents. A direct electron transfer mechanism is preferred for the fluorescence quenching. Since the kinetic data show the identity of the mechanism between the fluorescence quenching and the photochemical reaction, the mechanism is supported by the long range type character of the reaction deduced from the product distribution. It is unreasonable to assume that a long range type electron transfer

$$^1\text{DMA} + \text{PhI} \begin{cases} \xrightarrow{k_r'} \text{DMA}^+ + \text{Ph}\cdot + \text{I}^- & (16) \\ \xrightarrow{k_q} \text{DMA} + \text{PhI} & (17) \end{cases}$$

$$1/\phi = \left(1 + \frac{k_q}{k_r'}\right) + \frac{k_d}{k_r'}\frac{1}{[\text{PhI}]} \quad (18)$$

$$F_0/F = 1 + (k_r' + k_q)\tau[\text{PhI}] \quad (19)$$

$$k_r'/k_d = 50\ \text{M}^{-1},\quad k_q/k_r' = 0.25$$

$$(k_r' + k_q)\tau = k_r\tau = 42\ \text{M}^{-1}$$

Scheme 2.

takes place by way of a discrete intermediate such as an exciplex. The direct electron transfer mechanism is shown in Scheme 2.

On the other hand, all the results clearly show that the mechanism for chlorobenzene and bromobenzene differs from the case of iodobenzene. The short range character of ETR suggested from the product distribution may imply such a close contact intermediate as an exciplex or an ion pair shown in Scheme 1. The fluorescence data on the formation of exciplexes suggest an exciplex intermediacy, though the exciplex formation in non-polar solvents may exhibit no direct evidence for the exciplex intermediacy in methanol.[29]

For mechanistic elucidation, the rate data obtained from the quantum yield measurements will be briefly discussed. Although the life of ^{1}DMA has not been reported, it can be approximately replaced with the singlet life of aniline (3.2 nsec in ethanol).[30] If this is the case, the reaction rates (k_r and k_r') for chlorobenzene, bromobenzene and iodobenzene can be estimated to be respectively 1.8×10^9, 5.1×10^9 and 19×10^9 $\text{M}^{-1}\,\text{sec}^{-1}$, which are close to the diffusion rate in methanol (ca. 10^{10} $\text{M}^{-1}\,\text{sec}^{-1}$). Since it is well established that the formation of exciplexes and ETR occur in a diffusion or a near diffusion rate,[2-4,23] the rate data can support also the mechanisms in Schemes 1 and 2. The fact that k_r increases in the order of chlorobenzene, bromobenzene, and iodobenzene may reflect the order of the electron affinities of the halobenzenes.

Singlet excitation transfer, if it occurs, is endothermic, since the absorption of DMA appears at a longer wavelength than in any halobenzenes. If this is the case, near diffusion rates cannot be obtained, and the singlet excitation transfer mechanism can be excluded. A triplet excitation transfer mechanism can be also ruled out by sensitization experiments (*vide supra*).

Experimental

General. Spectroscopic analyses of the organic products were carried out as follows; the NMR spectra with a high Hitachi Perkin-Elmer R-20 spectrophotometer, IR

25) The electron affinities might correlate with polarographic half-wave potentials $E_{1/2}$. If this is the case, the electron affinities of bromobenzene will be slightly higher than that of chlorobenzene, since the half-wave potentials are reported to be -2.58 V for chlorobenzene and -2.32 V for bromobenzene; M. F. Thomas and B. Stevens, "Molecular Luminescence," ed. by E. C. Lim, W. A. Benjamin, Inc., New York (1969), p. 158.

26) No evidence could be obtained on the formation of EDA-complexes in the ground state. The UV spectra of DMA were the same in both the presence and the absence of 0.1 M halobenzenes. Even though chlorobenzene and bromobenzene were used as solvent, the maximum of ^1L_b band shifted only 2—3 nm to longer wavelength, and no new absorption could be observed.

27) K. Kaneta and M. Koizumi, This Bulletin, **40**, 2254 (1967).

28) a) Since all of the fluorescence spectra were uncorrected, no explicit first order correlation between ionization potentials and the emission maxima could be obtained. b) P. G. Farrel and J. Newton, *J. Phys. Chem.*, **69**, 3506 (1965).

29) The fluorescence quenching mechanism in polar solvents has not been established satisfactorily. Weller stated direct electron transfer mechanism,[3] while Mataga suggested exciplex mechanism for a short range type of ETR.[4,23]

spectra with a Hitachi EPI-S2 spectrophotometer, UV spectra with a Hitachi 124 spectrophotometer, fluorescence spectra with a Hitachi MPF-2A spectrofluorometer and mass spectra with a Hitachi RMS-4 spectrometer. Yields and the product ratios were determined by vpc with a Simadzu GC-2C under the conditions described previously.[12] Solvents were purified as usual. TEA was refluxed over potassium hydroxide and distilled. Chlorobenzene and bromobenzene were washed three times with concentrated sulfuric acid, three times with water, dried over anhydrous calcium chloride and distilled through a column packed with stainless steel helices. Iodobenzene was washed twice with a dilute aqueous solution of sodium thiosulfate, three times with water, dried over calcium chloride and distilled through the column. The tertiary aromatic amines were refluxed with an excess of acetic anhydride and acidified with hydrochloric acid. The acidified solutions were treated five times with ether and basified with sodium hydroxide. The amines separated from the aqueous layers were then treated as usual. All of the amines were distilled under nitrogen stream *in vacuo* before use. Acetone was purified by the ordinary method.[31] Acetophenone and propiophenone were purified by fractional distillation under reduced pressure.

Quantum Yields. Methanolic solutions (5 m*l*) containing 1.0 M DMA, 0.1 M TEA and 0.025—0.2 M halobenzenes were degassed and sealed in 10 mm o. d. Pyrex tubes, which were then irradiated on a merry-go-round apparatus at room temperature through a filter solution with a path length of 1 cm containing 0.2 g potassium chromate made up to 1 *l* with distilled water with a high pressure mercury arc. After the relative quantum yields were determined, the quantum yields at 0.2 M chlorobenzene, 0.2 M bromobenzene and 0.025 M iodobenzene were determined to be 0.26_4, 0.41_3, and 0.49 by potassium ferrioxalate actinometry,[19] respectively. The values were constant at 0.5—10% conversion within 10% experimental errors.

Sensitization Studies. Samples of *t*-butyl alcohol solutions containing 0.1 M halobenzenes and 0.1 M ketones were prepared, degassed and irradiated through a Pyrex glass with a high pressure mercury arc. The amounts of benzene formed and halobenzenes consumed were determined by vpc.

Photochemical Reaction in Preparative Scale. As a typical run, the photochemical reaction of DMA with bromobenzene will be described. A methanolic solution (30 m*l*) containing 4 g DMA, 4 g bromobenzene and 5 m*l* TEA in a Pyrex tube was irradiated for 45 hr with a high pressure mercury arc. The amounts of the products and of bromobenzene consumed were determined by vpc analyses of an aliquot of the photolysate (5 m*l*). It was found that 450 mg of benzene, 790 mg of *o*-dimethylaminodiphenyl and 96 mg of *p*-dimethylaminodiphenyl were formed at about 50% consumption of bromobenzene. After removal of the solvent fraction under reduced pressure at room temperature, 5 m*l* of benzene was added to the residue and cooled on an ice bath. TEA hydrobromide (2.32 g) was then filtered off, washed with benzene and recrystallized from 2-propanol. Found: C, 39.67; H, 9.09; N, 7.68; Br, 43.70%. Calcd for $C_6H_{16}NBr$: C, 39.59; H, 8.85; N, 7.69; Br, 43.90%.

After removal of benzene and the unreacted materials from the filtrate, further distillation gave crude *o*-dimethylaminodiphenyl, which was redistilled, bp 80°C/1 mmHg; $\tau(CCl_4)$ 7.5 (s, 6H) and 3.1—2.3 (m, 9H). The product was converted into its picrate, mp 184—186°C (dec.). Found; C, 56.72; H, 4.12; N, 13.09%. Calcd for $C_{20}H_{18}N_4O_7$; C, 56.34; H, 4.26; N, 13.14%.

Finally, the residue was chromatographed on silica gel. After *o*-dimethylaminodiphenyl was eluted with 10% of benzene in hexane, further elution with 1 : 1-mixture of benzene - hexane gave *p*-dimethylaminodiphenyl, which was recrystallized from methanol, mp 118—119°C. Found: C, 85.30; H, 7.63; N, 6.84%. Calcd for $C_{14}H_{15}N$: C, 85.24; H, 7.66; N, 7.10%.

Preparation of DMA-d_6. DMA-d_6 was obtained by alkylation of aniline[32] with perdeuterated trimethyl phosphate prepared from methanol-d_4 and phosphorus oxychloride, and purified by preparative vpc on a 3 m Apiezon column at 160°C, bp 84°C/15 mmHg. The IR spectrum showed a characteristic absorption of aromatic C–H bond at 3030 cm^{-1} and aliphatic C–D bond at 2000—2200 cm^{-1} (4 peaks), while absorption of aliphatic C–H at 2900 cm^{-1} region could not be observed. The NMR spectra showed only the signals of aromatic protons at τ 2.8—3.7 as a multiplet.

Photochemical Reaction of DMA-d_6. A methanolic solution containing 0.7 M DMA-d_6, 0.7 M TEA and 2 M chlorobenzene or bromobenzene was prepared. In the case of iodobenzene, the concentration was set in 0.2 M in order to avoid direct photolysis of iodobenzene. The samples (4 m*l*) were degassed and irradiated in the same way as in the quantum yield measurements. The photolysates were subjected directyl to vpc-mass spectrometric analyses. The vpc was operated with an 1 m ODPN column plus an 1 m PEG-200 column at 70°C. Table 7 lists the relative intensities at *m/e* 78 and 79 of benzene-h_6 and of the benzene fractions obtained from the photolyses, from which the contents of benzene-d_1 were determined.

The Photochemical Reaction of Some Ketoximes and Their Derivatives

Tadashi SATO, Takeshi INOUE, and Koichi YAMAMOTO
Department of Applied Chemistry, Waseda University, Shinjuku-ku, Tokyo
(Received October 8, 1971)

The photochemical reaction of mesityl oxide oxime was investigated. In protic solvents, the reaction *via* oxaziridine proceeded, while in aprotic solvents, *syn-anti* isomerization was the main reaction pattern. A cyclobutanol formation, which is a new type of reaction in the oxime system, was observed. The photochemical reactions on some other ketoximes and their derivatives were also investigated.

Recently several workers have investigated the photochemistry of oximes and their derivatives. The reactions can be classified into four types; (1) *syn-anti* isomerization,[1] (2) photo-Beckmann rearrangement,[2] (3) nitrile formation,[3] and (4) ketone formation.[4] deMayo[2a,5] proposed a mechanism *via* the oxaziridine formed for the polar state of oxime for the photo-induced conversion of benzaldehyde oxime into benzamide with an intramolecular oxygen migration. The reaction scheme through the intermediacy of the oxaziridine for the photo-Beckmann rearrangement and ketone formation from oximes has been confirmed in an indirect way by Mukai *et al.*[2d,6] These authors have also discussed possible states of excited states in the photochemistry of some α,β-unsaturated ketoximes.

We investigated photochemical reactions on several ketoximes and their *O*-methyl ethers, thus disclosing several new results.

Results

When mesityl oxide oxime (**1a**, a mixture of *anti*[7] 78% and *syn* 22%) containing 5% of isomesityl oxide oxime (**2a**) was irradiated with Pyrex-filtered light in methanol, mesityl oxide (**1b**), isomesityl oxide (**2b**), a cyclobutanol, **3**, and two amides, **4** and **5**, were obtained. Product identification was carried out spectroscopically with samples collected by preparative gas chromatography. The yields of the products were obtained by gas-chromatographic analysis; they are plotted against irradiation time in Fig. 1. It was confirmed that the irradiated reaction mixture was stable upon further standing under the present reaction conditions, but without the light. Since **2a** is supposed to be stable to the Pyrex-filtered light, in view of the lack of reactivity of the saturated ketoximes (such as cyclohexanone oxime) to this light source, the **2a** present in the starting material as a contaminant was used as the internal reference in the analysis by gas chromatography. It was found that the products and product distribution obtained from the photolysis

a) A: The solvent was removed through a column under an ordinary pressure, and the residue was analyzed by gas chromatography. B: The solvent was removed *in vacuo* and the residue was analyzed by gas chromatography. C: The solvent was removed *in vacuo*, the residue was distilled under a reduced pressure, and the distillate was analyzed by gas chromatography. D: The solvent was removed *in vacuo*, the residue was diluted with ether and washed with an aqueous sodium bicarbonate solution, the ether was removed, and the residue was fractionated on an alumina column with chloroform.

b) Identification was carried out on pure samples obtained by preparative gas chromatography, except for samples marked with an asterisk, which contained the isomer indicated in the parentheses. **1b**, **2b**, **7**, **10**, and camphor: the retention times as shown by gas chromatography and the IR spectra were identical with those of the authentic samples. **3**: MS: *m/e* 98 (P). The IR and NMR spectra showed peaks identical with the reported values.[13] **4**: MS: *m/e* 113 (P). IR (CCl_4): 3300 (s), 1660 (vs) and 1505 cm^{-1} (vs). NMR (CCl_4): δ 1.67 (s, 6H), 2.07 (s, 3H), 6.56 (d, $J=12$ Hz, 1H) and 8.65 (bs, 1H). **5*** (containing **4**): NMR ($CDCl_3$): δ 1.80 (s, 3H), 2.10 (s, 3H), 2.73 (d, $J=5$ Hz, 3H), 5.47 (bs, 1H) and 5.82 (bs, 1H). *cis-anti*-**1c*** (containing *trans*-anti-**1c**): NMR ($CDCl_3$): δ 1.73 (s, 3H), 6.10 and 6.40 (AB type q, $J=12$ Hz, 2H), 6.85 (m, 5H) and 7.73 (bs, 1H). *cis-anti*-**1d**: IR (neat): 1054 (s), 895 (s), 775 (m) and 695 cm^{-1} (m). NMR ($CDCl_3$): δ 1.76 (s, 3H), 3.82 s, 3H), 6.25 and 6.54 (AB type q, $J=12$ Hz, 2H) and 7.15 (s, 5H). **11**: mp 133—136°C. IR ($CHCl_3$): 3400 (w) and 1660 cm^{-1} (vs). Found: C, 71.91; H, 10.55; N, 8.29%. Calcd for $C_{10}H_{17}NO$: C, 71.81; H, 10.25; N, 8.38%.

c) See Fig. 1.

d) Isobutyl methyl ketone.

e) Unidentified.

of **1a** were greatly solvent-dependent. The results are summarized in Table 1. Evidently, *syn-anti* isomerization became the major reaction pattern in nonpolar solvents, while only one amide, **4**, was obtained selectively in an acidic solvent. Compounds **1c**, **1d**, **8**, and **9** were also irradiated under the conditions specified in Table 1. The structure **11** was assigned to the product from **9** in view of the results of the elemental analysis, the amide carbonyl band in the IR spectrum at 1660 cm^{-1}, and the absence of an olefinic proton signal in the NMR spectrum. The

melting point (133—136°C) of this compound was lower than that of the reported value (156—160°C)[8] for **11**, but the possibility of the alternative structure of α-camphidone was excluded in view of the still higher melting point of α-camphidone (230—232°C).

Discussion

Oxime Disappearance. Figure 1 shows that the amount of mesityl oxide (**1b**) increases to reach a maximum and then decreases during the last stages of the reaction. As it has already been pointed out,[9] and has been confirmed in the present study, that **1b** is stable to the Pyrex-filtered light under various conditions, the decrease in the amount of **1b** upon prolonged irradiation can be explained by assuming that the curve is actually a plot of the amount of a photolabile intermediate from which the ketone is formed during the work-up of the reaction mixture. In view of the previous proposals, oxaziridine, **6**, is the most probable

8) M. Nakazaki and K. Naemura, This Bulletin, **37**, 532 (1964).

9) N. C. Yang and M. J. Jorgensen, *Tetrahedron Lett.*, **1964**, 1203.

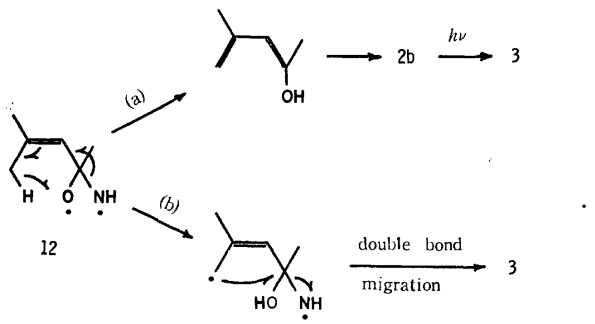
candidate for the intermediate; this is consistent with the proposed scheme that the oxaziridine intermediate is formed in the initial step of the irradiation of oxime.

The formation of these products (**1b**, **2b**, **3**—**5**), which can be assumed to be secondary products from **6**, was greatly depressed when the photolysis was carried out in ether; the *syn-anti* isomerization became a major reaction pattern, instead (Table 1). Similarly, the amide formation from benzylideneacetone oxime (**1c**) upon the irradiation in methanol[2d] was replaced by an exclusive *cis-trans* isomerization when the irradiation was carried out in ether. Benzylideneacetone oxime *O*-methyl ether (**1d**) also underwent only *cis-trans* isomerization, even in methanol. These findings definitely support the argument by de Mayo[5] that an ionic dissociation of oxime hydrogen might be a necessary step in the formation of an oxaziridine intermediate. In a similar sense, the formation of 6-hexanelactam and hexanamide from cyclohexanone oxime upon irradiation (quartz) in methanol[2b] was greatly retarded, and an azine, **7**, became the main product upon the irradiation (quartz) of cyclohexanone oxime *O*-methyl ether (**8**) in methanol. Probably homolytic N–O bond fission, followed by dimerization, became dominant in this case. Both isomerizations (*cis-trans* and *syn-anti*) seemed to proceed through singlet states, because the reactions were not affected by the presence of piperylene in the range of quencher concentrations of 0.1—1M. **1a** indicates a weak n–π^* band at 310 nm (π–π^* at 235 nm) in the UV spectrum, while the n–π^* bands of **1c** and **1d** are completely covered with strong π–π^* bands at 284 nm. It seems reasonable to assume that the π–π^* state induces a *cis-trans* isomerization, while the n–π^* state induces a *syn-anti* isomerization.

Amide Formation. We found that the amide formation is also subject to a solvent effect. In contrast with the formation of two amides, **4** and **5**, upon the irradiation of **1a** in methanol, only one amide, **4**, was obtained upon the photolysis of **1a** in methanol *containing acetic acid.* Evidently a selective migration of the olefinic group occurs in methanol - acetic acid, while both alkyl and olefinic migrations occur non-selectively in methanol. We interpret the present result in terms of the difference in degree of protonation to the intermediate oxaziridine. That is, in an acidic solvent, protonation to an excited state of the oxaziridine would be effective, and this would induce a heterolytic N–O bond fission, as is shown in **6**, giving rise to a selective migration of the olefinic group; this seems likely in view of the preferential migratory aptitude of the olefinic group over the alkyl group in the reaction involving electron-deficient nitrogen.[10] However, in methanol, the proton-donating power of the solvent is weak and homolytic N–O bond fission in the excited oxaziridine would become dominant, thus inducing a non-selective migration of olefinic and alkyl groups. In contrast with the results obtained above, an exclusive migration of olefinic group in methanol has been reported in the styryl ketone oxime system;[2d] this result was also confirmed with **1c** in the present study. These results seem reasonable because, in this system, the phenyl group would effectively stabilize the transition state for the olefinic-group migration, thus favoring the heterolytic N–O bond fission even in a non-acidic solvent.

We also observed that the acidic solvent greatly favors the Beckmann-type rearrangement. Previously we investigated the photolysis of camphor oxime (**9**) in methanol and obtained Beckmann-fragmentation products (for instance, **10**) as well as camphor.[3a] It is probable that the Beckmann-fragmentation products arise through a homolytic cleavage of the N–O bond, as is shown in **9**, while camphor arises from the oxaziridine intermediate, which, because of the thermal unstability due to the ring strain, decomposes into camphor before it can be subject to a photochemical reaction. On the contrary, a lactam, **11**, was the product when the irradiation was carried out in an acidic solvent. Probably the Beckmann–type rearrangement became preferable because of the protonation of the excited state of the oxaziridine intermediate. The same type of reaction has been reported with the adamantanone oxime system.[11]

Cyclobutanol Formation. Although the γ-hydrogen abstraction in excited carbonyl compounds is a well-known type-II reaction, mesityl oxide is photostable under the conditions examined so far.[9] This lack of reactivity has been attributed to the assumption that the lowest state is the π–π^* triplet, which exhibits substantially reduced reactivity in intramolecular hydrogen abstraction.[12] Therefore, it is notable that a cyclobutanol, **3**, which is an expected but not realized product from mesityl oxide, was obtained from the oxime.



As the possible routes for the formation of **3**, we propose mechanisms (a) and (b) from a radical derived from oxaziridine (**12**). A scheme through an intermediacy of **12** was deduced from the fact that the formation of **3** was accompanied by the formation of two amides, **4** and **5**. When the irradiation was carried out in an acidic medium, where the possibility of a heterolytic cleavage of the N–O bond has been speculated about (*vide supra*), the formation of **3** was negligible (<1%). We consider that the mechanism (a),

12) P. J. Wagner, *Accounts Chem. Res.*, **4**, 168 (1971). Experiments questioning this assumption has been reported: R. A. Schneider and J. Meinwald, *J. Amer. Chem. Soc.*, **89**, 2023 (1967).

which involves isomesityl oxide (**2b**) as an intermediate, is preferable to (b) in view of the long induction period for the formation of **3** as compared with the formation of amides (Fig. 1). Isomesityl oxide was actually identified in the reaction mixture, but its quantitative analysis was unsuccessful because the peak on the gas chromatography overlapped with that of an unidentifiable component. The photochemical transformation of isomesityl oxide into cyclobutanol, **3**, has been established.[13] The reaction corresponding to the well-known type-II reaction in carbonyl compounds is a new type of reaction in the oxime system.

Experimental

The IR spectra were measured on a Hitachi EPI-G3 spectrometer, while the NMR spectra were obtained on a JEOL MH-60 (60 MHz) spectrometer, using TMS as the internal reference. The mass spectra were determined on a Hitachi RMS-4 mass spectrometer, using an ionization energy of 70 eV.

Mesityl Oxide Oximes. The material prepared by the method reported by Harries[14] was a mixture of *anti* (66%), *syn* (21%), and isomesityl oxide oxime (13%), as judged from the results of gas-chromatographic and NMR-spectroscopic analysis. Isomesityl oxide oxime and a mixture of *anti* and *syn* were isolated in preparative gas chromatography. The mixture of *anti* and *syn* isomers: IR (CCl_4): 3370 (s), 1670 (m) and 968 cm^{-1} (s). NMR (CCl_4): δ 1.76—2.15 (m), 5.65 (m) for the olefinic proton of the *anti*-isomer,[15] 6.03 (m) for the olefinic proton of the *syn*-isomer and 9.67 (bs). Isomesityl oxide oxime: IR (CCl_4): 3250 (s), 1655 (m), 945 (m) and 896 cm^{-1} (s). NMR (CCl_4): δ 1.70 (s, 3H), 1.82 (s, 3H), 2.90 (s, 2H), 4.93 (s, 2H) and 8.63 (bs, 1H).

The material was further fractionated, and a mixture of *anti* (75%), *syn* (20%), and isomesityl oxide oxime (5%) was used for the photoreaction.

trans-anti-*Benzylideneacetone Oxime* O-*Methyl Ether* (**1d**). Into a solution of *trans-anti*-benzylideneacetone oxime (16 g, mp 116°C, lit,[16] mp 113—115°C) in anhydrous benzene (50 m*l*), we added sodium amide (4 g) at 30°C. The mixture was stirred for 15—16 hr, and then the solid was collected on a glass filter. The material was washed with benzene and dried *in vacuo*. The solid was suspended in ether (50 m*l*), methyl iodide (43 g) was added, and the mixture was refluxed for 20 hr under a slight pressure (with a mercury seal). The mixture was then filtered from a solid, the solvent was removed, and the residue was distilled. Bp 110—115°C/2—3 mmHg. IR (neat): 1053 (s), 965 (m), 750 (m) and 690 cm^{-1} (m). NMR (CCl_4): δ 1.96 (s, 3H), 3.88 (s, 3H), 6.67 (s, 2H) and 7.18 (m, 5H).

Camphor Oxime. Mp 117.5°C. (lit,[17] mp 117.5—118°C).

Cyclohexanone Oxime O-*Methyl Ether.* Bp 50—51°C/10 mmHg. (lit,[18] bp 50°C/12 mmHg.)

Photolysis. The irradiation was carried out with a Riko high-pressure UVL-100P ultraviolet mercury lamp. The results are summarized in Table 1.

(Received October 11, 1971)

1-*t*-Butyl-3-amino-, 1-*t*-butyl-3-aminomethyl-, and 1-*t*-butyl-2-aminomethylazetidine were prepared by the ammonolysis of 1-*t*-butyl-3-azetidinyl tosylate, and by the reduction of 1-*t*-butyl-3-cyano, and 1-*t*-butyl-2-cyano-azetidine respectively. In the deamination, both of the first two azetidines gave only the corresponding alcohols, 1-*t*-butyl-3-azetidinol and 1-*t*-butyl-3-hydroxymethylazetidine, while the last one was found to afford two products, 1-*t*-butyl-2-hydroxymethylazetidine and 1-*t*-butyl-3-hydroxypyrrolidine. The deamination products were identified as the corresponding acetates.

Rearrangements involving carbonium ions in small-ring compounds[1] or involving the nucleophilic participation of the amino group in strainless alicyclic amines[2] are already known. With regard to the highly strained azetidines, reactions which closely resemble the above rearrangements have also been reported very recently by Gaertner,[3] Deyrup and Moyer,[4]

and Masuda *et al.*[5] Here, we will present the results of the deamination of the title compounds.[6] It is of interest to see if the cation so generated can be attacked by the nitrogen atom in the ring to give ring-contraction or ring-expansion products.

1-*t*-Butyl-3-aminoazetidine (I) was prepared according to a method reported before.[7] 1-*t*-Butyl-3-aminomethylazetidine (II) was prepared by the lithium aluminum hydride reduction of 1-*t*-butyl-3-cyanoazetidine.[8] The reduction of 1-*t*-butyl-2-cyanoazetidine[9] with lithium aluminum hydride offered a third amine, 1-*t*-butyl-2-aminomethylazetidine (III).[10] The infrared spectrum of the undistilled amine, II, shows the characteristic bands of a primary amino group at 3360 and 3290 cm^{-1} and an NH bending band at 1590 cm^{-1}, while that of the product III shows bands at 3360, 3280, and 1590 cm^{-1}. The results of the elemental analyses and spectroscopic studies of the dipicrates and phenylthioureas derived from the amines were completely consistent with the structures I, II, and III respectively (see Experimental). The homogeneity of the amines was also examined by vpc before deamination.

The amine I was allowed to react with sodium nitrite in aqueous acetic acid; the reaction mixture was then acetylated with acetic anhydride and analyzed by tlc and vpc. Only one product, 1-*t*-butyl-3-acetoxyazetidine (IV), was detected. The product, IV, isolated by vpc was found to be identical (IR, tlc, and vpc) with the authentic sample synthesized independently from the reaction of 1-*t*-butyl-3-azetidinol (V) and acetic anhydride.[6,11] The results of the elemental analysis were in agreement with the structure.

The deamination of the amine II was carried out in the same way, and the reaction mixture was analyzed before being treated with acetic anhydride. The mixture, which contained nearly equal amounts of 1-*t*-butyl-3-hydroxymethylazetidine (VI) and its acetate (VII) (detected by vpc), was then hydrolyzed to give VI as its only product. The infrared spectrum shows a broad absorption between 3500—3100 cm^{-1} for the hydroxyl group; the results of elemental analysis also coincided with the structure VI. For the purpose of confirmation, the deamination of II was performed again, and the reaction product was identified after acetylation. This time, only 1-*t*-butyl-3-acetoxymethylazetidine (VII) was obtained. The infrared spectrum of the product shows a strong ester carbonyl absorption at 1745 cm^{-1}. The NMR spectrum (CCl_4) exhibits a singlet at τ 9.10 (9H, *t*-Bu), a singlet at 8.03 (3H, CH_3CO), a multiplet between 7.67 and 7.25 (1H, ring methine), a triplet at 7.09 (2H, ring methylene), a triplet at 6.79 (2H, with the center split, ring methylene) and a doublet at 5.90 (2H, J= 6.8 Hz, methylene adjacent to ester oxygen). The results of the elemental analysis of the product and its picrate also agreed with the proposed structure, VII.

According to the same procedure, the amine III, in the deamination, was found to produce 1-*t*-butyl-2-acetoxymethylazetidine (IX) and the ring-expansion product, 1-*t*-butyl-3-acetoxypyrrolidine (X), in a vpc ratio of 45.6 : 54.6. The component with the shorter vpc retention time was spectrally (IR and NMR: Fig. 1) identical with the authentic sample of 1-*t*-butyl-2-acetoxymethylazetidine IX (see Experimental) prepared by the acetylation of the 1-*t*-butyl-2-hydroxymethylazetidine (VIII) which had been

5) T. Masuda, A. Chinone, and M. Ohta, This Bulletin, **43**, 3287 (1970).

6) Some of the results have been taken from the Ph. D. thesis of T. Chen, Tokyo Institute of Technology, March (1968).

7) T. Chen, H. Kato, and M. Ohta, This Bulletin, **41**, 712 (1968).

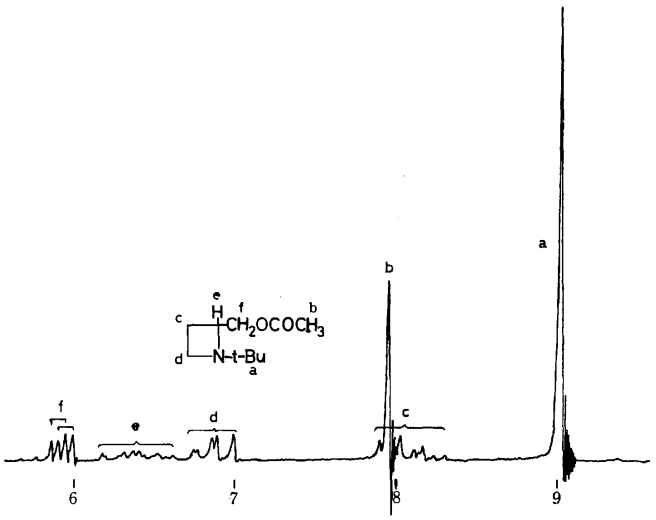

Fig. 1. The NMR spectrum of 1-*t*-butyl-2-acetoxymethylazetidine.

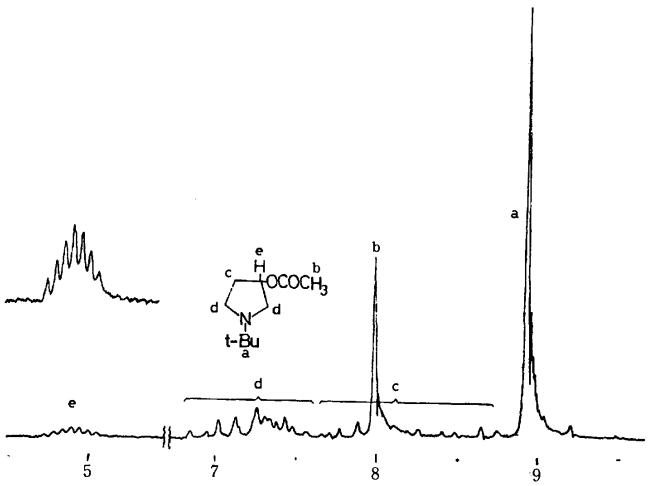

Fig. 2. The NMR spectrum of 1-*t*-butyl-3-acetoxypyrrolidine.

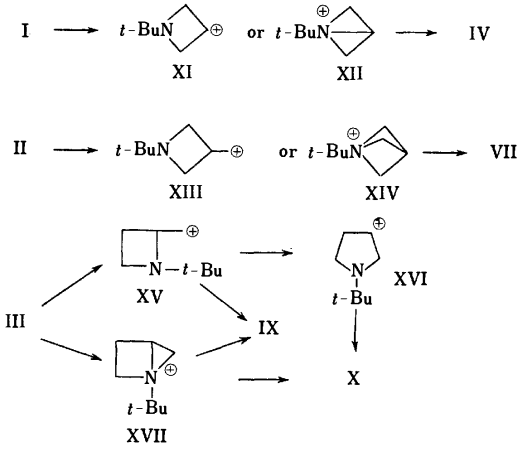
obtained by the reduction of 1-*t*-butyl-2-methoxycarbonylazetidine[5] with lithium aluminum hydride. The second compound isolated by vpc was considered to be 1-*t*-butyl-3-acetoxypyrrolidine (X) by the use of the spectroscopic method and by elemental analysis. The general pattern of the infrared spectrum of X is markedly different from that of IX; it has a strong absorption at 1740 cm^{-1} for the ester carbonyl group. The NMR spectrum ($CDCl_3$, Fig. 2) of X exhibits a singlet at τ 8.93 (9H, *t*-Bu), a singlet at 8.01 (3H, CH_3CO), a multiplet between 8.29 and 7.65 (2H, the methylene on the 4-carbon of the ring), a multiplet between 7.50 and 6.81 (4H, the two methylenes adjacent to the ring nitrogen), and a septet centered at 4.90 (1H, J=3.1 Hz, the asymmetric methine proton on the 3-carbon of the ring). A similar splitting of the methine proton in 1-*t*-butyl-2-aminomethylazetidine has also been observed by Rodebaugh and Cromwell.[12]

The fact that the ring contraction was not observed in the deamination of the amine I is in fair agreement with most previously-reported causes of replacement reactions involving 3-azetidinium cations, XI, which have a tendency to keep the ring unchanged rather than to contract it, though there are a few exceptions.[3,7,8] In the case of the amine II, 3-acetoxymethylazetidine, VII, should be formed from either the azabicyclo[1.1.1]pentyl cation, XIV (nitrogen atom participation), or the azetidinylmethyl cation, XIII. The formation of the ring-expansion product X by the deamination of the amine III may be expansion product X by the deamination of the amine III may be explained by the participation of the nitrogen atom (*via* the azabicyclo[2.1.0]pentyl cation, XVII) or, alternatively, by a simple 1,2-sigmatropic rearrangement of the 2-azetidinylmethyl cation, XV→ XVI. The absence of a ring-enlargement product in the deamination of II lends support to the probable nitrogen atom participation.



Experimental[13]

1-t-Butyl-3-aminoazetidine (I). This compound was prepared from 1-*t*-butyl-3-azetidinyl tosylate and a saturated methanolic solution of ammonia.[7] The fraction boiling at 71°C/20 mmHg was taken for the deamination. IR: 3370, 3290, 1600, 1390, 1365 cm^{-1}. Vpc: Carbowax 20 M on Diasolid A 4 mm × 225 cm 90°C, He 60 m*l*/min, retention time, 16 min; SE30 on Varaport 30, 1/4 in × 5 ft 75°C, N_2 60 m*l*/min, retention time, 3.8 min.

Dipicrate of I: Mp 198—200°C (decomp.).

Found: C, 39.15; H, 3.85; N, 19.32%. Calcd for $C_{19}H_{22}N_8O_{14}$: C, 38.91; H, 3.78; N, 19.10%.

1-*t*-Butyl-3-phenylthioureidoazetidine: Mp 141°C.

Found: N, 16.16%. Calcd for $C_{14}H_{21}N_3S$: N, 15.95%.

1-t-Butyl-3-cyanoazetidine. This was prepared in a 73% yield (3.5 g) from 10 g of 1-*t*-butyl-3-azetidinyl tosylate and 6.8 g of potassium cyanide in 100 m*l* of methanol.[8] Bp 46—47°C/2 mmHg. IR: 2240, 1390 and 1365 cm^{-1}. Vpc: Porapak Q 1/8 in × 5.7 ft 75°C, N_2 35 m*l*/min, reten-

13) All melting and boiling points are uncorrected. The melting points were measured on a micro hot state. The infrared spectra were taken on neat liquid or on KBr tablets, and the NMR spectra were determined on Varian A 60-D at 60 MHz, tetramethylsilane being used as the internal standard. The vpc were run on Shimadzu Type GC-1B Gas Chromatograph, Varian Aerograph Series 1200, Varian Aerograph Model 705, and Varian Model 90-F-3 alternatively.

tion time, 10.2 min; SE30 on Varaport 30,1/4 in × 5 ft 80°C, N_2 60 ml/min, retention time, 12 min.

Found: C, 69.78; H, 10.03; N, 20.21%. Calcd for $C_8H_{14}N_2$: C, 69.52; H, 10.21; N, 20.27%.

Picrate Mp 203—205°C.

1-t-Butyl-3-aminomethylazetidine (II). The reduction of 2.9 g (0.021 mol) of 1-*t*-butyl-3-cyanoazetidine with 0.9 g of lithium aluminum hydride in 80 ml of absolute ether yielded 2.2 g (74%) of a pale yellow liquid which could not be purified by distillation since it bubbled vigorously over the distillation flask when heated up to 90°C/19 mmHg. This crude product was found homogeneous by vpc and was used in the deamination. IR: 3360, 3290, 1590, 1390, and 1364 cm^{-1}. n_D^{25} 1.4645. vpc: SE30 on Varaport 30, 1/8 in × 6 ft 70°C, N_2 30 ml/min, retention time, 7.2 min.

Dipicrate of II: Mp 230°C (decomp.).

Found: C, 40.26; H, 4.20; N, 18.88%. Calcd for $C_{20}H_{24}N_8O_{14}$: C, 40.01; H, 4.03; N, 18.66%.

1-*t*-Butyl-3-phenylthioureidomethylazetidine: Mp 99—100.5°C. IR: 3470, 3150, 1600, and 1530 cm^{-1}.

Found: C, 64.72; H, 8.28; N, 15.45%. Calcd for $C_{15}H_{23}N_3S$: C, 64.94; H, 8.36; N, 15.15%.

1-t-Butyl-2-cyanoazetidine.[9] This compound was obtained by the reaction of 6.8 g of 1-*t*-butylazetidine-2-carboxamide and a solution of triphenylphosphine dibromide (prepared from 13.8 g of triphenylphosphine, 8.4 g of bromine, and 10.6 g of triethylamine) in 75 ml of acetonitrile. A colorless oil (3 g, 50% yield) was obtained. Bp 43°C/1 mmHg. $n_D^{24.5}$ 1.4482. IR: 2240, 1385, and 1355 cm^{-1}.

Picrate: Mp 150—151°C.

Found: C, 46.00; H, 4.50; N, 19.14%. Calcd for $C_{14}H_{17}N_5O_7$: C, 45.78; H, 4.69; N, 19.07%.

1-t-Butyl-2-aminomethylazetidine (III).[12] The reduction of 3 g (0.022 mol) of 1-*t*-butyl-2-cyanoazetidine with 1 g of lithium aluminum hydride in 140 ml of absolute ether gave 2.5 g (80%) of a pale yellow liquid; this liquid was not purified by distillation for the same reason as has been given above. IR: 3360, 3280, 1590, 1388, and 1362 cm^{-1}. $n_D^{24.5}$ 1.4666. Vpc: SE30 on Varaport 30, 1/8 in × 6 ft 70°C, N_2 30 ml/min, retention time, 6 min.

Dipicrate of III: Mp 196.5—197.5°C.

Found: C, 39.72; H, 4.14; N, 18.81%. Calcd for $C_{20}H_{24}N_8O_{14}$: C, 40.01; H, 4.03; N, 18.66%.

1-*t*-Butyl-2-phenylthioureidomethylazetidine: Mp 105—105.5°C. IR: 3220, 3160, 1600, 1540 cm^{-1}.

Found: C, 64.66; H, 8.19; N, 15.43%. Calcd for $C_{15}H_{23}N_3S$: C, 64.94; H, 8.35; N, 15.14%.

1-t-Butyl-3-acetoxyazetidine (IV) from 1-t-Butyl-3-azetidinol (V).[6,11] This was prepared by the acetylation of 5.6 g (0.043 mol) of V with 6 g (0.059 mol) of acetic anhydride at room temperature for 5 hr. After neutralization with sodium carbonate, by extraction with ether an subsequent distillation 6.7 g (91% yield) of a colorless liquid boiling at 30—31°C/0.5 mmHg were obtained. n_D^{24} 1.4383. IR: 1745, 1377, and 1365 cm^{-1}. NMR (CCl_4; τ): 9.08 (9H, singlet), 8.04 (3H, singlet), 7.02 (2H, triplet), 6.60 (2H, triplet), 5.35—5.07 (1H, multiplet). Tlc: Tōyō (Japan) thin-layer chromatosheet (silica gel), R_f=0.38 (acetone). Vpc: Apiezon Grease L on Diasolid A 4 mm × 300 cm 152°C, He 60 ml/min, retention time, 5.2 min; Carbowax 20 M on Diasolid A 4 mm × 300 cm 162°C, He 60 ml/min, retention time, 5 min; SE30 on Varaport 30, 1/4 in × 5 ft, 75°C, N_2 60 ml/min, retention time, 9.8 min.

Found: C, 62.39; H, 9.76; N, 7.81%. Calcd for $C_9H_{17}NO_2$: C, 63.13; H, 10.00; N, 8.18%.

Picrate of IV: Mp 150.5—152.5°C.

Found: C, 44.71; H, 4.82; N, 14.28%. Calcd for $C_{15}H_{20}N_4O_9$: C, 45.00; H, 5.04; N, 14.00%.

1-t-Butyl-2-hydroxymethylazetidine (VIII).[5] From 14.4 g (0.09 mol) of 1-*t*-butyl-2-methoxycarbonylazetidine and 2.5 g of lithium aluminum hydride in absolute ether, 8.3 g (68.8% yield) of a colorless oil, bp 38—40.5°C/0.5 mmHg, were obtained. n_D^{21} 1.4624. IR: a broad peak at 3500—3200, 1380 and 1360 cm^{-1}.

Found: C, 66.86; H, 12.11; N, 9.08%. Calcd for $C_8H_{17}NO$: C, 67.29; H, 11.95; N, 9.07%.

Picrate of VIII: Mp 190—191°C (decomp.).

Found: C, 45.09; H, 5.25; N, 15.32%. Calcd for $C_{14}H_{20}N_4O_8$: C, 45.16; H, 5.41; N, 15.05%.

1-t-Butyl-2-acetoxymethylazetidine (IX) from VIII. The acetylation of 3 g (0.021 mol) of VIII with 2.3 g (0.022 mol) of acetic anhydride gave 3 g (77.3% yield) of a colorless oil. Bp 88.5—89.5°C/19 mmHg. $n_D^{25.4}$ 1.4450. IR: 1750, 1390 and 1370 cm^{-1}. NMR ($CDCl_3$, τ): (Fig. 1), 9.03 (9H, singlet), 7.96 (3H, singlet), 8.34—7.85 (2H, multiplet), 7.04—6.65 (2H, multiplet), 6.64—6.17 (1H, multiplet), 5.95 (1H, doublet, $J\simeq$5.6 Hz), 5.9 (1H, doublet, J=5.5 Hz). Vpc: SE30 on Varaport 30, 1/8 in × 6 ft 70°C, N_2 30 ml/min, retention time, 17.3 min; SE30 on Varaport 30, 1/4 in × 5 ft 80°C, N_2 60 ml/min, retention time, 11. 6 min.

Found: C, 64.58; H, 10.04; N, 7.46%. Calcd for $C_{10}H_{19}NO_2$: C, 64.83; H, 10.33; N, 7.56%.

Picrate of IX: Mp 129—130°C (decomp.).

Found: C, 46.36; H, 5.13; N, 13.78%. Calcd for $C_{16}H_{22}N_4O_9$: C, 46.37; H, 5.35; N, 13.52%.

Deamination of 1-t-Butyl-3-aminoazetidine (I). A solution of 1.1 g (0.015 mol) of sodium mitrite in 6 ml of water was slowly stirred into a solution of 1.2 g (0.01 mol) of I in 7.2 g of 50% acetic acid cooled with ice-salt. After 5 hr, the reaction mixture was made alkaline with sodium carbonate and was extracted with ether. After the subsequent removal of the ether, 2 ml of acetic anhydride were stirred into the deamination mixture with cooling and the stirring was continued at room temperature for five hours. Then the solution was made alkaline with excess sodium carbonate, extracted with ether, and dried over magnesium sulfate overnight. The ether was removed, and the residue was analyzed by vpc and tlc. Only one component, with a R_f value of 0.38 (acetone) was detected by tlc (similar to the authentic sample, IV, under the same conditions). Vpc: SE30 on Varaport 30, 1/4 in × 5 ft 75°C, N_2 60 ml/min, retention time, a very small peak at 2.6 min and a main peak at 9.8 min, with a peak area ratio of 6 : 94. The other vpc data were identical with those of IV. The fraction corresponding to the smaller peak, isolated by vpc, did not form a picrate and may be not an amine. The IR spectrum of the main product isolated by vpc was completely identical with that of the authentic sample of IV.

Picrate of the main product: Mp 150—152°C.

Found: C, 44.91; H, 4.76%. Calcd for $C_{15}H_{20}N_4O_9$: C, 45.00; H, 5.04%.

Deamination of 1-t-Butyl-3-aminomethylazetidine (II). (A) The amine II (1.4 g, 0.01 mol) was deaminated with 1.5 g (0.02 mol) of sodium nitrite in 50% acetic acid in a manner similar to that described above (omitting the acetylation in this experiment). The deamination mixture, which consisted of nearly equal amounts of 1-*t*-butyl-3-hydroxymethylazetidine (VI) and its acetate (VII) (detected by vpc), was then warmed with aqueous sodium hydroxide at 55°C for 3 hr and extracted with ether. After the removal of the ether, a part of the crude product was reserved for vpc analysis, and the remainder was distilled *in vacuo* to give 0.5 g of pure VI. Bp 66—68°C/0.5 mmHg, n_D^{25} 1.4626. IR: 3500—3100(broad), 1385 and 1360 cm^{-1}.

Vpc: only one compound presented; SE30 on Varaport 30, 1/8 in ×6 ft 70°C, N_2 30 m*l*/min, retention time, 8.8 min; SE30 on Varaport 30, 1/4 in × 5 ft 80°C, N_2 60 m*l*/min, retention time, 13.6 min.

Found: C, 66.81; H, 11.72; N, 9.48%. Calcd for $C_8H_{17}NO$: C, 67.08; H, 11.97; N, 9.78%.

Picrate of VI: Mp 143—144°C.

Found: N, 15.51%. Calcd for $C_{14}H_{20}N_4O_8$: 15.05%.

(B) The deamination of II was carried out again with 2 g (0.014 mol) of II and 1.5 g (0.022 mol) of sodium nitrite in 50% acetic acid; the deamination product was then allowed to react with acetic anhydride as in the deamination of I, and then it was analyzed. Both the crude product and the distilled product consist of only 1-*t*-butyl-3-acetoxymethylazetidine (VII), a colorless liquid boiling at 57—58°C/0.5 mmHg, n_D^{25} 1.4421. IR: 1745, 1390 and 1370 cm^{-1}. NMR: see the Discussion. Vpc: SE30 on Varaport 30, 1/4 in × 5 ft 80°C, N_2 60 m*l*/min, retention time, 29.8 min.

Found: C, 64.90; H, 10.60; N, 7.85%. Calcd for $C_{10}H_{19}NO_2$: C, 64.83; H, 10.34; N, 7.56%.

Picrate of VII: Mp 114°C.

Found: C, 46.10; H, 5.40; N, 13.82%. Calcd for $C_{16}H_{22}N_4O_9$: C, 46.38; H, 5.35; N, 13.52%.

*Deamination of 1-*t*-Butyl-2-aminomethylazetidine (III).* The amine III (2 g, 0.014 mol) in 10 m*l* of 50% acetic acid was allowed to react with 1.6 g (0.025 mol) of sodium nitrite in 10 m*l* of water; the products were similarly identified as their acetates. Vpc analyses showed that both the crude substance and the distilled (the fraction boiling between 40—78°C/18 mmHg was collected) substance were composed of two products in the ratio of 45.6 : 54.4 (vpc peak area).

The first product was isolated by vpc: SE30 on Varaport 30, 1/8 in × 6 ft 70°C, N_2 30 m*l*/min, retention time, 17.3 min; SE30 on Varaport 30, 1/4 in × 5 ft 80°C, N_2 60 m*l*/min, retention time, 11.6 min. The IR and NMR spectra and the results of the vpc analyses showed this compound to be identical with the authentic sample of IX prepared from VIII.

Found: C, 64.61; H, 10.17; N, 7.81%. Calcd for $C_{10}H_{19}NO_2$: C, 64.83; H, 10.33; N, 7.56%.

The second product (X) was also isolated by vpc: SE 30 on Varaport 30, 1/8 in × 6 ft 70°C, N_2 30 m*l*/min, retention time, 22.6 min; SE30 on Varaport 30, 1/4 in × 5 ft 80°C, N_2 60 m*l*/min, retention time, 14.7 min. IR: 1740, 1393 and 1370 cm^{-1}. NMR: see Fig. 2.

Found: C, 64.93; H, 10.07; N, 7.38%. Calcd for $C_{10}H_{19}NO_2$: C, 64.83; H, 10.33; N, 7.56%.

The authors are indebted to Professor Hiroshi Kato of Shinshu University, Japan, for his invaluable discussions and to Professor Yu-shia Cheng of National Taiwan University for allowing us to use the gas chromatograph there.

One of the authors, Teng-yueh Chen, wishes also to thank the National Council for the Science Development of China for a research grant.

Palladium-catalyzed Reactions of 1,3-Dienes with Active Methylene Compounds. IV.[1] Palladium-diphosphine Complex Catalysts

Kuniyuki TAKAHASHI, Akihisa MIYAKE, and Go HATA

Basic Research Laboratory, Toray Industries, Inc., Tebiro, Kamakura, Kanagawa-ken

(Received October 18, 1971)

Active methylene compounds, such as acetylacetone and ethyl acetoacetate, reacted with 1,3-butadiene in the presence of palladium-diphosphine complex catalysts to yield two 1 : 1 adducts, **1** and **2**. Primary and secondary amines also afforded two 1 : 1 adducts, **10** and **11**. Isoprene, 1,3-pentadiene, and 2,4-hexadiene also reacted with the active methylene compounds and the amines in a manner similar to that of 1,3-butadiene. The most effective and easily available catalyst is the combination of $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$ and sodium phenoxide.

Recently, the reactions of 1,3-butadiene with active hydrogen compounds by means of palladium catalysts have been reported to afford 2,7-octadienyl derivatives of active hydrogen compounds.[2-5] For example, the addition of 1,3-butadiene to active methylene compounds to which two electronegative groups are attached gives the corresponding 2,7-octadienyl derivatives.[5] In the reactions, tertiaryphosphine complexes of palladium are quite effective catalysts or catalyst components. The reactions seem to proceed through the coordination of the two molecules of 1,3-butadiene to the metal atom. A coordination of a bidentate donor is expected to have an effect on the number of the coordinated 1,3-butadiene molecule. We have investigated the catalytic behavior of bidentate phosphine complexes of palladium in the reactions of 1,3-dienes with active hydrogen compounds such as active methylene compounds, and with primary and secondary amines. In contrast to the reaction catalyzed by the unidentate phosphine complexes of palladium,[4,5] this reaction has been found to give 1 : 1 adducts. In the iron- or cobalt-catalyzed reaction of

1,3-butadiene with ethylene,[6] the coordination of bidentate diphosphine ligands such as $PhPCH_2CH_2PPh_2$ was found to have a drastic effect on the catalytic behavior as a result of the decrease in the number of coordination sites for the 1,3-dienes, thus yielding 1,4-hexadiene quite selectively. The reaction reported in this paper is another example of the change in the catalytic behavior by the coordination of the bidentate diphosphine ligands.

A part of this work has been reported in a preliminary communication.[1] The present paper will describe the reaction in detail.

This type of reaction has been applied to active methylene compounds, such as acetylacetone and ethyl acetoacetate, and to primary and secondary amines. Substituted 1,3-butadienes, such as isoprene, 1,3-pentadiene, and 2,4-hexadiene, reacted with the active hydrogen compounds to afford 1 : 1 adducts. However other active hydrogen compounds, such as alcohols, phenols, and carboxylic acids, did not give 1 : 1 adducts in the reaction with 1,3-dienes.

An active and easily available catalyst can be prepared by mixing $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$ and sodium phenoxide. A combination of palladium chloride, $Ph_2PCH_2CH_2PPh_2$ or $Ph_2PCH_2CH_2CH_2PPh_2$, and sodium phenoxide, one of palladium acetate and $Ph_2PCH_2CH_2PPh_2$, and a zerovalent palladium complex, $Pd(Ph_2PCH_2CH_2PPh_2)_2$, are also effective catalysts. In the reactions of amines, the presence of phenol has been found to enhance the catalytic activity.

The reaction products were identified by means of elemental analysis, molecular-weight measurements, vpc, and IR and NMR spectroscopies.

The reaction of 1,3-butadiene with active methylene compounds gave two 1 : 1 adducts, **1** and **2**, and 1 : 2 adducts, **3**. The 1 : 2 adducts were not isolated, but they were confirmed not to be 2,7-octadienyl derivatives[5] by a comparison of their vpc retention times with those of the octadienyl derivatives.

$$\mathrm{R^1_{R^2}}\!\!>\!\!CH{-}\underset{\displaystyle CH_3}{\underset{|}{CH}}{-}CH{=}CH_2 \quad \textbf{1}$$

$$+\ \mathrm{R^1_{R^2}}\!\!>\!\!CH{-}CH_2CH{=}CHCH_3 \quad \textbf{2}$$

$$+\ \mathrm{R^1_{R^2}}\!\!>\!\!C\!\!<\!\!\begin{matrix}C_4H_9\\C_4H_9\end{matrix} \quad \textbf{3}$$

	R^1	R^2
a	$COCH_3$	$COCH_3$
b	$COCH_3$	$COOC_2H_5$
c	$COOC_2H_5$	$COOC_2H_5$

The results of the reactions of 1,3-butadiene with the active methylene compounds catalyzed by $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$ and sodium phenoxide are summarized in Table 1. The infrared spectrum of **1** shows absorptions due to the out-of-plane deformation of $-CH{=}CH_2$ near 920 and 998 cm^{-1}, while that of **2** exhibited an absorption due to the out-of-plane deformation of *trans* $-CH{=}CH-$ near 965 cm^{-1} and no absorption due to *cis* $-CH{=}CH-$.

These reactions proceeded fairly rapidly at 150°C. The reaction of acetylacetone with 1,3-butadiene in the presence of $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$ and sodium phenoxide gave **1a**, **2a**, and **3a**. In the presence of a large excess of 1,3-butadiene, **3a** was the major product. Ethyl acetoacetate and diethyl malonate reacted with the diene to give **1b**, **2b**, and **3b**, and **1c** and **2c**, respectively. The reactivity of diethyl malonate was smaller than that of acetylacetone. No 1 : 2 adduct of diethyl malonate and 1,3-butadiene was observed.

2-Oxocyclododecanecarbaldehyde reacted with 1,3-butadiene to afford 2-oxo-2-(2-butenyl)cyclododecanecarbaldehyde. The reaction was accompanied by the partial elimination of the formyl group of the product.

The combination of $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$ and sodium phenoxide was the most efficient catalyst. The diphosphine complex, $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$, showed no catalytic activity. The addition of sodium phenoxide activated the palladium complex. A combination of palladium acetate and $Ph_2PCH_2CH_2PPh_2$, and one of $Pd(NO_2)_2(NH_3)_2$ and $Ph_2PCH_2CH_2PPh_2$, were effective catalysts without any sodium phenoxide. A diphosphine complex of Pd(0), $Pd(Ph_2PCH_2CH_2PPh_2)_2$, also catalyzed the reaction, although the activity was low. The presence of phenol or sodium phenoxide increased the catalytic activity of the complex of Pd(0) remarkably. The chain length of the ditertiaryphosphines, $Ph_2P(CH_2)_nPPh_2$ (n=1,2,3,4), was found to have a great effect on the catalytic behavior in the reaction of ethyl aectoacetate with 1,3-butadiene, as is shown in Table 3. It is clear that $Ph_2P(CH_2)_nPPh_2$ (n=2,3) is favorable ligand for the formation of the 1 : 1 adducts. The reaction using $Ph_2P(CH_2)_4PPh_2$ as a catalyst component gave mainly a 1 : 2 adduct, ethyl 2-acetyl-4,9-decadienoate, plus a small amount of the 1 : 1 adducts. The former diphosphines would form stable chelate rings with the palladium atom. However, the chelation of the latter diphosphine is much less favored, for the diphosphine behaves like a unidentate ligand.[5] α,α'-Dipyridyl and 2-(diphenylphosphine)-ethyl phenyl sulfide, $Ph_2PCH_2CH_2SPh$, showed a ligand effect on the products similar to that of $Ph_2P(CH_2)_nPPh_2$ (n=2,3).

Isoprene reacted with acetylacetone to give three kinds of 1 : 1 adducts with unidentified 2 : 1 adducts. The first product to emerge in the vpc (Silicone DC 550 column) was identified as **4** by IR and NMR-spectroscopic measurements.

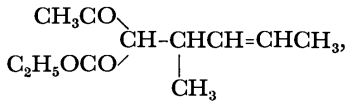
6

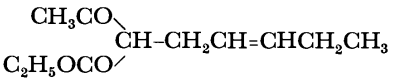
The compound **4** showed an IR absorption at 884 cm^{-1} due to the out-of-plane deformation of $>C=CH_2$, and NMR signals at 9.05 (3H, d, J=6.0 Hz), 8.30 (3H, s), 7.75 and 7.99 (6H, two s), 6.7—7.3(1H, m), 6.22(1H, d, J=11.0 Hz), and 5.25(2H, s). The spectrum of the second product to emerge showed a pair of triplet signals at 6.43 and 6.23 (J=7.5 Hz) due to the active methine hydrogen atom. This indicates that the product consists of two components. The IR spectrum exhibited no absorption characteristic of the $>C=CH_2$ or $-CH=CH_2$ bond, indicating that the products are not derived from the 1,2-addition of the active methylene to isoprene, but from the 1,4-addition. From the above spectral characteristics, the product can reasonably be estimated to be a mixture of **5** and **6**.

Ethyl acetoacetate also reacted with isoprene to give products similar to those derived from the 1,2- and 1,4-addition of the active methylene to isoprene.

The addition of 1,3-pentadiene to ethyl acetoacetate yielded two 1 : 1 adducts, **7** and **8**, in 61 and 7% yields respectively.

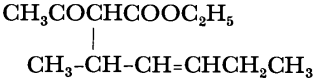


7



8

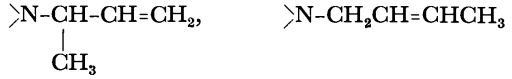
The reaction of 2,4-hexadiene with ethyl acetoacetate afforded a 1 : 1 adduct, **9**, selectively. The reactivity of the diene was much lower than those of 1,3-butadiene and isoprene. The results of the reaction



9

of active methylene compounds with substituted 1,3-butadienes are summarized in Table 4.

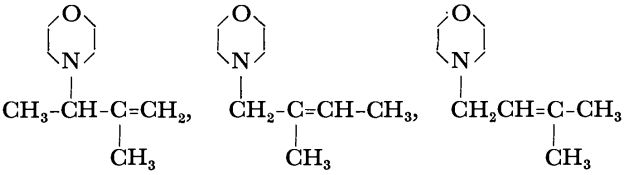
Primary and secondary amines also reacted with 1,3-butadiene in the presence of palladium-diphosphine complex catalysts to afford two 1 : 1 adducts, **10** and **11**. The results are shown in Table 5. The catalytic activity was remarkably enhanced by the addition of a small amount of phenol.



10 **11**

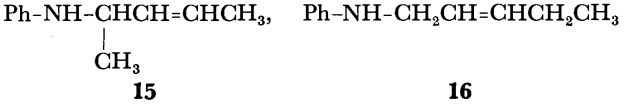
A change in the amount of phenol affected the yields of the products and the ratio of **11** to **10**, which was investigated in the reaction of piperidine with 1,3-butadiene. In the presence of a large amount of phenol, *N*-(2-butenyl)piperidine was the predominant product, as is shown in Table 5.

It is interesting to note that the reactivity of amines was associated with their basicity.[7] The more basic amines are more reactive. The reaction of morpholine (pK=9.61) and aniline (pK=9.42) gave the 1 : 1 adducts in 79 and 67% yields respectively. On the other hand, the reaction of less basic amines, such as *n*-butylamine (pK=3.39) and piperidine (pK=2.80), afforded the 1 : 1 adducts in 19 and 29% yields respectively.



12 **13** **14**

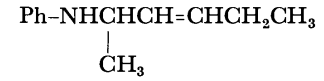
The addition of isoprene to morpholine in the presence of $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$, sodium phenoxide, and phenol resulted in a formation of 1 : 1 adducts, **12**, **13**, and **14**, in 9, 30, and 16% yields respectively.



15 **16**

The reaction of 1,3-pentadiene with aniline gave two kinds of 1 : 1 adducts, **15** and **16**, in 52 and 5% yields respectively. No 2 : 1 adduct was formed.

The addition of 2,4-hexadiene to aniline also afforded a 1 : 1 adduct, **17**.



17

Experimental

Reagents. $Ph_2P(CH_2)_nPPh_2$,[8] $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$,[9] $Pd(Ph_2PCH_2CH_2PPh_2)_2$,[9] $Pd(OCOCH_3)_2$,[10] $Pd(acac)_2$,[11] and $Pd(NO_2)_2(NH_3)_2$[12] were prepared by the previously-reported methods.

Acetylacetone, ethyl acetoacetate, diethyl malonate, and amines were purified by distillation. 2-Oxocyclododecanecarbaldehyde[13] was prepared according to the procedure

described before.

The purification of 1,3-butadiene was accomplished by the vaporization of the liquid diene containing triethylaluminum. Isoprene, 1,3-pentadiene, and 2,4-hexadiene were distilled under an argon atmosphere.

General Procedure for the Reaction of Active Methylene Compounds and Amines with 1,3-Butadiene. A 100 m*l* stainless steel autoclave was charged with an active methylene compound or amine and catalyst components. The liquid 1,3-butadiene was vaporized in order to condense it in an autoclave chilled with dry ice and methanol which had been evacuated beforehand. The reaction was carried out by stirring at 140—150°C. The reaction mixture was distilled and analyzed by vpc. The products were separated by fractional distillation and by the use of preparative gas chromatography. The analytical and physical data of the products are listed in Tables 6 and 7.

Reaction of Acetylacetone with 1,3-Butadiene. A mixture of 0.2 mol of acetylacetone, 0.3 mol of 1,3-butadiene, 0.25 mmol of $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$, and 2.5 mmol of sodium phenoxide was stirred at 140—151°C for 2 hr. The products consisted of **1a** (5.3 g, 17%), **2a** (13.2 g, 43%), **3a** (2.1 g, 5%), and a residue (1.6 g). The spectroscopic data of the products are as follows: **1a** ν_{max} 1722 and 1700 cm^{-1} (β-diketone), 1644, 998 and 922 cm^{-1} (-CH=CH_2); τ 9.03 (d, J=6.5 Hz, CH_3-C-C=), 7.95 and 7.87 (CH_3CO-), 6.7—7.3 (m, CO-C-CH-), 6.45 (d, J=10.0 Hz, CO-CH-CO) and 4.0—5.2 (m, olefinic protons), **2a** ν_{max} 1725, 1701 and 1605 cm^{-1} (β=diketone), 968 cm^{-1} (*trans* -CH=CH-); 8.36 (d, J=6.0 Hz, CH_3-C=), 7.95 and 7.92 (CH_3CO-), 7.70—7.35 (br. t, CO-C-CH_2-C=, keto form), 7.09 (br, s, CO-C-CH_2-C=, enol form), 6.40 (t, J=7.0 Hz, CO-CH-CO, keto form), and 4.8—4.4 (m, olefinic protons).

Reaction of 2-Oxocyclododecanecarbaldehyde with 1,3-Butadiene. A mixture of 0.036 mol of 2-oxocyclododecanecarbaldehyde, 0.1 mol of 1,3-butadiene, 0.18 mmol of $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$, and 1.8 mmol of phenoxide was stirred at 138—142°C for 15 hr. The distillation of the resultant solution gave 4.9 g of a fraction boiling at 168—170°C/3 mmHg. The IR spectrum of the fraction showed an absorption due to the out-of-plane deformation of *trans* -CH=CH- near 960 cm^{-1}, and no absorptions due to the out-of-plane deformation of -CH=CH_2. The intensity of the NMR signal due to -CHO corresponded to only about 0.2 H (τ 1.39, s). This fact indicates that the decarbonylation from the aldehyde group of the first formed product, 1-(2-butenyl)-2-oxocyclododecanecarbaldehyde, takes place. The treatment of the fraction with sodium ethoxide in ethanol gave 2-(2-butenyl)cyclododecanone. It exhibited the following spectral characteristics: ν_{max} 1708 cm^{-1} (>C=O) and 965 cm^{-1} (*trans* -CH=CH-); τ 4.8—4.3 (m, olefinic protons).

Reaction of Acetylacetone with Isoprene. A mixture of 0.1 mol of acetylacetone, 0.15 mol of isoprene, 0.25 mmol of $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$, and 2.5 mmol of sodium phenoxide was stirred at 136—146°C for 2 hr to afford **4** (1.1 g, 7%) and a mixture of **5** and **6** (10.1 g, 60%). The product **4** showed the following spectral characteristics: ν_{max} 1710 and 1700 cm^{-1} (β-diketone), 1644 and 898 cm^{-1} (>C=CH_2); τ 9.05 (d, J=6.0 Hz, CH_3-C-C=), 8.30 (s, CH_3C=), 7.99 and 7.75 (CH_3CO-), 7.3—6.7 (m, -CH-C-CO-), 6.22 (d, J=11.0 Hz, -CH-CO-), and 5.25 (s, CH_2=C-).

Reaction of Ethyl Acetoacetate with 1,3-Pentadiene. A mixture of 0.1 mol of ethyl acetoacetate, 0.15 mol of 1,3-pentadiene, 0.25 mmol of $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$, and 2.5 mmol of sodium phenoxide was stirred at 137—148°C for 15 hr to yield **7** (12.0 g, 61%) and **8** (1.4 g, 7%). The product **7** showed the following spectral characteristics: ν_{max} 1745 and 1715 cm^{-1} (keto ester), 970 cm^{-1} (*trans* -CH=CH-); 9.05 and 9.01 (two d, J=6.5 Hz, CH_3-C-C=), 8.80 and 8.76 (two t, J=7.0 Hz, CH_3C-O-), 8.41 (d, J=5.0 Hz, CH_3-C=), 7.95 and 7.91 (two s, CH_3CO-), 6.81 (d, J=10.0 Hz, -CO-CH-CO-), 5.92 and 5.87 (two q, J=7.0 Hz, -O-CH_2-C), and 4.9—4.3 (m, olefinic protons). Two kinds of signals due to acetyl, ethyl, and one of the methyl groups on the side chain indicate that the compound is a mixture of the *erythro* and *threo* isomers. The product **8**

a) X=-$CH(CH_3)CH=CH_2$, Y=-$CH_2CH=CHCH_3$.

showed the following spectral characteristics: ν_{max} 1745 and 1715 cm^{-1} (keto ester), 1648 and 967 cm^{-1} (*trans* -CH=CH-); τ 9.05 (t, $J=7.5$ Hz, CH_3C-C=), 8.75 (t, $J=7.0$ Hz, CH_3C-O-), 8.20—7.75 (m, C-CH_2-C=), 7.90 (s, CH_3CO-), 7.56 (t, $J=7.0$ Hz, -CO-C-CH_2-C), 6.68 (t, $J=7.0$ Hz, -CO-CH-CO-), 5.87 (q, $J=7.0$ Hz, -O-CH_2-C), and 4.9—4.3 (m, olefinic protons).

Reaction of Ethyl Acetoacetate with 2,4-Hexadiene. The reaction was carried out for 24 hr under the same conditions as those used in the reaction of ethyl acetoacetate with 1,3-pentadiene. The product (9.6 g, 45%) was identified as **9**: ν_{max} 1745 and 1715 cm^{-1} (keto ester), 1650 and 968 cm^{-1} (*trans* -CH=CH-); τ 9.1—8.8 (m, CH_3-C-C= and CH_3-C-C-CO), 8.68 and 8.66 (two t, $J=7.0$ Hz, -O-C-CH_3). 8.1—7.7 (m, C-CH_2-C=), 7.81 and 7.76 (two s, CH_3CO-), 7.4—6.8 (m, C-CH-C=), 6.60 (d, $J=10.0$ Hz, -CO-CH-CO-), 5.80 and 5.75 (two q, $J=7.0$ Hz, -O-CH_2-C), and 4.8—4.2 (m, olefinic protons).

Reaction of Aniline with 1,3-Butadiene. A mixture of 0.1 mol of aniline, 0.15 mol of 1,3-butadiene, 0.25 mmol of $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$, 2.5 mmol of sodium phenoxide, and 2.5 mmol of phenol was stirred at 85° for 3 hr to afford *N*-(1-methyl-2-propenyl)aniline (8.4 g, 57%) and *N*-(2-butenyl) aniline (1.4 g, 10%). The former product showed the following spectral characteristics: ν_{max} 3430 cm^{-1} (N-H), 1644, 992, and 915 cm^{-1} (-CH=CH_2); τ 8.77 (d, $J=7.0$ Hz, CH_3-C-C=), 6.60 (s, -NH-), 6.3—5.8 (m, -N-CH-), 5.15—4.27 (m, -CH=CH_2), and 3.65—2.75 (m, phenyl protons). *N*-(2-Butenyl)aniline exhibited the following spectral characteristics: ν_{max} 3410 cm^{-1} (N-H), 963 cm^{-1} (*trans* -CH=CH-); 8.35 (d, $J=5.0$ Hz, CH_3-C=), 6.55 s, N-H), 6.5—6.25 (m, -N-CH_2-C=), 4.8—4.1 (m, olefinic protons), and 3.65—2.75 (m, phenyl protons).

Reaction of Morpholine with Isoprene. A mixture of 0.1 mol of morpholine, 0.15 mol of isoprene, 0.25 mmol of $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$, 2.5 mmol of sodium phenoxide, and 2.5 mmol of phenol was stirred at 140—146°C for 2 hr to yield **12** (1.4 g, 9%), **13** (4.7 g, 30%), **14** (2.4 g, 16%), and a small amount of *N*-(dimethyl-2,7-octadienyl)morpholine. The products showed the following spectroscopic data: **12**: ν_{max} 1653 and 896 cm^{-1} (>C=CH_2); τ 8.93 (d, $J=6.5$ Hz, CH_3-C-C=), 8.36 (s, CH_3-C=), 7.7 and 6.45 (protons of morpholine), 7.34 (q, $J=6.5$ Hz, C-CH-C=), 5.29 and 5.22 (olefinic protons); **13**: ν_{max} 1674 (>C=C<); τ 8.44 (d, $J=3.0$ Hz, CH_3-C-N-), 8.42 (s, CH_3-C=), 7.55 and 6.45 (morpholine protons), 7.28 (s, -N-CH_2-C=), and 4.85—4.5 (m, -C=CH-); **14**: ν_{max} 1676 cm^{-1} (>C=C<); τ 8.40 and 8.31 (two s, =$C(CH_3)_2$), 7.70 and 6.50 (morpholine protons), 7.18 (d, $J=7.0$ Hz, -N-CH_2-C=), and 4.85 (t, $J=7.0$ Hz, -N-C-CH=).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1191—1198 (1972)

Phenolyses of 1-Adamantyl Chloride, Bromide, and *p*-Toluenesulfonate in Binary Mixtures of Phenol with Benzene. The Rates and the Product Distribution

Kunio Okamoto, Kôichi Matsubara, and Tomomi Kinoshita

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received October 25, 1971)

Adamantyl derivatives, the bridgehead substrates, have been chosen as the reference compounds in the assessment of the ionizing power of phenolic solvents in the S_N1-type solvolysis. The S_N1-phenolyses of 1-adamantyl chloride, bromide, and *p*-toluenesulfonate have been studied at several temperatures in binary mixtures of phenol with benzene; the enthalpies and entropies of activation have been calculated. Phenolysis has also been made on *t*-butyl chloride in order to estimate the Grunwald-Winstein *Y* values for the phenol-benzene solvents. The solvolysis rates of 1-adamantyl compounds, including the literature values, have been correlated with the *Y* values and also with the dielectric constants ($(D-1)/(2D+1)$). A significant deviation is found for the phenolic solvents in both correlations; this deviation is discussed in terms of the electrophilic assistance by hydrogen-bonding of the phenolic solvents to the leaving group. The isolated phenolysis products have been characterized as 1-adamantyl phenyl ether, *o*-, and *p*-1-adamantylphenols. The product compositions for the reactions of the ion-pair intermediate with the phenol molecule and with the phenoxide ion have been estimated on the basis of the variation in the overall product compositions, caused by the increase in the concentrations of the added phenoxide or amine.

In previous studies of the phenolysis rates for *t*-butyl halides,[1] benzyl chloride,[1] 1-phenylethyl derivatives,[2] and benzhydryl bromide,[1] it has been demonstrated that phenol is a typical solvolytic solvent and that it is prominent[3] in giving hydrogen-bonding electrophilic assistance to the ionization of these substrates. However, little study has been made of the quantitative assessment of its solvolytic ionizing power.

Because the adamantyl system has no possibilities for elimination or for rear-side solvent attack, and because, consequently, its solvolysis rate exactly reflects the rate of the ionization process, Schleyer and his collaborators[4] recently suggested the use of 1-adamantyl bromide as a reference compound for the assessment of the ionizing power of a solvolytic solvent.

In the present paper we will report on the results of the assessment of the ionizing power of the phenolic

solvent by the use of this new reference system, including 1-adamantyl chloride, bromide, and *p*-toluenesulfonate; we will also report on the distribution of 1-adamantyl phenyl ether, *o*-, and *p*-1-adamantylphenols in the phenolysis products.

Results

Phenolysis Rate in Binary Mixtures of Phenol with Benzene. The rates of phenolysis for 1-adamantyl chloride, bromide, and *p*-toluenesulfonate (0.05 M for each) were determined titrimetrically in the presence of 0.05 M triethylamine at several temperatures between 25 and 100°C for binary mixtures of 10, 20, 30, 50, and 70 wt% phenol with benzene. A good first-order behavior was observed for each run. The results are tabulated in Table 1.

a) Extrapolated from data at the other temperatures.
b) k_1 (80% aq. EtOH, 25.0°C) = 9.26×10^{-6} (sec^{-1}) (A. H. Fainberg and S. Winstein, *J. Amer. Chem. Soc.*, **78**, 2770 (1956)).

For the evaluation of the Grunwald-Winstein Y values[5] for these phenolic solvents, the phenolysis rates of *t*-butyl chloride in various phenol-benzene mixtures were also determined in the presence of triethylamine at several temperatures between 25 and 100°C; the results are presented in Table 2, along with the Y values.

The activation parameters for the adamantyl system, calculated from the data of Table 1, are presented in Table 3. The $\Delta H^{\neq}$ values for the phenolic solvents are smaller than those (19—27 kcal/mol) observed for such other hydroxylic solvents[4,6] as aqueous ethanol, aqueous methanol, aqueous dioxane, aqueous tetrahydrofuran, aqueous dimethyl sulfoxide, acetic acid, and formic acid; the $\Delta S^{\neq}$ values are more negative than the $\Delta S^{\neq}$ values (−2——18 eu) for the other hydroxylic solvents.[4,6] The activation parameters for *t*-butyl chloride are also presented in Table 3.

In order to examine the effect of the triethylamine concentration upon the first-order rate constant, the phenolysis rate for 1-adamantyl bromide was determined in a 50 wt% phenol-benzene solvent with variable triethylamine concentrations between 0.00 and 0.10 M at 50.0°C. The results are presented in Table 4. The rate constants are almost invariant in the concentration range employed.

The Product Distribution for the Phenolysis. The reaction mixture from the phenolysis of 1-adamantyl bromide in 50 wt% phenol-benzene at 50°C was chromatographed over silica gel after a usual work-up. The structures of the isolated products (1-adamantyl phenyl ether, *o*-, and *p*-1-adamantylphenols) were assigned on the basis of the elemental compositions and the NMR and IR spectra. The details of the physical constants for these products are described in Table 8 (see Experimental section).

The runs for the product distribution analysis were carried out in a base concentration about ten times greater than the substrate concentration; the composition was assayed by gas chromatography. The effects of added triethylamine and sodium phenoxide upon the product compositions are tabulated in Tables 5 and 6.

Rearrangement of 1-Adamantyl Phenyl Ether. It has been known that the *sec*- or *tert*-alkyl phenyl ether readily undergoes rearrangement to give *o*- and *p*-alkylphenols under an acidic catalyst.[7] In fact, in the absence of triethylamine, no phenyl ether was found in the phenolysis products of 1-adamantyl bromide, because of the rapid rearrangement of the phenyl ether to the *o*- and *p*-1-adamantylphenols, a rearrangement caused by the liberated HBr under the phenolysis conditions (Table 5). Therefore, the possibility of the rearrangement for 1-adamantyl phenyl ether could not be eliminated even with the acidity of the solvent phenol. However, we observed no rearrangement of the phenyl ether in the 50 wt% phenol-benzene solvent at 100°C in a 20-hr reaction.

Discussion

The S_N1 Character of the Phenolysis of 1-Adamantyl Derivatives. The effect of added triethylamine upon the titrimetric first-order rate constants for 1-adamantyl bromide are illustrated in Fig. 1 (see also Table 4). The rate constants are almost independent of the concentrations of triethylamine except in the concentration range lower than 0.0050 M. This constancy obviously indicates the S_N1 character of this phenolysis. However, a definite decrease in the rate constant in the absence of an added base indicates that there exists a small amount of "return" in the course of the ionization,[6] one of the simplest reaction schemes to account for the return process may be described as follows:

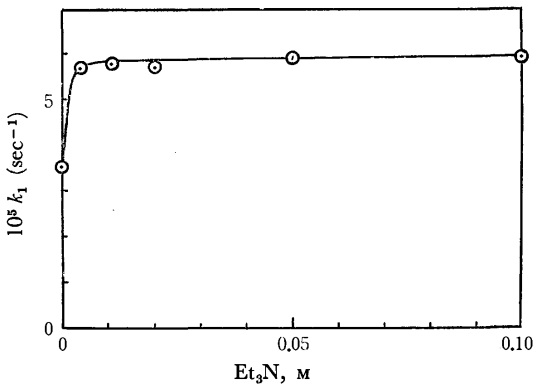

Fig. 1. The effect of added triethylamine upon the titrimetric first-order rate constants for 1-adamantyl bromide in the 1 : 1 (by wt.) Phenol-benzene solvent at 50.0°C.

$$RX \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [\text{Ion-pair Intermediate}] \xrightarrow{k_2[PhOH]+k_{2'}[PhO^{\ominus}]} \text{Products}$$

7) *Cf.* C. K. Ingold, "Structure and Mechanism in Organic Chemistry," 2nd ed., Cornell University Press, Ithaca and London (1969), pp. 904—906.

According to this scheme, we can express the total rate constant, $k_{obs.}$, by Eq. (1);

$$k_{obs.} = \frac{k_1(k_2[PhOH]+k_2'[PhO^{\ominus}])}{k_{-1}+k_2[PhOH]+k_2'[PhO^{\ominus}]} \quad (1)$$

When the magnitude of $(k_2[PhOH]+k_2'[PhO^{\ominus}])$ in Eq. (1) becomes much greater than that of k_{-1} at higher concentrations of $PhO^{\ominus}$, $k_{obs.}$ will virtually agree with k_1 (an ionization rate constant); on the contrary, in the absence of the phenoxide ion ($[PhO^{\ominus}]=0.00$), $k_{obs.}$ is expressed by Eq. (2);

$$k_{obs.} = \frac{k_1k_2[PhOH]}{k_{-1}+k_2[PhOH]} \quad (2)$$

Thus, if these equations apply to this phenolysis, we can calculate the rate ratio k_{-1}/k_2 to be 3.43 for the phenolysis of 1-adamantyl bromide in the 50 wt% phenol-benzene solvent at 50°C, assuming that $k_{obs.}$ at the 0.10 M triethylamine concentration is practically equal to k_1 (see Fig. 1).

In the phenolysis of 1-phenylethyl chloride, we observed a similar decrease in the titrimetric rate constant, k_t, at the lower concentrations of the added base.[8] In this case, the polarimetric rate constant, k_α, was found to be greater than the k_t value are the whole range of base concentrations; furthermore, the gap between k_α and k_t actually widened as the base concentration increased. From this fact we suggested the existence of two successive S_N1 intermediates in the phenolysis of 1-phenylethyl chloride.

In view of the observation for the 1-phenylethyl system, we can not exclusively rule out the possibility of the existence of two successive intermediates for the 1-adamantyl phenolysis, although we have tentatively treated the 1-adamantyl case as a phenolysis with a single ion-pair intermediate in the above reaction scheme. In order to work out a final solution for this problem, we would have to measure directly an intrinsic ionization rate constant, k_1, which may be afforded by the assessment of the oxygen-18 scrambling rate in the phenolysis, using the substrate containing the oxygen-18 atom in the carboxylic-leaving group; this remains a topic for future study.

Ionizing Power for the Phenol-Benzene Solvent. A plot of the logarithms of the rate constants (25°C) for 1-adamantyl bromide and *p*-toluenesulfonate *vs.* the Grunwald-Winstein *Y* values[5] is shown in Fig. 2. The open circles represent the values for the phenol-benzene solvents; the closed circles for 1-adamantyl bromide and *p*-toluenesulfonate designate, respectively the values cited by Schleyer *et al.*[4] and by Kevill *et al.*[6]

It is immediately obvious that the points for phenol-benzene solvents show significant deviations for both bromide and tosylate. Among the reported values, the points for aqueous trifluoroethanol[4] (1-adamantyl bromide) and for acetic acid (1-adamantyl tosylate) also deviate significantly. These anomalies may be ascribed to the results of the specific-substrate and leaving-group interaction.[4] If the extent of the ion-pair return for these phenolysis conditions is not significantly high, the high deviation of the phenolic solvent may be attributed to its high ability of hydrogen-bonding to the leaving group. This feature of the phenolic solvent has been suggested on the basis of the fact[3] that the substantial rate acceleration by *p*-nitrophenol in the acetolysis of *t*-butyl bromide is completely lost in the case of *o*-nitrophenol, the *intermolecular* hydrogen-bonding power of which is reduced or prevented by its *intramolecular* hydrogen-bonding.

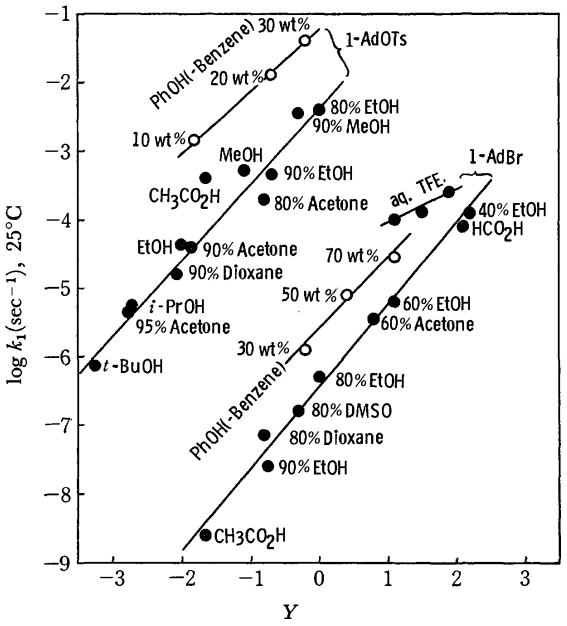

Fig. 2. Correlations of the 1-adamantyl solvolysis rates with Grunwald-Winstein *Y* values.

Since the role of the solvolytic solvent is generally ascribed to the electrostatic stabilization of the transition state,[4,9] it is of interest to express this general solvent effect on the solvolysis rates for 1-adamantyl and *t*-butyl systems by the use of a measure for the electrostatic solvation energy.

When we assume the transition state for the solvolysis to be a polarized molecule with a strong dipole moment, it is convenient to use a dielectric constant as a measure of the electrostatic solvation energy and to use the Eyring-Laidler treatment[10] in the assessment of the general solvent effect.

When we denote, following their treatment, the free-energies for the electrostatic solvation process for the molecule (RX) in the initial state and the molecule (RX^*) in the transition state by the expression proposed by Kirkwood,[11] the rate constants of the S_N1 solvolysis can be expressed as follows:[9]

$$\ln k_{obs.} + C = \left(\frac{N}{RT}\right)\left(\frac{D-1}{2D+1}\right)\left(\frac{\mu_{RX}^2}{r_{RX}^3} - \frac{\mu_{RX^*}^2}{r_{RX^*}^3}\right) + \frac{\Phi_{RX}-\Phi_{RX^*}}{RT} \quad (3)$$

8) K. Okamoto, K. Takeuchi, and H. Shingu, This Bulletin, **35**, 525 (1962).

where N is the Avogadro number, μ and r are the dipole moment (Debye unit) and the molecular radius (Å), respectively, D is the dielectric constant of the solvent, and the Φ's are non-electrostatic terms for the solvation process of RX and RX*.

Provided that the non-electrostatic terms are negligibly small or independent of the nature of the solvents, a plot of $\ln k_{obs.}$ (or $\log k_{obs.}$) *vs.* $(D-1)/(2D+1)$ should give a straight line. The plots of the $\log k_{obs.}$'s for 1-adamantyl derivatives and for *t*-butyl chloride *vs.* $(D-1)/(2D+1)$ for various solvents are shown in Figs. 3, 4, and 5. Among a variety of solvents, the phenol - benzene solvent and also the acetic acid solvent deviate far from the points expected for the linear relation between $\log k$ for the other hydroxylic solvents *vs.* $(D-1)/(2D+1)$, indicating that the non-electrostatic terms for these solvents are quite different in nature from the other solvents; thus, the gap from the straight line would mostly be a reflexion of the electrophilic acceleration by hydrogen-bonding, the existence of which has been suggested from the dispersion of the phenolic solvent and the acetic acid solvent in the $\log k$ *vs.* Y correlation (Fig. 2).

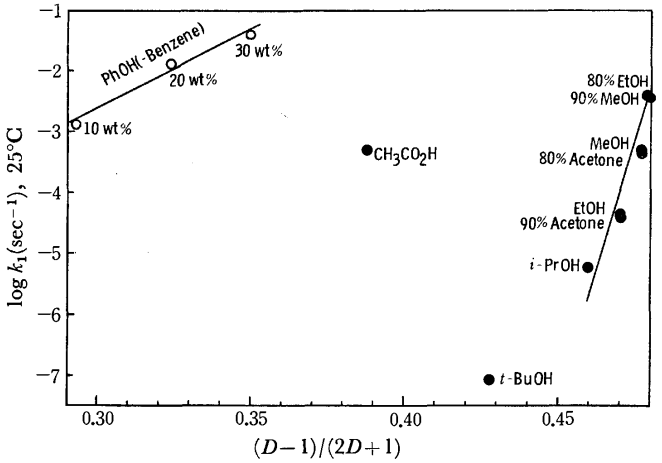

Fig. 4. The correlation of 1-adamantyl tosylate solvolysis rates with $(D-1)/(2D+1)$.

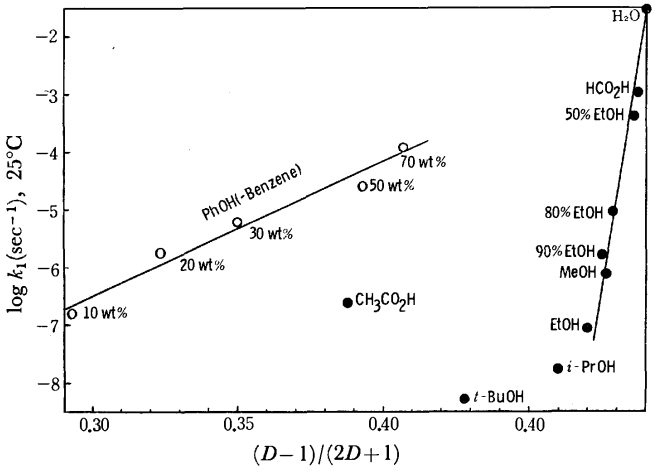

Fig. 5. The correlation of *t*-butyl chloride solvolysis rates with $(D-1)/(2D+1)$.

The Product Distribution for the Phenol and the Phenoxide Reactions. As is presented in the above reaction scheme, in the reaction media which contain sodium phenoxide (or triethylamine), there probably exist two kinds of nucleophiles, the phenol molecule and the phenoxide ion (or its ion-pair); it is of interest to estimate the distribution of the products with regard to each nucleophile.

The distribution for the products which stem from the reaction of the phenol molecule with the S_N1 intermediate can be graphically estimated by plotting the product compositions (r_{ether}, r_{ortho}, and r_{para}) *vs.* the concentrations of the added sodium phenoxide or triethylamine, and subsequently by extrapolating the r values (%) to a zero concentration of the added nucleophile. This is illustrated in Fig. 6 for the phenolysis of 1-adamantyl chloride in the 50 wt% phenol-benzene solvent at 100°C.

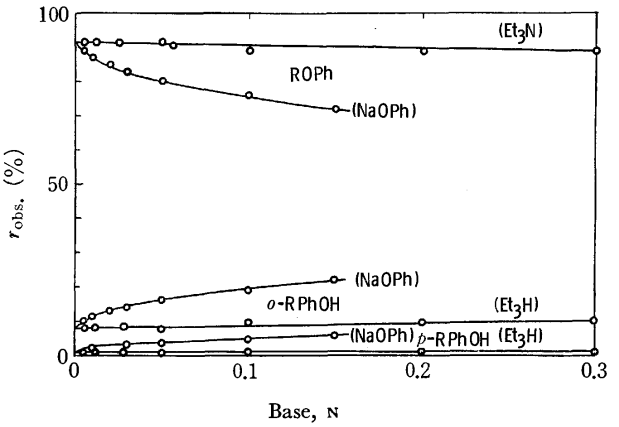

Fig. 6. The product distribution for 1-adamantyl chloride phenolysis in the presence of sodium phenoxide or triethylamine at 100.0°C.

The results of such estimations for chloride, bromide, and tosylate are tabulated in Table 7. The product distributions for the three substrates are in fair agreement with each other, irrespective of the nature of the leaving group and the reaction temperature; this may indicate the structural resemblance of the ion-pair intermediate for each substrate.

For the phenolysis with triethylamine, the product composition is less affected by the increase in the amine

Table 7. Product distributions for the reactions of the phenol molecule and tme phenoxide ion

	The reaction of the phenoxide ion			
RCl[a)]	100.0	70	23	9.0

a) The (k_2'/k_2) values for ROPh, *o*-RPhOH, and *p*-RPhOH are respectively 128, 134, and 56.

concentration compared with case of sodium phenoxide (Fig. 6). This can probably to be attributed to the lower dissociation degree of the phenol-triethylamine adduct into the free phenoxide ion.

The distribution of the products derived from the reaction of the phenoxide ion with the intermediate can be estimated by the following procedure. Provided that the phenoxide-ion concentrations are virtually constant at high ratios (>10) of the phenoxide concentration and the substrate concentration, we can derive the following equations (Eqs. (4), (5), and (6)) which express the relationships between the observed overall distributions of the products ($r_{obs.,\ ether}$, $r_{obs.,\ ortho}$, and $r_{obs.,\ para}$) and the estimated proportions of the products for the phenoxide reaction ($r_{i,\ ether}$, $r_{i,\ ortho}$, and $r_{i,\ para}$) and for the phenol reaction ($r_{m,\ ether}$, $r_{m,\ ortho}$, and $r_{m,\ para}$). The inferior letters, i, m, ether, *ortho*, and *para*, denote the phenoxide ion, the phenol molecule, 1-adamantyl phenyl ether, *o*-1-adamantylphenol, and *p*-1-adamantylphenol, respectively.

$$\mathrm{RX} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [\text{Ion-pair intermediate}] \longrightarrow \begin{cases} \xrightarrow{k_2[\mathrm{PhOH}]} \underset{r_{m,\ ether}}{\mathrm{ROPh}} + \underset{r_{m,\ ortho}}{o\text{-RPhOH}} + \underset{r_{m,\ para}}{p\text{-RPhOH}} \\ \xrightarrow{k_2'[\mathrm{PhO}^{\ominus}]} \underset{r_{i,\ ether}}{\mathrm{ROPh}} + \underset{r_{i,\ ortho}}{o\text{-RPhOH}} + \underset{r_{i,\ para}}{p\text{-RPhOH}} \end{cases}$$

$$r_{obs.,\ ether} \equiv \frac{[\mathrm{ROPh}]_\infty}{[\mathrm{ROPh}]_\infty + [o\text{-RPhOH}]_\infty + [p\text{-RPhOH}]_\infty} = \frac{k_2[\mathrm{PhOH}] \times r_{m,\ ether} + k_2'[\mathrm{PhO}^{\ominus}] \times r_{i,\ ether}}{k_2[\mathrm{PhOH}] + k_2'[\mathrm{PhO}^{\ominus}]} \quad (4)$$

$$r_{obs.,\ ortho} \equiv \frac{[o\text{-RPhOH}]_\infty}{[\mathrm{ROPh}]_\infty + [o\text{-RPhOH}]_\infty + [p\text{-RPhOH}]_\infty} = \frac{k_2[\mathrm{PhOH}] \times r_{m,\ ortho} + k_2'[\mathrm{PhO}^{\ominus}] \times r_{i,\ ortho}}{k_2[\mathrm{PhOH}] + k_2'[\mathrm{PhO}^{\ominus}]} \quad (5)$$

$$r_{obs.,\ para} \equiv \frac{[p\text{-RPhOH}]_\infty}{[\mathrm{ROPh}]_\infty + [o\text{-RPhOH}]_\infty + [p\text{-RPhOH}]_\infty} = \frac{k_2[\mathrm{PhOH}] \times r_{m,\ para} + k_2'[\mathrm{PhO}^{\ominus}] \times r_{i,\ para}}{k_2[\mathrm{PhOH}] + k_2'[\mathrm{PhO}^{\ominus}]} \quad (6)$$

Eqs. (4), (5), and (6) are transformed into Eq. (7), in which x denotes ether, *ortho*, or *para*.

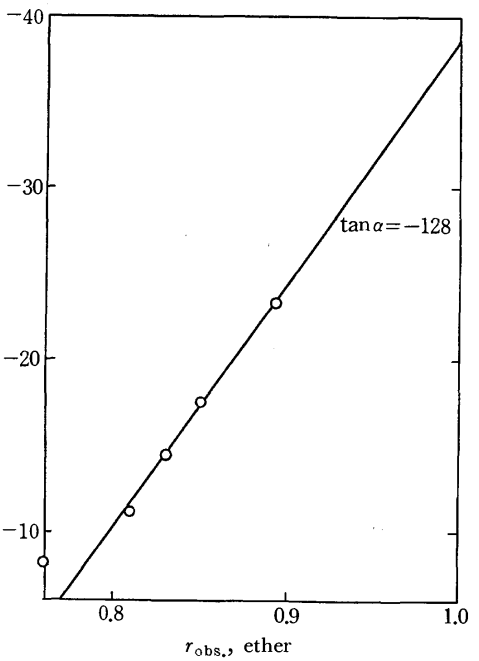

Fig. 7. Examination of the correlation shown in Fig. (6) for the distribution of 1-adamantyl phenyl ether in the 1-adamantyl chloride phenolysis products.

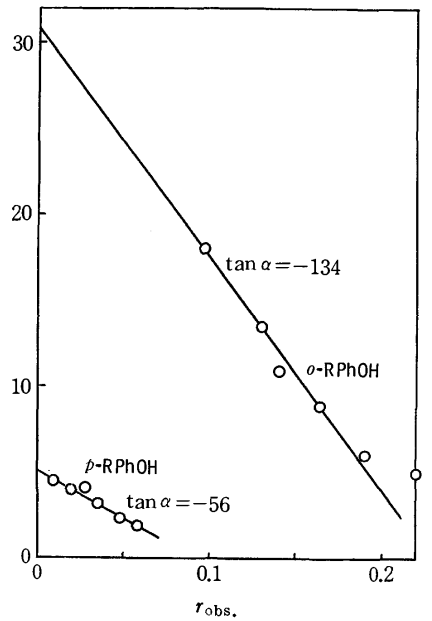

Fig. 8. Examination of the correlation shown in Eq. (6) for the distribution of *o*- and *p*-adamantylphenols in the 1-adamantyl chloride phenolysis products.

$$\frac{(r_{obs.,\ x} - r_{m,\ x})}{([\mathrm{PhO}^{\ominus}]/[\mathrm{PhOH}])} = \left(\frac{k_2'}{k_2}\right) r_{obs.,\ x} + \left(\frac{k_2'}{k_2}\right) r_{i,\ x} \quad (7)$$

In the reaction medium, the phenoxide ion may be dissolved as an ion-pair or as an aggregate at somewhat higher concentrations. However, in the lower concentrations we may consider that the phenoxide ion almost completely dissociates and that the ion concentration may be approximately equal to that of the added sodium phenoxide. Thus, using Eq. (7), we can evaluate the values for $r_{i,\ x}$ and for (k_2'/k_2) from the observed values for $r_{obs.,\ x}$, $r_{m,\ x}$ and $([\mathrm{PhO}^{\ominus}]/$

[PhOH]); a graphical procedure for the estimation of $r_{i,x}$'s is illustrated in Figs. (7) and (8) by plotting the amounts of the left side of Eq. (7) against $r_{obs\cdot,x}$ (see Table 6) for 1-adamantyl chloride. The results thus obtained for $r_{i,x}$ values are presented in Table 7. As is shown in Table 7, the sum of the $r_{i,x}$ values amounts to 102%. Therefore, the expected error limits for this estimation may be about 2% or less. The larger amount of carbon alkylation observed in the phenoxide reaction is in marked contrast to the results for the phenol reactions.

Experimental[12)]

Materials. 1-Adamantyl chloride mp 165.0—166.0°C (lit,[13)] 165°C), 1-adamantyl bromide mp 118.5—119.0°C (lit,[14)] 119—120°C), and 1-adamantyl *p*-toluenesulfonate mp 76—79°C (lit,[6)] 72—79°C) were prepared by the reported methods.[6,13)] Phenol, benzene, and triethylamine were fractionated just prior to use. Titration with a Karl Fischer reagent indicated the water content of phenol to be less than 10^{-2} M. The sodium phenoxide was prepared by refluxing the toluene solution of phenol with sodium metal.

Rate Measurement. Most of the measurements were carried out by a sealed ampoule technique; for the reactions which were rapid at lower temperatures, an aliquot method was employed. For the more rapid reactions of 1-adamantyl tosylate, a single sample for a specified reaction time was prepared as follows. A benzene solution of the tosylate and a triethylamine solution in 45 wt% phenol-(-benzene) were each temperature-equilibrated at 25°C, then they were mixed in a glass-stoppered reaction vessel at 25°C to make 30 wt% phenol (-benzene) solution; after a specified length of time, the reaction was interrupted by the addition of a large quantity of acetone, which had been cooled in Dry Ice-methanol, to the reaction vessel. For the phenolysis of 1-adamantyl bromide, carried out in the absence of a base, the free-space in the ampoule was filled with the HBr liberated in th course of the phenolysis. In that case, the ampoule had been cooled in liquid-nitrogen before it was opened in a large quantity of acetone which contained a small amount of aqueous NaOH.

The titrating solutions were, for the titration in acetic acid used as a stop-solvent, 0.05 N perchloric acid in acetic acid and, for the titration in an acetone solution, 0.01 N aqueous HCl. The indicators used were respectively crystal violet (in acetic acid) and lacmoid (in EtOH). All the rate data were treated graphically, and in each case the reaction was followed to at least 70% reaction and a smooth linear first-order relationship was obtained.

1-Adamantyl Bromide Phenolysis Products. 1-Adamantyl bromide (1.505 g, 7.00 mmol) was dissolved in 68 m*l* of a 1 : 1 (by wt.) mixture of phenol and benzene, containing triethylamine (1 m*l*, 7.17 mmol). After 28 hr (about 10 half-lives) at 50°C, the solution was diluted with 200 m*l* of ether, washed with 10% aqueous NaOH (25 m*l*×5) and 20% aqueous NaCl (100 m*l*×2), and dried ($MgSO_4$); most of solvent was then removed by distillation. A part (1/22 by wt.) of the residual liquid was examined by gas chromatography. The remainder was evaporated and separated by chromatography on silica gel (50 g) to give 0.866 g of 1-adamantyl phenyl ether (the eluent, 2 : 1 (by vol.) hexane-benzene), a 1 : 1 mixture (0.691 g) of 1-adamantyl phenyl, ether and *o*-1-adamantylphenol (1 : 2 hexane-benzene), and 0.048 g of *p*-1-adamantylphenol (20 : 1 benzene-ether). A mixture of the phenyl ether and the *ortho*-phenol was rechromatographed on alumina to give pure *o*-1-adamantylphenol (the eluent, 1 : 1 ether-ethanol). The structures of these products were assigned on the basis of the following spectral data and elemental compositions (Table 8). The gas-chromatographical analysis of a part of the reaction mixture, which had been taken out before the column chro-

matography, revealed the presence of 1-adamantyl phenyl ether, *o*-, and *p*-1-adamantylphenols in the ratio of 88.9 : 8.2 : 2.9 (see below).

Product Distribution Analysis by Gas Chromatography. To several mg of an adamantyl compound, placed in a 2-m*l* ampoule, we added 1 m*l* of a phenol - benzene (1 : 1 by wt.) mixture which also contained a specified amount of triethylamine or sodium phenoxide. The sealed ampoule was kept at a reaction temperature for 10 half-lives. The reaction mixture was diluted with 30 m*l* of benzene, washed with 10% aq. NaOH (3 m*l*) and 10% aq. NaCl (10 m*l*), dried ($MgSO_4$), and distilled to leave 0.3—0.5 m*l* of the residual liquid, which was analyzed by gas chromatography using a 2-m Apiezon Grease column at 200°C.

Measurement of the Dielectric Constant. A resonance method was used; the frequency of the oscillator was 1 MHz, and the calibration of the test condenser, equipped with two circular platinum plates, was carried out using water, acetic acid, and acetic anhydride as the standard liquids. The results are presented in Table 9.

The Substituent Effect. I. Normal Substituent Constants from the Hydrolysis of Substituted-benzyl Benzoates

Yasuhide YUKAWA, Yuho TSUNO, and Masami SAWADA

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

(Received October 28, 1971)

The rates of the alkaline hydrolyses of 24 *m*- and *p*-substituted-benzyl benzoates were measured in 70% (v/v) aqueous acetone at 25°C. The given set of σ^0 constants was precisely identical with our standard set derived from *m*- and *p*-substituted ethyl phenylacetates. The general utility of σ^0 constants is demonstrated for unexalted and exalted resonance reactivities as the reference scale in our LArSR equation:

$$\log k/k_0 = \rho(\sigma^0 + r^+\Delta\bar{\sigma}_R^+ + r^-\Delta\bar{\sigma}_R^-)$$

The accommodation of extensive data makes it evident that the Hammett equation in its original form[1] fails to correlate the substituent effect of *para* electron-releasing groups on the electrophilic reactivity with the same line, such as *meta* substituents.[2-4] The resonance theory clearly anticipates that the conjugatively electron-releasing *para* substituents can interact strongly by resonance with the electron-deficient reaction center and that, in consequence, such *para* substituents deviate from the correlation line of the uninteracting substituents.[2-7] The effect of the resonance interaction can vary with reactions, depending on the degree of electron deficiency of the reaction site at the transition state relative to the ground state (or the final to initial state). The effect of *meta* substituents is approximately independent of such an interaction, so as to give generally satisfactory correlations with the Hammett σ_m values.[6,7] It is, therefore, necessary to introduce an additional term for *para* substituent effects taking this interaction into account in order to improve the Hammett relation for these reactions.

With this point in mind, we proposed Eq. (1) for correlating the effect of substituents on the electrophilic reaction of benzene derivatives;[8,9]

$$\log k/k_0 = \rho(\sigma^0 + r\Delta\bar{\sigma}_R^+) \quad (1)$$

where r is the variable describing the degree of resonance, and where the parameter, $\Delta\bar{\sigma}_R^+$, which corresponds to $\sigma^+ - \sigma^0$ in Brown and Okamoto's scale,[3] is the substituent constant measuring the capacity of substituents to donate electrons by resonance.

σ^0 is the substituent constant defined originally by Taft[5,6] as the measure of the insulated substituted phenyl polar effect; we practically determined a set of reliable σ^0 values from the substituent effects on the alkaline hydrolysis of ethyl phenylacetates.[9]

The generality of this linear aromatic substituent reactivity (LArSR) relationship (1) was demonstrated by applying it to about 70 representative reactions with excellent precision.[9] Thereafter, our LArSR Eq. (1) has been utilized to describe the substituent effects on various electrophilic reactions and to elucidate the mechanism of reactions by a number of investigators.[9]

The same type of treatment has been shown to apply to the effects of conjugatively electron-attracting (+R) substituents on σ^--type nucleophilic reactions.[9] Eq. (1) can be thus modified as a generalized form to Eq. (2);

$$\log k/k_0 = \rho\sigma^0 + \phi^{\pm} \quad (2)$$

$$\phi^+ = \rho r^+\Delta\bar{\sigma}_R^+ \text{ and } \phi^- = \rho r^-\Delta\bar{\sigma}_R^-$$

where $\Delta\bar{\sigma}_R$ is defined in the same way as $\Delta\bar{\sigma}_R^+$ by the quantities, $\sigma^- - \sigma^0$, for *para* +R substituents. Eq. (2) is essentially a separation of the general substituent effect on benzene reactivities into the insulated aryl polar effect, $\rho\sigma^0$, and additional pi-resonance exaltation effects, ϕ^+ and ϕ^-.

In view of the importance of the σ^0 constant as the standard of our LArSR relationship, and also of other relevant equations, it is necessary to examine more critically the generality of our set of σ^0 constants in practical reactivity correlations. In this connection, we have derived a set of σ^0-type substituent constants from the substituent effect on the alkaline hydrolysis of substituted benzyl esters of benzoic acid, where additional pi-electronic interaction of substituents with the reaction center is precluded structurally by an intervening methylene group.

The present paper will be mainly concerned with a comparison of this new set of substituent constants with our standard set of σ^0 constants, and also with a statistical examination of the applicability and limitation of these substituent constants.

Experimental

Materials. Almost all of the *meta*- and *para*-substituted-benzyl benzoates were successfully prepared by the esterification of benzoyl chloride with the corresponding carbinols in pyridine.[10] Carbinols were obtained from the appropriate ethyl or methyl benzoates by the $LiAlH_4$ reduction[11] except for nitro derivatives. *m*- and *p*-Nitrobenzyl alcohols were obtained by the Meerwein-Ponndorf reduction[12] of the corresponding aldehydes. Next, five benzyl esters were obtained as follows.

m- *or* p-*Methylsulfonylbenzyl Benzoate*: A mixture of *m*- or *p*-methylmercaptobenzyl benzoate (7 g), glacial acetic acid (40 m*l*), and 30% aq. hydrogen peroxide (11 m*l*), was heated under reflux for 4 hr. After the usual procedure, the crude methylsulfonylbenzyl benzoate (6 g) obtained was recrystallized from benzene - hexane or benzene - ligroin.

p-*Methylsulfinylbenzyl Benzoate*: *p*-Methylmercaptobenzyl benzoate (6 g) and 30% aq. hydrogen peroxide (11 m*l*) in acetone (200 m*l*) were allowed to stand at room temperature for 6 days. After the removal of the solvent, the residue was taken up in benzene and ether. The organic layer was washed with an aq. Na_2CO_3 solution and dried. A solid product (5.5 g) was recrystallized from aq. EtOH or benzene - ligroin to give colorless needles.

m- *or* p-*Cyanobenzyl Benzoate*: A solution of *m*- or *p*-bromobenzyl benzoate and cuprous cyanide in DMF was refluxed for 4 hr. The hot solution was then treated by Friedman's method.[13] Recrystallization from ligroin - benzene or 80% aq. EtOH gave pure esters.

All of the esters were purified by fractionation or recrystallization. The physical constants and the elemental analysis

data of these esters are listed in Table 1.

Solvent. Acetone which had been treated with potassium permanganate was distilled, dried over potassium carbonate, and fractionated. The stock solution of 70% aqueous acetone was made up by mixing 70 parts (by volume) of acetone with 30 parts (by volume) of freshly-boiled, deionized water.

Kinetic Measurements. The rates of the alkaline hydrolyses of all the arylcarbinyl benzoates were determined in a 70% (v/v) aqueous acetone solution at 25.00°C±0.01 by means of the usual titration method. The procedure employed for those measurements was essentially the same as that described in the literature.[14] The aqueous acetone solution of sodium hydroxide was freshly prepared and standardized frequently. The reaction was started by mixing up solutions containing exactly equimolar amounts of the ester and alkali to give an initial concentration of about 0.02 mol/*l* in the final mixture. Ten m*l* samples were withdrawn from the reaction flask at appropriate intervals, quenched with 10 m*l* of a HCl solution of a known concentration (about 0.03—0.04 N) and about 10 m*l* of acetone, and back-titrated with a standardized NaOH solution of about 0.02 N, bromothymol blue being used as the indicator. The end point was obtained by comparison with the color standard of sodium benzoate in 70% aq. acetone containing the same amount of indicator as was used in the titration. For nitro, cyano, methylsulfinyl, and methylsulfonyl derivatives, a low initial concentration of about 0.01 mol/*l* was employed because of the higher reaction rate to be followed by titration, and a 15 m*l* aliquot was utilized in each titration.

The initial titer, C_0, was determined by the use of the alkaline solution alone. All runs which involved more than 11 measurements followed the second-order kinetic law, covering up to an 80% reaction. The bimolecular rate constant, k_2, was obtained from the plot of $(C_x-C_0)/t$ against C_x, where C_x was the titer at $t=X$. The experimental uncertainty of a run was estimated to be much better than 2%, and the rate constants from repeated runs agreed within ±2% or better.

Results and Discussion

Table 2 lists the rate constants of the hydrolyses of 24 *m*- and *p*-substituted-benzyl benzoates in 70% (v/v) aqueous acetone at 25°. A precise Hammett relation was followed only by *meta* substituted and *para* +R substituted derivatives. The reaction constant, ρ_m, was obtained by fitting a regression line to log k against σ_m for *meta* substituents (including unsubstituted one); $\rho_m=0.981$, $(\log k_0)_{calc}=-2.169$; correlation coefficient, 0.999, and standard deviation, ±0.005.[15] From the structural features of the present system, it can be expected that the substituent effect can be described in terms of the σ^0 constants.

The plot of log k/k_0 against σ^0 gives an excellent straight line for all *meta* and *para* substituents, as is shown in Fig. 1. The ρ value obtained by least-squares fitting was 0.978 with a satisfactorily high precision; correlation coefficient, 0.999, and standard deviation, ±0.010.[16] The correlational parameters are identical

to the above ρ_m and intercept within the precision on the order of experimental uncertainty. These facts indicate that alkaline hydrolysis of arylcarbinyl benzoates is a typical σ^0 reactivity in which any additional resonance effect of the direct conjugation between aryl groups and the reaction center is completely absent.

As has been pointed out frequently, most of σ^0 reactivities available are comparatively less sensitive to the substituent change because of the attenuating effect by intervening methylene. Naturally, the uncertainty involved in the derived set of substituent constants is inevitably larger. The fact that the present reaction resulted in an excellent σ^0 plot with a relatively high ρ value is highly appreciated; thus, this reaction may be utilized as the secondary reference in the determination of σ^0 constants. Apparent

σ^0 values calculated by using the ρ_m value of 0.981 are given in Table 3, together with our previous set of σ^0 values, which were determined by the alkaline hydrolysis of ethyl phenylacetates.[9] Taft's values[5] are also given for the sake of comparison. The present set agrees generally with our previous set of σ^0 values within ±0.01 in σ unit. Good agreement is also found between ours and Taft's set of σ^0 values within the usual limits of precision of substituent constants.

In the last column of the table, the standard set of σ values is also included for further comparison. The difference between σ^0 and σ is significant for conjugatively electron-releasing (−R) *para* substituents; the σ^0 values are less effectively electron-releasing than the σ values for all these *para* groups. This, of course, arises from the effective through-conjugation of these −R groups with the reaction center, COOH, in the σ-reference reaction, pK_a of benzoic acids. On the other hand, no significant difference between the two sets is observed in conjugatively electron-attract-

ing (+R) *para* substituents where no through-conjugation with the conjugatively electron-attracting reaction center, COOH, is effectively operative in σ-reactivities.

In *para* electron-attracting groups, the nitro group gives a slightly higher σ_p^0 value, 0.82, than the σ_p value, but for others the σ_p values appear to be generally applicable as substitute for the σ^0 values. The σ^0 values for $SOCH_3$ and SO_2CH_3 do not appear to have been well-examined, but the obtained values are practically in accord with the corresponding σ values. *Meta*- and *para*-cyano groups give slightly higher values than the corresponding σ values, but consistent behavior was observed for the cyano groups in the hydrolysis of ethyl benzoates in aqueous ethanol.[17]

The apparent σ^0 value for the *p*-methoxy group, −0.15, is obviously different from the standard σ^0 value, −0.10. Taft has statistically derived dual σ^0 constants for this group, −0.16 in non-aqueous solutions and −0.12 in aqueous solutions.[5] The substituent constant for the methoxy group is considerably sensitive to the solvent change; this variation may be due to the change in the degree of the hydrogen-bonding interaction of the solvent with the basic oxygen of the methoxy group. In the case of the *p*-phenoxy group, the solvent interaction with the substituent will be less effective because of the lower basicity of the oxygen and because of the highly-crowded circumstances around it.

The solvent effect on the substituent constants may be expected to operate more or less effectively for all

17) Y. Yukawa, Y. Tsuno, and M. Sawada, unpublished.

polar substituent groups, not only for electron-releasing groups but also for electron-attracting groups. Despite the minor variation due mostly to the solvent modification of the nature of the substituent groups, a set of finite substituent constants appears to be practically determined for most of the substituent groups.

Before we determine the most reliable set of σ^0 constants, it appears necessary to check more critically the applicability of these constants to general σ^0-type reactivities. As far as we are aware, not many more than a dozen sets of data on σ^0 reactivities in which the through-conjugation is precluded by the structure are available in the literature. Table 4 includes the correlational parameters for these sets of reactivities, obtained by the least-squares application with σ^0 constants, while Table 5 lists the sets of apparent σ_0 values obtained from the respective reactions using the correlation parameters shown in Table 4. In these calculations, we have employed the selected σ^0 values given in the first column of Table 3 as the primary standard. For well-behaving *para* substituents, σ_p^0 values taken in principle from our standard set were employed, but for *meta* substituents the standard σ_m values were employed instead of σ_m^0.

The correlations resulted are excellent, as measured by correlation coefficients higher than 0.99, in all cases. The uncertainty in the apparent σ^0 value is estimated to be within 0.02 σ-unit for most of the substituents in each series, although it depends largely upon the magnitude of ρ's.

If the σ^0 values were applicable only to precise correlations of the reactivities of the specified structure insulated by intervening methylene, their utility would be so limited as to be of little value. However, their exist a substantial number of reactivities which are practically correlated by σ^0 values within the limits of the usual precision of fit. Table 6 shows the results of σ^0 correlations for such a class of reactivities of interest. The results are of practical importance not only in examining the generality of σ^0, but also in estimating the σ^0 values for substituents other than those involved in the σ^0 resorting, since the substituents involved in the former specified class of reactivities are limited in fact to the substituents of the so-called

well-behaving category. The apparent substituent constants derived are given in Table 7.

The substituent constant, σ^0, is a measure of the substituent effect referred to the special case of Eq. (2), where both ϕ^+ and ϕ^- are diminished to zero (i.e., $r^+=r^-=0$). These reactivities may be classified as the apparent σ^0 class reactivity, regardless of the reaction mechanism or the interaction mechanism of substituents and the reaction center. Davis's data on the ion-pair formation of substituted benzoic acids with diphenylguanidine (Entry 15) are highly instructive. The course of the reaction may be compared with that of the acid dissociation of benzoic acids, where −R *para* substituents exhibit a substantial pi-resonance exaltation to give Hammett σ values ($r^+=0.27$). The excellent fit to the σ^0 of the −R *para* groups in the ion-pair formation may perhaps be due to the cancellation of the exalted resonance interactions of substituents and the reaction center between the initial and final states. In Entry 18 (the pK_a of phenoxyacetic acids), −R *para* groups such as cyano and nitro groups indicate the exalted contribution to a considerable extent (see Table 7). In this system, the through-conjugation with the reaction site is, of course, inhibited by the intervening methylene, while the insulated pi-system is extended to the phenoxy lone-pair orbital with which the direct resonance interaction of +R *para* groups is possible. Thus, the conjugative electron-withdrawal of +R groups can be relatively exalted as compared with that of the same groups attached to the insulated benzene pi-system.

In general reactivities, both ϕ^+ and ϕ^- terms, or, often, either one of them, are exalted to varying extents, as is evidenced by the wide applicability of Eq. (2). The extent of contributions from both terms varies continuously, depending upon reactions, but the relative importance of the two terms is independent of each other. As a general trend, however, a significant contribution of one of them is accompanied by an insignificant or, usually, a minimized contribution of the other. The effect of −R substituents in the σ^--type reactivities may be minimized to follow σ^0 constants, regardless of the exalted resonance contribution from +R *para* substituents, since no significant additional resonance interaction can be expected between −R *para* substituents and the electron-donative reaction center. The reactivities which correspond to the case of $r^->0$ and $r^+=0$ in Eq. (2) can thus be utilized to examine the significance of σ^0 values for −R *para* substituents.

Entry 22 is a typical example of such a case. In this reaction, +R *para* substituents give a high r^- value of 0.52 characteristic of σ^--type nucleophilic reactivities, which −R *para* substituents fit the ρ_m line with σ_p^0 values. The −R group in more strongly σ^--type reactivities, such as the pK_a of phenols, may be expected to give good correlations with the σ_p^0 values. This is actually true for weak −R *para* substituents in the reaction (Entry 23); however, the examination of the effect of strongly electron-releasing groups suffers from the levelling effect.

The entries of Table 6 thus consist of two classes of reactivities; one corresponds to the case of $r^+=r^-=0$ (Entries 15—18), and the other, to $r^+=0$ but $r^->0$ (Entries 19—23). The former class reactivities are correlated with the σ^0 values in closely the same way, otherwise noted, as for the specified class of reactivities given in Table 4. The latter class satisfies the partial σ^0 correlations, and the correlational data of this class are based upon all *meta* substituents and only −R *para* substituents.

It is clear that the σ^0 values for the respective substituents in the specified σ^0 reactivity class (in Table 5) are not different from those in the apparent σ^0 reactivity class, and that, furtheremore, there is no essential difference in the apparent σ^0 values for −R substituents between the class $r^+=0$ but $r^->0$ and the above two classes. The constancy of the apparent σ^0 values appears to be of a comparable order for *meta* and *para* substituents, or a little better for the former substituents. The respective values are all in good agreement with those of our sets given in Table 3. A set of averaged σ^0 values is given for the respective substituents in the first column of Table 8. The average deviation is less than ±0.02 for all the substituents. The values marked in Tables 5 and 7 were not included in the averaging. As has been mentioned before,

the *p*-methoxy group appears to require also another special value, −0.15, for the reactivity in a non-aqueous solution or in a less aqueous one as well as the usual value of −0.100. For the *p*-fluoro group, a constant value, 0.20, is obtained from these entries except for the dissociations of benzylammonium ions, for which another σ^0 value, 0.09, appears to be required.

All the *meta* substituents gave values of σ^0 identical with the corresponding σ_m values. As is shown in Table 3, the present reaction results in considerably higher σ^0 values for both *meta* and *para* cyano groups. The average set gives the same value for *meta* cyano group, but for *p*-cyano group gives a value rather close to the σ_p value. However, the considerably large average deviation and the insufficient number of entries make this conclusion less significant.

As a summary of these results, the set in the last column of Table 8 can be proposed as the most reliable set of σ^0 constants. The values for representative *meta* substituents are taken from the standard σ_m values, which are derived by definition from the pK_a's of benzoic acids in water (25°C). For several substituents of which the standard σ values are unknown, σ^0 values from our studies are selected. The values for *para* substituents are generally taken from our previous set of $\sigma_p{}^0$ values derived from the alkaline hydrolysis of ethyl phenylacetates. Although the set of averaged values might also be taken as the standard, we prefer to define the standard set by a single set of data since the averaged value is subject to change depending on the number of data entries. This definition is reasonable since the agreement of the set with the averaged set is well within the practical limits of uncertainty of Hammett-type substituent constants.

This set of σ^0 values may, we believe, be reliable to the order of 0.01 σ-unit for most of the substituents. The σ^0 values for *p*-NMe_2 and *p*-OH are not, however, regarded as equally reliable as those for other groups because of the insufficient number of existing data. Further examination for these substituents is now in progress. The σ^0 constants selected for +R *para* substituents are not well-established except for the *p*-nitro group. For *p*-SO_2Me and *p*-SOMe, even their standard σ values have not yet been well-established; additional data must be obtained.

Our proposed set of σ^0 values is not intended for direct application to the limited class of σ^0 reactivities, but for general use as a reference substituent constant in our LArSR equation; the σ^0 constants are referred to the unexalted substituent effect (*i.e.*, $r^+=r^-=0$), and they give, by definition, the resonance substituent constants, $\Delta\bar{\sigma}_R^+$ or $\Delta\bar{\sigma}_R^-$, as the increments from σ^+ or σ^-.

In general applications of our LArSR equation as well as in the derivation of σ^0, σ^+, and σ^- constants, the determination of appropriate ρ values should be required. Since the effect of *para* substituents usually involves a certain extent of resonance exaltation, the ρ value must be practically determined by the correlation of the *meta*-reactivities with the σ_m values. That is, the ρ value and all these treatments are based primarily upon the assumption of the reaction independency of the *meta*-substituent effects, or on the assumption of the constancy of σ_m values. This is the reason why we have selected the standard σ_m values for the above set of σ^0 values for well-behaving *meta* substituents.

The set of $\sigma_p{}^0$ values is derived from the data in aqueous organic solvents. Since the standard σ values are given by the changes in the pK_a values of benzoic acids in pure water, we have to take into account the solvent change of substituent constants when we compare the present set with the corresponding σ values. However, the substituent constants obtained in aqueous organic solutions appear to be practically of a wider application in describing the substituent effects on general organic reactivities, because most of the data are obtained not in purely aqueous solutions, but in aqueous organic solutions.

The Substituent Effect. II. Normal Substituent Constants for Polynuclear Aryls from the Hydrolysis of Arylcarbinyl Benzoates

Masami SAWADA, Yuho TSUNO, and Yasuhide YUKAWA

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

(Received October 28, 1971)

The rates of the alkaline hydrolysis of 9 polynuclear arylcarbinyl benzoates were measured in 70% (v/v) aqueous acetone at 25°C. The new set of σ^0 values for polynuclear aryls was obtained, using the ρ_m value established by the hydrolysis of *m*- and *p*-substituted-benzyl benzoates. In the present reaction, it is possible to assume that the peri-hydrogen steric effect is practically absent, bacause *o*-tolyl derivative gives a σ^0 value comparable with that of *p*-tolyl, and 1-naphthyl with that of 2-naphthyl. The set thus obtained can be successfully described in terms of two components; self-atom polarizability and Streitwieser's inductive index, $\sum r_{ij}^{-1}$.

The correlation of the reactivities of polynuclear aromatic hydrocarbon systems with various molecular orbital reactivity indices is very significant as a connection of the empirical results with the theory.[1] Almost all of the previous comparisons have been based on a neglect of the contribution of substantial inductive effects of polynuclear aryls.[2] In a more exact approach, a consideration of this effect is required. In order to obtain empirically information about the inductive effect, it is useful to introduce the concept of a normal substituent constant,[3] σ^0, for polynuclear aryls, an insulated aryl polar effect relative to the parent phenyl group.

In our previous papers,[4,5] it has been shown that the LArSR relationship is generally applicable to the electrophilic reactivities of the substituted benzene system:

$$\log k/k_0 = \rho(\sigma^0 + r^+ \Delta\bar{\sigma}_R^+)$$

Therefore, it can naturally be expected that the above treatment can be extended without any modification to a correlation of the polynuclear aryl reactivities.[6] In view of the importance of the σ^0 constants as a standard for the above treatment, it is necessary first of all to examine the normal substituent constants for polynuclear aryls. Thus, we have studied the alkaline hydrolysis of polynuclear arylcarbinyl benzoates in 70% aqueous acetone, $ArCH_2OCOPh$. As has been described in the foregoing paper, it has been established that the hydrolysis of *m*- and *p*-substituted-benzyl benzoates under the same conditions[5] can be correlated by σ^0, giving a comparatively large ρ_m of 0.981.

The rate constants obtained for polynuclear aryl derivatives are given in Table 1. The σ^0 constant represents the total electronic effect of substituted phenyl groups arising in response to the perturbation due to the change in the reaction site within the aryl pi-framework; this effect is in turn transmitted to the site without any additional pi-delocalization. This concept of σ^0 definition may be extended without modification to polynuclear aryl residues as well as to substituted phenyl groups. It is, then, quite reasonable to derive a set of σ^0 constants for polynuclear aryl moieties from the present insulated system. The apparent substituent constants for polynuclear aryl groups are calculated in the same way as for *m*- and *p*- substituted phenyl groups, using the ρ_m value of 0.981 and $\log k_0 = -2.169$ for the unsubstituted phenyl group. They are given in Table 1. From the uncertainty involved in the σ^0 values for substituted phenyl groups, the value may be estimated to be reliable to the order of ± 0.01.

TABLE 1. RATE CONSTANTS OF HYDROLYSIS OF ARYLCARBINYL BENZOATES AND σ^0 VALUES FOR POLYNUCLEAR ARYLS

Aryl	$10^3 \times k_2$ [a]	σ^0
Phenyl	6.74	0.000
p-Tolyl	5.13	−0.124[b]
o-Tolyl	4.97	
4-Biphenylyl	7.35	0.039[b]
3-Biphenylyl	6.85	0.005
2-Fluorenyl	6.78	0.001
1-Naphthyl	7.54	0.048
2-Naphthyl	7.74	0.062[b]
2-Phenanthryl	9.12	0.131
3-Phenanthryl	8.67	0.109
9-Phenanthryl	8.74	0.113
9-Anthryl	6.84	0.004

a) $l \cdot mol^{-1} \cdot sec^{-1}$. b) Ref. 4.

The σ^0 values obtained are positive for all the polynuclear aryls, that is, all electron-attracting as compared with the reference, the unsubstituted phenyl group. It is worthy of note that the value of σ^0 appears to change mainly dependent upon the number of rings. Naphthyls give nearly the same values of σ^0 around 0.05; this is in clear contrast with the results obtained in the other typical insulated reactivities, such as the alkaline hydrolysis of ethyl arylacetates.[7] Similarly, phenanthryl indicates σ^0 values of the same order of magnitude for three positions.

A very interesting feature in the hydrolysis of arylcarbinyl benzoates is that the 1-naphthyl derivative gives a rate comparable with that of the 2-naphthyl derivative and the *o*-tolyl one comparable with that of the *p*-tolyl one. In the case of the hydrolysis of ethyl arylacetates in aqueous ethanol,[7] the 2-naphthyl group gives an identical apparent σ^0, while the 1-naphthyl group gives a completely different value (−0.35) from the value in the present reaction. These seems to be a clear difference between the present data and those of the hydrolysis of arylacetic esters. The 1-/2-naphthyl and *o*-/*p*-tolyl rate ratios of insulated reactivities and also the other relevant reactivities are listed in Table 2. The dependency of the ratio on the reaction appears to be nearly the same for both naphthyl and tolyl derivatives, as is to be expected from the geometrical similarity. The different dependency can be reasonably attributed to the structural feature of the present system. As compared with arylacetic esters, the reaction site carbonyl of the arylcarbinyl benzoate is located one oxygen atom far from the aryl moiety.

Berliner *et al.* have recently reported the rates of the alkaline hydrolysis of methyl arylacetates.[8] Figure 1 shows the plots of log $k/k_{(Ph)}$ in aqueous methanol at 25°C against the σ^0 values. Unhindered aryls apparently fall on or close to a line, whereas the deviations are significant for hindered 1-naphthyl and 9-phenanthryl, and twice as much remarkable for 9-anthryl, which possesses two peri-hydrogens. The disposition can be, of course, attributable to the difference in the locations of the reaction site carbonyls of the two systems. The steric hindrance with peri-hydrogen to the attacking hydroxide ion is significantly operative in the arylacetates, but it should be far less effective in the present system. This is evident from the comparison shown in Table 2.

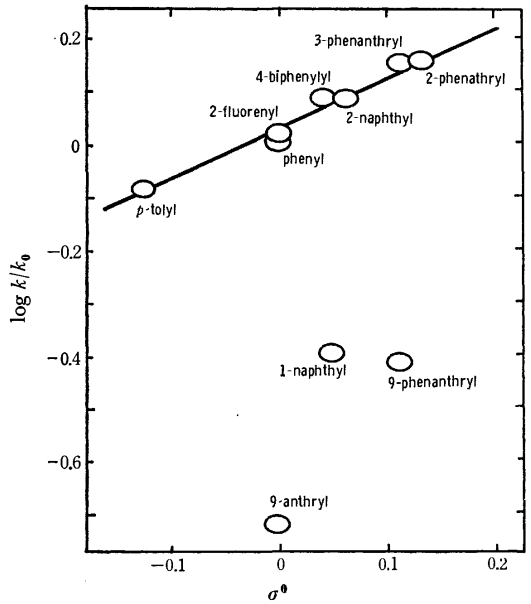

Fig. 1. Plots of the rates of hydrolysis of methyl arylacetates against σ^0.

It is perhaps not unreasonable to presume that the steric hindrance with peri-hydrogen is effectively absent in the present system. The present set of σ^0 values for polynuclear aryl groups might be regarded as parameters measuring only electronic effects and practically including no steric effect. As has been mentioned before, the steric effect does not appear to be practically effective in the dissociation of arylacetic or arylpropionic acids; the reactivity ratio of α-/β-naphthyl, 1.05, is comparable with that in the present reaction.[9] Unfortunately, no data for further comparison are available; indeed, even if they will be, the experimental uncertainty would outweigh the minor variation in σ^0 due to the structural changes of

Table 2. Rate ratios (k^1/k^2 for naphthyl and k^o/k^p for tolyl) of insulated and other relevant reactivities

Reaction	k^1/k^2	k^o/k^p
Benzyl benzoates+OH^- in 70% aq. acetone	0.97[a]	0.97[a]

polynuclear aromatic hydrocarbons, for the extremely small ρ value of the dissociation.

The noticeable features of the present system, the structurally insulated reactivity with a relatively large ρ value and practically no steric effect with peri-hydrogen, may sufficiently justify our attempt to determine an extended set of σ^0 values for polynuclear aryl groups on the basis of the present data. The derivative set of σ^0 values probably consists of idealized substituent constants, especially for hindered aryl moieties. Since the steric effect with peri-hydrogen is generally severe in the existing reactivity data, as may be seen in the hydrolysis of arylacetic esters, the present set of σ^0 values is not expected to serve widely as a reference for the simple linear free energy relationship, even for σ^0 reactivity data,

$$\log k/k_{(\mathrm{Ph})} = \rho\sigma^0$$

but instead the set will serve as a reference in estimating the importance of the peri interaction of given systems from the deviations of the hindered derivatives from the $\rho\sigma^0$ correlations.

It appears certain that the set has another important advantage in comparing the empirically derived electronic effects with theory at the various sites in the polynuclear aryl pi-system. As the theory predicts, the electronically most active site in the aryl pi-system being in common the hindered position, a reliable comparison of the electronic effects covering a significant extent of the variation in the theoretical index is possible with the present data, which include the reactivities of hindered sites.

Attempts have been made in vain by various investigators to ascertain the linear free energy relationship for the reactivities of polynuclear aromatic hydrocarbon derivatives, and further attempts have been also made to correlate them with the numerical index from simple MO theory.

As has been described in a previous paper on the analysis of substituent effects in *m*- and *p*-substituted phenyl derivatives, the standard substituent constant can be given by the combination of two intrinsic terms, inductive and pi-electronic effects.[10]

$$\sigma^0 = \sigma_i + \sigma_\pi$$

The σ^0 constant for polynuclear aryls might be similarly separable into the corresponding two terms. The inductive effect (σ_i) for polynuclear aryls might be referable to the electronegativities of additional sp^2-carbon atoms and might, then, have an electron-attracting character. Therefore, this might depend not only on the size, but also on the position of the site, of the respective aryls. The pi-electronic effect (σ_π) is the effect of only pi-electrons; it should be compared with the reactivity indices obtained by the simple MO theory.

As a theoretical scale measuring the σ_π effect involved in σ^0, self-atom polarizability, π_{rr}, (or free valence) would appear to be the most suitable,[1] for this theoretical index corresponds to the perturbation within the pi-electron framework of the aromatic system without reflecting the exo-conjugation interaction with the reaction site.

On the other hand, there seems to exist no appropriate theoretical indices of the inductive strength of polynuclear aryl groups. Streitwieser and Lawler recently proposed, as the inductive index, the relative quantity, Σr_{ij}^{-1}, in which r_{ij} denotes the distance of every carbon atom in the aromatic system from the carbon carrying the reaction site or from the side chain to which the reaction site is attached.[11] The plots of σ^0 against this set of inductive indices, as is shown in Fig. 2, resulted in a scattered pattern. Un-

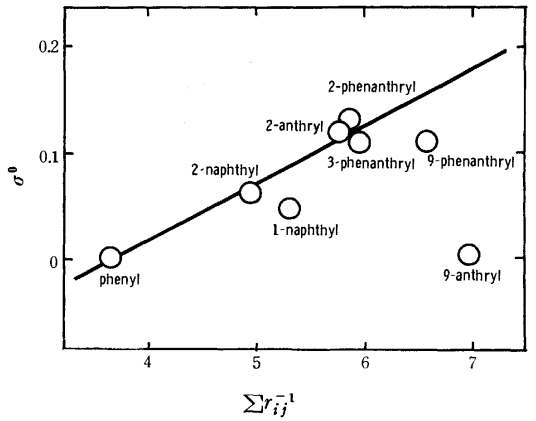

Fig. 2. σ^0 plotted against Streitwieser's inductive indices.

hindered aryls apparently lie close to a line, whereas a serious deviation is observed here also for hindered 9-anthryl and less significant deviations are noted for 1-naphthyl and 9-phenanthryl groups. Since no steric hindrance with peri-hydrogen is assumed, as has been mentioned above, the disposition of these groups may be attributable mainly to the substantial change in their pi-electronic effect. It is apparent that the groups which fall along the correlation line have π_{rr} values of the same magnitude, while, on the other hand, 1-naphthyl and 9-phenanthryl groups have relatively large π_{rr} values and fall below the line. The 9-anthryl group, which possesses an extremely high π_{rr} value, exhibits a serious deviation. The deviations from the line are apparently proportional to the differences in the corresponding π_{rr} values. On least-squares fitting, the σ^0 values can be correlated with both indices by the equation:

$$\sigma^0 = 0.06\Delta(\Sigma r_{ij}^{-1}) + 1.51\pi_{rr} + 0.06$$

The correlation[12] is rather surprisingly significant; standard deviation=±0.011, and correlation coefficient=0.984.

While this treatment is actually no more than a crude approximation, it suggests the possibility of the empirical separation of the σ^0 values for polynuclear aryls into inductive polar and pi-electronic effects. Polynuclear aryl groups in σ^0 reactivities apparently

exert an electron-attracting inductive contribution by their intrinsic electronegativity of additional rings, but instead they exert the electron-donative pi-electronic contribution by additional pi-system to a considerable extent. These groups could be treated practically in the range from σ^0- to σ^+-type reactivities, as has been done successfully with the +I, —R-type substituents, such as the *p*-phenyl substituent. The treatment of the effect of the polynuclear aryl derivatives on the electrophilic reactivities will be discussed in another paper.[6]

Experimental

Materials. All the polynuclear arylcarbinyl benzoates were prepared by the esterification of benzoyl chloride with the corresponding carbinols in pyridine. The carbinols were obtained from the appropriate ethyl or methyl carboxylates by $LiAlH_4$[13] or $NaBH_4$[14] reduction, except for the 9-anthryl derivative, which was derived from the corresponding aldehyde. All of the esters were purified by fractionation or recrystallization. The physical constants and the elemental analysis data are listed in Table 3.

Kinetic Measurements. The rates of the alkaline hydrolyses of all the arylcarbinyl benzoates were determined in a 70% (v/v) aqueous acetone solution at 25°C. The procedure employed for these measurements was generally the same as that described in the previous paper.[5] For less soluble esters, such as 2-fluorenyl, 2- and 3-phenanthryl, and 9-anthryl derivatives, a low initial concentration, 0.01 mol/*l*, was employed, and a 15 m*l* aliquot was utilized in each titration. Since the 9-phenanthryl ester was hardly soluble under these conditions, a more diluted initial concentration, 0.005 mol/*l*, and a larger aliquot, 20 m*l*, was utilized. When the rate determination was carried out for *m*-nitro derivative under these conditions, no concentration effect was observed. As the 1- and 2-anthryl esters were insufficiently soluble even under more diluted conditions, the rate constants of these compounds could not be determined practically.

All runs which involved more than 12 measurements followed the second-order kinetic law, covering reactions up to an extent of 80%. The experimental uncertainty of a run was estimated to be much less than 2%, and the bimolecular rate constants from repeated runs agreed within ±2% or better.

Table 3. Physical constants and analytical data of arylcarbinyl benzoates

Aryl	Mp or Bp (mmHg)	Carbon		Hydrogen	
		Found	Calcd	Found	Calcd

The Substituent Effect. III. The Basicities of Polynuclear Aryl Methyl Ketones

Yasuhide YUKAWA, Yuho TSUNO, and Masami SAWADA

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka

(Received October 28, 1971)

The basicities of nine polynuclear aryl methyl ketones have been determined spectrophotometrically in various aqueous sulfuric acid solutions. The electronic effects of unhindered polynuclear aryls on pK_{BH^+} can be successfully correlated with our LArSR equation,

$$\log k/k_0 = \rho(\sigma^0 + r\Delta\bar{\sigma}_R^+),$$

using ρ and r values established from *meta*- and *para*-substituted acetophenones. The applicability of this equation to polynuclear aryls is also shown for some other electrophilic reactivities. The $\Delta\bar{\sigma}_R^+$ parameters for polynuclear aryls are derived empirically from the solvolysis of α-arylethyl chlorides; these show a good linearity with the theoretical reactivity indices of the localization energies.

In our continuing studies of the substituent effect on chemical reactivities, it has been established that the linear aromatic substituent reactivity (LArSR) relationship (1)[1-3] is generally applicable with an excellent precision to electrophilic reactions of substituted benzene derivatives;

$$\log k/k_0 = \rho(\sigma^0 + r\Delta\bar{\sigma}_R^+) \quad (1)$$

where r is the variable characteristic of the reaction system describing the degree of the resonance exaltation and where $\Delta\bar{\sigma}_R^+$ is the substituent constant to donate electron by resonance. This equation is a bisecting description of the substituent effect in terms of the unexalted polar effect of substituted phenyl groups and the aryl resonance exaltation effect. Eq. (1) is immediately followed by Eq. (2):

$$1/\rho \log k/k_0 = \sigma^0 + r\Delta\bar{\sigma}_R^+ \quad (2)$$

As has been shown in previous papers,[1,3] the apparent substituent constants of a given *para* substituent generally exhibit a linear correlation, with a substantial slope, against r values for varying reactions. 4-Biphenylyl derivatives satisfy the above equation over a wide range of r. For 2-fluorenyl derivatives we obtained a similar plot with a slope of −0.49 and an intercept of 0.00, as is shown in Fig. 1. These findings mean that the apparent substituent constants for both derivatives can be successfully described in terms of the unexalted aryl polar effect, σ^0, and the exalted resonance effect, $r\Delta\bar{\sigma}_R^+$.

Even for condensed polynuclear aromatic hydrocarbons, such as naphthalene and phenanthrene, the above treatment can be also applicable as is shown in Fig. 2. The changes in the apparent substituent constants of 2-naphthyl are found to be a linear function of r, while those of 1-naphthyl do not satisfy the linear dependence on r. The random scatterings of the latter suggest that the steric interaction of peri-hydrogen with the reaction site depends on the nature of reactions. The linearity of the former is an evidence for the constancy of the resonance substituent constant for the 2-naphthyl group. Therefore, it might be expected that Eq. (1) can be extended so as to correlate the reactivity changes of polynuclear aromatic hydrocarbons, besides those with peri-hydrogen interaction, using ρ and r values established from a series of substituted benzene reactivities.

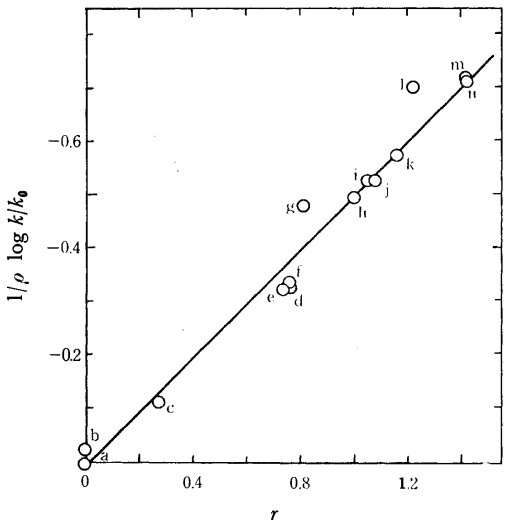

Fig. 1. Relation between apparent substituent constants for 2-fluorenyl group and r values.

Soc.*, **84**, 1661 (1962). m) Molecular bromination, L. M. Stock and H. C. Brown, *ibid* **84**, 1661 (1962). n) Molecular bromination, L. Altschuler and E. Berliner, *ibid.*, **88**, 5837 (1966). From the linearity with the above bromination, ρ and r in this bromination are calculated to be −9.87 and 1.42, respectively.

As a more simplified treatment, Streitwieser has proposed a Hammett-type equation (3) for polynuclear aryl reactivities, in which the reference reaction in the solvolysis of polynuclear arylcarbinyl chlorides in 80% aq. ethanol.[4]

$$\log k/k_0 = \rho\sigma_{Ar} \quad (3)$$

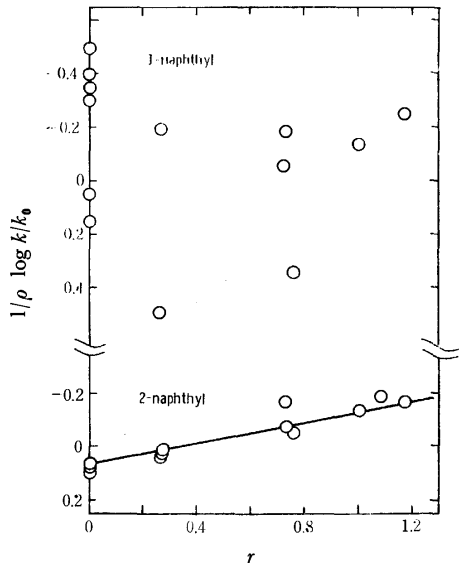

Fig. 2. Relation between apparent substituent constants for 1-naphthyl or 2-naphthyl group and r values.

He has shown a good applicability of Eq. (3) for some solvolysis reactions through a carbonium-ion intermediate. Several authors have utilized this equation and have derived revised or secondary σ values for polynuclear aryls.[5,6] However, the application of this equation is limited to the reaction system analogous to the reference system. This limitation probably arises from the neglect of the varying contribution of the resonance component to the electronic effect of polynuclear aryls.

In a previous paper, a set of σ^0 values for polynuclear aryl moieties was determined by the hydrolysis of arylcarbinyl benzoates and a set of $\Delta\bar{\sigma}_R^+$ values (in Brown Okamoto's σ^+ scale), from the solvolysis of α-arylethyl chlorides, the r value of which was 1.16. According to the LArSR approach, the solvolysis of the polynuclear $ArCH_2X$ system is treated with an extremely high r value of *ca.* 1.6 (see Discussion).

In order to verify this treatment, it is necessary and of interest to study the polynuclear reactivity changes which give the r of an intermediate value. From this point of view, the basicities of aryl methyl ketones was chosen because the r had been established to be 0.76 from that of substituted acetophenones. We have determined the dissociation constants for the conjugate acids of some polynuclear aryl methyl ketones, and have examined whether the electronic effects of polynuclear aryls on pK_{BH^+} could be treated by means of Eq. (1).

Experimental

Materials. The 1-naphthyl and 2-naphthyl methyl ketones were obtained commercially. The former was purified by recrystallization of the picrate, followed by fractional distillation of the regenerated ketone. No impurity was detected by vapor-phase chromatography. The other ketones were prepared by the method described in the literature. The 4-biphenylyl,[7] 2-fluorenyl,[8] 3-phenanthryl,[9] and 1-anthryl[10] methyl ketones were prepared by the Friedel-Crafts acetylation of the corresponding hydrocarbons. The 2-phenanthryl methyl ketone was obtained by the dehydrogenation of (9,10-dihydro) phenanthryl methyl ketone with sulfur.[11]

The 9-phenanthryl isomer was prepared from 9-carbomethoxyphenanthrene by the method of Mosettig and Kamp.[12] The 2-anthryl compound was derived from 9-anthryl ketone by isomerization with $AlCl_3$.[13]

Each isomer of the phenanthryl or anthryl methyl ketone was purified by column chromatography with Al_2O_3, followed by repeated recrystallizations from the appropriate solvents. The absorption spectra (λ_{max} and $\log \varepsilon$) in 95% EtOH were identical with those given in the organic electronic spectral data. The physical properties and analytical data are listed in Table 1.

Sulfuric Acid. Twenty stock solutions of different concentrations of sulfuric acid, ranging from 41.9% to 93.7 % by weight, were prepared by dilution with freshly-distilled water of sulfuric acid which had been purified by three re-solidifications on cooling. In these solutions no optical impurities were observed in the range of wavelengths measured.

The concentrations of the solutions were determined by titrating weighed samples with a satndard NaOH aqueous solution of about 1 N. The H_0 values of the above solutions were obtained by interpolation from a standard curve constructed using the revised values evaluated by Jorgenson and Hartter.[14]

Spectrophotometric Measurements. The method adopted for preparing the appropriate concentration of a ketone in aq. sulfuric acid was essentially the same as that described by Stewart and Yates.[15] A sample weighed on a microbalance was dissolved in 250 m*l* of anhydrous acetone, from which 0.5 m*l* aliquots were pipetted into a 10 m*l* volumetric flask. After the acetone had been carefully evaporated under a moderately reduced pressure, the flask was made up to volume with appropriate acid solutions. The concentration of the sample solution was about 10^{-5} mol/*l*. In the cases of 2- and 9-phenanthryl and 2-anthryl ketones, the solubilities into diluted acids were not so sufficient enough that the step-by-step dilution method was employed in these diluted acids.

The extinction coefficients were measured at room temperature with covered quartz cells of a 1 cm path length using a Hitachi Perkin-Elemr UV-VIS spectrophotometer. A solvent blank of the same concentration of acid as that containing a ketone was employed.

The pK_{BH^+} values were determined by the isosbestic-point method.[16] The isosbestic point was selected as an

intersecting point of two absorption curves for the sulfuric acid of the appropriate concentration, at which a ketone was protonated by approximately 50% (see Table 3). After one series of absorption curves had been shifted laterally to its point, the wavelength for the maximum peak of the fully protonated ketone in the visible wavelength region was taken as a reading wavelength. The extinction coefficients in various acids were measured at the above wavelength, chosen on the basis of the shifted curves, and were used to determine pK_{BH^+}.

Results

In the spectrum of each ketone at a higher concentration of acid, we observed a strong absorption band in the visible wavelength region (around 350—600 mμ); it seemed that this might possibly be a *P*-band characteristic of the π-π^* transition of polynuclear aromatic compound. This resulted in a large red shift and a change in the intensity of the *P*-band in going from the neutral ketone to the conjugated acid. We took note of the behavior of this terminal *P*-band and determined the pK_{BH^+} values by means of the isosbestic-point method. Stewart and Yates[15] had employed the method of Davis and Geissman[17] to obtain the pK_{BH^+} values of *m*- and *p*-substituted acetophenones. As a preliminary experiment, we chose the 2-naphthyl ketone and followed their procedure to determine the pK_{BH^+} value from their reported wavelength pair. The derived value agreed with theirs. However, the different choice of wavelength pair gave rather different pK_{BH^+} value. As would be anticipated, the spectra of polynuclear aryl ketones in aq. sulfuric acid had some characteristic bands in the UV and visible regions, which were not sufficiently separated. In such spectra the pK_{BH^+} value based on the Davis approach appeared to be less reliable because of the inclusion of a different kind of band.

To take the highest concentration of acid utilized, as a reference of the 100% protonation, would be

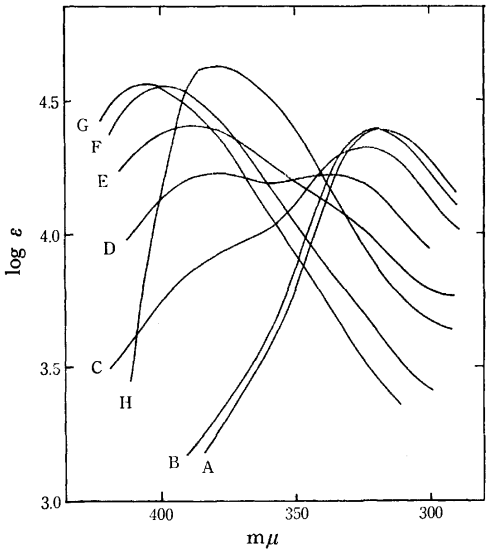

Fig. 3. UV spectra of 2-fluorenyl methyl ketone in various aq. sulfuric acid.
A; 47.2%, B; 52.7%, C; 61.1%, D; 66.8%, E; 71.6% F; 81.1%; G; 89.0%, H; 93.7% aq. H_2SO_4

at best unappropriate in determining the pK_{BH^+} by the isosbestic-point method, because it seems possible that aromatic hydrocarbon is subject to sulfonation and/or deacylation with higher concentrations of acid.[18] A typical example is shown in Fig. 3, which represents the spectra of the 2-fluorenyl methyl ketone. In the range from 47.2 to 89.0% acid, regular lateral changes were observed, while in 93.7% acid the absorption peak moved suddenly toward the lower wavelength. At concentrations higher than 89.0%, the initial yellow solutions were appreciably decolorized as time went on, and the higher the concentration of sulfuric acid, the faster the rate of change. These findings might be ascribed to certain reactions of the aromatic ketone with sulfuric acid, but not to a simple medium effect on the spectra. Similar features were

also obtained for several of the other ketones studied. The reference concentrations chosen, at which a ketone would be completely protonated free from unfavorable reactions, are listed in Table 2. Stewart *et al.* were unable to determine the pK_{BH^+} values of 2-fluorenyl and 4-biphenylyl ketones because of their odd-shaped plots.[15] Their failure might be due to the unappropriate choice of 95% acid as the reference of complete protonation.

The plot of the extinction coefficient chosen *vs.* H_0 showed a good sigmoid titration curve, with flat arms in each ketone (see Fig. 4). Although, in the case of some other weak bases, vertical shifts on spectra due to the medium effect of higher concentrations of acid had been observed,[19] such shifts appeared to be small at the higher concentrations of sulfuric acid

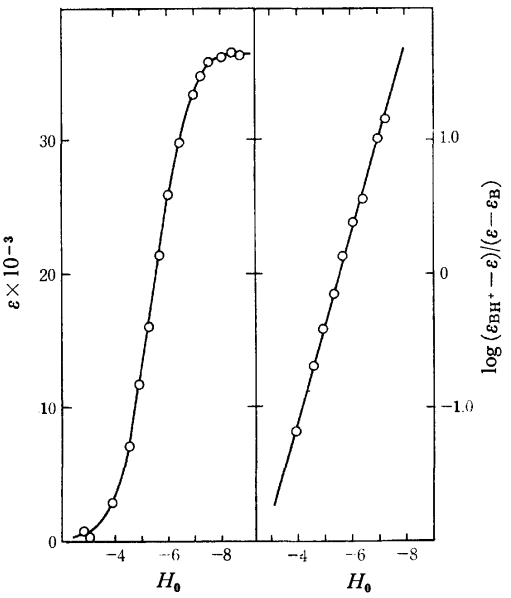

Fig. 4. Extinction coefficient ($\varepsilon \times 10^{-3}$) and $\log(\varepsilon_{BH^+}-\varepsilon)/(\varepsilon-\varepsilon_B)$ plotted against H_0 for 2-fluorenyl methyl ketone.

studied. The pK_{BH^+} value was determined graphically to read the H_0 value, giving $1/2(\varepsilon_{BH^+}+\varepsilon_B)$ on the basis of the sigmoid curve, where ε_{BH^+} and ε_B were the averaged extinction coefficients of completely protonated and unprotonated ketones respectively at the wavelength chosen. The H_0 value of the sulfuric acid, in which the ε value was taken as ε_{BH^+} or ε_B, was at least 2 H_0 units below or above the H_0 corresponding to 50% protonation.

As required by the Hammett-base equation,[20] the logarithms of the ionization ratios must be linear functions of H_0 with intercept equal an to pK_{BH^+}:

$$pK_{BH^+} = H_0 + \log [BH^+]/[B]$$

The other method to determine pK_{BH^+} is to find the intercept by least-square calculations. The ionization ratio, $[B]/[BH^+]$, was calculated by $(\varepsilon_{BH^+}-\varepsilon)/(\varepsilon-\varepsilon_B)$. The extinction coefficients used were the same as those in the former method. The plot thus obtained showed a good linearity in the region corresponding to $\log [B]/[BH^+] = \pm 1.0$ (see Fig. 4). The two methods gave identical pK_{BH^+} values within the limits of experimental uncertainty of 0.02 pK unit. The mean values are listed in Table 2. The values of 1-naphthyl and 1-anthryl ketones were slightly different from the previously-reported data.[21] This is probably due to a different choice of the acid concentration for complete protonation.

However, the values of the obtained slopes were equivalent to 0.72. If polynuclear aryl methyl ketones are to follow precisely the Hammett-base postulate, the slope should be equal to unity. This discrepancy might be mostly caused by the failure of the assumption on activity coefficients.[20] Similar findings have been reported for other non-charged weak bases,

such as substituted dimethylanilines,[22] benzamides,[23] benzophenones,[24] and diphenyl sulfoxides.[25,26] In view of the fact that the acidity function of the H_0 type depends strongly on the functional base, this result may indicate the possibility that a new acidity function applied to the protonation equilibria of aryl methyl ketones can be constructed.

Discussion

To examine the applicability of our LArSR Eq. (1), it is necessary first of all to evaluate the $\Delta\bar{\sigma}_R^+$ values for polynuclear aryls using the same scale as those for substituted benzenes. The numercial values of $\Delta\bar{\sigma}_R^+$ for substituted benzenes were defined by the subtraction of σ^0 from Brown and Okamoto's σ^+.[1] Since rate data are not available for polynuclear aryls in Brown's σ^+ series,[27] we have chosen the solvolysis of α-arylethyl chlorides in 80% aq. acetone as the secondary reference reaction. From our rate data[29] and Berliner's,[30] the $\Delta\bar{\sigma}_R^+$ values can be derived, using the precise ρ and r values established and, in addition, the σ^0 for polynuclear aryls already reported.[31] The resulting $\Delta\bar{\sigma}_R^+$ parameters, which are measures of the electron-releasing ability of polynuclear aryls by resonance relative to the parent benzene nucleus, are listed in Table 3 together with σ^0.

TABLE 3. σ^0 AND $\Delta\sigma_R^+$ PARAMETERS FOR POLYNUCLEAR ARYLS

In a previous paper,[1] we have mentioned that the literature data on the pK_{BH^+} of *m*- and *p*-substituted acetophenones, which were obtained using Paul's H_0 scale,[20] can be correlated rather excellently by means of Eq. (1). Since the present data are based upon Jorgenson's recent H_0 scale,[14] correction of the published pK_{BH^+} values is required to compare the two series of ketones on the same recent scale.[32] The corrected pK_{BH^+} values for twelve *m*- and *p*-substituted acetophenones can be also correlated satisfactorily by Eq. (1). Using the method of least squares, ρ and r are calculated to be 2.58 and 0.76 respectively. Even when the present polynuclear aryl methyl ketones are included in the least-square calculations, no significant change is observed in ρ, r, and the correlation coefficient (2.57, 0.74, and 0.997 respectively). The total correlation is illustrated in Fig. 5. In order to visualized the degree of the contribution of the resonance component in this protonation, the quantities, $1/\rho \log k/k_0 - \sigma^0$, are plotted against $\Delta\bar{\sigma}_R^+$ in Fig. 6. The correlation line determined by the points of polynuclear aryls is in complete agreement with that of

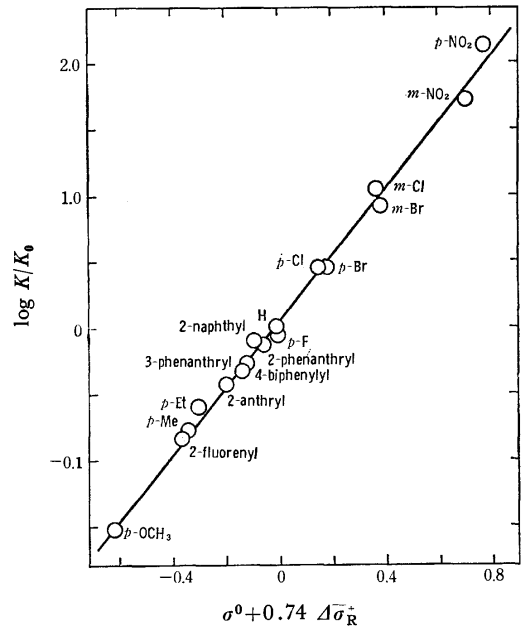

Fig. 5. The LArSR plot for dissociation of conjugate acids of aryl methyl ketones.

27) Brown *et al.* have evaluated σ^+ values for some polynuclear aryls on the basis of the linearity between the solvolysis of aryldimethylcarbinyl chlorides and that of arylmethylcarbinyl chlorides.[28] However, according to our calculations, r of the latter is 1.16 and is slightly different from that of the former being 1.00 by definition. So, their values are not so adequate.

32) A convenient method of converting previous pK_{BH^+} to the one in recent scale was described in the literature. On the basis of plotted curve of recent H_0 *vs.* previous H_0, the previous pK_{BH^+} could be directly converted to the recent one. In order to check the applicability of this procedure, pK_{BH^+} for the present ketones with previous scale was converted in the above method. The converted pK_{BH^+} agreed closely with the pK_{BH^+} based on the recent scale within 0.02 pK unit.

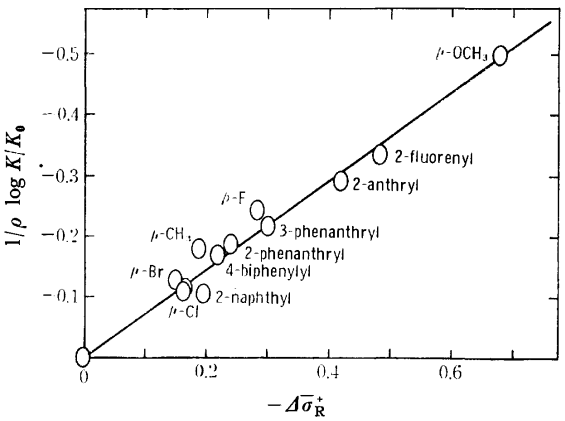

Fig. 6. Resonance contribution in the dissociation of the conjugate acids of aryl methyl ketones.

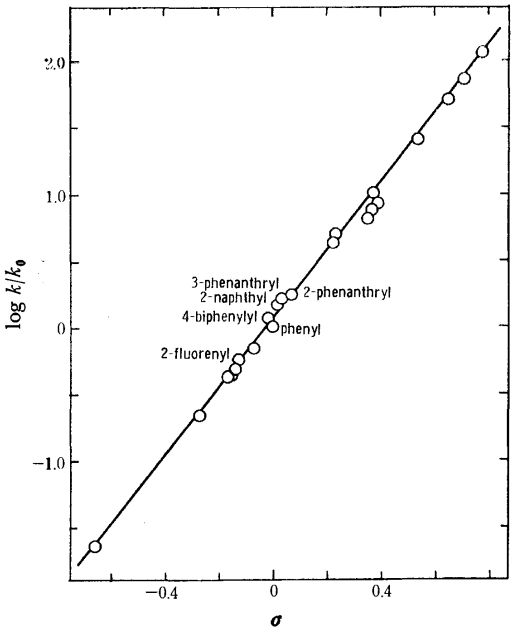

Fig. 7. Hammett plot for the alkaline hydrolysis of ethyl arylcarboxylates in 85% aq. ethanol.

p-substituted benzenes. The identical correlations indicate that the relative basicities of polynuclear aryl methyl ketones can be described by Eq. (1).

Such a treatment of polynuclear aryls has been also applied successfully to our recent data on the alkaline hydrolysis of ethyl arylcarboxylates in 85% aq. EtOH.[34] Since the apparent substituent constants of *para* electron-releasing groups for the above hydrolysis have been analyzed to have a r value of 0.25. The resulting points for polynuclear aryls fall on the line given by the *m*- and *p*-substituents, as is clear in Fig. 7.

It might be expected that the present treatment could be naturally applied to the correlation of reactivity changes for the solvolysis of the $ArCH_2X$ system.[4,5,35] Unfortunately, the definite ρ value and, in consequence, the definite r value can not be estimated for this reaction system.[1,5] However, the relative reactivities for polynuclear aryls in this system can be correlated using the approximate r value of 1.6.

Reactivity data for 2-naphthalene-like polynuclear aryls measured under the same experimental conditions (solvent, temperature, etc.) as those used for *m*- and *p*-substituted benzenes are very scarce in the literature; only the reactions the correlational data of which are summarized in Table 4 are available. The ρ and r values listed are mostly quoted from the results in our previous report.[1] The values of $1/\rho \log k/k_0$ for the 2-, 3-phenanthryl, and 2-anthryl[36] reactivities are plotted against r, as Fig. 8 shows. Satisfactory linear correlations are obtained for the respective unhindered polynuclear aryls. The most important features are that the three straight lines cover a wide variation in r values (0.0—1.6) and that, consequently, the $\Delta\bar{\sigma}_R^+$ values for the respective aryls remain constant in spite of the considerable variations in ρ and r. These facts indicate that Eq. (1) can be generally applicable to correlate polynuclear aryl reactivities as well as substituted benzene reactivities.

A similar linearity appears to be obtained for the 2-(9,10-dihydro)phenanthryl group. There are few reported data other than those for the protodesilylation of aryltrimethylsilane[37] and the solvolysis of α-arylethyl

Table 4. Summary of electrophilic reactivities for unhindered polynuclear aryls measured under the same experimental conditions as those for substituted benzenes

Reaction	ρ	r

chloride.[29] Although additional data should be necessary to examine the numerical value, the $\Delta\bar{\sigma}_R^+$ value for this group can be estimated to be approximately −0.37 on the basis of the above treatment. It is worth noting that the capabilities of biphenyl-type compounds for electron-donation by resonance, $\Delta\bar{\sigma}_R^+$, increase in the order: 4-biphenylyl<2-(9-10-dihydro)phenanthryl<2-fluorenyl. This order can be clearly explained on the basis of the increasing coplanarity between both benzene rings of the biphenyl component.

In the treatment of the reactivity data with theoretical reactivity indices derived from molecular orbital calculations, various authors have directly compared the logarithmus of the relative rates for polynuclear aryl derivatives with various simple MO indices.[4,5,10,38] We consider their approachs to be based on a neglect of the changes in the electronic energy due to the σ-framework effect for the respective polynuclear aryls. We have ourselves successfully separated the substituent effects of substituted benzene reactivities into two terms, the reaction-independent σ-inductive effect and the reaction-variable π-electronic effect.[3,39] On the basis of the same sort of consideration, it may be reasonable to say that the electronic effect on polynuclear aryls also contains the contribution of the σ-inductive effect as well as that of the π-electronic effect. The former may be referable to the electronegativities of the sp^2-carbon σ-framework; it should be characteristic of the reacting position, and also of the size of the polynuclear aromatic ring. On the other hand, the simple MO reactivity index depends on the nature of only the π-electron framework. Therefore, it would be more reasonable to compare a MO index with the quantity that the σ-inductive effect is removed from the observed electronic effect. Such quantities would correspond to $1/\rho \log k/k_0 - \sigma^0$ or residual $r\Delta\bar{\sigma}_R^+$ in our treatment, if the contribution of the σ-inductive effect of polynuclear aryls is independent of the reactions and remain constant.

For the solvolysis of α-arylethyl chlorides,[29,30] a plot of $1/\rho \log k/k_0 - \sigma^0$ against the localization energy, Lr^+,[4] derived from the simple HMO method, is shown in Fig. 9 as a typical example. In practise, 2-naphthalene-like groups show a remarkable linear correlation, and 1-naphthalene-like groups, large deviations. The latter feature is naturally due to peri-hydrogen steric effects. More precisely, the points of 4-biphenylyl and 2-phenanthryl deviate slightly from the correlation line. The minor deviation of the former can presumably be ascribed to the unpreferable Lr^+ value itself, because the different bond order or bond length on the pivot bond in biphenyl is not reflected in the HMO calculations. On the other hand, there is no plausible explanation of the minor deviation of the latter.[40] Of course, the same sorts of features are obtained in such a plot of the present basicity data and other reactivity data on the reactions listed in Table 4. The obtained linear correlation, which indicates a linearity between $\Delta\bar{\sigma}_R^+$ and Lr^+, may be sufficient to indicate a theoretical justification of our analysis of the electronic effect on polynuclear electrophilic reactivities.

The Base-catalyzed Condensation of α-Haloaldehydes with Dichloroacetates

Akira TAKEDA, Sadao TSUBOI, Satoshi WADA, and Hiroshi KATO

Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama

(Received October 29, 1971)

The reaction of aliphatic α-haloaldehydes with methyl dichloroacetate in the presence of sodium methoxide was carried out. α-Chloroaldehydes afforded 2,4-dichloro-2,3-epoxyalkanoates (**5**), whereas α-bromoaldehydes gave 2,2-dichloro-3,4-epoxyalkanoate (**7**). The attempted epoxy-carbonyl rearrangement of **5** with hydrogen chloride or thionyl chloride failed. The thermal decomposition of methyl 2,4-dichloro-2,3-epoxynonanoate (**5c**) at 300—400°C afforded methyl 3-chloro-2-oxo-3-nonenoate (**9c**), and the similar treatment of methyl 2,4-dichloro-4-methyl-2,3-epoxypentanoate (**5a**) afforded a mixture of methyl 3,4-dichloro-4-methyl-2-oxopentanoate (**6a**), methyl 3-chloro-4-methyl-2-oxo-3-pentenoate (**9a**), and methyl 3-chloro-4-methyl-2-oxo-4-pentenoate (**10**). The treatment of **5** with thiourea in methanol gave the thiazole derivative (**15**), but neither sodiomalonate nor sodioacetoacetate reacted with **5**.

The base-catalyzed condensation of aldehydes with the dichloroacetic ester has been reported by several authors.[1-4] It is known that the reaction affords α-chloroglycidic esters (**1**) and the α-chloropyruvic ester (**2**). Compound **2** is produced by the epoxy-carbonyl rearrangement of **1**:[4]

$$RCHO + Cl_2CHCO_2R' \longrightarrow R\text{-}\underset{\diagdown O \diagup}{CH\text{-}C}(Cl)\text{-}CO_2R' \quad \mathbf{1}$$

$$\longrightarrow R\text{-}CH(Cl)C(=O)CO_2R' \quad \mathbf{2}$$

Aliphatic aldehydes with a longer chain, such as heptanal, hexanal, and nonanal, usually give rearranged products (**2**). On the contrary, acetaldehyde and propionaldehyde yield the corresponding α-chloroglycidates (**1**) predominantly. Furthermore, 2-chloro-2,3-epoxyisocaproate resists the epoxy-carbonyl rearrangement with hydrogen chloride.[4] As an extension of previous work,[4] we carried out the Darzens-type condensation of aliphatic α-haloaldehydes with methyl dichloroacetate in the presence of sodium methoxide in order to establish a synthetic route to obtain 2-chloro-4-halogeno-2,3-epoxyalkanoate (**5**) and 3-chloro-4-halogeno-2-oxoalkanoate (**6**). The present report will describe the results of this reaction and will discuss the chemical properties and the structural chacacterization of the products. The yields, boiling points, and analytical results of the products are listed in Table 1.

Two pathways can be postulated for the elimination of the halogen atom of the possible intermediate (**4**), as is shown in Scheme 1. One involves the formation of the glycidates, **5**, which might further undergo an epoxy-carbonyl rearrangement to **6** (Route 1). In the other, the halogen atom originating from α-haloaldehyde is eliminated to produce 2,2-dichloro-3,4-epoxyalkanoate (**7**) (Route 2).

TABLE 1. PRODUCTS FROM THE REACTION OF α-HALOALDEHYDES WITH METHYL DICHLOROACETATE

α-Haloaldehyde RR′C(X)–CHO			Products[a]		Yield, %	Bp, °C/mmHg	Found, %		Calcd, %	
R	R′	X	Code	Structure			C	H	C	H
CH_3	CH_3	Cl	**5a**	$(CH_3)_2CClCH(O)CClCO_2Me$	34	86—89/3	39.51	4.70	39.46	4.73

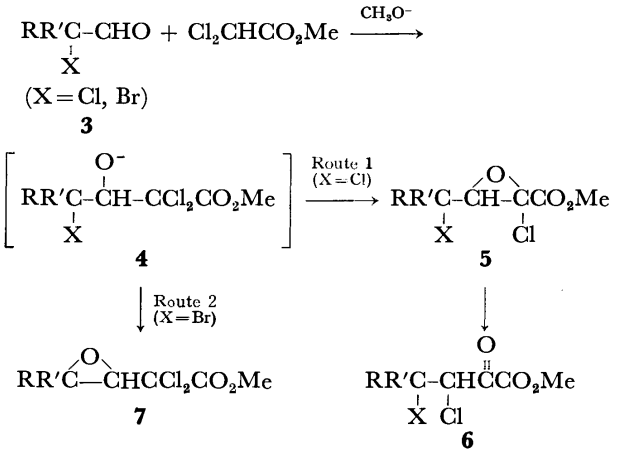
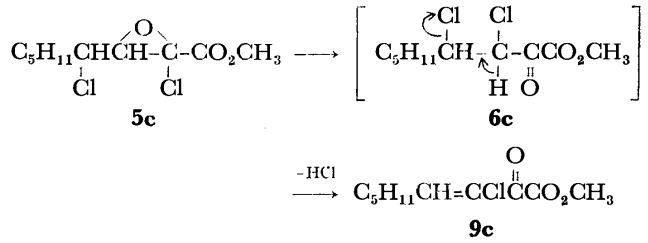


Scheme 1

The reaction of α-chloroaldehyde with dichloroacetates usually gave 2,4-dichloro-2,3-epoxyalkanoate (**5**) in a 30—55% yield. α-Chloroheptanal, however, gave a small amount (8% yield) of methyl 2,2-dichloro-3,4-epoxynonanoate (**7c**) in addition to methyl 2,4-dichloro-2,3-epoxynonanoate (**5c**). This indicates that the halogen atoms at the α and γ positions in the intermediacy (**4c**) compete as leaving groups. Indeed, α-bromoaldehydes afforded only 2,2-dichloro-3,4-epoxyalkanoate (**7**) under the same reaction conditions, even though in poor yields (10—15%), without the formation of **5**. Both compounds, **5** and **7**, were stable enough to be distillable under reduced pressure. For the structural assignment of these compounds, the NMR spectra, especially the multiplet (1H) at τ 5.8—6.2 (**5c**, C_4-methine proton) and the multiplet (1H) at τ 6.73 (**7c**, C_4-epoxide methine proton), were instructive.

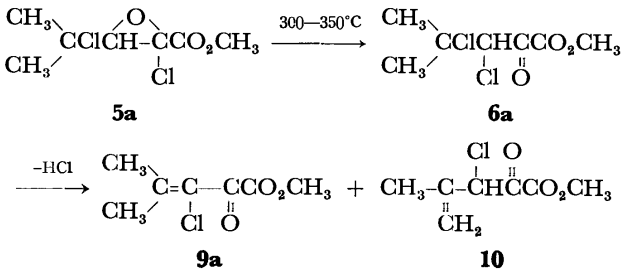
The esters **5** were treated with dry hydrogen chloride in ether at 0°C in order to investigate their facility at undergoing epoxy-carbonyl rearrangement, but the starting material was recovered unchanged, without any formation of pyruvates, **6**. Furthermore, the treatment of methyl 2,4-dichloro-2,3-epoxynonanoate (**5c**) with dry hydrogen chloride in ether at the reflux temperature, or even with excess thionyl chloride at the reflux temperature, still had no effect on its transformation to **6**. The hydrolysis of **5c** with 10% H_2SO_4 afforded only 2,4-dichloro-2,3-epoxynonanoic acid (**8**). Since the acidic hydrolysis of glycidate usually causes decarboxylative elmination thus producing ketone or aldehyde,[5,6] it is rather surprising that the acid **8** can be isolated as stable crystals. The acid **8** was again transformed to **5c** with diazomethane. The larger stability of the esters **5** as compared to α-monochloroglycidate (**1**) under treatment with hydrogen chloride or thionyl chloride may be accounted for by assuming that the migration of the chlorine atom at C_2 is hindered by the electrical repulsion which the chlorine atom attached to C_4 exerts.

The transformation of **5** to **6** was performed pyrolytically; it was usually accompanied by a secondary elimination of hydrogen chloride. The distillation of **5c** at 300—400°C (oven temperature) under an atmosphere of nitrogen gave only methyl 3-chloro-2-oxo-3-nonenoate (**9c**). The IR bands of **9c** at 1740, 1690, and 1610 cm^{-1} are characteristic of the α,β-unsaturated ketoester. The triplet at τ 2.8 (J=7 Hz) in the NMR spectrum of **9c** represents the signal from the C_4-vinyl proton. These data all support the structure of **9c**. For the formation of **9c**, the rearranged product, **6c**,

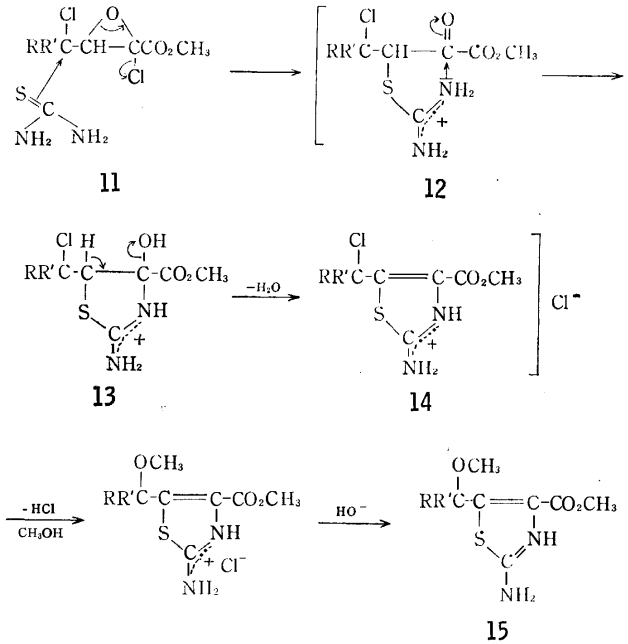


Scheme 2

might be the intermediate from which the more acidic hydrogen at C_3 is eliminated. This mechanism is supported by the pyrolysis of 4-methyl-2,4-dichloro-2,3-epoxypentanoate (**5a**), where the rearranged product **6a** has been isolated. The distillation of **5a** at 300—350°C gave a mixture of three components, methyl 3,4-dichloro-4-methyl-2-oxopentanoate (**6a**, 17%), methyl 3-chloro-4-methyl-2-oxo-3-pentenoate (**9a**, 9%), and methyl 3-chloro-4-methyl-2-oxo-4-pentenoate (**10**, 72%). The reaction sequence is shown in Scheme 3. The treatment of **6a** with triethylamine resulted in the formation of **9a** (37%).



Scheme 3



Scheme 4

5) M. Mousseron and R. Granger, *Compt. Rend.*, **218**, 358 (1944).
6) G. Darzens, *ibid.*, **195**, 884 (1932).

Although carbanions, such as sodiomalonate and sodioacetoacetate, were unreactive with **5** in methanol or dioxane, thiourea reacted with **5** in methanol to give the corresponding thiazole derivative (**15**). The possible pathway of the formation of **15** is shown in Scheme 4. Since 2-chloro-2,3-epoxyalkanoate has been known to produce the thiazole derivative readily,[4] it is reasonable to assume that the chlorinated thiazole derivative (**14**), which was formed intermediately, readily underwent solvolysis with methanol.

Experimental

The melting points and boiling points are uncorrected. The microanalyses were carried out by Mr. Eiichiro Amano of our laboratory. The analytical determinations by glpc were performed on a Hitachi K-53 model gas chromatograph (3 mm o.d.×1 m, 10% Apiezon Grease L on Chromosorb W), and the preparative isolations by glpc were performed on a Yanagimoto GCG-550T model gas chromatograph (3 mm o.d.×2.25 m, 10% Apiezon Grease L on Chromosorb W). We are indebted to Dr. Akira Suzuki and Mr. Shigezo Shimokawa, both of Hokkaido University, and to Mr. Hiroshi Ooyama, Hokko Chemical Industry Co., Ltd., for the NMR measurements.

The α-chloroaldehydes used in this experiment were prepared by the method of Stevens[7,8] by treating aldehydes with sulfuryl chloride: α-chloroisobutanal, bp 86—90°C (lit,[7] bp 86—88°C), yield 38%; α-chlorobutanal, bp 36—37°C/50 mmHg (lit,[8] bp 104—110°C), yield 27%; α-chloroheptanal, bp 76—79°C/24 mmHg (lit,[8] bp 36—38°C/2 mmHg), yield 78%. The α-bromoaldehydes were obtained by the direct bromination of aldehydes with bromine:[9,10] α-bromoheptanal, bp 75—78°C/4 mmHg (lit,[9] bp 81—82°C/3 mmHg), yield 40%; α-bromobutanal, bp 47—50°C/21 mmHg (lit,[10] bp 33°C/15 mmHg), yield 10%.

The following experiments are shown as typical runs.

Methyl 2,4-Dichloro-2,3-epoxy-4-methylpentanoate (5a). Powdered sodium methoxide (5.5 g, 0.1 mol) was added with caution to a mixture of freshly-distilled α-chloroisobutanal (10.6 g, 0.1 mol) and methyl dichloroacetate (14.3 g, 0.1 mol) dissolved in 60 m*l* of dry ether, at 5—10°C. After the addition had been completed, the heterogeneous reaction mixture was allowed to warm up to room temperature and then refluxed for 1.5 hr. The ethereal extract was washed several times with water and dried over Na_2SO_4. After the removal of the solvent, it was distilled to give 7.2 g (34%) of **5a**: bp 86—89°C/3 mmHg; IR (cm^{-1}, liquid) 1750 (ester C=O); NMR (τ, $CDCl_3$) 6.15 (s, 3H, $-COOCH_3$), 6.27 (s, 1H, $-CH(O)-CCl-$), 8.23 (s, 6H, $(CH_3)_2CCl-$).

Methyl 2,4-Dichloro-2,3-epoxynonanoate (5c). Powdered sodium methoxide (6.8 g, 0.125 mol) was added with caution to a mixture of freshly-distilled α-chloroheptanal (14.8 g, 0.1 mol) and methyl dichloroacetate (14.3 g, 0.1 mol) dissolved in dry ether (30 m*l*), at 0±1°C. The mixture was stirred for 1.5 hr at room temperature and then treated with water. The ethereal layer was separated, washed several times with water, and dried over Na_2SO_4. After the removal of the solvent, it was distilled giving 10.3 g (40% yield)[11] of the liquid, which was collected at 119—126°C/3 mmHg. Glpc analysis showed it to consist of two components. The peaks, retention times (min), and integrated percentages[12] are as follows: 1, 15.5, 8; 2, 17.1, 92. Component 1 was collected by preparative glpc and was identified as methyl 2,2-dichloro-3,4-epoxynonanoate (**7c**) by a comparison of its IR data and retention time with those of an authentic sample (see next section). Component 2 (**5c**) was purified similarly and analyzed: IR (cm^{-1}, liquid) 1760 (ester C=O); NMR (τ, $CDCl_3$) 6.08 (s, 3H, $-COOCH_3$), 5.8—6.2 (m, 1H, $-(CH_2)_4C\underline{H}(O)Cl-$), 6.4 (d, 1H, $-CH(O)-C(Cl)-$), 8.0—8.8 (m, 8H, $CH_3(C\underline{H}_2)_4-$), 9.03 (t, 3H, J=5 Hz, $C\underline{H}_3(CH_2)_4-$).

Methyl 2,2-Dichloro-3,4-epoxynonanoate (7c). Into a solution of α-bromoheptanal (15.0 g, 0.077 mol) and methyl dichloroacetate (11.0 g, 0.077 mol) in dry ether (30 m*l*), sodium methoxide (5.1 g, 0.096 mol) was stirred at 0±1°C. After the addition had been completed, the reaction mixture was allowed to warm up to room temperature. Stirring was continued for 1.5 hr. After the subsequent addition of water, the ethereal layer was separated, washed several times with water, dried over Na_2SO_4, and concentrated. A residual, thick yellow oil was distilled to give 3.0 g (15%) of **7c**: bp 107—112°C/2 mmHg; IR (cm^{-1}, liquid) 1750, 1760 (ester C=O); NMR (τ, $CDCl_3$) 6.1 (s, 3H, $-COOCH_3$), 6.52 (d, 1H, J=2.5 Hz, $-CH(O)-C\underline{H}CCl_2-$), 8.2—8.9 (m, 8H, $CH_3(C\underline{H}_2)_4-$), 9.09 (d, 3H, $C\underline{H}_3(CH_2)_4-$). A considerable amount of an undesirable resinous material was formed in this reaction and was discarded as a residue.

2,4-Dichloro-2,3-epoxynonanoic Acid (8). In a 50-m*l* three-necked, round-bottomed flask equipped with a dropping funnel, a mechanical stirrer, and a reflux condenser fitted with a drying tube, were placed dry methanol (20 m*l*) and sodium (0.46 g, 0.02 mol). While the mixture was being stirred at 0°C, 5.0 g (0.02 mol) of methyl 2,4-dichloro-2,3-epoxynonanoate (**5c**) and then 0.5 m*l* of water were added slowly. The solution was allowed to warm up to room temperature and then stirred for 3 hr. The sodium salt of the acid, **8**, precipitated in the solution was collected by filtration and washed with absolute methanol and ether. The salt was treated with a mixed solution of 2 m*l* of concentrated hydrochloric acid and 10 m*l* of water. The organic layer was extracted with ether, washed with water, and dried over Na_2SO_4. After the removal of the solvent, white needles were obtained. Recrystallization from *n*-hexane gave 1.5 g (31%) of white needles; mp 36—37°C; IR (cm^{-1}, liquid[13]) 2650 and 2500 (acid OH), 1738 (acid C=O).

Found: C, 44.43; H, 5.83%. Calcd for $C_9H_{14}Cl_2O_3$: C, 44.83; H, 5.83%.

The esterification of the above acid, **8** (1.7 g, 0.0071 mol), was carried out with diazomethane in ether. The removal of the solvent left a thick yellow liquid which, on distillation, gave 0.9 g of a clean oil: bp 126—127°C/5 mmHg. It was identified as **5c** by a comparison of IR and glpc with those of an authentic sample.

Thermal Decomposition of Methyl 2,4-Dichloro-2,3-epoxynonanoate (5c). The distillation of **5c** (2.5 g, 0.0098 mol) was carried out by heating it at 300—400°C with a mantle heater under an atmosphere of nitrogen. A thick yellow oil (2.0 g)

11) Estimated as compound **5c**.
12) Observed on a 1-m 10% Apiezon Grease L on Chromosorb W column. Column temp., 150°C; carrier gas, N_2 (0.5 kg/cm², 42 ml/min); detector, FID.
13) The IR spectrum of **8** was measured on warm NaCl prisms.

was distilled at 240—250°C under the evolution of hydrogen chloride. The glpc analysis of the oil showed two peaks.[12] The peaks, retention times (min), and integrated percentages are as follows: 1, 11.6, 62; 2, 17.2, 38. Component 1 (major constituent), collected by preparative glpc, was identified as methyl 3-chloro-2-oxo-3-nonenoate (**9c**): IR (cm^{-1}, liquid) 1740 (ester C=O), 1690 (conjugated keto C=O), 1610 (conjugated C=C).

Found: C, 54.89; H, 6.98%. Calcd for $C_{10}H_{15}ClO_3$: C, 54.92; H, 6.91%.

The spectral data of component 2 (minor constituent) were identical with those of **5c**.

Thermal Decomposition of Methyl 2,4-Dichloro-2,3-epoxy-4-methylpentanoate (5a). The distillation of **5a** (7 g, 0.033 mol) was carried out in the same manner as in the foregoing experiment on **5c**. A thick yellow oil (5.6 g) came out at 200—210°C under the evolution of hydrogen chloride. It gave a clean oil (5.1 g) on distillation under reduced pressure: bp 119—124°C/44 mmHg. Glpc analysis[14] showed three peaks, with retention times (min) of 4.5, 8.0, and 9.5 respectively, and in an area ratio of 72: 10: 18. The crude product was fractionated into components by preparative glpc. The spectral data and analyses of these components are as follows (components, retention times,[14] IR, NMR, analysis): Component 1: 4.0 min; IR (cm^{-1}, liquid) 1750 (ester C=O), 1735 (keto C=O), 1640, 1610 (C=C); NMR (τ, $CDCl_3$) 4.38 (s, 1H, $-\underset{\underset{H}{|}}{C}ClCOCO_2CH_3$), 4.78 (s, 2H, $CH_3-\overset{\overset{CH_2}{||}}{C}-$), 6.11 (s, 3H, $-COOCH_3$), 8.13 (s, 3H, $C\underline{H}_3-\overset{\overset{CH_2}{||}}{C}-$). Found: C, 47.29; H, 4.95%. Calcd for $C_7H_9ClO_3$: C, 47.61; H, 5.14%. Component 2: 5.6 min; IR (cm^{-1}, liquid) 1740 (ester C=O), 1685 (conjugated keto C=O) and 1590 (conjugated C=C); NMR (τ, $CDCl_3$) 6.12 (s, 3H, $-COOCH_3$), 7.76 (s, 3H, $C\underline{H}_3-\overset{\overset{CH_3}{|}}{C}=CCl-$) and 7.88 (s, 3H, $CH_3-\overset{\overset{C\underline{H}_3}{|}}{C}=CCl-$). Found: C, 47.32; H, 5.24. Calcd for $C_7H_9ClO_3$: C, 47.61; H, 5.14. Component 3: 7.2 min; IR (cm^{-1}, liquid) 1760 (ester C=O) and 1740 (keto C=O); NMR (τ, $CDCl_3$) 3.98 (s, 1H, $-\underset{\underset{H}{|}}{C}Cl-CO-$), 6.12 (s, 3H, $-COOCH_3$), 8.35 (s, 3H, $C\underline{H}_3-\underset{\underset{CH_3}{|}}{C}ClCHCl-$) and 8.48 (s, 3H, $CH_3-\underset{\underset{C\underline{H}_3}{|}}{C}ClCHCl-$). Found: C, 39.80; H, 4.67%. Calcd for $C_7H_{10}Cl_2O_3$: C, 39.46; H, 4.73%. On the basis of these data, components 1, 2, and 3 are identified as methyl 3-chloro-4-methyl-2-oxo-4-pentenoate (**10**), methyl 3-chloro-4-methyl-2-oxo-3-pentenoate (**9a**), and methyl 3,4-dichloro-4-methyl-2-oxopentanoate (**6a**) respectively. The conjugation of the double bond with the keto carbonyl group is obvious in compound **9a**, while it is not in compound **11**. Compound **9a** has no double bond.

Dehydrochlorination of 6a with Triethylamine. To a solution of gas-chromatographically-pure sample of **6a** (12 mg, 5.6×10^{-5} mol) in dry ether (0.1 m*l*), was added triethyl amine (0.0145 g, 1.4×10^{-4} mol) at room temperature. After the solution had been shaken upon occasion for 30 min, the excess of triethylamine was removed by evaporation. The glpc analysis of the residual oil showed two peaks which corresponded to **9a** and **6a** in retention times, *i.e.*, 8.0 min and 9.5 min respectively. By referring to the peak areas it can be estimated that 37% of the starting material (**6a**) has been transformed to **9a**.

2-Amino-4-methoxycarbonyl-5-(1-methoxyhexyl)thiazole (15c). A solution of **5c** (1.2 g 0.0047 mol) and thiourea (0.36 g, 0.0047 mol) in methanol (10 m*l*) was refluxed for 18 hr. The mixture was diluted with water and made alkaline with aqueous ammonia. The organic layer was extracted with ether, washed with water, and dried over Na_2SO_4. After the removal of the solvent, 0.9 g of a brownish-green oil (**15c** of *ca.* 80% purity by thin layer chromatography[15]) was obtained. A pure sample of **15c** was collected by preparative tlc for microanalyses and spectra determinations: R_f 0.2; IR (cm^{-1}, liquid) 3400, 3300, 3110, 2920, 1707, 1620, 1540, 1220; NMR (τ, $CDCl_3$) 4.1 (s, 2H, $-NH_2$), 4.9 (t, 1H, $J=6$ Hz, $C_5H_{11}-C\underline{H}OCH_3-$), 6.18 (s, 3H, $-COOCH_3$), 6.71 (s, 3H, $-OCH_3$), 8.1—8.9 (m, 8H, $CH_3(C\underline{H}_2)_4-$), 9.1 (t, 3H, $J=4.5$ Hz, $C\underline{H}_3(CH_2)_4-$).

Found: C, 52.98; H, 7.32; N, 10.08%. Calcd for $C_{12}H_{20}N_2O_3S$: C, 52.92; H, 7.40; N, 10.28%.

2-Amino-4-methoxycarbonyl-5-(1-methoxyisopropyl)thiazole (15a) A solution of **5a** (2.1 g, 0.01 mol) and thiourea (0.76 g, 0.01 mol) in methanol (15 m*l*) was refluxed for 15 hr. By treating the mixture in ways similar to those used in the case of **15c**, 0.9 g of a pale yellow oil (**15a** of *ca.* 80% purity by tlc[15]) was obtained. The analytical sample of **15a** was prepared by tlc: R_f 0.15; IR (cm^{-1}, liquid) 3400, 3320, 3120, 2960, 1610, 1620, 1540, 1215; NMR (τ, $CDCl_3$) 4.02 (s, 2H, $-NH_2$), 6.12 (s, 3H, $-COOCH_3$), 6.71 (s, 3H, $-OCH_3$,) 8.33 (s, 6H, $2CH_3-$).

Found: C, 46.84; H, 6.15; N, 11.84%. Calcd for $C_9H_{14}N_2O_3S$: C, 46.94; H, 6.13; N, 12.16%.

The Accelerated Reaction of 2,2-Diphenyl-1-picrylhydrazyl with Cupric 3-(1-Butenyl)-2,4-pentanedionate in Frozen Solutions and Its ESR Spectra[1]

Kaku UEHARA, Kiyohiro KAMEI, Makoto TANAKA, and Niro MURATA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka

(Received November 1, 1971)

The rate enhancements upon freezing in the reaction of 2,2-diphenyl-1-picrylhydrazyl (DPPH) with cupric 3-(1-butenyl)-2,4-pentanedionate (3-α-butenylacetylacetonate) were studied in benzene, dioxane, and cyclohexane. It was observed that the degree of the rate enhancements in frozen solutions varied remarkably with the kind of solvent. The order of the accelerating effect was as follows: benzene>dioxane>cyclohexane. Upon freezing, the hyperfine structure in the ESR spectra of DPPH collapsed into a single line, but the peak-to-peak line width (ΔH_{pp}) changed appreciably with the solvents used. The order of the values of ΔH_{pp} was as follows: cyclohexane >dioxane>benzene. These results suggest that the enhancement of the rate in a frozen solution is due to the increased concentration of reactants in the liquid region existing among the crystalline solvents.

Metal acetylacetonate reacts with a stable free radical, 2,2-diphenyl-1-picrylhydrazyl (DPPH), to yield 2,2-diphenyl-1-picrylhydrazine (DPPH-H); the reaction gives first-order kinetics for each reactant.[2] In an earlier

$$\text{DPPH} + \text{Cu(R-acac)}_2 \xrightarrow{k} \text{DPPH-H} + \text{other product}$$

paper,[3] it has been reported that this reaction is remarkably accelerated when a benzene solution of the reactants is frozen. This study was undertaken in an attempt to elucidate the frozen effect in more detail.

Enhanced rates in frozen solutions for the catalytic hydrolysis of the penicilline β-lactam and some other reactions have been reported, and several possible explanations have been offered for the frozen effect.[4-13] Pincock *et al.* have reported that there are highly concentrated liquid regions among the crystalline solvents when a dilute solution containing two reactants is frozen and that the reaction between the two reactants might be markedly accelerated by the concentration effect.[4-9] Grant *et al.* have described how the acceleration of the reaction in frozen solutions can be attributed to other effects, including the higher proton mobility, the imposition of a favorable positional orientation between reactants, the participation of the ice crystal surface as a replacement for a catalyst molecule, and the change in the dielectric constant of the reaction media upon freezing.[10-13]

In the reaction of DPPH with cupric 3-α-butenylacetylacetonate, the rate of the reaction was observed to be remarkably accelerated in benzene, but not appreciably so in cyclohexane, when the solutions were frozen. This solvent effect on the frozen reaction was considered on the basis of the ESR spectra of DPPH in these frozen solvents.

Experimental

Materials. DPPH and cupric 3-α-butenylacetylacetonate were prepared in the way shown in a preceding paper.[2] The solvents were purified by the ordinary method and were distilled before use.

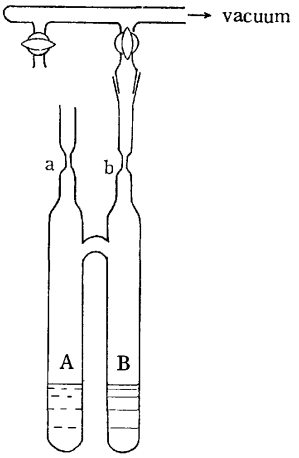

Fig. 1. Schematic drawing of the apparatus.

Apparatus and Procedure. The H-shaped tubes illustrated in Fig. 1 were used as the reaction cells. The solution of DPPH in A and the solution of the cupric chelate in B were simultaneously frozen in liquid nitrogen. The H-shaped tube was joined to a high-vacuum line after the tube had been sealed at the neck (a). Each solution was out-gassed by three freeze-thaw cycles under 10^{-5} mmHg, and then the H-shaped tube was sealed at (b). The solutions in A and B were warmed to room temperature and mixed thoroughly. The sealed tube was then immersed quickly into a dry ice–methanol mixture. The tube was allowed to remain submerged for a period of time to ensure complete freezing.

Kinetic Method. The reaction was followed by the photometric measurement of the DPPH concentration using a EPS-3T Hitachi spectrometer. After having been removed from the dry ice–methanol bath, the reaction tube was placed in a methanol–water bath thermostated at the desired temperature. Upon warming to the temperature, the solutions remained solidly frozen. The tube was withdrawn from the bath after a certain lapse of time. To determine the concentration of DPPH, the frozen sample was melted at 25°C and the optical density of the solution at 525 mμ was measured as soon as possible after the tube was opened.

ESR Spectra. The ESR spectra of DPPH or cupric chelate in frozen solutions were recorded by means of a JES-3BX ESR spectrometer of Japan Electron Optics, using the X-band at the temperature of liquid nitrogen. Before measurement, the cubet containing the solution was immersed into a dry ice–methanol mixture for a period of time in a manner similar to that in the kinetic run.

Results and Discussion

The effect of the solvent on the reaction rate in frozen solutions was studied. In Fig. 2, the plots of the reaction rate against the reaction temperature in a few solvents are shown. The rate has a maximum at −3°C for benzene (mp 5.5°C), at 8°C for dioxane (mp 11.7°C), and at 3°C for cyclohexane (mp 6.5°C). The maximum rates in these solvents appeared not at the freezing points of these solvents, but 3—9°C below them.

Pincock and Kiovsky[5-8] have also observed the appearance of the maximum rate several degrees below the freezing points of the solvents in some frozen systems and have explained it on the basis of the concentration effect. The maximum rate described above seems to result from a decrease in the rate constant and an increase in the concentration of the solute in the liquid region as the temperature is lowered.

The rate enhancement on freezing for a few solvents is shown in Table 1. The order of the rate enhancement is as follows:

benzene (24.1)>dioxane (5.39)>cyclohexane (2.42).

The values in parentheses show the ratio between the rate in the frozen solution at the temperature of the maximum rate and the rate determined by the extrapolation of the Arrhenius plot in liquid solutions to the

temperature of the maximum rate (Fig. 3).

Several recent papers have referred to the ESR spectra of DPPH and the spatial distribution of DPPH in frozen solutions. Roggin *et al.*[14] measured the ESR spectra of DPPH in a frozen benzene solution and reported that, upon freezing, the hyperfine structure of DPPH collapsed into a single line with a total width significantly less than that of the hyperfine spread and approximately equal to that observed for the concentrated polycrystalline DPPH. They have explained this phenomenon on the basis of the fact that DPPH is concentrated in small crystallites in which exchange interaction, which averages out the hyperfine structure, can occur. Ayscough *et al.*[15] studied the ESR spectra of deaerated frozen solutions of DPPH in various solvents and found that there were wide differences in line width, hyperfine splittings, and saturation behavior. They showed that the ESR spectra could be divided into three groups: (a) strong, exchange-narrowed line spectra (width from peak to peak, ΔH_{pp}=2—4 gauss); (b) broader, unresolved line spectra (ΔH_{pp}=10—20 gauss); (c) poorly resolved, five-line spectra. It has been explained that the spectra of group (b) result from some DPPH in the form of crystallites and some in a solid solution.

From these papers, it is clear that there is some correlation between the ESR spectra and the spatial distribution of DPPH in frozen solutions. Therefore, an investigation by means of the ESR spectra was carried out in order to obtain a possible explanation of the above solvent effects on the rate enhancements upon freezing.

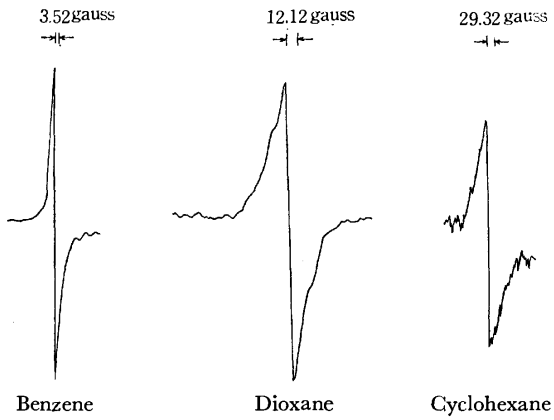

Fig. 4. ESR spectra of DPPH in the frozen solutions and peak to peak line width ΔH_{pp} (gauss).

The ESR spectra of DPPH in frozen solutions for the three solvents, benzene, dioxane, and cyclohexane, at the temperature of liquid nitrogen are shown in Fig. 4. The spectra in frozen benzene belonged to Group (a), as had been reported. On the other hand, the spectra in frozen dioxane and cyclohexane were found to belong to Group (b) in Ayscough's classification. The order of the magnitude of the ΔH_{pp} of DPPH in the frozen solution for the three solvents was as follows:

benzene (3.52 gauss)<dioxane (12.12 gauss)<cyclohexane (29.32 gauss).

The value of ΔH_{pp} in frozen benzene agreed with that of powder DPPH.[16] This proves that, in the benzene solution, DPPH is highly concentrated in small crystallites upon freezing. On the other hand, the value of ΔH_{pp} in frozen cyclohexane was remarkably large. This suggests that, in frozen cyclohexane solution, DPPH is scarcely concentrated at all in the form of crystallites and that almost all of the DPPH is in solid solution.

It was found that the ΔH_{pp} value of the ESR spectra in frozen solutions are closely related to the rate enhancement upon freezing in the reaction of DPPH with cupric 3-α-butenylacetylacetonate. That is, the smaller ΔH_{pp} value, the larger will be the rate enhancement upon freezing. This relationship between the ΔH_{pp} value and the rate enhancement suggests that the rate enhancement upon freezing in the reaction of DPPH with metal acetylacetonates is to be explained by the concentration effect mentioned by Pincock and Kiovsky.[5-8]

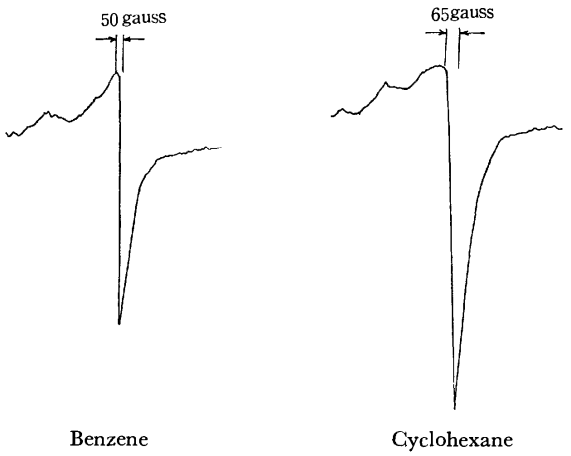

Fig. 5. ESR spectra of Cu(3-α-butenyl-acac)$_2$ in frozen solutions.

The ESR spectra of cupric 3-α-butenylacetylacetonate were also measured in a few frozen solutions, but they can not be discussed in detail. As is shown in Fig. 5, the ΔH_{pp} of the cupric chelate in a frozen benzene solution seems to be more narrow than that in frozen cyclohexane. Tominaga and Fujiwara[17] have reported that, in a frozen benzene solution containing 0.2M Co(acac)$_3$ at the temperature of dry ice, the most solute molecules are precipitated as microcrystals.

The facts presented above suggest that the reaction of DPPH with metal acetylacetonate in these frozen solutions is accelerated by the concentration of both reactants in the liquid region among the crystalline solvents upon freezing.

Oxygen Exchange of Benzenesulfinic Acids in Water[1]

Michio KOBAYASHI, Hiroshi MINATO, and Yoshikuni OGI

Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo

(Received November 9, 1971)

When arenesulfinic acids were heated in water ($H_2{}^{18}O$, 1.52 atom%) at 90—100°C for several hours, the ^{18}O contents of the disproportionation products (thiolsulfonate and sulfonic acid) and the sulfinic acid recovered were approximately the same. The rate of oxygen exchange of *p*-toluenesulfinic acid was much faster than that of methyl phenyl sulfoxide, whereas the rate of oxygen exchange of benzoic acid was much slower than that of benzaldehyde. A mechanism consistent with the kinetic results is proposed for the oxygen-exchange reaction, involving the formation of the sulfinic anhydride (sulfinylsulfone) as an intermediate.

It has long been known that a benzenesulfinic acid yields a thiolsulfonate and a benzenesulfonic acid by disproportionation.[2]

$$3ArSO_2H \longrightarrow ArSO_2SAr + ArSO_3H$$

Kice and his co-workers investigated the mechanism of this reaction in detail; they proposed that the initial step of this multi-step reaction is reversible formation of a sulfinylsulfone.[3]

$$2ArSO_2H \underset{+H_2O}{\overset{-H_2O}{\rightleftharpoons}} Ar\text{-}S(=O)\text{-}S(=O)\text{-}Ar$$

Carbonyl compounds such as aldehydes or carboxylic acids undergo oxygen exchange in water *via* a tetrahedral intermediate, and the rate is first order in the carbonyl compound.[4]

$$R\text{-}C(=O)\text{-}R \underset{-H_2O}{\overset{+H_2O}{\rightleftharpoons}} R\text{-}C(OH)_2\text{-}R$$

Since the nature of the oxygen exchange of sulfinic acids appears to be so different from that of the well-known oxygen exchange of carbonyl compounds, a detailed study of this interesting reaction has been carried out, and the results will be described in this paper.

Experimental

Disproportionation of Arenesulfinic Acid in Water-^{18}O. *p*-Bromobenzenesulfinic acid was precipitated by mixing its sodium salt and dilute sulfuric acid in water, the crystals thus formed were washed well with water and dried. An ampoule containing 1.2 g of *p*-bromobenzenesulfinic acid and 3 m*l* of water (^{18}O content, 1.52%) (not all sulfinic acid dissolved in the water at room temperature) was heated at 90±5°C for 12 hr. Crystals of the thiolsulfonate appeared after 2 hr of heating. After 12 hr the crystals of thiolsulfonate were filtered off while the solution was still hot, recrystallized twice from benzene, identified by infrared spectroscopy, and then subjected to the ^{18}O analysis which will be described below.

When the mother liquor was cooled, unchanged sulfinic acid precipitated as white crystals; these crystals were filtered and then converted to the acid's sodium salt by addition of a sodium hydrogen carbonate solution. The well-dried sodium sulfinate was converted, by heating it in an ampoule with 2 g of benzyl bromide, into *p*-bromophenyl benzyl sulfone, which was recrystallized from hexane and then subjected to the ^{18}O analysis.

$$BrC_6H_4SO_2Na + PhCH_2Br \longrightarrow BrC_6H_4\text{-}S(=O)_2\text{-}CH_2Ph$$

When an aqueous solution of *S*-benzylisothiuronium chloride was added to the filtrate from the mother liquor, crystals of *S*-benzylisothiuronium *p*-bromobenzenesulfonate appeared; these crystals were filtered, recrystallized from hexane, and then subjected to the ^{18}O analysis. The products of disproportionation of *p*-toluenesulfinic acid and *p*-nitrobenzenesulfinic acid under similar conditions were separated and analyzed by the same procedure.

Rates of Oxygen Exchange of p-*Bromobenzenesulfinic Acid and* p-*Toluenesulfinic Acid.* Sodium salts of the sulfinic acids were converted to the corresponding sulfinic acids by the method described above. By the use of purified dioxane and water (^{18}O content, 1.52 mol %), 1.131M solution of *p*-bromobenzenesulfinic acid and 1.324M solution of *p*-toluenesulfinic acid in 30% (v/v) aqueous dioxane were prepared. Aliquots (4 m*l* each) of these solutions were sealed in ampoules, which were then placed in a constant-temperature bath.

After suitable intervals, ampoules were removed from the bath and the reaction was stopped by cooling the ampoules in ice-water and by then converting the acids to sodium sulfinates. By separate experiments it was established that no oxygen exchange of sulfinic acids took place in alkaline media. Evaporation of the solvent *in vacuo* yielded white crystals of sodium sulfinate and excess sodium carbonate. These crystals were dried well *in vacuo* at 90—100°C, and were then allowed to react with benzyl bromide at 105—110°C for 7—10 hr. Then, 50 m*l* of water and 50 m*l* of ether were added to the mixture, and the ethereal solution containing an aryl benzyl sulfone was dried over magnesium sulfate. Evaporation of the ether yielded crude crystals of the sulfone, which were then recrystallized from hexane. From each ampoule, 200—400 mg of a sulfone was obtained.

Synthesis of p-*Bromobenzenesulfinic Acid-^{18}O.* *p*-Bromobenzenesulfinic acid (5 g) was heated in 15 m*l* of water (^{18}O, 1.52 mol %) at 90°C for 2 hr. The solution was cooled with ice, and the crystals thus obtained were filtered. In order to remove completely any *p*-bromobenzenesulfonic acid which might be present in these crystals, the crystals were quickly recrystallized from ordinary water and then

4) E. S. Gould, "Mechanism and Structure in Organic Chemistry," Henry Holt and Co., New York (1959), p. 539.

thoroughly dried. The excess oxygen-18 content was 1.232 atom %.

Comparison of the Rates of Oxygen Exchange between p-*Toluenesulfinic Acid and Methyl Phenyl Sulfoxide.* In 19 ml of 30% (v/v) aqueous ($H_2{}^{18}O$, 1.52 atom %) dioxane, 3 g of methyl phenyl sulfoxide and 1.7 g of *p*-toluenesulfinic acid were mixed; the solution was then divided into two ampoules, which were placed in a bath at 60°C. One ampoule was removed after 5 hr of heating, while the other was removed after 23.3 hr.

The reaction was stopped by addition of a 5% sodium carbonate solution, after which the sulfoxide was extracted by chloroform. The chloroform solution was dried over magnesium sulfate; the subsequent evaporation of the solvent yielded crude sulfoxide, which was then purified by distillation under reduced pressure (102°C/2 mmHg). The sodium sulfinate present in the aqueous layer was analyzed in a manner similar to that described above.

Comparison of the Rates of Oxygen Exchange between Benzoic Acid and Benzaldehyde. Into 10 ml of 30% (v/v) aqueous ($H_2{}^{18}O$, 1.52 atom %) dioxane, 2.5 g of benzoic acid and 1 g of benzaldehyde were mixed; an ampoule containing the solution was then heated at 60°C for 5 hr. Then a 5% sodium carbonate solution was added, and the benzaldehyde was extracted with 50 ml of benzene. The benzene solution was dried over anhydrous magnesium sulfate; the subsequent evaporation of the solvent yielded benzaldehyde, which was then purified by distillation under reduced pressure. The aqueous layer was acidified with a dilute hydrochloric acid solution, and the benzoic acid was extracted with ether. The ethereal solution was dried over anhydrous magnesium sulfate; the subsequent evaporation of the solvent yielded crude benzoic acid, which was then recrystallized from hexane.

Analysis of Samples Containing Oxygen-18. By the method reported by Rittenberg,[5] a sample was pyrolyzed in the presence of mercuric chloride and mercuric cyanide at 400°C for 4 hr; the carbon dioxide thus obtained was analyzed by mass spectrometry.

Results and Discussion

At 90°C a 1.25M aqueous solution ($H_2{}^{18}O$, 1.52 atom %) of *p*-bromobenzenesulfinic acid was heated in an ampoule for 12 hr. Similar reactions were carried out with a 4.0M aqueous solution of *p*-toluenesulfinic acid at 100°C for 2 hr and with a 1.5M aqueous solution of *p*-nitrobenzenesulfinic acid at 100°C for 5 hr. The results of the mass-spectrometric analyses of the sulfinic acid recovered are summarized in Table 1.

5) D. Rittenberg and L. Ponticorvo, *Int. J. Appl. Radiat. Isotopes.*, **1**, 208 (1956).

The fact that both the sulfinic acid and the reaction products contain approximately the same amount of oxygen-18 indicates that the rate of oxygen exchange is considerably faster than that of disproportionation.

Carbonyl compounds such as carboxylic acids or aldehydes undergo oxygen exchange in water in the presence of an acid, and the rate is first order in the substrate. The rates of oxygen exchange of benzoic acid and benzaldehyde and those of *p*-toluenesulfinic acid and methyl phenyl sulfoxide were determined, the results are summarized in Table 2.

Table 2. Comparison of the rates of oxygen exchange[a]

	Excess oxygen-18 atom %	
	5 hr	23.3 hr
p-$CH_3C_6H_4SO_2H$	0.06	0.28
CH_3–S–Ph ‖ O	0.03	0.03
Ph–CO_2H	0.01	—
Ph–CHO	0.80	—

a) In 30% (v/v) aqueous ($H_2{}^{18}O$) dioxane, at 60°C.

In the pair of the carbonyl compounds, the rate of oxygen exchange of the aldehyde was much faster than that of the acid, whereas in the pair of the sulfinyl compounds the rate of oxygen exchange of the acid was much faster than that of the sulfoxide, which underwent almost no exchange of oxygen even when it was heated at 60°C for 23.3 hr.

These findings suggest that the mechanism of oxygen exchange of a sulfinic acid is quite different from that of a carbonyl compound.

Kice and his co-workers proposed that the initial step of the disproportionation of a benzenesulfinic acid is reversible formation of a sulfinylsulfone,[2] the following reaction scheme seems plausible as the mechanism for incorporation of oxygen-18 in the sulfinic acid recovered:

$$RSO_2H + RSO_2H \underset{k_{b'}+H_2O}{\overset{k_{f'}-H_2O}{\rightleftharpoons}} RSO_2SOR \underset{k_{f'}-H_2O}{\overset{k_{b'}+H_2O^*}{\rightleftharpoons}} RSO_2^*H + RSO_2H$$

$$\Big\downarrow k_d$$

disproportionation products

The rate of increase of the labelled sulfinic acid, RSO_2^*H, is expressed by the following:

$$\frac{d[RSO_2^*H]}{dt} = k_b[RSO_2SOR][H_2O^*] - k_f[RSO_2^*H][RSO_2H]_T \quad (T = \text{total})$$

By a steady-state assumption for the sulfinylsulfone, the following equations are obtained:

$$\frac{d[RSO_2SOR]}{dt} = k_f[RSO_2H]_T{}^2 - k_b[RSO_2SOR][H_2O]_T - k_d[RSO_2SOR] = 0$$

$$\frac{d[RSO_2^*H]}{dt} = \frac{k_f k_b[H_2O^*]}{k_d + k_b[H_2O]_T}[RSO_2H]_T{}^2 - k_f[RSO_2^*H][RSO_2H]_T$$

When $k_b[H_2O]_T \gg k_d$,

$$\frac{d[RSO_2^*H]}{dt} = k_f[RSO_2H]_T^2\left(\frac{[H_2O^*]}{[H_2O]_T} - \frac{[RSO_2^*H]}{[RSO_2H]_T}\right)$$

$$\frac{d([RSO_2^*H]/[RSO_2H]_T)}{dt} = k_f[RSO_2H]_T\{([H_2O^*]/[H_2O]_T) - ([RSO_2^*H]/[RSO_2H]_T)\}$$

Since both $[RSO_2H]_T$ and $([H_2O^*]/[H_2O]_T)$ are approximately constant under mild conditions,

$$k_f = (1/[RSO_2H]_T \cdot t) \ln [([H_2O^*]/[H_2O]_T)/\{([H_2O^*]/[H_2O]_T) - ([RSO_2^*H]/[RSO_2H]_T)\}]$$

The rates of increase of oxygen-18 in the sulfinic acids recovered were measured, and found to follow the first-order equation described above. The results are shown in Table 3.

TABLE 3. RATES OF ^{18}O-INCREASE IN BENZENESULFINIC ACIDS IN 30% (v/v) AQUEOUS DIOXANE

Sulfinic Acid		*p*-$MeC_6H_4SO_2H$	*p*-$BrC_6H_4SO_2H$	$PhSO_2H$
$[RSO_2H]_0$ (mol/*l*)		1.32	1.13	1.30
$H_2{}^{18}O$ (atom %)		1.52	1.52	1.52
$10^7 \times k_f$ (M^{-1} sec^{-1})	20.0°C	1.37	2.49	1.42
	40.0°C	12.9	17.4	8.28
	60.0°C	110	—	35.5
	65.0°C	—	133	—
E_a (kcal/mol)		21.5	17.4	15.6
$\Delta S^{\neq}$ (e. u.)		−21.9	−31.3	−29.4

It is often desirable to prepare ^{18}O-labelled benzenesulfinic acids, which can easily be converted to ^{18}O-labelled sulfoxides and other derivatives; for this purpose the rate constants in Table 3 are valuable for predicting the rates of ^{18}O-incorporation. Under mild conditions, k_d is much smaller than $k_b[H_2O]_T$, and $k_f[RSO_2H]^2$ is approximately equal to the rate of production of the ^{18}O-labelled sufinic acids.

Kice and his co-workers observed that the exchange of oxygen was first-order in a sulfinic acid when a sulfinic acid-^{18}O was subjected to oxygen exchange in acetic aicd containing sulfuric acid as the catalyst or in 60% aqueous dioxane containing perchloric acid and sodium bromide.[6] However, their experimental conditions are quite different from those of the present investigation; the concentration of the mineral acid added as the catalyst was greater than, or equal to, the concentration of a sulfinic acid, and the concentration of a sulfinic acid was very low. Under such highly acidic conditions, it seems likely that the oxygen exchange takes place through a reaction between a protonated sulfinic acid and water, thus it is understandable why the rate was first-order in the sulfinic acid under their conditions.

If the oxygen exchange under our reaction conditions is due to the direct reaction between a sulfinic acid and $H_2{}^{18}O$, the rate of increase in the ^{18}O-content in the sulfinic acid must be independent of the initial concentration of the sulfinic acid. If the oxygen exchange takes place *via* the sulfinylsulfone formed by bimolecular dehydration of the sulfinic acid, the rate of increase in the ^{18}O-content must be greater when the initial concentration of the sulfinic acid is greater.

TABLE 4. INCREASE OF ^{18}O-CONTENT IN BENZENESULFINIC ACID IN 30% (v/v) AQUEOUS DIOXANE[a]

$[PhSO_2H]_0$ (mol/*l*)	Excess oxygen-18 atom % in $PhSO_2H$				
	40°C		60°C		
	24 hr	72 hr	5 hr	7 hr	10 hr
0.649	0.297	0.423	—	0.335	0.371
1.298	0.419	0.551	0.302	—	0.402

a) $H_2{}^{18}O$ atom %, 1.52.

The rates of oxygen exchange were determined in solutions of different sulfinic acid concentrations; the results are summarized in Table 4. The rates of exchange are faster in the solutions with greater sulfinic acid concentrations, this finding made unlikely any direct reaction between the sulfinic acid and water under our experimental conditions.

Aminosugars. XIX. On the Structure of 2-Deoxy-2-guanidino-D-glucose[1]

Juji YOSHIMURA, Tetsuo SEKIYA, and Takao IIDA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received November 25, 1971)

It was found that 2-deoxy-2-guanidino-D-glucose prepared by guanidination of 2-amino-2-deoxy-D-glucose with cyanamide exists mainly as α-D-glucofurano[1′,2′;4,5]-2-imino-imidazolidine (*5*) which is easily converted into 2-imino-4-(D-*arabino*-tetrahydroxybutyl)imidazoline-4 (*6*) under alkaline conditions. Acetylation of *5* and *6* gave the corresponding hexa- and heptaacetate (*7* and *8*), respectively. Warming of *7* in alcohols gave addition compounds of alcohols to the imino double bond, and deacetylation with sodium alcoholate at a room temperature yielded 2-acetamido-4-(D-*arabino*-tetrahydroxybutyl)imidazole (*10*). Similar treatment of *8* in ethanol at elevated temperature gave an unknown addition compound in which two *N*-acetyl groups were eliminated, and deacetylation with a small amount of sodium methylate yielded a mixture of (2*R*,*S*)-2-acetamido-2-methoxy-4-(D-*arabino*-tetraacetoxybutyl)imidazoline-4 and tetra-*O*-acetyl derivative of *10* which was also obtained by acetylation of *10*.

Several natural guanidino-compounds such as streptidine,[2] viomycidine,[3] and tetrodotoxin[4] are known about their strong biological activities. Among them, the aminal ring between the guanidino and aldehyde group in tetrodotoxin is interesting in the structural feature. Odo and Kono[5] reported that 2-deoxy-2-guanidino-D-glucose hydrochloride which was obtained by guanidination of 2-deoxy-2-amino-D-glucose hydrochloride with cyanamide exists in an equilibration between the usual lactol (**1**) and the imidazoline ring structures (**2**) in aqueous solutions.

In this paper, the authors have found that 2-deoxy-2-guanidino-D-glucose exists mainly as α-D-glucofurano-[1′,2′;4,5]-2-imino-imidazolidine (**3**) which is easily converted to 4-(D-*arabino*-tetrahydroxybutyl)imidazoline-4 (**4**) under alkaline conditions, and examined a few chemical properties of them.

Results and Discussion

A neutral solution of 2-amino-2-deoxy-D-glucose hydrochloride and cyanamide in water was heated at 60°C for 7 hr, and then picric acid in methanol was added to the reaction mixture. After standing at 0°C for 2 days, the known picrate of needles (**3**)[5]; mp 180°C, and a new granular picrate (**4**); mp 178°C, were obtained in 23.6% and 15.4% yield, respectively. These picrates were then converted into hydrochlorides (**5** and **6**), respectively. Both of them were negative to ninhydrin, Fehling, and Sakaguchi reactions, and distinguishable each other in specific rotations and C–O stretching absorptions in the region between 1000—1100 cm^{-1} in IR spectra. No mutarotation of them indicated the absence of **1** in solutions.

Moreover, in UV spectrum, **5** showed no absorption other than end absorptions (<210 nm), but **6** had a maximum at 212 nm (ε 1.057×10^4). NMR spectra of **5** and **6** showed two characteristic doublets at 3.55 and 5.07 τ, and two singlets at 2.77 and 4.60 τ, respectively. These facts indicated a glucofurano-configuration for the former and a heterocyclic structure for the latter. Furthermore, the conversion of **5** to **6** was found in alkaline conditions. The doublet at 3.55 τ in NMR spectrum of **5** instantly disappeared by addition of alkali, and a singlet at 2.89 τ appeared, which is shifted to 2.77 τ by acidification. A maximum at 208 nm was also observed in UV spectrum of **5** at pH 10.4. Such a conversion was also occured by adjustment of the pH of a solution of **5** with Amberlite IRA-410, and in fact, **6** was isolated by acidification in 80% yield. Further conversion of **6** to an unknown compound by standing the alkalline solution for 2 or 3 days was indicated with the disappearance of characteristic singlet, however, no definite compound could be isolated.

In order to clarify the structures, **5** and **6** was respectively acetylated with acetic anhydride in pyridine to the corresponding hexaacetate (**7**) and heptaacetate (**8**) in 83.3 and 50% yields. Both compounds showed UV absorptions of λ_{max}^{EtOH} 219 nm (ε 1.5×10^4) and 253 nm (ε 3.4×10^3), respectively. The NMR spectrum of **7** (Fig. 1) assigned by double resonance technique gave a very similar pattern of the ring-proton signals to 3′,5′,6′-tri-*O*-acetyl-α-D-glucofurano[1′,2′;4,5]-*N*-acetyloxazolidine-2-thion,[6] indicating the presence of α-D-glucofuranose configuration, and two acetyl signals appeared in lower field than other four acetyl signals are assignable to imino-acetyl and N_3-acetyl also by analogy to this compound. Therefore, **7** was determined to be 3′,5′,6′-tri-*O*-acetyl-α-D-glucofurano[1′,2′;4,5]-2-acetylimino-1,3-diacetylimidazolidine. It is interesting that such a ring formation in **7** as in glycosylamines is also seen in viomycidine[2] or anhydrotetro-

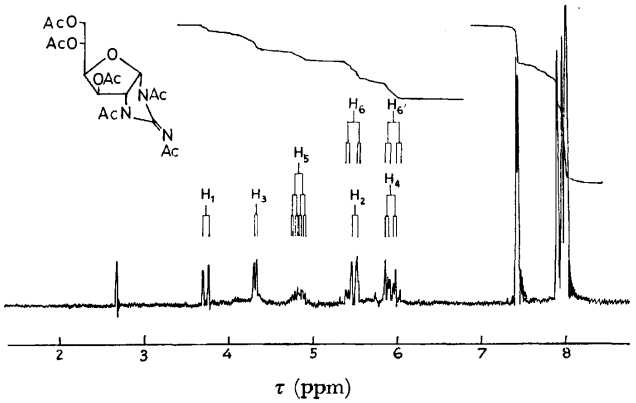

Fig. 1. The NMR spectrum of **7**.

dotoxin.[3]

On the other hand, the NMR spectrum of **8** (Fig. 2) showed again a closely similar pattern of sugar-chain protons to 2-methoxycarbonyl-4-(D-*arabino*-tetraacetoxybutyl)imidazole obtained by the reaction of 2-amino-2-deoxy-D-glucose and the corresponding iminoether,[7] indicating the presence of a five-membered heterocyclic structure. However, the difference of UV absorption between 8 and this compound (λ_{max} 260 nm; ε 1.05×10^4) and the presence of three acetyl groups in the heterocyclic part indicate a non-conjugated system. Consequently, **8** was concluded to be 2-acetylimino-1,3-diacetyl-4-(D-arabino-tetraacetoxybutyl)imidazolin-4.

Transformation of **1** to **3** or **4** mentioned above will be explained as follows (Scheme 1). Dehydration between the guanidino and aldehyde groups in the oxo-form of **1** give easily the intramolecular Schiff base which is equilibrating with the more stable imidazolidine structure at the pH region lower than 7. At a higher pH region, a prototropic shift is caused by the action of hydroxide ions to give the imidazoline derivative irreversibly. At the end of the condensation reaction of 2-amino-2-deoxy-D-glucose with cyanamide, the pH of the solution adjusted to 7 at the biginning has changed to 8.3. This change will be attributed to the reason for the formation of **3** and **4** at the same time. The participation of lone-paired electrons of nitrogen in the intramolecular Schiff base to the resonance stabilization of the imidazoline ring will accerelate the prototropic shift in the convesion into **4**.

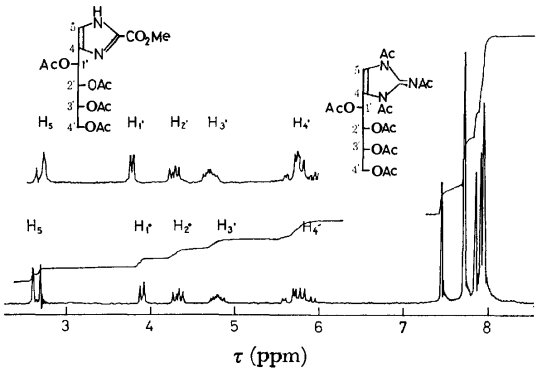

Fig. 2. The NMR spectrum of **8**.

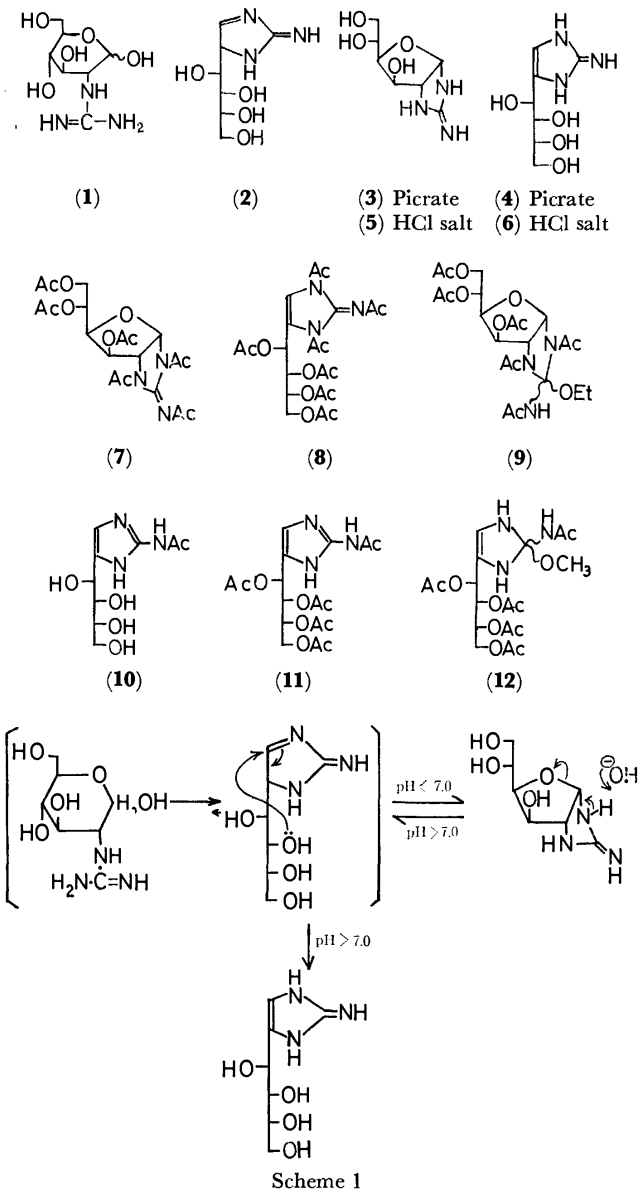

Scheme 1

On the other hand, it was found that **7** was converted to an addition product of ethanol (**9**) in 66% yield by heating it in ethanol at 60°C for 4 hr. IR spectrum of **9** showed the appearrance of characteristic absorptions of N–H (3250, 3200, and 1540 cm^{-1}), and the NMR spectrum two kinds of ethyl signals (C–CH_3 at 8.78 and 8.84 τ; O–CH_2– at 6.31 and 6.89 τ), indicating the addition of ethanol to the 2-imino bond from the both side. Formation of analogous addition compound of methanol or isopropyl alcohol were also ascertained with NMR spectra. A similar reaction was reported in the case of triacetyl-2-imino-imidazolidine.[8] Similar treatment of **8** in ethanol at an elevated temperature gave also an addition compound in which elimination of two *N*-acetyl groups was indicated by NMR spectrum, however, no definite compound could be isolated.

Moreover, an attempted deacetylation of **7** with sodium methoxide at a room temperature gave 2-acetamido-5-(D-*arabino*-tetrahydroxymethyl)imidazole

7) J. Yoshimura, K. Fujimori, Y. Sugiyama, and H. Ando, *ibid.*, **44**, 3131 (1971).

8) R. Greenhalgh and R. A. B. Bannard, *Can. J. Chem.*, **39**, 1017 (1961).

(**10**) in 80% yield. Reacetylation of **10** by the usual method gave a mixture of the corresponding *N,O*-pentaacetate (**11**) and another product. The presence of two kind of C_4- and C′-proton signals indicate that the structure of the latter is similar to the former. One attempted acetylation of **6** gave incidentally **11** as the main product, from which pure sample was isolated by preparative thin layer chromatography. Comparatively large molecular coefficency of the absorption of **11** [λ_{max}^{EtOH} 246 nm (ε 7.08×10^3)] and the presence of characteristic absorptions of secondary amide (1675 and 1520 cm^{-1}), esters (1745 cm^{-1}), monoacetylguanidine (1595 cm^{-1})[8] in IR spectrum indicated the presence of imidazole structure in **11**. Because of its insolubility NMR and UV spectrum of **10** could not be examined, however, the IR spectrum showed absorptions of secondary amide (1675 and 1530 cm^{-1}), monoacetylguanidine (1600 cm^{-1}), and characteristic C–O stretching in the region between 1000—1100 cm^{-1} as was observed that of **4** and **6**.

For the transformations of **7** to **10** and **10** to **11**, the following considerations will be given; (i) treatment of **7** with sodium methoxide caused the elimination of feasible *N*-acetyl groups attached to guanidine-type structure[9] as well as de-*O*-acetylation, and moreover, the skeletal conversion as shown in Scheme 1 is accompanied with the shift of *exo*-double bond to give more stable imidazole structure. Thus, the usual 2-acetamido group in **10** is remained intact. (ii) Because *N*-acetylation of heterocycles such as imidazole can be accomplished only by refluxing with acetic anhydride,[10] the usual acetylation of **10** gave the *N,O*-pentaacetate.

Similar deacetylation of **8** with a small amount of sodium methoxide gave again a mixture of **11** and another addition compound of methanol. From the integration of NMR spectrum the latter was deduced to be (2*R,S*)-2-acetamido-2-methoxy-4-(D-*arabino*-tetraacetoxybutyl)imidazoline-4 (**12**). The analitical data of the mixture consisted with that a mixture of them in the ratio estimated from the NMR spectrum. Treatment of **11** with excess amounts of ethoxide gave again crude **10**. These results indicate that guanidine-type *N*-acetyl groups are more labile than *O*-acetyl groups, and nucleophilic additions to the *exo*-double bond in **8** are also possible depending on condition used.

Many works on electrophillic reactions of triheterocarbonium ions including oxygen, nitrogen and sulfur as heteroatoms[11] have been done, but, the trinitrogen-system of guanidines has been considered to be rather stable than others. The result obtained in this work seems likely to suggest that *N*-acylation activates this system, and more simple model compound will be suitable to study for this aspect.

Experimental

All melting points are uncorrected. The solutions were evaporated under diminished pressure at a bath temperature not exceeding 45°C. Specific rotations were measured in a 0.5-dm tube, with a Carl Zeiss LEP Al Polarimeter. The IR spectra were recorded with a Hitachi Model EPI-GS grating IR spectrophotometer. The NMR spectra were taken with a JMN-4H-100MHz Spectrometer in deuteriochloroform unless otherwise stated, using tetramethylsilane as an internal standard. Chemical shifts and coupling constants were recorded in τ and Hz units, and IR frequencies in cm^{-1}.

α-D-Glucofurano[1′,2′;4,5]-2-iminoimidazolidine picrate (3) and 2-imino-4-(D-arabino-tetrahydroxybutyl)imidazoline picrate (4). A solution of D-glucosamine hydrochloride (4.30 g, 20 mmol) and cyanamide (1.26 g, 30 mmol) in water (20 m*l*) was neutralized with 5N-sodium hydroxide to pH 7.0, stirred at 60°C for 7 hr, and then picric acid (10.2 g) in methanol (140 m*l*) was added to the reaction mixture. After standing this solution at 0°C for 2 days, picrate of needle crystal (**3**) was obtained in 23.6% yield (2.02 g). Mp 180°C; IR: 1670 (C=N), 1560 (NO_2).

Found: C, 35.96; H, 3.70; N, 19.38%. Calcd for $C_{13}H_{16}N_6O_{11}$: C, 36.13; H, 3.73; N, 19.44%.

The mother liquor was suitably concentrated, and the precipitate appeared was gathered. This powder (8.50 g) was washed three times with benzene (25 m*l*) at 60°C to remove excess picric acid. The residue was recrystallized from hot water to give granular picrate (**4**) (1.33 g) in 15.4% yield. Mp 178°C; IR: 1680 (C=C), 1668 (C=N), 1550 (NO_2).

Found: C, 35.96; H, 3.76; N, 20.47%. Calcd for $C_{13}H_{16}N_6O_{11}$: C, 36.13; H, 3.73; N, 19.44%.

α-D-Glucofurano[1′,2′;4,5]-2-iminoimidazolidine hydrochloride (5). To a solution of **3** (1.4 g) in water (30 m*l*) was added 10% hydrochloric acid (10 m*l*) at 50°C, kept at the same temperature for ten minutes and then cooled to room temperature. After separating picric acid by filteration, the mother liquor was extracted several times with ether (15 m*l*× 5) to remove the picric acid. The water solution was adjusted to pH 5.0 with Amberlite IRA-410, decolorized with active carbon, concentrated, and the residual sirup was crystallized by addition of ethanol to give 0.6 g (77%) of colorless prisms which was recrystallized from water-ethanol. IR: 1674 (C=N); NMR (D_2O): 3.55 ($H_{1'}$; d, $J_{1,2}$=6.3); 5.07 ($H_{2'}$; d); 5.17 (1H; s) and 5.5—6.0 (4H; m), ($H_{3'}$, $H_{4'}$, $H_{5'}$, $H_{6'a}$, $H_{6'b}$). $[\alpha]_D^{23}$ −25.4° (*c* 1.0, water).

Found: C, 35.08; H, 6.07; N, 17.46%. Calcd for $C_7H_{14}N_3O_4Cl$: C, 35.07; H, 5.89; N, 17.53%.

2-Imino-4-(D-arabino-tetrahydroxybutyl)imidazoline-4 hydrochloride (6). The picrate **4** (1.0 g) was treated by the same method as mentioned above, and the corresponding hydrochloride was obtained as colorless needles in 72% (0.4 g) yield. Mp 171°C; $[\alpha]_D^{23}$ −11.7° (*c* 1.0, water); IR: 1664 and 1575 (C=N and C=C); NMR (D_2O): 2.77 (H_5; s); 4.60 ($H_{1'}$; s); 5.6—5.9 ($H_{2'}$, $H_{3'}$, $H_{4'a}$, $H_{4'b}$, m).

Found: C, 34.48; H, 5.59; N, 17.69%. Calcd for $C_7H_{14}N_3O_4Cl$: C, 35.07; H, 5.89; N, 17.53%.

Conversion of 5 into 6. A solution of **5** (1.00 g) in water (30 m*l*) was adjusted to pH 11.8 with Amberlite IRA-410 and kept at room temperature for thirty minutes. After checking the appearrance of the UV absorption (λ_{max} 208 nm) the solution was adjusted to pH 4.8 with 4N-HCl (*ca.* 8 m*l*), and evaporated to give a sirup which was crystallized by addition of ethanol. Yield, 0.8 g (80%). Physical properties of this crystals consisted with the authentic specimen.

3′,5′,6′-Tri-O-Acetyl-α-D-glucofurano[1′,2′;4,5]-2-acetylimino-1,3-diacetylimidazolidine (7). To a suspension of **5** (1.20 g, 5.0 mmol) in pyridine (8.0 m*l*) was added acetic anhydride

(6.0 ml, 64 mmol) with stirring under cooling at 0°C. After standing the reaction mixture at room temperature for 2 days, it was poured into ice-water (30 ml) with stirring to give white crystals, which was gathered on a filter paper, washed with cold water, and then recrystallized from chloroform–petroleum ether. Yield, 1.89 g (83.3%); mp 155°C; $[\alpha]_D^{23}$ +26.0° (*c* 2.00, chloroform); IR: 1745 (OAc), 1685 (C=N), 1640 (*tert.* amide); NMR: 3.73 ($H_{1'}$; d, $J_{1',2'}=6.5$), 5.49 ($H_{2'}$; d), 4.32 ($H_{3'}$; d, $J_{3',4'}=3.0$), 5.91 ($H_{4'}$; q, $J_{4',5'}=10.0$), 4.82 ($H_{5'}$; oct, $J_{5',6'a}=3.0$), 5.47 ($H_{6'a}$; q, $J_{6'a,b}=12.5$), 5.94 ($H_{6'b}$; q, $J_{5',6'b}=5.5$), 7.42 and 7.44 (N_3-Ac and imino-Ac), 7.90, 7.96, and 8.01 (N_1-Ac and 3×OAc).

Found: C, 50.01; H, 5.89; N, 9.23%. Calcd for $C_{19}H_{25}N_3O_{10}$: C, 50.11; H, 5.53; N, 9.23%.

*2-Acetylimino-1,3-diacetyl-4-(*D-arabino-*tetraacetoxybutyl)imidazoline-4 (**8**).* To a suspension of **6** (0.6 g, 2.5 mmol) in pyridine was added acetic anhydride (3.0 ml), and the reaction mixture was treated by the usual method to give the heptaacetate (0.65 g) in 50% yield, which was recrystallized from chloroform-petroleum ether. Mp 151°C; $[\alpha]_D^{23}$ −13.6° (*c* 1.01, chloroform); IR: 1740 (OAc), 1720 (NAc); NMR: 2.61 (H_5; s), 3.89 ($H_{1'}$; d, $J_{1',2'}=4.5$), 4.32 ($H_{2'}$; q, $J_{2',3'}=8.5$), 4.77 ($H_{3'}$; sex, $J_{3',4'a}=3.0$, $J_{3',4'b}=6.0$), 5.66 ($H_{4'a}$; q, $J_{4'a,b}=12.0$), 5.86 ($H_{4'b}$; q), 7.45 (-NAc), 7.72 (2 NAc), 7.86, 7.92, and 7.95 (4 OAc).

Found: C, 49.85; H, 5.41; N, 9.02%. Calcd for $C_{21}H_{27}N_3O_{11}$: C, 50.11; H, 5.53; N, 9.23%.

*3',5',6'-Tri-*O*-acetyl-α-*D*-glucofurano[1',2';4,5]-(2*R,S*)-2-acetamido-1,3-diacetyl-2-ethoxyimidazolidine (**9**).* A solution of **7** (0.45 g, 1.0 mmol) in ethanol (5 ml) was heated at 60°C for 4 hr, and the crystals appeared was filtered to give colorless crystals (0.33 g) in 66% yield. Mp 225°C (decom); IR: 3250, 3200, 1540 (NH).

Found: C, 50.00; H, 6.13; N, 8.52%. Calcd for $C_{21}H_{31}N_3O_{11}$: C, 50.29; H, 6.13; N, 8.78%.

*2-Acetamido-5-(*D-arabino-*tetrahydroxybutyl)imidazole (**10**).* To a solution of **7** (470 mg, 1.04 mmol) in aboslute methanol was added two drops of 2N-sodium methoxide at room temperature, and then white solid precipitated was filtered, washed with absolute methanol to give 0.2 g (79%) of the monoacetate. Mp 200°C (decomp). It was insoluble in methanol, water and DMSO. IR: 1675 and 1530 (*sec*-amide), 1600 (mono-acetylguanidine).

Found: C, 44.10; H, 6.72; N, 17.63%. Calcd for $C_9H_{17}N_3O_6$: C, 44.08; H, 6.17; N, 17.14%.

*2-Acetamido-5-(*D-arabino-tetraacetoxybutyl)imidazole (**11**).*

*i) From **6**;* To a suspension of **6** (0.48 g, 2 mmol) in pyridine was added acetic anhydride (0.3 ml) under cooling at 0°C. After stirring at room temperature for two days on a magnetic stirrer, the warm reaction mixture was poured into ice water (30 ml). As any crystals could not be obtained, the resulted solution was extracted four times with chloroform (40 ml), and the extracts were washed with 2N-sulfuric acid (30 ml), saturated aqueous sodium bicarbonate (30 ml) and water. The extract was then evaporated to give a sirup (0.53 g). This sirup showed three bands on preparative tlc (Wakogel B-5 UA; 10% methanol in benzene), and the main band which had the greatest R_f value was collected, and eluted with chloroform to give a sirup in 21% (0.17 g) yield. $[\alpha]_D^{23}$ −10.8° (*c* 0.52, ethanol); UV: λ_{max}^{EtOH} 246 nm (ε 7.08×10³); IR: 1740 (OAc), 1680 and 1520 (*sec*-amide), 1595 (monoacetylguanidine); NMR: 3.22 (H_4; s), 3.96 ($H_{1'}$; d, $J_{1',2'}=4.8$), 4.47 ($H_{2'}$; q, $J_{2',3'}=7.0$), 4.12 ($H_{3'}$; m), 5.76 ($H_{4'a}$; q, $J_{3',4'a}=3.5$, $J_{4'ab}=13.0$), 5.90 ($H_{4'b}$; q, $J_{3',4'b}=5.8$), 7.73 (NAc), 7.92, 7.96, and 7.98 (OAc).

Found: C, 49.72; H, 6.05; N, 9.53%. Calcd for $C_{17}H_{24}N_3O_9$: C, 49.27; H, 5.84; N, 10.14%.

*ii) From **10**;* To a solution of **10** (0.11 g, 0.45 mmol) in pyridine (1 ml) was added acetic anhydride (1 ml) at room temperature, and the reaction mixture was kept for three days with stirring, poured into ice–water. The resulted solution was extracted with benzene, and the extract was evaporated to give a sirup. This sirup showed the presence of two kinds of products in the NMR spectrum in which a series of proton chemical shifts of the main product consisted with that of **11**. Another one showed H_5-proton signal at 2.98 τ (s) and $H_{1'}$ at 4.03 τ (d, $J_{1',2'}=5.0$), respectively.

*Attempted deacetylation of **8** with sodium methoxide.* To a solution of **8** (0.5 g, 1 mmol) in absolute methanol (2 ml) was added five drops of 2N-sodium methoxide at room temperature. After standing overnight, the reaction mixture was neutralized with five drops of 2N-acetic acid and evaporated. A solution of the resulted sirup in chloroform (10 ml) was washed three times with water, dried and evaporated. The resulted sirup showed two bands on a preparative tlc (Wakogel B-5 UA; 10% methanol in benzene), and the main band which had larger R_f value was collected. The NMR sepctrum of the resulted sirup indicated the presence of two products in which the proton chemical shifts of the main product consisted with that of **11**. Another one showed H_5-proton signal at 3.23 τ (s), $H_{1'}$ at 4.01 τ (d, $J_{1',2'}=4.8$), OCH_3 at 6.79 τ (s) indicating the presence of the addition product of methanol. The ratio of the both compounds was deduced to be 3: 1 from intensities of OCH_3 and other proton signals. UV spectrum of the mixture showed at 247 nm. (Found: C, 48.78; H, 5.58; N, 9.52%. Calcd as 3: 1 mixture of the both compounds: C, 49.39; H, 5.95; N, 9.88%).

Ionic Decomposition of Phenylazotriphenylmethane in Trifluoroacetic Acid[1]

Nobumasa KAMIGATA, Michio KOBAYASHI, and Hiroshi MINATO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo

(Received December 13, 1971)

Acid-catalyzed decomposition of phenylazotriphenylmethane was studied in mixtures of benzene and large excess concentration of trifluoroacetic acid. The decomposition was of first order and the rate was much faster than that in pure aromatic solvents. The values of activation energy (E_a=22.3 kcal/mol) and activation entropy ($\Delta S^{\neq}$=−5.2 e.u.) fit the isokinetic relationship established for the ionic decomposition of benzenediazonium tetrafluoroborate in aprotic polar solvents and of phenylazo *p*-tolyl sulfone in mixtures of benzene and trifluoroacetic acid. The reaction products were benzene, biphenyl, benzophenone, triphenylmethane, triphenylmethyl alcohol and nitrogen. Orientations and partial rate factors for the phenylation of monosubstituted benzenes indicated that not phenyl radical but phenyl cation was produced as an intermediate. Further, the UV spectrum of PAT in benzene and trifluoroacetic acid shows λ_{max} at 403 mμ (log ε 4.48) and λ_{max} at 427 mμ (log ε 4.48). However, the UV spectrum of PAT in benzene and in the absence of trifluoroacetic acid has no absorption in this range. The formation of triphenylmethyl alcohol and the UV spectra of PAT in acid solution indicate that triphenylmethyl cation was formed as an intermediate. A plausible mechanism was discussed.

Benzenediazonium salts in aprotic polar solvents spontaneously decompose, yielding phenyl cation;[2] but they can generate phenyl radical when nitrite ion,[3] hydroxide ion[4] or pyridine[5] are added.

Phenylazo *p*-tolyl sulfone decomposes homolytically when such basic agents as pyridine, quinoline, and magnesium oxide are present,[6] but in the absence of such basic agents autocatalytic ionic decomposition takes place, yielding phenyl cation.[7]

However, there have been no papers reporting on the heterolytic decomposition of phenylazotriphenylmethane (PAT), which has been considered to be a good dependable source for phenyl radical.[8]

More recently, Takeuchi, Nagai, and Tokura reported that triphenylmethyl radical generated from PAT was converted to triphenylmethyl cation when SO_2 and O_2 were present in the reaction system.[9]

During a systematic investigation on the decomposition of arylazo compounds in our laboratories, it has been found that PAT decomposes quite rapidly with evolution of nitrogen under strongly acidic conditions. In order to determine whether this fast decomposition is homolytic or heterolytic, products of the decomposition have been analyzed and isomer distributions for phenylation of substituted benzenes have been studied.

In this papar, the results of this investigation will be described, and the mechanism of the reaction will be discussed.

Results and Discussion

Kinetic Studies. When a solution of PAT (1.00 g) in benzene (15.6 g) was mixed with trifluoroacetic acid (35.0 g), rapid evolution of nitrogen took place. The decomposition was of first order in PAT as shown in Fig. 1. The rate constants determined were compared with those for the decomposition of PAT in pure benzene,[10] and the results are summarized in Table 1. The values of the activation parameters were calculated (E_a=22.3 kcal/mol, $\Delta S^{\neq}$=−5.2 e.u.). These

▲: Decomposition of p-TsN_2Ph in C_6H_6–CF_3CO_2H[6]
(f: p-TsN_2Ph/CF_3CO_2H=5.89 mol/mol, g: p-TsN_2Ph/CF_3CO_2H=2.95 mol/mol)

activation parameters fit surprisingly well the isokinetic relationship established for the decomposition of benzenediazonium tetrafluoroborate in various aprotic polar solvents[11] and for the decomposition of phenylazo p-tolyl sulfone in a mixture of benzene and trifluoroacetic acid,[7] as shown in Fig. 2 (β=311°K). The activation parameters are quite different from those reported[10] for the homolytic decomposition of PAT (E_a=27 kcal/mol, $\Delta S^{\neq}$=5 e.u.). These findings suggest that the decomposition of PAT in this medium is not homolysis but heterolysis. The fact that the activation parameters found fit the isokinetic relationship established for the decomposition of benzenediazonium ions suggests that benzenediazonium ion is an intermedate in this system and the rate-determining step is the decomposition of the diazonium ion.

$$Ph\text{-}N{=}N\text{-}CPh_3 \xrightarrow{CF_3CO_2H} PhN_2^+ \xrightarrow{\text{rate-determining step}} Ph^+ + N_2$$

Products Studies. PAT was decomposed in a mixture of benzene and trifluoroacetic acid at 40°C and the reaction products are summarized in Table 2. Evolution of nitrogen was almost quantitative (93—95%) and the yield of benzene was high in contrast to low yield of biphenyl and triphenylmethane; these results are quite different from those reported for homolysis of PAT.[8] In addition, a trace of benzophenone and a considerable amount of triphenylmethyl alcohol were produced, but no triphenylmethyl peroxide was found though the reaction was carried out under air. The formation of triphenylmethyl alcohol suggests that triphenylmethyl cation was produced as the intermediate, and then converted to triphenylmethyl alcohol.

$$Ph\text{-}N{=}N\text{-}CPh_3 \xrightarrow{CF_3CO_2H} Ph_3C^+ \xrightarrow{H_2O} Ph_3COH$$

Kinetic studies and product studies described above show that benzenediazonium ion and triphenylmethyl cation were formed as the intermediates from PAT. These results are abnormal and very surprising.

$$Ph\text{-}N{=}N\text{-}CPh_3 \longrightarrow Ph^+ + N_2 + Ph_3C^+$$

a) PAT (1.51g) was dissolved in C_6H_6 (23.5g) and CF_3CO_2H (50.0g): (Expt. 1).
b) PAT (1.42g) was dissolved in CF_3CO_2H (44.2g): (Expt. 2).

UV Spectra of PAT in Benzene and Trifluoroacetic Acid. In order to ascertain the formation of trityl cation in this medium, the UV spectrum of PAT was measured in benzene and trifluoroacetic acid at room temperature. The spectrum is shown in Fig. 3. The values of log ε at 403 mμ and 427 mμ were 4.48; no absorptions were observed in this range, when trifluoroacetic acid was absent. The UV absorptions reported for trityl cation are as follows:

Trityl chloride:[12] $\lambda_{max}^{98\%H_2SO_4}$ 430 mμ (log ε 4.58)
Gomberg's trityl:[13] $\lambda_{max}^{H_3PO_4}$ 400 mμ and 440 mμ(log ε 4.5)
Gomberg's trityl:[13] $\lambda_{max}^{POCl_3}$ 420 mμ and 440 mμ(log ε 4.2)

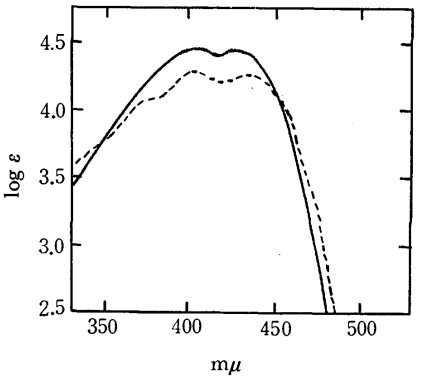

Fig. 3. The absorption spectrum of PAT in C_6H_6–CF_3CO_2H
—— PAT in C_6H_6–CF_3CO_2H
- - - Gomberg's trityl in liq. SO_2–O_2[9]

11) K. Ishida, N. Kobori, M. Kobayashi, and H. Minato, This Bulletin, **43**, 285 (1970).
12) A. G. Evans, J. A. G. Jones, and G. O. Osborne, *J. Chem. Soc.*, **1954**, 3803.
13) T. L. Chu and S. I. Weissman, *J. Chem. Phys.*, **22**, 21 (1954).

Therefore, the peaks at 403 mμ and 427 mμ in trifluoroacetic acid are ascribable to the presence of trityl cation in this medium. The values of log ε in our experiments are quite similar to the value reported[12] (log ε 4.58), and this means that PAT in trifluoroacetic acid is transformed to trityl cation to the same extent as the trityl chloride in 98% sulfuric acid.

Table 3. Orientation (%) and partial rate factors for the phenylation of PhX with PAT in CF_3CO_2H at 40°C

Phenylation of Substituted Benzenes with PAT in Trifluoroacetic Acid. Isomer distributions and partial rate factors for the phenylation of substituted benzenes with PAT in trifluoroacetic acid were determined at 40°C. The results are summarized in Table 3. The MeO, Et, and Cl groups behaved as *o,p*-directors and accelerated the phenylation, whereas the NO_2 group behaved as a *m*-director, and retarded the phenylation. These results are quite different from the results of phenylation with phenyl radicals generated from benzoyl peroxide[14] or *N*-nitrosoacetanilide[15] but similar to the phenylation with phenyl cations generated from benzenediazonium tetrafluoroborate in aprotic polar solvents[2] and phenylazo *p*-tolyl sulfone in trifluoroacetic acid.[7] Figure 4 is the Hammett plots for the phenylation *versus* σ^+, which followed a good straight line except for the points for *p*-OMe and *m*-NO_2 groups. In the case of the phenylation of PhX with phenyl

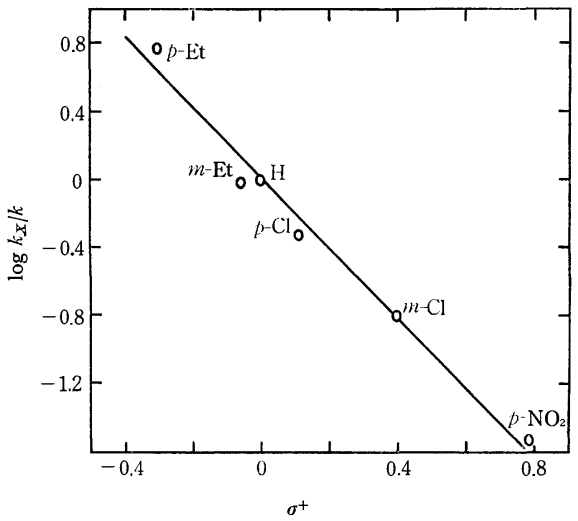

Fig. 4. The Hammett plots for the phenylation of PhX with PAT in CF_3CO_2H at 40°C.
$\rho = -2.1$

cation generated from benzenediazonium tetrafluoroborate, the points for *p*-OMe and *m*-NO_2 also deviated from a straight line in the Hammett plots.[2] The ρ value ($\rho = -2.1$) is a larger negative value than those obtained for the phenylation with benzenediazonium tetrafluoroborate ($\rho = -0.82$)[1] or phenylazo *p*-tolyl sulfone ($\rho = -0.10$).[7] This means that the decomposition of benzenediazonium ion in trifluoroacetic acid is more sensitive to the electron supply of substituents. Brown and Wirkkala reported that the relative rate of bromination of toluene and benzene (k_T/k_B) was 605 in 85% CH_3CO_2H and 2580 in CF_3CO_2H.[16]

Plausible Reaction Mechanism. Since the formation of trityl cation was instantaneous and almost quantitative upon addition of trifluoroacetic acid, trityl ion must be present before the rate-determining step. The red color of trityl cation did not fade when such nucleophiles as water was absent in the medium. When water was added to the mixture, the red color disappeared instantaneously.

It is of interest to determine what kind of chemical species are present in the mixture when the mixture changed from yellow to red upon addition of trifluoroacetic acid. When water was added about 20 sec after addition of trifluoroacetic acid, the products isolated from the benzene layer contained more triphenylmethane and less triphenylcarbinol, whereas the main product was triphenylcarbinol when water was added about 60 sec after addition of trifluoroacetic acid. The results are shown in Table 4.

Table 4. Products of hydrolysis of PAT–C_6H_6–CF_3CO_2H mixture

	Time interval between addition of CF_3CO_2H and that of H_2O	Products (mol/100 mol PAT)		
		Ph_3CH	Ph_3COH	Expt. 7	about 20 sec	58.9	30.9	45
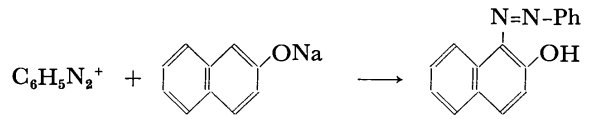
Expt. 8	about 60 sec	2.9	86.0	54

When the aqueous layer was separated and added to a 10% sodium β-naphthoxide solution, the coupling product was produced in good yield, indicating the presence of benzenediazonium ion in the mixture.



A mechanism which is consistent with these results is shown below.

The mechanism shown requires that the reaction between phenyl cation and triphenylmethane produces benzene and triphenylmethyl cation. Taft[17] and Abramovitch[18] proposed that phenyl cation is in equi-

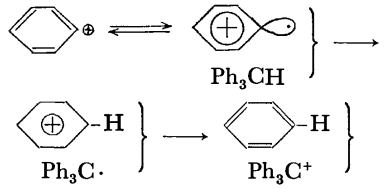
librium with a diradical cation.

other canonical forms

The formation of triphenylmethyl cation from triphenylmethane would be better explained in terms of hydrogen abstraction by a diradical cation rather than hydride transfer.



In order to prove that phenyl cation can oxidize triphenylmethane to triphenylmethyl cation, the phenyl cation produced from another source, benzenediazonium tetrafluoroborate (Exp. 3) or phenylazo *p*-tolyl sulfone (Exp. 4), were let to react with triphenylmethane in benzene-trifluoroacetic acid. Triphenylmethyl alcohol was found indeed as one of the products, though its yield was not so high (0.023 and 0.027 mol per mol of the benzenediazonium tetrafluoroborate and phenylazo *p*-tolyl sulfone, respectively). The lower yield in comparison with the yield in the case of the PAT–CF_3CO_2H system can be ascribed to the occurrence of the reaction in cage in the case of the PAT–CF_3CO_2H system. The yield must have been lowered by the reaction between phenyl cation and benzene, which was used to dissolve the triphenylmethane.

In an attempt to produce a system which resembles a mixture of PAT and trifluoroacetic acid, benzenediazonium trifluoroacetate was synthesized and dissolved in benzene containing triphenylmethane and trifluoroacetic acid. However, only a trace amount of triphenylcarbinol was found as a product by glc. These findings show that the tertiary hydrogen of triphenylmethane is very efficiently abstracted by phenyl cation in a cage, but much less efficiently in a system formed by simply mixing a diazonium ion and triphenylmethane.

According to the mechanism proposed, the amount of diphenyl produced must be comparable to that of triphenylmethane, and the amount of triphenylcarbinol must be comparable to that of benzene. The results in Table 2 are approximately in agreement with this mechanism.

Experimental

Materials. Phenylazotriphenylmethane was prepared by the bromine-water oxidation of phenylhydrazotriphenylmethane,[19] which was synthesized from the reaction between phenylhydrazine and triphenylmethyl chloride in ether.[20] Crude PAT was recrystallized from benzene–ethanol, mp 111—112°C (decomp.). Benzenediazonium tetrafluoroborate,[21] phenylazo *p*-tolyl sulfone[22] and benzenediazonium trifluoroacetate[23] were prepared according to the method described in the literature. Benzene, ethylbenzene, and chlorobenzene were washed with concentrated sulfuric acid and water successively, dried over calcium chloride, and distilled. Boiling points were 80, 135.5, and 131°C, respectively. Anisole was washed with an aqueous sodium hydroxide solution and water, dried over calcium chloride, and then distilled; bp 153°C. Nitrobenzene was washed repeatedly with a potassium dichromate solution and water, dried over calcium chloride, and distilled; bp 95.5°C/18 mmHg. Trifluoroacetic acid of Wako Pure Chemical Industries Limited was used without further purification. Isomeric ethylbiphenyls, methoxybiphenyls, chlorobiphenyls, and nitrobiphenyls were prepared as the reference compounds by the methods described in the literature.[24] They were purified by elution chromatography, distillation or recrystallization, and their melting points and boiling points agreed with the values reported in the literature. Triphenylmethane was prepared by lithium aluminum hydride reduction of

triphenylmethyl chloride in ether and recrystallized from methanol, mp 92°C. Triphenylcarbinol was prepared by hydrolysis of triphenylmethyl chloride with an aqueous sodium hydroxide solution, and recrystallized from ethanol, mp 164°C.

Kinetic Measurements. PAT (1.00 g) was dissolved in benzene (15.6 g) and trifluoroacetic acid (35.0 g), and was decomposed in a water bath, the temperature of which was regulated within ± 0.1°C. The rate of decomposition was followed by measuring the evolution of nitrogen gas by use of a gas burette, and the total yield of nitrogen was determined.

Products of Decomposition of PAT in C_6H_6-CF_3COOH. Experiment 1: PAT (1.51 g) was decomposed in benzene (23.5 g) and trifluoroacetic acid (50.0 g) at 40°C. After the decomposition was over, the reaction mixture was washed successively with water, a 5% sodium hydrogen carbonate solution and water, and then dried over anhydrous magnesium sulfate. The nitrogen gas evolved was identified by gas chromatography with a Shimadzu GC-3AH (Molecular Sieve 5A 1m Column). The amounts of diphenyl, benzophenone, and triphenylmethane produced were determined by a Hitachi Gas Chromatograph K-53 on a column packed with 10% Apiezon L on Chromosorb W, on the basis of the comparison with the gas chromatograms of authentic samples. Triphenylmethyl alcohol was isolated by elution chromatography (alumina–benzene), identified by means of its IR spectrum and its melting point (164°C), and the weight was determined.

Products of Decomposition of PAT in CF_3COOH. Experiment 2: PAT (1.42 g) was decomposed in trifluoroacetic acid (44.2 g) at 40°C. The amount of benzene produced was determined by gas chromatography. The amounts of benzophenone, triphenylmethane and triphenylmethyl alcohol were determined according to the methods described above.

Phenylation of Monosubstituted Benzenes with PAT. PAT (1.00 g) was dissolved in an equimolar mixture of benzene and a substituted benzene (total aromatics, 50 mol per mol of PAT), and trifluoroacetic acid (35.0 g) was added to this solution. The flask containing the solution was placed in a bath at 40 ± 0.1°C, and the decomposition was followed by measuring the rate of evolution of nitrogen. After the evolution of nitrogen ceased, the reaction mixture was washed with water, a 5% sodium hydrogen carbonate solution and water, and dried over anhydrous magnesium sulfate, and then the amounts of substituted biphenyl isomers were determined by a Hitachi Gas Chromatograph K-53 (Apiezon L 10% on Chromosorb W).

Since the presence of a great quantity of a substituted benzene made the gas chromatographic determination of substituted biphenyls unreliable due to the tailing, the determination was made after about 70% of aromatic solvents were evaporated. Biphenyl isomers were identified by comparison of their retention times with those of the authentic samples.

Not benzene but chlorobenzene was used as the standard for the competitive phenylation, since unsubstituted biphenyl easily sublimes during the evaporation of substituted benzenes. The reactivity of each position of substituted benzenes was calculated relative to the reactivity of the *ortho* position of chlorobenzene. The partial rate factor of the *ortho* position of chlorobenzene was determined by an experiment carried out without evaporation of aromatic solvents. The partial rate factors of various substituted benzenes were calculated by the following equation.

$$k_x/k = (k_x/k_{o\text{-Cl}}) \times (k_{o\text{-Cl}}/k)$$

where,

k_x/k: partial rate factor for phenylation of PhX at the x (*o*-, *m*-, or *p*-) position

$k_x/k_{o\text{-Cl}}$: relative rate of phenylation at the x position of PhX against the *ortho* position of chlorobenzene

$k_{o\text{-Cl}}/k$: partial rate factor for phenylation at the *ortho* position of chlorobenzene

Spectra Measurements. UV and IR spectra were recorded with a Hitachi EPS-3T and Hitachi EPU-S2 spectrophotometer, respectively.

Decomposition of Benzenediazonium Tetrafluoroborate in the Presence of Triphenylmethane. Experiment 3: Benzenediazonium tetrafluoroborate (1.866 g) and triphenylmethane (0.650 g) were dissolved in a mixture of benzene (20 g) and trifluoroacetic acid (30 g). The diazonium salt was decomposed at 40°C overnight. The reaction mixture was washed successively with water, a 5% aqueous sodium carbonate solution and water. Triphenylmethyl alcohol was determined by gas chromatography (SE 30 on Chromosorb W). Yield, 58 mg (0.023 mol per mol of the diazonium salt).

Decomposition of Phenylazo p-*Tolyl Sulfone in the Presence of Triphenylmethane. Experiment 4*: Phenylazo *p*-tolyl sulfone (1.16 g) and triphenylmethane (0.94 g) were dissolved in a mixture of benzene (25 g) and trifluoroacetic acid (30 g). The azosulfone was decomposed for 20 hr in a water bath regulated at 40°C. The reaction mixture was washed successively with water, a 5% aqueous sodium carbonate solution and water. Triphenylmethyl alcohol was isolated by elution chromatography and identified by comparison of its IR spectrum with that of an authentic sample. Yield, 32 mg (0.027 mol per mol of the azosulfone).

Decomposition of Benzenediazonium Trifluoroacetate in the Presence of Triphenylmethane. Experiment 5: Benzenediazonium trifluoroacetate (2.0 g) and triphenylmethane (0.576 g) were dissolved in benzene (10 g) and trifluoroacetic acid (13 g) and stirred vigorously. The diazonium acetate was decomposed at room temperature overnight. The reaction mixture was treated in the manner described in Expt. 1, and triphenylmethyl alcohol was analyzed by glc; a trace of triphenylmethyl alcohol was detected.

Experiment 6: Benzenediazonium trifluoroacetate (2.0 g) and triphenylmethane (0.618 g) were dissolved in benzene (11 g), and stirred vigorously. The diazonium acetate was decomposed at room temperature overnight. The reaction mixture was treated in the manner described in Expt 2, and triphenylmethyl alcohol was analyzed quantitatively by glc; a trace of triphenylmethyl alcohol was detected.

Products of Hydrolysis of PAT–C_6H_6–CF_3CO_2H Mixture. Experiment 7: About 20 sec after the addition of CF_3CO_2H (30 g) to a benzene (20 g) solution of PAT (1.69 g), ice water was added. The aqueous layer was added to a 10% NaOH solution containing β-naphthol (1.4 g), and α-phenylazo-β-naphthol formed was filtered and dried; 0.508 g (45%).

The organic layer was treated in the manner described in Expt. 1, and the amounts of triphenylmethane and triphenylmethanol were determined by glc. Results are shown in Table 4.

Experiment 8: About 60 sec after the addition of CF_3CO_2H (30 g) to a benzene (20 g) solution of PAT (1.55 g), ice water was added. Evolution of nitrogen before addition of water was very little. The mixture was treated in the manner described in Expt 7. Results are shown in Table 4.

Properties of Polysarcosine Dodecylamide of Low Molecular Weight

Asahi SUZUKI*

Department of Biology, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received July 5, 1971)

Properties of polysarcosine dodecylamide (*N*-dodecylpolysarcosineamide) in aqueous solution vary systematically with the degree of polymerization of the polymer, since the hydrophilic part of this amphiphilic polymer is proportional to the degree of polymerization.[1] However, unexpected properties were observed with polysarcosine dodecylamide of low molecular weight, which was synthesized (degree of polymerization: 5) and its properties examined. *N,N'*-dimethyldiketopiperazine was prepared and its properties were compared with that of polysarcosine dodecylamide of low molecular weight synthesized by Izumi *et al.*[1] From the results, it is concluded that the abnormal properties of polysarcosine dodecylamide of low molecular weight reported previously are caused by the presence of *N,N'*-dimethyldiketopiperazine in the products of polymerization.

Experimental

Polysarcosine dodecylamide was prepared by polymerization of *N*-carboxy-sarcosine anhydride in dioxane with dodecylamine as initiator.[1] *N*-carboxy-sarcosine anhydride was made from sarcosine by the phosgene method.[2] A solution of 0.483 g of dodecylamine in dioxane (59 m*l*) was added with vigorous stirring to a solution of 1.5 g of *N*-carboxy-sarcosine anhydride in dioxane (100 m*l*) at room temperature. The molar ratio of anhydride to initiator, [A]/[I], was chosen to be 5. The reaction mixture was put to stand overnight at room temperature. The polymer was precipitated by pouring the reaction mixture into ethyl ether. A white waxy solid was obtained. This polymer is denoted by PSD-5S.

Found: C, 54.64; H, 9.39; N, 15.44%. Calcd for $C_{27}H_{52}N_6O_5$: C, 59.97; H, 9.69; N, 15.54%.

N,N'-dimethyldiketopiperazine was obtained by heating sarcosine at 215°C for about 3 hr.[3] The product was recrystallized 3 times from ethanol and obtained as clear needles, mp 144°C, molecular weight 142 (by mass spectrum).

Needle-like crystals were extracted from the materials denoted by PSDA-5[1] with ethanol. 0.637 g of PSDA-5 was dissolved in 12 m*l* of ethanol. A trace amount of white powder was removed from the solution by filtration. The filtrate was evaporated to about 2 m*l* under reduced pressure, and needle-like crystals, mp 144°C, molecular weight 142 (by mass spectrum), were obtained at about −15°C. The crystals showed no melting point depression (144°C) on being mixed with *N,N'*-dimethyldiketopiperazine.

Found: C, 50.42; H, 7.09; N, 19.70%. Calcd for $C_6H_{10}N_2O_2$: C, 50.69; H, 7.09; N, 19.71%.

Surface tension was measured by the drop-weight method. Measurements of electric conductance were performed with an AC-bridge (Yokogawa, 4225A). The cell constant was 0.535, as calibrated with 0.01M potassium chloride. All measurements were carried out at 25°C. NMR spectra were recorded with a Varian A-60 apparatus. Polymers were dissolved in D_2O at a concentration of 10 wt%. IR spectra were determined in KBr pellet with a Yamaco ISG-25 spectrometer. Mass spectra were measured with a Hitachi RMU-6E operating at 70 eV.

Results and Discussion

The surface tension (γ) *vs.* concentration (c) curve for PSD-5S in aqueous solution is shown in Fig. 1. The results obtained by Izumi *et al.*[1] are also shown in Fig. 1. The critical micelle concentration (CMC) of PSD-5S was found to be 0.033 g/d*l*. The present preparation gave a much clearer CMC and a much smaller surface tension than those calculated from the γ-c curve obtained by Izumi *et al.*[1] The specific conductance (κ) *vs.* concentration (c) curve for PSD-5S is shown in Fig. 2. The value of κ_0 obtained by extrapolating the concentration to zero is in accord with the value of water. The CMC value at the bend in

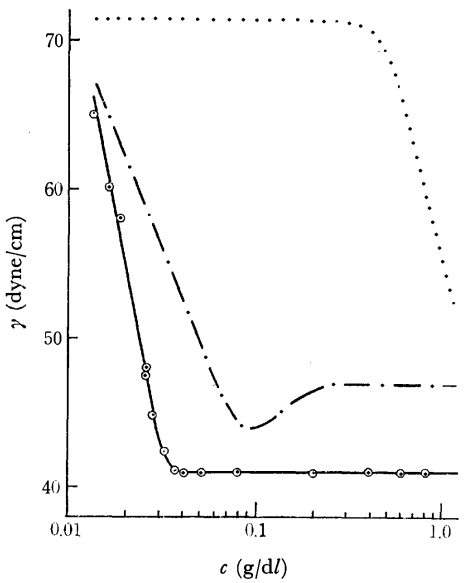

Fig. 1. Surface tension (γ) *vs.* concentration (c) curve for PSD-5S (-⊙-⊙-) at 25°C
(PSDA-5; ·····, PSDA-10; -·-·-, reported by Izumi *et al.*)

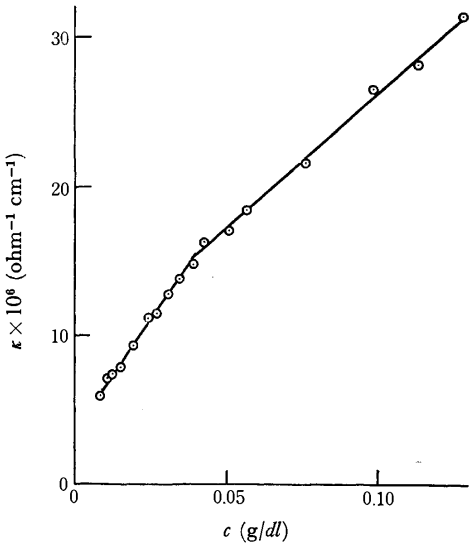

Fig. 2. Specific conductance (κ) *vs.* concentration (c) curve for PSD-5S at 25°C.

the κ-c curve was 0.04 g/d*l*. The NMR spectrum for PSD-5S is shown in Fig. 3. The degree of polymerization was found to be 5.2 from the ratio of the integrated signal from the dodecylamine residue and that from the sarcosine residue. This approximately corresponded to the ratio of anhydride to initiator.

With aqueous solution of *N,N'*-dimethyldiketopiperazine of concentration up to 1 g/d*l*, no decrease in surface tension was observed and the value of the specific conductance was $(2.5—2.8)\times10^{-6}$ ohm^{-1}cm^{-1}, which corresponds to that of water. The NMR spectrum of *N,N'*-dimethyldiketopiperazine had two single peaks, as shown in Fig. 3. The spectrum is similar

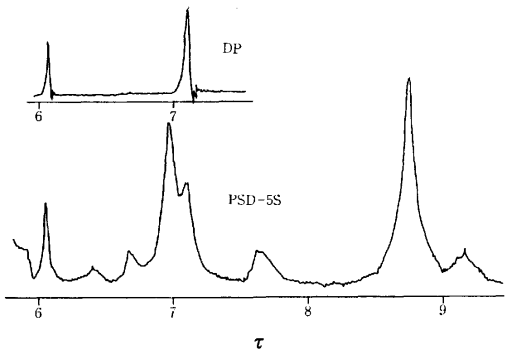

Fig. 3. NMR spectra of polysarcosine dodecylamide (PSD-5S) and *N,N'*-dimethyldiketopiperazine (DP) in D_2O at 60MHz.

to that for PSDA-5.[1]

The fragmentation pattern in the mass spectrum of needle-like crystals extracted from PSDA-5 was in accord with that of *N,N'*-dimethyldiketopiperazine and molecular weights of these compounds were estimated to be 142. The IR spectrum of needle-like crystals was similar to that of *N,N'*-dimethyldiketopiperazine. The compound extracted from PSDA-5 was proved to be identical with *N,N'*-dimethyldiketopiperazine by the mixed melting point, elemental analysis, and studies of its IR, NMR, and mass spectra.

Thus, it is concluded that the materials reported to be polysarcosine dodecylamide, (PSDA-5) are composed mainly of *N,N'*-dimethyldiketopiperazine. The formation of *N,N'*-dimethyldiketopiperazine during polymerization of PSDA-5 might depend on the conditions for polymerization; the initiator was added to the reaction mixture in a very high concentration and at a high temperature of about 80°C.

The ^{60}Co Recoil Reactions in the Benzene Solutions of Tris(nitrosonaphtholato)cobalt(III)

Takeshi TOMINAGA and Takuhiko SAKAI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received July 30, 1971)

While several works had been reported on the hot-atom chemistry of organic solutions of organometallic compounds[1,2] the hot-atom reactions of irradiated organic solutions of metal complexes had not been studied before our preliminary work on the tris(acetylacetonato)cobalt(III) benzene solutions.[3] We have thus far investigated the ^{60}Co and ^{51}Cr recoil reactions in neutron-irradiated benzene solutions of tris(acetylacetonato)cobalt(III)[3,4] and tris(acetylacetonato)chromium(III)[5] and found that metallic salts can well be used as scavengers to suppress the thermal reactions.

In the present article we will report that a similar scavenger effect of metallic salts can be observed in the irradiated benzene solutions of other chelate complexes, such as tris(nitrosonaphtholato)cobalt(III), and that the apparently high retentions in solid tris(nitrosonaphtholato)cobalt(III)[6] may be ascribed to the thermal reactions taking place in the solutions of the irradiated solid complexes.

6) N. Saito, T. Tominaga, and H. Sano, This Bulletin, **35**, 1739 (1962).

Experimental

The procedures used in preparing the solutions with various scavengers and the conditions of irradiation are similar to those described previously.[3,4]

The 0.01 M solutions of tris(α-nitroso-β-naphtholato)cobalt(III) and tris(β-nitroso-α-naphtholato)cobalt(III) in benzene containing 10% (by volume) of ethanol and various amounts of metallic salts as scavengers were prepared and irradiated with thermal neutrons (flux: 5×10^{11} n/cm^2·sec) for 5 min at room temperature in a TRIGA Mark II reactor. Solid samples of the above complexes were irradiated with thermal neutrons for 5 min in dry ice and then dissolved in benzene containing 10% (by volume) of ethanol and metallic salts. The irradiated benzene solution or the solution of the irradiated solid was diluted to 5 m*l* with benzene and extracted with three 5-m*l* portions of (1: 1) nitric acid.[6] The radioactivity of each fraction was measured with a well-type NaI scintillation counter at least one week after the neutron irradiation. The ^{60}Co retention, or the radiochemical yield of the parent chemical form, was obtained as a percentage of the total ^{60}Co activity found in the organic phase. No significant decomposition of the target complexes was observed during irradiation.

Results and Discussion

The effects of the scavenger salts on the ^{60}Co retention are summarized in Figs. 1 and 2.

The ^{60}Co Retention in the Irradiated Solutions. While the apparent ^{60}Co retentions in the irradiated 0.01 M solutions of both complexes were as high as 80—90% in the absence of scavengers, they decreased sharply with an increase in the concentration of the salts of such metals as cobalt and copper.[7] The nickel salt appeared to be less effective as a scavenger, and the magnesium salt had practically no effect on the retention. As in the case of the acetylacetone complexes,[4,5] it seems that salts of the metals which can form more stable complexes with free nitrosonaphthols work as more effective scavengers. Carbon tetrachloride showed a slight scavenger effect.

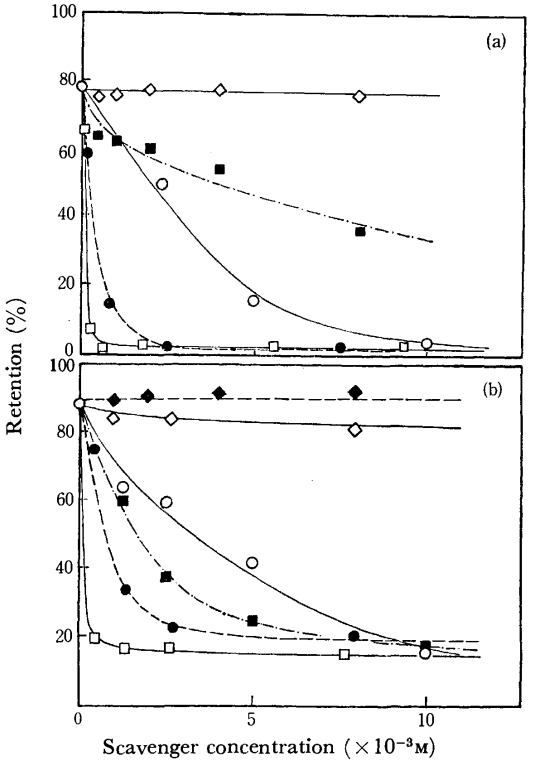

Fig. 1. Scavenger effect of various metallic salts on ^{60}Co retention (a) in the irradiated 0.01 M solutions of tris(α-nitroso-β-naphtholato)cobalt(III) and (b) in the 0.01 M solutions of irradiated solid tris(α-nitroso-β-naphtholato)cobalt(III).
—□— $CoCl_2$; —○— $CuCl_2\cdot2H_2O$;
--●-- $Cu(CH_3CO_2)_2\cdot H_2O$; -·-■-·- $NiCl_2\cdot6H_2O$;
—◇— $MgCl_2\cdot6H_2O$; --◆-- $ZnCl_2$;
--◪-- $MnCl_2\cdot4H_2O$. (Symbols common to Figs. 1 and 2).

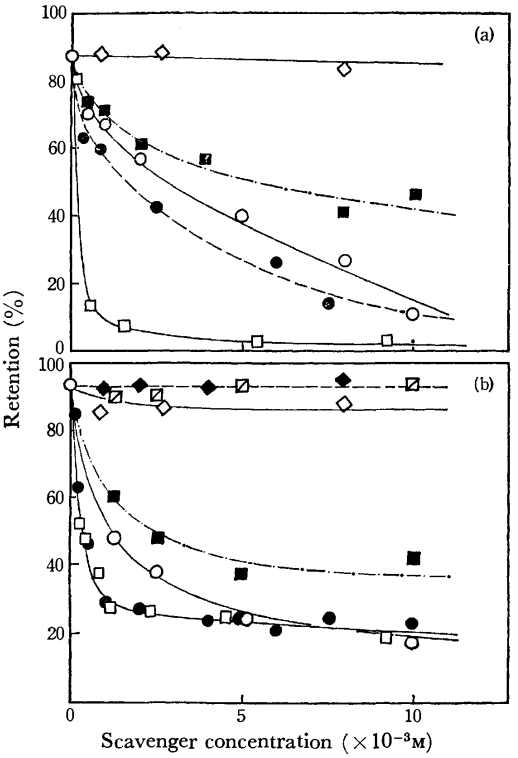

Fig. 2. Scavenger effect of various metallic salts on ^{60}Co retention (a) in the irradiated 0.01 M solutions of tris(β-nitroso-α-naphtholato)cobalt(III) and (b) in the 0.01 M solutions of irradiated solid tris(β-nitroso-α-naphtholato)-cobalt(III).

The ^{60}Co Retention in the Irradiated Solid. The apparent retentions in the irradiated solids were nearly 90% when dissolved in scavenger-free benzene, whereas they decreased to 15—20% when dissolved in benzene containing cobalt or copper salts. This indicates that the thermal reactions after the dissolution of the irradiated solid contribute greatly to the apparently high retentions in solids. The nickel salt was a less effective scavenger, and the magnesium, zinc, and manganese salts had no scavenger effects. The effects of the scavenger salts on the retention in solids seem essentially similar to those observed in the irradiated solutions.

In conclusion, it has been confirmed that the use of adequate scavengers (such as metallic salts) which can suppress the thermal reactions will be useful in determining the primary retention in irradiated solutions or the true retention in irradiated solids.

The authors wish to thank Professor Nobufusa Saito of the University of Tokyo for his encouragement and support during this work.

7) The lowest retention observed in the well-scavenged solutions was 1.1—1.6%.

The Nonstoichiometry of Gadolinium Ditelluride

Koichi NIIHARA, Toetsu SHISHIDO, and Seishi YAJIMA

The Research Institute for Iron, Steel, and Other Metals, Tohoku University, Sendai

(Received August 13, 1971)

The following compounds are found in the rare earth-tellurium system:[1-3] LnTe, Ln_3Te_4, Ln_2Te_3, Ln_4Te_7, $LnTe_2$, $LnTe_3$, and $LnTe_4$, where Ln=rare earth elements. In these tellurides, the ditellurides have the tetragonal lattice (Fe_2As type). In the La–Te[2] and Nd–Te[4] systems, the ditellurides are stable over a large homogeneity range. The *a* parameter of the ditellurides, in both systems, increases monotonously with the increase in Te content in the homogeneity range represented by the $LnTe_{2\pm x}$ formula. The *c* parameter of the lanthanum ditelluride decreases in the monotone with the increase in the content, but in the neodymium ditelluride it has a minimum value at the composition of $NdTe_{1.96}$.

In the case of heavier rare earth elements than gadolinium, there have been few investigations of the nonstoichiometric properties of the ditellurides. In this article the preparation of pure gadolinium ditellurides and their nonstoichiometric properties will be described.

Experimental

The gadolinium was prepared in our laboratory by the calcium reduction of GdF_3 in tantalum containers under a purified argon atmosphere, and was then refined by arc-melting and electron-beam melting. The purity of the gadolinium obtained by this method was approximately 99.9%. Tellurium of 99.999% purity was obtained from Wako Chemical Industies, Ltd., Tokyo. The gadolinium ditellurides were prepared in double-compartment quartz tubes.

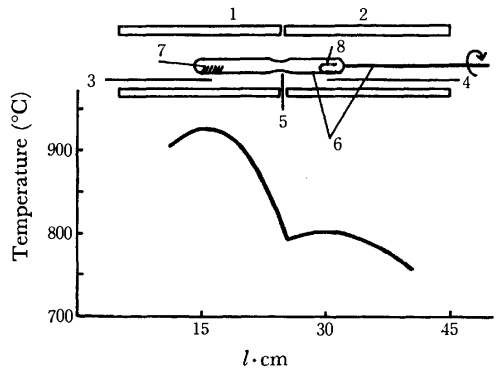

Fig. 1. Temperature distribution in the separate two-zone furnace. 1, 2) furnace; 3, 4, 5) thermocuples; 6) quarz tube and bar; 7) tellurium; 8) Ta boat and gadolinium metal

Finely-ground gadolinium was placed in one side and tellurium in the other side. Gadolinium was placed in tantalum crucibles in order to avoid direct contact with the quartz tube. In this way, the direct contact of gadolinium and tellurium, which might cause an explosion, was avoided. After the evacuating of the quartz tube to 10^{-5} mmHg, the tube was sealed and placed in a horizontal tublar furnace which had two heating zones. A sketch of the reaction apparatus and the temperature distribution in the separated two-zone furnace are shown in Fig. 1. The sealed quartz tube in the furnace was rotated at the rate of 50—100 rpm/min. The temperature of the gadolinium part was raised to 800°C from room temperature at a heating rate of 200°C/hr. The temperature of the tellurium part was 100—150°C higher than that of the gadolinium side. The quartz tube was held under the given conditions for 7—10 hr, until the tellurium had completely reacted, and was then cooled slowly to room temperature. The samples were investigated by chemical and X-ray analysis. The prepared powder was homogenous in its external appearance. The X-ray powder patterns were taken with a Debye-Scherrer camera using FeK_α radiation. These patterns were used to identify the phase present in polyphase samples and to determine the lattice parameters. The densities of the samples were determined by means of a pycnometer.

Results and Discussion

The powder of $GdTe_2$ shows a dark-violet color. From the X-ray diffraction pattern of $GdTe_2$, this phase appeared to be isostructural with the previously-reported tetragonal $GdTe_2$[3] (Fe_2As type). The lattice parameters of the stoichiometric $GdTe_2$ were $a=4.317$ Å, $c=8.951$ Å, and $c/a=2.073$.

In order to determine the range of the homogeneity of $GdTe_{2\pm x}$, samples were synthesized in the composition range of $GdTe_{1.7}$–$GdTe_{2.2}$ (63 at% to 68.7 at% of Te). For the gadolinium-rich side, the limit of the homogeneity phase was situated at approximately $GdTe_{1.77}$ (63.8 at% Te). A sample containing 63.6% Te ($GdTe_{1.75}$) was composed of two phases, a rhombic lattice (Gd_2Te_3) and a tetragonal lattice ($GdTe_2$). A sample containing 64.0 at% Te ($GdTe_{1.78}$) was constituted of pure $GdTe_{2-x}$ with a tetragonal lattice. On the tellurium-rich side, the limit of homogeneity was located at the composition of $GdTe_{2.10}$ (67.7 at% Te). In more tellurium-rich side, both phases, $GdTe_{2+x}$ and $GdTe_3$, appeared. These experimental results make it clear that the homogeneity range of $GdTe_{2\pm x}$ is situated from $GdTe_{1.77}$ to $GdTe_{2.10}$. The lattice parameter varied conspicuously with the variation in the nonstoichiometric composition, but the relation between them was not linear. The variations in the lattice parameters and *c*/*a* ratio are plotted against the Te/Gd atomic ratio in Fig. 2. The figure shows that the lattice parameter, *a*, increases with an increase in the

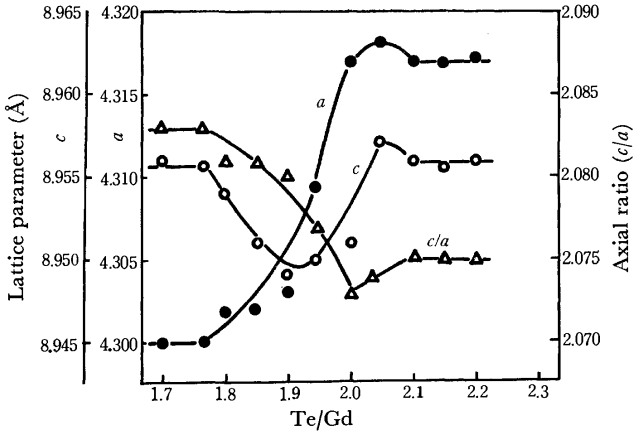

Fig. 2. The variation of the lattice parameters and the axial ratio against Te/Gd ratio in gadolinium detelluride.

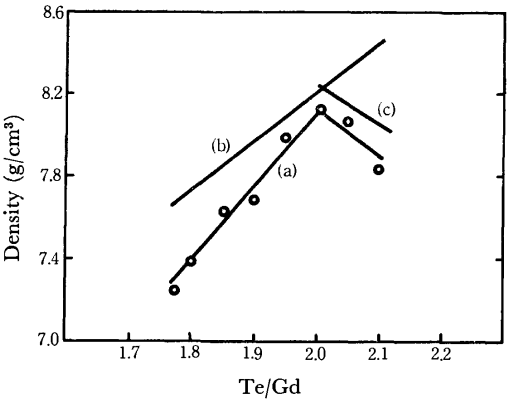

Fig. 3. The variation of density against nonstoichiometric composition of gadolinium ditelluride. (a): experimental value, (b) and (c): X-ray density calculated on the assumption of $GdTe_{2\pm x}$ or $Gd_{1-x}Te_2$, respectively.

tellurium concentration and that the lattice parameter, c, reaches its minimum value at the composition of $GdTe_{1.92}$. The relation between the axial ratio, c/a, and concentration ratio, Te/Gd, shows an anomaly at the composition of $GdTe_{2.0}$. From these facts, it may be seen that the types of defects in the crystal structures are different between the two regions of Te/Gd$<$2 and Te/Gd$>$2.

In Fig. 3 the variation in the densities in the homogeneity range is plotted against the Te/Gd ratio. The line (a) shows the experimental values. The lines (b) and (c) are the densities calculated on the assumption that the nonstoichiometric composition can be indicated by the $GdTe_{2\pm x}$ formula and the $Gd_{1-x}Te_2$ formula respectively. The experimental results show the same tendency as the values of the line (b) in the region of Te/Gd$<$2 and the same as the values of the line (c) in the region of Te/Gd$>$2.

From these variations in the lattice parameters, the axial ratio, c/a, and the densities, it seems probable that tellurium vacancies form in the region of Te/Gd$<$2 and that gadolinium vacancies from in the region of Te/Gd$>$2. Therefore, the homogeneity range of the gadolinium ditelluride is located form $GdTe_{1.77}$ to $Gd_{0.95}Te_2$.

Lin and Steinfink[4] investigated the neodymium ditelluride. According to their work, the variation in the lattice parameters of neodymium ditelluride appeared in the homogeneity range of $NdTe_{1.75}$ to $NdTe_{2.10}$. The tendency of the variation in the lattice parameters is similar to that of gadolinium ditelluride, which was studied in our experiment. It may be seen that the homogeneity range of the neodymium ditelluride is located from $NdTe_{1.75}$ to $Nd_{0.95}Te_2$.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1240—1242(1972)

Photochemical Reactions of Diphenylacetylene with Enaminoesters[1)]

Mituyosi KAWANISI, Kinjiro MATSUNAGA, and Norioki MIYAMOTO

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto, 606

(Received August 13, 1971)

As a consequence of our continuing interest in the behavior of enamines in photochemistry[2,3)] we have investigated the photochemical reaction of diphenylacetylene (I) with 3-alkylaminocrotonate (II) or 3-dialkylaminocrotonate (III), and found that the reaction resulted in the formation of heterocyclic compounds. This unprecedented result is the subject of this note.

When a benzene solution of I and IIa was irradiated by means of a high pressure Hg lamp and the reaction mixture was chromatographed on an alumina column, the following compounds were obtained: 4,5-diphenyl-1,6-dimethyl-2-pyridone (IVa) (19%), ethyl 4,5-diphenyl-1,2-dimethylpyrrole-3-carboxylate (Va) (4%), a mixture of photodimers of I[4)] along with some unidentified materials (trace).

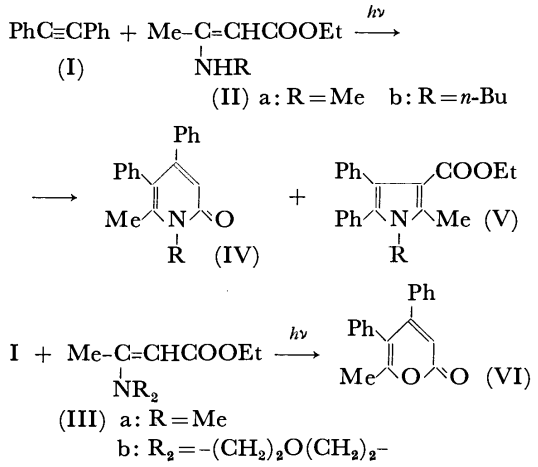
The structure of IVa was assigned by spectroscopic methods and the conclusive evidence for the structure was obtained by the following chemical transformations. Hauser reported that the reaction of benzyl methyl ketone with benzoylacetonitrile in the presence of PPA gave a pyridone whose structure was estimated as VII

1) A part of this work was presented at the 24th Annual Meeting of the Chemical Society of Japan (1971).

2) M. Kawanisi, K. Kamogawa, T. Okada, and H. Nozaki, *Tetrahedron*, **24**, 6557 (1968).

3) N. Miyamoto, M. Kawanisi, and H. Nozaki, the 24th Annual Meeting of the Chemical Society of Japan, Osaka (1971).

4) G. Büchi, C. W. Perry, and G. W. Robb, *J. Org. Chem.*, **27**, 4016 (1962).



or VIII.[5] We have reinvestigated this reaction, and the pyridone obtained was scrutinized by means of NMR for the benzylic protons, but there was none. Thus the structure VII was established for the reaction product.

Methylation of VII with dimethyl sulfate in alkaline medium[6] proceeded in a selective manner giving an *N*-methylated pyridone which was identical in all respects with the photochemical product IVa.

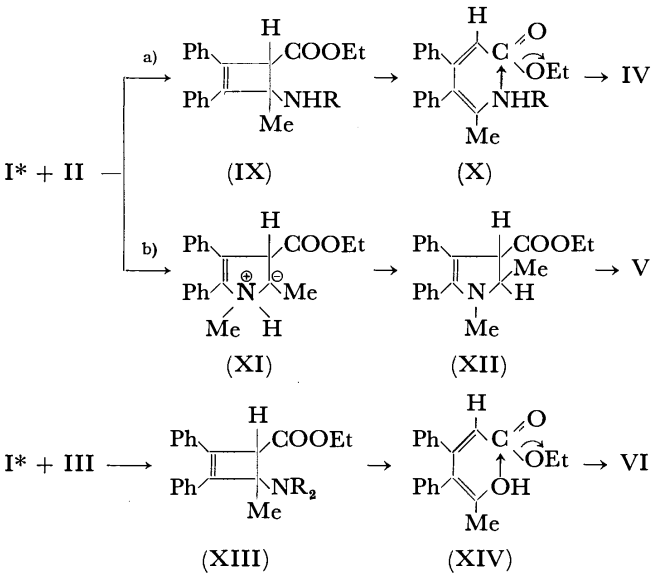
The structure of Va was established by spectroscopic methods as well as the independent synthesis described by Huisgen from *N*-acetyl-*N*-methylphenylglycine and ethyl phenylpropiolate.[7]

The reaction of IIb proceeded similarly and IVb was obtained in 28% yield. The spectroscopic data for IVb were essentially identical with those of IVa. In this case no Vb was isolated probably due to the difficulty in separation.

When a mixture of I and IIIa or IIIb was treated similarly, 4,5-diphenyl-6-methyl-2-pyrone (VI) (8% and 2%, respectively) was obtained. The structure of VI was established by spectroscopic methods as well as by the independent synthesis.[8]

Although the intermediate products are not identified yet, the mechanism for the formation of IV, V, and VI is tentatively considered as follows. The reactions of some electrophilic acetylenes with enamines or enaminoesters have been well documented,[9] whereas the electrophilic nature of excited simple acetylenes such as I have been demonstrated in the cycloaddition of I with dihydropyran.[10] Consequently it may be safely stated that the photoexcited I might react with II in two ways giving a) a cyclobutene IX and b) an ionic intermediate XI. Ring opening of IX to X followed by reclosure may give IV, while proton shift in XI followed by aromatization will afford V.

On the other hand the cycloaddition of the photoexcited I with III might give XIII, ring opening and hydrolysis followed by reclosure will lead to VI. The reason why hydrolysis takes place in the case of XIII and does not in the case of X is still obscure. However, we feel that NH-hydrogen seems to be responsible to some extent for the reaction.



Experimental

All boiling and melting points are uncorrected. Microanalyses were performed at the Elemental Analyses Center of Kyoto University. The IR spectra were recorded in neat liquid film or as KBr pellets on a Shimadzu IR-27G spectrometer. The NMR spectra were taken on a JOEL C-60-H spectrometer in CCl_4 solutions and TMS as an internal standard. The UV spectra were obtained in ethanol solutions on Shimadzu MPS-50L spectrophotometer.

Reagents. The starting materials I, IIa, and IIIa were prepared according to the published methods and have following properties; I, mp 64—66°C (lit.[11,12] mp 60—61°C), IR: 1600, 1490, 1070, 910, 760, 690 cm^{-1}, NMR: δ 7.1—7.5 (10H), UV: λ_{max} 265 nm (ε=21800), 275 (24100), 280 (31900), 289 (23000), 297 (28000). IIa, bp 107—108°C/17 mmHg (lit.[13] bp 105—106°C/15 mmHg), IR: 3310, 2990, 1950, 1650, 1610, 1265, 1160, 780 cm^{-1}, NMR: δ 1.2 (t, 3H), 1.9 (s, 3H), 2.9 (d, 3H), 4.0 (q, 2H), 8.4 (1H), UV: λ_{max} 282 nm (ε=16600). IIIa, bp 87—89°C/3 mmHg (lit.[14] bp 131.2—132.2°C/15 mmHg), IR: 1695, 1585, 1140 cm^{-1}, NMR: δ 1.2 (t, 3H), 2.4 (s, 3H), 2.9 (s, 6H), 3.95 (q, 2H), 4.4 (s, 1H), UV: λ_{max} 284 nm (ε=28200).

3-Butylaminocrotonate (IIb): A mixture of ethyl acetoacetate (13 g, 0.1 mol) and *n*-butylamine (7.3 g, 0.1 mol) in benzene was refluxed for several hr and the water formed was removed continuously in a Dean-Stark apparatus. The reaction mixture was concentrated *in vacuo* and repeatedly distilled throuth Vigreaux column to give IIb quantitatively as a colorless liquid, bp 86.5—87°C/3.5 mmHg (lit.[15] bp 129.5—131°C/14 mmHg), IR: 3290, 2960, 2860, 1650, 1610, 1265, 1170, 1140, 780 cm^{-1}, NMR: δ 1.0—1.5 (10H), 1.9 (s, 3H), 3.2 (q, 2H), 4.0 (q, 2H), 4.3 (s, 1H), 8.5 (1H), UV: λ_{max} 300 nm (ε=23000).

3-Morpholinocrotonate (IIIb): A mixture of ethyl acetoacetate (19.5 g; 0.15 mol) and morpholine (16 g; 0.18 mol) and *p*-toluenesulfonic acid in benzene was refluxed and the water formed was removed continuously. The reaction mixture was concentrated *in vacuo* and distilled to give IIIb, bp 120—122°C/5 mmHg, IR: 1690, 1595, 1140, 1120 cm^{-1}, NMR: δ 1.2 (t, 3H), 2.35 (s, 3H), 3.05—3.25 (4H), 3.5—3.75 (4H), 4.0 (q, 2H), 4.65 (s, 1H), UV: λ_{max} 283 nm (ε=20500). Found: C, 60.05; H, 8.53; N, 6.7%. Calcd for $C_{10}H_{17}O_3N$: C, 60.28; H, 8.60; N, 7.03%.

UV Irradiation. Solutions of I (590 mg; 3.3 mol) and IIa, IIb (a, 720 mg; b, 920 mg; each 5 mmol) or IIIa, IIIb (a, 790 mg; b, 1.0 g; each 5 mmol) in benzene (20 m*l*) were irradiated by means of a high pressure Hg lamp for 150 hr and the solvent was removed by distillation *in vacuo*. The residues were chromatographed on an alumina column to give IV, V, and VI, respectively. 4,5-Diphenyl-1,6-dimethyl-2-pyridone (IVa), mp 166.5—169°C, obtained by photolysis had following properties. IR: 3060, 2960, 1650, 1580, 1515, 1490, 860, 770, 700 cm^{-1}, NMR: δ 2.1 (s, 3H), 3.5 (s, 3H), 6.4 (s, 1H), 7.0—7.1 (10H), UV: λ_{max} 243 nm (ε= 17500), 324 (5880). Found: C, 82.66; H, 6.21; N, 4.95%. Calcd for $C_{19}H_{17}ON$: C, 82.88; H, 6.22; N, 5.09%. 1-Butyl-4,5-diphenyl-6-methyl-2-pyridone (IVb), mp 191—192.5°C, obtained by photolysis had following properties. IR: 3060, 2970, 1650, 1515, 1495, 865, 770, 705, 700 cm^{-1}, NMR: δ 1.0 (t, 3H), 1.3—2.0 (4H), 2.3 (s, 3H), 4.2 (t, 2H), 6.6 (s, 3H), 1.3—2.0 (10H), UV: λ_{max} 244 nm (ε=19000), 323 (6200). Found: C, 83.15; H, 7.11; N, 4.33. Cacld for $C_{22}H_{23}ON$: C, 83.24; H, 7.30; N, 4.41%. Ethyl 4,5-diphenyl-1,2-dimethylpyrrole-3-carboxylate (V), mp 116.5—117.5°C, obtained by photolysis had following properties. IR: 3060, 2930, 1690, 1600, 1280, 1160, 750, 690 cm^{-1}, NMR: δ 0.9 (t, 2H), 2.5 (s, 3H), 3.35 (s, 3H), 3.9 (q, 2H), 6.9—7.1 (10H), UV: λ_{max} 230 nm (ε=28900), 277 (15400), MS: *m/e* 319 (M^+), 290 (M^+-29), 274 (M^+-45). The MS supports the structure of IV. The authentic specimen prepared by the published method[7] had spectral properties quite identical with those of the photochemical product (V), and showed no depression of the mixed mp. 4,5-Diphenyl-6-methyl-2-pyrone (VI), mp 136—136.5°C (lit.[7] 135°C) obtained by photolysis had following properties. IR: 3060, 1720, 1630, 1530, 1495, 860, 770, 700 cm^{-1}, NMR: δ 2.2 (s, 3H), 6.2 (s, 1H), 6.85—7.25 (10H), UV: λ_{max} 233 nm (ε=16200), 282 (6800), 314 (5800).

Methylation of VII. A sample (1.82 g; 6.9 mmol) of V, mp 258—262°C (lit[4] mp 264—266°C), was dissolved in a warm, freshly prepared solution of sodium (0.8 g) in methanol (20 m*l*). After cooling to room temperature, dimethyl sulfate (5 g; 0.04 mol) was added with stirring in the course of 15 min. After refluxing for 12 hr, the solution was made strongly alkaline by adding aqueous sodium hydroxide (25%), and the mixture was poured into ice water. The precipitates were collected by filtration and recrystallized from ether, mp 169—171°C. The spectra of the compound was completely superimposable with the one of IVa obtained photochemically.

The authors wish to thank Professor Hitosi Nozaki for help and stimulating discussion.

(Received August 16, 1971)

Cinnamomum reticulatum Hay. [*Mat. Fl. Formos.* 239 (1911); *Icon. Pl. Formos.*, **5**, 160, f. 53, e (1915)] (Japanese name, *Hamagusu*) of the Lauraceae is an endemic plant growing only on the Hengchun (Kōsyun) Peninsula in Taiwan. It is a small tree which grows at low altitudes.[3]

We have examined the essential oil of this rare and very interesting plant. The yield of the oil is 0.56% in the fresh shoots, the chemical composition of the oil is in Table 1.

The characteristics of this oil are an abundance of *l*-linalool (as much as 97% of the oil), and an absence of camphor and phenol ethers.

These phenomena show that this plant may be a relic of the nearest species to the mother plant of the genus *Cinnamomum*, at least as seen from the viewpoint of the chemical systematics.[4] The existence of a small

d) The compositions of sesquiterpene alcohols were calculated from the gas chromatogram of the oxygenated compounds, separated from the fraction IV by chromatography using ether as the eluent.

amount of nerolidol as a sesquiterpenoid compound is also accordant with this supposition.

Experimental

Material. On September 4, 1969, the material was gathered from a tree (diameter of trunk at a height of one meter: 15 cmφ; height of the tree: *ca.* 7 m) which had been transplanted from the seashore to the garden of the Hengchun Branch of the Forestry Institute of Taiwan. The material (2.0 kg; the average length of a shoot: 23 cm; its weight: 11.0 g, consisting of 82% leaves, and 18% branchlets; size of leaf: 30×50 mm) was brought to Japan by air, and on September 10 the half-dried sample (1.2 kg) was subjected to steam distillation. The distilled oil was extracted with ether and then dried over anhydrous sodium sulfate. The oil (11.2 g), obtained in a yield 0.56% of the fresh material, had the following properties: d_4^{30} 0.8493, n_D^{30} 1.4584, α_D^{27} −14.40°, A.V. 0.25, E.V. 4.60.

Gas-liquid Chromatographic Analysis. The gas-liquid chromatography (glc) was carried out with a Shimadzu GC-1B Model apparatus equipped with a thermal conductivity detector. A 150×0.5 cm stainless steel column was packed with PEG 6000 (30%) on celite 545 (100 mesh). Hydrogen was used as the carrier gas. The percentages of the constituents of the oil were calculated from the areas of the peaks of the gas chromatogram.

Separation and Identification of the Individual Components. The oil (10.0 g) was fractionated, by distillation under reduced pressure in a current of nitrogen with a Widmer column, into the following four fractions: I, −87°C/20 mmHg, 1.0 m*l*; II, 87—89°C/20 mmHg, 3.0 m*l*; III, 89°C/20 mmHg, 2.0 m*l*; IV, residual, 4.5 g.

Each fraction was then further separated into hydrocarbons and oxygenated compounds by alumina-column chromatography. The main components were isolated by preparative glc using a PEG 6000 column and were identified by a comparison of the IR spectra and retention times (*Rt.*) of glc with those of authentic samples. Some minor compounds were identified by a comparison of the *Rt*s. with those of authentic samples by the use of PEG 6000 and Silicone DC-550 columns.

The results are shown in Table 1.

Cordial thanks are due to Dr. Kōichi Koshimizu of Kyoto University, who brought the sample of *C. reticulatum* at our request on the occasion of his visiting Taiwan.

Studies on the Derivatives of Thiiranes. I. Synthesis of Some New Sulfonyl Compounds from 2-Chloromethylthiirane

Tsunehiko KUWAMURA, Eiichi KAMEYAMA, and Motoki NAKAJIMA*

Department of Synthetic Chemistry, Faculty of Engineering, Gunma University, Tenjincho, Kiryu

(Received August 23, 1971)

A number of investigations have been published on the ring-opening reactions of unsymmetrical thiiranes.[1] In order to synthesize a reactive aliphatic suflonyl compound, we allowed 2-chloromethylthiirane (**1**) to react with hydrogen chloride and chlorine in water, and confirmed that ring-cleavage of **1** took place preferentially at the primary carbon-sulfur bond giving predominantly the normal products as shown in Scheme 1.[2] This is in accord with the result of Schwartz[3] but contrary to the earlier observations.[4,5]

We have investigated the reactions of 1,3-dichloropropane-2-sulfonyl chloride (**3**) with bases of various basicities, and obtained several new olefinic sulfonyl compounds and their derivatives as shown in Scheme 1. Physical properties and analytical data of these compounds are listed in Table 1. Vinyl compounds **4** and **5** obtained in high yields in these reactions have two reactive substituents which differ from each other in reactivity. They could be used as new monomers for synthesis of reactive polymers and interesting intermediates for derivatives of sulfonic acid.

Experimental

All the boiling points and melting points are uncorrected. The NMR spectra were taken on a Varian A-60D or HA-100 Spectrophotometer in carbon tetrachloride unless otherwise stated. Chemical shifts are presented in terms of δ value. All the liquid products were purified by fractional distillation *in vacuo* in a stream of N_2 to obtain a single peak on glc.

Material. Compound **1** was prepared by the method of Culvenor and his coworkers,[6] bp 79—81°C/114 mmHg, n_D^{10} 1.5297, d_4^{10} 1.2277.

Addition of Hydrogen Chloride to 1. Into **1** (40 g) was gradually introduced gaseous HCl with stirring at 5—10°C. After an equimolar amount (13.1 g) of HCl had been taken out, bubbling was continued at 10°C for 1 hr. Removal of excess HCl and distillation of the residue gave 38.8 g of **2**, bp 104—106°C/88 mmHg, n_D^{10} 1.5301, d_4^{10} 1.3338.

Found: C, 25.12; H, 4.18; Cl, 49.7; S, 22.0%. Cacld for $C_3H_6Cl_2S$; C, 24.82; H, 4.17; Cl, 48.9; S, 22.1%.

a) At 10°C.

CH_2). From the NMR spectrum the ratio of 2-thiol *vs.* 1-thiol in the product was determined to be 98: 2. By treatment of **1** with concd. HCl,[4] **2** containing 5 mol% of 1-thiol was obtained in 50—55% yields.

1,3-Dichloropropane-2-sulfonyl Chloride (3). The reaction of **1** and **2** containing 2% 1-thiol with chlorine in water was carried out under similar conditions to those of the method of Stewart[5] for the oxidation of **1**. From both materials the identical product **3** (d_4^{20} 1.6014) was obtained in good yields. IR (neat), 1379 (SO_2), 1169 (SO_2), 774 (C–S) cm^{-1}; 100 MHz NMR (in benzene), A 3.04 (m, 1H, CH), B 3.40 (q, 2H, CH_2), C 3.57 (q, 2H, CH_2), J_{BC}=12.5, J_{AB}=6.0, J_{AC}=4.0 Hz.

3-Chloropropene-2-sulfonyl Chloride (4). To an ether solution of **3** cooled to −75°C was added dropwise an equimolar amount of triethylamine. The mixture was stirred for 2 hr and filtered. Distillation of the filtrate gave **4** in 74% yield. IR (neat), 3126, 1375 (SO_2), 1182 (SO_2), 1154, 974, 758 (C–S) cm^{-1}; 60 MHz NMR, A 4.41 (q, 2H, $C\underline{H}_2Cl$), B 6.35 (m, 1H, CH_2=C *cis* proton against $-CH_2Cl$), C 6.58 (m, 1H, CH_2=C *trans*), J_{AB}=1.7, J_{BC}=2.0, J_{AC}=1.0 Hz. An identical product was also obtained in 41% yield by the treatment of **6** with an excess of thionyl chloride.

Ethyl 3-Chloropropene-2-sulfonate (5). Ethanolysis of **4** in ether gave **5** in 76% yield. IR (in CCl_4), 3114, 1636 (C=C), 1369 (SO_2), 1133—1191 (SO_2), 1001 (C–O), 915 (S–O) cm^{-1}; 60 MHz NMR, A 4.16 (q, 2H, $C\underline{H}_2CH_3$), B 4.30 (q, 2H, CH_2Cl), C 6.25 (q, 1H, CH_2=C *cis* proton against $-CH_2Cl$), D 6.40 (q, 1H, CH_2=C *trans*), J_{BC}=1.5, J_{BD}=0.7, J_{CD}=1.9 Hz.

3-Chloropropene-2-sulfonic Acid (6). Hydrolysis of **3** in dioxane and distillation of the reaction mixture gave a heavy oil **6** in 69% yield, identical with the hydrolysis product of **5**. 60 MHz NMR (in $CDCl_3$), 4.13 (q, 2H, CH_2Cl), 6.17 (q, 1H, CH_2=C *cis* proton against $-CH_2Cl$), 6.41 (q, 1H, CH_2=C *trans*), 11.02 (s, 1H, SO_3H).

Ethanolysis of 3. A solution of **3** (10.6 g), ethanol (13.8 g) and carbon tetrachloride (23 m*l*) was refluxed for 20 hr. After removal of the solvent, the residue was fractionally distilled to yield two fractions, 4.5 g of **5** and 2.4 g of **6**.

Reaction of 3 with N-*Methylaniline.* Aniline (10.6 g) was added dropwise to an ether solution of **3** (7.0 g) cooled to −65°C. The mixture was gradually warmed up to room temperature, stirred for 10 hr and then filtered. Removal of ether from the filtrate gave a paste-like residue. The residue was dissolved in acetone–water (volume ratio, 10: 1), and the resulting solution was allowed to stand to give 5.0 g (45%) of **7**. IR (KBr), 3460 (OH), 3050, 2890, 1240 (SO_2), 1165 (SO_2), 1030, 725 (phenyl) cm^{-1}. 60 MHz NMR (in D_2O) of Na salt of *7*, 3.05 (s, 3H, NCH_3), 4.30 (s, 2H, CH_2N), 5.28 (s, 1H, CH_2=C *trans* proton against $-SO_2Na$), 5.88 (s, 1H, CH_2=C *cis*). In the case of a 4—5 molar ratio (the aniline: **3**), concentration of the filtrate from the reaction mixture gave another crystalline product **8** in 60—65% yield.

Reaction of 3 with Sodium Ethoxide. To a solution of **3** (21.2 g) in ethanol was added dropwise with stirring an ethanol solution of sodium ethoxide (7.13 g of metallic sodium) at −3—4°C. The mixture was neutralized, filtered and then distilled to yield 8.0 g (33%) of a colorless oil **9**. IR (neat), 1375, 1345 (SO_2), 1165 (SO_2), 1110 (C–O–C), 1000 (C–O), 920 (S–O) cm^{-1}. 60 MHz NMR (in $CDCl_3$), 1.17 (t, 6H, $C\underline{H}_3CH_2$–OCH_2), 1.31 (t, 3H, $C\underline{H}_3CH_2O_3S$), 3.50 (q, 4H, $CH_3C\underline{H}_2OCH_2$), 3.80 (d, 4H, $EtOC\underline{H}_2$), 3.43 (m, 1H, CH), 4.27 (q, 2H, $CH_3C\underline{H}_2O_3S$).

Hydrolysis of **9** with alcohol–NaOH gave **10**. IR (KBr), 1185 (broad, SO_2), 1110 (C–O–C), 1050 (S–O) cm^{-1}. 60 MHz NMR (in D_2O), 1.35 (t, 6H, CH_3), 3.41 (m, 1H, CH), 3.77 (q, 4H, $C\underline{H}_2CH_3$), 4.02 (d, 4H, $EtOC\underline{H}_2$).

The authors wish to thank Dr. M. C. Woods for providing facility for NMR measurement and his helpful advice on the analysis of NMR spectra. They are also indebted to E. Fuchita and N. Shimizu for their assistance in the experiment.

Hydrogen-Deuterium Exchange in 1,4,5- and 1,3,5-Trimethyltetrazolium Iodides

Tyûzô Isida, Shin-ichirô Fujimori, Kiyoshi Nabika, Keiiti Sisido, and Sinpei Kozima*

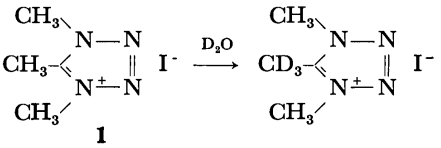
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto, 606

**Department of Chemistry, College of Liberal Arts and Sciences, Kyoto University, Sakyo-ku, Kyoto, 606*

(Received August 25, 1971)

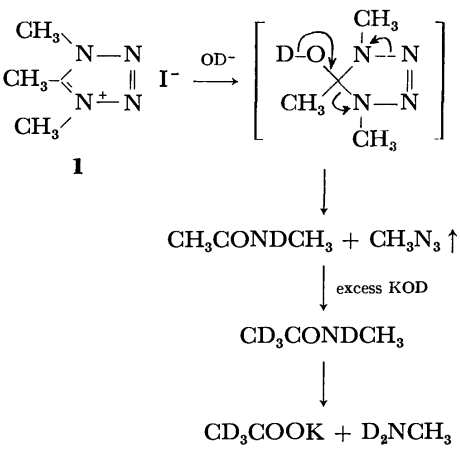
Considerable attentions are directed to the C–H/C–D exchange reaction of ring protons in azoles such as thiazoles,[1] thiazolium salt,[2] pyrazolium, and imidazolium salts,[3] 1,4-,[3-5] 1,3-,[6] and 2,3-disubstituted tetrazolium salts.[3] These investigations were focused on C–H bond which is sp^2 hybridized at carbon. The most acidic 1,4-disubstituted tetrazolium salt undergoes rapid hydrogen-deuterium exchange on the 5-carbon even in 2N-DCl *via* ylide formation.[3,5] As for the deuterium exchange of methyl protons of substituted azoles where C–H bonds are sp^3 hybridized at carbon, there has been a report concerning with 3- or 5-methylisothiazole.[7] This paper presents the C–H/C–D exchange of methyl protons of 1,4,5- and 1,3,5-trimethyltetrazolium iodides[8] in basic D_2O solutions containing pD buffer mixtures.

On standing a deuterium oxide solution of 1,4,5-trimethyltetrazolium iodide (**1**) at room temperature, deuterium exchange of the 5-methyl protons occurred slowly and the hydrogen was completely replaced by deuterium in a week. When the H/D exchange was carried out in D_2O at pD 8.40, 9.34, and 10.50, the rate of deuterium incorporation increased under more basic conditions; $t_{1/2}$ 50 min at pD 8.40, $t_{1/2}$ 15 min at pD 9.34, $t_{1/2}$ 12 min at pD 10.50. The half-life, $t_{1/2}$, of the exchange was measured by following the disappearance of the peak at δ 2.95 ppm in the NMR spectrum. There was found no exchange of the *N*-methyl protons of **1** under the above conditions.



1

Under more basic condition (pD 13.50) the 1,4,5-trimethyl salt **1** underwent rapid decomposition with vigorous gas evolution. The gas was determined to be methylazide by the mass spectrum; a parent ion at *m/e* 57. When **1** was dissolved in deuterium oxide containing less than one-equivalent of potassium deuteroxide in an NMR tube, there appeared a couple of single peaks at δ 2.01 and 2.73 ppm assigned to acetyl and *N*-methyl protons of *N*-d_1-methylacetamide at the expense of the peaks at δ 2.95 and 4.27 ppm associated with **1**, and some amount of the original peaks at δ 2.95 and 4.27 ppm still remained maintaining the starting integral ratio of 1 : 2, respectively. This showed that the rapid hydrolytic decomposition occurred before H/D exchange. In the presence of excess potassium deuteroxide, the original peaks at δ 2.95 and 4.27 ppm disappeared showing complete decomposition of **1** into *N*-d_1-methylacetamide. On standing overnight, the acetyl protons of *N*-methylacetamide were exchanged with deuterium, which was displayed by the disappearance of the peak at δ 2.01 ppm associated with the acetyl protons, and further hydrolysis of the deuterated *N*-methylacetamide occurred slowly to give potassium d_3-acetate and *N*-d_2-methylamine whose peak was found at δ 2.30 ppm. This hydrolysis was also confirmed by following the change in the NMR spectrum of the authentic *N*-methylacetamide in potassium deuteroxide solution. These results showed that the reaction proceeded as follows:



Duffin[9] reported the analogous hydrolytic decomposition of 1,5-dimethyl-4-phenyltetrazolium iodide in an aqueous 50% potassium hydroxide solution yielding phenylazide and methylamine.

In the case of 1,3,5-trimethyltetrazolium iodide (**2**), much slower H/D exchange was found even under fairly basic condition; $t_{1/2}$ 3115 min at pD 11.05. This is compatible with the easier deuterium exchange of the ring proton of 1,4-dimethyltetrazolium salt than the 1,3-dimethyl isomer.[6] When **2** was dissolved in more basic deuterium oxide, pD 13.50, there occurred no hydrolytic decomposition of **2**, but an additional H/D exchange of the 3-protons, $t_{1/2}$ 26 min, as well

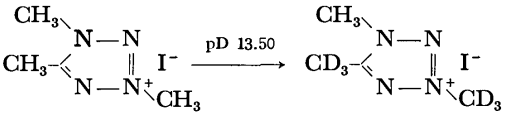
as the rapid exchange of the 5-methyl protons (too fast to be measured). It must be notable that there was no exchange of the 1-methyl protons of **2** even under the strongly basic condition. Analogous selective deuterium exchange of the 3-methyl protons of 1,3-dimethyltetrazolium chloride was found by Norris and Henry.[6] The inertness of the 1-methyl protons of **2** as well as **1** could be attributed to the lower acidity of the 1-methyl protons than the 3-methyl ones. This might be brought about by the electron donation from the adjacent 5-carbon atom and the 5-methyl group into the 1-nitrogen atom, whereas, there might be comparatively less electron donation from the 2- and 4-nitrogen atoms to the 3-nitrogen atom.



2

Experimental

1,4,5- and 1,3,5-Trimethyltetrazolium iodides were prepared by the reaction of 5-methyltetrazole with methyl iodide.[8]

The kinetics were run by following the changes in the NMR spectra at 23°C. The NMR spectra were determined at 60 MHz with a JEOL C-60HL spectrometer. The integral ratios were referred to an external standard acetonitrile kept in a capillary. The exchange was nicely first order over two half-lives, the substrate concentration was approximately 0.5 molar, and little rate variation was observed between 0.27—0.82M. D_2O buffer solutions of pD 8.40, 9.34, and 10.50 were made from Atkins-Pantin buffer mixture[10] (KCl–Na_2CO_3–H_3BO_3), and that of pD 11.05 from Menzel one[11] ($NaHCO_3$–Na_2CO_3). Measured pD values were uncorrected for differance between pH and pD. The buffer capacities were sufficient to maintain the same pD value on addition of the substrate. The mass spectrum was measured by Hitachi RMS-4 Mass Spectrometer.

The Formation of Solid Addition Compounds between Several *para*-Substituted Benzoic Acids and Piperidine

Setsuo KASHINO, Keiko KANEI, and Shigeo HASEGAWA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received August 27, 1971)

The formation of solid 1: 1 and 2: 1 addition compounds from benzoic acid and piperidine has previously been reported.[1]

This paper will describe the formation of the same type of addition compound from several *para*-substituted benzoic acids and piperidine, and will present some characteristic features of the infrared spectra of these compounds.

Experimental

Materials. The piperidine (GR-grade reagent) was used without further purification. The *p*-methyl-, *p*-chloro-, *p*-bromo-, and *p*-nitrobenzoic acids (each GR grade reagent) were recrystallized from benzene and dried over $CaCl_2$. Sodium salts of these substituted benzoic acids were prepared by the neutralization of the acids with a standard aqueous solution of sodium hydroxide. All the salts were dried at 110°C. The potassium hydrogen dibenzoate was prepared by the method described by Skinner *et al.*[2] The benzene was dried over metallic sodium and distilled.

The Addition Compound Formation. The 1: 1 addition compounds of *p*-methyl-, *p*-chloro-, *p*-bromo-, and *p*-nitrobenzoic acids with piperidine were prepared as follows: in a warm benzene solution of piperidine, an equimolar amount of the acid was dissolved. When the solution was then left to stand in a desiccator, crystals were separated out. They were recrystallized from benzene and then dried over $CaCl_2$.

p-Methylbenzoic acid–piperidine 1: 1 addition compound: mp 119°C.

Found: C, 70.45; H, 8.31; N, 5.86%. Calcd for $C_{13}H_{19}NO_2$: C, 70.56; H, 8.65; N, 6.33%.

p-Chlorobenzoic acid–piperidine 1: 1 addition compound: mp 121°C.

Found: C, 59.15; H, 6.46; N, 5.50%. Cacld for $C_{12}H_{16}NO_2Cl$: C, 59.63; H, 6.67; N, 5.80%.

p-Bromobenzoic acid–piperidine 1: 1 addition compound: mp 120°C.

Found: C, 50.16; H, 5.98; N, 4.82%. Calcd for $C_{12}H_{16}NO_2Br$: C, 50.37; H, 5.64; N, 4.89%.

p-Nitrobenzoic acid–piperidine 1: 1 addition compound: mp 158°C.

Found: C, 57.17; H, 6.25; N, 11.01%. Calcd for $C_{12}H_{16}N_2O_4$: C, 57.13; H, 6.39; N, 11.10%.

The 2: 1 addition compounds of *p*-methyl-, *p*-chloro-, and *p*-nitrobenzoic acids with piperidine were prepared by dissolving equimolar quantities of each acid and the 1: 1 addition compound in hot benzene, and by then allowing the solution to cool; they were recrystallized from benzene and then dried over $CaCl_2$.

p-Methylbenzoic acid-piperidine 2: 1 addition compound: mp 113°C.

Found: C, 70.75; H, 7.48; N, 3.98%. Calcd for $C_{21}H_{27}NO_4$: C, 70.56; H, 7.61; N, 3.92%.

p-Chlorobenzoic acid–piperidine 2: 1 addition compound: mp 140°C.

1) S. Kashino, This Bulletin, **41**, 248 (1968).

2) J. M. Skinner, G. M. D. Stewart, and J. C. Speakman, *J. Chem. Soc.*, **1954**, 180.

Found: C, 58.18; H, 5.20; N, 3.58%. Calcd for $C_{19}H_{21}NO_4Cl_2$: C, 57.30; H, 5.32; N, 3.52%.

p-Nitrobenzoic acid–piperidine 2: 1 addition compound: mp 177°C.

Found: C, 54.72; H, 4.88; N, 10.03%. Calcd for $C_{19}H_{21}N_3O_8$: C, 54.41; H, 5.05; N, 10.02%.

The Infrared Spectra. The infrared spectra were obtained by the usual KBr disk method at room temperature, using a Nihon-Bunko IR-S spectrophotometer.

Results and Discussion

In the infrared spectra of the 1: 1 addition compounds, no band characteristic of an un-ionized carboxyl group near 1700 cm^{-1} is observed, whereas antisymmetric and symmetric carboxylate stretching bands are observed near 1550 and 1400 cm^{-1} respectively. The peak positions of these bands are listed in Table 1, along with those of the corresponding sodium benzoates.

TABLE 1. THE CO_2^- STRETCHING FREQUENCIES OF THE *para*-SUBSTITUTED BENZOIC ACID-PIPERIDINE 1: 1 ADDITION COMPOUNDS (A) IN COMPARISON WITH THE CORRESPONDING SODIUM BENZOATES (B)

Substituent	Antisymmetric stretching ferquencies (cm^{-1})		Symmetric stretching frequencies (cm^{-1})	
	A	B	A	B
CH_3	1540	1540	1378	1414
H	1550[a]	1552[b]	1385[a]	1413[b]
Cl	1540	1436	1382	1406
Br	1525	1548	1375	1427
NO_2	1560	1578	—	—

a) Data from Ref. 1. b) Data from Ref. 3.

The spectra of the 1: 1 addition compounds were very similar to those of the corresponding sodium salts. Therefore, it may be concluded that the acid moiety in these 1: 1 addition compounds is almost fully ionized. However, it should be noted that the symmetric carboxylate stretchings of the addition compounds show lower values than those of the corresponding sodium salts. Since the vibrational frequency in a solid may be influenced by a number of factors,[3] no conclusive explanation of this behavior can be made. The X-ray crystallographic analysis of these adducts is now in progress.

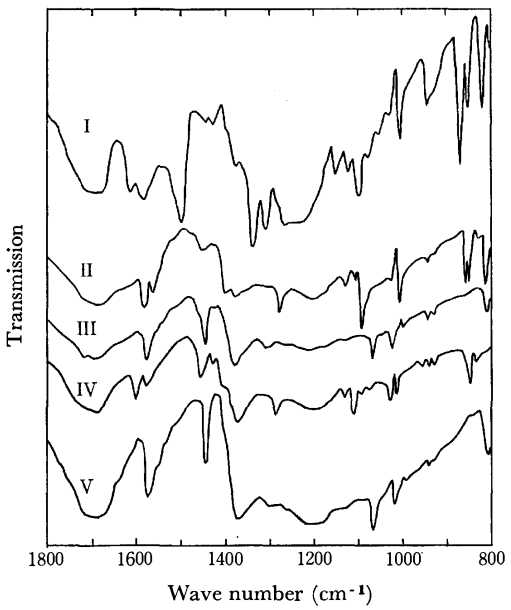

Fig. 1. Infrared spectra of the *para*-substituted benzoic acid-piperidine 2: 1 addition compounds (I—IV) and potassium hydrogen dibenzoate (V).
Substituent: I, NO_2; II, Cl; III, H; IV, CH_3

The infrared spectra of the 2: 1 addition compounds are shown in Fig. 1, along with those of potassium hydrogen dibenzoate.

The crystal structures of a series of acidic potassium salts of carboxylic acids have been studied by Speakman and his co-workers.[2,4-6] They have shown that, in many of these compounds, but not in potassium hydrogen di-*p*-nitrobenzoate,[4] the acid residues are joined to form dimers by a short and effectively symmetrical hydrogen bond.[2] According to Shrivastava and Speakman,[4] a characteristic feature of the infrared spectra of such compounds with a symmetrical hydrogen bond is a high background absorption spreading for several hundred wave numbers in the low-frequency region.

It may be noted here that all the present 2: 1 addition compounds apart from that of *p*-nitrobenzoic acid have a high background absorption in the region about 800—1100 cm^{-1}; these absorptions are very similar to those of the acidic potassium salts studied by Speakman and his co-workers.[2,5]

Cyanomethylation Products of *dl*- and *meso*-Diphenylethylenediamines*

Tairoku YANO, Hiroshi KOBAYASHI, and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka, 812

(Received September 6, 1971)

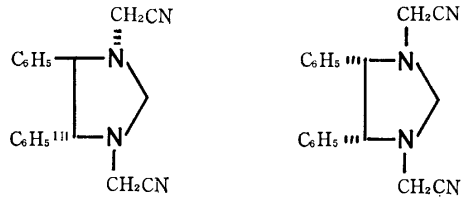
During the course of investigation of syntheses and chelating behaviors of complexane-type ligands, we found that *dl*-diphenylethylenedinitrirotetraacetic acid was obtained by carboxymethylation of *dl*-diphenylethylenediamine, and the *meso*-isomer gave 2-oxo-5,6-diphenylpiperazine-1,4-diacetic acid, but not the expected *meso*-dinitrirotetraacetic acid.[1]

Kroll and Gordon reported the synthesis of cyclohexane-*cis*-1,2-dinitrirotetraacetic acid from *cis*-1,2-diaminocyclohexane *via* a cyanomethylated intermediate.[2]

In order to obtain the corresponding tetraacetic acid *via dl*- and *meso*-diphenyl-*N,N,N',N'*-tetrakis(cyanomethyl)ethylenediamines, cyanomethylation was attempted on the respective diamines using hydrocyanic acid and formaldehyde. However, the reaction products were not the tetrakiscyanomethylated compound, but the imidazolidine derivatives. In this paper we report on the structure with reference to the solvent effects in the proton chemical shifts of the compounds.

Results and Discussion

From the results of elemental analyses and spectroscopic data, the reaction products from *dl*- and *meso*-diphenylethylenediamines were found to be 4α,5β-diphenyl-1α,3β-bis(cyanomethyl)imidazolidine (I) and 4α,5α-diphenyl-1β,3β-bis(cyanomethyl)imidazolidine (II), respectively.



Structure (I) and (II)

NMR spectral data of (I) and (II) in various solvents and at various temperatures are summarized in Table 1. The patterns of the NMR spectrum of (I) at −30°C are the same as those at 80°C except for slight shifts in signals.

It is of interest to note that two cyanomethyl protons show a quartet signal centered at 3.55 and 3.59 ppm with J=17.7 and 17.5 Hz in deuteriochloroform for (I) and (II), respectively. However, the protons in benzene solution show a singlet at 2.72 and a broad one at 2.77 ppm for (I) and (II), respectively. The results suggest that two cyanomethyl groups are equivalent in a magnetic field but not the two protons on each cyanomethyl group due to the asymmetric effect

Table 1. Proton chemical shifts of (I) and (II) in various solvents (δ, ppm)

Solute	Proton	$CDCl_3$	C_6H_6	C_6H_5Br	C_5H_5N
(I)	$-CH_2CN$[a]	3.55[b] (3.58[c])	2.72[b] (2.78[d])	3.13[b] (3.00[d])	3.71[b] (3.65[d])
	$>CH_2$	3.85 (3.89)	3.76 (3.75)	3.79 (3.79)	4.04 (4.00)
	$-CH<$	4.28 (4.33)	3.78 (3.83)	4.03 (4.05)	4.38 (4.34)

of the imidazolidine ring nitrogen to which the cyanomethyl group attached, while in a benzene solution the asymmetric effect of nitrogen was suppressed owing to the association of the benzene molecule to the solute molecule.

A singlet signal at 3.85 ppm and a quartet one centered at 4.09 ppm with $J=3.4$ Hz for (I) and (II), respectively, can be attributed to the methylene protons interposed between two nitrogens on the ring. The methine protons appeared as a singlet at 4.28 and 4.29 ppm for (I) and (II), respectively.

The solvent-induced shift for protons are shown in Table 2. The solvent affected the methine proton to a greater extent than the methylene proton on the ring for (I), whereas the methylene protons in (II) were more affected than the methine proton. The difference was considered to be due to the fact that the benzene molecule is associated to the solute molecule in a different manner for (I) and (II) because of the different configurations of (I) and (II).

Superimposed proton signals for each pair of the substituents on the imidazolidine ring of (I) and (II), and splitting of the methylene protons interposed between two ring nitrogens of (II) indicated C_2 and σ symmetries effectively in NMR time scale for (I) and (II), respectively. Study with a molecular model showed significant steric hindrance between the phenyl and the cyanomethyl groups, favoring *trans* configuration for the substituents concerned.

A question remains whether cyanomethylation took place after the imidazolidine ring was formed[3] or a tricyanomethylated diamine once formed liberated hydrocyanic acid to form the imidazolidine ring.[4] The actual reaction conditions suggest that the former process is more probable.

Experimental

Chemical shifts were measured on a Varian A-60 spectrometer using TMS as an internal reference. The concentrations of the sample solution were approximately 10%.

Material. *dl*- and *meso*-Diphenylethylenediamines were synthesized from benzaldehyde according to the method in literature.[5-7]

4α,5β-Diphenyl-1α,3β-bis(cyanomethyl)imidazolidine (I). An aqueous 36% formaldehyde (1.4 g, 0.019 mol) and 0.93 g (0.019 mol) of sodium cyanide were added successively to a cold solution of 1.34 g (0.0047 mol) *dl*-diphenylethylenediamine dihydrochloride in 1.2N hydrochloric acid and the resulting mixture was kept in a pressure bottle. The mixture was allowed to stand for 3 days at room temperature. The precipitate obtained was recrystallized from methanol. $\nu_{C\equiv N}$, 2220 cm^{-1}; mp 130—131°C, yield 60%.

Found: C, 75.49; H, 5.99; N, 18.54%. Calcd for $C_{19}H_{18}N_4$: C, 75.50; H, 5.96; N, 18.54%.

4α,5α-Diphenyl-1β,3β-bis(cyanomethyl)imidazolidine (II) was synthesized in a similar manner to that described above. A methanol soluble fraction of the product was recrystallized from ethanol. $\nu_{C\equiv N}$, 2230 cm^{-1}; mp 163—164°C, yield 36%.

Found: C, 75.32; H, 5.83; N, 18.87%.

An Interpretation of Mass Spectra by Simple LCAO MO Calculation. II. Derivatives of Benzene and Chlorobenzene

Susumu TAJIMA, Yoshio NIWA, Nobuhide WASADA, and Toshikazu TSUCHIYA

Government Chemical Industrial Research Institute, Tokyo, Honmachi, Shibuya-ku, Tokyo

(Received September 10, 1971)

Other than the well-known quasi-equilibrium theory,[1] several methods for the theoretical interpretation of the mass spectra of larger organic compounds have been reported.[2-5] In a previous paper,[6] we described that a simple relation was found between the summation of the intensities of certain peaks and the partial bond order, as calculated by simple LCAO MO method, for a frontier electron of the bond ruptured in the cases of the derivatives of aniline and anisole. The present note will report that the same relation holds for the derivatives of benzene and chlorobenzene.

The mass spectra were obtained with a CEC 21-103C mass spectrometer. The following derivatives of benzene were investigated: phenol, anisole, aniline, benzaldehyde, toluene, benzoic acid, and nitrobenzene; the following *o*-, *m*-, and *p*-derivatives of chlorobenzene were also investigated: hydroxychlorobenzene, methoxychlorobenzene, aminochlorobenzene, chlorobenzaldehyde, methylchlorobenzene, chlorobenzoic acid, and

nitrochlorobenzene. All the samples studied were of a research grade, were obtained from the Tokyo Kasei Co., Ltd., and were used without further purification. The experimental conditions have been described previously.[6]

The following daughter ions are produced from the molecular ion, $R\text{-}C_6H_4\text{-}X^+$, by electron impact:

$$R\text{-}C_6H_4\text{-}X^+ \longrightarrow R\text{-}C_6H_4^+ + X, \text{ and } R\text{-}C_6H_4 + X^+ \quad (1)$$

where R denotes the common substituent, H or Cl, in the derivatives of benzene or chlorobenzene respectively, and where X denotes the other substituent, such as OH or OCH_3.

We examined the correlation between the ion intensity, I, given by Eq. (2), and the partial bond order, P^h, of the bond between the aromatic moiety and the substituent, X, for a frontier electron.

$$I = 100 \times (R\text{-}C_6H_4^+ + X^+)/\sum I_i \quad (2)$$

$\sum I_i$ denotes the summation of the total ion intensities. The parameters used in the calculation of P^h were quoted from the accepted values in the literature.[7,8]

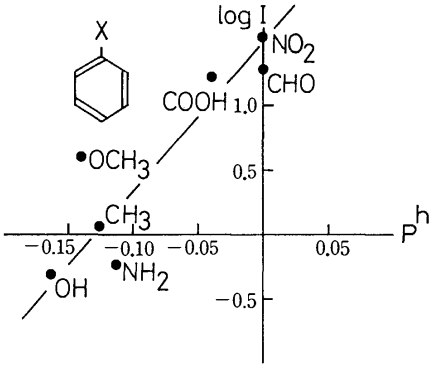

Fig. 1. log I *versus* partial bond order, P^h, of the frontier electron for benzene derivatives.

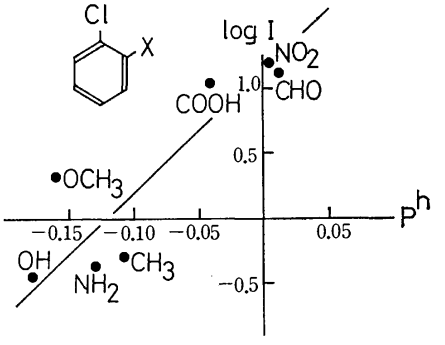

Fig. 2. log I *versus* partial bond order, P^h, of the frontier electron for *o*-chlorobenzene derivatives.

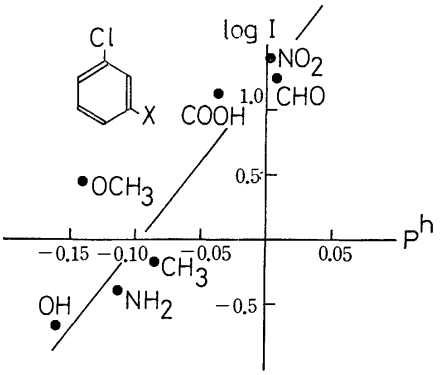

Fig. 3. log I *versus* partial bond order, P^h, of the frontier electron for *m*-chlorobenzene derivatives.

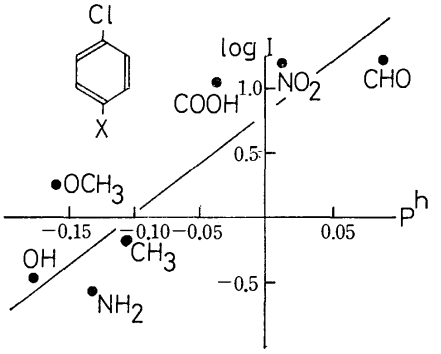

Fig. 4. log I *versus* partial bond order, P^h, of the frontier electron for *p*-chlorobenzene derivatives.

In Figures 1—4, plots of log I *versus* P^h for the derivatives of benzene and for the *o*-, *m*-, and *p*-derivatives of chlorobenzene are plotted. From each figure, we can see a simple relation: the larger the value of P^h, the larger the log I, just as in a previous paper.[6]

Almost every compound studied here exhibited a metastable peak corresponding to the decomposition $M^+ \rightarrow R\text{-}C_6H_4^+ + X$. This means that the half-life of the molecular ions of these compounds is about 10^{-5}—10^{-6} sec.[1] The life time of an ion in its excited states is considered to be less than 10^{-8} sec.[9,10] Therefore, at least a part of the ions shown in Eq. (1) may be considered to be produced by the following mechanism: a molecular ion in its excited state is not decomposed immediately after its production by electron impact, but the ion falls into its ground state by radiationless transitions; then it decomposes eventually to the daughter ions. The correlations indicated in Figs. 1—4 can be explained in the same way as in the previous report.[6]

Reactions of 2,4,4,6-Tetrabromo-2,5-cyclohexadien-1-one with Alkenes in the Presence of Weak Bases[1]

Motohiro TSUBOTA, Masaki Iso, and Kazuo SUZUKI

Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Ishii-cho, Utsunomiya

(Received September 14, 1971)

Schmidt and his co-workers[2] reported on the formation of 1-bromo-2-methoxycyclohexane by the reaction of 2,4,4,6-tetrabromo-2,5-cyclohexadien-1-one (**1**) with cyclohexene in methanol. As with other 4-bromo-2,5-cyclohexadien-1-ones,[3] one of the bromine atoms at the 4-position in **1** is presumed to react as a bromonium species in the reaction. This paper deals with the reaction of **1** with alkenes in the presence of several weak bases.

β-Bromo-α-methoxyethylbenzene (**3a**) was obtained in good yield by the reaction of **1** with styrene in methanol. Under similar conditions, β-bromo-α-methoxyethyl *n*-butyl ether (**3b**) and 4-bromo-3-methoxy-3-methyl-1-butene (**3c**) were obtained from *n*-butyl vinyl ether and isoprene, respectively. The reaction conditions and the results are summarized in Table 1.

	2a,3a	**2b,3b**	**2c,3c**
R^1	C_6H_5	*n*-C_4H_9O	H
R^2	H	H	CH_3
R^3	H	H	$CH{=}CH_2$

It can be assumed that in the addition process a transitory bromonium species is formed in the initial step by the attack of a nucleophilic reagent under mild conditions, and then the bromonium species reacts with the double bond in alkenes.

The above addition reaction was further applied to the preparation of some bifunctional adducts of cyclohexene, which can be used for syntheses.

trans-1-Bromo-2-hydroxycyclohexane (**6a**),[4] *trans*-1-bromo-2-chlorocyclohexane (**6b**), *trans*-1,2-dibromocyclohexane (**6c**), and *trans*-1-acetoxy-2-bromocyclohexane (**6d**) were obtained by the reaction of **1** with cyclohexene in the presence of various bases (see Table 1).

	a	**b**	**c**	**d**
X^1	*p*-$CH_3C_6H_4SO_3$	Cl	Br	CH_3CO_2
X^2	OH	Cl	Br	CH_3CO_2

These reactions are suitable for the preparation of bifunctional adducts of alkenes in view of simple procedure, mild conditions, and high yield.

Experimental

All melting points and boiling points are uncorrected. The mass spectra were measured with a Hitachi RMU-6L spectrometer; ionizing voltage: 70 eV, evaporation temperature: 95°C. The NMR spectra were obtained with a Japan

TABLE 1. SUMMARY OF THE REACTIONS OF **1** WITH ALKENES

3) B. Miller, *J. Org. Chem.*, **28**, 345 (1963).

4) The hydroxy group in **6a** (in this case) is presumably a result of the addition of solvent water.

Electron Optics, JNM-6C spectrometer, using TMS as an internal standard. The IR spectra were recorded in neat liquid using a JASCO model IR-G spectrophotometer (Japan spectroscopic Co., Ltd.). The GLC data were obtained with a GCG-550T apparatus (Yanagimoto Mfg. Co., Ltd.), using a column containing 5% silicone SE-30 on Celite 545 AW.

Materials. Compounds **3a**—**c** were characterized by NMR and mass spectra.

3a: NMR (in CCl_4): 6.68 (CH_3, s), 6.54 (CH_2, q), 5.63 (CH, t), 2.65 (C_6H_5, s): Mass: *m/e* 216, 214 ($C_6H_5CH(OCH_3)$-CH_2Br), 185, 183 ($C_6H_5CHCH_2Br$), 121 ($C_6H_5CHOCH_3$): (Found: Br, 36.7%).

3b: NMR (in CCl_4): 9.05 (CH_3, m), 8.52 (CH_2, m), 6.70 ($BrCH_2$, d), 6.65 (OCH_3, s), 6.45 (OCH_2, m), 5.41 (OCH, t): Mass: *m/e* 181, 179 ($BrCH_2CHOC_4H_9$-*n*), 139, 137 ($BrCH_2CHOCH_3$), 117 ($CH_3OCHOC_4H_9$-*n*): (Found: Br, 36.2%).

3c: NMR (in CCl_4): 8.65 (CH_3, s), 6.83 ($BrCH_2$, s), 6.72 (OCH_3, s), 4.85, 4.70, 4.43 ($CH{=}CH_2$): Mass: *m/e* 165, 163 ($CH_2{=}CHC(OCH_3)CH_2Br$), 99 ($CH_2{=}CHC(OCH_3)$-$(CH_3)CH_2$), 85 ($CH_2{=}CHC(OCH_3)CH_3$), 55 ($CH_2{=}CHCH$-CH_3).

The structures of **6a**—**d** were confirmed by direct comparison of their retention times in GLC and IR spectra with those of authentic samples.[5-7]

2,4,4,6-Tetrabromo-2,5-cyclohexadien-1-one (1). Bromine (8.0 g, 5 mmol) was added in small portions to a solution of 2,4,6-tribromophenol (12.3 g, 4 mmol) in methanol-acetic acid (1:1) (60 m*l*) at 2—3°C. After 1 hour, 10% aqueous sodium carbonate solution (50 m*l*) was added. The yellow precipitates were collected, washed with water and methanol, and dried over anhydrous phosphorus pentoxide in a vacuum desiccator. Yield, 15.0 g (90%), mp 136°C (dec.) (lit.[8] 125°C (dec.)).

Reaction of 1 with an Alkene. As a typical example, the reaction of 1 with styrene is described: (for details, see Table 1). To a well-stirred solution of styrene (**2a**) (2.6 mmol) in methanol, **1** (1.3 mmol) was added at −2—4°C. Stirring was continued for 1.5 hr (solid **1** disappeared), the reaction mixture was poured into 10% aqueous sodium carbonate solution, and the aqueous layer was extracted with *n*-hexane. The organic layer was washed with water and dried over anhydrous potassium carbonate. After *n*-hexane was evaporated, the residue was distilled under reduced pressure to afford **3a** (91%), bp 116—119°C/17 mmHg. The carbonate solution was acidified with concentrated hydrochloric acid, and the precipitates were filtered and washed with water to give 2,4,6-tribromophenol, mp 91—93°C (92%).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1253—1254(1972)

p-Nitrophenyl Formate as a Reagent for Preparing *N*-Formyl-hexosamines[1]

Kazuhiko YAMAMOTO

Department of Chemistry, College of Science, Osaka University, Toyonaka, Osaka

(Received September 16, 1971)

In the course of a study of the substrate specificity of *N*-acetyl-β-D-glucosaminidase [EC. 3.2.1.30], *N*-formyl derivatives of *p*-nitrophenyl 2-amino-2-deoxy-β-D-glucopyranoside (I), 2-amino-2-deoxy-D-glucose (II), and 2-amino-2-deoxy-D-galactose (III) were required. The *N*-formylation of derivatives of II is usually achieved by a reaction in a mixture of formic acid and acetic anhydride,[2] by the pyrolysis of amine-formate,[3] or by the O→N acyl exchange of the formyl ester with sodium methoxide as the catalyst.[4] However, these known methods could not be applied to quite labile I because of their drastic conditions.

An attempt was made to use the active formyl ester for the *N*-formylation of I. *p*-Nitrophenyl formate, which had been used in the preparation of *N*-formyl amino acid,[5,6] was examined and found to be a suitable reagent. Further application of this reagent to II or III was also successful in the preparation of *N*-formyl-derivatives of II and III under milder conditions and by a simpler procedure.

After reporting[7] the use of *p*-nitrophenyl formate in the preparation of *p*-nitrophenyl 2-formylamino-2-deoxy-β-D-glucopyranoside, Pal and Mukerjee[8] reported the *N*-acylation of II using the *p*-nitrophenyl esters of acetic acid, benzoic acid, and stearic acid as the active esters. Active esters such as the *p*-nitrophenyl esters of organic acids seem to be very suitable for use in the *N*-acylation of D-hexosamines and their derivatives, as the reaction is performed under mild conditions. The further reaction of *p*-nitrophenyl formate with *p*-nitrophenyl 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-β-D-glucopyranoside hydrochloride[9] yielded the corresponding *N*-formyl derivative.

Experimental

The melting point was measured by means of a micro-melting-point apparatus (Yanagimoto Seisakusho) and was not corrected. The optical rotation was measured by means of a Rudolph (Model-200) photoelectric polarimeter at room temperature.

p-Nitrophenyl formate was prepared by the method of Okawa and Hase[6] and showed a mp of 74—76°C (lit, mp 75—77°C).

p-*Nitrophenyl 2-Formylamino-3,4,6-tri*-O-*acetyl-2-deoxy-β*-D-*glucopyranoside.* To a solution of *p*-nitrophenyl 2-amino-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranoside hydrochloride[7] (300 mg) in 30 m*l* of dimethylformamide, 0.1 m*l* of triethylamine was added, and then *p*-nitrophenyl formate (400 mg) in 15 m*l* of tetrahydrofuran was added, drop by drop. After the reaction mixture had been stirred in ice-bath for 3 hr, the slightly yellow solution was concentrated *in vacuo* (1—3 mmHg) to a syrup. The syrupy residue, dissolved in 100 m*l* of chloroform, was washed with a cold saturated sodium bicarbonate solution and finally with water. The chloroform layer which had been dried over anhydrous magnesium sulfate was evaporated *in vacuo* to dryness. The crystallization of the colorless residue from ethanol afforded 220 mg of *p*-nitrophenyl 2-formylamino-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranoside, which melted at 216—218°C. $[\alpha]_D^{19°} = -47.0$ (*c* 0.477, in acetone). Found: C, 50.05; H, 4.87; N, 6.16%. Calcd for $C_{19}H_{22}O_{11}N_2$: C, 50.22; H, 4.88; N, 6.16%.

2-Formylamino-2-deoxy-D-*glucose.* 2-Amino-2-deoxy-D-glucose hydrochloride (500 mg) was dissolved in 10 m*l* of water containing 10 m*l* of Dowex-1 (carbonate form) under cooling in an ice bath.[10] After the mixture had then been stirred for 1 hr, the ion exchange resin was removed by filtration. To the filtrate (10 m*l*) we then added 40 m*l* of tetrahydrofuran and 1.0 m*l* of pyridine, and then *p*-nitrophenyl formate (1000 mg) in 20 m*l* of tetrahydrofuran, drop by drop. After the reaction had been continued in an ice bath for 3 hr under stirring, the tetrahydrofuran was evaporated *in vacuo* and the residual aqueous solution, freed form the precipitate, was passed through a Dowex-50 (acidic from) column. The effluent was washed three times with chloroform and neutralized with Dowex-1 (carbonate form). The solution was then evaporated *in vacuo* to dryness, and the residual solid was crystallized from ethanol and ether to give 370 mg of 2-formylamino-2-deoxy-D-glucose, which melted at 112—118°C. $[\alpha]_D^{25°} = +30.9$ (Reading after 2 hr; *c* 0.905, in water). Found: C, 40.25; H, 6.33; N, 6.60%. Calcd for $C_7H_{13}O_6N$: C, 40.58; H, 6.33; N, 6.76%.

2-Formylamino-2-deoxy-D-*galactose.* A treatement of 2-amino-2-deoxy-D-galactose hydrochloride (500 mg) similar to that of 2-amino-2-deoxy-D-glucose gave 300 mg of 2-formylamino-2-deoxy-D-galactose, which melted at 162—164°C (dec.). $[\alpha]_D^{25°} = +80.8$ (Reading after 2 hr, *c* 1.06, in water). Found: C, 40.53; H, 6.45; N, 6.57%. Calcd for $C_7H_{13}O_6N$; C, 40.58; H, 6.33; N, 6.76%.

The author expresses his deep gratitude to Professor Y. Matsushima (Faculty of Science, Osaka University) for the continued interest and support throughout this work and to Dr. S. Sakakibara (Institute for protein research, Osaka University) for suggestion and advice relating to this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1254—1256 (1972)

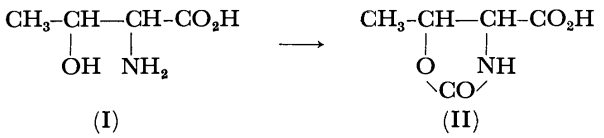
Oxazolidone Derivatives of Hydroxyamino Acids. VII.[1] Syntheses and Properties of DL-*trans*-3-Benzoyl-5-methyl-2-oxo-oxazolidine-4-carboxylic Acid and Its Derivatives.

Toshishige INUI

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received September 18, 1971)

Threonine (I) was cyclized by the reaction with phosgene to give an oxazolidonecarboxylic acid (II).[2] It was thought to be of interest to study the reaction of phosgene with *N*-benzoylthreonine. The reaction



(I) (II)

of II with benzoyl chloride as well as the formation of *trans*-*N*-benzoylmethyloxazolidonecarboxylic acid (IVa) by direct cyclization of *N*-benzoyl-DL-threonine (IIIa) with phosgene in alkaline solution were unsuccessful. According to the method given previously,[1] IIIa was treated with phosgene in benzene in the presence of *N*,*N*-dimethylaniline. The expected *O*-chlorocarbonyl compound (Va) was obtained. Cyclization of this intermediate Va to IVa was not achieved and an azlactone VI was obtained.

In a similar way, methyl *N*-benzoyl-DL-threoninate (IIIb) was treated with phosgene to give *O*-chlorocar-

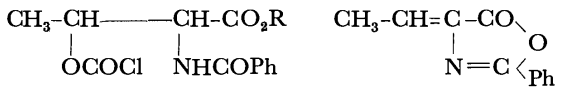
2) T. Kaneko and T. Inui, *Nippon Kagaku Zasshi*, **82**, 1075 (1961); T. Inui and T. Kaneko, *ibid.*, **82**, 1078 (1961).



(V) (VI)

a: R=H b: R=CH_3
c: R=CH_2Ph

bonyl derivative Vb. Compound Vb was cyclized to methyl DL-*trans*-3-benzoyl-5-methyl-2-oxo-oxazolidine-4-carboxylate (IVb) when refluxed in xylene for 1—2 hr. When IVb was hydrolyzed in alkaline medium, elimination of the benzoyl group took place and DL-*trans*-5-methyl-2-oxo-oxazolidine-4-carboxylic acid (II) was obtained in the place of IVa. From this finding, the selective cleavage of threonine peptides is suggested.[3]

Benzyl *N*-benzoyl-DL-threoninate (IIIc) was converted with phosgene into the corresponding oxazolidone ester IVc through its *O*-chlorocarbonyl intermediate Vc. Catalytic hydrogenation of IVc with 5% palladium on carbon gave an acidic IVa. Treatment of IVa with thionyl chloride in benzene gave acid chloride (VII) which was converted into methyl ester IVb. VII was treated with aniline to give its an ilide. It is expected that this result will be useful for the synthesis of peptides containing modified threonine residues.

Experimental[4]

Reaction of N-*Benzoyl-*DL-*threonine (IIIa) with Phosgene. a) In Alkaline Solution*: To a solution of IIIa[5] (5.5 g, 0.025 mol) in 10% aqueous potassium hydroxide solution (60 m*l*, 0.107 mol) was added a solution of phosgene (3.0 g, 0.030 mol) in toluene (10 m*l*) at 0°C for 35 min and the reaction mixture was stirred at 0°C for 2 hr. After the organic layer had been removed, IIIa was recovered on acidification of the aqueous layer with concentrated hydrochloric acid. Yield, 3.9 g (recovery 71%), mp 146—147°C. A mixed melting point with an authentic sample showed no depression. The IR spectra were also identical with those of an authentic sample.

b) In Benzene Solution: Phosgene was passed through a suspension of IIIa (4.5 g, 0.02 mol) and *N,N*-dimethylaniline (1.0 g, 0.008 mol) in benzene (70 m*l*) at 5—8°C for 30 min. The reaction mixture was stirred for 4 hr below 20°C. Carbon dioxide (or nitrogen) was passed through the solution to remove excess phosgene. The benzene solution was washed with dilute hydrochloric acid and water. The dried solution was evaporated *in vacuo* to give Va. Yield, 3.9 g (67%), mp 125—126°C (decomp.) after recrystallization from ethyl acetate - petroleum ether (50—90°C).

Found: C, 50.94; H, 4.43; N, 5.02; Cl, 12.21%. Calcd for $C_{12}H_{12}O_5NCl$: C, 50.45; H, 4.23; N, 4.96; Cl, 12.41%.

N-Benzoyl-2-aminocrotonic Acid Azlactone (VI). A solution of Va (0.3 g, 0.001 mol) in xylene (3 m*l*) was refluxed for 1.3 hr and evaporated *in vacuo* to give VI. Yield, 0.15 g (76%). It gave a negative Beilstein's test. Its IR spectra were identical with those of an authentic sample.[6]

Methyl N-*Benzoyl-*O-*chlorocarbonyl-*DL-*threoninate (Vb)*. In a similar way to that for the preparation of Va, phosgene was passed through a suspension of IIIb[7] (4.7 g, 0.02 mol) and *N,N*-dimethylaniline (2.4 g, 0.02 mol) in benzene (70 m*l*) at 5—8°C for 30 min. Vb was obtained as crystals from the reaction mixture. Yield, 4.9 g (83%), mp 81—82°C after recrystallization from benzene - petroleum ether (50—90°C).

Found: C, 52.35; H, 4.67; N, 4.97; Cl, 12.34%. Calcd for $C_{13}H_{14}O_5NCl$: C, 52.09; H, 4.71; N, 4.70; Cl, 11.84%.

Methyl DL-trans-*3-Benzoyl-5-methyl-2-oxo-oxazolidine-4-carboxylate (IVb)*. A solution of Vb (6.0 g, 0.02 mol) in xylene (60 m*l*) was refluxed for 1.5 hr. The solution was evaporated *in vacuo* to give IVb as crystals. Yield, 4.0 g (75%), mp 115—117°C and 116—117°C after recrystallization from ethyl acetate - petroleum ether (50—90°C). IR (Nujol mull): 1800, 1780 (C=O in the oxazolidone ring), 1750 (C=O in the ester group), 1680 cm^{-1} (C=O in the benzoyl group).

Found: C, 59.36; H, 5.03; N, 5.16%. Calcd for $C_{13}H_{13}O_5N$: C, 59.31; H, 4.98; N, 5.32%.

Hydrolysis of IVb with hydrochloric acid (1 : 1, v/v) gave DL-threonine. The properties of this sample were identical with those of an authentic sample.

DL-trans-*5-Methyl-2-oxo-oxazolidine-4-carboxylic Acid (II)*. To a suspension of IVb (1.3 g, 0.005 mol) in methanol (5 m*l*) was added 1N methanolic potassium hydroxide solution (6.0 m*l*, 0.006 mol) and the reaction mixture was kept for 3.5 hr at room temperature. After diluting with water, the separated oil was extracted with ethyl acetate. Methyl benzoate was isolated from the extract as a sweet-smelling oil. Yield, 0.5 g (70%). Its IR spectra were identical with those of an authentic sample.

The aqueous layer separated from ethyl acetate extract was acidified with concentrated hydrochloric acid and evaporated *in vacuo* to dryness. The residue was extracted three times with hot ethyl acetate, and the evaporation of the combined extracts gave II. Yield, 0.5 g (70%), mp 126—127°C after recrystallization from ethyl acetate; lit,[2] mp 127—128°C. A mixed melting point with an authentic sample showed no depression.

Benzyl N-*Benzoyl-*O-*chlorocarbonyl-*DL-*threoninate (Vc)*. In a similar way to that for the preparation of Va, phosgene was passed through a suspension of IIIc[8] (12.5 g, 0.04 mol) and *N,N*-dimethylaniline (4.8 g, 0.04 mol) in benzene (140 m*l*) at 5°C for 30 min. Vc was obtained as crystals from the reaction mixture. Yield, 12.4 g (83%), mp 82—83°C after recrystallization from benzene - petroleum ether (50—90°C).

Found: C, 60.96; H, 4.92; N, 3.43; Cl, 9.23%. Calcd for $C_{19}H_{18}O_5NCl$: C, 60.72; H, 4.83; N, 3.73; Cl, 9.43%.

Benzyl DL-trans-*3-Benzoyl-5-methyl-2-oxo-oxazolidine-4-carboxylate (IVc)*. A solution of Vc (10.0 g, 0.026 mol) in xylene (100 m*l*) was refluxed for 2 hr. IVc was obtained from the solution. Yield, 7.1 g (76%), mp 69—70°C after recrystallization from benzene - petroleum ether (50—90°C). IR (Nujol mull): 1800 (C=O in the oxazolidone ring), 1755 (C=O in the ester group), 1680 cm^{-1} (C=O in the benzoyl group).

Found: C, 69.67; H, 5.34; N, 3.62; sol., 9.53%. Calcd for $C_{19}H_{17}O_5N \cdot 1/6C_6H_6$: C, 69.83; H, 5.33; N, 3.70; sol., 10.32%.

Drying over phosphorus pentoxide *in vacuo* raised the melting point to 79—80°C.
