DL-trans-*3-Benzoyl-5-methyl-2-oxo-oxazolidine-4-carboxylic Chloride (VII).* A suspension of IVa (1.5 g, 0.006 mol) in a mixture of thionyl chloride (3 m*l*) and benzene (10 m*l*) was warmed on a water bath for 2.5 hr. The resulting solution was evaporated *in vacuo* to give crystals. Yield, 1.6 g (100%), mp 67—70°C. IR (Nujol mull): 1810, 1795 (C=O in the oxazolidone ring and the acid chloride group), 1690 cm^{-1} (C=O in the benzoyl group).

Treatment of VII with methanol gave IVb in good yield, mp 113—115°C. Its IR spectra were identical with those of the product obtained from Vb by the cyclization process.

Treatment of VII with aniline in benzene gave DL-*trans*-3-benzoyl-5-methyl-2-oxo-oxazolidine-4-carboxanilide in a yield of 70%, mp 122—123°C after recrystallization from dioxane-petroleum ether (50—90°C).

Found: C, 63.28; H, 6.34; N, 6.37%. Calcd for $C_{18}H_{16}O_4N_2 \cdot 1.5C_4H_8O_2$: C, 63.14; H, 6.18; N, 6.14%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1256—1257(1972)

The Addition of Ferrocenylpalladium Chloride to Conjugated Dienes

Akira KASAHARA and Taeko IZUMI

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa-shi, Yamagata

(Received September 22, 1971)

The addition reactions of conjugated dienes with various transition-metal compounds have been studied by many workers. For example, cobalt hydrocarbonyl,[1] methyl or acetylcobalt tetracarbonyl,[2] manganese hydrocarbonyl,[3] methyl-manganese pentacarbonyl,[4] and palladium chloride[5] add to butadiene to form π-allyl metal complexes by way of 1,4 addition reactions. Furthermore, Heck[6] has reported that arylpalladium chlorides, prepared *in situ* from aryl-mercury compounds and lithium palladium chloride, react with conjugated dienes to form 1-arylmethyl-π-allyl-palladium chloride dimers in moderate yields. We have now found that ferrocenylpalladium chloride will also add to conjugated dienes.

The reactions of conjugated dienes with ferrocenylpalladium chloride, prepared *in situ* from ferrocenylmercuric chloride and lithium palladium chloride in acetonitrile, gave 1-ferrocenylmethyl-π-allylpalladium chloride derivatives, plus a small amount of biferrocenyl (III). The products were isolated by evaporating the solvent and by then chromatographing the crude products on alumina. Butadiene, isoprene, and 2,3-dimethylbutadiene all gave the expected π-allylpalladium chlorides (IIA, IIB, and IIC). However, the reaction of methyl sorbate with ferrocenylpalladium chloride resulted in the formation of methyl 5-ferrocenyl sorbate (IV); this reaction seems to proceed though the π-allylic intermediate (V). The evidence for the nature of the organic ligand in the binuclear π-allylic palladium chloride complexes comes from NMR and IR spectra, and the chloro-bridged binuclear structure for these compounds is supported by the conversion into the mononuclear acetylacetonate derivatives, pyridine derivatives, and triphenylphosphine derivatives.

Experimental[7]

Materials. The ferrocenylmercuric chloride was prepared according to the method described by Fish and Rosenblum.[8]

The Preparation of Chloro-π-allylic Palladium Complexes. Lithium palladium chloride solutions were prepared by stirring 0.42 g (10 mmol) of anhydrous lithium chloride with 1.77 g (10 mmol) of anhydrous palladium chloride overnight at room temperature in 100 m*l* of acetonitrile. Into this lithium palladium chloride solution, a mixture of 4.20 g (10 mmol) of ferrocenylmercuric chloride and diolefins in a fourfold equivalent amount was then stirred at room temperature. In the reaction with butadiene, butadiene was added, by bubbling, to the reaction mixture under atmospheric pressure. The products were isolated by filtering to remove the solvent. The residue was dissolved in methylene chloride; subsequent recrystallization from ethanol afforded yellow crystals (mp 228—229°C, 6—10% yields), which were identified as biferrocenyl[9] by a comparison of the IR spectrum and by a mixed-melting-point determinations with an authentic sample. Further elution with methylene chloride and recrystallization from benzene-cyclohexane afforded the yellow product.

1-Ferrocenylmethyl-π-allylpalladium Chloride Dimer (II A). Mp 145—147°C (dec.). Yield, 35%. IR spectrum: 237, 255 cm^{-1} (Pd–Cl bridge). NMR sepctrum: 2.67 (d, J= 6.0 Hz, H_a), 2.70 (d-d, J=11.0 and 0.3 Hz, H_e), 3.65 (d-d, J=7.0 and 0.3 Hz, H_d), 3.80 (d-t, J=11.0 and 6.0 Hz, H_b), 4.09 (s, ferrocene ring protons), 5.32 ppm (m, H_c).

Found: C, 44.22; H, 4.08%. Calcd for $C_{28}H_{30}Fe_2Pd_2Cl_2$: C, 44.12; H, 3.96%.

1-Ferrocenylmethyl-2-methyl-π-allylpalladium Chloride Dimer (II B). Mp 157—159°C (dec.). Yield, 24%. IR spectrum: 237, 255 cm^{-1} (Pd–Cl bridge). NMR spectrum: 2.11 (s, CH_3), 2.67 (d, J=0.5 Hz, H_e), 2.72 (d, J=5.5 Hz, H_a), 3.70 (d, J=0.5 Hz, H_d), 3.93 (t, J=5.5 Hz, H_b), 4.08 ppm (s, ferrocene ring protons). Found: C, 45.65; H, 4.45%. Calcd for $C_{30}H_{34}Fe_2Pd_2Cl_2$: C, 45.60; H, 4.33%.

1-Ferrocenylmethyl-1,2-dimethyl-π-allylpalladium Chloride Dimer (II C). Mp 127—129°C. Yield, 29%. IR spectrum: 237, 255 cm^{-1} (Pd–Cl bridge). NMR spectrum: 2.13 (s, CH_3 on the terminal carbon atom of the π-allyl group), 2.18 (s, CH_3 on the central carbon atom of the π-allyl group), 2.65 (d, J=0.5 Hz, H_e), 2.70 (s, H_a), 3.78 (d, J=0.5 Hz, H_d), 4.08 (s, ferrocene ring protons).

Found: C, 47.10; H, 4.77%. Calcd for $C_{32}H_{38}Fe_2Pd_2Cl_2$: C, 47.04; H, 4.68%.

The Preparation of π-Allylic Palladium Acetylacetonate Complexes. The corresponding chloro-complex (0.4 g) in benzene was mixed with a solution of thallium acetylacetonate (5% excess) in benzene and kept at room temperature for 30 min. After the thallous chloride had then been filtered off, the filtrate was evaporated to dryness; the residue was recrystallized from benzene - light petroleum to give pale yellow crystals.

1-Ferrocenylmethyl-π-allylpalladium Acetylacetonate. Mp 93—94°C (dec.). Found: C, 51.47; H, 5.01%. Calcd for $C_{19}H_{22}OFePd$: C, 51.31; H, 4.94%.

1-Ferrocenylmethyl-2-methyl-π-allylpalladium Acetylacetonate. Mp 140—141°C (dec.).

Found: C, 52.62; H, 5.38%. Calcd for $C_{20}H_{24}OFePd$: C, 52.36; H, 5.27%.

1-Ferrocenylmethyl-1,2-dimethyl-π-allylpalladium Acetylacetonate. Mp 69—70°C (dec.).

Found: C, 53.50; H, 5.65%. Calcd for $C_{21}H_{26}OFePd$: C, 53.35; H, 5.54%.

The Preparation of Chloro-(π-allyl)-pyridine-palladium Complexes. A solution of the chloro-bridged palladium complex (0.10 g) in methylene chloride was treated with a solution of pyridine (5% excess) in ether. After 10 min, the solvent was removed under reduced pressure; the residue was then recrystallized from benzene - cyclohexane to give pale yellow crystals.

Chloro-(1-ferrocenylmethyl-π-allyl)-pyridine Palladium. Mp 116—118°C (dec.).

Found: C, 49.81; H, 4.45; N, 3.17%. Calcd for $C_{19}H_{20}NFePdCl$: C, 49.59; H, 4.38; N, 3.04%.

Chloro-(1-ferrocenylmethyl-2-methyl-π-allyl)-pyridine Palladium. Mp 118—120°C (dec.).

Found: C, 50.83; H, 4.69; N, 3.11%. Calcd for $C_{20}H_{22}NFePdCl$: C, 50.65; H, 4.67; N, 2.97%.

Chloro-(1-ferrocenylmethyl-1,2-dimethyl-π-allyl)-pyridine Palladium. Mp 110—112°C.

Found: C, 51.70; H, 4.99; N, 2.98%. Calcd for $C_{21}H_{24}NFePdCl$: C, 51.66; H, 4.95; N, 2.86%.

The Preparation of Chloro-(π-allyl)-triphenylphosphine-palladium Complexes. To a solution of the chloro-bridged complex (0.10 g) in warm benzene (20 m*l*), a solution of triphenylphosphine (5% excess) in benzene was added; the resultant mixture was rapidly cooled to *ca.* 8°C. Pale yellow crystals were then filtered off and recrystallized from benzene - cyclohexane.

Chloro-(1-ferrocenylmethyl-π-allyl)-triphenylphosphine Palladium. Mp 142—144°C.

Found: C, 59.91; H, 4.79%. Calcd for $C_{32}H_{30}PFePdCl$: C, 59.73; H, 4.70%.

Chloro-(1-ferrocenylmethyl-2-methyl-π-allyl)-triphenylphosphine Palladium. Mp 103—105°C.

Found: C, 60.22; H, 5.13%. Calcd for $C_{33}H_{32}PFePdCl$: C, 60.29; H, 5.05%.

Chloro-(1-ferrocenylmethyl-1,2-dimethyl-π-allyl)-triphenylphosphine Palladium. Mp 107—109°C.

Found: C, 60.87; H, 5.21%. Calcd for $C_{34}H_{34}PFePdCl$: C, 60.82; H, 5.10%.

Methyl 5-Ferrocenyl Sorbate (IV). A mixture of 4.2 g (10 mmol) of ferrocenylmercuric chloride, 4.8 g (40 mmol) of methyl sorbate, and a lithium palladium chloride solution (prepared from 1.77 g of palladium chloride, 0.42 g of lithium chloride, and 100 m*l* of acetonitrile) was stirred at room temperature for 12 hr; the products were then isolated as in the preparation of chloro-π-allylic palladium complexes. The products were chromatographed on alumina. First elution with methylene chloride afforded yellow crystals (mp 228—229°C, 10% yields), which were identified as biferrocenyl. Further elution with methylene chloride and recrystallization from benzene - cyclohexane afforded yellow crystals (mp 44—45°C, 28% yields), which were identified as methyl 5-ferrocenyl sorbate on the basis of their IR and NMR spectra.

IR spectrum: 1712, 1641, 1620 cm^{-1}. NMR spectrum: 2.08 (s, CH_3), 3.69 (s, OCH_3), 4.05, 4.29, 4.40 (ferrocene ring protons) 5.80, 6.48, 7.68 ppm (ABX pattern, H_a, H_c, and H_b).

Found: C, 68.58; H, 5.81%. Calcd for $C_{17}H_{18}O_2Fe$: C, 68.56; H, 5.72%.

7) All melting points are uncorrected. The NMR spectra were measured on a Hitachi H-60 spectrometer at 60 MHz in $CDCl_3$, using tetramethylsilane as the internal reference. The chemical shifts are given in ppm.

Alkoxysilanes. VI. The Preparation of Alkoxysiloxy Derivatives of Zirconium and Tin

Yoshimoto ABE,* Kiyoshi HAYAMA, and Ichiro KIJIMA

Department of Industrial Chemistry, Faculty of Engineering, Science University of Tokyo Kagurazaka, Shinjuku-ku, Tokyo

(Received October 6, 1971)

Tetrakis(tri-*t*-butoxysiloxy)zirconium (I) or tin (III), bis(tri-*t*-butoxysiloxy)diisopropoxyzirconium (II) or di-*t*-butoxytin (IV), and bis(tri-*t*-butoxysiloxy)bis(acetylacetonato)zirconium (V) or tin (VI) were prepared in the same way as in the cases of antimony[1] and titanium:[2]

$$M(OR)_4 + n(Bu^tO)_3SiOH \longrightarrow [(Bu^tO)_3SiO]_nM(OR)_{4-n} + nROH$$

where M=Zr, $n=4$ (I); $n=2$ (II) and M=Sn, $n=4$ (III); $n=2$ (IV)

$$(Acac)_2M(OR)_2 + 2(Bu^tO)_3SiOH \longrightarrow [(Bu^tO)_3SiO]_2M(Acac)_2 + 2ROH$$

where M=Zr (V) and M=Sn (VI).

The results of the elemental analysis and of the measurements of the IR and NMR spectra are given in Table 1. As compared to the cases of silicon[3] and titanium, (I) and (III) were more easily formed, probably indicating that the increase in the atomic radii of these metals led to an easy introduction of the tri-*t*-butoxysiloxy group. The results of the molecular-weight determination indicated that (I) and (II) are dimeric.[4] They may have an associated structure built up by a zirconosiloxane bridge similar to the alkoxy bridge in metal alkoxide.[5] It was observed that the absorption peaks due to the Si–O–M bond[6] shifted toward higher wave numbers with an increase in the atomic weight of the metals (Ti<Zr<Sn), and that the proton signals of the *t*-butyl group shifted toward an appreciably lower field in the sequence of Ti<Zr<Sn. (V) was very stable and could be distilled, while the other products were decomposed at relative low temperatures.

The preparation of a polymeric substance with Si–O–M bond was attempted; the reaction of zirconium tetraisopropoxide with di-*t*-butoxysilanediol in the molar ratio of 1:2 or 1:3 (alkoxide: silanediol) gave a glassy solid with a relatively low decomposition point (140—150 or 120—130°C). With bis(tri-*t*-butoxysiloxy)silanediol, a highly viscous liquid was obtained. On the other hand, the reaction of tin tetra-*t*-butoxide with this diol gave a white crystal which was identified as having a unit structure $[-Sn(OBu^t)_2-O-Si[O-Si(OBu^t)_3]_2-O-]_n$. The reaction of bis(acetylacetonato)-diisopropoxyzirconium with di-*t*-butoxysilanediol afforded polybis(acetylacetonato)zirconosiloxane, which was confirmed to have the structure of $[-Zr(Acac)_2-O-Si(OBu^t)_2-O-]_n$ ($n \fallingdotseq 4$). In order to compare the thermal stability of this compound with that of polytitanosiloxane,[2] the TGA curve was measured. The results showed that the polyzirconosiloxane was more stable than the polytitanosiloxanes; the weight loss of

the former was about 30% at 200°C, whereas that of the latter was about 50% at the same temperature.

The reaction of the zirconium or tin acetylacetonato chelate with bis(tri-*t*-butoxysiloxy)silanediol, on the other hand, gave recrystallizable products with a Si–O–M bond. Although the molecular weight was not measured, the results of the elemental analysis and a study of the IR and NMR spectra indicated that the structure may correspond to:

$$\begin{matrix} \text{Acac} & \text{OR} \\ (\text{-M—O—Si-O-})_n & (\text{R}=(\text{Bu}^t\text{O})_3\text{Si}). \\ \text{Acac} & \text{OR} \end{matrix}$$

Experimental

Materials. The alkoxysilanols were prepared by a method previously described.[2,3] Zirconium tetraisopropoxide was obtained by the distillation of a commercially-available zirconium tetraisopropoxide isopropyl alcohol adduct (bp 195—196°C/3 mmHg).[7] Bis(acetylacetonato)diisopropoxyzirconium was afforded by the distillation of the reaction mixture after a mixture of zirconium tetraisopropoxide, acetylacetone, andbenzene had been refluxed for 1 hr (bp 140—142°C/2 mmHg). Tin tetra-*t*-butoxide (bp 82—83°C/1 mmHg) was prepared by the reaction of tin tetrachloride with *t*-butyl alcohol in the presence of diethylamine. The isolation of bis(acetylacetonato)di-*t*-butoxytin was attempted, but the attempt failed because of its decomposition upon distillation (at about 160°C/1—2 mmHg). The refore, the unpurified tin chelate obtained by the reaction of tin tetra-*t*-butoxide with acetylacetone in benzene was used as the starting material.

Preparation of Compounds (I)—(IV). A mixture of metal tetraalkoxide or bis(acetylacetonato)dialkoxymetal, tri-*t*-butoxysilanol (the molar ratio of the silanol to metal alkoxides was 2: 1 or 4: 1),[8] and benzene was refluxed for 1 hr. After the solvent had been removed along with the alcohol formed, the residue was distilled or recrystallized. The compounds thus obtained are given in Table 1.

The Reaction of Zirconium Tetraisopropoxide with Di-t-butoxysilanediol. A mixture of 4.5 g (0.0137 mol) of the alkoxide, 5.7 g (0.0274 mol) of the diol, and 40 m*l* of ethyl ether was refluxed for 1 hr. The removal of the solvent *in vacuo* gave 7.3 g of a pale yellow solid; mp 140—150°C (decomposed). Found: C, 31.40; H, 6.80; Si, 9.73; Zr, 29.42%. On the other hand, the reaction of 3.2 g (0.098 mol) of the alkoxide and 8.2 g (0.391 mol) of the diol gave 8.1 g of a pale yellow solid; mp 120—130°C (decomposed). Found: C, 30.06; H, 6.75; Si, 15.31; Zr, 15.93%. These polymeric substances were very soluble in common organic solvents.

Polybis(acetylacetonato)zirconosiloxane. A mixture of bis(acetylacetonato)diisopropoxyzirconium, di-*t*-butoxysilanediol, and toluene was refluxed for 1 hr. After the solvent had been removed at 100°C *in vacuo*, the residue was further heated for 2 hr to give a dark brown solid; mp 80—90°C. Found: C, 42.65; H, 6.45; Si, 5.43%; mol. wt, 2000. Calcd for $C_{18}H_{32}O_8SiZr$: C, 43.60; H, 6.52; Si, 5.76%; mol. wt, $495\times n$.

The Reaction of Bis(acetylacetonato)diisopropoxyzirconium or di-t-butoxytin with Bis(tri-t-butoxysiloxy)silanediol. A mixture of 8.2 g (0.0201 mol) of bis(acetylacetonato)diisopropoxyzirconium, 11.9 g (0.0201 mol) of the diol, and 40 m*l* of toluene was refluxed for 1 hr. After the solvent had been removed at 160°C, the subsequent evaporation of the solvent *in vacuo* yielded 17.6 g of a dark yellow solid, which was then recrystallized from *n*-hexane to give 10.6 g (56%) of white granular crystals; mp 222—223°C. Found: C, 45.85; H, 7.97; Si, 10.03%. Calcd for $(C_{34}H_{68}O_{14}Si_3Zr)_n$: C, 46.60; H, 7.82; Si, 9.61%. IR: 960 and 925 (shlouder) ($\nu_{Si-O-Zr}$) cm^{-1}. NMR: 8.72 (Bu^t), 8.06 (Me), and 4.52 (=CH–)τ.

On the other hand, the reaction between bis(acetylacetonato)di-*t*-butoxytin (5.3 g, 0.0112 mol) and the diol (6.6 g, 0.0112 mol) in 50 m*l* of benzene gave 3.2 g of white needle crystals; mp 138—145°C (recrystallized from *n*-hexane; decomposed at 185—190°C). Found: C, 46.27; H, 8.26; Si, 9.48; Sn, 13.19%. Calcd for $(C_{34}H_{68}O_{14}Si_3Sn)_n$: C, 46.84; H, 7.86; Si, 9.67; Sn, 13.61%. IR: 960, 934, and 904 (shoulder) ($\nu_{Si-O-Zr}$) cm^{-1}. NMR: 8.72 (Bu^t), 8.82 (Me), and 4.76 (=CH–, doublet) τ.

Analysis. The silicon was determined by a method described in a previous report. The zirconium was determined to be zirconium dioxide after a weighed sample had been hydrolyzed by means of an aqueous alcohol solution. The tin was determined by iodometry after a weighed sample had been decomposed in concentrated hydrochloric acid containing lead under a carbon dioxide atmosphere.

The authors wish to thank Professor Yojiro Tsuzuki for his helpful advice and interest.

7) The authors wish to thank the Matsumoto Pharmaceutical Co. for supplying the zirconium tetraisopropoxide isopropyl alcohol adduct.

8) Reagents for (I): 6.3 g (0.0193 mol, $Zr(OPr^i)_4$), 21.1 g (0.0799 mol, $(Bu^tO)_3SiOH$; (II): 11.2 (0.0343), 18.8 (0.0712); (III): 5.8 (0.0141, $Sn(OBu^t)_4$), 14.9 (0.0564); (IV): 9.4 (0.0229), 12.1 (0.0458); (V): 9.6 (0.0236, $(Acac)_2Zr(OPr^i)_2$), 12.5 (0.0473); (VI): 5.9 (0.0128, $(Acac)_2Sn(OBu^t)_2$, 7.1 (0.0269).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1260—1261(1972)

The Effect of the Temperature on the Formation of Solvated Electrons and Hydrogen in the Photolysis of a Methanolic Solution of Potassium Iodide

Hiroshi SEKI, Hiroo ISHIDA, and Masashi IMAMURA
The Institute of Physical and Chemical Research, Wako, Saitama

(Received October 18, 1971)

In a previous paper[1] we reported the photochemical formation of the solvated electron and its reactions in methanolic solutions of potassium iodide. The solvated electrons in methanol decompose with a rate constant of 5.4×10^5 sec^{-1} to form hydrogen. Hydrogen is also produced from UV-irradiated CH_3OD solutions; its isotopic composition was found to be nearly 100% HD. It was concluded, therfore, that the reaction:

$$e^-_{solv} \longrightarrow H + CH_3O^- \qquad (1)$$

does occur in methanolic solutions, followed by:

$$H + CH_3OH \longrightarrow H_2 + CH_2OH \qquad (2)$$

Reaction (1) had been assumed to occur in the radiolysis of methanol;[2-4] our previous result gave a sound basis to this assumption.

The temperature dependence of the rate constant of Reaction (1) has been determined with the radiolytic system by somewhat indirect procedures.[3] In this study, we determined the quantum yields of hydrogen from UV-irradiated methanolic solutions of potassium iodide at temperatures between −15 and 85°C, as well as those of the solvated electrons scavengeable by nitrous oxide. Both quantum yields were found to fit the Arrhenius equation, the energies of activation being obtained.

Experimental

The chemicals and procedures were essentially the same as those previously reported.[1] UV-irradiations at temperatures lower and higher than room temperature were carried out by placing irradiation ampoules in a Dewar vessel equipped with quartz windows. For experiments above 0°C, the ampoule was immersed in water thermostated at the desired temperatures. For experiments below 0°C, dry nitrogen gas which had been cooled with liquid nitrogen to the desired temperatures was blown into the Dewar vessel through copper tubing.

The concentrations of N_2O in methanolic solutions at various temperatures were calculated by using Bunsen absorption coefficients estimated by extrapolating the existing data in pure methanol.[5] All the solutions contained 0.1 M KI and were irradiated with UV light centered at 254 nm, as previously.[1]

Results and Discussion

Table 1 lists the quantum yields of N_2 from 0.1 M KI solutions containing N_2O and those of H_2 in the absence of N_2O at various temperatures.

Table 1. Temperature dependence of $\Phi(N_2)$ and $\Phi(H_2)$

Temp °C	$\Phi(N_2)$[a]	$\Phi(H_2)$[b]
−15	0.46±0.01 (6—9)	0.13±0.01
3	0.51±0.01 (5—6)	0.22±0.01
25	0.58±0.01 (1—5)	0.35±0.01
60	0.69±0.02 (3—4)	0.57±0.02
85	0.78±0.01 (3—4)	0.69±0.01

a) The quantum yields at N_2O concentrations in 10^{-2} M given in parentheses
b) The quantum yields for 0.1 M KI solutions not containing N_2O

As has been reported previously,[1] with an increase in the concentration of N_2O, $\Phi(H_2)$ decreases rapidly to null at about 5×10^{-4} M N_2O and $\Phi(N_2)$ reaches a plateau value of 0.59 above 1.2×10^{-2} M at 25°C. The same plateau value as for $\Phi(N_2)$ was obtained for $\Phi(H_2)$ with acid solutions. (Hydrogen ions react with e^-_{solv} to produce H atoms.) We have, therefore, concluded that N_2 is produced solely by the reaction of N_2O with e^-_{solv} in a stoichiometric ratio of $N_2/e^-_{solv}=1$. Furthermore, $\Phi(N_2)$ was observed to keep its plateau value of 0.59 over the N_2O concentration range studied ($(1—5)\times10^{-2}$ M).

These results may indicate that N_2O scavenges, in these concentration ranges, all the e^-_{solv} produced by the reaction:

$$I^{-*}_{solv} \longrightarrow I_{solv} + e^-_{solv} \qquad (3)$$

competing with the deactivation process:

$$I^{-*}_{solv} \longrightarrow I^-_{solv} + \text{energy} \qquad (4)$$

The quantum yields of N_2 in Table 1 were obtained at N_2O concentrations of $(1—9)\times10^{-2}$ M; therefore, these values may be regarded as the limiting quantum yields of e^-_{solv} produced by Reaction (3).

Thus, $\Phi(e^-_{solv})$ may be expressed by:

$$\Phi(e^-_{solv}) = \Phi(N_2) = \frac{k_3}{k_3+k_4} \qquad (i)$$

Since the deactivation of I^{*-}_{solv} is a collisional process, k_4 may be expected to be proportional to $T^{1/2}$. On the other hand, k_3 should be regulated by the rate of rotational movements in methanol and should, therefore, be proportional to the fluidity. Since the temperature dependence of the viscosity is given by $\eta = A'\exp(B/\boldsymbol{R}T)$, k_3 may be expressed by:

1) H. Seki and M. Imamura, This Bulletin, **44**, 1538 (1971).
2) J. H. Baxendale and F. W. Mellows, *J. Amer. Chem. Soc.*, **83**, 4720 (1961).
3) K. N. Jha and G. R. Freeman, *J. Chem. Phys.*, **48**, 5480 (1968).
4) F. S. Dainton, G. A. Salmon, and P. Wardman, *Proc. Roy. Soc.* (London), *A*, **313**, 1 (1969).
5) A. Seidell, "Solubilities of Inorganic and Metal Organic Compounds," Vol. 2, 4th Ed., American Chemical Society, Washington, D. C. (1965), p. 802.

$$k_3 = A_3\exp(-E_3/\boldsymbol{R}T) \quad \text{(ii)}$$

where E_3 is expected to be equal to B.

From Eqs. (i) and (ii), it seems that the temperautre dependence of $\Phi(e^-_{solv})$ can be approximately expressed by Eq. (iii):

$$\ln\left(\frac{1}{\Phi(e^-_{solv})}-1\right)=\ln\frac{k_4}{A_3}+\frac{E_3}{\boldsymbol{R}T} \quad \text{(iii)}$$

From the plot according to Eq. (iii) shown in Fig. 1, E_3=2.7 kcal/mol is obtained. This value is close to the constant, B, for methanol (2.3 kcal/mol) in the same temperature range as that used in this study. In aqueous solutions the corresponding value of 4.7± 0.5 kcal/mol has been obtained (B=4.5 kcal/mol).[6]

Previously we have not decided whether or not all the e^-_{solv} scavengeable with N_2O (Φ=0.59) are free and participate in the H_2-formation process in the absence of N_2O. Figure 2 shows the homogeneous-kinetics plot of the data obtained at room temperature (25°C) according to this equation:

$$\frac{1}{\Phi(N_2)}=\frac{1}{\Phi(e^-_{solv})}\left(1+\frac{k_1+k_x[X]}{k_{N_2O}[N_2O]}\right) \quad \text{(iv)}$$

Here, X represents the reactive species (toward e^-_{solv}) not producing H atom (*i.e.*, I or I_2^- and/or impurity, if any). The straight line connecting points at low N_2O concentrations (10^{-4}M) can be extrapolated to $1/\Phi(N_2)=1.7$ or $\Phi(N_2)=0.59$, which is in agreement with the plateau value of $\Phi(N_2)$ obtained at (1—5)× 10^{-2}M N_2O. These results indicate that all the e^-_{solv} scavengeable with N_2O at concentrations of (1—5)× 10^{-2}M are free and can produce H_2 in the absence of N_2O.[7]

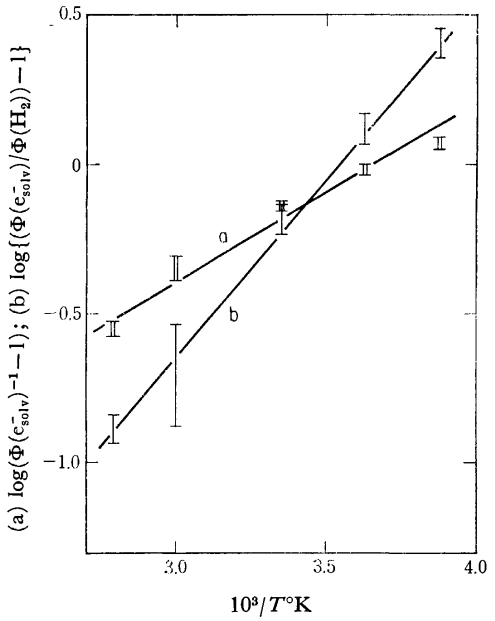

Fig. 1. Arrhenius plots for (a) $\Phi(e^-_{solv})$ and (b) $\Phi(H_2)$ according to Eqs. (iii) and (v).

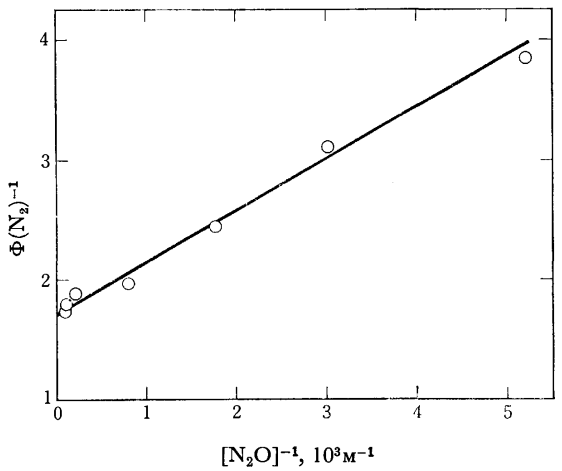

Fig. 2. A homogeneous-kinetics plot of $\Phi(N_2)$ for KI solutions containing N_2O at 25°C according to Eq. (iv).

Since H_2 is produced solely by Reactions (1) and (2), and since the rate of the latter reaction is about 100 times faster than the former, $\Phi(H_2)$ at each temperature is expressed by:

$$\Phi(H_2)=\Phi(e^-_{solv})\times\frac{A_1\exp(-E_1/\boldsymbol{R}T)}{A_1\exp(-E_1/\boldsymbol{R}T)+A_x\exp(-E_x/\boldsymbol{R}T)[X]}$$

or:

$$\ln\left(\frac{\Phi(e^-_{solv})}{\Phi(H_2)}-1\right)=\ln\frac{A_x}{A_1}[X]+\frac{E_1-E_x}{\boldsymbol{R}T} \quad \text{(v)}$$

The plot according to Eq. (v) is shown in Fig. 1, from which E_1-E_x=5.4 kcal/mol. As has been stated above, X is a general expression for reactive species toward e^-_{solv}; therefore, its rate constant, k_x, may be regarded as very close to a diffusion-controlled one. If we take $E_x\simeq$2.8 kcal/mol,[3] $E_1\simeq$8 kcal/mol is obtained. The entropy of activation, ΔS^*, can be estimated from the values of k_1[1] and E_1 to be −6 cal/deg·mol.

The value of E_1 estimated by Jha and Freeman[3] is 3.7 kcal/mol, lower than the present one. They estimated E_1 from the temperature dependence of the rate-constant ratio, $k(e^-_{solv}+N_2O)/k_1$, obtained from plots of $1/G(N_2)$ *vs.* $1/[N_2O]$ at −97, 25, and 150°C. There is, however, an ambiguity about the N_2O concentration at 150°C that was estimated by a long extrapolation of the Bunsen coefficient. Furthermore, their value of the rate-constant ratio of 1.1×10^4M^{-1} at 25°C is too low. This value can be expected to be $(2—3)\times10^4$M^{-1} on the basis of the reasonable values of $k(e^-_{solv}+N_2O)=1.3\times10^{10}$M^{-1} sec^{-1} [1,4,8] and $k_1=(4—6)\times10^5$ sec^{-1};[1,3,9] in fact, we have ourselves obtained 2.4×10^4M^{-1} for $k(e^-_{solv}+N_2O)/k_1$ in a previous paper.[1] The present disagreement in E_1 may be in part due to such reasons, though no quantiative accounts are available at this moment.

It does not seem that the value of E_1 is necessarily equal to that of the dielectric relaxation, as was suggested by Jha and Freeman.[3] Since E_1 should be used not only to rearrange the solvent structure but also to form an activated state producing CH_3O^- and H, E_1 may be expected to be higher than the activation energy of the dielectric relaxation.

6) F. S. Dainton and S. R. Logan, *Proc. Roy. Soc.* (London), *A*, **287**, 281 (1965).

7) This conclusion does not necessarily rule out the effect of the solvent cage in which geminate recombination may take place since the concentration of N_2O employed was not high enough.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1262—1263(1972)

Kinetic Studies of Association and Dissociation Reactions of Congo Red by the Temperature-Jump Method

Tatsuya YASUNAGA and Sadakatsu NISHIKAWA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received October 20, 1971)

The association of dye in an aqueous solution has been widely studied through the application of the polarograghic[1] or spectroscopical methods.[2-7] However, there is little information available concerning the kinetics of the association and dissociation reactions of dye.[8] The present study was undertaken in order to obtain kinetic and thermodynamic information concerning the association and dissociation of congo red by the use of the temperature-jump method.

Experimental

The techniques and apparatus used were fully described in a previous paper.[9] The temperature-jump, of about 4°C, was caused by discharging a 0.1 μF capacitor, charged to approximately 20 kV, through the solution. The wavelength of observation was 500 mμ. The congo red was kindly provided in an extremely pure form by Professor Suzawa.* The inoic strength of the solution was adjusted to $\mu=0.1$ by the addition of NaCl. All the solutions were prepared using distilled, air-free water in order to prevent the formation of air bubbles upon the discharge of the capacitor. The reciprocal relaxation time, τ^{-1}, was calculated from the plots of $-\log \Delta C$ *vs.* the time, where ΔC is the deviation of the concentration from its equilibrium value. The method of least-squares was employed to calculate the most probable values of the rate constants.

Results and Discussion

Table 1 shows the mean reciprocal relaxation times obtained from this study in the concentration range of 10^{-6} to 10^{-5}M at various temperatures. The dependence of the relaxation time on pH was not observed. This means that the observed relaxation phenomena are not associated with the hydrogen ion. Now, let us assume the following association-dissociation equilibrium at a low concentration of the dye:

$$2A \underset{k_2}{\overset{k_1}{\rightleftharpoons}} A_2 \qquad (1)$$

Table 1. THE RECIPROCAL RELAXATION TIME AT VARIOUS TEMPERATURES

$C_0\times 10^6$	$(1/\tau)_{av}$, sec^{-1}		
	13°C	17°C	22°C
1	—	93	—
2	62	118	—
3	69	142	182
4	66	133	183
5	67	162	213
6	62	153	231
7	68	141	244
8	67	174	259
9	73	171	253
10	89	196	—

where A and A_2 are the monomer and the dimer of the dye, and where k_1 and k_2 are the forward and backward rate constants respectively. The rate of association for this system is, then, given by:

$$\frac{d[A_2]}{dt} = k_1[A]^2 - k_2[A_2] \qquad (2)$$

The reciprocal relaxation time is related to the rate constants and the monomer concentration at equilibrium, $[A]_0$, as follows:

$$\tau^{-1} = 4k_1[A]_0 + k_2 \qquad (3)$$

Equation (3) can be rewritten in terms of the total concentration, C_0, by the use of the $C_0=[A]_0+2[A_2]_0$ and $k_2/k_1=[A]_0^2/[A_2]_0=K$ relationships. Therefore,

$$\tau^{-2} = 8k_1k_2C_0 + k_2^2 \qquad (4)$$

where K is the equilibrium constant. Figure 1 shows plots of τ^{-2} *vs.* C_0. The rate constants were calculated from the intercepts and slopes using the least-squares method. These values are listed in Table 2.

Table 2. The kinetic values for the association and dissociation reaction of congo red at various temperatures

	13°C	17°C	22°C
k_1, 10^6 sec^{-1} M^{-1}	0.70±0.16	3.5 ±0.8	6.7 ±1.5
k_2, 10^2 sec^{-1}	0.55±0.05	0.92±0.10	1.2 ±0.2
K, 10^{-4} M	0.79±0.26	0.26±0.09	0.17±0.05

According to Eyring's rate theory, the rate constant, k_i, is related to the activation energy, the activation enthalpy and the activation entropy as is the next equation:

$$k_i = PT\exp\left(-\frac{\Delta F_i^*}{RT}\right) = PT\exp\left(-\frac{\Delta H_i^* - T\Delta S_i^*}{RT}\right) \quad (5)$$

where P is the constant, R is the gas constant, T is the absolute temperature, ΔF_i^* is the activation energy, ΔH_i^* is the activation enthalpy, and ΔS_i^* is the activation entropy. Figure 2 shows the plots of $\ln(k_i/T)$ *vs.* $1/T$. The activation enthalpies were obtained from the slopes, while the enthalpy change was calculated from

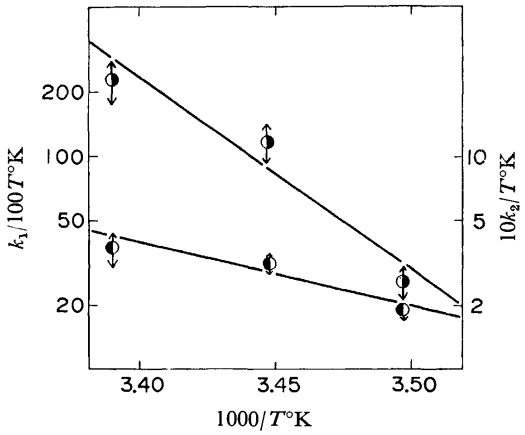

Fig. 2. Temperature dependence of rate constants in the association and dissociation reaction of congo red: ◑, k_1; ◐, k_2.

the difference between the activation enthalpies in the two states. Furthermore, the changes in the free energy and the entropy were calculated by the use of the $\Delta F = -RT\ln K$ and $\Delta F = \Delta H - T\Delta S$ relationships. These values are $\Delta H_1^* = 41$ kcal/mol, $\Delta H_2^* = 15$ kcal/mol, $\Delta H = \Delta H_1^* - \Delta H_2^* = 26$ kcal/mol, $\Delta F = \Delta F_1^* - \Delta F_2^* = -5.4$ kcal/mol at 13°C, -6.1 kcal/mol at 17°C, -6.5 kcal/mol at 22°C, and $\Delta S \cong 110$ cal/mol·deg.

The single relaxation phenomena and the linearity of the plots of τ^{-2} *vs.* C_0 show that the relaxation phenomena obtained in this study are attributable to the disturbance of the monomer-dimer equilibrium of congo red in the concentration range of 10^{-6} to 10^{-5}M. This proves that only the monomer and dimer of congo red exist in this concentration range at $\mu = 0.1$. In general, it has been reported that the polymerization of dyestuffs does not stop at the dimeric state, but often proceeds to trimers and higher polymers. Though even in the more concentrated solutions the relaxation spectra could be observed, they were not characterized by a single relaxation time. This shows that the higher polymers exist in the solutions of more than 10^{-5}M.

Only a few reports have been published containing thermodynamic information about the association of dyes.[4,7] It is, however, noteworthy that the changes in enthalpy and entropy obtained for the monomer-dimer equilibrium of congo red are large when compared with those obtained for other dyes.[4,7] The large change in entropy shows that the association and dissociation reactions of congo red are entropy-controled. The positive entropy change for dimer formation must be a consequence of the decreased structuring of the solvent about the dimers, and consequently the dimeric state must be stabilized with an increase in the temperature. As the congo red molecule, however, has a very complex structure, it is difficult to determine how dyes aggregate structurally. Further studies of analogous systems by relaxation methods will lead to a clarification of the aggregation mechanism of congo red.

The Mass Spectra of Several Ferrocenoyl Compounds

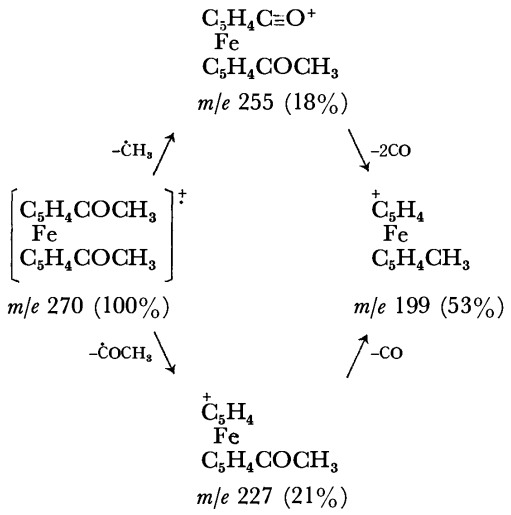
Hiromu IMAI

Faculty of Engineering, Kansai University, Senriyama, Suita-shi, Osaka

(Received November 10, 1971)

Since 1955, beginning with the work of Friedman *et al.*,[1] some reports on the mass spectra of ferrocene[2-4] and its derivatives[5,6] have appeared. The fragmentation of disubstituted ferrocenoyl compounds has never been reported, however, though the mass spectra of some monosubstituted ferrocenoyl compounds has examined by Mandelbaum and Cais.[6] In this paper, it is my purpose to report on the fragmentation of several ferrocenoyl compounds, 1,1'-diacetylferrocene (I), 1,1'-ferrocenedicarboxylic acid (II), and mono- and 1,1'-bisacetoacetylferrocene (III) and (IV).

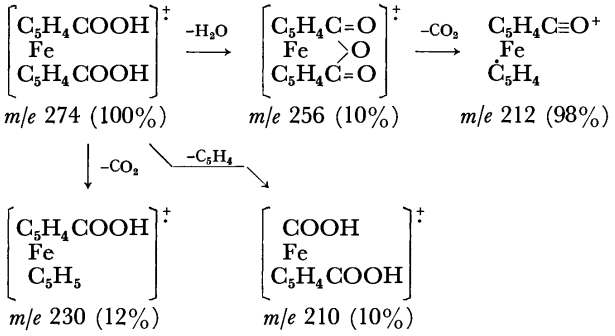
1,1'-Diacetylferrocene (I). I was ascertained to be cleavaged at *m/e* 199 by the following two paths: (a) the *m/e* 270→255→199 sequence was indicated by the appearance of metastable peaks at *m/e* 240.8 and 155.3, while (b) the *m/e* 270→227→199 sequence was suggested by the metastable peaks at *m/e* 190.8 and 174.4. The fragmentation described above is shown in Scheme 1.



Scheme 1

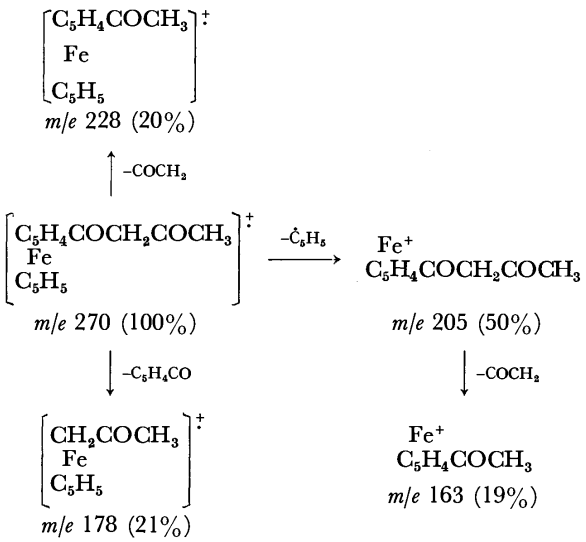
The *m/e* 163 ($Fe^+C_5H_4COCH_3$), which appeared in the spectrum of monoacetylferrocene,[6] was also observed (relative intensity 19%) in the spectrum of I. This fragment ion might be produced by the loss of $\dot{C}_5H_4COCH_3$ from the molecular ion or by that of C_5H_4 from the *m/e* 227.

1,1'-Ferrocenedicarboxylic Acid (II). The following fragmentation was observed from the spectrum of II: (a) a sequence of *m/e* 274→256 (molecular ion of anhydride of II)→212, supported by the metastable peaks at *m/e* 239.2 and 175.6, corresponding to the loss of water and carbon dioxide in that order, and (b) the *m/e* 230 corresponding to the molecular ion of ferrocenemonocarboxylic acid and the rearrangement ion, *m/e* 210, produced from the *m/e* 274 by the loss of carbon dioxide and C_5H_4 respectively. This *m/e* 230 might be transferred to the fragment ion of $Fe^+C_5H_4COOH$ (*m/e* 165, 39%) and $HOFeC_5H_5$ (*m/e* 138, 25%), as has been reported by Mandelbaum and Cais.[6] The main paths of the fragmentation are shown in Scheme 2.



Scheme 2

Mono- and 1,1'-Bisacetoacetylferrocene (III) and (IV). There are three routes for the cleavage of III: (a) the *m/e* 270→205→163 sequence was supported by the metastable peaks at *m/e* 155.6 and 129.6, (b) the *m/e* 228 appeared upon the loss of $COCH_2$ from the *m/e* 270 (a metastable peak at *m/e* 192.5), (c) the rearrangement ion, *m/e* 178, appeared upon the loss of C_5H_4CO from



Scheme 3

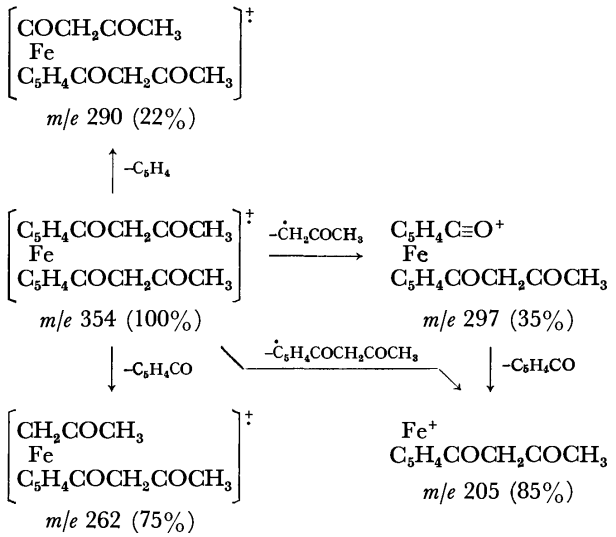
2) E. Schumacher and R. Taubenest, *Helv. Chim. Acta*, **47**, 1525 (1964).
3) R. G. Denning and R. A. D. Wentworth, *J. Amer. Chem. Soc.*, **88**, 4619 (1966).
4) J. Mueller and L. D'or, *J. Organometal. Chem.*, **10**, 313 (1967).
5) D. T. Roberts, W. F. Little, and M. M. Bursey, *J. Amer. Chem. Soc.*, **89**, 4917, 6156 (1967).
6) A. Mandelbaum and M. Cais, *Tetrahedron Lett.*, **51**, 3847 (1964).

the *m/e* 270 (a metastable peak at *m/e* 117.3). These results are given in Scheme 3.

It can be presumed that the *m/e* 228 corresponding to molecular ion of monoacetylferrocene is decomposed to $C_5H_5FeC_5H_4C{\equiv}O^+$ (*m/e* 213, 12%) or $Fe^+C_5H_4CO\text{-}CH_3$ (*m/e* 163, 19%) upon the loss of $\dot{C}H_3$ or $\dot{C}_5H_5$,[6] while the *m/e* 178 resulting from the rearrangement is decomposed to $Fe^+CH_2COCH_3$ (*m/e* 113, 5.2%).

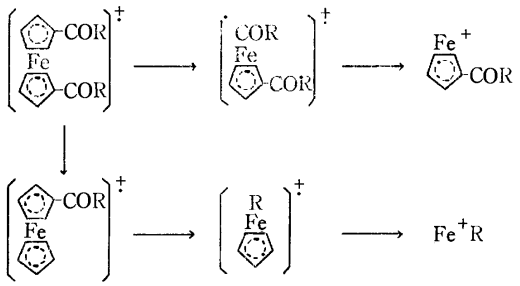
The fragmentation of IV can be explained as follows: (a) the *m/e* 354→297→205 sequence was supported by the metastable peaks at *m/e* 249.2 and 141.5, while the *m/e* 205 was formed by the loss of $\dot{C}_5H_4COCH_2\text{-}COCH_3$ from the *m/e* 354 (a metastable peak at *m/e* 118.7), and (b) both rearrangement ions, *m/e* 290 and 262, were formed from the *m/e* 354 by the loss of C_5H_4 and C_5H_4CO respectively (a metastable ion at *m/e* 235.9 for 354→290 and *m/e* 193.9 for 354→262). These results are shown in Scheme 4.



Scheme 4

Both ions of *m/e* 290 and 262 might be also transferred to *m/e* 205. This *m/e* 205 would seem to be further decomposed by a path similar to that shown in Scheme 3 because of the appearance of the *m/e* 163 (46%). As the other fragment ions, the *m/e* 270 (12%), corresponding to the molecular ion of I or III, and the *m/e* 178 (20%), which was confirmed by the cleavage of III, were observed in the spectrum.

The above results can be summarized as follows. (1) For the mono- and 1,1′-di-substituted ferrocenoyl compounds, II, III, and IV, but not I, the common mechanisms by which the rearrangement ions appear are given by:



(R=OH or CH_2COCH_3)

(2) The fragment ions, such as $C_5H_5Fe^+C_5H_4$ (*m/e* 185), $\dot{C}_5H_4Fe^+C_5H_4$ (*m/e* 184), $Fe^+C_5H_5$ (*m/e* 121), $Fe^+\dot{C}_5H_4$ (*m/e* 120), and Fe^+ (*m/e* 56), observed by Mandelbaum *et al.*[6] were also observed by the cleavages of the fragment ions shown in Schemes 1, 2, 3, and 4.

Experimental

The mass spectra were obtained by means of a Japan Electron Optics Co., Ltd., JMS-01SG Mattauch-Herzog double-focussing mass spectrometer, at an ionizing voltage of 75 V, an emission current of 100 μA, and an accelerating voltage of 6.4 kV. The oven was maintained at 150°C.

1,1′-Diacetylferrocene (I). I was prepared from ferrocene by the method of Rosenblum and Woodward.[7] Recrystallization from benzene yielded a product with a mp of 130—131°C (lit,[7] mp 130—131°C).

1,1′-Ferrocenedicarboxylic Acid (II). II was prepared from I using the iodine-oxidation method.[8] The refined product decomposed at about 250°C (lit,[8] at more than 240°C decomp.).

Monoacetoacetylferrocene (III). III was prepared by the condensation of ethyl acetate with monoacetylferrocene in the presence of sodium amide.[9] Recrystallization from *n*-hexane yielded a product with a mp of 97—98°C (lit,[10] mp 97.5—98.5°C).

1,1′-Bisacetoacetylferrocene (IV). IV was prepared from I by the same method as III. Recrystallization from benzene yielded a product with a mp of 143—144°C (lit,[11] mp 142.5—144°C).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1266—1267(1972)

Multiple-Quantum Transitions in the EPR Spectra of Atomic Sulfur

Mamoru JINGUJI, Yuji MORI, and Ikuzo TANAKA

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo

(Received November 20, 1971)

The multiple-quantum transitions of atoms[1,2] and diatomic molecules[3] in the gas-phase EPR spectra have been reported and have attracted the attention of several scientists both theoretically and experimentally. The two-quantum transitions[1] in the EPR of $O(^3P_2)$ in the gas phase were among the first multiple-quantum transitions to be observed. The three- and four-quantum transitions to be observed. The three- and four-quantum transitions of $O(^3P_2)$ and the two-quantum transitions of $O(^3P_1)$ were observed by McDonald.[4] The EPR multiple-quantum transitions of S atoms have not yet been reported, however, in spite of the observation of the single-quantum transitions of S atoms by Brown[5] in 1966.

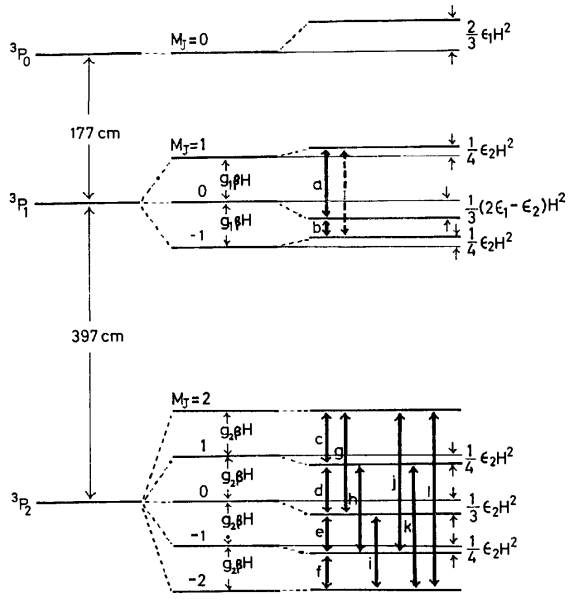

Fig. 1. Magnetic energy levels of the ground ^3P term in S atom (not to scale).
$\varepsilon_1=\beta^2/(177\ hc)$, $\varepsilon_2=\beta^2/(397\ hc)$ erg gauss^{-2}.

We have now observed the multiple-quantum transitions of $S(^3P_2)$ atoms. S atoms were produced in a 10-mm-i.d. quartz tube which passed through the center of a TE_{011}-mode EPR cavity resonant at 9168.64 MHz. A microwave discharge (2450 MHz, 100 W) was maintained in the flowing of wet H_2 40 cm upstream from the center of the cavity. Hydrogen sulfide was introduced at a point 5 cm upstream.

It is well known that the ground state of S atoms is the ^3P state and that it splits into three levels, $^3P_0$, $^3P_1$, and $^3P_2$, as a result of the spin-orbit interaction in the same manner as the O atom. The energy differences[6] are 177 cm^{-1} ($^3P_0$—$^3P_1$) and 397 cm^{-1} ($^3P_1$—$^3P_2$). The energy level diagram is schematically shown in Fig. 1. In the middle the diagram represents the linear Zeeman effect, while the quadratic level displacements are shown on the right side. The observed spectrum of the single-quantum transitions of S atoms is shown in Fig. 2, together with the spectrum of $O(^3P_2)$ for comparison. The four lines of $S(^3P_2)$ and the two lines of $S(^3P_1)$ are labeled from *a* though *f*, corresponding to the transitions shown in Fig. 1. The total pressure was kept at 0.05 Torr in order to achieve a better resolution of the spectra. The information required for its analysis may be obtained from the work of Radford and Hughes[7] on the spectrum of O atoms. As is shown in Table 1, the measured quadratic field splittings are in fair agreement with the spin-orbit coupling predictions, in spite of the possible errors in the measurement of the fine-structure separations of Fig. 1. The magnetic field was measured relative to the line positions of the spectrum of O atoms. The observed *g* factors for the $^3P_1$ and $^3P_2$ states of the S atom were the same as those reported by Brown.[5]

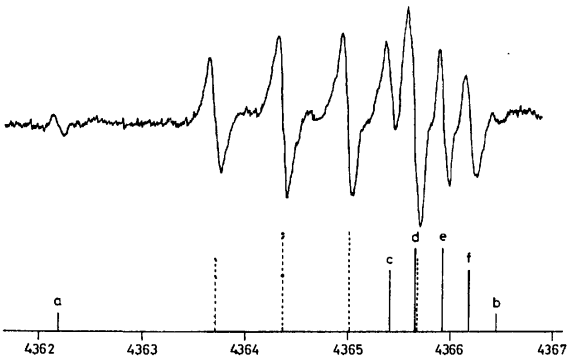

Fig. 2. EPR spectrum of S atom. O atom $J=2$ lines are shown for comparison.

We wish to report on an experiment demonstrating the multiple-quantum transitions among the Zeeman

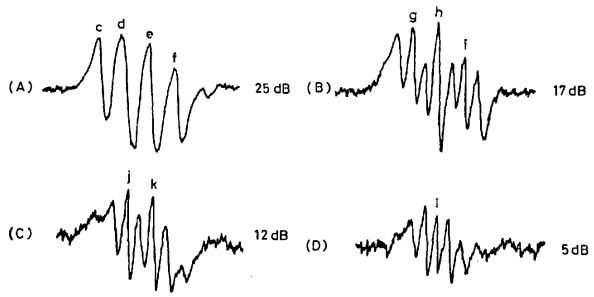

Fig. 3. EPR spectra of $S(^3P_2)$ showing the multiple-quantum transitions at increasing values of incident microwave power. Lines are labeled to correspond with Fig. 1.

levels of $S(^3P_2)$. At the pressure of 0.05 Torr, the spectrum was changed continuously as the microwave power was increased from a 25 to a 5 dB attenuation. The spectra showing the stages of these changes are presented in Fig. 3. At the 25-dB attenuation, only the single-quantum transitions (Fig. 3(A)) were detected. At this pressure, the linewidth of the single-quantum transition was 87 mG, corresponding to the relaxation time of 1.0 μsec. When the power was increased, the single-quantum transitions showed saturation broadening, and three new lines appeared between each two of the four lines of $S(^3P_2)$; the width of these new lines was approximately half the linewidth of the single-quantum transitions. The three new lines were assigned to the two-quantum transitions ($\Delta M_J=\pm 2$), which were more predominant in the spectrum at the 17-dB attenuation (Fig. 3(B)). A further increase in the microwave power produced two additional lines between the three lines of the two-quantum transitions, which could be interpreted as the three-quantum transitions ($\Delta M_J=\pm 3$). The single-quantum transitions vanished in the noise level, and the two-quantum transitions showed saturation broadening. At the 12-dB attenuation, the three-quantum transitions gave the strongest lines in the spectrum (Fig. 3(C)). Finally, between each two of the three-quantum transitions the four-quantum transition ($\Delta M_J=\pm 4$) could be detected at the 5-dB attenuation (Fig. 3(D)). Thus, by virtue of the different saturation properties of the various transitions, all the possible multiple-quantum transitions of $S(^3P_2)$ were observed. The two-quantum transitions of $S(^3P_1)$ were expected to be observable, but they could not be detected, probably because of the lower concentration of $S(^3P_1)$.

The theory of the multiple-quantum transitions in O atoms was developed by Hughes and Geiger,[1] it may be applied here to the case of S atoms. The linewidths of the multiple-quantum transitions were noticeably smaller than those of the single-quantum transitions, as would be expected from their theory. We estimated the minimum linewidths of the single-, two-, three-, and four-quantum transitions to be 87, 45, 35, and 33 mG respectively, though no completely-resolved lines were observed because of the rapid onset of pressure broadening. The three- and four-quantum transition lines may have been less sharpened experimentally than would theoretically be expected because of the 100 kHz modulation. It can also be expected from the theory that the intensities of the two- and three-quantum transitions are proportional to the square and cube of the microwave power respectively. This relation is confirmed by the experimental results shown in Fig. 4 (A) and (B).

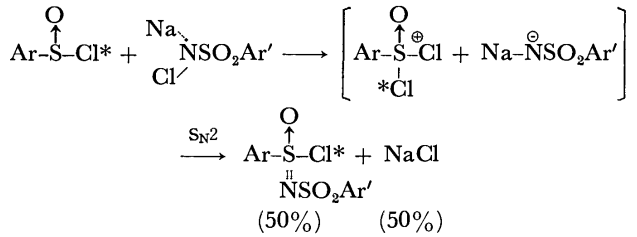
(Received May 26, 1971)

Recently, *N*-arenesulfonylareneiminosulfonyl chlorides were synthesized by the reaction of arenesulfinyl chlorides with dry *N*-arenesulfonyl chloramide,[2)] while *N*-alkaneiminosulfonyl chlorides were also prepared by treating the corresponding sulfinyl chlorides with *N,N*-dichloramine.[3)] However, the mechanism of the formation of these compounds has not been clarified. Therefore, in order to understand the nature of the reaction a tracer study on the reaction of *p*-toluenesulfinyl chloride-^{36}Cl with chloramine-T was carried out both in benzene and in THF solutions. This paper describes a detailed account and implications of the tracer experiments.

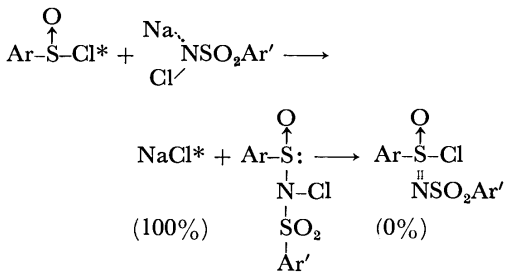
Results and Discussion

Following three mechanistic routes *i.e.* (1), (2), and (3) may be conceivable for this reaction.

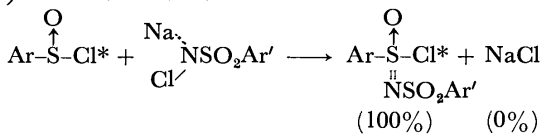
(1) Initial Halogenation and Subsequent Nucleophilic Replacement.



(2) Initial S_N2 Process Followed by Rearrangement of Chlorine Atom.

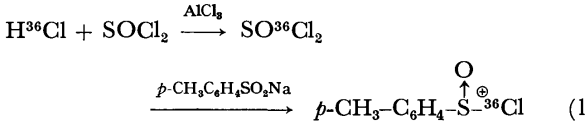


(3) Nitrene Mechanism.



According to the first mechanism the sulfinyl chloride is chlorinated first by chloramine-T to form the dichlorosulfoxonium cation intermediate which upon nucleophilic attack of sulfonyl amide anion gives the product. Since the two chlorine atoms in the cation intermediate are equivalent, the iminosulfonyl chloride thus formed will retain 50% of the original ^{36}Cl-activity. The second mechanism which involves the initial nucleophilic attack of *N*-chlorosulfonyl function on sulfinyl chloride to form *N*-chlorosulfonylsulfineamide intermediate and the subsequent intramolecular migration of chlorine is quite reasonable and requires the final product to contain no ^{36}Cl-activity. The last mechanism which assumes the initial nitrene formation from chloramine-T will give the final product holding all the ^{36}Cl activity.

p-Toluenesulfinyl chloride-^{36}Cl was synthesized by the scheme outlined in Eq. (1).



The reaction between *p*-toluenesulfinyl chloride-^{36}Cl thus obtained and dry chloramine-T was carried out in refluxing dry benzene or in dry THF at room temperature (Eq. 2). Since chloramine-T is insoluble in benzene, the reaction mixture is heterogeneous in benzene, while that in THF is homogeneous. In order to measure the ^{36}Cl activity, *p*-toluenesulfinyl chloride-^{36}Cl was oxidized to *p*-toluenesulfonyl chloride-^{36}Cl which was used as the standard sample. Meanwhile, the activity of the product, *N*-*p*-toluenesulfonyl-toluene-iminosulfonyl chloride-^{36}Cl, without further treatment, was measured with a liquid scintillation counter.

Furthermore, in order to check the possible chlorine atom exchange between the original sulfinyl chloride and iminosulfinyl chloride or sodium chloride obtained, an equimolar mixture of the ^{36}Cl-labeled sulfinyl chloride (4.85×10^4 dpm/mmol), the inactive iminosulfonyl chloride and sodium chloride was treated under the same condition as described above. Then it was found that the recovered iminosulfonyl chloride was incorporated with very little ^{36}Cl activity (1.21×10^2 dpm/mmol only, 0.25%), probably by the contamination during work up, indicating that actually ^{36}Cl-exchange between the starting material and the products did not take place. The above experimental results are summarized in Table 1.

The reaction proceeds faster in THF than in benzene and the value of the ^{36}Cl-activity of the product formed in THF is only 7.3%, while that formed in benzene is 23.7%. Perhaps, the sodium atom of chloramine-T

Table 1. The ^{36}Cl-counting data

Solvent	Condition	^{36}Cl-activity (dpm/mmol) $CH_3-C_6H_4-\overset{+}{S}(\rightarrow O)-{}^*Cl$	^{36}Cl-activity (dpm/mmol) $CH_3-C_6H_4-S(\rightarrow O)(=NTs)-{}^*Cl$
benzene	reflux 1 hr heterogeneous	4.85×10^4 (100%)	1.15×10^4 (23.7%)
THF	room temp. 1 hr homogeneous	4.85×10^4 (100%)	0.352×10^4 (7.3%)

is better solvated by THF than in benzene and hence the initial nucleophilic substitution of chloramine-T anion on the *p*-toluenesulfinyl chloride is facilitated, while the subsequent cleavage and migration of chlorine from the N-atom to the S-atom of the *N*-chlorosulfonyl-sulfinyl amide would also be faster in THF than in benzene. On the other hand, the reaction in benzene ought to be slow and somewhat different since the reaction mixture is heterogeneous and hence the reaction of the sulfinyl chloride would have to react with unionized chloramine. Therefore, it is somewhat complicated, though the main pathway would be a simple S_N2 process.

Thus the second mechanism which involves the initial nucleophilic attack of chloramine-T anion on the sulfinyl chloride and the subsequent chlorine migration seems to be the most plausible.

Experimental

The Preparation of Toluenesulfinyl Chloride-^{36}Cl. A small amount of aluminum chloride and sodium sulfate was added to 10 m*l* of thionyl chloride, then to this solution added 0.1 m*l* of active 3.55N hydrochloric acid-^{36}Cl (about 0.3 mCi/m*l*). After two hours, the solution was diluted with inactive thionyl chloride and then distilled twice.

p-Toluenesufinyl chloride-^{36}Cl was prepared by the same way as in the previous case[3] from the reaction of 19 m*l* of freshly distilled thionyl chloride-^{36}Cl with 7.4 g of sodium salt of toluenesulfinic acid.[5]

Oxidation of p-*Toluenesulfinyl Chloride-^{36}Cl.* An aliquote (about 0.2 m*l*) of *p*-toluenesulfinyl chloride-^{36}Cl was added to a solution of 1 g of anhydrous chromic acid in 5 m*l* of acetic acid. After half an hour, the reaction mixture was quenched into water, and then extracted twice with ether. The crude *p*-tosyl chloride-^{36}Cl thus obtained was recrystallized from ethanol - water.

The Reaction of p-*Toluenesulfinyl Chloride-^{36}Cl with Chloramine-T.* The reaction in benzene was carried out according to the procedure used by Levchenko and his co-workers.[2] The reaction in tetrahydrofuran was carried out at room temperature for one hour. The subsequent treatment of the product was performed in the same way as in benzene. The crude *N*-*p*-toluenesulfonyl-*p*-toluenеiminosulfonyl chloride thus obtained was recrystallized twice, from methanol, yield 70%, mp 76—77°C.

Measurement of the Activities. All the compounds were counted by a liquid scintillation counter (TRI-CARB), in toluene solution using POPOP and POP as scintillators.

We wish to thank Dr. M. Hamada of the Radiation Center of Osaka Prefecture, for his advices and affording facilities for the measurement of the activities.

SHORT COMMUNICATIONS

p-Quinols from the Nitration Product of Dihaloprehnitenes

Hitomi SUZUKI and Kiyomi NAKAMURA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received December 27, 1971)

Nitration of halopentamethylbenzenes and dihalotetramethylbenzenes with fuming nitric acid gives, as a major product, benzyl nitrate or bis(nitro-oxymethyl)-benzene.[1,2] The crude product usually contains small amounts of carbonyl by-products arising from the oxidation of the nitro-oxymethyl compounds.[3] In a previous paper,[2] it was reported that 5,6-dihaloprehnitenes (5,6-dihalo-1,2,3,4-tetramethylbenzenes) are unusual in their ability to form a substantial amount (*ca.* 10—15%) of carbonyl compounds, the major component of which is now identified as 6-halo-4-nitro-2,3,4,5-tetramethyl-2,5-cyclohexadien-1-one (II), a new class of anomalous nitration product.

When 5,6-dichloroprehnitene was treated with fuming nitric acid (d=1.5) in dichloromethane at −5—0°C and the product mixture was subjected to chromatographic separation over alumina, using light petroleum, benzene and diethyl ether as eluents, the fractions eluted with a mixture of benzene and diethyl ether gave a carbonyl compound melting at 178—179°C as large prisms. The result of elemental analysis was consistent with the composition $C_{10}H_{13}ClO_2$ (Found: C, 60.0; H, 6.8; Cl, 17.3; O, 16.0%. Calcd for $C_{10}H_{13}ClO_2$: C, 59.8; H, 6.5; Cl, 17.5; O, 16.2%), and its infrared spectrum (in Nujol) showed prominent peaks at 766, 774, 902, 1073, 1083 (C–OH), 1224, 1270 (C–C=O), 1612 (C=C), 1636 (C=O), and 3400 cm^{-1} (OH). The possibility that the product is benzaldehyde or benzoic acid was immediately ruled out by its ^1H NMR spectrum (100 MHz, $CDCl_3$), which exhibited signals of four methyl groups (8.61, 8.19, 7.94, and 7.80 τ) and a hydroxyl group (*ca.* 7.0 τ). Ultraviolet spectrum (in CH_3OH) showed absorptions at 246—247 nm (log ε=4.08) and 286—287 nm (log ε= 3.34), which are characteristic of cross-conjugated cyclohexadienones. Comparison of the chemical shifts of its methyl groups with those of known polymethylcyclohexadienones readily revealed the presence of chlorine atom at a position next to the carbonyl group. The mass spectrum had a molecular ion peak at m/e 200, and fragment ion peaks at m/e 185 (M−CH_3), 165 (M−Cl), 157 (M−CH_3−CO), and 137 (M−Cl−CO). These spectral evidences permit the formulation of the ketonic product as *6-chloro-4-hydroxy-2,3,4,5-tetramethyl-2,5-cyclohexadien-1-one* (I, X=Cl). Since the infrared and ^1H NMR spectra of the original mixture had no indication of the presence of I, the quinol seems to be derived from the initially formed *6-chloro-4-nitro-2,3,4,5-tetramethyl-2,5-cyclohexadien-1-one* (II, X= Cl) through hydrolysis during the chromatographic treatment over alumina. The nitro group at 4-position of these systems is known to be subject to a facile hydrolysis.[4]

6-Bromo-4-hydroxy-2,3,4,5-tetramethyl-2,5-cyclohexadien-1-one (I, X=Br; mp 190—191°C) was similarly obtained from 5,6-dibromoprehnitene. IR: 739, 1070, 1085, 1216, 1260, 1607, 1637, and 3420 cm^{-1}; NMR: 8.64, 8.20, 7.98, 7.80 (CH_3), and *ca.* 7.3 τ (OH); UV: 248—249 (log ε=4.06) and 284—287 nm (log ε=3.30). Found: C, 49.0; H, 5.4%. Calcd for $C_{10}H_{13}BrO_2$: C, 49.0; H, 5.4%.

We suggest that the unusual product I is formed by the reaction sequence depicted in the Scheme. As the reaction seems to possess some synthetic potentials, the scope of the anomaly is being investigated.

A Long-range Effect of Weaker π-Accepting Ligands, $M(C_6H_5)_3$ (M=P, As, and Sb), on the ^{119}Sn-Mössbauer Quadrupole Splitting in the R_3Sn-$Mn(CO)_4M(C_6H_5)_3$ Compounds

Satoru ONAKA and Hirotoshi SANO*,**

Department of Chemistry, Nagoya Institute of Technology, Showa-ku, Nagoya
**Department of Chemistry, Faculty of Science, Ochanomizu University, Bunkyo-ku, Tokyo*

(Received December 10, 1971)

We have recently reported that $(C_6H_5)_{3-x}X_xSn$–$Mn(CO)_5$ compounds show a smaller quadrupole splitting than their methyl analogues, $(CH_3)_{3-x}X_xSn$–$Mn(CO)_5$ (X=Cl and Br).[1] This finding has been interpreted in terms of the π-delocalizing effect of the phenyl group in $(C_6H_5)_{3-x}X_xSn$–$Mn(CO)_5$. It has also been pointed out that the π-interaction between tin and manganese atoms may affect the quadrupole splitting (Q.S.) in the ^{119}Sn-Mössbauer spectra of these compounds. The present studies were undertaken in order to provide evidence of the π-delocalizing effect of the phenyl group upon the Q. S. and to elucidate the π-interaction between tin and manganese atoms. For this purpose, the effect of the substitution of the CO group in R_3Sn–$Mn(CO)_5$ with a weaker π-accepting ligand L (L= $P(C_6H_5)_3$, $As(C_6H_5)_3$, or $Sb(C_6H_5)_3$) was studied.[2,3]

$(C_6H_5)_3Sn$–$Mn(CO)_4P(C_6H_5)_3$ and $(C_6H_5)_3Sn$–$Mn(CO)_4As(C_6H_5)_3$ were prepared by the method of Gorsich.[4] The other compounds not found in the literature were prepared by the direct replacement of CO with a ligand, L. The ^{119}Sn–Mössbauer spectra were measured against a barium stannate source moving in a constant acceleration mode at room temperature. The sample was used as an absorber and was kept at 79°K in a cryostat.

As is shown in Table 1, such a replacement causes no appreciable change in the isomer shift (I.S.), but it does cause a remarkable decrease in the Q.S. in methyl compounds; *i.e.*, $(CH_3)_3Sn$–$Mn(CO)_5$ gives a clearly-resolved quadrupole split spectrum, whereas $(CH_3)_3$-Sn–$Mn(CO)_4L$ gives a non-resolved spectrum, as is illustrated in Fig. 1. These results mean that the

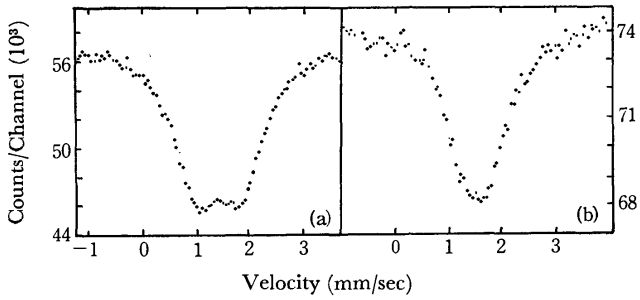

Fig. 1. Mössbaure spectra of (a) $(CH_3)_3Sn$–$Mn(CO)_5$ and (b) $(CH_3)_3Sn$–$Mn(CO)_4P(C_6H_5)_3$.

σ-characters of the Sn–Mn bond are not affected enough to be detected by the Mössbauer spectroscopy. It seems reasonable to conclude that the origin of the change in the electron distribution around the tin nucleus for methyl derivatives is due to the change in the π-interaction between tin and manganese atoms.[5]

IR spectroscopic study shows that these compounds have two peaks in the CO stretching region. The IR data and the results of the single crystal X-ray diffraction analysis for $(C_6H_5)_3Sn$–$Mn(CO)_4P(C_6H_5)_3$ indicate a *trans* configuration for all the substituted compounds; *i.e.*, the ligand, L, is coordinated to the manganese atom at the *trans* position with regard to the tin atom. In this *trans* configuration, the tin atom is supposed to compete with the ligand, L, for the d_π-electrons of the manganese atom. As the π-accepting ability of the ligand, L, is weaker than that of the substituted CO,[2,3] the d_π-electrons of manganese atom are forced to enter both the vacant 5*d* orbitals of the tin atom and the CO π-antibonding orbitals.[6] Thus, the π-accepting ability of the ligand, L, influences the efg around the tin nucleus through the π-electrons of the manganese atom. Such a long-range effect through the π-interaction should not be overlooked, although it has not yet been reported.[7]

The reason why the zero quadrupole splitting in $(C_6H_5)_3Sn$–$Mn(CO)_5$ is not affected by the replacement of CO with L may well be explained in terms of the predominant π-delocalizing effect of the phenyl groups attached to the tin atom.[1]

TABLE 1. ^{119}Sn-MÖSSBAUER PARAMETERS

Compound	I.S.[a] (mm/sec)	Q.S. (mm/sec)
$(CH_3)_3Sn$–$Mn(CO)_4P(C_6H_5)_3$	1.27	~0
$(CH_3)_3Sn$–$Mn(CO)_4As(C_6H_5)_3$	1.28	~0
$(CH_3)_3Sn$–$Mn(CO)_5$	1.33	0.61
$(C_6H_5)_3Sn$–$Mn(CO)_4(C_6H_5)_3$	1.43	0
$(C_6H_5)_3Sn$–$Mn(CO)_4As(C_6H_5)_3$	1.38	0
$(C_6H_5)_3Sn$–$Mn(CO)_4Sb(C_6H_5)_3$	1.40	0
$(C_6H_5)_3Sn$–$Mn(CO)_5$	1.41	0

Ionic Photodissociation of Some Weak Charge Transfer Complexes of Tetracyanoethylene with n-Type Donor Molecules

Yohji Achiba, Shunji Katsumata, and Katsumi Kimura

Physical Chemistry Laboratory, Institute of Applied Electricity Hokkaido University, Sapporo

(Received December 27, 1971)

During the last few years, several reports have appeared on ionic dissociation by photo-excitation of weak charge transfer (CT) complexes.[1-6] Potashnik *et al.*[4] and Masuhara *et al.*[5] studied spectroscopically the mechanisms of the ionic photo-dissociation process of some weak CT complexes composed of π-type donors and acceptors. We here report on preliminary results of the steady-state UV photolysis and flash photolysis of several weak CT complexes of tetracyanoethylene (TCNE) with tetrahydrofuran (THF), dioxane, acetonitrile, benzene and hexamethylbenzene. It is known that TCNE forms CT complexes with ether,[7] THF,[8] and dioxane[8] as n-type donors in nonpolar solvents at room temperature. We recently found that a weak CT complex is formed between donor acetonitrile and acceptor TCNE with an equilibrium constant of 1.86 *l*/mol at 25°C.[6]

Table 1. Wavelengths of the CT-band maxima (in nm units) of several TCNE complexes

Electron Donor	at 25°C			at 77°K

benzene		380[c]	384[f]		380[c]
hexamethylbenzene		525[c]	545[f]	528 and	562[c]

a) The donor was used as a solvent. b) In ether-isopentane (1:1 and 1:2). c) In methylcyclohexane-isopentane (1:2). d) In ether (Ref. 7). e) In chloroform (Ref. 8). f) In dichloromethane (Ref. 7).

Ether, THF, dioxane, and acetonitrile were used as rigid solvents at 77°K. Since these rigid matrices are somewhat opaque, we used a 0.1-cm quartz cell capable of measuring absorption spectra with a Cary spectrophotometer, Model 15. Low-temperature photolyses of the rigid solutions were carried out with a high-pressure mercury lamp through Toshiba filter glasses UV-31 and -35 with which lights of wavelength shorter than 310 and 350 nm, respectively, are cut off. When ether, THF, dioxane, and acetonitrile were used as donor molecules, the CT bands are significantly enhanced and shifted to a shorter wavelength by freezing the solutions, as shown in Table 1. For the TCNE complexes with benzene and hexamethylbenzene, however, no such blue shifts were observed by freezing the solutions. The observed remarkable blue shifts seem to be a characteristic of the n-type CT complexes. The large blue shift (3000 cm^{-1}) observed for the CT band of the TCNE-acetonitrile system suggests that acetonitrile molecule acts as an n-type donor for TCNE.

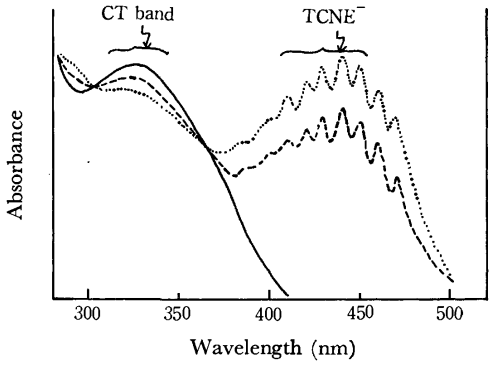

Fig. 1. Electronic absorption spectra showing the formation of TCNE⁻ by excitation of the CT band of the TCNE-dioxane complex in a dioxane rigid matrix at 77°K. Curve (——): before irradiation, and curves (·····) and (------): after irradiation through UV-31 and -35 respectively.

When a dioxane rigid matrix containing TCNE (10^{-3}M) was irradiated at 77°K by exciting the CT band of the TCNE-dioxane complex, the rigid matrix turned yellow, showing a new broad absorption band with vibrational structure exactly the same as that reported for the TCNE anion ($TCNE^-$), as shown in Fig. 1.

The same stable $TCNE^-$ species can be produced by the CT-band excitation in the cases of ether, THF and acetonitrile matrices at 77°K. We thus conclude that the ionic photodissociation takes place in the excited states of these complexes. It should be mentioned that in the case of the TCNE complexes with benzene and with hexamethylbenzene, no stable $TCNE^-$ species was formed by exciting their CTbands in a methylcyclohexane-isopentane matrix at 77°K.

Further photolytical experiments were performed with deaerated solutions containing TCNE (10^{-4}M) and one of the donors (about 1M) in dichloromethane by means of the flash spectroscopic technique. As a result, the transient $TCNE^-$ absorption spectrum was observed within 50 μsec in all the cases.[9] It should be mentioned that either in the absence of these donors or in the presence of oxygen no transient absorptions were detected.

Observation of Triplet-Triplet Absorption Spectra of Nitronaphthalenes by Means of Flash Excitation Technique

Nobuaki KANAMARU, Shigeo OKAJIMA, and Katsumi KIMURA

Physical Chemistry Laboratory, Institute of Applied Electricity, Hokkaido University, Sapporo

(Received December 31, 1971)

Aromatic hydrocarbons with the nitro group are known to have some peculiar characteristics in electronic structure and photochemical reactivity. Phosphorescence life times of nitrosubstituted aromatics are considerably shorter than those of non-substituted aromatics in spite of the nature of π-π^* type of the lowest triplet states of the aromatics having the nitro group.[1-4] Nitrobenzene is the only exception whose lowest triplet state is assigned to n-π^* type.[2,3] In order to obtain further information on characteristics of the triplet states of nitroaromatics, it seems important to measure their triplet-triplet (T-T) absorption spectra. So far, no reports have been published on T-T absorption spectra of nitroaromatics. This might be attributed to the short life times of their lowest triplet states and also to their reactivities. We report for the first time the T-T absorption spectra of some nitroaromatics obtained with a flash spectroscopic technique.[5]

Flash experiments of 1- and 2-nitronaphthalenes were carried out with various deaerated solutions (in n-hexane, liquid paraffin, ethanol, ether, and tetrachloromethane) at room temperature, and also with an ether–isopentane–alcohol (EPA, 5: 5: 2) glass at 77°K, giving transient absorption spectra in all cases. It was found that the transient absorption spectra are almost independent of the solvents. Typical spectra obtained with ethanol solutions of 1- and 2-nitronaphthalenes (1×10^{-4}M) are shown in Fig. 1. Each of the transient absorption spectra could be ascribed to only one sort of intermediate in either 1- or 2-nitronaphthalene. Life times of the transient absorptions in various solutions at room temperature were too short for an accurate measurement of decay curves. Intrinsic life times of the transient absorptions seem to be at most about 10 μsec at room temperature. It should be mentioned that the addition of oxygen remarkably reduces the intensities of the transient absorptions.

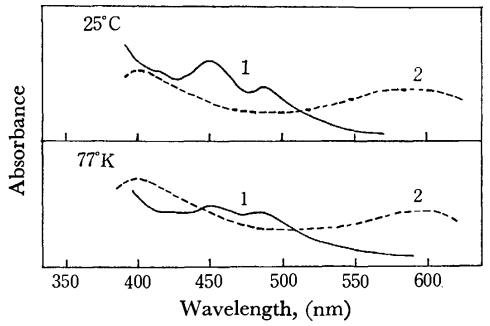

Fig. 1. Transient absorption spectra observed immediately (~0 μsec) after the flash irradiation of 1-nitronaphthalene (curve 1) and of 2-nitronaphthalene (curve 2) in deaerated ethanol solutions at room temperature and in EPA glasses at 77°K.

Transient absorption spectra obtained in the EPA glass at 77°K which are very similar to those obtained at room temperature are compared in Fig. 1. The decay curves of the transient absorptions observed at 77°K could be analyzed in terms of 60 ± 10 msec and 242 ± 10 msec for 1- and 2-nitronaphthalenes respectively in EPA at 77°K.

In order to compare the life time of the transient absorptions with that of phosphorescence under the same conditions, we also measured the phosphorescence life time for 1- and 2-nitronaphthalenes in EPA at 77°K with a Hitachi MPF-2A fluorescence spectrophotometer. As a result, we obtained a phosphorescence life time of 50 ± 2 msec for 1-nitronaphthalene, which is in good agreement with the reported values of 50 msec[1] and 47 msec[3], while a life time of 240 ± 6 msec was obtained for the phosphorescence of 2-nitronaphthalene.[6] Since the phosphorescence life times we obtained are in agreement with those of the transient absorptions within experimental limits of error, we conclude that the transient absorption spectra observed at room temperature as well as at 77°K can be assigned to the absorption spectra due to T-T transitions of 1- and 2-nitronaphthalenes.

4) E. C. Lim and J. Stanislaus, *Chem. Phys. Lett.*, **6**, 195 (1970).
5) The duration times of photolysisflash and spectroflash lamps are 5.0 and 3.5 μsec, respectively, quartz cells 10 cm long and 1 cm long being used at room temperature and 77°K, respectively. The output energy was about 400 joules. Transient absorption spectra were recorded photographically and their decay curves were followed photoelectrically.
6) The value 240 ± 6 msec differs somewhat from that reported by Rusakowicz and Testa who obtained a value of 206 msec in EPA at 77°K.[3] The difference might be attributed to the difference in experimental methods: We measured the decay curve of phosphorescence after cutting off stationary exciting light, while they employed the method of flash excitation.[3]

Stereospecific Dehydrobromination of *dl*- and *meso*-2,3-Dibromobutanes over Solid Catalysts

Makoto Misono and Yukio Yoneda

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received December 20, 1971)

We have observed that the elimination of hydrogen bromide from the isomeric 2,3-dibromobutanes occurs in a stereospecific manner over some basic solid catalysts, giving products expected to be obtained by *anti*-elimination.

Elimination reactions in homogeneous liquid phase in the presence of basic catalyst usually proceeds stereospecifically by *anti*-elimination in *E*2 mechanism.[1] However, very few such stereospecific eliminations have been observed in the case of vapor phase elimination over solid catalyst. Non-catalytic debromination of 2,3-dibromobutanes with zinc was reported to give products expected by *anti*-elimination.[2] Pines and Manassen[3] postulated *anti*-elimination on the basis of the distribution of products obtained from the dehydration of cyclic alcohols such as menthol and neomenthol over alumina. Andreu *et al.*[4] reported that the dehydrobromination of 2,3-dibromobutanes over calcium chloride, sulfate and phosphate proceeded in a completely non-stereospecific way, leading them to propose an *E*1-like mechanism. If the elimination takes place by an *E*2-like mechanism as suggested by Pines and Manassen,[3] two sites on the surface of catalyst should simultaneously attack a reactant molecule, one from one side of the molecular plane and the other from the opposite side. It is of interest, also in this sense, to determine the steric course of reaction over solid catalyst.

We studied the products from the reaction of *meso*- and *dl*-2,3-dibromobutanes over sodium hydroxide and carbonate supported on silica gel (*ca.* 5 wt%) by a pulse technique at 120—200°C using hydrogen as a carrier gas. *dl*-2,3-Dibromobutane was prepared from *cis*-2-butene and bromine in methylene chloride. *meso*-2,3-Dibromobutane was prepared from *trans*-2-butene under the same conditions. Catalysts were prepared by impregnation on silica gel (Wako Chemicals, Q-12) from aqueous solution of each salt. Hydrogen was deoxygenated by a "Deoxo" purifier and dried by a dry ice trap. Products were analyzed by a glpc which was directly connected to a reactor and equipped with double columns, a dimethylsulfolane column for butene analysis and an Apiezon-grease column for the analysis of the rest. When necessary, products were analyzed after being collected with a trap inserted between the reactor and the glpc.

Table 1 Products from the elimination reaction of *dl*- and *meso*-2,3-dibromobutanes at 170°C

Catalyst	Reactant 2,3-Dibromobutane	% Conversion to 2-bromo-2-butene (-HBr) *trans*	2-bromo-2-butene (-HBr) *cis*	2-butene (-Br_2) *trans*	2-butene (-Br_2) *cis*
NaOH-SiO_2	*dl*-	6.3	<0.3	<0.1	0.6
	meso-	<0.3	5.3	0.8	<0.1
Na_2CO_3-SiO_2	*dl*-	8.0	<0.3	<0.1	0.8
	meso-	<0.5	6.5	1.1	<0.1

Typical results are given in Table 1. No reaction of 2-bromo-2-butenes or butenes was detected under these conditions. Stereospecific *anti*-elimination is clearly seen in this table; *dl*-2,3-dibromobutane gave *trans*-2-bromo-2-butene and *meso*-2,3-dibromobutane gave *cis*-2-bromo-2-butene. The stereoselectivity was higher than 90% for both cases in the temperature range investigated. Butene, coming from minor reaction of debromination, also showed a stereospecific *anti*-elimination. In addition, it was noted that *dl*-2,3-dibromobutane reacted faster than *meso*-2,3-dibromobutane in dehydrobromination, while the latter reacted faster in debromination, indicating favorable formation of *trans*-olefins in both reactions. This is likely due to an eclipsing effect between two methyl groups at the transition state.

Over silica gel, which was slightly acidic, no bromobutenes were formed, but formation of butenes expected by *anti*-debromination was observed together with a small amount of butadiene.

Electrochemical Fluorination of *N*-Nitrosodiethylamine[1]

Nobuatsu WATANABE, Masatake HARUTA, and Byongte CHANG

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received May 31, 1971)

The fluorination of $(C_2H_5)_2N$–NO at a nickel anode under a variety of operating conditions resulted in the formation of liquid products such as $(CF_3)_2C_2F_5N$, $(C_2F_5)_2CF_3N$, $(C_2F_5)_3N$, and the compounds containing C–N groups together with gaseous fragmentation products such as CF_4, C_2F_6, CHF_3, NF_3, and N_2. Current efficiency of total gaseous products increased appreciably as the concentration of substrate and current density became higher. Effect of electrolysis temperature was so characteristic as observed in the fluorination of triethylamine that there existed the temperature at which a maximum value of current efficiency was given. On the basis of both the experimental results on the effects of operating conditions and the electrochemical measurements in hydrogen fluoride solutions of Et_2N–NO, mechanism of the fluorination reaction was discussed and compared with those of diethylamine and triethylamine.

Our previous work on the electrochemical fluorination of *n*-propyl, diethyl and triethyl amines[2] has shown that these amines underwent not only substitution reaction of hydrogen for fluorine but also simultaneous fragmentation reaction of C–N and C–C bonds in the molecule, and that the fragmentation reaction was appreciably affected by various operating conditions. Since it is reasonably expected that these substitution and fragmentation reactions are subject to an influence of a substituent in an amine molecule as well as the operating conditions, Et_2N–NO was chosen as a substrate to examine effect of *N*-nitroso group on the fluorination reaction. Many studies have been done on chemical or electrochemical fluorination of a series of representative amines, but no work on the fluorination of nitroso amine has yet been done. Effects of substrate concentration, electrolysis temperature and current density on the fluorination of Et_2N–NO were investigated by means of the method reported previously.[2]

Experimental

Materials. Et_2N–NO was prepared from diethylamine hydrochloride and sodium nitrite by the usual method.[3]

$$(C_2H_5)_2NH\cdot HCl + NaNO_2 \xrightarrow{2N\text{-HCl aq. soln.}} (C_2H_5)_2N\text{-}N{=}O + NaCl + H_2O$$

The prepared material was identified by its known infrared spectrum. The purity was checked up to be more than 99.5% by gas chromatography. The anhydrous hydrogen fluoride (purity 99.9%) was supplied by Daikin Co. Ltd.

Method. The apparatus and experimental methods used here were virtually identical with those described before.[2] The electrolytic cell used in the present study was an iron cylindrical vessel having a capacity of 700 m*l*, containing a pack of alternate nickel anodes and cathodes (99.9% in purity and 1 mm in thickness, effective anode area 3 dm^2). The liquid products collected in a dry ice–methanol trap were rectified in a low temperature precision still. Preparative separation of each fraction obtained by rectification was carried out with gas chromatography using Porapack R as column packing.

Results

Gaseous products. Results of the electrofluorination of *N*-nitrosodiethylamine under a variety of operating conditions are given in Table 1. Et_2N–NO yielded C_2F_6, NF_3, CF_4, CHF_3, N_2, and CO_2 as principal gaseous products and relatively small amounts of imperfectly fluorinated CHF_2CF_3, CHF_2CHF_2, and CH_2F_2. The current efficiency of each product was calculated according to the equation based on a discharge of fluorine ion as follows.

$$F^- \longrightarrow F\cdot + e \quad (1)$$

$$\rangle N\text{-}NO + 2F\cdot \longrightarrow N_2 + OF_2 \quad (2)$$

$$\rangle N\text{-} + 3F\cdot \longrightarrow NF_3 \quad (3)$$

$$\rangle C\langle + 2H_2O + 4F\cdot \longrightarrow CO_2 + 4HF \quad (4)$$

$$-C_2H_5 + 13F\cdot \longrightarrow 2CF_4 + 5HF \quad (5)$$

$$-C_2H_5 + 11F\cdot \longrightarrow C_2F_6 + 5HF \quad (6)$$

$$-C_2H_5 + 9F\cdot \longrightarrow 2CHF_3 + 3HF \quad (7)$$

$$-C_2H_5 + 5F\cdot \longrightarrow 2CH_2F_2 + HF \quad (8)$$

$$-C_2H_5 + 9F\cdot \longrightarrow CHF_2CF_3 + 4HF \quad (9)$$

$$-C_2H_5 + 7F\cdot \longrightarrow CHF_2CHF_2 + 3HF \quad (10)$$

The products obtained were identified by their known infrared spectra[4] except for CHF_2CHF_2 and N_2. N_2 was identified by gas chromatography equipped with Molecular Sieve 5A. CHF_2CHF_2 was identified by infrared and mass spectra as its spectral data were not given in the literature. Its infrared spectrum shows a strong absorption band at 8.9 μ and its mass spectrum is shown in Table 2.

The current efficiency for F_2 and OF_2 evolution was 0.3—1.0% for 2.4 mol% solution and 0.7—1.5% for 0.3 mol% solution, which indicated a tendency to increase with decreasing concentration. The current efficiency for dissolution of nickel electrode, calculated from the weight change before and at the end of electrolysis assuming that nickel dissolved as Ni^{2+} ion,

TABLE 2. MASS SPECTRUM OF CHF_2CHF_2

m/e	Pattern coefficient	+Ion
51	100	CHF_2
83	44.3	CHF_2CHF
101	13.4	CHF_2CF_2
102	6.6	CHF_2CHF_2

amounted to 0.85%. This value is about three times as large as those in the fluorinations of diethylamine and triethylamine.

1) Effect of Substrate Concentration: In Fig. 1 are given the total current efficiencies of both anode and cathode gaseous products at three different concentrations 0.3, 2.4, and 12.7 mol% under the constant electrolysis temperature 5±1°C and current density 10 mA/cm². The current efficiency of total gases produced at the anode increases linearly with the logarithm of substrate concentration. The current efficiency for hydrogen evolution also increases with concentration but it does not exceed 40% at 0.3 mol%. Such a low value would be due to the recombination of hydrogen with fluorine which cannot be used for fluorination because of low concentration. On the assumption that the difference of current efficiency between gaseous anode products and hydrogen evolved at cathode is associated with the current efficiency of high boiling liquid products, it would be relatively advantageous to set up concentration around 2.5 mol% for the formation of liquid products less subject to the cleavage reaction. Figure 2 shows a trend that the molar formation ratios of imperfectly fluorinated CHF_2CF_3 and CHF_3 decrease with increasing concentration whereas those of C_2F_6, NF_3, and CF_4 increase. Molar ratio of NF_3 to N_2 is 0.31, 0.65, and 0.97 for 0.3, 2.4, and 12.7 mol% solution, respectively, which shows an increasing trend with concentration. Therefore, it is readily understood that concentration contributes to an acceleration of rate of fluorination. Molar ratio of C_2F_6 to NF_3 is about two, irrespective of substrate concentration, which is similar value as observed in the electrofluorination of diethylamine. The molar ratio of fluorinated ethanes C_2F_6, CHF_2CF_3, and CHF_2CHF_2 to fluorinated methanes CF_4, CHF_3, and CH_2F_2 increases with concentration; 2.18, 2.23, and 3.67 at 0.3, 2.4, and 12.7 mol%, respectively. This indicates that the higher the concentration is, the more readily C–N bonds are cleaved than C–C bonds.

temperature: 5±1°C current density: 10 mA/cm²

2) Effect of Electrolysis Temperature: Figure 3 shows the effect of electrolysis temperature on the total current efficiency of gaseous products under constant concentration and current density. The total current efficiency increases rapidly in the range of −15—6°C at 2.4 mol%. On the other hand, there exists the tem-

1 and 2: 2.4 mol%, 3 and 4: 12.7 mol%

perature at which a maximum value of current efficiency is given at 12.7 mol%. It is obvious that the temperature dependence of current efficiency is not due to the recombination of fluorine with hydrogen, since the current efficiency of hydrogen evolution always exceeds 90%. The current efficiency of gaseous products for 12.7 mol% solution is always very high in the temperature range investigated and the maximum value reaches 87.2%, which implies that fragmentation takes place vigorously in the liquid phase. The relation is given in Fig. 4 between the current efficiencies of principal gaseous products and temperature for 2.4 mol% solution. The current efficiencies of NF_3 and CF_4 increased slightly while that of CHF_2CF_3 decreased slightly. An appreciable increase in the current efficiency was observed only for C_2F_6. It is also

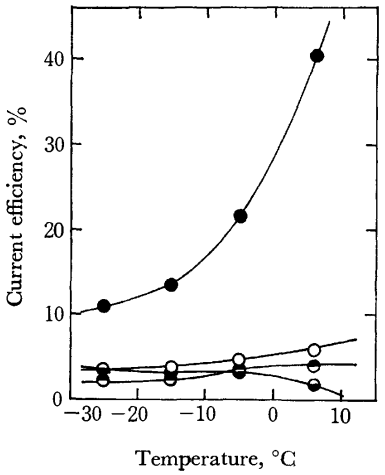

Fig. 4. Effect of temperature on the current efficiencies of principal gaseous products.

●: 2.4 mol%, ○: 12.7 mol%
current density: 20 mA/cm²

observed for 12.7 mol% solution that the current efficiency of C_2F_6 determines the temperature dependence of the total current efficiency of gaseous products. Since the molar formation ratios of CHF_3 and CHF_2-CF_3 decrease with temperature whereas that of C_2F_6 noticeably increases, it is evident that rate of fluorination is accelerated with increasing temperature. Figure 5 shows that molar ratio of C_2F_6 and CHF_2CF_3 to CF_4 and CHF_3 increases with temperature for 2.4 mol% solution, whereas it decreases for 12.7 mol% solution. As the boiling points of hexafluoroethane and pentafluoroethane are low compared with the electrolysis temperature, −78 and −23°C, respectively, it may scarecely occur that these fluorinated ethanes are subjected to further fluorination to yield fluorinated methanes. The fluorinated methanes may be produced from the scisson of C–C bonds before the breaking of C–N bonds occurs. Since most of the cleavage of C–C bonds would be thought to take place before C–N bonds are cleaved as stated above, the more readily C–N bonds are cleaved, the larger becomes the molar ratio of fluorinated ethanes to fluorinated methanes. Therefore, in order to restrain the breaking of C–N bonds, low concentration of Et_2N–NO and low temperature are prefered. But, if concentration is high, high temperature is prefered to low temperature.

In the case of Et_3N there existed the temperatures at which maximum values of current efficiency were given for both 2 and 10 mol% solutions, but only for 12.7 mol% solution in the case of Et_2N–NO. The fact that the temperature at the maximum value of current efficiency for 2 mol% solution of Et_3N was shifted to 7°C from −25°C for 10 mol% solution implies that the maximum value of current efficiency for 2.4 mol% solution of Et_2N–NO would be given at temperature higher than 15°C. Thus, it can also be concluded for the electrofluorination of Et_2N–NO that temperature has two opposing factors affecting the cleavage of bonds in a molecule: Solubilities of fluorinated products in HF solution is high at low temperature, and more likely to be exposed to further attack by fluorine. Low temperature makes, on the other hand, the fluorination reaction proceed mildly by taking away a large amount

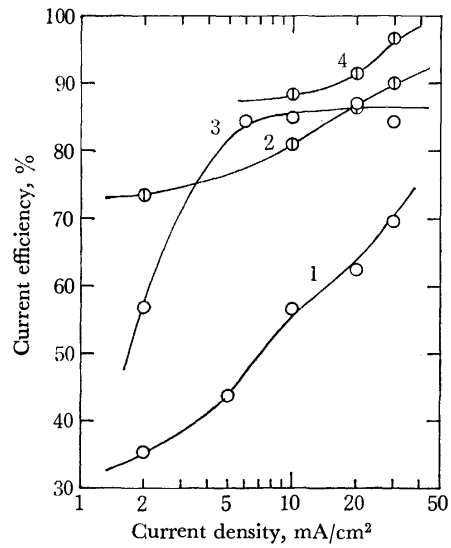

Fig. 6. Effect of current density on the total current efficiency of gaseous products.
○: anode, ◫: cathode
1 and 2: 2.4 mol%, 3 and 4: 12.7 mol%
temperature: 7±2°C

of heat of reaction. At high temperature, the reverse is the case.

3) Effect of Current Density: Effect of current density on the total current efficiency of gaseous products is shown in Fig. 6. A remarkable increase in current efficiency is observed for 2.4 mol% solution, while for 12.7 mol% solution it comes up to such a high value as 85% after a remarkable increase in the range of 2—5 mA/cm². The current efficiency for hydrogen evolution also shows an upward tendency with current density. It was observed that the increase in total current efficiency was mainly due to an increase in that of C_2F_6. Therefore it is understood that cleavage of C–N bonds occurs as current density becomes higher. Figure 7 shows the dependence of molar formation ratios of principal gaseous products on current density. C–N bonds are more readily cleaved than C–C bonds as current density is increased, since the ratio of C_2F_6 and CHF_2CF_3 to CF_4 and CHF_3 increases with current density. A tendency was observed that molar formation ratios of C_2F_6 and NF_3 increased with current density, while those of CHF_3 and CHF_2CF_3 decreased. This tendency is due to the fact that an increase in current density leads to higher concentration of fluorine and then to an acceleration of fluorination rate. The acceleration of rate of fluorination by increasing current density is also evidenced by the change of molar ratio of NF_3 to N_2; 0.17, 0.45, 0.65, 1.8, and 2.5 at 2, 5, 10, 20, and 30 mA/cm², respectively.

Liquid Products. Et_2N–NO fluorinated electrochemically gave a large number of liquid products together with the gaseous products descrbied above. Identification was carried out only on five principal liquid products, since the other liquid products were not obtained in sufficient amounts. Three of the principal liquid products were perfluorinated alkylation products $(C_2F_5)_2CF_3N$, $(C_2F_5)_3N$, and $(CF_3)_2C_2F_5N$. The first two were identified by their infrared spectra.[5] The last one was identified by its spectral data obtained in our laboratory.[2] Structural determination of the other two liquid products was unsuccessful. Nevertheless, some significant information on their structures was obtained by their infrared and ^1H NMR spectra. Their boiling points are above 70°C. Infrared spectrum of the lower boiling product (I) exibited absorption bands at 5.25 and 5.48 μ besides in the C–F stretching region, while that of the higher boiling one (II) exibited at 5.56 μ. These infrared absorptions may be assigned to the C=N stretching vibration.[6] The ^1H NMR spectra showed that both of them contained five hydrogen atoms. From the ^{19}F and ^1H NMR spectra the structure of II is supposed to be $CH_2FCH{=}NCH_2CF_3$, to which that of I would be analogous. These unsaturated compounds probably resulted from decomposition of the partially fluorinated dialkyl nitrosamines condensed in cold trap according to the following reaction;

$$R_1CHF\diagdown \atop R_2\diagup N\text{–}NO \xrightarrow{\text{decomposition at room temperature}} R_1CH{=}NR_2 + NOF \qquad (11)$$

Young *et al.*[7] described that although the dialkyl nitrosamines were reasonably stable thermodynamically and hydrolytically, the fluorinated compounds were unstable and lost the nitroso group readily due to increasing electronegativity of the alkyl groups. The formation of partially fluorinated dialkyl nitrosamines seemed to be apparent by appearance of a blue color presumably due to NO in liquid products condensed in cold trap.[7]

Electrochemical Measurements in HF–Et_2N–NO Solutions. The anodic behavior of nickel in liquid hydrogen fluoride (HF) containing Et_2N–NO has been investigated. The electrolytic cell and experimental procedures used in this study were essentially the same as those described in the preceding paper.[8] The reference electrode was Hg/Hg_2F_2, and potentials are reported *vs.* Hg/Hg_2F_2 at

5) C. M. Sharts, *J. Org. Chem.*, **33**, 1008 (1968).

0°C. Galvanostatic anodic polarization data were obtained on nickel electrodes in 2.5 and 10 mol% solutions in the current density range 0.01—50.0 mA/cm². Tafel-like region was observed in the range of 0.1—2.0 mA/cm² with slopes of about 440 and 280 mV/decade at the concentrations of 2.5 and 10 mol%, respectively. These values of Tafel slope are themselves unusually high, but relatively much smaller than the values obtained for diethylamine, triethylamine,[2] acetonitrile, and malononitrile.[9]

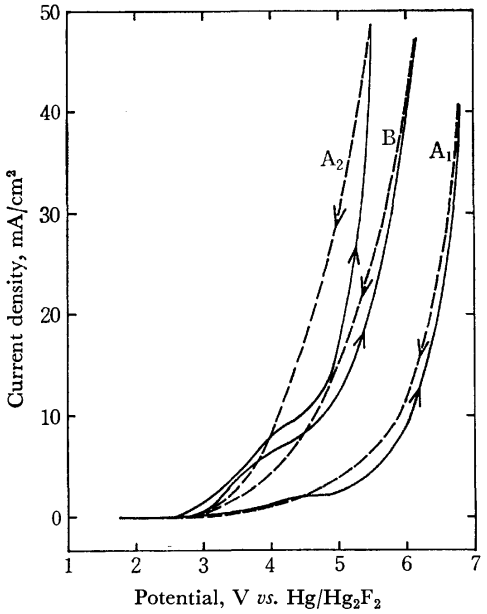

Fig. 8. Polarization curves for nickel in HF solutions of Et_2N–NO obtained by potential sweep method
A_1: new nickel in 10 mol% solution
A_2: nickel anodically polarized at 4.5V for 12 hr in 10 mol% solution
B: new nickel in 2.5 mol% solution
temperature: 0°C scan rate: 1V/min

Figure 8 shows polarization curves obtained by potential sweep method. Curves A_1 and B give the polarization curves on new nickel anodes in 10 and 2.5 mol% solutions, respectively. Compared the curve A_1 with B, it is evident that overpotential in HF solution is increased with increasing concentration of Et_2N–NO. It is also evident that nickel electrode is fairly activated when anodically biased at high potential, since an appreciable decrease in overpotential is observed on the nickel electrode anodically biased at 4.5 V for 12 hr, as shown in curve A_2 in Fig. 8. A plateau appeared around 4 V in all the curves, which is always observed for the anodic behavior of nickel in HF solution.

Figure 9 shows a polarization curve obtained by sweeping potential from 4.5 V with a scan rate of 0.2 V/sec. Cathodic current is observed below 2.4 V in curve 1, while a sharp increase in anodic current is observed above 2.6 in curve 2. The reversible fluorine potential in anhydrous hydrogen fluoride at −20°C has been reported to be +2.62 V *vs.* Hg/Hg_2F_2 by Hackerman *et al.*[10] Assuming that the cathodic current is a reduction current of fluorine adsorbed on the nickel anode, the cathodic charge required to reduce the fluorine is estimated to be about 1.3 mcoul/cm². This value is close to that in HF solution containing triethylamine.[2]

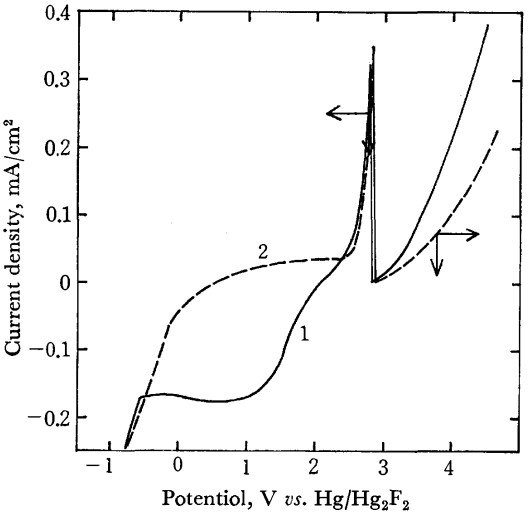

Fig. 9. Cathodic reduction curve of anodically polarized nickel electrode in 10 mol% solution.
scan rate: 0.2V/sec. temperature: 0°C

Discussion

In the present investigation on the electrochemical fluorination of Et_2N–NO, formation of the five liquid products and nine gaseous products was confirmed. However, nitrosyl fluoride which had been reasonably expected to be produced was not found in the products under any electrolysis conditions. This would be attributable to the following three reasons. Firstly, nitrosyl fluoride which is produced on the anode reacts with water contained a little in HF solution.[11]

$$2NOF + H_2O \longrightarrow NO + NO_2 + 2HF \qquad (12)$$

Secondly, it reacts with metal, rubber, or glass within the system before reaching the cold trap.[7] Finally, it reacts with hydrogen fluoride to form complexes.[12]

$$NOF + nHF \longrightarrow NO^+F(HF)_n^- \qquad (13)$$

Since the anhydrous hydrogen fluoride used was dried by pre-electrolysis passing a periodic reverse current and neither NO (bp, −151.8°C) nor NO_2 (bp, 21.3°C) was detected, and since fluorination was performed at relatively low temperature, the first and second reasons would not be essential. The last one would be a chief reason for the fact that formation of NOF was not confirmed. Although NOF is formed, it remains as complex with hydrogen fluoride in HF solution and can not be detected outside the electrolytic cell.

Figure 10 shows the total current efficiencies of gaseous products in the fluorination of Et_2NH, Et_2N–NO, and Et_3N under the same operating condition. The total current efficiency of gaseous products with

current density: 10mA/cm²

Et_2N–NO is slightly less than that with Et_2NH, but about twice as high as that with Et_3N. Since the total current efficiency of gaseous products is dependent upon the amount of cleavage, it may be concluded that the fluorination of Et_2NH and Et_2N–NO is accompanied with violent fragmentation, on the other hand fragmentation is noticeably restrained in the fluorination of Et_3N. Relation between substrate concentration and molar ratio of fluorinated ethanes to fluorinated methanes is given in Fig. 11 for Et_2N–NO and Et_3N. The

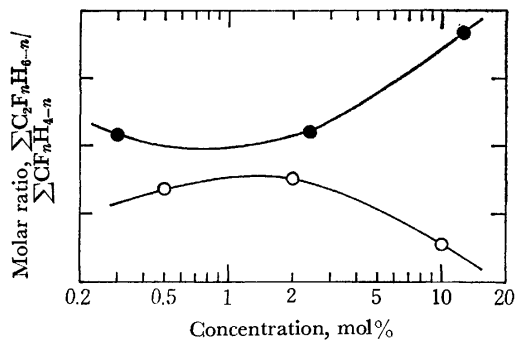

Fig. 11. Dependence of molar ratio of fluorinated ethanes to fluorinated methanes on concentration.
●: Et_2N–NO, ○: Et_3N temperature: 5 ± 1°C
current density: 10mA/cm²

values for Et_2N–NO are higher at any concentrations, which indicates that Et_2N–NO undergoes degradation more readily by the cleavage of C–N bonds than Et_3N. As concentration becomes higher, the molar ratio for Et_2N–NO increases while that for Et_3N decreases. This is indicative that C–N bonds are cleaved more preferentially than C–C bonds with increasing concentration in the fluorination of Et_2N–NO, on the contrary less preferentially in the fluorination of Et_3N. Thus it could be attributed to the stable C–N bonds against cleavage that the fluorination of Et_3N resulted in the formation of significant amounts of liquid products having the structure of the parent molecule. Et_2NH, on the other hand, did not yield detectable amounts of liquid products, since C–N bonds were almost completely cleaved. Et_2N–NO characteristically yielded as alkylation products the three completely fluorinated tertiary amines. In addition to them, the partially fluorinated dialkyl nitrosamines free from the cleavage of N–N bonds were thought to be formed. Formation of the above liquid products in the fluorination of Et_2N–NO indicates significant effects of *N*-nitroso group on the fluorination of dialkyl amines. Difference between the fluorination reaction of Et_2N–NO and that of Et_2NH also appeared in the effect of temperature on the formation of gaseous products. The maximum value of total current efficiency of gaseous products was not found at any temperatures ranged from −40 to +30°C in the fluorination of Et_2NH, whereas it was given around 5°C for 12.7 mol% solution in the fluorination of Et_2N–NO. In view of temperature effect on the formation of gaseous products, Et_2N–NO lies between Et_2NH and Et_3N. Assuming that the temperature effect is mainly due to steric hindrance by a substituent, effect of steric hindrance is in the order $H < NO < C_2H_5$, which is consistent with experimental results.

Although the fluorination of Et_2N–NO seems to proceed simultaneously by numerous routes, a representative mechanism is postulated which accounts for the scission and alkylation observed during the fluorination. During the replacement of hydrogen by fluorine a part of partially fluorinated dialkyl nitrosamines are bubbled out of a cell;

$$\text{cold trap} \xleftarrow{\text{decomposition}} CF_3CH_2N{=}CHCH_2F \quad \text{(II)}$$
$$\uparrow \text{bubbled out}$$
$$(C_2H_5)_2N\text{-}N{=}O \xrightarrow{\cdot F} (CF_3CH_2)(CH_2FCHF)N\text{-}N{=}O \qquad (15)$$

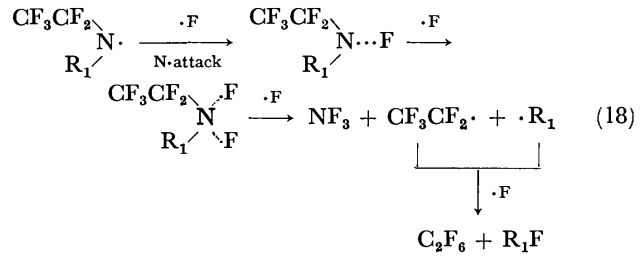
Most of the partially fluorinated dialkyl nitrosamines are followed by further fluorination since they still remain in the liquid phase because of their high solubilities in HF solution and high boiling points. During the fluorination at this stage, they are subjected to scission of bonds in molecules. Under milder operating conditions, especially at low concentration of substrate and low current density, cleavage of C–N bonds by carbon attack favorably occurs;

$$(CF_3CF_2)(R_1)N\text{-}N{=}O \xrightarrow[\text{C-attack}]{\cdot F} C_2F_6 + R_1F + N_2 + OF_2 \qquad (16)$$
(R_1; fluorinated alkyl group)

This is evidenced by the small molar ratio of NF_3 to N_2 at low concentration and low current density. As the operating conditions become vigorous, especially at the current density of 20—30 mA/cm², cleavage of N–N bonds takes place more readily than that of C–N bonds;

$$(CF_3CF_2)(R_1)N\text{-}N{=}O \xrightarrow[\text{N-attack}]{\cdot F} (CF_3CF_2)(R_1)N\cdot + NOF \qquad (17)$$
$$\downarrow HF$$
$$NO^+(FHF)^-$$

The fluorinated dialkyl amine radicals are successively attacked by fluorine until NF_3 is formed;



(18)

Fluorinated primary and secondary amines were completely absent in the products obtained in the fluorination of Et_2N–NO, which had been claimed as one of the characteristic features in electrochemical fluorination of nitrogen-containing compounds.[13] Nitrogen in an amine molecule is specifically oriented to Ni electrode, so that it is preferentially attacked by fluorine. NF_3 is formed probably through the transient state of fluorinated secondary and primary amines which are adsorbed on the nickel anode, as described in equation 18. This process would be explained well if fluorination took place between a loose complex of NiF_2 and ·F or F_2 and the substrate adsorbed on the anodic film.[14] The perfluoro dialkyl amine radicals are alkylated at nitrogen with perfluoro carbon radicals to produce perfluoro tertiary amines;

Magnetic Circular Dichroism Studies on High-intensity Bands of d^8 Square-planar Metal Halides

Hajime KATÔ

Department of Chemistry, Faculty of Science, Kobe University, Kobe

(Received July 6, 1971)

The magnetic circular dichroism (MCD) of certain d^8 square-planar metal halides is studied theoretically on the basis of the molecular orbital theory. The ground state wavefunctions of $PtCl_4^{2-}$ and $PdCl_4^{2-}$ are calculated by the semi-empirical ASMO SCF MO method for valence electron systems. The line shape of the MCD of the allowed transition is investigated in detail; the calculated line shape is in good agreement with the observed line shape. The results strongly suggest that the transitions at 43400 cm^{-1} and 46200 cm^{-1} in $PtCl_4^{2-}$ are $^1A_{1g}\rightarrow{}^1A_{2u}(b_{2u}—3b_{1g}$ and $3a_{1g}—2a_{2u})$ and $^1A_{1g}\rightarrow{}^1E_u(5d—6p)$ respectively, and that the transition at 44900 cm^{-1} in $PdCl_4^{2-}$ is $^1A_{1g}\rightarrow{}^1E_u(1)$.

The electronic spectra of the d^8 square-planar metal halide complexes have been studied by many investigators,[1] and the spectrum has been assigned variously depending on the choice of the ordering of the orbital energy.[2-5] Interest has been focused on the absorption spectrum of $PtCl_4^{2-}$, the assignment of which has many different possibilities. The weak absorption spectrum of a single crystal of K_2PtCl_4 below 36000 cm^{-1} was observed with light polarized parallel to and normal to the symmetry axis of the $PtCl_4^{2-}$ ion.[3] The results of these observations have narrowed the assignment possibilities considerably. However, the polarized spectrum for the high-intensity band has not been reported because of the experimental difficulties.

The MCD spectra below 36000 cm^{-1} for a solution of K_2PtCl_4 in dilute HCl were first reported by Martin, Foss, and their coworkers.[6] The MCD spectra of $PtCl_4^{2-}$, $PdCl_4^{2-}$, $PdBr_4^{2-}$, $AuCl_4^-$, $AuBr_4^-$, and $Pd(NH_3)_4^{2+}$ in solution and K_2PtCl_4 crystal at 4°K

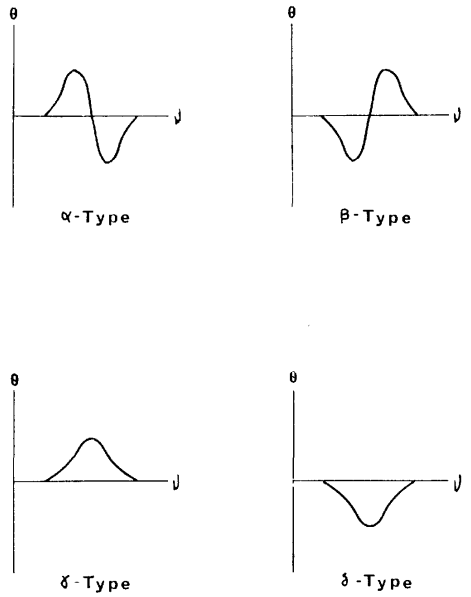

Fig. 1. The characteristic behavior of MCD in the vicinity of wave number corresponding to electronic absorption bands.

over the visible-UV spectral region were reported by McCaffery, Schatz, and Stephens.[7] The MCD curve exhibits its most striking characteristics in the vicinity of wavelengths corresponding to the electronic absorption bands. Some characteristic curves are shown in Fig. 1; we shall call them α-type, β-type, γ-type, and δ-type curves. The main features of the MCD curve around the absorption bands have been outlined previously,[8-10] and it has been shown that the MCD changes sign (α- or β-type) at the absorption maximum only when the excited state or the ground state is degenerate. However, the information which can be obtained from the difference between the α-type and β-type curves has not yet been used sufficiently. Further efforts in these areas are important, and considerable studies are expected.

In this paper, theoretical studies will be carried out on the MCD of the high-intensity bands of d^8 square-planar metal halides from the viewpoint of the MO theory. The line-shape of the MCD is studied in detail, and the observed bands are assigned on the basis of the line-shape analysis. As we will show later, this assignment does not depend strongly on the ordering of the calculated orbital energies. We give a quantitative discussion of the MCD intensity in $PtCl_4^{2-}$ and $PdCl_4^{2-}$, and it is then extended to the interpretation of the high-intensity bands in $PdBr_4^{2-}$, $AuCl_4^-$, and $AuBr_4^-$.

Calculations

A. Theory and MO Formulation. The quantum mechanical theory of MCD was developed around 1930,[11-14] and recently the quantitative expressions for the dispersion have been reported.[9,15,16] The contributions of the $a\rightarrow j$ transition to the MCD of molecules under a longitudinal magnetic field, H_s, along the z-axis are expressed as molar ellipticities in degrees deciliter decimeter^{-1} mole^{-1} gauss^{-1};[9]

$$[\theta(a\rightarrow j)]_M = \frac{18N}{\pi N_a^{(0)} H_s}\theta(a\rightarrow j) \tag{1}$$

where N is Avogadro's number, $N_a{}^{(0)}$, the number of molecules in the unperturbed state, a^0, per unit of volume, and $\theta(a\rightarrow j)$, the observed ellipticity in radians cm^{-1} given by:

$$\theta(a\rightarrow j) = -\frac{4\pi N_a}{\hbar c}\frac{\omega^3\Gamma_{ja}}{(\omega_{ja}^2-\omega^2)^2+\omega^2\Gamma_{ja}^2}Q(a\rightarrow j) \tag{2}$$

$$\begin{aligned}\theta(a\rightarrow j) = Im\{&\langle\Phi_a{}^0|m_x|\Phi_j{}^0\rangle\langle\Phi_j{}^0|m_y|\Phi_a{}^0\rangle \\ &+ H_s\sum_{k\neq a}(\langle\Phi_k{}^0|\mu_z|\Phi_a{}^0\rangle^*\langle\Phi_k{}^0|m_x|\Phi_j{}^0\rangle\langle\Phi_j{}^0|m_y|\Phi_a{}^0\rangle \\ &+ \langle\Phi_k{}^0|\mu_z|\Phi_a{}^0\rangle\langle\Phi_j{}^0|m_y|\Phi_k{}^0\rangle\langle\Phi_a{}^0|m_x|\Phi_j{}^0\rangle)/\hbar\omega_{ka}^0 \\ &+ H_s\sum_{k\neq j}(\langle\Phi_k{}^0|\mu_z|\Phi_j{}^0\rangle^*\langle\Phi_k{}^0|m_y|\Phi_a{}^0\rangle\langle\Phi_a{}^0|m_x|\Phi_j{}^0\rangle \\ &+ \langle\Phi_k{}^0|\mu_z|\Phi_j{}^0\rangle\langle\Phi_a{}^0|m_x|\Phi_k{}^0\rangle\langle\Phi_j{}^0|m_y|\Phi_a{}^0\rangle)/\hbar\omega_{kj}^0\},\end{aligned} \tag{3}$$

where $\boldsymbol{m}=\sum_i e_i\boldsymbol{r}_i$, $\boldsymbol{\mu}=\sum_i\frac{e_i}{2m_ic}[(\boldsymbol{r}_i\times\boldsymbol{p}_i)+2\boldsymbol{s}_i]$, N_a is the number of molecules in the state, a, per unit of volume in the presence of H_s, and Γ_{ja} is the band width at the half-maximum height of the $a\rightarrow j$ spectral line. The wavefunctions, $\Phi_a{}^0$, $\Phi_j{}^0$, and $\Phi_k{}^0$, are the eigenfunctions of the unperturbed states. If the a^0 and j^0 states are m-fold and n-fold degenerate respectively, the $\theta(a\rightarrow j)$ is given by $\theta(a\rightarrow j)=\sum_{m=1}^{m}\sum_{n=1}^{n}\theta(a_m\rightarrow j_n)$, and the degenerate state wavefunctions are required to diagonalize the magnetic moment, μ_z, in each degenerate state.

For the electronically-allowed transition $a\rightarrow j$ (that is, $\langle\Phi_a|\boldsymbol{m}|\Phi_j\rangle\neq 0$) of a complex with O_h, D_{4h}, and D_{4d} symmetry, the matrix elements, $\langle\Phi_a|\mu|\Phi_j\rangle$ and $\langle\Phi_a|\boldsymbol{\xi}|\Phi_j\rangle$ (where $\boldsymbol{\xi}=\sum_i e_i^2/(4m_ic^2)[\boldsymbol{r}_i(\boldsymbol{r}_i\cdot\boldsymbol{H}_s)-\boldsymbol{H}_s(\boldsymbol{r}_i\cdot\boldsymbol{r}_i)]$), are always equal to zero, because of symmetry properties.

In the present studies of d^8 square-planar metal halides, we choose the Cartesian coordinate system with its origin at the position of the metal atom and with the z-axis perpendicular to the molecular plane. In these complexes, the first term in Eq. (3) is non-zero only when the external magnetic field, $\boldsymbol{H}_s$, is applied in the z-direction. The ground state, a^0, is non-degenerate. Averaging over all the molecular orientations,[9] we obtain:

$$\begin{aligned}[\theta(a\rightarrow j)]_M = -\frac{720N}{\hbar c}\sum_{n=1}^{n}&\frac{\omega^3\Gamma_{j_na}}{(\omega_{j_na}^2-\omega^2)^2+\omega^2\Gamma_{j_na}^2} \\ &\times\{Q_A(a\rightarrow j_n)/H_s+Q_B(a\rightarrow j_n)\}\end{aligned} \tag{4}$$

16) P. J. Stephens, Theoretical Studies of Magneto-optical Phenomena (Doctoral thesis, Oxford Univ., Oxford 1964).

$$Q_A(a\to j_n) = \frac{1}{3}Im\{\langle\Phi_a^0|m_x|\Phi_{j_n}^0\rangle\langle\Phi_{j_n}^0|m_y|\Phi_a^0\rangle\} \quad (5)$$

and:

$$Q_B(a\to j_n) = \frac{1}{3}Im\{\langle\Phi_a^0|\boldsymbol{m}|\Phi_{j_n}^0\rangle\cdot\sum_{k\neq a}\frac{1}{\hbar\omega_{ka}^0}\langle\Phi_k^0|\boldsymbol{m}|\Phi_{j_n}^0\rangle \times\langle\Phi_k^0|\mu|\Phi_a^0\rangle + \langle\Phi_a^0|m|\Phi_{j_n}^0\rangle \cdot\sum_{k\neq j}\frac{1}{\hbar\omega_{kj_n}^0}\langle\Phi_k^0|\mu|\Phi_{j_n}^0\rangle\times\langle\Phi_k^0|m|\Phi_a^0\rangle\} \quad (6)$$

The wavefunctions for the ground state, a^0, and the excited state, j^0, can be constructed from the normalized anti-symmetrized product functions:

$$\Phi_a{}^0 = |a\bar{a}b\bar{b}|,\ \Phi_j{}^0 = \frac{1}{\sqrt{2}}\{|j\bar{a}b\bar{b}| - |\bar{j}ab\bar{b}|\} \quad (7)$$

where a and $\bar{a}$ denote the molecular orbitals, φ_a, with the spin functions of α and β respectively. The excited-state wavefunction, $\Phi_k{}^0$, must satisfy the conditions; $\langle\Phi_a{}^0|\boldsymbol{m}|\Phi_k{}^0\rangle\neq 0$ and $\langle\Phi_k{}^0|\boldsymbol{\mu}|\Phi_j{}^0\rangle\neq 0$.

Hence, the wavefunctions must be written as;

$$\Phi_k{}^0(a\to k) = \frac{1}{\sqrt{2}}\{|k\bar{a}b\bar{b}| - |\bar{k}ab\bar{b}|\}$$

or

$$\Phi_k{}^0(b\to j) = \frac{1}{\sqrt{2}}\{|a\bar{a}j\bar{b}| - |a\bar{a}\bar{j}b|\} \quad (8)$$

Then, in the molecular orbital form:

$$Q_A(a\to j) = \frac{2}{3}Im\{\langle a|m_x|j\rangle\langle j|m_y|a\rangle\} \quad (9)$$

and:

$$Q_B(a\to j) = \frac{2}{3}Im\left\{\langle a|\boldsymbol{m}|j\rangle\cdot\sum_k^{vac}\frac{1}{\hbar\omega_{k(a\to k)a}}\langle k|\boldsymbol{m}|j\rangle\times\langle k|\boldsymbol{\mu}|b\rangle + \langle a|\boldsymbol{m}|j\rangle\cdot\sum_{k\neq j}^{vac}\frac{1}{\hbar\omega_{k(a\to k)j}}\langle k|\boldsymbol{\mu}|j\rangle\times\langle k|\boldsymbol{m}|a\rangle\right\} - \frac{2}{3}Im\left\{\langle a|\boldsymbol{m}|j\rangle\cdot\sum_{b\neq a}^{occ}\frac{1}{\hbar\omega_{k(b\to j)a}}\langle a|\boldsymbol{m}|b\rangle\times\langle j|\boldsymbol{\mu}|b\rangle + \langle a|\boldsymbol{m}|j\rangle\cdot\sum_b^{occ}\frac{1}{\hbar\omega_{k(b\to j)j}}\langle a|\boldsymbol{\mu}|b\rangle\times\langle j|\boldsymbol{m}|b\rangle\right\} \quad (10)$$

B. Molecular Orbitals. Yonezawa and his coworkers[17] have proposed a semi-empirical SCF molecular orbital treatment for valence electron systems and have successfully applied it to various small molecules. The present MO calculation is similar to their treatment, but the previous method is improved so as to make it applicable to metal complexes. In the present MO treatment, all valence electrons in a compound are taken into account and all the overlap integrals are considered.

The molecular orbitals, φ's, are expressed as linear combinations of all the valence atomic orbitals, χ_r's, centered on the various atoms of the molecule:

$$\varphi_i = \sum_r C_{ir}\chi_r.$$

We take as χ_r the Slater-type atomic orbital, while the orbital exponents, ζ's, are taken from the tabulations of Clementi.[18] For a closed-shell molecule, the Roothaan SCF equation[19] is written as follows:

$$\sum_r C_{ir}(F_{rs}-S_{rs}\varepsilon) = 0 \quad (s = 1, 2, \cdots) \quad (11)$$

where:

$$F_{rs} = H_{rs} + \sum_{t,u}P_{tu}\{(rs|tu) - 0.5(rt|su)\}, \quad (12)$$

$$S_{rs} = \int\chi_r\chi_s d\tau, \quad (13)$$

$$H_{rs} = \int\chi_r(\mu)H_\mu^{core}\chi_s(\mu)d\tau_\mu, \quad (14)$$

$$(rs|tu) = \int\chi_r(\mu)\chi_s(\mu)\frac{1}{r_{\mu\nu}}\chi_t(\nu)\chi_u(\nu)d\tau_\mu d\tau_\nu, \quad (15)$$

$$P_{tu} = 2\sum_i^{occ}C_{it}C_{iu}. \quad (16)$$

The atomic integrals in the above equations are evaluated by the following approximations. For the electron repulsion integrals, $(rs|tu)$, the Mulliken approximation is adopted;[20]

$$(rs|tu) = 0.25S_{rs}S_{tu}\{(rr|tt) + (rr|uu) + (ss|tt) + (ss|uu)\}.$$

The one-center and two-center Coulomb repulsion integrals are calculated by means of:[21,22]

$$(rr|rr) = I_p{}^r - E_A{}^r,\ (rr|ss) = \frac{1}{R+a}$$

where $2/a = (rr|rr) + (ss|ss)$ and where R is the distance between the centers of r and s. The valence-state electron affinity, E_A, is assumed to be equal to the

$6p)_{Pt}=4.56$, and $(5d5d|5d5d)_{Pt}=8.60$.

The H_{rr} is given by:

$$H_{rr} = U_{rr} + \sum_{B \neq A} (B|rr) \tag{17}$$

where:

$$U_{rr} = \int \chi_r(\mu) \left\{ -\frac{1}{2} \Delta(\mu) - \frac{Z_A}{r_{\mu A}} \right\} \chi_r(\mu) d\tau_\mu,$$

$$(B|rr) = -\int \chi_r(\mu) \frac{Z_B}{r_{\mu B}} \chi_r(\mu) d\tau_\mu$$

and where Z_A is the number of the valence electrons on the A atom. The molecular integrals, U_{rr} and $(B|rr)$, are approximated by:

$$U_{rr} = -I_r - (N_r - 1)(rr|rr) - \sum_{r' \neq r} N_{r'}(rr|r'r'), \tag{18}$$

$$(B|rr) = -Z_B(s_B s_B|rr), \tag{19}$$

where s_B refers to the valence s-orbital on the B atom.

The $H_{rs(r \neq s)}$ is approximated by:

$$H_{rs} = KS_{rs}(H_{rr} + H_{ss}) \tag{20}$$

where K is a constant taken to be 0.54 in the present calculations.

The molecular orbital energies of $PtCl_4^{2-}$ calculated by the present method are compared with the results of the other MO calculations in Table 1. The lowest vacant (*L.V.*) and the highest occupied (*H.O.*) orbital energies obtained by the present calculation are in good accordance with the values of the electron affinities and the ionization potentials. The obtained d-orbital ordering, $x^2-y^2 > xy > xz, yz > z^2$, is in agreement with the results obtained by others,[4,5] and this ordering is found to be invariant with a variation in the constant K (in Eq. (20)) from 0.53 to 0.56. The orbital energies of the occupied MO's are very close to each other, but this is not serious in the present studies of the MCD of d^8 square-planar complexes. The total charge distribution on Pt is calculated to be +0.310; the details of the electron distribution are $(5d)_{Pt}$; 8.212, $(6s)_{Pt}$: 0.960, $(6p)_{Pt}$: 0.618. The Pt–Cl bond order is calculated to be 0.489.

Calculations were carried out also on $PdCl_4^{2-}$. The MO energies and MO coefficients are presented in Tables 2*a* and 2*b*. The results on $PdCl_4^{2-}$ are nearly equal to those found for $PtCl_4^{2-}$, and the ordering of the MO energies is exactly the same as those of $PtCl_4^{2-}$.

C. Analysis of MCD. As may easily be found from the character table of D_{4h}, the transitions from the ground state, $^1A_{1g}$, to the excited states, $^1A_{2u}$'s or ^1E_u's, are the only allowed transitions. The allowed transitions the calculated excitation energy of which is less than 10 eV are presented in Table 3. The possible allowed transitions, considered previously as the observed high-intensity bands, are all included in the following five transitions: $^1A_{1g} \rightarrow {}^1E_u(1)$: $[3e_u - 3b_{1g}]$, $^1A_{1g} \rightarrow {}^1E_u(d\text{-}p)$: $[2e_g - 2a_{2u}]$, $^1A_{1g} \rightarrow {}^1E_u(2)$: $[2e_u - 3b_{1g}]$, $^1A_{1g} \rightarrow {}^1A_{2u}(1)$: $[b_{2u} - 3b_{1g}]$, and $^1A_{1g} \rightarrow {}^1A_{2u}(d\text{-}p)$: $[3a_{1g} - 2a_{2u}]$. The calculations of Q_A and Q_B by Eq. (9) and (10) were made for these five possible transitions of $PtCl_4^{2-}$; the results are shown in Table 4. The molecular integrals, $\langle k|\boldsymbol{m}|l\rangle$ and $\langle k|\boldsymbol{\mu}|l\rangle$, are accurately evaluated.

a) Values at H_s=50000 gauss

It should be noted that the molecular integrals, $\langle \chi_A|\boldsymbol{\mu}|\chi_B\rangle$'s, are not Hermitian in some cases if χ_A and χ_B are not atomic orbitals centered on the same atom. In order to eliminate this difficulty, alternative approximate calculations were made. In these approximate calculations, we neglected the $\langle \chi_A|\boldsymbol{\mu}|\chi_B\rangle$ integral if χ_A and χ_B were on different atoms. A comparison of accurately and approximately calculated values of the Zeeman energies and Q_B for each transition in $PtCl_4^{2-}$ is shown in Table 5. The difference between these results is small and is not very important in interpreting the present MCD spectrum.

a) Values at $H_s=50000$ gauss

Then, we calculated the Zeeman energies and Q_B for each transition in $PdCl_4^{2-}$ by the alternative approximate method described above; the calculated results of Q_A and Q_B are shown in Table 6. The values of the corresponding transitions in $PdCl_4^{2-}$ and $PtCl_4^{2-}$ are very similar to each other. In the above calculations, the effect of spin-orbit coupling is not considered. The atomic constants defined by Condon and Shortley[24] determine the magnitude of the effect. The values of the spin-orbit coupling constant, ζ, for the Cl, Pd, and Pt atoms are listed by McClure[25] as $\zeta_{3p}^{Cl}=587$ cm^{-1}, $\zeta_{4d}^{Pt}=1410$ cm^{-1}, and $\zeta_{5d}^{Pt}=4060$ cm^{-1}. The perturbed ground-state wavefunction is given approximately by:

$$\Phi_{A_{1g}}=\Phi^0_{A_{1g}}-\frac{\langle\Phi^0_{A_{2g}:[2b_{2g}-3b_{1g}]}|\zeta^{Pt}_{5d}|\Phi^0_{A_{1g}}\rangle}{\delta E(2b_{2g}-3b_{1g})}\Phi^0_{A_{2g}:[2b_{2g}-3b_{1g}]}-\frac{\langle\Phi^0_{E_g:[2e_g-3b_{1g}]}|\zeta^{Pt}_{5d}|\Phi^0_{A_{1g}}\rangle}{\delta E(2e_g-3b_{1g})}\Phi^0_{E_g:[2e_g-3b_{1g}]} \quad (21)$$

The order of magnitude of the mixing coefficient can be easily estimated; the numerator is, at most, of the order of magnitude of 4000 cm^{-1} ($=\zeta_{5d}^{Pt}$), and the denominator is larger than 20000 cm^{-1}, as may esaily be found from the observed bands. Therefore, the mixing coefficients are smaller than 0.2. Hence, the effect of spin-orbit coupling on the ground-state wavefunction is not significant in the present calculations. The excited-state wavefunctions are also perturbed, but in order to interpret the electronic transition it is not necessary to include this effect in the calculation of high-intensity bands.

Discussion

The theoretical calculations of Q_A and Q_B are necessary in order to interpret the MCD spectrum. The value of Q_A determines whether the observed MCD curve is α-type or β-type; if the value of Q_A for a lower component of the excited state split by the Zeeman energy is positive, then the observed MCD curve is β-type. The values of Q_A and the Zeeman energy can be simply determined by the character of the state wavefunctions; this situation does not depend strongly on the method of the MO calculation. Some of the observed MCD curves for d^8 square-planar metal halides are very similar to each other; this fact suggests that the common assignments hold for these bands. Especially, the higher energy bands of $PdCl_4^{2-}$, $PdBr_4^{2-}$, $AuCl_4^-$, and $AuBr_4^-$ show strongly β-type MCD. Gray and Ballhausen[3c] identified the higher energy band as $^1A_{1g}\rightarrow{}^1E_u(2)$, Jørgensen[1i] suggested the band to be $^1A_{1g}\rightarrow{}^1E_u(2)$, and Basch and Gray[4] later adopted Jørgensen's assignment on the basis of their MO calculation. The results of the numerical calculation for $PdCl_4^{2-}$ shown in Table 6 predict the characteristic types of the MCD curves: the $^1A_{1g}\rightarrow{}^1E_u(1)$ transition is the β-type, the $^1A_{1g}\rightarrow{}^1E_u(2)$ and $^1A_{1g}\rightarrow{}^1E_u(d\text{-}p)$ transitions are both α-type, the $^1A_{1g}\rightarrow{}^1A_{2u}(1)$ transition is γ-type, and the $^1A_{1g}\rightarrow{}^1A_{2u}(d\text{-}p)$ transition is δ-type. The results of the numerical calculation for $PtCl_4^{2-}$ shown in Table 4 also predict the same characterstic types of MCD curves as those of the corresponding transitions for $PdCl_4^{2-}$. We may therefore assign the higher energy bands of $PdCl_4^{2-}$, $PdBr_4^{2-}$, $AuCl_4^-$, and $AuBr_4^-$ to the $^1A_{1g}\rightarrow{}^1E_u(1)$ transitions. We have calculated the line shape of the MCD by taking the center of MCD at the observed value; $\omega_{ja}\simeq44900$ cm^{-1}; the external magnetic field, $H_s=50000$ gauss, and the band width at half the height of the $a\rightarrow j$ spectral line; $\Gamma_{ja}=7000$ cm^{-1} (*cf.* Fig. 2). The agreement of the calculated MCD curve with the observed one is very good. We may conclude, therefore, that the theory and the experiment are in adequate agreement and the present study of the MCD spectra supports the assignment of the $^1A_{1g}\rightarrow{}^1E_u(1)$ transition. The main feature of the MCD line of shape is determined by Q_A, but the details of the contributions to Q_B from each mixing excited state are interesting; they are shown in Table 7. It should be noted that the magnitude of $Q_B(^1A_{1g}\rightarrow{}^1E_u(1))$ is mainly determined by the contribution from the perturbing excited state: $[2b_{2g}—3b_{1g}]$.

$[2e_g-3b_{1g}]$	0.0323
$[2b_{2g}-3b_{1g}]$	0.4545
$[1e_u-3b_{1g}]$	−0.0084
$[2e_u-3b_{1g}]$	−0.0272
Total	=0.3923

The weaker bands of $AuCl_4^-$ and $AuBr_4^-$ show the γ-type MCD line shape; we consider these bands to be due to only a $^1A_{1g}\rightarrow{}^1A_{2u}(1)$ transition. McCaffery, Schatz, and Stephens[7] suggested that they are composite $^1A_{1g}\rightarrow{}^1A_{2g}+{}^1E_u(1)$ transitions, but the observed intensity of the corresponding absorption band is too small. The present assignments are reasonable in that the magnitude of the calculated transition moment is in accordance with the observed intensity of the absorption band.

Unfortunately, the MCD of the lower energy band at 35800 cm^{-1} of $PdCl_4^{2-}$ has not been reported, but the MCD of $PdBr_4^{2-}$ gives as instructive information on the lower band. The MCD of the band at 30100 cm^{-1} of $PdBr_4^{2-}$ is α-type; it is possibly the $^1A_{1g}\rightarrow{}^1E_u(2)$ or $^1A_{1g}\rightarrow{}^1E_u(d\text{-}p)$ transition. The $^1A_{1g}\rightarrow{}^1E_u(2)$ transition will be on a higher energy side than the $^1A_{1g}\rightarrow{}^1E_u(1)$ transition. It thus seems reasonable to identify it as the $^1A_{1g}\rightarrow{}^1E_u(d\text{-}p)$ transition; this assignment is in agreement with the following assignment of the band at 46200 cm^{-1} in $PtCl_4^{2-}$.

The MCD of the relatively intense band of $PtCl_4^{2-}$ is more complicated than those of paradium halides. Gray and Ballhausen[3c] originally assigned the band to $^1A_{1g}\rightarrow{}^1A_{2u}(1)$, and later Basch and Gray[4] assigned the same band to the two allowed transitions, $^1A_{1g}\rightarrow{}^1A_{2u}(1)$ and $^1A_{1g}\rightarrow{}^1E_u(1)$. The MO calculations on $PtCl_4^{2-}$ by Cotton and Harris[5] predict the band to be the $^1A_{1g}\rightarrow{}^1A_{2u}(d\text{-}p)$ transition. McCaffery, Schatz, and Stephens[7] assigned the shoulder at 43400 cm^{-1} to the $^1A_{1g}\rightarrow{}^1A_{2u}(1)+{}^1E_u(1)$ transition on the basis of the common feature of the shapes of the MCD of this shoulder and on the basis of the lowest energy band in $PdBr_4^{2-}$, while the main band at 46200 cm^{-1} was assigned to the $^1A_{1g}\rightarrow{}^1A_{2u}(d\text{-}p)$ transition by them. However, the quantitative calculation does not support their assignments. The $^1A_{1g}\rightarrow{}^1E_u(1)$ transition is predicted in the above discussion to show strong β-type MCD curves, and the transition is expected to be in a higher energy region, though it is observed in $PdBr_4^{2-}$. The MCD of $PdBr_4^{2-}$ also suggests that the $^1A_{1g}\rightarrow{}^1E_u$ $(d\text{-}p)$ transition will be found among the lower energy bands. We assign the main band at 46200 cm^{-1} to the $^1A_{1g}\rightarrow{}^1E_u(d\text{-}p)$ transition. The $^1A_{1g}\rightarrow{}^1A_{2u}(1)$ transition which is assigned to the lowest energy band in $AuCl_4^-$ and $AuBr_4^-$ will be assigned to the shoulder band at 43400 cm^{-1}. In order to understand the MCD line shape, we should further assign the $^1A_{1g}\rightarrow{}^1A_{1u}(d\text{-}p)$ transitions to the same shoulder band. Taking the center of MCD at the observed point, the external magnetic field H_s=50000 cm^{-1}, the width at half the height of a band of the shape Γ_{ja}=5000 cm^{-1} for the 43400 cm^{-1} band and Γ_{ja}=7000 cm^{-1} for the 46200 cm^{-1} band, we have calculated the shape of the MCD; the results are shown in Fig. 3. The agreement with the observed MCD line shape is good. The details of the analysis of the contribution to $Q_B(2e_g-2a_{2u})$, $Q_B(b_{2u}-3b_{1g})$, and $Q_B(3a_{1g}-2a_{2u})$ from each mixing

excited state are shown in Table 8. It may be noted that the magnitude of the above Q_B is mainly determined by the contributions from the mixing excited states, $[3a_{1g}-2a_{2u}]$, $[2e_g-2a_{2u}]$, and $[1e_g-3b_{1g}]$ respectively. Especially, we have used the observed values of 43400 cm^{-1} and 46200 cm^{-1} as the excitation energies to the excited states, $[3a_{1g}-2a_{2u}]$ and $[2e_g-2a_{2u}]$ respectively; these are the dominant mixing states.

The present study of the MCD line shape has clarified a number of problems with regard to the assignment of high-intensity bands in d^8 square-planar metal halides. The present assignments are summarized in Table 9, and they are there compared with the previous assignments of others. In some cases, the quantitative calculation is essential; then the MCD becomes the more useful method for understanding the electronic structures of molecules.

The author is grateful to Dr. T. Katô for a very instructive discussion of this article. He also wishes to thank Professor T. Yonezawa and Professor H. Kato for their generous support of this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1288—1291(1972)

The Catalytic Oxidation of Carbon Monoxide on Zirconium Dioxide

Takuya HAMAMURA, Yoshito ONISHI, and Yasuo IIZUKA

Department of Chemistry, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto

(Received July 19, 1971)

The catalytic oxidation of carbon monoxide on zirconium dioxide was kinetically examined in order to compare with the results of titanium dioxide. The experiment was carried out under gas pressures of 10^{-2}—100 mmHg at 400—550°C. The reaction rate was proportional to P_{CO} and did not depend upon P_{O_2}, and there was no retarding effect by carbon dioxide. The rate constant of this oxidation reaction almost agreed with that of the reduction of zirconium dioxide by carbon monoxide. The reaction mechanism could be explained in the same manner as that on titanium dioxide. The catalytic activity of zirconium dioxide for this reaction was almost the same as that of rutile. The activation energy was about 12.5 kcal/mol, and this value was intermediate between those of anatase and rutile. The same relation was obtained in the activation energies of the thermal desorption of surface oxygen from these catalysts.

The correlation between the crystal form and the catalytic activity of titanium dioxide has been examined in this laboratory using rutile and anatase.[1-4] It was found that both rutile and anatase showed the same reaction mechanism for the oxidations of carbon monoxide and hydrogen, but the activity of rutile was much larger than that of anatase for the two reactions. The activation energies of two reactions on anatase were larger by about 10 kcal/mol than those on rutile, and these differences almost coincided with that in activation energies of the thermal desorption of surface oxygen atoms from the catalysts between two crystal forms.

Zirconium, likewise titanium, belongs to the group IVA elements in the periodic table, and its electronic configuration (Kr core) $4d^25s^2$ is very similar to that of titanium (Ar core) $3d^24s^2$. Therefore, it is interesting to study the catalytic action of zirconium dioxide for comparison to that of titanium dioxide. The report about

the carbon monoxide oxidation on zirconium dioxide can scarcely be found in the literature.[5]

Experimental

Two kinds of samples were used in the present investigation. One was obtained from the Nippon Gaishi Company (ZrO_2-1), and the other from the Zirconium Corporation of America (ZrO_2-2). Both samples are pure zirconium dioxide from which hafnia was separated. These samples were heated at 1200°C for 3 hr in a fused quartz tube to vaporize the volatile contaminants as well as to develop their crystal lattices. The BET surface areas of ZrO_2-1 and -2 were 3.8 and 1.0 m^2/g, respectively. Both of them were found to have the monoclinic crystal forms by the X-ray powder method.

Carbon monoxide and oxygen from commercial cylinders were purified by fractional distillation using liquid nitrogen. The apparatus used was essentially the same as before.[1] Since the formed carbon dioxide was caught in the trap, the rate of reaction was determined by measuring the total pressure. The experiments were carried out under the pressure range of 1—10 cmHg, and the pressure change was measured by using a mercury manometer. The McLeod gauge was used for the reaction at the gas pressure of about 10^{-2} mmHg. At such a low pressure the gas diffusion was thought to be so fast that the circulating pump was cut from the reaction system.

The sample of about 5 g was introduced into the apparatus and evacuated to 10^{-6} mmHg. Prior to the measurements, the sample was heated at 800°C in circulating oxygen of 5 cmHg for 3 hr to clean its surface.

Results and Discussion

Catalytic Activity. The oxidation rate of carbon monoxide on zirconium dioxide was measured by using a mixed gas with a composition of $CO/O_2=2/1$ in temperature range of 400—550°C and under pressures of 10^{-2}—100 mmHg. The oxidation rate is plotted against the total pressure in Fig. 1. The reaction is clearly of the first order with respect to the total pressure. In order to examine the effect of carbon dioxide, measurements were carried out by using a dry ice trap to mix the formed carbon dioxide into the reactant gas. However, no retarding effect by carbon dioxide was found. Therefore, the reaction rate can be expressed by the following equation:

$$d(CO_2)/dt = 2/3k \cdot P \qquad (1)$$

where k is a constant. The Arrhenius plots of k on ZrO_2-1 and -2 are given in Fig. 2 together with those on rutile and anatase. The ZrO_2-1 and -2 show almost the same values in their catalytic activities per unit of the surface area and in their activation energies, although they are different both in their specific surface areas and their conditions of formations.

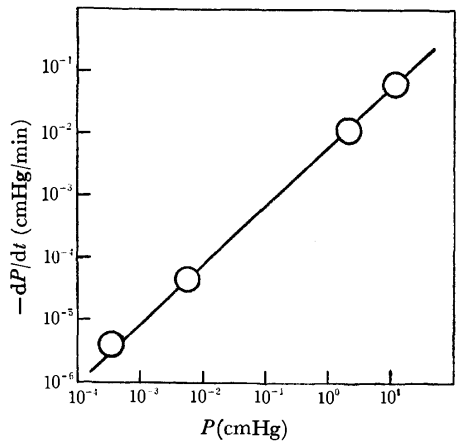

Fig. 1. Effect of total pressure on the reaction rate at 550°C on ZrO_2-1.

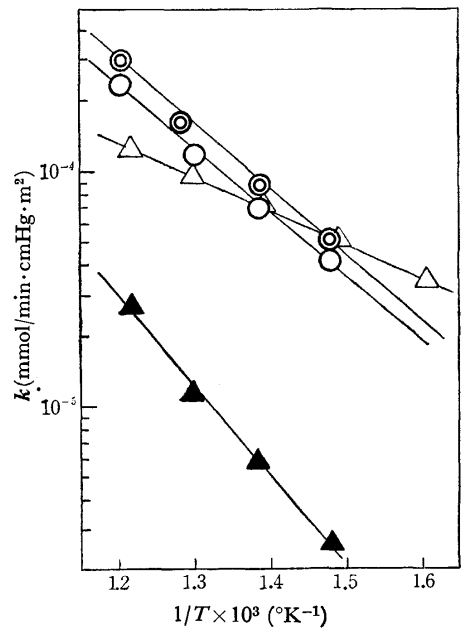

Fig. 2. Effect of temperature on the reaction rate constant.
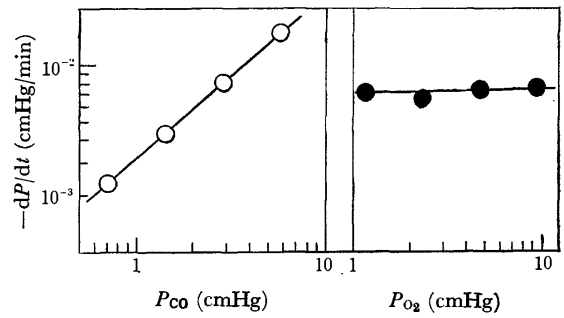
○: ZrO_2-1 ◎: ZrO_2·2 ▲: Anatase △: Rutile

Comparing with titanium dioxide,[1] the catalytic activity of zirconium dioxide is approximately on the same level with that of rutile. As for the activation energy, zirconium dioxide shows the intermediate value of 12.5 kcal/mol between rutile, 6.7 kcal/mol, and anatase, 16.0 kcal/mol.

Effect of Partial Pressures of Carbon Monoxide and Oxygen on the Reaction Rate. To examine the effect of partial pressures of carbon monoxide and oxygen on the reaction rate, the reaction rate was measured keeping the initial partial pressure of oxygen constant and



Fib. 3. Kinetics of the oxidation of carbon monoxide for ZrO_2-2 at 550°C. Open circles refer to constant O_2 pressure ($P_{O_2}=2.84$ cmHg) and varying CO pressures. Filled circles refer to constant CO pressure ($P_{CO}=2.35$ cmHg) and varying O_2 pressures.

5) C. J. Engelder and L. E. Miller, *J. Phys. Chem.*, **36**, 1345 (1932).

changing the partial pressure of carbon monoxide, or *vice versa*. The results are shown in Fig. 3. The reaction rate is nearly of the first order with respect to the carbon monoxide pressure P_{CO} and independent of the oxygen pressure P_{O_2}. Consequently, the reaction rate can be expressed by the following equation:

$$d(CO_2)/dt \simeq k \cdot P_{CO} \quad (2)$$

where k is a constant which is the same as that in Eq. (1).

Reaction of Carbon Monoxide with Surface Oxygen of Zirconium Dioxide. The catalyst pretreated in oxygen at 800°C for 3 hr was cooled to the reaction temperature and evacuated. When carbon monoxide, at a pressure of about 10^{-2} mmHg, was introduced into the reaction system, it reacted with the surface oxygen of the catalyst and the formed carbon dioxide was caught in the trap. It was confirmed that the amount of consumed carbon monoxide agreed well with that of the carbon dioxide caught in the trap. This fact shows that the amount of carbon monoxide which may be adsorbed on the surface of the catalyst is negligible compared with that of carbon monoxide oxidized to carbon dioxide and that the carbon dioxide formed on the surface of the catalyst immediately desorbs from there. The rate of formation of carbon dioxide was found to be proportional to P_{CO}:

$$d(CO_2)/dt = k_{CO} \cdot P_{CO} \quad (3)$$

where k_{CO} is the reduction rate constant of zirconium dioxide by carbon monoxide. The Arrhenius plots of k_{CO} on ZrO_2-1 are shown in Fig. 4 together with that of the oxidation rate constant k. It is obvious that k_{CO} almost agrees with k.

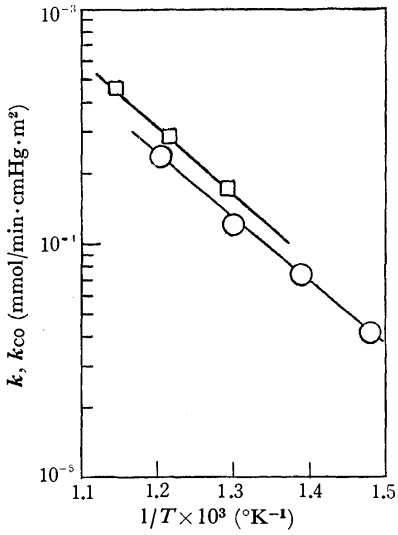


Fig. 4. Effect of temperature on the rate constant of oxidation of carbon monoxide k and that of reduction of ZrO_2 by carbon monoxide k_{CO}.
○: k □: k_{CO}

The catalyst was reduced by carbon monoxide of about 3 cmHg for 30 min, then oxygen of about 10^{-2} mmHg was introduced to measure the uptake rate of oxygen by the catalyst. It was found that the uptake rate of the reduced zirconium dioxide was far faster than the reduction rate of the catalyst by carbon monoxide.

Mechanism of the Oxidation of Carbon Monoxide on Zirconium Dioxide. Since 1) the reaction rate is proportional to P_{CO} and does not depend upon P_{O_2}, 2) the rate constant of the oxidation of carbon monoxide on zirconium dioxide almost agrees with that of the reduction of zirconium dioxide by carbon monoxide, and 3) the oxygen uptake rate of the reduced zirconium dioxide is much faster than the reduction rate of zirconium dioxide by carbon monoxide, the mechanism of this reaction can be explained in the same manner as that on titanium dioxide,[1,2] cupric oxide,[6] and nickel oxide.[7]

The reaction consists of two processes; 1) carbon monoxide which collides with the surface of the catalyst reacts with the surface oxygen of the catalyst and the carbon dioxide thus formed immediately desorbs, leaving an oxygen defect on the surface and 2) the oxygen defect thus formed is refilled with oxygen from the gas phase. Therefore, the reaction steps can be expressed as follows:

$$CO(g) + O(s) \longrightarrow CO_2(g) + (s) \quad (4)$$
$$(s) + 1/2O_2 \longrightarrow O(s) \quad (5)$$

where O(s) refers to the surface oxygen of the catalyst and (s) the oxygen defect on the surface. The step (5) is much faster than the step (4), so the overall reaction rate is proportional to P_{CO}.

Desorption of the Surface Oxygen. The catalyst pretreated in oxygen at 800°C was cooled down to 600°C and evacuated until the gas desorption became almost imperceptible. When the catalyst thus pretreated was heated to a temperature above 600°C, the oxygen desorption was detected and the desorption rate could be determined by measuring the pressure of oxygen, which was collected in a fixed volume by a compressing pump. The experimental results on zirconium dioxide are shown in Fig. 5 together with those on anatase

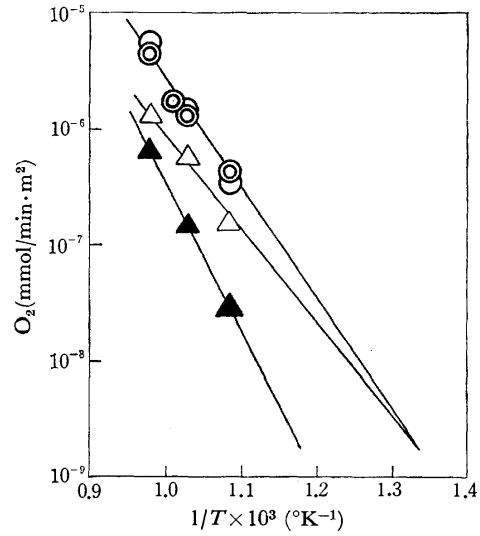

Fig. 5. Effect of temperature on the thermal desorption rate of surface oxygen.

and rutile. The activation energy of the desorption of the surface oxygen of zirconium dioxide was about 44.0 kcal/mol. This value lies between those of anatase, 57.8 kcal/mol and rutile, 38.4 kcal/mol, which seems to correspond to the relation about the activation energies of the oxidation of carbon monoxide on these oxides. Furthermore, extrapolating the data to the temperature range of the oxidation reaction, it is found that zirconium dioxide shows almost the same level of the desorption rate of oxygen as rutile. This fact again seems to correspond to the resemblance between rutile and zirconium dioxide with respect to their catalytic activities. All these results indicate that there is a close relation between titanium dioxide and zirconium dioxide in their catalytic actions.

The authors wish to express their deep thanks to Professors Yasuro Nakazawa and Masayoshi Ihara of Kyoto Technical University for their kind advices and discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1291—1294(1972)

Molecular Structure of Propane

Takao IIJIMA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received August 16, 1971)

The structure of propane has been investigated by gas electron diffraction. The thermal average distances r_g and r_a-angles determined with the estimated limits of error were: C–C = 1.532±0.003 Å, C–H = 1.107±0.005 Å, ∠CCC = 112±1°, and ∠HCH(CH_3) = 107±3°. By combining the diffraction results with the microwave data, the zero-point average structure has also been determined.

The structures of ethane and four *n*-hydrocarbons from butane to heptane were previously determined by gas-phase electron diffraction.[1,2] Somehow propane has been missing in this group of diffraction data. Lide investigated the microwave spectra of propane and its isotopic species,[3] and determined the substitution coordinates and the structure parameters. However, the C–C distance 1.526 Å he obtained was outside the range of the thermal average C–C distances 1.531—1.534 Å, of other *n*-hydrocarbons determined by electron diffraction, beyond the stated uncertainties. As was commented by Lide himself,[4] the existence of this difference was not surprising, in view of the different nature of the averaging over vibrational motions.

The present study was initiated for the purpose of filling up the list of the structure data of simple *n*-hydrocarbons. The C–C r_g distance has been determined to be 1.532±0.003 Å. Further by applying an appropriate correction for the vibrational effect, the microwave data have been combined with the diffraction result, and the structure parameters have been determined for the zero-point average configuration.

Electron Diffraction

The diffraction photographs were taken and analyzed by our routine procedures of recent sector-microphotometer method.[5] Experimental conditions were as follows: accelerating voltage was 42 kV, camera distance 109.3 mm, beam current 0.1 μA, and exposure time 4 min. Carbon disulfide was used as the reference substance. The results of the least-squares analysis for three best plates are summarized in Table 1. The indices of resolution were 0.94—0.98. All the nonbonded distances other than listed in the table were restricted under the geometrical constraint of r_a parameters. The HCH angle of the methylene group was assumed to be 106.1°, the value given by Lide.[3] The

C_{2v} symmetry of the whole molecule and the C_{3v} symmetry of the methyl tops were assumed. The conformation of the methyl hydrogens was taken as determined by Lide,[3] namely, the in-plane hydrogen is in the *trans* position to the C–C bond. All the mean amplitudes were fixed at the calculated values.

The present least-squares analysis did not follow an orthodox constrained procedure[6] but a more simplified method was employed. The four independent parameters were adjusted by the ordinary non-constrained least-squares routine, the dependent parameters being fixed. The dependent parameters were, however, recomputed and reset at every cycle of the least-squares iteration, by the use of the new values of the independent parameters. This method is practically useful but the standard deviations might be slightly larger than the values the exact constrained procedure would give.

The observed and calculated molecular intensity curves are shown in Fig. 1.[7]

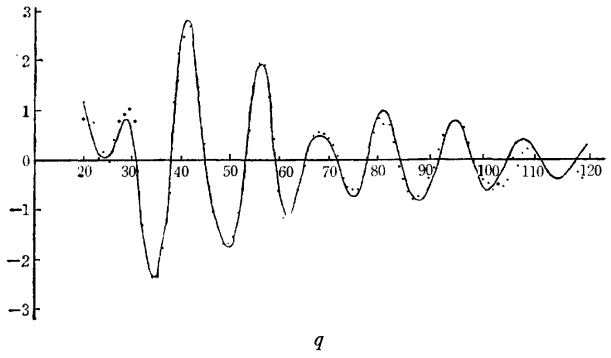

Fig. 1. Molecular intensity curve of propane calculated by the best-fit parameters. Dots indicate observed values.

The parallel and perpendicular mean amplitudes were calculated by the use of the force constants determined by Schachtschneider and Snyder.[8] Their constants were slightly readjusted to obtain better coincidence between the calculated and observed frequencies, because the structure parameters of the present study were not exactly the same as their values. Furthermore, the torsional constants were so adjusted as to give the frequencies determined by Hirota, Matsumura, and Morino.[9] For this purpose, an additional force constant which couples the two of the torsional internal coordinates had to be introduced. The calculated values of the mean amplitudes and the non-linear shrinkage correction Δ are listed in Table 2. The quantity $\Delta = r_a - r_\alpha$ was given by $(<\Delta\rho^2> - 2\,l^2)/2r$, where $<\Delta\rho^2>$ is the perpendicular mean amplitude of the atom pair concerned.[10]

Table 2. Mean amplitudes and shrinkage corrections of propane at 288°K (in 10^{-4} Å units)[a]

	l	Δ[b]		l	Δ[b]
C_1–C_2	496	4	$H_4\cdots H_5$	1299	78
$C_2\cdots C_3$	698	−15	$H_6\cdots H_7$	1283	355
$C_2\cdots H_6$	786	249	$H_4\cdots H_6$	1783	59
C_1–H_4	793	93	$H_4\cdots H_7$	1854	19
$C_1\cdots H_6$	1087	110	$H_4\cdots H_8$	1303	71

$C_2\cdots H_{10}$	1691	−12	$H_7\cdots H_{10}$	2448	2
$C_2\cdots H_4$	1075	20	$H_6\cdots H_{10}$	1784	32
			$H_7\cdots H_{11}$	2791	−244

a) The numbering of atoms are as follows: $C_1H_{4,5}$, methylene; $C_2H_{6,7,8}$, one methyl top; $C_3H_{9,10,11}$, the other methyl top. H_6 and H_9 lie on the CCC plane. H_7, H_4, and H_{10} are above the plane.
b) $\Delta = r_a - r_\alpha$.

Zero-point Average Structure

The effective moments of inertia of the normal species were converted to the zero-point moments of inertia, by applying the vibrational correction. The procedure has been established for ordinary molecules.[11] In the present study, the calculation was performed by an extended method applicable to a molecule containing internal rotors.[12] However, a recent investigation has revealed that the method used in the present study is not very exact but that a term proportional to the angular velocity of torsional motion should be added to the Eckart and Sayvetz conditions.[13] According to the rigorous treatment of a one-top problem the error due to the neglect of this term is of the order of 0.03 amu Å^2 for acetaldehyde.[13] Such an amount of error is not serious in the determination of the structure parameters with accuracy of 0.1% or so.

By assuming boldly that the same situation holds for propane, the zero-point average structure was de-

termined from both moments of inertia given in Table 3 and the diffraction results in Table 1. The r_a^0 or r_z distances, C–C, C–H(CH_3), and C–H(CH_2) were varied along the direction of the possible uncertainty of the scale factor. For each set of these distances, the remaining structure parameters, ∠HCH(CH_3), ∠HCH(CH_2), and ∠CCC can be determined from the three moments of inertia. Thus further judgment for the reasonableness of the obtained set was made by requiring that the ∠HCH(CH_3) and ∠CCC should not be outside the rather large limits of error of the ϕ_a angles given by the diffraction results.

The best set of the structure parameters thus obtained are shown in Table 4. The uncertainties of the parameters are roughly assessed to be 0.2%.

It should be noted that the average structure of Table 4 corresponds to the state where the torsional motion is frozen. Therefore the mean amplitude corrections applied to obtain r_a^0 from r_g were calculated without the torsional freedom, while the amplitude-quantities listed in Table 2 include the torsional motion as well as the vibrational motions.

The author wishes to thank Professor Masao Kimura, Hokkaido University, for his encouragement throughout this work. Numerical calculations were carried out on a FACOM 230-60 of the Hokkaido University Computing Center and also on a FACOM 270-20 of Professor Kimio Ohno's laboratory, whom the author wishes to thank for allowing him to use the facilities.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1293—1299(1972)

Bromination of Aliphatic Ketones with Copper(II) Bromide in Organic Solvents. I. The Reaction of Acetone with Copper(II) Bromide in Methanol

Yoshitane KOJIMA and Shinichi KAWAGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Osaka, 558

(Received August 16, 1971)

The reaction between acetone and methanol to form acetone dimethylacetal attains equilibrium quickly under the influence of copper(II) bromide. Reaction of both acetone and acetone dimethylacetal with copper(II) bromide thus proceed simultaneously to produce copper(I) bromide, hydrogen bromide, and brominated substrates. The mass balances of these reactions were established. On account of the retarding effect of copper(I) bromide and the enhancing effect of hydrogen bromide, the time course of reaction is too complicated to be analyzed, and the initial rate formula was determined. Two reaction pathways were suggested and copper(II) bromide was considered to play dual roles as a catalyst and a brominating agent in either case. The acid-catalyzed reactions were also found to follow a two-term rate law, one being independent of and the other first-order with respect to copper(II) bromide.

Copper(II) bromide is highly soluble in acetone and reacts with the solvent resulting in copper(I) bromide. Kosower, *et al.* reported halogenation reactions of various ketones with copper(II) chloride and bromide in dimethylformamide.[1] Castro and his coworkers also described halogenations of unsaturated compounds with copper(II) halides in boiling alcohols.[2] Kinetic studies of copper(II) chloride reactions were performed by Kochi[3] with acetone in aqueous solutions and by Lorenzini and Walling[4] with butylaldehyde and isobutylaldehyde in aqueous isopropyl alcohol. However, detailed kinetic studies of reactions between anhydrous copper(II) bromide and ketones in inert organic solvents have not been reported.

Reactivities of various organic solvents with copper(II) bromide have been examined, and methanol and dimethylformamide were found to be most suitable as unreactive solvents. Thus, we started the kinetic study of the reaction between copper(II) bromide and acetone in methanol. Unfortunately, however, this system has turned out to be complicated on account of the rapid acetal formation in the presence of copper(II) bromide.

Experimental

Materials. Organic solvents were purified by standard methods,[5] and their purities were checked by the vapor phase chromatography. The water contents of methanol and acetone were measured by the Karl-Fischer method to be 3.8×10^{-3} and 2.2×10^{-2}M, respectively. Anhydrous copper(II) bromide was supplied by Kishida Chemical Co. Ltd. The contaminant copper(I) bromide was checked by titration with a cerium(IV) ammonium sulfate solution. Found for two

specimens: Cu, 28.60; Br, 71.38% and Cu, 28.34; Br, 71.58%. Calcd for $CuBr_2$: Cu, 28.45; Br, 71.55%.

Copper(I) bromide was prepared by reduction of copper(II) sulfate with sodium sulfite in an aqueous solution containing potassium bromide.[6] Sodium acetylacetonate was prepared by adding an aqueous solution of sodium hydroxide to a methanol solution of acetylacetone, and recrystallized from methanol. Commercial tetraethylammonium bromide was used without further purification. Dry methanol solutions of perchloric acid were prepared by passing dry methanol solutions of sodium perchlorate through a column of dried acid form cation exchange resin Dowex 50WX8 (100—200 mesh).[7] A stream of nitrogen was bubbled through boiling deionized water prior to use for quenching of the reaction mixture.

Identification and Determination of Reaction Products. After the desired period of reaction, volatile substances were distilled under reduced pressure. The residue was a mixture of copper(I) bromide and copper(II) bromide. To determine the copper(I) content, the whole residue was dissolved in a sulfuric acid solution containing iron(III) ammonium sulfate and iron(II) ions produced were titrated with an aqueous solution of cerium(IV) ammonium sulfate.[3] For the determination of total copper and bromine, the residue was dissolved in aqueous ammonia. Bromine was determined gravimetrically as silver bromide and copper by electrolysis.

The distillate was composed of methanol, acetone, and brominated substrates. Each component was identified by comparison of the gas-chromatogram with that of the authentic specimen and also by IR and NMR assays when possible. The combined quantity of hydrogen bromide and methyl bromide was measured by titration with an aqueous solution of sodium hydroxide using methyl red as an indicator. The amount of brominated substrates was determined by iodometry.[8]

Kinetics. A methanol solution of copper(II) bromide was thermostated (±0.02°C) in a three-necked flask equipped with a stirrer, a nitrogen gas inlet tube, and an outlet tube containing calcium chloride. The reaction started when thermostated acetone was added to this solution. At appropriate time intervals aliquots were withdrawn from the reacting mixture and quenched in cold sulfuric acid solutions of iron(III) ammonium sulfate. Iron(II) produced was determined by titration with a standardized sulfuric acid (0.5N) solution of cerium(IV) ammonium sulfate (0.01—0.05N).[3] The initial concentration of copper(II) bromide was determined in advance by the EDTA titration with murexide as an indicator.[9]

Equilibrium Determination of the Reaction between Acetone and Methanol. The reaction between acetone and methanol forming acetone dimethylacetal is quite slow, but it attains equilibrium fairly rapidly, within 5 min at the latest, in the presence of copper(II) bromide. The reaction mixture was poured into a methanol solution of sodium acetylacetonate cooled in a dry ice-methanol bath. The equilibrium was thus frozen by chelation of copper and neutralization of acid produced. The solution was then submitted to the gas-chromatographic separation through a column (3 m×4 mm in diameter) containing diglycerol (5%) and silicone grease (5%) carried on Neosorb NCS (63°C, hydrogen gas flow: 20 cc/min), and the equilibrium contents of acetone and acetone dimethylacetal were determined.

Results

Stoichiometry of Reactions of Copper(II) Bromide with Acetone and Acetone Dimethylacetal in Methanol. About 2 g of copper(II) bromide was dissolved in 20 ml of methanol, to which 4—5 ml of acetone or acetone dimethylacetal was added and allowed to react at room temperature for about 2 hr. The reaction mixtures were then analyzed by the method described in Experimental and the results are summarized in Table 1.

The distillation residue was composed of copper(I) bromide and copper(II) bromide, and the composition is given by the following equations:

$$CuBr = 2(\text{Total Cu}) - Br$$

$$CuBr_2 = Br - \text{Total Cu}$$

The mass balance is accounted for in the accuracy better than 95% in the case of acetone, but only around 90% for the acetal. Reactions occurring in the earlier stage of this system can thus be represented by the following equations:

$$(CH_3)_2CO + 2CH_3OH \overset{\text{fast}}{\rightleftharpoons} (CH_3)_2C(OCH_3)_2 + H_2O \quad (1)$$

$$(CH_3)_2CO + 2CuBr_2 \longrightarrow CH_3COCH_2Br + 2CuBr + HBr \quad (2)$$

$$(CH_3)_2C(OCH_3)_2 + 2CuBr_2 \longrightarrow CH_3(CH_2Br)C(OCH_3)_2 + 2CuBr + HBr \quad (3)$$

$$HBr + CH_3OH \overset{\text{fast}}{\rightleftharpoons} CH_3Br + H_2O \quad (4)$$

Monobromoacetone dimethylacetal was identified not only by IR and NMR assays but also by isolation as

Table 1. Products of reactions between copper(II) bromide and acetone or acetone dimethylacetal

neat liquid. Found: C, 33.10; H, 5.98; Br (by iodometry), 45.2%. Calcd for $C_5H_{11}O_2Br$: C, 32.81; H, 6.06; Br, 43.2%. In the course of vacuum distillation of the reaction mixture from copper(II) bromide and acetone dimethylacetal, white needles separated out. Found: C, 23.08; H, 3.90%. Calcd for $C_5H_{10}O_2Br_2$: C, 22.93; H, 3.85%. NMR spectrum of this compound in CCl_4 shows CH_2Br signal at 3.72 τ and OCH_3 peak at 3.46 τ with the intensity ratio of 2: 3, but has no absorption assignable to CH_3. Thus the compound was identified as α,α'-dibromoacetone dimethylacetal, mp 61—63°C (lit. 63.5°C). The usual iodometric determination of bromine at room temperature was not useful for this compound, but disclosed about 90% of the theoretical value at around 50°C.

By means of the gas chromatographic measurements described earlier, the equilibrium constant of the acetal formation reaction (1), $K=[(CH_3)_2C(OCH_3)_2][H_2O]/[(CH_3)_2CO][CH_3OH]^2$, was determined to be 6.6×10^{-4}M^{-1} at 0°C and 5.5×10^{-4}M^{-1} at 8.15°C. These values are close to 6.5×10^{-4}M^{-1} at 10°C and 4.0×10^{-4}M^{-1} at 25°C obtained spectrophotometrically by Bell, *et al.*[10]

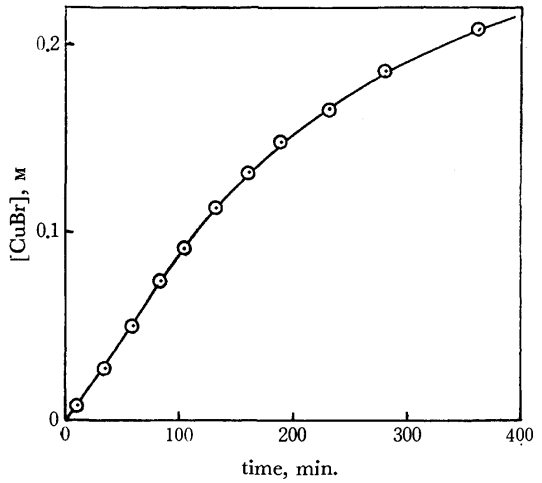

Fig. 1. A kinetic run of the reaction between copper(II) bromide and acetone in methanol at 0°C. Initial concentrations: $[CuBr_2]=0.234$M, $[acetone]=1.78$M.

The Rate Equation for the Reaction of Copper(II) Bromide with Acetone and Acetone dimethylacetal. A kinetic run of the title reaction shows complicated feature as illustrated by the curve in Fig. 1. The rate of decrease of copper(II) bromide can'not be formulated by a simple rate law concerning the concentration of copper(II) bromide. Complicating factors involve the retarding effect of copper(I) bromide and the accelerating effect of hydrogen bromide, both accumulating with the progress of reaction. Thus the complete analysis of each kinetic run was difficult and effects of various factors were examined on the initial rate (R_0) which was defined by the initial linear portion of the [CuBr] *vs.* time curve.

Plots of R_0/[acetone] *vs.* [acetal]/[acetone] gave straight lines at constant $[CuBr_2]$ as illustrated in

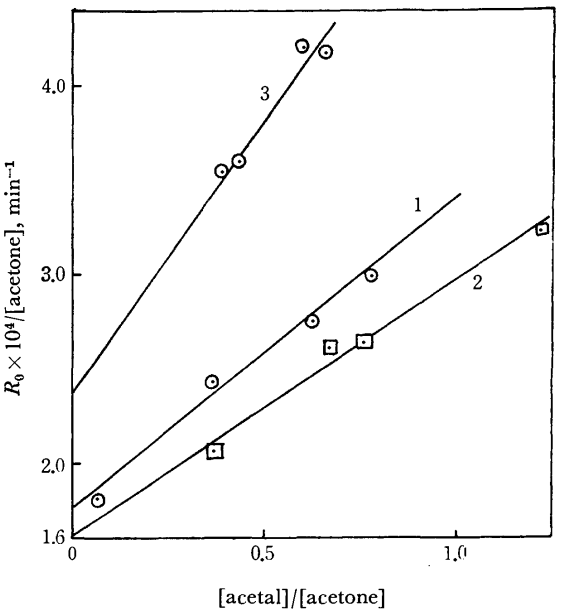

Fig. 2. Linear plots of initial rate data. Line 1: $[CuBr_2]=0.658$M, 0°C; line 2: $[CuBr_2]=0.368$M. 8.15°C; line 3: $[CuBr_2]=0.142$M, 22.05°C.

Fig. 2. Both of the intercept and the slope of these straight lines increase with the concentration of copper(II) bromide, conforming to the rate Eq. (5),

$$R_0 = (k_1'+k_2'[CuBr_2])[CuBr_2][acetone] + (k_1''+k_2''[CuBr_2])[CuBr_2][acetal] \quad (5)$$

where acetal stands for acetone dimethylacetal. The concentrations of acetone and acetal in the reaction mixture were measured at several time intervals and confirmed to be unchanged from the initial equilibrium value governed by the mixing ratio of acetone and methanol.

Table 2. Rate constants referring to the rate equation (5) for reactions of copper(II) bromide with acetone and acetone dimethylacetal

Temp. °C	$k_1'\times10^5$ M^{-1}sec^{-1}	$k_2'\times10^5$ M^{-2}sec^{-1}	$k_1''\times10^5$ M^{-1}sec^{-1}	$k_2''\times10^5$ M^{-2}sec^{-1}
0	~0	0.68	~0	0.62
8.15	0.12	1.73	0.04	1.52
22.05	1.10	13.5	1.19	12.4

Observed values of rate constants are summarized in Table 2. Activation energies referring to the third-order rate constants k_2' and k_2'' are both 22.0 kcal/mol, and frequency factors are 2.46×10^{12} and 2.29×10^{12}M^{-2} sec^{-1}, respectively. It is worth noting that the second-order rate constant is smaller than one tenth of the third-order rate constant in either case, vanishing at 0°C. Furthermore, the corresponding constants for acetone and acetone dimethylacetal lie quite close together. Taking into account the poor accuracy in gas chromatographic determinations of these two substrates, it might be allowed to presume that $k_1'=k_1''$ and $k_2'=k_2''$, that is, acetone and the acetal are brominated at equal rates. Then Eq. (5) is simplified as (6). In fact straight lines are obtained by plotting

0	~0	0.66
8.15	0.08	1.67
22.05	1.13	13.0

Retardation Effect of Copper(I) Bromide. Copper(I) bromide is insoluble in methanol and acetone, but it is dissolved appreciably in the solvents with the coexistence of copper(II) bromide. The solubilization of copper(I) halide is well known to be effected by halide ions forming complex ions. Similar effect may be brought about by the addition of copper(II) halide. McConnell and Davidson, for example, suggested the existence of Cu_2Cl_3 to interpret the interaction absorption of solutions containing copper(I), copper(II), and low concentrations of chloride ion.[11] In the present system, copper(I) bromide may also be considered to be solubilized by the interaction with copper(II) bromide as represented by Eq. (7),

$$CuBr + nCuBr_2 = CuBr \cdot nCuBr_2 \quad (7)$$

Addition of copper(I) bromide to the reaction mixture lowers the initial rate remarkably. If the retarding effect of copper(I) bromide is caused by the partial deactivation of copper(II) bromide according to Eq. (7), the reduced rate at 0°C may be represented by Eq. (8) since k_1 in Eq. (6) is zero at 0°C.

$$R_0 = k_2([acetone] + [acetal])([CuBr_2] - n[CuBr])^2 \quad (8)$$

If much less quantity of copper(I) bromide is added to copper(II) bromide, Eq. (8) can be approximated by

11) H. McConnell and N. Davidson, *J. Amer. Chem. Soc.*, **72**, 3168 (1950).

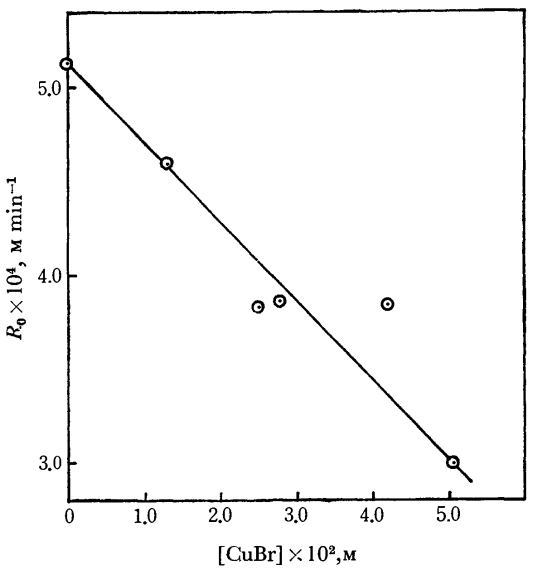

Fig. 4. The retarding effect of copper(I) bromide at 0°C. $[CuBr_2]=0.401$M, $[acetone]+[acetal]=7.47$M.

Eq. (9). In Fig. 4 are plotted the initial rates measured at constant concentrations of copper(II) bromide and acetone against the concentration of copper(I) bromide added. From the slope and the intercept of this straight line n was obtained as 1.6.

$$R_0 = k_2([acetone] + [acetal]) \times ([CuBr_2] - 2n[CuBr])[CuBr_2] \quad (9)$$

Addition of tetraethylammonium bromide also suppressed the bromination reaction of copper(II) bromide as shown in Table 4. This is probably caused by coordination of bromide ions to copper(II) forming complex anions such as $CuBr_3^-$ and $CuBr_4^{2-}$.

Acid-catalyzed Reactions of Copper(II) Bromide with Acetone and Acetone Dimethylacetal. If dry acids such as hydrogen bromide, perchloric acid, and *p*-toluenesulfonic acid are added in advance, the initial rate of the reaction is increased linearly with the acid concentration. The initial rate of the acid-catalyzed reaction ΔR_0 was calculated as the difference between the initial rates in the presence and absence of an acid. Figure

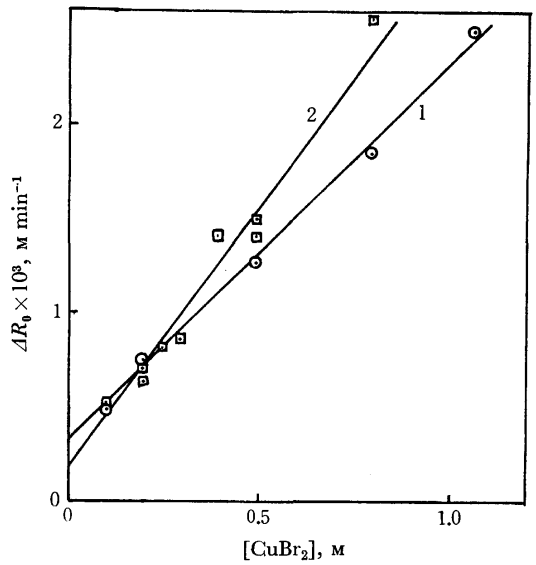

Fig. 5. The initial rate of acid-catalyzed reaction of copper(II) bromide with acetone and acetone dimethylacetal as a function of the concentration of copper(II) bromide at 0°C. Line 1: [$HClO_4$]=0.0318M, [acetone]+[acetal]=4.56M: Line 2: [*p*-toluenesulfonic acid]=0.0406M, [acetone]+[acetal]=4.56M.

5 shows the dependence of ΔR_0 upon the concentration of copper(II) bromide at constant concentrations of perchloric acid or *p*-toluenesulfonic acid and acetone. The linear relationship between ΔR_0 and [$CuBr_2$] reveals that there exist two reaction pathways, one being independent of and the other first-order with respect to copper(II) bromide. At constant concentrations of copper(II) bromide and perchloric acid ΔR_0 increased with the concentration of acetone. However, the interrelation was not linear but represented by a Langmuir-type curve as illustrated in Fig. 6.

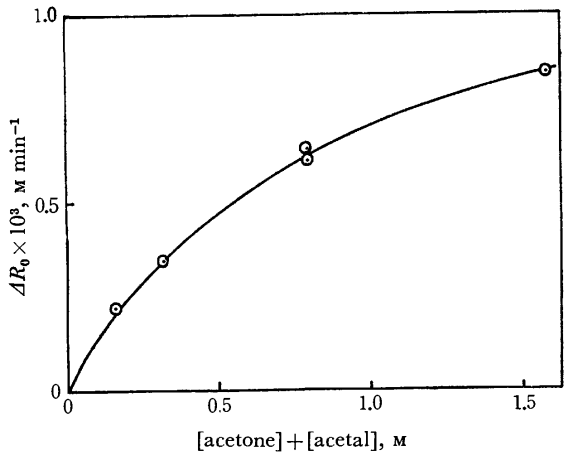

Fig. 6. The initial rate of acid-catalyzed reaction of copper(II) bromide with acetone and acetone dimethylacetal as a function of the combined concentration of acetone and the acetal at 0°C. [$HClO_4$]=0.034M, [$CuBr_2$]=0.659M.

Discussion

The reaction between acetone and methanol seemed troublesome for study of the reaction of copper(II) bromide with acetone, but fortunately the equilibria of acetal formation reactions are established so quickly in the presence of copper(II) bromide and the amount of hemiacetal is known to be so minute[10] that a single equilibrium (1) needs to be considered. Furthermore approximately equal rates of reactions of acetone and acetone dimethylacetal towards copper(II) bromide simplified the analysis of rate data.

It has been well established that the acid catalyzed halogenation of acetone in aqueous solutions is preceded by the rate-controlling enolization steps:[12]

$$\mathrm{CH_3C(=O)CH_3 + HA \rightleftharpoons CH_3C^{+}(OH)CH_3 + A^-} \quad (10)$$

$$\mathrm{CH_3C^{+}(OH)CH_3 + A^- \longrightarrow CH_3C(OH)CH_2 + HA} \quad (11)$$

By analogy, the first steps in reactions of copper(II) bromide with acetone and the acetal may be coordination of substrate molecules to copper atoms (Eqs. (12) and (13)). Partial ionizations of copper(II) bromide itself and of substrate complexes will be at rapid equilibrium, and both the neutral and charged complexes are conceivable to be equally effective in succeeding reactions.

$$\mathrm{(CH_3)_2CO + CuBr_2 \overset{K_1}{\rightleftharpoons} (CH_3)_2CO\cdot CuBr_2 \rightleftharpoons CH_3C(=O^{+}\cdot CuBr)CH_3 + Br^-} \quad (12)$$

(A)

$$\mathrm{(CH_3)_2C(OCH_3)_2 + CuBr_2 \overset{K_2}{\rightleftharpoons} (CH_3)_2C(OCH_3)_2\cdot CuBr_2 \rightleftharpoons CH_3C(OCH_3)(OCH_3)(^{+}CuBr)CH_3 + Br^-} \quad (13)$$

(B)

Although Kochi[3] reported that the initial rate of the reaction between acetone and copper(II) chloride in water was one-half order in gross copper(II), the observed initial rate Eq. (5) or (6) in the present study reflects the existence of two kinds of transition states for each substrate, one containing another copper(II) bromide and the other not. Thus steps (14) through (17) are presumed to be rate-controlling.

$$\mathrm{A + S \overset{k_3}{\longrightarrow} CH_3C(OCuBr)CH_2 + HS^+} \quad (14)$$

$$\mathrm{A + CuBr_2 \overset{k_4}{\longrightarrow} CH_3C(OCuBr)CH_2 + CuBr^+ + HBr} \quad (15)$$

$$\mathrm{B \overset{k_5}{\longrightarrow} CH_3C(OCH_3)CH_2 + CuBr^+ + CH_3OH} \quad (16)$$

$$\mathrm{B + CuBr_2 \overset{k_6}{\longrightarrow} CH_3C(OCH_3)CH_2 + CuBr(OCH_3) + CuBr^+ + HBr} \quad (17)$$

Here S stands for a proton acceptor which may be a methanol molecule. The detailed scheme for bromina-

12) R. P. Bell and Y. Yates, *J. Chem. Soc.*, **1962**, 1927.

tion of acetone dimethylacetal is very difficult to envisage, but is just assumed to involve an enolic ether as visualized in Eq. (16). In steps (15) and (17) copper(II) bromide is supposed to act as a proton acceptor in accordance with the second term with respect to copper(II) bromide in Eq. (5). Succeeding steps in which enolate intermediates are brominated by copper(II) bromide should be fast. Then the overall reaction rate is represented by Eq. (18),

$$\text{rate} = (k_3+k_4[CuBr_2])[A] + (k_5+k_6[CuBr_2])[B]. \quad (18)$$

Substituting equilibrium values of [A] and [B] derived from Eqs. (12) and (13) to Eq. (18),

$$\text{rate} = \{(k_3+k_4[CuBr_2])K_1[CuBr_2][\text{acetone}] + (k_5+k_6[CuBr_2])K_2[CuBr_2][\text{acetal}]\}/(1+K_1[\text{acetone}]+K_2[\text{acetal}]). \quad (19)$$

If $1 \gg (K_1[\text{acetone}]+K_2[\text{acetal}])$, the rate Eq. (19) reduces to the observed rate law (5) with $k_1'=k_3K_1$, $k_2'=k_4K_1$, $k_1''=k_5K_2$, and $k_2''=k_6K_2$.

Mechanisms of bromination of enolic molecules by copper(II) bromide in succeeding steps are not clear at all. Castro, *et al.*[2] obtained a rate equation independent of allyl alcohol, rate$=k[CuBr_2]^2$, for bromination of allyl alcohol by copper(II) bromide in refluxing methanol and attributed the rate expression to the reversible dissociation of copper(II) bromide to molecular bromine.

$$2CuBr_2 \rightleftarrows 2CuBr + Br_2$$

Similar possibility may not be denied for the present system although it seems less probable since the equilibrium concentration of bromine will be very low at 0°C. Alternatively copper(II) bromide itself might brominate an enolate molecule.

The retardation by copper(I) bromide was attributed to the association with copper(II) bromide invalidating 1.6 times as many molecules of the latter. Similar retarding effect of copper(I) chloride was also observed by Lorenzini and Walling[4] in reactions of copper(II) chloride with butyraldehydes in aqueous isopropyl alcohol and by Kochi[3] in the reaction of copper(II) chloride with acetone in water.

Bromide ions were found to act as a retarder in the present system. On the contrary, chloride ions were reported to stimulate reactions both by the Walling group and Kochi. This discrepancy is due to the difference in the reaction media. As discussed above copper(II) halide plays a dual function. The activity of copper(II) halide as a catalyst would be $CuX^+ > CuX_2 > CuX_3^-$, while effectiveness as a halogenating agent should be $CuX^+ < CuX_2 < CuX_3^-$. In aqueous solutions ionization of copper(II) halide (Eq. (20)) is extensive, and the halogenating capacity is rather

$$CuX_2 \rightleftarrows CuX^+ + X^- \quad (20)$$

poor. Addition of chloride ions reverts the equilibrium (20) to the left, increasing the chlorinating efficiency. On the other hand in methanol the ionization (20) is less significant and excess bromide ions added will enhance the addition equilibrium (21),[13]

$$CuX_2 + X^- \rightleftarrows CuX_3^- \quad (21)$$

thus diminishing the catalytic ability of copper(II). In reaction systems containing some acid the coordinative activation of an acetone molecule is effected by a proton, and copper(II) bromide only needs to function as a brominating agent. In such a case addition of bromide ions should increase the reaction rate. In fact, although the initial rate of reaction between copper(II) bromide (0.073M) and acetone (1.30M) in methanol containing perchloric acid (0.026M) was 9.7×10^{-7}M/sec at 0°C, addition of tetraethylammonium bromide in excess (0.27M) raised the rate to 5.8×10^{-6}M/sec. A methanol solution of copper(II) bromide at such a concentration shows a brown color, but changes to purple by addition of excess bromide ions[14] suggesting formations of $CuBr_3^-$ and $CuBr_4^{2-}$.

In analogy to Eqs. (10) and (11) for the reaction with bromine, the following scheme is presumed for the acid catalyzed reactions of copper(II) bromide with acetone and acetal. The concentration of acids employed was usually less than 0.15M and the complete

$$\mathrm{CH_3\!\!>\!\!C\!=\!O} + HS^+ \overset{K_7}{\rightleftarrows} \left[\mathrm{CH_3\!\!>\!\!C\!-\!OH}\right]^+ + S \quad (22)$$
(C)

$$\mathrm{CH_3\!\!>\!\!C(OCH_3)_2} + HS^+ \overset{K_8}{\rightleftarrows} \left[\mathrm{CH_3\!\!>\!\!C(H)(OCH_3)_2}\right]^+ + S \quad (23)$$
(D)

$$C + S \xrightarrow{k_9} \mathrm{CH_3\!\!>\!\!C\!-\!OH} + HS^+ \quad (24)$$

$$C + CuBr_2 \xrightarrow{k_{10}} \mathrm{CH_3\!\!>\!\!C\!-\!OH} + CuBr^+ + HBr \quad (25)$$

$$D \xrightarrow{k_{11}} \mathrm{CH_3\!\!>\!\!C\!-\!OCH_3} + CH_3OH_2^+ \quad (26)$$

$$D + CuBr_2 \xrightarrow{k_{12}} \mathrm{CH_3\!\!>\!\!C\!-\!OCH_3} + CH_3OH + CuBr^+ + HBr \quad (27)$$

dissociation could be assumed, HS^+ then standing for the protonated methanol molecule. From Eqs. (22) and (23) concentrations of protonated substrates C and D are represented by

$$[C] = K_7[HA]_0[\text{acetone}]/([\text{MeOH}]+K_7[\text{acetone}]+K_8[\text{acetal}])$$

$$[D] = K_8[HA]_0[\text{acetal}]/([\text{MeOH}]+K_7[\text{acetone}]+K_8[\text{acetal}])$$

where $[HA]_0$ stands for the total concentration of the acid employed. Then the rate of the acid-catalyzed reaction, namely the difference between rates in the presence and absence of an acid, can be written as

$$\Delta(\text{rate}) = \{(k_9+k_{10}[CuBr_2])K_7[\text{acetone}] + (k_{11}+k_{12}[CuBr_2])K_8[\text{acetal}]\}[HA]_0/([\text{MeOH}]+K_7[\text{acetone}]+K_8[\text{acetal}]) \quad (28)$$

If it is presumed that $k_9=k_{11}=k_a$, $k_{10}=k_{12}=k_b$, and $K_7=K_8=K$, Eq. (28) reduces to Eq. (29):

13) J. C. Barnes and D. N. Hume, *Inorg. Chem.*, **2**, 444 (1963).

14) S. Matsuo, *Nippon Kagaku Zasshi*, **83**, 1229 (1962).

$$\Delta(\text{rate}) = (k_a + k_b[CuBr_2])[HA]_0 K([\text{acetone}] + [\text{acetal}])/\{[\text{MeOH}] + K([\text{acetone}] + [\text{acetal}])\} \quad (29)$$

Braude[15] determined the equilibrium constants K_B^s of the proton-transfer reactions $SH^+ + B \rightleftarrows BH^+ + S$ between the solvated proton SH^+ and the proton-accepting indicator (B), *p*-nitroaniline. The value of K_B^s was 9, 20, 31, and 53 for water, dioxane, ethanol, and acetone, respectively, indicating that the basicity decreases in the order, water > dioxane > ethanol > acetone. The relative basic strengths of water, methanol, and ethanol were also reported[16] to be 1 : 0.13 : 0.33 or 1 : 0.13 : 0.22. These two sets of data indicate that the basicity of acetone is very similar to that of methanol, namely the equilibrium constant K_7 of the proton-transfer equilibrium (22) is close to one. K_8 will not be larger than K_7. Then, in the denominator of Eq. (29), [MeOH] is much larger than the second term in the concentration region of acetone employed (Fig. 5). Equation (29) may thus be approximated by Eq. (30),

$$\Delta(\text{rate}) = (k_a + k_b[CuBr_2])[HA]_0 K([\text{acetone}] + [\text{acetal}])/[\text{MeOH}] \quad (30)$$

The rate equation (30) for the acid-catalyzed reaction well conforms with observed dependences of the initial rate on the concentrations of acid (first order) and copper(II) bromide (Fig. 5), but contradicts the observed acetone dependence (Fig. 6). Equation (30) requires a straight line relationship as observed in Fig. 3, but actual data gave such a Langmuir-type curve. This discrepancy could be attributed to water formation in the reaction (1). As described in Experimental, the equilibrium constant of the acetal formation reaction (1) was determined to be 6.6×10^{-4}M^{-1} at 0°C. If it is put that $[H_2O] = [\text{acetal}]$, $[H_2O] = [\text{MeOH}]$ $(K[\text{acetone}])^{1/2}$ and takes rather large values as 0.2M when [acetone]=0.1 and [MeOH]=25M, and 0.6M when [acetone]=1 and [MeOH]=23M. Under such circumstances appreciable portions of protons are trapped by water molecules and the proton transfer equilibria to be taken into account are intractably complex. Qualitatively speaking, however, with the increase in the acetone concentration employed, the concentration of water is increased and the fraction of protons transferred to acetone moleculs is decreased. This might be concluded as the reason why the rate of the acid-catalyzed reaction is not enhanced in proportion to the acetone concentration (Fig. 6).

The authors are grateful to Dr. T. Ogura for his valuable discussion. Thanks are also due to Mr. J. Gohda for elemental analysis and IR measurements, and to Mr. K. Noda of the Osaka Municipal Technical Research Institute for NMR measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1299—1305(1972)

Ionization Energies and Rydberg States of Tetraaminoethylenes

Yoshihiro NAKATO, Masaru OZAKI,* and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received September 13, 1971)

Absorption spectra and photo-ionization curves of tetrakis (dimethylamino) ethylene, (TMAE), and 1,1′,3,3′-tetramethyl-$\Delta^{2,2'}$-bi(imidazolidine), (TMBI), have been studied. It has been found that these compounds have very low ionization potentials (about 5.4 eV), which are even comparable with that of the lithium atom. The first ionization potentials of these compounds are nearly the same, although both their absorption spectra and their photo-ionization curves are considerably different from each other. These results can be explained semi-quantitatively by use of the results of simple, semi-empirical molecular orbital calculation with inclusion of direct interaction between four lone-pair orbitals on the N atoms, which was found to be important at the "perpendicular" structure. The first absorption bands of these molecules are assigned to the Rydberg bands, lying quite unusually near the visible region. The quantum defect δ is found to be 0.7 for the lowest Rydberg state of TMAE. The size of the Rydberg orbital for this state is estimated to be 2.9 Å from the maximum radial density, which is comparable with the core size. Higher Rydberg series are also observed for TMBI.

Ionization potentials of organic compounds are one of the key quantities in the studies of electronic processes in organic materials, such as organic semi-conductors, organic photo-conductors, and formation and reactions of electron-donor-acceptor complexes. The gas-phase ionization potentials of organic compounds reported so far lie in the range of about 7 to 12 eV.[1] Recently, we have found that tetrakis (dimethylamino)-ethylene, (TMAE), and 1,1′,3,3′-tetramethyl-$\Delta^{2,2'}$-bi-(imidazolidine), (TMBI), have extremely low ionization

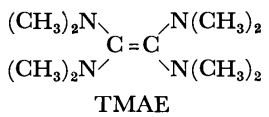
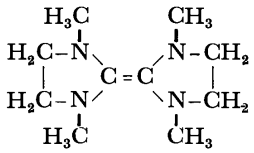
potentials, about 5.4 eV, in spite of their relatively simple molecular structures.[2]



TMAE



TMBI

The fact that dialkylamino groups have strong electron donating properties is well known. Tetraaminoethylenes have as many such groups as possible for a substituted ethylene, and hence are very strong electron-donors. The chemical properties of these interesting compounds have been studied extensively and they are characterized as electron-rich olefins[3] or as strong electron donors.[4]

The knowledge on the electronic structures of tetraaminoethylenes is, however, still rather limited. The electron donor strength, the bonding and the electronic spectra for TMAE were interpreted by a simple HMO calculation.[4] The electronic spectra were also explained qualitatively in terms of intramolecular charge transfer mechanism.[5]

There have been some difficulties, both experimental and theoretical, in the study of the electronic structure of the tetraaminoethylenes. In the first place, they are strongly reactive to oxygen, emitting strong luminescences. The experiments with them must, therefore, be made with extreme care. Secondly, there is some ambiguity as to their molecular conformations. It is expected that a large steric repulsion exists between four dialkylamino groups. This may prevent the tetraaminoethylenes from taking the "planar" structures and make their conformations more or less uncertain. The "non-planar" structure may lead to a breakdown of the π-electron approximation. Namely, the lone-pair orbitals on the N atoms overlap not only with the π-orbitals on the C atoms, but also directly with the other lone-pair orbitals, and with the σ-orbitals. Finally, the role of the molecular Rydberg states in the low-lying excited levels has been overlooked.

In the present paper, the results of measurements on the photo-ionization curves, ionization potentials and absorption spectra will be reported, together with the discussions on the electronic structures and ionization potentials of free molecules in the gas phase, based on the MO calculations of these molecules.

Experimental

Both TMAE and TMBI were prepared according to the literature.[6] Crude products were distilled in an atmosphere of nitrogen under reduced pressure. They were then degassed and distilled repeatedly in a vacuum line, and stored in evacuated glass ampoules with breakable seals. *n*-Pentane, isopentane, and methylcyclohexane were passed through silica gel columns, left overnight in contact with sodium wire and distilled. All the sample solutions were prepared by dissolving TMAE or TMBI through breakable seals into solvents after they had been completely deoxygenated. Absorption spectra of TMAE and TMBI at room temperature were measured by using various cells with pass length ranging from 1.0 to 10 cm.

Absorption spectra in the wavelength region longer than 190 nm were measured in a Cary Model 15 spectrophotometer. Both absorption spectra and photo-ionization curves in the wavelength region between 300 and 155 nm were measured by a 0.5 meter Nalumi vacuum monochromator. It has a Bausch and Lomb concave grating (concave radius 498.1 mm, ruled area 30 mm × 51 mm, 600 grooves/mm, blazed at 1500 Å, blaze angle 2°35′). The plate factor of the monochromator is calculated to be 28.3 Å/mm when the grating is used in the first order at $\lambda = 150$ nm. The slit width used was normally 200 μ. The light source used is a hot-cathode-type hydrogen-discharge lamp from Mitsubishi Electric Corp., operated at 0.9 A and 70 V, which emits photons of the wavelengths longer than 155 nm. A Toshiba 7696 photomultiplier (S-11 type) covered with a sodium salicylate thin film is used as a photon detector. Emission lines from mercury and hydrogen lamps were used to calibrate the wavelength scale. The stray light was found to be less than 3% of the total light from the exit slit around 160 and 180 nm.

Photon absorption and photocurrent were measured as functions of photon energy in the same run. A pyrex cell used has two quartz windows (transparent down to 155 nm) and two collecting-electrodes held parallel to each other by means of tungsten wire-pyrex seals, the resistance between which was 3×10^{15} ohms at 25°C. Photocurrent was measured by Takeda Riken vibrating reed electrometer, TR-84M. The applied voltage between electrodes was 5 to 10 V in normal use. In the above experimental conditions, the minimum photocurrent detected was about 2.0×10^{-15} A. Estimating the light intensity at some 10^9 photons/sec from the photomultiplier output, the photo-ionization yield ($= \sigma_i/\sigma$) can be measured to be at least 2×10^{-5}, if it is assumed roughly that one half the incident light was absorbed by the sample vapor (where σ and σ_i are absorption and photo-ionization cross sections, respectively).

Results

Absorption spectrum of TMAE in the vapor phase is shown in Fig. 1. At least four transitions may be involved in the spectrum which are centered at 29.0, 38.5, 44.8, and 53.0 kK. The first (29.0 kK) and the second (38.5 kK) bands agree closely with those reported by Winberg, Downing, and Coffman,[7] and the fourth (53.0 kK) agrees with that by Hori, Kimura, and Tsubomura.[5] Some structures are seen in the region around the fourth band. Near ultraviolet absorption spectra of TMAE in MP solutions, both at room temperature and 77°K, are given in Fig. 2 together with that in the gas phase, where MP is a mixed solvent consisting of methylcyclohexane and isopentane in a volume ratio of 1 : 1. Similar spectrum was ob-

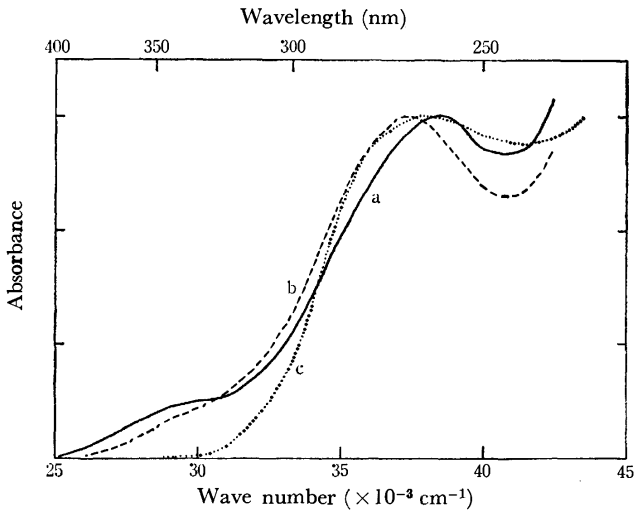

Fig. 2. The absorption spectra of TMAE in the near UV region; curve a (——) for the vapor, curve b(- - - - -) for an MP solution at room temperature and cruve c(·····) for the same solution as 77°K. The profile around the second band (38 kK) of cruve c is somewhat ambiguous, because the matrix became a little opaque.

tained in an *n*-pentane solution or in an ether solution, and a maximum was found at 45.5 kK. The absorption maxima previously reported are 37.3 kK in *n*-heptane, tetrahydrofuran and acetonitrile,[5] and 37.0 and 45.2 kK in *n*-decane.[8] The agreements are good.

Absorption spectra of TMBI both in the vapor and in an *n*-pentane solution are shown in Fig. 3. Vapor absorption begins at about 25.0 kK and increases towards higher wave numbers with a few inflexions (32.8 not clear, 35.7, 40.8 kK). The first peak is located at 50.5 kK. The second seems to exist at around 60 kK or higher.

It should be noted here that the first band of TMAE shifts to higher wave numbers in an MP solution at room temperature compared with that in the vapor although the second band shifts rather inversely. The first band is apparently missing at 77°K. The

absorption spectrum at wave numbers lower than 45 kK for TMBI in the vapor is also apparently missing in an *n*-pentane solution.

Very recently, several studies concerning the Rydberg states in condensed media were made.[9,10] The main conclusion is that the Rydberg band is sensitive to the environments surrounding the molecule. It moves to shorter wavelengths when it is placed in the condensed phase or even in the gaseous state at high pressure.[11] The first band of TMAE and the bands in the near UV of TMBI show behaviors similar to the Rydberg bands reported in these papers, so that it may be concluded that they are Rydberg bands. It may also be concluded that the second and third bands of TMAE and the 50.5 kK band of TMBI are non-Rydberg bands from their insensitiveness to the environments. The fourth band of TMAE also seems to be non-Rydberg, because it is too strong to be assigned to the Rydberg band. This conclusion is supported by the molecular orbital calculation.

It must be pointed out here that the gas-phase absorption spectrum of TMAE seems to contain an underlying continuous absorption which increases in intensity towards higher wave numbers, as seen in Fig. 1. This may be concluded to correspond to the transitions to the higher Rydberg series and the ionization-continuum. A similar feature is seen for the gas-phase spectrum of TMBI in Fig. 3.

Figure 4 shows the photo-ionization curves for TMAE. Curve a shows the relative photo-ionization cross section, σ_i^{rel}, as a function of photon energy, E, and curve b is the first derivative curve ($d\sigma_i^{rel}/dE$ *vs.* E). σ_i^{rel} was calculated at every 10 Å by using the equation, $\sigma_i=\sigma\cdot i/(I_0-I)$, where σ, i, and I_0-I are the relative absorption cross section, photocurrent and relative light

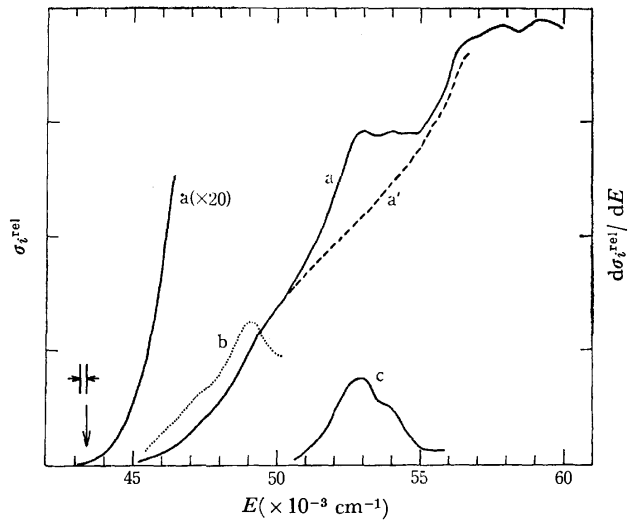

Fig. 4. Gas-phase photo-ionization of TMAE; curve a shows σ_i^{rel} *vs* E and curve b $d\sigma_i^{rel}/dE$ *vs.* E. Curve a is divided into curve a' and c in the energy region around 53 kK, which are estimated to correspond to the contributions of the direct ionization and the auto-ionization, respectively, (See text.). The threshold for photo-ionization is shown by an arrow. The energy spread of the photon beam at the threshold is also indicated.

intensity absorbed by the sample vapor, respectively. The onset of the ionization is rather gradual. Such a feature is common to those reported for aliphatic and aromatic amino compounds.[12,13] In such cases, it is difficult to determine the adiabatic ionization potentials accurately. We have, therefore, taken the point of appearence of σ_i^{rel} as an upper limit for the first adiabatic ionization potential.

Curve a has three steepest slopes at 49, 52, and 56 kK, and curve b has maxima at these positions, as shown only for the first steepest slope in Fig. 4. According to Morrison's method,[12] the first vertical ionization potential for TMAE can be determined to be 49.3 kK from the maximum of curve b. The second steepest slope at 52 kK, however, seems to be attributable to the auto-ionization from the fourth band of TMAE, rather than to the second (direct) ionization. The estimated curve for the direct ionization is shown as curve a' (a broken line) and the difference between the curves a and a' is shown as curve c, which corresponds to the contribution due to the auto-ionization. This interpretation may be supported by the fact that curve c agrees very well with the fourth band in Fig. 1. If this is the case, the second vertical ionization potential may be estimated to lie in 55—56 kK.

Photo-ionization curves for TMBI are shown in Fig. 5, from which the ionization potentials can be determined in the same way. The auto-ionization also seems to occur, but is not so clear. The first vertical ionization potential estimated to lie around 49 kK is, therefore, made somewhat uncertain. The second photo-ionization seems to start at about 57 kK.

Photo-ionization curves in the higher wave number regions ($\gtrsim$57—58 kK), both in Figs. 4 and 5, seem to be less reliable, because of the line spectrum of the hydrogen lamp used as the light source.

The observed ionization potentials are summarized in Table 1, together with those reported in the literature.

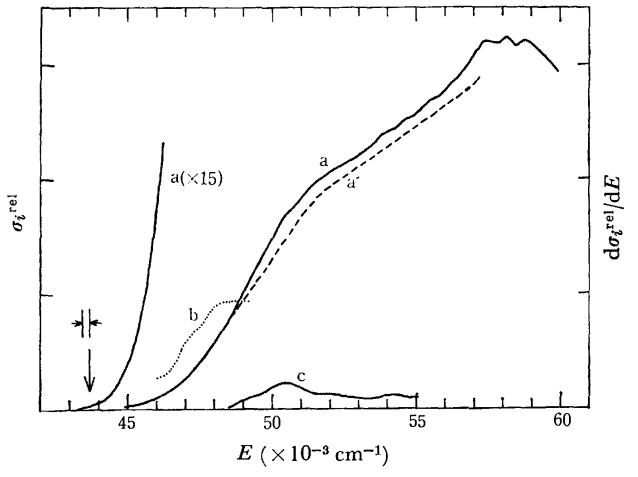

Fig. 5. Gas-phase photo-ionization of TMBI. Each curve and mark are indicated in the similar manner as in Fig. 4.

a) From the appearance potential of the parent ion in the mass spectrum; N. Wiberg and J.W. Buchler, unpublished.

b) Calculated from the difference in the charge-transfer absorption maxima for TMAE and dimethylaniline as the donors and nitrobenzene as the common acceptor, where 7.35 eV for the ionization potential of dimethylaniline was used; Ref. 15). This should be compared with the vertical value obtained by us.

c) These are only tentatively estimated values.

MO Calculations

In order to understand the experimental results, it seems worthwhile to make theoretical calculations of the electronic energies. For the purpose to find the orbital energies of filled π-MO's and to characterize the π-π^* type transitions, a simple semi-empirical molecular orbital calculation was made using only the $2p\pi$-AO's on the C atoms and the lone-pair AO's on the N atoms. Each of the lone-pair AO's is assumed to be one of the sp^3 hybrid orbitals of the nitrogen atom. The details of the method of calculation is given in the Appendix.

The molecular conformations of tetraaminoethylenes have not been fully established. The planar $N_2C{=}CN_2$ skeleton can at least be assumed for the ground state. The inspection of the molecular model shows that the

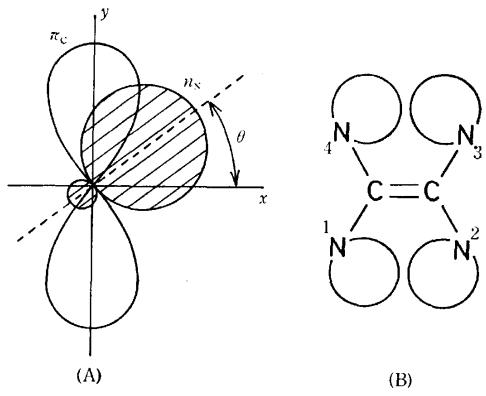

Fig. 6. (A), A projection of a nitrogen lone-pair AO and a carbon $2p\pi$-AO on the xy plane perpendicular to the C–N bond. The angle θ is indicated. (B), The "perpendicular" structure of tetraaminoethylenes. Only the $N_2C{=}CN_2$ skeleton and four lone-pair orbitals are illustrated.

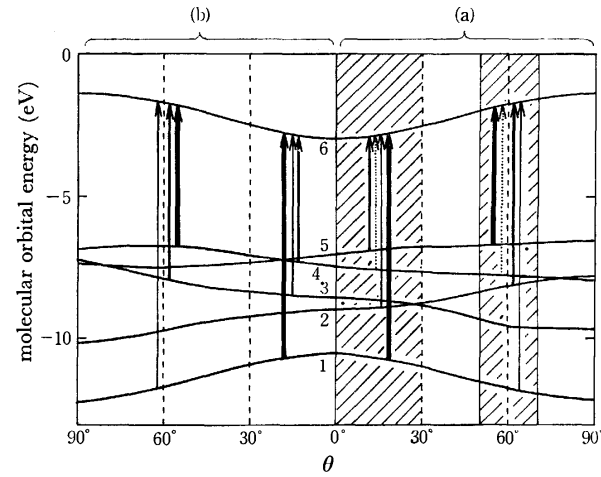

Fig. 7. Molecular orbital energies for tetraaminoethylenes. Each molecular orbital energy is plotted as a function of θ, for two types of conformations, (a) and (b). The Slater's parameter (μ) used is 1.80.

four dimethylamino groups have some freedom of twisting around each of the four C–N bonds. Let the direction of a C–N bond be the z-axis, and we draw the projectories of carbon $2p\pi$-AO and nitrogen lone-pair AO on the xy plane as shown in Fig. 6 (A). Then, the angle θ as shown in Fig. 6 (A) can be the best parameter to define the conformation of the dimethylamino group. The C–N resonance interaction (β_{CN} in the Appendix) makes the "planar" structure ($\theta=90°$ in Fig. 6 (A)) the most preferable, which is, however, more or less prevented by the mutual steric repulsion between the crowded methyl groups. The infrared absorption spectrum of TMAE shows no band in the $\nu_{C=C}$ regions,[14] whereas an intense $\nu_{C=C}$ band (1630 cm^{-1}) appears in the Raman spectra.[7] TMAE also gives only one sharp proton signal in the NMR spectrum.[7,14] All these results suggest that the molecular conformation is symmetric with respect to the C=C bond. At present, the most reasonable model for TMAE in the ground state seems to be a "perpendicular" structure ($\theta=0°$) under wobbly motion proposed by Hammond and Knipe,[15] in which the $(CH_3)_2N$ groups are vibrating about a position "perpendicular" to the $N_2C{=}CN_2$ plane. TMBI gives two sharp proton signals in the NMR spectrum. The steric repulsion between the methyl groups for TMBI seems to be much less than that for TMAE, but may still be large enough to prevent the complete "planar" structure.

The complexity of the problem arises from the fact that each of the four dimethylamino groups has a certain free domain of wobbly motion, and there are quite a number of possible conformations for TMAE. For TMBI, the situation is somewhat similar, although there is a geometrical restriction of cyclization for the twisting motions. In order to describe various conformations, we start from the "perpendicular" structure, in which all lone-pair orbitals lie on the $N_2C{=}CN_2$ plane in the manner as shown in Fig. 6 (B), and construct all other conformations by twisting dialkylamino groups about the C–N bonds with angles of θ_i, where $i(=1,2,3,4)$ is numbering of dialkylamino groups as shown in Fig. 6 (B). The angle θ_i is defined so as to have a positive value on twisting the lone-pair orbital upwards.

The calculation has been made for various possible conformations, *i.e.*, at various θ_i values each independent of others. Part of the results obtained is shown in Fig. 7. Here, the molecular orbital energies are plotted as a function of θ for two types of conformations: (a), $\theta_1=\theta_3=-\theta_2=-\theta_4$ $(=\theta)$ and (b), $\theta_1=\theta_4=-\theta_2=-\theta_3$ $(=\theta)$. Each of these two types of conformations, especially (a), is expected to have the least steric repulsion between the methyl groups. The orbital energies of the four lone-pair orbitals are split by the direct N–N interaction into those of four MO's at the "perpendicular" structure ($\theta=0°$). As the angle θ increases, this N–N interaction decreases, while the interaction between N and π_C becomes important. Consequently, somewhat complicated curves with several cross-points are obtained, as seen in Fig. 7.

Of the six MO's, which are numbered at $\theta=0°$ as shown in Fig. 7, the lower five are filled with electrons, and only the highest is vacant. Allowed transitions under the approximation described in the Appendix[16] are indicated by arrows in Fig. 7; those having strong transition moments by thick arrows and those having weak transition moments by thin arrows. Arrows with dotted lines indicate those with negligibly small transition probabilities. The transition probabilities are found to depend strongly on θ. From the consideration of steric hindrances, it is assumed that the allowable region of θ for TMAE is from 0° to 30° and that for

15) P. R. Hammond and R. H. Knipe, *J. Amer. Chem. Soc.* **89**, 6063 (1967).

16) The transition moments calculated for the conformation (a) under the approximation described in the Appendix are as follows, $\mu(6\leftarrow5)^2$: $\mu(6\leftarrow4)^2$: $\mu(6\leftarrow2)^2$: $\mu(6\leftarrow1)^2=0.00$: 0.00: 0.00: 1.00 at $\theta=0°$; 0.69: 0.00: 0.29: 0.54 at $\theta=30°$; 1.29: 0.02: 0.54: 0.17 at $\theta=60°$; 1.45: 0.04: 0.56: 0.08 at $\theta=90°$, where $\mu(n\leftarrow m)^2$ indicates the square of the transition moment from the m-th MO to the n-th MO in Fig. 7 relatively. The transition, $6\leftarrow3$, is symmetry forbidden for the conformation (a). The transition moments change continuously with θ. Similar results are obtained for the conformation (b).

TMBI from 50° to 70°, which are marked by hatching for the conformation (a) in Fig. 7.

The results obtained are summarized as follows.

(1) The energy of the highest filled MO is nearly the same in the two regions; $\theta=0°$—$30°$ and $50°$—$70°$, as seen from Fig. 7. (Inversion of the highest filled MO's occurs for the conformation (b)). This result agrees with the observation that TMAE and TMBI have almost equal ionization potentials. The low ionization potentials of these molecules compared with the alkylamine and ethylene seem to be caused mainly by the direct N–N interaction for TMAE and mainly by the C–N resonance interaction for TMBI.[17]

(2) We have concluded in the previous section that the first band of TMAE (Fig. 1) is of Rydberg nature. From the results of calculation made for the conformation (a) in the region $0°\lesssim\theta\lesssim30°$, it is shown that the 6←1 transition indicated in Fig. 7 is mainly of the nature of π-π^* transition in the ethylenic group and is therefore very strong. The transitions, 6←5 and 6←2, are shown to be forbidden at $\theta=0°$ but become considerably strong near $\theta=30°$.[16] The theoretical predictions for the relative intensities of these three transitions agree fairly well with those observed for the second, third, and fourth bands in the TMAE absorption spectrum, though they are made somewhat ambiguous owing to the presence of the underlying continuum, as mentioned in the preceding section. The transition, 6←4, is predicted to be negligibly weak, and is probably hidden by other strong bands. Similar good agreements are also found for the conformation (b) in the region $0°\lesssim\theta\lesssim30°$.

(3) In the region $50°\lesssim\theta\lesssim70°$, the transition energies are much larger than the corresponding transition energies at $\theta=0°$—$30°$ both for the conformations (a) and (b). This explains very nicely the marked blue-shift of absorption bands observed for TMBI compared with those for TMAE, since it has been concluded in the previous section that the 50.5 kK band of TMBI corresponds to the lowest allowed valence transition (6←5 in Fig. 7(a) or 6←4 in Fig. 7(b)).

We have assumed that TMAE and TMBI take the structure represented by either the conformation (a) or the conformation (b). These two conformations are expected to be preferred owing to their least steric repulsions between methyl groups. It might be possible, however, that TMAE and TMBI take structures represented by mixtures of these two and other conformations with the less steric repulsions between the methyl groups. Even in such cases, the above-mentioned conclusion is not substantially altered.

Discussions

The above mentioned calculated and observed results seem to provide fairly convincing explanation as to the question why TMAE and TMBI have nearly the same ionization potentials (*Ip*'s), although they are expected to have different conformations.

Although the first vertical *Ip*'s of TMAE and TMBI are easy to determine from the σ_i^{rel} curves, only the upper limits are obtained for the adiabatic *Ip*'s. It seems, however, very likely from the following consideration that these observed limits lie close to the true adiabatic *Ip*'s. The nuclear configuration of TMAE in the Rydberg state is expected to be similar to that of the positive ion, as pointed out for ethylene.[11] Therefore, the difference between the adiabatic and vertical energies for the Rydberg transition will be nearly equal to that for the ionization. The difference between the vertical and adiabatic energies for the first Rydberg transition of TMAE is estimated fairly accurately to be about 0.6 eV, because the adiabatic energy for this transition can be obtained from the overlapping part of the absorption and fluorescence spectra. The difference between the observed limit for the adiabatic *Ip* and the vertical *Ip* determined in the present work for TMAE is about 0.7 eV as seen from Table 1, which is in fairly good agreement with the difference between vertical and adiabatic energies of the first Rydberg transition.

The large differences between the vertical and adiabatic *Ip*'s for both TMAE and TMBI should be attributable to large change of the molecular conformations upon ionization. It is suggested that $TMAE^+$ has nearly "planar" structure from the ESR studies.[4,18] It must also be pointed out that a large difference (~0.7 eV) was reported even for aliphatic amines,[13] possibly because of the change of the molecular shapes from the pyramidal structures to the planar.

We have assigned the first band of TMAE and a number of low-lying bands of TMBI to the Rydberg bands on the basis of their characteristic behaviors in solutions compared with those in the vapor. The higher series for TMAE may be covered by the stonger second band corresponding to the transition to the valence state. These unusually low-lying Rydberg states for tetraaminoethylenes are naturally expected from their very low *Ip*'s.

The term values of Rydberg states in molecules fall into a series, expressed in the form,

$$T = RZ^2/(n^*)^2 = RZ^2/(n-\delta)^2,$$

where, Z is the charge on the core, R the Rydberg constant, n^* the effective principal quantum number. From this equation, and using the adiabatic *Ip* and the wavelength at the center of the overlap between the first absorption band and the fluorescence spectrum, n^* is calculated to be 2.3. If this band is assumed to be the first member of the series ($n=3$), δ then becomes 0.7. The empirical δ-values reported for the Rydberg series of molecules built-up from atoms of the first period are 0.9—1.2 for *ns*-series, 0.3—0.5 for *np*-series and 0.1 for *nd*-series.[19] Deviation of the quantum defect, δ, for the first Rydberg state of TMAE from

17) Strictly speaking, the interaction with the σ-electrons must be included, especially at small θ. It is, however, expected from a simple consideration that this interaction causes little change for the highest filled MO in Fig. 7. R. Hoffmann, A. Imamura, and W. J. Hehre, *J. Amer. Chem. Soc.*, **90**, 1499 (1968).

either those for *ns* or *np*-series, as seen above, may be attributable to the large departure of the core potential from spherical symmetry. The size of the Rydberg MO can be roughly estimated from the equation, $r_0=(n-\delta)^2a_0/Z$, where a_0 is 0.529 Å and r_0 is the *r*-value at which the radial density has its maximum. We obtain $r_0=2.9$ Å for the first Rydberg state of TMAE. On the other hand, it is thought that the positive charge of the core is located mainly on the four equivalent N atoms, since the highest filled MO consists mainly of the four lone-pair orbitals on the N atoms. The size of the core is, therefore, comparable with r_0 obtained above, since the N–N distances of TMAE are about 2.7 and 2.4 Å.

A large Stokes' shift between the first absorption and fluorescence bands is observed for TMAE. This large Stokes' shift was attributed by some authors to the conformational change of the fluorescent state of TMAE from the ground state, in the former of which the two N_2C halves are assumed to be perpendicular to each other in the N_2C=CN_2 skeleton.[4,9] This explanation seems to assume that the first band is due to a π-π^* type transition. As discussed in the foregoing of this section, however, it seems more likely that the fluorescent state takes a structure similar to $TMAE^+$, in which the planarity of the skeleton is maintained.

Appendix

A simple LCAO MO theory is used in this work. Normalized symmetry orbitals, ξ_i, are first constructed as follows,

$$\begin{aligned}
\xi_1 &= (2+2S_{CC})^{-1/2}(\chi_{Ca}+\chi_{Cb})\\
\xi_2 &= (2-2S_{CC})^{-1/2}(\chi_{Ca}-\chi_{Cb})\\
\xi_3 &= 2^{-1}(\chi_{N1}+\chi_{N2}+\chi_{N3}+\chi_{N4})\\
\xi_4 &= 2^{-1}(\chi_{N1}+\chi_{N2}-\chi_{N3}-\chi_{N4})\\
\xi_5 &= 2^{-1}(\chi_{N1}-\chi_{N2}-\chi_{N3}+\chi_{N4})\\
\xi_6 &= 2^{-1}(\chi_{N1}-\chi_{N2}+\chi_{N3}-\chi_{N4})
\end{aligned}$$

where χ_{Ca} and χ_{Cb} indicate the two $2p\pi$-AO's on the C atoms of the C=C group and χ_{Ni} the lone-pair AO on the *i*-th N atom (Fig. 6(B)). The MO's of the whole molecule, ϕ, are, then, expressed as follows,

$$\phi = \sum c_i\xi_i$$

where c_i is a proper coefficient. The overlap integrals, S_{NN} and S_{CN}, are neglected, while S_{CC} is included and taken to be 0.257.

The two matrix elements, H_{11} and H_{22} ($H_{ii}=\int\xi_i H\xi_i d\tau$ where H indicates the effective one-electron Hamiltonian of the whole molecule), are assumed to be equal to -10.5 and -3.0 eV, respectively, empirically from the ionization potential and the excitation energy to the first excited singlet ($^1\sum_u^+$) state of ethylene. The four matrix elements, H_{33}, H_{44}, H_{55}, and H_{66}, are given as simple sums of the nitrogen Coulomb integral, α_N, and various resonance integrals between two nitrogen atoms, β_{NN}. α_N is taken to be -8.0 eV from the vertical ionization potential estimated for $N(C_2H_5)_3$. The β_{NN}'s are found to play an important role in the case of TMAE and included in the calculation, although they were neglected in the MO calculations made for TMAE previously.[4] These integrals are calculated from the equations of the type, $\beta_{NN}=S_{NN}(\beta_{CC}/S_{CC})$, where S_{NN} is the overlap integral between two nitrogen atoms, and β_{CC} and S_{CC} are taken to be -3.8 eV and 0.257, respectively. The calculation of S_{NN} is made by the use of Mulliken's table.[20] The Slater's parameter ($\mu=Z_{eff}/n^*$) for a nitrogen $2p$ AO calculated by ordinary Slater's rule is 1.95. However, a little smaller value may be more suited for a μ value of a nitrogen lone-pair AO. In the present work, calculations were made using two μ values of 1.95 and 1.80. It turned out that there was almost no substantial difference between the results obtained for the two μ values. The off-diagonal matrix elements, H_{ij} ($i\neq j$), are expressed in terms of β_{CN}, the resonance integral between the adjacent C and N atoms, which is calculated from the equation, $\beta_{CN}=0.8\beta_{CC}\sin\theta$, where β_{CC} is taken to be -2.5 eV by considering that the C–N distance is longer than the C=C distance of ethylene and θ is the twisting angle of the dialkylamino group defined before. The other parameters used are as follows; the bond distance, R(C=C)$=1.34$ Å, R(=C–N)$=1.37$ Å and the bond angle, $\angle$NCN$=\angle$NCC$=120°$.

Transition moments are calculated by assuming $\int\chi_p r\chi_q d\tau=0$ if $p\neq q$. The center of the charge density of the lone-pair AO is assumed to lie at 0.3 Å away from the nitrogen nucleus in the direction of the sp^3 hybrid orbital.

Radiolyses of Mixtures of Ammonia and Hydrocarbons. II. Formation of Hydrogen from Mixtures of Ammonia and Olefins (Ethylene, Propylene and Butadiene)

Kumao HAMANOUE, Jiro OKAMOTO, Okihiro TOKUNAGA, and Akibumi DANNO

Japan Atomic Energy Research Institute, Tokai Research Establishment, Tokai-mura, Naka-gun, Ibaraki-ken

(Received September 17, 1971)

γ-radiolyses of gaseous mixtures of ammonia and olefins (ethylene, propylene and butadiene) have been investigated over the whole composition range of mixtures, and consideration was given on the primary processes of hydrogen formation. From the extrapolated values of $G(H_2)$ obtained in the γ-radiolyses of the mixture of ammonia and olefins, it was found that the non-scavengeable $G(H_2)$ of ammonia, ethylene, propylene and butadiene were 0.68—0.72, 1.26, 1.06, and 0.33, respectively. Gas-phase radiolyses of ammonia–perdeuterated olefin mixtures have also been investigated. From kinetic calculation on the data of isotopic mixtures of hydrogen, the following results were obtained; 1) both thermal and non-scavengeable hydrogen molecules are produced by the γ-radiolysis of ammonia, and the non-scavengeable hydrogen molecules are produced for the most part by a unimolecular process, 2) almost all the hydrogen molecules produced by the γ-radiolyses of olefins (ethylene, propylene, and butadiene) are non-scavengeable; a unimolecular process plays an important role in the case of ethylene, and in other cases a bimolecular process. $G(H_2)$ of the butadiene radiolysis is very small compared with that of other olefins and with the calculated value of butadiene, *i.e.*, $G(H_2)<1$. The discrepancies can be interpreted in terms of the addition reaction of the "hot" hydrogen radicals to butadiene to form *t*-2-butene.

The radiolyses of olefins have been studied extensively. In particular, the primary process of hydrogen formation was investigated in detail by Hatano *et al.* on the simple olefins (ethylene, propylene, butene-1 and butene-2) under the action of the γ-ray radiation.[1-6] They concluded that almost all the hydrogen molecules produced were non-scavengeable and produced by the decomposition of the so-called "Super-excited state" proposed by Platzman.[7-12] Generally, it is well known that thermal hydrogen radical reacts quickly with olefins to form alkyl radicals, namely, the olefins are good radical scavengers.[13] Many works have also been carried out on the radiolysis of ammonia. The results have led to the conclusion that the G values of non-scavengeable hydrogen molecules are 0.64—0.84 and those of thermal (scavengeable) hydrogen radicals are 5—12.[14-20] It can be said that ammonia is a good donor of the thermal hydrogen radical.

Thus, it is interesting to study the γ-radiolysis of the mixture of ammonia and olefin. We have reported on the radiolysis of the gaseous mixture of ethylene and ammonia.[21] In this paper we will report on the results of γ-radiolyses of gaseous mixtures of ammonia and olefins (ethylene, propylene and butadiene). Consideration is given to the primary processes of hydrogen formation.

Experimental

Matheson pure-grade ammonia, ethylene, propylene and butadiene were purified by the same method as described in part I.[21] The purity of these purified gases was determined by gas chromatographic analyses to be greater than 99.9%. Ethylene-d_4, propylene-d_6, and butadiene-d_6, were purchased from Merck, Sharp and Dohme Ltd. (isotopic purity 98 at. %D), and were subjected to trap-to-trap distillation. The reactant gas, a mixture of ammonia and olefin, was led into a 3.1 m*l* pyrex glass ampoule at constant pressure of 4 atm. Irradiation was carried out at room temperature by Co-60 γ-rays at the exposure-dose rate of 6.0×10^5 R/hr. Unless otherwise stated, samples were irradiated to a total dose of 2.88×10^7 R. Analyses of products (hydrocarbon and hydrogen) were carried out by the same method as described in part I,[21] and those of isotopic hydrogens were carried out with a Hitachi RMS-4 mass spectrometer. We confirmed the formation of ethylamine in the mixture of ammonia and ethylene. No amines were observed in the mixtures of ammonia and propylene or butadiene.

Results

In the radiolyses of pure propylene and of a mixture of ammonia and propylene or butadiene, the yields of

hydrogen increased linearly with irradiation doses up to at least 5.0×10^7 R. The same results were obtained in the case of pure ammonia and pure ethylene by Eyre and Smithies[14] and by Hatano *et al.*[5]

Figure 1 shows the pressure dependence of hydrogen formation. Pressure effects are very small in the range 1—4 atm.

The relationship between hydrogen formation and the concentration of olefin is shown in Fig. 2. It is obvious that $G(H_2)$ of ammonia is reduced rapidly by the addition of a small amount of ethylene or propylene, and then increases linearly with increasing concentration of the olefins. In the case of butadiene, a marked decrease is also observed by the addition of a small amount of butadiene. $G(H_2)$ is then reduced monotonously by the further addition of butadiene.

Figure 3 shows the relationship between the G values of the main products which seem to be formed from thermal hydrogen radicals, and the concentration of olefins.

The gas-phase radiolyses of ammonia–perdeuterated olefins mixtures (C_2D_4, C_3D_6, C_4D_6) have also been investigated. The isotopic compositions of HD are comparatively small, *i.e.*, 7—12% at most. The relationship between the concentrations of perdeuterated olefins and D_2/HD or H_2/HD are given in Figs. 4 and 5.

Figures 6 and 7 shows the temperature dependence of hydrogen formation in a mixture of C_3H_6–NH_3 and C_4H_6–NH_3, respectively. So far no explanation has been given on the maximum values near 0°C. Bp and mp denote the boiling and melting points of ammonia, propylene and butadiene, respectively.

Discussion

It is obvious from Fig. 1 that there is little change in $G(H_2)$ in the gas-phase radiolysis of ammonia in the pressure range 1—4 atm, namely, $G(H_2)=3.14\pm0.11$. Willis *et al.* studied the radiolysis of ammonia by electron beams and found that $G(H_2)$ was constant, *i.e.*, $G(H_2)=3.58\pm0.08$, in the pressure range 1—2.25 atm.[15] The same results were obtained by Jones *et al.* in the pressure range 500—700 mmHg, but they found an increase at lower pressure.[17] Eyre and Smithies[14] studied the effects of pressure, temperature, dose and additives on the radiolysis of ammonia, and found that $G(H_2)$ is unaffected in the pressure range 100—700 mmHg. They obtained the G value of non-scavengeable hydrogen molecule and that of scavengeable hydrogen radical as follows.

$$G^*(H_2) = 0.70 \pm 0.02,\ G(H) = 7.0 \pm 0.6,$$

where $G^*(H_2)$ is the G value of non-scavengeable hydrogen molecule.

In our experiments in the radiolyses of pure olefins or of mixtures of ammonia and olefins, small pressure dependence of $G(H_2)$ above 1 atm can be observed. Marked increase in $G(H_2)$ at a lower pressure may presumably be attributed to the enhanced decrease of the collisional deactivation of excited state.

The initial sharp fall in $G(H_2)$ caused by the addition of a small amount of olefins is consistent with the fact that the olefins are good radical scavengers (Fig. 2). In the case of ethylene or propylene, $G(H_2)$ increased linearly with the increase of the concentration of olefins.

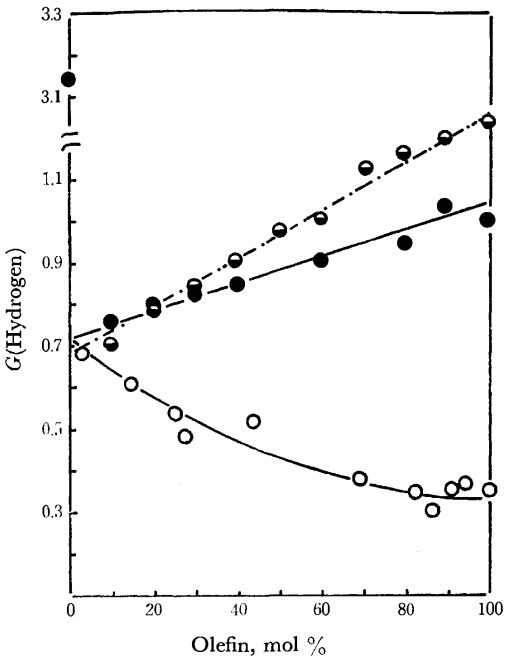

Fig. 2. Variation of hydrogen formation as a function of the concentration of C_2H_4, C_3H_6 and C_4H_6
◒: C_2H_4–NH_3, ●: C_3H_6–NH_3, ○: C_4H_6–NH_3

This suggests that they are due to non-scavengeable hydrogen from olefins. In the case of butadiene, the results is the opposite. However, the limiting values of $G(H_2)$, obtained by the extrapolation of the linear part of the curve to zero mol% olefins, namely 100 mol% ammonia, are nearly the same, *viz.*, $G_{NH_3}(H_2)=0.68$ with ethylene, 0.72 with propylene and butadiene. The values are in good agreement with the value of non-scavengeable hydrogen molecule ($G^*_{NH_3}(H_2)=0.70\pm0.02$).[14] The values obtained by extrapolating to 100 mol% olefins are 1.26, 1.06, and 0.33 for ethylene, propylene and butadiene, respectively. The data except for butadiene are in good agreement with those formerly obtained.[4-6,14,22-24]

Hatano *et al.* investigated the mechanism of hydrogen formation in the radiolysis of liquid olefins (RH_2).[1-6] They proposed a possible role of the superexcited state (RH_2**); hydrogen molecule is formed by the decomposition of RH_2** by reaction (1) or (2), either by a unimolecular process directly yielding molecular hydrogen or by a bimolecular process yielding hot hydrogen radical (H*) which abstracts hydrogen from the reactant.

$$RH_2^{**} \begin{cases} \longrightarrow H_2 + R & (1) \\ \longrightarrow H^* + RH & (2) \end{cases}$$

The G value of hydrogen formation by the decomposition of the superexcited state is derived by the optical approximation introduced by Platzman.[7-12]

$$G = \frac{100}{W}\frac{M_d^2}{M_i^2} \qquad (3)$$

where M_d^2 and M_i^2 are the dipole matrix elements squared for dissociation and for ionization, respectively. The calculated results show that the quantities M_d^2 and M_i^2 are directly proportional to the number of carbon atoms in the hydrocarbons. The G values were calculated from the results. The values obtained are in good agreement with those of experimental values for ethylene, propylene, butene-1 and butene-2. Thus we might conclude that the linear portion of Fig. 2 is due to non-scavengeable hydrogen molecule from olefin.

No report seems to have been published on the radiolysis of butadiene. However, if we assume that the hydrogen molecules produced by the radiolysis of butadiene are non-scavengeable like those of other olefins, then the G value, *i.e.*, $G(H_2)=0.33$, is much smaller than that of other olefins or that calculated by Hatano,[6] *i.e.*, $G(H_2)>1$. The discrepancies suggest that the "hot" hydrogen radical may partly react with butadiene to form a different product from hydrogen molecule.

In Fig. 3, it is obvious that the G values of products in the radiolyses of mixtures of ammonia and ethylene

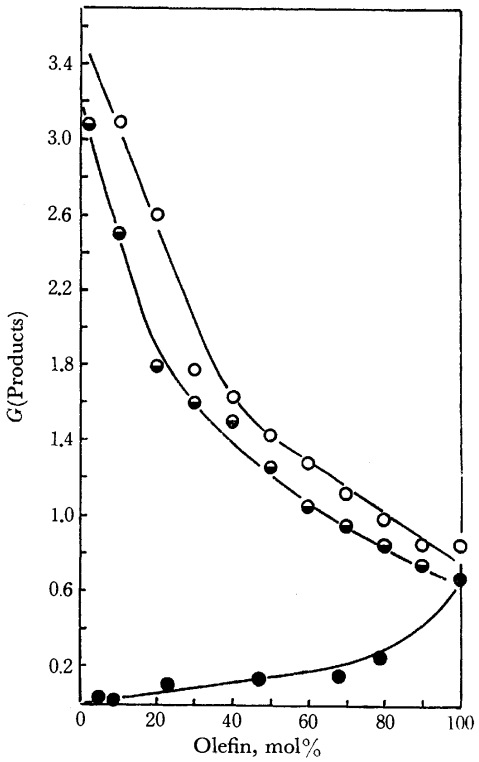

Fig. 3. Variation of the formation of major products as a function of the concentration of C_2H_4, C_3H_6 and C_4H_6

24) F. W. Lampe, *Radiation Res.*, **10**, 691 (1959).
25) The mechanism of the formation of *t*-2-butene is not known at present. Assuming that it may be formed by the following reaction in which one hot radical participates;

$C_4H_7^* + C_4H_6$ (or NH_3) $\rightarrow$ *t*-2-butene,

then, $G^*(H_2)$ is 0.99. An alternative explanation may be that two hot radicals participate in

$C_4H_7^* + C_4H_7^* \rightarrow$ *t*-2-butene,

in this case, $G^*(H_2)=0.33+2G(t\text{-}2\text{-butene})=1.65$.

or propylene decrease with the increase of the concentration of olefins. This can be explained from the fact that the G values of thermal hydrogen radical from olefins are comparatively small and from ammonia very large. In the case of propylene, the extrapolation of the curve to 100 mol% ammonia gives the value 3.5, the corresponding G value of hydrogen radical then being 7.0. This value agrees with the initial G value of hydrogen radical, $G(H)=7.0\pm0.6$[14] and $G(H)=7.2\pm0.5$.[16]

In the case of ethylene, if we take account of the formation of ethylamine, the corresponding value is 6.4 which shows also good agreement.

These results lead to the conclusion that the thermal hydrogen radicals produced by the γ-radiolysis add quickly to olefins in the case of ethylene and propylene. In the latter, the formation of amines is negligible. In contrast, the G value of *t*-2-butene which seems to be the main product from butadiene shows a different behaviour. If the product is formed by the reaction of thermal hydrogen radical and butadiene, G(*t*-2-butene) may decrease with the increase of the concentration of butadiene as in the case of ethylene and propylene. *t*-2-Butene should be formed by the reaction of hot hydrogen radical and butadiene, and the thermal hydrogen radical might react with butadiene to form higher hydrocarbon products.

Thus, we can explain the increase of G(*t*-2-butene) and the decrease of $G(H_2)$ to be due to increasing concentration of butadiene.

$G(H_2)$ of pure butadiene is 0.33, and it is obvious from Fig. 3 that G(*t*-2-butene) is 0.66. Assuming that $G^*(H_2)$ is equal to $G(H_2)+G$(*t*-2-butene), then $G^*(H_2)$ is 0.99,[25] which agrees well with the value calculated by Hatano[6] and with values of other olefins.

Tachikawa *et al.*,[26-28] and Tominaga and Rowland[29] investigated the hot-atom chemistry of recoil tritium, and found correlations between hot-yeilds of HT and bond-dissociation energies of hydrocarbons, halomethanes and amines. Thus it is reasonable to consider that the hydrogen abstraction reaction of hot hydrogen radicals produced by the γ-radiolyses might be affected by bond-dissociation energies.

In the radiolyses of mixtures of ammonia and perdeuterated hydrocarbons (C_2D_4, C_3D_6, C_4D_6), the isotopic composition of HD is comparatively small, *i.e.*, 7—12% at most. In the mixture of C_3H_6 and C_3D_6 (C_3H_6=50 mol%), the isotopic composition of HD is 15—16%. The lower value of HD in the system of NH_3–C_3D_6 than in the system of C_3H_6–C_3D_6 may indicate two posibilities; etiher a small G value of hot hydrogen radical from ammonia, or a larger bond-dissociation energy of ammonia than that of olefin.

Eyre and Smithies[14] proposed that the non-scavengeable hydrogen molecule probably arises for the most part from the decomposition of the excited ammonia molecule (NH_3**) *via* reaction (4):

$$NH_3^{**} \longrightarrow NH + H_2 \quad (4)$$

An alternative explanation is that some hot hydrogen radicals (H*) are formed and they may abstract hydrogen from ammonia:

$$NH_3^{**} \longrightarrow NH_2 + H^* \quad (5)$$

Thus, the hydrogen abstraction reaction in the mixed system of ammonia and olefin can be expressed as follows.

$$H^* + NH_3 \longrightarrow H_2 \quad (6)$$

$$H^* + RD_2 \longrightarrow HD \quad (7)$$

On the other hand, perdeuterated olefin (RD_2) might be decomposed by the following reactions.

$$RD_2^{**} \longrightarrow D_2 + R \quad (8)$$

$$RD_2^{**} \longrightarrow D^* + RD \quad (9)$$

$$D^* + RD_2 \longrightarrow D_2 \quad (10)$$

$$D^* + NH_3 \longrightarrow HD \quad (11)$$

Assuming the steady-state condition for the concentrations of the intermediate species H* and D*, we can derive the following equations by a simple kinetic treatment.

$$\lim_{[RD_2]\to 0} HD/D_2 = \frac{k_9}{k_8} + \frac{k_5k_7}{k_6k_8} \quad (12)$$

$$\lim_{[NH_3]\to 0} HD/H_2 = \frac{k_5}{k_4} + \frac{k_9k_{11}}{k_4k_{10}} \quad (13)$$

In the radiolysis of C_4D_6–NH_3 mixture, we have taken account of the following reaction besides reactions (10) and (11).

$$D^* + RD_2 \longrightarrow \text{No hydrogen molecule} \quad (14)$$

In this case, HD/D_2 is given by the same equation as that of Eq. (12), but HD/H_2 is given by the following equation.

$$\lim_{[NH_3]\to 0} HD/H_2 = \frac{k_5}{k_4} + \frac{k_9k_{11}}{k_4(k_{10}+k_{14})} \quad (15)$$

The results obtained from Figs. 4 and 5 and Eqs. (12), (13), and (15) are shown in Table 2. The values

TABLE 2. LIMITING VALUES OF D_2/HD AND HD/H_2

Olefin	$\left(\frac{k_9}{k_8}+\frac{k_5k_7}{k_6k_8}\right)^{-1}$	$\frac{k_5}{k_4}+\frac{k_9k_{11}}{k_4k_{10}}$	$\frac{k_8}{k_9}$ [a]
C_2H_4	2.4	0.36	2.4
C_3H_6	0.4	0.86	0.4
C_4H_6	0.5	0.39[b]	

a) Ref. 5. b) $\frac{k_5}{k_4}+\frac{k_9+k_{11}}{k_4(k_{10}+k_{14})}$

of k_8/k_9 which were obtained by Hatano *et al.*[5] in the system of RH_2–RD_2 are also listed in the last column. Comparing our results with those of Hatano *et al.*, we obtain the following equations.

$$\frac{k_9}{k_8}=\frac{k_9}{k_8}+\frac{k_5k_7}{k_6k_8} \tag{16}$$

$$k_5 \simeq 0 \tag{17}$$

$$\frac{k_5}{k_4}<0.36 \tag{18}$$

The results lead to the following conclusions.

1) Non-scavengeable hydrogen molecules produced by the radiolysis of ammonia are mainly produced by reaction (4), or by a unimolecular process. Bimolecular processes like reaction (5) are much less important.

2) Almost all the hydrogen molecules produced by the γ-radiolyses of ethylene and propylene are non-scavengeable, 71% in the former and 29% in the latter are unimolecular processes.

3) Almost all the hydrogen molecules produced by the γ-radiolysis of butadiene are also non-scavengeable, and k_8/k_9 is 0.5. Consequently, 33% is due to a unimolecular process. Hot hydrogen radicals produced can react with butadiene not only by abstraction reaction of hydrogen, but also by addition reaction to butadiene.

We have assumed that the hot hydrogen radical can add to butadiene. This indicates that the energy of the hot hydrogen radical might not be so high, and the reaction in which this hot radical participates might be temperature dependent. As shown in Figs. 6 and 7, $G(H_2)$ changes with temperature. The change includes the effect of the change of phase of the reaction system.

The Effects of Pre-irradiation Treatments on the Chemical Behavior of ^{64}Cu Recoil Atoms in Neutron-irradiated Copper Phthalocyanine

Hiroshi KUDO

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki

(Received September 30, 1971)

The chemical behavior of ^{64}Cu recoil atoms was studied in copper phthalocyanine which had been quenched from an elevated temperature or exposed to ^{60}Co γ-rays before the neutron irradiation. In the quenched β-crystal, the initial retention was found to increase with an increase in the temperature of pre-irradiation heating, while the plateau retention of the post-neutron annealing reaction decreased. These results were compared with those for cadmium phthalocyanine and were understood in terms of "dislocation" in the crystal, the recoil atoms being assumed to be trapped and stabilized in the "dislocation." Although the variations were small, the irradiation with ^{60}Co γ-rays caused a change in the chemical behavior of the recoil atom. The role of some radiation-induced species were discussed.

A series of studies[1-5] have reported that the bulk properties of the target crystal have a marked influence on the chemical consequence of ^{64}Cu recoil atoms in neutron-irradiated copper phthalocyanine. Both the initial retention and the thermal-annealing process depended on the crystal structure, the size and shape of grains, and the concentration of defects in the solids.

The pre-irradiation treatments, involving quenching and irradiation with ionizing radiation, are well known to sensitize the material to the thermal-annealing reaction.[6-11] In the previous studies concerned with the chemical behavior of ^{115}Cd recoil atoms in cadmium phthalocyanine,[12,13] it was suggested that the central metal vacancies introduced in the target by quenching had a strong effect on the subsequent course of the thermal-annealing reaction of the recoil atom.

The present investigation was undertaken in order to see if a similar effect was observed for ^{64}Cu recoil atoms in copper phthalocyanine. The experiment was expected to provide some useful information for the understanding of the detailed scope of the chemical behavior of recoil atoms in the crystalline metal phthalocyanines.

Experimental

Target Material. α-Copper phthalocyanine from Dainippon Ink and Chemicals was carefully purified by recrystallization from sulfuric acid. The β-copper phthalocyanine was obtained by suspending the α-crystal in benzene at 80°C for 2 hr. The X-ray powder diffraction pattern, the electron micrograph, and the thermogram of the materials were recorded.

Irradiation. The neutron irradiation of copper phthalocyanine was performed at the temperature of dry ice (−78°C) for 10 sec in the nuclear reactor, JRR-2, of the Japan Atomic Energy Research Institute. The thermal neutron flux at the irradiation position was 5.7×10^{13} n/cm^2/sec, and the γ-ray dose rate was 1×10^8 R/hr.

For the pre-irradiation treatments with γ-rays, the target was irradiated by means of a 16 kCi ^{60}Co γ-ray source to a dose of 1.1×10^7 R or 1.0×10^8 R at temperatures of −78 and 20°C. The target was then irradiated in JRR-2 for 10 sec at the temperature of dry ice.

Chemical Treatments and Radioactivity Measurements. The procedures of the chemical separation and the thermal treatments used here were virtually identical with those described in the previous paper.[4]

In the quenching experiment, the targets were heated to a specified temperature for 5 hr in an electric furnace and then cooled quickly in liquid nitrogen. The target was stored in dry ice until the neutron irradiation.

The radioactivity was measured by means of a Baird Atomic single-channel γ-ray spectrometer, using the NaI(Tl) crystal as the detector.

Results

It has already been reported that the initial retentions[14] of ^{64}Cu recoil atoms in neutron-irradiated copper phthalocyanine are 5.5% for the α-crystal and 13.5% for the β-crystal,[1,2,4] and that the α-crystal is converted to the β-crystal by heating above 250°C.[4,15,16] The influence of heating the α-crystal prior to the neutron irradiation was examined. The results presented in Fig. 1 show that the initial retention increased, as would be expected, when the target was subjected to

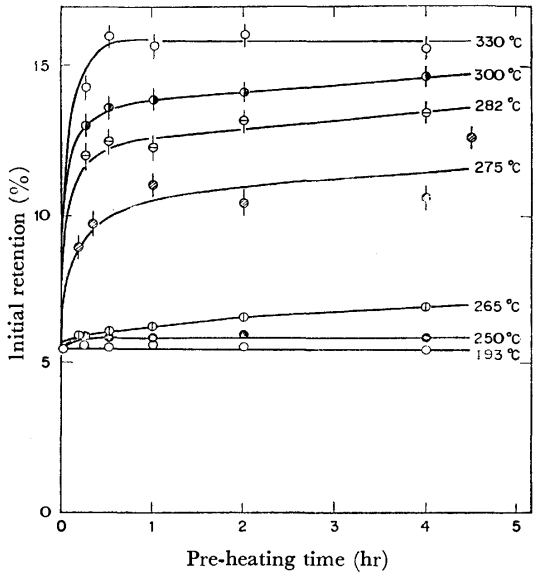

Fig. 1. The change in the initial retention of ^{64}Cu recoil atoms in α-copper phthalocyanine which has been heated before the neutron irradiation.

pre-irradiation heating (pre-heating) above 250°C, reflecting the α-β crystal structural transformation of copper phthalocyanine. The initial retention of the target pre-heated at 330°C reached a slightly higher value than that of the untreated β-crystal. This will be discussed further in the following section.

Table 1 lists the initial retentions of β-copper phthalocyanine pre-heated for 5 hr at various temperatures. It was found that the value increased with an increase in the temperature of pre-heating. Table 2 lists the thermal-annealing data of the pre-heated target in comparison with those of the untreated target. The annealing time of 5 hr was chosen because of the time at which the retention had reached the plateau. The data for the pre-heated α-crystal were the same as those observed for the pre-heated β-crystal. This may be attributed to the fact that the α-crystal has been completely transformed to the β-crystal by pre-heating, as is shown in Fig. 1.

		Untreated	13.5±0.3

The initial retentions of α- and β-copper phthalocyanine, which has been exposed to the ^{60}Co γ-rays before the neutron irradiation, are listed in Table 3. One can find almost the same initial retentions for the α-crystal between the untreated and the γ-irradiated targets. For the β-crystal, however, the initial retention was found to increase or decrease depending on the irradiation temperature of the γ-rays; the initial retention was a little higher at −78°C and lower at 20°C. Figure 2 shows the isothermal-annealing curve of ^{64}Cu recoil atoms in β-copper phthalocyanine which has been irradiated with γ-rays to dose of 1.0×10^8 R before the

neutron irradiation, unlike the untreated target. The annealing curve at 290°C (Stage II) showed a different pattern from that of the untreated target—an increase in the plateau value of the retention. Only a small change in the annealing process was observed at 210°C (Stage I).

Discussion

As is shown in Tables 1 and 2, the heat treatment before the neutron irradiation (pre-heating) raised the initial retention and lowered the plateau of the post-neutron annealing curve in both Stage I and Stage II. It has been reported for tris-acetylacetonatocobalt(III) and -chromium(III) complexes[17] that heating the crystals before the neutron irradiation decreased the initial retention and reduced the thermal annealing reaction. In the case of pre-heating for cadmium phthalocyanine,[13] the initial retention was found to decrease, while the annealable portion increased. These results have been interpreted in terms of defects in the solids, but the role of the defects may vary from one compound to another.

The results obtained for cadmium phthalocyanine, from which the central metal was easily removed, were interpreted in terms of the central vacancy in the crystal, but this interpretation is not valid in the case of copper phthalocyanine, in which the bond strength between the central metal and the ligand is very strong. The central metal of copper phthalocyanine is quite stable under thermal treatment,[18-20] and the metal can not be removed from the central position of the complex. For ionic crystals[10,11] effects similar to those of copper phthalocyanine have been reported. The pre-irradiation heating raised the initial retention and decreased the annealable portion. These results were explained in terms of the thermal removal of defects from the lattice, suggesting that a small fraction of (n,γ)-activated recoils were stabilized only in a reduced state in the lattice by interaction with a "reducing" inherent crystal defect. However, this explanation does not seem applicable to the molecular crystal of copper phthalocyanine.

For copper phthalocyanine it seems possible that the effective crystal imperfection is not a point defect, as has been described for the ionic crystals, but a "dislocation" (a line defect) or a disorder of the molecular configuration, introduced through the recrystallization. Dislocations are thermodynamically unstable, since the enthalpy change associated with the formation of a dislocation is extremely large and since the entropy change is very small.[21] This kind of crystal imperfection can be removed from solids by heat treatment. In the electron micrograph of the α-crystal used here, a large number of "gaps" (separated from one another by some 100's of Å) were observed, while these gaps disappeared in the β-crystal which had been transformed from the α-crystal by heat treatment above 250°C. Dislocations being assumed to trap and stabilize the recoil atom, the results presented in Table 1 may be explained in connection with the "dislocation" in crystalline copper phthalocyanine. The decrease in the "dislocation" with the increase in the temperature of pre-heating should raise the initial retention of ^{64}Cu recoil atoms and reduce the annealable portion in copper phthalocyanine because of the reduction of diffusion processes controlled by the dislocation.

Contrary to the case of cadmium phthalocyanine,[13] the ionizing radiation caused a change in the chemical behavior of ^{64}Cu recoil atoms in copper phthalocyanine. Although the variations were small, the effect of irradiation with ^{60}Co γ-rays for β-copper phthalocyanine seems dependent upon the irradiation temperature of γ-rays. The irradiation at −78°C raised the initial retention and enhanced the thermal-annealing reaction. On the other hand, the initial retention of the target exposed to the ^{60}Co γ-rays at 20°C decreased slightly. The pattern of the isothermal annealing curve was different from that of the other case. An increase in the annealable portion in the Stage-II process (290°C) was seen in both cases.

The temperature dependence observed here may imply that the species produced by the ionizing radiation are different depending on whether the target is irradiated at 20°C or −78°C. The intermediate oxidized species might be produced in the solid under the γ-ray irradiation at 20°C. The intermediate species can be reversed to the parent complex by heat treatment,[22] so that the retention increases in the Stage-II annealing process. The decrease in the initial retention may be ascribed to the fact that the intermediate species stabilize the recoil atom placed in the interstitial position.

In the case of γ-ray irradiation at −78°C, the species which affect the behavior of recoil atoms may be some radiation-induced acceptor which can raise the initial retention. A previous investigation[5] has already revealed that the electron acceptor in the crystalline phthalocyanine is effective in increasing the initial retention of recoil atoms in the complex. However, more experimental data must be accumulated to clarify the effect of ionizing radiation, especially the radiation-induced acceptor.

The author wishes to express his thanks to Professor T. Shiokawa and Dr. K. Yoshihara of Tohoku University for their kind guidance throughout this study. He also wishes to thank Dr. H. Amano and Dr. H. Baba of the Japan Atomic Energy Research Institute for their useful suggestions and discussions.

(Received October 16, 1971)

The pH-induced helix-coil transition of the complex of Cu(II)-poly(α,L-glutamic acid) was studied with polarographic method. The diffusion current was found to change very sharply in a narrow range of pH and this change depended on the amount of Cu(II) ions. The half-wave potential of the complex was also dependent on pH and mixing ratio. The effect of Cu(II) ions on the secondary structure of the polymer was discussed from the viewpoint that the helix-coil transition of PGA is responsible for the change of the mode of binding interaction between Cu(II) ions and PGA sites. Based on the data of diffusion currents *versus* mixing ratios, the helical fractions of the complex at pH 3.4 and 4.0 were evaluated to be 0.37 and 0.11, respectively. From a value of the diffusion coefficient of the complex at pH 5.0, the molecular size in a random-coil form was calculated to be approximately 70 Å in diameter. The coordination number of the complex in the coiled form depended on the mixing ratio; the number was 3.4 in excess of polymer and 0.2—0.3 for the mixing ratio between 3.2 and 13. These values were discussed in terms of the possible mechanism of coordination. Finally, the activation energy of diffusion was obtained for complexes in helical and random-coil forms.

Biopolymers such as nucleic acids and proteins have been known to form specific and/or non-specific complexes with many physiologically important metallic ions. These complexes have been demonstrated to play significant roles in enzymatic or photosynthetic reactions *in vivo*. Towards the ultimate understanding of this complicated biological function, the elucidation of the mechanism of such complex formation *in vitro* has been attempted by means of various physico-chemical methods such as spectroscopy,[2] optical rotatory dispersion,[3] magnetic resonances,[4] potentiometric titration,[5] and polarography.[6]

Synthetic water-soluble homopolyamino acids have usually been employed, as the simplest model compound of natural proteins, to study the effects of secondary structures and conformational transitions upon the complex formation with metallic ions.[7] Among these polymers, the most frequently used one is poly(α,L-glutamic acid), PGA, which has ionizable carboxyl side chain groups and can undergo pH-induced helix-coil transitions. This polymer as such and complexes with metallic ions have also been investigated with aforementioned methods; however, very little has been unraveled regarding the ionic processes of the ligands (*i.e.*, polymer residues) from electrochemical points of view. Recently, some polarographic data of Cu(II)–PGA in the pH-induced helix-coil transition region were provided for the first time.[6]

Besides the numerous applications to metal–amino acids complex formation,[8] polarographic methods are useful in the study of (1) biopolymers which have intrinsic groups reducible at the dropping mercury electrode and (2) those to which some reducible metallic ions are attached extrinsically as a detecting probe. Earlier, Tanford reported that the polarographic limiting current of metallic ions decreased with increase in pH in the presence of bovine serum albumin.[9] He also noted that this observation was due to some complex formation between the protein and metallic ions. However, he was unable to elaborate his result in terms of the conformational transition of the protein. Saroff and Mark[10] also found similar results in the study of serum albumin in the presence of mercury or zinc. Rao and Lal[11] studied the complex formation of zinc and cadmium with native and chemically modified bovine serum albumin. Malik and his associates studied the interaction of copper[12] and lead[13] with transfusion gelatin. Recently, Malik and Jindal[14] reported the binding of copper(II) and cadmium with ovalbumin. Although these proteins are known to have a large fraction of helix,[15] none of these workers has attempted to correlate the secondary structure and the ability of binding to the metallic ions.

that the polarographic diffusion current of the Cu(II)–PGA complex changes with pH in the region between 3.6 and 6.0 and we noted that this change parallels the pH-induced helix-coil transition of PGA. In this paper, we present a further quantitative and detailed work on the pH-induced helix-coil transition of the Cu(II)–PGA complex in aqueous solutions. Our emphasis will lie on the following points: (1) the contribution of the Cu(II) ion to the conformational transition of PGA which can be established from the study of the effect of pH on the diffusion current, $(i_d)_p$, at various molar mixing ratios, R, of glutamic acid residue to Cu(II) ion, (2) the bonding models of Cu(II)–PGA complex which can be estimated from the relation between half-wave potential, $E_{1/2}$, and mixing ratio at various pH's, and (3) the interaction of Cu(II) ions with PGA in either helical or random-coil conformation which can be evaluated from the activation energy of diffusion calculated from the data of temperature effect on diffusion current of Cu(II)–PGA.

Experimental

Materials. PGA, which is in the form of sodium salt, was supplied from Ajinomoto Co., Inc. and used without further purification. An average degree of polymerization of 700-800 was estimated from the intrinsic viscosity in 2M sodium chloride solution at pH 7.0. The mean residue weight of sodium polyglutamate was taken to be 169.[16] Cupric chloride, sodium chloride, and hydrochloric acid were all of analytical grade.

Preparation of sample solutions. In order to maintain the ionic strength of the Cu(II)–PGA complex solution throughout this work at a constant level of 7.5×10^{-3} (which is equal to the final concentration of chloride ions in solution), the sample solution was prepared in such a way that a desired pH value was obtained by adding both hydrochloric acid and sodium chloride solution (which was employed as supporting electrolyte) in appropriate proportions. A stock PGA solution of 1.5 g/100 m*l* or 8×10^{-2}M was diluted prior to measurements. The molar mixing ratios, R, were controlled by varying the concentration of PGA at a constant Cu(II) concentration which was kept to be 5×10^{-4}M in all measurements.

Polarographic measurements. Polarographic limiting currents were measured with a Yanagimoto Model P-8 polarograph. Each current-potential curve was manually obtained by plotting the current at intervals of 10 mV potentials. Since the removal of dissolved oxygen is essential but the bubbling nitrogen gas through a sample solution at low pH causes a separation of fibrous Cu(II)–PGA, it was necessary to degas a hydrochloric acid-containing Cu(II) solution in a glass vessel, which has a narrow outlet and a gas inlet capillary, and a PGA solution in a polarographic cell individually before mixing. These two solutions were then mixed very slowly to avoid precipitation. The mixing order was always a Cu(II) solution to a PGA solution. With this method of mixing the sample solution was successfully prepared at a pH as low as 2.7. After 20 min of degassing, flushing of nitrogen gas was continued while current-potential plots were recorded. The value of $E_{1/2}$ was determined by plotting $\log[i/(i_d-i)]$ against dropping mercury electrode potential. Thus the intercept at $\log[i/(i_d-i)]=0$ yields $E_{1/2}$ and the slope of the plot is a measure of reversibility (see Discussion). A glass capillary, which has a flow rate of 1.0 mg/sec and a drop time of 8.0 sec, was used as dropping mercury electrode.

Verification of polarographic diffusion current. The polarographic limiting currents were measured at four different heights of a mercury column for both helical and coiled Cu(II)–PGA complex solutions. A strictly linear curve was obtained for each solution when the limiting current was plotted against the square root of the height of mercury column. These curves could be extrapolated to intercept the origin for both solutions. Therefore, the limiting current of Cu(II)–PGA solutions at such a low supporting electrolyte concentration as 7.5×10^{-3}M could be confirmed to be diffusion current.

Temperature was kept at 25±0.05°C except when the dependence of diffusion current on temperature was studied.

pH measurements were carried out with a Toa Electronics Model HM-5A pH-meter.

Results

Current-Potential Curves with Variation of pH. Current-potential curves obtained in the pH region between 3.0 and 6.0 with a fixed R value of 16 are shown in Fig. 1. All curves, whose half-wave potentials range from +0.01 to −0.07 V *vs.* S.C.E., are well-defined and reversible. In the pH region between 2.7 and 3.2, where PGA alone is known to be in a helical form, the current-potential curve is almost the same as that of a Cu(II) solution. As the pH of the Cu(II)–PGA solution is increased, the diffusion current decreases steadily. However, when the pH becomes higher than 4.5, the diffusion current approaches a finite value as can be seen from the figure. This polarographic behavior indicates that the formation of Cu(II)–PGA complex depends on pH.

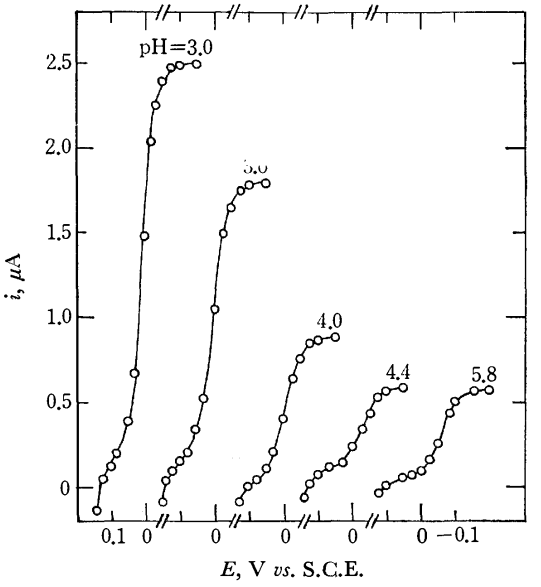

Fig. 1. The pH dependence of current-potential curves of Cu(II)–PGA at $R=16$. R=[PGA]/[Cu(II)]

The Relation between Diffusion Current and pH at Various Mixing Ratios. In Fig. 2, the diffusion currents are plotted against pH at various values of R. Each curve, which shifts toward high pH with decreasing R, shows a sharp decrease in $(i_d)_p$ that is confined in

16) K. Yamaoka, *Biopolymers*, **2**, 219 (1964).

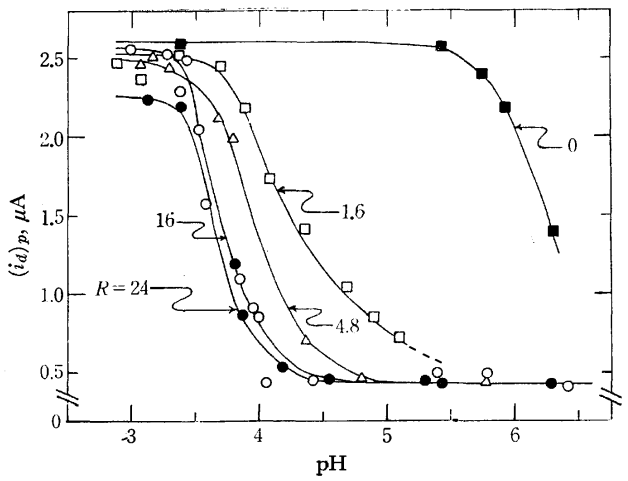

Fig. 2. The relation between diffusion current and pH for Cu(II)–PGA at various values of R as a parameter.[17]

a relatively narrow range of pH. No such change was observed for the Cu(II) aquocomplex solutions ($R=0$) in the same pH range between 3.0 and 5.4; however, the diffusion current gradually decreases as the pH value becomes higher than 5.4. This appears to be due to the formation of insoluble cupric hydroxide.[9] It should be noted here that the shape of the curves in Fig. 2 resembles very closely the pH-induced helix-coil transition of aqueous PGA and further that the shift of the curves as affected by the change in R is very similar to the trend induced by addition of various monovalent neutral salts.[17] This suggests that the Cu(II) ions coordinated with PGA ligands play an important role in the conformational transition of PGA. These conformational transition curves for R of 24, 16, and 4.8 are all similar in shape and approach a finite value which is independent of pH higher than 5.0. The measurements for R higher than 24 were not carried out, since the $(i_d)_p$–pH plot at $R=24$ could be almost superimposed upon that of $R=16$. On the other hand, as R decreases, not only the inflection point of each curve displaces for the higher pH, but also the slope becomes much more gradual (compare $R=24$ with 1.6). The polarographic measurement for $R=1.6$ was limited only up to pH around 5 due to the appearance of coagulated complex.

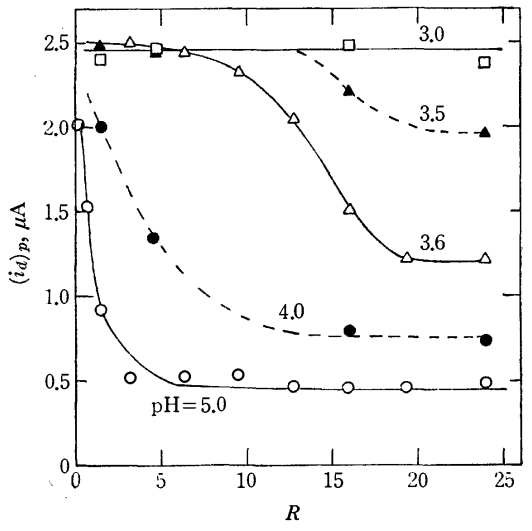

Fig. 3. The relation between diffusion current and mixing ratio at various pH's. Filled circles and triangles (dotted curves) are points read from the curves shown in Fig. 2.

The Relation between Diffusion Current and Mixing Ratio at Various pH's. In Fig. 3, the plots of $(i_d)_p$ *versus* R are shown at some representative pH's. Each of these curves shows its own characteristics. At pH 3.0, where the curves in Fig. 2 reach an upper plateau and apparently the Cu(II)–PGA complexes have the same gross conformation, presumably a rigid helix, the $(i_d)_p$–R curve is almost linear and independent of the values of R examined. At pH 3.6, where the complex may be a mixture of molecules in helical and in random-coil conformation or may possess the helical and random-coil segments in a single molecule, the $(i_d)_p$–R plot decreases gradually but steadily in the R region between 7 and 20, beyond which the curve levels off. Now, in the curve at pH 5.0, where the complex appears to be in a completely random-coil form as judged from $(i_d)_p$–pH curves in Fig. 2, the $(i_d)_p$ values decrease very sharply even at smaller values of R (between 0 and 3); beyond this, however, this curve approaches another plateau. It should be noted that this plateau is much lower than the one at pH 3.6 (see Discussion).

The Relation between Half-Wave Potential and Mixing Ratio at Two Extreme pH's. In Fig. 4, the effect of R on the half-wave potential is shown at the same two pH's as those in Fig. 3. The variation of $E_{1/2}$ with R is obvious at pH 5.0, but no such change is observed at pH 3.0 and 3.6 (not shown).

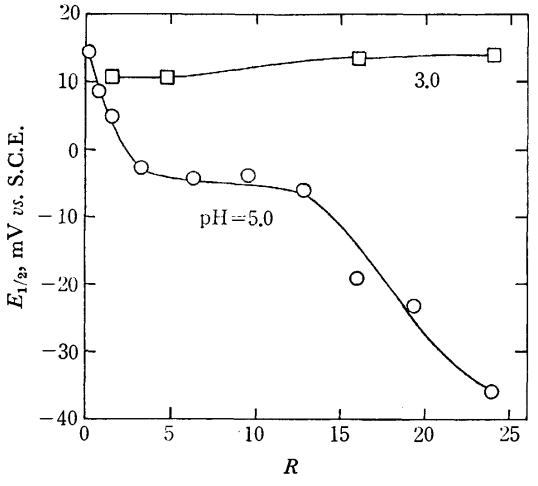

Fig. 4. The relation between the half-wave potential $E_{1/2}$ and the mixing ratio at pH's 3.0 and 5.0

The Effect of Temperature upon Diffusion Current at Two Extreme pH's. In order to obtain the activation energy of diffusion, Q_D, for the complexes in helical (pH 2.7) and random-coil (pH 5.0) conformations, diffusion currents were measured at four temperatures, 10, 20, 30, and 40°C. In Fig. 5, the plots of $\log[(i_d)_p/(m^{2/3}t^{1/6})]$ *versus* $1/T$ are shown at those pH's and at $R=16$. The slopes of the straight lines was found to be −470 and −760 (in degrees) at pH's of 2.7 (curve

17) Triton X-100 (0.01%) was used for the $R=0$ solution.

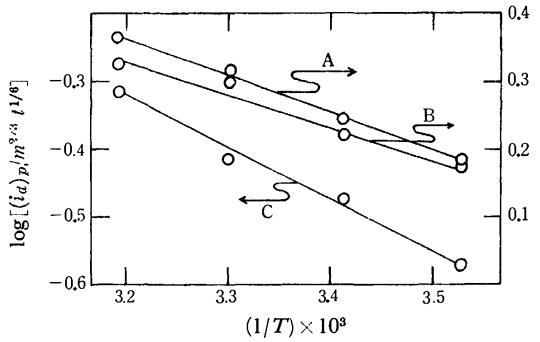

Fig. 5. The effect of temperature upon diffusion current.
Curve A: Cu(II) aquocomplex at pH 3.0;
Curve B: Cu(II)–PGA complex at pH 2.7;
Curve C: Cu(II)–PGA complex at pH 5.0.
Arrows indicate the ordinate to be referred to.

B) and 5.0 (curve C), respectively. A value of −550 was obtained for Cu(II) aquocomplex at pH 3.0 (curve A) for comparison. From these values the activation energy of diffusion can be calculated with the following equation derived by Vlček.[19]

$$\log\frac{(i_d)_p}{m^{2/3}t^{1/6}} = \log(0.627\cdot n\cdot C\cdot F\cdot D_0^{1/2}) - \frac{\frac{1}{2}Q_D}{2.3RT} \quad (1)$$

where C is the concentration of Cu(II) ions; F, the Faraday constant; D_0, a constant. The values of activation energy for Cu(II)–PGA complexes at two pH's and for Cu(II) aquocomplex at pH 3.0 are listed in Table 1.

Table 1. The activation energy of diffusion, Q_D

Sample	pH	R	Q_D (kcal)
Cu(II)–PGA (helical)	2.7	16	4.3
Cu(II)–PGA (random)	5.0	16	6.9
Cu(II) (aquo)	3.0	0	5.0

Discussion

The Role of the Cu(II) Ion in the Conformational Transition of PGA. The observed fact that the diffusion current of Cu(II)–PGA complexes at various values of R abruptly increases with decrease in pH, as shown in Fig. 2, should correspond to the pH-induced helix-coil transition of PGA. This conclusion on the behavior of $(i_d)_p$–pH curves of Cu(II)–PGA complexes is strongly supported by an independent experiment, under the conditions similar to those in this work, of the complex between Cu(II) and monomeric sodium glutamate which shows that the diffusion current does not change over the pH range between 3 and 7.[20] Moreover, the almost parallel shifts of the $(i_d)_p$–pH curves toward higher pH with decrease in R in Fig. 2 might be interpreted that the formation of such Cu(II)-rich complex stabilizes the secondary or helical structure of the polymer.[7]

It is interesting to compare the present results with the report by Takesada *et al.*[7] who noted that the pH-induced helix-coil transition curves in the presence of Cu(II) ions, studied by the method of optical rotatory dispersion, shifted in a similar manner. They observed that, although up to R larger than 20 the transition behavior of Cu(II)–PGA solutions was very close to that of a PGA solution, the slope of the pH-induced transition curves for values of R smaller than 6.6 became more gradual. They attributed their observation to the retention of a helical structure even at a relatively high pH region in the presence of a sufficient number of Cu(II) ions. The transition points in their work range from pH 6.3 to 7.1 (polymer concentration, 0.1 mg/m*l*), whereas the polarographic transition points in our study defined as the midpoint of the increment of diffusion currents, were confined between pH 3.7 and 4.5 (polymer concentration, 1.5 mg/m*l*). This discrepancy is beyond the experimental error and is unable to be attributed to the difference in concentration of polymer or neutral salt.[7] Whether or not it results from the difference in experimental methods employed remains to be resolved.

It is true, in fact, that the polarographic transition point is dependent on the concentrations of the Cu(II) ion and the ligand. As shown in the earlier paper,[6] the point was located at pH 4.2 for the Cu(II)–PGA complex in which the concentrations of the Cu(II) ion, PGA and NaCl were all kept at one-fifth of those employed in this work (in both cases R remained at 16). This is compared in Fig. 6 where the difference of one-half pH unit for two transition points is clearly noted. It should be stated here that the same trend was reported by Takesada *et al.*[7]

The Estimation of the Helical Content of the Complex at Various Values of R. Based on the plots in Fig. 3, it is possible to estimate the helical content of the Cu(II)–PGA complexes in a certain range of R at a

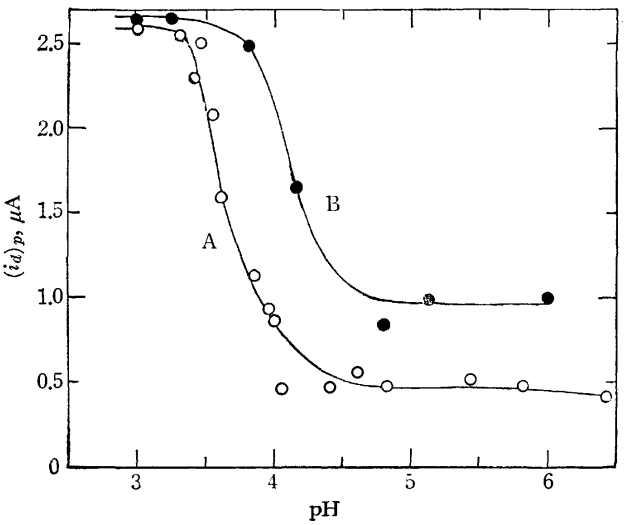

Fig. 6. The diffusion current *vs.* pH curves for two Cu(II)-GPA samples having the same R value of 16 but different concentrations for individual components.
Curve A: $[Cu(II)]=5\times10^{-4}$M, $[PGA]=8\times10^{-3}$M, $[NaCl]=7.5\times10^{-3}$M.
Curve B: $[Cu(II)]=10^{-4}$M, $[PGA]=1.6\times10^{-3}$M, $[NaCl]=1.5\times10^{-3}$M.
The scale of $(i_d)_p$ for curve B is expanded by a factor of 5. These data are taken from Ref. 6.

19) A. A. Vlček, *Collection Czechoslov. Chem. Commun.*, **24**, 3538 (1959).
20) To be published.

given pH. Here, we make the following assumptions. (1) The value of the diffusion current at pH 3.0, which is designated as $(i_d)_p^h$, represents the diffusion current of a Cu(II)–PGA helix. (2) Similarly the diffusion current of the complex at pH 5.0 in the range of R larger than 5 is due to random-coil PGA molecules which completely coordinate to all Cu(II) ions present in solution; this value is designated as $(i_d)_p^r$. The helical fraction, f_h, at a given pH and R, at which the observed diffusion current is $(i_d)_p$, is then given by the following expression

$$f_h = \frac{(i_d)_p - (i_d)_p{}^r}{(i_d)_p{}^h - (i_d)_p{}^r} \tag{2}$$

For a Cu(II)–PGA complex at pH 3.6, f_h is calculated to be about 0.37 in the range of R larger than 20 where $(i_d)_p$ is constant. Similarly an estimate is made for the complex at pH 4.0, in which f_h is 0.11 in the range of R larger than approximately 10.

Now, the question arises on what extent of helical fraction a complex possesses at a given pH and R where the diffusion current is continuously changing (*i.e.*, in the range of R between 5 and 18 for pH 3.6 and between 0 and nearly 10 for pH 4.0, *cf.* Fig. 3). There are two interpretations possible from the present data only. At first, the helical fraction of the complex at a fixed pH of 3.6 steadily increases as R becomes smaller, *i.e.*, the more Cu(II) ions are added, the more stable does the helix become. This is the view promoted by Takesada *et al.*[7] based on the results of an ORD study; however, this interpretation is not unique. An alternative is that the steady increase in $(i_d)_p$ for R smaller than 18 is in actuality the reflection of a chemical process in which the number of the bound Cu(II) ions remains constant at a certain level regardless of apparent values of R; in other words, the increase in $(i_d)_p$ is mostly due to free Cu(II) ions. If this is true, the notion that the presence of the Cu(II) ion in PGA facilitates or enhances the helical formation must critically be reexamined.

The Estimation of the Molecular Size of the Complex from Diffusion Currents. From analysis of diffusion currents, we are able to estimate the molecular size of Cu(II)–PGA complex in a random-coil conformation and to obtain some insight into the mechanism of the interaction between the Cu(II) ion and PGA in a helical conformation. Assuming that the Cu(II)–PGA complex at pH 5.0 is an impenetrable, rigid sphere and that the Stokes-Einstein equation (Eq. (3)) can be applied to the polarographic diffusion process prior to electrode reduction, the radius of such a sphere, r, can be estimated by

$$r = \frac{RT}{N}\frac{1}{6\pi\eta D} \tag{3}$$

where R is gas constant; N, the Avogadro number; T, the absolute temperature (=298°K); η, the viscosity of water ($=0.89\times10^{-3}$ g/cm·sec at 25°C). The diffusion coefficient, D, is calculated with the aid of Ilkovič's equation;

$$D = \left[\frac{(i_d)_p}{605\cdot n\cdot C\cdot m^{2/3}\cdot t^{1/6}}\right]^2 \tag{4}$$

where the following numerical values are adopted:

Table 2. Diffusion coefficients and other pertinent data

	Concentration (mM)	pH	Mixing ratio	$(i_d)_p$ μA	$D\times10^7$ cm²/sec
Cu(II)–PGA	0.5	5.0	16	0.37	7.36
Cu(II)–PGA	0.5	3.0	16	2.50	77.3
Cu(II)–PGA	0.1	5.0	16	0.20	9.00
Cu(II)–PGA	0.1	3.0	16	0.50	68.0
Cu(II)	0.5	3.0	0	2.60	78.0
Cu(II)	0.1	3.0	0	0.53	63.0
Cu(II)	—	—	—	—	72.0[a]

a) I. M. Kolthoff, and J. J. Lingane, "Polarography", Vol. 1, Interscience Publishers, New York, N. Y., (1952) p. 52.
b) S. Inoue, and H. Imai, This Bulletin, **33**, 149 (1960).

$(i_d)_p=0.37$ μA, $C=0.5$ mM, $n=2$, $m=0.989$ mg/sec, $t=8.14$ sec at pH 5.0. In Table 2 the diffusion coefficients of the complexes and other pertinent data are tabulated. As can be seen from Table 2, the diffusion coefficients calculated from our data are in good agreement with those of previous workers. The radius of the assumed sphere of the Cu(II)–PGA complex at pH 5.0 is then calculated to be 33 Å, the value of which yields a molecular volume of 1.5×10^5 Å³. This value is quite consistent with a calculated volume for PGA (details will be published in due course).

The Estimation of the Coordination Number of Cu(II)–PGA Complexes in a Random Conformation. If an electrode reaction proceeds reversibly[21] by the reduction of a complexed Cu(II) ion to a metallic state at the dropping mercury electrode, then the following expression can be applied to obtain the coordination number, j, of such a complex at a given temperature.[22]

$$\frac{d(E_{1/2})}{d(\log C_x)} = -j\frac{0.0591}{n} \tag{5}$$

Thus, from the slope of the $E_{1/2}$-log C_x curve, a value of j can be evaluated. To derive this expression the following assumptions are made:[21] (1) the diffusion current constants of both metallic ion and complex are independent of the respective concentrations, (2) a term containing the activity coefficients of chemical species in solution may be dropped out, and (3) C_x should be the concentration of the free ligands which, however, can be approximated as the total concentration of ligands.

In Fig. 4, the $E_{1/2}$ of Cu(II)–PGA complex was shown to vary in a distinctive manner with the value of R at pH 5.0 where the complex is in a random form, in contrast with the $(i_d)_p$ which, as shown in Fig. 3, remained constant for R larger than 5.0. The $E_{1/2}$ values were replotted in Fig. 7 against the logarithm of the total concentration of PGA in solution, C_x, which is equal to R times the concentration of the Cu(II) ion. Two linear portions cross at log $C_x=-2.2$. From the slope of the straight line A, a j value of 3.4 is yielded. Simi-

21) This assumption was verified by determining the slope of a plot of $\log[(i/(i_d)_p-i)]$ versus electrode potentials. A value of two was assumed for n.
22) D. R. Crow, "Polarography of Metal Complexes", Academic Press, London, 1969, p. 62.

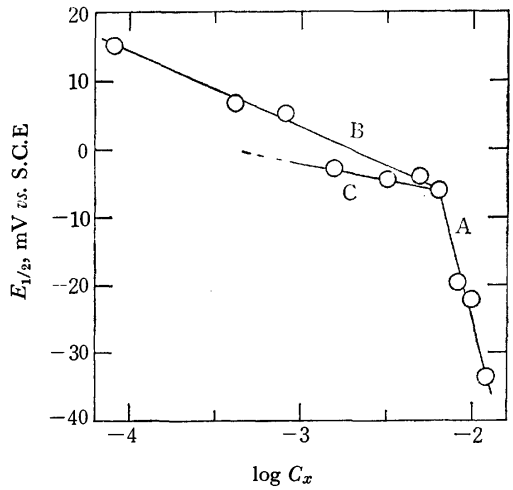

Fig. 7. The Relation between half-wave potential and logarithm of the total concentration of PGA at pH=5.0 and R=16. $C_x=R\cdot$[Cu(II)]

larly, the lines B and C result in j values of 0.34 and 0.17, respectively. It should be noted that the portions A and C correspond to the range of R (from 3 to 24) where $(i_d)_p$ remains unchanged (see Fig. 3). From these j values it is clear that the number of binding sites on each PGA residue changes with the value of R or the concentration of PGA. The coordination number of 3.4 (which reduces to 2.9 when the concentration of free ligands is taken for C_x) indicates that approximately three peptide residues coordinate to each Cu(II) ion as an average. Since each residue possesses three capable sites—amide nitrogen and oxygen atoms and a carboxyl side chain, nine binding sites at maximum are allowable to participate in complex formation. The exact number or stereochemistry, however, is undeterminable.

Assumed that the sharp increase in $(i_d)_p$ at pH 5.0 ($R<3$) shown in Fig. 3 is entirely due to the free Cu(II) ion released from the complex and, consequently, the line B has no meaning, the j value of 0.17 from line C should be interpreted as due to that each PGA residue apparently coordinates to about five Cu(II) ions. This result excludes the possibility that the same type of chelation as occurred in portion A also exists. Therefore, a most plausible mode of binding in portion C is an electrical or ionic pairing with PGA residue. However, if the entire portion of B is meaningful and the whole change in the $(i_d)_p$–R curve at pH 5.0 is assumed to be caused by the electrostatic interaction as described in Results, the j value of 0.34 means that each residue coordinates to three Cu(II) ions. The differentiation of these two ideas awaits a further study. In any case the data in Fig. 7 clearly show that the binding mode of Cu(II) ion to PGA residue changes with the mixing ratio even if the gross conformation of the complex is random-coil.

The Activation Energy of Cu(II)–PGA Complexes in Helical and Coiled Conformations. As can be seen in Figs. 3 and 4, the binding mode of Cu(II)–PGA complex in helical form should differ from that in coiled form. The data in these figures should reflect the difference of the diffusion of these complexes toward the electrode prior to electrode reduction. The difference between the value of Q_D of the Cu(II)–PGA complex at pH 2.7 and that of the complex at pH 5.0 listed in Table 1 clearly indicates that the mechanism of diffusion is affected by the secondary structure of Cu(II)–PGA complex. The finding that the Q_D value of the complex in helical conformation is almost the same as that of the free Cu(II) aquocomplex suggests that the interaction between Cu(II) ion and helical PGA molecule is weak, if any; hence, the loose interaction is likely to be ionic in nature. As the complex diffuses toward electrode, the loosely bound Cu(II) ions may be unsheathed or "zipped-off" to reduce at the electrode surface. The activation energy of diffusion for Cu(II)–PGA complex at pH 5.0 is 60% greater than that at pH 2.7. This means that Cu(II) ions are tightly or coordinately bound with PGA in the coiled region, and that the complex diffuses to the surface as a whole. Or alternatively, the amount of energy corresponding to break the bonds between Cu(II) ion and PGA is required to make unbound free aquo-ions diffuse.

Finally, from the present and earlier studies,[6] it is concluded that the relationship between the polarographic diffusion current and pH is clearly established and definitely reflects the pH-induced helix-coil transition of Cu(II)–PGA complex. These polarographic studies enable to provide rich information on characteristics of the complex in aqueous solutions such as molecular size, helical fraction, mode of coordination, and activation energy of diffusion.

Many thanks are due to our colleague, Dr. Y. Tadokoro of Hiroshima University, for determining the molecular weight of PGA and also for participating in discussion and reading this manuscript. The authors are indebted to Ajinomoto Co., Inc. for supplying PGA samples used in this work.

An MO-theoretical Study of the Nucleophilic Bimolecular Ring-opening of Ethylene Oxide

Hiroshi FUJIMOTO, Motohiro KATATA, Shinichi YAMABE, and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received October 30, 1971)

The results of an approximate molecular orbital (MO) calculation of the interaction energy of the ring-opening of ethylene oxide by a hydride ion are presented. The method of calculation is based upon the isolated-molecule approximation. The interaction energy was divided into the Coulomb, exchange, delocalization, and polarization interaction terms, and the changes in these four terms with the progress of the reaction were investigated. The wave function of the combined system of ethylene oxide and a hydride ion was obtained by the configuration interaction (CI) procedure. The changes in the electron populations of ethylene oxide and the hydride ion were calculated from the ground-state CI wave function. Among the unoccupied MO's of ethylene oxide, two low-lying unoccupied MO's were shown to be of special importance in the electron transfer from the attacking anion to ethylene oxide. The effect of the deformation of the molecular shape upon the interaction energy and the intermolecular bond formation is also discussed.

In order to elucidate the origin of the stereoselectivity in chemical reactions, several MO calculations of intermolecular interaction have been carried out.[1-5] These approaches have all intended to discuss the favorable path of several kinds of reaction in light of our knowledge of the MO's of the two reactants in an isolated state. Although the applications of these studies have been limited to the early stage of chemical interaction, they have been believed to be able to give rather detailed information about chemical reactions. The interaction energy between two systems can reasonably be divided into several terms,[4,6,7] to examine what kinds of interactions are important in a given reaction. We previously represented the interaction energy as approximately the sum of four terms, the Coulomb, exchange, delocalization, and polarization interaction energies.[8] Some succinct expressions for these terms were obtained by adopting LCAO SCF MO's. A discussion has also been presented on the role of each of these four terms in determining the favorable path of the bimolecular nucleophilic substitution reaction of methyl chloride, based upon the results of approximate numerical calculations.[9]

It is well known that the bimolecular nucleophilic ring-opening reaction of epoxides takes place stereoselectively, with the preferential occurrence of the inversion at the carbon atom to be attacked by the anion.[10] In the present paper we will discuss the effect of the four energy terms on the determination of the favorable path of the ring-opening of ethylene oxide. The attacking anion is simply represented by a hydride ion. A possible influence of the molecular deformation upon the ease of interaction will also be investigated.

Interaction Energy

The method of the present calculation is based on the concept of the isolated-molecule approximation. That is, the interaction energy between a hydride ion and ethylene oxide, and the changes in the electron populations due to the interaction, are expressed in terms of MO's, which are obtained with respect to each of the two species in the isolated state. We represent the wave function of the interacting system composed of a hydride ion and ethylene oxide as approximately (the symbols are the same as those in Ref. 8);

$$\Psi = C_0\Psi_0 + \sum_j^{\text{uno}} C_{h\to j}\Psi_{h\to j} + \sum_i^{\text{occ}}\sum_j^{\text{uno}} C_{i\to j}\Psi_{i\to j} \qquad (1)$$

where i and j denote the occupied and unoccupied MO's of ethylene oxide, and where h denotes the doubly-occupied orbital of the hydride ion. Although it may be interesting to include outer-shell orbitals, tentatively we do not regard unoccupied orbitals for the hydride ion. Then, the interaction energy, ΔW, between the two may be given approximately by:

$$\Delta W = \varepsilon_Q + \varepsilon_K - D - \Pi \qquad (2)$$

where ε_Q is the Coulomb interaction energy, ε_K is the exchange interaction energy, D is the delocalization interaction energy, and Π is the polarization interaction energy. The last two terms can be expressed in the second-order perturbation forms, provided the interaction is not yet strong.[8]

Calculation on Isolated Molecules

The MO's of ethylene oxide were obtained by a semi-empirical valence-electrons SCF MO method. The method of calculation and the approximations employed are the same as those used in the previous calculation.[9] In Fig. 1 are shown the MO levels.

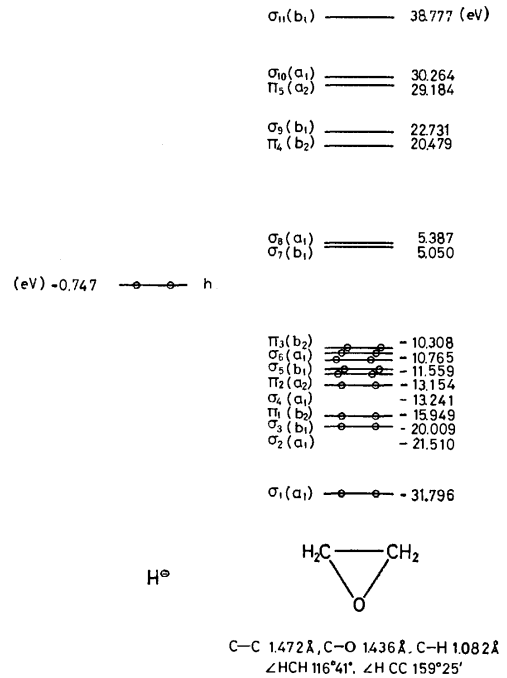

Fig. 1. MO energy levels of ethylene oxide and hydride ion.

The calculated ionization potential is 10.31 eV, showing a good agreement with the observed value, 10.562 eV.[11] There exist two relatively low-lying unoccupied MO's, having almost the same energy. Here, both of these two MO's may be regarded as the lowest unoccupied (LU) MO's. One of them belongs to the irreducible representation, a_1, and the other, to b_1, of the C_{2v} point group. The shapes of these two MO's are illustrated in Fig. 2. It is noted that both of these two MO's have nodes between carbons and oxygen. The energy level of the hydride ion was taken to be −0.747 eV, equal to the minus electron affinity value

Calculation of the Interaction Energy

Table 1 gives the results of the calculation of the

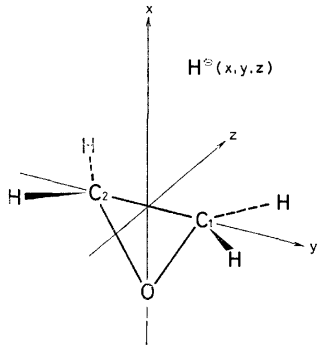

Fig. 4. A schematic representation of assumed reaction models.

interaction energy terms with respect to several assumed models. Each model corresponds to a location of the approaching hydride ion, as is indicated in Fig. 4. The interaction energies have been obtained in a manner similar to that used in previous calculations.[9,12] In the early stage of interaction, in which the hydride ion is distant, the Coulomb interaction term is dominant among the four energy terms. As the hydride ion gets near to ethylene oxide, the exchange and delocalization interaction terms rapidly increase. Because of the crudeness of the approximations employed, the relative magnitudes of the four energies are not trustworthy in a quantitative sense. The present calculation may, rather, be regarded as disclosing, only qualitatively, the possible directing effects of the four energy terms in this reaction. That is, it may be said that the Coulomb term favors the attack of the anion along the principal axis, while the other three require the approach of the anion apart from that axis. The delocalization interaction energy depends greatly on the nodal properties of the LUMO's. When the anion approaches ethylene oxide in a manner like Models Ia, Ib, Ic, ···, the 1*s* orbital of the hydride ion interacts with only one of the LUMO's with the a_1 symmetry, while in the course IIa, IIb, IIc, ···, or IIIa, IIIb, IIIc, ···, the hydride 1*s* orbital can overlap with both of the two LUMO's. The polarization interaction is found to be less important than the delocalization interaction as hydride comes nearer to ethylene oxide. The comparison of Models VI and VII with Models Ib—Vb seems to indicate the preference of inversion at the carbon atom to be attacked by the anion; this is in accordance with the experimental results.[10]

As the reaction proceeds, the initial molecular geometry of the reactant changes. The deformation in the molecular structure is accompanied by changes in the interaction energy terms through the changes in spatial functions and MO energy levels. In order to examine this problem, we have carried out further calculations

12) One-center core attraction integrals $v_{att}=\int t(1)(-Z_\alpha e^2/r_{\alpha 1})t(1)dv(1)$ (the AO t belongs to the nucleus α) were evaluated in a different way from the previous calculation. They were modified so as to make the quantity $\{v_{att}+\sum_{t'}^{\alpha} n_{t'}(t't'|t't')\}$ give the same value both for the non-empirically calculated and for the semi-empirically estimated cases, where $n_{t'}$ means the occupation number of the AO t' of the atom α.

a) in Å

while altering the shape of ethylene oxide. Here, we tentatively stretch the C_1–O bond by 0.2 Å. Although this value is arbitrary, such a configuration would be rather in conformity with the deformation along the reaction path. By this deformation, the LUMO's, which are nearly degenerate in ethylene oxide of the symmetrical configuration, split by about 3.8 eV. The shape of the LUMO of the deformed ethylene oxide is shown in Fig. 5. Table 2 presents the results of the calculation of the interaction energy for some assumed locations of the approaching hydride ion with respect to the deformed ethylene oxide. The results in Table 2 seem to indicate that the departure of the hydride ion from the bisecting axis of the C–C bond is assisted by the deformation of the ring. We find the most significant influence of the molecular deformation on the energy term D. It is interesting that the delocalization energy is large when the hydride ion approaches from the direction of the maximum extension of the LUMO of ethylene oxide. The effect of the molecular deformation appears to be a matter of gerat significance in applying the isolated-molecule approximation.

Electron Populations

The coefficients of Eq. (1) calculated for the lowest energy state of the combined system of two reacting species are shown in Table 3. We can see that the most contributing term to Ψ except Ψ_0 is the charge-transferred configuration from the hydride ion into the a_1 LUMO, and that the next contributing is that from the hydride orbital into the b_1 LUMO of the symmetrical-form ethylene oxide. The preferential contribution of a_1 MO to b_1 MO is attributable to the nodal properties of these MO's. The deformation of the nuclear configuration also promotes the mixing of charge-transferred states, as is clear from the comparison of Models IIIb and III′ in Table 3. In obtaining the wave functions, the locally-excited configurations of ethylene oxide were tentatively neglected, since they were thought to have little influence upon the intermolecular electron transfer.

The changes in the electron populations due to the interaction can be calculated by the use of Eq. (1).[13] The AO bond populations between the hydride 1s orbital and the AO's of the carbon atoms of ethylene oxide, obtained from the ground-state CI wave function, are shown in Table 4. The bond formation between the hydride ion and the carbon atom of ethylene oxide under attack is most effective in the model in which the delocalization interaction energy is the largest. The AO of the carbon atom 1, which plays the most dominant role in the formation of the intermolecular bond with the hydride ion, is the p_x orbital, which has its maximum extension in the direction of the approach of the anion. In order to calculate the AO populations of both reactants, we should divide the effused fraction of electrons over the intermolecular region through the overlapping of the AO's h of hydride and t of ethylene oxide into two parts, the one constituting a part of the AO population of the AO h, and the other, that of the AO t. This partitioning may be an extension of Mulliken's population analysis to intermolecular AO pairs.[14] The changes in the atomic populations and in the atomic-bond

14) R. S. Mulliken, *J. Chem. Phys.*, **23**, 1833, 1841, 2338, 2343 (1955).

populations of ethylene oxide are shown in Fig. 6 with respect to some of the models mentioned before. The figures in parentheses indicate the changes in atomic-bond populations from those in an isolated state. The atomic-bond populations of the C–O bonds decrease in the case of the interaction with the hydride ion. The results in Table 4 and in Fig. 6 demonstrate that both the formation of new bonds and the weakening of old bonds are accelerated by the molecular deformation. This result is consistent with our previous proposition that the cooperation of the electron delocalization with the change in the molecular shape is a possible driving force in chemical reactions.[15]

Conclusion

We have presented the results of a semi-empirical calculation of the chemical interaction energy and the bond interchange in the ring-opening reaction of ethylene oxide with a hydride ion. Because of the simplification of the reaction model and the crudeness of the calculation, we must refrain from drawing any decisive conclusion about the reaction path from our present results. We can only remark that the path of the approach of the hydride ion to ethylene oxide is very likely to be governed by a delicate balance of the four energy terms presented here. Among charge-transferred states, the one in which an electron of the hydride ion is transferred into the LUMO of ethylene oxide is most important. Molecular deformation along the reaction path appears to be of considerable significance, influencing the ease of the chemical interaction. The effect has been found to be striking in the delocalization interaction energy. The present calculation should not be looked upon as necessarily intending to search for the reaction coordinate leading to the transition state of this special reaction. They will better serve to provide a rough estimate of the directing effect of the four energy terms, and of the bond interchange with respect to some locations of the attacking anion, in the early stage of the reaction. We hope only that we can extend the calculations to a region of moderate interaction.

It is a pleasure to express our gratitude to the Data Processing Center, Kyoto University, for its generous permission to use the FACOM 230·60 computer.

The Amine Sensitization of the Fluorescence of Tris-(dibenzoylmethano)europium(III)

Tadashi FUKUZAWA and Nozomu EBARA

College of General Education, The University of Tokyo, Tokyo

(Received July 8, 1971)

The effect of amines on the efficiency of fluorescence of tris(dibenzoylmethano)europium(III) has been investigated in a methanol solution. Amines with low pK_b values seem to form 1 : 1 complexes with the chelate, and the change in the fluorescence intensity of the chelate is due exclusively to the formation of a complex, which fluoresces more strongly than the chelate itself. It seems that the sensitization of the fluorescence is due to the change in the relaxation lifetime. In the case of amines with aromatic moieties, sensitization through energy transfer may also take place, but this never occurs unless the amine molecule is present in the complex. The structure of the complex and the mechanism of sensitization are discussed.

Fluorescence in rare-earth chelates has been a subject of extensive study[1-5] because of its prospective applicability in laser devices. The excitation of the chelates in a wavelength region where only the ligands absorb light results in high yields of a sharp emission characteristic of the rare-earth metal ions. The intramolecular energy-transfer process has been investigated by Crosby, Whan, and Alire,[6] who compared the fluorescence of several rare-earth chelates and concluded that the transfer of energy from the ligands to resonance levels of metals took place *via* the triplet states of the ligands. Bhaumik and El-Sayed[7] have studied the sensitization of the fluorescence of the chelates by benzophenone and supported the above mechanism.

On the other hand, the third-body effect on the fluorescence efficiency of chelates has been investigated by

several authors,[8,9] in the expectation that an increase in the fluorescence quantum yield might favor its laser activity. These authors found that the addition of several amines or alkylphosphine oxides greatly affected the quantum yields of the europium resonance fluorescence in the solid state. These investigations, however, lacked quantitative treatment and involved no apposite mechanism of sensitization. Systematic studies are required to account for the sensitization scheme in the fluorescence of europium chelates. The present paper will deal with the effect of several amines on the fluorescence yield of tris(dibenzoylmethano)europium(III) (EuD_3) in a methanol solution.

Experimental

Materials. Tris(dibenzoylmethano)europium(III) was prepared from europium oxide and dibenzoylmethane according to the method of Charles and Perrotto.[10] Yellow prisms, mp 231°C.

Tris(dibenzoylmethano)cobalt(III) was prepared from cobalt oxide and dibenzoylmethane according to the method of Ginestra and Marucci.[11] Green prisms, mp 232°C.

The amines used were G. R.-grade triethylamine, piperidine, octylamine, benzylamine, 4-aminopyridine, *N*-1-naphthylethylenediamine, 9-aminoacridine, pyridine, aniline, *N*-methylaniline, *N*,*N*-dimethylaniline, acridine, 1-naphthylamine, *N*,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine, and 2,5-diphenyloxazole; they were purified repeatedly by vacuum distilation or by recystallization.

Commercially-available spectrograde methanol, chloroform, and tetrahydrofuran were used as solvents without further purification.

Methods of Measurements. The absorption spectra were measured with a Hitachi EPS-2 type spectrophotometer, using 10 mm × 10 mm quartz cells. It is very important to note that the difference spectrum exhibited a marked irregularity when both the reference and sample solutions showed large extinctions. Therefore, care was taken to avoid this wavelength range.

The fluorescence excitation spectra were measured as follows. The sample solutions contained in a 1 mm × 10 mm quartz cell were excited with a 500 W Xenon arc through a Beckmann monochrometer. The radiation from the light source was modulated with a sector and was focused by a quartz lens at a normal incidence on the 10-mm surface of the cell. The fluorescence radiation emitted through the 1-mm surface of the cell was led into a photomultiplier, HTV 374, through several filters. The output of the photomultiplier was amplified with a PAR 122 Lock-in amplifier and displayed on a Toa EPR-2T recorder.

Results and Discussion

Complex Formation. Tris(dibenzoylmethano)europium(III) (EuD_3) and triethylamine were mixed at 15°C in a methanol solution, the concentration of the former being kept constant (7.67×10^{-5} mol/*l*), while that of the latter was varied. The solutions were left standing for more than 30 min, and then the difference spectra of the solutions were measured against a EuD_3 reference solution of the same concentration as that of the sample solutions (Fig. 1). A new peak appeared near 390 mμ, at which the amine did not absorb light, and the chelate absorption peak at 352 mμ seemed to shift gradually towards a shorter wavelength. The spectrum showed isosbestic points and indicated that a single complex was formed.

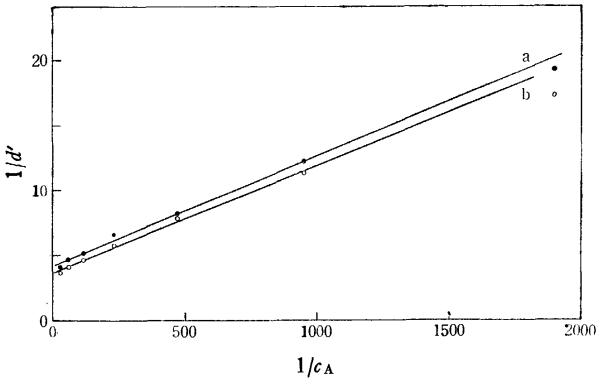

Fig. 2. Plot of $1/d'$ against $1/c_A$ for the mixtures of EuD_3 and triethylamine
a. at 384 mμ, b. at 396 mμ

The plot of $1/d'$ at several wavelengths against $1/c_A$ according to the following equation gave straight lines (Fig. 2), which showed that an equilibrium was reached between the chelate and the triethylamine to form a 1 : 1 complex[12];

$$1/d' = (1+1/c_EK)/(\varepsilon_C-\varepsilon_E)c_A + 1/(\varepsilon_C-\varepsilon_E)c_E$$

where d' is the optical density of the difference spectrum; c_E and c_A, the initial concentrations of the chelate and

amine respectively; ε_E and ε_C the molar extinction coefficients of the chelate and the complex respectively, and K, the equilibrium constant.

Similar plots gave similar straight lines when piperidine, octylamine, benzylamine, 4-aminopyridine, and *N*-1-naphthylethylenediamine were used instead of triethylamine (Fig. 3). The calculated equilibrium constants are listed in Table 1. In the case of 9-aminoacridine, the regular change in the spectrum indicated that a complex was formed, but the change was too small to allow an evaluation of the equilibrium constant.

	tetramethyl-phenylenediamine	6.76		
	diphenyloxazole	—		

a) $F(C)$: calculated fluorescence intensity of the complex
b) value of ethylenediamine

On the other hand, aromatic amines such as pyridine, aniline, *N*-methylaniline, *N*,*N*-dimethylaniline, acridine, 1-naphthylamine, *N*,*N*,*N'*,*N'*-tetramethylphenylenediamine, and 3,5-dipehnyloxazole showed no evidence of forming complexes.

An inspection of Table 1 suggests that the ease with which the complex is formed is determined mainly by the following two factors:

1) Only amines with low pK_b values (lower than 5 in the present case) tend to form complexes. This parallelism is not consistent with the other properties of amines, such as the ionization potentials and the dipole moments.

2) The steric factor affects the equilibrium constant. The equilibrium constant is greater for primary amines and smaller for secondary or tertiary amines. In the case of 9-aminoacridine the equilibrium constant seems to be small, probably because of the dense steric disposition in the proximity of ring nitrogen.

Charles and Ohlmann[8] have prepared solid 1 : 2 complexes of EuD_3 with several amines involving pyridine and aniline (a 1 : 1 complex in the latter case) and have suggested that the amine is attached directly to the europium atom. This assumption has been supported by later workers[13-15] because of its consistency with current theory and with the experimental results, as exemplified by an X-ray analysis of a hydrated EDTA complex of lanthanum $LaAH_4\cdot7H_2O$ (AH_4 means the acidic form of EDTA) by Hoard *et al.*,[16] who showed that four of seven water molecules in the crystal were bonded directly to the La atom. They nevertheless did not reject the possibility that some of the complexes were formed by a van der Waals force (or a charge-transfer force) between the amine and the ligand. It is evident that the present result conforms to the assumption of Charles, in which a dative bond is formed between europium and nitrogen by the intrusion of amine molecules into the ligands.

To confirm the assumption more directly, we have prepared tris(dibenzoylmethano)cobalt(III) (CoD_3) and examined whether it could form complexes with amines in tetrahydrofuran or in chloroform. As the coordination number of Co(III) is six, and since it never exceeds six, the formation of a complex, if ever, must involve interaction between the amine and the ligand. Our experiment showed that CoD_3 formed no complex with triethylamine. It is hoped that the NMR chemical shift measurement of the NH proton in a complex of EuD_3 with a primary or secondary amine will reveal unambiguously the bonding aspect.[17-19]

The present experiment differed from that of Charles

in that the complex was 1: 1 rather than 1: 2 and in that pyridine and aniline formed no complex: this is not surprising, because the amine molecule had to replace the already-bonded solvent molecule to form a complex in the solution. In fact, the spectra of the mixture solutions of EuD_3 and aliphatic amines turned out to change within a short time after mixing, with the above consideration. The details of the time dependence will be presented elsewhere.

Fluorescence. The above mixed solutions of EuD_3 and amines have been subjected to the measurement of their fluorescence excitation spectrum. The excitation of the chelate in the ultraviolet region gave rise to a sharp red emission which peaked at 612 mμ; this was identified with the europium resonance fluorescence from $^5D_0$ to $^7F_2$.[2] In the case of amine which did not fluoresce, such as triethylamine, piperidine, or octylamine, the excitation spectra of the mixed solutions were measured with this emission peak alone. When amine itself fluoresced, as in 1-naphthylamine, the excitation spectra of a chelate solution (E), amine solutions (A) of various concentrations, and mixed solutions (M) in which the concentrations of the solutes were the same as in E and A were measured either with a 612 mμ emission (e) using Toshiba filters VR-60 and UV-39 or with an appropriate wavelength range (a) in which the amine fluorescence had an appreciable oscillator strength, but neither the amine nor chelate absorbed radiation. In the cases of 1-naphthylamine and *N*-1-naphthylethylenediamine, for example, the 422—520 mμ region using a combination of filters, UV-39, VV-42, and VY-44, was found to be appropriate.

For the sake of conciseness and clarification, the following notations are adopted:

F(A) and F(E)
fluorescence intensities of the amine solution and the chelate solution respectively

F(M)
fluorescence intensity of the mixed solution

F_A(M) and F_E(M)
parts of F(M) due to amine and europium respectively, so that $F_A(M)+F_E(M)=F(M)$

F^e and F^a as in F^e(A)
fluorescence intensities measured at 612 mμ (e) and at (a)

The excitation wavelength and the concentration of the amine are not specified.

The intensities were corrected for absorption and the emission of the partner molecules as follows:

1) The fluorescence of amine occasionally had a nonvanishing intensity, even at 612 mμ, at which point the europium fluorescence was to be measured (perhaps due to the low resolution of the filters). To obtain the intensity of the europium fluorescence at this wavelength in the mixture, F_E^e(M), the portion of the intensity due to amine, F_A^e(M), must be subtracted from the observed value, F^e(M). As the amine fluorescence was found to be affected strongly by the presence of a chelate, as will be shown later, F_A^e(M) can not be equated with F^e(A), but is obtained by:

$$F_A^e(M) = F^e(A) \times F^a(M)/F^a(A)$$

It is to be recalled that the effect of absorption on the above values has already been eliminated.

On the contrary, the observed fluorescence intensity, F^a(M), can be ascribed solely to amine, so that only the succeeding correction applies in this case.

2) The amine and chelate absorbed radiation at the same time in the exciting wavelength range, thereby reducing mutually the number of photons which, otherwise, were to be absorbed by the partner molecules. This was taken into account by multiplying the respective intensity values, F_E(M) or F_A(M), by:

$$f = (c\varepsilon+c'\varepsilon')[1-\exp(-c\varepsilon l)]/c\varepsilon[1-\exp\{-(c\varepsilon+c'\varepsilon')l\}]$$

where l is the cell length (0.1 cm). The other notations, c, c', ε, and ε', require some comment; c (c') represents the concentration, and ε (ε'), the extinction coefficient, at the exciting wavelength. When the fluorescence of the amine is going to be modified, the unprimed numbers, c and ε, refer to the chelate and the primed numbers, c' and ε', to the amine. Inversely, when the fluorescence of the chelate is going to be modified, the former refer to the amine, and the latter, to the chelate. In what follows, the intensity values, F_E(M) and F_A(M), are to be understood as already corrected for this factor.

3) The amine fluorescence was partly absorbed by the chelate. The extent of this factor could not be evaluated, but it seemed to be small and was disregarded.

A) Amines Which Do Not Form Complexes: Amines of the second group in Table 1 did not form complexes. The excitation spectrum of the EuD_3 solution F_E^e(E or M) did not change on the addition of these amines over the whole range of excitation wavelengths covering 370 mμ. In the case of 1-naphthylamine, for example, the radiation of 300 mμ excited the amine molecule almost exclusively, and F_E^e(M) was very weak. An increase in the amine concentration did not seem to affect the intensity, indicating that no transfer of energy from the amine to chelate took place. This also the case for aniline and pyridine, which were excited at 280 and 260 mμ respectively. It is concluded that free amine molecules, excited or unexcited, do not affect the fluorescence of the EuD_3 in solution.

B) Amines Which Form Complexes: Amines of the first group in Table 1 formed complexes. When these amines were added to the solution of EuD_3, the F_E^e(M) increased markedly on excitation at 370 mμ as the concentrations of amines increased. As most of the amines involved did not absorb any exciting radiation, excitation transfer from the amine molecule to the chelate molecule did not account for the sensitization. Moreover, the dielectric behavior of the solvent, which might affect the fluorescence intensity, did not change noticeably upon the addition of amine of such low concentrations. This is consistent with the fact that the addition of ketones, such as acetone or cyclohexanone, to a similar extent affected neither the absorption spectrum nor the fluorescence quantum yield.[20]

The fluorescence intensities, $F_E^e(M)/F^e(E)$, were plotted against the optical densities, d', of the difference spectra of the solutions near the peak of the band of the EuD_3-amine complex; they gave straight lines (Figs. 4

20) Unpublished data.

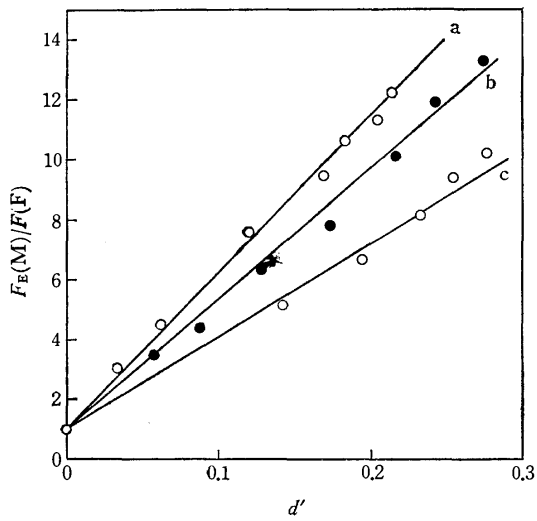

Fig. 4. Plots of $F_E(M)/F(E)$ against the optical density of the difference spectrum a. piperidine, b. triethylamine, c. octylamine concentrations are the same as in Figs. 1—3.

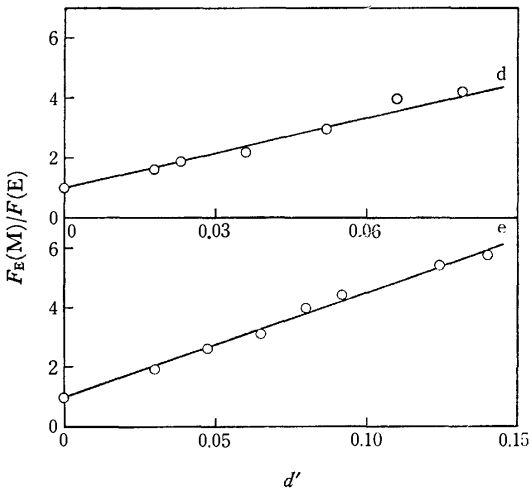

Fig. 5. Plots of $F_E(M)/F(E)$ against the optical density of the difference spectrum. The concentrations are the same as in Fig. 3. d. 4-aminopyridine, e. benzylamine

and 5). As d' is proportional to the concentration of the complex, as can be shown easily, the change in the fluorescence intensity, which is also proportional to it, should be attributed solely to the complex formation. The sensitization mechanism involving long-range interaction can again be ruled out. It follows, from our knowledge of the equilibrium constants and the intensity-optical density plits, that the fluorescence efficiencies of the complexes in a methanol solution are 4 to 12 times as high as that of the uncomplexed chelate (Table 1).

In the case of *N*-1-naphthylethylenediamine, the $F_E^e(M)/F^e(E)$ ratio was plotted at each of these excitation wavelengths, 370, 330, and 290 mμ. These wavelengths, were chosen for the following reasons. The radiation of 370 mμ excited almost exclusively the ligand of the chelate, the radiation of 290 mμ excited mainly the amine, and that of 330 mμ, excited both the chelate and amine. All of the plots showed a good linearity, but the slope was the greatest for the last plot (Fig. 6). As the slope of the plot for 370 mμ is a measure of the increase in the quantum yield of the fluores-

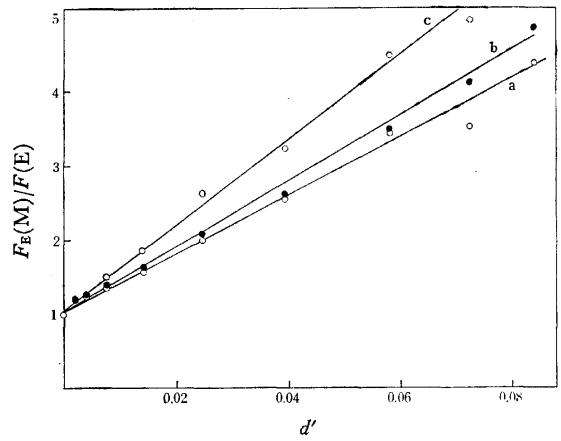

Fig. 6. Plots of $F_E(M)/F(E)$ for *N*-1-naphthylethylenediamine against the optical density of the difference spectrum.
a: excited at 370 mμ, b: 330 mμ, c: 290 mμ.

cence of the chelate by complex formation, it must be invariant under a change in the excitation wavelength, provided only that the ligand is excited at its first absorption band, as was the case for aliphatic amine complexes. Therefore, the increase in the slope should be attributed to the cooperative excitation-transfer process which took place from the amine to the chelate.

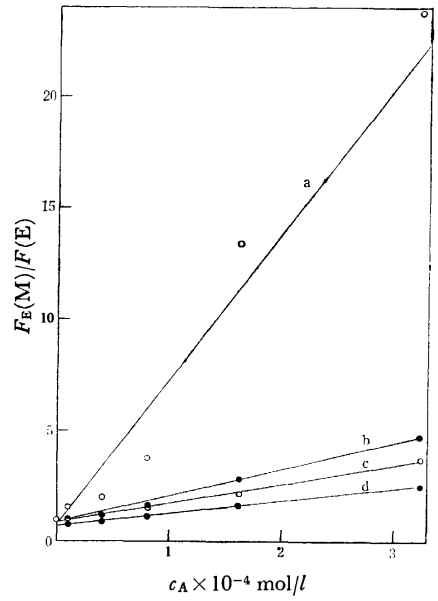

Fig. 7. Plots of $F_E(M)/F(E)$ for 9-aminoacridine against the concentration of amine.
a: excited at 410 mμ, b: 390 mμ, c: 370 mμ, d: 340 mμ

This was also the case for 9-aminoacridine. In Fig. 7, $F_E^e(M)/F^e(E)$ is plotted against the concentration of amine, as the optical density is not available because of the superposition of the amine absorption. The radiation of 370 or 340 mμ mainly excites the chelate, but that of 390 or 410 mμ mainly excites the amine. The latter two plots have larger slopes than the former.

The linearity of the $F_E^e(M)/F^e(E)$ ratio of *N*-1-naphthylethylenediamine against d', and the fact that naphthylamine, which failed to form a complex, did not affect the $F_E^e(M)$, suggest that the energy transfer takes place only from the amine molecule which is attached

to europium. Here again, the long-range or collisional-transfer mechanism can be discarded.

On the other hand, the excitation spectrum of the complex with benzylamine or aminopyridine fell to zero intensity near 260 mμ, although the amine absorbed radiation at this wavelength. It seemed, therefore, that the energy transfer did not take place in these complexes.

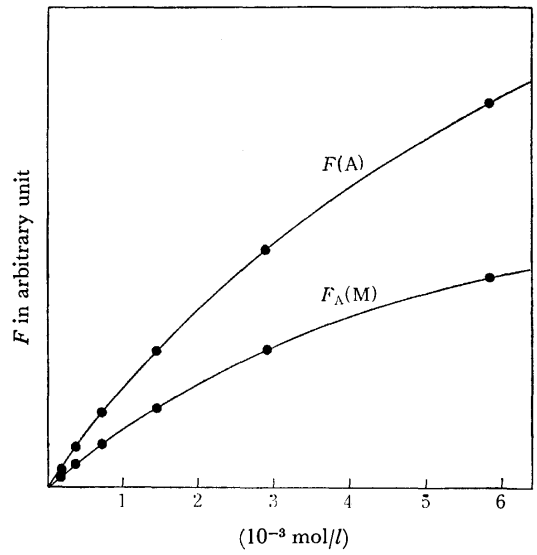

Fig. 8. Plots of $F_A(M)$ and $F(A)$ for aniline against the concentration of amine.

C) Fluorescence of Amine: Figure 8 shows the effect of the concentration on the fluorescence intensity of aniline, both in the absence and in the presence of the chelate, $F^a(A)$ and $F_A^a(M)$, on the excitation at 280 mμ, the peak of the excitation spectrum of aniline. Their ratio, $F_A^a(M)/F^a(A)$, is almost constant irrespective of the concentration of aniline: it amounts to 0.58. This suggests that the encounter-quenching mechanism accounts for the effect. The same is the case for tetramethylphenylenediamine on excitation at 330 mμ, the intensity ratio of which is 0.55 (Fig. 9).

When the amine forms a complex, the encounter-quenching mechanism applies only to free amine molecules and the $F_A^a(M)/F^a(A)$ ratio is expected to depend upon the concentration of amine, because the amount of the complex is most proportional to the latter. Unfortunately, in the cases of *N*-1-naphthylethylenediamine and 9-aminoacridine, both of which formed complexes, the expected concentration dependence could not be ascertained. Probably, the absorption of amine trailed into the transmission range of the filter with which the fluorescence was measured, and this precluded any exact determination of the fluorescence intensity. However, a comparison of 1-naphthylamine and *N*-1-naphthylethylenediamine showed that the fluorescence of naphthylamine was quenched to a somewhat smaller extent when the amine molecule was attached to the chelate.

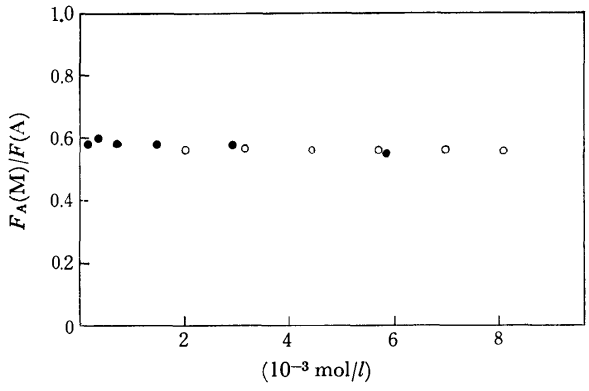

Fig. 9. Plots of $F_A(M)/F(A)$ against the concentration of amine.
●: aniline, ○: tetraemthylphenylenediamine

D) Mechanism of Sensitization: It seems to be established that the sensitization of the fluorescence of EuD_3 with amine take place solely by way of complex formation, and that two processes compete in the sensitization: sensitization involving energy transfer, and that not involving energy transfer. The following mechanisms are likely to hold.

1) Sensitization involving no energy transfer: There seem to be two concerted mechanisms; both serve to increase the relaxation lifetime of the chelate. Sensitization in the solid state, in which there is no participation of a solvent, suggests that the piling up of ligand molecules is responsible for it. The intrusion of amine molecules may restrict the free arrangement of ligand molecules so that the equilibrium structures of the ground state and the excited state of the complex become alike. This may reduce the Franck-Condon factor and suppress the radiationless process.

In solution, the fluorescence intensity of EuD_3 is a function of the nature of the solvent.[20] The solvent molecules seem to attach to the europium atom and exchange easily with other free solvent molecules. This may favor a radiationless transition by providing an energy continuum like that of predissociation near the energy levels of the chelate, thus invoking Fano configuration interaction,[21,22] or by bringing anharmonicity to the vibrational wavefunctions. Amines form comparatively rigid bonds and may interrupt this process.

2) Sensitization involving energy transfer: Excitation transfer takes place only from the ligand amine molecule, not from the free amine molecule. The collision of the free amine and the chelate only results in the quenching of the fluorescence of amine (but not of the fluorescence of the chelate). This suggests that the amine excitation energy is transferred directly to the europium atom, not through the ligand dibenzoylmethane molecule. This was strongly supported by the fact that 9-aminoacridine, the triplet and singlet levels of which lie below the corresponding levels of the ligand of the chelate, transfers its energy to the chelate, while the reverse process does not occur. This, in turn, gives support to the assumption that the complex is formed by an amine-europium bond.

The absence of energy transfer in benzylamine and in 4-aminopyridine still remains a problem. It may be due either to the intensity of the light source being too low to excite the amine to a detectable amount or to the energy separation being too large for crossing over to occur in the transfer process.

Acidity and Acid Strength of Zeolite Catalysts

Misako IKEMOTO, Kazuo TSUTSUMI, and Hiroshi TAKAHASHI
Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo
(Received August 17, 1971)

The influence of pretreatment temperature, silica-to-alumina mole ratio, the kind of cation and degree of cation exchange on the number of acid sites, and the acid strength of zeolite catalysts were examined by means of amine titration. Strong acid sites whose H_0 function is lower than -8.2 were analyzed by ultraviolet spectroscopy. Though H-zeolites have fairly strong acid sites ($-10.8<H_0<-8.2$), the number of acid sites decreases with the decrease of the silica-to-alumina mole ratio, as a result of the collapse of the zeolite structure. Ca-zeolites have an acid site distribution similar to that of H-zeolites only when the silica-to-alumina mole ratio is larger than 4.6. Only La-form Y-zeolite has strong acid sites ($H_0<-10.8$). When the degree of La-exchange exceeds 85 mol%, zeolite shows an acid coloration even with dinitrotoluene with $pK_a-12.8$.

In recent years, near-faujasite zeolite catalysts have been used in various reactions,[1] and their surface acidity has been investigated by means of infrared spectroscopy,[2-8] and titration with a base in nonaqueous solutions.[9,10] However, the nature of acid sites has not yet been clarified.

Hirshler measured the acidity of Linde Molecular Sieves 10X, 13X, and Li-X[11] by using Hammett indicators and H_R indicators, which form stable carbonium ions on the catalytic surface.[9] He showed that the acidity of 13X is very weak and only develops a red color with butter yellow, while both Li-X and Ca-X possess strong acid sites.

Otouma *et al.* studied the acid character of X and Y zeolites replaced by hydrogen, calcium and lanthanum ions by means of Hammett indicators,[10] and found characteristic features of the acid sites of zeolite catalysts. The number of acid sites is generally larger on the zeolites (2—3 meq/g) than on an amorphous silica-alumina cracking catalyst (0.5 meq/g). The acid strength is more widely distributed in the zeolites ($H_0=+3.3\sim-8.2$) than in silica-alumina ($H_0<-8.2$). The acid sites increase not only in number but also in strength with the advance of ion exchange.

The present investigation deals with a study of the effects of pretreatment temperature, the silica-to-alumina mole ratio, and the ion exchange on the surface acidity of faujasite-type zeolites. The nonaqueous titration method using Hammett indicators was applied for measurement of the acid sites.[12,13] Though it has been reported that zeolite has a strong acid character, little work has been carried out on the strong acid sites ($H_0<-8.2$). Information was obtained also on the strong acid centers on zeolite by a spectrophotometric method.

Experimental

Of the zeolite samples used in this study, Na–$X_{2.5}$[14] and Na–$Y_{5.0}$ were Linde Molecular Sieves 13X and SK-40, respectively, and Na–$Y_{3.25}$, Na–$Y_{3.85}$, and Na–$Y_{4.6}$ were synthesized from silica-alumina gel and sodium hydroxide. The calcium-, lanthanum-, or ammonium-exchange was performed by immersing the sodium-form zeolite in an aqueous solution of respective metal chlorides or ammonium chloride. Treatment was repeated several times in order to obtain a high degree of exchange. The samples were then collected by filtration, washed until no chloride ion was detected with silver nitrate and finally dried. The degree of exchange was determined by chemical analysis and flame photometry.

All the indicators were Wako Pure Chemicals Co. products. They were purified by recrystallization from benzene.

Cyclohexane was Dotite Spectrosol and was dried with a Linde Molecular Sieve 4A. *n*-Butylamine (Wako S grade) was purified by distillation and dried with a Linde Molecular Sieve 4A.

The Hammett indicators are listed, together with their pK_a's in Table I. Color changes of BY, DCA, BAP, and AQ are visible and the measurements were carried out with powdered samples. Since both acid and basic forms of absorbed PNT and DNT are colorless, the measurements were made by the aid of a spectrophotometer. Thin wafers were used as samples. Fifty mg of powdered zeolite was pressed into pellets between stainless steel blocks. The wafer "thickness" was 20 mg/cm^2.

The samples were placed in a vessel evacuated to 10^{-3}

Torr, and the temperature was then slowly raised to the desired temperature and kept constant for 5 hr under 10^{-5} Torr.

Acidity measurements were carried out as follows. The sample was transferred from the evacuated vessel to a test tube in a dry-box. Two m*l* of dry cyclohexane and a proper amount of a 0.1N solution of *n*-butylamine in cyclohexane were added. After the test tube was maintained at 60°C for 3 days, a few drops of 0.1% solution of the indicator in cyclohexane were added. After 2 days, it was determined whether the sample was basic or acidic to the indicator, either with the naked eye or by the use of a UV spectrophotometer.

Results and Discussion

Effect of Pretreatment Temperature. Figures 1 and 2 illustrate the correlation between the pretreatment temperature and the number of acid sites of the Ca- and NH_4-form zeolites at $H_0=+3.3$. The number of acid sites of Ca-zeolites increases to a maximum and then gradually decreases when the pretreatment temperature is raised. The number of acid sites of Ca-zeolite with a lower ratio of silica-to-alumina changes greatly with the pretreatment temperature, while that of Ca-zeolite with a higher ratio remains nearly constant. Since the zeolites with lower silica-to-alumina ratios have a relatively large number of Al atoms, the bond distance between Ca^{2+} and AlO_2^- ions is small. Thus, it is difficult to break the bonds and only a small number of acid sites was measured with the sample evacuated at a lower temperature.

As clearly shown in Fig. 2, the acidity of H-form zeolites[15] is greatly influenced by silica-to-alumina ratio.

○: H-$X_{2.5}$ (H^+, 86 mol%)

The zeolite with a lower ratio showed a small number of acid sites at any pretreatment temperature, since it is thermally unstable and easily loses its crystallinity with heat treatment, when acid sites are lost. On the other hand, the zeolite with a higher ratio showed as many sites as Ca-zeolite because of its high thermal stability.

of Ca- and H-zeolite were investigated. The distribution of acidity is shown in Figs. 3 and 4.

The maximum acidity in Ca-zeolite was 2.0 meq/g for Ca-$X_{2.5}$ and 2.5 meq/g for Ca-$Y_{5.0}$. The Ca-zeolites with silica-to-alumina mole ratios greater than 4.6 possess strong acid sites ($H_0 < -8.2$). However, the acid sites of Ca-zeolites with lower ratios of silica-to-alumina are distributed over a wide range of acid strength. The results agree with the fact that a strong electrostatic field is generated by heat treatment and easily produces H^+ ions in zeolites with a higher ratio of silica-to-alumina.[16] Though a decrease in the amount of alumina gives rise to a decrease in the number of cations, it makes the distance between cations and anions longer. As a result, separation between the positive and the negative charges becomes easier. Thus a strong electrostatic-field is generated and water is highly polarized.

On the other hand, H-zeolites with a higher ratio of silica-to-alumina possess acid sites as strong as those of Ca-zeolites. However, the number of acid sites of H-zeolites with a lower ratio is small due to the collapse of the structure resulting from the treatment. The higher the silica-to-alumina mole ratio, the less the number of anions in the zeolite structure. Protons with a low electric shield then become mobile and form strong acid sites.

Effect of Ion Exchange. Influence of the ion exchange of Ca^{2+} and La^{3+} ions on acidity was investigated. The acidity of Ca–Na–$Y_{3.25}$ and La–Na–$Y_{3.25}$ as a function of the degree of ion-exchange is shown in Fig. 5.

The number of acid sites of Ca–Na–$Y_{3.25}$ is nearly equal to that of Na–$Y_{3.25}$ when the Ca exchange is lower than 40%, but increases rapidly above 80%. When sodium ions are replaced by calcium ions, calcium ions enter energetically stable sites in the beginning and the formation of acid sites by heat treatment is difficult.[17] Since the number of acid sites with H_0 values higher than −5.6 is almost constant, independent of ion exchange, the acid centers formed through calcium ion exchange have H_0 values lower than −5.6.

The acidity property of low-exchange sample is consistent with the fact that the electrostatic-field strength and the cumene-cracking activity of these samples were almost the same as those of the Na-form zeolites.[17,18] The divalent cations strongly prefer the S_I cation sites connected to the large cavity through pores of about 2Å in diameter. As the pores are not large enough for the organic molecules to pass through, the cation-exchange does not influence the properties mentioned above.

In the case of the exchange with La^{3+} ion, the acidity measured with BY begins to increase in proportional to the degree of exchange above 20%. Since La^{3+} ion is highly charged, the bonds between La^{3+} and AlO_2^- ions are distorted remarkably, and many acid sites are formed even at lower exchange. Compared with the acidity measured with AQ, this acidity is distributed in a wider domain when the degree of exchange is 60% or less, and the acid sites with H_0 values lower than −8.2 are formed only above 60%.

Measurement of Strong Acid Sites. The UV spectra of PNT and DNT adsorbed on zeolites are shown in Figs. 6 and 7, respectively. The band at about 350 mμ in Fig. 6 is assigned to the acid form of PNT adsorbed

The results indicate that H–Y zeolite and H-mordenite which are considered to have a strong acid character, from the measurement with AQ, show basic colors of PNT and DNT. Their acid strength is therefore distributed in the H_0 range from −8.2 to −10.8. On the other hand, La–Y zeolites show acidic colors of both PNT and DNT as shown in Figs. 8 and 9. Thus, La–Y zeolites have very strong acid sites with H_0 values lower than −12.8. It is clear that the acid strength of La–Y is dependent on the degree of La-exchange. The La–Na–$Y_{3.25}$ showed an acid color of PNT when La-exchange exceeds 70% and even an acid color of DNT above 85%.

Such a strong acidity of La-form zeolite can be compared with that of fuming sulfuric acid. It turns out from this acidity that the cumene-cracking activity of La-form zeolite is much higher than that of H- and Ca-form zeolites.[18]

A Theoretical Consideration of the Electron-scavenging Process In Liquid Hydrocarbons. III. Integral Transforms of the Distribution Functions

Hideo YAMAZAKI and Kyoji SHINSAKA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received September 16, 1971)

The relations of integral transforms between various distribution functions are discussed using the potential control approximation ignoring the diffusion term in the Smoluchowski equation; the initial spatial distribution of the electron-ion pair or the initial distribution of electrons from the central ion core in a spur, $\chi(r, 0)$; the relative G-value of electron recombination, $G(k_sC_s)$, as a function of the concentration of the scavenger and the rate constant; the time dependence of the electron concentration, $N(t)$, after pulse irradiation; and the relaxation time spectrum, $K(n)$, of the decay of the electron concentration after pulse irradiation or of the weight function, $K(n)$, in the initial exponential distribution of thermalized electrons in a spur are shown to be connected by the square diagram of Laplace transforms:

$$\begin{array}{ccc} K(n) & \xrightarrow{\text{Laplace Transform}} & \chi(r, 0) \\ \Big\downarrow \text{Laplace Transform} & & \Big\downarrow \text{Laplace Transform} \\ N(t) & \xrightarrow{\text{Laplace Transform}} & G(k_sC_s) \end{array}$$

By the use of this relation, the various distribution functions are evaluated from the empirical formulas of $G(k_sC_s)$ proposed by Schuler *et al.* and by Hummel.

Recently many experimental results of various methods of the radiolysis of liquid hydrocarbons have been accumulated, and it has been shown that the quantities measured are connected by the functional relations. Schuler *et al.*[1] proposed that the concentration dependence of the G-value of electron recombination and the change in ionic species after pulse radiolysis as a function of the time were related by the Laplace transform. Sato and Oka[2] and Tatsuya[3] found that the initial distribution of the electron-ion pair and the G-value of the electron recombination as a function of the scavenger concentration were interchangeable by the Laplace transform. In their studies, no information about the spatial distribution of electrons from the Smoluchowski equation is necessary in deriving these relations between functions. In a previous paper[4] the inverse Laplace transform was used by the present authors to obtain the lifetime spectrum in the decay function of the electron concentration, based on the Smoluchowski equation.

In this paper it is shown that, in addition to these rather phenomenological relations, the lifetime spectrum of the decay of the electron concentration is equivalent to the weight function of the superposition of the initial distribution. Four functions, $\chi(r,0)$, $G(k_sC_s)$, $N(t)$, and $K(n)$, which indicate the initial distribution of electrons from the central ion core in a spur, the concentration dependence of the G-value of the electron recombination, the time dependence of the electron concentration, and the relaxation time spectrum respectively, can be related by the Laplace transform by using the approximate solution ignoring the diffusion term of the Smoluchowski equation from the microscopic point of view. Thus, the experimental results are interconnected by these relations and depend on each other.

Theory

A. The Four Characteristic Functions and Their Transformations. Phenomenological treatment is possible for the relation between the relative G-value of the electron recombination as a function of the scavenger concentration, $G(k_sC_s)$, and the electron concentration after pulse irradiation, $N(t)$, and for that between $G(k_sC_s)$and the initial distribution of electrons, $\chi(r,0)$. However, the introduction of the distribution functions of the electron concentration as spatial and time functions is necessary in order to describe these relations in detail and to extend them. An extended form of the Smoluchowski equation is used to obtain the approximate distribution function of electrons and to treat the effect of the spur.

The extended form of Smoluchowski equation for the spatial distribution of electrons in a spherical spur is expressed by Eq. (1)[4]:

$$\frac{\partial C(r,t)}{\partial t} = D\frac{\partial^2 C(r,t)}{\partial r^2} + \left(\frac{2D}{r} + \frac{\alpha}{r_2}\right)\frac{\partial C(r,t)}{\partial r} - \beta C(r,t) \quad (1)$$

where r, t, D, and $C(r, t)$ refer to the radial distance, the time, the diffusion constant, and the distribution function of electrons, and where α and β are constants and are given by:

$$\alpha = N^+eu/\varepsilon \quad (2)$$

$$\beta = k_sC_s, \quad (3)$$

where N^+ is the average number of ions in the core, e is the electron charge, u is the mobility of electrons, ε is

the dielectric constant, k_s is the rate constant of scavenging, and C_s is the concentration of the scavenger. The successive approximation of the potential control case is convenient in obtaining the solution.[4] The solution of the zeroth order equation,

$$\frac{\partial \chi_0(r,t)}{\partial t} = \frac{\alpha}{r^2}\frac{\partial \chi_0(r,t)}{\partial r} - \beta\chi_0(r,t) \tag{4}$$

is given by:

$$\chi_0(r,t) = \int_0^\infty K_0(n)\exp(-\beta t - n\alpha t - nr^3/3)\mathrm{d}n \tag{5}$$

Thus, the approximate solution is given by the superposition of the exponential function with a weight function, $K_0(n)$. The initial distribution is expressed by:

$$\chi_0(\sqrt[3]{3\xi}, 0) = \int_0^\infty K_0(n)\exp(-n\xi)\mathrm{d}n \tag{6}$$

by the substitution of the distance by $\xi = r^3/3$. In Eq. (6) the initial distribution is expressed by the Laplace transform of $K_0(n)$. Therefore, the weight function in the spur distribution, $K_0(n)$, is evaluated by the inverse Laplace transform of the initial distribution function and is given by:

$$K_0(n) = \frac{1}{2\pi i}\int_{C-i\infty}^{C+i\infty}\chi_0(\sqrt[3]{3\xi}, 0)\exp(n\xi)\mathrm{d}\xi \tag{7}$$

The total number, $N_0(t)$, of the electrons is obtained by the integration of the distribution function of electrons over a spur and is expressed by:

$$N_0(t) = 4\pi\int_{R_0}^\infty \chi_0(r,t)r^2\mathrm{d}r \tag{8}$$

where R_0 is the reaction radius of the recombination between an electron and an ion. Then, $N_0(t)$ is evaluated by Eqs. (5) and (8):

$$N_0(t) = 4\pi\int_0^\infty K_0(n)g_0(n, R_0)\exp(-n\alpha t)\mathrm{d}n \tag{9}$$

where $g_0(n, R_0)$ is given by:

$$g_0(n, R_0) = \exp(-nR_0^3/3)/n \tag{10}$$

The lifetime spectrum of the electrons, $K_0(n)$, is evaluated by the inverse Laplace transform:[4]

$$K_0(n)g_0(n, R_0) = \frac{1}{8\pi^2 i}\int_{C-i\infty}^{C+i\infty} N_0(p/\alpha)\exp(np)\mathrm{d}p \tag{11}$$

The decay of the electron concentration after pulse irradiation was treated by Schuler *et al.*,[1] and for an infinitesimal short duration of pulse irradiation the relation between $N_0(t)$ and $G(\beta)$ was given by:

$$G(\beta) = -\int_0^\infty \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{N_0(t)}{N_0(0)}\right)\exp(-\beta t)\mathrm{d}t \tag{12}$$

where $G(\beta)$ is the portion of the G-value of electron recombination. Then, the inverse Laplace transform yields $N_0(t)$ by:

$$-\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{N_0(t)}{N_0(0)}\right) = \frac{1}{2\pi i}\int_{C-i\infty}^{C+i\infty} G(\beta)\exp(\beta t)\mathrm{d}\beta \tag{13}$$

A similar relation was obtained between the initial distribution of electrons and the G-value of the electron recombination or the scavenging process, if the effect of the diffusion term of electron is ignored, where the position of the electron at time t after pulse irradiation is determined by a time-distance relation.[5] $G(\beta)$ is expressed in terms of the Laplace transform of the initial distribution of electrons by:

$$G(\beta) = \frac{\int_0^\infty \chi_0(\sqrt[3]{3\xi + R_0^3}, 0)\exp(-\beta\xi/\alpha)\mathrm{d}\xi}{\int_0^\infty \chi_0(\sqrt[3]{3\xi + R_0^3}, 0)\mathrm{d}\xi} \tag{14}$$

where R_0 is the reaction radius. The inverse Laplace transform yields the initial distribution by:

$$\frac{\chi_0(\sqrt[3]{3\xi + R_0^3}, 0)}{\int_0^\infty \chi_0(\sqrt[3]{3\xi + R_0^3}, 0)\mathrm{d}\xi} = \frac{1}{2\pi i}\int_{C-i\infty}^{C+\infty t} G(\beta)\exp(\beta\xi/\alpha)\mathrm{d}\beta \tag{15}$$

As a summary of these transforms of the four characteristic functions, the flow chart of the transformations is given in Fig. 1.

Therefore, $G(\beta)$ is expressed in terms of $K_0(n)$ by using the double Laplace transform *via* $\chi_0(\sqrt{3\xi}, 0)$ or $N_0(t)$ in this flow chart:

$$G(\beta) = \frac{\int_0^\infty\int_0^\infty \exp\{-\beta\xi/\alpha - n(\xi + R_0^3/3)\}K_0(n)\mathrm{d}n\mathrm{d}\xi}{\int_0^\infty (K_0(n)/n)\exp(-nR_0^3/3)\mathrm{d}n} \tag{16}$$

The transforms in the higher-order approximations, including the effect of diffusion, are given in Appendix A.

B. Example of Distribution Functions. As the first example of this scheme, the superpositions of the δ-functions as $K_0(n)$ in Eqs. (6) and (9) are considered in Eq. (17).

The operations[6] of the Laplace transforms on $K_0(n)$ yield $\chi_0(\sqrt[3]{3\xi}, 0)$ and $N_0(t)$, and the double Laplace transform either *via* $\chi_0(\sqrt[3]{3\xi}, 0)$ or $N_0(t)$ in Fig. 1 yields $G(\beta)$:

$$K_0(n) = \sum_i f_i\delta(n - n_i) \tag{17}$$

where f_i are constants:

$$\frac{N_0(t)}{N_0(0)} = \sum_i (f_i/n_i)\exp(-R_0^3 n_i/3 - \alpha n_i t)\Big/ \sum_i (f_i/n_i)\exp(-R_0^3 n_i/3) \tag{18}$$

$$G(\beta) = \sum_i \frac{(f_i/n_i)\exp(-R_0^3 n_i/3)}{1 + \beta/\alpha n_i}\Big/\sum_i (f_i/n_i)\exp(-R_0^3 n_i/3) \tag{19}$$

$$\chi_0(r, 0) = \sum_i f_i \exp(-n_i r^3/3) \tag{20}$$

Equations (18) and (20) show that the decay function and the initial distribution can be expressed as a superposition of the exponential functions. Such a decay function of the electron concentration was observed by Yoshida[7] in hydrocarbon glass. In Eq. (19) the G-value of the recombination or the scavenging process is represented as a linear combination of functions of the Stern-Volmer or Langmuir type. Such a type of scavenger dependence was approximately verified in a previous paper.[8]

5) F. Williams, *J. Amer. Chem. Soc.*, **86**, 3954 (1964).
6) For example, H. Bateman, "Tables of Integral Transforms. I," McGraw-Hill Book Co. Inc., New York (1954).
7) H. Yoshida, *Ann. Repts. Reactor Inst. Kyoto Univ.*, **3**, 153 (1970).
8) H. Yamazaki and K. Shinsaka, This Bulletin, **43**, 2713 (1970).

As the second example, $G(\beta)$ as a function of the square root of the concentration of the scavenger was proposed by Schuler *et al.*[1] as in Eq. (21) for a wide range of scavenger concentrations:

$$G(\beta) = 1/(1+\sqrt{A\beta}) \quad (21)$$

where A is a constant. A comparison between Schuler's expression and the present one for $G(\beta)$ is given in Appendix B. The operations[6] of the inverse Laplace and double inverse Laplace transforms of Eq. (21) yield $N_0(t)$, $\chi_0(\sqrt[3]{3\xi}, 0)$ and $K_0(n)$ for the case of the square-root dependence on the scavenger concentration:

$$\frac{N_0(t)}{N_0(0)} = 1 - 2\sqrt{\frac{\alpha t}{\pi}} + \frac{1}{\sqrt{\alpha}}\int_0^t \exp(t/\alpha)\mathrm{Erfc}(\sqrt{t/\alpha})\mathrm{d}t \quad (22)$$

$$\chi_0(\sqrt[3]{3\xi+R_0^3}, 0)/\int_0^\infty \chi_0(\sqrt[3]{3\xi+R_0^3}, 0)\mathrm{d}\xi = \left\{\sqrt{\frac{1}{\pi\xi A\alpha}} - \frac{1}{A\alpha}\exp(\xi/A\alpha)\right\}\mathrm{Erfc}(\sqrt{\xi/A\alpha}) \quad (23)$$

and

$$K_0(n) = \frac{\sqrt{nA\alpha}}{\pi(1+nA\alpha)}\exp(nR_0^3/3) \quad (0<nR_0^3/3<1) \quad (24)$$

As the third example, Hummel's formula[9] for the G-value as the function of the concentration of the scavenger, corresponding to Eqs. (19) and (21), was expressed by:

$$G(\beta) = \exp(-\sqrt{A\beta}) \quad (25)$$

Similarly, $N_0(t)$, $\chi_0(\sqrt[3]{3\xi}, 0)$ and $K_0(n)$ can be obtained by using inverse Laplace transforms:[6]

$$\frac{N_0(t)}{N_0(0)} = 1 - \frac{1}{2}\sqrt{\frac{A}{\pi}}\int_0^t t^{-3/2}\exp(-A/4t)\mathrm{d}t \quad (26)$$

$$\frac{\chi_0(\sqrt[3]{3\xi+R_0^3}, 0)}{\int_0^\infty \chi_0(\sqrt[3]{3\xi+R_0^3}, 0)\mathrm{d}\xi} = \frac{1}{2}\sqrt{\frac{A\alpha}{\pi\xi^3}}\exp(-\alpha A/4\xi) \quad (27)$$

and

$$K_0(n) = \frac{1}{\pi}\sin(\sqrt{nA\alpha})\exp(nR_0^3/3) \quad (0<nR_0^3/3<1) \quad (28)$$

Discussion

The various measurements for obtaining $N_0(t)$, $G(\beta)$, $\chi_0(r, 0)$ and $K_0(n)$ are interconnected. In view of this relation, the experiment of the pulse radiolysis, the scavenging method with product analysis, and the relaxation time measurement of the ESR spectrum to get information on the spatial distribution are all needed under the same conditions. As to $K_0(n)$, the first term in the expansion of $K_0(n)$ in Eq. (28) as a power series of n gives the same term as that of Eq. (24). The actual calculation to obtain the initial distribution from the results of the scavenging method was carried out by Sato and Oka[2] on the basis of Freeman's method of calculation.[10] They obtained equations corresponding to Eqs. (23) and (27). According to their calculation, the initial distributions due to Schuler's and Hummel's expressions of the G-value are almost the same for large values of r; this corresponds to the fact that the weight functions, $K_0(n)$, for Schuler's and Hummel's expressions are approximated by the same equation for the small values of n. Thus, $\chi_0(r, 0)$ can be estimated indirectly from $G(\beta)$, because $G(\beta)$ has been obtained experimentally in the presence of various scavengers. A few experiments have been made to obtain direct information about $\chi_0(r, 0)$, for example, by relaxation-time measurement in liquid hydrocarbons. In a preliminary result of the measurement of the relaxation-time of ESR, the distribution of electrons showed heterogeneity in the glass state.[11]

In the present pulse radiolysis for the determination of $N_0(t)$, the electron-ion recombination process can be detectable at low temperatures[12,13] where the lifetime of the recombination increases over μ sec. At low temperatures, however, the equilibrium between bound and unbound electrons, e_t^- and e_m^-, must be considered, and this factor has to be added to the fundamental equation. If the rate of equilibration between e_t^- and e_m^- is fast, Eq. (1) can be rewritten as:

$$(1+K)\frac{\partial C_m}{\partial t} = D\frac{\partial^2 C_m}{\partial r^2} + \left(\frac{2D}{r} + \frac{\alpha}{r^2}\right)\frac{\partial C_m}{\partial r} - \beta C_m \quad (K = k_m/k_t = C_t/C_m) \quad (29)$$

where C_m and C_t are the distributions of unbound and bound electrons, k_m and k_t are the rate constants of equilibration between unbound and bound states, and K is an equilibrium constant between the bound and unbound states of electrons. The extremely small apparent values of the electron mobility, the diffusion constant, and the rate constant can be expected for a large values of K. Even when the coefficients in the equation are different, the equation remains in the same form in this approximation. In various types of distribution functions, the superposition of δ-functions for $K_0(n)$ and, therefore, the superposition of exponential functions for $N_0(t)$, are natural and reasonable, as is shown in the examples.

The square diagram of the Laplace transform in Fig. 1 was obtained by the zeroth order approximation, ignoring the diffusion term in the Smoluchowski equa-

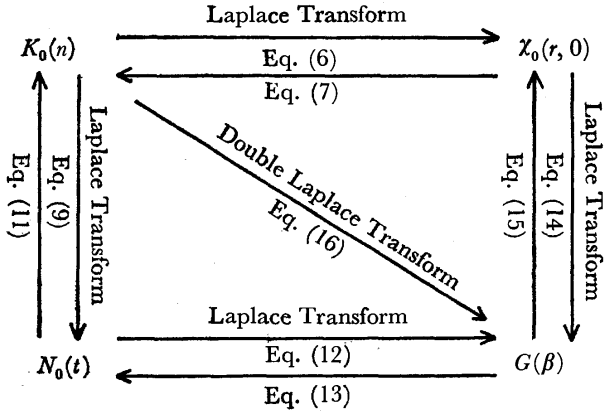

Fig. 1. Flow chart of the Laplace transorms of various distribution functions; $K_0(n)$, $\chi_0(r, 0)$, $N_0(t)$, and $G(\beta)$.

tion. If the higher-order approximation including the diffusion term is used, the Laplace transform in the scheme should be replaced by a more complicated form of the integral transforms, as is shown in Appendix A. The validity of the potential control approximation can be discussed in the following two ways. In the first place, the Onsager radius has an order of magnitude of several hundreds Ångström in the liquid hydrocarbons, and most of the electrons ejected from the parent ions are within this region and are still localized in the range of the Coulomb field of the parent ions. Therefore, the potential term is more effective than the diffusion term for most of the electrons in the region inside of the Onsager radius. In the second place, it is most likely that the thermalized electrons do not show any sharp spatial distribution; this is because of diffused energy spectrum of the electrons ejected and because of the random collisions of thermalization. Moreover, the spatial distribution is broadened with time. The transport of the electrons by diffusional motion in one direction is quite small, because the second derivative of the electron distribution by the distance is negligibly small for the smoothed distribution.

The authors wish to thank Professor Shoji Shida and Dr. Shin Sato of Tokyo Institute of Technology and Dr. Kenji Fueki of Nagoya University for reading the preliminary manuscript of this paper and for their helpful discussions, and Dr. H. A. Gillis of the National Research Council, Ottawa, for his kind communication. The authors also wish to thank Misses Hisako Yamaguchi and Toshiko Kitagawa for typing the manuscripts of this series of reports.

Appendix

A. The Higher-order Approximation. The s-th order equation is given by a recurrent equation:

$$\frac{\partial \chi_s(r,t)}{\partial t} = D\frac{\partial^2 \chi_{s-1}(r,t)}{\partial r^2} + \frac{2D}{r}\frac{\partial \chi_{s-1}(r,t)}{\partial r} + \frac{\alpha}{r^2}\frac{\partial \chi_s(r,t)}{\partial r} - \beta\chi_s(r,t) \quad \text{(A-1)}$$

The s-th order of approximation can be written by:

$$\chi_s(r,t) = \int_0^\infty K_s(n)H_s(n,\alpha,D,r)\exp(-\beta t - n\alpha t - nr^3/3)\mathrm{d}n \quad \text{(A-2)}$$

where H_s is a function of n, α, D, and r; several examples of the explicit form are given by:

$$H_0(n,\alpha,D,r) = 1 \quad \text{(A-3)}$$

$$H_1(n,\alpha,D,r) = 1 + nDr^4/\alpha - n^2Dr^7/7\alpha \quad \text{(A-4)}$$

$$H_2(n,\alpha,D,r) = 1 + nDr^4/\alpha - n^2Dr^7/7\alpha - 4nD^2r^5/\alpha^2 + 5n^2D^2r^8/2\alpha^2 - 24n^3D^2r^{11}/77\alpha^2 + n^4D^2r^{14}/98\alpha^2 \quad \text{(A-5)}$$

In the case of a pure recombination, (β=0), the initial distribution can be expressed by:

$$\chi_s(\sqrt[3]{3\xi}, 0) = \int_0^\infty K_s(n)H_s(n,\alpha,D,\sqrt[3]{3\xi})\exp(-n\xi)\mathrm{d}n, \quad \text{(A-6)}$$

using the substitution, $r^3/3=\xi$, From Eqs. (8) and (A-2), $N_s(t)$ is given by:

$$N_s(t) = 4\pi\int_0^\infty K_s(n)g_s(n,\alpha,D,R_0)\exp(-n\alpha t)\mathrm{d}n \quad \text{(A-7)}$$

where $g_s(n,\alpha,D,R_0)$ is given by the integral of $H_s(n,\alpha,D,\sqrt[3]{3\xi})$:

$$g_s(n,\alpha,D,R_0) = \int_{R_0^3/3}^\infty H_s(n,\alpha,D,\sqrt[3]{3\xi})\exp(-n\xi)\mathrm{d}\xi \quad \text{(A-8)}$$

The relaxation time spectrum, $K(n)$, can be expressed by the use of the inverse Laplace transform of the dependence of the electron concentration in the system:

$$K_s(n)g_s(n,\alpha,D,R_0) = \frac{1}{8\pi^2 i}\int_{C-i\infty}^{C+i\infty} N_s(p/\alpha)\exp(np)\mathrm{d}p \quad \text{(A-9)}$$

Equations (12) and (13) are valid for the relation between the functions of $N_s(t)$ and $G_s(t)$ in the presence of diffusion, because this relation is phenomenological and does not need the Smoluchowski equation as a basis for discussion. However, the $\chi_s(r,0)$ and $G_s(\beta)$ functions are not directly connected by a Laplace transform, because the relation between t and r^3 can be held only by disregarding the diffusion term. A complicated relation can be obtained by the transforms *via* $K_s(n)$ and $N_s(t)$:

$$\chi_s(\sqrt[3]{3\xi},0) = \int_0^\infty \frac{N_s(0)H_s(n,\alpha,D,\sqrt[3]{3\xi})}{8\pi^2 i g_s(n,\alpha,D,R_0)}\exp(-n\xi) \times\left[\int_{C-i\infty}^{C+i\infty}\left\{\int_{p/\alpha}^\infty \frac{1}{2\pi i}\int_{C-i\infty}^{C+i\infty} G(\beta)\exp(\beta t)\mathrm{d}\beta\right\}\mathrm{d}t\right] \times\exp(np)\mathrm{d}p\Big]\mathrm{d}n \quad \text{(A-10)}$$

B. The Expressions for G(β). This equation is expressed by $G(p)=G_{ft}+G_{gt}\sqrt{A\beta}/(1+\sqrt{A\beta})$, where $G(p)$, G_{ft}, and G_{gt} are the G-values of the yields of the secondary products from the ionic reaction and those of free and germinate electrons respectively. A fraction, $F(c)$, undergoing the reaction of germinate pairs with the scavenger solute is expressed by:

$$F(c) = [G(p)-G_{ft}]/G_{gt} \quad \text{(B-1)}$$

where c is the concentration of the solute. $F(c)$ is represented using the Laplace transform of the life-time distribution, $f(t)$:

$$F(c) = 1 - \int_0^\infty \exp(-kct)f(t)\mathrm{d}t \quad \text{(B-2)}$$

where k is the rate constant with the solute. The life-time distribution is given by the differentiation of the fraction, $F(t)$, of the ion pair at time t, which is equal to the $N(t)/N(0)$ used in this paper:

$$f(t) = -\mathrm{d}F(t)/\mathrm{d}t \quad \text{(B-3)}$$

The relative G-value or fraction of recombination, $G(\beta)$, considered in this paper is expressed by:

$$G(\beta) = \frac{G_{gt}-G_{gt}\sqrt{A\beta}/(1+\sqrt{A\beta})}{G_{gt}} = 1/(1+\sqrt{A\beta}) \quad \text{(B-4)}$$

Equilibrium of Urea Synthesis. I.

Shigeru INOUE, Kazumichi KANAI, and Eiji OTSUKA

Central Research Laboratory (Ofuna) Mitsui Toatsu Chemicals, Inc., Totsuka-ku, Yokohama

(Received September 17, 1971)

A test of the equilibrium conversion of CO_2 to urea was carried out using a batch autoclave. Some results different from those reported by Frèjacques were obtained, as was expected from the latest data on commercial urea plants. The equilibrium conversion reached its maximum value at about 195°C by 5—15% higher than that reported by Frèjacques. On the contrary, at temperatures above 200°C the value was lower, and falled rapidly with the raise of temperature. This phenomenon may be due to the mechanism of the equilibrium of urea synthesis, and not to the experimental method, as our sampling was made directly from the liquid phase. The equilibrium conversion, x, may be expressed with respect to NH_3/CO_2, a, H_2O/CO_2, b, and temperature, t, as

$$x = \left(0.2616a - 0.01945a^2 + 0.0382ab - 0.1160b - 0.02732a\left(\frac{t}{100}\right) - 0.1030b\left(\frac{t}{100}\right) + 1.640\left(\frac{t}{100}\right) - 0.1394\left(\frac{t}{100}\right)^3 - 1.869\right) \times 100(\%)$$

Therefore, a limited conversion exists in the conventional urea process.

Many investigators have reported the values of actual conversion for commercial reactors by means of the Frèjacques nomograph,[1] and it seemed that the values thus obtained have been taken as the actual conversion in the process (not multiplied by a factor).

Howerver, from the analysis of data obtained with commercial scale reactors, it has become clear that the conversion for the reactor might well be higher than that reported by Frèjacques.

If this is true, the urea process should be improved. In order to confirm this possibility, the static equilibrium conversion should be examined.

For this purpose we measured the equilibrium conversion by an improved method using a batch autoclave, especially with regard to the method of sampling.

The original points of the present report are that, first, the sampling was made directly from the liquid phase and, second, it was made clear that the equilibrium conversion reaches its maximum value at a certain temperature.

The reason why "the direct sampling" must be emphasized is as follows: the popular interpretation of the existence of the maximum conversion depends on the effect of the loading density on the autoclave,[2] because the analyzed value for the equilibrium conversion is based not on the liquid phase, but on the total amount of $NH_4CO_2NH_2$ charged into the autoclave; otherwise, it is thought that a sampling operation might disturb the equilibrium. That is, the higher the temperature becomes in the autocalve at a certain loading density, the less $NH_4CO_2NH_2$ remains in the liquid phase because of the increased amount of NH_3 and CO_2 transferred into the gas phase. Thus, even though the conversion in the liquid phase increases because of the higher temperature, the amount of urea formed may become less above a certain temperature. Therefore, the (apparent) conversion based on the total amount of $NH_4CO_2NH_2$ charged into the autoclave reaches its maximum value at a certain temperature. Therefore, the larger the loading density is, the higher is the temperature of the maximum conversion.

Therefore, we think that this factor—the loading density—has caused the misunderstanding of the analysis or troubles in many cases. By our improved experimental method, the effect of the loading density can be removed; thus, the consideration of the equilibrium of urea synthesis becomes clearer than before.

In the present paper, our experimental results and a comparison with those of Frèjacques will be mainly described, while in the next paper some theoretical arguments will be presented.

Conventional Theory

Although urea synthesis has been developed on a large scale since 1950, the basic research on the equilibrium conversion was done long before, and many reports have been published.

The experimental method has been as follows: $NH_4CO_2NH_2$ (solid) is charged into a steel-made bomb or a glass tube, which is then sealed. After the contents had reached the equilibrium state, all of them in the bomb or in the tube were taken out as a sample for analysis; therefore, the eqiuilibrium conversion was calculated on the amount of urea formed relative to the total amount of $NH_4CO_2NH_2$ charged into the bomb or tube. Thus, the conversion was not a real value, but an apparent one.

In this case, the real value was estimated by an extrapolation (from various loading densities) or by a calibration for the gas phase. Even by these unsatisfactory methods, the effects of the excess NH_3, the excess water, and the temperature on the equilibrium conversion are rather clear for the most part.

Therefore, besides NH_3/CO_2, H_2O/CO_2, and the temperature, the parameter of the loading density is neces-

1) M. Frèjacques, *Chimie et Industrie*, **60**, No. 1, 22, (1948).

2) A. Baranski and A. Fulinski, *Chim. Ind. Gen. Chim.*, **99**, No. 11, 1605—1618 (1968).

sary to express the equilibrium conversion. Frèjacques, however, reported that the equilibrium conversion is dependent on NH_3/CO_2, H_2O/CO_2, and the temperature only as is expressed below:

$$\frac{x(x+b)(1+a+b-x)}{(1-x)(a-2x)^2} = K(t) \quad (1)$$

where a: molar ratio of NH_3/CO_2 in the total feed,
b: molar ratio of H_2O/CO_2 in the total feed,
K: equilibrium constant dependent on the temperature,
and x: conversion of CO_2 to urea, expressed in fractions of the total CO_2 in the total feed.

The equilibrium constant, $K(t)$, based on a stoichiometric mixture, was assumed also to be valid for a non-stoichiometric mixture; that is,

$$K(t) = \frac{x_{st}^2(3-x_{st})}{4(1-x_{st})^3} \quad (2)$$

where x_{st} is the equilibrium conversion when $a=2$, $b=0$ (for a stoichiometric mixture).
here $K(t)$ is an increasing, monotonous function with respect to the temperature.

Therefore, in most nonstoichiometric cases, the equilibrium conversion has also been supposed to increase as the temperature becomes higher.

Since his publication, no new basic research on the equilibrium conversion has been reported; interpretations have mainly been reported.

The actual conversion in a reactor effluent of an industrial scale was fairly consistent with Eq. (1) within the limits of the accuracy of measurement at that time, so it was thought that the equilibrium conversion obtained by means of Eq. (1) could be adopted for a reactor effluent in all processes.

Although the above description is sufficient for understanding fundamental matters, it will be convenient, in order to facilitate comparison with our results, that more details are given on the Frèjacques theory.

In Eq. (1) the equilibrium conversion is independent of $NH_4CO_2NH_2$, which is an intermediate in this equilibrium system, but, judging from the fact that, under a sufficient pressure, CO_2 converts to $NH_4CO_2NH_2$ completely either with excess NH_3 or without it, we think that the conversion of CO_2 to urea must be determined by the equilibrium between $NH_4CO_2NH_2$ and urea plus water; there is, then, some error in the expression of Eq. (1).

On the other hand, there has been an assumption that excess NH_3 decreases the activity of formed water since it promotes the reverse reaction. Next, with regard to the effect of temperature, it has been supposed that the equilibrium conversion increases as the temperature becomes higher unless by-products such as biuret and cyanuric acid (which are condensates of urea after deammoniation) are formed increasingly; however, considering that the temperature of the experiment at that time did not exceed 185°C, we think that the equilibrium conversion at temperatures higher than the above was estimated by extrapolation.

Nevertheless, the above trend seems reasonable, as the urea formation from $NH_4CO_2NH_2$ is an endothermic reaction.

The effect of excess NH_3 or water is deduced by a partial differentiation of x with respect to a or b as follows:

$$f(x, a, b) = x(x+b)(1+a+b-x) - K(t)(1-x)(a-2x)^2 = 0$$

$$\frac{\partial x}{\partial a} = -\frac{f_a(x, a, b)}{f_x(x, a, b)}, \quad \frac{\partial x}{\partial b} = -\frac{f_b(x, a, b)}{f_x(x, a, b)} \quad (3)$$

where the temperature is constant.

Under usual conditions, a is about 4.0, b is about 0.5 and the temperature is about 190°C; therefore, $\partial x/\partial a$ is about 0.08[3] and $\partial x/\partial b$ is about 0.16, a value which is not remarkably affected by b.

Experimental

The apparatus used was a batch autoclave with an induction heater which could heat up the contents rapidly, thus making it possible to measure the reaction velocity correctly.

As has been mentioned above, our measurement is characterized by its sampling method; that is, a direct sampling from the liquid phase was made with a rubber bladder.

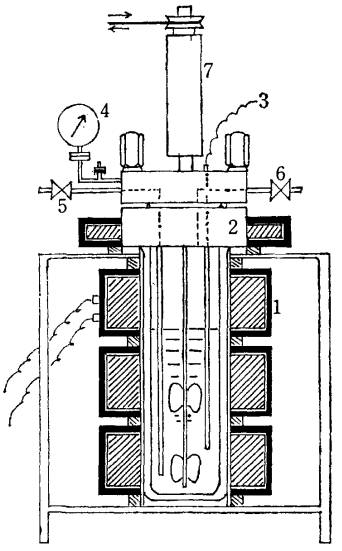

Fig. 1. Batch autoclave.
1: Induction heater, 2: Autoclave (Ti-lined), 3: Thermocouple, 4: Pressure gauge, 5: Sampling valve (liq.), 6: Sampling valve (gas), 7: Agitator

Apparatus. The apparatus is composed of the following three units: an autoclave with an agitator, an induction heater, and a temperature controller with its related meters.

Autoclave: As is shown in Fig. 1, this is a stainless steel batch autoclave lined with titanium; the inner volume is about 3 liters. All of the parts, such as the cover, the pipes, and the valves, are made of titanium alloy, because stainless steel is much corroded by the urea solution at higher temperatures. The agitator is a rotary type working by magnetic induction.

Heater and Others: This heater is composed of four induction coils, as is shown in Fig. 1 tightly fitted to the autoclave. The total output amounts to 35 kW. The temperature of the solution in the autoclave reaches 200°C from room temperature in only 12 min. The input current for heating is controlled with a pulse-type.

3) This figure corresponds to the increase in conversion when the excess of NH_3 is increased by 50%.

a) Final value reached at the equilibrium state.
b) Molar ratio in a taken sample (equal to that in the liquid phase in the autoclave).
c) $NH_4CO_2NH_2$ was used as the starting material instead of urea plus water.

Procedure. For experimental convenience, the charge of materials into the autoclave in most cases was carried out as follows; at first urea plus water (1 : 1 molar ratio) was charged in instead of $NH_4CO_2NH_2$; next, excess water, and at last, excess NH_3 in the liquid state, was charged in. The total amount charged was about 2.1 kg, which corresponded to about 0.7 g/cc of the so-called loading density. In order to confirm the completion of the equilibrium, $NH_4CO_2NH_2$ was sometimes used as the starting material.

The autoclave was purged of air before the charge of liquid NH_3 by light evacuation. After the finish of the charge, heating was started, and then, after a given temperature of the autoclave had been reached, the autoclave was kept at the constant condition for 1—2 hr or longer. Then, after the confirmation of no change in pressure, a sample of liquid (also sometimes one of gas) was directly taken out from the liquid phase in the autoclave (also sometimes from the gas phase) using a weighed rubber bladder with water in it for dilution. About a 15 g sample was taken out and then analyzed by the following methods.

Analysis. After the above sampled solution had been diluted in a volumetric flask, each component was determined in aliquots by taking out a portion.

Urea: drying and weighing method

NH_3: back titration after the removal of CO_2 by excess H_2SO_4

CO_2: gravimetry as $BaCO_3$,[4] which is precipitated by $Ba(NO_3)_2$

Biuret: colorimetry by the cupric complex salt method.

The amount of pure urea is obtained by the subtraction of the amount of the biuret.

H_2O: a residue (assuming that the amount of any other component is negligible.)

In addition to the determinations of the above components, detections for cyanuric acid, melamine, *etc.* are carried out qualitatively if necessary.

Results

Although some experiments for reaction velocity were carried out, only the results on the equilibrium state will be shown in detail in this paper.

The periods of keeping the solution at a given temperature, was 1—2 hr when the temperature was above 180°C, and about 5 hr when it was below 180°C. The ranges of experimental conditions were as follows:

NH_3/CO_2 (mol) $\fallingdotseq 3$—5

H_2O/CO_2 (mol) $\fallingdotseq 0$—1.0

Temperature $\fallingdotseq 170$—220°C

The results are shown in Table 1 and in Figs. 2—6. The ratio, R_F, of the equilibrium conversion observed to that of Frèjacques is also shown by the percentages in Table 1.

Discussion

Experimental Data. First, the effects of three factors, NH_3/CO_2, H_2O/CO_2, and temperature, on the equilibrium conversion will be mentioned and compared with those reported by Frèjacques.

4) When volumetry by CO_2 gas evolution by means of conc. H_2SO_4 is used, the error caused by the hydrolysis of urea becomes a problem.

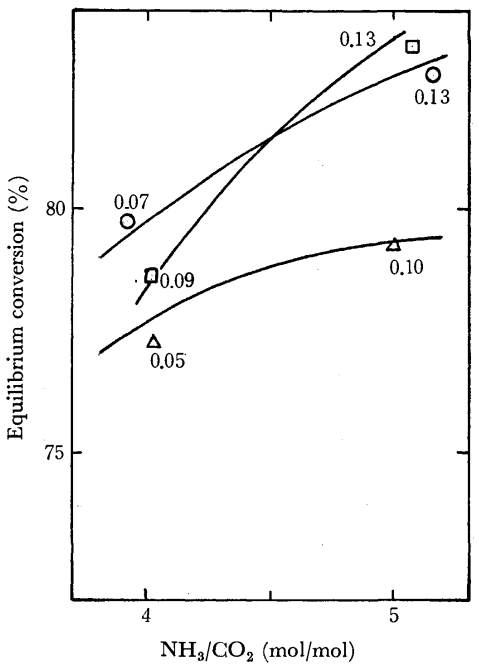

Fig. 2. Effect of NH_3/CO_2 on equil. conversion.

-□- 176.5°C, -○- 196.5°C, -△- 216.5°C

Effect of NH_3/CO_2 (*Cf.* Fig. 2): The tendency for the rate of increase to become slower with an increase in the NH_3/CO_2 ratio is similar to that reported by Frèjacques. That is, $\partial^2 x/\partial a^2 < 0$, the increase in the equilibrium conversion is 1—1.5% per 0.2 of the increase in NH_3/CO_2 (corresponding to a 10% excess of NH_3), and at temperatures higher than 200°C the effect of NH_3/CO_2 is not so much as that reported by Frèjacques.

Effect of H_2O/CO_2 (*Cf.* Figs. 3, 4): In Fig. 3, some relations between the equilibrium conversion and H_2O/CO_2 are shown at several temperatures.

As is shown in Figs. 1—4, a reduction rate of the

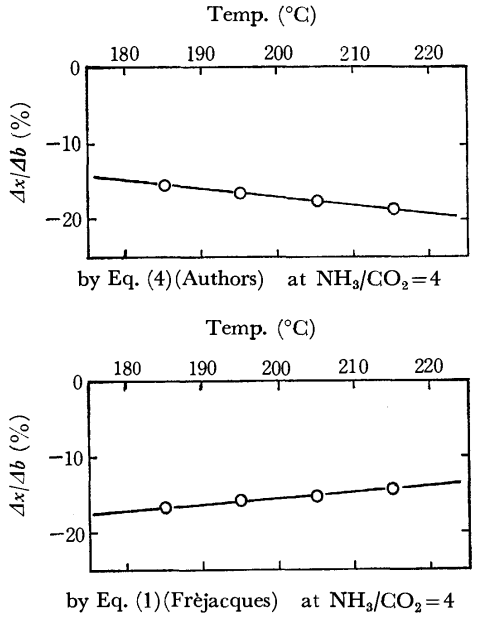

Fig. 4. Temperature dependence of reduction rate of equil. conversion.

equilibrium conversion per 1.0 of Δb becomes larger when the temperature rises, while, on the contrary, it gradually becomes smaller in Frèjacques' case.

Therefore, the ratio, R_F, is rather larger than 100% at higher H_2O/CO_2 ratios when the temperature is low, but, inversely, it is smaller when the temperature is high. The inversion temperature lies around 200°C.

Effect of Temperature (*Cf.* Fig. 5): This is the most important finding in this report. The equilibrium conversion has its maximum value at a temperature which lies between 190 and 195°C when NH_3/CO_2 is about 4.

Therefore, the observed equilibrium conversion is higher than that of Frèjacques at temperatures lower

than about 200°C, while, on the contrary, it is lower at temperatures higher than 200°C.

In Fig. 6 the ratio, R_F of our conversion to that of Frèjacques at the equilibrium state is shown; the figure shows that the equilibrium conversion is higher by 5—15% under the conventional conditions of urea synthesis.

When NH_3/CO_2 changes to 5.0, the temperature giving the maximum equilibrium conversion seems to lie lower than 190°C.

By-products. It has been reported that the decrease in the equilibrium conversion is also due to the increased formation of by-products,[1] *e.g.*, biuret and cyanuric acid, besides the effect of the loading density. It is thought that this can, to some extent, be prevented by the addition of a large amount of excess NH_3; in order to confirm this, we determined the above by-products qualitatively or quantitatively. We found that biuret increases a little at higher temperatures and at lower NH_3/CO_2 ratios, but that, under other conditions, the quantity is far from that quantity which corresponds to the reduction of the equilibrium conversion, while no substantial amounts of cyanuric acid and melamine were detected. Furthermore, the amount of total carbon at the loading of materials was nearly equal to that indicated by analyzed value. Therefore, it can be concluded that the reduction of the equilibrium conversion is not due to the by-product formation.

Table 2. Effect of loading densities on the equilibrium conversion

	A	B	C
Loading density γ(g/cc)	0.8	0.5	0.3

b) Conversion estimated from those under near conditions at a loading density of $\gamma=0.7$

TABLE 3. COMPARISON OF EQUILIBRIUM CONSTANT WITH THAT OF FRÈJACQUES

Temp (°C)	NH_3/CO_2 (mol/mol)	H_2O/CO_2 (mol/mol)	$K_{Frèjacques}$	K_{obsd}
176.5	4.06	0.53	1.142	2.096
	4.99	0.86		2.353
196.5	4.03	0.30	1.561	2.593
	5.36	0.39		2.069
216.5	4.09	0.51	2.149	1.501
	5.17	0.90		1.241

Effect of the Loading Densities. As our data were based on the direct sampling from the liquid phase, it is thought that there is no effect of the loading density on the equilibrium conversion. However, in order to confirm this, some experiments with various loading densities were carried out; the results were nearly independent of the loading densities, as is shown in Table 2.

We also reconfirmed the existence of the temperature giving the maximum conversion using a continuous autoclave which was substantially filled with a urea solution.

Equilibrium Constant. According to the trends of our data, which are very different from the equation reported by Frèjacques, it is natural that the equilibrium constant obtained by Eq. (1) is also different from that of Frèjacques. Some examples are shown in Table 3.

Effect on Processes. From the above-mentioned results, no increase in the equilibrium conversion by raising the temperature can be expected; luckily, the urea reactors were operated at the temperature about 190°C for other reasons—to solve the problems of the reactor materials, pressure, the excess of NH_3, *etc.*

We think that the good equalities between the conversion in the process and that in Frèjacques' equation were due to such factors as the structure of the reactors and the operating conditions.

From another point of view, this means that actual conversion can approach equilibrium if we add some device to the reactor.

Of course economic considerations are necessary, and in this connection the design of the urea reactor would be assisted by reaction kinetics engineering.

Expansion of the Equation of the Equilibrium Conversion

As the equilibrium constant is also affected by the NH_3/CO_2 composition, a simple calculation from a equation like Eq. (1) is impossible. Therefore we obtained Eq. (4) by expansion with respect to a, b, and t, taking the character of our results into consideration. Thus, x is expressed:

$$x = C_1a + C_2a^2 + C_3ab + C_4b + C_5a\left(\frac{t}{100}\right) + C_6b\left(\frac{t}{100}\right) + C_7\left(\frac{t}{100}\right) + C_8\left(\frac{t}{100}\right)^3 + C_9 \quad (4)$$

Where C_i is a factor which was determined by the method of least squares using the data in Table 1. Each C_i value thus obtained is shown in Table 4.

TABLE 4. C_i's OF Eq. (4)

C_1	0.2616	C_6	−0.1030
C_2	−0.01945	C_7	1.640
C_3	0.0382	C_8	−0.1394
C_4	−0.1160	C_9	−1.869
C_5	−0.02732		

By $\partial x/\partial t=0$, the temperatures giving the maximum conversion are, found to be 192°C, 190°C, and 189°C for $a=3$, 4, and 5 respectively, where $b=0$ in all cases.

The differences between the calculated and the observed equilibrium conversions are within 2% in absolute error in 80% of all the data, as is shown in Fig. 7. Therefore, Eq. (4) is useful enough for a simple estimation of the equilibrium conversion.

Although the higher a is, the lower the said temperature seems to be, according to the above values, this is not certain because the data for low a values are few.

180	5.0	1.0	63.5	70.2	73.5

a) Values obtained by means of Frèjacques' monograph
b) Experimental values in Ref. 5

If this is true, however, it is a very interesting phenomenon.

An attempt like Eq. (4) was reported in Ref. 5 (*cf.* Eq. (5)), but the equilibrium conversion of this report lies between our data and those of Frèjacques; some examples are shown in Table 5. We suppose that the difference is due to a different experimental method.

The term of pressure in Eq. (5) is substantially not essential, from our point of view. The effects of NH_3/CO_2, H_2O/CO_2, and the temperature are very similar with our data, but this is supposed to be by chance because the highest temperature in Ref. 5 does not exceed 190°C.

$$x = 34.28\,a - 1.770\,a^2 - 29.30\,b + 3.699\,ab + 0.09129\,t - 0.07482\,at - 5.395\times10^{-6}\,t^3 + 0.002293\,P - 112.1 \quad (5)$$

In Fig. 8 smoothed curves of the equilibrium conversion for the case of $NH_3/CO_2=4.0$ are compared with those of Frèjacques.

The authors gratefully acknowledge, the help of their co-workers, Mr. Hironori Ito, Mr. Tomoyoshi Maekawa, Mr. Goro Komiya, and Mr. Katsumi Kagechika, who carried out all of the experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1345—1348(1972)

Infrared Intensities of Sodium, Calcium, and Potassium Hydroxide Crystals

Toshio KAMISUKI and Shiro MAEDA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received October 5, 1971)

The absolute intensities of OH^- and OD^- stretching absorptions in Na, Ca, and K hydroxide crystals have been measured in the films formed on a quartz window. The thickness of the films was determined by chemical or flame photometric analysis of the solution in which the sample film had been dissolved. The expected difference between OH^- and OD^- in the dipole-moment derivative, $(d\mu/dr)_{OD}$—$(d\mu/dr)_{OH}$, was observed to be in excellent or moderate agreement with the theoretical value given from Ellison's equation for Na and Ca. This result also proves that the polarization of $d\mu/dr$ is in the O^-–$H^+(D^+)$ direction in these cases. As for K hydroxides, although the numeric results are rather dubious, the intensities are apparently by far greater than the two others, confirming the hydrogen-bond formation in this crystals, as suggested by the crystal structure and vibrational frequencies.

The infrared intensity of ionic species provides significant knowledge about the charge distribution in ions, but it has been scarcely investigated as yet except for the measurements of NH_4^+ by Ferriso and Hornig[1] and of BH_4^- by Shull and Schatz,[2] as far as we know. In the present investigation, the intensities of OH^- and OD^- stretching vibrations in Na, Ca, and K hydroxide crystals were measured; they have an unsymmetrical charge distribution, unlike the above two examples.

For a charged diatomic molecule, AB, with a net charge of Qe, Ellison[3] has derived the following expression for the dipole-moment derivative with respect to the vibrational coordinate:

$$(d\mu/dr)_e = e\{(1/2)[Q_a - Q_b - Q(M_a - M_b)/(M_a + M_b)] - N(d\bar{z}_{em}/dr)\}, \quad (1)$$

where M_α and eQ_α are the mass and the charge of a nucleus, α; where N is the number of electrons in a molecule, and where $\bar{z}_{em}$ is the averaged z coordinate (directed B→A) of an electron in the molecule relative to the midpoint between the nuclei.

Now, it can easily be seen from Eq. (1) that the difference in dipole-moment derivatives between isotopic molecules, AB and A′B, is given by:

$$(d\mu/dr)_{A'B} - (d\mu/dr)_{AB} = -eQM_b(M_a' - M_a)/[(M_a + M_b)(M_a' + M_b)], \quad (2)$$

where the subscript e representing the equilibrium value is omitted. For the hydroxide ion of $Q = -1$, it proves to be:

$$(d\mu/dr)_{DO} - (d\mu/dr)_{HO} = 0.251\text{D/Å}. \quad (3)$$

That is to say, the derivative for OD^- is always biased to the O^-–D^+ direction against the corresponding OH^- value by 0.251 D/Å, quite independently of the chemical or physical state of the ions. It is interesting, therefore,

to see how closely this theoretical value is realized in experimental observations for typical metal hydroxides. On the other hand, such an experiment implies a means of estimating the amount of the net charge, Q, when sufficiently accurate measurements are possible.

Experimental

The infrared spectra were measured in thin solid films formed on the surface of a quartz window, which was transparent enough up to the wavelength of ν_{OD} absorption. In the preparation of Na and K hydroxides, the metal was deposited on the window in a vacuum infrared cell at first; then H_2O or D_2O vapour was introduced at a pressure of 10^{-1}—10^{-2} Torr for the reaction. The partial production of the hydrate was easily detected by observing the spectrum, and it was restored to an unhydrous one without difficultly by heating under evacuation. For Ca, separate apparatus equipped with a powerful heater was used for similar procedures, and the completed sample was transferred to the cell for the spectral measurements.

The infrared absorption measurements were limited to the OH^- and OD^- stretching bands because of absorption by the substrate. The spectrum was recorded at room temperature and at a low temperature with liquid N_2. The spectral slit width was chosen so as to be always less than one-third of the apparent band width; in that way the effect of the finite slit width on the integrated intensity could be neglected.

After recording the spectra, the Na and K hydroxide films were dissolved into a small amount of distilled water, and then its metal concentration was determined by flame photometry to give the thickness of the original films.[4] Ca hydroxide films were dissolved into dilute hydrochloric acid. After the residual HCl had been removed by evaporation to dryness, the remaining solid was dissolved in water again and titrated with EDTA.

Results and Discussion

Figure 1 shows the Beer's law plots of the experimental quantity:

$$B' = \int_{\text{band}} \ln (T_0/T) d\nu,$$

where T_0/T is the observed transmittance; the integrated absorption coefficient:

$$A = \int \alpha d\nu$$

was obtained as the limiting slope of these curves. The results are given in Table 1. It is noticeable that the OD^- *vs.* OH^- intensity ratio is definitely greater than the expected value for a neutral case, 1/2, in every case.

The good linearity of the Na and Ca plots in Fig. 1 shows that the thickness of the films was sufficiently uniform and had been determined accurately. The composite error may be estimated at about 15% in these two cases. On the other hand, the rather gross scatter in the K data, probably due to the poor uniformity of films because of its extremely hygroscopic nature, indicates a considerably greater composite error, one of some 30%.

NaOH, NaOD Let us consider the results for NaOH and NaOD first. Ernst[5] has shown by X-rays that the crystal has an orthorhombic lattice with Na and O positions, as is shown in Fig. 2. On the other hand, infrared[6,7] and Raman[6,8] investigations have shown that the two hydroxide ions present in a primitive unit cell are related to each other by a center of symmetry. The allignment of O–H axes has been concluded by Busing to be parallel to the c-axis after taking account of other factors, so that the

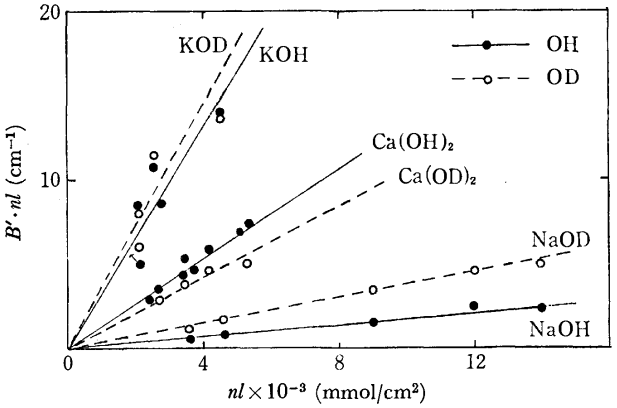

Fig. 1. Beer's law plots for intergrated intensities.

TABLE 1.

Substance	Frequency (cm^{-1}) 25°C	Frequency (cm^{-1}) −165°C	A(−165°C) (cm/mM)	$d\mu/dQ$ [a] ((D/Å)·amu$^{-1/2}$)	$d\mu/dr$ [a] (D/Å)
NaOH	3638	3643	3.8×10^2	0.262	0.255
NaOD	2680	2683	7.8×10^2	0.375	0.502
KOH	3595	3561, 3538 [b]	6.8×10^3	1.11	1.08
KOD	2655	2615, 2587 [b]	7.0×10^3	1.12	1.50

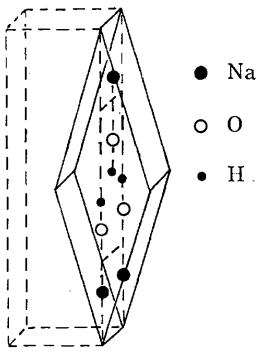

Fig. 2. Crystal structure of NaOH.

structure is described by the space group D_{2h}^{17}.

The infrared active mode of OH(OD) stretching vibration is represented by a unit-cell symmetry coordinate:

$$S_1 = (1/\sqrt{2})(r-r') \tag{4}$$

where r and r' are a pair of O–H(D) stretching coordinates in a unit cell. According to the crystal structure quoted above, the coordinate, S_1, may be allowed to mix only with a translational lattice vibration represented by a unit cell symmetry coordinate:

$$S_2 = (1/\sqrt{2})(R-R') \tag{5}$$

where R and R' are a pair of Na^+—OH^- coordinates in the unit cell. Slight as it may be, such a mixing of modes might influence the $\nu_{OH(OD)}$ intensity more or less significantly because the dipole-moment derivative, $\partial\mu/\partial S_2$, is apparently very great.

The symmetry coordinates above can be given in terms of unit-cell normal coordinates, Q_1 and Q_2, by:

$$\begin{aligned} S_1 &= L_{11}Q_1 + L_{12}Q_2 \\ S_2 &= L_{21}Q_1 + L_{22}Q_2 \end{aligned} \tag{6}$$

Then, the derivative with respect to the normal coordinate may be expressed as:

$$\begin{aligned} \partial\mu/\partial Q_1 &= L_{11}(\partial\mu/\partial S_1) + L_{21}(\partial\mu/\partial S_2) \\ &= \sqrt{2}\,[L_{11}(\partial\mu/\partial r) + L_{21}(\partial\mu/\partial R)], \end{aligned} \tag{7}$$

which is related to the observed intensity by:

$$A_t = \frac{N\pi}{3c^2n}\left(\frac{n^2+2}{3}\right)^2\left(\frac{\partial\mu}{\partial Q_i}\right)^2. \tag{8}$$

Equation (8) includes the correction factor given by Polo and Wilson[9] for the effective radiation field in a medium with a refractive index of n, where N is the number of molecules per cm^3, and c, the velocity of light in a vacuum.

Now, $\partial\mu/\partial R$ may be assumed to be roughly equal to the electronic charge, $e=4.80\times10^{-10}$esu. On the other hand, it can be shown straightforwardly from a fundamental equation that:

$$\frac{L_{21}}{L_{11}} = -\frac{(\mu_{Na}+\mu_{OH})f_{Rr}}{(\mu_{Na}+\mu_{OH})F_R-\lambda_1}, \tag{9}$$

where μ_M is the reciprocal of the mass of M, $\lambda_1=4\pi^2c^2\nu_1^2$ (ν_1 in cm^{-1}), and, where f_{Rr} and F_R are the force constants defined in the expression for the potential energy:

$$2V = F_r(r^2+r'^2) + F_R(R^2+R'^2) + 2f_{Rr}(rR+r'R'). \tag{10}$$

As it is certain that:

$$\lambda_1 \simeq (\mu_O+\mu_H)F_r \gg (\mu_{Na}+\mu_{OH})F_R \simeq \lambda_2, \tag{11}$$

Eq. (9) may be approximated as follows:

$$\frac{L_{21}}{L_{11}} \simeq \frac{f_{Rr}}{F_r}\left(\frac{\mu_{Na}+\mu_{OH(OD)}}{\mu_O+\mu_{H(D)}}\right) = \left(\frac{f_{Rr}}{F_r}\right)\times\begin{cases}0.096 & \text{(NaOH)}\\ 0.176 & \text{(NaOD)}\end{cases} \tag{12}$$

Although the lattice frequency concerned is not known, it may be reasonably approximated by the highest frequency of the translational mode estimated by Buchanan[7] based on the summation side band, *i.e.*, 296 cm^{-1} for NaOH and 286 cm^{-1} for NaOD. Force constants consistent with these frequencies, together with the observed ν_{OH} and ν_{OD} values, are obtained as follows:

$$F_r = 8.01,\ F_R = 0.46,\ f_{Rr} = 0.05 \text{ mdyne/Å}$$

Therefore, L_{11} may be almost exactly equal to $G_{11}^{1/2}=(\mu_O+\mu_{H(D)})^{1/2}$ ignoring L_{12} in Eq. (6). Therefore, it may be seen that $L_{21}(\partial\mu/\partial S_2)$ in Eq. (7) is no more than 0.005 D/Å for both OH^- and OD^-, so that the effect of lattice-mode mixing may be scarcely significant except when $|\partial\mu/\partial Q_1|$ is by far smaller than in the present observations.

Thus, we can now straightforwardly give $\partial\mu/\partial r$ as is shown in Table 1. The difference in the derivative between OD^- and OH^- is:

$$(\partial\mu/\partial r)_{OD} - (\partial\mu/\partial r)_{OH} = 0.247\ D/Å, \tag{13}$$

which is in very good agreement with the theoretical expectation, 0.251 D/Å. In addition, the positive value of (13) confirms that $\partial\mu/\partial r$ is of an O^-H^+(or O^-D^+) polarization in both OH^- and OD^-.

$Ca(OH)_2$, $Ca(OD)_2$ X-ray studies[10-12] have indicated that the crystal structure of $Ca(OH)_2$ has the hexagonal symmetry of the D_{3d}^3 space group, and that the hydrogen positions were determined to be as is shown in Fig. 3 by neutron diffraction.[13] The unit cell contains one $Ca(OH)_2$ "molecule," whose two OH^- ions are related to each other by a center of symmetry and are arranged in parallel with the

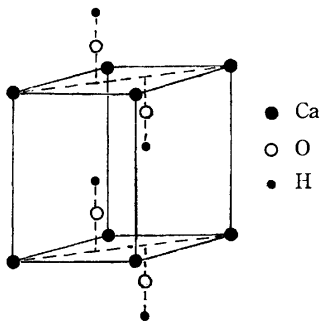

Fig. 3. Crystal structure of $Ca(OH)_2$.

hexagonal axis. Therefore, the coupling between the O–H(D) stretching and translational lattice vibrations can be considered in essentially the same way as in NaOH. Thus, it is easily confirmed that the effect of lattice vibration on the $\nu_{OH(D)}$ intensity is no more than trivial in this case, too.

The quantity corresponding to (3) comes to be:

$$(\partial\mu/\partial r)_{OD^-} - (\partial\mu/\partial r)_{OH^-} = 0.15\ D/\text{Å}$$

which is appreciably smaller than the theoretically expected value, 0.251 D/Å, but still demonstrates the O^-H^+ (or O^-D^+) polarization of the derivatives. On the other hand, the values of $\partial\mu/\partial r$ are themselves definitely greater than those of the Na hydroxides. As the close proximity of the $\nu_{OH(OD)}$ frequencies for Na and Ca suggests little difference in the features of the O–H bonding electrons, the electronic condition of the metal···OH binding may be mainly responsible for the above difference in $\partial\mu/\partial r$. A possible inference is that the Ca···OH binding is of a slightly more covalent nature than Na···OH, so that the former has more vibronic coupling with the O–H stretching motion than the latter.

KOH, KOD Considerably greater intensities than the previous two were obtained for *K* compounds, confirming the formation of hydrogen bonds in this crystal, as suggested by the X-ray results[14] and the infrared frequency.[15] The poor agreement between the observed value,

$$(\partial\mu/\partial r)_{OD} - (\partial\mu/\partial r)_{OH} = 0.42\ D/\text{Å}$$

and the theoretical value, 0.251 D/Å, is probably due to experimental errors, as the scatter of the data was rather gross, as may be seen in Fig. 1. The appearance of the films, which was rather rough compared with that of the two others, suggests that the poor uniformity films caused such a scattering in this case.

A remarkable fact is the extreme dependence of the intensity on the temperature. Even the thickest sample recorded on Fig. 1 gives only a trace of absorption, about one-tenth of the low temperature value, at room temperature. This is in corespondence with the frequency shift caused by the temperature, as may be seen in Table 1, suggesting the temperature dependence of the hydrogen-bond strength.

Finally, mention may be made of the possible formation of the oriented crystals. For $Ca(OH)_2$, no appreciable orientation effect was found when the spectrum was recorded by tilting the sample film against the light beam by some 45°. The layer structure of this crystal suggests an orientation with *a*, *c*-axis perpendicular to the plate as most probable; for this, the above observation may be a sensitive test. For Na and K compounds, it was difficult to perform a similar test effectively, because of their hygroscopic natures. However, Busing[6] has concluded that the orientation effect is absent in NaOH by observing it with various substrate materials, and also by comparing it with a directly-evaporated NaOH film. The close agreement of the observed $(\partial\mu/\partial r)_{OD}-(\partial\mu/\partial r)_{OH}$ value with the theoretical value for randomly-oriented crystals seems to support the above conclusion.

A Study on the Nature of the Electronic Absorption Bands of Formylpyrroles and Acetylpyrroles[1)]

Taku MATSUO and Hideto SHOSENJI*

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received October 11, 1971)

The electronic spectra of formyl- and acetylpyrroles were studied from both experimental and theoretical viewpoints. On the basis of the solvent effect and pH-dependence of the absorption spectra, the lowest energy transitions of 2- and 3-acetylpyrroles and the corresponding formylpyrroles, as well as the second lowest energy transitions of 3-acylpyrroles, were suggested to be accompanied by the electron-transfer from the pyrryl to carbonyl group. As to 1-acetylpyrrole (or 1-formylpyrrole), the longest wavelength absorption bands disappeared when the conjugation between the pyrryl and carbonyl groups were inhibited by steric hindrance. Solvent effects on the absorption band, however, were so small that the extent of electron-transfer was considered to change little during the transition. The results of VESCF MO calculations also supported the above suggestion based on experimental observations. The behaviors of the second lowest energy transitions of 1- and 2-acylpyrroles were too complicated to be accounted for straightforwardly.

Aside from pyrrole itself, no theoretical studies have been made on the electronic spectra of substituted pyrroles. In the case of monosubstituted benzenes, the composite-molecule method has been successfully applied to interpret electronic spectra. Taking the case of benzaldehyde, as an example, the absorption band at 43 kK was assigned to an intramolecular charge-transfer band from calculations based on the composite-molecule method.[2)] Similar treatment is expected to be successful also in the case of substituted pyrroles because the pyrryl group is known to be a good electron donor as can be seen in studies on charge-transfer complexes[3)] and the electronic spectra of 1-(*p*-substituted phenyl)-pyrroles.[4)] Since the ionization potential of a pyrryl group is lower than that of a phenyl group, the charge-transfer configuration is expected to make a significant contribution to the electronic structures of pyrrole derivatives with a carbonyl group. In fact, the internal rotation around the C–N bond in 1-acylpyrroles was found to be fairly restricted due to the presence of double bond character ascribed to the contribution of charge-transfer configurations.[5)]

In the present study, we investigated the characteristic absorption bands of formyl- and acetylpyrroles in the ultraviolet region which is usually accessible, to examine how well one can interpret the nature of these spectra on the basis of the electron transfer from the pyrryl to carbonyl group.

Results and Discussion

The lowest energy electronic transition of pyrrole is located at 47.6 kK. If an acyl group is attached to a pyrryl group, strong characteristic absorption bands are found for each isomer in the region between 35 and 45 kK (Fig. 1). The electronic spectra of formylpyrroles closely resemble those of the corresponding acetylpyrroles. The observed absorption maxima of these compounds together with their 1-methyl-substituted derivatives are listed in Table 1.

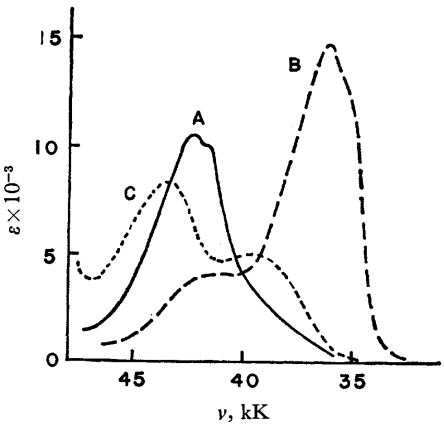

Fig. 1. The ultraviolet absorption spectra of acetylpyrroles in *n*-hexane.
A, 1-acetylpyrrole; B, 2-acetylpyrrole; C, 3-acetylpyrrole.

If the contribution of charge-transfer configurations in the electronic structure is more significant in an excited state than in the ground state, the corresponding absorption band should show an appreciable red-shift as the polarity of solvent increases. The behavior of the first absorption band of 2-acetylpyrrole is in accordance with this expectation. As an alternative explanation for the red-shift observed in the ethanol solution, the hydrogen bonding between pyrrole and ethanol molecules might be suggested. However, the absorption maximum of the first band of 1-methyl-2-acetylpyrrole is located very close to that of 2-acetylpyrrole not only in *n*-hexane but also in ethanol. The same situation is also encountered when we compare the first absorption bands of 2-formylpyrrole and 1-methyl-2-formylpyrrole. It is thus very unlikely that the hydrogen bonding plays an important role in the solvent-induced red-shift given in Table 1. The second absorption bands of 2-acetylpyrroles and 2-formylpyrroles, on the other hand, are not shifted appreciably by the change of solvent from *n*-hexane to alcohol.

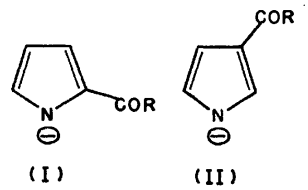
a) The values are in kK units. Errors are within 0.1 kK unless specified.
b) The values are in 10^3 *l*/mol·cm units. Errors are within 100 *l*/mol·cm except for the case of the shoulder of an absorption band, where the error may be twice as large as that for the case of a distinct peak.
c) The shoulder of an absorption band. Errors are estimated to be within 0.3 kK.
d) The absorption maximum could not be located on account of the band being hidden under the tail of the second absorption band.

In the case of 3-acetylpyrrole and its 1-methyl-substituted derivative, both the first and the second absorption bands show a red-shift when the solvent is changed from *n*-hexane to ethanol. In order to further investigate the electronic origin of the above described absorption bands of 2- and 3-acylpyrroles, we measured the electronic spectra in alkaline solutions. The results are shown in Figs. 2 and 3 for 2-formylpyrrole and 3-acetylpyrrole, respectively. In both cases, the longest wavelength absorption bands in 10N sodium hydroxide are found in a considerably longer wavelength region in neutral solutions. The spectra of 2-acetylpyrrole show a similar pH-dependence as observed in the case of 2-formylpyrrole. In alkaline solutions, these compounds are considered to exist as the anions as shown by structures (I) and (II).[6]



Since the ionization potential of the pyrryl anion should be considerably lower than that of neutral species, the large red-shift in alkaline solutions can be taken as sufficient evidence for assigning the absorptions to charge-transfer bands.

The longest wavelength absorption band of 1-acetylpyrrole is almost the same as that of 1-formylpyrrole, both of them being found in energy regions lower by about 5 kK than that of pyrrole. The absorption bands of 1-formylpyrrole, as well as those of 1-acetylpyrrole, consist of two components: a strong main peak (Band A) at about 42 kK and its shoulder (Band B) at approximately 38 kK. As to 1-formyl- and 1-acetylpyrrole, Band B is observed only as a small hump on the tail of Band A. On substitution of the proton at the 2-position by a methyl group, Band B appears clearly because

A, in water; B, in 10N aqueous sodium hydroxide solution.

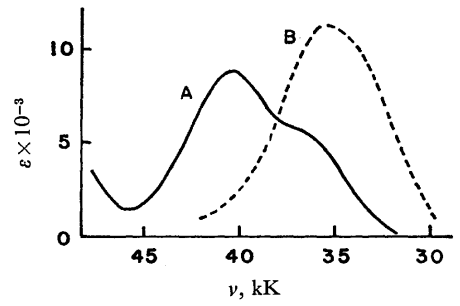

Fig. 3. The pH-dependence of the absorption spectra of 3-acetylpyrrole.
A, in water; B, in 10N aqueous sodium hydroxide solution.

6) Bonino and Mirone isolated the sodium salt of 2-formylpyrrole.[7] On inspecting the IR spectra, they concluded that the NH proton dissociated to yield the sodium salt. The evidence for the presence of anions (I) and (II) is also given by the fact that a methyl group is introduced to the nitrogen atom of 2-formylpyrrole,[8] 2-acetylpyrrole,[9] and 3-acetylpyrrole (present experiment), respectively, when the alkaline solutions are treated with dimethyl sulfate.

a hypochromic effect is observed on Band A while Band B is slightly shifted to longer wavelength with no change in its intensity. The absorption maximum of 2-methyl-1-acetylpyrrole in the vapor phase is slightly shifted to longer wavelength in comparison with that in the solution, but the shapes of the spectra in the two phases are essentially the same. The intensity of Band B is rather weak ($f \sim 0.02$), but stronger than that of ordinary n-π^* absorption bands. The solution spectra are not affected even by the addition of trifluoroacetic acid. Thus we can disregard the possible contribution of the lone pair electrons of the carbonyl group to the appearance of the absorption bands. In other words, both Bands A and B are assigned to π–π^* transitions. In the case of 2,5-dimethyl-1-acetylpyrrole, the plane of the acetyl group is twisted to almost a perpendicular position to that of the pyrryl group. As a consequence, both Band A and B disappear as can be seen in Fig. 4. The above results are also summarized in Table 2. It is clearly understood that the conjugation between the pyrryl and carbonyl groups is definitely required for the presence of both Bands A and B. Introduction of methyl groups into the 3- and 4-positions of the pyrryl group causes a large red-shift (1.8 kK) of Band A of 1-acetylpyrrole. Band B, on the other hand, is not affected and almost concealed under the shifted Band A (Fig. 4). Considering the fact that the first charge-transfer band of the chloranil complex of 3-methylpyrrole is also shifted to a wavelength longer by 1.7 kK than that of the chloranil-pyrrole system,[3] we would like to assign Band A to the intramolecular charge-transfer band. However, on the basis of the solvent effects, it is difficult to assign either Band A or B to charge-transfer absorptions, because the absorption maxima of these bands of 2-methyl-1-acetylpyrrole are hardly shifted by the change of the solvent from n-hexane to ethanol.

The results are well accounted for if one assigns the longest wavelength absorption bands of 2- and 3-acetylpyrroles to charge-transfer bands. This is also true for 2- and 3-formylpyrroles. In the case of 1-acetyl- or 1-formylpyrrole, however, it is difficult to assign the longest wavelength absorption band to charge-transfer absorption straightforwardly.

In the NMR spectroscopic rate studies, on the other hand, the barrier to internal rotation in 1-formyl- or 1-acetylpyrrole has been found to be clearly higher than that in the isomers correspondingly substituted at the 2- or 3-position.[5,10] The result indicates that the ionic form (III) makes more significant contribution to the ground state of the 1-substituted pyrroles than the ionic forms (IV) and (V) to the ground states of 2- and 3-acylpyrroles, respectively.

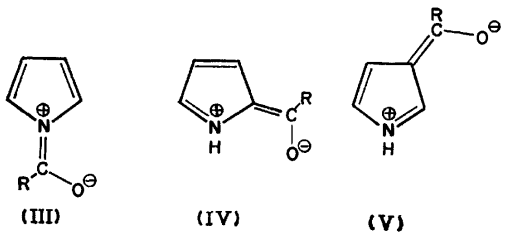
d) The absorption maximum could not be located on account of the band being hidden under the tail of Band A.



In order to explain the above results, spectroscopic differences between the isomers of formyl- or acetylpyrroles and the electronic structures of these molecules were examined by the use of pi-electron approximation. Brown and Heffernan's VESCF MO with CI was adopted for this purpose. Geometries of the investigated molecules were estimated from those of the closely related compounds.[11] The one-center electron repulsion integrals were calculated by the use of Paolini's approximation,[15] and the two-center integrals were

10) L. Arlinger, K.-I. Dahlqvist, and S. Forsén, *Acta Chem. Scand.*, **24**, 672 (1970).
11) The geometry of the pyrryl group was assumed to be the same as that of pyrrole itself.[12] Referring to the cases of acetamides[13] and acetaldehyde,[14] it was assumed that the bond between the pyrryl and carbonyl groups is either 1.36 Å (1-acylpyrroles) or 1.4 Å (2- and 3-acylpyrroles), and also that the bond bisects the angle between the adjacent two bonds in the pyrryl group. Similarly, the bond length of the carbonyl group was assumed to be 1.21 Å. The bond angles associated with the carbonyl carbon were taken to be those for the ideal sp^2 hybridization.

evaluated by the use of the Nishimoto and Mataga equation. The penetration integrals were not taken into consideration. Pariser and Parr's formula was used for the estimation of the core resonance integrals (H_{pq}), except for the case of $H_{C=O}$, where Tanaka's value for formamide (−3.35 eV)[16] was adopted. The valence ionization potentials were estimated by means of Brown's approximation based on the effective nuclear charges on the atoms.[17] The lower nine of the singly-excited configurations were included in the CI calculation. The values thus obtained for transition energy, oscillator strength and the electronic configurations mainly contributing to the relevant, low excited states of the acylpyrroles are given in Table 3. The coefficients for the $2p$ orbital of each atom in the relevant π orbitals are shown in Fig. 5. The results for only one conformer of each isomer are shown here, because no significant difference between the rotamers was found as far as the carbonyl group was assumed to be coplanar with the pyrryl group. Similarly, the difference between acetyl and formyl groups was also disregarded in the calculation, because the observed electronic spectra of formylpyrroles are almost the same as those of the corresponding acetylpyrroles in the investigated region.

The calculated π–π^* transition energies are higher than the values obtained experimentally by approximately 1 eV. It is clear that more advanced treatment is required to obtain a satisfactorily quantitative agreement between the observed and the calculated values. Several important features of the electronic spectra of acylpyrroles are noticed, however, even in the present results. On the basis of the data in Table 3, it is expected that two absorption bands for each isomer will be found in the energy region (200—300 mμ), and that the lowest energy transition of 2-acylpyrroles will be found at the longest wavelength side as a rather strong peak, which is distinctly separated from those of the other isomers. These predictions are in fair agreement with observations. On examination of the electron configurations concerned, it is easily found also that these low energy transitions are originated from the simultaneous excitation of both the pyrryl and the carbonyl groups. In other words, a strong conjugation between the two groups are theoretically required for the presence of the observed absorption bands, as was verified in the case of methylsubstituted 1-acetylpyrrole (Fig. 4).

TABLE 3. CALCULATED VALUES FOR THE TRANSITION ENERGY (ΔE_k), OSCILLATOR STRENGTH (f_k), AND WAVE FUNCTIONS (Φ_k) FOR LOW-EXCITED STATES OF ACYLPYRROLES

ΔE_k (eV)	f_k	Φ_k[a]
1-Acylpyrrole		
5.87	0.23	$0.875\Phi_{35}-0.446\Phi_{46}$
6.03	0.20	$0.997\Phi_{45}+0.045\Phi_{26}$
7.53	0.16	$0.828\Phi_{47}+0.387\Phi_{36}$
2-Acylpyrrole		
5.55	0.42	$0.902\Phi_{45}+0.372\Phi_{35}$
5.89	0.23	$0.751\Phi_{35}+0.468\Phi_{46}$
7.04	0.33	$0.748\Phi_{46}-0.459\Phi_{35}$
3-Acylpyrrole		
5.85	0.01	$0.765\Phi_{35}-0.540\Phi_{46}$
6.07	0.24	$0.942\Phi_{45}+0.251\Phi_{35}$
6.60	0.71	$0.781\Phi_{46}+0.561\Phi_{35}$

a) Φ_{ij} denotes an electronic configuration which is obtained by the promotion of a π electron from the ith MO to the jth MO, when the pi-electron approximation was adopted in the calculation. The most important two electronic configurations for each energy level are shown for the sake of simplicity.

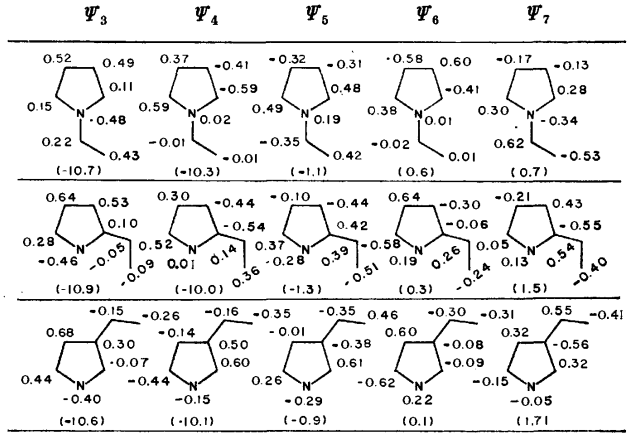

Fig. 5. The coefficients for the atomic orbitals in the relevant MO associated with the low energy transitions of acylpyrroles. The energy of each orbital, in eV units, is given by the numeral in parentheses under the corresponding structure.

TABLE 4. π-ELECTRON DENSITY ON THE CARBONYL GROUP OF ACYLPYRROLES IN THE GROUND STATE AND THE TWO LOW-EXCITED STATES

Compound	Ground State	1st Excited State	2nd Excited State
1-Acylpyrrole	0.065	0.056	0.383
2-Acylpyrrole	0.024	0.313	0.163
3-Acylpyrrole	0.026	0.162	0.226

The π electron densities on the carbonyl groups were evaluated in order to find an explanation for the different solvent-induced shifts of the absorption maxima of the acylpyrroles. The results are shown in Table 4. The extent of electron transfer in the ground state from the pyrryl to carbonyl group in 1-acylpyrrole is suggested to be larger than that in 2- and 3-acylpyrroles. This is in line with the fact that the barrier to internal rotation of carbonyl group in 1-acylpyrrole is higher than that in 2- and 3-acylpyrroles. In the first excited state, the π electron densities on the carbonyl groups of 2- and 3-acylpyrroles increase in comparison with those in the ground states. Thus, the first absorption bands of these compounds in ethanol are shifted to longer wavelength than those in n-hexane (Table 1). Similarly, the negligibly small solvent effects on the absorption bands of 1-acylpyrroles can be accounted for by the minute change in the calculated π electron density on the carbonyl group on going from the ground state to the first excited state.

The situation is much more complicated in the case

16) J. Tanaka, *Nippon Kagaku Zasshi*, **78**, 1636 (1957).
17) R. D. Brown and M. L. Heffernan, *Aust. J. Chem.*, **12**, 554 (1959).

of the second excited states of acylpyrroles. The correlation between the solvent-induced shift and the change in electron density at the carbonyl group is found only in the case of 3-acylpyrroles. From the values given in Table 4 we might expect a fairly strong solvent-dependence of the absorption due to the second lowest energy transition of 1-acylpyrrole. The experimental results are not in agreement with this expectation. Almost the same thing could be said with the second excited states of 2-acylpyrroles. It should be remembered that Band A of 1-acetylpyrrole shows an appreciable red-shift (1.8 kK) on the introduction of methyl groups at the 3- and 4-positions. A possible case might be where the π electron is actually transferred from the pyrryl to carbonyl group in the second excited state as indicated by calculation and also by the effect of methyl substitution at the 3- and 4-positions of 1-acetylpyrrole. The migration of π electrons thus induced might be counter-balanced by the polarization of σ electrons.

Experimental

Materials. The following compounds were prepared according to the method described in the literature given in parentheses or its modification: 1-formylpyrrole (Ref. 18, bp 81—83°C/60.5 mmHg), 1-acetylpyrrole (Ref. 19, bp 86.5°C/29 mmHg), 3,4-dimethyl-1-acetylpyrrole (Ref. 19, bp 120°C/27 mmHg), 2-methyl-1-acetylpyrrole (Ref. 20, bp 94—95°C/27.5 mmHg), 2,5-dimethyl-1-acetylpyrrole (Ref. 20, bp 110°C/23 mmHg), 2-formylpyrrole (Ref. 21, mp 44.4—44.9°C), 1-methyl-2-formylpyrrole (Ref. 21, bp 87—92°C/22 mmHg), 2-acetylpyrrole (Ref. 22, mp 92.0—92.7°C), 1-methyl-2-acetylpyrrole (Ref. 23, bp 92.3—94.0°C/22 mmHg), 3-acetylpyrrole (Ref. 24, mp 115.9—116.5°C), 1-methyl-3-acetylpyrrole (Ref. 9, bp 97.5—102.0°C/3 mmHg). All the above compounds were identified by elementary analyses, IR, and NMR spectra.

n-Hexane and ethanol were purchased from Wako Pure Chemicals Industries Ltd. They were repeatedly purified by the usual methods until they proved to be pure spectroscopically.

Spectroscopic Measurements. The electronic spectra were measured with a Bausch & Lomb Spectronic 505 Recording Spectrophotometer at temperatures between 17 and 19°C. The concentrations of the solutions were between 10^{-4} and 10^{-5} mol/*l*.

The authors are greatly indebted to the members of the Computer Center, Kyushu University, for their help in carrying out the VESCF MO calculations on a model OKITAC-5090H computer. Thanks are also due to Mr. Hajime Koga for his help in the study of the solvent effect on the spectra of 2-methyl-1-acetylpyrrole.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1353—1357(1972)

The Isomerization of Propylene Oxide on Metal Phosphate Catalysts

Toshinobu IMANAKA, Yasuaki OKAMOTO, and Shiichiro TERANISHI
Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Osaka
(Received October 13, 1971)

The isomerization of propylene oxide was carried out on metal phosphate catalysts. The main products were allyl alcohol, propionaldehyde, acetone, and 1-propanol. It was found that allyl alcohol is produced by acid-base bifunctional catalysts, acetone, by basic-site catalysts only, and propionaldehyde, by acid-site catalysts. 1-Propanol may be produced by the hydrogen-transfer reaction of allyl alcohol. The conversion to propionaldehyde is proportional to the acidity of the catalyst, the strength of which is stronger than $H_0=+4.8$. The sum of the conversions to allyl alcohol, acetone, and 1-propanol correlate linearly with the observed basicity ($H_0 \geqq +7.2$) of the catalyst. The selectivity and activity are determined by the basic and acidic properties of the catalyst. The mechanisms of the propylene oxide isomerization are also discussed.

The activity and selectivity for a reaction on solid acids and bases are considered to be determined by the acidic and basic properties of the catalysts, and it is important to clarify the reaction between the acidic and basic properties of the catalysts and the selectivities and activities for the reactions. The relations between the activities and the observed acidities or basicities have already been reported by many workers.[1-4] However, as regards the relationship between the selectivity and the acidic and basic properties of the catalysts, little work has been done. Misono and his co-workers[5,6]

have reported that the selectivities for the *n*-butene isomerization reaction over metal sulfates are determined by the acid strength of the catalyst. According to Niiyama and E. Echigoya[7] the selectivity for the dehydration and dehydrogenation of alcohols over acid-base bifunctional catalysts is controlled by the acid and base properties of catalysts. In our preceding paper,[8] the selectivity for the propylene-oxide isomerization on zeolite catalysts was determined by the acid strength of the catalysts. In this paper, the selectivity and activity for the propylene-oxide isomerization over metal phosphates will be investigated with respect to the acidic and basic properties of the catalysts.

Propylene oxide is generally isomerized to acetone, propionaldehyde, and allyl alcohol, but only a trace of allyl alcohol wasproduced on zeolite catalysts.[8] Fowler and Fitzpatrick[9] have reported that basic lithium phosphate has a high selectivity to allyl alcohol. It has been reported by Mathieu and co-workers[10,11] that propylene oxide is isomerized to allyl alcohol by basic sites on lithium phosphates and to propionaldehyde by acid sites on the 3.9 $Cr_2O_3 \cdot 1.1\ WO_3 \cdot 1.8\ H_2O$ catalyst.

The isomerization of propylene oxide on metal phosphates will be studied here. The relations between the selectivities and activities and the acidic and basic characteristics of catalysts are discussed. Moreover, a possible reaction mechanism of the isomerization is also discussed.

Experimental

Materials. The catalysts used were as follows: $NaLi_2PO_4$ (basic lithium phosphate), KLi_2PO_4, Na_2LiPO_4, K_2LiPO_4, $AlPO_4$, $Mg_3(PO_4)_2$, $Ca_3(PO_4)_2$, and Li_3PO_4. Basic lithium phosphate was prepared according to the method by Fowler and Fritzpatrick.[9] KLi_2PO_4, Na_2LiPO_4, and K_2LiPO_4 were prepared from potassium phosphate monobasic, sodium phosphate dibasic, and potassium phosphate dibasic respectively by neutralizing them with equivalent amounts of lithium hydroxide at 40°C. The following procedures were the same as those for basic lithium phosphate. The other reagents were commercial grade.

Procedures. The reactions were carried out using a usual pulse reactor in helium gas as the carrier. The catalysts (about 20 mg) were heated at a reaction temperature for about 2 hr in streaming helium before the reaction, The amount of reactant injected was 2 μl. Deactivation of the catalysts used was observed, and the material balance was found to hold approximately in this reaction.

The acidic and basic strengths of catalysts which had been heated at 300°C for 2 hr in air were measured by the conventional indicator method using a Hammett indicator. The acid and base contents were determined by the simple titration method, using *n*-butylamine and benzoic acid as the titers respectively.

Results and Discussion

The acid and basic strengths, the acidity ($H_0 \leq +6.8$ and $+4.8$), the basicity ($H_0 \geq +7.2$), and the surface area measured by the BET method are listed in Table 1 for each catalyst. Lithium phosphate has only acidic character, but Li_2MPO_4- and LiM_2PO_4-type phosphates (M=Na or K) have both basic and acidic properties. The product distributions of propylene oxide isomerization are shown in Table 2. The "other products" in the last column of Table 2 contain acrolein, polymers, and condensed products. Only small amounts of gaseous products and acetaldehyde, which may be products decomposed of propylene oxide and other products, are formed. High selectivities for allyl alcohol were obtained with sodium- or potassium-type lithium phosphates. The activation energies for allyl alcohol, acetone, propionaldehyde, 1-propanol, acetaldehyde, and gaseous products were 13.2, 6.1, 12.9, 12.0, 12.3, and 6.6 kcal/mol respectively over a basic lithium phosphate catalyst.

Generally, it is known[12-14] that when the oxygen atom of propylene oxide is attacked by a proton, the epoxide ring opens at the oxygen-α carbon linkage, and that when the β carbon is attacked by an anion, propylene oxide gives a product in which the oxygen-β carbon bond breaks. On the basis of these facts, it can be estimated that propionaldehyde is produced on acid

sites and that acetone is formed on basic sites. The poisoning effects of pyridine and dichloroacetic acid on the propylene oxide isomerization reaction were investigated in order to confirm these estimations. Figures 1a and 1b show the effects of pyridine injected with reactants over basic lithium phosphate. The conversions to propionaldehyde, allyl alcohol, and *n*-propanol decrease gradually with an increase in the amount of pyridine added, but those to acetone, acetaldehyde, and gaseous products increase with added pyridine. Without catalysts, only smallamounts of gaseous products and acetaldehyde were produced, and no effects of pyridine were observed. Hence, pyridine shows no catalytic effects in the gas phase. Consequently, it is considered that pyridine is adsorbed on acid sites and makes a basic site strong by means of an inductive effect.

Figures 2a and 2b show the effects of dichloroacetic acid on the reaction. The conversions to acetone, allyl alcohol, 1-propanol, and acetaldehyde decrease gradually with the addition of dichloroacetic acid, but those to propionaldehyde and gaseous products are un-

changed. Therefore, it may be concluded that propionaldehyde is produced on acid sites; acetone, acetaldehyde, and gaseous products, on basic sites, and allyl alcohol and 1-propanol, on acid-base bifunctional sites.

According to Table 2, a calcium phosphate catalyst produces larger amount of 1-propanol than do the other catalysts investigated. 1-Propanol is hydrogenated compound of propylene oxide, allyl alcohol, and propionaldehyde. The addition of water to the reaction system has no effect on the formation of 1-propanol. Moreover, in the case of the isomerization of propylene oxide, the amount of acrolein formed over calcium phosphate is 7.1% in the product distribution, but in the case of other catalysts, it is smaller than 1%. Hence, it is considered that the hydrogen atoms in 1-propanol come from the reactant and/or products by hydrogen-transfer reaction. The difference between the amount of 1-propanol and that of acrolein is deduced to be due to the fact that acrolein makes polymers easily. According to Figs. 1 and 2, the amount of 1-propanol gradually decreases as that of allyl alcohol does upon pyridine and dichloroacetic acid poisoning. Since the hydrogen-transfer reaction is considered to be catalyzed by basic sites, according to Schachter and Pines,[15] allyl alcohol must be at least concerned in the 1-propanol formation. Therefore, it may be deduced that 1-propanol and acrolein are produced by the hydrogen-transfer reactions between allyl alcohol and propylene oxide, propionaldehyde, and allyl alcohol.

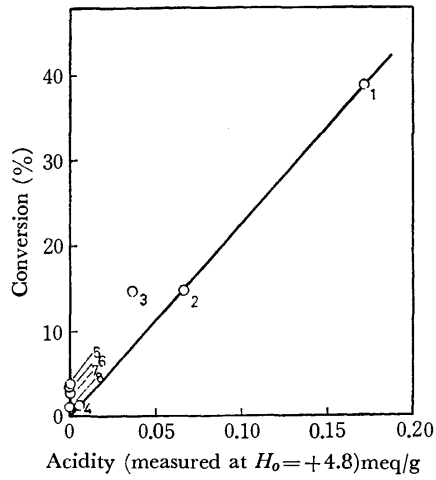

Fig. 3. Correlation between the conversion of propionaldehyde and the acidity measured at H_0=+4.8
1: $AlPO_4$, 2: $Ca_3(PO_4)_2$, 3: $Mg_3(PO_4)_2$, 4: Li_3PO_4, 6: KLi_2PO_4, 7: Na_2LiPO_4, 8: Li_2NaPO_4

The relationship between the conversion to propionaldehyde and the amount of the acid site, the strength of which is stronger than H_0=4.8, is shown in Fig. 3. However, there was no correlation when the acid content measured at H_0=+6.8 was taken into consideration. Therefore, it may be concluded that propionaldehyde is formed on stronger acid sites than H_0=+4.8. This conclusion is consistent with the results estimated from the propylene-oxide isomerization over a series of zeolite catalysts.[8] Figure 4 shows the

relation between the observed basicity (H_0=+7.2) and the sum of the conversions to acetone, allyl alcohol, and 1-propanol. Acetaldehyde and gaseous products were disregarded in view of the small amounts of them formed. However, there were no good correlation between the basicity and the respective conversion to them. Consequently, acetone, allyl alcohol, and 1-propanol are considered to be formed competitively over basic sites.

The formation of allyl alcohol needs both acid and basic sites. However, the Li_2NaPO_4 catalyst, which is most active in allyl alcohol formation, has only weak acid (H_0=+6.8). Therefore, it may be concluded that the acid sites which are active for allyl alcohol production are weak ones. According to Fig. 1, the amount of propionaldehyde decreases more rapidly than that of allyl alcohol does. This fact supports our conclusion. As regards the selectivities of acetone and allyl alcohol, the strong base is considered to be favorable for allyl alcohol formation from the following facts. According to Table 1 and Table 2, the Li_2NaPO_4, Li_2KPO_4, $LiNa_2PO_4$, and LiK_2PO_4 catalysts have stronger basic sites and higher selectivities of acetone and propionaldehyde than do the other catalysts. Therefore, it can be concluded that the selectivity and the activity for the propylene oxide isomerization are controlled by the acidic and basic properties of the catalyst.

On the basis of these facts, the reaction mechanisms may be considered to be as follows. In the case of allyl alcohol formation, propylene oxide is adsorbed on the basic site, thus forming carbanion, the carbanion attacks acid sites and the epoxide ring is opened to produce allyl alcohol consequently. The rate-determining step of allyl alcohol formation is considered to be the proton-abstraction process on basic sites on the basis of the facts that the formation of allyl alcohol is controlled by the basicity of the catalyst. As regards acetone, the β carbon of propylene oxide attacks the basic site and the

oxygen-β carbon bond is broken. In the case of propionaldehyde, propylene oxide adsorbs with the oxygen atom on the acid site and the oxygen-α carbon linkage opens. The stronger the acid strength, the more easily the bond is broken, as was shown in the preceding paper.[8)]

Intermolecular Hydrogen Transfer Reactions in the Excited States of EDA-Complexes of Benzophenone with Aromatic Amines at Low Temperature

Satoshi ARIMITSU* and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received October 18, 1971)

Electronic absorption and emission spectra of the mixtures of benzophenone and aromatic amines have been studied in rigid solutions. From absorption spectral measurements, it has been concluded that benzophenone as an acceptor forms the molecular complexes with various aromatic amines as donors. Emission spectra different from those of the component molecules were observed at longer wavelengths in the same systems. The maxima of the anomalous emission spectra of these systems were found to shift slightly to lower frequencies with the decrease in the ionization potentials of donor molecules. On account of their decay times, the emissions may be ascribed to the phosphorescence of benzophenone-aromatic amine complexes. Photolysis of benzophenone-aromatic amine complexes in rigid matrices always resulted in the appearance of the visible absorption spectrum of benzoketyl radical, together with ESR spectra, the analysis of which indicated that there is an interacting pair of radicals which is in the combined triplet ($S=1$) state. From the evaluation of the zero field splitting constants, the average distances between the interacting radicals were estimated. These results suggest that intermolecular hydrogen atom transfer from aromatic amines to benzophenone occurs, yielding the ketyl and aromatic amine radicals which lie close to each other. The reaction was found to proceed by way of the lowest excited triplet state of benzophenone.

The photochemical reactions of aromatic ketones as correlated with the nature of their excited electronic structures have been an interesting subject in photochemistry. As the results of numerous investigations, it has been confirmed that ketones at the lowest $^3(n,\pi^*)$ state were photoreduced easily, while those at the lowest $^3(\pi,\pi^*)$ state were scarcely photoreduced.[1] The spectra of the photochemical reaction intermediates of these ketones, such as the triplet species and the ketyl radicals, have been obtained.[2-6]

Recently, Cohen and co-workers found that the yields of benzopinacol and related compounds from benzophenone and its derivatives get higher in aliphatic amines.[7] They proposed that the photoreduction may be facilitated by initial electron transfer from the amine to the excited ketones, leading to charge transfer complexes or pairs of ions, followed by proton transfer and electron redistribution. However, no evidence has been presented suggesting the formation of charge transfer complexes between aromatic ketones in the excited state and aliphatic amines in the ground state.

We have reported in a short communication that the photoreduction of benzophenone (BP) in *N,N*-dimethylaniline (DMA) and 2-methyltetrahydrofuran (2MTHF) mixed solvent occurs easily, producing ketyl radical at the temperature of liquid nitrogen.[8] Since no ketyl radical was found appreciably by the photolysis of BP in 2MTHF solution at 77°K, we pointed out that the charge transfer complex formation between BP and DMA, suggested by an electronic absorption measurement, is a prerequisite for the formation of ketyl radical.

In the present paper, more detailed studies on the BP-aromatic amine systems will be reported, and the photoreactivity and photoreaction mechanism of the charge transfer complexes of BP with aromatic amines will be discussed in relation with the electronic structure and the charge transfer interaction in the excited molecular complex.

Experimental

Materials. BP was purified by recrystallization from ethanol and sublimation twice in vacuum. Aromatic amines

used were aniline (AN), *N*-methylaniline (NMA), *N,N*-dimethylaniline (DMA), *N,N*-diethylaniline (DEA), and *N*-methyldiphenylamine (NMDPA). Aniline and *N*-methylaniline were purified by distillation under reduced pressure. All other amines were refluxed with acetic anhydride for several hours, and purified by fractional distillation. The amines were kept in a deoxygenated condition. 2-Methyltetrahydrofuran (2MTHF) was dried with sodium and purified by distillation. The solvent used as a transparent organic matrix was a mixture of 2MTHF and aromatic amine (3: 1 by volume). The concentration of the solution of BP was about 5×10^{-3}M in most experiments. All samples studied were deaerated by the usual method with an evacuating system.

Apparatus. Photolysis was carried out by use of a 500-W super high-pressure mercury lamp, combined with Toshiba UV-D25 and UV-35 glass filters transparent in the wavelengths from 350 to 400 nm. The absorption spectra were measured with a Cary 15 spectrophotometer. The emission spectra were measured with an Amino-Bowman spectrophotofluorimeter equipped with a photomultiplier of RCA Type R213. The emission decay time was measured by using a Xe-flash lamp and the discharge from a tungsten air gap having duration times of *ca.* 10 μsec and 100 nsec, respectively. ESR spectra were measured at 77°K by a JES-3BX spectrometer of Japan Electron Optics using X-band with 100 kHz field modulation.

Results and Discussion

Absorption Spectra of Benzophenone - Aromatic Amines. The electronic absorption spectrum of BP in the near ultraviolet region shows vibrational structures at low temperature, assigned to the (n,π^*) transition (Fig. 1a). On the other hand, the spectrum of BP in *N,N*-diethylaniline (DEA) shows a quite different shape in the same region at 77°K as shown by spectrum b in Fig. 1, which was obtained by subtracting the absorption of DEA. The difference between these two spectra is obviously much greater than to be explained by the solvent effects, but seems to suggest a molecular complex formation between BP and DEA. The spectrum of Fig. 1b then may be interpreted as an (n,π^*) band of BP broadened by the coupling with the intermolecular vibration within the complex. From the electronic nature of benzophenone, it seems most probable that BP acts as an electron acceptor and *N,N*-diethylaniline (DEA) acts as a donor. Similar spectra, which suggest the formation of complex, have been observed for BP in various mixed solutions of 2MTHF and aromatic amines at 77°K. As the electronic absorption spectrum of BP in triethylamine solution does not change appreciably from that of BP in 2MTHF at 77°K, the interaction in this case seems to be very weak.

Emission Spectra of Benzophenone - Aromatic Amines. The phosphorescence spectrum of BP observed in 2MTHF solution at 77°K, having characteristic vibrational structures, is shown by spectrum a in Fig. 2. The emission spectrum of BP in a mixed solution (1 vol. DMA–3 vol. 2MTHF) at 77°K is shown by spectrum b in Fig. 2. From the comparison between these spectra, it may be seen that spectrum b is composed of spectrum a plus an additional emission lying at the longer wavelengths. Spectrum c is obtained by subtracting spectrum a from b. The emission spectrum c thus obtained is undoubtedly due to neither BP nor DMA. Moreover, the excitation spectrum obtained for the emission at 495 nm, where the emission is mostly composed of spectrum c, is fairly similar to that of the absorption of charge transfer complex of BP with DMA, while that observed for the emission at 412 nm is in good agreement with that of the absorption of BP at 77°K. Therefore, it may safely be concluded that the emission corresponding to curve c is due to BP–DMA complex.

The emission spectra of BP complexes with DMA, DEA, and NMDPA are shown in Fig. 3. The emission maxima show a tendency to shift to the longer wavelength with decreasing the ionization potentials of donor molecules. These results, together with the finding that these emission spectra shift to longer wavelengths with increase in the dielectric constant of the solvent indicate that the excited state of the BP complexes has the charge transfer nature.

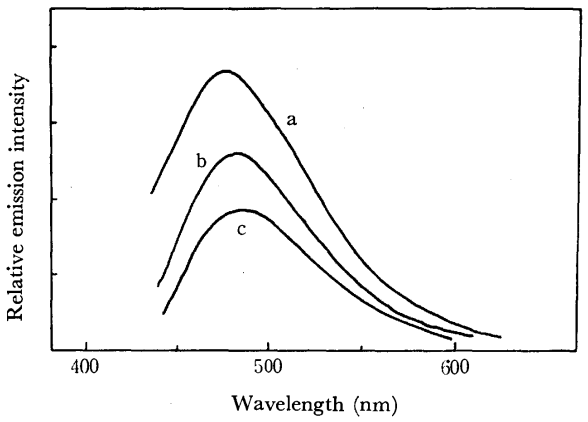

Fig. 3. Emission spectra of benzophenone complexes with various aromatic amines at 77°K.
a: *N,N*-dimethylaniline, b: *N,N*-diethylaniline, c: *N*-methyldiphenylamine

It was also found that the emission of the BP–DMA complex is quenched remarkably by ethanol used as a solvent instead of 2MTHF.

In order to get further information on the emission of the complexes, we also measured the emission decay-time. The phosphorescence of BP in 2MTHF decays exponentially with a decay time of 5 msec at 77°K. In the presence of aromatic amines at 77°K, the emission decay curve revealed that there are two components, one with a decay constant of 2.6 msec and another with a decay constant of *ca.* 10 μsec. The former may be assigned to an emission due to free BP, and the latter may be assigned to complexed BP, corresponding to the emission spectrum of Fig. 2c. It may be appropriate to conclude that the emission is due to the CT phosphorescence of the BP complex with the aromatic amine. The phosphorescent state of the complex may be mainly the locally excited $^3(n,\pi^*)$ configuration of BP mixed with the charge transfer configuration, since the peak positions of the phosphorescence spectra of complexes shift only slightly by changing the ionization potentials of donor molecules. The remarkable change of the phosphorescence life-time of BP-aromatic amine complex compared with that of free BP may be caused

by the configuration interaction and spin-orbit coupling between the charge transfer and locally excited configurations. This problem is discussed in some detail by Iwata, *et al.*[9]

Hydrogen Abstraction of Benzophenone in Low Temperature Matrices. When the ternary solution of BP-aromatic amine-2MTHF was irradiated at the temperature of liquid nitrogen, the matrices colored red. The electronic absorption spectra after the photolysis of the solutions of BP–NMA, BP–DMA, BP–DEA, and BP–NMDPA in 2MTHF at 77°K are shown in Figs. 4 and 5. These absorption spectra disappeared after warming.

At a glance, these electronic absorption spectra are very similar to that of the ketyl radical obtained by flash photolysis of BP in ethanol or iso-pentane at room temperature.[5,6] Therefore, we may safely conclude that the main product is the ketyl radical. By more careful inspection of the spectra obtained, it is noticed that there is at least one more component, for instance, at about 445 nm in the case of DMA.

In the case of BP in a mixed solution of aniline and 2MTHF, the yield of ketyl radical was found to be about one tenth that for DMA and other aromatic amines mentioned above. It seems, therefore, that the presence of the alkyl group at the nitrogen atom is necessary for facilitating the hydrogen abstraction reaction.

The ketyl radical was also produced by the photolysis of BP in the solution of DMA and trichloro-trifluoroethane, the latter of which has no hydrogen atom to abstract. This result definitely indicates that the ketyl radical is produced as a result of hydrogen atom transfer from DMA to BP. The comparison of the absorption spectra shown in Figs. 4 and 5 with the absorption spectrum of ketyl radical obtained before[5] indicates that there are some components having absorptions in the region from 400 to 500 nm. In the case of the BP–DMA system, a clear peak is observed at 450 nm. In the present circumstances, these absorptions might be tentatively attributed to the radicals formed by the hydrogen abstraction from the alkyl group of the methylanilines; for example, $\phi\text{–N}\langle^{CH_3}_{CH_2}$, in the case of BP–DMA.

9) S. Iwata, J. Tanaka, and S. Nagakura, *J. Chem. Phys.*, **47**, 2203 (1967).

Since no ketyl radical was found noticeably by the photolysis of BP in the aniline-trichlorotrifluoroethane solution, it seems reasonable to assume that the hydrogen atom of the solvent is abstracted in the photoreduction of BP-aniline system.

These conclusions are confirmed by the measurement of ESR spectra and the excitation spectrum of the ketyl radical emission, which will be described in the following section.

When the solution of BP in a mixture of aliphatic amine, such as triethylamine, and ether was irradiated at 77°K, no ketyl radical was found appreciably. This result is in harmony with our observation of the absorption spectrum of the same system, which suggests no complex formation between BP and triethylamine in the ground state. It has also been found that photoreduction of BP proceeds only slightly in a solution of DMA and ethanol, contrary to the solution of DMA and 2MTHF.

Emission Spectrum of Ketyl Radical. We have tried to measure the luminescence spectrum of the ketyl radical using the photolysis products of BP complexes with aromatic amines. The emission spectrum observed in the case of the BP–DMA complex is shown in Fig. 5. The mirror symmetry relation between absorption and emission spectra can be seen. The excitation spectrum for the ketyl radical emission is in good agreement with the absorption spectrum of ketyl radical formed by the photolysis of BP–DMA complex, except that the absorption band with peak at 445 nm attributed to DMA radical was not found in the excitation spectrum.

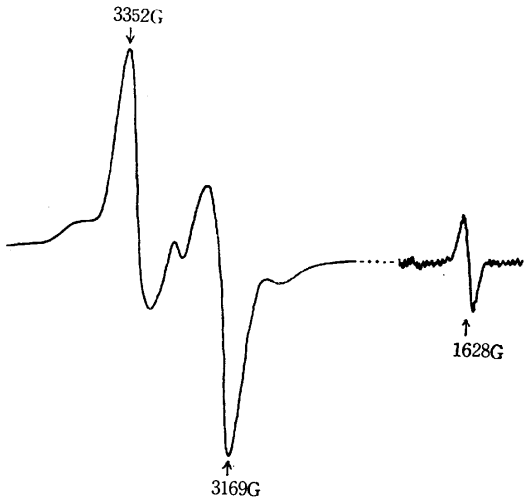

Fig. 6. ESR spectrum of benzophenone in *N*-methyldiphenylamine-2-methyltetrahydrofuran irradiated at 77°K: (ν= 9143 MHz).

ESR Spectra of Irradiated BP-Aromatic Amine Complexes. Figure 6 shows a typical ESR spectrum obtained after the photolysis of BP in NMDPA–2MTHF rigid glass at 77°K. This spectrum can be interpreted clearly on the basis of randomly oriented radical pairs in the triplet state ($S=1$).[10] In some cases, the absorption due to a free radical was observed slightly at the region of $g=2$ in addition to the spectrum as shown in Fig. 6. Photolysis of BP complexes with NMA, DMA, and DEA in 2MTHF also showed the similar ESR spectra. In case where the fine structure constant E is assumed to be zero, the ESR spectrum of a triplet radical pair is predicted to consist of a band due to the forbidden $\Delta m=\pm 2$ transitions at magnetic field strength $H=h\nu/2g\beta$, and two pairs of bands due to the allowed $\Delta m=\pm 1$ transitions having separations D and $2D$ with the center at the magnetic field strength $H=h\nu/g\beta$. D represents here the zero field splitting constant and ν the resonance microwave frequency.

TABLE 1. ZERO-FIELD SPLITTING CONSTANT (D) AND AVERAGE DISTANCE OF THE RADICAL PAIRS BETWEEN KETYL AND AROMATIC AMINE RADICALS, CALCULATED FROM OBSERVED ESR SPECTRA OF THE IRRADIATION PRODUCTS OF BENZOPHENONE-AROMATIC AMINE COMPLEXES

Aromatic Amine	D (gauss)	R (Å)
Aniline	<95	<6.64
N-methylaniline	162	5.55
N, *N*-dimethylaniline	154	5.64
N, *N*-diethylaniline	128	6.00
N-methyldiphenylamine	166	5.48

The ESR spectra obtained in the present work unambiguously lead to the conclusion that radical pairs in the triplet state are obtained. Although there have been some investigations on the ESR spectra of radical pairs made of equal radicals,[11] the studies on radical pairs composed of different species are rather scarce.[12] Table 1 shows the D values obtained from the experimentally observed separation corresponding to $2D$. One can see from Table 1 that the zero field splitting constants change from one to another. This result suports our previous conclusion that the ketyl radical is produced as a result of intermolecular hydrogen atom transfer from aromatic amine to BP, because, if the hydrogen atom is abstracted from the solvent molecule, the D values should be the same in all systems.

The ESR spectrum observed for photolyzed BP-aniline complex is somewhat different from that of BP–NMDPA complex at 77°K as shown in Fig. 7, the zero-field splitting constant being about 95 gauss, at most, which is fairly small compared with other values obtained in the present work. This small separation, together with the apparent absence of the weak absorption bands corresponding to the $2D$ separation, might arouse the suspicion that the spectrum is not due to the triplet species. However, it seems unlikely that this spectrum is due to separated free radicals ($S=1/2$), because a splitting of about 95 gauss is inadequately large for an ESR spectrum of any aromatic free radicals. Moreover, it was also confirmed that the spectrum is not ascribed to the solvent radicals produced by a

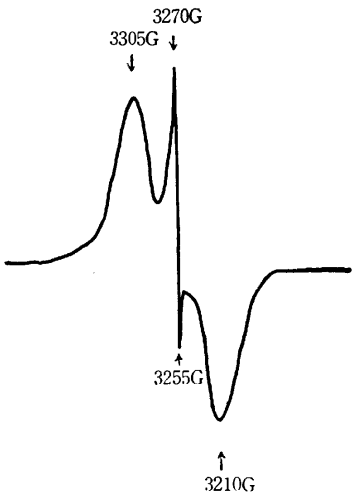

Fig. 7. ESR spectrum of benzophenone in aniline-2-methyltetrahydrofuran irradiated at 77°K: (ν=9135 MHz). The sharp ESR signal shown by arrows at 3270 G and 3255 G seems to be a radical species formed by dark reaction, because it was obtained for the BP-aniline-2MTHF mixture before irradiation.

photosensitization reaction. The most plausible interpretation for this spectrum is that the ketyl radical formed by direct hydrogen abstraction of BP from 2MTHF intracts with a 2MTHF radical. This is consistent with our experimental result described before that BP–AN complex in trichlorotrifluoroethane does not yield ketyl radical detectably.

The average distance R(Å) between radicals can be calculated using a point-spin-density approximation discussed by Kurita[13] as follows:

$$R^3(\text{Å}) = \frac{27800}{D(\text{gauss})}$$

The R values thus obtained are summarized in Table 1. In the case of BP–NMDPA complex, the average distance is the shortest of all cases. This might, however, be due to the theoretical approximation applied to a radical pair, because the unpaired electrons are distributed over the molecular framework of the component radicals, resulting in a slight underestimation of the average distance between radicals as the radicals get larger.

It seems curious that two radicals coexist stably at the temperature of liquid nitrogen within a short distance from each other as concluded in the present work. The reason for this may be attributed to a large resonance stabilization of these radicals owing to the delocalization of the unpaired electrons preventing a chemical bond formation or back transfer of hydrogen atom.

Photochemical Reaction Mechanism and Reactivity of BP Complexes. As is described in previous sections, we found that the photoreduction of BP undergoes easily in the solution of aniline derivatives and 2MTHF at 77°K. But the use of ethanol as the solvent instead of 2MTHF retards it to a great extent. Correspondingly, it has been found that the phosphorescence of BP complexes with aromatic amines is quenched remarkably by ethanol. This further gives support to the conclusion that photoreduction of the ketone in BP complexes undergoes through the triplet state of BP–aromatic amine complex.

In the case of BP–aniline complex, it has been concluded that hydrogen atom is abstracted from the solvent instead of aniline. As the yield of ketyl radical in this case is only about one tenth that in other cases, the hydrogen abstraction from solvent to BP is thought to be very slow. It seems plausible to attribute the difference in the photo-reactivity between aniline and other donors, to the presence of the *N*-methyl group. Although the reason for this effect of methyl group is not quite clear, it may be attributable to a steric circumstance for *N*-methylanilines, bringing a hydrogen atom at a closer position to the oxygen atom of BP in the complex.

The last question we have to answer is why photoreactivity of BP is much more enhanced in the molecular complex than in free BP. As mentioned before, the photoreduction of BP complexes undergoes most probably *via* the lowest triplet state, which is mainly of the locally excited $^3(n,\pi^*)$ character, with inclusion of a slight charge transfer character. That $^3(n,\pi^*)$ state is the state which undergoes hydrogen abstraction was demostrated by a paper by Porter and Suppan.[14] Our subsequent paper will give evidences for the necessary character of excited states for systems more directly related with the present problem. Therefore, the hydrogen abstraction reaction must essentially be a radical reaction and such a process as the electron transfer followed by proton jump from the aniline derivative to BP is unlikely. The reason why the hydrogen transfer is fascilitated by a comlpex formation between the anilines and BP may be as follows: 1) The binding of the complex may realize a geometric configuration where the hydrogen of the aniline derivative is situated at a position better for the abstraction reaction. 2) A slight mixing of the charge transfer character in the $^3(n,\pi^*)$ state may cause a change in the electron distribution, for example, a change in the orbital exponent of the oxygen n-orbital, which decreases the activation barrier for the hydrogen abstraction reaction.

The authors wish to thank Professor Koichi Ito for discussions on the interpretations of the ESR spectra.

Polarized Absorption Spectra of Crystals of Indole and Its Related Compounds

Yukio YAMAMOTO and Jiro TANAKA

Department of Chemistry, Faculty of Science, University of Nagoya, Chikusa-ku, Nagoya

(Received October 22, 1971)

The polarized absorption spectra of crystals of indole derivatives have been measured in order to confirm the presence of two types of electronic transitions, ^1L_b and ^1L_a, in the long-wavelength absorption region, and in order to determine the direction of their transition moments. The polarization spectra show that the ^1A—^1L_b electronic transition forms a sharp absroption band with vibrational structures lying below a broader absorption band of the ^1A—^1L_a transition. The transition memont direction of the ^1L_b makes an angle of 54° to the long axis of the molecule, while that of the ^1L_a lies at an angle of −38° to the same axis. These results were compared with the results of theoretical calculations of the P-P-P SCF MO-CI method.

The excited states of indole and its related compounds have been studied by many workers by means of absorption and emission spectral measurements in solution.[1-8] The absorption band of indole and tryptophan in the region of 40000—32250 cm^{-1} (250—310 nm) is composed of two different types of electronic transitions.[1,2] One is ^1A—^1L_b, with maxima at 34800 cm^{-1} (287 nm) and 35850 cm^{-1} (279 nm), while the other is the ^1A—^1L_a type forming a broad band with a maximum at 36200 cm^{-1} (276 nm). We have studied the polarized absorption spectra of crystals in order to clarify the vibrational structures of the ^1L_b and ^1L_a electronic levels and to find the direction of their transition moments. This study may be important in connection with the circular dichroism and chromophore interactions of tryptophan and its derivatives.

Experimental

The ultraviolet absorption spectrum of the solution was measured by means of a Carl-Zeiss PMQ-II-type spectrophotometer. The absorption spectra of crystals were obtained by the use of the microspectrophotometer described previously.[9]

Materials. The indole was of a special grade from the Tokyo Chemical Industry Co. and was purified by recrystallization from an ethanol-water mixture and by column chromatography. The crystal used for the spectral measurement was obtained from a methylcyclohexane solution. The 3-indolylacetic acid was purchased from the Nakarai Chemical Co. and was purified by recrystallization. The crystal obtained from chloroform had a form of diamond-shaped plates. The glycyl-L-tryptophan was of a pfs grade purchased from the Sigma Chemical Co. and was used without further purification. The glycyl-L-tryptophan dihydrate was obtained in the form of plate-like crystals from water-methylcellsolve solutions.

Results and Discussion

Absorption Spectra of Crystals. **1)** *Indole*: The crystal structure of indole has not yet been determined. The crystal used for the absorption measurement had an elongated plate-like shape and was thin enough to have an adequate optical density for the spectral measurement. Figure 1 shows the absorption spectrum of the indole crystal produced by a light polarized along the *X*-axis (the vibration direction of the faster ray), which shows maxima at 34250 cm^{-1} (292 nm), 35100 cm^{-1} (285 nm) and 36350—37000 cm^{-1} (275—270 nm), and one produced by a light polarized along the *Z*-axis (the vibration direction of the slower ray), which shows peaks at 34500 cm^{-1} (290 nm), 35350 cm^{-1} (283 nm) and 36650 cm^{-1} (273 nm). These vibrational peaks show a good correspondence to those of the solution spectrum.[1] The 0-0 absorption band of the indole

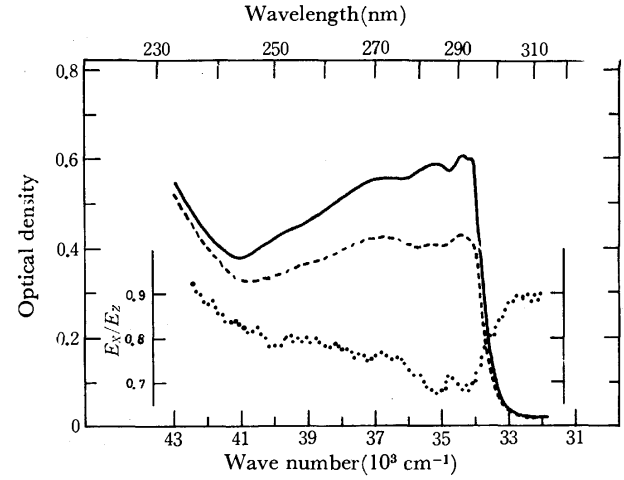

Fig. 1. The polarized absorption spectrum of the single crystal of indole.
The solid and broken lines show the spectrum parallel to the *Z*-axis and the *X*-axis in the crystals respectively. The dotted line indicates the polarization ratio (E_x:E_z). The polarization ratio in the 32400—33700 cm^{-1} region was obtained using a thicker plate which had the optical density of 0.75 at 33400 cm^{-1} for the absorption parallel to the *Z*-axis.

crystal is red-shifted nearly 600 cm^{-1} relative to that of indole in *n*-hexane. In order to compare the absorption intensity produced by the light along the *X*-axis with that produced by the light along the *Z*-axis, the polarization ratio ($E_x : E_z$) as a function of the wavenumber was plotted. In the region of 32350 to 33500 cm^{-1} (309 to 298 nm), the polarization ratio has a higher value, 0.9. With an increase in the wavenumber, the polarization ratio is markedly reduced, having its minimum at 34100 cm^{-1} (293 nm). In the 35450—36750 cm^{-1} (283—272 nm) range, there is an increase in the polarization ratio and it has a maximum at 37000 cm^{-1} (270 nm). Thus, the variation in the polarization ratio suggests that the long-wavelength absorption band consists of two different electronic transitions, $^1A—^1L_b$ and $^1A—^1L_a$, and that the former transition forms a sharp absorption band lying below a broader absorption band due to the latter type of transition. The constancy of the polarization ratio in the 32350—33500 cm^{-1} region and in the 37000—40800 cm^{-1} region indicates that the absorptions in these regions are composed of mainly the $^1A—^1L_a$ transition. The reduction in the polarization ratio in the range from 33500 to 34100 cm^{-1} may be due to the increase in the contribution of the $^1A—^1L_b$ transition. Therefore, it is clear that the first two vibrational maxima at 34250 and 35100 cm^{-1} for the *X*-axis (34500 and 35350 cm^{-1} for the *Z*-axis) belong to the $^1A—^1L_b$ transition and that the broad band near 36350—37000 cm^{-1} for the *X*-axis (36650 cm^{-1} for the *Z*-axis) to the $^1A—^1L_a$ transition. These results are in good correspondence to the results obtained for the absorption polarization spectrum of the fluorescence of tryptophan and indole solutions.[1,2,10]

2) 3-Indolylacetic Acid: According to Karle *et al.*,[11] the crystal belongs to the space group of $P2_1/c$, with four molecules per unit cell. The (100) face develops, and the projection of molecules onto this face is shown in Fig. 2(a). The molecules form a dimeric structure with hydrogen bonds between the acid groups; the NH group in indole is not involved in any hydrogen bonding. The crystalline absorption spectrum was measured with the (100) face by a light polarized along the *b* axis and the *c* axis. Figure 2(b) shows the ^1L_b and ^1L_a absorption bands with six or more vibrational structures. The absorption peaks were clearly seen at 32940, 33550, 34600, 35400, 37250, and 38750 cm^{-1} (303.5, 298, 289, 282.5, 268.5, and 258 nm) in the absorption spectrum by means of the light polarized along the *b* axis, while they are clearly seen at 33000, 33620, 34540, 35340, 36950, and 38050 cm^{-1} (303, 297.5, 289.5, 283, 271, and 263 nm) in that along the *c* axis. The long-wavelength edge of the absorption band in the crystal is displaced by about 1500 cm^{-1} as compared with that in solution. At room temperature, it is difficult to guess accurately the band splitting: therefore, we have examined the peaks with care. The observed band splittings ($\nu_{//c}—\nu_{//b}$) are 60, 70, −60, −60, −300, and −700 cm^{-1} for the first, second, third, fourth, fifth, and sixth bands respectively. The experimental error is within 25 cm^{-1}. The band splittings of the higher bands are reversed in sign in comparison with the first two bands; this may suggest that the splitting of the band series is mainly due to the electronic transition of the $^1A—^1L_b$ type and that the higher bands may be affected by the $^1A—^1L_a$ electronic transition. The polarization ratio ($E_c : E_b$) against the wavenumber is shown in Fig. 2(b). In the 30600—32000 cm^{-1} (327—312 nm) region, the polarization ratio has a constant value of 0.9, which indicates that the absorption band in this region is due to the $^1A—^1L_a$ transition. The increase in the polarization ratio in the 32150—33200

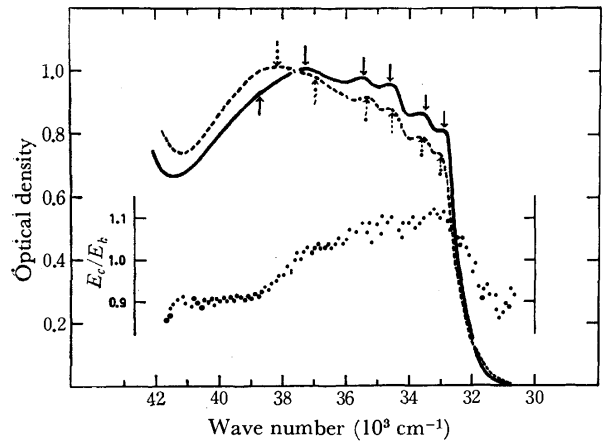

Fig. 2(b). The polarized absorption spectrum in the (100) plane of the single crystal of 3-indolylacetic acid.
The solid and broken lines show the spectrum parallel to the *c* axis and the *b* axis respectively.
The dotted line indicates the polarization ratio (E_c:E_d). The polarization ratio in the 30800—32200 cm^{-1} was obtained using a thicker plate which had the optical density of 0.62 at 32000 cm^{-1} for the absorption parallel to the a axis.

cm^{-1} (311—301 nm) region reflects the gradual increase in the contribution of the ^1A—^1L_b transition, while the maximum at 32900 cm^{-1} (304 nm) corresponds to the 0–0 band of the ^1L_b transition. The increase in the ^1L_a transition may be responsible for the reduction in the polarization ratio from 34500 to 37700 cm^{-1} (from 290 to 265 nm). Above 37600 cm^{-1} (266 nm) the polarization ratio retains a nearly constant value of 0.9, which shows that the absorption band in this region may be predominantly due to the ^1A—^1L_a transition. The overlapping of the ^1A—^1L_b and ^1A—^1L_a transitions in the long-wavelength absorption band makes it difficult to determine the transition-moment directions of the ^1L_b and ^1L_a states. However, it may be possible to resolve the observed absorption spectrum into two types of electronic transitions, ^1A—^1L_b and ^1A—^1L_a, because the location and the vibrational structures of the ^1A—^1L_b transition have already been determined. The procedure of dividing the long-wavelength absorption band into the ^1L_b and ^1L_a bands was as follows. The absorption band below 32000 cm^{-1} and that above 37500 cm^{-1} may be due to only the ^1A—^1L_a transition; therefore the absorption band due to the ^1A—^1L_a transition was supposedly figured in the 32000—37500 cm^{-1} region to be linked with the absorption curves in the former and the latter regions. Thus, the *b*-axis polarized absorption band due to the ^1L_a transition was obtained. Then, the *c*-axis polarized absorption band originated from the same transition was obtained in the same way; the polarization ratio is 0.9 ($E_c : E_b$). The absorption band belonging to the ^1A—^1L_b transition was determined as the rest of the band after the ^1L_a band was subtracted from the observed spectrum. The thickness of the crystal could not be reliably estimated, and this made it impossible to obtain the oscillator strength. Nevertheless, it is possible to obtain the oscillator strength ratio (f_c^{exp}/f_b^{exp}) by integrating the observed absorption spectra parallel to the *b* and *c* axes. The direction of the transition moment of the ^1L_b and ^1L_a states was determined by the use of the corresponding oscillator strength ratios, namely, $f_c^{exp}(^1L_b)/f_b^{exp}(^1L_b)$ and $f_c^{exp}(^1L_a)/f_b^{exp}(^1L_a)$ respectively. The transition-moment direction of the ^1L_b state makes an angle of $+57$ or $-57°$ to the *b* axis, while that of the ^1L_a state lies at an angle of $+42$ or $-42°$ to the same axis.

3) Glycyl-L-tryptophan Dihydrate: The crystal structure of glycyl-L-tryptophan dihydrate has been determined by Pasternak.[12] The crystal is monoclinic, and the space group is $P2_1$, with two molecules per unit cell. The projection of the molecules in the unit cell onto the (001) plane, which is the developed face, is shown in Fig. 3(a). The optical properties of the crystal had been described in the literature,[12] and the axes were easily determined by a polarization microscope. The crystalline absorption spectra of glycyl-L-tryptophan dihydrate are shown in Fig. 3(b), together with the polarization spectrum. The crystalline absorption spectra obtained by the light polarized parallel to the *a* axis and the *b* axis have maxima at 33100, 34000, 35000, and 36100 cm^{-1} (302, 294, 285.5, and 277 nm), and

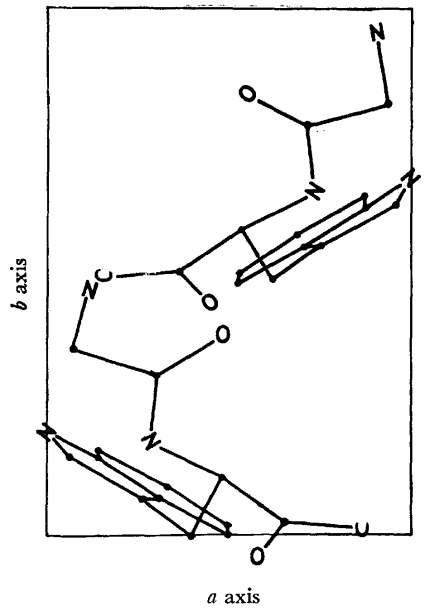

Fig. 3(a). Projection of the two molecules in the unit cell of glycyl-L-tryptophan dihydrate onto the (001) plane.

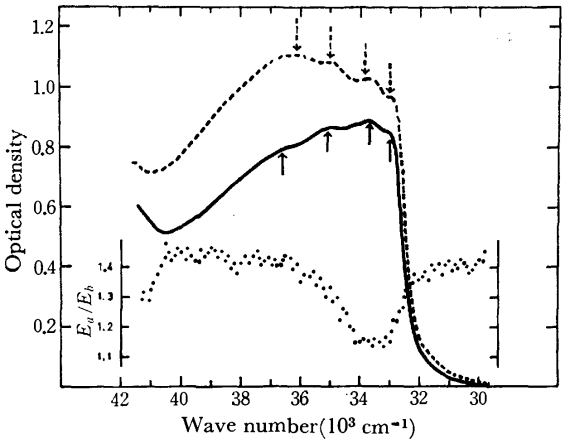

Fig. 3(b). The polarized absorption spectrum in the (001) plane of the single crystal of glycyl-L-tryptopahan dihydrate. The solid and broken lines show the spectrum parallel to the b axis and the a axis respectively. The dotted line indicates the polarization ratio (E_a:E_b). The polarization ratio in the 29800—32300 cm^{-1} was obtained using a thicker plate which had the optical density of 0.78 at 32000 cm^{-1} for the absorption parallel to the *a* axis.

33000, 33800, 35100, and 36750 cm^{-1} (303, 295.5, 285, and 272 nm) respectively. These absorption peaks are in good correspondence with those of the solution spectrum. The band splittings of the first two bands are reversed in sign compared with those of the higher bands, similar to the case of 3-indolylacetic acid. The polarization ratio (E_a: E_b) changes with the variation in the wavenumber, as is shown in the case of the indole or 3-indolylacetic acid crystal. In the 30000—31600 cm^{-1} (333—317 nm) region, the polarization ratio is calculated to be nearly 1.4. With an increase in wavenumber, the polarization ratio is sharply reduced; it has its minimum value of 1.15 at 33300 cm^{-1} (300 nm). In the range from 33900 to 36000 cm^{-1} (295 to 278 nm),

12) R. A. Pasternak, *Acta Crystallogr.*, **9**, 341 (1956).

there is an increase in the polarization ratio, and it has its maximum value of 1.4 at 36500 cm^{-1} (274 nm). Thus, the ^1A—^1L_b transition appears at from 31600 to 36350 cm^{-1} (316 to 275 nm), overlapping with the ^1A—^1L_a transition. This overlapping of the ^1L_b and ^1L_a transitions makes it difficult to determine the corresponding transition-moment directions. Therefore, the observed absorption spectrum was resolved into the bands due to the ^1A—^1L_b and the ^1A—^1L_a transitions in the same way as has been described in the case of the 3-indolylacetic acid crystal. With the use of the oscillator strength ratio of the ^1L_b transition ($f_a^{exp}(^1L_b)$: $f_b^{exp}(^1L_b)$) and that of the ^1L_a transition ($f_a^{exp}(^1L_a)$: $f_b^{exp}(^1L_a)$), the corresponding transition-moment directions were estimated. The direction of the transition-moment of the ^1L_b state makes an angle of +41 or −41° to the *a* axis, while that of the ^1L_a state lies at an angle of +30 or −30° to the same axis. When the transition-moment direction obtained from glycyl-L-tryptophan dihydrate was compared with that obtained from 3-indolylacetic acid, it was clear that the direction of the angle of −41 and −30° to the *a* axis in the former crystal coincides with the direction of the angle of −57 and +42° to the *b* axis in the latter crystal for the ^1L_b and ^1L_a states respectively. The experimental error is within 5°.

Determination of the Transition-moment Direction of the ^1L_b and ^1L_a States. According to the polarized absorption spectra of glycyl-L-tryptophan dihydrate and 3-indolylacetic acid crystals, the directions of the transition moments of the ^1L_b and ^1L_a states were determined to be as is shown in Fig. 4. The transition-moment direction of the ^1L_b and ^1L_a states determined from the 3-indolylacetic acid crystal, which is oriented −57 and +42° to the *b* axis, makes angles of +49 and −42° to the long axis of the indole molecule respectively. On the other hand, the orientations of −41 and −30° to the *a* axis, as determined from glycyl-L-tryptophan dihydrate crystal, corresponds to angles of +58 and −35° to the long axis of the indole molecule for the ^1L_b and ^1L_a states respectively. Thus, the orientation of the ^1L_b state makes an angle of +58 or +49° to the long axis of the molecule, while that of the ^1L_a state lies at an angle of −35 or −42° to the same axis. These results

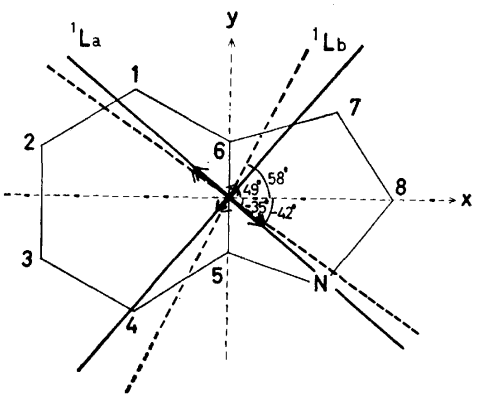

Fig. 4. Transition moments of the ^1L_b and ^1L_a states determined experimentally. The solid line was obtained by the ploarized absorption spectrum of 3-indolylacetic acid and the broken line by that of glycyl-L-tryptophan dihydrate.

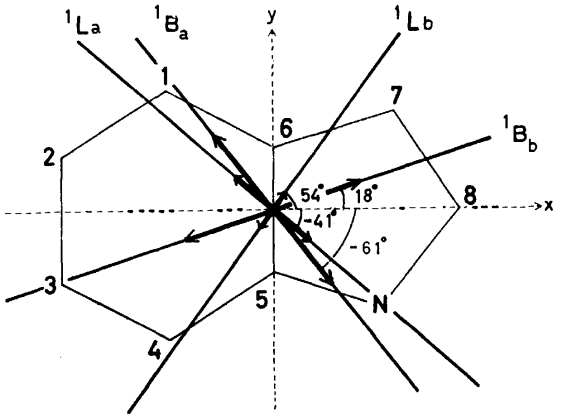

Fig. 5. The theroretical predictions of the transition moments of the four lowest excited singlet states (^1L_b, ^1L_a, ^1B_b, and ^1B_a) of indole.

are in satisfactory agreement with the theoretical orientations of +54 and −41° for the ^1L_b and ^1L_a states respectively, as is shown in Fig. 5. The mutual orientation angle between the ^1L_b and ^1L_a states is about 92° in both molecules, which is in reasonable agreement with the results obtained from the absorption polarization of the indole fluorescence.[1,8] The long-wavelength absorption spectrum of tryptophan in an aqueous solution is shown in Fig. 6, where the proposed resolution into the ^1A—^1L_b and ^1A—^1L_a bands is given. The location and absorption intensity of the ^1A—^1L_b transition were estimated with the help of the results described hitherto. The experimental oscillator strength (f^{exp}) may be obtained from the following equation, $f^{exp}=4.33\times10^{-9}\times\int\varepsilon(\sigma)\,d\sigma$, where $\varepsilon(\sigma)$ is a molar absorption coefficient and where σ means the wavenumber (cm^{-1}). Using the resolved absorption bands shown in Fig. 6, we have found the experimental oscillator strengths to be 0.010 and 0.112 for the ^1A—^1L_b and ^1A—^1L_a transitions. With these experimental oscillator strengths, the magnitude of the transition moments ($|r_{mn}|$) was estimated by means of this equation: $f=1.085\times10^{-5}\times\sigma\times|r_{mn}|^2$. They are 0.15 Å and

TABLE 1. THEORETICAL PREDICTIONS OF THE SINGLET EXCITED STATES OF INDOLE[a)]

State symbols	State energy[b)]	Transition-moment length		Oscillator strength	Orientation angle[d)]
		r_x[c)]	r_y[c)]		
^1L_b	4.51 (4.4)[e)]	0.161 Å	0.186 Å	0.024 (0.010)	54° (54°)
^1L_a	4.72 (4.6)	0.427 Å	−0.368 Å	0.133 (0.112)	−41° (−38°)
^1B_b	5.82 (5.8)	0.990 Å	0.320 Å	0.553 (0.680)	18°
^1B_a	6.49 (6.2)	0.668 Å	−0.864 Å	0.676	−61°

a) The calculated values were obtained by the P-P-P SCF MO-CI method.
b) The state energies are given in the electron volt (eV) unit.
c) The coordinate designations of x and y correspond to the long and short axis of the indole molecule, as is shown in Fig. 4 or 5.
d) The angle of the transition moment to the long axis (the x axis) of the molecule.
e) The values in the brackets are the experimental results.

0.54 Å for the ^1A—^1L_b and ^1A—^1L_a transitions respectively; these values are a little smaller than the results obtained from the theoretical calculations (0.25 Å and 0.57 Å).

Theoretical Calculation. The P-P-P SCF MO-CI calculations of indole has been done by many workers,[8,13-15] but their results were still not in satisfactory agreement with the experimental results. Momicchioli and Rastelli[13] used only four singly-excited configurations; later Song and Kurtin[8] employed a considerably larger number of configurations (20—25) in their P-P-P SCF MO-CI calculations. Their results on the polarizations are in reasonable agreement with the experimental results, but those on the transition energies and oscillator strengths are not so satisfactory. Recently, Evleth[15] made calculations employing 10 singly-excited and 5 additional doubly-excited configurations. His results on transition energies and oscillator strengths agree well with the observed ones; nevertheless, the transition-moment directions are inconsistent with the experimental results. We have considered all singly-excited configurations in the P-P-P SCF MO-CI calculation of indole and used the geometrical structure of the molecule taken from the data of the Xray analysis of glycyl-L-tryptophan dihydrate[12] or 3-indolylacetic acid crystal.[11] The Coulomb, resonance, and one-center repulsion parameters incorporated in this calculation were the same as have usually been used.[14] The values of the resonance integral at any distance were estimated by the following equation[16]:

$$\beta(r) = \beta^\circ \exp[4.599(1.397 - r)]$$

The results of our calculation for the four lowest singlet-excited states are listed in Table 1, where the state energies, the oscillator strengths, the transition-moment lengths, and the angles of the transition moments to the long axis of the molecule are presented. The calculated spectral features of the ^1A—^1L_b and ^1A—^1L_a transitions are in satisfactory agreement with the observed ones. Although the calculated energies of the ^1L_b and ^1L_a states are a little higher than the experimental ones, the values are in good agreement with the observed spectral characteristic that the ^1L_b and ^1L_a excited states are closely spaced. The experimental polarizations of the ^1A—^1B_b and ^1A—^1B_a transitions are still unknown; however, the calculated transition energies of the ^1B_b and ^1B_a states are reasonably correlated with the observed transition energies.

These calculations were carried out by the use of a computer program written by Dr. Masashi Tanaka of our laboratory, to whom our thanks are due. The calculation was carried out with the HITAC 5050E at the computation center of the University of Tokyo.

The Crystal and Molecular Structure of Bis(L-prolinamidato)-nickel(II) Dihydrate

Tomitake TSUKIHARA, Yukiteru KATSUBE, Kumiko FUJIMORI, and Yoshihisa ISHIMURA

Faculty of Engineering, Tottori University, Tottori

(Received November 1, 1971)

The crystal structure of bis(L-prolinamidato)nickel(II) dihydrate has been determined by three dimensional X-ray analysis. The crystals are vermilion needles and belong to the space group $P2_1$. . The unit cell has dimensions $a=10.915$, $b=7.319$, $c=9.445$ Å, $\beta=112.6°$ and contains two structure units. The structure has been solved using Patterson synthesis, minimum function and Fourier synthesis and refined by diagonal and block-diagonal least-squares methods on 1115 independent reflections. The final R value was 0.054. The nickel atom exhibits square planar coordination. Two proline-amide molecules are approximately related to each other by a two fold axis and these two ligand molecules coordinate to the central nickel atom in *trans* form. The oxygen atom of water does not coordinate to the nickel atom.

It is well known that nickel(II) complexes have octahedral, tetrahedral or square planar coordination. From the spectroscopic studies of the complexes of glycine-, L-alanine-, L-leucine-, and L-proline-amides, Komorita *et al.*[1,2] proposed that the nickel atom exhibits a square planar coordination and two ligand molecules are coordinated to the central nickel atom with four nitrogen atoms in *trans* form. The present study was undertaken to establish the configuration about the nickel of bis(L-prolinamidato)nickel(II) complex in solid state.

Experimental

The vermilion needle crystals of bis(L-prolinamidato)nickel-(II) dihydrate were kindly supplied by Dr. T. Komorita. Preliminary Weissenberg and oscillation photographs established that the crystal was monoclinic with the b axis along the needle axis. The systematic extinction of $(0k0)$ for k odd restricted the space group to $P2_1$. The crystal data are listed in Table 1.

TABLE 1. CRYSTAL DATA

Ni (L-$C_5H_9N_2O)_2\cdot 2H_2O$		M. W.=321.02
Monoclinic		$P2_1$
$a=10.915$ Å	$b=7.319$ Å	$c=9.445$ Å
$\alpha=\gamma=90.0°$	$\beta=112.6°$	
$D_{cal}=1.51$ g/cm³		
$D_{obs}=1.53$ g/cm³		(by floatation)

A nickel filtered Cu-K_α radiation was used to collect intensity data for all the reflections in the range $0°<\theta<60°$ within the octants (hkl) and $(\bar{h}kl)$. All the intensities were measured on a Rigaku Denki computer-controlled four-circle diffractometer. A crystal of approximate dimensions $0.03\times0.15\times0.04$ mm³ was used for the intensity measurement of 1115 reflections. The ω-2θ scan technique was employed with a scan speed 2°/min by ω, and the back grounds were measured for 10.0 sec at each start and end points of a scan range. A scan range of ω for each reflection was calculated by the formula $\Delta\omega=1.50°+0.15°\tan(\theta)$. Attenuators were automatically inserted when the maximum counting rate exceeded 8000 cps. The intensities were corrected only for Lorentz and polarization factors.

Measurement of the two reference reflections (500) and (060) was repeated for every thirty reflections. For 52 repetitions of the measurement, $|F_0(500)|=97.13\pm0.72$ and $|F_0(060)|=50.84\pm0.93$.

Structure Determination and Refinement

A trial structure derived from the three-dimensional

2) T. Komorita, private communication.

Patterson synthesis, minimum function and Fourier synthesis was refined to $R=0.12$, ($R=\sum||F_o|-|F_c||/\sum|F_o|$), by using a diagonal least-squares program which minimizes the function $\sum(|F_o|-k|F_c|)^2$ with individual isotropic thermal parameters for all the non-hydrogen atoms. The atomic scattering factors were taken from International Tables for X-ray Crystallography (1962). Three cycles of block-diagonal least-squares refinement of the positional and the thermal parameters of all the non-hydrogen atoms with a program written by Dr. T.

Ashida gave a value of R of 0.09. To take into account the anomalous scattering by nickel atom, $\Delta f'(-3.1)$ and $\Delta f''(0.6)$ were included in the calculations of the refinement. An $(F_o—F_c)$ synthesis revealed all the hydrogen atoms in the complex. After several cycles of the refinement of the positional parameters, of the anisotropic thermal parameters for the non-hydrogen atoms and of the isotropic thermal parameters for hydrogen atoms, the R value decreased to 0.054. The final parameters of all atoms, and $|F_o|$ and $|F_c|$ are listed in Tables 2 and 3,[3] respectively. The standard deviations in positional parameters were: for Ni, 0.0015 Å, for O, N, and C, 0.012 Å and for H, 0.12 Å. The final composite electron density map is given in Fig. 2.

Molecular and Crystal Structure

The nickel atom exhibits four fold coordination, and lies on the plane formed by the four ligand atoms: two imino-nitrogen atoms and two amide-nitrogen atoms which exhibit sp^3 and sp^2 configuration, respectively (Fig. 3). The environment around the nickel atom indicates the coordination dsp^2 configuration. Two proline-amide molecules of the same complex are approximately related to each other by a two fold axis, so that the two ligand molecules coordinate to the central nickel atom in *trans* form. Two of the four bond distances between nickel and nitrogen atoms, Ni–NA1 and Ni–NB1, are significantly shorter than the other two, Ni–NA7 and Ni–NB7. These four bonds

A copy may be secured by citing the Document number and by remitting, in advance, ¥400 for photo prints. Pay by check or money order payable to: Chemical Society of Japan.

are shorter than those of $(Ni(H_2O)_2(pyridine\text{-}2\text{-}carboxamide)_2Cl_2$, (Ni–N, 2.02 Å),[4] in which the nickel atom exhibits octahedral coordination. Nawata *et al.*[5] reported the same observation in Ni(pyridine-2-carboxamidato)$_2$ dihydrate in which the nickel atom exhibited square planar coordination. The observations are consistent with theory. The bond angles around the nickel atom deviate from that of dsp^2 configuration by about five degrees. The distortion is not great from the viewpoint of molecular orbital theory.

Table 6 gives the equations of the least-squares planes and the distances of individual atoms from the planes. The two γ-carbon atoms of pyrrolidine ring, CA(3) and CB(3), are not displaced from the respective rings as much as those formed in acetyl-L-proline-*N*-methylamide[6] and other proline derivatives in which the nitrogen atom of pyrrolidine ring exhibits sp^2 configuration. Kim and Jeffey[7] compared the geometries of pyrrolidine rings with each other in which nitrogen atoms have sp^3 configuration. Both the two pyrrolidine rings in this crystal take the same puckered form as that in hydroxy-L-proline.[8]

The subscripts indicate the same operations as in Table 5.

The molecular packing in the crystal is shown in Fig. 4. Tables 7 and 8 give all the hydrogen bonding schemes with distances and angles. The two amide groups of neighbouring complexes are bound to each other through the two NH···O hydrogen bonds. The hydrogen bonds between non-equivalent water molecules, and those between water and imino carbonyl group of the complex construct the framework of this crystal structure. There are no intermolecular contact between nickel atom and oxygen atom of water.

The authors express their thanks to Dr. T. Komorita for valuable discussions.

(Received November 11, 1971)

The excess Gibbs energy of mixing, G^E; the excess enthalpy of mixing, H^E, and the excess volume of the mixing, V^E, of the tetraethylene glycol diethyl ether+water system have been measured as functions of the composition at 25°C. The G^E, which has been determined through the isopiestic measurement of the water activity, is positive over the entire range of composition and has its maximum at 40 mol% ether. As has been found for analogous systems, the *s*-curve of H^E is again found; that is, H^E is large and negative (exothermic) in the water-rich region and positive (endothermic) in the ether-rich region. The V^E is negative over the whole range of composition and has a minimum at 23 mol% ether. These results are discussed in the light of the structural modifications of water in the immediate neighborhood of the ether molecule.

That the structural modifications of water play an important role in the dissolution of hydrocarbons into water is now widely accepted. In order to investigate such a phenomenon, aqueous solutions of ethers are, in practice, probably the most convenient because the interaction between the polar group (ether oxygen) and water is not so strong, despite their elevated miscibility with water, that the effect of a polar group on the solution property can be minimized.

In a previous paper,[1] the enthalpies of the mixing of water with diethylene glycol diethyl ether and with some cyclic ethers were measured, and it was concluded that the water-water interaction persisted even in the ether-rich region (80 mol% ether, for example). In the present paper, the excess Gibbs free energy of mix-

ing, G^E; the excess enthaply of mixing, H^E; the excess entropy of mixing, S^E, and the excess volume of mixing, V^E, for the tetraethylene glycol diethyl ether+water system have been determined. The purpose of this paper is to see if the above-mentioned conclusion,[1] derived only from the concentration dependence of the partial molal excess enthalpy of water, H_1^E, is consistent with the behavior of the partial molal excess entropy of water, S_1^E, as well.

Tetraethylene glycol diethyl ether was chosen because the aqueous solution properties of such a compound can give fundamental information for many complicated systems, such as, for example, polyethylene glycol+water and a non-ionic surfactant with an oxyethylene chain as a hydrophilic group+water. Other advantages of this compound are its complete miscibility with water at room temperature and its low vapor pressure (less than 10^{-5} mmHg at 25°C), low enough to permit accurate determination of the water activity. No thermodynamic data for the present system have been reported.

Experimental

Materials. The tetraethylene glycol diethyl ether (3,6,9,12,15-pentaoxaheptadecane, which we will denote by TGDE hereafter) was synthesized by the condensation reaction (Williamson reaction) of β-ethoxy β′-chlorodiethyl ether ($ClCH_2CH_2OCH_2CH_2OCH_2CH_3$) (I) with the sodium salt of β-diethoxy ethyl alcohol ($NaOCH_2CH_2OCH_2CH_2OCH_2CH_3$) (II). Both reactants were prepared from commercially-available β-diethoxy ethyl alcohol (diethylene glycol monoethyl ether). The compound I was prepared according to the procedure of Hurd and others,[2] who synthesized β-ethoxy ethyl chloride. Some physical properties and analytical data for the compound I were as follows; bp 179.5—180.5°C/760 mmHg; n_D^{25} 1.4279.

Found: C, 47.12; H, 8.73; Cl, 23.45%. Calcd for $C_6H_{13}O_2Cl$: C, 47.22; H, 8.56; Cl, 23.23%.

The compound I was added, drop by drop, to the compound II dissolved in diethylene glycol monoethyl ether (reaction solvent), and then the mixture was heated under reflux for several hours at 110—130°C. After cooling, the organic layer was separated and distilled under reduced pressure. The crude product (120—125°C/2 mmHg) was re-distilled from sodium. The TGDE prepared in this way was further purified by fractional distillation under a vacuum. It was stored in an ampoule and then further distilled just before use. The analytical data and some physical properties of TGDE are summarized in Table 1.

a) determined by the cryoscopic method in benzene solution.
b) determined by the Karl Fischer titration method.

Vapor-pressure Measurements. The vapor pressure of the water of the aqueous solution of TGDE was determined by the isopiestic method. The apparatus was generally analogous to that used by Robinson and Stokes,[5] but with considerable simplifications. Four or six cylindrical glass dishes (20 mm in diameter and 50 mm deep) were put on a copper block (100 mm in diameter and 20 mm thick) placed within a cylindrical, separable flask (1000 m*l*). Small amounts of grease were placed between the block and each dish to maintain good thermal conact. The equilibrium concentration was determined by weight. At the same time, the amount of water was checked by the Karl Fischer titration method and by refractive-index measurements. Sodium chloride solutions (in the region less than 50 mol% TGDE) and calcium chloride solutions (in the region greater than 50 mol% TGDE) were used as reference solutions. The water activities were obtained by the graphical interpolation of the activity-concentration relation given by Robinson and Stokes.[6]

Enthalpy of Mixing Measurements. The calorimeter used to measure the enthalpies of mixing was the same as that described earlier.[1] At high mole fractions of TGDE, the enthalpies of mixing were determined by measuring the heat when the pure TGDE was mixed with an aqueous solution of TGDE of a known composition. The accuracy of measurement was $\pm 3\,J\cdot mol^{-1}$ at $x<0.5$ and $\pm 5\,J\cdot mol^{-1}$ at $x>0.5$ (x is the mole fraction of TGDE).

Density and Phase-separation Temperature Measurements. The density of the TGDE+water mixture was measured in a 10-m*l* pyknometer which had been calibrated with distilled water. The liquid - liquid phase separation temperature was

determined by heating (or cooling) solutions sealed in ampoules. The temperature shown in Fig. 1 is the average of the two temperatures; the temperature at which the phase separation occurred when the solution was heated slowly, and the one at which the solution became clear again upon slow cooling. The difference between the two temperatures was less than 1°C in all cases.

Results and Discussion

The liquid - liquid phase diagram for the TGDE+water system is shown in Fig. 1, in which the logarithms of x is plotted on the abscissa. This system has a lower critical solution temperature, one which is equal to 89.5°C. The critical concentration is about $x=0.072$. At 120°C, for example, a solution of $x\approx0.01$ is in equilibrium with a solution of $x\approx0.2$. The fact that the ether-rich phase still has a considerable amount of water indicates that the water molecules surrounding the ether molecule are appreciably stabilized. Four mixtures of mole fractions of 0.22, 0.33, 0.61, and 0.71 have been heated to 150°C. No separation of a second liquid phase is observed.

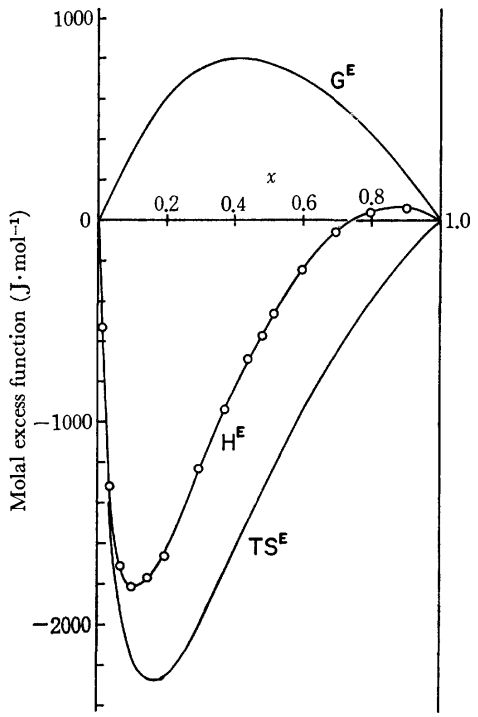

Fig. 2. The molal excess functions of the TGDE+water system at 25°C.

The enthalpies of the mixing, H^E, of the TGDE+water system at 25°C are presented in Table 2 and are shown in Fig. 2. The same general behavior as has been observed for the ethylene glycol dimethyl ether+water[7] and diethylene glycol diethyl ether+water[1] systems is also found for the present system; that is, the H^E is large and negative (exothermic) in the water-rich region and positive (endothermic) in the ether-rich region. However, the exothermicity is, as a whole, more remarkable in this system than in either of the systems cited above.

As has been mentioned earlier,[1] the exothermic heat of mixing in the water-rich region is probably attributable to the structural modifications of water around the ether molecule. The large exothermic heat of mixing observed in the present system, compared with that of diethylene glycol diethyl ether and of ethylene glycol dimethyl ether, is consistent with the prediction that the effect due to the structural modifications of water is more remarkable in an aqueous solution of large hydrocarbon molecules than in one of small ones, when compared at the same mole fraction.

The isopiestic data for the TGDE+water system at 25°C are summarized in Table 3. The second and third columns give the isotonic concentration (in molality) of the reference solutions, which are in equilibrium with the aqueous solution of TGDE with the mole fraction x. The fourth column gives the activity of water, a_1, while the last column gives the activity coefficient of water, γ_1, which is defined by the relation: $\gamma_1=a_1/(1-x)$. The water activity shows a positive deviation from ideality over most of the composition range, though a negative deviation is observed in the water-rich region ($x<0.1$).

The activity coefficient of TGDE γ_2 is calculated by using the Gibbs-Duhem equation. From these results,

7) E. Tommila and V. Turkki, *Suom. Kemistilehti*, **40B**, 207 (1967).

the molal excess Gibbs energy of mixing, G^E, is obtained; it is plotted in Fig. 2. The G^E is defined by the following equation:

$$G^E = RT\{(1-x)\ln\gamma_1 + x\ln\gamma_2\}.$$

Figure 2 also includes the excess entropy of mixing multiplied by the absolute temperature, T, TS^E, which is merely the difference between H^E and G^E. The concentration dependence of these excess functions is similar to that of the 1,4-dioxane+water system.[8] As may be seen from Fig. 2, the concentration dependence of H^E (and of TS^E) is peculiar in contrast to that of G^E, which is positive over the entire range of composition and is approximately symmetrical with a relatively small maximum ($805\ J\cdot mol^{-1}$) at $x\approx0.4$. Thus, we can expect that information about the dissolution state of each component may be drawn from the analysis of H^E and (or) TS^E rather from than that of G^E.

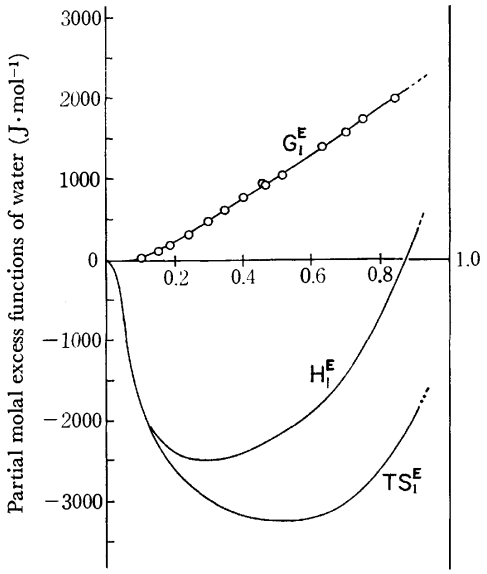

Fig. 3. The partial molal excess functions of water in the TGDE+water system at 25°C.

In Fig. 3, the partial molal excess functions of water in the TGDE+water system at 25°C are plotted against x. The G_1^E is calculated from the vapor-pressure data (Table 3) using the relation: $G_1^E = RT\ln\gamma_1$. The H_1^E is obtained by the graphical differentiation of the H^E *vs.* x curve (Fig. 2). The TS_1^E quantity is simply the difference between H_1^E and G_1^E.

In the previous paper,[1] as a reasonable explanation of the concentration dependence of H_1^E for the aqueous solution of diethylene glycol diethyl ether and of some cyclic ethers, it has been suggested that the hydrogen-bond formation between water molecules is dominant even in the ether-rich region, and that, with an increasing water concentration, the solvating layer of the ether molecule is gradually constructed through this water-water interaction. A similar explanation will hold for the present system, since the H_1^E *vs.* x curve is essentially similar to that of the previous systems. However, it is not only of interest, but also of importance, to see if the concentration dependence of the S_1^E is also consistent with this view. In conclusion, we can say that, judging from the following discussion, the behavior of S_1^E can also be interpreted in the same way.

In the initial stage, for instance $x>0.8$, added water molecules will form hydrogen bonds with the ether oxygen atoms. The value of S_1^E in this region will reflect the state of the water molecule, which is subject to the restraint of the ether. If such a hydrogen-bond formation continues until all of the oxygen atoms form at least one hydrogen bond with water, the value of S_1^E at a high mole fraction of ether would continue up to, say, $x=0.3$ or less. However, as may be seen from Fig. 3, the S_1^E decreases remarkably with an increase in the water concentration. This behavior is consistent with the above idea that an alternative, more ordered arrangement of the water molecule arises even at high mole fractions of the ether.

Now, some care must be taken in choosing an ideal entropy for the definition of an excess entropy of mixing. Since the TGDE molecule is a chain molecule whose chain length is comparable to that of heptadecane, it is reasonable to use, instead of $-R\ln(1-x)$ as before, the following expression for a partial molal excess entropy of water in an ideal solution, S_1^{ideal}:

$$S_1^{ideal} = -R\{\ln(1-\phi)+\phi(1-1/M)\}$$

where ϕ is the volume fraction of the TGDE and, where M is the ratio of the molal volume of the ether to that of water, which is equal to 14.3 at 25°C. However, the concentration dependence of this newly-defined S_1^E is essentially similar to that of the previous S_1^E, though the numerical value becomes much more negative. As a result of this, the above-mentioned interpretation of the S_1^E curve need not be changed.

The excess volume of mixing, V^E, is shown in Fig. 4, together with the partial molal excess volumes of the mixing of both components, V_1^E and V_2^E. The V_1^E and V_2^E are obtained by the graphical differentiation

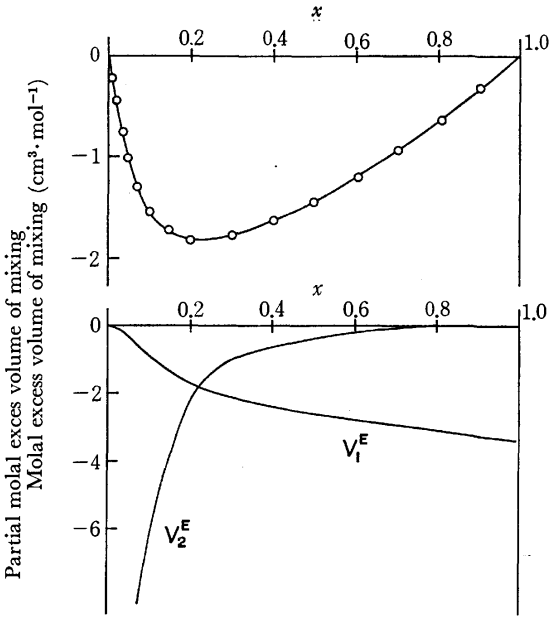

Fig. 4. The molal excess volume of mixing and the partial molal excess volume of mixing for the TGDR+water system at 25°C.

8) J. R. Goates and R. J. Sullivan, *J. Phys. Chem.*, **62**, 188 (1958).

of the V^E *vs.* x curve. The V^E is negative over the entire range of composition and has its minimum (-1.82 cm^3·mol^{-1}) at $x=0.23$. The V_2^E decreases appreciably with an increase in the water mole fraction and reaches about -23 cm^3·mol^{-1} at an infinite dilution. The V_1^E is about -3.4 cm^3·mol^{-1} at $x\rightarrow 1$, which means a 19% depression in the molal volume of normal water. This appreciable contraction may be ascribed to the breakdown of the bulky structure characteristic of liquid water when it is dissolved in a large amount of ether. In the intermediate region, ($0.2<x<0.8$, for instance) V_1^E is $-2\sim-3$ cm^3·mol^{-1}. This indicates that the water layer surrounding the ether is more dense than normal water. This observation is presumably related to the dense structure of water that would exist in the "iceberg" structure.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1375—1380(1972)

On the Electron-transfer Reaction Rate between Different Molecular Species of Aromatic Hydrocarbons as Measured by ESR

Kosaku SUGA and Shigeru AOYAGUI*

Faculty of Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received December 9, 1971)

The rate constants of electron-transfer reactions between the anthracene anion radical and pyrene, and those between the former radical and 1,2-benzanthracene, were measured by the ESR method in tetrahydrofuran containing 20 mM of tetra-*n*-butylammonium perchlorate. In the analysis of the experimental results, correction of the ESR line width was made for the change in the radical concentration caused by the addition of neutral molecules. The rate constants thus obtained were $(2.0\pm0.4)\times10^{7}\,M^{-1}sec^{-1}$ and $(8.1\pm1.0)\times10^{7}\,M^{-1}sec^{-1}$ respectively at 25°C. Under the same experimental conditions, the rate constants of the electron exchange of anthracene and pyrene with their respective anions were about one-tenth of the rate constants of free anions. This fact led us to the supposition that the anion radicals had been combined with tetra-*n*-butylammonium ions into stable ion-pairs in our experiment. A semi-empirical method was proposed for the theoretical calculation of the rate constant according to the theory of R. A. Marcus. The agreement of the observed and the calculated rate constants was satisfactory. Further discussion of the dependence of the rate constant on the standard free energy of reaction was made in connection with the so-called "Linear Free Energy Relationship."

Kinetic studies of electron-transfer reactions in liquid solutions have been reported mainly on metal-complex ions. They have been summarized in several review articles.[1-3] The theoretical treatments have also been made by many investigators, and several excellent theoretical works have been presented, especially on the rate of electron-transfer reactions with outer-sphere mechanisms.[4-8]

However, there have been only a few experimental investigations of the kinetics of the electron-transfer reactions of organic compounds. Probably this is due to the difficulty in the measuring technique, which can be attributed to their large reaction rate and to the instability of the anion radicals. As to theoretical treatments of them, very few investigations have been done. The kinetic study of the electron-transfer reaction of organic compounds began with an electron spin resonance measurement of the rate of the electron exchange between naphthalene and its anion radical by Ward and Weissman;[9] this was followed by measurements of several kinds of anion radicals under various conditions. However, there has been no systematic experimental work which can be the basis for theoretical work. The difficulty is thought to be due to the formation of ion-pairs between anion radicals and cations.

It is known that the radical anions prepared by the reduction of aromatic hydrocarbons with alkali metals form ion-pairs with alkali metal ions in ethereal solvents with low dielectric constants, such as tetrahydrofuran (THF) and methyltetrahydrofuran. Further, the ion-pairs are in several different states, which are dependent on the nature of both the solvent and the cation.[10] These circumstances have troublesome influences on the analysis of the electron-transfer rate.

We have been engaged in experimental work to investigate the dependence of the rate of the electron transfer upon some of the physico-chemical parameters of the reaction, such as the standard free energy of the reaction (ΔG°), the dielectric constant of the solvent, the molecular radius of the reactants, and the temperature. The free anion radicals were expected to be generated by

the electrolytic reduction of hydrocarbons, in which tetraalkylammonium salt was used as a supporting electrolyte. However, it was found that, when tetra-*n*-alkylammonium perchlorate was added to the solution, the ESR spectrum of the solution of the radicals produced by the reduction with alkali metals did not have any hyperfine splittings due to alkali ions. This result suggested that the anion radicals could form stabler ion-pairs with tetraalkylammonium ions than those with alkali metal ions; this idea has been supported by other experiments.[11,12] Therefore, the investigation of the electron-transfer reaction of the free anion radical cannot be made in the presence of tetraalkylammonium ions. However, in this case, some new information may be obtained on the electron-transfer reaction of the stable ion-pairs themselves. The electron-transfer reaction of the ion-pairs of the hydrocarbon anion radicals with cations besides metal ions have never been investigated.

This paper will treat the electron-transfer rate from the ion-pairs of anthracene anions with tetra-*n*-butylammonium ions to hydrocarbons other than anthracene in order to examine its dependency on ΔG°. Until now the measurements of the electron-transfer rate by the ESR method have been carried out exclusively of the electron-transfer between the same species of molecules, *e.g.*, between naphthalene and its anion radical.[9] Measurements must be made for a couple of different molecular species for the dependence of the electron-transfer rate upon ΔG° to be investigated. Measurements on such a couple can, in principle, be made with the ESR method. In the following reaction of an anion radical, R_1^-, with a neutral molecule, R_2,

$$R_1^- + R_2 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} R_1 + R_2^-$$

the rate constant, k_1, can be determined by the line-broadening of the spectrum of R_1^- after adding R_2, if the coexistence of R_2^- in the solution does not disturb the observation of the ESR spectrum of R_1^-. In practice, however, the measurement is possible only when ΔG° is positive, *i.e.*, when the position of the equilibrium of the reaction is located on the left-hand side of the equation. Moreover, there is another restriction on the value of ΔG°. When the ΔG° of the reaction is large, the equilibrium is located on far left-hand side of the reaction; consequently, the reaction rate is too slow to be measurable with this method. Hence, the ΔG° values of reactions the rates of which are measurable range within about 0—0.3 eV. The electron-transfer reactions dealt with in this paper are those between anthracene anion radicals and 1,2-benzanthracene, and those between anthracene anion radicals and pyrene, the ΔG° values of which are 0.052 eV and 0.113 eV respectively.[13]

Experimental

The aromatic hydrocarbons used, anthracene, pyrene, and 1,2-benzanthracene, were obtained by the recrystallization of the commercial reagents from benzene or ethyl alcohol.

Tetra-*n*-butylammonium perchlorate was prepared by adding an excess of perchloric acid to an aqueous solution of tetra-*n*-butylammonium iodide and then by filtering the precipitate. It was recrystallized from water first, and then from ethyl acetate. Tetra-*n*-butylammonium iodide was synthesized by the usual method from tri-*n*-butylamine and *n*-butyl iodide.

Tetrahydrofuran was used as a solvent throughout this investigation. It was refluxed over sodium metal, distilled, and then allowed to stand over sodium metal in a vaccum for a week. After the evolution of hydrogen gas had ceased, the solvent was distilled and stored in an ampoule containing anthracene and sodium metal in a vacuum in order to remove the trace of both oxygen and water. The stored solution was deep blue because of the presence of anthracene anion radicals. The solution of mono-negative ion radicals of hydrocarbons was prepared by the usual method, using a solvent redistilled from the stored solution.

The measurements of the ESR spectra were made with a JEOL JES-3BS spectrometer operated at about 9.7 kMHz, with 100 kHz field modulation and with a modulation amplitude of 0.03—0.08 gauss.

The rates of the electron-transfer reactions were determined from the increase in the linewidth of the ESR spectra of the radical anions after the addition of a known amount of neutral molecules. The measurements were carried out at 25°C.

The concentrations of the anion radicals were determined with a Shimadzu MPS-50L multipurpose autorecording spectrophotometer.

Results

The anthracene anion radicals prepared by the reduction of anthracene with sodium metal in THF yielded a rather unresolved ESR spectrum, as is shown in Fig. 1a. This spectrum evidently exhibited the hyperfine splittings due to a sodium nucleus, the coupling constant of which was about 0.5 gauss. On the other hand, no sign of hyperfine splittings due to sodium were seen in the spectrum of the solution of the anth-

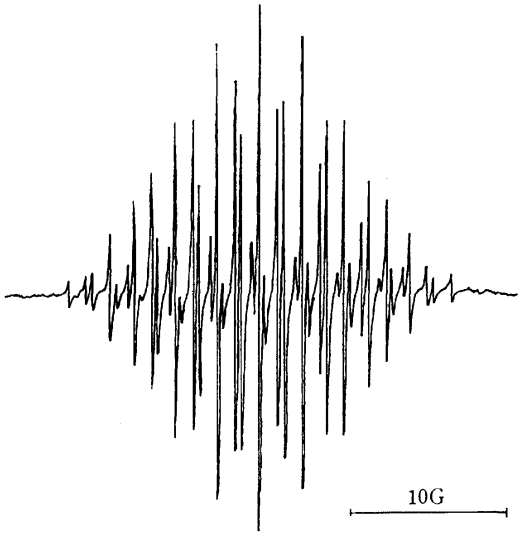

Fig. 1b. ESR spectrum of anthracene anion radical prepared by sodium reduction in THF and added by 20 mM of tetra-*n*-butylammonium perchlorate.

racene anion containing 20 mM of tetrabutylammonium perchlorate, though it was prepared in the way described above. The latter spectrum was a normal one with hyperfine splittings due to just three kinds of protons, as is shown in Fig. 1b. These results suggest that the sodium ion in the ion-pair had been replaced by the tetrabutylammonium ion.

The rates of electron-transfer reactions can be determined by measuring the increase in the linewidth after the addition of neutral molecules. However, this is the case only when the concentration of anion radicals is kept unchanged before and after the addition of neutral molecules. This is because a part of the linewidth of the ESR spectrum of anion radicals is caused by the spin-exchange interaction, the rate of which is dependent on the concentration of anion radicals. In the electron-transfer reactions between different molecular species, the initial concentration of the anion radical is decreased both by the following equilibrating reaction:

$$R_1^- + R_2 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} R_1 + R_2^- \qquad (1)$$

and by the decomposition of the anion radicals, accompanied by the addition of neutral molecules. Accordingly, the linewidth should be corrected for the change in the concentration of anion radicals in this experiment.

It is necessary to examine the dependence of the linewidth upon the concentration of anion radicals in order to make a linewidth correction. Figure 2 shows this relation obtained experimentally. The concentration of anion radicals was determined by the use of the electronic spectra, the extinction coefficient by Balk *et al.* being used.[14] Figure 3 shows a typical spectrum of the anthracene anion radical; it is almost identical with that obtained by Balk *et al.* The plot of the observed linewidth against the radical concentration was linear, as is shown in Fig. 2. Such a dependence of the linewidth on the radical concentration is thought to be due to the spin-exchange interaction. The second-order rate constant of the spin-exchange process in solution can be calculated by the analysis of the relation in Fig. 2. It is 4.8×10^9M^{-1}sec^{-1}, a nearly diffusion-controlled value. The theoretical value of the diffusion-controlled rate constant in THF at 25°C[15] is 7.1×10^9M^{-1}sec^{-1}.

In our measurements of the rates by the ESR method, the concentration of anion radicals before the addition of the neutral molecules was determined by means of the relation shown in Fig. 2, and their concentration after addition, by means of the relative intensity of the central hyperfine lines. The intensity is defined here as the product of the derivative half amplitude (I) and the square of the peak-to-peak linewidth (ΔH_{pp}), on the

assumption that the Lorentzian line shape is unchanged after the addition of neutral molecules. It may be confirmed from Fig. 4 that the concentration obtained by the above method is in agreement with that determined spectroscopically.

When the equilibrium of the reaction (1) is attained, the linewidth, $\Delta H_{pp}(R_1^-)$, of the ESR spectrum of the anion radical, R_1^-, is given by the following equation:

$$\Delta H_{pp}(R_1^-) = c_1 + c_2[R_1^-] + c_3[R_1] + c_4[R_2^-] + c_5[R_2] \quad (2)$$

where $[R_1^-]$, $[R_1]$, $[R_2^-]$, and $[R_2]$ are the concentrations of the individual species. The five terms on the right-hand side of the equation are as follows: the first term is the linewidth intrinsic to the anion radical R_1^-; the second term is the linewidth due to the spin-exchange interaction between R_1^- ions; the third term is due to the electron transfer between R_1^- and R_1; the fourth term is due to the spin exchange interaction between R_1^- and R_2^-; the fifth term is due to the electron transfer between R_1^- and R_2. The c_1 and c_2 constants are obtainable from Fig. 2. The c_3 constant is estimated by means of the rate constant of the electron-transfer reaction between R_1^- and R_1. The fourth term in Eq. (2) is the linewidth due to the spin-exchange interaction between R_1^- and R_2^-, which may be diffusion-controlled, as is the interaction between R_1^- ions. Consequently, c_4 can be taken to be equal to c_2. It is c_5 that must be determined here. Its determination is feasible if $[R_1^-]$, $[R_2^-]$, $[R_1]$, and $[R_2]$ were known. Since $[R_1^-]$, $[R_1]$, and the added quantity of R_2 are already known, $[R_2^-]$ and $[R_2]$ can be evaluated by means of the mass action law, in which the equilibrium constant, K, is calculated from the difference in the standard reduction potential, ΔE°, between R_1 and R_2 by the use of the equation $K=\exp(\Delta E^\circ F/RT)$.

The contributions of each term in Eq. (2) to the linewidth are illustrated in Fig. 5. The symbolic notations A, P, and B means anthracene, pyrene, and 1,2-benzanthracene resectively. The uppermost plot in Fig. 5 is the plot of the observed linewidth against the concentration of added neutral molecules. The next lower plot indicates the linewidth due to the first four terms on the right-hand side of Eq. (2), each of them

being evaluated by the above method. The third plot from the top shows the contribution of the first three terms of Eq. (2) to the linewidth. Accordingly, the difference between two upper plots is the linewidth attributed to the electron transfer between the different molecular species in question. This is shown as the lowermost plot in the figures. It was because of the cancelling effect of the decrease in the radical concentration of the linewidth that an increase in the measured

Discussion

The observed rate constants of the electron transfer between the same molecular species in Table 1 are seen to be about one-tenth of the rate constants for the free anions or their solvent-separated ion-pairs which were obtained with sodium metal in 1,2-dimethoxyethane (DME).[16] This suggests that A^- forms an ion-pair with the tetra-*n*-butylammonium ion (Bu_4N^+) in THF, although the ESR spectrum of A^- after the addition of tetrabutylammonium perchlorate does not have hyperfine splittings due to any of alkali ion, nitrogen atom, or protons in Bu_4N^+. The details of the effect of the ion-pairing of anion radicals with Bu_4N^+ ions on the electron-transfer rate will be reported later.

The rate constants of the electron-transfer reactions between different kinds of molecules are smaller for larger ΔG° values, as is shown in Table 1. The rate constant of the reaction between A^- and P was about one-tenth of that reported by Lyons *et al.*,[17] who worked with potassium and DME. The latter was $1.9\times10^8 M^{-1}sec^{-1}$. Although the extent of ion-pair formation between A^- and K^+ is not clear in their experiment, it is considered that the large rate constant is attributable to the large concentration of free ions or solvent-separated ion-pairs.[18]

The theories on the electron-transfer process which have been proposed should be examined in order to make a quantitative discussion of the ΔG° dependence of the electron-transfer rate. There have been several theoretical investigations of the electron-transfer processes of metal complex ions.[2-8] Marcus' work on those reactions which proceed with an outer-sphere mechanism and which are not accompanied by the formation or the rupture of the chemical bonds is thought to be the most outstanding.[4-7] The activation free energy of the electron-transfer reactions is obtained in this theory by calculating the energy of the reorientation of the solvent molecules in the vicinity of the discharging complex ions to form the activated complex, on the assumptions that the metal complex ions are the spheres of the conductor and that the solvent is a dielectrically unsaturated continuum. Moreover, the energy of the expansion and shrinkage of the inner coordination shell for the formation of the activated complex was also taken into consideration in the calculation of the activation free energy.[5-7]

According to the theory, the rate constant of the electron-transfer reaction, in which one of the reactants is neutral and the number of the transferring electron is one, is given by the following equation:[4-7]

$$k_1 = Z\exp(-\Delta G^*/RT) \tag{4}$$

where ΔG^* satisfies the equations:

$$\Delta G^* = (1/4)(1+\Delta G^\circ/\lambda)^2\lambda \tag{5}$$

$$\lambda = \lambda_0 + \lambda_i \tag{6}$$

$$\lambda_0 = e^2(1/2a_1 + 1/2a_2 - 1/r)(1/D_{op} - 1/D_s) \tag{7}$$

In these equations, Z is the bimolecular collision number of the hypothetical uncharged species in solution; e is the electric charge of the electron; λ_o and λ_i, the contributions to λ from the solvent and the inner coordination shell respectively; a_1 and a_2, the respective radii of the reactants; r, the distance between the centers of the reactants in the activated complex, and D_s and D_{op}, the static and the optical dielectric constants respectively.

In the present electron-transfer reaction of the organic ion radical, the model of Marcus is not consistent with the features of this reaction in two respects: the reactants are planar, and the anion radicals form ion-pairs. However, if λ is treated as a parameter which can be determined experimentally, no non-empirical estimation of those factors appearing in Eqs. (5) to (7)

16) N. Hirota, "Radical Ions," ed. by E. T. Kaiser, and L. Kevan, Interscience Publishers, New York, N. Y. (1968).

17) L. E. Lyons, J. E. Moore, and G. C. Morris, *Aust. J. Chem.*, **21**, 2789 (1968).

18) This value is inconsistent with our own unpublished data, $0.97\times10^8 M^{-1}sec^{-1}$, which was obtained with sodium metal and DME.

will be necessary. Accordingly, the examination of the dependence of the rate constants on ΔG° can be made by comparing the experimental value of the rate constant with that calculated by the above-mentioned method. In the electron-transfer reactions between the same species of molecules as those between anthracene and its anion radical, the ΔG° of the reaction is equal to zero and, accordingly, $\Delta G^* = \lambda/4$; therefore, the value of λ can be determined from the experimental value of the rate constant, if Z is given.

Generally, the value of λ is different for each reaction. As is shown in Table 1, however, the rate constants of the electron-transfer reactions between the ion-pair of the anion radical with the tetrabutylammonium ion and its parent molecule were nearly equal, *e.g.*, those of the reactions between $A^-Bu_4N^+$ and A, and between $P^-Bu_4N^+$ and P, were 2.0×10^8 and $2.3\times10^8 M^{-1}sec^{-1}$ respectively. If it is assumed that Z is 10^{11}, λ for $A^-Bu_4N^+$ and $P^-Bu_4N^+$ are of nearly equal values, *i.e.*, 14.7 and 14.4 kcal·mol^{-1} respectively. Because the λ of the cross electron-transfer reaction is thought to be equal to the mean value of the λ of the original reactions,[6] the λ values for the reactions $A^-+P=A+P^-$ and $A^-+B=A+B^-$ may be equal to that of $A^-+A=A+A^-$. Although there is some uncertainty in the value of Z, the value of 10^{11} proposed by Marcus[6] was taken here. ΔG° was calculated with the use of the data of the reduction potential of hydrocarbons by Chaudhuri *et al.*,[13] which were obtained in THF by means of potentiometric titration. The observed and the calculated values are both listed in Table 2; they

TABLE 2. COMPARISON OF THE OBSERVED AND THE CALCULATED VALUES OF RATE CONSTANT OF ELECTRON TRANSFER REACTIONS BETWEEN DIFFERENT MOLECULAR SPECIES

Reaction	ΔG°(eV)	k_1^{obs}($M^{-1}sec^{-1}$)	k_1^{theor}($M^{-1}sec^{-1}$)
$A^-+B=A+B^-$	0.052	8.1×10^7	7.0×10^7
$A^-+P=A+P^-$	0.113	2.0×10^7	1.9×10^7

are in agreement with one other. Although there is some difficulty in the non-empirical application of Marcus' theory to the electron-transfer reactions of organic ion radicals, the above results show that the ΔG°-dependence of the rate constants of those reactions

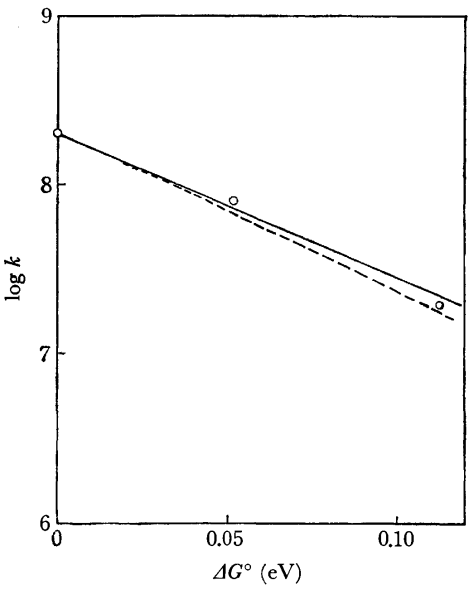

Fig. 7. Dependence of the rate constant of electron transfer reaction upon standard free energy of reaction (ΔG°). ○, observed value; ------, calculated value; ——, calculated value with the second order term in ΔG° being neglected.

can be calculated with this theory when λ is considered as a parameter.

It is known that there is a so-called "Linear Free Energy Relationship" between the rate constant of the chemical reaction and the standard free energy of the reaction; that is, there is a linear relation between ln k and ΔG°:

$$\ln k = A - \alpha\Delta G^\circ/RT \qquad (8)$$

where A and α are constants. The theory of Marcus shows that the quadratic term in ΔG° must also be included in the relation. If the quadratic term in the expansion of Eq. (4) is neglected, the value of 0.5 will correspond to the value of α in Eq. (8).[6] The plots of log k_1^{obs} and log k_1^{theor} against ΔG° are shown in Fig. 7, where a straight line drawn between log k and ΔG° by neglecting the quadratic term in Eq. (5) is also shown. On the basis of these results only it is difficult to decide whether or not the quadratic term in ΔG° contributes to the activation free energy. However, it is clear that the coefficient of the linear term is nearly equal to 0.5.

A Dilatometric Study of Compatible Polymer Mixtures

Saburo AKIYAMA

Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei, Tokyo

(Received April 15, 1971)

Polymer mixtures of poly(vinyl nitrate) ($PVONO_2$), and poly(vinyl acetate) (PVOAc), which had previously been concluded to be compatible with each other, were investigated by the dilatometric method. As a result, a characteristic behavior of the mixtures was observed. Each mixture showed a single glass-transition temperature (T_g) over the whole range of composition; this temperature was higher than those of pure polymers in the middle region of composition. The transition temperatures of the mixtures obeyed a modified Gordon-Taylor expression. The thermal expansion coefficients of the mixtures are discussed in relation to the effect of blending.

The investigation of compatible polymer mixtures is quite interesting as a means to know the possible behavior of polymer mixtures and to achieve a proper definition of compatibility.

There are only few polymer pairs which are compatible with each other. Especially, it is very difficult to make a compatible mixture with a pair of chemically-different polymers over a whole range of composition. Bohn[1] recently listed, from literature, thirteen examples of polymer pairs for which compatibility has been established, at least over a certain composition range. Among those polymers which are chemically quite different from each other, there are only a few pairs in which the compatibility is established over the whole range of their compositions. These are PVC(polyvinylchloride)/NBR(arcylonitile butadiene rubber)[2,3] and natural rubber/poly(butadiene)(Russian SKB).[4]

Other reports have shown by means of dynamic mechanical study[5] and by studying the heat of mixing[6,7] that PVOAc/nitrocellulose and PMMA (polymethyl methacrylate)/nitrocellulose are compatible pairs while the PIPA(polyisopropyl acrylate)/PIPMA(polyisopropyl methacrylate) pair has been established by dilatometric study[8] and the SBR(styrene butadiene rubber)/BR(butadiene rubber)[9] and phenol resin/NBR[10] pairs, by dynamic mechanical study.

We have studied the compatibility of mixtures of $PVONO_2$ and PVOAc. Several data, such as the temperature variation in the refractive indices and the mechanical properties ($T_{D\max}$), together with the observation under a phase-contrast microscope, have been taken to confirm the compatiblity of these mixtures, and it has been concluded that compatibility is observed in this pair with regard to these properties.[11,12]

In this paper, the thermal expansion of the polymer mixtures was investigated with dilatometers which are of the same type as that constructed by Bekkedahl.[13] In this dilatometric study, the present author also found that the glass-transition temperatures of the mixtures are slightly higher than those of the pure polymers. In addition, it is shown that the glass-transition temperatures of the mixtures satisfy the modified Gordon-Taylor equation introduced by Jenckel[14] and by Uematsu[15] for the copolymer system [Eq. (1)]:

$$T_{g12} = \frac{W_1\Delta\alpha_1 T_{g1} + W_2\Delta\alpha_2 T_{g2}}{W_1\Delta\alpha_1 + W_2\Delta\alpha_2} + \frac{W_1 W_2 \Delta k}{W_1\Delta\alpha_1 + W_2\Delta\alpha_2} \quad (1)$$

where T_{g12} is the glass-transition temperature of the mixture containing the weight fractions, W_1 and W_2, of two pure polymers, whose glass-transition temperatures are T_{g1} and T_{g2} respectively.

$$\Delta\alpha_1 = \alpha_{l1} - \alpha_{g1},\ \Delta\alpha_2 = \alpha_{l2} - \alpha_{g2} \text{ and } \Delta k = \bar{k} - k.$$

α_g and α_l are the volume expansion coefficients in the glassy and liquid states respectively. The 1 and 2 subscripts refer to two pure polymers, 1(PVOAc) and 2($PVONO_2$). $\bar{k}$ and k are parameters representing the volume change on mixing, as expressed by the following equations:

$$\bar{V} = W_1\bar{V}_1 + W_2\bar{V}_2 + \bar{k}W_1W_2$$
$$V = W_1V_1 + W_2V_2 + kW_1W_2 \quad (2)$$

where $\bar{V}$ and V are the specific volumes of a mixture in the glassy and liquid states respectively. The change in the specific volume with the temperature is assumed to be linear.

Experimental

The poly(vinyl nitrate) ($PVONO_2$) used for this work was obtained by the nitration[11] of a commercial sample of poly(vinyl alcohol) (PVA) with a degree of polymerization (DP) of 1700. The degree of nitration was 94.8 mol%. The poly(vinyl acetate) (PVOAc) used was a purified sample of a commercial product with a DP of 1800. Five specimens of polymer mixtures, BII-1, -3, -5, -7, and -9, were prepared from mixed solutions of $PVONO_2$ and PVOAc by evaporating the solvent. The mixing ratios of $PVONO_2$ to PVOAc in these samples were, in weight, 9/1, 7/3, 5/5, 3/7, and 1/9

respectively, as is shown in Table 1. The conditions of preparation were given in detail in earlier reports.[11,12]

The specific volume of each specimen was measured at 25°C by the density gradient method. An aqueous solution of $CdCl_2$ was used for $PVONO_2$, BII-1, -3, and -5, and a $CaCl_2$ solution, for BII-5, -7, -9, and PVOAc. The temperature variation in the specific volume was determined by a method well-known in dilatometry.[13]

Dilatometry. The dilatometers were constructed of Pyrex glass and had a reservoir volume of about 20 cc. The measuring section was constructed of a precisely-bored capillary tube with a cross section of 0.01640—0.01642 cm^2. Each capillary was checked for uniformity and was calibrated with a mercury bead by the use of a travelling microscope. The volume of the reservoir was also determined by calibration with mercury. Tiny pieces of polymer samples without a void were cut off, weighed amounts of the tiny films were placed into the dilatometers, and then glass tubes were carefully shielded in order not to pyrolyze them. A special-grade commercial mercury was then charged on the top of the polymer samples while it was still under a vacuum. After breaking the vacuum, the mercury-filled dilatometers were allowed to rest for more than 24 hr at room temperature. They were then put into a water-ice bath maintained at 0——3°C. After a temperature equilibrium had been established, the temperature was raised at a rate of 20°C/hr and readings taken at 1°C intervals on a cathetometer which could be read to 0.005 cm. The glass-transition temperatures (T_g) and the volume-expansion coefficients below T_g (α_g) and above T_g (α_l) were obtained by this dilatometric measurement at the temperature elevation rate of 0.3—0.5 deg/min. The average standard estimations of the error in dv/dT were 1.5×10^{-6} cc/g°C in the glassy region and 3.0×10^{-6} cc/g°C in the rubbery region. The obtained T_g values were defined as the intersection of the straight-line portions of the plots of the specific volume *versus* the temperature.

Results and Discussion

Figure 1 shows the specific volume-*versus*-temperature curves obtained for $PVONO_2$, BII-1, BII-3, BII-5, BII-7, BII-9, and PVOAc. In the case of $PVONO_2$, it is noteworthy that the expansion does not show a linear increment above 55°C on account of the thermal degradation of $PVONO_2$. Table 1 summarizes the values of dv/dT, α_g, α_l, and T_g for the samples used. The calculated values for T_g were obtained from Eq. (1) using the following values:

$T_{g1} = 302.4$°K (PVOAc), $T_{g2} = 303.1$°K ($PVONO_2$),

$\alpha_1 = 2.88\times10^{-4}$, $\alpha_2 = 5.09\times10^{-4}$, and $\Delta k = 0.0097$.

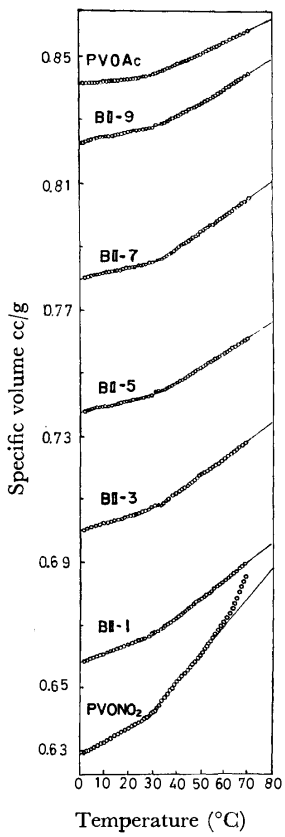

Fig. 1. Thermal expansion of $PVONO_2$, PVOAc, and mixtures.

To obtain the Δk value, we first read off a set of the values of the specific volume, $\bar{V}$ and V, say, at 0°C in the glassy state and at 50°C in the rubbery state, from the curves in Fig. 1. These values of $\bar{V}$ and V are plotted against W_1W_2 in Fig. 2. Then, we obtain, from the slopes of the straight lines, $\bar{k}=0.0205$ (cc/g) and $k=0.0108$; hence, the value of $\Delta k=0.0097$ is obtained [see Eq. (2)].

Figure 3 shows the glass-transition temperature, T_g, as a function of the weight fraction of PVOAc in the mixture. The full curve represents the calculated values of T_g given by Eq. (1), while the black and open circles are the experimental values obtained from the temperature dependencies of the refractive indices[11] and of the specific volumes respectively. It may be seen that the theoretical curve is in better agreement with the values obtained from the refractive indices.

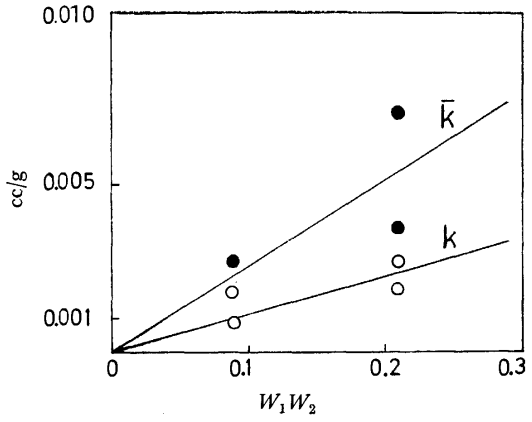

Fig. 2. Determination of $\bar{k}$ and k for $PVONO_2$ and PVOAc mixtures.
$\bar{V}-(W_1\bar{V}_2+W_2\bar{V}_2)$ and $V-(W_1V_1+W_2V_2)$ are plotted for W_1W_2 by Eq. (2).
From the slopes, $\bar{k}=0.0205$, $k=0.0108$ (cc/g).
(●, glassy state; ○, rubbery state)

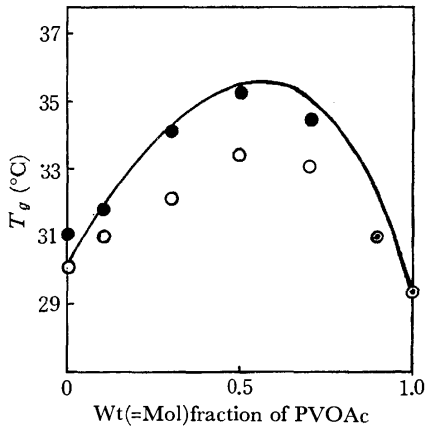

Fig. 3. Glass transition temperatures of PVOAc, $PVONO_2$, and their mixtures. The modified Gordon-Taylor expression is plotted using Eq. (1) (——). Experimental data obtained by means of refractometer (●) and by means of dilatometer (○).

Equation (2) appears to be insufficient to explain these experimental results completely. The small difference between the T_g values obtained by the two methods might be attributed to the errors due to the position of the thermometer and to the difference in experimental techniques (for example, the temperature-elevation rate). By the refractometric method we can avoid errors due to porosities in the samples better than by dilatometry; therefore, slightly higher values can be expected with the former method.

Figure 4 is a plot of the expansion coefficient as a function of the composition for the $PVONO_2$/PVOAc system. Small amounts of PVOAc can reduce the expansion of $PVONO_2$ quite effectively, but in the middle composition region, both α_g and α_l are nearly constant. It is clear that the α_g and α_l values of the mixtures deviate down from the straight lines. This depression in the expansion coefficients from additivity may result from an attractive interaction between the polar groups of the polymer pair.

By other measurements, such as those by means of a phase-contrast microscope, by mechanical damping (by

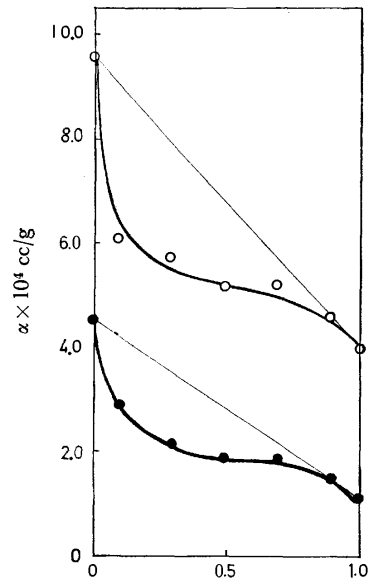

Fig. 4. Thermal expansion coefficients of $PVONO_2$, PVOAc, PVOAc, and their mixtures. (○, above T_g; ●, below T_g)

torsion pendulum[16]), and by the infrared spectra, the compatibility of this system has already been confirmed, and the characteristic behavior of the mixtures has been explained in forms of the interaction between the $-ONO_2$ and $-OCOCH_3$ polar groups. With the purpose of obtaining further evidence for this, studies of a low-molecular liquid mixtures of the nitric acid ester and the acetic acid ester, regarded as model compounds of the polymers, are now in progress by means of NMR and heat of mixing.

Recently Murakami[17] reported that a larger difference between the thermal-expansion coefficients of the homopolymers causes a rise in the T_g of the blend as a result of thermal stress. For the present compatible system, however it will be difficult to explain the results by this factor alone, although the large difference between the expansion coefficients may contribute to the rise in the T_g to some extent. As for the applicability of the Gordon-Taylor equation used for the copolymer in compatible mixtures, Koyama *et al.*[5] reported that, for the PVOAc/Nitrocellulose and PMMA/Nitrocellulose systems, the T_g varies with the composition according to this equation; Koleske and Lundberg[18] reported that the same was true for the poly ε-caprolactone/PVC system. However, Krause and Roman[8] found that, for PIPA/PIPMA mixtures, this equation was not applicable and argued that a new theoretical treatment was needed for their compatible mixtures. Therefore, by using only this equation it is quite difficult to determine whether or not they are compatible pairs.

By electron microscopic observations, Matsuo[19] re-

cently showed that the PVC/NBR blends are not completely compatible and indicated that the micro heterogeneously-dispersed particles are less than 100 Å in diameter. Electron-microscopic observation will also be necessary to ascertain the morphology of this $PVONO_2$/PVOAc system accurately.

From the studies of the $PVONO_2$/PVOAc system, it is generally expected that the compatibility may be established when the intermolecular interaction between the mixed polymers has as strong an influence on the system as the intramolecular interaction.

Conclusions

By means of applying the dilatometric method to compatible mixtures of $PVONO_2$ and PVOAc, we arrived at the following conclusions:

(1) The mixtures showed higher glass-transition temperatures than both of the homopolymers.

(2) The transition data of the mixtures approximately obeyed the modified Gordon-Taylor equation.

(3) The fairly large depression of the expansion coefficients (Fig. 4) indicates the existence of a certain interaction between the polymer pairs.

The author wishes to express his thanks to Dr. Rokuro Kaneko of this University for his continued encouragement and discussions, and also to Teruo Iwanami and Satoshi Yamashita for their helpful assistance in carrying out the experiments.

On the Long-range Interactions between Two Hydrogen Atoms and Two Helium Atoms

Tokio YAMABE, Shingo ISHIMARU, and Kenichi FUKUI
Department of Hydrocarbon Chemistry, Kyoto University, Kyoto
(Received November 11, 1971)

The numerical results of the interaction energy between two hydrogen atoms and two helium atoms are examined with the use of exact formulae of the second-order perturbation energy using the Unsöld approximation. It is found that the analytic expression gives a good long-range interaction energy between two hydrogen atoms comparable to the best variational results so far obtained. In the case of two helium atoms, the result lies in between experimental data for large nuclear distances; this seems to support the reliability of the present estimation. Finally, the effectiveness of the Unsöld approximation is remarked on.

In calculating the dispersion energy between two atoms, it happens that the multipole expansion of the perturbation leads to nonconvergent results.[1] To solve this difficulty, exact analytical expressions of the second-order perturbation energy within the framework of the Unsöld approximation have been derived by several authors for the hydrogen molecule ion[2] and for two hydrogen atoms and two helium atoms.[3] One particularly useful advantage is that they are so simple that one can use them for further calculations of the chemical or physical properties of atoms and molecules. On the other hand, a recent calculation[4] using the variation-perturbation technique, even though it avoided the divergence difficulty, is still given in expanded form in each angular component and is, as a consequence, too complicate to be applied to further calculations. Therefore, it is important to investigate whether or not the results obtained by the Unsöld approximation are numerically reliable, especially at a large separation. In the present paper, we will examine the numerical results with the use of the formulae previously obtained in two hydrogen and two helium cases[3] and will compare them with those of several authors.

On the interatomic force between two hydrogen atoms, many calculations have hitherto been carried out by both the variation and perturbation techniques. Among them, one of the most reliable techniques for the potential values in the range of $R>4.5$, where R is the interatomic separation in atomic units, is the variational technique proposed by Hirschfelder-Linnett with a nonexpanded Hamiltonian[5] for $4.5<R<8.0$, and another is that of Pauling and Beach,[6] with an expanded form for $9.0<R<12.0$. The present second-order perturbation energy is comparable to the above-mentioned values. Furthermore, the limit of the Unsöld approximation with the conventional asymptotic expansion is made clear numerically.

In the case of two helium atoms, the best theoretical potential curve is given by superimposing the results of Rosen, Margenau, and Page.[7] Unfortunately, the

Bird, "Molecular Theory of Gasses and Liquids," John Wiley and Sons, Inc., New York, 1954, p. 1067.

curve lies under the experimental curves[8,9] for separations larger than 3.8 Å, although one has, of course, to consider the error involved in the experimental data. On the other hand, the interaction energy estimated in this paper lies between these values, at $R>4.0$ Å; this seems to support the present results. It seems that it would be of interest to examine whether or not this discrepancy is attributable to an essential error which is often brought about in the perturbation treatment. In this aspect, the dispersion energy is discussed in relation to that reported by Margenau and Page. Other theoretical calculations due to the molecular orbital theories have been made by several authors.[10,11] None of them gives satisfactory results in the van der Waals region.

In the last section of this paper, the theoretical foundation of the applicability of the Unsöld approximation is discussed with the use of a variational approach, which confirms the effectiveness of the Unsöld approximation, taking the ground-state energy of the system as the average excitation energy.

The Interaction Energy between Two Hydrogen Atoms

It is well known that, in the framework of the Unsöld approximation, the second-order perturbation energy $E_2(R)$, of the interaction between two hydrogen atoms in their ground states may be represented as follows:

$$E_2(R) = \frac{(H'^2)_{00} - (H')^2_{00}}{\langle \Delta E \rangle_{\mathrm{AV}}}. \tag{1}$$

$\langle \Delta E \rangle_{\mathrm{AV}}$ is an "average excitation energy" after Unsöld. $(H')_{00}$ and $(H'^2)_{00}$ are given by:

$$\begin{Bmatrix} (H')_{00} \\ (H'^2)_{00} \end{Bmatrix} = \iint \phi^2_{Ha}(1)\phi^2_{Hb}(2) \begin{Bmatrix} H' \\ H'^2 \end{Bmatrix} \mathrm{d}v_1 \mathrm{d}v_2, \tag{2}$$

where H' is the usual perturbation at an interatomic distance of R;

$$H' = \frac{1}{R} - \frac{1}{r_{1b}} - \frac{1}{r_{2a}} + \frac{1}{r_{12}} \text{ (in atomic units)},$$

ϕ_{Ha} and ϕ_{Hb} are the $1s$ functions of the a and b, hydrogen atoms and the exchange of two electrons, 1 and 2, is neglected.

In our previous paper,[3] Eq. (1) was evaluated exactly without resorting to a series expansion and was given in a closed analytical form applicable to an arbitrary interatomic distance, R, as follows:

$$(H')_{00} = \mathrm{e}^{-2R}\left(R^{-1} + \frac{5}{8} - \frac{3}{4}R - \frac{1}{6}R^2\right) \equiv U(R), \tag{3}$$

$$(H'^2)_{00} = V_{\mathrm{S}}(R) + V_{\mathrm{L}}(R) \equiv V(R), \tag{4}$$

$$V_{\mathrm{S}}(R) = V_1(R)\mathrm{e}^{-2R} + V_2(R)\mathrm{e}^{-4R} + \mathrm{e}^{2R}Ei(-4R)\left(4 - \frac{2}{R}\right), \tag{5}$$

$$V_{\mathrm{L}}(R) = \frac{1}{R^2} - \frac{7}{12} + \mathrm{e}^{2R}Ei(-2R)\left(\frac{11}{16R} - \frac{11}{8} - \frac{1}{2}R + \frac{1}{6}R^2\right) + \mathrm{e}^{-2R}\tilde{E}i(2R)\left(-\frac{11}{16R} - \frac{11}{8} + \frac{1}{2}R + \frac{1}{6}R^2\right), \tag{6}$$

where:

$$V_1(R) = -\frac{2}{R^2} + \left(4 + \frac{2}{R}\right)\log 4\gamma R - \frac{11}{4R} - \frac{9}{2} + \frac{5}{3}R,$$

$$V_2(R) = 2 + \frac{4}{R} + \frac{2}{R^2},$$

$$Ei(-x) = -\int_x^\infty \frac{\mathrm{e}^{-t}}{t}\mathrm{d}t, \quad \tilde{E}i(x) = -\int_{-x}^\infty \frac{\mathrm{e}^{-t}}{t}\mathrm{d}t$$

and where $\log \gamma$ is Euler's constant, 0.5772156649·····.

Some interesting features of the $V_{\mathrm{S}}(R)$ and $V_{\mathrm{L}}(R)$ functions presented above may be remarked on (Fig. 1). The $V_{\mathrm{S}}(R)$ function is the part of $V(R)$, which attenuates exponentially with increase in R, while the $V_{\mathrm{L}}(R)$ function is the origin of the well-known expression of asymptotic expansion in the inverse powers of R for large R values.

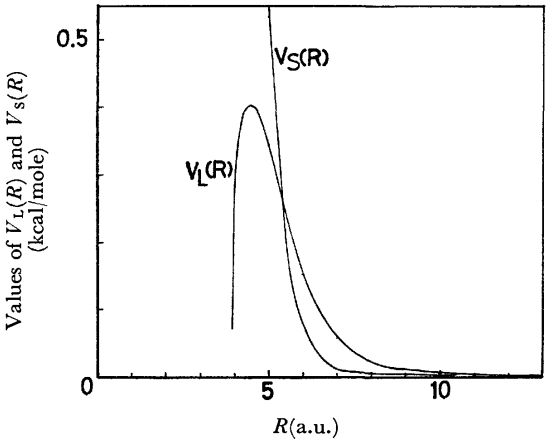

Fig. 1. The functions $V_{\mathrm{L}}(R)$ and $V_{\mathrm{S}}(R)$.

$$V_{\mathrm{L}}(R) \sim \frac{6}{R^6} + \frac{135}{R^8} + \frac{7875}{2}\cdot\frac{1}{R^{10}} + \cdots. \tag{7}$$

It may be seen in Fig. 1 that the value of $V_{\mathrm{S}}(R)$ prevails over $V_{\mathrm{L}}(R)$ at $R<5$, while at $R>7$ the latter is predominant. Therefore, Eq. (6) for $V_{\mathrm{L}}(R)$ or its asymptotic expansion, Eq. (7), with a limited number of terms, can not be a good approximation of the total interaction energy unless $R \gtrsim 8$. Moreover, it is noticeable that the $V_{\mathrm{L}}(R)$ has a maximum value of 0.40502 kcal/mol at $R=4.5$. Accordingly, the value of the interaction energy does not exceed *ca.* 0.4 kcal/mol so long as Eqs. (6) or (7) is adopted as the approximation of the total interaction energy.

In order to compare our results with the best potential energy curves previously obtained by Hirschfelder-Linnett[5] and Pauling-Beach,[6] we make the choice of $\langle \Delta E \rangle_{\mathrm{AV}}$, *i.e.* $\langle \Delta E \rangle_{\mathrm{AV}} = E_0 = -1.0$ a.u., as was previously suggested by Lennard-Jones.[12] Following this approximation, Eq. (1) and the total energy, E, are rewritten as:

$$E_2(R) = \frac{(H'^2)_{00} - (H')^2_{00}}{E_0} = U^2(R) - V(R), \tag{8}$$

12) J. E. Lennard-Jones, *Proc. Roy. Soc.* (London), **A129**, 598 (1930).

$$E \sim E_0 + (H')_{00} + E_2(R). \quad (9)$$

As was pointed out by Dalgarno and Lewis,[13] the asymptotic form of Eq. (8) (equivalent to Eq. (7)) provides a good approximation to the variational calculation.[6] Moreover, the variational calculation gives $-6.49\,R^{-6}$ as the first leading term in its expanded form, while the present estimation gives $-6.00\,R^{-6}$ for the corresponding term. These facts imply that the above-mentioned choice of $<\Delta E>_{AV}$ is appropriate.

a) From Ref. 6. b) From Ref. 5.

In Table 1, the interaction energies between two hydrogen atoms at several interatomic separations larger than 6.0 are shown. Except for one case, at $R=12$, the present results give values below those of Pauling and Beach, which were obtained by the variational calculation taking the perturbation of the first three terms of the asymptotic expansion. Furthermore, at $6<R<7$, our results come close to the energy curve of Hirschfelder-Linnett obtained variationally by the use of the exact H' and by a trial function consisting of 1s functions with a variable exponent and corrected by considering all possible states of electron configurations and polarization effects. In the longer range, $8<R<12$, the present calculations give a lower energy curve than the previous results. As expected, the contribution of the first-order energy becomes negligibly small at all these distances.

The Interaction Energy between Two Helium Atoms

In the case of two helium atoms, the interaction energy was derived in a way analogous to the case of H_2, that is, by using the Unsöld approximation and by neglecting the electron exchange. The same discussion as that in the case of two hydrogen atoms is possible with respect to the $V(ZR)$ function, in which R is the distance between two helium nuclei in atomic units and in which Z is the effective nuclear charge of the isolated helium atom.

We chose the approximate wavefunction, $(Z^3/\pi)e^{-Z(r_1+r_2)}$, as the unperturbed state of an isolated helium atom in the ground state, where r_1 and r_2 are the distances from the nucleus of the 1 and 2 electrons respectively. This function gives the energy of $-Z^2$, and the optimum value of Z is 27/16. The second-order perturbation energy is obtained for two cases, in which $<\Delta E>_{AV}$ is approximated by the ground-state energy $(-Z^2)$ and by the ionization potential (-0.903695). These cases are denoted by $E_2{}^U$ and $E_2{}^L$ respectively. Following to Unsöld,[14] the value of $E_2{}^L$ is a lower limit to the second-order perturbation energy. The sum of the first- and second-order perturbation energies of these two cases are denoted by E^U and E^L respectively; they are tabulated in Table 2 together with the experimental and theoretical estimations. The present results give lower energy values than does the molecular orbital theory.[10,11] On the other hand, E^U gives higher values, over the whole range, than the combined results of Rosen, Margenau and Page (RMP), which consist of first- and second-order perturbation energies, including the electron exchange, and which are presumably the best theoretical potential energy curves so far obtained. However, in the $R>3.8$ Å range, the energies of RMP are always lower than both the experimental values,[8,9] whereas E^U lies between them. In this connection, it is worthwhile examining the dispersion energies obtained by these two theoretical approaches in the $4\text{ Å}<R<5\text{ Å}$ range in more detail. The results are indicated in Table 3. At $R=3.8$ Å, the difference be-

14) A. Unsöld, *Z. Phys.*, **43**, 374 (1927).

tween E_2^U and the value of Margenau and Page is 76×10^{-7}; this value is 56×10^{-7} at $R=4.0$ Å and 15×10^{-7} at $R=5.0$ Å. By adding these values to the interaction energies of RMP, one obtains the energies through the second-order perturbation energies, including the effect of electron exchange and lying at least between two experimental data. The corrected values of the interaction energy are shown in the last column of Table 2. In our previous paper, the present authors obtained the approximate dispersion energy of -1.63 R^{-6} (R in a.u.) for E_2^L. The value of the above coefficient is 0.517 for E_2^U, while Margenau reported 1.45. The former value is obviously too small, but the latter is in good agreement with the other results estimated by many authors over the last ten years.[15] However, as will be shown in the next section, the energy through E_2^U will give nearly an upper limit to the long-range interaction energy.

In the $R<4.0$ Å range, it is necessary to consider the electron exchange. Adding the approximate first-order exchange energy[16] to the above interaction energy gives an equilibrium distance of 3.2 Å, which roughly agrees with the experimental result of 2.8—3.0 Å.[8,9]

A Remark on the Applicability of the Unsöld Approximation

In the above discussions, in the cases of both two hydrogen and two helium atoms, it is clear that the analytical formula of the second-order perturbation energy on the basis of the Unsöld approximation gives a good descrpition of the long-range interaction. Here, a theoretical foundation may be required as to the applicability of the Unsöld approach.

For the sake of simplicity, we will discuss the case of the interaction of two hydrogen atoms. According to the variational principle,[17] and by the use of the variation function:

$$\psi = \phi_{Ha}(1)\phi_{Hb}(2)(1+AH'), \tag{10}$$

one obtains:

$$\begin{aligned} E \leqq E_0 &+ (H')_{00} + [(2A-E_0A^2)(H')_{00}-(H')_{00}^2 \\ &+A^2\{(H'H_0H')_{00}+(H'^3)_{00}-E_0(H')_{00}^2 \\ &-(H')_{00}(H'^2)_{00}\}]/[1+2A(H')_{00}+A^2(H'^2)_{00}], \end{aligned} \tag{11}$$

where A is the variational parameter, H_0 is the unperturbed Hamiltonian operator, and $(H'H_0H')_{00}$ and (H'^3) are integrals defined similarly to Eq. (2). At large separations, $(H')_{00}$ and $(H'^2)_{00}$ are small compared with unity (*e.g.*, at $R=8$ a.u., $(H')_{00}=-1.8\times10^{-6}$ and $(H'^2)_{00}=4.1\times10^{-5}$ a.u.); hence, they are negligible in the denominator of the third term in the right-hand side of Eq. (11), since A is found to be of the order of unity in the neibourhood of the minimum value of the righthand side of Eq. (11). Thus, Eq. (11) may be rewritten as:

$$\begin{aligned} E \lesssim E_0 &+ (H')_{00} + (2A-E_0A^2)\{(H'^2)_{00}-(H')_{00}^2\} \\ &+ A^2\{(H'H_0H')_{00}+(H'^3)_{00}\}. \end{aligned} \tag{12}$$

Up to the present, no exact evaluation of $(H'H_0H')_{00}$ or $(H'^3)_{00}$ has been found in the literature.

It may be permitted at large separations to estimate the relative magnitude of the integrals in Eq. (12) by the first leading terms of their asymptotic expansion.[18] The results are:

$$(H'^2)_{00} \sim -\frac{6}{R^6}, \tag{13}$$

$$(H'H_0H')_{00} \sim +\frac{45}{2}\frac{1}{R^8}, \tag{14}$$

$$(H'^3)_{00} \sim -\frac{2430}{R^{11}}. \tag{15}$$

At $R=8$, these one-term approximations give $(H'H_0H')_{00}\sim-0.0625\,\tilde{a}$ and $(H'^3)_{00}\sim+0.0124\,\tilde{a}$, while at $R=10$, $(H'H_0H')_{00}\sim-0.0375\,\tilde{a}$ and $(H'^3)_{00}\sim+0.0041\,\tilde{a}$ respectively. Where $\tilde{a}$ represents the values of $-6/R^6$ at each R. Consequently, if R is so large that the residual main term $(H'H_0H')_{00}$ can be neglected, Eq. (12) may be reduced to:

$$E \lesssim E_0 + (H')_{00} + (2A-E_0A^2)\{(H'^2)_{00}-(H')_{00}^2\}. \tag{16}$$

The right-hand side of this equation approaches approximately from the upper side to the upper limit of Eq. (11) with an increase in R. Now, we can easily find that Eq. (16) has a minimum with respect to the variation in A when $A=1/E_0$, in which case Eq. (16) becomes:

$$E \lesssim E_0 + (H')_{00} + \frac{(H'^2)_{00}-(H')_{00}^2}{E_0}. \tag{17}$$

The right-hand side of Eq. (17) agrees with Eq. (9). From the above discussions, it may be concluded that, if the energy of two isolated hydrogen atoms, E_0, is adopted for the value of $<\Delta E>_{AV}$ in the Unsöld approximation, the results give almost an upper limit for the energy; therefore, our previous result[3] and the numerical estimation presented in this paper are reliable. For a long-range interaction of two helium atoms, there is no essentially new problem and one will be able to treat it in the same way as in the case of two hydrogen atoms.

It becomes clear from the theoretical and numerical aspects that, if one uses the Unsöld approximation with the choice of the ground-state energy of the system considered as the average excitation energy, the resulting formula obtained analytically gives an energy value very close to the upper limit of the exact one. The evidence encourages us to investigate long-range forces between atoms and molecules, which are especially interesting in view of the chemical bond formation, in the simple manner described above.

The evidence reported in this paper may support the conclusion that the dispersion force is of the same nature as the chemical bond formation, being only a portion abstracted as acting at larger distances than ordinary bond lengths.

15) The data are summarized in the following paper: G. Starkshall and R. G. Gordon, *J. Chem. Phys.*, **54**, 663 (1971).

16) K. Fukui, "Quantum Chemistry," Asakura-Shoten, Inc., Tokyo 1968, p. 337.

17) L. I. Shiff, "Quantum Mechanics," second ed., McGraw-Hill Book Co., 1955, p. 179.

18) Mathematically, the integrals, $(H'H_0H')_{00}$ and $(H'^3)_{00}$ are infinite. However, one can avoid this difficulty in the manner previously developed by the present authors (This Bulletin, **43**, 2012 (1970)) and so find results not very different from those obtained by the use of the asymptotic expansion. A more detailed discussion of this point will be presented elsewhere.

The Behavior of Indium(III) Complexes in Several Distribution Systems. II. The Extraction of Indium(III) Halide and Thiocyanate Complexes into 4-Methyl-2-Pentanone, 4-Methyl-2-Pentanol, or Nitrobenzene

Yuko HASEGAWA, Hiroshi TAKEUCHI, and Tatsuya SEKINE

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received March 12, 1971)

The solvent extraction of indium(III) from a bromide, iodide, or thiocyanate solution into 4-methyl-2-pentanone(MIBK), 4-methyl-2-pentanol(hexol), or nitrobenzene was determined by using a ^{114m}In tracer. The extraction was, in general, most effective with MIBK and poorest with nitrobenzene, except from iodide solutions. The extraction with a certain solvent was always better from iodide solutions than from bromide solutions. The extraction from thiocyanate solutions was better than that from iodide solutions in some cases, but it was poorer in other cases, and it was better than that from bromide solutions except with nitrobenzene. Furthermore, it was found that the distribution ratio, determined as a function of the ligand concentration, was always poorer when the aqueous phase contained only the sodium salt of these ligands than when it was 4M Na(X, ClO_4) (where X denotes the ligand anion). The extractions from 4M Na(X, ClO_4) were analyzed by using the stability constants for the indium complexes with these ligands in the aqueous phase, and the extraction equilibria were determined. From these results, it was concluded that these polar solvents extract not only the uncharged complex, InX_3, but also the cationic and/or anionic indium complexes as ion-pairs, with the oppositely charged ions in the background salt, and that, in some cases, the solvent extracts only charged indium species. Thus, the difference in the distribution ratio in the presence and in the absence of the background sodium perchlorate was concluded to be caused not only by the change in the activities due to the change in the total salt concentration, but also by the extraction of ion-pairs of charged indium(III) species, which should be very much enhanced by the presence of the bulk perchlorate.

In Part I of this series,[1] it was reported that indium (III) forms complexes with various uninegative ligands and that the bromide, iodide, and thiocyanate complexes are extractable into hexane containing tributylphosphate (TBP). These extraction curves were explained in terms of a successive complex formation and the extraction of the uncharged complex, InX_3 (where X^- is a uninegative ligand), into this non-polar organic solvent containing a small amount of the coordinating extractant.

In the lower ligand-concentration region in these systems, an increase in the amount of extractable uncharged complex is caused by an increase in the ligand-concentration; consequently, it enhances the distribution ratio.

In the higher ligand-concentration region, where higher anionic complexes are formed, on the other hand, the distribution ratio decreases upon an increase in the ligand-concentration, because these charged complexes are usually unextractable into non-polar organic solvents. However, if the solvent is a polar one, it is supposed that the anionic complexes may also be extracted as ion-pairs with other cations in the aqueous phase, and the distribution ratio in such systems might increase, even in the higher ligand-concentration region.

The present paper will describe the results of experiments carried out along with this line. Three polar organic solvents, 4-methyl-2-pentanone(MIBK), 4-methyl-2-pentanol (hexol), and nitrobenzene, were employed as the organic solvents. The aqueous phases equilibrated with these organic solvents were similar to that in the previous study.[1]

The equilibrium constants at 25°C were determined by a successive approximation analysis of the distribution data graphically.

Experimental

Most of the experimental procedures were the same as those described in the previous study.[1] The indium-114*m* tracer was obtained from the Radio Chemical Center, England. The 4-methyl-2-pentanone and hexol were obtained from Kanto Kagaku Co. and the Tokyo Kasei Co. respectively; they were washed with 0.1M perchloric acid, water, and 0.1M sodium hydroxide successively, and then several times with water. The nitrobenzene was also obtained from the Kanto Kagaku Co. The sodium perchlorate was prepared from perchloric acid and sodium carbonate and was recrystallized three times from water. The other reagents were of an analytical grade and were used without further purification.

Aqueous solutions containing indium(III) labelled with the indium-114*m* tracer, and various amounts of the ligand and sodium perchlorate solutions, together with one of these solvents, were placed in stoppered glass tubes (volume, 20 m*l*). The initial volume of each phase was 5 m*l*, and the aqueous phase was adjusted to be a constant ionic medium of 4M sodium perchlorate, unless otherwise mentioned. The hydrogen-ion concentration was 1×10^{-2}M for the experiments on the bromide and iodide complexes, but it was about 1×10^{-3}M for the thiocyanate complexes, and the initial concentration of indium in the aqueous phase was about 2.5×10^{-6}M. All of the procedures were carried out in a thermostatted room at 25°C. The two phases in the tubes were agitated mechanically for about two hours and then centrifuged. The γ-radioactivity of these samples was measured with a scintillation counter (NaI), and the distribution ratio was calculated as;

$$D = \frac{\gamma\text{-count-rate per m}l\text{ of the org. phase}}{\gamma\text{-count-rate per m}l\text{ of the aq. phase}}$$

Results

Figures 1 to 3 give the extraction of indium(III) into the three organic solvents as a function of the ligand concentration in the aqueous phase, together with the extraction into hexane-containing TBP which has been

already given in Part I.[1] It will be seen from the figures that the distribution curves in the three polar organic solvent systems are rather different from that in the TBP-hexane system. As will be described later, this is due to the extraction of anionic complexes, such as InX_4^- and InX_5^{2-}, as well as to that of the uncharged complex; furthermore, that of cationic species is also assumed in some systems.

The following equilibrium was first assumed in order to explain the distribution ratio of the indium(III) measured experimentally (the complexes higher than the InX_5^{2-} were assumed to be very small, because they were found to be negligible under these conditions)[1]:

$$D = \frac{[\mathrm{In(III)}]_{org,t}}{[\mathrm{In(III)}]_{aq,t}} = \frac{[InX_3]_{org}+[InX_4]_{org,t}+[InX_5]_{org,t}}{[In^{3+}]+[InX^{2+}]+[InX_2^+]+[InX_3]+[InX_4^-]+[InX_5^{2-}]} \quad (1)$$

The stability constant of the "nth" indium complex with a uninegative ligand, X^-, is defined as:

$$\beta_n = \frac{[InX_n^{3-n}]}{[In^{3+}][X^-]^n} \quad (2)$$

The distribution constant for the uncharged complex is defined as:

$$K_{DM3} = \frac{[InX_3]_{org}}{[InX_3]} \quad (3)$$

The following constants were also defined for the extraction of the negatively-charged complexes:

$$K_{DM4} = \frac{[InX_4]_{org,t}}{[InX_4^-]} \quad (4)$$

$$K_{DM5} = \frac{[InX_5]_{org,t}}{[InX_5^{2-}]} \quad (5)$$

Here, the term $[InX_n]_{org,t}$ denotes the total concentration of those chemical species in the organic phase containing negatively-charged indium(III) complexes (*cf.* Eq. (15) or (16)), such as Na_2InX_5, $NaInX_5^-$, and InX_5^{2-}.

When the above-mentioned constants are introduced into Eq. (1), the following equation is obtained:

$$D = \frac{K_{DM3}\beta_3[X^-]^3 + K_{DM4}\beta_4[X^-]^4 + K_{DM5}\beta_5[X^-]^5}{1+\beta_1[X^-]+\beta_2[X^-]^2+\beta_3[X^-]^3+\beta_4[X^-]^4+\beta_5[X^-]^5} \quad (6)$$

An attempt was made to analyze the data in Figs. 1 to 3 graphically by using Eq. (6). However, it was not possible to explain by Eq. (6) the distribution behavior in the lowest ligand-concentration region because the distribution curves approach constant values in this region at these constant ionic medium solutions. This was assumed to be due to an extraction of positively-charged indium(III) species, InX_n^{3-n} (where $0 \leq n < 3$), most probably as ion-pairs with perchlorate ions. From this, the distribution ratio of indium(III) was assumed to be as follows:

$$D = \frac{[InX_0]_{org,t}+[InX_1]_{org,t}+[InX_2]_{org,t}+[InX_3]_{org}+[InX_4]_{org,t}+[InX_5]_{org,t}}{[In^{3+}]+[InX^{2+}]+[InX_2^+]+[InX_3]+[InX_4^-]+[InX_5^{2-}]} \quad (7)$$

Considering the extraction of these cationic indium(III) species, the following constants were also defined:

$$K_{DM0} = \frac{[InX_0]_{org,t}}{[In^{3+}]} \quad (8)$$

$$K_{DM1} = \frac{[InX_1]_{org,t}}{[InX_1^{2+}]} \quad (9)$$

$$K_{DM2} = \frac{[InX_2]_{org,t}}{[InX_2^+]} \quad (10)$$

A further detailed discussion of these constants will be given later. By introducing these constants and the constants in Eq. (6) into Eq. (7), the following equation could be obtained:

$$D = \frac{K_{DM0}+K_{DM1}\beta_1[X^-]+\cdots+K_{DM5}\beta_5[X^-]^5}{1+\beta_1[X^-]+\cdots+\beta_5[X^-]^5} \quad (11)$$

Equation (11) indicates that the distribution ratio in the lowest ligand-concentration or in the absence of the ligand ions can be denoted by K_{DM0} in Eq. (8). The value of K_{DM0} was very small in the extraction with nitrobenzene (log $D = \sim -4$), but the values were rather larger in the other two solvents.

However, the constancy of the distribution constant, K_{DM1} or K_{DM2}, should not be kept when the perchlorate concentration in the aqueous phase can not be regarded as 4M. Consequently, the following expression would be more reasonable than Eq. (11):

$$D = \frac{Kex_{0,3}[ClO_4^-]^3 + Kex_{1,2}[ClO_4^-]^2[X^-] + Kex_{2,1}[ClO_4^-][X^-]^2 + Kex_{3,0}[X^-]^3 + Kex_4[X^-]^4[Na^+] + Kex_5[X^-]^5[Na^+]^2}{1+\beta_1[X^-]+\beta_2[X^-]^2+\beta_3[X^-]^3+\beta_4[X^-]^4+\beta_5[X^-]^5} \quad (12)$$

where $Kex_{a,(3-a)}$ and Kex_b are the extraction constants of cationic or neutral species and anionic species respectively and where they are expressed as follows:

$$In^{3+} + aX^- + (3-a)ClO_4^- \rightleftarrows InX_a(ClO_4)_{3-a}(org) \quad (0 \leq a \leq 3)$$

$$Kex_{a,(3-a)} = \frac{[InX_a(ClO_4)_{3-a}]_{org}}{[In^{3+}][X^-]^a[ClO_4^-]^{3-a}} \quad (13)$$

$$In^{3+} + bX^- + (b-3)Na^+ \rightleftarrows Na_{b-3}InX_b(org) \quad (b \geq 3)$$

$$Kex_b = \frac{[Na_{b-3}InX_b]_{org}}{[In^{3+}][X^-]^b[Na^+]^{b-3}} \quad (14)$$

The effect of the dissociation of the ion-pairs in the organic phase will be considered later.

The graphic analysis of the distribution data in Figs. 1 to 3 was carried out as follows. The stability constants already determined in Part I[1] and the extraction constants of uncharged species were introduced into Eq. (12). The distribution ratio was calculated as a function of the ligand concentration. When a deviation of the calculated curve from the experimental data was observed, the constants were improved. This successive approximation was continued until the best-fit curve was found. The final equilibrium constants were determined from the best-fit curve. The solid curves in the figures are the extraction curves calculated by the use of the constants.

The equilibrium constants obtained by such a graphic analysis of the data in Figs. 1 to 3 are shown in Tables 1(a) to (d).

Figures 4(A) to 4(C) show the percentage distribution of each species in the organic phase and the aqueous phase calculated from the values in Tables 1(a) to (d). The equilibrium constants were determined by using the experimental data obtained when the ligand concentration is less than 1M. Thus, the calculated extraction curves in Figs. 1 to 3 are drawn only for the experimental data obtained in the ligand-concentration region below 1M. In some systems, however, the distribution ratio was too large to determine accurately when the ligand-concentration was lower than 1M (the extraction of iodide into MIBK or nitrobenzene, or that of thiocyanate into MIBK). In such systems, the graphic analysis of the data were made by using those in the $10^{-3} < D < 10^3$ region. The percentage of the indium (III) species in the organic phase in these systems was calculated in these ligand-concentration regions which are given in Figs. 4(A) to 4(C). The figures show that the extraction of indium species containing perchlorate ions is remarkable, especially into hexol.

In the present study, the salt concentration was kept at 4M by the use of sodium perchlorate. In usual experimental work in analytical chemistry, however, the ionic concentration changes with a change in the ligand-concentration. In order to ascertain the effect of added sodium perchlorate on the distribution behavior of indium(III), some experiments were carried out in the

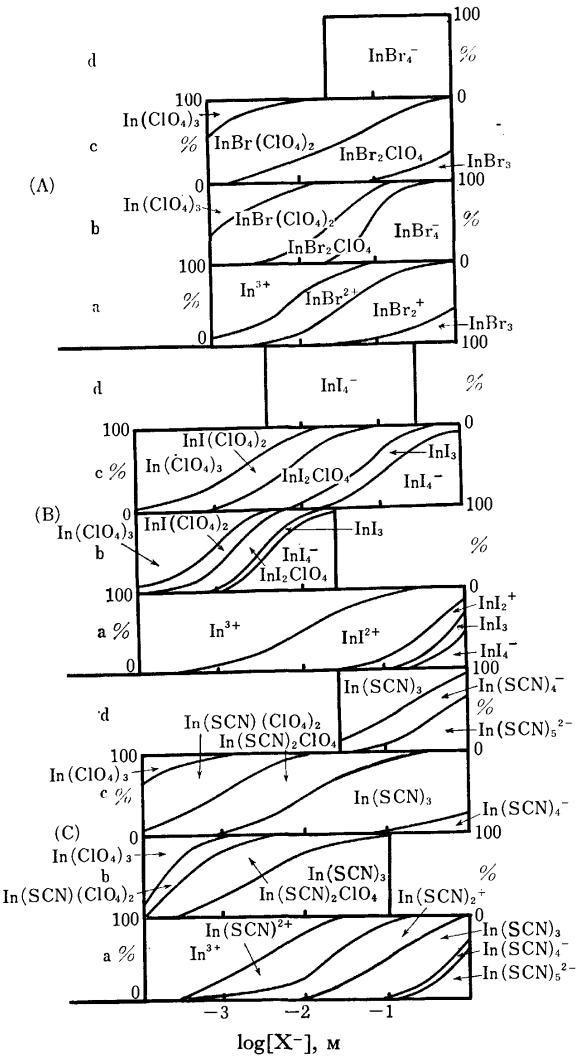

Fig. 4. The percentage distribution of In(III) species in 4M constant ionic medium containing bromide (A), iodide (B) or thiocyanate ions (C) and in the organic solvents equilibrated with the aqueous phase, within the ligand concentration range measured experimentally.

absence of perchlorate ions. Figures 5 to 7 give the distribution ratios in bromide, iodide, and thiocyanate systems where sodium perchlorate is absent in the aqueous phase. The solid curves in these figures are the extraction curves obtained in the 4M constant ionic medium; they have been taken from Figs. 1 to 3 in order to make a comparison with these experimental data. The distribution ratio decreases abruptly with a decrease in the ligand concentration when the ionic concentration changes. In other words, the distribution ratio of indium(III) is very much enhanced by the presence of the sodium perchlorate in the aqueous phase.

The results given above may be summarized as follows: i) The extraction curves into these three polar solvents are quite different from that into hexane containing a small amount of TBP, which could be regarded as an essentially non-polar solvent. This can be explained by saying that the only extractable species into hexane solutions is the uncharged complex, InX_3, while those extractable into polar solvents include not only the uncharged complex but also the ion-pairs of

the cationic species and/or the anionic ones. ii) MIBK extracts both anionic and cationic species. The extraction of anionic thiocyanate species into MIBK was not confirmed in the ligand-concentration region studied. However, it is possible that the extraction of the anionic species occurs when the ligand concentration is higher

(above 5×10^{-2}M). The extraction of indium(III) complexes from the 4M constant ionic media with MIBK is usually better than with the other two solvents. The extraction with MIBK is always the best when sodium perchlorate is absent in the aqueous phase. iii) Nitrobenzene, which has a much higher dielectric constant but a smaller solvation ability, extracts the ion-pairs of anionic complexes better than uncharged ones; furthermore, the extraction from the thiocyanate system is extremely inferior to that from other systems. iv) The distribution curves obatined by introducing the constants in Tables 1(a) to (d) as defined by Eqs. (2), (13), and (14), into Eq. (12) were found to fit with the data. Thus, it was concluded that the assumptions for the complex species in the two phases and the equilibrium constants for them listed in Tables 1(a) to (d) can explain the results within the limits of experimental accuracy.

Discussion

Not very much seems to know about the dissociation of ion-pairs in the organic phase of solvent extraction systems. However, the dissociation in the organic phase should be one of the most important factors to be taken into account in order to make a reasonable analysis of the experimental data. In the present study, this has been treated as follows.

As may be seen from Eqs. (4), (5), (8), (9), and (10), the concentration ratios of the charged species in the two phases are assumed to be constant, or it is assumed that Eq. (12) can be substituted for Eq. (7) only by using the extraction constant of the ion-pairs despite the

possibility of the dissociation of the ion-pairs in the organic phase. However, this should not be true from a general standpoint.

As has been pointed out,[2] the total concentration of the fourth or the fifth anionic complexes in the organic phase can be described as follows if the ion-pairs are partially dissociated in the organic phase:

$$[InX_4]_{org,t} = [NaInX_4]_{org} + [InX_4^-]_{org} \quad (15)$$

$$[InX_5]_{org,t} = [Na_2InX_5]_{org} + [NaInX_5^-]_{org} + [InX_5^{2-}]_{org} \quad (16)$$

The dissociation of the ion-pairs in the organic phase can be denoted as follows:

$$Na_{b-3}InX_b(org) \rightleftarrows (Na_{b-3-n}InX_b)^{n-}_{org} + nNa^+(org)$$

$$Kdiss_{b,n} = \frac{[Na_{b-3-n}InX_b^{n-}]_{org}[Na^+]^n_{org}}{[Na_{b-3}InX_b]_{org}} \quad (17)$$

where b is larger than 3.

By introducing Eqs. (14) and (17) into Eq. (15), the following equation is obtained:

$$[InX_4]_{org,t} = Kex_4[In^{3+}][X^-]^4[Na^+](1+Kdiss_{4,1}[Na^+]^{-1}_{org}) \quad (18)$$

Equation (18) shows that the concentration of the anionic complex in the organic phase is proportional to that of sodium ions in the aqueous phase if no dissociation of the ion-pairs occurs. On the other hand, when the ion-pairs dissociate and charged species are formed in the organic phase, the concentration of the ion-pairs is also dependent on the sodium concentration in the organic phase. In the present study, the aqueous sodium ion concentration was kept as 4M and the extraction of hydrogen or hydroxide ions could be disregarded. Thus, the sodium concentration in the organic phase could be described from the point of view of electrical neutrality as:

$$[Na^+]_{org} = [ClO_4^-]_{org} + [X^-]_{org} + [InX_4^-]_{org} + [NaInX_5^-]_{org} + 2[InX_5^{2-}]_{org} \quad (19)$$

According to the previous papers, the sodium concentration in nitrobenzene, MIBK, and hexol in an equilibrium with 4M sodium perchlorate are 4×10^{-4}M,[3] 6×10^{-2}M, and 1×10^{-2}M[4] respectively. The organic phases studied in this work could contain sodium ions which are produced by the dissociation of the extracted ion-pairs of anionic indium(III) complexes other than those produced by the dissociation of the sodium perchlorate. However, since the indium(III) concentration is very low (the initial aqueous concentration is about 3×10^{-6}M), the contribution of the sodium ions from the ion-pairs of the complexes to the total sodium ion concentration in the organic phase should be very small when the aqueous phase can be regarded as nearly a 4M sodium perchlorate solution.

From this, the total sodium ion concentration in the organic phase given in Eq. (19) can be regarded as constant; consequently, the values in parentheses in Eq. (18) should also be constant in the present study. Thus, it should be reasonable to assume that the ratio of the total concentrations of the fourth complex in the two phases denoted by K_{DM4} in Eq. (4) is a constant under the conditions employed here. For a similar reason, the concentration ratio of the fifth complex may also be assumed to be a constant, K_{DM5}, as is given in Eq. (5).

As may be seen from Eq. (19), the above assumption is not valid when the extraction of the ligand salt is no longer negligible, because the extraction of sodium salts as ion-pairs and their dissociation in the organic phase can be generally assumed when the anion is different. Thus, the extraction data in the higher ligand-concentrations could not be treated by assuming the constancy of K_{DM4} and K_{DM5}.

A similar problem is also present in the analysis of the extraction of ion-apirs with perchlorate ions. The problem of the extracted ion-pairs of cationic species with perchlorate ions should also be considered like the dissociation of sodium ions. When they partially dissociate in the organic phase, the total concentration of indium(III) species may be denoted as follows:

$$[InX_0]_{org,t} = [In(ClO_4)_3]_{org} + [In(ClO_4)_2^+]_{org} + [InClO_4^{2+}]_{org} + [In^{3+}]_{org} \quad (20)$$

$$[InX_1]_{org,t} = [InX(ClO_4)_2]_{org} + [InXClO_4^+]_{org} + [InX^{2+}]_{org} \quad (21)$$

$$[InX_2]_{org,t} = [InX_2ClO_4]_{org} + [InX_2^+]_{org} \quad (22)$$

The dissociation of the second ion-pair in the organic phase may be described as:

$$InX_2ClO_4(org) \rightleftarrows InX_2^+(org) + ClO_4^-(org)$$

$$Kdiss'_{2,1} = \frac{[InX_2^+]_{org}[ClO_4^-]_{org}}{[InX_2ClO_4]_{org}} \quad (23)$$

From Eqs. (13) and (23), Eq. (22) may be described as:

$$[InX_2]_{org,t} = Kex_{2,1}[In^{3+}][X^-]^2[ClO_4^-] \times (1+Kdiss'_{2,1}[ClO_4]^{-1}_{org}) \quad (24)$$

A similar but more complicated treatment is necessary for the term of $[InX_0]_{org,t}$ or $[InX_1]_{org,t}$.

Thus, like as the contribution of the sodium ions in the analysis of the extraction data of anionic complexes, the contribution of the perchlorate ions should be taken into account when the ion-pairs of cationic complexes with perchlorate ions dissociate in the organic phase. The concentration of perchlorate ions in the organic phase is dependent not only on the perchlorate concentration in the aqueous phase, but also on the total concentration of the dissociated ion-pairs of indium(III) species with perchlorate ions. However, for the same reason discussed in connection with the sodium concentration in the organic phase (that is, the concentration of indium(III) is much smaller than that of sodium perchlorate in the oragnic phase), it is possible to assume that the concentration ratio of cationic indium(III) species in the two phases denoted by Eq. (8), (9), or (10) is constant under the conditions employed in this study. Furthermore, the data obtained in solutions up to a ligand-concentration of 1M, where 25% of the perchlorate ions is replaced by the ligand anion, have been analyzed statistically. It seems to be very difficult to know if an aqueous solution containing 1M ligand salt in the 4M total salt can still be regarded practically as

2) T. Sekine and T. Ishii, This Bulletin, **43**, 2422 (1970).
3) T. Sekine and D. Dyrssen, *Anal. Chim. Acta*, **45**, 433 (1969).
4) Y. Hasegawa, T. Ishii, and T. Sekine, This Bulletin, **44**, 275 (1971).

a 4M sodium perchlorate solution in the above statistical analysis. The present authors, however, consider that this is not very unreasonable because the constants which have been determined on the above assumption seem to explain the experimental data well, as can be seen from Figs. 1 to 3. Actually, the data fit the calculated curve well, even in the highest ligand concentration region studied, except for the extraction of the thiocyanate complexes in the highest ligand-concentration region into nitrobenzene.

As can be seen from Figs. 5 to 7, the extraction curves from sodium salt solutions of the ligand anions containing no sodium perchlorate (the total concentration is not kept constant) were quite different from the extraction curves in the 4M constant ionic media systems. As has been shown in Figs. 4(A) to 4(C), the majority of the extracted indium(III) species from the 4M sodium perchlorate media consist of charged indium(III) species in these polar solvents: moreover, as may be seen from Eq. (13) or (14), the extraction of these charged species is dependent not only on the concentration of ligand anions, but also on the concentration of sodium ions or of perchlorate ions. In the aqueous solutions containing no sodium perchlorate, the concentration of perchlorate ions is zero and that of sodium ions is always lower than 4M. Thus, no extraction of ion-pairs with cationic species and perchlorate ions, and much less extraction of ion-pairs with the anionic species and sodium ions, should occur from these aqueous solutions; this should be one of the reasons for the poorer extractions of indium(III) from these aqueous solutions than from 4M sodium perchlorate constant ionic media.

However, the above explanation may not cover all the reasons for these poorer extractions. As can be seen from Eq. (12), the distribution ratio is also dependent on the stability constants of the aqueous complexes, β_n, and the distribution constants, K_{DMn}. When the ionic concentration changes, the activity coefficients of each species may be changed, and then the constants defined by the stoichiometric concentration scale should also be changed. These influences of the background salt on the distribution behavior of the indium(III) complexes will be reported on in a more quantitative manner in the following papers of this series.

The aqueous phase in analytical work usually contains only the ligand anions and no perchlorate ions. The extraction from constant ionic media is here different from the data of analytical experiments. For example, the extraction curve of indium(III) from 4M Na(SCN, ClO_4) into hexol or TBP-hexane has a peak where the ligand concentration is about 2×10^{-1}M; on the other hand, the extraction curves from thiocyanate solutions decrease with the decrease in the anion concentration, and also, according to the extraction of ion-pairs with perchlorate ions, the curves are very different from each other in the lower ligand-concentration region. The analysis of the equilibrium in such systems, in which the ionic concentrations are not kept constant, is very difficult.

The extraction of a charged indium(III) species which was negligible in quantity into hexane containing a small amount of TBP is very remarkable in these polar solvents. For the extraction of charged species as ion pairs, both solvation on the central metal ion and a polar nature (or a high dielectric constant) of the organic solvent are important. The solvation should be largest in MIBK, and this is probably the reason why MIBK shows the best extraction in most cases. The tendency for the large extraction of anionic complexes into nitrobenzene, which does not have a large ability for the solvation, may be due to the very high dielectric constant of this solvent. These properties in hexol are between those of these two organic solvents, and the intermolecular hydrogen bonds in this solvent must play an important role, although further information on the distribution equilibria of various species will be necessary before a detailed discussion of the extraction behavior will become possible.

The authors are grateful to Messrs. Shigeyoshi Ikegami and Hiroshi Iwasaki of the present laboratory for their experimental aids. Part of this work has been carried out in the Laboratory of Nuclear and Analytical Chemistry, Institute of Physical and Chemical Research. The authors are also grateful to Professor Nobufusa Saito, the head of that laboratory.

Fluorometric Determination of Aluminum and Gallium with Superchrome Garnet Y

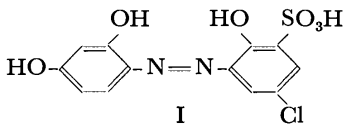
Keizo HIRAKI

Department of Chemistry, Faculty of Science and Technology, Kinki University, Kowakae, Higashi-Osaka

(Received July 7, 1971)

A sensitive fluorometric determination of aluminum and gallium with Superchrome Garnet Y was described. The reagent reacts with aluminum and gallium to form complexes with reddish yellow fluorescence of emission maximum at 562 and 565 nm respectively. Several conditions for the determination, such as the pH of the solution, the reagent concentration, the time of standing *etc.* were investigated, and the composition of the complexes was determined. The maximum fluorescence intensity of the aluminum complex was found at pH 5 (heated for 10 min at 50°C), and that of the gallium complex, at pH 3. The fluorescence were stable at least for 2 hr. By using Superchrome Garnet Y, 0.02—4 μg of aluminum and 0.5—30 μg of gallium in 25 m*l* solution could be determined. Scandium and indium also formed fluorescent complexes. Iron(III), cobalt(II), copper(II), zirconium(IV), vanadate(V), and chromate(VI) ions interfered with the determination.

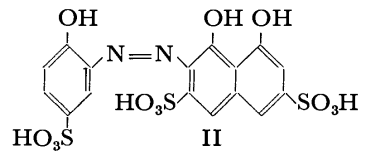
In the course of the investigation on the fluorometric determination of various metal ions with a series of *o,o'*-dihydroxyazo compounds, the author found that lumogallion [3-(2,4-dihydroxyphenylazo)-2-hydroxy-5-chlorobenzenesulfonic acid] (I) was a sensitive



I

reagent for the determination of aluminum and gallium, appliciable to the determination of aluminum in sea water.[1-3]

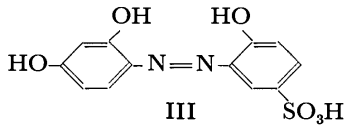
Mordant Blue 31 [2-(2-hydroxy-5-sulfophenylazo)-1, 8-dihydroxynaphthalene-3,6-disulfonic acid] (II) was



II

also a useful reagent for aluminum, gallium and scandium, and the fluorometric methods were proposed in a recent paper.[4]

Freeman and White[5] studied the configuration and the bond type of *o,o'*-dihydroxy azo compounds, which was favorable to form fluorescent metal complexes. According to their consideration, Superchrome Garnet Y [3-(2,4-dihydroxyphenylazo)-4-hydroxybenzenesulfonic acid] (III) seemed to be a very sensitive fluorescent reagent.



III

However, no quantitative investigation with this reagent has been carried out, except Powell and Saylor's research on the fluorometric determination of traces of fluoride using aluminum-Superchrome Garnet Y complex.[6]

The present author found that Superchrome Garnet Y was more sensitive than lumogallion for aluminum and gallium, and that scandium and indium also formed the fluorescent complexes, applicable to the fluorometric determination. In the present paper, the fundamental conditions for the determination of aluminum, gallium, scandium and indium with this reagent were described.

Reagent and Apparatus

Synthesis of Superchrome Garnet Y. 1-Amino-2-phenol-5-sulfonic acid dissolved in 6N hydrochloric acid was diazotized with an equivalent amount of sodium nitrite under ice-cooling. The cooled diazonium salt solution was added to resorcinol dissolved in about 6N sodium hydroxide under cooling below 5°C. The azo compound thus obtained was repeatedly recrystallized from 6N hydrochloric acid, and dried at room temperature in a desiccator on silica gel.

Solutions. Superchrome Garnet Y solution; 0.1 g of Superchrome Garnet Y was dissolved in redistilled water and diluted to a liter.

Standard solution of aluminum; 1.6803 g of alum was dissolved in water, and after 5 m*l* of concentrated hydrochloric acid was added, diluted to 100 m*l* with water. The stock solution was diluted with water to prepare a solution containing 1.00 μg of aluminum per m*l*.

Stock solution of gallium, scandium and indium were prepared by dissolving the 99.99%, 99.9%, and 99.99% pure oxides with 6N hydrochloric acid, respectively, and the standard solutions were prepared by suitable dilution from the stock solution.

Rhodamine B solution; 0.1 g of Rhodamine B was dissolved in water and diluted to 100 m*l*. The stock solution was diluted with water to make solutions containing 0.168 and 0.05 μg rhodamine B per m*l*. The former solution was sufficiently stable for several months, while the latter was unstable and must be freshly prepared every five days. These solutions were used as reference standards to adjust the sensitivity of the instrument.

All other chemicals used in the present work were special grade. Ethanol, hydrochloric acid and ammonia were dis-

tilled until the fluorescence disappeared. Redistilled water was used throughout the procedures.

Apparatus. Fluorescence spectra and the intensity were measured with a Hitachi spectrophotometer, Model G-3 (exciting source; 150 W Xenon lamp). A Hitachi-Horiba glass electrode pH meter, Model M-5, was used for the pH measurements.

Experimental

Fluorescence Spectra of the Metal Complexes of Superchrome Garnet Y. Superchrome Garnet Y reacted with aluminum, gallium, scandium, and indium to form complexes with orange fluorescence. Aluminum-Superchrome Garnet Y complex exhibited the excitation maxima at 365 and 485 nm and the fluorescence emission maximum at 562 nm; the gallium complex showed excitation maxima at 365 and 485 nm and the fluorescence maximum at 565 nm; the scandium complex had the excitation and the emission maximum at 482 and 575 nm respectively; and the indium complex, at 480 and 565 nm respectively. Spectra of Superchrome Garnet Y complexes are shown in Figs. 1 and 2.

Fluorescence Procedure for the Determination of Metals. 1) *Aluminum*: To 15—20 m*l* of the sample solution containing 0.1—4 μg of aluminum were added 0.7 m*l* of 0.01% Superchrome Garnet Y and 2 m*l* of 20% ammonium acetate and the pH was adjusted to 5 with dilute hydrochloric acid or ammonia. The solution was diluted to 25 m*l* with water and then kept at 50°C for 10 min. After cooling, the fluorescence intensity was measured by using a Rhodamine B solution as the reference standard.

2) *Gallium*: To the sample solution containing 0.5—30 μg of gallium were added 0.8 or 1.7 m*l* of 0.01% reagent and 2 m*l* of 20% ammonium acetate and the pH was adjusted to 3. The solution was diluted to 25 m*l* and then the fluorescence intensity was measured.

3) *Scandium and Indium*: Scandium (5—40 μg) was determined by the same procedure as in the case of gallium, but the pH was adjusted to 5.5. Indium (5—30 μg) was determined in the case of the same manner as aluminum, but 2 m*l* of the reagent solution was used.

Results and Discussion

Effect of Time of Standing. At room temperature, the aluminum and the indium complex needed 120 minutes' standing until they showed the full fluorescence. If the solutions were heated at 50°C, the fluorescence intensity readily reached the maximum. The fluorescence of the gallium and the scandium complex was fully developed within a few minutes after the preparation of the solutions.

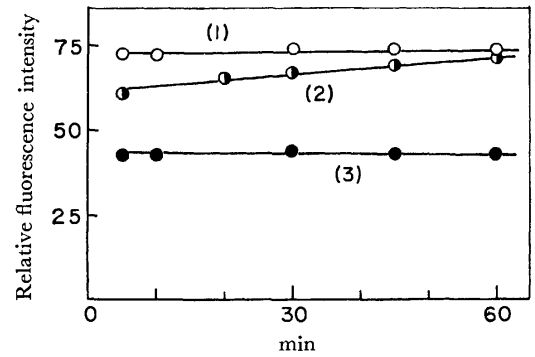

Fig. 3. Stability of fluorescence intensity of Superchrome Garnet Y complexes.
(1): Al 0.5 μg, digested at room temp., 485 nm/562 nm, fluorometer readings was setted at 40 div. with 0.168 μg rhodamine B/m*l* reference solution.
(2): Al 0.5 μg, digested at 50°C 10 min, 485 nm/562 nm, 40 div.
(3): Ga 5 μg, digested at room temp., 485 nm/565 nm, 20 div.

In all cases, the fluorescence was stable at least for 2 hr after reaching the maximum intensity. Figure 3 shows the stability of the fluorescent complexes of aluminum and gallium.

Effect of pH. The intensity of the fluorescence of metal complex was measured over a wide range of pH values. The results are shown in Fig. 4.

The aluminum and the indium complex showed maximum fluorescence intensity at pH 5, the scandium complex at pH 5.5, and the gallium complex showed

the maximum in more acidic medium, near pH 3.

Effect of Concentration of Superchrome Garnet Y. The various amounts of Superchrome Garnet Y were added to the solutions containing 0.5 or 3.5 μg of aluminum, 5 or 25 μg of gallium, and the fluorescence intensity of the solution was measured at the optimum pH. Figure 5 shows the effect of the amounts of Superchrome Garnet Y on the fluorescence intensity.

The results indicated that 0.3 m*l* of 0.01% Superchrome Garnet Y solution was required for 0.5 μg of aluminum in 25 m*l* of solution and 0.7 m*l* for 3.5 μg of aluminum. In the case of gallium, 0.8 m*l* of the reagent solution was needed for up to 5 μg per 25 m*l* and 1.7 m*l* for 25 μg. For the determination of scandium and indium, 2 m*l* of 0.01% Superchrome Garnet Y solution was needed.

Standing time	10 min., 50°C		10 min., room temp.		10 min., room temp.	10 min., 50°C
0.01%-reagent solution (ml)	0.3	0.7	0.8	1.7	2.0	2.0
Determinable range (μg/25 ml)	0.02—1.0	0.02—4.0	0.5—7.0	0.5—30	5—40	5—30
Fluorescence intensity at 60 div. per 1 μg	195		25.5		0.8	0.3
F. I. ratio {weight[a]	650		85		2.7	1
F. I. ratio {molar[b]	1463		494		1	10

a) This ratio was expressed in values relative to a fluorescence intensity of the indium complex for 1 μg In/25ml. (60 div., *vs.* 0.168 μg rhodamine B/ml)
b) This ratio was expressed in values relative to a fluorescence intensity of the scandium complex for 1 mol Sc/*l*. (60 div., *vs.* 0.168 μg rhodamine B/ml)

Calibration Curves. Figures 6, 7, and 8 show the calibration curves for aluminum, gallium, scandium and indium, respectively, which were obtained by the above-mentioned procedures. The sensitivity of the fluorometer was regulated by setting up the fluorescence of a standard Rhodamine B solution (0.168 μg/ml or 0.05 μg/ml) at an appropriate position of the reading (10—60 division). Aluminum, gallium, scandium, and indium can be determined in the following ranges with an average error of 3 percent; Al: 0.02—4 μg, Ga: 0.5—30 μg, Sc: 5—40 μg, In: 5—30 μg. A linear relationship exists between the fluorescence intensity and the metal ion concentration. The conditions for the fluorometric determination of these metal ions were summarized in Table 1.

For the determination of indium, 0.05 μg Rhodamine B per ml solution was used as the reference standard in order to raise the sensitivity of the fluorometer. Use of the dilute reference standard solution enabled the determination of aluminum, gallium, and scandium in lower concentrations, but the error was increased. The errors might be mainly due to two reasons; the lowering of the stability of the fluorometer resulting from the too high sensitivity, and the change of the concentration of Rhodamine B caused by the adsorption on the vessel wall that would be negligible in the concentrated standard.

Table 2. Effect of diverse ions

Ion	Added as	(μg)	Al found (μg)[a]	Diverse ion added (μg)	Ga found (μg)[b]

(IV), vanadium(V), and chromate(VI) ions reduced the fluorescence intensity, but the following ions did not interfere; beryllium(II), calcium(II), cadmium(II), strontium(II), manganese(II), nickel(II), tin(II), magnesium(II), indium(III), gallium(III), scandium(III), lanthanum(III), yttrium(III), europium(III), thallium (III), zinc(II), selenium(IV), thorium(IV), molybdate (VI), and uranyl(VI) ions. In the determination of gallium, aluminum(III) gave positive error, and quadruple amounts of cobalt(II), copper(II), iron(III), zirconium(IV), vanadium(V), molybdate(VI), and chromate(VI) ions reduced the fluorescence, but other ions, presented in Table 1, did not interfere.

Determination of Metal to Ligand Ratio. The mole ratio of metal to ligand in the metal complexes of Superchrome Garnet Y was determined fluorometrically by the continuous variation method and the mole ratio method. Because the aluminum complex formed slowly at room temperature the metal to ligand ratio was also kinetically determined.

The results are shown in Figs. 9 (continuous variation method), 10 (mole ratio method) and 11 (kinetic method). Figures 9 and 10 indicate that both aluminum and gallium form the 1: 1 complex. Figure 11 shows that the formation of the aluminum complex follows the second-order kinetics, and therefore, supports the above-mentioned composition.

The author wishes to express his appreciation to Professor Tsunenobu Shigematsu (Institute for Chemical Research, Kyoto University) and Professor Yasuharu Nishikawa (Faculty of Science and Technology, Kinki University) for their kind advices and suggestions throughout the investigation.

The Nitration of Nickel(II)-, and Copper(II)-complexes of Bis(salicylaldehyde)ethylenediimine

Motonori TAMAKI, Isao MASUDA, and Koichiro SHINRA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita

(Received July 12, 1971)

The M(Salen) complexes (where M=Ni^{II}, Cu^{II}, Co^{II}-NO, and $V^{IV}O$, and where Salen=bis(salicylaldehyde)-ethylenediiminato dianion) were reacted with nitric oxide in organic solvents in the air. The free ligand can only form a compound with the formula of $SalenH_2 \cdot 2HNO_3$, while the complexes with M=Ni or Cu gave NO_2-substituted complexes, M(5,5'-dinitro-Salen), in almost quantitative yields. In the cases of Co(Salen)NO and VO(Salen), no substitution reaction on the phenyl ring took place, but they formed a nitric acid adduct, Co(Salen)NO$\cdot n HNO_3 \cdot n H_2O$ ($n=1$ and 2) and VO(Salen)$\cdot HNO_3 \cdot H_2O$. The reactions are thought to proceed by means of a process involving a nitric acid. The reactivity of the Ni- and Cu-Salen complexes is explained in terms of a π-electron localization at the 5- and 5'-positions of the phenyl rings resulting from $d_\pi \rightarrow p_\pi$ back bonding. A lack of a similar substitution reaction in Co(NO)- and VO-Salen complexes is explained as being due to the lower stability in the metal-Salen bonding.

In previous studies of the reaction of the transition metal complexes with nitric oxide, it has been reported that Ni(II), Cu(II), and Pd(II) complexes of bis(acetylacetone)ethylenediimine, and Pd(II) complexes of acetylacetone and its derivatives react at the γ-position of the metal chelate rings to form α-imine-oxime-type complexes,[1,2] whereas in the case of Co(II) complexes of bis(acetylacetone)ethylenediimine and bis(benzoylacetone)ethylenediimine, a nitrosyl complex binding NO as an axial ligand is obtained.[3]

The present work will deal with the reaction of NO with Cu(II) and Ni(II) chelates, including bis(salicylaldehyde)ethylenediimine,[4] to produce NO_2-substituted complexes, M(5,5'-dinitro-Salen) (M=Ni and Cu).

Experimental

Materials. $SalenH_2$ and its metal complexes were prepared according to the method described in the references.

Reaction with Nitric Oxide. In the following experiments, NO was bubbled through the solution in air.

Ni(5,5'-dinitro-Salen)$\cdot 1.5H_2O$. A 1.5 g portion of Ni(Salen)[5] was dissolved in 100 m*l* of acetonitrile. Bubbling NO through the solution at room temperature then resulted in the precipitation of an orange compound. After bubbling for two hours, the NO in the solution was driven off by N_2 gas; then the precipitates were collected by filtration. The compound was recrystallized from a large volume of acetonitrile to give fine crystals with an orange color (complex **1**). Complex **1** is soluble in acetonitrile and acetone. Yield, 1 g.

Found: C, 43.58; H, 3.21; N, 12.47%. Calcd for $NiC_{16}H_{15}N_4O_{7.5}$: C, 43.47; H, 3.43; N, 12.68%.

The complex **1** could also be obtained by a similar reaction in a chloroform solution. The greenish precipitates which separated were recrystallized from an acetonitrile solution to give orange crystals. The analytical and IR spectral data were consistent with those of the complex **1**.

Found: C, 43.85; H, 3.32; N, 12.41%. Calcd for $NiC_{16}H_{15}N_4O_{7.5}$: C, 43.47; H, 3.43; N, 12.68%.

Cu(5,5'-dinitro-Salen). One gram of Cu(Salen)[5] was dissolved in 150 m*l* of chloroform; when NO was then bubbled through this solution at room temperature for about three hours, brownish precipitates were separated. The NO in the solution was driven off by N_2 gas, and the precipitates were collected on a filter and washed with chloroform and then with ether. The precipitates were recrystallized from an anhydrous acetonitrile solution to give greenish-brown needles (complex **2**).

Found: C, 45.26; H, 2.87; N, 13.50%. Calcd for $CuC_{16}H_{12}N_4O_6$: C, 45.77; H, 2.86; N, 13.35%.

The same compound was also obtained by a reaction in an acetonitrile solution. The complex **2** including its water molecule, tends to crystallize when it is allowed to stand in a solution of an organic solvent in air; 2.5 hydrates are obtained from an acetonitrile solution, and 0.5 hydrates, from an acetone solution.

Co(Salen)NO$\cdot HNO_3 \cdot H_2O$. One gram of Co(Salen)NO[6] was dissolved in 150 m*l* of chloroform. NO gas was bubbled through this solution for five hours. The green complex thus precipitated was collected by filtration and was recrystallized from a mixed acetonitrile-ether solution as green crystals (complex **3**). Yield, 0.5 g.

Found: Co, 13.25; C, 44.41; H, 3.56; N, 13.02%. Calcd for $CoC_{16}H_{17}N_4O_7$: Co, 13.51; C, 44.04; H, 3.94; N, 12.84%.

Co(Salen)NO$\cdot 2HNO_3 \cdot 2H_2O$. The reaction that was carried out in an acetonitrile solution resulted in the precipitation of a brownish-green compound. This was then recrystallized from a mixed acetonitrile-ether solution.

Found: Co, 11.50; C, 37.11; H, 3.45; N, 13.81%. Calcd for $CoC_{16}H_{20}N_5O_{11}$: Co, 11.39; C, 37.14; H, 3.90; N, 13.54%.

VO(Salen)$\cdot HNO_3 \cdot H_2O$. A similar reaction of VO(Salen)[7] in a chloroform solution gave dark violet precipitates, which were then recrystallized from methanol.

Found: C, 46.85; H, 3.96; N, 10.03%. Calcd for $VC_{16}H_{17}N_3O_7$: C, 46.39; H, 4.10; N, 10.15%.

$SalenH_2 \cdot 2HNO_3$. Two grams of $SalenH_2$ were dissolved in 100 m*l* of chloroform; then NO was bubbled through the solution for about two hours. The white precipitates

which resulted were washed with chloroform. Yield, 1.5 g.

Found: C, 47.95; H, 4.49; N, 14.40%. Calcd for $C_{16}H_{16}N_4O_8$: C, 48.21; H, 4.21; N, 14.28%.

The addition of $NiCl_2 \cdot 6H_2O$ to an aqueous alkaline solution of $SalenH_2 \cdot 2HNO_3$ resulted in the precipitation of reddish-orange crystals, which were then recrystallized from chloroform. The elementary analytical and IR spectral data indicated the compound to be Ni(Salen).

Found: C, 58.86; H, 4.41; N, 8.55%. Calcd for $NiC_{16}H_{14}N_2O_2$: C, 59.12; H, 4.35; N, 8.62%.

The recrystallization of the $SalenH_2 \cdot 2HNO_3$ from methanol or ethanol gave thin plates whose analytical data correspond to those of (ethylenediamine)$2HNO_3$. This compound is thought to be a hydrolytic product of $SalenH_2 \cdot 2HNO_3$.

Found: C, 13.00; H, 5.37; N, 30.22%. Calcd for $C_2H_{10}N_4O_6$: C, 12.90; H, 5.43; N, 30.10%.

In an acetonitrile solution, $SalenH_2$ reacted with NO to produce (ethylenediamine)$2HNO_3$.

Measurements. The IR spectra were measured in Nujol or in hexachlorobutadiene, using a Hitachi 225 grating spectrometer for the 4000—200 cm^{-1} region and a JASCO IR-G spectrometer for the 4000—400 cm^{-1} region. The magnetic susceptibilities were determined at room temperature by the Gouy method. The electronic absorption spectra were obtained with a Hitachi EPS-3 spectrophotometer. The conductance measurements were made at 25°C using a Universal Bridge Model 4225A, Yokogawa Electric Works, Ltd.

Results and Discussion

Ni(Salen) and Cu(Salen) reacted with NO in the air, in chloroform or in acetonitrile, to form an orange-colored compound (complex **1**) or a greenish-brown compound (complex **2**) respectively. As will be discussed below, these compounds have been confirmed to be 5,5′-dinitro-substituted complexes.

In general, it would not be reasonable to expect a remarkable difference in the IR spectra between metal complexes with 5,5′- and with 3,3′-dinitro-Salen.[4] However, it can clearly be seen in the spectra (Fig. 1) of the Ni(II)-complexes with 5,5′- and 3,3′-dinitro-Salen prepared as authentic compounds[8] that: i) of the two bands at about 1600 cm^{-1}, the one at the higher wave number is more intense than the one at the lower wave number for the 5,5′-dinitro-complex, while the former is weaker than the latter for the 3,3′-dinitro-complex, and ii) the band about 1300 cm^{-1} is broader for the 5,5′-dinitro-complex. The IR spectrum of the complex **2** exhibits the characteristic feature of the 5,5′-dinitro-complex (Fig. 1). Thus, the complex **1** can be considered to be Ni^{II}(5,5′-dinitro-Salen)$\cdot 1.5H_2O$. Similarly, an inspection of the IR spectrum (Fig. 2) leads us to conclude that the complex **2** can be formulated as: Cu^{II}(5,5′-dinitro-Salen).[9,10]

a) The frequencies of the complex **1** is identical to the curve 1.

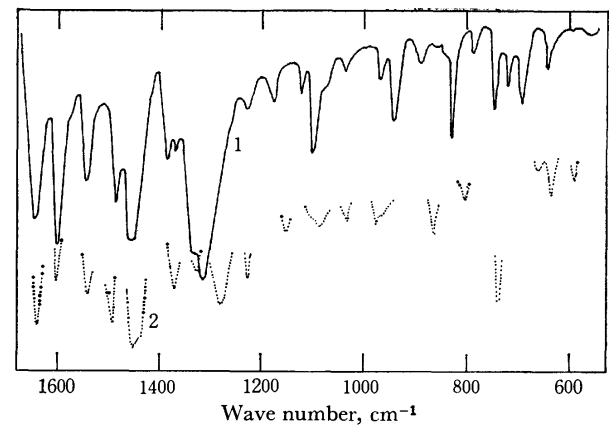

Fig. 2. IR spectra of Cu(5,5′-dinitro-Salen);[a] ——, and Cu(3,3′-dinitro-Salen); ·····, in Nujol.
a) The frequencies of the complex **2** is identical to the curve 1.

The reaction of the free ligand ($SalenH_2$) with NO in a chloroform solution produced neither a nitroso- nor a nitro-substituted compound, but only formed the precipitates of a compound corresponding to the $SalenH_2 \cdot 2HNO_3$ formula. This was characterized as a nitric acid adduct of the Schiff base by reaction with the Ni^{2+} ion in an aqueous solution, thus forming Ni(Salen), and by recrystallization from methanol or ethanol, by which it was converted into (ethylenediamine)$2HNO_3$ in an almost quantitative yield.

As has been described above, the reactions resulted in the formation of the nitric acid adduct of the free ligand and the nitro-substituted metal-Salen complex. Moreover, the reactions can not be observed to occur with pure NO; that is solutions of $SalenH_2$ or its Ni- and Cu-complexes did not react with NO in the absence of air. Thus, the reactions may be thought to proceed by means of a process involving a nitric acid. Further, it is likely that the complex formation of $SalenH_2$ with the Ni^{2+} or Cu^{2+} ion makes it easy for the nitration reaction to take place at the 5- and 5′-positions of the phenyl rings. In the complexes, this can tentatively

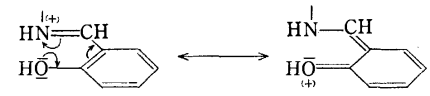
8) E. J. Olszewski and D. F. Martin, *J. Inorg. Nucl. Chem.*, **26**, 1577 (1964).

9) C. S. Marvel and N. Tarköy, *J. Amer. Chem. Soc.*, **77**, 5820 (1955).

10) T. Tanaka, *ibid.*, **80**, 4108 (1958); This Bulletin, **33**, 259 (1960).

be explained in terms of an electrophilic substitution reaction at the 5- and 5′-positions of the phenyl rings caused by a π-electron localization, as is shown in (a′).

(a) (a′)



(b) (b′)

It is probable that the coordination bond between the nitrogen atom and the metal ion can participate in the mesomeric system through the $d_\pi \rightarrow p_\pi$ back donation, thus increasing π-localization on the 5- and 5′-positions.

On the other hand, the free $SalenH_2$ tends to form a proton-addition compound which may act to decrease the degree of π-localization on the 5- and 5′-carbons, as is shown in (b′).[11]

11) The adducts of Cu(Salen) with phenol and propionic acid are prepared by Tanaka, in Ref. 10.

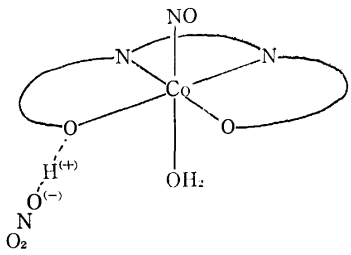

Fig. 5.

It should be noted that, in the case of the Co(Salen)-NO, no similar substitution reaction could be observed. It has already been reported that, by reaction with NO in organic solvents, Co(Salen) easily produces Co(Salen)-NO,[6] wherein the Salen is coordinated to the cobalt ion in the plane, as in the cases of Ni(II)- and Cu(II)-Salen. Hence, it seems possible to expect a similar nitration reaction to take place in the case of Co(Salen)NO. However, in fact, Co(Salen)NO afforded only a diamagnetic compound (complex **3**) which can be formulated as a nitric acid adduct, $Co(Salen)NO \cdot HNO_3 \cdot H_2O$. The IR spectrum of this adduct (Fig. 3) obviously differs from that of the Co(II) complexes with 5,5′- and 3,3′-dinitro-$SalenH_2$,[6] and possesses the characteristic absorptions for the NO group at 1640 cm^{-1} and for the NO_3^- group (ν_3) at about 1300 cm^{-1}.[12] The electronic absorption spectrum of this compound (Fig. 4) shows a maximum at 39.1×10^3 cm^{-1} which quite resembles Co(Salen)NO. On the other hand, in the $18—20 \times 10^3$ cm^{-1} region its spectrum differs remarkably from that of Co(Salen)NO and does not show the characteristic peak of penta-coordinate, diamagnetic Co(II) complexes.[3] Judging from these observations and the analytical data, a skeletal structure for this adduct is tentatively drawn in Fig. 5. When reacted in an acetonitrile solution, Co(Salen)NO binds two moles of HNO_3. In the case of VO(Salen), $VO(Salen) \cdot HNO_3 \cdot H_2O$ was separated by a similar reaction in a chloroform solution. The conductance data shown in Table 1 seem to be consistent with the formula of the adduct of the VO-complex. The adduct of the Co-complex shows less conductivity than would be expected for a 1 : 1 electrolyte.

The lack of a similar substitution reaction for Co(Salen)NO may be explained as follows. There seem to be no numerical data available for discussing the relative stabilities of a series of the metal-Salen com-

Table 1. Electric conductance; in acetonitrile

	Concn. (M)	Molar conductance ($cm^2/\Omega \cdot mol$)
$Co(Salen)NO \cdot HNO_3 \cdot H_2O$ (complex **3**)	1/250	2.43
$VO(Salen) \cdot HNO \cdot H_2O$	1/500	45.1
VO(Salen)	1/250	0.270
$[Co(dmgH)_2(py)_2]Cl$[a]	1/250	60.5

a) dmgH and py represent dimethylglyoximato monoanion and pyridine, respectively.

12) K. Nakamoto, "Infrared Spectra of Inorganic and Coordination compounds," John Wiley, & Sons, New York and London (1962), p.90.

plexes. However, judging from the common order of the stability constants,[13] Ni(II)- and Cu(II)-complexes may be expected to be the most stable of the Salen complexes used in the present work. When the bond of Co–N is more unstable, the degree of the $d_\pi \rightarrow p_\pi$ back donation is assumed to be more decreased in the metal complexes other than Ni and Cu. In the cases of the Co(NO)- and VO-complexes, the further formation of the bonding with the axial ligand may also cause a weakening of the bonding between metal and Salen.[14]

Trace Analysis of Metals by ESR. I. Microdetermination of Copper by Means of Solvent Extraction of Copper(II) Diethyldithiocarbamate

Daijiro YAMAMOTO, Tuneo FUKUMOTO, and Noriaki IKAWA
Faculty of Agriculture, Meiji University, Ikuta, Kawasaki-shi

(Received July 22, 1971)

A new method was developed for the direct determination of copper using ESR. Cupric diethyldithiocarbamate complex dissolved in benzene shows a unique ESR spectrum. The bivalent complex in benzene gave a very strong ESR signal with intensity sensitive to 0.005 ppm of Cu(II)-ion. Thus the ESR signal can be utilized for the trace analysis of Cu(II)-ion. The ESR signal intensity was linear in the ranges 1.0—0.1 γ/m*l* and 0.1—0.01 γ/m*l* of Cu(II)-ion. Mg^{2+}, Fe^{2+}, Ba^{2+}, Mn^{2+}, Zn^{2+}, Co^{2+}, Pb^{2+}, Ni^{2+}, I^-, Br^-, and NO_3^- did not interfere with the determination, while Hg^{2+} and CN^- did. Comparing this method with photometric determination, we see that a very low content of Cu(II)-ion can be determined with a very small amount of sample.

It is known that Cu(II) forms various paramagnetic Cu(II) complexes which show characteristic ESR spectra.[1-3] In a previous paper, ESR spectra of powder and solution of Cu(II) complexes were reported,[4] for which seventeen samples were prepared by the usual methods. In the present study, a new method was developed for the rapid solvent extraction and direct determination of Cu(II) using ESR. Powdered $(DDC)_2Cu$, the Cu(II) complex, showed the known broad absorption spectrum whereas hyperfine structure was observed in a benzene solution, *i.e.*, the ESR spectrum was split into four lines. In the case of cupric dithiocarbamates the ESR spectra were very narrow and sharp. The second signal, counted from higher magnetic field, was dominant and its height was proportional to the amount of Cu(II) in a certain concentration range. The signal could be found even in the very dilute solution of Cu(II)-ion. Thus the application of ESR signal to the trace analysis of Cu(II)-ion is possible.

Experimental

Apparatus. The ESR measurement was carried out with a Hitachi X-band spectrometer, Model MPU-3. The magnetic field was modulated at 100 kHz. A Hitachi-Perkin Elmer spectrophotometer, Model 139, was used for the absorption spectra and colorimetric analysis. The measurements were carried out with 1 cm glass cell.

Reagents. Sodium diethyldithiocarbamate(DDCNa) was of JIS special grade from Kokusan Kagaku Co., Ltd. A standard solution of Cu(II) was prepared by dissolving 78.592 mg of $CuSO_4 5H_2O$ of JIS special grade in 200 m*l* twice distilled water. Other reagents were of guaranteed grade from Kokusan Kagaku Co., Ltd. and used without further purification.

Preparation of the Sample Solution. One m*l* of 0.2% aqueous solution of DDCNa was added into 1 m*l* of the solution containing Cu(II)-ion. The pH was regulated to 1—2 with hydrochloric acid, and 1.0 m*l* of benzene was poured into the mixture. After shaking for a few minutes $(DDC)_2Cu$ was extracted entirely into the benzene layer, and 0.1 m*l* of the solution was taken for examination by ESR.

Results and Discussion

ESR spectrum of $(DDC)_2Cu$. $(DDC)_2Cu$ in benzene showed a unique ESR spectrum as shown in Fig. 1. Owing to the existence of nuclear spin (3/2) of ^{63}Cu and ^{65}Cu four splitting absorption bands appeared. The second signal counted from higher magnetic field was dominant, and its height was proportional to the amount of Cu(II)-ion in a certain range. Thus the second signal intensity was used for the determination of Cu(II)-ion concentration.

TABLE 1. COMPARISON OF SIGNAL INTENSITIES IN SOLVENTS

Organic solvent	Signal intensity
Benzene	100
Carbon tetrachloride	96.7
Carbon disulfide	94.8
Ethylbenzene	66.2
Xylene	62.3
Toluene	60.0

Signal intensity of $(DDC)_2Cu$ complex in benzene is taken as 100.

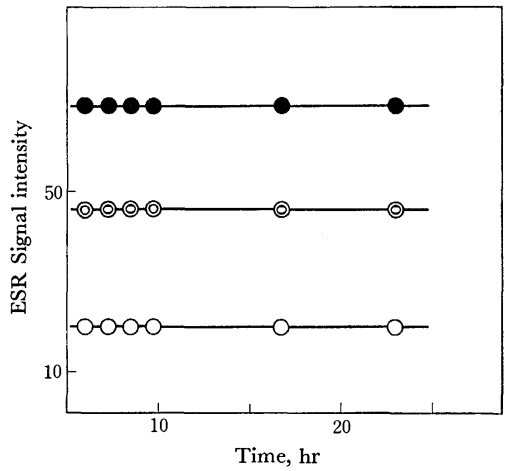

Fig. 2. Effect of time of standing.
●: 10.0γ/ml, ◎: 1.0γ/ml, ○: 0.1γ/ml.

Effect of Organic Solvents on Extraction. Extraction was carried out by the above procedure. ESR spectra of six solutions of $(DDC)_2Cu$ in different organic solvents were measured. The signal intensities are shown in Table 1. We see that the maximum ESR signal intensity is obtained in the benzene solution.

Effect of Time of Standing. The ESR signal intensity of the solution extracted at pH 2.0, was determined as a function of the time elapsed after the preparation of the solution. As shown in Fig. 2, no change was observed in the ESR signal intensities over a period of 24 hr.

Effect of pH on Extraction. The effect of pH on the extraction was examined. The signal intensities obtained from solutions of 0.1 γ/ml, 1.0 γ/ml, and 10.0 γ/ml Cu(II)-ion were constant in the pH range 1.0—7.0 as shown in Fig. 3. However, the range pH 1—2 was chosen to avoid the extraction of other metal ions such as Mn^{2+}, Fe^{2+}, Ni^{2+}.

0.1017	68.8	69.7

All values are means of five measurements.
a) 0.1 m*l* of 100 times diluted solution
b) 5.0 m*l* of 10 times diluted solution

Effect of Diverse Ions. The effect of 13 ions on the determination of Cu(II) was examined. The results are summarized in Table 2. CN^- and Hg^{2+} interfere with the determination.

Calibration Curve for the Determination of Cu(II). The calibration curve for the Cu(II)-ion was determined from the height of the second signal at different Cu(II)-ion concentrations. In Fig. 4, the ordinate is in an arbitrary scale.

Comparison with usual Photometric Determination. For the sake of comparison, the Cu content in aluminium foil were determined by the usual photometric and ESR methods. About 100 mg of aluminium foil was dissolved in 6N-HCl with a small amount of concd. nitric acid and diluted to 100 m*l* with water. The solution was used as a sample. Determination of Cu content was carried out by the usual photometric method.[5] Comparison of results from ESR and photometric methods is given in Table 3. We see that the ESR method can be used for the determination of a very low content of Cu(II)-ion with a very small amount of sample.

The authors are grateful to Dr. N. Iso for his interest and valuable suggestions.

Trace Analysis of Metals by ESR. II. Indirect Microdetermination of Mercury(II) with Tetraethylthiuram disulfide Copper(II) Complex[1]

Daijiro YAMAMOTO and Noriaki IKAWA
Faculty of Agriculture, Meiji University, Ikuta, Kawasaki-shi

(Received July 22, 1971)

A method was devised for the indirect microdetermination of mercury by means of ESR. Tetraethylthiuram disulfide(TET)-Cu(II) complex dissolved in benzene showed a characteristic ESR spectrum. Quantitative determination of a small amount of mercury(II) was made by application of the replacement reaction of TET-Cu(II) by mercury(II)-ion in a benzene solution:

$$\text{TET-Cu} + \text{Hg}^{2+} \rightarrow \text{TET-Hg} + \text{Cu}^{2+}$$

The ratio of metal to ligand was considered to be 1 : 1 in the complex. 1.0—0.1 γ/m*l* and 0.1—0.01 γ/m*l* of mercury was determined rapidly in the presence of Mg^{2+}, Fe^{2+}, Ba^{2+}, Mn^{2+}, Zn^{2+}, Co^{2+}, Pb^{2+}, Ni^{2+}, I^-, Br^-, NO_3^-, and Cl^- ions. CN^- interfered with the determination. From a comparison of this and photometric methods a very small amount of mercury(II) ion can be determined with a very small amount of sample.

Spectrophotometric determination of mercury(II) with dithizone, dithiocarbamates, and cupric diethyldithiocarbamate ($(DDC)_2Cu$)[2,3] has been reported. Determination with $(DDC)_2Cu$ was indirect and the following replacement reaction was used.

$$(DDC)_2Cu + Hg^{2+} \longrightarrow (DDC)_2Hg + Cu^{2+}$$

The decolorization which takes place in the solution by the replacement reaction was utilized in the spectrophotometric measurement. ESR spectra of $(DDC)_2Cu$ complex in various organic solvents have been reported.[4,5] A small amount of copper could be determined by means of ESR. $(DDC)_2Cu$ complex dissolved in benzene showed a characteristic ESR spectrum. The signal intensity was sensitive to 0.005 ppm of copper(II) ion.

In the present study, tetraethylthiuram disulfide (TET) was used in place of DDC, since TET-Cu(II) complex has the same structure as that of DDC-Cu(II),[6] and TET was cheaper than DDCNa. The TET-Cu(II) complex in benzene gave a strong ESR signal

and its intensity was sensitive to 0.005 ppm of Cu(II) ion. The ESR spectrum was split into four narrow lines. The intensity of the second signal, counted from higher magnetic field, was dominant and its height was proportional to the amount of Cu(II) in a certain concentration range. Thus the diminution of the ESR signal intensity could be used for the trace analysis of mercury(II).

Experimental

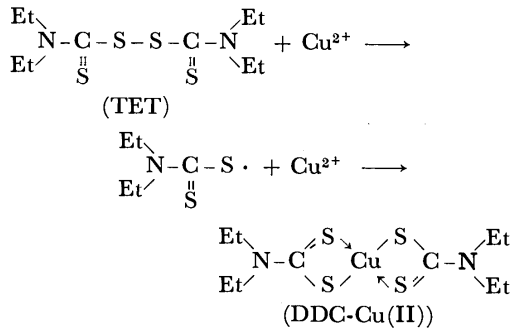
Apparatus. ESR measurements were carried out at room temperature with a Hitachi X-band spectrometer, Model MPU-3. The magnetic field was modulated at 100 KHz. Absorption spectra measurements and colorimetric analysis were carried out with a Hitachi-Perkin Elmer Spectrophotometer, Model 139 using a 1 cm glass cell.

Reagents. TET used in the experiments was of JIS special grade from Tokyo Kasei Kogyo Ltd. A pure TET was prepared by recrystallization in a hot mixture of ethanol and carbon tetrachloride. Standard mercury(II) solution was prepared as follows. Distilled mercury was dissolved in concd. nitric acid and diluted with water to the concentration 10 γ/ml. Other reagents were of guaranteed grade from Kokusan Kagaku Co., Ltd. and used without further purification.

Preparation of TET-Cu Complex. The complex was prepared by mixing 1.0% ethanolic solution of TET(ligand) and saturated cupric sulfate solution. Bluish brown precipitate was washed with water-ethanol mixture.

Results and Discussion

ESR Spectrum of TET-Cu Complex. TET-Cu complex in benzene showed a characteristic ESR spectrum.[4] This spectrum was the same as one of $(DDC)_2$-Cu in benzene.[4] The formation of TET-Cu might be as follows;



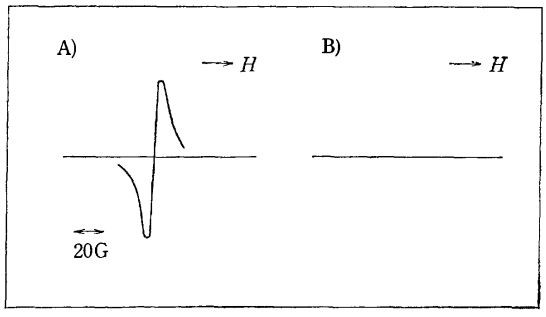


Fig. 1. ESR spectrum after replacement reaction of Hg(II) ion with Cu(II) in TET-Cu complex.
A): Before reaction, B): After reaction.

From the results we see that the second signal, counted from higher magnetic field, was dominant and its height is proportional to the amount of copper in certain

ranges. Thus the second signal intensity was used for the determination of copper(II) concentration.[5]

Replacement Reaction of Mercury(II) with Copper(II) in TET-Cu Complex. One ml of 0.00015M mercury-(II) solution was mixed with 1.0 ml of 0.00015M TET-Cu benzene solution. After shaking for a few minutes, the brownish yellow benzene layer disappeared completely showing the accomplishment of the replacement reaction.

One tenth ml of the benzene layer was taken for examination. The ESR spectrum after replacement reaction of mercury(II) with Cu(II) in TET-Cu complex in benzene (0.00015M, Cu(II) content) showed ESR spectrum as shown in Fig. 1. The spectrum disappeared when the benzene layer was taken. This shows the accomplishment of replacement reaction. The metal to ligand ratio of the complex was considered to be 1 : 1. Therefore, the overall replacement reaction between TET-Cu and mercury(II)-ion can be given by

$$\text{TET-Cu} + Hg^{2+} \longrightarrow \text{TET-Hg} + Cu^{2+}$$

Decrease of TET-Cu Concentration by Mercury(II) Ion. Decrease of TET-Cu concentration due to the replacement by mercury(II) ion was determined by ESR. The original concentration of copper(II) was 1.0 γ/ml or 0.5 γ/ml, and the mercury(II) concentration ranges were 0.1—0.01 γ/ml and 1.0—0.1 γ/ml. The intensity of the second signal peak height was used for the measurement. The results are given in Fig. 2.

Table 2. Comparison of ESR method with photometric method

Hg (γ/ml)	ESR method[a] (γ/ml)	Photometric[b] method (γ/ml)
100	102	101
250	252	253
500	503	501

All values are the means of five measurements.
a) 0.1 ml of 100 times diluted solution
b) 5.0 ml of 10 times diluted solution

Calibration Curve for the Determination of Mercury. From the results, calibration curves for the determination of mercury were prepared in the mercury(II) ion concentration ranges 0.1—0.01 γ/ml and 1.0—0.1 γ/ml, respectively. Figure 3 shows that the ESR signal intensities are linear in the above ranges.

Effect of pH on Solvent Extraction. The effect of pH on the replacement reaction was examined. The signal intensities of the solution of 0.1 γ/ml, 1.0 γ/ml, and 10.0 γ/ml mercury(II) were constant within experimental error in the pH range 1 to 7, as shown in Fig. 4.

Effect of Diverse Ions. The effect of diverse ions on the determination of mercury(II) was examined with 13 different ions. The results are summarized in Table 1. We see that CN^- interferes with determination of mercury(II).

Comparison with the Usual Photometric Method. For the sake of comparison the mercury(II) contents in $HgCl_2$ were determined by the usual photometric[2] and ESR methods. 135.4 mg $HgCl_2$ was dissolved in water and diluted to 100 ml. This was used as the sample. Comparison of the ESR and photometric methods is given in Table 2.

The authors are grateful to Dr. N. Iso for his interest and valuable suggestions.

Trace Analysis of Metals by ESR. III. Determination of Silver by Solvent Extraction with Tetraethylthiuram disulfide Silver(II) Complex[1]

Daijiro YAMAMOTO and Fumiaki OZEKI
Faculty of Agriculture, Meiji University, Ikuta, Kawasaki-shi

(Received July 22, 1971)

A new method was worked out for the determination of silver using ESR. Bivalent complex of silver with tetraethylthiuram disulfide extracted with carbon disulfide, benzene, carbon tetrachloride, xylene, ethylbenzene, toluene, chloroform, and organic solvents was stable. The complex in carbon disulfide gave a very strong ESR signal, the sensitivity being 0.1 ppb. The amount of solution required was 1 m*l*. Colorimetric method can also be applied. However, the sensitivity was lower than that of ESR method. Silver was determined photometrically at 620 nm as a complex with tetraethylthiuram disulfide. The absorption followed Beer's law in the range 10—100 ppm of silver concentration at 620 nm. Bivalent silver complex could be selectively extracted in the presence of several ions, except copper(II) and mercury(II). Results of the continuous variation method indicate that the silver(II) - tetraethylthiuram disulfide ratio in the complex is 1 : 1.

Bivalent silver (Ag(II)) compounds have long been known to be paramagnetic with electron configuration $4d^9$.[2-4] It is possible to infer the existence of this oxidation state from a study of the ESR spectra. Most measurements were carried out at 77°K under the irradiation of γ-ray or X-ray.[5-9] Studies of the ESR spectra at room temperature, however, have been only reported by McMillan, Ag^{2+} in nitric solution,[5] and by Vänngård, Ag(II)-thiuram disulfides.[10-12]

Many methods have been reported on the determination of silver. A spectrophotometric method using dithizone,[13] sodium diethyldithiocarbamate,[14] or *p*-dimethylaminobenzylidenerhodanine[15] has been reported. The sensitivities were in the order of ppm. The sensitivities of electoanalysis, atomic absorption spectrophotometrical analysis, emission spectrochemical analysis, and activation analysis were in the range 0.1—1 ppm.[16]

If silver is stable in Ag(II) complex and extracted in organic solvents, a minute amount of silver can be determined by ESR. Thus we attempted to prepare the stable complexes of Ag(II) and to extract them with organic solvents. Various Ag(II) complexes were prepared by oxidation with ammonium persulfate on Ag(I) complex. The ESR spectra of the solid Ag(II) complexes with dithizone, *o*-(1.10)phenanthroline, 8-hydroxyquinoline, picolinic acid, 2-aminopyrimidine, α-nitroso-β-naphthol, or ethylphenyldithiocarbamate could be observed at room temperature. However, these Ag(II) complexes could not be extracted in organic solvents. A Ag(II) complex which can be extracted with organic solvents was reported by Vänngård.[10] Ag(I) *N,N*-dialkyldithiocarbamates were mixed with the corresponding thiuram disulfides in benzene, and Ag(II) complexes were extracted in benzene layer. We found that Ag(II) complexes with tetraethylthiuram disulfide (TET), tetramethylthiuram disulfide (TMT), dipentamethylenethiuram tetrasulfide (DPTTS) and 2,2-dithio-bis-benzothiazole (DBT) prepared by mixing of Ag(I)-diethyldithiocarbamate complex with the above reagents, could be extracted with organic solvents.

Experimental

Reagents. A standard silver solution was prepared by dissolving 0.543 g of a silver nitrate in 100 m*l* of water distilled twice in a quartz apparatus. This solution was then diluted to the required concentration. 10^{-3}M solutions of TET, TMT, DBT, and DPTTS were prepared by dissolving the reagent in organic solvents. The 10^{-3}M solution of sodium diethyldithiocarbamate (DDCNa) was prepared by dissolving DDCNa in 100 m*l* of distilled water. The McIlvaine buffer solution was made from citric acid and Na_2HPO_4. The Menzel buffer solution was made from Na_2CO_3 and $NaHCO_3$. All reagents and organic solvents in the experiments were of JIS special grade and used without further purification.

Apparatus. The ESR spectra were measured in organic solutions at room temperature with a Hitachi X-band ESR spectrometer, Model MPU-3, equipped with a 100 KHz field modulation unit. Absorption spectra were measured with a Hitachi spectrophotometer, Model EPS-3, using a 1 cm glass cell.

Standard Procedure for Extraction. To 1 m*l* of sample

solution containing 10^{-6}M of silver were added 1 m*l* of the DDCNa solution and 1 m*l* of the TET (or TMT, DBT, DPTTS) solution. After being shaken for one minute, and left to stand for ten minutes, 0.2 m*l* of the organic solvent layer was drawn off into an ESR cell. The ESR spectrum was measured with sweeping a rate 100 Gauss/15 min. Extraction for the measurement of absorption spectra was carried out in the same way, the volume of each solution being 5 m*l*.

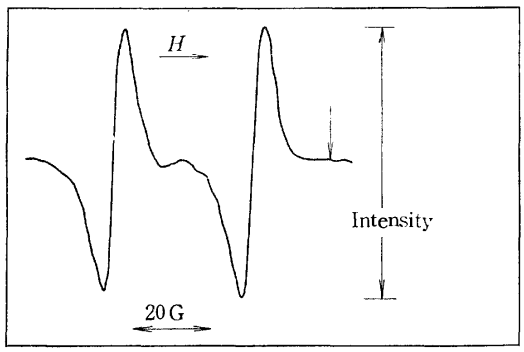

Fig. 1. ESR spectrum of TET-Ag(II) complex in organic solvent at room temperature. The perpendicular arrow in this figure indicates the resonacne filed of solid DPPH.

Results and Discussion

ESR Spectra and Absorption Spectra. Figure 1 shows a typical ESR spectrum obtained from carbon disulfide solution of TET-Ag(II) complex. The two lines of equal intensity ESR spectrum were due to the hyperfine interaction of the nuclear spin of 1/2. Super hyperfine splitting due to magnetic interaction with the nuclei of silver, ^{107}Ag and ^{109}Ag, which have the nuclear magnetic moment of −0.1130 and −0.1299, respectively, was not observed in the case of high field modulation such as 6—10 Gauss. The ESR spectra of the silver(II) complexes with TET, TMT, DBT, and DPTTS were almost the same. The *g*-values were 2.017, and both line widths were 4.7 Gauss. The ESR signal intensity was calculated by the signal height in the high magnetic field as shown in Fig. 1. The ESR signal intensity was proportional to silver concentration.

The typical absorption spectra shown in Fig. 2 were obtained for 10^{-4}M of silver solution. No absorbance maximum of the reagent (curve 2) exists in the wavelength range (Fig. 2). Appearance of the maximum in the absorption spectrum can be attributed to the formation of Ag(II) complex between the reagent cation and the complex anion.

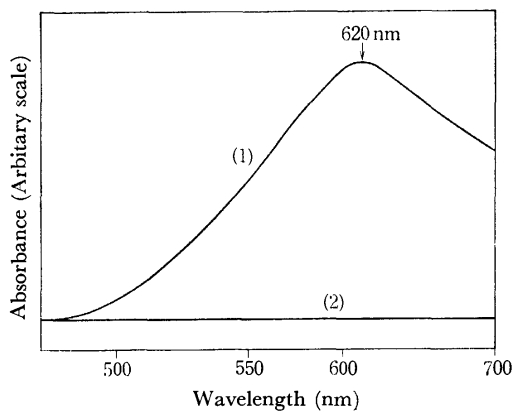

Fig. 2. Absorption spectra.

2) TET in CS_2 solution.

Table 1. ESR signal intensities by the different combinations of solvents and reagents

	TET	TMT	DBT	DPTTS
CS_2	100.0	8.9	—	5.0
C_6H_6	27.2	4.4	—	—
CCl_4	12.1	1.3	—	—
$C_6H_5CH_3$	5.3	1.5	—	—
$C_6H_4(CH_3)_2$	4.5	1.1	—	—
$C_6H_5C_2H_5$	4.3	1.1	—	—

Signal intensity of TET-Ag(II) complex in carbon disulfide is taken as 100.0. — shows that ESR signal is obtained only at maximum ESR sensitivity.

Solvents and Reagents. The following solvents and reagents were examined for their ability to extract the Ag(II) complex; carbon disulfide, benzene, carbon tetrachloride, xylene, toluene, and ethylbenzene; TET, TMT, DBT, and DPTTS. The test solutions were made by extracting 10^{-6}M silver nitrate. The results are shown in Table 1. The carbon disulfide and TET pair was found to be the best for extracting the Ag(II) complex, and was thus chosen for the experiments.

Effect of Time of Standing. The stability of the TET-Ag(II) complex in the solvent was determined by measuring the ESR signal intensity. The ESR signal intensity of TET-Ag(II) complex of the solution remained almost constant for at least 8 hr after preparation.

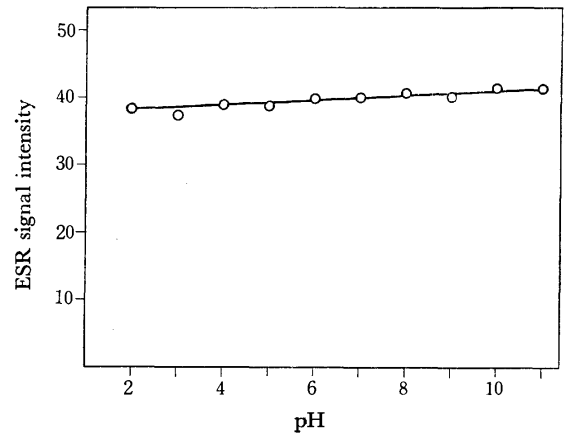

Fig. 3. Effect of pH on ESR signal intensity. Each test solution consists of 5 m*l* buffer solution and 10^{-6}M TET-Ag(II).

Effect of pH. Figure 3 shows a typical pH dependence of the extraction ability. The test solutions were made by extracting 10^{-6}M of silver nitrate in the pH range 2—11. The ESR signals are slightly larger on the alkaline side. The amount of buffer solution per 3 m*l* of the test solution was found to have no effect on the ESR signal intensity over the range 5—10 m*l*.

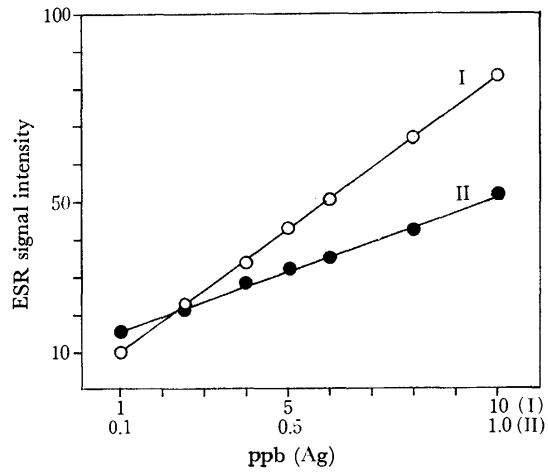

Fig. 4. Calibration curves by ESR method.

Calibration Curve for Silver and Sensitivity of the ESR method. The calibration curve for silver determination was prepared by the ESR signal intensity. Figure 4 shows typical calibration curves. We see that a linear relationship holds between the signal intensity and the silver concentration in the narrow ranges 1—0.1 ppb and 10—1 ppb. The sensitivity of the determination was 0.1 ppb. The total amount of sample solution required was only 1 m*l*.

Beer's Law and Spectrophotometric Sensitivity. The linearity between the absorbance of the TET-Ag II) complex and silver concentration was examined by varying the silver concentration and by measuring the absorbance at wavelength of 620 nm. The Ag(II) complex was found to follow Beer's law up to the silver concentration of at least 10 ppm at 620 nm.

Ag: 10^{-6}M, Ions: 10^{-3}M, 10^{-4}M, 10^{-5}M. 10, 100, and 1000 indicate that added diverse ion concentrations are of 10, 100, and 1000 times, respectively, to silver concentration. + Interference, — No interference

Effect of Diverse Ions. The effect of diverse ions was examined for a sample containing 10^{-6}M of silver nitrate. The results are shown in Table 2. Concentrations of the 1000—10 times of silver concentration ion were examined. Ag(II) complex could be selectively extracted in the presence of several ions. Mercury(II) and copper(II) ion interfered with extraction. Copper(II) could be separated, but not mercury(II).

Separation of Copper(II). The large solubility of $(DDC)_2Cu$ and very small solubility of DDC-Ag(I) in benzene were utilized for the separation of copper and silver. To 2 m*l* of the copper-silver mixture were added 10 m*l* of the 2% DDCNa, 20 m*l* of benzene and 1 m*l* of the 1N-HCl. The mixture was then shaken. After the organic layer was separated from the aqueous layer, 1 m*l* of a DDCNa solution and 1 m*l* of a TET-carbon disulfide solution were added to an aqueous solution. In the case of a large amount of copper the procedure was repeated several times. The ESR signal intensity was compared with that of standard TET-Ag(II) complex. The results are shown in Table 3. Copper(II) ion concentrations examined varied from 10000 to 100 times silver concentration. From the standard deviation shown in Table 3, we see that the interference of copper(II) ion diminished to some extent.

Composition of TET-Ag(II) Complex. The composition of the TET-Ag(II) complex was determined by the continuous variation method. The results are

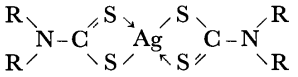
●: TET and Ag(II) by absorbance at 620 nm,
□: TMT and Ag(II) by ESR,
■: TMT and Ag(II) by absorbance at 620 nm.

shown in Fig. 5. The curves were obtained by measuring the absorbance at 620 nm, and the ESR signal. The resulting curves have a maximum at 0.5 mol fraction of Ag(II), indicating TET-Ag(II) ion ratio 1 : 1, and TMT-Ag(II) ion ratio 1 : 1. Ag(II) complexes may have the following structure.



$R = C_2H_5$, CH_3

Reaction. When Ag(I) complex with DDC was mixed with TET, TMT, DBT, and DPTTS in organic solvent, the complexes with TET, TMT, DBT, and DPTTS were found to be extractable with organic solvents. Thus we assumed the mechanism of the complex formation. When DDCNa and TET were used, the reactions can be written as follows.

$$\text{DDCNa} + \text{Ag}^+ \longrightarrow \text{DDC-Ag(I)} + \text{Na}^+$$

$$\text{DDC-Ag(I)} + \text{TET} \longrightarrow \text{TET-Ag(II)} + \text{DDC}^-$$

The reaction of DDC-Ag(I) with TMT, DBT, or DPTTS was assumed to be same as that of DDCAg(I) with TET. These Ag(II) complexes gave strong ESR signal intensity.

When DDCNa and EDTA were used, and Ag(I) complexes with 2-aminopyrimidine, 8-hydroxyquinoline, α-nitroso-β-naphthol, dithizone, or *o*-(1.10)phenanthroline were mixed with TET-carbon disulfide solution, the products gave ESR spectra. Thus Ag(II) complexes were assumed to be prepared. Since it requires a long time for Ag(II) complexes to be stabilized and the ESR signal intensity obtained is weak, these complexes could not be used. The reaction, however, may be caused by the existence of DDC acid as impurity during the course of TET production.

The authors are grateful to Dr. N. Iso for his interest and valuable suggestions.

Nickel(II) Complexes of 1,5-Dialkyl-2,4-pentanediones[1]

Isao Yoshida, Hiroshi KOBAYASHI, and Keihei UENO[2]

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka

(Received September 2, 1971)

Bis(heptane-3,5-dionato)nickel(II) monohydrate [Ni(DNPM)$_2$·H$_2$O], bis(nonane-4,6-dionato)nickel(II) monohydrate [Ni(DNBM)$_2$·H$_2$O], bis(2,6-dimethylheptane-3,5-dionato)nickel(II) monohydrate [Ni(DIBM)$_2$·H$_2$O], bis(2,8-dimethylnonane-4,6-dionato)nickel(II) monohydrate [Ni(DIVM)$_2$·H$_2$O] and bis(tridecane-6,8-dionato)nickel(II) monohydrate [Ni(DNCM)$_2$·H$_2$O] were prepared, and a dimeric octahedral structure was proposed for each of them by means of spectroscopic studies. These dimeric chelates, (NiL$_2$·H$_2$O)$_2$ were stable in solid state, however they disproportionated in non-coordinating solvents to afford dimeric monohydrates, Ni$_2$L$_4$·H$_2$O, and monomeric dihydrates, NiL$_2$·2H$_2$O. DTA studies show that these monohydrates dehydrate in two steps and that the temperature of dehydration decreases in the order of the ligands, DNPM, DNBM, DIBM, DIVM, and DNCM. The dehydrated chelates are green in the neighborhood of room temperature while they changed into red at an elevated temperature. This thermochromism indicates that the chelates are in the trimeric octahedral form at low temperature and in monomeric tetra-coordinated square planar form at high temperature. On the other hand a nickel(II) chelate of 2,2,6,6-tetramethylheptane-3,5-dione (DPVM) was obtained as a penta-coordinated monodioxane adduct from aqueous dioxane. The coordinated dioxane was readily released to afford a monomeric tetra-coordinate square planar, red colored complex, Ni(DPVM)$_2$.

Extensive investigations have been worked out on nickel(II) chelates of pentane-2,4-dione, of which bis-(pentane-2,4-dionato)nickel(II) dihydrate can be most easily obtained. The coordination structure of this dihydrate is known to be similar to that of bis(pentane-2,4-dionato)cobalt(II) dihydrate,[3] in which two water molecules coordinate to the central cobalt ion in a planar bis(pentane-2,4-dionato)cobalt unit on both sides along z axis.[4]

It is also well known that the dehydration of this chelate affords the anhydrous trimeric chelate, in which nickel ion is octahedrally coordinated.[5] However, when the terminal methyl groups in pentane-2,4-dione are replaced with *t*-butyl groups, the steric hindrance among the substituents completely prevents trimerization and the chelate behaves as a spin-paired, red colored planar chelate.[6] This structure is maintained in solid state as well as in non-coordinating solvents.

In this connection, it is of great interest to investigate on the chelating behavior and the properties of the chelates of pentane-2,4-dione derivatives, in which the terminal methyl groups are replaced by various alkyl groups such as ethyl, *n*-propyl, isopropyl, isobutyl, *tert*-

butyl, and *n*-pentyl group.

Although these ligands are reported in the literature, and some of their nickel(II) chelates have been synthesized, very few detailed investigations have been carried out.[6] This paper is to report on the synthesis of nickel(II) chelates of the following six ligands; heptane-3,5-dione (or dipropionylmethane, DNPM), nonane-4,6-dione (or di-*n*-butyrylmethane, DNBM), 2,6-dimethylheptane-3,5-dione (or diisobutyrylmethane, DIBM), 2,8-dimethylnonane-4,6-dione (or diisovalerylmethane, DIVM), 2,2,6,6-tetramethylheptane-3,5-dione(or dipivaloylmethane, DPVM) and tridecane-6,8-dione(or di-*n*-caproylmethane, DNCM), and on the structural studies concerning these chelates chiefly by spectroscopic methods.

Experimental

Synthesis of Ligands. The ligands were synthesized by the standard procedure described by Adams and Hauser[7] with slight modifications. The corresponding methyl-ketone and ethyl ester were condensed in the presence of sodium amide, and the resulting crude diketone was isolated as a copper(II) chelate, from which the diketone was liberated by decomposing with 10% sulfuric acid, followed by extraction with ether and fractionation. The results of elemental analyses of the ligands are summarized in Table 1.

Preparation of Nickel(II) Chelates. All chelates were prepared by the procedure as described below. To a solution containing 1.5 g (0.005 mol) of nickel nitrate hexahydrate in 12 m*l* of water and 8 m*l* of methanol, was added a solution of 0.01 mol of a ligand in 5 m*l* of methanol. Then, 6 m*l* of 1.5M sodium hydroxide solution was added to the mixture with vigorous stirring, from which green complex precipitated immediately. The product was recrystallized from an appropriate solvent and was dried over phosphorous pentoxide in vacuum at room temperature. The appearance, solvent used for recrystallization, yield, and the result of elemental analyses of each chelate are summarized in Table 2.

A careful dehydration of the hydrated chelates at about 180°C in vacuum afforded the anhydrous chelates, which were also green and were hygroscopic.

Spectral Measurements. Solid reflectance spectra were measured with a Hitachi EPU-2A spectrophotometer with

7) J. T. Adams and C. R. Hauser, *J. Amer. Chem. Soc.*, **66**, 1220 (1944).

a diffuse reflectance attachment. Absorption spectra in visible and ultraviolet regions were measured with a Hitachi EPS-2 and Hitachi 124 spectrophotometer respectively. Visible absorption spectra of the anhydrous chelates in toluene at elevated temperature were measured with a Hitachi 139 spectrophotometer with a high temperature attachment. Infrared absorption spectra were measured with a JASCO-DS-403G spectrophotometer on Nujol mull samples.

Molecular Weight Measurement. Molecular weight of the chelates was determined in toluene at 37°C with a Mechlolab's 301A vapour pressure osmometer. The standard material for the caribration curve was $Cu(DNBM)_2$, which was analytically pure and it's molecular weight was checked previously using α-naphthol as a primary standard.

Results and Discussion

Structural Study on DNPM, DNBM, DIBM, DIVM-, and DNCM Chelates. The result of elemental analysis of the nickel(II) chelates (except dipivaloylmethanato-nickel to be described later) agrees well with a molecular formula of $NiL_2 \cdot H_2O$ where L represents a β-diketonato monoanion. A sharp, relatively strong absorption band in 3350—3400 cm^{-1} region is observed in IR spectra of these chelates as shown in Fig. 1, indicating the presence of coordinated water. Although the above results seem to suggest a penta-coordinate structure, the diffuse reflectance spectra of solid samples, which are shown in Fig. 2 and Table 3, are very much similar to that of bis(pentane-2,4-dionato)nickel(II) dihydrate which is a typical hexa-coordinate octahedral

nickel(II) chelate. Thus, it is reasonable to assume that the chelates are of dimeric structure, in which two $NiL_2 \cdot H_2O$ units are joined by two bridging oxygens as shown in Fig. 5 (I). Other possibility such as the double deck structure proposed for DNBM chelate of trimethyl platinum(IV),[8] can not be accepted in this case because the ionic radius of nickel(II) ion is too small in comparison with the van der Waals radius of terminal alkyl groups which prevents the approach of second unit from above or below of the nickel(II) ion in the first unit.

It has been known that the chloroform solution of trimeric bis(pentane-2,4-dionato)nickel(II) shows two bands in ultraviolet region at 33800 and 37700 cm^{-1}, and they merge into a single band at 34000 cm^{-1} when

8) A. G. Swallow and M. R. Truter, *Proc. Roy. Soc.* (London), **254A**, 205 (1960).

ethanol is added to the chloroform solution.[9] According to Cotton and Fackler,[6] this spectral change is related with the coordination of ethanol to nickel ion resulting in the depolymerization of trimeric nickel chelate to give a mononuclear $NiL_2 \cdot 2EtOH$. The two bands of the trimeric form are assigned to two types of chelate rings, *i.e.* one is the non-bridging chelate ring and the other the bridging chelate ring, respectively. The single band observed in the mononuclear ethanol-adduct is, as being obvious from its coordination structure, ascribable to the non-bridging chelate ring.

a) in chloroform. b) in ethanol.

As shown in Table 4, the UV spectra of the 1,5-dialkyl-2,4-pentanedionatonickel(II) chelates in cyclohexane solutions are very much similar to that of trimeric bis(pentane-2,4-dionato)nickel(II) in chloroform. The spectral change which is observed when ethanol is added to these cyclohexane solutions is also quite similar to that of the pentane-2,4-dionato chelate described above. The result, combined with their compositions and the spectral evidences in the visible and infrared regions, supports strongly the dimeric structure of bis(1,5-dialkyl-2,4-pentanedionato)nickel of type $NiL_2 \cdot H_2O$.

Table 5. Molecular weights of $NiL_2 \cdot H_2O$ in toluene at 37°C

molecular formula	calcd	found	found/calcd
$(Ni(DNPM)_2 \cdot H_2O)_2$	661.82	532	0.81
$(Ni(DNBM)_2 \cdot H_2O)_2$	773.82	588	0.77
$(Ni(DIBM)_2 \cdot H_2O)_2$	773.82	618	0.80
$(Ni(DIVM)_2 \cdot H_2O)_2$	885.86	575	0.65
$(Ni(DNCM)_2 \cdot H_2O)_2$	997.82	708	0.71

The molecular weights of these chelates, however, show somewhat odd values in toluene at 37°C as summarized in Table 5. The values are about 0.75± 0.1 of dimeric molecular weights. Thus, a certain kind of rearrangement of the chelate might occur even in a

non-coordinating solvent such as toluene, while the octahedral structure is retained as suggested by the visible absorption spectra which are shown in Fig. 3. The structural change of the chelate after dissolution in such solvents can be traced also by observing the time dependence of the UV spectral change in cyclohexane which is also one of the non-coordinating solvents, as shown in Fig. 4. Although we are not successful in identifying the rearrangement products in solution, one of the possible scheme of the rearrangement may be such as shown in Fig. 5. As to the binuclear chelate (II) in Fig. 5, a similar structure was assigned to pyridine-tetrakis(pentane-2,4-dionato)dinickel, $[(NiL_2)_2 \cdot Py]$, which was isolated as a reaction intermediate when trimeric nickel chelate was dissolved in pyridine.[10] If it is assumed that the reactions (1) and (2) proceed until completion, three moles of $(NiL_2 \cdot H_2O)_2$ give each two moles of (II) and (III), thus the resulting solution giving an apparent molecular weight of three quarters of the formular weight of $(NiL_2 \cdot H_2O)_2$.

In addition to the structural change in solution, it is of interest to see if the dehydration of binuclear $NiL_2 \cdot H_2O$ chelate affords polymeric anhydrous nickel(II) chelate in solid state in a similar manner to the case of pentane-2,4-dionato chelate. In this connection, the dehydration process of the solid chelates was followed by differential thermal analysis (DTA) in nitrogen atmosphere with combined use of infrared spectroscopy. Although thermogravimetric analysis was also attempted, the present nickel chelates sublimed so easily, that no quantitative result on dehydration process could be obtained. As shown in Fig. 6, the DTA curves of the nickel chelates are characterized with four endothermic peaks, A, B, C, and D. When DTA was carried out in air, intense exothermic peak was observed generally in the range of 300—380°C which could be assigned to the oxidative decomposition of the sample. Of the four peaks, the first two seem to be related with the dehydration of the chelate, since the sample decreased the intensity of ν_{OH} band at 3300 cm^{-1} region when it was heated above the temperature corresponding to the peaks A and B. The resulting nickel chelate, which was still green, is considered to be polymeric structure such as trimeric bis(pentane-2,4-dionato)nickel(II). The latter two peaks, C and D, may be related with some sort of structural change of anhydrous chelates, however, little more informations could be obtained except that all four peaks were found to be irreversible ones. It is interesting to note, with this respect, that the respective temperatures corresponding to the peaks A and B decrease with increasing size of alkyl groups introduced to pentane-2,4-dione. This result may be interpreted as an effect of the hydrophobic nature of alkyl groups surrounding the coordinated water molecule. It is also safe to conclude that the replacement of terminal methyl groups of pentane-2,4-dione with higher alkyl groups except *t*-butyl group, is not a decisive factor to prevent the formation of an oxygen-bridged polymeric octahedral nickel chelate. An additional peak F of $Ni(DIVM)_2 \cdot H_2O$ and $Ni(DPVM)_2$·dioxane, was definitely due to the melting of samples as verified

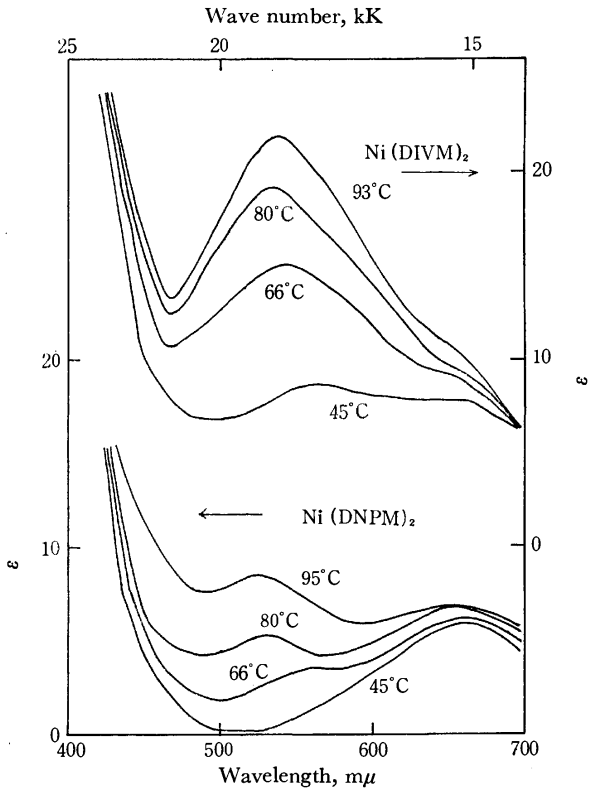

Fig. 7. Visible spectra of $Ni(DNPM)_2$ and $Ni(DIVM)_2$, in toluene at four temperatures, concentration about 1/100M.

10) J. P. Fackler, Jr., *J. Amer. Chem. Soc.*, **84**, 24 (1962).

by melting point measurement.

As described in the experimental section, the anhydrous octahedral green nickel(II) chelates could be obtained by heating the hydrated chelates in vacuum. Although the molecular weights of the anhydrous chelates at room temperature could not be determined because of the experimental difficulty, the spectral evidence for the octahedral structure and the metal-ligand ratio strongly suggest the polymeric structure similar to bis(pentane-2,4-dioanto)nickel(II).

Absorption spectra were measured on the anhydrous chelates of the present ligands in toluene over the temperature range of 45—95°C. Typical examples are illustrated in Fig. 7. The peak at 650 nm, which is observable at lower temperature, is most distinct for pentane-2,4-dionato chelate, and becomes less distinct when the terminal methyl groups are replaced with bulkier alkyl groups. With elevating temperature, a new peak becomes noticable at around 520 nm and overshadows the peak at 650 nm in the extreme case.

A similar thermochromic effect has been reported by Cotton and Fackler[6] with $Ni(DIBM)_2$, and was rationalized by reversible interconversion between polymeric octahedral and monomeric square planar structures.

The pentane-2,4-dionato- and dipivaloylmethanato chelates, however, show no spectral change in this temperature range; the former shows a single peak at 650 nm while the latter only at 520 nm throughout the temperature elevation. Of the remaining chelates, the spectral changes increase in the order of $Ni(DNPM)_2 < Ni(DNBM)_2 < Ni(DNCM)_2 < Ni(DIVM)_2 < Ni(DIBM)_2$, which parallels to the bulkiness of the terminal alkyl groups. These results clearly indicate that the peak at around 520 nm is assignable to the monomeric square planar structure, while the peak at 650 nm is due to the polymeric octahedral one, and that bulkier alkyl groups introduced on the 1- and 5-positions of pentane-2,4-dione favor the square planar configuration of the nickel chelates. In the extreme case of dipivaloylmethane, which has *t*-butyl groups on the both ends, the nickel chelate, $Ni(DPVM)_2$, takes a square planar structure even at room temperature.

Structural Study on DPVM Chelate. The properties of nickel DPVM chelate are different in many respects from those of other alkyl substituted pentane-2,4-dione. The result of elemental analysis on the light blue chelate agrees with a formula of NiL_2·dioxane. Infrared absorption spectrum also supports the existence of dioxane and the absence of water.

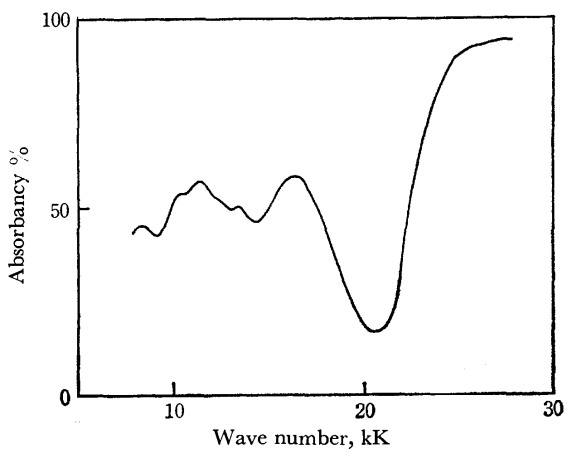

Fig. 8. Electronic reflectance spectrum of the solid $Ni(DPVM)_2$·dioxane.

A diffuse reflectance spectrum of the solid dioxane adduct in visible region which is shown in Fig. 8 and in Table 3, is quite different from the spectra which are typical to octahedral, tetrahedral or planar nickel(II) complexes. According to the result by Ciampolini who analyzed the energy levels of penta-coordinate nickel(II) complex of D_{3h} or C_{4v} symmetry,[11] the spectrum of $Ni(DPVM)_2$·dioxane is similar to that of C_{4v} symmetry, indicating that the chelate is monomeric penta-coordinate square pyramidal structure.

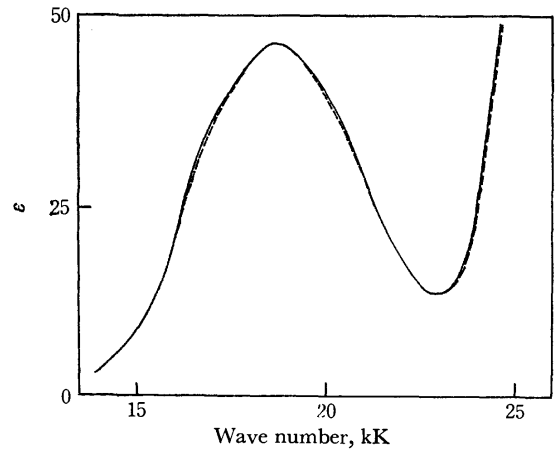

Fig. 9. Electronic absorption spectra of the $Ni(DPVM)_2$·dioxane (----) and $Ni(DPVM)_2$(——) in tolene.

When the light blue dioxane adduct is dissolved in toluene, it turned red, giving a spectrum as shown in Fig. 9. If the dioxane adduct is heated at 100°C in vacuum, it afforded a red chelate of the formula of $Ni(DPVM)_2$ with a monomeric molecular weight. The visible absorption spectrum of the toluene solution of red chelate was found to be identical with that obtained by dissolving light blue dioxane adduct in toluene as shown in Fig. 9. According to Cotton, this spectrum can be assigned to a diamagnetic tetra-coordinate square planar complex.[6] Thus, the dissolution of dioxane adduct in non-coordinating solvent at room temperature, results in the dissociation of coordinated dioxane, and no further rearrangement of the chelate could be observed.

Interestingly, $Ni(DPVM)_2$ does not accept coordinated water but does dioxane which is known to be much weaker ligand than water. A DTA study indicated that the coordinated dioxane dissociated at 188°C (peak A) and the resulting $Ni(DPVM)_2$ melted at 230°C (peak F). The preference of dioxane to water molecule as a secondary ligand to $Ni(DPVM)_2$ is again indicative that the hydrophobic dioxane molecule may receive less repulsion from the neighboring *t*-butyl groups than does water molecule. The relative easiness of dissociation in non-coordinating solvents, which is contrary to the result observed by DTA study, may be

11) C. Ciampolini, *Inorg. Chem.*, **5**, 35 (1966).

explained by the solvation of dissociated dioxane. The formation of red planar chelate after the dissociation of dioxane also suggests that the terminal *t*-butyl groups are bulky enough to prevent the formation of oxygen-bridged polymeric structure even at room temperature.

Reaction Rates and Mechanisms of the Formation of Gallium(III), Indium(III), and Thallium(III) Complexes with Semi-Xylenol Orange in Aqueous Solutions

Yoichi KAWAI, Tetsuro TAKAHASHI,* Katsuyuki HAYASHI,** Taira IMAMURA, Hiroaki NAKAYAMA,*** and Masatoshi FUJIMOTO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received September 6, 1971)

The kinetics for the complex formation of Ga(III), In(III), and Tl(III) with Semi-Xylenol Orange (SXO) in acid solutions were studied by stopped-flow technique. Kinetic results are interpreted in terms of a two-step mechanism involving pre-equilibrium. The increase in the reaction rate with decreasing hydrogen ion concentration is interpreted as the sum of several parallel pathways including monohydroxo metal ions and a few charge types of the ligand. The mechanisms and the rates of the three different d^{10}-system metal ions are discussed. The phenomena of the slower increase in absorbance of Ga(III)-SXO complex after the rapid increase and the slow color fading of Tl(III)-SXO complex are also discussed.

Although there have been a large number of investigations on the kinetics of metal complex formation in aqueous solutions,[1,2] relatively meager kinetic data have been reported for trivalent d^{10}-system metal ions.[3-6] This arises mainly from the limited number of simple inorganic or organic ligands suitable for kinetic measurements for Ga(III), In(III), and Tl(III).

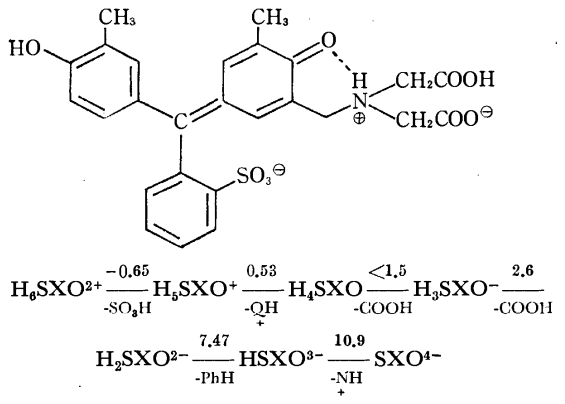

Fig. 1. Semi-Xylenol Orange (SXO) in the form of $[H_3SXO]^-$ and the acid dissociation constants (pK_a).[10]

In the present study, Semi-Xylenol Orange (SXO) has been chosen as a ligand, which forms 1 : 1 complexes with Ga(III), In(III), and Tl(III). The SXO complexes have absorption maxima in the visible range with sufficiently large absorption coefficients (see Fig. 1).

Characteristic rate constants for the water substitution in the inner coordination sphere of aquo-ions are listed[1] as 10^0—10^1, $10^{1.5}$—$10^{2.5}$, and 10^4—10^5 sec^{-1} for Ga(III), In(III), and Tl(III), respectively. These are obtained only from the extrapolation of the rate data for other charge types, by assuming that log k (k: rate constant) correlates linearly with the inverse of ionic radius for non-transition group and d^{10}-system ions. Though divalent d^{10}-metal ions were reported to satisfy the correlation, trivalent d^{10}-metal ions do not necessarily behave in the similar way, as is seen for the correlation of ionization potential and hydration energy with ionic radius.[7]

Experimental

Materials. The solution of Ga(III) perchlorate was prepared by dissolving metallic gallium (99.99% Wako) in perchloric acid (Reagent Grade, Wako). Aqueous In(III) perchlorate was prepared by dissolving indium oxide (Koso) in slight excess of perchloric acid. Aqueous Tl(III) perchlorate was made by electrolytically oxidizing Tl(I) perchlorate[8] which was prepared from thallium(I) acetate (BDH) and recrystallized.

7) Within a non-transition group the heat of hydration and the ionization potential vary inversely with the ionic radius. Crystal field correction acts well for the first transition series. On the other hand the correlation is almost worth nothing for trivalent d^{10}-system ions.

8) G. Biedermann, *Arkiv Kemi*, **5**, 441 (1953).

The concentration of each metal ion in the stock solution was standardized by titrating with EDTA.[9]

Sodium perchlorate (Reagent Grade, Koso) was dissolved in distilled water. In order to remove the trace amounts of impurities the concentrated aqueous solution was filtered through a quantitative filter paper after being kept several days. The concentration was determined by passing an aliquot of the solution through a column of cation-exchange resin (Dowex 50W-X8) in the hydrogen form and titrating the effluent with standard sodium hydroxide.

SXO was synthesized from *o*-Cresol Red, iminodiacetic acid and formaldehyde by the Mannich condensation and purified by means of cellulose column chromatography.[10] The acid form of SXO was obtained by passing the fraction of SXO through a column of cation-exchange resin in the hydrogen form. The purity of the SXO was checked by paper chromatography, and only one spot was observed. The elemental analysis agrees with the results of the previous workers.[10]

Found: C, 56.22; H, 5.39; N, 2.24; S, 4.90%. Calcd for $C_{26}H_{25}O_9NS \cdot H_2O$: C, 57.24; H, 4.99; N, 2.57; S, 5.89%.

Procedure. A Hitachi spectrophotometer model EPS-3T was used for spectral measurements. Yanagimoto SPS-1 Stopped-Flow apparatus with a 4-jet mixing chamber and 2 mm or 10 mm optical cell was used for kinetic measurements. The changes in absorbance were photographed on the storage screen of oscilloscope.

All measurements were made at 25.0±0.2°C. Hydrogen ion concentration and ionic strength were adjusted using $HClO_4$ and $NaClO_4$. The pH values were measured with a Horiba pH meter Model P calibrated with a standard buffer solution.

Results

Two forms of complexes of SXO with the metals M(III) were observed in the different pH region by the spectroscopic measurements. The composition of these complexes in solutions was determined to be 1 : 1 by means of the continuous variation method. Absorption maxima of the acid-form complexes are at 532 nm (pH=1.60), 529 nm (pH=3.10) and 538 nm ([H]=1.0M) for Ga(III), In(III), and Tl(III), respectively, and those of the alkaline-form complexes are at 470 nm (pH=4.0), 480 nm (pH=4.50), and 492 nm (pH=6.0) for Ga(III), In(III), and Tl(III), respectively. In order to minimize hydrolysis and polymerization of the metal ions, kinetic measurements were performed in the acid media by following the absorbance at the λ_{max} of the acid-form complex.

When metal(III) ion concentrations were at least in 10-fold excess over those of SXO, a pseudo-first-order kinetics was obeyed in most cases. Pseudo-first-order rate constants k_{obs} were evaluated from the slopes of such plots as

$$k_{obs} = -\mathrm{d} \ln (D_\infty - D_t)/\mathrm{d}t$$

where D_∞ and D_t represent the absorbances at the end of the reaction and at time t respectively. No significant dependence was observed for k_{obs} on the initial concentration of SXO. Plots of the observed pseudo-first-order rate constant k_{obs} against [M(III)] for Ga(III) and In(III) are not straight lines but curves (Figs. 2 and 3). Assuming the one step mechanism such plots should give a straight line with a slope k_f and an intercept k_r,

$$\mathrm{M(III)} + \mathrm{SXO} \underset{k_r}{\overset{k_f}{\rightleftharpoons}} \mathrm{M(III)SXO}$$

$$k_{obs} = k_f[\mathrm{M(III)}] + k_r \qquad (1)$$

The curves can thus be interpreted in terms of the two-

step mechanisms.

$$M(III) + SXO \overset{K_p}{\rightleftharpoons} M(III)\cdots SXO$$

(K_p: pre-equilibrium constant)

$$M(III)\cdots SXO \underset{\overleftarrow{k}}{\overset{\vec{k}}{\rightleftharpoons}} M(III)SXO$$

Since the metal ion is in large excess over SXO, and is regarded as constant during the reactions, k_{obs} can be written as a function of [M(III)]

$$k_{obs} = \frac{\vec{k}K_p[M(III)]}{1+K_p[M(III)]} + \overleftarrow{k} \qquad (2)$$

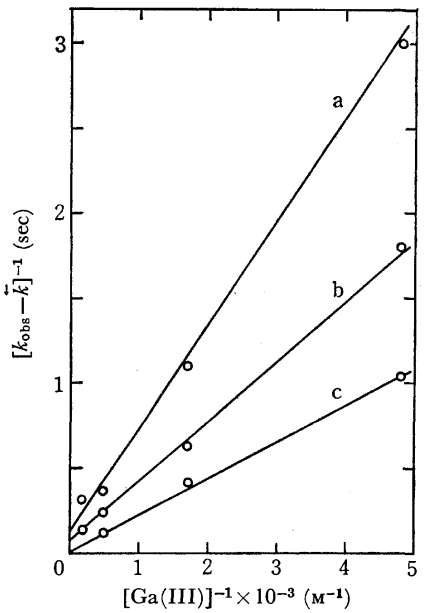

Fig. 4. Plot of $1/(k_{obs}-\overleftarrow{k})$ *vs.* inverse of the total concentration of Ga(III) for Ga(III)-SXO at various hydrogen ion concentrations.
(a): pH=2.40±0.02; (b): pH=2.65±0.02; (c): pH=2.90±0.02.

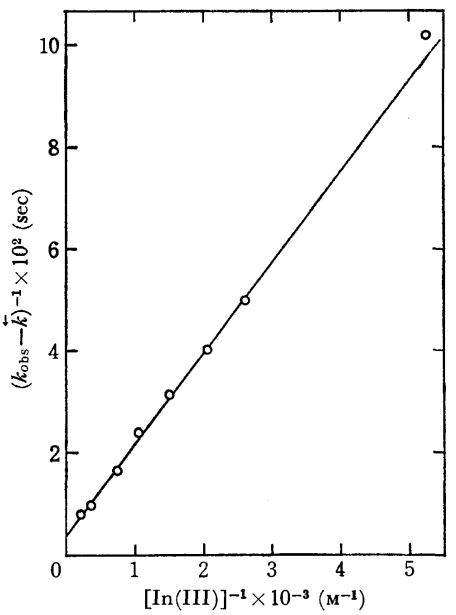

Fig. 5. Plot of $1/(k_{obs}-\overleftarrow{k})$ *vs.* inverse of the total concentration of In(III) for In(III)-SXO at pH=1.96±0.02.

Figures 4 and 5 show a linear plot of $1/(k_{obs}-\overleftarrow{k})$ *versus* $1/[M(III)]$ for Ga(III) and In(III) respectively. We have for the present no evidence of the actual structure of the intermediate M(III)···SXO; it may or may not be so-called ion pair.

If the M(III) concentration is sufficiently low, namely $1 \gg K_p[M(III)]$, Eq. (2) is reduced to Eq. (1) (namely $\vec{k}K_p = k_f$ and $\overleftarrow{k} = k_r$), and the plot of k_{obs} *versus* [M(III)] becomes linear. Actually in the case of Tl(III), plots of k_{obs} against [Tl(III)] were linear under the experimental condition (Fig. 6).

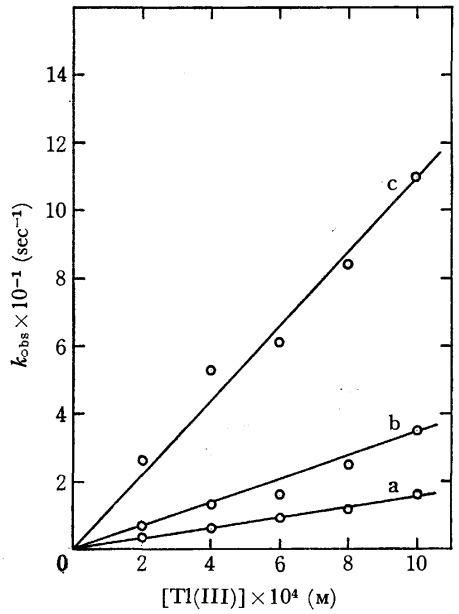

Fig. 6. Plot of k_{obs} *vs.* total concentration of Tl(III) at 25.0°C, ionic strength 2.0 and at various hydrogen ion concentrations.
(a): [H]=0.5M; (b): [H]=0.3M; (c): [H]=0.1M.

In the present work the values of k_f for Ga(III), In(III), and Tl(III) are discussed. It is difficult to discuss k_r, as the plots of k_{obs} *versus* [M(III)] have intercepts almost near the origin in most cases. This is consistent with the large value of apparent stability constants K_c=[M(III)SXO]/[M(III)][SXO]. The apparent stability constants are 1.4×10^5M (pH=2.1), 1.0×10^5M (pH=3.0), and 7.9×10^5M ([H]=5×10^{-2}M) for Ga(III), In(III), and Tl(III), respectively.

The increase of k_f with decreasing [H] is interpreted by considering the acid dissociation of aquo ion M^{3+} and SXO.

$$M(OH_2)_n^{3+} \rightleftharpoons M(OH_2)_{n-1}(OH)^{2+} + H^+ \qquad K_{a1}$$

$$M(OH_2)_{n-1}(OH)^{2+} \rightleftharpoons M(OH_2)_{n-2}(OH)_2^{+} + H^+ \qquad K_{a2}$$

$$H_6SXO^{2+} \rightleftharpoons H_5SXO^{+} + H^+ \qquad K_1$$

$$H_5SXO^{+} \rightleftharpoons H_4SXO + H^+ \qquad K_2$$

$$H_4SXO \rightleftharpoons H_3SXO^{-} + H^+ \qquad K_3$$

$$H_3SXO^{-} \rightleftharpoons H_2SXO^{2-} + H^+ \qquad K_4$$

All the possible chemical species and equilibria are summarized above, polynuclear hydroxo complexes being neglected under the experimental conditions.[12] Second-order rate constants are defined as follows;

$$\begin{cases} M^{3+} + H_6SXO^{2+} \xrightarrow{k_{11}} MOH^{2+} + H_6SXO^{2+} \xrightarrow{k_{21}} M(OH)_2^{+} + H_6SXO^{2+} \xrightarrow{k_{31}} \\ M^{3+} + H_5SXO^{+} \xrightarrow{k_{12}} MOH^{2+} + H_5SXO^{+} \xrightarrow{k_{22}} M(OH)_2^{+} + H_5SXO^{+} \xrightarrow{k_{32}} \\ M^{3+} + H_4SXO \xrightarrow{k_{13}} MOH^{2+} + H_4SXO \xrightarrow{k_{23}} M(OH)_2^{+} + H_4SXO \xrightarrow{k_{33}} \\ M^{3+} + H_3SXO^{-} \xrightarrow{k_{14}} MOH^{2+} + H_3SXO^{-} \xrightarrow{k_{24}} M(OH)_2^{+} + H_3SXO^{-} \xrightarrow{k_{34}} \\ M^{3+} + H_2SXO^{2-} \xrightarrow{k_{15}} MOH^{2+} + H_2SXO^{2-} \xrightarrow{k_{25}} M(OH)_2^{+} + H_2SXO^{2-} \xrightarrow{k_{35}} \end{cases}$$

The proton transfer of SXO was found to proceed fast as compared to the complex formation, as in the time range of complex formation no relaxation was observed by the pH-jump on mixing SXO with perchloric acid. The hydrolysis of M(III) is known to be fast as compared to the complex formation reactions.[11] Acid dissociation constants of SXO were reported to be $10^{+0.65}$, $10^{-0.53}$, $10^{-1.5}$, and $10^{-2.6}$M for K_1, K_2, K_3, and K_4 respectively (0.1M KNO_3, 25°C).[10]

Ga(III)-SXO. The acid dissociation constants of Ga(III) are reported to be $K_{a1}=10^{-2.8}$M and $K_{a2}=10^{-3.5}$M ($I\rightarrow 0$, 18°C).[12] H_4SXO, H_3SXO^-, and H_2SXO^{2-} are predominant charge types of the ligand under the experimental conditions. The contribution of $Ga(OH)_2^+$ was neglected. Following equation expresses k_f.

$$k_f = [k_{13}[H]^3 + (k_{14}K_3+k_{23}K_{a1})[H]^2 + (k_{15}K_3K_4 + k_{24}K_3K_{a1})[H] + k_{25}K_3K_4K_{a1}]/([H]+K_{a1}) \times ([H]^2+K_3[H]+K_3K_4)$$

In the Fig. 7 $k_f\times([H]+K_{a1})([H]^2+K_3[H]+K_3K_4)$ is plotted against [H][13] to give a straight line. The linearity can be interpreted by assuming that the rate constants k_{25}, and k_{24} and/or k_{15} are sufficiently larger than the others. The term of $k_{25}K_3K_4K_{a1}$ corresponds to the intercept, and the term of $(k_{15}K_3K_4+k_{24}K_3K_{a1})$ to the slope of the plots, so that the values of k_{15} and k_{24} are indistinguishable.[14,15] Following values of k_{15} and k_{24} have been calculated by attributing the slope only to the term $k_{15}K_3K_4$ and to $k_{24}K_3K_{a1}$ respectively: $k_{15}=6.9\times10^2$M^{-1}sec^{-1} and $k_{24}=1.1\times10^3$M^{-1}sec^{-1}. From the intercept k_{25} is obtained as 1.2×10^4M^{-1}sec^{-1}.

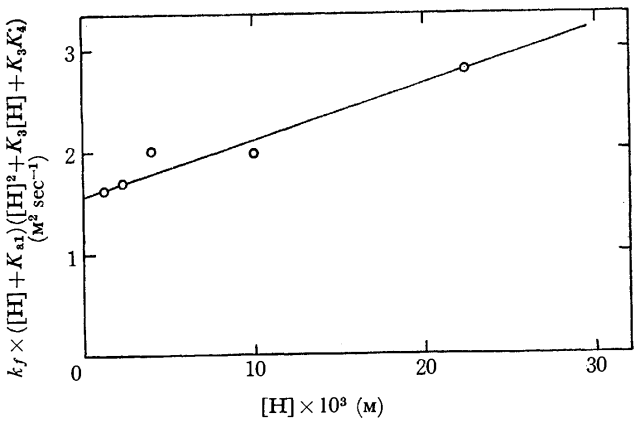

Fig. 7. Plot of $k_f([H]+K_{a1})([H]^2+K_3[H]+K_3K_4)$ *vs.* hydrogen ion concentration for Ga(III)-SXO at 25.0°C and ionic strength of 0.1.

In the case of Ga(III), we shall have to refer to the relatively slow increase in optical density. Exponential changes of optical density was really observed on the oscilloscope as mentioned above, but the absorbance of the complex usually still increases gradually even 2 hr after mixing. Under the extreme condition of high pH and high Ga(III) concentration, exponential signal was not observed as shown in Fig. 8.

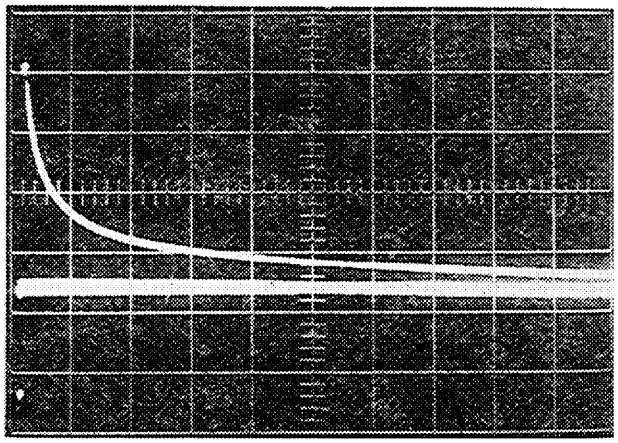

Fig. 8. Stopped-flow signal at 532 nm under the condition of $[Ga(III)]_0=6.0\times10^{-3}$M, $[SXO]_0=2.0\times10^{-5}$M, ionic strength 0.1, pH=2.9 and 25.0°C; vertical scale: absorbance 0.1/div; horizontal scale: 500 msec/div.

In(III)-SXO. The acid dissociation constants of In(III) are reported to be $K_{a1}=10^{-4.4}$M and $K_{a2}=10^{-3.9}$M (3M $NaClO_4$, 25°C).[12] Under the experimental conditions, $In(OH_2)_n^{3+}$ is the predominant chemical species of In(III), and H_4SXO, H_3SXO^-, and H_2SXO^{2-} are the predominant charge types of SXO. If the increase of k_f with decreasing [H] is attributed to the three charge types of the ligand, k_f is expressed as

$$k_f = \frac{k_{13}[H]^2+k_{14}K_3[H]+k_{15}K_3K_4}{[H]^2+K_3[H]+K_3K_4}$$

The plot of $k_f\times([H]^2+K_3[H]+K_3K_4)$ against [H] should show a second order increase, but shows a decrease as shown in Fig. 9. Therefore the reaction mechanism involving only $In(OH_2)_n^{3+}$ should be excluded, and the hydrolysis of $In(OH_2)_n^{3+}$ must be taken into account. The rate constant k_f is expressed

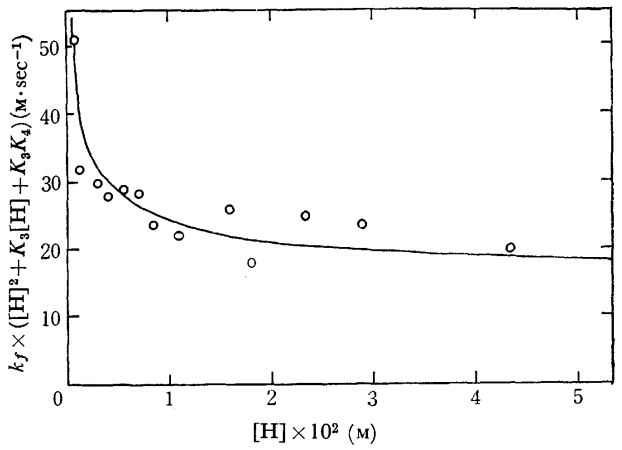

Fig. 9. Plot of $k_f([H]^2+K_3[H]+K_3K_4)$ *vs.* hydrogen ion concentration for In(III)-SXO at 25.0°C and ionic strength 0.1.

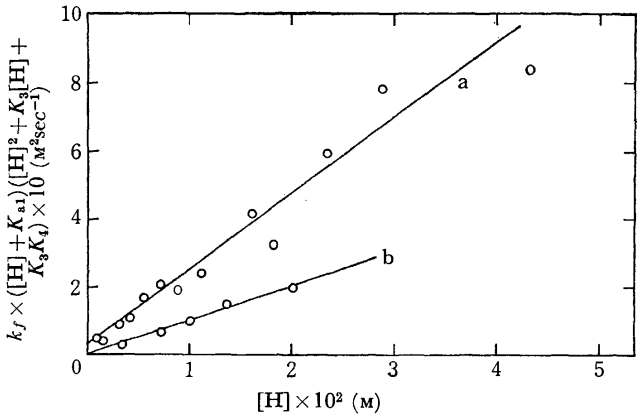

Fig. 10. Plot of $k_f([H]+K_{a1})([H]^2+K_3[H]+K_3K_4)$ *vs.* hydrogen ion concentration for In(III)-SXO at 25.0°C and ionic strength 0.1 (a) and 2.0 (b).

by the same equation as given for Ga(III). In Fig. 10, $k_f\times([H]+K_{a1})([H]^2+K_3[H]+K_3K_4)$ is plotted against [H]. The linearity of the plot is also interpreted by the same assumption as made for Ga(III). The values of k_{25}, k_{24}, and k_{15} are 3.1×10^6, 5.0×10^6, and 2.8×10^5M^{-1}sec^{-1} respectively.

In the case of In(III), absorbance of the complex, remains constant for more than 24 hr.

Tl(III)-SXO. The acid dissociation constants of Tl(III) are quite large as compared to Ga(III) or In(III), namely, $K_{a1}=10^{-1.14}$M and $K_{a2}=10^{-1.49}$M (3M $NaClO_4$, 25°C).[12] Measurements were necessarily made at high hydrogen ion concentrations, and ionic strength was adjusted to 2.0. Under the experimental conditions, H_5SXO^+, H_4SXO, and H_3SXO^- are the predominant charge types of SXO, and we neglected the contribution of $Tl(OH)_2^+$. The rate constant k_f is expressed as

$$k_f = [k_{12}[H]^3 + (k_{13}K_2+k_{22}K_{a1})[H]^2 + (k_{14}K_2K_3 + k_{23}K_2K_{a1})[H] + k_{24}K_3K_4K_{a1}]/([H]+K_{a1}) \times([H]^2+K_2[H]+K_2K_3).$$

Figure 11 shows the plot of $k_f\times([H]+K_{a1})([H]^2+K_2[H]+K_2K_3)$ against [H],[16] giving k_{24}, k_{23}, and k_{14}

16) These were calculated on the added acid concentrations.

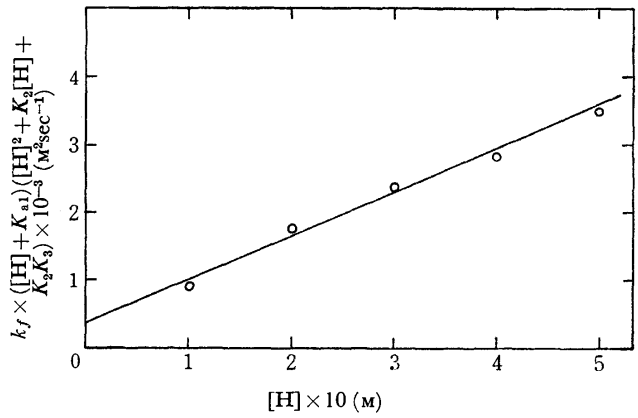

Fig. 11. Plot of $k_f([H]+K_{a1})([H]^2+K_2[H]+K_2K_3)$ *vs.* hydrogen ion concentration for Tl(III)-SXO at 25.0°C and ionic strength 2.0.

as 5.3×10^5, 3.0×10^5, and 7.0×10^5M^{-1}sec^{-1} respectively.

Unlike the case of Ga(III) or In(III), absorbance of the Tl(III)-SXO complex decreases gradually with time. The complex formation of Tl(III) is, however, much faster than the color fading, and the signals obtained on the screen of the oscilloscope are always exponential curves under the experimental conditions. The rate of color fading increases with decreasing hydrogen ion concentration.

Discussion

The non-linearity of the plot k_{obs} against [M(III)] was interpreted in terms of two-step mechanism including pre-equilibrium (Figs. 2 and 3). Apparent pre-equilibrium constant can be obtained from the slope and the intercept of the plot (Figs. 4 and 5), following the Eq. (2). Apparent pre-equilibrium constants for Ga(III)-SXO and In(III)-SXO are in the order of magnitude of 10^2M^{-1}. Although this value of K_p is relatively large, ion pair formation constant for 2+ and 2− ions is expected to be of the same order.

It will be difficult to discuss this apparent value of K_p precisely, because the rate equation is not so simple as Eq. (2), when several charge types of the ligand and the metal ions are taken into account; K_p is a function of [H] and k_f is not simply a product of K_p and a constant.

Only the rate constants k_{24} can be discussed among the three metal ions.[17] The order of the values of k_{24} is $InOH^{2+}>TlOH^{2+}>GaOH^{2+}$. The value of k_{24} for Tl(III) is obtained at ionic strength 2.0, whereas that for Ga(III) or In(III) is at ionic strength 0.1. Kinetic measurements for In(III) were also made at ionic strength 2.0. The results are shown in Fig. 10. The concentrations of hydrogen ion were determined by calibrating the measured pH values from ionic strength 2.0 ($NaClO_4$) to 0.1.

17) The value of k_{24} is indistinguishable from k_{15} as mentioned above, but it seems probable that k_{15} may be neglected. Generally speaking, the rate constants for MOH^{2+} are roughly 10^2 times larger than those for M^{3+} for the same charge type of ligands, as is shown for Fe(III).[14] The values of k_{15} obtained above are close to those of k_{25}. This will be improbable.

TABLE 1. KINETIC RESULTS FOR THE COMPLEX FORMATION OF Ga(III), In(III), AND Tl(III) WITH SXO, AT 25.0°C

	k_{25} M^{-1} sec^{-1}	k_{24} M^{-1} sec^{-1}	k_{15} M^{-1} sec^{-1}	k_{23} M^{-1} sec^{-1}	k_{14} M^{-1} sec^{-1}	I
Ga(III)	1.2×10^4	1.1×10^3	(6.9×10^2)			0.1
In(III)	3.1×10^6	5.0×10^6	(2.8×10^5)			0.1
	10^6	2.2×10^6	(1.3×10^5)			2.0
Tl(III)		5.3×10^5		3.0×10^5	(7.0×10^5)	2.0

In spite of the high $NaClO_4$ concentration, the pseudo-first-order rate constants k_{obs} are at most three times less than those obtained at ionic strength 0.1 and the results are summarized in Table 1. The order of the values of k_{24} is still that described above, namely, $InOH^{2+}>TlOH^{2+}>GaOH^{2+}$.

As SXO is a multidentate ligand, the complex formation process consists of several steps. The outer-sphere complex must be formed first, regardless of the successive mechanism. An inner-sphere coordinated water molecule is substituted by one of the coordinating groups of SXO next. The dissociation of the water molecule is the rate-determining, if the complex formation proceeds following the Eigen-Tamm mechanism.[1] It seems probable that the first coordination to the metal occurs through one of the carboxyl groups of SXO. The other carboxyl group, the nitrogen of the imino group and the oxygen of the phenol or quinone coordinate to the metal successively. If the pre-equilibrium constant K_p discussed above does not correspond to the ion-pair formation constant, the intermediate M(III)···L must be some species formed in these steps. As the coloration of the complex will be resulted from the coordination of the oxygen of the phenol or quinone which is directly connected with the π electron system of the ligand, the intermediate must be formed before the coordination of the phenol oxygen. Then the rate-determining step which may be S_N1 or S_N2 follows; for example the slow cleavage of the hydrogen bond between the imino nitrogen and the phenolic or the quinone oxygen was expected. The measurements of the rate of the proton dissociation reaction was tried by means of the temperature-jump technique. But no signal was observed in our experiment.

Kinetic data to date for trivalent d^{10}-system ions are summarized in Table 2. It is reported that the complex formation of Ga(III) proceeds *via* S_N2 mechanism.[4,5] Dividing the rate constant k_{25} for Ga(III)-SXO by ion-pair formation constant K_{ip}, that is assumed to be 80,[18] yields 10^2 sec^{-1}, which is less than the rate constant of the water exchange reaction. The rate constant for Ga^{3+} is lower than that for $GaOH^{2+}$ and then is much lower than that for water substitution reaction of Ga(III). This large difference between the water substitution and the complex formation rate for Ga(III) does not conflict with the S_N2 mechanism. But the fact that the complexing rate for Ga^{3+} is lower than that for $GaOH^{2+}$, which is also observed in the case of the complex formation with SO_4^{2-}, is inconsistent with the S_N2 mechanism from a coulombic point of view.

The complexing rate of $InOH^{2+}$ with SO_4^{2-} is reported to be $2.5\times10^7M^{-1}sec^{-1}$.[4] Assuming the ion-pair formation constant to be $80M^{-1}$, the rate of substitution is $3\times10^5sec^{-1}$.

The complexing rate of In^{3+} with murexide is reported to be $2\times10^6M^{-1}sec^{-1}$.[3] As the measurements are carried out at relatively high pH of 3.0—4.4, the contribution of $InOH^{2+}$ must be large. Attributing this rate constant to that for $InOH^{2+}$, and assuming the ion-pair formation constant to be $5M^{-1}$, first-order rate constant is 4×10^5 sec^{-1}. Estimating the value of ion-pair formation constant for k_{25} and k_{24} to be $80M^{-1}$ and $5M^{-1}$ respectively, we obtain the first-order rate constants 4×10^4 sec^{-1} and 1×10^6 sec^{-1} for k_{25} and k_{24} respectively. So the first-order rate constant for $InOH^{2+}$ is about 10^5 sec^{-1} in every case.

So far as we know, no data have been reported for the rate of complex formation of Tl(III). If the situations for $TlOH^{2+}$ is the same as those for $InOH^{2+}$ mentioned above, *viz.*, the elimination of the coordinated water molecule from the metal ion plays an important role, ionic radius will be a measure of coulombic factor of water elimination. But in effect the order of reactivity is different from that of ionic radius: despite of its larger ionic radius Tl(III) reacts relatively slowly as compared to In(III). This phenom-

TABLE 2. RATE CONSTANTS REPORTED FOR THE COMPLEX FORMATION OF Ga(III) AND In(III) WITH VARIOUS LIGANDS

M(III)	Ga(III)				In(III)			
Ligand	MTB[a] M^{-1} sec^{-1}	SO_4^{2-} [b] M^{-1} sec^{-1}		OH_2[c] sec^{-1}	Murexide[d] M^{-1} sec^{-1}		SO_4^{2-} [b] M^{-1} sec^{-1}

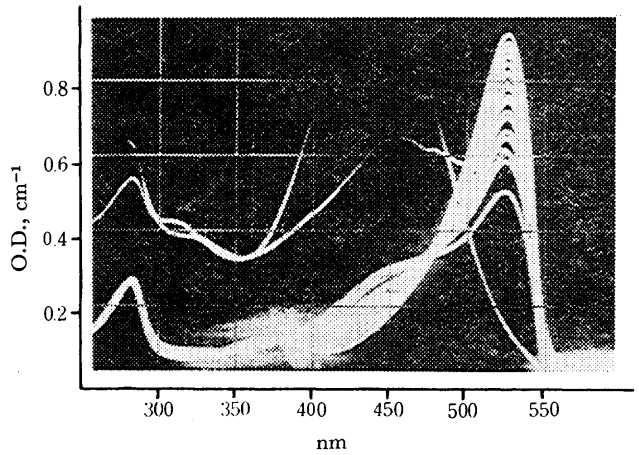

Fig. 12. Change in absorption spectra of Ga(III)-SXO during *ca.* 5 sec after mixing measured by the rapid-scan spectrometer. Each scan needs 300 msec. $[Ga(III)]_0=2.1\times10^{-3}$ M, $[SXO]_0=2.0\times10^{-5}$ M, pH=1.60, ionic strength 0.1, 25.0°C.

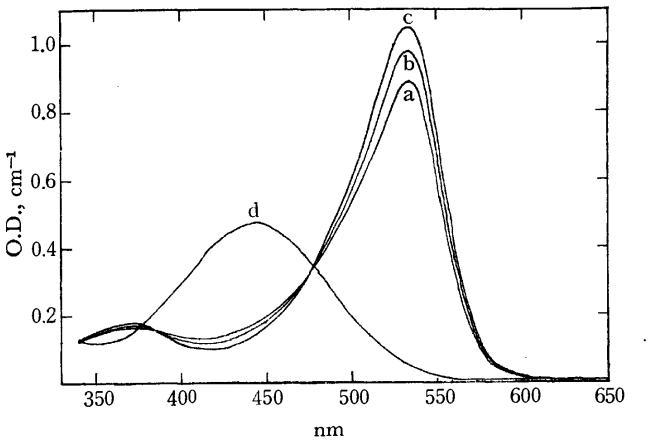

Fig. 13. Slow spectral change of Ga(III)-SXO system at (a): 2 min, (b): 20 min and (c): 600 min after mixing under the same conditions as those in Fig. 12, and (d): the spectrum of SXO.

enon may have some relation with the large electron affinity, large acid dissociation constant and relatively large hydration energy of Tl(III). All these properties are interpreted by the large electron attractive force of thallium(III) ion.

The slower increase in absorbance of Ga(III)-SXO complex after the rapid increase is an interesting phenomenon. Figures 12 and 13 show the change of absorption spectrum of Ga(III)-SXO system measured with a rapid-scan spectrophotometer and that measured with a usual spectrophotometer respectively. Isosbestic points are found at 340, 380, and 475 nm in both spectra, and no significant shift of spectra is observed. These results lead us to the mechanism involving only one final product and some slow processes for some of the reaction components. It would be reasonable to assume that some polymerized or aggregated forms of the reactants may cause such very slow process, though it was not experimentally ascertained. The similar slow processes were also observed in the complex formation between trivalent iron and SXO.

The slow decrease in absorbance in the visible region of Tl(III)-SXO complex is due to the oxidation of SXO by Tl(III), since the similar color fading were also found with the oxidizing agents as Fe(III), Co(III), and Ce(IV), and by anodic oxidation.

The authors wish to thank Professor H. Baba, Research Institute of Applied Electricity of our University, for his permission to use the rapid-scan spectrometer.

Ultraviolet and Infrared Spectra of Cupferron and Neocupferron

Tetsuhiko YOSHIMURA, Chie MIYAKE, and Shosuke IMOTO

Department of Nuclear Engineering, Faculty of Engineering, Osaka University, Suita, Osaka

(Received September 6, 1971)

N-nitroso-*N*-phenylhydroxylamine, *N*-nitroso-α-naphthylhydroxylamine, and their sodium salts have been prepared from the ammonium salt of *N*-nitroso-*N*-phenylhydroxylamine (cupferron) and the ammonium salt of *N*-nitroso-α-naphthylhydroxylamine (neocupferron) respectively. The measurements of the UV spectra in solution and the IR spectra with Nujol mull have been carried out on these compounds, including their ammonium salts. The solvent effect and the deuteration effect on the IR spectra have also been examined for the compounds with a hydroxyl group. The formation of a rather strong hydrogen bonding in these aromatic nitrosohydroxylamines has been confirmed from the deuteration effect on the IR spectra and from the solvent effect on the UV and IR spectra. These compounds and their salts have shown the absorption band considered to be a charge-transfer band in the UV spectra, and they have also shown the N=O stretching mode between 1450 and 1468 cm^{-1} corresponding to those of nitrosamines in the IR spectra with the HCB mull.

Ammonium salts of *N*-nitroso-*N*-phenylhydroxylamine and *N*-nitroso-α-naphthylhydroxylamine, which are called cupferron and neocupferron respectively, are well known as analytical reagents for various metallic ions, such as those of transition elements and rare earth elements.[1] They coordinate the metallic ion as a bidentate ligand, forming a chelate which is less soluble in water. In spite of their usefulness, however, few investigations have been made on the molecular structure and the spectroscopic properties of these compounds. For cupferron, some data on the ultraviolet and infrared spectra were reported by Piskorz and Urbanski, but without any detailed analysis.[2] On the other hand, the spectroscopic properties of other *N*-nitroso compounds, nitrosamine and nitrosohydroxylamine have been investigated by many workers. Haszeldine *et al.* carried out a systematic study of the ultraviolet and infrared spectra of *N*-nitroso compounds, and pointed out that the $n\rightarrow\pi^*$ band of the nitroso group usually observed with nitrosamines was absent in the ultraviolet spectra of *N*-alkyl-*N*-nitrosohydroxylamine.[3,4] Bellamy *et al.* and Williams *et al.* investigated the solvent effect of infrared absorption bands for various nitrosamines and assigned some absorption bands to the N=O, N–N, and C–N stretching vibrations.[5,6] Because there is a possibility of inter- or intra-molecular hydrogen bondings between the nitroso group and the hydroxyl group in nitrosohydroxylamines, the ultraviolet and infrared spectra may be very complicated.

The present paper will report on the ultraviolet and infrared spectra of cupferron, neocupferron, and related compounds, as well as on the deuteration effect for the hydroxyl group in *N*-nitrosophenylhydroxylamine and the solvent effect in various organic solvents on the infrared spectra.

Experimental

Materials. Cupferron, which will be designated by NH_4cupf hereafter (Nakarai Chemicals, Ltd., GR grade), was purified by recrystallization from methanol. Neocupferron, which will be designated by NH_4ncupf hereafter (Fluka AG. Buchs SG, Switzerland), was purified by recrystallization from a mixed solvent of methanol and ethyl ether. Since cupferron, neocupferron, and related compounds gradually decomposed in air and in solution at room temperature, all the operations during the syntheses and purification were carried out with the solutions kept at the temperature of ice. All the other reagents were of a GR grade and were used without further purification.

N-*Nitroso*-N-*phenylhydroxylamine (Hcupf)*: Ten milliliters of a 6N hydrochloric acid solution was added to an aqueous solution of NH_4cupf (10 g in 100 m*l* of H_2O). The white-colored precipitant was filtered and repeatedly washed with water. The product was purified several times by recrystallization from acetone and dried in a vacuum. The Hcupf thus obtained was very soluble in organic solvents, but was only slightly soluble in water. The Hcupf was very unstable in both air and organic solvents at room temperature.

Found: C, 51.88; H, 4.18; N, 20.29%. Calcd: C, 52.18; H, 4.38; N, 20.21%.

N-*Nitroso-α-naphthylhydroxylamine (Hncupf)*: The preparation of Hncupf was carried out in the same way as in the case of Hcupf. Hncupf was thus obtained as faint yellow-colored crystals and was less stable than Hcupf. The solubility of Hncupf in a solvent was found to be nearly same as that of Hcupf.

Found: C, 65.21; H, 4.14; N, 14.08%. Calcd: C, 63.82; H, 4.29; N, 14.89%.

Na Salt of Hcupf (Nacupf): NH_4cupf (1.6 g) was dissolved in a 1N NaOH solution (10 m*l*). The solution was heated for several hours at about 80°C and then cooled to room temperature. The white crystals thus precipitated were then recrystallized from a water-acetone mixed solvent. The Nacupf was very soluble in water, but was insoluble in organic solvents.

Found: C, 45.18; H, 3.13; N, 17.37%. Calcd: C, 45.01; H, 3.15; N, 17.50%.

Na Salt of Hncupf (Nancupf): The preparation of Nancupf was carried out in the same way as in the case of Nacupf. This salt was recrystallized from acetone. The Nancupf, obtaned as faintly-yellow-colored crystals, was very soluble in water, slightly soluble in polar organic solvents, such as acetone and methanol, and insoluble in non-polar solvents. The Nancupf was slightly hygroscopic. From the results of

chemical analysis and infrared spectroscopy, this salt was confirmed to be a hydrate.

Found: C, 55.13; H, 3.25; N, 12.98%. Calcd for Nancupf·$\frac{1}{2}H_2O$: C, 54.80; H, 3.68; N, 12.78%.

Deuteration of Hcupf. The deuteration of Hcupf was carried out by recrystallizing Hcupf seven times from an acetone-D_2O mixed solvent in an argon gas atmosphere while cooling in ice water. Before the deuteration, the acetone was dried by bubbling in argon gas. The product thus obtained was, however, partly deuterated Hcupf. D_2O (99.5%) by E. Merck was used.

Measurements. The ultraviolet spectra and infrared absorption spectra were recorded on a HITACHI ESP-3T type and a HITACHI-PERKIN-ELMER Model 225 type IR grating spectrophotometer respectively, where Nujol mull, HCB mull, and solution techniques were used. Most of the solvents in the UV and IR measurements were spectrograde reagents (E. Merck and Nakarai Chemicals, Ltd.). Since both the Hcupf and Hncupf were very unstable in solutions, it was impossible to determine the concentration of the solution in the IR measurements. Deuterated Hcupf was treated in a N_2 atmosphere.

Results and Discussion

UV Spectra. The ultraviolet spectra of Hcupf and Nacupf are shown in Figs. 1 and 2 respectively. In Table 1 are tabulated the wavelengths and molar extinction coefficients of the absorption maxima and minima observed with various solvents. The absorption spectra of Nacupf and NH_4cupf are similar to each other, but are different from those of Hcupf. The 290 mμ band observed with Nacupf and NH_4cupf shifts to 260 mμ for Hcupf, and the 220 mμ band of the former shifts to a shorter wavelength for the latter, where the band appears as a shoulder. The 220 mμ band of Nacupf and NH_4cupf and the 260 mμ band of Hcupf do not show any remarkable solvent effects, but the 290 mμ band of the former is sensitive to solvents, *i.e.*, it shows a blue shift with the change of the solvent from

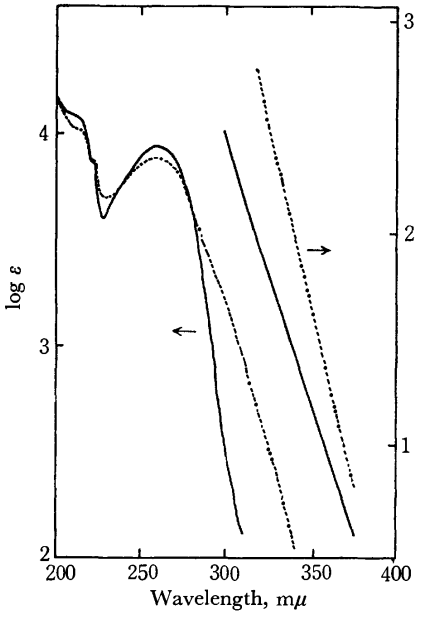

Fig. 1. UV spectra of Hcupf in *n*-heptane (——) and in methanol(- - - - -).

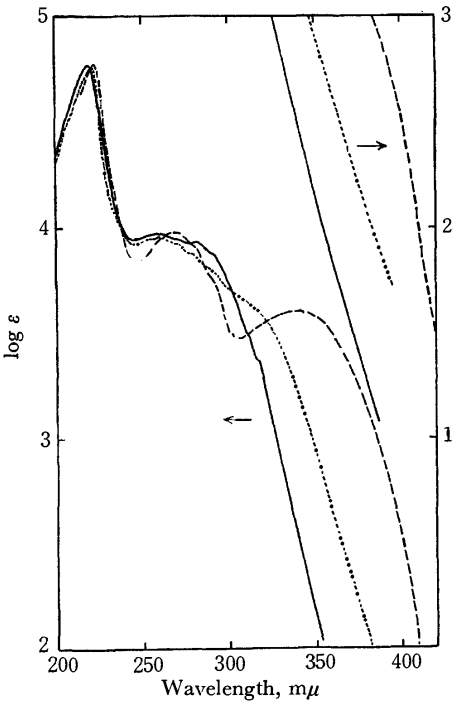

Fig. 2. UV spectra of Nancupf in water(——), in ethanol (·····), and in tetrahydrofuran(- - - -).

alcohol to water. The 260 mμ band of Hcupf or the 290 mμ band of NH_4cupf and Nacupf is not present in *N*-alkyl-*N*-nitrosohydroxylamine,[3] but it is too intense to be identified as originating only from the $A_{1g}\rightarrow B_{2u}$ transition band of benzene. Since the nitroso group is a strong electron acceptor,[7] and since the hydroxyl group as well as the phenyl ring are electron donors, this band is considered to be essentially a charge-transfer band generally sensitive to solvents. That it is insensitive to solvents for Hcupf is looked upon as being due to the presence of strong hydrogen bonding. The shoulder around the 210 mμ of Hcupf and the 220 mμ bands of NH_4cupf and Nacupf may be assigned to be the $A_{1g}\rightarrow B_{1u}$ transition band of the benzene ring, since it shows little solvent effect.

The spectra of Hncupf, Nancupf, and NH_4ncupf are very similar to each other and may all be considered to originate mainly from the naphthyl group, though the 339 mμ band for Nancupf in THF is not found in the others. The band around 220 mμ corresponds to the $A_{1g}\rightarrow E_{1u}$ transition; the band around 280 mμ with a structure to the $A_{1g}\rightarrow B_{1u}$ transition, and the 329 mμ band observed as a shoulder, to the $A_{1g}\rightarrow B_{2u}$. Though Hncupf is also considered to form hydrogen bonding, its effect upon the UV absorption spectra is not observed. For Nancupf and NH_4ncupf, a new band appears as a shoulder around 310 mμ when they are dissolved in ethanol; for Nancupf, this band is shifted to a longer wavelength as the polarity of the solvent decreases, finally resolving into a single peak at 339 mμ with THF. This band is considered to correspond to the 260 mμ band of Hcupf and can be assigned to the charge-transfer band. Thus the bands around 280 mμ

a) The spectra of these compounds exhibited a structure between about 260 and 300 mμ, and in the table their absorption maxima are shown.
"str." is an abbreviation for the appearance of a structure in the absorption band.

of Hncupf, NH_4ncupf, and Nancupf seem to consist of the $A_{1g} \rightarrow B_{1u}$ transition of naphthalene superposed on the charge-transfer transition.

The Lack of $n \rightarrow \pi^*$ Bands in the UV Region. Hcupf and its salts are white in the polycrystalline state and colorless in solution. Hncupf and its salts are faintly yellow both in the polycrystalline state and in solution. *C*-nitroso compounds are also colorless or pale yellow in the crystalline form, in which they exist as a dimer, but their monomer in solution is green or blue. Most of the nitrosamine derivatives are known to be yellow in the liquid state.[3,4] The color of the monomer *C*-nitroso compounds and nitrosamine derivatives originates from the $n \rightarrow \pi^*$ transition bands of the nitroso group, which are observed in the nitrosamine derivatives around 350 mμ and in the monomer of *C*-nitroso compounds around 700 mμ.[8,9] Generally, in *N*-nitroso compounds there was no absorption band corresponding to the 700 mμ band appearing in monomer *C*-nitroso compounds, a band which is interpreted as one of the $n \rightarrow \pi^*$ transition bands that originate from the excitation of a non-bonding electron of the nitrogen atom to the anti-bonding π^* orbital. In order to explain this phenomenon, Haszeldin assumed that the non-bonding electron of the nitrogen atom in the nitroso group might be used to form the dimer, just as in the case of the dimer of *C*-nitroso compounds.[3,4] The presence of dimers in *N*-nitroso compounds, however, has been denied by Williams *et al.* and by Layne *et al.* on the basis of IR and UV measurements respectively.[6,10] Since it is impossible for cupferron, neocupferron, and their salts to be dimerized at the nitrogen atoms of nitroso groups because of the steric hindrance, the $n \rightarrow \pi^*$ transition band near 700 mμ could appear according to the assumption by Haszeldin *et al.* Nevertheless, no absorption bands are observed near 700 mμ in these compounds, just as in the case of other *N*-nitroso compounds.

In the spectra of Hcupf, Hncupf, and their salts, the $n \rightarrow \pi^*$ transition band around 350 mμ is also absent, although it is usually observed in nitrosamine derivatives. As for the reason why this is absent in the spectra of *N*-nitrosohydroxylamine, Haszeldin *et al.* suggested the possibility of inter- or intra-molecular hydrogen

bonding.[3] As will be discussed later, Hcupf and Hncupf are considered to form hydrogen bonding, but in Nacupf and Nancupf there is no possibility of forming hydrogen bonds. As a reason for the absence of the $n\rightarrow\pi^*$ transition band for *N*-nitrosohydroxylamine, there seems to be a possibility that the $n\rightarrow\pi^*$ band may be hidden by the intense bands of the shorter-wavelength side.

The Hcupf is very unstable in organic solvents; for example, it gradually decomposes into the green solution of *C*-nitroso compounds, meanwhile forming some colorless gas and a water-soluble precipitant. This solution exhibits absorption maxima at 283 mμ, 305 mμ, and 760 mμ, showing the formation of nitrosobenzene.[11,12]

It may be considered, therefore, that the strength of the N–N bond in Hcupf is relatively week.

IR Spectra. In Figs. 3—5 are shown the IR spectra of Hcupf, Hncupf, and partly deuterated Hcupf respectively. The peak wave numbers of the IR spectra and the tentative assignments of each band are tabulated in Table 2. All the compounds exhibited absorption bands corresponding to the vibrations of the aromatic ring, such as 690 and 750 cm^{-1} of the CH out-of-plane deformation, characteristic of the mono-substituted benzene. Particularly in the region between 1700 cm^{-1} and 1000 cm^{-1}, however, the spectra were very complicated by possible interactions between the substituent vibration and the aromatic-ring vibration. In this region, the spectra of the ammonium salts and sodium salts were very similar to each other, but the spectra of compounds with hydroxyl groups were different from those of the salts, just as was observed in the UV spectra. In the frequency region higher than 1700 cm^{-1} these appeared intense bands originating from the vibrations of CH stretching (benzene) and OH stretching, and from the NH_4^+ ion vibrations, which will be discussed later. Since Hcupf and Hncupf are soluble in various organic solvents, the measurement for solvent effects was carried out; the data obtained for the main peaks are shown in Tables 3 and 4, where it may be seen that most absorption peaks either shift to a slightly lower wave number side with the increasing polarity of solvents or are insensitive to solvents.

The bands around 1460 cm^{-1} and 1060 cm^{-1} of Hcupf and its salts were assigned to the N=O and the N–N stretching modes respectively, analogously with those of the nitrosamines. These bands of Hcupf were observed on a higher frequency side than the corresponding ones of Nacupf and NH_4cupf, and they scarcely shifted with the polarity of the solvents. This behavior is different from that of the nitrosamines, in which $\nu_{N=O}$ shifts to a lower frequency, and ν_{N-N}, to a higher frequency, with the increasing polarity of

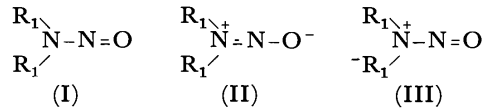
a) The polarity of the solvent increases from cyclohexane to methylene iodide.

Table 4. Frequencies, cm^{-1}, of Hncupf in various solvents

Solvent[a)]								
Carbontetrachloride	1448	1250	1074	1062	998	912	—	656
Carbondisulfide	—	1254	1074	1062	998	911	766	656
Methylenebromide	1436	—	1070	1059	999	912	769	—
Methyleneiodide	1435	1252	—	—	998	912	768	657

a) The polarity of the solvent increases from carbon tetrachloride to methylene iodide.

solvents. According to Williams *et al.*,[6] the solvent effect of nitrosamines can be explained by assuming the following resonance structures:

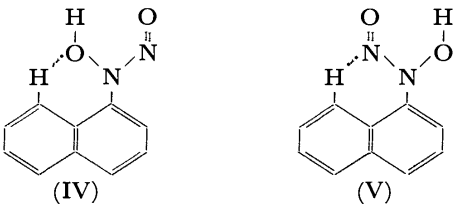


(I) (II) (III)

If the polarity of the solvents increases, the contribution of the structure II will increase, thus giving rise to a lowering of the frequency of N=O stretching vibration and a raising of the frequency for N–N. The reason why Hcupf, contrary to the case of nitrosamines, did not exhibit the solvent effect is considered to be that the relatively strong hydrogen bonding in Hcupf leading to a dimer may exclude the resonance structures which are sensitive to solvents. The large shift of the strong band assigned to the N–N=O deformation mode from 581 cm^{-1} for NH_4cupf and from 584 cm^{-1} for Nacupf to 647 cm^{-1} for Hcupf could also be due to the formation of hydrogen bonding in Hcupf.

In the partly-deuterated Hcupf, the intensity of the broad absorption bands at 713 and 743 cm^{-1} of Hcupf, which are absent in NH_4cupf and Nacupf, is much decreased and strong new broad bands are found at 531 and 548 cm^{-1}. Thus the bands at 713 and 743 cm^{-1} can be assigned to the γ_{OH} mode, and those at 531 and 548 cm^{-1}, to the γ_{OD} mode. The new band at 1030 cm^{-1} can be attributed to the δ_{OD} mode, and the corresponding δ_{OH} band, which is expected to appear near 1400 cm^{-1}, is observed as a shoulder at 1397 cm^{-1}. Deuteration also affects the frequency of the N–O stretching vibration, which appears as a strong and characteristic band at 922 cm^{-1} in Hcupf (at 907 cm^{-1} in NH_4cupf and Nacupf). In the deuterated Hcupf, the intensity of the band at 922 cm^{-1} was decreased and at 873 cm^{-1} there was found a strong new band which was considered to be the N–O band shifted to a lower frequency by the deuteration. A new band found at 1153 cm^{-1} has not yet been assigned.

In Hncupf and its salts, the bands of the CH out-of-plane deformation, being characteristic of α-substituted naphthalene, are found around 800 cm^{-1} and 750 cm^{-1}. The band at the former wave number is due to three adjacent ring hydrogen atoms, while the band at the latter is due to four adjacent ring hydrogen atoms. Each band of them is split into two or three subbands in the spectra measured with Nujol mull. As the splitting of the band around 800 cm^{-1} was observed even in the CS_2 solution, this splitting is considered not to be due to the inter-molecular interaction, but it may originate from the interaction between a ring hydrogen and substituents as follows:



(IV) (V)

The bands around 1450 cm^{-1} and 990 cm^{-1} can be assigned to the N=O and N–N stretching modes respectively, just as in the case of cupferrons. In the neocupferrons, the band of N=O stretching mode is lowered in frequency and decreased in intensity compared to that of cupferrons. This behavior may be explained by a weakening of the double-bond character due to the increase in the electron-accepting property of the naphthyl group and the contribution of the structure V. The band of the N–O stretching mode is found around 900 cm^{-1} at nearly the same wave number as in the cases of the Hcupf and its salts.

IR Spectra in the Frequency Region Higher than 1700 cm^{-1}. Figure 6 shows the spectra of Hcupf and deuterated Hcupf between 2000 and 3500 cm^{-1} as measured with the HCB mull and in a CCl_4 solution. The broad band of Hcupf observed with the maximum at 2980 cm^{-1} (solid) can be assigned to the bonded OH stretching mode. In the deuterated Hcupf it is weakened, however, and a new band is found with maxima around 2240 and 2260 cm^{-1}. Both bands can be assigned to the bonded OD stretching mode. In a CCl_4 solution these ν_{OH} and ν_{OD} bands shift to a lower frequency side by 70 cm^{-1} and 100 cm^{-1} respectively. In the Hncupf, however, the broad band with the maximum at 2910

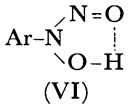
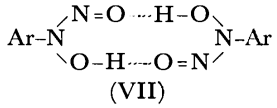
a) X=H or D, b) A=solid, B=solution in CCl_4, c) Solution in CS_2.

cm^{-1} (solid), which corresponds to the 2980 cm^{-1} band of Hcupf, shifts to a frequency lower by only 10 cm^{-1} in CS_2 solution. The free OH stretching band was not found for either Hcupf or Hncupf not only in non-polar solvents, such as CCl_4 and CS_2, but also in proton donor solvents, such as $CHCl_3$ and $CHBr_3$. Since no change was ever observed with the bands related to the substituent in the proton-donor solvents, these compounds are considered not to form hydrogen bonding with solvents. Besides, the ν_{OH} bands are observed at relatively lower frequencies (2980 cm^{-1} for Hcupf), and the strong broad band of γ_{OH} mode is found at relatively higher frequencies (730 cm^{-1} for Hcupf and 685 cm^{-1} for Hncupf), so it is reasonable to conclude that Hcupf and Hncupf form a considerably strong hydrogen bonding, as is also to be expected on the basis of UV spectra and from the solvent effect upon the IR spectra in the frequency region lower than 1700 cm^{-1}. At present it is impossible to determine whether the hydrogen bonding is an intra-molecular type (VI) or an inter-molecular association type (VII), but the bimolecular type is considered to be more reasonable, as the stronger hydrogen bonding is sterically favored.



(VI)



(VII)

The absorption bands related to hydrogen bonding for Hcupf, deuterated Hcupf, and Hncupf are summarized in Table 5.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1430—1433(1972)

Spectrophotometric Study on The Extraction of The Ternary Complex Composed of Cobalt(II), 8-Hydroxyquinoline-5-sulphonic Acid and Zephiramine

Tomihito KAMBARA and Masao SUGAWARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received November 30, 1971)

8-Hydroxyquinoline-5-sulphonic acid (H_2QS) reacts with cobalt(II) in the presence of zephiramine (tetradecyl-dimethyl-benzyl-ammonium chloride) and gives a yellow green association complex. The ternary complex having an absorption maximum at 405 nm can be extracted into chloroform at pH 6.8—9.3. Beer's law holds for 2.73—33.0 μg of cobalt(II); molar absorptivity, 1.39×10^4 $cm^{-1}mol^{-1}l$. The composition of cobalt(II)-H_2QS complexes in water is 1:1 at pH 4.4, 1:2 at pH 5.8, and 1:3 at pH 7.6. The composition of the ternary complex is estimated to be $[Co^{2+}(QS^{2-})_2(HQS^-)(Z^+)_3]_o$. The equilibrium constant for the extraction

$$K=\frac{[Co^{2+}(QS^{2-})_2(HQS^-)(Z^+)_3]_o}{[Co^{2+}][(HQS^-Z^+)]_o^3[OH^-]^2}$$

was determined. It was found that $\log K=29.01\pm1.86$.

The solvent extraction of the ion-pair formed by the interaction of 8-hydroxyquinoline-5-sulphonic acid-metal chelate anions with cation of zephiramine (tetradecyl-dimethyl-benzyl-ammonium chloride) has been applied to the spectrophotometric determination of iron(III),[1] nickel(II),[2] and copper(II).[3] Matsuo *et al.*[4] proposed the extraction of thiocyanatocobaltate(II) complex anion with zephiramine into chloroform. In this paper, fundamental conditions for the spectrophotometric determination of cobalt(II) and the composition of the ternary complex formed are discussed: 8-hydroxyquinoline-5-sulphonic acid (H_2QS) reacts with cobalt(II)[5,6] and gives a water soluble chelate, which can be extracted into chloroform in the presence of zephiramine (Z^+Cl^-). The intensity of the yellow green coloration with an absorption maximum at 405 nm in chloroform is proportional to the amount of cobalt(II) in the aqueous layer.

Experimental

Reagents. *Cobalt(II) Standard Solution*: 2.3795 g of cobalt chloride (Wako Chemicals Co., guaranteed reagent) was dissolved into 10 m*l* of hydrochloric acid and diluted to 1 liter with deionized water. The solution was standardized with EDTA-titration using murexide as an indicator, and found to contain 586 μg of cobalt(II) per m*l*. The solution was diluted as required.

H_2QS Solution: 1.00×10^{-3}M solution was prepared by dissolving H_2QS (Wako Chemicals Co.) into water.

Zephiramine Solution: 5.00×10^{-3}M solution was prepared by dissolving Dotite zephiramine into water.

Buffer Solutions: Acetate buffer solution, pH 3.4—5.6;

1) T. Kambara, S. Matsumae, and K. Hasebe, *Bunseki Kagaku*, **19**, 462 (1970).
2) T. Kambara, M. Sugawara, and K. Hasebe, *ibid.*, **19**, 1239 (1970).
3) T. Kambara, M. Maeyama, and K. Hasebe, *ibid.*, **20**, 1249 (1971).
4) H. Matsuo, S. Chaki, and S. Hara, *ibid.*, **14**, 935 (1965).
5) C. F. Richard, R. L. Gustafson, and A. E. Martell, *J. Amer. Chem. Soc.*, **81**, 1033 (1959).
6) L. G. Sillén and A. E. Martell, Ed., "Stability Constants of Metal-Ion Complexes," The Chemical Society London (1964), p. 609.

Stock solutions of 0.1M sodium acetate and 0.1M acetic acid were prepared and mixed in appropriate proportions. Phosphate buffer solution, pH 6.3—8.3; Stock solutions of 0.1M disodium phosphate dihydrate and 0.1M potassium phosphate dibasic were prepared and mixed as required. Borate buffer solution, pH 9.1—10.5; 0.1M borax solution was mixed with 0.1M hydrochloric acid or 0.1M sodium hydroxide.

Chloroform and other reagents were all of analytical reagent grade.

Apparatus. Spectrophotometric measurements were carried out with a Shimadzu Model QV-5 spectrophotometer with 10-mm cells. The pH was measured with a Hitachi-Horiba, Model F-5, glass electrode pH meter. A shaker of Iwaki KM was used.

Established Procedure. Take 29.3 μg of cobalt(II) in a 100-m*l* separatory funnel and add 10 m*l* of the H_2QS solution and 3 m*l* of the zephiramine solution. Adjust pH to 7.3—7.5 with 15 m*l* of phosphate buffer solution and dilute to 50 m*l* with deionized water. Add 10 m*l* of chloroform, shake the mixture for 15 min and then allow the layers to separate for 10 min. Draw off the chloroform layer into a beaker containing anhydrous sodium sulphate and transfer the extract into a cell. Measure the absorbance at 405 nm against the reagent blank obtained in the same way.

Results and Discussion

Absorption Spectra. The absorption spectra of the aqueous layer and the organic extract obtained by the above procedure are given in Figs. 1 and 2, respectively. With increasing pH values, the absorption maxima of the cobalt(II)-H_2QS complexes in water shifted to longer wavelengths, *viz.*, 365 nm at pH 4.7, 370 nm at pH 5.3, and 375 nm at pH 7.9.

The ternary complex formed by the interaction of zephiramine with cobalt(II)-H_2QS complex anion had an absorption maximum at 405 nm both in the aqueous and organic layers (Figs. 1 and 2).

The bathochromic effect is probably due to the increment of molecular cross section caused by the combination with zephiramine. An ion-pair of H_2QS with zephiramine was also extracted but the absorbance at 405 nm was very low.

Effect of pH. The aqueous layer containing 29.3 μg of cobalt(II) was adjusted to various pH values and treated by the above procedure. It was found that the extraction of the ternary complex began at pH 3.0 and the pH range for the optimum extraction was 6.8—9.3 with phosphate and borate buffer solutions. Yamamoto[7] and Tôei[8] successfully employed nitrobenzene for the extraction of ion-pairs of tetracyanatonickelate(II) anion with bis(1,10-phenanthroline)iron(II) chelate cation and alkaline metals with picrate anion, respectively. Extraction with nitrobenzene was carried out by the above procedure. The absorbance measurement was made at 430 nm, the wavelength of the absorption maximum of the nitrobenzene extract. The optimum pH range was 7.6—8.3.

Effect of H_2QS Concentration. With the concentrations of cobalt(II) and zephiramine kept constant, various amounts of H_2QS were added and extraction was carried out by the above procedure. The absorbance of the organic layer was found to be constant and maximum in the concentration range 7—30-fold mol of H_2QS to cobalt(II). However, H_2QS in concentration higher than 30-fold of cobalt(II) lowered the absorbance of the extract. Therefore, the H_2QS concentration was kept to 20-fold to cobalt(II).

Effect of Zephiramine Concentration. The zephiramine concentration was varied for a series of extractions while the cobalt(II) and H_2QS concentrations were kept constant. The absorbance of the extract was measured against the reagent blank. It was found that the optimum molar concentration of zephiramine lies in 20—40-fold of cobalt(II). Further addition of zephiramine increases the absorbance of the extract gradually. Thus the concentration of zephiramine was kept to 30-fold of cobalt(II) throughout the procedure.

7) Y. Yamamoto, T. Kumamaru, S. Miura, and S. Kimura, *Nippon Kagaku Zasshi*, **92**, 64 (1971).
8) M. Yamane, T. Iwachido, and K. Tôei, This Bulletin, **44**, 745 (1971).

Effect of Shaking Time. The shaking time was varied from 30 sec to 30 min. Stable and constant absorbance of the extract was found for a shaking time longer than 10 min.

Extractability, Distribution Ratio, and Molar Absorptivity. Extractability under optimum conditions was determined by repetition of the extraction procedure on the same aqueous layer. A 50 m*l* portion of the aqueous layer containing 29.3 μg of cobalt(II) was shaken with 10 m*l* of chloroform. Twenty five milliliters of separated aqueous layer was again shaken with 5 m*l* of chloroform, followed by re-extraction on the 20 m*l* of the aqueous layer with 4 m*l* of chloroform. Absorbances A_1, A_2, and A_3 of each extract in sequence were measured. The extractability is then given by

$$E_{max} = \frac{A_1}{A_1+A_2+A_3} \times 100$$

$$= \frac{0.650}{0.650+0.038+0.002} \times 100 = 94.2\%$$

where A_i is the absorbance of each extract at 405 nm. Thus, distribution ratio D_{max} is

$$D_{max} = \frac{E_{max}}{100-E_{max}} \times \frac{V_w}{V_0} = 69.3$$

Molar absorptivity ε of the ternary complex calculated by using absorbance A_1 and E_{max} is

$$\varepsilon = 1.39 \times 10^4 \text{ cm}^{-1} \text{ mol}^{-1} \, l$$

The molar absorptivity is larger than 8500, that of the oxine complex $CoOx_2(C_4H_9NH_2)_2$.[9] In the case of the extraction with nitrobenzene, 98.5% of cobalt(II) was extracted by one extraction and the distribution ratio was 337.4. However, the molar absorptivity was 1.09×10^4.

Calibration Curve. Varying amounts of cobalt(II) were added to the aqueous layer and extraction was carried out. For the first extract, Beer's law holds for 2.73—33.0 μg of cobalt(II). Sandell's sensitivity for the absorbance of 0.001 is 0.0042 μg/cm^2. The relative standard deviation obtained by 7 measurements was 0.63% for the 29.3 μg of cobalt(II).

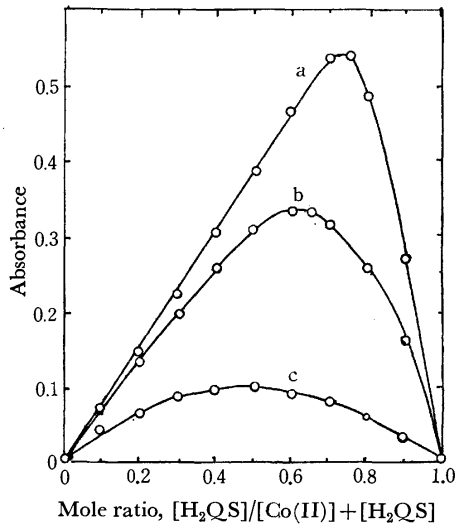

Fig. 3. Continuous variation method applied to Co(II)-H_2QS chelate in water
[Co(II)]+[H_2QS]=2.00×10^{-4}M,
Curve (a) pH 7.6, Wavelength: 375 nm,
(b) pH 5.8, Wavelength: 370 nm,
(c) pH 4.4, Wavelength: 365 nm.

Composition of Cobalt(II)-H_2QS Complexes. The results of continuous variation method (Fig. 3) indicate that molar ratios of H_2QS to cobalt(II) are 1:1 at pH 4.4, 2:1 at pH 5.8, and 3:1 at pH 7.6. The same results were obtained also by the mole ratio method. The results coincide with those by the potentiometric method.[5]

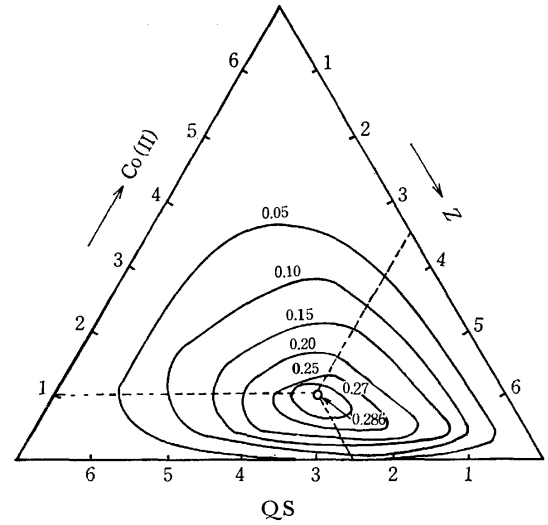

Fig. 4. Continuous variation method applied to the three-component system of Co(II)-QS-Z complex
V_w=50 m*l*, V_0=10 m*l*, [Co(II)]$_w$+[QS]$_w$+[Z]$_w$=7.00×10^{-5}M, pH 7.4, Wavelength: 405 nm,
Reference: Chloroform,
Numerals show the absorbance of organic layer.

Composition of the Ternary Complex. Determination of the composition of the ternary complex in the organic layer was attempted by means of the triangular coordinate method for three-component system.[1-3] The sum of the initial concentrations of cobalt(II), H_2QS and zephiramine in the aqueous layer being kept to 7.00×10^{-5}M, extraction was carried out at 74 points of various compositions. The absorbance of the extract was measured against chloroform. The contours in Fig. 4 show a composition of equal absorbance. The maximum absorbance was obtained in the composition of cobalt(II): H_2QS: zephiramine=1:2.5:3.5. However, results of the continuous variation method applied to the system of the cobalt(II)-H_2QS complex in the presence of excess zephiramine indicated that the composition of the ternary complex was cobalt(II): H_2QS: zephiramine=1:3:3. The same result was also obtained by applying the mole ratio method. We see that the contour which indicates the absorbance of 0.050 partially overlaps the QS-axis (Fig. 4). Deviation of the triangular method from continuous variation and mole ratio methods therefore seems to be due to the effect of absorption by the ion-pair of H_2QS with zephiramine. Thus, the composition of the ternary complex was estimated to be $[Co^{2+}(QS^{2-})_2(HQS^-)(Z^+)_3]_0$.

Equilibrium Constant For Extraction of The Ternary

9) F. Umland, *Z. Anal. Chem.*, **190**, 186 (1962).

Complex. When the ternary complex is extracted into chloroform, the extraction equilibrium is given as follows:

$$Co^{2+} + 3[(HQS^{-}Z^{+})]_o + 2OH^{-} = [Co^{2+}(QS^{2-})_2(HQS^{-})(Z^{+})_3]_o + 2H_2O \quad (1)$$

where suffix o indicates the organic layer. The equilibrium constant K is given by

$$K = \frac{[Co^{2+}(QS^{2-})_2(HQS^{-})(Z^{+})_3]_o}{[Co^{2+}][(HQS^{-}Z^{+})]_o^3[OH^{-}]^2} \quad (2)$$

The initial concentration of cobalt(II) in 50 m*l* aqueous layer is kept at *C, those of H_2QS and zephiramine at 3*C and the pH of the aqueous layer at 7.4, and the layer is shaken with 10 m*l* of chloroform. The absorbance of the organic layer is measured against chloroform after equilibrium is attained. The concentration of the ternary complex in the organic layer C_T is calculated from the molar absorptivity. Equation (2) is then expressed by

$$K = \frac{C_T}{\left[*C - \frac{10}{50}C_T\right]\left[\frac{50}{10}\times 3*C - 3C_T\right]^3[OH^{-}]^2} \quad (3)$$

The results obtained with various values of initial concentration *C are shown in Table I. The logarithm of the equilibrium constant is 29.01±1.86.

Table 1. Equilibrium constant of Co(II)-QS-Z ternary complex shown by Eq. (1)—(3)

*C (M)	Absorbance	C_T (M)	pH	log K
1.0×10^{-5}	0.256	1.84×10^{-5}	7.34	28.15
5.0×10^{-6}	0.095	6.83×10^{-6}	7.35	29.29

The Reaction and Reaction Products of μ-O_2-Dicobalt Ammine Complexes with Nitrites, Thiocyanates, *etc.*[1]

Takashi SHIBAHARA and Masayasu MORI

Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received December 14, 1971)

In a neutral solution $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{4+}$ was found to react with NO_2^- and SCN^- to give $[NO_2(en)_2CoO_2Co(en)_2NO_2]^{2+}$ and $[SCN(en)_2CoO_2Co(en)_2NCS]^{2+}$ respectively, without causing any cleavage of the O_2-bridge, while in an acid solution it was found to be oxidized by NO_2^- to a μ-superoxo (O_2^-) complex ion, $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{5+}$. The latter is not affected by NO_2^-, in contrast with $[(en)_2Co(\mu\text{-}NH_2,O_2)Co(en)_2]^{4+}$, in which the O_2^--bridge is replaced by an NO_2^--bridge. The $[NO_2(en)_2CoO_2Co(en)_2NO_2]^{2+}$ formed as described reacts with CN^- to give $[Co_2(CN)_6(en)_2O_2]^{2-}$. The EPR spectra of some new μ-superoxo complexes which were synthesized by oxidizing some of the above μ-peroxo complexes were measured and compared with those of similar complexes. Infrared and electronic spectra were also taken.

The reactions of binuclear complexes of cobalt, in which two cobalt atoms are connected by both NH_2 and O_2 ligands, have been studied by many investigators, and various specific features have been found, as is shown by the following examples:

$$[(NH_3)_4Co^{NH_2}_{O_2}Co(NH_3)_4]^{4+} \xrightarrow[H^+]{NO_2^-}$$

μ-superoxo, green

$$[(NH_3)_4Co^{NH_2}_{NO_2}Co(NH_3)_4]^{4+} \quad (1)^{2}$$

orange

$$[(NH_3)_4Co^{NH_2}_{O_2}Co(NH_3)_4]^{4+} \xrightarrow[H^+]{SO_3^{2-}}$$

μ-superoxo, green

$$[(NH_3)_4Co^{NH_2}_{SO_4}Co(NH_3)_4]^{3+} \quad (2)^{3}$$

reddish violet

The reactions of the $[(NH_3)_5CoO_2Co(NH_3)_5]^{n+}$ complexes (n=4, 5), containing an O_2 single bridge, were also studied; in this case, the cleavage of the O_2-bridge and the formation of a mononuclear cobalt(III) ammine complex and/or a cobalt(II) ion is the usual mode of reaction:

$$[(NH_3)_5CoO_2Co(NH_3)_5]^{5+} \xrightarrow[H^+]{NO_2^-}$$

μ-superoxo, green

$$[CoOH_2(NH_3)_5]^{3+} + Co^{2+} \quad (3)^{4}$$

$$[(NH_3)_5CoO_2Co(NH_3)_5]^{4+} \xrightarrow[H^+]{}$$

μ-peroxo, brown

$$2Co^{2+} + O_2 + 10NH_3 \quad (4)^{5}$$

However, the last two examples do not seem to depend solely on the nature of the O_2 bridge, since the starting material itself is comparatively unstable. In this respect, the reaction of the more stable single-O_2-bridged

complex, $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{n+}$, was thought to reflect the nature of the O_2 bridge more clearly. Therefore, we started to study the reaction of this complex with nitrites, thiocyanates, sulfites, etc. As a result, several new compounds with a peroxo or a superoxo bridge were obtained; they were examined by various spectroscopic techniques, such as UV, IR, and EPR.

Experimental

Reaction and Preparation. *1. μ-Peroxobis[amminebis(ethylenediamine)cobalt(III)] Triperchlorate Nitrate Dihydrate*: This compound was prepared by the method of Duffy *et al.*[6] Though they described the compound as a tetraperchlorate dihydrate, a definite amount of the nitrate ion has been detected in the sample even after multiple recrystallizations with sodium perchlorate. The nitrate ion was determined as follows: the anions were separated by passing a solution through cation-exchange resin in the Na-form (DIAION SK#1), the nitrate ion was reduced to ammonia using Devarda's alloy, and the ammonia which came over by distillation was titrated.

Found: Co, 14.18; C, 11.73; H, 4.89; N(total), 18.79; NO_3^-, 7.69%. Calcd for $[NH_3(en)_2CoO_2Co(en)_2NH_3](ClO_4)_3\cdot NO_3\cdot 2H_2O$: Co, 14.36; C, 11.71; H, 5.16; N(total), 18.78; NO_3^-, 7.56%.

2. Reaction of $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{4+}$ with NO_2^- in an Acid Solution: Brown μ-peroxobis[amminebis(ethylenediamine)cobalt(III)] triperchlorate nitrate dihydrate was added to an acid solution (0.05N HCl) of sodium nitrite. The solution immediately turned green. The electronic spectrum of the green solution was identical with that of $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{5+}$, which had been prepared by oxidizing the same starting 4+ ion with chlorine gas.

3. Reaction of $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{4+}$ with NO_2^- in a Neutral Solution at Room Temperature: *3·1. Preparation of μ-Peroxobis[nitrobis(ethylenediamine)cobalt(III)] Dinitrate Tetrahydrate*: Thirty-three grams of μ-peroxobis[amminebis(ethylenediamine)cobalt(III)] triperchlorate nitrate dihydrate (2 above) was added to 500 ml of water containing 27 g of potassium nitrite. After this solution had been cooled in an ice bath, it was filtered and the precipitate (mainly potassium perchlorate) was discarded. The brown solution was evaporated almost to dryness using a rotary evaporator, while the temperature was kept at approximately 30°C. The product was washed successively with 50% ethanol, 95% ethanol, and ethyl ether. Yield, 20 g. This product will be named A. On the dissolution of 5 g of A in 80 ml of water at 40°C, followed by filtration and cooling, black crystals were precipitated. These crystals were washed with 95% ethanol and ethyl ether. Yield, 2 g.

Found: C, 14.21; H, 5.87; N, 24.95%. Calcd for $[NO_2(en)_2CoO_2Co(en)_2NO_2](NO_3)_2\cdot 4H_2O$: C, 14.19; H, 5.94; N, 24.80%.

3·2. Preparation of μ-Peroxobis[nitrobis(ethylenediamine)cobalt(III)] Dithionate Pentahydrate: Ten grams of sodium dithionate dihydrate was added to 10 g of A in 1 l of water. The brown precipitate that deposited was collected by filtration and washed successively with cold water, 95% ethanol, and ethyl ether, and then air-dried. Yield, 9.4 g. The sample (1 g) was recrystallized by dissolving it in 2 l of water at 30°C and by then adding 10 g of sodium dithionate dihydrate to the cooled, filtered solution. The brown crystalline material that was thus deposited was collected, washed, and dried as above. Yield, 0.3 g.

Found: Co, 16.38; C, 13.71; H, 5.81; N, 19.45%. Calcd for $[NO_2(en)_2CoO_2Co(en)_2NO_2]S_2O_6\cdot 5H_2O$: Co, 16.09; C, 13.12; H, 5.78; N, 19.15%.

3·3. Preparation of μ-Peroxobis[nitrobis(ethylenediamine)cobalt(III)] Dichloride Tetrahydrate: The A product (1 g; *cf.* 3·1), dissolved in 80 ml of water, was added to the top of the anion-exchange resin, Cl-form (DIAION SA#100), which was then washed with water. The effluent was evaporated to dryness with a rotary evaporator. The brown product was washed with 95% ethanol and ethyl ether. Yield, 0.1 g. It is very soluble in water.

Found: C, 15.91; H, 6.74; N, 22.64%. Calcd for $[NO_2(en)_2CoO_2Co(en)_2NO_2]Cl_2\cdot 4H_2O$: C, 15.37; H, 6.45; N, 22.56%.

4. The Oxidation Product of the μ-Peroxobis[nitrobis(ethylenediamine)cobalt(III)] Complex: *4·1. μ-Superoxobis[nitrobis(ethylenediamine)cobalt(III)] Triperchlorate Dihydrate*: Three grams of brown μ-peroxobis[nitrobis(ethylenediamine)cobalt(III)] dithionate pentahydrate (*cf.* 3·2) was stirred into 200 ml of a 0.2N hydrochloric acid solution, while a slow stream of chlorine gas was bubbled through the solution. As portions of the solid were added, the solution turned green. After about 5 min, the unreacted solid was filtered off and twenty grams of sodium perchlorate monohydrate was added to the ice-cooled filtrate. The green precipitate that deposited was collected by filtration and washed successively with water, 95% ethanol, and ethyl ether. Yield, 1.3 g. To recrystallize, as much of the sample as possible (1 g) was dissolved in 400 ml of water at 25°C, and then 5 g of sodium perchlorate monohydrate was added to the cooled filtered solution. The green crystalline material that was thus deposited was collected and washed as above. Yield, 0.8 g.

Found: Co, 14.25; C, 11.87; H, 4.42; N, 17.49%. Calcd for $[NO_2(en)_2CoO_2Co(en)_2NO_2](ClO_4)_3\cdot 2H_2O$: Co, 14.42; C, 11.78; H, 4.44; N, 17.17%.

4·2. μ-Superoxobis[nitrobis(ethylenediamine)cobalt(III)] Trithiocyanate Dihydrate: This complex was prepared similarly, using sodium thiocyanate instead of sodium perchlorate.

Found: Co, 17.04; C, 19.54; H, 5.25; N, 27.45; S, 14.66%. Calcd for $[NO_2(en)_2CoO_2Co(en)_2NO_2](SCN)_3\cdot 2H_2O$: Co, 17.03; C, 19.10; H, 5.24; N, 26.30; S, 13.88%.

4–3. μ-Superoxobis[nitrobis(ethylenediamine)cobalt(III)] Sesquisulfate Tetrahydrate: Five-tenths of a gram of the triperchlorate dihydrate (4·1 above) was dissolved in 60 ml of 6N sulfuric acid. Five hundred milliliters of ethanol was then stirred into the filtered solution. The green precipitate that was thus deposited was collected and washed successively with 95% ethanol and ethyl ether. Yield, 0.4 g. The sample (0.4 g) was recrystallized by dissolving it in 20 ml of a 0.5N sulfuric acid solution at room temperature and by then adding 50 ml of 95% ethanol to the filtered cooled solution. Yield, 0.2 g.

Found: Co, 16.58; C, 13.73; H, 5.29; N, 19.97%. Calcd for $[NO_2(en)_2CoO_2Co(en)_2NO_2]_2(SO_4)_3\cdot 8H_2O$: Co, 16.87; C, 13.75; H, 5.77; N, 20.05%.

5. Reaction of $[NO_2(en)_2CoO_2Co(en)_2NO_2]^{2+}$ with NO_2^- in a Neutral Solution at a High Temperature. The formation of trans-$[Co(NO_2)_2(en)_2]NO_3$: Twenty milliliters of water containing 0.7 g of μ-peroxobis[nitrobis(ethylenediamine)cobalt(III)] dinitrate tetrahydrate (*cf.* 3·1) and 1 g of sodium nitrite were warmed on a water bath at about 80°C for 2 hr. During the process, water was sometimes supplied. While hot, the solution was filtered, and a little 14N nitric acid was added to the filtered, cooled solution. The yellow crystals that

6) D. L. Duffy, D. A. House, and J. A. Weil, *J. Inorg. Nucl. Chem.*, **31**, 2053 (1969).

were thus deposited were filtered and washed with 95% ethanol and ethyl ether. Yield, 0.3 g.

Found: Co, 17.01; C, 14.38; H, 5.46; N, 29.13%. Calcd for $[Co(NO_2)_2(en)_2]NO_3$: Co, 17.68; C, 14.42; H, 4.84; N, 29.41%. The complex was concluded to be *trans* isomer by a comparison of its electronic spectrum with that of the known sample.

6. Reaction of $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{4+}$ *with* SCN^-: Sixteen and four-tenths grams of μ-peroxobis[amminebis(ethylenediamine)cobalt(III)] triperchlorate nitrate dihydrate was added to a stirred solution of 15.6 g of potassium thiocyanate in 250 m*l* of water. The crude product (14 g) was obtained by the vacuum evaporation of this mixture, as in the case of 3·1. This product was named B. Five grams of B was dissolved in 250 m*l* of water at 40°C, and 50 g of sodium perchlorate monohydrate was added to the cooled filtrate. The brown precipitate that was thus deposited was collected by filtration and washed with 95% ethanol and ethyl ether. Yield, 3.6 g. The sample (3.6 g) was recrystallized by dissolving it in 250 m*l* of water at 40°C and by adding $NaClO_4 \cdot H_2O$ (50 g) to the cooled, filtered solution. The brown crystalline material that was thus deposited was collected and washed as above. Yield, 1.7 g.

Found: Co, 15.18; C, 16.09; H, 5.21; N, 18.36; S, 7.98%. Calcd for $[SCN(en)_2CoO_2Co(en)_2NCS](ClO_4)_2 \cdot 4H_2O$: Co, 15.16; C, 15.46; H, 5.18; N, 18.02; S, 8.25%.

7. Oxidation Product of $[SCN(en)_2CoO_2Co(en)_2NCS]^{2+}$: Ten milliliters of 14N nitric acid was added to 1 g of B (Exp. 6). The green solution obtained by this procedure was cooled in a refrigerator. The green crystals that deposited were washed with a little cold water, methanol, and ethyl ether. Yield, 0.1 g.

Found: C, 11.96; H, 5.21; N, 27.17%. Calcd for $[NH_3(en)_2CoO_2Co(en)_2NH_3](NO_3)_5 \cdot 2H_2O$: C, 12,46; H, 5.46; N, 27.13%.

8. Reaction of $[NO_2(en)_2CoO_2Co(en)_2NO_2]^{2+}$ *with* CN^-. *Preparation of* $K_2[Co_2(CN)_6(en)_2O_2] \cdot 5H_2O$: Two hundred milliliters of a solution containing 14 g of μ-peroxobis[nitrobis(ethylenediamine)cobalt(III)] dinitrate tetrahydrate and 26 g of potassium cyanide were warmed in a water bath at 35°C for 5 hr. Six hundred milliliters of methanol was added to the cooled, filtered solution. The precipitate that was thus deposited was filtered and washed with ethanol and ethyl ether. Yield, 7 g. The sample (7 g) was recrystallized by dissolution in 15 m*l* of water and filtration; this was followed by the successive addition of 20 m*l* of water and 200 m*l* of methanol. The precipitate that was thus deposited was again filtered and washed as above. Yield, 4.6 g. Recrystallization was repeated by dissolving this recrystallized sample (4 g) in 10 m*l* of water at 40°C and by stirring 10 m*l* of methanol (50°C) into the filtered solution. This solution was cooled in a refrigerator. The fragile, crystalline, red-brown precipitate that was thus deposited was washed with 60% methanol, pure methanol, and ethyl ether. Yield, 0.35 g.

Found: Co, 19.71; C, 20.40; H, 4.77; N, 23.71; K, 13.60%. Calcd for $K_2[Co_2(CN)_6(en)_2O_2] \cdot 5H_2O$: Co, 19.83; C, 20.21; H, 4.41; N, 23.59; K, 13.16%.

9. Oxidation Product of $[Co_2(CN)_6(en)_2O_2]^{2-}$. *The Preparation of* $H[Co_2(CN)_6(en)_2O_2] \cdot 4H_2O$: Five tenths of a gram of red-brown $K_2[Co_2(CN)_6(en)_2O_2] \cdot 4H_2O$ was added to 5 m*l* of water while a stream of chlorine gas was bubbled in. The violet solution obtained by this procedure was added to the cation-exchange resin in the H-form (DIAION SK#1) which had been washed with water. The effluent was then stirred into acetone (150 m*l*). The violet precipitate was washed with acetone. Yield 0.3 g.

Found: Co 23.40; C 25.23; H 5.18; N 28.34; H^+ (neutralization titration) 0.200%. Calcd for $H[Co_2(CN)_6(en)_2O_2] \cdot 4H_2O$: Co 23.62; C, 24.08; H, 5.05; N, 28.10; H^+, 0.201%.

10. Reaction of $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{4+}$ *with* SO_3^{2-}: Sixteen and four-tenths grams of μ-peroxobis[amminebis(ethylenediamine)cobalt(III)] triperchlorate nitrate dihydrate was stirred into a solution of 25.2 g of potassium sulfite in 200 m*l* of water. A crude yellow product (25 g) was obtained by the vacuum evaporation of this mixture, as in the case of 3·1. The sample was recrystallized from a dilute sodium sulfite solution. The electronic spectrum was identical with that of *trans*-$[Co(SO_3)_2(en)_2]^-$, which was prepared from *trans*-$[CoCl_2(en)_2]^+$ by a known method.[7]

Apparatus. The visible and UV absorption measurements were carried out with a Hitachi EPS-3T spectrometer. IR spectra were recorded on a Jasco IR-E spectrometer, while the EPR spectra were recorded on a JEOL JES-3B spectrometer at room temperature. The pH measurements were carried out with a Hitachi-Horiba M-5 pH meter.

Results and Discussion

The reaction scheme elucidated in the present research is summarized in Chart 1. Some characteristic features will now be discussed in detail.

Reaction of $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{n+}$ $(n=4, 5)$ *with* NO_2^-. As expected, $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{n+}$ is far more stable than $[(NH_3)_5CoO_2Co(NH_3)_5]^{n+}$; in fact, the Co-$O_2$-Co linkage in the former showed a remarkable stability to various reagents in a neutral solution. Thus, at room temperature, the μ-peroxo complex $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{4+}$ in a neutral solution reacts with NO_2^- to give a new μ-peroxo complex $[NO_2(en)_2CoO_2Co(en)_2NO_2]^{2+}$, without any cleavage of the O_2-bridge (Exp. 3). This is thought to be the first example in which the O_2-bridge remains intact in the reaction of the μ-O_2 complex with NO_2^- (Compare with the cases shown in Eqs. (1) and (3)). At about 80°C, $[NO_2(en)_2CoO_2Co(en)_2NO_2]^{2+}$ further reacts with NO_2^- to give *trans*-$[Co(NO_2)_2(en)_2]^+$ (Exp. 5), but it seems difficult to discuss the steric configuration of the starting material, since rearrangement may occur in the course of the reaction. Sasaki *et al.* reported that NH_3 in $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{4+}$ is replaced comparatively easily, and that in water the complex is readily changed to $[(en)_2Co(\mu\text{-}OH,O_2)Co(en)_2]^{3+}$.[8] It thus seemed worthwhile to test if $[(en)_2Co(\mu\text{-}OH,O_2)Co(en)_2]^{3+}$ is the intermediate product in our reaction on the way from $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{4+}$ to $[NO_2(en)_2CoO_2Co(en)_2NO_2]^{2+}$. This possibility was eliminated, however, since $[(en)_2Co(\mu\text{-}OH,O_2)Co(en)_2]^{3+}$, which had been prepared by the method of Foong *et al.*,[9] did not react with NO_2^- to give $[NO_2(en)_2CoO_2Co(en)_2NO_2]^{2+}$. However, it is still possible that an aquo-substituted complex, $[H_2O(en)_2CoO_2Co(en)_2OH_2]^{4+}$, is formed as an intermediate product.

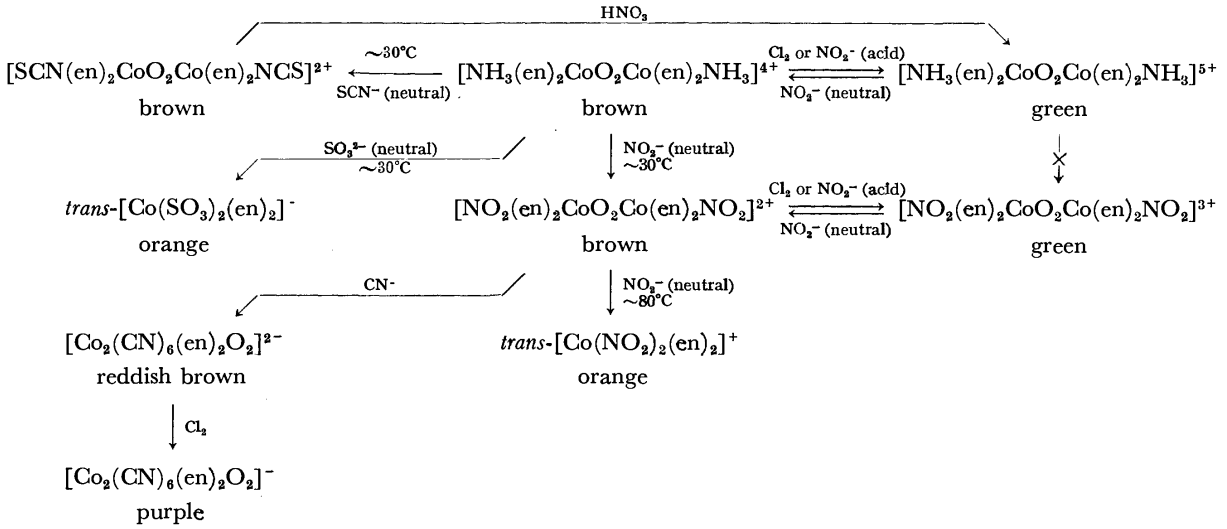

Chart 1. Reaction scheme of μ-O_2 dicobalt complexes

In an acid solution, the μ-peroxo complex $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{4+}$ is easily oxidized by NO_2^- to the corresponding μ-superoxo complex $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{5+}$ (Exp. 2), and the latter does not further react with NO_2^- to give $[NO_2(en)_2CoO_2Co(en)_2NO_2]^{3+}$. In other words, the NH_3 in the μ-superoxo complex $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{5+}$ is not replaced by NO_2^-, in contrast with the NH_3 in the corresponding μ-peroxo (4+) complex (see above). Nor is the O_2-bridge in $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{5+}$ replaced by NO_2^-. This is in contrast with the reaction of the double-bridged complex with NO_2^- cited in Eq. (1). Thus, the additional NH_2-bridge seems to play an important role in the transformation of the O_2-bridge to the NO_2-bridge. Davies *et al.* explained the easier reduction of $[(en)_2Co(\mu\text{-}NH_2,O_2)Co(en)_2]^{4+}$ by I^- by supposing that the presence of the NH_2-bridge places more strain on the O_2-bridge and places it more outside of the complex.[10] This idea may also explain the present situation.

The nitro-substituted μ-superoxo complex $[NO_2(en)_2CoO_2Co(en)_2NO_2]^{3+}$ may be obtained by the oxidation of the corresponding μ-peroxo (2+) ion described above by Cl_2 or even by NO_2^- (Exp. 4).

Reaction of $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{4+}$ *with* SCN^-. In a neutral solution, $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{4+}$ reacts with SCN^- to give $[SCN(en)_2CoO_2Co(en)_2NCS]^{2+}$ (Exp. 6) similarly to the case of $[NO_2(en)_2CoO_2Co(en)_2NO_2]^{2+}$. The preparation of the corresponding μ-superoxo complex has not yet been successful, for the reagents that oxidize the peroxo bridge to superoxo bridge also oxidize SCN^- to NH_3 (Exp. 7). The latter oxidation reaction is known to occur in mononuclear thiocyanato cobalt complexes as well. The above reaction shows that SCN^- coordinates to Co through the nitrogen atom.

Reaction of $[NO_2(en)_2CoO_2Co(en)_2NO_2]^{2+}$ *with* CN^-. $[NO_2(en)_2CoO_2Co(en)_2NO_2]^{2+}$ has been found to react with CN^- to give another new μ-peroxo complex $[Co_2(CN)_6(en)_2O_2]^{2-}$ (Exp. 8), which is then oxidized by chlorine gas to the corresponding μ-superoxo (1—) complex ion. The titration curve (Fig. 1) of $H[Co_2(CN)_6(en)_2O_2]\cdot 4H_2O$ (Exp. 9) showed it to be a strong acid. Analysis by the decomposition of $K_2[Co_2(CN)_6(en)_2O_2]\cdot 5H_2O$ with 12N hydrochloric acid, followed by the use of cation-exchange resin, showed that $[(CN)_5CoO_2Co(en)_2CN]^{2-}$ was the major component, accom-

panied by a small quantity of isomeric $[(CN)_3enCoO_2Coen(CN)_3]^{2-}$ (*cf.* Ref. 11).

Reaction of $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{4+}$ *with* SO_3^{2-}. In a neutral solution at room temperature, $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{4+}$ reacts with SO_3^{2-} to give *trans*-$[Co(SO_3)_2(en)_2]^-$ with a cleavage of the O_2-bridge; this is in contrast with the reaction of $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{4+}$ with NO_2^-. Further experiments are in progress.

Electronic, IR, and EPR Spectra. The electronic spectra of the μ-peroxo and μ-superoxo complexes, obtained mainly in the present research, are shown in Figs. 2 and 3 respectively. The spectra of the μ-peroxo complexes (Fig. 2) have similar broad absorption peaks at about 33 kK; they have no clear peaks in the visible region, and the complexes are generally brown. On the other hand, every spectrum of the μ-superoxo complexes (Fig. 3) has characteristic absorption peaks in the visible and ultraviolet regions. The one lying in the 14—18 kK range has a log ε value of about 3, and its position change appreciably with the ligands in the order of the spectrochemical series. The positions of the peaks appearing at about 21 and 33 kK are not much affected by the change in ligands. Some assignments of the absorption bands of μ-superoxo complexes have been offered by several investigators,[12-15] but none of these seems to be conclusive, and further works will be required to explain the spectra satisfactorily. The strong absorption at 28 kK in the spectrum of $[NO_2(en)_2CoO_2Co(en)_2NO_2](ClO_4)_3\cdot 2H_2O$ (Fig. 3) is considered to be the specific absorption band due to NO_2^- ligands. The IR spectra in the NaCl region proved the existence of NO_2, SCN, and CN in related complexes.

The room-temperature EPR spectra are shown in Fig. 4 for the paramagnetic μ-superoxo complexes. The appearance of the hyperfine structure depends upon the experimental conditions, and, in the case of aqueous solutions, considerably concentrated solutions are required. Some of these results, together with those of other workers relevant to the following discussion, are collected in Table 1. It may be seen from the table that the change in ligands does not affect the Zeeman splitting factor, g, very sensitively, but that

it does affect the cobalt hyperfine coupling consant, A_{Co}. The low A_{Co} values in cyano- and nitro-substituted complexes suggest that there is less spin density on the ^{59}Co nuclei in these complexes.[11] This may be explained in terms of the lowering of the t_{2g} orbitals caused by π-bonding, and by the subsequent decrease of the hole density therein.

The authors wish to thank Mr. Y. Miura for the EPR measurements and Mr. J. Goda for the elemental analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1438—1442(1972)

The Electrochemical Behavior of the Low-valent Transititon-metal Complexes. I. Nickel-2,2′-Dipyridyl Complexes.

Akira MISONO, Yasuzo UCHIDA, Takamichi YAMAGISHI, and Hironori KAGEYAMA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received December 15, 1971)

The electrochemical behavior of zero-valent nickel-2,2′-dipyridyl complexes ($Ni(dipy)_2$, $Ni(CH_2CHCN)_2(dipy)$, and $Ni(NCCHCHCN)_2(dipy)$) was examined in a hexamethylphosphoric triamide solution by polarographic and ESR measurements. In the polarography, these complexes were first reduced at a very anodic potential ($E_{1/2}$: about -0.6——-0.8 V *vs.* Ag wire). At this reduction step, the anion radical of the complex was observed for all the complexes by means of ESR analysis. The spectra of the anion radicals and their *g*-values suggested the localization of an unpaired electron on the ligand side. The addition of 2,2′-dipyridyl to the solution increased the height of the second wave, the half-wave potential of which was also more anodic than that of free 2,2′-dipyridyl, and the anion radical of 2,2′-dipyridyl was observed at this reduction step. It was concluded that the dianion species formed at the second reduction step dissociated to give the 2,2′-dipyridyl anion radical, and that the anion radical of the complex was reproduced in the presence of excess 2,2′-dipyridyl.

2,2′-Dipyridyl, with a fairly cathodic reduction potential, are comparable to that of naphthalene,[1] easily coordinates to the transition metal of a high oxidation state as a strong donor. On the other hand, dipyridyl has an acceptor level, as well as a donor level, so as to make it possible to coordinate to the low-valent transition metal.

It seemed that it would be interesting to perform a study of the electrochemical behavior of low-valent transition-metal complexes in relation to the evaluation of the charge distribution on the complexes of lower oxidation state, and the stability of the reduced complex. In basic and polar media, transition-metal complexes of lower oxidation states, such as the anion radical or the dianion species, are expected to exist fairly stably. Hexamethylphosphoric triamide (HMPT), with a large basicity, has been reported to have a potential ability to solvate the alkali metals and anion radicals of aromatic compounds.[2] Therefore, HMPT is an appropriate solvent for the electrochemical study of low-valent transition-metal complexes. The present authors made a study of the electrochemical behavior of zero-valent nickel-dipyridyl complexes in the HMPT solution and found interesting phenomena using polarographic and ESR techniques.

Experimental

Materials. The examined complexes were bis(2,2′-dipyridyl)nickel, bis(acrylonitrile)(2,2′-dipyridyl)nickel, and bis(fumaronitrile)(2,2′-dipyridyl)nickel. The bis(2,2′-dipyridyl)nickel was obtained by de-ethylation from diethyldipyridylnickel in the presence of 2,2′-dipyridyl, which had itself been prepared by the reduction of nickel acetylacetonate with diethylaluminum mono ethoxide in the presence of excess dipyridyl in tetrahydrofuran.[3] After the solution had stood for a long time following the reduction, a dark green complex of bis(2,2′-dipyridyl)nickel precipitated from the solution.

Bis(acrylonitrile)nickel was prepared by the reaction of acrylonitrile with nickel tetracarbonyl in tetrahydrofuran.[4] This complex was treated with excess 2,2′-dipyridyl in ether, refluxing for several hours gave reddish-brown bis(acrylonitrile)(2,2′-dipyridyl)nickel.

The bis(fumaronitrile)(2,2′-dipyridyl)nickel (dark brown) was prepared similarly. 2,2′-Dipyridyl was purified by the sublimation of the reagent, followed by recrystallization from *n*-hexane. Acrylonitrile was fractionally distilled after drying calcium chloride.

Fumaronitrile was recrystallized from ether-hexane.

Tetra-*n*-butylammonium perchlorate was obtained by adding hydroperchloric acid to aqueous tetra-*n*-butylammonium bromide, and it was recrystallized from hot water three times after washing with cold water. HMPT was refluxed over calcium hydride for several hours and was then fractionally

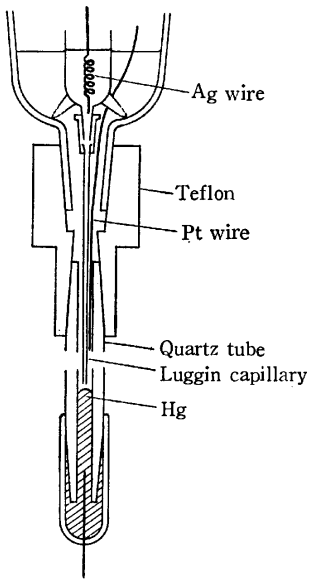

Fig. 1. Electrolytic cell for ESR measurement.

distilled under reduced nitrogen pressure.

Apparatus and Procedure. The polarographic analysis was performed using an H-type cell with a side arm to enable the insertion of an Ag-wire reference electrode.

The cathode was a dropping mercury electrode. The concentration of the complexes was generally 5.0×10^{-3} mol/*l*, while that of tetra-*n*-butylammonium perchlorate was 2.0×10^{-1} mol/*l*. The polarograph used was a Yanagimoto Model PB-105. For the ESR analysis, a electrolytic cell as is shown in Fig. 1 was used. The silver wire used as the reference electrode was dipped into a solution in a small reservoir equipped with a Luggin capillary, whose tip was set near the mercury surface to conduct the controlled potential electrolysis. A platinum wire was used as an anode, it was set about 3 cm from the mercury surface. The complex solution had the same composition as that used for the polarograghic analysis. The ESR spectra were recorded using a JEOL Model JS-3BS-X spectrometer. The electronic spectra of the complex in the HMPT solution were recorded using a Shimadzu MPS-50L spectrophotometer. The complexes to be examined were all air-sensitive, so the preparation and measurement of the complex solutions were performed under nitrogen purified by activated copper.

Results and Disscusion

Polarographic Results on the Complexes. The complexes were stable to only a small degree in solvents, such as acetonitrile, tetrahydrofuran, or ethyleneglycol dimethylether, but they were readily soluble in HMPT, giving strongly colored solutions, as is indicated in Table 1.

Table 1. The color of nickel-dipyridyl complexes

Complex	Solid state	HMPT solution (λ_{max} in mμ)
$Ni(dipy)_2$	dark green	dark green (680)
$Ni(AN)_2(dipy)$	reddish-brown	dark reddish-brown (570, 430, 340)
$Ni(FN)_2(dipy)$	dark brown	dark red (520)

AN: acrylonitrile FN: fumaronitrile

Table 2. Polarographic results on the complexes in HMPT

Compound	Half-wave potential $-E$ V *vs.* Ag wire	Wave height ratio
$Ni(dipy)_2$	0.73 1.00 1.25 1.60 2.05 (67.0) (73.1)[a)]	1.0 : 0.9 : 0.5 : 0.4 : 3.5
$Ni(AN)_2(dipy)$	0.67 1.32 1.94 (65.7) (115.0)	1.0 : 0.9 : 0.1
$Ni(FN)_2(dipy)$	0.87 1.68 2.25 (80.1) (93.7)	1.0 : 1.0 : 0.2
$Ni(AN)_2$	1.74	
$Ni(FN)_2$	1.93	
dipyridyl	2.37 2.80	1.0 : 0.7

$(C_4H_9)_4NClO_4$ concentration 2×10^{-1} mol/*l*

The complexes were stable in HMPT, the color of which did not change over a week under nitrogen.

The polarographic results are shown in Table 2. The first wave of three complexes lie in the range of -0.6——-0.8 V *vs.* Ag wire, which is far anodic than the first reduction wave of dipyridyl and also more anodic than those of acrylonitrile and fumaronitrile. For comparison, bis(acrylonitrile)nickel and bis(fumaronitrile)nickel were also examined. They were reduced at about -1.7——-1.9 V, indicating that the species to be reduced at -0.6——-0.8 V contained dipyridyl in the molecule, at least in the cases of nitrile-containing complexes. The stability of π-coordinated acrylonitrile or fumaronitrile in neutral complexes was affirmed by the CN stretching in the IR spectra of the solid complex, its HMPT solution, and the free nitrile in HMPT. The first reduction step was fairly reversible for $Ni(dipy)_2$ and $Ni(AN)_2(dipy)$.

For $Ni(FN)_2(dipy)$, the first step was less reversible than the former two. The electron to be transfered was supposed to be one from the slope of the reduction wave for all three complexes. The complexes were, therefore, considered to be reduced to form the anion radical.

At this reduction step, no color change was apparent except in $Ni(AN)_2(dipy)$ under prolonged reduction. In the case of $Ni(AN)_2(dipy)$, the solution turned a deep red from a dark reddish-brown as a result of one-electron transfer.

The 1 : 1 ratio of the heights of the first and the second waves in all the dipyridyl complexes indicates a one-electron transfer in the second wave as well as in the first, though the second wave is less reversible than the first. It has previously been reported that nickel complexes containing *o*-mercaptoaniline or thiobenzoylhydrazine readily undergo one-electron transfer steps to give mono- and dianions.[5)]

The bis(dipyridyl)nickel showed three more reduction waves with comparatively large wave heights, so a reduction state farther than the dianion may be expected. Tris(2,2'-dipyridyl)chromium has previously been reported to be reduced to the hexa-anion stage,

5) R. H. Holm, A. L. Balch, A. Davisdon, A. H. Maki, and T. E. Berry, *ibid.*, **89**, 2866 (1967).

$Ca_3[Cr(dipy)_3]\cdot 7NH_3$.[6]

For nitrile-containing complexes, the steps after the second are very small in height.

Since HMPT with a donor- and an acceptor-level can also coordinate to a low-valent transition metal, it is probable that coordinated dipyridyl is replaced by HMPT to lower the effective concentration of dipyridyl complexes below the calculated value. In the case of violet-colored bis(dipyridyl)iron, its HMPT solution slowly turned to brown from violet, and this color change was suppressed by the addition of more than 10-fold molar amount of dipyridyl to the complex solution.[7] The addition of dipyridyl to the nickel-dipyridyl complex solution, did not affect the height and potential of the first step.

This indicates that HMPT does not replace the coordinated dipyridyl of the examined neutral nickel-dipyridyl complexes.

The second wave increased in height upon the addition of dipyridyl, though the half-wave potential of this step scarcely changed in three complexes. Some steps after the second were also affected. The effect of the addition of dipyridyl is shown in Figs. 2 and 3 for $Ni(dipy)_2$ and $Ni(FN)_2(dipy)$. In the case of $Ni(dipy)_2$, dipyridyl addition increased the height of the second, fourth, and fifth waves, the third being left unchanged. Further, the waves became less reversible as their height was increased by dipyridyl addition. In Table 3, the change in the slope of the second wave is shown for $Ni(dipy)_2$. The change in the height and reversibility of the second wave suggests that added dipyridyl takes part in this reduction step and that its rate of coordination to the metal is slow.

In the presence of the complexes of 5×10^{-3} mol/l, the reduction waves with considerably cathodic potential could not be successfully observed because of the disturbance in the wave shapes. By decreasing the concentration of the complex, those waves were, however, observed in the case of $Ni(dipy)_2$, as is indicated in Fig. 4. The concentration of the complex was 3×10^{-4} mol/l, and that of added dipyridyl was 3×10^{-2} mol/l. The reduction wave of free dipyridyl was observed after the waves in which the complex was considered to take part. After a prolonged reduction (for

20 min) of this solution at about −2.0 V *vs.* Ag wire, the color of the solution (dark green) faded and the resulting polarogram showed only the reduction waves of dipyridyl. This result may be attributable to the unstability of the reduced species at −2.0 V in spite of the presence of a large excess of dipyridyl. As is shown in Figs. 2 and 4, the ratio of the second and fourth wave-heights in the polarogram of $Ni(dipy)_2$ is dependent on the concentrations of the complex and dipyridyl.

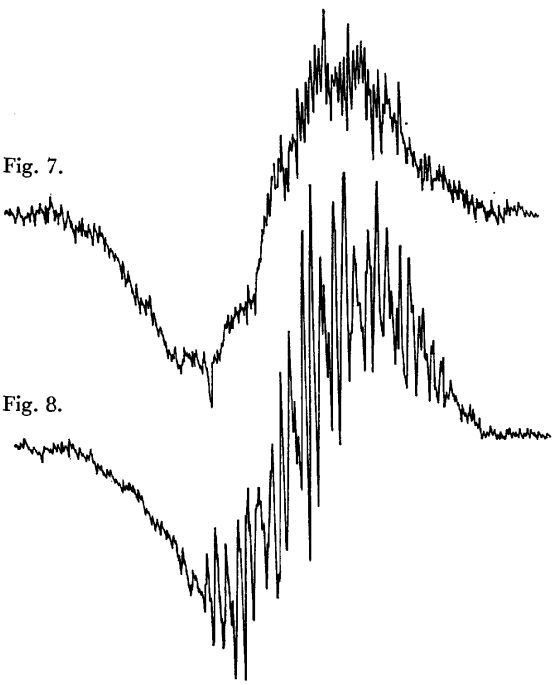

Fig. 7. ESR signal in the electrolysis of Ni $FN)_2$ dipy) at −1.07 V.

Fig. 8. ESR signal in the electrolysis of $Ni(FN)_2$(dipy) at −1.7 V.

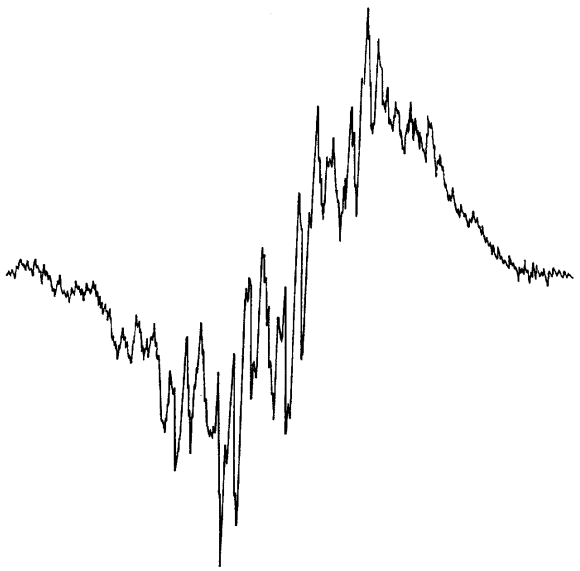

Fig. 9. ESR signal in the electrolysis of $Ni(AN)_2$(dipy) at −0.8 V.

ESR Measurements. In electrolysis at the potential sufficient cathodic to cause the first reduction step, the signal attributable to the anion radical of the complex was observed for all the nickel complexes, as is shown in Figs. 5, 7, and 9. The complexes before reduction, naturally, gave no ESR signal. Zero-valent nickel has a d^{10} configuration, so the unpaired electron of the complex anion radical seems to be mainly localized on the ligand side. For $Ni(dipy)_2$, no signal with a well-defined hyperfine structure could be obtained.

For $Ni(AN)_2$(dipy) and $Ni(FN)_2$(dipy), a comparatively well-defined structure was obtained. The spectra indicated the localization of the unpaired electron on the ligand side, compared with those obtained for the anion radicals of dipyridyl and dipyridyl metal carbonyl complexes.[8]

The *g*-values of the complex anion radicals were as follows; $Ni(dipy)_2$, 2.0036; $Ni(AN)_2$(dipy), 2.0009; $Ni(FN)_2$(dipy), 2.0013 (dipyridyl, 2.0023). They were close to that of the dipyridyl anion radical. This also indicates the spin localization of the ligand side.

It was noted that the electrolysis at the second reduction step produced the anion radical of dipyridyl.

The intensity of this signal increased upon the addition of dipyridyl to the solution. The set potential was more anodic by 0.6—1.3 V than the half-wave potential of free dipyridyl. In Figs. 6 and 8, the signal attributable to the anion radical of dipyridyl is shown. This dipyridyl anion radical was stable in HMPT and was observed to be overlapped with another signal with an ill-defined structure. Without excess dipyridyl, the first anion radical-signal of the complex was again observed by shifting the set potential to the first reduction step, but the signal intensity was lower than before.

Taking into account the polarographic results at the second step, it was concluded that the dianion species of

8) R. E. Dessy, R. B. King, and M. Waldrop, *J. Amer. Chem. Soc.*, **88**, 5112 (1966); R. E. Dessy, Intern. Symp. on the Synthetic and Mechanistic Aspects of Electro-organic Chemistry, 63 (1968).

the complex was formed by two one-electron transfer steps and that the dipyridyl anion radical was formed by the dissociation of this dianion species. To the authors' knowledge, this is the first time the dipyridyl anion radical has been formed at a far more anodic potential than the reduction potential of free dipyridyl in aprotic solvents.[9]

The polarographic results suggested the formation of the species with unpaired electron upon further reduction, for example, in the case of $Ni(dipy)_2$. Its ESR analysis was, however, impossible because of the presence of stable dipyridyl anion radical with a half-wave potential of about -2.8 V *vs.* Ag wire. This potential was more cathodic than the fifth reduction step in the polarography of $Ni(dipy)_2$. In the experiments with the complexes containing nitriles, the signal which corresponds to the anion radical of acrylonitrile or fumaronitrile was not detected. This suggests that π-coordinated acrylonitrile or fumaronitrile is stable in the complex dianion species.

The present authors also attempted the electrolysis of bis(dipyridyl)iron. The $Fe(dipy)_2$-HMPT solution was unstable and gave a disturbed polarogram, from which no clear-cut information was obtained, but the ESR analysis at the potential corresponding to the second step recorded the anion radical of dipyridyl. This potential was more anodic than the reduction potential of dipyridyl, too.

In the examined systems, the solvent HMPT was considered to have an important role. Its ability to solvate anions is greater than tetrahydrofuran or acetonitrile. The reduction potential to obtain the complex anion radical from $Ni(dipy)_2$ in HMPT was far anodic than that reported in acetonitrile.[10] The solvation mechanism of neutral complexes and derived complex anion radicals in HMPT is not yet clear and needs to be studied further.

The dissociation of dianion species produces a paramagnetic species containing a nickel atom, along with the formation of a dipyridyl anion radical, and the former coordinated by dipyridyl to reproduce complex anion radical species in the presence of excess dipyridyl.

Therefore, the degree of dissociation increases upon the addition of dipyridyl because of the difference in the stability between anion radicals and dianion species.

Were it not for the free dipyridyl in the solution, HMPT would coordinate to the above paramagnetic species.

The ill-defined signal in Figs. 6 and 8 may supposedly be ascribed to the complex anion radical and/or species derived from the previous paramagnetic species and HMPT.

As a mechanism of the electro-reduction of nickel-dipyridyl complexes, the following mechanism was proposed, for example, in the case of $Ni(dipy)_2$.

1st step

$$Ni(dipy)_2 + e^- \rightleftharpoons [Ni(dipy)_2]^-$$

2nd step

$$[Ni(dipy)_2]^- + e^- \rightleftharpoons [Ni(dipy)]^{2-}$$

$$[Ni(dipy)_2]^{2-} \rightleftharpoons [Ni(dipy)]^- + [dipy]^-$$

$$[Ni(dipy)]^- + dipy \rightleftharpoons [Ni(dipy)_2]^-$$

$$[Ni(dipy)]^- + HMPT \rightleftharpoons [Ni(dipy)(HMPT)]^-$$

Stereochemical Studies of Metal Chelates. IX.[1] The Preparation and Stereochemistry of Cobalt(III) Complexes Coordinated with the *meso*-Form of 3,6-Diaza-2,7-dimethyl-1,8-diaminooctane

Masahiko SABURI and Sadao YOSHIKAWA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 16, 1971)

The *meso*-form of 3,6-diaza-2,7-dimethyl-1,8-diaminooctane (*meso*-3,8-dimetrien), one of the triethylenetetramine derivatives, was prepared. Dinitro- and dichlorocobalt(III) complexes with this ligand were also prepared and characterized. The *Δ-cis-β(SS)* and/or the *Δ-cis-β(RR)* configuration were assigned to these complexes. The *trans*-dichlorocobalt(III) complex of *meso*-3,8-dimetrien derived from the *cis-β*-dichloro complex was determined to have the *meso-trans* configuration (the absolute configurations of the coordinated secondary nitrogen atoms were antimeric to each other, namely, *R* and *S*), on the basis of proton magnetic resonance measurements.

We have investigated the stereoisomerism of cobalt(III) complexes coordinated with triethylenetetramine (=trien) derivatives substituted with methyl groups at various carbon atoms of trien. Almost all of them were optically active enantiomorphs and showed a remarkable stereospecificity when coordinated.[2-5] The studies of complexes with substituted triens have occasionally served to elucidate the stereochemistry of the unsubstituted trien complex. The structures of the probable isomers so far proposed[3-7] are shown in Fig. 1. The structural features for these isomers have been discussed in detail in previous papers.[4,5] The presence of all the isomers except for the *meso-trans* form (*trans*-(*RS*)[8] form) has been proven for diacidocobalt(III) complexes with trien and/or its derivatives.[3-5]

Studies of trien derivatives[3-5] have pointed out the importance of the conformational rigidity attending to the chelate ring with the *C*-substituted methyl group, which tends to take the equatorial orientation with regard to the chelate ring. The 3,6-diaza-2(*S*),7(*S*)-dimethyl-1,8-diaminooctane (=(3*S*,8*S*)-dimetrien), for example, yielded the *Δ-cis-β(RS)* isomer,[4,5] among others. The isolation of the *Δ-cis-β(RS)* isomer was attributed to the effect of the methyl groups of the ligand used. It was difficult to obtain the *Δ-cis-β(RS)* and its enantiomeric forms in the case of trien complexes.[6] This suggests that any isomeric forms not isolated for unsubstituted trien might be obtained by employing trien derivatives substituted with methyl group(s) at the suitable position(s) and of the appropriate configuration(s).

As has been mentioned above, the *meso-trans* form is the only isomer not hitherto detected for complexes of trien or its derivatives. The most conspicuous characteristic of the *meso-trans* form is the fact that the two outer chelate rings have opposed conformations (*δ* and *λ*). This isomeric form might be obtained if methyl groups are introduced into a trien derivatives so that the two side chelate rings adopt the configurations opposed to each other. With this in view, we prepared the *meso*-form of 3,6-diaza-2,7-dimethyl-1,8-diaminooctane (*meso*-3,8-dimetrien), which is the epimer of (3*S*,

8*S*)-dimetrien, as is indicated in Fig. 2. Some cobalt(III) complexes with *meso*-3,8-dimetrien were prepared and characterized. It was decided that the *trans*-dichloro complex with this ligand had the *meso-trans* configuration.

Experimental

Racemic alanine amide was prepared by the usual method.[9] Oxalyl chloride was prepared by the method of Staudinger.[10]

Tetramide Mixture. Racemic alanine amide (46.0 g) and sodium carbonate (25.0 g) were dissolved in 200 m*l* of water, and the solution was cooled in an ice bath. Oxalyl chloride (27.6 g) dissolved in 150 m*l* of benzene was added dropwise with vigorous stirring using a blender. After the addition was completed, stirring was continued for 10 min; the resultant white precipitates were filtered off, washed with water, methanol, and ether, and dried under vacuum. Yield, 37.8 g.

Separation of meso- *and* racemic-*Tetramide.* 5.0 g of the tetramide mixture were dissolved in 100 m*l* of boiling acetic acid, and then the solution was cooled to room temperature. After 4 hr, the white crystals which separated were collected by decantation. The crystals were washed with methanol and air-dried. This fraction was almost pure *meso*-tetramide. Yield, 1.5 g. The decanted solution was stood at room temperature overnight; the crystals which appeared were filtered off, and then washed and dried, as in the case of the first fraction. Yield, 1.0 g. The second fraction was *meso*-tetramide containing a small portion of the racemic form; recrystallization from acetic acid gave the pure product.

racemic-Tetramide was recovered from the filtrate of the second crop by the evaporation of the solvent. The product was contaminated with a small amount of the *meso*-isomer.

Found for *meso*-tetramide: C, 41.66; H, 6.02; N, 23.94%. Found for *racemic*-tetramide: C, 41.74; H, 6.15; N, 23.37%. Calcd for $C_8H_{14}N_4O_4$: C, 41.74; H, 6.13; N, 24.34%.

Preparation of meso-*3,6-Diaza-2,7-dimethyl-1,8-diaminooctane (*meso-*3,8-dimetrien).* To 150 m*l* of anhydrous tetrahydrofuran were added 8.0 g of lithium aluminum hydride in small portions, followed by 6.9 g of well-pulverized *meso*-tetramide in small portions. The mixture was stirred and heated under reflux for 24 hr and then cooled to room temperature. 15.5 m*l* of water diluted with 30 m*l* of tetrahydrofuran was added dropwise to the mixture with vigorous stirring. The resultant slurry was stirred for 30 min, filtered off, and washed with tetrahydrofuran (100 m*l*). The residue was extracted by boiling with tetrahydrofuran (100 m*l*) for 1 hr and then filtered again. After this procedure had been repeated, the extracts and filtrates were combined and concentrated under reduced pressure. The oily residue was dissolved in 100 m*l* of ethanol, and the solution was saturated with dry hydrogen chloride gas. The white precipitates were collected and dissolved in warm water. Ethanol was added, while hot, until the solution became turbid, and then the solution was cooled to room temperature. The white crystals of the hydrochloride salt of the desired tetramine were collected, washed with ethanol and ether and dried under vacuum. Yield, 3.5 g. Found: C, 28.49; H, 8.48; N, 15.83%. Calcd for $C_8H_{22}N_4 \cdot 4HCl \cdot H_2O$: C, 28.41; H, 8.35; N, 16.57%.

Preparation of racemic-*3,6-Diaza-2,7-dimethyl-1,8-diaminooctane (*rac-*3,8-dimetrien).* This was prepared by the same procedures as were used for the *meso* form, but employing *racemic*-tetramide in place of *meso*-tetramide. The desired product was isolated as the hydrochroride. Found: C, 29.57; H, 7.88; N, 17.74%. Calcd for $C_8H_{22}N_4 \cdot 4HCl$: C, 30.02; H, 8.18; N, 17.50%.

cis-*β-Dinitro(*meso-*3,6-diaza-2,7-dimethyl-1,8-diaminooctane-cobalt(III) Chloride Sesquihydrate (*cis-*β-[Co(*meso-*3,8-dimetrien)(NO$_2$)$_2$]Cl·1.5H$_2$O).* To a solution of *meso*-3,8-dimetrien·4HCl (3.40 g) and $LiOH \cdot H_2O$ (1.25 g) in 40 m*l* of water, $CoCl_2 \cdot 6H_2O$ (2.38 g) and $NaNO_2$ (1.47 g) were added successively. The resultant solution was aerated with carbon dioxide-free air for 5 hr. The yellow-brown crystals which thus appeared were filtered off and washed with a small volume of cold water. Yield, 1.15 g. The second crop could be obtained by concentrating the combined filtrate and washings to a volume of 15 m*l*, followed by cooling in a refrigerator overnight. This crop was collected and washed with cold water and ethanol. Yield, 1.20 g. A further product was recovered from the filtrate. Total yield, 3.00 g. All the products were recrystallized from warm water. Found: C, 24.93; H, 6.56; N, 21.66%. Calcd for $[Co(C_8H_{22}N_4)(NO_2)_2]Cl \cdot 1.5H_2O$: C, 24.78; H, 6.50; N, 21.68%.

Resolution of cis-*β-*[*Co(*meso-*3,8-dimetrien)(NO$_2$)$_2$]Cl·1.5H$_2$O.* A 2 g sample of *cis-β-*[Co(*meso-*3,8-dimetrien)(NO$_2$)$_2$]Cl·1.5H$_2$O was dessolved in 15 m*l* of warm water. To the solution was added an aqueous solution of ammonium α-bromocamphor-π-sulfonate (1.60 g). Yellow precipitates began to separate immediately. After the mixture had stood at room temperature overnight, the precipitates were filtered off and washed with ethanol. Yield, 2.90 g. These crystals were dissolved in boiling methanol (150 m*l*), and the resultant solution was cooled and allowed to stand overnight. The crystals which separated were collected, washed with ethanol and ether, and air-dried. Yield, 1.25 g. $[\alpha]_D^{20}+147°$ ($c=0.2$, H_2O). The product was the pure diastereomer salt of the *Λ* isomer. Found: C, 33.21; H, 6.05; N, 12.53%. Calcd for $[Co(C_8H_{22}N_4)(NO_2)_2](C_9H_{14}BrO_4S) \cdot CH_3OH$: C, 32.98; H, 6.15; N, 12.82%.

The α-bromocamphor-π-sulfonate salt of the *Λ*-isomer obtained as above was ground with excess $NaClO_4$ and a small volume of water in a mortar. The yellow crystals thus obtained were collected and recrystallized from warm water. $[\alpha]_D^{20}+180°$ ($c=1.0$, H_2O). Found: C, 22.41; H, 5.33; N, 19.94%. Calcd for $[Co(C_8H_{22}N_4)(NO_2)_2]ClO_4$: C, 22.62; H, 5.38; N, 19.79%.

The *Δ* isomer which remains in the filtrate could not be isolated as the optically pure form.

cis-*β-Dichloro(*meso-*3,6-diaza-2,7-dimethyl-1,8-diaminooctane)-cobalt(III) Chloride Hemihydrate (*cis-*β-[Co(*meso-*3,8-dimetrien)Cl$_2$]·0.5H$_2$O).* 1.70 g of *meso*-3,8-dimetrien·4HCl and 0.625 g of $LiOH \cdot H_2O$ were dissolved in 20 m*l* of water, and then 1.19 g of $CoCl_2 \cdot 6H_2O$ was added. The resultant solution was aerated with carbon dioxide-free air for 7 hr. To the solution were added 10 m*l* of concentrated HCl, and the resultant solution was then evaporated on a water bath below 50°C. When a small portion of purple crystals began to separate, heating was stopped and ethanol (20 m*l*) was added. After the mixture had stood in a refrigerator overnight, the purple crystals which separated were filtered off, washed with methanol, acetone, and ether, and dried under vacuum. The product was recrystallized from dilute HCl. Found: C, 27.51; H, 6.92; N, 15.86%. Calcd for $[Co(C_8H_{22}N_4)Cl_2]Cl \cdot 0.5H_2O$: C, 27.56; H, 6.65; N, 16.07%.

trans-*Dichloro(*meso-*3,6-diaza-2,7-dimethyl-1,8-diaminooctane)-cobalt(III) Perchlorate (*trans-[*Co(*meso-*3,8-Dimetrien)Cl$_2$]ClO$_4$).* A 0.2 g sample of *cis-β-*[Co(*meso-*3,8-dimetrien)Cl$_2$]Cl·0.5H$_2$O was added to 100 m*l* of anhydrous methanol, and the mixture

9) P.S. Yang and M.R. Rising, *J. Amer. Chem. Soc.*, **53**, 3183 (1931).

10) H. Staudinger, *Ber.*, **41**, 3563 (1908).

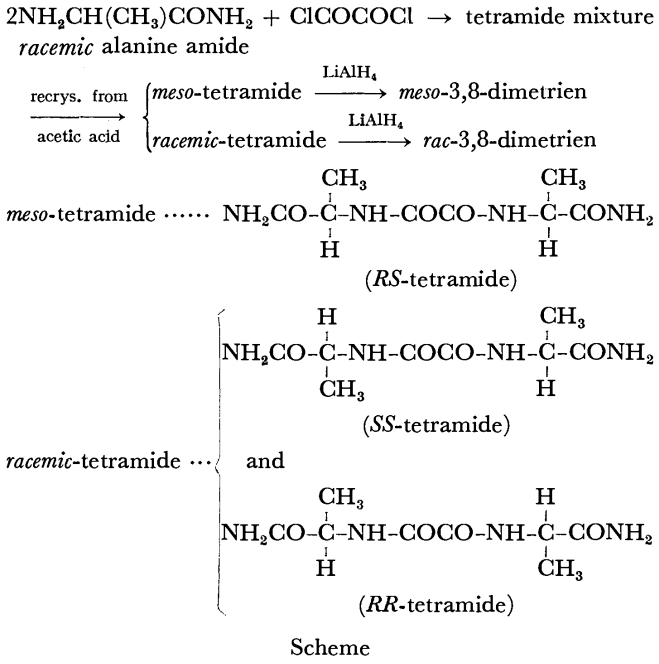
was heated under reflux for 6 hr. The resultant red-brown solution was filtered and concentrated in a rotary evaporator almost to dryness. To the residue were added 3 m*l* of methanol and a excess amount of solid $LiClO_4$, and the mixture was scratched with a glass rod. The crystals which appeared were collected and washed with ethanol and ether. The product thus obtained was the desired complex contaminated with perchlorate salt of the unchanged *cis-β* isomer. This crude product was treated with 20 m*l* of methanol with gentle heating, after which the sparingly soluble *cis-β* form was removed by filtration. The pure *trans* isomer was obtained from the filtrate after concentration in a rotary evaporator. The product was filtered off, and washed with ethanol and ether. The product was recrystallized from concentrated HCl. Found: C, 23.46; H, 5.63; N, 13.84%. Calcd for $[Co(C_8H_{22}N_4)Cl_2]ClO_4$: C, 23.81; H, 5.50; N, 13.88%.

trans-*Dichloro(*racemic-*3,6-diaza-2,7-dimethyl-1,8-diaminooctane)cobalt(III) Perchlorate* (trans-[*Co(*rac-*3,8-dimetrien)*Cl_2]-ClO_4). A 1.60 g sample of *rac*-3,8-dimetrien·4HCl and 0.625 g sample of $LiOH \cdot H_2O$ were dissolved in 25 m*l* of water, and then 1.19 g of $CoCl_2 \cdot 6H_2O$ were added. The solution was aerated with carbon dioxide free air for 7 hr, and then 10 m*l* of concentrated HCl were added. The resultant solution was concentrated on a water bath below 50°C. When a small quantity of dark green crystals began to form, heating was stopped and the mixture was cooled in a refrigerator overnight. The dark green crystals which thus separated were filtered off, washed with methanol, acetone, and ether, and dried under vacuum. The dark green crystals were dissolved in hot methanol (100 m*l*), and the solution was refluxed for 2 hr. To the resultant green solution were added an excess amount of solid $LiClO_4$, and the methanol was removed under reduced pressure. The green crystals which separated were the desired complex. The products were collected, washed with methanol and acetone, and air-dried. Found: C, 24.27; H, 5.67; N, 13.82%. Calcd for $[Co(C_8H_{22}N_4)Cl_2]ClO_4$: C, 23.81; H, 5.50; N, 13.88%.

Measurements. The visible and ultraviolet absorption spectra were obtained with a Shimadzu MPS-50L spectrophotometer. The circular dichroism spectrum was measured with a JASCO J-20 automatic spectropolarimeter. The absorption spectrum for the *cis-β* dichloro isomer was obtained in a concentrated HCl solution in order to avoid the aquation of the complex. The absorption spectra for the *trans*-dichloro isomers were obtained in a methanol solution, while the absorption and CD spectra for the dinitro complex were obtained in an aqueous solution. The proton magnetic resonance spectra for the *trans*-dichloro complexes were obtained with a JNM C-60 spectrometer in a hexadeuterodimethyl sulfoxide solution immediately after dissolution. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate was used as the internal standard reference. The infrared spectra were obtained with a JASCO DS-301 spectrophotometer by means of the KBr disk method.

Results and Discussion

(3*S*,8*S*)-Dimetrien has been prepared by the lithium aluminum hydride reduction of a tetramide obtained by the reaction of *S*-alanine amide (2 mol) with oxalyl chloride (1 mol) (designated hereafter as *SS*-tetramide).[4] If the *meso*-tetramide (or *RS*-tetramide), which contains an *S*-alanine moiety on one branch and an *R*-alanine moiety on the other, is available, the desired trien derivative, *meso*-3,8-dimetrien, may be readily prepared by the same procedure.



Scheme

However, the reaction of racemic alanine amide (2 mol) with oxalyl chloride (1 mol) must give a "tetramide mixture" composed of *SS*-, *RR*-, and *RS*-tetramide (See Scheme). The *SS*- and *RR*-tetramide are enantiomeric to each other, and an equimolar mixture of them may be designated as *racemic*-tetramide. The *RS*-tetramide is, on the other hand, diastereoisomeric with the racemic form. The above "tetramide mixture" must contain the *racemic*- and *meso*-tetramide in equal amounts.

The separation of the tetramide mixture into the *meso* and the *racemic* forms can be achieved by fractional crystallization from hot acetic acid. The more soluble and the less soluble parts fractionated as above showed infrared spectra evidently different to each other. Further, both fractions were distinguished in thin-layer chromatography, using cellulose powder (MN 300, Macherey, Nagel & Co.) as the absorbent and a pyridine - water mixture (82: 12) as the developing solvent. The R_f value for the less soluble fraction was nearly zero, while that for the more soluble fraction was 0.83. The *SS* tetramide, which was expected to have the same R_f value as the *racemic*-tetramide, showed a chromatogram identical with that of the more soluble fraction. Therefore, the more soluble and the less soluble fraction were identified as the *racemic*- and the *meso*-tetramide respectively.

The *meso*-3,8-dimetrien was obtained by the lithium aluminum hydride reduction of the *meso*-tetramide. In a similar way, the *rac*-3,8-dimetrien was prepared for the sake of comparison. The distinction of these ligands will be clarified by the differences in their complexes, such as *trans*-dichlorocobalt(III) complexes.

Among the possible isomers of trien complexes shown in Fig. 1, there are two isomers which adopt opposed conformations with respect to both of the outer chelate rings, *i.e.*, *Δ-cis-β(RR)* (and its antipodes) and *meso-trans* (*trans(RS)*) form. It was expected that the com-

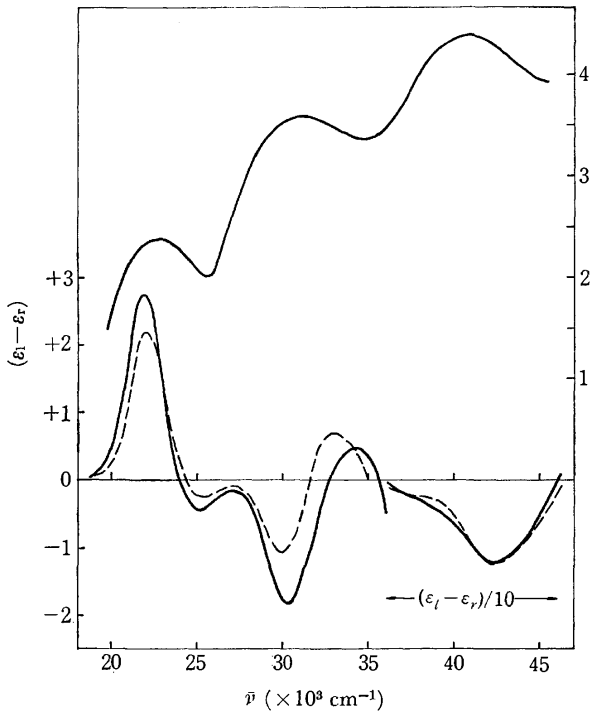


Fig. 3. Absorption and CD curves of *Λ-cis-β*-Co(*meso*-3,8-dimetrien)$(NO_2)_2^+$ ion (——) and CD curve of *Λ-cis-β*(*SS*)-Co(trien)$(NO_2)_2^+$ ion (----).

plexes with *meso*-3,8-dimetrien might give rise to these two geometries stereoselectively, since the present ligand prefers the λ conformation for one arm (the *R* absolute configuration site) and the δ conformation for the other (the *S* configuration site). However, the *meso-trans* geometry must be less stable than the *cis-β* form. In the former structure, the central chelate ring adopts an eclipsed envelope conformation, while all the three chelate rings take gauche conformations in the latter case. Therefore, the most preferred structure for *meso*-3,8-dimetrien complexes may be the *cis-β* configuration (*Δ-β*(*RR*) and *Λ-β*(*SS*)).

The dinitrocobalt(III) complex of *meso*-3,8-dimetrien showed the absorption spectrum given in Fig. 3. The second absorption band was found at 31,250 cm^{-1}, indicating the *cis* configuration of the complex. The absorption maxima for the *cis* isomers of the $Co(N)_4(NO_2)_2^+$ type were found at about 31,000 cm^{-1}, while those of the *trans* isomers were found in the vicinity of 29,000 cm^{-1}.[11] Such a tendency of absorption spectra was also observed in the case of dinitro complexes with some trien derivatives.[12]

The Co(*meso*-3,8-dimetrien)$(NO_2)_2^+$ ion was resolved into the optically active form using ammonium α-bromocamphor-π-sulfonate as the resolving agent. The $(+)_D$-enantiomorph isolated from the less soluble diastereoisomer salt showed the CD curve given in Fig. 3. This curve has a dominant positive CD peak ($\Delta\varepsilon = +2.75$), along with a minor negative peak ($\Delta\varepsilon = -0.46$), in the first absorption band region, indicating the *Λ* absolute configuration.[5] Further, this CD curve

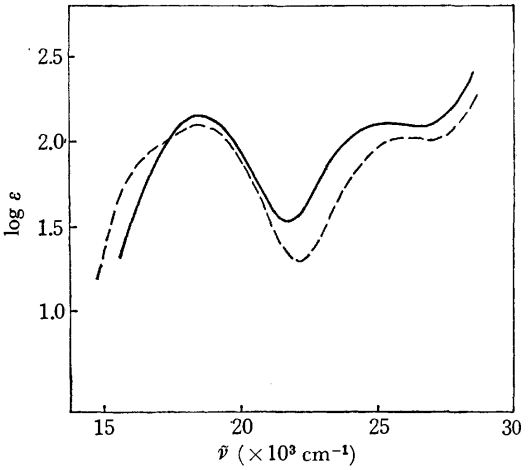

Fig. 4. Absorption curves of *cis-β*-Co(*meso*-3,8-dimetrien)Cl_2^+ ion (——) and *Λ-cis-α*-Co(3*S*, 8*S*)-dimetrien)Cl_2^+ion (----).

markedly resembles that of the *Λ-cis-β*-(*SS*)-Co(trien)-$(NO_2)_2^+$ ion, as shown in Fig. 3. The dinitro complex of some trien derivatives which have configurations other than the *Λ-β*(*SS*) or *Δ-β*(*RR*) geometry (*i.e.*, the *Λ-α*-(*RR*) and *Δ-β*(*RS*) forms) showed CD patterns different from this (*Λ-β*(*SS*)) geometry.[5] Hence, it was established that the dinitrocobalt(III) complex of *meso*-3,8-dimetrien have the *Λ-β*(*SS*)[13] and *Δ-β*(*RR*) configurations, as expected previously.

The dichlorocobalt(III) complex of *meso*-3,8-dimetrien prepared by the usual method was purple and showed the visible absorption curve given in Fig. 4. It has been recognized that the *cis-α* isomers of dichloro complexes with trien or its derivatives have a shoulder on the shorter wave number side of the first absorption band. The absorption curve of the *Λ-cis-α*-Co((3*S*,8*S*)-dimetrien)Cl_2^+ ion is shown for the sake of comparison in Fig. 4. For the *cis-β* configuration, such a shoulder has not been detected in the corresponding region in spite of the geometry of the *cis-β* isomers (*Λ-β*(*SS*) and

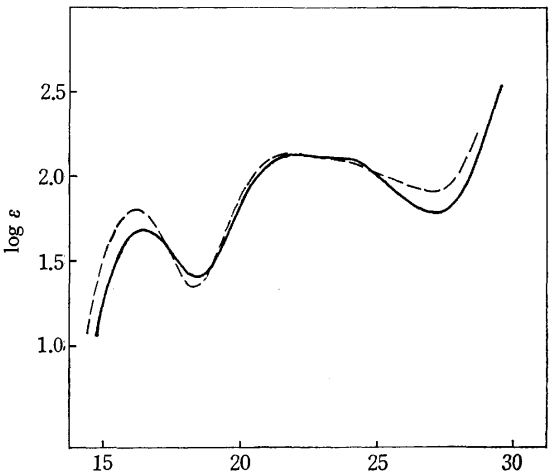

Fig. 5. Absorption curves of *trans*-Co(*meso*-3,8-dimetrien)Cl_2^+ ion (——) and *trans*-Co(*rac*-3,8-dimetrien)Cl_2^+ ion (----).

13) The absolute configuration of the coordinated secondary nitrogen center is represented by *R* and *S*, neglecting the substituted methyl groups. See ref. (4) and (5).

Λ-β(RS) or their enantiomorphs).[4] No shoulder was observed in the first absorption band of the *meso*-3,8-dimetrien complex either (Fig. 4). Therefore, the present complex should have the *cis*-β configuration. Further, this complex ion probably takes the Λ-β(SS) and/or Λ-β(RR) configurations in the same manner as the corresponding dinitro complex.

When this *cis*-β dichloro complex suspended in methanol was heated under reflux, a red-brown solution was obtained, from which the *trans*-dichloro isomer of *meso*-3,8-dimetrien was isolated. The absorption spectra of this *trans* isomer and of the *trans*-Co(*rac*-3,8-dimetrien)-Cl_2^+ ion are shown in Fig. 5. These curves are apparently different from each other, reflecting the difference in the structures of the ligands. The absorption curve of the *rac*-3,8-dimetrien complex was identical with that of the (3S,8S)-dimetrien complex,[4] as expected.

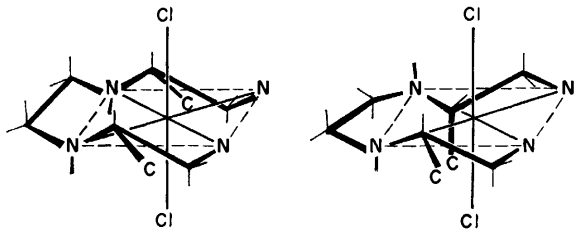

Fig. 6. Possible structures of *trans*-Co(*meso*-3,8-dimetrien)Cl_2^+ ion; (a) *meso-trans* and (b) *racemic-trans* (*SS* enantiomer).

There are two possible structures for the *trans* complexes of *meso*-3,8-dimetrien; they are illustrated in Fig. 6. In the *meso-trans* configuration, both of the methyl groups are situated equatorially. On the other hand, one of the methyl groups has the axial, and the other has the equatorial orientation for the *racemic-trans* configuration. (One of the enantiomers, the *trans*(SS) isomer, is represented in Fig. 6).

The PMR measurements may be useful in determining the actual structure of the *trans*-Co(*meso*-3,8-dimetrien)-Cl_2^+ ion. If the complex takes the *meso-trans* configuration, the PMR signals for the methyl groups should be observed as only one doublet. On the contrary, the methyl signals would be, in principle, observed as two doublets of equal intensity for the *racemic-trans* form.

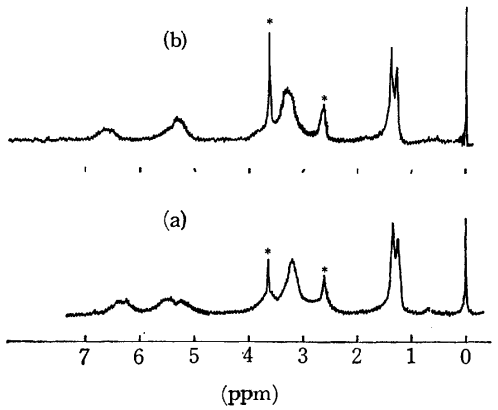

Fig. 7. PMR spectra of *trans*-Co(*meso*-3,8-dimetrien)Cl_2^+ ion (a) and *trans*-Co(*rac*-3,8-dimetrien)Cl_2^+ ion (b) in DMSO-d_6 (* are due to DMSO-d_6).

The PMR spectrum of the *trans*-dichloro complex of *meso*-3,8-dimetrien is shown in Fig. 7. The methyl signals were observed as a single soublet at about 1.3 ppm, indicating that the present complex has the *meso-trans* geometry. The PMR spectrum of the *rac*-3,8-dimetrien complex is given for the sake of comparison. The present complex also showed a single doublet for the methyl signals. However, the difference between the *meso*- and *rac*-3,8-dimetrien complexes was revealed clearly in the region of the N-bonded proton signals, which were found in the region of 5—7 ppm as broad peaks.

It was concluded, therefore, that the *trans*-dichloro complex of *meso*-3,8-dimetrien has the *meso-trans* configuration. Thus, it was clarified that the steric effects of methyl groups introduced into the trien backbone with appropriate configurations make it possible to obtain specific geometrical isomer(s) which would not be obtained in the case of non-substituted trien complexes.

Intramolecular Hydrogen Bonding in α-Keto and α-Alkoxy Carboxylic Acids. VIII. o-Methoxy-Substituted Phenoxyacetic and Phenylthioacetic Acids

Minoru HIROTA and Go HIRANO

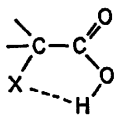
Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama

(Received June 24, 1970)

The infrared spectra in the O–H stretching region of several *ortho*-substituted phenoxyacetic and phenylthioacetic acids were determined in dilute carbon tetrachloride solutions. The O–H stretching absorption of phenoxyacetic acids carrying *o*-methoxy-substituents shows three absorption maxima, all of these being attributed to the monomeric species, and they are assigned to the free O–H group, the O–H group hydrogen bonded with α-phenoxy oxygen atom and the O–H group hydrogen bonded with methoxyl oxygen atom in the order of decreasing frequency. The O–H stretching absorption at the lower frequency of *o*-methoxyphenylthioacetic acids is also assigned to the hydrogen bonded monomeric species in which the chelation occurs between the carboxylic O–H group and the methoxyl oxygen atom.

From the previous investigations of the present authors,[1-9] the existence, as well as the steric and electronic behaviors, of the intramolecular hydrogen bonding (shown in (**1**)) in some carboxylic acids has become definite. The conclusion of these investigations shows (i) that only the acids with α-alkoxy groups ($n=1$) can form intramolecular hydrogen bonds in the homologous sereis $RO(CH_2)_nCOOH$, and (ii) that the occurrence of the hydrogen bonding is limited only when the hydrogen accepting group is an alkoxy, aryloxy, or oxo group.

In this paper, the intramolecular hydrogen bonding of the titled compounds is discussed, and it is shown that the methoxy groups at the *ortho* positions of phenoxyacetic and phenylthioacetic acids can participate as hydrogen acceptors in the COOH···O hydrogen bonding.



(1)

Expreimental

Preparation of Materials. All phenols employed in the preparation of phenoxyacetic acids are known and were prepared by the methods described previously.[10] Substituted phenoxyacetic acids were prepared either by the condensation of the phenol with chloroacetic acid in strongly alkaline aqueous medium,[11] or by the action of ethyl chloroacetate on the sodium phenoxide without the presence of solvents[12] followed by saponification. The following phenoxyacetic acids (shown in Table 1) were thus prepared and used in the further investigations. Most of the benzenethiols were prepared from the corresponding anilines by the action of potassium ethylxanthate,[13] and the others by the reduction of the corresponding benzenesulfonyl chlorides.[14] The phenylthioacetic acids were prepared by the methods similar to those of phenoxyacetic acids. The physical properties and the elementary analyses are shown in Table 2. Phenylpropionic acids and other materials were either prepared by the methods described or purchased commercial products, and used after appropriate purification.

Measurement of Infrared Spectra. The infrared spectra were recorded on a Perkin Elmer 112G grating infrared spectrophotometer in the O–H stretching region. The measurement was carried out in a carbon tetrachloride solution at a concentration less than 0.002 mol/*l*. The dimeric association of the carboxylic acids were not significant in this concentration range. To distinguish the absorption bands due to the dimer from those of the monomer, the concentration dependences of their absorption intensities were also measured with some typical acids.

The wave numbers, the extinction coefficients, and the half-widths of the overlapping bands were obtained by the least square calculations employing an NEAC 2230 computer.

Results and Discussion

The O–H stretching spectra are listed in Table 3 for phenoxyacetic acids, in Table 4 for phenylthioacetic acids and in Table 5 for some related compounds, and some typical spectra were illustrated in Figs. 1 and 2.

The intramolecular hydrogen bonding in aryloxyacetic acids without *ortho* substituent has been studied by the present authors,[2-5] and it has been shown that the acids have two absorptions in the O–H stretching region. The envelope of each absorption band could be approximated with the Lorentz function within experimental errors. The typical of them is phenoxyacetic acid (Fig. 1a) which has two O–H stretching absorptions at 3527 cm^{-1} and 3488 cm^{-1}. These absorptions are assigned to the free monomeric form **2** and intramolec-

ularly hydrogen bonded monomeric form **3**, respectively. The O–H absorptions of *ortho*-substituted phenoxyacetic acids are essentially the same as the unsubstituted ones when the *ortho*-substituents are not hydrogen acceptors. Thus, *o*-methylphenoxyacetic acid has two absorptions at 3529 and 3485 cm^{-1} attributable to the free and hydrogen bonded monomeric forms, respectively.

However, a third absorption band (band IV of *ortho*-methoxy-derivatives) is observed when the *ortho*-substituent can act as hydrogen acceptor. The bands IV of *o*-methoxy-substituted acids appear at frequencies between 3400 and 3300 cm^{-1} and their halfwidths $\Delta\nu_{1/2}$, about 100 cm^{-1}, are by far larger than the absorption bands I and II. The *o*-methoxyphenylthioacetic acids also absorb at about 3330 cm^{-1} (as exemplified by the absorption band at 3352 cm^{-1} of *o*-methoxyphenylthioacetic acid (No. 16) and the one at 3333 cm^{-1} of 2,6-dimethoxyphenylthioacetic acid (No. 17)) and the halfwidths of these absorption bands are again near 100 cm^{-1}. Thus, the bands IV of *o*-methoxy substituted phenoxyacetic acids and the bands at the similar frequencies of *o*-methoxy-substituted phenylthioacetic acids might be absorption bands caused by the same kind of molecular interaction. The arylthioacetic acid without *o*-methoxy groups has only one absorption band attributable to the free monomeric form in the O–H stretching region. As the absorption has been assigned to the monomeric species the only plausible assignment for the band at a lower frequency is that it arises from the carboxylic hydroxyl group intramolecularly hydrogen bonded to the oxygen atom of the *o*-methoxyl group.

(4)

The authors have concluded that the existence of the COOH···O hydrogen bond of alkoxy- or aryloxy-acetic acid was limited to the case in which the acid forms a five-membered chelate ring by the hydrogen bond formation. The result above shows that an eight-membered chelate ring will be formed by the COOH··· O hydrogen bond, and is an exception of the earlier generalization. But the *o*-methoxy-substituents of these acids are located at a close distance from the carboxyl

group when the molecule takes a suitable conformation, and the hydrogen bond formation is not so unusual if the hydrogen bonding is mainly controlled by the steric accessibility of the donor hydroxyl group and an oxygen acceptor.

The fact that the band IV arises from the unassociated monomeric species is verified by the measurement of the concentration dependence of the O–H spectra carried out with some of these acids. An example is shown in Fig. 3 in which the O–H spectrum of 2,6-dimethoxyphenylthioacetic acid is illustrated at three different concentrations. In Fig. 3, the molar extinction coefficients of both the 3533 cm^{-1} band (band I) and the 3333 cm^{-1} band (band IV) increase as the concentration decreases. The increase in intensity can be interpreted that the monomeric species is more favorable at lower concentrations. The absorption due to the dimer lies in the frequency range between 3200 and 2500 cm^{-1}, and the isosbestic point near 3275 cm^{-1} indicates the

existence of the monomer-dimer equilibrium.[15]

To determine the extent of the existence of the COOH···OCH_3 hydrogen bond of this type, the O–H stretching absorptions of *o*-methoxy-substituted *β*-phenylpropionic and *cis*-cinnamic acids were observed, and the absence of the COOH···OCH_3 hydrogen bond was concluded because no absorption bands other than the free monomeric species appear in the O–H stretching region (as shown in Table 5).

The ultraviolet spectral studies on *cis*-cinnamic acids show that their aromatic rings and ethylenic linkages do not lie in the same plane, and angles between the two chromophores are estimated to be about 40° by comparison of the absorption intensities of the *cis* and the *trans* isomers.[16] In *cis-o*-methoxycinnamic acid, a much larger angle between the aryl and the ethylenic groups is expected from is lower intensity in π-π^* transition, though the calculation of the exact value for this angle is meaningless because the approximation does not hold in a case of such large steric hindrance.[17] Anyhow, the deviation of the aryl ring from the planar conformation increases the distance between the *o*-methoxy and the carboxyl groups in *cis-o*-methoxycinnamic acid and makes it difficult to form the intramolecular hydrogen bond.

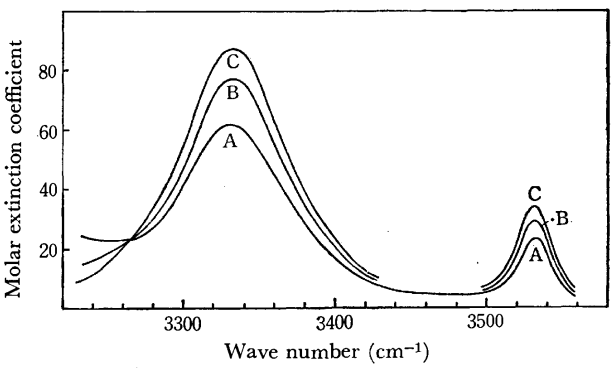

Fig. 3. Concentration Dependence of the O–H Absorption Bands of 2,6-Dimethoxyphenylthioacetic Acid. Spectra A, B, and C are measured in carbon tetrachloride at concentrations 3.048×10^{-3}, 1.016×10^{-3}, and 5.08×10^{-4} mol/*l*, respectively.

15) The measurement of the infrared spectra was carried out at a concentration less than 0.002 mol/*l* in order to lessen the effect of concentration. Nevertheless, the absolute values of the intensity are less significant quantities than their ratios.

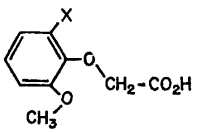
16) Y. Urushibara and M. Hirota, *Nippon Kagaku Zasshi*, **82**, 354, 358 (1961).

17) E. A. Braude and F. Sondheimer, *J. Chem. Soc.*, **1955**, 3754,

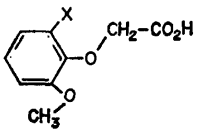
The absence of the intramolecular hydrogen bond in β-(*o*-methoxyphenyl)propionic acid is explained in the following way. Difference in conformation between aryloxyacetic acids and β-aryloxypropionic acids may arise from the absence of the β-hydrogen atoms and aryl-oxygen conjugation in the former compound. The former factor restricts the conformations of the rotamers about the C_β-C_α bond of the β-arylpropionic acid, and may affect unfavorably on the hydrogen bond formation. The aryl-oxygen conjugation in phenoxy group enforces the essentially planar Ar–O–C conformation (either (**5**) or (**6**)) to the *o*-methoxyphenoxyacetic acid.[18] Thus the carboxyl group is located in the neighborhood of the *o*-methoxyl group in the conformation (**5**). The freedom of the rotation about the phenyl-β-carbon bond in β-aryloxypropionic acid may act as an entropically unfavorable factor to the hydrogen bond formation.

The other fact to be interpreted is why the intramolecular hydrogen bond is present in *o*-methoxyphenoxyacetic acid while it is absent in β-methoxypropionic acid.[1] The presence of the eight-membered intramolecular hydrogen bond is understood if the carboxyl group can form hydrogen bond maintaining the energetically favorable *cis*[19]-conformation (which is about 2 kcal/mol more stable than the *trans*).[20] The β-methoxypropionic acid should take the *trans*[19] conformation to form the intramolecular hydrogen bond. The *cis* conformation of the carboxyl group is very probable from the spectral data of the same compounds in the carbonyl stretching region.

The integrated intensity ratio A_{IV}/A_I corresponds to the ratio of the COOH···OCH_3 hydrogen bonded species to the free monomeric species, which represents how favorable the hydrogen bonded conformation is, and $\Delta\nu$ is assumed to be linear with the energy of hydrogen bond formation.[21] The parallel relation between the A_{IV}/A_I and $\Delta\nu$ is observed with the *o*-methoxyphenoxyacetic acids (No. 6—9) in Table 3 as expected from their definitions. In this series of carboxylic acids, the A_{IV}/A_I, as well as $\Delta\nu$ values indicate that the intramolecular hydrogen bond becomes more favorable in the following order of 6-substituent: H<Br<CH_3. The bulky 6-substituent presumably favors the intramolecular hydrogen bond of this type by preventing the carboxylic acid to take the "*s-trans*" conformation[25] (**6**) which is unfavorable for the hydrogen bond formation.



"*s-cis*" conformation
(**5**)



"*s-trans*" conformation
(**6**)

Another weak absorption (band III in Table 3) may exist at about 3440 cm^{-1}. But the existence and the assignment is not certain and to be further investigated.

The authors are grateful to Prof. M. Ōki of the University of Tokyo and to Prof. H. Kakiuchi of Yokohama National University for their valuable advice. The authors also wish to express their hearty thanks to Prof. T. Shimanouchi and Prof. I. Nakagawa of the University of Tokyo for their useful suggestions and their kind permission to use infrared spectrophotometers.

18) The coplanarity is supported by comparing the ultraviolet spectra of the *o*-methoxyphenoxyacetic acid (λ_{max} 276.5 nm, ε_{max} 2790) with catechol dimethyl ether (λ_{max} 277 nm, ε_{max} 2920). Assuming the angle between the phenyl and the C–O–C planes (20°) as estimated from UV data and that the carboxyl O–H group lies 30° above the O=C–O plane in the *cis* conformation,[22] the conformation (**5**) of the hydrogen bonded species were plausible, from the Stewart's molecular models. In the assumed conformer the ArO and the carboxyl C=O grous take the most stable eclipsed conformation.[23]

19) On the nomenclature of the carboxyl conformation, see Ref. 22.

25) The term "*s-trans*" and *s-cis*" refers to the conformations in which the methoxyl and carboxymethyl groups are the opposite and the same sides with respect to the C_{Ar}–O_{CH_2} bond, respectively. They are indifferent to the *cis* and *trans* conformations of carboxyl groups.

Photooxidation of 1,4-Dihyropyridines

Oyo MITSUNOBU, Shozo MATSUMOTO, Makoto WADA, and Hiroaki MASUDA

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Megurisawa-cho, Setagaya-ku, Tokyo

(Received July 3, 1971)

1,4-Dihydropyridines were successfully photooxidized to corresponding pyridines under suitable conditions. The substituents of the dihydropyridines, reaction mediums, and atmospheres affect the course of the reactions. When diethyl 2,6-dimethyl-1,4-dihydropyridine-3,5-dicarboxylate (**1a**), diethyl 1,4-dihydropyridine-3,5-dicarboxylate (**1b**), 2,6-dimethyl-3,5-diacetyl-1,4-dihydropyridine (**1c**), and 3,5-diacetyl-1,4-dihydropyridine (**1d**) were irradiated by a super high pressure mercury lamp with filter in ethanol under air or oxygen, corresponding pyridines, diethyl 2,6-dimethylpyridine-3,5-dicarboxylate (**2a**), diethyl pyridine-3,5-dicarboxylate (**2b**), 2,6-dimethyl-3,5-diacethylpyridine (**2c**), and 3,5-diacetylpyridine (**2d**) were formed in good yields. Irradiation of **1a**, **1c**, and **1d** in acetonitrile afforded **2a**, **2c**, and **2d** irrespective of their atomosphere, oxygen or nitrogen. On the other hand, photolysis of **1b** by the same lamp and filter in ethanol or acetonitrile in an atmosphere of nitrogen resulted in the formation of photodimer (**3**) which on irradiation by low pressure mercury lamp in acetonitrile dissociated to **1b** followed by photooxidation giving **2b**. Diethyl 1-acetyl-1,4-dihydropyridine-3,5-dicarbolxyate (**4e**) and 1,3,5-triacetyl-1,4-dihydropyridine (**4f**) afforded **2b** and **2d** in fairly good yields when the photolyses were carried out in an atmosphere of air in ethanol or acetonitrile.

The pyridine nucleotides, with their reduced forms, play a role in biological oxidation-reduction process and in biological hydroxylation of substrates by molecular oxygen.[1,2] For the chemical models of the process, the non-photochemical reaction of 1,4-dihydropyridine derivatives with a variety of hydrogen acceptor compounds has been widely investigated.[1,3]

Recently, Abelson, *et al.*[4] have examined the photolysis of reduced nicotinamide-adenine dinucleotide (NADH) and have speculated as to biological significance of the photoproducts. There are few reports, however, of the photochemical reactions of 1,4-dihydropyridines and NADH.[5-7] Eisner *et al.*[8] have demonstrated that on irradiation with medium pressure mercury lamp through a Pyrex filter in an atmosphere of nitrogen, diethyl 1,4-dihydropyridine-3,5-dicarboxylate in *t*-butyl alcohol afforded photodimer as a main product.

In the course of the investigation on the reactions coupled to oxidation-reduction systems, it was found that on irradiation of 1,4-dihydropyridines (**1**) under appropriate conditions the corresponding pyridines were formed in good yields.[9]

Irradiation of 1,4-Dihydropyridines in Ethanol under Oxygen Atmosphere. When diethyl 2,6-dimethyl-1,4-dihydropyridine-3,5-dicarboxylate (**1a**) in ethanol was irradiated under air, the oxidized product, diethyl 2,6-dimethylpyridine-3,5-dicarboxylate (**2a**) was formed as indicated by UV spectrum and thin layer chromatography (tlc) (Fig. 1). As shown in Fig. 1, isosbestic points were observed at 219 mμ, 265 mμ, and 300 mμ. Under similar conditions (ethanol, irradiation under air), diethyl 1,4-dihydropyridine-3,5-dicarboxylate (**1b**) and 2,6-dimethyl-3,5-diacetyl-1,4-dihydropyridine (**1c**) gave diethyl pyridine-3,5-dicarboxylate (**2b**) and 2,6-dimethyl-3,5-diacetylpyridine (**2c**), respectively (Fig. 2, 3).

a: R=CH_3, R′=$COOC_2H_5$ **b**: R=H, R′=$COOC_2H_5$
c: R=CH_3, R′=$COCH_3$ **d**: R=H, R′=$COCH_3$

When 3,5-diacetyl-1,4-dihydropyridine (**1d**) in ethanol was irradiated in an atmosphere of oxygen, a new absorption maximum was appeared at 313 mμ as decrease of a maximum at 397 mμ of **1d**. Further irradiation caused a decrease of the new peak and 3,5-diacetylpyridine (**2d**) was simultaneously formed (Fig. 4). The appearance of the absorption maximum at 313 mμ may be attributed to the formation of an intermediate.

Irradiation of 1,4-Dihydropyridines in Ethanol under Nitrogen Atmosphere. Similar to the results obtained by Eisner *et al.*,[8] the irradiation of **1b** or **1c** in ethanol under nitrogen atmosphere resulted in the formation of

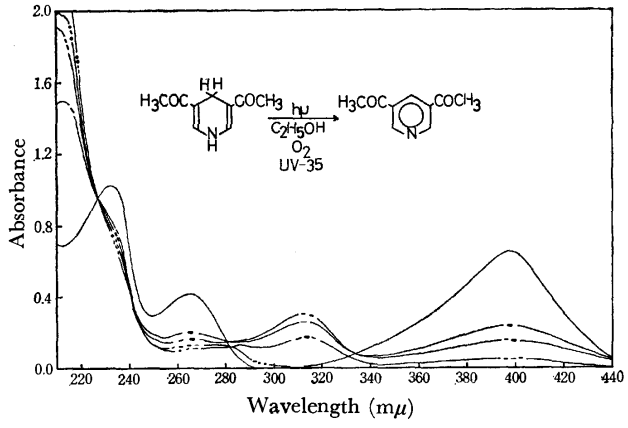

Fig. 4. Photolysis of 3,5-diacetyl-1,4-dihydropyridine (**1d**). —— Before irradiation,—·— after 10 min,—··— after 20 min, —·—·— after 40 min,—·—··— after 460 min.

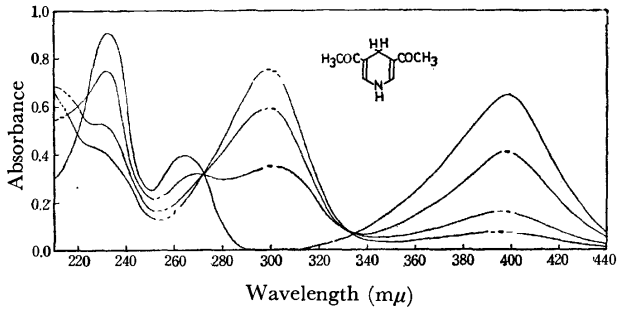

Fig. 5. Photolysis of 3,5-diacetyl-1,4-dihydropyridine (**1d**) in ethanol under an atomosphere of nitrogen using 100W immersion lamp.—— Before irradiation,—·— after 70 hr,—··— after 150 hr,—·····— after 300 hr. A new peak at 298 mμ may due the formation of photodimer.

a photodimer (**3**, λ_{max} 279 mμ) or 3-acetyl-2,6-dimethyl-5-α-hydroxyethylpyridine, respectively. The photodimer was isolated in an 81% yield. Under similar conditions, **1d** gave a new product (λ_{max} 298 mμ) which we presumed to be corresponding dimer as judged by its UV spectrum (Fig. 5). The attempt to isolate and confirm the structure of the compound was not made.

Photolysis of **1a** under similar conditions showed little spectral change; irradiation for 12 hr resulted in a decrease in the absorption maximum no less than 17% of the initial extinction.

Irradiation of 1,4-Dihydropyridines in Acetonitrile under Nitrogen or Oxygen. When acetonitrile was used as the solvent in the above experiments, **1a**, **1c**, and **1d** were oxidized to **2a**, **2c**, and **2d** irrespective of their atmosphere, nitrogen or oxygen. On irradiation of **1d** in acetonitrile under nitrogen atmosphere, **2d** was isolated in a 74% yield. Irradiation of **1b** under oxygen led to the formation of **2b**, while irradiation of **1b** under nitrogen led to dimerization to **3** which was isolated in a 74% yield.

It was noteworthy that when a solution of **3** in acetonitrile was irradiated without filter under an atmosphere of nitrogen, the solution fluoresced a blue color and new absorption maxima were appeared at 372 mμ and 220 mμ. Further irradiation caused disappearance of the peak at 372 mμ and **2b** was formed as indicated by UV spectrum (Fig. 6). This result suggests that the **3** is rather stable toward ultraviolet light of wavelength

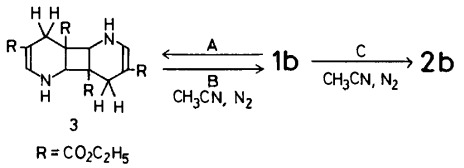
above 310 mμ, whereas the **3** dissociated to **1b** followed by oxidation to **2b** by ultraviolet light of wavelength below 310 mμ. This assumption was proved by a separate experiment in which **1b** was oxidized to **2b** on irradiation with low pressure mercury lamp.

Contrary to the photolysis of the **3** in acetonitrile, the irradiation of the **3** in ethanol resulted in the formation of only a small amount of **2b** along with many side products as indicated by tlc.[11]



3
R=$CO_2C_2H_5$

A: high pressure Hg lamp with UV-35 filter
B: high pressure Hg lamp without filter
C: low pressure Hg lamp without filter

These results are summarized in Table 1.

Photolysis of 1-Substituted-1,4-dihydropyridines. Loev and Snader[12] have demonstrated that in the nitrous acid oxidation of 1,4-dihydropyridines, the most likely mechanism is that involves initial attack at 1-position. Thus, 1-methyl, 1-benzyl, and 1-acetyl-1,4-dihydropyridines were irradiated in order to investigate the influence of the substituents at 1-position.

When diethyl 1,2,6-trimethyl-1,4-dihydropyridine-3,5-dicarboxylate (**4a**), diethyl 1-methyl-1,4-dihydropyridine-3,5-dicarboxylate (**4b**), 1-methyl-3,5-diacetyl-1,4-dihydropyridine (**4c**), and 1-benzyl-3,5-diacetyl-1,4-dihydropyridine (**4d**) were irradiated and the reaction mixtures were monitored by tlc, only small amounts of the corresponding pyridines were formed along with many side products under the conditions examined (in ethanol or acetonitrile; under an atmosphere of nitrogen or oxygen). Although the possibilities of the formation of 1-alkylpyridinium salts could not be excluded, further attempts to isolate and determine the structures of the products were not be made.

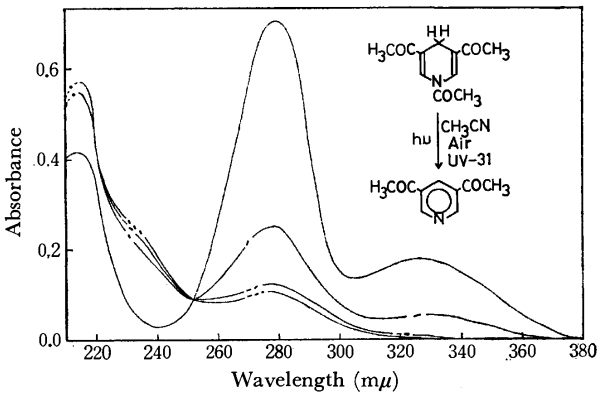


Fig. 7. Photolysis of 1,3,5-triacetyl-1,4-dihydropyridine (**4f**).
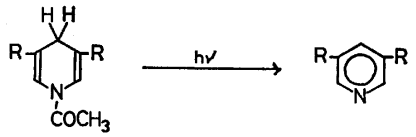
—— Before irradiation, ——— after 10 min, —·— after 25 min, —··— after 45 min.

Contrary to the cases of 1-alkyl-1,4-dihydropyridines diethyl 1-acetyl-1,4-dihydropyridine-3,5-dicarboxylate (**4e**) and 1,3,5-triacetyl-1,4-dihydropyridine (**4f**) afforded corresponding pyridines in fairly good yields when the photolyses were carried out in an atmosphere of air in ethanol or acetonitrile (Fig. 7). While **4e** is stable in ethanol at room temperature, **4f** decomposed to 3,5-diacetyl-1,4-dihydropyridine during blowing oxygen or nitrogen through the reaction vessel before irradiation. This result suggests that **4f** is an active acylating reagent. The use of 1-acyl and 1-phosphoryl-1,4-dihydropyridines for the acylation and phosphorylation of active hydrogen compounds are now under investigation.



4e: R=$COOC_2H_5$ **2b**: R=$COOC_2H_5$

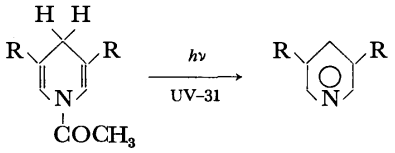
11) The photolysis was carried out by means of super high pressure mercury lamp without filter under an atmosphere of nitrogen or oxygen.
12) B. Loev and K. M. Snader, *J. Org. Chem.*, **30**, 1914 (1965).

Being irradiated under nitrogen atmosphere, **4e** and **4f** gave no expected pyridines, **2b** and **2d** but many side products were formed as indicated by tlc irrespective of their solvents, ethanol or acetonitrile. The results are summarized in Table 2.

Table 2. Photolysis of 1-acetyl-1,4-dihydropyridines



4e: R=$COOC_2H_5$ **2b**: R=$COOC_2H_5$
4f: R=$COCH_3$ **2d**: R=$COCH_3$

Atmosphere		Solvent and Reactant: Ethanol 4e	Ethanol 4f	Acetonitrile 4e	Acetonitrile 4f
O_2	Concentration of **4** $\times 10^5$ mol/*l*	3.55	4.07	3.62	3.44
	Product	**2b**	a)	**2b**	**2d**

	Product	b)	a)	b)	b)

a) **4f** decomposed to 3,5-diacetyl-1,4-dihydropyridine during the oxygen was bubbled through the reaction vessel before irradiation.

b) Only small amount of the corresponding pyridines were formed along with many side products.

The results reported in this paper indicate that the photooxidation of 1,4-dihydropyridines to pyridines depends on the atmosphere and solvents used and under certain conditions, corresponding pyridines were formed in good yields. As have been pointed out by Eisner *et al.*[8] the substituents at 2,6-position also affect the course of the reaction. 1,4-Dihydropyridines without substituents at 2,6-positions such as diethyl 1,4-dihydropyridine-3,5-dicarboxylate afforded corresponding dimers on irradiation with ultraviolet light of wavelength above 310 mμ (N_2, in ethanol or acetonitrile). While, photolysis by means of ultraviolet light of short wavelength, **1b** was oxidized to diethyl pyridine-3,5-dicarboxylate (**2b**; N_2, in acetonitrile).

Further investigation on the photoreduction of various classes of substrates by means of 1,4-dihydropyridines are in progress.

Experimental

The UV spectra were obtained with a Hitachi EPS-3T spectrometer. The IR spectra were taken at Nippon Bunko IR-G spectrometer (KBr disk). The thin layer chromatograms were prepared on silica gel PF_{254} (Merck) and developed with chloroform, ethyl acetate or acetonitrile.

Diethyl 2,6-dimethyl-1,4-dihydropyridine-3,5-dicarboxylate (**1a**),[13] diethyl 1,4-dihydropyridine-3,5-dicarboxylate (**1b**),[14] 2,6-dimethyl-3,5-diacetyl-1,4-dihydropyridine (**1c**),[15] 3,5-diacetyl-1,4-dihydropyridine (**1d**),[16] diethyl 1,2,6-trimethyl-1,4-dihydropyridine-3,5-dicarboxylate (**4a**),[14] diethyl 1-methyl-1,4-dihydropyridine-3,5-dicarboxylate (**4b**),[14] 1-methyl-3,5-diacetyl-1,4-dihydropyridine (**4c**),[14] and 1,3,5-triacetyl-1,4-dihydropyridine (**4f**),[17] were prepared by known procedures. Acetonitrile was purified by distilling from phosphorus pentoxide.[18] Ethanol was dried and purified by known procedure.[19]

*Preparation of 1-Benzyl-3,5-diacetyl-1,4-dihydropyridine (**4d**).* 3,5-diacetyl-1,4-dihydropyridine (0.0696 g) and sodium hydride (0.0683 g) in dimethoxyethane (8 m*l*) were stirred for 30 min at room temperature. Benzyl chloride (0.5 m*l*) was added and stirring was continued for an additional 5 hr. The solution was filtered through a hyflo-super-cel and the filtrate was evaporated to dryness under reduced pressure. After two crystallization from ethyl acetate, the dihydropyridine was obtained yellow crystals, mp 159—160°C. Found: C, 74.43; H, 6.51%. Calcd for $C_{16}H_{17}NO_2$: C, 75.27; H, 6.61%.

*Preparation of Diethyl 1-Acetyl-1,4-dihydro-3,5-dicarboxylate (**4e**).* Under nitrogen atmosphere, diethyl 1,4-dihydropyridine-3,5-dicarboxylate (0.5 g) and sodium hydride (0.6 g) in dimethoxyethane (50 m*l*) were stirred for 30 min at room temperature. Acetyl chloride (6 m*l*) was added and stirring was continued for an additional 2 hr. The mixture was filtered through a hyflo-super-cel and the filtrate was evaporated to dryness under reduced pressure. After recrystallization from acetonitrile, the dihydropyridine was obtained as white crystals, mp 113—114°C. Found: C, 59.68; H, 6.44%. Calcd for $C_{13}H_{17}NO_5$; C, 58.42; H, 6.41%.

General Photolysis Procedures. A solution of 1,4-dihydropyridine (**1**) in ethanol or acetonitrile in a quartz vessel (5 cm×5 cm diameter) was irradiated by super high pressure mercury lamp (Ushio Electric Co., Type SH-250) with UV-35 (Toshiba Electric Co., opaque below 325 mμ, 50% transmission at 350 mμ, 80% transmission above 400 mμ) or UV-31 filter (opaque below 250 mμ, 50% transmission at 310 mμ, 90% transmission above 350 mμ). Nitrogen or oxygen was bubbled throughout the reaction and aliquots of 4 m*l* were removed after appropriate time intervals followed by spectrophotometric measurement.

When the photolyses were carried out in air, the solutions were placed in an absorption spectrum quartz cell of optical path 1.0 cm and irradiated through the filter.

The pyridines produced were identified by comparison of R_f values of tlc with those of authentic samples after the reaction mixtures were concentrated to a small volume.

For the preparative scale experiments, the reactions were carried out in a three necked flask using a 100 W high pressure immersion lamp (Osawa, Type NY-2).

*Photolysis of 3,5-Diacetyl-1,4-dihydropyridine (**1d**) in Acetonitrile under an Atmosphere of Nitrogen.* A solution of **1d** (0.330 g) in acetonitrile (400 m*l*) was stirred for 21 hr while irradiating with a 100 W high pressure immersion mercury lamp. Nitrogen was bubbled throughout the reaction. After the solution was evaporated to dryness under reduced pressure, the residue

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1457—1460(1972)

Dimerization and Isotopic Mixing of Ethylene by a Palladium Complex Catalyst

Taketsugu KITAMURA, Ken-ichi MARUYA, Yoshihiko MORO-OKA, and Atsumu OZAKI

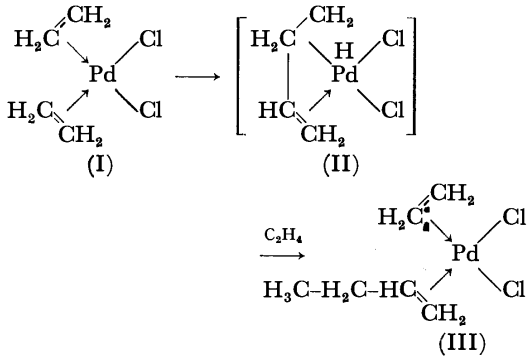
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received July 5, 1971)

Dimerization and accompanied isotopic exchange of ethylene were studied with dichlorobis(benzonitrile)-palladium(II) complex in benzene solution. Dimerization as well as isotopic exchange take place simultaneously after an induction period, the extent of which is reduced by the presence of hydrogen releasing olefin such as 3-methyl-1-butene. Kinetics of dimerization is of first order in ethylene, but the dimerization rate does not immediately respond to the change in ethylene pressure. The results are interpreted in terms of a preformed palladium hydride complex.

The dimerization of olefin catalyzed by palladium salts has been studied by a number of workers[2-7] since its discovery by Gemert and Wilkinson.[1] Although the catalyst species were varied among palladium chloride or its complex with benzonitrile and di-μ-chlorobis-(ethylene)palladium, *etc.*, the real active species in the dimerization seem to be a monomeric palladium-olefin complex[2] soluble in organic solvents. The following information has been obtained on the dimerization reaction: The rate of dimerization is proportional to concentrations of palladium salt and ethylene.[4] Co-dimerization of ethylene takes place in the presence of other olefin,[6,7] although ethylene is most reactive in the dimerization.[7] There is a remarkable solvent effect.[3,5,7] It is also known that the palladium catalyst catalyzes the isomerization of olefin.[7]

The mechanisms of dimerization so far proposed[2-7] can be summarized into two schemes: (1) A palladium hydride intermediate as adopted for butene isomerization by Cramer and Lindsey is assumed, according to the mechanism proposed by Barlow *et al.*[7] (2) A five co-ordinate hydride complex(II) as an intermediate is assumed according to the mechanism proposed by Ketley *et al.*[2] and is shown in the following. A detailed study was made by Kawamoto, Tatani, Imanaka, and Teranishi[6c] by means of solvent effect and deuterium labeled reactant, styrene-d_3.



On the other hand in the study of the mechanism of ethylene dimerization with nickel oxide-silica catalyst,[9] it was found that a rapid isotopic mixing in ethylene takes place prior to the dimerization and both the isotopic mixing and dimerization are simultaneously poisoned by a very small amount of CO. Since both

reactions commonly require an intermolecular hydrogen transfer, the results suggest that the ability of the catalyst to cause the isotopic mixing in ethylene is a requisite for the dimerization catalyst and the dissociation of ethylene to form a nickel hydride is involved in the path way of dimerization.

Thus it is of interest to study the isotopic mixing during the course of dimerization by different catalysts in a homogeneous system. This paper deals with such a study of ethylene dimerization by the benzonitrile-palladium complex.

Experimental

Materials. Dichloro-bis-benzonitrile-palladium(II) complex was prepared by the method of Kharasch.[10] Benzene was treated with metallic sodium prior to distillation in dry nitrogen stream and was preserved and transferred in dry nitrogen. C_2D_4 was prepared by deuterogenation of C_2D_2 at room temperature over a Girdler (58A) Pd catalyst and separated from impurities by means of gas chromatography using a silica gel column. C_2D_2 was obtained by reaction of D_2O with CaC_2 which had been evacuated at 400°C for 150 hr.

Procedures. The reactions were carried out in a small flask with stirring under constant pressure at 36°C. The ethylene concentration in the solvent was confirmed to be proportional to the ethylene pressure. The rate of dimerization was determined from the amount of ethylene absorbed into the catalyst solution. Isotopic analyses were carried out by mass spectrometry with an ionization voltage of 10 eV.

Results

1. The Effect of Ethylene Concentration on the Rate of Dimerization. Ethylene dimerization by the palladium complex is much slower in benzene than in polar solvents,[6] but benzene was chosen as solvent because the slow reaction was convenient for studying the effects of reaction conditions. Figure 1 shows the time course of absorption of ethylene where 0.5 mmol of $PdCl_2(\phi CN)_2$ complex was used. In the initial period, 0.5 mmol of ethylene which is equimolar to the amount of catalyst is absorbed to form the ethylene complex. The amount of initial absorption is independent of ethylene pressure as shown by runs A and B. The absorption due to the dimerization begins after a few hours of induction period, which decreases with the increase in ethylene pressure. The rate of absorption increases with time and attains a steady value about 15—18 hr after the introduction of ethylene into the reactor. The steady rate of absorption is taken as the rate of dimerization of ethylene.

The reaction product was exclusively butenes with a composition of 1-butene 4%, *cis*-2-butene 36%, and *trans*-2-butene 60% which is close to the value corresponding to the equilibrium of isomerization.

According to Kawamoto *et al.*,[4] the kinetics of the dimerization by $Pd_2Cl_4(C_2H_4)_2$ complex in dioxane is as follows:

$$\text{Rate} = k[\text{Pd complex}]^{1.0}[C_2H_4]^{1.0} \quad (1)$$

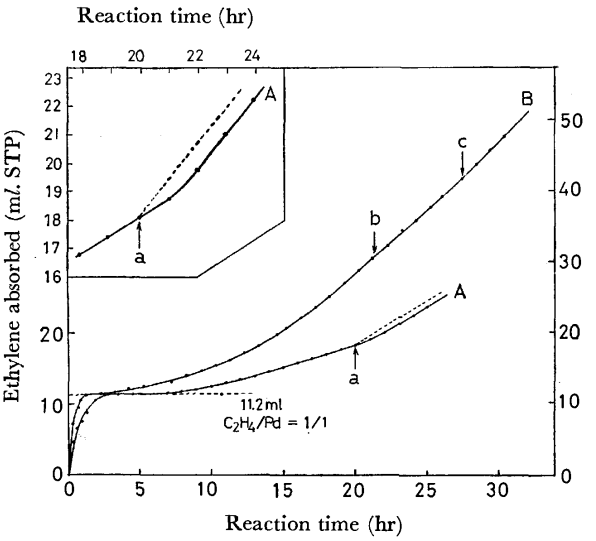

Fig. 1. Time course of ethylene dimerization by $PdCl_2(CN)_2$ catalyst (0.5 mmol) in benzene (50 m*l*) at 36°C under following pressures.
A: 168 mmHg changed to 579 mmHg at a
B: 596 mmHg changed to 131 mmHg at b and to 596 mmHg at c.

The present results is in line with this equation with respect to ethylene concentration as deduced from the results in Fig. 1, where about 3.5 times difference in the ethylene pressure causes a 3.0 times difference in the steady rate. Proportionality with the concentration of Pd complex was confirmed by separate runs.

A further study of the kinetic behavior of the dimerization was made by a pressure jump method as shown at point "a", Fig. 1, where the ethylene pressure was jumped up to about 3.5 times the initial level. However, as we see from the magnified scale, there is no immediate response in the reaction rate, which stays at the initial value for about 1 hr before beginning to increase and attains another steady value about 3 hr later. The response is further delayed in the case of pressure drop (point "b") where the ethylene concentration is reduced to about three tenths. The reaction rates in the following 6 hr is completely unchanged and the pressure jump up to the previous value made again after 6 hr (point "c") causes little change in the rate of absorption. This slow response of the reaction rate to the sudden change in ethylene pressure was further confirmed by repeated changes in the range of 131 to 600 mmHg which corresponded to ethylene concentration of 2.14×10^{-2} to 9.64×10^{-2} mol/*l*. This result demonstrates that the apparent first order kinetics with respect to ethylene does not directly reflect the kinetic nature of the rate determining step for the ethylene dimerization.

2. Isotopic Exchange between Olefins. A mixture of C_2H_4 and C_2D_4 was introduced into the reaction vessel under the reaction conditions of dimerization, and the isotopic distribution in the remaining ethylene was followed by intermittent analyses. Figure 2 shows the time course of individual isotopic species. It is clear that the palladium complex is activated for the isotopic exchange after a while of induction period and that ethylene exchanges one hydrogen atom at a time. It is

10) M. S. Kharasch, R. C. Seyler, and T. R. Mayo, *J. Amer. Chem. Soc.*, **60**, 882 (1938).

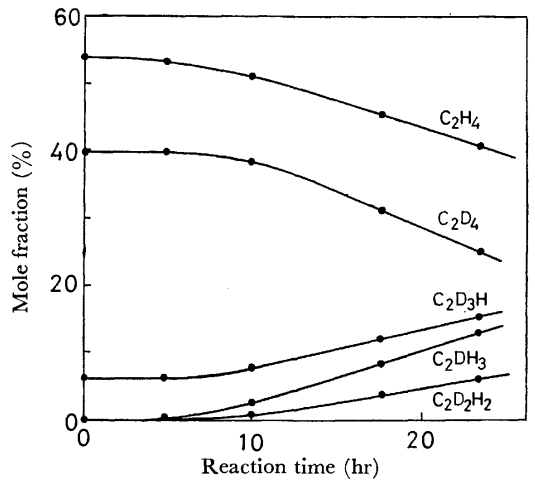

Fig. 2. C_2H_4–C_2D_4 exchange reaction by $PdCl_2(\phi CN)_2$ (0.5 mmol) in benzene (50 ml) at 36°C.

noteworthy that the induction period for the exchange is in agreement with that for the dimerization. That is, both reactions set in simultaneously. This demonstrates that a common active species, possibly a hydride, is responsible for the two reactions. It is also suggested that the hydride might be formed by reacting with ethylene.

3. The Effect of added Olefin on the Rate of Ethylene Dimerization. If the dimerization is promoted by a hydride complex whose hydrogen is provided by ethylene, the rate of dimerization would be enhanced by the presence of an olefin whose hydrogen is readily dissociated. Thus the runs of ethylene dimerization

Table 1. Effects of added olefins on the extent of induction period and rate of dimerization at 36°C and 150 mmHg of ethylene pressure

Added olefin (mmol)		Induction Period (hr)	Rate of Dimerization (ml STP/hr)
None		15—20	~0.9
1-Butene	0.05	17	0.9
1-Butene	0.2	10	0.95
1-Butene	0.5	8	1.0
1-Butene	0.8	5	1.1
trans-2-C′$_4$	0.6	17	~0.9
3-Me-1-C′$_4$	0.14	7	1.4
3-Me-1-C′$_4$	0.6	5	2.8

C′$_4$: butene, Me: methyl

were carried out in the presence of olefins which were mostly about equimolar to the amount of catalyst. The results are shown in Table 1. It is revealed that the hydrogen-releasing olefins such as 3-methyl-1-butene and 1-butene give rise to a decrease in the induction period with the extent increasing with the amount of added olefin. This decrease in the induction period is accompanied by a remarkable increase in the rate of ethylene dimerization in the case of 3-methyl-1-butene which is known to be most liable to release its hydrogen. The extent of enhancement is nearly proportional to the amount of 3-methyl-1-butene added. *trans*-2-Butene which is less liable to release hydrogen gives rise to no decrease in the induction period. In view of this fact, the rather small extent in the enhancement by butene-1 as compared with the decrease in the induction period may be due to the isomerization of added 1-butene to 2-butene.

Product analyses showed no formation of codimer or dimer of the added olefin. This is reasonable because the amount of added olefin is rather small, and ethylene is most reactive in dimerization among olefins.[7]

Discussion

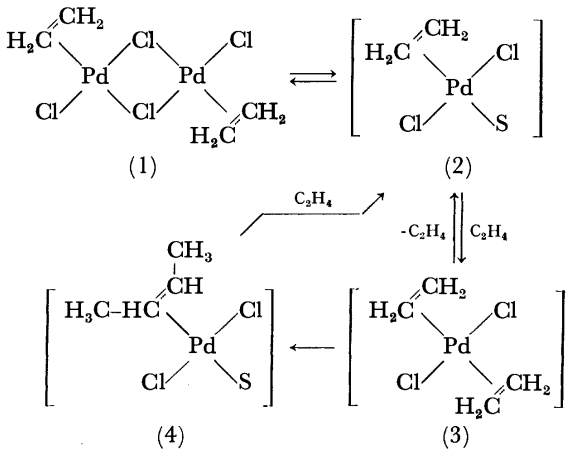
The results are summarized as follows. (1) Although the rate of ethylene dimerization is consistent with the first order kinetics with respect to ethylene, the response of the rate to the ethylene pressure change is considerably delayed.

(2) The palladium-benzonitrile complex is activated after a while of induction period for two reactions simultaneously, ethylene dimerization and isotopic exchange in ethylene.

(3) The presence of hydrogen-releasing olefin decreases the extent of induction period and enhances the rate of dimerization without formation of codimer.

The observed delay in the response to pressure change seems to be caused by the step responsible for the induction period. The delayed response and the apparent first order kinetics can be understood if the equilibrated concentration of active intermediate formed in the induction period is proportional to ethylene pressure and the steady rate of dimerization is proportional to the concentration of this active intermediate.

The kinetics of ethylene dimerization by palladium complex in dioxane has been interpreted in terms of the following scheme:[4]



where a steady state of dimerization is attained by cyclic reactions (2)→(3)→(4)→(2), steps (3)→(4) being rate-determining. However, this scheme is inadequate for the present case because it is inconsistent with the delayed response.

Kawamoto *et al.*[6c] proposed a mechanism with a

hydride shift between coordinated olefins, on the basis of a tracer study of codimerization of styrene-d_3 with light ethylene. However, we found that the isotopic exchange between reacting olefins takes place ahead of the dimerization. Since this kind of exchange cannot be ignored in the case proposed by Kawamoto *et al.*, the interpretation of the tracer work seems to be open to question.

On the other hand the results (2) and (3) suggest that a palladium hydride complex whose hydrogen is provided by olefin is responsible for the ethylene dimerization. The observed effects of added olefin could not be due to the formation of codimer. Since 3-methyl-1-butene which is most effective both in decreasing the induction period and enhancing the rate of dimerization is admittedly liable to liberate its tertiary hydrogen, the observed effects of added olefin can be interpreted to be formation of an active hydride complex which catalyzes both the dimerization and the isotopic exchange. The scheme implies that the hydride complex responsible for the dimerization is necessarily preformed by a reaction of the palladium complex with olefin. The ready isomerization of 1-butene as demonstrated by the attainment of isomerization equilibrium in the dimerization product is also consistent with the presence of preformed hydride complex. In the case of five-coordinate hydride scheme[2] or concerted hydride shift scheme[6c] for dimerization, a separate scheme is required for the isomerization and isotopic exchange, whereas the preformed hydride can account for all of three reactions in terms of palladium alkyl intermediate,[7,8] as follows:

$$\begin{array}{l} \qquad\qquad\qquad\qquad\qquad\qquad \mathrm{PdD} + \mathrm{C_2D_3H}\ \text{(exchange)} \\ \qquad\qquad\qquad\qquad\qquad\qquad\quad \uparrow \\ \mathrm{Pd\text{-}H} + \mathrm{C_2D_4} \longrightarrow \mathrm{Pd\text{-}C_2D_4H} \xrightarrow{C_2H_4} \mathrm{Pd\text{-}C_2H_4\text{-}C_2D_4H} \\ \qquad\qquad\quad \longrightarrow \mathrm{Pd\text{-}H} + \mathrm{C_4H_4D_4}\ \text{(dimerization)} \end{array}$$

$$\begin{array}{l} \mathrm{Pd\text{-}H} + \text{1-}\mathrm{C_4H_8} \longrightarrow \mathrm{Pd\text{-}C_4H_9} \longrightarrow \\ \qquad\qquad\qquad\qquad\qquad\qquad \mathrm{PdH} + \text{2-}\mathrm{C_4H_8}\ \text{(isomerization)} \end{array}$$

If the preformed hydride is necessary for the dimerization, the observed induction period should be ascribed to the slow formation of the hydride complex from olefin. The delayed response of the dimerization rate to pressure change is reasonable if the equilibrium concentration of hydride complex is proportional to olefin concentration. Thus the mechanism of hydride formation is important. The present results seem to suggest a dissociation of olefin to form a hydride. The palladium hydride is known to exist[11] although it is unstable.

Synthesis of N^{δ}-Hydroxyornithine

Yoshikazu Isowa, Toshiyuki Takashima, Muneki Ohmori, Hideaki Kurita, Masanari Sato, and Kaoru Mori

Sagami Chemical Research Center, Ohnuma, Sagamihara, Kanagawa

(Received August 5, 1971)

N^{δ}-Tosyl-N^{δ}-benzyloxy-DL-ornithine was synthesized starting from γ-(N-tosyl-N-benzyloxy)-aminopropyl bromide and diethyl acetamidomalonate and resolved enzymatically to give the L- and D-isomers. Removal of one or both of protecting groups gave N^{δ}-benzyloxyornithine or N^{δ}-hydroxyornithine. The reduction product of N^{δ}-hydroxy-L-ornithine was identical with authentic L-ornithine.

N^{δ}-Hydroxyornithine is one of the most commonly found constituents of naturally occurring peptides.[1] In these compounds the α-amino and the carboxyl group of a N^{δ}-hydroxyornithine residue are linked by amide bonds to form a cyclic hexapeptide and the hydroxyamino group is present in the form of a hydroxamic acid derivative. These peptides, for example, ferrichrome[2] and albomycin[3] have been found to have potent microbial growth factor or antibiotic activities.

Synthesis of N^{δ}-hydroxyornithine have been attempted by two group of workers, but the amino acid was not isolated.[4,5]

This paper presents the successful synthesis of N^{δ}-hydroxyornithine *via* optical resolution of N^{δ}-tosyl-N^{δ}-benzyloxy-DL-ornithine and subsequent removal of the tosyl and benzyl groups.

O-Benzylhydroxylamine(I) was first converted into the tosyl derivative(II), which was alkylated with 1,3-dibromopropane to γ-(N-tosyl-N-benzyloxy)-aminopropyl bromide(III). This was allowed to react with diethyl sodio-acetamidomalonate, and the product was heated with concentrated hydrochloric acid–acetic acid to yield racemic N^{δ}-tosyl-N^{δ}-benzyloxyornithine(DL-V).

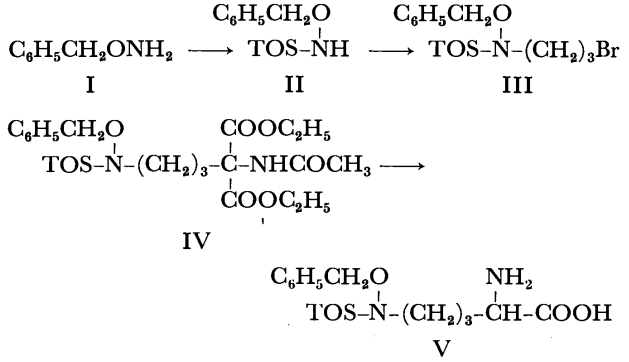

Fig. 1

Optically active N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithine and its D-isomer were prepared by enzymatic resolution of the N^{α}-acetyl-N^{δ}-tosyl-N^{δ}-benzyloxy-DL-ornithine (DL-VI) with aniline in the presence of papain. The resulting N^{α}-acetyl-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithine anilide (L-VII) and N^{α}-acetyl-N^{δ}-tosyl-N^{δ}-benzyloxy-D-ornithine (D-VI) showed $[\alpha]_D^{25}$ −53.4° and $[\alpha]_D^{25}$ −18.1° in chloroform solution. N^{δ}-Tosyl-N^{δ}-benzyloxy-L-ornithine and its D-isomer (L–V and D–V) were prepared by acid hydrolysis in hydrochloric acid–acetic acid solution. The amino acid (L-V and D-V) thus obtained exhibited optical rotation of $[\alpha]_D^{23.5}$ +20.7° and $[\alpha]_D^{25}$ −21.0°, respectively, in acetic acid solution.

DL-VI was also obtained by racemization of D-VI using acetic anhydride or acetic anhydide–acetic acid.

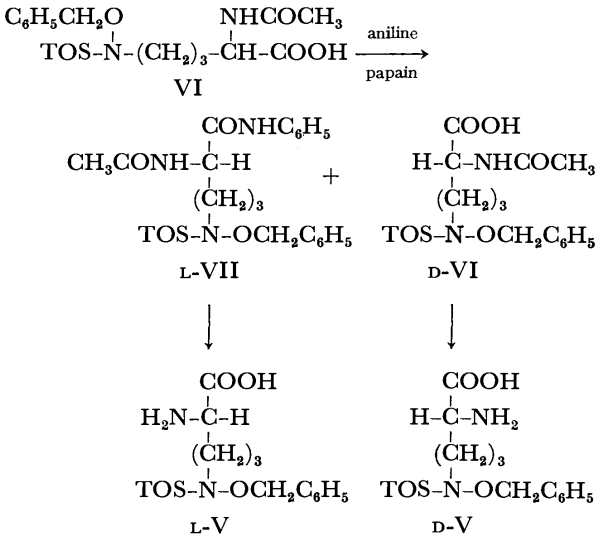

Fig. 2

As a mild method for the removal of a tosyl group in the synthesis of relatively unstable compounds, Weisblat *et al.*[6] used 30% hydrogen bromide in acetic acid in the presence of phenol at room temperature. They described detosylation of *N*-substituted sulfonamides, such as TOS–NRR′; R,R′=H, alkyl, aryl, acyl or alkoxycarbonyl. However similar condition has never been applied for detosylation of tosylhydroxamate series, TOS–N(OR)R′; R=$CH_2C_6H_5$, R′=alkyl. The removal of a tosyl group from the amino acid (V) was accomplished by the

action of 36% hydrogen bromide in acetic acid in the presence of phenol at room temperature for 50 hr to give N^{δ}-benzyloxy-DL-ornithine monohydrobromide (DL-VIII·HBr). Similar treatment of the D- and L-amino acid (D- and L-V) with this reagent gave the corresponding D- and L-N^{δ}-benzyloxy derivatives (D- and L-VIII).

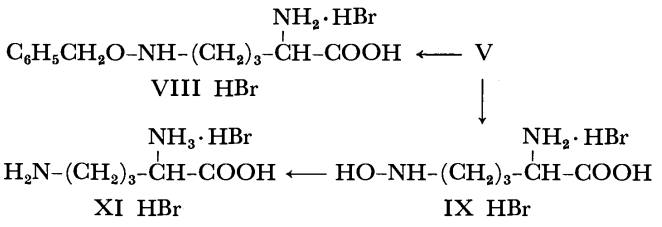

Fig. 3

Simultaneous cleavage of the tosyl and benzyl group from the amino acid (D-, L-, and DL-V) was carried out by the action of the above described reagent at room temperature for 10 days to give N^{δ}-hydroxyornithine monohydrobromide (D-, L-, and DL-IX), which showed blue color with ninhydrin and gave red color with the triphenyltetrazolium reagent.[7] The salt (X) of N^{δ}-hydroxy-DL-ornithine with one mole of 2-nitro-1,3-indanedione was obtained from DL-IX HBr by the procedure of Rogers.[4]

L- and D-IX were hydrogenated to give L- and D-ornithine monohydrobromide (L- and D-XI) in the presence of palladium charcoal.

It was demonstrated by measurements of the melting point, infrared spectrum, optical rotation, and elemental analysis that the L-isomer(XI) was identical with authentic L-ornithine monohydrobromide.

Experimental

Melting points were all determined with a Yanagimoto electric micromelting point apparatus and are uncorrected, and optical rotations were measured with a Yanagimoto automatic polarimeter OR-50.

O-Benzylhydroxylamine (I). It was prepared by the method described by Fuller and King.[8]

O-Benzyl-N-tosylhydroxylamine (II). To a chilled solution of *O*-benzylhydroxylamine (246 g, 2.0 mol) in pyridine (300 m*l*), a solution of *p*-toluenesulfonyl chloride (381 g, 2.0 mol) in pyridine was added slowly during 2 hr. The solution was stirred at room temperature for 2 hr and allowed to stand overnight. The material precipitated was filtered off and the filtrate was evaporated *in vacuo*. The residual oil was extracted with ethyl acetate (1.2 *l*) and the organic layer was washed with 2N hydrochloric acid and water, dried over sodium sulfate, and then evaporated *in vacuo*. The residual oil was solidified by adding petroleum ether. The product was recrystallized from ethyl acetate–petroleum ether; yield 454 g (82%), mp 93—97°C.

Found: C, 60.79; H, 5.45; N, 4.92%. Calcd for $C_{14}H_{15}NO_3S$: C, 60.64; H, 5.45; N, 5.05%.

γ-(N-Tosyl-N-benzyloxy)-aminopropyl Bromide (III). To a solution of sodium (23 g, 1.0 g-Atom) in ethanol (1.2 *l*) was added II (277 g, 1.0 mol) with vigorous stirring at 70°C. After a clear solution was obtained, trimethylene dibromide (404 g, 2.0 mol) was added. The mixture was refluxed for 8 hr, and evaporated *in vacuo* to give oily material, which was extracted with ethyl acetate and the organic layer was thoroughly washed with water and dried over sodium sulfate. Evaporation of the solvent afforded oily product which was crystallized from ethyl acetate–*n*-hexane; yield 350 g (88%), mp 73—77°C.

Found: C, 51.36; H, 5.11; N, 3.69%. Calcd for $C_{17}H_{20}O_3NSBr$: C, 51.26; H, 5.06; N, 3.51%.

Diethyl γ-(N-Tosyl-N-benzyloxy)-aminopropyl Acetamidomalonate (IV). To a solution of sodium (18.4 g, 0.8 g-Atom) in ethanol (1.5 *l*) was added diethyl acetamidomalonate (174 g, 0.8 mol) while stirring. After 5 min, III (319 g, 0.8 mol) was added and the mixture was refluxed for 8 hr. The solvent was then removed *in vacuo* and the residue was extracted with chloroform. The chloroform solution was successively washed with water, dilute hydrochloric acid and water, dried over magnesium sulfate, and evaporated *in vacuo*. The oily residue was crystallized from ethyl acetate–petroleum ether and then from ethanol; yield 299 g (70%), mp 135—138°C.

Found: C, 58.68; H, 6.12; N, 4.99%. Calcd for $C_{26}H_{34}N_2O_8S$: C, 58.42; H, 6.41; N, 5.24%.

N^{δ}-Tosyl-N^{δ}-benzyloxy-DL-ornithine (DL-V). A solution of IV (160 g, 0.3 mol) in a mixture of acetic acid (1.2 *l*) and concentrated hydrochloric acid (480 m*l*) was heated under gentle reflux for 8 hr. The solution was evaporated *in vacuo* and 14% aqueous ammonia was added to the residue. The resulting solid was collected by filtration, washed with water, and recrystallized from acetic acid–water; yield 106 g (90%), mp 207—210°C (decomp.).

Found: C, 57.84; H, 6.04; N, 6.89%. Calcd for $C_{19}H_{24}N_2O_5S$: C, 58.15; H, 6.17; N, 7.14%.

N^{α}-Acetyl-N^{δ}-tosyl-N^{δ}-benzyloxy-DL-ornithine (DL-VI). DL-V (70 g, 0.18 mol) was mixed with glacial acetic acid (420 m*l*) and warmed with gentle stirring to give a clear solution. The solution was cooled for several minutes and acetic anhydride (26 m*l*, 0.25 mol) was carefully added. The resulting solution was warmed to 80°C with stirring, held at this temperature for 5 hr and then evaporated *in vacuo*. The syrupy residue was taken up in a minimum quantity of ethyl acetate and the solution was chilled. After standing for 2 hr at 5°C, the crystals separated. Recrystallization from ethyl acetate gave colorless crystals; yield 58 g (75%), mp 142.5—144.0°C.

Found: C, 57.93; H, 6.01; N, 6.29%. Calcd for $C_{21}H_{26}N_2O_6S$: C, 58.05; H, 6.03; N, 6.45%.

Resolution of N^{α}-Acetyl-N^{δ}-tosyl-N^{δ}-benzyloxy-DL-ornithine (DL-VI). a) N^{α}-Acetyl-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithine Anilide (L-VII). DL-Acetylamino acid (DL-VI) (74 g, 0.171 mol) was dissolved in 0.75N sodium hydroxide (600 m*l*) and the solution adjusted to pH 6.05—6.20 with 0.5M citric aicd. The solution was diluted with distilled water to the final volume of 1.2 *l*. Papain (20 g) was added to the solution together with freshly distilled aniline (20 m*l*) and cysteine hydrochloride monohydrate (10 g). The mixture was incubated for 36 hr at 38°C; the anilide deposited was filtered off, washed with water, 7% aqueous ammonia and water.

Recrystallization from *n*-propyl alcohol gave colorless crystals; yield 40 g (92%), mp 203—205°C, $[\alpha]_D^{25}$ −53.4° (*c* 1, chloroform).

Found: C, 63.25; H, 6.07; N, 8.14%. Calcd for $C_{27}H_{31}N_3O_5S$: C, 63.64; H, 6.13; N, 8.25%.

7) G. A. Snow, *J. Chem. Soc.*, **1954**, 2588.
8) A. T. Fuller and H. King, *ibid.*, **1947**, 963.

b) N^{α}-*Acetyl*-N^{δ}-*tosyl*-N^{δ}-*benzyloxy*-D-*ornithine (*D-*VI).* The above filtrate, combined with the washings was adjusted to pH 2 with 5N hydrochloric acid. Then the precipitated material was filtered off, washed with water and dried. Recrystallization from ethyl acetate gave colorless crystals; yield 32.4 g (88%), mp 131.0—133.5°C, $[\alpha]_D^{25}$ −18.1° (*c* 1, chloroform).

Found: C, 58.00; H, 5.91; N, 6.06%. Calcd for $C_{21}H_{26}N_2O_6S$: C, 58.05; H, 6.03; N, 6.45%.

N^{δ}-*Tosyl*-N^{δ}-*benzyloxy*-L-*ornithine (*L-*V).* L-VII (40 g, 78.7 mmol) was dissolved in glacial acetic acid (300 m*l*) while gently warming and concentrated hydrochloric acid (120 m*l*) was carefully added. After refluxing for 8 hr, the solution was evaporated *in vacuo* and aqueous ammonia was added to the residue. After standing for 2 hr at 5°C, the deposits were filtered off with suction, washed with water, and dried. Recrystallization from dilute acetic acid gave 25.8 g (83%), mp 222.5—224.8°C (decomp.), $[\alpha]_D^{23.5}$ +20.7° (*c* 3, acetic acid).

Found: C, 57.98; H, 6.46; N, 7.38%. Calcd for $C_{19}H_{24}N_2O_5S$: C, 58.15; H, 6.16; N, 7.14%.

N^{δ}-*Tosyl*-N^{δ}-*benzyloxy*-D-*ornithine (*D-*V).* This was obtained from D-VI by the method described above. Yield 86%, mp 220—223°C (decomp.) (from dilute acetic acid), $[\alpha]_D^{25}$ −21.0° (*c* 2, acetic acid).

Found: N, 7.25%. Calcd for $C_{19}H_{24}N_2O_5S$: N, 7.14%.

N^{δ}-*Benzyloxy*-L-*ornithine Monohydrobromide (*L-*VIII HBr).* To 18 m*l* of a solution of 36% hydrogen bromide-acetic acid and phenol (2.5 g) in a glass-stoppered bottle, L-V (3.92 g, 10 mmol) was added at room temperature. After stirring for 50 hr, the solution was evaporated to dryness *in vacuo* at 35°C. The residual oil was triturated several times with ether and dissolved in water (50 m*l*). The solution was washed repeatedly with ether and then kept in a refrigerator overnight, the crystals deposited was removed by filtration and the filtrate was evaporated *in vacuo* at 35°C. The above residue was dissolved in water (5 m*l*). The solution was adjusted to pH 4—5 with pyridine, and addition of ethanol (30 m*l*) and ether (50 m*l*) yielded crystals, which were purified by dissolving them in water and adding ethanol-ether. D- and DL-V were treated in the same manner to yield the corresponding D- and DL-VIII·HBr. The results are summarized in Table 1.

N^{δ}-*Benzyloxy*-DL-*ornithine (*DL-*VIII).* This was obtained from V by the method described above, except that the solution was adjusted to pH 8 by adding aqueous ammonia. The solution was evaporated to dryness again. The residue was crystallized from water-ethanol (Yield 53%), mp 195—203°C (decomp.). It gave positive ninhydrin test and negative Beilstein test. For the analysis, the product was recrystallized from water-ethanol.

Found: C, 60.43; H, 7.57; N, 11.58%. Calcd for $C_{12}H_{18}N_2O_3$: C, 60.48; H, 7.61; N, 11.76%.

N^{δ}-*Hydroxyornithine Monohydrobromide (IX·HBr).* To a mixture of 36% hydrogen bromide-acetic acid (18 m*l*) and phenol (2 g) in a glass-stoppered bottle, V (3.92 g, 10 mmol) was added at room temperature. After stirring for 10 days at room temperature, the solution was evaporated *in vacuo* at 50°C. The residual oil was triturated with ether. The residue was dissolved in water (50 m*l*) and the solution was washed repeatedly with ether and then evaporated *in vacuo* below 50°C. The residual oil was dissolved again in water (2 m*l*), the solution was adjusted to pH 4—5 with pyridine, and addition of ethanol deposited crystals. For analysis, the product was recrystallized from water-ethanol. Ninhydrin, triphenyltetrazolium, and Beilstein tests were all positive. The results are summarized in Table 2.

manner with a 72% yield. This was positive to ninhydrin test and negative to triphenyltetrazolium test. The results are summarized in Table 3.

Racemization of N^{α}-*acetyl*-N^{δ}-*tosyl*-N^{δ}-*benzyloxy*-D-*ornithine (*D-*VI).* *a)*: A solution of D-VI (21.7 g, 0.05 mol) in acetic anhydride (40 m*l*) was heated at 120°C for 2 hr, and then evaporated *in vacuo*. The residual pale yellow syrup was dissolved in acetone (30 m*l*) and water (10 m*l*) was added. The mixture was stirred for 2 hr at room temperature and evaporated *in vacuo*. The residual syrup was dissolved in hot ethyl acetate (30 m*l*), and the racemic compound (VI), which precipitated on standing in a deep freezer, was collected, yield 16.4 g, mp 137—139°C. Recrystallization from ethyl acetate raised the melting point to 139.5—141°C. The product was optically inactive in chloroform solution.

b): A solution of D-VI (21.7 g) in a mixture of acetic acid (30 m*l*) and acetic anhydride (7 m*l*) was refluxed for 75 min, and then evaporated *in vacuo*. DL-VI was obtained with the same treatment as described above. Yield 16.1 g, mp 136°C. Recrystallization from ethyl acetate raised the melting point to 139—140°C. The product showed no optical rotation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1464—1466(1972)

Acylation of N^{δ}-Benzyloxyornithine

Sagami Chemical Research Center, Ohnuma, Sagamihara, Kanagawa

(Received August 5, 1971)

Acetylation of N^{δ}-benzyloxyornithine monohydrobromide (I·HBr) with acetic anhydride gave the N^{δ}-acetylated product, which yielded N^{δ}-acetyl-N^{δ}-hydroxyornithine by catalytic reduction. On the other hand, acetylation or alkoxycarbonylation of N^{δ}-benzyloxyornithine(I) proceeded through N^{α}-acetylation, followed by spontaneous cyclization to form lactams, which yielded cyclic hydroxamic acids on catalytic reduction. These hydroxamic acid and N^{δ}-acetyl-N^{δ}-hydroxyornithine were readily hydrolyzed to give N^{δ}-hydroxyornithine.

In the preceding paper,[1] it was shown that N^{δ}-tosyl-N^{δ}-benzyloxyornithine gave N^{δ}-benzyloxyornithine(I) by detosylation under mild conditions. Since its benzyloxyamino-group may be converted into a hydroxamic group, I is expected to be used as a starting material for the synthesis of amino acid derivatives and peptides such as N^{δ}-acetyl-N^{δ}-hydroxyornithine,[2] rhodotorulic acid[3] and ferrichrome.[4] The present paper reports the behavior of I toward acylation.

Treatment of optically active or racemic N^{δ}-benzyloxyornithine monohydrobromide (L-, D-, and DL-I·HBr) with acetic anhydride in water yielded a viscous oily product (II), which gave, on catalytic hydrogenation with palladium on charcoal, optically active or racemic N^{δ}-acetyl-N^{δ}-hydroxyornithine (L-, D-, and DL-III). The results are summarized in Table 1.

NMR (D_2O) for DL-III: δ; 3.70 ppm (3H, δ-methylene and α-methine), 2.13 (3H, acetyl methyl protons), 1.80 (4H, β, γ-ethylene protons).

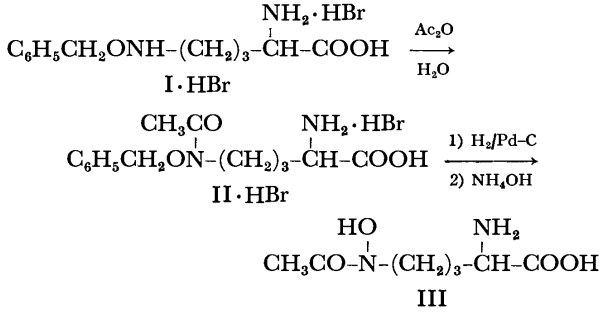

Fig. 1

Since these products gave positive ninhydrin- and ferric-test and negative triphenyltetrazolium reaction, their structure is established as formulated III in Fig. 1. Emery considered N^{δ}-acetyl-N^{δ}-hydroxy-L-ornithine (L-III) as a precursor in ferrichrome biosynthesis and prepared it from N^{δ}-hydroxyornithine obtained by the hydrolysis of fusarinine.[2] The melting point of our synthetic L-III was the same as that of Emery's product. No racemization occurred during the above mentioned synthesis of III, because hydrolysis and subsequent catalytic reduction of D-III gave D-ornithine monohydrochloride (D-V·HCl), $[\alpha]_D^{22}$ −12.2° (c 1, water), the optical activity of authentic L-isomer monohydrochloride obtained commercially being $[\alpha]_D^{22}$ +12.2° (c 1, water).

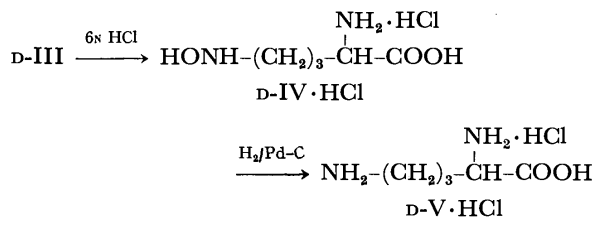

Fig. 2

It should be mentioned that N^{δ}-hydroxyornithine monohydrochloride (L-, and D-IV·HCl) has not been obtained previously, although isolation of the corresponding monohydrobromide was described in the preceding paper.[1] Further, L- and D-IV gave salts with 2-nitroindane-1,3-dione (L- and D-VI) by the procedure of Rogers.[5] Treatment of free I with two and a half equivalents of acetic anhydride in acetic acid afforded 1-benzyloxy-3-acetaminopiperidone (VII), instead of the expected product, N^{α}-acetyl-N^{δ}-acetyl-N^{δ}-benzyloxyornithine (VIII). The lactam (VII) was also obtained from I by treatment with one equivalent of *p*-nitrophenyl acetate in the presence of benzyltrimethylammonium hydroxide (Triton B) in dioxane followed by neutralization. Analogous lactam deivatives (IX and X) were obtained from free I. Attempted N^{α}-acylation of N^{δ}-benzyloxyornithine always resulted in spontaneous cyclization to give lactams.

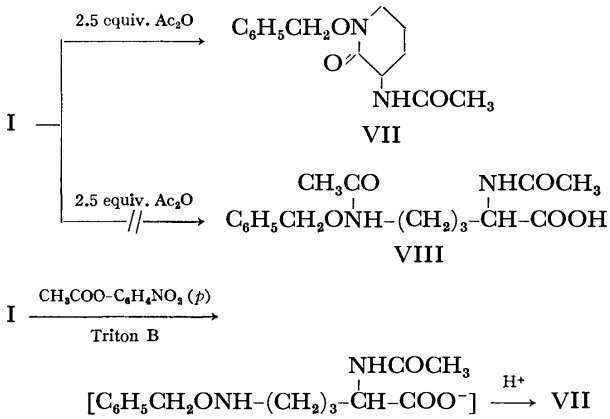

Fig. 3

It was found that the lactam (VII) reacts with hydrazine monohydrate to give N^{α}-acetyl-N^{δ}-benzyloxyornithine hydrazide (XI). Catalytic hydrogenation of VII and IX with palladium on charcoal yielded 1-hydroxy-3-acylaminopiperidones, XII and XIII. Treatment of D-XIII with 2N hydrochloric acid in dioxane afforded D-1-hydroxy-3-amino-2-piperidone monohydrochloride (XIV·HCl). It melted at 177—179°C. This is the same melting point as that of the monohydrochloride obtained from fusarinine,[4] although the latter is probably the optical enantiomorph (L-form). Finally, hydrolysis of D-XIV·HCl with 6N hydrochloric acid yielded N^{δ}-hydroxy-D-ornithine monohydrochloride.

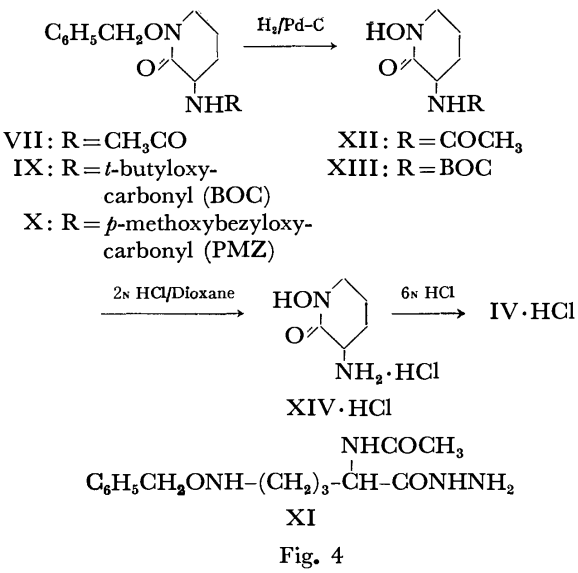

Fig. 4

Experimental

Melting points were all determined with a Yanagimoto electric micromelting point apparatus and are uncorrected, and optical rotations were measured with a Yanagimoto automatic polarimeter OR-50. Nuclear magnetic resonance spectra were taken on a Hitachi Perkin-Elmer R-20 High Resolution NMR spectrometer using tetramethylsilane as an internal standard.

N^{δ}-Benzyloxyornithine (I). This compound was prepared as monohydrobromide by the procedure described in the preceding paper.[1]

L-I·HBr: mp 155—157°C (decomp.), $[\alpha]_D^{27}+9.0°$ (*c* 1, water)
D-I·HBr: mp 155—157°C (decomp.), $[\alpha]_D^{22}-8.4°$ (*c* 1, water)

Free amino acid was obtained from monohydrobromide by treatment with aqueous ammonia. L-I: mp 198—202°C (decomp.), D-I: mp 198—205°C (decomp.).

N^{δ}-Acetyl-N^{δ}-benzyloxy-D-ornithine Monohydrobromide (D-II·HBr). To a solution of D-I·HBr (0.957 g, 3 mmol) in water (5 m*l*), acetic anhydride (0.375 m*l*) was added at room temperature. After it had been stirred for 1 hr at 50°C, the reaction mixture was evaporated *in vacuo*. The residual oil was used for subsequent operation without further purification.

The DL- and L-isomer were obtained as oily products in the same manner.

N^{δ}-Acetyl-N^{δ}-hydroxy-D-ornithine (D-III). A solution of D-II in methanol (15 m*l*) was hydrogenated in the presence of 5% palladium charcoal (0.15 g) at room temperature for 17 hr. The filtrate obtained from the reduction mixture was evaporated *in vacuo*. The residual oil was dissolved in water (0.15 m*l*), the solution was adjusted to pH 8—9 with aqueous ammonia, and addition of ethanol to the solution yielded crystals. Recrystallization from water-ethanol gave colorless crystals. The DL- and L-isomer were obtained in the same manner. The results are summarized in Table 1. Ninhydrin- and ferric chloride tests were positive and triphenyltetrazolium test was negative with these products.

N^{δ}-Hydroxy-D-ornithine Monohydrochloride (D-IV·HCl). D-III (0.37 g, 1.95 mmol) was hydrolyzed with 6N hydrochloric acid (15 m*l*) at 100°C, until ferric test became negative. The reaction mixture was evaporated to dryness *in vacuo* and the treatment was repeated after the addition of water. The residue was dissolved in water, the solution was adjusted to pH 4—5 with pyridine and evaporated to dryness *in vacuo*.

The residue was crystallized from water-ethanol-ether. Yield 78%, mp 179—181°C (decomp.), $[\alpha]_D^{19}-11.6°$ (*c* 1, water), positive triphenyltetrazolium, ninhydrin, and negative ferric chloride tests.

Found: C, 32.98; H, 6.78; N, 15.20%. Calcd for $C_5H_{13}N_2O_3Cl$: C, 32.52; H, 7.10; N, 15.18%.

L-Isomer (L-IV·HCl) was obtained from L-III bv the same procedure. Mp 178—180°C (decomp.), $[\alpha]_D^{19}+11.4°$ (*c* 0.5, water).

Found: C, 32.62; H, 7.29; N, 15.05%. Calcd for $C_5H_{13}N_2O_3Cl$: C, 32.52; H, 7.10; N, 15.18%.

N^{δ}-Hydroxy-D-ornithine Mono-2-nitro-1,3-indanedione (D-VI). This was obtained from D-IV by the procedure of Rogers.[5] Bright yellow crystals, mp 220—227°C (decomp.).

Found: C, 49.38; H, 5.11; N, 12.14%. Calcd for $C_{14}H_{17}N_3O_7$: C, 49.56; H, 5.05; N, 12.38%.

The L-isomer (L-VI) was obtained from L-IV by the same procedure. Bright yellow crystals, mp 221—227°C (decomp.).

D-Ornithine Monohydrochloride (D-V·HCl). A solution of D-IV (0.239 g, 1.3 mmol) in water (5 m*l*) was hydrogenated in the presence of 10% palladium charcoal (0.1 g) at room temperature, until the tetrazolium test became negative. The filtrate from the reduction mixture was evaporated *in vacuo* to give a crystalline product. Recrystallization from water-ethanol gave the desired product. Yield 92%, mp 242—245°C (decomp.), $[\alpha]_D^{22}-12.2°$ (*c* 1, water). (L-Ornithine monohydrochloride (obtained commercially). Mp 240—245°C (decomp.), $[\alpha]_D^{22}+12.2°$ (*c* 1, water)).

Found: C, 35.48; H, 7.84; N, 16.33%. Calcd for $C_5H_{13}N_2O_2Cl$: C, 35.61; H, 7.77; N, 16.62%.

DL-1-Benzyloxy-3-acetylaminopiperidone (DL-VII). DL-I (2.23 g, 0.01 mol) was dissolved in acetic acid (10 m*l*) by boiling and after the solution was allowed to cool for 1—2 min acetic anhydride (2.5 m*l*) was added in portions. The resulting solution was heated under reflux for 2 min and allowed to cool to room temperature. The reaction mixture was evaporated *in vacuo* and the evaporation was repeated after addition of water to the residue. The resulting crystals were taken up in ethyl acetate and the solution was washed repeatedly with water. The organic layer was dried over sodium sulfate and evaporated to dryness. The resulting crystalline residue was purified by recrystallization from ethyl acetate. Yield 46%, mp 151—152°C, ninhydrin, tetrazolium, and ferric chloride tests negative.

NMR (DMSO-d_6): δ; 8.10 ppm (1H, *N*-proton), 7.40 (5H, phenyl protons), 4.87 (2H, *O*-methylene protons), 4.30 (1H, C_3-proton), 3.45 (2H, C_6-protons), 1.86 (7H, C_4, C_5, and acetyl protons).

Found: C, 63.98; H, 6.77; N, 10.62%. Calcd for $C_{14}H_{18}N_2O_3$: C, 64.10; H, 6.92; N, 10.68%.

DL-1-Benzyloxy-3-t-butyloxycarbonylaminopiperidone (IX). To a suspension of DL-I (0.476 g, 2 mmol) in methanol (5 m*l*), 40% benzyltrimethylammonium hydroxide (0.94 m*l*) was added and the mixture was stirred until the suspension went into a clear solution. The resulting solution was evaporated *in vacuo* and the residue was evaporated successively with ethanol and benzene. To a solution of the residue in *t*-buthanol (4 m*l*), *t*-butyl 2,4,5-trichlorophenyl carbonate (0.601 g, 2.02 mmol) was added and stirred for 15 hr at 50—55°C. The reaction mixture was evaporated *in vacuo* and the residue was taken up in water. The solution was washed repeatedly with ether and was adjusted to pH 3.0—3.5 with solid citric acid. The deposit was extracted with ethyl acetate and the extract was washed with water, dried over sodium sulfate and evaporated *in vacuo*. The residue was crystallized from ethyl acetate-*n*-hexane; yield 50%. For analysis, the product was recrystallized from *n*-hexane, mp 116—117°C, ninhydrin, tetrazolium, and ferric chloride tests negative.

Found: C, 63.75; H, 8.10; N, 8.55%. Calcd for $C_{17}H_{24}N_2O_4$: C, 63.72; H, 7.55; N, 8.75%.

D-1-Benzyloxy-3-p-methoxybenzyloxycarbonylaminopiperidone (D-X). The product was obtained from D-I by the method described above, except that *p*-methoxybenzyl 2,4,5-trichlorophenyl carbonate and dioxane as solvent were used. The product was recrystallized from ethyl acetate-*n*-hexane. Yield 61%, mp 112—114°C, $[\alpha]_D^{24}-43.2°$ (*c* 1, ethyl acetate).

Found: C, 65.58; H, 6.33; N, 7.23%. Calcd for $C_{21}H_{24}N_2O_5$: C, 65.61; H, 6.29; N, 7.29%.

N^{α}-Acetyl-N^{δ}-benzyloxy-DL-ornithine Hydrazide (DL-XI). A solution of DL-VII (0.262 g, 1 mmol) and hydrazine monohydrate (0.1 m*l*) in dioxane (10 m*l*) was warmed for 2 hr at 100—110°C and evaporated *in vacuo*. The residue was crystallized from ethanol-ether. Yield 83%. For analysis, the product was recrystallized from ethanol-ether, mp 101—105°C, ninhydrin, tetrazolium, and ferric chloride tests negative.

Found: C, 57.37; H, 7.26; N, 18.90%. Calcd for $C_{14}H_{22}N_4O_3$: C, 57.12; H, 7.54; N, 19.04%.

DL-1-Hydroxy-3-acetylaminopiperidone (DL-XII). A solution of DL-VII (0.262 g, 1 mmol) in methanol (5 m*l*) was hydrogenated in the presence of 5% palladium charcoal (0.05 g) at room temperature for 24 hr. The filtrate from the reduction mixture was evaporated *in vacuo*. The residual crystalline product was recrystallized from methanol. Yield 76%, mp 203—205°C, negative ninhydrin, and tetrazolium tests, and positive ferric chloride test.

Found: C, 48.92; H, 7.22; N, 16.17%. Calcd for $C_7H_{12}N_2O_3$: C, 48.82; H, 7.03; N, 16.27%.

D-1-Hydroxy-3-amino-2-piperidone Hydrochloride (D-XIV·HCl). A solution of D-IX (1.46 g, 4.55 mmol) in methanol (20 m*l*) was hydrogenated in the presence of 5% palladium charcoal (0.25 g) at room temperature for 14 hr. The filtrate from the mixture was evaporated *in vacuo* (ferric positive and ninhydrin test negative). The resulting oily residue was treated with 2N hydrogen chloride-dioxane (44 m*l*) for 2 hr at room temperature. The reaction mixture was evaporated *in vacuo* and the residual oil crystallized from ethanol. Recrystallization from methanol-ethanol gave colorless crystals. Yield 51%, mp 208—215°C (decomp.), $[\alpha]_D^{24}-0.8°$ (*c* 0.83, water), ferric positive and tetrazolium test negative. The ninhydrin test gave yellow color.

Found: C, 36.08; H, 6.44; N, 16.56; Cl, 21.48%. Calcd for $C_5H_{11}N_2O_2Cl$: C, 36.04; H, 6.66; N, 16.82; Cl, 21.28%.

N^{δ}-Hydroxy-D-ornithine Monohydrochloride (D-IV·HCl). D-XIV (0.25 g, 1.5 mmol) was hydrolyzed with 6N hydrochloric acid (15 m*l*) at 100°C for 30 min, when the mixture gave negative ferric test. The reaction mixture was evaporated to dryness *in vacuo* and the evaporation was repeated after the addition of ethanol. The residue was crystallized from water-ethanol. The crystals were collected by filtration and recrystallized from water-ethanol. Yield 54%, mp 177—179.5°C, $[\alpha]_D^{24}-12.0°$ (*c* 1, water), tetrazolium and ninhydrin tests positive and ferric chloride test negative.

Found: C, 32.63; H, 6.92; N, 15.08%. Calcd for $C_5H_{13}N_2O_3Cl$: C, 32.52; H, 7.10; N, 15.18%.

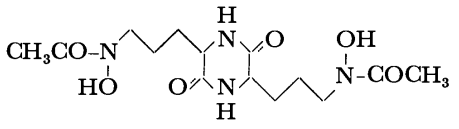
Synthesis of Rhodotorulic Acid

Yoshikazu Isowa, Toshiyuki Takashima, Muneki Ohmori,
Hideaki Kurita, Masanari Sato, and Kaoru Mori
Sagami Chemical Research Center, Ohnuma, Sagamihara, Kanagawa

(Received August 5, 1971)

Rhodotorulic acid (I) was synthesized by a series of reaction starting from N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithine. Detosylation and acetylation of intermediate, cyclo-di-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithyl (LL-IX), afforded cyclo-di-N^{δ}-acetyl-N^{δ}-benzyloxy-L-ornithyl (LL-XI), which, on reductive debenzylation, gave rhodotorulic acid.

Rhodotorulic acid was first obtained by Atkin and Neilands[1] from supernatants of iron-deficient culture of a red yeast, *Rhodotorula pilimanae*. They found a potent growth-factor activity in this compound in assays with Arthrobacter species and determined its structure to be cyclo-di-N^{δ}-acetyl-N^{δ}-hydroxy-L-ornithyl (LL-I). We have succeeded in synthesizing rhodotorulic acid (LL-I); the DD-isomer was also prepared.



LL-I

Fig. 1

The synthetic route is shown in Fig. 2.

Fig. 2. The abbreviations which are not listed in *Biochemistry* **5**, 1445 (1966), are H-HyOrn-OH for N^{δ}-hydroxyornithine and H-HyOrn-OH for N^{δ}-tosyl-N^{δ}-benzyloxyornithine.
N^{δ}-(TOS, *O*-BZL)

N^{α}-Benzyloxycarbonyl-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithine (L-III) was obtained by benzyloxycarbonylation of N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithine (L-II).[2] A *t*-butyloxycarbonyl derivative (L-IV) was prepared by the reaction of L-II with *t*-butyl 2,4,5-trichlorophenyl carbonate in the presence of benzyltrimethylammonium hydroxide. By the reaction of the methyl ester (L-V) with the carbobenzoxy or *t*-butyloxycarbonyl amino acid (L-III or L-V) *via* the mixed anhydride, benzyloxycarbonyl-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithyl-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithine methyl ester (LL-VI) or the corresponding N^{α}-*t*-butyloxycarbonyl-dipeptide methyl ester (LL-VII) was obtained. Treatment of LL-VI or LL-VII with an excess of hydrogen bromide - acetic acid or hydrogen chloride - ethyl acetate, N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithyl-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithine methyl ester hydrobromide or hydrochloride (LL-VIII HX) was obtained. Cyclo-di-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithyl (LL-IX) was formed by the action of excess of ammonia on LL-VIII HX in methanol at

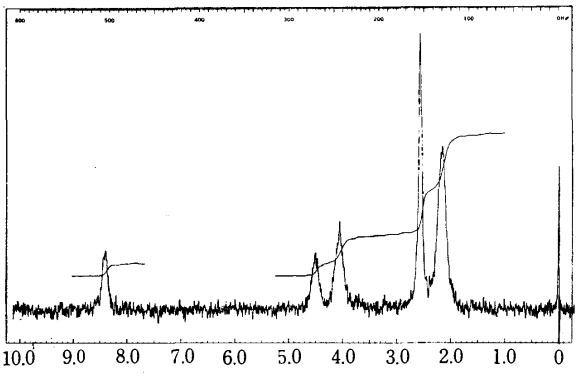

Fig. 3. NMR spectrum of synthetic rhodotorulic acid in trifluoroacetic acid.

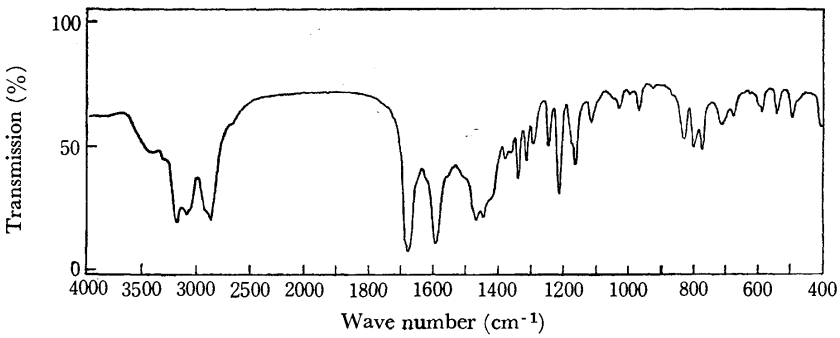

Fig. 4. IR spectrum of synthetic rhodotorulic acid.

room temperature.[3] The tosyl group of LL-IX was removed by treatment with 36% hydrogen bromide-acetic acid and phenol for 50 hr at room tempeature to yield cyclo-di-N^{δ}-benzyloxy-L-ornithyl dihydrobromide (LL-X 2HBr). LL-X 2HBr was converted into the acetyl derivative (LL-XI) with an excess of acetic anhydride in pyridine. Hydrogenation of LL-XI in methyl alcohol in the presence of palladium charcoal at room temperatue gave cyclo-di-N^{δ}-acetyl-N^{δ}-hydroxy-L-ornithyl; rhodotorulic acid (LL-I). The DD-isomer of rhodotorulic acid, DD-I, was also prepared in a similar manner. The synthetic rhodotorulic acid and its DD-isomer, LL-I and DD-I, exhibited specific rotations of $-28.5°$ (*c* 1, water, at 25°C) and $+28.0°$ (*c* 0.6, water, at 24°C) respectively. These products gave a positive ferric chloride test. The identity of the synthetic rhodotorulic acid with natural rhodotorulic acid[1] was substantiated through spectral comparison (IR and NMR) (Fig. 3 and 4).

The synthetic rhodotorulic acid was hydrogenated in the presence of Raney nickel catalyst to cyclo-di-N^{δ}-acetyl-L-ornithyl (LL-XII), which was identified by comparison of the melting points, optical rotations, IR and NMR spectra with authentic sample (XXIII) prepared from L-ornithine (Fig. 6).

Experimental

Melting points of all the synthetic compounds were determined with a Yanagimoto electric micromelting point apparatus and are uncorrected. Optical rotations were measured with a Yanagimoto automatic polarimeter OR-50. Nuclear magnetic resonance spectra were run on a Hitachi Perkin-Elmer R-20 High Resolution NMR spectrometer, using tetramethylsilane as an internal standard. Molecular weight was determined with a Hitachi Perkin-Elmer 115 molecular weight apparatus.

N^{δ}-*Tosyl*-N^{δ}-*benzyloxyornithine (*L-*II and* D-*II).* The compound was prepared by the procedure described in the previous paper.[2]

L-II: mp 222.5—224.8°C (decomp.), $[\alpha]_D^{23.5}$ $+20.7°$ (*c* 3, acetic acid);

D-II: mp 217—223°C (decomp.), $[\alpha]_D^{25}$ $-21.0°$ (*c* 2, acetic acid).

N^{α}-*Benzyloxycarbonyl*-N^{δ}-*tosyl*-N^{δ}-*benzyloxy*-L-*ornithine (*L-*III).* It was obtained from L-II by the usual procedure, using a mixture of tetrahydrofuran and water as the solvent. The colorless oily product solidified to a glass. Yield 93%, $[\alpha]_D^{23}$ $-2.0°$ (*c* 2, acetic acid).

Found: N, 5.24%. Calcd for $C_{27}H_{30}N_2O_7S$: N, 5.32%.

N^{α}-t-*Butyloxycarbonyl*-N^{δ}-*tosyl*-N^{δ}-*benzyloxy*-L-*ornithine (*L-*IV).* To a suspension of L-II (15.7 g, 40 mmol) in methanol (80 m*l*), 40% benzyltrimethylammonium hydroxide (Triton B) (18.8 m*l*) was added. After stirring for 2 hr at room temperature, the solution was evaporated *in vacuo* at 50°C. The residue was then evaporated twice more with dimethylformamide *in vacuo* at 50°C in order to remove traces of water. The resulting syrup was dissolved in *t*-butanol (80 m*l*) and *t*-butyl 2,4,5-trichlorophenyl carbonate (11.9 g, 40 mmol) was added. After gentle stirring for 20 hr at 50—55°C, the reaction mixture was evaporated *in vacuo* and the residue taken up in water (70 m*l*). The solution was washed repeatedly with ether and acidified with M citric acid to about pH 3. The oily material thus deposited was extracted with ethyl acetate (600 m*l*). The extract was washed with water, dried over magnesium sulfate and evaporated *in vacuo*. The residue was crystallized from ethyl acetate - petroleum ether. Yield 18.5 g (94%), mp 58—66°C, $[\alpha]_D^{25}$ $+11.2°$ (*c* 1, ethanol).

Found: C, 58.74; H, 6.54; N, 5.40%. Calcd for $C_{24}H_{32}N_2O_7S$: C, 58.52; H, 6.55; N, 5.69%.

N^{α}-t-*Butyloxycarbonyl*-N^{δ}-*tosyl*-N^{δ}-*benzyloxy*-D-*ornithine (*D-*IV).* It was prepared in the same manner as described for the preparation of L-IV. Yield, 97.5%, mp 59—65°C and $[\alpha]_D^{25}$ $-9.0°$ (*c* 2, ethanol).

Found: C, 58.59; H, 6.75; N, 5.68%. Calcd for $C_{24}H_{32}N_2O_7S$: C, 58.52; H, 6.55; N, 5.69%.

N^{δ}-*Tosyl*-N^{δ}-*benzyloxy*-L-*ornithine Methyl Ester Hydrochloride (*L-*V HCl).* It was prepared from L-II by the usual

procedure. Recrystallization was effected from methanol - ether. Yield 83%, mp 151—152.5°C, $[\alpha]_D^{25}$ +18.9° (*c* 2, methanol).

Found: C, 54.18; H, 6.46; N, 6.14%. Calcd for $C_{20}H_{27}N_2O_5SCl$: C, 54.23; H, 6.14; N, 6.33%.

N^{δ}-*Tosyl*-N^{δ}-*benzyloxy*-D-*ornithine Methyl Ester Hydrochloride (*D-*V HCl)*. D-V HCl was obtained through the same method as described above. Yield 96%, mp 149—150°C and $[\alpha]_D^{24.5}$ −19.3° (*c* 1, methanol).

N^{α}-*Benzyloxycarbonyl*-N^{δ}-*tosyl*-N^{δ}-*benzyloxy*-L-*ornithyl*-N^{δ}-*tosyl*-N^{δ}-*benzyloxy*-L-*ornithine Methyl Ester (*LL-*VI)*. To a chilled solution of L-III (4.90 g, 9.3 mmol) and triethylamine (1.31 m*l*) in tetrahydrofuran (45 m*l*), isobutyl chloroformate (1.26 m*l*, 9.3 mmol) was added at −10°C. After 20 min, a mixture of V HCl (4.24 g, 9.3 mmol) and triethylamine (1.31 m*l*) in *N,N*-dimethylformamide (25 m*l*) was added to the above solution. The mixture was stirred overnight at room temperature. After the mixture had been evaporated *in vacuo*, the product was dissolved in ethyl acetate (50 m*l*). The solution was washed successively with N hydrochloric acid, water, 0.5M sodium bicarbonate, and water, and dried over anhydrous sodium sulfate. The filtered solution was evaporated to dryness *in vacuo*. The residual colorless oil resisted to attempt to crystallization. Yield 8.4 g, (98%).

Found: C, 61.59; H, 6.12; N, 6.25%. Calcd for $C_{47}H_{54}N_4O_{11}S_2$: C, 61.70; H, 5.95; N, 6.13%.

N^{δ}-*Tosyl*-N^{δ}-*benzyloxy*-L-*ornithyl*-N^{δ}-*tosyl*-N^{δ}-*benzyloxy*-L-*ornithine Methyl Ester Hydrobromide (VII HBr)*. To a solution of LL-VI (8.3 g, 9.1 mmol) in acetic acid (6.5 ml), 36% hydrogen bromide - acetic acid (8.2 m*l*) was added. After 90 min, the solution was evaporated *in vacuo*. The reisdual oil was triturated with ether. Yield of the oily product, 6.3 g (79%).

N^{α}-t-*Butyloxycarbonyl*-N^{δ}-*tosyl*-N^{δ}-*benzyloxy*-L-*ornithyl*-N^{δ}-*tosyl*-N^{δ}-*benzyloxy*-L-*ornithine Methyl Ester (*LL-*VII)*. This compound was prepared by coupling L-IV with L-V by the mixed anhydride method as described above; yield 96.7%, mp 63—69°C, $[\alpha]_D^{25}$ +1.1° (*c* 1, ethyl acetate).

Found: C, 60.09; H, 6.65; N, 6.10%. Calcd for $C_{44}H_{56}N_4O_{11}S_2$: C, 59.98; H, 6.41; N, 6.37%.

N^{δ}-*Tosyl*-N^{δ}-*benzyloxy*-L-*ornithyl*-N^{δ}-*tosyl*-N^{δ}-*benzyloxy*-L-*ornithine Methyl Ester Hydrochloride (*LL-*VIII HCl)*. To a solution of LL-VII (18.76 g, 21.3 mmol) in ethyl acetate (30 m*l*), 3N hydrogen chloride in ethyl acetate (80 m*l*) was added. The solution, being allowed to stand at room temperature for 2 hr, was evaporated *in vacuo* and the oily residue crystallized by addition of ether. Yield 16.10 g (92.5%), mp 100—105°C, $[\alpha]_D^{25}$ +12.10° (*c* 1, methanol).

Found: C, 56.98; H, 6.24; N, 6.58%. Calcd for $C_{39}H_{49}N_4O_9S_2Cl$: C, 57.30; H, 6.04; N, 6.85%.

N^{α}-t-*Butyloxycarbonyl*-N^{δ}-*tosyl*-N^{δ}-*benzyloxy*-D-*ornithyl*-N^{δ}-*tosyl*-N^{δ}-*benzyloxy*-D-*ornithine Methyl Ester (*DD-*VII)*. DD-VII was obtained by the same procedure as described above. Yield 90.3%, mp 63—69°C and $[\alpha]_D^{25}$ −1.4° (*c* 1, ethyl acetate).

Found: C, 60.01; H, 6.69; N, 6.03%. Calcd for $C_{44}H_{56}N_4O_{11}S_2$: C, 59.98; H, 6.41; N, 6.37%.

N^{δ}-*Tosyl*-N^{δ}-*benzyloxy*-D-*ornithyl*-N^{δ}-*tosyl*-N^{δ}-*benzyloxy*-D-*ornithine Methyl Ester Hydrochloride (*DD-*VIII HCl)*. This compound was prepared from DD-VII by the same method as that described for the corresponding LL-dipeptide ester hydrochloride LL-VIII HCl.

Cyclo-di-N^{δ}-*tosyl*-N^{δ}-*benzyloxy*-L-*ornithyl (*LL-*IX)*. This compound was prepared according to the general procedure.[3]

(a) From LL-*VIII HBr*: A solution of LL-VIII HBr (3.95 g, 4.59 mmol) in methanol (50 m*l*), previously saturated with dry ammonia at 0°C, was stored in a glass-stoppered bottle at room temperature for 2 days. A mass of crystals deposited was collected. The mother liquor was concentrated to dryness and crystalline residue was filtered with the aid of water. Recrystallization from methanol gave colorless crystals. Yield 1.9 g (54%), mp 197—199°C, $[\alpha]_D^{25.5}$ −31.5° (*c* 2, dimethylformamide).

Found: C, 61.15; H, 5.85; N, 7.48; S, 8.59%. Calcd for $C_{38}H_{44}N_4O_8S_2$: C, 60.94; H, 5.92; N, 7.48; S, 8.56%.

(b) From LL-*VIII HCl*: Similar treatment of LL-VIII HCl with ammonia gave LL-IX. Yield 47.7%, mp 174—175°C, $[\alpha]_D^{25.5}$ −31.3° (*c* 2, dimethylformamide).

Cyclo-di-N^{δ}-*benzyloxy*-L-*ornithyl Dihydrobromide (*LL-*X 2HBr)*. To a solution of 36% hydrogen bromide - acetic acid (20 m*l*) and phenol (5 g) in a glass-stoppered bottle, LL-IX (1.88 g, 2.5 mmol) was added at room temperature. After stirring for 50 hr at room temperature, the solution was evaporated *in vacuo* at 30°C. The residual oil was crystallized by addition of ether. Crystals were filtered off and washed with ethanol and ether. Yield 0.78 g (52%). The product was recrystallized from water - ethanol, mp 183—186°C, $[\alpha]_D^{22}$ −12.0° (*c* 0.5, methanol).

Found: C, 47.51; H, 5.81; N, 9.10%. Calcd for $C_{24}H_{32}N_4O_4$ 2HBr: C, 47.85; H, 5.69; N, 9.30%.

Cyclo-di-N^{δ}-*acetyl*-N^{δ}-*benzyloxy*-L-*ornithyl (*LL-*XI)*. LL-X 2HBr (0.78 g, 1.3 mmol) was mixed with pyridine (6.5 m*l*) and acetic anhydride (6.5 m*l*). After stirring for 20 hr at room temperature, the reaction mixture was evaporated to a syrup *in vacuo*. The residue was evaporated twice with water in order to decompose any acetic anhydride present. The final residue was taken up in ethyl acetate (30 m*l*) and the solution was repeatedly washed with water. The organic layer was dried over anhydrous sodium sulfate and evaporated to dryness *in vacuo*. The residue was triturated with ether to yield a crude crystalline product, which was purified from ethanol - ether. Yield 68%, mp 97—99°C, $[\alpha]_D^{20}$ −16.4° (*c* 1, ethanol).

Found: C, 63.97; H, 6.86; N, 10.62%. Calcd for $C_{28}H_{36}N_4O_6$: C, 64.10; H, 6.92; N, 10.68%.

Cyclo-di-N^{δ}-*acetyl*-N^{δ}-*hydroxy*-L-*ornithyl*; *Rhodotorulic Acid (*LL-*I)*. A solution of LL-XI (0.46 g, 0.88 mmol) in methanol (25 m*l*) was hydrogenated in the presence of 5% palladium charcoal (0.75 g) for 20 hr at room temperature. After the addition of methanol (25 m*l*), the reaction mixture was warmed to 70°C and the catalyst was filtered off while hot. The filtrate was evaporated *in vacuo* at room temperature. The residual crystals were recrystallized from boiling water. Yield 0.2 g (66%), mp 217—218.5°C, (decomp.), $[\alpha]_D^{25}$ −28.8° (*c* 1, water).

Found: C, 48.81; H, 7.07; N, 16.18%. Calcd for $C_{14}H_{24}N_4O_6$: C, 48.83; H, 7.03; N, 16.27%.

The substance gave negative ninhydrin- and triphenyltetrazolium tests and positive ferric chloride test. NMR spectrum; Fig. 3, IR spectrum; Fig. 4.

DD-IX, DD-X 2HBr, DD-XI, and DD-I were prepared by the same methods as described for the preparation of the corresponding LL-isomers.

Cyclo-di-N^{δ}-*tosyl*-N^{δ}-*benzyloxy*-D-*ornithyl (*DD-*IX)*. Yield 38.8%, mp 173—175°C, $[\alpha]_D^{25.5}$ +32.1° (*c* 2, dimethylformamide).

Found: C, 60.75; H, 5.90; N, 7.27%. Calcd for $C_{38}H_{44}N_4O_8S_2$: C, 60.94; H, 5.92; N, 7.48%.

Cyclo-di-N^{δ}-*benzyloxy*-D-*ornithyl Dihydrobromide (*DD-*X 2HBr)*. Yield 33.4%, mp 183—185°C (decomp.), $[\alpha]_D^{22}$ +12.8° (*c* 0.5, methanol).

Found: C, 47.88; H, 5.64; N, 9.35%. Calcd for $C_{24}H_{34}N_4O_4Br_2$: C, 47.85; H, 5.69; N, 9.30%.

Cyclo-di-N^{δ}-*acetyl*-N^{δ}-*benzyloxy*-D-*ornithyl (*DD-*XI)*. Yield

20.7%, mp 97—99°C, $[\alpha]_D^{20}$ −16.7° (*c* 0.3, ethanol).

Found: C, 63.93; H, 6.86; N, 10.74%. Calcd for $C_{28}H_{36}N_4O_6$: C, 64.10; H, 6.92; N, 10.68%.

*Cyclo-di-*N$^{\delta}$*-acetyl-*N$^{\delta}$*-hydroxy-*D*-ornithyl (*DD*-I)*; DD*-Isomer of Rhodotorulic Acid.* Yield 35%, mp 216—218.5°C (decomp.), $[\alpha]_D^{24}$ +28.0° (*c* 0.6, water).

Found: C, 48.72; H, 6.88; N, 16.05%. Calcd for $C_{14}H_{24}N_4O_6$: C, 48.83; H, 7.03; N, 16.27%.

*Catalytic Reduction of Rhodotorulic Acid (*LL*-I) to Cyclo-di-*N$^{\delta}$*-acetyl-*L*-ornithyl (*LL*-XII).* A suspension of LL-I (0.15 g, 0.44 mmol) in methanol (100 m*l*) was hydrogenated in the presence of Raney nickel (1 spatula) under atmospheric pressure at room temperature. After 6 days, the reaction mixture was warmed to 70°C in order to dissolve the precipitated product and filtered. The filtrate was evaporated *in vacuo* and the remaining crystals were recrystallized from boiling methanol. Yield 65 mg (48%), mp 270—275°C (decomp.), (lit,[1] mp *ca.* 265°C) and $[\alpha]_D^{25}$ −34.8° (*c* 0.5, water).

NMR (CF_3COOH): δ; 8.75 ppm (2H, side-chain amide protons), 8.33 (2H, ring-amide protons), 4.42 (2H, ring-carbon protons), 3.67 (4H, side-chain methylene protons adjacent to nitrogen), 2.52 (6H, acetyl methyl protons), 2.09 (8H, ethylene protons).

Found: C, 53.86; H, 7.95; N, 17.89%. Calcd for $C_{14}H_{24}N_4O_4$: C, 53.83; H, 7.74; N, 17.94%.

N$^{\alpha}$*-t-Butyloxycarbonyl-*N$^{\delta}$*-benzyloxycarbonyl-*L*-ornithine (XIII).*

a): XIII was obtained as a syrup according to the same procedure for the D-isomer[4] from N^{δ}-benzyloxycarbonyl-L-ornithine using *t*-butyloxycarbonyl azide as *t*-butyloxycarbonylating reagent, except that magnesium oxide was used instead of sodium bicarbonate. Yield 41%, $[\alpha]_D^{25}$ +10.1° (*c* 1, ethyl acetate), (lit,[5] BOC-L-Orn(δ-Z)-OH, $[\alpha]_{578}^{18-25}$ −8.9° (*c* 1, acetic acid)).

b): XIII was also prepared according to the method of Broadbent *et al.*,[6] using *t*-butyl 2,4,5-trichlorophenyl carbonate. Yield 84%.

N$^{\alpha}$*-t-Butyloxycarbonyl-*N$^{\delta}$*-benzyloxycarbonyl-*L*-ornithine* p*-Nitrophenyl Ester (XIV).* This compound was obtained from XIII and *p*-nitrophenol according to the same procedure for the D-isomer,[4] except that ethyl acetate was used as the solvent. Yield 86%, mp 113—114.5°C (from ethyl acetate-petroleum ether), $[\alpha]_D^{25}$ −20.4° (*c* 1, ethyl acetate).

Found: C, 59.31; H, 6.29; N, 8.50%. Calcd for $C_{24}H_{29}N_3O_8$: C, 59.13; H, 6.00; N, 8.62%.

N$^{\delta}$*-Benzyloxycarbonyl-*L*-ornithine* p*-Nitrophenyl Ester Hydrochloride (XV).* To a suspension of XIV (9.74 g, 0.02 mol) in ethyl acetate (80 m*l*) was added 5N hydrogen chloride in ethyl acetate (40 m*l*). After 1 hr, crystals were collected with the aid of dry ether. Yield 8.3 g (98%), mp 164.5—167.5°C, $[\alpha]_D^{25}$ +27.3° (*c* 1, methanol).

Found: C, 53.74; H, 5.44; N, 10.05%. Calcd for $C_{19}H_{22}N_3O_6Cl$: C, 53.84; H, 5.23; N, 9.92%.

N$^{\alpha}$*-t-Butyloxycarbonyl-*N$^{\delta}$*-benzyloxycarbonyl-*L*-ornithyl-*N$^{\delta}$*-benzyloxycarbonyl-*L*-ornithine Methyl Ester (XVI).* *a)*: To a stirred mixture of XIII (9.86 g, 26.9 mmol) and Woodward reagent K (7.08 g, 28 mmol) in dimethylformamide (70 m*l*) was added triethylamine (4.1 m*l*, 30 mmol) at 0°C. After 2 hr, N^{δ}-benzyloxycarbonyl-L-ornithine methyl ester hydrochloride (8.51 g, 26.9 mmol) and triethylamine (4.1 m*l*) were added. The reaction mixture was stirred for 20 hr and then evaporated. The residual semi-solid was dissolved in ethyl acetate, and the solution was washed successively with water (three times), M sodium bicarbonate, water, 10% citric acid and water (three times), dried and evaporated. The oily residue was solidified by addition of petroleum ether. Recrystallization from ethyl acetate-petroleum ether gave XVI. Yield 10.9 g (67%), mp 73.0—74.5°C, $[\alpha]_D^{25}$ −10.7° (*c* 1, methanol).

Found: C, 60.98; H, 7.31; N, 8.89%. Calcd for $C_{32}H_{44}N_4O_9$: C, 61.13; H, 7.05; N, 8.91%.

b): To a stirred suspension of N^{δ}-benzyloxycarbonyl-L-ornithine methyl ester hydrochloride (7.03 g, 22.2 mmol) in chloroform (100 m*l*) was added triethylamine (4.48 g, 44.4 mmol) at 0°C. After 10 min, XIV (10.8 g, 22.2 mmol) was added. The mixture was stirred at 0°C for 15 min and at room temperature for 20 hr. Chloroform (100 m*l*) was added and the mixture was treated as described above except that the chloroform layer was washed with M sodium bicarbonate for the removal of the resultant *p*-nitrophenol. Yield 10 g (74%), mp 70—74°C, $[\alpha]_D^{25}$ −11.5° (*c* 1, methanol).

Found: C, 60.96; H, 7.20; N, 9.16%. Calcd for $C_{32}H_{44}N_4O_9$: C, 61.13; H, 7.05; N, 8.91%.

N$^{\delta}$*-Benzyloxycarbonyl-*L*-ornithyl-*N$^{\delta}$*-benzyloxycarbonyl-*L*-ornithine Methyl Ester Hydrochloride (XVII).* This compound was obtained through the same method as described above.

a): *From XVI-a*, mp 102—117°C, $[\alpha]_D^{25}$ +8.4° (*c* 1, methanol).

Found: N, 10.13%. Calcd for $C_{27}H_{37}N_4O_7Cl$: N, 9.92%.

b): *From XVI-b*, $[\alpha]_D^{25}$ +8.2° (*c* 1, methanol).

N$^{\alpha}$*-t-Butyloxycarbonyl-*N$^{\delta}$*-benzyloxycarbonyl-*L*-ornithyl-*N$^{\delta}$*-benzyloxycarbonyl-*L*-ornithine (XVIII).* To a stirred solution of XVI (6.28 g, 0.01 mol) in dioxane was added N sodium hydroxide (12 m*l*). The mixture was stirred overnight and acidified with 2N hydrochloric acid. The separated oil was extracted with ethyl acetate. Ethyl acetate layer was dried and evaporated to an oil. Yield 5.7 g (93%), $[\alpha]_D^{25}$ −3.5° (*c* 1, methanol).

Found: C, 60.08; H, 6.78; N, 8.86%. Calcd for $C_{31}H_{42}N_4O_9$: C, 60.57; H, 6.89; N, 9.12%.

N$^{\alpha}$*-t-Butyloxycarbonyl-*N$^{\delta}$*-benzyloxycarbonyl-*L*-ornithyl-*N$^{\delta}$*-benzyloxycarbonyl-*L*-ornithine* p*-Nitrophenyl Ester (XIX).* *a)*: A mixture of XVIII (3.15 g, 5.13 mmol) and di-*p*-nitrophenyl sulfite (1.07 g, 5.5 mmol) in pyridine was stirred at 0°C for 12 hr and at room temperature for 2 days. Resultant pale yellow solution was poured into N hydrochloric acid (150 m*l*). Semisolid precipitated was extracted with ethyl acetate. The organic layer was washed with saturated sodium chloride solution, dried and evaporated to give crystals. Yield 1.58 g (42%), mp 113.5—116°C, $[\alpha]_D^{25}$ −23.1° (*c* 1, methanol). Recrystallization from methanol-ether gave an analytical sample.

Found: C, 60.40; H, 6.28; N, 9.66%. Calcd for $C_{37}H_{45}N_5O_{11}$: C, 60.41; H, 6.12; N, 9.52%.

b): To a mechanically stirred mixture of XIII (7.7 g, 21 mmol) and XV (8.92 g, 21 mmol) in acetonitrile (200 m*l*), was added triethylamine (2.9 m*l*, 21 mmol) at 0°C. After 40 min, dicyclohexylcarbodiimide (4.4 g, 22 mmol) in a small portion of acetonitrile was added and the mixture was stirred overnight at room temperature. The deposits were collected and extracted with hot tetrahydrofuran (350 m*l*). The tetrahydrofuran was evaporated and the remaining crystals were collected with the aid of dry ether. Yield 7.21 g (47%), mp 116.5—118.5°C, $[\alpha]_D^{25}$ −26.2° (*c* 1, methanol).

N$^{\delta}$*-Benzyloxycarbonyl-*L*-ornithyl-*N$^{\delta}$*-benzyloxycarbonyl-*L*-ornithine* p*-Nitrophenyl Ester Hydrochloride (XX).* To a suspension of XIX (2.94 g, 4 mmol) in ethyl acetate (10 m*l*) was added 5N hydrogen chloride in ethyl acetate (28 m*l*). After 2 hr, the ethyl acetate was evaporated and the remaining crystals were collected with the aid of dry ether. Yield 2.36 g (88%),

4) T. Kato and N. Izumiya, This Bulletin, **39**, 2242 (1966).
5) E. Schnabel, *Ann. Chem.*, **702**, 188 (1967).
6) W. Broadbent, J. S. Morley, and B. E. Stone, *J. Chem. Soc., C*, **1967**, 2632.

mp 124—128°C, $[\alpha]_D^{25}$ +27.3° (*c* 1, methanol).

Found: N, 10.53%. Calcd for $C_{32}H_{38}N_5O_9Cl$: N, 10.42%.

*Cyclo-di-*N$^{\delta}$*-benzyloxycarbonyl-*L*-ornithyl (XXI).* XX (2 g, 2.98 mmol) in the mixture of dimethylformamide (40 m*l*) and acetic acid (10 m*l*) was dropped over a period of 3 hr in the preheated pyridine (500 m*l*) at 70°C under vigorous stirring. Stirring was continued overnight at room temperature and the pyridine was evaporated. To the residue was added water and crystals were collected, 1.0 g (68%), mp 236—239°C (from dimethylformamide), $[\alpha]_D^{25}$ −19.5° (*c* 1, dimethylformamide). IR (KBr): 3325, 3175, 1690, 1550 cm^{-1}.

Found: C, 62.98; H, 6.32; N, 11.16; mol wt 470. Calcd for $C_{26}H_{32}N_4O_6$: C, 62.90; H, 6.50; N, 11.29%; mol wt 496.

*Cyclo-di-*L*-ornithyl Dihydrobromide (XXII).* XXI (10 g, 20.4 mmol) was treated with 20% hydrogen bromide in acetic acid (100 m*l*) with occasional shaking. A clear solution resulted and soon after a copious mass precipitated. After 6 hr, 20% hydrogen bromide in acetic acid (100 m*l*) was added again. After standing overnight, dry ether was added. The precipitate was collected and washed with ether. Yield 7.41 g (95%), mp 240—250°C (decomp.), $[\alpha]_D^{25}$ −28.1° (*c* 1, water).

Found: C, 30.36; H, 5.92; N, 13.80%. Calcd for $C_{10}H_{22}N_4O_2Br_2$: C, 30.78; H, 5.68; N, 14.36%.

*Cyclo-di-*N$^{\delta}$*-acetyl-*L*-ornithyl (XXIII). a)*: XXII (390 mg, 1 mmol) in pyridine (5 m*l*) was stirred at 50°C for 25 min. Thereafter acetic anhydride was added and stirring was continued for 5 hr at 50°C. The crystals were collected and washed successively with methanol, water and again methanol. Yield 250 mg (80%), mp 277—279°C (lit,[1] mp *ca.* 265°C), $[\alpha]_D^{21}$ −33.5° (*c* 1, water). IR (KBr): 3290, 3195, 3090, 1680, 1630, 1550 cm^{-1}.

Found: C, 53.89; H, 7.99; N, 17.75%. Calcd for $C_{14}H_{24}N_4O_4$: C, 53.83; H, 7.74; N, 17.94%.

b): To a stirred suspension of XXII (390 mg) in pyridine (5 m*l*) was added triethylamine (0.28 m*l*). After 30 min, *p*-nitrophenyl acetate (724 mg, 4 mmol) was added at room temperature. After one day, the crystals were collected. Yield 190 mg (61%), mp 278—279°C (from methanol), $[\alpha]_D^{21.5}$ −34.6° (*c* 1, water).

c): To a stirred solution of sodium bicarbonate (168 mg, 2 mmol) in water (1 m*l*) was added XXII (390 mg). After 10 min, acetic anhydride (0.3 m*l*) was added at 0°C. The homogeneous solution was stirred for 10 min at 0°C and then for 90 min at room temperature. The deposited crystals were collected. Yield 120 mg (38%), mp 278—281°C (from methanol), $[\alpha]_D^{22}$ −36.2° (*c* 1, water).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1471—1473(1972)

Preparation and Thermal Decomposition of 1,4,5- and 1,3,5-Trimethyltetrazolium Iodides

(Received August 14, 1971)

1,4,5- and 1,3,5-Trimethyltetrazolium iodides were prepared by the reaction of methyl iodide with 1,5- and 2,5-dimethyltetrazoles, and the reaction of methyl iodide with 5-methyltetrazole. The latter method is more facile for the preparation of these iodides. Upon thermal decomposition of the 1,3,5-trimethyl salt at 130°C, the 1-methyl group was eliminated predominantly to yield 2,5-dimethyltetrazole. When the 1,4,5-trimethyl salt was decomposed at 270°C, a mixture of 1,5- and 2,5-dimethyltetrazole was obtained in 74% and 21% yields, respectively. For the formation of 2,5-dimethyltetrazole from the 1,4,5-trimethyl salt, there has been shown an intermolecular methylation scheme that the 1,4,5-trimethyl salt methylated 1,5-dimethyltetrazole being formed *in situ* to give the 1,3,5-trimethyl salt.

In our previous paper,[1] quantitative isomerization of 1-alkyl-5-phenyltetrazole into the 2-alkyl isomer in the presence of alkyl iodide has been reported. The study of thermal decomposition of 1,3- and 1,4-dialkyl-5-phenyltetrazolium iodides revealed that 2-alkyl-5-phenyltetrazole was produced predominantly from the 1,3-dialkyl salt. The 1,4-dialkyl salt, more stable than the 1,3-dialkyl salt, was decomposed at 130°C to produce 1-alkyl-5-phenyltetrazole. As an extention of the preceding work, this paper presents a study of the preparation and thermal decomposition of 1,4,5- and 1,3,5-trimethyltetrazolium iodides.

As for the study of 5-methyltetrazolium iodides, there has been only one patent[2] in which was reported the preparation of 1,4,5-trimethyltetrazolium iodide (**1**) by the reaction of 1,5-dimethyltetrazole (**2**) with methyl iodide. In view of the formation of 1,3-dimethyl-5-phenyltetrazolium iodide as well as the 1,4-dimethyl salt from 1-methyl-5-phenyltetrazole,[1] formation of 1,3,5-trimethyltetrazolium iodide (**3**) from **2** was expected. However, in the reaction of **2** with methyl iodide carried out at 100°C for 2 hr or at room temperature for 10 days, the 1,4,5-trimethyl salt **1** was produced selectively without the formation of the other isomeric tetrazolium salts. The selective methylation at 4-nitrogen in 1,5-dimethyltetrazole might be

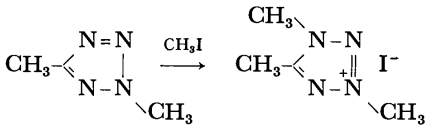
2 **1**

attributed to more electron-donating property of the 5-methyl group than that of the 5-phenyl group. The structure of the colorless crystals **1**, (mp 266°[3] decomp) has been identified by the NMR spectrum which has two singlets at δ 4.27 ppm assigned to a couple of equivalent *N*-methyl protons and δ 2.95 ppm to 5-methyl protons.

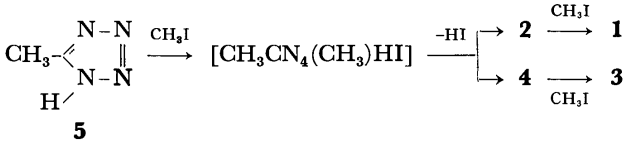
Preparation of 1,3,5-trimethyltetrazolium iodide (**3**) was carried out by the reaction of 2,5-dimethyltetrazole (**4**)[4] with methyl iodide at room temperature for a long time (90 days).



4 **3**

In the NMR spectrum of **3** prepared herewith, there were three singlets at δ 2.82, 4.34 and 4.62 ppm which could be assigned to the 5-, 1-, and 3-methyl protons, respectively. The similar assignment was reported with 1,3-dimethyltetrazolium iodide[5] and 1,3-dimethyl-5-phenyltetrazolium iodide.[1]

The above preparation of the 1,4,5-trimethyl salt **1** or the 1,3,5-trimethyl salt **3** from 1,5-dimethyltetrazole **2** or 2,5-dimethyltetrazole **4**, respectively, however, is not a convenient method, compared with the following facile one using readily prepared 5-methyltetrazole (**5**) as the starting material. When **5** was heated in an excess of methyl iodide at 40°C for 10 days, a mixture of **1** and **3** (68:32) was obtained in 77% yield together with hydrogen iodide, methane and iodine. Separation of **1** and **3** was carried out by the selective extraction of **3** from the mixture with acetone. The remaining crystals undissolved in acetone were identified as pure **1**. The crystalline **3** was precipitated by the addition of diethyl ether to the acetone extract. In the first step of this reaction there might be formed 1,5- and 2,5-dimethyltetrazole hydrogen iodides, $CH_3CN_4(CH_3)HI$, as intermediates. These compounds not isolated yet are considered to be unstable under the reaction condition and eliminated readily hydrogen iodide to produce **2** and **4** which reacted with methyl iodide to give **1** and **3**, respectively. A part of the liberated hydrogen iodide reduced methyl iodide to give iodine and methane.[6]



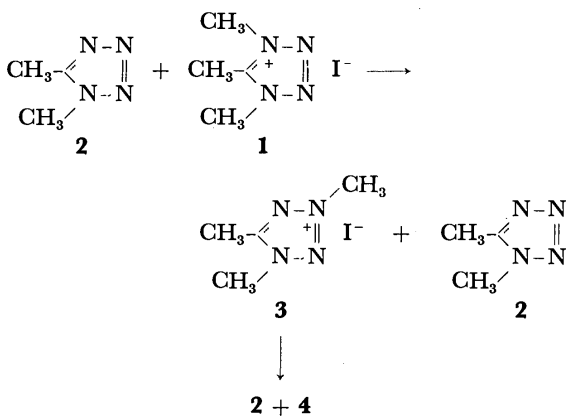
5

Thermal decomposition of tetrazolium salts has never been studied in detail until our recent investigation[1] of 1,3-dimethyl-5-phenyltetrazolium iodide (**6**) and the 1,4-dimethyl-5-phenyl salt (**7**). In the case of the 5-phenyltetrazolium salts, the 1,3-dimethyl salt **6** decomposed at a lower temperature (dp below 70°C) than the 1,4-dimethyl salt **7** (dp 130°C). The analogous relation has been found between the 1,3,5-trimethyl salt **3** (dp 130°C) and 1,4,5-trimethyl salt **1** (dp 266°C).

Thermal treatment of 1,3,5-trimethyltetrazolium iodide at 135°C for 30 min gave a mixture of 1,5-dimethyltetrazole **2** and 2,5-dimethyltetrazole **4** in a ratio of 15:85. 1-Methyl group was liberated predominantly to yield **4**. This is consistent with the selective elimination of the 1-methyl group in the thermal decomposition of **6**.[1] When decomposition of **3** was carried out at 180°C and 270°C, there were obtained mixtures of **2** and **4** in ratios of 42:58 and 60:40, respectively. The selectivity in the elimination of methyl iodide decreased with the elevation of the decomposition temperature.

Thermal decomposition of 1,4,5-trimethyltetrazolium iodide **1** was carried out at 270°C, a slightly higher temperature than the decomposition point 266°C, for 3 min to afford 2,5-dimethyltetrazole **4** in 21% yield as well as 1,5-dimethyltetrazole **2** (74%) together with methyl iodide. The product **4** should be formed in the course of the thermal decomposition

of **1**, since there was no formation of **4** when pure **2** was heated at 270°C. For the formation of **4**, the following experiment showed an intermolecular methylation scheme: 1,5-dimethyltetrazole **2** formed *in situ* from 1,4,5-trimethyl salt **1** was methylated by the remaining **1** to give intermediate **3**, whose decomposition products were **2** and **4** as described above.



When thermal decomposition of **1** was carried out in the presence of 1-methyl-5-phenyltetrazole (**8**) at 270°C, there were obtained 2-methyl-5-phenyltetrazole (**9**) (23% yield based on **8**) together with **2** and **4**. It has already been established[1] that **9** was obtained from 1,3-dimethyl-5-phenyltetrazolium iodide (**6**) which was formed by the reaction of **8** with methyl iodide, and that in the absence of methyl iodide there was no

3) The reported decomposition point was 216°C.[2]

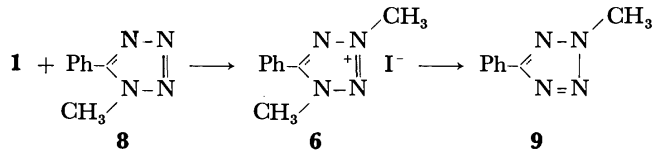
formation of **9** from **8**. Thus **8** was apparently methylated by **1** to produce **6** which liberated the 1-methyl group predominantly to yield **9** under the reaction condition. This result presented a sufficient support for the intermolecular methylation by the quaternary salt **1**.



8 **6** **9**

Experimental

Reaction of 1,5-Dimethyltetrazole (2) with Methyl Iodide. A solution of 0.125 g (1.30 mmol) of **2**[4] in 10 m*l* of methyl iodide was heated in a sealed glass bottle at 100°C for 5 hr. Upon cooling to room temperature, colorless needles were precipitated. The crystals isolated by filtration were identified as 1,4,5-trimethyltetrazolium iodide (**1**), by the elemental analysis and the NMR spectrum, 0.239 g (77.2%), dp (decomposition point) 266°, (lit,[2] dp 216°). NMR [D_2O, sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal standard] δ 2.95 (s, 3H, 5-methyl protons), δ 4.27 ppm (s, 6H, 1,4-dimethyl protons), IR (Nujol) 1590 (vs), 1540 (m), 1355 (w), 1330 (w), 1240 (w), 1213 (w), 1043 (sh), 1030 (vs), 766 (vs), 618 cm^{-1}(m).

Found: C, 20.00; H, 3.78; N, 23.34%. Calcd for $C_4H_9N_4I$: C, 20.01; H, 3.78; N, 23.34%. Evaporation of methyl iodide of the filtrate gave 0.011 g (8.8%) of **2** recovered unchanged.

Reaction of **2** with methyl iodide was also carried out at room temperature in an NMR tube. After 10 days, a singlet at δ 4.05 ppm assigned to the 1-methyl protons of **2** disappeared completely. Colorless needles precipitated were identified as pure **1** by the mixed decomposition point determination and by the IR and NMR spectra.

Reaction of 5-Methyltetrazole (5) with Methyl Iodide. To a methanol solution of 1.378 g (16.4 mmol) of **5**[4,7] was added a large excess of methyl iodide. After 10 days heating at 40°C, the reaction mixture was cooled to precipitate yellowish crystals which were filtered and washed with acetone twice to give 1.795 g of pure **1**. The collected filtrate was evaporated off to dryness *in vacuo* without heating. To the residual crystals was added 10 m*l* of acetone to give additional 0.225 g of **1** insoluble in acetone (in total, 2.020 g (51.2%) of **1**), and to the acetone solution was added 100 m*l* of dry ether to precipitate 1.04 g (26.4%) of crystals. By the additional reprecipitation procedure there were obtained colorless crystals, dp 130°C, whose structure was determined as 1,3,5-trimethyltetrazolium iodide (**3**) by the NMR spectrum (D_2O, DSS): δ 2.82 (s, 3H, 5-methyl protons), δ 4.34 (s, 3H, 1-methyl), δ 4.62 ppm (s, 3H, 3-methyl), IR (Nujol) 1554 (vs), 1336 (m), 1293 (m), 1077 (m), 1038 (s), 1026 (m), 808 cm^{-1} (vs). Elemental analysis was given up because of its highly deliquescent property.

Reaction of 2,5-Dimethyltetrazole (4) with Methyl Iodide. A solution of **4**[4] in methyl iodide was kept at room temperature in an NMR tube. After 90 days, two singlets at δ 2.53 and δ 4.30 ppm assigned to the 5- and the 2-methyl protons of **4** disappeared. A pale yellowish oily substance insoluble in methyl iodide was separated by decantation, dissolved in 1 m*l* of acetone followed by the addition of dry ether to precipitate colorless needles which were identified as **3** by the NMR and the IR spectra.

Thermal Decomposition of 1,4,5-Trimethyltetrazolium Iodide (1). Thermal decomposition of 1.2354 g (5.14 mmol) of crystalline **1** was carried out at 270°C for 5 min in a small Claisen flask heated in a molten metal bath. Methyl iodide, **4** and a part of **2** were distilled out to be trapped through a cold condenser. After pyrolysis the condenser was rinsed with additional amount of methyl iodide to collect the whole distillate. It was calculated from the total weight and the integral ratio of the NMR spectrum that the distillate contained 0.024 g of **2** and 0.102 g (21.3%) of **4**. Pure **4** was isolated by preparative gas chromatography, bp 97—98°C /760 mmHg (lit.,[4] bp 57—57.2°C/13 mmHg). The chemical shifts of **4** in the NMR spectrum were coincided with the reported ones.[4] To the residue (0.5025 g) in the flask was added 20 m*l* of acetone to separate the starting ingredient **1** unchanged. The insoluble **1** (0.090 g) was removed by filtration, and the acetone of the filtrate was evaporated *in vacuo* to give 0.3466 g of pure **2**. In total, 0.370 g (73.5%) of **2** was obtained by the pyrolysis.

Thermal decomposition of **1** was also carried out in an NMR tube. To the top of the tube was attached an effective condenser made of a long (30 cm) needle of a syringe. The needle was cooled outside by dry-ice, and the syringe was packed with granulated calcium chloride. Crystalline **1** (0.0718 g) was heated in the tube at 270°C for 3 min. After cooling the tube in an ice bath, 0.4 m*l* of deuterochloroform was added through the needle, and NMR spectrum was measured. The starting iodide **1** was completely decomposed. The distribution of **2** and **4** produced was found to be 72: 28. This is in good agreement with the former isolation results indicating little loss of vaporizable **4** in this micro-procedure. Analogous equipments were used in the following experiments.

Thermal Decomposition of 1 in the Presence of 1-Methyl-5-phenyltetrazole (8). A mixture of 0.067 g (0.279 mmol) of **1** and 0.011 g (0.069 mmol) of **8** was heated at 270°C for 3 min in an NMR tube with the cooled needles as described above. After the mixture was cooled to room temperature, methyl iodide and 2,5-dimethyltetrazole **4** were evaporated off *in vacuo*, since the chemical shifts of **4** in the NMR spectrum was close to those of 2-methyl-5-phenyltetrazole (**9**). After evaporation of **4**, the residue was dissolved in deuterochloroform and the NMR spectrum was measured. The ratio of **8** and **9** was determined as 23: 77 by the integral ratio of the peaks at δ 4.18 and 4.38 ppm,[1] respectively.

Thermal Treatment of 2 at 270°C. In an NMR tube was heated 0.0464 g of **2** at 270°C for 30 min. After the tube was cooled in an ice bath, 0.4 m*l* of deuterochloroform was added through the needle, and NMR spectrum was measured. There was not detected even a trace of **4** in the NMR spectrum indicating no formation of **4** from **2** on heating at the decomposition condition at 270°C.

Thermal Decomposition of 1,3,5-Trimethyltetrazolium Iodide (3). On heating **3** at 135°C for 30 min in an NMR tube as described above, a mixture of **2** and **4** was obtained in a ratio of 14: 86 which was determined by NMR analysis. Analogous decompositions of **3** at 180°C for 15 min and at 270°C for 3 min gave mixtures of **2** and **4** in ratios of 42: 58 and 60: 40, respectively.

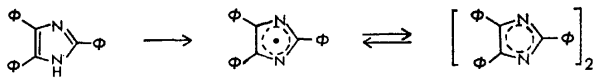
Structures of Three Isomeric Dimers of 2,4,5-Triphenylimidazolyl[1]

Hideo TANINO, Tadao KONDO, Kunisuke OKADA, and Toshio GOTO
Department of Agricultural Chemistry, Nagoya University, Chikusa, Nagoya
(Received August 23, 1971)

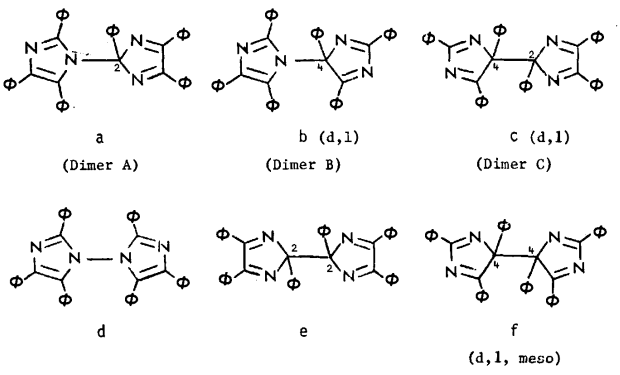
In addition of the piezochromic and the photochromic (dimer A) dimers of 2,4,5-triphenylimidazolyl, two new isomeric dimers were prepared; one (dimer B) being photochromic and the other (dimer C) non-photochromic. Several *p*-substituted derivatives of the dimers were also prepared. By comparison of their NMR and IR spectra, structures (a), (b), and (c) were assigned to the dimers A, B, and C, respectively. On treatment with hydrochloric acid in ethanol, dimer A underwent heterolytic cleavage and gave a mixture of 2-ethoxy-2*H*- and 4-ethoxy-4*H*-2,4,5-triphenylisoimidazole, and 2,4,5-triphenylimidazole.

2,4,5-Triphenylimidazole (lophine) (I) is one of the well-known chemiluminescent substances[2-5] and the recent studies[3-7] on the luminescence mechanism suggested that the lophyl radical is the first intermediate of the luminescence. Another interesting feature of this compound is that it forms on oxidation a photochromic and a piezochromic dimer.[4,8,9] Thus, oxidation of lophine with ferricyanide produces violet lophyl radical which rapidly dimerizes to give the unstable piezochromic dimer. This dimer, when dissolved in benzene, isomerizes rapidly to the photochromic dimer (dimer A) (IA). Photochromism and piezochromism of these dimers have been assumed to be due to the reversible dissociation of these dimers to lophyl radical.[4,8-10]



(I) radical dimer

Although initially the hydrazine structure (d) was suggested *a priori* for the dimer A.[4,11] White and Sonnenberg[9] pointed out the possibility of six dimer structures (a—f)[12] provided that the imidazole rings are linked together, and assigned the structures (f) and (a) for the piezochromic dimer and dimer A, respectively, mainly by comparisons of infrared spectra of these compounds measured in solid states with the model compounds. This assignments, however, would not be considered conclusive and require further confirmation.[13]



Besides these two dimers we have succeeded in preparing further two new dimers; one (dimer B) (IB) is photochromic and the other (dimer C) (IC) is non-photochromic. Thus, piezochromic dimer of I, when refluxed in benzene in the dark, afforded an equilibrium mixture of the three dimers, A, B, and C, which were separated by means of tlc on silica gel. Photochromic dimers, A and B, are interconvertible by UV irradiation, while dimer C is not affected by the light.

While NMR spectrum of the piezochromic dimer could not be measured due to its instability in solutions,

other three dimers, A, B, and C, could give their NMR spectra, but these spectra were too complicated to be analyzed (Fig. 1). Therefore, we have synthesized lophines (II–IX) having mono-, di-, and tri-*p*-substituents on the phenyl groups; each compound in turn has been oxidized to the three dimers corresponding to the lophyl dimers, A, B, and C, as shown in the Table 1. The structural correlation of these dimers to the parent lophyl dimers has been carried out by careful comparisons of the chemical shifts and coupling patterns of their NMR spectra, characteristic IR bands between 1400 and 1700 cm^{-1}, R_f values on tlc, and photochromic property. Some of the characteristic properties of the three series of dimers are as follows. Dimer A series gives no NMR signal at a lower field than 8 ppm, whereas a two-proton signal appears around 8.3 ppm in the NMR spectra of dimer B and C series. Furthermore, NMR spectra of dimer B series show a characteristically broad signal around 6.5 ppm. Dimer B and C series give a very strong IR band around 1600 cm^{-1}; a compound which belongs to the latter series always gives a bond at a higher frequency than that of the corresponding compound in the former series. Dimer A series of compounds also gives IR band around 1600 cm^{-1}, but intensity of this band is distinctly lower than those of other series. The data are summerized in Tables 2 and 3. The *p*-substituted phenyl groups gave A_2X_2 or A_2B_2 type NMR signals which could be analyzed fairly easily, and at the same time, the signals of the substituents such as CH_3 and OCH_3 could also be used for the structural elucidation. Selection of suitable compounds and suitable NMR conditions (temperature, solvents, *etc.*) made analysis of the signals possible. The results are as follows:

(1) Since the NMR spectrum of dimer B of 2,4,5-tri(*p*-tolyl)imidazolyl (IVB) shows well separated six A_2X_2 patterns of the tolyl grops (Fig. 3b;[14] all of the ortho coupling constants are 8.5 Hz) and six methyl singlets (solvent, $CDCl_3$; δ 1.98, 2.14, 2.17, 2.22, 2.35, and 2.48 ppm), dimer B has six magnetically different phenyl groups and hence the structure (b)[12] must be assigned for the dimer B.

14) The NMR spectrum of dimer B of tri(*p*-tolyl)imidazolyl (IVB) at room temperature shows a broad signal at 6.39 (in $CDCl_3$) ppm, which is spin coupled with the doublet at 7.48 ppm. This broad signal becomes a doublet by elevation of the measuring temperature to 60°C. This phenomenon would be attributable to the restricted rotation of a phenyl group about the C–C bond between the phenyl and the imidazole ring. This characteristic broad band can be used for identification of a series of dimer B (Table 2). Further discussion on this phenomenon will be reported elsewhere.

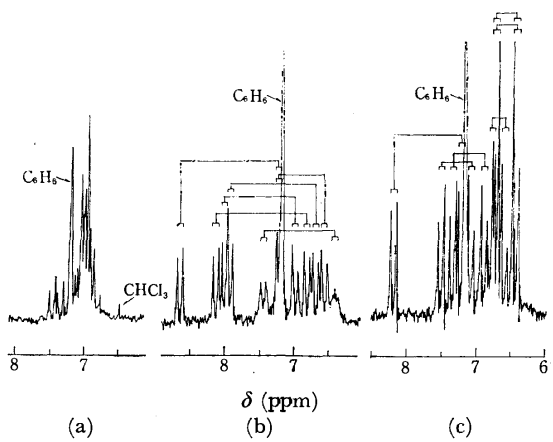

Fig. 3. NMR spectra of dimers of 2,4,5-triarylimidazolyl.
(a) Dimer A of 2.4,5-tri(*p*-chlorophenyl)imidazolyl (VIIA) in C_6D_6+$CDCl_3$ (3:2).
(b) Dimer B of 2,4,5-tri(*p*-tolyl)imidazolyl (IVB) in C_6D_6; the spin couplings indicated were confirmed by spin decoupling experiments.
(c) Dimer C of 2,4,5-tri(*p*-chlorophenyl)imidazolyl (VIIC) in C_6D_6; the spin couplings indicated (except one) were confirmed by spin decoupling experiments.

(2) The NMR spectrum of dimer C of 2,4,5-tri(*p*-chlorophenyl)imidazolyl (VIIC) in benzene-d_6 (Fig. 3c) shows in addition to well separated four A_2X_2 (or A_2B_2) patterns, each of which corresponds to four protons, an A_2B_2 pattern corresponding to eight protons, which indicates the presence of a pair of magnetically equivalent *p*-chlorophenyl groups (all of the ortho coupling constants are 8.5 Hz). This was further confirmed by analysis of the methyl signals of tri(*p*-tolyl)imidazolyl dimer C (IVC) (Fig. 4); there always exists a singlet signal corresponding to two methyl groups. Hence, the possible structures for dimer C are restricted to (a) or (c).[15]

(3) Dimer B and C have a low-field signal (δ *ca.* 8.4 ppm in $CDCl_3$) (Fig. 1 and Table 2), which is attributable to two ortho-protons of one of the two 2-phenyl groups, since the low-field signal becomes A_2X_2 pattern by introduction of a *p*-substituent on the 2-phenyl group of the dimer B and C (Table 2). Such a low-field signal exists in the NMR spectrum of 3-ethoxy-2,4,5-triphenyl-4*H*-isoimidazole (I-4), but not in those of 2-ethoxy-2,4,5-triphenyl-2*H*-isoimidazole (I-2) and *N*-methyl-2,4,5-triphenylimidazole (I-N) (Fig. 2), indicating that the signal is due to the 2-phenyl group of 4*H*-isoimidazole ring. Incidentally, the signal at δ 8.18 ppm in the NMR spectrum of the 4-ethoxy derivative (I-4) corresponds to the ortho protons in the 4-phenyl group, since (V-4) and (VI-4) gave in this region a signal having A_2 part of A_2X_2Y and A_2X_2 patterns, respectively; the low-field shift of this signal being attributable to the attachment of oxygen atom at 4-position. Dimer B and C, therefore, have a 2,4,5-triphenyl-4*H*-isoimidazolyl group linked at C_4; thus, possible structures being (b), (c), and (f). Since the structure of dimer C is already restricted to (a) or (c), above results indicate that the structure of dimer C must be represented by (c).[12]

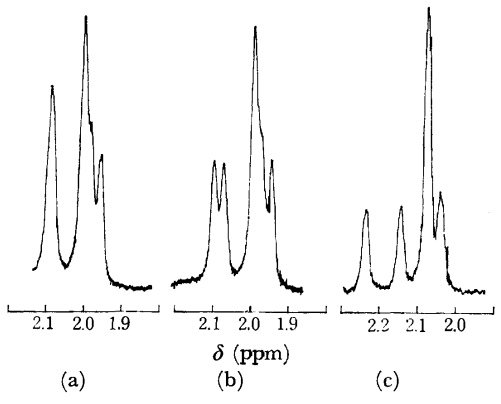

Fig. 4. Methyl signals in the NMR spectra of dimer C of 2,4,5-tri-(*p*-toyl)imidazolyl (IVC).
(a) in C_6D_6; (b) in C_6D_6+$CDCl_3$ (4:1); (c) in C_6D_6+$CDCl_3$ (4:5).

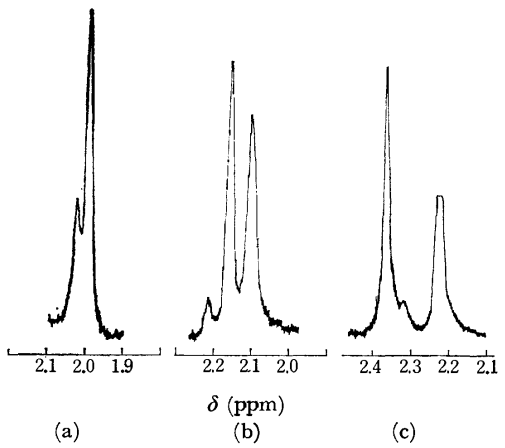

Fig. 5. Methyl signals in the NMR spectra of dimer A of 2-phenyl-4,5-di(*p*-tolyl)imidazolyl (IIIA). (a) in C_6D_6; (b) in C_6D_6+$CDCl_3$ (1:1); (c) in $CDCl_3$.

(4) The NMR signals of dimer A (Fig. 1a) appears in a narrow range (6.8—7.7 ppm in $CDCl_3$) and not well resolved, but analysis of the methyl signals of dimer A of 4,5-di(*p*-tolyl)-2-phenylimidazolyl (IIIA) indicates that two of the four methyl groups are in a magnetically identical environment (Fig. 5), whereas each of other two methyl groups is in a different environment from others. Since 4*H*-isoimidazolyl moiety is not involved in this dimer, structure (a) must be assigned to dimer A. This assignment is also supported by the NMR spectrum of the dimer A of 2,4,5-tri(*p*-chlorophenyl)imidazolyl (Fig. 3a), which indicates that at least the symmetrical structures, (d), (e), and (f), can be excluded (two-proton doublets at 7.34 and 7.46 ppm).

Infrared spectra also support these assignments (Fig. 6 and Table 3). The 4-ethoxy compound (I-4) has a very strong IR band at 1612 cm^{-1}, whereas 2-ethoxy (I-2) and *N*-methyl (I-N) compounds have only a medium but sharp band around 1600 cm^{-1}; thus, the strong band at 1612 cm^{-1} indicates the presence of 4*H*-isoimidazole ring. Dimer B and C, which have a

15) Structure (c) has an asymmetric carbon atom, and hence two phenyl groups at the 4 and 5 positions of 2*H*-isoimidazolyl group is in principle magnetically non-equivalent, but magnetic influence of the asymmetric center would be negligibly small, since it is far apart from the phenyl groups.

a) and b): see footnotes of Table 1; EA: ethyl acetate.
c) D. M. White and J. Sonnenberg, *J. Org. Chem.*, **29**, 1926 (1964): I-N: mp 143.5—144.5°C.

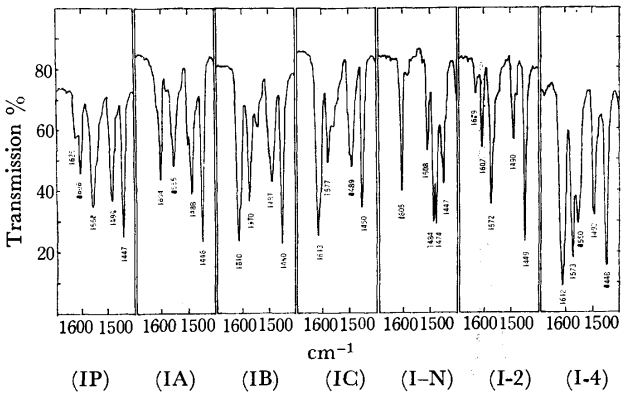

Fig. 6. IR spectra between 1400 and 1700 cm^{-1} in KBr disc. IP: piezochromic dimer of I; IA: dimer A of I; IB: dimer B of I; IC: dimer C of I; I-N: *N*-methyltriphenylimidazole; I-2: 2-ethoxytriphenylisoimidazole; I-4: 4-ethoxytriphenylisoimidazole.

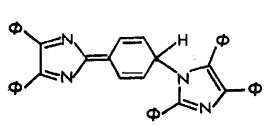
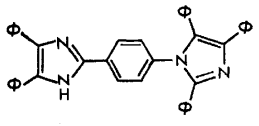
4*H*-isoimidazole ring, indeed show a strong band at *ca.* 1610 cm^{-1}. On the other hand, a sharp medium band is present at 1604 cm^{-1} in the IR spectrum of dimer A indicating the absence of 4*H*-isoimidazole ring and the presence of 2*H*-iso- and/or imidazole ring.[16]



g

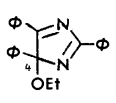


h

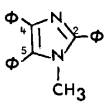
Since these three dimers can be prepared without difficulty from tri-*p*-substituted lophines, the structures involving the linkage at the *p*-position of one of the phenyl groups such as structure (g) are excluded.[17] Furthermore, since they show no NH band in their IR spectra as indicated by White and Sonnenberg[9] and since they can be interconverted thermally, the structures such as (h), in which a triphenylimidazole is substituted at a *p*-position of a phenyl group of another triphenylimidazole, are excluded.

It is of interest to note that the photochromic dimers, A and B, have the central C–N bond, whereas non-photochromic dimer C has the central C–C bond. In the former case the excitation energy is transferred from the aromatic imidazole ring to the central C–N bond, which is directly attached to the aromatic ring, whereas in the latter case, it is not, since the central C–C bond is separated by an sp^3 carbon atom from the conjugated systems.

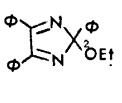
2-Ethoxy-2*H*- (I-2) and 4-ethoxy-4*H*-2,4,5-triphenylisoimidazole (I-4) were prepared from lophyl dimer A (IA) by dissolving in ethanol and treating with dilute hydrochloric acid; the central C–N bond of this dimer being cleaved heterolytically. The 4-ethoxy compound



(I-4)



(I-N)



(I-2)

(I-4) has an asymmeric carbon atom and hence its NMR spectrum (Fig. 2) shows non-equivalence of the methylene protons in the ethoxy group, whereas only a quartet signal was observed for the methylene protons in the case of 2-ethoxy compound (I-2). Derivatives of these ethoxy compounds are listed in Table 4. The 4-ethoxy compound (VIII-4) seems to be more stable

16) The piezochromic dimer is rapidly converted to dimer A by dissolving it in organic solvents such as benzene, ethyl acetate, chloroform, acetone, and ether and followed by immediate evaporation at room temperature. Hence, its NMR, UV, and IR spectra in solutions could not be obtained. IR spectrum taken in KBr disc is only the available physical data for structural analysis. Although White and Sonnenberg[9] suggested the structure (f) for the piezochromic dimer by analysis of its IR spectrum; the piezochromic dimer shows only a medium band at 1606 cm^{-1} with a shoulder at 1625 cm^{-1}, and hence the structure (e) (or less probably (d)) would be more probable than (f). The piezochromic dimers obtained from other lophine derivatives may be impure compounds contaminated with the starting lophine derivative and the corresponding dimer A.

17) The structure of dimer of triphenylmethyl has recently been revised from the symmetric hexaphenylethane to the asymmetric structure similar to (g). H. Lankamp, W. Th. Nauta, and C. MacLean, *Tetrahedron Lett.*, **1968**, 249; H. A. Staab, H. Brettschneider, and H. Brunner, *Chem. Ber.*, **103**, 1101 (1970).

than 2-ethoxy compound (VIII-2), since the latter isomerizes to the former by treatment with acid.

N-Methyllophine (I-N) was prepared by treatment with dimethyl sulfate and potassium carbonate in boiling acetone. Synthesized derivatives of the *N*-methyl compound are listed in Table 4.

Experimental

All melting points are uncorrected. IR spectra were recorded on a JASCO IR-G grating spectrophotometer and NMR spectra on a JEOL 4H-100 (100 MHz) spectrometer. Chemical shifts are expressed in ppm from internal tetramethylsilane (δ-value) and coupling constants in Hz.

Lophine (I) and Substituted Lophines (II-IX). These compounds were synthesized by the method of Davidson *et al.*[18] by refluxing the appropriate benzil with the appropriate aldehyde and ammonium acetate in acetic acid for *ca.* 1 hr. The reaction mixture was then poured into ice-water and the precipitated product was collected. (Solvent in parentheses was used for crystallization) Lophine (I), colorless needles (methanol), mp 275—276°C, lit, 274—275°C.[19] 2-*p*-Tolyl-4,5-diphenylimidazole (II), needles (methanol), mp 233—237°C, lit, mp 234—235°C.[19] 2-Phenyl-4,5-di(*p*-tolyl)imidazole (III), needles (ethanol), mp 269—271°C. Found: C, 85.31; H, 6.18; N, 8.62%. Calcd for $C_{23}H_{20}N_2O_2 \cdot 2H_2O$: C, 70.39; H, 6.16; N, 7.14%.

Piezochromic Dimers of Lophine and Substituted Lophines. According to the method of White and Sonnenberg,[9] to a solution of lophine (2 g) in 95% ethanol (200 m*l*) containing potassium hydroxide (24 g) was added under ice cooling at 5—10°C with stirring 1% aqueous potassium ferricyanide (900 m*l*) in a period of 3 hr and the mixture was stirred for additional 1 hr. The precipitated solid was collected on a filter, washed with water and dried over phosphorus pentoxide to give piezochromic dimer as pale violet powder, mp *ca.* 141°C (yield 95%), lit, 187.5—188.5°C,[9] 191—192°C.[10] Piezochromic dimers from substituted lophines (II—IX) were also prepared in a similar way, but IR spectra indicated that they may be impure and contaminated with the corresponding dimer A and starting material. Melting points (decomp.) are as follows: piezochromic dimer from II, mp 109—112°C; from III, 128—132°C; from IV, mp *ca.* 122°C; from V, mp 110—124°C, lit, 195—200°C,[9] 205—207°C;[10] from VII, mp *ca.* 123°C, lit, 105—115°C;[9] from VIII, mp *ca.* 111°C; from IX, mp *ca.* 125°C.

Dimer A of Lophine and Substituted Lophines (IA—IXA). The dimers, IA, VA, VIA, VIIA, VIIIA, and IXA, were prepared by crystallization of the corresponding piezochromic dimer from benzene–*n*-hexane (Table 1). The *p*-methyl derivatives, IIA, IIIA, and IVA, could not be obtained in a pure state from the corresponding piezochromic dimer by crystallizations, and hence they were prepared from the corresponding dimer B in the following way. A solution of IIB (200 mg) in benzene (15 m*l*) was irradiated with a fluorescent lamp (National High-light, 15 W) at room temperature for 13 hr and then evaporated to dryness *in vacuo*. Dimer A was separated from the remaining solid by means of silica gel tlc as a dark brown amorphous solid, which was crystallized from benzene–*n*-hexane yielding IIA (136 mg) as a crystalline powder. IIB (7 mg) was also recovered.

Dimers B and C of Lophine and Substituted Lophines. A solution of piezochromic dimer of lophine (300 mg) in benzene (15 m*l*) was refluxed for 20 hr and then evaporated to dryness *in vacuo* to give a yellow amorphous solid. The solid was subjected to silica gel tlc (Kieselgel $PF_{254+366}$; benzene: ethyl acetate = 20: 1) in the dark to afford three dimers, A, B, and C, each of which was purified by crystallization from a suitable solvent. The fraction of dimer A was usually contaminated with the monomer and this method was not suitable for preparation of dimer A. Dimers B and C of substituted lophines (II—VIII) were prepared in a similar way from the appropriate piezochromic dimer (Table 1).

Preparation of Three Dimers, A, B, and C, by Oxidation with Lead Dioxide. A mixture of lophine (2 g) and lead dioxide (8 g), which was freshly prepared from lead tetraacetate by treatment with water, in benzene (150 m*l*) was refluxed with stirring for 20 hr and filtered while in hot through Hyflo-supercel. The filtrate on evaporation to a small volume precipitated white crystals (195 mg, lophine), which were filtered off. The filtrate was evaporated to dryness *in vacuo* and the residue was subjected to tlc as described above to give three components, which were identical with the dimers, A, B, and C. Yields (crude) were 475 mg (dimer A), 340 mg (dimer B), and 809 mg (dimer C). Lophine (195 mg) was also recovered.

*2-Ethoxy-2,4,5-triphenyl-2*H*-isoimidazole (I-2) and 4-Ethoxy-2,4,5-triphenyl-4*H*-isoimidazole (I-4) and Their Derivatives.* A solution of the dimer IA (1 g) in dichloromethane (80 m*l*) and ethanol (160 m*l*) was treated with a drop of concentrated hydrochloric acid and the mixture was refluxed for 3 hr. After neutralization with dil. aqueous sodium hydrogen carbonate, the reaction mixture was evaporated to dryness *in vacuo* and the residue was extracted with chloroform. The chloroform extract was evaporated and the residue was subjected to tlc on silica gel (benzene: ethyl acetate = 20: 1) to give 4-ethoxy compound (I-4) (112 mg), 2-ethoxy compound (I-2) (115 mg), lophine (I) (276 mg) and recovered IA (271 mg) (Table 4). 4-Ethoxy compound (I-4) could not be crystallized but mass (*m/e* 340), NMR (Fig. 2), and IR (Fig. 6) spectra indicate its identity. Other 2-ethoxy and 4-ethoxy compounds of substituted lophines listed in Table 4 were prepared in a similar way from the appropriate dimer A.

*Conversion of 2-Ethoxy-2-anisyl-4,5-diphenyl-2*H*-isoimidazole (VIII-2) to 4-Ethoxy-2-anisyl-4,5-diphenyl-4*H*-isoimidazole (VIII-4).* A solution of VIII-2 (30 mg) in ethanol (3 m*l*) was treated with a drop of hydrochloric acid in ethanol (concentrated HCl: ethanol = 1: 9) and the mixture was allowed to stand at room temperature for 3 days. After neutraliza-

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1480—1482(1972)

The Biosynthesis of Linalool in *Cinnamomum Camphora* Sieb. *var. linalooliferum* Fujita[1)]

Takayuki SUGA, Tsuyoshi SHISHIBORI, and Michie BUKEO

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received September 9, 1971)

The labelling pattern in linalool biosynthesized from [2-^{14}C] mevalonic acid in *Cinnamomum Camphora* Sieb. *var. linalooliferum* Fujita was found to be consistent with the predicted biosynthetic pathway involving the condensation of isopentenyl pyrophosphate with 3,3-dimethylallyl pyrophosphate. The radioactivities at C-4 and C-8 (and/or C-10) were about equal, in contrast to the asymmetric pattern of labelling observed for bicyclic monoterpenes, which contained a tracer predominantly in one position of the skeleton derived from isopentenyl pyrophosphate. The efficiency of the incorporation of the tracer into linalool was almost independent of the season of the examination, although a slight increase was observed in the season of the active growth of the plant.

The biosynthesis of monoterpenes from mevalonic acid (MVA) involves the condensation of isopentenyl pyrophosphate (IPP) (I) with 3,3-dimethylallyl pyrophosphate (DMAPP) (II) directed towards the formation of geranyl pyrophosphate (GPP) (III) or neryl pyrophosphate, the presumed precursors of acyclic and cyclic monoterpenes respectively.[2)] Recently, thujane derivatives and camphor biosynthesized from [2-^{14}C] MVA were shown[3,4)] to contain their tracer to a great extent at one ring position derived from such a tracer-containing precursor as IPP (I), but not DMAPP (II). Such examples of preferential labelling being detected for one of the participating C_5-units have also been reported on sesquiterpenes, coriamyrtin and tutin,[5)] though other investigators[6)] have observed an equal distribution of labelling in tutin. In order to clarify the generality of these unexpected results, we have tested the labelling pattern and its seasonal variation in linalool biosynthesized from [2-^{14}C] MVA in *Cinnamomum Camphora* Sieb. *var. linalooliferum* Fujita (Hōsho in Japanese). In the biosynthesis of linalool, which is an acyclic monoterpene probably derived from GPP (III) in the initial stages, the situation was different from those observed for the bicyclic monoterpenes.[3,4)]

Results

Efficiency of the Incorporation of a Tracer. In order to test the seasonal variation of the incorporation of the tracer, [2-^{14}C] MVA was applied by stem-feeding into the leaves at three different seasons, April, July, and November. The results of the incorporation of the tracer into linalool are shown in Table 1.

TABLE 1. SEASONAL VARIATIONS OF ESSENTIAL OIL AND LINALOOL AND OF THE INCORPORATION OF [2-^{14}C] MVA INTO LINALOOL

	April	July	November
Essential oil (w/w%)[a)]	0.48	1.20	1.64
Linalool (w/w%)[a)]	0.27	0.60	0.85

C-9, by permanganate-periodate oxidation.[7,8] Acetone was degraded to iodoform containing a tracer from C-8 and C-10 and to acetic acid. Acetic acid thus produced was further cleaved to methylamine and to carbon dioxide containing a tracer originating from C-7. The lactone (V) was subjected to Kuhn-Roth oxidation[9] to obtain acetic acid containing a tracer from C-1 to C-3 and C-9. Linalool and all its degradation products were converted into barium carbonate by Van Slyke-Folch oxidation[10] in order to determine their specific activities. The results are shown in Table 2.

Table 2. Specific radioactivities of linalool and its degradation products

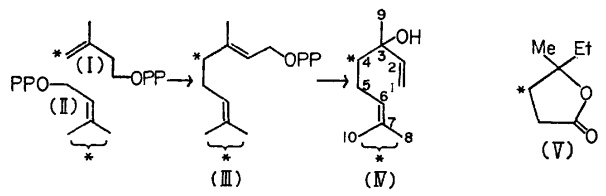
Compounds (Carbons originated from IV)	Specific radioactivity, dpm/mM (%)		
	April	July	November
Linalool (C-1—C-10)	5717	6169	607
Iodoform (C-8 and/or C-10)	1025(17.9)	1335(21.6)	124(20.4)
Acetic acid (C-7, 8, and /or C-7, 10)	1206(21.1)	1524(24.7)	154(25.3)
Methylamine (C-8 and/or C-10)	972(17.0)		
Carbon dioxide (C-7)	114(2.0)		
4-Methyl-4-hexanolide (C-1—C-6, and C-9)	3167(55.4)	3274(53.1)	331(54.4)
Acetic acid (C-1—C-3, and C-9)	363(6.3)	265(4.3)	26(4.2)

Seasonal Variation in Labelling Patterns. The labelling patterns of linalool obtained from the feeding experiments were determined at three different seasons of growth; the results are shown in Table 2.

Discussion

Both the yield of the essential oil and the content of linalool increased with the growth of the plant, as is shown in Table 1. A similar trend has previously been reported[11] in the same plant. Though a slight increase in the incorporation of the tracer into linalool was observed in July, which is the actively-growing season of *C. Camphora*, the efficiency of incorporation was judged to be almost independent of the season, as the increment was too small to discuss any seasonal dependence. The incorporations are, although low, similar to the values found in analogous experiments.[3,4,12]

The extensive degradation of linalool, obtained from feeding in July, revealed the location of 46% of the



* indicates ^{14}C; OPP indicates a pyrophosphate group.

incorporated tracer on acetone and that of the residual activities (54%) on the lactone (V). Acetic acid derived from the lactone (V) showed, unfavorably, a small activity. This is presumably attributable to the incorporation of the C_1-pool which resulted from the degradation of a small amount of the applied MVA.[13,14] Thus, the main site of labelling on the lactone (V) was, on biogenetic grounds, considered to be the position which corresponds to the C-4 of linalool (IV). With respect to the pattern of labelling, the results obtained above have made us conclude as follows: (a) The pattern of labelling observed for linalool is consistent with the biosynthetic mechanism shown in the Scheme. (b) The specific activities at C-4 and C-8 (and/or C-10), originating from IPP (I) and DMAPP (II) respectively, are nearly equal. The almost balanced pattern of labelling in linalool, an alicyclic monoterpene, is in contrast with the asymmetric pattern of labelling observed for some cyclic monoterpenes.[3,4] The equality of the labelling means that the skeleton results from the condensation of IPP (I) with DMAPP (II), both of which have the same specific activities. It thus appears that the formation of DMAPP (II) in the plant under these conditions is caused by the isomerization of the radioactive IPP (I) generated from the applied [2-^{14}C] MVA. (c) The methyl group and the terminal methylene of IPP (I) are non-equivalent, in the same manner as they are in the biosynthesis of other mono- and higher-terpenes.[15,16]

It has been supposed[3] that the season affects the amount of enzymes, which in turn cause the asymmetrical labelling in thujone. We have now examined the seasonal effect on the radioactivities at C-4 and C-8 of linalool biosynthesized in *C. Camphora*. The specific radioactivities in July and November were comparable for the two carbon atoms (Table 2), but they were slightly unbalanced in April, the sprouting season of this plant. These facts seem to indicate that the active enzyme catalyzing the conversion of IPP (I) to DMAPP (II) may not be sufficient in the sprouting season. Thus, the condensation of the labelled IPP (I) with the unlabelled DMAPP (II) derived from the metabolic pool would lead to the low radioactivities in the part of the skeleton originating from DMAPP (II). However, the unbalance of radioactivities in April was very slight as compared with that in the cases of thujane derivatives[3] and camphor.[4] Although it has been suggested[3,4] that the asymmetrical labelling may be general for the biosynthesis of monoterpenes in leaves of higher plants, the

radioactivities derived from [2-^{14}C] MVA, on the contrary, were found to be almost equally distributed between the C-4 and C-8 of linalool, an alicyclic monoterpene.

Experimental

Materials. Specimens of *C. Camphora* were grown from young trees obtained from the experimental farm of the Soda Perfumery Co., Kagoshima Prefecture, Japan. Feeding experiments were carried out on small terminal branches (*ca.* 15 cm long) of three-year-old plants, from April to November. *C. Camphora* sprouts from March to April; the growth is more active in July than in November.

Administration of the Labelled Compound. A phosphate buffered solution (40 m*l*, pH 7.38) of [2-^{14}C] MVA (0.1 mCi, 17 μM), and ATP (0.1 mM) was fed through a cut-stem into small twigs (*ca.* 150 g). Immediately before use, the MVA lactone was converted into the potassium salt of MVA by a potassium hydroxide solution. After the solution had been fed in, the foliage was maintained in a phosphate-buffered solution (pH 7.38) for one day before harvesting.

Isolation of Radioactive Linalool. The harvested leaves and stems were subjected to steam distillation. The oil thus obtained (0.71 g) was subjected to column chromatography on silica gel (less than 0.08 mm, Merck). Elution by a mixture of *n*-hexane with increasing amounts of ethyl acetate afforded radioactive linalool (0.40 g), which was judged to be pure by analytical tlc and glc.

Degradation of Linalool. Linalool (598 mg) in methanol (3 m*l*) was selectively hydrogenated on Adams platinum oxide (4 mg) to 1,2-dihydrolinalool (600 mg). The dihydrolinalool (200 mg) was oxidized with a permanganate-periodate reagent[7,8] for 24 hr. After the excess oxidant had been reduced with a minimum of sodium bisulfite, the weakly alkaline solution was steam-distilled. The ether extraction of the acidified residual solution afforded 4-methyl-4-hexanolide (V) (98 mg; its *S*-benzylthiouronium salt, mp 132—133°C, lit,[17] mp 132—132.5°C). The aqueous distillate was subjected to hypoiodite oxidation. Iodoform (369 mg) filtered off was purified by sublimation at reduced pressure. The filtrate was acidified with sulfuric acid and treated with silver sulfate to remove iodine. The mixture was then steam-distilled. The evaporation of the neutralized distillate afforded acetic acid as the sodium salt (38 mg). The salt was purified by means of the addition of dry ether to its dry ethanol solution. The Schmidt reaction[18] of the purified salt afforded carbon dioxide and methylamine, which were then converted to barium carbonate and its hydrochloride respectively. The Kuhn-Roth oxidation[9] of 4-methyl-4-hexanolide (V) (71 mg) gave acetic acid as the sodium salt (94 mg); this was then refined as above.

Radioassay. Linalool and all its degradation products were converted to barium carbonate by Van Slyke-Folch oxidation, and aliquots of barium carbonate were counted on planchets at an infinite thickness under a Aloka TDC R 1361 2π-gas-flow detector. The counting error for the values shown in Tables 1 and 2 is about $\pm$3%.

The authors are thankful to Professor Emeritus T. Matsuura of Hiroshima University for his encouragement, to the Soda Perfumery Co., Ltd., Tokyo, for its gift of the plant, and to the Takasago Perfumery Co., Ltd., Tokyo, for its gift of linalool.

Chlorination of Olefins with Thallium(III) Chloride Tetrahydrate[1)]

Sakae UEMURA, Osamu SASAKI, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received September 13, 1971)

In CCl_4, $TlCl_3 \cdot 4H_2O$ reacted with mono- and diolefins to give *vic*-dichlorinated compounds (I) in 20—41% yields together with monochlorinated ones (II). The yields of I were intensely increased by adding $CuCl_2 \cdot 2H_2O$ or $FeCl_3$ and bubbling oxygen into the reaction system, although such additives alone gave none of I in CCl_4. In acetic acid, the reaction gave diacetoxylated compound. As to the *vic*-dichlorination, it was proposed that the reacting species was a polarized form of dimeric $TlCl_3$ and not free chlorine evolved from $TlCl_3 \cdot 4H_2O$.

Compared to a number of studies on the reactions of aromatic compounds with Lewis acid halides of metals or metalloids,[2)] the study on the behavior of olefins toward such chlorides is limited to only two cases using $CuCl_2$[3-7)] and $SbCl_5$[8)] in liquid or gas phases. Recently, we have found that aromatic carboxylation and chlorination occur by heating aromatic compounds with $TlCl_3 \cdot 4H_2O$ in CCl_4 solvent.[9)] An attempt to

extend this reaction to olefins resulted in the formation of only chlorinated compounds. The characteristics of this chlorination of olefins are described in this report, with a comparison to the results of the reaction using $CuCl_2$ or $SbCl_5$. Although the fact has been known that $TlCl_3 \cdot 4H_2O$ can be used as a catalyst for the synthesis of propylene chlorohydrin from propylene in aqueous medium,[10] this is the first report of the chlorination of olefins with $TlCl_3 \cdot 4H_2O$.

Results and Discussion

The reaction was carried out by adding or bubbling olefinic hydrocarbons into a stirred CCl_4 solution containing $TlCl_3 \cdot 4H_2O$ at refluxing temperature (77°C). Because of the low melting point (37°C) and the insolubility into CCl_4 of $TlCl_3 \cdot 4H_2O$, the solution was heterogeneous with the molten thallium salt. Dichlorinated (I) and monochlorinated hydrocarbons (II) were obtained as organic products, but none of hydrocarbons chlorinated at allylic position were found. Some typical data are summarized in Table 1. Because of the thallium(III) chloride-catalyzed hydrolysis of CCl_4,[11] this reaction accompanied the evolution of hydrogen chloride and phosgene regardless of the addition of olefinic component. I and II may be formed through Eqs. 1 and 2, respectively.

The formation of I occurred rather smoothly with 1- and 2-octenes, cyclohexene and buta-1,3-diene, and the

$$>C{=}C< + TlCl_3 \longrightarrow \underset{Cl\ \ Cl}{>C{-}C<}\ (I) + TlCl + 4H_2O \quad (1)$$

$$\left.\begin{aligned} CCl_4 + TlCl_3 \cdot 4H_2O &\longrightarrow \\ & COCl_2 + 2HCl + TlCl_3 \cdot 2H_2O \\ >C{=}C< + HCl &\longrightarrow \underset{H\ \ Cl}{>C{-}C<}\ (II) \end{aligned}\right\} \quad (2)$$

yields of which were 41, 27, 19, and 36%, respectively, on the basis of the amounts of the consumed Tl^{3+} salt. In the reaction with styrene, dimerization to yield 1,3-diphenyl-1-butene was the main reaction even at 50°C. In cases of cyclooctene and 1,3- and 1,5-cyclooctadienes, considerable amounts of II were formed but the yields of I were very poor. When buta-1,3-diene was used as a substrate, both 1,2- and 1,4-additions occurred and their ratio (1,4-dichloro-2-butene/3,4-dichloro-1-butene) was 0.83 for 2 hrs' reaction at refluxing temperature. It is premature to consider this ratio as a consequence of kinetic control, since a separate experiment showed that in this reaction condition 1,2-dichloroisomer readily converted to 1,4-one.[13] It must be noted here, however, that the 1,4-dichlorinated compound is consisted of *cis*- and *trans*-isomers in *ca.* 1: 3 ratio, although usual chlorination with chlorine gas gives only stable *trans*-isomer.[14] This may suggest the participation of the species other than Cl_2 molecule. The formation of the *cis*-isomer was also observed in the chlorination of buta-1,3-diene with $SbCl_5$ in CCl_4.[8] In addition, both facts have been known that free chlorine is not involved in aromatic chlorination using $TlCl_3 \cdot 4H_2O$ in CCl_4[15] and that $TlCl_3 \cdot 4H_2O$ does not evolve chlorine gas by heating at 110°C.[16] Hence, it seems very unlikely that this

10) K. Tanaka, G. Inoue, and N. Kominami, presented at the 22nd Annual Meeing of the Chemical Society of Japan, Tokyo, April, 1969, Vol. IV, p. 2549.

11) In one experiment using 25 mmol of $TlCl_3 \cdot 4H_2O$ and 100 ml of CCl_4 with stirring for 2 hr at 77°C, 29.7 mmol of phosgene and 141 mmol of hydrogen chloride were obtained. Details on the catalytic hydrolysis of trichloromethyl compounds were reported separately.[12]

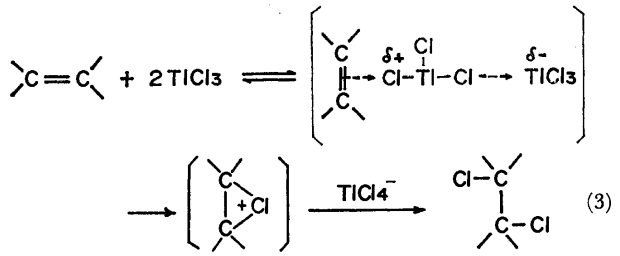
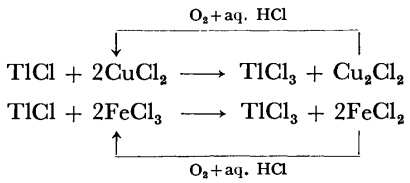
reaction proceeds through addition of free chlorine evolved from $TlCl_3 \cdot 4H_2O$. The configurational analyses of I from cyclohexene and *cis*-2-octene (see Table 1) showed that this chlorination proceeds mainly in *trans* fashion as in the case of $CuCl_2$ chlorination in acetic acid or acetonitrile solvent.[5] Although a detailed mechanistic study was not carried out, a route involving the initial attack of a polarized $TlCl_3$ (probably in its dimeric form) on olefin would be reasonable.[17]



(3)

As thallium(III) chloride is reduced to thallium(I) chloride in this reaction, it is expected that the yield of I would increase if Tl^{1+} can be oxidized to Tl^{3+} by other metal salts. Thus, in the chlorination of cyclohexene with $TlCl_3 \cdot 4H_2O$, the addition of $CuCl_2 \cdot 2H_2O$ or $FeCl_3$ and the introduction of oxygen into the reaction system resulted in a significant increase in yields of I. Separate experiments showed that $CuCl_2 \cdot 2H_2O$ or $FeCl_3$ alone gave none of I in CCl_4 solvent, and it can safely be said that these chlorides oxidized Tl^{+1} to Tl^{+3} state as shown in Eq. 4. Since Cu^{1+} or Fe^{2+} salt formed here was readily oxidized to Cu^{2+} or Fe^{3+} state by oxygen respectively, probably under the coexistence of hydrochloric acid (see Eq. 2), the addition of an equivalent amount of these chlorides would not be required. As shown in Table 1, $CuCl_2 \cdot 2H_2O$ is more effective oxidant than $FeCl_3$ to TlCl.



(4)

Although chlorination with $CuCl_2$ proceeded smoothly in acetic acid containing sodium acetate, alcohol or acetonitrile,[5] the reaction using $TlCl_3 \cdot 4H_2O$ in such solvents did not give any chlorinated product. In acetic acid containing sodium acetate (20 mmol) and $TlCl_3 \cdot 4H_2O$ (25 mmol), cyclohexene gave only a mixture of *cis*- and *trans*-1,2-diacetoxycyclohexane (8.75 mmol) for 2 hrs' reaction at 117°C. Similarly, styrene gave 1,2-diacetoxy-1-phenylethane (1.35 mmol), 1,3-diphenyl-1-butene (1.0 mmol) and a large amount of resinous residue. The formation of these products can be explained by the oxidation of olefins with thallium(III) acetate which might be formed in this reaction system. In acetonitrile, the formation of a complex $[TlCl_2(CH_3CN)_4TlCl_4]$[18] from $TlCl_3 \cdot 4H_2O$ and the solvent stopped the reaction.

Experimental

Materials. The organic materials were commercial products of the purest grade and were distilled and checked by gas chromatography. The inorganic metal chlorides were also commercial materials of an analytical grade and were used without purification.

Experimental Procedure. Olefinic substrates were added to mixtures of carbon tetrachloride and thallium(III) chloride tetrahydrate at refluxing temperature (77°C). After removing the evolved hydrogen chloride and phosgene by the stream of nitrogen into an ethereal solution of aniline, the reaction mixture were filtered from the resulting inorganic materials, and the filtrate was washed with water, dried over Na_2SO_4 and concentrated to *ca.* 10 m*l* by distillation of the solvent. The yields of the chlorinated products were calculated on the basis of the glc analysis of this residue using cyclohexanone or tetrachloroethylene as an internal standard. The amount of remaining Tl^{3+} salt was determined by iodometry.

Authentic Samples for Glc Analysis. Chlorocyclohexane, 3,4-dichloro-1-butene and 1,4-dichloro-2-butene were commercial products. 1,2-Dichlorooctane, 2,3-dichlorooctane (*erythro-threo* mixture), *trans*-1,2-dichlorocyclohexane, α,β-dichloroethylbenzene,[5] 1,2-dichlorocyclooctane, 5,6-dichlorocyclooctane (*trans-cis* mixture),[19] and α,β-diacetoxyethylbenzene[20] were prepared by the reported methods. 2-Chlorooctane was prepared from 2-octanol and thionyl chloride in pyridine;[21] bp 67—67.5°C/22 mmHg. *Threo*-2,3-dichlorooctane was prepared from the reaction of *cis*-2-octene with chlorine in chloroform; bp 104°C/25 mmHg, NMR τ 5.6—6.2 (m, 11H), 9.1 (t, 3H). *cis*-1,2-Dichlorocyclohexane was prepared from the reaction of *trans*-2-chlorocyclohexanol (bp 102—103°C/47 mmHg, prepared from cyclohexene[22]) and thionyl chloride in pyridine;[23] bp 68°C/6 mmHg, NMR: τ 5.5—5.8 (m, 2H), 7.5—8.8 (m, 8H). Chlorocyclooctane was isolated from the distillate (bp 82—90°C/21 mmHg) by preparative glc [PEG 6000 (25%)-Chromosorb-W 1.5 m column; carrier gas, He 120 m*l*/min at 150°C]; NMR: τ 5.6—6.0 (m, 1H), 7.75—8.2 (m, 4H), 8.2—8.65 (m, 10H). *cis*-1,4-Dichloro-2-butene was prepared as a mixture with *trans*-isomer (*trans*/*cis*=*ca.* 2) by the reaction of buta-1,3-diene with $SbCl_5$ in CCl_4;[8] bp 51—53°C/22 mmHg (Found: C, 37.64; H, 4.72%. Calcd for $C_4H_6Cl_2$: C, 38.44; H, 4.84%). NMR of *cis-trans* mixture: τ 3.95—4.3 (m, 2H), 5.8—6.0 (m, 4H). 1,2-Diacetoxycyclohexane (*trans-cis* mixture) was prepared as a mixture with cyclopentyl diacetoxymethane by heating cyclohexene and thallium(III) acetate in acetic acid at 70°C for 2 hr; bp 101—105°C/7 mmHg (reported[24] bp 112—120°C/12 mmHg).

Analytical Instruments. The IR and NMR spectra were measured with a Hitachi EPI-S2 apparatus and a Varian A-60 apparatus respectively. Gas chromatographies were carried out by Shimadzu 5APTF and 4APT [PEG 6000 (25%)-Chromosorb-W 3 m and Apiezon-L (30%) 1 m columns] apparatus.

17) See Ref. 2, p. 113. In the aromatic chlorination with this salt under similar conditions, we have recently obtained some results suggesting that an ionized form, $TlCl_2^+$, is preferable to the unionized one as actual attacking species.

The Base-catalyzed Condensation of *o*-Nitropropiophenone*

Takeo SAKAN, Shoji HAYASHI, and Toshio MIWA
Faculty of Science, Osaka City University, Sumiyoshiku, Osaka
(Received September 22, 1971)

Treatment of *o*-nitropropiophenone with sodium acetylide in liquid ammonia at −70°C gave a yellow phenol, $C_{18}H_{18}O_3N_2$, as a major product. The permanganate oxidation of the phenol gave 2-(1-carbamoylethyl)-2-methyl-3-indolinone, which was synthesized independently. From this result and the spectral data, the structure of the phenol was postulated to be 1-(*o*-hydroxyphenyl) derivative of the above indolinone. The neutral fraction of the reaction mixture gave three new compounds: 3-(*o*-Nitrophenyl)-1-pentyn-3-ol, 2-methyl-2-(2-methyl-3-indolinon-2-yl)-3(2*H*)-benzofuranone, and 3,3a-dihydro-2-hydroxy-3,3a-dimethyl-2-(*o*-nitrophenyl)-4(2*H*)-isoxazolo[2,3-*a*]indolone. Their structures were assigned from their spectral data. A mechanism for the formation of these products as well as for the base-catalyzed condensation of *o*-nitroacetophenone is discussed.

A previous paper[1] from this laboratory reported that *o*-nitroacetophenone underwent a peculiar *o*-substituent interaction to form an orange-red product, compound A, along with *o*-nitrobenzoic acid when the ketone was treated with sodium acetylide in liquid ammonia at a temperature of −70°C. Compound A was proved to be 1,3-dihydroxy-3-methyl-2-(*o*-nitrophenacylidene)-indoline.[2] The base-catalyzed condensation of *o*-nitropropiophenone was studied in order to inquire into the mechanism of the formation of compound A. This paper deals with the elucidation of the structure of the condensation products of *o*-nitropropiophenone.

o-Nitropropiophenone was previously prepared either by the nitration of propiophenone[3] or by the reaction of *o*-nitrobenzaldehyde with diazoethane.[4] We prepared the ketone by the acylation of di-*t*-butyl methylmalonate with *o*-nitrobenzoyl chloride followed by decarboxylative hydrolysis in 57% overall yield based on *o*-nitrobenzoic acid. The purity of the ketone was confirmed both by gas-chromatography and by NMR spectroscopy.

Treatment of *o*-nitropropiophenone with sodium acetylide under the same condition as that in the condensation of *o*-nitroacetophenone[1] gave yellow crystals, $C_{18}H_{18}O_3N_2$, melting at 214°C, in a yield of 54—56%. The formation of the compound by the use of sodium amide instead of sodium acetylide indicated that the acetylide did not participate in the reaction. The yellow product will be referred to as compound C in this paper.

Compound C is a weakly acidic compound (pK_a 9.5) soluble in 2N sodium hydroxide solution; it is also soluble in concentrated hydrochloric acid. The weak acidity of compound C may be attributed to a phenolic hydroxyl. The presence of the function was not detected by the ferric chloride test, but inferred from a positive ferricyanide test[5] and from the coupling reaction with *p*-nitrobenzenediazonium salt.[6] The methylation of compound C with diazomethane gave a monomethyl ether, $C_{19}H_{20}O_3N_2$; the acetylation with acetic anhydride and pyridine at a room temperature led to a monoacetyl derivative, $C_{20}H_{20}O_4N_2$, whereas heating with acetic anhydride in the presence of sodium acetate gave a diacetyl derivative, $C_{22}H_{22}O_5N_2$.[7]

The IR spectrum of compound C shows the presence of the carbonyl group and the absence of the nitro group in the molecule. Its 3000-cm^{-1} region contains a broad band of a bonded hydroxyl group besides two sharp peaks at 3520 and 3405 cm^{-1}. The disappearance of the broad band by methylation or acetylation as well as the appearance of a new band at *ca.* 1760 cm^{-1} by acetylation allowed to assign the phenolic hydroxyl to the broad band.

The ultraviolet spectra of compound C and its derivatives reveal an absorption band at 400 nm characteristic of the pseudoindoxyl.[8] A bathochromic shift by 25 nm of the maximum of compound C by the addition of alkali suggests that the phenolic function may be associated with the pseudoindoxyl system. The carbonyl bands in the infrared spectra of these compounds are also compatible with those of pseudoindoxyls.[8a] The fact that the characteristic absorption band at 400 nm remained unchanged on diacetylation requires that the indoxyl ring be substituted at the nitrogen atom.[9]

The NMR spectrum[10] of compound C shows the presence of a tertiary methyl (singlet at 1.38 ppm), a secondary methyl (doublet at 1.42 ppm), and a methine

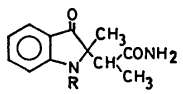
(quartet at 2.88 ppm) group. The complicated bands between 6.3 and 7.7 ppm correspond to eight aromatic protons. The phenolic proton appears at 10.9 ppm, the location of a rather low-magnetic field being due to a hydrogen bonding.[11] A broad band near 6 ppm (2 protons) suggests the presence of a primary amide group, to which two sharp peaks in the 3000-cm^{-1} region of the infrared spectrum (see above) may be attributed.

The presence of the amide group was confirmed by the acid hydrolysis of compound C followed by the identification of ammonium ion by paper chromatography.[12] On the other hand, no evolution of carbon dioxide in the hydrolysis indicated that the carbamoyl group was not attached to the α-carbon atom of the indoxyl nucleus directly. Any definite organic compounds were not characterized from the hydrolysis product.

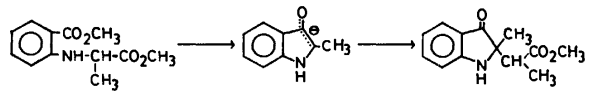
The hydrogenation of compound C either over Raney nickel under high pressure or in the presence of platinum oxide under atmospheric pressure gave a tetrahydro-compound. Tetrahydro-compound C is a phenol (pK_a 9.0), giving a positive reaction with *p*-nitrobenzenediazonium salt. This compound gave a monomethyl ether on methylation with diazomethane. The ultraviolet absorption spectra of tetrahydro-compound C and its methyl ether show no absorption band of the pseudoindoxyl system at 400 nm, but possess a new maximum at 330 nm. The spectral data of these compounds correspond to those of *N*-aryl-β-acylvinylamines (λ_{max} near 340 nm).[13] The survival of the phenolic function during the hydrogenation of the pseudoindoxyl system[8a] allowed to locate the hydroxyl group on the *N*-phenyl nucleus. From these observations structure I was postulated for compound C.



I: R=*x*-Hydroxyphenyl II: R=H

The carbon skeleton of the indoxyl nucleus was verified by the oxidative degradation of compound C. The permangenate oxidation of compound C gave a neutral compound, $C_{12}H_{14}O_2N_2$, mp 228°C. This was identified with 2-(1-carbamoylethyl)-2-methyl-3-indolinone (II), which was synthesized as follows.

Giovannini *et al.*[14] reported that the Dieckmann condensation of *N*-(*o*-ethoxycarbonylphenyl)alanine ethyl ester under atmospheric oxygen yielded 2,2'-dimethyl-[2,2'-bisindoline]-3,3'-dione (VI) instead of the expected 2-methyl-3-indolinone. In the absence of oxygen, this reaction should give the enolate anion (IV) of 2-methyl-3-indolinone, which would be alkylated with α-bromopropionate to give the ester V corresponding to the amide II. Actually, the alkylation of the Dieckmann condensation product of the dimethyl ester III[15] under the atmosphere of nitrogen occurred expectedly to give the ester V along with the *o*-alkylation product VII, the latter being not isolated but detected by the NMR spectrum of the crude product. Chromatography of the crude product gave the ester V as a crystalline state. The ester V was heated with ammonia in a sealed tube at 100°C for 8 hr to give the amide II.



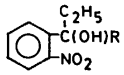
III IV V

VI VII

Although no direct proof was obtained about the position of the hydroxyl group on the *N*-phenyl nucleus, the existence of an intramolecular hydrogen bonding of the phenolic hydroxyl group inferred from the IR and NMR spectra may sufficiently allow to locate the group at the *ortho* position to the nitrogen. Hence, the structure of compound C was postulated to be 2-(1-carbamoylethyl)-1-(*o*-hydroxyphenyl)-2-methyl-3-indolinone (I, *x*=*o*).[16]

Chromatography on silicic acid of the neutral fraction of several runs of the condensation gave an oil, $C_{11}H_{11}O_3N$, and two crystalline products, $C_{18}H_{16}O_5N_2$ and $C_{18}H_{15}O_3N$, along with the unchanged ketone.

The IR spectrum of the oil revealed the presence of the hydroxyl, terminal alkyne, and nitro functions, but no carbonyl groups in it. Therefore, the oil was assumed to be 3-(*o*-nitrophenyl)-1-pentyn-3-ol (VIII), the expected product of the condensation of *o*-nitropropiophenone with sodium acetylide. The NMR spectrum of this compound is compatible with this structure. The permanganate oxidation of this compound gave a crystalline acid, $C_{10}H_{11}O_5N$, mp 154—156°C, which was assumed to be 2-hydroxy-2-(*o*-nitrophenyl)propionic acid (IX).



VIII: R=C≡CH IX: R=CO_2H

One of the crystalline products, $C_{18}H_{15}O_3N$, melting at 206—207°C, was assigned the structure of 2-methyl-2-(2-methyl-3-indolinon-2-yl)-3(2*H*)-benzofuranone (X) from its spectral data. The ultraviolet absorption spectrum of this compound showed maxima at 229, 335, and 390 nm and a shoulder at 255 nm. The absorption band at 390 nm is that characteristic of the psuedoindoxyl system and the band at 335 nm may be attri-

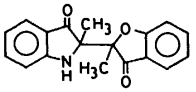
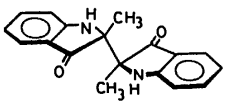
16) Attempt was made to determine the location of the hydroxyl group by the analysis of the aromatic region of the 100-MHz NMR spectrum of tetrahydro-compound C in DMSO-d_6; however, the pattern was too complicated to assign *o*-substituted benzene. The authors thank the Japan Electron Optics Laboratories for the measurement.

buted to the coumaranone system.[17] The infrared spectrum revealed the absorptions corresponding to the N–H (3400 cm^{-1}) and carbonyl (1700 cm^{-1}) groups. The existence of the two methyl groups was confirmed by two singlets (1.65 and 1.75 ppm) in the NMR spectrum.

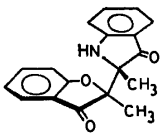


X

2,2-Dimethyl-3-indolinone shows its methyl signal at 1.32 ppm.[18] The methyl signal of the biindoxyl VI appears at 1.17 ppm, indicating a shielding effect by the keto group on the other nucleus. On the other hand, the methyl signals of the compound X is shifted extensively downfield, suggesting that the methyl groups are deshielded by the keto group on the other nucleus. These observations may be explained by postulating that the biindoxyl is a *meso* compound and the compound X is a racemoid, assuming conformations as shown in XI and XII, respectively. The conformation XII is apparently due to the compensation of the steric hindrance of two ethyl groups and of the dipole-dipole interaction between two keto groups.

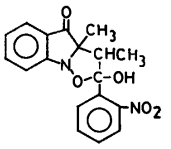


XI

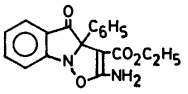


XII

Another crystalline product, $C_{18}H_{16}O_5N_2$, decomposing at 150°C, was tentatively postulated to be 3,3a-dihydro-2-hydroxy-3,3a-dimethyl-2-(*o*-nitrophenyl)-4-(2*H*)-isoxazolo[2,3-*a*]indolone (XIII) from the spectral data. Its infrared spectrum suggested the presence of the hydroxyl, carbonyl, and nitro groups. The NMR spectrum showed the existence of a tertiary methyl (1.58 ppm, singlet) and a secondary methyl (1.24 ppm, doublet) in accordance with the structure. The ultraviolet spectrum with maxima at 240, 310, and 360 nm needs some comments. 1-Hydroxy-2,2-dimethyl-3-indolinone has an absorption band at 381 nm;[19] the hypsochromic shift compared with that of 2,2-dimethyl-3-indolinone (391 nm[18]) may be due to the electrostatic attraction for the lone electron pair on the nitrogen atom exerted by the electro-negative oxygen. The *cis*-fusion of the isoxazolidine ring in the compound XIII would force the nitrogen atom to assume an sp^3-like configuration unfavorable for the unshared electron pair to conjugate with the carbonyl group, causing hence a hypsochromic shift of the absorption characteristic of the pseudoindoxyl system. This assumption is supported by the fact that the isoxazoloindolone XIV possesses an absorption band at 313 nm corresponding to the band at 310 nm of compound XIII and shows no absorption maximum over 350 nm.[20]



XIII

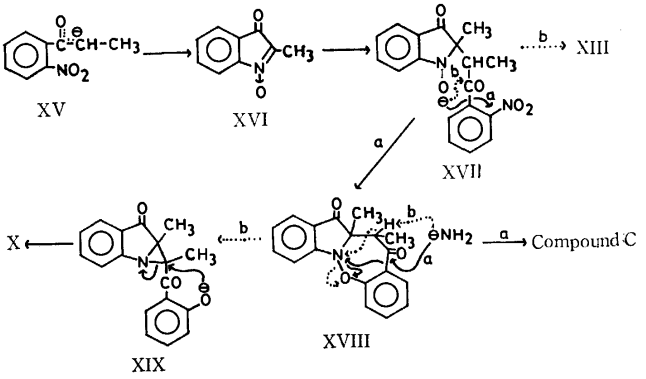


XIV

Treatment of the compound XIII with sodium amide in liquid ammonia yielded the compound X as a major product.

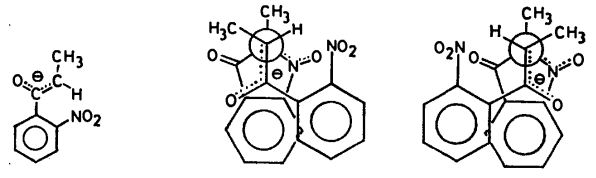
This observation and the fact that every crystalline product in this condensation was obtained as a single isomer, as inferred from the results of NMR spectroscopy, require the mechanism for the reaction to involve stereochemical consideration.

It has been pointed out[21] that the base-catalyzed condensation of *o*-nitrobenzoyl derivatives undergo cyclization to isatogens. In our case, 2-methylisatogen XVI is to be formed in the first step. Such isatogens are susceptible to nucleophilic addition at the carbon-nitrogen double bond.[22] The attack of another molecule of the enolate anion XV will produce either of the diastereoisomeric anions XVII. The attacking enolate anion should have the conformation as shown in XX because of the steric repulsion between the methyl and phenyl groups, on the one hand, and of the dipole-dipole repulsion between the carbonyl and nitro groups, on the other. The addition through the transition



XV XVI XVII XIX XVIII

state XXI will be followed by the replacement of the nitro group by the *N*-oxide anion to form a seven-membered ring intermediate XVIII with two methyl groups in *trans*-relationship. On the other hand, the addition through the transition state XXII will cause the attack of the *N*-oxide anion on the carbonyl group rather than on the nitro group to give the compound XIII with two methyl groups in *cis* configuration.



XX XXI XXII

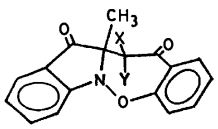
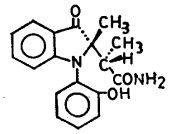
22) D. A. Patterson and D. G. Wibberley, *J. Chem. Soc.*, **1965**, 1706.

Inspection of the framework molecular models of the intermediate XVIII proposes the conformation XXIII as the most favorite one.[23] Although the compound XIII was isolated as a by-product, the compound also may be transformed into the intermediate XVIII on prolonged exposure to sodium amide. In this case, the intermediate XVIII should have two methyl groups in *cis* relationship as shown in XXIV. The abstraction of the equatorial α-proton of the carbonyl group in XXIII will be more difficult than that of the axial α-proton in XXIV because of the stereoelectronic effect. In the former case, the attack of the amide anion to the carbonyl becomes prevailing and the reaction will proceed through the course a in XVIII to give compound C.[24] On the basis of these assumptions, compound C is expected to have two methyl groups in such a relative configuration as shown in XXV.

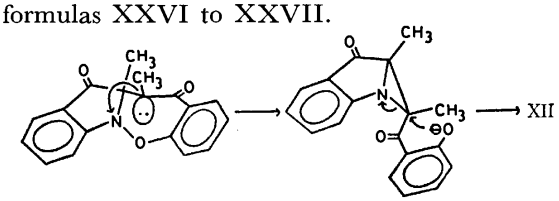


XXIII: X=H, Y=CH_3
XXIV: X=CH_3, Y=H



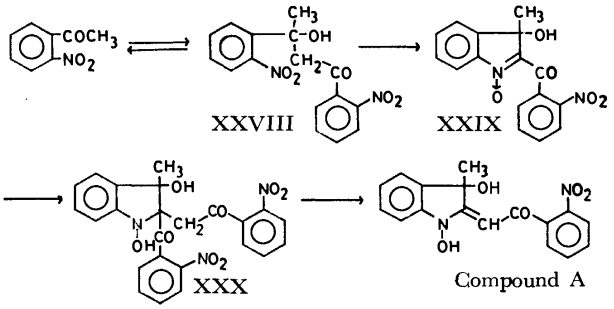
XXV

When the abstraction of the α-proton of the carbonyl group is assisted by the stereoelectronic effect, the resulting carbanion will attack on the nitrogen atom to form an aziridine intermediate XIX with liberation of a phenoxide anion,[25] which will cleave the aziridine ring to give the compound X. Since the stereochemistry of the compound X was proposed to be XII, these transformation would take a stereochemical course as shown in formulas XXVI to XXVII.



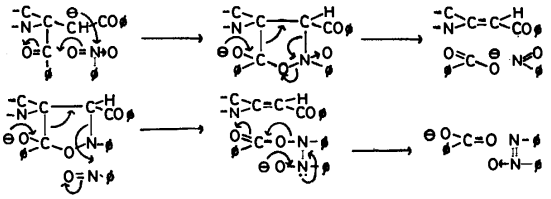
XXVI XXVII

Now, the attention is turned to the mechanism for the formation of compound A (see above). In this case, the first step of the reaction is assumed to be the aldol condensation of *o*-nitroacetophenone.[26] The product XXVIII will undergo a cyclization similar to that of *o*-nitropropiophenone to give a nitrone XXIX,[27] which will be transformed into an *N*-hydroxyindoline XXX by the addition of another mole of the enolate anion of *o*-nitroacetophenone. The oxidative deacylation of the indoline will give compound A.



XXVIII XXIX XXX Compound A

The final step needs further comment. The simple Haller-Bauer reaction[28] of XXX with base should give aliphatic carboxylic acid derivatives as observed in the case of compound C. The formation of *o*-nitrobenzoic acid in this reaction requires another type of cleavage with simultaneous oxidation. This cleavage is well interpreted by the partial structures shown in Chart 1. The participation of *o*-nitroacetophenone in this oxidation was verified by the isolation of *o,o'*-azoxyacetophenone from the neutral fraction of the reaction. This compound was identified with an authentic sample synthesized according to a procedure for the preparation of *p,p'*-azoxyacetophenone.[29]



φ=*o*-Acetyl- or *o*-nitrophenyl
Chart 1

In conclusion, it is noteworthy that no alkynol was obtained from the neutral fraction of the condensation of *o*-nitroacetophenone in contrast with the formation of the alkynol VIII in the case of *o*-nitropropiophenone.

Experimental[30]

o-Nitropropiophenone. A mixture of 66.6 g (0.289 mol) of di-*t*-butyl methylmalonate[31] and 19.0 g (0.433 mol) of

23) The possibility for the nitrogen atom to assume an sp^3-like configuration cannot be precluded; however, in this case also, the environment around the carbonyl group in the seven-membered ring is not changed so much.

24) Methoxyamine reacts with Grignard compounds to give corresponding amines. R. Brown and W. E. Jones, *J. Chem. Soc.*, **1946**, 781.

25) O. C. Dermer and G. E. Ham, "Ethyleneimine and Other Aziridines," Academic Press, New York (1969), p. 59.

26) With *o*-nitropropiophenone also, the aldol condenstion may be possible; however, the condensate corresponding to XXVIII cannot be cyclized to an isatogen and will be reversed to the original ketone in this case.

27) Both of the nitro groups have the opportunity to react with the methylene group. The triagonal carbon of the keto group might prevent the formation of a five-membered ring. Actually, 1,3-bis(*o*-nitrophenyl)-1-propanone gave 1-hydroxy-2-(*o*-nitrobenzoyl)indole rather than 2-benzylisatogen (N. Nakatsuka and T. Miwa, unpublished work).

28) K. E. Hamlin and A. W. Weston, "Organic Reactions," Vol. IX, John Wiley, New York (1957), p. 1.

30) All melting points are not corrected. Unless otherwise noted, UV, IR, and NMR spectra were measured in solution in 95% ethanol, chloroform, and deuteriochloroform, and presented in λ_{max} nm (log ε), ν_{max} cm^{-1}, and δ ppm, respectively. The instruments used for the measurements are a Hitachi model EPS-2 recording spectrophotometer, a Hitachi model EPI-2 infrared spectrophotometer, and a JEOLCO model C-60 spectrometer. The authors are much indebted to Mr. Jun'ichi Goda for the elemental analyses.

31) Pure material of this ester (bp 94—95°C/7 mmHg) was prepared from the corresponding acid (mp 134—136°C) and isobutylene in *ca.* 60% yield according to a general method for the *t*-butyl ester [R. E. Strube, "Organic Syntheses," Vol. 37, p. 34 (1957)].

54.4% sodium hydride dispersed in mineral oil (washed several times with benzene) in 1500 m*l* of dry benzene was heated under reflux with stirring for 2 hr. To the mixture was added a solution of *o*-nitrobenzoyl chloride, prepared from 48.3 g (0.289 mol) of *o*-nitrobenzoic acid and 57.9 g (0.289 mol) of phosphorus pentachloride, in 60 m*l* of dry benzene at room temperature over a period of 1 hr. The mixture was refluxed for 2 hr and then left to stand overnight. The excess of sodium hydride was decomposed by the addition of *p*-toluenesulfonic acid monohydrate. The salts were removed by filtration and the solvent was distilled off completely. The residue was heated under reflux with 75 m*l* of acetic acid, 9 m*l* of concentrated sulfuric acid and 50 m*l* of water for 5 hr. After cooling, the reaction mixture was made alkaline with 20% aqueous sodium hydroxide and extracted with ether. After drying and evaporation of the solvent, the residue was distilled under reduced pressure to give 29.7 g (57.3%) of *o*-nitropropiophenone boiling at 144—145°C/8 mmHg. Gas chromatography of this sample on silicone grease showed a single peak. UV: 259 (3.70). IR: 1704 (C=O); 1531, 1348, 855 (NO_2). NMR (CCl_4): 1.17^t (3H), 2.75^q (2H), $7.35—8.25^m$ (4H). (Found: C, 59.68; H, 5.28; N, 7.37%).

The Condensation of o-*Nitropropiophenone by Sodium Acetylide.* A mixture of 0.77 g (0.033 mol) of sodium and 150 m*l* of liquid ammonia was saturated with acetylene. The mixture was cooled to −70°C and a solution of 9 g (0.05 mol) of *o*-nitropropiophenone in 15 m*l* of dry ether was added in one portion. A violent reaction took place and the temperature of the mixture reached −50°C. After stirring at −70°C for 1 hr, 1.5 g (0.028 mol) of ammonium chloride was added and the liquid ammonia evaporated while about 150 m*l* of ether was added. The resulting yellow crystals were filtered and washed with water. Recrystallization of the crystals from ethanol gave 2.2 g of compound C, melting at 213—214°C. The filtrate was washed successively with 5% aqueous sodium hydrogen carbonate, 2N hydrochloric acid and 2N aqueous sodium hydroxide. The neutral fraction was processed as described below. The washing with 2N aqueous sodium hydroxide was acidified with sulfuric acid and extracted with ether. The ethereal extract was dried and evaporated to give 2.1 g of compound C, melting at 206—209°C. Total yield was 55.6%. Several recrystallization from ethanol gave a pure sample melting at 214°C. UV: 232 (4.54), 260^{sh} (4.07), 281^{sh} (3.90), 400 (3.69). UV (0.5N NaOH–EtOH): 237 (4.51), 300 (3.93), 425 (3.53). IR: 3520, 3405 (NH); 3300—2800 (OH); 1687 (C=O). NMR: 1.38^s (3H), 1.42^d (3H), 2.88^q (1H), $5.57—6.13^b$ (2H), $6.38—7.64^m$ (8H), 10.90^s (1H).

Found: C, 69.93; H, 5.97; N, 9.05%; C-Methyl group[32] 0.65; mol wt (Rast), 279. Calcd for $C_{18}H_{18}O_3N_2$: C, 69.66; H, 5.85; N, 9.03%; mol wt, 310.

The above-mentioned neutral fraction from several runs were combined and treated with benzene. After removal of insoluble material by filtration, the solvent was distilled off under reduced pressure. The residue (*ca.* 30 g) was chromatographed on 200 g of silicic acid (Mallincrodt, 100 mesh AR) and eluted with methylene chloride-benzene (2.5: 1, v/v). Fractions 1 to 5 were collected in each 200 m*l*. Fraction 2 gave pure *o*-nitropropiophenone. Fraction 6 to 13 were collected in each 300 m*l*. Fraction 6 gave the alkynol VIII. High-vacuum distillation of this fraction gave a yellow oil, bp 90°C (bath temperature)/10^{-3} mmHg. IR (neat)[33]: 3580 (OH); 3310 (≡CH); 2340 (C≡C); 1540, 1360, 860 (NO_2). NMR: 1.04^t (3H), 2.12^q (2H), 2.50^s (1H), 7.05^b (1H), $7.2—7.8^m$ (4H).

Found: C, 64.27; H, 5.51; N, 6.69%. Calcd for $C_{11}H_{11}O_3N$: C, 64.38; H, 5.40; N, 6.83%.

Fraction 8 gave yellow crystals, which, after recrystallization from ethanol, melted to a red liquid at 206—207°C. UV: 229 (4.44), 251^{sh} (4.16), 335 (3.62), 390 (3.51). IR:[33] 3400 (NH); 1700 (C=O). NMR: 1.65^s (3H), 1.75^s (3H), 4.50^s (1H), $6.5—7.8^m$ (8H).

Found: C, 73.54; H, 5.21; N, 4.80%. Calcd for $C_{18}H_{15}O_3N$: C, 73.70; H, 5.15; N, 4.78%.

Fraction 13 gave faintly colored crystals, which, after two recrystallizations from benzene-hexane, decomposed at 150°C. UV: 236 (4.40), 310 (3.32), 360 (3.23). IR:[33] *ca.* 3500 (OH); 1710 (C=O); 1540, 1355, 860 (NO_2). NMR: 1.24^d (3H), 1.58^s (3H), 3.12^q (1H), 3.37^s (1H), $7.0—7.7^m$ (8H).

Found: C, 63.65; H, 4.90; N, 8.10%. Calcd for $C_{18}H_{16}O_5N_2$: C, 63.52; H, 4.74; N, 8.23%.

The condensation using sodium amide instead of the acetylide under the same condition gave 46.4% yield of compound C.

Methylation of Compound C. Into a solution of 1.0 g (3.2 mmol) of compound C in a mixture of each 100 m*l* of ether and methanol was added ethereal solution of diazomethane prepared from 10 g of *N*-nitrosomethylurea. After being left to stand overnight, the mixture was treated with acetic acid to decompose excess of diazomethane and the solvent evaporated under reduced pressure, giving 867 mg (87%) of pale yellow crystals, which, after recrystallization from aqueous methanol, melting at 224.5—225°C. UV: 230.5 (4.48), 281 (3.77), 393 (3.66). IR: 3510, 3402 (NH); 1684 (C=O).

Found: C, 70.42; H, 6.21; N, 8.57%. Calcd for $C_{19}H_{20}O_3N_2$: C, 70.35; H, 6.22; N, 8.64%.

Acetylation of Compound C. *a) With Acetic Anhydride and Sodium Acetate*: A mixture of 300 mg (0.97 mmol) of compound C, 9 m*l* of acetic anhydride and 90 mg of anhydrous sodium acetate was boiled under reflux for one hour. After decomposition of the excess anhydride with water, the separated crystals were filtered and dried, to give 244 mg (64%) of yellow needles, mp 195—197°C. Recrystallization from aqueous methanol gave pure sample, mp 196.5°C. UV: 231 (4.48), 386 (3.64). IR: 3380, 3245, 3200, 3140 (NH); 1758, 1734, 1696 (C=O).

Found: C, 67.03; H, 5.56; N, 7.25%. Calcd for $C_{22}H_{22}O_5N_2$: C, 66.99; H, 5.62; N, 7.10%.

b) With Acetic Anhydride and Pyridine: A solution of 75 mg (0.26 mmol) of compound C in 0.5 m*l* of pyridine was treated with 0.08 m*l* of acetic anhydride and left to stand at room temperature for 2 hr, during which almost colorless crystals separated out. After the addition of ether, the solvent was decanted; the crystals were washed with ether and recrystallized from aqueous ethanol, giving pure sample melting at 229—230°C. IR: 3550, 3410 (NH); 1765, 1690 (C=O).

Found: C, 68.06; H, 5.88; N, 7.90%. Calcd for $C_{20}H_{20}O_4N_2$: C, 68.17; H, 5.72; N, 7.95%.

Acid Hydrolysis of Compound C. A mixture of 300 mg (0.97 mmol) of compound C and 15 m*l* of 6N hydrochloric acid was refluxed under the atmosphere of nitrogen for one and a half hours. No carbon dioxide was evolved during the reaction. After filtration from a solid material which could not be led to any crystalline derivatives, the filtrate, after concentration, was chromatographed on "Toyo" No. 51 filter paper, using ethanol - concentrated hydrochloric acid - water (7: 1: 2 v/v) as solvent. Detection of spots was made accord-

33) IR spectra of these compounds are taken on a spectrophotometer Model IR-E of Japan Spectroscopic Co.

ing to Steel.[12] The R_f value was 0.36.

Hydrogenation of Compound C. *a) Under High Pressure*: A mixture of 200 mg of compound C, 2 m*l* of Raney nickel and 40 m*l* of ethanol was hydrogenated at a hydrogen pressure of 80 atm and 110°C for 2 hr. After filtration of the catalyst, the solvent was removed under reduced pressure to give crystals, which, after recrystallization from aqueous ethanol, melted at 243°C. UV: 285 (3.50), 330 (4.06). IR: 3500, 3395 (NH); 3300—2800 (OH); 1660 (C=O).

Found: C, 69.00; H, 7.18; N, 8.76%. Calcd for $C_{18}H_{22}O_3N_2$: C, 68.77; H, 7.05; N, 8.91%.

b) Under Atmospheric Pressure: A solution of 200 mg of compound C in 10 m*l* of glacial acetic acid was hydrogenated in the presence of 100 mg of platinum oxide until the solution had lost the yellow color. After filtration, the solvent was evaporated under reduced pressure. Trituration of the residue with aqueous alcohol caused crystallization. The crystals were identified with the above mentioned tetrahydro-compound C by IR spectroscopy.

Methylation of Tetrahydro-compound C. Methylation of the tetrahydro derivative with diazomethane under the same condition as that of compound C gave a methyl ether melting at 223—224°C. UV: 285 (3.31), 330 (4.04). IR: 3480, 3376 (NH); 1671 (C=O).

Found: C, 68.92; H, 7.51; N, 8.70%. Calcd for $C_{19}H_{24}O_3N_2$: C, 69.49; H, 7.37; N, 8.53%.

Permanganate Oxidation of Compound C. Into a stirred solution of 465 mg (1.5 mmol) of compound C in aqueous potassium hydroxide (1.0 g of potassium hydroxide in 200 m*l* of water) was added each 158 mg (1 mmol) of finely powdered potassium permanganate. On the addition of eighteen portions, the color of the permanganate remained for 2 hr. The color was discharged by the addition of 0.4 m*l* of 30% of hydrogen peroxide and manganese dioxide was filtered off. The filtrate was extracted several times with ether and the combined extracts were washed with 2N sodium hydroxide, dried and evaporated to give 32 mg of crystals, which, after recrystallization from ethanol, melted at 228°C. UV: 233 (4.40), 255^{sh} (3.80), 400 (3.60). IR: 3520, 3470, 3405, 3350 (NH); 1690^{sh}, 1676 (C=O).

Found: C, 66.12; H, 6.67; N, 12.18%.[34] Calcd for $C_{12}H_{14}O_2N_2$: C, 66.03; H, 6.47; N, 12.84%.

A little amount of this compound was heated with acetic anhydride under reflux for 4 hr. After removal of the solvent under reduced pressure, the residue showed UV maxima at 233 and 334 nm.

2-(1-Methoxycarbonylethyl)-2-methyl-3-indolinone. Into a suspension of 1.92 g (44 mmol) of 54.5% sodium hydride dispersed in mineral oil in 400 m*l* of benzene was added a solution of 9.5 g (40 mmol) of *N*-(*o*-methoxycarbonylphenyl)-alanine methyl ester[15] (bp 137—140°C/2 mmHg) in 10 m*l* of benzene under atmosphere of nitrogen. The mixture was refluxed for 6 hr, during which about 800 m*l* of hydrogen was evolved, and cooled with ice-water. Into the mixture was added 7.5 g (45 mmol) of methyl α-bromopropionate and the mixture was left to stand at room temperature for 21 hr and then refluxed for 7 hr. After addition of 0.5 m*l* of acetic acid, water and ether, the organic layer was separated, washed with 2N hydrochloric acid and 2N sodium hydroxide successively and dried over anhydrous sodium sulfate. The residue obtained by the evaporation of the solvent showed the presence of the desired ester V and the *O*-alkylated product VII[35] (*ca.* 10:8) as major products. The crude product dissolved in benzene was applied to a column of 160 g of active alumina (Wako) and eluted with 2 *l* of benzene.[36] After evaporation of the benzene, the residue (4.00 g) was chromatographed again on 100 g of alumina and eluted with benzene. The fractions were collected after a yellow band reached the bottom of the column. The first 100-m*l* fraction gave a yellow oil. Thereafter, thirteen 100-m*l* fractions gave yellow crystals, which, after recrystallization from hexane, gave 0.77 g of pure ester V, melting at 53—54°C. IR: 3460 (NH); 1722, 1693 (C=O). NMR: 0.93^d (3H), 1.30^s (3H), 2.95^q (1H), 3.72^s (3H), *ca.* 5^b (1H), 6.5—7.2^m (4H).

Found: C, 67.06; H, 6.75; N, 5.84%. Calcd for $C_{13}H_{15}O_3N$: C, 66.93; H, 6.48; N, 6.01%.

2-(1-Carbamoylethyl)-2-methyl-3-indolinone. A mixture of 0.21 g (0.9 mmol) of the above ester V and 2 m*l* of 28% aqueous ammonia was heated in a sealed tube in a boiling water bath for 10 hr. On cooling, crystals separated and they were washed with water and dried; mp 230°C (Found: C, 65.70; H, 6.35; N, 12.76%). IR spectrum was completely identical with that of the specimen obtained above by the permanganate oxidation of compound C.

Permanganate Oxidation of the Alkynol VIII. Into a solution of 1 g of the alkynol VIII contaminated by *o*-nitropropiophenone in acetone was added powdered potassium permanganate in small portions until the purple color remained. After 3 hrs' stirring at room temperature, the excess permanganate was decomposed with methanol and manganese dioxide was filtered off. The filtrate was evaporated under reduced pressure and the residue taken into ether and water. The separated aqueous solution was acidified with hydrochloric acid, extracted with ether. The evaporation of the ether solution, after drying, gave crystals, which, after recrystallization from hexane-ether, melted at 154—156°C.

Found: C, 53.36; H, 4.90; N, 6.15%. Calcd for $C_{10}H_{11}O_5N$: C, 53.33; H, 4.92; N, 6.22%.

The Reaction of Compound XI with Sodium Amide. Into a solution of sodium amide in liquid ammonia (prepared from 126 mg (5.5 mmol) of sodium and 20 m*l* of liquid ammonia) was added a solution of 213 mg (0.63 mmol) of compound XI in one portion at −70°C. The mixture was stirred for 30 min and 400 mg (7 mmol) of ammonium chloride was added. The liquid ammonia was evaporated while ether was added. Evaporation of the ether solution left 160 mg of a residue, which was chromatographed on 5 g of silicic acid and eluted with dichloromethane - benzene (2.5:1, v/v). Evaporation of the solvent gave 90 mg of crystals, which was identified with compound X by comparison of the infrared spectra.

o,o'-*Azoxyacetophenone.* *a) From the Reaction Mixture of o-Nitroacetophenone*: The neutral fraction of the reaction mixture of *o*-nitroacetophenone with sodium acetylide in liquid ammonia[1] was subjected to steam distillation. Essentially no distillate was obtained. The residue in the distillation flask was dissolved in ether, the solution washed with dilute sulfuric acid, and the solvent evaporated. The residue was

34) The poor result of this nitrogen analysis is apparently due to concomitant impurity; however, this substance is very difficult to purify, another sample, which was purified by repeated sublimations and recrystallizations, giving much worse results in the elemental analyses.

35) The following peaks in the NMR spectrum of the crude product are assigned to this compound: 1.58^d (3H), 2.26^s (1H), 3.69^s (3H), 4.71^q (1H), 8.6^{bs} (1H).

36) The *O*-alkylation product is slightly more polar on silicic acid than the desired ester. Prolonged contact with silicic acid seems to hydrolyze this by-product; no *O*-alkylation product was isolated after repeated chromatography on silicic acid.

distilled under a 7-mmHg pressure until the bath temperature reached 200°C to give *o*-nitroacetophenone as the distillate. The residue was dissolved in hot ethanol. After removal of a black resin which deposited immediately after cooling by decantation, the solution was treated with charcoal and left to stand overnight to separate brown crystals, which, after recrystallization from ethanol, melted at 117—119°C. IR (Nujol): 1688, 1676 (C=O); 1478 (azoxy).

Found: C, 68.24; H, 5.24; N, 9.90%. Calcd for $C_{16}H_{14}O_3N_2$: C, 68.07; H, 5.00; N, 9.92%.

b) Synthesis: This compound was prepared from *o*-nitroacetophenone following a procedure for the preparation of *p,p'*-azoxyacetophenone by Clark *et al.*[29] *o*-Nitroacetophenone ethylene ketal was obtained, after distillation (bp 98—100°C/0.05 mmHg) followed by trituration with methanol, in 65% yield, mp 67°C. IR: 1535, 1375, 860 (NO_2); 1040 (ketal). NMR (CCl_4): 1.76^s (3H), 3.4—4.1^m (A_2B_2, 4H), 7.2—7.7^m (4H). (Found: C, 57.23; H, 5.40; N, 6.49%. Calcd for $C_{10}H_{11}O_4N$: C, 57.41; H, 5.30; N, 6.70%). Refluxing the nitro ketal with alkaline zinc dust for 5 hr gave *o,o'*-azoxyacetophenone bis-ethylene ketal in 28% yield, mp 206°C. Prolonged refluxing did not improve the yield. IR: 1470 (azoxy); 1040 (ketal). (Found: C, 64.77; H, 6.07; N, 7.49%. Calcd for $C_{20}H_{22}O_5N_2$: C, 64.85; H, 5.99; N, 7.56%). The acid hydrolysis of the ketal gave *o,o'*-azoxyacetophenone in 64% yield, mp 116—118°C. The IR spectrum of this compound was completely identical with that of the specimen obtained in a).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1491—1493(1972)

Hydrogen Transfer Polymerization of Malononitrile

Nariyoshi KAWABATA,* Chung Kuang CHEN, and Shinzo YAMASHITA
Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto
(Received October 15, 1971)

Treatment of malononitrile with a catalytic amount of cuprous chloride and triethylamine under a nitrogen atmosphere resulted in the formation of solid polymer in high yield. The polymer was soluble in dimethyl sulfoxide, pyridine and hexamethylphosphoramide but insoluble in other organic solvents. The polymer was characterized by elemental analyses and IR and NMR spectra to have a mixed structure of an enamine form, $-[C(CN)=C(NH_2)]-_n$, and a ketimine form, $-[CH(CN)-C(=NH)]-_n$.

Only a few publications are available on the polymerization of malononitrile. Korshak *et al.*[1] made an attempt to polymerize malononitrile by the polyrecombination mechanism, *i.e.*,

$$CH_2(CN)_2 \xrightarrow{\cdot R} \left\{\begin{matrix} CN \\ | \\ C \\ | \\ CN \end{matrix}\right\}_n \quad (1)$$

but found the participation of nitrile group in the polymerization reaction.

$$CH_2(CN)_2 \xrightarrow{\cdot R} \left\{\begin{matrix} C=N \\ | \\ CH_2CN \end{matrix}\right\}_n \quad (2)$$

Whang *et al.*[2] followed up this reaction but obtained oily material from malononitrile. Jones[3] studied on the base-catalyzed polycondensation of mono- and dinitriles involving the reaction,

$$RCN \xrightarrow[\text{base}]{} \left\{\begin{matrix} C=N \\ | \\ R \end{matrix}\right\}_n \quad (3)$$

and obtained black, hard, and insoluble solid from malononitrile.

The authors have found the polymerization of malononitrile by the hydrogen transfer mechanism in the presence of cuprous chloride and triethylamine under a nitrogen atmosphere.

$$CH_2(CN)_2 \xrightarrow[\text{under } N_2]{Cu_2Cl_2,\ Et_3N} \left\{\begin{matrix} C=C \\ | \quad | \\ CN\ NH_2 \end{matrix}\right\}_n - \left\{\begin{matrix} CH-C \\ | \quad \| \\ CN\ NH \end{matrix}\right\}_{n'} \quad (4)$$

The mechanism of this polymerization might be related to the Thorpe reaction, *i.e.*, base-catalyzed condensation of nitrile.

$$RCH_2CN + R'CH_2CN \xrightarrow[\text{base}]{} R-\underset{\substack{| \\ CN}}{CH}-\underset{\substack{| \quad \| \\ CN\ NH}}{C}-CH_2R' \quad (5)$$

The Thorpe reaction gives mainly the dimer, β-iminonitrile, but in some cases trimer and its cyclized products. Condensation of malononitrile by the Thorpe reaction is also reported to give dimer, trimer, and cyclized trimers.[4] There appears to be, however, no report of the condensation of malononitrile to afford tetramer, higher oligomer nor polymer of the above type.

Experimental

Elemental analyses were performed at the Elemental Analyses Center of Kyoto University. IR spectra were recorded on a Japan Spectroscopic Co. Model 402G spectrometer. NMR spectra were obtained with a Japan Electron Optics Lab. Model 4H-100 spectrometer using tetramethylsilane as the external standard.

Materials. Malononitrile and triethylamine were puri-

fied by distillation. Guaranteed reagent of cuprous chloride was used without further purification. Nitrogen was purified by passing through a tube containing copper turnings in a furnace at 170°C followed by drying with silica gel and molecular sieves. Solvents were purified by the usual methods.[5] Other chemicals were commercially available and used without further purification.

Procedure. Polymerizations were carried out under a nitrogen atmosphere in pyrex test tubes with magnetic stirring. The polymer was recovered by pouring into a large excess of water, and was purified by reprecipitation from dimethyl sulfoxide - water system followed by drying under high vacuum over phosphorus pentoxide for prolonged periods. Viscosity measurements of polymer solutions were made in dimethyl sulfoxide at 30°C with a Ubbelohde-type dilution viscometer. Number average molecular weight of polymers was determined by ebullioscopy in pyridine using a Cottrell-type ebulliometer.

Results and Discussion

Malononitrile polymerizes easily in the presence of catalytic amount of cuprous salt and tertiary amine. For example, when 3.2 m*l* (50 mmol) of malononitrile was heated in 5.0 m*l* of tetrahydrofuran at 60°C in the presence of 1 mol% of cuprous chloride and 4 mol% of triethylamine under a nitrogen atmosphere for 19.5 hr, polymer was obtained in 91% yield. The polymer became a nearly colorless (slightly brown) powder after purification. Melting point of the polymer was higher than 300°C. The polymer was soluble in dimethyl sulfoxide, pyridine, and hexamethylphosphoramide, but insoluble in other organic solvents and water. The intrinsic viscosity of the polymer determined in dimethyl sulfoxide at 30°C was 0.044 d*l*/g. The number average molecular weight of the polymer determined in pyridine was about 1700,[6] *i.e.*, the degree of polymerization was about 26. Many experiments were carried out in order to increase both molecular weight and yield of the resulting polymer. Some of good results are given in Table 1. No catalyst more suitable than cuprous salt - tertiary amine system could be found for this polymerization reaction. Nitrogen atmosphere is desirable because the cuprous salt - tertiary amine system is a catalyst for air oxidation of organic compounds.

Table 1. Polymerization of malononitrile[a]

Solvent	(m*l*)	Et_3N/Cu_2Cl_2 mol ratio	Temp. (°C)	Time (hr)	Conv. (%)	$[\eta]$[b] (d*l*/g)
Dimethyl sulfoxide	4.5	2	50	43	82	0.043
Dimethyl sulfoxide	4.1	8	50	68	80	0.044
Dimethyl sulfoxide	4.0	4	50	43	82	0.041
Nitrobenzene	5.0	4	50	21	88	0.041
Tetrahydrofuran	5.0	4	60	19.5	91	0.044

a) Malononitrile, 3.2 m*l* (50 mmol); cuprous chloride, 0.1 g (1 mol% for the monomer); polymerizations were carried out under a nitrogen atmosphere.
b) Viscosity of polymalononitrile was measured at 30°C in dimethyl sulfoxide.

Elemental analyses of the polymer gave the following results; Found: C, 54.41, 54.88; H, 3.19, 2.91; N, 41.29, 41.23%. Calcd for $(C_3H_2N_2)_n$: C, 54.54; H, 3.05; N, 42.41%. These results indicate that the polymer has the same empirical formula as the monomer, *i.e.*, there would be no possibility of dehydrogenation nor hydrolysis during the polymerization.[7]

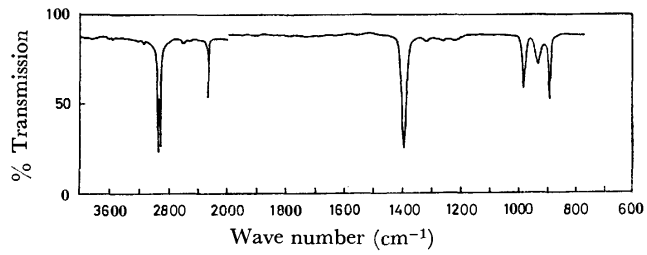

Fig. 1. IR spectrum of malononitrile monomer.

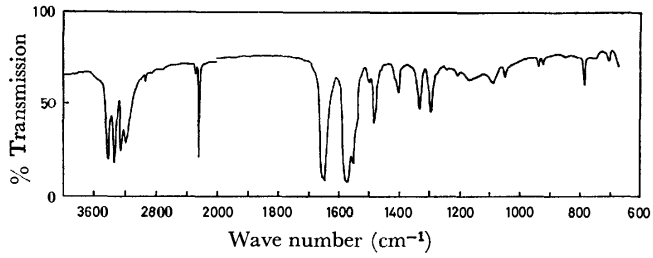

Fig. 2. IR spectrum of polymalononitrile in a KBr disk.

The IR spectrum of malononitrile monomer and that of the polymer in a KBr disk are shown in Figs. 1 and 2, respectively. The absorptions due to the methylene group of malononitrile monomer at 2938 and 2967 cm^{-1} disappeared during the polymerization. Absorptions between 3100—3500 cm^{-1} of the polymer are due to NH and/or NH_2 stretching vibrations, because the polymer has no oxygen as was pointed out by elemental analyses. The appearance of NH and/or NH_2 group together with the disappearance of the methylene group during the polymerization indicates the hydrogen transfer mechanism of the reaction. The authors concluded that the polymer has a mixed structure of an enamine form (I) and a ketimine form (II).

I II

As will be discussed later, IR and NMR spectra of the polymer are consistent with this conclusion. The absorptions at 3323 and 3399 cm^{-1} can be assigned to the NH_2 group of structure I, and those at 3167 and 3239 cm^{-1} to the NH group of structure II.[8] The absorptions of NH stretching vibration of ketimines are

5) J. A. Riddick and W. B. Bunger, "Organic Solvents," Wiley-Interscience, New York (1970).
6) Two experiments gave 1500 and 1900 as the number average molecular weight of the polymer.
7) The observed nitrogen content of the polymer is somewhat lower than the calculated value. However, this result is probably due to slightly difficult combustion of the polymer.
8) The reason of this splitting into two absorptions will be discussed later.

reported to appear in the range of 3205—3236 cm^{-1}.[9] The weak absorption at 2919 cm^{-1} can be assigned to the stretching vibration of methine group of II. The absorptions at 2219 and 2267 cm^{-1} can be attributed to nitrile groups of I and II, respectively. The absorption at 1647 cm^{-1} may be due to C=C group of I and C=N group of II. The absorption at 1573 cm^{-1} may be ascribable to deformation vibration of NH and NH_2 groups.

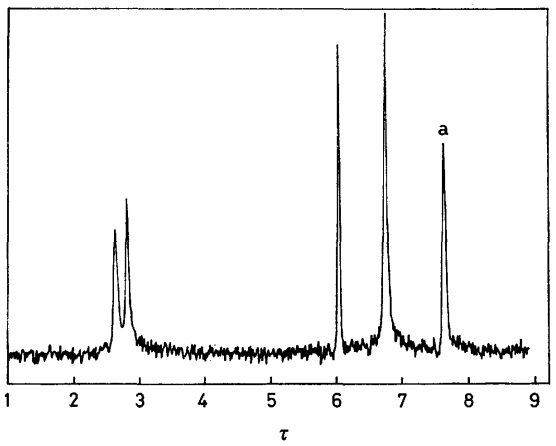

Fig. 3. Proton magnetic resonance spectrum of 5 wt % solution of polymalononitrile in dimethyl-d_6 sulfoxide. a: CH_3SOCH_3.

The NMR spectrum of the polymer obtained in dimethyl-d_6 sulfoxide is shown in Fig. 3. The peak at 6.04 τ can be assigned to NH_2 protons of structure I. The intensity of the peak at 6.75 τ is nearly equal to the total intensity of the two peaks at 2.63 and 2.82 τ. The former can be ascribable to CH proton and the latter two peaks to NH proton of structure II, respectively. Few data are available for NMR spectra of ketimines, but is reported to appear at 0.6 τ in the case of diphenylketimine.[10] The splitting of IR absorption

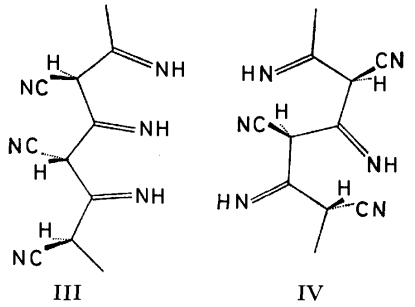

Fig. 4. Two types of possible steric circumstances around imino group of polymalononitrile.

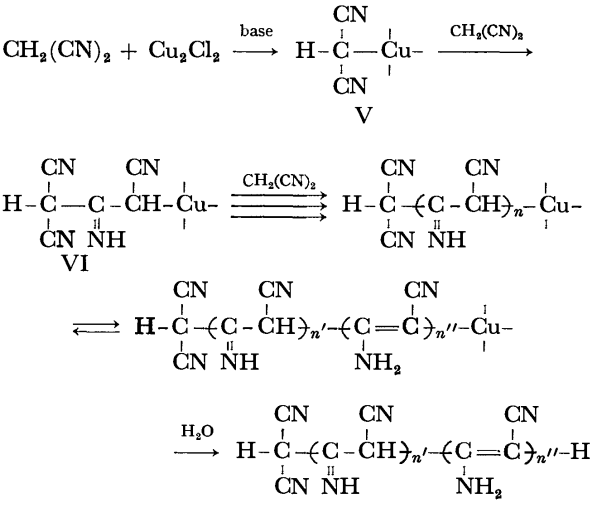
of NH stretching vibration and that of NMR peak assigned to NH proton of structure II suggest that there are two types of imino groups in the polymer. Molecular model suggests the possibility of two types of steric circumstances around imino group, *i.e.*, *pseudo-isotactic* structure III and *pseudo-syndiotactic* structure IV with respect to the imino group, which are illustrated in Fig. 4.

The intensity ratio of the NMR absorption at 6.04 τ to that at 6.75 τ was 1 : 2.3. The ratio was not sensitive to change of concentration in the range of 1—10%. This result shows that in dimethyl sulfoxide solution, about 20% of monomer units have the enamine structure and the residual 80% the ketimine structure. This result consists with the general observation that the ketimine structure is more stable in the ketimine - enamine tautomerism.

Though the authors have no evidence concerning the mechanism of this polymerization, it would be reasonable to speculate as follows;



The formation of an organocopper compound V is conceivable, since the reaction of 1-hexyne with cuprous chloride and ammonia is reported to give 1-hexynylcopper.[11] The formation of VI by the reaction of V with malononitrile is also conceivable, because diethyl β-imino-α-cyano-α'-sodioglutarate VII is reported to be obtained by the following reaction.[12]

Intramolecular Hydrogen Bonding of *ortho*-Substituted Benzenethiols

Takahiro KOBAYASHI, Akihiko YAMASHITA, Yoshihiro FURUYA, Rumiko HORIE, and Minoru HIROTA

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama

(Received November 1, 1971)

From the infrared, NMR, and dipole moment measurements on several substituted benzenethiols, the intramolecular hydrogen bonding in *o*-halo, *o*-methoxy, *o*-nitro, and *o*-carbomethoxybenzenethiols is verified. Five-membered S–H···X hydrogen bonds cause remarkable enhancements of their S–H stretching absorptions without considerable frequency shifts. The favorable *s-cis* conformations in these thiols are also proved by comparing their experimental dipole moments with theoretical values. By far stronger hydrogen bond is observed in *o*-carbomethoxybenzenethiols which can form six-membered chelate ring by the intramolecular hydrogen bonding.

Several investigations on the hydrogen bonding of thiols have been reported and the hydrogen donating properties of the sulfhydryl groups have been discussed.[1-9] From these investigations, it is assumed that the hydrogen donating power of the S–H group is rather weak and that thiols behave as softer acids than alcohols and phenols in case of hydrogen bond formation. The existence of such weak hydrogen bonds can be best investigated by NMR spectroscopy. Thus the S–H···S intermolecular hydrogen bond in ethyl mercaptan[2] and the S–H···O intramolecular hydrogen bond[10] have been verified by this method. The present authors also reported on the PMR spectra of *o*-methoxy- and 2,6-dimethoxy-benzenethiols, and concluded the existence of the intramolecular hydrogen bonds by the comparison with the behaviors of the corresponding phenols.[11]

In order to establish the extent and the limit of the existence of the S–H···X intramolecular hydrogen bonds and to compare their relative strengths for various hydrogen acceptors, the PMR, IR, and dipole moments of several *ortho*-substituted benzenethiols were determined and the existence of the intramolecular hydrogen bonds were concluded in benzenethiols carrying alkoxy-, halogeno-, nitro-, alkoxycarbonyl-substituents at the *ortho*-positions.

Experimental

Materials. *p*-Toluenethiol, *p*-methoxybenzenethiol, *o*-toluenethiol, 2-bromo-4-methylbenzenethiol, *o*-iodobenzenethiol, *o*-methoxybenzenethiol, and 2,6-dimethoxybenzenethiol were prepared according to the method reported by Sutar.[12] *o*-Nitrobenzenethiol was obtained by the reduction of 2,2′-dinitrodiphenyl disulfide.[13] All of these thiols were known compounds and were purified by repeated recrystallization or fractional distillation until their physical constants agree with those reported in literatures.[12-16]

All solvents used were commercially available spectro-grade ones or were purified by the usual methods. The solvents were dried over appropriate desiccants and re-distilled when necessary.

Spectral and Dielectric Measurements. Infrared spectra in the S–H stretching region were measured with a Perkin-Elmer 112G infrared spectrophotometer. The measurements were carried out on a dilute solution of the thiol in carbon tetrachloride or chloroform employing a quartz cell of 2 cm in path length.

Proton magnetic resonance spectra were determined with a JEOL JNM-C60H spectrometer. The spectra were obtained over a wide range of concentrations (0.1 to 100% of solute) in carbon tetrachloride and chloroform-*d* to ascertain the existance of the intramolecular hydrogen bonds.

Dielectric constants of the benzene or carbon tetrachloride solution of the thiols were determined at 25°C, except the case of temperature dependence measurement, using a heterodyne apparatus. The dipole moment values were calculated by employing the method of Halverstadt and Kumler[17] from the dielectric constants of the solutions at varying concentrations. The molar refraction was calculated from the bond refraction values in the literature.[18]

Results and Discussion

Infrared S–H stretching absorptions and chemical shifts of the S–H protons at infinite dilution are given in Table 1. The thiols No. 1 to 4 are those without intramolecular hydrogen bonds, and intermolecular hydrogen bonding is also excluded by the measurement

in extremely dilute solution of inert solvents. Their S–H absorption have rather low intensities ($\varepsilon_{max}=3$ in CCl_4) and not affected considerably by the introduction of *ortho* and *para* substituents, if the *ortho* substituents are incapable of forming intramolecular hydrogen bonds. On the other hand, the introduction of the hydrogen accepting substituents at the *ortho* position causes a remarkable increase in intensity as shown in Table 1. The absolute values of the integrated intensity is larger in chloroform than in carbon tetrachloride, while the intensity enhancement is more predominant in latter solvent. In contrast to the remarkable increase in intensity, the S–H absorption frequencies are not affected by the introduction of the hydrogen accepting substituents except the case of *o*-carbomethoxybenzenethiol. The introduction of a methyl group forming no intramolecular hydrogen bond to the *ortho*-position does not strengthen the S–H intensity, and the steric effect caused by the *ortho*-substituent might not be responsible for the intensity enhancement. The possibility of the electronic effect (mesomeric effect) is excluded by the fact that the intensity of the S–H absorption is little affected by the methoxy substituent in *p*-methoxybenzenethiol. In analogy with the substituent effect on the ν_{O-H} intensities of substituted phenols,[19] the electron donating character of the methoxy group at the *ortho*- or *para*-position is expected to decrease the intensity of S–H absorption. Thus the observed increase in intensity cannot be explained by the electronic effect.

Fig. 1. The S–H stretching absorptions of *p*-toluenethiol (1a) and 2,6-dimethoxybenzenethiol (1b) in carbon tetrachloride–dimethyl sulfoxide mixtures.
A: 5.24 wt% DMSO in CCl_4, B: 1.36 wt% DMSO in CCl_4, C: 0.686 wt% DMSO in CCl_4, D: 100 wt% CCl_4.

In conclusion, the enhancement of the intensity might be attributed to the intramolecular hydrogen bond formation. Such an evidence was obtained by the investigation on the intermolecular interaction of the thiols with some solvents having proton accepting ability. The ν_{SH} intensities of *p*-toluenethiol (1) and 2,6-dimethoxybenzenethiol (8) are recorded in several sol-

	$\Delta\nu_{1/2}$ (cm^{-1})	35.8	37.0	42.5	29.0

vents and listed in Table 2. The thiols selected in Table 2. are the typicals of the intermolecular and intramolecular hydrogen bonded ones, respectively. Of the usual benzenethiols without *ortho*-hydrogen acceptor (1), the S–H absorption band tend to be more intense and broader when measured in hydrogen accepting solvents. (See also Fig. 1) However, the S–H absorption of 2,6-dimethoxybenzenethiol (8) is not remarkably affected by such solvents. In this compound, the S–H group is shielded by the two methoxy groups, and the solvent molecules are hardly accessible to the S–H group. Hence, the intermolecular hydrogen bonding might not disturb the intramolecular hydrogen bond of the latter thiol to a considerable extent. The increase in intensity is quite general with the intramolecularly hydrogen-bonded compounds carrying O–H and N–H groups.[20] Some experiments also showed that the S–H groups participating in the hydrogen bonds have stronger S–H absorptions.[21]

In the case of rather weak hydrogen bond, both the hydrogen bonded and the free X–H absorption bands must be observed. However, only one absorption band assigned to the S–H stretching vibration can be observed in most cases, though some weak bands whose origins are uncertain appear in the spectra of some thiols. The spectra in Fig. 2 show that the ν_{S-H} bands are intensified remarkably by the introduction of the additional hydrogen accepting substituent to the 6-positions of the 2-methoxy- and 2-bromobenzenethiols. This means that the hydrogen bonded form is increased by the introduction of the second substituent, and the existence of free *s-trans* form (II) is expected in the benzenethiol carrying one hydrogen accepting substituent at the *ortho* position. Because of the absence of the remarkable hydrogen bond shift, weaker S–H absorptions of the free species might be masked by the stronger S–H absorptions of the intramolecularly hydrogen bonded species. The S–H stretching spectrum of *o*-carbomethoxybenzenethiol in Fig. 3 shows the appearance of an additional band of low intensity in normal S–H stretching region, which can be assigned to the free S–H stretching vibration.

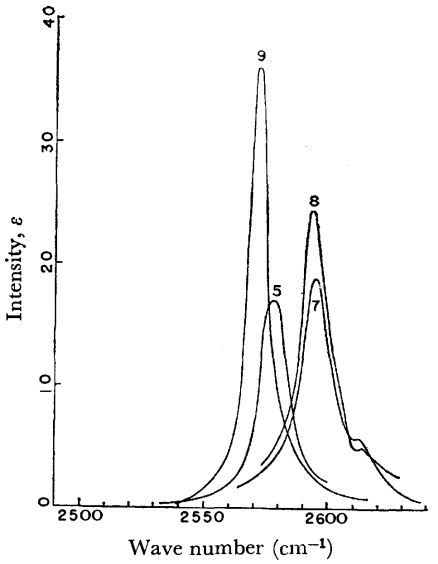

Fig. 2. The S–H stretching absorptions of 2-X- and 2,6-di-X-benzenethiols in carbon tetrachloride.

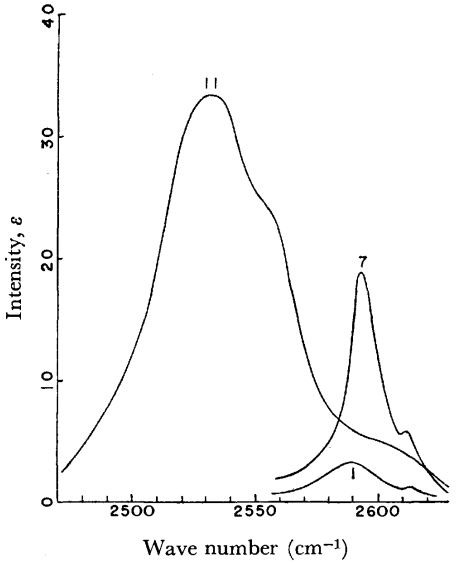

Fig. 3. The S–H stretching absorptions of the typical benzenethiols with five-membered and six-membered hydrogen bonded chelates (in carbon tetrachloride).

The PMR chemical shifts of the S–H protons in very dilute solutions are also given in Table 1. As reported previously by the present authors,[11] the PMR spectra are useful in the discussion of the hydrogen bonding of thiols and the chemical shifts of S–H protons at infinite dilution displace to considerably lower fields when the thiols exist as the intramolecularly hydrogen bonded forms. Thus, the usual thiols ((1) to (3) in Table 1) have δ_{SH} values ranging 3.0 to 3.3 ppm in carbon tetrachloride and 3.2 to 3.4 ppm in chloroform-*d*, while the thiols carrying *ortho* hydrogen accepting substituents have δ_{SH} values ranging 3.6 to 5.3 ppm and 3.7 to 4.8 ppm, respectively, in the above solvents. The ν_{S-H} intensity *vs.* δ_{SH} plot is illustrated in Fig. 4, and a fairly good linear relation is observed even though no correction for the magnetic anisotropy effect by the substituents are taken into accounts.

Additional evidence for the intramolecular hydrogen

21) A. Wagner, H. J. Becker, and K. G. Kottenhahn, *Chem. Ber.*, **89**, 1708 (1956).

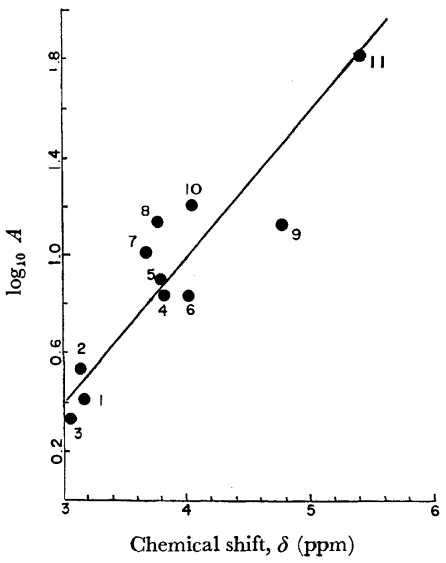

Fig. 4. Integrated intensity (A_{SH}) *vs.* SH chemical shift (δ_{SH}) plot.

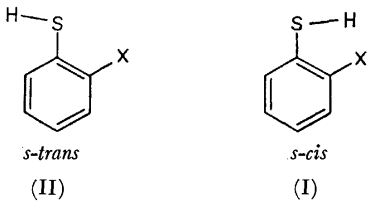
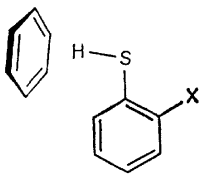
bonding in benzenethiols with *ortho*-substituents of hydrogen accepting ability is supplied by the dipole moment data given in Table 3. The theoretical dipole moment for each conformation is calculated from the group moments in Table 4.[22] When *o*-halo- and *o*-nitrobenzenethiols form intramolecular hydrogen bond, the *s-cis* conformation (I) of these thiols should exist more favorably than the corresponding *s-trans* conformation. To obtain the ratios of *s-cis* and *s-trans* conformations, the experimental dipole moment values of the thiols are assumed to be expressed as the resultants of the mean squares of the theoretical dipole moments of the two conformers, and the following equation is employed,

$$\mu^2 = \frac{\mu_t^2 N_t + \mu_c^2 N_c}{N_t + N_c}$$

where μ_t and μ_c, N_t and N_c are the theoretical dipole moments and the numbers of the molecules of *s-trans* and *s-cis* conformers, respectively. Thus the experimental dipole moment 0.90 D of *o*-toluenethiol (3) in benzene solution at 25°C gives the result that 87% of the molecules take *trans* conformation and the rest of them have *cis* conformation. This means that *cis* conformation is unfavorable, and might be due to the steric hindrance between the methyl and sulydrylfh hydrogen atoms. On the other hand, the observed dipole moments of *o*-chloro-, 2-bromo-4-methyl-, and *o*-nitrobenzenethiols are closer to the theoretical values for *s-cis* conformations. When dissolved in benzene, 85%, 84%, and 76% of them, respectively, exist as *cis* conformations, and the proportions of *cis* conformers increase further when dissolved in carbon tetrachloride. The conclusions on the conformations obtained from the dipole moment measurements again supports the existence of intramolecular hydrogen bonding. Increased population of *s-trans* conformers in benzene solutions is explained by the stabilization caused by the S–H···π intermolecular interaction with the solvent molecules, as illustrated by (III).





(III)

The dipole moment of *o*-methoxybenzenethiol does not agree with the favorable *s-cis* conformation. This may arise from the smaller difference of the theoretical dipole moments between *s-cis* and *s-trans* conformers and from the ambiguity of the direction of methoxy group moment caused by the rotation around the C–O bond.

In conclusion, the intramolecular S–H···X hydrogen bonds exist in some *ortho*-substituted benzenethiols forming both five-membered and six-membered chelate rings. Similar to the corresponding phenols, benzenethiols with *o*-methoxy-, *o*-chloro-, *o*-bromo-, *o*-iodo-, *o*-

2-NO_2	1.15	140°
2-$COOCH_3$	1.35	151°

Then, some discussions will be given on the stereochemistry of the intramolecular hydrogen bond of this type. The H···X distances *d* and S–H–X angles were calculated by assuming the geometry in Fig. 5 for the *cis* conformers and the results were listed in Table 5.

23) Bond lengths and bond angles employed were taken from a) "Kagaku Benran," Fundamental Volume II, ed. by Chem.Soc. Japan, Maruzen Book Co., Tokyo (1966) p. 1209 and b) "Kagaku Benran," ed. by Chem. Soc. Japan, Maruzen Book Co., Tokyo (1958) p. 966.

The main factors determining the strength of the intramolecular hydrogen bond are i) the kinds of the hydrogen donating and accepting groups, ii) the linearity of the hydrogen bond, and iii) the distance between the donor and the acceptor atoms. In the discussion on the stereochemistry, the latter two factors play important roles. The hydrogen bond becomes stronger when the hydrogen atom comes closer to the accepting atom and when the S–H···X arrangement is nearer to the linear one. In these points of view, the six-membered chelation is stronger than the five-membered one, which is in agreement with the above results. The most suitable S–H···X distance values are rarely found in the previous investigations. However, the O–H···X distances are reported by many authors[24] and the O–H···Cl and the O–H···O distances in hydrogen bonded molecules are 3.1 to 3.2 Å and 2.5 to 2.8 Å, respectively. The H···X distances are then 1.5 to 1.8 Å and 2.1 to 2.2 Å. The calculated X···H distances in Table 5 are mostly within these ranges, but the H···O distance in *o*-nitrobenzenethiol[10] is rather too short, and the repulsive force between the atoms may cause the deviation from the planar six-membered ring. This could be a reason why the intramolecular hydrogen bond in (10) is weaker than expected.

The authors are grateful to Prof. H. Kakiuchi of Yokohama National University for his kind and valuable advice and to Prof. T. Shimozawa of Saitama University for his useful advice and kind guidance in constructing the apparatus for dielectric constant measurement. They also wish to express their hearty thanks to Prof. T. Shimanouchi and Prof. I. Nakagawa of the University of Tokyo for their kind permission to use infrared spectrophotometers.

Reactions of Aryloxycopper(I) with Organic Halides

Takao KAWAKI and Harukichi HASHIMOTO*

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo
**Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai*

(Received August 23, 1971)

Some aryloxycoppers were synthesized by the interaction of phenylcopper with phenols and then characterized. The reaction of aryloxycopper and organic halide in diglyme generally gave the corresponding ether. From these and other results, it is suggested that aryloxycopper(I) is an intermediate in the Ullmann condensation, *etc.*

A number of reactions utilizing cuprous salts have been reported by numerous investigators. However, the preparations and reactions of alkoxy- or aryloxycopper(I), as well as of $CuOCOCH_3$, Cu(acac) and $CuNO_3$, have not been studied thoroughly, though Costa[1] reported the preparation of unstable methoxycopper(I) and its decomposition reaction. Aryloxycopper(I) has been assumed to be an intermediate of some copper-promoted reaction.[2,3] Weingarten[4,5] reported that aryloxycopper(I) is an intermediate of the Ullmann condensation reaction. In the oxidative coupling reaction of substituted phenols, this compound was also reported by Hay and his co-workers[6] to play an important role. The aim of this work is to examine the preparation of aryloxycopper(I) and its reactivity.

Results and Discussion

Preparation and Properties of Phenoxycopper(I). Phenoxycopper(I) was prepared by adding a small excess of phenol to phenylcopper suspended in anhydrous diethyl ether; the details will be specified in the Experimental section. Phenoxycopper(I) is a violet micro-crystalline, oxygen-sensitive compound; it is soluble in dyglime and DMF and insoluble in benzene and ether.

Group Ib metal halides in the low oxidation state are well known to form stable complexes with triphenylphosphine (PPh_3). Recently, several investigators have reported halogenocopper(I) complexes with PPh_3.[7,8] Phenoxycopper(I) also formed a complex with the composition of $Cu(OPh)(PPh_3)_3$ by refluxing with PPh_3 in benzene. This complex is a white crystalline compound, stable to oxygen and soluble in an organic solvent.

Reactions of Aryloxycopper(I) with Organic Halides. Cuprous salts promoted the reaction of aryl halide with alkali metal phenoxide to give aryl ether.[5,9] This reaction was suggested, from the study of the ESR, to be a nucleophilic replacement reaction of the ate complex of phenoxycopper(I) on aryl halide. It appeared to be interesting to investigate the reactions of aryloxycopper(I) with organic halides in connection with the Ullmann condensation reaction. Table 1 shows the results of the reactions between aryloxycopper(I) and some organic halides. It is obvious that, under mild conditions, these reactions do not proceed successfully, but under rigorous conditions they proceed to obtain the corresponding ethers. In the reaction of No. 2, diphenyl ether was obtained from bromobenzene in a 38% yield. This result gives some support to the

hypothesis that aryloxycopper(I) is an intermediate of the Ullmann condensation reaction.

To investigate the substituent effects, *p*-methyl-, *p*-nitro-, and *p*-methoxyphenoxycopper(I) were prepared and reacted with bromobenzene, but only *p*-methylphenoxycopper(I) gave the corresponding ether. The result may be due to the fact that *p*-nitro- and *p*-methoxyphenoxycopper(I) were insoluble in diglyme. The reaction of phenoxycopper(I) with allyl chloride is abnormal with respect to producing *o*-allylphenol and several high-boiling by-products at room temperature. The formation of *o*-allylphenol can not be attributed to a Claisen rearrangement of the resulting allyl phenyl ether under very mild reaction conditions used.

TABLE 2. THE EFFECT OF LIGANDS IN THE REACTION OF CuOPh WITH PhBr AT 125°C FOR 17 hr IN DIGLYME

Ligand	Ligand/CuOPh (mol/mol)	Yield of PhOPh(%)
—	0	38
Pyridine	3	46
PPh_3	3	8.2

The effect of the addition of pyridine or PPh_3 in the reaction of phenoxycopper(I) and bromobenzene is shown in Table 2. The addition of pyridine increased the yield of diphenyl ether, and that of PPh_3 decreased significantly the yield of diphenyl ether. Bacon and his co-worker[2] proposed the following four-centered mechanism for the halogen exchange of ary halide with cuprous salts:

$$ArX + CuY \rightleftharpoons \left[\begin{matrix} & X & \\ Ar & & Cu \\ & Y & \end{matrix}\right] \longrightarrow ArY + CuX$$

X; Y=Cl, Br, I

The above reaction of phenoxycopper(I) with bromobenzene may be thought to proceed through a similar process.

Reactions of Phenoxycopper(I) with Acyl Halides. Phenoxycopper(I) as well as other metal alkoxides reacted with acyl halides very rapidly at room temperature to form the corresponding ester. For example, phenoxycopper(I) was reacted with benzoyl chloride and acetyl chloride in ether at room temperature for 2 hr to produce phenyl benzoate (74% yield) and phenyl acetate (64% yield) respectively.

Oxidation of 2,6-Di-t-butylphenoxycopper(I). 2,6-Di-*t*-butylphenoxycopper(I) was prepared by the same method as phenoxycopper(I) and was oxidized by passing air through its suspension in ether to give only 2,2′,6,6′-tetra-*t*-butyldiphenoquinone as the reaction product. It has been reported[6] that the oxidative coupling of 2,6-di-*t*-butylphenol catalyzed with cuprous chloride and pyridine also gave 2,2′,6,6′-tetra-*t*-butyldiphenoquinone. It seems from the results of this experiment that aryloxycopper(I) is an intermediate of the oxidative coupling of phenols catalyzed with copper salts.

Experimental

Preparation of Phenoxycopper(I). Phenlycopper was prepared according to the directions of Costa.[10] Phenyllithium (0.02 mol) was added to cuprous bromide (0.02 mol) suspended in absolute ether at −10°C under a nitrogen atmosphere. The resulting white precipitate of phenylcopper was washed several times with ether under the applied pressure of nitrogen.

To the above phenylcopper (0.02 mol) suspended in fresh ether at room temperature, we added a slight excess of phenol under nitrogen; the mixture was then stirred for 2 hr. The resulting violet solid of CuOPh was washed several times with ether and dried under nitrogen. The IR spectra showed the absorption bands of a trace of unreacted phenylcopper, which had little influence on the following reactions. The other aryloxycoppers were prepared in a similar way.

Preparation of Cu(OPh)(PPh_3)$_3$. PPh_3 (0.04 mol) was added to CuOPh (0.01 mol) suspended in benzene, after which the mixture was refluxed for 5 hr. The reaction mixture was then concentrated to deposit Cu(OPh)(PPh_3)$_3$.

Found: C, 76.16; H, 5.25; Cu, 6.38%. Calcd for $C_{60}H_{50}OP_3Cu$: C, 76.62; H, 5.25; Cu, 6.70%.

Reactions of Aryloxycopper with Organic Halides. All the reactions were carried out *in situ* without any drying of the aryloxycoppers prepared as described above. Organic halide (0.02 mol) was added to CuOAr (0.02 mol) suspended in ether under nitrogen, after which the mixture was heated under the conditions shown in Table 1. The yields of the products were determined by gas chromatography.

Reactions of Phenoxycopper(I) with Acyl Halides. Acetyl chloride or benzoyl chloride (0.02 mol) was added to phenoxycopper(I) (0.02 mol) suspended in ether as described above, and the mixture was stirred at room temperature for 2 hr.

Oxidation of 2,6-Di-t-butylphenoxycopper(I). Oxygen was bubbled into a suspension of 2,6-di-*t*-butylphenoxycopper in ether at room temperature for 10 hr. The mixture was hydrolyzed with dilute hydrochloric acid, and then the ether layer was separated. The ether was subsequently removed to give solid 2,2′,6,6′-tetra-*t*-butyldiphenoquinone in a yield of 16%; this substance was identified by elemental analysis, IR, and NMR and by its failure to depress the melting point of an authentic sample.

The Synthesis and Configuration of Fukiic Acid Derivatives[1)]

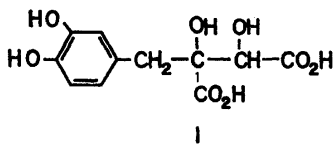
Takashi MATSUMOTO, Kazuo HIDAKA, Teruko NAKAYAMA, and Kenji FUKUI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

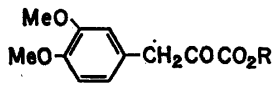
(Received October 1, 1971)

The methylation of 3,4-dimethoxyphenylpyruvic acid (II) gave the corresponding methyl ester (III), which was then subjected to a Wittig reaction with carbomethoxymethylenetriphenylphosphorane to give the corresponding fumaric (IVa) and maleic (IVb) acid derivatives in a 1: 3 ratio. The *cis*-hydroxylation of IVa and IVb with an aqueous solution of potassium permanganate and magnesium sulfate gave methyl (±)-*threo*-2,3-dihydroxy-4-(3,4-dimethoxyphenyl)-3-methoxycarbonylbutyrate (Va) and its (±)-*erythro*-isomer (Vb) respectively. The dimethyl esters, (±)-Va and (±)-Vb, were converted to the corresponding monomethyl esters, (±)-VIIa and (±)-VIIb respectively, *via* two dicarboxylic acid derivatives, (±)-VIa and (±)-VIb. The resolution of (±)-VIIb with brucine gave (+)-VIIb and (−)-VIIb, which were then converted to (+)-Vb and (+)-VIb and to (−)-Vb and (−)-VIb respectively. The synthetic (+)-Vb was shown to be identical with the natural *O,O'*-dimethylfukiic acid dimethyl ester by a mixed fusion and by comparisons of their IR and NMR spectra. From the present study it is evident that natural fukiic acid has an *erythro* configuration.

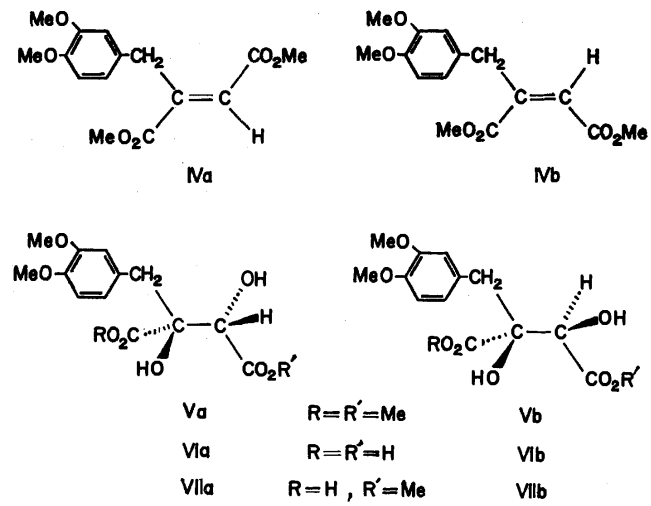
Recently a new polyphenol, fukinolic acid, was isolated from the leaves, leaf stems, and flower stalks of *Petasites japonicus* by Sakamura *et al.*[2)] They have also been reported that the alkaline hydrolysis of fukinolic acid gave caffeic acid and a new acid, named fukiic acid, in a molar ratio of 1: 1. Although no physical properties of fukiic acid have been reported except the *Rf* value on paper chromatography, its structure was proposed to be 2,3-dihydroxy-4-(3,4-dihydroxyphenyl)-3-carboxybutyric acid (I) on the basis of the analytical and spectroscopic studies of its derivatives. Two racemic modifications (*threo* and *erythro*) are possible for I. However, since the stereochemistry of fukiic acid has not yet been reported, the present authors attempted a total synthesis of fukiic acid derivatives in order to confirm the proposed structure and to elucidate the stereochemistry of fukiic acid. The present paper will describe a stereospecific synthesis of fukiic acid derivatives and their stereochemistry. For their synthesis, 3, 4-dimethoxyphenylpyruvic acid (II) was chosen as the starting substance, and the acid (II) was methylated with one equivalent of diazomethane to give the corresponding methyl ester (III). The Wittig reaction[3)] of III with carbomethoxymethylenetriphenylphosphorane afforded a 96% yield of a mixture of geometric isomers, which were then successfully separated, by means of



I



II R=H
III R=Me



column chromatography on silica gel, into two crystalline esters in a 1: 3 ratio. It is well known that the ylids stabilized by an adjacent carbonyl function yield, as the predominant product, the isomer in which the carbonyl function is *trans* to the larger group at the beta carbon atom. In the NMR spectra it is also known that the signal of a *cis*-vinyl proton to the methoxycarbonyl group is to be found at a field lower than that of the corresponding *trans*-vinyl proton. The chemical shifts of the olefinic protons in the above minor (mp 49—50°C) and major (mp 56.5—57°C) esters were observed at δ *ca.* 6.8 ppm and at δ 5.67 ppm respectively. Therefore, the structures of the minor and major esters were identified as the 1-(3,4-dimethoxybenzyl)fumaric acid dimethyl ester (IVa) and the 1-(3,4-dimethoxybenzyl)maleic acid dimethyl ester (IVb) respectively. These assignments were further supported by the chemical shifts of the methylene protons in IVa and IVb. That is, IVa showed the signal of the methylene protons at δ 4.12 ppm, suggesting the presence of a *cis*-methoxycarbonyl group relative to the methylene protons, because IVb showed the corresponding signal at δ 3.61 ppm. The hydroxylation of IVa and IVb in methanol with an aqueous solution of potassium permanganate and magnesium sulfate at −20°C gave the corresponding diols, (±)-Va (mp 93—94°C) and (±)-Vb (mp 142°C) respectively. Since it is well

1) A preliminary communication concerning this work appeared in *Chem. Lett.*, **1972**, 1.

2) S. Sakamura, T. Yoshihara, and K. Toyoda, *Agr. Biol. Chem.* (Tokyo), **33**, 1795 (1969).

3) A. Maercker, "Organic Reactions," Vol. 14, Wiley, New York (1965), p. 270.

known that an aqueous solution of potassium permanganate reacts with olefins to add two hydroxyl functions to the double bond in a *cis* manner, the structures of the above diols were identified as methyl (±)-*threo*-2,3-dihydroxy-4-(3,4-dimethoxyphenyl)-3-methoxycarbonylbutyrate for Va and its (±)-*erythro*-isomer for Vb. The dimethyl esters, (±)-Va and (±)-Vb, were then hydrolyzed with aqueous potassium hydroxide to the corresponding dicarboxylic acid derivatives, (±)-VIa and (±)-VIb, which were subsequently methylated back into (±)-Va and (±)-Vb with diazomethane. This proved that there was no configurational change during the hydrolyses of (±)-Va and (±)-Vb. The NMR spectra of (±)-Vb in $CDCl_3$ and of (±)-VIb in $(CD_3)_2CO$ showed signals due to the methylene protons at δ 3.05 and 3.27 ppm, and at δ 3.06 and 3.26 ppm, respectively as well-defined AB-type quartets, while the spectra of (±)-Va in $CDCl_3$ and (±)-VIa in $(CD_3)_2CO$ showed the corresponding signals at δ 3.07 ppm as a singlet, and at δ 3.16 ppm as a slightly separated doublet, respectively. In the NMR spectrum of the natural fukiic acid monomethyl ester in $(CD_3)_2CO$, Sakamura *et al.*[2] had reported that the signal of the methylene protons was observed at δ 2.94 and 3.14 ppm as an AB-type quartet. From the similarity of these NMR spectra in the synthetic and natural compounds, it seemed that fukiic acid had an *erythro* configuration.

To obtain further confirmation by a direct comparison of the optically-active synthetic compound with the corresponding natural sample, the resolution of the synthetic racemate was carried out as follows. Since an attempt at the resolution of (±)-VIb was not encouraging, it was converted to the corresponding monomethyl ester, (±)-VIIb (mp 185—186°C), by treatment with methanol containing a small amount of concentrated hydrochloric acid. The (±)-VIIb acid in methanol was successfully resolved by means of brucine, and one of the diastereomeric salts (mp 185—186°C dec.) was decomposed with dilute hydrochloric acid to give (+)-VIIb, mp 138—139°C, $[\alpha]_D$+40.8° (methanol). The mother liquor, after the separation of the above brucine

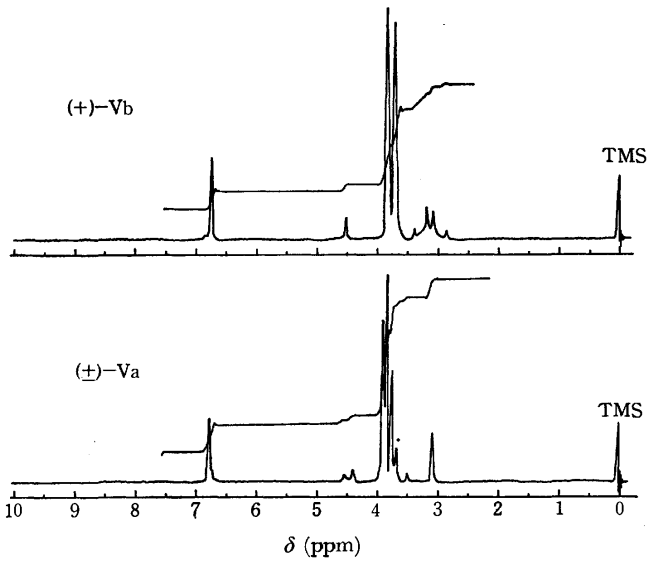


Fig. 1. NMR spectra of synthetic (+)-Vb and (±)-Va in $CDCl_3$.

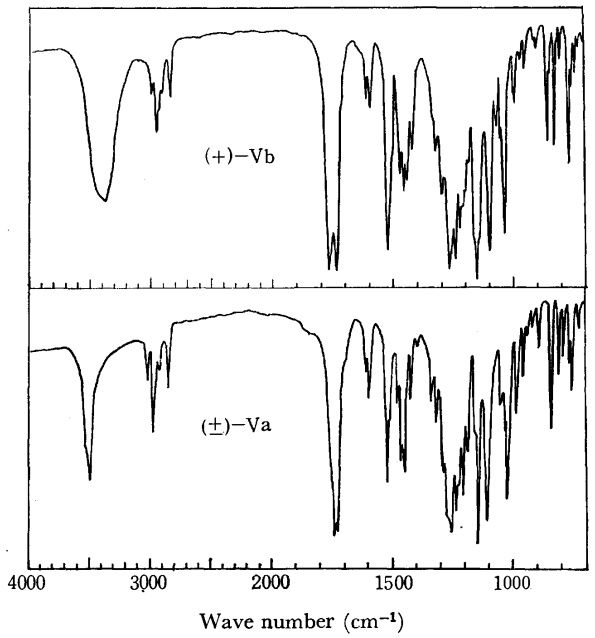

Fig. 2. IR spectra of synthetic (+)-Vb and (±)-Va in KBr.

salt, was also treated with dilute hydrochloric acid to give (−)-VIIb, mp 138—139°C, $[\alpha]_D$−38.0° (methanol). The alkaline hydrolyses of (+)-VIIb and (−)-VIIb gave (+)-VIb, mp 104—106°C, $[\alpha]_D$+40.3° (methanol) and (−)-VIb, mp 104—106°C, $[\alpha]_D$−40.5° (methanol), respectively. The methylation of (+)-VIb or (+)-VIIb with diazomethane gave (+)-Vb, mp 116—117°C, $[\alpha]_D$+40.5° (methanol), which was shown to be identical with the natural *O,O'*-dimethylfukiic acid dimethyl ester by a mixed-melting-point determination and by comparisons of their IR and NMR spectra. The acids, (−)-VIb, and (−)-VIIb, were also methylated with diazomethane to (−)-Vb, mp 116—117°C, $[\alpha]_D$−39.7° (methanol). (±)-VIa was also converted to the corresponding monomethyl ester, (±)-VIIa, mp 159—160°C.

From the present study, it is evident that natural fukiic acid has an *erythro* confiugration.[4]

Experimental

All the melting points are uncorrected. The NMR spectra were taken on a Hitachi Model R-20 NMR spectrometer (60 MHz), using tetramethylsilane as the internal standard. Their chemical shifts are presented in terms of δ values; s: singlet; d: doublet; dd: double doublet; t: triplet; m: multiplet. The optical rotation measurements were carried out by the use of a Yanagimoto OR-50 direct-reading polarimeter. The length of the cell used was 1 cm. The column chromatography was performed on Merck silica gel (0.08 mm).

Methyl 3,4-Dimethoxyphenylpyruvate (III). An ether solution (34 m*l*) containing diazomethane (0.56 g: 0.0134 mol) was stirred into a suspension of 3,4-dimethoxyphenylpyruvic

4) In a recent private communication from Professor S. Sakamura, he stated that his group also reached the same conclusion on the basis of a different synthesis of the (±)-*O,O'*-dimethylfukiic acid dimethyl ester, and that they also have identified the absolute configuration of fukiic acid; the details of their work were submitted to *Tetrahedron Lett.* and *Agr. Biol. Chem.* (Tokyo).

acid (II) (3.00 g: 0.0134 mol) in acetone (20 m*l*) with cooling in an ice–water bath. After the addition was complete, the mixture was filtered to remove a small amount of the starting acid (II), and then the filtrate was immediately evaporated under a vacuum. The residue was recrystallized from aqueous methanol to give pale yellow crystals (III); mp 99—102°C; yield, 2.10 g. NMR in $CDCl_3$: 3.89 (9H, s, 2-OC$\underline{H}_3$ and -$CO_2C\underline{H}_3$), 6.42 (2H, dd, J=1.5 and 8 Hz, -C$\underline{H}_2$-), 6.85 (1H, d, J=8 Hz), 7.28 (1H, dd, J=1.5 and 8 Hz), 7.49 (1H, d, J=1.5 Hz).

Found: C, 60.77; H, 5.93%. Calcd for $C_{12}H_{14}O_5$: C, 60.50; H, 5.92%.

1-(3,4-Dimethoxybenzyl)fumaric Acid Dimethyl Ester (IVa) and 1-(3,4-Dimethoxybenzyl)maleic Acid Dimethyl Ester (IVb). A mixture of the ester (III: 10.0 g), carbomethoxymethylenetriphenylphosphorane (14.6 g), and dry benzene (200 m*l*) was refluxed for 2 hr under a stream of nitrogen and then evaporated under a vacuum. The residue was extracted with ether, and the extract, after the removal of the ether, was chromatographed on silica gel, using benzene containing 7% and then 50% ether as the eluents. The first fraction gave IVa (2.943 g), which was recrystallized from ether containing petroleum ether to give pale yellow crystals; mp 49—50°C. NMR in $CDCl_3$: 3.74 and 3.79 (each 3H and s, 2-$CO_2C\underline{H}_3$), 3.82 (6H, s, 2-OC$\underline{H}_3$), 4.12 (2H, s, -C$\underline{H}_2$-), 6.78—6.95 (4H, m, aromatic (3H) and olefinic (1H) protons).

Found: C, 61.46; H, 6.35%. Calcd for $C_{15}H_{18}O_6$: C, 61.21; H, 6.17%.

The second fraction gave IVb (8.876 g) which was also recrystallized from ether containing petroleum ether to give colorless crystals; mp 56.5—57°C. A mixed-melting-point determination with the above IVa (mp 49—50°C) gave 34.5—36°C. NMR in $CDCl_3$: 3.61 (2H, d, J=1.5 Hz, -C$\underline{H}_2$-), 3.70 and 3.78 (each 3H and s, 2-$CO_2C\underline{H}_3$), 3.85 (6H, s, 2-OC$\underline{H}_3$), 5.67 (1H, t, J=1.5 Hz, =C$\underline{H}CO_2CH_3$), 6.68—6.83 (3H, m, aromatic protons).

Found: C, 61.16; H, 6.15%. Calcd for $C_{15}H_{18}O_6$: C, 61.21; H, 6.17%.

Methyl (±)-threo- (Va) and Methyl (±)-erythro-2,3-Dihydroxy-4-(3,4-dimethoxyphenyl)-3-methoxycarbonylbutyrate (Vb). *a)*: A solution of potassium permanganate (6.12 g) and magnesium sulfate heptahydrate (9.55 g) in water (270 m*l*) was stirred, drop by drop, into a solution of IVb (8.80 g) in methanol (255 m*l*) for 110 min at −20±2°C. The mixture was further stirred for 3 hr at this temperature, and then aqueous sodium bisulfite was added. The mixture was evaporated under a vacuum to remove the methanol, saturated with sodium chloride, and extracted with ethyl acetate, which was then washed with a saturated sodium chloride solution. After drying over sodium sulfate and removing the solvent, the residual solid was recrystallized from acetone to give methyl (±)-*erythro*-2,3-dihydroxy-4-(3,4-dimethoxyphenyl)-3-methoxycarbonylbutyrate (Vb) as colorless crystals; mp 142°C; yield, 4.17 g. NMR in $CDCl_3$: 3.28 (1H, s, -O$\underline{H}$), 3.28 (1H, d, J=8.5 Hz, -CH(O$\underline{H}$)-), 3.05 and 3.27 (2H, each d and J=14 Hz, -C$\underline{H}_2$-), 3.74 and 3.82 (each 6H and s, 2-$CO_2C\underline{H}_3$ and 2-OC$\underline{H}_3$), 4.54 (1H, d, J=8.5 Hz, -C$\underline{H}$(OH)-), 6.72 (3H, s, aromatic protons).

Found: C, 54.84; H, 6.10%. Calcd for $C_{15}H_{20}O_8$: C, 54.87; H, 6.14%.

b): A solution of IVa (1.09 g) in methanol was also hydroxylated with an aqueous potassium permanganate solution by a method similar to that used for (±)-Vb. The crude product was recrystallized from ether containing petroleum ether to give methyl (±)-*threo*-2,3-dihydroxy-4-(3,4-dimethoxyphenyl)-3-methoxycarbonylbutyrate (Va) as colorless crystals; mp 93—94°C; yield, 708 mg. NMR in $CDCl_3$: 3.07 (2H, s, -C$\underline{H}_2$-), 3.58 (1H, d, J=9 Hz, -CH(O$\underline{H}$)-), 3.71 (3H), 3.81 (6H), and 3.84 (3H) (each s, 2-$CO_2C\underline{H}_3$ and 2-OC$\underline{H}_3$), 4.43 (1H, d, J=9 Hz, -C$\underline{H}$(OH)-), 6.75 (3H, s, aromatic protons).

Found: C, 55.10; H, 6.16%. Calcd for $C_{15}H_{20}O_8$: C, 54.87; H, 6.14%.

(±)-threo- (VIa) and (±)-erythro-2,3-Dihydroxy-4-(3,4-dimethoxyphenyl)-3-carboxybutyric Acid (VIb). *a)*: A mixture of (±)-Vb (1.10 g) and aqueous potassium hydroxide (5%: 15 m*l*) was stirred on a steam bath for 40 min. After cooling, the mixture was acidified with dilute hydrochloric acid, saturated with sodium chloride, and then extracted with ethyl acetate. The extract, after having been washed with a saturated sodium chloride solution, was dried over sodium sulfate and then evaporated under a vacuum. The residue was recrystallized from acetone containing petroleum ether to give (±)-*erythro*-2,3-dihydroxy-4-(3,4-dimethoxyphenyl)-3-carboxybutyric acid (VIb) as colorless crystals; mp 179—180.5°C; yield, 830 mg. NMR in $(CD_3)_2CO$: 3.06 and 3.26 (2H, each d and J=13 Hz, -C$\underline{H}_2$-), 3.73 (6H, s, 2-OC$\underline{H}_3$), 4.57 (1H, s, -C$\underline{H}$(OH)-), 6.78 and 6.83 (3H, aromatic protons).

Found: C, 52.30; H, 5.54%. Calcd for $C_{13}H_{16}O_8$: C, 52.00; H, 5.37%.

The above (±)-VIb in acetone was methylated with diazomethane to give, after crystallization, colorless crystals (mp 142°C), which were shown to be identical with (±)-Vb by a mixed-melting-point determination and by a comparison of their IR spectra.

b): The dimethyl ester, (±)-Va, was also hydrolyzed with aqueous potassium hydroxide by a method similar to that used for (±)-VIb. The crude product was recrystallized from acetone to give (±)-*threo*-2,3-dihydroxy-4-(3,4-dimethoxyphenyl)-3-carboxybutyric acid (VIa) as colorless crystals; mp 112—115°C.

Found: C, 49.22; H, 5.81%. Calcd for $C_{13}H_{16}O_8 \cdot H_2O$: C, 49.06; H, 5.70%.

The above crystals were dissolved in acetone containing benzene, and the solution was then evaporated to dryness under a vacuum. The residue was recrystallized from acetone containing petroleum ether to give colorless crystals; mp 188—190°C. NMR in $(CD_3)_2CO$: 3.16 (2H, slightly separated d, -C$\underline{H}_2$-), 3.75 (6H, s, 2-OC$\underline{H}_3$), 4.43 (1H, s, -C$\underline{H}$(OH)-), 6.81 and 6.87 (3H, aromatic protons).

Found: C, 51.70; H, 5.37%. Calcd for $C_{13}H_{16}O_8$: C, 52.00; H, 5.37%.

The methylation of (±)-VIa with diazomethane gave (±)-Va.

Methyl (±)-threo- (VIIa) and Methyl (±)-erythro-2,3-Dihydroxy-4-(3,4-dimethoxyphenyl)-3-carboxybutyrate (VIIb). *a)*: A solution of (±)-VIb (200 mg) in methanol (3.0 m*l*) containing one drop of concentrated hydrochloric acid was allowed to stand at room temperature for 2 hr and then evaporated under a vacuum. The residue was recrystallized from a mixture of acetone and petroleum ether to give the corresponding monomethyl ester, (±)-VIIb (mp 185—186°C) as colorless crystals; yield, 110 mg. NMR in pyridine-d_5: 3.60 (9H, s, -$CO_2C\underline{H}_3$ and 2-OC$\underline{H}_3$), 3.62 and 3.83 (2H, each d, and J=14 Hz, -C$\underline{H}_2$-), 5.26 (1H, s, -C$\underline{H}$(OH)-).

Found: C, 53.52; H, 5.80%. Calcd for $C_{14}H_{18}O_8$: C, 53.50; H, 5.77%.

b): A mixture of (±)-VIa (1.20 g), concentrated hydrochloric acid (1.2 m*l*), and methanol (20 m*l*) was allowed to stand overnight at room temperature and was then evaporated under a vacuum. The residue was purified by means of column chromatography. A column was prepared from

a suspension of silica gel (100 g) in a mixture of benzene (400 ml) and acetone (140 ml) containing dilute sulfuric acid (20%: 6.0 ml). Elution was carried out with benzene containing 30% acetone to give a solid (1.02 g), which was then recrystallized from a mixture of acetone and petroleum ether to give the monomethyl ester, (±)-VIIa, as colorless crystals; mp 159—160°C; yield, 863 mg. NMR in $(CD_3)_2CO$: 3.04 (2H, s, $-C\underline{H}_2-$), 3.71 (6H) and 3.76 (3H) (each s, $-CO_2C\underline{H}_3$ and 2-$OC\underline{H}_3$), 4.40 (1H, s, $-C\underline{H}(OH)-$), 6.78 and 6.88 (3H, aromatic protons).

Found: C, 53.63; H, 5.73%. Calcd for $C_{14}H_{18}O_8$: C, 53.50; H, 5.77%.

Resolution of (±)-VIIb with Brucine. a): Brucine dihydrate (595 mg) was dissolved in a hot solution of (±)-VIIb (433 mg) in methanol (8.0 ml), after which the solution was allowed to stand at room temperature. The precipitates were collected, washed with acetone, and then recrystallized from methanol to give colorless crystals; mp 185—186°C dec.; yield, 490 mg. A mixed-melting-point determination with (±)-VIIb (mp 185—186°C) showed 175—178°C.

Found: C, 61.15; H, 6.13; N, 3.81%. Calcd for $C_{37}H_{44}O_{12}N_2 \cdot H_2O$: C, 61.00; H, 6.38; N, 3.86%.

A suspension of the above brucine salt (255 mg) in dilute hydrochloric acid (2N: 5.0 ml) was extracted with ethyl acetate. The extract was washed with water, dried over sodium sulfate, and then evaporated under a vacuum. The residue (132 mg) was recrystallized from a mixture of acetone and petroleum ether to give (+)-VIIb as colorless crystals; mp 138—139°C, $[\alpha]_D^{28}$+40.8° (*c* 1.25, methanol); yield, 114 mg.

Found: C, 50.82; H, 6.20%. Calcd for $C_{14}H_{18}O_8 \cdot H_2O$: C, 50.60; H, 6.07%.

b): The mother liquor in *a)*, after the separation of the brucine salt (490 mg: mp 185—186°C dec.), was evaporated under a vacuum. The residue was suspended in dilute hydrochloric acid (2N: 5.0 ml) and then treated by a method similar to that used for (+)-VIIb. The crude product was recrystallized from a mixture of acetone and petroleum ether to give (−)-VIIb as colorless crystals; mp 138—139°C, $[\alpha]_D^{28}$−38.0° (*c* 0.72, methanol); yield, 104 mg.

Found: C, 50.68; H, 5.98%. Calcd for $C_{14}H_{18}O_8 \cdot H_2O$: C, 50.60; H, 6.07%.

Hydrolyses of (+)-VIIb and (−)-VIIb. a): (+)-VIIb (245 mg) was hydrolyzed with aqueous potassium hydroxide (5%: 3.0 ml) by a method similar to that used for (±)-VIb. The crude product was recrystallized from a mixture of acetone and petroleum ether to give (+)-VIb as colorless crystals; mp 104—106°C, $[\alpha]_D^{28}$+40.3° (*c* 0.72, methanol); yield, 124 mg.

Found: C, 49.18; H, 5.75%. Calcd for $C_{13}H_{16}O_8 \cdot H_2O$: C, 49.06; H, 5.70%.

b): Similarly, (−)-VIIb was also hydrolyzed to (−)-VIb; mp 104—106°C, $[\alpha]_D^{25}$−40.5° (*c* 0.79, methanol).

Found: C, 49.27; H, 5.81%. Calcd for $C_{13}H_{16}O_8 \cdot H_2O$: C, 49.06; H, 5.70%.

(+)- and (−)-O,O'-Dimethylfukiic Acid Dimethyl Ester (Vb). a): The treatment of (+)-VIb or (+)-VIIb with diazomethane gave (+)-Vb as colorless crystals; mp 116—117°C, $[\alpha]_D^{26}$+40.5° (*c* 0.78, methanol).

Found: C, 54.89; H, 6.11%. Calcd for $C_{15}H_{20}O_8$: C, 54.87; H, 6.14%.

The synthetic (+)-Vb was shown to be identical with the natural *O,O'*-dimethylfukiic acid dimethyl ester (mp 117—118°C) by a mixed-melting-point determination and by comparisons of their IR and NMR spectra.

b): Similarly, (−)-VIb or (−)-VIIb was also methylated with diazomethane to (−)-Vb; mp 116—117°C, $[\alpha]_D^{26}$−39.7° (*c* 0.78, methanol).

Found: C, 55.04; H, 6.08%. Calcd for $C_{15}H_{20}O_8$: C, 54.87; H, 6.14%.

The authors are grateful to Professor S. Sakamura, Department of Agricultural Chemistry, Faculty of Agriculture, Hokkaido University, for his permission to publish this work and for the generous supply of a sample and copies of IR and NMR spectra of natural *O,O'*-dimethylfukiic acid dimethyl ester. Thanks are also due to Assistant Professor S. Yasuda, Department of Chemistry, Faculty of General Education of this University, for the measurements of the optical rotation.

Oxidation by Transition Metal Complexes. III. Oxidation of Cinnamaldehyde Catalyzed by Rhodium Compounds

Kiyotomi TAKAO, Masami WAYAKU, Yuzo FUJIWARA,
Toshinobu IMANAKA, and Shiichiro TERANISHI
Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Osaka
(Received November 4, 1971)

The catalytic activity of $RhCl(PPh_3)_3$ and $RhCl(CO)(PPh_3)_2$ for oxidations of styrene and cinnamaldehyde has been studied. Under oxygen atmosphere, these complexes can cause catalytically oxidation of cinnamaldehyde to give benzaldehyde, glyoxal, benzene and styrene. The reaction is complicated because decarbonylation reaction takes place with oxidation, and the carbonyl complex formed plays a catalytic role for the oxidation.

In previous papers,[1,2] we reported on the catalytic oxidation of styrene and methylstyrenes with some rhodium compounds under oxygen stream to produce the corresponding aldehydes and ketones.

In connection with this work, the catalytic oxidation of cinnamaldehyde by the rhodium complexes was investigated. It was found that some rhodium complexes have catalytic functions for oxidation, but the reaction is complicated because decarbonylation reaction also takes place at the same time. Cinnamaldehyde gave benzaldehyde and glyoxal by oxidation, and styrene and benzene by decarbonylation. It becomes apparent that the oxidation reaction might proceed *via* the carbonyl complex, $RhCl(CO)(PPh_3)_2$ formed by decarbonylation of the starting aldehyde. In the present paper we wish to report on the oxidation of cinnamaldehyde with rhodium complexes.

Results and Discussion

Catalytic oxidation of styrene with iridium and rhodium complexes under oxygen atmosphere[1,2] give benzaldehyde and acetophenone. The complex $RhCl(PPh_3)_3$ is known to be an efficient catalyst for decarbonylation of aldehydes.[3-6]

In order to investigate the relation between oxidation and decarbonylation, the relation between product concentrations and the time for the oxidation of styrene in toluene was examined.

The result is given in Fig. 1. We see that the concentration of benzaldehyde increases with reaction time very slowly during the first hour and then increases rapidly. After 8 hr, the yield of benzaldehyde became almost constant and reached 213%.[7]

Acetophenone was also formed in 13% yield. A 3% yield of benzene was attained by the decarbonylation of benzaldehyde.

From the fact that both oxidation and decarbonylation reactions take place simultaneously, we examined the decarbonylation of cinnamaldehyde with a $RhCl(PPh_3)_3$ catalyst before studying the oxidation of cinnamaldehyde.

Mixtures of the reactant cinnamaldehyde and $RhCl(PPh_3)_3$ in toluene were heated at 80°C for 8 hr under nitrogen stream.

Figure 2 shows that cinnamaldehyde easily undergoes decarbonylation to give styrene.

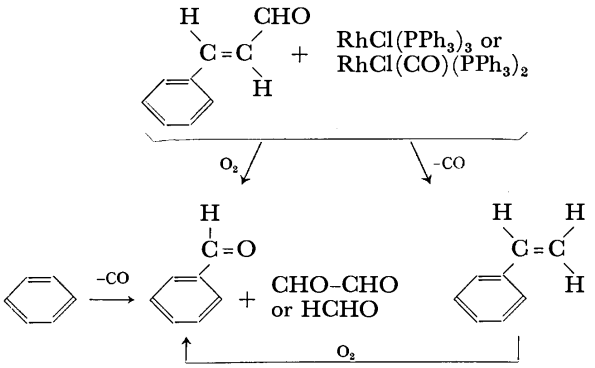
$RhCl(CO)(PPh_3)_2$	Toluene	9	30	968	trace

a) Yields are based on the catalyst used.



Scheme 1. Reaction scheme in the oxidation of cinnamaldehyde.

Oxidation reaction of cinnamaldehyde was then carried out under constant bubbling of oxygen (Table 1 and Scheme 1). The products were benzaldehyde (248%), styrene (97%), benzene (45%), glyoxal, and formaldehyde. The relation between the product concentration and the time for the oxidation reaction is given in Fig. 3.

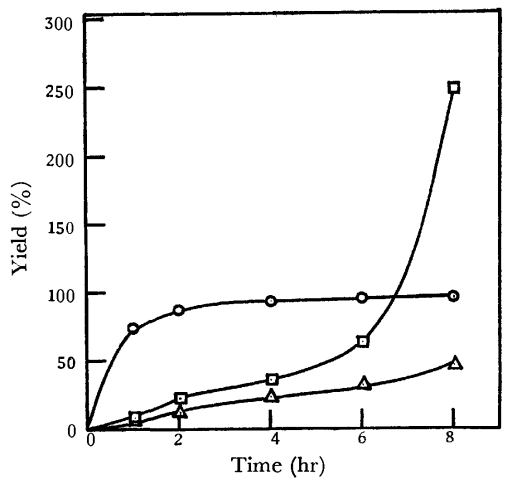


Fig. 3. Oxidation of cinnamaldehyde with $RhCl(PPh_3)_3$ in toluene.
□: Benzaldehyde, ○: Styrene, △: Benzene

It can be said that benzaldehyde is produced from the C=C double-bond cleavage of both cinnamaldehyde and styrene derived from the decarbonylation of cinnamadehyde. The fact that oxidation of both styrene and cinnamaldehyde has an induction period and involves decarbonylation reaction suggests that some rhodium carbonyl complexes formed play an important role for the oxidation catalyst. $RhCl(CO)(PPh_3)_2$ was obtained from the reaction mixtures. We therefore, examined the catalytic activity of the rhodium complex $RhCl(CO)(PPh_3)_2$ for oxidation reaction. Oxidation of cinnamaldehyde was carried out in the presence of $RhCl(CO)(PPh_3)_2$ under similar conditions. It was found that the carbonyl complex has remarkably high activity for the oxidation catalyst. A plot of the yields of products *versus* reaction time is given in Fig. 4.

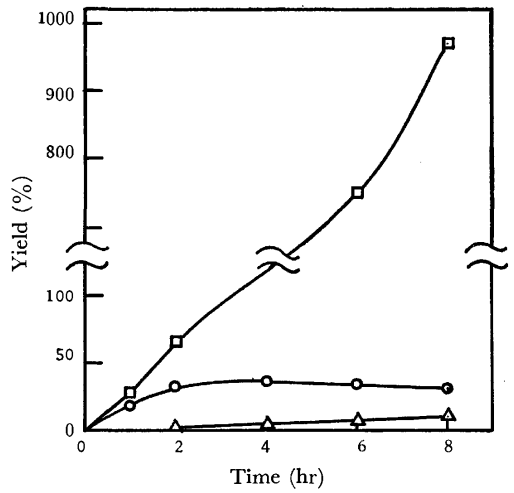

Fig. 4. Oxidation of cinnamaldehyde with $RhCl(CO)(PPh_3)_2$ in tolune.
□: Benzaldehyde. ○: Styrene. △: Benzene

The yield of benzaldehyde increased with reaction time and reached 968% after 8 hr.

On the other hand decarbonylation of aldehydes is very slow. The yield of styrene (30%) hardly changed with time and benzene derived from benzaldehyde was obtained in only 9% yield. The product distribution in the $RhCl(PPh_3)_3$ catalyst after the induction period (one hour) is very similar to that in the $RhCl(CO)(PPh_3)_2$ catalyst.

These results show that the $RhCl(PPh_3)_3$ catalyzed oxidation might proceed *via* the carbonyl complex, $RhCl(CO)(PPh_3)_2$.[8]

We reported that the catalytic oxidation of styrene with rhodium complexes undergoes a remarkable solvent effect.[2] Such an effect was also observed in the oxidation of cinnamaldehyde.

The catalytic oxidation of cinnamaldehyde with $RhCl(PPh_3)_3$ in ethanol gave styrene (127%) and acetophenone (8%).

8) $RhCl(CO)(PPh_3)_2$ liberates carbon monoxide during the catalytic decarbonylation.[5]

Alcohol is not a good solvent for the C=C double-bond cleavage.

Experimental

Materials and Analysis. All temperatures were uncorrected. Vpc analysis was made by a Yanagimoto G-8 gas chromatograph using Apiezon-L, Silicone OV-17 or Diethyl phthalate columns. Toluene and ethanol were purified as mentioned previously.[1] Cinnamaldehyde was dried over anhydrous magnesium sulfate and distilled.

Preparation of Rhodium Complexes. Chlorotris(triphenylphosphine)rhodium(I), $RhCl(PPh_3)_3$ and chlorocarbonylbis(triphenylphosphine)rhodium(I), $RhCl(CO)(PPh_3)_2$ were prepared by the method of Osborn *et al.*[9]

General Procedure for Oxidation by the Rhodium Complexes. The rhodium complex and cinnamaldehyde were dissolved in a solvent such as toluene. Under constant bubbling of oxygen the solution was heated at 80°C for 8 hr. After evaporation of the solvent, isolation of the products was carried out by gas or column chromatography.

9) J. A. Osborn, F. H. Jardine, J. F. Young, and G. Wilkinson, *J. Chem. Soc., C*, **1966**, 1711.

Oxidation of Cinnamaldehyde by Rhodium Complexes. In a flask similar to that described previously[1] was placed a mixture containing 2.83 g (3.06 mmol) of $RhCl(PPh_3)_3$, 15.5g (0.117 mol) of cinnamaldehyde and 150 m*l* of toluene as a solvent. The oxidation reaction was carried out at 80°C with constant bubbling of oxygen for 8 hr. At appropriate intervals, a portion of the solvent was analyzed as usual. After evaporation of the solvent under reduced pressure, the residual material was chromatographed on a silica-gel column (30 g). Elution with one liter of ether gave triphenylphosphine oxide. In addition, elution with 500 m*l* of methanol gave dark brown complexes. The complexes were further chromatographed on a silica-gel column to give a considerable amount of carbonyl complex $RhCl(CO)(PPh_3)_2$ and unidentified complexes (mp 210—213°C (decomp.)) which gave no carbonyl absorption. From vpc analysis and isolation of the solvent cinnamaldehyde, 0.97 g (248%) of benzaldehyde, 0.31 g (97%) of styrene, 0.11 g (45%) of benzene, glyoxal, and formaldehyde were obtained. From vpc analysis (activated carbon column) of the outlet gas, carbon monoxide was determined. In the case of the reaction in ethanol as solvent, we obtained cinnamaldehyde, 0.39 g (127%) of styrene and 0.03 g (8%) of acetophenone. The complex $RhCl(CO)(PPh_3)_2$ was isolated from the reaction mixtures.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1507—1515(1972)

Mercaptoacetate Derivatives. I. Reaction of Thiocyanatoacetic Esters with Aldehydes[1)]

Toshio HAYASHI

The Institute of Physical and Chemical Research, Wako, Saitama

(Received October 5, 1971)

An equimolar reaction of thiocyanatoacetic esters with aromatic aldehydes in the presence of sodium hydride, followed by treatment with hydrogen chloride, led to a mixture of 4-alkoxycarbonyl-5-aryl-2-imino-1,3-oxathiolane hydrochloride (**3**) and α-(*S*-carbamoylthio)-β-chlorodihydrocinnamic ester (**4**). When excess aldehyde was used in the reaction, a small amount of 2,10-bis(α-chlorobenzyl)-4,8-dioxo-6-phenyl-5,7-diaza-3,9-dithiaundecanedioate (**5**) was obtained, together with the products **3** and **4**. The NMR studies revealed that product **3** isolated exists all in one isomer which has the 4-ester and 5-aryl groups *cis* about a single bond in the ring. It was suggested that product **4** was formed by rearrangement of the *trans* isomer of **3**.

In a previous paper[2)] it was shown that the reaction of thiocyanatoacetic esters (**1**) with aldehydes occurs in the presence of potassium carbonate or fluoride to give a mixture of 5-substituted-*N*-carbamoyl-2-imino-4-alkoxy carbonyl-1,3-oxathiolanes (**2**) and α,β-unsaturated esters. In the course of study, it was found that sodium hydride is also an effective condensing agent for this reaction. The reaction of **1** with an aromatic aldehyde in the presence of sodium hydride, when followed by treatment with dry hydrogen chloride, led to a mixture of 2-imino-4-alkoxycarbonyl-5-aryl-1,3-oxathiolane hydrochloride (**3**) and two unexpected compounds (**4** and **5**).

1) Presented in part at the Autumn Meeting of the Chemical Society of Japan, Sapporo, August 29th (1970).

2) S. Kambe, T. Hayashi, H. Yasuda, and H. Midorikawa, This Bulletin, **44**, 1357 (1971).

Results and Discussion

An equimolar reaction of **1** and an aromatic aldehyde in the presence of sodium hydride at room temperature, on prolonged standing, produced cinnamic ester exclusively. However, the reaction, when conducted at −5°C and followed by treatment with dry hydrogen chloride, afforded a mixture of two solid compounds **3** and **4** in good yield. These compounds could be separated easily by utilizing the difference of the solubility in acetone. The ratios of the two components, as evaluated from the integration of the area under the appropriate NMR signals, varied widely with aldehydes used. The yields and physical properties of **3** and **4** are summarized in Tables 1 and 2, respectively. When excess aldehyde was used in the reaction, a small amount of high-melting compound (**5**), along with **3** and **4**, was

obtained. The yield and physical properties of **5** are summarized in Table 3. As can be seen from the Table, the yields of **3** and **4** are extremely low, when benzaldehydes having an electron-donating substituent are used. Aliphatic aldehydes and ketones did not give any solid compound. In contrast, the reactions with benzaldehydes having an electron-attractive group produced **3** and **4** in fair to excellent yield. It was found that the esters **4** with an electron-donating group on the benzene nucleus decompose gradually in solid state and more rapidly in the solutions.

The structural assignments were made on the basis of elemental analysis, spectral studies, and chemical reactivity. As shown in the Tables, **3** and **4** have the

br=broad, s=strong, m=medium.

same molecular formula, but their IR, NMR, and mass spectra showed marked differences (Figs. 1 to 6). In the IR spectrum of **3b** (KBr pellet), a complex series of absorptions between 3500 and 2500 cm^{-1} suggests the presence of the imine hydrochloride, while with **4b**, rather sharp bands in the ranges 3410—3182 cm^{-1} are due to the NH_2 stretching vibrations. These assignments may be supported by the following facts: **3**'s were readily soluble in water and when treated with silver nitrate reagent, showed a positive test for chloride ion. Convincing evidence for the structure of **3** may be supplied by the fact that **3b**, when treated with an equimolar amount of potassium cyanate, produced *N*-carbamoyl-2-imino-4-ethoxycarbonyl-5-phenyl-1,3-oxathiolane (**2b**), which was synthesized alternatively in previous papers.[2,3] Hence, the structure of **3** was determined to be 2-imino-4-alkoxycarbonyl-5-aryl-1,3-oxathiolane hydrochloride. The NMR and mass spectra support this assignment. In the mass spectrum of **3b** (Fig. 5), one observed a M–HCl ion as the highest mass peak, which is not seen in the spectrum of **4b**. Subsequent fragmentations may proceed in the way shown in Scheme 2. The base peak appears at *m/e* 135, which may correspond to C_6H_5–C_2H_2S.

In the spectrum of **4b**, a rearrangement peak (M–HOCN) is observed at *m/e* 244, which may arise by the four-center mechanism from the molecular ion. Similar rearrangement peak has been observed in the case of *S*-methyl phenylthiocarbonate[4] and *S*-(2-chloropropyl)-thiocarbamate.[5] The base peak at *m/e* 125 and an abundant peak at *m/e* 211 evidently contain a chloride atom, because the peaks are accompanied by a +2 isotope peak amounting to about a third of the intensity. Other abundant peaks appear at the same positions as observed in the case of **3b**. A plausible explanation for these fragmentation processes is depicted in Scheme 2. It is postulated that **4b** has the structure of ethyl α-*S*-carbamoylthio-β-chloro-dihydrocinnamate. The IR and NMR spectra of **4b** (Figs. 2 and 4) are in agreement with this assignment. The spectral data of **4** are summarized in Tables 6 and 7. The chemical shifts of the α-protons are in the ranges 4.67 to 4.89 ppm and those

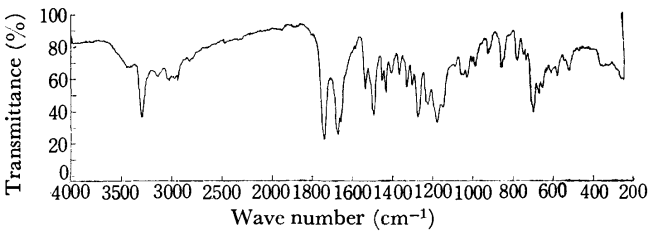

Fig. 7. IR spectrum of **5b** (KBr pellet).

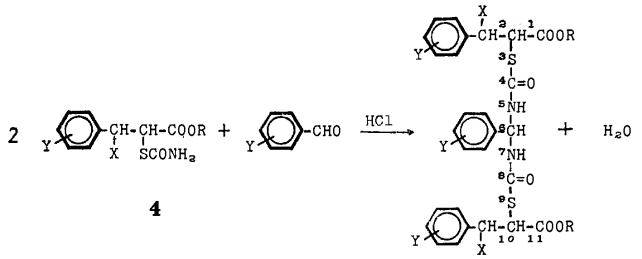
5) See the experimental section.

of the β-protons are in the ranges 5.30 to 5.54 ppm, except for **4g**.

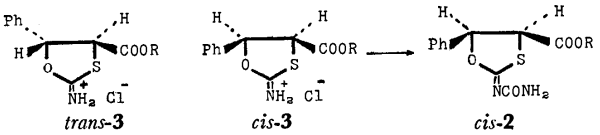
The analytical and spectral data of the high-melting solid products (**5**) are summarized in Tables 3, 8, and 9. The NMR spectrum revealed that the condensation occurred between the NH_2 groups of **4** and the C=O group of an aldehyde. In the spectrum of **5e** (Fig. 8), a triplet at 6.23 ppm and a doublet at 9.15 ppm (J= 7.6 Hz), whose coupling was confirmed by double resonance experiment, are attributable to the proton at the 6-position and the two NH protons, respectively, this being indicative of the NH–CH–NH system. This assignment may be supported by the fact that **5** was alternatively synthesized by treating a mixture of **4** and an aldehyde (mole ratio=2: 1) with dry hydrogen chloride. In Table 9, the chemical shifts of the corresponding **4**'s



4 **5**

are given along with those of **5**'s for comparison. The signals of the H_α, H_β, and alkoxycarbonyl protons for **5** appeared at almost the same positions as those for **4**. The IR spectrum showed a single absorption band in the NH stretching frequency region (Fig. 7 and Table 8). On the basis of the above data, the structure of **5** was determined to be 2,10-bis(α-chlorobenzyl)-4,8-dioxo-6-phenyl-5,7-diaza-3,9-dithiaundecanedioate.

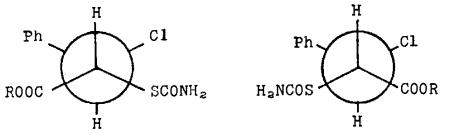
Geometric Configurations. 2-Imino-4-alkoxycarbonyl-5-aryl-1,3-oxathiolane hydrochlorides (**3**) can exist in two isomeric forms, relative to arrangements of the aryl and alkoxycarbonyl groups about a single bond in the ring. The isolated **5**, which proved to contain



trans-**3** *cis*-**3** *cis*-**2**

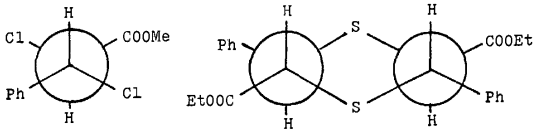
only one isomer, when treated with an equimolar amount of sodium cyanate, led to the *cis* isomer of the corresponding *N*-carbamoyl drivative (**2**), whose geometric configuration was established in a previous paper.[3] It may be safely assumed that the geometric configuration is retained during the conversion of **3** to **2**. Therefore, **3** has the *cis* configuration. Further supports for this may be supplied by the fact that the alkoxycarbonyl protons of **3** are located at higher field by *ca.* 0.50 ppm rather than those of the corresponding ester **4**, and that the $J_{\alpha\beta}$ values for **3** are in the ranges 6.1±0.1 Hz. It was established in a previous paper[3] that the *cis* forms for **2** have the alkoxycarbonyl signals at higher field by *ca.* 0.50 ppm than the *trans* forms, whose alkoxycarbonyl protons appear at almost the same positions as the ordinary esters, and that the $J_{\alpha\beta}$ values for the *cis* forms are in the range of 6.0 to 6.4 Hz. Presumably, the conformations of **3** do not differ too greatly from those of **2**.

The product **4** can exist in two diastereoisomeric forms as shown below. However, the NMR spectra revealed that all the products **4** obtained in the



threo-s *erythro*-s

present work consisted of single diastereomer. The vicinal $J_{\alpha\beta}$ values for **4** are consistently 11.3±0.1 Hz except for **4c**. It was reported that the $J_{\alpha\beta}$ values for *erythro*- and *threo*-α,β-dichlorodihydrocinnamic esters are 11.0 and 8.6 Hz, respectively[6] and that the $J_{\alpha\beta}$ value for methyl *erythro*-*p*-methoxy-α,β-dibromodihydrocinnamate is 12.0 Hz.[7] The *erythro* forms of α,β-dihalodihydrocinnamic esters are considered to be heavily populated in a conformation having the two protons in *trans* position as shown.[8] Since the electro-



9

negativities of the carbamoylthio group and the chlorine atom are estimated to be almost the same,[9] the displacement of the α-chlorine atom by the carbamoylthio group should not lead to any significant effect on the magnitude of the $J_{\alpha\beta}$ value. Therefore, the Karplus rule[10] suggests that products **4** may be present predominantly in a conformation with the two protons in *trans* positions as shown above, whether *threo*-s or *erythro*-s.[11] If the steric requirement of the alkoxycarbonyl group would be larger than that of the carbamoylthio group, **4** might have the *erythro*-s configuration, and if the reverse would be true, the *threo*-s.[12] If the carbamoylthio group would be bulkier than the alkoxycarbonyl group, the displacement of the ethoxycarbonyl by the bulkier group should lead to the decrease in the $J_{\alpha\beta}$ value. However, the introduction of the *tert*-butyl group into the ester moiety made no change on the $J_{\alpha\beta}$

value. Barbieux and Martin[13] reported that in the case of ethyl α,β-dialkyl-*p*-methoxydihydrocinnamates, the $J_{\alpha\beta}$ values are not a reliable indication of configurations, but that the chemical shifts of the ester protons are located at higher field for the *threo* forms by *ca.* 0.27 to 0.33 ppm than for the *erythro* forms, presumably due to the long-range shielding of the benzene ring. Examination of available data on α,β-dihalodihydrocinnamic esters also demonstrates that the ester protons resonate at higher field for the *threo* isomers by *ca.* 0.3 ppm than for the *erythro* isomers. On the other hand, it is interesting to observe that the chemical shifts of the ester protons for 2,5-diphenyl-3,6-diethoxycarbonyl-1,4-dithiane (**9**) appear at higher field by *ca.* 0.30 ppm than those of the ordinary ester. Since the $J_{\alpha\beta}$ value (10.5 Hz) indicates that the protons are in the axial conformation, the phenyl and ester groups should be present in the *equatorial* conformation. Therefore, as shown above, the spatial relationships of the phenyl and ester groups are the same for the dithiane **9** and the *threo*-s form of **4**. Consequently, if **4** has the *threo*-s configuration, the ester protons should resonate at higher field by *ca.* 0.3 ppm rather than the ordinary ester protons. However, the observed chemical shifts for the ester protons of **4** are at almost the same position as the ordinary ester, this being suggestive of the *erythro*-s configuration. All attempts to detect the *threo*-s form were unsuccessful and the solvent effects on the $J_{\alpha\beta}$ value for **4** were not observed.

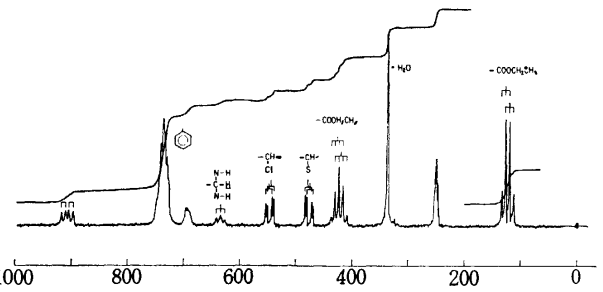

Fig. 9. NMR spectrum of **5b** in DMSO-d_6 (100 MHz).

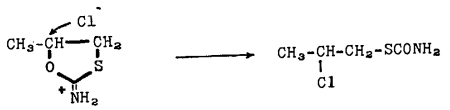
One further problem to explain concerns the NMR spectra of product **5** (Table 9 and Fig. 9). As can be seen from Fig. 9, all the signals are duplicated with almost equal intensities. This is not due to the magnetic non-equivalence of the two cinnamate moieties in a molecule of **5**, because in the case of **5d**, two sets of signals with unequal intensities (**5d**: **5d'**=2.1: 1) were observed. Therefore, this duplication should be attributed to the presence of two chemical species. A plausible explanation is that the two enantiomers of **4** condenced with an aldehyde to give new diastereomers, which showed slightly different chemical shifts.

Reaction Mechanism. A possible mechanistic pathways for the reaction of the ester **1** with aldehydes are proposed in Scheme 1. There is little doubt that the reactions proceed through the intermediacy of α-thiocyanato-β-hydroxydihydrocinnamic ester (**6**) and 2-imino-4-alkoxycarbonyl-5-aryl-1,3-oxathiolane (**7**). The pathway leading to α,β-epithio-ester (**8**) is analogous to the route established by van Tamelen[14] for the conversion of oxiranes to thiiranes. Accordingly, this reaction has been at first considered to be a convenient one-step synthetic route to unknown α,β-epithio-esters.[15] However, the α,β-epithio-esters are unstable and readily lose sulfur, forming cinnamic esters.[16] In fact, when the reactions were conducted at room temperature and followed by prolonged standing, cinnamic esters were exclusively obtained.

The most probable route leading to ester **4** from hydrochloride **3** would be considered to be the molecular rearrangement of the hydrochloride **3**. It is known that 2-imino-1,3-oxathiolane hydrochloride readily isomerize on heating or prolonged standing into *S*-alkyl thiocarbamate.[17,18] However, it is suprising that



hydrochloride **3** resisted all our attempts to effect ring-opening, only starting material being recovered. Under the more drastic conditions, cinnamic esters and unidentified decompsotion compounds were obtained. A possible explanation may be offered as follows. There is a marked difference in the reaction rates between the *cis* and *trans* isomers of **3**, presumably due to the steric reason. Similar stereoselectivity has been observed before in the case of three-membered ring.[19] All attempts to detect the *trans* isomer of **3** have failed, but when the reaction mixture was neutralized carefully with hydrogen chloride gas at low temperature, *trans*-*N*-carbamoyl derivative **2** was obtained in 10% yield. Since it was confirmed that *cis*-**2** could not be isomerized into *trans*-**2**,[3] this means that *trans*-**7** should exist in the reaction mixture. Presumably, *trans*-**3** may be attacked very rapidly at the 5-position by halide ion to give the ester **4**, whereas *cis*-**3** may resist to be attacked by the halide ion and therefore, can be isolated as the hydrochloride **3**. This speculation may be supported by the fact that *trans*-**2**, when treated with hydrochloric acid, is readily converted into α-(ureidocarbonylthio)-β-chlorodihydrocinnamic ester (**10**), whereas *cis*-**2** does not undergo the ring-opening under the similar conditions.

Furthermore, if *trans*-**3** would undergo an S_N2-type ring opening reaction, as in the case of the reaction of aziridines with hydrochloric acid,[20] only the *erythro*-s isomer should be produced as shown below. If the reaction would proceed by an S_N1-type mechanism, a mixture of two diastereomers should be obtained. The results suggest that the rearrangement of *trans*-**3** to **4** might be an S_N2-type reaction. Further studies on the mechanism for this are now in progress.

Experimental

All the melting points are uncorrected. NMR spectra were obtained with Varian HA-100D and JEOL C-60 spectrometers in DMSO-d_6, acetone-d_6, and $CDCl_3$ solutions using tetramethylsilane as internal standard. IR spectra were determined in KBr pellet using a Perkin-Elmer 521 spectrophotometer. Mass spectra were taken with a JMS-01SG instrument operating at 75 eV.

Preparation of Thiocyanatoacetic Esters (1). The esters were prepared by a modification of Heintz's method.[21] A mixture of chloroacetic ester (1 mol) and ammonium thiocyanate (1.5 mol) in 200 m*l* of ethanol was stirred at 50°C for 3 hr. After cooling the mixture, the precipitated ammonium chloride was removed by filtration, and the filtrate was concentrated under reduced pressure. The deposited ammonium chloride was again removed by filtration and washed with ether. The filtrate and the washings were combined and washed with a small amount of water. The ethereal solution was subjected to distillation, bp 108—109°C/12 mmHg for methyl ester, 108—111°C/8 mmHg for ethyl ester, and 110—112°C/8 mmHg for *tert*-butyl ester. *tert*-Butyl ester is a new compound. IR (neat): 2160 (νSC≡N), and 1736 cm^{-1} (νC=O).

Found: C, 48.61; H, 6.41; N, 7.72; S, 18.04%. Calcd for $C_7H_{11}NO_2S$: C, 48.56; H, 6.41; N, 8.09; S, 18.52%.

Reaction of Thiocyanatoacetic Esters (1) with an Aldehyde in the Presence of Sodium Hydride. General Procedure: In a three-necked round-bottomed flask fitted with an apparatus specially designed for addition of sodium hydride, a thermometer, and a reflux condenser protected with a calcium chloride tube, was placed thiocyanatoacetic ester (0.03 mol), an aldehyde (0.03 mol) and 40 m*l* of dried glyme. After the air in the flask was replaced with dry nitrogen, the flask was cooled to −5°C in a freezing mixture. Sodium hydride (0.03 mol) was slowly added to the solution so that the temperature did not rise over −2°C. After the addition of sodium hydride was over, the solution was stirred at −5°C for additional 30 min. Dry hydrogen chloride gas was passed through the solution below 0°C for 10 min, and the resulting sodium chloride was removed by filtration. The solvent was removed under reduced pressure and the residue was washed with ether repeatedly, until colored materials were removed. A fraction of the solid products was subjected to the NMR analysis for the measurement of the ratio of **3** to **4**. The solid products were dissolved in 15 m*l* of acetone and the insoluble material was collected on a filter. The filtrate was concentrated on a steam bath to yield a purple-tinged white needles (**4**). The acetone-insoluble material obtained above was dissolved in ethanol and an insoluble solid was removed by filtration. The filtrate was concentrated under reduced pressure to give almost pure hydrochloride **3**.[22]

Reaction of Thiocyanatoacetic Esters (1) with Excess Aldehyde in the Presence of Sodium Hydride. A solution of thiocyanatoacetic ester (0.03 mol) and an aldehyde (0.05 mol) in 40 m*l* of dry glyme was treated with 0.03 mol of sodium hydride, as described above. The reaction mixture was saturated with dry hydrogen chloride, the resulting sodium chloride was removed by filtration, and the filtrate was concentrated under reduced pressure. The residues were washed with ether and then dissolved in 20 m*l* of acetone. The insoluble materials were washed with 20 m*l* of ethanol and recrystallized from glyme–ethanol (1:1) to give compound **5**. The washings were concentrated to yield hydrochloride **3**. The acetone solution obtained above, when the solvent was removed, gave ester **4**, which was recrystallized from ethanol.

Reaction of Thiocyanatoacetic Esters (1) with an Aldehyde in the Presence of Potassium Carbonate. A mixture of thiocyanatoacetic ester (0.03 mol) and an aldehyde (0.03 mol) in 20 m*l* of moist ether was stirred in the presence of potassium carbonate (5.0 g) at room temperature for 4 hr. After the catalyst was removed by filtration and washed with 20 m*l* of acetone, the filtrate and the washings were combined and then saturated with dry hydrogen chloride. The solvents were removed by blowing air on the solution and the resulting solid products were washed with ether. Hydrochloride **3** and ester **4** were separated and purified as described above. It was found that this method gave a higher yield of **3** than the method using sodium hydride.

Conversion of Hydrochloride 3 to Ester 4. To a solution of hydrochloride **3** (1.5 g) in 3 m*l* of water was added a solution of sodium cyanate (0.4 g) in 2.0 m*l* of water and the solution was allowed to stand at room temperature for 10 min. The resulting precipitate was recystallized from ethanol, mp 159—160°C. The mixture of this crystals with an authentic sample of *trans*-**2b** did not show a depression in melting point.

Preparation of Compound 5 from Ester 4 and an Aldehyde. General Procedure: A mixture of ester **4** (0.01 mol) and an aldehyde (0.005 mol) in 10 m*l* of glyme was saturated with dry hydrogen chloride and then allowed to stand overnight in a refrigerator. The resulting crystals were collected on a filter, washed with ether, and then recrystallized from glyme–ethanol mixture (1:1). In some cases, crystals did not appear in the solutions, but concentration and cooling of the solution yielded the product **5**.

Conversion of 2-Imino-5-methyl-1,3-oxathiolane Hydrochloride into S-(2-chloropropyl)thiocarbamate. 2-Imino-5-methyl-1,3-oxathiolane hydrochloride was prepared according to the method of Price and Kirk.[23] The white needles were very hygroscopic, mp 115—118°C (lit,[23] 112—115°C). IR (KBr) 3100—2800 cm^{-1} (νNH_3), 1660 (νC=N); NMR (DMSO-d_6) δ 1.56 (CH_3, d, J_{ab}=6.6 Hz), 3.95 (CH_a, J_{ab}=11.4, J_{ax}=5.9 or 8.6), 3.97 (CH_b, m, J_{ab}=11.4, J_{bx}=8.6 or 5.9), 5.48 (CH_x, m), and 11.85 (NH_3, broad); Mass spectra, molecular

ion *m/e* 153, base peak *m/e* 117, and a peak at *m/e* 74.

2-Imino-5-methyl-1,3-oxathiolane hydrochloride (2.0 g) was heated to 120°C for 30 min. The solid was recrystallized from ether–carbon tetrachloride mixture (1: 1), mp 92°C. IR (KBr) 3380, 3320, 3210, 3180 cm^{-1} (ν NH_2), and 1655 (ν C=O). NMR ($CDCl_3$) δ 1.57 (CH_3, d, J=6.6 Hz), 3.26 (CH_2, d, J=6.0), 5.17 (CH, m), and 5.87 (NH_2, broad); molecular ion, *m/e* 153, 117 (M−HCl), 110 (M−HOCN), and base peak *m/e* 74.

Found: C, 31.08; H, 5.12; N, 9.33; S, 20.64; Cl, 23.06%. Calcd for C_4H_8NOSCl: C, 31.27; H, 5.25; N, 9.12; S, 20.87; Cl, 23.08%.

Attempted Rearrangement of cis-**3b** *to* **4b**. *a)*: A solution of 0.5 g of *cis*-**3b** in 5 m*l* of glyme was bubbled with dry hydrogen chloride gas for five min, and then allowed to stand at room temperature for two days. Concentration of the solution gave the starting material only.

b): In a round-bottomed flask was placed 0.3 g of *cis*-**3b** and then heated to the melting point for five min. The solid mass was washed with ether and then recrystallized from ethanol. The melting point measurement and IR spectrum of the crystals were in agreement with those of *cis*-**3b**. The residue obtained from the washings proved to be ethyl cinnamate by glc.

c): A solution of 0.3 g of *cis*-**3b** in 5 m*l* of 99% ethanol was saturated with hydrogen chloride gas and then refluxed for 30 min. Concentration of the solution gave a high-melting product, which did not melt at 250°C. The structure of this product remains unsolved.

Conversion of trans-**2b** *to* **10b**. Dry hydrogen chloride was passed through 5.0 m*l* of glacial acetic acid for five min, and then 0.5 g of *trans*-*N*-carbamoyl-2-imino-4-ethoxycarbonyl-5-phenyl-1,3-oxathiolane (*trans*-**2b**) was dissolved. The solution was kept at 100°C for three min and then acetic acid was removed under reduced pressure. The residue was recrystallized from ethanol to give 0.3 g of **10b** melting at 167—168.5°C. IR spectrum (KBr pellet) 3397, 3320, 3215 cm^{-1} (ν NH_2 and ν NH), 1748 (ester C=O), 1730 (carbamoyl C=O), 1674 (allophanate C=O), and 1620 cm^{-1} (δ NH_2). NMR spectrum (acetone-d_6) 1.27 ppm (ester CH_3, t), 4.25 (ester CH_2, q), 4.85 (H_α, d, J=11.0 Hz), 5.39 (H_β, d, J=11.0), 6.80 (NH_2, br), 7.40 (C_6H_5, m), and 9.70 (NH, br).

Found: C, 46.90; H, 4.58; N, 8.49; S, 9.61; Cl, 10.13%. Calcd for $C_{13}H_{15}N_2O_4SCl$: C, 47.20; H, 4.57; N, 8.47; S, 9.69; Cl, 10.72%.

Attempted Conversion of cis-**2b** *to* **10b**. Dry hydrogen chloride was passed through 5.0 m*l* of glacial acetic acid for five min, and then 0.5 g of *cis*-*N*-carbamoyl-2-imino-4-ethoxycarbonyl-5-phenyl-1,3-oxathiolane (*cis*-**2b**) was dissolved. The solution was kept at 100°C for five min, and then acetic acid was removed under reduced pressure. The residue was recrystallized from ethanol to give the starting material.

The author wishes to express his thanks to Dr. Hiroshi Midorikawa of this institute and Mr. Satoshi Kambe of Oyama Technical College for fruitful discussions of the problems. Thanks are also due to Messrs. Tetsuro Yokono and Ko-ichi Iyama and Miss Makiko Akano for generous assistance in carrying out the experiments.

(Received October 22, 1971)

Ethylmesitylene reacts with fuming nitric acid in dichloromethane at −5—0°C to give mononitroethylmesitylene, 3,5-dimethyl-4-ethylbenzyl nitrate, 2-nitro-3,5-dimethyl-4-ethylbenzyl nitrate and a dinitroethyltrimethylcyclohexenone, while on nitration with mixed acid it yields mono and dinitro derivatives as the major products, together with minor quantities of 2-nitro- and 2,6-dinitro-3,5-dimethyl-4-ethylbenzyl nitrates, diphenylmethanes, and unidentified nitro-carbonyl compounds, possibly nitrobenzaldehydes. Similar results are obtained from the nitration of *n*-propylmesitylene. If the hydrocarbons are nitrated by adding into a large excess of the nitrating agent, the major product is 2,6-dinitro-3,5-dimethyl-4-alkylbenzyl nitrate soon after the reaction, or 2,6-dinitro-3,5-dimethyl-4-alkylbenzaldehyde when the mixture is left to stand at room temperature. The nitro compound melting at 123°C, obtained by Smith and Kiess[2] from the nitration of ethylmesitylene and described as trinitro-4-ethyl-*o*-xylene, is identified as 2,6-dinitro-3,5-dimethyl-4-ethylbenzyl nitrate. An uncharacterized nitration product (mp 135°C) from *n*-propylmesitylene, obtained by Töhl and Tripke,[3] is found most likely to be 2,6-dinitro-3,5-dimethyl-4-*n*-propylbenzyl nitrate (mp 139—140°C).

Action of electrophilic reagent upon polyalkylbenzenes sometimes results in the migration of alkyl groups, giving products of orientation quite different from those predicted by the ordinary substitution rules. Such anomalies are frequently met and well documented

particularly in the sulfonation and acylation.[4] Meanwhile, the nitration of polyalkylbenzenes has generally been recognized not to involve such alkyl rearrangement, and therefore, their polynitro derivatives have been widely used for the characterization of isomeric series of polyalkylbenzenes.

Literature so far contains one exception which seems to involve both displacement and intramolecular migration of alkyl groups during the nitration. Töhl and Tripke[3] nitrated ethylmesitylene (2-ethyl-1,3,5-trimethylbenzene) with fuming nitric acid and obtained the product melting at 123°C, to which they assigned the dinitro structure on the basis of elemental analysis. Their claim was later re-examined by Smith and Kiess,[2] who showed that the hydrocarbon can afford two different nitro compounds depending on the nitrating conditions employed. When ethylmesitylene dissolved in chloroform was thoroughly stirred with sulfuric acid and slowly nitrated with fuming nitric acid at 0°C, the product was white needles melting at 110—111°C. Elemental analysis and chemical behavior were consistent with its formulation as dinitroethylmesitylene. However, treatment of the hydrocarbon with mixed acid (H_2SO_4 - HNO_3, 2: 1 v/v) at 0°C furnished the nitro compound of Töhl and Tripke, mp 123°C, which showed a large depression in melting point on admixture with the above nitro compound of mp 110—111°C. It did not afford on reduction with stannous chloride the expected diamino compound but gave an unidentified yellow substance melting at 255°C. Elemental analysis was close to that of a trinitroethylxylene, but the substance was found neither to be trinitro-4-ethyl-*m*-xylene (mp 129°C) nor trinitro-2-ethyl-*m*-xylene (mp 181°C), which could arise from ethylmesitylene through the displacement of one of methyl groups by nitro group. Hence they suggested the higher melting nitro compound as trinitro-4-ethyl-*o*-xylene (mp 121°C) on the evidences obtained from analysis and mixed melting determination. The formation of trinitro-4-ethyl-*o*-xylene from ethylmesitylene requires the intramolecular migration of at least one alkyl group during the nitration. In the lights of our present knowledge, such isomerization of polyalkylbenzenes seems to be quite unusual. Thus we have re-examined the early workers' results with the aims to solve the discrepancies in the literature as well as to ascertain if the nitration of ethylmesitylene can in fact lead to the claimed rearrangement of alkyl groups.

When a solution of ethylmesitylene in dichloromethane was treated with excess of fuming nitric acid (d=1.5) at −5—0°C, a dark red oily substance was obtained, which showed strong infrared bands due to benzyl nitrate at 1532 and 1364 (NO_2); 1648, 1272, and 844 cm^{-1} (ONO_2); a prominent PMR peak due to CH_2ONO_2 at 4.75 τ. Weak infrared bands due to carbonyl and hydroxyl groups were also observed at around 1700 and 3400—3500 cm^{-1}. Chromatography on alumina of the product mixture gave besides unchanged hydrocarbon (17%) mononitroethylmesitylene (42%) from light petroleum eluates, bis(4-ethyl-3,5-dimethylbenzyl) ether (3%) and nitro-carbonyl compounds (*ca.* 7%) from light petroleum - benzene mixture eluates, and 3,5-dimethyl-4-ethylbenzyl alcohol (7%) from ether eluates.[5] Bis-benzyl ether and benzyl alcohol were probably the secondary products from benzyl nitrate formed during the elution through activated alumina.

Chromatography on silica gel of the same product mixture proved to be unsatisfactory for the separation of nitro compounds from nitrooxymethyl compounds. However, a new alicyclic nitro-ketone, 5,6-dinitro-2,4,6-trimethyl-3-ethyl-3-cyclohexen-1-one (mp 140—141°C, crude yield 3—4%) was obtained as fine needles from the nitro-carbonyl fractions eluted with benzene-light petroleum mixture. The proof of structure for this unexpected product will be treated in the subsequent paper.[6]

When the nitration of the hydrocarbon was conducted by adding into the large excess of fuming nitric acid at −5—0°C, the major product which readily deposited from the dark reaction mixture was white needles melting at 120—122°C, the product described by Töhl and Tripke as dinitroethylmesitylene and by Smith and Kiess as trinitroethylxylene. The result of C, H analysis was quite close to that of trinitroethylxylene, as had been reported by American workers. However, its infrared spectrum contained prominent bands due to $-ONO_2$ group at 1645, 1270, and 843 cm^{-1} besides the expected absorptions of nitro group at 1530 and 1363 cm^{-1}, while PMR spectrum depicted the presence of one ethyl group (3H, 8.83 t; 2H, 7.21 q; J=8 Hz), two equivalent methyl groups (6H, 7.71 s) and one methylene group (2H, 4.67 s). These spectral evidences unambiguously show that the nitro compound melting at 123°C is not trinitro-4-ethyl-*o*-xylene but 2,6-dinitro-3,5-dimethyl-4-ethylbenzyl nitrate. In spite of its narrow melting range and brilliant crystalline form, the PMR spectrum revealed that the benzyl nitrate was usually accompanied by a small amount of dinitroethylmesitylene. It was quite tedious to remove this minor impurity without a considerable loss of the material. Obviously, the earlier workers have taken the less pure nitrate for trinitroethylxylene, since the presence of the dinitro derivative as impurity can contribute to the increase in the carbon content of the product. We can therefore conclude that the nitration of ethylmesitylene does not involve any rearrangement of alkyl groups under the ordinary conditions of the reaction.

Action of mixed acid (H_2SO_4 - HNO_3, 1:1 w/w) upon ethylmesitylene in dichloromethane at −5—0°C gave an oily substance, which on alumina chromatography gave besides unchanged starting material (*ca.* 4%) mononitro and dinitro derivatives (24 and 26%, respectively) as the major products from light petro-

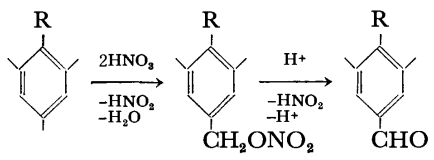
leum eluates, diphenylmethane and nitro-carbonyl compounds (less than 4%) from light petroleum-benzene eluates, and a mixture of nitrobenzyl alcohols (8%) from ether eluates. Diphenylmethane was probably formed by the sulfuric acid-catalyzed condensation of 2-nitro-3,5-dimethyl-4-ethylbenzyl nitrate with mononitroethylmesitylene.[7] The main component of the nitro-carbonyl fractions was presumably nitrobenzaldehydes, which could arise from nitrobenzyl nitrates under the influence of sulfuric acid.[8]

In connection with the present work, the nitration of *n*-propylmesitylene was re-examined with the expectation that the uncharacterized compound melting at 135°C, obtained by Töhl and Tripke[3] in the nitration of *n*-propylmesitylene, might be also a benzyl nitrate. A solution of the hydrocarbon in dichloromethane was treated with fuming nitric acid at −5—0°C to give a dark yellow oil, which on chromatography over alumina was separated into unchanged hydrocarbon (2%), mononitro-*n*-propylmesitylene (59%), impure bis(3,5-dimethyl-4-*n*-propylbenzyl) ether (3%), nitro-carbonyl compounds (*ca.* 5%), and 3,5-dimethyl-4-*n*-propylbenzyl alcohol (4%) and its nitro derivatives (2%).

When the nitration was conducted by dissolving the hydrocarbon into a large excess of cold fuming nitric acid, appreciable amounts of crystalline product were soon precipitated from the reaction mixture, which was immediately collected on a glass filter and recrystallized from a mixture of ligroin and dichloromethane. Colorless plates thus obtained melted at 139—140°C and had the formula $C_{12}H_{16}N_3O_7$. It showed infrared bands for nitro group at 1530 and 1361 cm^{-1} and those for nitrooxy group at 1644, 1277, and 857 cm^{-1}. Its PMR spectrum contained peaks due to one *n*-propyl group (3H, 8.95 t, J=7 Hz; 2H, 8.37—8.62 m; and 2H, 7.28 t, J=7 Hz), two equivalent methyl groups (6H, 7.72 s), and one methylene group (2H, 4.69 s). These analytical and spectral data were only compatible with the formulation of the product as 2,6-dinitro-3,5-dimethyl-4-*n*-propylbenzyl nitrate. Since there is no reason to believe that *n*-propylmesitylene behaves on nitration differently from ethylmesitylene, the product of Töhl and Tripke seems most likely to be the above nitrate although the original paper contains no detail to confirm its structure. If the hydrocarbon was dissolved into excess of fuming nitric acid in a ice-salt bath and the mixture was allowed to stand overnight without adding further amounts of ice, the well crystallized solid which separated on the surface of the acid medium was mainly 2,6-dinitro-3,5-dimethyl-4-*n*-propylbenzaldehyde. The initially formed benzyl nitrate was no doubt converted into the aldehyde under the influence of acid reagent.



R: Et or *n*-Pr

The syrupy product obtained by the nitration of *n*-propylmesitylene with mixed acid gave by similar chromatographic treatment unchanged hydrocarbon (3%), mononitro and dinitro derivatives (5 and 33%, respectively), diphenylmethane and nitro-carbonyl compounds (less than 2%), and a mixture of nitrobenzyl alcohols (11%). The last compounds were secondary reaction products of nitrobenzyl nitrates formed during the chromatographic treatment over activated alumina.

Experimental

Ethylmesitylene [bp 104—105°C/25 mmHg. PMR: ethyl (3H 8.96 t, 2H 7.48 q, J=8 Hz), methyl (3H 7.84 s; 6H 7.80 s), and aromatic H (2H 3.36 s)] and *n*-propylmesitylene [bp 117—119°C/28 mmHg. PMR: *n*-Pr (3H 9.04 t, J=7 Hz; 2H 8.39—8.71 m; 2H 7.53 t, J=7 Hz), Me (3H 7.86 s; 6H 7.80 s), and aromatic H (2H 3.38 s)] were prepared by the Friedel-Crafts acylation of mesitylene, followed by the Clemmensen reduction of the corresponding mesitoyl ketones.[9,10]

Infrared spectra were measured on Nujol mulls with a Jasco 402G spectrophotometer and only prominent peaks are recorded. PMR spectra were determined in deuteriochloroform or carbon tetrachloride solutions with a Varian A-60A spectrometer and a JEOLCO PS-100 spectrometer against internal TMS.

The representative results obtained from the nitration with fuming nitric acid and mixed acid are shown below.

Nitrations with Fuming Nitric Acid. a): Fuming nitric acid (d=1.50, 8.4 g) was added dropwise to a magnetically stirred solution of ethylmesitylene (7.4 g) in dichloromethane (30 m*l*) at −5—0°C over a period of 30 min, and after the end of addition, the mixture was stirred at room temperature for additional 1 hr. The mixture was diluted with water and the organic part was thoroughly washed with water and dilute aqueous sodium bicarbonate. After drying over anhydrous sodium sulfate, the solvent was evaporated to give a yellow oily mixture (*ca.* 10 g), part of which (7.0 g) was subjected to chromatographic resolution over alumina using light petroleum as eluant to give unchanged hydrocarbon (bp 97—98°C/22 mmHg, 1.2 g) and *2-nitro-4-ethyl-1,3,5-trimethylbenzene* (3.0 g). The latter was a pale yellow liquid boiling at 113—114°C/3 mmHg: IR: 792, 847, 869, 1022, 1038, 1059, 1183, 1369, and 1530 cm^{-1}; PMR (CCl_4): Et (3H 8.90 t, 2H 7.38 q; J=8 Hz), Me (6H 7.84 s; 3H 7.72 s), and aromatic H (1H 3.20 s). It gave on reduction with stannous chloride a liquid amine, which was treated with acetic anhydride to give *2,4,6-trimethyl-3-ethylacetanilide*, mp 161—162°C.

Found: C, 76.07; H, 9.34%. Calcd for $C_{13}H_{19}NO$: C, 76.10; H, 9.27%.

The benzene eluates gave an impure bisbenzyl ether as a pale yellow oil (0.2 g) and a mixture of nitro-carbonyl compounds as a light brown syrup (0.5 g). The major component of the former was identified as *bis(4-ethyl-3,5-dimethylbenzyl) ether* by infrared absorptions (786, 863, 1010, 1092, 1061, and 1140 cm^{-1}) and PMR peaks (CCl_4; Et (3H 8.92 t; 2H 7.42 q; J=8 Hz), Me (6H 7.74 s), $-CH_2O-$ (2H 5.71 s), and aromatic H (2H 3.17 s)), although it could not be ob-

tained in pure form. The latter mixture showed a complicated pattern of infrared spectrum with prominent carbonyl bands at 1750, 1720, and 1677 cm^{-1}. No attempt was made to resolve them.

Further elution with ether gave colorless needles (0.5 g) melting at 72—74°C, identified as *4-ethyl-3,5-dimethylbenzyl alcohol* by analysis, infrared spectrum (730, 866, 998, 1046, 1143, and 3220 cm^{-1}), and PMR spectrum (CCl_4; Et (3H 8.93 t, 2H 7.41 q; $J=7$ Hz), Me (6H 7.74 s), OH (1H, 8.56 broad), CH_2 (2H 5.62 s), and aromatic H (2H 3.18 s)).

Found: C, 80.58; H, 9.52%. Calcd for $C_{11}H_{16}O$: C, 80.49; H, 9.76%.

b): Similar treatment of the nitration product (7.0 g) from *n*-propylmesitylene gave unchanged hydrocarbon (bp 110—111°C/19 mmHg, 0.15 g) and *2-nitro-4-n-propyl-1,3,5-trimethylbenzene* (113—114°C/2 mmHg, 4.1 g) from light petroleum eluates. The latter was slightly yellow oil, which readily solidified to large prisms (mp 34—35°C) and had infrared bands at 798, 840, 869, 1035, 1367, and 1521 cm^{-1}; PMR peaks at 8.99 (Me t, $J=8$ Hz), 8.42—8.67 (CH_2, m), 7.84 (2Me, s), 7.74 (Me, s), and 3.23 τ (aromatic H, s). It gave on reduction with stannous chloride and the subsequent treatment with acetic anhydride *3-n-propyl-2,4,6-trimethylacetanilide*, mp 163—164°C (lit,[3] mp 161°C).

Impure *bis(4-n-propyl-3,5-dimethylbenzyl) ether* (0.2 g) and a mixture of nitro-carbonyl compounds (0.35 g) were obtained from benzene eluates. The former product could not be isolated in crystalline form and had infrared bands at 862, 1091, and 1140 cm^{-1}; PMR peaks (CCl_4) at 9.01 (Me, t, $J=8$ Hz), 8.64—8.42 (CH_2, m), 7.75 (2Me, s), 5.73 (CH_2O, s), and 3.19 τ (aromatic H, s).

Elution with ether gave *4-n-propyl-3,5-dimethylbenzyl alcohol* (0.3 g), which crystallized from ethanol as white needles and melted at 68—69°C. IR: 732, 867, 1002, 1039, and 3200—3300 cm^{-1}; PMR (CCl_4): *n*-Pr (3H 9.00 t, $J=8$ Hz; 2H 8.40—8.76 m; 2H 7.48 t, $J=8$ Hz), OH (1H 8.44 broad), Me (6H 7.74 s), CH_2 (2H 5.63 s), and aromatic H (2H 3.18 s).

Found: C, 81.04; H, 10.41%. Calcd for $C_{12}H_{18}O$: C, 80.90; H, 10.11%.

c): Ethylmesitylene (7.4 g) was added dropwise to the fuming nitric acid (20 m*l*) during the course of 30 min at −5—0°C and the mixture slurried with precipitated crystals was rapidly filtered through a sintered glass filter to leave a white crystalline cake, which was crystallized from a mixture of *n*-hexane and dichloromethane as white needles, mp 120—122°C. It was identified as *2,6-dinitro-3,5-dimethyl-4-ethylbenzyl nitrate* on the basis of elemental analysis and spectral properties. IR: 727, 749, 759, 843, 860, 962, 993, 1059, 1270, 1363, 1530, and 1645 cm^{-1}.

Found: C, 44.27; H, 4.55%. Calcd for $C_{11}H_{14}N_2O_4$ (dinitroethylmesitylene): C, 55.46; H, 5.88%. Calcd for $C_{10}H_{11}N_3O_6$ (trinitroethylxylene): C, 44.61; H, 4.09%. Calcd for $C_{11}H_{13}N_3O_7$ (dinitrodimethylethylbenzyl nitrate): C, 44.15; H, 4.35%.

When the reaction mixture was quenched by pouring into excess of water, the precipitated nitrate was accompanied by appreciable amounts of dinitroethylmesitylene, and complete removal of the latter by simple recrystallization was quite difficult to effect.

d): A similar treatment of *n*-propylmesitylene gave *2,6-dinitro-3,5-dimethyl-4-n-propylbenzyl nitrate* as large plates, mp 139—140°C. IR: 754, 857, 873, 993, 1277, 1361, 1530, and 1644 cm^{-1}.

Found: C, 46.51; H, 4.96%. Calcd for $C_{12}H_{15}N_3O_7$: C, 46.01; H, 4.83%.

If the reaction mixture was left to stand at room temperature for a day or two, a large quantity of a crystalline solid was obtained. On recrystallization from a mixture of ligroin and dichloromethane, it gave colorless fine needles which began to sinter at around 135—140°C and melted away at 152—162°C. Elemental analysis and spectral properties agreed with the structure of *2,6-dinitro-3,5-dimethyl-4-n-propylbenzaldehyde*. IR: 743, 787, 862, 913, 1028, 1057, 1288, 1360, 1455, 1528, 1545, and 1709 cm^{-1}; PMR ($CDCl_3$): *n*-Pr (3H 8.92 t, $J=7$ Hz; 2H 8.35—8.58 m; 2H 7.28 t, $J=7$ Hz), Me (6H 7.70 s), and CHO (1H 0.26 s).

Found: C, 54.60; H, 5.52; N, 10.46%. Calcd for $C_{12}H_{14}N_2O_5$: C, 54.15; H, 5.30; N, 10.52%.

On storage under diffused light, it gradually became greenish yellow.

Nitrations with Mixed Acid. a): Ethylmesitylene (7.4 g) was dissolved in dichloromethane (30 m*l*) and the solution was stirred thoroughly with concentrated sulfuric acid (11.7 g) at −5—0°C. Fuming nitric acid (11.7 g, $d=1.5$) was introduced during the course of 30 min and the reaction mixture was worked up as usual to yield an oil (10.5 g), part of which (5 g) was chromatographed on alumina to give unchanged hydrocarbon (0.18 g), 2-nitro-4-ethyl-1,3,5-trimethylbenzene (1.2 g), and *2,6-dinitro-4-ethyl-1,3,5-trimethylbenzene* (mp 110—111°C, 1.3 g) from light petroleum eluates. The dinitro compound showed the PMR peaks at 8.85 (Me t, $J=7$ Hz), 7.79 (2Me s), 7.29 (CH_2 q, $J=7$ Hz), and 7.90 τ (Me s), and IR bands at 762, 781, 807, 856, 866, 1045, 1202, 1369, and 1529 cm^{-1}. Benzene eluted a diphenylmethane (mp 186—188°C, *ca.* 0.1 g) and nitro-carbonyl compounds (0.2 g). The former product had peaks at 8.87 (Me t), 7.95 (Me s), 7.83 (Me s), 7.64 (3Me s), 7.36 (CH_2 q), 6.13 (CH_2 s), and 3.77 τ (aromatic H s) in the PMR spectrum, and was probably a dinitropentamethyldiethyldiphenylmethane, although no attempt was made to clarify its structure. Ether eluted a mixture of mono and dinitroethyldimethylbenzyl alcohols as a dark glassy substance (*ca.* 0.4 g). *2-Nitro-3,5-dimethyl-4-ethylbenzyl alcohol* had IR bands: 755, 795, 849, 878, 1006, 1048, 1368, 1529, and 3360—3380 cm^{-1}, and PMR peaks: Et (3H 8.92 t, 2H 7.45 q; $J=7$ Hz), Me (3H, 7.84 s; 3H 7.71 s), CH_2 (2H 5.69 s), and aromatic H (1H 2.96 s).

b): On a similar treatment of the nitration product (7.0 g) from *n*-propylmesitylene gave unchanged hydrocarbon (*ca.* 0.2 g), 2-nitro-4-*n*-propyl-1,3,5-trimethylbenzene (0.35 g), and *2,6-dinitro-4-n-propyl-1,3,5-trimethylbenzene* (mp 117—118 °C; lit,[3] mp 93—94°C, 2.3 g) from light petroleum eluates. The dinitro compound had IR bands: 741, 797, 854, 864, 886, 1023, 1055, 1363, and 1521 cm^{-1}, and PMR peaks: *n*-Pr (3H 8.95 t, 2H 8.30—8.68 m, 2H 7.34 t), and Me (3H 7.88 s; 6H 7.78 s). Benzene eluted a small amount of a diphenylmethane (0.1 g) and nitro-carbonyl compounds (0.1 g). The former showed PMR peaks at 8.98 (Me t, $J=8$ Hz), 8.64—8.42 (CH_2 m), 7.98 (Me s), 7.87 (Me s), 7.78 (Me s), 7.41 (CH_2 t), 6.18 (CH_2 s), and 3.88 τ (aromatic H s), and was probably a dinitropentamethyldi-*n*-propyldiphenylmethane, although it could not be obtained in quantity sufficient for positive identification. Further elution with ether gave a mixture of nitrodimethyl-*n*-propylbenzyl alcohols as a dark red glass, which had PMR peaks due to *n*-propyl group at 9.01 (3H t, $J=7$ Hz), 8.46—8.77 (2H m), and 7.47 (2H t, $J=7$ Hz); those due to two methyl groups at 7.88 and 7.75; and those due to hydroxyl, methylene, and ring protons at 6.41 (broad), 5.74, and 2.98 τ, respectively.

The Substituent Effect. IV. Proton NMR Chemical Shifts of Phenols

Yuho Tsuno, Mizue Fujio, Yoshio Takai, and Yasuhide Yukawa
Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Suita, Osaka

(Received October 28, 1971)

NMR chemical shifts of the hydroxyl proton of *m*- and *p*-substituted phenols were determined in aprotic DMF and DMSO solutions. The effect of substituents on the hydroxy chemical shift was correlated much more excellently with our LArSR relationship, $\Delta\delta=\rho(\sigma^0+r\Delta\bar{\sigma}_R^-)$, than with simple Hammett equation, $\rho\sigma^0$ or $\rho\sigma^-$. The correlation resulted in $\rho=1.655$ and $r=0.639$ in DMF with correlation coefficient 0.9992 and $\rho=1.530$ and $r=0.673$ in DMSO with a correlation coefficient 0.9990. Anisotropy effect of any substituent was not significant. The deviations of particular substituents were ascribed to the modification of the electronic characters of substituents due to strong substituent-solvent interactions in DMF (or DMSO). The inductive and resonance substituent constants, $(\sigma_i)_{DMF}$ and $(\Delta\bar{\sigma}_R^-)_{DMF}$, were determined, on the basis of the assumption that the solvent-modification of a given substituent is practically the same at both *meta* and *para* positions.

As described in foregoing papers,[1,2] it had been established that the *Linear Aromatic Substituent-Reactivity* (LArSR) *relationship* (1) could be generally applicable to the substituent effect on both the chemical reactivities, log k/k_0, and physical properties, $P-P_0$, of *meta*- and *para*-substituted benzene derivatives.

$$\log(k/k_0) \text{ or } P-P_0=\rho\bar{\sigma}=\rho(\sigma^0+r^+\Delta\bar{\sigma}_R^++r^-\Delta\bar{\sigma}_R^-) \quad (1)$$

σ^0 is the standard substituent constant which does not involve any additional π-electronic interaction with the reaction center. $\Delta\bar{\sigma}_R^+$ and $\Delta\bar{\sigma}_R^-$ are the resonance substituent constants describing the capabilities for π-electron delocalization (resonance) of conjugatively electron releasing ($-R$) and electron attracting ($+R$) *para* substituents respectively. r^+ and r^- are the resonance reaction constants measuring the extents of effectively exalted resonance interactions of $-R$ and $+R$ substituents in a given system.

This equation implies that the apparent substituent constant $\bar{\sigma}$ can be given by the combination of three terms in bracket at right hand, when a unique ρ value is determined for a given system. Either of the two additional terms plays a significant role in the chemical reactivities in which the benzene conjugation system could be extended fully or partially to the reaction center. In general chemical reactivities, r^+ and r^- are not necessarily equivalent in a given system but are usually independent of each other. The requirement of independent r^+ and r^- values is a characteristic of our LArSR relationship, which subsequently requires the separate statistical applications to conjugatively electron releasing and attracting *para* substituents respectively.

It is believed that the generality of the LArSR Eq. (1) to the effect of electron releasing substituents in electrophilic exalted conjugation reactions, *i.e.*, the applicability of the second term in bracket, has been examined well by ourselves[2-4] and also by many investigators.[2,5-7] Whereas, practical role of the third term for the electron attracting substituent in nucleophilic exalted conjugation systems has not yet been examined enough, for the lack of appropriate data covering over a wide variety of substituents.[2,8] It has been thus highly desirable to obtain the reactivity data and physical data which would enable further testing of the applicability of the last term in the Eq. (1).

In the course of our continuing study of the substituent effect in aromatic derivatives, we have treated several series of NMR chemical shifts of *meta* and *para*-substituted benzene side-chain protons in terms of Hammett-type substituent parameters.[9] The treatment by means of Eq. (1) has appeared to be generally successful for existing data. However, it is rather common that the Hammett-type correlation of proton NMR chemical shifts suffers from the difficulties due to relatively significant role of specific magnetic effects from particular substituents. Our previous results were

also not quite free from these effects enough to permit the critical test of the applicability of Eq. (1). Our recent data on the chemical shift of ring protons of substituted benzenes in various solvents were correlated with Eq. (1) satisfactorily, but several nagging qualitative problems have still remained.[10]

Among a number of recent communications on the subject, Ouellette[11] reported that the hydroxyl proton resonance of *meta* and *para*-substituted phenols in dimethylsulfoxide solution exhibited remarkably magnified substituent chemical shifts and pointed out that the substituent chemical shifts were linearly correlated by Hammett σ^- constants with impressive accuracy. However, upon the Hammett-type treatment including our preliminary data, we arrived at somewhat different conclusions regarding the correlation of substituent contributions in this system. The hydroxyl chemical shifts were not so satisfactorily correlated, as had been reported, with a single set of ordinary σ^- parameters, but were found to be treated much more excellently with an aid of our LArSR Eq. (1).[12] As far as we were aware, this series of substituent chemical shifts appeared to be most precisely described by means of the reactivity substituent parameters. From these facts, we directed our attention to obtain more extensive data for the substituent effect on the NMR chemical shifts of the hydroxyl proton of *meta* and *para*-substituted phenols in various solvents.

The present paper mainly concerns the general treatment based on our LArSR equation of substituent effects on the hydroxyl chemical shifts of phenols in dimethylformamide. Later, Traynham and Tribble have reported a new set of data for phenol-hydroxyl chemical shifts in DMSO solution,[13] and our shift values, in cases where direct comparison is possible, agree well with data reported by these investigators. However, substituents involved in their determination are still insufficient for our purpose. Then, a full set of our data in DMSO are also included in this paper, in order to permit direct comparison of data obtained in a single study.

Experimental

Phenols. All the phenols used were thoroughly purified by repeated fractionations or recrystallizations from appropriate solvents, and for some phenols purification was effected by further sublimations of purified samples. The mps and other physical constants agreed well with established values.

About a half of *m*- and *p*-substituted phenols used in this series of studies were obtained from commercial sources except those given below.

Following phenols were prepared by the usual diazonium method from corresponding anilines available in pure form. Diazonium sulfates were decomposed by dropwise addition to 36% aqueous sulfuric acid solution at about 80°C and the phenols produced were steam-distilled or extracted by appropriate solvents; m-*Bromophenol*, bp 94—96°C/6 mmHg, lit,[14] bp 135—140°C/12 mmHg; m-*Fluorophenol*, bp 90°C/58 mmHg, lit,[14] bp 108°C/70 mmHg; m-*Trifluoromethylphenol*, bp 73—74°C/15 mmHg, lit,[15] bp 85.5—86.5°C/25 mmHg; m-*Phenoxyphenol*, bp 148°C/4 mmHg, lit,[14] bp 150°C/4.5 mmHg; p-*Fluorophenol*, mp 45—45.5°C recrystallized from *n*-hexane, lit,[14] mp 46.5°C; m-*Iodophenol*, mp 38.5—39.5°C recrystallized from benzene - *n*-hexane, lit,[14] mp 40°C; *3,5-Dichlorophenol*, mp 66°C recrystallized from *n*-hexane, lit,[14] mp 68°C.

p-*Trifluoromethylphenol* (bp 60°C/15 mmHg, lit,[16] bp 71.5—72°C/8 mmHg) was obtained from *p*-trifluoromethylaniline, which was prepared according to the direction of Jones[16] by fluorine-exchange of *p*-tribromomethylnitrobenzene with SbF_5 into trifluoromethylnitrobenzene followed by reduction with $SnCl_2$ in ethanol-hydrochloric acid solution.

p-N,N-*Dimethylaminophenol* was derived from *p*-anisidine. Methylation of anisidine with dimethyl sulfate gave dimethylaminoanisole (bp 146°C/38 mmHg), which was demethylated by boiling with conc. hydroiodic acid to the phenol and purified by recrystallizations from ligroin, mp 77°C, lit,[17] mp 77.5—78°C.

m-Aminophenol was converted into m-*Acetaminophenol* by the acetylation in aqueous acetic acid with acetic anhydride and purified by recrystallizations from water, mp 148—149°C, lit,[18] mp 148°C.

p-Aminophenol was converted into p-*Iodophenol* (mp 92.5—93.5°C recrystallized from ligroin, lit,[19] mp 93—94°C), by literature method and also into p-*Cyanophenol* (mp 111—112°C recrystallized from benzene, lit,[20] mp 113°C) by the Sandmeyer reaction of the diazonium salt with cuprous cyanide.

m-*Cyanophenol* (mp 80°C from benzene - *n*-hexane, lit,[21] mp 82°C) was obtained according to the procedure of Clemm by the dehydration of m-*Hydroxybenzaldoxime* (mp 89.5°C from benzene, lit,[21] mp 87.5°C) with acetic anhydride followed by the hydrolysis of the acetate.

p-*Hydroxybenzylidenaniline* was prepared by the condensation of *p*-hydroxybenzaldehyde with aniline in ether solution (mp 197—198°C, recrystallized from ethanol, lit,[22] mp 194—195°C). p-*Benzylidenaminophenol* was similarly prepared from benzaldehyde and *p*-aminophenol, mp 189—190°C, recrystallized from ethanol, lit,[23] mp 181°C.

Hydroxybenzophenones were obtained by the cleavage of the methyl ether of methoxybenzophenones by heating under reflux for 12 hr with hydrobromic acid - acetic acid mixture (3 vol. Ac_2O, 5 vol. AcOH, and 5 vol. 48% aqueous HBr). m-*Hydroxybenzophenone*, mp 117°C from benzene - ethanol and petroleum ether, lit,[14] mp 116°C; p-*Hydroxybenzophenone*, mp 133°C from benzene, lit,[14] mp 130—132°C.

p-*Phenoxyphenol* was obtained in the similar way from *p*-methoxydiphenyl ether and recrystallized from benzene - *n*-hexane, mp 85—86°C, lit,[14] mp 84—85°C.

m-*Methylmercaptophenol* was prepared by the ether-cleavage of *m*-methoxyphenyl methyl sulfide with hydrobromic acid

in acetic acid solution (bp 141.5°C/8 mmHg, lit,[24] bp 154—156°C/17—18 mmHg). *m*-Methoxyphenyl methyl sulfide was obtained from anisidine by the modification of the direction given by Grice[25] for *m*-methylmercaptobenzoic acid, bp 125.5°C/17 mmHg. Oxidation of *m*-methylmercaptophenyl acetate, mp 39°C (lit,[24] mp 40—41°C), with hydrogen peroxide in acetic acid according to the direction of Bordwell gave *m*-methylsulfonylphenyl acetate, which yielded on hydrolysis with 10% aqueous sodium hydroxide m-*Methylsulfonylphenol*, in good yield (mp 81—82°C recrystallized from benzene - chloroform, lit,[24] mp 83—84°C). p-*Methylsulfonylphenol* was similarly obtained from methylmercaptophenol (mp 85°C from light petroleum, lit,[24] mp 84—85°C) by oxidation of the acetate with hydrogen peroxide in acetic acid, followed by hydrolysis of *p*-methylsulfonylphenyl acetate resulted; mp 92°C from benzene - chloroform mixture, lit,[24] mp 95—96°C.

p-*Thiocyanophenol* was prepared by the usual procedure given by Bordwell and was purified by recrystallizations from benzene - *n*-hexane, mp 61°C, lit,[26] mp 62—63°C.

Hydroxynitrostyrenes were prepared by condensation of corresponding hydroxybenzaldehydes with nitromethane; m-*Hydroxynitrostyrene*, mp 141—141.5°C from benzene - ethanol, lit,[27] mp 136—137°C; p-*Hydroxynitrostyrene*, mp 166—167°C from benzene - ethanol, lit,[28] mp 165—166°C.

m-Hydroxybenzaldoxime was converted by Field's direction[29] with nickel acetate into m-*Hydroxybenzamide*, mp 171—172°C from benzene - ethanol, lit,[30] mp 169—170°C.

Ethyl p-*hydroxycinnamate* (mp 76°C recrystallizations from benzene - *n*-hexane) was prepared by the condensation of *p*-hydroxybenzaldehyde with malonic acid, followed by esterification of cinnamic acid produced.[31] m-*Isomer* (mp 66.5—67.5°C, recrystallizations from benzene - *n*-hexane, lit,[32] mp 70—71°C) was also prepared by the similar procedure.[31]

Solvent. Dimethylsulfoxide was dried for 4 days, boiled under reflux for one day over calcium hydride and fractionally distilled under reduced pressure. The middle fraction bp 100.5°C at 39 mmHg was stored over molecular sieve and distilled before use.

Dimethylformamide which had been prepurified by the literature method was treated with molecular sieve and fractionated under reduced pressure, bp 58°C at 25 mm.

NMR Spectra. The proton resonance spectrum of the phenol hydroxyl group was recorded on a Hitachi-Perkin Elmer R-20 spectrometer, operating at 60 MHz. The probe temperature was maintained at 34.0°C. The measurement was made by freshly prepared DMF or DMSO solutions at the concentration in the range 1.0—0.05M. The solvent peak provided a convenient reference signal. The low field ^{13}C–H satellite of DMF or DMSO solvent main peak was utilized as the general internal standard throughout the series of chemical shift measurement. The shift value was determined by direct counting of peak to peak frequency differences from the standard satellite peak, and calibrated to the shift value from TMS in the usual way. At the concentration range studied, the line width of the hydroxyl resonance signal was generally 1.5 Hz or less, but in some cases was a little broader (2—3 Hz). The broad signal of hydroquinone, 7—8 Hz at 0.5M, was the worst case, and appeared to be diffused more on dilution. The shift values were determined repeatedly at least three different concentrations in the range lower than 0.5M, using independently prepared solution. The values were reproducible to ±0.2 Hz at a given concentration for all samples. Resonance position of a given phenol generally tended to shift very slightly toward high field on dilution, but mostly approached to or remained a constant within ±0.2 Hz at the concentration below 0.25M, independent of concentrations covering over more than 4 folds dilution. A minor dilution shift was apparent in 6 derivatives among 50 substituted phenols to an extent of 2.0—2.5 Hz through a wide range of the concentration 0.5—0.05M in either DMF or DMSO solution. To approximate actual chemical shift values at infinite dilution conditions, the measurement was extended to that in high dilute solutions possible

Table 1. Chemical shifts of hydroxyl protons of *m*, and *p*-substituted phenols

to give no further shift exceeding over a measurement error of ± 0.2 Hz by additional dilution with an equal volume of solvent. It can be then estimated that in nearly all instances the discrepancy from the infinite dilution value does not exceed ± 0.4 Hz, even for the least favorable case. Results are summarized in Table 1.

Result

In either dimethylsulfoxide (DMSO) or dimethylformamide (DMF) solution, phenols carrying various *meta* and *para*-substituents resulted in the stabilized NMR resonance signals of hydroxyl protons. As mentioned by previous workers,[11-13] the concentration dependence of the shift was not significant in these solvents in contrast to the dilution shift as much as 1 ppm observed in carbon tetrachloride solution.[33]

Table 1 lists the chemical shift values of the hydroxyl protons of *meta* and *para*-substituted phenols at approximately infinite dilution in DMF and DMSO solutions. It may be estimated that the uncertainty in the listed values of chemical shifts does not exceed ± 0.005 ppm. The hydroxyl chemical shift varies in either solution over a range of 2.7 ppm with respect to substituent changes. Then, the experimental uncertainty is effectively regarded as being negligible in comparison with the divergent chemical shift variation due to substituent changes. The present results in DMSO solution are generally in good agreement with those reported by Traynham[13] and Ouellette.[11] The latter author reported consistently lower (less shielded) values by *ca.* 0.04 ppm than the present data, but the relative substituent chemical shift values agree well with the present values within usual experimental error.

One of the important facts, as seen in the result in Table 1, is the proportionality between the substituent shifts in both DMF and DMSO solvents. The correlation is given by

$$\Delta\delta_{\mathrm{DMSO}} = 0.951\Delta\delta_{\mathrm{DMF}}$$

The precision can be measured by the standard deviation ± 0.022 and the correlation coefficient 0.9992. The similar linearity is observed for literature data of the phenol substituent chemical shifts in HMPA (Hexamethylphosphoramide)[35]

$$\Delta\delta_{\mathrm{HMPA}} = 1.1\Delta\delta_{\mathrm{DMF}}$$

In addition, a series of our recent data in acetonitrile can be also correlated linearly to the shift data in DMF with a coefficient of 0.68.[34] The variation of the chemical shift in a series of substituted phenols are appreciably magnified in either of these solvents as compared with those in carbon tetrachloride. The slope of these correlations appears qualitatively to vary in parallel to the low-field shift of hydroxyl resonance position of a given phenol in respective solvents, and the susceptibility of hydroxyl shifts to substituent changes varies dependent upon the solvent basicity or the hydrogen bond acceptor strength of solvents. Nevertheless, it is clear that the apparent substituent constant $\bar{\sigma}$ remains practically the same in either of these solvents, to a precision on the order of experimental error. Any particular effect on substituent constants is not significant among these solvents. Accordingly, the discussion followed will treat the results in DMF solution conveniently as a representative series of the substituent effects on the hydroxyl chemical shift in these solvents.

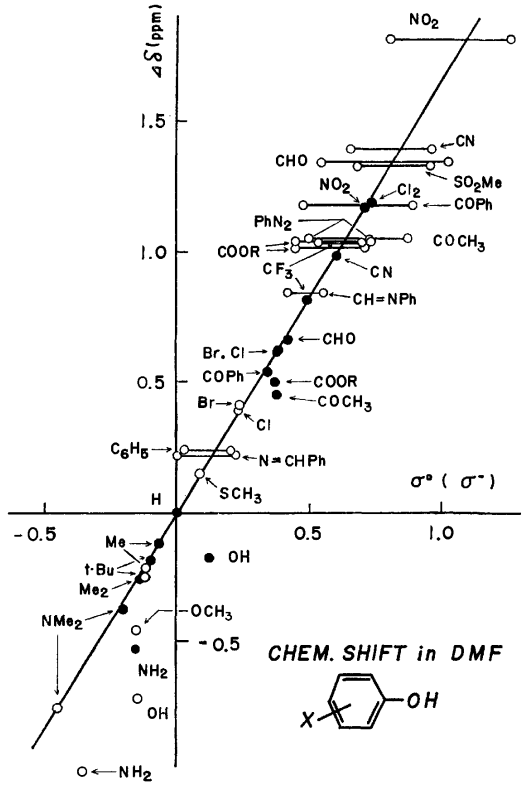

Fig. 1. Hammett plot of hydroxyl chemical shifts of phenols in DMF; open circle for *para* and closed circle for *meta* substituents.

In Fig. 1, the relative substituent chemical shifts of hydroxyl proton are plotted against corresponding σ^0 and σ_p^- constants. Contrary to the results reported by Ouellette[11] considerable scatterings are observed as a whole figure. Deviations from the σ^0 correlation line are more significant in *para* than in *meta*-substituents, while they appear to be rather systematic. The direct employment of any other ordinary set of substituent constants does not improve significantly the overall correlation. However, it should be noticed that most of the *m*-substituent chemical shifts are excellently described by σ_m constants. This is in clear contrast to the behavior of the *meta* ring proton of mono-substituted benzenes which provide apparently a better correlation with σ_p^0 values[10] and the ^{19}F shielding parameters for *meta*-substituted fluorobenzenes[36] which correlate with σ_I constants alone. Among 30 *meta*-substituents examined,

deviations are obvious only for amino, acetamino, and hydroxy, and detectable to a minor extent for methoxy, acetyl and carboalkoxy groups.[37] These deviations do not appear to be similar to the characteristic deviations observed in the chemical shift of the usual side-chain or ring protons at *meta* position.

Values in bracket are the values to be used for the data in aqueous organic solutions, and given in italic are less reliable.

The hydroxy chemical shift for *meta* substituents diverges along a straight line for σ_m over a range of 1.5 ppm, which will be wide enough to determine the reliable ρ_m-line as a standard for the discussion of substituent effect. The substituent parameter values utilized in the following calculations are listed in Table 2. Nineteen well-behaving *meta*-substituents give a precise straight correlation, on employment of the method of least squares,

$$\Delta\delta_{DMF}^{OH} = 1.656\sigma_m - 0.019$$

the standard deviation being ±0.016 and the correlation coefficient 0.9994. On the basis of this ρ_m value, a set of apparent substituent constants can be determined from this series. They are listed in Table 3. A comparable set can be derived also from the shift data in DMSO solution, where *meta* substituents provide similarly ρ_m value of 1.529 ($s=\pm0.022$ and $R=0.9987$), and the apparent $\bar{\sigma}$ values for all *meta* substituents coincide precisely with the values derived from DMF data.

The apparent substituent constants $\bar{\sigma}_p$ for conjugatively electron attracting ($+R$) *para* substituents all lie in between corresponding σ^0 and σ^- values. The resonance contribution of these *para* substituents to the hydroxyl chemical shift appears to be relatively less effective than that in the phenol dissociation measured by σ^- constants. It may be expected that our LArSR Eq. (1) will enable to correlate the hydroxyl chemical shifts of these groups.

On the least squares application of Eq. (1) to the hydroxyl chemical shifts for these groups including well-behaving *meta*-substituents (total number 31), an excellent linear correlation (Fig. 2) is resulted in

$$\Delta\delta_{DMF}^{OH} = 1.655(\sigma^0 + 0.639\Delta\bar{\sigma}_R^-) - 0.016 \quad (2)$$

The standard deviation from the regression line is ±0.022 and the correlation coefficient 0.9992. The ρ

37) The latter three substituents could be fitted closer to the line by the use of σ_m values given for aqueous organic solution.

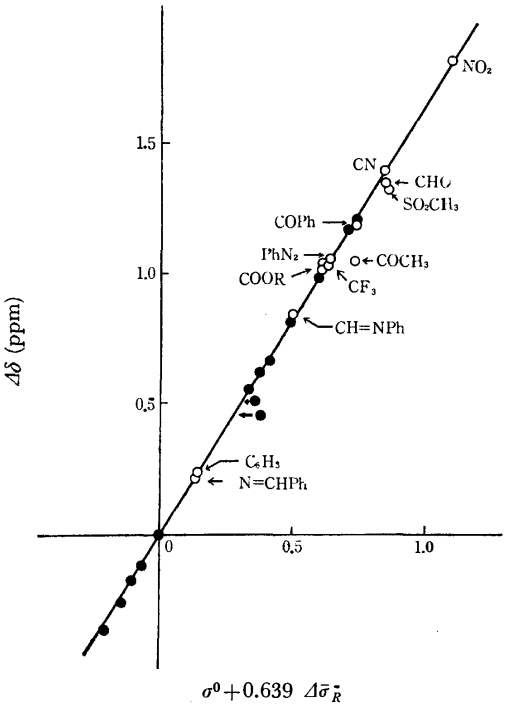

Fig. 2. LArSR plot for hydroxyl proton chemical shifts in DMF; open circle for $+R$ *para* substituents and closed circle for *meta* substituents.

value derived is identical with that obtained from *meta* substituents alone. The same treatment can be applied also to the shifts in the latter solution with analogous precision.[38]

$$\Delta\delta^{OH}_{DMSO} = 1.530(\sigma^0+0.673\Delta\bar{\sigma}_R) - 0.004$$

It is evident from these results that the hydroxyl chemical shifts of substituted phenols in these solvents can be treated quite successfully by means of our LArSR Eq. (1) in the same way as the general chemical reactivity changes, at least as far as conjugatively electron attracting groups are concerned.

On the other hand, the analogous treatment of conjugatively electron releasing ($-R$) *para* substituents based on Eq. (1), unfortunately, does not appear to be successful. The fit to the Eq. (1) should imply the existence of a certain proportionality between the increments of apparent $\bar{\sigma}_p$ from σ^0_p values and the corresponding $\Delta\bar{\sigma}^+_R$ parameters throughout a series of *para* $-R$ substituents. However, the apparent enhancement, $\bar{\sigma}_p-\sigma^0_p$, is significant for amino, hydroxy, acetamino, and methoxy groups, but is not significant for the remainder. A contrast is clear in the comparison of the behaviors of *p*-amino and *p*-dimethylamino substituents, in spite of their comparable and potential resonance capabilities in general chemical reactivities. In practice, no clear-cut correlation was observed for these $-R$ substituents between the enhancements $\bar{\sigma}_p-\sigma^0_p$ and the corresponding $\Delta\bar{\sigma}^+_R$ values. It is however to be mentioned that the substituent which gives the anomalous resonance enhancement $\bar{\sigma}_p-\sigma^0_p$ at *para* position does exhibit the anomalous effect, the exalted electron donation, also at *meta* position.

38) Correlation coefficient $R=0.9990$ and standard deviation $s=\pm0.023$.

Discussion

It is frequently noted that the substituent effect on the NMR chemical shift is not described so successfully by the ordinary substituent parameters which were derived from chemical reactivities.[9b] Even in chemical reactivities, in general, a single set of Hammett-type substituent constants such as σ, σ^+, and σ^- can not always provide a good description of the actual substituent contribution. The degree of resonance contribution from substituents, relative to their polar or inductive contribution, depends evidently upon the structure of the system and of the detection center and also upon the nature of the detection variables. The susceptibility of the proton NMR chemical shift to the π-electronic (resonance) contribution relative to the σ-electronic (or field) effect from substituents may differ from the relative π-electronic contributions in the reactivity changes of similar structural system. Such the effect should be taken into account, as a first approximation, by the aid of our LArSR relationship or other relevant equations.[39]

A most serious problem we often have encountered with the treatment of substituent effects on proton NMR chemical shifts is the fact that the *meta* substituent chemical shifts do not apparently follow σ_m values, and furthermore, the different ρ-values are often required for respective series of *meta* and *para* substituent chemical shifts. These provide a difficulty in determining unique ρ-value for a given system as generally assumed in the correlation of chemical reactivities. It is then an appreciated feature of the present data that the *meta* substituent chemical shifts can be precisely correlated with σ_m values and most of *para* substituent chemical shifts are described by the combination of σ^0_p and $\Delta\bar{\sigma}_R$ parameters, giving the same ρ value for both series.

Another difficulty in the treatment of substituent chemical shifts is the serious deviations of certain substituents arising from their specific magnetic contributions. Although deviations are significant for several substituents in the present series, the direction and magnitude of deviations are dissimilar to those expected from the nature of anisotropic substituents. The difference in the nature of deviations is evident in the comparison with the α-proton of substituted toluenes. It is clear that any specific magnetic contributions are of little practical consequence and the effects, if present, are relatively unimportant in the chemical shifts of phenol protons in these solvents examined. The hydroxyl chemical shift should be predominantly controlled by the charge produced or the electron density at the hydroxyl oxygen atom, which in turn should be determined by the intramolecular electronic interaction with substituents.

The hydrogen-bonding interaction of the hydroxyl

39) P. R. Wells, *Chem. Rev.*, **63**, 171 (1963); C. D. Ritchie and W. F. Sager, "Progress in Physical Organic Chemistry," Vol. II, Interscience, New York (1964), p. 323; P. R. Wells, S. Grisdale, *ibid.*, **84**, 3539 (1962).

function with a hydrogen-bonding acceptor solvent plays evidently an important role in magnifying the substituent chemical shifts and also in fitting to the Hammett-type relationship. The state of phenol molecules reflected on the hydroxyl chemical shift must closely resemble the intermediate state for the acid dissociation of phenols. Intramolecular electronic interactions of substituents with the acquired charge at the phenol oxygen in the present system may be close to those in the phenoxide-ion. The large positive value of ρ and high r-value for conjugatively electron attracting *para* substituents justify the above explanation. What is actually observed in the present system would be the substituent effect on the hydrogen bonding measured by the proton chemical shift as the detection variable. Thus, it is not surprising that the substituent effect in the present system can be treated in the same way as those in the general chemical processes.

In view of the significance of fit to the correlation (2) of well-behaving substituents, dispositions of certain particular substituents, especially of several electron releasing groups, should be significant. The deviations can not be referred to the experimental error, but it is evident that some extraneous effects are operating in these groups. The precision within 0.010 in σ-unit would be high enough to permit the quantitative discussion of the extraneous effects producing significant deviations.

It should be noticed here that the present data are obtained from the measurement in anhydrous aprotic solvents. Several workers have pointed out the importance of the solvent effects on the NMR chemical shift and have offered a variety of rationalizations for the phenomena.[40] Most of these rationalizations are based primarily on the intermolecular long range magnetic effect induced from the solvent molecule specifically oriented to solute molecule. It may be expected that the substituent-solvent interaction should take an important part of the solute-solvent interactions in usual aromatic molecules, since the substituent is one of the most polar sites of the solute molecule. The long range magnetic effect might not be so significant from the solvent molecule which coordinates to the substituent located far from the detecting function, while the effect of variation in the electronic nature of particular substituent due to strong interaction with solvent could not be neglected. The parameters of a given substituent should be subject to change by the modification of its electronic characters by the solvent-substituent interaction. Evidence has been accummulated which indicates that substituent effects on aromatic reactivities are not generally independent of solvents.[41,42] Since the standard sets of substituent parameters were derived from the measurement in water (or aqueous organic solutions) where donative hydrogen bonding to substituents is highly important, certain deviations of particular substituents might be produced in the correlation of the data in aprotic solvents, upon employment of definite sets of parameters. Thus, it might be plausible to refer the deviations observed in the above correlation primarily to the effect of solvent-modification of substituent effects.

We should examine, first of all, the effect of *meta* substituents where no significant change is expected in the relative contribution of resonance from one series to another. Among a series of *meta* substituents, hydroxyl and amino groups exhibit exceptionally large deviations from the correlation (2); the apparent σ_m values of these groups are more negative than the ordinary σ_m values. It is qualitatively expected that not only these two but all the substituent which possesses a lone electron pair on the α-atom would be more electron releasing in hydrogen-bond acceptor solvents than estimated from the σ values in aqueous solution, from which donative hydrogen-bonding is effective. As a matter of fact, however, this effect does not appear so serious for general $-R$ *meta* substituents (except the above two particular groups) in the present system. Perhaps the small but real deviation of *m*-methoxy group may be referred to this effect. The loss of hydrogen-bond donation in non-aqueous solution can also explain reasonably the deviations of *m*-acetyl and *m*-carboalkoxy groups. Amino and hydroxyl groups, on the other hand, behave as the effective hydrogen-bond donor to DMF and DMSO solvents. The negative charge at hydroxyl oxygen or amino nitrogen due to hydrogen bonding with an acceptor solvent can make these groups further electron releasing, while such an effect would not be significant in aqueous solutions. Ritchie has recently noted the similar behavior of these groups in the dissociation of substituted benzoic acids in DMF solution.[43]

From these facts, it appears necessary to utilize the substituent constant characteristic of a substituent in given solvents. It does not appear unreasonable, as a useful approximation, to assume that the apparent substituent constant in a given solvent is to be the ordinary effect characteristic of the "solvent-modified substituent," or of *the existing solvent-coordinated substituent species whose electronic character is effectively modified.* This assumption may be practically useful in view of facts that the modifications of parameters are required only for certain particular substituents and also that finite parameter values can be adopted to these groups for respective solvent classes, since for any particular substituent there is a consistent behavior in the range of solvents.

The effect of the solvent-modification should be operative with the same substituent at *para* position as well as *meta* position. This can be evidently shown in

Fig. 1 as the deviations of particular substituents at both *para* and *meta* positions. Either of these substituents brings about the deviations of the same direction and of a comparable order of magnitude from both positions (or of a little greater extent from *para* position). This might partly validate the present discussion based on "solvent-modified substituent." For the correlation of *para* substituents, it is necessary to determine characteristic r-values of the system. Conjugatively electron attracting substituents in the present system (in DMF) give an r^- value, 0.639, but it is difficult to determine a unique r^+ value for conjugatively electron releasing substituents as mentioned in Result. However, as apparent substituent constants for most of $-R$ substituents do not differ from their original σ^0 values within the order of experimental uncertainty, excluding the substituents carrying an acidic hydrogen at the α-atom, we may estimate the r^+ value for electron releasing resonance contribution being approximately zero.

Previous investigators[11,13] have employed the standard σ_p values (*i.e.*, more exalted resonance scale, $r^+=0.27$) for *para* substituents instead of σ_p^0 values ($r^+=0.00$). *p*-Amino and *p*-hydroxyl groups fall near the line when they are correlated with σ_p values, while the subsequent deviations are resulted in the other groups, and such the treatment offers a difficulty in explaining why the substituent carrying an active α-hydrogen exerts the enhanced electron donation especially at *meta* position. Since the strongly electron donative detection center $-\overset{\delta-}{O}\cdots\overset{\delta+}{H}$ should prevent the additional resonance interaction with *para* $-R$ substituents, no significant resonance exaltation is expected for these *para* substituents. It appears thus more likely to refer the apparent σ-values for $-R$ *para* substituents in the present system to the σ^0, or the substituent parameters closely in the σ^0 scale, of the solvent-modified substituents rather than to the standard σ value.

In contrast to the complicated behaviors of $-R$ substituents, the effect of conjugatively electron attracting *para* substituents can be treated rather successfully as mentioned above. Figure 3 demonstrates the correlation between apparent enhancements, $\bar{\sigma}_p-\sigma_p^0$, of $+R$ *para* substituents in DMF solution and the corresponding $\Delta\bar{\sigma}_R^-$ parameters. Most of substituents fall on or near the straight line with a slope corresponding to the r value of 0.64. Carbonyl and sulfonyl derivatives exhibit weaker electron attracting effects than expected from the correlation, and deviations are most serious in $CONH_2$ and SO_2NH_2 groups.

The standard $\Delta\bar{\sigma}_R^-$ parameters ($=\sigma_p^--\sigma_p^0$), should be the resonance parameters referable to the substituent groups effectively modified by water. To the contrary, the ordinate ($\bar{\sigma}_p-\sigma_p^0$), the apparent enhancement from the standard σ^0, should include the specific effect referable to the change in the solvent-substituent interaction in DMF (or DMSO) from that in water. This effect might cause substantial deviations for particular substituent, while the correlation in Fig. 2 or Fig. 3 is satisfactory for most of substituents, besides some carbonyl and sulfonyl groups which exert weaker electron attracting effect than expected. The reduction observed can be attributed to the fact that in aqueous

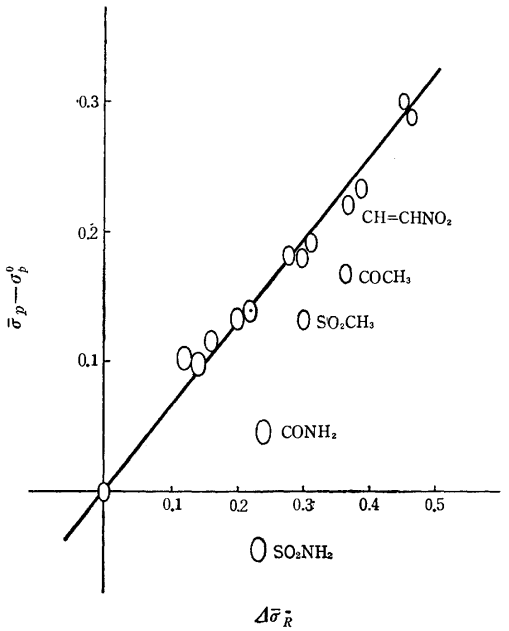

Fig. 3. The plot of the apparent resonance enhancements, $\bar{\sigma}_p-\sigma_p^0$, against standard $\Delta\bar{\sigma}_R^-$ values for $+R$ substituents.

solution the electron withdrawal of the carbonyl or sulfonyl is enhanced by virtue of its ability to disperse an acquired negative charge into the solvent through hydrogen bonding, but in either DMF or DMSO solution such an effect is inhibited. The consistent fact has been observed in the chemical reactivities.[42] The apparent σ_p^- value of *p*-acetyl group derived from the dissociation of phenols decreases from 0.87 in water to 0.80 in organic solvents, but no significant deduction is observed in σ_p^- of *p*-aldehyde group, in good accordance with the present result. The same effect may be also effective for other substituents. With $CONH_2$ and SO_2NH_2 groups, the similar effect discussed above for amino group could be also operative and hence the overall apparent effect is much more significant in these than the other carbonyl and sulfonyl groups.

The substituent-solvent interaction might afford the substantial changes in the inductive and then σ^0 parameters as well as in the resonance parameters of respective substituents. Therefore, the apparent enhancements from the standard σ^0 values, $\bar{\sigma}_p-\sigma_p^0$, are not merely referable to the exalted resonance contribution of substituents, but certain reflection of the change in the inductive component of solvent-modified substituents should be taken into consideration for the analysis of these parameters. Although the direct estimations of actual σ^0, inductive substituent constant σ_I, and resonance substituent constant σ_π, for solvent-modified substituents are not immediately possible, the following indirect methods may be applied as a useful approximation.

Inductive and π-Electronic Parameters in DMF

On the statistical analysis of the reaction-dependency of substituent constants, we have emphasized that the substituent effect on benzene reactivities could be sepa-

rable, to a first approximation, into the inductive σ_I and π-electonic σ_π effects. *Para* and *meta* substituent effects can be expressed generally by a *Linear Substituent Free Energy* (LSFE) *Relationship* (3),[1,3]

$$\log (k/k_0)_p = \rho\bar{\sigma}_p = \rho(\sigma_I + q_r^+\sigma_\pi^+ + q_r^-\sigma_\pi^-) \quad (3)$$

$$\log (k/k_0)_m = \rho\bar{\sigma}_m = \rho(1.17\sigma_I + 0.50\sigma_\pi^\pm) \quad (3')$$

σ_I is the inductive substituent constant, independent of the varying contribution of resonance effect. σ_π^+ and σ_π^- are the parameter measuring the capability of substituents to donate or withdraw electron through π-electronic delocalization. σ_π^+ corresponds numerically to 0.42 $\Delta\bar{\sigma}_R^+$ and σ_π^- to 0.73 $\Delta\bar{\sigma}_R^-$ in our LArSR Eq. (1).[44] q_r^+ and q_r^- are the characteristic variables of a given reaction or a given system, measuring the degree of π-electronic interaction with the detection center, and are in general mutually independent. Both q_r^+ and q_r^- are standardized in σ_p^0 scale to be unity; *i.e.*, $\sigma_p^0 = 1.00\ \sigma_I + 1.00\ \sigma_\pi^\pm$. As evident from the reaction-independence of σ_m values, the contribution of σ_π remains a constant, 0.50, in *meta* reactivities regardless of wide variations of reaction type. The fact that the inductive contribution from *meta* substituents is 1.17 times more effective, generally independent of reactions, than that from *para* substituents is a characteristic feature of our LSFE relationship. Combining both equations, can be derived the equations, in which the effect of inductive component is canceled out; for conjugatively electron attracting groups,

$$\log (k/k_0)_p - 0.85 \log (k/k_0)_m = \rho C^-\sigma_\pi^- \quad (4)$$

and for conjugatively electron releasing groups,

$$\log (k/k_0)_p - 0.85 \log (k/k_0)_m = \rho C^+\sigma_\pi^+ \quad (4')$$

where $C^\pm$ are practical constants corresponding to $q_r^\pm - 0.425$. Equation (4) is the *linear resonance free energy relationship* which can be practically utilized for the estimation of resonance parameters, without inquiring inductive parameters. If the operation of the same inductive contribution ratio might be assumed for the present system, this equation may be applied for the determination of resonance parameters of solvent-modified substituents. Equation (4) can be modified for ready applications for $+R$ substituents in the form;

$$1/\rho(\Delta\delta_p^{OH} - 0.85\Delta\delta_m^{OH}) = \bar{\sigma}_p - 0.85\bar{\sigma}_m = C_M^-(\sigma_\pi^-)_M = 0.73C_M^-(\Delta\bar{\sigma}_R^-)_M \quad (5)$$

C_M^- is a coefficient describing the effective resonance contribution of the system in a given medium M and should remain a constant for all $+R$ substituents. $(\sigma_\pi^-)_M$ or $(\Delta\bar{\sigma}_R^-)_M$ indicates the corresponding resonance parameter of the solvent-modified substituent in M. The same type of equation can be derived for $-R$ substituents; the right hand side of Eq. (5) is given by

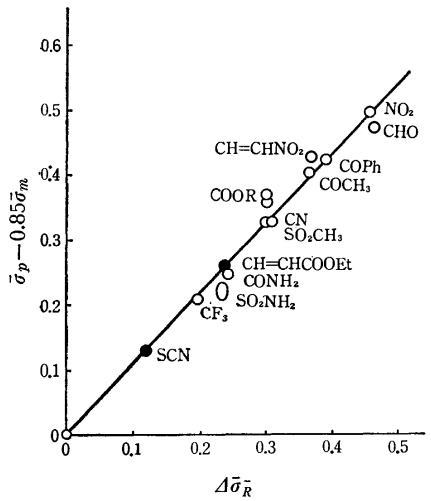

Fig. 4. The plot of the quantities, $\bar{\sigma}_p - 0.85\bar{\sigma}_m$, against standard $\Delta\bar{\sigma}_R^-$ values, for $+R$ substituents.

$$= C_M^+(\sigma_\pi^+)_M = 0.42C_M^+(\Delta\bar{\sigma}_R^+)_M \quad (5')$$

The coefficient C_M^+ is usually not equal to C_M^-.

In Fig. 4 the quantities $(\bar{\sigma}_p - 0.85\ \bar{\sigma}_m)$ for $+R$ substituents in DMF solution are plotted against the standard $\Delta\bar{\sigma}_R^-$. The correlation resulted is unexpectedly excellent. The significant deviations of acetyl and methylsulfonyl groups observed in Fig. 3 are not apparent, and it is really surprising that carbamido group just falls on the line. SO_2NH_2 group also appears to satisfy the correlation when the solvent-modified $\bar{\sigma}_m$ value derived from the NH proton chemical shifts of anilines and acetanilides is employed, though we were unable to prepare *m*-sulfonamido-phenol in pure form. The deviations from the line are at most within 0.05 in σ unit. A linear correlation with closely the same order of precision can be obtained for the corresponding quantities in DMSO solution.

It would be then concluded that the solvent-modification of substituent by DMF or DMSO does not affect significantly the resonance parameters so far as are concerned the conjugatively electron attracting substituents. The variation of the apparent substituent constants of these groups in aprotic DMF would be caused predominantly by the solvent-modification of the inductive nature of substituents. On the basis of the apparent slope of the above correlation line 1.09 which corresponds to 0.73 C_M^-, $(\Delta\bar{\sigma}_R^-)_{DMF}$ values can be derived. Since the slope 1.09 should correspond to 0.73 $(q_r^- - 0.425)$, according to Eqs. (3) and (5), $(\sigma_I)_{DMF}$ can be derived by using Eq. (6).

$$(\sigma_I)_{DMF} = \bar{\sigma}_p - 0.73q_r^-(\Delta\bar{\sigma}_R^-)_{DMF} = \bar{\sigma}_p - 1.40(\Delta\bar{\sigma}_R^-)_{DMF} \quad (6)$$

By the combination of $(\sigma_I)_{DMF}$ and $(\Delta\bar{\sigma}_R^-)_{DMF}$, we can calculate a set of $(\sigma^0)_{DMF}$ for $+R$ substituents modified by DMF solvent. These apparent sets of parameters are summarized in Table 4.

The new parameters for styryl derivative groups appear to be practically useful, even though certain but probably minor solvent-modification should be taken into account. As discussed in the above, the differences of $(\sigma_p^0)_{DMF}$ from the standard σ_p^0 are signifi-

44) $\Delta\bar{\sigma}_R^-$ values given in Table 2 and employed in this study are those derived from the most reliable set of σ_p^- values which have been determined from reliable pK_a values of phenols, anilines, and dimethylanilines in water. In a previous paper (Ref. 1a) we have noted preliminarily, on the basis of σ_p^- values in the literature, that σ_π^- corresponds to 0.81 $\Delta\bar{\sigma}_R^-$. However, detailed examination of the above new set of σ_p^- values indicates that σ_π^-, the π-electronic effect of $+R$ substituents in σ_p^0 scale should correspond to 0.73 $\Delta\bar{\sigma}_R^-$. Full data and relevant discussions will be published in the near future.

cant in carbonyl derivatives and remarkable in amide groups and they are clearly a reflection of the solvent-modification of the inductive components.

Evidences for the solvent-dependence of inductive parameters have been presented on the basis of various studies,[39] among which Taft's study of σ_I using ^{19}F NMR chemical shifts of substituted fluorobenzenes is the most practical and comprehensive.[36] He pointed out that ^{19}F substituent chemical shifts of *m*-substituted fluorobenzenes were correlated linearly with his σ_I parameters, derived from chemical reactivities. This is true in the case of the relative substituent chemical shifts in aqueous methanol, whereas the relative shift in DMF solution does not give so excellent plot against the σ_I.[41] The deviation might primarily arise as a result of solvent-modification in the inductive component of substituents. The analogous variation is expected to be involved in the present DMF system, and in fact $(\sigma_i)_{DMF}$ are found to correlate linearly with the ^{19}F *m*-substituent chemical shifts in DMF solution. If the substituent chemical shift of *m*-substituted fluorobenzenes, as Taft assumed, being a linear function of inductive parameters is valid, it is then suggested that the present set of $(\sigma_i)_{DMF}$ evaluates reasonably the inductive effect of the substituents solvated by DMF solvent, and subsequently, this may also offer an evidence justifying the above estimation of resonance parameters in DMF. Even though the test may not yet be regarded as critical, these treatments may have promising applicability to appropriate systems.

For conjugatively electron releasing ($-R$) substituents, the quantities $(\bar{\sigma}_p - 0.85\,\bar{\sigma}_m)$ are practically not proportional to the standard $\Delta\bar{\sigma}_R^+$ values. However, in view of the significance of the fit of $+R$ substituents to the above treatment (5), the *para*/*meta* inductive contribution ratio of 0.85 would be assumed for $-R$ substituents. It may be also assumed that the quantities $(\bar{\sigma}_p - 0.85\,\bar{\sigma}_m)$ for $-R$ groups in DMF solution are proportional to $(\Delta\bar{\sigma}_R^+)_{DMF}$. In order to practify the separation of substituent effect into σ_i and $\Delta\bar{\sigma}_R^+$ (or σ_π^+) contributions in the present system, it is necessary first to provide the C_{DMF}^+ scale of $(\Delta\bar{\sigma}_R^+)_{DMF}$ contribution. As discussed in the foregoing section, if the present set of apparent $\bar{\sigma}_p$ for $-R$ groups could be referable to the σ_p^0 for solvent-modified substituents in DMF solution, the scale of $(\Delta\bar{\sigma}_R^+)_{DMF}$ or the C_{DMF}^+ value for $-R$ substituents can be estimated to be 0.575 on the basis of *meta*/*para* σ_π-contribution ratio of 0.50 which is a characteristic of the σ^0 scale. Namely, the resonance contribution of these substituents might be roughly approximated by means of Eq. (7)

$$(\bar{\sigma}_p - 0.85\bar{\sigma}_m) = 0.242(\Delta\bar{\sigma}_R^+)_{DMF} \qquad (7)$$

This may lead to the crude estimation of $(\sigma_i)_{DMF}$ values for $-R$ substituents by

$$(\sigma_i)_{DMF} = \bar{\sigma}_p - 1.74(\bar{\sigma}_p - 0.85\bar{\sigma}_m)$$
$$= 1.48\bar{\sigma}_m - 0.74\bar{\sigma}_p$$

Table 5. Modified substituent parameters in DMF for $-R$ groups

OH	−1.39	0.17
NMe_2	−1.07	0.01
NH_2	−1.37	−0.01

The results are summarized in Table 5. Although the crudeness of derivation does not permit the detailed discussion of these results, Table 5, as a whole, indicates that both $(\Delta\bar{\sigma}_R^+)_{DMF}$ and $(\sigma_i)_{DMF}$ derived are considerably modified from the standard values. This fact is in contrast with the result for conjugatively electron attracting substituents (Table 4). The solvent-modification of inductive effect appears serious for OH, NH_2, and $NHCOCH_3$ groups. The exaltation of π-electronic parameter is also most remarkable for these groups. The above treatment stands on the basis that the solvent-modification of substituents could be practically regarded as a minor perturbation as compared with the change in the electronic nature of the detection function, and the apparent nature of the modified substituent might be sufficiently invariable in *meta* and *para* positions in the system of interest. This may generally hold in usual chemical reactivities, while in the present case, especially of hydrogen-bond donor substituents, such as amino, hydroxyl and acetamino groups, the solvent-modification should no longer be a minor perturbation but a change of comparable importance with that of the detection function. There seems to be the possibility for these particular groups to result in the failure of the above treatment. Despite such the possible limitation of application, $(\sigma_i)_{DMF}$ values for most of $-R$ substituents including these particular groups can be correlated linearly with reasonable precision to $\Delta\Delta\delta_{m\text{-}X}^F$ values of *m*-substituted fluorobenzenes in DMF solution. This may suggest that the error induced from

this treatment could not be so serious.

Since related facts of interest have been available from our studies of the substituent chemical shifts of phenols and of amino protons of acetanilides and anilines in various aprotic solvents, the further discussion will be presented in accompanying papers.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1529—1533(1972)

Location of the Sulfate Groups in κ-Carrageenan from *Gigartina Tenella*

Susumu HIRASE and Kyoko WATANABE

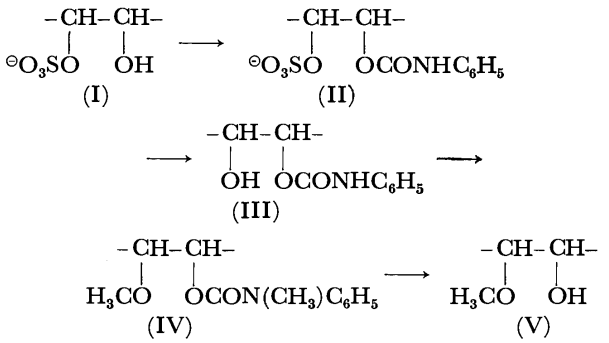
Department of Chemistry, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Kyoto

(Received November 8, 1971)

Location of the sulfate groups in κ-carrageenan from *G. tenella* has been re-investigated by adapting the method, which was devised by Bouveng for locating the acetyl groups in hemicellulose. In this method, the sulfate groups were replaced by methyl groups through a series of reactions consisting of blocking the free hydroxyl groups with phenylcarbamoyl groups, removing the sulfate groups and methylating the newly formed hydroxyl groups. The blocking substituents were then removed, and the positions of the methoxyl groups were investigated by the standard method. The results have shown, in accordance with the conclusion based on the methylation data, that one forth of the 1,4-linked 3,6-anhydro-D-galactose residues are 2-sulfated and that the 1,3-linked D-galactose residues are 4-sulfated. No evidence was obtained to indicate the presence of D-galactose 2,6-disulfate, which had been presumed by other workers. The problem concerning the acyl migration of the blocking groups during the process has also been discussed.

In our paper,[1] the structure of κ-carrageenan from *Gigartina tenella* has been investigated mainly by the methylation method. It has been concluded that the κ-carrageenan is composed of the residues of 1,3-linked β-D-galactose 4-sulfate (95 mol), 1,4-linked α-D-galactose 6-sulfate (5 mol), and 1,4-linked 3,6-anhydro-α-D-galactose (67 mol) and its 2-sulfate (24 mol), the 1,3- and 1,4-linked residues being repeated alternatingly to form a chain of the macro-molecule. This structure has been in approximate accordance with those reported by Anderson and his co-workers[2,3] for κ-carrageenans obtained from other species of *Gigartina* as well as from *Chondrus crisps*. The only difference is that they suggested the presence of a small amount of 1,4-linked D-galactose 2,6-disulfate residues in their polysaccharide samples. With this in mind, the location of the sulfate groups has been re-examined by the different method of investigation.

In the present work, the method devised by Bouveng for locating *O*-acetyl groups in hemicellulose[4,5] has been adapted for the purpose of locating sulfate groups. The method involves a series of reactions consisting of blocking the free hydroxyl groups with phenylcarbamoyl groups (I→II), removing the sulfate groups (II→III), methylating the newly formed hydroxyl groups (III→IV), removing the blocking groups (IV→V), breaking down the macro-molecule, and then identifying the fragments. The positions of methoxyl groups in the final products have been expected to indicate the positions of sulfate groups in the native polysaccharide.



In applying the Bouveng's procedure to our own purpose, modification was needed in several respects. In the step I→II, κ-carrageenan in sodium or potassium salt was difficult to react with phenylisocyanate because of its insolubility in the reaction medium. This difficulty was overcome by converting the metal salt into cetyl pyridinium salt, which was found soluble in pyridine so that the complete phenylcarbamoylation was effected. For removing sulfate groups (the step II→III), on the basis of some preliminary experiments, the phenylcarbamoate(II) was heated in a mixture of dioxane and methanol containing 0.5% hydrogen chloride at 80°C for 3 hr. By this treatment, the sulfate groups were mostly released. But the macro-molecule was degraded by the concurrent methanolysis of the

anhydro-galactoside linkages to form a mixture of oligosaccharide derivatives, whose average degree of polymerization was about six as determined by the methoxyl content. Examination of a part of the product by paper chromatography, after removal of the blocking substituents, showed the presence of carrabiose dimethyl acetal as well as higher oligosaccharide derivatives. The desulfated, partially degraded phenylcarbamoate(III) was next treated with trityl chloride to protect the primary hydroxyl groups, which might have been formed from galactose 6-sulfate residues, otherwise the phenylcarbamoyl groups would be migrated[4] from C_4 to C_6 during the succeeding step (III→IV) of methylation. The methylated product was then subjected to reductive removal of the blocking groups followed by detritylation and subsequent complete methanolysis.

TABLE 1. THE SUGARS IDENTIFIED IN THE FINAL PRODUCTS OF METHANOLYSIS

D-Galactose	Mol ratio[a]	3,6-Anhydro-D-galactose	Mol ratio[a]
non-methylated	1.0	non-methylated	1.0
3-*O*-methylated	0.66	2-*O*-methylated	0.24
4-*O*-methylated	1.64	5-*O*-methylated	0.84
3,4-di-*O*-methylated	2.44	2,5-di-*O*-methylated	0.38

a) The molar ratios are separately based on the respective non-methylated sugars.

The final product of methanolysis was a mixture of methyl glycosides or dimethyl acetals of the sugars listed in Table 1. These compounds were identified by isolation after separation on columns as well as by paper chromatography, thin layer chromatography, gas liquid chromatography and paper electrophoresis.

From these results, location of the sulfate groups in the polysaccharide is to be discussed. In the first place, the discussion is focussed to the distribution of the sulfate groups on anhydro-galactose residues. The methoxyl groups of C_5 in the final products are ascribed to the opening of pyranose rings during the process. When, as has already been described, anhydro-galactoside linkages were cleaved during the step II→III, the anhydro-sugar residues concerned would be undoubtedly changed from the pyranose structure to dimethyl acetal with the open chain structure,[6] forming thereby the free C_5-hydroxyl groups available for methylation in the succeeding step. While, the methoxyl groups on C_2 in the final products are ascribed to 2-sulfate groups. Thus, the relative yields of the anhydro-sugars (Table 1) show that non-sulfated and 2-sulfated anhydro-galactose residues exist in the proportion of 3: 1 in the native polysaccharide in exact agreement with the conclusion reported in our paper.[1] This agreement proves that the present carbamoylation-methylation analysis is effective in locating the sulfate groups on anhydro-galactose residues.

The discussion is now turned to the distribution of the sulfate groups on D-galactose residues. The presence of 3,4-di-*O*-methyl-D-galactose in the final products provides evidence that 1,3-linked D-galactose 4-sulfate residues exist in the polysaccharide in accordance again with the result reported in our paper.[1] In similar consideration, the positions of methoxyl groups in 3-*O*- and 4-*O*-methyl-D-galactoses may appear to indicate the positions of glycoside linkages and sulfate linkages, respectively, of D-galactose residues. However, no definite conclusion is obtainable from these mono-*O*-methyl-galactoses, because a part of the *O*-phenylcarbamoyl groups has been migrated between *cis* hydroxyl groups at C_3 and C_4 by the action of silver oxide during the methylation (III→IV). The occurrence of this migration has been proved by treating agarose from *Gelidium amansii* in exactly the same manner as in the case of κ-carrageenan. Since the agarose is a practically sulfate-free polysaccharide consisting of alternatingly repeated residues of 1,3-linked β-D-galactose and 1,4-linked 3,6-anhydro-α-L-galactose,[7] cleavage of the anhydro-galactoside linkages during the step II→III should produce free hydroxyl groups only at C_3 of D-galactose residues. Nevertheless, in the final products, a considerable amount of 4-*O*-methylgalactose was detected in addition to 3-*O*-methylgalactose. This result can be accounted for by the occurrence of migration of a part of the carbamoyl groups from C_4 to C_3. As for the non-methylated D-galactose in the final products from κ-carrageenan, the interpretation thereof is again ambiguous, because the sugar may be derived from any of the D-galactose non-sulfate, 4-sulfate and 6-sulfate residues, if these residues have survived the step II→III.

Thus the analysis by the present carbamoylation-methylation method seems to be of limited value as to the distribution of the sulfate groups on D-galactose residues. However, an important information would be obtainable as to the 2-sulfation of D-galactose residues. Anderson and his co-workers pointed out the presence of a small amount of the sugar sulfate residue, which formed 3,6-anhydro-galactose by alkaline treatment after periodate oxidation of their samples of κ-carrageenan.[2,3] They presumed this residue to be 1, 4-linked D-galactose 2,6-disulfate. Analysis of our polysaccharide sample by their method showed that there existed a very small amount of a similar residue. If this residue is presumed to be 1,4-linked D-galactose 2, 6-disulfate as Anderson and his coworkers did, 2-*O*-methylgalactose is then expected to be present in the final products of the carbamoylation-methylation method. In spite of careful examination, no trace of this sugar was detected. It follows from this result that neither galactose 2-sulfate nor 2,6-disulfate exist in our polysaccharide sample. The contradiction in the result between the two methods of analysis might be ascribed to an unavoidable experimental error of either method, because the amount of the residue under question is very small, if present. Another possible explanation is to presume the residue under question to be 1,4-linked D-galactose 3-sulfate, which would behave in the same manner as the 2,6-disulfate in periodate

oxidation followed by alkaline treatment, and which would not give 2-*O*-methylgalactose in the carbamoylation-methylation experiment. Further work will be needed to solve this problem.

General and Analytical Methods. General and analytical methods have been described in our paper[1] except those described below. The solvent I) benzene-ethyl acetate (3:2) was used for paper chromatography (pc), and L) benzene-ethyl acetate-water (40:15:trace) for thin layer chromatography (tlc), in addition to those (A—H and J—K, respectively) descrived before.

Gas Liquid Chromatography (glc). The columns used for glc were (a) 5% neopentylglycol succinate-chromosorb W, (b) 2.5% SE-30-chromosorb W and (c) 5% polyethylene glycol-chromosorb W, the length being 1 m unless otherwise stated. The final methanolysis product to be analysed was a complicated mixture consisting of methyl glycosides and dimethyl acetals of partially methylated galactoses and 3,6-anhydro-galactoses so that it was needed to analyse anhydro-galactose derivatives separately from galactose derivatives. For identifying the former derivatives was used the method B described in our paper,[1] in which anhydro-sugar derivatives were selectively converted into diethyl dithioacetal trimethylsilyl ethers. Analyses were carried out on the columns b at 160°C and c at 180°C as well as on the column a described before. For identifying galactose derivatives, the method D and E described below were devised. Furthermore, the method F described below was used for the sample of the relatively simple composition as in the case of a fraction obtained from column chromatography.

Method D: The sample to be analysed was hydrolysed with 1N-sulfuric acid at 100°C for 16 hr. During this treatment, anhydro-galactose derivatives were completely degraded. The remaining partially methylated galactoses were converted into diethyl dithioacetal trimethylsilyl ethers,[8] and analysed on the columns a at 160°C, b at 190°C and c at 180°C.

Method E: The partially methylated galactoses obtained in the method D were converted into diethyl dithioacetal acetates,[8] and analysed on the columns a at 215°C and b at 200°C.

Method F: Methyl glycosides or dimethyl acetals of partially methylated sugars were trimethylsilylated in the usual manner, and analysed on the columns a at 135°C, and b (2 m) at 160°C or 190°C.

Cetyl Pyridinium Salt of κ-Carrageenan. To a solution of κ-carrageenan (8 g) in water (240 m*l*), cetyl pyridinium chloride (8 g) in water was added with stirring. The precipitates, which formed, were collected by centrifugation, washed successively with water, methanol and again water, and dried *in vacuo*. The cetyl pyridinium salt was obtained as colorless powder (11.3 g). Found: N, 2.1%. Calcd for the polymer composed of galactose (1.0), 3,6-anhydro-galactose (0.91) and sulfate (1.24):[1] N, 2.26%.

Phenylcarbamoylation (I→II). To the cetyl pyridinium salt (11.3 g), which had been dried over phosphorus pentoxide at 40°C in vacuum overnight, dry pyridine (300 m*l*) and phenylisocyanate (25 g) were added. The mixture was heated at 100°C, when the salt was gradually dissolved within 1 hr. After being heated for 6 more hr, the reaction solution was left for 24 hr at room temperature. Ethanol (50 m*l*) was then added to destroy the excess of the reagent. The solution was centrifuged to remove small amounts of insoluble matter, and evaporated. The product was precipitated with 99% ethanol, the phenylcarbamoate (II) being obtained as slightly colored powder (14 g); $[\alpha]_D^{28}+75°$ (*c* 1.0 in pyridine). Found: SO_3, 8.9; N, 5.5%. Calcd for the phenylcarbamoate of the polymer with the composition described above: SO_3, 9.14; N, 5.04%.

Desulfation (II→III). A solution of the above-obtained phenylcarbamoate (14 g) in a mixture of dry dioxane (280 m*l*) and 1% methanolic hydrogen chloride (280 m*l*) was refluxed for 3 hr. The reaction mixture was neutralized with barium carbonate, filtered, evaporated to a small volume, and re-dissolved in chloroform. The solution was washed 3 times with water, dried with magnesium sulfate, and evaporated to a small volume, to which was added dry hexane. The product (III) was precipitated as powder (12.5 g); $[\alpha]_D^{24}+28.0°$ (*c* 0.78 in pyridine). Found: CH_3O, 3.3; SO_3, 0.5%. The methoxyl content indicated that the polymer was degraded to *O*-phenylcarbamoylated hexasaccharide dimethyl acetal in average. A portion of the product in dry dioxane was treated with lithium aluminum hydride to remove the phenyl-carbamoyl groups. Examination of the product by pc (solvent A, spray c) showed the presence of carrabiose dimethyl acetal as well as higher oligosaccharide derivatives.

Tritylation of III. The above-obtained product (12.5 g), which had been completely dried over phosphorus pentoxide, was dissolved in dry pyridine (75 m*l*). Trityl chloride (5.7 g) was added, and the mixture was left at 40°C for 2 days. After destroying the excess of the reagent by addition of water (10 m*l*), the mixture was disolved in chloroform, and the solution was washed successively with potassium hydrogen sulfate solution, sodium bicarbonate solution and water, dried with magnesium sulfate, and evaporated to a syrup, which was then dissolved in methanol and left aside in a refrigerator. Trityl carbinol, which crystallized, was filtered off, and the filtrate was evaporated to dryness (11.0 g); $[\alpha]_D^{24}+26.7°$ (*c* 0.72 in pyridine).

Methylation (III→IV). The tritylated product (11.0 g) obtained above in *N,N*-dimethylformamide[9] (130 m*l*) was shaken with iodomethane (50 g) and silver oxide (20 g) for 0.5—1.0 hr. Additional iodomethane (50 g) and silver oxide (20 g) were added, and the mixture was shaken for 24 hr. This methylation was repeated two more times. The reaction mixture was filtered, and evaporated at 90°C to a syrup, which was then dissolved in chloroform. The solution was washed successively with 10% potassium cyanide solution and water, dried with magnesium sulfate, and evaporated to a

8) Retention times of reference compounds and other experimental details will be published later.

9) R. Kuhn, H. Trischmann, and I. Löw, *Angew. Chem.*, **67**, 32 (1955).

thin syrup. Addition of hexane precipitated the product (IV) (8.4 g), which was filtered off, and dried *in vacuo* over phosphorus pentoxide at 40°C; $[\alpha]_D^{26}+30.8°$ (*c* 0.64 in pyridine).

Decarbamoylation (IV→V). The methylated product (8.4 g) obtained above was dissolved in dry tetrahydrofuran (200 m*l*), lithium aluminum hydride (3 g) added slowly, and the mixture was refluxed for 4 hr. Methanol (10 m*l*) and water (10 m*l*) were added slowly, and aluminum hydroxide was filtered off, and washed with methanol-water (1:1). The combined filtrate and washings were neutralized with dilute phosphoric acid and filtered again. The filtrate was extracted with hexane to remove an oily reduction product, and the residual solution was evaporated to dryness (7.0 g).

Detritylation and Methanolysis. The product (7.0 g) obtained above was refluxed with 1% methanolic hydrogen chloride (50 m*l*) for 2 hr, neutralized with silver carbonate and filtered. The filtrate was deionized with Amberlite IR-120 (70 m*l*) and IR-45 (150 m*l*), and evaporated to a syrup (3.6 g), $[\alpha]_D^{24}+9.3°$ (*c* 0.4 in methanol), which was again treated with 2% methanolic hydrogen chloride (50 m*l*) at 80°C for 22 hr. The reaction solution was treated in the usual manner, and the product was obtained as a syrup (3.4 g); $[\alpha]_D^{24}+60.1°$ (*c* 0.7 in water).

Analysis of the Methanolysis Products. Examination of the syrup obtained above by pc (solvent D, I, spray c) and tlc (solvent K) indicated the presence of dimethyl acetals of AG, 2MAG, 5MAG, and 25MAG and methyl glycoside of 2MAG. Quantitative determination was carried out by glc (method B, column a and b), and the result was expressed in the molar ratio (Table 1). On the other hand, a portion of the syrup was hydrolysed with 1N-hydrochloric acid at 100°C for 16 hr. The hydrolysate contained galactose, 3MG, 4MG, and 34MG as shown by pc (solvent A, B, C, E, G, and H, spray a and b), paper electrophoresis, and glc (method D and E). The results of quantitative determination by glc using the columns a, b and c were in good mutual agreement, and the mean values expressed in the molar ratio were given in Table 1.

Separation of the Methanolysis Products. A part of the methanolysis products (2.0 g), obtained above, was applied to a starch-Celite 545 column (5.5×46 cm), which was then eluted with butanol-water (6:1). The effuluents were checked by a resorcinol reagent, an anthrone reagent, pc (solvent D and I) and/or tlc (solvent J and K). Fractions showing similar contents were combined, and evaporated to give Fractions I, II, and III. These fractions were combined with similar fractions obtained from the remaining portion of the methanolysis products (1.4 g).

Fraction I. Yield 0.99 g. This fraction was shown to be a mixture of dimethyl acetals of 25MAG, 2MAG, and 5MAG and methyl glycoside of 2MAG by pc (solvent D and I, spray c) and tlc (solvent K and L). Separation and isolation of these components was achieved only when chromatography was repeated several times using different columns and different solvent mixtures. The yields were low mainly because of mechanical loss during the repeated treatment. Fraction I (0.99 g) was applied to a Dowex 1×4 column (OH form, 5×80 cm) and eluted by distilled water to give three fractions, I-1, I-2, and I-3 which were checked by pc (solvent D and I), tlc (solvent K and L) and glc (method F, column a, b and c).

Fraction I-1 (80 mg) was a mixture of dimethyl acetals of 25MAG and 5MAG. The mixture was separated on an alumina column (2×26 cm). 25MAG dimethyl acetal was eluted with benzene-ethanol (15:1), and obtained as a syrup (57 mg); $[\alpha]_D^{26}+22.9°$ (*c* 4.21 in water). It was converted into crystalline 3,6-anhydro-2,5-di-*O*-methyl-D-galactonic acid in the usual way;[10] mp and mmp 165—166°C, $[\alpha]_D^{25}+59.0°$ (*c* 0.64 in water). (Found: C, 46.42; H, 6.33; OCH_3, 30.18%). The alumina column was then eluted with benzene-ethanol (2:1) to give 5MAG dimethyl acetal (5 mg).

Fraction I-2 (0.44 g) was shown by pc to be 5MAG dimethyl acetal contaminated with a small amount of 2MAG dimethyl acetal. Seeding with a synthetic sample[11] afforded crystalline 5MAG dimethyl acetal, which was then recrystallized twice from ethyl acetate-benzene-hexane (1:1:2), yield 0.33 g; mp and mmp 53.5—54.5°C, $[\alpha]_D^{20}+42.6°$ (*c* 0.59 in water), (Found: C, 48.79; H, 8.23; OCH_3, 40.99%). This compound was further identified by conversion into its *p*-nitrobenzoate;[11] mp and mmp 143—145°C, $[\alpha]_D^{20}+66.1°$ (*c* 1.15 in chloroform), (Found: C, 52.92; H, 4.66; N, 5.26; OCH_3, 16.52%). The mother liquor of the crystallization showed the presence of 2MAG dimethyl acetal in addition to 5MAG dimethyl acetal by pc, tlc, and glc. Then the mixture was separated on a Sephadex LH-20 column (2×24 cm) with chloroform as a solvent. 5MAG (4 mg) was the faster-moving component, which was followed by 2MAG (15 mg); $[\alpha]_D^{28}+27.4°$ (*c* 1.48 in water). This compound was identified by conversion into crystalline 3,6-anhydro-2-*O*-methyl-D-galactonic acid in the usual manner; mp 142°C, $[\alpha]_D^{25}+65.2°$ (*c* 0.31 in water),[2] (Found: C, 42.98; H, 7.15%).

Fraction I-3 (53 mg) was a mixture of dimethyl acetal of 5MAG and methyl glycoside of 2MAG. The mixture was separated on an alumina column (2×26 cm) with benzene-ethanol (15:1) as solvent. The 2MAG derivative was the faster moving component, and was obtained as a syrup (13 mg), $[\alpha]_D^{26}-65.1°$ (*c* 1.06 in water), which was identified again by conversion into crystalline anhydro-2-*O*-methyl-3,6-D-galactonic acid;[2] mp and mmp 141.5°C, $[\alpha]_D^{25}+63.9°$ (*c* 0.15 in water).

Fraction II. Yield 1.32 g. This fraction was shown to be a mixture of dimethyl acetal of AG and methyl glycoside of 34MG by pc (solvent A, D and I) and tlc (solvent J and K). The mixture (1.32 g) was placed on a Dowex 1×4 (OH form, 3×30 cm) column. The methyl glycosides of 34MG were readily eluted with water, and obtained as a syrup (0.85 g); $[\alpha]_D^{29}+146°$ (*c* 1.2 in water). The syrup was hydrolysed with 1N-sulfuric acid at 100°C for 4 hr, and the product was twice recrystallized from methanol-ethyl acetate, 34MG being obtained as prisms;[12,13] mp and mmp 169—171°C, $[\alpha]_D^{21}+105.8°\rightarrow+126.3°$ (*c* 0.43 in water), (Found: C, 46.02; H, 7.65; OCH_3, 30.1%).

The Dowex column was then eluted with 0.2M-ammonium carbonate solution, and the effluent was deionized by Amberlite IR-120 and IR-45, and evaporated to dryness. AG dimethyl acetal was obtained as a syrup (0.45 g); $[\alpha]_D^{29}+38.9°$ (*c* 0.90 in water). It was converted into AG diphenyl hydrazone in the usual manner;[10] mp and mmp 154—156°C, $[\alpha]_D^{19}+24.5°$ (*c* 0.66 in methanol), (Found: C, 65.61; H, 6.24; N, 8.37%).

Fraction III. Yield 0.96 g. This fraction was shown to be a mixture of methyl galactosides and their mono-*O*-methyl derivatives and a small amount of oligosaccharide derivatives by pc (solvent A) and tlc (solvent J and K). The mixture (0.96 g) was hydrolysed with 1N-sulfuric acid for 4 hr in the usual manner to give a mixture of reducing sugars (0.92 g). Crystallization from methanol afforded D-galactose (0.36 g); mp and mmp 164—165°C, $[\alpha]_D^{20}+118.1°$—

+80.4° (*c* 0.91 in water), (Found: C, 40.14; H, 6.63%). The mother liquor was evaporated to a syrup (0.45 g), which was then separated on a starch-Celite 545 column (3×30 cm) with butanol-water (6:1). Three fractions III-1, III-2, and III-3 were obtained as checked by pc (solvent A, B, C, and E).

Fraction III-1 (42 mg) showed a single spot of 34MG by pc and crystallized on standing.

Fraction III-2 (0.19 g) was shown to be a mixture of 3MG and 4MG by pc (solvent A, E, G, and H), glc (method D, column a and b; method E, column a, and b), and paper electrophoresis. On standing, 4MG crystallized. It was recrystallized from water-methanol (36 mg);[14] mp and mmp 209—211°C, $[\alpha]_D^{29}$ +64.76→+89.46° (*c* 0.43 in water). (Found: C, 43.16; H, 7.20; OCH_3, 15.8%).

The mother liquor was evaporated to a syrup (0.14 g), which was then placed on a Dowex 1×4 (borate form, 2×16 cm) column. Elution with water afforded 4MG (13 mg). The eluant was then replaced by 0.03M-potassium borate solution. The effluent was treated with Amberlite IR-120 to remove potassium ion, and the resulting acidic solution was evaporated to dryness. Boric acid was removed by repeated addition of methanol to the residue followed by evaporation. The final product was obtained as a syrup (0.1 g); $[\alpha]_D^{31}$ +80.7° (*c* 0.82 in water). This syrup was indistinguishable in pc (solvent G, spray a and b), glc (method D, column a and b), and paper electrophoresis[15] from the sample of 3MG, which was synthesized by the method of Ball and Jones.[16] Crystallization of either of the syrup obtained above and the synthesized one was unsuccessful.

Fraction III-3 (0.14 g) was shown to be a mixture of galactose and a small amount of oligosaccharide by pc (solvent A, B and C). On standing, D-galactose crystallized (70 mg); mp and mmp 164—166.5°C.

Alkaline Treatment of κ-Carrageenan after Periodate Oxidation. According to the method of Anderson and his co-workers,[2] κ-carrageenan (0.5 g) was treated with 0.05M-sodium periodate solution (100 m*l*) at room temperature for 75 hr in the dark. After destroying the excess of the oxidant with ethylene glycol, potassium borohydride (1.5 g) was added. The solution was diluted to 500 m*l*, left for 2 days, and dialysed against running water. The dialysate was divided into two halves, one of which was used to analyse the sugars, and the other one was subjected to the treatment with potassium hydroxide at 80°C for 4 hr in the usual manner and subsequent analysis of the sugars. Comparison of the analytical results showed that 3% of the total galactose residues existed as the periodate-resistant sulfate residues, which were convertible into 3,6-anhydro-galactose by the alkaline treatment.

Experiments on Agarose from G. amansii. A series of reactions was performed in a similar manner to the case of κ-carrageenan. Dry agarose (2.0 g) suspended in dry *N*,*N*-dimethylformamide (70 m*l*) was heated with phenylisocyanate (10 m*l*) at 100°C for 10 hr. The phenylcarbamoate (4.6 g), obtained as powders, was treated with a boiling mixture of dioxane (40 m*l*) and 2% methanolic hydrogen chloride (40 m*l*) for 2 hr. The product (4.2 g), a part of which on removal of the carbamoyl group showed the presence of agarobiose dimethyl acetal as well as higher oligosaccharide derivatives by pc (solvent D, spray c), was methylated repeatedly by the Kuhn's method.[9] The methylated product (4.6 g) in dry tetrahydrofuran (50 m*l*) was refluxed with lithium aluminum hydride (1.0 g) for 4 hr, and the resulting decarbamoylated product (1.1 g) was subjected to complete methanolysis. The final product was obtained as a syrup (0.9 g).

Examination by pc (solvent D and I, spray c) and tlc (solvent K) showed the presence of dimethyl acetals of 3,6-anhydro-galactose and its 5-methyl ether. While, hydrolysis of the above final product followed by examination by pc (solvent C, E, G and H, spray a and b) showed the presence of galactose and its 3- and 4-methyl ether. Quantitative glc (method D, columns a, b and c) showed that galactose and its 3- and 4-methyl ethers existed in the molar proportions of 100:43:13.

Studies of Acyl and Thioacyl Isocyanates. VIII.[1] Cycloaddition Reactions of Benzoyl and Thiobenzoyl Isocyanates with Carbodiimides

Otohiko Tsuge and Kazuko Sakai

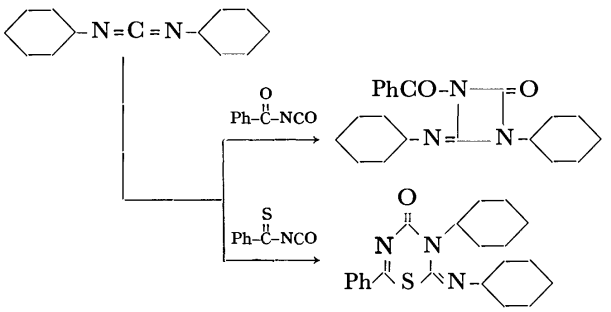
Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka

(Received November 15, 1971)

The investigations of cycloaddition reactions of benzoyl and thiobenzoyl isocyanates with carbodiimides have shown that the adducts formed from benzoyl isocyanates and *N,N'*-dicyclohexylcarbodiimide are the corresponding (4+2) cycloadducts, and not the (2+2) cycloadducts proposed by Neidlein. The reaction of isocyanates with *N,N'*-diphenylcarbodiimide at 0°C gave (2+2) cycloadducts, which were thermally isomerized into the corresponding (4+2) cycloadducts. Benzoyl isocyanates reacted with *N*-cyclohexyl-*N'*-phenylcarbodiimide to give (4+2) cycloadducts of isocyanates to the cyclohexyl-N=C bond in the carbodiimide. On treatment with neutral alumina, (4+2) cycloadducts were easily isomerized into 1,3,5-triazines. Thiobenzoyl isocyanate reacted with both the N=C bonds of the carbodiimide to afford two isomeric (4+2) cycloadducts. It has been found that benzoyl isocyanates reacted with *N*-phenyl-*N'*-*o*-tolylcarbodiimide to yield the corresponding (4+2) cycloadducts of isocyanates to the *o*-tolyl-N=C bond and/or the isomeric 1,3,5-oxadiazin-6-ones, depending on the nature of the substituent in the isocyanate. Reaction paths for the formation of the product are also discussed.

During the last few years, cycloaddition reactions of carbodiimides with various reagents have been extensively investigated.[2]

Neidlein[3] reported that benzoyl isocyanate reacts with *N,N'*-dicyclohexylcarbodiimide to form a (2+2) cycloadduct, while Goerdeler and Schenk[4] reported that the cycloaddition of thiobenzoyl isocyanate to the same carbodiimide gave a (4+2) cycloadduct.



In the dimerization[5] and cycloaddition to anils,[6] benzoyl isocyanates gave (4+2) cycloadducts but no (2+2) cycloadducts. Formation of the (2+2) cycloadduct reported by Neidlein[3] would be the first example of (2+2) cycloaddition of benzoyl isocyanate to a C=N bond.

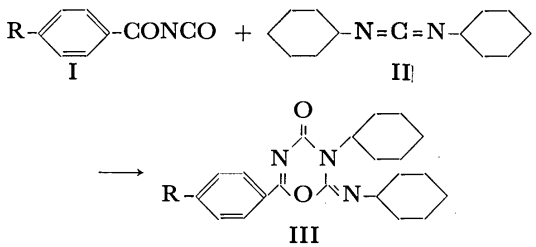
Acoordingly, the cycloaddition reactions of benzoyl isocyanates with carbodiimides were of special interest to us. This paper deals with the cycloaddition reactions of benzoyl and thiobenzoyl isocyanates with symmetrical and asymmetrical carbodiimides.

Results and Discussion

Cycloadditions to Symmetrical Carbodiimides. The reaction of benzoyl isocyanate (Ia) with an equimolar amount of *N,N'*-dicyclohexylcarbodiimide (II) in a benzene–diethyl ether solution at 0°C or at room temperature gave the 1:1 adduct IIIa of Ia and II. From a comparison of the melting point and UV spectrum of IIIa with those of the adduct reported by Neidlein,[3] the adduct IIIa obtained here was found to be the same one obtained by Neidlein.

The absorption bands in the range 1300—1750 cm^{-1} in the IR spectrum of IIIa are very similar to those in the spectra of 3-benzyl-2,6-diphenyl-2*H*-1,3,5-oxadiazin-4(3*H*)-one[6] and of the (4+2) cycloadduct[4] of thiobenzoyl isocyanate to II. The correlation between the intensities and the wave numbers of $\nu_{C=O}$ and $\nu_{C=N}$ in the three compounds is similar to that between the intensity and the wave number of $\nu_{C=O}$ and $\nu_{C=C}$ in γ-pyrone.[5]

Consequently, it can be assumed that IIIa is the (4+2) cycloadduct, 3-cyclohexyl-2-cyclohexylimino-6-phenyl-2*H*-1,3,5-oxadiazin-4(3*H*)-one, rather than the (2+2) cycloadduct proposed by Neidlein.[3]



a: R=H, b; R=Cl, c: R=NO_2, d: R=OMe

Similar reactions of *p*-substituted benzoyl isocyanates (Ib—Id) with II gave the corresponding (4+2) cycloadducts (IIIb—IIId). The yields, physical properties and elemental analyses of III are summarized in Table 1.

On the other hand, with *N,N'*-diphenylcarbodiimide (IV) at 0°C, benzoyl isocyanate (Ia) gave the corre-

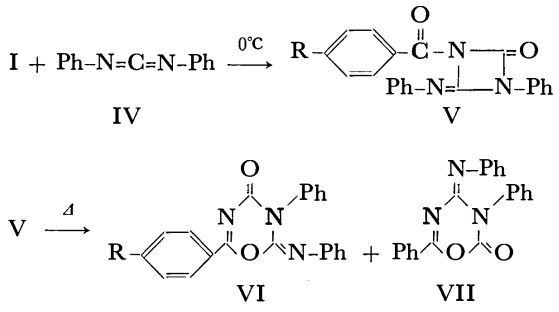
sponding 1:1 adduct Va. From the characteristic $\nu_{C=O}$ at 1880 cm^{-1} in the IR spectrum as well as from the result of thermal isomerization, the structure of Va was established to be the (2+2) cycloadduct, 1-benzoyl-3-phenyl-2-phenylimino-1,3-diazetidin-4-one.

The (2+2) cycloadduct Va was thermally isomerized into the (4+2) cycloadduct, 3,6-diphenyl-2-phenylimino-2*H*-1,3,5-oxadiazin-4(3*H*)-one (VIa); a small amount of isomeric 1,3,5-oxadiazin-6-one VII was also formed.

Similar reactions of *p*-substituted benzoyl isocyanates (Ib—Ic) with IV at 0°C gave the corresponding (2+2) cycloadducts Vb and Vc, which on thermal isomerization afforded good yields of the corresponding (4+2) cycloadducts, VIb and VIc respectively.

The reaction of Ia with IV in a refluxing benzene–ether solution gave VIa and VII, but Va was not formed.

The proposed structures VI and VII were confirmed by spectral studies. The IR spectrum of VIa is similar to that of (4+2) cycloadducts III, while the absorption



a: R=H, b: R=Cl, c: R=NO_2

bands in VII is similar to those of 2,4-diphenyl-1,3,5-oxadiazin-6-one.[5] Correlation between the intensity and wave number of $\nu_{C=O}$ and $\nu_{C=N}$ in the spectrum of VII is also similar to that between the intensity and wave number of $\nu_{C=O}$ and $\nu_{C=C}$ in α-pyrone.[5]

The physical properties and results of elemental analyses of V, VI, and VII are given in Tables 2 and 3 respectively.

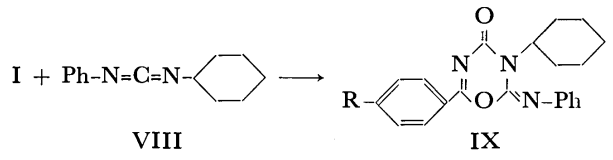
Cycloaddition to Asymmetrical Carbodiimides. The isocyanates would be expected to attack competitively both C=N bonds of asymmetrical carbodiimides.

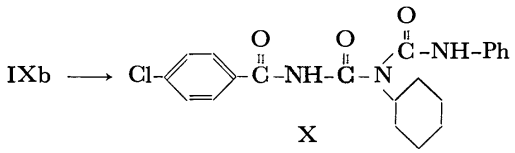
The reactions of benzoyl isocyanates (I) with *N*-cyclohexyl-*N'*-phenylcarbodiimide (VIII) gave the corresponding 1:1 adducts IX of I and VIII in good yields.

From the similarity between the IR spectra of IX and the (4+2) cycloadducts III and VI, the structures of the adducts IX were assumed to be (4+2) cycloadducts.



VIII IX

a: R=H, b: R=Cl, c: R=NO_2, d: R=OMe



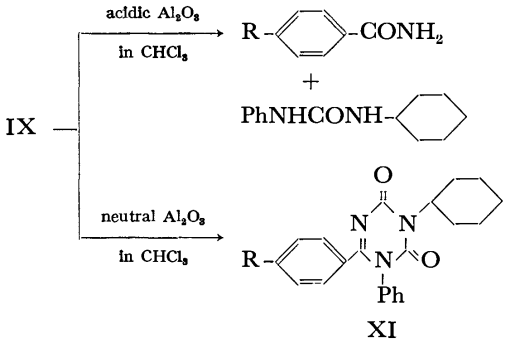
X

Hydrolysis of IXb with dilute hydrochloric acid gave 1-cyclohexyl-1-phenylcarbamoyl-3-*p*-chlorobenzoylurea (X). This indicates that the adduct IXb is 6-*p*-chlorophenyl-3-cyclohexyl-2-phenylimino-2*H*-1,3,5-oxadiazin-4(3*H*)-one, whose structure corresponds to the (4+2) cycloadduct of the isocyanate Ib to the cyclohexyl-N=C bond in VIII.

Thus, it could be concluded that all the adducts of IX are (4+2) cycloadducts of the isocyanates to the cyclohexyl-N=C bond of carbodiimide VIII.

The yields, physical properties and results of elemental analyses of IX are summarized in Table 4.

Treatment of the adducts IX with acidic alumina in chloroform gave the corresponding benzamide and 1-cyclohexyl-3-phenylurea, while similar treatment with neutral alumina afforded the isomeric 1,3,5-triazine-2,6-diones XI.



a: R=H, b: R=Cl, c: R=NO_2, d: R=OMe

The yields, physical properties, and results of elemental analyses of XI are given in Table 5.

Further confirmation of these assignments was provided by the mass spectral studies. The mass spectrum of IXb showed the parent peak (M^+) at *m/e* 381 and other peaks at *m/e* 299 (M^+-), 200 (M^+-ArCONCO), 181 (ArCONCO$^+$), 162 (299$^+-$ArCN), 139 (ArCO$^+$), 119 (PhNCO$^+$), and 118 (PhN=C=NH$^+$, base peak). In the mass spectrum of XIb, the parent peak (M^+) appeared at *m/e* 381, together with major peaks at *m/e* 300, 299 (M^+-), base peak), 257 (300$^+-$HCNO), 256 (299$^+-$HCNO), 215 (ArC=$\overset{+}{N}$HPh), 214 (Ar–C≡$\overset{+}{N}$–Ph), 163 (300$^+-$ArCN),

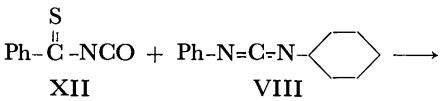
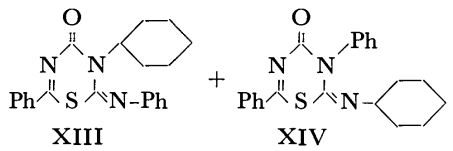
138 ($ArC\equiv\overset{+}{N}H$), and 119 ($PhNCO^+$).[7]

Thiobenzoyl isocyanate (XII) reacted with VIII to give two isomeric cycloadducts, XIII (mp 146.5—147.5°C) and XIV (mp 160°C), in 23 and 20% yields, respectively.

On the basis of IR and NMR spectra, structures XIII and XIV were assigned to (4+2) cycloadducts of the isocyanate to the cyclohexyl–N=C bond and to the phenyl–N=C bond of VIII, respectively.



XII VIII

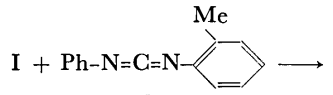


XIII XIV

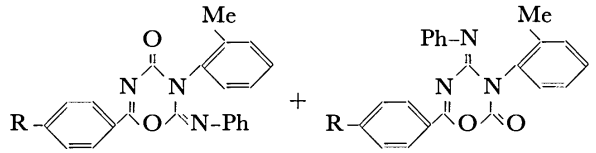
In the NMR spectrum of (4+2) cycloadduct IXb the methine-proton of *N*-cyclohexyl ring appears at δ 4.4—5.0 ppm as a multiplet, and the spectrum of (4+2) cycloadduct IIIa gives two methine-protons at δ 3.4—4.0 $\left(=N-\underset{H}{\text{C}}<\right)$ and 4.3—5.0 ppm $\left(-\overset{|}{N}-\underset{H}{\text{C}}<\right)$. The spectra of XIII and XIV show a multiplet at δ 4.8—5.2 ppm $\left(-\overset{|}{N}-\underset{H}{\text{C}}<\right)$ and one at δ 3.2—3.9 ppm $\left(=N-\underset{H}{\text{C}}<\right)$.

Cycloadditions of benzoyl isocyanates (I) to *N*-phenyl-*N'*-*o*-tolylcarbodiimide (XV) were investigated; the results are given in Table 6. The products XVI and/or XVII were formed, depending on the nature of the substituents in the isocyanate. Crystals obtained from the reaction of Id with XV were found to be a mixture of XVId and XVIId by the IR spectrum. An attempt to separate XVId from the crystals by recrystallization was unsuccessful.

On the basis of the IR spectra, the adducts XVI were confirmed to be the corresponding (4+2)cycloadducts. It is evident from the results of chemical conversions that compounds XVI are the 6-aryl-2-phenylimino-3-*o*-tolyl-2*H*-1,3,5-oxadiazin-4(3*H*)-ones, whose structures correspond to the (4+2) cycloadducts of the isocyanates to the *o*-tolyl-N=C bond in XV.

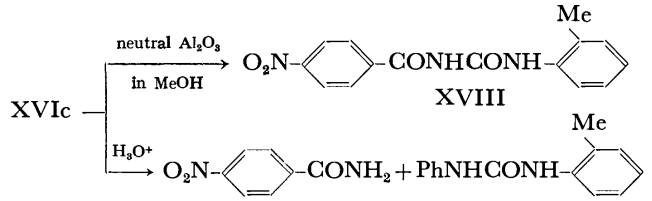


XV



XVI XVII

a: R=H, b: R=Cl, c: R=NO_2, d: R=OMe



XVIII

Treatment of the adduct XVIc with neutral alumina in methanol gave 1-*p*-nitrobenzoyl-3-*o*-tolylurea (XVIII), while XVIc was hydrolyzed with dilute hydrochloric acid to afford *p*-nitrobenzamide and 1-phenyl-3-*o*-tolylurea.

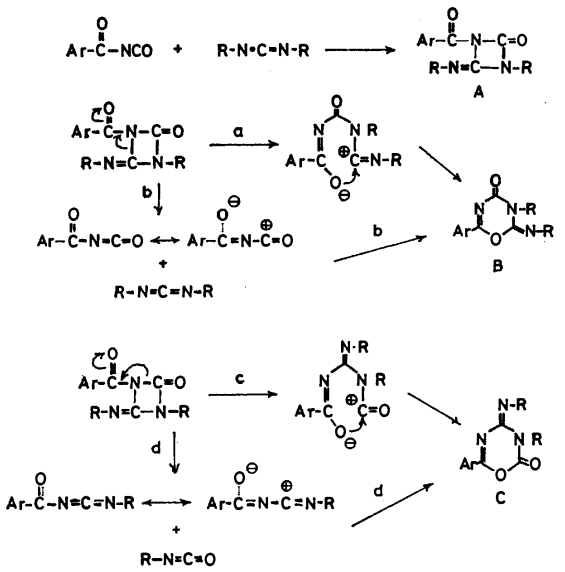
Isomeric adducts XVIIa and XVIId were assumed from the similarity between the IR spectra of XVII and VII, to be the corresponding 1,3,5-oxadiazin-6-ones.

Formation Pathways of the Products. The reaction pathways of the isocyanates and carbodiimides can be considered as follows.

As shown in Scheme 1, the isocyanate reacts with the carbodiimide to give first (2+2) cycloadduct (**A**). In fact, (2+2) cycloadducts V were obtained in the reaction of isocyanates I with carbodiimide IV at 0°C. Since (2+2) cycloadduct (**A**) is thermally unstable, it is converted to (4+2) cycloadduct (**B**) through either isomerization (path a) or 1,4-cycloaddition after dissociation into its components (path b).

On the other hand, 1,3,5-oxadiazin-6-one (**C**) obtained by the thermal isomerization of (2+2) cycloadduct Va or from the reaction of isocyanates I with carbodiimide XV, might be formed through either

7) Ar represents the *p*-chlorophenyl group.

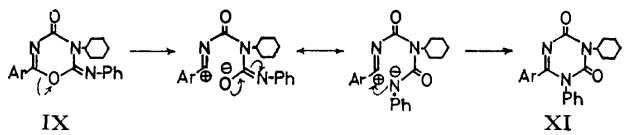


Scheme 1

isomerization (path c) or 1,4-cycloaddition after dissociation into aryl isocyanate and asymmetrical aroyl carbodiimide (path d).

However, isomerization paths a and c would seem to be more reasonable than the dissociation routes b and d. Indeed, no cross-over products, which would be expected from the reactions of isocyanate (Ar–C(=O)–NCO) with carbodiimide (Ar–C(=O)–N=C=N–R) and of isocyanate (RNCO) with carbodiimide (R–N=C=N–R), were formed in all the reactions.

Although the exact course of the formation of 1,3,5-triazine-2,6-diones XI from (4+2) cycloadducts IX and neutral alumina is not clear, we proposed the following sequence: if the ring opening of IX occurs, it would then recyclize to 1,3,5-triazine XI.



IX XI

A similar ring opening followed by recyclization was observed in the isomerization of the adduct of benzoylsulfene to carbodiimide.[8]

Experimental

All the melting points are uncorrected. The IR spectra were recorded on a Nippon Bunko IR-S spectrometer, and the UV spectra were measured with a Shimadzu SV-50A spectrophotometer. The NMR spectra were determined at 60 MHz with a Hitachi R-20 NMR spectrometer with TMS as the internal reference. The mass spectra were obtained on a Hitachi RMS-4 mass spectrometer with a direct inlet and an ionization energy of 70 eV.

Materials. *p*-Substituted benzoyl isocyanates (Ia—Id)[5] and thiobenzoyl isocyanate (XII)[9] were prepared by the methods reported previously.

N,N'-Dicyclohexylcarbodiimide (II), bp 155—156°C/10 mmHg (lit,[10] bp 148—152°C/11 mmHg), and *N,N'*-diphenylcarbodiimide (IV), bp 119—120°C/0.2—0.3 mmHg (lit,[11] bp 110—112°C/0.2 mmHg), were prepared according to the reported methods.

N-Cyclohexyl-*N'*-phenylcarbodiimide (VIII). The carbodiimide was obtained from *N*-cyclohexyl-*N'*-phenylthiourea by a method similar to that described by Iwakura and Noguchi.[12] A mixture of *N*-cyclohexyl-*N'*-phenylthiourea (38 g), commercial sodium hypochlorite (650 g), 40% aqueous sodium hydroxide solution (180 m*l*) and toluene (200 m*l*) was stirred at 70°C for 2 hr. After the reaction mixture was cooled, the aqueous layer was separated and then extracted with toluene. The combined toluene solution was washed with water and dried over anhydrous sodium sulfate. After evaporation of the toluene, the residue was distilled over active copper powder,[13] affording VIII (16 g), bp 139—140°C/4 mmHg. $\nu_{N=C=N}$: 2180 cm^{-1}. M$^+$: *m/e* 200.

N-Phenyl-*N'*-*o*-tolylcarbodiimide (XV). The carbodiimide was prepared according to a method similar to that described by Meakins and Moss.[14] Yellow mercuric oxide (35.6 g) was added in portions to a refluxing solution of *N*-phenyl-*N'*-*o*-tolylthiourea (20 g) and sulfur (0.2 g) in acetone (400 m*l*). After the reaction mixture was boiled for 20 min, the precipitate was collected and washed with acetone (100 m*l*). The combined acetone solution was dried over anhydrous sodium sulfate and concentrated *in vacuo*, leaving a residue. Since the residue was transformed into *N,N'*-diphenyl- and -di-*o*-tolylcarbodiimide on distillation, the residue was purified by chromatography on neutral alumina using petroleum benzine as an eluent. $\nu_{N=C=N}$ 2180 cm^{-1}. M$^+$: *m/e* 208.

Reaction of I with II. A solution of 0.7 g of II in 5 m*l* of benzene–diethyl ether mixture (1:1) was added dropwise to a solution of 0.5 g of Ia in 2 m*l* of benzene at 0°C. The reaction mixture was stirred at room temperature for a few minutes, during which time crystals were formed. Filtration gave colorless crystals, which on recrystallization from benzene–petroleum benzine (bp 45—60°C) mixture afforded (4+2) cycloadduct IIIa, mp 142—143°C, as colorless prisms. Yield, 0.6 g (54%).

Similar reactions of Ib—Id with II afforded the corresponding (4+2) cycloadducts IIIb—IIId. The results are given in Table 1.

Reaction of I with IV. *i)*: To a solution of 1.2 g of Ia in 10 m*l* of benzene was added dropwise a solution of 1.6 g of IV in 10 m*l* of benzene–diethyl ether mixture (1:1) at 0°C. After the reaction mixture was stirred at the same temperature for 24 hr, filtration gave colorless crystals. Recrystallization from dichloromethane–petroleum benzine (bp 35—45°C) mixture afforded 1.5 g (55%) of (2+2) cycloadduct Va, mp 112—113°C (decomp.), as colorless needles.

Similar reactions of Ib and Ic with IV gave the corresponding (2+2) cycloadducts Vb and Vc. The results are summarized in Table 2.

ii): A solution of 1.0 g of Ia and 1.32 g of IV in a mixture of 15 m*l* of benzene and 5 m*l* of diethyl ether was stirred at room temperature for 2 hr, and then at 70°C for 5 hr. The reaction mixture was concentrated *in vacuo* to leave a residue, which crystallized on trituration with petroleum benzine (bp 40—50°C). The crystals were separated into more soluble and less soluble parts by fractional crystallization. The former was recrystallized from ethanol to give 0.69 g (30%) of 3,6-diphenyl-4-phenylimino-2*H*-1,3,5-oxadiazin-2-(3*H*)-one (VII), mp 204—205°C (decomp.), as yellow needles.

Found: C, 73.82; H, 4.43; N, 12.29%. Calcd for $C_{21}H_{15}O_2N_3$: C, 73.89; H, 4.43; N, 12.31%.

Recrystallization of the latter from ethanol afforded 0.29 g (12%) of (4+2) cycloadduct VIa, mp 179—179.5°C, as yellow prisms.

Thermal Isomerization of (2+2) Cycloadduct V. Thermal isomerization of V in the solid state was carried out in a test tube at 120°C (oil bath) for 2 hr. After cooling, the product was triturated with petroleum benzine (bp 40—50°C) to yield crystals. Recrystallization from ethanol afforded isomeric (4+2) cycloadduct VI. The results are given in Table 3.

Reaction of I with VIII. A solution of 0.7 g of Ia and 1.0 g of VIII in a mixture of 18 m*l* of benzene and 8 m*l* of diethyl ether was stirred at 70°C for 1.5 hr. The reaction mixture was then concentrated *in vacuo* to leave a residue, which crystallized on trituration with petroleum benzine (bp 35—50°C). Recrystallization from *n*-pentane afforded 1.3 g (75%) of (4+2) cycloadduct IXa, mp 128—129°C, as colorless needles.

Similar reactions of Ib—Id with VIII gave the corresponding (4+2) cycloadducts IXb—IXd. The results are summarized in Table 4.

Hydrolysis of IXb with Hydrochloric Acid. A suspension of 0.5 g of IXb in 5 m*l* of 1N hydrochloric acid was stirred at room temperature for 3 hr. The solution was filtered to give crystals. Recrystallization from methanol gave 0.36 g (69%) of 1-cyclohexyl-1-phenylcarbamoyl-3-*p*-chlorobenzoylurea (X), mp 131—132°C, as colorless needles.

Found: C, 63.12; H, 5.60; N, 10.62%. Calcd for $C_{21}H_{22}O_3N_3Cl$: C, 63.08; H, 5.51; N, 10.52%.

IR (KBr) cm^{-1}: ν_{NH} 3245, 3230. ν_{CO} 1715, 1680, 1660.

Isomerization of IX with Neutral Alumina. After a mixture of 0.65 g of IXa and 20 g of neutral alumina in 35 m*l* of chloroform was stirred at room temperature for 1 hr, the alumina was collected and washed with chloroform. The combined chloroform solution was concentrated *in vacuo* to leave crystals. Recrystallization from petroleum benzine (bp 60—90°C) gave 0.21 g (32.4%) of the 1,3,5-triazine-2,6-dione XIa, mp 255.5—256°C, as colorless prisms.

The results of similar isomerizations of IXb—IXd with neutral alumina are summarized in Table 5.

Reaction of XII with VIII. To a solution of XII generated *in situ* from 0.93 g of 2-phenylthiazoline-4,5-dione[15] in 20 m*l* of xylene was added 0.97 g of VIII. After the reaction mixture was stirred at room temperature for 3 hr, the xylene was evaporated *in vacuo* to leave crystals. Recrystallization from diethyl ether gave 0.36 g (20%) of the (4+2) cycloadduct XIV, mp 160°C, as colorless needles.

Found: C, 69.65; H, 5.68; N, 11.51%. Calcd for $C_{21}H_{21}ON_3S$: C, 69.40; H, 5.83; N, 11.56%. M^+: *m/e* 363.

IR (KBr) cm^{-1}: $\nu_{C=O}$ 1700 (sh), $\nu_{C=N}$ 1690, 1610.

The mother liquor was concentrated to leave a residue, which on chromatography on neutral alumina using chloroform as an eluent afforded crystals. Recrystallization from petroleum benzine (bp 60—90°C) gave 0.41 g (23%) of the isomeric (4+2) cycloadduct XIII, mp 146.5—147.5°C, as yellow prisms.

Found: C, 69.66; H, 5.65; N, 11.25%. Calcd for $C_{21}H_{21}ON_3S$: C, 69.40; H, 5.83; N, 11.56%. M^+: *m/e* 363.

IR (KBr) cm^{-1}: $\nu_{C=O}$ 1720 (sh), $\nu_{C=N}$ 1700, 1610.

Reaction of I with XV. A solution of 0.7 g of Ib and 0.8 g of XV in a mixture of 18 m*l* of benzene and 8 m*l* of diethyl ether was stirred at 70°C for 4 hr. The reaction mixture was then concentrated to leave a residue which was triturated with petroleum benzine (bp 35—50°C) to form crystals. Recrystallization from *n*-pentane gave 0.85 g (57%) of (4+2) cycloadduct XVI, mp 141—142°C, as yellow prisms.

Similar reactions of Ia and Id with XV gave a mixture of the corresponding (4+2) cycloadducts XVIa and XVId, and isomers XVIIa and XVIId. By repeated fractional recrystallization from *n*-pentane, XVIa, XVIIa, and XVIId were isolated in pure form but not XVId. The results are given in Table 6.

Hydrolysis of XVIc. A mixture of 0.5 g of XVIc and 15 g of neutral alumina in 30 m*l* of methanol was stirred at room temperature for 1.5 hr. The alumina was then collected and washed with methanol and the combined methanol solution concentrated *in vacuo* to leave a residue. Several recrystallizations from methanol gave 0.16 g (42.5%) of 1-*p*-nitrobenzoyl-3-*o*-tolylurea (XVIII), mp 232—233°C, which was identical with the authentic sample prepared from *p*-nitrobenzoyl isocyanate and *o*-toluidine.

Found: C, 60.45; H, 4.30; N, 14.34%. Calcd for $C_{15}H_{13}O_4N_3$: C, 60.19; H, 4.38; N, 14.04%.

IR (KBr) cm^{-1}: ν_{NH} 3240, 3170. $\nu_{C=O}$ 1720, 1690 (sh), 1670 (sh).

Preparation of Reinforcing Fillers from Japanese Acid Clays with Lime and by Calcination. I. Availability of Raw Materials for Preparing Hard Clay and the Properties of Products

Hideki RAI and Junkichi YAMADA*

Engineering Research Institute, Faculty of Engineering, The University of Tokyo, Yayoi, Bunkyo-ku, Tokyo

(Received May 11, 1971)

Reinforcing fillers for elastomers were prepared from three representative specimens of Japanese acid clay by treatment with hydrated lime (CaO 10%), subsequent calcination (600°C, 1.5 hr), and mechanical disintegration. Physicochemical properties of the products such as hygroscopicity, pH, diphenylguanidine (DPG) adsorption, specific gravity, and bulk density were determined in comparison with those of raw materials. Morphological and structural features were investigated by means of electron microscopy, X-ray diffraction, infrared and far infrared spectroscopy, DTA, and TGA. The reinforcing effects on SBR-1502 were compared with those of Dixie Clay and Silene EF. The following results were obtained. (1) Acid clays containing montmorillonite and α-cristobalite as principal constituents are suitable for the preparation of the fillers, but not the clay containing halloysite mineral as a major component in the randomly mixed-layers of kaolinite and montmorillonite with no excess silica. (2) Irreversible contraction as well as the formation of calcium silicates took place in montmorillonite minerals. Calcium silicate is formed in two states, one covering the surface of montmorillonite minerals and the other being set free. This gives rise to remarkable changes in adsorptivity, pH, swelling, bulk density, and specific gravity. Thus it becomes possible to use acid clays as reinforcing fillers. Hygroscopicity and the pH could be made about the same as those of Silene EF. The DPG adsorption capacities could be reduced as low as that of Dixie Clay. The products thus obtained greatly increased in bulk density and exhibited an average property of Dixie Clay and Silene EF in reinforcing SBR-1502.

Elastomer reinforcement with inorganic fillers seems to be influenced by their properties. Specific surface area and the available functional groups of the filler play the most important role.[1-3]

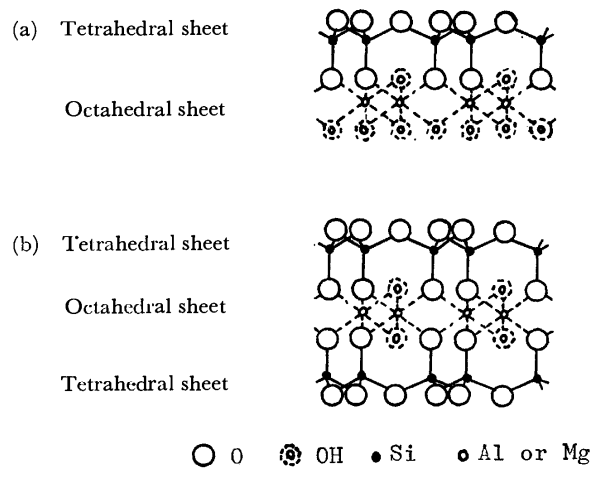

Fig. 1. Base structures of a two-sheet mineral (a) and a three-sheet mineral (b) (schematic).

Kaolinite is composed of a hydrated aluminum silicate with a two-layer type sheet structure as shown in Fig. 1-(a). Reinforcement of elastomers with kaolinite has been attributed to the effective hydroxyl groups of the external crystal surfaces and the fineness.[4]

Since kaolinite resource is small in Japan, we have attempted to prepare a reinforcing filler such as hard clay from Japanese acid clays. Acid clays generally contain montmorillonite minerals of three-layer type sheet structure as shown in Fig. 1-(b) accompanying some hydrous amorphous silica.[5] Their primary particles are finer than those of kaolinite.[6]

In view of the similarity in the constitutional units, fineness and functional groups between montmorillonite and kaolinite, the acid clays can be used as a material of reinforcing fillers. However, the structural factors[5c,7] such as substitutions in the tetrahedral and/or octahedral sheet, nonconformity in the layers, and lattice defects of montmorillonite give rise to too great adsorption, cation exchange, swelling, and catalytic activity.

If such surface activity could be controlled keeping fineness and effective hydroxyl groups unchanged, acid clays can be transformed into hard clay. Attempts were made from this viewpoint. Thermal treatment caused dehydroxylation as well as dehydration. Dehydroxylation gave rise not only to an irreversible contraction but also the polycondensation in the interlayers, reducing the adsorptivity noticeably. Caking or sintering of the minute particles which took place during the course of thermal treatment made it difficult for the products to be disintegrated mechanically or rehydroxylated even in wet milling. Thermal treat-

Table 1. Characteristics of acid clays

Sample	Symbol	Mineralogical composition	Structural formula	Excess silica	Locality
Kuramitsu acid clay	**K**	More halloysite than montmorillonite in randomly mixed layers	$(Al_{1.60}Fe_{0.13}Mg_{0.26})(Si_4)$ - $O_{10}(OH)_2X_{0.33}$	<1%	Kuramitsu, Sugaya-mura, Kitakambara-gun, Niigata Prefecture
Matsune acid clay	**M**	Normal montmorillonite, only	$(Al_{1.48}Fe_{0.06}Mg_{0.50})(Si_4)$ - $O_{10}(OH)_2X_{0.33}$ - $3.36\,SiO_2\ 0.31\,H_2O$	34	Matsune, Kushibiki-mura, Higashitagawa-gun, Yamagata Prefecture
Nakajo acid clay	**N**	More abnormal montmorillonite than normal one	$(Al_{1.35}Fe_{0.15}Mg_{0.55})(Si_4)$ - $O_{10}(OH)_2X_{0.33}$ - $0.08\,SiO_2\ 0.48\,H_2O$	13	Nakajo-machi, Kitakambara-gun, Niigata Prefecture

ment diminished markedly the reinforcing effects of the fillers. Treatment with alkali only afforded alkali-montmorillonites and hydrous alkali silicates which still showed considerable rehydration. The surface activity did not decrease satisfactorily. Caking which took place on drying made it difficult for particles to be pulverized. The residual alkali caused an early scorching of loaded compound and poor aging resistance of the vulcanizate.

Treatment with a proper alkali such as hydrated lime and subsequent calcination caused the fixation of the applied cation in the cavities of the tetrahedral sheets as well as an irreversible contraction. Formation of calcium silicates with excess silica, covering external and internal surfaces of the montmorillonite crystallites or existing in an isolated state, improve the properties.

This paper describes the preliminary results on the preparation of reinforcing fillers from acid clays. Three representative specimens of acid clays, Nakajo (**N**), Matsune (**M**), and Kuramitsu (**K**) were first treated with lime (CaO 10%) and then calcined at 600°C for 1.5 hr. Their physicochemical properties such as hygroscopicity, pH, DPG adsorption, specific gravity, and bulk density were determined. The mineralogical features were investigated by means of electron microscopy, X-ray diffraction, infrared and far infrared spectroscopy, DTA, and TGA. The reinforcing effects on SBR-1502 were examined in comparison with those of Dixie Clay and Silene EF. Availability of the acid clays as a raw material for hard clay was discussed.

Experimental

Raw Materials. *Acid Clays*: Specimens from Mizusawa Chem. Ind. Co. were used (Table 1). Five kilograms of the air dried, massive specimens[8] of light yellowish gray (**N**) consisting of montmorillonites (the amount of abnormal montmorillonite is greater than that of normal one) containing excess silica (13%) were crushed in an iron mortar, sifted through a 6 mesh screen of Tylor standard sieves and then subjected to homogeneous mixing. The white powdery (**M**) consisting only of normal montmorillonite containing excess silica (34%) and light yellowish gray (**K**) containing halloysite as a major component in the randomly mixed-layers of kaolinite and montmorillonite with no excess silica were also studied.

Quick Lime: Calcium oxide of reagent grade with grain sizes 10—30 cm^3 was pulverized and grains smaller than 60 mesh were chosen.

8) grain size, *ca.* 30—120 cm^3.

Preparation of Reinforcing Fillers. Acid clay (150 g), water (1000 m*l*), and quick lime (CaO, 10% in wt. of the acid clay dehydrated at 110°C for 4 hr) were put into a porcelain ball mill of about 3 *l* containing 2 kg of porcelain balls of diameter 10 mm, and ground at 40 rpm for 1 hr at room temperature. The slurry of acid clay was filtered, dried at 110°C, and calcined at 600°C for 1.5 hr. The resulting product was subjected to wet milling at 40 rpm for 18 hr at room temperature. It was then diluted with water to about 10% slurry and passed through a 200 mesh sieve to remove coarse particles. After the finer particles obtained by filtration were dried at 110°C, the dehydrated product was pulverized with an atomizer.

Determination of Physicochemical Properties. The following properties were studied.

Hygroscopicity: One gram of the specimen which had been exposed to the air for 24 hr at room temperature was taken into a 10 m*l* weighing bottle and dried at 110°C in an electric oven to a constant weight. The loss in weight (%) before and after drying was determined as a measure of hygroscopicity.

pH: The value was determined by the JIS K 6221 (1960) method[9] with a pH meter with a glass electrode.

DPG adsorption: The adsorptivity for vulcanizing accelerator was estimated by means of a method which is a modification of the one for carbon black.[10] Reagents were prepared as follows: (a) 0.01N DPG ethanol solution. DPG (2.11 g) was dissolved in 1 *l* of ethanol (purity 99.7%) followed by filtration. (b) Bromophenol blue (BPB). 0.1% ethanol solution was prepared for the use as an indicator. Estimation of DPG adsorption was carried out as follows: Two grams of the specimen dried at 110°C for 3 hr just before assay was taken into a 200 m*l* conical flask with a stopper. After addition of 100 m*l* of the 0.01N DPG ethanol solution the flask was closed and the following treatment was carried out 5 times: Shaking of the flask for 1 min and then putting it to stand for 5 min. The resulting mixture was centrifuged for 10 min at 3000—3500 rpm. Ten milliliters of the supernatant liquid was then taken for titration with a 0.01N HCl standard solution in the presence of 3 drops of the BPB ethanol solution. The original blue solution turned green at the end of titration. Blank tests were carried out simultaneously. The amount S of the DPG adsorbed by 10 kg of the dehydrated filler was estimated by the following equation from the average of two measurements for each specimen.

$$S = \frac{211 \cdot f \cdot (B - C)}{W} \times 10^4$$

9) Japanese Industrial Standards (JIS) K 6221-60 (1960); American Standards for Testing Materials (ASTM) D 1512-57T (1957).

10) W. B. Wiegand and J. W. Snyder, *Ind. Eng. Chem.*, **23**, 646 (1931).

where

f = factor of the 0.01N HCl solution

B = volume (ml) of the 0.01N HCl solution consumed in the blank test

C = volume (ml) of the 0.01N HCl solution consumed in the test

W = weight (g) of the dehydrated filler applied

211 = molecular weight of DPG

Specific Gravity: One gram of the specimen was dried at 110°C for 2 hr, following the ASTM D 135-39 method A.[11] Kerosene (bp 70—100°C/2 mmHg) was used as an immersion liquid (D_4^{30} 0.7811).

Bulk Density: The measuring cylinder method[12] was applied.

Morphological and Structural Studies. The shape, size, and structural features both of the fillers and raw materials were investigated by means of electron microscopy, X-ray diffraction, infrared and far infrared spectroscopy, DTA, and TGA.

Electron Microscopy: Studies were carried out with a JEOL (Japan Electron Optics Laboratory Co.) JEM-6AS electron microscope operating at 50 kV.

X-Ray Diffraction: The patterns were obtained with a Rigaku Denki Geigerflex diffractometer using nickel filtered Cu-$K\alpha$ radiation, 30 kV, 12 mA, rate meter 16, multiplier 1, time constant 4 sec, slits 1°–1°–0.2 mm, scanning speed 2° (2θ)/min, chart speed 1 cm/min.

Infrared and Far Infrared Spectroscopy: Measurements were carried out with a JASCO Model DS-403G spectrophotometer through a KBr disc and Nujol mull in the regions 4000—200 and 4000—2800 cm^{-1}, respectively.

DTA and TGA. Thermal analyses were carried out with a Rigaku Denki Thermoflex differential thremogravimetric analyser up to 1300°C with a heating rate 10°C/min.

Structural formulas of the acid clays and the contents of excess silica were calculated by Otsubo's method[13] from the data of chemical analysis (Table 1).

Table 2. Constituents (PHR) of compounds

SBR-1502	100	Vulcanizing accelerator, DM	1.5
Zinc oxide	5	Vulcanizing accelerator, TT	0.25
Sulfur	2	Antioxidant, D	1.0
Stearic acid	2	Reinforcing filler	75

Compounding Test. A master batch containing elastomer (SBR-1502), zinc oxide, sulfur, stearic acid, dibenzothiazoyle disulfide (DM), tetramethylthiuram disulfide (TT), and phenyl-β-naphthylamine (D) was loaded with the reinforcing filler and masticated with a test-roll (6″×8″, frontroll) under the following conditions: Number of revolution 17 rpm; speed ratio of the front and back rolls 1 : 1; roll temperature 55±5°C. The constituents of the compounds are given in Table 2. A test piece (diameter 70 mm, thickness 3 mm) was made from this compound by vulcanization at 150±3°C under a pressure of 1500 lb/in² for 8, 12, and 16 min and tested according to the JIS K 6301-62 (1962) method.[14] Tensile strength (kg/cm²), modulus (300%, kg/cm²) and elongation (%) were measured with a Schopper tensile tester. Hardness after 30 sec was determined with a spring tester. Data were taken from the average of four measurements. Values not reaching 80% of the maximum value were discarded. When one value is exceptional the average of the three measurements was taken. If two values are abnormal one 80% value is added to the normal ones. If three values are abnormal two 80% values are added.

Results

Physicochemical Properties. Surface Properties: The hygroscopicity of the fillers became less than half of that of the specimens. The adsorptivity for the DPG became smaller than 1/3—1/5 of the original values. The pH values 4.52—5.95 turned 9.80—8.45 (Fig. 2).

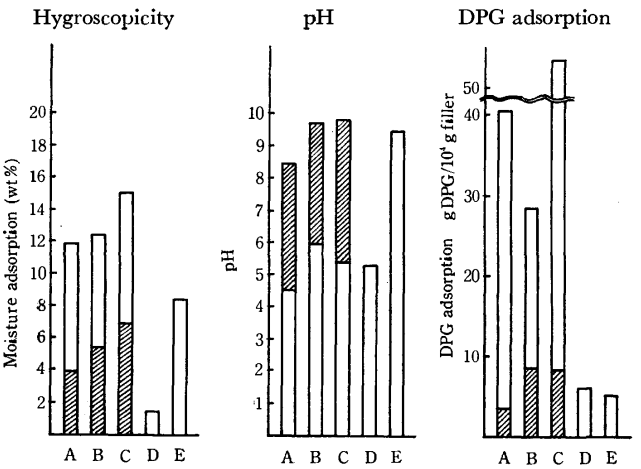

Fig. 2. Effect of treatment with lime (CaO 10%) and calcination (600°C, 1.5 hr) on hygroscopicity, pH, and DPG adsorption of the specimens in comparrison with those of Dixie Clay and Silene EF. Bar graphs indicate the results for original clays and reference fillers and hatched bars the prepared fillers.
A: Kuramitsu acid clay and **K** hard clay B: Matsune acid clay and **M** hard clay C: Nakajo acid clay and **N** hard clay D: Dixie Clay E: Silene EF

Table 3. Specific gravity and bulk density of the fillers in comparison with those of the original acid clays and reference fillers

Variety	Specific gravity		Bulk density cc/g
	Hard clay	Acid clay	
Kuramitsu-series	2.3946	2.4958	2.25
Matsune-series	2.2298	2.3891	3.02
Nakajo-series	2.3032	2.4755	2.54
Dixic Clay	2.5684	—	1.38
Silene EF	2.0989	—	4.05

Specific Gravity and Bulk Density: The maximum specific gravity of the specimens was in the order **K**<**N**<**M**. The prepared fillers showed the same order with 4—7% decrease in the values. The values of bulk density were also found to be in the same order **K**<**N**<**M**. This is in line with the amount of excess silica and the decrease in iron contents (**K** 2.93; **N** 2.75; **M** 0.79%) in the raw materials. The results agreed with the distribution observed by electron microscopy.

Morphological and Structural Features. Morphological Studies: *Shape and Size*: Hard clay **K** contains grains of maximum size, and hard clays **M** and **N**

contain small plate-shaped particles (Fig. 3). The grain size decrease with the increase of excess silica and the decrease of iron content.

New Minerals: A small amount of needle-like or cylindrical crystallites of calcium silicate hydrates[15] is contained in hard clays **M** and **N** but not in **K**. This was confirmed by selected-area electron diffraction. The less the content of excess silica, the less the formation of calcium silicate hydrates. However, the crystallites are large in size.

Investigation on Structural Features: *a) Infrared and Far Infrared Spectra*: The diagnostic bands[16] of montmorillonite in acid clays **M** and **N** changed with the treatment with lime and subsequent calcination as follows (Fig. 4). The bands around 3630 (νO–H, free), 3330—3420 (νO–H, hydrogen bonded), and 1630—1635 cm^{-1} (δO–H) diminished noticeably, and those around 913 (δAl^{3+}–O–H) and 838 cm^{-1} (δFe^{3+}–O–H) disappeared completely. Among the bands of layer-lattice silicates in the regions 900—1200 (νSi–O) and 400—650 cm^{-1}, the band around 1083—1100 cm^{-1} related to colloidal silica[17] and/or ion saturation[18] and the band 520 cm^{-1} related to (Si–O–Al^{VI})[19] decreased markedly. The bands around 1033—1036 (νSi–O) and 470 cm^{-1} (δSi–O) related to the skeletal vibrations of the tetrahedrons of montmorillonite shifted towards higher frequencies overlapping the adjacent bands, giving one single, strong, and broader band around 1055 and 475 cm^{-1}, respectively. The band at 795 cm^{-1} (δSi–O, hydrated amorphous silica)[17] became broader with a slight diminution in intensity and a shift towards 791 cm^{-1}. The other weak bands at 617—621, 568—574, 431, 355, and 340 cm^{-1} characteristic of montmorillonite almost disappeared. New distinct bands ascribable to calcium silicate (1483—1472 and 858—856 cm^{-1})[20] and calcite (1435, 875, 715, and 318 cm^{-1})[21] appeared. The intensity of the former increased and that of the latter decreased with the increase in the amount of excess silica.

In the case of hard clay **K** the bands at 3714 (νO–H, free in the halloysite lattices),[16] 3638 (νO–H, free in the montmorillonite lattices),[16] 3434 (νO–H, hydrogen bonded) and 1630 cm^{-1} (δO–H) diminished markedly, while the bands of kandite minerals at 912 (Al^{3+}–O–H), 791 and 751 (Si–O–Al^{VI}, in-plane and perpendicular, respectively), 698 and 436 (δSi–O), 342 and 272 cm^{-1} disappeared completely. The prominent bands of skeletal vibrations at 1100, 1030, and 1010 (νSi–O), 541 (Si–O–Al^{VI}) and 470 cm^{-1} (δSi–O) similarly turned to single bands and became less prominent at 1046 and 467 cm^{-1}, respectively. These bands were much broader and markedly smaller than those of the original acid clay and the other hard clays **M** and **N**. Feeble absorption bands of calcium silicate (1472 cm^{-1}) and calcite (1434, 875, 715, and 319 cm^{-1}) were observed. This suggests that a considerable sintering of the minute crystallites as well as the collapse of the layer-lattices took place during the course of treatment.

b) DTA and TGA Thermograms: In the DTA

thermograms of the hard clays **M** and **N** prepared from the specimens containing montmorillonite and α-cristobalite as principal constituents, the diagnostic peaks of montmorillonite disappeared or diminished considerably (Fig. 5). Endothermic reactions: Dehydration (100—300°C, strong and sharp), dehydroxylation (500—750°C, strong and broad) and phase transition (820—910°C, strong or medium). Exothermic reactions: Oxidation of the organic matter adsorbed (around 350°C, medium), spinel or β-quartz (around 1000°C, strong and broad or sharp), β-cristobalite, mullite or cordierite (around 1150°C, medium). The fusion points of the specimens were observed to be around 1300°C and those of the fillers around 1170°C. Some new peaks appeared around 180 (due to the first endothermic reaction, very broad and strong), 678 (due to the second endothermic reaction, rather sharp and strong) and 930—950°C (due to the first exothermic reaction, very strong and sharp). They were attributed to calcium silicate hydrate.[23] No endothermic peak attributable to the decomposition of free alkali $Ca(OH)_2$ was found. However, a weak one ascribable to calcium carbonate[24] appeared around 795°C, suggesting the presence of a small amount of calcite. The amount estimated from the area of the endothermic peak was less than 3%. This seemed to decrease with the increase in the amount of excess silica.

In the case of hard clay **K** the characteristic peaks in the specimen also diminished or disappeared completely. Endothermic reaction: Dehydration (100—300°C, strong and broad), dehydroxylation of halloysite (586°C, very strong and sharp) and montmorillonite (around 695°C, strong and broad) and phase transition (855, 1190, and 1258°C, medium). Exothermic reaction: Phase transition related to halloysite (906 and 1208°C, very strong and sharp). The filler showed broad and strong endothermic peaks (195 and 639°C) and a relatively strong and sharp exothermic peak (953°C) which could be attributed to calcium silicate and aluminate, accompanied by several peaks (1053, 1109, and 1158°C).

The fillers exhibited similar profiles of TGA thermograms, which nearly corresponded to an intermediate of acid clay **M** and Silene EF. The former consists mainly of normal montmorillonite with excess silica, the latter being a hydrous calcium silicate (Fig. 6). The weight loss of hard clay **K** is greater than that of raw material. This suggests that dehydroxylation occurred to a greater extent during the course of calcination as compared with the rehydration during the course of wet milling. The weight loss of the other hard clays **M** and **N** decreased with the increase of the amount of excess silica in raw material due to the formation of hydrous calcium silicates.

The results agreed with those of infrared and far

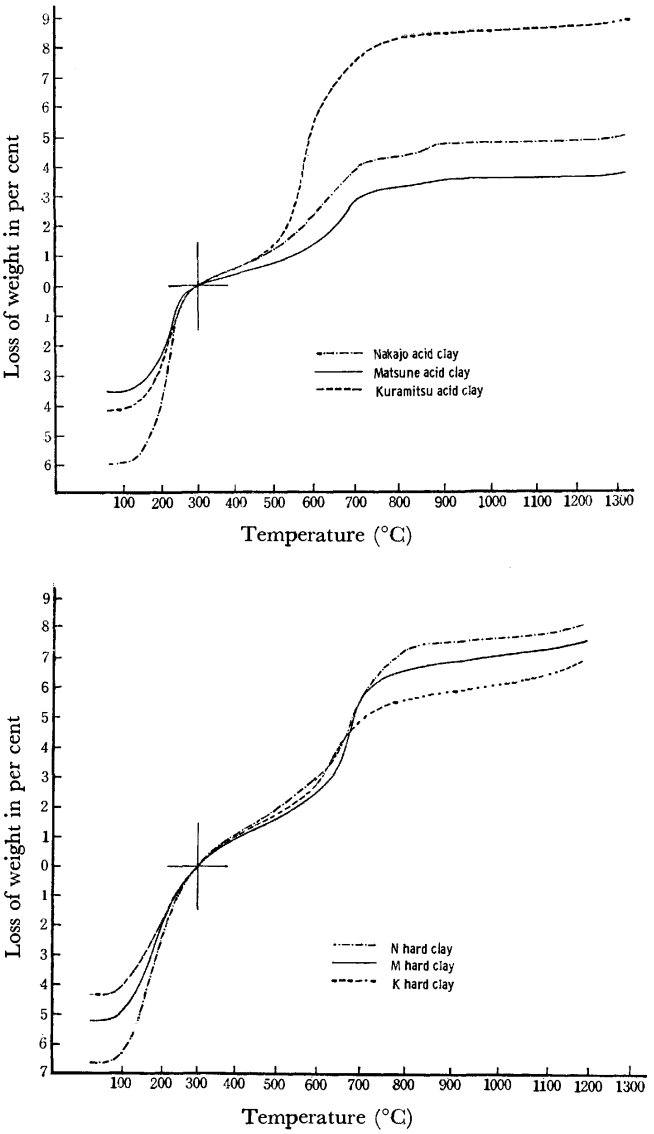

Fig. 6. TGA thermograms of the fillers (CaO 10%, calcined at 600°C for 1.5 hr) in comparison with those of original acid clays.

infrared spectroscopy and X-ray diffraction.

c) X-Ray Powder Diffraction Patterns:[25] The treatment of the original acid clays with hydrated lime (CaO 10%) caused a slight shift from 15.4 to 13.7 Å in the basal reflections as a result of the formation of Ca-montmorillonite. The intensities of the prominent basal reflections related to the amounts of interlayer water did not change much. New reflections appeared which were ascribed to the calcium silicate hydrates (3.03 and 2.72 Å) which are very similar to Taylor's CSH[15b] and calcite (3.83, 3.03, 2.53, and 2.28 Å).[26] A slight decrease in the intensities of the α-cristobalite was observed as well. Subsequent calcination (600°C, 1.5 hr) caused an irreversible contraction along *c*-axis in the montmorillonite and the disappearance of basal

reflections. However, the crystal lattices remained with no serious collapse (Fig. 7). Amounts of calcium silicate hydrates and calcite estimated from the intensities of the X-ray reflections varied as follows. The former increased with an increase in the amount of excess silica α-cristobalite in raw material, and the latter decreased. This agreed with the results obtained for the structural features of fillers.

In hard clay **K** the distinct reflections of halloysite observable in the raw material disappeared almost completely, and those of montmorillonite diminished more markedly than in hard clays **M** and **N**. Only weak reflections of calcium silicate hydrate and calcite were observed together with that of unreacted quartz (3.34 Å).

Table 4. Reinforcing effects of the fillers on SBR-1502, derived from acid clays with lime (CaO 10%) and calcination (600°C, 1.5 hr)

Reinforcing filler	Vulcanization time, min	Tensile strength kg/cm²	300% Modulus kg/cm²	Elongation %	Hardness JIS
K hard clay	8	31.1	14.4	559	52
	12	34.9	13.9	559	52
	16	28.1	13.8	553	53
M hard clay	8	67.6	20.8	739	50
	12	59.4	20.9	732	52
	16	57.3	20.5	717	53
N hard clay	8	59.8	16.4	742	51
	12	59.3	16.4	726	52
	16	52.3	16.8	693	52
Silene EF	8	46.1	28.1	429	59
	12	50.7	26.7	486	61
	16	44.6	28.3	418	65
Dixie Clay	8	96.9	23.5	759	53
	12	93.0	25.3	720	55
	16	94.9	26.4	705	55

Reinforcing Effects on SBR-1502. The reinforcing effects of the fillers were compared with those of Dixie Clay and Silene EF (Table 4). The results obtained under the optimum vulcanizing conditions are given in Figs. 8 (a)—(b).

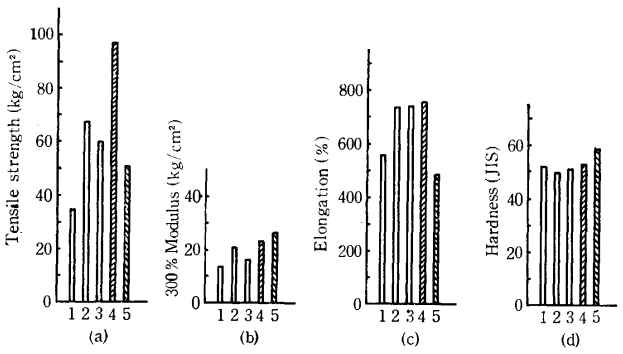

Fig. 8. Reinforcing effects of the prepared fillers (CaO 10%, calcined at 600°C for 1.5 hr) on SBR-1502 in comparison with those of Dixie Clay and Silene EF. Inscriptions are as follows:
(a): Tensile strength (kg/cm²), (b): 300% Modulus (kg/cm²)
(c): Elongation (%), (d): Hardness (JIS),
(1): **K** hard clay, (2): **M** hard clay, (3): **N** hard clay,
(4): Dixie Clay, (5): Silene EF

Tensile strength (kg/in²): The compounds obtained by loading hard clay **M** or **N** exhibited 70% or a little less tensile strength than that of Dixie Clay (Fig. 8-a). It is much greater than that of Silene EF. In the case of hard clay **K** only 35% value of Dixie Clay or one half of hard clay **M** was obtained.

Modulus (300%, kg/in²): The compounds obtained by loading the fillers gave lower modulus than those containing a reference filler Dixie Clay or Silene EF (Fig. 8-b).

Elongation (%): The compound obtained by loading the fillers exhibited fairly larger elongation as compared with those containing one of the reference fillers (Fig. 8(c)). Even the compound containing hard clay **K** showed much greater value than that of Silene EF. However, hardly any significant difference was observed between the compounds containing hard clay **M** and **N**.

Hardness: The compounds obtained by loading the fillers gave the hardness very close to that of Dixie Clay but smaller than that of Silene EF (Fig. 8-d).

The results show that the hard clays make the reinforcing effects on SBR-1502 increase with the increase in the amount of excess silica, the decrease in particle sizes, and the increase of the amount of remaining effective hydroxyl groups.

Discussion

The physicochemical and morphological studies on the fillers suggest that treatment with lime and subsequent calcination make the acid clays hydrophobic as well as basic. The fillers showed a noticeable diminution in their adsorptivity for the vulcanizing agent and moisture. Facility of crushing the products is closely related to both the mineralogical composition and the content of excess silica α-cristobalite.

Investigation of the structures of the fillers by X-ray diffraction, infrared and far infrared spectroscopy, and thermal analyses revealed the following. The above treatment caused an irreversible shrinkage along *c*-axis in montmorillonite as well as the formation of calcium silicate hydrates with the excess silica which covered the internal and external surfaces of the crystallites. This contributes in improving surface activity such as hygroscopicity, DPG adsorption capacity, swelling, and pH, and ease for the crushing of products. The formation of calcite is assumed to be originated from the carbonation of free alkali during the course of treatment.

Acid clay **K** containing halloysite as a major constituent in the randomly mixed-layers of kaolinite and montmorillonite with no excess silica, is considered to be more susceptible to treatment with lime and calcination than the acid clays **M** and **N** consisting mainly of normal and/or abnormal montmorillonites containing excess silica. This gives rise to an appreciable sintering as well as collapse in the layer lattices, which cause a glassification and caking of the minute crystallites or the primary particles due to the depression of fusion point by alkali treatment. The fact that hard clay **K** showed coarser particles, less bulk density, lower diminution in the specific gravity, greater decrease in the adsorptivity, and lower pH than those of the other two fillers **M** and **N**, can be attributed to its high susceptivility to the foregoing treatment.

The results on the reinforcement of SBR-1502 suggest that acid clays such as **M** or **N** can be used to prepare a reinforcing filler, but not an acid clay like **K**. Acid clay **M** (white) has the merit of providing a less colored product than that of acid clay **N** (light yellowish gray); the former contains less iron and more excess silica. The compound obtained by loading hard clay **M** gave much better reinforcing properties such as tensile strength, modulus, elongation, and hardness than that containing hard clay **N**. Thus acid clay **M** is considered to be a more suitable raw material.

Suito and Arakawa[4] reported on the reinforcing effects of hard clay on SBR-1502, a commercial reinforcing filler (kaolinite treated thermally up to 800°C). This suggests that the interaction between the hydroxyl radicals and the compounded elastomer molecules plays the most important role. The precise mechanism of the reinforcing effects has not been clarified. However, the markedly lower reinforcing effects of hard clay **K** as compared with those of the hard clays **M** and **N**, could be explained in terms of remarkable reduction of the specific surface area and the available hydroxyl groups.

The authors are greatly indebted to the late Prof. T. Kuwata and Associate Prof. J. Kumanotani for their encouragement, help, and valuable discussion, and Y. Sugawara, Mizusawa Chem. Ind. Co. for providing samples of acid clay. Thanks are also due Messrs. Y. Kubo, S. Yamamiya, H. Mitsui, and K. Adachi for their technical help in the experiments of X-ray diffraction, infrared and far infrared spectroscopy, and electron micrography, respectively.

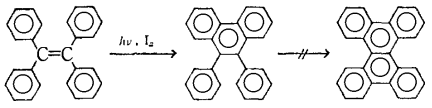
Photocyclization of *o*-Terphenyl-Type Compounds and Reactivity Indices[1]

Takeo SATO and Toshifumi MORITA*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo
**Department of Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma*

(Received March 12, 1971)

The photocyclodehydrogenation of stilbene and *o*-terphenyl type compounds has been throughly explored and is utilized as a synthetic means for a number of polycondensed aromatic and heteroaromatic compounds.[1,2]

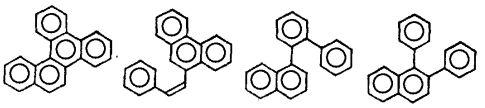


I II

For certain type of compounds, however, the photocyclization reaction did not take place: Mallory and co-workers[3] reported the failure to obtain dibenzo[*g,p*]chrysene (II) by the attempted photolysis reaction of 9,10-diphenylphenanthrene (I), although the formation of the latter was easily achieved by the irradiation of tetraphenylethylene in the presence of iodine. They attributed the inertness of I toward further cyclization reaction to a low electron density on the carbon atoms undergoing coupling. The failure of cyclization with 1,2,3-triphenylazulene,[4] 1,2,3,4- and 1,2,4,5-tetraphenylbenzenes[5] and 1,2,3-triphenylnaphthalene[5] was explained by steric reasons. 1,1′-Binaphthyl was also found to resist toward cyclization.[6] We have reported the failure of the attempted photocyclization of diphenylquaterphenyl (XVII),[1] although 2,2′-diphenylbiphenyl (XII) was smoothly converted to dibenzo[*fg, op*]naphthacene.[1,7]

For compounds where different way of cyclization is possible, some give more than one product but others result in a selective cyclization. The cyclization of 1,2-dipyridylethylene[8] or styrylpyridines[9] was shown to be possible in a dual way or more, whereas 1,2-di-β-naphthylethylene[10] gave only benzo[*g,h,i*]perylene, indicating that two other possible cyclization modes are unimportant.

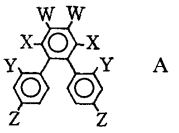
When several routes are conceivable for the construction of a certain ring system the selection of the method is left to one's choice or is determined by the availability of the starting materials. For example, benzo[*g*]chrysene (III) will be produced from either IV,[11] V,[12] or VI (not tested).



III IV V VI

In order to give a measure for the occurrence or otherwise of the cyclization reaction, to predict the product where several routes are conceivable, and to select the most efficient way to a given ring system, one can rely on the calculation of the reaction indices.

We have carried out the calculation of free valence numbers and localization energies for a series of *o*-terphenyl type compounds by the simple HMO method, expecting these figures be served as a criterion for the occurrence of the photocyclization reaction. Model compounds we studied are shown by a general formula A, where phenyl group(s) is introduced at W—Z positions. The *o*-terphenyl–triphenylene reaction is selected, since it is regarded as the basic reaction for the synthesis of polycondensed aromatics.[1,7,13,14]



A

From these models we may learn both the electronic and steric effects of the phenyl substitution on the cyclization of *o*-terphenyl compounds. Phenyl group(s) at X or Y position is capable of entering into further cyclization reactions.

The sum of free valence numbers in the first excited state, $\sum Fr^*$, was calculated for the atoms undergoing photo-coupling, location of which being shown by a dotted line. These figures together with localization energies, L^*, are summarized in Table 1. Compounds

L^*	3.320	3.349	3.427	3.458	3.369	3.423	3.537	--- 3.484 IIIII 3.485	IIIII 3.426 --- 3.421	3.601	3.589

a) Free valence numbers shown in the Table are the sum of the values obtained for the atoms undergoing coupling, the location of which being shown by --- or IIIII

I through XIII, listed in the order of decreasing $\sum Fr^*$, were successfully converted to the corresponding polycondensed aromatic compounds by the photolysis reactions using iodine as an oxidant.[1,7,13,14)]

Compounds XV and XVI were reported to be inert under the conditions studied.[5)] The reaction of XIV is not examined yet.

Critical values deduced from Table 1 are $\sum Fr^* > 0.95$ and $L^* < 3.54$, for which the cyclization is possible. Recently Laarhoven and co-workers[5)] proposed that the reaction is possible if $\sum Fr^* > 1$ and $L^* < 3.45$. They considered the photocyclization of tetraphenylethylene, $\sum Fr^* = 0.965$, to be exceptional, although from our results the conversion to I could be predictable. The Table by Laarhoven[5)] listing non-photocyclizing cases appear to contain those compounds of which inertness is explainable not by the free valence consideration but from two other reasons; 1) non-existence of the intermediate dihydro structures, and 2) steric inhibition by neighboring bulky groups.

The failure due to the first case include the lack of cyclization in α,α'-dinaphthyl,[6)] and a related compound.[5)] Assumably a steric factor becomes important when more than four benzene rings occupy vicinal position as in XV[5)] since 1,2,3-triphenylbenzene VIII is photocyclizable.[1,7)] A fused ring with a phenyl substitution is considered to cause a similar steric inhibition. This explains the inertness of II, 1,2,3-triphenylnaphthalene,[5)] 1,2,3-triphenylazulene *etc.*[4)]

In the cases of VIII and XII, a double cyclization reaction occurred and yet we could not trap intermediate XI. This is understood since XI is also a photocyclizable molecule.

The failure of XVI to undergo photocyclization, however, can not be explained and should be treated as exceptional.

More refined treatments considering the non-planarity of the molecule will make the situation clearer.

As far as the simple molecular orbital calculations concern, further accurate discussions could not be done. Some investigaters[15–17)] have made calculations to see if a relation exists for excited states between static and dynamic reactivity indices. However, they have not found out any correlation at all and the situation is the same in the present work as is seen in Fig. 1.

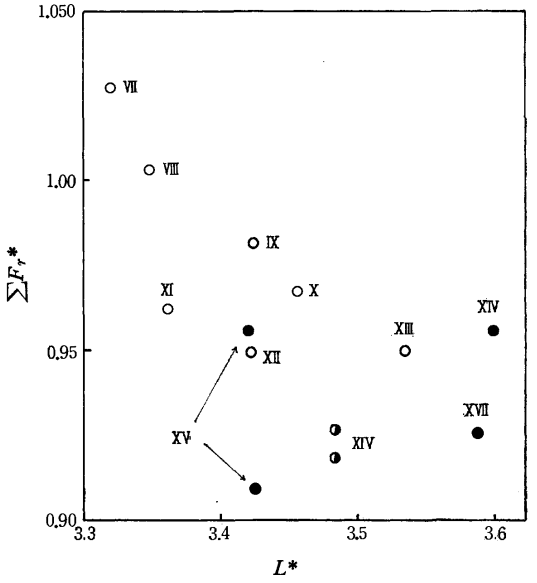

Fig. 1. The relation between $\sum Fr^*$ and L^* for those compounds that underwent photocyclization (○) and that did not (●). Compound XIV (◑) has not been examined.

The failure in obtaining a relationship between static and dynamic reactivity indices would be presumably due to the following factors: 1) Firstly, excited state molecular orbitals used in estimating reactivity indices are those obtained from minimization of ground state energy and not of excited state energy. 2) Secondly, localization energies are usually expressed in terms of π-electron energies. In discussing reactivity of molecules, localization energies should be expressed in terms of bond energies as pointed out by Dewar *et al.*[18,19)] Some improvements might be expected, if we do this.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1550—1551(1972)

A Theoretical Account of the Catalytic Behavior of Sulfonium Compounds in Oxidation Reactions

Katsutoshi OHKUBO and Hirokazu KANAEDA

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami-machi, Kumamoto

(Received July 30, 1971)

In previous papers,[1,2] it has been emphasized that sulfonium compounds are the most effective catalysts in hydrocarbon oxidations among various onium compounds containing central atoms of C, N, O, P, S, As, Se, and Te, and that their catalytic activities are appreciably affected by the difference in counter anions and substituents attached to the central sulfur. This distinguished activity of the sulfonium compounds was well explained by their catalytic activations of molecular oxygen on the basis of the interaction between the partially-occupied sulfur *d*-orbitals and O_2: a strong $d\sigma$-$p\sigma$ type interaction between the sulfur d_{xz} (or d_{yz}) orbital and the $(1\pi_g)_z$-orbital of O_2, and a weak interaction between the sulfur d_{xy}-orbital and the $(1\pi_g)_y$-orbital of O_2.[3] The present study will try to clarify the catalytic behavior of the sulfonium compounds in oxidation reactions using an extended Hückel method[4] augmented by sulfur *d*-orbitals.

First, we will discuss the role of the counter anion and the substituents of the sulfonium compound in the catalytic activity. As Table 1 indicates, there is a parallelism between the catalytic activity (as estimated

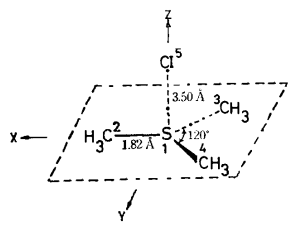
a) S–C bond corresponds to 1S-2C bond of $(CH_3)_3SCl$ illustrated in the following figure:



1) K. Fukui, K. Ohkubo, and T. Yamabe, This Bulletin, **42**, 312 (1969).
2) K. Ohkubo, *Tetrahedron Lett.*, **1971**, 2571, 2897.
3) K. Ohkubo and T. Yamabe, This Bulletin, **44**, 1183 (1971).
4) R. Hoffmann, *J. Chem. Phys.*, **39**, 1397 (1963); *ibid.*, **40**, 2474, 2480, 2745 (1964); the Coulomb integrals of the sulfur *d*-orbital and the oxygen 2*p*-orbital were taken to be −7.00 eV and −13.61 eV respectively.

by the maximum reaction rate, R_{max}) and the AO populations of the d_{xz}, d_{yz}, or d_{xy} sulfur orbital, with some irregularities caused by the gap between the configurations of the sulfonium compounds in the present calculations and those in the reaction system, or by some steric hindrances to the interaction between sulfonium compounds and O_2. This partial occupation of the sulfur *d*-orbitals is a result of the d–π interactions with the counter anion and the substituents, as can be seen from the electronic property of $(CH_3)_3SCl$ in Table 2, in which the electronic property of $(CH_3)_3S^+$ has been recorded in order to suggest the contribution of the counter chlorine. The counter anion and the substituents thus contribute to the partial occupation of the sulfur *d*-orbitals of the sulfonium compounds.

Second, let us discuss the interaction between the sulfonium compounds and molecular oxygen. The most likely mode of the interaction of molecular oxygen is parallel to the ligand plane of the sulfonium and occurs in the range of the distance between the sulfonium catalyst and O_2, 2.5—3.0 Å.[2] The d_{xz} (or d_{yz}) sulfur orbital of the sulfonium catalyst contributes predominantly to the catalytic activation of O_2 by means of interaction with the $(1\pi_g)_z$-orbital of O_2, as is shown in Fig. 1.[5]

Third, it is of interest to investigate the process of the hydrogen abstraction of the $(CH_3)_3SCl$–O_2 system

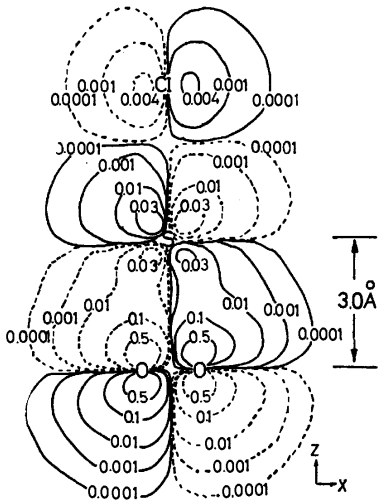


Fig. 1. The contour diagram for HO MO of the interacting system. This MO mainly comes from the interaction between $(1\pi_g)_z$ of O_2 and d_{xz} of $(CH_3)_3SCl$. (Solid and dotted curves indicate positive and negative MO-signs respectively.)

5) The contour diagram portrayed in Fig. 1 indicates the highest occupied molecular orbital (HO MO) of $(CH_3)_3SCl$–O_2. The $(1\pi_g)_z$-orbital of O_2 occupied most strongly the HO MO, in which, except for the d_{xz} orbital, the *p* and *d* orbitals of the central sulfur have negligible eigenvetors.

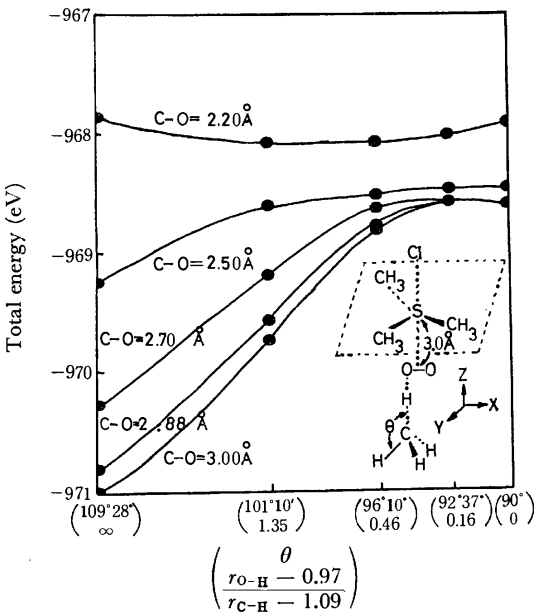

Fig. 2. Total energy changes in the process of hydrogen abstraction due to the stretching of the C–H and the variation of the bond angle of H–C–H (θ).

from hydrocarbons (CH_4 was used for the sake of simplicity of computation). The process was simulated by the stretching of the C–H in CH_4 (from C–H= 1.09 Å to H–O=0.97 Å), together with the change in the sp^3-hybrid structure of CH_4 to the sp^2-hybrid one, with the residual moiety retaining its equilibrium geometries (see Fig. 2). As Fig. 2 indicates, the transition state of the process seems to be situated near θ=92°37′, and the most plausible C–O distance falls in the range of 2.70—2.50 Å. The apparent activation energies calculated were 0.759 eV (2.50 Å), 1.652 eV (2.70 Å), 2.17 eV (2.88 Å), and 2.43 eV (3.00 Å), where the values in parentheses stand for the C–O distances. Some remarks should be here made: the activation energy in the other mode of interaction between the $(1\pi_g)_y$-orbital of O_2 and CH_4 was found to be higher than that in the interaction illustrated in Fig. 2 (for instance, 2.42 eV at C–O= 2.88 Å). In the hydrogen abstraction of O_2, O_2^-, and O_2^{2-} from CH_4 without sulfonium catalysts, the least activation energies were evaluated to be 2.04 eV (C–O=3.2 Å), 3.01 eV (C–O=3.5 Å), and 3.26 eV (C–O=3.8 Å) respectively; In other distances of C–O, the activation energies were higher. Sulfonium catalysts thus activate molecular oxygen and lower the activation energy required for the hydrogen abstraction from hydrocarbons.

The calculations were carried out on the FACOM 230.60 Computer at the Computation Center of Kyushu University.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1552—1553(1972)

Conformations of the Ester. VII. The Conformations of Chloroformates[1)]

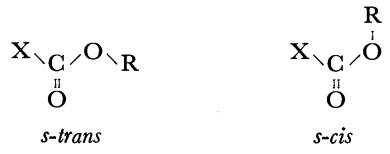
Michinori Ōki and Hiroshi Nakanishi

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received September 3, 1971)

In earlier papers from this laboratory, it has been shown that acetates[2)] and other carboxylate esters exist as *s-trans* conformers only, whereas two conformational isomers (*s-trans* and *s-cis*) exist in some formates,[3)] carbamates,[4)] carbonates,[5)] and monothiocarbonates.[1)]

In formates, the *s-trans* conformer is more stable than the *s-cis*, while in the others, which have an electronegative atom connected with the carbonyl group, the *s-cis* conformer is more stable than the *s-trans*.



s-trans *s-cis*

X = CH_3, H, NR_2, OR, SR, Cl

Since the electronegativity of chlorine is greater than that of nitrogen and oxygen, it seemed that it would be of interest to study the case of chloroformates. Since the chlorine atom is larger than nitrogen and oxygen, the steric repulsion between X (N or O) and R in the *s-cis* conformation is expected to be smaller in carbamates and carbonates than that between Cl and R in chloroformates. Thus, the steric and electronic effects may counterbalance each other in chloroformates in determining the conformational preference to some extent.

As to the conformation of haloformates, several papers have been published. The haloformates had most commonly been reported to exist as *s-cis* conformers, judging from the data of dipole moments[6-8)] and NMR spectra.[8)] However, an exception has been reported by O'Gorman *et al.*,[9)] who postulated that the conformation is *s-trans*; they based their postulate on the electron scattering spectral data.

From our experience so far, it seems that the infrared spectral study may throw light on this problem. Thus, the infrared spectra of some chloroformates have been carefully observed, and NMR spectra have been measured at low temperatures.

Experimental

Methyl and ethyl chloroformates were of commercial origin. Isopropyl chloroformate was prepared from phosgene and isopropyl alcohol and phenyl chloroformate from phosgene and sodium phenoxide. The esters were purified by distillation before the measurements. The purity was checked by means of the NMR spectra and the infrared spectra. The spectra were measured with previously-described spectrometers.[5)]

Results and Discussion

Infrared Spectra. There have been several reports on the carbonyl stretching absorption of chloroformates, but no one has yet discussed the shape of the carbonyl absorption. The results obtained with carbon tetrachloride and acetonitrile solutions are shown in Table 1. Apparently, methyl, ethyl, and isopropyl chloroformates show two carbonyl absorptions. Since the solvent effect is not very large, the bifurcation of the carbonyl absorption may not originate from Fermi resonance,[10)] but from the existence of the *s-cis* and *s-trans* conformers.

Table 1. Carbonyl absorption of chloroformates $ClCO_2R$

Compound		Solvent: CCl_4 c=0.0004 mol/*l*		Solvent: CH_3CN c=0.02 mol/*l*	
I	Me	1770cm^{-1}	(266)	1767cm^{-1}	(277)
		1786	(613)	1786	(1363)
II	Et	1765	(36)	1768	(35)
		1778	(1161)	1779	(1021)
III	*i*-Pr	1761	(64)	1763	(64)
		1777	(1140)	1777	(1461)
IV	Ph	1790	(1477)	1788	(1106)

The dipole moments of the two conformers are calculated to be 1.6 D for the *s-trans* and 2.0 D for the *s-cis*. Since the *s-cis* conformer is more polar than the *s-trans*, the population of the former will become greater in the polar solvent than in the nonpolar. Table 1 shows that the intensity of the band at the higher frequency becomes larger in acetonitrile than in carbon tetrachloride, indicating that the band at the higher frequency may be assigned to the *s-cis* conformer. This assignment is also in accordance with the consideration of the arrangement of the bond dipoles (see the figure below): apparently, the stretching of the carbonyl bond in the *s-cis* conformation needs more energy. All of these results are consistent with the idea that the *s-cis* conformer is more stable than the *s-trans* in chloroformates.

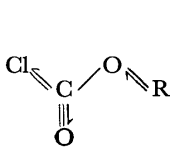
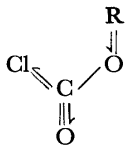
4) M. Ōki and H. Nakanishi, *ibid.*, **44**, 3148 (1971).
5) M. Ōki and H. Nakanishi, *ibid.*, **44**, 3419 (1971).
6) S. Mizushima and M. Kubo, *ibid.*, **13**, 174 (1938).
7) E. Bock and D. Iwacha, *Can. J. Chem.*, **45**, 3177 (1967).
8) E. Bock, D. Iwacha, H. Hutton, and A. Queen, *ibid.*, **46**, 1645 (1968).
9) J. M. O'Gorman, W. Shand, Jr., and V. Shomaker, *J. Amer. Chem. Soc.*, **72**, 4222 (1950).
10) The solvent effect on the intensities of the carbonyl absorptions is very large if the bifuraction has its origin at the Fermi resonance. The detailed discussions were given in a previous paper.[2)]



s-trans



s-cis

Methyl chloroformate has two absorptions in the carbonyl overtone region, at 3538 cm^{-1} (ε=6.3) and 3506 cm^{-1} (ε=0.32), in crabon tetrachloride (c=0.01 mol/l). This result lends further support to the idea that there are two conformational isomers in chloroformates. If the origin of the bifurcation of the carbonyl band were Fermi resonance, there would have been only one absorption in the overtone region.

Nuclear Magnetic Resonance Spectra. The NMR spectra of methyl chloroformate were measured at various temperatures in CS_2–CH_2Cl_2. A sharp singlet of methyl protons at 3.95 ppm from TMS is observed at room temperature, whereas the peak height decreases as the temperature is lowered. The peak height at −100°C is about a half of that at 23°C, whereas the peak height of standard TMS remains almost unchanged. This broadening of the methyl peak can best be interpreted by assuming the existence of conformational isomers.

The results of the infrared and NMR spectra and the discussions given above clearly show that alkyl formates have two conformers and that the *s-cis* conformer is more stable than the *s-trans*. Since the chlorine atom (1.80 Å)[11] is larger than hydrogen (1.2 Å) and a little smaller than the methyl group (2.0 Å), the *s-trans* conformation should be favored over the *s-cis* in view of the steric requirement. Therefore, the fact that the *s-cis* conformer is more stable in reality suggests that the electronic effect is the most important factor in determining the conformational preference.

11) The numbers in parentheses refer to the van der Waals radii.

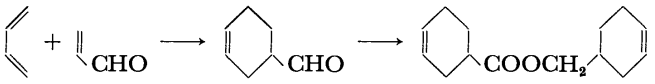
The Reaction of α,β-Unsaturated Aldehydes with 1,3-Dienes in the Presence of Alkylaluminums

Shingo MIYAJIMA and Takashi INUKAI

The Central Research Laboratories, Chisso Corporation, Kamariya, Kanazawa-ku, Yokohama

(Received September 18, 1971)

The reaction mixture in suspension form, prepared from 3 $AlEt_3$–$TiCl_4$ in heptane, is known to catalyze the Diels-Alder reactions of α,β-unsaturated aldehydes with 1,3-dienes followed by the Tishchenko condensation of the resulting 3-cyclohexenecarboxaldehyde (I) to give the bicyclic ester (II).[1]



(I) (II)

On the other hand the solid catalyst, prepared from 2 $AlEt_2Cl$–$TiCl_4$ and washed with octane, was reported to be useful for preparation of I.[2] Although the question as to the chemical species of the catalytic activity is left open, these catalyzed Diels-Alder reactions are regarded as those related to general Lewis acid catalyzed reactions of dienophiles carrying carbonyl functions.[3] We now tried $AlEt_3$, $AlEt_2Cl$, and $AlEtCl_2$ as the catalysts for the reactions of acrolein, methacrolein, and crotonaldehyde with dienes in search of a more satisfactory catalyst than those so far known.[1,2,3c]

Results

The reactions between acroleins and dienes proceed with moderate rates at normal temperature and pressure in benzene solution in the presence of suitable aluminum compounds. The reaction conditions and results are summarized in Table 1.

It appears that $AlEt_3$ is too weak as a Lewis acid to catalyze the reaction and that the catalytic activity

increases as the acidity of catalysts increases by substitution with chlorine atoms. For acid sensitive acrolein and methacrolein, however, aluminum chloride seems to be too drastic, and brings about much tar formation, as in the cases with $SnCl_4 \cdot 5H_2O$.[3c,4] So far as we have experienced $AlEtCl_2$ is the generally recommendable catalyst for aldehyde dienophiles.[5]

$AlEt_2Cl$ is unique in that it leads to the Tishchenko condensation product II leaving not more than trace of I. An aluminum alkoxide compound, that is active in catalyzing Tishchenko condensation, is naturally assumed to form *in situ*.[6]

The reaction product formed from crotonaldehyde and butadiene by the present method is pure *trans*-6-methyl-3-cyclohexenecarboxaldehyde at the initial stage of the reaction, conforming to the well-known stereochemistry of the Diels-Alder reactions, but it undergoes acid-catalyzed transformation to a *ca.* 2.7: 1 mixture of the *trans* and *cis* isomers before synthetically acceptable yield is attained.

Experimental

General Procedure. Under exclusion of oxygen and moisture, an aldehyde (0.5 mol) solution in benzene (100 m*l*) was added dropwise into a solution or suspension (in the case of $AlCl_3$) of catalyst (0.05 mol) in benzene (500 m*l*) with stirring in 5 hr, and concurrently a slight excess of a diene was slowly bubbled into the reaction mixture which was kept at 20±1°C by external cooling. After standing overnight at room temperature the mixture was treated with water (250 m*l*), the benzene layer dried with anhydrous magnesium sulfate, and the reaction product isolated by fractional distillation under reduced pressure.

Reaction Products. 3-Cyclohexenecarboxaldehyde, 1-methyl-3-cyclohexenecarboxaldehyde, and 4,6-dimethyl-3-cyclohexenecarboxaldehyde were identified by agreement of physical properties of themselves and their crystalline derivatives with those of the authentic samples: semicarbazone of 1-methyl-3-cyclohexenecarboxaldehyde, mp 174°C, (Found: C, 59.7; H, 8.3; N, 23.1%. Calcd for $C_9H_{15}N_3O$: C, 59.64; H, 8.34; N, 23.18%.). 3-Methyl-3-cyclohexenecarboxaldehyde (III) obtained by the catalytic reaction showed the same bp (59.5—61°C/12 mmHg) and IR spectrum as the authentic sample,[7] but the glpc analysis with a tricresyl phosphate column showed two peaks in an area ratio of *ca.* 2.7: 1. The major peak coincided with that of pure *trans*-III[7] in the retention time, and the minor peak with that of *cis*-III formed by thermal isomerization[8] of *trans*-III. The identification was further supported by the fact that both the reaction product and *trans*-III gave the identical *trans* to *cis* peak ratio of 1.4: 1 after thermal isomerization at 240°C. 3-Cyclohexenylmethyl 3-cyclohexenecarboxylate (II), bp 109—112°C/0.56 mmHg (lit,[1] 108—109°C/0.6 mmHg), was identified by hydrolyzing it into 3-cyclohexenylcarbinol and 3-cyclohexenecarboxylic acid: *p*-nitrobenzoate of the carbinol, mp 60—61°C (lit,[9] 60—62°C); *p*-bromophenacyl ester of the acid, mp 81.5—82.5°C (lit,[1] 81.5—82°C).

4) Unpublished work.

5) $AlEtCl_2$ was recently reported to catalyze the Diels-Alder reaction of acrylonitrile too [J. Furukawa, E. Kobayashi, K. Haga, and Y. Iseda, *Polymer Journal*, **2**, 475 (1971)].

6) We are not in a position to study the reaction of alkylaluminums with acrolein, but it may be worth noting that $AlEt_2Cl$ reacts with acrolein to give off ethylene and from acid hydrolysis of the reaction mixture was isolated 0.3 mol of allyl alcohol per mol of $AlEt_2Cl$, indicating the formation of $CH_2{=}CH{-}CH_2OAl(Et)Cl$.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1554—1556(1972)

An Attempted Synthesis of 3,6-Epidithio-2,5-piperazinedione by Cyclization of *N,N'*-dialkyl-2,2'-dithiodicinnamamide

Juji YOSHIMURA and Yuichi SUGIYAMA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received September 21, 1971)

It has been known that several antibiotics such as gliotoxin[1] and sporidesmin[2] have a characteristic partial structure of 3,6-epidithio-2,5-piperazinedione skeleton (**1**), and the numbers of analogous antibiotics are yet increasing.[3,4] Recently, Trown,[5] and Poisel and Schmidt[6] have reported the synthesis of 1,4-dimethyl-3,6-epidithio-2,5-piperazinedione (**1a**; R=R''=H, R'=R'''=CH_3) by substitution of 3,6-dibromo-1,4-dimethyl-2,5-piperazinedione with sodium thioacetate followed by hydrolysis and oxidation, however, that of the corresponding alkyl derivatives (**1b**; R=methyl, hydroxymethyl) has not yet appeared in literatures.

On the other hand, it is known that an amide group can be added to unsaturated carbons such as olefins[7]

and carbonyls,[8] and in fact, *N*-aryl-pyruvamide was dimerized to 1,4-diaryl-3,6-dihydroxy-3,6-dimethyl-2,5-piperazinedione[9] by treatment with aqueous ammonia. Therefore, it was considered that dimerization of 2-thiopyruvamide (or corresponding enthiol (**2**)) may offer the desired intermediate for the synthesis of **1b**.

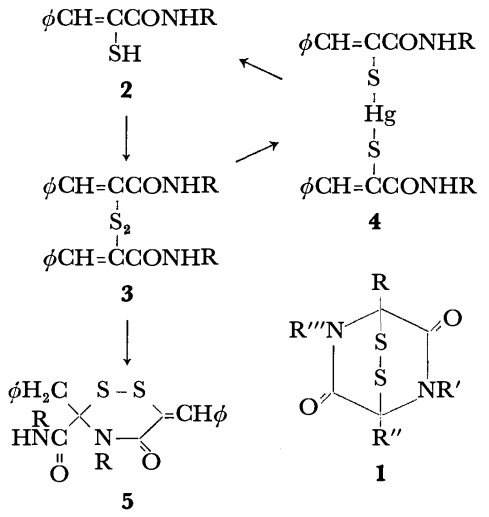
In this paper, the authors attempted to synthesize **1b** by dimeriaztion of *N*-alkyl-2-mercaptocinnamamide (**2**), or by intramolecular additive cyclization of *N,N'*-dialkyl-2,2'-dithiodicinnamamide (**3**).

Results and Discussion

As an analogous conversion of β-keto-acidamide to β-thio-analogue,[10] *N*-cyclohexyl-phenylglyoxylamide[11] was treated with hydrogen sulfide in ethanol saturated with dried hydrogen chloride at −90°C for 3 days, but only *N*-cyclohexyl-2,2-diethoxy-2-phenyl-acetamide (Found: C, 70.60; H, 9.29; N, 4.77%. Calcd for $C_{18}H_{27}NO_3$: C, 70.79; H, 8.91; N, 4.59%.) was obtained in 79% yield, and the same reaction at −10—+6°C for 10 hr gave white powder ($C_{28}H_{36}N_2O_2S_3$) in 68% yield, which could not be characterized. Moreover, attempted elimination of hydrogen sulfide from 2,2'-tetrathiodipropionanilide by thermal degradation or by treatment with heavy metals were unsuccessful.

On the other hand, 2,2'-dithiodicinnamyl chloride was synthesized by treatment of the free acid[12] in chloroform with phophorus pentachloride. Treatment of this unstable chloride with alkylamine gave no expected **3**, however, dropwise addition of the chloride in benzene to alkylamine hydrochloride in dimethylformamide under cooling gave **3** (R=methyl, ethyl, propyl, isopropyl, *n*-butyl) in 14—41% yield.

Attempted reduction of **3** to **2** with acetic acid and zinc was unsuccessful. Considering that **3** and **2** might be unstable both in alkaline and acid condition, reductive insertion reaction was tried by use of cuprous oxide or mercuric dichloride in the presence of potassium metabisulfate. In the former case **3** was recovered, but in the latter, the corresponding mercaptide (**4**) was afforded quantitatively, by adding triethylamine dropwise. Treatment of **4** with hydrogen sulfide gave no desired product, however, only *N*-isopropyl-2-mercaptocinnamamide (**2a**) was obtained in 45% yield. **2a** was successfully oxidized to **3d** by air, but conversion of **2a** to **1b** was not tried, because of its unstability.



Scheme 1

Table 1. Physical constants and analytical data of new compounds

	R'	Mp (°C)	Yield (%)	Found (Calcd),% C	H	N	S
2a	Isopropyl	78	45	64.59 (65.14)	6.60 (6.83)	6.38 (6.33)	13.81 (14.47)
3a	Methy	138	14	63.52 (62.49)	5.89 (5.24)	7.38 (7.29)	16.10 (16.15)
3b	Ethyl	158	41	64.13 (64.06)	6.00 (5.87)	6.89 (6.79)	15.72 (15.52)
3c	Propyl	120	28	65.16 (65.44)	6.62 (6.41)	6.58 (6.36)	14.62 (14.53)
3d	Isopropyl	153	31	65.71 (65.44)	6.34 (6.41)	6.51 (6.36)	14.66 (14.53)
3e	*n*-Butyl	116	31	66.56 (66.65)	6.62 (6.88)	6.15 (5.98)	13.68 (13.67)
4a	Methyl	197	100	41.31 (41.05)	3.66 (3.45)	4.89 (4.79)	— —
4b	Ethyl	171	100	42.94 (43.11)	3.92 (3.95)	4.65 (4.56)	— —
4c	Propyl	163	100	45.00 (44.95)	4.45 (4.40)	4.36 (4.37)	— —
4d	Isopropyl	194	100	44.97 (44.95)	4.21 (4.40)	4.28 (4.37)	— —
4e	*n*-Butyl	154	100	46.89 (46.66)	4.84 (4.82)	4.22 (4.19)	— —
5a	Ethyl	234	10	64.00 (64.06)	6.07 (5.87)	6.60 (6.79)	15.33 (15.52)
5b	Isopropyl	240	1	65.72 (65.44)	6.37 (6.41)	6.38 (6.36)	14.26 (14.53)

In order to cyclize intramolecularly, **3b** and **3d** were treated with triethylamine to give 4-alkyl-3-alkylaminocarbonyl-3-benzyl-6-benzylidene-5-oxo-3,4',5,6-tetrahydro-1,2,4-dithiazine (**5a**; R=ethyl, **5b**; R=isopropyl) in 10 and 1% yield, respectively, accompanied with intractable sirup which seems to be intermolecular reaction products or degradated products. The structure of **5** was deduced from elemental analysis and the following facts. The existence of two triplet signals (τ 8.95, 9.35) of C-methyl protons of **5a** in NMR spectrum indicates that the two nitrogen atoms are in the different circumstances. Moreover, the presence of peaks *m/e* 379 (5a—SH) and 407 (5b—SH), and 308 (5a—$CONHC_2H_5$—S) and 322 (5b—$CONHC_3H_7$—S) in mass spectra of **5a** and **5b** (Fig. 1) indicated the presence of another intramolecular bond, in addition to a disulfide bond.

From these facts, it will be concluded that only one intramolecular cyclization was occured, because of a steric hindrance.

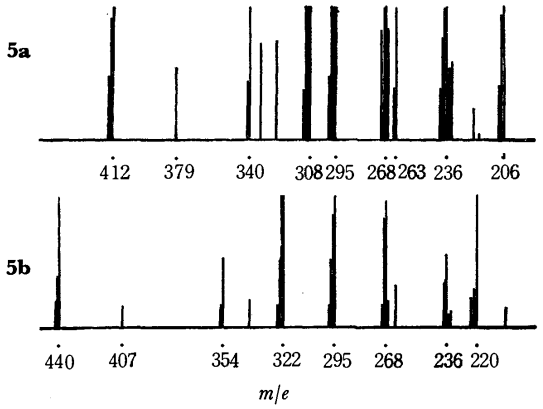

Fig. 1. Mass spectra of **5a** (R=ethyl, MW 412) and **5b** (R=Isopr., MW 440).

Experimental

All the melting points are uncorrected. The solutions were evaporated under reduced pressure at a bath temperature not exceeding 40°C. The infrared spectra were measured in KBr discs, and the NMR spectra were determined at 100 MHz with a JNM-100H spectrometer, using TMS as an internal reference. The mass spectra were obtained on a Hitachi RMU6E mass spectrometer, using a direct inlet and an ionization energy of 70 eV.

2,2′-Tetrathiodipropionanilide. Sulfur monochloride (0.34 g, 2.5 mmol) was added dropwise to 2-mercaptopropionanilide (0.9 g, 5 mmol)[13] in dried ether (100 m*l*) under cooling with ice-salt. This reaction mixture was allowed to stand for 1 day at room temperature, and white crystals deposited was filtered. Yield 0.9 g (73%); mp 134°C. Found: C, 50.92; H, 5.04; N, 6.68; S, 29.95%. Calcd for $C_{18}H_{20}N_2O_2S_4$: C, 50.94; H, 4.75; N, 6.60; S, 30.16%. IR (cm^{-1}): 3250 (N–H), 1650 (C=O).

General Synthesis of N,N′-*dialkyl-2,2′-dithiodicinnamamide (3).* A suspension of 2,2′-dithiodicinnamic acid (36 g, 0.1 mol) and excess amount of phosphorus pentachloride in chloroform mixed under cooling was stirred for 1 day at room temperature. After removal of phosphorus oxychloride, the resulted sirup was dissolved in water-free benzene, and then insoluble phosphorus pentachloride was filtered off. This filtrate was added dropwise into the dimethylformamide solution of alkylamine hydrochloride (0.2 mol) cooled with ice-salt. After standing for two hours at room temperature, this reaction mixture was neutralyzed with aqueous sodium bicarbonate and extracted with chloroform. The extract was washed with water, and concentrated to a viscous solution which gave white crystals. For example, *N*-ethyl derivative (**3b**) showed; IR (cm^{-1}): 3240 (N–H), 1620 (C=O). NMR (τ) in $CDCl_3$: 2.0 (s, 2H), 6.68 (m, 4H), 8.82 (t, 6H).

General Synthesis of Mercuric Biscinnamamide-2-thiolate (4). A suspended solution made by successive addition of water (100 m*l*) and potassium metabisulfate (2.0 g, 9 mmol) to a solution of **3** (4.5 mmol) and mercuric dichloride (2.0 g, 7.4 mmol) in methanol (500 m*l*), was stirred for 30 min. Further addition of a small amount of triethylamine gave white precipitates of **4**. After removal of methanol, precipitates were filtered and recrystallized from methanol to give white crystals.

N-*Isopropyl-2-mercaptocinnamamide (2a).* Hg thiolate (**4d**, 3.2 g, 4.9 mmol) and potassium sulfide (1 g, 9 mmol) were dissolved in water to give mercuric sulfide. After filtration, the filtrate was added into 5% solution of acetic acid in water (500 m*l*) to give **2a**, which was recrystallized from ethanol. IR (cm^{-1}): 3270 (N–H), 2550 (S–H).

4-Alkyl-3-alkylaminocarbonyl-3-benzyl-6-benzylidene-5-oxo-3,4,5,6-tetrahydro-1,2,4-dithiazine (5a and 5b). A solution of **3b** (1 g, 2.4 mmol) in chloroform was gradually added into the solution of triethylamine in chloroform for 30 min. After standing for 30 min at room temperature, the solution was concentrated, and the resulted powder was crystallized from chloroform–petroleum ether to give white crystals of **5a**. IR (cm^{-1}): 3300 (N–H), 1625 (C=O). NMR (τ) in DMSO (d_6): 8.95 (t, 3H), 9.35 (t, 3H). In the case of **5b**, it showed; IR (cm^{-1}): 3290 (N–H), 1620 (C=O).

The authors are indebted to Mr. K. Fukukawa for NMR measurements.

An Approach for Calculation of n,π^* State Energies of Some Carbonyl Molecules Within the Framework of the Semi-Empirical SCF-MO-CI Method

Kozo INUZUKA and Ralph S. BECKER*

Department of Applied Science, Tokyo Electrical Engineering College, Kanda, Chiyoda-ku, Tokyo
**Department of Chemistry, University of Houston, Houston, Texas 77004, U.S.A.*

(Received September 25, 1971)

Electronic state energies (π,π^*) of many organic molecules have been calculated by the Pariser-Parr and Pople SCF–MO–CI methods.[1,2] Such approaches have proven successful for the electronic properties of π,π^* states, but their application to n,π^* state energy calculations is scarce. One reason is the difficulty of obtaining good values for the electronic repulsion integrals between n and π electrons. Lindner *et al.*[3] used the Ohno approximation[4] for such integrals to calculate n,π^* state properties of nitrogen-heterocyclics. However, the state energies were not in agreement with experiment. Sidman[5] carried out n,π^* state energy calculations for several carbonyl molecules within the framework of the P–P–P SCF–MO–CI method. The assumption was made that the n-orbital energy of the carbonyl molecules is constant, and the value, −10.50 eV, was assigned to it throughout the calculations. The electronic repulsion integral between n and π electrons was obtained by the Pariser-Parr approximation.[1] The assumption that the n-orbital energy of carbonyl group is constant appeared reasonable since it is known that there is not such a large variation in the n-orbital energy as in the π-orbital energy within similar carbonyl molecules. However, such an assumption may not give good calculated results when we use the SCF–MO's and the energies obtained using different approximations for the electronic repulsion integrals. In addition, it may not be valid for different values of the parameters such as resonance integral, ionization potential, electron affinity or effective nuclear charge of the atomic orbital.

On the other hand, Plotnikov[6] carried out SCF–MO calculation for n,π^* and π,π^* state energies of different kinds of organic molecules taking into account their n-orbital energies and using proper approximation for repulsion integrals between n and π electrons. His calculated results were in good agreement with experimental values. In view of the difficulties encountered in calculating n,π^* transition energies in agreement with experiment, we have examined different approximations for the two-center repulsion integrals in order to obtain better absolute agreement for the π,π^* and n,π^* state energies, particularly for the latter. In this paper, the n-orbital energies and n,π^* state energies were calculated using both Mataga-Nishimoto (M–N)[7] and Pariser-Parr (P–P)[1] approximations.

Methods of Calculation

All calculations were carried out by means of the usual semi-empirical SCF–MO–CI method:

$$\sum_{\nu} F_{\mu\nu} c_{i\nu} = \varepsilon_i c_{i\mu} \tag{1}$$

$$F_{\mu\mu} = -I_\mu + (1/2)P_{\mu\mu}\gamma_{\mu\mu} + \sum_{\nu\neq\mu}(P_{\nu\nu}-1)\gamma_{\mu\nu} \tag{2}$$

$$F_{\mu\nu} = \beta_{\mu\nu} - (1/2)P_{\mu\nu}\gamma_{\mu\nu} \tag{3}$$

$$\gamma_{\mu\mu} = I_\mu - A_\mu \tag{4}$$

where I_μ and A_μ are the ionization potential and electron affinity of atom μ, and $P_{\mu\mu}$ is the electron charge density on atom μ. $\beta_{\mu\nu}$ is the resonance integral for the nearest neighbor atoms μ and ν. Numerical values used for the skeletal structures of *trans*-acrolein,[8] *trans*-2,4-pentadienal, benzaldehyde, and *trans*-cinnamaldehyde were, respectively, 1.36 Å for the carbon double bond, 1.46 Å for the single bond, 1.22 Å for the carbonyl group, and 1.39 Å for the benzene ring. The value 120° was assigned to the C–C–C and C–C–O bond angles.

The n,π^* and π,π^* transition energies were calculated by the following equations.

$$^1E_{jk} = \varepsilon_k - \varepsilon_j - J_{jk} + 2K_{jk} \tag{5}$$

$$^3E_{jk} = \varepsilon_k - \varepsilon_j - J_{jk} \tag{6}$$

where ε_k is the energy of k-th molecular orbital, J_{jk} Coulomb integral over the MO's j and k, and K_{jk} an exchange integral. The n,π^* and π,π^* state energies were calculated including all singly excited configurations.

The SCF–MO's and π,π^* transition energies of these four molecules were calculated using the Pariser-Parr approximation[1] for the electronic repulsion integral between π electrons with Z_c=3.25 and Z_o=4.55. The resonance integral β_{co} of the carbonyl group was obtained by Kon's equation,[9] and the value −2.67 eV was used for the four molecules. The value of β_{cc} for the nearest neighbour carbon atoms was treated as a parameter and adjusted for each molecule to fit the calculated π,π^* state energy to the experimental value.

The n-orbital on the oxygen atom is assumed to be a pure $2p\pi$ atomic orbital. The n-orbital energy ε_n was obtained from the following equation.[3]

$$\varepsilon_n = U_n + \sum_{\mu \neq o}(P_{\mu\mu}-1)\gamma_{\mu n} + (P_{oo}-1)(\gamma_{no}-\delta_{no}/2) \quad (7)$$

where U_n is treated as a parameter for the *n*-electron, and the value −14.75 eV[10] was used. The two one-center integrals concerning the oxygen atom, γ_{no} and δ_{no} represent $\langle n_o\pi_o|r_{12}^{-1}|n_o\pi_o\rangle$ and $\langle n_o\pi_o|r_{12}^{-1}|\pi_o n_o\rangle$, respectively. The value 12.865 eV[5] was used for the former integral and the value 0.903 eV[11] for the latter one. The $\gamma_{\mu n}$ is a two-center atomic repulsion integral between the π-electron of the carbon atom μ and the *n*-electron of the oxygen atom. The $\gamma_{\mu n}$ was calculated by the usual Matage-Nishimoto and Pariser-Parr approximations.

Results and Discussion

The calculated results are shown in Table 1. The data show that the n,π^* state energies calculated by M–N approximation are higher than those by P–P approximation, and somewhat higher than the corresponding observed values. However, the calculated n,π^* state energies using the P–P approximation are lower than the corresponding observed values.

The lowest singlet state of the molecules is assigned as the n,π^* state as shown in Table 1. The relative order of the calculated lowest n,π^* and π,π^* singlet state by both approximations is in accordance with the observed order (*cf.* Table 1).

The observed lowest triplet states of acrolein[12–14] and benzaldehyde[15] are assigned to be n,π^* states. The calculated n,π^* triplet state energies by M–N approximation are higher than the calculated π,π^* triplet states, but the corresponding states by P–P approximation are lower than the calculated π,π^* triplet state energies. The relative order of n,π^* and π,π^* triplet states of acrolein and benzaldehyde using P–P approximation is in harmony with the observed order; however, the values of calculated n,π^* triplet states, 2.771 eV (acrolein) and 2.780 eV (benzaldehyde) differ slightly form the observed values 3.01 eV[12,13] and 3.22 eV[15] for acrolein and benzaldehyde, respectively. In the case of *trans*-2,4-pentadienal, the theoretical n,π^* triplet state energy by both approximations, M–N (3.311 eV) and P–P (2.714 eV) is higher than the corresponding π,π^* triplet state energy (2.048 eV). We can not compare the theoretical values with experimental values (no data) for 2,4-pentadienal. However, the theoretical result and the small energy difference between the n,π^* and π,π^* triplet states of acrolein[12,16] suggest that the lowest triplet state of polyenals with polyene chains longer than acrolein may be assigned to the π,π^* triplet state. It is interesting that our calculated n,π^* state energies of acrolein and 2,4-pentadienal using M–N approximation show a good correspondence with those of crotonaldehyde and sorbaldehyde by Plotnikov.[6] Parallel state energy ordering is obtained for *trans*-cinnamaldehyde (n,π^* states higher than π,π^* states). Judging from the present calculated results, the lower triplet state of cinnamaldehyde may be assigned to the π,π^* state.

The calculated n-orbital energies of the molecules are shown in Table 1. The energies are almost the same for all molecules by means of either M–N or P–P approximation although the absolute values depend upon the choice of approximation. The result is in agreement with the assumption by Sidman[5] that the n-orbital energy in carbonyl group is approximately constant, although our absolute magnitude is greater.

If the value of U_n in Eq. (7) and/or the numerical values in the Mataga-Nishimoto and Pariser-Parr's electronic repulsion integrals between the n- and π-electrons are taken as parameters and adjusted properly, better calculated results for the n,π^* state energy and the n-orbital energy may be expected. The method is also applicable to n,π^* state energy calculations for N-heterocyclics.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1559—1560(1972)

Some Reactions of Hydrazino- and Aminophosphonium Bromides

Koh-ichi YAMADA and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received October 1, 1971)

Hydrazonophosphorane has two reaction sites, P=N bond and amino group, and reacts with carbonyl compounds to give hydrazones[1] and phosphazines,[2] respectively.

A reaction at both sites being expected, excess amount of phenyl isocyanate was allowed to react with hydrazonotriphenylphosphorane (I) produced *in situ* from the corresponding phosphonium bromide and potassium *t*-butoxide. The product was *N*-(phenylcarbamoylazomethylene)aniline (II) (12%).

$$\underset{\text{I}}{Ph_3P{=}NNH_2} + 2PhNCO \xrightarrow{-Ph_3PO}$$

$$[PhN{=}C{=}NNHCONHPh] \longrightarrow \underset{\text{II}}{PhN{=}CH{-}N{=}NCONHPh}$$

Oxidation of I was carried out with mercuric oxide at −60°C, the formation of triphenyldiazophosphorane (III) being anticipated, but the reaction products isolated were triphenylphosphine (10%) and oxide (65%).

$$\underset{\text{I}}{Ph_3P{=}NNH_2} \xrightarrow{HgO} \underset{\text{III}}{[Ph_3PN_2]} \xrightarrow{-N_2} Ph_3P \xrightarrow{HgO} Ph_3P{=}O$$

Formation of triphenylphosphine strongly suggests the presence of III as an intermediate. However, III could not be trapped with styrene or diphenylacetylene. III seems to be too unstable to be isolated. Oxidation of I with bromine or lead tetraacetate gave analogous results.

No report has appeared on the reactivity of the amino group in aminotriphenylphosphonium bromide (IV). IV did not react with phenyl isocyanate, but in the presence of triethylamine gave *N*-phenylcarbamoyliminotriphenylphosphorane (V) in a good yield.

$$\underset{\text{IV}}{Ph_3\overset{+}{P}NH_2\ Br^-} + R{-}N{=}C{=}X \xrightarrow{Et_3N} Ph_3P{=}NCXNHR$$

V: R=Ph, X=O; VI: R=Ph, X=S
VII: R=*c*-C_6H_{11}, X=*c*-$C_6H_{11}N$

Phenyl isothiocyanate and dicyclohexyl carbodiimide reacted similarly, but *N*-sulfinylaniline gave only tarry material. Acyl and tosyl chlorides gave VIII—X

Table 1. *N*-Substituted iminotriphenylphosphoranes from IV

similarly.

$$Ph_3\overset{+}{P}NH_2\ Br^- + R\text{-}Cl \xrightarrow{2Et_3N} Ph_3P{=}N\text{-}R$$

IV — VIII: R=PhCO; IX: R=MeCO; X: R=*p*-$MeC_6H_4SO_2$

The results are summarized in Table 1. The low yield of *N*-acetyl compound (IX) is attributable to easy hydrolysis.

These *N*-substituted iminophosphoranes are usually prepared from iminophosphorane[3,4,8] prepared from IV and sodium in liquid ammonia. In the present method, however, *N*-substituted iminophosphoranes are directly obtained from IV in high yields.

In the course of preparation of IV,[9] it was found that addition of triethylamine gave triphenyl(triphenylphosphoranylideneamino)phosphonium tribromide (XI), which differs from the corresponding bromide,[10,11] in the place of IV in 40% yield. Addition of triethylamine does more harm than good in the preparation of IV.

$$Ph_3PBr_2 \xrightarrow{NH_3} Ph_3\overset{+}{P}NH_2\ Br^- \xrightarrow[Et_3N]{Ph_3PBr_2} (Ph_3P{=}N\text{-}PPh_3)^+\ Br_3^-$$

IV — XI

Experimental

Materials. Hydrazinotriphenylphosphonium bromide was prepared according to literature,[12] mp 218—220°C (lit, 210—212°C). Aminotriphenylphosphonium bromide (IV) was prepared from triphenylphosphine dibromide and ammonia gas,[9] mp 242.5—244°C (lit, 243°C).

Reaction of Hydrazonotriphenylphosphorane (I) with Mercuric Oxide. To 0.05 mol of potassium *t*-butoxide in 200 m*l* of anhydrous ether was added 14.9 g (0.04 mol) of hydrazinotriphenylphosphonium bromide with stirring under nitrogen. After filtration of inorganic precipitate under nitrogen, 8.6 g (0.04 mol) of yellow mercuric oxide was added to the deep red filtrate (I) at −50——60°C. The mixture was stirred for 30 min and the temperature was gradually raised, during which time small bubbles evolved constantly. Precipitates were filtered off at room temperature and the filtrate was evaporated *in vacuo*. The residue was washed with ether to give 7.2 g (64.7%) of triphenylphosphine oxide, mp 153—155°C (from ether). The ethereal washings were evaporated to give 1 g (9.6%) of triphenylphosphine, mp 75—77°C (from petroleum ether).

Reaction of I with Phenyl Isocyanate. Phenyl isocyanate (3 g, 25.2 mmol) was added at room temperature to an ether solution (10 m*l*) of I, prepared from 3.73 g (10 mmol) of the phosphonium bromide, and the reaction mixture was chromatographed on alumina after concentration. After elution of triphenylphosphine oxide with benzene, elution with benzene - dichloromethane (1:1) gave 0.3 g (12%) of brown crystals (II), mp 185—186°C (dec) (from ethyl acetate-petroleum ether (1:3)). IR: 3320 (N–H), 3080 (C–H), 1670 (C=O), 1610 (C=N), and 1560 cm^{-1} (N–H, N=N). MS: *m/e* 252 (M^+).

Found: C, 66.94; H, 4.42; N, 22.41%. Calcd for $C_{14}H_{12}N_4O$: C, 66.66; H, 4.79; N, 22.21%.

Preparation of N-Substituted Iminophosphoranes. Typical procedures are described.

a) With Phenyl Isocyanate: Phenyl isocyanate (3.6 g, 0.03 mol) in acetonitrile (30 m*l*) was added dropwise to a suspension of 10.7 g (0.03 mol) of IV in 70 m*l* of acetonitrile containing 3.5 g (0.035 mol) of triethylamine with stirring at −30——40°C for 2 hr. The mixture was stirred at room temperature for one hour, then cooled to −40°C and 150 m*l* of ether was added. The precipitate thus obtained was washed three times with 200 m*l* of water, and dissolved in 200 m*l* of benzene to remove unchanged IV. The benzene solution was dried over anhydrous sodium sulfate. Removal of solvent gave 11.3 g (95%) of white crystals (V), mp 181—182°C (from ethanol).

b) With Dicyclohexyl Carbodiimide: A mixture of 5.3 g (0.015 mol) of IV, 3.1 g (0.015 mol) of the carbodiimide and 2 g (0.02 mol) of triethylamine was refluxed in 50 m*l* of acetonitrile for 6 hr, and 150 m*l* of ether was added at room temperature. After washing with 100 m*l* of water, removal of the solvent gave 5.1 g (70.4%) of iminophosphorane (VII), mp 138—142°C (from acetonitrile). IR: 3300 (N–H), 1610 (C=N), 1560 (N–H), 1305 (P=N), and 1110 cm^{-1} (P–Ph). VII was slowly hydrolyzed with moisture in air to triphenylphosphine oxide (mp 155°C) and dicyclohexylurea (mp 229—230°C). It was, therefore, difficult to obtain an analytically pure sample.

Triphenyl(triphenylphosphoranylideneamino)phosphonium Tribromide. Triethylamine (13.1 g, 0.13 mol) was added to a suspension of triphenyldibromophosphorane (42.2 g, 0.1 mol) in chlorobenzene (120 m*l*) at 95°C, ammonia gas being passed. After stirring for one hour, the mixture was treated in the usual manner. Orange-yellow crystals thus obtained (31 g, 39.8%), mp 170—175°C, were recrystallized twice from acetonitrile, mp 191.5—193.5°C.

Found: C, 56.01; H, 3.82; N, 1.87; Br, 30.14%. Calcd for $C_{36}H_{30}NP_2Br_3$: C, 55.56; H, 3.89; N, 1.80; Br, 30.80%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1561—1562(1972)

A Simple Preparation of 2,3-Dimethylenebicyclo[2.2.1]hept-5-ene

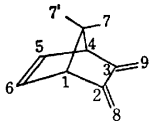
Takashi TODA, Tadanori OHYA, and Toshio MUKAI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai-shi

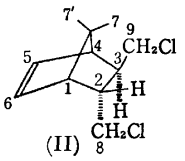
(Received October 1, 1971)

2,3-Dimethylenebicyclo[2.2.1]hept-5-ene (I) is a compound possessing an interesting triene system and can be used as a starting material to synthesize many other polycyclic compounds. This compound was already synthesized by Alder and his co-workers;[1] however, their procedure contained multi-step of reactions and seems not to be suitable for large scale preparation. We have been interested in the chemistry of this triene compound and found a simple preparation method of I which was composed of two step reactions. This procedure is presented in this report.

Diels-Alder reaction of cyclopentadiene and *trans*-1,4-dichlorobut-2-ene gave *trans*-2,3-dichloromethyl-bicyclo-[2.2.1]hept-5-ene (II) accompanied with small amounts of isomeric products of II. Dehydrochlorination of II by Hock's method[2] which had been successfully applied to dehydrohalogenation of analogous compounds resulted in the recovery of the starting substance. After several fruitless trials, we found that treatment of II with potassium hydroxide in DMSO afforded the desired compound in 55—65% yield.



(I)



(II)

NMR spectra of I and II are shown in Table 1. The assignment of all hydrogens of I and II was done by double and triple resonance technique. H_7 of I shows a long-range coupling with H_5 and H_6 which nicely accords with W-rule[3] and this type long-range coupling is also observed between H_1 and H_5 (H_4 and H_6). The coupling constants ($J_{1,2}$ and $J_{3,4}$) of II can be explained from the fact that the dihedral angle between H_1 and H_2 and that between H_3 and H_4 are nearly 45° and 90° respectively, which values are agree with those of the Dreiding model of II. It should be noted that the spectrum indicated non-equivalency of methylene hydrogens of C_8 and C_9.

The mass spectrum of II shows a very intense peak at mass 66 and other peak's intensities are less 1/10 than that of the peak at 66: *m/e* (relative intensities); 190 (parent, 1.40), 105 (1.68), 91 (1.12), 67 (66+1, 6.20), 66 ($M-C_4H_6Cl_2$, 100), and 54 (1.07). The ratio of the intensities of the isotope peaks of the parent ion nicely accords with the reported values:[4] *m/e* (relative intensities); 190, 192, and 194 (100, 65, and 10). Therefore, *retro*-Diels-Alder type reaction is the most significant fragmentation of electron impact of II. On the other hand, the mass spectrum of I is as follows: *m/e* (relative intensities); 118 (parent, 76), 117 (M-1, 100), 103 ($M-CH_2$, 11), 91 ($117-C_2H_2$, 21), 78 (10), and 66 ($M-C_4H_4$, 61). In this case, a hydrogen was probably taken off from the methylene bridge and the base peak was formed. Although the main fragmentation is also *retro*-Diels-Alder type one, the intensity of mass 66 peak is not strong compared with that in the case of II. The reason of this may be due to the formation of unfavorable cummulene fragment. This property is parallel with thermally stable nature of I.[5]

Experimental[6]

trans-2,3-Dichloromethyl-bicyclo[2.2.1]hept-5-ene (II) A mixture of 8.26 g of 1,4-dichloro-2-butene, 5.26 g of freshly distilled cyclopentadiene and 6 ml of benzene in a sealed glass tube was heated in an autoclave which was also filled with benzene. An oil bath (or electric heater) used should be

heated at 180°C before the reaction and the temperature should be kept at 180±5°C during the reaction. After cooling, the benzene was removed under reduced pressure and then the residue was distilled fractionally. II was obtained as a colorless oil (7.35 g), bp 117°C/16 mmHg; average yields of II are 50—60%. ν (oil neat); 3070, 2960, 2905, 1460, 1445, 1325, 1285, 1265, and 710 cm^{-1}.

Found: C, 56.84; H, 6.50%. Calcd for $C_9H_{10}Cl_2$: C, 56.56; H, 6.33%.

2,3-Dimethylenebicyclo[2.2.1]hept-5-ene (I). A solution of 6.65 g of II and 7.0 g of potassium hydroxide in 30 m*l* of DMSO which contained 3 m*l* of water was put in a Claisen flask and heated for 6 hr at 160±5°C under gentle stream of nitrogen. As the reaction proceeded, oily products were distilled out and collected in an flask cooled in an ice bath. The collected products were washed well with water, extracted with ether, and the combined ether layers were dried over sodium sulfate. After the drying reagent and the ether had been removed, the obtained products were distilled fractionally to give 2.63 g of I; bp 142°C (lit, bp 142°C);[1] average yields of I are 55—65%. λ_{MeOH}^{max}; 242 mμ (log ε, 3.97). ν (oil neat); 3060, 2957, 2855, 1640, 1420, 1308, 880, 792, 765, and 678 cm^{-1}.

The oily product afforded an adduct, mp 121°C, in 95% yield on reacting with maleic anhydride.

The mass spectra were measured at 70 eV by indirect method.

The authors are indebted to the Hitachi Chemical Co. for the gift of cyclopentadiene dimer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1562—1564(1972)

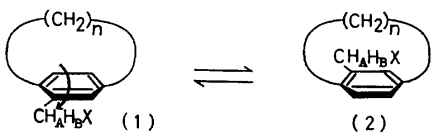
Hindered Rotation in [12]Paracyclophanes[1)]

Masao NAKAZAKI, Koji YAMAMOTO, and Susumu OKAMOTO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received October 19, 1971)

In our preceding communication,[2)] we examined the rates of internal rotation of the benzene rings in a series of [*n*]paracyclophane derivatives with CH_2X side chains on the benzene nucleus, by taking advantage of the phenomenon that the diastereotopic methylene protons (H_A, H_B) become indistinguishable on rapid interconversion between the conformational enantiomers (**1**), (**2**) on NMR time scale.



(1) (2)

In this communication, we report an NMR analysis of the hindered rotation in [12]paracyclophane deirvatives (**3**), (**4**) with substituents on benzylic positions of the bridges.

(3) a,X=Br
b,X=OAc
c,X=OH

(4) a,X=Br
b,X=OAc
c,X=OH

Bromination of [12]paracyclophane[3)] with *N*-bromosuccinimide in carbon tetrachloride afforded a mixture of dibromides which could be separated by recrystallization from *n*-hexane into *cis*-1,12-dibromo[12]paracyclophane (**3a**), mp 172—173°C and *trans*-1,12-dibromo[12]paracyclophane (**4a**), mp 155—156°C. Each of these dibromides was converted into the *cis*-diacetate (**3b**), mp 64—65°C and the *trans*-diacetate (**4b**), mp 82—83°C. Alkaline hydrolysis of the diacetates (**3b**) and (**4b**) gave the *cis*-diol (**3c**), mp 180—181°C and *trans*-diol (**4c**), mp 174—175°C respectively.

Their *cis*- and *trans*-configurational assignments are based on the following observations of their NMR spectra[4)] (Fig. 1, 2).

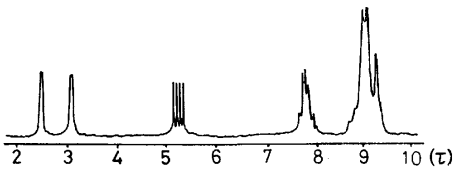

Fig. 1. 100-MHz NMR spectrum of *cis*-1,12-dibromo[12]-paracyclophane (**3a**) in CS_2 at +42°C.

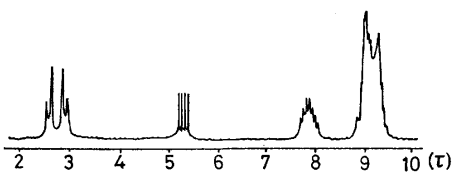

Fig. 2. 100-MHz NMR spectrum of *trans*-1,12-dibromo[12]-paracyclophane (**4a**) in CCl_4 at +25°C.

The *cis*-dibromide (**3a**) has C_s symmetry and its aromatic protons can be grouped into two enantiotopic pairs, $H_A/H_{A'}$ and $H_B/H_{B'}$, and the stereochemical

1) Presented in part before the 22nd Annual Meeting of the Chemical Society of Japan, Tokyo, March, 1969.

3) D. J. Cram and H. Daeniker, *J. Amer. Chem. Soc.*, **76**, 2743 (1954); D. J. Cram, N. L. Allinger, and H. Steinberg, *ibid.*, **76**, 6132 (1954).

4) NMR spectra were taken on a Nucleomagnetic Resonance Spectrometer, JNM-4H-100, Japan Electron-Optics Laboratory Co., Ltd.

relationship between H_A and $H_{B'}$ (or between $H_{A'}$ and H_B) is diastereotopic.

C_2 symmetry of the *trans*-isomer (**4a**) generates two homotopic pairs $H_A/H_{A'}$ and $H_B/H_{B'}$: all the stereochemical relationships between these pairs in turn are diastereotopic.

Being proximate to the bromine atoms, the protons H_A and $H_{A'}$ are expected to be more heavily deshielded than H_B and $H_{B'}$ in both *cis*- and *trans*-dibromides. From their molecular geometries, the chemical shift difference between the diastereotopic set of protons H_A and H_B of the *cis*-isomer (**3a**) is expected much lager than that of the *trans*-isomer (**4a**). This consideration suggests that the dibromide (mp 172—173°C) with larger chemical shift difference (0.6 ppm) has the *cis*-configuration, and another dibromide (mp 155—156°C) exhibiting smaller chemical shift difference has the *trans*-configuration. This conclusion is further supported by their coupling patterns. In the *cis*-dibromide, it is safe to assume that the coupling constants J_{AB}(*para*) and $J_{AB'}$(*meta*) are negligibly small, and the same is also true for the coupling constants within the enantiotopic pairs, *i.e.* $J_{AA'}\approx 0$, $J_{BB'}\approx 0$. And these degeneracies explain a surprisingly simple resonance pattern of the *cis*-compound in aromatic region, which is otherwise expected to show a rather complicated AA'BB' pattern. In the same token, AA'BB' type[5] of spin coupling pattern in the *trans*-dibromide (**4a**) is reduced to become resemble a simple AB quartet due to the relatively large magnitudes of *ortho*-coupling constants (J_{AB}, $J_{A'B'}$) and negligibly small coupling constants between the protons in *para* and *meta* positions ($J_{AB'}\approx 0$, $J_{AA'}\approx 0$).

On warming, the benzene nucleus of the *cis*-dibromide (**3a**) becomes to rotate through the loop of the polymethylene bridge rendering the diastereotopic sets of protons ($H_AH_{A'}$ and $H_BH_{B'}$) indistinguishable on NMR time scale.

Figure 3 shows typical temperature dependence (71—148°C in diglyme) of the NMR spectrum in aromatic region of the *cis*-dibromide (**3a**), together with the calculated spectra generated for a range of values of the pre-exchange life time τ using the density matrix procedure,[6] in which approximation that all coupling constants are zero was made.

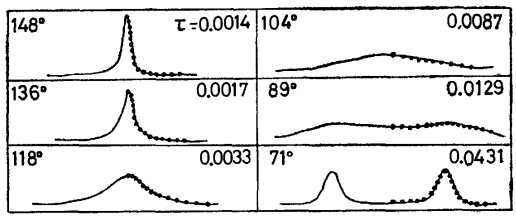

Fig. 3. Observed (——) and calculated (·····) spectra for the aromatic protons of *cis*-1,12-dibromo[12]paracyclophane (**3a**) as a function of temperature. (Solvent: diglyme)

5) These unique AA'BB' spin systems around a benzene nucleus are peculiar to these rather queer benzene derivatives with C_s and C_2 symmetry respectively.

6) C. S. Johnson, Jr., *Advan. Magnetic Resonance*, **1**, 35 (1965). These calculated spectra were made up with the aid of a program written for NEAC-2200 Computer, Osaka University Computation Center.

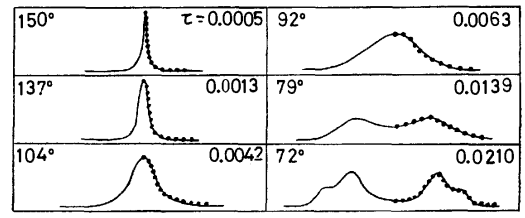

Fig. 4. Observed (——) and calculated (——) spectra for the aromatic protons of *trans*-1,12-dibromo[12]paracyclophane (**4a**) as a function of temperature. (Solvent: hexachloro-1,3-butadiene)

Also, in aromatic region of the *trans*-dibromide (**4a**) (in hexachlorobutadiene), the quartet changes to a broad doublet at 79°C, then coalesces into a broad singlet at 92°C which further transforms into a sharp singlet in higher temperature. In Fig. 4 are shown this temperature dependent NMR spectra with their calculated spectra which were computed on the approximation $J_{AB'}=0$ and $J_{AA'}=0$.

Table 1. Coupling constants and chemical shifts used in variable-temperature analysis

Compd	Solvent	Temp. range (°C)	δ_{AB} (Hz)	J_{AB} (Hz)	T_c (°C)	E_a (kcal/mol)
(**3a**)	c	20—159	50.5		104	12.8±0.8
	b	18—160	56.0		105	13.2±0.5
(**3b**)	c	19—158	29.7		113	13.1±0.6
	b	20—155	28.0		111	12.6±0.5

(**4b**)	c	15—163	7.7	8.5	92	12.2±0.4
	a	14—151	10.8	8.4	91	12.8±0.6
(**4c**)	c	17—160	28.6	9.2	139	18.1±0.8

E_a: Arrhenius activation energy; T_c: coalescence temperature a: hexachloro-1,3-butadiene; b: nitrobenzene-d_5; c: diglyme

Arrhenius plots of these data afforded E_a listed in Table 1, which also lists the chemical-shift differences and coupling constants employed in these calculations. From Table 1, it is clear that each pair of *cis*- and *trans*-isomers shows relatively small differences in their activation energies of internal rotation. Remarkably high activation energies found in the *cis*-diol and *trans*-diol should be ascribed to intermolecular hydrogen bonds.

Experimental

cis-1,12-Dibromo[12]paracyclophane (3a) and trans-1,12-dibromo[12]paracyclophane (4a). A mixture of 5 g of [12]-paracyclophane,[3] 7.7 g of *N*-bromosuccinimide, and 1400 m*l* of carbon tetrachloride was refluxed for 10 hr. The warm solution was filtered to remove succinimide, and evaporated to dryness. The residue was refluxed for 3 hr with 200 m*l* of *n*-hexane, and the undissolved white solide was recrystallized 3 times from *n*-hexane–benzene to give 4.8 g (58%) of the *cis*-dibromide **3a**, mp 172—173°C. Found: C, 53.68; H, 6.50; Br, 39.80%. Calcd for $C_{18}H_{26}Br_2$: C, 53.75; H, 6.51; Br, 39.74%.

Evaporation of mother liquor gave a residue which was

recrystallized 4 times from *n*-hexane to give 0.6 g (7%) of the *trans*-dibromide **4a**, mp 155—156°C. Found: C, 53.61; H, 6.55; Br, 39.83%. Calcd for $C_{18}H_{26}Br_2$: C, 53.75; H, 6.51; Br, 39.74%.

cis-*1,12-Diacetoxy*[*12*]*paracyclophane* (***3b***). A mixture of the *cis*-dibromide **3a** (0.5g), 0.5 g of sodium acetate, and 5 m*l* of acetic acid was refluxed for 16 hr. The warm mixture was filtered to remove sodium bromide, and the filtrate was evaporated *in vacuo*. The residue was cooled, diluted with water, and extracted with ether. The ether layer was washed with water, diluted sodium bicarbonate, and water. The solution was dried, evaporated, and the residue was recrystallized 2 times from *n*-hexane to give 0.33 g (73%) of **3b**, mp 64—65°C. Found: C, 73.18; H, 8.88%. Calcd for $C_{22}H_{32}O_4$: C, 73.30; H, 8.95%.

cis-*1,12-Dihydroxy*[*12*]*paracyclophane* (***3c***). To a solution of 0.7 g of potassium hydroxide in 6 m*l* of ethanol was added 0.25 g of the *cis*-diacetate **3b**, and the mixture was refluxed for 10 hr. The reaction mixture was poured into 20 m*l* of water and extracted with chloroform. The chloroform layer was washed with water, dried and evaporated. The residual solid was recrystallized 3 times from benzene to give 0.11 g (57%) of **3c**, mp 180—181°C. Found: C, 78.08; H, 10.18%. Calcd for $C_{18}H_{28}O_2$: C, 78.21; H, 10.21%.

trans-*1,12-Diacetoxy*[*12*]*paracyclophane* (***4b***). Reaction of the *trans*-dibromide **4a** (0.5 g) with sodium acetate was carried out in a manner similar to that described for the preparation of *cis*-diacetate **3b**. Recrystallization from ethanol gave 0.32 g (71%) of **4b**, mp 82—83°C. Found: C, 73.43; H, 8.92%. Calcd for $C_{22}H_{32}O_4$: C, 73.30; H, 8.95%.

trans-*1,12-Dihydroxy*[*12*]*paracyclophane* (***4c***). Alkaline hydrolysis of 0.25 of the *trans*-diacetate **4b** was carried out in a manner similar to the preparation of *cis*-diol **3c**. Recrystallization from benzene gave 0.12 g (63%) of **4c**, mp 174—175°C. Found: C, 78.11; H, 10.19%. Calcd for $C_{18}H_{28}O_2$: C, 78.21; H, 10.21%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1564—1565(1972)

The Crystal Structure of *o*-Nitrobenzamide

Kumiko FUJIMORI, Tomitake TSUKIHARA, Yukiteru KATSUBE, and Jiro YAMAMOTO
Faculty of Engineering, Tottori University, Tottori

(Received October 27, 1971)

There are several types of molecular arrangement connected by hydrogen bonds[1-6] in the crystals of the derivatives of benzamide. It seems that a substituent group of benzamide influences the crystal structure. It is impossible, however, to discuss the effect of substituent on molecular arrangement at the present stage, because little is known about the crystal structure of the derivatives of benzamide. The present structure determination of *o*-nitrobenzamide has been undertaken as a part of a series of investigations on the crystal structures of aromatic carboxyamide.

Experimental

The crystal grown from alcohol solution was a transparent needle elongated along the *c* axis. The physical and crystal data are shown in Table 1. The unit cell dimensions were determined by the rotation and Weissenberg photographs about *b* and *c* axes. Intensities of 1494 independent reflections were measured visually on equi-inclination Weissenberg photographs of 0—3 layers around the *c* axis and of 0—8 layers around the *b* axis, with the use of Cu-K_α radiation. Intensities were corrected only for the usual Lorentz and polarization factors.

Table 1. Crystal data

$C_6H_4(NO_2)(CONH_2)$		M.W.=166.14
Monoclinic		$P2_1/a$
$a=12.01$Å	$b=12.79$Å	$c=5.03$Å

$D_{cal}=1.44$g/cm^3		
$D_{obs}=1.43$g/cm^3	(by floatation)	

Structure Determination and Refinement

The orientation of the benzene ring was easily determined by the three-dimensional Patterson function. The three-dimensional coordinates of the atoms in the molecule for a probable orientation were at first determined by trial and successive Fourier methods. The coordinates of the atoms thus obtained were refined by the diagonal-matrix least-squares method with isotropic temperature factors. All the hydrogen atoms were revealed by (F_o-F_c) synthesis, at the stage of 0.15 of the *R* factor. Further refinements including hydrogen atoms were made by the block-diagonal-matrix least-squares method. The final *R* factor obtained was 0.136 for all the reflections but it was 0.108 excluding unobserved reflections. The atomic parameters are given in Table 2.

Structure Description and Discussion

The intramolecular bond lengths and angles are shown in Fig. 1. All the values seem to be reasonable.

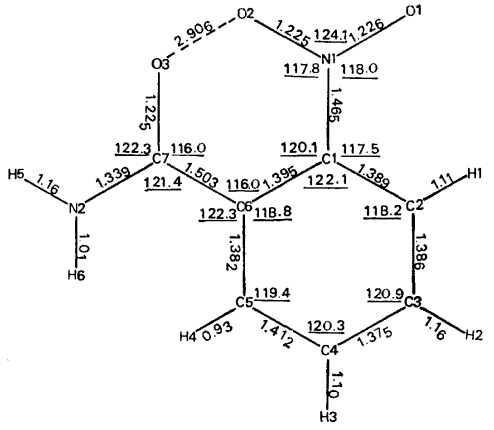

Fig. 1. Intramolecular distances (Å) and angles (°).

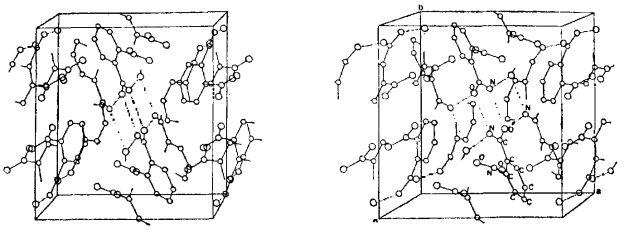

Fig. 3. The crystal structure of *o*-nitrobenzamide shown by a stereo pair, broken lines showing hydrogen bonds.

The average estimated standard deviation of bond lengths between non-hydrogen atoms is about 0.008 Å.

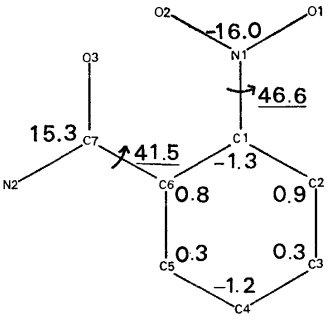

Fig. 2. The deviations ($\times10^2$Å) from the least-squares plane formed by the six carbon atoms of the benzene ring, and rotation angles of amide and nitro groups from the plane of the benzene ring.

The equation of the best plane of the benzene ring and the deviations of the atoms from the plane are given in Fig. 2. The planes of the amide and nitro groups rotate from that of the benzene ring at about 42 and 47 degrees, respectively. The arrangement of molecules in the unit cell is shown in Fig. 3 by a stereoscopic pair. There are two NH···O hydrogen bonds; the first set, 2.94 Å, forms a dimer across the center of symmetry, and the second set, 2.82 Å, links the dimers to form an endless chain extended along the *c* axis. A similar hydrogen bonding scheme has been found in the crystal of benzamide[1] and *m*-methylbenzamide.[2] The NO_2 group does not participate in the hydrogen bonds.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1566(1972)

A Remark on the Importance of Particular Orbital Interaction in the Dimerization of Methylenes

Hiroshi FUJIMOTO, Shinichi YAMABE, and Kenichi FUKUI
Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received October 30, 1971)

Hoffmann discussed the mode of the approach of two singlet methylenes to form an ethylene molecule, suggesting the preference of a non-least-motion path to the least-motion path.[1] The dimerization of methylenes was also investigated by Kollmar using the CNDO MO method,[2] and by Sustmann and Binsch applying their perturbation calculation method.[3] In our own recent papers,[4,5] the interaction energy between two species has been discussed by dividing it into the Coulomb, exchange, delocalization, and polarization terms, and the important role of the delocalization interaction in representing the bond interchange in chemical reactions has been pointed out. In this note we will present the results of an approximate MO calculation on the dimerization of singlet methylenes.

Table 1 gives the four energies which have been obtained much as in our previous calculation.[6] The necessary variables in order to determine the relative positions of the two singlet methylenes are defined in Fig. 1. We see that Model III is the best among the three. It may also be noted that the superiority of Model III to Model I and to Model II is based mainly on the small unstabilization due to the exchange interaction and to the large stabilization due to the delocalization interaction. The contributions of the Coulomb interaction energy and the polarization interaction energy are both rather small, reflecting the fact that methylene is a neutral species. The exchange interaction energy is supposed to depend on the sum of the squares of the overlap integrals between the occupied MO's of two methylenes.[4] Such a relation can easily be confirmed by comparing the ε_K in Table 1 and the $\sum_i^{occ}\sum_k^{occ} S_{ik}^2$ in Table 2. The delocalization term comes from the mixing of charge-transferred electron configurations into the adiabatically interacting state. Among the various charge-transferred states, the one in which an electron is transferred from the highest occupied (HO) MO of one molecule into the lowest unoccupied (LU) MO of another molecule, and the converse, are usually the most important in governing the course of chemical reactions. In Table 2 are also presented the absolute values of the overlap integrals between the HOMO of one methylene and the LUMO of another. We find a close parallelism between the magnitudes of the energy, D, and the sums of the squares of the overlap integrals between these particular MO's.

Thus, the present calculation demonstrates that two singlet methylenes favor approaching in such a way as to make small the overlappings of occupied MO's and to gain an effective orbital interaction between the HOMO of one methylene and the LUMO of another. This seems to be a general feature of chemical interactions between two neutral systems.

TABLE 1. THE CALCULATED RESULTS OF THE INTERACTION ENERGIES

	Model I	Model II	Model III
ε_Q eV	0.102	0.067	0.054
ε_K eV	0.356	0.148	0.139
D eV	0.015	0.223	0.291
Π eV	0.010	0.004	0.003

ε_Q: Coulomb energy, ε_K: exchange energy, D: delocalization energy, Π: polarization energy

	Model I	Model II	Model III
R(Å)	3.0	3.0	3.0
θ(°)	90	44	6
ϕ(°)	0	0	78

Fig. 1. Assumed reaction models. (Model I corresponds to the least-motion path, and Model III to the non-least-motion path.[1])

TABLE 2. THE ORBITAL OVERLAPPINGS BETWEEN TWO METHYLENES

	Model I	Model II	Model III
$\sum_i^{occ}\sum_k^{occ} S_{ik}^2$	0.00668	0.00285	0.00279
$S_{HO^1,\,LU^2}$	0	0.0346	0.0575
$S_{HO^2,\,LU^1}$	0	0.0346	0.0112

HO^1 means the HOMO of methylene 1 and LU^2 the LUMO of methylene 2. (see Fig. 1) S_{ik} is the overlap integral between the ith MO of one methylene and the kth MO of another methylene. $\sum_i^{occ}\sum_k^{occ}$ implies the summation over all the combinations of occupied MO's of two methylenes.

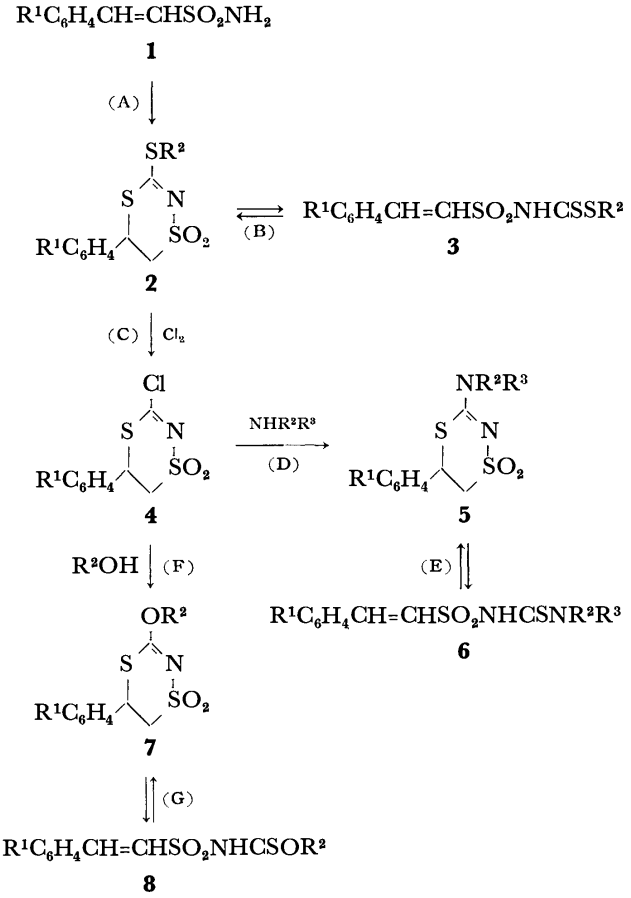
The Synthesis of the 3-Substituted 1,4,2-Dithiazine 1,1-Dioxides[1)]

Kiyoshi HASEGAWA and Syuzi HIROOKA

Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Takaoka-shi

(Received November 1, 1971)

Our previous report[2)] has dealt with the synthesis, cleavage, and structural elucidation of a new heterocycle, 3-monoalkylamino-5-phenyl-1,1-dioxo-5, 6-dihydro-1,4, 2-dithiazine (**5**). This paper will describe the general procedures for the synthesis and cleavage of 3-sub-stituted 1,4,2-dithiazine-1,1-dioxides, which are outlined below:



Results

The reaction of $R^1C_6H_4CH{=}CHSO_2NH_2$ with NaOH, CS_2, and R^2X yielded 3-alkylthio-5-phenyl-1,1-dioxo-5,6-dihydro-1,4,2-dithiazines (**2**). The mechanism is assumed to involve the intermediate of  , which is an intramolecular Michael cycloadduct of $R^1C_6H_4CH{=}CHSO_2N{=}C(SNa)_2$ (Step (A)). The structure of **2** was confirmed by studying its IR, NMR, and mass spectra and by elemental analyses. The C–S bond in **2** could be split to yield *N*-(2-phenylethene-1-sulfonyl) dithiocarbamates, **3**, in strongly basic media (pH≥13.40). They tend to undergo ring-closure to **2** when preserved for long periods. Cycloadducts, **2**, were again obtained from **3** by intramolecular Michael cycloaddition in weakly basic media (pH≤12.55, Step (B)) and also by dissolving it in alcohol, even at room temperature. A mixture of **2** and **3** was obtained when the pH of the solution was between 12.55 and 13.40. The treatment of **2** with chlorine afforded 3-chloro derivatives, **4** (Step (C)). Ammonia, mono-, and dialkylamines attacked **4** at the chlorine atom to form **5** (Step (D)). They were also formed by the Michael cycloaddition of *N*-(2-phenylethene-1-sulfonyl)-*N'*,*N'*-dialkylthioureas, **6**, which are reverse Michael reaction products (Step (E)). *N'*-hydrogen derivatives of **6** are unstable and undergo rapid ring-closure, giving a rather impure product. Thioureas, **6b** and **6c**, were cycloadded upon melting, and **6a**, at 104—106°C before melting. Alcohols reacted with **4** to form 3-alkoxy derivatives, **7** (Step (F)). They were also prepared by the Michael cycloaddition of *O*-alkyl *N*-(2-phenylethene-1-sulfonyl)thiocarbamates, **8**, which are also reverse Michael reaction products of **7** (Step (G)). Solid **8** was stable at room temperature, but was easily cycloadded to give **7** when dissolved in warm alcohol. The results are summarized in Tables 1 and 2.

Experimental

*3-Methylthio-5-phenyl-1,1-dioxo-5,6-dihydro-1,4,2-dithiazine (**2a**).* *Step (A)*: To a stirred solution of 2-phenylethene-1-sulfonamide (18.3 g, 0.100 mol) in DMF (180 m*l*), we added NaOH (4.0 g, 0.100 mol) in water (8 m*l*) at room temperature, and then CS_2 (5.7 g, 0.075 mol) was added at 20—30°C. After 10 min, NaOH (4.0 g, 0.100 mol) in water (8 m*l*) and CS_2 (5.7 g, 0.075 mol) were added, and the mixture was stirred for 2 hr; then $(CH_3O)_2SO_2$ (25.2 g, 0.200 mol) was added, portion by portion, at 20—35°C. The yellow reaction mixture was stirred for 2 hr at room temperature, poured into ice water (1000 m*l*), and left to stand overnight. The yellow solid which formed was filtered to give 26.0 g (95%) of **2a**. Recrystallization from methanol gave colorless crystals. IR (KBr): 1535 ($\nu_{N=C}$), 1320 and 1135 cm^{-1} (ν_{SO_2}). NMR ($CDCl_3$): δ 2.58 (s, 3H, CH_3), 3.43 (q, 1H, H_A), 3.80 (q, 1H, H_C), 5.16 (q, 1H, H_B), J_{AC}= 14.0 Hz, J_{AB}=12.0 Hz, J_{BC}=3.6 Hz, 7.41±0.03 (5H, phenyl). MS: *m/e* 121 ($C_6H_5CS^+$), 273 (M^+).

Step (B): When **3a** (1.09 g, 0.004 mol) was dissolved in a warm 0.1M K_2CO_3 solution (40 m*l*, 0.004 mol), the **2a** began to separate out in a few minutes. After the mixture had then been kept overnight, it was filtered to give 0.98 g (90%) of **2a**.

*Methyl N-(2-Phenylethene-1-sulfonyl)dithiocarbamate (**3a**).* To **2a** (6.90 g, 0.025 mol) in acetone (100 m*l*), we added a 1.0N NaOH solution (50 m*l*, 0.050 mol), and then the mixture was stirred for 1 hr at room temperature. The acetone was

1) Presented at the 25th Annual Meeting of the Chemical Society of Japan, Tokyo, October, 1971.

removed *in vacuo*, and the residual solution was acidified with concd. HCl to give 6.80 g (98%) of **3a**. Recrystallization from benzene–petroleum ether gave yellow crystals. IR (KBr): 3170 (ν_{NH}), 1620 ($\nu_{C=C}$), 1360 and 1150 cm^{-1} (ν_{SO_2}). NMR ($CDCl_3$): δ 2.59 (s, 3H, CH_3), 7.14 (d, 1H, H_A), 7.84 (d, 1H, H_B), J_{AB}=15.0 Hz, 7.48±0.03 (5H, phenyl).

3-Chloro-5-phenyl-1,1-dioxo-5,6-dihydro-1,4,2-dithiazine (4a). Excess chlorine was bubbled through a solution of **2a** (16.4 g, 0.060 mol) in chloroform (120 m*l*) cooled to 0—5°C over a 1-hr period. The colorless solution turned orange and yielded methanesulfenyl chloride. The chloroform was removed *in vacuo*, CCl_4 (20 m*l*) was added to the crystals, and the mixture was filtered to give 14.8 g (94%) of **4a**. Recrystallization from CCl_4 gave colorless crystals.

3-Dimethylamino-5-phenyl-1,1-dioxo-5,6-dihydro-1,4,2-dithiazine (5b). *Step (D)*: To **4a** (1.60 g, 0.006 mol) in chloroform (20 m*l*), we added 40% aqueous dimethylamine (1.37 g, 0.012 mol), after which the reaction mixture was stirred for 1 hr at room temperature. The chloroform was then removed *in vacuo*, and water (20 m*l*) was added to the residue. The cooled precipitate was filtered to give 1.62 g (98%) of **5b**. Recrystallization from methanol gave colorless crystals.

3-Methoxy-5-phenyl-1,1-dioxo-5,6-dihydro-1,4,2-dithiazine (7a). *Step (F)*: A solution of **4a** (2.62 g, 0.010 mol) in methanol (30 m*l*) was refluxed for 2 hr, diluted with water (10 m*l*), and then cooled overnight. The crystals which formed were filtered to give 2.47 g (96%) of **7a**. Recrystallization from methanol gave colorless crystals.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1569(1972)

The Synthesis of 3,4-Di-*O*-methyl-D-galactose

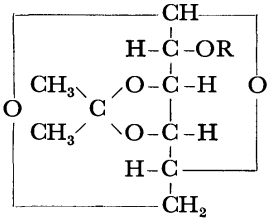
Susumu HIRASE and Kyoko WATANABE

Department of Chemistry, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Kyoto

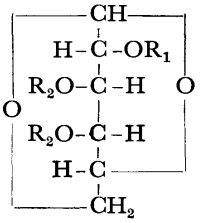
(Received November 6, 1971)

Partially methylated sugars are important for the structural investigation of polysaccharides. In the course of our studies on the polysaccharide from certain species of red seaweeds, 3,4-di-*O*-methyl-D-galactose has been needed as a reference compound. This partially methylated sugar was synthesized by Bacon and Bell.[1] But their method of synthesis has the disadvantages that the starting compound (methyl 3,4-*O*-isopropylidene-β-D-galactopyranoside) was obtained in a low yield,[2] and that the succeeding step involves the use of nitrogen pentoxide, which is inconvenient to handle. We have carried out the synthesis through the different route reported below.

1,6-Anhydro-3,4-*O*-isopropylidene-β-D-galactopyranose(I), prepared by the method of Hann and Hudson,[3] has been used as a starting compound. Its free hydroxyl group at C_2 was first blocked with a phenylcarbamoyl group (I→II). The *O*-isopropylidene group was then removed by methanolysis (II→III). The newly fromed hydroxyl groups at C_3 and C_4 were methylated (III→IV), and the blocking substituent was removed reductively with lithium aluminum hydride (IV→V).[4] Finally, the 1,6-anhydro-ring was opened. The product was identical in the physical constants with 3,4-di-*O*-methyl-β-D-galactose, which had been reported by Bacon and Bell. The intermediates (II—V) are the new compounds. Since these compounds crystallize well except IV, and the yield was considerably high in each step, the synthesis has been performed very easily.



(I) R=H
(II) R=CONHC$_6$H$_5$



(III) $\begin{cases} R_1=CONHC_6H_5 \\ R_2=H \end{cases}$
(IV) $\begin{cases} R_1=CON(CH_3)C_6H_5 \\ R_2=CH_3 \end{cases}$
(V) $\begin{cases} R_1=H \\ R_2=CH_3 \end{cases}$

Experimental

Solutions were evaporated under reduced pressure in a rotary evaporator. Melting points were measured on a micro hot stage with Yanagimoto apparatus Model MP-S2.

1,6-Anhydro-3,4-O-isopropylidene-2-O-phenylcarbamoyl-β-D-galactopyranose(II). To a solution of I[3] (5.0 g) in dry pyridine (50 m*l*), phenylisocyanate (3.5 g) was added, and the mixture was heated at 100°C for 2 hr. Evaporation of the solution gave the crystalline II, which was triturated with ethanol and filtered; yield 7.9 g (100%), mp 226—228°C. It was recrystallized twice from ethanol (600 m*l*); needles, mp 229.5—230.5°C, $[\alpha]_D^{25}$ −30.0° (*c* 1.0 in chloroform).

Found: C, 59.87; H, 6.02; N, 4.38%. Calcd for $C_{16}H_{19}O_6N$: C, 59.80; H, 5.96; N, 4.36%.

1,6-Anhydro-2-O-phenylcarbamoyl-β-D-galactopyranose(III). A solution of II (7.0 g) in 1% methanolic hydrogen chloride (200 m*l*) was refluxed for 3 hr, neutralized with silver carbonate, and filtered. Evaporation of the filtrate gave crystalline III; yield 5.8 g (95%), mp 158—161°C. It was recrystallized twice from water; needles, mp 162—163°C, $[\alpha]_D^{25}$ +24.7° (*c* 0.85 in methanol).

Found: C, 55.55; H, 5.41; N, 5.05%. Calcd for $C_{13}H_{15}O_6N$: C, 55.51; H, 5.38; N, 4.98%.

1,6-Anhydro-3,4-di-O-methyl-2-O-(N-methyl-phenylcarbamoyl)-β-D-galactopyranose (IV). The compound III (3.0 g) was methylated twice with iodomethane (20 m*l*) and silver oxide (20 g) in *N*,*N*-dimethylformamide (30 m*l*) by the method of Kuhn and his coworkers.[5] The product was obtained as a slightly colored syrup; yield 2.8 g (82%), $[\alpha]_D^{25}$ +14.9° (*c* 0.75 in chloroform). (Found: OCH_3, 19.0%).

1,6-Anhydro-3,4-di-O-methyl-β-D-galactopyranose (V). According to the procedure of Bouveng,[4] IV (2.7 g) was treated with excess lithium aluminum hydride (0.7 g) in boiling tetrahydrofuran for 3 hr. The syrupy crude product obtained was purified by dissolution in water and extraction with hexane to remove an oily material. Evaporation of the aqueous solution gave crystalline V; yield 1.5 g (94%), mp 76—79°C. It was further purified by recrystallization twice from a mixture of ethyl acetate and hexane (3:5 v/v); tetragonals, mp 81°C, $[\alpha]_D^{25}$ −41.1° (*c* 0.90 in water).

Found: C, 50.52; H, 7.41%. Calcd for $C_8H_{14}O_5$: C, 50.56; H, 7.61%.

3,4-Di-O-methyl-β-D-galactose. The compound V (1.2 g) was hydrolysed with 4% hydrochloric acid (40 m*l*) at 100°C for 4 hr, at which time the optical rotation of the solution reached the constant value ($[\alpha]_D$ −41→+113°). The hydrochloric acid was removed by neutralization with silver carbonate and filtration. Evaporation of the filtrate afforded crystalline 3,4-di-*O*-methyl-β-D-galactose; yield 1.2 g (92%), mp 164—166°C. It was recrystallized from a small volume of methanol; mp 170—171°C, $[\alpha]_D^{20}$ +90.2→+117.3° (*c* 0.92 in water). Literature values are mp 164—166°C and $[\alpha]_D^{20}$ +95.7→+117.1° in water.[1] (Found: C, 46.10; H, 7.79; OCH_3, 22.0%).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1570—1571(1972)

The Deacylation of β-Diketones in the Presence of Copper(II)-β-Diketonates in Methanol[1]

Kaku UEHARA, Seiichi SHIONOIRI, Makoto TANAKA, and Niro MURATA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka

(Received November 15, 1971)

In a previous paper[2] we reported that the copper(II) chelate of 3-α-butenylacetylacetone shows a high activity as an initiator of the radical polymerization of styrene and methyl methacrylate, that the polymerization proceeds *via* the reduction of Cu(II), and that the ligand is bound to the polymer chain. Furthermore, it has been found that the copper(II) chelate of 3-*n*-butylacetylacetone shows a moderate activity, while the chelate of acetylacetone, $Cu(acac)_2$, is an inefficient initiator.[2] We now wish to report a novel reaction of these β-diketones catalyzed by their copper(II) chelates.

When 3-α-butenylacetylacetone was heated with its copper(II) chelate in methanol under atmospheric air at 70°C, 4-hepten-2-one was obtained. In the course of the reaction, some metallic copper was precipitated. In the reaction carried out under pure oxygen, however, 4-hepten-2-one was formed without the precipitation of metallic copper. It was found that the copper(II) chelate decomposed in methanol to give 4-hepten-2-one, that metallic copper and/or cuprous oxide was precipitated when the solution was heated, and that the precipitation was delayed by the addition of a free ligand. It has also been reported that when the ligand is added to the metallic copper or cuprous oxide in hot methanol under atmospheric air, the copper(II) chelate is reformed.[3]

The deacylation of 3-α-butenylacetylacetone was very slow in tetrahydrofuran or benzene, and did not occur in the absence of the copper(II) chelate.

When 3-*n*-butylacetylacetone was heated with its copper(II) chelate in methanol, 2-heptanone was obtained. The reaction was slower than that of 3-α-butenylacetylacetone. When acetylacetone was heated with $Cu(acac)_2$ in methanol, however, no reaction occurred.

The experimental results in the present study suggest that the deacylation of β-diketones catalyzed by their copper(II) chelates proceeds *via* the reduction of Cu(II); the following cycle may be considered, although the reaction mechanism is yet unclear. The present reaction seems to be interesting as a new route of forming β,γ-unsaturated ketones.

Experimental

Materials. The 3-α-butenylacetylacetone, the 3-*n*-butylacetylacetone, and their copper(II) chelates were prepared in the way described in a previous paper.[2] The acetylacetone and $Cu(acac)_2$ were G.R.-grade reagents. The solvents were purified by the ordinary method and were distilled before use.

Deacylation of 3-α-butenylacetylacetone. A solution of 3-α-butenylacetylacetone (37 g, 0.24 mol) and its copper(II) chelate (3.6 g, 0.01 mol) in methanol (200 m*l*) was heated under reflux at 70°C for 24 hr, during which period metallic copper was gradually precipitated. The reaction mixture was then subjected to distillation. From the volatile fraction, methanol was recovered. From the second fraction (bp 52—55°C/18 mmHg, n_D^{25} 1.4297, d_4^{25} 0.8423), 4-hepten-2-one (**1**) was obtained in a yield of 31% (8.4 g).

Semicarbazone of **1**, mp 105.5°C; Found: C, 57.32; H, 9.09; N, 24.74%, Calcd for $C_8H_{15}ON_3$: C, 56.78; H, 8.93; N, 24.89%. 2,4-Dinitrophenylhydrazone of **1**, mp 121°C; Found: C, 52.77; H, 5.21; N, 19.45%, Calcd for $C_{13}H_{16}O_4N_4$: C, 53.42; H, 5.52; N, 19.18%. The IR spectrum of **1** showed sharp absorption peaks at 1714 cm^{-1} and 970 cm^{-1}. The former was attributed to the C=O group, and the latter, to the *trans* C=C group. The UV spectrum of **1** showed an absorption at 277 mμ (methanol). The NMR spectrum of **1** showed signals at 9.00 (3H, t, $CH_2C\underline{H}_3$), 7.95 (3H, s, $COC\underline{H}_3$), 7.90 (2H, m, $CH_3C\underline{H}_2CH$=), 6.98 (2H, d, $-C\underline{H}_2-CO-$), and 4.50 (2H, q, CH=CH). The mass spectrum of **1** showed the parent peak at *m/e* 112 and fragment peaks at *m/e* 97 $(CH_2CH{=}CHCH_2COCH_3)^+$, *m/e* 83 $(CH{=}CHCH_2COCH_3)^+$, *m/e* 69 $(CH_3CH_2CH{=}CHCH_2)^+$, *m/e* 55 $(CH_3CH_2-$

$CH{=}CH)^+$, and *m/e* 43 $(CH_3CO)^+$.

Deacylation of Copper(II) Chelate of 3-α-Butenylacetylacetone. A 0.1-g portion of the copper(II) chelate of 3-α-butenylacetylacetone was dissolved in 5 m*l* of methanol, and then the mixture was heated under reflux at 70°C for 24 hr, during which period a mixture of metallic copper and cuprous oxide precipitated and the green color of the solution disappeared. After the precipitate had then been filtered off, the methanol was evapolated from the filtrate. The residue was analyzed by gas chromatography. 4-Hepten-2-one was identified by a comparison of its retention time with that of an authentic sample prepared above by means of a Shimadzu GC 4APT gas chromatograph using a silicon gum SE 52 column.

Deacylation of 3-n-Butylacetylacetone. A solution of 3-*n*-butylacetylacetone (15 g, 0.095 mol) and its copper(II) chelate (1.5 g, 0.006 mol) in methanol (500 m*l*) was heated under reflux at 70°C for 48 hr. The reaction mixture was then subjected to distillation. From the volatile fraction, methanol was recovered. From the second fraction (bp 47—50°C/18 mmHg, n_D^{25} 1.4189, d_4^{25} 0.8394), 2-heptanone (**2**) was obtained in a yield of 4.5% (1.0 g). Semicarbazone of **2**, mp 105.5°C; Found: C, 55.94; H, 9.54; N, 24.17%. Calcd for $C_8H_{17}ON_3$: C, 56.11; H, 10.00; N, 24.55%. The IR, UV, NMR, and mass spectra of **2** were closely analogous to those of an authentic sample of 2-heptanone (G.R.-grade reagent).

Spectral Measurements. The IR spectra were measured as a liquid film by means of a Hitachi Model EPI-S2 infrared spectrometer. The UV spectra were measured using a Hitachi recording spectrophotometer, Model EPS-3T. The NMR spectra were determined by means of a Hitachi Model R-20 spectrometer. Tetramethylsilane was used as the internal standard, and CCl_4 was used as the solvent. The mass spectra were recorded on a Hitachi Model RMU-6E mass spectrometer under the following conditions: chamber voltage 80 V, total emission current 80 μA, vacuum 2×10^{-6} mmHg, sample temp. 160°C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1571—1574(1972)

A Theoretical Account of the Correlation between the Electronic Properties of Onium Compounds and Their Catalytic Activities in the Liquid-phase Oxidation of Hydrocarbons

Katsutoshi OHKUBO and Hirokazu KANAEDA

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami-machi, Kumamoto

(Received November 17, 1971)

Previous studies[1,2] have suggested that onium compounds catalyze the liquid-phase oxidation of hydrocarbons. The catalytic activity of onium compounds containing C, N, O, P, S, As, Se, and Te as their onium central atoms is directly affected by the difference in the central atoms and indirectly by that in the counteranions and the substituents attached to the central atom. The larger the alkyl groups possessing the electron-donor property employed as substituents, the higher the catalytic acitvity, while the counteranions of phosphate, sulfate, *etc.* are more active than those of halides. As has been suggested by the spectroscopic[3] and theoretical[4,5] investigations of the possible interaction between the onium compound and molecular oxygen, these experimental phenomena can be considered to be immediately related to the catalytic activation of O_2. The present theoretical study with a semiempirical ASMO SCF method and an extended Hückel method[6] including all the valence electrons in a molecule appeared significant in elucidating the correlation between the electronic properties of onium compounds and their catalytic activities in the liquid-phase oxidation of such hydrocarbons as cumene and α-pinene.[1,2] The silyl compound will also be considered in this report for the sake of comparison.

First, we will discuss the molecular geometries of onium compounds (trimethyl- or tetramethyl-onium chlorides were used) from the energetic point of view. According to the total energies of the compounds listed in Table 1, the stable geometries of the trimethyl onium chlorides (carbonium, oxonium, sulfonium, selenonium, and telluronium) were found in those taking the planar structures of onium cations, while tetramethylonium chlorides (ammonium, phosphonium, and arsonium chlorides) have cations with tetrahedral forms.

Some mention should be made here of the geometries of onium compounds. An experimental finding has

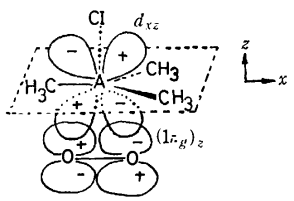
$(CH_3)_3TeCl$	0.339	0.021	1.980	0.073	0.153	0.45	

These data except bond populations were supplied by the ASMO SCF calculations on the most energetically stable onium chlorides: the bond populations were calculated by the extended Hückel method.

a) R_{max} and those in parentheses stand for the rates in cumene and α-pinene oxidations respectively. Without an onium catalyst, $R_{max}\times 10^4$ was 0.17 or 0.34 mol/l sec in cumene or α-pinene oxidation respectively.



already demonstrated that the planar C_{3v} symmetry is the most plausible for the molecular geometry of the carbonium compound,[7] which is analogous with that of an oxonium compound. With respect to the bond length between the central atom and the counteranion, we can predict the ionic bond length on the baiss of the reaction system containing polar oxidation products, such as hydroperoxides and alcohols, although the present calculations on carbonium and oxonium chlorides do not provide the minimum values of their potential surfaces. Concerning the plausibility of the ionic bond length between the central atom and the counteranion, our previous detailed calculations on trimethylsulfonium chloride also supported this concept.[3-5] Therefore, the ionic bond length can be adopted for the other onium chlorides, though some

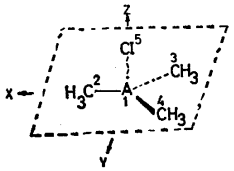
These data were supplied by EHMO calculations.

a) A–C bond corresponds to 1A-2C bond of $(CH_3)_3ACl$ illustrated in the following figure:



discrepancies yet remain in regard to the configuration of the silyl chloride. Moreover, the planar C_{3v} structure of trimethylsulfonium chloride[3-5] may also support the analogous structures (planar C_{3v} ones) of onium chlorides containing Group VI elements as onium central atoms.

Secondly, the discussion will be developed with respect to the correlation between the electronic properties of onium compounds and their catalytic activities as oxidation catalysts. The order of the activity was found to be as follows: carbonium<ammonium< oxonium; (silyl)<phosphonium≲sulfonium; arsonium≃(telluronium)<selenonium. Among these-onium compounds, third-row onium compounds are most effective. The relatively low activity of the second-row onium compounds is probably due to the fact that their onium central atoms possess only the $2p_z$-orbital utilized for the interaction with the $(1\pi_g)_z$-orbital of O_2; the $2p_z$-orbital may not be so effective as d_{xz} and d_{yz} orbitals, in view of the orbital energy and the orbital overlap with the $(1\pi_g)_z$-orbital of O_2 (as to the mode of the interaction between the onium catalyst and O_2, see the simple model[8] in Table 2). Another reason why the activity of the compound is low is that these onium compounds, especially the carbonium compound, are unstable and ionic. There exists, however, a parallelism between the catalytic activity of the second-row onium compounds and the atomic orbital (AO) population of the p_z-orbital of their central atoms (see Table 2). Some remarks should be here made. The catalytic activity is defined by the maximum reaction rate (R_{max} in Table 2), which is itself estimated from the quantity of O_2 absorbed (mol) in cumene (10 m*l*) or α-pinene (10 m*l*) oxidation at 85°C during the formation of a quantity of the hydroperoxides equal to that of the O_2 absorbed.

Concerning the electronic properties of third-, fourth-, and fifth-row onium compounds, they are characterized by their spatially far-reaching, partially-occupied d_{xz} (or d_{yz}) and d_{xy} orbitals utilized for the interaction with the $(1\pi_g)_z$ and the $(1\pi_g)_y$ of O_2 on the basis of a strong $d\sigma$-$p\sigma$ type overlap and a weak $d\pi$-$p\pi$ type overlap[4] respectively. The remarkable activity of sulfonium and phosphonium compounds is the result of the low-lying, partially-occupied $3d_{xz}$ (or $3d_{yz}$) and $3d_{xy}$ orbitals. The silyl compound, however, exhibits a low activity because of the vacant $3p_z$-orbital. The order of the activity is also in good agreement with that of the AO population of the d_{xz} (or d_{yz}) or the d_{xy}, as may be seen from Table 2. In the cases of phosphonium and arsonium compounds, some steric hindrances by the substituents of the interaction between the onium catalyst and O_2 should be taken into consideration. The partial electron occupation of the d-orbitals is the result of the d-π interactions between the d-orbitals of the central atom and the pi-orbitals of the counteranion or the substituents. From this point of view, the contributions of neighboring atoms (C and Cl) to the partial electron occupation of the d_{xz} or the d_{xy} are confirmed by the d-π overlaps recorded in Table 3.

The relatively low activity of the fourth- or fifth-row onium compounds may be ascribed to the diffuse $4d$ or $5d$ orbitals, especially $4d_{xz}$ or $5d_{xz}$, of their central arsenium, selenium, or tellurium. This diffuseness of the d-orbitals depresses their orbital overlaps with the $(1\pi_g)_z$-orbital of O_2 and is reflected in the orbital contour map of the next higher MO to the lowest unoccupied MO (LU+1 MO) of $(CH_3)_3TeCl$, as may

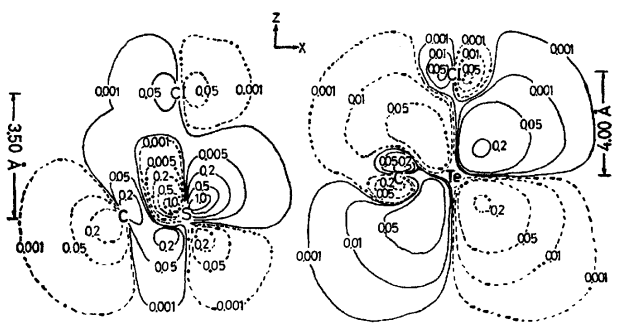


Fig. 1. Orbital contour maps of the LU+1 MOs of $(CH_3)_3SCl$ and $(CH_3)_3TeCl$. These MOs mainly come from the sulfur d_{xz}, carbon p_x and p_z, and chlorine p_x in the x-z cross section. (Solid and dotted curves indicate positive and negative MO-signs respectively.)

8) For detailed models of the interaction, see Ref. 4.

be seen when we compare the map with that of the LU+1 MO of $(CH_3)_3\overset{+}{S}Cl$ (see Fig. 1).

Finally, it may be concluded that the partially-occupied 3*d*-orbitals are most effective for the catalytic activation of molecular oxygen, and that onium compounds possessing them on their central atoms exhibit a catalysis analogous with those of transition-metal catalysts.

The calculations were carried out on a FACOM 230.60 computer at the computation center of the University of Kyushu.

An MO Interpretation of the Chemical Shifts of the Binding Energies of Inner-shell Electrons. II. A Study of Intramolecular Shifts

Kazuhiro ISHIDA, Hiroshi KATO,* Hiroshi NAKATSUJI, and Teijiro YONEZAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto

**Department of General Education, Nagoya University, Nagoya*

(Received December 4, 1971)

The relationship between chemical shifts in the binding energies of inner-shell electrons and molecular-charge distributions has been pointed out.[1] For adenine and cytosine molecules, however, Barber and Clark[2] concluded that a "simple relationship between 'shifts' in binding energies and 'charge distributions' can be misleading." In a previous paper,[3] we have derived the following correlation formula between the chemical shifts and molecular-charge distributions within a MO framework:

$$\delta\Delta\varepsilon_s(X, Y) = [Q_A(X) - Q_A(Y)]\gamma_{AA} + \sum_{B(\neq A)}^{\text{in } X} Q_B(X)\gamma_{AB}(X) - \sum_{B(\neq A)}^{\text{in } Y} Q_B(Y)\gamma_{AB}(Y)$$

where $\delta\Delta\varepsilon_s(X,Y)$ denotes the chemical shifts of an inner-shell electron, s, on an atom, A, in a chemical environment, X, from that in another environment, Y. $Q_A(X)$, $Q_B(Y)$, and so on denote the net charges on the A, B, *etc.* atoms in the X, Y, *etc.* environments respectively. γ_{AA} denotes a one-center average Coulomb interaction between inner and valence electrons on an A atom. $\gamma_{AB}(X)$ denotes a two-center average Coulomb interaction between inner electrons on an A atom and valence electrons on a B atom in an X environment.

For inter-molecular shifts of simple molecules, the results by the above formula almost entirely accorded with the experimentally obtained values. In the present note, we will report an application of the above formula to the intra-molecular shifts of adenine and cytosine molecules. The results are shown in Table 1 for carbon 1s and nitrogen 1s. Figures 1 and 2 show the plots of the observed binding energies against the calculated $\Delta\varepsilon_s$[4] values for carbon 1s and for nitrogen 1s respectively. The figures illustrate that the correlations are fairly satisfactory. Especially, the correlation is quantitatively good for the carbon 1s of adenine in Fig. 1, in view of the fact that the solid line is drawn at 45 degree with respect to the horizontal axis. For the nitrogen 1s, the correlations are rather good, but not quantitative, as shown in Fig. 2. In view of the non-empirical calculations done on limited bases by Mely and Pullman[5] and by Clementi,[6] deviation of the observed binding energy from the calculated orbital energy can be not said to be constant (except for the carbon 1s of adenine). Therefore, the different slopes in Fig. 2 most probably arise from the fact that the above deviation is not constant.

TABLE 1. CALCULATED $\Delta\varepsilon_s$ AND OBSERVED BINDING ENERGIES

Molecule	1s Binding		
	Atom	Energy[a] (±0.3 eV)	$\Delta\varepsilon_s$ (eV)
	C-5	284.7	−0.44

3) H. Kato, K. A. Ishida, H. Nakatsuji, and T. Yonezawa, This Bulletin, **44**, 2587 (1971).

4) We calculated the $\Delta\varepsilon_s$ with $\Delta\varepsilon_s(X) = Q_A(X)\gamma_{AA} + \sum_{B(\neq A)}^{\text{in } X} Q_B(X)\cdot\gamma_{AB}(X)$, using approximate net charges which has been obtained by the CNDO/2 method.

5) B. Mely and A. Pullman, *Theor. Chim. Acta*, **13**, 278 (1969).

6) E. Clementi, *Int. J. Quant. Chem.*, **IIIs**, 179 (1969).

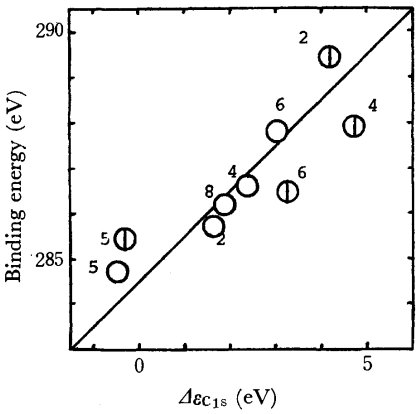

Fig. 1. Observed binding energy *vs.* calculated $\Delta\varepsilon_s$ plots for carbon 1*s* in adenine and cytosine.

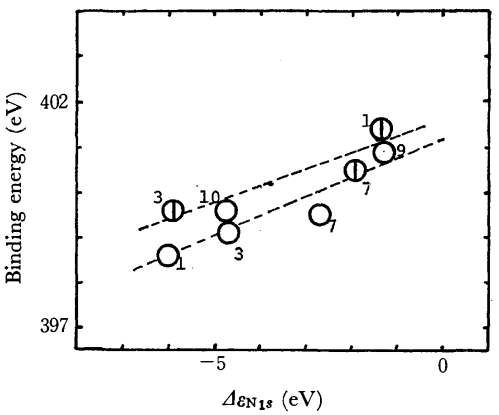

Fig. 2. Observed binding energy *vs.* calculated $\Delta\varepsilon_s$ plots for nitrogen 1*s* in adenine and cytosine.

The above formula means that the chemical shifts of the binding energies should be correlated with charge distributions, though not with simple local charges. Therefore, the previously-refered to suggestion by Barber and Clark is not valid in the present case.

From the above brief discussions we conclude that our formula is useful for the assignment of intra-molecular shifts so long as approximate net charges obtained by a semi-empirical method are used.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1575—1576(1972)

The Polarization Measurement of He-Ne Laser Excitation Raman Lines of Liquid Acetone

Tsunetake FUJIYAMA and Takehiko SHIMANOUCHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received December 8, 1971)

Liquid acetone shows three Raman lines, near 530, 490, and 390 cm^{-1}, in the low-frequency region. These bands arise from the three deformation vibrations of the C–CO–C skeleton, namely, the CCC deformation (ν_8, a_1 species), the in-plane CO bending (ν_{18}, b_1 species), and the out-of-plane CO bending (ν_{23}, b_2 species). However, the assignments of these three lines have not yet been settled.[1] Some authors[2–4] assign ν_8 to the 490 cm^{-1} band, ν_{18}, to the 530 cm^{-1} band, and ν_{23} to the 390 cm^{-1} band, while others[5–7] reverse the assignments of ν_8 and ν_{23}.

Mikami-Abe[8] measured the infrared band envelopes of the 475, 409, and 320 cm^{-1} bands of acetone-d_6 in the gaseous state. The 409 cm^{-1} band shows the C-type envelope, which favors the second set of assignments. Alkins and Lippincott[9] measured the depolarization degree of Raman lines of liquid acetone using He–Ne laser excitation. The 490 cm^{-1} band was observed to be strongly polarized, thus supporting the first set of assignments.

TABLE 1. DEPOLARIZATION RATIOS

Compound	$\Delta\nu$ (cm^{-1})	ρ (Ref. 9)	ρ (present results)
Acetone	394	0.76	0.774
	489	0.18	0.770
	531	0.80	0.792
	788	0.11	0.123
Chloroform	262	0.76	0.746
	366	0.11	0.114
	668	0.03	0.041
Methylene iodide	121	0.26	0.284
	485	0.10	0.092

Recently we measured the depolarization degree of the Raman lines of basic compounds and found that the observed value of the 490 cm^{-1} band of liquid acetone was considerably different from that observed by Alkins and Lippincott, although those of the other bands are in good agreement (Table 1). This finding obviates the idea that the 490 cm^{-1} line belongs to the a_1 species.

Experimental

Acetone was purified by vacuum distillation, and its purity was checked by gas chromatography. The Raman spectra were recorded by means of a laser Raman spectrophotometer which had been constructed in our laboratory.[10] A Spex 1401 double monochromator was used as part of the equipment.

The polarized spectra were measured by the standard 90° scattering method, in which the polarization direction of the post-sample analyzer is fixed perpendicular to the direction of the monochromator slit. The pre-sample half-wave plate was used to rotate the direction of the polarization of the incident light. The exciting laser beam was passed only once through the cubic sample-cell, the edges of which were covered with sheets of black paper. The observation of the aperture was confined within an arc of 12 degrees. The polarization ratios were calculated from the relative band areas corresponding to the incident lights polarized parallel to and perpendicular to the polarization direction of the post-sample analyser.

Reduction of Some 7-Halonorcaranes with Tri-*n*-butyltin Hydride

Teiichi ANDO, Kiyotaka WAKABAYASHI, Hiroki YAMANAKA,* and Wataru FUNASAKA

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida-Honmachi, Sakyo-ku, Kyoto

**Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto*

(Received December 15, 1971)

It has been found that the reduction of 1-chloro-(or -bromo-)1-fluorocyclopropanes with tri-*n*-butyltin hydride at 0—135°C generally proceeds stereospecifically, *i.e.*, with a complete retention of the configuration.[1,2] Thus, 7-*exo*-chloro-7-*endo*-fluoronorcarane gives 7-*endo*-fluoronorcarane exclusively, and 7-*endo*-chloro-7-*exo*-fluoronorcarane gives 7-*exo*-fluoronorcarane exclusively. Since the reduction of organic halides with organotin hydrides is known to be a radical process,[3] this result must be interpreted as being due to the pyramidal structure of the intermediately-formed 7-fluoro-7-norcaryl radical and the slow rate of its inversion of configuration relative to its hydrogen abstraction.

As was mentioned in the previous paper,[2] the reduction of 7-bromo-7-chloronorcarane shows a lower degree of stereospecificity; one of its geometrical isomers, 7-*exo*-bromo-7-*endo*-chloronorcarane, gives a 76: 24 mixture of 7-*endo*- and -*exo*-chloronorcarane when reduced with tri-*n*-butyltin hydride at 0°C. Analogous results have very recently been reported by Altman and Baldwin.[4] Obviously, the inversion of the 7-chloro-7-norcaryl radical can compete with hydrogen abstraction even at 0°C, resulting in the decrease of stereospecificity.

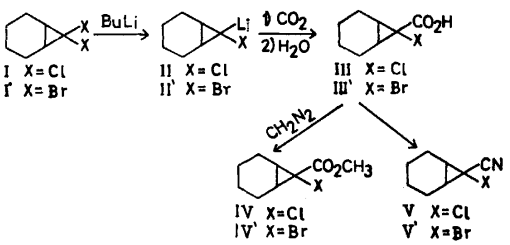
In contrast, the reduction of the geometrical isomers of 1-bromo-1-trifluoromethyl-2-phenylcyclopropane with triphenyltin hydride has been reported to give a mixture of the two possible geometrical isomers of the same composition, irrespective of the geometry of the starting material.[5]

These experimental facts suggest that the configurational stability of cyclopropyl radicals is strongly affected by the nature of the substituent at the 1-position.

The present paper will deal with studies of the reduction of 7-methoxycarbonyl- and 7-cyano-substituted 7-chloro-(or -bromo-)norcarane with tri-*n*-butyltin hydride, carried out in order to ascertain the effect of substituents at the 7-position upon the configurational stability of 7-norcaryl radicals.

Results and Discussion

The norcarane derivatives employed for the present study, *i.e.*, methyl 7-chloro-(or -bromo-)norcarane-7-carboxylate (IV or IV′) and 7-chloro-(or -bromo-)-norcarane-7-nitrile (V or V′), were prepared from the corresponding carboxylic acids (III and III′), which had been synthesized by applying the method of Köbrich and Goyert[6] to 7,7-dichloro-(and -dibromo-)-norcarane (I and I′):



It was found that, although 7,7-dichloronorcarane (I) gave a mixture of the two geometrical isomers of the chloro acid (III), 7,7-dibromonorcarane (I′) gave little, if any, of the *endo*-bromo isomer of 7-bromo-norcarane-7-carboxylic acid (III′), even when the reaction (treatment with *n*-butyllithium followed by

$N\equiv C$, Br (V'a)	119/13	1.5249 (16)	(2230)	—	47.76	48.02	5.05	4.73	6.72	7.00

carbonation) was conducted at −150 to −140°C. The assignment of the *exo*-bromo configuration to the isolated product was based on the methanolysis of the reaction mixture at the same temperature, which gave predominantly the *exo*-bromo isomer of 7-bromonorcarane.[7,8] Probably the *endo*-bromo lithium carbenoid (II', X=*endo*-Br), if formed, had reacted with the tetrahydrofuran solvent to form 7-*exo*-(2-tetrahydrofuryl)norcarane[6] before carbon dioxide was added to the reaction mixture. The possibility cannot be excluded, however, that the *endo*-bromo carbenoid isomerizes to the *exo*-bromo carbenoid under the reaction conditions.

Each of the geometrical isomers of 7-chloronorcarane-7-carboxylic acid (III), as well as 7-*exo*-bromonorcarane-7-*endo*-carboxylic acid (III'a), was converted to the corresponding methyl ester or nitrile by the usual methods. The assignment of configuration to the products is straightforward, since no configurational change should occur during these transformations.

The properties of the hitherto-unknown 7-substituted 7-chloro-(or -bromo-)norcaranes thus prepared are shown in Table 1.

The reduction of the chloro (or bromo) esters and nitriles was performed by treating them with a slight excess of tri-*n*-butyltin hydride under the variety of conditions shown in Table 2. The yields of the reduction product were about 90% for the esters and about 70% for the nitriles. The isomer distributions in the product, which were determined by vpc before distillation, are also listed in Table 2.

As is evident from Table 2, the isomer ratios in the product were nearly identical in all experimental runs. This implies that the 7-methoxycarbonyl- or -cyano-7-norcaryl radical, which would be intermediately formed in the process of the reduction, is either pyramidal but inverts its configuration so rapidly that it behaves as if it were planar, or is in fact planar. Very probably the p-π conjugation between the π-electrons in the methoxycarbonyl or the cyano group and the p-electron at the radical center lowers the energy barrier for the inversion of the configuration of these radicals.

Table 2. Reduction of 7-substituted 7-halonorcaranes

Compound reduced	Reaction condition: Catalyst	Temp., (°C)	Time, (hr)	Isomer ratio in product (*endo*-: *exo*-)
IVa	AIBN	80	8	93:7
	DTBP	140	4	92:8
IVb	AIBN	80	8	94:6
	DTBP	140	4	93:7
IV'a	None	0	2	95:5
	None	110	2	93:7
	None	170	2	90:10
Va	AIBN	80	8	93:7
	DTBP	140	4	92:8
Vb	AIBN	80	8	94:6
	DTBP	140	4	92:8
V'a	None	0	2	97:3
	None	110	2	94:6
	None	170	2	91:9

The predominant formation of the *endo*-substituted isomers in these reductions must be due to the greater steric repulsion in the hydrogen transfer from the tin hydride to the *endo* side of the radical than to the *exo* side. The increase in the relative amount of the *exo*-substituted product with the increase in the reaction temperature may be explained on the same ground.

Experimental

The proton NMR spectra were recorded on a JEOL C-60H spectrometer in carbon tetrachloride with tetramethylsilane (TMS) as the internal reference. The chemical shifts (δ) are expressed in ppm downfield from TMS. In vapor-phase chromatography (vpc), a Golay column of 0.5 mm × 45 m (BDS 45) was used for analytical purposes, and a column of 10 mm × 0.8 m (30% Silicone Grease on 60—80 mesh Celite 550), for preparative purposes. The isomer distributions in the products were determined from the peak areas in vpc before distillation.

Reduction of 7-Substituted 7-Halonorcaranes with Tri-n-butyltin Hydride. The reduction of chloro derivatives was effected by heating a mixture of an isomerically-pure substrate (IVa, IVb, Va, or Vb) and a slight excess of tri-*n*-butyltin hydride under nitrogen with stirring in the presence of a small amount

of azobisisobutyronitrile (AIBN) or di-*t*-butyl peroxide (DTBP). For bromo derivatives (IV'a or V'a), tri-*n*-butyltin hydride was gradually added to a substrate kept at a constant temperature. The reaction conditions and the isomer distributions in the products are shown in Table 2. The identification of the products was made by preparing authentic samples of norcarane-7-*endo*- or -*exo*-carboxylic acid by the method of Skell and Etter,[9] converting them to the corresponding methyl esters or nitriles in the usual way and then comparing their physical properties (IR, NMR, and mass spectra as well as retention times in vpc) with those of the products. Generally, the *endo* esters or nitriles had a shorter retention time than the *exo* isomers. The properties of the products are summarized in Table 3, together with the results of elemental analyses.

SHORT COMMUNICATIONS

Hydrolysis of Adenosine 5′-Triphosphate in the Presence of Various Polyamines

Shinnichiro SUZUKI, Tadayoshi HIGASHIYAMA, Kazuko UEDA, and Akitsugu NAKAHARA
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka
(Received January 31, 1972)

We have recently investigated the non-enzymatic hydrolysis of adenosine 5′-triphosphate (ATP) with various polyamines in order to find a clue to the ATPase function. We observed that ATP is hydrolyzed effectively and specifically with some amines.

Aqueous solutions of ATP (1×10^{-3}M) containing polyamine hydrochloride (1×10^{-3}M) adjusted at a series of pH values with small quantities of hydrochloric acid or sodium hydroxides, were heated at 60°C for 3 hr. The reaction products, orthophosphate (Pi)[1] and/or pyrophosphate (PPi),[1] were determined by the methods of Martin and Doty[2] and of Tetas and Lowenstein,[3] respectively. For some particularly important data on the amount of Pi and PPi, the results were re-examined on the basis of the amount of nucleotides such as ATP, ADP, and AMP by Cohn-Carter method,[4] showing a satisfactory coincidence with each other. The results of ATP hydrolysis with polyamines, *viz.*, $NH_2CH_2CH_2(NHCH_2CH_2)_nNH_2$ (n=0, 1, 2, 3, and 4) are given in Fig. 1.

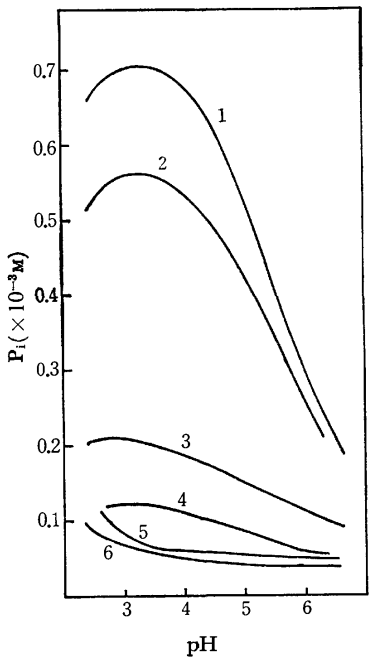

Fig. 1. The results of hydrolysis reactions of ATP with polyamines at various pH values.
1: pentaen (n=4), 2: tetraen (n=3), 3: trien (n=2), 4: dien (n=1), 5: en (n=0), 6: in the absence of amine
experimental error: within 2 to 3%

We see that hydrolyses with pentaen,[5] tetraen, trien, or dien show a maximum at pH range 3—4, and the behaviors of pentaen and tetraen show remarkably high activities. The reaction of ATP with pentaen or tetraen also exhibited excellent specificity, producing only ADP and Pi. Figure 2 shows plots of the yields of Pi against ATP-amine ratio. The breaks in the two curves which occur at a 1:1, amine: ATP system suggest that the intermediates in the hydrolysis reactions consist of equimolecular amounts of ATP and amine. Hydrolysis reactions in the presence of dien(N 2 N 2 N),[6] spmd(N 3 N 4 N), ditn(N 3 N 3 N), trien (N 2 N 2-N 2 N), spmn(N 3 N 4 N 3 N), and dheen (O 2 N-2 N 2 O) were also carried out in water–dioxane (3:2) mixture. The spmd and ditn, and spmn and dheen showed no reaction activities compared with dien and trien, respectively. Of special interest is the fact that no alcohol group in dheen molecule shows activity, and the number of the methylene chains between two nitrogen atoms in a polyamine is extremely important for the hydrolysis reaction.

It may be suggested that there are intermolecular hydrogen bondings between the amino groups of polyamine and the parts of adenine ring, ribose ring and phosphate chain in ATP to activate the phosphate group so that the hydrolytic attack of water molecule becomes easier.

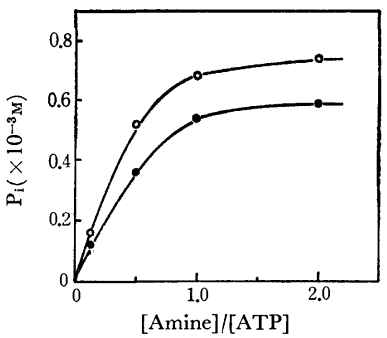

Fig. 2. The reaction activities against the ratio of polyamines.

Evidence of a π-Allyl Intermediate in the Deuterium Propylene Exchange Reaction over $C_{24}K$

Toshihiko KONDO, Masaru ICHIKAWA, Shuji SAITO, and Kenzi TAMARU*

Sagami Chemical Research Center, Ohnuma, Sagamihara, Kanagawa

**Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo*

(Received December 24, 1971)

The deuterium propylene exchange reaction was studied over the potassium graphite intercalation compound $C_{24}K$. The deep blue $C_{24}K$[1] was prepared by heating 2.0 g of spectroscopic powder graphite (Union Carbide Co.) with *ca.* 0.5 g of distilled potassium metal in *vacuo* at 380°C for 24 hr. A conventional closed circulating system was used to study the exchange reaction. Mass and microwave spectroscopic techniques[2] were used to determine the deuterium content and its distribution in the propylene.

Deuterium (*ca.* 200 mmHg) was circulated over $C_{24}K$ at 120°C for about 15 hr and the system was then evacuated for about 10 min. When a mixture of propylene and D_2 was introduced onto the catalyst at 120°C, simultaneous deuteration and exchange of the propylene took place. The amounts of the various propylenes d_1, d_2,$\cdots d_6$, were determined by mass spectrometry, using an ionization voltage of 10 V to avoid fragmentation. No propylene-d_6 was detected throughout the reaction. The hydrogen exchange reaction did not proceed through a multiple exchange process, but through successive single exchange steps.

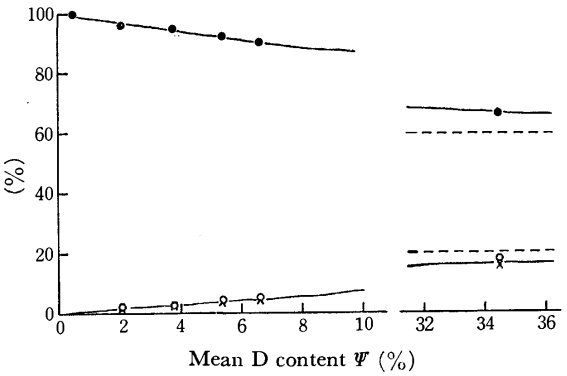

Fig. 1. Hyperfine deuterium distribution of propylene-d_1 at 120°C over $C_{24}K$.
Mean deuterium content Ψ is represented by the equation $\Psi=100(\sum_{i=1}^{6} id_i/6\sum_{i=0}^{6} d_i)$. ●: 3-$d_1$, ×: *cis*-1-$d_1$, ○: *trans*-1-$d_1$

The results of microwave spectroscopic measurements of propylene-d_1, C_3H_5D, as shown in Fig. 1, demonstrated that propylene-3-d_1, $CH_2DCH{=}CH_2$, was the only reaction product in the initial stage of the reaction. As the reaction proceeded, *cis*-1-d_1 and *trans*-1-d_1[3] propylene were formed. However, no propylene-2-d_1, $CH_3CD{=}CH_2$, was observed during the reaction. This indicates that the normal propyl species ($CH_3CH_2\overset{*}{C}H_2$) is not the intermediate of this exchange reaction. Also, the isopropyl species ($CH_3\overset{*}{C}HCH_3$) cannot be the intermediate since it should give a deuterium distribution of 60% 3-d_1, 20% *trans*-1-d_1, and 20% *cis*-1-d_1 which should not vary with reaction time. Accordingly, the intermediate of this exchange reaction cannot be of the half-hydrogenated state of propylene.

If the exchange reaction proceeded by the concerted mechanism (push-pull mechanism),[4] propylene-3-d_1 should predominate in the initial stage of the reaction and be followed by *cis*-1-d_1 and *trans*-1-d_1 propylene. The deuterium distribution of propylene-d_1 in the concerted mechanism shows good agreement with the results in Fig. 1.

TABLE 1. HYPERFINE DEUTERIUM DISTRIBUTION OF PROPYLENE-d_2 IN THE INITIAL STAGE OF THE REACTION ($\Psi=6.6\%$) AT 120°C OVER $C_{24}K$

1,1-d_2	3 (%)
cis-1,3-d_2	22
trans-1,3-d_2	25
3,3-d_2	50

However, the deuterium distribution of propylene-d_2, $C_3H_4D_2$, as shown in Table 1, cannot be explained by a concerted mechanism, because this mechanism would require an initial $C_3H_4D_2$ propylene distribution of 50% *cis*-1,3-d_2 and 50% *trans*-1,3-d_2. In contrast, the results in Table 1 show that the main product in the initial stage is propylene-3,3-d_2, $CHD_2{-}CH{=}CH_2$, (50%) and that the *cis*-1,3-d_2 and *trans*-1,3-d_2 propylene account for only 22% and 25%, respectively, of the total propylene-d_2. This initial distribution of propylene-d_2 indicates that in the reaction intermediate 1 and 3-carbons are equivalent.

The propylene-d_1 distribution shown in Fig. 1 can also be explained by a π-allyl intermediate ($CH_2{=}\overset{*}{C}H{=}CH_2$) mechanism.[5] The mechanism would predict an initial propylene-d_2 distribution of 50% 3,3-d_2, 25% *cis*-1,3-d_2, and 25% *trans*-1,3-d_2. The distribution is in good agreement with that given in Table 1. Other dissociative intermediates (*e.g.*, $CH_2{-}\overset{*}{C}H{=}CH_2$, $CH_3{-}\overset{*}{C}{=}\overset{*}{C}H_2$, $CH_3{-}\overset{*}{C}H{=}\overset{*}{C}H$) are also excluded by our results. It is thus concluded that the intermediate of the exchange reaction of propylene with deuterium over $C_{24}K$ is most probably the π-allyl species, and definitely neither an associative nor dissociative species and no concerted mechanism is involved.

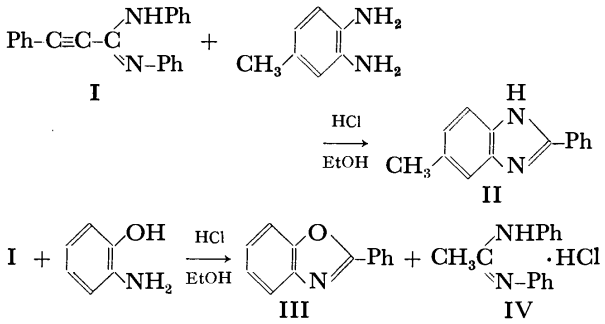
A Novel Cleavage of Carbon-Carbon Triple Bond

Hiroshi FUJITA, Rokuro ENDO, Keisuke MURAYAMA, and Takeshi ICHII
Central Research Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo

(Received December 25, 1971)

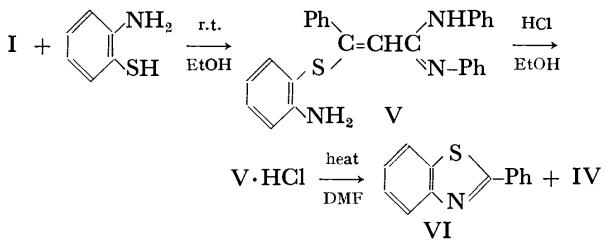
In our studies of phenylpropiolamidines, nucleophilic addition occurred predominantly at the β-carbon of the acetylenic bond in an acidic medium, and reactions with bifunctional nucleophiles (*e.g.* NH_2OH) afforded five membered heterocyclic compounds such as isoxazoles.[1)]

Although *N,N'*-diphenylphenylpropiolamidine (I) exhibited behavior similar to phenylpropiolate in the above cases, reaction of I with 4-methyl-*o*-phenylenediamine[2)] in boiling ethanolic hydrogen chloride proceeded characteristically to furnish 5-methyl-2-phenylbenzimidazole (II; mp 248—248.5°C), as a result of cleavage of the acetylenic bond.

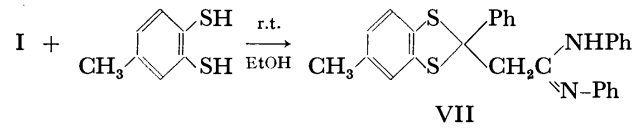


In the reaction of I with *o*-aminophenol in the presence of hydrogen chloride, *N,N'*-diphenylacetamidine was obtained as a hydrochloride (IV; mp 224—226°C), together with 2-phenylbenzoxazole (III; mp 103—104°C). The acetamidine formation indicated clearly that acetylenic bond fission had occurred.

o-Aminobenzenethiol reacted with I in ethanol to give 2-(*o*-aminophenylthio)-*N,N'*-diphenylcinnamamidine [V; mp 150—151°C. Found: C, 77.33; H, 5.62; N, 9.78; S, 7.66%. Calcd for $C_{27}H_{23}N_3S$: C, 76.93; H, 5.50; N, 9.97; S, 7.60%. NMR (δ in acetone-d_6): 5.54 (s, =CH–)]. Heating of V·HCl (mp 186.5—187°C) for a short time in dimethylformamide afforded 2-phenylbenzothiazole (VI; mp 114—115°C) and IV respectively, in good yields.

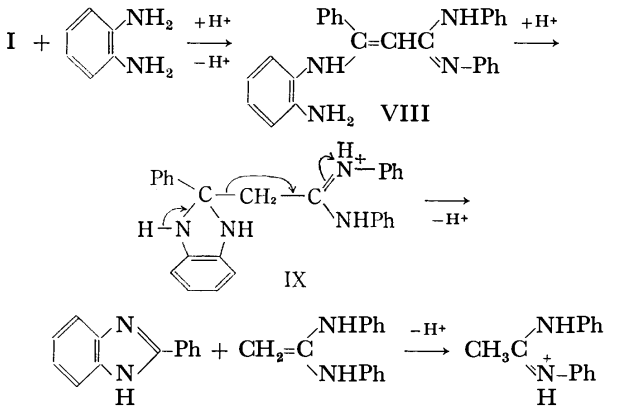


The reaction of I with toluene-3,4-dithiol gave 2-(*N,N'*-diphenylamidinomethyl)-5-methyl-2-phenyl-1,3-benzodithiol [VII; mp 139.5—141°C. Found: C, 74.61; H, 5.24; N, 6.22; S, 14.32%. Calcd for $C_{28}H_{24}N_2S_2$: C, 74.30; H, 5.34; N, 6.19; S, 14.17%. NMR (δ in $CDCl_3$): 3.52 (2H, s, CH_2). Mass (*m/e*): 452 (M^+), 243 (5-methyl-2-phenyl-1,3-benzodithiolium cation)].



This reaction shows that a second nucleophilic attack can take place at the β-carbon of the acetylenic bond.

The mechanism of the cleavage of the triple bond followed by the formation of benzimidazole, benzoxazole, or benzothiazole can thus be considered as shown in Scheme 1.



Scheme 1

The smooth fission of the carbon-carbon triple bond in the protonated propiolamidine system under such mild reaction conditions might be explained by successive nucleophilic additions at the β-carbon of the acetylenic bond, followed by a fragmentation process, which would be due to the stronger electron withdrawing character of the protonated amidine group. Although the stereochemical aspects of this reaction are not clear, it is presumed that an activated enediamine form of protonated VIII (X in Scheme 2) readily undergoes prototropic change to XI, which is attacked predominantly at the β-carbon by the second nucleophilic function, as shown in Scheme 2.

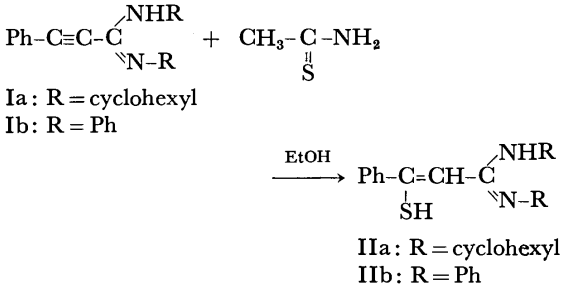
A New Route to Nitriles from Thioamides

Hiroshi FUJITA, Rokuro ENDO, and Keisuke MURAYAMA
Central Research Laboratories, Sankyo Co. Ltd., Hiromachi, Shinagawa-ku, Tokyo
(Received December 28, 1971)

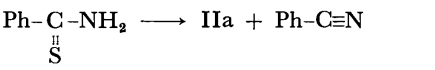
In the preceding paper,[1] we reported that a new cleavage reaction of a carbon-carbon triple bond occurred in the protonated propiolamidine system. In this paper, a new kind of fragmentation reaction is described, involving reactions of phenylpropiolamidines with thioamides, thioureas, and thiosemicarbazides.

The reaction of *N,N'*-dicyclohexylphenylpropiolamidine (Ia) with thioacetamide in boiling ethanol gave *N,N'*-dicyclohexyl-*β*-mercaptocinnamamidine [IIa; mp 158—159°C. Found: C, 73.43; H, 8.65; N, 8.13; S, 9.39%. Calcd for $C_{21}H_{30}N_2S$: C, 73.64; H, 8.83; N, 8.16; S, 9.36%. NMR (*δ* in $CDCl_3$): 6.26 (1H, s, =CH–)] in 50% yield, while dimethyl acetylenedicarboxylate and methyl propiolate reacted with thioacetamide to give (1'-iminoethyl)thiodimethyl fumarate and *cis,cis*- and *cis,trans*-dimethyl-*β*-thiodiacrylic esters, respectively.[2] Subsequently, IIa afforded 5-cyclohexylamino-3-phenylisoxazole (mp 128—129°C)[3] by the reaction with hydroxylamine hydrochloride.



Ia: R = cyclohexyl
Ib: R = Ph

A reaction of Ia with thiobenzamide also gave IIa and benzonitrile in 53 and 65% yield, respectively. The reaction provided a convenient synthetic route to nitriles from thioamides under mild, neutral conditions.



Both reactions of Ia with 1-phenylthiourea and with 1,3-diphenylthiourea gave IIa in 32 and 39% yield, respectively, but thiourea and 1,3-di-*n*-butylthiourea failed to react with Ia and the thioureas were predominantly recovered. This shows that the acidity of N–H in thioureas would be a factor influencing the reaction.

N,N'-Diphenylphenylpropiolamidine (Ib) reacted with 4-phenylthiosemicarbazide to afford *N,N'*-diphenyl-*β*-mercaptocinnamamidine [IIb: mp 162—164°C. Found: C, 76.43; H, 5.28; N, 8.60; S, 9.79%. Calcd for $C_{21}H_{18}N_2S$: C, 76.33; H, 5.49; N, 8.48; S, 9.70%. NMR (*δ* in $CDCl_3$): 6.47 (1H, s, =CH–)] in 16% yield: IIb was also obtained by reaction of Ib with thioacetamide, but in a poorer yield than IIa. The difference in yield suggests that the basicity of the amidine function plays an important role in the reaction. Addition of hydrogen chloride slightly improved the yield of IIb. Thiosemicarbazide also reacted with Ia to give IIa.

Thiol synthesis using thioamides is common and the cleavage of the C–S bond is usually carried out by alkaline hydrolysis. The facile fission of the C–S bond under such mild conditions as in the above cases may be attributed to the heterolytic fragmentation reaction. Although the proton source is not clear, we assume that the driving force of the fragmentation reaction would be due to the electron withdrawing character of the protonated amidine moiety, as shown in Scheme 1, since a thioamide could act as the proton source. This would also support the view that both the basicity of the amidine nitrogen and the acidity of N–H in the thioureas seem to be the important factors in promoting the reaction.

Preparation and Properties of Methylcopper-triphenylphosphine Complexes[1)]

Akio YAMAMOTO, Akira MIYASHITA, Takakazu YAMAMOTO, and Sakuji IKEDA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro, Tokyo

(Received December 2, 1971)

Alkyl and aryl copper complexes are considered to be involved in various copper-catalyzed organic reactions.[2)] A number of reports have been given on the preparation of alkyl and aryl copper complexes by reactions of copper salts with alkyllithium,[3)] alkylzinc,[4)] Grignard reagents,[3,5)] and tetraalkyllead.[6)] Most of the complexes, however, have been prepared *in situ* and the unequivocal isolation of a pure alkyl copper complex free from the alkylating agent does not seem to have been reported so far.

Alkyl copper complexes are thermally unstable. Attempts to stabilize the copper-alkyl bond by addition of ligands such as triphenylphosphine and α,α′-dipyridyl have been unsuccessful.[4,5a)] These ligands are claimed to have no stabilizing effects and the methylcopper complexes with these ligands are reported to decompose explosively even at a low temperature.

We wish to report the preparation of moderately stable methylcopper complexes from copper acetylacetonate, dimethylaluminium ethoxide and triphenylphosphine (in a ratio of 1:3:4) below −10C° in toluene and diethyl ether under nitrogen in a similar way to that for the preparation of other alkyltransition metal complexes.[7)]

$$Cu(acac)_2 + Al(CH_3)_2OC_2H_5 + PPh_3 \xrightarrow{\text{toluene}} CuCH_3(PPh_3)_3\cdot C_6H_5CH_3 \quad (\mathbf{1})$$

$$Cu(acac)_2 + Al(CH_3)_2OC_2H_5 + PPh_3 \xrightarrow{\text{ether}} CuCH_3(PPh_3)_2\cdot {}^1/_2(C_2H_5)_2O \quad (\mathbf{2})$$

Complexes **1** and **2** isolated as light yellow needles and crystalline powder, containing toluene and ether as solvents of crystallization, were characterized by elemental analysis, IR and NMR spectroscopy and chemical reactions.

Found: C, 72.8; H, 5.8; Cu, 10.0; $P(C_6H_5)_3$,[10)] 81—88%; CH_3/Cu, 1.01; $(C_2H_5)_2O$/Cu, 0.43. Calcd for $CuCH_3\{P(C_6H_5)_3\}_2\cdot {}^1/_2(C_2H_5)_2O$ (**2**): C, 73.2; H, 6.0; Cu, 9.9; $P(C_6H_5)_3$, 82.0%; CH_3/Cu, 1.00; $(C_2H_5)_2$ O/Cu, 0.5. NMR: τ 10.3 (s, 3H, CH_3–Cu).

The methyl copper complexes are thermally moderately stable in contrast to the behavior of $CuCH_3(PPh_3)_3$ prepared by Costa *et al.*;[5a)] **1** decomposes gradually over 0°C and **2** can be kept at room temperature in the solid state in nitrogen in the dark. These methylcopper complexes are light-sensitive and are decomposed by UV light releasing methane. On alcoholysis and acidolysis **1** and **2** released quantitative amounts of CH_4; the reaction with D_2SO_4 yielded only CH_3D. The possibility of a structure with copper bonded to the *ortho*-carbon of a phenyl group of triphenylphosphine was excluded in view of the absence of deuterium introduced to triphenylphosphine after the acidolysis with D_2SO_4, as proved by mass spectrometric examination of water formed by degradative oxidation of the triphenylphosphine ligands in the presence of copper oxide. On pyrolysis at 85°C **1** gave CH_4 and C_2H_6 in a ratio of 1:2 and **2** released CH_4, C_2H_6, and C_2H_4 in a ratio of 1:4.5:0.5. Reaction of **1** with ethyl iodide gave methane and propane in a ratio of about 1:1; **2** reacted with ethyl iodide yielding methane and propane in a ratio of 3:2 with a trace of butane. Carbon monoxide was inserted into the methyl–copper bond affording acetone.

Vinyl monomers such as acrylonitrile, methacrylonitrile, methyl acrylate, methyl methacrylate and 2-vinyl pyridine were polymerized with **1**. In general complex **2** showed lesser polymerization activities for these monomers.[11)]

The Stereospecific Rearrangement of 1,3,5-Cycloheptatriene-7-carboxaldehyde Dimethyl Acetal to *cis*-β-Methoxystyrene

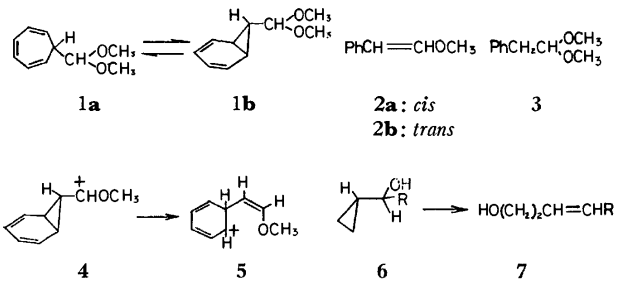
Haruki TSURUTA, Kazuyuki TOMISAWA, and Toshio MUKAI
Department of Chemistry, Faculty of Science Tohoku University, Sendai

(Received October 22, 1971)

During our continuing studies of the intramolecular addition of a carbene located at a side chain to the cycloheptatriene ring,[1] 1,3,5-cycloheptatriene-7-carboxaldehyde dimethylacetal (**1**)[2] has emerged as a promising potential precursor to generate 1,3,5-cycloheptatriene-7-methylene, because the 2,4-dinitrophenylhydrazone of the aldehyde was successfully synthesized from **1** in a high yield without any isolation of the aldehyde.[2,3] Thus, we tried to prepare the corresponding tosylhydrazone or hydrazone, which is a precursor of the carbene, from Compound **1** by the application of a similar manner; however, this attempt was unsuccessful. Instead, we found a curious rearrangement of **1** during the hydrolysis of **1** and wish to report the outlines of the result obtained.

Dimethylacetals of 1,3,5-cycloheptatriene-3-carboxaldehyde[4] and 1-formylbicyclo[3.2.0]hepta-3,6-diene,[5] upon treatment with methanolic hydrochloric acid, provided the corresponding aldehydes, whereas the dimethylacetal (**1**) on treatment with dilute hydrochloric acid, afforded only a rearranged product, phenylacetaldehyde.[2,3] On the other hand, when **1** was warmed in anhydrous acetic acid, a clean reaction took place and *cis*-β-methoxystyrene (**2a**) was mainly formed (the ratio of *cis* to *trans* was 5). The structure of **2a** was established on the basis of the NMR (J= 7.0 Hz, *cis* –CH=CH–) and by a comparison of the retention time in vpc with that of an authentic sample. The rearrangement was a first-order reaction $k = 1.46 \times 10^{-5}$ sec^{-1} at 40°C),[6] and the *cis*: *trans* ratio (about 5) was almost constant from 40 to 60°C. In addition, the prolonged heating of **1** under the same conditions (20 hr at 40°C) resulted in the slow formation of phenylacetaldehyde dimethylacetal (**3**).[3] The possibility of interconversion between *cis*- (**2a**) and *trans*-β-methoxystyrene (**2b**) and of the formation of **2a** or **2b** by the elimination of methanol from **3** could be excluded by the following control experiments. When the *cis*-isomer (**2a**) was subjected to the solvolysis at 60°C for 4 hr in the presence of one equivalent of methanol-d_4, deuterium incorporation took place only in **3**, and the formation of *trans*-isomer (**2b**) was not observed, indicating that **3** is a secondary product. Under the same conditions, the product (**3**) was stable, in addition, the *trans*-isomer (**2b**) was not converted into the *cis*-isomer (**2a**). These facts established that *cis*-β-methoxystyrene (**2a**) was directly formed from 1,3,5-cycloheptatriene-7-carboxaldehyde dimethylacetal (**1**) by stereospecific rearrangement.

In the solvolysis of 1,3,5-cycloheptatrien-7-ylmethylcarbinol 3,5-dinitrobenzoate, Sargent *et al.* observed a novel type of rate enhancement promoted by the participation of the cyclopropane ring which exists in its valence isomer, the norcaradiene form.[7]



Similarly, the enhancement in the rate of the solvolysis of **1** can be attributed to the assistance of the cyclopropane ring of the corresponding norcaradiene form (**1b**). The styrene derivative (**2**) should be produced from the norcaradienylcarbinyl cation (**4**) by the cleavage of the cyclopropane ring to the homoallyl cation (**5**), followed by aromatization leading to β-methoxystyrene (**2**).[3,7,8] Thus, this rearrangement can be seen as an example of the general cyclopropylcarbinol-homoallyl carbinol rearrangement, as is shown from **6** to **7**. The geometry of the homoallyl carbinols obtained by this rearrangement has been widely studied.[9] For example, 1-cyclopropyl-1-methoxyethane[10] and (bicyclo[4.1.0]heptan-7-yl)benzyl alcohol,[11] upon solvolysis, rearranged to the corresponding *trans*-allyl derivatives, but not to *cis*-isomers. The preferable formation of *cis*-β-methoxystyrene (**2a**) from **1** is in sharp contrast to these examples. Therefore, the present results raise interesting questions concerning the conformation of the intermediate in the norcaradienylcarbinyl-styryl rearrangement (**4**→**5**), especially as to the location of the methoxy group in the transition state.

The Determination of the Diffusion Coefficient and the Maximum Surface Concentration of Polyvinylpyrrolidone by Means of a Hanging Mercury Drop Electrode

Tadashi Yoshida, Tetsuya Ohsaka, and Shigemitsu Nomoto

Applied Electrochemical Laboratory, Graduate School of Science and Engineering, Waseda University, Nishi-okubo, Shinjuku-ku, Tokyo, 160

(Received April 20, 1971)

Subsequently to the previous work with a dropping mercury electrode (DME), the diffusion coefficient (D) and the maximum surface concentration (Γ_m) for polyvinylpyrrolidone (PVP) were determined in a 1N sulfuric acid solution by means of a hanging mercury drop electrode (HMDE). The values of D and Γ_m for PVP were obtained separately by means of the equation for a semi-infinite spherical diffusion for HMDE. The results for D were compared with the values evaluated from the Stokes-Einstein equation or with those previously published. The results for Γ_m are also shown in comparison with those values to be expected from the data obtained by the use of DME or HMDE on the assumption of linear diffusion and D, or in comparison with the results published by Jehring. It was also confirmed that the HMDE used by the authors is almost satisfactory for the determination of D and Γ_m in this case.

In most cases, the adsorption process of organic high polymers is mainly diffusion-controlled; such a process for PVP (polyvinylpyrrolidone)[1] has been discussed by the authors on the basis of the results obtained with the DME (dropping mercury electrode) in a previous paper.[2] It is necessary to assume the diffusion coefficient (D) of adsorbates in order to evaluate the maximum surface concentration (Γ_m) with the Koryta equation; however, the maximum surface concentration and the diffusion coefficient may be computed separately by using a equation based on the spherical diffusion for HMDE (hanging mercury drop electrode). Moreover, the results obtained by the use of HMDE under the diffusion-controlled adsorption will be reported in this paper with reference to the values of D and Γ_m published[3-5] or obtained[2] by the authors with the DME.

Experimental

Apparatus. The equipment used for the HMDE was made from Pyrex glass except for some parts of the microsyringe; it is sketched in Fig. 1. The differential capacity was measured at the frequency of 1 kHz with an impedance bridge of a transformer-connected type described in the previous paper.[2] A platinum wire ring[6] was used as the counter electrode, and all the potentials were measured and described with reference to the saturated calomel electrode (SCE). Further, almost all the measurements with the HMDE were made at −500 mV (SCE)[7] in an atmosphere of purified nitrogen kept at 20°C without stirring, except in the case shown in Fig. 3.

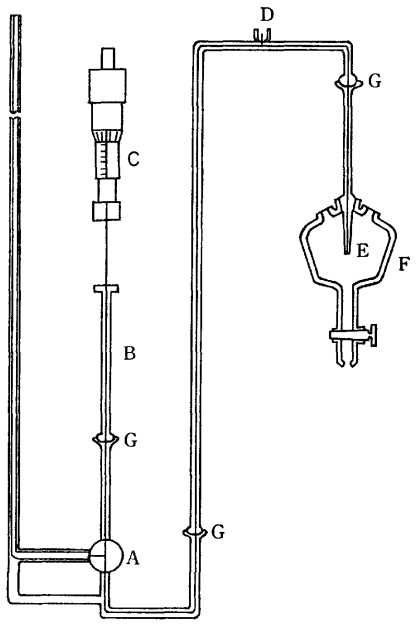

Fig. 1. Equipment for HMDE.
A: Cock, B: Microsyringe, C: Micrometer, D: Pt wire, E: Capillary, F: Cell, G: Ball-joint.

Materials. The mercury used in the present experiment was distilled twice *in vacuo* after being treated in the usual way. For the investigation, four kinds of the PVP prepared by BASF as chemical-grade reagents were used without any further purification; their mean molecular weights ($\bar{M}$) were 10000, 26000, 37000, and 750000 respectively. All the solutions were prepared with guaranteed reagents and triply-distilled water.

Purification of the Solution. Because of the fact that even a trace of impurities influences the results observed with the HMDE, the sulfuric acid solution, prepared as described above, was always standardized after treatment with granular active charcoal and then it was subjected to preelectrolysis over about 10 hours at −500 mV (SCE) in an atmosphere of purified nitrogen just before use.

Procedure for Observation with HMDE. The mercury drop ("E" in Fig. 1) of the HMDE was polarized at the potential of −500 mV (SCE) in a sulfuric acid solution which had been carefully purified and deaerated; then a definite

7) The saturated adsorption of PVP was always attainable at this potential, as has been described in the previous paper.[2]

amount of mercury was forced out by means of a micrometer connected with the microsyringe (shown as "C" and "B" in Fig. 1), just before the observation was started in pursuit of the time dependence of the differential capacity at the mercury interface, the starting time of observation being put at zero. The surface area of a mercury drop for the HMDE was determined from its differential capacity with reference to the value per unit area of mercury obtained with the DME under the same conditions; the result was also compared with that derived from the volume of mercury forced out by the microsyringe ("B" in Fig. 1). The radius of a drop was found to be 0.047 cm.

Theoretical

Relation for the Semi-Infinite Linear Diffusion. In the case of the adsorption controlled by the diffusion of adsorbates, the surface concentration (Γ_t) at the time (t) on a planar electrode is given by:[8,9]

$$\Gamma_t = (2/\pi^{1/2})D^{1/2}at^{1/2} \quad (1)$$

where Γ_t, D, a, and t are the surface concentration of adsorbates at time t in mol/cm^2, its diffusion coefficient in cm^2/sec, its bulk concentration in mol/cm^3, and the time from the beginning of its adsorption in sec respcetively. By substituting the above expression for Γ_t into the relation introduced by Frumkin,[10] we obtain:

$$\theta = \Gamma_t/\Gamma_m = (C_0-C)/(C_0-C_1) \quad (2)$$

it may be written as follows:[9]

$$C = C_0 - 1.13(C_0-C_1)D^{1/2}\Gamma_m^{-1}at^{1/2} \quad (3)$$

where C is the differential capacity per unit of area in μF/cm^2; θ, the coverage; C_0 and C_1, the differential capacities for $\theta=0$ and $\theta=1$ respectively, and Γ_m, the maximum surface concentration in mol/cm^2, that is, the value of Γ_t at $\theta=1$.

Relation for the Semi-Infinite Spherical Diffusion. Fick's law for the diffusional process on a spherical electrode is written by:[11]

$$\partial a/\partial t = D\{\partial^2 a/\partial r^2 + (2/r)(\partial a/\partial r)\} \quad (4)$$

where r is the radius distance from the center of the spherical electrode. When the initial and boundary conditions are substituted in Eq. (4), Eq. (5)[12] is obtained by the Laplace transformation:

$$\Gamma_m = (2/\pi^{1/2})D^{1/2}at_m^{1/2} + Dat_m/r_0 \quad (5)$$

where t_m is the time required to form a monolayer in sec, and r_0, the radius of the spherical electrode in cm. It follows from the rearangement of the above equation that:

$$(at_m^{1/2})^{-1} = (2D^{1/2})/(\pi^{1/2}\Gamma_m) + (Dt_m^{1/2})/(r_0\Gamma_m) \quad (6)$$

where a plot of $(at_m^{1/2})^{-1}$ against $(t_m^{1/2})$ gives a linear relation with a slope of $(D/\Gamma_m r_0)$ and an intercept of $(2D^{1/2}/\pi^{1/2}\Gamma_m)$; therefore, the slope and the intercept are denoted by "K" and "L" respectively, for convenience. The values of Γ_m and D may be computed from K and L as follows, while the values of K and L are obtainable from the experimental data:

$$\left.\begin{aligned}\Gamma_m &= (4r_0K)/(\pi L^2) = D/(Kr_0)\\ D &= (4r_0^2K^2)/(\pi L^2)\end{aligned}\right\} \quad (7)$$

Results

Purification Effect for a Solution. The sulfuric acid solution to be observed was carefully purified as has been stated previously, because of the high sensitiveness of a HMDE for contamination compared with that of a DME. An example, illustrating the wide difference between the solutions prepared with or without the treatment, is given in Fig. 2. The results shown in Fig. 2 confirm that the active charcoal treatment is very effective in the purification; the differential capacity decreases rapidly with the time in the case of the blank 1N sulfuric acid solution prepared without treatment, whereas only a slight decrease with time was observed in the case of that purified with active charcoal.

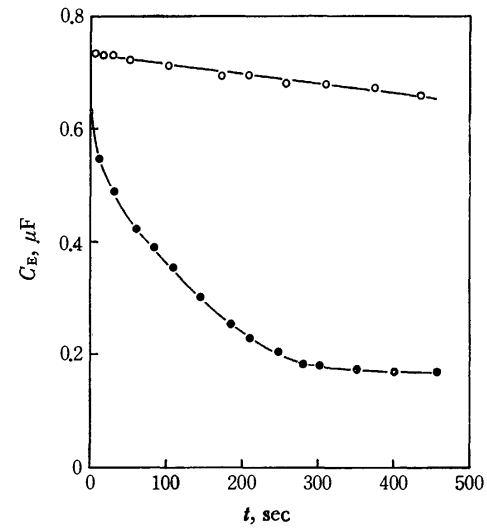

Fig. 2. Pretreatment effect with active charcoal.
20°C, Observed at −500 mV (SCE), 1N sulfuric acid solution,
-○-: Solution with pretreatment of charcoal,
-●-: Solution without pretreatment of charcoal.

Stirring Effect for a Solution. For the case observed with a 1N sulfuric acid solution containing 1.0 mg per litre of PVP ($\bar{M}$=10000), the variation in the differential capacity with the time is shown in Fig. 3, where the results were obtained with or without the stirring of the solution by nitrogen bubbling. When the bubbling was started, the differential capacity for the solution containing PVP decreased more rapidly until the minimum differential capacity was-attained than in the case without bubbling. It may be considered from the above that the process for PVP adsorption is mainly controlled by the diffusion until the saturated adsorption is achieved.

Differential Capacity vs. Time Relation. The C_E *vs.* t curves in Fig. 4-(a) were observed with extremely dilute solutions of PVP ($\bar{M}$=10000). It appears that the minimum differential capacity depends to some extent upon the bulk concentration and that the adsorp-

Where C_E is the observed differential capacity (μF/electrode surface).

tion equilibrium may take place even for the condition of $\theta<1$ in this case. However, the minimum differential capacity for this case gradually decreased with the time. Therefore, for extremely dilute solutions of PVP, it is considered that the saturated adsorption of PVP may occur after a very long time, or that the differential capacity corresponding to an adsorption equilibrium may be slowly depressed by a trace of impurities left in the solution. On the other hand, in the case of Fig. 4-(b), observed with a relatively concentrated solution of PVP as compared with that of the above case, the minimum differential capacities were nearly constant, independently of the bulk concentration, although a slight dependence of the minimum capacity on the concentration was still observed. In a plot similar to the above, observed with PVP of $\bar{M}$=750000, the minimum differential capacities always reached a common value, regardless of the bulk concentration. The time required to attain the minimum capacity of the constant value for the PVP of $\bar{M}$=750000 was about two or three times that in the case with one of $\bar{M}$=10000, in the same bulk concentration in mg per litre.

Discussion

Application of the Semi-Infinite Linear Diffusion (C_E vs. $t^{1/2}$). Equation (3) makes it clear that the differential capacity for the solution containing adsorbates

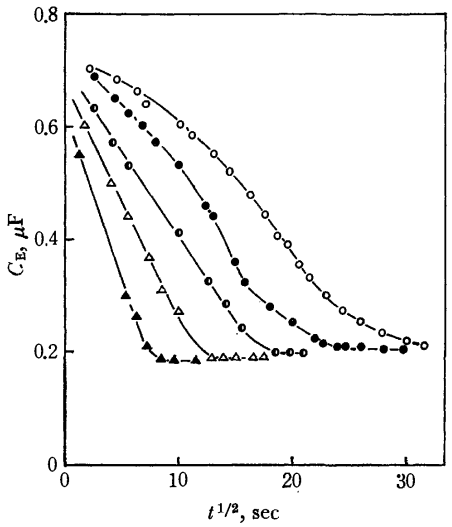

Fig. 5. Relation between differential capacity and square root of time.
20°C, Observed at −500 mV (SCE), 1N sulfuric acid solution+PVP ($\bar{M}$=10000),

decreases linearly with $t^{1/2}$ or a. In Fig. 5, the differential capacity decreases with $t^{1/2}$, until finally it shows a constant value for the saturated adsorption, regardless of the bulk concentration. The time required to form a complete monolayer (t_m) was obtained by extrapolating these two linear relations, as has been described in the previous paper.[2] In the case of relatively concentrated solution of PVP, nearly linear plots were obtained for the diffusion process within about 100 sec, as was to be expected from Eq. (3). However, in the case of the relatively dilute solution in this case, the curves were remarkably depressed and deviated from the linear relation of Eq. (3), especially after about 100 sec. The above deviation was not due to the relation expected from a spherical diffusion, shown in Fig. 6. Consequently, such a deviation is considered to be due to the convection besides the diffusion; therefore, the effect of the convection may be neglected within a relatively short time, such as about 100 sec.

Accordingly, the examination was made mainly on the basis of the data observed within a relatively short time, when the effect due to the convection may be neglected.

The value of the differential capacity at the starting time of t=0 should be a constant, independently of the concentration of PVP. The discrepancy nevertheless observed may be due to the slight difference

among mercury drops resulting from the different operations of the HMDE.

In the next place, by substituting the observed value of t_m into Eq. (3), we can evaluate Γ_m by assuming the diffusion coefficient of PVP; the results will be given later in comparison with the data derived in the other way.

Application of the Semi-Infinite Spherical Diffusion ($(at_m^{1/2})^{-1}$ *vs.* $t_m^{1/2}$). As has previously been stated, the values of Γ_m and D cannot be evaluated separately by the equation for the linear diffusion process unless one of them is determined or postulated; therefore, only the ratio of (D/Γ_m^2) is obtainable in this case. However, the value either for Γ_m or D can be evaluated separately using the relation for the spherical diffusion process, as is given by Eq. (6) in relation to a HMDE.

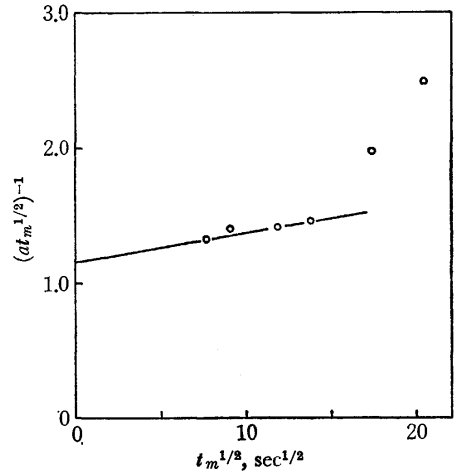

Fig. 6. Relation between $(at_m^{1/2})^{-1}$ and $t_m^{1/2}$.
20°C, Observed at −500 mV (SCE), 1N sulfuric acid solution+PVP ($\bar{M}$=10000).

The relation $(at_m^{1/2})^{-1}$ *vs.* $t_m^{1/2}$ based on Eq. (6) is illustrated in Fig. 6 for the PVP of $\bar{M}$=10000 as an example; it rises steeply from the saturation time (t_m) of about 200 sec. Such a deviation observed for a relatively long saturation time can be attributed mainly to the effect of the convection pointed out previously. Therefore, a linear relation obtained for a saturation time, of less than about 200 sec may be approximately regarded as a reasonable result for the purpose. Accordingly, the values of Γ_m and D were computed, respectively, from the slope and the intercept observed for the linear relation, as above.

Diffusion Coefficient of PVP. The diffusion coefficient of PVP has been measured by the electrophoresis[3] or diffusional sedimentation method,[4] while an approximate value for colloidal particles or large molecules was frequently estimated through the well-known Stokes-Einstein equation in the case of an unknown conductivity. Meanwhile, the Stokes-Einstein equation holds only in the case where the moving particles or molecules are nearly spherical and very large in size compared with the molecules of the solvent.

The results for D in this paper were derived from Eq. (6), related to a spherical diffusion, or from the Stokes-Einstein equation; these results are shown in Table 1 in comparison with the published values.[3,4] Further, the results obtained by Scholtan's relation[4] between D and $\bar{M}$ are also quoted in Table 1 for reference. As is shown in Table 1, the results obtained by the present authors seem to be reasonable apart from the case for the PVP of $\bar{M}$=37000.

Maximum Surface Concentration of PVP. The values of Γ_m for the PVP of several $\bar{M}$'s obtained directly by Eq. (6) are shown in Table 2 with reference to the results derived on the assumption of linear diffusion and the values of D; the D values[13] used in the previous paper[2] were also assumed for the case of the HMDE. The results by Jehring[5] are also quoted there for reference. The values resulting form the HMDE or DME[2] were always measured at −500 mV (SCE) in a 1N sulfuric acid solution at 20°C, whereas those by Jehring[5] were obtained at −1100 mV (SCE) in a 0.5M potassium chloride solution at 25°C.

Table 1. Diffusion coefficient of PVP
($\times 10^7$ cm²/sec)

$\bar{M}$	I[a]	II[b]	III[c]	IV[d]	V[e]
10000	10.3	10.5			10.0
12100				9.15	
13000			7.55		
21000			5.94 6.33		
23000			5.87		
25500				6.20	
26000	7.28	7.65			6.21
32000			4.81		
32500				6.00	
36000			4.24		
37000	9.52	6.78			5.21
39200				4.50	
41500			4.14

584000				1.35	
750000	1.27	2.50			1.15
1129000				0.70	

a) The results derived from the equation for spherical diffusion [*cf.* Eqs. (5) and (6)].
b) The calculated results from the Stokes-Einstein equation, *i.e.* $D=2.96\times10^{-7}/(\eta V^{1/3})$, where η in dyn·sec·cm^{-2} and V in $\bar{M}$/density.
c) The values by the electrophoresis method (*cf.* Ref. 3).
d) The values by the sedimentation method (*cf.* Ref. 4).
e) The values calculated with $D=1.00\times10^{-4}\bar{M}^{-0.5}$ (cm²/sec) (*cf.* Ref. 4).

It was found previously[2] that the saturated adsorption of PVP is attained promptly at −500 mV (SCE) in a 1N sulfuric acid solution in the case of a relatively high bulk concentration, while Jehring[5] also investigated the Γ_m for PVP under conditions when the saturated adsorption was achieved easily. Accordingly, the values of Γ_m reported by Jehring[5] may be compared approximately with the present authors' results.

The data in Table 2 are illustrated in Fig. 7, where the results obtained with the DME[2] are approximately in agreement with those reported by Jehring.[5]

13) Here $D=10.3\times10^{-7}$ (cm²/sec) for $\bar{M}$=10000, 7.3×10^{-7} (cm²/sec) for $\bar{M}$=26000, 5.1×10^{-7} (cm²/sec) for $\bar{M}$=37000, and 1.2×10^{-7} (cm²/sec) for $\bar{M}$=750000.

Table 2. Maximum surface concentration of PVP ($\times 10^{12}$ mol/cm^2)

$\bar{M}$	HMDE[a)]	HMDE[b)]	DME[c)]	Jehring[d)]
10000	9.98	8.10	6.67	
11500				6.06
25000				3.29
26000	3.10	2.85	2.92	
37000	2.90	1.80	2.02	
38000				1.98
750000	0.101	0.075	0.090	0.089

a) The results obtained directly with the equation for spherical diffusion.
b) The results obtained on the assumption of linear diffusion and D (*cf.* Ref. 13).
c) The results by the previous paper.[2)]
d) The values[5)] by A.C. polarography observed at −1100 mV (SCE) in 0.5M potassium chloride kept at 25°C.

Therefore, it may be considered for PVP that the dependence of Γ_m upon the electrolyte and the polarized potential is almost negligible under the above conditions.

In Fig. 7, with reference to the results derived from the equation for linear diffusion, the values obtained by the HMDE are approximately in accordance with those obtained by the DME.[2)] On the other hand, the results obtained directly by the equation of spherical diffusion with regard to the HMDE are somewhat large as compared with both results mentioned above.

It is considered from the above results that nearly reliable values of the D or Γ_m of PVP were obtained by means of the HMDE shown in Fig. 1.

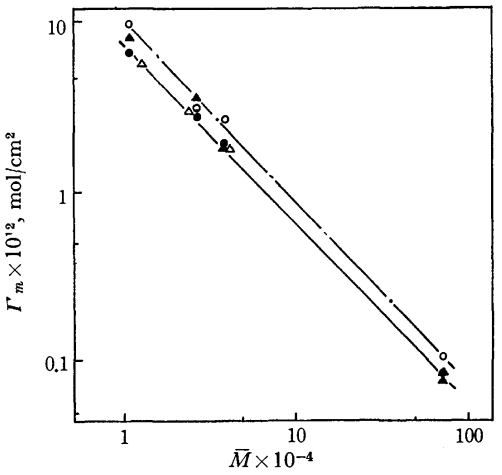

Fig. 7. Relation between Γ_m and $\bar{M}$.
-○-: Values with HMDE, derived from the equation for spherical diffusion.
▲: Values with HMDE, derived from the equation for linear diffusion.
-●-: Values with DME,[2)] derived from the assumption of D as described in the text.

The authors would like to express their appreciation to Mr. Shoji Tanaka and Mr. Osamu Yoshioka for the earnest assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1589—1594(1972)

Electronic Structures of Thianthrene, Phenothiazine, and Related Heterocyclic Compounds

Mamoru KAMIYA
Shizuoka College of Pharmacy, Oshika, Shizuoka-shi

(Received July 29, 1971)

Systematic studies were made on thianthrene, phenoxathiin, diphenylene dioxide, phenothiazine, and phenoxazine for the correlation between the folded structure and electronic spectra in terms of the semiempirical SCF–MO–CI method. The calculated results are in good agreement with the experimental results, the folded structure being prominent in the sulfur-containing molecules. The dihedral angle dependency of the all valence-electronic energy and ionization potential was also studied by the extended Hückel method.

Electronic structures of the heterocyclic compounds thianthrene, phenoxathiin, diphenylene dioxide, phenothiazine, and phenoxazine are of interest since the data on dipole moment[1] and X-ray analysis[2] indicate that these compounds, sulfur-containing ones in particular, are of non-planar spacial configurations folded about the central axis joining the heteroatoms. Several molecular orbital studies have been undertaken in order to survey the correlations between the extent of the folded structure and various physico-chemical properties. As regards the Hückel MO studies, the best integral values for the thianthrene analogs were studied by Kuboyama referring to the energies of the charge-transfer bands.[3] The value of the dihedral angle of thianthrene was predicted by Chandra in terms of the

electronic and strain energies.[4] The spacial configuration and electronic properties of phenothiazine were studied by Malrieu and Pullman,[5] and by Bloor *et al.*[6] from a biological viewpoint. With respect to the SCF MO study, Wratten and Ali performed a P–P–P type calculation on the neutral molecule and cation radical of diphenylene dioxide by making adequate allowance for non-planarity.[7] An analogous calculation was applied by the present author to a series of the related heterocyclic compounds.[8] It seems, however, that no systematic calculation has been published concerning at least the dihedral angle dependence of the electronic spectra and also the hybridization state of the heteroatoms.

The calculations in this paper have been performed in order to supply such deficient data.

Calculation Method

In the semiempirical SCF MO method (P–P–P approximation)[9] the valence-state ionization potential (I) and electron affinity (A) of the π-orbitals are taken as follows referring to the data given by Hinze and Jaffé.[10]

I(=C–) 11.16 eV, I(–O–) 32.90, I(–S–) 23.59, I(–$\overset{|}{\underset{|}{N}}$–) 26.70

A(=C–) 0.03 eV, A(–O–) 11.37, A(–S–) 10.54, A(–$\overset{|}{\underset{|}{N}}$–) 9.26

The two-center repulsion integral is obtained by the Nishimoto-Mataga formula.[11] For the sake of comparison the core-resonance integral is evaluated by the following two methods. In method I, the integral β_{rs} is evaluated for all atomic pairs by the equation $\beta_{rs}=-\frac{1}{2}S_{rs}(I_r+I_s)$, where the overlap integral S_{rs} is calculated on the basis of the Slater type atomic orbitals. In method II, β_{rs} is evaluated for neighbouring pairs by the variable β procedure,[12] where the parametrization is taken as follows.

$$\beta_{C-C} = -0.51P_{C-C} - 1.84$$
$$\beta_{C-O} = -0.56P_{C-O} - 2.20$$
$$\beta_{C-N} = -0.53P_{C-N} - 2.02$$
$$\beta_{C-S} = -0.33P_{C-S} - 1.80$$

Here, P_{rs} corresponds to the usual π-bond order, and to allow for non-planarity the β_{C-X} (X=heteroatom) is corrected by the equation $\beta_{C-X}(\alpha)=\beta_{C-X}(O)\cos\alpha$, where the $\beta_{C-X}(O)$ is the value for the planar structure, and the value of α is the distortion angle from planarity. In both methods all singly excited configurations are allowed to interact.

b) The observed spectral data of I, II, and III are quoted from:
B. Lamatte *et al.*, *J. Chim. Phys.*, **63**, 369 (1966).
Those of IV from: R. J. Warren *et al.*, *J. Pharm. Sci.*, **55**, 144 (1966).
Those of V from: M. P. Olmsted *et al.*, *J. Org. Chem.*, **26**, 1901 (1961).
Here, the 4.13 eV band of I alone is taken from: L, Lang,
"Absorption Spectra in the Ultraviolet and Visible Region," Part II, Akadémiai Kiado, Budapest (1961).

In the extended Hückel method[13] parametrizations of the Coulomb integrals are done with the data by Pritchard and Skinner.[14]

All the bond lengths in the aromatic ring are assumed to be 1.395 Å, and the C–H and N–H bond lengths are taken to be 1.08 and 1.012 Å, respectively. The intramolecular coordinate axes and numbering of the related molecules are given in Fig. 1.

Results and Discussion

Electronic Spectra. In this calculation the dihedral angle is varied in the range 180—120°. Table 1 shows the dihedral angle dependency of the calculated results for the second π-π^* transition, since this transition can be correlated with the longest wavelength band of each spectrum. By method I the calculated value of the transition energy is in the order I<IV<II<V<III, and by method II in the order V<IV<III<II<I. We see that method I indicates more clearly the effects of the folded structure upon the calculated values of the transition energy and oscillator strength.

Table 2 shows the calculated results obtained in a proper range of the dihedral angle as compared to experimental data. It is known that method I gives superior results for molecules not containing the sulfur atom, and method II for the sulfur-containing molecules. As for thianthrene, all the observed values of the transition energies except the lowest value are in good agreement with the values calculated by method II at the dihedral angle 120—130°. The lowest observed bands of thianthrene and phenoxathiin appear to be correlated with both the second and third transi-

tions. In fact, the polarized excitation spectrum of phenoxathiin indicates that the lowest observed band consists of perpendicularly polarized transitions which may be assigned to the second and third transitions.[15] The observed bands of diphenylene dioxide except the band at 4.29 eV are in good accord with the transitions calculated by method I at the dihedral angle 180—170°. It should be mentioned that the third transition of diphenylene dioxide, which is forbidden at planar structure, is slightly enhanced by molecular deformation.

The lowest observed bands of phenothiazine and phenoxazine can be well correlated with the second transition. The second observed bands of these molecules are situated fairly close to both the fourth (y-polarized) and fifth (x-polarized) transitions. In fact, the polarized excitation spectra of these molecules indicate that the second observed bands are composed of two transitions with perpendicular polarization directions.[15] On the other hand, the calculated values of lowest $^3(\pi,\pi^*)$ excitation energy tend to become lower than the experimental values, *i.e.*, 2.4 eV for phenothiazine and 2.6 eV for phenoxazine.[16]

In conclusion, the present calculations on the electronic spectra show that the folded structure is prominently associated with the sulfur-containing molecules in line with the experimental results on dipole moment or crystal structure.[17] Thus, it can be said that the p-orbital model of the sulfur atom adopted is enough for explanation of the electronic spectra.

c) experimental data

Thianthrene (I)	7.80 eV	
Phenoxathiin (II)	7.98	Taken from: B. Lamatte *et al.*, *J. Chim. Phys.*, **63**, 369 (1966).
Diphenylene dioxide (III)	8.10	
phenothiazine (IV)	7.28	Taken from: M.Kinoshita, This Bulletin, **35**, 1609 (1962).

15) H. H. Mantsch and J. Dehler, *Can. J. Chem.*, **47**, 3173 (1969).
16) J. M. Lhoste, M. Ptak, and D. Lexa, *J. Chim. Phys. Physicochim. Biol.*, **65**, 1876 (1968).
17) From a summary of the data in (1) and (2), it is known that diphenylene dioxide is nearly planar, and the dihedral angle for thianthrene and phenoxathiin is 120—130° and that for phenothiazine 140—150°.

theory (EHT). The valence angle of the heteroatoms in a non-folded molecule is tentatively taken to be 120°, since it is not known which value of the valence angle would be appropriate for this case.

Table 3 shows the dihedral angle dependency of the all valence electronic energy. The energy values for thianthrene and phenoxathiin are liable to yield a slight energy minimum around the dihedral angle 170°, but those for diphenylene dioxide go on increasing as the molecule folds. This theoretical finding appears to be in line with the fact that the former two molecules have appreciably folded structures. Conclusive remarks about the dihedral angle dependency of the stability of the folded structure should be avoided, because the strain energy term possibly due to the difference between the assumed and preferred values of the C–S–C bond angle is neglected.

EHT calculations on the two possible spacial configurations of phenothiazine, to be referred to as H intra and H extra according to the notation by Malrieu and Pullman,[5] indicate that the all valence electronic energy of H intra is by 0.2 eV lower than that of H extra in agreement with the ordering of the HMO energies they obtained.

Vertical ionization potentials calculated by Koopmans' theorem are given in Table 4. The values obtained by the EHT method are considerably higher than the experimental data. The dihedral angle dependency of the atomic orbital coefficients of the heteroatoms in the highest occupied molecular orbitals (HOMO) is also given for thianthrene, diphenylene dioxide and phenothiazine because these molecules are known to be typical electron-donors. The EHT ionization potential of thianthrene tends to diminish by molecular deformation. The decrease is accompanied by increase of the S($3P_y$) coefficient and decrease of the S($3P_z$) coefficient. On the other hand, the HOMO coefficient of the oxygen atom in diphenylene dioxide is largely concentrated upon the $2P_z$-orbital. This might indicate that the effect of the lone-pair orbital hybridization to electron donating property is associated with thianthrene to a greater extent than with diphenylene dioxide. The EHT ionization potential of phenothiazine is slightly lowered in going from H intra to H extra. This is followed by a remarkable increase of the N($2P_y$) orbital component in the HOMO. The ionization potentials calculated by the P–P–P method increase with the degree of folding of the molecules. The data calculated by method II well fit the relative ordering of the experimental data.

Chemical Reactivity. The P–P–P method has been found useful for explaining the observed electronic spectra. A brief comment is given on the chemical reactivities in terms of the reactivity indices obtained from the SCF MO coefficients. These heterocyclic molecules are characterized by enhanced electrophilic substitution reactions and ready formation of charge-transfer complexes. The frontier electron densities for electrophilic reaction ($f_r^{(E)}$) were calculated. The $f_r^{(E)}$ values do not change much by the change of dihedral angle (Table 5). The data on phenothiazine and phenoxazine calculated by method II well explain the fact that position 3 is a preferable site for electrophilic reagents in a number of electrophilic reactions. The calculated data on diphenylene dioxide and thianthrene indicate that the β-position is the preferable site for electrophilic attack. The calculated data on phenoxathiin can not explain the fact that electrophilic substitutions such as bromination, formylation or chloromethylation proceed at positions 2 or 8, *i.e.*, *para* to the oxygen atom. Such unexpected directing effects of the oxygen atom have been attributed by Mantsch and Dehler to the formation of a stable complex at the sulfur atom, such as evidenced by an isolable phenoxathiin-dibromide complex.[15]

The Infrared Spectra of Addition Compounds of Hydrogen and Deuterium Cyanides with Boron Tribromide

Isao KANESAKA, Yoshiyuki HASE, and Kiyoyasu KAWAI
Faculty of Literature and Science, Toyama University, Gofuku, Toyama
(Received August 10, 1971)

The infrared spectra of addition compounds of hydrogen and deuterium cyanides with boron tribromide have been measured in the frequency region from 4000 to 200 cm^{-1}, and the normal frequencies have been proposed on the basis of the C_{3v} symmetry for four isotopic compounds, HCN·$^{10}BBr_3$, HCN·$^{11}BBr_3$, DCN·$^{10}BBr_3$, and DCN·$^{11}BBr_3$. The force constants have been calculated on the assumption of a modified Urey-Bradley force field, and the shift of the vibrational frequencies by the coordination has been discussed.

The infrared spectra of the addition compounds of hydrogen and deuterium cyanides with boron trichloride have been studied previously, and the observed spectra have been assigned on the basis of the C_{3v} symmetry, the isotopic effect of H and D or of ^{10}B and ^{11}B being taken account of.[1] The force constants of those compounds have also been calculated.[2]

In many of the addition compounds of R–C≡N with metal halides, in which R is H, D, Cl, Br, CH_3, or C_6H_5, the C≡N stretching frequency has been found to become higher than that of the parent R–C≡N.[1,3-9] Purcell and Drago[8] have explained that the shift of the C≡N stretching frequency in the addition compounds of acetonitrile is due mainly to the increase in the C≡N stretching force constant by coordination. In the addition compounds of hydrogen and deuterium cyanides, however, it has been found that the shift is due mainly to the mechanical coupling and only partly to the increase in the force constant.[1,2] The vibrational spectra of the addition compounds of trimethylamine with boron trihalides have been studied in detail, and the vibrational assignments of the observed frequencies have been proposed on the basis of the isotopic shift and the trend of the frequencies.[10]

In the present paper, the infrared spectra of the addition compounds of hydrogen and deuterium cyanides with boron tribromide will be studied, and the force constants of those compounds will be calculated.

Experimental

The hydrogen cyanide, deuterium cyanide, and boron tribromide were prepared by the ordinary method and were purified by fractional distillation *in vacuo*. The addition compound, HCN·BBr_3 or DCN·BBr_3, was prepared by the reaction of boron tribromide dissolved in cyclopentane with hydrogen or deuterium cyanide, after the method described by Woolf[11] in his study of the addition compounds of cyanogen halides.

The addition compounds were covered with cyclohexane or carbon tetrachloride to prevent them from hydrolysis and were then dispersed on KRS-5 plates, and their infrared

spectra were recorded in the range from 200 to 4000 cm^{-1}. The observed frequencies are expected to be accurate within the limit of ± 5 cm^{-1} for the 4000—2000 cm^{-1} region and ± 2 cm^{-1} for the 2000—200 cm^{-1} region; their assignments are listed in Table 1, in which the two asterisked weak bands are attributable to the addition compound of hydrogen cyanide, which was present in deuterium cyanide as an impurity, with boron tribromide.

Assignments

On the basis of an examination of the structures of certain boron trihalide complexes, it seems reasonable to expect that the addition compound of hydrogen or deuterium cyanide with boron tribromide, $XCN \cdot BBr_3$, where X is H or D, possesses the C_{3v} symmetry. Accordingly, ten normal vibrations, of which five belong to A_1 species and five to E species, can be expected for each compound, and all of them can be expected to be active in the infrared spectra.

In the spectra of $HCN \cdot BBr_3$, six strong and one medium bands were observed. The two bands at 3120 and 2197 cm^{-1} are easily assigned to the C–H and C≡N stretching vibrations respectively. The isotopic shift of the ^{11}B–N and ^{10}B–N stretching frequencies is estimated to be about 30 cm^{-1} from the calculation of the normal frequencies of this type of compound. Taking account of this isotopic shift, the natural abundance of ^{11}B and ^{10}B, and the relative intensities of the observed bands, we assigned the band at 750 cm^{-1} to the ^{11}B–N stretching vibration and the weak band at 777 cm^{-1} to the ^{10}B–N stretching vibration. The isotopic shift of asymmetric ^{11}B–Br and ^{10}B–Br stretching frequencies is also estimated to be about 30 cm^{-1}; this shift has been found to be 29 cm^{-1} for $(CH_3)_3N \cdot BBr_3$.[10] Since the band at 662 cm^{-1} is too weak to assign to a normal vibration, and since this frequency was not observed in the spectra of $DCN \cdot BBr_3$, we assigned the two bands at 674 and 696 cm^{-1} to the asymmetric ^{11}B–Br and ^{10}B–Br stretching vibrations respectively. The band at 318 cm^{-1} was assigned to both the symmetric ^{11}B–Br and ^{10}B–Br stretching vibrations, and the medium band at 363 cm^{-1}, to C≡N–B bending vibration. In addition to those bands, several weak bands were observed. The two bands at 795 and 207 cm^{-1} may be assigned to the H–C≡N and N–B–Br bending vibrations respectively. The remaining weak bands were assigned as combination or overtone bands, for which we propose two normal frequencies, 188 and 150 cm^{-1}.

The bands observed in the spectra of $DCN \cdot BBr_3$ were assigned by comparing their frequencies with those assigned to the normal vibrations of $HCN \cdot BBr_3$ or $DCN \cdot BCl_3$.[1] The two strong bands at 2594 and 1942 cm^{-1} and the medium band at 656 cm^{-1} are easily attributable to the coordinated DCN group. From the tentative assignment of the weak bands as combination or overtone bands, three normal frequencies were proposed, as is shown in Table 1.

The normal frequencies thus assigned for four isotopic compounds, $HCN \cdot {}^{10}BBr_3$, $HCN \cdot {}^{11}BBr_3$, $DCN \cdot {}^{10}BBr_3$, and $DCN \cdot {}^{11}BBr_3$, are listed in Table 2.

Table 2. The normal frequencies of $XCN \cdot BBr_3$[a] (cm^{-1})

Species	Mode	$HCN \cdot {}^{10}BBr_3$	$HCN \cdot {}^{11}BBr_3$	$DCN \cdot {}^{10}BBr_3$	$DCN \cdot {}^{11}BBr_3$

a) X=H or D.

Normal Coordinate Analysis

In order to confirm the assignment of the observed frequencies and calculate the force constants, a normal coordinate analysis was carried out for the four isotopic compounds on the assumption of a modified Urey-Bradley force field which contains two bending-bending interaction constants, I[CNB,NBBr] and I[HCN,CNB] or I[DCN,CNB].

The interatomic distances were assumed to be B–Br= 1.95, N–B=1.56, C≡N=1.16, and C–H or C–D= 1.07 Å, and the valence angle was assumed to be tetrahedral for the $NBBr_3$ group.

Since the harmonic oscillator approximation was applied in this analysis, the C–H and C≡N stretching force constants of the addition compounds of hydrogen cyanide, K[C–H] and K[C≡N], were expected to be considerably different from the C–D and C≡N stretching force constants of the addition compounds of deuterium cyanide, K[C–D] and K[C≡N], as has been found for free hydrogen and deuterium cyanides or the addition compounds of those cyanides.[2] It may probably be assumed that the same values of force constants can be applied to the addition compounds with boron ten and those with boron eleven, and that F' (linear repulsive force constant) is $-0.1F$ (repulsive force constant) as usual. Accordingly, fourteen force constants were calculated from the normal frequencies listed in Table 2 by the least-squares method.

The numerical calculation was carried out by means of a computer program reported previously,[12] using an electronic computer HITAC 5020E, at the Computer Center of The University of Tokyo. The calculated force constants are listed in Table 3, along with those of the parent compounds[13] and those of the addition compounds of hydrogen and deuterium cyanides with boron trichloride, which are listed for the sake of comparison. The mean deviation of the calculated frequencies from the observed ones is 2.4 cm^{-1}, while the largest is 6.9 cm^{-1}.

The potential energy distributions (PED), defined as $(PED)_{ij}=(L_{ij})^2 \times (F_s)_{ii}/\lambda_j \times 100$, where λ_j is the jth

frequency parameter, $(F_s)_{ii}$ is the ith diagonal element of the symmetry force constants, and L_{ij} is the L-matrix element, were also calculated; they are listed in Tables 4—7.

Discussion

From the values listed in Tables 4—7, it is found that the vibrational assignments listed in Table 2 are reasonable. The isotopic product ratios derived experimentally from the observed frequencies and theoretically from the masses of atoms and geometrical structure are shown in Table 8; it is also found that those four isotopic compounds obey the product rule.

In Table 9, the shifts of the C≡N stretching, C–H or C–D stretching, and H–C≡N or D–C≡N bending vibrations are summarized; they correspond to the difference between the frequencies of the parent hydrogen or deuterium cyanide,[14] that is, 2097, 3311, and 712, or 1925, 2630, and 569 cm^{-1}, and those of the

addition compounds listed in Table 2 or, for the sake of comparison, those of the addition compounds with boron trichloride.[1] From Table 9, one may notice that the shifts of the frequencies are, on the whole, more significant in the addition compounds with boron tribromide than in those with boron trichloride. This may be caused by the difference between the Lewis acidity of the boron trichloride and boron tribromide: the latter exhibits a stronger acidity than the former.[15,16] This difference also appears in the N–B stretching force constants listed in Table 3; it is reasonably certain that the dative N–B bond in the addition compounds with boron tribromide is stronger than that in those with boron trichloride.

As has been found with regard to the force constants of the addition compounds of hydrogen and deuterium cyanides with boron trichloride,[2] there are indications that the K[C–H] or K[C–D] of the addition compounds of hydrogen or deuterium cyanide with boron tribromide is smaller than that of free cyanides, and that the K[C≡N] of the addition compounds is slightly larger than, or nearly the same as, that of the cyanides, as is shown in Table 3. This suggests that the shift of the C≡N stretching frequency is due not only to the increase in the force constant, but also to the mechanical coupling of this vibration with the C–H or C–D stretching vibration. The appearance of the C≡N stretching frequency in the lower-frequency region in the addition compounds of deuterium cyanide with boron tribromide than in those with boron trichloride may also be explained in terms of the mechanical coupling.

The B–Br stretching force constant of the addition compounds given in Table 3 is considerably smaller than that of free boron tribromide. This indicates that the strength of the B–Br bond in the addition compounds decreases considerably as a result of the change in the hybridization from sp^2 to sp^3 at the boron atom and as a result of the increase in the polarity in the bond as well as the C–H or C–D bond of the addition compounds.

The N–^{10}B or N–^{11}B stretching frequency has been found to be 720 or 689 cm^{-1} respectively in the addition compounds of trimethylamine with boron tribromide;[10] it seems reasonable to consider that the dative N–B bond in the addition compounds of hydrogen or deuterium cyanide is stronger than that in those of trimethylamine.

The authors wish to express their gratitude to Professor Hiromu Murata of Hiroshima University and to Dr. Isao Suzuki of The University of Tokyo for their useful suggestions.

An Interstitial-Electron Model for the Structure of Metals and Alloys I. Description of Model for Metallic Binding

Oliver JOHNSON

Research Institute for Catalysis, Hokkaido University, Sapporo

(Received August 9, 1971)

Application of the Hellmann-Feynman Theorem to Metals has led to an interstitial-electron model in which there is some localization of itinerant electron density in octahedral or tetrahedral interstices of close-packed metal ion cores. A flat maximum of electron density at centers of interstices is proposed as well as preferential occupancy of either octahedral or tetrahedral interstices. Such occupancy is rather precisely determined by the requirements of minimum electron-electron repulsion and of opposite spins for electrons in adjacent interstices. Writing the interstitial-electron structure of a metal in terms of interstice occupancy thus includes electron correlation effects. The interstitial-electron structures are instantaneous pictures of electron density which are representative of the highly dynamic situation of electrons in metals. The model leads to localization of *d*-electrons on the metal-ion core when interstices are fully occupied by itinerant electrons, *i.e.* at M^{6+}. The presence of vacant interstices is required for metallic properties. On the basis of the model, chemical binding in metals differs from that in polyhedral molecules or metal cluster compounds only in the greater delocalization of electron density in metals. The concepts of the interstitial-electron model are closer to those of the method of pseudopotentials than to the Bloch Band Theory although all of these descriptions of metals can be considered equivalent.

The starting point of all discussions of chemical binding must be with electrons and positive nuclei. It is generally accepted that in the metallic state the valence electrons of the metal atom are given up to the whole metal structure as itinerant electrons ($\bar{e}$) which are relatively free to move throughout the lattice of positive ion cores. Intuitively, it seems likely that the maximum binding of such a lattice would be obtained by an optimum distribution of the itinerant electrons within the octahedral and tetrahedral interstices of the metal lattice, *i.e.* some localization of electron density rather than a uniform distribution of electron density. A model with uniform electron density is probably more appropriate for a liquid metal than a solid metal.

In the Band Theory of Metals the wave functions of the itinerant electrons are considered to be extended through the whole lattice and itinerant electrons are described as occupying energy bands. In this paper an interstitial-electron model is presented in which the itinerant electron density is considered to be localized in lattice interstices and presumably, itinerant electron wave functions are not associated with a single atomic core. Since the interstitial-electron model will be developed in terms of spatial location of electrons (*i.e.* electrons-in-interstices) it will not be possible to make direct comparisons to Band Theory which uses energy-momentum coordinates. However, it will be shown that the model can be related to some of the results of the method of pseudopotentials. The view is taken that the interstitial-electron description of metals is equivalent to that of electrons in energy bands, and where energies of electrons are involved, use will be made of Band Theory concepts such as Fermi level and Band width. The model will be presented with a minimum reference to Band Theory of metals since, there have been excellent recent reviews on the topic.[1-3]

1. Background of Interstitial-Electron Model

This paper will give the details of an interstitial-electron model for the structure of metals, and the model will be used in a following series of papers to formulate electronic structure for metals (Part II), to interpret properties of metals (III) including magnetic properties (IV), to explain the formation and structure of intermetallic phases (*e.g.* Cu_5Zn_8) (V) and to give a physical interpretation of superconductivity (VI).

It is difficult to give credit to the large number of investigators who have discussed some aspect of the importance of interstices in metals and related solids. The first proposal of electrons-in-interstices for metals was by Lorentz.[4] Electron pairs at positions of potential minima was proposed for noble metals by Fajans,[5] and Bent[6] has included metals in his tangent-sphere models with electron pairs occupying anionic positions. The model builds as well on important foundations laid by the essentially metallurgical approach of Hume-Rothery[7] and others. The new feature of the present paper is to take the interstitial-model as a definitive description of the metallic state which can incorporate all the quantum chemical aspects of chemical binding including electron correlation and spin. The detailed consideration of the geometry of the HCP and CCP close-packed metals and the BCC metals along with the pattern of interstices in these structures is an integral part of the model.

The Hellmann-Feynman viewpoint[8] offers a means of relating the idea of electron density in interstices to

general discussions of chemical binding. Berlin and Fajans[9] pointed out clearly that a complete description of chemical binding in a diatomic molecule could be based on considerations of interactions of positively charged atomic cores and electrons. Berlin's[8] analysis of the Hellmann-Feynman Theorem was to point out that at equilibrium the classical coulomb forces exerted by the quantum-mechanical electron distribution on the nuclei must precisely balance the forces of nuclear-nuclear repulsion. The electron density between nuclei in homopolar molecules exerts an attractive force on each nucleus and pulls them together (*i.e.* exerts a binding force). Electron density outside of a critical nodal surface attracts the near nucleus so much more than the far nucleus that there is a net force tending to separate the nuclei, an anti-binding force.

Bader and Jones[10] have applied the Hellmann-Feynman Theorem to many molecules, and this viewpoint has been extended to polyatomic molecules by Bader *et al.*[11] and Bader and Preston.[12] Bader and co-workers have discussed chemical binding by comparing calculated electron densities in molecules with one electron wave functions and resultant electron densities for the constituent atoms. The Berlin analysis of the Hellmann-Feynman Theorem leads to the expectation of a triangular binding region for a triatomic molecule and to a pyramidal binding region for a tetratomic molecule; these are also the conclusions of Bader *et al.* for H_2O and NH_3 based on density difference diagrams.[11,12] Wannier[13] has recently applied the Hellmann-Feynman Theorem to the problem of cohesion in metals. The Hellmann-Feynman viewpoint has been extensively applied to molecules by Bader,[11] Roux and Daudel,[14] Pollisar and Harris,[15] Boyd[16] and Marron,[17] and it appears to be a very fruitful way to discuss chemical binding. The interstitial-electron model proposes a localization of electron density in interstices of a metal structure, and the Hellmann-Feynman Theorem provides a rigorous basis for treatment of forces between electrons and metal ion cores in this binding region.

In extending this viewpoint to metals it is convenient at the same time to define the positive ion core more precisely for a metal. Except for transition metals the ion cores are closed shells of electrons, equivalent to rare gas shells. Berlin[8] has shown that such electrons exert a binding force in molecules since they exert no net force on the nucleus to which they are symmetrical but attract the other nucleus. However, the valence electrons in metals hardly penetrate these ion cores, and the problem of wave functions for itinerant electrons is greatly simplified if it is assumed that the metal positive on cores are not penetrated by valence electrons. This places an additional restriction on the binding region for itinerant electrons in a metal. The binding region in metals is defined by the model as the interstices of the metal lattice, and it is proposed that there are $\bar{e}$ or $\bar{e}_2$ in the octahedral or tetrahedral interstices, *i.e.* electron density centered on the interstice. "Shapes of binding regions" in polyatomic molecules and metals have been discussed more in detail elsewhere.[17a]

Fajans[18] has developed the concept of binding regions in molecules in his Quanticule Theory in terms of quantization of electron or groups of electrons with respect to the positive field of a single nucleus or more than one nuclei. The electronic structure for the tetrahedral molecule B_4Cl_4 is written $[(4B^{3+})\ (\bar{e}_8),\ 4Cl^-]$ where the $(\bar{e}_8)$ group of electrons is termed a quanticule. In the Hellmann-Feynman viewpoint this corresponds to 8 electrons in the tetrahedral binding region which extends out from each triangular face of the tetrahedron. Gillespie[19] has proposed that there are 4 $(\bar{e}_2)$ on the triangular faces of the B_4Cl_4 molecule. When the requirements of electron repulsion and electron spin are imposed on the 8 electrons in the binding region, it seems very reasonable that electrons would be found in the 4 binding regions associated with the triangular faces of the tetrahedral molecule. Delocalization of electrons, as compared to $\bar{e}_2$ between ions, has been proposed by Fajans[18] for benzene and pyrrol and is a widely used concept in Molecular Orbital Theory.

The proposed model for the electronic structure of metals has been discussed thus far in terms of electron density of itinerant electrons in metal interstices. As projected such a model can treat metal properties in a qualitative or semiquantitative way on an electrostatic basis. It is of interest to consider what kind of wave function could represent electron density localized in metal interstice. Non-overlapping wave functions centered on an interstice could be the floating spherical gaussian functions such as used by Frost[20] and also recently by Linnett.[21] The similarity of the present model to Gillespie's[22] treatment of electrons in molecules extends as well to his specification of electron wave functions which are non-overlapping and not centered on atoms. The movement of electrons between such orbitals (or binding regions) will be discussed further in considering the average *vs.* instantaneous electron distribution.

2. Postulates of the Interstitial-Electron Model

The basic postulates of the interstitial-electron model will be given, and this will be followed by a complete

description of metal lattices which form the basis of the model. Each of the postulates will be discussed in detail and justifications offered.

I. In a metal the valence electrons belong to the whole structure as itinerant (or conduction) electrons, $\bar{e}$.

$$M \longrightarrow \underset{\text{ion core}}{M^{n+}} + n\bar{e}$$

II. Interstices of the close-packed metal structure are taken as the location of $\bar{e}$. Electron density is centered on an interstice, and there is a flat maximum at the interstice center. It can also be considered that the binding regions for metal electrons are the tetrahedral(tet) and octahedral(oct) interstices.

III. There is preferential $\bar{e}$ occupancy of oct or tet interstices depending on which interstice provides most effective screening from adjacent $\bar{e}$ by positive ion cores.

IV. There are opposite electron spins for $\bar{e}$ in the adjacent interstices with minimum screening. This corresponds to interstices joined by a triangle of metal ion cores.

V. Before the number of $\bar{e}$ reaches 6, the *d*-electrons are localized on the metal ion core, *e.g.* Mn^{7+} (d^5), $2\bar{e}$. The number 6 corresponds to the filling of the 2 tet and 1 oct interstice per M^{n+} with 2 electrons each.

VI. Itinerant electrons in interstices act as ligands and determine the degeneracy of the *d*-electrons localized on the ion core and, thus, their magnetic properties.

VII. For metallic properties there must be some vacant interstices in the metal structure.

VIII. The shape of the oct or tet binding region can change with occupancy since repulsion exerted by electrons in adjacent interstices defines the boundary of the binding region.[17a] Mutual polarization of itinerant electrons and ion cores also modify electron density and "shape of the binding region".

3. Description of the Interstitial-Electron Model

Metal structures have been traditionally discussed in terms of models of close-packed spheres. These are especially useful to show the positions of the tetrahedral(tet) and octahedral(oct) interstices, but it must be emphasized that the observed metal lattice is that of an array of metal ion cores and that the electron density at the periphery of the so-called close-packed spheres is very low. Except for transition metals the metal ion cores are closed shells (rare gas shells).

The interstitial-electron model is based on the postulate that in the array of metal ion cores the maximum attraction of these cores by the electrons is obtained when there is some degree of localization of the electron density in the interstices of the structure. A careful consideration of the geometry of each of the close-packed metal structures as well as the pattern of interstices within each structure shows that there are very important differences in interstice distance and arrangement. Each structure will be considered in detail to illustrate the proposed location of electrons according to the interstitial-electron model. The most complete discussion of interstices in crystal lattices has been given by Gehman[23] for Cubic Close Packing (CCP) and for Hexagonal Close Packing (HCP). Gehman emphasized that the occupancy of tetrahedral interstices was the key for understanding the CCP structure of compounds and that octahedral interstices were the key to HCP structures. The present discussion considers electrons in the interstices rather than anions or cations as in Gehman's paper and adds the Body Centered Cubic Structure (BCC). The placement of electrons in interstices offers a natural way to incorporate electron correlation which now becomes inherent in the symmetry of electrons in interstices.

The use of "electron-in-an-interstice" individualizes the electrons in a many-electron system. This is a good approximation[8] and a physically fruitful way to discuss electrons in a metal. This gives an *instantaneous picture* of electron density in oct and tet interstices and includes both occupied and vacant interstices. In the application of the interstitial-electron model it is considered that vacant interstices are required for metallic properties, *e.g.* electrical conductivity. The designation of electron occupancy of interstices (the interstitial-electron structure) is then an instantaneous picture of a highly dynamic situation in which the detailed arrangement is mobile, but the average situation is stationary with high correlation of electronic motion. The model and the interstitial-electron structures to be given are based on short-range correlation of electron position and motion, but the electrons in this arrangement are free to move because of absence of long range correlation of electron repulsions (see *e.g.* Lomer[1]). In the dynamic situation of rapid electron movement and lattice vibrations, the movement of electrons from one orbital to another with many energy states possible is not unlike the models discussed by Hubbard.

The average itinerant electron density is accurately represented by the instantaneous picture of electrons in interstices, and a time average picture results when the total number of electrons in an interstice type is fractionally distributed over the total number of interstices of that kind. In addition to localization of electron density in one interstice as compared to another (oct more than tet), there can be spatial localization of electron density within one type of interstice (maximum density in center *vs.* more complex distribution). The latter kind of localization may be more important in metal alloys and intermetallic phases and will be discussed in Part V.

Close-packed metal lattices have 2 tetrahedral and 1 octahedral interstice per metal ion core. The interstitial-electron model places electrons in these interstices in the way which gives the maximum screening of positive ion cores by electrons and the minimum electron-electron repulsion. The screening of the electrons from each other by the positive ion cores is very effective, and it is generally assumed[1] that effects of other electrons are screened out within 1 atomic cell. This is also taken to be the case for the interstitial-electron model, and the model can specify which adjacent electrons are least efficiently screened by consideration of geometry of lattices. It will now be

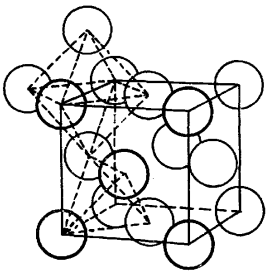
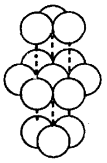
CCP Unit Cell

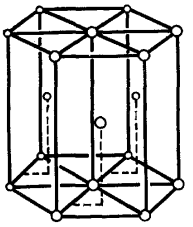


Location of oct and tet interstices
(The CCP unit cell of $4M^{n+}$ has 4 oct interstices per unit cell on centers of each edge and at the center of the unit cell. The 8 tet interstices per unit cell form a cube around each M^{n+}.)

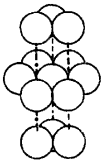


Packing of layers in CCP

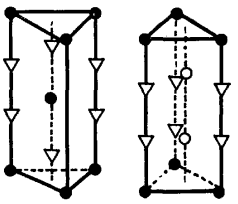
Fig. 1. Structure and location of interstices in CCP metals.



HCP unit cell



Packing of layers in HCP



Location of oct and tet interstices (●=ion core, ○=oct, ▽=tet).
The HCP unit cell of $2M^{n+}$ has 2 oct interstices within the cell. Oct interstices form a trigonal prism around M^{n+}. The 4 tet intersices per unit cell are along the *c*-axis in pairs between all M^{n+}. They form a double set of tetrahedra around M^{n+} (C_{3h} symmetry).

Fig. 2. Structure and location of interstices in hexagonal close packed metals.

shown how the geometry and symmetry of the interstices can lead to definitive assignments of electrons to the interstices in different metal structures.

In the CCP structure shown in Fig. 1 there is a symmetrical arrangement of interconnected octahedral and tetrahedral interstices. The screening between octahedral electrons and tetrahedral electrons is by a triangle of close-packed metal ion cores. Tetrahedral and octahedral electrons are screened from each other by metal ion cores along a tetrahedral edge. Thus, the important distance establishing electron-electron repulsion is that between tetrahedral and octahedral interstices in CCP or 0.61 *a*, where *a* is the distance of closest approach. The maximum screening occurs between tet interstices. This comes about because an oct interstice is joined to 12 other oct interstices by 12 edges and to 6 tet by triangular faces while a tet interstice is joined to 6 adjacent tet interstices by edges and to four oct interstices by triangular faces. It can be concluded that in the absence of other controlling factors CCP metals will show a preference for tetrahedral occupancy of interstices by itinerant electrons. Interstice Distances for CCP, HCP, and BCC structures are given in Table 1.

The HCP structure shown in Fig. 2 has interconnected octahedral interstices in a line perpendicular to the layers. This is a consequence of the above arrangement of close-packed layers. The tetrahedral interstices occur in interconnected pairs which are screened from other pairs by an ion core. Thus, in the HCP metals all interstices are involved in mutual electron-electron repulsions. The distances between them are the following: oct-oct, 0.82 *a*; oct-tet, 0.61 *a*; tet-tet, 0.41 *a*. The latter, very short distance is only applicable when over 1/2 of the tet interstices are occupied. For low $\bar{e}$ occupancy there will be a preference for tet occupancy because with 1 $\bar{e}$ per tet there is screening by ion cores. With 2 $\bar{e}$ in tet there is strong $\bar{e}$-$\bar{e}$ repulsion in tet, and the greater interstice distance for oct-oct makes for a preference for octahedral interstice occupancy in HCP. These conclusions as to interstice preference agree with the conclusions of Gehman based on metal compounds.

The distorted HCP structures require special treatment. When the *c*/*a* ratio is greater than 1.633 *a* as in Zn or Cd there is an increase in oct-oct distance which is greater than the oct-tet increase. The octahedral preference is enhanced. However, when there is less than half occupancy of tet interstices as is the case for Zn, there is a stronger tet preference since these electrons are completely screened from each other by ion cores just as in Normal HCP. The HCP lattices with the opposite distortion, *c*/*a* less than 1.633 *a*, can be considered to have the pair of tet interstices changed to a single bi-pyramidal (bipyr) interstice.[24] This is the structure observed for Be, Sc, Y, and a few other metals. Since the structure now has 1 oct and 1 bipyr interstice per metal ion core, this structure differs greatly from the normal metal with 1 oct and 2 tet interstices per ion core. There are 2 factors influencing occupancy here; the tet interstices are the ones completely screened by an ion core but the oct-oct distance is much greater than oct-tet. Becasue of spin restrictions there appears to be a restriction on oct occupancy in this type of distorted HCP (see discussion below).

The BCC structures are not close-packed, but inter-

TABLE 1. INTERSTICE DISTANCES IN METAL STRUCTURES[a]

Distance	CCP	HCP	BCC
Unit Cell Edge	1.414	1[b]	1.155
tet-tet ($^1/_2$)	1	1	0.82
tet-tet	0.71	0.41	0.41,0.58
oct-oct	1	0.82	0.41,0.58
oct-tet	0.61	0.61	—
M^{n+}-oct	0.71	0.71	0.58,0.81
M^{n+}-tet	0.61	0.61	0.645[c]

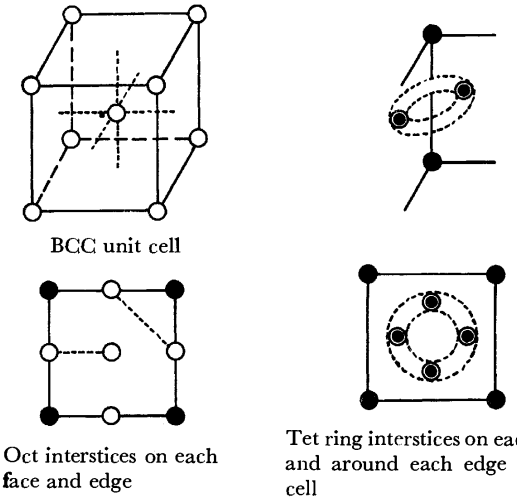

Fig. 3. Structure and location of interstices for body centered cubic metals.

stices can also be defined for BCC metals. The octahedral interstices shown in Fig. 3 are not symmetrical, *i.e.* there are 4 M^{n+} at 0.81 *a* and $2M^{n+}$ at 0.58 *a* (or *vice versa*). Such oct interstices are at centers of faces and the middle of edges of the unit cell. There are also tetrahedral interstices in the BCC structure. Tet interstices are formed by 2 body center M^{n+} and two corner M^{n+}, and 4 are located on each face at the (0,1/2,1/4) positions. Both types of interstices are joined by triangular faces of ion cores, so there is less screening of electrons by ion cores (and more volume between metal ion cores) in the BCC structure than in CCP or HCP structures. It is unlikely that both the closely spaced oct and tet interstices could be occupied by electrons. It is also expected in view of the similarity in energies of the BCC and close-packed structures that there would be the same number of interstitial electrons in BCC metals as CCP or HCP metals. Thus, the maximum number of electrons expected would be 2 electrons per face (one interstice) or two electrons per edge in octahedral interstices or 2 electrons per face in tetrahedral interstices. Any of these possibilities gives a total of 12 electrons per unit cell or 6 electrons per ion core as a maximum.

In comparing the screening of electrons by ion cores in BCC it was noticed that although both oct and tet interstices were joined through triangular faces, the orientation of tet interstices caused the binding regions of one tet interstice to extend well into an adjacent tet interstice. This observation along with the close proximity of the tet interstices makes it likely that the binding region is continuous for tet interstices on a face (and likewise around the corresponding interstices around an edge). This would place a ring of tetrahedral interstices on each face (f. tet) and likewise a ring of interstices centered on the middle of each edge (e. tet) and perpendicular to the face tet rings. The two sets of rings are interlocking. This interstitial-electron distribution for BCC metals[17a] corresponds to the areas of negative magnetization observed in neutron diffraction studies by Shull and Mock for BCC iron. This first physical explanation of these neutron diffraction observations is discussed further in Part IV. The CCP and HCP lattices had no comparable ring structure of interstices.

The symmetry of the tetrahedral interstices in BCC as well as the freedom of motion of electrons makes it more likely that tet interstices rather that oct interstices are occupied in BCC metals. Some possible exceptions will be noted for intermetallic phases as discussed in Part V.

As seen in Fig. 3 the distances for oct interstices vary from 0.8 for two oct edge interstices and 0.58 for an oct edge and oct face. The latter interstices are not effectively screened by ion cores. The distances for the interlocking rings of tet interstices have the same distances from centers of rings as those for oct (see Table 1). The distances are larger when all the tet rings are not occupied by 1 electron each. In BCC the symmetry of face tet and edge tet is identical, so there is no preference for occupancy of either type of tet interstice in this structure (see spin restrictions below, however.)

It is inherent in the interstitial-electron model that after 3 itinerant $\bar{e}$ are present there must be pairing of electrons in the interstices, and that after 6 electrons are present there must be localization of any additional electrons on the metal ion core as *d*-electrons or "bound" electrons. It has been postulated that vacancies in interstices are necessary for metallic properties so the localization is expected after 5 electrons are present. There is an additional possibility of some localization on cores after 3 electrons as an alternative to electron pairing in interstices. For transition metals past group 5 (*e.g.*,/V^{5+}, 5 $\bar{e}$/BCC), there will be localization of *d*-electrons. The interstitial-electron model will specify location of the itinerant electrons in these metals. Since the itinerant electrons in the instantaneous picture can be considered as ligands around the metal ion core, the degeneracy of the *d*-orbitals is determined and thus the magnetic properties of the transition metal. These structures are discussed in Part IV.

The intersitial-electron model leads to formulae for the electronic structure of metals which specify the metal ion core charge and the number of itinerant electrons in octahedral or tetrahedral interstices. It will be seen below that spin restrictions limit the electron preference for oct interstices in HCP and for tet interstices in CCP with the result that electron density differences in the two types of interstices are not large. In addition to this localization of electron density according to interstice type, there can be localization within the interstice. The model postulates that there will be a maximum of electron density at the centers of interstices. In view of rapid electron motion this probably will be a very flat maximum in electron density. Postulate VIII mentions variations in electron density with occupancy and with polarization effects; these will be discussed in Part III in connection with lattice distortions and properties of metals.

4. Restrictions on Metal Electrons Due to Electron-Spin

The model defines the binding region of electrons and location of electron density as corresponding to

octahedral or tetrahedral interstices in close packed metals and to the interlocking ring tet interstices in BCC metals. When electrons are in adjacent interstices which are not well screened by ion cores (*i.e.* adjacent interstices joined by triangular faces), greater repulsion is expected when the adjacent electrons have the same spin. Thus, in keeping with the Pauli Principle, it is postulated that electrons in such adjacent interstices have opposite spins. It follows then from the model that in CCP, electrons in tet interstices have opposite spins from electrons in oct interstices. In HCP the electron spins must alternate within both oct and tet interstices and between adjacent oct and tet as well because all these interstices are interconnected by triangular faces. In BCC structures adjacent electrons in tet rings will have opposite spins. It can be seen that because of these spin restrictions there is a correlation of electron motion due to spin as well as the correlation due to $\bar{e}$ repulsions and that both are determined by the symmetry of the ion cores and interstices.

Without motion of ion cores there could be a large number of electrons in the whole metal lattice with the same 4 quantum numbers. However, the lattice vibration gives rise to a large number of small energy variations. These energy differences also allow several electrons of the same spin around a given ion core. It should be noted that the restrictions due to electron spin became more important as the total number of itinerant electrons per metal ion core increases, *e.g.* with only 1 $\bar{e}$, spins can be random in BCC. When there are more than 3 electrons there must be pairing of electrons in some interstices for all metal structures. The details of such electron distribution is discussed in Part II for each metal. It will be assumed that at normal temperatures there are sufficient energy variations of $\bar{e}$ in interstices to make the most severe restrictions of the Pauli Principle inapplicable, *i.e.* all interstices can potentially be occupied by electrons. This is discussed further in Part VI on Superconductivity. The above interpretation of the Pauli Principle is similar to that of Bader and Preston[12] who discuss the relation of electron density to the usual orbital considerations in applying the Pauli Principle. Bent[6] has used the term "Pauli Mechanics" to emphasize the importance of the Pauli Principle in chemistry.

The restrictions on interstice occupancy due to electron spin can oppose the preference for tet occupancy in CCP and oct occupancy in HCP which was based on distance of electrons and their screening from adjacent electrons by ion cores. Since there is only low paramagnetism for most metals there must be roughly equal occupancy of oct and tet interstices for CCP metals to give equal spins of each kind. The preference for tet occupancy could only be satisfied in these cases by electron pairing in tet interstices. It will be seen in Part II that this probably occurs for some metals and in Part IV that unbalanced itinerant electron spins do occur in some of the ferromagnetic metals.

In regular HCP there is alternation of spins in both tet and oct interstices, so there is essentially no restriction on occupancy due to spin. However, in the HCP structures with c/a less than 1.633 the bipyramidal intersticies are in two sets which adjoin two oct interstices in a line. For this arrangement to give opposite spins in adjacent interstices only 1/2 oct can be occupied by single electrons if all the tet are occupied. Other ratios apply when a fraction of the tet interstices are occupied.

Since so many metals are weakly paramagnetic it must be assumed that the spin restrictions are more important than the interstice preference suggested by interstice distance and $\bar{e}$ screening by ion cores.

5. Occupancy of Interstices in Metals by Electrons

The criterion as to whether an interstice will be occupied by an itinerant electron ultimately must depend on relative energies of the electrons in the metal structure. An attempt will be made to list the various factors that determine electron energies in metals and to assess the effect of each. From the interstitial-electron model the following factors are expected to influence the energies of itinerant electrons: (1). The number, symmetry, and positive field strength of M^{n+} around an interstice. (2). The distance between neighboring M^{n+} and between itinerant electrons in interstices and M^{n+}. (3). Volume available for $\bar{e}$ in the interstice. (4). Distance of $\bar{e}$ neighbors and the extent of screening by M^{n+}. (5). Spins of neighboring $\bar{e}$ and their screening. (6). Extent of pairing of $\bar{e}$ in interstices. (7). Presence of localized *d*-electrons or bound electrons on M^{n+}. (8). Magnitude of lattice vibrations.

The attraction of $\bar{e}$ due to (1) must balance the repulsions of itinerant electrons and the ion-core repulsions. Similarly, there is a balancing of effects due to potential in the interstice and the volume (3). Presence of localized *d*-electrons affect both symmetry and field of M^{n+} and must be treated as special cases (See Part IV).

When comparing metals of approximately equal fields of M^{n+} and with equal numbers of itinerant electrons the decisive factors are then the $\bar{e}$-$\bar{e}$ repulsions (determined by the screening by ion cores and distance) and spin restrictions. Thus, in the majority of metals a decision as to interstice occupancy can be made on the basis of obtaining the minimum itinerant electron repulsion while at the same time balancing itinerant $\bar{e}$ spin. This is accomplished by a maximum spreading of $\bar{e}$ through the structure in preferred interstices while also satisfying the requirement for maximum screening of ion core repulsions.

Lattice vibrations have not been discussed in relation to the interstice occupancy. The instantaneous picture which will be used to specify electronic structures always has an imbalance of electron energies, since there is greater screening of ion core repulsions in a region where the interstice is occupied by an electron than when it is vacant. A rapid movement of electrons is expected to lead to a time-average picture in which

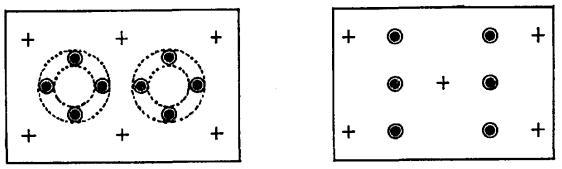
25) C. C. Shull and H. A. Mook, *Phys. Rev. Lett.*, **15**, 184 (1966).

there is electron density in all interstices. Lattice vibrations play an important role in this dynamic picture. At every change in positions of ion cores in the lattice vibration, all of the electron energies are shifted from equilibrium. Rapid movement of electrons is expected to restore equilibrium and optimum binding for the new state. As pointed out earlier the average electron density distribution in all the interstices can still retain the degree of preference for oct occupancy or tet occupancy, if this is present in the instantaneous picture of specific interstice occupancy, since the same correlation effects are in operation during electron motion.

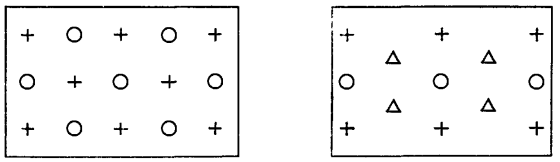
Two examples will be given to illustrate the use of the interstitial-electron model in defining the electronic structure of a metal. Sodium metal has the BCC structure, and thus two Na^+ and two itinerant electrons per unit cell. Since there is no interstice preference in BCC these $\bar{e}$ are expected to occupy 1 f.tet and 1 e.tet ring (or 2 f.tet and 4 e.tet per unit cell).

$$|2Na^+,\ \bar{e}_{f.tet},\ \bar{e}_{e.tet}|BCC$$

The instantaneous picture of electron occupancy can be described as having $\bar{e}$ in tet rings on upper and lower horizontal faces and $\bar{e}$ in tet rings on 4 vertical edges. There is 1/6 occupancy of interstices, and since there is not likely to be interaction of electrons so widely spread, spins can be random. In the time-average picture there is equal electron density on all faces and edges. This is shown in Fig. 4a.



4a. Sodium Metal (100 plane) 4b. Na (110 plane)



4c. Copper Metal (100 plane) 4d. Cu (110 plane)

Fig. 4. Electron density on different crystal planes of Na and Cu metals.
(⊙=tet rings, ○=oct interstices, △=tet interstices, +=ion cores)

Copper metal has the CCP structure in which $\bar{e}$ has tet preference. However, since copper is diamagnetic, there must be balancing of spins which can come about by equal occupancy of oct and tet interstices. The structure for Cu is written for the unit cell of 4 Cu^+ and 4 $\bar{e}$:

$$|4Cu^+,\ 2\bar{e}_{oct},\ 2\bar{e}_{tet}|CCP$$

This represents 1/2 occupancy of oct and 1/4 occupancy of tet by $\bar{e}$ and the average $\bar{e}$ density is shown in Fig. 4c.

All of the metals of Groups I—V will be treated in Part II and those of Groups VI—VIII in Part IV.

6. The Interstitial-Electron Model and Metal Alloys

Metallic structures for alloys of 2 or more metals can be written in the same way as for pure metals. There will be an array of M_a^{n+} and M_b^{m+} metal ion cores with $(n+m)$ itinerant electrons in interstices. When the electric fields around the ion cores of the two metals are similar there will be no disruption of the periodic potential of the lattice, so electrons will move freely throughout the structure, and no change in metallic properties in general is expected. A general formula for a CCP alloy with equal distribution of electrons in oct and tet would be:

$$|M_a^{n+},\ M_b^{m+},\ \frac{1}{2}(n+m)\bar{e}_{oct},\ \frac{1}{2}(n+m)\bar{e}_{tet}|CCP$$

Some degree of localization in interstices would be expected as m and n are further apart or as the size of M_a and M_b differs. The variety of alloys probably results from the possibility of this kind of localization of itinerant electrons. The intermetallic phases discussed in Part V have abnormally large localizations of electron density with formation of electron pairs in certain interstices.

7. Discussion

The interstitial-electron model emphasizes the spatial distribution of electrons in metal structures. This makes it possible to consider metal properties in terms of occupied or vacant interstices, and the "degree of localization" of electrons will be useful in discussing deviations from ideal metallic behavior. The high degree of interstitial delocalization of electron density in metals contrasts strongly with the high degree of localization in a solid structure such as diamond, with electron pairs between all of the ions. The $\bar{e}$ localization in metals proposed in the interstitial electron model is more closely related to the $\bar{e}$ localization in metal cluster compounds and metal complexes than to the electron distribution in polar or non-polar molecules. It may be clarifying to relate the interstitial-electron model to other models and theories of metals.

Raich and Good[26] have proposed an electrostatic-type model for metals using uniform electron density between cores, whereas the present model proposes some degree of interstitial localization of electron density. Wannier *et al.*[13] have recently demonstrated that application of the Hellmann-Feynmann theorem to metals makes some localization of electron density necessary in metals to account for cohesion. The magnitude of this localization is consistent with that suggested in this paper and for metals discussed in Part II. Girifalco[27] has suggested the kind of wave functions possible for a localized description of electron density in metals. Hubbard[28] has made proposals for considerations of structure in the electron density.

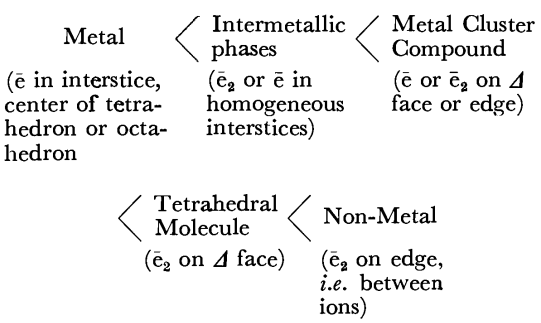
26) J. C. Raich and R. H. Good, Jr., *J. Phys. Chem. Solids*, **26**, 1061 (1965).
27) L. A. Girifalco, *Int. J. Quantum Chem.*, IIIS, 879 (1970).
28) J. Hubbard, *Proc. Roy. Soc.*, **A244**, 199 (1958).

The above authors provide some background and justification for the interstitial-electron model used in this paper. Further justification arises from purely classical considerations of electrons in metals. Harrison has pointed out that an itinerant $\bar{e}$ has its greatest velocity near an ion core, and thus spends most of its time in regions away from the ion cores. The present model defines this region as the center of interstices. Discussion of hydrogen in metal[19] places the hydrogen at the centers of interstices where there is greatest concentration of electron density. Thornber[30] has shown that "atomic" electron states are required to explain optical transitions rather than $\bar{e}$ in energy bands.

Other discussions of localized binding such as those of Pauling[31] and Engle-Brewer[32] appear to be further from band theory than the present model. It is of interest to consider how the highly successful Brewer-Engel Correlation might be related to the concepts of the interstitial-electron model. It is a possibility that the s, sp, and sp^2 (or d_xs, d_xsp, and d_xsp^2) binding proposed by Engel places electron density in spatial directions closely corresponding to the interstitial localization proposed in this paper. The orbital constructions of Trost[33] and the band structures proposed for transition metals by Goodenough[34] both emphasize the spatial extension of d-electrons in metals. The present model considers the itinerant electrons as ligands rather than the adjacent transition metal ion core, and is thus only indirectly related to the models of Trost and Goodenough. The differences will be treated in detail in the discussion of magnetic properties of metals in Part IV. The present model treats itinerant electrons in molecular orbitals (as does band theory) and not in atomic orbitals.

The method of pseudopotentials in metals[35] appears to be an extremely useful concept which has some striking similarities to the interstitial electron model. Ziman[3,36] has termed the screened ion core a "pseudo-atom". This ion core with its localized charge density interacts weakly with its neighbors. This appears the same as the manner ion cores are treated in the interstitial-electron model, and Ziman[3] emphasized that the method of pseudopotentials derives from and is entirely equivalent to band theory of metals. The "orthogonalization hole" in the method of pseudopotentials has its counterpart in the non-penetrable ion core postulated for the interstitial-electron model. The form factor[35] appears related in the two, while the structure factor in the interstitial-electron model would deal with the geometry of $\bar{e}$ in interstices rather than of the ion cores. It will be seen in Part II that the electronic structure of Al as derived from the interstitial-electron model has the same degree of localization of electron density in tet interstices as found by Harrison[35] in calculations of electron density for Al by the method of pseudopotentials. This is illustrated by data in Part II. Other models for metals in which there is some localization of electrons have also been discussed by Hubbard,[28] Cutler,[37] Szas and Mcguinn,[38] and Gombas.[39]

The concept of binding regions is useful in relating metallic binding to that in molecules and in non-metallic solids. For the tetrahedral and octahedral interstices shown in Fig. 1 and 2 there are single electrons or electron pairs in these interstices. For tetrahedral molecules, *e.g.* with 8 valence electrons, as discussed above there could be an $(\bar{e})_8$ closed shell or four electron pairs centered on triangular faces of the tetrahedron. For octahedral molecules with 12 valence electrons there can be electron pairs centered on 6 faces. There can be single electrons in these positions for metal clusters of these geometries in complexes containing metal clusters, and these can be considered intermediate between metals and polyatomic molecules. When the C.N. is low as in Silicon (diamond structure, tetrahedral arrangement), $(\bar{e})_2$ will be along edges of the tetrahedron to give the usual kind of binding in non-metallic solids, *i.e.*, electron pairs between all the ion cores. The increasing localization of electrons for these substances is as follows:



The interstitial-electron model thus treats metallic binding in the same way as other forms of chemical binding and shows that metallic binding is unique in its high degree of delocalization of $\bar{e}$ density.

An Interstitial-Electron Model for the Structure of Metals and Alloys II. Electronic Structure of Metals of Groups I—V

Oliver JOHNSON

Research Institute for Catalysis, Hokkaido University, Sapporo

(Received August 9, 1971)

The interstitial-electron model leads to metal structures which are instantaneous pictures of electron distribution written in terms of metal ion core charge M^{n+} (n=valency) and numbers of electrons in octahedral or tetrahedral interstices. On the average there are $\bar{e}$ in all interstices, and the degree of electron localization is small in metals. Decisions as to electron occupancy of interstices are primarily based on considerations of $\bar{e}$ spin and of screening of $\bar{e}$ by ion cores, but electronic heat capacity, Hall coefficient and anisotropy in magnetic susceptibility are of use in making decisions on electron occupancy of interstices. For univalent metals there is little localization of $\bar{e}$ because of the large excess of vacant interstices. This is also true when interstices approach full occupancy by $(\bar{e})_2$ as in M^{4+} and M^{5+}. Among divalent and trivalent metals the preferential occupancy of interstices leads to considerable localization of $\bar{e}$ density for Be, Sc, Y, and Tl. This high degree of localization is a consequence of mutual polarization of ion cores and $\bar{e}$; it accounts for the lattice distortion in these metals and leads to other unusual properties.

The interstitial-electron model for the structure of metals is described in detail in Part I.[1] In order to write such electronic structures for metals, the proper ion core charge (M^{n+}) or valency must be chosen as well as the interstice occupancy by these itinerant or conduction electrons ($\bar{e}$). The itinerant electrons will occupy preferentially the octahedral (oct) or tetrahedral (tet) interstice (I) which offers the maximum screening of its electron from neighboring $\bar{e}$ by positive ion cores and (2) which places $\bar{e}$ of parallel spin farthest away from each other. It turns out for CCP and HCP structures that $\bar{e}$ in adjacent interstices connected by a triangle of ion cores must have opposite spins.

There is a preference for tet occupancy in CCP, no preference in BCC, and a preference which depends on the number of $\bar{e}$ in HCP. For normal HCP lattices there is probably equal oct and tet preference for 1 $\bar{e}/M^{n+}$ since the $\bar{e}$ are widely separated. Since the second $\bar{e}$ in the tet paired interstice is at a short distance ($0.41a$) from the first, at $2\bar{e}$/ion core there will be 1 oct and 1 tet occupied. There will now be tet preference for a second $\bar{e}$ rather than pairing in oct so that at 3 $\bar{e}$ there will be 1 oct and 2 tet occupied. After 3 $\bar{e}$ there is oct preference, again because of the short interstice distance in tet paired interstices. These interstices are shown in Fig. 2 and in Part I. The same preferences for interstice occupancy are expected to hold for the HCP lattice with c/a greater than 1.633 (Zn and Cd).

For HCP lattices with c/a less than 1.633 (Li, Be, Sc) the tet preference is modified by special spin requirements. When all of the bipyramidal interstices (1 BP instead of 2 tet) are occupied, only 1/2 of the oct interstices can be occupied by unpaired electrons. Thus, after 1 1/2 $\bar{e}$, pairing must occur in BP interstices. Between 3 and 4 $\bar{e}$ there is probably pairing in both types of interstices. Figure 2 illustrates these interstices. The model provides for free movement of electrons between occupied and vacant interstices, but the average electron distribution retains a degree of localization of electron density. Electron correlation is a built-in feature of the model due to (1) the geometry of interstices, (2) the effects of screening of $\bar{e}$ repulsions by ion cores and (3) the spin restrictions based on type of interstice.

This paper will treat the metals of Group I—V and will propose electronic structures for all of them in terms of the metal ion core charge and numbers of electrons in oct and tet interstices. These will be illustrated by electron density diagrams for different crystal planes for representative metals. Metals beyond Group V have localized d-electrons and are discussed separately along with their magnetic properties in Part IV.

1. Interstitial-Electronic Structures of Metals

No attempt will be made to use the interstitial-electron model to predict types of lattice for various metals. The differences in energy between HCP and CCP, *e.g.*, are very small.[2] The model will be used to specify the spatial location of electrons in Group I—V metals, and it will be shown in Part III that such a description of a metal can give considerable insight into the many unusual gradations of metal properties.

In assigning electrons to interstices as discussed above the primary guides will be an assessment of screening of $\bar{e}$ by ion cores in a given structure and the restrictions on electron spin. Whenever unusual features such as lattice distortion or asymmetry in magnetic susceptibility indicate definite electron distributions, these data will be taken into account in assigning electrons to interstices. Since electron pairing in interstices requires considerable energy the minimum number of $(\bar{e})_2$ will be proposed for higher valent metals.

1.1 Alkali Metals. The BCC structure observed for Li, Na, K, Rb, and Cs at ordinary temperatures has 2 M^{n+} per unit cell and the 2 itinerant electrons are expected to occupy tet ring interstices (See Part I). The structure for potassium metal can be written

2) W. R. Harrison, "Pseudopotentials in the Theory of Metals," W. A. Benjamin, Inc, N. Y., (1966).

$$|2K^+,\ 2\bar{e}_{tet.\ rings}|BCC.$$

An instantaneous picture of the electron distribution could be occupancy of 2 face tet and 4 edge tet per unit cell. On the average there would be 1/6 occupancy of the interstices by electrons where the interstices are the interlocking rings described in Part 1. To illustrate the electron densities indicated by the model, areas of electron concentration (flat maximum) are shown for different crystal planes on Fig. 1.

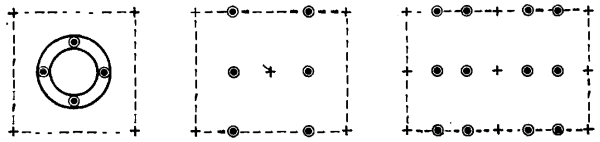

Fig. 1a. Location of interstitial electrons in BCC metals (100, 110, and 111 plane)
(⊙=electron in tetrahedral rings)

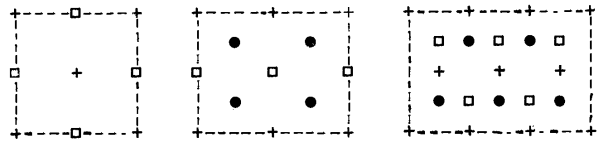

Fig. 1b. Location of interstitial electrons in CCP metals (100, 110, and 111 plane)
(□=oct interstices, ●=tet interstices, +=positive ion cores)

The same structures are expected for Na, Rb, and Cs as given for K. Lithium has certain unusual properties, *e.g.* a higher electronic heat capacity and magnetic susceptibility than Na, and a relatively large lattice displacement. These differences suggest a weaker field of the ion core for Li which might arise from some localization of electron density in one type of interstice or asymmetry of electron density in an interstice.

Both Na and Li form HCP structures at low temperatures. That for Na has a normal *c*/*a* ratio and is written with equal $\bar{e}$ distribution in oct and tet interstices:

$$|2Na^+,\ \bar{e}_{oct},\ \bar{e}_{tet}|HCP$$

On the average there is 1/2 occupancy of oct interstices and 1/4 occupancy of tet interstices. The HCP structure of Li has a *c*/*a* ratio of 1.563, and this distortion changes 2 tet interstices to a single bipyramidal (BP) interstice. The following structure suggests a greater number of $\bar{e}$ in BP interstices which give greater screening of $\bar{e}$ by ion cores than oct:

$$\left|2Li^+,\ \underset{BP}{\bar{e}_{1+n}},\ \underset{oct}{\bar{e}_{1-n}}\right|HCP$$

the value of n is believed to be small (0.1) since the relative preference for BP is reduced for all $\bar{e}$ over 1.

In view of the small ($1s^2$) ion core for Li^+, unusual properties are not unexpected. They occur as well for Li^+ in solution and for Li compounds and have been interpreted[3] as an especially strong local interaction of Li^+ with cations or solvent molecules. In Li metal, polarization of the $\bar{e}$ cloud could lead to asymmetry in $\bar{e}$ distribution in interstices. Any distortion from optimum $\bar{e}$ distribution would be equivalent to weaker binding forces for Li^+. The general nature of the distortion would be to increase $\bar{e}$ density around the cores. The lattice distortion observed represents the lowest energy arrangement for Li^+ ion cores and the polarized $\bar{e}$ cloud.

1.2 Noble Metals. Although there is a preference for tet occupancy in CCP metals the diamagnetism of Cu, Ag, and Au requires that there be equal numbers of itinerant electrons of each spin. The following structure is proposed for these metals with Cu as example:

$$|4Cu^{11+}(d^{10}),\ 2\bar{e}_{oct},\ 2\bar{e}_{tet}|CCP$$

Placement of electron pairs in tet interstices to satisfy the preference for tet occupancy in CCP is unlikely for a monovalent metal with so many vacant interstices. No properties of copper indicate any special localization. The differences between the alkali and noble metals arise mainly from the larger and more polarizable outer 18-electron shell of Cu, Ag, and Au. The ion core is written above to show the *d*-shell for copper. Because of the poor screening[4] provided by the *d* and *f* electrons the ion core for noble metals has a relatively stronger field than in alkali metals. Itinerant electrons can interpenetrate such ion cores, and the non-rare-gas shell ion core constitutes an exception to the proposed non-penetrability of ion cores. The way electrons are distributed on the (1,1,0) face of a copper unit cell is shown in Fig. 1. This can be considered to show $\bar{e}$ in binding regions as discussed in Part I. The extension of *d*-orbitals into interstitial regions should also be part of such diagrams. This aspect is treated fully in the discussion of magnetic properties in Part IV.

a) Structure at high temperature

1.3 Alkaline Earth Metals, Zinc, and Cadmium. All three lattice types are represented in the alkaline earth metals. As shown in Table 1 an equal distribution in oct and tet interstices is proposed for Ca, Mg, Sr, and Ba in the different lattices. The equal oct and tet preference is quite certain for CCP calcium; it then follows that similar distribution of $\bar{e}$ occurs in HCP and BCC structures since there is very little energy difference between these structures. Beryllium is the unusual metal in the alkaline earth group. Its HCP lattice with *c*/*a* of 1.567 has the same kind of distortion as Li in the HCP form. Also, Be is diamagnetic while the other alkaline earth metals have the usual weak paramagnetism of metals. Be has a large positive Hall coefficient,[5] which is discussed in Part III and

2e. Row of oct interstices

Fig. 2. Interstitial electrons in HCP metals. (●=tet interstices, □=oct interstices)

connected with presence of electron pairs in the structure. Thus, a different structure is proposed for Be metal with $(\bar{e}_2)$ in BP interstices (See Fig. 2). This localization of electron density in BP interstices explains the above properties as well as the anisotropy of the diamagnetism. The hardness of Be also reflects localization of electron density.

The localization of $\bar{e}$ in one interstice in Be metal results from the requirement that only 1 unpaired $\bar{e}$ can be in the 2 oct Interstices adjacent to a BP interstice. As with Li the strong polarization of $\bar{e}$ by the $1s^2$ core of Be^{2+} leads to a distorted lattice to satisfy energy requirements. There is anisotropy of the diamagnetic susceptibility of Be with values of -21.4 parallel to c-axis and -7.2 perpendicular to c-axis (at 300°C).[6] This is probably the result of the greater density of Be^{2+} cores and $\bar{e}$ in the parallel direction.

Zinc and Cadmium form HCP structures with strong axial distortion ($c/a=1.856$ and 1.88, respectively). There are no restrictions on spin since there can be an alternation of spins in both oct and tet interstices as in the normal HCP lattice. The electronic structure for Zinc must also reflect the magnetic susceptibility of Zinc which when corrected for the diamagnetism of the core is weakly paramagnetic.[6]

The Zn^{2+} core contains d-electrons and in addition to its high+field this ion core is very deformable compared to rare gas shells (Mg^{2+}, Ca^{2+}) and there will be interpenetration of the $Zn^{12+}(d^{10})$ core by $\bar{e}$. This leads to a different localization or asymmetry of $\bar{e}$ in interstices than observed for Be. It is assumed in the structure written below that there is a small localization as $(\bar{e})_2$ in oct.

$$\left|2Zn^{12+}(d^{10}),\ 1.8\bar{e}_{tet},\ 1.8\bar{e}_{oct},\ (\bar{e}_2)_{\substack{0.2\\oct}}\right| HCP$$

As with Be the greater diamagnetic susceptibility[6] is observed for Zn in the direction parallel to the axis. In this case it must be the distortion of the ion core in this direction which leads to the small anisotropy. The smaller localization of $\bar{e}$ in tet is compatible with greater extension of d-orbitals along the c-axis.

Cadmium metal must have a very similar structure. The structure proposed below has greater electron localization than for Zn to account for the higher diamagnetic susceptibility of Cd *i.e.* diamagnetic when correction is made for the core diamagnetism.[4]

$$\left|2Cd^{2+},\ 1.6\bar{e}_{tet},\ 1.6\bar{e}_{oct},\ (\bar{e}_2)_{\substack{0.4\\oct}}\right| HCP$$

The anisotropy[6] of the diamagnetic susceptibility is very high for Cd and has a large decrease with decreasing temperature. This is expected for the more polarizable Cd and also is in keeping with greater localization of $\bar{e}$ in oct. Placement of electrons in unit cells are shown for some of these Group II metals in Fig. 2. Mercury is discussed in section 9 with other non-close packed metals.

1.4 Trivalent Metals. HCP structures are more prevalent for trivalent metals than CCP, and BCC structures are not observed. The CCP structure for Al can be specified rather closely. Because there are more itinerant electrons and because there must be equal numbers of single electrons in oct and tet interstices for balancing of electron spin, there will be electron pairs in all of the trivalent metals. For the CCP structure of Al the pairing is expected for tet interstices. The following structure has the minimum amount of electron pairing:

$$|4Al^{3+},\ 2(\bar{e}_2)_{tet},\ 4\bar{e}_{tet},\ 4\bar{e}_{oct}|\ CCP$$

This structure has 66% of the electron density in tet interstices. It is also important that the structure leaves some interstices vacant. A smaller fraction of pairs in tet would also require pairing in oct interstices which is not reasonable in CCP lattices. More pairs in tet would lead to some vacant tet interstices which is not reasonable considering the extra energy required for electron pairing. The above structure with 66% of electron density in tet then seems optimum for Al. This will have the same $\bar{e}$ distribution as Cu (Fig. 1). It is of interest that this is a very similar result to that of Harrison[2] who calculated electron density for CCP Al by the method of pseudopotentials. In Fig. 3 which is Harrison's electron density map for Al the tet interstices are indicated. These are regions of slightly greater electron density than the oct regions also indicated in Fig. 3. An estimate of electron density from the contour lines gives 60—70% of the interstitial electrons in the tet interstice region. This can be taken as an independent confirmation of the kind of localization of electrons proposed in the interstitial-electron model. Including $\bar{e}$ around cores, Harrison estimates a small interstitial localization.

Although indium has a tetragonally distorted CCP lattice ($a_0=3.244$, $c_0=4.938$), there is no property

6) W. M. Lomer and W. E. Gardner, *Prog. Metals Science*, **14**, 145 (1969).

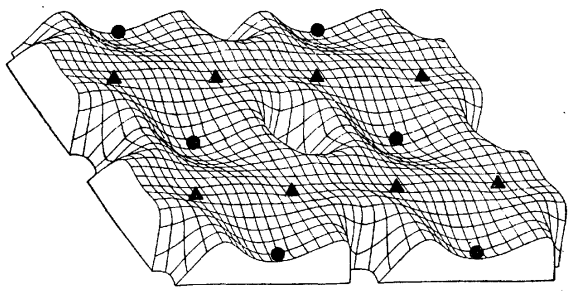

Fig. 3. Relative electron density on a (1, 1, 0) plane in aluminum.
(from W.A. Harrison, "Pseudopotentials in the Theory of Metals," W.A. Benjamin, Inc., New York, 1966)
(▲=$\bar{e}$ in tet interstices,
●=$\bar{e}$ in oct interstices from interstitial-electrom model.)

which indicates that the structure would differ markedly from that of Al. Since In^{3+} (or $In^{13+}(d^{10})$) has a deformable ion core like Zn, the distortion of the lattice is another example of a means of achieving the lowest energy structure.

The metals Sc and Y have relatively small ion cores ($3s^2$, $3p^6$) and are cations with strong positive field like Be and Li. If is not unexpected that they have HCP lattices with the same distortion ($c/a<1.633$). La is also classed with these metals although it has a more complex layer structure. Tl has an especially strong positive field because of the poor screening by its $4f$ electrons. This apparently puts it with Sc, Y, and La in spite of its deformable character.

The following structure is proposed for the metals Sc, Y, La, and Tl:

$$|2M^{3+}, \bar{e}_{1/2BP}, (\bar{e}_2)_{1\frac{1}{2}BP}, e_{1/2oct}, (\bar{e}_2)_{oct}|HCP$$

This structure has the maximum number of unpaired electrons compatable with spin requirements in this type of HCP lattice. An alternate structure would be:

$$|2M^{3+}, 2\bar{e}_{oct}, 4\bar{e}_{BP}|HCP$$

In this case the occupancy of BP could be considered as 2 $\bar{e}$ or as $(\bar{e})_2$. The high value of electronic heat capacity indicates electrons at high energy levels. The observed 30% greater diamagnetic susceptibility for Sc in the direction of the c-axis is expected for this type of lattice distortion. For Tl the anisotropy is even greater. Gallium metal is discussed in section 9.

The rare earth metals are predominantly trivalent and differ from other trivalent metals in having the $4f$ electron shell occupied. Arrott[7] has surveyed the properties of the f-shell containing metals and concluded that with the exception of Eu and Yb, the rare earth metals donate 3 $\bar{e}$ to the metal lattice as itinerant electrons. It is because of the unusual stability of the half filled and completely filled f-shell that only 2 $\bar{e}$ are itinerant for Eu and Yb. The reduced number of itinerant electrons is shown by greater atomic volume, the BCC structure instead of close-packed, lower MP and lower cohesive energy for Eu and Yb than the other rare earth metals. Kasuya[8] has discussed the differences in properties and structures of the heavy and light rare earth metals.

The interstitial electron structure for Eu and Yb below is proposed to be the same as that of BCC Ba, with difference in properties expected from the very different ion cores in RE

$$|2M^{2+}, 4\bar{e}_{tet.\ rings}|BCC$$

For Pr and Nd which have normal La type HCP structures and for Ce which has HCP at high temperature the following interstitial-electron structure is proposed (similar interstices exist for the La-type lattice):

$$|2M^{3+}, 2\bar{e}_{oct}, 2\bar{e}_{tet}, (\bar{e}_2)_{tet}|HCP$$

alternative structure: $|2M^{3+}, 2\bar{e}_{oct}, 4\bar{e}_{tet}|HCP$

For the heavy Rare Earth Metals (Gd, Tb, Dy, Ho, Er, Tm) which have c/a ratios in the range 1.57—1.59 the following structure (like Sc) is proposed:

$$|2M^{3+}, \bar{e}_{1/2BP}, (\bar{e}_2)_{1\frac{1}{2}BP}, \bar{e}_{1/2oct}, (\bar{e}_2)_{oct}|HCP$$

Variations in $\bar{e}$ distribution are anticipated and may be estimated from Hall coefficients or magnetic anisotropy but no attempt will be made to evaluate them at this time.

The CCP structures for Ce and Pr are proposed to be the same as that for Al. The detailed structures of rare earth metals which are ferromagnetic will be discussed in a separate paper.

1.5 Tetravalent Metals. At ordinary temperature the structures for Ti and Zr are HCP with c/a ratios of 1.593 and 1.581 respectively. This distortion leads to oct and bipyramidal interstices and 4 itinerant electrons in 2 interstices would lead to only pairs and complete occupancy. These metals are paramagnetic and have a negative Hall coefficient so there must be unpaired electrons in these metals. Since the distortion is very small for these metals the bipyr (or tet) electrons need not be paired as was suggested also for trivalent metals. The following structure formulates Ti and Zr in this way:

$$|2M^{4+}, 2(\bar{e}_2)_{oct}, 4\bar{e}_{tet}|HCP$$

This electronic structure is also in keeping with the large electronic heat capacity for these metals. The absence of $(\bar{e})_2$ in tet may imply some asymmetry in $\bar{e}$ distribution within the tet interstices.

There are BCC structures for Hf and for Ti and Zr at high temperatures. The structure written below with a minimum of electron pairs has 1/3 occupancy of interstices by 2 $\bar{e}$ per ring which probably act as electron pairs. Since polymorphic structures do not differ greatly in energy this is an additional reason for considering the HCP structures of Ti and Zr as above with only 1/2 occupancy by electron pairs.

$$|2M^{4+}, 8\bar{e}_{tet.\ rings}|BCC$$

The latter structure shows how the BCC lattice can accomodate more electrons without extensive pairing. This arises because there is equal preference for and equal numbers of the two kinds of interstices (rings around face and edge).

The CCP structures for Pb and Th are formulated as follows:

7) A. Arrott in G. T. Rado, and H. Suhl, "Magnetism," Vol. II B, Acad. Press, N. Y., 1966, p. 339.
8) T. Kasuya, *ibid.*, p. 230.

$$|4M^{4+}, 4(\bar{e}_2)_{tet}, 4\bar{e}_{tet}, 4\bar{e}_{oct}|\,CCP$$

These electronic structure for Pb and Th have 75% of the electron density in tet interstices. This strong localization of $\bar{e}$ density is probably counter-balanced by distortion of the very deformable ion cores which contain both *d* and *f* shells.[4]

1.6 Pentavalent Metals. V, Nb, and Ta all have the BCC structure and can be formulated as follows with the minimum number of electron pairs (2/3 occupancy):

$$|2M^{5+}, 10e_{tet.\ rings}|\,BCC$$

The possible electronic structures for Bi, As, and Sb are discussed in the following section along with other metals which do not have close packed structures.

2. Interstitial-Electron Structures for Non-close-packed Metals

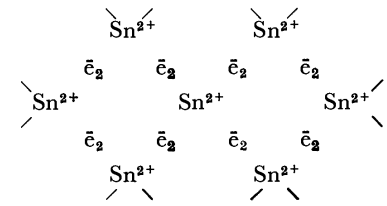
Mercury is a liquid at room temperature, and gallium melts just above room temperature. Solid mercury has a rhombohedral structure and the CN of Hg^{2+} is 6. Compared to a simple cubic lattice the interaxial angle is 70° 1/2. *Gallium* has an orthorhombic structure with two identical axes of its pseudotetragonal unit. There are 8 atoms per unit cell, a_0 and b_0 (1.5107) and c_0 (7.6448). There are 2 neighbours at 2.71, 2 at 2.80, and 1 at 2.44 Å. Bent[9] has pointed out that gallium sulfide has 2 Ga-Ga at short distance and 6Ga-Ga larger distances with the suggestion of electrons pairs in gallium metal where anions are placed in the sulfide. The interstitial electron model cannot specify the location of electrons in Ga and Hg. There are likely to be $-Ga^{3+}\ (\bar{e})_2\ Ga-^{3+}$ units in the structure along with single electrons in interstitial positions. The combination of long range and short range order probably accounts for the liquid state at low temperatures.

White tin is tetragonal with a_0 of 5.8197 and c_0 of 3.1748. Each ion core is surrounded by a distorted tetrahedron of Sn neighbours at 3.02 Å with 2 more Sn in the axial positions at 3.17 Å. Although white tin deviates from a close packed structure the interstices are related to those of CCP, and the structure proposed is similar to that of lead:

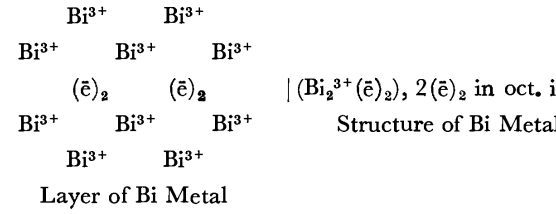
$$|4Sn^{4+}, 4(\bar{e}_2)_{tet}, 4\bar{e}_{tet}, 4\bar{e}_{oct}|\,Tetrag.$$

Some asymmetry in the $\bar{e}$ distribution within oct and within tet interstices is expected from the lattice distortion. The slightly greater diamagnetic susceptibility in the direction perpendicular to the *c*-axis[10] is compatable with ion core distortion and greater core numbers in that direction.

Gray tin has the diamond structure and is non-metallic. It will be mentioned to illustrate the difference in chemical binding. The distance of 2.80 Å between Sn^{4+} is about 10% less than for white tin. Electron pairs ($\bar{e}_2$) between all Sn^{4+} tetrahedrally arranged are expected as in Ge or diamond as written below:



Bismuth crystallizes in a puckered layer lattice with a CN of 3. It is unusual in that it has the highest diamagnetic susceptibility of all the metals.[10] In the tetragonal Bi_2O_3 lattice each Bi^{3+} has 6 O^{2-} neighbours (related to Mn_2O_3 lattice). In bismuth metal there is the counterpart of the octahedral hole in the puckered layer and if all the octahedral interstices are filled there remains an $(\bar{e})_2$ per 2 Bi^{3+}. This may well be within the layers as follows:



$|(Bi_2^{3+}(\bar{e})_2),\ 2(\bar{e})_2$ in oct. inter.|

Structure of Bi Metal

The filled octahedral interstices would explain the low electric conductivity and the $(\bar{e})_2$ associated with the layers can account for the very large diamagnetic susceptibility as well as the anisotropy of the diamagnetism.

The related elements As and Sb depart further from metallic behavior. The layer spacing increases from Bi to Sb to As and thus they deviate further than Bi from close-packed structures.

3. Conclusions

Electronic structures have been proposed for all the Group I—V metals. In most cases a precise electronic structure could be given in terms of $\bar{e}$ occupancy of interstices. In a few cases alternate structures or a range of possible occupancies was given. The areas of electron localization could also be indicated for various crystal faces in terms of the electron model. These represent electrons in the binding areas of the interstices in a metal and should be useful in interpreting both chemical and physical properties of metals.

The relation of $\bar{e}$ and $(\bar{e}_2)$ in metal interstices to a number of properties (*e.g.* Hall coefficient, magnetic susceptibility) has been used as a guide in formulating interstitial-electronic structures in some cases. It has been possible to correlate metal properties with the interstitial-electron distribution, and this is presented in detail in Part III. It may be possible to further refine the structures given in this paper on the basis of experimental data on metal properties.

The interstitial-electron structures proposed on the basis of simple rules for occupancy of interstices show the greatest localization of $\bar{e}$ density in just those HCP and CCP structures which are distorted from normal close packing. Ion cores with strong positive fields (*e.g.*, Li^+, Be^{2+}) are expected to polarize the itinerant $\bar{e}$ cloud. Ions containing *d* and *f* electrons[4] are expected also to have strong positive fields but these

9) H. Bent, *J. Chem. Educ.*, **45**, 768 (1968); **42**, 348 (1965).

non-rare gas shells are deformable and will be penetrated by itinerant electrons. These polarizing effects of and on itinerant electrons are held to be the cause of the lattice distortion. These polarization and interpenetration effects are less important when there are few $\bar{e}$ and when there are predominantly ($\bar{e}_2$) in the interstices and thus predominate for divalent and trivalent metals.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1612—1616(1972)

Convenient Quadratic Formulas for the Two-center Coulomb Repulsion Integrals in the Semiempirical LCAO-MO Method and the Significance of the Pariser-Parr Approximation[1)]

Yasuhiko GONDO and Yoshiya KANDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received August 25, 1971)

The coefficients in the Pariser-Parr-type quadratic formulas for the two-center Coulomb repulsion integrals encountered in the planar as well as the non-planar conjugated systems have been expressed as linear functions of the effective nuclear charges of the $2p$ atomic orbitals involved. The formulas thus obtained are applicable to those conjugated systems consisting of carbon, nitrogen, and oxygen atoms, and may well be useful in variable-electronegativity self-consistent field calculations on these systems. With some illustrative applications to spin densities and phosphorescent-state energies, it has been shown that the Pariser-Parr approximation gives better results than the Nishimoto-Mataga one, although the latter is successful in the prediction of electronic transitions within the singlet manifold. Incidentally, this was also the case for the phosphorescent-state zero-field splittings (Y. Gondo and Y. Kanda, This Bulletin, **43**, 3943 (1970)). The electric dipole moments have also been discussed.

As is well known, in the Pariser-Parr-Pople method[2,3)] the two-center Coulomb repulsion integrals are evaluated semiempirically for smaller interatomic distances, and several kinds of approximations have been proposed for this purpose.[4,5)] Among them, the Nishimoto-Mataga approximation[6)] is distinctly different from the others in giving nearest-neighbor values smaller than those of the others by nearly 2 eV.[5)] As for the others, they are practically identical with each other; the Pariser-Parr approximation may be regarded as a prototype. The Nishimoto-Mataga approximation has been employed quite extensively and frequently because of its simplicity, its successful prediction of electronic transitions within the singlet manifold, and also its easy adaptability to variable-electronegativity self-consistent field (VESCF) calculations.[7,8)]

However, in the prediction of triplet-state zero-field splittings (ZFS), for example, a Pariser-Parr-type (PP-type) quadratic formula is much better than a Nishimoto-Mataga-type (NM-type) one, as has previously been pointed out by the present authors.[9)] In addition, a PP-type formula gives better results with regard to the phosphorescent-triplet-state energies of neutral molecules and the spin densities in the molecular ions than does a NM-type formula, as will be described later. The electric dipole moments of neutral molecules will also be discussed.

Thus, if we have a PP-type formula as simple as a NM-type formula, it can be invoked as extensively and frequently as the latter. In this paper, it will be shown that the coefficients appearing in the PP approximation are linearly dependent on the effective nuclear charges of the AO's involved, subject to the Paoloni-type approximations[10)] for the one-center Coulomb repulsion integrals. All the two-center Coulomb repulsion integrals encountered in the planar as well as the non-planar conjugated systems consisting of carbon, nitrogen, and oxygen atoms have been studied jointly. The formulas thus obtained are easily adaptable to the VESCF calculations of these systems.

Incidentally, the very difference of 2 eV for the nearest neighbors is significant, as is suggested by the clearly different results on the various molecular properties mentioned above. Since this may be closely associated with the problem of electronic correlation in molecules,[11,12)] it is desirable to accumulate as many results as possible with the PP approximation as well in

order to gain a better understanding of this interesting but intractable problem. In this context, the convenient formulas we have obtained might be of some use.

General Remarks

The symbols σ, π, and $\bar{\pi}$ stand for $2p\sigma$, $2p\pi$, and $2p\bar{\pi}$ respectively.[13] In the planar conjugated systems, every two-center Coulomb repulsion integral $(pp|qq)$ is of the $(\pi_p\pi_p|\pi_q\pi_q)$ type, whereas this is not the case for the non-planar systems. Thus, we have the following expression, in general:[14]

$$\begin{aligned}(pp|qq) = {} & \omega_1(\sigma_p\sigma_p|\sigma_q\sigma_q) + \omega_2(\sigma_p\sigma_p|\pi_q\pi_q) \\ & + \omega_3(\pi_p\pi_p|\sigma_q\sigma_q) + \omega_4(\pi_p\pi_p|\pi_q\pi_q) \\ & + \omega_5(\pi_p\pi_p|\bar{\pi}_q\bar{\pi}_q) + \omega_6(\pi_p\bar{\pi}_p|\pi_q\bar{\pi}_q) \\ & + \omega_7(\sigma_p\pi_p|\sigma_q\pi_q), \end{aligned} \quad (1)$$

where the coefficients ω_1, ω_2,$\cdots$are determined by the relative orientation of the $2p$ AO's involved.

According to Pariser and Parr,[2] for interatomic distances smaller than 2.8 Å each of the basic integrals in Eq. (1) may be evaluated by means of the quadratic extrapolation formula:

$$(\mu_p\mu_p'|\nu_q\nu_q') = C_0 + C_1R + C_2R^2, \quad (2)$$

where μ, μ', ν, and ν' stand for σ, π, or $\bar{\pi}$, and where R is the pertinent interatomic distance. In addition, C_0 is defined by the relation:

$$C_0 = [(\mu_p\mu_p'|\nu_p\nu_p') + (\mu_q\mu_q'|\nu_q\nu_q')]/2. \quad (3)$$

The one-center integrals in Eq. (3) can be obtained through the expressions listed under "Semiempirical" heading in Table 1; these expressions have been derived

Table 1. One-center coulomb repulsion integrals involving $2p$ atomic orbitals[a]

Integral	Theoretical[b]	Semiempirical
$(\sigma\sigma\,|\,\sigma\sigma)=(\pi\pi\,|\,\pi\pi)$	$5.325\,Z$	$3.294\,Z$[c]
$(\sigma\sigma\,|\,\pi\pi)=(\pi\pi\,|\,\bar{\pi}\bar{\pi})$	$4.751\,Z$	$2.939\,Z$
$(\sigma\pi\,|\,\sigma\pi)=(\pi\bar{\pi}\,|\,\pi\bar{\pi})$	$0.2870\,Z$	$0.1775\,Z$

a) Z stands for the effective nuclear charge.
b) Obtained with the Slater-type AO's and the formulas given by Roothaan.[13]
c) Paoloni's relation.[10]

on an assumption of the same proportionality between the theoretical and the semiempirical values for every type of basic integral[15] as that for $(\pi\pi|\pi\pi)$, which is in turn based on Paoloni's relation.[10] These theoretical one-center integrals have been obtained with the Slater-type AO's and the formulas of Roothaan.[13] The effective nuclear charges used are 3.25, 3.90, and 4.55 for carbon, nitrogen, and oxygen respectively.

For interatomic distances larger than 2.8 Å, the multipole expansion formula can be used without decomposing $(pp|qq)$ into the basic integrals.[16] It should be noted that the multipole expansion formula has a simple dependence on the effective nuclear charges of the AO's involved; hence, it is easily adaptable to the VESCF calculation.

The C_1 and C_2 Coefficients

The Use of Multipole Expansion Formulas for Obtaining the C_1 *and* C_2 *Coefficients.* The coefficients, C_1 and C_2, of Eq. (2) for every basic integral in Eq. (1) have been determined originally with the C_0 of Eq. (3) and with the corresponding two-center integrals, obtained at 2.8 and 3.7 Å with the multipole expansion formulas.[16] The largest deviation of the integrals obtained with these formulas from those obtained with the theoretical formulas of Roothaan[13] has been found for the basic integral $(\sigma\sigma|\sigma\sigma)$; it is, at most, for example, 1% for the C–C pair at 2.75 Å. For the second to fifth basic integrals in Eq. (1), however, the deviations are of the order of 0.01% at the same distance. As for the rest, they are intrinsically very small quantities, and practically no deviations are found down to three decimal places in electron-volts at the same distance as above. In addition, the coefficient multiplying $(\sigma\sigma|\sigma\sigma)$ in Eq. (1) is usually small. Therefore, the use of the multipole expansion formulas may be justified.

Linear Dependence of C_1 *and* C_2 *on the Effective Nuclear Charges.* The coefficients, C_1 and C_2, thus obtained have been found expressible as linear functions of the effective nuclear charges of the AO's involved, as is shown in Fig. 1, for example, for the basic integral

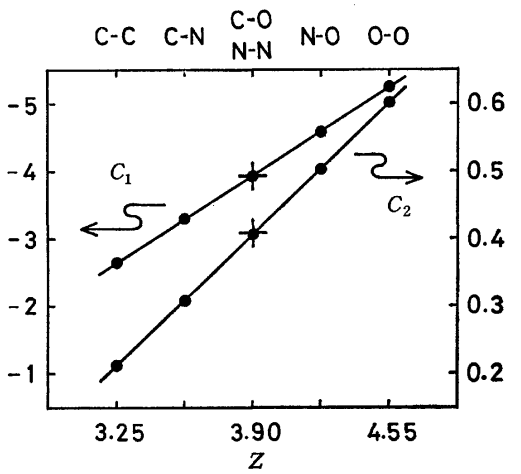

Fig. 1. Linear depencence of the C_1 and C_2 coefficients on the arithmetic mean of the effective nuclear charges of the AO's involved, Z, in the basic integral $(\pi\pi|\pi\pi)$. With Z=3.90, the crosses refer to the C–O pair.

$(\pi\pi|\pi\pi)$. The linear functions have been obtained through the method of least-squares; they are collected in Table 2. These results reproduce the integral values obtained with the original coefficients, C_1 and C_2, for example, at 1.5 Å within a margin of 0.3% for the first, 0.1% for the second to fifth, 0.4% for the sixth, and 1% for the last basic integral of Eq. (1). As has been mentioned above, in Eq. (1) the coefficient, ω_1, is usually small, and the last two basic integrals are of intrinsically very small quantity. Therefore, it may be concluded that the results collected in Table

$(\sigma\pi \mid \sigma\pi)$	$0.1775\,Z$	$0.0875-0.1293\,Z$	$-0.0224+0.0217\,Z$

a) Z stands for the arithmetic mean of the effective nuclear charges of the AO's involved. Lengths are given in angstroms, and energies, in electron-volts in Eq. (2).

2 reproduce the integral values calculated with the original coefficients within a margin of 0.1%.

Further Remarks on $(\pi\bar{\pi}|\pi\bar{\pi})$ and $(\sigma\pi|\sigma\pi)$. From the symmetry and R-dependence, the basic integrals, $(\pi\bar{\pi}|\pi\bar{\pi})$ and $(\sigma\pi|\sigma\pi)$, are distinguished from the rest. Since these integrals are themselves intrinsically very small, the relevant quadratic formulas sometimes give negative values, even for interatomic distances smaller than 3.0 Å, although they must be positive in principle. Further, the integral values are smaller than 0.02 eV at 3.0 Å. Therefore, it may be concluded that these basic integrals can be neglected if the interatomic distance is larger than 3.0 Å or if the calculated integral values are found to be negative.

Some Illustrative Applications

In this concluding section, as was mentioned in the introduction, some examples will be presented in order to illustrate the usefulness of the PP approximation through the use of the convenient formulas obtained in the preceding section, although these examples are chosen rather arbitrarily and are restricted to the planar conjugated systems. In what follows, the wavefunctions are calculated by means of a method described previously,[9,17] and by means of the effective nuclear charges of 3.25 and 3.90 for carbon and nitrogen respectively in the usual SCF scheme. In the VESCF calculations, the dependences of the effective nuclear charges and valence-state ionization potentials on the charge densities are incorporated by the use of the procedure adopted by Brown and Heffernan;[18] moreover, all the parameters are variable, unless otherwise specified.

The Energies of the Phosphorescent Triplet States. The excitation energies of the phosphorescent triplet states of some aromatic hydrocarbons and nitrogen heterocycles are predicted by the PP approximation much better than by the NM approximation, as is shown in Table 3. Tyutyulkov, Gochev, and Fratev[19] also noted this, and modified a NM formula in order to remedy this shortcoming. They stated that their formula was as simple as the original one and that it was successful in the prediction of singlet-singlet transitions. However, it hardly seems acceptable, not only in the sense that it has no correct asymptotic behavior for sufficiently large distances, such behavior as the original formula shows, but also in the sense that it gives significant deviations from the theoretical values at intermediate distances larger than 2.8 Å.

c) to g) Ref. 20 to 24 respectively.

Since the development of this kind of modification may be due to the need for a foumula as simple and useful as the NM one, the formulas proposed in this paper seem to acquire justification. In particular, any conjugated systems consisting of carbon, nitrogen, and oxygen atoms are within the scope of these formulas. Moreover, these are easily adaptable to the VESCF procedure, which has been demonstrated to be useful for the prediction of the electric dipole moments of various organic compounds.[8]

Incidentally, it should be noted that the approximation that gives better results on the state energies also leads to better results on the ZFS parameters.[9]

and the Spin Densities in Its Anion. Azulene is chosen for two reasons—first, because it is a non-alternant hydrocarbon, and second, because the complex problem of a correct allowance of the electronic effects of hetero-atoms does not, of course, arise.[8] The first reason is based on the observation of Ruedenberg[25] that the results of calculations on the polycyclic alternant hydrocarbons are more strongly dependent on their topological matrix than on the choice of repulsion or resonance integrals.

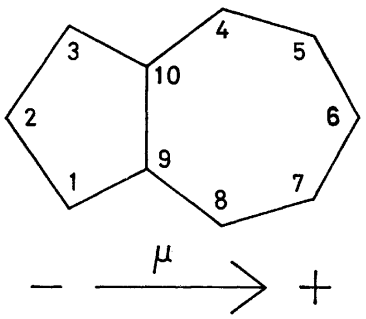

Fig. 2. The carbon skeleton of azulene and the defined positive direction of the electric dipole moment, μ, with the numbering of atoms.

The electric dipole moments obtained for the ground state by various methods are collected in Table 4, in which the contributions from the σ-electrons are not taken into account.[8] The molecular geometry adopted is based on the x-ray data after averaging according to the molecular symmetry.[27] As this table shows, the VESCF procedure and the inclusion of the next-nearest-neighbor resonance integrals[28] improve the results considerably.

a) Obtained by means of the V2 method, as defined in Table 4.
b) For the abbreviations, see the text.

Brown and Coller[8] have stated that the PP approximation has a tendency to give larger π-moments than the NM. However, this does not seem to be confirmed even by their own results. The present results on azulene also contradict this statement. The most characteristic difference between the NM and PP approximations seems to be that the latter gives larger absolute values to the net charge densities than the former; that is, the alternation in the charge distribution derived through the latter is more distinct than that due to the former, as can be seen, for example, from the entries of Table 5. This is also found for furan, pyrrole, and pyridine.[8] In the VESCF procedure, this characteristic difference seems to be blurred to an appreciable extent, but it still survives, as may be seen in Table 5. Brown and Coller[8] did not incorporate the dependence of $(pp|qq)$ integrals on the effective nuclear charges in their VESCF scheme; their scheme is obviously an improvement, as is revealed by a comparison of the relevant entries in Table 4.

Table 6. Calculated spin densities and expectation values of $\mathbf{S}^2$ for azulene anion after single annihilation[a]

The spin densities and the expectation values of $\mathbf{S}^2$ in the azulene anion are predicted by the PP approximation much better than by the NM, as Table 6 shows. This has also been confirmed with various aromatic nitrogen heterocycles.[7,31] By multiplying these spin densities by the Q^{H}_{CH} value of −23G for a CH bond in an aromatic system,[30] those from the PP approximation are found to reproduce the experimental splitting constants very well, whereas with those of the NM approximation no reasonable correspondence can be found between the theoretical and experimental values. Since, by and large, this is also the case for the other methods described in Table 4, the PP approximation seems undoubtedly much better than the NM for the calculation of spin densities.

Finally, it should be noted that the above excellent agreement obtained with the PP approximation is lost if Q^{H}_{CH} values inclusive of their variations with the bond angle[30] are used in place of the above value of −23G. Although this is an interesting finding, we prefer to refrain from a presentation of detailed results and from detailed discussions;[31] here, we intend mainly to show the significance of the PP approximation through the use of the convenient formulas obtained.

The calculations have been carried out on the FACOM 230-60 computer at the Computer Center of Kyushu University.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 1616—1619(1972)

Equilibrium of Urea Synthesis. II.

Shigeru INOUE, Kazumichi KANAI, and Eiji OTSUKA
Central Research Laboratory (Ofuna) Mitsui Toatsu Chemicals, Inc., Totsuka-ku, Yokohama

(Received September 17, 1971)

In the preceding paper (This Bulletin, **45**, 1339 (1972)) it was reported that the existence of the maximum equilibrium conversion was not due to the experimental method. For this phenomenon, we have presented the following interpretation. While $NH_4CO_2NH_2$ is converted to urea and water, it dissociates into NH_3 and CO_2 in the solution (not in the gas phase), and the degree of the dissociation increases exponentially as the temperature becomes higher, while the conversion to urea gradually increases. Therefore, at a certain temperature, the equilibrium conversion reaches its maximum value. Although it is nearly impossible to prove analytically the dissociation of $NH_4CO_2NH_2$ in the solution, we are sure of it from the following facts: 1) The dissociation of $NH_4CO_2NH_2$ is a great endothermic reaction, even under the conditions of urea synthesis. 2) The value of NH_3/CO_2 which gives the minimum equilibrium pressure at a usual temperature is not always equal to 2.0, but varies with the temperature. 3) The effect of H_2O/CO_2 on the equilibrium pressure varies with the temperature; that is, when the temperature is lower than about 200°C, an increase in H_2O/CO_2 reduces the equilibrium pressure, but when the temperature is higher than 200°C, an increase in H_2O/CO_2 makes the equilibrium pressure higher.

The dissociation of $NH_4CO_2NH_2$ in a solution has never been proved by means of chemical analysis, because experimentally it is nearly impossible to separate CO_2 in the form of carbamate from free CO_2. This has already been reported in Ref. 1.

However, in view of the fact that we carried out experiments over a broader range than in Ref. 1, many facts may be thought to suggest the dissociation of $NH_4CO_2NH_2$ in the solution. This point will be discussed.

Mechanism of the Equilibrium

In the preceding paper[2] we reported that the equilibrium conversion is independent of the loading density if the composition in the liquid phase is constant; therefore, other points must be investigated.

Our interpretation is that part of the $NH_4CO_2NH_2$ dissociates into NH_3 and CO_2 in the solution, and that this causes the temperature which gives the maximum equilibrium conversion. Thus, we presume two kinds of chemical equilibria in the solution, as is shown in Eqs. (1) and (2):

$$NH_4CO_2NH_2(soln) \rightleftarrows 2NH_3(soln) + CO_2(soln) \quad (1)$$

$$NH_4CO_2NH_2(soln) \rightleftarrows (NH_2)_2CO(soln) + H_2O(soln) \quad (2)$$

The equilibrium constants, K_1 and K_2, are defined as follows (the solutions are assumed to be ideal);

$$K_1(T) = \frac{x_{NH_3}^2 \cdot x_{CO_2}}{x_{carb}} \quad (3)$$

$$K_2(T) = \frac{x_u \cdot x_{H_2O}}{x_{carb}} \quad (4)$$

The equilibrium constant, $K_F(T)$, for the Frèjacques equation then becomes:

$$K_F(T) = \frac{K_2(T)}{K_1(T)} = \frac{x_u \cdot x_{H_2O}}{x_{NH_3}^2 \cdot x_{CO_2}} \quad (5)^{3)}$$

1) S. Kawasumi, *Journal of the Society of High Pressure Gas Industry*; **20**, No. 2, 4 (1956).

2) S. Inoue, K. Kanai, and E. Otsuka, **45**, 1339 (1972).

3) Although Eq. (5) is apparently the same as the Eq. (1) of Frèjacques reported in the previous paper, $K_F(T)$ is not equal to $K(t)$, because the molar fractions for each component are not equal in the two equations.

where x_{NH_3}, x_{CO_2}, x_u, x_{H_2O}, and x_{carb} denote the molar fractions of NH_3, CO_2, urea, H_2O, and carbamate respectively.

If $K_1(T)$ increases exponentially above a certain temperature compared with $K_2(T)$, as is shown in Fig. 1, the equilibrium constant, $K(t)$, in the previous paper reaches its maximum value near the temperature which results in the maximum equilibrium conversion.

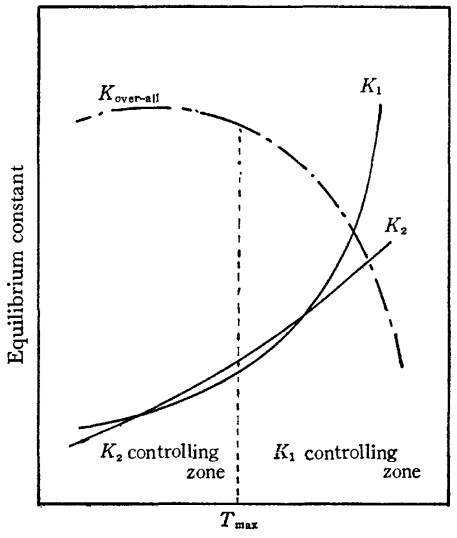

Fig. 1. Temperature dependence of $K_1(T)$, $K_2(T)$, and overall equilibirum constant.

Besides this, there is another presumption that when the urea formation of Eq. (2) change from an endothermic to an exothermic reaction at a certain temperature, the equilibrium conversion reaches its maximum value according to the Van't Hoff equation, because a high temperature—for example, 200°C—can not be easily attained in the urea reactor if the degree of dissociation of $NH_4CO_2NH_2$ is so large. However, our presumption seems to be true, judging from the following evidence.

Thermodynamic Discussion

Let the liquid composition be as follows before and after the reaction:

$$2NH_3 + CO_2 \overset{K_1(T)}{\rightleftarrows} \text{carb} \overset{K_2(T)}{\rightleftarrows} \text{urea} + H_2O \qquad (6)$$

before the reaction:

$$2m_N,\ 1,\ 0,\ 0,\ m_H,$$

after the reaction:

$$2(m_N - m_K - m_u),$$
$$m_c,\ m_K,\ m_u,\ m_u + m_H$$
$$\therefore\ \text{total} = 2m_N - 1 + 2m_c + m_u + m_H$$
$$(\because\ m_c + m_K + m_H = 1)$$

$$K_1(T) = \frac{(4m_N - 1 + m_c)^2 \cdot m_c}{(2m_N - 1 + 2m_c + m_u + m_H)^2(1 - m_u - m_c)} \qquad (7)$$

$$K_2(T) = \frac{m_u(m_u + m_H)}{(2m_N - 1 + 2m_c + m_u + m_H)^2(1 - m_u - m_c)} \qquad (8)$$

If it is assumed that $K_1(T)$ and $K_2(T)$ are dependent only on the temperature, the equilibrium conversion, m_u, can be obtained by solving Eqs. (7) and (8) at given NH_3/CO_2 ($=2m_N$) and H_2O/CO_2 ($=m_H$) ratios. Therefore, the temperature, T_{max}, giving the maximum equilibrium conversion is obtained by solving:

$$dm_u/dT = 0$$

However, neither m_c nor m_u is separable from the other in Eqs. (7) and (8), so it is difficult to obtain the derivative in a simple form.

On the other hand, it is doubtful whether or not the system or urea synthesis can be assumed to be ideal; therefore, we will show only the existence of the maximum conversion, using a simple model in the case of simultaneous equilibria.

Thus, let the following system be taken:

$$A \overset{K_A}{\rightleftarrows} C \overset{K_B}{\rightleftarrows} B$$

$a,\ 1-a-b,\ b,$ total $= 1$ mol

$$K_A = \frac{a}{1-a-b} \qquad (9)$$

$$K_B = \frac{b}{1-a-b} \qquad (10)$$

From Eqs. (9) and (10),

$$A = \frac{K_A(T)}{K_B(T)} \cdot b$$

We thus obtain:

$$b = \frac{K_B(T)}{1 + K_A(T) + K_B(T)} \qquad (11)$$

As b is dependent only on the temperature, the differentiation of b with respect to T affords:

$$K_B'(T)(1 + K_A(T)) = K_B(T) \cdot K_A'(T) \qquad (12)$$

Within a relatively narrow range of temperature, $K_A(T)$ and $K_B(T)$ may be expressed as follows:

$$A_0 - A_1 T = -RT \ln K_A,\ B_0 - B_1 T = -RT \ln K_B \qquad (13)$$

By the substitution of K_A and K_B in Eq. (12) with Eq. (13), and by solving Eq. (12) with respect to T, the temperature, T_{max}, giving the maximum conversion is obtained:

$$T_{max} = \frac{A_0}{R\left(\frac{A_1}{R} - \ln\frac{B_0}{A_0 - B_0}\right)} \qquad (14)$$

where $A_0 > B_0 > 0$.

If the logarithmic term is very small compared with the A_1/R, term:

$$T_{max} \doteqdot A_0/A_1 \qquad (15)$$

Therefore, T_{max} can be calculated if A_0, A_1, and B_0 are given. Now,

$$\Delta G = \Delta H - T\Delta S$$

By assuming ΔH and ΔS to be constant within a narrow range of temperature, A_0 or B_0 is replaced by ΔH, and also A_1 or B_1, by ΔS. Therefore, if ΔH and ΔS are given, T_{max} can be calculated.

Although it is very difficult to estimate these real values under the conditions of urea synthesis, if the values in Ref. 1 can be used, T_{max} can be obtained; that is,

$$A_0 = 15890,\ A_1 = 33.7,\ B_0 = 9160$$

$$\therefore\ T_{max} = \frac{15890}{33.7-4.575\log 1.36} = 482°K \quad (16)$$

$$\therefore\ t_{max} = 209°C$$

The value of T_{max} thus obtained is a little different from the actual one. This inconsistency is unavoidable in such a simple treatment.

We estimate the heat of dissociation of $NH_4CO_2NH_2$ in the solution at the temperature of urea synthesis, using a thermochemical cycle from the standard state of $NH_4CO_2NH_2$. It decreases with the rise in the temperature, but it does not turn out to be zero or minus, as is shown in Table 1. Therefore, it may be presumed that the dissociation of $NH_4CO_2NH_2$ in the solution takes place.

Table 1. Heat of dissociation of $NH_4CO_2NH_2$ (Estimated)

Temp	°C	160	180	200	220
ΔH	cal/mol	27074	24746	21993	20509

On the other hand, assuming that $K_1(T)$ and $K_2(T)$ are expressed as in Eq. (13), a value for A_0, which is approximately equal to the heat of the dissocation of $NH_4CO_2NH_2$ can be obtained in such a way that the optimum values of A_0, B_0, A_1, and B_1 are selected; the difference between the calculated and the observed conversion thus becomes a minimum when Eqs. (7) and (8) are solved simultaneouly for some given data. The value thus estimated is about 20 kcal/mol $NH_4CO_2NH_2$.

Discussion of the Equilibrium Pressure

The Minimum Equilibrium Pressure. The effect of NH_3/CO_2 (mol/mol) on the equilibrium pressure is shown in Fig. 2, where curves are drawn assuming a smoothed formula.

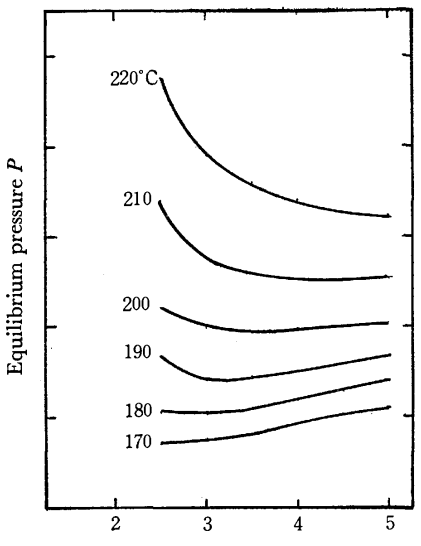

Fig. 2. Effect of NH_3/CO_2 on the equilibrium pressure.

The minimum equilibrium pressure at any temperature under the usual conditions of urea synthesis does not exist at 2.0 of NH_3/CO_2; as the temperature rises, the minimum point seems to move to higher values of NH_3/CO_2. Furthermore, the effect of NH_3/CO_2 on the equilibrium pressure at higher temperatures becomes slightly sensitive.

Table 2. Partial pressures of NH_3 and CO_2

Component	NH_3 [a]	CO_2 [b]	$NH_4CO_2NH_2$ [c] ($2NH_3+CO_2$)
mol/mol H_2O	1.0	0.022	1.0
Partial press. kg/cm²abs.	32.5	200	8.7 (5.8+2.9)

(at 120°C)
a) observed value by authors
b) Seidel's data collection
c) Calculated value by Raoult's law applied to the dissociation pressure by Frèjacques.

This can be understood according to the following explanation. Table 2 shows each partial pressure when NH_3, CO_2, or carbamate dissolves into one mole of H_2O.

It is evident that the partial pressure of CO_2, p_{CO_2}, is much greater than that of any other component because of physical absorption. As the partial pressure of H_2O, p_{H_2O}, is small compared to the total pressure, P: according to the mass action law and Raoult's law, the following equation is obtained:

$$P \doteqdot p_{NH_3} + p_{CO_2} \quad (17)$$

Then, by combining Eq. (17) with Eq. (18), Eq. (19) is obtained:

$$K_P(T) = (f_N p'_{NH_3})^2 (f_c p'_{CO_2}) \quad (18)$$

where p_{NH_3} and p_{CO_2} are actual partial pressures, and where p'_{NH_3} and p'_{CO_2} are ideal partial pressures;

$$P \doteqdot f_N p'_{NH_3} + K_P(T)/(f_N p'_{NH_3})^2 \quad (19)$$

therefore, f_N and f_C are factors which inidcate deviation from an ideal solution. By the partial differentiation of Eq. (19) with respect to p'_{NH_3}, Eq. (20) is obtained:

$$\frac{\partial P}{\partial p'_{NH_3}} = \frac{\partial f_N}{\partial p'_{NH_3}} \cdot p'_{NH_3} + f_N - 2\left(\frac{f_c p_{CO_2}}{f_N} \cdot \frac{\partial f_N}{\partial p'_{NH_3}} + \frac{f_c p'_{CO_2}}{p'_{NH_3}}\right) \quad (20)$$

Now, by supposing that f_N is independent of the p'_{NH_3}-compositions in the solution, and that $\partial f_N/\partial p'_{NH_3}=0$, at the minimum pressure, Eq. (20) becomes Eq. (21):

$$\frac{\partial P}{\partial p'_{NH_3}} = f_N - 2\frac{f_c p'_{CO_2}}{p'_{NH_3}} = 0 \quad (21)$$

$$p'_{NH_3}/p'_{CO_2} = 2f_c/f_N \quad (22)$$

As p'_{NH_3}/p'_{CO_2} is the ratio of the partial pressure of NH_3 to that of CO_2 in equilibrium with the solution, this is also the molar ratio of NH_3 to CO_2 in the solution. When we think that NH_3 dissolves by chemical absorption, while CO_2 dissolves by physical absorption, $f_c \gg f_N$.

Since NH_3/CO_2, which gives the minimum equilibrium pressure, is greater than 2, and since the effect

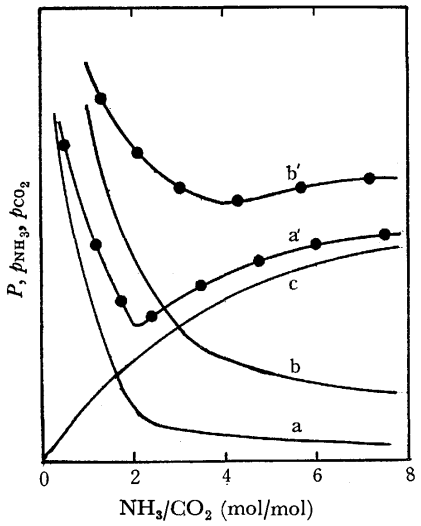

Fig. 3. Partial and total equilibrium pressure profile *vs.* NH_3/CO_2.
at const. temperature
a: p_{CO_2}, a': P when $fc=f_N$
b: p_{CO_2}, b': P when $fc>f_N$
c: p_{NH_3} of NH_3aq.

of the temperature on f_c is much greater than that on f_N, when the temperature becomes higher, the minimum equilibrium pressure moves to the side of higher NH_3/CO_2 ratios, we think.

If $NH_4CO_2NH_2$ does not dissociate into NH_3 and CO_2, and if the system is assumed to be ideal, the equilibrium pressure naturally reaches its minimum value when NH_3/CO_2 is just equal to 2. Figure 3 indicates the above state schematically.

However, NH_3 and CO_2 in the solution partially neutrallize each other, so p_{NH_3} and p_{CO_2} may be considered to be greatly reduced. Furthermore, the urea which is contained in the solution of urea synthesis is also a solvent for NH_3 and carbamate, so p_{NH_3} and p_{CO_2} are lower than in the case of no urea. From these considerations, the actual equilibrium pressure can be said not to be so great as was estimated from such data as those in Table 2.

Effect of H_2O/CO_2. While the increase in H_2O/CO_2, a solvent for carbamate, brings about a lowering of the equilibrium pressure, it also lowers the amount of urea to be formed, and urea is also a solvent for carbamate. Therefore, it is thought that the equilibrium pressure remains almost unchanged, or is reduced to some extent, with the increase in H_2O/CO_2, depending on the temperature.

The experimental data, however, show that, at a lower temperature, the equilibrium pressure is gradually reduced as H_2O/CO_2 increases and that, on the contrary, at a temperature higher than 200°C, it increases as H_2O/CO_2 increases (*cf.* Table 1 in the preceding paper).

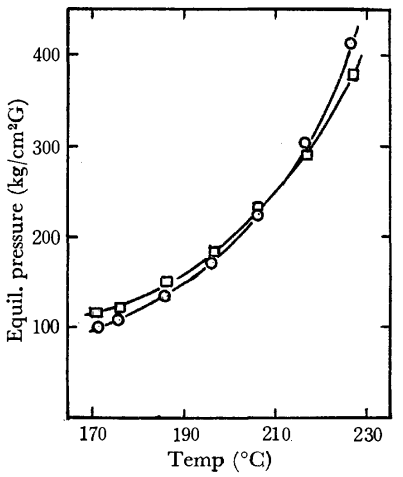

Fig. 4. Temperature dependence of the equilibrium pressure at various H_2O/CO_2.
at $NH_3/CO_2\fallingdotseq4$
-□- $H_2O/CO_2\fallingdotseq0.1$ -○- $H_2O/CO_2\fallingdotseq0.9$

Some examples are shown in Fig. 4. For this phenomenon we have the following interpretation. That is, when the temperature is low, the equilibrium pressure stays almost constat, or is reduced, with an increase in H_2O/CO_2 because of the low degree of dissociation of $NH_4CO_2NH_2$ in the solution.

When the temperature is high, however, the equilibrium pressure becomes higher because of the high degree of dissociation of $NH_4CO_2NH_2$ in the solution,[4] because the partial pressures of free NH_3 and CO_2 are much greater than the partial pressure of $NH_4CO_2NH_2$ in the solution.

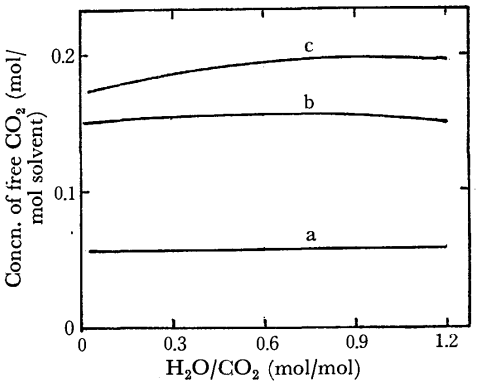

Fig. 5. Effect of H_2O/CO_2 on the conc. of free CO_2 in the solution.
a: 160°C, b: 190°C, c:220°C

The authors owed much computational aid to Mr. Kenji Yoshida. Here we gratefully acknowledge him.

4) Figure 5 shows the concentration of free CO_2 in the solution due to the dissociation of $NH_4CO_2NH_2$, when the solvent effect of formed urea are taken into consideration.

The Solvent Extraction of Iron(III) in Perchlorate Solutions Containing Chloride or Bromide Ions with 2-Thenoyltrifluoroacetone and Trioctylphosphine Oxide

Tatsuya SEKINE and Toshihiro TETSUKA

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received July 29, 1971)

Iron(III) in aqueous solutions, in which $[H^+]=1.0$M, $[Na^+]=3.0$M, and $[L^-]+[ClO_4^-]=4.0$M, where L^- is a chloride or bromide ion, was extracted with thenoyltrifluoroacetone (TTA) in carbon tetrachloride or with trioctylphosphine oxide (TOPO) in hexane. From the TTA extraction, it was concluded that iron(III) formed the first and the second complexes with both chloride ($\beta_1=10^{0.88}$ and $\beta_2=10^{0.80}$) and bromide ($\beta_1=10^{-0.10}$ and $\beta_2=10^{0.00}$) ions in the aqueous phase. The distribution data of iron(III) with TOPO were then explained in terms of the extraction of the ion-pairs, $Fe(ClO_4)_3$, $FeL(ClO_4)_2$, and $FeL_2(ClO_4)$, by using these stability constants. When the aqueous phase contained only chloride or bromide ions, and no perchlorate ion, the increase in the extraction with the increase in the halide ion concentration was much larger than that observed when the aqueous phase contained both halide and perchlorate ions. From the determination of the extraction of hydrogen ions and halide ions with TOPO, the extracted species in the absence of a perchlorate ion were identified as FeL_3 and/or $HFeL_4$. It was concluded that the difference in the extraction of iron(III) when a perchlorate ion was present and when it was absent is mainly caused by (i) the extraction of perchloric acid, which combines with TOPO in the organic phase and interferes with the extraction of the iron(III) halide complexes, and (ii) the extraction of iron(III) species containing one or more perchlorate ions which are large enough to be extractable with TOPO in the organic phase.

The solvent extraction of iron(III) in hydrochloric acid with diethylether was one of the earliest examples of the application of this experimental technique.[1,2] However, the chemical equilibria involved in such solvent extraction systems containing strong acids in the aqueous phase, and a polar solvent, such as an ether or a ketone, in the organic phase have not been analyzed very clearly, although Diamond and Tuck[3] and Marcus and Kertes[4] made comprehensive discussions of this problem.

The difficulties in the analysis of the thermodynamic equilibria involved in such systems are mainly due to the changes in the chemical properties of the organic phase caused by the extraction of the strong acid.

It has also been reported that iron(III) in hydrochloric acid is extractable with tributylphosphate (TBP)[5-9] or trioctylphosphine oxide (TOPO).[10,11] The chemical equilibria in these extraction systems, especially when the organic phase is a nonpolar solvent containing a small amount of one of these extractants, are assumed to be much simpler than those in extraction systems containing a polar solvent, because the extraction behavior of strong acids is much simpler when the organic solvent is nonpolar than when it is polar.

In the present investigation, the authors studied the chemical equilibria of iron(III) in aqueous sodium perchlorate solutions containing chloride or bromide ions and the extraction of iron(III) from these aqueous solutions into carbon tetrachloride containing TTA or into hexane containing TOPO. They determined the stability constants of these halide complexes in the aqueous phase and the chemical form of the extracted species in the organic phase. From these results, they discussed the role of perchlorate ions in the extraction of iron(III) in such systems.

Experimental

Tracer and Reagents. The iron-59 tracer was obtained from the Union Carbide Corporation, USA. It was purified as follows: a 6N hydrochloric acid solution of the tracer was shaken with the same volume of methylisobutylketone (MIBK), and then the tracer was extracted into the organic phase. The organic phase was washed with an equal volume of 4N hydrochloric acid, and then the tracer was back-extracted into the same volume of water. The solution thus prepared was diluted with 0.01N nitric acid and used as the stock solution. The concentration of chloride ions back-extracted together with the tracer into the final aqueous solutions was assumed to be very small[12] ($[Cl^-]$ is 4×10^{-4}M in the stock tracer solution and, consequently it is 7×10^{-6}M in the final solution). Furthermore, since only 0.1 m*l* of this tracer solution was added to 5 m*l* of the aqueous phase, the nitrate concentration in the latter solution was also very low (2×10^{-4}M). The effect of these ions was checked by changing the amount of the tracer solution added to the aqueous phase, but no change in the distribution ratio of iron(III) was thus observed. The TTA and the TOPO were obtained from the Dojin-Do & Co. The MIBK was

obtained from the Tokyo Kasei Co. The MIBK was washed with 0.1N perchloric acid, water, and a 0.1N sodium hydroxide solution successively, and then several times with water. The sodium perchlorate was prepared from sodium carbonate and perchloric acid and recrystallized three times from water. The other reagents were of an analytical-grade and were used without further purification.

Procedures. All of the procedures were carried out in a thermostated room at 25°C. Stoppered glass tubes (volume, 20 m*l*) were used to equilibrate the two phases. A five-milliliter portion of an aqueous solution containing iron(III) (carrier-free iron-59 or a small amount of an iron(III) carrier prepared from an analytical-grade reagent and labelled by iron-59) and various amounts of the ligand and sodium perchlorate, and a 5-m*l* portion of carbon tetrachloride containing TTA or hexane containing TOPO were placed in the tubes. The aqueous phase contained 4M electrolytes, unless noted. The initial concentration of iron(III) ions in the aqueous phase was 2×10^{-4}M to 1×10^{-5}M in the TTA extraction system and about 10^{-8}M in the TOPO extraction system. The tubes containing the aqueous and organic phases were placed on a rotating framework, and the two phases were agitated mechanically (20 rpm) for 24 hr and then centrifuged. A four-milliliter portion was pipetted from each phase and transferred into a small test tube. The γ-radioactivity in the sample solutions was measured with a well-type (NaI) scintillation counter, and the distribution ratio of iron(III) was calculated as follows:

$$D = \frac{[\mathrm{Fe(III)}]_{org,total}}{[\mathrm{Fe(III)}]_{total}} = \frac{\gamma\text{-count-rate per m}l\text{ of the organic phase}}{\gamma\text{-count-rate per m}l\text{ of the aqueous phase}}$$

The titration of the hydrogen ion in the organic phase was made by using a standard barium hydroxide solution, with phenolphthalein as the indicator.

Statistical

The stability constants of iron(III) complexes with L^- in the aqueous phase may be described as follows;

$$\mathrm{Fe^{3+}} + n\mathrm{L^-} \rightleftarrows \mathrm{FeL}_n^{3-n}$$

$$\beta_n = \frac{[\mathrm{FeL}_n^{3-n}]}{[\mathrm{Fe^{3+}}][\mathrm{L^-}]^n} \quad (1)$$

The total iron(III) concentration in the aqueous solution may then be described as;

$$[\mathrm{Fe(III)}]_{total} = [\mathrm{Fe^{3+}}] + [\mathrm{FeL^{2+}}] + [\mathrm{FeL_2^+}] + \cdots + [\mathrm{FeL}_n^{3-n}] = [\mathrm{Fe^{3+}}](1+\sum\beta_n[\mathrm{L^-}]^n) \quad (2)$$

When iron(III) is extracted into the organic phase with an organophilic chelating acid, the distribution equilibrium may be described as;

$$\mathrm{Fe^{3+}} + 3\mathrm{HA(org)} \rightleftarrows \mathrm{FeA_3(org)} + 3\mathrm{H^+}$$

$$K_{ex} = \frac{[\mathrm{FeA_3}]_{org}[\mathrm{H^+}]^3}{[\mathrm{Fe^{3+}}][\mathrm{HA}]^3_{org}} \quad (3)$$

If no complex formation or no hydrolysis of iron(III) in the aqueous phase is assumed, the distribution ratio is given by (here the subscript "0" denotes no complex formation in the aqueous phase);

$$D_0 = \frac{[\mathrm{FeA_3}]_{org}}{[\mathrm{Fe^{3+}}]} = K_{ex}[\mathrm{HA}]^3_{org}[\mathrm{H^+}]^{-3} \quad (4)$$

However, when iron(III) forms complexes with L^-, in the aqueous phase, the distribution ratio is given from Eqs. (2) and (4) as;

$$D = \frac{[\mathrm{FeA_3}]_{org}}{[\mathrm{Fe^{3+}}]+[\mathrm{FeL^{2+}}]+[\mathrm{FeL_2^+}]+\cdots} = \frac{K_{ex}[\mathrm{HA}]^3_{org}[\mathrm{H^+}]^{-3}}{1+\beta_1[\mathrm{L^-}]+\beta_2[\mathrm{L^-}]^2+\cdots} \quad (5)$$

From Eq. (5), the following relation is obtained;

$$\log D[\mathrm{H^+}]^3[\mathrm{HA}]_{org}^{-3}K_{ex}^{-1} = -\log(1+\sum\beta_n[\mathrm{L^-}]^n) \quad (6)$$

As may be seen (*cf.* Fig. 1, Table 1(a)), the formation of only the first and the second complexes in the aqueous phase was assumed, and the data were found to be represented by the following equation;[13,14]

$$Y = -\log(1+\beta_1[\mathrm{L^-}]+\beta_2[\mathrm{L^-}]^2) \quad (7)$$

The plot may be fitted with a family of standard curves;

$$Y = -\log(1+pv+v^2),\ X = \log v \quad (8)$$

and the constants, β_1 and β_2, can be determined from the parameters of the "best-fit" standard curve.

It is possible that iron(III) in the aqueous phase is extracted with a neutral extractant, E, as various uncharged species containing the ligand anions, L^-, and/or perchlorate ions. The extraction equilibria can be described as follows;

$$\mathrm{Fe^{3+}} + a\mathrm{L^-} + (3-a)\mathrm{ClO_4^-} + e\mathrm{E}(org) \rightleftarrows \mathrm{FeL}_a(\mathrm{ClO_4})_{3-a}\mathrm{E}_e(org)$$

$$K_{ex'3-a.a} = \frac{[\mathrm{FeL}_a(\mathrm{ClO_4})_{3-a}\mathrm{E}_e]_{org}}{[\mathrm{Fe^{3+}}][\mathrm{L^-}]^a[\mathrm{ClO_4^-}]^{3-a}[\mathrm{E}]^e_{org}} \quad (9)$$

However, when the concentration of the extractant is kept constant throughout a series of experiments, the $[\mathrm{E}]^e_{org}$ term can be eliminated from the equation and the following equation can be used instead of Eq. (9);

$$K_{ex_{3-a.a}} = \frac{[\mathrm{FeL}_a(\mathrm{ClO_4})_{3-a}]_{org}}{[\mathrm{Fe^{3+}}][\mathrm{L^-}]^a[\mathrm{ClO_4^-}]^{3-a}} \quad (10)$$

It is also possible that ion-pairs of anionic iron(III) complexes with sodium in the background salt such as $\mathrm{Na^+Fe(ClO_4)_4^-}$ are extracted. However, as will be seen later, this type of extraction is negligible in the present study, and so it will not be considered here.

The distribution ratio under these conditions may, then, be described as;

$$D = \frac{[\mathrm{Fe(ClO_4)_3}]_{org}+[\mathrm{FeL(ClO_4)_2}]_{org}+[\mathrm{FeL_2(ClO_4)}]_{org}+[\mathrm{FeL_3}]_{org}}{[\mathrm{Fe^{3+}}]+[\mathrm{FeL^{2+}}]+[\mathrm{FeL_2^+}]+\cdots} \quad (11)$$

As will be seen, the data were found to be represented well if the formation of the first and the second complexes in the aqueous phase and the extraction of the ion-pairs with perchlorate ions, $\mathrm{Fe(ClO_4)_3}$, $\mathrm{FeL(ClO_4)_2}$, and $\mathrm{FeL_2(ClO_4)}$, were assumed (*cf.* Figs. 1, 3, and 4, Table 1); thus, by introducing the equilibrium constants, Eq. (11) can be rewritten as;

13) T. Sekine and M. Ono, This Bulletin, **38**, 2087 (1965).
14) T. Sekine and Y. Hasegawa, *ibid.*, **39**, 240 (1966).

$$D=\frac{K_{ex_{3,0}}[ClO_4^-]^3+K_{ex_{2,1}}[ClO_4^-]^2[L^-]+K_{ex_{1,2}}[ClO_4^-][L^-]^2}{1+\beta_1[L^-]+\beta_2[L^-]^2} \quad (12)$$

From Eq. (12), the following relation is obtained;

$$\log\frac{D(1+\beta_1[L^-]+\beta_2[L^-]^2)}{[ClO_4^-]^3} = \log K_{ex_{3,0}} + \log\left\{1+\frac{K_{ex_{2,1}}}{K_{ex_{3,0}}}\left(\frac{[L^-]}{[ClO_4^-]}\right)+\frac{K_{ex_{1,2}}}{K_{ex_{3,0}}}\left(\frac{[L^-]}{[ClO_4^-]}\right)^2\right\} \quad (13)$$

The plot may also be fitted with the following family of standard curves;[13,14]

$$Y=\log(1+pv+v^2),\ X=\log v \quad (14)$$

and the constants, $K_{ex_{3,0}}$, $K_{ex_{2,1}}$, and $K_{ex_{1,2}}$, can be determined from the curve-fitting.

Results

Rate of Extraction. In the present study, it was found that the extraction of iron(III) with TTA is a slow reaction, as had previously been reported.[15,16] It took almost 20 hr until the distribution equilibrium was reached under the conditions employed. The rate of the extraction of the uncharged species of iron(III) with TOPO was also small, especially when the ligand concentration in the 4M sodium perchlorate medium was very low (where only the $Fe(ClO_4)_3$ species is extracted). Thus, the mechanical agitation of the two phases was always carried out for 24 hr before they separated.

TTA Extraction from an Aqueous Phase Containing no Ligand. Since the hydrogen-ion concentration in most of the experiments in this work was 1.0M, the extraction of iron(III) from an aqueous solution containing 1.0M perchloric acid and 3.0M sodium perchlorate with TTA in carbon tetrachloride was determined as a function of the TTA concentration. It was found from these determinations that the $D_0[H^+]^3[HA]_{org}^{-3}$ values obtained are nearly constant (log K_{ex} is 3.99). Thus, as can be seen from Eq. (4), the TTA complexes in the aqueous phase are practically negligible in the aqueous phase. Since the hydrogen-ion concentration was kept constant, no information about the hydrolysis of iron(III) was obtained from these distribution data alone. However, as the previously reported values of the hydrolysis constants of iron(III) in 3M sodium perchlorate solutions[17] are $*K_1=[FeOH^{2+}][H^+]/[Fe^{3+}]=10^{-3.05}$, $*\beta_2=[Fe(OH)_2^+][H^+]^2/[Fe^{3+}]=10^{-6.31}$, and $*\beta_{22}=[Fe_2(OH)_2^{4+}][H^+]^2/[Fe^{3+}]^2=10^{-2.96}$, the hydrolysis in 4M sodium perchlorate media at hydrogen-ion concentrations higher than 1M can be regarded as negligible.

TTA Extraction from an Aqueous Phase Containing Chloride or Bromide Ions. Figure 1(a) gives the log $D[H^+]^3[HA]_{org}^{-3}K_{ex}^{-1}$ *vs.* log[L^-] plot (*cf.* Eq. (6)) when the aqueous phase contained chloride (open circles) or bromide (closed circles) ions in a 4M sodium perchlorate medium at the hydrogen-ion concentration of 1.0M. The stability constants were determined by

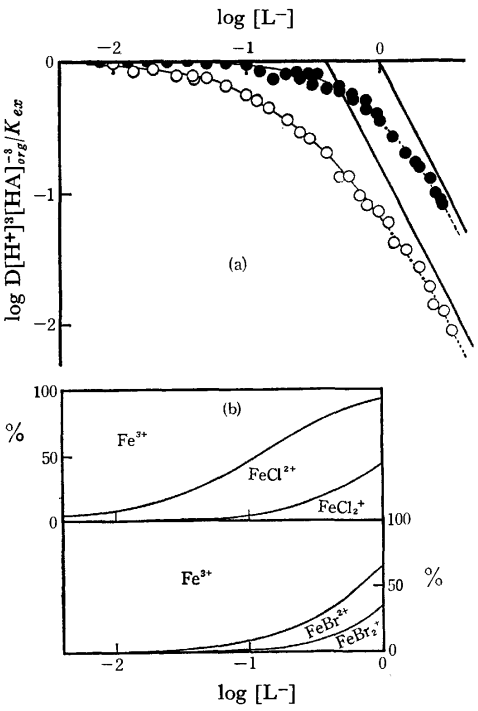

Fig. 1(a). Decrease in the TTA extraction of iron (III) as a function of the chloride (○) or bromide (●) concentration. Org. phase: carbon tetrachloride containing 0.1M TTA, Aq. phase: 4M perchlorate inoic medium in which $[H^+]=1.0$M, $[Na^+]=3.0$M, and $[L^-]+[ClO_4]=4.0$M. The solid cruves ($[L^-]<1.0$M) and the dotted lines ($[L^-]>1.0$M) are calculated by using the following equation and the stability constants in Table I(a):

using the data in the ligand-concentration region below 1.0M. By the curve-fitting, the stability constants for the first and the second complexes were determined to be as are listed in Table 1(a). The solid curves in Fig. 1(a) are the curves calculated from these constants. The dotted lines in Fig. 1(a) are calculated by using these constants for the ligand-concentration region above 1.0M.

Figure 1(b) gives the distribution of iron(III) complex species in the aqueous phase as a function of the ligand concentration.

TOPO Extraction from Aqueous Solutions Containing Chloride or Bromide Ions. The extraction of iron(III) with TOPO in hexane was reproducible only when the iron(III) concentration was very low; the distribution ratio was constant when the iron(III) concentration was changed between 10^{-8}M to 10^{-6}M, but it became lower than this value when the initial iron(III) concentration in the aqueous phase was above 10^{-5}M, the extraction being almost negligible when the iron(III) concentration was higher than 10^{-4}M. Thus, the initial iron(III) concentration in the aqueous phase was settled to be about 10^{-8}M.

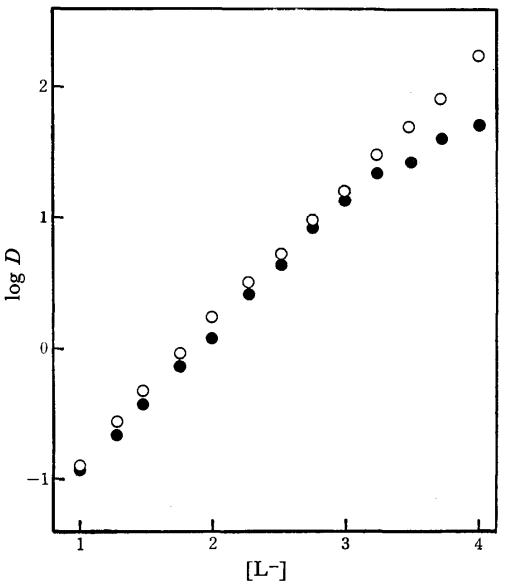

Fig. 2. TOPO extraction of iron (III) in the absence of perchlorate ions as a function of the chloride (○) or bromide (●) concentration in the aqueous phase. Org. phase: hexane containing 0.03 M TOPO, Aq. phase: aqueous solutions containing 1.0 M hydrohalic acid and various amounts of sodium halide but no perchlorate.

Figure 2 gives the extraction of iron(III) when the organic phase is hexane containing 0.03M TOPO and when the aqueous phase contains 1.0M hydrochloric acid and various amounts of sodium chloride, or when it contains 1.0M hydrobromic acid and various amounts of sodium bromide. The distribution ratio always increases with an increase in the halide concentration.

Figure 3 gives the extraction of iron(III) when the organic phase is also hexane containing 0.03M TOPO, but when the aqueous phase contains 1.0M hydrogen ions, 3.0M sodium ions and various amounts of perchlorate and chloride or bromide ions (prepared by mixing a solution containing 1.0M perchloric acid and

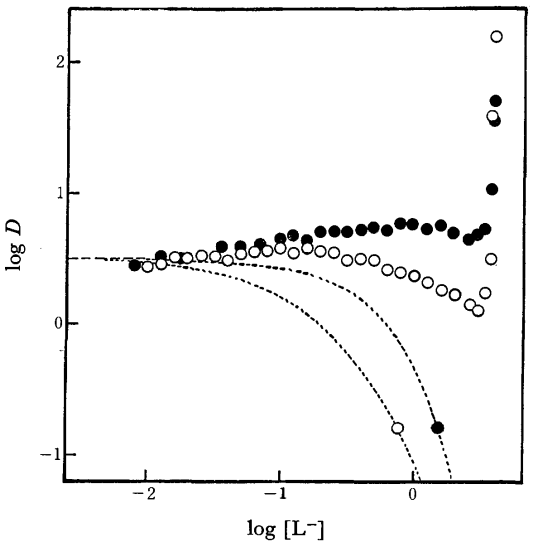

Fig. 3. TOPO extraction of iron(III) in the presence of perchlorate ions as a function of the chloride (○) or bromide (●) concentration. Org. phase: hexane containing 0.03M TOPO, Aq. phase: aqueous solutions in which $[H^+]=1.0$M, $[Na^+]=3.0$M, and $[L^-]+[ClO_4]=4.0$M. The broken line indicates the extraction in the absence of halide ions ($D=10^{0.50}$). The dotted lindes are the calculated curves (○: chloride system and ●: bromide system) assuming only the extraction of iron(III) perchlorate by using the equation, $\log D=\log K_{ex_{3,0}}[ClO_4^-]^3-\log(1+\beta_1[L^-]+\beta_2[L^-]^2)$ where β_1 and β_2 were taken from Table 1(a).

3.0M sodium perchlorate and a solution containing 1.0M hydrohalic acid and 3.0M sodium halide at various mixing ratios). The distribution ratio was $10^{0.50}$ (indicated by a broken line) when the aqueous phase was a perchlorate solution containing no halide ions.

As may be seen from Fig. 3, the distribution ratio is not changed very much by the halide ions when the

Org. phase: hexane containing 0.03M TOPO, Aq. phase: aqueous solutions in which $[H^+]=1.0$M, $[Na^+]=3.0$M, and $[L^-]+[ClO_4^-]=4.0$M. The solid curves are calculated by using the following equation and the constants in Table 1.
$\log D(1+\beta_1[L^-]+\beta_2[L^-]^2)/[ClO_4^-]^3=$
$\log\{K_{ex_{3,0}}+K_{ex_{2,1}}[L^-]/[ClO_4^-]+K_{ex_{1,2}}([L^-]/[ClO_4^-])^2\}$

concentration is lower than 3M, but it increases drastically in the region between 3M and 4M.

In order to determine the equilibrium constants in these extractions, the data were analyzed on the basis of Eq. (12). Figure 4 gives the $\log D(1+\beta_1[L^-]+\beta_2[L^-]^2)[ClO_4^-]^{-3}$ *vs.* $\log[L^-][ClO_4^-]^{-1}$ plot. Since the limitting slope for the plot in Fig. 4 is 0 or +2, it was concluded from Eq. (13) that the extracted species were $Fe(ClO_4)_3$, $FeL(ClO_4)_2$, and $FeL_2(ClO_4)$ in the ligand-concentration region below 1.0M and when the TOPO concentration was 0.03M. The extraction constants were determined by the curve-fitting of the plot in Fig. 4: they are listed in Table 1(b). The extraction of ion-pairs of the iron(III) ion, $Fe(ClO_4)_3$, and the first and the second complexes, $FeL(ClO_4)_2$ and $FeL_2(ClO_4)$, seems to explain the results in Fig. 3 reasonably, for if only the extraction of the $Fe(ClO_4)_3$ ion-pair occurs, the distribution ratio should decrease due to the complex formation in the aqueous phase and due to the decrease in the perchlorate concentration as the halide concentration increases. The dotted lines in Fig. 3 give the calculated curves assuming only the extraction of the $Fe(ClO_4)_3$ species, that is, assuming $D=K_{ex_3,0}[ClO_4^-]^3/(1+\beta_1[L^-]+\beta_2[L^-]^2)$. However, as may be seen from Fig. 3, the data experimentally observed are higher than these except in the very low ligand-concentration region. This is probably due to the extraction of halide complexes as ion-pairs, as was pointed out above. The solid curves in Fig. 4 are the curves calculated by using the constants listed in Table 1.

It was observed that the extraction from a solution containing 4.0M perchlorate ions ($[H^+]=1.0$M) or one containing 3.0M perchlorate and 1.0M bromide ions ($[H^+]=1.0$M) is proportional to the 1.5th order of the TOPO concentration in the 2×10^{-3}M to 3×10^{-2}M range. It was also found that the extraction from the 4.0M perchlorate ionic medium containing halide ions is practically independent of the hydrogen-ion concentration between 0.1M and 1.0M. Thus, the extracted species from these solutions should not contain protons. On the other hand, the extraction from 4.0M chloride or bromide solutions containing no perchlorate ions is dependent on the hydrogen-ion concentration, the distribution ratio when the hydrogen-ion concentration is 1.0M is about ten times larger than the distribution ratio when it is 0.1M; thus the iron(III) extracted from these solutions should, at least some part of it, contain protons.

In order to obtain further information, the extraction of hydrogen ions into the organic phase was determined.

Extraction of Acids into the Organic Phase. Table 2 gives the hydrogen-ion concentration determined by titration with barium hydroxide. It may be seen from Table 2(a) that the extraction of perchloric acid into hexane containing 0.03M TOPO is practically independent of the acid concentration, whereas that of hydrohalic acid increases as the acid concentration increases. It may be seen from Table 2(b) that the extraction of hydrogen ion from the aqueous phase containing perchlorate and halide ions is also independent of the composition of the aqueous phase. Its extraction in the absence of perchlorate ions is also dependent on the salt concentration. It was also found in the organic phase that precipitates of silver halide were always formed by the addition of a silver nitrate solution if no perchlorate was present in the aqueous phase, but no precipitate was formed if perchlorate ions were present in the aqueous phase together with the halide ions.

This fact indicates that all of the acid extracted from the aqueous halide solutions is perchloric acid as long as the solution contains perchlorate ions, and that the organic phase is saturated with perchloric acid by the following extraction:

$$H^+ + ClO_4^- + 2TOPO(org) \rightleftarrows (HClO_4)(TOPO)_2(org) \quad (15)$$

Since extraction from an aqueous phase containing no sodium salt gives the same results (Table 2(a)), the extraction of sodium perchlorate under these conditions is negligible.

Discussion

There have been several reports on the stability constants for iron(III) complexes with chloride or bromide ions.[17] The values reported for the chloride complexes ($\beta_1=10^{0.5}$ to $10^{1.0}$, $K_2\simeq10^{0.0}$) and for the bromide complex ($\beta_1\simeq10^{0.0}$) nearly agree with the present results. The higher complex, FeL_3 or FeL_4^-, may be very unstable, and the stability constants may be negligible even when the halide concentration is high.

The role of perchlorate ions and perchloric acid in the TOPO extraction system is remarkable. In the absence of perchlorate ions, the FeL_3 and the $HFeL_4$ (or $NaFeL_4$) species are possibly extracted into the organic phase, but these extractions are not remarkable when the halide concentration is lower than 2M (*cf.* Fig. 2). In the perchlorate ionic medium, the distribution of iron(III) is practically constant over a wide range of ligand concentration due to the extraction of ion-pairs, Fe^{3+}, FeL^{2+}, and FeL_2^+, with perchlorate ions.

Perchlorate solutions have often been used in order to control the activity of solutes in the aqueous phase. When such an aqueous phase is equilibrated with an organic phase, and when some portion of the anions is extracted together with hydrogen ion into the organic phase, the effect of the extracted acid should also be taken into account, because the extraction of the iron(III) species with TOPO combined with perchloric acid can be different from that with TOPO combined with hydrochloric or hydrobromic acid. However, under the conditions employed in the present study, the organic phase at equilibrium with the aqueous phase always contains 0.015M perchloric acid, even when 75% of the perchlorate ions is replaced by halide ions (*cf.* Table 2(b) and the fact that no halide ions were detected in these organic phases). Thus, the organic phase can be regarded as constant, even when the ligand ions are added to the aqueous phase. On the other hand, the extraction of the acid from the aqueous phase containing no perchlorate changes very much as the hydrogen ion or the salt concentration increases. Such changes in the composition in the aqueous phase should change not only the activity coefficients of the solutes in the aqueous phase, but also those in the organic phase.

The determination of the chemical form of the extracted species from chloride or bromide solutions containing no perchlorate seems to be difficult for the above reasons. However, from the observation described, the extracted species are assumed to be FeL_3 and/or $HFeL_4$. The extraction of these iron(III) halides seems to compete with the extraction of perchloric acid. Since the extraction of perchloric acid is effective, the addition of a small amount of perchlorate into the aqueous phase turns all the TOPO into the $(HClO_4)(TOPO)_2$ form. It is likely that the extraction of the FeL_3 and/or $HFeL_4$ species with this $(HClO_4)(TOPO)_2$ is much poorer than with free TOPO. This explains why the replacement of a small fraction of halide ions in the 4M halide solution by perchlorate ions causes a drastic decrease in the extraction of iron(III) (in the highest ligand-concentration range), as may be seen from Fig. 3.

The extraction of perchloric acid with TOPO in carbon tetrachloride was reported by Conocchioli, Tocher, and Diamond.[18] They described that the predominant species in the organic phase is the ion-pair $H_3O^+3TOPO\cdot ClO_4^-$ when the acid concentration is low enough, but for high concentrations of acid, the predominant species is $H^+TOPO\cdot ClO_4^-$. This does not agree with the present observation, which was made by using hexane as the diluent.

The Solvent Extraction of Zinc(II) in Sodium Perchlorate-halide Solutions with Trioctylphosphine Oxide

Hiromitsu MORIYA and Tatsuya SEKINE

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received September 28, 1971)

The solvent extraction of zinc(II) in 1M sodium perchlorate ionic media containing chloride, bromide, or iodide ions at 25°C was determined as a function of the halide-ion (X^-) concentration by using the zinc-65 tracer. From the extraction data with isopropyltropolone (IPT) in chloroform, the formation of the ZnX^+ complex was observed, but the stability constants of these complexes were not large ($ZnCl^+$: β_1 is $10^{0.00}$, $ZnBr^+$: β_1 is less than $10^{-0.5}$ and the formation of ZnI^+ is negligible), and the higher complexes were negligible in all cases. The extraction of zinc(II) from these media with methylisobutylketone (MIBK) was not effective, although the extracted species could be identified as ZnX_2. The extraction with trioctylphosphine oxide (TOPO) in hexane, on the other hand, was much better than that with MIBK. From the distribution ratio determined as a function of the halide and TOPO concentrations, the extracted species were concluded to be $Zn(ClO_4)_2(TOPO)_4$, $ZnX(ClO_4)(TOPO)_3$, and $ZnX_2(TOPO)_2$. The extraction constants for these species were determined by a graphic analysis of the data, and it was concluded that the extractabilities are larger in the order: iodide>bromide>chloride. From these data, it is clear that, if a suitable and effective neutral extractant is employed, the extractions of the above complexes are possible, even from aqueous solutions in which practically no complex is formed.

In a previous paper,[1] the present authors studied the solvent extraction of zinc(II) in 1M sodium perchlorate media containing various amounts of thiocyanate ions with trioctylphosphine oxide (TOPO) in hexane or methylisobutylketone (MIBK). They have reported, on the basis of these results, that zinc(II) in the aqueous phase forms the first, the second, and the third thiocyanate complexes, and that only the second one was extractable with TOPO in hexane, whereas both the second and the third complexes were extracted with MIBK.

After the above had been concluded, the authors desired to know further about the extraction of zinc(II) with the same extractants from aqueous solutions containing halide ions, which often form complexes somewhat similar to thiocyanate ions. The present paper will describe measurements of the stabilities and extractabilities of zinc(II) halide complexes from this standpoint. The results will be analyzed statistically, and some discussion will be made of the extraction of zinc(II) complexes, which are less stable in aqueous solutions than in organic solutions.

Experimental

The experiments were carried out in the same way described in the previous paper.[1] Zinc-65 was used for the determination of the distribution ratio of zinc(II). The organic solutions of the extractants and the aqueous solutions of the sodium salt were prepared in the manner described in the previous paper except that sodium chloride, bromide, or iodide solutions were prepared by dissolving an analytical-grade reagent and were added to the aqueous phase instead of sodium thiocyanate, as in the previous work. The concentrations of these ligand solutions were determined by gravimetry. The initial concentration of zinc(II) in the aqueous phase was 1×10^{-6}M, and the hydrogen-ion concentration at equilibrium was 10^{-4} to 10^{-5}M.

Statistical

As was also described,[1] the stability constants of zinc(II) complexes with an anionic ligand, X^-, in the aqueous phase can be determined from the decrease in the extraction of zinc(II) with a chelating extractant, HA, if the concentration of the extractant is kept constant:

$$D[H^+]^2/K = (1+\beta_1[X^-]+\beta_2[X^-]^2+\cdots) \quad (1)$$

where K is equal to $D_0[H^+]^2$ (D_0 is the distribution ratio in the absence of the ligand anions in the aqueous phase).

When the uncharged zinc(II) complex, ZnX_2, is extracted into the organic phase with e molecules of an organophilic extractant, E, the extraction equilibrium can be described as;

$$Zn^{2+} + 2X^- + eE(org) \rightleftarrows ZnX_2E_e(org)$$

$$K_{ex2,e} = \frac{[ZnX_2E_e]_{org}}{[Zn^{2+}][X^-]^2[E]^e_{org}} \quad (2)$$

However, if the concentration of the extractant, $[E]_{org}$, is kept constant over a series of experiments, this term can be eliminated, then;

$$K_{ex2} = \frac{[ZnX_2]_{org}}{[Zn^{2+}][X^-]^2} = K_{ex2,0} + K_{ex2,1}[E]_{org} + \cdots + K_{ex2,e}[E]^e_{org} \quad (3)$$

Furthermore, when zinc(II) species combining with perchlorate ions are extracted, the equilibrium can be described in the same manner as in Eqs. (2) and (3);

$$Zn^{2+} + X^- + ClO_4^- + eE(org) \rightleftarrows ZnX(ClO_4)E_e(org)$$

$$K_{ex1,e} = \frac{[ZnX(ClO_4)E_e]_{org}}{[Zn^{2+}][X^-][ClO_4^-][E]^e_{org}} \quad (4)$$

$$K_{ex1} = \frac{[ZnX(ClO_4)]_{org}}{[Zn^{2+}][X^-][ClO_4^-]} \quad (5)$$

$$Zn^{2+} + 2ClO_4^- + eE(org) \rightleftarrows Zn(ClO_4)_2E_e(org)$$

$$K_{ex0,e} = \frac{[Zn(ClO_4)_2E_e]_{org}}{[Zn^{2+}][ClO_4^-]^2[E]^e_{org}} \quad (6)$$

$$K_{ex0} = \frac{[Zn(ClO_4)_2]_{org}}{[Zn^{2+}][ClO_4^-]} \quad (7)$$

1) H. Moriya and T. Sekine, This Bulletin, 44, 3347 (1971).

It should be possible to evolve a general expression for the distribution ratios in such systems. However, in this study, the following equations are introduced, assuming that each zinc(II) species in the organic phase forms only one kind of solvate with the extractant and that it can be described as $Zn(ClO_4)_2E_{e0}$, $ZnX(ClO_4)E_{e1}$, or ZnX_2E_{e2}. The distribution ratio can then be described as;

$$D = \frac{[Zn(ClO_4)_2E_{e0}]_{org} + [ZnX(ClO_4)E_{e1}]_{org} + [ZnX_2E_{e2}]_{org}}{[Zn^{2+}] + [ZnX^+] + \cdots} \quad (8)$$

$$= \frac{K_{ex0,e0}[ClO_4^-][E]_{org}^{e0} + K_{ex1,e1}[X^-][ClO_4^-][E]_{org}^{e1} + K_{ex2,e2}[X^-]^2[E]_{org}^{e2}}{1 + \sum\beta_n[X^-]^n} \quad (9)$$

$$= \frac{K_{ex0}[ClO_4^-]^2 + K_{ex1}[X^-][ClO_4^-] + K_{ex2}[X^-]^2}{1 + \sum\beta_n[X^-]^n} \quad (10)$$

When a series of extractions are carried out at a certain concentration of the extractant, it is clear from Eq. (10) that;

$$Y = \left(\frac{D(1+\sum\beta_1[X^-]+\cdots)}{[ClO_4^-]^2} - K_{ex0}\right) \times \frac{[ClO_4^-]}{[X^-]}$$

$$= K_{ex1} + K_{ex2}\frac{[X^-]}{[ClO_4^-]} \quad (11)$$

The extraction constant, K_{ex0} or $K_{ex0,e0}$, can be determined from the extraction data in the absence of the ligand, and the other constants in Eq. (11) can be determined from the log$Y$ *vs.* log$[X^-]/[ClO_4^-]$ plot, by a curve-fitting method with the following standard curve, as has been described;[2-4]

$$Y = \log(1+v);\ X = \log v \quad (12)$$

When the extraction constants, K_{ex0}, K_{ex1}, and K_{ex2}, are determined at various concentrations of the extractant, the solvation number, $e0$, $e1$, and $e2$, can be determined from the slope of the log K_{exe} *vs.* log$[E]_{org}$ plot, because, for example, as the above assumption, Eq. (3) can be rewritten as;

$$\log K_{ex2} = \log K_{ex2,e} + e \log [E]_{org} \quad (13)$$

and K_{exe} can be obtained by a calculation based on Eq. (13).

Results

The results were reproducible, and the recovery of the zinc(II) tracer from the two phases was quantitative within the limit of experimental accuracy.

Extraction with IPT. As has been described,[1] the extraction of zinc(II) in 1M sodium perchlorate with IPT is proportional to the square of the hydrogen-ion concentration, and the value of K in Eq. (1) is $10^{-8.38}$ when the IPT concentration is 0.1M in chloroform. When the perchlorate ions in the aqueous phase were replaced with chloride ions, a decrease in the extraction of zinc(II) was observed. On the other hand, when they were replaced with bromide ions, the decrease was much smaller, and with iodide ions, the decrease was practically negligible in the ligand concentration range below 0.5M. The results in the chloride and the bromide systems are given in Fig. 1. From these

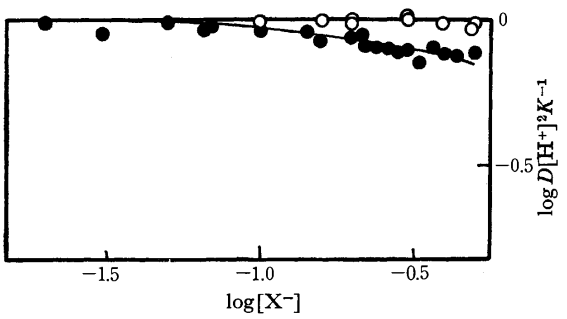

Fig. 1. Decrease in the IPT extraction of Zn(II) as a function of the ligand concentration.
Org. phase. $CHCl_3$ containing 0.1M TPT

The solid curve indicates (K is defined by Eq. (1)
log$D[H^+]^2K^{-1}$=log $(1+1.0\times[Cl^-])$

results, the stability constants were determined by the curve-fitting method and were found to be;

$ZnCl^+$: $\log\beta_1 = 0.00$

$ZnBr^+$: $\log\beta_1 < -0.5$

ZnI^+: very small

The higher complexes were concluded to be negligible.

Extraction with MIBK. The extraction of zinc(II) in 1M sodium perchlorate solutions containing no ligand or in 1M Na(Cl,ClO_4) with MIBK was found to be very low. The distribution ratio was, in both cases, less than 10^{-3}. The extraction of zinc(II) from 1M Na(Br,ClO_4) or in 1M Na(I,ClO_4) was also poor. The distribution ratio was $10^{-2.3}$ and $10^{-1.6}$ when the aqueous phase contained 0.5M bromide and 0.5M iodide ions, respectively, (and consequently, in both cases, 0.5M perchlorate was also present). The extraction was proportional to the square of the ligand concentration. The following extraction constants in Eq. (3) were determined from these results;

Extraction of $ZnCl_2$: $\log K_{ex2} < -2.5$

Extraction of $ZnBr_2$: $\log K_{ex2} = -1.7$

Extraction of ZnI_2: $\log K_{ex2} = -1.0$

Extraction with TOPO in Hexane. Zinc(II) in 1M sodium perchlorate containing no ligand is extractable with TOPO in hexane, and the extraction is proportional to the fourth power of the TOPO concentration, as is given in Table 1.

The extraction of zinc(II) from 1M Na(X,ClO_4) with TOPO in hexane was determined as a function of the ligand concentration at certain TOPO concentrations.

		av.	5.42

The slopes of the curves obtained at the same ligand concentration are larger in this order; iodide>bromide>chloride. Figure 2 gives the extraction with 1×10^{-2}M TOPO as an example of these experiments.

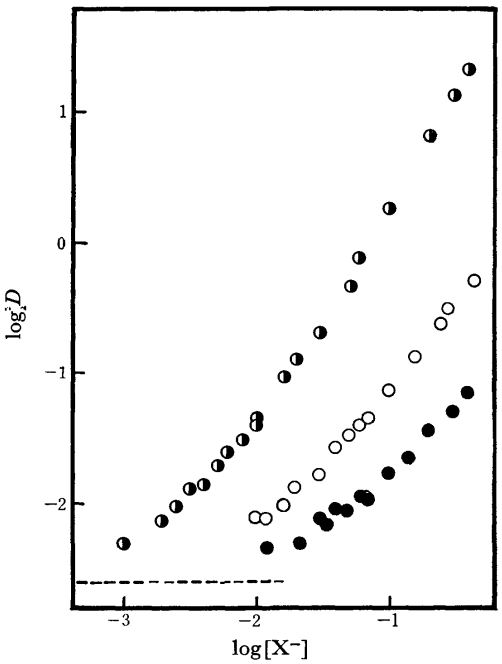

Fig. 2. Extraction of zinc(II) in 1M Na(X, ClO_4) with 1.0×10^{-2}M TOPO in hexane determined as a function of the ligand concentration.
(●: Cl^- ○: Br^- ◑: I^-)
The broken line indicates the extraction in the absence of halide ion ($\log D=-2.60$)

In order to determine the extraction constants in Eqs. (3), (5), and (7), the distribution ratio, the ligand concentration, the perchlorate concentration (that is, $1-[X^-]$M), and the K_{ex0} value in Table 1 were introduced into Eq. (11), and on the basis of the values thus calculated, the $\log Y$ *vs.* $\log[X^-]/[ClO_4^-]$ plot was made. It is given in Figs. 3, 4, or 5. The extraction constants were determined from these figures by the curve-fitting method. The solid curves in these figures show the best-fit curves. When a large part of the background perchlorate ions are replaced by the ligand anions, changes in the activity coefficients of solutes could occur. Thus, the extraction constants were determined by using the data in the ligand-concentration range below 0.5M. Thus, the fitted standard curves above this concentration, that is, at $\log[X^-]/[ClO_4^-]$ ratios higher than zero, are given by broken lines. The extraction constants thus obtained are given in Table 2. It was found that the slopes of the $\log k_{exe}$ *vs.* $\log[TOPO]_{org}$ plots were +4, +3, and +2 for K_{ex0}, K_{ex1}, and K_{ex2}, respectively, for all of the extractable complexes containing one of these three ligands. The extraction constants defined by Eqs. (2), (4), and (6) were determined from these data; they are also listed in Tables 1 and 2.

Discussion

The stability constants of zinc(II) halide complexes have been determined by many authors by using various

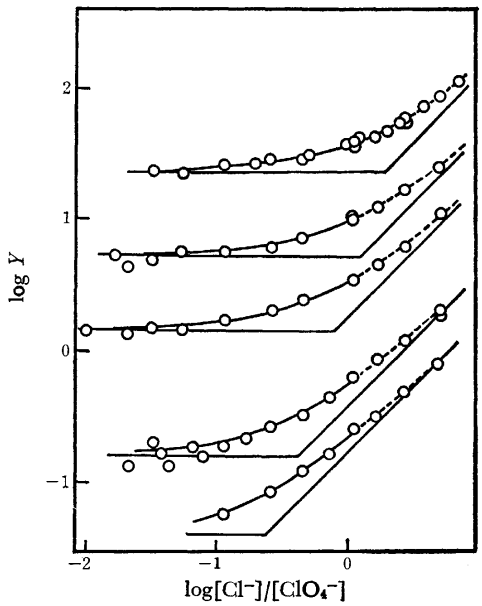

Fig. 3.

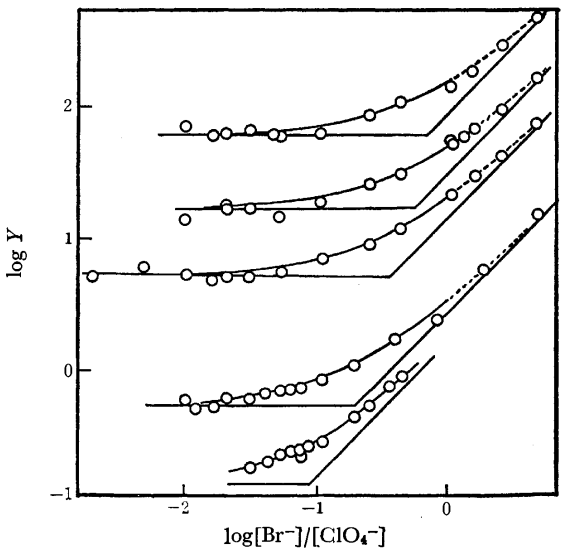

Fig. 4.

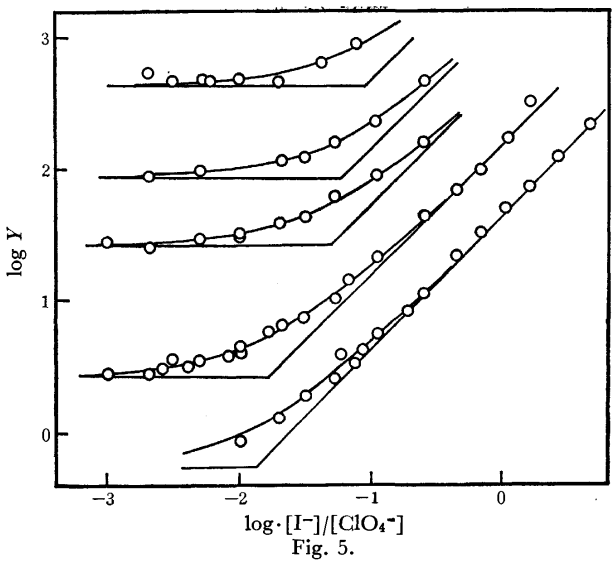

Fig. 5.

Fig. 3 to 5. Extraction of zinc(II) in 1M Na(X, ClO_4) with TOPO in hexane at various concentrations.
The data are plotted according to Eq. (11). The solid curves are $\log Y=\log(K_{ex1}+K_{ex2}[X^-]/[ClO_4])$ were K_{ex1} and K_{ex2} are taken from Table 2.
The aqueous phase contains chloride (Fig. 3), bromide (Fig. 4) or iodide ions (Fig. 5).
The concentration of TOPO in hexane is 5×10^{-2}M, 3×10^{-2}M, 2×10^{-2}M, 1×10^{-2}M or 6×10^{-3}M (top to bottom).

experiments methods.[5] The values determined in different ionic media are rather scattered. However, it is the general tendency for the stability constants for the first chloride complex at higher ionic concentrations to be around one ($\log\beta_1$ is −0.19 in 3M $NaClO_4$,[6] 0.30 in 4M $NaClO_4$,[7] and 0.2 in 1M $NaClO_4$[8]), and for those of the first bromide complex to be smaller than those of the chloride complex ($\log\beta_1$ is −0.60 in 3M $NaClO_4$[6]). These values practically agree with the present results. Some authors have also reported higher chloride or bromide complexes which are generally less stable than the first complex. However, the present authors could not determine any complexes higher than ZnX^+ from the results in Fig. 1. The stability constants determined by Morris and his coworkers in a 0.69M ionic medium by an ion-exchange method,[9] and in a 1M perchloric acid medium by a solvent extraction method with dinonylnaphthalene sulfonic acid[10] ($\log\beta_1=0.83$, $\log\beta_2=0.56$, $\log\beta_3=0.66$ for the chloride complexes and $\log\beta_1=0.10$, $\log\beta_2=-0.12$ for the bromide complexes), are obviously larger than the present results.

The extracted zinc(II) species with MIBK in the organic phase is assumed to be ZnX_2, and those with TOPO in hexane are assumed to be $Zn(ClO_4)_2$, $ZnX(ClO_4)$, and ZnX_2. Practically the only zinc(II) species in the aqueous phase, on the other hand, is the Zn^{2+} species in the bromide or iodide system, while the zinc(II) species are the Zn^{2+} and $ZnCl^+$ species in the chloride system. This indicates that the interaction between the metal ion and the ligand anions, or those between the metal ion and the perchlorate ions, are much stronger in the organic phase than in the aqueous phase, in which all the cations and anions are in a hydrated and uncomplexed form except for the $ZnCl^+$ species.

The dissociation of the extracted species in the organic phase should not be important in hexane, which is a low dielectric solvent, and it may be negligible in MIBK, which extracts only the $ZnBr_2$ or ZnI_2 complex.

No direct information is available on the nature of the bond in the extracted species from only the distribution data. However, the results in Table 2 indicate rather clearly the four coordination of znic(II) in the organic phase, although it is not possible to know if one or two molecules of water are coextracted with the metal species. Since the solvation numbers for the $Zn(ClO_4)_2$, $ZnX(ClO_4)$, and ZnX_2 species are four, three, and two, respectively, it can be assumed that the interaction between metal ion and the perchlorate ions are electrostatic and that those between the metal ion and the halide ions are coordinative. This also suggests that, among the four coordination positions of zinc(II), those unoccupied by the ligand anions are solvated with TOPO in the organic phase. The

extraction of the thiocyanate complex in the previous study was also estimated to be $Zn(SCN)_2(TOPO)_2$.[1]

Thus, it can reasonably be concluded that, for example, the extracted zinc(II) iodide is not an ion-pair of Zn^{2+} and the large iodide ions, but is a coordination complex which is stable only in these organic solvents and is completely dissociated in the aqueous phase.

In the previous paper,[1] the distribution ratio of zinc(II) between hexane containing TOPO and aqueous thiocyanate solutions was described in terms of the formation of zinc(II) complexes in the aqueous phase and the extraction of the uncharged complex species. This extraction was represented by the distribution constant;

$$K_{DM} = [ZnX_2]_{org,tot}/[ZnX_2] \quad (14)$$

As can be seen from Eqs. (3) and (14), the extraction constant of the second complex is the product of the stability constant of the ZnX_2 species in the aqueous phase and the distribution constant of this species, that is, $K_{ex_2}=K_{DM}\beta_2$. The extraction constant of the zinc-(II) thiocyanate complex with TOPO, $K_{ex_2,2}$ in Eq. (2), can be calculated from the constants in the previous paper[1] to be $10^{8.76}$. In the present study, however, the determination of the β_2 and K_{DM} was not possible. Thus, the extraction constant, K_{ex_2}, is used in order to describe the distribution equilibrium.

It is remarkable that the extractabilities of the complexes given in Figs. 2 to 5 or in Table 2 and in the previous paper[1] are larger in the order of; chloride$<$ bromide$<$iodide$<$thiocyanate. The most stable thiocyanate complex ($\log\beta_1=0.57$, $\log\beta_2=1.32$, and $\log\beta_3=1.18$) shows the highest extractability, but among the three halide complexes, the magnitude of the extractabilities shows an inverse order to the stability of the complexes in the aqueous phase.

Without any further information about these constants, it seems to be impossible to make a more detailed discussion of the extractability of these complexes. However, the fact that iodide, which forms the least stable complex (most probably the value of β_2 is also larger in the same order as β_1), is extracted better than bromide or chloride is probably due to the larger molecular size or the larger aquophobic tendency of the ZnI_2 species. The much higher extractability of the thiocyanate complex is probably mainly due to the greater stability of the $Zn(SCN)_2$ species than those of these bis-halide complexes.

It is remarkable that the extraction with the neutral extractant takes place even when no measurable amount of the extracted metal complexes are present in the aqueous phase. Such extractions, however, are very commonly observed when chelating extractants are employed for the metal extraction. Actually, in many metal extractions with chelating agents, HA, the distribution ratio can be denoted by $D=[MA_m]_{org}/[M^{m+}]$.

When the stability of the extractable species in the aqueous phase is low, the extraction of the species is obviously low. As has been pointed out,[11] the K_{DM} in Eq. (14) is the product of the distribution constant of the uncharged species between the diluent and the aqueous phase and the terms of the adduct formation constants between the metal complex and the extractant. From this point of view, the use of a strongly basic extractant such as TOPO is always suitable. However, the effect on its extractablilty of the stability and the molecular size of the complex is complicated. It seems to be common that the extractability of the larger halide complexes is higher than the smaller halide complexes if the stability constants of the former is larger. However, we have not found any general principle for the order of the extractability of halide complexes when the stabilities of the complexes of a smaller molecular size are higher than those of a larger molecular size.

Part of this study was carried out at the Laboratory of Nuclear and Analytical Chemistry, Institute of Physical and Chemical Research. The authors are grateful to Professor Nobufusa Saito, the head of the Laboratory.

Least-Squares Determination of Molecular Structures from Gaseous Electron-Diffraction Data. II. Polynomial Expression of Background

Shuzo Shibata
Department of Chemistry, Shizuoka University, Oya, Shizuoka, Japan
(Received October 6, 1971)

A new least-squares method has been devised for interpreting electron-diffraction data by comparison of an experimental background with a calculated background. The former is derived from an experimental total intensity by assuming a molecular model. The latter is approximated by a polynomial function. A computer program is written to refine structural parameters of a molecule so as to yield a smooth background. The characteristic of the present method is that it does not need any bias depending upon human judgement throughout an analysis. The distinctive features of the procedure are discussed, and the application of this method to structure determination of several molecules is also described.

Since a molecular intensity is not directly observable in electron-diffraction experiment, the procedure of drawing a background through an experimental intensity has been used as a bias to obtain a molecular intensity. In the past this background has often been frozen throughout an analysis; consequently, an uncertainty in the background probably leads to errors in final values of molecular parameters. Therefore, a method with no operator bias is desirable. In a previous paper[1] the criteria for smoothness of a background were presented and a least-squares method was given, that refines molecular parameters to make the background as smooth as possible. The purpose of this paper is to report another method which is based on quite the same viewpoint as the previous method. In the present method a background was expressed by a polynomial function, of which the parameters were allowed to vary freely in every iteration of the least-squares calculation. Bartell *et al.*[2] presented recently a least-squares analysis of total intensity, where a background was presented in terms of a polynomial with an exponential function. The present method does not essentially differ from it except that the best fit between experimental and calculated backgrounds, instead of that between total intensities, is sought by the refinements of molecular parameters and background parameters. Moreover, this method is mathematically rather simple and works without any initial guesses of background parameters.

Procedure

Criterion. An experimental total intensity is divided by an atomic background calculated by means of the scattering theory. Such leveling does not usually yield a horizontal background which cleaves molecular oscillations, but yields a considerably curved background because of imperfections of theory and experiment. However, it was found that this curved background can be approximated satisfactory in terms of a polynomial function, as described below.

A background I_b is provided from both a leveled experimental total intensity I_t and a molecular intensity M which is calculated for an assumed model by use of the relation (5) in Ref. 1. If a molecular model is strictly correct, the background should have no sudden fluctuation over the whole range of scattering angles. On the other hand, if the model is not correct, the background may have some fluctuations with a frequency similar to that of the molecular intensity. Thus, molecular parameters should be adjusted so as to make the background smooth. In the present method, the criterion for smoothness of a background is expressed as follows:

$$P_n = \sum_i w_i[I_b(q_i) - \sum_n a_n q_i^n]^2 = \text{minimum} \qquad (1)$$

Here w_i is a suitable weighting function, and $I_b = I_t/(1+RM)$, where R is an index of resolution. The equation means the minimization of the sum of the squares of the difference between an experimental and a calculated background over experimental points. Smoothness of the background is guaranteed by the degree of the polynomial. This method which we refer to as the *smooth-background method* differs from the usual method in that a background is never frozen and is refined with molecular parameters, and therefore it can determine values of molecular parameters without accompanying the uncertainties arising from a fixed background. The mathematical formulation of this method is omitted here since the details were described in other papers on the least-squares method.[3,4]

Sectional Smooth-background Method. The number of unknowns in a normal equation is generally equal to $(2m+1)+(n+1)$, if molecular parameters of interatomic distances and mean amplitudes with an index of resolution are varied independently to determine the structure of a molecule having m atomic pairs by use of a polynomial of nth degree. When a molecule consists of many atoms, the number of molecular parameters to be determined is large even if the symmetry of a molecule is taken into consideration. In the structure analysis of such a molecule, it seems difficult to solve the normal equation and get a good convergence of a standard deviation. This may be

1) S. Shibata and L. S. Bartell, *J. Mol. Structure*, **9**, 1 (1971).

mainly attributable to the unreasonable expansion of parameters at the initial values and to the correlation among the parameters. To avoid such difficulty, a program has been written so as to first solve the normal equation for a part of molecular parameters with all of background parameters and other molecular parameters being fixed, and then to repeat this procedure alternatively with respect to another part of molecular parameters. After the initial values of the molecular parameters are improved sufficiently by the iteration of such block-diagram calculations, it is possible to obtain reasonable solutions of the complete normal equation with a good convergence. Correlation between molecular parameters should be taken into consideration with respect to the division of molecular parameters into groups. This sectional method can determine a structure of the molecule involving more than thirty interatomic distances as independent parameters, as described in the Application.

In contrast to the above analysis in which all interatomic distances are refined independently, a few parameters are allowed to vary with background parameters in consideration of geometric constrains. The geometrical consistency is maintained by the procedure in Ref. 5 at all stages through the analysis.

Fitting of Background. Some of the most probable backgrounds used for radial distributions are fitted in terms of various analytical functions, and a polynomial was found to be a good approximate function. In general, a background for a short camera range of $q \gtrsim 20$ is leveled fairly well; and it can be approximated satisfactory with the polynomials of low degree, *e.g.*, $n=5$, within an error of 0.3%. Significance test[6] shows that a fitting by lower degree polynomials may be rejected at 0.005 significance level. Nevertheless, a background for a long camera range of $q \gtrsim 10$ has often a hump in the range of small scattering angles and falls off rapidly inside this range; a fit of the jump by polynomials sometimes disturbs the remainder of the background curve. In such a case, however, polynomials of higher degree, *e.g.*, $n=7$, can fit the background within the above error. Moreover, the use of μ background cited in Ref. 1 is probably a better method because the fitting by the polynomial of higher degree causes a large correlation between molecular parameters, and the final parameters determined are usually accompanied by large errors.

Correlation Between Data Points. Correlation coefficients ρ_k between data points q_t and q_{t+k} are computed by the usual way with use of the residuals of backgrounds I_b with respect to data of various molecules, assuming that all the correlation coefficients for constant interval are equal and that all the standard deviations for data points are also equal. The result indicates that they can be expressed approximately by the function $\exp(-\gamma_n|k|\Delta q)$, where Δq is the interval between observations.[7] The correlation matrix can therefore be expressed as follows:

$$\begin{vmatrix} 1 & \rho_1 & \rho_2 & \rho_3 \cdots \\ \rho_1 & 1 & \rho_1 & \rho_2 \cdots \\ \rho_2 & \rho_1 & 1 & \rho_1 \cdots \\ \cdots & & & \rho_2 \quad \rho_1 \quad 1 \end{vmatrix} \tag{2}$$

where all off-diagonal elements are included. The values of the parameter γ_n is slightly dependent on the degree n of a polynomial used for a fit of the background. A higher degree polynomial gives a smaller correlation coefficient, but it can be estimated to be about 0.4 for ρ_1, *i.e.*, $\gamma \sim 1$ Å. However, if a background is manually drawn, a correlation between data points is often significantly increased to about 0.8 for ρ_1, *i.e.*, $\gamma \sim 0.2$ Å.

The inverse of the correlation matrix for which the $i\ j$ elements are $\exp(-\gamma_n|i-j|\Delta q)$ can be simply expressed as,

$$\begin{vmatrix} 1 & p & 0 & 0 & 0 \cdots 0 \\ p & 1 & p & 0 & 0 \cdots 0 \\ 0 & p & 1 & p & 0 \cdots 0 \\ 0 & 0 & 0 & 0 & 0 \cdots 0 \quad p \quad 1 \end{vmatrix} \tag{3}$$

where

$$\begin{aligned} p &= -\exp(-\gamma_n \Delta q)/[1+\exp(-2\gamma_n \Delta q)] \\ &= -\rho_1/(1+\rho_1^2) \end{aligned} \tag{4}$$

This form is identical with the relation (13) in Ref. 8, where the above form of the inverse matrix is assumed. The inverse matrix corresponds to the weight matrix w_{ij} in the following relation:

$$\begin{aligned} P_n' &= \sum_i \sum_j w_{ij}[I_b(q_i) - \sum_n a_n q_i^n][I_b(q_j) - \sum_n a_n q_j^n] \\ &= \text{minimum} \end{aligned} \tag{5}$$

where the diagonal weight matrix elements w_t in the Eq. (1) are taken to be unity for simplicity.

For example, in the data of water[9] for the camera distance of 11 cm, the values of correlation parameter γ_n are 0.90 and 1.05 Å for $n=5$ and 7, respectively. Table 1 lists the molecular parameters and their errors for water obtained by the smooth-background method. A consideration of the correlation between data points increased the errors by a factor of about 1.4, if γ_n of 0.9 Å, *i.e.*, p of -0.35 is used, as seen in the table.

Applications

An application of the smooth-background method for the determination of molecular structures is described, as examples, for carbon tetrachloride, water[9] and bis-(acetylacetonato)palladium(II).[10] The analysis of CCl_4 is illustrated in Fig. 1. The backgrounds were expressed by means of a polynomial of the 7th degree for both long and short camera distance data. The convergence of molecular parameters is shown in Fig. 2 for both data. The C–Cl and Cl–Cl distances were refined independently of each other.

In the analysis of H_2O by both long and short camera distance data, polynomials of various degree were used

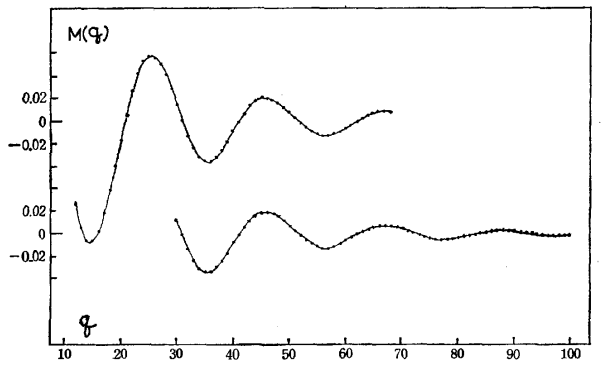

Fig. 3. Experimental and calculated molecular intesities M for H_2O.
The solid curves are the calculated molecular intensities obtained by the smooth-background method using the polynomials of the 5th degree. The upper curve corresponds to the long camera distance and the lower corresponds to the short camera distance. The dots are observations. Both curves correspond to P^*_5 (L) and P_5 (S) in Table 1, respectively.

the limits of errors. The derived parameters for O–H in H_2O are listed in Table 1, where the results obtained by use of the polynomials of 5th and 7th degrees are compared with each other. Table 2 shows the correlation matrix of parameters for water obtained from the analysis using the 5th degree polynomial as the background intensity. The use of higher degree polynomial resulted in larger correlation between molecular parameters, and consequently, increased errors in molecular parameters as seen in Table 1. This seems to be enhanced in the case of a long camera distance data, and therefore, the use of μ background is desirable, as shown in Table 1. Figure 3 shows the experimental and calculated molecular intensities.

As an example of the structure determination of a complex molecule, the structure analysis of Pd-$(C_5H_7O_2)_2$ is described. The three following calculations were compared with respect to the convergence of the standard deviation: 1) all of thirty-two interatomic distances were varied independently, 2) these distances were divided into four sets of eight distances and the least-squares calculation was performed successively by the use of the sectional method described above, 3) four interatomic distances and three bond angles were varied independently and other distances were changed according to the geometrical constraint remains. In these calculations it was assumed that

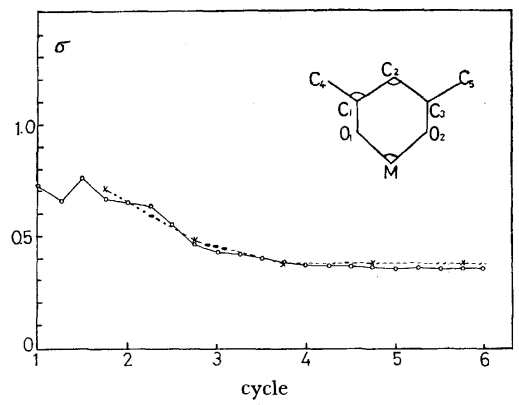

Fig. 4. The standard deviations at each cycle of the calculation for the analysis of $Pd(C_5H_7O_2)_2$.
——, case 2; -------, case 3 in the text. Independent parameters in the case 3 are as follows; interatomic distances of M-O_1, M-C_2, C_1-C_2, C_1-C_4 and bond angles of O_1MO_2, $C_1C_2C_3$, and $C_2C_1C_4$.

the molecule takes a planar form and the ligand of acetylacetone $C_5H_7O_2$ has the symmetry of C_{2v}. The first case could not give any convergence of the standard deviation. The second and third cases gave the good convergence given in Fig. 4; moreover, the computing time required for the second case was about twice for the third case. Generally, the present smooth-background method gave a relatively slow convergence of solutions in comparison with the previous method using the slope and curvature criteria.[1)]

Conclusion

The present method seems to be useful for the determination of interatomic distances and mean-amplitudes of vibrations because it is basically simple and straightforward. Electron-diffraction data are handled successively by a digital computer without manual processing of data. Numerical input data to the program routine are digital microphotometer readings. The present method does not need initial guess of background parameters, and thus it removes an operator bias from the analysis of molecular structure by the electron-diffraction method.

Elimination Reactions of Ethylene Halohydrins on Solid Catalysts

Isao MOCHIDA, Yasuhide ANJU, Akio KATO, and Tetsuro SEIYAMA
Department of Applied Chemistry, Faculty of Engineering, Kyushu Universtiy, Fukuoka
(Received November 4, 1971)

Elimination reactions of ethylene chlorohydrin and ethylene bromohydrin were studied over solid acids, solid bases, and metals supported by silica gel at 300°C using a microcatalytic gas chromatographic technique in order to elucidate the relationship between the elimination selectivity and the nature of active sites. Acetaldehyde was exclusively formed on solid acids and MgO. However, ethylene oxide as well was formed on solid bases. The ratio seems to depend on the basic strength of the solid bases. On the metals, ethylene was formed in addition to acetaldehyde. The former was the principal product on Pd and Pt. From these results, it was concluded that acetaldehyde was formed on acidic sites by halide-ion abstraction; ethylene oxide, on basic sites by proton abstraction, and ethylene, on less polar sites of metals by halogen atom abstraction.

It has been reported in previous papers that the halogen anion and proton abstractions play important roles in the catalytic elimination of hydrogen halide from haloethanes on solid acids and bases respectively.[1] On the other hand, OH-group abstraction has been thought to be important in the dehydration of ethanol on solid acids.[2] The elimination reactions of halohydrins on solid acids and bases may be interesting because the roles of two functional groups, halogen and OH, can be investigated under the same conditions. In this elimination several kinds of reaction products can be expected. This selectivity should reflect the acid-base character of the catalysts.

On the other hand, olefins are formed from halohydrins by metals such as magnesium and zinc in an acidic medium.[3] This result means that the metal surface has another kind of active site for the reactant.[4]

In the present research, the eliminations of two halohydrins were observed on solid acids, solid bases, and metals supported by silica gel, using the microcatalytic gas-chromatographic technique, mainly at 300°C. The poisoning effect of *n*-butylamine was also examined. The mechanisms of the elimination and the function of the catalysts were deduced from the reactivities of the reagents and the activities and selectivities of the catalysts on the basis of linear-free-energy-relationships.[1]

Experimental

Reagents. The ethylene chlorohydrin and ethylene bromohydrin (G.R.) were obtained from the Tokyo Kasei Co. They were used without further purifucation.

Catalysts. The solid acids and bases used in this work were described in previous papers.[1,2] Their abbreviations are summarized in Table 1. The metal catalysts were obtained by impregnating silica gel (Wako) with 0.4 mg-atom/g of each metal salt (Cu, Ag, Co, Ni: nitrate, Au, Pd, Pt: chloride, Fe: hydroxide) and by then drying it at 120°C in the air. They were all reduced in the reactor at 300°C except for Fe, Co, and Ni (Fe, Co: 450°C, Ni: 400°C) by hydrogen gas before the reaction.

Procedures. The reaction rates and selectivities were measured with the pulse technique with a hydrogen carrier in the temperature range from 200°C to 450°C. The hydrogenolysis of halohydrins on Pd, Pt, and Ni was observed, but it was small compared with the other eliminations. Polyethylene glycol (PEG 1000) was used in an analytical column (60°C, 2 m) to get the conversion data, and a 4-m portion of PEG 1000 was used at room temperature for the determination of the ethylene oxide/acetaldehyde ratio. The reaction rates (ml/g·min) were calculated by dividing the conversion with the contact time below its value of 20%. The details of the experiments were described in previous papers.[1,2]

Results

Elimination of Halohydrins on Solid Acids and Bases. Ethylene halohydrins may give vinyl halide upon dehydration; vinyl alcohol and its isomers, by dehydrohalogenation, and ethylene, by the use of dehypohaloic acid. Only acetaldehyde was formed from halohydrins on solid acids. Ethylene oxide and acetaldehyde were formed on all the solid bases except MgO. The formation of ethylene oxide has also been reported in elimination in an alkaline solution.[5]

1) The Reactivities of Ethylene Chlorohydrin and Ethylene Bromohydrin: The catalytic activities of solid acids and bases are shown in Fig. 1. The activities were cal-

culated from the first pulse. The total elimination reactivities of ethylene chlorohydrin were taken in the abscissa, and the rates of acetaldehyde and ethylene-oxide formation from ethylene chlorohydrin and ethylene bromohydrin were taken in the ordinate. The rates of acetaldehyde formation from ethylene bromohydrin were larger than those from ethylene chlorohydrin throughout the solid acids and bases. In contrast, as to the rates of ethylene oxide formation, ethylene chlorohydrin was more reactive than ethylene bromohydrin except in the case of SrO.

The rate of acetaldehyde formation was larger on solid acids than on solid bases, except for the case of MgO. Among the so-called basic oxides, their activities for acetaldehyde formation increased with the decrease in the basicity (K_2O>Na_2O, and SrO> CaO>MgO), whereas the activity for ethylene-oxide formation was the reverse. The catalytic behavior of MgO was close to that of typical solid acids, as has also been observed in the dehydrohalogenation of 1,2-dibromoethane and isopropyl halides.[1b]

2) Poisoning Effect: The decrease in catalytic activities with regard to ethylene-oxide formation was very striking from pulse to pulse on solid bases, but not so with regard to acetaldehyde formation on either acidic or basic solids. In the former case, the activities were almost lost by the first pulse. This poisoning effect may be due to the adsorption of hydrogen halide, one of the elimination products, onto the basic site. The poisoning of catalysts with *n*-butylamine suppressed acetaldehyde formation very much on solid acids and bases, but it did not affect ethylene oxide formation at all. These poisoning effects, in accordance with the variation in activities shown in Fig. 1, indicate that acidic sites and basic sites play an important role in the acetaldehyde and ethylene-oxide formations respectively.

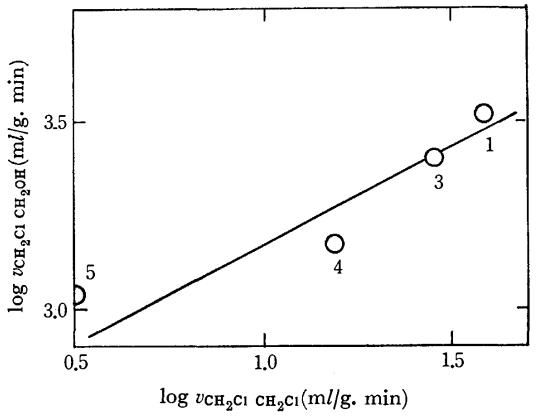

Fig. 2. Correlation between the rates of dehydrochlorination of 1,2-dichloroethane ($v_{CH_2Cl\ CH_2Cl}$) and ethylene chlorohydrin ($CH_2Cl\ CH_2OH$). The former are taken in the abscissa and the latter in the ordinate.
Numbers refer to Table 1.

3) A Comparison between the Dehydrochlorination Reactivities of 1,2-Dichloroethane and Ethylene Chlorohydrin: Between the reactivities of chlorohydrin and 1,2-dichloroethane on some solid acids, a certain correlation can be observed, as is shown in Fig. 2; this suggests a similarity in mechanism for the two dehydrochlorinations. The reactivity of ethylene chlorohydrin was larger than that of 1,2-dichloroethane by two orders of magnitude. Ethylene chlorohydrin was more reactive than 1,2-dichloroethane on solid bases, too. However, no correlation between the two reactivities could be found on solid bases.

Elimination of Halohydrins on Metals Supported by Silica Gel. *1) Catalytic Activities and Selectivities of Metals*: Acetaldehyde and ethylene were formed from halohydrins on metals supported by silica gel. The catalytic activity was increased, but the selectivity did not change, with the amount of metal mounted, as is shown in Fig. 3. Furthermore, the selectivities of non-supported metals (Cu, Ni, Pd) were equal to those of metals supported by silica gel, although the activity per unit weight of the supported metals was much larger than that of unsupported metals. These facts indicate that silica gel does not affect the catalytic selectivity. The catalytic activities of supported metals are shown in Fig. 4. Ethylene bromohydrin was more reactive for both product formations than ethylene chlorohydrin, as was observed for the acetaldehyde formation on solid acids. The selectivities (rate of ethylene formation/total rate of elimination) are shown as a function of the standard heats of the formation of metal chloride per chlorine atom (ΔH°_f)[6] in Fig. 5. There are volcano correlations, with the highest selectivity at Pt. Such a volcano relation has also been observed in the dechlorination of 1,2-dichloropropane.[4] Generally speaking, the more reactive bromohydrin was less selective for ethylene formation than was chlorohydrin.

The apparent activation energies for the acetaldehyde formation are larger than those for the ethylene formation, as is shown in Table 2.

Table 2. Apparent activation energies of HCl or HClO elimination from ethylene chlorohydrin on metals

Catalysts	Acetaldehyde (–HCl)	Ethylene (–HClO)
Cu–SiO_2	15 kcal/mol	4 kcal/mol
Ag–SiO_2	12	9
Au–SiO_2	21	15
Fe–SiO_2	14	a)
Co–SiO_2	12	9
Ni–SiO_2	14	14
Pd–SiO_2	a)	10.5
Pt–SiO_2	a)	10

a) Activity was too small to be measured.

2) The Poisoning Effect: The poisoning effect with *n*-butylamine was severe for the acetaldehyde formation, but was negligible for the ethylene formation, among all the metal catalysts examined.

The catalytic activities of all the metals except Pd and Pt for acetaldehyde and ethylene formations decreased to a half of the original activity upon a pulse injection. Pd and Pt showed no activity change from pulse to pulse.

3) A Comparison between the Dechlorination of 1,2-dichloroethane and Dehypochloric Acid of Ethylene Chloro-

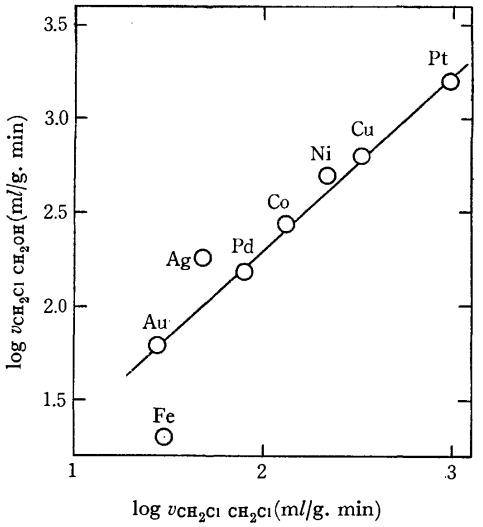

Fig. 6. Correlation between the rates of dechlorination of 1,2-dichloroethane ($v_{CH_2Cl\ CH_2Cl}$) and those of dehypochloric acid of ethylene chlorohydrin ($v_{CH_2Cl\ CH_2OH}$) at 300°C.
The former are taken in the abscissa and the latter in the ordinate.

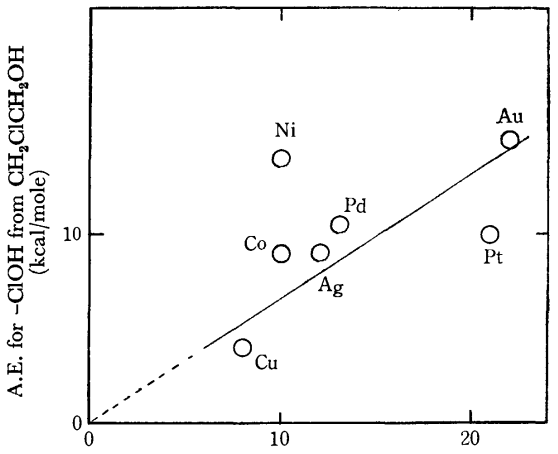

Fig. 7. Correlation of apparent activation energies between dechlorination of 1,2-dichloroethane and dehypochloric acid of ethylene chlorohydrin.

hydrin on Metals: A good correlation was recognized between the dechlorination-reactivities of 1,2-dichloroethane[4] and the dehypochloric-acid-reactivities of ethylene chlorohydrin, as is shown in Fig. 6. Furthermore, the activation energies of the two elimination reactions on the same metal were also correlated with each other, as is shown in Fig. 7. Both correlations were observed between the corresponding reactions of 1,2-dibromoethane and ethylene bromohydrin. Such correlations indicate that the ethylene formation from halohydrins proceeds through a mechanism similar to that of the dehalogenation of haloethanes.

Discussion

Acetaldehyde Formation. Acetaldehyde is formed on acidic sites, as has been described above. The following facts suggest that the halogen-abstraction step is important. 1) There is a good correlation between the reactivities of 1,2-dichloroethane and ethylene chlorohydrin on solid acids, as is shown in Fig. 2. 2) Bromohydrin, the C–Br bond of which is weaker than the C–Cl bond of ethylene chlorohydrin, was more reactive than chlorohydrin. From these findings, it seems that acetaldehyde formation may proceed through a mechanism by which the halogen is eliminated as an anion in the first stage, and then the β proton may leave through an $\alpha\beta$ elimination mechanism to give vinyl alcohol, which isomerizes immediately to acetaldehyde:

$$CH_2OHCH_2X \xrightarrow{-X^-} CH_2OHCH_2^+ \xrightarrow{-H^+} CHOH{=}CH_2 \longrightarrow CH_3CHO$$

As alumina had a higher catalytic activity than silica-alumina, it is difficult to assume only protonic acid as the active site for the acetaldehyde formation. Such a situation was also observed in the dehydration of ethanol.[2] The higher reactivity of halohydrin in comparison with that of 1,2-dichloroethane may be due to the interaction between the hydroxyl group of halohydrin with acid sites in the same manner as in the dehydration of ethanol, in addition to the difference in enthalpy changes between the two reactions.[7]

The linear correlation observed through solid acids and bases (Fig. 1) and the similar poisoning effect may indicate an analogous mechanism for the acetaldehyde formation on solid bases.

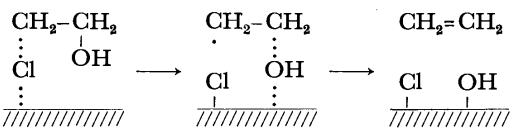
Similar poisoning effects of *n*-butylamine and the higher reactivity of ethylene bromohydrin than ethylene chlorohydrin were also observed for the reactions on metal catalysts as well as on solid acids, indicating a similar mechanism for acetaldehyde formation on metals. The acidic nature of the metal atom may be due to its vacant *d*- or *f*-orbitals.

Ethylene Oxide Formation. Ethylene oxide was formed on the catalysts which were located on the left side of Fig. 1, that is, the solid bases. The poisoning effect of HX was remarkable for the ethylene-oxide formation. Therefore, the active site for the ethylene-oxide formation may be basic. Basic sites may eliminate the proton from the hydroxyl group at first:

$$CH_2XCH_2OH \xrightarrow{-H^+} CH_2XCH_2O^- \xrightarrow{-X^-} CH_2{-}CH_2 \quad (O)$$

This scheme is the same one as that suggested for the reaction in basic media.[8] According to this scheme, the reactivity may depend on the acidity of the hydrogen atom to be eliminated. Thus, the reactivity difference between chloro- and bromohydrins can be understood. The higher acidity of the hydrogen in the OH group than in the CH group may also explain the higher reactivity of halohydrin in comparison with haloethanes on solid bases.

Ethylene Formation on Metals. The larger reactivity of bromohydrin than that of chlorohydrin suggested the importance of the halogen-abstraction step for the ethylene formation. The correlations of the activities and activation energies of metals for the ethylene formation with those for the dechlorination of 1,2-dichloroethane in Figs. 6 and 7 indicate the similarity of the rate-determining steps in these two reactions. The poisoning with *n*-butylamine does not affect the ethylene formation, in contrast to the acetaldehyde formation, which is considered to proceed through the ionic mechanism on metals described above. Therefore, the following mechanism is considered to hold for the ethylene formation on metals:



It is interesting that the less electronegative and higher back-donating metals, such as Pt and Pd, show a high selectivity for ethylene formation.

7) $\Delta Hf^\circ_{(298)} = -39.86$, -70.3, 8.4, and -31.0 (kcal/mol) for acetaldehyde, ethylene chlorohydrin, vinyl chloride, and 1,2-dichloroethane respectively. (D. R. Stull, E. F. Westrum, and G. C. Sinke, "The Chemical Thermodynamics of Organic Compounds," Wiley, New York 1968, p. 641.

Intersystem Crossing Quantum Yields of Phthalazine and Pyridazine[1]

Takeshi TAKEMURA, Kohzaburo YAMAMOTO, Iwao YAMAZAKI, and Hiroaki BABA
Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo
(Received November 15, 1971)

The quantum yields of $S_1 \rightarrow T_1$ intersystem crossing have been determined for phthalazine and pyridazine in EPA at 77°K by using the technique of T–T energy transfer. Phthalazine and pyridazine were used as the energy donor, and naphthalene-h_8 and naphthalene-d_8 as energy acceptor. The intersystem crossing quantum yields were found to be 0.49 for phthalazine and 0.24 for pyridazine. These values lead to the conclusion that the weakness or lack of phosphorescence in the compounds is due to an anomalously high rate of the radiationless transition from their phosphorescent triplet state as compared with the rate of the corresponding radiative transition.

The radiative and radiationless processes in nitrogen heterocyclic compounds have been studied extensively.[2-11] Although most of these compounds show strong phosphorescence, *ortho*-diazines such as pyridazine, phthalazine, and 9,10-diazaphenanthrene show either only very weak phosphorescence or none at all. Several attempts have been made to explain this phenomenon. El-Sayed proposed that the rate of $S_1 \rightarrow T_1$ intersystem crossing is low in pyridazine because the $^3(\pi,\pi^*)$ state lies above the lowest $^1(n,\pi^*)$ state and the only path for the intersystem crossing is $^1(n,\pi^*) \rightarrow {}^3(n,\pi^*)$, which should be slower than $^1(n,\pi^*) \rightarrow {}^3(\pi,\pi^*)$ by a factor of 10^3.[6] Cohen and Goodman attributed the lack of phosphorescence in pyridazine to an efficient intersystem crossing process from the phosphorescent triplet state to a low-lying excited singlet state.[7] Hochstrasser and Marzzacco suggested that the lack of phosphorescence is due to the fact that the $T_1 \rightarrow S_0$ radiationless process is much faster than the radiative one.[8] Thus, despite widespread interest the problem remains unsettled, little quantitative information being available concerning the radiationless transition.

We found recently that phthalazine gives no emission in hydrocarbon solvents, but it phosphoresces with a moderate intensity in polar solvents such as EPA.[2,3] It was suggested in addition that phthalazine has a high intersystem crossing quantum yield.[2]

With a view to elucidating the mechanism of excitation-energy relaxation in *ortho*-diazines, we measured quantitatively the intersystem crossing quantum yields of phthalazine and pyridazine in EPA rigid glass solution at 77°K, using the technique of T–T energy transfer.[12] Phthalazine and pyridazine were used as energy donor, and naphthalene-h_8 and naphthalene-d_8 as energy acceptor.

Experimental

Phthalazine (Aldrich Chemical Co.) was recrystallized from diethyl ether and then sublimed under reduced pressure. Pyridazine was purified by vacuum distillation. Naphthalene-h_8 and -d_8 (the latter was obtained from Merck, Sharp & Dohme of Canada) were purified by recrystallization or vacuum sublimation. Diethyl ether was carefully purified after the method described by Kanda and Shimada.[13] Isopentane was passed through a silica-gel column. Spectrograde ethyl alcohol was used without further purification. EPA (5:5:2 parts by volume of diethyl ether, isopentane and ethyl alcohol) was used as solvent. All the sample solutions were degassed by repeated freeze-thaw cycles.

Phosphorescence spectra were measured at 77°K with a Hitachi MPF-2A fluorescence spectrophotometer, equipped with a phosphoroscope.

The phosphorescence spectra were corrected for the spectral sensitivity of the system of monochromator and photomultiplier, using quinine sulfate in 1 N sulfuric acid and β-naphthol in acetic acid-sodium acetate buffer solution as standards.[14] The phosphorescence quantum yield of phthalazine was found to be 0.04 in a previous study,[3] and the quantum yields of naphthalene-h_8 and -d_8 were determined by comparing the corrected phosphorescence spectra of these compounds with the spectrum of phthalazine. In all systems of phthalazine-naphthalene-h_8 and -naphthalene-d_8, and pyridazine-naphthalene-d_8, excitation was carried out at 340 nm, where only the donor molecules show absorption.

Procedures

Intermolecular triplet-triplet excitation energy transfer is known to take place in systems where the energy levels of the lowest excited singlet state S_1^D and lowest triplet state T_1^D of the donor are bracketed by the same two levels of the acceptor, as illustrated in Fig. 1.

The present procedures for determining intersystem crossing quantum yields are based on the phenomenon of T–T energy transfer in rigid-glass solution. The following assumptions have been made: (1) The solute molecules are uniformly distributed in rigid-

glass solution. (2) All the unimolecular rate constants defined for the donor and acceptor (Fig. 1) are not affected by the presence of their respective partners, acceptor and donor. (3) The energy transfer from donor to acceptor occurs only through the path $T_1^D \rightarrow T_1^A$. These assumptions are generally recognized to be valid under the usual conditions.

In this study, two procedures A and B were employed according to two different cases; one where the emission can be observed from both donor and acceptor (Case A), and the other where the donor emission cannot be observed (Case B).

Procedure A. This is applicable only to Case A. A quantity called the quantum yield of sensitized phosphorescence γ_{SP} is available. The quantity was defined by Ermolaev[12] as

$$\gamma_{sp} = \frac{\Phi_{sp}^A}{\Phi_{PO}^D - \Phi_P^D} \quad (1)$$

where Φ_{SP}^A is the quantum yield of the sensitized phosphorescence of the acceptor, and Φ_{PO}^D and Φ_P^D are the quantum yields of the phosphorescence of the donor in the absence and in the presence of the acceptor, respectively. γ_{SP} can be obtained directly from the experiment. Equation (1) can be rewritten as[12]

$$\gamma_{sp} = \frac{\Phi_{ISC}^D}{\Phi_{PO}^D} \cdot \theta_P^A \quad (2)$$

with

$$\theta_P^A = \frac{\Phi_P^A}{\Phi_{ISC}^A} = \frac{k_P^A}{k_P^A + k_{PQ}^A} \quad (3)$$

where Φ_{ISC}^D and Φ_{ISC}^A are the intersystem crossing quantum yields of the donor and acceptor, respectively; Φ_{ISC}^D, for example, is given by

$$\Phi_{ISC}^D = k_{ISC}^D/(k_F^D + k_{FQ}^D + k_{ISC}^D)$$

Φ_P^A is the quantum yield of the phosphorescence of the acceptor, and θ_P^A represents the fraction of triplet molecules which phosphoresce.

Thus, if γ_{SP}, Φ_{PO}^D, and θ_P^A are known, Φ_{ISC}^D can be calculated from Eq. (2).

Procedure B. This is applicable to Cases A and B. If T–T energy transfer is assumed to be caused by the exchange mechanism, Φ_{SP}^A can be written in the form[12]

$$\Phi_{sp}^A = \Phi_{ISC}^D[1 - \exp(-VNC)]\theta_P^A \quad (4)$$

where V is the volume of the sphere of action of quenching, N the Avogadro number, and C the concentration of acceptor. It should be noted that $\exp(-VNC)$ represents the probability that there is no acceptor molecule in the volume V about an excited donor molecule, so that $\Phi_P^D/\Phi_{PO}^D = \exp(-VNC)$.

Differentiation of Φ_{SP}^A with respect to C leads to the form $d\Phi_{SP}^A/dC = \Phi_{ISC}^D\theta_P^A VN\exp(-VNC)$. Thus, we obtain

$$\ln(d\Phi_{sp}^A/dC) = \ln(\Phi_{ISC}^D\theta_P^A VN) - VNC \quad (5)$$

If Φ_{SP}^A as a function of C and θ_P^A are known, Φ_{ISC}^D and V can be obtained from a linear plot of $\ln(d\Phi_{SP}^A/dC)$ *vs.* C.

Results and Discussion

In order to determine the intersystem crossing quantum yield of phthalazine and pyridazine, we used these diazines as energy donor, and naphthalene-h_8

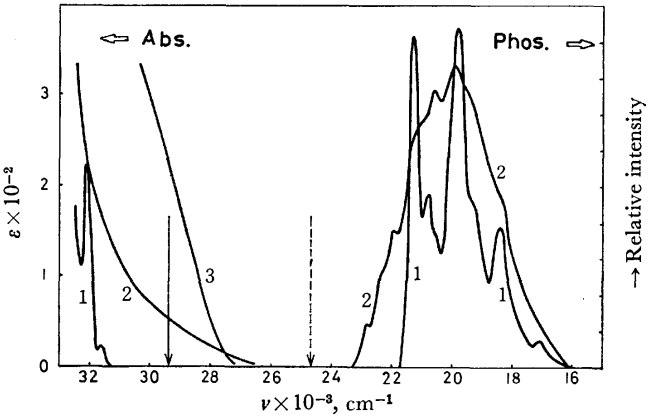

Fig. 2. Absorption and phosphorescence spectra of phthalazine and naphthalene-h_8, and absorption spectrum of pyridazine in EPA at 77°K. The phosphorescence spectra are uncorrected for the spectral sensitivity. 1,2 and 3 represent naphthalne-h_8, phthalazine and pyridazine, respectively.

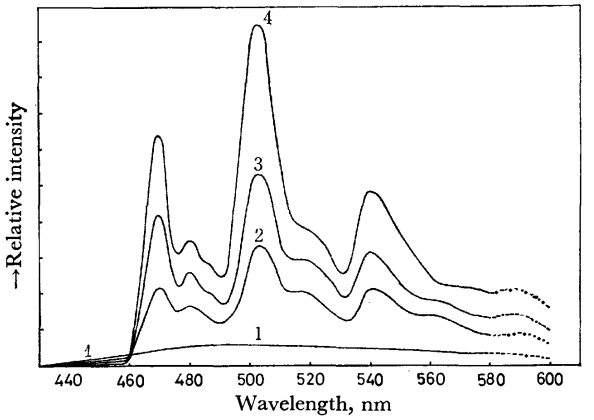

Fig. 3. Changes in the phosphorescence spectrum of phthalazine-naphthalene-d_8 system in EPA at 77°K caused by increase of the concentration of naphthalene-d_8. The concentrations of naphthalene-d_8: 1, 0; 2, 2.5×10^{-2}; 3, 5×10^{-2}; 4, 1×10^{-1} mol/l. The intensity of the phosphorescence spectra represents the relative quanta per unit wavelength interval.

and naphthalene-d_8 as energy acceptor. The absorption and phosphorescence spectra of phthalazine and naphthalene-h_8, and the absorption spectrum of pyridazine are shown in Fig. 2. The excitation frequency adopted throughout the T–T energy transfer experiments is indicated by a solid arrow, and the estimated position of electronic origin in the T_1 state of pyridazine by a dashed arrow. All the donor-acceptor combinations chosen satisfy the optimum conditions for the experiment of intermolecular T–T energy transfer.

Intersystem Crossing Quantum Yield of Phthalazine. The changes in the phosphorescence spectrum of phthalazine-naphthalene-d_8 system in EPA at 77°K caused by the increase in amount of naphthalene-d_8 are shown in Fig. 3. In the absence of phthalazine, no phosphorescence was observed from naphthalene-d_8 upon excitation at the frequency mentioned above. The spectral changes are therefore regarded as due solely to T–T energy transfer.

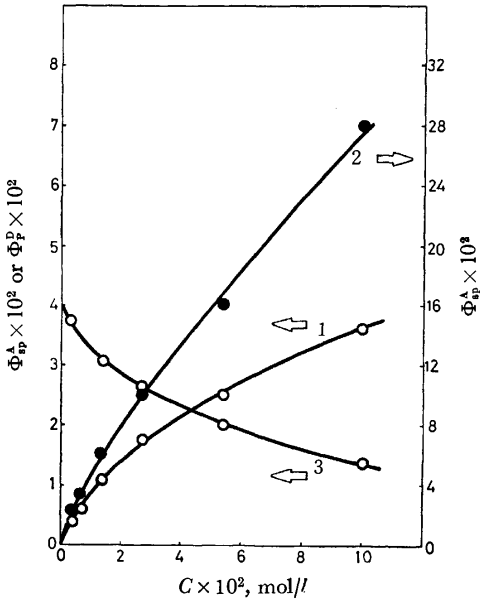

Fig. 4. Quantum yields of the sensitized phosphorescence Φ^A_{sp} of the acceptor, naphthalene-h_8 (1) or naphthalene-d_8 (2), as a function of the acceptor concentration C, and phosphorescence quantum yield Φ^D_p of the donor, phthalazine (3) as a function of C with naphthalene-d_8 as acceptor.

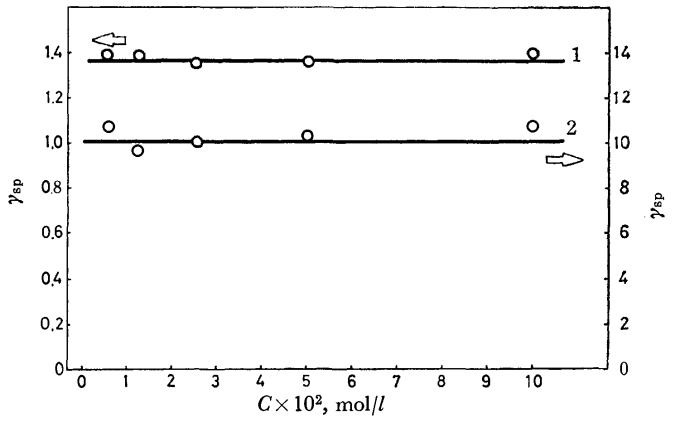

Fig. 5. Plots of γ_{sp} *vs.* C for donor-acceptor pairs: 1, phthalazine-naphthalene-h_8; 2, phthalazine-naphthalene-d_8.

TABLE 1. INTERSYSTEM CROSSING QUANTUM YIELDS OF PHTHALAZINE AND PYRIDAZINE

Donor	Acceptor	Procedure	Φ^D_{ISC}
Phthalazine	Naphthalene-h_8	A	0.45±0.05
Phthalazine	Naphthalene-d_8	A	0.50±0.05
Phthalazine	Naphthalene-h_8	B	0.51±0.05
Phthalazine	Naphthalene-d_8	B	0.48±0.05
Pyridazine	Naphthalene-d_8	B	0.24±0.05

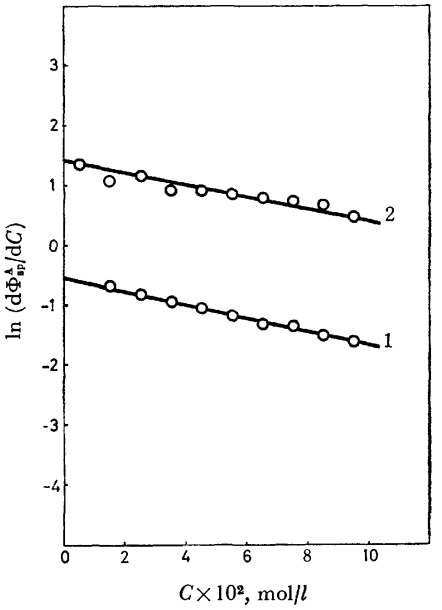

Fig. 6. Plots of $\ln(d\Phi^A_{SP}/dC)$ vs. C for donor-acceptor pairs: 1, phthalazine-naphthalene-h_8; 2, phthalazine-naphthalene-d_8.

The sensitized phosphorescence quantum yield Φ^A_{SP} of the acceptor, naphthalene-h_8 or naphthalene-d_8, as a function of C is shown in Fig. 4. A plot of the donor phosphorescence quantum yield *vs.* C with naphthalene-

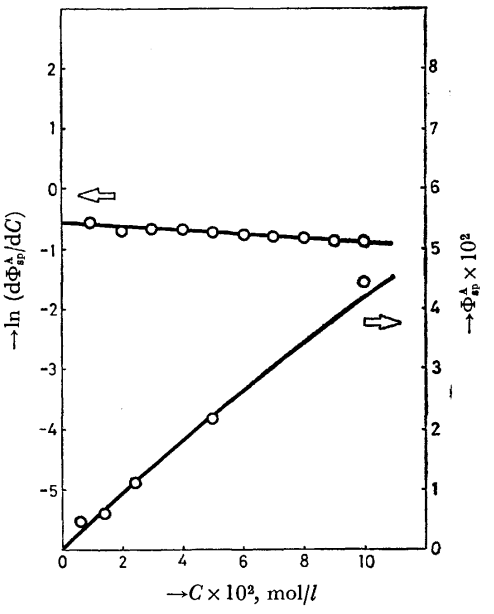

Fig. 7. Plots of Φ^A_{sp} and $\ln(d\Phi^A_{sp}/dC)$ *vs.* C for pyridazine-naphthalne-d_8 system.

d_8 as acceptor is also shown. Almost the same plot was obtained when naphthalene-h_8 was used as acceptor.

The sensitized phosphorescence quantum yields γ_{SP}, defined in Eq. (1), were calculated from the above data. Figure 5 shows plots of the resulting γ_{SP} values against the concentration of acceptor, C. As expected, γ_{SP} is independent of C, indicating the validity of the present treatment of the T–T energy transfer.

In EPA at 77°K, the phosphorescence quantum yield of phthalazine (Φ_{PO}^{D}) is known to be 0.04.[3] We found the phosphorescence quantum yields of naphthalene-h_8 and -d_8 to be 0.03 and 0.20, respectively. It has been reported that the intersystem crossing quantum yield is 0.25 for both naphthalene-h_8 and -d_8.[15] By using these values and the γ_{SP} values shown in Fig. 5, we determined the intersystem crossing quantum yield of phthalazine, Φ_{ISC}^{D}, in EPA at 77°K. The results are shown in Table 1.

On the other hand, $\ln(d\Phi_{SP}^{A}/dC)$ was plotted against C (Fig. 6). Analysis of the resulting straight lines by Eq. (5) also gives Φ_{ISC}^{D} (Table 1). The radius R of the sphere of action, defined by $V=(4\pi/3)R^3$, is found to be 15.8 Å.

From Table 1 we see that the Φ_{ISC}^{D} values for phthalazine obtained by Procedures A and B and with the use of naphthalene-h_8 and -d_8 agree within the limit of experimental error; the average value of Φ_{ISD}^{D} is 0.49. Also, the value of R, 15.8 Å, is seen to be reasonable in reference to the R values reported in the literature[12] for analogous donor-acceptor pairs involved in T–T energy transfer in rigid-glass solution, indicating that the excitation transfer occurs by the exchange mechanism.[12]

Intersystem Crossing Quantum Yield of Pyridazine. Although the lowest triplet state T_1 of pyridazine is not known, it should be of (n,π^*) type by the analogy of other monocyclic diazines. Then, the 0-0 band of the phosphorescence spectrum, if it appears at all, would be situated at about 400 nm (*cf.* Fig. 2).[7] Thus, with pyridazine as an energy donor, naphthalene can be chosen as an acceptor, as in the case of phthalazine. Because of the lack of phosphorescence, only Procedure B can be used for pyridazine.

The relation of Φ_{SP}^{A} to C for pyridazine-naphthalene-d_8 system is shown in Fig. 7, together with the relation of $\ln(d\Phi_{SP}^{A}/dC)$ to C. From these data and Eq. (5), $\Phi_{ISC}^{D}=0.24\pm0.05$ and $R=10$ Å are obtained immediately. This Φ_{ISC}^{D} value for pyridazine in EPA at 77°K is essentially the same as that reported by Cohen and Goodman,[7] although their value (0.2) was obtained from a photochemical measurement in fluid solution at room temperature. In addition, the R value mentioned above agrees with values in other analogous donor-acceptor systems.[12]

Thus, all the results obtained show that the excitation energy transfer from pyridazine to naphthalene-d_8 occurring under our experimental conditions is attributable to the exchange mechanism as in the case of phthalazine-naphthalene system.

Deactivation Path of Excitation Energy in Phthalazine and Pyridazine. The experimental results (Table 1) indicate that a fairly efficient intersystem crossing occurs between S_1^D and T_1^D to populate the T_1^D state in both phthalazine and pyridazine. The quantum yields of intersystem crossing in these *ortho*-diazines do not differ essentially from those of other diazines such as pyrazine, pyrimidine and quinoxaline. We are thus led to the conclusion that the deactivation of the excited *ortho*-diazine molecules occurs to a good extent *via* their phosphorescent triplet state, and that the weakness or lack of phosphorescence in the *ortho*-diazines is due to an anomalously fast rate of the radiationless transition from the triplet state.

Liquid-phase Adsorption from Binary Solutions on Silica Gel. The Apparent Separation Factors and the Distribution of Adsorption Sites

Tsutomu KAGIYA, Yūzō SUMIDA, and Toshihiro TACHI
Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto
(Received November 15, 1971)

The liquid-phase adsorption equilibrium of a cyclohexane-benzene mixture on a silica-gel surface, containing various quantities of physically-adsorbed water, has been studied at 30°C. The apparent separation factors (α^{ap}) have been determined on the assumption that this liquid-phase adsorption is of the Langmuir-type. It was found that the values of α^{ap} were, in general, markedly affected not only by the composition of binary solvents, but also by the amounts of physically-adsorbed water. In order to discuss this point quantitatively, the theoretical equation for estimating the apparent separation factors on a complicated solid surface having two or more types of adsorption sites has been derived on the basis of the theory of chemical equilibrium. The following three types of adsorption sites have been assumed to exist on the silica-gel surface used in this experiment: the surface silanol (σ_1), the monolayer of water (σ_2), and the multilayer of water (σ_3). The separation factors of the σ_1 and σ_3 were experimentally measured as 17.1 and 2.5. By best-fitting the above theoretical equation for α^{ap} with the observed values, the separation factor of the σ_2 site was taken to be 3.7 and the distribution of each adsorption site on the surface was determined.

It is well known that a solid surface consists of the various adsorption sites with different adsorptive capacities. In this sense, studies of the adsorption phenomena offer fundamental and interesting information on the distribution of the adsorption sites and on the chemical reactions on solid catalyst surfaces. Quantitative investigations of the adsorption behavior and the chemical structures of solid surfaces have long been made by using gravimetric methods,[1,2] spectroscopic methods,[3,4] thermodynamic methods,[5,6] and so on.[7,8] However, the quantitative studies have been restricted to the gas-solid interface, and sufficient systematic studies of the liquid-phase adsorption have not been made.[9-11]

In a previous paper,[12] the present authors studied the adsorption equilibria of various binary solutions on chromatographic silica-gel, and determined the separation factors and the numbers of moles in the adsorbed-phase. On the basis of this information, the microscopic behavior of the liquid-phase adsorption was discussed in relation to the adsorption models proposed.

In this study, the adsorption equilibria of cyclohexane-benzene mixtures have been studied on silica-gel, on which a small quantity of water had previously been adsorbed. The purposes of this work are (1) to elucidate the relationships between the apparent separation factor and the composition of solvents and/or the quantity of physically-adsorbed water, and (2) to gain information on the distribution of adsorption sites on the silica-gel surface on the basis of the simple models of adsorption sites.

Experimental

Materials. The spectro-grade cyclohexane and benzene were used as the adsorbates. They were dried with silica-gel and were then used without further purification. The adsorbent was silica-gel (100—200 mesh) for thin-layer chromatography; this silica-gel was commercially obtained. The silica-gel was dried at 160°C for 6 hr in an electric furnace,[13] and various amounts of water were physically-adsorbed to prepare four kinds of adsorbents (SG-1, 2, 3, and 4), which were of the different adsorptive capacities on the surface. The silica-gel dried at 160°C had the following characteristics: B.E.T. (N_2) area = 380—420 m²/g, and pH of aqueous suspension = 7.0.

Adsorption Equilibrium. Portions (about 10 ml) of a cyclohexane(S_1)–benzene(S_2) solution of a known composition were added to about 4 g of an accurately-weighed adsorbent in a glass ampoule. The sealed ampoule was placed in a constant-temperature bath controlled at 30±0.2°C and then allowed to equilibrate while being stirred frequently. The analysis of the equilibrium mixture was made by means of a Shimadzu gas-chromatography, GC-4AIT.

Determination of Amounts of Physically-adsorbed Water. The amounts of water physically-adsorbed on silica-gel were weighed by means of a Shimadzu micro-thermobalance, MTB-50.

Analysis of Experimental Data

The overall adsorption equilibrium of a binary solution (S_1–S_2) can be expressed as follows:

13) As will be described after, the fact that the physically-adsorbed water is nearly completely removed by the prolonged evacuation at about 160°C has been supported by many investigators, on the basis of the experimental data by the spectroscopic[3,4] and gravimetric techniques.[1]

$$(S_1)^\sigma + (S_2)^l \overset{\alpha^{ap}}{\rightleftarrows} (S_1)^l + (S_2)^\sigma \quad (1)$$

where the σ and l superscripts represent the adsorbed-phase and the liquid-phase respectively. If the surface of the adsorbent is a heterogeneous one consisting of various adsorption sites, then the apparent separation factor (α^{ap}) is defined as follows:

$$\alpha^{ap} \equiv \frac{n_1{}^l n_2{}^\sigma}{n_2{}^l n_1{}^\sigma} = \frac{n_1{}^l \sum_i n_2{}^{\sigma_i}}{n_2{}^l \sum_i n_1{}^{\sigma_i}} \quad (2)$$

where σ_i is the i-th adsorption site on the adsorbent; where $n_1{}^l$ and $n_2{}^l$ are, respectively, the numbers of moles of S_1 and S_2 in the equilibrium mixture (mol); where $n_1{}^{\sigma_i}$ and $n_2{}^{\sigma_i}$ are, respectively, the numbers of moles of S_1 and S_2 adsorbed on the σ_i site (mol), and where $n_1{}^\sigma = \sum_i n_1{}^{\sigma_i}$ and $n_2{}^\sigma = \sum_i n_2{}^{\sigma_i}$.

The numbers of moles of S_1 and S_2 in the adsorbed-phase, namely, $\sum_i n_1{}^{\sigma_i}$ and $\sum_i n_2{}^{\sigma_i}$, can be related to the Gibbs surface excess (Γ), defined by Eq. (3), by means of the following Eq. (4):[14]

$$\Gamma_2 \equiv \frac{n^0}{mS} \Delta x_2{}^l \quad (3)$$

$$\Gamma_2 = \frac{1}{mS}(x_1{}^l \sum_i n_2{}^{\sigma_i} - x_2{}^l \sum_i n_1{}^{\sigma_i}) \quad (4)$$

In these equations, m is the weight of the adsorbent (g); S, the surface area per unit of mass of the adsorbent (m^2/g); n^0, the total number of moles of the original mixture (mol), and $\Delta x_2{}^l$, the change in the mole fractions of S_2 in the solutions between before and after the adsorption.

On the other hand, supposing that the adsorption is of the Langmuir-type and that the effective molecular occupancies (A) of the two components in the adsorbed-phase are known in advance, then the surface area should be given by:[15,16]

$$S = \frac{N_A}{m}(A_1 \sum_i n_1{}^{\sigma_i} + A_2 \sum_i n_2{}^{\sigma_i}) \quad (5)$$

As has been described in the previous paper,[12] it is known that the adsorption of a cyclohexane-benzene solution on silica-gel is of the Langmuir-type. If the surface is almost completely covered by the preferentially-adsorbed component (S_2=benzene), we have:

$$S = \frac{n_{m2}^\sigma}{m} A_2 N_A \quad (6)$$

where n_{m2}^σ is the number of moles of S_2 required to form a perfect monolayer.

Since the ratio of A_1 and A_2 is a constant ($\beta = A_2/A_1$), the following equations are derived from Eqs. (3), (4), (5), and (6):

$$\sum_i n_1{}^{\sigma_i} = \frac{\beta(n_{m2}^\sigma x_1{}^l + n^0 \Delta x_1{}^l)}{x_1{}^l + \beta x_2{}^l} \quad (7)$$

and

$$\sum_i n_2{}^{\sigma_i} = \frac{\beta n_{m2}^\sigma x_2{}^l + n^0 \Delta x_2{}^l}{x_1{}^l + \beta x_2{}^l} \quad (8)$$

Hence, the apparent separation factor should be expressed by Eq. (9):[17]

$$\alpha^{ap} = \frac{\left(\beta \frac{n_{m2}^\sigma x_2{}^l}{m} + \frac{n^0 \Delta x_2{}^l}{m}\right) x_1{}^l}{\beta\left(\frac{n_{m2}^\sigma x_1{}^l}{m} + \frac{n^0 \Delta x_1{}^l}{m}\right) x_2{}^l} \quad (9)$$

As is obvious from Eq. (9), one can easily determine the apparent separation factor (α^{ap}) from the observed values of $x_1{}^l$ and $x_2{}^l$, if the values of β and n_{m2}^σ/m can be measured in any way. The effective molecular occupancies of benzene derivatives and cyclic ethers have already been reported.[12]

The value of n_{m2}^σ/m may be evaluated from the B.E.T. (N_2) area according to Eq. (6). However, there is a possibility of overestimating the value of S, because the molecular size of benzene is quite large compared with that of the nitrogen molecule. In order to avoid this risk, it is desirable to estimate directly the n_{m2}^σ/m value from the same experimental data of liquid-phase adsorption.

According to Everett,[14] the behavior of a perfect binary solution in contact with a Langmuir-type adsorbing surface can be discussed on the basis of the following equation:

$$\frac{x_1{}^l x_2{}^l}{n^0 \Delta x_2{}^l / m} = \frac{m}{n^\sigma}\left(x_2{}^l + \frac{1}{\alpha^{ap} - 1}\right) \quad (10)$$

where $n^\sigma = \sum_i n_1{}^{\sigma_i} + \sum_i n_2{}^{\sigma_i}$. Equation (10) shows that a good linear relationship holds over an entire concentration range between $m x_1{}^l x_2{}^l / n^0 \Delta x_2{}^l$ and $x_2{}^l$ if the values of α^{ap} and m/n^σ are both constant. In general, a curvature is observed in a low concentration range of a preferentially-adsorbed component (S_2) because of the existence of the various adsorption sites, the difference in the effective molecular occupancies of adsorbed components, and so on. It can, however, be expected that a linear relationship exists over a wide concentration range of S_2 when the adsorption power of S_2 is so large in comparison with that of S_1 that the surface can be almost entirely covered by S_2. The slope is nearly equal to m/n_{m2}^σ:

$$\frac{m}{n^\sigma} \simeq \frac{m}{n_{m2}^\sigma} \quad (11)$$

By substituting the n_{m2}^σ/m values obtained from the Everett plots and the β values into Eq. (9), one can examine the dependence of the composition of binary solvents on the apparent separation factors.

Results

The amounts of water adsorbed physically on silica-gel were measured; they are listed in Table 1.

Table 1. Lists of experimental results of liquid-phase adsorption of cyclohexane-benzene solution on silica-gel surface

Adsorbent	ω (mmol/g)	n_{m2}^σ/m (mmol/g)	$\bar{\alpha}^{ap}$	$\alpha^{ap}(x_2^l=1.0)$	$\alpha^{ap}(x_2^l=0)$

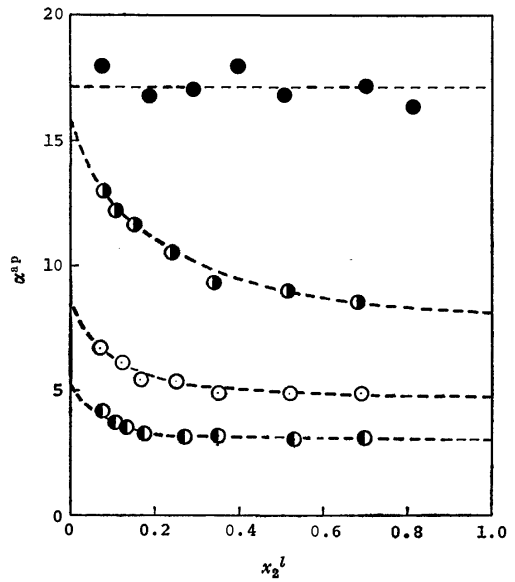

Fig. 2. Changes in apparent separation factors of cyclohexane (S_1)-benzene (S_2) mixture on various silica-gel surfaces. Silica-gel surface: ●, SG-1; ◑, SG-2; ○, SG-3; ◐, SG-4.

Figure 1 shows the analytical results for the adsorption of cyclohexane(S_1)-benzene(S_2) plotted according to Eq. (10). Although good linear relationships hold in the high concentration range of S_2, pronounced deviations are observed in the low concentration range. The degrees of deviations become larger as the amounts of adsorbed water increase. From the solpe and the intercept of the linear part in Fig. 1, the numbers of moles of adsorbed components in the high concentrations of S_2 were determined; they are listed in Table 1, together with the $\overline{\alpha^{ap}}$ values which correspond to the average values of the apparent separation factors at the high concentrations of S_2. It is obvious in Table 1 that the value of $\overline{\alpha^{ap}}$ decreases remarkably with the increase in the amount of adsorbed water, whereas the value of n_{m2}^{σ}/m is constant within the limits of experimental error. More noticeable is the fact that there exists a linear relationship over an entire concentration range when using silica-gel (SG-1) containing no physically-adsorbed water. As will be discussed below, the effective molecular occupancy of benzene is nearly equal to that of cyclohexane. Taking this fact into account, the correlation obtained for SG-1 may indicate that the α^{ap} value is to be regarded as a constant, independent of the composition of the solvents. In other words, it may be suggested that there is only one type of adsorption site on the surface of SG-1. Joining this suggestion with the results of the infrared-spectroscopic analysis of the structures of the silica-gel surface,[3,4] the surface of SG-1 is considered to be maximally hydroxylated.[1]

On the other hand, the effective molecular occupancy of benzene was reported in a previous paper to be 34.41 Å^2/molecule.[12] That of cyclohexane was calculated to be 38.46 Å^2/molecule from its molar volume on the assumption of a cube-shaped molecule. The β value is 0.895.

Using this β value and the n_{m2}^{σ}/m value in Table 1, the apparent separation factor in Eq. (9) was determined and plotted against the x_2^l, as is shown in Fig. 2. It was evident in Fig. 2 that the apparent separation factors (α^{ap}) decrease markedly with the increase in the quantity of adsorbed water. This corresponds to the fact that the adsorptive capacity of a site become small during the physical adsorption of water. Of interest is the fact that the α^{ap} value approaches the preferential coordination constant ($\alpha^{H_2O}=2.5$) of a cyclohexane-benzene solution to liquid water, which is the separation factor in the liquid-liquid interface.[18,19] It should also be noted that the α^{ap} values for SG-1 are constant, regardless of the solvent compositions,

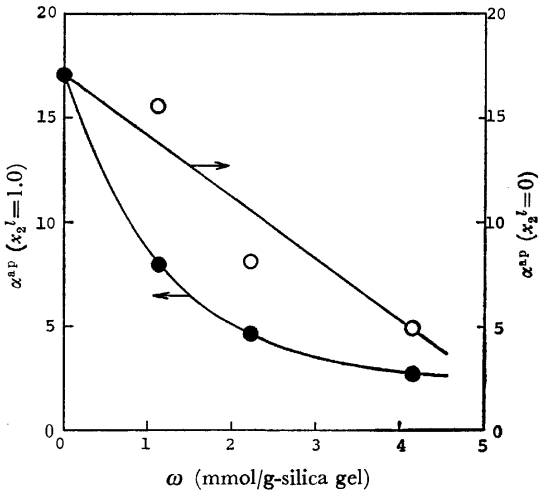

Fig. 3. Relationships between limited values of α^{ap} of cyclohexane (S_1)-benzene (S_2) mixture and amounts of physically-adsorbed water.

19) T. Kagiya, Y. Sumida, T. Watanabe, and T. Tachi, This Bulletin, **44**, 923 (1971).

while the α^{ap} values for SG-2, 3, and 4 vary with the changes in the solvent compositions. This may imply the existence of two or more types of adsorption sites on the silica-gel surface of SG-2, 3, and 4, the adsorptive capacities of which differ from each other. This problem will be discussed in the next section in connection with the models of various adsorption sites.

By extrapolating the α^{ap}–x_2^l curves to $x_2^l \to 0$ and $x_2^l \to 1$, the limited values of α^{ap} were determined; they are summarized in the last two columns of Table 1. Figure 3 shows the relationships between these limited values and the amounts of adsorbed water (ω); the $\alpha^{ap}(x_2^l=1.0)$ value decreases exponentially with the increase in the ω value, while the $\alpha^{ap}(x_2^l=0)$ value decreases almost linearly.

When we define x_2^σ as the mole fraction of S_2 in the whole adsorbed-phase, the values of x_2^σ can be expressed as follows:

$$x_2^\sigma = \frac{\alpha^{ap} x_2^l}{x_1^l + \alpha^{ap} x_2^l} \tag{12}$$

The relationships of x_2^l *vs.* x_2^σ are demonstrated in Fig. 4. The non-symmetric curves for SG-2, 3, and 4 are obviously due to the fact that the α^{ap} values change greatly with the compositions of the binary solvents.[19]

Discussion

Estimation of Apparent Separation Factors on the Basis of the Theory of Chemical Equilibrium. In the previous section, it has been indicated that the apparent separation factors are remarkably affected by both the quantity of physically-adsorbed water and the composition of the solvents. On the basis of the theory of chemical equilibrium, we examined first of all the dependence of both factors on the apparent separation factors.

In general, the silica-gel surface is well known to be a so-called heterogeneous adsorption surface, on which various adsorption sites with different adsorptive capacities are distributed. It can be considered, therefore, that the overall adsorption equilibrium of the binary solvents on such a solid surface can be expressed as the summation of the adsorption equilibria on all the adsorption sites:

$$\begin{array}{l} (S_1)^{\sigma_1} + (S_2)^l \overset{\alpha^{\sigma_1}}{\rightleftarrows} (S_1)^l + (S_2)^{\sigma_1} \\ (S_1)^{\sigma_2} + (S_2)^l \overset{\alpha^{\sigma_2}}{\rightleftarrows} (S_1)^l + (S_2)^{\sigma_2} \\ \vdots \quad\quad\quad \vdots \quad\quad\quad \vdots \quad\quad\quad \vdots \\ (S_1)^{\sigma_i} + (S_2)^l \overset{\alpha^{\sigma_i}}{\rightleftarrows} (S_1)^l + (S_2)^{\sigma_i} \\ \vdots \quad\quad\quad \vdots \quad\quad\quad \vdots \quad\quad\quad \vdots \end{array} \tag{13}$$

where $(S)^{\sigma_i}$ is the solvent component adsorbed on the adsorption site σ_i; $(S)^l$ is the solvent in the equilibrium mixture, and α^{σ_i} is the separation factor of the binary solvents on the σ_i site.

Each of the separation factors can be defined by:

$$\alpha^{\sigma_i} \equiv \frac{n_1^l n_2^{\sigma_i}}{n_2^l n_1^{\sigma_i}} \tag{14}$$

Hence, the apparent separation factor on the whole adsorption surface can be given as follows:

$$\alpha^{ap} = \frac{n_1^l \sum_i n_2^{\sigma_i}}{n_2^l \sum_i n_1^{\sigma_i}} = \frac{\sum_i n_2^{\sigma_i}}{\sum_i n_2^{\sigma_i}/\alpha^{\sigma_i}} \tag{15}$$

By using Eq. (14), the number of moles of adsorbed components on the σ_i site is:

$$n^{\sigma_i} = n_1^{\sigma_i} + n_2^{\sigma_i} = \left(1 + \frac{n_1^l}{\alpha^{\sigma_i} n_2^l}\right) n_2^{\sigma_i} \tag{16}$$

If the θ^{σ_i} is defined as the ratio of n^{σ_i} to the total number of moles of adsorbed components in the adsorbed-phase, then:

$$\theta^{\sigma_i} \equiv \frac{n^{\sigma_i}}{\sum_i n^{\sigma_i}} \tag{17}$$

Since the effective molecular occupancies of cyclohexane and benzene are nearly equal ($A_1 \simeq A_2$), the values of $\sum_i n^{\sigma_i}$ and n^{σ_i} can be approximated as follows:

$$\sum_i n^{\sigma_i} \simeq \frac{mS}{N_A A_2} \tag{18}$$

$$n^{\sigma_i} \simeq \frac{mS^{\sigma_i}}{N_A A_2} \tag{19}$$

where S^{σ_i} represents the surface area of the σ_i site, *i.e.*, $S = \sum S^{\sigma_i}$. Accordingly,

$$n_2^{\sigma_i} = \frac{\alpha^{\sigma_i} x_2^l}{x_1^l + \alpha^{\sigma_i} x_2^l} \theta^{\sigma_i} \frac{mS}{N_A A_2} \tag{20}$$

By substituting Eq. (20) into Eq. (15), we obtain:

$$\alpha^{ap} = \frac{\sum_i \alpha^{\sigma_i} \theta^{\sigma_i} / (x_1^l + \alpha^{\sigma_i} x_2^l)}{\sum_i \theta^{\sigma_i} / (x_1^l + \alpha^{\sigma_i} x_2^l)} \tag{21}$$

In Eq. (21), the α^{σ_i} value is the constant characteristic of the combination of the adsorption site and the binary solvent system, and the θ^{σ_i} is the factor (S^{σ_i}/S) depending on the distribution of the adsorption sites (or the adsorptive capacities) of the silica-gel surface. Therefore, even when using the same silica-gel and the same binary solvents, if there is a distribution of the adsorption sites on the surface, the apparent separation factor should change with the composition of the solvents. When x_2^l approaches 1.0, the α^{ap} values converge to a constant value:

$$\alpha^{ap}(x_2^l=1.0) = \frac{1}{\sum_i \theta^{\sigma}{}_i/\alpha^{\sigma}{}_i} \quad (22)$$

Similarly, by extrapolating to $x_2^l \to 0$:

$$\alpha^{ap}(x_2^l=0) = \sum_i \alpha^{\sigma}{}_i\theta^{\sigma}{}_i \quad (23)$$

Models of Adsorption Sites on the Silica-gel Surface. In order to discuss the analytical results obtained in Fig. 2 by using Eq. (21), we must determine the various types of adsorption sites on the silica-gel surface on which a small quantity of water has been previously adsorbed. Many experimental studies of the change in the silica-gel surface upon the adsorption of water have been made, and much reliable informations have been gathered.[3,20]

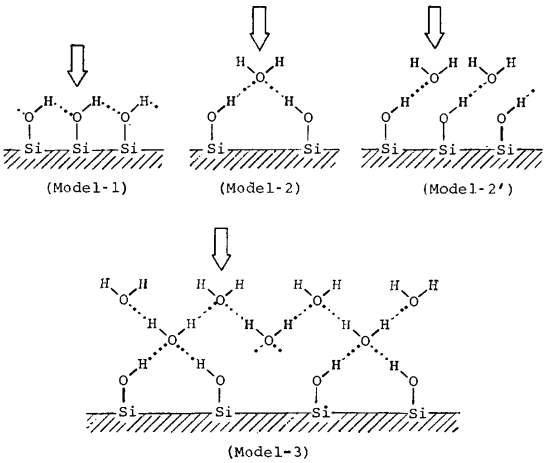

Fig. 5. Adsorption sites on silica-gel surface containing physically-adsorbed water.

From these combined infrared and gravimetric data,[1,3] it has been concluded that the physically-adsorbed water on silica-gel surface is almost completely removed by prolonged evacuation at 150—170°C, leaving a hydrogen-bonding surface formed between the adjacent silanol groups (Site Model-1 in Fig. 5). This has also been approximately, though not seriously, supported by Fripiat *et al.*[7] and Kiselev *et al.*[8] Moreover, Kiselev *et al.*[8] estimated, from their experimental results on the surface chemical reaction, that the number of surface hydroxyl groups is about 4.8 OH/100 Å^2, corresponding to one OH group per silicon atom on the surface. However, recent spectroscopic studies[21-23] have suggested the existence of three types of surface silanol, *i.e.*, the single, geminal, and paired silanol groups. In this study, the proper amounts of water were artifically adsorbed on silica-gel heated at 160°C. Therefore, the surface should be entirely covered with bridged silanol O–H groups.

The models of physically-adsorbed water have not been clear enough to permit the drawing of exact conclusions.[20] On the adsorption of a very small quantity of water, Kiselev *et al.*[7,24] proposed that a 1 : 2 hydrogen bonding was formed between one molecule of water and two adjacent surface silanols (Site Model-2), while Morimoto *et al.*[25] presented a 1 : 1 hydrogen bond mechanism (Site Model-2'). The 1 : 2 and 1 : 1 mechanisms may, of course, coexist on the surface.[20] If there are no clear-cut differences in the adsorptive capacities of the cyclohexane-benzene system on the 1 : 2 and 1 : 1 hydrogen-bonding surfaces, we can identify Model-2' with Model-2 with respect to the adsorptive capacity. This is almost certain, because the liquid-phase adsorptions on both Model-2 and Model-2' take place on the monolayer of water molecules bonded "directly" to the surface silanol.[26] A further physical-adsorption of water forms the multilayer coverage of water molecules (Site Model-3), where the liquid-phase adsorption occurs on the multilayer of water molecules bonded "indirectly" to the silanol.[26]

On the basis of such speculations, we conventionally classified the adsorption sites of silica-gel containing the physically-adsorbed water into the following three groups: Model-1 (the surface silanol, σ_1), Model-2 (the monolayer of water, σ_2), and Model-3 (the multilayer of water, σ_3).

Distribution of Adsorption Sites on the Silica-gel Surface. The next problem is to determine the separation factor

26) In the case of binary solvent system in which the proton-accepting power of solvent component is considerably large, compared with that of water, the solvent component may destroy the coverage of water molecules to adsorb "directly" to the surface silanol. However, the possibility can be neglected in the cyclohexane-benzene system employed here.

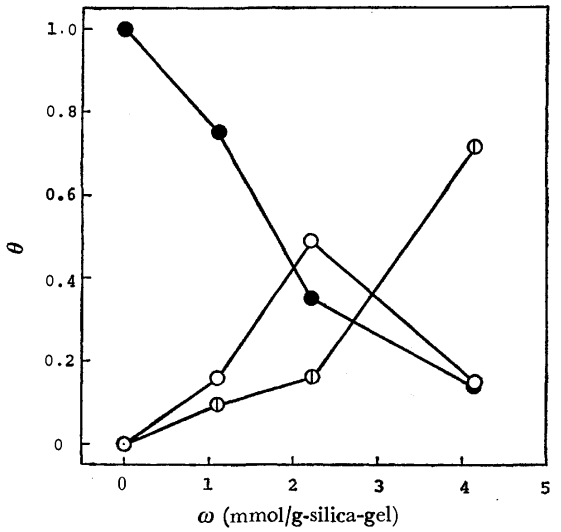

Fig. 7. Distribution of adsorption sites on silica-gel surfaces containing physically-adsorbed water.
Adsorption site: ●, σ_1; ○, σ_2; ⓘ, σ_3.

(α^{σ_i}) of cyclohexane-benzene on each adsorption site, σ_i. According to the above speculations, the surface of SG-1 is a so-called homogeneous σ_1 site. Therefore, the $\alpha^{\sigma}{}_1$ value can be taken to be 17.1 from the experimental data in Table 1. Supposing that, in Model-3, the silanol groups exert little influence on the adsorptive capacity of the adsorption surface, the value of α^{σ_3} on the multilayer of water may be considered to be approximately equal to the preferential coordination constant ($\alpha^{H_2O}=2.5$) to liquid water.[18,19]

The value of α^{σ_2} cannot be measured by the use of this experimental technique, since it is impossible to prepare artifically a complete monolayer of water molecules on the silica-gel surface. However, we calculated the α^{σ_2} value by using Eq. (21). That is, by simulating the experimental points of the apparent separation factors obtained from Eq. (9) with Eq. (21), in which the values of x_1^l, x_2^l, α^{σ_1}, and α^{σ_3} are known, the best-fitting α^{σ_2} value was determined, together with θ^{σ_1}, θ^{σ_2}, and θ^{σ_3} values. The value of α^{σ_2} was calculated to be 3.7. It is reasonable that the α^{σ_2} value is slightly larger than the α^{σ_3} value.

The agreement between the experimental results and the theoretical curves of Eq. (21) is shown in Fig. 6. Though slight deviations are observed in the low concentration range of benzene, they may be overcome by considering four or more types of adsorption sites. However, it can be considered, on the basis of the fairly good accordance, that the above speculation regarding adsorption sites is quite reasonable.

In Fig. 7, each of the calculated θ^{σ} values is plotted against the amounts of physically-adsorbed water (ω). The curves represent the distribution of the adsorption sites on the silica-gel surface. On the silica-gel surface (SG-2) containing a very small quantity of adsorbed water, the σ_1 site gradually decreases and the σ_2 and σ_3 sites gradually increase. On the surface of SG-3, the σ_2 site occupies about half of the adsorption surface. The further adsorption of water (SG-4) brings about decreases in the σ_1 and σ_2 sites and a prominent increase in the σ_3 site. These tendencies are also in harmony with chemical intuition.

On the basis of this discussion, it may be reasonable to conclude that Eq. (21) is useful in offering not only valuable information on the liquid-phase adsorption on complicated solid surface, but also microscopic information on the structures of the surface.

The Crystal and Molecular Structure of Dimethyltin Bis(*N,N*-dimethyldithiocarbamate)

(Received November 22, 1971)

The crystal and molecular structure of dimethyltin bis(*N,N*-dimethyldithiocarbamate), $[(CH_3)_2Sn\{S_2CN(CH_3)_2\}_2]$, has been determined by single crystal X-ray diffraction. The crystals are orthorhombic; *Fdd*2; $a=25.478\pm0.008$, $b=35.323\pm0.011$, $c=6.936\pm0.006$ Å, $Z=16$. The tin atom has a distorted octahedral environment. The tin atom and the four sulfur atoms lie approximately on the same plane, with two Sn–S bond distances of 2.515 ± 0.008 and 2.497 ± 0.008 Å and two longer Sn–S distances of 2.954 ± 0.007 and 3.061 ± 0.008 Å, while the methyl groups are in *trans* positions; average Sn–C$=2.15\pm0.04$ Å. The SnSC(S)N skeletons on both sides of the tin atom are approximately planar, and the average bond distances are S–C$=1.72\pm0.03$, C–N$=1.31\pm0.03$, and N–C(Me)$=1.49\pm0.04$ Å.

Many structural investigations have been reported on transition metal complexes of dialkyldithiocarbamates. Most of them have a typical octahedral structure. On the other hand, only a few structures of non-transition metal complexes have been reported.[1]

As a part of the structural studies of organotin compounds, we have recently reported[2] the crystal and molecular structure of dimethyltin chloride *N,N*-dimethyldithiocarbamate (to be abbreviated as Me_2Sn-Cl(dtc) hereafter). It has been found that the coordination around the tin atom is a distorted trigonal bipyramid, the two methyl groups being in equatorial positions.

Dimethyltin bis(*N,N*-dimethyldithiocarbamate)(to be abbreviated as $Me_2Sn(dtc)_2$ hereafter) is the *N,N*-dimethyldithiocarbamate substitute for $Me_2SnCl(dtc)$, and this complex must have a hexa-coordinated structure. IR and PMR investigations[3] have shown that the complex has a distorted octahedral configuration, the two methyl groups being in *trans* positions. In order to determine the exact configuration, crystal structure analysis has been undertaken by means of X-rays.

The present investigation will also contribute to the understanding of the bonding nature of the tin atom in penta- and hexa-coordinated dimethyltin complexes. Schlemper has determined the structure of dimethyltin bis(8-hydroxyquinolinate);[4] he found that the Me–Sn–Me angle ($110.7\pm0.8°$) is remarkably close to the tetrahedral angle. With the aid of a qualitative MO approach, he proposed that the bonding could involve sp^3 hybrid orbitals on the tin participating in the methyl groups and three-center bonds in the oxinate groups. It would be very interesting to determine whether the structure of $Me_2Sn(dtc)_2$ can be understood in terms of such a bonding scheme or not.

Experimental

The crystals were recrystallized from a chloroform-ethanol solution to form colorless needles elongated along the *c* axis.

Approximate unit-cell dimensions were obtained from osillation and Weissenberg photographs taken around the *c* axis, while the accurate cell dimensions were determined on a Rigaku automated four-circle diffractometer.

Crystal Data. $C_8H_{18}N_2S_4Sn$, *F.W.*$=389.1$, orthorhombic, $a=25.478\pm0.008$, $b=35.323\pm0.011$, and $c=6.936\pm0.006$ Å, $U=6242$ Å^3, $D_m=1.650$ and $D_x=1.656$ g·cm^{-3} for $Z=16$. The systematic absences (*hkl*: $h+k\neq2n$, $k+l\neq2n$; 0*kl*: $k+l\neq4n$: *h*0*l*: $h+l\neq4n$; *hk*0: $h\neq2n$, $k\neq2n$; *h*00: $h\neq4n$; 0*k*0: $k\neq4n$, and 00*l*: $l\neq4n$) uniquely define the space group as *Fdd*2.

The three-dimensional intensity data for $2\theta\leq45°$ were collected on the diffractometer at room temperature, using Zr-filtered Mo$K\alpha$ radiation. The integrated intensity was recorded by the ω-2θ scan technique:

Range of scan (in 2θ)$=(2.0+0.70\tan\theta_c)°$ and

Starting angle of the scan$=(2\theta_c-1.0)°$,

where θ_c is the calculated value of the Bragg angle for $\lambda(\text{Mo}K\alpha_1)=0.70926$ Å. At each end of the scan, the background counts were measured for 10 sec by the stationary crystal-stationary counter technique. The intensity data were corrected for the background counts and for the usual Lorentz and polarization effects. No absorption correction was applied, since the linear absorption coefficient is not very large ($\mu=21.1$ cm^{-1} for Mo$K\alpha$). Finally, two sets of 1143 independent reflections, $F(hkl)$'s and $F(\bar{h}\bar{k}\bar{l})$'s, were collected in order to consider the anomalous dispersion effect.

Determination and Refinement of the Structure

The initial coordinates of the tin atom were easily determined from the three-dimensional Patterson function computed by using $F(hkl)$'s. The four sulfur atoms could also be located from the Patterson and the minimum function, but two of them were located about 3.0 Å from the tin atom. The first Fourier synthesis was computed with the phases based on the tin atom only, and the four sulfur atoms were found at the positions expected from the Patterson function. The two nitrogen atoms and the four carbon atoms were then found in the Fourier map with the phases based on the tin and the four sulfur atoms. The

remaining four carbon atoms were found in the successive Fourier maps. At this stage, the structure factor calculation gave a discrepancy facor, $R=\sum||F_o|-|F_c||/\sum|F_o|$, of 0.20 for the $F(hkl)$ reflections. The atomic-scattering factors used were taken from those of Hanson and his co-workers.[5]

The block-diagonal least-squares refinement was carried out on a HITAC 5020E computer at the University of Tokyo, and also on a FACOM 230-60 computer at the Kyoto University, with a program, HBLS IV, written by Dr. T. Ashida.[6] Eight cycles of the refinement with isotropic temperature factors for all non-hydrogen atoms gave the R value of 0.17 for a set of $F(hkl)$ data. The anisotropic temperature factors for all non-hydrogen atoms were then introduced, and three cycles of the refinement reduced the R value to 0.095.

At this stage, the corrections for the anomalous dispersion effect were introduced for the tin and the sulfur atoms (for Mo$K\alpha$, $\Delta f'=-0.60$, $\Delta f''=1.90$ for Sn, and $\Delta f'=0.1$, $\Delta f''=0.2$ for S).[7]

The structure was refined using the combined data of $F(hkl)$ and $F(\bar{h}\bar{k}\bar{l})$ by starting from the coordinates representing the molecules of one direction of the polar axis and also from those of the opposite direction. Through refinement, the following weighting scheme was applied;

$$w = 1 \quad \text{for } F_o > 0$$
$$w = 0.2 \quad \text{for } F_o = 0$$

After several cycles, the refinement converged; the values of the R and the residual (defined as $\sum w(|F_o|-|F_c|)^2$) were 0.089 and 7385, respectively, for the coordinates representing the molecules of one direction of the polar axis, while those of the opposite direction were 0.092 and 7638. The relatively small values of the correction for the anomalous scattering of Sn and S atoms might have given such a small difference. This difference might not be significant, but the former structure was chosen as the final result only because it gave the smaller discrepancy. All of the coordinates of this structure are in good agreement with those of the opposite structure within the range of the estimated

standard deviations.

The final atomic coordinates and the anisotropic thermal parameters obtained by using the combined data are listed in Table 1. The observed and calculated structure factors are listed in Table 2.[8]

Results and Discussion

The Geometry Around the Tin Atom. The molecular structure and the numbering system of $Me_2Sn(dtc)_2$ are shown in Fig. 1. The bond distances and angles around the tin atom are given in Table 3.

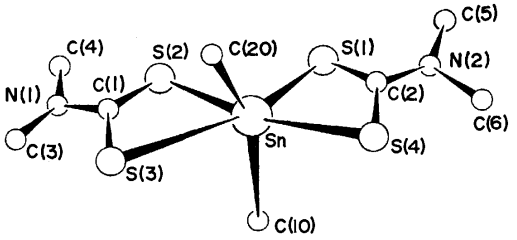

Fig. 1. Molecular structure of dimethyltin bis(*N*,*N*-dimethyldithiocarbamate) with the numbering of atoms.

The configuration about the tin atom could be described as a hexa-coordinated octahedron, with the two methyl groups attached to the tin atom in the *trans* positions. This configuration would be in agreement with the proposed structure. However this description would not correspond to that of the bonding nature.

It may be easily concluded by an inspection of Table 4, which lists the sulfur-metal bond distances and angles in some of the transition and non-transition metal complexes of dithiocarbamates, that there is a remarkable difference between them. In the transition metal complexes, all the sulfur-metal bond distances are almost equal, while there are two kinds of bond distances in the non-transition metal complexes.

In the present compound, the Sn–S(1) and Sn–S(2) bond distances (2.525(8) and 2.497(8) Å) are slightly longer than the sum of the covalent radii of Sn and S(2.44 Å);[22] they are nearly equal to those in $Me_3Sn(dtc)$[20,21] (2.47(1) Å) and the equatorial Sn–S bond in $Me_2SnCl(dtc)$[2] (2.48(1) Å). On the other hand, the Sn–S(3) and Sn–S(4) distances (2.954(7) and 3.061(8) Å) are significantly longer than the Sn–S(1) and Sn–S(2) bonds. These bonds might be considered as weak coordination bonds. Such weak metal-sulfur bonds have been found in other tin and arsenic complexes, but not in transition metal complexes. These facts suggest, that the bonding nature of the tin atom in the present complex is quite different from those in transition metal complexes. Furthermore, the C–Sn–C angle of 136(1)° shows an appreciable deviation from

the angle in the exact *trans* position (180°).

From these observations it might be considered that the bonding on the tin atom could involve sp^3 hybrid orbitals participating in covalent bonds to the two methyl groups and two sulfur atoms, S(1) and S(2). Since there are two additional tin-sulfur interactions (Sn–S(3) and Sn–S(4)), which originate from the electronegativity of S(3) and S(4) and the electropositivity of Sn, the steric effects of S(3) and S(4) would increase the C–Sn–C angle from a tetrahedral one to 136(1)° and would decrease the S(1)–Sn–S(2) angle to 82.7(3)°. Such a conception could explain why the sp^3 tin atom occasionally takes an apparently hexa-coordinated octahedral configuration.

Another approach to this problem has been proposed by Schlemper.[4] With regard to the structure of $(CH_3)_2Sn(C_9H_6NO)_2$, he postulated that the sp^3 tin atom has two normal covalent bonds to the methyl

groups, and the two 'three-center bonds' to the oxinate groups. In a way similar to Schlemper's,[4] the angles of C(10)–Sn–M(1), C(20)–Sn–M(1), C(10)–Sn–M(2), C(20)–Sn–M(2), and M(1)–Sn–M(2) were calculated to be 98, 94, 92, 95, and 153° respectively, where M(1) and M(2) are the midpoints of the lines connecting S(2) and S(3), and S(1) and S(4), respectively. None of these values is, however, a tetrahedral angle. It seems, then, that his conception can not be applied to the present compound.

The distortion of the tetrahedral configuration about the tin atom in $Me_3Sn(dtc)$,[20,21] in particular the widening of the average C–Sn–C angles (119(1) and 118(1)° respectively in monoclinic and orthorhombic forms) and the narrowing of the average C–Sn–S angle (95(1) and 95(1)°), can be well understood by the considerations described above. The short non-bonded Sn—S interactions (3.16 and 3.33 Å) affect the slight distortion of the tetrahedral configuration in $Me_3Sn(dtc)$. In $Me_2SnCl(dtc)$, the substitution of a methyl group by a chlorine atom results in an increase in the covalent character of the non-bonded Sn—S interaction, thus giving a shorter Sn—S distance (2.79(1) Å) and a higher distortion of the configuration about the tin atom. In the present complex, $Me_2Sn(dtc)_2$, the substitution of the methyl group by a (dtc) group changes the coordination number of the tin atom and gives a large distortion. The slightly longer Sn–S bond distances and the larger C–Sn–C angle in $Me_2Sn(dtc)_2$ may be due to the difference in the steric effect and the electronegativity of the ligand groups attached to the tin atom.

It has been suggested that a linear relation holds between the degree of *s*-character of the tin orbitals directed to the carbon atom and the PMR coupling constants.[26] The C–Sn–C bond angles and the coupling constants of some dimethyltin complexes are summarized in Table 5. As is shown in Table 5, however, the increase in the C–Sn–C angle is probably due not only to the *s*-character of the Sn–C bond, but also to the steric effect around the tin atom.

Geometry of the Ligand Group. The bond distances and angles in the ligand groups, *N,N*-Dimethyldithiocarbamate, are given in Table 6(a).

One of the two lignad groups is planar within ±0.03 Å; however, in the other group deviations from the least-squares plane are about ±0.1 Å (Table 6(b)). The dihedral angle between these planes is 10.1°.

The S(1)–C(2), S(4)–C(2), S(2)–C(1), and S(3)–C(1) distances are 1.75(2), 1.68(2), 1.73(3), and 1.73(3) Å respectively. These values are close to those in $Me_2SnCl(dtc)$, and also to those in other dialkyldithiocarbamates (Table 7). The differences in these bond distances are not significant within the limits of experimental error. The C(1)–N(1) and C(2)–N(2) distances of 1.32(3) and 1.30(3) Å are equal to those in other dithiocarbamate complexes. These values suggest that the carbon(sp^2)-nitrogen(sp^2) bond has a high double-bond character, as was to be expected from the IR studies; a similar conclusion was suggested for $Me_2Sn(dtc)_2$. The four N–C (alkyl) bond distances, 1.48(4), 1.49(4), 1.50(4), and 1.50(4) Å, are equal, within the limits of experimental error, to the N–C single-bond distance (1.48 Å).

Crystal Structure. The crystal structure of $Me_2Sn(dtc)_2$ projected onto the (001) plane is shown in Fig. 2. The short intermolecular atomic contacts less than 4.0 Å are summarized in Table 8. None of them is short enough to suggest any significant deviation from

An ESR Study of Some Substituted Pyridine *N*-Oxide Copper(II) Complexes

Derek P. FREYBERG, Toshiyuki ISOBE, and Seizo MISUMI
Inorganic Chemistry Laboratory, Faculty of Science, Kyushu University, Fukuoka

(Received December 6, 1971)

The ESR (methanol solution, frozen solution, powder, and single crystal) spectra of $[CuL_4](ClO_4)_2$, where L=pyridine *N*-oxide, α-picoline *N*-oxide, β-picoline *N*-oxide, γ-picoline *N*-oxide, and 2,6-lutidine *N*-oxide, and of $[CuL_6](ClO_4)_2$, where L=pyridine *N*-oxide and γ-picoline *N*-oxide, have been obtained. The preparation of hexa(γ-picoline *N*-oxide) copper(II) perchlorate is reported. The solution and frozen solution spectra indicate a very similar bonding in all the complexes, with moderately ionic metal-oxygen. The powder spectra reveal all the tetrakis complexes to be axially symmetric; though tetra(γ-picoline *N*-oxide) copper(II) perchlorate shows a reversal of the usual order of the *g*-values. This is explained in terms of the packing interactions within the crystal structure, rather than metal-ligand interaction. All the single crystal spectra are characteristic of axially symmetric complexes. Hexa(pyridine *N*-oxide)copper(II) perchlorate gives an isotropic ESR spectrum, but this does not seem to be due to exchange interaction. Hexa(γ-picoline *N*-oxide)copper(II) perchlorate gives an axial ESR spectrum with a considerable tetragonal misalignment.

Although there has been considerable interest in transition metal complexes with aromatic amine *N*-oxides (particularly pyridine *N*-oxide) in recent years,[1] the principal interest lies in copper(II) in binuclear complexes formed with *e.g.* $CuCl_2$. We report here the ESR (methanol solution, frozen methanol solution (−150°C), powder, and single crystal) spectra of $[CuL_4](ClO_4)_2$ where L=pyridine *N*-oxide (pyNO), α-picoline *N*-oxide (αNO), β-picoline *N*-oxide (βNO), γ-picoline *N*-oxide (γNO), and 2,6-lutidine *N*-oxide (lNO); and $[CuL_6](ClO_4)_2$ where L=pyNO and γNO. The preparation of $[Cu(\gamma NO)_6](ClO_4)_2$ is reported for the first time.

Experimental

The aromatic amine *N*-oxide ligands were prepared from the amines by the method of Ochiai.[2] The chloroform extract, after removal of the chloroform by rotary evaporation, was used without further purification. The copper(II) complexes were prepared by the usual methods.[3,4] $[Cu(\gamma NO)_6](ClO_4)_2$ was prepared by the reaction of hot acetone[5] solutions of $Cu(ClO_4)_2 \cdot 6H_2O$ and γNO in 1:20 mole ratio. On cooling, pale lime-green needles separated. They were filtered off, washed with acetone and dried over silica gel. If the filtrate is allowed to stand further, dark green crystals of $[Cu(\gamma NO)_4](ClO_4)_2$ and not $[Cu(\gamma NO)_6](ClO_4)_2$ are formed. Analysis: found C; 47.2, H; 4.61, N; 9.18%; calcd for $CuC_{36}H_{42}N_6O_{14}Cl_2$ C; 47.1, H; 4.61, N; 9.19%.

Reflection spectra of powdered samples and absorption spectra were taken on Hitachi EPS-3T and EPS-2 spectrophotometers, respectively. ESR spectra were taken on a JEOL JES ME-3X spectrometer with a variable temperature attachment operating at about 9.3 GHz. Calibration was made with a Mn^{2+}/MgO powder standard ($g_4=1.981$). Solutions for absorption and ESR measurements were approximately 1:20 Cu:L in MeOH. Single crystal spectra were taken on a holder similar to that described by Hathaway and Billing,[6] except that it was made of silica rod. The same face of the crystal can be mounted (using silicone grease) onto two mutually perpendicular faces of the rod, and the rod rotated in the spectrometer cavity. The crystal was thus rotated about three orthogonal axes, and spectra were taken every 15° in each rotation.

Results

The *g*- and *A*-values obtained from ESR spectra of the solution and frozen solution samples together with absorption maxima of the solutions are shown in Table 1.

The lNO spectra show a rather large $g_\parallel$ and A^*, but a low g^*. This might be due to steric interaction involving the methyl groups of ligand molecules. The value of α^2, a measure of the covalency of the metal-ligand bond,[7] changes very little indicating that the bonding in all cases is similar.

$[Cu(lNO)_4](ClO_4)_2$	2.241	2.054	4.5	15600
$[Cu(pyNO)_6](ClO_4)_2$	Isotropic	$g=2.189$	—	12300/9600sh
$[Cu(\gamma NO)_6](ClO_4)_2$	2.313	2.102	3.1	13000/10500sh

Notes: 1. $g_{\parallel}$, $g_{\perp}\pm0.005$; $\Delta E\pm50$ cm^{-1}
2. $G=(g_{\parallel}-2)/(g_{\perp}-2)$

The g-values obtained from ESR spectra of the powder samples together with reflection maxima of the complexes are shown in Table 2.

All the spectra are characteristic of axial symmetry[6] and the values of $g_{\parallel}$ and $g_{\perp}$ were obtained by the method of Kneubühl.[8] For the tetrakis complexes, the single crystal g-values were identical with the powder g-values within experimental error. The spectrum of $[Cu(\gamma NO)_6](ClO_4)_2$, despite analytical purity of the sample, displayed lines due to $[Cu(\gamma NO)_4](ClO_4)_2$ present as an impurity as well as to the hexakis complex. However, the g-value assignments were confirmed by the spectrum of $[Cu(\gamma NO)_6](ClO_4)_2$ diluted 1:500 in $[Zn(\gamma NO)_6](ClO_4)_2$, which gave $g_{\parallel}=2.326$, $A_{11}=110$ G, $g_{\perp}=2.087$, and $A_{\perp}=30$ G. The usual reason for the observation of an isotropic spectrum, as for $[Cu(pyNO)_6](ClO_4)_2$, is that the tetragonal axes are grossly misaligned. Exchange coupling[9] between local copper(II) ions does not seem to occur, as the spectrum of $[Zn(pyNO)_6](ClO_4)_2$ containing 1% Cu^{2+} is identical with that of the undiluted complex.

Discussion

The solution and frozen solution spectra display no unusual features; the ESR and solution spectra are very similar for all the complexes. Thus we can state that the bonding within a single unit is identical for all the complexes.

The powder spectra, on the other hand, show an unexpected feature, *viz.*, $g_{\perp}$ is greater than $g_{\parallel}$ for $[Cu(\gamma NO)_4](ClO_4)_2$ and not for any of the other complexes. The value of $G(=g_{\parallel}-2/g_{\perp}-2)$ has been used[9] to explain distortions from tetragonal symmetry. The result $G>4.0$ indicates good alignment of the tetragonal axes within the crystal, and $G<4.0$ indicates misalignment. Thus the αNO, βNO, and lNO complexes show aligned tetragonal axes and the pyNO complex shows misaligned ones. G has no meaning in the case where $g_{\perp}$ is greater than $g_{\parallel}$. Single crystal spectra of all the complexes followed the theoretical pattern for a complex with axial symmetry[10] *i.e.* $g^2=g_{\perp}^2\sin^2\theta+g_{\parallel}^2\cos^2\theta$ for rotations about two axes and $g=g_{\perp}$ for rotation about the third axis. These spectra confirmed the assignments of $g_{\parallel}$ and $g_{\perp}$ for the tetrakis complexes.

The reflection spectra of the five tetrakis complexes are all similar, and it is likely that the crystal environment is also similar. Hence, a reversal of the g-values for $[Cu(\gamma NO)_4](ClO_4)_2$ is unexpected. Usually, a value of $g_{\perp}$ greater than $g_{\parallel}$ indicates a d_z^2 ground state;[11] however, this gives a $g_{\parallel}$ close to the free electron value ($g=2.002$). In the present case, $g_{\parallel}=2.066$, a value considerably higher than is usual for d_z^2. Also, a d_z^2 ground state does not favour square planar coordination and is usually observed in trigonal complexes. For these reasons, and also because the solution and frozen solution spectra are similar to those of the other complexes, we conclude that the reversal of the g-values is not in the metal atom environment but in the crystal packing. This is supported by examination of structural models based on the crystal structure of $[Cu(pyO)_4](ClO_4)_2$ which has been described by Lee *et al.*[12] These models indicate that a methyl group in the α- or β-position does not significantly alter the size of the complex unit but γ-substitution does. It may be noted also, that the ESR spectrum of Cu^{2+} in $[Pd(\gamma NO)_4](ClO_4)_2$ is normal *i.e.* $g_{\parallel}>g_{\perp}$.

Transfer-hydrogenation and Transfer-hydrogenolysis. I. Transfer-hydrogenation of Cyclooctadienes Catalyzed by Dichlorobis(triphenylphosphine)iron(II)

Takeshi NISHIGUCHI and Kazuo FUKUZUMI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received December 9, 1971)

Hydrogen transfer from a number of organic compounds to olefins in a homogeneous system was studied. In the case of hydrogen transfer to 1,5-cyclooctadiene, using dichlorobis(triphenylphosphine)iron(II) as the catalyst, dihydroxybenzenes, such as pyrocatechol and hydroquinone, were much superior to *prim*- and *sec*-alcohols, 1-dodecanethiol, and cyclohexene as hydrogen donors.

In almost all catalytic hydrogenations of olefins, molecular hydrogen has been used as the hydrogen source. However, the hydrogenation in which hydrogen transfer from organic compounds takes place has also been reported;[1] it has been called transfer-hydrogenation,[2] transhydrogenation[3] or conjugated hydrogenation.[4] Transfer-hydrogenation has several advantages because it needs no hydrogen gas. For example, the experimental operation is easy, and a completely homogeneous system is made available. It has been reported that primary alcohols, secondary alcohols,[4,5] and six-membered cyclic olefins[2] donate hydrogen to olefins to give aldehydes, ketones, and aromatic compounds respectively in the presence of heterogeneous catalysts, such as metallic palladium and nickel. As for the reactions of homogeneous systems, Itatani and Bailar have reported that methyl linoleate[6] or soybean oil[7] are hydrogenated to monoenes selectively under the pressure of nitrogen gas when benzene–methanol is used as the solvent and platinum or palladium complexes as the catalysts. In this case, methanol is inferred to be the hydrogen souce. It has also been reported that the hydrogenation of methyl linoleate occurs in the presence of dihalobis(triphenylphosphine)nickel(II) as the catalyst and tetrahydrofuran or benzene as the solvent.[8] Studies of homogeneous transfer-hydrogenation have thus far been performed incidentally to hydrogenation by molecular hydrogen; no systmatic investigation of the reaction conditions or the reaction mechanism has yet been undertaken. We also found that the olefin linkages of methyl linoleate were reduced in 2-propanol in the presence of bis(2,4-pentanedionato)nickel(II) under an atmosphere of nitrogen; however, the reproducibility of the reaction was discouragingly bad, perhaps because the catalyst decomposed to give an insoluble substance.[9]

The work reported here was undertaken in order to study transfer-hydrogenation systematically; some of the results have been reported in a preliminary communication.[10] There it was shown that $FeBr_2(PPh_3)_2$ and $FeCl_2(PPh_3)_2$ are the most active catalysts of the $MX_2(PPh_3)_2$ complexes, where M is Fe(II), Co(II), or Ni(II), and where X is Cl, Br, or I, and that 1,5-cyclooctadiene (1,5-COD), which is presumed to have the strongest coordinating ability of all the cycloolefins attempted, is most readily reduced.

Results and Discussion

The experiments in this study were carried out under conditions such as follows, unless otherwise noted. For instance, a dioxane solution of 1,5-COD (concn., 0.5M), dichlorobis(triphenylphosphine)iron(II) (0.05M), and pyrocatechol (2.0M), sealed in a Pyrex glass tube under a vacuum (10^{-2} mmHg), was heated at 200±1°C for six hours. Though the catalyst did not dissolve completely at room temperature, it did so at once at the reaction temperature and gave no insoluble materials until the end of the reaction. In this reaction, not only the hydrogenation of 1,5-COD to cyclooctene (COE) and cyclooctane (COA), but also the isomerization to 1,4- and 1,3-cyclooctadiene (1,4-COD and 1,3-COD), occurred. From the composition of the reaction mixtures, the following reaction parameters were derived: the selectivity is the percentage of COE in the reduced products, and the percentage of hydrogenation was calculated on the assumption that both double bonds of cyclooctadienes (COD) are reduced. (See the footnotes of Table 1.) Therefore, if the selectivity is 100%, the reaction may be regarded as having been completed at 50% hydrogenation. The percentage of conversion is the percentage of the 1,5-COD consumed. A part of the results are summarized in Table 1.

Hydrogen Donors. At first, *prim*- and *sec*-alcohols, and cyclohexene, which have been reported as hydrogen donors, were examined, but their ability to donate hydrogen was quite weak. Then, taking a hint from

a) 1,5-COD (concn., 0.5M), hydrogen donors(2.0M) and the catalyst (0.05M) were heated in dioxane for 6 hr.
b) Conversion of 1,5-COD to COA, COE, 1,3-COD and 1,4-COD.
c) Conversion of COD to COA and COE.
d) This is given by $\frac{2\times COA+COE}{2}$.
e) Given by $\frac{COE}{COA+COE}\times 100$.
f) The yield was too low to evaluate.

the reaction in which *p*-benzoquinone abstracts hydrogen from organic compounds to form hydroquinone,[1] we tried to use polyhydroxybenzenes with hydroxyl groups at the *ortho* or *para* positions as hydrogen donors; we founs that they were much superior to the other organic compounds tried. That is, the percentage of hydrogenation was 64—57% in the case of the polyhydroxybenzenes (Nos. 4—10 in Table 1), while it was less than 10% in the cases of the other compounds (Nos. 11—18). The order of the ability to give hydrogen, based on the percentage of hydrogenation, was found to be as follows: pyrogallol>pyrocatechol>hydroquinone$\gg$*n*-dodecanethiol>1-octanol>cyclohexene>2-octanol>*n*-dodecanol>*n*-dodecyl amine.
When *prim*- or *sec*-alcohols were used, small amounts of aldehydes or ketones were detected by IR analysis. However, when the polyhydroxybenzenes were used, a tarry material was formed and no quinones were identified. This might be at least partly attributable to the thermal instability of the quinones, though further study is needed. In fact, *o*- and *p*-benzoquinone gave tarry substances when heated in dioxane at 200°C.

Unexpectedly, as is shown in Table 1 and Figs. 5 and 6, not only were COA and COE formed, even if no hydrogen donor was added especially, but also the percentage of hydrogenation was higher in these cases (Nos. 18 and 23) than in the cases where the alcohols, *n*-dodecanethiol, cyclohexene and *n*-dodecyl amine, were used (Nos. 11—17 and 23). Hydrogen transfer from the solvent, dioxane, to 1,5-COD was inferred, for the possibility of the disproportionation of the diene may be rejected on the following grounds: cyclooctatrienes, which would result from the disproportionation of the diene, were not detected by gas-chromatographic analysis, and the total amount of the detected eight-membered cyclic hydrocarbons was almost equal to the amount of 1,5-COD charged as a reactant.

Effect of Gases in the Sealed Tubes. It is well known that some metal complexes react with oxygen or nitrogen,[11] and that radical reactions are apt to be influenced by the presence of oxygen. Therefore, the experiments under atmosphers of oxygen, air, nitrogen, and carbon dioxide were carried out (Nos. 5—8), and compared with the one done under a vacuum. The results showed that the compositions of the reaction mixtures were identical within the limits of experimental error under any gas or in a vacuum.

Reaction Temperature. The percentage of conversion was 16% at 160°C, 46% at 180°C, 97% at 200°C, and more than 99% at 240°C. As the reac-

tion temperature was raised, the percentage of hydrogenation also increased, but the selectivity had almost no connection with the reaction temperature at relatively high conversions.

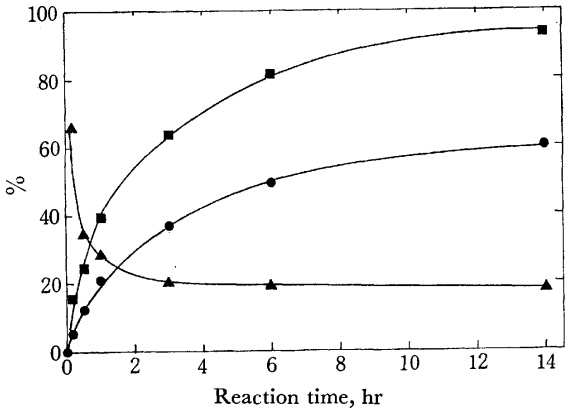

Fig. 2. Time dependence of the reaction parameters.
●: % Hydrogenation, ▲: Selectivity, ■: % Conversion

Reaction Time. At an early stage of the reaction, all the reaction parameters except that of the selectivity were in proportion to the reaction time (Figs. 1 and 2). The lack of an induction period suggests that the time for the formation of an active species is short, though induction periods have been reported in a few homogeneous hydrogenations.[12]

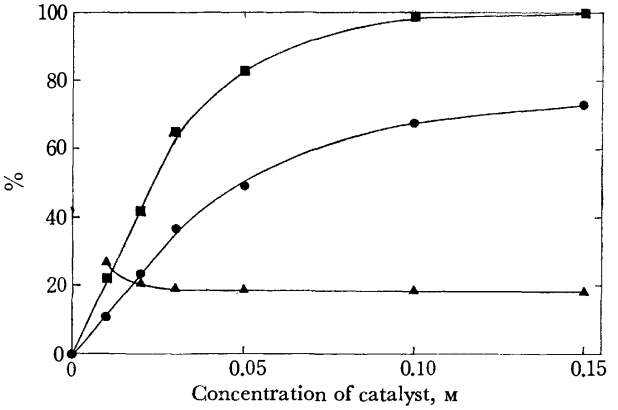

Fig. 4. Dependence of the reaction parameters on initial concenttation of the catalyst.
●: % Hydrogenation,
■: % Conversion, ▲: Selectivity

Concentration of the Catalyst. The percentage of hydrogenation and the percentage of conversion were proportional to the initial concentration of the catalyst below 0.05M (Figs. 3 and 4). This fact suggests that the rate of the hydrogenation is first order in relation to the initial concentration of the catalyst.

Concentration of Pyrocatechol. The influence of the

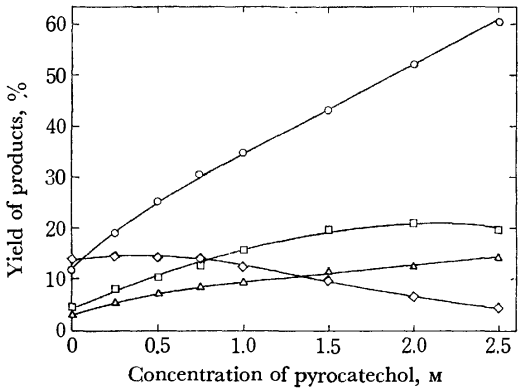

Fig. 5. Dependence of yield of the products on initial concentration of pyrocatechol.

initial concentration of a hydrogen donor was examined by the use of pyrocatechol, which has a strong ability to supply hydrogen and a high solubility (Figs. 5 and 6). The interpretation of the results was complicated by the fact that the solvent, dioxane, gave some hydrogen, as has been mentioned previously. If the hydrogen-donating capacity of the solvent is equal to that of pyrocatechol at a concentration of about 0.8M in the solvent, the percentage of hydrogenation and the percentage of conversion may have a linear relation to the initial concentration of pyrocatechol.

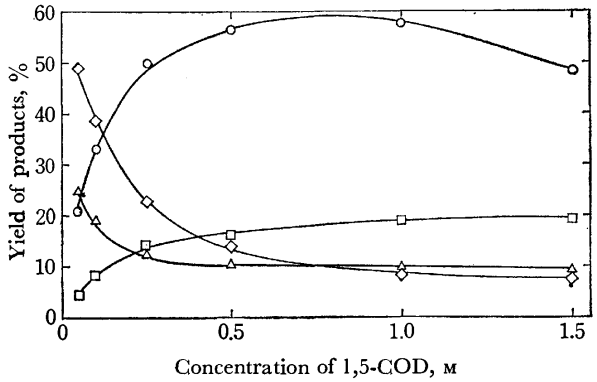

Fig. 7. Depencence of yield of the products on initial concentration of 1,5-COD.
○: COA, △: COE, □: 1,3-COD,
◇: 1,4-COD

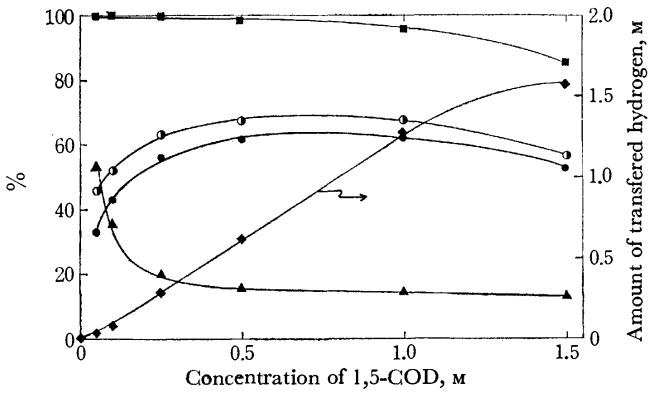

Fig. 8. Depencence of the reaction parameters and the amount of transfered hydrogen on initial concentration of 1,5-COD.

◑: % Conversion of COD, ▲: Selectivity, ◆: Amount of transfered hydrogen which is given by [% Hydrogenation] ×[Initial concentration of 1,5-COD]×1/100

Concentration of 1,5-COD. The percentage of hydrogenation and the percentage of conversion of COD were found to have maximum values against the initial concentration of 1,5-COD (Figs. 7 and 8). That is, the higher the concentration, the larger the degree of the hydrogenation, until it decreased, perhaps because of the deficiency of the hydrogen donor. This fact suggests that at least two 1,5-COD molecules are involved in the reduction and that they act not only as hydrogen acceptors, but also as ligands having the function of co-catalysts, for if merely one molecule of 1,5-COD is involved, the lower values of the parameters at the lower concentration of 1,5-COD cannot be explained. Therefore, it is difficult to decide whether the susceptibility of 1,5-COD to the reduction is due to its nature as a hydrogen acceptor or as a ligand in activating the catalyst. The amount of transferred hydrogen which caused the reduction was roughly proportional to the initial concentration of 1,5-COD at concentrations from 0.3M to 1.0M.

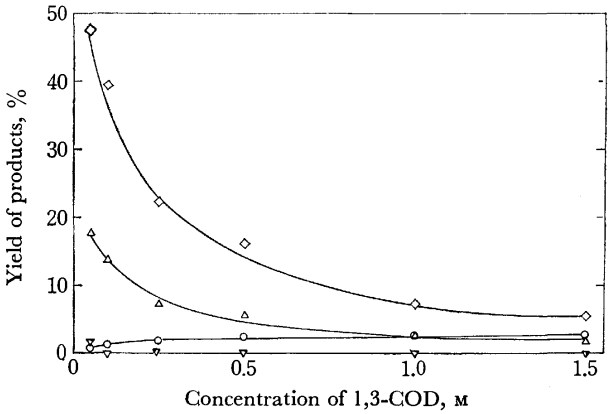

Fig. 9. Depencence of yield of the products on initial concentration of 1,3-COD.

◇: 1,4-COD

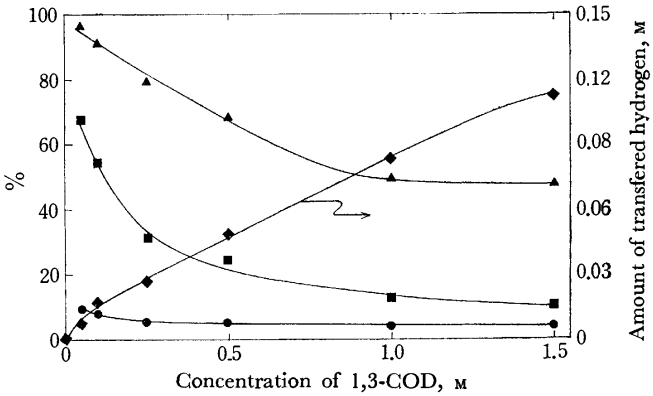

Fig. 10. Depencence of the reaction parameters and the amount of transfered hydgogen on initial concentration of 1,3-COD.
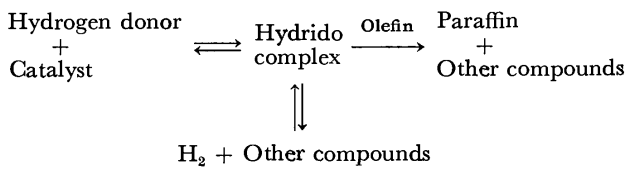
●: % Hydrogenation of 1,3-COD, ■: % Conversion of 1,3-COD, ▲: Selectivity, ◆: Amount of transfered hydgogen which is given by [% Hydrogenation]×[Initial concenration of 1,3-COD]×1/100

The lower the initial concentration of 1,5-COD, the higher the ratio of 1,4-COD in the reaction mixture. It can thus be inferred that the lower the concentration of COD at constant concentrations of the catalyst and the hydrogen donor, the easier it is to reach an equilibrium among COD. From this inference and our observations, the isomerization of 1,3-COD to 1,4-COD can be expected to occur more easily at a lower initial concentration of the conjugated diene; this expectation was confirmed (Figs. 9 and 10). 1,3-COD did not show such a co-catalystic action as 1,5-COD did, and the percentage of hydrogenation decreased constantly as the initial concentration of 1,3-COD increased.

General Discussion. It is well known that hydrido complexes are formed as active species not only in

homogeneous hydrogenation by molecular hydrogen, but also in the isomerization of olefins, where alcohols act as co-catalysts.[4,13] Moreover, hydrido complexes are obtained in the reaction of Rh(I), Os(I), Ir(I), and Pt(II) complexes with alcohols.[14] In analogy with these reactions, a hydrido complex is presumed to be involved as an active species in the transfer-hydrogenation.

It has been reported that alcohols give molecular hydrogen and carbonyl compounds when heated in the presence of catalysts in not only a heterogeneous but also in a homogeneous system.[15] Therefore, the evolution of molecular hydrogen during the transfer-hydrogenation reaction may not be so unreasonable. However, perhaps hydrogen is not transferred in the gaseous form in the reaction, for the evolution of molecular hydrogen from pyrocatechol was not observed upon heating at 200°C without the catalyst, and the hydrogenation of 1,5-COD by molecular hydrogen did not take place without the catalyst. Such a reaction as is shown in the following equation should not be regarded as a transfer-hydrogenation *via* molecular hydrogen.



The mechanistic study of the transfer-hydrogenation is now in progress.

Experimental

Materials. The dichlorobis(triphenylphosphine)iron(II) was prepared according to the method of Pignolet *et al.*[15] and was recrystallized from toluene. The dioxane, 1,5-COD, 1,3-COD and cyclohexene were purified by distillation over metallic sodium. The purified 1,5-COD was found to be contaminated with 0.2% of COA, 0.7% of COE, 0.5% of 1,3-COD, and 0.9% of 1,4-COD. The Pyrocatechol, hydroquinone, and pyrogallol were purified by recrystallization from benzene. All the other reagents were of a commercial G. R. grade. The mixture of cyclooctatrienes was prepared by the method of Cope and Hockstein.[16]

An Example of Transfer-hydrogenation. 1,5-COD (0.0541 g, 0.5 mmol), pyrocatechol (0.22 g, 2.0 mmol), and $FeCl_2(PPh_3)_2$ (0.0326 g, 0.05 mmol) were put into a Pyrex glass tube which had been sealed at one side. Into the mixture, dioxane was then stirred with a wire, and the total volume of the solution was made 1.0 m*l*. The solution was degassed with a Dry Ice-acetone bath and a vacuum line, and sealed in a vacuum (10^{-2} mmHg). The sealed tube was heated for 6 hr in a silicon-oil bath kept at 200±1°C. To analyze the reaction mixture, gas chromatography was performed at 80°C with a Hitachi Perkin-Elmer instrument equipped with a flame ionization detector. A 2 m×6 mm stainless steel column packed with 25% of 1,2,3-tris(2-cyanoethoxy)-propane on Celite 545 was used.

The other transfer-hydrogenations were carried out in the same way.

When the glass tubes were sealed under gases, the volume of the gases in the reaction vessels was three times that of the solution.

An Attempted Hydrogenation by Molecular Hydrogen without Catalysts. A dioxane solution of 1,5-COD (0.5M, 10 m*l*) was placed in a 50 m*l* stainless steel autoclave, and the air in the vessel was replaced with hydrogen of 10 atm. After being heated for 6 hr at 180°C, the solution was analyzed by gas chromatography.
