$(+)_{589}$-C_2-cis(O)-$[Co(L\text{-ser})_2en]I$. A saturated aqueous solution of potassium iodide was added to the concentrated eluate until a white precipitate of potassium perchlorate was no more produced, and then the precipitate was filtered out. To remove of iodine formed in the solution, following procedure was carried out. To a mixture of the filtrate and a little amount of ethanol, an appropriate amount of ether was added until two layers were formed. The resultant was transferred into a separatory funnel and was shaken well. A yellow ether layer, in which iodine dissolved, was removed, and the red aqueous solution containing the complex was more several times shaken with ether, until the ether layer became nearly colorless. Then the red solution was kept in a refrigerator overnight. The crystals deposited were filtered and washed well with methanol until impure colorless crystals were washed away. The crude complex was recrystallized from water by adding ethanol and ether. The red crystals were filtered, washed with ethanol-water mixture and ethanol, and dried in air. Yield: 0.07 g.

$(-)_{589}$-C_1-cis(O)-$[Co(L\text{-ser})_2en]I$. By adding a large amount of ethanol and ether to the concentrated eluate, the dark red oily substance was separated. The supernatant was decanted out, and the oily substance was stirred well with a large amount of ethanol until it became powdery. After kept in a refrigerator overnight, the red powder was filtered, washed with ethanol-water mixture and ethanol, and dried in air. When a small amount of acetone was added to an aqueous solution of the crude compound, a red crystalline substance was formed. After filtering out this substance, an excess of sodium iodide and ethanol were added to the mother liquor. Then the complex iodide deposited as red crystals. It was filtered, washed with ethanol-water mixture and ethanol, and dried in air. Yield 0.2 g.

$(+)_{589}$-C_1-cis(O)-$[Co(L\text{-ser})_2en]ClO_4$. A crude perchlorate was prepared by a similar method to that used for the isolation of $(-)_{589}$-C_1-*cis(O)*-isomer. It was recrystallized from water by adding acetone. The red crystals were filtered, washed with acetone-water mixture and acetone, and dried in air. Yield: 0.2 g.

$(-)_{589}$-C_2-cis(O)-$[Co(L\text{-ser})_2en]I \cdot 2H_2O \cdot 1/2serH$. This complex was isolated as pinkish red crystals from a concentrated sixth eluate by the same method as that used for the isolation of $(+)_{589}$-C_2-*cis(O)*-isomer. Yield: 0.04 g.

4) Measurements. The electronic absorption spectra were measured with a Beckman DU spectrophotometer. The CD spectra were recorded on a Roussel-Jouan Dichrograph and the ORD curves were checked with a Yanagimoto recording spectropolarimeter, Model-185. All measurements were made in aqueous solutions at room temperature.

Results and Discussion

Three geometrical isomers, *trans(O)*, C_2-*cis(O)*, and C_1-*cis(O)*, are possible for the bis(glycinato)-ethylenediaminecobalt(III) complex (Fig. 1). Of these isomers, *trans(O)* and C_1-*cis(O)* isomers were optically resolved with $(-)_{546}$-K[Co(edta)] and

C_2-*cis*(*O*) isomer. The six possible isomers of the bis(L-serinato)ethylenediaminecobalt(III) complex, Δ- and Λ-*trans*(*O*), Δ- and Λ-C_2-*cis*(*O*) and Δ- and Λ-C_1-*cis*(*O*), were completely separated by ion-exchange column chromatography. Their absorption and CD curves are shown in Figs. 3—5 and the curves of *trans*(*O*) isomers of bis(L-alaninato)ethylene-

diaminecobalt(III) complex in Fig. 6. The analytical data of the isomers obtained in this work are summarized in Table 1 and the spectral data in Tables 2 and 3.

Characterization of Isomers. The isomers from the first and second eluates in column chromatography of bis(L-serinato) complex can be assigned confidently to the *trans(O)* structure from the remarkable splitting of their first absorption bands (Fig. 3 and Table 2).[9] The isomers from the remaining four eluates are of *cis(O)* structure because of the symmetrical pattern of their first absorption bands (Figs. 4 and 5 and Table 2) and of the ion-exchange chromatographic behavior as described in "Experimental section." In a previous work,[9] we found that the second absorption band maximum of the C_2-*cis(O)* isomer of bis(glycinato)-ethylenediamine complex locates at higher energy than that of the C_1-*cis(O)* isomer and that the $\log(D_I/D_{II})$ value in the C_2-*cis(O)* isomer is larger in absolute value than that in the C_1-*cis(O)* isomer, where D_I and D_{II} are the optical densities at the absorption maxima of the first and the second absorption bands, respectively. The C_1-*cis(O)* and C_2-*cis(O)* structures of the bis(glycinato) complexes have been confirmed by PMR.[9] The second absorption bands of the present four *cis(O)* isomers are at 84.3, 83.3, 83.6, and 85.1×10^{13} sec^{-1} for the 3rd, 4th, 5th, and 6th eluates, respectively. From these values, it is assumed that the isomers from the 3rd and 6th eluates are C_2-*cis(O)* and the 4th and 5th C_1-*cis(O)*. This assignment brings about that the $\log(D_I/D_{II})$ value is −0.09 for each of the two C_2-*cis(O)* isomers, −0.02 for one C_1-*cis(O)* (from 4th eluate) and −0.04 for another C_1-*cis(O)* isomer (from 5th eluate).

It is well known that the absolute configuration of the cobalt(III) complexes with chelated α-aminoacidato ligands can be assigned from the sign of major CD band in the first absorption band region, *i.e.*, the Λ[12] complex has (−) major CD band and the Λ one (+).[7] The assignment was supported by Dabrowiak and Cooke[11] from their PMR study on several α-aminoacidato complexes including *trans(O)*-[Co(L-ala)$_2$en]$^+$. Therefore each of the $(+)_{589}$-isomers in the present work has Λ-configuration and each of the $(-)_{589}$-isomers Λ-configuration (Figs. 2—6 and Table 3). According-

			91.5	(−0.11)

a) In the unit of 10^{13} sec^{-1}.

ly, it is concluded that the six L-serinato isomers obtained are *Λ-trans(O)*, *Λ-trans(O)*, *Λ-C_2-cis(O)*, *Δ-C_1-cis(O)*, *Λ-C_1-cis(O)*, and *Δ-C_2-cis(O)* in the elution order, which agrees also with that found in the case of [Co(ox)(L-ser)$_2$]$^-$.

The iodide of *Δ-C_2-cis(O)*-[Co(L-ser)$_2$en]$^+$ isomer was isolated with L-serine (Table 1). This fact suggests that the coordinated L-serinate ion is partly freed from the coordination sphere in the isolation process. This suggestion is supported from the fact that the yield of C_2-*cis(O)* isomer was considerably low in comparison with that of C_1-*cis(O)* isomer in the case of [Co(gly)$_2$en]$^+$ or [Co(L-ser)$_2$en]$^+$ and that the optical resolution of C_2-*cis(O)*-[Co(gly)$_2$en]$^+$ was unsuccessful because of the partial decomposition. Similar low yields were also reported for the C_2-*cis(O)*-isomers of bis(glycinato)(D-propylenediamine)cobalt(III)[6] and bis(L-hydrogenaspartato)(D-propylenediamine)cobalt(III)[13] complexes. Though it seems from these facts that the C_2-*cis(O)* structure is less stable than the

13) Y. Kojima and M. Shibata, *ibid.* **10**, 2382 (1971).

C_1-cis(O) structure, further studies should be carried out for substantiation of this remark.

Circular Dichroism Spectra. In the first absorption band region, the *trans(O)* isomer shows two CD bands of same sign whose dominant peak is in the lower energy side. This agrees well with the pattern, which is predicted from the CD spectra of the *trans(N)* oxalatobis(α-aminoacidato) complexes.[4,7] It appears that, of the *trans(O)* isomers here studied, *Λ-trans(O)*-[Co(L-ala)$_2$en]$^+$ somewhat deviates from the group behavior in CD (Fig. 6). It has been known that the configurational and vicinal contributions to CD are almost separable and additive for the cobalt(III) complexes with optically active α-aminoacidato ligands.[1,7] From this viewpoint, the following relationships were applied for the CD curves of L-serinato and L-alaninato isomers.

$$\Delta\varepsilon(2\text{L}) = 1/2\{\Delta\varepsilon(\Lambda_{2\text{L}}) + \Delta\varepsilon(\Delta_{2\text{L}})\}$$
$$\Delta\varepsilon(\Lambda) = 1/2\{\Delta\varepsilon(\Lambda_{2\text{L}}) - \Delta\varepsilon(\Delta_{2\text{L}})\}$$

Each calculated configurational curve agrees with the observed curve of the corresponding glycinato isomer (Fig. 7). For this reason, there is nothing strange about the CD curve of *Λ-trans(O)*-[Co(L-ala)$_2$en]$^+$, whose configurational CD also consists of two bands in the first absorption band region.

The CD patterns of C_1- and *C_2-cis(O)* isomers are not so distinctive in the first absorption band region (Figs. 4, 5 and 7). In the second absorption band region, however, the CD pattern of the *C_1-cis(O)* isomer differs significantly from that of the *C_2-cis(O)* isomer. That is, the *C_1-cis(O)* isomer shows well split three CD bands whose signs are +, −, and +, listing from lower energy for the *Λ* isomer (Figs. 2 and 5), whereas the *C_2-cis(O)* and *trans(O)* isomers show one or two CD bands in appearance. The same relationship was also observed for the CD spectra of the C_1 and C_2 isomers of oxalatobis(α-aminoacidato) complexes.[7] These facts suggest that the CD pattern in the second band region favorably reflects the symmetry of the complex ion.

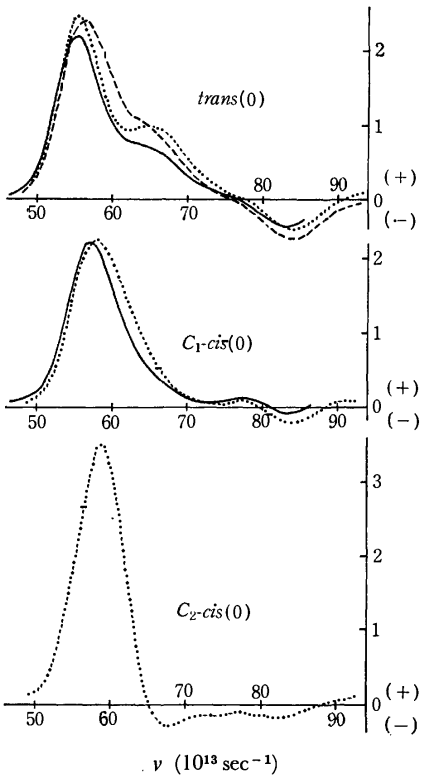

Fig. 7. Configurational effect curve of *Λ-trans(O)*-, *Λ-C_1*- and *Λ-C_2-cis(O)*-[Co(L-ser)$_2$en]$^+$ (·····) and *trans(O)*-[Co(L-ala)$_2$en]$^+$ (----); and observed curves of *Λ-trans(O)*- and *Λ-C_1-cis(O)*-[Co(gly)$_2$en]$^+$ (——).

Studies on New Derivatives of 8-Quinolinol as Chelating Agents. II. Chelate Formation of Some Aminomethyl Derivatives Derived from 8-Hydroxyquinoline-2-carbaldehyde with Metal Ions

Takehisa HATA and Toyozo UNO

Faculty of pharmaceutical Sciences, Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received October 30, 1971)

The reactions of new oxine derivatives with additional coordinative sites, 8-hydroxyquinoline-2-carbaldehyde, 2-(*p*-chlorophenylaminomethyl)-, 2-(naphthylaminomethyl)-, 2-(*p*-tolylaminomethyl)-, and 2-(*o*-hydroxyphenylaminomethyl)-8-hydroxyquinoline, and *N,N'*-bis(8-hydroxy-2-quinolylmethyl)ethylenediamine (abbreviated as HQA, CAMHQ, NAMHQ, TAMHQ, PAMHQ, and BHQED respectively), with Cu^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}, Mn^{2+}, Mg^{2+}, and Ca^{2+} were investigated by potentiometric and spectrophotometric methods. The stability constants of the metal chelates were determined in a 50 v/v % aqueous dioxane solution at 25°C. The stability constants of metal chelates of HQA, NAMHQ, CAMHQ, and TAMHQ with a ligand-to-metal ratio of 2 : 1 are lower than those of oxine. In these ligands, steric hindrance due to the aminomethyl group results in lower stability constants of the metal chelates. PAMHQ reacts as a terdentate ligand with Cu^{2+}, Mn^{2+}, Mg^{2+}, and Ca^{2+} to form 1 : 1 chelates by coordination with quinoline nitrogen and two phenolate oxygens. BHQED reacts with Cu^{2+}, Co^{2+}, Ni^{2+}, Cd^{2+}, and Mn^{2+} to form a protonated chelate, MHL^+, in the acid region, while, in the neutral region, one proton is released from the protonated chelate to form a deprotonated chelate, ML, by coordination with six donor groups, namely, two imino and hydroxyl groups, and two quinoline nitrogens. BHQED acts as a sexadentate ligand to form the most stable chelates among these oxine derivatives.

In a previous paper,[1] we reported the syntheses of new oxine derivatives, such as 8-hydroxyquinoline-2-carbaldehyde(HQA), 2-(*p*-chlorophenylaminomethyl)-8-hydroxyquinoline(CAMHQ), 2-(naphthylaminomethyl)-8-hydroxyquinoline(NAMHQ), 2-(*p*-tolylaminomethyl)-8-hydroxyquinoline(TAMHQ), 2-(*o*-hydroxyphenylaminomethyl)-8-hydroxyquinoline(PAMHQ), and *N,N'*-bis-(8-hydroxy-2-quinolylmethyl)ethylenediamine(BHQED), with additional coordinative sites. Their color reactions with metal ions and acid dissociation constants were also reported.

The influence of the introduction of the additional groups into these ligands may be reflected in the stability of the metal chelates in the following way. If additional coordinative groups, such as aminomethyl, imino, and hydroxyl groups, participate in the coordination, the formation of stable multidentate chelates may be expected. On the contrary, the steric hindrance of these groups at the 2 position may lower the stability of the metal chelates. In this case, the effect of these groups may be greater than that of the alkyl and aryl groups, which have been known to lower the stability of the metal chelates by their steric hindrance. The effect of the additional coordinative groups on the chelate formation may be discussed through a comparison of the stability of the metal chelates formed from these ligands with that of the metal chelates of oxine. From these points of view, we investigated the chelate formation of the oxine derivatives in a 50 v/v % aqueous dioxane solution by potentiometric and spectrophotometric methods.

Experimental

Reagents. The preparations of 8-hydroxyquinoline-2-carbaldehyde, 2-(*p*-chlorophenylaminomethyl)-, 2-(naphthylaminoethyl)-, 2-(*p*-tolylaminomethyl)-, 2-(*o*-hydroxyphenylaminomethyl)-8-hydroxyquinoline, and *N,N'*-bis-(8-hydroxy-2-quinolylmethyl)ethylenediamine were described in the previous paper.[1] Stock solutions of metal chlorides and and perchlorates were standardized by titration with EDTA. All the other compounds used were of a reagent-grade purity.

Potentiometric Titration. The details of the experimental conditions and the method have been described previously.[1] As the ligands and the metal chelates are in soluble in water, the titrations were carried out in a 50 v/v % aqueous dioxane. A solution containing a ligand (10^{-3} M), perchloric acid (10^{-3} M for HQA, CAMHQ, NAMHQ, TAMHQ, and PAMHQ, and 2×10^{-3} M for BHQED), and metal chloride or perchlorates (from 5×10^{-4} M to 10^{-2} M) was titrated with a standard KOH solution.

Spectrophotometric Measurements. The absorption spectra were measured with a Hitachi recording spectrophotometer model 124, and measurements were made in a 50 v/v% aqueous dioxane solution. The pH of the solutions was adjusted with KOH and $HClO_4$ solutions or a Walpole buffer (CH_3COOH–CH_3COONa).

Results and Discussion

HQA, NAMHQ, CAMHQ, and TAMHQ. The results of the molar-ratio method showed that HQA, CAMHQ, and NAMHQ react with metal ions to form 2 : 1 ligand-to-metal chelates. Accordingly, the titration was carried out in the molar ratio of 2 : 1. With HQA, CAMHQ, and NAMHQ, similar curves were obtained. The titration curves of HQA in the presence and the absence of metal ions are shown in Fig. 1. In the cases of Co^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}, Mn^{2+}, Mg^{2+}, and Ca^{2+}, each titration curve of the three ligands gives an inflection at $a=1$, indicating that the dissociation reaction of the proton from the ligand occurs between $a=0$ and $a=1$, and that the formation of metal chelates occurs between $a=1$ and $a=2$. However, as is shown in Fig. 2, the titration curves of TAMHQ-metal systems differ from those of HQA-, CAMHQ-, and NAMHQ-metal systems. With all the metal ions except for Cu^{2+} and Ni^{2+}, the titration curves

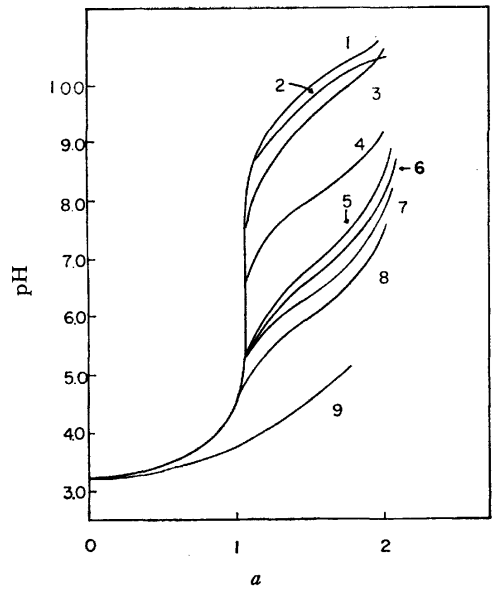

Fig. 1. Potentiometric titration curves of molar ratio of HQA to metal ions 2 : 1 in 50 v/v% aqueous dioxane solution at 25°C μ=0.1(KCl); abscissa a represents moles of KOH added per mole of ligand; curve 1, ligand; 2, Ca^{2+}; 3, Mg^{2+}; 4, Mn^{2+}; 5, Cd^{2+}; 6, Ni^{2+}; 7, Co^{2+}; 8, Zn^{2+}; 9, Cu^{2+}.

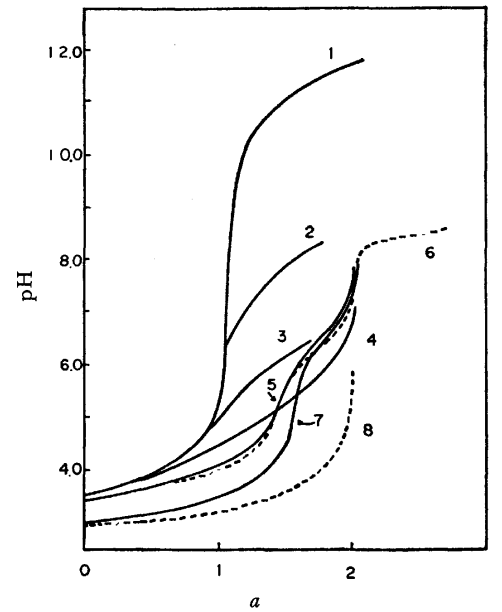

Fig. 2. Potentiometric titration curves of molar ratio of TAMHQ to metal ions 2 : 1 and 1 : 1; the solid line and broken line represent the curves of molar ratio 2 : 1 and 1 : 1, respectively; curve 1, ligand; 2, Mn^{2+}; 3, Cd^{2+}; 4, Zn^{2+}; 5 and 6, Ni^{2+}; 7 and 8, Cu^{2+}.

are analogous to those of HQA, CAMHQ, and NAMHQ, and they show an inflection at a=1. However, with Cu^{2+}, the curve of the 2 : 1 molar ratio gives an inflection at a=1.5, while in the curve of the 1 : 1 molar ratio, an inflection is no longer observed at a=1.5. The titration curves for the Cu^{2+} ion suggest the following reaction process. The dissociation reaction of the proton from the ligand and the formation reaction of the 1 : 1 chelate CuL^+ occur

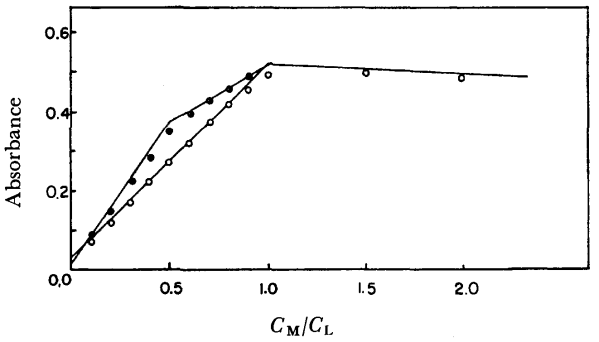

Fig. 3. The determination of molar ratio of TAMHQ to Cu^{2+} in 50 v/v% aqueous dioxane solution; abscissa represents the molar ratio of metal to ligand; ○, pH 4.80; ◑, pH 6.92.

simultaneously between a=0 and a=1.5, and this chelate reacts with the second ligand to form the 2 : 1 chelate ML_2 in the 2 : 1 molar ratio solution. On the other hand, in the 1 : 1 solution, the ligand reacts with the Cu^{2+} ion to release two protons and form the 1 : 1 chelate in one step.

$$H_2L^+ \rightleftharpoons HL + H^+ \qquad K_2=\frac{[HL][H^+]}{[H_2L^+]} \tag{1}$$

$$Cu^{2+} + L^- \rightleftharpoons CuL^+ \qquad K_{ML}=\frac{[CuL^+]}{[Cu^{2+}][L^-]} \tag{2}$$

$$CuL^+ + L^- \rightleftharpoons CuL_2 \qquad K_{ML_2}=\frac{[CuL_2]}{[CuL^+][L^-]} \tag{3}$$

In fact, the results of the molar-ratio method given in Fig. 3 show that TAMHQ forms the 1 : 1 chelate below pH 4.80 and the 2 : 1 chelate together with the 1 : 1 chelate at about pH 6.90. With Ni^{2+}, the titration curves of the 2 : 1 and 1 : 1 molar ratios are identical between a=0 and a=2, but the hydrolysis of the Ni^{2+} ion occurs at about a=2 in the 1 : 1 solution. From these facts, it is considered that TAMHQ reacts with the Ni^{2+} ion to form a protonated chelate, M·HL·L between a=0 and a=1.5; then one proton is released to form a deprotonated 2 : 1 chelate, ML_2, between a=1.5 and a=2 in both solution:

$$Ni^{2+} + HL + L^- \rightleftharpoons Ni\cdot HL\cdot L \qquad K=\frac{[Ni\cdot HL\cdot L^+]}{[Ni^{2+}]\cdot[HL]\cdot[L^-]} \tag{4}$$

$$Ni\cdot HL\cdot L^+ \rightleftharpoons NiL_2 + H^+ \qquad K_C=\frac{[NiL_2]\cdot[H^+]}{[Ni\cdot HL\cdot L^+]} \tag{5}$$

The equilibrium constants, K and K_C, given in Reactions (4) and (5) are calculated from the data in the regions between a=0.3 and a=1.2, and between a=1.6 and a=1.9, respectively. The results obtained from the 2 : 1 and 1 : 1 curves coincide to give log K=13.45 and pK_C=6.62 respectively.

The stability constants of 2 : 1 ligand-to-metal chelates were calculated by Bjerrum's method,[2] as modified by Irving and Rossotti,[3] from the following equations:

2) J. Bjerrum, "Metal Ammine Formation in Aqueous solution," P. Haase and Sons, Copenhagen, 1941.

3) G. Irving and H. S. Rossoti, *J. Chem. Soc.*, **1953**, 3397.

$$[L]=\frac{C_L+[HClO_4]+[OH^-]-[KOH]-[H^+]}{[P]} \quad (6)$$

$$\bar{n}=\frac{C_L-Q\cdot[L]}{C_M} \quad (7)$$

where $P=[H^+]/K_1+2\cdot[H^+]^2/K_1\cdot K_2$, and $Q=1+[H^+]/K_1+[H^+]^2/K_1\cdot K_2$; n is the average number of ligands bound per metal ion, C_L and C_M are the total ligand concentration and the total metal concentration respectively, and K_1 and K_2 are acid dissociation constants. The values of $\bar{n}$ and [L] at each point of the titration curves were calculated from Eqs. (6) and (7). From these data, the formation curves were plotted. The step-by-step stability constants, K_{ML} and K_{ML_2}, were calculated by the least-squares method by the use of Eq. (8):

$$\frac{\bar{n}}{(\bar{n}-1)\cdot[L]}=\frac{(2-\bar{n})\cdot[L]}{(\bar{n}-1)}K_{ML}\cdot K_{ML_2}-K_{ML} \quad (8)$$

When the precipitation was observed in the course of titration, the stability constants were estimated apporoximately from the values of pL at $\bar{n}=0.5$ and $\bar{n}=1.5$. From the values of K_{ML}, K_{ML_2}, and [L], $\bar{n}$ was recalculated by Eq. (9) and theoretical formation curves were plotted:

$$\bar{n}=\frac{K_{ML}\cdot[L]+2\cdot K_{ML}\cdot K_{ML_2}\cdot[L]^2}{1+K_{ML}\cdot[L]+K_{ML}\cdot K_{ML_2}\cdot[L]^2} \quad (9)$$

The theoretical curve and the experimental plots of the TAMHQ metal chelates are shown in Fig. 4. The theoretical curve is in good agreement with the experimental plots. The stability constants are summarized in Table 1, along with the acid dissociation constants, and are compared with those of oxine.

As may be seen in Table 1, the stability constants of the metal chelates of four ligands, HQA, CAMHQ, NAMHQ, and TAMHQ, are lower than those of oxine. These results can be explained as follows. The basicity of these ligands is lower than that of oxine. These ligands do not behave as terdentate ligands, but as bidentate ligands toward metal ions; that is, the quinoline nitrogen and phenolate oxygen for four ligands participate in coordination to metal ions to form 2 : 1 chelates. Moreover, the aminomethyl group introduced at the 2 position induces a large steric hindrance. Accordingly, their metal chelates should be lower in stability than those of oxine, as is observed in the cases of 2-aryl- and 2-alkyl-8-hydroxyquinoline.[4,5]

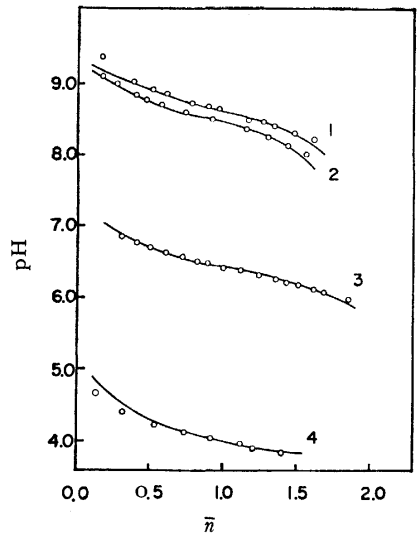

Fig. 4. The formation curves of TAMHQ-metal chelates; solid line represents the theoretical formation curves; curve 1, Zn^{2+}; 2, Co^{2+}; 3, Mn^{2+}; 4, Mg^{2+}.

The stability of metal chelates in these ligands decreases in the order of $Cu^{2+}>Zn^{2+}>Co^{2+}\sim Ni^{2+}>Cd^{2+}>Mn^{2+}$. It is noteworthy that this order is in agreement with that in 2-alkyl-8-hydroxyquinoline and is different from that of oxine, that is, Mellor-Mallery's order[6]: $Cu^{2+}>Ni^{2+}>Co^{2+}>Zn^{2+}>Cd^{2+}>Mn^{2+}$.

PAMHQ. The titration curves of the 1 : 1 and 2 : 1 molar ratios are shown in Fig. 5. In the presence of any metal ion except Zn^{2+}, the titration curves of the 2 : 1 molar ratio are almost identical

with the curves for TAMHQ. This observation indicates that PAMHQ reacts with metal ions to form 2 : 1 protonated chelates by the coordination of metal ions with quinoline nitrogen and phenolate oxygen in the quinoline ring in the same manner as TAMHQ. In fact, as is apparent from Table 2, the stability constants of 2 : 1 protonated chelates of PAMHQ are comparable with those of the four ligands described above, and are lower than those of oxine.

However, the curves of the 1 : 1 molar ratio differ from those of the 2 : 1 molar ratio. With Cu^{2+}, the titration curve gives an inflection at $a=2$, and at this point the color of the 1 : 1 molar ratio solution changes from green to a brownish red, while the color of the 2 : 1 molar ratio solution changes from light green to a brownish yellow. The absorption spectra of the 1 : 1 molar ratio solution at the various pH values given in Fig. 6 show that in the low pH region, only one band is observed, with an absorption maximum at 380 nm, whereas the absorption spectra change in accordance with the increase in pH to show two absorption bands with absorption maxima at 480 and 580 nm in the region above pH 6.0. From these facts, it is clear

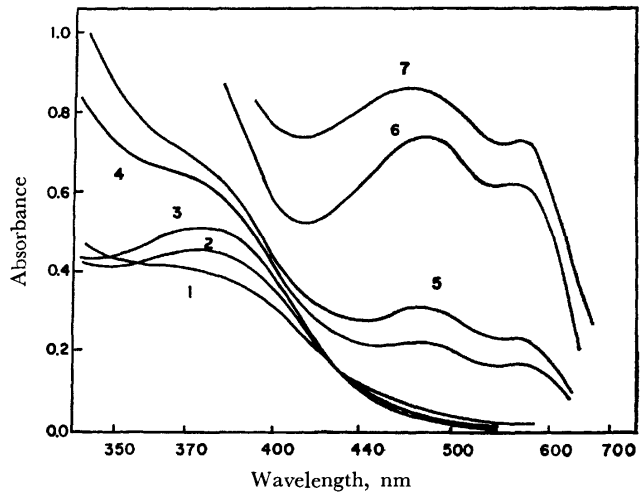

Fig. 6. Absorption spectra of molar ratio of PAMHQ to Cu^{2+} 1 : 1 solution in 50 v/v% aqueous dioxane at various pH; PAMHQ=$Cu^{2+}=2\times10^{-4}$ M; curve 1, pH 3.60; 2, 4.20; 3, 5.95; 4, 7.10; 5, 7.90; 6, 8.00; 7, 8.88.

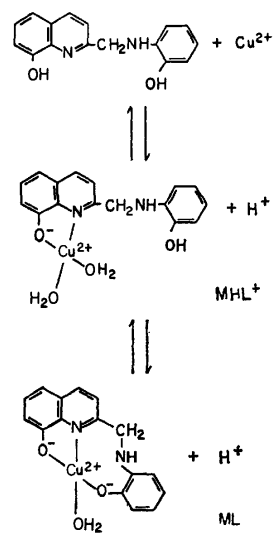

Chart 1. PAMHQ-Cu^{2+} chelate.

that two different chelating species exist in the 1 : 1 solution. That is, as may be seen in Chart 1, PAMHQ reacts with the Cu^{2+} ion to form the protonated chelate $CuHL^+$ between $a=0$ and $a=2$ by the coordination of the Cu^{2+} ion with quinoline nitrogen and phenolate oxygen in the quinoline ring, and then one proton is released from the protonated chelate and the CuL chelate is formed by coordination with phenolate oygen in benzene ring. The spectral change with the time shown in Fig. 7 reveals that the equilibrium of Reaction (10) is rapid, but Reaction (11), the conversion of $CuHL^+$ into CuL, is slow.

$$Cu^{2+} + HL^- \rightleftarrows CuHL^+ \quad K_{CuHL^+} = \frac{[CuHL^+]}{[Cu^{2+}]\cdot[HL^-]} \tag{10}$$

$$CuHL^+ \rightleftarrows CuL + H^+ \quad K^{H^+}_{CuHL^+} = \frac{[CuL]\cdot[H^+]}{[CuHL^+]} \tag{11}$$

Accordingly, the stability constants were calculated from the data of the curve which was obtained by the titration for 2.25 hr. The results are given in Table 2, together with the over-all stability constant, K_{CuL}; it is clear that the stability constants are higher than that of oxine.

However, with Ni^{2+}, and Zn^{2+}, the titration curves of the 1 : 1 and 1 : 10 molar ratios exhibit an inflection at $a=1.5$, indicating that three protons are displaced from the ligand in two steps. Judging from the fact that the three curves of the 2 : 1, 1 : 1, and 1 : 10 molar ratios give an inflection at $a=1.5$, it is considered that the same reaction occurs between $a=0$ and $a=1.5$ in each solution. That is, as was observed for the TAMHQ–Ni^{2+} system, PAMHQ reacts first with the Ni^{2+} ion to form a 2 : 1 protonated chelate, $Ni\cdot H_2L\cdot HL$, between $a=0$ and $a=1.5$, and then this chelate reacts with the free Ni^{2+} ion to release 1.5 protons and to form a 1 : 1 chelate, NiL, between $a=1.5$ $a=3$ in the 1 : 1 solution.

With Mn^{2+}, Mg^{2+}, and Ca^{2+}, the initial reaction, that is, the one-proton dissociation reaction from the ligand, is followed by the two-proton displacement reaction in the 1 : 1 and 1 : 10 molar ratios solutions. This fact indicates that PAMHQ reacts with these metal ions to form a 1 : 1 terdentate chelate by coordination with two phenolate oxygens and quinoline nitrogen. The stability constants of 1 : 1 deprotonated chelates are higher than those of oxine, as is shown in Table 2.

Although the reaction mechanism of PAMHQ–Ni^{2+} and Zn^{2+} has not been completely clarified, it is obvious from the above discussion that PAMHQ reacts with Cu^{2+}, Mn^{2+}, Mg^{2+}, and Ca^{2+} to form terdentate chelates and that their stabilities are higher than those of the chelates of oxine.

BHQED. This ligand has two hydroxyl and imino groups, and two quinoline nitrogens, and is expected to act as a multidentate ligand toward metal ions to form 1 : 1 ligand-to-metal chelates. The titration curves obtained in the equivalent (1 : 1) and excess (1 : 10) molar ratios of ligand to metal are shown in Fig. 8. The shapes of the curves clearly show the different types of reactions observed, involving the formation of deprotonated chelates as well as various protonated chelates.

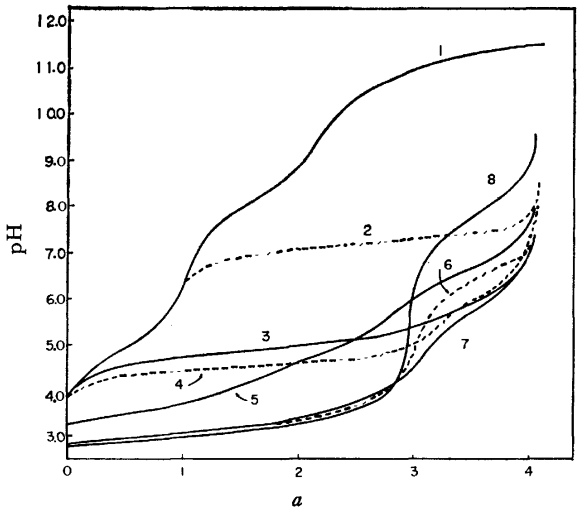

Fig. 8. Potentiometric titration curves of the equivalent and the excess molar ratio of BHQED to metal ions; solid line and broken line represent the equivalent and excess curves, respectively; curve 1, ligand; 2, Mg^{2+}; 3 and 4, Mn^{2+}; 5 and 6 Ni^{2+}; 7, Co^{2+}; 8, Cu^{2+}.

In the cases of Cu^{2+} and Mn^{2+}, the equivalent curves have an inflection at $a=3$ and, moreover, a flat buffer region between $a=0$ and $a=3$. These facts indicate that three protons are displaced from the ligand in one step to form a monoprotonated chelate, MHL^+, and that one proton is then dissociated from this chelate to form a deprotonated chelate, ML:

$$M^{2+} + HL^- \rightleftarrows MHL^+ \quad K^{M}_{ML_2} = \frac{[MHL]}{[M^{2+}]\cdot[HL^-]} \tag{12}$$

$$MHL^+ \rightleftarrows ML + H^+ \quad K^{H^+}_{MHL^+} = \frac{[ML]\cdot[H^+]}{[MHL^+]} \tag{13}$$

The equilibrium constants were calculated by the use of Eqs. (14) and (15) from the data in the regions between $a=0.5$ and $a=2.5$, and between $a=3.2$ and $a=3.9$, respectively.

$$K_{MHL^+} = \frac{C_L\cdot(\varepsilon-\sigma)\cdot\varepsilon+\alpha\cdot\sigma\cdot\varepsilon}{\{\varepsilon\cdot(C_M-C_L)+\sigma(C_L-\alpha)\}\cdot(C_L-\alpha)} \tag{14}$$

$$K^{H^+}_{MHL^+} = \frac{(\alpha-C_M)\cdot[H^+]}{(2\cdot C_M-\alpha)} = \frac{(\alpha-C_L)\cdot[H^+]}{(2\cdot C_L-\alpha)} \tag{15}$$

Where $\varepsilon=[H^+]/K_2+2\cdot[H^+]^2/K_2\cdot K_3+3\cdot[H^+]^3/K_2\cdot K_3\cdot K_4$, $\sigma=1+[H^+]/K_2+[H^+]^2/K_2\cdot K_3+[H^+]^3/K_2\cdot K_3\cdot K_4$, and $\alpha=[KOH]+[H^+]-[OH^-]-[HClO_4]$; C_M and C_L are the total ligand concentration and the total metal concentration respectively, and K_2, K_3, and K_4 are the respective acid dissociation constants. With Co^{2+}, Ni^{2+}, and Cd^{2+}, the initial reaction is a two-proton displacement to form a diprotonated chelate:

$$M^{2+} + H_2L \rightleftarrows MH_2L^{2+} \quad K^{M}_{ML_2} = \frac{[MH_2L^{2+}]}{[M^{2+}]\cdot[H_2L]}$$

This is followed by a dissociation reaction:

$$MH_2L^{2+} \rightleftarrows MHL^+ + H^+ \quad K^{H^+}_{MH_2L} = \frac{[MHL^+]\cdot[H^+]}{[MH_2L^{2+}]}$$

$$MHL^+ \rightleftarrows ML + H^+ \quad K^{H^+}_{MHL^+} = \frac{[ML]\cdot[H^+]}{[MHL^+]}$$

The equilibrium constants for each step can be calculated because there is a suitable buffer region.

With Mg^{2+}, the excess curve shows that Mg^{2+} is not bound until at least one proton is displaced from the ligand because of the weaker binding ability of this metal ion to the ligand; this follows the displacement of three protons to form a deprotonated chelate between $a=1$ and $a=4$. The data of the excess curve were employed in the previous paper for the evaluation of the stability constants by the use of Schwarzenbach's method.[7] The equilibrium constants are summarized, along with the overall stability constants, in Table 3.

TABLE 3. THE STABILITY CONSTANTS OF METAL CHELATES OF *N,N'*-BIS(8-HYDROXY-2-QUINOLYLMETHYL)ETHYLENEDIAMINE(BHQED), $\mu=0.1$, 25°C

Cations	log $K^{H^+}_{MH_2L}$	log $K^{H^+}_{MHL^+}$	log $K^{M}_{MH_2L}$	log $K^{M}_{MHL^+}$	log K_{ML}
Cu^{2+}		7.89		20.0	23.5
Co^{2+}	3.59	5.99	12.49	19.0	22.5
Ni^{2+}	5.20	6.79	9.59	14.2	18.9
Cd^{2+}	3.91	7.78	10.62	17.4	22.0
Mn^{2+}		6.20		12.4	17.6
Mg^{2+}					10.2
	pK_1	pK_2	pK_3	pK_4	
H^+	11.38	10.81	8.15	5.12	

In the presence of Cu^{2+}, Co^{2+}, Ni^{2+}, Cd^{2+}, and Mn^{2+}, but not Mg^{2+}, BHQED reacts with these metal ions to form a monoprotonated chelate, MHL^+, and this reaction is followed by the dissociation of one proton from this chelate to form a deprotonated chelate, ML. As is shown in Table 3, the dissociation constants, $K^{H^+}_{MHL^+}$ of these metal chelates decrease in the order: $Cu^{2+}>Cd^{2+}>Ni^{2+}>Mn^{2+}>Co^{2+}$. This order shows that the $K^{H^+}_{MHL^+}$ values of Co^{2+} and Mn^{2+} chelates, which are considered to have an octahedral structure, are lower than those of the Cu^{2+}, Ni^{2+}, and Cd^{2+}

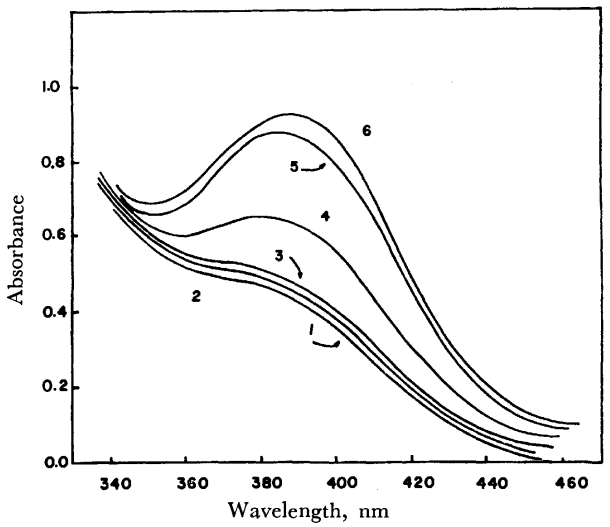

Fig. 9. Absorption spectra of BHQED-Cu^{2+} chelate at various pH in 50 v/v% aqueous dioxane solution; BHQED=$Cu^{2+}=2\times10^{-4}$ M; curve 1, pH 3.12; 2, 3.72; 3, 6.00; 4, 7.32; 5, 8.08; 6, 10.66.

7) G. Schwarzenbach, *Helv. Chem. Acta*, **33**, 947 (1950).

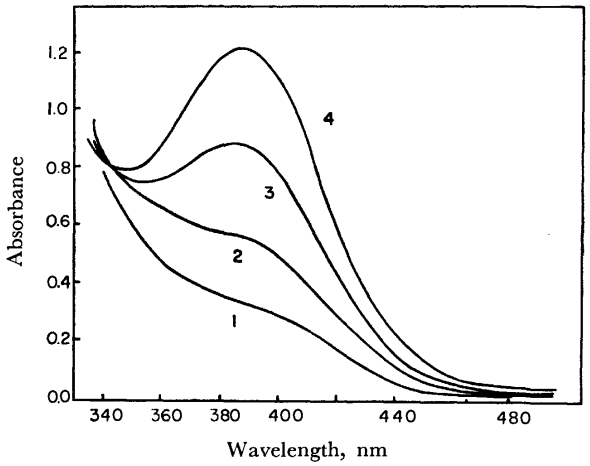

Fig. 10. Absorption spectra of BHQED-Co^{2+} chelate at various pH in 50 v/v% aqueous dioxane solution; BHQED=$Co^{2+}=2\times10^{-4}$ M; curve 1, pH 3.09; 2, 3.92; 3, 5.45; 4, 8.05.

chelates, which have square planar, or tetrahedral structures. As is indicated in Figs. 9 and 10, in the BHQED-Cu^{2+} system the spectral change is not observed in the region from pH 3.1 to 6.0, but as the pH is increased above 6.0 the intensity of the band (max. 389 nm) increases with an increase in the pH and remains constant above pH 9.0. In the BHQED-Co^{2+} system, the absorption band changes gradually with the change of pH in the region from pH 2.0 to 4.0 and greatly at about pH 6.0. These facts indicate that the one-proton displacement reaction is not the dissociation of the proton from the coordinated water, but the dissociation of the proton from the free hydroxyl group in the quinoline ring. Moreover, with Cu^{2+}, the conversion of MHL^+ into ML does not occur with ease in the acid region from about pH 2.5 to 6.0 because the protonated chelate exists stably in this pH region as a square planar chelate by coordination of the Cu^{2+} ion with two imino nitrogens and phenolate oxygen. Above pH 6.0, this chelate rearranges to have a distorted octahedral structure by coordination with another phenolate oxygen and also by weaker coordination with two quinoline nitrogens in the fifth and the sixth positions above and below the plane. The reaction scheme is given in Chart 2. With Co^{2+}, the conversion occurs readily in a lower pH region than Cu^{2+}, because the Co^{2+} chelate tends to be arranged

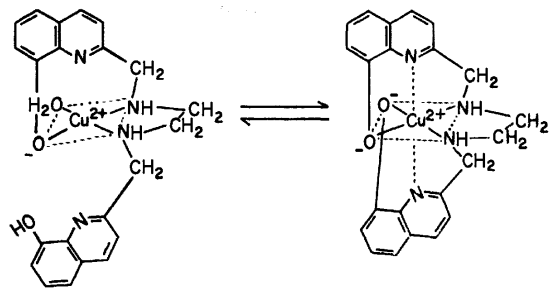

Chart 2. BHQED-Cu^{2+} chelate.

Table 4. Comparison of stability constants of BHQED, HBED, EDAMP, and Trien metal chelates

Cation	BHQED log K_{ML}	HBED log K_{ML}	EDAMP log K_{ML}	Trien log K_{ML}	ΔK (BHQED-HBED)	ΔK (BHQED-EDAMP)	ΔK (BHQED-Trien)
Cu^{2+}	23.5	21.38	16.3	20.5	2.1	7.3	8.1
Co^{2+}	22.5	19.89	12.8	11.0	2.7	11.0	12.8
Ni^{2+}	18.8	19.31	12.7	14.1	−0.4	6.1	4.7
Cd^{2+}	22.0	17.52	9.9	10.0	4.5	12.1	12.0
Mn^{2+}	17.6	14.78	5.9	4.9	3.8	11.7	6.6

from the structure formed by coordination with three donor groups to a more stable octahedral structure by coordination with two imino nitrogens and phenolate oxygens and by equivalent coordination with two quinoline nitrogens in the fifth and the sixth positions above and below the plane. From the above discussion, it is clear that BHQED behaves as a sexadentate ligand toward metal ions.

This conclusion is supported by a comparison of the BHQED-metal chelate with triethylenetetramine (trien),[8] ethylenebis-(2-aminomethyl)pyridine (EDAMP)-,[9] and *N,N'*-di(2-hydroxybenzyl)ethylenediamine-*N,N'*-diacetic acid(HBED)[10]-metal chelates. The stability constants of these metal chelates are given in Table 4. From the increment of the stability constants of BHQED-metal chelates over the trien and EDAMP metal chelates seen in Table 4, the importance of the contribution of quinoline nitrogens to the stabilities of the chelates may be roughly estimated. The metal ions of a higher coordination number, Co^{2+}, Cd^{2+}, and Mn^{2+}, show a large increment of the stability for the BHQED-metal chelates, causing the more favorable steric arrangement of the quinoline nitrogens. On the other hand, the smaller increment observed for the Cu^{2+} ion indicates that these three ligands react with the Cu^{2+} ion to form a stable, square, planar chelate, although there is also a contribution of the quinoline nitrogens in the BHQED chelate, as is shown in Chart 3. Moreover, HBED acts as a sexadentate ligand toward metal ions in the same manner as does BHQED. With Cu^{2+}, HBED forms a stable, distorted, octahedral chelate by coordination with two amino nitrogens and two phenolate oxygens and by weaker coordination with two carboxylate oxygens in the fifth and the sixth positions above and below the plane. In fact, the stability constant of the BHQED-Cu^{2+} chelate is slightly higher than that of the HBED-Cu^{2+} chelate compared with that of the trien- and EDAMP-Cu^{2+} chelates.

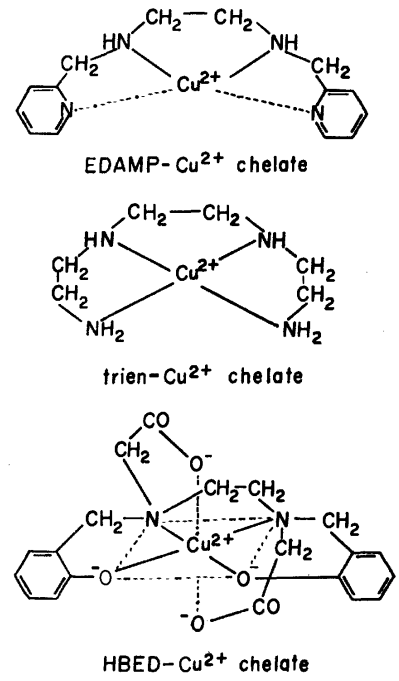

Chart 3. Cu^{2+} chelate of EDAMP, trien, and HBED.

The fact that BHQED forms the most stable chelates among various oxine derivatives is probably due to the sterically-favorable arrangement of bonds when all six donor groups of the ligand are involved in the coordination of metal ion.

Spectra and *Keto-Enol* Equilibrium of Benzoylacetanilides

Ahmad Sami A. S. Shawali, Magdi M. Naoum, and Saad A. Ibrahim
Department of Chemistry, Faculty of Science, University of Cairo, Giza, Egypt, UAR

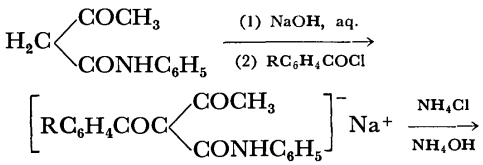
(Received September 6, 1971)

A series of twelve monosubstituted benzoylacetanilides have been prepared by condensation of acetoacetanilide with substituted benzoylchlorides. IR and UV spectral data are presented and discussed. The benzoyl CO stretching frequencies were correlated with σ^+ ($\bar{\nu}=34.97\sigma^+ + 1705$; $r=0.983$). The effect of substituents in the benzoyl moiety on the *keto-enol* equilibrium, has also been investigated. The data were correlated by the equation: $\log K=0.865\sigma^+ - 0.615$; $r=0.988$.

While several investigations on benzoylacetanilides have been made concerning their reactions[1] and acidities,[2] meagre data are available on their spectral characteristics. Furthermore, although there are several reports dealing with the effects of substituents on the *keto-enol* equilibria in systems such as benzoylacetones,[3] 2-benzoylcyclanones,[4] and ethyl benzoylacetates,[5] benzoylacetanilides (I) have not been included in these analyses.

In the present communication, we wish to present a convenient method for the preparation of substituted benzoylacetanilide together with their spectral (IR and UV) characteristics. This report also contains the results of a study of the *keto-enol* equilibrium of such compounds and the effect of substituents on it.

Synthesis. Of the various methods that have been reported[6] for the synthesis of aroylacetanilides, the only generally useful one has been the condensation of equimolecular amounts of ethyl aroylacetate with the appropriate arylamine at elevated temperatures. Since most of the ethyl esters of aroylacetic acids are not commercially available, it was of interest to find an alternate short and general method that could be employed for the synthesis of aroylacetanilides. The conversion of ethyl benzoylacetoacetate to ethyl benzoylacetate[7] with ammonium chloride and ammonium hydroxide suggests that acylation of acetoacetanilide and the decomposition of the resulting 2-aroylacetoacetanilide might be a general reaction which has been long overlooked. We have, in fact, found that aroylacetanilides (I) can be conveniently prepared from acetoacetanilide according to the reaction sequence outlined in Scheme 1. Twelve compounds (Ia—l), four of which are new, were prepared this way.



$RC_6H_4COCH_2CONHC_6H_6 + CH_3COOH$

f, R=4-Cl	l, R=4-NO_2

Scheme 1

Infrared Spectra. The infrared absorption maxima of aroylacetanilides (Ia—l) and their assignments are given in Table 1. The most significant feature of these spectra is the presence and location of the carbonyl stretching bands. In the carbonyl region, benzoylacetanilide (Id) possesses two strong bands, one near 1705 and the second 1669 cm^{-1}. By analogy to acetoacetanilide[8] these bands are assigned to the benzoyl and anilide carbonyl groups, respectively. The appearance of the bonzoyl CO group and the complete absence of any OH band suggest that benzoylacetanilide and its substituted derivatives, under the conditions of measurement, exist almost in the *keto* form. The data indicate also that the position of the aroyl CO band depends, to a large extent, upon the nature of the substituent present. As shown in Table 1, as the character of the substituent (*meta* or *para* to the CO group) changes progressively from electron donating to electron withdrawing, the value of ν_{CO} increases.

Good correlations of carbonyl stretching frequencies with Hammett constants have been reported for acetophenones,[9] benzophenones,[10] benzoyl chlorides,[11] and chalcones.[12] The application of the Hammett

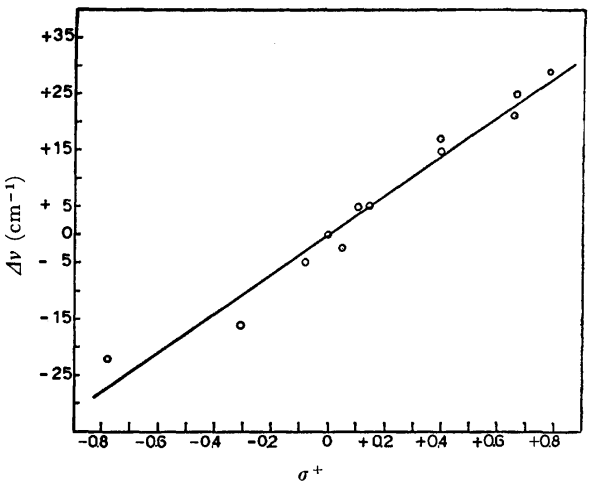

Fig. 1. Plot of $\Delta\nu$ *vs.* the substituent σ^+ for benzoylacetanilides.

equation to the CO frequencies of aroylacetanilides (Ia—l) is shown in Fig. 1, in which $\Delta\bar{\nu}$ is plotted against σ^+ values; $\Delta\bar{\nu}=\bar{\nu}_R-\bar{\nu}_H$. The values of the slope and intercept were calculated by the least-squares method.[15] The best straight line fit corresponds to the equation:

$$\bar{\nu}=34.97\sigma^+ +1705;\ r=0.983$$

The ρ of value ~35 obtained for benzoylacetanilides indicates a shift of ~35 cm^{-1} per unit of σ^+ constant, which is, within statistical limits, three times as much as the ρ for acetophenones series ($\rho=12.33$).[9,12] This relatively high sensitivity of the strength of the CO double bond to substituents suggests strongly that there is appreciable orbital overlap between the phenyl and carbonyl groups of the present series in solid state.

Table 2. Ultraviolet spectra of substituted benzoylacetanilides

Compound No.	Ethanol λ_{max}, nm(log ε)		Cyclohexane λ_{max}, nm (log ε)

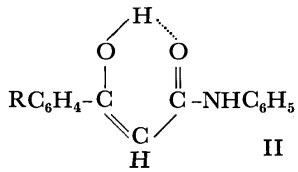
Il	345(4.15)	257(4.29)	334(4.19)	248(4.23)

Ultraviolet Spectra. The ultraviolet spectral data for benzoylacetanilides in cyclohexane and ethanol are presented in Table 2. The absorption pattern was, in each case, characterized by the presence of two bands: Band A usually is located in the region of 305—350 nm, and Band B in the 240—280 nm region. The data also indicate that for the compounds studied Band A exhibits a bathochromic displacement as the solvent is varied from cyclohexane to ethanol.

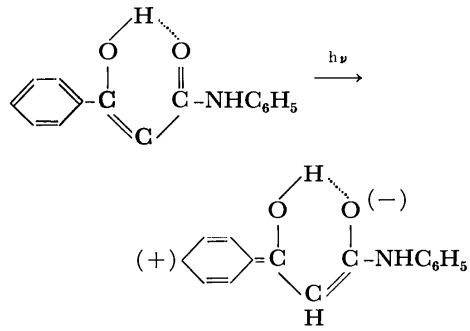
It has been reported that λ_{max} values (log ε 4 to 5 in every case) for the chromophoric systems: Ar–C=C–C=O, Ar–CO–C=C–, Ar–CO–CH_2–CO–, and Ar–C(=O)–CH=C(–O–H···O)– are 281—307, 248—283, 253 and 300 nm, respectively.[13] Accordingly, the A and B bands in the electronic absorption spectra of benzoylacetanilides can be assigned to the cinnamoyl and benzoyl chromophoric groups of the *enol* and *keto* forms respectively. Further, the fact that the λ_{max} values of the A bands are all larger than 300 nm provides evidence that the aroyl carbonyl rather than the anilide carbonyl is involved in enolization of the benzoylacetanilides as shown in structure II.



II

The position of λ_{max} of band A of benzoylacetanilides cannot be attributed to a bathochromic effect of the OH on the Ar–C=C–CO– system because it has been observed that the auxochromic effect of the OH and CH_3O groups on such a system does not shift λ_{max} beyond the 300 nm region.[13]

The shift of λ_{max} with a change of solvent is in the direction expected for a transition in which absorption produces a more polar excited state.



The Keto-Enol *Equilibrium.* As expected, the lowest *enol* per cent (Table 3) is observed for the *p*-methoxyl group and the highest for the nitro group. The values of the equilibrium data as $\log(K/K_0)$ for the enolization reaction have been correlated with the substituent constant σ^+ as taken from Ritchie and Sager.[14] Figure 2 illustrates such a correlation. It is seen that the *meta*- and *para*-substituted benzoylacetanilides follow the Hammett equation closely.

A computer program was written to carry out the least-squares and statistical treatment of the date with the sigma constants according to the method of Jaffé.[15] The twelve values set of K in Table 3 best fit a straight line indicated by the equation: $\log K = 0.865\,\sigma^+ - 0.615$; ($r=0.988$; $s=0.033$). The magnitude of the reaction constant ρ of value 0.865 is, within statistical limits, very close to the reaction constant for ethyl benzoylacetates (0.967).[5] This suggests that in the compounds studied the effects of coplanarity, resonance, inductive, and dipole interactions appear to be parallel to the same effects in ethyl benzoylacetate tautomeric equilibrium.

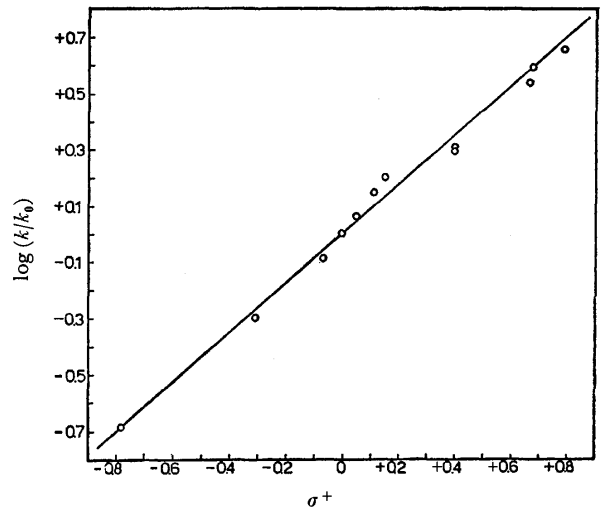


Fig. 2. Plot of $\log(k/k_0)$ *vs.* the substituent σ^+ for benzoylacetanilides.

TABLE 3. TAUTOMERIC EQUILIBRIUM AND SIGMA SUBSTITUENT CONSTANTS

Compound No.	*Enol*, %	K	$\log K/K_0$	σ^+

Ig	24.3	0.320	0.097	0.15
Ih	33.4	0.501	0.292	0.40
Ii	34.8	0.534	0.300	0.40
Ij	46.8	0.879	0.536	0.66
Ik	49.8	0.993	0.589	0.67
Il	54.06	1.176	0.662	0.79

Furthermore, the data indicate that *enol* stability is determined by both mesomeric electronic delocalization[16a,b] and inductive electron withdrawal.[16c] From the value and sign of ρ, it is clear that electron donor substituents (methyl and methoxyl) lend more stability to the *keto* form than the enol form. It is logical, therefore, to conclude that the *enol* system is less electron deficient (electron demanding) than is the single carbonyl group.

Experimental

Melting points were determined on a Fischer-Johns hot stage. Elemental analyses were performed by microanalysis

Laboratory, National Research Center, Dokki, Giza, Egypt. All solvents employed in this study were of spectral quality. Acetoacetanilide was prepared from ethyl acetoacetate and aniline by a method previously described[18] All yields reported relate to the recrystallized material.

Preparation of Aroylacetanilides. Acetoacetanilide (0.1 mol) was dissolved in 60 m*l* of 20% aqueous sodium hydroxide solution. The resulting solution was externally cooled by an ice bath and stirred by a magnetic stirrer. When the temperature of the solution reaches 2°C aroyl chloride (0.1 mol) was added from a dropping funnel, if liquid or in 0.1 g increments if solid, while the temperature of the reaction mixture was kept below 5°C. After all the acid chloride was added, the mixture was stirred for half an hour at 5°C; and for additional 30 min at room temperature. The reaction mixture was then diluted with 15 m*l* of 25% aqueous ammonium hydroxide solution containing 5.4 g (0.1 mol) of ammonium chloride and stirred for 5 minutes. The resulting mixture was heated to 40—50°C, left to stand overnight at room temperature, and filtered. Recrystallisation of the crude product from ethanol or dilute ethanol gave aroylacetanilide in 40—50% yield. The mp of the previously reported compounds agree with the literature values. The following aroylacetanilides ($RC_6H_4COCH_2CONHC_6H_5$) are new: R=4-Br, mp 144—145°C, Found: C, 56.61; H, 3.95; N, 4.10; Br, 24.98%. Calcd for $C_{15}H_{12}BrNO_2$: C, 56.60; H, 3.77; N, 4.40; Br, 25.16%. R=3-Cl, mp 127—128°C. Found: C, 66.17; H, 4.57; N, 5.20; Cl, 12.96 %. Calcd for $C_{15}H_{12}ClNO_2$: C, 65.81; H, 4.39; N, 5.12; Cl, 12.98%. R=3-Br, mp 123—124°C, Found: C, 56.60; H, 3.90; N, 4.01; Br, 25.32%. Calcd for $C_{15}H_{12}BrNO_2$: C, 56.60; H, 3.77; N, 4.40; Br, 25.16%. R=4-CN, mp 140—142°C, Found: C, 72.75; H, 4.39; N, 10.58%. Calcd for $C_{16}H_{12}N_2O_2$: C, 72.72; H, 4.54; N, 10.60%.

Measurement of Spectra. The IR spectra were measured using a Perkin-Elmer model 377 double beam recording spectrophotometer, with sodium chloride optics. All compounds were recorded as potassium bromide pellets.

The UV spectra were determined using a Beckmann DK recording spectrophotometer. Matched quartz cells were used. Stock solutions for each compound were prepared by dissolving an accurately weighed amount of the sample in 50 m*l* of ethanol or cyclohexane. Solution with concentrations of 10^{-3} to 10^{-5} M were prepared by dilution of the stock solution using certified National Bureau of Standards 2- and 5-m*l* pipets and 10-m*l* volumetric flasks. In all cases solutions were allowed to equilibrate at least 24 hr in the dark before spectra were measured. Data determined are listed in Tables 1 and 2.

Determination of Percentage of Enol. The *enol* content was determined at equilibrium. A weighed sample of benzoylacetanilide (approximately 0.2 g) was dissolved in 50 m*l* of anhydrous absolute methanol. The solution was allowed to stand for 24 hr in a constant temperature water bath at 25±1°C in the dark. After this time, the modified bromine titration procedure[19] was used to determine the percentage of *enol*, with results given in Table 3. That the equilibrium is attained, is ensured by the fact that the *enol* per cent determined after extending the equilibrium time to 48 and 72 hr is similar to that determined after 24 hr. The maximum deviation of single determinations from the average of three to five determinations for each compounds was ±1 or less.

Studies on Benzoquinolines [*f*] and [*h*]. Part I

Rameshwar P. TIAGI and Bhuwan C. JOSHI

Chemical Laboratories, University of Rajasthan, Jaipur-4, India

(Received March 8, 1971)

2-Chloro-4-methyl and 2-methyl-4-chloro-benzo[*h*]quinolines, 1-chloro-3-methyl- and 1-methyl-3-chloro-benzo[*f*]quinolines were converted into corresponding hydrazino derivatives. Structural studies of the hydrazino compounds and their derivatives were carried out. Chlorine atom in a position adjacent to nitrogen of the ring was found to be more reactive than in that away from nitrogen in benzo[*f*] and [*h*]quinolines. Cyclisation of hydrazino derivatives by nitrous and formic acids occurred at position 2 in 1-methyl-3-hydrazinobenzo[*f*]-quinoline and at position 3 in the case of 2-hydrazino-4-methylbenzo[*h*]quinoline, respectively, while in the case of 1-hydrazino-3-methylbenzo[*f*]quinoline, at position 10 and in 4-hydrazino-2-methylbenzo[*h*]quinoline, at position 5, respectively.

1-Methyl-3-chloro- and 1-chloro-3-methyl-benzo[*f*]-quinolines (IA and IB), and 2-chloro-4-methyl- and 2-methyl-4-chloro-benzo[*h*]quinolines (IC and ID) were prepared by the usual methods.[1-3] The chloro compounds IA—ID did not react with hydrazine hydrate (80%) when the reactions were carried out in low boiling solvents such as alcohol and dioxane. However, in hot glycerol the corresponding hydrazino derivatives (IIA—IID) were obtained. The hydrazino derivatives IIA and IIC were obtained under refluxing for 6—8 hr, while compounds IIB and IID were obtained when the time of refluxing was extended to 10—12 hr. This indicates the greater reactivity of chlorine at a position adjacent to nitrogen as compared to that away from nitrogen. Such differences in reac-

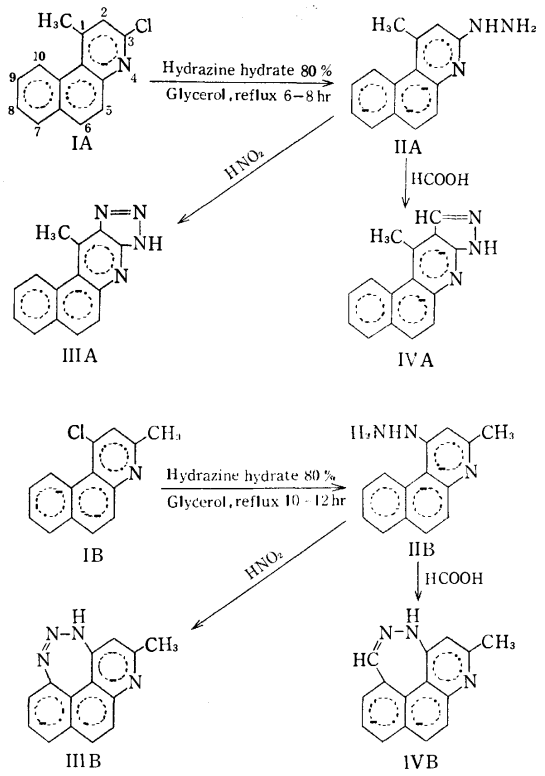
tivities were observed in the quinoline compounds.[4]

4-Chloroquinaldine with hydrazine under drastic conditions gave 3-methyl-5-(*o*-aminophenyl)pyrazole, an isomer of 2-methyl-4-hydrazinoquinoline.[5] However, this was not observed in the case of the above compounds (IA—ID) wherein hydrazino derivatives (IIA—IID) were obtained.



IA IIA IIIA IVA IB IIB IIIB IVB

Elemental analysis of the compounds IIA—IID suggested the formula $C_{14}H_{13}N_3$. NMR spectrum of IIB indicated the presence of six aromatic protons (δ 7.6—8.05 ppm) and one aromatic proton as singlet (δ 7.05 ppm). Protons at nitrogen were found at δ 1.6 and δ 1.2 ppm, while methyl protons ($C-CH_3$) as a singlet at δ 2.60 ppm. All the data supported hydrazino structure for IIB. The positions of various protons in compounds IIA, IIC, and IID were more or less similar to IIB.

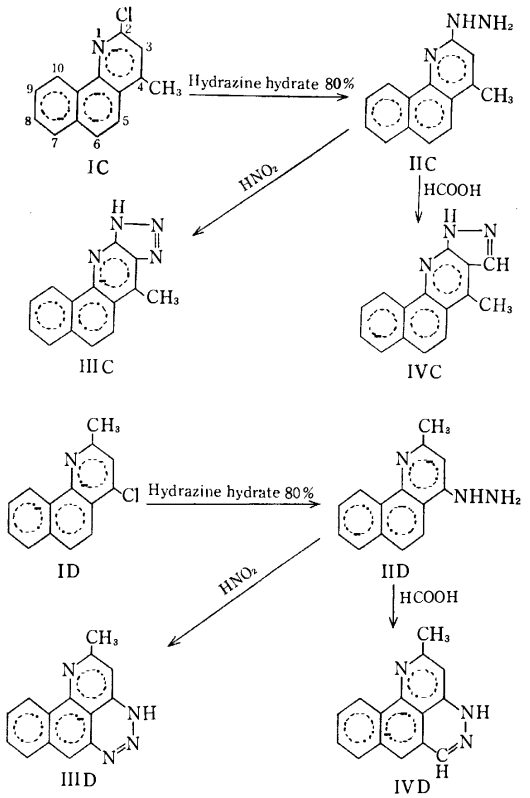
Hydrazino derivatives (IIA—IID) reacted with nitrous acid to give compounds IIIA—IIID ($C_{14}H_{10}N_4$). NMR studies of IIIB indicated the presence of methyl (δ 2.65 ppm), -NH(δ 8.35 ppm), five aromatic (δ 7.6—8.05 ppm) and one aromatic (δ 7.05 ppm) protons. The absence of the protons of $-NH-NH_2$ (δ 1.2, 1.6 ppm) as indicated in the NMR spectrum of IIB, along with the presence of a -NH proton at δ 8.35 ppm, indicated the formation of 3-methylbenzo[*f*]-1′,2′,3′-triazepino[4′,7′:1,10]quinoline.

It appeared that the intermediate $RNHN_2^+Cl^-$ from IIB to IIIB must have cyclised at position 10 instead of position 2 as there was still an indication of the aromatic proton as a singlet (δ 7.05 ppm) in IIIB which was also present in IIB. But in IIIA, no proton was found at position 2 as there was no indication of the aromatic proton at δ 7.05 ppm in the NMR spectrum. However, the positions of six aromatic protons (at positions 5, 6, 7, 8, 9, and 10), methyl and -NH protons were found to be more or less similar to those in IIA.

When the hydrazino derivatives (IIA—IID) were treated with formic acid, compounds of molecular formula $C_{15}H_{11}N_3$ (IVA—IVD) were obtained. NMR spectrum of IVA indicated the absence of the proton at 2 (as singlet at δ 7.05 ppm), along with the presence of methyl protons (δ 2.5 ppm singlet), -NH proton (δ 8.85 ppm) and N=CH (δ 6.5 ppm) proton. This also indicated the presence of methyl and six aromatic protons almost in similar positions as in IIA. In the NMR spectrum of IVB, the presence of methyl protons (δ 2.55 ppm singlet), one aromatic proton (δ 7.05 ppm), six aromatic protons (δ 7.5—8.05 ppm), NH proton (δ 8.4 ppm) and the absence of a proton at δ 6.5 ppm were evident. It appears that the cyclisation occurred at 10 and not at 2, since the aromatic proton at the position 2 was found as a singlet (δ 7.05 ppm).

4) R. J. Rowlett and R. E. Lutz, *J. Amer. Chem. Soc.*, **68**, 1288, (1946).

5) E. Koenigs and J. Freund, *Chem. Ber.*, **80**, 143, (1947).



Formation of IIIC, IIID, IVC, and IVD could be explained similarly.

Experimental

All the melting points are uncorrected. Micro analyses were performed by C.D.R.I., Lucknow. NMR spectra were made on a Varian A-60 model in $CDCl_3$ as a solvent and TMS as an internal indicator. Chemical Shifts are given in ppm (δ).

1-Methyl-3-hydrazinobenzo[f]*quinoline(IIA).* 2.27 g (0.01 mol) of 1-methyl-3-chlorobenzo[*f*]quinoline (IA) was dissolved in glycerol and the solution was refluxed. To the hot reaction mixture, hydrazine hydrate (80%, 0.06 g, 0.015 mol) was gradually added with constant stirring. After the addition of hydrazine hydrate was completed, the reaction mixture was refluxed for 6—8 hr. The mixture was cooled and poured into ice-cold water. The solid was filtered and dissolved in the least amount of methanol. The methanolic solution was filtered and was kept at 0°C for 24 hr. The compound (mp 141—142°C; yield, 1.36 g, 60%) thus obtained showed no chlorine. Tlc examination gave one spot (R_f, 0.54) using dioxane as a solvent and Silica Gel G as an adsorbent.

Found: C, 74.98%; H, 6.02%; N, 19.04%. Calcd for $C_{14}H_{13}N_3$: C, 75.33%; H, 5.82; N, 18.83%.

Similarly, IB yielded 1-hydrazino-3-methylbenzo[*f*]-quinoline (IIB) with a refluxing time of 10—12 hr. Yield 51%, mp 161—162°C (R_f, 0.72).

Found: N, 19.28%. Calcd for $C_{14}H_{13}N_3$: N, 18.83%.

2-Hydrazino-4-methylbenzo[*h*]quinoline(IIC) was prepared from IC mp 116—117°C, yield 58% (R_f 0.79).

Found: N, 19.32%. Calcd for $C_{14}H_{13}N_3$: N, 18.83%.

ID yielded 2-methyl-4-hydrazinobenzo[*h*]quinoline (II-D) with a refluxing time of 10—12 hr in 48% yield mp 170—171°C (R_f, 0.68).

Found: N, 19.02%. Calcd for $C_{14}H_{13}N_3$: N, 18.83%.

1-Methylbenzo[f]*-1,2,3-triazolo*[*4,5*-b]*quinoline (IIIA).* 0.5 g of 1-methyl-3-hydrazinobenzo[*f*]quinoline(IIA) was dissolved in dilute hydrochloric acid. The ice-cold solution was kept at 0—2°C. The ice-cold saturated solution of sodium nitrite was added cautiously till brown fumes were evolved. The reaction mixture was shaken well during the course of addition, and was then decomposed with cold water. The solid was filtered and washed 3—4 times with water (till washings gave no positive test for ionic chlorine). It was crystallized from ethanol (mp 214—215°C).

Found: C, 71.5; H, 4.52; N, 23.62%. Calcd for $C_{14}H_{10}N_4$: C, 71.78; H, 4.27; N, 23.93%.

Similarly, IIB yielded 3-methyl-1′-*H*-benzo[*h*]-1′,2′,3′-triazepino[4′,7′ : 1, 10]quinoline (IIIB) (mp 180—181°C).

Found: N, 23.62%. Calcd for $C_{14}H_{10}N_4$: N, 23.93%. IIC yielded 4-methylbenzo[*h*]-1,2,3-triazolo[4,5-*b*]quinoline (IIIC) (mp 160—161°C).

Found: N, 23.68%. Calcd for $C_{14}H_{10}N_4$: N, 23.93%. and IID, yielded 2-methyl-1′-*H*-benzo[*h*]-1′,2′,3′-triazino-[4′, 6′ : 4, 5]quinoline (IIID): (mp 189—190°C).

Found: N, 23.58%. Calcd for $C_{14}H_{10}N_4$: N, 23.93%.

1-Methylbenzo[f]*-1,2-pyrazolo*[*4,5*-b]*quinoline (IVA).* To a well stirred hot solution of 0.5 g of 1-methyl-3-hydrazinobenzo[*f*]quinoline in redistilled dioxane (with a little sodium acetate), formic acid in excess was cautiously added. The mixture was then refluxed for 4—5 hr on a sand bath. The reaction mixture was cooled and poured into ice-cold water and kept overnight at 0°C. The solid obtained was filtered, washed 3—4 times with water and was crystallised from acetone (mp 260—261°C).

Found: C, 74.07%; H, 4.82%; N, 17.28%. Calcd for $C_{15}H_{11}N_3 \cdot 1/2H_2O$; C, 74.38%; H, 4.95%, N, 17.35%. Similarly, IIB yielded 3-methyl-1′-*H*-benzo[*f*]-1′,2′-diazepino[4′, 7′ : 1, 10]quinoline (IVB), mp (215—216°C).

Found: N, 17.02%. Calcd for $C_{15}H_{11}N_3 \cdot 1/2H_2O$: N, 17.35%. IIC yielded 4-methylbenzo[*h*]-1,2-pyrazolo-[4,5-*b*]quinoline(IVC) (mp 204—205°C).

Found: N, 16.88%. Calcd for $C_{15}H_{11}N_3 \cdot 1/2H_2O$: N, 17.35%, IID, yielded 2-methyl-2′-*H*-benzo[*h*]-1′,2′-pyrazino[3′,5′:4,5]quinoline (IVD) (mp 224—225°C).

Found: N, 16.82%. Calcd for $C_{15}H_{11}N_3 \cdot 1/2H_2O$: N, 17.35%.

The authors express their thanks to the Head of the Chemistry Department for providing the necessary facilities and to Dr. (Mrs.) Reena Ramchandran for making available NMR spectra of the compounds.

The CNDO/2 Study of Barbararyl Cation and Its Isomeric $C_9H_9^+$ Systems

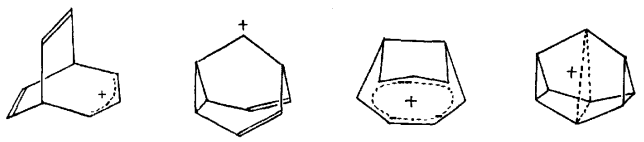
Shigeo YONEDA,[1a,c] Saul WINSTEIN,[1b] and Zen-ichi YOSHIDA[1c,d]

Department of Chemistry, University of California, Los Angeles, California, 90024, U.S.A. and Department of Synthetic Chemistry, Kyoto University, Yoshida, Kyoto

(Received July 16, 1971)

The geometrical and electronic structures of $C_9H_9^+$ systems have been studied applying CNDO-2 method. The calculated results are used to discuss the stabilities of the structures for $C_9H_9^+$ system and their electronic states. It is suggested that the carbonium ion which has a D_{3h} symmetry (IV) enjoys much stabilization energy, whereas bicyclo[3.2.2]nonatrienyl cation (I) is less stable than IV. The stability of IV can be explained by unusual delocalization of its electrons over the molecule.

A considerable amount of attention has been recently focussed on $C_9H_9^+$ systems such as bicyclo[3.2.2]-nonatrienyl (I), 9-barbararyl (II) and bishomotropylium (III) cations.[2-5] The direct observation of II and III by NMR at low temperature was recently reported by Winstein and his co-workers.[4b] On the other hand, based on the results of deuterium scrambling reaction, Schleyer[3] has proposed the presence of the reaction intermediate species (or the transition state) as presented in IV, which undergoes effective threefold symmetrization.



(I) (II) (III) (IV)

The approach using molecular orbital calculations is helpful in investigating the stabilities and the electronic states of these systems. Although experiences with semiempirical molecular orbital methods suggest that they are capable of yielding very satisfactory geometrical data, it seems to be almost impossible to apply semiempirical MO method to $C_9H_9^+$ systems because of their large number of internal degrees of freedom (3N−6).

We have succeeded in carrying out the complete MO treatment for IV and I by considering the appropriate symmetry properties. First of all, all the bond angles and the bond lengths for the symmetrical structure (IV) were varied, and the most stable symmetrical structure was obtained. After that, the energy change by the possible deformations was examined. As a result, the calculated potential energy surface clearly indicates that the structure IV represents an energy minimum.

For the structure at the energy minimum, a population analysis[6] was carried out. The electron densities and the overlap populations demonstrated unusual delocalization in the structure IV. The similar MO treatment for I was carried out, even though much computing time was required due to the large number of internal degrees of freedom compared with the case of IV. The energy minimum obtained for I was much higher than that for IV, as expected from the theory of "bicycloaromaticity" proposed by Goldstein,[3a,3b] indicating I to be bicycloantiaromatic.

Method of Calculation

Our treatment is fundamentally composed of the following two steps; 1) the determination of the most stable structure by minimizing the molecular energy with respect to internal coordinates, 2) the estimation of the electron densities and the overlap populations in the structure of energy minimum.

The method of calculation employed in this study is CNDO-2 by Pople and Segal.[7] The model initially chosen has a D_{3h} symmetry [IV] as depicted in Fig. 1.

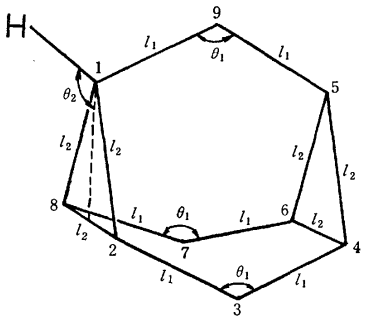


Fig. 1. Geometrical parameters for IV.

In the D_{3h} symmetrical structure, variable geometrical parameters are the bond lengths, $l_1(C_2C_3=C_3C_4=C_6C_7=C_7V_8=C_1C_9=C_9C_5)$, $l_2(C_1C_2=C_2C_8=C_8C_1=C_4C_5=C_5C_6=C_6C_4)$ and the bond angle $\theta_1(\angle C_2C_3C_4=\angle C_1C_9C_5=\angle C_8C_7C_6)$. The bond angle θ_2 is also a geometrical parameter to whose change, however, molecular energy is fairly insensitive. A bond length of 1.09 Å assumed for all C–H bonds. The calculation was

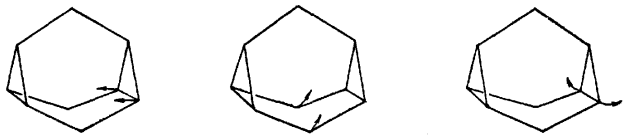
organized as follows. The bond length l_1 was first calculated by minimizing the molecular energy, assuming $l_2=1.54$ Å and $\theta_1=\theta_2=120°$. Using the calculated value for l_1(1.40 Å), the value of 115° for θ_1 was obtained, and then with these value of l_1 and θ_1, the bond length l_2 was calculated. With the new values for θ_1 and l_2, l_1 was recalculated. This process was repeated until an absolute minimum in energy with respect to l_1, l_2 and θ_1 was obtained. Fixing the final values for l_1, l_2 and θ_1, the best bond angle θ_2 was obtained.

Thus, after the most stable symmetrical structure was obtained by changing all the bond lengths and the bond angles, the change of the molecular energy with respect to several possible deformations was examined. All the bond angles and bond lengths were varied independently or simultaneously as shown in the examples below.



A B C

A similar treatment of bicyclo[3.2.2]nonatrienyl cation (I) was carried out. In this case, main geometrical parameters are the bond angles θ_1, θ_2, θ_3 and θ_4 as shown in Fig. 2. The coordinates of C_6, C_7, C_8 and C_9 was first calculated for changes in θ_1 and θ_2, assuming $\theta_3=120°$, $C_2C_3=C_3C_4=1.40$Å, $C_1C_2=C_4C_5=C_1C_7=C_1C_8=C_5C_6=C_5C_9=1.52$ Å and $C_6C_7=C_8C_9=1.34$Å according to the literature.[8] The coordinates for the protons H_2, H_3, H_4, H_6, H_7, H_8 and H_9 are calculated on the assumption that they lie in each corresponding plane and the C_1H_1 and the C_5H_5 bonds are at equal angles from the other bonds at C_1 and C_5, respectively. Using θ_1 and θ_2 obtained from the first computation (both 70°), the bond angles θ_3 and θ_4 were varied and determined by minimizing the molecular energy. This process was repeated until the energy minimum was obtained with respect to θ_1, θ_2, θ_3 and θ_4. Finally, using this set of bond angles, the changes in the molecular energy were tested by varying each bond length. In the present calculations the angles were calculated to within 1° and the bond lengths within 0.01 Å, respectively.

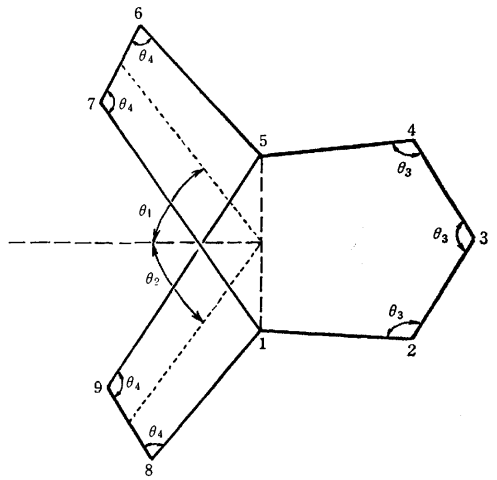


Fig. 2. Geometrical parameters for I.

8) J. A. Pople and M. Gordon, *J. Amer. Chem. Soc.*, **89**, 4253 (1967).

The electron densities and the overlap populations for the structure (IV) and (I) were calculated and presented in Fig. 3 and 4, respectively.

Results and Discussion

From the calculation for (IV) changing all the geometrical parameters, the molecular energy for the most stable symmetrical structures was calculated to be −70.0733 a.u. In this structure, the bond lengths $l_1=1.41$ Å, $l_2=1.52$ Å and the bond angles $\theta_1=115°$ and $\theta_2=120°$. Any small geometrical deformation did not lower the energy of the symmetrical structure. It is clear that the structure IV is at least one of the minima on the potential energy surface. The electronic densities and the overlap populations for this structure are shown in Fig. 3. The positive

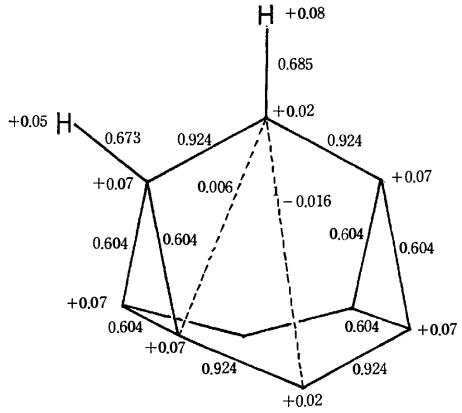

Fig. 3. The electronic charges and the overlap populations for IV.

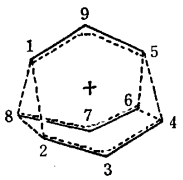
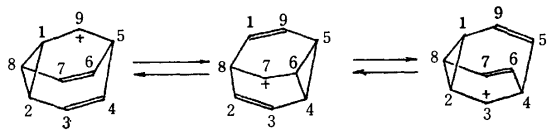
charge was delocalized over all the carbon atoms as might be expected. An important aspect for this D_{3h} symmetrical structure is that the overlap populations for l_1 correspond to that for an aromatic bond, since the value of 0.924 for l_1 is comparable to that of benzene (0.960), whereas the value of 0.604 for l_2 is smaller than that of a typical sp^3 C–C bond, 0.704, which is obtained for the C–C bond in neopentane. Accordingly, the electronic state of IV could be visualized in (IV'). It is immediately obvious from this representation that IV is stabilized by cyclopropylcarbinyl resonance. There are six equivalent cyclopropylcarbinyl fragments, $C_8C_2C_1C_9$, $C_1C_8C_2C_3$, $C_2C_1C_8C_7$, $C_4C_5C_6C_7$, $C_5C_6C_4C_3$ and $C_6C_4C_5C_9$, as is seen in IV'. In other words, IV is a highly homoconjugated system.



(IV')

The prediction of much stability in IV supports the observation by Schleyer *et al.*[4c] that deuterium distributed almost exclusively between C_3, C_7 and C_9 in the solvolysis of 9-D-barbararyl tosylate. In the study of the direct observation of II by NMR, Winstein and his coworkers[5b] suggested a facile divinylcyclopropylcarbinyl-divinylcyclopropylcarbinyl rearrangement as given in the following mechanism, with which Schleyer



IIa IIb IIc

et al. also agreed in their recent paper.[4b] According to the present calculation, this rearrangement can be facilitated through the symmetrical intermediate IV'.

The calculation of the energy of the species derived from IV by simultaneous large deformations (A, B and C) might approach that for II. The computations were attempted several times, but a lower molecular energy was not obtained. As an attempt to find an energy minimum of II on the potential surface seemed to consume too much time, a laborious complete treatment was not carried out.

A similar theoretical treatment for another $C_9H_9^+$ system, bicyclo[3.2.2]nonatrienyl cation (I), yielded the bond angles, 69°, 69°, 126° and 119° for θ_1, θ_2, θ_3 and θ_4, respectively, and the bond lengths, 1.52 Å, 1.40 Å and 1.34 Å for $C_1C_2=C_1C_7=C_1C_8=C_4C_5=C_5C_6=C_5C_9$, $C_2C_3=C_3C_4$ and $C_6C_7=C_8C_9$, respectively, at its energy minimum geometry. The calculated molecular energy of −70.0361 a.u. was much higher than that

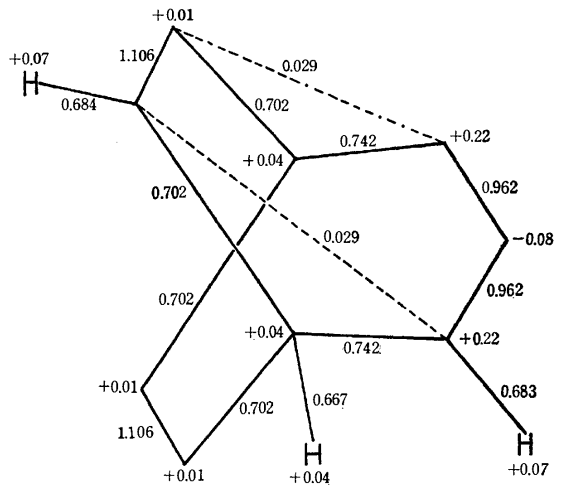


Fig. 4. The electronic charges and the overlap populations for I.

for IV, in accordance with the antibicycloaromaticity of I. In the five membered systems such as $C_2C_3C_4$-C_9C_8 and $C_2C_3C_4C_6C_7$ in Fig. 4, the small overlap populations (0.029) clearly indicate that the systems are antihomoaromatic.

A similar MO calculation for bishomotropylium ion (III), which should be the most stable $C_9H_9^+$ system, is now under investigation.[9]

We should like to thank Dr. P. Ahlberg and Dr. D. Blagdon for assistance in many illuminating discussions.

9) From a calculation for III choosing an appropriate set of geometrical parameters, an molecular energy (−70.0691 a.u.), much more stable than I and comparable to IV, has already been obtained.

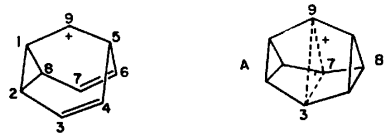
The 9-Barbaralyl Cation

Roald HOFFMANN, W.-D. STOHRER, and M. J. GOLDSTEIN
Department of Chemistry, Cornell University, Ithaca, N.Y., U.S.A.

(Received August 12, 1971)

We find that the 9-barbaralyl cation assumes a structure with 3-fold symmetry in which there is an interesting orbital pattern caused by strong conjugative interaction of the central *p* orbitals with the cyclopropane rings. We think this symmetrical cation is identical with the transition state for the Cope rearrangement of 9-barbaralyl cation.

At −135°C, in super acid media, the 9-barbaralyl cation **1** undergoes a sequence of rapid rearrangements which renders all protons equivalent on the NMR time scale.[1] Under solvolytic conditions evidence for a somewhat faster and less degenerate rearrangement



1 **2**

has been obtained.[2] In this process positions 3,7,9 are made equivalent, as are 1,2,4,5,6, and 8.

Several mechanisms may be written for both the partially degenerate and totally degenerate rearrangements.[1-3] For the former process an attractive transition state or intermediate which in its molecular symmetry reflects the degeneracy of the rearrangement is the D_{3h} $C_9H_9^+$ cation **2** suggested by Schleyer and coworkers.[2a,b] It also accidentally represents a confluence of four areas of our interest: the ability of a cyclopropyl group to enter into conjugation,[4] the concept of through-bond coupling,[5] the modification of the Cope rearrangement,[6] the structure and rearrangements of $(XH)_n$ species.[7] We present here an analysis of its electronic structure.

Consider the interaction of the Walsh orbitals[4,8] of cyclopropane rings A and B of **2** with the set of three *p* orbitals at C_3, C_7 and C_9. These latter three orbitals

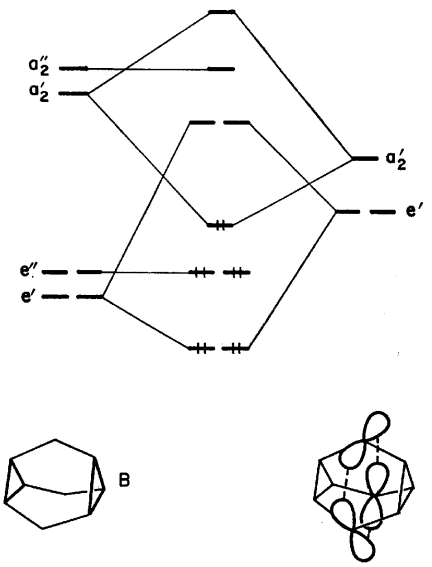


Fig. 1. Interaction of cyclopropane ring orbitals (left) with orbitals of carbons 3, 7, and 9 (right).

also generate a Walsh set, with a doubly degenerate e′ orbital below a nondegenerate a_2', but the splitting between e′ and a_2' must be much smaller than in a normal cyclopropane because the C_3–C_7 distance is long. Figure 1 shows the interaction of the orbitals of rings A and B with this inner set. The following points emerge:

1) The highest occupied MO is a_2'. Interaction of the inner set with the Walsh orbitals of rings A and B reverses the direct overlap determined ordering e′ below a_2'. This is because the overlap of a C_3 *p* orbital with the optimally aligned Walsh orbitals of rings A and B is greater than its overlap with C_7 or C_9 *p* orbitals. In an extended Hückel calculation on **2** with CCC angles of 120° at C_3, C_7, and C_9 the a_2' orbital emerges 2.0 eV below e′.

2) The shape of the a_2' orbital is given in **3** below. Since it is composed of the a_2' combination of inner orbitals mixed in a bonding way with the antibonding a_2' combination of outer ring orbitals it leads to stronger C_1–C_9, weaker C_1–C_2 bonds (only one member of the symmetry related set is given). a_2' is 3–7, 3–9, 7–9 antibonding, and so representation **2**, if it implies any such bonding, is inappropriate.[9]

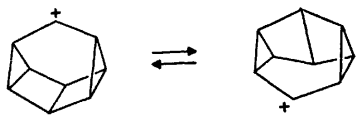
3

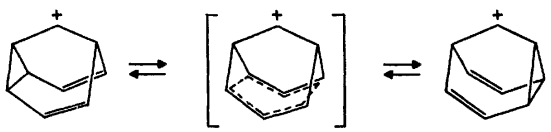
3) The collapse of **2** to **4** is a symmetry forbidden process. This is perhaps easiest seen by noting that the new 3–7 σ bond in **4** is symmetric with respect



4 **4'**

to reflection in the symmetry plane perpendicular to that bond, but the occupied a_2' orbital of **2** is antisymmetric. Thus the hypothetical rearrangement of **4** to **4'** where the cationic center shifts from say C_7 to C_3 cannot proceed *via* the transition state or intermediate **2**. A less symmetrical circumvention, like that we have discovered in $C_5H_5^+$,[7c] is here made geometrically unlikely.

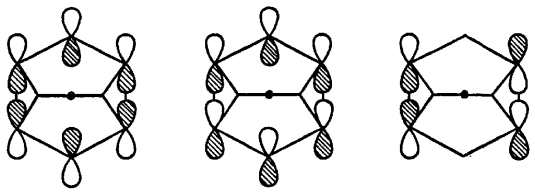
We now turn to the relationship of cation **2**, its electronic structure described in Fig. 1, to the transition state **5** for the degenerate Cope rearrangement of **1**⇌**1'**. This rearrangement was considered but dis-



1 **5** **1'**

carded as a source of degeneracy in the rearrangements of the 9-barbaralyl and 9-methyl-9-barbaralyl cations by Ahlberg, Grutzner, Harris, and Winstein.[1,10] The basis for discounting the occurrence of a Cope rearrangement was apparently the trend in Cope rearrangement activation energies on going from barbaralone to protonated barbaralone.[10] However we would like to reconsider the transition state **5** in view of its geometrical similarity to cation **2**.

The interconversion of **2** and **5** is a symmetry allowed process. Let us classify levels with respect to the mirror plane containing carbons 1, 9, and 5. The occupied levels in transition state **5** (or collapsed cation **1**) are two symmetric levels and one antisymmetric, shown schematically below.[6] (The view is along the



S_1 A S_2

C_2 axis, from the top toward C_9). These correlate directly to the occupied levels of **2**: S_1 and S_2 go to form the 2–8 and 4–6 σ bonds, while A by mixing with the empty p orbital at C_9 goes over into the crucial a_2' orbital of **2**.

Given the structural similarities of **2** and **5** and the fact that they have similar electronic configurations we think it is highly likely that they are not distinct molecules but one and the same species. Whether this is a transition state or intermediate can be only decided by calculations better than the ones at our command. But we propose that the rearrangement of the 9-barbaralyl cation merges with the Cope rearrangement of the same molecule—the midpoint of that reaction is of D_{3h} symmetry and simply has three possible collapse channels.

We are grateful to P. v. R. Schleyer for a discussion this problem and R. Platt for assistance with some calculations. The stay of W. -D. S. at Cornell was made possible by a grant from the Deutsche Forschungsgemeinschaft. Our work was supported by the National Science Foundation and the National Institutes of Health.

Syntheses of Substituted Phenyl-2-thienyliodonium Halides and Their Pyrolysis Reactions

Yorinobu YAMADA and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 2, 1971)

Various substituted phenyl-2-thienyliodonium halides were prepared by the reaction of thiophene with substituted phenyliodoso acetates in acetic anhydride–concentrated sulfuric acid. In the pyrolysis reaction of substituted phenyl-2-thienyliodonium chlorides it was found that the chloride ion selectively attacked the 1-carbon of the phenyl group. The product ratios in the pyrolysis reaction of substituted phenyl-2-thienyliodonium bromides can be explained on the basis of a bimolecular aromatic nucleophilic substitution except for *p*-chlorophenyl-2-thienyliodonium bromide. In the case of *p*-chloro substituted derivative an interesting effect of *p*-chloro group was observed. The pyrolysis reaction of substituted phenyl-2-thienyliodonium iodides gave substituted phenyl iodides and 2-iodothiophene. The solution reaction of phenyl-2-thienyliodonium halides in *N,N*-dimethylformamide gave halobenzene and 2-iodothiophene. These results suggest that the reaction proceeds *via* an interaction between the halide ion and the phenyl group in a trigonal-bipyramidal structure.

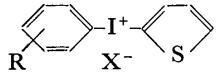
Many reactions of diaryliodonium salts with various nucleophiles have been studied.[1] However, scarcely any reactions of phenyl-2-thienyliodonium salts containing the thienyl group as a ligand of iodonium salts have been reported except for the electroreduction and the nucleophilic displacement with sulfite ion in water by Beringer and his co-workers.[2] They reported that the replacement of the phenyl group in diphenyliodonium cation by the 2-thienyl group increases the ease of electroreduction and the susceptibility to nucleophilic attack. When phenyl-2-thienyliodonium cation was cleaved by sulfite ion in water, the ratio of attack on the thiophene ring to that on the benzene ring was 2: 1.

$$\mathrm{Ph\text{–}I^{+}\text{–}Th} + \mathrm{SO_3^{2-}} \longrightarrow \begin{cases} \mathrm{PhSO_3^-} + \mathrm{ThI} \\ \mathrm{ThSO_3^-} + \mathrm{PhI} \end{cases} \quad (1)$$

They attributed such a result to the predominant resonance interaction between the iodine and the phenyl ring or to the difference in electronegativity between the phenyl and 2-thienyl groups.

We have investigated the synthesis of polymeric iodonium salt ($\mathrm{PSJ^+X^-}$) containing the polystyryl structure as one of the ligands and the possibility of their application to synthetic chemistry.[3]

Various substituted phenyl-2-thienyliodonium halides (I) were synthesized and allowed to react in the molten state for investigation of the difference in reactivity between the substituted phenyl and thienyl groups.



(I)

Results and Discussion

Syntheses of Substituted Phenyl-2-thienyliodonium Halides. Phenyl-2-thienyliodonium salts can be synthesized in three ways. The first method is the reaction of iodosobenzene with thiophene in acetic acid–acetic anhydride–sulfuric acid (Yield 49%).[2]

$$\mathrm{PhIO} + \mathrm{ThH} + \mathrm{H_2SO_4} + \mathrm{Ac_2O} \longrightarrow \mathrm{Ph\text{–}I^{+}\text{–}Th} + \mathrm{HSO_4^-} + 2\mathrm{AcOH} \quad (2)$$

The second method is the reaction of iodosobenzene diacetate with thiophene in acetic acid–acetic anhydride–trifluoroacetic acid (Yield 92%).[2]

$$\mathrm{PhI(OAc)_2} + \mathrm{ThH} + \mathrm{CF_3COOH} \longrightarrow \mathrm{Ph\text{–}I^{+}\text{–}Th} + \mathrm{CF_3COO^-} + 2\mathrm{AcOH} \quad (3)$$

The third is the reaction of 2-thienyllithium with phenyl(*trans*-chlorovinyl)iodonium chloride in toluene giving phenyl-2-thienyliodonium salt in 38% yield.[4]

$$\mathrm{ThLi} + \begin{matrix} \mathrm{H} \\ \mathrm{Cl} \end{matrix}\!\!\diagdown\!\!\diagup\!\!\begin{matrix} \mathrm{I^{+}\text{–}Ph} \\ \mathrm{H} \end{matrix} \mathrm{Cl^-} \longrightarrow \mathrm{Th\text{–}I^{+}\text{–}Ph\ Cl^-} + \mathrm{LiCl} + \mathrm{CH{\equiv}CH} \quad (4)$$

We prepared the substituted phenyl-2-thienyliodonium salts by modifying the reaction (3), *viz.*, the substituted phenyliodoso diacetate was allowed to react in the presence of concentrated sulfuric acid in acetic anhydride.

$$\mathrm{ArI(OAc)_2} + \mathrm{ThH} + \mathrm{H_2SO_4} \longrightarrow \mathrm{Ar\text{–}I^{+}\text{–}Th\ HSO_4^-} + 2\mathrm{AcOH} \quad (5)$$

The desired iodonium halides were precipitated by adding the aqueous solution of corresponding metal halides to the reaction mixture obtained. The results are summarized in Table 1. The structures were confirmed by elemental analysis and infrared spectrum. The solubility in polar solvents such as water, methanol, and *N,N*-dimethylformamide (DMF) decreases in the order, chloride>bromide>iodide.

Pyrolysis Reactions of Iodonium Halides in the Molten State. There are two paths as shown below in the nucleophilic displacement of substituted diphenyliodonium salt in the solution.

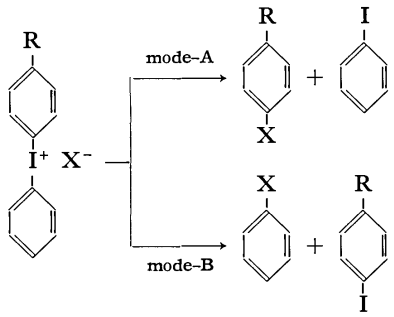
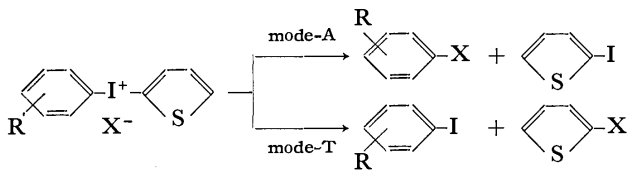
a) Lit. gives 217—225°C.
b) Lit. gives 170—174°C.
c) Lit. gives 129—132°C: F. M. Beringer, R. A. Falk, and M. Leff, *J. Amer. Chem. Soc.*, **80**, 4279 (1958).
d) The corresponding iodonium chlorides were not isolated because of their poor crystallizability.



When the substituent of phenyl group is electron-releasing, the reaction of mode-B predominates and *vice versa*, and the rate of the reaction is always faster in the latter than in the former. Similarly, there are two paths conceivable for the reaction of substituted phenyl-2-thienyliodonium salts as follows.



The results of a number of pyrolysis reactions conducted for 5 min. at 235°C are summarized in Table 2. It is clear that the product ratios show a selective nucleophilic attack of the chloride ion on the phenyl ring regardless of the effect of substituent group. However, the product ratios in the case of the iodonium bromide can be explained on the basis of a bimolecular aromatic nucleophilic substitution except for the reaction of *p*-chlorophenyl-2-thienyliodonium bromide. In the case of phenyl-2-thienyliodonium iodide substituted phenyl iodide and 2-thienyliodide alone were obtained.

TABLE 2. CLEAVAGE TENDENCY OF SUBSTITUTED PHENYL-2-THIENYLIODONIUM HALIDES

Substituted group	Counter anion	Mode-A : Mode-T (mol %)	
H	Cl^-	100	0
m-Cl	Cl^-	100	0
p-Cl	Cl^-	100	0
m-Me	Cl^-	100	0
H	Br^-	100	0
m-Cl	Br^-	100	0
p-Cl	Br^-	76.1	23.9
m-Me	Br^-	100	0
p-Me	Br^-	70.7	29.3
p-MeO	Br^-	60.0	40.0

In every case biaryl, bithienyl, and 2-thienylarene which are considered to be produced in a free radical process were not found by glc analysis. It is of interest that the pyrolysis reaction of the iodonium chloride proceeds *via* the reaction of mode-A alone.

In general, the thiophene ring is more susceptible to the nucleophilic substitution than the benzene ring.[5] As an example, it was reported that the nucleophilic substitution on 2-bromo-5-nitrothiophene was more than one hundred times faster than that on *p*-bromonitrobenzene.[6] Therefore, some factors other than electronic effect should be taken into account for the predominant reactivity of benzene ring obtained in our experiment.

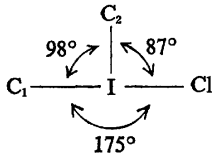
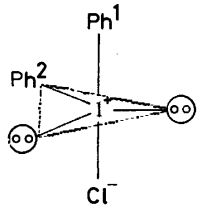
Khotsyanova has studied the crystal structure of diphenyliodonium chloride.[7] The molecular is T-shaped, containing a linear C_1 (1-carbon at one phenyl ring) –I–Cl group perpendicular to a C_2 (1-carbon at another phenyl ring) –I group as shown in II.



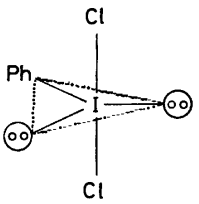
$C_1-I=C_2-I=2.08$ Å
$I-Cl=3.08$ Å

(II)

Taking into account the two lone pairs the molecule should have trigonal-bipyramidal structure (III), the one phenyl ring and two lone pairs on the equatorial position, another phenyl ring and the chloride ion at the apices.



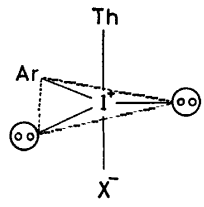
(III)



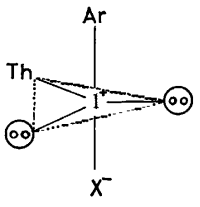
(IV)

Such a trigonal-bipyramidal structure has also been reported for the case of iodobenzene dichloride as shown in IV.[8]

In view of these facts the substituted phenyl-2-thienyliodonium halide should have a trigonal-bipyramidal structure (Va), the phenyl ring and two lone pairs on the equatorial position and the thienyl ring and halogen atom at the apices. On the basis of this assumption the reaction is considered to proceed *via* the overlap of π-orbital of the aryl group and



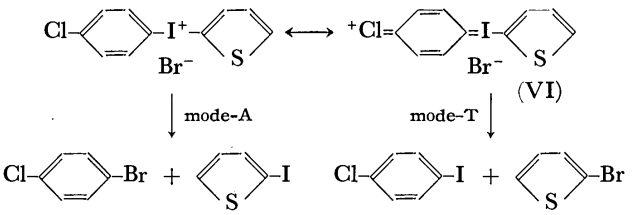
(Va)



(Vb)

the *p*-orbital of halide ion with concomitant cleavage of the bond between the 1-carbon of the aryl group and iodine atom. A similar type of reaction which proceeds through the orbital interaction of the halide ion and the aryl group has been reported for the pyrolysis reaction of triarylsulfonium halides.[9] If the aryl-2-thienyliodonium halide exists in a structure such as Vb, it is expected that the formation of 2-halothiophene predominates. However, hardly any 2-chlorothiophene was produced in the case of the iodonium chlorides. Furthermore, 2-bromothiophene was not produced except for *p*-chloro-, *p*-methyl-, and *p*-methoxy-substituted derivatives in the case of the iodonium bromides. It is reasonable to assume that the more electronegative thienyl ring compared to phenyl ring is located in the site opposite to the halide anion because of their electronic repulsion.[10] These results suggest a structure such as Va rather than Vb in the transition state.

The proton chemical shifts (δ-value) of substituted phenyl-2-thienyliodonium bromides are greater (0.01—0.27 ppm) than those of the corresponding chlorides.[11] Thus, the chloride ion is found to be situated in the position more closely to the iodine atom than the bromide ion (that is, the I–Cl bond occupies more covalent character in comparison with the I–Br bond,[12] and the positive charge on the iodine atom of the iodonium bromide is greater than that of the iodonium chloride. The preferred chloride-aryl coupling over bromide-aryl coupling arises since the bond between aromatic-1-carbon and iodine atom of the iodonium bromide acquires a double bond character through the resonance of the substituent as compared with that of the iodonium chloride. Thus, the reaction of mode-A is liable to occur in the case of the iodonium chlorides compared to that of mode-T by the effective orbital interaction between the aryl ring and the chloride ion. On the other hand, the bromide ion attacked not only the aryl ring (mode-A) but also the thienyl ring (mode-T) in the case of *p*-chloro-, *p*-methyl-, and *p*-methoxyphenyl-2-thienyliodonium bromides. *p*-Methyl and *p*-methoxy substituents prevent the reaction of mode-A owing to their electron-releasing effect. In the *p*-chloro substituent, however, the occurence of the reaction of mode-T could not be explained on the basis of the inductive effect of the *p*-chloro group. The resonance structure (VI) participating with the lone pair of the chlorine atom makes the reaction of mode-T possible. The bond linking the $-I^+$-2-thienyl group to the aromatic ring acquires a double



bond character, making it more difficult to be broken. As shown in Table 3, the increase in λ_{max} in going from *m*-substituted or unsubstituted to *p*-chlorophenyl-

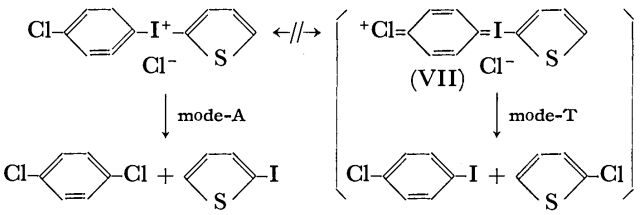
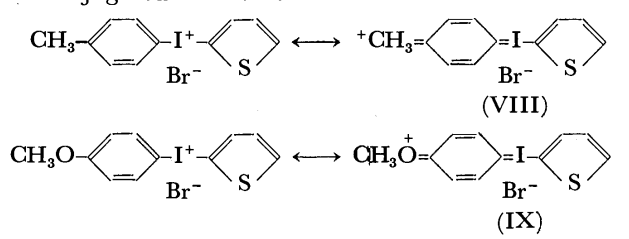
TABLE 3. UV SPECTRA OF SUBSTITUTED PHENYL-2-THIENYLIODONIUM HALIDES (in Methanol)

Substituted group	Counter anion	λ_{max} (nm)	log ε
H	Cl^-	241	4.03
m-Cl	Cl^-	240	3.98
p-Cl	Cl^-	241	4.20
m-Me	Cl^-	239	4.02
H	Br^-	238	3.88
m-Cl	Br^-	240	3.97
p-Cl	Br^-	244	4.13
m-Me	Br^-	239	4.17
p-Me	Br^-	242	4.11
p-MeO	Br^-	254	4.19

2-thienyliodonium bromide suggests the presence of such a conjugated system. If the resonance structure such as VI contributes to the reaction, the iodine atom and the bromide ion become far apart in contrast to the case of absence of such a resonance structure and orbital interaction will occur between not only the bromide ion and the aryl ring but also between the bromide ion and the thienyl ring. Thus, the reaction of not only mode-A but also of mode-T occurs. In the case of *m*-chloro substituted derivative the reaction of mode-T did not occur since the resonance structure due to the lone pair of the chlorine atom was not possible. It is also understandable from the small difference in λ_{max} between phenyl- and *m*-chlorophenyl-2-thienyliodonium bromide. In the case of the iodonium chloride, the contribution of the resonance structure such as VII is neglected from the ultraviolet spectra data. The λ_{max} in *p*-chlorophenyl-2-thienyliodonium chloride is much the same as that in *m*-chlorophenyl-2-thienyliodonium or phenyl-2-thienyliodonium chloride.



In view of the results of *p*-chlorophenyl-2-thienyliodonium bromide it is considered that the cleavage tendencies of *p*-methoxy- and *p*-methyl-phenyl-2-thienyliodonium bromide are ascribed not only to the inductive effect of the substituent group but also to the conjugated structure:



The difference in λ_{max} between *m*- and *p*-methylphenyl-2-thienyliodonium bromide suggests the presence of the hyperconjugated system such as VIII. The absence of the reaction of mode-T in the case of *m*-methylphenyl-2-thienyliodonium bromide suggests a larger contribution of the resonance effect to the occurrence of the reaction than that of the inductive effect. The significant increase in λ_{max} in going from the unsubstituted phenyl-2-thienyliodonium bromide to *p*-methoxyphenyl-2-thienyliodonium bromide suggests the presence of the conjugated system such as IX. The large difference in λ_{max} between *p*-methyl- and *p*-methoxyphenyl-2-thienyliodonium bromide reflects on the mode of reaction *viz.*, the reaction of mode-T is liable to take place in the case of *p*-methoxy substituted derivative in comparison with *p*-methyl substituted derivative.

Beringer and his co-worker also reported on the possibility of the conjugation on *p*-methoxy and *p*-methyl groups in diphenyliodonium salt from the study of ultraviolet spectra.[13] Such a conjugated system has also been reported in the case of *p*-methyl- and *p*-methoxyphenyl diazonium salts.[14]

When the halide ions (Cl^-, Br^-) were allowed to react with phenyl-2-thienyliodonium ion in DMF, the results were similar to that of pyrolysis reaction, *viz.*, only the reaction of mode-A occurred. When the nitrite or thiocyanate ion was used as a nucleophile in DMF, only the reaction of mode-A occurred to give nitrobenzene or phenyl isothiocyanate and 2-iodothiophene, respectively. In the reaction of phenyl-2-thienyliodonium ion with sulfite ion, the ratio of mode-A to mode-T is 1 : 2.

It was found that the iodonium halides containing the thienyl group as a ligand exhibited high activity against a variety of microorganisms, especially against pseudomonas aeruginosa. It has been reported that 2,5-thiophenediyl-bis(phenyliodonium salts) are bioactive against various microorganisms.[15] While the question in toxicity remains unsettled, these distinctive bioactivities resulting from a combination of iodonium and thienyl structures are very interesting.

Experimental

All the melting points are uncorrected. The electronic spectra were obtained on a Hitachi EPS-3T Spectrometer at room temperature using a well-matched pair of 1 cm-cells. Gas chromatographic analysis was carried out with a Hitachi Gas Chromatograph 023-5051 at 100°C using chlorobenzene as an internal standard. Column used was placed with Silicon DC 703 (20%) on Celite 545 (stainless tube 1 m).

Materials. Thiophene of commercial grade was used without further purification. Substituted phenyl iodides were prepared by standard procedure from the corresponding aniline derivatives. 2-Iodothiophene was prepared from thiophene and iodine in the presence of mercuric oxide.[16] 2-Bromothiophene was prepared from thiophene and bro-

mine.[17] Substituted phenyl iodine diacetates were prepared by modification of the method of Leffler and Story.[18] The other substituted phenyl iodine diacetates were prepared by a procedure similar to that given for *m*-chlorophenyl iodine diacetate as follows. To a mixture of 51.6 g (0.22 mol) of *m*-chloroiodobenzene and 140 m*l* of purified acetic acid was added dropwise with stirring 110 g (0.43 mol) of 30%-peracetic acid. The flask was chilled with an ice–water bath during the course of slow addition (0.5 hr). The solution was stirred at 10°C for three additional hours and then allowed to stand overnight at room temperature. The solvent was evaporated *in vacuo*. The remaining white crystals were washed with petroleum ether and dried under reduced pressure to give 66.7 g (85.2%) of the product. Purity was estimated iodometrically to be better than 99.8%.

Syntheses of Substituted Phenyl-2-thienyliodonium Halides. Substituted phenyl-2-thienyliodonium halides were prepared by a procedure similar to that given for *p*-chlorophenyl-2-thienyliodonium halides. To a well-stirred mixture of 10.8 g (0.03 mol) of *p*-chlorophenyliodoso diacetate, 5 g (0.06 mol) of thiophene, and 100 m*l* of acetic anhydride kept below 5°C was added 4 m*l* of concentrated sulfuric acid over one hour. After having been stirred under 10°C for 2 hr, the reaction mixture was diluted with 200 m*l* of water, extracted with ether until color was no longer removed and treated with activated carbon. Addition of 10 g of potassium iodide in water gave a colorless precipitate, which was collected, washed with water and methanol and dried to yield 7.88 g of *p*-chlorophenyl-2-thienyliodonium iodide. From similar reaction mixtures *p*-chlorophenyl-2-thienyliodonium bromide and *p*-chlorophenyl-2-thienyliodonium chloride were also obtained. The bromide and the chloride were recrystallized from methanol but the iodide was not recrystallized because of its poor solubility. The results are shown in Table 1.

Pyrolysis Reactions of Substituted Phenyl-2-thienyliodonium Halides. Each iodonium halide in Table 1 was pyrolyzed in a 15 mm Pyrex tube about 15 cm long, sealed at one end at 245±5°C until the reaction was complete. About 10 cm of the sealed end of the tube was immersed into an oil bath, the remainder of the tube being used as an air condenser. In all cases the composition of the pyrolyzates were determined by means of gas chromatograph. Identification of the products was accompanied by means of retention time. In no case was any significant amount of unexpected product found. All the iodonium halides, when pyrolyzed, gave the products expected from their thermal decomposition. Resolution and appropriate shape of the halide peaks obtained in the chromatograms of the pyrolyzates were sufficient to permit determination of the relative ratios of the halides formed in each pyrolyzate. Approximate peak areas were obtained by multiplying the peak height by the peak width at half height. In the case of the bromide the reaction mode was determined from the amounts of 2-iodothiophene and 2-bromothiophene, and in the case of the chloride from the amounts of 2-iodothiophene and the corresponding substituted phenyl iodide, respectively.

Reaction of Phenyl-2-thienyliodonium Ion with Various Nucleophiles in DMF. The mixture of 0.97 g (0.0025 mol) of phenyl-2-thienyliodonium perchlorate and 0.65 g (0.005 mol) of sodium sulfite dissolved in 50 m*l* of DMF and 30 m*l* of water was held at 100°C for 5 hr. At the end of the reaction the reaction mixture was poured into cold water, extracted with ether two times and the extract was dried over anhydrous sodium sulfate. On removing the solvent by distillation, the residual mixture was redissolved in a small quantity of ether and then the amounts of iodobenzene and 2-iodothiophene were determined by glc analysis. When chloride or bromide ion was used as a nucleophile, 0.97 g (0.0025 mol) of the iodonium perchlorate and 0.29 g (0.005 mol) of sodium chloride or 0.52 g (0.005 mol) of sodium bromide dissolved in 50 m*l* of DMF was held at 100°C for 5 hr. When nitrite or thiocyanate ion was used as a nucleophile, 0.97 g (0.0025 mol) of the iodonium perchlorate and 0.35 g (0.005 mol) of sodium nitrite or 0.49 g (0.005 mol) of potassium thiocyanate dissolved in 40 m*l* of DMF and 10 m*l* of water was held at 100°C for 5 hr. In each case the subsequent experiment was carried out in the same way as mentioned above.

The Reaction of Dicarbonyl Compounds with Potassium in the Presence of Trimethylsilyl Chloride

Takashi MURAKAWA, Koji FUJII, Shinji MURAI, and Shigeru TSUTSUMI

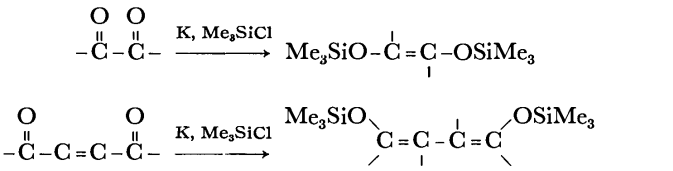
Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received February 24, 1972)

The reaction of dicarbonyl compounds with potassium in the presence of trimethylsilyl chloride was studied. The carbonyl compounds were benzil (II), 9,10-phenanthroquinone (III), *p*-benzoquinone (IV), disodium salt of tetrahydroxy-*p*-benzoquinone (V), and *trans*-dibenzoylethylene (VI), as well as benzophenone (I). I and II gave bistrimethylsiloxy compounds in good yields, but III did not react under the same conditions. 1,4-Bistrimethylsiloxybenzene and 1,4-diphenyl-1,4-bistrimethylsiloxybutadiene were obtained from IV and VI respectively. A similar conjugate reductive silylation was successful with V affording hexakistrimethylsiloxybenzene in 35% yield.

In the presence of trialkylsilyl chlorides, monoketones undergo reductive dimerization to pinacol bissilyl ethers with magnesium or alkali metals.[1-3] 1,2-Bistrimethylsiloxy alkenes were obtained when acyloin condensation was carried out in the presence of trimethylsilyl chloride.[4,5] Since the modified acyloin condensation is very likely to involve reductive silylation of 1,2-diketone intermediates,[6] it seems to be of interest to study the reduction of dicarbonyl compounds with alkali metal in the presence of trimethylsilyl chloride. A few studies have been reported on the reductive silylation of diketones. Rühlman treated benzil with alkali metal and trimethylsilyl chloride to give two isomeric enediol-disilyl ethers. However, no effort was made to establish the structure of each isomer.[4a] Recently Bouas-Laurent reported the reductive silylation of quinones with magnesium, bistrimethylsiloxy arenes being obtained.[7]

The present work deals with the reaction of dicarbonyl compounds with potassium in the presence of trimethylsilyl chloride. The compounds studied were benzil (II), 9,10-phenanthroquinone (III), *p*-benzoquinone (IV), disodium salt of tetrahydroxy-*p*-benzoquinone (V),[8] and *trans*-dibenzoylethylen (VI), as well as benzophenone (I). The following conjugate reductive silylation would be expected for the 1,2- and 1,4-dicarbonyl compounds:



Potassium was used as a reducing metal because it melts above 64°C and can provide a clean metal surface during the course of reaction. The standard procedure of the reaction is as follows. Trimethylsilyl chloride in a slight excess was added to a mixture of a ketone, melted potassium and a solvent over a period of 2 hr at 60—70°C. When the total amount of trimethylsilyl chloride was added at the beginning of the reaction, the same products were obtained but in a lower yield probably because of impurities formed on the metal surface. The results are shown in Table 1.

Benzophenone (I) gave VII which was identical with that prepared separately by the trimethylsilylation of benzopinacol. The observed wide range of melting point might be attributed to the dissociation of VII into diphenyl(trimethylsiloxy)methyl radical as suggested by Calas *et al.*[1] From benzil (II), *cis*- and *trans*-1,2-bistrimethylsiloxy-1,2-diphenylethylene (VIIIa and VIIIb respectively) were obtained in good yields. The assignment of the isomer was based on the IR spectra. The *cis*-isomer VIIIa showed an absorption due to the double bond at 1620 cm^{-1}, while the *trans*-isomer VIIIb showed no double bond absorption usually observed for a double bond at the center of symmetry.[9] The high melting point of VIIIb might also support this assignment. The ratio of VIIIa to VIIIb was 70: 30. The predominant formation of VIIIa could be explained by the stabilization of *cis*-radical-anion.[10] 9,10-Phenanthroquinone (III) which is considered to have *s-cis* configuration of II resisted completely to react under the present con-

TABLE 1. REDUCTIVE SILYLATION OF CARBONYL COMPOUNDS

Exp. No.	Material	Solvent	Product	Yield (%)
1	$C_6H_5CC_6H_5$ (I)	Toluene	$(Me_3Si-O-C(C_6H_5)_2-)_2$ (VII)	72
2	$C_6H_5C-CC_6H_5$ (II)	Benzene	$C_6H_5(Me_3SiO)C=C(C_6H_5)OSiMe_3$ (VIIIa) and $Me_3SiOC(C_6H_5)=C(C_6H_5)OSiMe_3$ (VIIIb)	88 *cis/trans*=70/30
3	(III)	Benzene	No reaction	
4	(IV)	Benzene	No reaction	
		THF	$Me_3SiO-C_6H_4-OSiMe_3$ (IX)	28
5	(V)	THF	$(Me_3SiO)_3C_6H_3-OSiMe_3$ (X)	35
6	(VI)	Benzene	$C_6H_5(Me_3SiO)C=C(H)-C(OSiMe_3)=C(H)-C_6H_5$ (XIa) or $Me_3SiOC(H)=C(C_6H_5)-C(H)=C(H)-OSiMe_3$ (XIb)	12

ditions.[11] The double bond in the dianion of ene-diol formed by reduction in the case of II might bring the originally separated two phenyl groups into one π-net work increasing *ca.* 18 kcal/mol of the delocalization energy of the system.[10] On the other hand, two phenyl groups of III are originally coupled and the effect of introducing a double bond at 9,10-position by the reduction with alkali metal might decrease the delocalization energy as compared with that of III.[12] The reaction of *trans*-dibenzoylethylene (VI), a 1,4-diketone, gave a bistrimethylsiloxybutadine (XI) whose NMR spectra showed one sharp singlet due to the trimethylsilyl group. Of the three possible isomers for XI, *trans-trans-* or *cis-cis*-1,4-diphenyl-1,4-bistrimethylsiloxybutadine (XIb or XIa) is consistent with the NMR data, but not for the *cis-trans* isomer with two nonequivalent trimethylsilyl groups. The low yield of XI might be due to polymerization of the product.

The 1,6-conjugate reductive silylation was extended to *p*-quinones. The reaction of *p*-benzoquinone (IV) in benzene gave 1,4-bistrimethylsiloxybenzene (IX) when tetrahydrofuran was used as a solvent. A similar conjugate reductive silylation was successful with disodium salt of tetrahydroxy-*p*-benzoquinone (V) affording hexakistrimethylsiloxybenzene (X) is 35% yield. Inspection of a model of X revealed the existence of two representative structures; one with

11) However, III was reported to undergo reductive silylation with magnesium.[7] The difference from potassium and magnesium is not clear.

a) Obtained in CCl_4. *s*: singlet, *m*: multiplet. b) There was an additional strong absorption at 890 cm^{-1}. c) The mass and UV spectroscopic data were reported elsewhere.[8] d) Lit,[1] 158°C decomp. e) Lit,[4a] bp 142—143.5/2 mmHg f) Lit,[4a] 109.5—110°C. g) Lit[7] 49—50°C.

all the silicon and oxygen atoms in the same plane of benzene ring and the other in which only the six oxygen atoms lie in the plane of the ring leaving the six silicon atoms outside (alternatively above and below) the plane. Low temperature NMR study was carried out in the hope of obtaining information on the non-equivalent methyl groups which might arise. However, the one sharp singlet (τ 9.86 in CCl_4 at room temperature) remained unchanged even at −100°C (in ether-pentane). This could be accounted for in different way, such as (a) as being due to the methyl protons lying too far apart to be affected by aromatic π-electrons or (b) to free rotation about the bonds in trimethylsilyl groups. No conclusive evidence of the structure of X has so far been obtained.

The reductive silylation has been proven to be a good synthetic method for compounds such as X and XI which might be otherwise difficult to obtain.

Experimental

The starting materials, ketone, diketones, and quinones were commercially available except for *trans*-1,2-dibenzoylethylene.[13] All the reactions were carried out under dry nitrogen. Boiling and melting points were uncorrected.

General Procedure. To a rapidly stirred mixture of 0.1 mol of carbonyl compound and potassium (0.1 g atom for I and 0.2 g atom for II—IV, and VI, and 0.4 g atom for V) in an appropriate solvent was added a slight excess of trimethylsilyl chloride (above the amount of potassium used) over a period of 2 hr at 60—70°C. The reaction mixture was then cooled to room temperature and left to stand overnight. Filtration of potassium chloride followed by evaporation of the solvent afforded the product mixture. This was found to contain merely starting carbonyl compounds in the case of Expts. 3 and 4 (in benzene). In Expts. 1, 4 (in THF), 5, and 6, the resulting product mixture was solids and was recrystallized from hexane to give pure silylated compounds VII, IX, X, and XI, in the yields shown in Table 1. In Expt. 2, the product mixture was a yellow liquid which on standing partially crystallized. The solids were collected by filtration and crystallized from hexane to give VIIIb, colorless rhombic crystals. The filtrate was distilled under reduced pressure and afforded VIIIa, a colorless liquid, bp 160—161°C/8 mmHg. The *cis*/*trans* ratio was determined from the NMR spectrum of the mixture.

The authors are indebted to Shin-etsu Kagaku Kogyo Co. Ltd. for the supply of trimethylsilyl chloride.

Bromine Addition to Cyanonorbornene Derivatives[1]

Shōichi KIKKAWA, Masakatsu NOMURA, Yōichirō UNO,
Masaaki MATSUBARA, and Yūji YANAGIDA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita
(Received October 30, 1971)

The addition reactions of *endo*-5-cyanonorbornene, *trans-endo,exo*-5,6-dicyanonorbornene, *cis-endo*-5,6-dicyanonorbornene, and *cis-exo*-5,6-dicyanonorbornene with bromine have been studied. The assignments of the configurations of bromine adducts were determined mainly on the basis of the NMR spectra. As to *trans-endo,exo*-5,6-dicyanonorbornene, reaction mixtures have been found to contain *trans* and *exo-cis* adducts. The reaction conditions involving the proportions of these isomers and a rationale for the formation of the *exo-cis* adduct are discussed. *cis-endo*-5,6-Dicyanonorbornene and *cis-exo*-5,6-dicyanonorbornene gave the *exo-cis* adduct and the *trans* adduct respectively. The stereochemistry of bromine atoms may be explained in terms of a steric factor. A kinetic study showed that these addition reactions in solution in acetic acid obey the second-order rate law and that the magnitudes of the rate constants are in the order; *cis-exo*-5,6-dicyanonorbornene>*trans-endo,exo*-5,6-dicyanonorbornene>*cis-endo*-5,6-dicyanonorbornene.

Recently Traylor[2] noted that *cis*-electrophilic additions to a wide variety of bicycloheptene structures have been established and that several explanation have been proffered for the observation of *exo-cis* additions to norbornenes—the twist-strain theory, molecular electrophilic addition, torsional effects, and so on.

However, concerning halogen additions to norbornene derivatives bearing electronegative substituents, much attention has been paid only to the bromination of the cyclopentadiene–maleic anhydride adduct.[3-5] Kwart and Kaplan[5] explained the *exo-cis* addition of bromine to the *endo*-adduct on the basis of steric hindrance or *endo*-carbonyl participation.

As part of a study of the electronic and steric effects in the stereochemistry of halogen additions to norbornene derivatives, we have investigated the halogenation of four cyanonorbornenes, *endo*-5-cyanonorbornene, *trans-endo, exo*-5,6-dicyanonorbornene, *cis-endo*-5,6-dicyanonorbornene, and *cis-exo*-5,6-dicyanonorbornene. First, the confirmation of the halogen adduct and the structural assignment have been studied; secondly, in order to study the reactivity of bromine to four substrates, the kinetics of bromination in dry acetic acid have been investigated and the magnitudes of the rate constants have been deduced by the second-order approximate treatment of the resulting kinetic data.

Experimental[6]

Reagents. *a)* endo-*5-Cyanonorbornene (Substrate I)*: The procedure of Alder, Heimbach, and Reubke[7] was followed, using 1 mol of freshly-distilled cyclopentadiene (67 g) and 1 mol of acrylonitrile (53 g). The resulting reaction mixture was separated into the *exo*-adduct (bp 81—84°C/10.5 mmHg, 18 g; lit,[7] 80—85°C/12 mmHg) and the *endo*-adduct (bp 99°C/26 mmHg, 37 g; lit,[7] 88°C/12 mmHg) by fractional distillation. Both adducts were confirmed to be more than 99% pure by glc analysis.

b) trans-endo,exo-*5,6-Dicyanonorbornene (Substrate II)*: The procedure of Blomquist and Winslow[8] was followed. From 0.1 mol (7.8 g) of fumaronitrile prepared in the usual way and 0.11 mol (9 m*l*) of cyclopentadiene in 50 m*l* of ethanol, we obtained 11.5 g (83%) of the substrate II, which showed a mp of 103—104°C (lit,[8] 95.5—96°C) on recrystallization from ethanol. (Found: C, 74.77; H, 5.59; N, 19.08%.)

c) cis-endo-*5,6-Dicyanonorbornene (Substrate III) and* cis-exo-*5,6-Dicyanonorbornene (Substrate IV)*: As the crude malenitrile prepared from maleamide as described by Blomquist[8] contained considerable amounts of fumaronitrile and another component, malenitrile (mp 30—32°C, lit,[8] 30—31°C) was purified by liquid-column chromatography (elute, benzene; silica gel, 100 mesh). Gas chromatography indicated a purity of 99%. The procedure of Blomquist[8] was followed using 0.02 mol (1.56 g) of malenitrile and 0.024 mol (2 m*l*) of cyclopentadiene. The fractional recrystallization of the resulting reaction mixture gave 2.0 g of the *endo* adduct, which was also confirmed to be pure by a comparison with the NMR spectrum of the crude adduct in d_6-DMSO (mp 163—165°C; Found: C, 74.77; H, 5.52; N, 19.33%; lit,[8] 155—156°C) and 0.2 g of the *exo* adduct (mp 108—110°C; lit,[9] 108—110°C).

Bromination of Substrate I with Bromine. A solution of bromine (8.0 g, 0.05 mol) in 25 m*l* of carbon tetrachloride was stirred, drop by drop, into a solution of Substrate I (6.0 g, 0.05 mol) in 50 m*l* of carbon tetrachloride over a 30-min period at 0°C. After the stirring had been continued for an additional 3 hr, a solid separated. This material[10] weighed 10.5 g; it was recrystallized from ethanol (mp 154—156°C) and confirmed to be dibromide by elemental analysis

10) Abbreviated as I-*t* hereafter.

and by a study of its mass spectrum. The stereochemistry of the bromine atoms was estimated to be *trans* by studying the NMR spectrum. Found: C, 34.64; H, 2.98; N, 5.20%; Calcd for $C_8H_9NBr_2$: C, 34.45; H, 3.25; N, 5.20%; M^+: 277 (1), 279 (2), 281 (1).[11]

NMR spectrum (in $CDCl_3$): τ: 6.35 [2H, m, W_h (band width at half-height)]=*ca.* 4 Hz, H-*endo* 5 and H-*endo* 6,[12] 7.00 (2H, d,q,. J=4.6, 5.4, and 1.8 Hz, H-*exo* 5 and H-*exo* 6), (in d_6-DMSO): τ: 5.65 (2H, m, W_h=*ca.* 4 Hz) 5.88 (2H, d,t,. J=4.6, 5.4, and 1.8 Hz).

Chlorination of Substrate I with Chlorine. Chlorine gas (3.6 g, 0.05 mol) was passed through a solution of Substrate I (8.0 g, 0.05 mol) in 50 m*l* of carbon tetrachloride with stirring over a period of about one hour at 0°C.

The crystalline product (5.0 g) was separated by filtration on a glass filter, and the filtrate was evaporated to dryness; this afforded a small amount of an oily product (about 1.0 g). The crystalline product purified by means of liquid-column chromatography (elute, chloroform; silica gel, 100 mesh) (mp 141—143°C) was confirmed to be dichloride by elemental analysis and by a study of the mass spectrum. The stereochemistry of chlorine atoms of the dichloride was identified as *trans* on the basis of the similarity of its NMR spectrum with that of the dibromide. Found: C, 50.75; H, 4.70; N, 7.30%; Calcd for $C_8H_9NCl_2$: C, 50.75; H, 4.77; N, 7.36%. M^+: 189 (9), 191 (6), 193 (1).

The oily product when distilled yielded a distillate boiling at 93°C/10^{-3} mmHg (0.6 g). The gas-chromatographic separation of the distillate afforded a colorless liquid which was estimated to consist of *endo*-5-cyano-*anti* or *syn*-7-chloronorbornene (23%) and 5-chloro-2-cyano-nortricyclene (77%) by means of elemental analysis and a study of the mass spectrum and NMR spectrum ($CDCl_3$). Found: C, 62.30; H, 4.75; N, 9.23%. Calcd for C_8H_8NCl: C, 62.56; H, 5.25; N, 9.12%. M^+: 153 (3), 155 (1).

Assignments of the Spectral Data of the Liquid Product. *endo*-5-Cyano-*anti* or *syn*-7-chloronorbornene; H_1, H_2 protons, 3.84 ppm, H_7 proton, 5.85 ppm. $C_5H_5Cl^+$: 110 (3), 112 (1), retro Diels-Alder fraction.[16] 5-Chloro-2-cyano-nortricyclene; H_5 proton, 5.67 ppm. IR, 805 cm^{-1} (800—810 cm^{-1})[17] characteristic absorption of nortricyclene.

Bromination of Substrate II with Bromine. A few milliliters of a bromine solution containing 8.0 g of bromine in 25 m*l* of carbon tetrachloride was stirred into a solution of Substrate II (7.5 g, 0.05 mol) in 50 m*l* of carbon tetrachloride, but the bromine color did not disappear immediately; therefore, the residual bromine solution was added under reflux over a period of 30 min, and the stirring was continued for an additional 4 hr. The separated crystalline compound (10.0 g) was filtered from a hot reaction solution and recrystallized from benzene; mp 205—206°C.[18] The stereochemistry of bromine atoms was estimated to be *exo-cis* on the basis of NMR spectrum in the d_6-DMSO solution. Found: C, 35.64; H, 2.68; N, 9.20%; Calcd for $C_9H_8Br_2N_2$: C, 35.56; H, 2.65; N, 9.22%; M^+: 302 (1), 304 (2), 306 (1).

The above procedure was also followed on the same scale in an acetic acid solution at 30°C. The residue resulting after the evaporation of the acetic acid was recrystallized from benzene; mp 150—180°C (9.7 g). This material (2.0g) was dissolved in 20 m*l* of hot ethanol, and the less soluble material filtered while still hot was recrystallized from toluene (mp 206.5—207.5°C (0.2 g)), corresponding to the *exo-cis* adduct. Then the crystalline compound which separated on standing from the ethanol mother liquor was once more dissolved in about 15 m*l* of hot ethanol. The less soluble material was removed by filtration, whereupon about 0.8 g of crystals separated from the ethanol mother liquor. The resulting solid was recrystallized from ethanol; mp 138—140°C (0.5 g). The stereochemistry of bromine atoms in this adduct[19] was estimated to be *trans* on the basis of the NMR spectrum in the d_6-DMSO solution. [τ: 5.22 (1H, d, d,. J=3.8 and 4.5 Hz, H-*exo* 5 or H-*exo* 6), 5.89 (1H, t, J=~3.0 Hz, H-*endo* 6 or H-*endo* 5), 6.16 (1H, t, J=4.5 Hz, H-*exo* 2), 6.50 (1H, d, d,. J=2.1 and 5.0 Hz), 7.06 (2H, m, H-1 and 4), 7.81 (1H, forming the one part of the AB system, H-7a), 8.10 (1H, forming the other part of the AB system, H-7b)]. Found: C, 35.75; H, 2.63; N, 9.37%. Calcd for $C_9H_8Br_2N_2$: C, 35.56; H, 2.65; N, 9.22%.

Bromination of Substrate III with Bromine. Substrate III (1.44 g, 0.01 mol) dissolved in 90 m*l* of acetic acid was treated with 1.9 g (0.012 mol) of bromine dissolved in 30 m*l* of acetic acid. After stirring had been continued for three days at room temperature, a crystalline product separated. This material weighed 2.2 g and was identified as a crude *exo-cis* adduct (mp 289—290°C[20] (recrystallized from 1-propanol)). Found: C, 35.83; H, 2.60; N, 9.04%. Calcd for $C_9H_8N_2Br_2$: C, 35.56; H, 2.65; N, 9.22%. The mother liquor was evaporated to dryness, leaving a further quantity (0.2 g) of the *exo-cis* adduct, as was confirmed by the NMR spectrum (see Table 3).

Bromination of Substrate IV with Bromine. A solution of bromine (0.019 g, 0.012 mol) in 5 m*l* of acetic acid was added to a dark brown measured flask containing a solution of Substrate IV (0.145 g, 0.01 mol) in 17 m*l* of acetic acid, and then the mixture was allowed to stand at 30°C for 3 hr. After the end of the reaction, the solvent was evaporated and the resulting product was recrystallized from ethanol; mp 179—182°C[21] (0.15 g). The stereochemistry of bromine atoms was confirmed to be *trans* on the basis of the NMR spectrum of the d_6-DMSO solution (see Table 3). Found: C, 35.63; H, 2.66; N, 9.33%. Calcd for $C_9H_8N_2Br_2$: C, 35.56; H, 2.65; N, 9.22%.

Determination of the Rate of Addition. The rate of addition was determined by the titration method which was similar to that of Buckles and his co-workers.[22]

Solutions of the substrate in about 80 m*l* of acetic acid were warmed to bath temperature in a 100-m*l*, dark brown, measured flask, into which a stock solution of bromine in acetic acid was then pipetted and mixed. The acetic acid was then rapidly added to make a vloume of 100 m*l*. At appropriate intervals, 5.0-m*l* samples were pipetted into a

11) The number in brackets shows the ratio of the peak strength.

12) If the stereochemistry of the two bromine atoms is assumed to be *exo-cis*, the broad absorption (W_h=4 Hz) at 6.35 ppm can not be explained on the basis of the reported magnitude of the *endo-endo* coupling constants (approximately 6—7 Hz);[13-15] therefore, the stereochemistry was suggested to be *trans*.

flask containing 50 ml of a 2.5% KI methanol solution. The flask was swirled 5 times and then allowed to stand for 1 min, after which the iodine was titrated with a standard thiosulfate solution (1/50N) with a starch indicator.

The time for the start of the reaction was taken as the time at which half of the bromine solution was out of the pipet. The time for the stop of the reaction was determined in a manner similar to that used for the start of the reaction.

In the case of Substrate IV, rate-measurements experiments were carried out on the scale of one-fifth, as in the above description.

Assignment of Spectral Lines. In Fig. 1 are shown the decoupled spectra of compound II-*c* (mp 206.5—207.5°C) in the d_6-DMSO solution obtained using the frequency-sweep technique (Hitachi-R 20—60 spectrophotometer).[23] Part A shows the normal spectrum. The absorption at τ 7.05 is readily identified as the result of the bridge-head protons by means of the broad patterns resulting from several coupling interactions. The low-field absorption centered at τ 5.35 (doublet of quartets) is also identified as the result of two hydrogens attached to the brominated carbons on the basis of its chemical shifts[24] and integrated areas. The absorption at τ 8.03 shows the C_7 AB pattern. On the basis of the discussion presented above, the two residual absorptions at τ 6.30 and τ 6.63 are assigned as 2-*endo* or 3-*exo* hydrogens. Part B shows the spectrum obtained upon the irradiation of the C_1, C_4 protons at τ 7.05. First, the appearance of the upfield part of the C_7 AB pattern changes to a triplet of doublets. The coupling constant values (1.8 Hz) are reasonable as a zigzag, long-range coupling. Secondly, the irradiation at τ 7.05 alters the pair of doublets at τ 6.30 to only one doublet in order to remove 4.5 Hz coupling. The value of 4.5 Hz corresponds to the coupling between the bridge proton C_1 or C_4 and the C_2 *exo* or C_3 *endo* proton respectively, since the absorption at τ 6.30 may be assigned to either the 2-*exo* or 3-*endo* proton. The magnitude of the coupling between the C_4 proton and the C_3 *endo* proton was expected to be almost zero because of the unfavorable vicinal dihedral angle,[25] so the resonance at τ 6.30 is confirmed as the 2-*exo* proton. Thus the 4.5 Hz coupling between the C_1 and C_2 *exo* protons is established. The irradiation of the upper-field part of the C_7 AB pattern (Part C in Fig. 1) eliminates the splitting, 1.8 Hz, of C_5, C_6 hydrogens at τ 5.35. By combining the results of Part B and Part C, the 1.8 Hz splitting is established as a zigzag, long-range coupling between C_5 *endo* or C_6 *endo* hydrogen[26] and C_{7b} hydrogen. Thus, $J_{5\text{-}endo,\ 6\text{-}endo}$ and $J_{7b,7a}$ are confirmed to be 6.3 Hz and 11.7 Hz respectively. Therefore, the stereochemistry of bromine atoms is established as *exo-cis*.

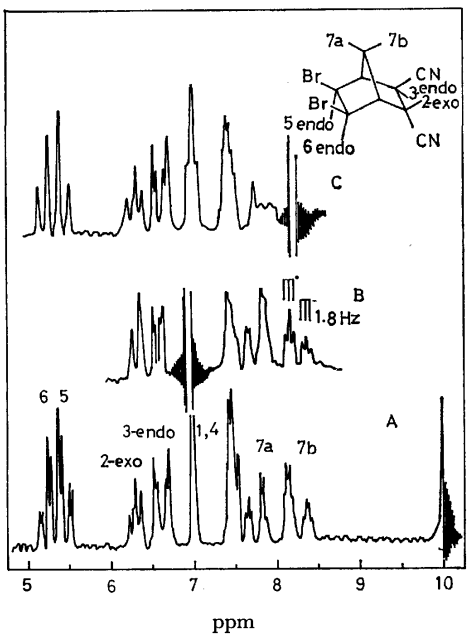

Fig. 1. NMR spectra of compound II-*c* in solution in d_6-DMSO A: normal; B: decoupled from protons 1,4; C: decoupled from proton 7b.

The stereochemistry of compound II-*t* is established as *trans* on the basis of the decoupling experiments involving

	$J_{7a,\ 7b}$=11.7, $J_{5\text{-}endo,\ 6\text{-}endo}$=6.3, $J_{2\text{-}exo,\ 3\text{-}endo}$=5.7, $J_{2\text{-}exo,\ 1}$=4.5, $J_{7b,\ 5\text{- or }6\text{-}endo}$=1.8.						
	6.25	6.62	7.13	5.50	5.31	7.89	8.29
	$J_{7a,\ 7b}$=12.0, $J_{5\text{-}endo,\ 6\text{-}endo}$=6.3, $J_{2\text{-}exo,\ 3\text{-}endo}$=5.4, $J_{2\text{-}exo,\ 1}$=5.4, $J_{7b,\ 5\text{- or }6\text{-}endo}$=2.1.						
	6.31	6.31	7.03	5.28	5.28	7.87	8.38
	$J_{7a,\ 7b}$=10.8, $J_{7b,\ 5\text{- or }6\text{-}endo}$=2.4.						
	6.37	6.37	7.05	5.84	5.30	7.75	8.01
	$J_{7a,\ 7b}$=11.8, $J_{7b,\ 5\text{-}endo}$=2.1, $J_{5\text{-}endo,\ 6\text{-}exo}$=3.9, $J_{6\text{-}exo,\ 1}$=3.9.						

a) Values are shifts in τ-units.
b) Chemical shifts represent the positions of band centers.
c) The stereochemistry was estimated on the basis of the similarity of NMR spectrum of the material (small quantity, broad range of mp near 124°C) obtained from chlorination of substrate II in hot CCl_4 solution to that of compound II-*c*.

23) Measurements were carried out by Mr. Yoshio Takai of The Institute of Scientific and Industrial Research, Osaka University.
24) P. M. Subramanian, M. T. Emerson, and N. A. Lebel, *J. Org. Chem.*, **30**, 2624 (1965).
25) M. Karplus, *J. Chem. Phys.*, **30**, 11 (1959).
26) The low-field peak (τ 5.26) among C_5, C_6 *endo* protons may be assigned to the C_6 *endo* proton since the C_6 *endo* proton is favorably situated for shielding by the C_2 *endo* cyano group;[27] this explanation seems to be in good agreement with the fact that two C_5, C_6 *endo* protons of III-*c* show a signal at τ 5.28 (in d_6-DMSO).
27) J. M. Jackman and G. Y. Sarkis, This Bulletin, **42**, 1179 (1969).

trans-5-chloro-6-iodo-*trans*-2,3-norbornanedicarbonitrile[28] and the arguments presented in Footnote[12], but the question of whether the C_6 proton is *exo* or *endo* remains unresolved and is now under investigation. Therefore, the absorptions of the appearance of a triplet at τ 5.89 and τ 6.16 (described before) are substantially duplicates of two doublets, so the coupling constants, 5.0, 2.1, 4.5, and 3.8 Hz, can be assigned to $J_{2\text{-}exo,3\text{-}endo}$, $J_{7a,3\text{-}endo}$, $J_{5\text{-}exo,4}$ (or $J_{6\text{-}exo,1}$), and $J_{5\text{-}exo,6\text{-}endo}$ (or $J_{5\text{-}endo,6\text{-}exo}$) respectively.

The stereochemistry of compound III-*c* is confirmed to be *exo-cis* as follows. The doublet (1.8 Hz splitting) at τ 5.28 corresponds to C_5, C_6 hydrogens attached to the carbons bearing bromine atoms, as is shown by the chemical shifts and integrated areas, so it is reasonable to consider that the 1.8 Hz coupling may be attributed to the long-range coupling between C_5 *endo* or C_6 *endo* and C_{7b} hydrogen. The stereochemistry of compound IV-*t* is confirmed *trans* in a way similar to that used for compound II-*t*. The assigned chemical shifts and coupling constants are listed in Table 1.

Discussion

Fortunately, the rates of bromine addition to Substrates II, III, and IV in the measurable region could be obtained by the conventional titration method. The concentrations of bromine against the reaction time are plotted in Fig. 2 for the addition reactions of bromine to Substrates II, III, and IV. The finding on *cis-endo*-5,6-norbornene-carboxylic anhydride (Substrate V) is also plotted for the sake of comparison. Figure 2 shows that the reactivity falls in this sequence; Substrate IV>II>III≃V, indicating that the *endo* orientation of cyano groups retards the addition reactions of bromine. The stereochemical results obtained here would seem to suggest that, in this addition reaction, *exo*-substituents exert such a steric influence on the rate-determining transition state as to reduce the rate of addition; that is, it may be considered that the entering bromide ion in the transition state may be sterically hindered by the *endo*-cyano group so

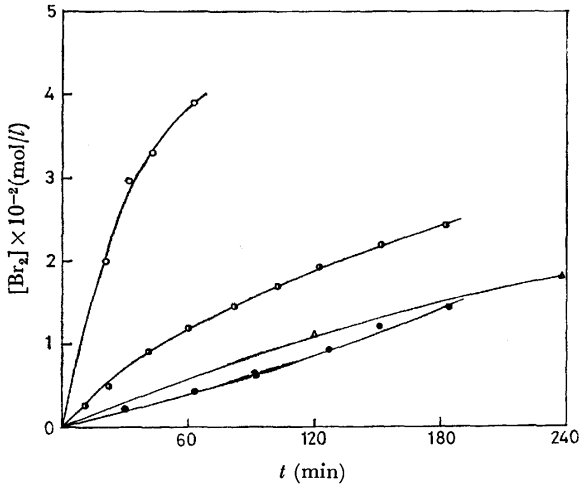

Fig. 2. Plots of consumed bromine against time for bromine addition reactions
○: Substrate IV (29.8°C); △: Substrate III (29.9°C);
◑: Substrate II (30.1°C); ●: Substrate V (30.0°C).

28) The NMR spectrum of this compound will be discussed in detail elsewhere.

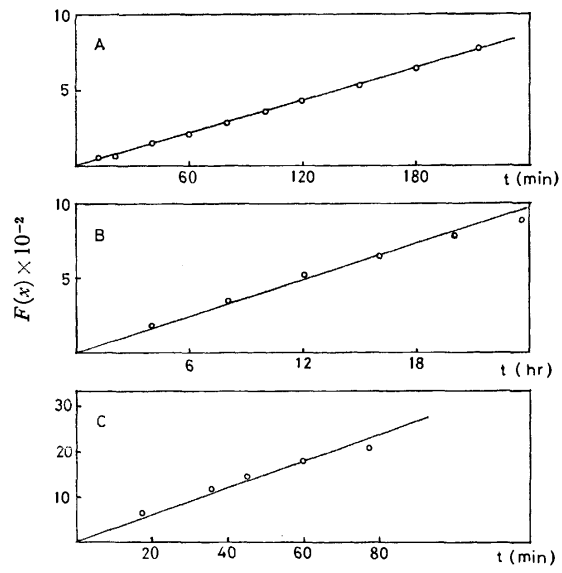

Fig. 3. Typical plots of second-order bromination rates
A: Data for substrate II at 30.1°C (*a*: 6.072×10^{-2} mol/*l* *b*: 4.995×10^{-2} mol/*l*) B: Data for substrate III at 29.9°C (*a*: 5.991×10^{-2} mol/*l*, *b*: 4.960×10^{-2} mol/*l*) C: Data for substrate IV at 29.8°C (*a*: 5.994×10^{-2} mol/*l*, *b*: 4.970×10^{-2} mol/*l*) $F(x)=\log[b(a-x)/a(b-x)]$ a=initial bromine concentration, b=initial substrate concentration, x=bromine reacted at time t.

that the *endo* orientation of substituents may produce a much greater rate reduction. This explanation[29] does not contradict the kinetic results to be described below.

Figure 3 shows the rate data treated by a second-order rate equation ($dx/dt=k\times[Br_2]\times[Sub]$).

Table 2. Rate constants for bromination of substrates (II, III, and IV) in acetic acid

Substrate	Temp (°C)	10^4 k (*l*/mol sec)	Concentration (mol/*l*)
II	30.1	12.78 (52.0)[a]	0.05
	29.9	16.90 (52.0)	0.05
	19.9	8.84 (42.7)	0.05
	20.0	17.07 (80.8)	0.1
	30.1	26.32 (89.0)	0.1
III	29.9	6.05 (60.0)	0.05
	19.9	1.59 (32.8)	0.05
IV	29.8	121.5 (79.0)	0.05
	28.9	122.3 (78.1)	0.05
V	30.0	5.17 (27.4)	0.05
	29.9	7.28 (37.9)	0.05

a) Numbers in brackets indicate the percentage of completion where plots of log $[b(a-x)/a(b-x)]$, *versus* time were linear.

29) Kwart and Miller,[30] in a kinetic study of the addition of 2,4-dinitrobenzenesulfenyl chloride to *cis-exo*-5,6-norbornene-carboxylic anhydride and Substrate V in glacial acetic acid, have explained the lower reactivity of the latter in terms of the field effect, by which they suggested that the nucleophilic character of the double bond may be reduced preferably in the case of the *endo*-anhydride. This view corresponds to the situation in which the *exo*-side attacking of a reagent and the formation of the intermediate cation may be the rate-determining steps.

30) H. Kwart and L. J. Miller, *J. Amer. Chem. Soc.*, **83**, 4552 (1961).

Table 3. Bromination of substrates (II, III, and IV)

Substrate	Solvent	Reaction time	Temp (°C)	Yield (%)	*cis* (%)	*trans* (%)
II	CCl_4	2 hr	76.8	89	67	33
	CCl_4	24 hr	30.0	96[a)]	54	46
	AcOH	6 hr	20.0	100[a)]	23	77
	AcOH	2.5 hr	28.9	90[a)]	24	76
	AcOH	5.5 hr	39.5	100[a)]	45	55
III	AcOH	3 days	room temp	80	100	0
IV	AcOH	3 hr	30.0	55	11	89

a) A solution of bromine (1.76 g 0.011 mol) in 90 m*l* acetic acid and substrate II (1.44 g, 0.01 mol) were introduced in a dark brown measured flask immersed in the aquarium provided with a mercury thermoregulator. The crude product obtained after removal of acetic acid was washed with *n*-hexane to remove a trace of acetic acid and submitted to quantitative analysis.

As to Substrate II, the data were best fitted by the second-order rate law, but the plots of the rate data of Substrate III treated by the second-order rate law show a slight downward trend while the plots of the rate data of Substrate IV treated by the second-order rate law also show a downward trend. However, in the present study, it is considered reasonable, in attempting to know the order of magnitude of rate constants, to assume that the rate approxinately fits the second-order rate law.[31)]

The rate constants deduced above are summarized in Table 2. The bromination of Substrate II was also carried out in carbon tetrachloride, but in this solvent no such clean-cut results were obtained. A relatively rapid consumption of bromine was observed after an arbitrary interval from the start of reaction, suggesting that the reaction in this solvent was homolytic. This trend (homolytic) was also observed in the bromination of Substrate II in acetic acid at 39.5°C.

Table 3 summarizes the approximate compositions of the dibromide mixtures obtained under various reaction conditions; they were calculated on the basis of a NMR-spectra analysis in the d_6-DMSO solution.

Table 3 shows that, in a carbon tetrachloride solution, the *exo* adduct of Substrate II predominates over the *trans* adduct of Substrate II, and this reaction in carbon tetrachloride is found to show a partial homolytic character, as was discussed in the part concerning rate study. In acetic acid at 39.5°C, where the bromination was considered to be partially homolytic on the basis of the rate study, the proportion of the *exo-cis* adduct increased. This type of observation of an *exo-cis* adduct increase with an increase in the homolytic character has been reported by Berson and his coworkers[4,32,33)] for the bromination of the maleic anhydride adduct of furan and cyclopentadiene. As to the bromination of the anhydride adduct of furan, only a *trans* adduct was obtained in a polar solvent such as acetic acid.

However, in the present study, the *exo-cis* adduct (23—24%) has been obtained with a residual *trans* adduct in acetic acid at 20 or 30°C.

Judging from the rate data at 20 or 30°C, the reaction in acetic acid may be considered to proceed by the heterolytic mechanism, so the formation of the *exo-cis* adduct may be explained by the steric concept that the attacking reagent bromide ion suffers a repulsive, non-bonded interaction with the *endo* cyano group of Substrate II in the *endo* direction. The stereochemistry of the bromine addition of Substrates III and IV shown in Table 3 may be explained in terms of the steric hindrance described above.

31) When treated by a third-order rate equation ($dx/dt = k \times [Br_2]^2 \times [Sub]$), the rate data gave less precise results.

Peptides Containing Aminophosphonic Acids. I. Reactivity of α-Aminobenzylphosphonic Acid

Kiyoshi YAMAUCHI, Masayoshi KINOSHITA, and Minoru IMOTO*

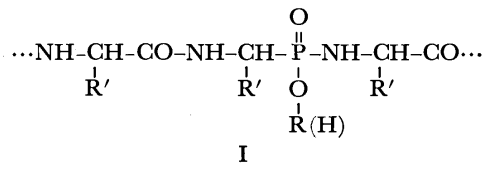
Department of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka

(Received January 14, 1972)

The chemical reactivity of α-aminobenzylphosphonic acid was investigated in order to survey the methods for incorporating aminophosphonic acids into a peptide chain. The investigation revealed that i) a dipeptide analog linked with a phosphonamide bond could be produced by the reaction of *C*-protected amino acid with the *N*-protected aminophosphonomonochloridate, and that ii) amino groups of the aminophosphonic acid possessed a reactivity similar to those of amino acids, and were capable of coupling with *N*-protected amino acids by means of dicyclohexylcarbodiimide.

Since the recent discovery of β-aminoethylphosphonic acid from sea animals, such as rumen protozoa and anthopleura elegantissima,[1,2] the aminophosphonic acids have attracted considerable biological interest not only because of their structural similarity to amino acids, but also because of their excellent metal-chelating properties, especially for calcium and ferric ions.[3]

This paper is concerned with the reactivity of aminophosphonic acids, and α-aminobenzylphosphonic acid was employed as a model compound to search the route for the preparation of phosphorus analogs of enzymes or peptides, which are chemically modified by replacing some amino acids with their phosphonic acid analogs or by inserting aminophosphonic acids into a peptide chain, as is shown below (I). α-Aminobenzylphosphonic acid can be obtained in a sizable quantity from a simple reaction of benzaldehyde, diethyl phosphite, and ammonia.[4]

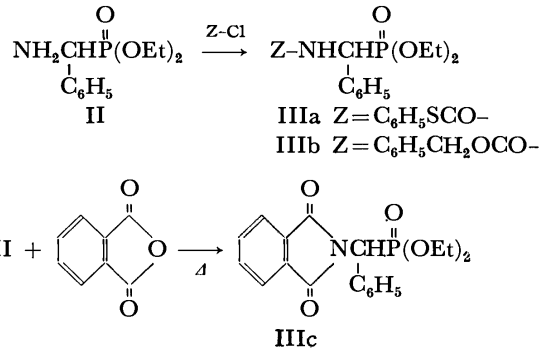


I

Results and Discussion

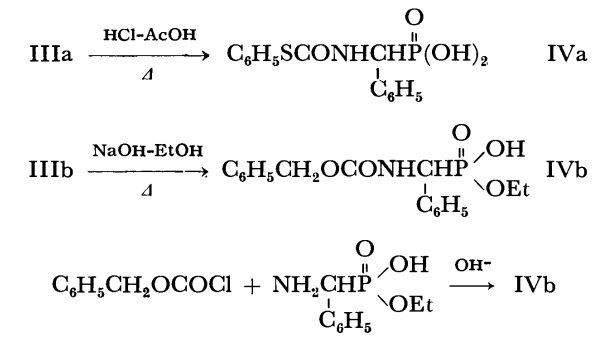
As in peptide synthesis, the reactivity of aminophosphonic acids for the following four steps must be studied in order to construct peptides with aminophosphonic acids; i) the protection of the amino and the phosphonic acid groups, ii) the activation of the phosphonic acid group, iii) coupling reactions to form an amide bond or a phosphonamide bond, and iv) the removal of the protecting groups.

For Step i, when diethyl α-aminobenzylphosphonate (II), in which the phosphonic acid function is already blocked by ethyl groups, was treated with the usual



masking reagents for the amino group[5] (*e.g.* thiophenoxycarbonyl chloride, benzyloxycarbonyl chloride, and phthalic anhydride), the corresponding *N*-protected derivatives (IIIa—c) were produced in 79%, 98%, and 51% yields respectively. These results and a coupling reaction with a free carboxyl group, which will be described later, indicate that amino groups of aminophosphonic acids have reactivity similar to those of amino acids.

The removal of ethyl groups was then attempted from phosphonic acid groups of these compounds. Thus, IIIa, upon treatment with HCl-acetic acid, produced IVa, whereas upon alkaline hydrolysis IIIa only underwent decomposition.



On the other hand, when IIIb was treated with an ethanolic sodium hydroxide solution, the half ester (IVb) was generated; this half ester could also be synthesized through the reaction of ethyl hydrogen α-aminobenzylphosphonate with benzyloxycarbonyl chloride.

These *N*-protected aminobenzylphosphonic acid

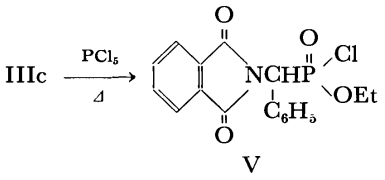
derivatives, however, did not condense to form any phosphonamide with ethyl glycinate by means of dicyclohexylcarbodiimide (DCC).

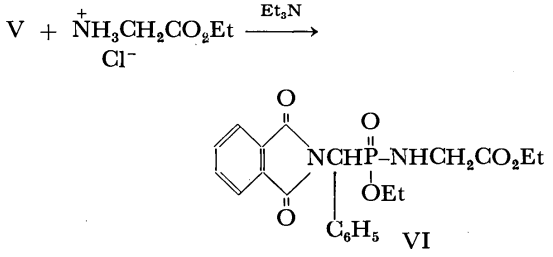
$$\text{IVa or IVb} + NH_2CH_2CO_2C_2H_5 \xrightarrow{DCC} \text{No reaction}$$

Therefore, another route was estimated–the activation of the phosphonic acid group of II (Step ii) through its conversion to its phosphonochloridate. This transformation was easily accomplished by the reaction of IIIc with a slight excess of phosphorus pentachloride, thus producing ethyl phthalimidobenzylphosphonochloridate (V). The process is quite similar to that used for chlorination of phthalylamino acids with the same reagent.[6]



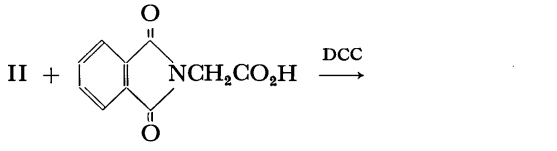
V

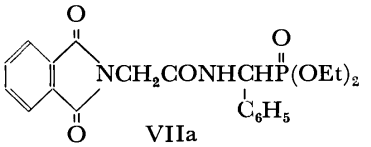
When the chloride (V) was subsequently allowed to react with ethyl glycinate, the dipeptide (VI) was formed in a 70% yield (Step iii), showing the extension of peptides from phosphinyl to amino groups.



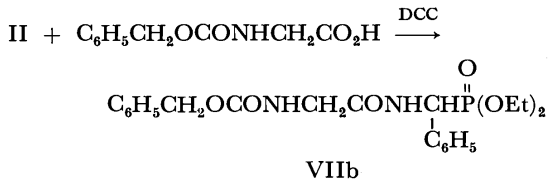
VI

The remaining step necessary for the introduction of aminophosphonic acids into a peptide chain is to place an amino acid to the left of the aminophosphonic acid. This process was examined by the reaction of II with *N*-protected amino acids, using DCC. The successful formation of the dipeptide analogs (VIIa—b) in 74—95% yields ensures that a peptide linkage can be obtained by procedures similar to those employed in the usual peptide synthesis.[5,7]





VIIa



VIIb

Using the experimental results above obtained, we have studied the synthesis of tripeptides with aminomethylphosphonic acid in the center. These results and the attempted removal of the protecting groups (Step iv) will be discussed in a subsequent paper.

Experimental

The melting points (mp) are uncorrected. The infrared spectra were measured by means of a Jasco, Model IR-G spectrometer. The nuclear magnetic resonance spectra (NMR) were recorded with a Hitachi-Perkin-Elmer appratus, Model R-20.

Preparation of Diethyl α-Aminobenzylphosphonate (II). The hydrochloride of II was synthesized according to the procedure of Chalmers and Kosolapoff[4] using benzaldehyde (25.4 g, 0.24 mol), diethyl phosphite (33.0 g, 0.24 mol), and ammonia (excess); mp 158—159°C, 26.4 g, 40% (lit,[4] 159—160°C, 31%).

To the hydrochloride of II (10.0 g, 0.036 mol) suspended in ether (70 m*l*) was added 4N sodium hydroxide, keeping the temperature of the mixture below 3°C with an ice–water bath. Enough anhydrous potassium carbonate was then added to the mixture until the water layer disappeared. The ether layer gave a clear liquid of II (6.13 g, 70%) after the evaporation of the solvent. The decomposition of II took place during vacuum distillation. IR (neat), 3350 (w), 3275 (w), 3030 (w), 2980 (m), 1600 (w), 1490 (w), 1235 (s), 1030 (s), 960 (s), 690 (m) cm^{-1}; NMR ($CDCl_3$), τ 2.7 (complex m, 5, phenyl), 5.89 (d, 1, C<u>H</u>), 4.20 (complex m, 4, C<u>H</u>$_2$), 8.85 (qua, 6, C<u>H</u>$_3$). The ester was found pure from thin-layer and gas chromatographies.

Protection of Amino Group of II. *A) With Thiophenoxycarbonyl Chloride*: Thiophenoxycarbonyl chloride (3.50 g, 20.4 mmol) was added to a solution of II (9.50 g, 39.0 mmol) in THF (70 m*l*). After the mixture had been stirred at room temperature overnight, the resulting white crystals of the hydrochloride of II were filtered out, and the solvent was removed from the filtrate. The addition of petroleum ether to the residue produced diethyl *N*-thiophenoxycarbonyl-α-aminobenzylphosphonate (IVa) as white needle crystals; 6.0 g, 80%; mp 136—137°C (THF–petroleum ether); IR (KBr), 3350 (m), 3150 (m), 2950 (m), 1670 (s), 1540 (s), 1240 (s), 1020 (s), 970 (m), 700 (m) cm^{-1}; NMR ($CDCl_3$), τ 1.9 (broad d, N<u>H</u>), 2.5 (complex m, 5, phenyl), 4.67 (qua, 1, C<u>H</u>C$_6$H$_5$), 5.76 (qui, 2, C<u>H</u>$_2$CH$_3$), 6.13 (complex six, 2, C<u>H</u>$_2$CH$_3$), 8.64 and 8.91 (t, 3, CH$_2$C<u>H</u>$_3$).

Found: C, 56.95; H, 5.90; N, 3.84%. Calcd for $C_{18}H_{22}NO_4PS$: C, 56.98; H, 5.85; N, 3.69%.

B) With Benzyloxycarbonyl Chloride: To amine (II) (7.00 g, 28.8 mmol) dissolved in tetrahydrofuran (THF) (100 m*l*) was added benzyloxycarbonyl chloride (2.50 g, 14.7 mmol) at room temperature with stirring vigorously. Soon after the addition, the hydrochloride of II precipitated as white crystals. After stirring at room temperature overnight, the reaction mixture was filtered to remove the hydrochloride of II (3.80 g). The filtrate was then concentrated to give a yellow residue which was crystallized from ether to give needle crystals of IVb; 5.30 g, 98%; mp 108—109°C (from ether); IR (KBr); 3200 (m), 3050 (m), 1705 (s), 1550 (s), 1260 (s), 1020 (s), 970 (s), 690 (m) cm^{-1}; NMR ($CDCl_3$)

τ 2.62 (complex m, 5, phenyl), 3.80 (broad, 1, NH), 4.80 (qua, 1, $C\underline{H}C_6H_5$), 4.85 (s, 2, $C\underline{H}_2C_6H_5$), 5.6—6.5 (complex m, 4, $C\underline{H}_2CH_3$), 8.75 and 8.94 (two t, 6, $CH_2C\underline{H}_3$).

Found: C, 60.44; H, 6.56; N, 3.93%. Calcd for $C_{19}H_{24}NO_5P$: C, 60.47; H, 6.41; N, 3.70%.

C) With Phthalic Anhydride: A mixture of II (6.51 g, 26.6 mmol) and phthalic anhydride (3.94 g, 26.6 mmol) was heated at 170—180°C for 2 hr. The resulting viscous liquid was dissolved in chloroform (7 m*l*) and chromatographed on alumina. Diethyl phthalimidobenzylphosphonate (IIIc) was eluted with ethyl acetate; 5.0 g, 51%; mp 101—103°C (ether); IR (KBr), 2990 (w), 1770 (w), 1710 (s), 1380 (s), 1255 (s), 1050 (s), 730 (m) cm^{-1}; NMR ($CDCl_3$), τ 2.20 (complex m, 5, phenyl), 2.65 (complex m, 4, phthalyl), 6.20 (d, 1, C$\underline{H}$), 5.75 (six, 4, two $C\underline{H}_2$), 8.75 (t, 6, $C\underline{H}_3$).

Found: C, 61.30; H, 5.41; N, 3.75%. Calcd for $C_{19}H_{20}NO_5P$: C, 61.12; H, 5.40; N, 3.75%.

Hydrolysis of IIIa. A mixture of IIIa (1.65 g, 4.20 mmol), concentrated hydrochloric acid (3 m*l*), and acetic acid (3.5 m*l*) was refluxed for 30 min. The reaction mixture was then diluted with water (8 m*l*) and the solution was stored in an ice-box. The resulting crystals (IVa) were separated, washed with water and dried; 150 g, 75%; mp 142—143°C ($CHCl_3$–acetone); IR (KBr), 3350 (w), 1650 (s), 1620 (m), 1520 (m), 1200 (s), 1050 (m), 950 (m), 750 (w) cm^{-1}; NMR (DMSO-d_6), τ 0.9 (broad, 1, POH), 2.60 (complex m, 10, two phenyl), 3.30 (broad, 1, NH), 4.90 (qua, 1, $C\underline{H}C_6H_5$).

Found: C, 50.93; H, 4.85; N, 4.25%. Calcd for $C_{14}H_{14}NO_4PS\cdot 0.5H_2O$: C, 50.61; H, 4.55; N, 4.21%.

Hydrolysis of IIIb. Compound IIIb (1.0 g, 2.65 mmol) was dissolved in a mixture of 0.4N sodium hydroxide (10 m*l*) and ethanol (10 m*l*), after which the solution was heated at 80°C for one hour. The solvent was then evaporated under reduced pressure, giving a white paste-like residue, which was dissolved in 20 m*l* of water, and pH of the solution was adjusted to about 3 by the addition of concentrated hydrochloric acid. The white solid (IVb) obtained was separated and recrystallized from petroleum ether–chloroform, 0.59 g, 64%, mp 182—183°C; IR (KBr), 3250 (w), 1710 (s), 1540 (s), 1250 (s), 1040 (m), 700 (m) cm^{-1}; NMR ($CDCl_3$), τ 2.5 (complex m, 10, two phenyl), 7.40 (broad s, 1, NH), 6.80 (qua, 1, C$\underline{H}$), 5.15 (s, 2, $C\underline{H}_2C_6H_5$), 5.95 (qua, 2, $C\underline{H}_2$), 8.75 (t, 3, $C\underline{H}_3$).

Found: C, 57.24; H, 5.81; N, 4.47%. Calcd for $C_{17}H_{20}NO_5P\cdot 0.5H_2O$: C, 56.98; H, 5.90; N, 3.91%.

Reaction of Ethyl Hydrogen α-Aminobenzylphosphonate with Benzyloxycarbonyl Chloride. To the ester (1.58 g, 0.075 mol) suspended in water (30 m*l*) was mixed with benzyloxycarbonyl chloride (1.5 g, 0.088 mol) at room temperature. 4N Sodium hydroxide (5 m*l*) was then added to the mixture and a solution was stirred for 10 min. After the unreacted chloride had been removed by extraction with ether, the pH of the aqueous solution was adjusted to 5 by the addition of concentrated hydrochloric acid, the solution was then concentrated as much as possible under reduced pressure. The extraction of the residue with chloroform and the evaporation of the solvent from the organic layer gave a clear substance which upon mixing with petroleum ether afforded IVb as white crystals; 0.8 g, 31%; mp 183—184°C (acetone). The IR and NMR spectra were identical with those of an authentic sample produced from the hydrolysis of IIIb.

Attempted Coupling of IVa or IVb with Ethyl Glycinate. A mixture of IVa (0.64 g, 1.9 mmol) or IVb (0.40 g, 0.11 mmol), an equivalent amount of ethyl glycinate, and DCC (2 equivalents) in DMF (10 m*l*) was stored at room temperature for a week. No precipitate of dicyclohexylurea appeared, showing that the coupling reaction did not take place in this system.

O-Ethyl Phthalimidobenzylphosphonochloridate (V). A mixture of IIIc (2.70 g, 7.25 mmol), phosphorus pentachloride (1.52 g, 7.30 mmol) and benzene (5 m*l*) was heated for 6.5 hr. The light-boiling substances were then removed under reduced pressure. The residue[8] was mixed with petroleum ether–ether (1:1) and cooled in a methanol–dry ice bath to give a white solid (V); 2.1 g, 80%; mp up to 85°C; IR (0.1 mm $CHCl_3$ liquid cell), 3030 (w), 1770 (m), 1725 (s), 1470 (m), 1370 (s), 1275 (s), 1030 (s), 970 (s), 545 (m) cm^{-1}; NMR ($CDCl_3$) τ 2.2 (complex m, 5, phenyl), 2.6 (complex m, 4, phthalyl), 4.05 (qua, 1, CH), 5.70 (m, 2, CH_2), 8.70 (qua, 3, CH_3). The elemental analysis of V was replaced with that of *O*-ethyl hydrogen phthalimidobenzylphosphonate, which had been obtained from the reaction of V with an excess of water in an 80% yield; mp 181—183°C; IR (KBr), 2980 (w), 1760 (w), 1710 (s), 1375 (s), 1200 (s), 1020 (s), 720 (m) cm^{-1}: NMR ($CDCl_3$), τ 1.8—3.0 (complex m, 9, phthalyl and phenyl), 4.20 (d, 1, C$\underline{H}$), 5.87 (qua, 2, $C\underline{H}_2$), 8.80 (qua, 3, $C\underline{H}_3$).

Found: C, 59.42; H, 4.68; N, 3.81%. Calcd for $C_{17}H_{16}NO_5P$: C, 59.13; H, 4.67; N, 4.05%.

Preparation of VI. Compound (IIIc) (2.22 g, 5.95 mmol) was allowed to react with phosphorus pentachloride (1.23 g, 5.90 mmol) in benzene (10 m*l*) to give the chloride as an oily substance, it was dissolved in THF (10 m*l*) and added to a chloroform (30 m*l*) solution of ethyl glycinate hydrochloride (0.9 g, 6.5 mmol) containing triethylamine (5.0 g, 50 mmol) at room temperature. The solution was then stirred overnight and washed with water. The chloroform layer was dried over Drierite and concentrated to about 5 m*l*. Column chromatography on silicic acid was then carried out on the solution. Elution with ether afforded VI (1.8 g, 70%) as a clear oil. The distillation of the product failed because of decomposition, its IR and NMR spectra were however, consistent with the assigned structure; IR (neat), 3350 (w), 3050 (w), 2980 (m), 1765 (w), 1710 (s), 1620 (w), 1495 (w), 1375 (s), 1250 (s), 1030 (s), 750 (m), 710 (s) cm^{-1}; NMR ($CDCl_3$) τ 2.2 (complex m, 5, phenyl), 2.65 (complex m, 4, phthalyl), 4.20 (qua, 1, CH), 5.5—6.3 (complex m, 7, $POC\underline{H}_2$, $N\underline{H}C\underline{H}_2CO_2C\underline{H}_2$), 8.78 and 8.85 (two t, 6, $C\underline{H}_3$).

Preparation of VIIa. A mixture of phthalyl-glycine (0.95 g, 0.467 mmol), II (1.13 g, 0.467 mmol), DCC (1.50 g, 0.73 mmol), and THF (15 m*l*) was stirred overnight at room temperature. Acetic acid (1 m*l*) and water (2 m*l*) were then added to the reaction mixture, and stirring was continued for 2 hr. The resulting dicyclohexylurea was filtered out, and the solvent was removed from the filtrate by means of a rotary evaporator at a water-bath temperature below 50°C. Chloroform (30 m*l*) was added to the residue, and the solution was washed with 10% sodium bicarbonate and water. The organic solution was concentrated to about 2.5 m*l*, giving a viscous oil which was subsequently crystallized from benzene to generate clear crystals; 1.90 g, 95%; mp 195—196°C; IR 3250 (m), 3030 (w), 2980 (m), 1730 (s), 1555 (m), 1420 (m), 1230 (s), 1030 (s), 720 (m) cm^{-1}; NMR ($CDCl_3$) τ 0.80 (d, 1, NH), 1.9—2.7 (complex m, 9, phenyl and phthalyl), 4.33 (qua, 1, $C\underline{H}C_6H_5$), 5.50 (s, 2, $C\underline{H}_2CO$), 5.60—6.60 (complex m, 4, $C\underline{H}_2CH_3$), 8.55 and 8.92 (two, t, 6, $C\underline{H}_3$).

Found: C, 58.82; H, 5.40; N, 6.30%. Calcd for $C_{21}H_{23}$-

8) The successive reactions were carried out using the oily residue directly, since which was almost pure according to the NMR spectrum but showed considerable difficulty in crystallization.

N_2O_6P: C, 58.60; H, 5.38; N, 6.51%.

Preparation of VIIb. A procedure similar to that used for the preparation of VIIa was carried out for a mixture of *N*-benzyloxycarbonylglycine (1.50 g, 7.18 mmol), II (1.75 g, 7.18 mmol), DCC (3.19 mmol), and THF (15 m*l*) to form VIIb as white crystals; 2.30 g, 74%; mp 88—89°C (ether); IR (KBr), 3250 (m), 3050 (w), 1720 (s), 1680 (s), 1550 (s), 1220 (s), 1160 (m), 1020 (s), 700 (m) cm^{-1}. NMR ($CDCl_3$) τ 1.45 (broad d, 1, N$\underline{H}$), 2.7 (complex m, 10, two, phenyl), 4.20 (broad t, 1, CON$\underline{H}C\underline{H}_2$), 4.42 (qua, 1, PC$\underline{H}C_6H_5$), 4.92 (s, 2, C$\underline{H}_2C_6H_5$), 5.85 (qui, 2, C$\underline{H}_2CH_3$), 6.10 (qui, 2, C$\underline{H}_2CH_3$), 8.72 and 8.96 (two t, 6, C$\underline{H}_3$).

Found: C, 58.28; H, 6.48; N, 6.45%. Calcd for $C_{21}H_{27}N_2O_6P$: C, 58.19; H, 6.78; N, 6.46%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2531—2534 (1972)

Peptides Containing Aminophosphonic Acids. II. The Synthesis of Tripeptide Analogs

Kiyoshi YAMAUCHI, Masayoshi KINOSHITA, and Minoru IMOTO*

Department of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka

(Received January 14, 1972)

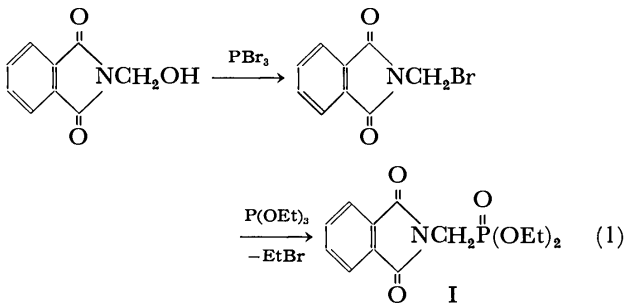
The synthesis of tripeptides containing aminophosphonic acid was attempted as follows. Diethyl phthalylimidomethyl phosphonate (I) was chlorinated with phosphorus pentachloride to the phosphonomonochloridate (II), which was then coupled with amino acid ethyl esters to give the corresponding dipeptides (IIIa—c). The phthalyl groups of III were removed with hydrazine, and the resulting free amines were subsequently combined with phthalyl-amino acids by means of dicyclohexylcarbodiimide to produce the tripeptide analogs (IVa—c) in good yields.

In the preceding paper[1] we described the reactivity of α-aminobenzylphosphonic acid in connection with exploring a synthetic route for incorporating aminophosphonic acids into a peptide chain; we found that i) the reaction of *C*-protected amino acids with the *N*-protected aminophosphonomonochloridate could produce the corresponding dipeptide analogs linked through the phosphonamide bond, and ii) the amino group of aminophosphonic acids possessed a reactivity similar to that of amino acids and was capable of coupling with carboxyl groups of amino acids by means of dicyclohexylcarbodiimide (DCC).

In this paper we wish to report the synthesis of tripeptide analogs containing aminomethylphosphonic acid in the center. Aminophosphonic acid may be considered as the simplest phosphonic acid analog of glycine, and it would give readily crystallizable products than those obtained from α-aminobenzylphosphonic acid[1] because of less steric hindrance and the lack of an asymmetric carbon. Furthermore, the synthesis of tripeptides may offer a suitable guideline for the preparation of phosphorus analogs of higher peptides.

Results and Discussion

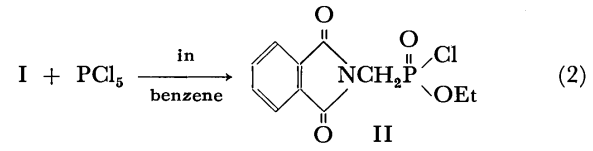
On the basis of the results of the previous work,[1] aminomethylphosphonic acid, the amino and phosphonic acid groups of which were blocked with phthalyl and ethyl groups respectively, was prepared by the following route. *N*-Hydroxylmethylphthalimide was brominated by phosphorus tribromide to produce *N*-bromomethylphthalimide in a 78% yield, the latter substance was then allowed to react with triethyl phosphite to generate diethyl phthalimidomethylphosphonate (I) in an 82% yield (Eq. (1)).



(1)

I

To activate the phosphonic-acid function for coupling with amino acids, compound I was treated with a slight excess of phosphorus pentachloride in benzene, giving crystalline ethyl phthalimidomethylphosphonochloridate (II) quantitatively (Eq. (2)). The chloride (II) showed a typical acid chloride character.[2]



(2)

II

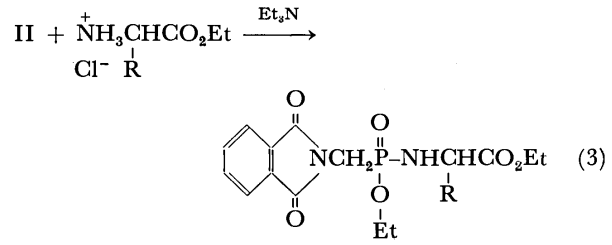
Amino acid ethyl ester hydrochlorides were then coupled with II in the presence of triethylamine,

* Present address: Department of Applied Chemistry, Kansai University, Suita, Osaka.

1) K. Yamauchi, M. Kinoshita, and M. Imoto, This Bulletin, **45**, 2528 (1972).

2) The chloride (II) showed the typical acid chloride character. Thus, when II was allowed to react with water, amines, and alcohols, the corresponding products, *e.g.*, ethyl hydrogenphosphonate, phosphonamides, and esters, were obtained in good yields.

thus producing dipeptide analogs (IIIa—c) in 70—88% yields (Eq. (3)).

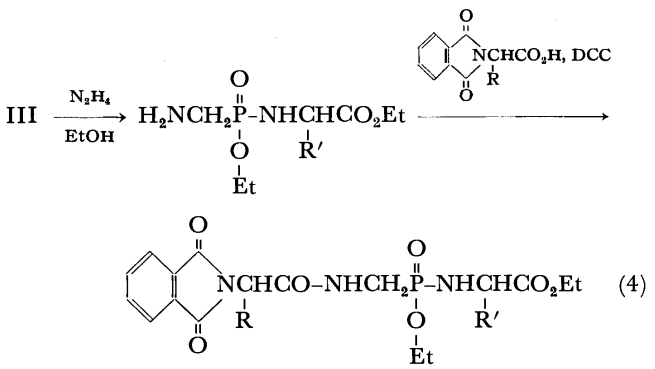


(3)

IIIa: R=H (PHT-gly-gly-OEt)
IIIb: R=*d*, *l*-CH_3 (PHT-gly-ala-OEt)
IIIc: R=*l*-$CH_2C_6H_5$ (PHT-gly-phe-OEt)

The attempted reactions of II with plain amino acids failed, though the procedure used was similar to that employed in the reactions of *N*-protected amino acid chlorides with amino acids, which has been reported to produce dipeptides.[3]

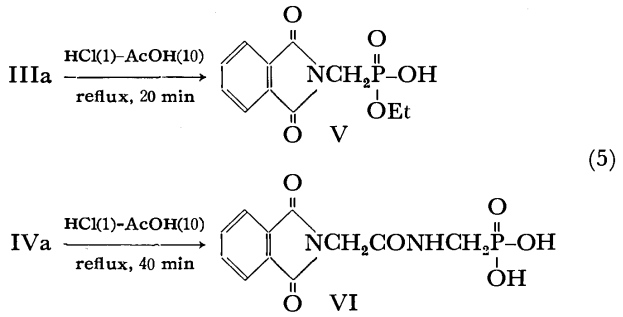
For the transformation of III into tripeptides which have aminomethylphosphonic acid in the center, the phthalyl group of III must be removed to give the corresponding free amines. This process was easily accomplished through the treatment of III with one equivalent of ethanolic hydrazine under mild conditions. The resulting amines were subsequently allowed to couple with phthalyl-amino acids, using DCC as the condensing agent, and produced tripeptide analogs (IVa—c) in 70—75% yields, (Eq. (4)). The procedure employed here was similar to those used in peptide synthesis.[4]



(4)

IVa: R=H, R′=H (PHT-gly-gly-gly-OEt)
IVb: R=H, R′=*l*-$CH_2C_6H_5$ (PHT-gly-gly-phe-OEt)
IVc: R=*l*-$CH_2C_6H_5$, R′=H (PHT-phe-gly-gly-OEt)

Concerning the removal of protecting groups, the phthalyl groups of the above compounds may be deblocked by hydrazine, as shown in the conversion of III to IV. The removal of the ethyl groups from carboxylic and phosphonic acid groups, however, was difficult, since P–N bond cleavage took place exclusively upon a mild acid treatment (Eq. (5)). Thus, when heated in a mixture of hydrochloric acid and acetic acid, IIIa produced the half ester (V) after 20 min, whereas IVa gave the phosphonic acid derivative (IV) within 40 min.



(5)

For the extension of the peptide chain, however, the presence of the carbonyl ester part does not provide any obstacles when the phthalyl groups is replaced with other *N*-protecting groups in the –CONH-bond-forming step (Eq. 4) and when an azide method is employed for the activation of carboxylic acid group. Work on these problems is now in progress and will be described later.

Experimental

The melting points (mp) are uncorrected. The infrared spectra (IR) were run on a Jasco Model IR-G spectrometer. The nuclear magnetic resonance spectra (NMR) were recorded with a Hitachi-Perkin-Elmer appratus, Model R-20. The optical rotations were obtained using a Yanagimoto Photomagnetic Polarimeter, Model OR-10.

Preparation of Diethyl Phthalimidomethylphosphonate (I). A) N-*Bromomethylphthalimide*: A mixture of *N*-hydroxymethylphthalimide (50.0 g, 0.282 mol) and phosphorus tribromide (77.0 g, 0.285 mol) was warmed until a dark-orange solution resulted. The cooled reaction mixture was poured into ice water to give a gray solid, which was then washed with water, dried, and crystallized from chloroform to produce *N*-bromophthalimide; 53.0 g, 78%; mp 149—150°C (lit,[5] 148°C).

B): *N*-Bromomethylphthalimide (39.5 g, 0.165 mol) and triethyl phosphite (27.4 g, 0.165 mol) were placed in a 200 m*l* round-bottom flask equipped with a distilling column, and then heated gently to initiate a reaction. After the exothermic reaction had subsided, the heating of the flask was continued for one hour, during which time the distillation of ethyl bromide stopped. Chloroform (100 m*l*) was added to the cooled reaction mixture, and the solution was washed with water (100 m*l*×3). The organic solution was dried over Drierlite and concentrated. The addition of petroleum ether to the residue gave white crystals (I); 40.0 g, 82%; mp 67°C (*n*-hexane); IR (KBr), 1770 (w), 1715 (s), 1240 (s), 1050 (s), 980 (m) cm^{-1}; NMR ($CDCl_3$) τ 1.85 (s, 4, phthal), 5.58 (qui, 4, $C\underline{H}_2$), 5.70 (d, 2, $C\underline{H}_2PO$), 8.60 (t, 6, $C\underline{H}_3$).

Found: C, 52.74; H, 5.44; N, 4.76%. Calcd for $C_{13}H_{16}NO_5P$: C, 52.52; H, 5.42; N, 4.71%.

Preparation of O-*Ethyl Phthalimidomethylphosphonochloridate (II)*. Compound I (6.27 g, 21.0 mmol), phosphorus pentachloride (4.67 g, 22.5 mmol), and dry benzene (20 m*l*) were refluxed for 15 hr. The solvent was then distilled out under reduced pressure to give a clear residue which, upon standing at

room temperature, solidified as white crystals. Recrystallization from dry tetrahydrofuran(THF)–ether gave needle crystals; 5.6 g, 93%; mp 92—94°C; IR ($CHCl_3$), 1780 (w), 1725 (s), 1600 (w), 1385 (s), 1300 (m), 1250 (m), 710 (m) cm^{-1}; NMR ($CDCl_3$), τ 1.8 (complex m, 4, phthalyl), 5.40 (d, 2, $C\underline{H}_2P$), 5.50 (complex m, 2, $POC\underline{H}_2$), 8.55 (qua, 3, $C\underline{H}_3$).

Found: C, 46.21; H, 4.03; N, 5.10; Cl, 12.76%. Calcd for $C_{11}H_{11}ClNO_4P$: C, 45.93; H, 3.85; N, 4.87; Cl, 12.33%.

Since the chloride (II) was produced quantitatively in an almost pure state, it was used for the successive reactions directly, without recrystallization.

Preparation of Phosphorus Analogs of Dipeptide (III). *PHT-gly-gly-OEt (IIIa)*: To a chloroform (70 m*l*) solution of ethyl glycinate hydrochloride (4.65 g, 0.033 mol) was added triethylamine (15 m*l*) with cooling by an ice-water bath. Chloride (II) (9.65 g, 0.034 mol), which was dissolved in THF (70 m*l*), was then added drop by drop over 15 min with stirring vigorously. After the completion of the addition, the reaction mixture was stirred for 10 hr. The resulting triethylamine hydrochloride was filtered out; the filtrate was concentrated to about 20 m*l* and diluted with chloroform to 100 m*l*, after which the solution was washed once with 10% sodium bicarbonate and then with water. The evaporation of the solvent and the addition of ether to the residue yielded white crystals. Recrystallization from ether–THF gave 10.5 g (88%) of IIIa; mp 132—133°C; IR (KBr), 3200 (w), 1750 (w), 1710 (s), 1220 (s) cm^{-1}; NMR ($CDCl_3$); τ 1.8 (complex m, 4, phthalyl), 5.6 (complex m, 4, $POC\underline{H}_2$, $CO_2C\underline{H}_2$), 5.77 (s, 2, $NC\underline{H}_2CO$), 4.02 (d, 2, $NC\underline{H}_2P$), 8.75 (two t, 6, $POCHCH_3$, $COCH_2C\underline{H}_3$).

Found: C, 51.09; H, 5.20; N, 7.68%. Calcd for $C_{15}H_{19}N_2O_6P$: C, 50.84; H, 5.40; N, 7.90%.

PHT-gly-ala-OEt (IIIb): The procedure similar to that used for the preparation of IIIa was employed, using II (5.80 g, 0.020 mol) and *d,l*-alanine ethyl ester hydrochloride (3.10 g, 0.020 mol) to produce IIIb as clear crystals; 5.1 g, 70%; mp 126—127°C) petroleum ether–THF); IR (KBr), 3150 (w), 1740 (w), 1710 (s), 1400 (s), 1200 (s), 1150 (s), 1040 (s), 720 (s) cm^{-1}. NMR ($CDCl_3$) τ 2.15 (complex m, 4, phthalyl), 5.6—6.2 (complex m, 7, $NC\underline{H}_2POC\underline{H}_2$, $C\underline{H}CH_3$, $COC\underline{H}_2$), 6.4 (broad, 1, $PN\underline{H}$), 8.55 (d, 3, $CHC\underline{H}_3$), 8.70 and 8.73 (t, 3, $COCH_2C\underline{H}_3$, or $POCH_2C\underline{H}_3$).

Found: C, 52.24; H, 5.66; N, 7.57%. Calcd for $C_{16}H_{21}N_2O_6P$: C, 52.19; H, 5.75; N, 7.61%.

PHT-gly-l-phe-OEt (IIIc): The chloride (7.00 g, 0.0243 mol) was allowed to react with *l*-phenylalanine ethyl ester hydrochloride (5.60 g, 0.025 mol) in a manner similar to that used in the synthesis of IIIa to form IIIc as clear crystals; 9.2 g, 83%; mp 94—95°C (ether–THF); IR (KBr), 3350 (w), 1760 (w), 1710 (s), 1390 (s), 1220 (s), 1110 (s), 960 (s) cm^{-1}; NMR ($CDCl_3$), τ 2.20 (complex m, 4, phthalyl), 5.6—6.5 (complex m, 7, $NC\underline{H}_2P$, $POC\underline{H}_2$, $C\underline{H}CO_2C\underline{H}_2$), 6.90 (d, 2, $C\underline{H}_2C_6H_5$), 8.80 (two t, 6, $POCH_2C\underline{H}_3$, $COCH_2C\underline{H}_3$); $[\alpha]_D^{21}$ +8.97° ($CHCl_3$, *c* 4.2).

Found: C, 58.15; H, 5.55; N, 6.16%. Calcd for $C_{22}H_{25}N_2O_6P \cdot 0.5H_2O$: C, 58.27; H, 5.78; N, 6.17%.

Preparation of Phosphorus Analogs of Tripeptide. *PHT-gly-gly-gly-OEt (IVa)*: Compound IIIa (1.50 g, 4.22 mol) was dissolved in ethanol (15 m*l*) and the solution was mixed with 1N ethanolic hydrazine (4.5 m*l*). After the reaction mixture had been kept at room temperature overnight, the resulting solid was filtered out and the filtrate was concentrated by a rotary evaporator at the water-bath temperature below 45°C. Since a white solid appeared upon the addition of THF to the residue, the solution was again filtered. The evaporation of the solvent from the filtrate gave gly-gly-OEt as a liquid. The amine thus obtained and phthalyl-glycine (0.83 g, 4.05 mmol) were dissolved in dry THF (10 m*l*), with which dicyclohexylcarbodiimide (1.0 g, 4.85 mmol) had been mixed. The solution was then kept at room temperature overnight. Water (1 m*l*) and acetic acid (0.5 m*l*) were subsequently added to the reaction mixture, after which it was allowed to stand at room temperature for 2 hr. The resulting dicyclohexylurea was removed, and the remaining solution was concentrated as much as possible. The residue was diluted with chloroform (20 m*l*) and neutrallized with 10% sodium bicarbonate. After the organic solution had then been dried over Drierite, the solvent was removed to give a light-yellow liquid. Upon the addition of ether, IVa appeared as white crystals; 1.1 g, 70%; mp 186—187°C (THF); IR (KBr), 3300 (w), 3200 (w), 1770 (w), 1710 (s), 1660 (m), 1560 (m), 1420 (m), 1200 (s), 1040 (m), 960 (m) cm^{-1}; NMR ($CDCl_3$), τ 2.3 (m, 4, phthalyl), 5.50 (s, 2, $C\underline{H}_2$-phthalyl), 5.90 (qua, 4, $COC\underline{H}_2$, $POC\underline{H}_2$), 6.0—6.6 (complex m, 5, $NHC\underline{H}_2PN\underline{H}C\underline{H}_2$), 8.70 (t, 3, $COCH_2C\underline{H}_3$), 8.76 (qua, 3, $POCH_2C\underline{H}_3$).

Found: C, 49.60; H, 5.28; N, 10.07%. Calcd for $C_{17}H_{22}N_3O_7P$: C, 49.63; H, 5.39; N, 10.21%.

PHT-gly-gly-phe-OEt (IVb): The phthalyl group was removed from IIIc (1.58 g, 3.50 mmol) with 1N ethanolic hydrazine (4.0 m*l*) in a manner similar to the procedure described in the preparation of IVa. The amine (about 1.59 g) was then coupled with phthalyl-glycine (0.70 g, 3.4 mmol) by DCC (1.0 g). The reaction mixture was processed as described above to produce IVb; 1.45 g, 75%; mp 164—166°C (THF); IR (KBr), 3250 (w), 3200 (w), 1715 (s), 1660 (m), 1550 (w), 1410 (m), 1190 (s), 1030 (s), 700 (m) cm^{-1}; NMR ($CDCl_3$), τ 2.1 (complex m, 5, phthalyl, CONH), 2.6 (complex m, 5, phenyl), 5.5—7.2 (complex m, 12, $C\underline{H}_2$ phthalyl, $C\underline{H}_2P(OC\underline{H}_2-)N\underline{H}C\underline{H}C\underline{H}_2C_6H_5$, $COC\underline{H}_2$), 8.5—9.2 (complex m, 6, $POCH_2C\underline{H}_3$, $COCH_2C\underline{H}_3$); $[\alpha]_D^{19}$ −27.3° ($CHCl_3$, *c* 6.1).

Found: C, 58.23; H, 5.50; N, 8.43%. Calcd for $C_{24}H_{28}N_3O_7P$: C, 57.48; H, 5.62; N, 8.37%.

PHT-l-phe-gly-gly-OEt (IVc): After IIIa (2.0 g, 5.65 mmol) had been treated with 1N hydrazine (6 m*l*), the resulting amine (1.22 g) was coupled with phthalyl-*l*-phenylalanine (1.67 g, 5.65 mmol) by DCC (1.5 g) in THF (20 m*l*). The mixture was handled in a way similar to that used with IVa to generate a light-yellow oil; this oil was then column-chromatographed on silicic acid to give IVc as a clear oil; 2.0 g, 70%; IR ($CHCl_3$); 3200 (m), 1770 (w), 1740 (m), 1710 (s), 1670 (m), 1520 (m), 1375 (s), 1190 (s), 1130 (s), 960 (m), 710 (s) cm^{-1}; NMR ($CDCl_3$) τ 2.0 (broad m, 1, $CON\underline{H}$), 2.3 (complex m, 4, phthalyl), 2.78 (s, 5, phenyl), 4.80 (qua, 1, $PON\underline{H}$), 5.6—6.7 (complex m, 11, $C\underline{H}C\underline{H}_2$-$C_6H_5$, $C\underline{H}_2POC\underline{H}_2$, $C\underline{H}COC\underline{H}_2$), 8.6—9.0 (two t, 6, $COCH_2$-$C\underline{H}_3$, $POCH_2C\underline{H}_3$); $[\alpha]_D^{19}$ −75.47° ($CHCl_3$, *c* 14.5).

Found: C, 57.10; H, 5.91; N, 8.12%. Calcd for $C_{24}H_{28}N_3O_7P$: C, 57.48; H, 5.62; N, 8.37%.

Acid Hydrolysis of IIIa. Compound IIIa (0.67 g, 18.9 mmol) was dissolved in 7 m*l* of a mixture of concentrated hydrochloric acid and acetic acid (1: 10), and then the solution was refluxed for 20 min. Water was added to the cooled reaction mixture, and the resulting solution was concentrated under a reduced pressure to give a white solid, this solid subsequently crystallized from THF to produce ethyl hydrogen phthalimidomethylphosphonate; 0.3 g, 59%; mp 205°C; IR (KBr), 3000—2500 (broad w), 1775 (w), 1725 (s), 1400 (m), 1205 (m), 1035 (s), 720 (s) cm^{-1}.

Found: C, 48.92; H, 4.54; N, 5.01%. Calcd for $C_{11}H_{12}NO_5P$: C, 49.07; H, 4.49; N, 5.20%.

Acid Hydrolysis of IVa. A similar procedure was employed for IVa (0.055 g, 0.13 mmol) using 5 m*l* of the

acid solution and taking a refluxing time of 40 min to produce phthalyl-glycylaminomethylphosphonic acid; 0.03 g, 75%; mp 192—194°C, IR (KBr), 3250 (w), 1770 (w), 1725 (s), 1660 (m), 1420 (m), 1100—1200 (m), 1000 (m), 960 (m), 720 (m) cm^{-1}; NMR (D_2O), 2.30 (s, 4, phthalyl), 5.70 (s, 2, $NC\underline{H}_2CO$), 6.55 (d, 2, $C\underline{H}_2P$).

Found: C, 44.62; H, 3.98; N, 9.05%. Calcd for $C_{11}H_{11}N_2O_6P$: C, 44.30; H, 3.71; N, 9.40%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2534—2537 (1972)

Products from the Reaction of Dinitrotetramethylbenzenes with Fuming Nitric Acid. A New Route to Some Polynitro Carbonyl Compounds[1)]

Hitomi SUZUKI* and Kiyomi NAKAMURA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received January 22, 1972)

Reaction of dinitrotetramethylbenzenes with fuming nitric acid has been investigated. 5,6-Dinitro-1,2,3,4-tetramethylbenzene undergoes a slow oxidation to give 2,3,4,5-tetranitro-2,3,6,6-tetramethylcyclohex-4-enone in 82—87% yield, which is thermally unstable and upon heating readily converted into 4,5-dinitro-2,3,6,6-tetramethylcyclohexa-2,4-dienone losing two molecules of nitrogen dioxide. 4,6-Dinitro-1,2,3,5-tetramethylbenzene reacts readily with cold fuming nitric acid, giving 2,6-dinitro-3,4,5-trimethylbenzaldehyde in 76—84% yield, together with small amounts of 2,6-dinitro-3,4,5-trimethylphenylnitromethane, 2,6-dinitro-3,4,5-trimethylbenzoic acid, and 2,6-dinitro-3,4,5-trimethylbenzyl alcohol. 3,6-Dinitro-1,2,4,5-tetramethylbenzene is stable towards the action of fuming nitric acid, but is slowly converted into 3,6-dinitro-2,4,5-trimethylbenzyl nitrate on being heated with mixed acid at 40—50°C. The mode of formation of unusual products is briefly discussed.

On treatment with an excess of ordinary nitrating agent, tetraalkylbenzenes give dinitrotetraalkylbenzenes as the final product. Because of good crystallization and moderate melting range, dinitro derivatives are often used for the characterization of liquid hydrocarbons. We have reported that fuming nitric acid nitrooxylated the alkyl side-chain of fully substituted derivatives of polyalkylbenzenes to yield the benzylic compounds.[2)] The reaction is of electrophilic character and remarkably retarded by the presence of deactivating substituents such as nitro or carboxyl groups, although pentamethylnitrobenzene and pentamethylbenzoic acid can undergo a slow side-chain nitrooxylation at ortho methyl groups.[3,4)] It is expected, therefore, that the doubly deactivated dinitrotetramethylbenzenes are quite stable towards further action of the nitrating agent. However, dinitro derivatives of 1,2,3,4-tetramethylbenzene (prehnitene) and 1,2,3,5-tetramethylbenzene (isodurene) are found to react with fuming nitric acid with moderate ease to produce a tetranitrocyclohexenone or a dinitrobenzaldehyde, respectively, in good yields.

When a solution of 5,6-dinitro-1,2,3,4-tetramethylbenzene (5,6-dinitroprehnitene, DNP) in cold fuming nitric acid (d=1.50) was stood at room temperature for several days, it reacted with the nitrating agent with gentle liberation of nitrogen dioxide. Quenching with water, followed by careful crystallization of the precipitate from a mixture of dichloromethane and light petroleum (bp 40—50°C) gave nearly colorless prisms (I), $C_{10}H_{12}N_4O_9$, in 82—87% yield, which melted at 111—114°C with complete decomposition. Its mass spectrum showed fragment ion peaks derived from the non-detectable molecular ion at m/e 286 ($M-NO_2$), 256 ($M-NO_2-NO$), and 240 ($M-2NO_2$). Its infrared spectrum suggested the formation of an unsaturated nitro carbonyl compound (1742 (C=O), 1674 (C=C), 1540—1580 (NO_2, broad), 1328—1337 (NO_2, broad), and 846 cm^{-1} (NO_2)). Its ^1H NMR spectrum (100 MHz, $CDCl_3$) with four singlets at 8.71, 8.51, 8.11, and 7.67 τ indicated the presence of four methyl groups. The possibility of formation of the conjugated carbonyl compound was ruled out by the absence of ultraviolet maximum (in MeOH) above 220 nm.

Nitro carbonyl compound (I) was thermally unstable and, when heated gently in carbon tetrachloride, it readily released nitrogen dioxide and was converted into a bright yellow substance (II), $C_{10}H_{12}N_2O_5$, mp 94—96°C. The mass spectrum was very similar to that of I, except for the lack of two minor peaks at m/e 286 and 256. The peak at m/e 240 indicated the formation of II from I by the loss of two molecules of nitrogen dioxide. Its infrared spectrum showed the conjugated carbonyl bands at 1684, 1644 (C=O), and 1617 cm^{-1} (C=C), and absorption bands due to the conjugated nitro groups at 1533—1543 and 1365 cm^{-1}. The ultraviolet spectrum (in MeOH) had a maximum at 296—298 nm ($\log \varepsilon$=3.66) in accord with the

presence of a 2,4-cyclohexadienone system.[5] The ^1H NMR spectrum of II consisted of three singlets at 8.56, 7.94 and 7.81 τ, with relative areas 2 : 1 : 1. The signal at 8.56 τ was due to the *gem*-dimethyl on C-6. If we make a reasonable assumption that the vicinal disposition of two nitro groups in DNP remains intact during the course of reaction, the two *gem*-methyl groups should be located next to the *vic*-dinitro grouping; otherwise they will absorb at around 8.7—8.9 τ.[6] The significant low-field shift is attributed to the location of the methyl groups in a deshielding region of the neighboring nitro group.[7] The inductive and electric field effects would also contribute. The two signals at 7.81 and 7.94 τ could be assigned to the methyl groups on C-2 and C-3, respectively. Examination of a scale model shows that the most preferred conformation of the two nitro groups in II is the one in which the C-5 nitro group is nearly coplanar with the ring to minimize steric crowding, while the C-4 nitro group is twisted considerably out of the ring plane to decrease unfavorable electrostatic interaction between two polar functionalities.[8] The C-3 methyl will then be placed out of the center of the deshielding region of the C-4 nitro group and be subject to reduced deshielding. The C-2 methyl group would be deeply deshielded by the combined effect of the nitro and carbonyl groups. These spectral evidences allowed for II the formulation of *4,5-dinitro-2,3,6,6-tetramethylcyclohexa-2,4-dienone*. Further proof of the structure is obtained from the mass spectrum, which showed prominent peaks at *m/e* 194 (M−Me−NO−H), 166 (M−Me−NO−CHO), 152 (M−2Me−NO−CO), 150 (M−2Me−2NO), 148 (M−2NO_2), and a peak cluster at *m/e* 119—124, Very strong peaks at *m/e* 108, 105, 93, 91, 79, 78, and 77 indicate a structure closely related to the benzenoid compound.

Nitro carbonyl compound (I) was, therefore formulated as *2,3,4,5-tetranitro-2,3,6,6-tetramethylcyclohex-4-enone*, whose most preferred structure was suggested from the molecular model shown in Fig. 1, two molecules of nitrogen dioxide being added to the unsaturated bond of II in a *trans* manner. The marked non-equivalence of the geminal methyl groups at 8.71 and 8.51 τ is probably due to the anisotropic effect of the neighboring carbonyl and nitro groups. The easy elimination of two nitrogen dioxide molecules from I suggests the crowding of the nitro and carbonyl groups in half-chair conformer.

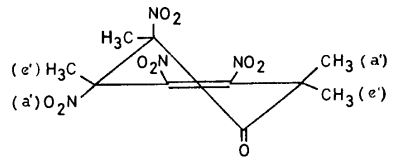

Fig. 1.

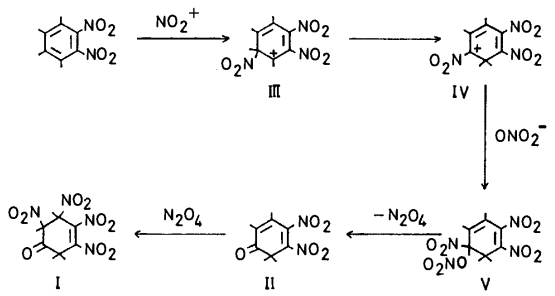
Formation of ketone (I) could be accounted for by the following sequence involving the addition-elimination process and the Wagner-Meerwein migration of methyl group (Scheme 1). Since the *vic*-dinitro



Scheme 1.

grouping deactivates the neighboring positions strongly, the initial attack of the nitronium ion would occur at the 2-position of DNP to form benzenonium ion (III), in which the methyl group at the attacking site will migrate to the more positively charged carbon atom at the 1-position. The nitrate anion will add to ion (IV) thus formed to give an unstable nitro nitrate (V), from which nitrogen dioxide is eliminated to yield ketone (II). Addition of nitrogen dioxide to II, probably in a homolytic fashion, will give I as the final product. This is probably the first example of the intramolecular migration of the ring methyl group observed in nitration. The migration of the methyl group from side-chain to nucleus has been reported by Myhre in the nitration of 1,3,5-tri-*t*-butylbenzene.[9]

4,6-Dinitro-1,2,3,5-tetramethylbenzene (4,6-dinitroisodurene, DNI) dissolved in cold fuming nitric acid soon began to react with active liberation of nitrogen dioxide. The major product, mp 163—164°C, had a molecular formula $C_{10}H_{10}N_2O_5$ and was identified as 2,6-dinitro-3,4,5-trimethylbenzaldehyde (XI) on the basis of its spectral data. In addition to XI, small amounts of 2,6-dinitro-3,4,5-trimethylphenylnitromethane (XII), 2,6-dinitro-3,4,5-trimethylbenzoic acid, and 2,6-dinitro-3,4,5-trimethylbenzyl alcohol were obtained as by-products. Aldehyde (XI) might be formed by the acid-catalyzed decomposition of the initially fromed 2,6-dinitro-3,4,5-trimethylbenzyl nitrate (IX). Similar reactions have been observed in our previous work.[10] Several mechanistic routes could explain the fromation of XI, high regio-selectivity suggesting the ionic character of the reaction. One of the possible pathways is shown in Scheme 2.

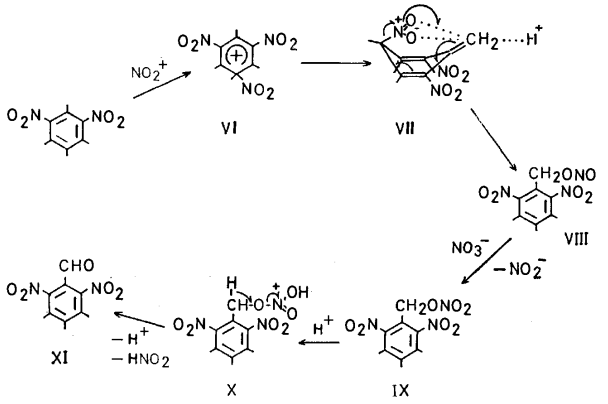
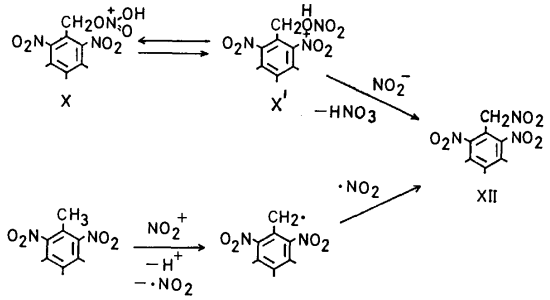


Scheme 2.

The initial attack of the nitronium ion will occur mainly at 2-position of DNI to give ion VI, which can be most effectively stabilized by three methyl groups. Proton release will take place preferentially from the most highly activated C-5 methyl group flanked both sides by nitro groups, leading to the intermediate stage (VII), in which the C-2 nitro group and the C-5 methylene group are not so far apart as to exclude the presence of *any* interaction between the oxygen atom of the C-2 nitro group and the methylene carbon atom. Fission of the C-2–NO_2 bond, followed by the redistribution of electrons in the activated complex will result in the transfer of the nitro group from the C-2 to the methylene carbon, yielding benzyl ester (VIII). Migration of the nitro group to the remote *para* position in preference to the neighboring *ortho* position may be rationalized by assuming that the transition state of the migration resembles the benzylic intermediate rather than the methylenecyclohexadiene, and is stabilized more effectively by the electron-donating methyl group at para position. This interpretation is in agreement with the fact that the nitration of polymethylbenzenes carried out in a dilute acetic acid solution affords a considerable amount of benzyl nitrate along with benzyl acetate at a very early stage of the reaction, and that the ratio of side-chain nitrooxylation and ring nitration is nearly independent of the concentration of nitric acid and added electrolyte.[4] A sort of tight-associated ion-pair may intervene and play some role in the process. The process is formally analogous to the thermal isomerization of 4-methylene-1-ethyl-1,2,3,5,6-pentamethylcyclohexa-2,5-diene to pentamethyl-*n*-propylbenzene, although the latter reaction is known to proceed through radical mechanism.[11] In the presence of excess nitric acid, benzyl nitrite (VIII) is not hightly stable and is readily converted into nitrate (IX). IX will then be protonated to form the conjugated acid (X), in which the fission of the N–O bond will give rise to the formation of benzaldehyde (XI) and the nitrous acid. The sulfuric acid-catalyzed transformation of the benzyl nitrate into the benzaldehyde has been reported to form some amounts of the benzoic acid as a by-product.[12]

Both the ionic mechanism and the one-electron transfer process could explain the formation of phenylnitromethane (XII) (Scheme 3). At present we prefer the view that nitromethane (XII) is derived from the benzyl ester through the nucleophilic displacement on the benzylic carbon of the conjugate acid (X′), although the situation is not clear as yet.[13]

Of three isomeric dinitrotetramethylbenzenes, 3,6-dinitro-1,2,4,5-tetramethylbenzene (3,6-dinitrodurene, DND) was the least soluble in fuming nitric acid. It was quite stable towards the oxidative action of the nitrating agent and mostly recovered unchanged even after a fortnight on being left to stand at room temperature. Protonation of the nitro group seems to have been the major reaction that had occurred. The infrared spectrum of the recovered material indicated the presence of some carbonyl compounds, but the product could not be identified because of the very small quantity. On being heated with a large excess of mixed acid (H_2SO_4:HNO_3=1:1 v/v) at 40—50°C, DND underwent a slow side-chain nitrooxylation to give 3,6-dinitro-2,4,5-trimethylbenzyl nitrate in good yield. Reduced reactivity of 1,4-dinitro system towards the electrophilic attack was well observed.



Scheme 3.

The present unusual reaction seems to provide a novel, simple route to some polynitro carbonyl compounds which are otherwise not readily accessible. The reaction is closely dependent on the orientation of the alkyl groups in the ring, and a facile destruction of the aromatic ring upon nitration may be characteristic of the vicinal polyalkylbenzene derivatives.

Experimental

All melting points were determined with a hot-stage apparatus and are uncorrected. Infrared spectra were run as Nujol on a Jasco DS-402G spectrophotometer and only prominent peaks were recorded. ^1H NMR measurements were carried out on a JEOLCO PS-100 spectrometer with deuteriochloroform as solvent and tetramethylsilane as an internal standard. Ultraviolet spectra were recorded in methanol solution of a Shimadzu QV-50 spectrophotometer. The mass spectra were obtained by Dr. A. Ohno of Sagami

11) R. N. Berezina, V. G. Schubin, and V. A. Koptyug, *Zh. Vses. Khim. Obshchest.*, **1968**, 356; V. G. Schubin, R. N. Berezina, and V. A. Koptyug, *Zh. Org. Khim.*, **6**, 2262 (1970).

12) S. D. Ross, E. R. Coburn, and M. Finkelstein, *J. Org. Chem.*, **33**, 589 (1968).

13) In view of the high propensity that the nitro compounds have to undergo protonation on nitro groups rather than release of one electron from the deactivated nucleus, the intermediary formation of the radical cation from DNI seems to be less probable in the strong protogenic acid medium.

Chemical Research Center, to whom the authors are indebted.

5,6-Dinitro-1,2,3,4-tetramethylbenzene (mp 178—179°C), 4,6-dinitro-1,2,3,5-tetramethylbenzene (mp 181—182°C), and 3,6-dinitro-1,2,4,5-tetramethylbenzene (mp 210—211°C) were prepared from the corresponding hydrocarbons by the ordinary procedure.

Reactions of Dinitrotetramethylbenzenes with Fuming Nitric Acid. 5,6-Dinitro-1,2,3,4-tetramethylbenzene (DNP). DNP (7.5 g) was dissolved in small portions in cold fuming nitric acid (d=1.5, 60 m*l*) to give a clear yellow solution. The color of the solution gradually turned dark red and a fume of nitrogen dioxide began to evolve slowly. The mixture was allowed to stand under hood at room temperature for several days, during the course of which the initial dark color faded to a light yellow. On being diluted with an excess of water, a pasty precipitate was obtained which, on being left to stand, gradually solidified to a white crystalline cake. The product was filtered, thoroughly washed with water, and dissolved into a minimum amount of dichloromethane. The solution was warmed at 35—40°C, light petroleum (bp 40—50°C) was added drop by drop until the solution became slightly cloudy, and the solution was left to cool under cover. Care should be taken to avoid excess heating. Faintly yellow prisms soon began to separate (8.8—9.4 g). Any attempt to crystallize the product from the hot solvent led to extensive decomposition of the product. On the basis of elemental analysis, infrared, ultraviolet, ^{1}H NMR, and mass spectral data, the product was formulated as *2,3,4,5-tetranitro-2,3,6,6-tetramethylcyclohex-4-enone (I)*. IR: 697, 732, 763, 785, 824, 846, 912, 976, 995, 1024, 1032, 1066, 1084, 1126, 1155, 1182, 1240, 1328—1337, 1540—1580, 1674, and 1742 cm^{-1}.

Found: C, 36.23; 36.42; H, 3.58; 3.78; N, 16.76; O, 43.37%. Calcd for $C_{10}H_{12}N_4O_9$: C, 36.16; H, 3.64; N, 16.87; O, 43.34%.

The ketone was thermally unstable and melted at 111—114°C with complete decomposition. When crystallization was attempted by dissolving I in hot carbon tetrachloride, nitrogen dioxide was liberated and a bright yellow substance, mp 94—96°C, was obtained. This was identified as *4,5-dinitro-2,3,6,6-tetramethylcyclohexa-2,4-dienone (II)* on the basis of spectral evidences. IR: 714, 736, 777, 849, 999, 1048, 1198, 1245, 1272, 1299, 1533—1540, 1617, 1644, and 1684 cm^{-1}.

Found: C, 49.92; H, 5.02%. Calcd for $C_{10}H_{12}N_2O_5$: C, 50.00; H, 5.04%.

4,6-Dinitro-1,2,3,5-tetramethylbenzene (DNI). A solution of DNI (7.2 g) in fuming nitric acid (60 m*l*), when stood at room temperature, soon began to liberate red fume. After the cease of reaction, the solution was diluted with water and a white crystalline precipitate was filtered, washed with dilute aqueous sodium hydrogen carbonate, and dissolved in a mixture of dichloromethane and light petroleum, from which the major product was readily separated as large prisms (5.9—6.4 g), mp 163—164°C after recrystallization several times, and identified as *2,6-dinitro-3,4,5-trimethylbenzaldehyde (XI)*. IR: 699, 778, 861, 896, 1023, 1052, 1285, 1359, 1532, and 1712 cm^{-1}; ^{1}H NMR: 7.66 (2 Me), 7.52 (Me), and 0.16 τ (CHO).

Found: C, 50.12; H, 4.29%. Calcd for $C_{10}H_{10}N_2O_5$: C, 50.42; H, 4.23%.

The aldehyde was stable towards spontaneous oxidation, but soon became yellow or light brown on storage under diffused light.

A less soluble minor part was fractionally recrystallized from ligroin to give fine needles (*ca.* 0.5 g), $C_{10}H_{11}N_3O_6$, mp 158—159°C. It showed ^{1}H NMR peaks at 7.65 (2 Me), 7.56 (Me), and 4.58 τ (CH_2), and IR bands at 711, 766, 785, 855, 878, 898, 1057, 1288, 1317, 1360, 1535, and 1567 cm^{-1}, and was identified as *2,6-dinitro-3,4,5-trimethylphenylnitromethane.*

Found: C, 44.69; H, 4.18%. Calcd for $C_{10}H_{11}N_3O_6$: C, 44.61; H, 4.12%.

Another minor product, mp 193—195°C, was *2,6-dinitro-3,4,5-trimethylbenzyl alcohol.* IR: 776, 857, 868, 1010, 1043, 1055, 1365, 1535, and 3530 cm^{-1}.

Found: C, 50.08; H, 5.09%. Calcd for $C_{10}H_{12}N_2O_5$: C, 50.00; H, 5.04%.

The aqueous sodium hydrogen carbonate washing of the product was neutralized with hydrochloric acid to give a white precipitate, which on recrystallization several times from aqueous ethanol gave fine needles (*ca.* 0.5 g), mp 233—236°C with decomposition, and was identified as *2,6-dinitro-3,4,5-trimethylbenzoic acid.* IR: 662, 721, 781, 857, 896, 1168, 1360, 1535, 1753, and 3300 cm^{-1}.

Found: C, 47.43; H, 3.76%. Calcd for $C_{10}H_{10}N_2O_6$:C, 47.25; H, 3.97%.

3,6-Dinitro-1,2,4,5-tetramethylbenzene (DND). DND (4.5 g) was dissolved in a large excess of mixed acid (40 m*l*; H_2SO_4: HNO_3 (d=1.5) =1: 1 v/v), and the solution was kept at 40—50°C for several hours and then at around 60°C for 0.5 hr. A Kinetic Study of the Polymerization of Acrylic Acid in the Presence of Polyvinylpyrrolidone

Ryo MURAMATSU and Takeo SHIMIDZU

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto

(Received January 25, 1972)

The polymerization of acrylic acid (AA) in a dilute aqueous solution in the presence of polyvinylpyrrolidone (PVP) has been studied kinetically, with the extent of polymerization followed by a bromometric titration method. The rate of the polymerization changed characteristically with the amount of PVP in the solution and went through a maximum at a certain initial mole ratio of PVP and AA, $[PVP]_0/[AA]_0$, under a constant $[AA]_0$ value. The mole ratio which gave the maximum rate was almost proportional to the reciprocal of $[AA]_0$. In the course of the polymerization, a polymer complex consisting of PVP and polymerized AA was precipitated. Its composition, $(PAA)_c/(PVP)_c$, has been found to be different as the polymerization conditions are varied. Hardly no comparable data between the bromometric method and a turbidimetric method used to measure the rate were obtained. The influence of PVP on the polymerization was assumed to be caused by the local concentration of AA in the vicinity of PVP. A mechanism based on the effect of the local concentration, the "polymer atmosphere binding mechanism," has been found to explain the experimental results well.

Ferguson and Shah have described that the polymerization of acrylic acid (AA) in the presence of polyvinylpyrrolidone (PVP) in a dilute aqueous solution exhibits kinetically the characteristics of a "replica polymerization."[1] In their study, the rate of the polymerization was observed to go through a maximum at an equimolar ratio of PVP and AA under a constant AA concentration. Such a phenomenon has been explained as a "replica polymerization," a "matrix polymerization," or a "template polymerization." Many polymerization systems have been investigated in connection with the matrix polymerization—for example, the polymerizations of 4-vinylpyridine in the presence of polystyrenesulfonic acid or polyacrylic acid by Kabanov *et al.*,[2] that of acrylic acid in the presence of polyethylenimine by Bamford and Shiiki[3] and by Ferguson and Shah,[4] that of methacrylic acid in the presence of polyvinylpyrrolidone by Sakaguchi *et al.*,[5] that of methacrylic acid in the presence of poly-*N*-vinyl-5-methyl-2-oxazolidone by Okawara *et al.*,[6] that of 4-vinylpyridine in the presence of polymaleic anhydride by Kinoshita *et al.*,[7] and that of methacrylic acid or acrylic acid in the presence of polyethylene glycol by Osada.[8]

The interactions between the monomer and the polymer in those polymerization systems are various and multiform in their qualities and strengths. As regards the interaction between a simple electrolyte and a polyelectrolyte, for example, the site binding of simple electrolytes to polyelectrolytes and also the local concentration of simple electrolytes in the vicinity of polyelectrolytes have been considered.[9] These things have also been dealt with in ionic reactions in the presence of polyelectrolytes.[10] Except for the perfect replica polymerization shown in the polymerization of methacrylic acid or acrylic acid using Novolak resins by Kämmerer *et al.*,[11] the replica polymerization could not be declared until the exact duplication of such information on a polymer templates as the molecular weight has been proved, as Kinoshita has reported.[7]

In the present experiment, the polymerization of acrylic acid (AA) in the presence of polyvinylpyrrolidone (PVP) in a dilute aqueous solution, a similar polymerization system which Ferguson and Shah have studied kinetically by a turbidimetric method,[1] has been investigated, with the rate of the polymerization followed by measuring the quantities of an unreacted monomer, AA. In connection with the result concerning the peculiar influence of PVP on the rate of the polymerization of AA, the local concentration of AA in the vicinity of the PVP molecule in the polymerization will be discussed.

Experimental

Materials. Acrylic acid (AA) was purified by sublimation at a pressure below 10^{-1} mmHg. Quantities of double bonds more than 97 mol% in the sublimate were detected by bromometric titration analysis. The polyvinylpyrrolidone (PVP) was of a commercial origin and was purified with water and acetone. The PVP of M.W. 24500 was used unless otherwise stated. The polyacrylic acid (PAA) was obtained by the acidification of a commercial sodium polyacrylate with HCl or by the polymerization of AA in an aqueous solution, and was purified by dialysis. The potassium persulfate ($K_2S_2O_8$), used as an initiator, *N*-methylpyrrolidone (MP), and propionic acid (PA) were all of commercial origin, and they were purified in the usual manners.

Polymerization Reaction. The polymerizations of AA were carried out in sealed ampules. Each aqueous solution of AA, PVP, and $K_2S_2O_8$ was charged in an ampule (10 m*l*) and frozen in turn without mixing those portions, and then sealed under nitrogen. The sealed ampules were shaken in a thermostat maintained at 74±0.1°C for a given time.

Measurement of the Rate of the Polymerization. The rate of the polymerization of AA was followed by measuring the quantities of the unreacted AA by the Lucass-Pressman method, a bromometric titration method.[12] The additions of bromine were carried out at 40—50°C for 5 min. The effects of $[K_2S_2O_8]$ and [PVP] on the addition of bromine to the unreacted AA were negligible.

Analysis of the Composition of the Polymer Complex. A polymer complex which was precipitated in the course of the polymerization of AA in the presence of PVP, the polymer complex (A), was separated by the centrifugation of the reaction solution and then washed with water three times. The composition of the polymer complex (A) was determined by elemental analysis. It was difficult to find any solvent system which could dissociate or dissolve the polymer complex (A) completely. Therefore, the molecular weight of PAA polymerized in the presence of PVP could not be detected. On the other hand, a polymer complex which was formed in mixing PAA and PVP, the polymer complex (B), was purified and analyzed by the same method in order to compare it with the polymer complex (A).

Examination of a Turbidimetric Method Used in Following the Extent of the Polymerization. Both the change in the turbidity with the extent of the polymerization of AA in the presence of PVP and the turbidity caused by mixing PAA and PVP were measured in a jacketed turbidity cell (glass; optical path, 2.20 cm; volume, 35 m*l*) or a standard cell (optical path, 1.00 cm), using a hand-made turbidimeter and a Beckman DB-G spectrophotometer.

Results

Some typical time-conversion curves are shown in Fig. 1. The time-conversion curve of the polymerization of AA in the presence of PVP could be treated as a straight line at the range of 30—60% conversion, as may be seen in Fig. 1, Curve A. As the temperature of this reaction system did not reach a given temperature at the early stage of the polymerization, it is difficult to measure the initial rate accurately. The rate of the polymerization was obtained from the slope of the linear part in the time-conversion curve. The time-conversion curve of the polymerization of AA without PVP is shown as Curve B. In both cases, *N*-methylpyrrolidone (MP), which would be a monomeric analog of PVP, was found to have no effect on the rate of the polymerization, so it is assumed that the pyrrolidone group does not affect the reactivity of AA and the decomposition of $K_2S_2O_8$.

The influence of PVP on the rate of the polymerization is shown in Fig. 2. Under constant initial concentrations of AA, $[AA]_0$, and $K_2S_2O_8$, $[K_2S_2O_8]_0$, the rate of the polymerization went through a maximum at a certain ratio of PVP and AA, $[PVP]_0/[AA]_0$. A similar tendency has been described in, for instance, the studies of the polymerizations of AA in the presence of polyethylenimine,[3,4] of that of methacrylic acid in the presence of poly-*N*-vinyl-5-methyl-2-oxazolidone,[6] and of that of *N*-vinyl-2-oxazolidone in the presence of polymethacrylic acid.[13]

13) T. Endo, R. Numazawa, and M. Okawara, *Makromol. Chem.*, **146**, 247 (1971).

The ratios of $[PVP]_0/[AA]_0$ at which the rates were maximum, $\{[PVP]_0/[AA]_0\}_{max}$, were almost proportional to the reciprocal of $[AA]_0$. Moreover, the concentrations of PVP at $\{[PVP]_0/[AA]_0\}_{max}$ were about 2.5×10^{-2} mol/l. As for the viscosity of the reaction solution, $\eta_{sp}/[PVP]_0$, it did not change remarkably in the vicinity of the PVP concentration of 2.5×10^{-2} mol/l, as is shown in Fig. 3. From those results, the theory that the acceleration of the rate is caused by a conformational change in PVP can be rejected.

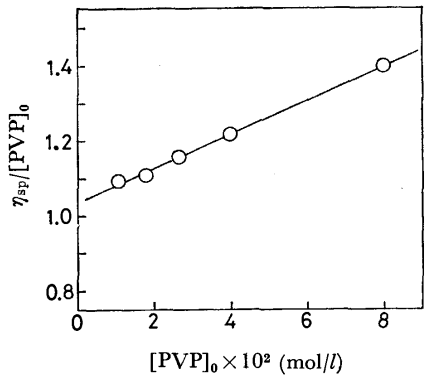

Fig. 3. Viscosity of the reaction solution.
$[PA]_0=2.0\times10^{-2}$ (mol/l);
$[K_2S_2O_8]_0=7.4\times10^{-3}$ (mol/l); 74±0.1°C.

If this polymerization system were a "replica polymerization system," $\{[PVP]_0/[AA]_0\}_{max}$ would be a constant under different $[AA]_0$ values and would not decrease as $[AA]_0$ becomes higher. It seems rather unlikely, then, that the present polymerization is the "replica polymerization," although there is no direct evidence on this point. Ferguson and Shah have described that the rate of the polymerization went through a maximum rate of 14.7×10^{-4} mol/l·sec at almost the same PVP concentration as AA when $[AA]_0$ was 2×10^{-2} mol/l.[1] This rate was remarkably different from the 4.2×10^{-6} mol/l·sec found in our work. This difference will be discussed later. In Fig. 4, the rate calculated from the AA consumption

as measured by the bromometric titration method, and the rate calculated from the yield of the polymer complex (A) formed in the course of the polymerization of AA in the presence of PVP are shown. The rate obtained by the polymer-complex weighing method differs from that obtained by the titration method; this difference will also be discussed later.

The influence of propionic acid (PA), a non-polymerizable analog of the AA monomer, on the rate of the polymerization is shown in Fig. 5. PA had no effect on the rate of polymerization. This result also leads to a negation of hypothesis of the "replica polymerization" for this polymerization system.

Figure 6 shows the dependence of $[AA]_0$ on the rate of the polymerization. Apparently, the rate of the polymerization of AA with PVP was proportional to the 1.9 powers of $[AA]_0$, while the rate without PVP was proportional to the 1.5 powers of $[AA]_0$.

The dependence of the initiator concentration, $[K_2S_2O_8]_0$, on the rate of the polymerization was also studied, as is shown in Fig. 7. The rate was almost proportional to the 0.5 power of $[K_2S_2O_8]_0$

at constant AA and PVP concentrations. The rate of the polymerization of AA without PVP has been reported to be proportional to the 0.5 power of the persulfate initiator.[14] These results indicate that the acceleration of the rate of the polymerization of AA in the presence of PVP was not caused by the trapping of radicals in the precipitated phase, the so-called "gel-effect."

Table 1 shows the yield and composition, $(PAA)_c/(PVP)_c$, of the polymer complex (A) precipitated in the course of the polymerization of AA in the presence of PVP. Fig. 8 shows the influence of $[PVP]_0$ on $(PVP)_c/(PAA)_c$ in the polymer complex (A). Even at a constant $[AA]_0$, value where the amounts of PAA formed were similar, the $(PVP)_c/(PAA)_c$ ratios in the polymer complexes (A) were different from one another, and they became smaller as $[PVP]_0$ became smaller. The concentrations of PVP and AA also affected the composition of the polymer complex (A), $(PAA)_c/(PVP)_c$, even though the $[PVP]_0/[AA]_0$ ratios were the same (No. 6, No. 8, in Table 1). Even when the $[AA]_0/[PVP]_0$ ratio was large and the amount of polymerized AA was larger than $[PVP]_0$, not all of the PVP was found in the polymer complex (A) (No. 1—8 in Table 1). These results indicate that not all the polymerized AA formed the polymer complex (A) with an equimolar ratio of PAA and PVP and that the polymer complex (A) formation was not complete. The difference between the rate calculated from the yield of the polymer complex (A) and that calculated from the consumption of AA, as is seen in Fig. 4, can explained as a non-quantification in the formation of the polymer complex (A). The molecular weight of the PVP used also affects the formation of the polymer complex (A) (No. 1, 4, 9, and 10 in Table 1).

14) H. Ito, S. Shimizu, and S. Suzuki, *Kogyo Kagaku Zasshi*, **58**, 194 (1955).

Figure 9 shows the yield of the polymer complex (B) formed by mixing PAA and PVP, $(PAA)_c/[PAA]_0$, and the composition of the polymer complex (B), $(PAA)_c/(PVP)_c$. Much as in the discussion of the polymer complex (A), it can be said that the PAA and PVP which did not take part in the formation of the polymer complex (B) still remained in the solution phase. Further, the yield and the composition of the polymer complex (B) depended on the molecular weight of PAA. The ratio in the polymer complex (B), $(PAA)_c/(PVP)_c$, formed with the PAA of a higher molecular weight was larger than that formed with the PAA of a lower molecular weight. The ratio in the polymer complex (A) (No. 9 in Table 1) was smaller than that of the polymer complex (B) formed with the PAA of M.W.=5300. These results suggest that the molecular weight of the polymerized AA in the presence of PVP is probably lower than 5300.

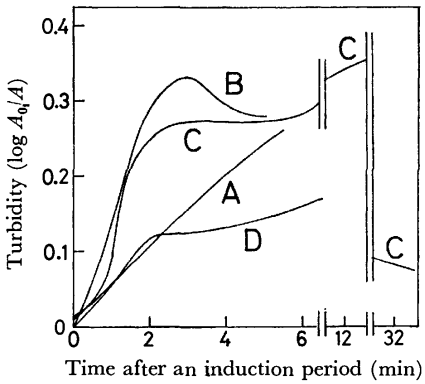

Fig. 10. Variation of turbidity with extent of the polymerization of AA.

Stirring; A, non; B, gentle; C, moderate; D, vigorous.

The turbidimetric method for measuring the extent of the polymerization of AA was examined. After an induction period of 7—13 min the turbidity of the polymerization system increased greatly, went through a maximum, and then decreased, as is shwon in Fig. 10. The variation in the turbidity depended on the stirring of the polymerization system. To compare the bromometric titration method with the turbidimetric method, an aliquot of the reaction mixture, which is shown as Curve C in Fig. 10, was provided for the bromometric titration. From the titration, the conversions in the polymerization of AA were found to increase (conversions of 64% at 12 min and 86% at 32 min, respectively) in spite of the decrease in the turbidity. This shows that the correlation between the turbidity and the conversion was not simple.

The change in the turbidity observed when a concentrated PAA solution was added to a PVP solution in the turbidity cell was also studied (Fig. 11). The turbidity increased greatly within 10 sec after the addition of the PAA solution, went through a maximum, then decreased and reached an equilibrium 2—3 min later. To this solution, a portion of the PAA solution was additionally introduced; the turbidity then changed as before. A linear relationship between the amount

of PAA and the equilibrium turbidity was observed; *cf.* the D line in Fig. 11. If the D line is adopted as a calibration curve of the polymerized AA in the polymerization, the rate of the polymerization, shown as Curve C in Fig. 10, should be 5×10^{-4} mol/l·sec. This value is similar to that Ferguson and Shah obtained (14.7×10^{-4} mol/l·sec). However, if we adopt the data at the maximum turbidity, the corresponding PAA should be about 200% to the fed-in AA. From these results, it may be considered that it is unreliable to measure the rate of the polymerization by following the turbidity.

Figure 12 shows the turbidity observed when a PAA solution was added to a PVP solution under various conditions. In this case, the turbidity was observed through a photocell (optical path, 1.00 cm) after mixing and shaking the PVP-$K_2S_2O_8$ solution and the PAA solution. As the linear relationship between the turbidity and $[PAA]_0$ was not obtained in the range of over 5×10^{-4} mol/l of $[PAA]_0$, this method could not be applied in our study.

Dscussion

The polymerization in the present study can not be explained as a "replica polymerization," because the mole ratio, $[PVP]_0/[AA]_0$, at which the rate of the polymerization was at its maximum changed with the $[AA]_0$ value (as is shown in Fig. 2), PA did not affect the rate of the polymerization (as is shown in Fig. 5), and the composition of the polymer complex (A) varied with the complex-forming conditions (Table 1).

Here, two simple model mechanisms may be considered:

A) specific-site binding mechanism ("replica polymerization"-AA adsorbed on PVP polymerizes) and B) polymer-atmosphere binding mechanism (AA drawn atmospherically by PVP polymerizes).

A) Mechanisms of Specific-site Binding. *Case A-1*): The adsorption of AA on PVP follows Langmuir's adsorption isotherm, and both adsorbed AA and not-adsorbed AA polymerize. The adsorption may be expressed as follows:

$$[P] + [M_f] \overset{K}{\rightleftarrows} [PM],$$
$$\theta = [PM]/[P]_0 = [M_f]/([M_f]+1/K)$$

where $[M_f]$ and $[PM]$ are not-adsorbed and adsorbed AA respectively and where $[M]_0$ and $[P]_0$ are volume-average concentrations of AA and PVP respectively (they are defined as $[PM]+[M_f]=[M]_0$, $[PM]+[P]=[P]_0$). K is an equilibrium constant of adsorption, and θ is the fraction of the adsorbed sites.

i) An adsorbed AA can migrate freely on PVP, and the rate of the polymerization of PVP is proportional to the adsorbed AA, (θ); the rate of the polymerization, V, can be expressed as:

$$V = [P]_0k_3\theta + k_4[M_f]^{1.5} = k_3[PM] + k_4[M_f]^{1.5} \quad \text{(A-1-1)}$$

where k_3 and k_4 are the rate constants of the polymerization of adsorbed AA on PVP and of not-adsorbed AA respectively.

ii) The rate of the polymerization of the adsorbed AA is proportional to the average length of the continuous sequence of AA molecules adsorbed on PVP, which is expressed as:

$$\nu = (1-\theta)\sum_{p=1}^{\infty}P\theta^{p-1} = 1/(1-\theta)$$

where p is the length of the continuous sequence of the AA adsorbed on PVP. The rate can, then be expressed as:

$$V = k_3[PM]/(1-\theta) + k_4[M_f]^{1.5} \quad \text{(A-1-2)}$$

Case A-2): An adsorption of AA on PVP follows Freundlich's adsorption isotherm ($n=2$)

$$\theta = [PM]/[P]_0 = a[M_f]^{1/2}$$

similar to i), then,

$$V = k_3[PM] + k_4[M_f]^{1.5} \quad \text{(A-2-1)}$$
$$V = k_3[PM]/(1-\theta) + k_4[M_f]^{1.5} \quad \text{(A-2-2)}$$

The calculated rates followed by (A-1-1), (A-1-2), (A-2-1), and (A-2-2) were all monotonous increasing functions with respect to $[PVP]_0$ and did not agree with the characteristics of the experimental results shown in Fig. 2.

Case A-3): Bamford *et al.* have presented the following expression for the polymerization on a template.[3]

$$V = C\exp(-\alpha Z^{\beta}/kT)[X]$$

where α and β are arbitrary constants, where C is the total radical concentration, where Z is $[P]/[PM]$, and where $[X]$ is $[PM]$. The total rate should be considered to be the sum of the rates of polymerization on and apart from the template. Accordingly, the following equation can be obtained:

$$V = C\exp\{-\alpha([P]/[PM]^{\beta}/kT\}[PM] + k_4[M_f]^{1.5} \quad \text{(A-3)}$$

The rate curve calculated by Eq. (A-3) using the numerical values of $K=22.2$ (l/mol) (K is Langmuir's adsorption constant), $C\exp(-\alpha/kT)/k_4=4.0375$, and $\beta=1.81946$, which were obtained from the initial and the optimum conditions of the experimental data, is shown as Curve E in Fig. 2. This curve deviates much from the experimental results obtained at higher concentrations of PVP. In addition, the fact that Eq. (A-3) gave similar values of $\{[PVP]_0/[AA]_0\}_{max}$ at different $[AA]_0$ values differs from the experimental results.

It is difficult to obtain an expression which agrees well with the characteristics of the experimental data in the present study, considering the mechanisms of specific-site binding.

B) A Mechamism of Polymer-Atmosphere Binding. A local concentration of AA can be expected to be distributed continuously in the reaction system. However, to simplify the discussion, the reaction system is assumed to be divided into two domains. One is a polymer domain where AA is concentrated in the vicinity of PVP (the volume fraction is f, the concentrations of PVP and AA in the polymer domain are $[P_p]$ and $[M_p]$ respectively), and the other is a free domain (the volume fraction is $1-f$, and the concentration of AA is $[M_f]$). Because MP did not affect the rate of the polymerization (Fig. 1), and because the dependence of the initiator on the rate of the polymerization of AA differed little in either the presence or absence of PVP (Fig. 7), the fundamental reaction mechanisms in both domains are assumed to be the same as in a homogeneous reaction system. As the PVP is a linear vinyl polymer, the shape of this polymer domain can be considered to be a cylinder along the chain of PVP. The total length of this cylinder is proportional to $[PVP]_0$. The $f/(1-f)$, ratio will increase with $[PVP]_0$ and decrease with $[AA]_0$. The contribution of $[AA]_0$ to the ratio is not simple, since the domain, f, will be set through an interdependence of $[M_f]$ and $[M_p]$. Thus, the following expression may be assumed:

$$f/(1-f) = [P]_0/a$$

where a is a function of the monomer and where $[P]_0$ is the volume average concentration of PVP. Considering the equilibrium and the stoichiometry:

$$[M_f] + [P_p] \overset{K}{\rightleftarrows} [M_p] \quad (K;\ \text{equilibrium constant})$$

$$f[M_p] + (1-f)[M_f] = [M]_0, \quad f[P_p] = [P]_0$$

where $[M]_0$ is the volume-average concentration of AA. Then, the overall rate of polymerization of AA, V can be expressed as follows:

$$V = fk[M_p]^{1.5} + (1-f)k[M_f]^{1.5}$$
$$= k[M]_0^{1.5}\{[P]_0([P]_0+a)^2+a([P]_0+a)^{0.5}(1/K)^{1.5}\}/$$
$$([P]_0^2+a[P]_0+a/K)^{1.5} \qquad (B)$$

As to the influence of PVP on the rate of the polymerization when $[AA]_0$ is 5×10^{-2} mol/l, the rate curve calculated by means of Eq. (B) with $K=64.7$ (l/mol) and $a=0.2$ is shown as Curve A in Fig. 2. The calculated rate curves with $a=0.38$ ($[AA]_0=2\times10^{-2}$ mol/l) and $a=0.19$ ($[AA]_0=10\times10^{-2}$ mol/l) are also shown as Curves B and C respectively. These curves agree well with the experimental data. Thus, a was found to be a function of $[AA]_0$, and it increased as $[AA]_0$ decreased. According to these results, the following empirical formula of a was obtained:

$$a = 1.2[M]_0 + 0.007/[M]_0$$

Using this formula, the relation between $[AA]_0$ and f was found to be as is shown in Fig. 13. At higher concentrations of $[AA]_0$, f decreased with $[AA]_0$. Regarding this phenomenon, two tentative considerations will be made. One is a shrinking of PVP by AA; the other is a shielding of PVP by AA according to a Debye-Hückel theory. As to the dependence of $[AA]_0$ on the rate of the polymerization the rate curve calculated by means of Eq. (B) with $K=64.7$ (l/mol) and $a=1.2[M]_0+0.007/[M]_0$ is shown as Curve A in Fig. 6. This calculated rate curve was found to agree with the experimental data and to be apparently proportional to the 1.9 powers of $[AA]_0$. As to the influence of PA on the rate of the polymerization, if the influence of PA to PVP is similar to that of AA to PVP, the rate V', may be expressed as follows:

$$V' = ([M_{AA}]_0/[M]_0)^{1.5}V \qquad (B')$$

where $[M]_0$ is $[M_{AA}]_0+[M_{PA}]_0$ and where $[M_{AA}]_0$, and $[M_{PA}]_0$ are the volume-average concentrations of AA and PA respectively. The calculated rate, V', defined by Eq. (B') with $K=67.4$ (l/mol) and $a=1.2[M]_0+0.007/[M]_0$ was apparently independent of the $[PA]_0$ values, which are shown as Curves A and B ($V'_{(B)PA=0}=9\times10^{-6}$ mol/l·sec) in Fig. 5. As has been mentioned above, the polymerization of AA in the presence of PVP in the present study can be explained well by a mechanism considering the locally-concentrated AA in the vicinity of PVP. Moreover, this consideration can also be applied to the other reaction system. Endo, Numazawa, and Okawara[6] have described that the rate of the polymerization of methacrylic acid (MAA) in the presence of poly-*N*-vinyloxazolidone (PNVOx) went through a maximum at [PNVOx]/[MAA] being unity. By applying Eq. (B) to their results without any further consideration, the calculated rate curve was found rather to fit their experimental data with $K=300$ (l/mol) and $a=0.07$. The larger K value obtained in their polymerization system can be explained reasonably as arising from a different magnitude of the interactive fource.

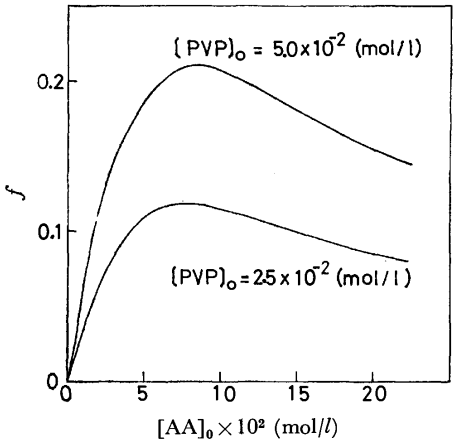

Fig. 13. Relation between $[AA]_0$ and f.

The authors are very grateful to Professor Kenichi Fukui, head of their laboratory, for his unfailing encouragement. Also, the authors are indebted to Mr. Teiji Kobayashi for his help in part of the measurements.

Asymmetric Hydrogenation of C=O Double Bond with Modified Raney Nickel. XXI. The Effect of Water on the Asymmetric Activity of the Catalyst

Toshio NINOMIYA*

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received January 26, 1972)

The effect of water added to the hydrogenation system of methyl acetoacetate was investigated on catalysts modified with L-amino acids, their derivatives, and D- or L-hydroxy acids. In the absence of water, catalysts modified with all L-amino acids except L-serine and L-proline gave methyl $D_s(-)$-3-hydroxybutyrate, and in the presence of water all the catalysts modified with L-amino acids gave methyl $L_s(+)$-3-hydroxybutyrate. On the other hand, the catalysts modified with L- or D-hydroxy acids were not affected by the addition of water and gave an $L_s(+)$ or $D_s(-)$ hydrogenation product respectively. In the presence of water, the catalyst modified with the L-valine methyl ester gave an $L_s(+)$ product, while the catalysts modified with *N*-acetyl L-amino acids were not affected by water. As a whole, it was concluded that water added to the hydrogenation system affected the amino group of the modifying reagent on the catalyst surface, which might play an important role in the asymmetric control of the substrate approaching the catalyst surface. The water in the hydrogenation system also promoted the hydrogenation rate, regardless of the modifying reagents.

In a previous report on the investigation of asymmetric hydrogenation with Raney nickel catalysts modified with optically-active amino acids or hydroxy acids,[1] the catalysts modified with L-glutamic acid, L-valine, and L-alanine were demonstrated to show (+) asymmetric activities upon the addition of water, and it was concluded that water affected the asymmetric site of the catalyst rather than the position of the keto-enol equilibrium of the substrate, methyl acetoacetate.[2]

It seemed that an investigation of the effect of water on the asymmetric site of the catalyst would be important and informative in connection with the clarification of the asymmetric hydrogenation mechanism. The present work is intended to make clear the effect of the water.

The present paper will report on the effect of water on the asymmetric activities of the catalysts modified with L-amino acids, *N*-acetyl L-amino acids, L-amino acid methyl ester, L-amino acid nickel chelate, and L- or D-hydroxy acids. Also, the role of the amino group of the modifying reagent, L-amino acid, will be discussed in connection with the effect of water.

As as whole, it can be deduced that the amino group of L-amino acid plays an important role in the asymmetric control of the substrate approaching the catalyst surface.

The influence of water on the hydrogenation rate will also be referred to.

Experimental

The preparation and the modification of the Raney nickel catalyst, the hydrogenation of methyl acetoacetate, the addition of water to the hydrogenation system, and the measurement of the asymmetric activity of the catalyst were performed in the manner described in the previous paper.[1]

As the Raney nickel alloy, 1.5 g of R-Ni ND (from Kawaken Fine Chemicals Co., Ltd., lot 1949) was used, and as the substrate for hydrogenation was used 0.15 mol of methyl acetoacetate (from the Nippon Synthetic Chemical Industry Co., Ltd., lot 70).

Results and Discussion

Figures 1-1 and 1-2 shows the asymmetric activities of the catalysts modified with L-leucine (L-Leu), L-phenylalanine (L-Phe), L-tryptophan (L-Try), L-methionine (L-Met), L-threonine (L-Thr), L-serine

—□—: L-2-hydroxy-3-phenylpropionic acid

(L-Ser), L-proline (L-Pro) and L-histidine (L-His) in the hydrogenation of methyl acetoacetate (MAA) with the addition of water. As is shown in Fig. 1, with the addition of water the catalysts modified with L-Leu, L-Phe, L-Try, L-Met, L-Thr, and L-His showed (+) asymmetric activity, while without any addition of water these catalysts showed (−) asymmetric activity. The catalysts modified with L-Ser and L-Pro, having (+) asymmetric activities in the absence of water, showed higher (+) asymmetric activities in the presence of water. Compared with the catalysts modified with other L-amino acids, the catalyst modified with L-His was little affected by water and showed only (+) asymmetric activity with the addition of 6 m*l* of water.

Figure 2 shows the effect of water on the catalysts modified with D-tartaric acid, L-2-hydroxy-3-methylbutyric acid, and L-2-hydroxy-3-phenylpropionic acid. The added water did not cause the inversion of the asymmetric direction when the catalysts were modified with these hydroxy acids.

As can be seen in Figs. 1 and 2, the catalysts modified with L-amino acids showed (+) asymmetric activities in the presence of water, while the catalysts modified with D- or L-hydroxy acids were not affected by water.

The above facts clearly show that the effect of water is characteristic of the catalysts modified with L-amino

acids. In the previous paper,[1] the water added to the hydrogenation system was demonstrated to influence the asymmetric sites of the catalysts modified with L-amino acids.

In order to investigate in detail the effect of water on the asymmetric site of the catalyst modified with L-amino acids, the effect of water on the catalysts modified with *N*-acetyl L-amino acids and the L-amino acid methyl ester was examined.

Figure 3 shows the effect of water on the catalysts modified with *N*-acetyl L-isoleucine, *N*-acetyl L-phenylalanine, and *N*-acetyl L-alanine. As may be seen in Fig. 3, even in the presence of water these catalysts showed (−) asymmetric activities and did not show (+) asymmetric activities; this was in striking contrast to the catalysts modified with L-Ileu, L-Phe, and L-Ala. The above facts suggest that the sensitivities of the catalyst to water may be decreased by the acetylation of the amino group.

Figure 4 shows the effect of water on the asymmetric activities of catalysts modified with the L-valine methyl ester and *N*-acetyl L-valine. As may be seen in Fig. 4, in the presence of water the catalyst modified with the L-valine methyl ester showed (+) asymmetric activity, while the catalyst modified with *N*-acetyl L-valine showed (−) asymmetric activity. The above facts make it clear that the free amino group may be affected by water and bring the catalyst (+) asymmetric activity. From the standpoint of the above discussion, the effect of the water on the asymmetric activity of the catalyst modified with L-histidine shown in Figs. 1–1 can be explained as follows; L-histidine, well known as a strong chelating reagent, can be adsorbed as a tridentate on the catalyst surface, and, because of both the steric and electrostatic effects of the imidazole group neighboring the amino group, the amino group may be hardly affected at all by a small amount of water added to the hydrogenation system.

Figure 5 illustrates the effect of water on the catalyst modified with the L-valine nickel chelate. As is illustrated in Fig. 5, the catalyst modified with the L-valine nickel chelate, which showed a much higher (−) asymmetric activity than the catalyst modified with L-valine in the absence of water, also gave (+) asymmetric activity in the presence of water, as did the catalyst modified with L-valine. The amino group of the L-valine nickel chelate is considered to be in a nearly free state, because, as is shown in Fig. 6, the nickel L-valine complex had adsorption bands corresponding to the ν_s and ν_{as} of NH_2 around 3300 cm^{-1}, while crystalline L-valine showed absorption bands around 3000 cm^{-1} assigned to the ν_s and ν_{as} of NH_3^+. Accordingly, the catalyst modified with the L-valine nickel chelate is considered to be easily affected by water to show (+) asymmetric activity.

The above discussion shows that water can affect the free amino group of the L-amino acid used as the modifying reagent and cause the inversion of the asymmetric activity and/or give higher (+) asymmetric activity to the catalyst modified with L-amino acid. From the fact that the catalyst modified with the L-valine methyl ester behaved toward water like that modified with L-valine, as is shown in Fig. 4, but showed a far lower (−) asymmetric activity than that modified with L-valine, it seems that the carboxyl group of the modifying reagent is independent of the effect of water and probably participates in the stable

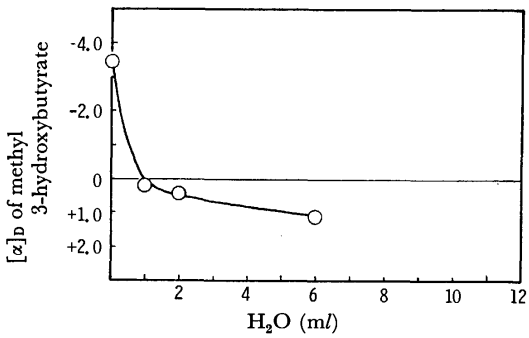

Fig. 5. Effect of additional water on asymmetric activity of catalyst. (Modification with L-valine nickel chelate at 0°C)

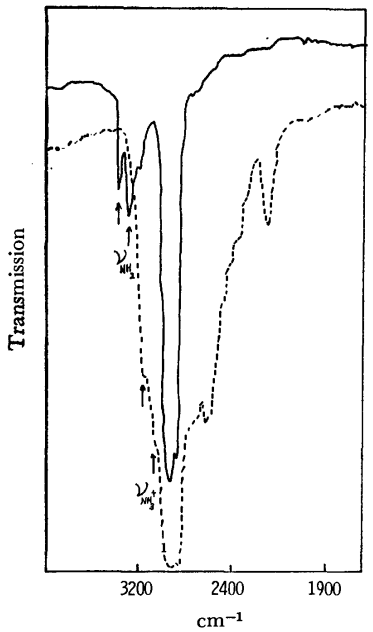

Fig. 6. IR spectra of Ni[L-Val]$_2$ (Nujol, ——) and L-Val (Nujol, ——).

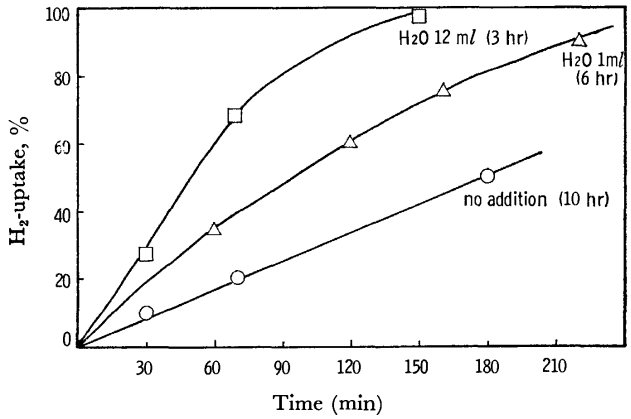

Fig. 7. Effect of additional water on hydrogenation rate. (Modified with D-tartaric acid at 0°C, pH 5.0)

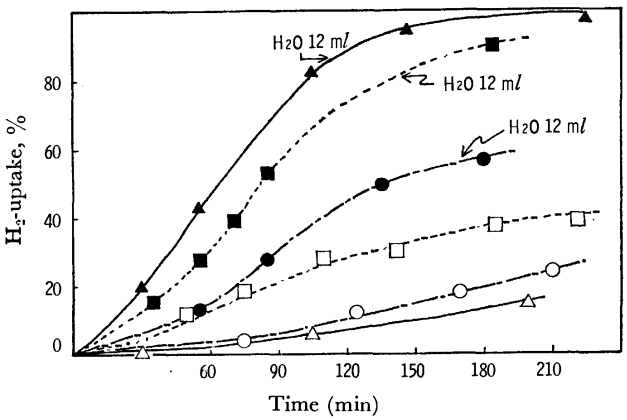

Fig. 8. Effect of additional water on hydrogenation rate.

—○—: Modification with L-3-methyl-2-hydroxybutyric acid at 0°C
—□—: Modification with *N*-acetyl L-isoleucine at 0°C

adsorption of the modifying reagent on the catalyst surface. As a whole, it can be concluded that the amino group of L-amino acid plays an important role in the asymmetric control of the substrate approaching the catalyst surface.

In Fig. 7 the hydrogenation rate is plotted against the amount of water added to the hydrogenation system in the modification with D-tartaric acid. As is illustrated in Fig. 7, the addition of 12 m*l* of water brought about the promotion of the hydrogenation rate and carried the hydrogenation to completion in about 3 hr, while the standard hydrogenation, without any addition of water, took about 10 hr.

A similar promotion of the hydrogenation rate was also observed when the catalysts were modified with L-valine, L-2-hydroxy-3-methylbutyric acid, and *N*-acetyl L-isoleucine, as is shown in Fig. 8.

From the above facts it can be concluded that the water added to the hydrogenation system promotes the hydrogenation rate, independent of the kind of modifying reagent used in the asymmetric hydrogenation of methyl acetoacetate.

The author wishes to express his thanks to Professor Yoshiharu Izumi for his valuable advice and encouragement throughout this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2548—2550 (1972)

Asymmetric Hydrogenation of C=O Double Bond with Modified Raney Nickel. XXII

Toshio NINOMIYA*

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received January 26, 1972)

The state of the amino acid molecule used as a modifying reagent on a catalyst surface was investigated. From the relationship between the asymmetric activities of the catalysts modified with L-valine and its derivatives and the stability constants of the nickel chelates of L-valine and its derivatives, it was concluded that L-valine adsorbs like a ligand of the chelate on the catalyst surface. This conclusion was also supported by the finding that the asymmetric activity of the catalyst modified with the nickel L-valine chelate was higher than those of the catalysts modified with L-valine and its derivatives. Also, the asymmetric activities of the catalysts modified with L-histidine, L-serine, and L-proline, and with the nickel chelates of the above three L-amino acids were discussed on the basis of the stability constants of the nickel chelates of the above three L-amino acids, it was concluded that two conditions at least are necessary for the modifying reagent to be effective; it must adsorb stably on the catalyst surface, and it must have a structure affording effective asymmetric control of the substrate.

In a series of investigations of asymmetric hydrogenation by our research group, it has been reported that the catalysts modified with *O*-acetyl D-tartaric acid, *O*-benzoyl D-tartaric acid, and the D-tartaric acid diethyl ester show lower (−) asymmetric activities than the catalyst modified with D-tartaric acid, and also that the catalysts modified with *N,N*-dimethyl-L-glutamic acid and *N*-cyanoethyl-L-glutamic acid have lower (−) asymmetric activities than the catalyst modified with L-glutamic acid.[1] From the above results, it was conclusively inferred that a hydroxyl group or an amino group and a carboxyl group are desirable modifying reagents to produce the high asymmetric activity of the catalyst.

However, no systematic information about the adsorption state of the modifying reagent on the catalyst surface has been obtained. The present work was undertaken in order to elucidate the adsorption state of the modifying reagent, L-amino acid, on the catalyst surface. As the modifying reagents, monoamino monocarboxylic acids were mainly used by virtue of the ease of analysis of the state of the modifying reagent on the catalyst surface.

The adsorption form of amino acid formed by the chelation on the catalyst surface is discussed on the correlation between the asymmetric activity of the catalyst and the stability constant of the nickel chelate of the modifying reagent. Furthermore, the essential chemical character of the modifying reagent in the asymmetric hydrogenation is discussed.

Experimental

The preparation of the modified Raney nickel catalyst, the hydrogenation of methyl acetoacetate, and the measurement of the asymmetric activity of the catalyst were done as described in a previous paper.[2]

Results and Discussion

Table 1 indicates the asymmetric activities of the catalysts modified with L-valine and its derivatives. As Table 1 indicates, the catalyst modified with L-valine showed a higher (−) asymmetric activity than the

catalysts modified with *N*-acetylated L-valine, L-valine methyl ester, and L-valinol.

From the information provided by co-ordination chemistry, L-amino acids are well known as usual chelating reagents for transition metals, and it is also known that the stability constants of the metal chelates of L-amino acids are depressed by the chemical derivation of the amino group or carboxyl group.[3)]

On the basis of the above facts, the decrease in the (−) asymmetric activity of the catalyst by the chemical derivation of the amino or carboxyl group of the modifying reagent, as is shown in Table 1 seems to depend on the depression of the stability of the chemical adsorption of the modifying reagent on the catalyst surface by the chemical derivation, and the modifying reagent, L-valine, seems to be adsorbed as a ligand of the chelate on the catalyst surface.

Table 2. The asymmetric activities of the catalysts modified with L-Ileu, L-Phe, L-Met and their metal chelates

Table 2 lists the asymmetric activities of the catalysts modified with L-isoleucine (L-Ileu). L-phenylalanine (L-Phe), and L-methionine (L-Met) and those nickel chelates. As is listed in Table 2, the asymmetric activities of the catalysts modified with the nickel chelates of the above three L-amino acids were nearly equal to or higher than those of the catalysts modified with the corresponding L-amino acids. The catalysts modified with *N*-acetyl L-isoleucine and *N*-acetyl L-phenylalanine showed far lower (−) asymmetric activities than those modified with L-Ileu and L-Phe respectively. The low (−) asymmetric activities of the catalysts modified with *N*-acetyl L-isoleucine and *N*-acetyl L-phenylalanine probably result from the less stable adsorption of *N*-acetyl L-isoleucine and *N*-acetyl L-phenylalanine on the catalyst surface than that of L-Ileu and L-Phe. These results also support the above-mentioned deduction that the L-amino acid used as the modifying reagent adsorbs like a ligand of the chelate on the catalyst surface.

Table 2 also shows that the catalyst modified with the *trans* nickel L-isoleucine chelate and a higher (−) asymmetric activity, while, the catalyst modified with the *cis* copper L-isoleucine chelate had a lower (−) asymmetric activity, than the catalyst modified with L-Ileu. These results may be interpreted as follows: in the modification of the *trans* nickel L-isoleucine chelate, both secondary butyl groups of the nickel L-Ileu chelate stretch out on the same side from the chelate-ring plane and the chelate adsorbs through the *d*-electron as the less sterically-hindered side on the catalyst surface, as is illustrated in Fig. 1.

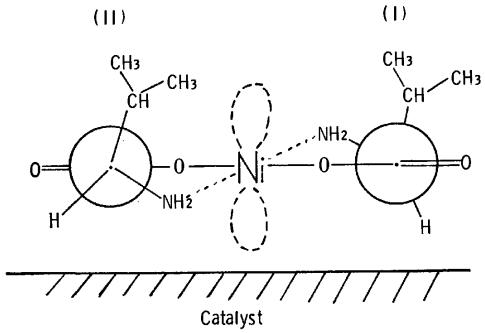

Fig. 1. Proposed adsorption state of *trans* nickel L-isoleucine chelate.

When the substrate, methyl acetoacetate, approaches the catalyst surface, if the interaction of the substrate with the right modifying reagent molecule (I) in Fig. 1, fit for the asymmetric hydrogenation, the left molecule (II) should strongly reject the substrate, and *vice versa*.

Consequently, in the modification of *trans* nickel L-isoleucine chelate, the push-pull effect by both modifying molecules, I and II, on the asymmetric control of the substrate would cause higher (−) asymmetric activity than in the modification with L-Ileu, which produces mixture of *cis* and *trans* forms on the

catalyst surface. On the other hand, in the case of modification with the *cis* copper L-isoleucine chelate naturally hinders the adsorption of the chelate, so that the *cis* chelate adsorbs less stably than L-Ileu and the *trans* chelate. The catalyst modified with the *cis* chelate would give a lower (−) asymmetric activity than those modified with the *trans* nickel L-isoleucine chelate and L-Ileu.

The above discussion is also supported by the fact that the catalyst modified with the nickel L-valine chelate shows far more (−) asymmetric activity than that catalyst modified with L-valine. The high asymmetric activities of the catalysts modified with the *trans* nickel L-valine chelate and the *trans* copper L-valine chelate, shown in Table 1, seem to be due to stable adsorption by the *d*-electron of nickel or copper metal on the catalyst surface.

TABLE 3. THE ASYMMETRIC ACTIVITIES OF THE CATALYSTS MODIFIED WITH L-Ser, L-Thr, L-Pro, L-His AND THEIR NICKEL CHELATES

Modifying reagent	Solvent	concn. %	Modifying condition		$[\alpha]_D$ of Methyl 3-hydroxybutyrate
			Temp. (°C)	Time (min)

R-Ni ND (Kawaken Fine Chemicals Co., Ltd.) lot 1949, 1.5 g.
MAA (The Nippon Synthetic Chemical Industry Co., Ltd.) lot 70, 0.15 mol.

Table 3 lists the asymmetric activities of the catalysts modified with L-serine (L-Ser), L-threonine (L-Thr), L-proline (L-Pro), and L-histidine (L-His) and the nickel chelates of those L-amino acids.

As is listed in Table 3, all the catalysts modified with L-His, L-Ser, L-Thr, and L-Pro showed smaller asymmetric activies than the catalysts modified with L-Val, L-Ileu, and L-Phe, shown in Tables 1 and 2, and they did not always show the (−) asymmetric direction.

The stability constants of nickel chelates of Pro, Ser, and His are known to be equal or greater than that of Val,[3,4] and the above discussion suggests that the stable adsorption of the modifying reagent, *i.e.*, chelation, on the catalyst surface can cause a high asymmetric activity in the catalyst. However, contrary to expectation, the asymmetric activities of the catalysts modified with L-Pro, L-Ser, L-His and L-Thr are less than that of the one modified with Val. The above phenomena can be explained as follows: though Pro, Ser, His and perhaps Thr can adsorb stably on the catalyst surface, their asymmetric control ability to the substrate would be far less effective than that of L-Val, L-Ileu, and L-Phe.

Also, as is shown in Table 3, catalysts modified with nickel chelates of L-His, L-Ser, L-Thr and L-Pro gave lower asymmetric activities than catalysts modified with L-His, L-Ser, L-Thr, and L-Pro respectively. In according for the above fact, it can be considered that all the six bonding electrons of nickel metal are completely occupied by two tridentate-ligand molecules and that the nickel chelate of those ligands will be attached to the catalyst surface only by weak physical adsorption, so that the catalysts modified with these nickel chelates show low asymmetric activities.

On the basis of the above discussion as a whole, it can be concluded that the modifying reagent, L-monoamino monocarboxylic acid, should adsorb like a ligand of the chelate on the catalyst surface and that two conditions at least are necessary in a desirable modifying reagent in the asymmetric hydrogenation; it must adsorb stably on the catalyst surface and it must have a structure affording effective asymmetric control of the substrate.

The author wishes to express his sincere thanks to Professor Yoshiharu Izumi for his valuable advice and encouragement throughout this work.

Asymmetric Hydrogenation of C=O Double Bond with Modified Raney Nickel Catalyst. XXIII

Toshio NINOMIYA*

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received January 26, 1972)

The ultraviolet spectra of acetylacetone and methyl acetoacetate adsorbed on evaporated nickel film modified with amino or hydroxy acid were measured. The spectroscopic data suggested that the adsorbed species of acetylacetone was affected by the modifying pH, that the interaction between acetylacetone and the hydroxy acid was different from that between acetylacetone and the amino acid, and also that methyl acetoacetate, similar to acetylacetone, chemisorbed with a pseudo aromatic ring on the nickel surface. Consequently, the above results strongly support the theory that in the asymmetic hydrogenation, the substrate, acetylacetone or methyl acetoacetate, approaches the catalyst surface in a form like a pseudo aromatic ring, that it is asymmetrically controlled by the modifying reagent adsorbed on the catalyst surface, and, further, that the ease of the adsorption of the substrate onto the catalyst determines the rate of asymmetric hydrogenation.

In the course of the investigation of asymmetric hydrogenation with modified Raney nickel catalysts, many kinds of ketones have been used as the substrate for the asymmetric hydrogenation; β-ketoester and β-diketone have been demonstrated to be the most suitable substrates.[1] However, the approach mechanism of the substrate to the catalyst surface has not been made clear. The clarification of the approach-mechanism of the substrate to the catalyst surface would give important information for solving the mechanism of the asymmetric hydrogenation.

The present work is intended to make clear the approach-mechanism of the acetylacetone (Hacac) and methyl acetoacetate (MAA) substrates to the catalyst surface.

In a previous short communication[2] the absorption spectra of Hacac adsorbed on evaporated nickel film modified with D-tartaric acid have been reported. The present paper will report, in detail, on the adsorption state of the substrate, Hacac or MAA, onto evaporated nickel film modified with optically-active amino or hydroxy acid.

The experimental procedure developed by Kishi *et al.*[3] was improved. The adsorption spectra of Hacac adsorbed on the nickel film modified at various modifying pH values suggested that the adsorbed species of Hacac on the nickel film can be changed by changing the modifying pH and that Hacac can be adsorbed with ease on the nickel surface with an increase in the modifying pH.

Moreover, from the fact that, at the same modifying pH the absorption spectra of Hacac on the nickel film modified with tartaric acid were different from those of Hacac on the nickel film modified with glutamic acid, it was concluded that the substrate, in approaching the nickel surface, is affected characteristically by the asymmetric control of the modifying reagent adsorbed on the nickel surface and that the asymmetric control mechanism by hydroxy acid for the substrate was different from that by amino acid because of the difference in the chemical interaction between the hydroxy group and the amino group with the substrate.

As for MAA, which is similar to Hacac, it was made clear that MAA chemisorbs like a chelate with a pseudo aromatic ring on the nickel surface, and the ease of the adsorption of MAA on the evaporated nickel film modified with an optically-active compound was parallel with the asymmetric hydrogenation rate of MAA in the presence of a catalyst modified by the corresponding modifying reagent.

Experimental

The experimental apparatus developed by Kishi[3] was improved and used; *cf.* Fig. 1. The evaporation conditions of nickel onto the quartz windows was the same as the conditions reported by Kishi.[3] After the nickel had been evaporated onto the quartz windows, the break-off seal (G) was broken by means of the glass-coated magnet (H) and a 2% modifying aqueous solution (I), which had been degassed, was gently introduced into the quartz cell. At 0°C for 30 min, the nickel surface was modified by the modifying aqueous solution. Then, the modifying aqueous solution was transported into I, the modified nickel film was washed twice with water, and the water was evaporated from the ultraviolet cell. The substrate, acetylacetone or methyl acetoacetate, was introduced into the cell, and then the ultraviolet spectra were recorded on a Hitachi EPS-2 spectrophotometer equipped with a liquid nitrogen trap.

The GR-grade acetylacetone was obtained from Nakarai Pure Chemicals, while the methyl acetoacetate was obtained from The Nippon Synthetic Chemical Co., Ltd., both were distilled several times under a vacuum. The purity of the nickel wire is 99.5%.

Results and Discussion

1) Adsorption of Acetylacetone (Hacac). Figure 2 illustrates the absorption spectra of Hacac adsorbed on the evaporated nickel film modified with D-tartaric acid at pH 2.0, 5.0, and 9.0. As is illustrated in Fig. 2, in the modification at pH 2.0 a weak band was observed around 280 mμ after a 30-min exposure

to acetylacetone, and the band maximum shifted to a longer wavelength after 18 hr. In the modification at pH 5.0, absorption peaks were observed at 306, 316, and 322 mμ after 16 hr; these peaks became one at 303—306 mμ after 24 hr. In the treatment at pH 9.0, three intensive bands were observed at 306, 313, and 319 mμ after 15 hr.

The maximum peak at 303 mμ was assigned to an absorption peak of the π-π^* transition of adsorbed $acac^-$ in the study by Kishi *et al.*[2] of the absorption spectrum of Hacac adsorbed on the unmodified nickel film.

Tanabe,[4] one of our research group, suggested that, in the modification with a free tartaric acid aqueous solution (pH 2.0), one of the carboxyl groups of tartaric acid is bound to the catalyst surface, while the other, being undissociated, stretches out from the nickel surface and is dissociated by the neutralization, with an increase in the modifying pH.

On the basis of the above information, the results in Fig. 2 can be explained by the following proposition. In the modification at pH 2.0, the acidic β-carboxyl group stretching out from the nickel surface could hinder the enolization of Hacac, which would favor Hacac making a stable adsorption with a chelation from on the nickel surface; consequently, enol-form Hacac could hardly adsorb on the nickel surface. Hence, we observed the shift of adsorption maximum at 303 mμ, which was seen in the adsorption of Hacac on the unmodified nickel surface, to at shorter wavelength position.

In the modification at pH 5.0, the acidity of the β-carboxyl group of tartaric acid should be mostly neutralized; therefore, acetylacetone can adsorb with a stable pseudo aromatic ring on the nickel surface because there is little hindrance by the acidity of the β-carboxyl group, and the absorption band can be considered to show a maximum peak at 303—306 mμ.

In the treatment at pH 9.0, both carboxyl groups of tartaric acid were mostly neutralized, the amounts of tartaric acid adsorbed were moderately small compared with the amounts adsorbed in the modification at pH 5.0,[5] and acetylacetone would adsorb more easily

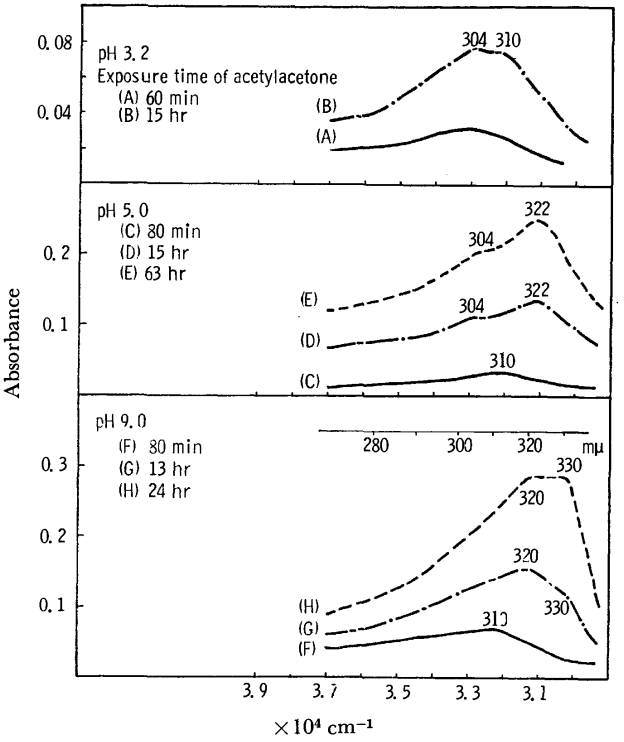

Fig. 3. Ultraviolet spectra of acetylacetone adsorbed on nickel film with preadsorbed L-glutamic acid at pH 3.2, 5.0, and 9.0.

4) T. Tanabe, This Bulletin, to be published.
5) S. Tatsumi, This Bulletin, **41**, 408 (1968).

than at pH 5.0. Thus, the chemical circumstances on the catalyst surface at pH 9.0 were different from those at pH 5.0. Therefore, the absorption spectrum of Hacac at pH 9.0 is considerably different from that at pH 5.0 as is shown in Fig. 2.

Figure 3 displays the absorption spectra of Hacac adsorbed on the nickel film modified with L-glutamic acid at pH 3.2, 5.0, and 9.0. As is illustrated in Fig. 3, in the modification at pH 3.2 two weak bands, at 304 mμ and 310 mμ, were observed after 15 hr's exposure to acetylacetone.

With an increase in the modifying pH value, the bands of adsorbed Hacac shifted to longer wavelength positions and their intensities increased. The above shift of the adsorption bands with an increase in the modifying pH must be due to the effect or γ-carboxyl group of L-glutamic acid, as in the modification with tartaric acid.

On the basis of the above facts and discussion, it is clear that the approaching form of the substrate was affected by the chemical circumstances of the modifying reagent on the nickel surface; that is, in acidic circumstances acetylacetone could hardly take the enol form while in neutral or basic circumstances acetylacetone could take the enol form and could stably adsorb with a pseudo aromatic ring on the nickel surface.

Moreover, a remarkable difference between Figs. 2 and 3 was observed at the same modifying pH. That is, at both pH 5.0 and pH 9.0 the absorption spectra in the modification with tartaric acid were different from those in the modification with glutamic acid. This important difference in the absorption spectra is due to the difference in chemical interaction between the substrate and the modifying reagent, probably because of the difference in reactivity to the substrate between the amino group of amino acid and the hydroxy group of hydroxy acid. For example, the amino group can behave as a base to the substrate, acetylacetone, the enol form of which may act as an acid, and can also form a Schiff base with the ketone group of the substrate, while the hydroxy group acting as an acid can make a hydrogen bond with the ketone group of the substrate.

This difference in chemical interaction between the amino and the hydroxy groups and the carbonyl group of the substrate seems to result in a difference in asymmetric direction between the catalysts modified with L- (or D-) amino acid and L- (or D-) hydroxy acid. As a matter of fact, the catalysts modified with L-aspartic acid show (−) asymmetric activity, while the catalysts modified with L-malic acid show (+) asymmetric activity, in the asymmetric hydrogenation of methyl acetoacetate.[6]

In conclusion, the above phenomenon supports strongly the idea that, in the asymmetric hydrogenation, the substrate approaching the catalyst surface is perturbed and affected asymmetrically by the modifying reagent on the catalyst surface.

2) Adsorption of Methyl Acetoacetate. Figure 4 illustrates the absorption spectra of methyl acetoacetate (MAA) adsorbed on the unmodified nickel film. As is illustrated in Fig. 4, a broad band was observed at 285 mμ. The band did not disappear upon the use of a liquid nitrogen trap, although the band at 239 mμ due to vapor MAA disappeared upon the use of a liquid nitrogen trap. In addition, the intensity of the band increased with an increase in the time of exposure to MAA, and upon exposure to acetic acid vapor the band disappeared instantly.

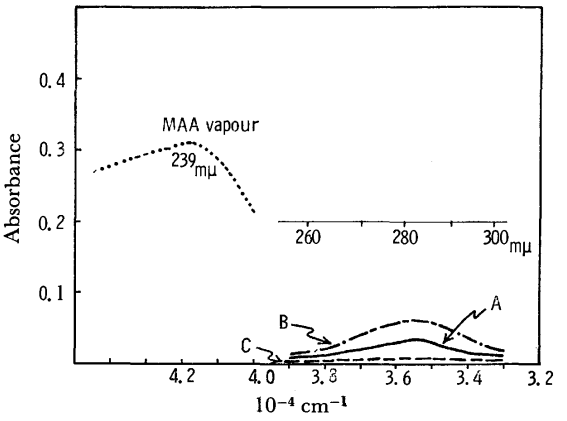

Fig. 4. Ultraviolet spectra of methyl acetoacetate adsorbed on nickel film (without preadsorption).
A: 60 min B: 18 hr C: 30 sec after AcOH

The above facts support the idea that the band at 285 mμ is to be ascribed to the chemisorbed species of MAA on the nickel film. Further, from the fact that the position of the band maximum of chemisorbed MAA (285 mμ) is near that of nickel methyl acetoacetate (278 mμ in methanol), MAA can be concluded to chemisorb like a chelation form with a pseudo aromatic ring on the nickel surface.

Figure 5 shows the absorption spectra of MAA adsorbed on nickel film modified with L-valine, L-glutamic acid, L-histidine, and D-tartaric acid. As is shown in Fig. 5, the intensities of the absorption spectra originating from MAA adsorbed on the nickel surfaces modified with valine, glutamic acid, and histidine

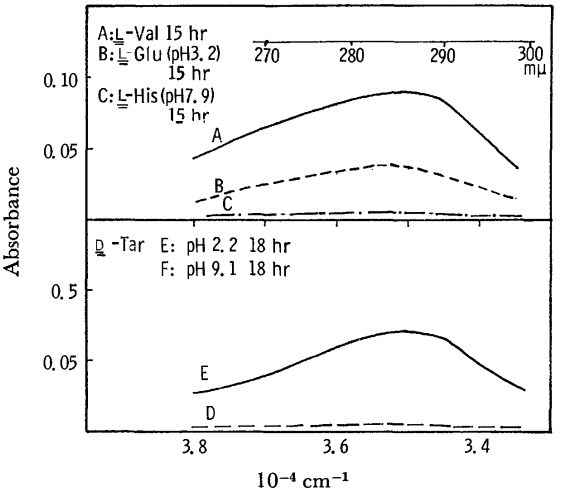

Fig. 5. Ultraviolet spectra of methyl acetoacetate adsorbed on nickel film with preadsorbed L-valine, L-glutamic acid, L-histidine, and D-tartaric acid.

6) Y. Izumi, S. Yajima, K. Okubo, and K. K. Babievsky, *ibid* **44**, 1416 (1971).

decreased in the following order; valine>glutamic acid≫ histidine. This order seems to be related to the hydrogenation rate of MAA in the presence of a catalyst modified with L-valine, L-glutamic acid, or L-histidine. That is, the hydrogenation of MAA with the catalyst modified with L-histidine took at least 2 times as long as the hydrogenation with catalysts modified with neutral L-amino acids.

Histidine can chelate strongly on the nickel surface because histidine can act as a tridentate chelating reagent,[7] while neutral L-amino acids acts as bidentate reagents. As a result, it can be considered that a nickel atom of the catalyst surface on which a histidine molecule should absorb strongly can hardly attract the substrate, while a nickel atom on which a neutral amino acid should adsorb can attract the substrate rather easily.

Therefore, the MAA substrate will probably approach the nickel surface modified with L-histidine with more difficulty than that modified with neutral L-amino acids.

In the modification with D-tartaric acid, the adsorption intensity at pH 2.2 was far weaker than that at pH 9.1. The phenomenon is probably due to the reason mentioned in the case of acetylacetone; that is, at pH 2.2, the β-carboxyl group, being undissociated, should hinder the enol-form adsorption of MAA, while at pH 9.1 the β-carboxyl group of D-tartaric acid is mostly neutralized and MAA can adsorb easily with the enol from on the nickel surface. The above results correspond to the facts shown in Fig. 6.

In Fig. 6, the percentage of hydrogenation is plotted against the hydrogenation time in the asymmetric hydrogenation with the catalysts modified with D-tartaric acid at pH 2.2 and pH 9.5 at 0°C. As is shown in Fig. 6, the hydrogenation rate in the modification at pH 2.2 is smaller than that as pH 9.5. From the above discussion, it is clear that the asymmetric hydrogenation rate of MAA depends on the degree of hindrance of the modifying reagent, which probably contains at least two factors, the strength of the chelation ability for amino acids and the acidity of the β-carboxyl group for a tartaric acid, in relation to a the substrate approaching the catalyst surface.

Asymmetric Hydrogenation of C=O Double Bond with Modified Raney Nickel. XXIV. The Effect of Unsaturated Compounds on the Asymmetric Activity of the Catalyst

Toshio NINOMIYA*

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received January 26, 1972)

Dehydroacetic acid and methyl *cis*-3-acetoxycrotonate were picked out as trace impurities of the substrate, methyl acetoacetate. The effects of dehydroacetic acid, methyl *cis*-3-acetoxycrotonate, and diketene, which is the starting material for the preparation of methyl acetoacetate, on the asymmetric activities of catalysts modified with L-amino acids were examined in the hydrogenation of methyl acetoacetate. The above three compounds, when added to the hydrogenation system, raised the asymmetric activity of the catalyst. Also, simple unsaturated compounds, such as acetone and diethyl maleate, has a similar effect on the catalyst. The effects of the above unsaturated compounds on the asymmetric activities of the catalysts modified with L-amino acids were discussed, and it was suggested that the unsaturated compounds adsorb on the catalyst surface and might scavenge the asymmetrically uncontrolled active hydrogen absorbed on the catalyst surface.

In the course of an investigation of asymmetric hydrogenation with Raney nickel catalysts modified with optically-active amino or hydroxy acids, it was often observed that a difference in the lot number of the substrate, methyl acetoacetate, caused an indefinite asymmetric activity in the catalyst. As one of the reasons for the above phenomenon, the contaminant components in the substrate can be considered to have an influence on the asymmetric activity of the catalyst.[1] The present investigation was carried out in order to confirm the trace components in the substrate and in order to clarify the effect of those trace components on the asymmetric activity of the catalyst.

As the trace components in methyl acetoacetate (The Nippon Synthetic Chemical Industry, Co., Ltd., lot 70), dehydroacetic acid (DHA) and methyl *cis*-3-acetoxycrotonate (MAC) were picked out from the substrate, and the effects of DHA, MAC, and diketene, which is the starting material for the preparation of the substrate, on the asymmetric activity of the catalysts modified with L-amino acids were tested.

From the fact that DHA, MAC, and diketene, being unsaturated compounds or hydrogen acceptors, have a great effect on the asymmetric activity of the catalyst, the effect of simple unsaturated compounds, such as acetone and diethyl maleate, on the asymmetric activities of the catalysts modified with L-amino acids was investigated further.

As a whole, the unsaturated compounds, which have ketone groups or C=C double bonds, caused a rise in the asymmetric activities of the catalysts modified with L-amino acids. The effect of unsaturated compounds on the asymmetric activity of the catalyst was discussed on the basis of the above results.

Results and Discussion

The gas chromatograms of three kinds of methyl acetoacetate, lot A, lot B, and lot 70, are shown in Fig. 1. As is indicated in Fig. 1, the contents of the trace components in methyl acetoacetate were different from one another. To confirm the trace component, in methyl acetoacetate (MAA), lot 70, the lot was rectified under reduced pressure and the trace components of the substrate were concentrated. As trace components, DHA and MAC were isolated and identified.

Figures 2 and 3 show the effect of DHA and MAC, when added to the hydrogenation system, on the assymmetric activities of the catalysts modified with L-glutamic acid and L-valine. The addition of DHA and MAC to the hydrogenation system raises, the (−) asymmetric activities of the catalysts modified with L-glutamic acid and L-valine.

Figure 3 also shows that, in the presence of the catalyst modified with L-valine, a more purified sub-

strate, one which had been obtained by the rectification of MAA lot 70, was hydrogenated in a lower asymmetric yield ($[\alpha]_D = -1.48$), while the addition of 300 mg of DHA to the above purified substrate caused a high asymmetric activity ($[\alpha]_D = -2.56$).

The above facts clearly indicate that the asymmetric activity of the catalyst shown in the hydrogenation of MAA lot 70 was intrinsically affected by the trace components of MAA lot 70, DHA, or MAC.

Furthermore, the possibility that MAA includes a small amount of diketene, because diketene is the starting material of MAA, led us to examine the effect of diketene on the asymmetric activity of the catalyst.

Figure 4 indicates the effect of diketene on the asymmetric activities of the catalysts modified with L-

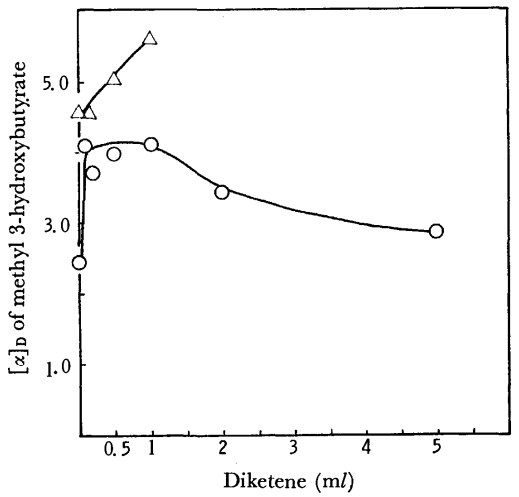

Fig. 4. Effect of added diketene on asymmetric activity of catalyst.
—△—: Modification with L-glutamic acid at 0°C, pH 5.0
—○—: Modification with L-valine at 0°C

glutamic acid and L-valine. As is illustrated in Fig. 4, diketene, when added to the hydrogenation system, raised the asymmetric activities of the catalysts modified with L-glutamic acid and L-valine.

From the results shown in Figs. 2, 3, and 4, it is clear that DHA, MAC, and diketene affect the asymmetric activities of the catalysts modified with L-amino acids in a similar manner. The above three substances have reducible groups, C=O and/or C=C in commons and it can be supposed that the treatment of the catalyst with simple unsaturated compounds, containing ketone groups or C=C double bonds may raise the asymmetric activities of the catalysts modified with L-amino acids.

The effect of simple unsaturated compounds on the asymmetric activities was examined with the catalysts modified with L-valine and L-alanine.

R-NiND (Kawaken Fine Chemical Co., Ltd.) lot 1949, 1.5 g. Substrate; Methyl acetoacetate (The Nippon Synthetic Chemical Industry Co. Ltd.) lot 70 0.15 mol.

Table 1 shows the effect of various reducible compounds on the asymmetric activities of the catalysts modified with L-valine and L-alanine. As is shown in Table 1, the treatment with various ketones and olefins raised the asymmetric activities of the catalysts in most cases. An interesting, remarkable difference was observed between the cases of diethyl maleate and diethyl fumarate; that is, the treatment of the catalyst with diethyl maleate gave a high asymmetric activity to the catalyst, while the treatment of the catalyst with diethyl fumarate lowered and strongly inhibited the hydrogenation.

On the basis of the above results it is clear that unsaturated compounds with ketone groups or C=C double bonds played an important role in raising the asymmetric activities of the catalysts modified with L-amino acids. Then, the unsaturated compounds which gave a high asymmetric activity to the catalyst were hydrogenated under asymmetric hydrogenation conditions.

As was reported in a previous paper,[2] saturated compounds, for example, ethanol and *n*-hexane, are known not to cause a rise in the asymmetric activities of the catalysts modified with L-amino acids. As a result, the effect of the hydrogenated products of the above unsaturated compounds can be disregarded. Moreover, as is shown in Table 1, the 90-sec pretreatment of the catalyst with the substrate, MAA iteself, as an unsaturated compound brought a higher asymmetric activity to the catalyst than no pretreatment, which is the standard asymmetric hydrogenation procedure. On the other hand, the present author has previously made it clear that MAA adsorbs with a pseudo aromatic ring on the catalyst surface.[3]

Therefore, the effect of unsaturated compounds might be associated with the absorbed hydrogen on the catalyst surface. On the whole, it can be concluded that the unsaturated compounds adsorb on the catalyst surface and that, at that stage, they might scavenge asymmetrically uncontrolled active hydrogen absorbed on the catalyst surface. Therefore, with regard to the above phenomenon, Izumi, one of our research group, has attempted to explain it by the hypothesis of a "Quasi liquid hydrogen layer."[4]

Experimental

The preparation and modification of the Raney nickel catalyst, the hydrogenation of methyl acetoacetate, and the measurement of the asymmetric activity of the catalyst were performed in the manner described in a previous paper.[5]

As the Raney nickel alloy, 1.5 g of R-Ni ND, lot 1949 (Kawaken Fine Chemicals Co., Ltd.), was used, and as the substrate we used 0.15 mol of methyl acetoacetate (MAA), lot 70, from the Nippon Synthetic Chemical Industry Co., Ltd.

Isolation and Identification of DHA and MAC. MAA, lot 70 (600 m*l*), was rectified under reduced pressure (15 mmHg) with a Podbielniak 13-mm Heli-Grid column and was then concentrated to 30 m*l*. The yellowish brown residue was cooled overnight in a refrigerator, and the yellowish precipitate was separated by filtration. The precipitate was recrystallized from an ethanol solution. Yield, 0.3 g; mp 105—110°C (capillary).

NMR: δ (10%, $CDCl_3$) 2.26 (3H, s, $CH_3 \cdot \underset{\underset{O}{|}}{C}=C$), 2.62 (3H, s, $CH_3 \cdot \underset{\underset{O}{|}}{C}-$), 5.93 (1H, s, C=CH–C), and 16.84 (1H, s, $\underset{\underset{O}{\|}}{C}-CH-\underset{\underset{O}{\|}}{C}=O$). IR: (KBr) 1720 (ketone), 1620—1640 and 1550 cm^{-1} (pyrone ring).

Found: C, 56.41; H, 4.83; N, 1.16%. Calcd for $C_8H_8O_4$: C, 57.14; H, 4.80; N, 0.00%.

From the above physicochemical data, the crystals were identified as dehydroacetic acid.

The filtrate was suspended in a nickel chloride aqueous solution ($NiCl_2 \cdot 6H_2O$ (24 g) in H_2O (50 m*l*)). To the above suspension solution, we slowly added a caustic soda solution (NaOH (8 g) in H_2O (50 m*l*)) under ice-water cooling, and the pH was adjusted about 7.

After the mixture had been stirred for 2 hr, the nickel methyl acetoacetate was filtered off and the filtrate was introduced into a gas-chromatogram apparatus, Varian 90-P3; the peak, R, shown in Fig. 1 was separately collected.

NMR: δ (1%, CCl_4) 2.04 (3H, s, CH_3–C), 2.21 (3H, s, CH_3–$\underset{\underset{O}{\|}}{C}$–), 3.57 (3H, s, O–$CH_3$), 6.49 (1H, s, C=CH–C). IR: (liquid film) 1710 and 1760 (esters) and 1660 cm^{-1} (C=C).

From the IR and NMR data and by identification[6] with synthetic *cis*-3-acetoxycrotonate, the R peak was identified as methyl *cis*-3-acetoxycrotonate (MAC).[1] Gas-chromatographic calculation showed the MAA lot 70 to contain 0.3% MAC.

Addition of DHA, MAC, and Diketone. A chemically pure grades of DHA and diketene (Wako Pure Chemical Industries, Ltd.) were used. The MAC was prepared by the method of Claisen.[6] DHA, MAC and diketene were all added to the substrate, MAA, which was then introduced into autoclave, and the reduction product, methyl 3-hydroxybutyrate, was fractionally distilled.

Treatment of the Catalyst with Simple Ketones or Olefins. The catalyst modified with an L-amino acid was immersed for 90 sec in 18 m*l* of a ketone or an olefin; by decantation the catalyst was separated from the ketone or the olefin with the aid of a magnet to retain the catalyst, and the catalyst was introduced with the substrate into the autoclave.

The author wishes to express his thanks to Professor Yoshiharu Izumi for his valuable advice and encouragement throughout this work, to Miss Kiku Koike and Mrs. Nobuko Okuhara for the elemental analysess to Drs. Yoshimoto Ohta and Kiichi Nishimura for their permission to use the fine distillation apparatus, and also to the Nippon Synthetic Chemical Industry Co., Ltd., for giving him information on the impurities contained in methyl acetoacetate.

The Autoxidation of Phenols Catalyzed by Phthalocyanine-Fe(II) and Salcomine-pyridine

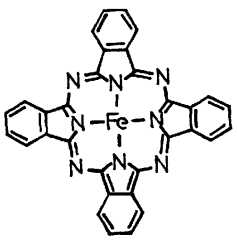
Masaru TADA and Takashi KATSU

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku, Tokyo, 160

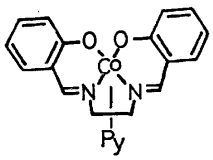
(Received February 4, 1972)

The autoxidation of 2,4,6-tri-*t*-butylphenol (**1**), 2,6-di-*t*-butylphenol (**2**), and 2,4-di-*t*-butylphenol (**3**) is catalyzed by phthalocyanine-Fe(II) (PC-Fe(II)) and salcomine-pyridine (SAL-Py). PC-Fe(II) gives, preferentially, the coupling product of such phenoxy radicals as **4**, **7**, and **8**. SAL-Py, on the other hand, gives *o*- and *p*-benzoquinones, such as **5** and **6**, resulting from the coupling of the phenoxy radical and the hydroperoxy radical. Metal phthalocyanines including Mn(II), Co(II), Ni(II), or Cu(II) as the central metal ion are inactive as catalysts for the oxidation. PC-Fe(II) does not catalyze the autoxidation of phenol itself and mono-alkylated phenols.

The autoxidation of phenols catalyzed by salcomine and its derivatives has drawn much attention in connection with the relation between the mode of oxidation and the states of the oxygen-adducts of salcomine.[1,2] On the other hand, the autoxidation of phenols catalyzed by ion complexes, which are assumed to be carriers of molecular oxygen, has not been reported except for the preliminary result on the autoxidation of poly-phenol catalyzed by phthalocyanine-Fe(II) (PC-Fe(II) hereinafter).[3] Our attention was directed to the catalytic activity of PC-Fe(II) in the autoxidation of organic compounds in connection with the structual similarity of PC-Fe(II) to a biologically-important hemin. In this paper we will report on the autoxidation of phenols catalyzed by PC-Fe(II). The autoxidation of phenols catalyzed by salcomine-pyridine (SAL-Py hereinafter) was also carried out in order to compare the modes of catalysis of the two catalysts.



PC-Fe(II)



SAL-Py

Results and Discussion

Several metal phthalocyanines including Mn(II), Co(II), Ni(II), or Cu(II) as the central metal ion were tested as catalysts for the oxidation 2,4,6-tri-*t*-butylphenol (**1**) and 2,6-di-*t*-butylphenol (**2**), but they were nearly all inactive; only PC-Fe(II) showed a strong catalytic activity. In contrast, Vogt *et al.* reported that the oxidation of 2,6-dimethylphenol was catalyzed by salcomines and not by the complexes in which the central metal ion of salcomine was replaced by Mn(II), Fe(II), Ni(II), or Cu(II).[1]

The distributions of the products from the oxidation of 2,4,6-tri-*t*-butylphenol (**1**), 2,6-di-*t*-butylphenol (**2**), and 2,4-di-*t*-butylphenol (**3**) are shown in Tables 1, 2, and 3 respectively.

The oxidation products from the three phenols **1**, **2**, and **3**, originate almost exclusively from the coupling of two phenoxy radicals when the oxidations are catalyzed by PC-Fe(II). The peroxide, **4**, must be formed by the coupling of two phenoxy radicals from **1** at a para-position through the bridge of molecular oxygen, as a result of the steric hindrance of a direct coupling. The biphenoquinone, **7**, must be formed by the further oxidation of biphenol **9**. On the oxidation of **3**, the biphenol **8** is not further oxidized[4] and an appreciable amount of the starting phenol, **3**, is recovered; the yield of **8** is improved to 88% by changing the solvent from methanol to tetrahydrofuran.

On the oxidations of **1**, **2**, and **3** catalyzed by SAL-Py, the coupling of a phenoxy radical and a hydroperoxy radical becomes more important. Thus two quinones, **5** and **6**, from the phenol **1** must be formed through the intermediates, **10** and **11** respectively, by the elimination of *t*-butyl alcohol. The first oxidation products, **12** and **13**, from the phenols **2** and **3** respectively, must be further transformed to afford the quinones **5** and **6**.

The mode of the autoxidation of *t*-butyl-substituted phenols catalyzed by PC-Fe(II) is similar to that of oxidations by a one-electron-transfer oxidizing agent, such as $K_3Fe(CN)_6$, PbO_2, or Ag_2O.[5,6,7] The autoxi-

dation catalyzed by SAL-Py, on the other hand, gives quinones preferentially; this characteristic is rather similar to that of cobalt- or copper-complexes, such as salcomine or CuCl-amine which have a high potential to combine with molecular oxygen.[1,8,9]

PC-Fe(II) does not catalyze the autoxidation of phenol itself and mono-alkylated phenols including *o*- and *p*-*t*-butylphenol, and *o*-, *m*-, and *p*-cresol. PC-Fe(II) catalyzes only the oxidation of phenols giving stable phenoxy radicals, including di- and tri-*t*-butylphenols, and gives the products derived from the coupling of two phenoxy radicals, either directly or through an oxygen bridge.

Experimental

Materials. Commercially available 2,4,6-tri-*t*-butylphenol (**1**), 2,6-di-*t*-butylphenol (**2**), and 2,4-di-*t*-butylphenol (**3**) were used after purification by recrystallization from ethanol; **1**, mp 131°C, or distillation under reduced pressure; **2**, 132—133°C/18 mmHg. **3**, 141—142°C/18 mmHg.

Catalysts. Metal phthalocyanines were prepared by the method of Dent-Linstead[10] from the chlorides of the corresponding metal and phthalonitrile, or by Gattermann's procedure[11] from the corresponding chlorides, phthalic anhydride, and urea. The crude phthalocyanines were successively washed with boiling methanol, hot diluted sulfuric acid, methanol, and ether. The phthalocyanines thus obtained were dried and kept in a desiccator until their use.

Salcomine-pyridine was prepared by the procedure of Bails-Calvin[12] from cobalt acetate, ethylenediamine, salicylaldehyde, and pyridine; the complex was kept in a vacuum desiccator until its use.

A General Procedure of Autoxidation. A methanol solution (100 m*l*) of one of the phenols (0.015 mol) was exposed to oxygen for 18 hr at room temperature in the presence of metal phthalocyanine (0.015 mol) or salcomine-pyridine (0.015 mol). The reaction mixture was magnetically stirred during the reaction period. After the evaporation of the solvent, the product was taken into ether and was purified by preparative layer chromatography on silica gel eluted with benzene.

Oxidation of 2,4,6-Tri-t-butylphenol (1). The oxidation products from 0.393 g of **1** were seperated by preparative layer chromatography to give three bands on the chromatogram. The extraction of the top, middle, and bottom bands gave peroxide **4** (0.341 g, 87%), *p*-quinone **5** (0.016 g, 4%) and *o*-quinone **6** (trace) respectively when catalyzed by PC-Fe(II). The autoxidation of the phenol **1** by SAL-Py gave the same products as those from the PC-Fe(II) catalysis, but the product distribution was different, as is shown in Table 1. The structures of the products were deduced to be **4**,[13] **5**,[14] and **6**[15] from a comparison of their melting points and infrared spectra.

Oxidation of 2,6-Di-t-butylphenol (2). The oxidation product of 0.309 g of the phenol **2** catalyzed by PC-Fe(II) showed only one spot on an analytical thin-layer chromatogram without any purification; it was identified as biphenoquinone **7**[16] (0.306 g, *ca.* 100%) by a comparison of the melting points and infrared spectra. The oxidation product of 0.309 g of **2** catalyzed by SAL-Py showed two bands on a preparative layer chromatogram; the lower band gave *o*-quinone **5** (0.232 g, 75%) as the major product, while biphenoquinone **7** (0.033 g, 11%) was given from the upper band.

Oxidation of 2,4-Di-t-butylphenol (3). The oxidation product of 0.309 g of **3** catalyzed by PC-Fe(II) gave two spots on an analytical thin-layer chromatogram; the lower spot corresponded to the starting phenol **3** (0.111 g, 36%). The oxidation product, the upper spot, was seperated by preparative layer chromatography to give biphenol **8** (0.176 g, 57%), which was found to be identical with the authentic sample[17] by a comparison of the melting points and infrared spectra. Preparative layer chromatography of the product from the reaction catalyzed by SAL-Py showed another band at the bottom of the chromatogram. The extraction of that band afforded *o*-quinone **6** (0.089 g, 29%) as the major product.

Polar Substituent Constants for Substituted Phenyl Groups. The Extended Taft Equation.

Yoichiro NAGAI, Hideyuki MATSUMOTO, Taichi NAKANO, and Hamao WATANABE
Department of Chemistry, Gunma University, Kiryu, Gunma

(Received February 17, 1972)

Values of the σ* constants have been defined for some *m*- and *p*-substituted phenyl groups from the ^{29}Si–H coupling constants for a series of *m*- and *p*-substituted phenylsilanes, phenylmethylsilanes, and phenyldimethylsilanes. The σ* constants for the groups, XC_6H_4, were found to be directly related to the Hammett σ constants for the ring substituents, X. From this correlation the σ* constants for a number of other substituted phenyl groups have also been calculated. Examples have been presented in which a simple relationship holds between the Taft polar substituent constants including the newly derived σ* constants and molecular properties for a series of compounds covering both aliphatic and aromatic substances. Correlations of reactivities with the extended σ* values have been illustrated and the implications of the results are discussed.

It is well known that there exist two important quantitative relationships of very great generality between structure and reactivity, *i.e.*, the Hammett and Taft equations.[1,2] The former applies within

$$\log K/K_0 = \rho\sigma \quad (1)$$

$$\log K/K_0 = \rho^*\sigma^* \quad (2)$$

a great number of reaction series of *m*- and *p*-substituted benzene derivatives, while the latter is followed by a considerable body of aliphatic reaction series involving a wide variety of functional groups, mechanisms, attacking reagents, experimental conditions, *etc.* Both of the two general relationships are based on a rather simple idea that the effect of structure on reaction rates, equilibrium constants, physical properties, *etc.*, is nearly always determined by a single principal factor, the polar effect of the substituent. Although this idea holds, of course, only when other factors such as resonance and steric effects are absent or negligible or vary linearly, there leaves no doubt that numerous instances indeed follow the linear free energy equations. The two relationships are thus associated with very nearly the same physical implications, but it is generally believed that Eq. (1) is applicable only to aromatic reaction series whereas the use of Eq. (2) is limited only to aliphatic reactions. In effect, the scales of the two sets of substituent constants differ much from each other. Since, however, the two linear polar energy relationships have almost identical physical meanings and mathematical forms, it would be anticipated that the two equations could be extended to merging if the two sets of substituent constants are directly related to one another.

An attempt has been made in this work to define Taft σ* values for some *m*- and *p*-substituted phenyl groups and to determine whether the Taft σ* constants so derived are linearly related to the Hammett σ constants. It was hoped that such relations would prove to be of value in studying polar effects of substituents on various molecular properties and that a comparison of these properties with the use of the extended Taft equation would indicate the presence or absence of other structural factors.

Polar Substituent Constants for Substituted Phenyl Groups

In order to obtain Taft's polar substituent constant (σ* values) for substituted phenyl groups, Nagai and coworkers selected NMR values of the ^{29}Si-H coupling constant for series of substituted phenylsilanes, phenylmethylsilanes, and phenyldimethylsilanes.[3] Evidence has been presented that a good correlation exists between reported values[4,5] of $J(^{29}\text{Si-H})$ for hydrosilanes of the general formula $R_1R_2R_3SiH$, where R's could be a phenyl(s), an alkyl(s) and a hydrogen(s), and the sum of the σ* constants for R_1, R_2, and R_3. The coupling constants follow the equation,

$$J(^{29}\text{Si-H}) = -10.21\sum\sigma^* - 182.9$$

with a correlation coeffecient of 0.994. It is thus possible to evaluate the polar substituent constant for a substisuted phenyl group in question by fitting its NMR parameter to the equation above. The σ* values so obtained for several substituted phenyl groups are listed in Table 1 in which probable errors are included. Since it has also been shown that the ^{29}Si-H coupling constants for each series of the arylhydrosilanes correlate well with Hammett's σ con-

Table 1. Polar substituent constants (σ*) for substituted phenyl groups as determined from the J (^{29}Si–H) values

Group	σ*	Probable error
p-$N(CH_3)_2C_6H_4$	0.16	±0.01
p-$CH_3OC_6H_4$	0.36	±0.01
p-$CH_3C_6H_4$	0.46	±0.01
m-$CH_3C_6H_4$	0.48	±0.002
p-ClC_6H_4	0.75	±0.01

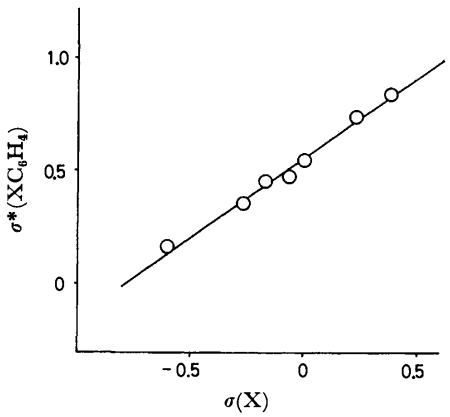

Fig. 1. Relationship between σ and σ^* constants.
σ^* $(XC_6H_4)=0.720\ \sigma(X)+0.575$

stants,[3] the σ^* constants listed in Table 1 are expected to be related to σ constants; two sets of substituent constants are plotted against each other in Fig. 1 which exhibits an excellent linear relationship with a correlation coefficient of 0.995. The regression line can be expressed in terms of the following equation.

$$\sigma^*(XC_6H_4) = 0.72\sigma(X) + 0.58 \qquad (3)$$

The value of the intercept, 0.58, agrees well within experimental error with the σ^* value for a phenyl group, 0.60. It follows then that with the use of Eq. (3) one can further proceed to define the σ^* values for a number of other XC_6H_4 groups by scaling σ values of substituents X to fit this expression. Some selected σ^* values thus calculated are summarized in Table 2.[6]

All the substituted phenyl groups listed in Table 2 are more electron-withdrawing than the methyl group as indicated by positive signs of the σ^* values. It is of interest to note that σ^* values of some of the substituted phenyl groups are lower than that of hydrogen, *i.e.*, 0.49. Thus such a substituted phenyl group is shown to be a weaker electron attractor than hydrogen. This is not unexpected since they contain substituents, X, which are +R (by Gould's classification[9]) in nature.

The correctness of the σ^* values for substituted phenyl groups presented in Table 2 can be tested by giving an example of their use for prediction purposes. Taft[2] has quoted the ionization of aliphatic carboxylic acids, RCOOH, in water at 25°C as a typical example of reactions following his equation. For this particular correlation, log $K=1.721\sigma^*$ -4.65. Values of the polar substituent constants for *m*- and *p*-substituted benzyl groups can readily be obtained from the values listed in Tables 1 and 2 taking the fall-off factor per methylene group to be 2.8 as suggested by Taft. From the correlation above together with the σ^* values for the benzyl groups, it is possible to predict values of the ionization constant for substituted phenylacetic acids which have been determined by Dippy and Williams.[10] The calculated and observed values of the ionization constant are given in Table 3 for comparison. The agreement between the two sets of values is excellent, thus confirming the σ^* values defined in this work to be quite satisfactory.

p-NO_2	−3.95	−3.85

6) The use of σ° (Ref. 7) or σ^n (Ref. 8) values also gives good correlations with the $J(^{29}Si\text{-}H)$ values, so that the σ° or σ^n values for substituted phenyl groups may be evaluated in a similar fashion. These substituent constants might provide a better choice since they represent inductive constants for the substituted phenyl groups relative to the unsubstituted phenyl group, although in general their values do not differ significantly from σ values. Nevertheless the authors prefer the correlation with σ because of its fundamental importance and of the greater number of substituents for which σ values are available.

Application of the New σ^* Constants

It is a matter of course that the σ^* values for *m*- and *p*-substituted phenyl groups can be used to correlated a vast number of reaction series with reasonable precisions since they are linearly related to Hammett's σ values. Their utility manifests itself, however, when properties of compounds R–Y are compared, where the groups, R, contain both aliphatic and aromatic substituents. Although not many investigations have been carried out covering such a wide range of compounds under a single set of experimental conditions, Nagai and coworkers have found two typical examples[3] following the extended Taft equation. The NMR ^{29}Si-H coupling constants for 30 aliphatic and aromatic hydrosilanes were correlated nicely with $\sum\sigma^*$, where $\sum\sigma^*$ is the sum of σ^* values for the groups on the central silicon atom (Fig. 2). In this relationship the slope is equal to -10.3 Hz/σ^* with a correlation coefficient of 0.996. Figure 3 illustrates a correlation of the methyl ^{13}C–H coupling constants for series of arylmethylsilanes and aryldimethylsilanes with σ^*. In this case $\rho^*=1.68$ Hz/σ^* and $\gamma=0.966$.

The correlation of the ionization of aliphatic[2] and aromatic[1] carboxylic acids gave a somewhat different picture as shown in Fig. 4. The two independent relationships found in this figure have comparable slopes, the aromatic line being below the aliphatic line by *ca.* 0.5 log unit. These findings furnish convincing justification for the concept that there is a substantial resonance stabilization in the reactant state of aromatic acids that is undoubtedly due to the interaction between an aromatic ring and the carbonyl function.

(b) Aromatic acids; $\log K=1.389\,\sigma^*-5.00$

Perhaps the most interesting generalization concerning the use of the σ^* values for substituted phenyl groups may be drawn from the rate data on the hydrogen abstraction from nuclear substituted aralkylhydrocarbons by polar radicals. In actuality, it has long been recognized that various electron-poor radicals display rather pronounced polar effects in their attack on hydrogens to be abstracted. This general trend has been frequently verified by a number of rate data on the benzylic hydrogen abstractions from series of substituted alkylbenzenes that have been treated within the framework of the Hammett relationship.[11] It is

11) It might be argued that reactivities of benzylic hydrogens toward abstracting polar reagent such as halogens, alkoxy, and trichloromethyl radicals are better correlated with σ^+ derived by Brown and Okamoto[12] than with σ. This idea has been first proposed by Russell[13] and supported later on by several other workers.[14–18] However, a survey of the existing rate data on the hydrogen abstraction revealed that there are also many instances[17] giving a somewhat better fit to the ordinary σ function rather than σ^+. Furthermore, even for some cases in which a better correlation with σ^+ has been reported with emphasis, the difference in the magnitude of correlation coefficient is not significant enough to warrant a definite adoption of the σ^+ correlation.[20]

generally accepted that few if any steric effects are observable on the rate of the hydrogen abstraction processes for a wide variety of structural change in substrate.[21] It is therefore expected that reactivities for benzylic hydrogens toward a given attacking radical species are related only to the polar effects of substituents if resonance effects are absent or constant.

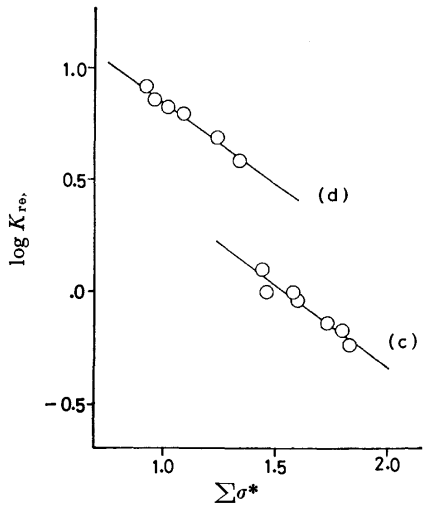

Fig. 5. Plots of relative reactivities for substituted toluenes and ethylbenzenes toward sulfuryl chloride *versus* σ^*.
(c) Toluenes; $\log k_{rel} = -0.741 \sum\sigma^* + 1.14$
(d) Ethylbenzenes; $\log k_{rel} = -0.731 \sum\sigma^* + 1.58$

Treatment of the relative reactivities (on a per hydrogen available basis) at 40°C for two series of alkylbenzenes, substituted toluenes and ethylbenzenes, toward sulfuryl chloride in carbon tetrachloride[22] by the Taft equation again gave two independent correlations as shown in Fig. 5. The ρ^* values for the two reaction series are essentially identical. However, the entire body of the rate data cannot be accomodated by a single line. The difference in positions of the two lines is likely to be accounted for by the accelerating hyperconjugation effects of the α-methyl group in ethylbenzene in the transition state which more or less resembles the product state, the benzylic radical. With regard to this point it seemed appropriate to inquire whether the rate data of silicon analogs of alkylbenzenes such as phenylsilane, phenylmethylsilane and phenyldimethylsilanes are incorporated with the extended Taft equation, since the contributing hybrid structures in the transition state of the hydrogen abstraction would require at least partly a silicon-carbon double bond which, unlike a carbon-carbon double bond, has never been positively detected.[23] Relative rate constants for these arylhydrosilanes at 80°C toward the trichloromethyl radical have been obtained in our previous work[24] and a plot of the relative rates *versus* σ^* is shown in Fig. 6. In this case there are once

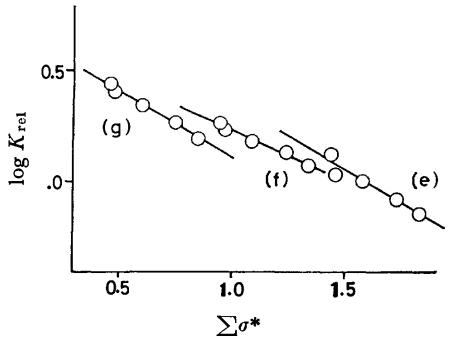

Fig. 6. Plots of relative reactivities for substituted phenylsilanes toward carbon tetrachloride *versus* σ^*.
(e) Phenylsilanes; $\log k_{rel} = -0.595 \sum\sigma^* + 0.943$
(f) Phenylmethylsilanes; $\log k_{rel} = -0.429 \sum\sigma^* + 0.652$
(g) Phenyldimethylsilanes; $\log k_{rel} = -0.601 \sum\sigma^* + 0.702$

again found three independent straight lines which are closely located each other with comparable σ^* values. However, the whole range of rate data can also be accommodated by a single relationship with an acceptable correlation coefficient, 0.98. This observation is in keeping with the expectation deduced from the inability of silicon to make a double bond and leads to a conclusion that the reactivities for the silicon series thus apparently depend upon solely the polar effects of substituents.

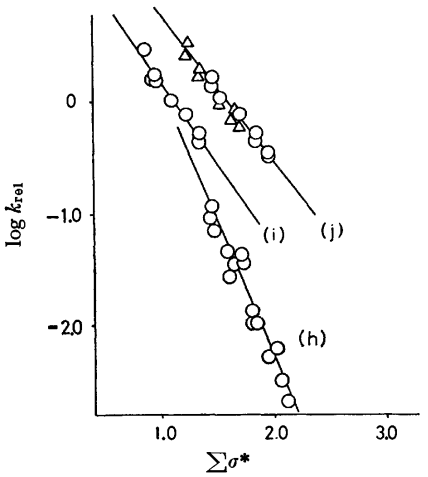

Fig. 7. Plots of relative reactivities for $XC_6H_4CH_2R$ toward the bromine atom in carbon tetrachloride at 80°C *versus* σ^*.
(h) R=hydrogen; $\log k_{rel} = -2.497 \sum\sigma^* + 2.652$
(i) R=methyl; $\log k_{rel} = -1.441 \sum\sigma^* + 1.606$
(j) R=phenyl (circles), R=vinyl (triangles); $\log k_{rel} = -1.309 \sum\sigma^* + 2.034$

Figure 7 shows correlations between $\sum\sigma^*$ and rates of hydrogen abstraction by the bromine atom from *m*- and *p*-substituted toluenes,[15] ethylbenzenes,[25] diphenylmethanes,[26] and allylbenzenes[26] in carbon tetrachloride at 80°C. To obtain the relative rates expressed in terms of k(toluene)=1, the rate ratio of toluene: ethylbenzene: diphenylmethane: allylbenzene was set to be 1: 23: 18: 25, the value being taken from a table compiled by Low and Lee.[26] Also the σ^* value for the vinyl group was calculated as

follows.

$$\sigma^*(CH_2{=}CH) = \sigma^*(CH_3CH{=}CH) - \{\sigma^*(CH_3CH_2CH_2) - \sigma^*(CH_3CH_2)\}$$
$$= +0.360 - (-0.115+0.100) = +0.375$$

As seen in Fig. 7, for the last three series ρ^* values are actually not distinguishable from each other. Among them diphenylmethanes and allylbenzenes seem to be correlated by a single line. The line formed by points for all of the ethylbenzenes is about 0.5 log unit below that defined by series of diphenylmethanes and allylbenzenes. Obviously the accelerating effects of the phenyl and vinyl groups due to resonance interaction with the odd electron developing in the transition state are of the same order of magnitude. The ρ^* value for reactions of toluenes is distinctly larger, in the absolute magnitude, than those for other series. The difference in structural dependence in the hydrogen abstraction from aralkylhydrocarbons has been one of the central subjects for recent years and results regarding this point have been explained mainly in terms of the degree of bond breaking in the transition state.[27] Thus the greater ρ^* values for the toluenes is reflected by the greater ratio of k_H/k_D[28] for the reaction of toluene (4.9) with the bromine atom compared to that for the reaction of ethylbenzene (2.7). Such an explanation advanced for the observed variation in the reaction constant for benzylic hydrogen reactivities toward free radicals implies that the linear free energy relationship would hold only within limited class of compounds. Such is found to be the case not only in this instance but also in many other reactions of the hydrogen abstraction which follow, but even in these cases one may obtain useful informations as to the detailed structure of the transition state.

Figure 8 refers to a similar treatment for bromination rates in chlorobenzene for toluenes (Br_2, 80°C),[19] cumenes (NBS, 70°C),[27] and neopentylbenzenes (NBS, 70°C).[29] Totherow and Gleicher[29] reported a value of 0.45 for the ratio of reactivities of k(neopentylbenzene)/k(toluene) at 70°C while Russell and coworkers[30] obtained a value of 14 for k(cumene)/k(toluene) at 40°C. Although these relative reactivities were determined under different conditions, these are fairly close to allow for direct comparison. The treatment yielded three straight lines with different slopes and this is expected for reactions which involve large differences in the degree of bond breaking in the transition state. It seems significant that the reaction of neopentylbenzenes with the bromine atom shows the smaller substituent dependence than that of toluenes in spite of the fact that neopentylbenzene has a relative rate of one-half that of toluene.[29] In general the ρ values for aralkylhydrocarbons appear to be related to the relative rates of reaction of the parent compounds;[14,31] the faster the reaction of a parent compound, the smaller the ρ value for the reaction series. For this reason the observed tendency for reactions of neopentylbenzenes is anomalous and in keeping with an explanation proposed by Totherow and Gleicher based on unfavorable steric interactions between a substrate and an attacking reagent.[29]

Comparison of chlorination rates for aliphatic and aromatic series of compounds with the aid of the Taft equation discloses yet another interesting point. Extensive studies have been made by Migita, Nagai, and Kosugi[32,33] of the chlorination of systematized series of aliphatic compounds under certain conditions,

while Russell and Williamson[34] have obtained relative rate data for the chlorination of a series of substituted toluenes including a wide range of substituents. Since both of the measurements were conducted under very nearly the same conditions, relative reactivities for compounds of either types can be readily compared with a considerable degree of reliability, if the two sets of rate data are combined. This can immediately be done since a reactivity ratio of k(toluene)/k(t-BuCl) was found by Russell[35] to be 1.1 : 0.12. The results were treated using the Taft equation to give correlations shown in Fig. 9. Strikingly enough, there were found two parallel lines and this finding indicates that the stabilization by resonance interaction between an aromatic ring and the reaction site amounts to about 0.5 log unit corresponding 0.7 kcal/mol. That is, this value holds regardless of the substituents present on the phenyl group.

Conclusions

Many useful informations as to the effect of structure on molecular properties can be obtained by correlating reactivities or physical measurements with a set of Taft polar substituent constants including values for substisuted phenyl groups which we have defined. Some instances following the extended Taft equation have been illustrated. The treatment of this type is especially instructive when comparing reactivities or physical properties of groups of benzylic type. The new polar substituent constants have general utility in the identification of the specific resonance or steric effects. Deviations from the extended Taft relationship provide a measure of such effects and this use of the σ^* values has been exemplified.

The authors are grateful to Professor T. Migita of Gunma University who made a number of valuable suggestions on this topic.

Restricted Rotation in Aromatic Ketones. I. Substituent Effects on the Barrier to Rotation about the Benzene-to-Carbonyl Bond[1)]

Nobuo NAKAMURA and Michinori ŌKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received February 23, 1972)

Several aryl isopropyl ketones and aryl benzyl ketones were synthesized and their NMR spectra were recorded at various temperatures. Their temperature dependence was accounted for in terms of the restricted rotation about the benzene-to-carbonyl bond, whose free energies of activation at the coalescence temperatures varied from 9 to 15 kcal/mol according to the steric effect of ortho substituents, the buttressing effect of meta substituents, and the steric effect of the side-chain groups.

Nuclear magnetic resonance spectroscopy has proved to be a powerful and convenient tool for the study of the relatively slow internal rotations, the representative being the PMR spectroscopic studies on amides, biphenyls, aromatic aldehydes, and diazoketones.[2)]

When the torsional process is slow enough and if the process produces the mirror images, there should exist a pair of optical antipodes even at the room temperature. Thus many successful results are to be seen in the resolution into the stable atropisomers whose pivot bonds are the sp^2-sp^2 hybridized. However, no example for which carbonyl carbon is involved as a carbon of sp^2-hybridization has been claimed to be resolved,[3)] though carbonyl group has been the subject of a large number of studies in organic chemistry because of its variety of reactions and reactivities.

The concept and the continuous interest in the torsional stereoisomerism led us to explore to what extent the rotation about the benzene-to-carbonyl bond could be hindered by the ortho substituents and to estimate whether the stable rotational isomers could be isolated at room temperature.

We now wish to report our results about the steric effects on the barrier to rotation about the benzene-to-carbonyl bond in some aromatic ketones using the

variable temperature NMR technique which does not need the prior optical resolution.

It is well known that in *o*-substituted and *o,o'*-disubstituted aromatic ketones carbonyl group is not coplanar with the benzene ring at the ground state as a consequence of the steric requirements. When the rotation in question is sufficiently restricted, there should result the following two conformers A and $\bar{A}$, the latter being the mirror image of the former when X and Y are different from the each other.

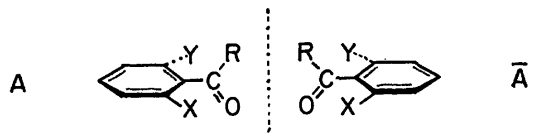

Fig. 1. Conformations of 2,6-disubstituted phenyl ketone.

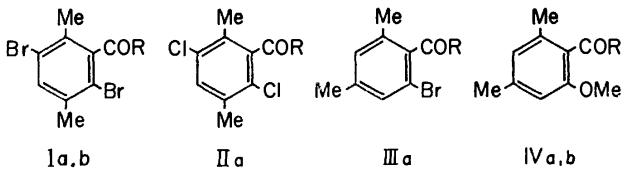
Then, if R carries a methylene group or geminal methyl groups, the nonequivalence of the protons concerned is expected as in the case of a biphenyl[2] and an ansanoid compound.[4] Thus isopropyl and benzyl groups were chosen for the side chain groups for the convenience of the synthesis. If the coalescence or the change in line-shapes of these signals is observed in the NMR spectra, it should be possible to derive the kinetic data involving the internal rotation.

As for X and Y, they should provide magnetic environments of large difference in order to facilitate the distinguishing of the enantiomeric protons. Thus methyl, chlorine, bromine or methoxy groups were used in this study.

Syntheses

The following six compounds were prepared by the routes shown in the scheme 1.



Ia,b IIa IIIa IVa,b

a, R = $CH(CH_3)_2$: b, R = CH_2Ph

The appropriate nitriles which had been obtained by the several steps were hydrolysed in two steps to afford in relatively high yields the corresponding carboxylic acids, which were then converted to the acid chlorides by the action of thionyl chloride.

Treatment of the acid chloride with an ethereal solution of excess of isopropylmagnesium bromide gave after one distillation a mixture of the desired ketone and the corresponding secondary alcohol in a molar ratio of about 1 : 3 as clarified by vpc analysis. This mixture was oxidized with chromic acid in aqueous acetic acid at 0°C, and the oxidation product was purified by distillation and/or column chromatography on silica gel to give Ia, Ib, IIa, and IIIa.

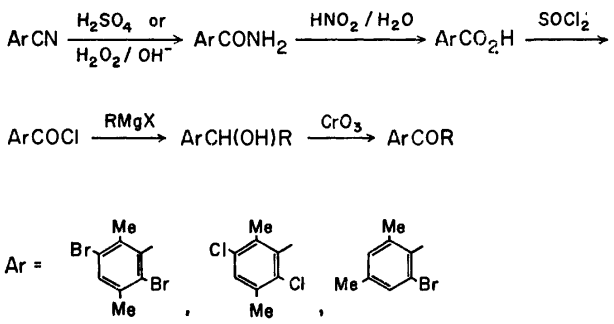
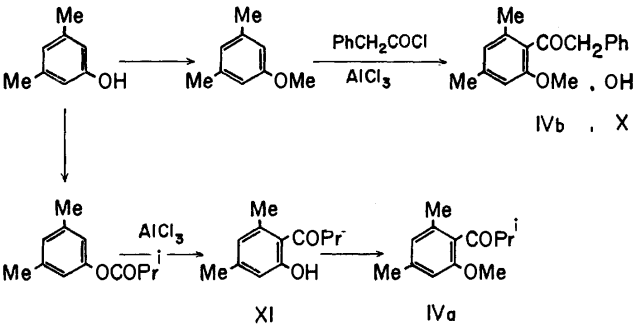


Scheme 1.



Scheme 2.

3,5-Xylenol was converted to the isobutyrate, which was treated with anhydrous aluminum chloride without solvent to rearrange to the phenolic ketone. The latter was then methylated to afford IVa. IVb was prepared by the Friedel-Crafts reaction of 3,5-dimethylanisol with phenylacetyl chloride in the presence of aluminum chloride (see Scheme 2).

Results

The NMR spectra of Ia in carbon tetrachloride, benzene, and pyridine were recorded at the ambient temperature, and the results were summarized in Table 1.

The methyl groups of isopropyl residue appeared as a sharp doublet (J=7 Hz, half-width 1.5 Hz) in carbon tetrachloride. However, when the solvent was changed to benzene and further to pyridine, the signals of isopropyl-methyl groups decreased in their heights, whose values relative to the methyl group attached directly to the aromatic ring were 1.0 in carbon tetrachloride, 0.54 in benzene, and 0.48 in pyridine. These figures apparently indicated that there were the chemical-shift differences between two methyl groups of the isopropyl-side-chain. That is, the rotation about the benzene-to-carbonyl bond was relatively slow on NMR time scale.

When the temperature of the pyridine solution was lowered to 18—20°C, the signal changed in its appearance to a single broad peak, which split into four peaks on further cooling and finally into the two sets of doublets at −35°C, the chemical-shift difference and the coupling constant being 13.5 Hz and 7.1 Hz, respectively. On the contrary, the signal increased in its height as the temperature was raised and at

Table 1. NMR Spectra of Ia in three solvents[a)]

Solvent	Chemical-shift[b)]			Peak-height Ratio (1/2)
	$CH(C\underline{H}_3)_2\cdots 1$	$C\underline{H}(CH_3)_2$	$Ar\text{–}C\underline{H}_3\cdots 2$	
CCl_4	1.19[d]	3.07[sep]	2.21[s], 2.37[s]	1.0
C_6H_6	1.03[d]	2.88[sep]	1.88[s], 2.07[s]	0.54

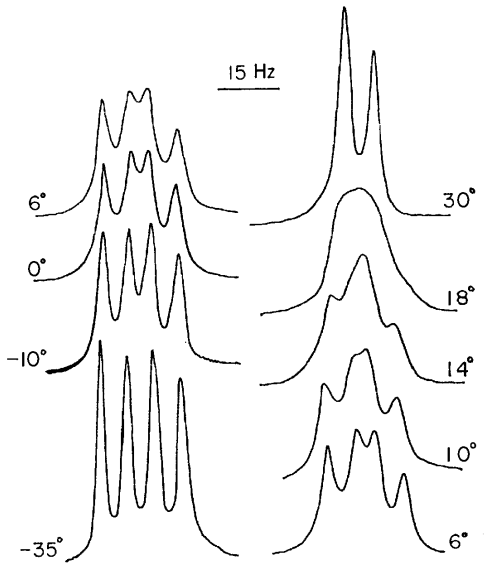

Fig. 2. Methyl signals of isopropyl group at various temperatures.

last a sharp doublet resulted at 60°C.

From these temperature dependence of the spectra shown in Fig. 2, the rates and free energies of activation for rotation were evaluated using the following approximation methods.[5)] For the isopropyl ketones, the approximate rates k_c at the coalescence temperatures T_c were calculated by

$$k_c = \frac{\pi\delta\nu}{\sqrt{2}} \quad (1)$$

and the free energies of activation by

$$\Delta G_c^{\ddagger} = 4.57\,T_c\left(9.97+\log_{10}\frac{T_c}{\delta\nu}\right) \quad (2)$$

whereas for the benzyl ketones, k_c and $\Delta G_c^{\ddagger}$ at T_c were calculated by

$$k_c = \frac{\pi\sqrt{\delta\nu^2+6J^2}}{\sqrt{2}} \quad (3)$$

and

$$\Delta G_c^{\ddagger} = 4.57\,T_c\left(9.97+\log_{10}\frac{T_c}{\sqrt{\delta\nu^2+6J^2}}\right) \quad (4)$$

The variable-temperature spectra of the other compounds were also taken and the results together with those of Ia were sammarized in Tables 2 and 3.

In each case, the coalescence temperature for the isopropyl ketone was assigned to the temperature at which a single broad peak was observed ($\delta\nu > J_{CH_3CH}$) or at which two broad peaks were observed ($\delta\nu < J_{CH_3CH}$).

As the chemical-shift difference of the two methyls in IIIa could not obtained experimentally, $\delta\nu$ of 13.5 Hz was assumed for IIIa because the free energy of activation at the coalescence temperature was mainly decided by the T_c value as shown in Eq. (2), and because the two ortho substituents of IIIa were the same as those of Ia, for which $\delta\nu$ of 13.5 Hz had been obtained experimentally. Substitution of $T_c=-77$°C and $\delta\nu=13.5$ Hz in Eq. (2) gave the $\Delta G_c^{\ddagger}$ value of 10 kcal/mol for IIIa. Similarly, the free energy of activation for IVa was estimated to be about 9 kcal/mol at the experimental coalescence temperature of −95°C, the same chemical-shift difference and coupling constant being assumed for compound IVb with those of Ib.

Discussion

Comparison of the free energies of activation gives the following sequence in the decreasing order:

Ia > IIa—Ib > IIIa > IVa—IVb

The free energies of activation of the ketones studied here are equal or greater than those of benzaldehyde studied by Anet. This fact is apparently ascribed to the steric effects of the ortho substituents and side chain. When Ia is compared with IIIa, that is, when the compounds with the same pair of substituents at 2,6-positions but with the different substitution patterns, the former being 2,3,5,6-tetrasubstituted and the latter 2,4,6-trisubstituted, are compared with each other, the barrier to rotation in the former is greater than that in the latter by 5 kcal/mol.

This surprisingly large value can be best accounted for by the idea that the buttressing effect of the meta substituents is operating substantially in Ia. Such an effect is well known especially for biphenyl derivatives, where 10—2000 times of the slow-down effect on the rate of racemization are reported.[6)]

6) L. N. Ferguson, "The Modern Structural Theory of Organic Chemistry", Japanese language ed., Tokyo Kagaku Dojin, Tokyo (1965), p. 286. See also M. Rieger and F. H. Westheimer, *J. Amer. Chem. Soc.*, **72**, 19 (1950), where about 10^5 times of the slow-down effect of the 5,5′-diiodo substituents on the racemization of 3,3′-dicarboxy-5,5′,6,6′-tetraiodobiphenyl is reported. This effect corresponds to the about 7 kcal/mol difference of the free energies of activation.

TABLE 2. NMR PARAMETERS AND FREE ENERGIES OF ACTIVATION FOR ROTATION

Comparison of the data of Ia and IIa gives the difference of the barriers by 2.5 kcal/mol, which clearly shows the effectiveness of the steric hindrance, the former having a larger substituent in an ortho position than the latter.[7]

The difference between IIIa and VIa is much lesser than that expected from the ground of van der Waals' radii. However, it may be necessary to obtain more accurate data to discuss the similarness or dissimilarness of the steric effect of the substituents in detail.

The steric effect of the side-chain groups may be also shown when Ia and Ib are compared. The magnitude of the difference in this case amounts to *ca.* 2.5 kcal/mol to indicate that the side-chain group is also involved in slowing down the rotation about the benzene-to-carbonyl bond.[8] It is, of course, understandable if the coplanar transition state for rotation is assumed, where the steric interference between the ortho substituents and the side-chain is playing the main role in determining the energy barrier.

Experimental

NMR spectra were recorded on either a Jeol Model JNM-C-60H, or a HITACHI Model R-20B spectrometer both operating at 60 MHz. Samples were run as dilute solutions in an apropriate solvent indicated using TMS as an internal reference. Chemical shifts are recorded as parts per million downfield from TMS on the δ scale. Sample temperatures were measured and calibrated by the chemical shift differences between the hydroxyl protons and the methylene protons of ethylene glycol for the higher temperatures, or by those between the hydroxyl proton and the methyl protons of methanol for the lower temperatures. IR spectra were taken with a HITACHI Model G-2 grating spectrophotometer. The purities of the oily final compounds were checked by analytical vpc using a Shimadzu GC-4APF gas chromatograph equipped with flame ionization detectors using nitrogen as carrier gas, the flow rate of which was set to 40 ml/min. Glass tubing columns, designed for on-column injection, 2 m in length and 3 mm of inner diameter, and packed with 10% SE-52 on Diasolid M of 60—80 mesh, were used. Melting points are uncorrected.

7) The van der Waals radii of bromine, chlorine and methyl groups are 1.95, 1.80, and 2.0 Å, respectively. L. Pauling, "Nature of the Chemical Bond", 3rd ed., Cornel U. P., Ithaca, N. Y. (1960), pp. 260, 263. The bond lengths of C(sp^3)–Br and C(sp^2)–Cl are 1.875 and 1.711 Å, respectively. M. G. Brown, *Trans. Faraday Soc.*, **55**, 694 (1959).

8) Slow-down of the internal rotation of amides due to the side-chain groups has been also reported. See A. Mannschreck, *Tetrahedron Lett.*, **1965**, 1341.

2,5-Dibromo-3,6-dimethylbenzonitrile (V). *(a)*: Diazotization of 2,5-Dibromo-3,6-dimethylaniline. To a solution of 42 g of the aniline in 360 m*l* of ethanol, 36 m*l* of concentrated sulfuric acid was added dropwise below 0°C, and the mixture was cooled to −10°C. To this mixture 20.5 g of butyl nitrite was added with vigorous stirring over a period of 30 min and the stirring was continued at this temperature for an additional 1 hr, at the end of which time 180 m*l* of cold ether was added and the mixture was stirred for 30 min to complete the separation of solid. The diazonium sulfate was collected on a glass filter, washed with cold anhydrous ethanol and finally dissolved in ice-water.

(b): The Sandmeyer Reaction. To a cuprous cyanide solution obtained from 100 g of cupric sulfate according to the standard method, the diazonium salt solution prepared in (*a*) was added slowly with vigorous stirring. The stirring was continued for 10 hr at room temperature and then at 50°C for 2 hr. After cooling, the organic layer was separated, washed with water, and dried over anhydrous sodium sulfate. The solvent was evaporated *in vacuo* and the crystalline residue was recrystallized from ethanol to yield 20.5 g (47% of the theoretical) of the desired product, mp 123°C.

Found: C, 37.20; H, 2.44; N, 4.85%. Calcd for $C_9H_7Br_2N$: C, 37.40; H, 2.88; N, 4.64%.

2,5-Dichloro-3,6-dimethylbenzonitrile (VII). VII was prepared in a similar way as described for (V), mp 109.5—111.0°C.

Found: C, 53.84; H, 3.81; N, 6.82%. Calcd for $C_9H_7Cl_2N$: C, 54.03; H, 3.53; N, 7.00%.

2,5-Dibromo-3,6-dimethylbenzoic Acid (VI). A mixture of 5.0 g of 2,5-dibromo-3,6-dimethylbenzonitrile, 10 m*l* of water and 30 m*l* of concentrated sulfuric acid was heated at 160°C for 1 hr, cooled to room temperature, and poured into 70 m*l* of cold water. The resulting solid was collected and recrystallized from ethanol to yield 3.0 g of 2,5-dibromo-3,6-dimethylbenzamide, mp 214—217°C. The half of the amide was dissolved in dilute sulfuric acid (obtained from 15 g of concentrated sulfuric acid and 7.6 g of water) and treated with 1 g of sodium nitrite in 1.5 m*l* of water at 0°C. The mixture was then maintained at 80—90°C for 10 min and again cooled to 0°C. The carboxylic acid was collected and dissolved in sodium bicarbonate solution, which was then acidified to give 1.3 g of the desired compound, mp 160°C. NMR ($CDCl_3$): 2.42 (3H, singlet), 2.49 (3H, singlet), 7.53 (1H, singlet), 9.08 (1H, singlet).

Found: C, 34.97; H, 2.40; Br, 52.56%. Calcd for $C_9H_8Br_2O_2$: C, 35.10; H, 2.62; Br, 51.89%.

6-Bromo-2,4-dimethylbenzoic Acid (IX). Starting from 2.5 g of 6-bromo-2,4-dimethylbenzonitrile,[9] 1.9 g of 6-bromo-2,4-dimethylbenzamide, mp 178—180°C, was obtained in a similar way as described for (VI). IR (Nujol): $\nu_{N=H}$ 3400, 3170 cm^{-1}, $\nu_{C=O}$ 1690 cm^{-1}. NMR ($CDCl_3$): 2.27 (3H, singlet), 2.33 (3H, singlet), 5.96 (1H, singlet), 6.48 (1H, singlet), 6.92 (1H, singlet), 7.15 (1H, singlet).

A mixture of 1.5 g of the amide, 14 g of concentrated sulfuric acid, and 7.6 g of water was treated with 1 g of sodium nitrite in 2 m*l* of water as described for (VI) to yield 1.3 g of the carboxylic acid, mp 153—155°C. IR (Nujol): $\nu_{C=O}$ 1700 cm^{-1}. NMR ($CDCl_3$): 2.27 (3H, singlet), 2.38 (3H. singlet), 6.93 (1H, singlet), 7.20 (1H, singlet), 9.64 (1H, singlet).

Found: C, 47.06; H, 4.16; Br, 35.21%. Calcd for $C_9H_9BrO_2$: C, 47.19; H, 3.96; Br, 34.88%.

2,5-Dichloro-3,6-dimethylbenzoic Acid (VIII). To a solution of 10 g of 2,5-dichloro-3,6-dimethylbenzonitrile in 140 m*l* of 95% ethanol, 4 m*l* of 6N sodium hydroxide solution was added followed by 60 m*l* of 30% hydrogen peroxide solution at 50°C. After heating for 2 hr at 50°C, the reaction mixture was neutralized with 5% sulfuric acid and diluted with water. The precipitated amide was collected, dissolved in 50% (v/v) sulfuric acid and treated with a saturated sodium nitrite solution as described for (VI). Yield 7 g, mp 145.5—148.0°C. NMR ($CDCl_3$): 3.31 (3H, singlet), 3.37 (3H, singlet), 7.26 (1H, singlet), 9.22 (1H, singlet). For the elemental analysis, the acid was methylated with diazomethane to the corresponding methyl ester, mp 36.5—37.0°C. NMR ($CDCl_3$): 2.28 (3H, singlet), 3.31 (3H, singlet), 3.94 (3H, singlet), 7.27 (1H, singlet).

Found: C, 51.37; H, 4.27; Cl, 30.62%. Calcd for $C_{10}H_{10}Cl_2O_2$: C, 51.53; H, 4.32; Cl, 30.42%.

2,5-Dibromo-3,6-dimethylphenyl Isopropyl Ketone (Ia). To an ethereal solution of isopropyl magnesium bromide prepared from 21 g of isopropyl bromide, 4.0 g of magnesium ribbon, and 70 m*l* of anhydrous ether under nitrogen atmosphere, a solution of 2,5-dibromo-3,6-dimethylbenzoyl chloride in anhydrous ether, prepared from 5.0 g of 2,5-dibromo-3,6-dimethylbenzoic acid and thionyl chloride, was added dropwise at room temperature. The stirring was continued for 2 hr after the addition was completed, at the end of which time the reaction mixture was poured into the mixture of crushed ice and hydrochloric acid. The organic layer was separated, washed and dried over anhydrous magnesium sulfate. The solvent was evaporated and the residual oil was chromatographed on silica gel to yield the desired ketone, yield 1.4 g, mp 24°C. The vpc analysis of the product showed only a single peak, whose retention time was 11.5 min at the column temperature of 180—200°C with the program rate being 2°C/min.

Found: C, 43.04; H, 3.95; Br, 48.01%. Calcd for $C_{12}H_{14}Br_2O$: C, 43.15; H, 4.22; Br, 47.84%.

2,5-Dibromo-3,6-dimethylphenyl Benzyl Ketone (Ib). A mixture of 4.0 g of 2,5-dibromo-3,6-dimethylbenzoic acid and 5 m*l* of thionyl chloride was heated. After the evolution of gases ceased, the excess of thionyl chloride was evaporated *in vacuo* and the residual solid was dissolved in 5 m*l* of anhydrous ether. The solution was again evaporated *in vacuo* to remove any thionyl chloride or hydrogen chloride. The acid chloride was dissolved in 80 m*l* of anhydrous ether, and added over a 1 hr period to an ethereal solution of benzyl magnesium chloride prepared from 25.5 g of benzyl chloride, 4.0 g of magnesium ribbon, and 100 m*l* of anhydrous ether under nitrogen atmosphere. The product was distilled under reduced pressure to give a fraction boiled at 200—210°C/2 mmHg. The distillate solidified and recrystallized from petroleum ether to afford the desired ketone, yield 2.0 g, mp 108—109°C. IR: $\nu_{C=O}$ 1713 cm^{-1} (liq.), 1705 cm^{-1} (solid). NMR (CCl_4): 1.92 (3H, singlet), 2.36 (3H, singlet), 3.99 (2H, singlet), 7.14 (5H, singlet), 7.35 (1H, singlet).

Found: C, 50.49; H, 3.64; Br, 42.02%. Calcd for $C_{16}H_{14}Br_2O$: C, 50.29; H, 3.69; Br, 41.83%.

2,4-Dimethyl-6-bromophenyl Isopropyl Ketone (IIIa). The reaction between 2,4-dimethyl-6-bromobenzoyl chloride from 6.9 g of the corresponding acid and isopropyl magnesium bromide from 37 g of isopropyl bromide afforded 4.5 g of an oil boiling at 113—116°C/2 mmHg, which was proved by vpc analysis to be a 1:3 mixture of the ketone and the corresponding secondary alcohol.

To a solution of the above mixture in 10 m*l* of acetic acid, a solution of 0.93 g of chromic anhydride in 40 m*l* of acetic acid and 13 m*l* of water was added at 0°C with vigorous stirring, which was continued for 30 min after the addition

9) A. S. Wheeler and R. E. Thomas, *J. Amer. Chem. Soc.*, **50**, 2287 (1928).

was completed. The reaction mixture was poured into ice-water and extracted with ether. The ether extract was washed with saturated sodium bicarbonate solution and with water and then dried over magnesium sulfate. The solvent was evaporated and the residual oil (*ca.* 4.3 g) was chromatographed on 129 g of silica gel and eluted with petroleum ether–benzene (5: 1). The yield of the ketone was 3.2 g. The vpc analysis of the product showed only a single peak, whose retention time was 9.3 min at the column temperature of 160—200°C with the program rate being 4°C/min. IR (neat): $\nu_{C=O}$ 1700 cm^{-1}. NMR (CCl_4): 1.16 (6H, doublet, J=7 Hz), 2.15 (3H, singlet), 2.26 (3H, singlet), 3.13 (1H, septet, J=7 Hz), 6.88 (1H, singlet), 7.11 (1H, singlet).

Found: C, 56.29; H, 5.98; Br, 31.54%. Calcd for $C_{12}H_{15}BrO$: C, 56.49; H, 5.93; Br, 31.32%.

2,5-Dichloro-3,5-dimethylphenyl Isopropyl Ketone (IIa). 2,5-Dichloro-3,6-dimethylbenzoyl chloride prepared from 6.6 g of the corresponding acid was treated similarly as above. Chromic acid oxidation of the products followed by chromatography on silica gel yielded 2.8 g of the desired ketone, the vpc analysis of which showed only a single peak; retention time, 8.2 min at the column temperature of 180—200°C with the program rate being 2°C/min. IR (neat): $\nu_{C=O}$ 1700 cm^{-1}. NMR (CCl_4): 1.18 (6H, doublet, J=7.5 Hz), 2.17 (3H, singlet), 2.34 (3H, singlet), 3.02 (1H, septet, J=7.5 Hz), 7.23 (1H, singlet).

Found: C, 58.93; H, 5.97; Cl, 28.81%. Calcd for $C_{12}H_{14}Cl_2O$: C, 58.79; H, 5.76; Cl, 28.92%.

2,4-Dimethyl-6-methoxyphenyl Benzyl Ketone (IVb). To 14.7 g of anhydrous aluminum chloride covered with 30 m*l* of carbon disulfide, a solution of 13.6 g of 3,5-dimethylanisole and 15.4 g of phenylacetyl chloride in 70 m*l* of carbon disulfide was added dropwise with vigorous stirring. The mixture was stirred at room temperature for 1 hr and then kept at the reflux temperature for an additional 1 hr. The mixture was cooled to room temperature and the solvent was removed by decantation. The residual complex was decomposed by the addition of 150 g of crushed ice and 50 m*l* of hydrochloric acid, and the mixture was extracted with benzene. The combined extract was washed with 5% sodium hydroxide solution, then with water, and dried over calcium chloride. After the removal of the solvent the residual oil was distilled under reduced pressure. Yield 7.5 g, bp 157—159°C/1 mmHg, $n_D^{23.2}$ 1.5685. IR (neat): 1670 cm^{-1}. NMR (CS_2): 1.82 (3H, singlet), 2.17 (3H, singlet), 3.64 (3H, singlet), 3.88 (2H, singlet), 6.40 (2H, singlet), 7.04 (5H, singlet).

Found: C, 80.44; H, 7.27%. Calcd for $C_{17}H_{18}O_2$: C, 80.28; H, 7.13%.

2,4-Dimethyl-6-hydroxyphenyl Benzyl Ketone (X). The alkaline wash of the benzene extract of (IVb) was acidified and the product extracted with ether. The ether extract was washed with water and dried over sodium sulfate. After the evaporation of the solvent, the residual oil was distilled to yield the *o*-hydroxy ketone. Yield 10.2 g, bp 168—173°C/1 mmHg, $n_D^{23.2}$ 1.5921. IR (neat): ν_{O-H} 3300 cm^{-1}, $\nu_{C=O}$ 1650 cm^{-1}. NMR (CS_2): 2.10 (3H, singlet), 2.33 (3H, singlet), 4.04 (2H, singlet), 6.35 (1H, singlet), 6.40 (1H, singlet), 7.08 (5H, singlet), 11.24 (1H, singlet).

Found: C, 79.71; H, 6.82%. Calcd for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%.

2,4-Dimethyl-6-hydroxyphenyl Isopropyl Ketone (XI). To 24 g of 3,5-dimethyl phenyl isobutyrate, bp 95°C/2 mmHg, was added 22 g of anhydrous aluminum chloride at once, and the mixture was heated at 90°C for a few minutes, at he end of which time the reaction temperature was raisetd to 120°C as fast as possible and maintained at 120°C for 10 min. The reaction was completed by heating the mixture at 140°C for 30 min. After cooling the reaction mixture was treated with 50 g of crushed ice and 30 m*l* of hydrochloric acid and steamdistilled. The *o*-hydroxy ketone was recrystallized from petroleum ether. Yield 6.0 g, mp 82—82.5°C and 91—91.5°C (dual mp). IR (Nujol): ν_{O-H} 3330 cm^{-1}, $\nu_{C=O}$ 1680 cm^{-1}. NMR (CCl_4): 1.15 (6H, doublet, J= 7.1 Hz), 2.20 (3H, singlet), 2.45 (3H, singlet), 3.40 (1H, septet, J=7.1 Hz), 6.40 (1H, singlet), 6.46 (1H, singlet), 10.62 (1H, singlet).

Found: C, 74.78; H, 8.31%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%.

2,4-Dimethyl-6-methoxyphenyl Isopropyl Ketone (IVa). The corresponding *o*-hydroxy ketone was methylated with dimethyl sulfate to afford the desired product. Bp 109—110°C/2 mmHg, $n_D^{23.2}$ 1.5118. IR (neat): $\nu_{C=O}$ 1680 cm^{-1}. NMR (CCl_4): 1.05 (6H, doublet, J=7.1 Hz), 2.08 (3H, singlet), 2.25 (3H, singlet), 3.00 (1H, septet, J=7.1 Hz), 3.74 (3H, singlet), 6.43 (1H, singlet), 6.49 (1H, singlet).

Found: C, 75.63; H, 8.97%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%.

Decarboxylative Alkylation in the Photolysis of Benzhydryl Esters

Shinsaku FUJITA, Yoshimi OZAKI, and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto

(Received February 29, 1972)

The photolysis of benzhydryl esters (**1a**—**1b**) results in decarboxylation, thus affording 1,1-diphenylalkanes, diphenylmethane, and 1,1,2,2-tetraphenylethane. The photochemistry of trityl and benzyl esters is also examined. The photochemical solvent incorporation proceeds in both radical and ionic senses. Most characteristically, the irradiation of **1a** in toluene gives 1,1,2-triphenylethane, whereas that of **1a** in methanol produces benzhydryl methyl ether. Such a dual nature of the photolysis is explained in terms of the intimate ion-radical pair hypothesis proposed by Walling.

Previously, we reported that the photoreaction of 1-phenylcycloalkenes in acetic acid gave 1-acetoxy-1-phenylcycloalkanes, and that further irradiation yielded 1-methyl-1-phenylcycloalkanes under decarboxylation.[1] The present report will describe an extension of the latter reaction to esters of mono-, di-, and triphenylated carbinols.[2]

The irradiation of 0.06—0.08 M solutions of benzhydryl esters (**1**) in benzene was effected by the use of a high-pressure mercury lamp. The photolysates were then subjected to gas-chromatographic (GC) analysis; the results are summarized in Table 1. Each component was separated by preparative-scale GC and was identified by comparing it with an authentic sample. The decarboxylation was the main process giving the corresponding 1,1-diphenylalkane (**2**).[4-7]

TABLE 1. PHOTOLYSIS OF **1a**—**1e** IN BENZENE[a)]

Ester	R	Irrad. time hr	Conv. %	Product, %		
				2[b)]	**3**	**4**
1a[8)]	Me	48	40	70	7	10
1b	Et	48	39	49	7	12
1c	Pr	48	46	48	7	6
1d		48	61	48	11	20
1e[9)]	$PhCH_2$	48	67	66	4	18

a) Irradiation was effected on 0.06 M—0.08 M solutions placed in quartz tubes (1.5ϕ×18 cm) with an external 200-W, high-pressure mercury lamp under nitrogen at room temperature.

b) Authentic samples of **2a**—**2c** (Ref. 4) were prepared by the hydrogenolysis of the corresponding alkyldiphenylcarbinol under acidic conditions (Ref. 5). The structures of **2d** (Ref. 6) and **2e** (Ref. 7) were established by means of their IR, NMR, and mass spectra. The yields were calculated on the basis of the consumed esters (**1**) and of the GC peak areas.

In each case, diphenylmethane (**3**)[10] and 1,1,2,2-tetraphenylethane (**4**)[11] were obtained as by-products.

This type of decarboxylation was a general process in the photolysis of other phenylcarbinyl esters. The alkylation was observed in the photolysis of benzyl cyclohexanecarboxylate (**5**), affording benzylcyclohexane (**6**) in a fair yield, **7** and **8** being by-products. The irradiation of trityl acetate (**9a**)[12] and propionate (**9b**)[12] gave 1,1,1-triphenylethane (**10a**)[13] and -propane (**10b**)[13] respectively. Triphenylmethane (**11**)[14] was detected as a by-product among the photolysates. Remarkably, however, the formation of the known stable trytyl "free" radical[15] was not supported by product analysis; neither the dimer[16] nor the peroxide arising therefrom was detected.[15] This is

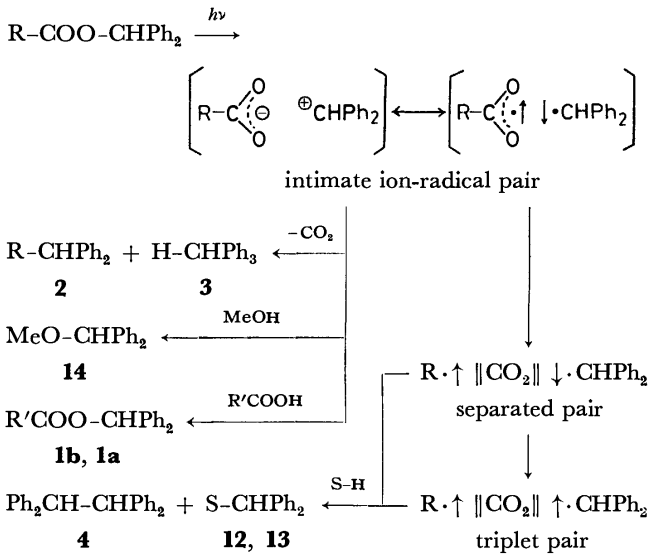
a) Yields are determined by GC analysis and values in parentheses refer to the ones based on the consumed **1a** or **1b**.

in sharp contrast with the formation of **4** and **7** in the photolysis of **1** and **5**.

To gain insight into the mechanics involved, the photolysis of benzhydryl acetate (**1a**) or propionate (**1b**) was effected in various solvents (Table 2). (1) With toluene as the solvent, 1,1,2-triphenylethane (**12**) was obtained, along with **2a**—**4** products (Run 2). The photolysis in tetrahydrofuran gave 2-benzhydryltetrahydrofuran (**13**) (Run 4). (2) The irradiation of **1a** in methanol gave benzhydryl methyl ether (**14**), a methanolysis product (Run 5).[17] The photolysis of the **1a** acetate in propionic acid gave a mixture of the unchanged **1a** and the transesterification product or the propionate (**1b**), as well as the hydrocarbons, **2a** and **2b**, arising from **1a** and **1b** respectively (Run 7). Similarly, **1b** in acetic acid gave **2a** along with **2b** on UV irradiation (Run 10). Benzhydryl acetate (**1a**) was also detected in the photolysate. Thus, photochemical solvolysis[17] *via* the benzhydryl cation preceded the decarboxylation in protic solvents. (3) The irradiation of (*S*)-(+)-benzhydryl 2-methylbutanoate ($[\alpha]_D$ +5.65) afforded 1,1-diphenyl-2-methylbutane ($[\alpha]_D$ +0.65), together with **3** and **4**. As all attempts to prepare an optically-pure sample of the hydrocarbon proved unsuccessful, the degree of the retention (or inversion) could not be estimated.[18]

Apparently, no complete dichotomy can be demonstrated between "radical" and "polar" photodecompositions. This reminds us of the hypothesis of intimate ion pair-radical pair intermediate proposed by Walling *et al.* for the thermolysis of diacyl peroxides.[20] An adaptation of this hypothesis to the present photolysis would account for the observed results indicated in Scheme 1. Very probably, the decarboxylative coupling products (**2**, **6**, and **10**) and the formal hydrogenolysates (**3** and **11**) are "polar"



Scheme 1.

products arising from the "intimate" ion-radical pair, which also gives rise to solvolysates (**14**, **1b**, and **1a**).[21] The "radical" products, such as **4**, **7**, **8**, **12**, and **13**, can be ascribed to the separated pair, the triplet pair, or, alternatively, to the "leaked" free radical. The absence of such "radical" products in the photolysis of trityl esters is explicable on the basis of a dominant contribution of the triphenylcarbonium-ion structure to the intimate ion pair-radical pair "resonance" and the facile collapse to the "polar" products. Such a dualistic nature of the photolysates is reminiscent of our previous observations[22] of the photochemical nucleophilic alkylation of benzopyridines by alkanoic acids proceeding under decarboxylation to give alkyl-

18) The photo-Fries rearrangement of aryl esters is accompanied by the decarboxylation process, which has been accounted for by a concerted mechanism. See Ref. 19.

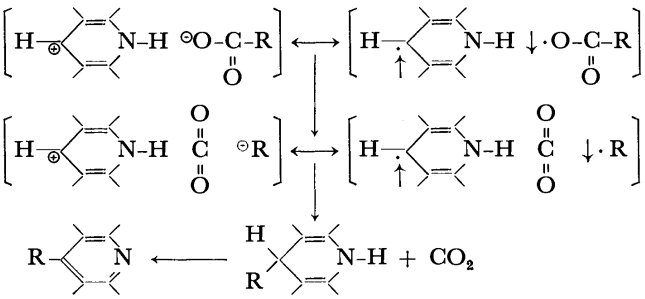
19) R. A. Finnegan and D. Knutson, *J. Amer. Chem. Soc.*, **89**, 1970 (1967).

20) C. Walling, H. P. Waits, J. Milovanovic, and C. G. Pappiannou, *ibid.*, **92**, 4927 (1970).

21) However, a concerted mechanism cannot be excluded in the decarboxylative alkylation. See footnote 18.

22) R. Noyori, M. Kato, M. Kawanisi, and H. Nozaki, *Tetrahedron*, **25**, 1125 (1969).

dihydro-derivatives. The reaction would also possibly involve several similar ion-radical pair intermediates:



Experimental

All the melting points are uncorrected. The NMR spectra were taken on a JEOL C-60-H spectrometer, the mass spectra, on a Hitachi RMU-6L, and the IR, on a Shimadzu IR-27G spectrometer. The optical rotations were determined on a Yanagimoto OR-50 polarimeter. The preparative GC was performed on High-vacuum Silicone Grease 30% on Celite 545 (2 m), using helium as the carrier gas. The product distributions were determined by GC (Silicone Grease SE 30, 5% on Celite 545, 0.75 m, flame-ionization detector, with nitrogen as the carrier), using benzophenone, tetraphenylethylene, benzhydryl propionate, and benzhydryl phenylacetate as internal standards.

*Benzhydryl Propionate (**1b**).* Propionic acid (18 m*l*, 0.24 mol), benzhydrol (16.0 g, 0.09 mol), and sulfuric acid (1 m*l*) were dissolved in ethylene chloride (60 m*l*), and the solution was heated to reflux for 23 hr. The reaction mixture was neutralized with aqueous sodium bicarbonate, extracted with ether, and washed with a saturated sodium chloride solution. The combined ethereal extracts were dried over sodium sulfate and concentrated. The residue was distilled to give **1b** (13.1 g, 63%); bp 122°C/1 mmHg. IR (neat): 3030, 1737, 1495, 1455, 1167, 1010, 741, 700 cm^{-1}. NMR (CCl_4): δ 7.23 (10H, s, Ph), 6.85 (s, 1H, $Ph_2C\underline{H}$), 2.35 (q, 2H, $CH_3C\underline{H}_2$), 1.10 (t, 3H, $C\underline{H}_3CH_2$). MS *m/e* (relative abundance): 240 (9), 184 (23), 167 (52), 166 (100), 165 (72), 77 (27).

Found: C, 79.9; H, 6.9%. Calcd for $C_{16}H_{16}O_2$: C, 80.0; H, 6.7%.

*Benzhydryl Butyrate (**1c**).* A mixture of butyric acid (4.4 g, 0.05 mol), benzhydrol (9.2 g, 0.05 mol), *p*-toluenesulfonic acid (1.1 g), and benzene (80 m*l*) was heated for 23 hr under reflux using a Dean-Stark separator. The usual subsequent work-up gave **1c** (6.9 g, 54%); bp 129°C/2 mmHg. IR (neat): 3026, 1735, 1495, 1249, 1168, 980, 742, 700 cm^{-1}. NMR (CCl_4): δ 7.23 (s, 10H, Ph), 6.85 (s, 1H, $Ph_2C\underline{H}$), 2.78 (t, 2H, $C\underline{H}_2CO$), 1.63 (m, 2H, $CH_3C\underline{H}_2$), 0.88 (t, 3H, CH_3). MS *m/e* (relative abundance): 254 (14), 184 (34), 167 (64), 166 (100), 165 (84), 77 (27), 43 (36).

Found: C, 80.4; H, 7.3%. Calcd for $C_{17}H_{18}O_2$: C, 80.3; H, 7.1%.

*Benzhydryl Cyclohexanecarboxylate (**1d**).* This was prepared from cyclohexanecarboxylic acid (3.2 g, 0.03 mol) and benzhydrol (4.6 g, 0.03 mol) as above. Yield: 6.0 g (82%); mp 52—53.5°C (*n*-hexane). IR (Nujol): 3026, 1729, 1496, 1241, 1190, 1163, 1130, 750, 697 cm^{-1}. NMR (CCl_4): δ 7.33 (s, 10H, Ph), 6.90 (s, 1H, $Ph_2C\underline{H}$), 2.66—1.00 (m, 11H, cyclohexyl). MS *m/e* (relative abundance): 294 (7), 184 (24), 167 (72), 166 (100), 165 (47), 83 (23), 55 (21).

Found: C, 81.3; H, 7.4%. Calcd for $C_{20}H_{22}O_2$: C, 81.6; H, 7.5%.

*Photolysis of Benzhydryl Esters (**1a**—**1e**) in Benzene. General Procedure.* A 0.06—0.08M solution (16 m*l*) of **1** in benzene was placed in a quartz tube and irradiated with a 200-W, high-pressure mercury lamp under nitrogen for 48 hr. The photoproducts were separated by preparative GC (190—200°C), purified by distillation or recrystallization and identified by comparison with authentic samples. The products isolated were 1,1-diphenylalkane (**2a**—**2e**), diphenylmethane (**3**), and 1,1,2,2-tetraphenylethane (**4**). The latter compound was precipitated from the reaction mixtures when they were left standing. The results are summarized in Table 1.

*Photolysis of Benzyl Cyclohexanecarboxylate (**5**).* A 0.1M solution (10 m*l*) of **5** in tetrahydrofuran was placed in a quartz tube and irradiated under a nitrogen atmosphere with a 200-W, high-pressure mercury lamp for 48 hr. Subsequent separation by GC afforded dibenzyl, benzylcyclohexane (**6**),[23] and 2-benzyltetrahydrofuran (**8**).[24] The results are found in the text.

*Photolysis of Trityl Esters (**9a** and **9b**) in Benzene.* A 0.06M solution (16 m*l*) of the ester in benzene was placed in a quartz tube and irradiated with a 200-W, high-pressure mercury lamp under a nitrogen atmosphere for 48 hr. The photoproducts were separated by GC and identified by comparison with authentic samples. The irradiation of **9a** gave 1,1,1-triphenylethane (**10a**) and triphenylmethane (**11**). The **9b** ester gave 1,1,1-triphenylpropane (**10b**) and **11** on UV irradiation. The dimer of triphenylmethyl could not be isolated in either case. The results are found in the text.

*Photolysis of **1a** and **1b** in Various Solvents. General Procedure.* Solutions (0.08M, 16 m*l*) of **1** in different solvents were placed in quartz tubes and irradiated at the same time with a 200-W, high-pressure mercury lamp under nitrogen for 48 hr. The photolysates in the case of acidic solvents were neutralized with aqueous sodium bicarbonate, extracted with ether, and dried over sodium sulfate. The photoproducts were then separated by GC; the results are summarized in Table 2.

2-Benzhydryltetrahydrofuran (**13**) was isolated in the photolysis in tetrahydrofuran; bp 140°C (bath temperature)/3 mmHg. IR (neat): 3024, 1600, 1495, 1454, 1065, 1030, 743, 700 cm^{-1}. NMR (CCl_4): δ 7.14 (s, 10H, Ph), 4.65—4.21 (m, 1H, α-methine), 3.73 (d, 1H, $Ph_2C\underline{H}$), 4.00—3.39 (m, 2H, α-methylene), 2.14—1.06 (m, 4H, methylenes). MS *m/e* (relative abundance): 238 (1), 167 (19), 71 (100), 44 (94).

Found: C, 85.8; H, 7.7%. Calcd for $C_{17}H_{18}O$: C, 85.7; H, 7.6%.

(+)-Benzhydryl 2-Methylbutanoate. Optically-active 2-methylbutanoic acid ($[\alpha]_D^{29}$ +15.35° (neat)), which was obtained by the oxidation of commercially-available, optically-active amyl alcohol ($[\alpha]_D^{29}$ −4.4° (neat), optical purity: 93%), was converted to its acid chloride.[19] The acid chloride (3.2 g, 0.03 mol) was slowly added to a solution of benzhydrol (4.0 g, 0.02 mol) in pyridine (5 m*l*) and benzene (5 m*l*). The mixture was heated to reflux for 1.5 hr, and the excess pyridine was removed by dil. hydrochloric acid and extracted with ether. The combined extracts were washed with aqueous sodium chloride and dried over sodium sulfate. Subsequent condensation and distillation gave the title ester as a slightly yellow liquid (5.9 g, 92%); bp 113°C/0.08 mmHg. $[\alpha]_D^{29}$ +5.65° (0.0397 g/m*l* CCl_4). IR (neat): 3030, 1739, 1498, 1446, 1173, 1142 cm^{-1}. NMR (CCl_4): δ 7.23 (s, 10H, Ph), 6.85 (s, 1H, $Ph_2C\underline{H}$), 2.75—2.10 (m, 1H, CH–CO), 2.00—1.15 (m, 2H, CH_2), 1.12 (d, 3H, $C\underline{H}_3CH$), 0.81 (t, 3H,

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2574—2577 (1972)

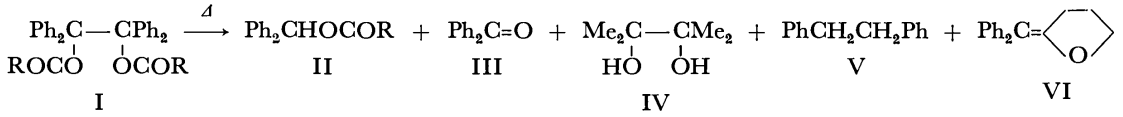
Thermolysis and Photolysis of Benzopinacol Dicarboxylates

Tamio SHIRAFUJI, Yasusi YAMAMOTO, and Hitosi NOZAKI
Department of Industrial Chemistry, Kyôto University, Yosida, Sakyô-ku, Kyôto
(Received April 1, 1972)

Thermal decomposition of benzopinacol dicarboxylates (I) results in the cleavage of the central carbon-carbon bond to afford benzhydryl esters (II) and benzophenone (III). Benzopinacol diacetate (Ia) in benzyl alcohol–benzene solution produces benzyl acetate *via* ionic reaction path, whereas Ia in THF–benzene or in toluene gives radical products such as 2-diphenylmethylenetetrahydrofuran and bibenzyl, respectively. Photolysis of I proceeds in the similar manner as thermolysis to afford II and III. The ester II is further decarboxylated photochemically to give 1,1-diphenylalkane, diphenylmethane, and 1,1,2,2-tetraphenylethane. The photochemical solvent incorporation of II proceeds in both radical and ionic sense. Such dual nature of the reaction products in thermolysis and photolysis of I and of the photodecarboxylation of II is explained in terms of the intimate ion-radical pair hypothesis proposed by Walling.

In continuation of the studies on copper carbenoids in a homogeneous system, we have found that Cu(II) carboxylates in aqueous DMF catalyze the decomposition of diphenyldiazomethane to afford benzopinacol dicarboxylates (I).[1] The reaction constitutes the only available approach to the novel class of ester I. The present report describes thermolysis and photolysis of these esters.

The Thermal Decomposition of I. Heating of 0.02—0.05 M benzene solutions of I in a sealed tube at 150—160°C under nitrogen atmosphere gave benzhydryl esters (II) and benzophenone (III). The results were summarized in Table 1. The similar reaction of I in benzene–2-propanol (1 : 1) afforded II as the main product besides III and acetone pinacol (IV). This is explained by assuming the homolysis of



I II III IV V VI

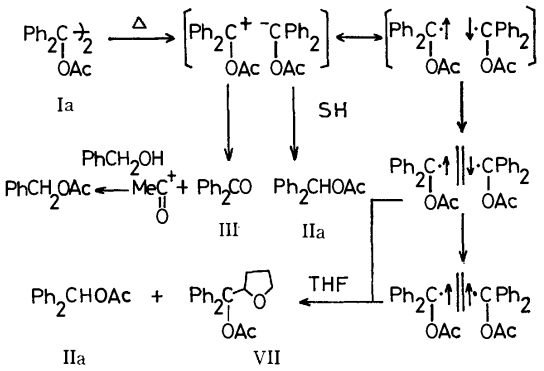
TABLE 1. THERMOLYSIS OF I IN VARIOUS SOLVENTS (150—160°C)

I	R	Solvents	Reaction time hr	Products (Yield in %)[a]		
				II	III	others
a	Me	PhH	10	12	78	—
		PhMe	5	10	70	V (tr)
		PhH–MeOH (1 : 1)	22	17	66	—
		PhH–THF (1 : 1)	17	27	51	VI (11)
		PhH-*iso*PrOH (1 : 1)	14	70	12	IV (19)
b	Et	PhH	15	22	58	—
		PhH-*iso*PrOH (1 : 1)	15	62	24	IV (24)
c	*n*-Pr	PhH	20	24	64	—
		PhH-*iso*PrOH (1 : 1)	20	70	14	IV (25)

a) Each value is based on the glc peak area and the recovery of I was negligible. The yields of IV are based on the starting amount of I.

1) T. Shirafuji, Y. Yamamoto, and H. Nozaki, *Tetrahedron*, **27**, 5353 (1971).

the central carbon-carbon bond of I and the subsequent hydrogen-transfer from 2-propanol to the resulting acetoxydiphenylmethyl radical.[2] The thermal decomposition of Ia in toluene gave bibenzyl (V) and the one in benzene–THF (1 : 1) 2-diphenylmethylenetetrahydrofuran (VI), respectively, along with IIa and III. Probably VI is ascribed to the loss of acetic acid from 2-acetoxydiphenylmethyltetrahydrofuran (VII) during the isolation process (distillation or column chromatography).[6] The isolation of V and VI is indicative of the homolysis of the carbon-carbon bond of I. Remarkably a product of ionic nature was isolated in the thermolysis of Ia in benzene–benzyl alcohol (1 : 1). Benzyl acetate was obtained, although in a trace amount, besides IIa and III. The ester is accounted for by assuming the intermediacy of acetyl cation arising from acetoxydiphenylcarbonium ion as formulated in Scheme 1.[7]



Scheme 1.

Such novel carbon-carbon bond cleavage of I in both radical and ionic sense may be explained by the adaptation of the hypothesis of intimate ion pair-radical pair intermediates as proposed by Walling *et al.* in the thermolysis of diacyl peroxides.[8] We may assume that a part of II and III,[9] and benzyl acetate are "polar" products arising from the intimate ion-radical pair. "Radical" products such as IV, V, VI, and therefore VII are ascribed to the separated pair, the triplet pair, or alternatively to the "leaked" free radical.

In each run described above, a trace amount of tetraphenylethylene was obtained.

The Photolysis of I. The irradiation of 0.02—0.05 M solutions of I in benzene was effected with a high pressure mercury lamp. The products were II, III, and 1,1-diphenylalkane (VIII) in addition to a trace each of diphenylmethane (IX) and 1,1,2,2-tetraphenylethane (X) as shown in Table 2. The irradiation of I in benzene–2-propanol (1 : 1) or in benzene–methanol (1 : 1) gave the respective benzhydryl ethers XI or XII along with II, VIII, IX, and X. On the other hand, the photolysis of Ia in benzene–THF gave VI and 2-benzhydryltetrahydrofuran (XIII) as well as IIa, III, VIIIa, IX and X. Compound VI is again ascribed to the thermal decomposition of VII in the glc separation process. With toluene as a solvent, V and 1,1,2-triphenylethane (XIV) were obtained besides IIa, III, VIIIa, IX, and X.

Presumably the photolysis of Ia gives the same "intimate" ion-radical pair as shown in Scheme 1 first.[8] The formation of IIa, III, and VII is explained analogously as above. The complication is due to further photodecomposition of II.[10]

It should be added that the above mentioned photodecomposition of II occurs in the presence of III, as both are produced in the photolysis of I. When a benzene solution of IIa and III in a mole ratio of 3 : 1 was irradiated, the result was only slightly reduced yield of VIIIa (9%) under 87% recovery of IIa in comparison with the photolysis of IIa in the absence of III affording VIIIa (15%) and 75% recovery of IIa. The photolysis of a mixture of IIa and III in a mole ratio of 1 : 5 did not proceed at all and resulted in the recovery of completely unchanged IIa and III. This is explained by assuming that benzophenone quenches the S_1 state of IIa effectively.[12] In fact, the fluorescence spectrum of IIa measured in 0.04 M ethanol solution indicated a band with max at 280 and 290 nm. Addition of equimolar amount of III

2) For the thermolysis, photolysis and related reactions of such polyphenylated ethanes as benzopinacol and *sym*-bis(trimethylsiloxy)tetraphenylethane, see Ref. 3, 4, and 5.

a) A trace amount of IX and X was obtained in every run.

to this solution completely quenched the fluorescence.[14]

Experimental

All the melting points and the boiling points are uncorrected. The microanalyses were performed by Mrs. K. Fujimoto. The IR spectra were obtained on a Shimadzu IR-27-G spectrophotometer, and the mass spectra on a Hitachi RMU-6L machine. The NMR spectra were taken in $CDCl_3$ or CCl_4 solution at 60 MHz on a JEOL C-60-H spectrometer and chemical shifts were given in ppm from TMS internal standard. NMR signals in singlet are designated as s, doublet as d, triplet as t, and multiplet as m. glc analyses and separations were performed with columns (1 m) packed with HVSG (30%) on Celite 545 or SE 30 (5%) on Chromosorb. Unless otherwise stated, irradiation was effected externally by means of a 200 W high pressure mercury lamp (quartz jacket) from a distance of 2 cm under nitrogen atmosphere at room temperature.

The General Procedure for Thermolysis of Benzopinacol Dicarboxylates (I). A benzene solution (20 m*l*) of I (1.0 mmol) in a sealed tube was heated at 150—160°C for 10—20 hr under nitrogen atmosphere. After distillation *in vacuo*, the reaction mixture was separated by glc to give benzhydryl carboxylate (II) and benzophenone (III). Each product was identical with the authentic samples (IR, MS, and glc retention times).[11] The yields of II and III, estimated on glc, were summarized in Table 1. The following description is concerned with the cases which cannot be covered sufficiently by Table 1.

The Thermolysis of Benzopinacol Diacetate (Ia) in Benzene–THF. A benzene–THF (1: 1) solution (20 m*l*) of Ia (0.30 g, 0.67 mmol) in a sealed tube was heated at 150—160°C for 17 hr under nitrogen atmosphere. Distillation of the reaction mixture *in vacuo* followed by glc separation gave benzhydryl acetate (IIa) (0.081 g, 27%), III (0.12 g, 51%) and 2-diphenylmethylenetetrahydrofuran (VI) (0.036 g, 11%). Compound VI formed an oil, bp 155—160°C/0.06 mmHg (bath temperature). IR (neat): 1645, 1600, 1176, 1075, 1040, 1028, 992 cm^{-1}. NMR (CCl_4, 10%): δ 7.50—7.10 (m, 10H, aromatic), 4.22 (t, 2H, $-OC\underline{H}_2-$), 2.50 (m, 2H, $=C(-O-)-C\underline{H}_2-$), and 1.97 (m, 2H, $-OCH_2C\underline{H}_2-$). MS (relative abundance): *m/e* 236 (M^+ 86), 180 (57), 165 (100), 77 (48).

Found: *m/e* 236.117 (M^+). Calcd for $C_{17}H_{16}O$: *m/e* 236.120.

The Thermolysis of Ia in Benzene–Benzyl Alcohol. A benzene–benzyl alcohol (1:1) solution (20 m*l*) of Ia (0.20 g, 0.44 mmol) in a sealed tube was heated at 150—160°C for 15 hr under nitrogen atmosphere. Distillation of the reaction mixture followed by glc separation gave IIa (0.17 g, 85%), III (0.008 g, 5%) and benzyl acetate (trace).

The General Procedure for Photolysis of Diester I. A benzene solution (20 m*l*) of I (1.0 mmol) in a quartz vessel was irradiated for 15—22 hr or more prolonged irradiation time (62.5 hr). The solvent was evaporated and the residue was washed with ether to give the recovery of I. The filtrate was again concentrated *in vacuo* and the residue was washed with methanol to give 1,1,2,2-tetraphenylethane (X). The filtrate was distilled and subjected to glc separation to give II, III, 1,1-diphenylalkane (VIII), and diphenylmethane (IX). Each product was identified by the comparison with the authentic samples[16-18] (IR, MS, and glc retention times). The yields of each product were estimated on glc as shown in Table 2. The following description is concerned with the cases which cannot be covered sufficiently by Table 2.

The Irradiation of Ia in Benzene–2-Propanol. A solution of Ia (0.20 g, 0.44 mmol) in benzene–2-propanol (1:1) (20 m*l*) was irradiated for 15 hr. Separation of the reaction mixture by distillation and by glc afforded acetone pinacol (0.006 g, 20%), IIa (0.012 g, 6%), VIIIa (0.042 g, 26%), IX (trace),

14) For the photolysis of *sym*-tetraphenylethane, see Ref. 15. The presence of *vic*-acetoxyls completely changes the reaction course.

X (trace), and benzhydryl isopropyl ether (XI) (0.066 g, 33%). The ether XI formed an oil, bp 110—115°C/0.1 mmHg (bath temperature). IR (neat): 1295, 1255, 1180, 1170, 1135, 1118, 1080, 1057, 1028, 935, 920, and 905 cm^{-1}. NMR (CCl_4, 15%): δ 7.40—7.00 (m, 10H, aromatic), 5.36 (s, 1H, $Ph_2C\underline{H}$–O–), 3.59 (m, 1H, –$C\underline{H}Me_2$), and 1.15 (d, 6H, methyl). MS (relative abundance): *m/e* 226 (M^+, 11), 182 (12), 167 (100), 152 (23), 107 (68), 105 (66), 77 (46).

Found: C, 84.8; H, 7.9%. Calcd for $C_{16}H_{18}O$: C, 84.9; H, 8.0%.

Independent synthesis of XI was performed according to the method similar to the reported one.[19] The IR spectrum and glc retention time were completely identical with those of the photoreaction product XI.

The Irradiation of Ia in Benzene–THF. A solution of Ia (0.20 g, 0.44 mmol) in benzene–THF (1:1) (20 m*l*) was irradiated for 15 hr. After distillation *in vacuo*, the reaction mixture was separated by glc to give IIa (0.044 g, 22%), III (trace), VI (0.044 g, 15%), VIIIa (0.036 g, 22%), IX (trace), X (trace), and 2-benzhydryltetrahydrofuran (XIII) (0.060 g, 28%). Compound XIII was identified by the comparison with the authentic sample (IR, NMR, MS, and glc retention time).[11a]

The Irradiation of Ia in Toluene. A solution of Ia (0.20 g, 0.44 mmol) in toluene (20 m*l*) was irradiated for 21 hr. Distillation of the reaction mixture *in vacuo* followed by glc separation gave bibenzyl (0.038 g, 39%), IIa (0.041 g, 21%), VIIIa (0.005 g, 3%), IX (trace), X (trace), and 1,1,2-triphenylethane (XIV) (0.017 g, 8%). Compound XIV was identical with the authentic sample (IR, NMR, MS, and glc retention time).[20]

The Irradiation of IIa in the Presence of Benzophenone. A solution of IIa (0.040 g, 0.18 mmol) and benzophenone (0.010 g, 0.06 mmol) in benzene (10 m*l*) was irradiated for 24 hr to afford VIIIa, IX, X, and recovered IIa. The yields of each component were shown in the text.

The authors are grateful to Mr. Yoshimi Ozaki for his assistance. Financial support from the Ministry of Education, Japanese Government, and from Toray Science Foundation is acknowledged with pleasure. They are grateful to Prof. G.W. Griffin at Louisiana State University in New Orleans for valuable suggestions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2577—2579 (1972)

Synthesis of Some Nucleoside Analogs of Substituted 1,2,3-Triazole

Osamu MAKABE, Shunzo FUKATSU, and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama

(Received March 28, 1972)

1-(β-D-Ribofuranosyl)-1,2,3-triazole-4-carboxamide (**4**) and 4-amino-1-(β-D-ribofuranosyl)-1,2,3-triazole-5-carboxamide (**7**) have been synthesized as an approach to obtain bioisosteres of pyrazomycin, an antiviral agent. The synthesis has been accomplished by condensation of blocked triazoles with tri-*O*-benzoyl-D-ribofuranosyl chloride in the presence of mercuric cyanide in nitromethane. UV spectral studies revealed the orientation of *N*-glycosidation in the substituted triazoles.

Current research in nucleoside antibiotics has stimulated an interest in synthesizing nucleoside analogs of a variety of heterocyclic bases. We interested in synthesizing some compounds related to pyrazomycin which was recently discovered by Gerzon *et al.*[1] Pyrazomycin (3-(β-D-ribofuranosyl)-4-hydroxypyrazole-5-carboxamide) is one of the rare *C*-nucleosides and an inhibitor of virus multiplication.

In this paper the syntheses of 1-(β-D-ribofuranosyl)-1,2,3-triazole-4-carboxamide (**4**) and 4-amino-1-(β-D-ribofuranosyl)-1,2,3-triazole-5-carboxamide (**7**) are described. In these compounds, the CH= group in pyrazomycin is replaced by ring nitrogen (an isosteric ring equivalent).

In the present synthesis, the coupling of blocked triazoles with a poly-*O*-acylribosyl halide was effected with mercuric cyanide in nitromethane[2] to give the blocked nucleosides. Another purpose of the present investigation was to study the orientation of *N*-glycosidation in substituted 1,2,3-triazole.

Condensation of 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl chloride[3] (**2**) with 4-ethoxycarbonyl-1,2,3-triazole[4] (**1**) or 5-acetamido-1,2,3-triazole-4-carboxamide[5] (**5**) in the presence of mercuric cyanide in nitromethane gave 1-(β-D-2′,3′,5′-tri-*O*-benzoylribofuranosyl)-4-ethoxycarbonyl-1,2,3-triazole (**3**) or 4-acetamido-1-(β-D-2′,3′,5′-tri-*O*-benzoylribofuranosyl)-1,2,3-triazole-5-carboxamide (**6**).

2) N. Yamaoka, K. Aso, and K. Matsuda, *J. Org. Chem.*, **30**, 149 (1965).

3) H. M. Kissman, C. Pidacks, and B. R. Baker, *J. Amer. Chem. Soc.*, **77**, 18 (1955).

4) S. Yamada, T. Mizoguchi, and A. Ayata, *J. Pharm. Soc. Japan, Yakugaku Zasshi*, **77**, 452 (1957).

5) S. Yamada, T. Mizoguchi, and A. Ayata, *ibid.*, **77**, 455 (1957).

Treatment of **3** with methanolic ammonia gave 1-(β-D-ribofuranosyl)-1,2,3-triazole-4-carboxamide (**4**). This compound proved to be identical to that recently prepared by G. Alonso *et al.*[6] by an alternative synthesis from a glycosyl azide and methyl propiolate.

Similar treatment of **6** with methanolic ammonia gave crude 4-acetamido-1-(β-D-ribofuranosyl)-1,2,3-triazole-5-carboxamide (**7'**). Further hydrolysis of crude **7'** with methanolic ammonia in a sealed tube at 80°C for 20 hr afforded 4-amino-1-(β-D-ribofuranosyl)-1,2,3-triazole-5-carboxamide (**7**).

In accord with expectation based on participation[7] of the *C*-2 benzoyl group of the halogenosugar (**2**), the above-mentioned condensations afforded β-anomers (**3** and **6**) respectively. The anomeric nature was established by their NMR spectra. The anomeric protons of **3** and **6** appeared as doublets with $J_{1',2'}$ values of 2.8 and 1.8 (in DMSO-d_6) respectively, indicating their β-configuration.[8]

Positions of substitution of the ribosyl moiety in the triazole bases were established by comparison of the ultraviolet spectra of **4** and **7** with those of *N*-methyl derivatives **12**, **8**, **9**, **10** of 1,2,3-triazole-4-carboxamide and 5-amino-1,2,3-triazole-4-carboxamide. The former *N*-methyl derivative (**12**) was prepared from 4-carboxy-1-*N*-methyl-1,2,3-triazole which was reported by Pedersen.[9] The latter three *N*-methyl derivatives (**8**, **9**, **10**) were prepared by the method reported by Albert and Tratt[10] and their UV spectra have here been determined. The absorption maxima and extinctions of **4** and **7** were compatible with those of 1-*N*-methyl-1,2,3-triazole-4-carboxamide (**12**) and 5-amino-3-*N*-methyl-1,2,3-triazole-4-carboxamide (**10**), respectively, as shown in Table 1. It should be noted that the ribosyl group is introduced to *N*-1 of the triazole ring in case of **1**, whereas, in case of **5**, the sugar group is introduced to *N*-3 of the triazole ring.

Chart 1.

Experimental

Thin-layer chromatography (tlc) was carried out on microscope slides coated with silica gel, and the spots were visualized with sulfuric acid. The NMR spectra were measured with a Varian A-60D spectrometer. Tetramethylsilane (τ 10.00; for the solution of deuteriodimethylsulfoxide) and sodium 4,4-dimethyl-4-silapentane-1-sulfonate (τ 10.00; for the solution of deuterium oxide) were used as internal standards.

1-(2',3',5'-Tri-O-benzoyl-β-D-ribofuranosyl)-4-ethoxycarbonyl-1,2,3-triazole (3). 2,3,5-Tri-*O*-benzoyl-D-ribofuranosyl chloride (**2**) (prepared[3] from 4.63 g (9.2 mmol) of 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-D-ribofuranose) was dissolved in nitromethane (25 ml) and the solution was added to a hot mixture of 4-ethoxycarbonyl-1,2,3-triazole (**1**) (1.31 g, 9.29 mmol), mercuric cyanide (2.33 g, 9.2 mmol), and Drierite (5 g) in nitromethane (70 ml). The mixture was refluxed for 2.5 hr with stirring. The hot suspension was filtered and the filter cake was washed thoroughly with ethylacetate. The filtrate and washings were combined and evaporated to dryness. The residue was dissolved in ethylacetate (5 ml) and silica gel (5 g) was added; the mixture was evaporated and the residue was chromatographed on a column of silica gel (150 g) with benzene and benzene–ethylacetate (19:1). The main portion eluted with the latter solvent system was evaporated to give **3**. Recrystallization from benzene, colorless needles, 2.99 g (54.9%); mp 168—170°C; $[\alpha]_D^{22}$ −74.8° (*c* 1.47, chloroform); UV: λ_{max} (methanol) 229 mμ (ε 48800); IR (KBr): 1730 (C=O), 710 cm^{-1} (phenyl); NMR (DMSO-d_6, τ): 0.93 (s, H-5), 3.17 (d, $J_{1',2'}$ 2.8 Hz, H-1'), 5.61 (q, *J* 7.0 Hz, $CO_2CH_2CH_3$), 8.68 (t, *J* 7.8 Hz, $CO_2CH_2CH_3$).

Found: C, 63.80; H, 4.62; N, 7.32%. Calcd for $C_{31}H_{27}$-

O_9N_3: C, 63.58; H, 4.65; N, 7.18%.

1-(β-D-Ribofuranosyl)-1,2,3-triazole-4-carboxamide (4). A solution of **3** (0.96 g, 1.6 mmol) in absolute methanol (40 m*l*) saturated with ammonia was kept at 0°C for 3 days. The solution was evaporated and the resulting syrup was chromatographed on a column of 40 g of silica gel (2.1×30 cm) with benzene–ethanol (10: 1), (6: 1), (4: 1), (1: 2), and ethanol. The last fraction gave a chromatographically homogeneous **4**. Recrystallization from water, colorless needles; 0.32 g (80%); mp 208°C (lit,[6] mp 204°C); $[\alpha]_D^{20}$ −57.3° (*c* 1.43, water) (lit,[6] $[\alpha]_D$ −51.5° (*c* 0.45, water)); UV: λ_{max} (water) 211 mμ (ε 12700); IR (KBr): 3420, 3300 (OH), 1637, 1615, 1560 cm^{-1} (amide); NMR (D_2O, τ): 1.17 (s, H-5), 3.92 (d, $J_{1',2'}$ 3.9 Hz, H-1').

Found: C, 39.23; H, 4.82; N, 22.41%. Calcd for $C_8H_{12}O_5N_4$: C, 39.34; H, 4.95; N, 22.94%.

4-Acetamido-1-(2',3',5'-tri-O-benzoyl-β-D-ribofuranosyl)-1,2,3-triazole-5-carboxamide (6). To a hot mixture of 5-acetamido-1,2,3-triazole-4-carboxamide (**5**) (0.97 g, 5.7 mmol), mercuric cyanide (1.45 g, 5.7 mmol) and Drierite (5.5 g) in nitromethane (140 m*l*), a solution of 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl chloride (**2**) (prepared from 2.87 g (5.7 mmol) of 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-D-ribofuranose) in nitromethane (30 m*l*) was added and the mixture was refluxed for 3 hr with stirring. The hot mixture was filtered, the filter cake was thoroughly washed with ethylacetate, and the filtrate and washings were combined and evaporated to dryness. The resulting gum was dissolved in methanol (5 m*l*), silica gel (5 g) was added and the suspension was evaporated to dryness. The residue was placed on a column of silica gel (140 g) and eluted successively with benzene–ethylacetate (19: 1, 440 m*l*), (9: 1, 960 m*l*), (4: 1, 1330 m*l*), and (2: 1, 1560 m*l*). Evaporation of the last fraction gave **6**, colorless glass, 1.63 g (48%). The product could not be crystallized, but it was chromatographycally homogeneous; $[\alpha]_D^{20}$ −73.0° (*c* 1.54, chloroform); UV: λ_{max} (methanol) 231 mμ (ε 10400); IR (KBr): 1730 (C=O, benzoyl), 1673, 1603, 1561 (amide), 713 cm^{-1} (phenyl); NMR (DMSO-d_6, τ): 3.32 (d, $J_{1',2'}$ 1.8 Hz, H-1').

Found: C, 60.59; H, 4.82; N, 11.26%. Calcd for $C_{31}H_{27}O_9N_5$: C, 60.68; H, 4.44; N, 11.42%.

4-Amino-1-(β-D-ribofuranosyl)-1,2,3-triazole-5-carboxamide (7). A solution of **6** (1.38 g, 2.25 mmol) in absolute methanol (200 m*l*) was saturated with ammonia at 0°C, kept at the same temperature for 3 days, and evaporated under diminished pressure at 40°C. A mixture of the residue and silica gel (1 g) in methanol was placed on a column of silica gel (40 g, 2.1×30 cm) and eluted successively with benzene and benzene–ethanol (9: 1). The latter fraction was evaporated to dryness. A solution of the residue (crude **7'**) in absolute methanol (10 m*l*) saturated with ammonia was placed in a sealed tube and kept at 80°C for 20 hr. After removal of the solvent under diminished pressure, the residue was taken in methanol and silica gel (500 mg) was added. The mixture was placed on a column of silica gel (30 g, 2.0×25 cm; packed with ethylacetate) and successively eluted with ethylacetate (70 m*l*) and ethylacetate–acetone (1: 1, 100 m*l*). Evaporation of the latter fraction gave **7**, colorless glass, chromatographycally homogeneous, 0.309 g (54%); $[\alpha]_D^{23}$ −52.4° (*c* 1.29, water); UV: λ_{max} (water) 200, 270 mμ (ε 11000, 6200); λ_{min} (water) 241 mμ (ε 1900); IR (KBr): 3340 (OH), 1660, 1605 cm^{-1} (amide); NMR (D_2O, τ): 4.27 (d, $J_{1',2'}$ 3.8 Hz, H-1').

Found: C, 36.92; H, 5.54; N, 26.55%. Calcd for $C_8H_{13}O_5N_5$: C, 37.07; H, 5.06; N, 27.02%.

1-Methyl-4-ethoxycarbonyl-1,2,3-triazole (11). A solution of 1-methyl-4-carboxy-1,2,3-triazole[8] (2.50 g, 16.1 mmol) in absolute ethanol (40 m*l*) saturated with dry hydrogen chloride was refluxed for 4 hr. After removal of the solvent, the resulting syrup was triturated with water (5 m*l*). Filtration yielded colorless powder, 2.00 g (65.4%). Recrystallization from water; mp 93—94.5°C.

Found: C, 46.50; H, 5.74; N, 27.22%. Calcd for $C_6H_9O_2N_3$: C, 46.44; H, 5.85; N, 27.08%.

1-Methyl-1,2,3-triazole-4-carboxamide (12). A suspension of **11** (1.01 g, 6.52 mmol) in absolute methanol (40 m*l*) saturated with ammonia was placed in a sealed tube and kept at 90°C for 5 hr. After cooling, the precipitate was filtered, 616 mg (75.0%). Recrystallization from 50% aqueous ethanol; sublimes at 150—220°C.

Found: C, 38.02; H, 4.45; N, 44.27%. Calcd for $C_4H_6ON_4$: C, 38.09; H, 4.80; N, 44.43%.

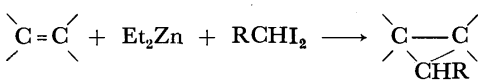
The authors wish to thank Mr. Saburo Nakada of our laboratory for microanalysis and Mr. Hiroshi Suzuki for technical assistance. We are also thankful to the Ministry of Education for a Scientific Research Grant-in-aid.

A Salt Effect on the Reaction of Zinc Carbenoid

Nariyoshi KAWABATA,* Shigeyoshi NODA, and Shinzo YAMASHITA
Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto
(Received April 10, 1972)

Bicyclo[4.1.0]heptane (norcarane) was obtained as the major product of the reaction of cyclohexene with diethylzinc and methylene iodide. In the presence of lithium halide or magnesium halide, however, the yield of norcarane considerably decreased. Large amounts of *n*-propyl and *n*-butyl iodides were formed which was interpreted in terms of an insertion mechanism, *viz.*, insertion of zinc carbenoid into the carbon-iodine bond of ethyl and *n*-propyl iodides.

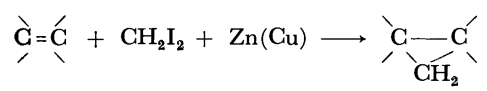
Reports were given on the synthesis of cyclopropane derivatives by the reaction of olefins with diethylzinc and *gem*-diiodoalkanes such as methylene, ethylidene and benzal iodides.[1]



(1)

(R=H, CH_3, C_6H_5)

The reaction presumably proceeds *via* an intermediate zinc carbenoid species,[1e] and is closely related to the Simmons-Smith reaction:[2]



(2)

However, reaction (1) proceeds much more rapidly and *gem*-diiodoalkane should be added slowly to moderate the reaction. Reaction (1) was modified by the use of ethylidene and benzal iodides instead of methylene iodide. Diethylzinc is inflammable in air, making the reaction impracticable. In order to get rid of this inconvenience, we tried to use diethylzinc prepare *in situ* from zinc halide and ethyllithium or ethylmagnesium halide *i.e.*, to carry out the reaction in the presence of lithium or magnesium halide, and found a remarkable effect of these metal halides on the mode of reaction (1).

The reaction of cyclohexene with diethylzinc and methylene iodide in benzene or ether gave bicyclo-[4.1.0]heptane (norcarane) in good yield.[1a,1b]

TABLE 1. REACTION OF CYCLOHEXENE WITH DIETHYLZINC AND METHYLENE IODIDE IN THE PRESENCE OF METAL HALIDE[a]

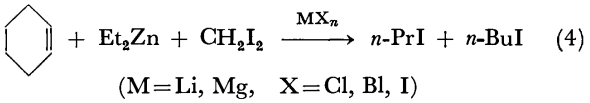
(3)

However, in the presence of lithium halide or magnesium halide, the yield of norcarane decreased considerably and large amounts of *n*-propyl and *n*-butyl iodides were formed.



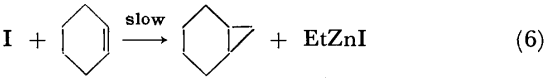
(4)

(M=Li, Mg, X=Cl, Bl, I)

Results are given in Table 1.

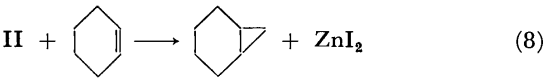
Hydrolysis of the reaction mixture at an early stage of reaction (3) produced large amounts of methyl and ethyl iodides,[1e] while the amount of norcarane was small at this stage. The formation of methyl iodide after hydrolysis indicates the presence of iodomethylzinc compounds[3] in the reaction mixture. Thus, the first step was concluded to be the formation of ethyl iodide and iodomethylzinc compounds, *e.g.*, $EtZnCH_2I$ (I). The reaction of iodomethylzinc compounds with cyclohexene to form norcarane is slower than the first step.

$$Et_2Zn + CH_2I_2 \xrightarrow{fast} EtI + \underset{I}{EtZnCH_2I} \quad (5)$$



(6)

$$EtZnI + CH_2I_2 \longrightarrow EtI + \underset{II}{IZnCH_2I} \quad (7)$$



(8)

The formation of *n*-propyl and *n*-butyl iodides can be ascribed to the reaction of iodomethylzinc compounds with ethyl and *n*-propyl iodides, respectively.

$$I + EtI \longrightarrow n\text{-}PrI + EtZnI \quad (9)$$

$$I + n\text{-}PrI \longrightarrow n\text{-}BuI + EtZnI \quad (10)$$

$$II + EtI \longrightarrow n\text{-}PrI + ZnI_2 \quad (11)$$

$$II + n\text{-}PrI \longrightarrow n\text{-}BuI + ZnI_2 \quad (12)$$

In the presence of lithium halide or magnesium halide, reactions (9), (10), (11), and (12) predominated over (6) and (8). Zinc iodide also showed the same sort of effect as that given in Table 1. The yield of norcarane was lower and that of *n*-propyl and *n*-butyl iodides higher in ether than in benzene. The difference can be attributed partly to the difference of solubility of zinc iodide formed by (11) and (12).

Two mechanisms are possible for reactions (9) to (12), one is a coupling reaction between iodomethylzinc compounds and ethyl iodide or *n*-propyl iodide. This mechanism is conceivable since the presence of magnesium halide enhances the coupling reaction of dialkylcadmium with acyl halide.[4] Dialkylcadmium prepared *in situ* from alkylmagnesium halide and cadmium halide in ether reacts with acyl halide to form ketone. However, isolated (salt-free) dialkylcadmium does not react with acyl halide.

$$R_2Cd + R'COX \xrightarrow{MgX'_2} RCOR' \quad (13)$$

The other mechanism is an insertion reaction of iodomethylzinc compounds into the carbon-iodine bond of ethyl iodide or *n*-propyl iodide.

In order to distinguish the two mechanisms, we carried out the reaction of cyclohexene with diethylzinc and bromoiodomethane, giving a small amount of norcarane, and large amounts of *n*-propyl, *n*-butyl, and ethyl iodides. However, ethyl, *n*-propyl, and *n*-butyl bromides were not detected. The results are given in Table 2.

The presence of a large amount of ethyl iodide and the absence of ethyl bromide indicate that the first step is (14) rather than (15).

$$Et_2Zn + ICH_2Br \longrightarrow EtI + BrCH_2ZnEt \quad (14)$$

$$Et_2Zn + ICH_2Br \longrightarrow EtBr + ICH_2ZnEt \quad (15)$$

The formation of *n*-propyl and *n*-butyl iodides instead of *n*-propyl and *n*-butyl bromides makes the insertion mechanism preferable to the coupling mechanism.

Coordination of lithium or magnesium halide to organozinc compounds during the reaction is conceivable. However, extensive physicochemical studies may be necessary before proposing a definite mechanism of this salt effect.

Experimental

Materials. Diethylzinc was prepared by the conventional method.[5] Ethylmagnesium halides were prepared from ethyl halide and magnesium turnings in ether. Concentration of ethylmagnesium halide was determined by an acid-base titration. Commercial products of anhydrous zinc

chloride and bromide were dried by rapidly heating *in vacuo*. Commercial anhydrous zinc iodide was dissolved in ether, dried by calcium hydride; the clear supernatant layer was transferred to a flask and ether was removed *in vacuo* at room temperature. All the zinc halides purified in this manner were completely soluble in ether. Commercial anhydrous lithium chloride was dried by heating *in vacuo*. Anhydrous lithium bromide was prepared by heating its monohydrate *in vacuo*. Anhydrous lithium iodide was prepared by dehydration of its trihydrate, *i.e.*, lithium iodide trihydrate was dissolved in ether, dried with calcium hydride; the clear supernatant layer was transferred to a flask, and ether was removed *in vacuo* at room temperature. Anhydrous magnesium iodide was prepared from magnesium trunings and iodine in ether. Bromoiodomethane was prepared by the conventional method.[6] Commercial cyclohexene, methylene iodide, ethyl bromide, ethyl iodide, *n*-propyl bromide, *n*-propyl iodide, *n*-butyl bromide, and *n*-butyl iodide were purified by distillation. Authentic sample of norcarane was prepared from cyclohexene, methylene iodide and diethylzinc.[1a] Purity was confirmed by vapor phase chromatography. Solvents were purified by the usual method.[7] Nitrogen was purified as described previously.[1b]

Procedure. A three-necked flask equipped with a thermometer, dropping funnel, three-way cock and magnetic stirring bar was evacuated and filled with dry nitrogen. Metal halide was dissolved in ether and added to the flask *via* a hypodermic syringe. Diethylzinc was then added similarly. The concentration of diethylzinc was made to be 1.00 or 0.50 mol/*l* at this stage by controlling the amount of solvent. Cyclohexene was added *via* a hypodermic syringe to this solution. Methylene iodide was then added through a dropping funnel over a period of half an hour while stirring at room temperature. After the addition the reaction mixture was allowed to stand at 35°C for 14 hr. The reaction mixture was successively poured into a saturated aqueous solution of ammonium chloride. The organic layer was analyzed by vapor phase chromatography. Yields of products were determined by vapor phase chromatography with calibration curves.

N,N,N′,N′-Tetramethylethylenediamine-Copper Salt-catalysed Coupling of Aryl Grignard Reagents with Alkyl and Aralkyl Halides

Kazuhiko ONUMA and Harukichi HASHIMOTO*

Department of Synthetic Chemistry, The University of Tokyo, Bunkyo-ku, Tokyo
**Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai*

(Received October 30, 1971)

In the presence of *N,N,N′,N′*-tetramethylethylenediamine (TMEDA) and a small amount of copper salt, phenyl- and *p*-tolylmagnesium bromides react with alkyl or benzyl halide to give cross-coupling products in benzene or in a benzene–diethyl ether solvent. Among the alkyl iodides, normal iodides are most reactive, while secondary iodides do not react under our conditions. As copper salts, CuCl, $CuCl_2$, $CuCl_2$(TMEDA), and CuBr are all efficient for catalysis. This newly-developed catalytic system of TMEDA-copper salt is thought to be useful for the syntheses of polyalkyl-substituted aromatic hydrocarbons. As the reaction mechanism, the intermediate formation of TMEDA-coordinated organocopper(I) species and the nucleophilic displacement is proposed.

In general, Grignard reagents react very slowly, or not at all, with organic halides, except for some activated molecules, such as allylic halides.[1] On the other hand it is well known that some transition metal salts catalyse these reactions efficiently for example, in the cobalt salt-catalysed "Kharasch reaction."[3] Recent works[4] have shown that, in these cobalt salt-catalysed reactions, zero-valent cobalt is a real catalytic species and that free radicals from organic halides are involved. In most of these metal salt-catalysed reactions, however, the cross coupling between the Grignard reagent and organic halide is not a predominant reaction.[5]

1) In some cases, reactions do occur by the use of a high temperature in high-boiling solvents or in neat, though the yields are generally low. It is also said that, in these high-temperature reactions, free radicals are involved.[2]

5) a) Products from homocoupling, disproportionation, hydrogen abstraction or other radical involved reactions are major products. b) Of course there are special cases where cross couplings take place efficiently, for example: copper salt catalysed reaction of acetylenic Grignard reagent with allyl halide,[6] vinyl halides react with Grignard reagents in the presence of iron affording cross coupling products in good yield,[7] alkyl Griganrd reagents react with alkyl halides by the catalysis of copper(I) halide.[8]

We previously reported that the copper(I)-ethylenediamine complex can reduce benzyl chloride (Eq. (1)[9,10]), and aryl Grignard reagents are known to be easily oxidised by high-valent transition metal salts, such as copper(II),[11] and iron(III)[12,13] (Eq. (2)):

$$PhCH_2Cl + Cu(I)(en)_n \longrightarrow PhCH_2CH_2Ph + Cu(II)(en)_n \quad (1)$$

$$RX \xrightarrow{Me^{(n-1)+}} R\text{-}R \quad (1')$$

$$ArMgX \xrightarrow{Me^{n+}} Ar\text{-}Ar \quad (2)$$

The combination of these two sets of reactions (Eqs. 1 and 2) suggests that the bidentate amine-copper salt system may be a good catalyst for the reaction between Grignard reagents and organic halides. From this point of view, we investigated the copper salt-*N,N,N',N'*-tetramethylethylenediamine(TMEDA)-catalysed reaction of aryl Grignard reagnets with alkyl and aralkyl halides. In this paper we will report that this system is a good catalyst for *cross* couplings.

$$ArMgX + RX' \xrightarrow[\text{copper salt}]{\text{TMEDA}} Ar\text{-}R \quad (3)$$

Experimental

Materials. The *N,N,N',N'*-tetramethylethylenediamine was prepared according to the method in the literature[14] and was cautiously distilled in nitrogen after having been refluxed on sodium. Commercial triethylamine was distilled on sodium. The reagent-grade alkyl iodides were used after distillation. The isobutyl and *sec*-butyl iodides were prepared from the corresponding alcohols.[15] All the substituted benzyl chlorides and benzyl chloride were used without further purification. Reagent-grade anhydrous cuprous chloride and bromide were further purified by the usual method. Anhydrous cupric chloride was obtained from the product of the dehydration of the dihydrate by heating *in vacuo* at 100°C for several days. $CuCl_2$ (TMEDA) was prepared by Bertini's method[16] in butanol.

The standard substances for glc, propyl-, isobutyl-, *sec*-butyl-, amyl- and isoamylbenzene, and *p*-methyl-, *p,p'*-dimethyl- and *p*-chlorodiphenylmethane were prepared by the method described in this paper on a larger scale. They were identified by NMR, IR, and elemental analysis.

The benzene solution of the Grignard reagent-TMEDA complex was prepared by dropping phenyl- or *p*-tolylmagnesium bromide into a benzene sloution of TMEDA in the presence of magnesium turnings at 50°C;[17] afterward the solution was filtered and stored under a nitrogen atmosphere. The concentration was determined by chelate titration, mostly about $2.2—2.9\times10^{-1}$ mol/*l*; 20—30 m*l* of the solution was used for a separate run. The Grignard reagent in diethyl ether was prepared in the usual manner and stored. The concentration was determined by acid-base titration.

Reaction Procedures. *Method A*: All the reactions were made under a nitrogen atmosphere. In a four-necked, round-bottomed flask equipped with a condenser, a thermometer, a nitrogen inlet, a dropping funnel, and a magnetic stirrer, 40 m*l* of benzene, organic halide, and a small amount of copper salt were placed. Then the reaction was started at 80°C by adding a benzene solution of the Grignard-TMEDA complex (25—30 m*l*) through the funnel. After completion, the reaction mixture was hydrolysed and extracted with ether, and the extract was condensed. The product analysis was made by glc with a 2 m Silicone DC550 column.

Method B: To the solution of organic halide, TMEDA, and copper salt in 40 m*l* of benzene, we dropped an ether solution of the Grignard reagent (20—25 m*l*) at 60°C. The other procedures were the same as in Method A.

Results and Discussion

As expected, cross coupling occurred between aryl Grignard reagents and alkyl or benzyl halides as a result of the use of the catalytic system of TMEDA-copper salt in benzene or in a benzene–ether solvent. As an amine ligand, TMEDA, is chosen because TMEDA has no active hydrogen and is known to be a good coordinating ligand not only for copper but also for a Grignard reagent.[18] The mole ratio of TMEDA to the Grignard reagent should be above one-to-one to obtain good results. On the other hand, the appropriate quantity of copper salt is around 5 mole percent. The use of an excess of copper salt usually increases unfavorable by-products. It should be noted that if one of pair of this catalytic system (TMEDA and copper salt) is absent, the reaction does not take place at all.

There are two methods for the reaction. In "Method A," a Grignard reagent-TMEDA complex prepared in benzene is allowed to react with organic halide in the presence of copper salt in benzene at 80°C. In "Method B," a Grignard reagent prepared in diethyl ether is dropped into a benzene solution of organic halide, TMEDA, and copper salt at 60°C. The ratio of benzene to ether is about 2:1.

$$\text{Method A}\quad ArMgBr(TMEDA) + RX \xrightarrow[\text{benzene}]{\text{copper salt}} Ar\text{-}R + MgBrX(TMEDA) \quad (4)$$

$$\text{Method B}\quad ArMgBr + RX \xrightarrow[\text{benzene-ether}]{\text{TMEDA, copper salt}} Ar\text{-}R + MgBrX \quad (5)$$

In THF or in diethyl ether, the reaction does not proceed.

Reactions with Alkyl Halides. Tables 1 and 2 show the results of the reaction of phenyl and *p*-tolylmagnesium bromide with a variety of alkyl halides. These results may be summarized as follows. i) The yields of cross-coupling products from the reaction of phenyl Grignard reagent with normal alkyl iodides

are generally good, and alkyl substitution on the aromatic ring does not affect the yields. This provides a useful synthetic procedure for a variety of alkyl-substituted aromatics. ii) Among alkyl halides, alkyl iodides are most reactive. iii) The steric effect is rather significant; that is, secondary iodides do not react, and the yields with alkyl iodides which are branched at the β or γ position are considerably decreased. iv) Method A is more susceptible to this steric effect.[19] v) In the case of methyl iodide, which is very reactive toward TMEDA,[20] Method B is not

19) This may be due to the fact that TMEDA is more tightly held to the complex in benzene than in benzene–ether solution.
20) TMEDA is fairly basic amine, especially in nonpolar solvent: P. Paoletti, R. Barbucci, A. Vacca, and A. Dei, *J. Chem. Soc., A*, **1971**, 310.

1.6	24	86
1.9	24	85
2.1	24	86

a) Based on alkyl halide.

applicable, but in Method A an ordinary reaction takes place smoothly, suggesting that coordinated TMEDA reacts no more with the iodide.

As the large steric hindrance may be partly attributable to the bulky TMEDA molecule, we tried to use triethylamine instead of TMEDA, but in the presence of triethylamine even normal alkyl iodides do not react. In Method B, as is shown in Tables 2 and 3, more than 1.6 times as much TMEDA as alkyl halide is necessary.[21]

The formation of biphenyl (or *p,p'*-bitolyl), which is the homocoupling product of Grignard reagent, as a by-product in the reaction is unavoidable; the yield is 10—25% in Method A and 2—4% in Method B. The increased percentage in Method A may be due to the relatively high reaction temperature.

Reactions with Benzyl Chlorides. The results of the reactions of phenyl and *p*-tolylmagnesium bromide with *p*-substituted benzyl chlorides are tabulated in Tables 4 and 5. Though the yields of the diphenylmethane derivatives are satisfactory, the *p*-methyl

substitution of a Grignard reagent reduces the reactivity somewhat.

The elucidation of the substituent effect on benzyl chloride is rather difficult, because a side reaction between benzyl chloride and TMEDA takes place. Concerning this, there are some experimental facts. a) In Method B, the optimum ratio of TMEDA to benzyl chloride is around 1.2:1 (Fig. 1) and the presence of an excess of TMEDA reduces the yield, in keen contrast to the case of alkyl iodide. b) Also, in Method A, the further addition of TMEDA can not increase the yield, but such a further addition of TMEDA evidently shortens the necessary reaction time. c) In the presence of an excess of TMEDA, scarcely no unreacted benzyl choride is recovered, suggesting that it disappeared as a quaternary ammonium salt after the treatment. It is clear form these results that active benzyl chloride reacts with a non-coordinated excess TMEDA molecule to form ammonium salt. Therefore, an excess of TMEDA can not increase the yield of the cross-coupling product. As alkyl iodides do not react with free TMEDA, an excess of TMEDA can serve only for the promotion of the reaction.

In the reaction with benzyl chloride, biphenyl, bibenzyl, and a small amount of toluene are also obtained as by-products. The rough percentages of these by-products are as follows. In Method A, the biphenyl derivatives are 5—25% and the bibenzyl derivatives are 1—10%. In Method B. the biphenyl derivatives are 3—7% and the bibenzyl derivatives are 1—4%. Generally speaking, Method B gives a little better results.

Copper Salts. The cupric chloride-TMEDA complex ($CuCl_2$TMEDA) was prepared and used as a catalyst, but the yield of cross coupling is only around 10%. In the presence of a large amount of TMEDA, that is, under ordinary reaction conditions, the catalytic activity of the $CuCl_2$TMEDA complex is just the same as that of cuprous chloride. This suggests that the coordination of TMEDA not only to copper but also to a Grignard reagent is important. The coordination of TMEDA must increase the carbanion character of the organic moiety of the Grignard reagent.[22]

$CuCl_2$ and CuBr as well as CuCl and $CuCl_2$TMEDA have similar reactivity. The use of copper(II) salt, however, increases the formation of biphenyl, only a little but obviously.

Other transition metal salts, such as ferric chloride, cobaltous chloride, and chromous chloride, can also bring about the reaction, but homocouplings are predominant, as in an ordinary "Kharasch reaction."

Reaction Mechanism. Some features of the reaction with alkyl halide can be summarized as follows: (i) The order of the reactivity of alkyl halide is $I \gg Br \gg Cl$. (ii) The steric hindrance is relatively large. iii) CH_3I and C_2H_5I are excellently reactive. These results suggest that the reaction type is very similar to the bimolecular nucleophilic displacement.

The addition of cyclohexene (a mild radical scavenger) or acrylonitrile does not affect it at all, showing that the formation of a free radical is unlikely. It can be said, therefore, that the mechanism of copper catalysis is different from that of cobalt,[4] silver,[23] or iron[7] salt, where the formation of a free radical by the reduction of an organic halide by a zero-valent metal is observed.

Tamura and Kochi[8] reported recently that, in the copper salt-catalysed coupling of an alkyl Grignard reagent with alkyl halide in THF, the formation of organocopper, followed by its nucleophilic displacement, is the key step in the catalysis; the results obtained here support this idea.

To make sure that the copper metal is not operative, the Grignard reagent was first allowed to react with a catalytic amount of cuprous chloride. When the deposition of copper metal began after 1 hr, alkyl iodide was added to this solution. The yield of the cross-coupling product by this procedure was significantly lowered. On the other hand, as has been mentioned already, the use of copper(II) salt as a

22) In case of organolithium compounds such polarizing effect is apparent: M. D. Rausch and D. J. Ciappenelli, *J. Organometal. Chem.*, **10**, 127 (1967); A. J. Chalk and T. J. Hoogeboom, *ibid.*, **11**, 615 (1968).

23) M. Tamura and J. Kochi, *J. Amer. Chem. Soc.*, **93**, 1483 (1971).

catalyst increases the biphenyl formation from the Grignard reagent, which means that copper(II) is first reduced to the copper(I) state by the Grignard reagent. The intermediate formation of the organocopper species from the Grignard reagent and copper(I) is, therefore, most probable. Organocuprate complexes are known to be very reactive toward alkyl and aryl halides.[24]

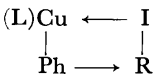
Thus, we propose as the reaction mechanism the formation of organocopper and its nucleophilic displacement;

$$(L)CuX + PhMgBr(L) \longrightarrow (L)CuPh + MgBrX(L)^{25)} \quad (6)$$

$$(L)CuPh + RI \longrightarrow Ph\text{-}R + (L)CuI^{26)} \quad (7)$$

L: TMEDA

The displacement may be assisted by copper:



Finally, we want to emphasize again that this reaction takes place only when the catalytic system of TMEDA-copper salt is present. TMEDA plays an important role as a coordinating ligand on both the Grignard reagent and copper.

24) E.J. Corey and G.H. Posner, *J. Amer. Chem. Soc.*, **89**, 3911 (1967); E.J. Corey and G.H. Posner, *ibid.*, **90**, 5615 (1968); G.M. Whitesides, W. F. Fischer, Jr., J. S. Filippo, Jr., R. W. Bashe, and H. O. House, *ibid.*, **91**, 4871 (1969).

25) It is possible that real organocopper species is not (L)CuPh but complexes with magnesium like LCuPh(MgBrXL): R. J. Depasquale and C. Tamborski, *J. Org. Chem.*, **34**, 1736 (1969).

26) Considering the effect of TMEDA coordination which can stabilize high valent state there can not be excluded the possibility of reaction path of Eq. 8:

$$LCuPh+RI \rightarrow ILCu(III)\cdot Ph\cdot R \rightarrow R\text{-}Ph+LCuI \quad (8)$$

such redox cycle is probable in copper catalysis but there are no evidence at present: H. O. House and W. F. Fischer, Jr., *J. Org. Chem.*, **33**, 949 (1968).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2586—2590 (1972)

The Codimerization of Butadiene and Ethylene Catalyzed by Cobaltous Chloride-Ditertiary Phosphine Complexes-Grignard Reagent-ROH. Effects of Ditertiary Phosphine Ligands and Alcohols

Teruhiko KAGAWA and Harukichi HASHIMOTO*

Department of Synthetic Chemistry, The University of Tokyo, Bunkyo-ku, Tokyo
**Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai*

(Received November 18, 1971)

Butadiene-ethylene codimerization is accomplished by means of the catalyst derived from the reactions of $CoCl_2(Ph_2P(CH_2)_nPPh_2)_m$ with a Grignard reagent and then with appropriate amounts of alcohols to obtain 1,4-*cis*-hexadiene selectively. The yield of 1,4-hexadiene depends on the number of ditertiary phosphine ligands (m), the methylene-chain length of the ligand (n), and the kind of alcohol. A hydride complex, $HCo(Ph_2P(CH_2)_2PPh_2)_2$ also has codimerization activity in the presence of both *n*-PrMgCl and alcohols. It is considered that the resulting alkoxymagnesium chloride activates the catalyst.

A number of transition-metal catalyst systems in the codimerization of ethylene and 1,3-butadiene have been investigated by many worker.[1a–j] These catalysts usually consist of a transition-metal salt or complex and organoaluminum compounds as the reducing agents, similar to the Ziegler-type polymerization catalysts,[2] and low valent organo-transition metal complexes have been suggested as the active intermediates. Codimerization catalyst systems, in which Grignard reagents are contained as reducing agents, have, however, been much less studied. It has been found in a patent[3] that 1,4-hexadiene can be prepared by the reaction of ethylene and butadiene in the presence of Fe (II) and a Grignard reagent. Greco and Carbonaro[4] reported that the $FeCl_3$–*i*-PrMgCl system was an active catalyst of butadiene dimerization and of butadiene-norbornadiene codimerization.

In earlier papers dealing with ethylene-butadiene codimerization reactions catalyzed by $CoCl_2(Ph_2P(CH_2)_nPPh_2)$–$AlEt_3$[5] and $NiCl_2$–$Ph_2P(CH_2)_nPPh_2$–

$AlEt_3$,[6] the present authors described how the ditertiary phosphine ligand affects product distribution in a striking manner.

In the present investigation, it will now be shown that, in the codimerization of ethylene and butadiene by $CoCl_2(Ph_2P(CH_2)_nPPh_2)_m$, Grignard reagent can be used as the reducing agent instead of organoaluminum compounds, provided that an appropriate amount of alcohol or acetone is present, and that 1,4-hexadiene is formed selectively by these catalyst systems. The effects of alcohols and ligands on the 1,4-hexadiene formation have also been studied.

Experimental

Reagents. Ethereal solutions of *n*-propylmagnesium chloride and phenylmagnesium bromide were prepared from Mg chips and *n*-propyl chloride, and from bromobenzene, respectively and were used after filtration. The concentrations of both Grignard reagents were determined by acid-base titration (1.5—2.0 mmol/g solution). Anhydrous cobaltous chloride and triphenylphosphine were obtained commercially, while ditertiary phosphines ($Ph_2P(CH_2)_nPPh_2$, n=2,3,4, and 6)[7] were prepared by the method described by Hewertson and Watson[8] and their purity confirmed by elementary analysis and a melting-point determination. DPE: mp 140—141°C (143—144°C),[8] Found: C, 78.25; H, 6.21%. Calcd: C, 78.39; H, 6.07%. DPP: mp 63.3—65.3°C (61—62°C),[9] Found: C, 78.66; H, 6.08%. Calcd: C, 78.62; H, 6.36%. DPB: mp 134°C (137—139°C),[10] Found: C, 78.78; H, 6.81%. Calcd: C, 78.85; H, 6.62%. DPH: mp 126—127°C, Found: C, 78.50; H, 6.86%. Calcd: C, 79.26; H, 7.11%. The cobalt complexes with the above ditertiary phosphines were prepared according to the reported methods.[11]

A hydride complex, $HCo(DPE)_2$, was obtained by the reduction of $CoCl_2(DPE)_2$ with $NaBH_4$ in ethanol and was used after the recrystallization of a benzene solution.[12] IR ν_{Co-H} 1884 cm^{-1} (KBr). Elementary analysis; Found: C, 72.79; H, 5.59%. Calcd: C, 72.89; H, 5.78%.

1,3-Butadiene (Nippon Petroleum Chem. Co., Ltd.) was dehydrated by passing it through anhydrous calcium chloride and molecular-sieve columns and was condensed in a measuring vessel in order to measure its volume. Ethylene (of the grade for polyethylene) was used with no further purification. The toluene, ether, alcohols, and acetone were purified by conventional methods, and were distilled and stocked in an atmosphere of nitrogen.

Procedure. Every operation was carried out under a vacuum or in an atmosphere of nitrogen.

Catalyst Preparation. Some typical experiments were carried out as follows. $CoCl_2$DPP–*n*-PrMgCl–ROH System. A 108 mg, (0.20 mmol) of $CoCl_2$DPP was suspended in 8 m*l* of toluene, and then 1.52 g portion of an ethereal solution of *n*-PrMgCl (2.91 mmol, Mg/Co=14.5) was added by a syringe; this solution was stirred with a magnetic stirrer at room temperature until reduction had proceeded completely to form a black solution. A calculated amount of an ethanol–toluene solution (0.572 g, 2.51 mmol of EtOH, EtOH/Co=12.5) was then added with agitation, whereupon an exothermic reaction occurred. This solution was used as the catalyst. Some other catalysts were made in a similar way.

$HCo(DPE)_2$–n-PrMgCl–ROH System. 0.943 g of an *n*-PrMgCl ether solution (1.92 mmol, Mg/Co=17.8) and 0.943 g of a *t*-butyl alcohol–toluene (1.92 mmol of *t*-BuOH, *t*-BuOH/Co=17.8) were added to a toluene suspension of 92 mg (0.11 mmol) of $HCo(DPE)_2$ (in this order), and this mixture was warmed to 40—50°C. The color stayed red throughout the reaction.

Oligomerization Reaction. A 100-m*l* stainless steel autoclave equipped with a magnetic stirrer was charged with the above catalyst solution and a calculated amount of butadiene (in this order). The temperature was then raised to 90—100°C, ethylene was injected to a pressure of approximately 50 kg/cm^2, and the reaction was carried out with agitation under a constant ethylene pressure. After 2.5 hr, the autoclave was cooled to room temperature and the catalyst was quenched by adding 2 m*l* of a methanol–HCl solution. The reaction solution was then washed with distilled water and dried on anhydrous sodium sulfate. After distillation, the products were analyzed by glc. The main product was 1,4-*cis*-hexadiene, which was identified by IR and NMR.

Isolation and Identification of $HCo(DPB)_2$. An ethereal solution of *n*-PrMgCl (6.72 mmol) was added at room temperature, to a stirred suspension of $CoCl_2$DPB (1.11 g, 2.00 mmol) and DPB (0.856 g, 2.01 mmol) in toluene (10 m*l*). The solution gradually became red. After filtration, *n*-hexane was added to the filtrate in order to precipitate the crystals. The resulting crystals were filtered off, dried, and recrystallised from the toluene solution by adding *n*-hexane. The dark-red crystalline compound was dried *in vacuo* at 40—50°C. Mp 158—159°C; Found: C, 73.99; H, 6.33%. Calcd for $C_{56}H_{57}P_4Co$: C, 73.76; H, 6.18%. Its proton magnetic spectrum in benzene shows a chemical shift at τ=27.2 assigned to the hydridic hydrogen of $HCo(DPB)_2$, which consists of a quintet with an intensity ratio of 1:4:6:4:1 and with a J_{PH} value of 28 Hz. However, its IR spectrum does not show any clearly-defined absorptions due to the cobalt-hydrogen stretching vibrations.

Result and Discussion

Butadiene-ethylene codimerization was catalyzed by adding appropriate amounts of alcohols to the reaction mixture of $CoCl_2$–$(Ph_2P(CH_2)_nPPh_2)_m$ (n=2, 3, and 4; m=1, 2) with ethereal *n*-propylmagnesium chloride in toluene, thus forming 1,4-hexadiene. In most cases, the selectivity of 1,4-hexadiene is so significantly high that the catalytic activity can be evaluated by means of the yield of 1,4-hexadiene based on the charged butadiene.

$CoCl_2(Ph_2P(CH_2)_nPPh_2)_m$–n-PrMgCl–Alcohol Systems. When *n*-propylmagnesium chloride was allowed to react with a cobaltous chloride-suspended toluene solution, the solution gradually turned black and a black precipitate was formed. This solution had no catalytic activity for 1,4-hexadiene formation. The reduction of cobaltous chloride with a Grignard reagent

has been known as the outset of a Kharasch reaction[13] and has been considered to proceed as follows;

$$2RMgX + CoX_2 \longrightarrow R_2Co + 2MgX_2$$

$$R_2Co \longrightarrow Co + 2R\cdot$$

In this reaction sequence, the formations of organocobalt and of metallic cobalt are assumed as intermediate steps, but it has also been suggested by several workers[14] that a magnesium-coordinated intermediate with a different composition depending upon the molar ratio of Mg/Co is formed.

The addition of an *n*-PrMgCl ether solution to $CoCl_2$DPP in toluene at room temperature brought about a rapid reaction, and the mixture became black. This solution had only a low activity (*ca.* 5% yield of 1,4-hexadiene). On the other hand, when an appropriate amount of alcohol or acetone was added to the above solution, the catalytic activity was drastically increased and the yield of 1,4-hexadiene rose to 70% or more. This behavior is shown in Fig. 1, in which the effect of the amounts of alcohols and acetone at a constant *n*-PrMgCl concentration is illustrated. Among alcohols, ethyl alcohol has a high activity over a wide range of EtOH/Co molar ratios. As can be seen from Fig. 1, the highest activity of 1,4-hexadiene formation is revealed at almost the same amount of alcohol as in the Grignard reagent, while at lower and higher molar ratios of alcohol/Co, the catalyst was deactivated. Acetone was effective in the same manner. Further, in the system of $CoCl_2$DPP–*n*-PrMgCl–large excess *t*-BuOH(*n*-PrMgCl/Co=2.2, *t*-BuOH/Co=34), the codimerization reaction proceeded only slightly. The above facts show that the remaining *n*-PrMgCl reacts with the added alcohol or acetone to give alkoxymagnesium chloride; the catalyst may be activated by the resulting ROMgCl,

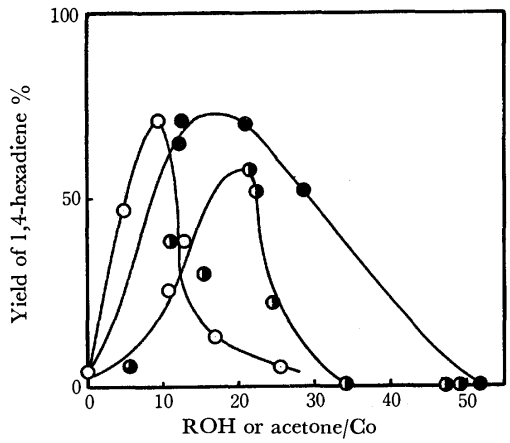

Fig. 1. Effect of molar ratio of ROH/Co or acetone/Co on yield of 1,4-hexadiene at constant concentration of *n*-PrMgCl $CoCl_2$DPP: 0.20 mmol. Reaction temperature: 90—100°C Reaction time: 2—2.5 hr

13) Mechanism of Kharasch reaction is reviewed in Ref. 14 b.
14) a) G. Costa, G. Mestroni, and G. Boscarato, *Ric. Sci. Rend., Sez. A*, **7**, 315 (1964) *Chem. Abstr.*, **63**, 18145h. b) M. H. Abraham and M. J. Hogarth, *J. Organometal. Chem.*, **12**, 1, 497 (1968).

not by the added alcohol itself.

On the other hand, using a mixture of a $CoCl_2$DPP-*n*-PrMgCl (1:2) reaction solution and *t*-BuOMgCl prepared previously from *t*-BuOH and *n*-PrMgCl as the catalyst, the yield of 1,4-hexadiene was found to be 14% (*t*-BuOMgCl/Co=12), but at a higher molar ratio (*t*-BuOMgCl/Co=20) the products were viscous liquids and higher oligomerization compounds were probably formed. The mixing order of catalyst components seems to be important in obtaining a highly active catalyst for butadiene-ethylene codimerization.

The temperature dependency of the codimerization reaction catalyzed by $CoCl_2$DPP–*n*-PrMgCl–*t*-BuOH system was studied and significant activity was revealed over 90°C; this tendency is similar to the case of the $CoCl_2(DPE)_2$–$AlEt_3$ system.[15]

The effects of the ligand, that is, the number of ditertiary phosphine ligands, "*m*", that of the methylene chain length between two phosphorus atoms, "*n*", and the kind of added alcohols (ROH; R=Me, Et, *i*-Pr and *t*-Bu) on the yield of 1,4-hexadiene in the system of $CoCl_2(Ph_2P(CH_2)_nPPh_2)_m$–*n*-PrMgCl–ROH are given in Table 1. The length of the methylene chain, "*n*", slightly affected the formation of 1,4-hexadiene except in the case of DPH, which had no catalytic activity; the following orders are obtained;

Table 1. Effect of ditertiary phosphine ligands and alcohols in $CoCl_2L_{(2)}$–*n*-PrMgCl–ROH systems

Complex	ROH	*n*-PrMgCl/Co	ROH/Co	Yield of 1,4-hexadiene[a] (%)

15) M. Iwamoto and S. Yuguchi, This Bulletin, **41**, 150 (1968).

$$CoCl_2DPP(n=3) \approx CoCl_2DPB(n=4) \gtrsim CoCl_2DPE(n=2) \gg CoCl_2DPH(n=6)$$

$$CoCl_2(DPE)_2 \gtrsim CoCl_2DPP + DPP \gtrsim CoCl_2DPB + DPB$$

The first order is the same as in the reported $CoCl_2(Ph_2P(CH_2)_nPPh_2)$–$AlEt_3$ system.[15] It shows that these ditertiary phosphine ligands (n=2, 3, and 4) stabilize the active intermediate by the formation of a chelate ring. The number of ditertiary phosphine ligands, "m", was closely related to the kinds of alcohol in activating the catalyst; the catalysts of $CoCl_2(DPE)_2$ and $CoCl_2L+L$ (L=DPP and DPB) (m=2) had a highly active character in combination with t-BuOH, but with MeOH only a small amount of 1,4-hexadiene was produced, while in the case of $CoCl_2L$ (L=DPE, DPP, and DPB) (m=1) the activity was roughly independent of the king of alcohol. In other words, the resulting t-BuOMgCl is a better co-catalyst than MeOMgCl in the $CoCl_2L_2$ and $CoCl_2L+L$ systems.

These results suggest that this catalytic codimerization reaction consists of two steps: one is the reduction of Co(II) complexes by the Grignard reagent, and the other is the activation of the resulting low-valent cobalt complex by alkoxymagnesium chloride. Therefore, a further investigation of butadiene-ethylene codimerizations catalyzed by low-valent cobalt complexes would be useful in accounting for these two steps.

Codimerization Reaction Catalyzed by a Hydride Complex $HCo(DPE)_2$. As low-valent cobalt complexes coordinated by the ditertiary phosphine, $HCo(DPE)_2$[16] and $Co(DPE)_2$[17] have been known. The hydride complex $HCo(DPE)_2$ shows codimerization activity only in the presence of both n-PrMgCl and alcohols, as is shown in Table 2. The order of activation is as follows:

$$t\text{-BuOH} > i\text{-PrOH} \approx \text{EtOH} > \text{MeOH}$$

This behavior is the same as in the $CoCl_2L_2$ (or $CoCl_2L+L$) + n-PrMgCl system described above, and the possibility of hydride-complex formation seems to be present in the later system.

On the other hand, a number of σ-bonded organo-transition-metal complexes stabilized by phosphine ligands[18] have been obtained in reactions of transition-metal complexes with Grignard reagents containing no β-hydrogen. With Grignard reagents having β-hydrogen, the σ-alkylmetal complexes formed may decompose to hydride-metal complexes because of their instability. In the reaction of $CoCl_2(DPE)_2$ or $CoCl_2L+L$ (L=DPP and DPB) with n-PrMgCl also, low-valent cobalt complexes must be formed. In fact, a new hydride complex, $HCo(DPB)_2$, was isolated from the reaction mixture of $CoCl_2DPB$, DPB and n-PrMgCl in a toluene–ether solvent at room temperature; it was later identified. In the case of $CoCl_2L$ (m=1), which has a ligand-deficient structure, there may be present another type of low-valent complex, which may be coordinated by a magnesium compound or a solvent.

The facts that $HCo(DPE)_2$ itself has no activity for codimerization reaction and that there is no influence on its activity by adding t-BuOH alone, while in the presence of both n-PrMgCl and t-BuOH a high activity is obtained (Table 2), show that the resulting ROMgCl also plays an important role in this system. It is said that a vacant coordination site is a major factor in influencing catalytic behavior in a homogeneous transition-metal catalyst. Iwamoto and his co-workers[19] reported that $HCo(DPE)_2$ reveals catalytic activity in the presence of some kinds of phenol, and they assumed an interaction between phosphorus atoms and phenol to make a vacant coordination site. Recently, Tolman[20] described how a nickel hydride $HNi(P(OEt)_3)^+_4$ catalyzed an ethylene-butadiene codimerization to give 1,4-hexadiene and that the rate-determining step in this system was ligand dissociation from $HNiL_4^+$ (L=$P(OEt)_3$). Therefore, alkoxymagnesium chloride may cause ligand dissociation in these cobalt-based catalysts.

$CoCl_2(Ph_2P(CH_2)_nPPh_2)_m$–PhMgBr–ROH Systems. When phenylmagnesium bromide was used as the reducing agent instead of n-propylmagnesium chloride, the 1,4-hexadiene formation reaction proceeded in the same way, but the yield was lower than that of the n-PrMgCl system. The results are listed in Table 3.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2590—2593 (1972)

Base-catalyzed Condensation of *o*-Nitroacetophenone. V. Hydrogenation of Compound A, a Condensation Product. Formation of a 4-Quinolone from an Indoline System

Toshio MIWA

Faculty of Science, Osaka City University Sumiyoshiku, Osaka

(Received January 24, 1972)

The catalytic hydrogenation of compound A, a base-catalyzed condensation product of *o*-nitroacetophenone, followed by treatment of the product with acid gave a 4-quinolone. The quinolone proved to be 2-[1-(*o*-aminophenyl)-1-hydroxyethyl]-4-quinolone by the oxidative degradation of the corresponding quinoline derivative.

In an attempt to isolate the basic fraction from the catalytic reduction mixture of compound A,[1] $C_{17}H_{14}O_5N_2$, a base-catalyzed condensation product of *o*-nitroacetophenone, there was obtained an amphoteric compound, $C_{17}H_{16}O_2N_2$, (I). Measurement of the *C*-methyl group of this compound gave a value of 0.71. Its ultraviolet spectrum shows an intensive maximum at 238 nm and characteristic twin maxima at 317 and 329 nm (Fig. 1). These absorption features are typical of 4-quinolones;[2] especially, the shape and location of the twin maxima and the disappearance of the bifurcation in acid solution suggest that a 2-substituted 4-quinolone structure is seemingly preferable to a 3-substituted one for this compound.[3]

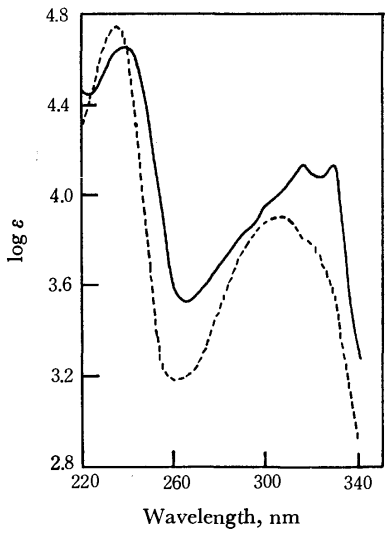

Fig. 1. UV spectra of the 4-quinolone I in ethanol (——) and in 0.1N hydrochloric acid (-----).

Acetylation of the compound I with acetic anhydride in aqueous alkali gave a monoacetyl derivative II, $C_{19}H_{18}O_3N_2$. Its infrared spectrum ($\nu_{C=O}$ 1667 cm^{-1}) indicated the compound to be an *N*-acetyl derivative. The ultraviolet absorption was similar to that of the compound I.

On the other hand, treatment of the alkaline solution of compound I with benzoyl chloride gave a dibenzoyl derivative III, $C_{31}H_{24}O_4N_2$. Its infrared spectrum ($\nu_{C=O}$ 1748 and 1667 cm^{-1}) showed that, besides the amino group, a phenolic hydroxyl group had been acylated. From the ultraviolet spectrum (Fig. 2), which lacks the bifurcation near 320 nm and resembles

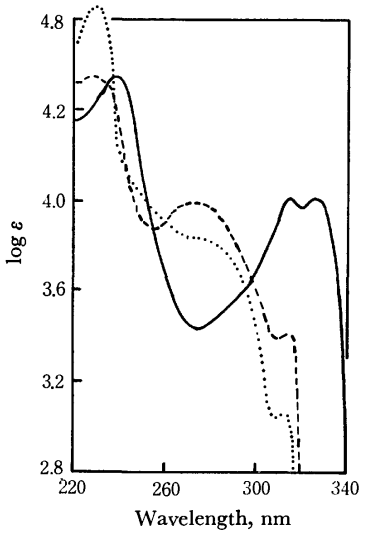

Fig. 2. UV spectra of the *N*-acetyl (——), *O,N*-dibenzoyl (-----), and *N*-acetyl (····) derivatives.

3) G. W. Ewing and E. A. Steck, *ibid.*, **68**, 2181 (1946); E. A. Steck, G. W. Ewing, and F. C. Nachod, *ibid.*, **71**, 238 (1949).

those of quinolines,[4] apparently the 4-hydroxyl group of the 4-quinolone nucleus was acylated. Methylation of the *N*-acetyl derivative II with diazomethane yielded a methyl ether IV, $C_{20}H_{20}O_3N_2$,[5] having an ultraviolet spectrum similar to the compound III.

From these observations, structures I, II, III, and IV were assigned to the compound I, its *N*-acetyl, *O*,*N*-dibenzoyl, and *N*-acetyl-*O*-methyl derivatives, respectively, the remaining inert oxygen function being tentatively assumed to be a tertiary alcohol.

III: R, R'=COC_6H_5
IV: R=$COCH_3$, R''=CH_3

To confirm these structures, attempts were made to convert the 4-quinolone system to a quinoline nucleus, which was seemingly suitable to oxidative degradation. Transformation of 4-quinolones to the corresponding quinolines has been effected usually through the 4-chloro compounds.[6]

For replacement of the 4-hydroxyl group by chlorine, refluxing with phosphorus oxychloride is recommended as the best method.[7] Treatment of the *N*-acetyl derivative II with the reagent led to a chloride V, $C_{19}H_{15}ON_2Cl$, with evolution of hydrogen chloride. Ultraviolet absorption (Fig. 3) of the chloride supported the formation of a quinoline nucleus sufficiently. Simultaneous formation of an oxazine ring,[8] consequently the presence of an *o*-acylamidobenzylalcohol system in II, was proved by lack of the 3000-cm^{-1} band, disappearance of the amide I band and existence of a C=N stretching band (1631 cm^{-1}) in the infrared spectrum as well as by appearance of a new maximum at 268 nm in the ultraviolet absorption.[9]

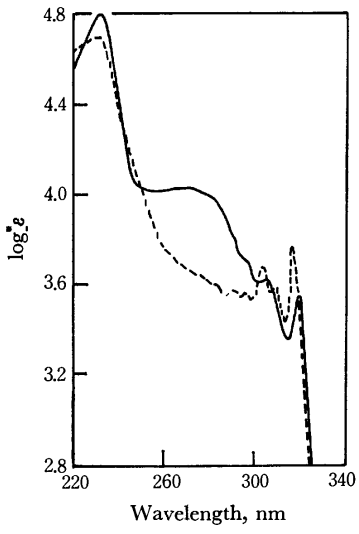

Fig. 3. UV spectra of the chloride V (——) and its hydrogenolysis product VI (– – –).

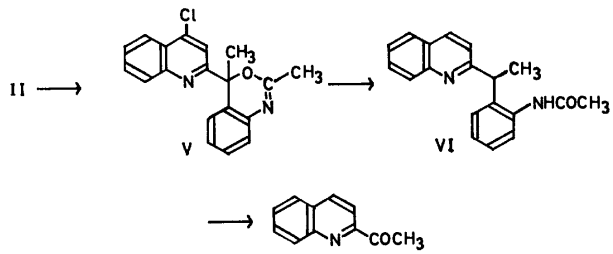
Hydrogenation of the chloride V over palladium-on-carbon in the presence of potassium acetate produced a chlorine-free compound VI, $C_{19}H_{18}ON_2$, infrared spectrum of which showed an amide I band at 1686 cm^{-1}, indicating re-formation of an amide function by hydrogenolysis of the oxazine ring.

The quinoline VI was hydrolyzed with dilute sulfuric acid and the resulting amine was immediately oxidized by addition of the Beckmann solution. From the basic volatile fraction, a methyl ketone was isolated as a semicarbazone, which decomposed at the same temperature as those of both 2- and 3-acetylquinolines; however, comparison of the infrared spectra established the semicarbazone from the oxidation product to be that of 2-acetylquinoline. Consequently, the compound I was confirmed to be 2-[1-(*o*-aminophenyl)-1-hydroxyethyl]-4-quinolone (I).



The acid catalysis in the rearrangement of the reduction product was verified by the spectral tracing of the reaction. The ultraviolet absorption of the crude reduction mixture showed a strong absorption at 380 nm reminiscent of compound A. Addition of one drop of dilute hydrochloric acid into the photometrical cell caused a momentary, striking change of the spectrum into one similar to that of the compound I in acid solution (see Experimental). The mechanism proposed in Chart 1 is obvious when the carbon skeleton of the 4-quinolone is compared with that of compound A.

This rearrangement provides a novel type of ring enlargement of a nitrogen heterocycle, different nitrogen atoms participating in the ring formation. Formation of the β-diaminoketone from the reduction product might be reversible; however, stabilization by the formation of the quinolone nucleus makes the last step

irreversible and the cleavage of the indoline ring is apparently the acid-catalyzed step.

Hydrogenation of compound A and its methyl ether in the presence of hydrochloric acid gave the compound I directly as expected.

Experimental

All melting points are not corrected. Unless otherwise noted, ultraviolet spectra were taken in ethanol and infrared spectra in Nujol mull; they are expressed in λ_{max} nm ($\log \varepsilon$) and ν_{max} cm^{-1}, respectively.

Hydrogenation of the Compound A Methyl Ether. 2-[1-(2-aminophenyl)-1-hydroxyethyl]-4-quinolone (I). An ethanol solution of 340 mg (1 mmol) of compound A methyl ether was shaken in the presence of 5% palladium-on-carbon under atmospheric pressure of hydrogen for 4 hr, during which 115 m*l* (*ca.* 18°C) of hydrogen was absorbed. Ultraviolet absorption taken immediately after the reduction (unknown concentration): λ_{max} ($-\log T$): 236 (0.818), 305 (0.150), and 403 (0.663). After addition of one drop of N hydrochloric acid (the same concentration): λ_{max} ($-\log T$): 235 (3.85), 304 (0.520), and 389 (0.320). After removal of the catalyst, followed by evaporation of the solvent *in vacuo*, the resulting residue was taken in N sulfuric acid and washed with ether. The aqueous solution was treated with active carbon, filtered and made faintly alkaline with aqueous ammonia to separate amorphous precipitates, which were collected by filtration, washed with water and dried; yield 195 mg. This material was used without further purification for formation of derivatives.

In one run, the precipitates were dissolved in ether and the ethereal solution was re-extracted with N sodium hydroxide. Neutralization of the alkaline solution with 2N hydrochloric acid produced precipitates again. After filtration of the precipitates, the mother liquor containing some ether was left to evaporate to deposit crystals, decomposing at 122°C. λ_{max} 238 (4.66), 317 (4.14), and 329 (4.13). $\lambda_{max}^{0.1N\ HCl}$ 235 (4.75) and 306 (3.91).

Found: C, 66.29; H, 6.35; N, 8.77%; *C*-methyl group:[10] 0.71. Calcd for $C_{17}H_{16}O_2N_2 \cdot 1.5H_2O$: C, 66.43; H, 6.23; N, 9.12%.

Hydrogenation of both compound A and its methyl ether over 5% palladium-on-carbon in the presence of equimolecular amount of hydrochloric acid gave similar results.

2-[1-(2-Acetamidophenyl)-1-hydroxyethyl]-4-quinolone (II). Crude compound I (159 mg) was dissolved in 4.2 m*l* of 2N sodium hydroxide. After removal of a little amount of insoluble material, the clear solution, chilled in an ice-bath, was treated with 0.2 m*l* of acetic anhydride. Trituration caused crystallization. Filtration, followed by washing with water and drying, yielded 128 mg of crystals, which, after recrystallization from aqueous ethanol, decomposed at 198—201°C. λ_{max} 239 (4.55), 315 (4.02), and 327 (4.03). ν_{max} 1664 and 1621 (C=O).

Found: C, 66.62; H, 5.58; N, 8.73%. Calcd for $C_{19}H_{18}O_3N_2 \cdot H_2O$: C, 67.04; H, 5.92; N, 8.23%.

2-[1-(2-Benzamidophenyl)-1-hydroxyethyl]-4-benzoyloxyquinoline (III). A solution of 168 mg of the crude compound I in 1.5 m*l* of 0.2N sodium hydroxide, chilled in ice, was treated with 0.1 m*l* of benzoyl chloride and triturated to deposit crystals, which weighed 100 mg. Recrystallization from methanol gave crystals melting at 169—170°C. λ_{max} 229 (4.55), 276 (3.99), and 315 (3.42). ν_{max} 1751 and 1669 (C=O). This material was analyzed after drying at 80°C for 1 hr.

Found: C, 75.51; H, 4.96; N, 5.80%. Calcd for $C_{31}H_{24}O_4N_2$: C, 76.21; H, 4.95; N, 5.73%.

2-[1-(2-Acetamidophenyl)-1-hydroxyethyl]-4-methoxyquinoline (IV). A suspension of 300 mg of the *N*-acetyl derivative II in 10 m*l* of methanol was treated with an ethereal solution of diazomethane prepared from 1.0 g of nitrosomethylurea. Evaporation of the solvent left crystals, which were recrystallized from 50% methanol to give *ca.* 170 mg of crystals melting at 168°C. λ_{max} 230 (4.86) and 313 (3.07). ν_{max} 1684 (C=O).

Found: C, 71.75; H, 6.18; N, 8.31%. Calcd for $C_{20}H_{20}O_3N_2$: C, 71.41; H, 5.99; N, 8.33%.

4-(4-Chloro-2-quinolyl)-2,4-dimethyl-4H-3,1-benzoxazine (V). A mixture of 0.80 g of the *N*-acetyl derivative II (monohydrate) and about 5 m*l* of phosphorus oxychloride was heated on a water bath, yielding a yellow solution immediately with evolution of hydrogen chloride. After being heated for 15 min, the mixture was removed from phosphorus oxychloride under reduced pressure and the residue poured into a mixture of ice and aqueous ammonia to separate brown precipitates. The mixture was extracted with ether; the extract was washed with sodium bicarbonate solution, dried and evaporated. Trituration of the residue with petroleum benzine yielded crystals, which, after filtration and subsequent washing with petroleum benzine, weighed 0.36 g. The crystals, after recrystallization from methanol–petroleum ether, melted at 125°C. λ_{max} 232 (4.80), 268 (4.03), 307 (3.62), and 320 (3.56). ν_{max} 1631 (C=N).

Found: C, 70.79; H, 4.98; N, 8.48%. Calcd for $C_{19}H_{15}ON_2Cl$: C, 70.69; H, 4.68; N, 8.68%.

2-[1-(2-Acetamidophenyl)ethyl]quinoline (VI). A mixture of 0.36 g of the chloride V, 0.20 g of sodium acetate trihydrate and 0.40 g of 5% palladium-on-carbon in 20 m*l* of ethanol containing 10 drops of water was hydrogenated at atmospheric pressure, absorbing 73 m*l* of hydrogen. After removal of the catalyst, evaporation of the solvent left a residue, which was taken in ether and washed with water. Evaporation of the dried ethereal solution left crystals, which, after recrystallization from ether–petroleum ether, weighed 0.21 g and melted at 115.5—116.5°C. λ_{max} 232 (4.70), 291 (3.58), 297 (3.56), 304 (3.68), 310 (3.57), and 317 (3.77). ν_{max} 1686 (C=O).

Found: C, 78.73; H, 6.35; N, 9.79%. Calcd for $C_{19}H_{18}ON_2$: C, 78.59; H, 6.25; N, 9.65%.

Oxidative Degradation into 2-Acetylquinoline. A mixture of 140 mg of the amide VI, 5 m*l* of water and 15 m*l* of N sulfuric acid was heated on a water bath for 8 hr. Into the cooled mixture, 8 m*l* of the Beckmann solution (prepared by dissolving 2.94 g of potassium dichromate in a little amount of water, adding 2.5 m*l* of concentrated sulfuric acid, and diluting to 25 m*l*) was added and stirred at the room temperature for 8 hr. After decomposition of the excess dichromate with ethanol, the mixture was made alkaline and extracted with ether. Evaporation of the ethereal solution gave a residue, which was distilled under a 5 Torr-pressure to give a fraction boiling at a bath temperature below 100°C. The distillate (λ_{max} 243 and 290), which gave a positive iodoform test, was converted into a semicarbazone (10 mg), decomposing at 239°C after recrystallization from ethanol. The infrared spectrum of the semicarbazone was not identical with that of 3-acetylquinoline[11] semicarbazone [mp 245°C

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2593—2597 (1972)

Aminocyclitols. XXVIII. Bromination of Inosamines and Inosadiamines

Tetsuo SUAMI, Seiichiro OGAWA, Shinichi YANAGIDA, and Kazuhiro NOJIMA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokahama

(Received January 22, 1972)

Bromination of four inosamines (*myo*-2 (**1**), *chiro*-1 (**2**), *muco*-1 (**3**), and *scyllo* (**4**)) and three inosadiamines (*neo*-1,4 (**11**), *muco*-1,5 (**14a,b**), and *muco*-1,4 (**19**)) with acetyl bromide and acetic anhydride in a sealed tube at 130—160°C has been studied. 2,5-Dibromo-2,5-dideoxy-*chiro*-inosamine-3 tetraacetate (**8**), was obtained from **1**, **2**, and **3**, and, as a monobromide, only 2-bromo-2-deoxy-*chiro*-inosamine-3 pentaacetate (**7**) could be isolated from the bromination product of **3**. From **11**, monobromide (**12**) and dibromide (**13**) were obtained. From **14a** or **14b**, 2-bromo-2-deoxy-*chiro*-inosadiamine-3,5 pentaacetate (**15**) was obtained, and, under a more drastic condition, **15** was further brominated to afford 1,5-dibromo-1,5-dideoxy-*chiro*-inosadiamine-2,4 tetraacetate (**16**). The bromo compounds so obtained were converted into the corresponding deoxy or dideoxy derivatives by hydrogenolysis. All the structures of the new compounds have been confirmed on the basis of proton magnetic resonance (PMR) spectroscopy using their acetyl derivatives. Considering from the structures of the bromides, a mechanism of a bromination reaction has been proposed.

In connection with the previous paper,[1] we wish to report the bromination of inosamines and inosadiamines with acetyl bromide and acetic anhydride at high temperature. Bromo-deoxyinosamines and -deoxy-inosadiamines are useful precursors for a preparation of the corresponding deoxy derivatives. We had already described the facile synthesis of 2-deoxy-streptamine from the key intermediary compound, 2-bromo-2-deoxystreptamine, which was obtained in a high yield by bromination of *myo*-inosadiamine-1,3.[2] In all the cases studies so far,[1-3] the hydroxyl groups vicinal and in *cis* position to an amino or acetamido group in aminocyclitols are preferentially displaced by bromine in a mixture of acetyl bromide and acetic anhydride. However, in the present report, it has been shown that, when there is a possibility of a displacement of more than one hydroxyl groups by bromine, a bromine atom was previously introduced in aminocyclitols following observed rule, whereas, the displacement of the second hydroxyl group was much influenced by a stereochemical and electronic environments.

When *myo*-inosamine-2 hydrochloride (**1**)[4] was treated with acetyl bromide in a sealed tube at 155—160°C for 8 hr, followed by acetylation, dibromo-dideoxyinosamine tetraacetate (**8**) was obtained mainly as a sole crystalline product in 32% yield. On treatment with acetyl bromide similarly as described above, both *N*-acetyl-*chiro*-inosamine-1 (**2**) and *N*-acetyl-*muco*-

inosamine-1 (**3**)[5] gave **8** in 16 and 11% yield, respectively. While, the reaction of **3** with acetyl bromide at 135—140°C for 4 hr gave bromo-deoxyinosamine pentaacetate (**7**) in 45% yield, along with a small amount of **8**. Hydrogenolysis of **7** and **8** in the presence of Amberlite IR-4B (OH^-) and Raney nickel T-4[6] afforded deoxy- (**9**) and dideoxy-inosamine (**10**) in 65 and 56% yield, respectively.

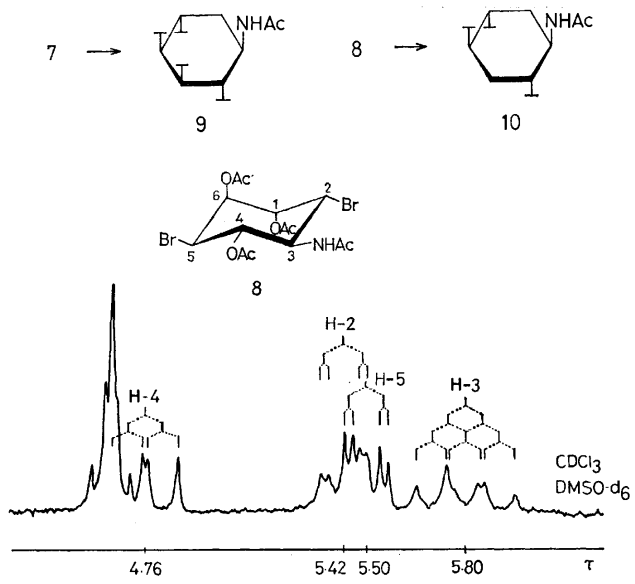

Fig. 1. Partial PMR spectrum of 2,5-dibromo-2,5-dideoxy-*chiro*-inosamine-3 tetraacetate (**8**) in a mixture of $CDCl_3$ and DMSO-d_6 at 100 MHz.

The structural elucidation of **7**, **8**, **9**, and **10** was carried out by means of the PMR spectroscopy. The PMR spectrum of **8** in a mixture of $CDCl_3$ and dimethylsulfoxide-d_6 (DMSO-d_6) at 100 MHz (Fig. 1) was in good accord with the structure, 2,5-dibromo-2,5-dideoxy-*chiro*-inosamine-3 tetraacetate. The wide sextet at τ 5.80 (J=9.5, 11.0, and 11.0 Hz) was assigned to C-3 proton that has two vicinal axial protons and indicated an axial-axial-axial arrangement for H-2, H-3, and H-4. Both H-2 and H-5 appeared as a quartet at τ 5.42 and 5.50, showing $J_{2,3}=J_{4,5}=11.0$ Hz and $J_{1,2}=J_{5,6}=2.0$ Hz, which was indicative of an equatorial-equatorial arrangement for H-1 and H-6. The wide doublet of doublet at τ 4.76 (J=9.5 and 11.0 Hz) was attributed to C-4 proton which demonstrated that one of the two bromine atoms is located at C-5. While, in the spectrum measured in $CDCl_3$, four acetyl methyl protons appeared at τ 7.78, 7.80, 7.88, and 8.00, which were assigned to an axial, an axial and an equatorial acetoxy, and an equatorial acetamido group, respectively.[7] Furthermore, the PMR spectrum of **10** in $CDCl_3$ at 100 MHz showed an octet at τ 5.75 which was assignable to H-3, since on deuteration it collapsed to a sextet. This result again indicated a diaxial arrangement for H-3 and H-4 and another bromine atom should attach equatorially to C-2. Therefore, the proposed structure of **8** was confirmed evidently.

In the PMR spectrum of **7** in $CDCl_3$, signals due to two protons attached to the carbon atoms having the acetamido group and bromine atom appeared around τ 5.50 as a complex multiplet, which probably suggested that they are located on a vicinal position. The acetyl methyl protons appeared as fine singlets at τ 7.83, 7.85, 7.92, 7.98, and 8.04, which were attributed to an axial, an axial, an equatorial and an equatorial acetoxy, and an equatorial acetamido group, respectively. Since **7** might be considered as the intermediary compound for **8** in the bromination reaction, its structure, taking an epimerization into account, should be either 2-bromo-2-deoxy-*chiro*-inosamine-3 or -*muco*-inosamine-3 pentaacetate. The latter might be likely the intermediary bromo-deoxy compound (**6**) from **2**, however, the formation of **6** could not be observed on bromination of **2** under a mild condition. Consequently, **7** was assigned to the former structure.

According to the results obtained, the mechanism of the bromination reaction might be proposed as follows. Initially, cyclic oxazolinium ions are formed between *cis* arranged acetamido and acetoxy groups by a front-side participation reaction.[8] Then they are opened by S_N2 attack of bromide ion to produce the bromo-deoxy compound (**5**, **6**, and **7**). Then, cyclic acetoxonium or oxazolinium ions are formed between remaining *cis* arranged groups and the cyclic ions are cleaved by nucleophlic attack of bromide ions or *trans*-situated adjacent groups.[9] The existence of an equilibrium (A⇄B⇄C⇄D) resulted from a rearrangement of a cyclic intermediary ion may be substantiated by the formation of the same dibromide **8** from **1**, **2**, and **3**, which additionally indicated that a bromide ion can only attack them in the most favorable configuration (B) satisfying the stereochemical and electronic requirement to afford one dibromide predominantly. For instance, in the similar halogenation reaction of cyclitols studied so far,[10] a vicinal dihalide has never been obtained.

Attempted bromination of *scyllo*-inosamine hydrochloride (**4**)[4] under a vigorous condition failed. Thus, even though the reaction temperature was raised up to 180°C, **4** was recovered as the hexaacetate from the reaction mixture. This result, like in the case of streptamine,[2] demonstrated that a formation of an intermediary oxazolinium ion initiates a nucleophilic attack of bromide ion.

Then the bromination of readily available *N*,*N*'-diacetyl-*neo*-inosadiamine-1,4 (**11**)[11] was attempted. On similar treatment with acetyl bromide and acetic anhydride (2: 1) at 145—150°C for 7 hr, **11** gave the acetates of bromodeoxyinosadiamine (**12**) and dibromo-

dideoxyinosadiamine (**13**) in a yield of 29 and 14%, respectively. By analogy with the proposed reaction mechanism, the structure of **12** and **13** may be deduced to be 5-bromo-5-deoxy-*myo*-inosadiamine-1,4 pentaacetate and 2,5-dibromo-2,5-dideoxy-*scyllo*-inosadiamine-1,4 tetraacetate, respectively. In the PMR spectrum of **12**, the signal due to one axial acetoxy group diminished and this accounted for one of the axial hydroxyl groups in **11** being replaced by bromine atom. The PMR spectrum of **13** gave two singlets in τ 8 region, indicating the symmetrical configuration of **13**. These PMR spectroscopic evidences are consistent with the proposed structures of **12** and **13**.

Secondarily, *N,N'*-diacetyl-*muco*-inosadiamine-1,5 (**14a**)[5] was subjected to the bromination reaction. It gave the bromo-deoxyinosadiamine pentaacetate (**15**) in 33% yield, on treatment with acetyl bromide and acetic anhydride (2: 1) at 140°C for 3 hr. While, when the same reaction was conducted at 145—150°C for 6 hr, the dibromo-dideoxyinosadiamine tetraacetate (**16**) was obtained mainly in 32% yield. From *muco*-inosadiamine-1,5 dihydrochloride (**14b**),[5] **16** was also obtained in 31% yield by a drastic condition. Hydrogenolysis of **15** and **16** afforded the corresponding deoxy- (**17**) and dideoxy-derivative (**18**) in 85 and 72% yield, respectively.

On the basis of the following PMR spectroscopic data, the structures of **15** and **16** were assigned to 2-bromo-2-deoxy-*chiro*-inosadiamine-3,5 pentaacetate and 1,5-dibromo-1,5-dideoxy-*chiro*-inosadiamine-2,4 tetraacetate, respectively, and **17** and **18** were assigned to the corresponding deoxy- and dideoxy-compound. The PMR spectrum of **15** in DMSO-d_6 revealed two singlets in an axial region of an acetoxy group, hence, one axial hydroxyl group in **14** must be replaced by bromine atom. Had the bromine atom been located at

a) PMR spectra were measured at 60 MHz, unless otherwise noted. Solvents were: A $CDCl_3$, B DMSO-d_6. The peak positions are given in τ-values.
b) Signal due to two equivalent methyl protons.
c) Measured at 100 MHz.

C-3, both **15** and **17** should have a symmetrical structure and their PMR spectra had to be simpler than those observed herein. Nonequivalence of the signals due to two axial acetoxy groups in **15** and two acetamido groups in **17** evidently indicated their unsymmetrical structures and the location of the bromine atom at C-2 (C-4) of **14**. The PMR spectrum of **18** showed three singlets (1 : 1 : 2) at τ 8 region, that were assigned to an axial and an equatorial acetoxy, and two equatorial acetamido groups, respectively. The signals due to ring protons were amenable to the first order analysis, that is, a narrow quintet at τ 4.97 (J=2.5 Hz) and a wide triplet at τ 5.93 (J=10.0 Hz) were readily assigned to H-6 and H-3 proton, respectively. A two protons octet at τ 5.73 (J=11.5, 10.0, 10.0, and 6.5 Hz) assignable to two equivalent protons at C-2 and C-4 showed that two acetamido groups were equivalent each other and adjacent to the equatorial acetoxy group and methylene protons. On the other hand, in the PMR spectrum of **16**, two singlets at τ 8.13 and 8.20 were assigned to the equatorial two acetamido groups. The presence of nonequivalent acetamido groups indicated that the arrangement of two bromine atoms adjacent to them should be 1,3-*trans* position. Therefore, the configuration of the bromine atom in **15** only remained equivocal. Since, in the PMR spectrum of **15** in DMSO-d_6, the signals corresponding to the ring protons attached to the carbon atoms having the acetamido groups and bromine atom appeared as a complex multiplet at τ 5.5—6.0, the configuration of the bromine

atom could not be determined by the first order analysis of them. However, by analogy with the proposed reaction mechanism of the bromination reaction, it might be reasonable that the cyclic oxazolinium ion initially formed is opened by a rearside attack of bromide ion and therefore the bromine atom in **15** is in *trans* configuration to the neighboring acetamido group. Then the second oxazolinium ion (E) seemed to be attacked by the adjacent *trans*-situated acetoxy group to produce another ion (F), which only undergoes nucleophilic attack of bromide ion to give **16**.

Bromination of *muco*-inosadiamine-1,4 dihydrochloride (**19**)[12] gave a complex mixture (at least four components were detected by tlc analysis) and no further isolation has been attempted.

Experimental

Melting points were determined on a Mitamura Riken micro hot stage and are uncorrected. PMR spectra were measured with a Varian A-60D (60 MHz) or HA-100D (100 MHz) spectrometer with tetramethylsilane as internal standard. IR spectra were recorded in KBr disks with Jasco IR-E infrared spectrophotometer. Tlc was performed on silica gel plates (Wakogel B-10) using methyl ethyl ketone–toluene (1 : 5 or 1 : 10) as the solvent system. The compounds were detected by heating with 30% sulfric acid. Evaporations were performed below 50°C under diminished pressure. Whenever pyridine was employed in a reaction, the residual pyridine was removed by repeated codistillation with dry toluene. All the compounds described in this paper are racemic.

N-*Acetyl*-chiro-*inosamine-1 (2).* *chiro*-Inosamine-1 hexaacetate[13] (3.0 g) was treated with methanol (20 m*l*), saturated with ammonia at 0—5°C, overnight at room temperature. Then the mixture was evaporated and the residue was recrystallized from 80% aqueous methanol to give colorless prisms (1.42 g, 41%) of **2**, mp 225—226°C (a transition was observed at 168—169°C). IR: 1640 and 1560 cm^{-1} (NHAc).

Found: C, 43.43; H, 6.84; N, 6.33%. Calcd for $C_8H_{15}NO_6$: C, 43.56; H, 7.06; N, 6.17%.

2-Bromo-2-deoxy-chiro-*inosamine-3 Pentaacetate (7).* A mixture of *N*-acetyl-*muco*-inosamine-1 (**3**)[5] (100 mg) and acetyl bromide (5 m*l*) was heated in a sealed tube at 135—140°C for 4 hr. After cooling to room temperature, the reaction mixture obtained from six sealed tubes was poured into ethanol (200 m*l*) and evaporated to dryness. The residue was treated with acetic anhydride (15 m*l*) and pyridine (15 m*l*) overnight at room temperature. Then an insoluble material was filtered off and the filtrate was evaporated to give crude crystals, which was recrystallized from ethanol to give crystals (602 mg, 45%) of **7**, mp 188—189°C. IR: 1750 (OAc), 1660 and 1575 cm^{-1} (NHAc).

Found: C, 42.73; H, 5.17; N, 3.45; Br, 18.04%. Calcd for $C_{16}H_{22}NO_9Br$: C, 42.50; H, 4.87; N, 3.10; Br, 17.70%.

2,5-Dibromo-2,5-dideoxy-chiro-*inosamine-3 Tetraacetate (8).* (a) A mixture of *myo*-inosamine-2 hydrochloride (**1**)[4] (150mg) and acetyl bromide (5 m*l*) was heated in a sealed tube at 155—160°C for 8 hr. The reaction mixture obtained from five sealed tubes was processed similarly as described under the preparation of **7**. The crude product was chromatographed on a column of activated aluminum oxide with chloroform. The eluates were evaporated to give an oily product which crystallized upon addition of ethanol to give crystals (615 mg, 32%) of **8**, mp 240—245°C. Recrystallization from ethanol afforded colorless needles (590 mg), mp 247—248°C. IR: 3240 (NH), 1755 (OAc), 1660 and 1580 cm^{-1} (NHAc).

Found: C, 35.72; H, 4.43; N, 3.08; Br, 33.52%. Calcd for $C_{14}H_{19}NO_7Br_2$: C, 35.56; H, 4.02; N, 2.96; Br, 33.90%.

(b) A mixture of **2** (220 mg) and acetyl bromide (4 m*l*) was heated in a sealed tube at 145—150°C for 6 hr. The reaction mixture obtained from three sealed tubes was processed as described in (a) to give crystals (223 mg, 16%) of **8**, mp 243—244°C.

(c) A mixture of **3** (100 mg) and acetyl bromide (5 m*l*) was heated in a sealed tube at 155—160°C for 8 hr. The reaction mixture obtained from ten sealed tubes was processed as described in (a) to give crystals (113 mg, 11%) of **8**, mp 244—245°C.

(d) Compound **2** was treated with acetyl bromide similarly as described under the preparation of **7**. *chiro*-Inosamine-1 hexaacetate was obtained in a high yield and tlc of the resulting reaction product showed one main component (*chiro*-inosamine-1 hexaacetate) along with two minor ones, one of which was shown to be corresponding to a reference sample of **8**. The unidentified component was considered to be the bromo-deoxy compound probably.

2-Deoxy-chiro-*inosamine-3 Pentaacetate (9).* A solution of **7** (350 mg) in 50% aqueous ethanol (20 m*l*) was catalytically hydrogenated in a Parr shaker type apparatus (4 kg/cm^2 of the initial hydrogen pressure) in the presence of Raney nickel T-4[6] and Amberlite IR-4B (OH^-) at 40—45°C for 20 hr. The catalyst and resin were removed by filtration and the filtrate was evaporated to give crude crystals (206 mg) which was recrystallized from ethanol to afford colorless needles (189 mg, 65%) of **9**, mp 208—209°C. IR: 1750 (OAc), 1660, 1640, and 1585 cm^{-1} (NHAc).

Found: C, 51.80; H, 6.29; N, 3.84%. Calcd for $C_{16}H_{23}NO_9$: C, 51.47; H, 6.21; N, 3.75%.

2,5-Dideoxy-chiro-*inosamine-3 Tetraacetate (10).* Compound **8** (297 mg) was hydrogenated similarly as described under the preparation of **9**. The crude crystals were recrystallized from ethanol to afford colorless crystals (110 mg 56%) of **10**, mp 149—151°C. IR: 1745 (OAc), 1640, and 1570 cm^{-1} (NHAc).

Found: C, 53.55; H, 7.24; N, 4.49%. Calcd for $C_{14}H_{23}NO_7$: C, 53.10; H, 7.26; N, 4.42%.

5-Bromo-5-deoxy-myo-*inosadiamine-1,4 Pentaacetate (12) and 2,5-Dibromo-2,5-dideoxy*-scyllo-*inosadiamine-1,4 Tetraacetate (13).* A mixture of *N,N'*-diacetyl-*neo*-inosadiamine-1,4 (**11**) (mp 324—326°C, lit,[11] 325—328°C) (104 mg), acetyl bromide (5 m*l*) and acetic anhydride (2 m*l*) was heated in a sealed tube at 145—150°C for 7 hr. Then the brown reaction mixture obtained from two sealed tubes was poured into cold ethanol (50 m*l*) and allowed to stand at room temperature overnight. The resulting precipitates were collected, dried and treated with acetic anhydride (3 m*l*) and pyridine (3 m*l*) overnight at room temperature. The acetate (13 mg) so obtained was identified with an authentic sample of *neo*-inosadiamine-1,4 hexaacetate[11] by IR spectral comparison. The alcoholic mother liquor was evaporated to dryness and the residue was acetylated as described above to give an oily product which crystallized upon addition of ethanol to afford crystals (54 mg, 15%) of **13**, mp 268—269°C. Recrystallization from ethanol gave an analytical sample of **13**, mp 272—273°C (decomp.). IR: 1750 (OAc), 1660, and 1540 cm^{-1} (NHAc).

Found: C, 35.78; H, 4.51; N, 6.11; Br, 33.31%. Calcd

12) T. Suami, F. W. Lichtenthaler, and S. Ogawa, This Bulletin, **40**, 1488 (1967).

for $C_{14}H_{20}N_2O_6Br_2$: C, 35.62; H, 4.27; N, 5.94; Br, 33.85%.

The mother liquor of **13** was condensed to a small volume and settled in a refrigerator overnight to give crystals (101 mg, 29%) of **12**, mp 257—259°C (decomp.). Recrystallization from ethanol gave colorless plates of **12**, mp 261—262°C (decomp.). IR: 1760 (OAc), 1655 and 1555 cm^{-1} (NHAc).

Found: C, 43.05; H, 5.64; N, 6.07; Br, 17.44%. Calcd for $C_{16}H_{23}N_2O_8Br$: C, 42.59; H, 5.14; N, 6.21; Br, 17.71%.

1,5-Dibromo-1,5-dideoxy-chiro-*inosadiamine-2,4 Tetraacetate (16).* (a) A mixture of *N,N'*-diacetyl-*muco*-inosadiamine-1,5 (**14a**)[5] (250 mg), acetyl bromide (4 m*l*) and acetic anhydride (2 m*l*) was heated in a sealed tube at 145—150°C for 6.5 hr. After keeping in a refrigerator overnight, the tube was opened carefully and the resulting precipitates were collected by filtration. The crude crystals were recrystallized from ethanol to afford crystals (420 mg, 32%) of **16**, mp 228—229°C (decomp.). IR: 1755 (OAc), 1660 and 1540 cm^{-1} (NHAc).

Found: C, 35.85; H, 4.53; N, 5.96; Br, 33.75%. Calcd for $C_{14}H_{20}N_2O_6Br_2$: C, 35.62; H, 4.27; N, 5.94; Br, 33.85%.

The filtrate of the reaction mixture was processed similarly as described under the preparation of **7** to give an oily product. Tlc showed a small proportion of a faster moving component along with **16** and *muco*-inosadiamine hexaacetate.[5]

(b) A mixture of *muco*-inosadiamine-1,5 dihydrochloride (**14b**)[5] (391 mg), acetyl bromide (4 m*l*) and acetic anhydride (2 m*l*) was heated in a sealed tube at 145—150°C for 6.5 hr. Then the reaction mixture was processed similarly as described in (a) to give crystals (226 mg, 31%) of **16**, mp 227—231°C (decomp.).

2-Bromo-2-deoxy-chiro-*inosadiamine-3,5 Pentaacetate (15).* A mixture of **14a** (209 mg), acetyl bromide (4 m*l*) and acetic anhydride (2 m*l*) was heated in a sealed tube at 140°C for 3 hr. After cooling to room temperature, the tube was opened and the precipitates were collected by filtration. Tlc of the reaction solution showed one main component along with one minor one, corresponding to a reference sample of **16**. The crude crystals were fractionally crystallized from ethanol to give crystals (104 mg, 29%) of **15**, mp 235—236°C, and crystals (15 mg, 4%) of **16**.

Found: C, 42.53; H, 5.30; N, 6.24; Br, 18.05%. Calcd for $C_{16}H_{23}N_2O_8Br$: C, 42.59; H, 5.14; N, 6.21; Br, 17.71%.

2-Deoxy-chiro-*inosadiamine-3,5 Pentaacetate (17).* Compound **15** (152 mg) was hydrogenated in 90% aqueous ethanol (30 m*l*) similarly as described under the preparation of **9**. The crude product was recrystallized from aqueous ethanol to give crystals (90 mg, 72%) of **17**, mp 290—293°C. IR: 1755 (OAc), 1650 and 1555 cm^{-1} (NHAc).

Found: C, 51.68; H, 6.74; N, 7.37%. Calcd for $C_{16}H_{24}N_2O_8$: C, 51.60; H, 6.50; N, 7.52%.

1,5-Dideoxy-chiro-*inosadiamine-2,4 Tetraacetate (18).* Compound **16** (675 mg) was hydrogenated similarly as described under the preparation of **17**. The crude crystals were recrystallized from ethanol to give colorless crystals (381 mg, 85%) of **18**, mp 260—262°C. IR: 1745 (OAc), 1660 and 1560 cm^{-1} (NHAc).

Found: C, 53.60; H, 7.29; N, 9.24%. Calcd for $C_{14}H_{22}N_2O_6$: C, 53.49; H, 7.05; N, 8.91%.

The authors are grateful to Professor Sumio Umezawa for his kind advice, to Mr. Saburo Nakada for his elementary analyses, and to Messrs. Hayashi Uchino, Yasutaro Yasuda, and Toshihide Ikeda for their assistance in the preparative experiments. The financial support from the Ministry of Education for this work is gratefully acknowledged.

Inositol Derivatives. IV.[1] Synthesis of Anhydro Derivatives of 1,2-*O*-Cyclohexylidene-inositol

Tetsuo SUAMI, Seiichiro OGAWA, Shuichi OKI, and Kumiko OHASHI
Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama
(Received March 1, 1972)

A reaction of 1,2-*O*-cyclohexylidene-*myo*-inositol tosylates with sodium methoxide in an appropriate solvent gave nine anhydro derivatives (mono- 6 and di-epoxide 3). The structures of new compounds were determined by proton magnetic resonance (PMR) spectroscopy and the reaction sequences.

Recent discovery of cyclohexane diepoxide tumor inhibitor, crotepoxide,[2] stimulated us to investigate a preparation of anhydro derivatives of inositols, which are also useful intermediary compounds for a synthesis of inositol derivatives.

In 1947, Schöpf and Arnold[3] first reported a synthesis of 2,3-anhydro-*allo*-inositol from conduritol A by a treatment with peracid. Later, Nakajima *et al.*[4] described six inositol epoxides (conduritol epoxides) which were obtained from five conduritols derived from benzene-glycol. Very recently, Gero *et al.*[5] have described the preparation of 1L- and DL-1,2-anhydro-*chiro*- and 1L-1,2-anhydro-*myo*-inositol, and their biological activities were

examined. However, inositol diepoxide has never been described until now.

In the present paper, we wish to report a synthesis of mono- and di-epoxides of inositols from 1,2-*O*-cyclohexylidene-*O*-*p*-toluenesulfonyl-*myo*-inositols[6] by a treatment with sodium methoxide in an appropriate solvent. The structures of new compounds were established mainly by way of their PMR spectroscopy and the reaction sequences.

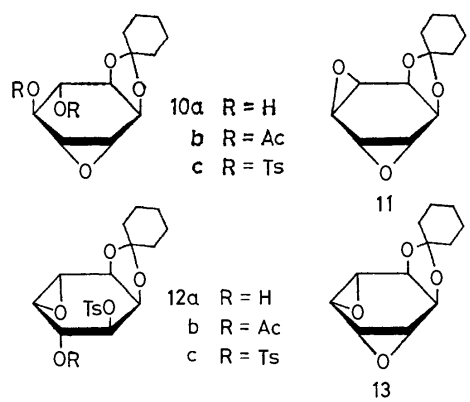
When 1,2-*O*-cyclohexylidene-3-*O*-*p*-toluenesulfonyl-*myo*-inositol (**1**) was treated with a slight excess of sodium methoxide in methanol at room temperature for 3 hr, 1,2-anhydro-5,6-*O*-cyclohexylidene-*chiro*-inositol (**10a**) was obtained almost exclusively in 80—90% yield.



Acetylation of **10a** with acetic anhydride and pyridine afforded the diacetate (**10b**). On treatment with *p*-toluenesulfonyl chloride in pyridine, **10a** gave the di-*O*-*p*-toluenesulfonate (**10c**). The PMR spectrum of **10b** in deuteriochloroform ($CDCl_3$) at 60 MHz (Fig. 1) was fully resolved by a first-order method and all signals were assigned unambiguously to the protons. The two protons (H-1 and H-2) attached to the epoxide ring appeared as two doublets ($J_{1,2}$ 3.0 Hz) at τ 6.73, and 6.51. Also small coupling constants ($J_{2,3}$ and $J_{1,6}$) were observed, which indicated that the epoxide ring was situated *trans* to the vicinal substituents.[7] The two protons (H-5 and H-6) appeared as double doublet and doublet ($J_{4,5}$ 8.0 Hz, $J_{5,6}$ 5.5 Hz) at τ 5.98 and 5.35, respectively. Therefore, the epoxide ring was shown to be located on C-1 and C-2. The remaining doublet and triplet ($J_{3,4}$ 8.0 Hz) at τ 5.06 and 4.80 were ascribed to H-3 and H-4, respectively. While, in the spectrum of **10c**, the two protons (H-1 and H-2) appeared as 2-proton singlet at τ 6.66. The triplet, 2-proton doublet, and triplet (J 6.0 Hz) appeared at τ 5.98, 5.33, and 5.16, which could be attributed to H-5, H-3 and H-6, and H-4, respectively. Consequently, the proposed structure was evidently confirmed by the PMR spectral data, and it was shown that a migration of an oxide-ring did not occur under the condition used.

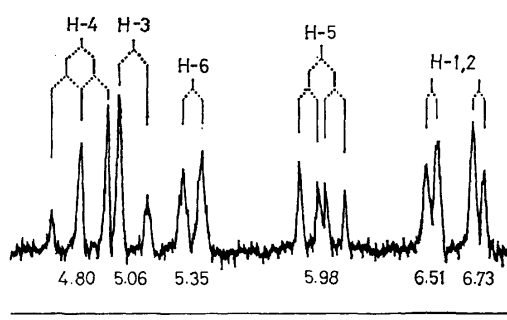


Fig. 1. Partial PMR spectrum of 3,4-*O*-acetyl-1,2-anhydro-5,6-*O*-cyclohexylidene-*chiro*-inositol (**10b**) in $CDCl_3$ at 60 MHz.

Five di-*O*-*p*-toluenesulfonyl derivatives of 1,2-*O*-cyclohexylidene-*myo*-inositol were then treated successively with sodium methoxide. The 3,6-di-*O*-*p*-toluenesulfonate (**2**)[6] was reacted with a slight excess of sodium methoxide in methanol overnight at room temperature to give the diepoxide (**11**) in 87% yield. The PMR spectrum of **11** in $CDCl_3$ (Fig. 2) revealed three multiplets (τ 6.73, 6.53, and 6.40) due to four protons attached to two epoxide rings, which was indicative of the unsymmetrical structure of **11**, hence, the epoxide rings were in *trans* arrangement each other. The two protons (H-3 and H-4) attached to the carbon atoms bonding to the cyclohexylidene group appeared at τ 5.59 and 5.36 as double doublet and broad doublet ($J_{3,4}$ 6.0 Hz, $J_{2,3}$ 3.0 Hz), respectively. Therefore, **11** was assigned to 1,2: 5,6-dianhydro-3,4-*O*-cyclohexylidene-*allo*-inositol.

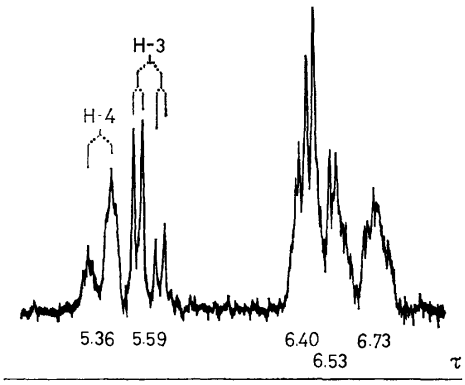

Fig. 2. Partial PMR spectrum of 1,2: 5,6-dianhydro-3,4-*O*-cyclohexylidene-*allo*-inositol (**11**) in $CDCl_3$ at 60 MHz.

By the similar treatment with sodium methoxide, the monoepoxide (**12a**) was obtained in a yield of 76% from the 3,5-di-*p*-toluenesulfonate (**3**).[6] A more drastic condition was needed for converting **3** into the

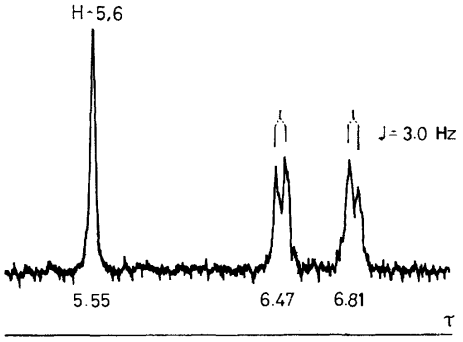

Fig. 3. Partial PMR spectrum of 1,2: 3,4-dianhydro-5,6-*O*-cyclohexylidene-*allo*-inositol (**13**) in $CDCl_3$ at 60 MHz.

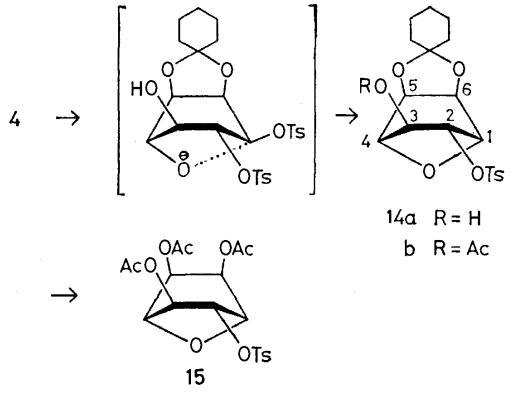
diepoxide **13**. Thus, **3** was treated with an excess of sodium methoxide in boiling 2-methoxyethanol for 10 min to afford **13** in 28% yield. Monitoring the reaction using thin layer chromatography (tlc), **12a** was found to be an intermediate compound for further epoxidation to **13**. Compound **12a** was transformed into the monoacetate (**12b**) and di-*p*-toluenesulfonate (**12c**), respectively, by the usual way. Since **12c** was shown to be different from **10c**, **12a** must be either 1,2-anhydro-5,6-*O*-cyclohexylidene-4-*O*-*p*-toluenesulfonyl- or 1,2-anhydro-4,5-*O*-cyclohexylidene-6-*O*-*p*-toluenesulfonyl-*neo*-inositol. The latter can not give the diepoxide and could be excluded, therefore, **12a** was assigned to the former structure. And **13** was deduced to be 1,2: 3,4-dianhydro-5,6-*O*-cyclohexylidene-*allo*-inositol. The PMR spectrum of **13** in $CDCl_3$ (Fig. 3) revealed a simple pattern of signals for the ring protons, showing a symmetrical 1,3-*cis* diepoxide structure of **13**. The signals for H-4 and H-3 protons of **12b** appeared as two double doublets ($J_{3,4}$ 9.0 Hz, $J_{4,5}$ 2.0 Hz, and $J_{2,3}$ 1.5 Hz) at τ 5.17 and 4.43, respectively. In **12c**, the lower double doublet (H-3) upshifted[6] relatively by *ca.* 0.3 ppm (τ 4.78), comparing with that of **12b**, which showed that the acetoxy group was located at C-3 position in **12b**.



On a similar treatment, the 3,4-di-*p*-toluenesulfonate (**4**)[6] gave the monoepoxide (**14a**) in 67% yield. Compound **14a** was converted into the oily acetate (**14b**). Removal of the cyclohexylidene group of **14a** with boiling 80% aqueous acetic acid, followed by acetylation, afforded the triacetate (**15**) in 69% yield. By analogy, a structure of **14a** was initially considered to be 1,2-anhydro-4,5-*O*-cyclohexylidene-3-*O*-*p*-toluenesulfonyl-*epi*-inositol. However, the PMR spectra of **14a**, **14b**, and **15** in $CDCl_3$ lacked the signals of 1,2-epoxide ring protons in the region of τ 6.40—6.90[8] (Fig. 4). Furthermore, when **4** was treated with an excess of sodium azide in boiling 2-methoxyethanol for 20 hr, **14a** was surprisingly obtained in 73% yield almost exclusively. Under the azidation condition described above, all the *p*-toluenesulfonates studied so far[9] were smoothly converted into the expected azido compounds *via* intermediate 1,2-epoxides. Since the 1,2-epoxide structure could not account for both the unusual stability for the powerful nucleophilic reagent and the spectral data, **14a** was assumed to be 1,4-anhydro-5,6-*O*-cyclohexylidene-2-*O*-*p*-toluenesulfonyl-*chiro*-inositol. Therefore, it might be considered that in the compound **4** an attack of 5-hydroxyl group on C-4 is restricted by a stereochemical environment, and then, another hydroxyl group on C-6 attacks rear-side of C-3 in a boat conformation to form a transannular epoxide (1,4-anhydro ring).

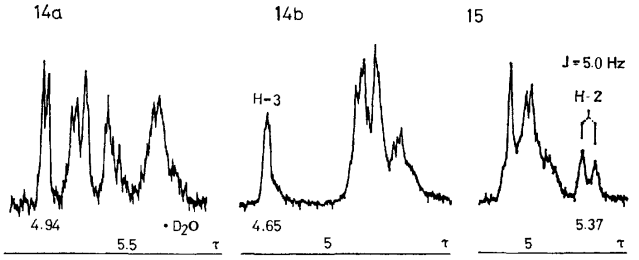


Fig. 4. Partial PMR spectra of 1,4-anhydro-5,6-*O*-cyclohexylidene-2-*O*-*p*-toluenesulfonyl-*chiro*-inositol (**14a**), its 3-*O*-acetate (**14b**), and 3,5,6-tri-*O*-acetyl-1,4-anhydro-2-*O*-*p*-toluenesulfonyl-*chiro*-inositol (**15**) in $CDCl_3$ at 60 MHz.

1-*O*-Benzoyl-2,3-*O*-cyclohexylidene-4,6-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**5**), which was obtained by a selective *p*-toluenesulfonylation of 1-*O*-benzoyl-2,3-*O*-cyclohexylidene-*myo*-inositol,[10] was subjected to an epoxidation to give the diepoxide (**16**) in 19% yield.

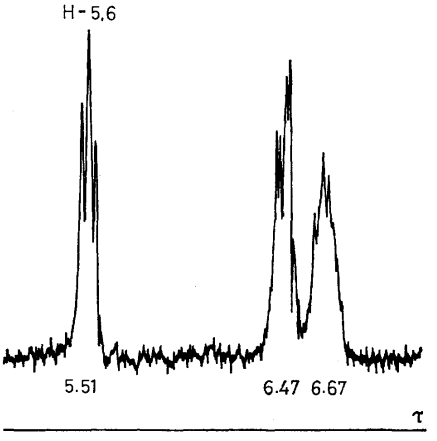

Fig. 5. Partial PMR spectrum of 1,2: 3,4-dianhydro-5,6-*O*-cyclohexylidene-*cis*-inositol (**16**) in $CDCl_3$ at 60 MHz.

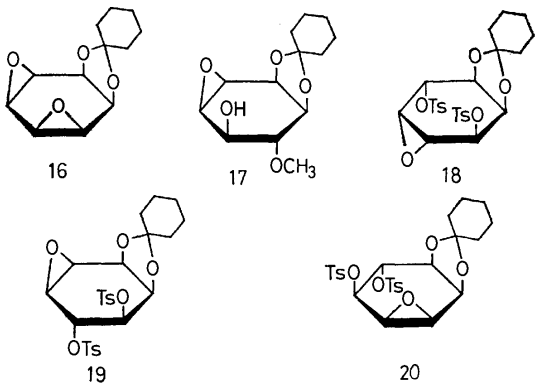
8) Observed in the PMR spectra of eleven epoxides prepared in this study.

9) T. Suami, S. Ogawa, T. Tanaka, and S. Oki, in preparation. A part of the work had been reported at the Annual Meeting of the Chemical Society of Japan, Osaka, April, 1971.

10) T. Suami, S. Ogawa, K. Ohashi, and S. Oki, This Bulletin, in press.

Monitoring the reaction by tlc, it was found that **5** was slowly converted into **16** and **16** so formed gradually reacted with methoxide ion to give rise to a monomethyl ether (**17**). Thus, when **5** was treated with 7 molar equivalent of sodium methoxide in methanol at room temperature for 2 days, **17** was obtained mainly in 48% yield. Considering from the reaction sequence, **16** was assigned to 1,2:3,4-dianhydro-5,6-*O*-cyclohexylidene-*cis*-inositol. The PMR spectrum of **16** in $CDCl_3$ (Fig. 5) revealed symmetrical three multiplets due to three pairs of equivalent protons at τ 6.67, 6.47, and 5.51, supporting the *cis*-1,3-diepoxide structure. Compound **17** was assigned to 2,3-anhydro-4,5-*O*-cyclohexylidene-6-*O*-methyl-*epi*-inositol by the PMR spectral data. In the PMR spectrum of **17**, all the signals could not be well resolved by a first-order method, except those due to the two protons on C-4 and C-5. Thus, the double doublet at τ 5.39 was assigned to H-4 proton ($J_{3,4}$ 3.0 Hz, $J_{4,5}$ 7.0 Hz), which was closely related to that of **20** (τ 5.40, $J_{3,4}$ 2.5 Hz, $J_{4,5}$ 7.0 Hz). The broad doublet at τ 5.74 (H-5) seemed to be corresponding to that of **20** (τ 5.89).



From 4-*O*-acetyl-1-*O*-benzoyl-2,3-*O*-cyclohexylidene-*myo*-inositol (**6**),[10] **11** was obtained in a yield of 69% by similar treatment with sodium methoxide.

Three tri-*O*-*p*-toluenesulfonyl derivatives of 1,2-*O*-cyclohexylidene-*myo*-inositol were treated analogously with sodium methoxide. The 3,5,6-tri-*p*-toluenesulfonate (**7**)[6] gave the monoepoxide (**18**) in 60% yield, which was shown to be different from **10c**. And, **18** was assigned to 1,2-anhydro-4,5-*O*-cyclohexylidene-3,6-di-*O*-*p*-toluenesulfonyl-*neo*-inositol. In **7**, an oxide anion at C-4 seemed to attack preferentially the 5-carbon atom to give rise to the 4,5-epoxide derivative. The PMR spectrum of **18** in $CDCl_3$ showed three multiplets at τ 6.46, 5.81, and 4.91, which were ascribed to H-1 and H-2, H-4 and H-5, and H-3 and H-6, respectively.

While, the 3,4,6-tri-*p*-toluenesulfonate (**8**)[6] gave, on a similar treatment, the monoepoxide (**19**) in 84% yield. Two structures were possible for **19**: 1,2-anhydro-3,4-*O*-cyclohexylidene-5,6-di-*O*-*p*-toluenesulfonyl- and 1,2-anhydro-4,5-*O*-cyclohexylidene-3,6-di-*O*-*p*-toluenesulfonyl-*epi*-inositol. If **19** had the latter structure, its PMR spectrum should rather resemble that of **18** than that of **12c**, but, substantially the resemblance between the spectra of **19** and **12c** was observed. An oxide anion at C-5 was also expected to attack 6-carbon atom favorably, considering from the result obtained in the case of **4**. Then **19** was assigned to the former structure.

The similar treatment of 1-*O*-benzoyl-2,3-*O*-cyclohexylidene-4,5,6-tri-*O*-*p*-toluenesulfonyl-*myo*-inositol (**9**)[10] with sodium methoxide afforded 2,3-anhydro-4,5-*O*-cyclohexylidene-1,6-*O*-*p*-toluenesulfonyl-*epi*-inositol (**20**) in 82% yield. The proposed structure was supported not only by the reaction sequence, but also by the PMR spectrum.

Experimental

Melting points were determined on a Mitamura Riken micro hot stage and are uncorrected. IR spectra were measured on a Jasco IR-E spectrophotometer in KBr disks. PMR spectra were measured on a Varian A-60D spectrometer at a concentration of *ca.* 10% deuteriochloroform ($CDCl_3$) or dimethyl sulfoxide-d_6 (DMSO-d_6) with tetramethylsilane as an internal standard. Chemical shifts are expressed in τ-values and signals are expressed as s (singlet), dd (double doublet), t (triplet), and m (complex multiplet). Values given for coupling constants are first-order. Tlc was performed using silica gel (Wakogel B-10, Wako Pure Chemical Industries Ltd.) using methyl ethyl ketone and toluene or benzene and ethyl acetate as the solvent system. The compounds were detected by heating at 100°C after spraying 30% sulfuric acid. Evaporation was performed by a rotary evaporator below 50°C under diminished pressure. Unless otherwise noted, methanol solution of sodium methoxide (0.1 M) used in this experiment was prepared by dissolving sodium (0.23 g) in absolute methanol (100 m*l*). All the compounds described in this paper are racemic.

*1,2-Anhydro-5,6-*O*-cyclohexylidene-*chiro*-inositol (**10a**).* 1,2-*O*-Cyclohexylidene-3-*O*-*p*-toluenesulfonyl-*myo*-inositol (**1**)[6] (5.0 g) was dissolved in hot methanol (100 m*l*) and cooled to room temperature. To the solution was added methanol (20 m*l*) containing 1.5 molar equivalent of sodium methoxide, and the mixture was kept at room temperature for 3 hr. Then the solution was evaporated to dryness and the residue was partitioned between chloroform and water. The organic layer was washed with water, dried over anhydrous sodium sulfate and evaporated to give practically pure crystals (2.63 g, 90%) of **10a**, mp 91—98°C. Recrystallization from ethanol-ether gave analytically pure needles (1.69 g, 58%), mp 109—110°C. PMR ($CDCl_3$): τ 6.68 (1-proton dd, $J_{1,2}$= 4.0 Hz, $J_{1,6}$=1.0 Hz, H-1), 6.50 (1-proton m, H-2), 5.90 (2-protons m, H-3,4), 5.60 (1-proton dd, $J_{4,5}$=4.0 Hz, $J_{5,6}$= 6.0 Hz, H-5), and 5.32 (1-proton d, H-6).

Found: C, 59.40; H, 7.29%. Calcd for $C_{12}H_{18}O_5$: C, 59.49; H, 7.49%.

*3,4-*O*-Acetyl-1,2-anhydro-5,6-*O*-cyclohexylidene-*chiro*-inositol (**10b**).* Compound **10a** (100 mg) was treated with acetic anhydride (0.5 m*l*) and pyridine (1 m*l*) overnight at room temperature. Then the mixture was poured into ice and water (25 m*l*), and the resulting colorless needles were collected by filtration: yield 124 mg (92%), mp 102—103°C. Recrystallization from ethanol afforded colorless prisms, which showed the same melting point.

Found: C, 59.25; H, 7.02%. Calcd for $C_{16}H_{22}O_7$: C, 58.88; H, 6.80%.

*1,2-Anhydro-5,6-*O*-cyclohexylidene-3,4-*O*-toluenesulfonyl-*chiro-*inositol (**10c**).* To a solution of **10a** (100 mg) in dry pyridine (2 m*l*) was added *p*-toluenesulfonyl chloride (0.24 g, 3 molar equivalent) and the mixture was kept at room temperature for 2 days. Tlc indicated two main components, probably two mono-*p*-toluenesulfonates, together with **10a**.

Then an additional portion of *p*-toluenesulfonyl chloride (470 mg, 6 molar equivalent) in dry pyridine (2 m*l*) was added to the mixture and the solution was kept at 25°C for 3 days. Then the reaction mixture was poured into ice and water and the resulting oily product was extracted with chloroform several times. The combined extracts were washed with water, dried over anhydrous sodium sulfate and evaporated to give an oily residue which crystallized upon addition of chloroform–ethanol to afford colorless crystals, (90 mg, 40%) of **10c**, mp 110—111°C. Recrystallization from the same solvent gave an analytical sample, mp 115—117°C. PMR ($CDCl_3$): τ 7.55 (6-protons s, 2 OTs), 6.66 (2-protons s, H-1,2), 5.98 (1-proton t, $J_{4,5}=J_{5,6}=6.0$ Hz, H-5), 5.33 (2-protons d, $J_{2,3}=J_{1,6}=0$ Hz, $J_{3,4}=6.0$ Hz, H-3,6), and 5.16 (1-proton t, H-4).

Found: C, 56.60; H, 5.37; S, 11.78%. Calcd for $C_{26}H_{30}O_9S_2$: C, 56.70; H, 5.49; S, 11.64%.

*1,2: 5,6-Dianhydro-3,4-*O*-cyclohexylidene*-allo-*inositol (11).* (a) To a solution of 1,2-*O*-cyclohexylidene-3,6-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**2**)[6] (2.0 g) in methanol (40 m*l*) was added methanolic sodium methoxide (7.3 m*l*, 2 molar equivalent) and the reaction mixture was kept overnight at room temperature. The residue remaining on evaporation of the solvent was extracted several times with ethyl acetate, and the combined extracts were evaporated to give a crystalline product. The crystals were digested with methanol and collected by filtration: yield 0.70 g (87%), mp 142—144°C. Recrystallization from chloroform–ethanol gave an analytical sample, mp 143—144°C.

Found: C, 64.64; H, 7.46%. Calcd for $C_{12}H_{16}O_4$: C, 64.26; H, 7.19%.

(b) Treatment of 4-*O*-acetyl-1-*O*-benzoyl-2,3-*O*-cyclohexylidene-5,6-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**6**)[10] (146 mg) with methanolic sodium methoxide (1.1 m*l*, 5 molar equivalent) in a mixture of chloroform (3 m*l*) and methanol (2 m*l*) similarly as described above afforded colorless plates (32 mg, 69%) of **11**, mp 141.5—143.5°C.

*1,2-Anhydro-5,6-*O*-cyclohexylidene-4-*O*-p-toluenesulfonyl-*neo-*inositol (12a).* To a solution of 1,2-*O*-cyclohexylidene-3,5-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**3**)[6] (0.20 g) in a mixture of chloroform (10 m*l*) and methanol (2 m*l*) was added methanolic sodium methoxide (1.1 m*l*, 3 molar equivalent) and the reaction mixture was kept overnight at room temperature. Then the mixture was processed similarly as described under the preparation of **11** to give the oily product, which crystallized upon addition of methanol. The crystals were digested with petroleum ether and collected by filtration: colorless needles, yield 0.11 g (76%), mp 142—144°C. An analytical sample was obtained by recrystallization from chloroform–ethanol: colorless prisms, mp 154—155°C.

Found: C, 57.75; H, 5.99; S, 8.38%. Calcd for $C_{19}H_{24}O_7S$: C, 57.55; H, 6.10; S, 8.09%.

*3-*O*-Acetyl-1,2-anhydro-5,6-*O*-cyclohexylidene-4-*O*-p-toluenesulfonyl-*neo-*inositol (12b).* Compound **12a** (62 mg) was acetylated with acetic anhydride (1 m*l*) and pyridine (2 m*l*) overnight at room temperature. The reaction mixture was then poured into ice and water and the precipitates were collected by filtration. Recrystallization from chloroform–ethanol gave colorless rods (58 mg, 85%) of **12a**, mp 149—150°C. PMR ($CDCl_3$): τ 8.14 (3-protons s, OAc), 7.53 (3-protons s, OTs), 6.82 and 6.55 (1-proton d, $J_{1,2}=4.0$ Hz, H-1 and H-2), 5.48 (2-protons m, H-5,6), 5.17 (1-proton dd, $J_{3,4}=9.0$ Hz, $J_{4,5}=2.0$ Hz, H-4), and 4.43 (1-proton dd, $J_{2,3}=1.5$ Hz, H-3).

Found: C, 57.53; H, 5.86; S, 7.44%. Calcd for $C_{21}H_{26}O_8S$: C, 57.50; H, 5.98; S, 7.31%.

*1,2-Anhydro-5,6-*O*-cyclohexylidene-3,4-di-*O*-p-toluenesulfonyl-*neo-*inositol (12c).* Compound **12a** (51 mg) in dry pyridine (2 m*l*) was treated with *p*-toluenesulfonyl chloride (74 mg, 3 molar equivalent) at room temperature for 3 days and then at 80—85°C for 10 min. The reaction mixture was poured into water (50 m*l*) and extracted with chloroform (20 m*l*) several times. The combined extracts were washed with water, dried over anhydrous sodium sulfate and evaporated to give an oily product. Tlc showed a main component together with several minor ones. Then the crude product was chromatographed on a column of silica gel (Wakogel C-200, 20 g) and eluted with methyl ethyl ketone–toluene (1:4). The main fractions were combined and evaporated to give a crystalline residue. Crystallization from chloroform–ethanol gave colorless prisms (48 mg, 47%) of **12c**, mp 168—168.5°C. PMR ($CDCl_3$): τ 7.55 (6-protons s, 2 OTs), 6.85 and 6.45 (1-proton dd, $J_{1,2}=4.0$ Hz, H-1 and H-2), 5.53 (2-protons s, H-5,6), 5.26 (1-proton dd, $J_{3,4}=9.0$ Hz, $J_{4,5}=1.5$ Hz, S-4), and 4.78 (1-proton dd, $J_{2,3}=1.5$ Hz, H-3).

Found: C, 56.66; H, 5.38; S, 11.71%. Calcd for $C_{26}H_{30}O_9S_2$: C, 56.70; H, 5.49; S, 11.64%.

*1,2: 3,4-Dianhydro-5,6-*O*-cyclohexylidene-*allo-*inositol (13).* To a solution of **3** (0.50 g) in 2-methoxyethanol (30 m*l*) was added methanolic sodium methoxide (2.7 m*l*, 3 molar equivalent) and the mixture was refluxed for 10 min. Monitoring the reaction by tlc, it was found that **12a**, as well as **3**, completely disappeared and **13** formed gradually underwent nucleophilic attack of methoxide ion to give rise to the slower moving component, probably a monomethyl ether. The brown reaction mixture was evaporated to dryness and the residue was extracted with ethyl acetate. Evaporation of the extracts gave a crystalline product which was chromatographed on a silica gel (20 g) and eluted with methyl ethyl ketone–toluene (1:4). The fractions containing the faster moving component were combined and evaporated to give colorless plates (56 mg, 28%) of **13**, mp 104—110°C. Recrystallization from ethyl acetate afforded an analytical sample, mp 111.5—112.5°C.

Found: C, 64.27; H, 6.95%. Calcd for $C_{12}H_{16}O_4$: C, 64.26; H, 7.19%.

*1,4-Anhydro-5,6-*O*-cyclohexylidene-2-*O*-p-toluenesulfonyl-*chiro-*inositol (14a).* (a) To a solution of 1,2-*O*-cyclohexylidene-3,4-*O*-*p*-toluenesulfonyl-*myo*-inositol (**4**)[6] (100 mg) in a mixture of chloroform (3 m*l*) and methanol (4 m*l*) was added methanolic sodium methoxide (0.36 m*l*, 2 molar equivalent) and the reaction mixture was kept overnight at room temperature. The mixture was processed similarly as described under the preparation of **11** to give an oily product which crystallized upon addition of ethanol to give colorless prisms (47 mg, 67%) of **14a**, mp 114—115°C. Recrystallization from ethanol afforded an analytical sample. The melting point did not change. PMR ($CDCl_3$): τ 7.53 (3-protons s, OTs).

Found: C, 57.57; H, 6.23; S, 8.07%. Calcd for $C_{19}H_{24}O_7S$: C, 57.30; H, 6.06; S, 8.08%.

(b) A mixture of **4** (1.08 g), sodium azide (1.09 g) and 90% aqueous 2-methoxyethanol (20 m*l*) was refluxed for 20 hr. Then the reaction mixture was evaporated to dryness and dried by repeated co-distillation with toluene. The residue was extracted with hot ethyl acetate and the extracts were evaporated to give colorless crystals (0.55 g, 73%) of **14a**, mp 114—116°C. This compound was identified with the product obtained in (a) by IR and PMR spectral comparison.

Compound **14a** was acetylated with acetic anhydride and pyridine in the usual way to give the oily acetate (**14b**). Tlc indicated a single spot in methyl ethyl ketone–toluene (1:4). PMR ($CDCl_3$): τ 8.08 (3-protons s, OAc) and 7.55 (3-protons s, OTs).

3,5,6-Tri-O-acetyl-1,4-anhydro-2-O-p-toluenesulfonyl-chiro-inositol (**15**). Compound **14a** (0.21 g) was refluxed with 80% aqueous acetic acid (10 ml) for 3 hr. The reaction mixture was evaporated to dryness and the residue was treated with acetic anhydride (5 ml) and pyridine (5 ml) overnight at room temperature. Then the mixture was evaporated with toluene to give a yellow oil, which was dissolved in ethyl acetate and chromatographed on a column of aluminum oxide (5 g). The eluate was evaporated to give a oily product which crystallized by trituration with ethanol: colorless crystals, yield 0.16 g (69%), mp 124.5—125.5°C. An analytical sample was obtained by recrystallization from ethanol, mp 125—126°C. PMR ($CDCl_3$): τ 7.98 (6-protons s, 2 OAc), 7.86 (3-protons s, OAc) and 7.53 (3-protons s, OTs).

Found: C, 51.51; H, 5.14; S, 7.52%. Calcd for $C_{19}H_{22}O_{10}S$: C, 51.60; H, 4.98; S, 7.24%.

*1,2: 3,4-Dianhydro-5,6-O-cyclohexylidene-*cis*-inositol* (**16**). To a solution of 1-*O*-benzoyl-2,3-*O*-cyclohexylidene-4,6-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**5**)[10] (0.30 g) in a mixture of methanol (4 ml) and methyl ethyl ketone (6 ml) was added methanolic sodium methoxide (1.6 ml, 3.5 molar equivalent) and the mixture was kept overnight at room temperature. Then the reaction mixture was processed similarly as described under the preparation of **11** to give an oily product. Tlc indicated two main components. The crude mixture was then chromatographed on a column of silica gel (20 g) and eluted with methyl ethyl ketone-toluene (1:3). The fractions containing the slower moving component were combined and evaporated to give colorless plates (19 mg, 19%) mp 129—131°C. An analytical sample was obtained by recrystallization from ethyl acetate–petroleum ether, mp 130—131°C.

Found: C, 64.04; H, 7.29%. Calcd for $C_{12}H_{16}O_4$: C, 64.26; H, 7.19%.

*2,3-Anhydro-4,5-O-cyclohexylidene-6-O-methyl-*epi*-inositol* (**17**). (a) To a solution of **5** (0.30 g) in a mixture of methanol (4 ml) and methyl ethyl ketone (6 ml) was added methanolic sodium methoxide (1.6 ml, 3.5 molar equivalent) and the solution was kept overnight at room temperature. Then an additional amount of methanolic sodium methoxide (1.6 ml) was added and, after 24 hr, the mixture was evaporated to dryness and the residue was processed similarly as described under the preparation of **11** to give crude crystals (66 mg, 48%). It was recrystallized from ethyl acetate–petroleum ether to afford colorless needles (48 mg) of **17**, mp 96—98°C. PMR ($CDCl_3$): τ 6.51 (2-protons m, H-2,3), 6.45 (3-protons s, OCH_3), and 6.10 (2-protons broad s, H-4,5).

Found: C, 61.16; H, 7.52%. Calcd for $C_{13}H_{20}O_5$: C, 60.91; H, 7.87%.

(b) Compound **5** (0.40 g) was dissolved in a mixture of chloroform (8 ml) and methanol (4 ml) and methanolic sodium methoxide (1.12 ml, 3.5 molar equivalent) was added. The mixture was kept at room temperature for 17 days and then processed similarly as described in (a) to give colorless crystals (40 mg, 20%) of **17**.

*1,2-Anhydro-4,5-O-cyclohexylidene-3,6-di-O-p-toluenesulfonyl-*neo*-inositol* (**18**). To a solution of 1,2-*O*-cyclohexylidene-3,5,6-tri-*O*-*p*-toluenesulfonyl-*myo*-inositol (**7**)[6] (0.20 g) in a mixture of chloroform (4 ml) and methanol (2 ml) was added methanolic sodium methoxide (0.56 ml, 2 molar equivalent) and the reaction mixture was kept at room temperature for 1 hr. Then the mixture was processed similarly as described under the preparation of **11** to give crude crystals. It was digested with methanol and collected by filtration: colorless needles, yield 91 mg (60%), mp 190—191°C. Recrystallization from chloroform–ethanol gave an analytical sample. The melting point did not change. PMR ($CDCl_3$); τ 7.57 (6-protons s, 2 OTs).

Found: C, 56.48; H, 5.39; S, 11.31%. Calcd for $C_{26}H_{30}O_9S_2$: C, 56.70; H, 5.49; S, 11.64%.

*1,2-Anhydro-3,4-O-cyclohexylidene-5,6-di-O-p-toluenesulfonyl-*epi*-inositol* (**19**). To a solution of 1,2-*O*-cyclohexylidene-3,4,6-tri-*O*-*p*-toluenesulfonyl-*myo*-inositol (**8**)[6] (0.10 g) in a mixture of chloroform (2 ml) and methanol (1 ml) was added methanolic sodium methoxide (0.14 ml, 1 molar equivalent) and the mixture was kept overnight at room temperature. Then the reaction mixture was processed similarly as described under the preparation of **11**. The crude crystals was recrystallized from chloroform–methanol to give colorless needles (64 mg, 84%) of **19**, mp 184—184.5°C. Recrystallization from the same solvent gave an analytical sample. PMR ($CDCl_3$): τ 7.53 (6-protons s, 2 OTs), 6.76 (1-proton t, $J_{1,2}$= 3.5 Hz, $J_{2,3}$=4.0 Hz, H-2), 6.61 (1-proton d, $J_{1,6}$=0 Hz, H-1), 5.34 (1-proton dd, $J_{4,5}$=3.0 Hz, $J_{5,6}$=8.0 Hz, H-5), and 5.08 (1-proton d, H-6).

Found: C, 57.07; H, 5.83; S, 11.37%. Cacld for $C_{26}H_{30}O_9S_2$: C, 56.70; H, 5.49; S, 11.64%.

*2,3-Anhydro-4,5-O-cyclohexylidene-1,6-di-O-p-toluenesulfonyl-*epi*-inositol* (**20**). To a solution of 1-*O*-benzoyl-2,3-*O*-cyclohexylidene-4,5,6-tri-*O*-*p*-toluenesulfonyl-*myo*-inositol (**9**)[10] (0.35 g) in a mixture of chloroform (5 ml) and methanol (5 ml) was added methanolic sodium methoxide (1.1 ml, 3 molar equivalent) and the mixture was kept at room temperature. After 15 min, colorless needles were crystallized out from the solution and the crystals were collected by filtration: yield 0.19 g (82%), mp 215.5—216°C. An analytical sample was obtained by recrystallization from chloroform-ethanol. The melting point did not change. PMR ($CDCl_3$): τ 7.56 and 7.53 (3-protons s, OTs), 6.52 (1-proton dd, $J_{2,3}$=4.0 Hz, $J_{3,4}$=2.5 Hz, H-3), 6.27 (1-proton d, $J_{1,2}$=0 Hz, H-2), and 5.40 (1-proton dd, $J_{4,5}$=7.0 Hz, H-4). (DMSO-d_6): τ 6.45 (2-protons m, H-2,3), 5.90 (1-proton t, $J_{4,5}$=$J_{5,6}$=7.5 Hz, H-5), 5.37 (1-proton dd, $J_{3,4}$=2.5 Hz, H-4), 5.33 (1-proton dd, $J_{1,6}$=9.5 Hz, H-6), and 4.79 (1-proton d, $J_{1,2}$=0 Hz, H-1).

Found: C, 56.36; H, 5.26; S, 11.50%. Calcd for $C_{26}H_{30}O_9S_2$: C, 56.70; H, 5.49; S, 11.64%.

The Synthesis and Reaction of Monohalogeno-*t*-butyloxycarbonylamino Acids

Takanobu OHNISHI, Hiroshi SUGANO, and Muneji MIYOSHI

Research Laboratory of Applied Biochemistry, Department of Synthetic Chemistry, Tanabe Seiyaku Co., Ltd. Kashima-cho, Higashiyodogawa-ku, Osaka

(Received January 29, 1972)

Monohalogeno-*t*-butyloxycarbonylamino acids (XBOC-amino acids) were synthesized by the use of the corresponding chloroformates in a basic aqueous solution. Several dipeptides containing XBOC-amino acid were also prepared. The cleavage of the XBOC group was successfully carried out not only under some acidic conditions, but also by heating in methanol or ethanol. In order to demonstrate the usefulness of this group in peptide synthesis, Z-Gly-Lys(Z)-Gly-OEt was synthesized *via* BrBOC-Lys(Z)-Gly-OEt, which had been treated by hot ethanol. Side reaction during the synthesis of XBOC-amino acids will also be described.

The *t*-butyloxycarbonyl (BOC) group is of considerable importance in peptide chemistry, especially in solid-phase synthesis. Since our collaborators reported a method in which the BOC group was introduced by reacting *t*-butyl chloroformate (BOC–Cl) with amino acids in an aqueous alkaline solution,[1] BOC-amino acids have been prepared as a commercial scale. Unfortunately, BOC–Cl is unstable even in inert organic solvents, such as ether, dichloromethane, and tetrahydrofuran, and it can not be stored for a long time at −20°C. Also, the BOC–Cl content in the solution can not be precisely estimated. For these reasons, many investigators have attempted to develop a new protecting group which can be easily synthesized.[2–5] Carpino *et al.* recently reported on the α-halogeno-*t*-butyloxycarbonyl (XBOC) group.[6] They found that α-bromo- and α-chloro-*t*-butyl chloroformate (BrBOC–Cl, ClBOC–Cl) were significantly more stable than BOC–Cl, and that, on treatment with anilines, the corresponding urethans were obtained, while the acylation reaction was generally unsuccessful with amino acid derivatives.

In the present paper, the authors will report on the synthesis, properties and application of BrBOC- and ClBOC-amino acids.[7]

Results

Synthesis of XBOC-amino Acids. α-Bromo- and α-chloro-*t*-butyl alcohol were prepared by Carpino's method, which had been employed for the preparation of α,α-dibromo-*t*-butyl alcohol.[6] These alcohols were converted into the corresponding chloroformates as the usual manner and were purified by distillation. The characterizations of the alcohols and the chloroformates were identical with those previously reported.[6]

The chloroformates were treated with amino acid esters in water–chloroform–tetrahydrofuran and with amino acids in an aqueous alkaline solution.

In order to confirm the structures of the BrBOC- and ClBOC-amino acid benzyl esters thus obtained, the esters were converted into the acids by saponification or hydrogenolysis; the yields were moderate (Eq. (1)).

$$\text{XBOC-Cl} + \underset{\displaystyle \underset{\displaystyle R}{|}}{\text{C}_6\text{H}_5\text{CH}_2\text{OCO-CH-NH}_2} \xrightarrow[\text{H}_2\text{O-CHCl}_3\text{-THF}]{\text{Et}_3\text{N}} \underset{\displaystyle \underset{\displaystyle R}{|}}{\text{XBOC-NHCHCO}_2\text{CH}_2\text{C}_6\text{H}_5} \xrightarrow[\text{or } \text{H}_2/\text{Pd}]{\text{OH}^-} \underset{\displaystyle \underset{\displaystyle R}{|}}{\text{XBOC-NHCHCOOH}} \quad (1)$$

R: amino acid side chain
X: Br, Cl

The results are shown in Tables 1 and 2.

XBOC-amino acids show IR spectra similar to those of BOC-amino acids (Fig. 1).

Cleavage of the XBOC Group. A relatively high stability of BrBOC and ClBOC groups is shown in the acidic reagents. Neither of them is completely cleaved when left standing in 10% hydrogen chloride in dioxane or anhydrous trifluoroacetic acid at room temperature for an hour.

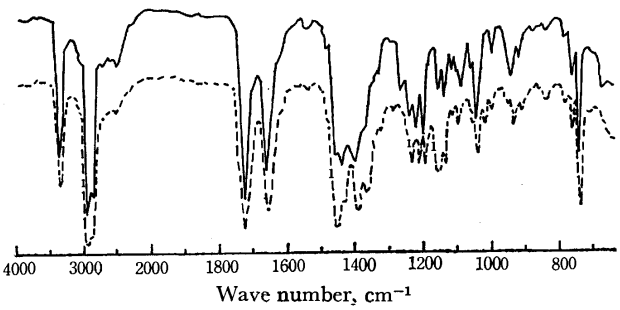

Fig. 1. IR spectra of BrBOC-Trp-OH (——) and BOC-Trp (– – –) in Nujol.

a) *c* 1, AcOH

The reduction of the XBOC-group to the BOC group by means of sodium borohydride in water, by means of hydrogenolysis in methanol over a palladium catalyst, or by means of electrolytic reduction does not proceed.

However, the BrBOC group is completely removed under the following conditions: heating in methanol or ethanol; borontrifluoride etherate in trifluoroacetic acid at room temperature for an hour; 4N hydrogen bromide in acetic acid, and sodium in liquid ammonia. The ClBOC group is completely cleaved by borontrifluoride etherate in trifluoroacetic acid, by 4N hydrogen bromide in acetic acid, and by sodium in liquid ammonia.

The cleavage of the BrBOC group by heating in methanol or ethanol is a unique deprotection technique. This reaction, named "self-cleavage" by Carpino, may proceed similarly to the self-cleavage of BrBOC-aniline (Eq. (2)).[6]

The selective cleavage of the BrBOC group may be possible, since other amino-protecting groups such as BOC and the benzyloxycarbonyl (Z) group are stable under heating in methanol or ethanol.

Peptide Synthesis. XBOC-amino acids were converted into dipeptides by the mixed anhydride (M.A.) method, which was the better than dicyclohexylcarbodiimide (DCCD) method (Table 3).

The tripeptide sequence, Z–Gly–Val–Gly–OMe, was then synthesized by the M.A. method, couplingZ–Gly–OH with H–Val–Gly–OMe prepared from BrBOC–

Table 3. Dipeptides containing α-halogeno-*t*-butyloxycarbonylamino acids

Products	Method	Yield (%)	Mp °C	$[\alpha]_D^{20a)}$	Analysis (Calcd) C %	H %	N %	Br or Cl %

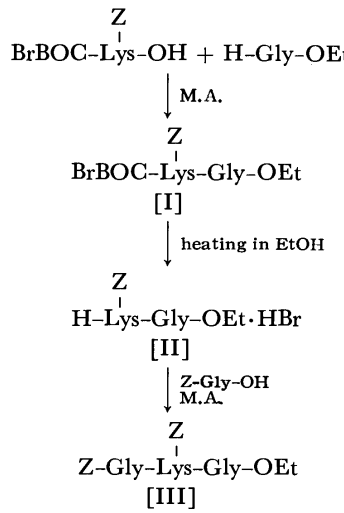
Val–Gly–OMe and ClBOC–Val–Gly–OMe.

The BrBOC group was removed on heating in methanol, and the ClBOC group was removed by the use of 4N hydrogen bromide in acetic acid. These tripeptides were identical with that obtained from Z–Val–Gly–OMe (Table 4).

The utility of the BrBOC group as an α-amino-protecting group of lysine is demonstrated as follows:



BrBOC–Lys(Z)–OH was coupled with H–Gly–OEt to yield BrBOC–Lys(Z)–Gly–OEt *via* the mixed anhydride in 69%. I was stirred under reflux in ethanol for an hour; dipeptide hydrobromide II was thus obtained in a pure state in a yield of 89%. II was condensed with Z–Gly–OH by the M.A. method to afford Z–Gly–Lys(Z)–Gly–OEt.

The characteristics of the tripeptide are identical with those previously reported.[9]

Thus, the BrBOC group is cleaved selectively by heating in ethanol, so it may be possible to use this group for the protection of amino acids in the synthesis of long, complicated peptides.

Side Reaction. In the reaction of the BrBOC–Cl with amino acids or amino acid esters, Carpino did not obtain the urethane derivatives, but the amine hydrobromides and the urea derivatives were isolated. The urea formation in the reaction of *t*-amyl chloroformate with amino acid esters in the presence of triethylamine in an anhydrous organic solvent has been described by Sakakibara and Itoh.[10] We have also found that the urea is largely formed by reacting BOC–Cl or benzyl chloroformate with amino acid esters under the same anhydrous conditions, and that the urea formation decreased when the reaction is carried out in an aqueous solvent. From this point of view, we tried to react the XBOC–Cl with amino acids and amino acid esters under aqueous conditions.

Although the desired XBOC-amino acids and esters were formed quantitatively under those conditions, it was found that the XBOC-amino acids or esters formed in the basic reaction solution were transformed into 2-oxazolidinones to a large extent if the solution was allowed to stand overnight. This phenomenon was also observed when pure BrBOC-amino acid dissolved in a 2N sodium hydroxide solution was stored for 24 hr

Experimental

α-Bromo-t-butyl Alcohol. To a slurry of *N*-bromosuccinimide (178 g) in water (400 m*l*), isobutene gas was bubbled under vigorous stirring at 15—20°C. After 30 min, all of the *N*-bromosuccinimide disappeared; stirring was then continued for an additional 30 min. The mixture was extracted several times with ether, the ether extract was dried over magnesium sulfate, and the solution was evaporated. The remaining oil was distilled to give the alcohol; yield, 105 g (70%); bp 55—56°C/25 mmHg. NMR δ (CCl_4): 1.28 (s, 6H, CH_3), 3.28 (s, 1H, OH), 3.42 (s, 2H, CH_2).

α-Chloro-t-butyl Alcohol. This was obtained from *N*-chlorosuccinimide (100 g), water (380 m*l*), and isobutene as described above except that isobutene was introduced at 60—65°C; yield, 45 g (59%); bp 51—52°C/55 mmHg.

α-Bromo-t-butyl Chloroformate. Into a solution of phosgene (65 g, 0.65 mol) and α-bromo-*t*-butyl alcohol (103 g, 0.65 mol) in ether (1000 m*l*), a solution of pyridine (51 g, 0.65 mol) in ether (500 m*l*) was added under stirring at −20——30°C. The mixture was stirred for 2 hr at −20°C and was then allowed to stand overnight at room temperature. The salt was filtered, and the ethereal solution was washed with ice-cold water and with a 3% sodium bicarbonate solution, and dried over magnesium sulfate. The solvent was distilled off, and the remaining oil was distilled to give the chloroformate; yield, 100 g (72%); bp 60—61°C/10 mmHg. IR: cm^{-1} (liq. film) 1770 (C=O); NMR δ ($CDCl_3$): 1.62 (s, 6H, CH_3), 3.63 (s, 2H, CH_2).

α-Chloro-t-butyl Chloroformate. This was obtained from phosgene (32 g, 0.32 mol), α-chloro-*t*-butyl alcohol (35 g, 0.32 mol), pyridine (25 g, 0.32 mol), and ether (600 m*l*) as described above; yield, 37 g (68%); bp 50—51°C/10 mmHg.

α-Bromo-t-butyloxycarbonylglycine Benzyl Ester (General Procedure for the Synthesis of BrBOC- and ClBOC-amino Acid Esters). To a solution of H-Gly-OBzl·TsOH[11] (17 g, 50 mmol) and triethylamine (14 m*l*) in chloroform (200 m*l*) and water (50 m*l*), a solution of α-bromo-*t*-butyl chloroformate (11 g, 50 mmol) in chloroform (100 m*l*) was added at −1—0°C over a 30-min period. After the mixture had been stirred for 1 hr at the same temperature, it was washed successively with N hydrochloric acid, a 4% sodium bicarbonate solution, and water, and then dried over magnesium sulfate in a refrigerator. The solvent was distilled off, and the remaining oil was crystallized by the addition of ethyl acetate and petroleum ether. The crystal (3 g (17%)) was shown to be the urea derivative by IR; mp 105—106°C. From the filtrate, after the removal of the solvent, there was obtained the α-bromo-*t*-butyloxycarbonylglycine benzyl ester, yield of oil, 11 g (61%). IR: cm^{-1} (liq. film) 1755, 1725 (C=O).

α-Bromo-t-butyloxycarbonylglycine From the Benzyl Ester.

a) By Catalytic Hydrogenolysis: A mixture of the α-bromo-*t*-butyloxycarbonylglycine benzyl ester (8 g) obtained above and a 5% palladium-carbon catalyst (500 mg) in methanol (50 m*l*) was hydrogenated for 2 hr at room temperature. After the removal of the catalyst and the solvent, the white crystals were filtered and recrystallized from ethyl acetate and petroleum ether; yield, 3.0 g (55%); mp 102—103°C.

Found: C, 33.32; H, 4.82; N, 5.45; Br, 30.53%. Calcd for $C_7H_{12}NO_4Br$: C, 33.09; H, 4.75; N, 5.49; Br, 31.44%.

b) By Alkaline Hydrolysis: A solution of the α-bromo-*t*-butyloxycarbonylglycine benzyl ester (3 g, 12 mmol) and N sodium hydroxide (12 m*l*) in tetrahydrofuran (50 m*l*) was stirred for 30 min at 0°C. The mixture was then acidified with N hydrochloric acid and was extracted several times with ethyl acetate. The ethyl acetate solution was washed with water and was dried over magnesium sulfate. It was treated as had been described above to give white crystals; yield, 1 g (33%); mp 102—103°C.

Found: C, 33.15; H, 4.95; N, 5.50; Br, 31.03%. Calcd for $C_7H_{12}NO_4Br$: C, 33.09; H, 4.75; N, 5.49; Br, 31.44%.

α-Bromo-t-butyloxycarbonyl-L-proline (General Procedure for the Synthesis of BrBOC- and ClBOC-amino Acids). A solution of α-bromo-*t*-butyl chloroformate (10.75 g, 50 mmol) in tetrahydrofuran (20 m*l*) was added slowly to a solution of L-proline (5.75 g, 50 mmol) in a mixture of tetrahydrofuran (30 m*l*)

11) L. Zervas, M. Winitz, and J. P. Greenstein, *J. Org. Chem.*, **22**, 1515 (1957).

and 2N sodium hydroxide (70 ml) at 0—2°C. The mixture was stirred vigorously during the addition of the chloroformate. The stirring was continued for a further hour at 0°C. At the end of this period, the reaction mixture was adjusted to pH 2—3 with N hydrochloric acid, and the product was extracted with ethyl acetate. The extract was washed with water and dried over magnesium sulfate in a refrigerator. After the solvent had been distilled off *in vacuo*, crystals were obtained; those crystals were then recrystallized from ethyl acetate and petroleum ether; yield, 11.5 g (78%). The physical constants of the material are shown in Table 1.

BrBOC-Val-Gly-OMe (General Procedure for the Synthesis of α-BrBOC- and α-ClBOC-dipeptides). To a solution of BrBOC-Val-OH (2.5 g, 10 mmol) and triethylamine (1.4 ml) in chloroform (50 ml), ethyl chloroformate (1.2 g, 11 mmol) was added drop by drop at −15——10°C. After 15 min a solution of H-Gly-OMe·HCl[12] (1.38 g, 11 mmol) and triethylamine (1.5 ml) in chloroform (50 ml) was added at −10——5°C. The mixture was stirred for a further hour at 0—10°C and then washed successively with N hydrochloric acid, a 4% sodium bicarbonate solution, and water. After drying over magnesium sulfate in a refrigerator, the solvent was distilled off *in vacuo* and the remaining oil was crystallized by the addition of petroleum ether. It was recrystallized from ethyl acetate and petroleum ether; yield, 2.1 g (65%). The physical constants of the material are shown in Table 3.

Z-Gly-Val-Gly-OMe. *a) From BrBOC-Val-Gly-OMe*: BrBOC-Val-Gly-OMe (3.6 g, 10 mmol) was refluxed in methanol for 1 hr. The solvent was distilled off, and the remaining H-Val-Gly-OMe·HBr was used without purification. To a solution of Z-Gly-OH[13] (2.1 g, 10 mmol) and triethylamine (1.5 ml) in chloroform (50 ml), ethyl chloroformate (1.1 g, 10 mmol) was added drop by drop at −15——10°C. After 15 min a solution of the H-Val-Gly-OMe·HBr obtained above and triethylamine (1.4 ml) in chloroform was added at −10——5°C. The mixture was stirred for 1 hr at 0—10°C and then washed successively with 3N hydrochloric acid, a 4% sodium bicarbonate solution, and water. After drying over magnesium sulfate, the solvent was distilled off and the remaining solid was recrystallized from ethyl acetate and petroleum ether; yield, 2.5 g (65%). The value of specific rotation and the melting point are shown in Table 4.

Found: C, 56.63; H, 6.48; N, 10.71%. Calcd for $C_{18}H_{25}N_3O_6$: C, 56.98; H, 6.64; N, 11.08%.

b) From ClBOC-Val-Gly-OMe: ClBOC-Val-Gly-OMe (1.6 g, 5 mmol) was dissolved in 4N hydrogen bromide in acetic acid (10 ml) at room temperature. After 1 hr, the solution was evaporated and the remaining oil was triturated with ether. The H-Val-Gly-OMe·HBr thus obtained was coupled with Z-Gly-OH (1.1 g, 5 mmol) as had been described above; yield, 1.1 g (59%). The data of this product are shown in Table 4.

c) From Z-Val-Gly-OMe: Z-Val-Gly-OMe[14] (1.6 g, 5 mmol) was hydrogenated over palladium black in methanol in the presence of 2.5 ml of a methanolic solution of 2N hydrogen chloride. The solution was filtered from the catalyst, and the filtrate was evaporated to dryness. The oily residue was coupled with Z-Gly-OH (1.1 g, 5 mmol) as had been described above, yield, 1.2 g (66%). Its properties agreed with those of the products obtained from ClBOC-Val-Gly-OMe or BrBOC-Val-Gly-OMe (see Table 4).

BrBOC-Lys(Z)-Gly-OEt (I). BrBOC-Lys(Z)-OH was obtained from BrBOC-Cl (11 g, 50 mmol) and H-Lys(Z)-OH[15] (14 g, 50 mmol) in a manner similar to that described for the preparation of BrBOC-Pro-OH. It was not crystallized and was used without purification; yield of oil, 20 g (87%). The oily BrBOC-Lys(Z)-OH (18.5 g, 40 mmol) thus obtained was coupled with H-Gly-OEt·HCl[12] (5.6 g, 40 mmol) by the mixed anhydride method described for the preparation of BrBOC-Val-Gly-OEt. The resultnig BrBOC-Lys(Z)-Gly-OEt was recrystallized from ethyl acetate and petroleum ether; yield, 16 g (80%); mp 91—93°C, $[\alpha]_D^{25}$ −10.5° (*c* 1, AcOEt).

Found: C, 50.78; H, 5.94; N, 7.75; Br, 14.44%. Calcd for $C_{23}H_{34}N_3O_7Br$: C, 50.83; H, 6.12; N, 7.73; Br, 14.70%.

H-Lys(Z)-Gly-OEt·HBr (II). I (5.4 g) was refluxed in EtOH (100 ml) for 1 hr. The solution was then evaporated, and the residue was recrystallized from ethanol and ether; yield, 4.0 g (89%); mp 137—140°C; $[\alpha]_D^{25}$ +13.0° (*c* 1, EtOH).

Found: C, 47.81; H, 6.41; N, 9.30; Br, 17.58%. Calcd for $C_{18}H_{28}N_3O_5Br$: C, 48.11; H, 6.29; N, 9.38; Br, 17.83%.

Z-Gly-Lys(Z)-Gly-OEt (III). To a solution of Z-Gly-OH (2.1 g, 10 mmol) and triethylamine (1.4 ml) in chloroform (50 ml), ethyl chloroformate (1.1 g, 10 mmol) was added at −12——10°C. After 15 min, a solution of (II) (4.5 g, 10 mmol) and triethylamine (1.4 ml) in chloroform (30 ml) was added, and the reaction mixture was stirred for 1 hr at 0—10°C. Then, it was washed with N hydrochloric acid, a 4% sodium bicarbonate solution, and water. After drying over magnesium sulfate, the solution was evaporated *in vacuo*, and the remaining oil was crystallized by the addition of petroleum ether. The crystal was recrystallized from ethyl acetate and petroleum ether; yield, 2.8 g (50.5%); mp 156—159°C; $[\alpha]_D^{25}$ −17.2° (*c* 1, AcOH). Lit,[9] mp 155—158°C, $[\alpha]_D^{25}$ −17.0° (*c* 1, AcOH).

Found: C, 60.12; H, 6.66; N, 9.99%. Calcd for $C_{28}H_{36}N_4O_8$: C, 60.36; H, 6.52; N, 10.07%.

(S)-5,5-dimethyl-3-(α-carboxyphenethyl)-2-oxazolidinone (General Procedure for the Preparation of 2-Oxazolidinone Derivatives).

a) From L-Phenylalanine and BrBOC-Cl: A solution of α-bromo-*t*-butyl chloroformate (11 g, 50 mmol) in tetrahydrofuran (20 ml) was added slowly to a solution of L-phenylalanine (8.2 g, 50 mmol) in a mixture of tetrahydrofuran (30 ml) and 2N sodium hydroxide (80 ml) at 0—2°C under stirring. The stirring was continued for a further 2 hr at 0°C, and then overnight at room temperature. The mixture was acidified with N hydrochloric acid and was extracted with ethyl acetate. The extract was dried over magnesium sulfate. After the solvent had been distilled off, crystals were obtained; they were recrystallized from ether and petroleum ether; yield, 4 g (42%). The data of this product are shown in Table 5.

b) From BrBOC-L-Phenylalanine: BrBOC-Phe-OH (3.44 g, 10 mmol) was dissolved in a mixture of N sodium hydroxide (12 ml) and MeOH (50 ml) at room temperature. After 24 hr, the solution was acidified with N hydrochloric acid and extracted with ethyl acetate. The extract was dried and evaporated to dryness. The residue was recrystallized from ether and petroleum ether; yield, 1.6 g (60%). Its properties agreed with those of the product described above.

A Simple Protecting Group Protection-Purification "Handle" for Polynucleotide Synthesis. II.

Kiyohiko TAJIMA and Tsujiaki HATA

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received January 31, 1972)

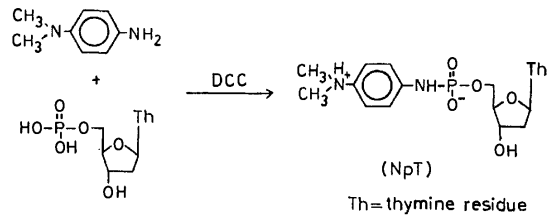
A new method for the synthesis of oligonucleotides by employing a protecting group protection-purification "handle" was investigated. It was found that 3′-*O*-acetylthymidylyl(5′→3′)thymidine 5′-phosphor[*p*-*N*,*N*-dimethylamino]anilidate (NpTpTOAc) was prepared in 65% yield from thymidine 5′-phosphor[*p*-*N*,*N*-dimethylamino]anilidate (NpT) and 3′-*O*-acetylthymidine 5′-phosphate (pTOAc) in the presence of triisopropylbenzenesulfonyl chloride (TPS). The NpTpTOAc was selectively isolated by the use of Dowex 50W-X2 and Amberlite IR-45 resins. After treatment of NpTpTOAc with 80% acetic acid, pTpTOAc was obtained in 60% yield based on pTOAc. Similarly, trinucleotide derivative, pTpTpTOAc, was isolated in 31% yield based on pTpTOAc.

Application of the solid phase method to oligonucleotide synthesis has recently been studied.[1] However, the desired sequence of oligonucleotides obtained is accompanied with several truncated and failure sequences as the purity of the product depends on the yield of coupling reactions on polymer supports, and only 100% yield in every coupling can prevent the formation of truncated and failure sequences.[2] Separation of oligonucleotides prepared by the present method seems to be more difficult than the usual method because the contents of truncated and failure sequences are uniformly much more than those of a true sequence. Especially, higher yields of coupling reactions except in the case of 100% yield would cause much difficulty. In order to remove the restriction of solid phase synthesis, a new synthetic method of oligonucleotides, in which true sequence of oligonucleotide may be selectively prepared without using column chromatography, has been established.[3]

The results of experiments for the preparation of oligothymidylates designed by a new method are described in this paper. The coupling reactions of nucleotide were carried out in solution in the absence of polymer. In the next stage, the desired oligonucleotide was seaprated from the other by-products using an ion exchange resin utilizing salt formation or molecular adsorption between the protecting group and the ion exchange resin by taking advantage of the separation on solid phase.

The protecting group (N) on nucleoside 5′-phosphate end is of importance, since during the course of the experiment the group acts as a protecting group of phosphate in the coupling reactions and also functions as a "handle" for separation. A basic *N*,*N*-dimethyl-*p*-phenylenediamino group was chosen as the protecting group on the nucleoside 5′-phosphate end. This was introduced to form a phosphoroanilidate linkage which could be cleaved easily by treatment with 80% acetic acid at 80°C for 3 hr.

Thymidine 5′-phosphoroanilidate (NpT) was prepared in 90% yield when thymidine 5′-phosphate was treated with *N*,*N*-dimethyl-*p*-phenylenediamine in the presence of dicyclohexylcarbodiimide (DCC) according to a modification of the procedure of Moffatt.[4] The NpT was purified and isolated from the reaction mixture by treatment with Dowex 50W-X2 (H^+ form) since the resin adsorbs NpT by a salt formation between sulfonic acid group of Dowex 50W-X2 and *N*,*N*-dimethyl anilino group of NpT, which excluded the formation of the inner salt of NpT.



NpT is stable pink oil and can be stored in dry pyridine at 0°C for more than one month. The possible self-condensation reaction[5] into the corresponding pyrophosphate, P^1,P^2-dithymidine 5′-pyrophosphate, was not observed even when it was treated with Dowex 50W-X2 (H^+ form).

When a mixture of 1.3 equivalent of NpT and 1 equivalent of 3′-*O*-acetylthymidine 5′-phosphate (pTOAc) was treated with 3 equivalent of triisopropylbenzenesulfonyl chloride (TPS) in dry pyridine at room temperature for 13 hr, the corresponding dinucleotide derivative, NpTpTOAc, was formed in 65% yield along with P^1,P^2-di-3′-*O*-acetylthymidine 5′-pyrophosphate $(pTOAc)_2$, the starting materials pTOAc and NpT being recovered. These compounds were detected by paper chromatography and the yield was determined spectrophotometrically.

After passing the mixture through a column of Dowex 50W-X2 (H^+ form), NpT was selectively adsorbed on the resin as described in the preparation

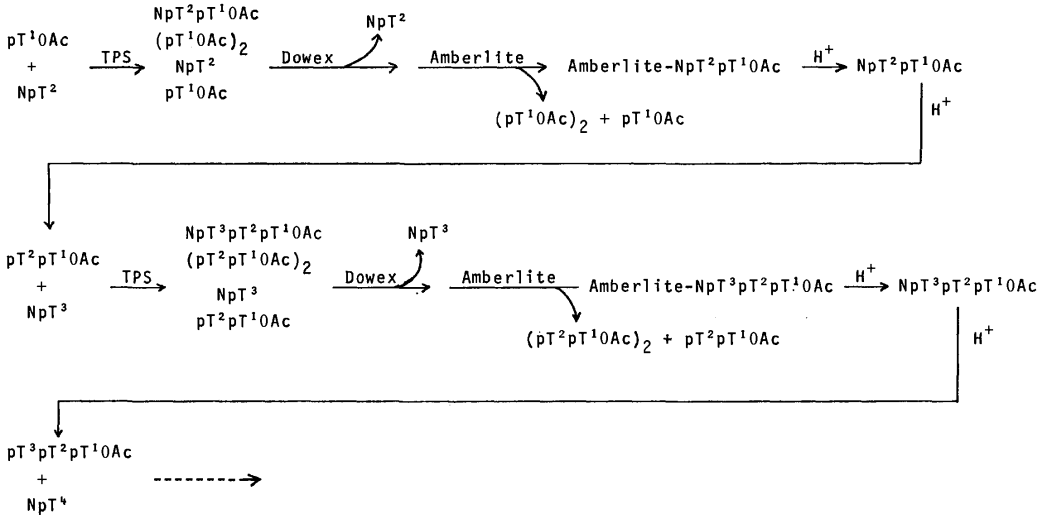

Chart 1. General synthetic scheme.

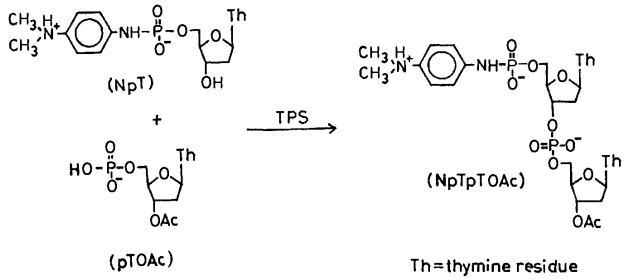

of NpT. The eluate containing NpTpTOAc, $(pTOAc)_2$ and pTOAc was neutralized with 0.1N sodium hydroxide. When the solution was passed through a column of Amberlite IR-45 (free base), NpTpTOAc was selectively adsorbed on the resin excluding adsorption of the other compounds, pTOAc and $(pTOAc)_2$. After washing the resin with neutral water, the resin was treated with 80% acetic acid and the eluate containing NpTpTOAc was heated at 80°C for 3 hr. The solution was concentrated under reduced pressure for removal of acetic acid, and the residue was dissolved in water. *N,N*-Dimethyl-*p*-phenylenediamine was removed by treatment of the aqueous solution with Dowex 50W-X2 (H^+ form). The eluate was lyophilized to remove a trace of moisture and stored in dry pyridine. pTpTOAc was isolated in 60% yield based on pTOAc.[6]

It is most probable that Amberlite IR-45 having anilino group includes *N,N*-dimethyl-*p*-phenylenediamino group of NpTpTOAc by a force of molecular adsorption. This was supported by the adsorption of the base *N,N*-dimethyl-*p*-phenylenediamine on the IR-45 resin. Further, when a mixture of 1 equivalent of pTpTOAc and 3 equivalent of NpT was treated with 3 equivalent of TPS in dry pyridine at room temperature for 14 hr, the corresponding trinucleotide derivative, NpTpTpTOAc, was obtained in 34% yield along with NpT and $(pTpTOAc)_2$.[7] pTpTpTOAc was isolated by means of a similar procedure (see Experimental) to that described for pTpTOAc.

A general synthetic scheme developed for oligothymidylate derivatives is outlined in Chart 1.

In conclusion, it should be noted that the use of the basic protecting group in oligonucleotide synthesis resulted in the selective preparation of oligonucleotides. The chain of oligomer propagates from the head, whereas in the solid phase method it propagates from the tail, *i.e.*, in the former, the oligonucleotide can be purified at each step where the protecting group N enacts the role of handle for separation. This is why the oligomer is selectively prepared. The principle of this method could be applied for the synthesis of polypeptides and other complex molecules.

Experimental

General Procedure. Paper chromatography was performed by a descending technique using Toyo Roshi No. 51 paper. Solvent systems used were: 2-propanol, concentrated ammonium hydroxide, water (7:1:2 v/v) (Solvent 712); ethanol, 1M ammonium acetate (7:3 v/v, pH=7.5) (Solvent 73). Pyridine was purified as follows; Commercial pyridine was distilled over *p*-toluenesulfonyl chloride, phosphorus pentoxide and over potassium hydroxide and stored over calcium hydride. 2,4,6-Triisopropylbenzenesulfonyl chloride (TPS) was prepared by a procedure in literature.[8] *N,N*-Dimethyl-*p*-phenylenediamine was purified by distillation (bp 79—82°C/0.7 mmHg), before use and stored in dry pyridine.

Preparation of NpT. A mixture of pyridinium salt of thymidine 5′-phosphate (0.5 mmol) and *N,N*-dimethyl-*p*-phenylenediamine (3 mmol) was combined with a mixture of water (1 ml) and *t*-butyl alcohol (5 ml). DCC (2.5 mmol) was then added. The mixture was heated under gentle reflux on a glycerin bath at 93—94°C for 3 hr and concentrated to dryness under reduced pressure. The residue was suspended in water (10 ml) and the suspension was washed with three portions of ether (3×10 ml). The aqueous layer was then extracted with three portions of chloroform and concentrated *in vacuo* (1 ml). This was applied to a column

6) Hydrolysis of the acetyl group from pTpTOAc was observed under acidic conditions. Acetylation with acetic anhydride afforded pure pTpTOAc in quantitative yield.

7) $(pTpTOAc)_2$ refers to P^1,P^2-di-3′-*O*-acetylthymidylyl(3′→5′)-thymidine 5′-pyrophosphate. No pTpTOAc was detected from the reaction mixture.

8) R. Lohrmann and H. G. Khorana, *J. Amer. Chem. Soc.*, **88**, 8296 (1966).

TABLE 1. CHROMATOGRAPHIC AND SPECTRAL PROPERTIES OF THE REPORTED COMPOUNDS

Compound	Pc[a] solvent		Spectral data[c] (in H_2O, pH=9)	
	712	73	λ_{max} (10^{-3} ε)	λ_{min} (mμ)
pT	0.20	0.22		
NpT	0.58		251 (17.2)	230
pTOAc	0.22	0.33		
NpTpTOAc	0.45		255 (25.0)	235
pTpTOAc	0.12	0.29		
pTpT[b]	0.09	0.19		
NpTpTpTOAc	0.24		266 (33.0)	236
pTpTpTOAc	0.05	0.12		
pTpTpT[b]	0.04	0.10		

a) Pc=paper chromatography.
b) The compound has been reported by Khorana and co-workers.[9] The R_f values of the compounds agree well with those given in literature. The oligothymidylates prepared by the present method were characterized by degradation to pT with snake *venom* phosphodiesterase and by mobility of the oligothymidylates relative to pT on paper electrophoresis (phosphate buffer, pH 8).
c) The ε_{max} values were obtained and calculated from those of the corresponding free thymidylates.

(1.5×15 cm) of Dowex 50W-X2 (H^+ form). The column was washed first with water (150 m*l*) and then eluted with 0.2N aqueous triethylamine. The eluate was concentrated to dryness under reduced pressure. NpT was obtained in 90% (7740 O.D.$_{251}$ units at pH 9) yield as pink oil which was chromatographically pure. Spectral data are given in Table 1.

Preparation of NpTpTOAc. Triethylammonium salt of NpT (0.13 mmol) and 3′-*O*-acetylthymidine 5′-phosphate (pTOAc) (0.1 mmol) were dissolved in pyridine (1 m*l*) and the mixture was concentrated to dryness. This was repeated five times for complete removal of moisture. The residue was dissolved in pyridine (0.3 m*l*) and TPS (0.3 mmol)was added. The mixture was allowed to stand at room temperature for 13 hr and water (0.3 m*l*) was added. After 3 hr, the solvent was removed *in vacuo* and the residue was suspended in water (3 m*l*). The aqueous solution was washed with ether and then with chloroform and concentrated to *ca.* 0.5 m*l*. The solution was applied to a column (1.5×5 cm) of Dowex 50W-X2 (H^+ form). The column was washed with water (300 m*l*). The eluate contains NpTpTOAc, $(pTOAc)_2$ and pTOAc. It was concentrated to *ca.* 2 m*l* and neutralized with 0.1N sodium hydroxide and then Amberlite IR-45 (free base) (3 m*l*) was added. After 30 min, the mixture was applied to a column (1.5×6 cm) of Amberlite IR-45 (free base). The column was washed with water (100 m*l*) for removal of $(pTOAc)_2$ and pTOAc and then 50% acetic acid (10 m*l*) was added. It was allowed to stand for 30 min. The column was eluted and washed with water. This was repeated once more. Eluate and washings were combined and concentrated *in vacuo*. NpTpTOAc was obtained in 65% (1625 O.D.$_{255}$ units at pH 9) yield as colorless oil which was chromatographically pure. The spectral data are given in Table 1.

Preparation of pTpTOAc. NpTpTOAc (0.06 mmol) was dissolved in 80% acetic acid (5 m*l*). The solution was allowed to stand at 80°C for 3 hr and concentrated to dryness. The residue was dissolved in water (1 m*l*) and applied to a column (1.5×2 cm) of Dowex 50W-X2 (H^+ form). The column was eluted with water and the eluate was concentrated. pTpTOAc was obtained in 92% yield based on NpTpTOAc and stored in dry pyridine. When hydrolysis of the acetyl group from pTpTOAc was observed, acetylation with acetic anhydride afforded pure pTpTOAc in quantitative yield.

Preparation of NpTpTpTOAc. pTpTOAc (0.015 mmol) and triethylammonium salt of NpT (0.045 mmol) were dissolved in pyridine (1 m*l*) and the mixture was concentrated to dryness. This was repeated five times for complete removal of moisture. The residue was then dissolved in pyridine (0.15 m*l*) and TPS (0.045 mmol) was added. The mixture was allowed to stand at room temperature for 14 hr and water (0.5 m*l*) was then added under cooling. It was allowed to stand at room temperature for 3 hr and then concentrated *in vacuo*. The residue was suspended in water (3 m*l*). The aqueous solution was washed with ether and with chloroform and then concentrated to *ca.* 0.5 m*l*. It was applied to a column (1.5×5 cm) of Dowex 50W-X2 (H^+ form). The column was eluted with water (150 m*l*). The eluate contains NpTpTpTOAc, $(pTpTOAc)_2$ and pTpTOAc. It was concentrated to *ca.* 1 m*l* and neutralized with 0.1N sodium hydroxide. Amberlite IR-45 (free base) was added to the solution. After being left to stand at room temperature for 30 min, it was applied to a column (1.5×5 cm) of Amberlite IR-45 (free base). The column was washed with water for removal of $(pTpTOAc)_2$ and pTpTOAc and then 50% acetic acid (10 m*l*) was added. The column was allowed to stand for 30 min, then eluted and washed with water. This was repeated once more. Eluate and washings were combined and concentrated under reduced pressure. NpTpTpTOAc was obtained in 31% (153 O.D.$_{266}$ units at pH 9) yield as colorless oil which was chromatographically pure. The spectral data are given in Table 1.

Preparation of pTpTpTOAc. NpTpTpTOAc (0.047 mmol) was dissolved in 80% acetic acid (2 m*l*). The solution was allowed to stand at 80°C for 3 hr and concentrated to dryness. The residue was dissolved in water (1 m*l*) and 1 m*l* of Dowex 50W-X2 (H^+ form) was added and allowed to stand at room temperature for 10 min. Dowex 50W-X2 was filtered and washed with water. Filtrate and washings were combined and concentrated *in vacuo*. pTpTpTOAc was obtained in 91% yield based on NpTpTpTOAc and stored in dry pyridine.

The authors heartily thank Professor Teruaki Mukaiyama for his encouragement and discussion throughout the investigation.

Total Syntheses of Carbohydrates. I. Dihydroxyacetone and DL-Erythrulose

Takashi ANDO,* Sachiko SHIOI, and Masazumi NAKAGAWA**

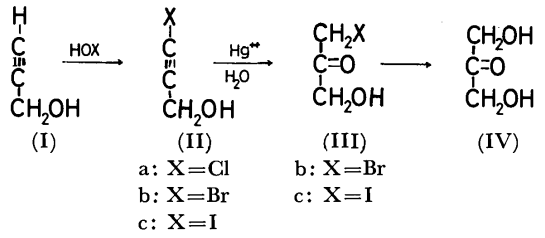
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka, 560

(Received January 24, 1972)

An improved method of preparation of halopropargyl alcohol is described. Hydration of halopropargyl alcohol followed by hydrolysis gave dihydroxyacetone which was identified as its dibenzoate. 2-Butyne-1,4-diol was converted into acetoxymethyl vinyl ketone. 1,4-Diacetoxy-3-bromobutan-2-one obtained by the addition of acetyl hypobromite to the vinyl ketone was treated with silver acetate to yield tri-*O*-acetyl-DL-erythrulose. Hydrolysis of the triacetate afforded DL-erythrulose which was identified as phenylhydrazone.

Since the pioneering work of R. Lespieau,[1] a number of papers have appeared on total syntheses of carbohydrates. Stereoselective synthesis of carbohydrates involves two problems; the construction of asymmetric centers bearing hydroxyl group with particular configuration, and the introduction of formyl- or keto-function at a desired position. The former can be solved in principle by (1) a stereoselective synthesis of an open chain olefinic compound followed by stereospecific hydroxylation, (2) stereospecific reactions of cyclic compounds such as reduced furans or pyrans, or (3) a combination of (1) and (2). Open chain compounds can usually be obtained by stereoselective half-reduction of acetylenic compounds. Construction of more than three asymmetric centers with a particular configuration in an open chain olefinic compound is usually difficult, but the versatile reactivity of an acetylenic compound, the precursor of an olefinic compound, provides various routes for the introduction of carbonyl function. Thus, the total syntheses of DL-erythrulose,[2] DL-apiose,[3] 2-deoxy-DL-*erythro*-pentose,[4,5] 2-deoxy-DL-*threo*-pentose,[5] the four isomers of DL-aldopentose,[6] ethyl glycoside of 3-amino-3-deoxy-DL-arabinose,[7] L-mycarose[8] and ethyl glycoside of DL-picrocin[9] were achieved starting from various acetylenic compounds.

We have studied total syntheses of carbohydrates starting from simple acetylenic or olefinic compounds, and wish to report on the total syntheses of dihydroxyacetone and DL-erythrulose.[10]



Scheme 1. Synthesis of dihydroxyacetone (IV).

The reported methods of preparation of dihydroxyacetone by chemical means such as isomerization of glyceraldehyde,[11] bromine oxidation of glycerol,[12] alkaline treatment followed by acid hydrolysis of 1,2-isopropylideneglyceryl chloride[13] and hydrolysis of 1,3-dichloroacetone[14] do not seem to be very satisfactory. As is shown in Scheme 1, we carried out the synthesis of dihydroxyacetone (IV) employing propargyl alcohol (I) as a starting material. Treatment of an ethynyl compound with hypohalite under strongly alkaline conditions is the usual method of preparation of haloacetylene.[15] However, the reaction conditions can not be applied to propargyl alcohol (I), since I and II are sensitive to strong base. Since the prolonged treatment of I with calcium hypohalite and calcium hydroxide in water resulted in recovery of I, alcohol (I) was converted into α-methoxyethyl ether derivative by the reaction with methyl vinyl ether. Treatment of the ether derivative with sodium hydroxide-calcium hypohalite in water followed by acid hydrolysis of the protective group afforded chloropropargyl alcohol (IIa) in a 53% yield. Bromopropargyl alcohol (IIb) could be prepared in a 65% yield by rapid addition of I to a mixture of calcium hypobromite, calcium hydroxide, water and ether at a temperature below −5°C.[16] When the reaction temperature is higher than this an appreciable amount of bromopropiolic acid is formed accompanied by a significant decrease in the yield of IIb. It is to be noted that calcium hypobromite can oxidize primary acetylenic alcohol to carboxylic acid leaving the acetyl-

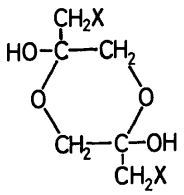
enic bond intact under weak alkaline conditions at a low temperature. The procedure of preparation of iodopropargyl alcohol (IIc) had to be modified because of the unstable nature of hypoiodite, *i.e.*, an aqueous solution of iodine–potassium iodide was added to an aqueous suspension of calcium hydroxide containing I. By this procedure, iodopropargyl alcohol (IIc) was obtained in a 56% yield.

Halopropargyl alcohols (IIa, IIb, and IIc) thus prepared were found to be rather unstable. The stability decreases with the increase in the atomic weight of halogen atom. Iodopropargyl alcohol (IIc) could be recrystallized from ether or petroleum ether to yield pure crystals (mp 39.5—41.0°C). Recrystallization of IIc from methanol or ethanol, however, gave a different substance (mp 153°C), which was assigned to be 2,3,3-triiodo-2-propen-1-ol on the basis of IR spectrum and the elemental analysis.

The hydration of halopropargyl alcohols (IIa, IIb, and IIc) was examined with two catalysts, an aqueous sulfuric acid containing mercuric sulfate (Reagent A)[17] and mercury-impregnated Dowex-60 (Reagent B).[18] Bromo- and iodopropargyl alcohols (IIb and IIc) gave smoothly corresponding haloketones (IIIb, 69% and IIIc, 53%) on treatment with Reagent A. On the other hand, the chloro-compound (IIa) gave no ketone under the same reaction conditions. Treatment of IIa under more drastic conditions resulted in a minor amount of a mercury containing substance, which seems to be an intermediate complex of hydration. Although the hydration of IIa and IIb could not be accomplished by Reagent B, IIc gave iodoketone (IIIc) in an 84% yield under these conditions. The marked difference in reactivity of halopropargyl alcohols (IIa, IIb, and IIc) may be explained in terms of the difference in electron donating power of halogen atoms. The hydration of acetylenic linkage is regarded as an electrophilic addition reaction catalyzed by mercuric ion.[17] Thus, the reaction is considered to be retarded by the presence of an electron attractive substituent and enhanced by an electron donating group. Haloacetylene can be regarded as a resonance hybrid of V and VI.

$$\underset{\text{(V)}}{RC{\equiv}C\text{–}X} \longleftrightarrow \underset{\text{(VI)}}{R\bar{C}{=}C{=}\overset{+}{X}}$$

The increase of contribution of VI in the sequence Cl<Br<I has been confirmed by the measurement of dipole moment of arylhaloacetylenes.[19] The IR spectra of halopropargyl alcohols (IIa, IIb, and IIc) exhibit absorptions due to $\nu_{C\equiv C}$ at 2250, 2240, and 2195 cm^{-1}, respectively, and the absorption intensity was found to be in the sequence IIa≈IIb>IIc. The IR spectral behavior observed in IIa—c is consistent with the conclusion obtained from the dipole moment measurement.



(VII)

The crystalline halogenohydroxyacetones (IIIb and IIIc) showed no carbonyl absorption in their IR spectra. This suggests that the halohydroxyacetones (IIIb—c) exist in the dimeric form (VII) in the solid state as in the case of dihydroxyacetone (IV). However, the IR spectrum of IIIc in liquid state exhibits absorption due to carbonyl group (1700 cm^{-1}) and ethylenic linkage (1620 cm^{-1}), which indicates that IIIc in solution exists in monomeric state at equilibrium of keto- and enol-forms. IIIb was found to be extremely unstable. Complete decomposition took place within about 1 hr at 30°C. IIIb could be kept in a refrigerator for a long time without change in appearance, but the melting point (75—76°C) lowered rapidly to *ca.* 50°C.

Dihydroxyacetone (IV) is extremely sensitive to acid and base. It decomposes or polymerizes easily in the presence of acid or alkali. Rearrangement to methylglyoxal or glyceraldehyde is also easily caused by acid or alkali. Consequently, the preparation of IV from its ester or ether derivative is difficult. It has been reported that the hydrolysis of diacetate of IV by means of weak alkali or water alone, or the hydrogenolysis of dityrityl or dibenzyl ether of IV gave fruitless results.[14] The hydrolysis of monoacetate IV with barium carbonate also gave only a trace of IV.[13] We have therefore employed an ester-exchange method which has been successfully applied to the conversion of bromoacetone to acetol[20] or 1-alkoxy-3-halogenopropan-2-one to 1-alkoxy-3-hydroxypropan-2-one.[21] Treatment of both IIIb and IIIc with anhydrous sodium formate in boiling anhydrous methanol gave a syrup. All attempts to crystallize the syrup were unsuccessful. However, the absence of methylglyoxal or glyceraldehyde was confirmed by various color reactions.[22] The syrup gave crystalline dibenzoate which gave a superimposable IR spectrum with that of an authentic specimen and showed no depression in mixed melting point. Syrupy IV obtained from IIIc was contaminated with potassium iodide and its removal was found to be difficult owing to the solubility of the salt in organic solvent. The best results were obtained with the use of bromo-compound (IIIb).

In 1952, Raphael reported on the synthesis of DL-erythrulose (XIII) starting from butynediol (VIII) *via* bromoketone (X).[2] In order to improve the preparation of bromoketone (X), a key substance of the present synthesis, we have studied the conversion of

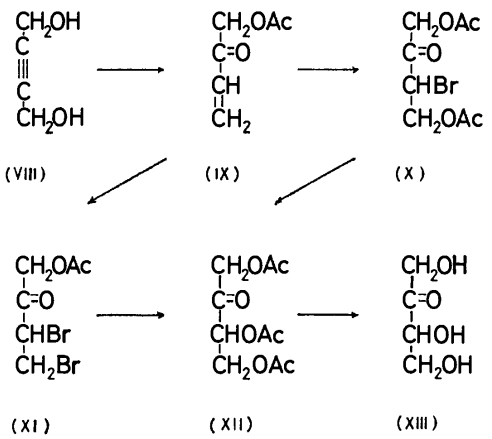

Scheme 2. Synthesis of DL-erythrulose (XIII).

acetoxymethyl vinyl ketone (IX) into bromoketone (X) (Scheme 2). Vinyl ketone (IX) was prepared according to a reported method.[23] It has been pointed out that a terminal double bond usually has low reactivity to electrophilic addition.[24,25] A double bond conjugated with an electron withdrawing group such as carbonyl is also inert to peracid oxidation.[26] Hydroxylation by means of alkaline hydrogen peroxide which is usually applied to double bond conjugated with carbonyl group can not be used, since the ester linkage in IX might be cleaved and the product is considered to be sensitive to alkali. The formation of bromohydrin by the reaction of *N*-bromoacetamide[27] or *N*-bromosuccinimide[2,24] in water is well-known. Bromohydrin acetates have been obtained by the reaction of *N*-bromoacetamide[28] or *N*-bromosuccinimide[29] in acetic acid. However, it is recognized that an ethylenic bond conjugated with carbonyl function except for α,β-unsaturated carboxylic acid reacts sluggishly with these reagents.[27,30]

In was found that the vinyl ketone (IX) is stable in acetic acid and a prolonged treatment with *N*-bromosuccinimide at room temperature affords the desired bromoketone (X) in a 46% yield. Bromoketone (X) which has been reported as a liquid[2] was obtained as fairly unstable crystals and gave a reasonable IR spectrum and satisfactory data of elemental analysis. As so far this seems to be the first instance of addition of acryl hypohalite to a double bond conjugated with carbonyl group. By the Raphael method,[2] bromoketone (X) was treated with silver acetate in acetic acid to yield tri-*O*-acetyl-DL-erythrulose (XII). Hydrolysis of triacetate (XII) by means of barium hydroxide[2] gave DL-erythrulose (XIII) as a syrup, which was identified as phenylhydrazone. Treatment of dibromoketone (XI) obtained by the addition of bromine to IX with silver acetate in acetic acid gave unsatisfactory results, and XIII could not be isolated in pure state.

Experimental

All the melting points are uncorrected. IR spectra were obtained on a Hitachi EPI-2 Spectrophotometer by Nujol mull method unless otherwise stated. Anhydrous acetic acid was prepared by the fractionation of acetic acid containing 5% of acetic anhydride which had been refluxed for 1 hr.

1-Methoxyethyl Propargyl Ether. Propargyl alcohol (I, 56 g) was added over a period of 50 min to methyl vinyl ether (110 m*l*) containing phosphoryl chloride (2—3 drops) at 0—8°C. After the mixture had been stirred for 3.5 hr at this temperature, it was left to stand overnight at room temperature. Excess methyl vinyl ether was removed by distillation, and the residue was washed successively with 10% sodium carbonate, 4N sodium hydroxide and water and dried (potassium carbonate). The propargyl ether was obtained as colorless liquid, 120.5 g (70%), bp 47—48°C/32—33 mmHg.

3-Chloro-2-propyn-1-ol (IIa). To a stirred mixture of sodium hydroxide (173 g), bleaching powder (85.2 g, corresponding to 0.72 molar equivalent of hypochlorite) and water (100 m*l*), was added 1-methoxyethyl propargyl ether (68.4 g, 0.6 mol) over a period of 25 min at 0°C. The mixture was stirred for 3.5 hr at room temperature and then left to stand overnight. After excess hypochlorite had been reduced by addition of sodium hydrogen sulfite (30 g), concentrated hydrochloric acid (430 m*l*) was added under cooling. The mixture was kept overnight at room temperature to complete hydrolysis of the protective group. The mixture was extracted with ether. The extract was washed with 1% sodium hydrogen carbonate solution and water and dried (sodium sulfate). The residue obtained by evaporation of the solvent was distilled twice *in vacuo* under nitrogen stream. IIa was obtained as colorless liquid, 29.2 g (53%), bp 49.5—50.5°C/13 mmHg, n_D^{20} 1.46916 [lit,[31] bp 68°C/35 mmHg, n_D^{20} 1.4727], IR (neat): 3300, 2920, 2870, 2250, 1420, 1360, 1225, 1080, 1005 cm^{-1}.

Found: C, 40.14; H, 3.40%. Calcd for C_3H_3OCl: C, 39.81; H, 3.38%.

p-*Nitrobenzoate*: Colorless rods, mp 113.4—114°C [lit,[32] mp 112°C].

3-Bromo-2-propyn-1-ol (IIb). Bromine (77 m*l*, 1.5 mol) was added over a period of 30 min to a stirred suspension of calcium hydroxide (185 g, 2.5 mol) in water (2 *l*) maintained at 0°C. An appreciable drop in temperature of the mixture was observed. Ether (800 m*l*) was added to the hypobromite solution (again the temperature decreased to −8°C) and propargyl alcohol (I, 72.9 g, 1.3 mol) was added over a 7 min-period under vigorous agitation. After the mixture had been stirred for 30 min below −5°C, the cooling bath was removed and stirring was continued for 3.5 hr. Sodium hydrogen sulfite (52 g, 0.5 mol) was added under cooling. After 20 min, concentrated hydrochloric acid (250 m*l*) was added to dissolve calcium hydroxide, and the organic layer was extracted with ether repeatedly (total 1700 m*l*). The combined ether solution was washed with a solution of ferrous sulfate (22 g) in dilute sulfuric acid (concd. sulfuric acid,

12 ml in water, 220 ml), and then with 10% aqueous solution of sodium carbonate. The residue obtained by evaporating the solvent was distilled to give IIb, colorless liquid, 114.8 g (65.4%), bp 42—46°C/2 mmHg. Redistillation of this material gave pure IIb, bp 45—46°C/2 mmHg, n_D^{25} 1.51486 [lit,[16] bp 41—42°C/1.5 mmHg, n_D^{25} 1.5146]. Pure IIb crystallized in a refrigerator. IR (neat): 3350—3400 (O–H), 2240 (C≡C), 1050 (C–O) cm^{-1}.

Found: C, 26.48; H, 2.45; Br, 58.77%. Calcd for C_3H_3OBr: C, 26.69; H, 2.24; Br, 59.21%.

3,5-Dinitrobenzoate: Yellow rods, mp 122—123°C (from ether) [lit,[16] mp 115—116°C].

Bromopropiolic acid, mp 85—86°C (from benzene followed by vacuum sublimation) [lit,[15] mp 84—86°C] was obtained from the washing (sodium carbonate solution) on acidification. When the reaction mixture was acidified with hydrochloric acid without reduction of hypobromite ion, 2,3,3-tribromo-2-propenoic acid, mp 119—120°C (from benzene followed by a vacuum sublimation) [lit,[33] mp 118°C] was obtained.

3-Iodo-2-propyn-1-ol (IIc). To a stirred mixture of calcium hydroxide (43 g, 0.58 mol), propargyl alcohol (I, 16.8 g, 0.3 mol) and water (500 ml) was added at 0°C a solution of iodine (76 g, 0.3 mol) and potassium iodide (76 g) in water (70 ml) over a period of 13 hr. Sodium hydrogen sulfite (10 g) and then concentrated hydrochloric acid (60 ml) were added to the reaction mixture. Extraction was carried out with ether. After washing (2% sodium hydrogen sulfite and then 10% sodium carbonate solutions) and drying (sodium sulfate), the solvent was removed. The residue, 30.6 g (56%), crystallized in a refrigerator. The crystals were recrystallized twice from petroleum ether to give pure IIc, colorless rods, mp 39.5—41°C [lit,[34] mp 43—44°C], IR: 3150, 2920, 2860, 2195, 1460, 1380, 1355, 1230, 1040, 1030, 980, 965 cm^{-1}.

Found: C, 19.75; H, 1.66; I, 70.45%. Calcd for C_3H_3OI: C, 19.80; H, 1.66; I, 69.75%.

IIc was found to be unstable and could not be kept without decomposition for a long time even in a refrigerator.

1-Bromo-3-hydroxypropan-2-one (IIIb). Mercuric oxide (16 g) was dissolved in a mixture of sulfuric acid (40 g) and water (200 ml) (Reagent A). Bromopropargyl alcohol (IIb, 81.0 g, 0.6 mol) was added under stirring to the solution at such a rate to maintain the temperature of reaction mixture at 40—50°C. The mixture was then stirred for further 1 hr. The insoluble material was filtered and washed with water. The combined washing and filtrate were nearly neutralized by gradual addition of sodium hydrogen carbonate, and repeatedly extracted with ether (total 2.5 l). The extract was washed with a saturated solution of sodium chloride and dried (sodium sulfate). The solvent was removed under reduced pressure at room temperature. Crystalline IIIb thus obtained was washed with ether (63.3 g, 68.7%). The crude material was dissolved in ethanol at 40°C and a small amount of insoluble material was removed by filtration. Concentration of the filtrate under reduced pressure at room temperature yielded IIIb, mp 75—76°C, contaminated with a trace of mercury compound which could not be removed by treatment with ion exchange resin. IR: 3430 (O–H) cm^{-1}. The absorption due to carbonyl group could not be observed.

Found: C, 23.30; H, 3.26; Br, 51.15%. Calcd for $C_3H_5O_2Br$: C, 23.55; H, 3.29; Br, 52.24%.

IIIb reduced Fehling's solution at room temperature, and was found to be extremely heat sensitive.

Benzoate: Fine needles, mp 133.5—134.5°C (from benzene). Found: C, 47.06; H, 3.54; Br, 30.79%. Calcd for $C_{10}H_9O_3Br$: C, 46.72; H, 3.53; Br, 31.08%.

1-Iodo-3-hydroxypropan-2-one (IIIc). *a) By Means of Reagent A*: Iodopropargyl alcohol (IIc, 3.6 g, 0.02 mol) was added over a period of 40 min to Reagent A prepared from mercuric oxide (0.5 g), concentrated sulfuric acid (2 g) and water (10 ml). The mixture was stirred for further 2 hr at 30°C. The reaction mixture was extracted repeatedly with ether and the extract was washed with 5% sodium hydrogen carbonate, 5% potassium iodide and a saturated sodium chloride solutions, successively and dried (sodium sulfate). The residue obtained by evaporation of the solvent under reduced pressure was kept in a refrigerator to give crystals, 2.1 g (53%). The crystals were recrystallized from ethyl acetate to yield pure IIIc, colorless hexagonal plates, mp 99.5—101°C. IR (liquid): 3420 (O–H) broad, 1700 (C=O), 1620 (C=C); IR (Nujol mull of the crystals): 3300 (O–H) cm^{-1}.

Found: C, 17.90; H, 2.45; I, 64.13%. Calcd for $C_3H_5O_2I$: C, 18.02; H, 2.52; I, 63.46%.

b) By Means of Reagent B: Mercury-impregnated Dowex-60 (Reagent B) was prepared according to the reported method.[18] Iodopropargyl alcohol (IIc, 36.4 g, 0.2 mol) was added over 30 min-period in a stirred mixture of Reagent B (12 g) and water (60 ml) at 35°C. After the mixture had been stirred for further 1.5 hr at the same temperature, the mixture was saturated with sodium chloride and extracted with ether. The extract was washed with 5% potassium hydroxide and a saturated sodium chloride solutions successively and dried (sodium sulfate). The solvent was removed under reduced pressure. The residue crystallized in a refrigerator (33.5 g, 84%). Pure material, 99.5—101°C was obtained according to the above procedure and gave an identical IR spectrum.

Dihydroxyacetone (IV). *a) From 1-Bromo-3-hydroxypropan-2-one (IIIb)*: A mixture of potassium formate (7.6 g, 0.09 mol), 1-bromo-3-hydroxypropan-2-one (IIIb, 9.2 g, 0.06 mol) and methanol (100 ml) was refluxed for 5 hr. The reaction mixture was concentrated to *ca.* 60 ml and mixed with ether (100 ml). The inorganic material deposited was removed by filtration. The filtrate was concentrated under reduced pressure to afford dihydroxyacetone (IV) as a syrup. The syrup was dissolved in ether–methanol and the insoluble material was removed. The syrup obtained by evaporation of the solvent under diminished pressure reduced Fehling's solution at room temperature, and gave positive color reactions characteristic of dihydroxyacetone with sodium nitroprusside, resorcinol, phloroglucinol and orcinol,[22] thus proving the absence of methylglyoxal or glyceraldehyde. Since the syrupy dihydroxyacetone (IV) could not be crystallized after treatment with ion exchange resin (Dowex 50WX8 and Dowex 3), it was converted into a dibenzoate by the usual method. The crude dibenzoate was recrystallized from ethanol to yield colorless needles, mp 120.5—121°C [lit,[11] mp 121°C].

Found: C, 68.49; H, 4.71%. Calcd for $C_{17}H_{14}O_5$: C, 68.45; H, 4.73%.

The dibenzoate showed no depression of melting point on admixture with a benzoate (mp 120.5°C) prepared from an authentic specimen of IV. The IR spectra of both were found to be superimposable.

b) From 1-Iodo-3-hydroxypropan-2-one (IIIc): By the procedure used in the case of bromo-hydroxypropanone (IIIb), IIIc could be converted into a crude IV as a red syrup con-

33) H. B. Hill, *J. Amer. Chem. Soc.*, **3**, 178 (1881).

34) R. Lespieau, *Ann. Chim.*, **11**, 269 (1897); A. M. Sladkov, L. Y. Ukhin, G. N. Gorshkova, M. A. Chubarova, A. G. Makhsumov, and V. I. Kasatochkin, *Zh. Org. Khim.*, **1**, 415 (1965); [*Chem. Abstr.*, **63**, 1718 (1965)].

taining a minor amount of potassium iodide. The crude material gave positive color reactions characteristic of IV[22] and reduced cold Fehling's solution. The crude IV gave a dibenzoate, mp 119—120°C, which was proved to be identical with that of an authentic dibenzoate of IV.

1-Acetoxy-3-buten-2-one (IX). Acetoxybutenone (IX) was prepared according to the reported method[23] with modification. The reaction mixture obtained from 2-butyne-1,4-diol (VIII, 21.5 g, 0.25 mol) was filtered and the filtrate was concentrated under reduced pressure to remove the major part of acetic acid and acetic anhydride. The concentrate was mixed with ether and the insoluble material was removed by filtration. The residue obtained by evaporation of the solvent was distilled *in vacuo*. Acetoxybutenone (IX) was obtained as a colorless liquid, 18.6 g (58%), bp 63—66°C/3.5 mmHg, n_D^{20} 1.43136 [lit,[23] bp 70°C/4 mmHg, n_D^{25} 1.4355].

IX was subjected immediately to the subsequent reaction.

1,4-Diacetoxy-3-bromobutan-2-one (X). Freshly prepared *N*-bromosuccinimide (33.5 g, 0.188 mol) was added to a solution of the vinyl ketone (IX, 18.6 g, 0.145 mol) in dry acetic acid (120 m*l*). The mixture was stirred at room temperature until the crystals of *N*-bromosuccinimide disappeared (3—4 days). The resulting solution was mixed with ether (700 m*l*), and a saturated solution of sodium hydrogen carbonate and then solid sodium hydrogen carbonate were added in small portions. The alkaline aqueous layer was extracted with ether (150 m*l*). The combined ether layer was dried and evaporated under reduced pressure, thus yielding a pale yellow liquid. The colorless crystals, 17.7 g (45.7%) obtained by trituration of the liquid with a small amount of ether were recrystallized from methanol or methanol-water to yield pure X, mp 49.0—49.5°C [lit,[2] bp 100—102°C/10^{-4} mmHg].

Found: C, 36.07; H, 4.24; Br, 29.82%. Calcd for $C_8H_{11}O_5Br$: C, 35.98; H, 4.15; Br, 29.92%.

It was found that X decomposes rapidly on a metal surface and should be handled with a glass spatula. An interesting difference was observed between the IR spectrum of crystalline X by Nujol mull method and that of liquid X by liquid film method. Liquid X exhibits a broad absorption in carbonyl region (1765—1740 cm^{-1}), but the absorption splits into two peaks (1767 and 1725 cm^{-1}) in the spectrum of crystalline X. The sharp absorption observed below 1500 cm^{-1} in the spectrum of crystalline X could not be observed in that of liquid X.

1-Acetoxy-3,4-dibromobutan-2-one (XI). Bromine (17.3 g, 0.108 mol) was added dropwise into an ice-cooled solution of IX (13.9 g, 0.108 mol) in carbon tetrachloride (40 m*l*). The mixture was left to stand overnight and the solvent was removed under diminished pressure. Distillation of the residue *in vacuo* yielded XI as a viscous yellow liquid, 24.0 g (76.7%), bp 103—105°C/1 mmHg, n_D^{25} 1.51567, IR (neat): 1765—1735 (C=O of ketone and ester), 1225 (C-O of ester) cm^{-1}.

Found: C, 25.36; H, 2.77; Br, 54.92%. Calcd for $C_6H_8O_3Br_2$: C, 25.06; H, 2.80; Br, 55.50%.

Tri-O-acetyl-DL-erythrulose (XII). *a) From 1,4-Diacetoxy-3-bromobutan-2-one (X):* A mixture of diacetoxybutanone (X, 15.4 g, 0.058 mol), dry silver acetate (16.5 g, 0.099 mol) and anhydrous acetic acid (140 m*l*) was refluxed for 6 hr. The reaction mixture was cooled and the solid deposited was filtered and washed with acetic acid. The combined filtrate and washing were mixed with dry sliver acetate (16.5 g, 0.099 mol). After the mixture had been refluxed for 3 hr, the solvent was removed under reduced pressure and the residue was extracted with ether. The residue obtained by evaporation of the solvent was distilled *in vacuo* to yield a light yellow viscous liquid, 3.4 g (23.9%), bp 73—124°C/6×10^{-4} mmHg. Redistillation of this material afforded XII as a viscous liquid, bp 90°C/3×10^{-4} mmHg, n_D^{18} 1.44946 [lit,[2] bp 108—110°C/10^{-4} mmHg, n_D^{18} 1.4545], IR (neat): 2940, 1770—1740 (C=O of ketone and ester), 1143, 1085, 1055, 1020, 975, 928, 875, 838 cm^{-1}.

Found: C, 48.49; H, 5.77%. Calcd for $C_{10}H_{14}O_7$: C, 48.78; H, 5.73%.

b) From 1-Acetoxy-3,4-dibromobutan-2-one (XI): A mixture of XI (14.4 g, 0.05 mol), dry silver acetate (28.4 g, 0.17 mol) and dry acetic acid (200 m*l*) was treated according to the procedure used in the case of X. A minor amount of viscous yellow liquid, bp 80—125°C/10^{-4} mmHg was obtained. Although the liquid gave a weak positive Beilstein test, the IR spectrum was found to be closely related to that of the product obtained from X [IR: 2920, 1760—1700 (C=O of ketone and ester), 1135, 1075, 1050, 1020, 935, 910, 875, 835 cm^{-1}]. Presumably the liquid contains XII as a major component. Further purification was not performed.

DL-Erythrulose (XIII). A mixture of barium hydroxide octahydrate (8 g), water (80 m*l*) and the triacetate (XII, 2.5 g) was kept at 0°C for 90 min with occasional shaking, after which the mixture was saturated with carbon dioxide and the barium carbonate formed was removed by filtration. 4N Sulfuric acid was added to the filtrate in a slight excess. After the barium sulfate precipitated had been removed by means of a centrifuge, the solution was concentrated *in vacuo* at a temperature below 23°C to one fourth in volume. The concentrated solution was treated with Dowex 30 and again concentrated *in vacuo* at a temperature below 20°C. The syrupy residue was placed in an evacuated desiccator containing phosphorus pentoxide, yielding DL-erythrulose (XIII) as viscous syrup, 0.8 g. The syrup reduced cold Fehling's solution instantaneously.

A mixture of XIII (0.2 g) and a solution of phenylhydrazine in 50% aqueous acetic acid was kept at room temperature for 10 days to give deep brown precipitate. This material was crystallized from benzene to yield DL-erythrulose osazone as yellow needles, mp 168—169°C [lit, mp 166—168°C;[2] mp 167°C[35]].

Financial support from Mr. Tokusuke Egawa, president of Kofuku-sogo Bank, is gratefully acknowledged.

Total Syntheses of Carbohydrates. II. DL-Erythrose and DL-Threose

Kenkichi SONOGASHIRA* and Masazumi NAKAGAWA**

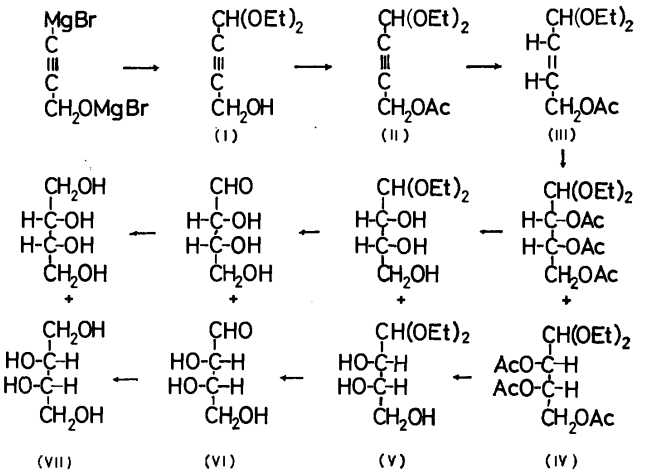
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received January 24, 1972)

Propargyl alcohol was converted into 4-acetoxy-*cis*-crotonaldehyde diethyl acetal (III) *via* three steps. *cis*-Hydroxylation of III with potassium permanganate followed by acetylation yielded tri-*O*-acetyl-DL-erythrose diethyl acetal (IV). Hydrolysis of IV afforded syrupy DL-erythrose (VI) which could be converted into erythritol (VII) and its dibenzylidene derivative. An acid hydrolysis of III gave 4-acetoxy-crotonaldehyde (VIII) which was converted into triacetyl-DL-threose diethyl acetal (XI) or DL-threose pentaacetate (XII). Hydrolysis of XI and XII gave syrupy DL-threose which could be identified as di-benzylidenethreitol.

The total syntheses of dihydroxyacetone and DL-*glycero*-tetrulose (DL-erythrulose) have been reported.[1] The present paper deals with the total syntheses of DL-etythrose (VII) and DL-threose (XIV). The syntheses were achieved by Glattfeld and Kribben by the Rosenmund reduction of the corresponding aldonic acid chloride derivative which had been derived from allyl alcohol using stereospecific reactions.[2] An excellent total synthesis of DL-threose (XIV) was reported by Schmid and Grob[3] by the *cis*-hydroxylation of *trans*-1,1,4-triacetoxy-2-butene which can be prepared from crotonaldehyde.

cis- and *trans*-Ethylenic compounds have now became readily available from acetylenic precursors by stereoselective half-reduction. Various methods of stereospecific *cis*- and *trans*-hydroxylation of ethylenic bond are also known. A combination of these two seems to offer a new possibility of stereospecific syntheses of carbohydrates.[4] In the present study, propargyl alcohol was used as a starting material.



Scheme 1. Synthesis of DL-erythrose (VII).

The reaction sequence of total synthesis of DL-erythrose (VII) is shown in Scheme 1. *Erythro*-configuration was accomplished by *cis*-hydroxylation of the *cis*-olefinic compound (III) with potassium permanganate. The reaction of ethyl orthoformate with bis-Grignard derivative of propargyl alcohol was carried out according to the reported method[5] with modification to afford C_4-acetal (I). C_4-acetal (I) gave *cis*-olefinic acetoxy-acetal (III) in a high yield by acetylation followed by half-reduction over the Lindlar catalyst.[6] The reduction of C_4-acetal (I) using the same catalyst gave *cis*-olefinic hydroxy-acetal only in a low yield presumably owing to the cleavage of acetal bond.

cis-Hydroxylation of III was carried out in the usual way with aqueous potassium permanganate at temperatures of 0—5°C. Introduction of carbon dioxide into the reaction mixture to neutralize the potassium hydroxide formed during the course of reaction gave no appreciable effect. The crude reaction product was acetylated with acetic anhydride and pyridine. The acetylated product was distilled *in vacuo* to give 2,3,4-tri-*O*-acetyl-DL-erythrose diethyl acetal (IV) in a 28% yeild together with a recovery of III. The results of elemental analysis and IR spectrum were found to be consistent with the assigned structure (IV). Treatment of IV with sodium methoxide in methanol at a low temperature afforded DL-erythrose diethyl acetal (V) as a fairly pure syrup. Syrup V was hydrolyzed with dilute sulfuric acid to yield colorless syrup of DL-erythrose (VI). Paper chromatography of VI thus obtained produced a spot exactly corresponding to

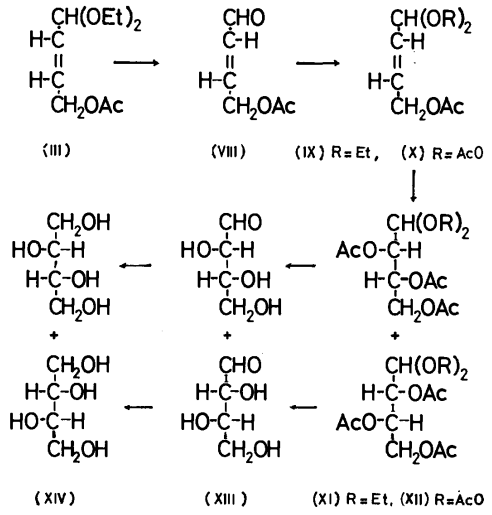
that of authentic D-erythrose.[7] Hydrogenation of VI over platinum catalyst yielded crystalline erythritol (VII) which gave a superimposable IR spectrum with that of an authentic specimen (Fig. 1). The mixed melting point of VII with an authentic erythritol showed no depression. Di-*O*-benzylidene derivative obtained from VII (mp 201—202°C) showed an identical melting point with the reported value (mp 201—202°C).[8] The IR spectrum of di-*O*-benzylidene erythritol is shown in Fig. 2 toghether with that of threitol derivative.

trans-Hydroxylation of *cis*-ethylenic linkage affords *threo*-configuration. However, all attempts at *trans*-hydroxylation of *cis*-acetoxy acetal (III) with performic, peracetic or perbenzoic acid were unsuccessful. 4-Acetoxy crotonic acid was isolated from the reaction product of performic or peracetic acid oxidation. This indicates that the hydrolysis of acetal bond may occur prior to the epoxidation of the ethylenic linkage. Consequently, an inverse route to *threo*-configuration, *i.e.*, *trans*-hydroxylation of *trans*-olefin, was investigated. Reduction of acetylenic alcohol (I) or its 4-*O*-tetrahydro-2-pyranyl derivative in liquid ammonia with sodium[9,10] and reduction of I with lithium aluminum hydride[11] were found to be infeasible for preparative



Scheme 2. Synthesis of DL-threose (XIV).

purposes owing to the poor yield of *trans*-ethylenic compound. *cis*-Ethylenic acetal (III) was hydrolyzed at room temperature (Scheme 2) with 70% aqueous formic or 50% aqueous acetic acid to give *trans*-ethylenic aldehyde (VIII),[12] which could be converted into *trans*-ethylenic acetal (IX, 64%) by the usual method.[13] *trans*-Ethylenic aldehyde diacetate (X, 71%) was also obtained by the actions of acetic anhydride and sulfuric acid on VIII. *cis*-Hydroxylation of *trans*-ethylenic acetal (IX) was carried out with an aqueous potassium permanganate at a low temperature introducing carbon dioxide into the reaction mixture. The product was acetylated without purification. The resulting acetylated material was distilled *in vacuo* to yield DL-threose derivative (XI, 14%) together with a recovery of IX. DL-Threose derivative (XI) thus prepared was treated successively with sodium methoxide in methanol and sulfuric acid to yeild DL-threose (XIII) as a syrup. The syrupy XIII was reduced over platinum catalyst, and the product was converted into crystalline di-*O*-benzylidene derivative. The benzylidene derivative showed an identical melting point (mp 218—219.5°C) with the reported value of di-*O*-benzylidene-DL-threitol (mp 220.5°C).[3] Di-*O*-benzylidene-erythritol has a much lower melting point than that of threitol derivative, and the IR spectra of these two dibenzylidene derivatives also show the difference seen in Fig. 2. The above results confirm the *threo*-configuration of XIII and XIV.

trans-Ethylenic triacetate (X) prepared by Schmid and Grob[3] from crotonaldehyde diacetate and used as an intermediate of the synthesis of DL-threose could be converted into DL-threose pentaacetate (XII) by their method on treatment with the Milas reagent[14] followed by acetylation. The hydrolysis of XII with sodium methoxide in methanol afforded syrupy DL-threose (XIII) which could be identified as di-*O*-benzylidene derivative of threitol (XIV).

The overall yield of DL-threose (XIII) from propargyl alcohol was found to be *ca.* 3.3% *via* acetal and 2.7% *via* triacetate (X).

Experimental

All the melting points are uncorrected. The IR spectra were obtained on a Hitachi EPI-2 Spectrophotometer.

1,1-Diethoxy-2-butyn-4-ol (I). A solution of propargyl alcohol (39.2 g, 0.7 mol) in tetrahydrofuran (50 m*l*) was added to a solution of ethylmagnesium bromide (prepared from magnesium, 36.5 g, 1.5 g-atom, ethyl bromide, 163.5 g. 1.5 mol and tetrahydrofuran, 400 m*l*) over a period of 1 hr. After the mixture had been refluxed for 3 hr, ethyl orthoformate (104 g, 0.7 mol) was added to the cooled mixture in one portion. The mixture was refluxed for 8 hr under stirring and stood overnight at room temperature. After a part of the solvent (*ca.* 200 m*l*) has been distilled off, the mixture was added to an ice-cooled solution of ammonium

acetate (200 g) in water (700 ml) and shaken with ether. The emulsion formed was broken by filtering through a layer of celite. The celite layer was washed with ether and the aqueous layer was extracted with the same solvent. The combined extracts and washings were dried (sodium sulfate) and the solvent was removed under reduced pressure. Distillation of the residue *in vacuo* afforded colorless liquid, bp 113—115°C/3 mmHg as main fraction. This material was redistilled to give pure I, 49.5 g (45%), bp 100—102°C/1.5 mmHg, n_D^{25} 1.4491 [lit,[5] bp 118—122°C/9 mmHg, bp 88°C/0.5 mmHg; n_D^{25} 1.4495, IR (neat): 3400 (O–H) cm^{-1}].

Found: C, 60.90; H, 8.97%. Calcd for $C_8H_{14}O_3$: C, 60.73; H, 8.92%.

Diethoxybutynol (I) was found to be unstable and turned pale yellow after several hours at room temperature, but could be kept without decomposition in a tightly stoppered flask in a refrigerator.

4-Acetoxy-1,1-diethoxy-2-butyne (II). A mixture of acetic anhydride (90 ml) and hydroxy acetal (I, 57.9 g, 0.365 mol) was heated to 95—100°C for 2 hr. The residue obtained by evaporation of acetic acid and acetic anhydride under reduced pressure was distilled *in vacuo* to give II as colorless liquid, bp 86—89°C/2.5 mmHg, 62.3 g (85.3%), n_D^{20} 1.4413, IR (neat): 1735, 1235 (CH_3CO_2–) cm^{-1}. An analytical specimen was obtained by redistillation of this material, bp 84°C/2.2 mmHg.

Found: C, 59.98; H, 8.06%. Calcd for $C_{10}H_{16}O_4$: C, 59.98; H, 8.05%.

II was found to be unstable and turned pale yellow on standing a few hours at room temperature. Acetylation of I with pyridine-acetic anhydride gave II in a low yield (56.2%).

*4-Acetoxy-*cis*-crotonaldehyde Diethyl Acetal (III).* II (20.0 g, 0.1 mol) in benzene (100 ml) was reduced over a Lindlar catalyst[6] (3.5 g) at 16°C. Uptake of 1 mol of hydrogen was observed over a period of 1.5 hr. The catalyst was removed by filtration and the solvent was distilled off under reduced pressure. Distillation of the residue *in vacuo* afforded III as colorless liquid, 19.2 g (96%), bp 91—93°C/4 mmHg, n_D^{20} 1.4318, IR (neat): 1730, 1235 (CH_3CO_2–), 1650 (–CH=CH–) cm^{-1}.

Found: C, 59.42; H, 8.95%. Calcd for $C_{10}H_{18}O_4$: C, 59.38; H, 8.97%.

*2,3,4-Tri-*O*-acetyl-*DL*-erythrose Diethyl Acetal (IV).* To a vigorously stirred suspension of III (10 g, 0.050 mol) in water (100 ml) was added an aqueous solution (420 ml) of potassium permanganate (7.5 g) over a period of 1.25 hr at 0—5°C. After the addition had been completed, the reaction mixture was warmed to 35°C to coagulate the manganese dioxide formed. The dioxide collected on a sintered glass filter was washed with methanol and water, successively. The washings were combined with the filtrate and concentrated to *ca.* 115 ml under reduced pressure at a temperature below 35°C. The concentrated solution (pH 6.0) was saturated with sodium chloride and repeatedly extracted with ether, and dried (sodium sulfate). The residue obtained by evaporation of the solvent under diminished pressure was mixed with anhydrous methanol and benzene, and the solvent were again removed under reduced pressure. The procedure was repeated twice, giving a syrupy residue (4.6 g, IR (neat): 3450 (O–H) cm^{-1}). The residue was mixed with acetic anhydride (10 ml) and pyridine (10 ml). The mixture was kept at room temperature for 24 hr and then at 40°C for 18 hr. The reaction mixture was concentrated under reduced pressure at a temperature below 30°C. The ice-cooled residue was poured onto ice-water (100 ml) and extracted with ether. The extract was washed successively with 1N hydrochloric acid saturated with sodium chloride, a saturated aqueous solution of sodium hydrogen carbonate and a saturated sodium chloride solution and dried (sodium sulfate). The viscous liquid obtained by evaporation of the solvent under reduced pressure was subjected to high vacuum distillation. Acetoxy-crotonaldehyde diethyl acetal (III) was recovered as a forerun, bp 60°C/10^{-4} mmHg. Triacetyl-erythrose diethyl acetal (IV) was obtained as colorless viscous liquid, bp 94—100°C/10^{-4} mmHg, 4.4 g (28%). The material was redistilled to give pure IV, bp 97—98°C/10^{-4} mmHg, n_D^{20} 1.4327.

Found: C, 52.57; H, 7.53%. Calcd for $C_{14}H_{24}O_8$: C, 52.49; H, 7.55%.

DL-Erythrose Diethyl Acetal (V). A solution of IV (2.4 g) in anhydrous methanol (15 ml) was chilled to −13°C and mixed with 0.10N solution of sodium methoxide in methanol (10.0 ml) which had been cooled to the same temperature. After the mixture had been kept at −20°C for 24 hr, it was exactly neutralized with 1N sulfuric acid. The mixture was concentrated under reduced pressure at 20—25°C. The residue containing crystals of sodium sulfate and sodium acetate was extracted with anhydrous ethanol (10 ml). The extract was evaporated again under reduced pressure. The procedure was repeated twice, yielding DL-erythrose diethyl acetal (V) as colorless syrup, IR (neat): 3420 (O–H) cm^{-1}. An analytical specimen was prepared on standing a small portion of the syrup in a highly evacuated desiccator containing phosphorus pentoxide.

Found: C, 49.31; H, 9.22%. Calcd for $C_8H_{18}O_5$: C, 49.47; H, 9.34%.

All attempts to crystallize V failed.

DL-Erythrose (VI). The syrupy diethyl acetal (IV) was dissolved in 1N sulfuric acid (20 ml) and the solution was left standing for 5 days at room temperature. After the solution had been neutralized with 1N sodium hydroxide solution, water was removed under reduced pressure at a temperature below 20°C. Anhydrous methanol was added to the residue and the sodium sulfate deposited was removed by filtration. The filtrate was evaporated *in vacuo*, and the residue was extracted with the same solvent. Evaporation of the solvent *in vacuo* gave colorless syrup, 2.5 g (95%). A small portion of the syrup was dried in a highly evacuated desiccator over phosphorus pentoxide and subjected to elemental analysis.

Found: C, 40.91; H, 6.80%. Calcd for $C_4H_8O_4$: C, 40.00; H, 6.71%.

The syrup reduced Fehling's solution at room temperature. Descending paper chromatography (Filter paper: Toyo Roshi No. 51; solvent system: (A) upper layer of *n*-butyl alcohol–benzene–pyridine–water (5:1:3:3) or (B) methyl ethyl ketone saturated with water; detection reagent: anilinium oxalate) of the syrup gave a spot (R_f 0.51 (A); R_f 0.85 (B)). An authentic D-erythrose prepared by the method of Perlin and Brice[7] gave a spot at the same R_f-value (R_f 0.51 (A); R_f 0.85 (B))

Syrupy DL-erythrose (VI, 0.3 g) dissolved in a small amount of water was mixed with a solution of phenylhydrazine (1.5 g) in 50% aqueous acetic acid. The mixture was placed on a water-bath kept at 50°C for 1 hr. The yellow crystalline mass deposited was recrystallized once from water and then twice from benzene to give pure osazone, mp 166—167°C (decomp.) [lit,[2c] mp 166—167°C (decomp.)].

Found: C, 64.50; H, 6.10; N, 18.29%. Cacld for $C_{16}H_{18}O_2N_4$: C, 64.41; H, 6.08; N, 18.78%.

*Erythritol and Di-*O*-benzylidene-erythritol.* Syrupy DL-erythrose (VI, 0.41 g) in methanol was reduced over platinum catalyst (prepared from platinum oxide, 25 mg) at 100°C for 2 hr (initial pressure of hydrogen: 44 atm.). The catalyst was removed by filtration and the filtrate was evaporated

under diminished pressure to give colorless crystals, 0.39 g. The crystals were recrystallized twice from a small amount of methanol to yield pure erythritol, mp 116.5—118.5°C, which showed no depression of melting point on admixture with an authentic specimen of erythritol, mp 117—118°C.

Found: C, 39.24; H, 8.22%. Calcd for $C_4H_{10}O_4$: C, 39.34; H, 8.25%.

Erythritol thus obtained was converted into di-*O*-benzylidene-erythritol according to the method of Fischer.[8] The benzylidene derivative showed melting point identical with that of reported value, mp 201—202°C [lit,[8] 201—202°C].

4-Acetoxy-crotonaldehyde (VIII). Acetoxy-*cis*-ethylenic acetal (III, 3.8 g) dissolved in a mixture of formic acid (5 m*l*) and water (2 m*l*) was kept at room temperature for 24 hr. Benzene was added to the residue obtained by evaporation of the mixture and benzene was again removed under reduced pressure. The residue was distilled *in vacuo* to give colorless liquid, bp 54—57°C/1 mmHg. Redistillation of this substance afforded pure 4-acetoxy-crotonaldehyde (VIII) as colorless liquid, 1.4 g (60%), bp 73—76°C/3 mmHg, n_D^{20} 1.4518, IR (neat): 1730, 1225 (CH_3CO_2–), 1680, 2760 (–CHO), 1640, 960 (*trans* –CH=CH–) cm^{-1}.

Found: C, 56.39; H, 6.89%. Calcd for $C_6H_8O_3$: C, 56.24; H, 6.29%.

2,4-Dinitrophenylhydrazone: mp 158—161°C (decomp.) (from ethanol).

Found: C, 46.28; H, 3.98; N, 18.04%. Calcd for $C_{12}H_{12}O_6N_4$: C, 46.76; H, 3.92; N, 18.18%.

4-Acetoxy-crotonaldehyde Diethyl Acetal (IX). Ethyl orthoformate (2.7 g, 0.02 mol) and ammonium nitrate (0.1 g) were added to a solution of *trans*-aldehyde (VIII, 2.65 g, 0.02 mol) in anhydrous ethanol (10 m*l*). The mixture was heated to 100°C and ethyl formate and ethanol were gradually distilled off through a Widmer column. Distillation of the residue *in vacuo* afforded colorless liquid, 1.55 g (37.2%), bp 77—80°C/1.5 mmHg. This material was redistilled to give pure IX, bp 74—75°C/1 mmHg, n_D^{20} 1.4328, IR (neat): 1765, 1230 (CH_3CO_2–), 1650, 950 (*trans* –CH=CH–) cm^{-1}.

Found: C, 59.10; H, 8.93%. Calcd for $C_{10}H_{18}O_4$: C, 59.38; H, 8.97%.

IX could be obtained in a much higher yield without isolation of VIII. After a solution of *cis*-acetal (III, 11.0 g, 0.055 mol) in 50% aqueous acetic acid (20 m*l*) had been kept at 40°C for 48 hr, the solvent was removed under reduced pressure. The residue was mixed with benzene and the solvent was again distilled off *in vacuo*. This procedure was repeated twice. Acetalization of the residue according to the above method yielded IX, 7.0 g (63.6%).

2,3,4-Tri-O-*acetyl*-DL-*threose Diethyl Acetal (XI).* An aqueous solution of potassium permanganate (6.65 g in 220 m*l* of water) was added dropwise to a vigorously stirred suspension of *trans*-acetal (IX, 9.4 g, 0.047 mol) in water (60 m*l*) over a period of 70 min. The mixture was kept at 0°C and carbon dioxide was continuously introduced into the mixture. The reaction mixture was worked up according to the method used for the preparation of tri-*O*-acetyl-erythrose diethyl acetal (IV). The crude acetoxy-dihydroxy-acetal (5.7 g) thus obtained was mixed with pyridine (12 m*l*) and acetic anhydride (12 m*l*). The mixture was allowed to stand at room temperature for 27 hr and then at 35°C for 21 hr. Deep brown liquid obtained by concentration of the mixture under reduced pressure was dissolved in ether. The ice-cooled ether solution was poured onto ice-water (100 m*l*). The mixture was saturated with sodium chloride and repeatedly extracted with ether. The extract was washed twice with 1N hydrochloric acid saturated with sodium chloride, once with a saturated sodium hydrogen carbonate solution and water and then dried (sodium sulfate). The residue obtained by evaporation of the solvent gave on a vacuum distillation a forerun (recovered IX, bp 60—70°C/6×10^{-4} mmHg, 3.2 g) and XI, colorless syrup, 1.4 g (14% based on consumed IX), n_D^{25} 1.4368.

4-Acetoxy-crotonaldehyde Diacetate (X). A solution of *cis*-ethylenic acetal (III, 15.8 g, 0.077 mol) in 50% aqueous acetic acid was kept at 40°C for 48 hr. The residue obtained by evaporation of the solvent under reduced pressure was mixed with acetic anhydride (30 m*l*). A few drops of concentrated sulfuric acid was added to the mixture under cooling with water. After the mixture had been kept at room temperature for 20 hr, powdered sodium acetate (0.6 g) was added and distilled to yield X as colorless viscous liquid, 12.6 g (71%), bp 122—124°C/1.8 mmHg [lit,[3] bp 102—104°C/1×10^{-2} mmHg], n_D^{20} 1.4414.

Found: C, 52.43; H, 6.41%. Calcd for $C_{10}H_{14}O_6$: C, 52.17; H, 6.13%.

DL-*Threose Pentaacetate (XII).* Acetoxy-crotonaldehyde diacetate (X, 4.4 g, 0.02 mol) was treated with Milas' reagent[14] according to the reported method.[3] Acetylation of the reaction product (IR: 3400 (O–H) cm^{-1}) by means of acetic anhydride (12 m*l*) and pyridine (12 m*l*) yielded XII as colorless liquid, 0.7 g (11%), bp 92—100°C/1×10^{-4} mmHg [lit,[3] bp 115—122°C/5×10^{-3} mmHg].

Found: C, 49.05; H, 5.90%. Calcd for $C_{14}H_{20}O_{10}$: C, 48.27; H, 5.79%.

DL-*Threose (XIII).* *a) By Hydrolysis of 2,3,4-Tri*-O-*acetyl*-DL-*threose Diethyl Acetal (XI)*: Hydrolysis of XI (14 g) according to the method used for triacetyl-DL-erythrose diethyl acetal (IV) afforded DL-threose (XIII) as light brown syrup (0.5 g). The syrup reduced cold Fehling's solution. The crude XIII was subjected to the reduction without purification.

b) By Hydrolysis of DL-*Threose Pentaacetate (XII)*: DL-Threose pentaacetate (0.7 g) in anhydrous methanol (30 m*l*) was mixed with 2% solution of sodium methoxide in anhydrous methanol (10 m*l*) at −10°C. The mixture was kept at the same temperature for 24 hr, and then was neutralized with 1N sulfuric acid. Sodium sulfate deposited was removed by filtration. The filtrate was concentrated under reduced pressure. The residue was mixed with anhydrous methanol and the sulfate was again removed. Concentration of the filtrate *in vacuo* afforded DL-threose (XIII) as a light brown syrup (0.2 g). The syrup reduced Fehling's solution at room temperature.

Di-O-*benzylidene-threitol.* *a) From* DL-*Threose Obtained from XI*: Syrupy DL-threose (XIII) obtained from XI in 75% aqueous ethanol was reduced over platinum catalyst (initial pressure: 70 atm; 100°C; 3 hr). The reduction product worked up according to the procedure employed in the preparation of erythritol (VII) gave threitol (XIV, 0.25 g) as a syrup. The syrup was mixed with benzaldehyde (0.75 m*l*) and hydrochloric acid (0.9 m*l*). After the mixture was kept at room temperature for 1 hr, it was extracted with chloroform. The extract was washed successively with a sodium hydrogen carbonate solution and water and dried. The residue obtained by evaporation of the solvent was dissolved in hot ethanol and treated with active charcoal to yield di-benzylidene-threitol as colorless needles, 200 mg, mp 218—219.5°C [lit,[3] 220.5°C], IR: *Cf.*, Fig. 2.

Found: C, 72.78; H, 6.12%. Calcd for $C_{18}H_{18}O_4$: C, 72.46; H, 6.08%.

b) From DL-*Threose Obtained from XII*: Crude DL-threose (XIII) obtained by the hydrolysis of XII was reduced according to the procedure for the preparation of VII. The light brown syrupy threitol (XIV) obtained was converted into

di-benzylidene-threitol, colorless needles, mp 218—219°C. This material showed no depression of melting point on admixture with di-benzylidene-threitol derived from XI. The IR spectrum was found to be superimposable with that of the benzylidene derivative obtained from XI.

The financial support extended by Mr. Tokusuke Egawa, president of Kofuku-sogo Bank, is gratefully acknowledged.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2620—2624 (1972)

Total Syntheses of Carbohydrates. III. DL-Glyceraldehyde and 2-Deoxy-DL-*erythro*-pentose

Kosuke MIMAKI, Michihiko MASUNARI, Gen NAKAMINAMI, and Masazumi NAKAGAWA*

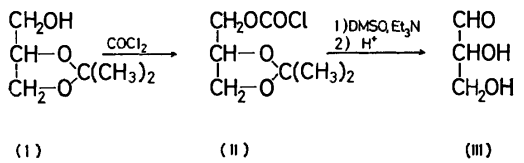
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received January 31, 1972)

The synthesis of DL-glyceraldehyde (III) by the Barton's oxidation of DL-isopropylideneglycerol (I) was described. 2-Deoxy-DL-*erythro*-pentose (IX) (2-deoxy-DL-ribose) has been synthesized by the Barton's oxidation of 2-deoxy-3,4-*O*-isopropylidene-5-*O*-(tetrahydro-2-pyranyl)-DL-*erythro*-pentitol (VIII) and by the hydroboration of DL-*erythro*-4-pentyn-1,2,3-triol (XI) followed by hydrogen peroxide oxidation. The latter method gave crystalline 2-deoxy-DL-*erythro*-pentose (IX) in a reasonable yield.

In the previous papers, we have reported the syntheses of dihydroxyacetone,[1] DL-*glycero*-tetrulose,[1] DL-threose[2] and DL-erythrose[2] starting from simple acetylenic compounds. Selective synthesis of *cis*- and *trans*-ethylenic compounds followed by stereospecific hydroxylation of ethylenic linkage and introduction of carbonyl function played important roles in the syntheses of these carbohydrates. In the present paper, we wish to report a new syntheses of DL-glyceraldehyde (III) and the syntheses of 2-deoxy-DL-*erythro*-pentose (IX) according to two different routes.

The Pfitzner-Moffatt reagent[3] has been proved to be adequate for the conversion of primary alcohol to aldehyde. However, disadvantage of application of this reagent[4] or the dimethylsulfoxide-acetic anhydride reagent[5] for carbohydrate synthesis has been pointed out by several authors. We have carried out the synthesis of DL-glyceraldehyde (III) by means of the Barton's oxidation[6] proving the usefulness of this procedure for carbohydrate synthesis. As is illustrated in Scheme 1, DL-isopropylideneglycerol (I) in dry ether was treated with phosgene in the presence of quinoline to give chloroformate (II) in a good yield. Purification of chloroformate (II) was achieved by a distillation under reduced pressure. However, the crude II could be used in the subsequent reaction without difficulty. Crude chlorofomate (II) was mixed with dimethyl sulfoxide resulting in evolution of carbon dioxide. After treatment with triethylamine, the protective group was hydrolyzed by means of ion-exchange resin. DL-Glyceralehyde (III) was obtained as syrupy liquid, and gave a single spot on tlc which corresponds exactly with that of an authentic specimen. The syrupy glyceradehyde (III) partly crystallized on standing. 2,4-Dinitrophenylhydrazone of III was obtained in a yield of 33% based on DL-isopropylideneglycerol (I).



(I) (II) (III)

Scheme 1. Synthesis of DL-glyceraldehyde (III). DMSO=dimethyl sulfoxide

The successful result of the Barton's oxidation prompted the present authors to the synthesis of 2-deoxy-DL-*erythro*-pentose (IX) employing the same oxidation reaction.

The total syntheses of 2-deoxy-*erythro*-pentose (IX) have been reported by Fraser and Raphael[7] and Weygand and Leube.[8] In the former case, the yield of the pentose was found to be unsatisfactory, however, anilide of 2-deoxy-*erythro*-pentose (IX) was obtained in an overall yield of 2.5% in the latter case using commercially available 1-methoxy-1-buten-3-yne as starting meterial.

The reaction sequence we have employed was shown in Scheme 2.

The reaction of lithium acetylide of tetrahydropyranyl ether derivative of propargyl alcohol (IV) in refluxing liquid ammonia with ethylene oxide gave

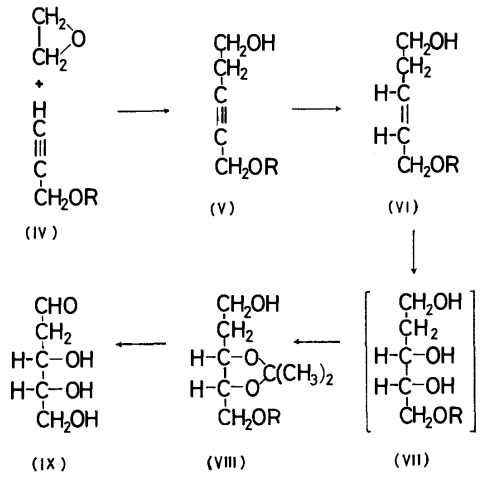

Scheme 2. Synthesis of 2-deoxy-DL-*erythro*-pentose (IX).
R=tetrahydropyranyl
The formulae of D-isomers are shown for brevity.

C_5-acetylenic compound (V) in a high yield. A half-reduction of V by means of Lindlar catalyst[9] afforded C_5-*cis*-ethylenic compound (VI). VI was treated with potassium permanganate to cause *cis*-hydroxylation of the *cis*-ethylenic bond. 3,4-*erythro*-Compound (VII) was obtained as a viscous syrup. Syrupy VII, which was proved to be fairly homogeneous by tlc, was subjected to the following reaction without purification. A difficulty was encountered in the conversion of VII to the corresponding acetonide (VIII). The reaction of VII with acetone in the presence of anhydrous cupric sulfate was followed by IR spectroscopy and tlc. The change of IR spectra indicated that the cleavage of tetrahydropyranyl group occurred accompanying an anomalous increase in the amount of dimethyldioxolane ring on heating the mixture under reflux. Therefore, the reaction was carried out at room temperature, and the reaction was quenched as soon as the spot of VII in tlc disappeared. Chromatographic purification of the reaction product on alumina gave crude isopropylidene derivative (VIII) in a low yield. The Barton's oxidation[6] of the crude VIII followed by acid hydrolysis of the protective groups resulted in a syrupy product, which gave a spot corresponding to that of authentic 2-deoxy-D-*erythro*-pentose. The crude 2-deoxy-DL-*etythro*-pentose (IX) thus obtained gave crystalline anilide in a low yield. The preparation of 2-deoxy-DL-*erythro*-pentose (IX) according to the reaction sequence indicated in Scheme 2 resulted in a rather unsatisfactory consequence. However, the usefulness of the Barton's oxidation in carbohydrate chemistry seems to remain for further investigation.

Preparation of aldehyde by addition of bis(1,2-dimethylpropyl)borane to terminal ethynyl group followed by oxidation with hydrogen peroxide has been reported by Brown and Zweifel.[10] Application of this method to a poly-ol having an ethynyl group is a conceivable route of synthesis of 2-deoxyaldose. DL-*erythro*-4-Pentyn-1,2,3-triol (XI),[11] a precursor for the synthesis of DL-*erythro*-pentose (IX), is a known compound prepared by *trans*-hydroxylation of *trans*-2-penten-4-yn-1-ol (X)[12] by means of performic acid. According to the reaction sequence illustrated in Scheme 3, the triol (XI) was treated with an excess of bis(1,2-dimethylpropyl)borane and the reaction product was oxidized with hydrogen peroxide under careful addition of 1N sodium hydroxide solution to neutralize the resulting boric acid, and to keep the pH of medium at 7.0—7.5. The control of pH is essential in this reaction. An appreciable decrease in the yield of IX was observed when the pH of medium increased to *ca.* 9. The reaction mixture was mixed with sodium hydrogen sulfite solution, and then deionized with ion-exchange resin. The syrup obtained by removing boric acid as methyl ester was treated with aniline according to the usual manner. The anilide thus obtained was found to be identical with that of an authentic D-IX and that of DL-IX which was prepared by another synthetic route.[13] The IR spectra of anilide derived from DL-IX and an authentic D-IX are recorded in Fig. 1. The yield of anilide of IX on the basis of ethynyl compound (XI) was found to be 20%, and the overall yield from epichlorohydrin was 3.8%. The free pentose (IX) obtained from anilide crystallized completely on seeding with a piece of crystal of an authentic D-isomer. The elemental analysis and the comparison of tlc with that of an authentic D-IX indicate that the crystals are 2-deoxy-*erythro*- pentose (IX). The pentose (IX) showed no optical activity over a wide range of wavelength indicating the crystallization of DL-isomer. This is the

first instance of crystalline 2-deoxy-DL-*erythro*-pentose (IX).

After completion of this study, an independent paper on the application of hydroboration for the synthesis of α,β-ethylenic aldose derivatives was published.[14]

Experimental

Silica Gel G (E. Merck, Darmstadt, Germany) was used for tlc. Anisaldehyde-sulfuric acid-acetic acid-ethanol[15a] (A), concentrated sulfuric acid[15b] (B) and diphenylamine-sulfuric acid-acetic acid[16] (C) were used as detection reagents. In the case of reagent (C), the splayed tlc plate was covered with another glass plate and baked at 90—100°C to develop the color. IR spectroscopy was performed with a Hitachi EPI-2 or a Japan Spectroscopic DS-402G Spectrophotometer. NMR spectra were obtained on Varian A-60 Spectrometer operated at 60 MHz using TMS as internal standard. All the melting points are uncorrected.

*1-O-Chloroformyl-2,3-O-isopropylidene-*DL*-glycerol (II).* A solution of DL-isopropylideneglycerol[17] (I, 13.2 g, 0.1 mol) and quinoline (12.9 g, 0.1 mol) in anhydrous ether (150 ml) was strongly chilled on an ice-salt bath. Phosgene passed through linseed oil and concentrated sulfuric acid was introduced for 2 hr into the chilled solution under stirring. Further stirring was continued for 30 min under cooling, and then for 2 hr at room temperature. The reaction mixture was filtered to remove quinoline hydrochloride with the aid of slight excess air pressure avoiding atmospheric moisture. Evaporation of the filtrate under reduced pressure yielded viscous light yellow liquid [15.6 g, 80%, IR (neat): 1784 (Cl-C=O), 1383, 1375, 842 (dimethyl dioxolane) cm^{-1}]. The crude chloroformate (II) could be used without purification in the subsequent reaction. Crude II turned to brown in a few days on standing at room temperature. A vacuum distillation of the crude material afforded pure II as colorless liquid, bp 75°C/7 mmHg, n_D^{25} 1.4381, NMR (CCl_4): δ 1.32 (3H, s) CH_3; δ 1.39 (3H, s) CH_3.

Found: C, 43.93; H, 5.75; Cl, 17.99%. Calcd for $C_7H_{11}O_4Cl$: C, 43.20; H, 5.70; Cl, 18.22%.

DL-*Glyceraldehyde (III).* Dimethyl sulfoxide (5 ml) was added to chloroformate (II, 973 mg, 5 mmol) at 10—15°C under vigorous evolution of carbon dioxide. After 2 min, the cooling bath was removed, and the mixture was stirred for 15 min at room temperature (>20°C). The mixture was then chilled on an ice-bath and mixed with triethylamine (607 mg, 6 mmol). After the mixture had been stirred for 3 min at the temperature, stirring was continued for 20 min at room temperature (>20°C). Triethylammonium chloride deposited was removed by filtration. The filtrate was mixed with a cation exchange resin [Amberlite IR-200 (H^+) in water (10 ml)]. After the mixture had been stirred for 2 hr under ice cooling, an anion exchange resin [Dowex-3 (OH^-)] was added to remove chloride ion. The resins were removed by filtration and washed with water. The combined filtrate and washing, which gave negative silver nitrate and Beilstein tests, were concentrated under reduced pressure at a temperature below 35°C. After most of the water had been distilled off, remaining dimethyl sulfoxide was removed under high vacuum at the same temperature. The resulting syrup reduced strongly the Tollens' and the Fehling's solutions. The absorption arising from dimethyldioxolane ring completely disappeared in the IR spectrum of the syrupy material. The syrup gave one spot (R_f 0.36) on tlc (solvent: acetone; detection reagent: A or B), and the spot of isomeric dihydroxyacetone (R_f 0.64) or another spot could not be observed. An acetone solution of the syrup was placed for a long time in a refrigerator, resulting in deposition of a small amount of colorless rods, mp 127—135°C [lit, mp 138°C,[18] mp 142.5°C[19]]. The colorless crystals gave identical tlc with that of an authentic specimen. An acetone solution of syrupy III obtained by another run gave a small amount of colorless powder. The substance showed no definite melting point, but underwent color change to brown at *ca.* 200°C. However, tlc and IR spectrum of the colorless solid were found to be identical with those of an authentic specimen (*Cf.*, Fig. 2). It has been reported that the melting point of DL-glyceraldehyde (III) varies widely depending on the rate of heating and the method of measurement.[20] Our observation seems to be related with this phenomenon.

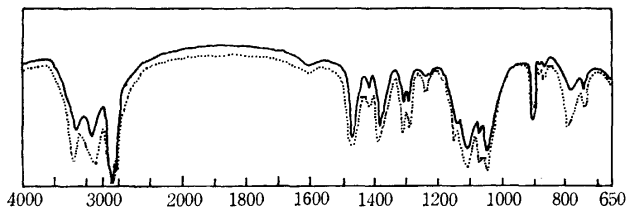

Fig. 2. IR spectra of DL-glyceraldehyde [mp *ca.* 200°C (decomp.)] (——) and an authentic DL-glyceraldehyde (·····), (Nujol mull).

2,4-Dinitrophenylhydrazone of DL*-Glyceraldehyde.* Syrupy DL-glyceraldehyde (III, 180 mg) was converted to the 2,4-dinitrophenylhydrazone (105.5 mg, 33% based on II) according to the reported method.[21] The hydrazone was recrystallized from ethyl acetate to give pure material, mp 169—169.5°C [lit,[21] mp 170°C]. 2,4-Dinitrophenylhydrazone thus prepared showed no depression of melting point on admixture with that of an authentic DL-glyceraldehyde, and the IR spectrum was superimposable with that of authentic specimen.

Found: C, 40.06; H, 3.85; N, 20.72%. Calcd for $C_9H_{10}O_6N_4$: C, 40.00; H, 3.73; N, 20.74%.

5-(Tetrahydro-2-pyranyloxy)-3-pentyn-1-ol (V). A solution of tetrahydropyranyl ether of propargyl alcohol[22] (IV, 60 g, 0.429 mol) in ether (36 ml) was added over a period of 1 hr to a stirred solution of lithium amide (prepared from lithium, 0.6 g, 0.87 g-atom) in liquid ammonia (600 ml). After the mixture had been stirred for 2 hr, ethylene oxide (60 ml, 1.2 mol) was added in a portion. The mixture was refluxed for 14.5 hr at a temperature of −26——30°C using a cold-finger reflux condenser containing dry ice-ethanol. After addition of a concentrated aqueous ammonia solution (6 ml), the ammonia was allowed to evaporate. The residue was mixed with water and extracted with ether. The extract

was washed with a saturated sodium chloride solution and dried (sodium sulfate). The residue obtained by evaporation of the solvent under reduced pressure was subjected to a vacuum distillation to give pure V as colorless liquid, bp 123—128°C/2 mmHg, n_D^{20} 1.4864, 57.9 g (73.5%) [lit,[23] bp 125—126°C/0.7 mmHg, n_D^{21} 1.4873]. IR (neat): 3440 (O–H), 2230 (–C≡C–), 902, 870, 815 (tetrahydropyranyl) cm^{-1}.

Found: C, 65.00; H, 8.72%. Calcd for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75%.

*5-(Tetrahydro-2-pyranyloxy)-3-*cis*-penten-1-ol (VI).* The acetylenic alcohol (V, 27.6 g, 0.15 mol) in ethyl acetate (150 m*l*) was reduced over Lindlar catalyst[9] (5.75 g) under an atomspheric pressure of hydrogen at room temperature. The uptake of hydrogen ceased after 4.5 hr (3520 m*l*, Calcd 3480 m*l*). The liquid obtained by evaporation of the solvent under diminished pressure was distilled *in vacuo* to yield pure VI as colorless liquid, bp 120—125°C/3 mmHg, n_D^{20} 1.4774, 25.0 g (90%), IR (neat): 3420 (O–H), 3015 (=C–H), 1662 (–C=C–), 902, 868, 814 (tetrahydropyranyl) cm^{-1}.

Found: C, 64.47; H, 9.71%. Calcd for $C_{10}H_{18}O_3$: C, 64.49; H, 9.74%.

*2-Deoxy-5-O-(tetrahydro-2-pyranyl)-*DL-erythro-*pentitol (VII).* To a solution of the ethylenic alcohol (VI, 45 g, 0.24 mol) in ethanol (450 m*l*) maintained at —40°C was added under vigorous agitation a solution of potassium permanganate (37.9 g, 0.24 mol) in water (700 m*l*) over a period of 13.5 hr. During this period, the temperature of reaction mixture was raised gradually to —20°C. After standing overnight, the reaction mixture was stirred at 35°C for 1 hr. Manganese dioxide was collected by filtration and washed with hot water. The combined filtrate and washings were salted out by the addition of anhydrous potassium carbonate. The organic layer was separated, and the aqueous layer was extracted with ether. The aqueous layer was then extracted with the same solvent for 24 hr using a continuous extractor. The organic layer was combined with the extracts and washed with a saturated solution of sodium chloride and dried (sodium sulfate). Evaporation of the solvent under reduced pressure afforded a light brown viscous syrup, 27.4 g (61%), tlc (solvent: ethyl acetate; detection reagent: A): R_f 0.15 (strong), 0.27 (weak), 0.35 (weak), 0.55 (medium), IR (neat): 3370 (O–H), 910, 870, 810 (tetrahydropyranyl) cm^{-1}. The spots at R_f 0.15 and 0.55 seem to be attributable to VII and VI, respectively. Since the purification was found to be difficult, the crude VII thus prepared was subjected to the following reaction.

*2-Deoxy-3,4-O-isopropylidene-5-O-(tetrahydro-2-pyranyl)-*DL-erythro-*pentitol (VIII).* A mixture of the crude VII (3.518 g), anhydrous cupric sulfate (17.6 g) and anhydrous acetone (352 m*l*) was stirred at room temperature. At 2 hr intervals, small samples of the solution were took out and examined by tlc (solvent: ethyl acetate; detection reagent: A). As soon as the spot of VII had disappeared (usually after 4—8 hr), cupric sulfate was removed by filtration to halt the reaction. The filtrate was concentrated under reduced pressure to give a pale yellow liquid (3.394 g). Tlc of the liquid exhibits a main spot at R_f *ca.* 0.7 and a minor spot at R_f *ca.* 0.9 (solvent: ethyl acetate; detection reagent: A). A 1 g-portion of the pale yellow liquid was chromatographed on alumina (E. Merck, activity III—IV, 100 g). The column was eluted with ethyl acetate and the eluant was fractionally collected (each 7 m*l*). The fractions 8 and 9 were homogeneous on tlc (R_f 0.9). The fraction 11 gave one spot at R_f 0.7, whereas the fractions 12—17 were found to be a mixture of two components (R_f 0.7 and 0.65). On evaporating the solvent under reduced pressure, the fraction 11 gave fairly pure VIII as a syrup (96 mg), IR (neat): 3420 (O–H), 1389, 1378, 845 (dimethyldioxolane), 907, 870, 810 (tetrahydropyranyl) cm^{-1}. NMR (DMSO-d_6): δ 1.26 (3H, s) CH_3, δ 1.31 (3H, s) CH_3, 4.55 (1H, broad s) $-CH\langle^{O}_{O}$.

Found: C, 60.99; H, 9.27%. Calcd for $C_{13}H_{24}O_5$: C, 59.98; H, 9.29%.

*2-Deoxy-*N*-phenyl-*DL-erythro-*pentosylamine.* *a) By the Barton's Oxidation*: Syrupy crude VIII (286 mg) obtained from the fractions 11—17 and quinoline (171 mg) were dissolved in anhydrous ether (20 m*l*). The solution was chilled on an ice-salt bath, into which a rapid stream of purified phosgene was introduced for 10 min. The reaction mixture was then stirred for 1 hr at 20°C. Quinoline hydrochloride deposited was filtered with the aid of slightly elevated air pressure avoiding atmospheric humidity. Concentration of the filtrate under reduced pressure yielded chloroformate as light yellow liquid [IR (neat): 1780 (Cl–C=O) cm^{-1}]. The crude chloroformate (355 mg) was mixed with dimethyl sulfoxide (5 m*l*) under stirring and external cooling (bath temperature: 10—15°C). After the exothermic reaction with evolution of carbon dioxide had subsided, the cooling bath was removed and the mixture was stirred at 20°C for 15 min. Then the ice-cooled reaction mixture was mixed with triethylamine (0.185 m*l*) and kept for 3 min at the same temperature. After stirring for 20 min at 20°C, amine hydrochloride deposit was removed. The filtrate was mixed with water (15 m*l*) under cooling, and extracted repeatedly with ether and dried (sodium sulfate). Evaporation of the solvent under diminished pressure gave a pale yellow liquid (205 mg). A mixture of the liquid (203 mg) and 0.1N hydrochloric acid (5 m*l*) was stirred overnight at room temperature. The liquid gradually dissolved in aqueous layer. After 18 hr, the mixture was treated with Dowex-3 (OH^-) to remove chloride ion, and 2-hydroxytetrahydropyran formed was extracted with ether. The aqueous layer was concentrated under reduced pressure at a temperature below 35°C. The syrupy residue was dried *in vacuo* over phosphorus pentoxide, yielding crude 2-deoxy-DL-*erythro*-pentose (IX, 89 mg). Tlc (solvent: acetone; detection reagent: B or C) gave a spot at R_f 0.60 which corresponds with that of an authentic D-isomer. A mixture of the syrupy IX (76 mg), aniline (0.103 m*l*), methanol (0.2 m*l*) and water (0.2 m*l*) was seeded with a trace amount of crystals of the anilide obtained from an authentic DL-IX and the mixture was kept in a refrigerator for a week. The crystals deposited were collected by filtration and washed with 50% aqueous methanol and ether, and then dried to yield the anilide of DL-IX as colorless leaflets (1 mg), mp 157—162°C (decomp.). The anilide thus obtained gave identical IR spectrum with that of the anilide by the method (b). (see, below).

b) By Hydroboration of DL-erythro-*4-Pentyn-1,2,3-triol (XI)*: A solution of bis(1,2-dimethylpropyl)borane was prepared according to the usual manner from a solution of 2-methyl-2-butene (4.6 g, 62.4 mmol) in tetrahydrofuran (20 m*l*) and a diborane stock solution (26.9 m*l*, 15.6 mmol). To the stirred solution of bis(1,2-dimethylpropyl)borane which was strongly cooled on an ice-salt bath was added in an atmosphere of nitrogen a solution of pentyn-triol (XI, 697 mg, 6 mmol) in tetrahydrofuran (5 m*l*) accompanying with evolution of hydrogen. The mixture was stirred for 30 min under ice-cooling, then for 2 hr at room temperature. After standing overnight at room temperature, water (120 m*l*) was added under ice-cooling and stirring. Hydrogen peroxide (15%, 13.6 m*l*) was then added dropwise over a period of 20 min to the

23) L. P. Wells, Istraeli 9220, *Chem. Abstr.*, **52**, 20058 (1958).

vigorously stirred mixture, simultaneously 1N sodium hydroxide solution was added in amall drops to keep the pH of mixture at 7.0—7.5. Further stirring was continued for 30 min under ice-cooling, then for 4 hr at room temperature. In order to decompose the excess of hydrogen peroxide, 1N sodium hydrogen sulfite solution was added to the ice-cooled mixture in 1 m*l* portion until the mixture gave negative iodine-starch test. The resulting solution was treated with Amberlite IR 200 (H^+) and Dowex-3 (OH^-) to remove sodium and sulfate ions. The deionized solution was evaporated *in vacuo* at a temperature below 35°C. The residue, a mixture of syrupy liquid and crystalline boric acid, was mixed with methanol, and evaporated under reduced pressure. The procedure was repeated 3 times to remove boric acid as methyl ester. The residue was dried *in vacuo* over phosphorus pentoxide to yield crude 2-deoxy-DL-*erythro*-pentose (IX) as a syrup (750 mg). The syrupy IX (369 mg) was mixed with aniline (0.256 m*l*), ethanol (2.13 m*l*) and waer (0.99 m*l*) and kept in a refrigerator. After 2 days, 90 mg of crystals of the anilide deposited, and second crop of the anilide (36 mg) was obtained from the mother liquor. [Total yield: 20% based on the acetylenic triol (XI)]. The crystals were recrystallized from methanol to afford colorless plates, mp 157—160°C (decomp.). [lit,[8] mp 154—155°C]. The IR spectrum of the anilide was found to be identical with those of anilides derived from an authentic D-IX and DL-IX prepared by a different route.[13] IR (Nujol mull): 3330, 3260 (OH, NH), 1606, 1500, 1445, 760, 698 (aromatic) cm^{-1} (*Cf.*, Fig. 1).

2-Deoxy-erythro-*pentose (IX).* According to the usual method,[24] a mixture of anilide (75 mg), benzaldehyde (0.075 m*l*), benzoic acid (7.5 mg) and water (2.25 m*l*) was stirred at room temperature for 22 hr, and then extracted 3 times with ether. The aqueous layer was concentrated *in vacuo* at a temperature below 35°C, thus yielding a colorless syrup. After the syrup had been kept over phosphorus pentoxide *in vacuo*, a small amount of ethyl acetate was added. The mixture crystallized on seeding with a trace of crystals of an authentic D-IX. The crystalline DL-IX (44 mg, 92%) was recrystallized from ethyl acetate to yield pure DL-IX, mp 86—89°C, tlc (detection reagent: C): R_f 0.60 (solvent: acetone); R_f 0.74 (solvent: methanol). The R_f values were found to be identical with those of authentic DL-IX and D-IX prepared by a different method.[13]

Found: C, 45.03; H, 7.52%. Calcd for $C_5H_{10}O_4$: C, 44.77; H, 7.52%.

(Received January 31, 1972)

5-Bromo-2,5-dideoxy-*threo*-pentono-γ-lactone (III) could be obtained stereoselectively from 3-hydroxy-4-pentenoic acid (I) by the reaction with *N*-bromosuccinimide in water. On successive treatment with an aqueous potassium hydroxide and an acid type cation exchange resin, bromolactone (III) gave stereoselectively 2-deoxy-*erythro*-pentono-γ-lactone (IV). Reduction of IV by means of bis(1,2-dimethylpropyl)borane afforded 2-deoxy-*erythro*-pentose (V). 3-Hydroxy-4-pentenoic acid (I) could be optically resolved. The (+)-acid yielded 2-deoxy-D-*erythro*-pentose (D-V) and the (−)-acid could be converted to 2-deoxy-L-*erythro*-pentose (L-V). 2,5-Dideoxy-*threo*-pentose (VIII) and 5-bromo-2,5-dideoxy-*threo*-pentose (IX) were obtained from bromo-lactone (III). Diethyl mercaptal of IX gave azido-compound (XI) in a low yield by the reaction with sodium azide. The conformation of γ-lactones (III, IV, and VII) and the mechanistic aspects of stereoselective reactions are discussed.

In the previous paper we reported the total synthesis of *rac*-2-deoxy-*erythro*-pentose.[1] The present paper deals with the syntheses of optically active forms of the carbohydrate. In spite of remarkable development of the total syntheses of carbohydrates, only two reports on total syntheses of optically active carbohydrates have been published. Fischer has reported the total syntheses of D- and L-mannoses, D- and L-glucoses and D-fructose starting from mannonic acid which had been derived from acrolein dibromide *via* DL-glucosazone.[2] After about 80 years, L-(−)-mycalose which is a constituent of various macrolide antibiotics was synthesized by Lemal, Pacht, and Woodward.[3] After the publication of preliminary report of the present paper,[4] the total synthesis of optically active kasuga-

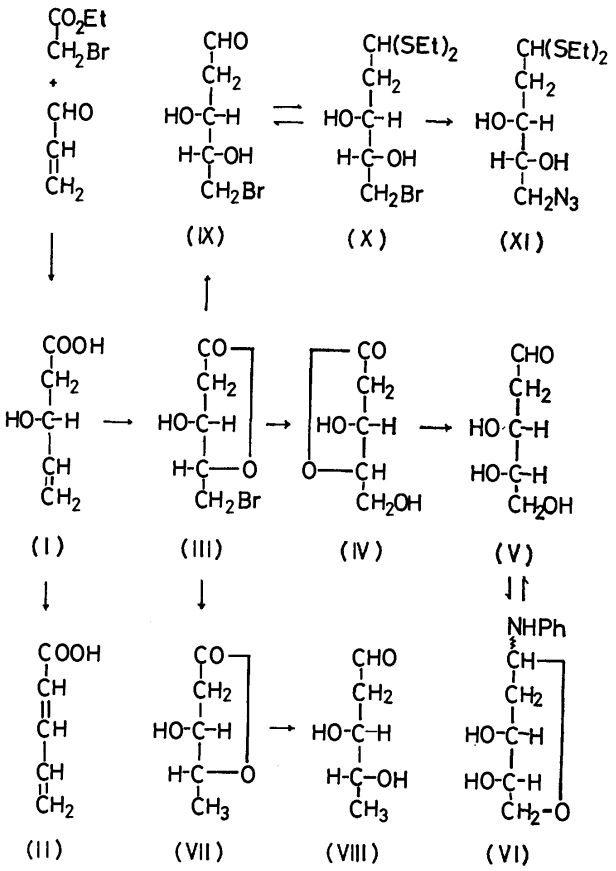
mycin has been briefly reported by two groups.[5]

The following scheme illustrates the reaction sequence of total synthesis of 2-deoxy-L-*erythro*-pentose, however, the same scheme will be used in the description of syntheses of DL- and D-forms of the carbohydrate.



Scheme 1. Syntheses of 2-deoxy-L-*erythro*-pentose (L-V) and related sugars.

The Reformatsky reaction of acrolein with ethyl bromoacetate followed by alkaline hydrolysis afforded DL-β-hydroxy acid (I). Owing to ready dehydration to form pentadienoic acid (II), β-hydroxy acid (I) should be handled with care. Treatment of DL-β-hydroxy acid (I) with 0.5 equivalent of quinine followed by decomposition of the salt afforded (−)-β-hydroxy acid [(−)-I] which gave ultimately 2-deoxy-L-*erythro*-pentose (L-V). The hydroxy acid (I) obtained from the mother liquor of the quinine salt was resolved by means of quinidine salt to give (+)-β-hydroxy acid [(+)-I] which could be converted to 2-deoxy-D-*erythro*-pentose (D-V). The subsequent reactions were carried out with DL-compounds in the first place and then with optically active forms. It has been well-known that a terminal mono-substituted double bond is resistant to peracid oxidation.[6] Therefore, hydroxylation by means of potassium permanganate[7] was first attempted. The acetyl derivative of β-hydroxy acid (I) was treated with an aqueous solution of potassium permanganate under a neutral condition. In spite of the consumption of permanganate, no identifiable product could be isolated from the reaction mixture. Consequently, indirect hydroxylation *via* halohydrin[8] was applied to the hydroxy acid (I). Treatment of β-hydroxy acid (I) with *N*-bromosuccinimide in water followed by a chromatographic purification on silica gel[9] yielded syrupy bromolactone (III) in a yield of 57%. The (−)-acid [(−)-I] gave (+)-III and the (+)-acid [(+)-I] resulted in (−)-III. The by-products were found to be a complex mixture of highly polar compounds and could not be purified. Bromolactone (III) thus obtained was found to be homogeneous without contamination with *erythro*-isomer on the basis of tlc and NMR spectroscopy. The tlc and NMR spectra of IV and VII which were derived from III (see, below) indicate that these lactones are free from their epimers. This fact also supports the homogenity of bromolactone (III). The analytical data of III and its phenylhydrazide, and the IR (C=O, 1795 cm^{-1} in $CHCl_3$: γ-lactone) and NMR spectral data (see, following part) of III are consistent with the assigned structure. The fact that an aqueous solution of optically active III showed practically no change of rotation over a period of 2 weeks affords an additional evidence for γ-lactone structure of III. The immediate change of rotation of (+)-bromolactone (III, $[\alpha]_D$ +51°, H_2O) to $[\alpha]_D$ −3.4° on addition of a drop of concentrated aqueous sodium hydroxide indicates that the configuration of $C_{(4)}$ should belong to D-series according to the Hudson's lactone rule.[10] Consequently, the *O*-function at $C_{(4)}$ should be written in the right side in Fischer's projection formula. As is stated below, because the configuration of $C_{(3)}$ in bromolactone (III) is undoubtedly retained during the course of derivation to 2-deoxy-L-*erythro*-pentose (V), the hydroxyl group at $C_{(3)}$ in (+)-bromolactone (III) which gave the L-form of V, should be written in the left side in Fischer's projection formula indicating that bromolactone (III) has *threo*-configuration. Further evidence for *threo*-configuration of III was obtained by the preparation of 2,5-dideoxy-pentono-lactone (VII). Reduction by means of tri-*n*-butyltin hydride,[11] which had not yet been used in the field of carbohydrate chemistry,[12] was successfully adopted for the conversion of bromolactone (III) to dideoxy-pentono-lactone (VII)

instead of the usual hydrogenolysis.[13] The isolation of dideoxy-lactone (VII) from the reaction mixture could be performed easily owing to the high solubility of VII in water. The spectroscopic data of 2,5-dideoxy-pentono-lactone (VII) were found to be consistent with the structure of VII [IR: 1783 cm^{-1} (γ-lactone); NMR: δ 1.25 (doublet, methyl H)]. Dideoxy-lactone obtained from (+)-bromolactone [(+)-III] showed dextrorotation in an aqueous solution and no change of rotation could be observed over 2 weeks supporting γ-lactone structure. The specific rotation of (+)-dideoxy-lactone [(+)-VII, $[\alpha]_D$ +58°] immediately changed to +13° on addition of a drop of concentrated aqueous solution of sodium hydroxide. This fact suggests that (+)-VII belongs to D-series. The NMR spectrum of VII could

be analyzed employing decoupling technique (Table 1). The coupling constants between hydrogen atoms attached to the lactone ring (J_{2-3}, $J_{2'-3}$, J_{3-4}) could be explained most satisfactory on the assumption that dideoxylactone (VII) belongs to *threo(cis)*-series and D-form of VII holds a conformation and configuration shown in Fig. 1. All of the conformation derived from

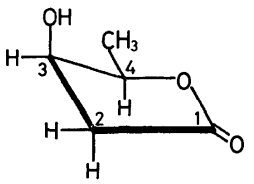

Fig. 1. Probable configuration and conformation of 2,5-dideoxy-D-*threo*-pentono-γ-lactone (D-VII).

erythro(trans)-configuration of VII gave no relevant explanation of the coupling constants. An examination of the Dreiding model of conformer shown in Fig. 1 indicates that the dihedral angles (ϕ) between neighboring hydrogen atoms should be as follows: $\phi_{2,3}$ 85—90°, $\phi_{2',3}$ 35—40°, and $\phi_{3,4}$ 40—50°. The calculation of J-values according to the method of Karplus[14] using modified J_0-value[15] and the estimated dihedral angles was performed. A fairly good agreement between observed and calculated J-values was obtained. The calculated J-values were found to be J_{2-3}=−0.28—−0.21, $J_{2'-3}$=5.94—5.2, and J_{3-4}=5.1—3.6. The unusual large dihedral angle between neighboring hydrogen atoms of *cis*-configuration in five membered ring ($\phi_{3,4}$ 40—50°) has been observed also in sugar derivatives.[15-17] Considering the presence of bulky methyl group in equatorial position and the planar shape of lactone grouping (C–CO–O–C),[18] the conformation illustrated in Fig. 1 seems to be highly probable.

The assignment of NMR spectrum of bromolactone (III) is summarized in Table 2, though there remains some uncertainty owing to poor resolution of the signals of $C_{(3)}$–H and $C_{(4)}$–H and overlap of the signal of water with them. The closely related coupling constants of bromolactone (III) with those of dideoxy-lactone (VII) indicate that D-bromolactone (D-III) has a similar conformation to D-VII shown in Fig. 1.

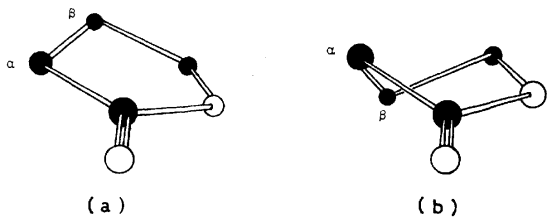

Fig. 2. Stable conformations of γ-lactone.

Mathieson[18] has pointed out that the stable conformation of γ-lactone is restricted to (a) and (b) in Fig. 2 in which C_β is either above or below the lactone plane owing to the preference of co-planarity of the five atoms of lactone group (C–CO–O–C). The location of C_β with respect to the lactone plane is related to the configuration at C_α. Considering the stable conformation of γ-lactone, a general rule has been proposed by Beecham[19] on the relation of the sign of Cotton effect of circular dichroism of $n\rightarrow\pi^*$ region of γ-lactone such as aldonolactone to the conformation of lactone ring. He has concluded that the sign of circular dichroism of aldono-γ-lactone is governed by the conformation of lactone ring independent on the configuration of substituent group other than C_α-position, and the conformation (a) and (b) are associated respectively with (+)- and (−)-Cotton effect. The lactones III and VII have no substituent

Table 3. CD and ORD spectra of D-III, D-VII, and L-IV

	ORD in H_2O [ϕ]	CD in H_2O $\Delta\varepsilon_{max}$
D-III	max: 220 nm, +2940°; min: 213 nm, +2820°	213 nm, +0.480
D-VII	max: 222 nm, +2560°; min: 210 nm, +2130°	213 nm, +0.502
L-IV	max: 222 nm, +1370°; min: 199 nm, −1480°	210 nm, +0.597

group at C_α, however, as stated above, D-III and D-VII seem to hold conformation (a). Consequently, D-III and D-VII should exhibit (+)-Cotton effect in their circular dichroism spectra. As is shown in Table 3, the observed results agreed with the anticipation affording a further evidence for the conformation of D-III and D-VII.

Treatment of bromolactone (III) with aqueous 1N potassium hydroxide at room temperature followed by standing at pH 1 for 24 hr afforded 2-deoxy-*erythro*-pentono-γ-lactone (IV) as a syrup in fairly high yield (63%). The syrupy γ-lactone (IV) was proved to be free from impurity on the basis of tlc, paper chromatography and NMR spectroscopy. The IR spectrum of IV and the elemental analysis of its phenylhydrazide were found to be consistent with the assigned structure. Although the syrupy IV derived from D- and L-bromolactones (III) showed somewhat lower $[\alpha]_D$-values as compared with a reported value,[20] the syrupy D- and L-IV could be used without purification in the subsequent reaction. D(+)-III and L(−)-III afforded L(−)-IV and D(+)-IV, respectively. Positive Cotton effect observed in the ORD and CD spectra of L(−)-IV (Table 3) indicates that L(−)-IV has conformation (a) in Fig. 2. Both of the bulky groups in IV, the hydroxyl group at $C_{(3)}$ and the hydroxymethyl group at $C_{(4)}$, take axial position in the conformation (a). An analogous rather unusual situation has been found in the conformation of D-ribono-γ-lactone.[21] The NMR spectrum of IV is recorded in Table 4. A confirmative information could not be obtained from the NMR data owing to the overlap of signal of $C_{(3)}$–H with that of $C_{(4)}$–H. The value of $J_{2'-3}$ is consistent with the conformation (a), however, the value of J_{2-3} is larger than the expected one. Accordingly, the possibility of the presence of a small fraction of conformation (b) can not be excluded. Inspection of the Dreiding model of conformation (b) revealed that the dihedral angles should be $\phi_{2,3}$ 160° and $\phi_{2',3}$ 35°. The coupling constants calculated using these angles are found to be as follows: J_{2-3} 8.87 and $J_{2'-3}$ 5.94.

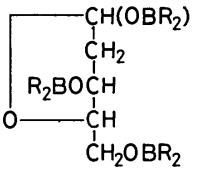
Reduction by means of sodium borohydride has been widely used for the conversion of aldono-γ-lactone to the corresponding aldose. However, treatments of 2-deoxy-lactone (IV) with the hydride under the usual conditions resulted in the recovery of IV. In view of the ease of reduction of α-hydroxy- and α-amino-esters to aldehydes,[22] the unsuccessful reduction of IV seems to be attributable to the absence of such substituent at α-position of IV. The reduction of IV could be achieved by the use of bis(1,2-dimethylpropyl)-borane (disiamylborane) which has been proposed by Brown and Bigley.[23] The reagent has been successfully applied for acylated aldono-lactones by Kohn, Samaritano, and Lerner.[24] The syrupy IV in anhydrous tetrahydrofuran was mixed with a large excess of disiamylborane. After the mixture had been stood over *ca.* 20 hr at room temperature, water was added to decompose the excess of reducing agent and to hydrolyze the borinate ester (XII) presumably formed. The



(XII)

R=-CH(CH$_3$)·CH(CH$_3$)$_2$

aqueous mixture was extracted with ether to remove dialkylborinic acid. Evaporation of the resulting aqueous layer afforded a syrup. Tlc of the syrup gave a spot which exactly corresponds to that of an authentic sample of 2-deoxy-*erythro*-pentose (V), and no other distinct spots could be observed. Treatment of the syrupy V with aniline according to the usual procedure[25] gave crystalline aniline derivative (61% based on lactone, IV). D-, L-, and DL-anilides thus prepared gave superimposable IR spectra with that of the anilide prepared from an authentic 2-deoxy-D-*erythro*-pentose. As summarized in Table 5, good coincidence of the melting points and specific rotations with those of reported values were found. The anilide (VI) yielded 2-deoxy-*erythro*-pentose (V) in a high yield (*ca.* 90%)

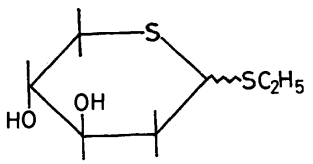
	L-V	+60°	+59°[20]

a) The value at equilibrium in pyridine.
b) The value at equilibrium in water.

on treatment with benzoic acid, benzaldehyde and water according to the usual procedure.[25] 2-Deoxy-D- and L-*erythro*-pentose (D- and L-V) initially obtained as syrup crystallized on standing for a few days. On the other hand, syrupy DL-V could be crystallized only after seeding with a small piece of crystal of an authentic D-V. 2-Deoxy-*erythro*-pentoses (D-, L-, and DL-V) showed no definite melting points indicating that they are mixture of α- and β-anomers. Tlc of crystalline 2-deoxy-*erythro*-pentoses gave spots just corresponding to that of authentic specimen. Also as recorded in Table 5, the specific rotations of D- and L-V were found to be identical with those of literature values. As a matter of course, D- and L-IV afforded D- and L-V, respectively. It should be noted that all the reactions proceed stereoselectively without any detectable formation of 2-deoxy-*threo*-pentose, an epimer of V. In view of the quite different physical properties of 2-deoxy-*threo*-pentose [D-isomer: $[\alpha]_D^{19}=-2°$ (H_2O)[32]] and its anilide [D-isomer: mp 137°C, $[\alpha]_D^{19}=-20°$ (H_2O);[32] DL-isomer: mp 145—146°C[28]] and the homogeneous nature of syrupy V as revealed by tlc, the formation of epimeric 2-deoxy-*threo*-pentose can be ignored. The over-all yields of DL-, L-, and D-V were found to be 9.3, 3.8, and 3.0%, respectively.

Independently and about the same time with the publication of preliminary report of the present study,[4] reduction of free aldonolactone to aldose by means of disiamylborane was reported.[33] The present authors have carried out the reduction of DL-bromolactone (III) and DL-dideoxy-lactone (VII) by the use of disiamylborane. DL-Dideoxy-lactone (VII) yielded 2,5-dideoxy-DL-*threo*-pentose (VIII) as a syrup. The syrup gave a strong spot on tlc accompanied by a few very weak spots. The syrup was converted to 2,4-dinitrophenylhydrazone (48% based on VII) which gave satisfactory elemental analysis and IR spectrum. Reduction of DL-bromolactone (III) afforded syrupy 5-bromo-2,5-dideoxy-DL-*threo*-pentose (IX). The syrupy IX was converted to crystalline diethylmercaptal (X, 38% based on III). Hydrolysis of X gave crystalline DL-IX. Bromopentose (IX) was found to be very unstable and decomposed at room temperature in a few days forming a black material. Mercaptal (X) was also rather unstable compound, but could be kept without decomposition in a refrigerator.

Because bromopentose (IX) seemed to be a potential precursor of aminopentose, bromomercaptal (X) was treated with sodium azide in boiling methanol to give 5-azido-compound (XI). After 30 hr, tlc of the reaction product gave no spot of bromomercaptal (X), but exhibits two main spots together with two minor spots. 5-Azido-compound (XI) could be obtained from one of the minor spot in a poor yield (9%). Conversion of XI to aminopentose had to be abandoned owing to the poor yield. The substances obtained from the two main spots gave no characteristic absorption other than hydroxyl group in their IR spectra. The same substances were obtained when bromomercaptal (X) was refluxed in methanol in the presence of sodium hydrogen carbonate. Therefore, the substances presumably concern with the anomer mixture of XIII.[34]



(XIII)

Treatment of bromomercaptal (X) with ammonia resulted in the formation of complex mixture and definite compound could not be identified.

Finally, we wish to give a brief account on the nature of stereoselectivety of the above-mentioned reactions.

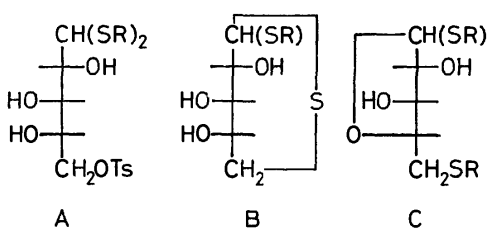
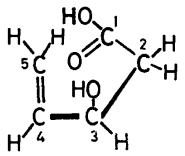
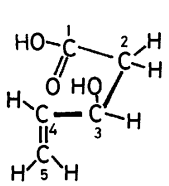
34) Recently, J. Harness and N. A. Hugher (*Chem. Commun.*, **1971**, 811) have reported the formation of furanose derivative (C) instead of cyclic sulfide (B) on heating an acetone solution of 5-*O*-*p*-toluenesulfonyl-L-arabinose diethyl or dibenzyl dithioacetal (A, R=Et or benzyl). Consequently, the possibility that the substance obtained from bromoacetal (X) has a structure analogous to C can not be excluded. Further investigation about this point is now in progress.



As previously described, reaction of β-hydroxy-γ,δ-ethylenic acid (I) with *N*-bromosuccinimide in water gave exclusively *threo*-isomer (III) and unexpectedly the formation of epimeric *erythro*-isomer could not be observed. Beacuse the intramolecular nucleophilic attack of carboxyl group has been recognized in the electrophilic addition reaction of γ,δ-ethylenic acid,[35] bromo-γ-lactone (III) may be formed directly by the participation of carboxyl group without intermediacy of bromo-dihydroxy acid. Therefore, it seems to be likely that hydroxy-ethylenic acid (I) holds preferentially the conformation XIV or XV in which the



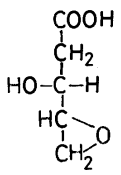
(XIV)



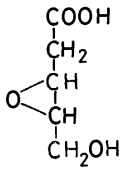
(XV)

carboxyl group situates in a proximity of the ethylenic bond. The hydroxyl group at $C_{(3)}$ and $C_{(5)}$ in conformation XIV are located in the same side with respect to the plane defined by $O-C_{(1)}-C_{(2)}-C_{(3)}-C_{(4)}$. On the contrary, the hydroxyl groups at $C_{(3)}$ and $C_{(5)}$ in conformation XV are situated in opposite side of the plane. Consequently, an additional stability would be rendered to the conformer XIV, because a hydrogen bonding between the hydroxyl group at $C_{(3)}$ and π-electron of the ethylenic bond[36] is possible only in XIV. If hydroxy-ethylenic acid (I) has the conformation XIV and bromonium ion attacks $C_{(5)}$ from the back side of carboxyl group being accompanied by simultaneous attack of carboxyl oxygen to $C_{(4)}$, the resulting bromolactone (III) should have *threo*-configuration.

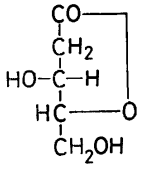
threo-Bromolactone (III) affords solely *erythro*-lactone (IV) without contamination of *threo*-isomer by the reaction with an aqueous potassium hydroxide followed by acid. This fact indicates that the ring opening of *threo*-epoxide (XVI) which is a possible reaction intermediate should occur at $C_{(4)}$ instead of $C_{(5)}$ with complete inversion of configuration. This is in accord with the general tendency of ring opening of epoxide, *i.e.*, usually epoxide ring is cleaved by acid at secondary carbon with inversion of configuration.[37] However, such a clear-cut result observed in the conversion of III into IV is rather unusual in saturated aliphatic epoxides. An intramolecular participation of carboxyl group again might have an important role in this reaction, *i.e.*, the carboxyl oxygen in XVI preferentially attacks $C_{(4)}$ to give γ-lactone (IV) rather than $C_{(5)}$ which leads to the formation of δ-lactone. The complete inversion at $C_{(4)}$ seems to be attributable to



(XVI)



(XVII)



(XVIII)

the intramolecular nature of attack and the rather high nucleophilicity of carboxyl group. The possibility of formation of epoxide (XVII) as a reaction intermediate which might be formed from XVI by the attack of hydroxyl group at $C_{(3)}$[38] can be ruled out, because the ring opening at either $C_{(3)}$ or $C_{(4)}$ of *erythro*-type XVII should result in the formation of 2-deoxy-*threo*-pentono-γ-lactone (XVIII) being in conflict with the observation. Therefore, it can be concluded that the configuration of $C_{(3)}$ in hydroxyethylenic acid (I) is kept intact throughout the reaction sequence. Accordingly, *R*-configuration of (−)-hydroxyethylenic acid [(−)-I] which gave 2-deoxy-L-*erythro*-pentose (L-V) and *S*-configuration of (+)-ethylenic acid [(+)-I], the precursor of 2-deoxy-D-*erythro*-pentose (D-V) are concluded.

Experimental

Melting points were measured on a Mettler EP2 apparatus and uncorrected. The IR spectra were obtained on a Hitachi EPI-2, EPI-S or a JACSO DS-402G spectrophotometer. The ORD and CD spectra were measured on a Yanagimoto ORD-185 and a JASCO ORD/UV-5 spectropolarimeters, and the NMR spectra, with a Varian A-60 or T-60, using tetramethylsilane or sodium 4,4-dimethylsilapentane sulfonate as internal standard. Double irradiation was performed on a JEOL JNM-4H-100 or JNM-C-60HL spectrometer. A commercial silica gel (E. Merck, Darmstadt, Germany, 70—325 mesh) was immersed in 60% aqueous acetic acid overnight and washed thoroughly with water until the filtrate gave a neutral test. After the washed silica gel had been kept at 120°C for 15 hr, it was used in the chromatography. Silica gel G (E. Merck, Darmstadt, Germany) was used as adsorbent in tlc. Benzene-ethyl acetate (1: 1) (A), acetone (B), methanol (C) and ethyl acetate-95% ethanol (20: 1) (D) were used as solvents. Iodine[39a] (a), hydroxamic acid reagent[39b] (b), Tollens' reagent[40] (c) and Dische's reagent[41] (d) were used as detection reagents. In the case of reagent (d), the sprayed glass was covered with another plate of glass and heated at 90—100°C to develop color reaction.

Ethyl 3-Hydroxy-4-pentenoate. In a nitrogen atmosphere, a 30 m*l* portion of a solution of ethyl bromoacetate (111 m*l*, 1 mol)[41] and acrolein (87 m*l*, 1.3 mol) in anhydrous benzene (250 m*l*) was added to zinc powder[43] (142 g, 2.17 g-atom)

43) The quality of zinc powder is essential in this reaction. Only the zinc powder of Mitsuwa Chemicals Co. gave satisfactory result.

activated with hydrochloric acid[44] and the mixture was stirred under careful heating. After the initial vigorous reaction had subsided, the remaining solution was added to the stirred mixture under careful heating in such a rate to maintain gentle reflux. After the addition of solution had been completed, the mixture was refluxed for further 30 min under stirring. The hot reaction mixture was poured into an ice-cooled 4N sulfuric acid (600 ml) under stirring. Greyish viscous insoluble material was removed by filtration and washed with ether. The washings were combined with the organic layer. The aqueous layer was extracted 6 times with ether. The total organic layer was washed once with a saturated sodium chloride solution and twice with a saturated solution of sodium chloride containing sodium hydrogen carbonate and dried (sodium sulfate). The residue obtained by evaporation of the solvent under reduced pressure was distilled under nitrogen atmosphere *in vacuo*. Ethyl 3-hydroxy-4-pentenoate was obtained as colorless liquid, 72 g (50%), bp 63—64°C/2 mmHg, n_D^{25} 1.4393. IR (neat): 3470 (O–H); 1735 (C=O); 995, 925 (–CH=CH_2) cm^{-1}.

Found: C, 58.60; H, 8.33%. Calcd for $C_7H_{12}O_3$: C, 58.31; H, 8.39%.

When the reaction was carried out in other solvents of low boiling points such as ether, diisopropyl ether or tetrahydrofuran, the control of exothermic reaction was difficult resulting in a poor yield.

N-Phenyl-3-hydroxy-4-pentenoamide. According to the reported method,[45] ethyl hydroxy-pentenoate was converted to crystalline anilide. To an ice-cooled solution of ethylmagnesium bromide [from magnesium (2 g), ethyl bromide (10 g) and ether (60 ml)] was added aniline (8 g) and then the pentenoate (6 g) under stirring. After the mixture had been stirred for 30 min at room temperature and then further 30 min at 40°C, the reaction mixture was poured into 2N hydrochloric acid (50 ml). The crystals obtained upon work-up of the ethereal layer were recrystallized twice from benzene, thus yielding pure anilide as colorless needles, mp 127.5—128.5°C. IR (Nujol mull): 3300, 3210, 3140, 3080 (OH and NH); 1665 (amide I), 1550 (amide II), 1315 (amide III); 1603, 757, 690 (C_6H_5–) cm^{-1}.

Found: C, 69.14; H, 6.87; N, 7.27%. Calcd for $C_{11}H_{13}NO_2$: C, 69.09; H, 6.85; N, 7.33%.

3-Hydroxy-4-pentenoic Acid (I). Ethyl 3-hydroxy-4-pentenoate (92.8 g, 0.644 mol) was added over a period of 45 min into an ice-cooled and stirred solution of potassium hydroxide (38.1 g, 0.68 mol) in water (635 ml). The mixture was stirred for 14 hr at room temperature and then stood over 12 hr at the same temperature. The reaction mixture was extracted 3 times with ether. The ice-cooled aqueous layer was made just acid to Congo red with concentrated hydrochloric acid (59 ml) and then saturated with sodium chloride. The aqueous layer was extracted 5 times with ether. The extract was washed 3 times with a saturated sodium chloride solution. The washings were combined with the aqueous layer and extracted with ether using a continuous extractor for 20 hr. The extract was washed according to the above-stated procedure. The total aqueous layer was again extracted by means of a continuous extractor for 20 hr. After washing procedure, the extract was combined with other ethereal extracts. The total extract was dried over sodium sulfate. The residue obtained by evaporating the solvent was distilled *in vacuo* under nitrogen atmosphere to give 3-hydroxy-4-pentenoic acid (I) as viscous colorless liquid, 63.5 g (85%), bp 95°C/1 mmHg, n_D^{30} 1.4630. IR (neat): *ca.* 3500—2500 (OH); 1715 (C=O); 995, 930 (–CH=CH_2) cm^{-1}.

Found: C, 51.56; H, 7.06%. Calcd for $C_5H_8O_3$: C, 51.72; H, 6.94%.

It was found that hydroxy-pentenoic acid (I) is easily dehydrated to give crystalline pentadienoic acid (II).[46] When the hydrolysis of I was carried out with 2N potassium hydroxide at room temperature for 2 days, II was obtained as main product.

Optical Resolution of 3-Hydroxy-4-pentenoic Acid (I). Hydroxy-pentenoic acid (I, 25.7 g, 0.222 mol) was added to a suspension of quinine (36 g, 0.111 mol) in hot water (295 ml) and shaken for a few min on a boiling water-bath. A slightly turbid solution thus obtained was treated with active charcoal. Crystals deposited mostly on standing the clear filtrate, otherwise the filtrate was seeded to cause crystallization. After standing in a refrigerator for 3 days, the crystals were collected by filtration and washed with water. The mother liquor was concentrated to one-half volume and stood over 8 days in a refrigerator, thus yielding second crop of crystals. The combined crystals (32 g) were recrystallized from water (295 ml), yielding colorless needles, 26.2 g, $[\alpha]_D^{24}=-137°$ ($c=1.1$, H_2O). The crystals showed no definite melting point, but most of the crystals melted at 117—122°C. The mother liquor of recrystallization gave second crop of crystals, 2.7 g, $[\alpha]_D^{18}=-134°$ ($c=1.1$, H_2O). The total yield was 57%. IR (Nujol mull): 1550, 1410 (–CO_2^-) cm^{-1}.

Found: C, 65.67; H, 7.54; N, 6.10%. Calcd for $C_{25}H_{32}O_5N_2 \cdot H_2O$: C, 65.48; H, 7.47; N, 6.11%.

The crystals lost its water of crystallization of heating to 65°C *in vacuo*, but the anhydrous crystals still showed no definite melting point (most of the crystals melted at 119—124°C).

Found: C, 67.92; H, 7.44; N, 6.33%. Calcd for $C_{25}H_{32}O_5N_2$: C, 68.16; H, 7.32; N, 6.36%.

Quinine salt monohydrate (25.1 g, 0.0548 mol) thus obtained was placed in a separatory funnel and mixed with sodium hydrogen carbonate (6 g, 0.071 mol), water (130 ml) and chloroform (500 ml). The mixture was shaken to dissolve the quinine salt. The organic layer was washed twice with water. The washings were combined with the aqueous layer and made just acid to Congo red with 6N hydrochloric acid under ice-cooling. The aqueous solution was treated according to the procedure used in the preparation of *rac*-hydroxy-pentenoic acid (I). (—)-I was obtained as pale yellow liquid, 4.6 g, (72%), $[\alpha]_D^{25}=-9.8°$ ($c=0.81$, H_2O). Ths material could be used without further purification in the subsequent reaction. A vacuum distillation of the crude material gave pure (—)-I as colorless viscous liquid, bp 107—109°C/3 mmHg, n_D^{20} 1.4658, $[\alpha]_D^{20}=-9.6°$ ($c=1.03$, H_2O), $[\alpha]_D^{17}=-26°$ ($c=1.35$, C_2H_5OH). Pure (—)-I crystallized in a refrigerator. The IR spectrum of (—)-I was found to be superimposable with that of racemic I.

Found: C, 51.57; H, 6.99%. Calcd for $C_5H_8O_3$: C, 51.72; H, 6.94%.

The initial mother liquor was concentrated to *ca.* 50 ml and mixed with sodium hydrogen carbonate (15 g). The crystals of quinine deposited were removed by filtration and washed with water. Partially resolved (+)-hydroxy-pentenoic acid, light yellow liquid, 12.8 g (50% recovery), $[\alpha]_D^{25}=+4.5°$ ($c=2.08$, H_2O) was obtained from the combined aqueous layer according to the previously described procedure. The specific rotation indicates that the optical

44) R. L. Shriner, "Organic Reactions," Vol. 1, John Wiley and Sons, Inc., New York (1942), p. 16.

45) D. V. N. Hardy, *J. Chem. Soc.*, **1936**, 398.

46) E. R. H. Jones, G. H. Whitham, and M. C. Whiting, *ibid.*, **1954**, 3201.

purity of the (+)-hydroxy-pentenoic acid should be 47%. In another run, partially resolved (+)-I having optical purity of 54% was obtained. Purified quinidine[47] (18.1 g, 0.056 mol) was mixed with partially resolved (+)-I [8.4 g, $[\alpha]_D=+14°$ (C_2H_5OH), optical purity=54%, corresponds to 0.056 mol of pure (+)-I] and water (25 m*l*). The mixture was heated to give a homogeneous solution. The solution was seeded with crystals of qunidine salt of I and kept at room temperature for 4 days. The crystals deposited were collected by filtration and washed with acetone. The crystals were recrystallized from acetone to give pure quinidine salt, colorless rods, 11.4 g (46%), $[\alpha]_D^{17}=+180°$ ($c=0.11$, H_2O). The crystals showed no definite melting point (130—149°C). IR (Nujol mull): 1594; 1404 ($-CO_2^-$) cm^{-1}.

Found: C, 68.00; H, 7.47; N, 6.32%. Calcd for $C_{25}H_{32}O_5N_2$: C, 68.16; H, 7.32; N, 6.36%.

Sodium hydrogen carbonate (2.5 g, 0.03 mol) was added to a solution of pure qunidine salt (11.4 g, 0.0259 mol) in water (40 m*l*). Quinidine initially deposited as liquid could be crystallized on seeding and removed by filtration. Treatment of the aqueous layer according to the procedure used in the preparation of (−)-I afforded slightly crude (+)-I as liquid, 2.8 g (93%), $[\alpha]_D^{17}=+26°$ ($c=1.01$, C_2H_5OH). The IR spectrum of this material was found to be superimposable with that of DL-isomer. This material was used in the following reaction without further purification. Vacuum distillation under nitrogen atmosphere of crude (+)-I obtained by another run yielded (+)-I as colorless liquid, bp 104—106°C/2 mmHg which crystallized on standing in a refrigerator, n_D^{25} 1.4633, $[\alpha]_D^{25}=+24°$ ($c=1.03$, C_2H_5OH).

Found: C, 51.13; H, 6.90%. Calcd for $C_5H_8O_3$: C, 51.72; H, 6.94%.

Second crop of qunidine salt was obtained from the aqueous mother liquor. Recrystallization of the crude salt from water gave 5.4 g of qunidine salt, $[\alpha]_D^{19}=+173°$ ($c=0.11$, H_2O).

Attempts to resolve (±)-I by means of cinchonine, cinchonidine, brucine, strychnine, and ephedrine gave fruitless results.

DL-*3-Acetoxy-4-pentenoic Acid.* A mixture of hydroxy-pentenoic acid (I, 24 g, 0.2 mol) and acetic anhydride (50 m*l*) was heated on a boiling water-bath for 2.5 hr. After the acetic anhydride and acetic acid formed had been removed under reduced pressure, water (40 m*l*) was added to the residue and kept at 60°C for 1 hr. The reaction mixture was saturated with sodium chloride and extracted with ether. The extract was dried over sodium sulfate. The residue obtained by evaporation of the solvent under reduced pressure was distilled *in vacuo* in a stream of nitrogen, yielding acetoxy-pentenoic acid as colorless liquid, 26.5 g (83%), bp 96.5—98°C/1.5 mmHg, n_D^{25} 1.4445, IR (neat): *ca.* 3600—2400 (OH): 1745, 1720 (C=O); 990, 935 ($-CH=CH_2$) cm^{-1}.

Found: C, 53.15; H, 6.34%. Calcd for $C_7H_{10}O_4$: C, 53.16; H, 6.37%.

Acetylation of I by means of pyridine-acetic anhydride gave predominantly pentadienoic acid.

5-Bromo-2,5-dideoxy-DL-, D-, *and* L-threo-*Pentono-γ-lactones (III).* A mixture of DL-β-hydroxy acid (I, 10.4 g, 0.09 mol), finely powdered *N*-bromosuccinimide[48] (17.7 g, 0.099 mol) and water (180 m*l*) was stirred at room temperature for 17 hr in a dark place. The resulting orange yellow clear solution was saturated with sodium chloride (55 g) and extracted with ether (50 m*l*×5). The ethereal extract was washed with a saturated sodium chloride solution containing 5% of sodium hydrogen sulfite (30 m*l*) and a saturated sodium chloride solution (20 m*l*×3), successively and dried (sodium sulfate). The residue obtained by evaporating the solvent under reduced pressure was placed in an evacuated desiccator containing phosphorus pentoxide. The yellowish brown syrup thus obtained (5.8 g) exhibited satisfactory IR spectrum and gave a strong spot of III at R_f 0.55 (solvent system: A, detection reagent: a or b) in the tlc accompanied with a faint coloration near the starting point.

The combined aqueous layer and washings were mixed with a saturated sodium chloride solution containing 5% of sodium sulfite (2 m*l*) to reduce liberated bromine and extracted with ether for 24 hr employing a continuous extractor. The ethereal extract containing crystals and oily material was chilled on an ice-bath. The crystals were collected by filtration and washed successively with ether and ethyl acetate which could be identified as succinimide on the basis of IR spectroscopy. Ethyl acetate was added to the combined filtrate and washings to dissolve separated oily material and dried (sodium sulfate). The residue obtained by evaporation of the solvent under diminished pressure was placed in an evacuated desiccator over phosphorus pentoxide, thus yielding second crop of yellow syrup (12.6 g). Because tlc (solvent system: A, detection reagent: a or b) of the syrup revealed that the main constituents of the syrup are bromolactone (III, R_f 0.55) and succinimide (R_f 0.4), the syrup (10 g) was subjected to a chromatography on silica gel (300 g) employing benzene-ethyl acetate (1: 1) as eluting solvent. The eluate was fractionated into 100 m*l* portions. Bromolactone (III, 5.2 g) contaminated with a small amount of succinimide was obtained from the fractions 3—10, which gave pure bromolactone (III, 3.34 g) on re-chromatography on silica gel. The total yield of pure III was found to be 57%, n_D^{20} 1.5214, IR ($CHCl_3$): 3610 (OH); 3460 (hydrogen bonded OH); 1795 (C=O) cm^{-1}. IR (neat): 3460 (hydrogen bonded OH); 1775 (C=O) cm^{-1}.

Found: C, 30.17; H, 3.92; Br, 40.72%. Calcd for $C_5H_7O_3Br$: C, 30.79; H, 3.62; Br, 40.97%.

A chromatography of the second crop of III on neutral alumina (Woelm, activity III) gave less satisfactory result.

Treatment of DL-bromolactone (III) in ethanol with phenylhydrazine gave phenylhydrazide which was recrystallized from ethanol to give pure material as colorless needles. The phenylhydrazide sintered at 135°C and decomposed at 137—138°C.

Found: C, 43.82; H, 5.04; N, 9.02; Br, 26.46%. Calcd for $C_{11}H_{15}BrN_2O_3$: C, 43.58; H, 4.99; N, 9.24; Br, 26.36%.

According to the procedure used in the preparation of DL-bromolactone (III), (−)-β-hydroxy-pentenoic acid [(−)-I, 7.275 g, 0.0627 mol], *N*-bromosuccinimide (12.3 g, 0.069 mol) and water (130 m*l*) gave D-bromolactone (D-III). The first crop [4.15 g, $[\alpha]_D^{25}=+45°$ (initial)→+44° (after 2 weeks) ($c=0.65$, H_2O)] gave an identical IR spectrum with that of pure DL-III and could be used in the following reaction without further purification. Chromatography of the second crop (9.89 g) on silca gel or neutral alumina afforded pure D-III. The total yield of pure D-III was 56%, n_D^{25} 1.5207, $[\alpha]_D^{25}=+54°$ (after 24 hr)→+50° (after 2 weeks) ($c=0.081$, H_2O).

Found: C, 30.95; H, 3.68; Br, 40.48%. Calcd for $C_5H_7O_3Br$: C, 30.79; H, 3.62; Br, 40.97%.

Phenylhydrazide of D-III was recrystallized from 2-propanol to give aggregate of colorless needles or plates, mp 132—135°C (decomp.) [with a pre-heated bath (115°C) and a rapid temperature increase, 6°C/min].

47) R. T. Major and J. Finkelstein, *J. Amer. Chem. Soc.*, **63**, 1368 (1941).

48) E. Campaigne and B. F. Tullar, "Organic Syntheses," Coll. Vol. IV, p. 921 (1963).

Found: C, 43.84; H, 5.06; N, 9.07; Br, 25.96%. Calcd for $C_{11}H_{15}BrN_2O_3$: C, 43.58; H, 4.99; N, 9.24; Br, 26.36%.

The reaction of (+)-hydroxy-pentenoic acid (2.8 g, 0.024 mol) with *N*-bromosuccinimide (4.7 g, 0.027 mol) in water (50 m*l*) afforded L-bromolactone (L-III). The first crop [1.54 g, $[\alpha]_D^{17}=-46°$ (initial)$\rightarrow[\alpha]_D^{20}=-46°$ (after 2 weeks) ($c=0.54$, H_2O)] could be used without purification in the subsequent reaction. The second and third crops (total 3.27 g) were subjected to chromatography on silica gel to give pure L-III. The total yield of pure L-III was found to be 2.47 g (52%).

2-Deoxy-DL-, L-, *and* D-erythro-*Pentono-γ-lactones (IV).* A mixture of DL-III (860 mg, 4.41 mmol) and 1N potassium hydroxide (9 m*l*, 9 mmol) in a tightly stoppered flask was swirled for 30 min in an ice-bath, and then kept at room temperature for 23 hr. The reaction mixture was treated with Amberlite IR 120 (H^+) to remove potassium ion and the resulting acid solution (pH *ca.* 1) was stood over 22 hr at room temperature. The solution was chilled on an ice-bath and treated with Dowex 3 (OH^-). The solution which gave negative Beilstein's test was concentrated under reduced pressure at a temperature below 30°C. The residue was placed in an evacuated desiccator containing phosphorus pentoxide, thus yielding 2-deoxy-DL-*erythro*-γ-lactone (DL-IV) as almost colorless syrup, 346 mg, (59%), n_D^{20} 1.4900, IR (neat): 3380 (OH); 1765 (C=O) cm^{-1}. The syrup gave one spot (R_f 0.58) on a paper chromatogram (solvent system: 1-butanol: acetic acid: water=4:1: 5,[47] detection reagent: silver nitrate-sodium hydroxide-ammonia,[49] filter paper: Toyo Roshi No. 51). Tlc (solvent: B, detection reagent: b or c) of the syrup gave a main spot at R_f 0.75 and in some cases very weak spots at R_f 0.6 and 0.42 were observed.

According to the usual manner, phenylhydrazide was obtained from the syrup (95 mg, 0.72 mmol) and phenylhydrazine (84 mg, 0.78 mmol) in ethanol (1 m*l*). The hydrazide was recrystallized from 2-propanol and then from acetone to give pure material, aggregate of colorless leaflets. The crystals were found to be a mixture of two dimorphic forms, mp 134—135°C and mp 140—142°C.

Found: C, 54.94; H, 6.73; N, 11.55%. Calcd for $C_{11}H_{16}O_4N_2$: C, 54.99; H, 6.71; N, 11.66%.

Treatment of D(+)-bromolactone (D-III, 260 mg, 1.33 mmol) according to the procedure used in the case of DL-isomer gave 2-deoxy-L-*erythro*-pentono-γ-lactone (L-IV, 109 mg, 62%) as a colorless syrup which showed a superimposable IR spectrum with that of DL-IV, n_D^{20} 1.4870, $[\alpha]_D^{15}=-8.5°$ (initial)$\rightarrow-9.8°$ (after 2 weeks) ($c=1.08$, H_2O). Phenylhydrazide obtained from L-IV also showed dimorphism, mp 122—123°C and mp 146—146.5°C [lit,[31] mp 145—146°C].

Found: C, 54.84; H, 6.66; N, 11.57%. Calcd for $C_{11}H_{16}O_4N_2$: C, 54.99; H, 6.71; N, 11.66%.

L(−)-Bromolactone (L-III, 1.5 g, 7.7 mmol) afforded 2-deoxy-D-*erythro*-pentono-lactone (D-IV, 647 mg, 63%), $[\alpha]_D^{20}=+4.9°$ (initial)$\rightarrow+6.8°$ (after 13 days) ($c=1.04$, H_2O). The spectrum of D-IV was found to be identical with that of DL-form.

2-Deoxy-N-*phenyl*-DL-, L-, *and* D-erythro-*Pentosylamine (VI).* A solution of bis(1,2-dimethylpropyl)borane was prepared according to the usual procedure from 2-methyl-2-butene (1.9 g, 27 mmol) in anhydrous tetrahydrofuran and a stock solution of diborane in the same solvent (concentration: 0.85 mmol/m*l*, 8 m*l*, 6.8 mmol). To the ice-cooled and stirred solution of bis(1,2-dimethylpropyl)borane was added a solution of slightly crude 2-deoxy-DL-*erythro*-pentono-γ-lactone (IV, 160 mg, 1.2 mmol) in anhydrous tetrahydrofuran (7 m*l*) in an atmosphere of nitrogen. Evolution of hydrogen was observed. After the mixture had been stirred at room temperature for 21 hr, water (30 m*l*) was added under cooling on an ice-bath, and then further stirring was continued for 40 min at room temperature. Ether was added to the reaction mixture and the ether layer was extracted twice with water. The second aqueous extract gave a negative test for the Dische's reagent.[42] The combined aqueous layer was extracted 3 times with ether. All ethereal layers were combined, and again extracted with water. Total aqueous layer was concentrated under reduced pressure at a temperature below 30°C. The resulting syrup was mixed with methanol and the solvent was removed under diminished pressure. This procedure was repeated 3 times. The syrup thus obtained was dried in an evacuated desiccator over phosphorus pentoxide. Tlc (solvent: B, detection reagent: d) of the pale yellow syrup thus prepared (154 mg) produced a strong spot at R_f 0.51 corresponding to that of an authentic D-V and a very weak spot at R_f 0.58. The syrup was mixed with an aniline solution (1.4 m*l*) prepared from aniline (1.8 m*l*), ethanol (15 m*l*) and water (7 m*l*), and the mixture was placed in a refrigerator. The crystals deposited were collected by filtration and washed successively with 50% aqueous methanol and ether, thus yielding fairly pure DL-VI as almost colorless needles, 153 mg (61% based on DL-IV). The crystals were recrystallized from ethanol to give pure DL-VI, colorless plates, mp 158—159°C (decomp.) (with a pre-heated bath (140°C)). The IR spectrum (Nujol mull) of DL-VI [3320, 3250 (OH, NH); 1605, 1500, 1445, 760, 695 (C_6H_5–) cm^{-1}] was found to be identical with that of an authentic D-VI.

Found: C, 62.98; H, 7.37; N, 6.55%. Calcd for $C_{11}H_{15}O_3N$: C, 63.14; H, 7.23; N, 6.69%.

Treatment of L-lactone (L-IV, 124 mg, 0.94 mmol) with 2-methyl-2-butene (1.7 g, 24 mmol) and the stock solution of diborane (6 mmol) according to the above-mentioned procedure resulted in L-VI (120 mg, 61% based on L-IV). Pure L-VI was obtained upon recrystallization from ethanol, mp 174—176°C (decomp.) (with a pre-heated bath (*ca.* 155°C) and a heating rate of 4°C/min), $[\alpha]_D^{14}$ ($c=1.28$, pyridine): −140° (after *ca.* 20 min); −81° (after 2 hr); −70° (after 7 hr); −55° (after 24 hr); −55° (after 29 hr). L-VI gave a superimposable IR spectrum (Nujol mull) with those of DL-VI and authentic D-VI.

Found: C, 63.21; H, 7.34; N, 6.69%. Calcd for $C_{11}H_{15}O_3N$: C, 63.14; H, 7.23; N, 6.69%.

D-Anilide (D-VI, 184 mg, 58%) was obtained from D-lactone (D-IV, 202 mg, 1.53 mmol), 2-methyl-2-butene (2.6 g, 37 mmol) and the stock solution of diborane (9 mmol). Slightly crude D-VI obtained was recrystallized from ethanol, thus yielding pure D-VI as colorless plates, mp 170—173°C (decomp.) (with a pre-heated bath (150°C) and a heating rate of 3—4°C/min), $[\alpha]_D^{20}$ ($c=1.02$, pyridine): +150° (after 10 min); +77° (after 4.5 hr); +56° (after 24 hr); +56° (after 28.5 hr). D-VI thus obtained showed an identical IR spectrum (Nujol mull) with that of an authentic D-VI.

Found: C, 63.19; H, 7.27; N, 6.62%. Calcd for $C_{11}H_{15}O_3N$: C, 63.14; H, 7.23; N, 6.69%.

2-Deoxy-DL-, L-, *and* D-erythro-*Pentoses (V).* A mixture of slightly crude DL-anilide (DL-VI, 193 mg, 0.923 mmol), benzaldehyde (0.2 m*l*, 1.9 mmol), benzoic acid (19 mg) and water (5.8 m*l*) was placed in a tightly stoppered flask and stirred for 24 hr at room temperature. Disappearance of crystals was observed after 1.5 hr resulting in separation of an oily material. After the mixture had been extracted

49) S. M. Partridge, *Biochem. J.*, **42**, 238 (1948).

3 times with ether, the aqueous layer was evaporated under reduced pressure at a temperature below 35°C. The residue was placed in an evacuated desiccator containing phosphorus pentoxide to give colorless syrup (133 mg, 88%). The syrup mixed with a small amount of ethyl acetate crystallized completely upon seeding with a tiny piece of crystal of an authentic 2-deoxy-D-*erythro*-pentose (D-V). The crystals were recrystallized from ethyl acetate to yield pure D-V, aggregate of colorless needles or plates. Fluctuation of melting point of D-V between 85—91°C was observed. D-V thus prepared gave identical tlc with that of an authentic specimen of 2-deoxy-D-*erythro*-pentose (R_f 0.52, solvent: B, detection reagent: d; R_f 0.73, solvent: C, detection reagent: d).

Found: C, 44.67; H, 7.42%. Calcd for $C_5H_{10}O_4$: C, 44.77; H, 7.52%.

Similar treatment of L-anilide (L-VI, 49 mg, 0.23 mmol) with benzaldehyde (0.05 m*l*) and benzoic acid (5 mg) in water (1.5 m*l*) afforded L-V as colorless syrup (32 mg). The syrup was triturated with a small amount of acetone-2-propanol (6: 1) and placed in a refrigerator. The colorless crystals deposited were filtered and washed successively with ethyl acetate and ether, thus yielding pure 2-deoxy-L-*erythro*-pentose (L-V, 26 mg, 84%), $[\alpha]_D^{15}$ ($c=1.06$, H_2O): +63° (after 19 min); +61.5° (after 26 min); +60° (after 1.25 hr); +60° (after 3 hr); +60° (after 4.75 hr). Tlc of L-V produced a spot (R_f 0.5, solvent: B, detection reagent: d) which exactly coincided with that of an authentic specimen of D-V.

Found: C, 44.76; H, 7.50%. Calcd for $C_5H_{10}O_4$: C, 44.77; H, 7.52%.

D-Anilide (D-VI, 91 mg, 0.44 mmol) was treated according to the above described procedure with benzaldehyde (0.1 m*l*), benzoic acid (9 mg) and water (2.8 m*l*). 2-Deoxy-D-*erythro*-pentose (D-V) was obtained in a yield of 91% (53 mg), $[\alpha]_D^{23}$ ($c=1.12$, H_2O): −56° (after 50 min); −56° (after 1.5 hr).

Found: C, 44.68; H, 7.52%. Calcd for $C_5H_{10}O_4$: C, 44.77; H, 7.52%.

2,5-Dideoxy-DL- *and* D-threo-*Pentono-γ-lactones (VII).* A mixture of DL-bromolactone (DL-III, 2.2 g, 0.011 mol), tri-*n*-butyltin hydride[50] (7.2 g, 0.025 mol) and anhydrous tetrahydrofuran (25 m*l*) was refluxed for 8 hr and then stood overnight at room temperature. The residue obtained by evaporation of the solvent under reduced pressure was mixed with water (50 m*l*) and petroleum benzine (bp 60—80°C, 15 m*l*). The benzine layer was washed with water (20 m*l*× 2). The aqueous layer was filtered and combined with the washings. The combined aqueous layer was washed with petroleum benzine. Total benzine layer was extracted twice with water. The extract was added to the combined aqueous layer and treated with a mixture of active charcoal and celite. The resulting clear solution was evaporated under reduced pressure at a temperature below 35°C. The residue was dried in an evacuated desiccator over phosphorus pentoxide to give colorless syrup, 1.1 g (85%). Tlc of the syrup produced a spot at R_f 0.2 (solvent system: A, detection reagent: a or b). Dideoxy-γ-lactone (VII) could be distilled *in vacuo*, bp 109°C/0.1 mmHg, n_D^{25} 1.4606 [lit,[51] bp 139—141°C/0.6 mmHg, n_D^{25} 1.4632], IR ($CHCl_3$): 3620, 3450 (OH); 1780 C=O) cm^{-1}.

Found: C, 50.91; H, 6.86%. Calcd for $C_5H_8O_3$: C, 51.72; H, 6.94%.

Phenylhydrazide of DL-VII was prepared according to the usual procedure and recrystallized from 2-propanol to give pure material, colorless plates, mp 120—122°C.

Found: C, 58.77; H, 7.23; N, 12.33%. Calcd for $C_{11}H_{16}O_3N_2$: C, 58.91; H, 7.19; N, 12.49%.

A mixture of D(+)-bromolactone (D-III, 2.04 g, 10.5 mmol), tri-*n*-butyltin hydride (6.7 g, 23 mmol) and anhydrous tetrahydrofuran (25 m*l*) was refluxed for 18 hr and then allowed to stand overnight at room temperature. Treatment of the reaction mixture according to the procedure used in the case of DL-isomer afforded dideoxy-D-*threo*-pentono-γ-lactone (D-VII), 1.14 g (93%), bp 107°C/0.3 mmHg, n_D^{20} 1.4583, $[\alpha]_D^{20}=+57°$ (after 4 hr)→+58° (after 2 weeks) ($c=0.98$, H_2O). D-VII gave an identical IR spectra (neat or in $CHCl_3$) with those of DL-VII.

Found: C, 51.98; H, 7.01%. Calcd for $C_5H_8O_3$: C, 51.72; H, 6.94%.

2,5-Dideoxy-DL-threo-*pentose (VIII).* Reduction of DL-dideoxy-pentono-lactone (DL-VII, 485 mg, 4.18 mmol) by means of bis(1,2-dimethylpropyl)borane prepared from 2-methyl-2-butene (6.4 g, 92 mmol) and a tetrahydrofuran solution of diborane (23 mmol) according to the procedure used in the reduction of 2-deoxy-pentono-lactone (IV) afforded DL-2,5-dideoxy-pentose (DL-VIII) as pale yellow syrup (575 mg). This substance reduced the Tollens' reagent and gave a positive test for the Dische's reagent.[40] Tlc (solvent system: D) of the syrup gave main spot at R_f 0.48 accompanying faint spots at R_f 0.68, 0.42, 0.34, and 0.18 (detection reagent: C). Only the main spot (R_f 0.48) could be observed when detection reagent d was used.

The syrupy DL-dideoxy-pentose (DL-VIII, 60 mg) was mixed with ethanol (1 m*l*) and a few small crystals of 2,4-dinitrophenylhydrazine was added to the refluxing solution, and when the crystals had dissolved, an additional small amount of the hydrazine was added to the solution. This procedure was repeated until no more dissolution of the hydrazine could be observed. Further reflux was continued (total 3 hr), and then the mixture was cooled. The resulting crystals were filtered and washed with ethanol. The filtrate gave second crop of crystals on addition of water. The crude crystals thus obtained (62 mg, 48% based on lactone, VII) were recrystallized successively from ethanol and ethyl acetate to give pure 2,4-dinitrophenylhydrazone of VIII, tiny yellow plates, mp 144.5—146.5°C. IR (KBr-disk): 3300, 3090 (OH, NH); 2970 (CH_3–); 1520, 1330 (–NO_2) cm^{-1}.

Found: C, 44.02; H, 4.90; N, 18.80%. Calcd for $C_{11}H_{14}O_6N_4$: C, 44.30; H, 4.73; N, 18.79%.

5-Bromo-2,5-dideoxy-DL-threo-*pentose Diethyl Dithioacetal (X).* The reaction of DL-bromolactone (DL-III, 585 mg, 3 mmol) with bis(1,2-dimethylpropyl)borane prepared from 2-methyl-2-butene (4.6 g, 66 mmol) and diborane (15.5 mmol) in tetrahydrofuran according to the method used in the case of 2-deoxy-pentono-lactone (IV) afforded a colorless syrup which gave positive test for the Dische's reagent (first crop: 427 mg; second crop was obtained from the ether extract containing disiamylborinic acid by extraction with water: 127 mg). The syrup (first crop, 255 mg) was mixed with ethanethiol (0.3 m*l*) and concentrated hydrochloric acid (1 m*l*) at room temperature resulting in instantaneous deposition of crystals with evolution of heat. After the mixture had been shaken for 15 min in an ice-bath, the slurry was mixed with water and the crystals were collected by filtration, washed thoroughly with water until neutral filtrate was obtained, and then washed with petroleum benzine, thus yielding thioacetal (X, 191 mg) as colorless needles. The second crop of syrup was treated according to the above

described procedure to give 20 mg of X. Total yield of X was 38% (based on III). Recrystallization of the crystals from petroleum benzine yielded pure X as white silky needles, mp 92.5—95°C (decomp.) (with a pre-heated bath (85°C) and a heating rate of 2°C/min), NMR ($CDCl_3$): δ 1.28 (6H, triplet, $J_{CH_3-CH_2}$ 7.6, CH_3). IR (KBr-disk): 3360 (OH); 2960 (CH_3–); 1415 (S–CH_2–) cm^{-1}.

Found: C, 35.81; H, 6.40; Br, 26.66; S, 21.13%. Calcd for $C_9H_{19}O_2BrS_2$: C, 35.64; H, 6.31; Br, 26.34; S, 21.14%.

5-Bromo-2,5-dideoxy-DL-threo-*pentose (IX).* DL-Thioacetal (DL-X, 97 mg, 0.32 mmol) in acetone (1 m*l*) and mercuric chloride (349 mg, 1.28 mmol) in acetone-water (1.5—0.2 m*l*) were mixed at room temperature with finely powdered cadmium carbonate (349 mg, commercial material had been washed with water and dried). After the mixture had been stirred for 24 hr, the insoluble material was removed by filtration and washed with acetone. The combined filtrate and washings were evaporated under reduced pressure in the presence of a small amount of cadmium carbonate. The residue was extracted 3 times with water (total 5 m*l*). The extract was treated with a mixture of Amberlite IR 120 (H^+) and Dowex 3 (OH^-) under ice-cooling. The ion exchange resins were removed by filtration and washed thoroughly with water. Concentration of the combined filtrate and washings *in vacuo* at a temperature below 35°C yielded a syrup. The syrup was dried in an evacuated desiccator over phosphorus pentoxide. The dried syrup (39 mg, 62%) was triturated with a small amount of ethyl acetate and kept in a refrigerator, resulting in complete crystallization. The crystals were recrystallized from ethyl acetate to give pure bromo-dideoxy-DL-*threo*-pentose (DL-IX) as colorless fine needles, mp 81.5—83.5°C (decomp.).

Found: C, 30.28; H, 4.49; Br, 41.76%. Calcd for $C_5H_9O_3Br$: C, 30.48; H, 4.60; Br, 40.56%.

DL-IX was found to be fairly unstable and in certain cases decomposition of DL-IX at room temperature to form black material was observed in a day.

5-Azido-2,5-dideoxy-DL-threo-*pentose Diethyl Dithoiacetal (XI).* A mixture of bromo-pentose mercaptal (X, 50 mg, 0.17 mmol) in methanol (5 m*l*) and sodium azide (87 mg, 1.3 mmol) in water (1.5 m*l*) was refluxed for 48 hr. The reaction mixture was evaporated under reduced pressure. The residue was mixed with methanol and again the solvent was removed *in vacuo*. This procedure was repeated to remove water completely. The residue thus obtained was extracted thoroughly with ethyl acetate. The residue obtained by evaporation of the solvent under reduced pressure was placed in an evacuated desiccator containing phosphorus pentoxide to give pale yellow syrup (30 mg). Preparative tlc of the syrup [silica gel G, thickness 0.5 mm; solvent system: chloroform-acetone (9: 1); detection reagent: iodine] resulted in the separation of the following substance: (a) R_f 0.6, almost colorless syrup, 8 mg, (b) R_f 0.35, colorless syrup, 11 mg, (c) R_f 0.17, colorless syrup, 4 mg (9%), IR (neat): 2100 ($-N_3$) cm^{-1}, (d) R_f 0.04, pale yellow syrup, 2 mg.

Study of Across-Space Intramolecular Charge-Transfer Interaction by Absorption and Fluorescence Spectroscopy

Kiyoshi MUTAI

Department of Chemistry, College of General Education, University of Tokyo, Komaba, Meguro, Tokyo

(Received July 21, 1971)

Across-space (through-space) intramolecular charge-transfer (CT) interaction has been observed in homologous series of p-$O_2NC_6H_4(CH_2)_nNHAr$ (I) and p-$O_2NC_6H_4(CH_2)_nNRAr$ (II). Introduction of an alkyl group to the amino nitrogen of I, thus producing II, generally increases the intensity of the CT absorption band. It also induces the red-shift of the band position in most cases owing to the increase of the basicity of the donor, while the blue-shift is observed in *ortho* substituted derivatives. The latter effect is explained by the steric inhibition of the delocalization of nitrogen lone-pair electrons. The CT fluorescence has been observed at room temperature in the lower homologs ($n=1$, 2, and rarely 3) of I and II. Higher intensity of the fluorescence is generally observed in $n=1$. The increase of intensity is observed when a small amount of benzene is added to a cyclohexane solution. The excitation spectrum shows two peaks; one at the ^1L_b transition wavelength of the amine moiety and the other at the CT absorption. The former suggests the possibility that an excited donor collides intramolecularly with a ground state acceptor part (p-nitrophenyl group) to form an excited CT state, and the latter presents a strong evidence for the origin of the fluorescence being the excited CT state.

Of the modes of intermolecular and intramolecular interactions arousing the interest of chemists, hydrogen bonding seems to have been studied most extensively in the past. However, during the last few years interest has grown in the study of intramolecular charge-transfer (CT) interaction.[1,2] This paper deals with the across-space[3] intramolecular CT effect, studied hitherto mainly by absorption spectroscopy with particular attention paid to the CT ground state. The present study is intended to provide information on the excited state of the intramolecular CT interaction with the aid of fluorescence spectroscopy as well as on the ground state.

Since the *intramolecular* CT interaction is subject to conformational restrictions, one can expect to observe spectral features differing from those of the *intermolecular* interaction in which the energetically most favorable conformation is exclusively assumed. Thus the characteristic aspects in the *intramolecular* interaction may provide valuable data for grasping the CT phenomenon. In *intramolecular* interaction the equilibrium constant between interacting and non-interacting molecules is independent of concentration so far as intermolecular interaction is negligible, and enables one to observe purely 1 : 1 interaction at low concentration even if the interaction is hardly detectable in an *intermolecular* case. This condition, of course, simplifies the interpretation of the spectral features.

h, Ar=2-$C_{10}H_7$

The compounds used for the present study are the homologous series of the type, p-$O_2NC_6H_4(CH_2)_nNHAr$ (I) and p-$O_2NC_6H_4(CH_2)_nNRAr$ (II), where R denotes methyl or ethyl groups, and Ar phenyl, p-tolyl, 2,4-dimethylphenyl, mesityl, p-anisyl, 2,5-dimethoxyphenyl or naphthyls. The CT interaction is expected between p-nitrophenyl (acceptor) and arylamino (donor) groups.

Results and Discussion

Absorption Spectra. Absorption spectra of the compounds of type I in carbon tetrachloride solution have been reported.[2] In the present study, a mixture of benzene–cyclohexane (1:4) was used as a common solvent for the measurement of absorption and fluorescence spectra. Addition of benzene to cyclohexane increases both the dissolving power of the solvent system and the intensity of the CT fluorescence. In order to show the effect of the number of methylene groups (n) and the difference between I and II series, some absorption curves are reproduced in Figs. 1 through 3. The data of the CT bands are summarized in Table 1. The CT band is obtained by subtracting a reference or standard spectrum from the spectrum of I or II. There are two ways for setting up the reference spectrum;[2] one is to adopt the spectrum of a sufficiently higher homolog (generally, a homolog with $n\geqq5$), and the other to adopt the sum of the spectra of the compounds having similar chromophores and simple struc-

tures. For practical reasons both methods are adopted. The latter is applied, to some derivatives of I and most of II, since their higher homologs are liquid at room temperature and difficult to be isolated in pure state because of their high boiling points. p-Nitrobutylbenzene and $ArNR-CH_2CH_3$ (R is hydrogen or alkyl) were used as model compounds. Thus the application of the different methods does not yield any significant difference in the CT band characteristics.[2)]

It is generally accepted that alkylation of the nitrogen of aniline or its derivative increases the π-basicity of the compound. Thus when I and II with the same Ar group are compared, II has a stronger electron-donor than I and is expected to have higher population of the CT interacting molecule, the situation leading to a higher intensity of the CT band of II at a longer wavelength than I. Hence, the introduction of an alkyl group to the amine nitrogen of I is a means to confirm the origin of the band as CT interaction.

As regards the band position, however, the prediction does not necessarily hold. We see from Table 1 that there are two groups of derivatives in which one reveals the shift of the band position to the long-wavelength side by the introduction of an alkyl goup to the amino nitrogen, as is observed in the cases of Ia, Ib, and Ie, and the other to the short-wavelength side as is observed in Ic, Id, and If. The effect observed in the latter group is contrary to expectation, but it can be understood if we note that all the Ar's in this group contain *ortho* substituent; that is, the *ortho* substituent hinders the orbital axis of the nitrogen lone-pair electrons from being pararell with p_π orbital axis of benzene, inducing less increase or even decrease of the π-basicity of NRAr group in comparison with the corresponding NHAr group. The group NH-2,4,6-$Me_3C_6H_2$ containing two

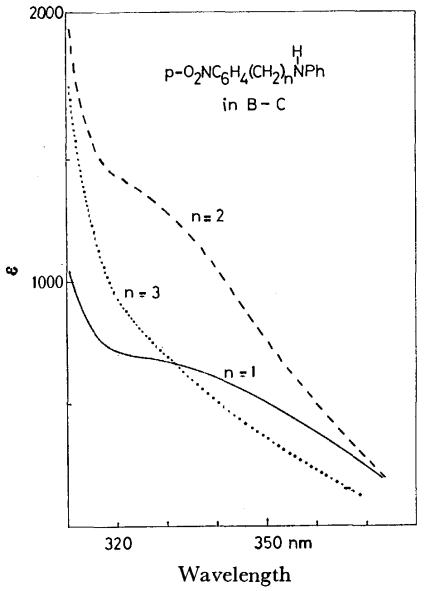

Fig. 1. Absorption spectra of p-$O_2NC_6H_4(CH_2)_n$NHPh (Ia) in long wavelength region in benzene-cyclohexane (1 : 4) mixture. Numerals attached to the curves denote the number of methylene group (n).

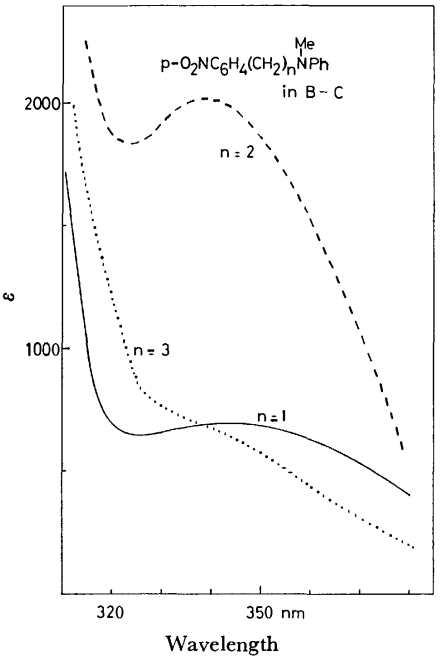

Fig. 2. Absorption spectra of p-$O_2NC_6H_4(CH_2)_n$NMePh (IIa) in long wavelength region in benzene-cyclohexane (1 : 4) mixture. Numerals attached to the curves denote the number of methylene group (n).

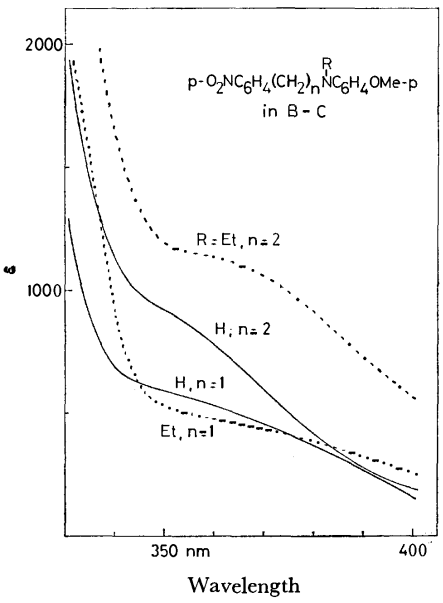

Fig. 3. Absorption spectra of p-$O_2NC_6H_4(CH_2)_nNRC_6H_4O$-Me-$p$ (Ie and IIe, R=Et) in long wavelength region in benzene–cyclohexane (1:4) mixture.

ortho methyls undergoes this steric effect (λ_{max} of Id at 326 and 316 nm $n=1$ and 2, respectively),[2] which is insignificant for NH-2,4-$Me_2C_6H_3$ group with one *ortho* methyl (λ_{max} of Ic at 350 and 339 nm in $n=1$ and 2, respectively). This steric inhibition of resonance has also been detected by means of the N–H stretching vibration,[2] dipole moment,[6] and ultraviolet absorption spectra of *N,N*-dimethylaniline derivatives.[7] Thus further introduction of a methyl group to the nitrogen of Id causes no further remarkable effect (only 3 nm of blue-shift in both $n=1$ and 2 of IId). On the other hand, we see from band positions of the derivatives of Ic and If that the steric effect makes no appreciable contribution when the nitrogen is a secondary amine type. Consequently it can be said that the introduction of an alkyl group to I increases the π-basicity of the donor only when the Ar group has no *ortho* substituent.

It seems strange that the decrease of the π-basicity of the donor is accompanied by an increase of intensity. However, examination of the CT band data shows a general relationship between the peak position and intensity; the shorter the λ_{max}, the higher the intensity. This phenomenon has also been observed in other solvents[2] and in some intermolecular CT complexes.[8-11] Although no satisfactory explanation has been given to this effect,[12] the abnormal increase of the intensity accompanied by blue-shift is in line with the general rule, and probably not with the increase of the number of interacting molecules.

Fluorescence Spectra. In the fluorescence spectra of I and II at room temperature, a fluorescence peak due to the excited state of the across-space intramolecular CT interaction was observed at 500—550 nm. Some CT fluorescence spectra are shown in Figs. 4 through 9 with excitation spectra. The peak was assigned as above for the following reasons. (1) The concentration of the solution used for measurement was less than 2×10^{-4} mol/l, which is dilute enough to exclude intermolecular interacting species. (2) The peak was observed only in the lower homologs and did not appear when the number of the methylenes (n) exceeds three. It should be remembered that the CT absorption band was observed in the lower homologs of $n\leqq4$. (3) Generally, the increase of the π-basicity of the donors owing to the introduction of electron-donating group(s) into the benzene ring or the nitrogen induced red-shift of the fluorescence peak (especially in $n=1$ homolog of I), reflecting the similar feature observed in the CT absorption spectrum. (4) The excitation spectrum showed a maximum at the λ_{max} of the corresponding CT absorption (Figs. 4—9). (1) and (2) provide evidences for intramolecular process. (3) and (4) suggest a close relationship between appearance of peak and CT interaction. The peak positions and their intensities are summarized in Tables 2 and 3.

a) Solvent Effects: The solvents used for the measurement of CT fluorescence are cyclohexane and benzene–cyclohexane (1:4, v/v) mixture. A slight blue-shift of the CT fluorescence is observed (Tables 2 and 3), when the solvent was changed from the latter to the former, and the effect is consistent with the shift of the CT absorption band[2] and also with that observed for intermolecular CT fluorescence.[13] In most cases addition of benzene to cyclohexane increased the intensity. The most significant effect is observed in the spectra of Ia ($n=1$ and 2) and Ib ($n=1$ and 2) which show no peak in cyclohexane. For these derivatives with weak donors the addition of benzene seems to be extraordinarily effective.

It is surprising, however, that the higher homolog of Ia ($n=3$) shows a peak in cyclohexane but not in benzene–cyclohexane system. The peak might be due to impurity, but this can be denied for the following reasons; a similar effect was observed in the series of Ib and IIa ($n=3$ shows the largest peak height), and the presence of an impurity which exhibits fluorescence even at a concentration less than 10^{-6} mol/l (since no impurity was detected by any other spectroscopic method, its concentration must be, at most, a few per cent to the sample compound) is incredible.

It is also noteworthy that the addition of benzene does not always result in the increase of intensity.

12) It has not yet been elucidated to what extent the spectra of the original chromophores undergo modifications in their band shapes on interaction. It is therefore difficult to discriminate whether the trend is "artificial" or inherent in CT interaction, as long as the CT band is obtained by subtraction of the reference spectrum, or the apparent peak position and intensity in the absorption curve are regarded as "true" as is often the case for intermolecular interaction.

		2	502	6.1	497	4.0
1-$C_{10}H_7$ (IIg)	Et	1	543	160	498	74

a) The intensity of p-$O_2NC_6H_4CH_2NH$-1-$C_{10}H_7$ (Ig) is taken as 100.
b) Owing to the low sensitivity of the photomultiplier (1P28) in long-wavelength region, the maximum does not appear in the range measured.

For instance, $n=1$ homologs of Id, Ie, and Ig exhibited no peak when dissolved in pure benzene as well as in 96% ethanol, while Ia showed the CT peak in benzene.

So far there is no satisfactory explanation for these phenomena caused by the added benzene and sufficient evidence to assign the effects to electronic origin (*e.g.* energy-transfer process) or to environmental origin (*e.g.* solvation), or both.

b) Peak Position and Intensity: A comparison of Tables 2 and 3 with Table 1 shows that there is no simple relationship between the maximum positions of the CT absorption band and the fluorescence. As regards CT absorption, it has been found that the longer the n ($n \leqq 3$), the shorter the wavelength of its λ_{max}, irrespective of solvent.[2] In benzene–cyclohexane system, most of the homologous series reveal the same tendency in their CT fluorescence bands. However, the tendency is reversed when the solvent was changed to cyclohexane. This might be due to the change of the potential energy curves of the CT ground and excited states caused by different solvation.

It is noteworthy that the peak position and intensity of $n=1$ homolog are generally more affected by solvent than $n=2$. A scale model shows only partial overlap of π-electron clouds of the donor and acceptor is allowed in $n=1$ because of the short methylene chain, but parallel plane conformation of the benzene rings is possible for $n=2$, the situation being the same both in I and II. The latter face-to-face conformation which permits sufficient overlap of the π-electron clouds is expected to be more stable than the conformation of $n=1$ and less susceptible to environmental factors. Probably this is the main reason for the fluorescence characteristics of $n=1$ being more sensitive to solvent.

For the series I ($n=1$) in benzene–cyclohexane, the CT fluorescence λ_{max} is in the order Ia<Ib<Ic<Id<Ie, which reflects the order of the electron-donating ability of Ar group and also nearly that of the λ_{max} of the CT absorption. The exception is Id, the CT absorption band of which is at the shortest wavelength due to the steric inhibition of delocalization of the nitrogen lone-pair electrons by two *ortho* methyls. Thus the fluorescence λ_{max} is expected at a shorter wavelength than Ia. However, since the most stable conformation of the excited state is achieved during much longer life time of fluorescence (about 10^{-9} sec) than conformational readjustment (about 10^{-12} sec) and the CT absorption observed is merely a vertical transi-

a) The ^1L_b transition of ArNREt in cyclohexane. b) Shoulder. c) A sharp peak (see Figs. 6 and 9).

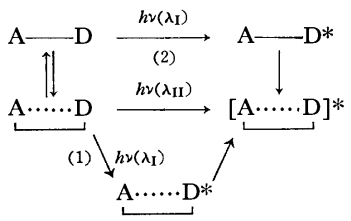
tion from the ground state, the "abnormal" behavior of Id might not be surprising if it is admitted that the most stable conformation of these two states differs.

c) Excitation Spectra of CT Fluorescence: Some typical examples of the excitation spectral curves are shown in Figs. 4 through 9. We see at a glance that a curve consists of two bands. One peak at shorter wavelength approximately agrees with the position of ^1L_b transition of ArNR-group, and the other with the CT absorption (see Tables 4 and 5). Agreement of these values can be said to be satisfactory, if we take into consideration some uncertainties possibly involved in both the excitation and absorption spectra (no correction has been made for the wavelength dependence of the sensitivity of the spectrometer).

The fact that the light having the same wavelength as CT absorption is effective for fluorescence is a strong evidence for the CT fluorescence.

It is interesting but puzzling that the excitation spectra of $n=2$ homologs of IIc—IIf showed a narrow but intense peak at about 410 nm (Fig. 9). The same phenomenon is also observed in some derivatives of I (Fig. 6). Appearance of this extra peak is restricted only to the $n=2$ homologs in both I and II series. No corresponding absorption is found in the absorption spectra of these compounds, and no convincing explanation has been obtained.

It is also interesting that the mere excitation of the amine moiety is effective for CT fluorescence. This suggests at least two processes possible for the appearance of the excited CT state; (1) only an amine moiety in a CT interacting molecule is excited and falls to the lowest excited singlet level of CT interaction releasing the excess energy nonradiatively. (2) An amine moiety free from the interaction absorbs light, and in its excited state during the stay collides with the *p*-nitrophenyl group at the other end of the methylene chain to form a CT interacting molecule in excited state. The processes are described in the following scheme, where A and D are the acceptor (*p*-nitrophenyl) and the donor (NRAr) groups, respectively (for λ_I and λ_{II}, see Tables 4 and 5).



From the viewpoint of energy level, ^1L_a band of *p*-nitrophenyl group at 265 nm (in heptane)[14] is higher than the ^1L_b of the amine moieties and the excitation of the nitrophenyl group should be effective in either process. Contrary to expectation no peak could be detected at the wavelength corresponding to this absorption. In this respect, it is notable that in 1,4-dimethoxybenzene — trinitrobenzene or — chloranil system the excitation of an acceptor results in the formation of donor cation,[15] suggesting that the encounter of the excited acceptor with the donor leads to the transient acceptor anion and donor cation likely to be formed when a CT complex is excited in polar solvent. Although there is no reason why this intermolecular process should not be observed in an intramolecular case, no satisfactory explanation has been found as yet.

Of the two processes, (2) is considered as more probable, since an excimer and an exciplex are formed in a similar process. The same process has been considered possible for the intermolecular CT interaction between anilines and oxygen molecule,[16] and between *N,N*-dimethylnaphthylamine and methyl benzoate.[17] As an evidence, it may be cited that the ratio of the apparent peak heights of the excitation spectrum, λ_{II}/λ_I, is in almost all the cases larger in $n=2$ than $n=1$ (for typical example, see Figs. 5 and 8). The ratio is independent of the quantum yield of the fluorescence and of the intensity distribution of light source, and, therefore, represents the relative effectiveness of two types of excitations. The larger value of $n=2$ homolog shows that the excitation of the CT state is more effective than that of the same band of $n=1$ homolog, or, in other words, the excitation of the amine moiety is less effective in $n=2$. According to process (2), the effect is explained as follows. The excited donor in $n=2$ homolog has a smaller chance to encounter the acceptor before transition to the ground state due to its longer chain length than $n=1$, the situation leading to the relative inefficiency of ^1L_b excitation and the increase of the relative effectiveness of CT band excitation.

Conclusion

It was suggested[2] that the interaction might be "contact charge-transfer",[18] but the occurrence of CT fluorescence indicates the presence of energy minimum in the excited energy level of the CT interaction. It might be said that in the interacting species some stable and unstable complexes are present whose stability depends mostly on conformational factors of the interacting groups.

Intramolecular excimer formation has been studied by several investigators,[19] who showed that strict conditions are required for the occurrence of the phenomenon. As an example, the number of methylene groups in Ar–$(CH_2)_n$–Ar system must be three for the observation of intramolecular excimer fluorescence. When the number is two, insufficient overlap of π-electron clouds in the aromatic rings prevents the radiative

process. If we compare the *number of atoms* separating donor and acceptor allowed for excimer fluorescence (only 3) with that allowed for CT fluorescence (2, 3, and in some cases 4), it is clear that the CT excited state depends to a smaller extent on conformational requirements as expected from its larger stabilizing energy.

Experimental

Electronic Absorption Studies. Spectra were recorded on a Shimadzu MPS-50L automatic recording spectrophotometer. Quartz cells of 1.0 cm in length were used. The concentration of benzene-cyclohexane solution was less than 2×10^{-3} mol/*l*.

Emission Studies. Fluorescence spectra were recorded at room temperature on an Aminco-Bowman spectrophotofluorometer. The concentration of both benzene-cyclohexane and cyclohexane solution was always in the range $1-2\times10^{-4}$ mol/*l*. In every measurement, the peak height of the CT fluorescence band p-$O_2NC_6H_4CH_2NH$-1-naphthyl (Ig, $n=1$) was determined in order to obtain a factor necessary for the adjustment of intensity fluctuation of incident light. The CT fluorescence intensities were given relative to that of this compound (relative intensity=100) in Tables 2 and 3. The fluorescence peak height of *N*-ethyl-1-naphthylamine is 8.5×10^4 (at 390 nm, corrected for the sensitivity of 1P28) in this scale. The excitation wavelength was 313 nm. The data in Tables 2 and 3, and fluorescence curves in Figs. 4—9 are corrected for the sensitivity of photomultiplier (1P28).[20] As a result, in some compounds ($n=1$ of Ie, IIe, and IIf) no peak was found in their corrected spectral curve, on account of large and uncertain correction factors in long wavelength region.

Excitation spectra were determined with the same spectrophotofluorometer equipped with an "off-axis ellipsoidal mirror condensing" system. No correction for the wavelength dependence of the sensitivity of the instrument was made.

Solvents. Spectrograde or guaranteed reagents were used after careful distillation.

Materials. Both types of compounds (I and II) were prepared as described in a previous paper.[2] The physical constants and results of elemental analyses of the new products are given in Table 6.

The author wishes to thank Dr. Akira Kuboyama, Government Chemical Industrial Research Institute, for permitting him to use the spectrophotofluorometer. He also wishes to express his gratitude to Professor Yoshiya Harada (University of Tokyo) and Dr. Jun-ichi Aihara (University of Hokkaido) for their valuable discussions and suggestions. Thanks are also due to the Matsunaga Science Foundation for financial support of this work.

Application of Factor Analysis to Polarography

Darryl G. HOWERY

Department of Chemistry, Brooklyn College of The City University of New York, Brooklyn, N. Y., U.S.A.

(Received May 9, 1972)

Chemical problems in which the observable is measurably dependent upon several variables are seldom amenable to detailed analysis. Recent applications of the mathematical method of factor analysis to some multidimensional chemical problems have led to new insights in the fields of nuclear magnetic resonance spectroscopy[1,2] and gas-liquid chromatography.[3,4] The results of factor analyzing a data matrix of polarographic half-wave potentials for five alkaline and four alkaline-earth metals in five polar solvents are presented here.

Any function being factor analyzed must be a linear sum of factors, where in addition each factor must be in the form of a separable product term.[1] For the half-wave potential of the i-th ion in the α-th solvent, we assume therefore that

$$E^0_{1/2,i,\alpha} = \sum_j I_{ij} V_{j\alpha} \qquad (1)$$

where I_{ij} is the j-th ion factor for the i-th ion, $V_{j\alpha}$ is the j-th solvent factor for the α-th solvent, and the sum is taken over the minimum number of abstract eigenvectors or controlling factors, j, necessary to span the data-matrix space. The reproduction portion of the factor analysis scheme allows one to find the minimum number of abstract eigenvectors, and the least-squares rotational portion of the scheme allows individual physically significant properties of both ions and solvents to be tested for possible identification with the abstract eigenvectors.

Procedure

The data matrix was taken from the compilation of Gutmann,[5] with the half-wave potentials measured relative to aqueous saturated calomel electrode being selected for factor analysis. Ions and solvents are listed in Table 1. All computations were performed on a FACOM 230-60 digital computer using the Fortran IV program developed by Malinowski and coworkers.[1]

Results and Discussion

Number of Controlling Factors. The reproduction portion of the factor analysis program enables one to reproduce the data matrix stepwise using the largest abstract eigenvector, the two largest eigenvectors, and so forth. When the agreement between the measured and the predicted half-wave potentials is overall reasonable considering the uncertainty of the measurement, the number of abstract eigenvectors used for that reproduction is taken to be equal to the number of independent controlling factors in the problem. The minimum number of factors required to adequately characterize the data space, information ordinarily not obtainable in complex problems, is thus determined. Examination of the error in the various reproductions leads one to conclude that the half-wave potential space is probably a three-factor space since with the three largest eigenvectors only seven points in the reproduced matrix are in error by more than 30 mV, the largest error being 58 mV. If the data for lithium and magnesium are ommitted from the matrix, the reproduction with three factors is not improved implying that the factors which account for irreversibility are still operative in the reduced-matrix space.

Test of Physically Significant Factors. The least-squares rotational part of the factor analysis scheme furnishes valuable insights into the factors governing the reduction process and in particular the ion-solvent interactions. A suspected chemical or physical property can be tested for identification as a fundamental factor of the space by seeing if a test vector composed of the values of that property associated with the row elements of the data matrix can be rotated mathematically onto an abstract eigenvector of the space. In a successful test the values for the property predicted by the factor analysis method must agree reasonably well with the corresponding points on the test vector. Even if some values of the property are not known or are suspect, the test can still be made since the program includes provisions for free-floating, *i.e.*, leaving blank, some points on the test vector.

A) Ion Factors: The ionic charge (see Table 1 for the results) and the reciprocal of the crystalline ionic radius both gave moderately good agreement between the test and the predicted vector. The lithium ion, the charge for which was free-floated in the ionic charge test, appears to behave more like a divalent ion. A test for the ionic potential, *i.e.*, the ionic charge divided by the crystalline ionic radius, gave the fair fit shown in Table 1. The values for Li^+ and Mg^{2+} were free-floated since the effective ionic potential quite possibly might differ from the conventional ionic potential for ions known to have high overvoltages in

Table 1. Tests for physically significant parameters

Ion	Ionic charge		Ionic potential	
	Test	Predicted	Test	Predicted
Li^+	(1.00)	2.03	(1.47)	1.88
Na^+	1.00	1.16	1.03	0.92
K^+	1.00	1.25	0.75	1.02
Rb^+	1.00	0.92	0.68	0.63
Cs^+	1.00	0.87	0.60	0.57
Mg^{2+}	2.00	2.17	(3.02)	2.07
Ca^{2+}	2.00	2.06	2.02	1.94
Sr^{2+}	2.00	1.76	1.78	1.62
Ba^{2+}	2.00	1.78	1.50	1.67

Solvent	ΔH_{vap}		$1/R'$		Donor number	
	Test	Predicted	Test	Predicted	Test	Predicted
DMSO	12.6	12.3	1.47	1.45	2.98	2.72
DMA	12.7	13.5	1.45	1.45	2.78	2.82
Water	10.5	11.4	1.39	1.41	1.80	2.19
PDC	11.9	11.5	1.22	1.21	1.51	1.43
MeCN	7.8	7.8	1.22	1.21	1.41	1.30

PDC=propylene dicarbonate. Three-factor space assumed for tests. Points in parenthesis on the test vectors were free-floated. Values for the crystalline ionic radius (A) were taken from "Handbook of Chemistry and Physics," ed. by R. C. Weast 46th Edition, Chemical Rubber Co., Cleveland (1964), p. F89; for the molar enthalpy of vaporization (kcal/mol), from reference 5 and from "Techniques of Organic Chemistry," ed. by A. Weissberger Vol. II, 3rd Edition, Wiley, New York, (1970); for the radial correction factor, from Ref. 7; and for the donor number, from Ref. 5.

water. Crystalline ionic radius, equivalent weight, solubility of the metal in mercury (g/100 g) and ionic polarizability do not appear to be factors since the fit was quite poor for each of the tests. A test for the solubility expressed as a mole fraction showed the proper trends but the fit was still rather poor.

B) Solvent Factors: Since mathematically in a three-factor space test points for all five solvents must be specified on a test vector, the lack of reported physical properties for PDC somewhat restricted the solvent properties which could be tested. Three solvent parameters tested moderately well (see Table 1 for the results): the molar enthalpy of vaporization, the donor number as defined by Gutmann,[6] and the reciprocal of a radial correction factor, R', proposed by Matsuura *et al.*[7] Boiling point (°K), dipole moment, molar polarization, dielectric constant, viscosity, Trouton's constant and the Hildebrand solubility parameter all gave sufficiently poor fits to be excluded as fundamental factors.

Since so little is known about the mathematical formulation of ion-solvent interactions especially when expressed in the form required by Eq. 1), speculation on the implications of the ion and solvent tests reported here seems premature. A major advantage of the method of factor analysis is that one can test an individual parameter in a many-factor space though lacking a theoretical model for the interaction.

If three independent ion factors or solvent factors are discovered, one can attempt to reproduce the data matrix using physically significant test vectors.[2,4] The reproduction using the set molar enthalpy of vaporization, donor number and $1/R'$ was surprisingly good, with the average of the column average errors being 28 mV. The solvent-factor space would appear to be spanned fairly well with these three factors.

The application of factor analysis to new areas of chemistry is being severely limited by the lack of large, complete, and accurate data matrices. At present, extensive data of the type required for comprehensive factor analysis studies are available as far as we know only in the field of gas-liquid chromatography.[8] The matrix employed in this study severely tested the factor analysis method since the number of solvents was so small compared to the number of factors required to span the space. Since experience has indicated that the number of rows and columns should preferably be at least twice the number of factors, the reproduction of the data matrix with three eigenvectors and the fit of the test vectors given in Table 1 are encouraging. More definitive conclusions to this complex problem should be possible if a larger data matrix were available.

Dr. K. Izutsu suggested this problem and furnished much valued advice. J. Okuda's help on programming, Professor T. Fujinaga's financing of the computer work, and the use of the Computer Center of Kyoto University are gratefully acknowledged.

Carbon-14 Isotope Effect on sp^2-sp^3 Hybridization in the Prototropic Equilibrium of *N*-Benzylidenebenzylamine

Yasuhide YUKAWA, Takashi ANDO, and Tetsuo OTSUBO

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka

(Received January 29, 1972)

Isotope effects on equilibria can be calculated exactly on the basis of mechanical properties of two stable states involved, which can be observed directly. Accurate determination and theoretical consideration of these effects serve to elucidate the more complex problem of inferring from observed kinetic isotope effects something about transition state structure. *N*-Benzylidenebenzylamine system is known to show a prototropic equilibrium (Eq. (1)) in the presence of a strong base.[1]

$$\mathrm{Ar\text{-}CH{=}N\text{-}CH_2\text{-}Ar' \rightleftarrows Ar\text{-}CH_2\text{-}N{=}CH\text{-}Ar'} \quad (1)$$

Substitution of an aliphatic carbon with a carbon-14 isotope should cause a carbon isotope effect on equilibrium (I⇄II).

$$\mathrm{Ph\text{-}{*}CH{=}N\text{-}CH_2\text{-}Ph \rightleftarrows Ph\text{-}{*}CH_2\text{-}N{=}CH\text{-}Ph}$$
$$\text{(I)} \qquad\qquad \text{(II)}$$

It is the effect accompanying the change in sp^2-sp^3 hybridization of a carbon atom.

Gamboa and coworkers reported the isotope fractionation of 60—70% in the equilibrium of the 1,3-diphenyl-1-propene system (Eq. (2)), but it seems

$$\mathrm{Ph\text{-}{*}CH{=}\overset{\displaystyle CH_3}{\overset{|}{C}}\text{-}CH_2\text{-}Ph \rightleftarrows Ph\text{-}{*}CH_2\text{-}\overset{\displaystyle CH_3}{\overset{|}{C}}{=}CH\text{-}Ph} \quad (2)$$

abnormally large.[2] On the other hand, Kresge and coworkers[3] observed a small reverse isotope effect in the ionization of triphenylmethyl chloride-1-^{13}C. In these respects, the carbon-14 isotope effect on the equilibrium (I⇄II) was measured and compared with a theoretically calculated value.

Results and Discussion

N-Benzylidenebenzylamine(methine-^{14}C) (I) was prepared by condensation of benzaldehyde(carbonyl-^{14}C) with benzylamine. The equilibrium was effected by the action of 30 parts of 1.45N alcoholic sodium ethoxide at 40.0 and 82.0°C. Definite portions of the reaction mixture were added into 2N hydrochloric acid solution of saturated 2,4-dinitrophenylhydrazine at appropriate time intervals. Precipitates of benzaldehyde 2,4-dinitrophenylhydrazone (III) were collected and purified by recrystallisation. Samples of III were oxidized with the Van Slyke-Folch mixture and the radioactivity of the carbon dioxide generated was measured by the ionization chamber counting method.

Table 1. Specific radioactivity data for the methyleneazomethine equilibrium at 40.0±0.1 and 82.0±0.1°C

No.	Compound	Temp (°C)	Time (hr)	Specific activity (mCi/mol)
1	I			1.0492±0.0011
2	III	40.0	0	1.0419±0.0009
3			1	0.9663
4			2	0.8237
5			4	0.6721
6			8	0.5798
7			24	0.5323±0.0007
8			36	0.5302±0.0005
9			50	0.5284±0.0003
10		82.0	0	1.0457±0.0001
11			0.5	0.5276±0.0008
12			1.0	0.5286±0.0005

The results are summarized in Table 1.

The small difference between the radioactivity of the starting material (I) and that of the 2,4-dinitrophenylhydrazone (III) at initial stage in each of thest two experiments can be attributed to the partial isomerization of I to II during the course of the preparation under mild basic conditions. It is apparent that the equilibrium was reached within 36 hr at 40°C and 30 min at 82°C. The equilibrium constant K, whose value corresponds to that of the isotope effect in this case, is calculated by Eq. (3);

$$K = [\mathrm{II}]/[\mathrm{I}] = (\mathrm{A}-\mathrm{B})/\mathrm{B} \quad (3)$$

where A is the specific activity of the starting material (I) and B is that of the 2,4-dinitrophenylhydrazone (III) at equilibrium. The results thus obtained show small isotope effects on the equilibrium: K=0.983±0.002 at 40.0°C and K=0.986±0.002 at 82.0°C. The equilibrium constants smaller than unity indicate that the equilibrium is in favor of the carbon-14 atom at the sp^2-position.

Theoretical values of isotope effects on equilibrium can be calculated by the Bigeleisen equation (Eq. (4)),[4]

$$K = 1 + \sum_i \left(\frac{1}{2} - \frac{1}{u_i} + \frac{1}{e^{u_i}-1}\right)\Delta u_i \quad (4)$$

where $u_i = \boldsymbol{h}c\omega_i/\boldsymbol{k}T$, Δu_i is the difference in u_i between isotopes, and ω_i is the wave number of the ith normal mode. For calculation of Eq. (4), only stretching vibrations were used, which are usually considered as the most effective factors of isotope effects. An observed infrared spectrum was analyzed and vibrational fre-

quencies were determined as follows:[5] C=N, 1640; C–N, 1200; C–H (in =CH–), 3030; C–H (in $-CH_2-$), 2865 and 2835 cm^{-1}. Stretching frequencies for carbon-carbon single bonds in =CH–Ph and $-CH_2-Ph$ were arbitrarily taken as 1050 and 1000 cm^{-1}, respectively. Frequencies for a carbon-14 isotope were calculated by the following relationship: $\omega_1/\omega_2=(\mu_2/\mu_1)^{1/2}$, where μ means a reduced mass. The equilibrium constants K calculated as above are 0.986 at 40°C and 0.987 at 82°C. Although inclusion of bending vibrations may give a better result, these calculated values are in fair agreement with the observed values, considering the errors in measurement of radioactivity and the simple approximation used for theoretical calculation.

Experimental

Material. Benzaldehyde(carbonyl-^{14}C) was prepared according to the procedure of Ott.[6]

N-Benzylidenebenzylamine(methine-^{14}C) (I). Benzaldehyde(carbonyl-^{14}C) was treated with 5.0 m*l* of benzylamine for 30 min at 80—90°C. After being cooled, the reaction mixture was diluted with 20 m*l* of ether. The ether solution was washed with 10 m*l* of 2% acetic acid, 10 m*l* of saturated sodium bicarbonate solution, and 20 m*l* of distilled water, successively, and finally dried over anhydrous potassium carbonate. The solvent was removed and the colorless oil remained was distilled under reduced pressure; bp 158.5°C/4.8 mmHg, yield 5.85 g (78.5%).

Methyleneazomethine Rearrangement. *N*-Benzylidenebenzylamine(methine-^{14}C) (I, 1.847 g) was added all at once into 60.204 g of 1.45N alcoholic sodium ethoxide in a reaction vessel preheated in a constant temperature bath at 40.0±0.1°C. Six m*l* aliquot of the reaction mixture was pipetted into 50 m*l* of 2N hydrochloric acid solution containing saturated 2,4-dinitrophenylhydrazine at appropriate time intervals. The solutions were kept to stand for 24 hr at 50°C for complete precipitation of 2,4-dinitrophenylhydrazone (III). After being cooled to room temperature, 10 m*l* of distilled water was added. Crystals of III were filtered, washed thoroughly with 2N hydrochloric acid and distilled water, successively, and then dried for 12 hr at 80—90°C. Samples of III purified by recrystallization three or four times from acetone were assayed for radioactivity.

In the same manner, 0.991 g of I was rearranged in 29.243 g of 1.45N alcoholic sodium ethoxide solution at 82.0±0.1°C.

Measurement of Radioactivity. About 10 mg of accurately weighed III was oxidized with the Van Slyke-Folch mixture[7] in a Nuclear-Chicago Model GW1 carbon glassware system, and the carbon dioxide generated was swept into a Model DC 250 ion chamber with tank carbon dioxide. The ion current was measured with a Nuclear-Chicago Model 6010 Dynacon electrometer system.

5) Infrared spectra were recorded on a JASCO Model DS-402G IR Spectrophotometer in carbon tetrachloride (4000—1300 cm^{-1}) and in carbon disulfide (1300—660 cm^{-1}).

An MO-Theoretical Account of the Catalytic Decomposition of Alkyl Hydroperoxides by Transition-metal Ions

Katsutoshi OHKUBO and Hirokazu KANAEDA

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami-machi, Kumamoto

(Received April 14, 1971)

Many chemical studies of the decomposition reactions of alkyl hydroperoxides with or without catalysts have been done during the last decade. The mechanism of the catalytic decomposition of the hydroperoxides by transition-metal ions has, however, been established on the basis of the Haber-Weiss mechanism,[1] and some aspects of the process of the reactions are still veiled. The present study has been undertaken in an attempt to elucidate the processes of the decomposition reactions, using the all-valence-electron ASMO SCF and extended Hückel (EHMO) methods involving metal *d*-orbitals of transition metals.

Method of Calculation

Three systems were investigated in this work: (a) the monomers and dimers of alkyl hydroperoxides (ROOH: R=H, CH_3, C_2H_5, n-C_3H_7, i-C_3H_7, and t-C_4H_9), (b) the nucleophilic attack of the transition-metal ion (Cr(II), Co(II), or Fe(II)) on CH_3OOH, and (c) the electrophilic attack of Co(III) on CH_3OOH. The zero-differential overlap approximated ASMO SCF[2] and EHMO methods were used in this paper; the one-center and two-center Coulomb repulsion integrals were estimated by the Pariser[3] and the Ohno[4] approximations respectively. In the EHMO method, the resonance integrals were evaluated by

1) F. Haber and P. Weiss, *Proc. Roy. Soc., Ser. A*, **147**, 233 (1939).

2) The ionization energies (and electron affinities) of Cr, Co, and Fe are cited from Ref. 8 (Ref. 10), Ref. 8 (Ref. 10), and Ref. 9 (Ref. 10) respectively. The ASMO SCF method used was almost the same as the method reported by H. Kato, H. Konoshi, and T. Yonezawa (This Bulletin, **40**, 1017 (1967)).

3) R. Pariser, *J. Chem. Phys.*, **21**, 568 (1953).

4) K. Ohno, *Theoret. Chim. Acta*, **2**, 568 (1953).

means of the Wolfsberg-Helmholtz approximation.[5]

Results and Discussion

First, we will interpret the unimolecular or the bimolecular decomposition[6] of ROOH in connection with the association of ROOH.[7] Figure 1 shows the changes in the total energies of ROOH dimers, together with those of monomers (R=H, CH_3, C_2H_5, n-C_3H_7, i-C_3H_7, and t-C_4H_9), due to the stretching of the O–H bonds, which resulted from the EHMO calculations. The ROOH monomers are slightly less stable than the ROOH dimers. In addition, the reactivity of the former to nucleophiles such as low-valent metal ions is higher than that of the latter; notice, for example, the reactivity indices ($^1/_2N^{LU}_{p\sigma}$), *i.e.*, the partial AO bond population in the lowest unoccupied (LU) MO, which is strongly localized in the O–O $p\sigma$-type orbital (see Table 1). Consequently, it is probable, at low concentrations of ROOH, that the unimolecular decomposition occurs predominantly either with or without catalysts.

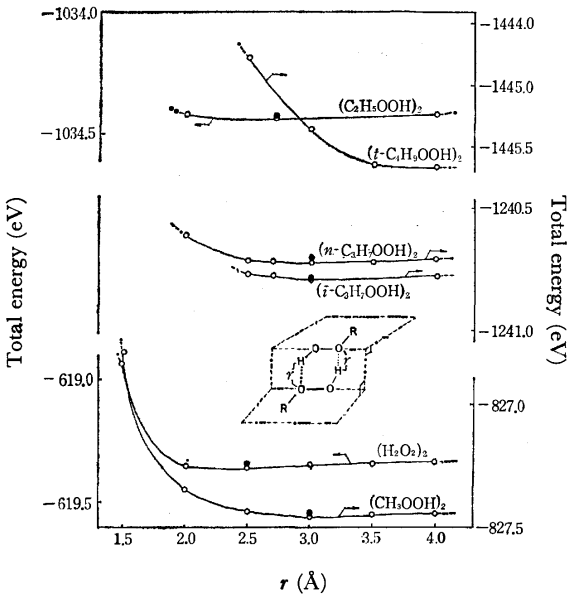

Fig. 1. Changes in the total energies of ROOH dimers as a function of the O–H distance (denoted by r), together with those of ROOH monomers.
(○: ROOH dimer; ●: ROOH monomer.)

Secondly, let us discuss the catalytic decomposition of ROOH by the transition-metal ions from the viewpoint of our experimental findings; about 95 mol% of the quantity of cumene hydroperoxide (the initial amount was 22.5 mmol) disappeared after 0.5 hr at 80°C in cumene (50 ml) containing Co(II) supplied by its stearate (0.33 mol/l), although, thermally, the hydroperoxide decomposed little even after 9.0 hr. Under the same reaction conditions, Ni(II), Fe(II), and Cr(III) lessened the quantity of the hydroperoxide

Table 1. Electronic properties and reactivities of ROOH and their dimers

ROOH and $(ROOH)_2$	O–H (Å)	Bond population of the O–O	$\frac{1}{2}N^{LU}_{p\sigma}$	Total energy (eV)

These results were obtained from the EHMO calculations.

by *ca.* 6, 4, and 17 mol% respectively. The order of the catalytic abilities of the low-valent transition metal ions for the hydroperoxide decomposition, *i.e.*, Co(II)>Ni(II)>Fe(II), can be well explained by the parallelism with that of the energy required for the electron-releasing from the metal ion to the antibonding O–O $p\sigma$ orbital, namely, with that of the orbital energies of the highest occupied (HO) AO of the metal ions (−7.84,[8] −9.24,[8] and −11.0 eV[9] respectively).

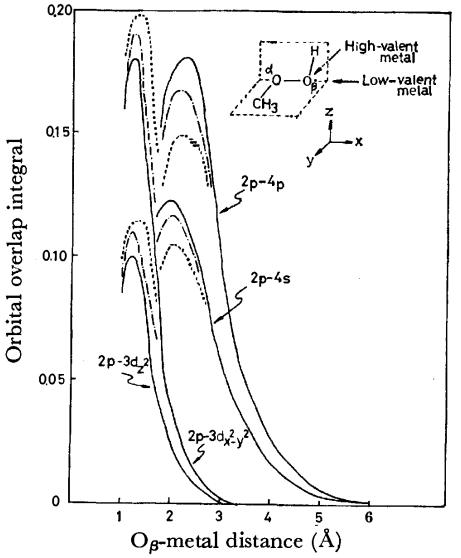

Fig. 2. Changes in orbital overlaps between oxygen p-orbitals and metal d-, s-, and p-orbital due to the variation of the O_β-metal distance. (——: Co; ·····: Cr; ——: Fe)

A more precise discussion should be made here with respect to the catalytic decomposition of ROOH by the metal ions. From the orbital overlaps between oxygen 2p and metal 3d AOs indicated in Fig. 2, the following two reactions can be expected in the O_β-metal region below 3.0 Å: the nucleophilic attack of a low-valent metal on the O–O $p\sigma$ orbital in the direction

TABLE 2. CHANGES IN THE ELECTRONIC STATES OF TRANSITION METAL IONS AND CH_3OOH ATTACKED BY LOW-VALENT METAL IONS

O_β-Metal ion distance (Å)	Atom population of metal	AO populations					
		Transition metal			CH_3OOH		
		$d_{x^2-y^2}$	d_{z^2}	d_{xy}	$O_\beta-p_y$	$O_\beta-p_x$	$O_\alpha-p_x$
	4.000(6.000)				1.996(1.996)	1.050(1.050)	0.983(0.983)
1.6	3.243(6.0)	0.327(1.615)	0.109(1.855)	0.038(0.037)	1.869(1.885)	1.558(1.189)	1.388(1.149)
1.5	(5.323)	(1.111)	(1.697)	(0.076)	(1.870)	(1.378)	(1.613)
1.4	3.218	0.315	0.135	0.089	1.813	1.639	1.490

These results were obtained from the ASMO SCF calculations.
Values and those in parentheses indicate the cases of Cr(II) and Fe(II) respectively.

of the O–O axis from the O_β side[10] and the electrophilic attack of a high-valent metal on the nonbonding lone-pair O_β $2p_y$-orbital (note the larger population and delocalizability to nucleophiles[11] of O_β as compared with those of O_α). In these attacks, the wholly unoccupied $4s$ and $4p$ orbitals situated at high-energy levels may not play an important direct role in the interaction of the metal ion with ROOH.

Thirdly, it is of interest to notice the changes in the electronic states of the transition-metal ions and ROOH by the interaction, which predominantly occurs near the maximum overlaps between oxygen $2p$ orbitals and metal d-orbitals, *i.e.*, near 1.5 Å (see Fig. 2). The orbital symmetry allows two pairs of overlaps: the dp-σ overlap between the O–O $p\sigma$ and $d_{x^2-y^2}$ and/or d_{z^2} and that between the nonbonding lone-pair O_β, p_y, and d_{xy}. In both attacks we recognized an electron-inflowing from the $d_{x^2-y^2}$ metal to the O–O $p\sigma$ and an electron-backdonation from the lone-pair, O_β p_y, to the d_{xy} metal, as can be seen from Table 2. It is necessary to mention here that the negative value of the bond population of the O–O in ROOH attacked by the metal ion within the O_β-metal distance of 2.0 Å indicates a scission of the O–O linkage, while, even at the O_β–S distance of 1.47 Å, the bond population of the O–O is positive in the case of the nucleophilic interaction of $(CH_3)_2S$ with CH_3OOH.[12] The remarkable ability of the transition-metal ions for the hydroperoxide decomposition was, for instance, thus reflected in the change in the electronic state of ROOH attacked by the metal ion.

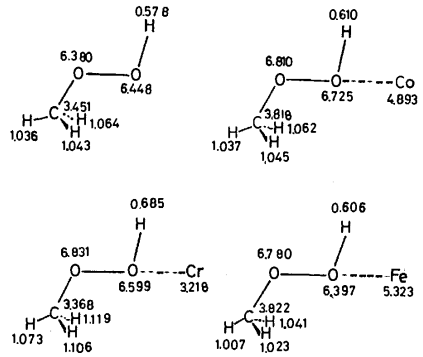

Fig. 3. Valence electron distributions of the systems of CH_3OOH–transition metal ion. (O_β–Co or Cr=1.5 Å; O_β–Fe=1.4 Å)

Finally, the valence-electron distributions of the CH_3OOH-metal ion systems are indicated in Fig. 3.

The calculations were carried out on the FACOM 230-60 computer at the Computer Center of Kyushu University.

Theoretical Consideration on the Electronic Structures of *trans*- and *cis*-Isomers of Acrolein and 2,4-Pentadienal

KOZO INUZUKA

Department of Applied Science, Tokyo Electrical Engineering College, Kanda, Chiyoda-ku, Tokyo

(Received February 7, 1972)

In the previous paper[1] an approach to n,π^*-state energy calculation was presented and the electronic structures of lower n,π^* and π,π^* states of several carbonyl molecules in the planar *trans* form were studied within the framework of the SCF–MO–CI approximation. Theoretical considerations suggest the possibility of the existence of *cis*-acrolein,[2] but its existence is not experimentally clear. Generally, no experimental evidence of the *cis*-form is known for such short polyene aldehydes as acrolein and pentadienal, but such longer ones as retinal, which corresponds to 2,4,6,8,10-dodecapentaenal in the π-electron system, have several *cis*-isomers.[3] In the case of retinal, its isomers play an important role in the vision mechanism of rhodopsin, and they have specific features in their optical behavior;[4] nevertheless, theoretical consideration of the electronic structure of *cis*-isomers of polyene aldehyde is still scarce. Therefore, it is of interest to make clear the electronic structure of *trans*- and *cis*-isomers of polyene aldehydes. The UV spectra of the conjugated enones and dienones have been well studied, and the empirical correlations of the UV absorption with the structure have become evident.[5,6] However, the band position of the n,π^* absorption spectrum for such a conjugated system as *trans*- and *cis*-polyene aldehydes is still unclear. In this paper the band positions of n,π^* and π,π^* states for *trans*- and *cis*-forms of acrolein and 2,4-pentadienal were studied by the same approach as was developed previously within the framework of the Pariser-Parr-Pople SCF–MO–CI method.[7,8] The P-P-type two-center repulsion integral[7] was used for the calculation of the π-electron system. The Mataga-Nishimoto approximation[9] was adopted for two-center repulsion integrals between n and π electrons.

In the previous paper[1] the value of -14.75 eV[10] was used for the parameter, U_n, in Eq. (7) corresponding to the n-orbital energy calculation. In this paper the value of -14.60 eV will tentatively be used for the U_n parameter in order to improve the calculated n,π^*-state energy.

The following numerical values[11] were used for the skeletal structures of acrolein and 2,4-pentadienal; 1.34 Å for the carbon double bond, 1.46 Å for the single bond, and 1.22 Å for the carbonyl group. The value of 120° was assigned to the C–C–C and C–C–O bond angles. All the calculations were carried out on the assumption of a planar structure for the present molecules.

Results and Discussion

The calculated results are listed in Table 1.

The intense absorption spectrum of acrolein is observed at 5.96 eV (208 nm), while the weak absorption band is observed at 3.71 eV (334 nm),[12] in an n-hexane solution. These observed values are assigned to the lowest π,π^* and n,π^* singlet states of acrolein.[12] These state energies correspond to the present calculated values, 5.960 eV (208 nm, $f=0.803$) for the π,π^* singlet state energy and 3.767 eV (329 nm) for the n,π^* singlet state energy.

On the other hand, the theoretical π,π^* and n,π^* singlet state energies of *cis*-acrolein are 5.608 eV (221 nm, 0.381) and 3.800 eV (326 nm). These results suggest that the π,π^* singlet state of *trans*-acrolein is higher than that of *cis*-acrolein and that the intensity of the former is larger than that of the latter. Those theoretical results correspond well with the observed results of the conjugated enones (from a to d)[13] shown in Fig. 1. The location of the n,π^* singlet state of

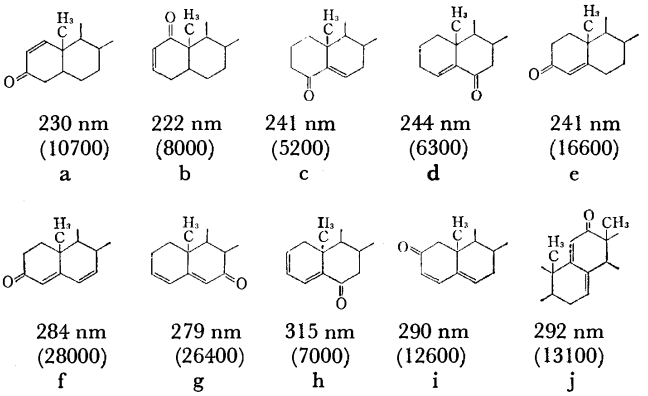

Fig. 1. Conjugated enones and dienones with the values of λ_{max} and intensities of their UV.[13]

a) eV in units; numbers in parentheses are in units of nm.
b) This f number corresponds to that of 2,4-hexadienal which was calculated from the data in Ref. 21.

cis-acrolein is a little bit higher than that of *trans*-acrolein, but there is no significant difference between the two n,π^* state energies; the difference may be within the range of accuracy of the present approximation.

The theoretical π,π^* triplet state energy of *trans*-acrolein, 2.935 eV is in good agreement with the observed value, 3.05 eV.[14] The corresponding value of *cis*-acrolein, 2.969 eV, is very close to that of *trans*-acrolein.

The calculated n,π^* triplet state energy of the *trans*-isomer, 3.255 eV, is still higher than the corresponding observed value, 3.01 eV,[15-17] although the present value is an improvement over the previous value, 3.405 eV.[1] According to the experimental results, the lowest triplet state of acrolein may be assigned to the n,π^* state, but both states are nearly degenerate. Therefore, the vibronic mixing of these states may be dominant.

The π,π^* singlet state of 2,4-pentadienal is observed at 4.79 eV (259 nm), and its n,π^* absorption spectrum is observed at 3.81 eV (325 nm), in an ethyl alcohol solution.[18] However, the n,π^* absorption spectrum of pentadienal appears at a shorter wavelength than that of acrolein, probably because of the solvent effect. The value of 4.79 eV may be assigned to the calculated π,π^* singlet state energy, 4.745 eV (261 nm, $f=1.245$), of the *trans*-isomer **A**. The calculated π,π^* singlet state energy and the oscillator strength of *trans*-pentadienal **A** are the largest of any other *cis*-isomers, as in the case of acrolein. This theoretical result is in harmony with the experimental results on the dienones (from f to j)[13] shown in Fig. 1. Figure 1 shows that the π,π^* singlet state and the intensity of *trans*-isomer are higher and larger than those of any *cis*-isomers. The calculated π,π^* singlet state energy and oscillator strength for the **D** isomer, 4.737 eV (262 nm) and 1.173, are larger than those of the **E** isomer, 4.376 eV (283 nm) and 0.595. Those results correspond well with the experimental results of the i or j and h compounds shown in Fig. 1.

The calculated n,π^* singlet energy of *trans*-2,4-pentadienal, 3.651 eV (340 nm), corresponds to the observed value, 3.81 eV (325 nm). The calculated n,π^* singlet state energies of *cis*-isomers lie within the range from 3.615 to 3.681 eV, as is shown in Table 1. It is interesting that there is no significant difference in the calculated n,π^* singlet state energy of *trans*- and *cis*-pentadienal isomers as there is in their π,π^* singlet state energy.

The calculated values of the π,π^* triplet state energies of pentadienal isomers lie within the range from 2.046 to 2.120 eV. The calculated lowest n,π^* triplet state energy of *trans*-pentadienal is 3.161 eV. The corresponding values of the *cis*-isomers range from 3.162 to 3.205 eV. These results suggest that the lowest π,π^* and n,π^* triplet states are almost constant in all the isomers.

The UV and optical rotatory dispersion curves of keto steroids containing *trans*- and *cis*-conjugated polyene aldehyde skeletal structures in their molecules may become experimental data for the comparison of the location of the n,π^* states of *trans*- and *cis*-isomers.

However, the conjugated system of the keto steroid as a model compound of an acrolein or pentadienal isomer may be different from the present model assumed for an acrolein or pentadienal isomer because of some twisting around a certain single or double bond, because of some deviation from planarity, and because of the effect of the other parts of the keto steroid attached to the conjugated system. Especially, the comparison of the theoretical values of the acrolein and pentadienal isomers with the spectroscopic data of the corresponding keto steroids for the n,π^* singlet- and triplet-state energies and the π,π^* triplet energy should be done carefully, because there is no such significant difference in the energy states of *trans*- and *cis*-isomers with respect to the n,π^* states and the π,π^* triplet state respectively. Also, their n,π^*- and π,π^*-state energies are affected by the twisting of the single or double bond. The twisting about the single bond brings about a blue shift of the π,π^* state, while the double-bond twisting brings about a red shift.[2,3] The same theoretical result[19,20] is also obtained for the n,π^* state.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2651—2652 (1972)

The Crystal and Molecular Structure of *p*-Bromobenzoic Acid

Kenji OHKURA*, Setsuo KASHINO, and Masao HAISA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received May 1, 1972)

In the course of X-ray crystallographic study of the 1:1 addition compound of *p*-bromobenzoic acid and piperidine,[1] it became desirable to determine the molecular structure of the parent acid itself. The unit cell dimensions and space group of *p*-bromobenzoic acid have already been determined by Toussaint,[2] who has also shown that the (*hk*0) Patterson projection closely resembles that of *p*-chlorobenzoic acid.[2] However, no further refinement of the structure has yet been undertaken. This paper presents the three-dimensional X-ray structure analysis of *p*-bromobenzoic acid.

Experimental

Crystals obtained by slow evaporation from ether solution were monoclinic needles elongated along the *c*-axis. Cell constants were determined from Weissenberg and oscillation photographs, and calibrated with sodium chloride.

Crystal data: *p*-bromobenzoic acid, $C_7H_5O_2Br$; M=201.0; mp=251°C, monoclinic, a=29.59(5), b=6.15(1), c=3.98(1) Å, β=95.5(1)°, U=720.4 Å^3, D_m=1.859, D_x=1.854 g·cm^{-3}, Z=4.

Linear absorption coefficient for Cu $K\alpha$(λ=1.5418 Å); μ=76.5 cm^{-1}. $F(000)$=392.

Absent spectra: *h*0*l* when *h* is odd, 0*k*0 when *k* is odd. Space group is $P2_1/a$.

The cell dimensions are substantially identical with those of Toussaint.[2]

Reflections were recorded with Cu $K\alpha$ radiation (1.5418 Å) by means of the equi-inclination Weissenberg technique, for the layers of *hk*0 to *hk*2, using a crystal of 0.19×0.20×1.5 mm. 837 independent non-zero reflections were measured visually, whose intensities ranged from 1 to 10165. The spot shape of the Weissenberg photographs of the *h*0*l* layer was unsuitable for intensity measurement so that these reflections were omitted in the refinement. Corrections were made for the Lorentz and polarization factors, and for the spot shape.

Structure Determination

Approximate positional parameters of all non-hydrogen atoms were obtained from two-dimensional sharpened Patterson projections onto (010) and (001). The structure thus obtained was refined by the block-diagonal least-squares method,[3] first with isotropic thermal parameters and then with anisotropic ones for the bromine and oxygen atoms. The weighting scheme used was:

$$\sqrt{w} = 0.0, \text{ if } F_o \leq F_{min}(2.0),$$

and

$$\sqrt{w} = 1.0, \text{ if } F_{min} < F_o \leq F_{max}(20.25),$$
$$\sqrt{w} = F_{max}/F_o, \text{ if } F_o > F_{max},$$

but zero weight was given for two strong reflections, 201 and 211, because they were seriously affected by extinction.

The R index became 0.102. At this stage, no atomic parameters shifted by as much as 0.3 σ, hence the refinement was terminated. The difference synthesis

3) Y. Okaya and T. Ashida, "HBLS IV, The Universal Crystallographic Computing System (I)," Japanese Crystallographic Association (1967), p. 65.

revealed only broad peaks corresponding to five hydrogen atoms.

Finally structure factors were calculated for all atoms including the hydrogen atoms, on the assumption of the C–H bond length of 1.08 Å, the O–H bond length of 1.05 Å, the normal bond angles, and the same isotropic temperature factors as those of the carbon or oxygen atoms to which they are attached. The final R index was 0.096 for 837 non-zero reflections.

The atomic scattering factors used in the calculation were those of Hanson, Herman, Lea, and Skillman.[4] The numerical calculations were performed with the aid of a HITAC 5020E computer of the Computer Center of The University of Tokyo.

Results and Discussion

The final atomic parameters are given in Table 1 and bond lengths and angles are listed in Table 2. Arrangement of molecules in a crystal, the selected intermolecular contacts, and the numbering of atoms are shown in Fig. 1.

Table 1. Final atomic parameters along with their estimated standard deviations within parentheses

V: $-x, -y, 1-z$
Molecules unnecessary for illustration are omitted.
------ Intermolecular contact, —— Hydrogen bond.

Pairs of molecules are linked through O–H–O hydrogen bonds (2.646±0.012 Å) forming dimers, and are stacked along the c-axis. Values for the O–H–O hydrogen bond length of *para*-substituted benzoic acids[5-9] range from 2.61 Å for *p*-aminobenzoic acid[5] to 2.65 Å for *p*-nitrobenzoic acid,[6] but no influence of *para*-substituents on the hydrogen bond length is discernible.

Unlike aliphatic carboxylic acids, *para*-substituted benzoic acids have no remarkable difference between the two C–O bond lengths in the carboxyl group. For example, those of terephthalic acid,[7] benzoic acid,[8] and *p*-toluic acid[9] are 1.262 and 1.272 Å, 1.24 and 1.29 Å, and 1.292 and 1.292 Å, respectively. However, *p*-bromobenzoic acid has two significantly different C–O bond lengths (1.225±0.014 and 1.307±0.013 Å) as found in *p*-nitrobenzoic acid[6] (1.222 and 1.319 Å), while *p*-bromobenzoate ion[1] has nearly equal bond lengths (1.255±0.011 and 1.281±0.011 Å).

Except the carboxyl C–O bond length, the remaining structural features of a *p*-bromobenzoic acid molecule are very similar to those of a *p*-bromobenzoate ion in the addition compound of *p*-bromobenzoic acid and piperidine.[1] The bond length of C(1)–C(7) (1.517 Å) is significantly shortened compared with the standard single bond value of 1.54 Å. The aromatic C–Br distance (1.902 Å) is slightly longer than the normally accepted value of 1.85 Å.[10] The carboxyl group is twisted out of the plane of the benzene ring by 5.8°.

Including intermolecular Br–Br distances (3.92 and 3.98 Å), all the intermolecular contacts correspond to normal van der Waals distances. The bromine atoms are in the *bc* cleavage plane.

Polarized Absorption Spectrum of Acridone

Hiroyasu INOUE, Toshihiko HOSHI,* and Junko YOSHINO*

Department of Applied Chemistry, Faculty of Technology, Kanagawa University, Kanagawa-ku, Yokohama
**Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo*

(Received December 25, 1971)

In previous papers, we reported the polarized absorption spectra of several aromatic compounds in stretched PVA sheets, and discussed the assignment of the electronic bands. Especially, as for a molecule of C_{2v} or D_{2h}, we could divide the absorption spectrum into two components, polarized parallel to and perpendicularly to the C_2-axis of the molecule.[1]

In the present paper, the divided spectra of acridone are determined, and the assignments of the electronic bands are established by a comparison of the observed results with theoretical ones.

Kokubun[2] measured the absorption and fluorescence spectra of acridone in various solvents, and discussed the assignment of the electronic bands. Zanker and Wittwer[3] compared the absorption and fluorescence polarization spectra of acridone with those of some hydroxyacridines.

Experimental

Materials. Commercially-available acridone was purified by repeated recrystallizations from ethanol.

Measurement of the Polarized Absorption Spectrum. The measurement and analysis of the polarized absorption spectrum were carried out following a method described elsewhere.[1,4]

Notations. The notations used in the figures of the polarized absorption spectrum and the divided spectra are as follows.

$D_{\parallel}$ and $D_{\perp}$: Absorbances measured for incident light polarized respectively parallel to and perpendicular to the stretched direction of the PVA sheet.

R_d: Ratio between $D_{\parallel}$ and $D_{\perp}$, $D_{\parallel}/D_{\perp}$.

R_s: Degree of stretching of the PVA sheet.

θ: Orientation angle, which means an angle between a transition moment for an electronic transition and an orientation axis of the molecule.

D: Absorbance in an unstretched PVA sheet.

D_x and D_y: Absorbances whose transition moments are along the X- and Y-axes of the molecule respectively. The D_x and D_y curves are called divided spectra.

Method of Calculation

The electronic transition energies and the oscillator strengths for acridone were calculated by means of the PPP approximation,[5] including the variable β method.[6] The valence-state ionization potentials and the electron affinities for carbon, oxygen, and nitrogen atoms were taken as $I_p(C)=11.42$ eV, $E_a(C)=0.58$ eV, $I_p(O)=33.0$ eV, $E_a(O)=11.47$ eV, $I_p(N)=14.16$ eV, and $E_a(N)=1.34$ eV. The two-center electron repulsion integrals were evaluated by using the Nishimoto-Mataga equation.[7] The resonance integrals, β_{rs}, were obtained by the equations:[6] $\beta_{CC}=-1.84-0.51P_{CC}$, $\beta_{CN}=-2.02-0.53P_{CN}$, and $\beta_{CO}=-2.20-0.56P_{CO}$, where P_{rs} is the bond order. All singly-excited configurations associated with the transitions between each of the five highest occupied levels and each of the five lowest vacant levels were included in the CI calculation. The geometry of the molecule used here is shown in Fig. 1. All the bond angles were assumed to be 120°.

acridone. The R_d values are the largest around 38.8 kK and the smallest around 24.9 kK in the observed wave number region. The orientation angles of the 38.8 kK and the 24.9 kK bands are, respectively, 30° and 63°. These bands seem to be polarized perpendicularly to each other, because the sum of the orientation angles mentioned above is nearly a right angle (30°+63°=93°). As in the cases of anthraquinones,[8] it is considered that the angle of the orientation axis against the X-axis is smaller than that against the Y-axis; therefore, the bands with large R_d values are considered to be polarized along the X-axis, and the bands with small R_d values, along the Y-axis. Since the 24.9 kK band is isolated from the other bands and since the R_d values of this band are almost constant, we can determine the divided spectra of this compound by using the polarization direction of the 24.9 kK band as the standard. As may be seen from the divided spectra in Fig. 3, the absorption spectrum of acridone below 50 kK consists of three X-polarized bands, at 31.8, 38.8, and 45.9 kK, and three Y-polarized bands, at 24.9, 38.2, and 42.6 kK.

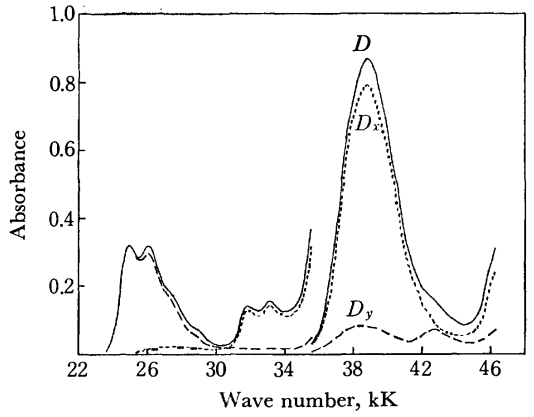

Fig. 3. The divided spectra of acridone.

According to Kokubun,[2] the two bands at 24.9 and 31.8 kK are to be assigned to the ^1L_a and the ^1L_b bands respectively; this assignment is not contradictory with the present results concerning the polarization directions. The observed results described above are compared with the theoretical ones in Fig. 4. The observed and the theoretical results are in good agreement, except for the position of the I transition. The two peaks of the D_y curve at 38.2 and 42.6 kK are due to different electronic transitions; they may correspond to two calculated transitions, IV and VII respectively. The 24.9 kK band is polarized along the Y-axis, and the >NH and >C=O groups have, respectively, electron-donating and electron-accepting characters, so the 24.9 kK band is expected to have a considerable intramolecular charge-transfer character. The calculated transition I is related to the electronic excitation from the ground state to the first excited state Ψ_I, $\Psi_I = -0.179\Psi_{5,11} + 0.328\Psi_{6,10} + 0.211\Psi_{7,12} + 0.890\Psi_{8,9} - 0.101\Psi_{8,12}$, where $\Psi_{i,j}$ is a configuration wave function associated with an one-electron excitation from the ith MO (ϕ_i) to the jth MO (ϕ_j). As is shown above, the coefficient of the $\Psi_{8,9}$ is relatively large; therefore, Ψ_I can be approximately represented by $\Psi_{8,9}$. The coefficients for the MO's, ϕ_8 and ϕ_9, are shown pictorially in Fig. 5. As may be seen from this figure, the electronic transition from ϕ_8 to ϕ_9 results in a considerable charge migration from the >NH group to the >C=O group. Hence, it can be deduced that the I transition is of the intramolecular charge-transfer type.

Spectrophotometric Studies of the Reaction of 2,2′,4,4′-Tetranitrodiphenylmethane with Bases in Various Solvents

Hiroyasu INOUE and Tadamitsu SAKURAI

Department of Applied Chemistry, Faculty of Technology, Kanagawa University, Kanagawa-ku, Yokohama

(Received February 5, 1972)

A methylene group between two electron-withdrawing moieties is active and is easily subjected to the elimination of a proton from the methylene group, thus yielding a carbanion. For several compounds of this category, the pK_a values have been determined by optical and electrometric measurements.[1-3] For example, 4,4′-dinitrodiphenylmethane has a fairly small pK_a value, 15.8.[2,3] Thus, 2,2′,4,4′-tetranitrodiphenylmethane (abbreviated hereafter to TND) can be expected to be a stronger carbon acid than 4,4′-dinitrodiphenylmethane, in view of the larger number of the nitro groups in TND. At present, however, few reports concerning the carbanion formation of TND have been published.

In this paper, the reaction of TND with such bases as NaOH and triethylamine (TEA) is investigated by means of optical measurements. Especially, solvent effects on the reaction are studied.

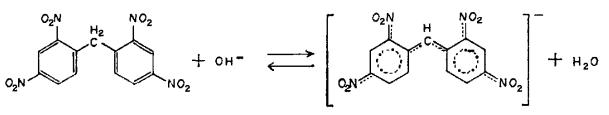
Experimental

Materials. The TND was prepared according to the method of Schöpff[4] and was recrystallized twice from acetic acid and several times from a benzene-ethanol mixed solvent; mp 171°C (lit,[4] 172°C). The solvents used here were purified by the standard procedure for each solvent. The TEA was distilled twice just before its use.

Measurements of Absorption Spectra. The ultraviolet and visible absorption spectra were measured with a Shimadzu Spectrophotometer QV-50, using 1-cm quartz cells. The temperature of the cell compartment was kept constant by circulating water from a constant-temperature bath.

Results and Discussion

When NaOH was added to solutions of TND in mixed solvents of organic solvent–water (4:1 in volume), the solutions immediately showed a blue color. The absorption spectra in a mixed solvent of methanol–water are shown in Fig. 1. If the basic solution is neutralized, the original spectrum (Curve I in Fig. 1) can be reproduced. The spectral change can safely be attributed to the carbanion formation of TND. The following equilibrium is considered to be established;



Some carbanions are known to cause disproportionation or electron transfer to the neutral species, thus giving radical anions.[5] In the case of TND, however no signal was observed in the ESR spectrum of the basic solution, so it was not necessary to consider any radicals of TND.

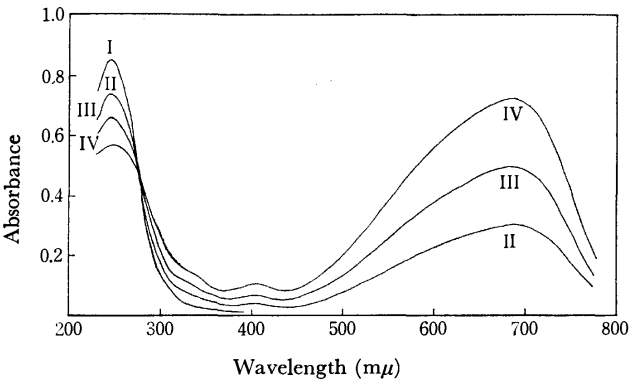


Fig. 1. The absorption spectra of the TND–NaOH system in a methanol–water (4:1) mixed solvent; [TND]=2.74×10⁻⁵M.
I; pH=5.8, II; 12.1, III; 12.6, IV; 13.0.

The equilibrium constant for the base-catalyzed reaction was determined by applying the Benesi-Hildebrand equation,[6] while the value of pK_a was obtained by the use of the following equation;

$$pK_a = pH - \log \frac{\frac{D}{\varepsilon}}{[AH]_0 - \frac{D}{\varepsilon}}$$

where $[AH]_0$ is the initial concentration of TND and where D and ε are, respectively, the absorbance and the molar extinction coefficient of the carbanion band

Table 1. The equilibrium constant, pK_a and the carbanion band for the TND–NaOH system in mixed solvents of organic solvent–water (4:1) at 25°C

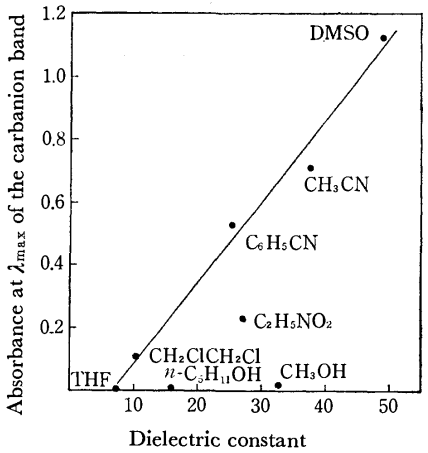

Fig. 2. Relation between the absorbances of the carbanion bands around 700 mμ and dielectric constants of the solvents; [TND]=2.5×10^{-5}M, [TEA]=0.143M.

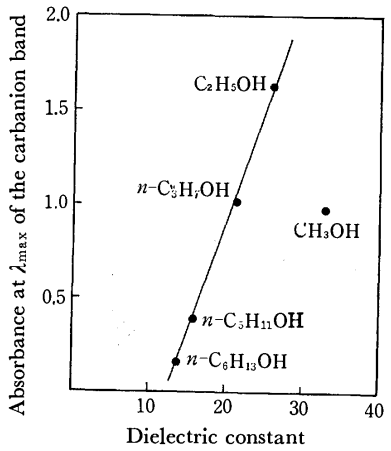

Fig. 3. Relation between the absorbances of the carbanion bands around 700 mμ and dielectric constants of the alcohols; [TND]=3.5×10^{-4}M, [TEA]=1.19M.

appearing around 700 mμ. The results are presented in Table 1.

Obviously, TND is a stronger carbon acid than 4,4′-dinitrodiphenylmethane. The results in Table 1 indicate that the polarity of the solvent used significantly influences the carbanion formation. Therefore, we considered a TND–TEA system in various solvents. TND reacts with TEA, showing a spectral change similar to that shown in Fig. 1. However, it was found that the reaction occurred only in solvents with dielectric constants larger than 7.39 (THF). A linear relationship was found to hold between the absorbance of the carbanion band around 700 mμ and the dielectric constant of the solvent used, as is shown in Fig. 2. This seems to indicate that the stabilization of the carbanion, probably by solvation, plays an important role in the reaction. As for the reaction in nitroethane or alcohols, factors other than the polarity of the solvent must be took into account, for their behavior is exceptional. Since these solvents can cause an interaction with TEA, the concentrations of the free TEA molecule decrease in these solvents. Nevertheless, in alcohols also the absorbance is related linearly to the dielectric constant, except in the case of methanol, as is shown in Fig. 3. The lower absorption intensity in methanol may indicate that the interaction of methanol with TEA is stronger than those of the other alcohols.

In the solvents with dielectric constants smaller than 7.39, the absorption spectrum changes only in the ultraviolet region upon the addition of TEA. From the relation between the concentration of TEA and the change in absorbance, it can be said that TND forms a 1 : 1 complex with TEA through hydrogen-bonding between the methylene group of TND and the N atom of TEA.

In 1,2-dichloroethane, the rate of the reaction was much slower than that in a solvent with a higher dielectric constant, in which the carbanion was formed immediately after the addition of TEA. Since the absorbance at 700 mμ increases quadratically with respect to time in the initial stage, an intermediate reaction step may exist between the reactants and the product.[7] At present, the hydrogen-bonded complex is inferred to be the intermediate, because the spectral change in the initial stage is similar to that observed in the less polar solvents.

Electrical Resistivity of Ternary Compounds, Graphite-Aluminum Bromide-Bromine

Tadashi SASA, Yoichi TAKAHASHI, and Takashi MUKAIBO

Department of Nuclear Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received March 24, 1972)

The formation of graphite lamellar compounds is believed to be accompanied with a transfer of electrons between graphite and reactant molecules. Electronic properties of various graphite lamellar compounds have been studied for investigating the nature of the chemical bonding and degree of charge-transfer between reactants and graphite layers.[1] It was found that the charge-transfer did not proceed to the complete ionization of reactant molecules in graphite layer interstices in many cases, and that the ratio of the number of transferred electrons to that of reactant molecules remained fractional. Hennig,[1] and Dzurus and Hennig[2] introduced a model in which only a part of the reactant molecules is completely ionized, making an ionic bonding between graphite layers, while the other molecules remain neutral and stabilize the ions by acting as spacers between them. The case of ternary compounds such as graphite–$AlCl_3$–Cl_2[2] was interpreted as follows: All the chlorine atoms in the compound are completely ionized while $AlCl_3$ molecules remain neutral and act as spacers of Cl^- ions. The mole ratio of $AlCl_3$ to Cl is found to be three for all the reactant concentrations, the chemical formula of the ternary compound being given as $C_n^+ \cdot Cl^- \cdot 3AlCl_3$ or $C_n^+ \cdot AlCl_4^- \cdot 2AlCl_3$.[2]

A mixture of $AlBr_3$ and Br_2 also formed a ternary lamellar compound with graphite, the ratio of $AlBr_3$ to Br in the compound being nearly three up to the bromine content of Br/C=0.014.[3,4] We measured the electrical resistivity of the ternary compound by changing the amount of reactants. The charge-transfer between the reactants and graphite is discussed.

Experimental

Pyrolytic graphite deposited at 1700°C and heat-treated at 2100°C was used as the sample. *C*-spacing and specific resistivity of the graphite were 3.417 Å and 6.0×10^{-4} Ω·cm, respectively. The graphite sample was cut into $1.5 \times 20 \times 0.2$ mm specimens. Platinum wires 0.2 mm in diameter were fixed tightly into small holes drilled on the specimen to make good electrical contacts.

The ternary lamellar compound, graphite–$AlBr_3$–Br_2, was prepared as follows: A controlled amount of bromine was doped in each graphite specimen resulting in the formation of a bromine residue compound. The bromine-doped graphite specimen was then allowed to react with $AlBr_3$ at 120°C in an evacuated reaction tube. After the reaction, the electrical resistivity of the specimen along the direction perpendicular to *c*-axis was measured *in situ* at room temperature by the four contact potentiometric method. Temperature dependence of the resistivity of the compound was found to be very small as compared with that of original graphite.

Results and Discussion

The electrical resistivity of graphite–$AlBr_3$–Br_2 is shown in Fig. 1 by a solid line (open circles). That of the graphite–bromine residue compound with different bromine concentrations measured prior to the reaction with $AlBr_3$ is shown by a dashed line (open triangles). The horizontal axis represents the concentration of free bromine in the ternary compound, in which Br in $AlBr_3$ is not included. The point shown by arrow II is the concentration at which a compound of the second stage structure (compound II, Ref. 4) is formed. The composition of the ternary compounds below this point is represented by $C_n 3AlBr_3 \cdot Br$.[3,4] The resistivity of the saturation compound of the ternary system (compound I, Ref. 4, with the first stage structure and the composition $C_9AlBr_3 \cdot Br_2$) prepared from the same graphite sample was also measured. Although the value of the ratio Br/C of this compound is far beyond the scale, the electrical resistivity indicated by arrow I is nearly the same as that of compound II.

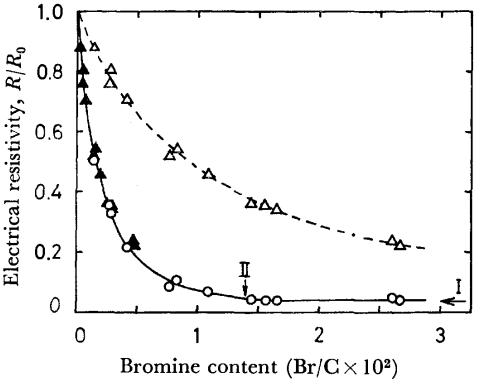

Fig. 1. Electrical resistivity of the graphite compound.
△: graphite bromine residue compound
○: graphite–$AlBr_3$–Br_2 ternary lamellar compound
▲: relation between the electrical resistivity and the assumed concentration of transferred electrons

The electrical resistivity of the bromine residue compound is lower than that of the original graphite. The absorption of $AlBr_3$ by the residue compound led to further decrease of resistivity. Thus it is considered that the addition of $AlBr_3$ in the interstices of graphite layers caused further transfer of electrons from graphite to reactants. With an increase of reactant concentra-

1) G. R. Hennig, "Progress in Inorganic Chemistry," Vol. 1, Interscience Publishers, New York, N. Y. (1959), p. 125.
2) M. L. Dzurus and G. R. Hennig, *J. Amer. Chem. Soc.*, **79**, 1051 (1957).
3) T. Sasa, Y. Takahashi, and T. Mukaibo, This Bulletin, **45**, 937 (1972).
4) T. Sasa, Y. Takahashi, and T. Mukaibo, *ibid.*, **45**, 2250 (1972).

tion in the ternary compound, the electrical resistivity decreased sharply down to the value of compound II. On the contrary, at concentrations beyond that for compound II up to that for compound I, the resistivity showed little change while the reactant contents increased greatly. Thus the fraction of the charge-transferred molecules in the intercalated reactant is considered to decrease considerably when the composition approaches that of compound I.

Hennig[1] reported that the ratio of the number of transferred electrons to that of bromine atoms was 1:5.5 in a graphite-bromine residue compound. A modified plotting of the electrical resistivity of the compound based on this assumption is also given in Fig. 1. Solid triangles show the relation of the electrical resistivity of bromine residue compound *vs.* $Br/C \times 1/5.5$, which represents the assumed concentration of transferred electrons. These plots agree quite well with the solid line representing the relation between he electrical resistivity and the bromine concentration in the ternary compound.

This agreement suggests that all the bromine molecules in the ternary compound are ionized. However, it should be pointed out that there is also a possibility of partial donation of electrons from graphite layers to $AlBr_3$ molecules. In the case of graphite–$FeCl_3$ compound,[5,6] the measurements of Mössbauer spectra suggest that all the intercalated $FeCl_3$ molecules equally take an active part in the charge-transfer.

It is difficult at present to determine whether the chemical formula of the compound is $C_n^+ \cdot Br^- \cdot 3AlBr_3$, or $C_n^+(Br)^{-\delta}(3AlBr_3)^{-\delta'}$. However, from our results it is concluded that bromine assumes a substantially large part in the charge-transfer between the reactants and graphite layers in the ternary compound, graphite–$AlBr_3$–Br_2.

Silyl Radicals. X. On the Mechanism of Uncatalyzed Reduction of Carbon Tetrachloride with Polysilicon Hydride[1]

Hideki SAKURAI, Mineo YAMAGATA, and Masashi MURAKAMI
Department of Chemistry, Faculty of Science, Tohoku University, Sendai, 980

(Received February 7, 1972)

Gilman and Harrell have reported first that polysilicon hydride such as tris(trimethylsilyl)silane reacted smoothly with carbon tetrachloride to give the corresponding chlorosilane without any added catalyst.[2]

The mechanism of the uncatalyzed reduction may be either a molecular reduction involving a four-centered transition state[3,4] or a free-radical chain reactions typically shown in the case of peroxide-catalyzed reduction of carbon tetrachloride with hydrosilanes.[5] The following evidence reported in this paper indicates the latter to be the case.

Both pentamethyldisilane and 1*H*-heptamethyltrisilane, dissolved in carbon tetrachloride, respectively, were converted quantitatively to the corresponding chlorosilanes by heating at 50°C for 38 hr. Addition of a small amount of a free-radical scavenger such as galvinoxyl[6] resulted in complete inhibition of the reduction of carbon tetrachloride with pentamethyldisilane even at 135°C. This is a strong indication of a free-radical nature of the uncatalyzed reaction.

$$Me_3SiSiMe_2H + CCl_4 \longrightarrow Me_3SiSiMe_2Cl + CHCl_3 \quad (1)$$

$$Me_3SiSiMe_2SiMe_2H + CCl_4 \longrightarrow Me_3SiSiMe_2SiMe_2Cl + CHCl_3 \quad (2)$$

Uncatalyzed reduction of carbon tetrachloride with monosilanes, such as *n*-propyldimethylsilane and triethylsilane, did not occur at 50°C. However, while triethylsilane alone did not react with an excess of carbon tetrachloride on heating at 80°C, addition of pentamethyldisilane resulted in conversion of both silanes to the corresponding chlorosilanes in good yields, and again the reaction was inhibited by galvinoxyl. These facts suggest a free-radical mechanism for the reaction. The co-chlorination of triethylsilane and pentamethyldisilane may be interpreted by the following sequence of reactions.

$$Me_5Si_2H \longrightarrow Me_5Si_2\cdot + (H\cdot) \quad (3)$$

$$Me_5Si_2\cdot + CCl_4 \longrightarrow Me_5Si_2Cl + CCl_3\cdot \quad (4)$$

$$Me_5Si_2H + CCl_3\cdot \longrightarrow Me_5Si_2\cdot + CHCl_3 \quad (5)$$

$$Et_3SiH + CCl_3\cdot \longrightarrow Et_3Si\cdot + CHCl_3 \quad (6)$$

$$Et_3Si\cdot + CCl_4 \longrightarrow Et_3SiCl + CCl_3\cdot \quad (7)$$

Pentamethyldisilane functions as an initiator in this scheme. The reaction of pentamethyldisilane with carbon tetrachloride could not be completed, when the mixture was degassed as thoroughly as possible. Therefore, oxygen plays some role at the initiation

step, although the precise mechanism is uncertain.

Pentamethyldisilane can also initiate the S_H2 reaction between an organodisilane and 1,2-dibromoethane.[7] Addition of a small amount of pentamethyldisilane to a mixture of hexamethyldisilane and 1,2-dibromoethane at 80°C resulted in complete conversion of hexamethyldisilane to trimethylbromosilane.

The relative reactivity of pentamethyldisilane to triethylsilane towards chlorination with carbon tetrachloride was determined in the presence and absence of an initiator, respectively. Since it is well established that reactions of silyl radicals with carbon tetrachloride (steps 4 and 7) are very rapid,[8] the steps 5 and 6 determine the relative reactivity which should be invariable regardless of the nature of initiation.

The reactivity ratio of pentamethyldisilane to triethylsilane in the uncatalyzed reaction was found to be 8.3 and 6.5 at 80.0°C. The dibenzoyl peroxide catalyzed reaction gave the value of 6.3 at 80.0°C. These two sets of values agree with each other fairly well although not perfectly.[13]

It is worthwhile to note that pentamethyldisilane is several times more reactive than triethylsilane toward carbon tetrachloride. The difference in the reactivity may arise from the more electron-positive nature of the pentamethyldisilanyl group than the monosilyl group,[9] which may play a role in a possible polar effect in the transition state of chlorine abstraction.[10]

Experimental

Materials. Pentamethyldisilane,[11] 1*H*-heptamethyltrisilane,[11] triethylsilane,[12] and galvinoxyl[6] were prepared according to literatures.

Uncatalyzed Reaction of Pentamethyldisilane with Carbon Tetrachloride in the Absence or the Presence of Galvinoxyl. A mixture of pentamethyldisilane (0.109 g, 0.83 mmol) and carbon tetrachloride (1.19 g, 7.73 mmol) in a sealed tube was placed in a thermostatted oil bath kept at 135±1°C for 1 hr. Inspection of the mixture by glc after addition of *m*-xylene (internal standard) revealed that it contained pentamethylchlorodisilane (0.85 mmol, 102%), chloroform and unchanged carbon tetrachloride. On the other hand, only a trace amount of pentamethylchlorodisilane was detected by glc with another mixture of pentamethyldisilane (0.119 g, 0.90 mmol) and carbon tetrachloride (1.12 g, 7.28 mmol), which contained 0.0057 g (0.014 mmol) of galvinoxyl, after heating at 135±1°C for 1 hr.

Competitive Chlorination of Pentamethyldisilane and Triethylsilane. *a) Uncatalyzed Thermal Reaction*: In small glass ampules (*ca.* 3 ml) were placed a solution of pentamethyldisilane and triethylsilane in carbon tetrachloride. Dry nitrogen was bubbled gently through the capilary for about 5 min and then ampules were sealed. These were immersed in an oil bath thermostatted at 80.0°C. After given intervals, ampules were picked up and mixtures were analyzed on glc.

b) Dibenzoyl Peroxide Catalyzed Reactions: Similarly mixtures of pentamethyldisilane, triethylsilane, and dibenzoyl peroxide in carbon tetrachloride were subjected to reaction.

c) Analytical Procedure: Products were identified by glc and NMR. For quantitative analyses an internal standard (*e.g.* *m*-xylene) was used. The relative reactivity was calculated by the equation.

$$(k_A/k_B) = \log([A_0]/[A_t])/\log([B_0]/[B_t])$$

where $[A_0]$ and $[A_t]$ are the concentrations of pentamethyldisilane (A) at the initial and a given time, respectively, and $[B_0]$ and $[B_t]$ have a similar significance for triethylsilane (B). Relative rates were calculated by the least squares method. Data are listed in Table 1.

Table 1. Competitive chlorination of Me_5Si_2H (A) and Et_3SiH (B) with CCl_4 at 80.0°

Photolytic Addition of Trichlorosilane to Acetone in the Gas Phase

Takaaki DOHMARU, Yoshio NAGATA, and Jitsuo TSURUGI
Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka

(Received May 1, 1972)

Although silyl radicals have long been known to add to a C=O bond of ketones,[1-5] detailed kinetics of this reaction has never been studied. Our previous works[6,7] on the reduction of alkyl aliphatic carboxylates with trichlorosilane (TCS), reported that the first step of this reaction is addition of trichlorosilyl radical to carbonyl of carboxylates. In connection with these works, we have examined the kinetic behavior of the photolytic addition of TCS to acetone in the gas phase. Using a gaschromatograph directly attached to a vacuum line, the reaction mixture was kept completely free from contact with air during analyses.

Experimental

Apparatus and Procedure. Photolyses and analyses were carried out on a conventional Pyrex vacuum line. The full light from a 50 W medium pressure mercury arc was admitted into a Pyrex reaction vessel of 5.88 cc which cuts off the light of a wavelength region shorter than about 2700 Å to prevent absorption by TCS. The reaction vessel was heated in an electrical furnace controlled to better than ±1°C. After the photolysis, the reaction mixture was transferred by a Toepler pump to a gas sampler which is directly connected to a gaschromatograph equipped with a Gow-Mac thermister detector. A 1 m glass column of 30% SE-30 on Chromosorb W was used at 43°C. Before a series of runs, the column was siliconized by TCS until a reproducible peak height of TCS was obtained.

Material. TCS was treated with quinoline to remove hydrogen chloride and distilled under atmospheric pressure. The distillate (bp 31.8—32.2°C) was further purified by vacuum distillation. Acetone was dried with anhydrous magnesium sulfate and distilled through a 50 cm fractionation column packed with glass Raschig rings. Isopropoxytrichlorosilane prepared previously in this laboratory[6] was used after degassing. All the materials were stored on the vacuum line at −78°C.

Results and Discussion

Rates, and hence quantum yields for product formation and reactant consumption were determined from concentration-time curves at various temperatures. A typical analytical curve at 253°C is shown in Fig. 1.

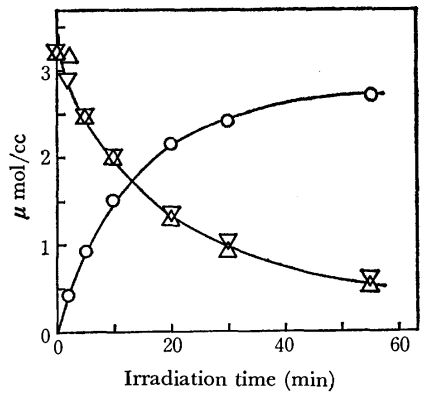

Fig. 1. Plots of the concentration of adduct, $(CH_3)_2CHO\text{-}SiCl_3$ (○) and of reactants, TCS (△) and acetone (▽) with irradiation time at 253°C.

From Fig. 1, each one mole of acetone and TCS is consumed and one mole of adduct (isopropoxytrichlorosilane) is formed; the following stoichiometric relation holds within the experimental error.

$$(CH_3)_2CO + HSiCl_3 = (CH_3)_2CHOSiCl_3 \qquad (A)$$

The initial rate of reaction was obtained from the initial slope of a concentration-time curve of adduct at a given temperature. The results were summerized in Table 1. Activation energy was calculated to be 6.7 kcal/mol.

In order to obtain the kinetic orders of the reaction, the variations in rate with the reactant concentration were examined at 125°C. The results are presented in Fig. 2 in which (a) shows a run with a constant TCS pressure of 50 Torr (2.01 μmol/cc) and acetone pressure of 50—150 Torr, and (b) with a constant acetone pressure of 50 Torr and TCS pressure of 50—150 Torr. Fairly good linear plots were obtained in both runs and the slopes of (a) and (b) were calculated to be 0.40 and 1.0, respectively. The rate of

TABLE 1. RATES OF REACTION AT VARIOUS TEMPERATURE

$[TCS]_0 = [Acetone]_0 = 3.27$ μmol/cc

Temp. (°C)	253[a]	188	138	78
Rate (μmol/cc min)	0.202	0.071	0.032	0.0075
Quantum Yield[b]	90	32	14	3

a) At this temperature, the mixture was allowed to stand in the reaction cell for about 30 min without irradiation, but no detectable reaction product was observed in spite of the possible molecular reaction between acetone and TCS.[8]

b) Acetone photolysis was used for actinometry.[9]

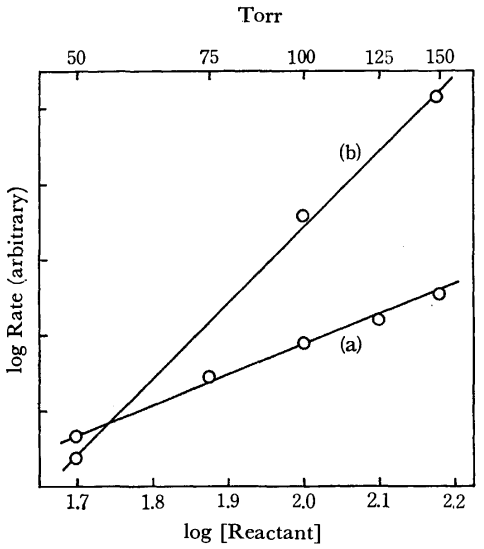

Fig. 2. Variation of rates of adduct formation with acetone concentration (a), and with TCS concentration (b) at 125°C.

adduct formation may be expressed by Eq. (B);

$$R_{adduct} \propto [\text{Acetone}]^{0.4}[\text{TCS}] \quad \text{(B)}$$

The results mentioned above are consistent with the following mechanism.

$$CH_3COCH_3 \longrightarrow 2\cdot CH_3 + CO \quad (1)$$

$$\cdot CH_3 + HSiCl_3 \longrightarrow CH_4 + \cdot SiCl_3 \quad (2)$$

$$\cdot SiCl_3 + CH_3COCH_3 \longrightarrow (CH_3)_2\dot{C}OSiCl_3 \quad (3)$$

$$(CH_3)_2\dot{C}OSiCl_3 + HSiCl_3 \longrightarrow (CH_3)_2CHOSiCl_3 + \cdot SiCl_3 \quad (4)$$

$$2(CH_3)_2\dot{C}OSiCl_3 \longrightarrow \text{products} \quad (5)$$

In our experimental conditions, TCS does not absorb light and only acetone contributes to an initiation reaction (1). Reactions (3) and (4) constitute chain propagating steps. Reaction (5) was assumed as a termination step, and will be seen to lead to the correct kinetic behavior. The steady-state treatment of the

$$R_{adduct} = k_4 k_5^{-1/2} I_a^{1/2}[\text{TCS}] \quad \text{(C)}$$

scheme leads to rate Eq. (C), where k_x denotes a rate constant of a reaction (x) and I_a does a rate of absorption of light. I_a may be considered to be directly proportional to an acetone concentration. Then, Eq. (C) leads to Eq. (D), which is in reasonable agreement

$$R_{adduct} \propto [\text{Acetone}]^{0.5}[\text{TCS}] \quad \text{(D)}$$

with the observations. The reaction chain is adequately long at 253°C, so that the overall variations of the concentration of the reactants and product may be explained in terms of reactions (3) and (4), the inspection of which leads to the stoichiometric Eq. (A). This was also confirmed by the result of Fig. 1. From Eq. (C), overall activation energy E_0 is equal to $E_4 - {}^1/_2 E_5$. The activation energy of a radical combination reaction such as reaction (5) may be generally assumed to be ~0 in the gas phase, so $E_4 \simeq E_0 = 6.7$ kcal/mol.

SHORT COMMUNICATIONS

Formation of Myrcene in the Sodium-catalyzed Oligomerization of Isoprene[1]

Kunihiko TAKABE, Takao KATAGIRI, and Juntaro TANAKA

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu-shi

(Received September 6, 1971)

Recently investigations[2] have been carried out on the metal complex-catalyzed oligomerization of isoprene. However, no information was obtained on the formation of myrcene (I) (7-methyl-3-methylene-1,6-octadiene), a very important monoterpene occurring in nature, directly from isoprene.

We have investigated the sodium-catalyzed polymerization of isoprene already reported,[3,4] under improved conditions, and found that the oligomers contained significant amounts of myrcene(I) and 6-isopropenyl-9-methyl-3-methylene-1,8-decadiene (II).

Isoprene reacted smoothly with sodium metal in benzene solution and the oligomers were obtained (Table 1). For example, isoprene (15 g) in benzene (20 m*l*) was allowed to react with lumps of sodium (0.5 g, about 1.5 mm cubes) at 40°C for 5 hr with stirring in a pressure bottle. The reaction mixture was then cooled and treated with 15 m*l* ethanol to decompose sodium and organosodium compounds. Distillation of the reaction products gave C_{10} fraction (0.7 g) at 55—60°C/15 mmHg, C_{15} fraction (0.3 g) at 60—63°C/1.0 mmHg and the residue[5] (0.7 g). The first fraction was found to contain 85% of I and the second 76% of II by IR, NMR, and mass spectrometry after gas chromatographic fractionation.[6]

ENDOR Study of Radical Mixture Formed on the Reduction of *p*-Xyloquinone[4]

Yashige KOTAKE and Keiji KUWATA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received May 25, 1972)

The central line of the ESR spectrum of a radical mixture may be very complicated when the spectra both contain odd numbers of lines centered at almost the same *g* value. But in this central line all the information of the system is contained. ENDOR is capable of extracting hyperfine splitting constants (hfsc) and the intensity change of the lines in both spectra independently because ENDOR detects the enhancement of an ESR line intensity when the radio frequency hits the NMR frequency of the proton in a radical. Only a couple of ENDOR lines above and below the NMR frequency of free proton appear for each group of equivalent protons. The assignment of the hfsc and the identification of the radical can be made clear from inspection of the ESR spectra. Moreover the kinetic behavior of the system may be studied much more easily than by using ESR technique.

Mixing C_2H_5ONa–C_2H_5OH with *p*-xyloquinone (2,5-dimethylbenzoquinone) produced radicals which showed ESR spectra as Figs. 1a—1c. In dilute ethanolic solution of C_2H_5ONa the spectrum was that of *p*-xylosemiquinone anion radical.[1] In the case that C_2H_5ONa concentration was high the spectra changed with time.

The ENDOR spectra at several reaction stages measured at the top of the first derivative ESR spectrum for the center line at −10°C are shown in Figs. 1d, 1e, and 1f. The ENDOR spectrometer used was constructed in our laboratory which consists of ordinary ESR spectrometer with 200 Hz field modulation and high power ENDOR attachment. This unit delivers maximum output of peak 600 watts sinusoidally modulated radio frequency power and its modulation frequency can be varied from 5 to 15 kHz. The field frequency lock was also used.[2] The comparison between Fig. 1b and 1e may show the advantage of ENDOR technique. Figure 1b consists of overlapped lines of two radicals except weak side lines, while the ENDOR spectrum shows three peaks above free proton frequency quite clearly. The hfsc's can be determined accurately. From the change in relative intensity, it is easy to tell that from which radical the line comes. In Table 1 accurate hfsc's are shown which were determined by the analysis of ENDOR spectra.

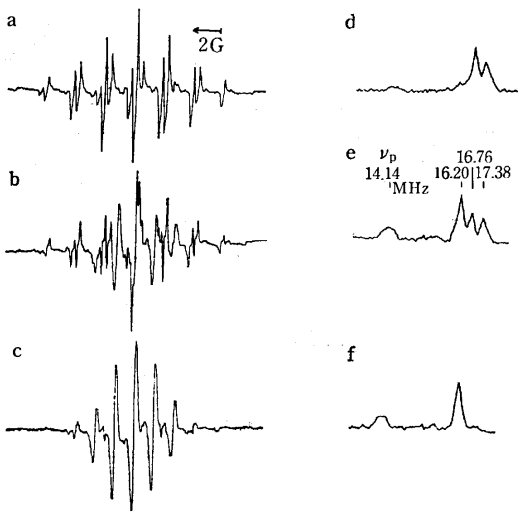

Fig. 1. ESR (a, b, c) and ENDOR (d, e, f) spectra of *p*-xyloquinone–C_2H_5ONa–C_2H_5OH system (quinone and C_2H_5ONa were in 1 : 2 molar ratio). a and d: just after mixing, b and e: after 5 hr at room temperature, c and f: after 3 days at room temperature.

TABLE 1.

Radical	hfsc (gauss)	Assignment
1	$a_1=1.87$	*p*-xylosemiquinone anion
	$a_2=2.31$	a_1: ring protons
		a_2: methyl protons
2	$a_1=1.47$	diethoxy-*p*-xylosemiquinone anion
	$a_2<0.2$	a_1: methyl protons
		a_2: ethoxy protons

Radical 1 in Table 1 can be ascribed to *p*-xylosemiquinone anion radical.[1] Radical 2 has protons which have a large hf coupling and very small one. The large coupling considering about the binomial distribution of the ESR spectrum is assigned to two methyl groups. And remaining coupling is ascribed to ethoxy protons by considering the further reaction in alkali–alcohol media.[3] The fact that ENDOR lines of these groups are rather broad may show that there are two residual small hf coupling which come from the methylene and methyl protons of ethoxy group.

In this reaction system, the two radicals could be identified by their ESR spectra. But by use of ENDOR technique two radicals were identified without the isolation of ESR spectra and the hfsc's were determined accurately even in a radical mixture. This seems to be one of the useful applications of ENDOR.

A Novel Route to Mixed Transition-Metal Complexes

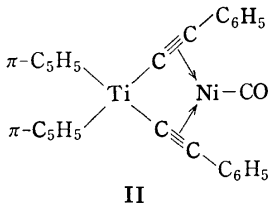
Katsutoshi YASUFUKU and Hiroshi YAMAZAKI
The Institute of Physical and Chemical Research, Wako-shi, Saitama
(Received March 21, 1972)

Preparation of complexes containing different transition metals has recently attracted much attention.[1,2] We report herewith on the preparation of mixed transition metal complexes in which metal atoms are joined by the alkynyl group.

Bis-π-cyclopentadienyl-bisphenylethynyltitanium (I)[3] reacted readily with nickel carbonyl in benzene at room temperature giving dark olive-green crystals (II) in good yield; mp 141—145°C (decomp.); NMR ($CDCl_3$, τ): 4.49 (s, C_5H_5) and 2.25—2.80 (m, C_6H_5); IR (KBr, ν, cm^{-1}): 1994 (vs, C≡O) and 1850 (C≡C coordinated). The data and the molecular weight (467.5 by vapor pressure osmometry and the molecular ion $[M]^+$ at *m/e* 466 followed by $[M-CO]^+$ at *m/e* 438 in the mass spectrum) suggest structure II.

$$(\pi\text{-}C_5H_5)_2Ti(C{\equiv}CC_6H_5)_2 + Ni(CO)_4 \longrightarrow$$

I

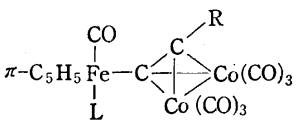


II

The propynyliron complex (IIIa)[4] reacted also readily with cobalt carbonyl giving black crystals

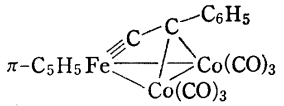
$$\pi\text{-}C_5H_5Fe(CO)(L)\text{-}C{\equiv}C\text{-}R + Co_2(CO)_8$$

IIIa-c



IVa-c

$\xrightarrow{-CO,\,L}$



V

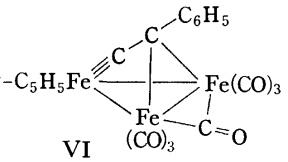
a (L: CO, R: CH_3)
b (L: CO, R: C_6H_5)
c (L: $PPhMe_2$, R: C_6H_5)

(IVa) in almost quantitative yield; mp 60—61°C; NMR: 5.01 (s, C_5H_5) and 7.32 (s, CH_3); IR (C_6H_{14}): 2065 (s), 2024 (vs), 1999 (s), and 1996 (sh) (terminal CO); Mass (*m/e*): 502 ($[M]^+$) and ions $[M-nCO]^+$ (n=1~8). The structure was assigned tentatively to IVa.

On the other hand, similar treatment of the phenylethynyliron complex (IIIb)[5] with the cobalt carbonyl afforded black crystals, $C_{19}H_{10}O_6FeCo_2$; mp 110—115°C (decomp.); Mass: 508 ($[M]^+$) and ions $[M-nCO]^+$ (n=1~6); IR: 2068 (s), 2026 (vs), 2000 (s), and 1986 (msh); NMR: 4.98 (s, C_5H_5) and 2.3—2.9 (m, C_6H_5). Structure V is postulated as a plausible one; unequivocal assignment being impossible with spectral data available at present. V might be formed *via* an intermediate IVb. Successful isolation of IVc, mp 91—94°C (decomp.), and its facile transformation into V support the above reaction sequence. Attempts to obtain a V analogue from IVa were not successful.

A similar triiron complex (VI), $C_{20}H_{10}O_7Fe_3$, mp 143—146°C, was obtained as brown crystals from the reaction of IIIb with iron nonacarbonyl in refluxing benzene; Mass: 530 ($[M]^+$) and ions $[M-nCO]^+$ (n=1~7); IR: 2053 (s), 2018 (vs), 2000 (s), 1996 (s), 1976 (s), and 1965 (s) (terminal CO) and 1870 (s, bridge CO).

$$IIIb + Fe_2(CO)_9 \longrightarrow$$

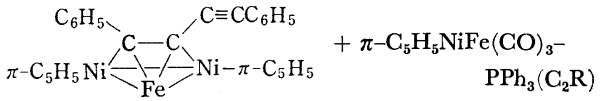


VI

Ethynylnickel complexes (VII) reacted also with the iron carbonyl giving mixed metal complexes. Reaction of VIIa with carbonyl gave the known olive-green crystalline compound VIII[6] and a new complex (IXa), mp 195—197°C, as brown crystals. Similarly, the carbomethoxy derivative (IXb), mp 202—204°C, was obtained from VIIb. Analysis of the mass and IR spectra support formula IX.

$$\pi\text{-}C_5H_5Ni(PPh_3)(C{\equiv}C\text{-}R) + Fe_2(CO)_9 \longrightarrow$$

VIIa, b



VIII

a (R:C_6H_5) b(R:CO_2CH_3)

Thus, the transition metal acetylide complexes exhibit high reactivity toward metal carbonyls and provide a new type of mixed transition metal clusters.

The Nuclear Magnetic Resonance Spectra of 2-Formylaminopyridine and 2-Formylamino-γ-picoline

Nobuko ENOMOTO and Michio KONDO

Central Research Laboratories, Sankyo Co., Ltd., Hiromachi 1-chome, Shinagawa-ku, Tokyo

(Received November 10, 1971)

The NMR spectra of 2-formylaminopyridine and 2-formylamino-γ-picoline have been recorded under various conditions. At low temperatures, these compounds were found to exist in two forms. In these two forms, the chemical shifts of the ring proton-3 differ much from each other because of the difference in the orientation of the formylamino group, which has a large magnetic anisotropy. The difference in the chemical shifts of the formyl protons in the two forms are too large to be explained by the anisotropic shielding effect of the pyridine-ring currents. At higher temperatures, the signal coalescence of these protons in two forms have been observed. The molecular structures of these compounds have been concluded to be planar.

A large magnetic anisotropy is associated with the amide group. The acetylation effect on the *ortho* proton chemical shifts was studied for a number of anilines, and it was shown that pronounced downfield shifts of the protons at the 6-position were observed when the molecules had substituents at the 2-position capable of forming intramolecular hydrogen bonds with the amide proton.[1-5]

This kind of intramolecular hydrogen bonding would be rather easily disrupted in polar solvents, such as dimethyl sulfoxide, which is well known as an agent for interacting with amide protons.[6] The free rotation around the C_{ring}–N bond thus induced by the disruption of the intramolecular hydrogen bond is reflected in the upfield shifts of the proton-6 in 2,4-dichloroacetanilide[2] or of 2,4-dinitroacetoanilide[2,7] in dimethyl sulfoxide, for example, as compared to the signals observed in chloroform.

In acetylaminopyridines, the conjugation interaction between the substituent and the pyridine ring is dependent upon the position of substitution. A remarkable deshielding shift of the proton-3 of 2-acetylaminopyridine was considered to be indicative of the planarity of the molecule, probably in the *endo* form.

It has been reported that acetanilide exists in the *endo* form,[8] whereas formanilide in solution coexists in both forms, *endo* and *exo*.[2,9]

In this paper we will present the NMR spectra of 2-formylaminopyridines under various conditions and make it clear that the large deshielding shift of the proton-3 is associated with molecules in the *endo* form.

Experimental

2-Aminopyridine was refluxed with excess formic acid for 5 hr. The water produced and the excess formic acid were distilled off under reduced pressures. The 2-formylaminopyridine was distilled out last. This fraction was submitted to redistillation and finally to recrystallization from benzene; mp 71°C.

Found: C, 59.17; H, 5.17; N, 22.77%. Calcd for $C_6H_6N_2O$: C, 59.01; H, 4.95; N, 22.94%.

2-Formylamino-γ-picoline was prepared in a similar way; mp 89°C.

Found: C, 62.01; H, 6.06; N, 20.63%. Calcd for $C_7H_8N_2O$: C, 61.75; H, 5.92; N, 20.58%.

Reasonable mass spectra were obtained for these two compounds.

The NMR spectra were recorded on a Varian A-60D spectrometer under various conditions. Temperatures could be controlled within ±2°C at higher temperatures, but only within ±4°C at lower temperatures. The concentration dependence of the chemical shifts was found to be negligible for any protons but amide protons. The figures reported in this paper were read from the spectra of solutions with a concentration of 10 w/v%.

Results and Discussion

Assignment. The low-field part of the spectrum of 2-formylamino-γ-picoline in di-*n*-propyl ketone is shown in Fig. 1. It is clear that there are two molecular species in solution at low temperatures. Following the general concept that $J_{trans} > J_{cis}$, the sharp doublet with a coupling constant of 11 Hz at 9.50 ppm was assigned to the formyl proton in the *exo* form. Another doublet with a smaller splitting, 2 Hz, at 8.63 ppm was ascribed to the formyl proton in the *endo* form. The lower-field resonance of the formyl proton in the *exo* form could be attributed to its closer proximity to the pyridine ring than the same proton in the *endo* form. This chemical-shift difference is much larger than that observed for formanilide.[9]

Bourn *et al.* estimated the chemical-shift difference of the formyl protons of formanilide at the *exo* and *endo* positions as about 0.25 ppm, using reasonable values for the bond lengths and assuming that all bond angles are 120° and that the moleclule is planar.[9]

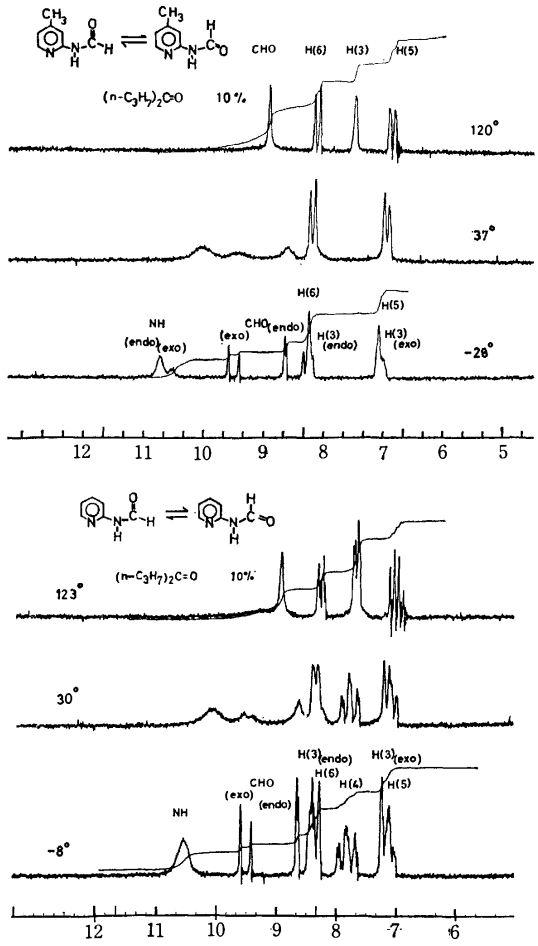

Fig. 1. The lowfield region of the NMR spectra of 2-formylamino-γ-picoline and 2-formylaminopyridine in di-*n*-propyl ketone at different temperatures.

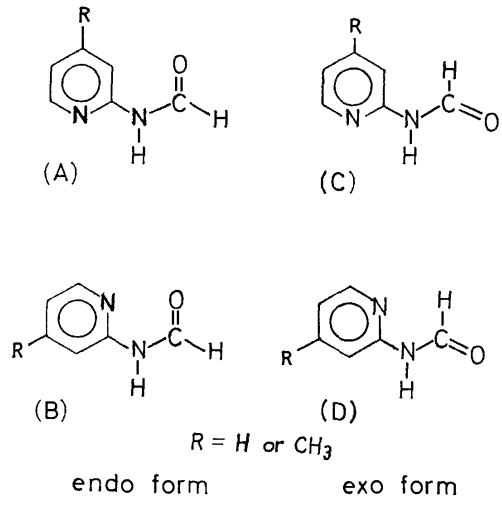
The difference of 0.87 ppm observed in the present case is too large to be explained by the anisotropic effect of the pyridine ring, because the latter is similar in size to that of the benzene ring. The formyl proton in the *exo* form might be subjected to a strong deshielding effect due to the lone-pair electrons on the ring nitrogen in the D configuration, because the flip-rotation about the C_{ring}–N_{amide} bond, C⇌D, seems to be very probable.

There are two other signals, at 10.73 and 10.62 ppm, which are easily assigned to the amide protons in the *exo* and *endo* forms respectively on the basis of their temperature dependence. The amide-proton signal shifts to higher fields on an increase in the temperature of the solution; this shift is due to diminished intermolecular interactions through the amide group.[9] The signal then undergoes a pronounced broadening due primarily to the intermolecular exchange of the amide protons.

Roughly speaking, there are two multiplets, at 7.0 and 8.2 ppm, and each multiplet has an intensity corresponding to more than one proton. The multiplet at lower fields is attributable to the ring proton-6 and the proton-3 in the *endo* form. The other multiplet signal arises from the proton-5 and the proton-3 in the *exo* form. These assignments of the proton-5 and -6 are consistent with the NMR parameters of unsubstituted pyridine.[10] The assignment of the signals of the proton-3 is based on the signal intensity.

At elevated temperatures, the signal for the proton-3 coalesces and appears at 7.53 ppm as a singlet with a



somewhat unresolved structure. A considerable rapid rotation around the amide bond, CO–NH, is responsible for this coalescence.[11] This rotation also causes the coalescence of the formyl proton signal with a linewidth comparable with that of the proton-3 signal.

From these observations, it is quite certain that the proton-3 experiences quite a different magnetic environment depending upon whether the molecules are in the *exo* form or in the *endo* form. On the other hand, the proton-5 or -6 has nearly the same value for the chemical shift in either form. Similarly, the signals of the methyl protons at the 4 position in the two rotamers almost overlap each other. These observation reflect a sharp distance-dependence of the anisotropy effect.

Arguments almost the same as those above are certainly applicable to the NMR spectrum of 2-formylaminopyridine at various temperatures, except for the fact that the ring-proton spectrum is somewhat complicated because of the presence of the proton-4.

Table 1 summarizes the results obtained under various conditions.

Chemical Shifts of Ring-proton-3 in the endo *and* exo *Forms.* In chloroform, acetone, and di-*n*-propyl ketone, the chemical shifts of the proton-3 in the two rotamers are nearly the same, suggesting that the molecular structures are also very similar in these solvents. In toluene, however, the chemical shift for the *exo* form is shifted to a field higher by about 0.6 ppm, whereas the *endo* form signal is shifted little with respect to those in chloroform solutions. This observation is also indicative of the reasonableness of the assumption that the lower-field signal of the proton-3 is associated with the *endo* form, for it is well known that the protons *trans* to the carbonyl oxygen with respect to the amide bond are more shielded than those in the *cis* position

when aromatic hydrocarbons are used as the solvents.[12] In a mixed solvent such as D_2O–DMSO-d_6, on the other hand, the chemical shift of the proton-3 in the *endo* form shows an upfield shift, probably due to a slight decrease in the deshielding effect of the amide group, which might be twisted slightly out of the plane of the pyridine ring, as has already been described in the introductory section for 2,4-dichloroacetanilide. This twisting could be attributed to the interactions of the amide group with the solvent molecules, water and dimethyl sulfoxide; both are representative solvents capable of interacting with solute molecules having polar groups through the formation of intermolecular hydrogen bonds.

Planarity of 2-Formylaminopyridine. The acetylation effect on the *ortho* protons is smaller in acetanilide than in 2-chloroacetanilide.[1] This difference is probably to be ascribed to the fact that the rotation around the C_{ring}–NH bond is free in the former, but is strongly restricted in the latter, which holds the molecule planar.

The chemical shift of the proton-3 of 2-formylaminopyridine in the *endo* form is about 8.2 ppm. Therefore, the "formylation" deshielding shift is about 1.85 ppm, because the chemical shift of the proton-3 in 2-aminopyridine is 6.35 ppm.[13] A similar value of 1.70 ppm has been reported as the "acetylation" shift for the proton-3 resonance of 2-aminopyridine.[2] Consistent with this, the proton-6 in 2,4-dichloroacetanilide, where the internal rotation around the C_{ring}–N_{amide} bond is strongly restricted by the intramolecular hydrogen bond, resonates at 8.32 ppm, lower by 1.66 ppm than the resonance of the corresponding proton in 2,4-dichloroaniline. The excellent agreement of these values seems to indicate a restricted rotation around the C_{ring}–N_{amide} in 2-formylaminopyridines.[14]

This is also supported by the fact that the chemical shifts of the 2 and 6 protons in *p*-formyltoluidide in chloroform are 7.37 and 7.11 ppm for the molecules in the *endo* and *exo* forms.[1] It is quite certain that this small difference in the chemical shifts for the two rotamers is attributable to the free rotation around the C_{ring}–N bond.

The downfield shift of the proton-3 in 2-acetylaminopyridine has been reported to be very large, suggesting that molecules have a planar structure. The

14) The authors have no idea about the flip-rotation about the C_{ring}–N_{amide} bond, A⇌B.

molecular planarity of this compound is reflected in other evidence wherein a weak, long-range coupling is observed between the amide proton and the proton-4.[15] Unfortunately, in the case of 2-formylaminopyridine, however, the corresponding long-range coupling could not be identified because of the superposition of the two signals corresponding to the two rotamers where the chemical shifts of the proton-4 are very similar to each other.

The large difference in the chemical shifts of the formyl protons in the *endo* and *exo* forms, already described, also strongly suggests the planarity of 2-formylaminopyridines.

From these facts, it seems very probable that 2-formylaminopyridines have planar structures near room temperature. The dipole interaction between the amide group at the position 2 and the pyridine ring is considered to be a main factor in keeping the molecule planar.[1] A similar situation occurs with α-dipyridyl, which has been determined to be planar and *trans* in chloroform.[16]

endo-exo *Equilibrium.* The *endo-exo* equilibrium can be evaluated only at low temperatures. Table 2 gives the *endo-exo* equilibrium constant, $R=I(endo)/I(exo)$, where $I(endo)$ and $I(exo)$ stand for the intensities of the signals from molecules in the *endo* and *exo* forms respectively. It is very interesting to note that the R value changes slightly with the change in solvent from chloroform to a mixed solvent of dimethyl sulfoxide and water (1 : 1). In the cases of thioacetanilide[17,18] and thioacetonaphthalide,[19] the corresponding R values are strongly dependent upon the polarity of solvents. In the case of formanilide, the addition of dimethyl sulfoxide to a chloroform solution caused an intensification of the *endo*-signal.[20] This trend is contrary to the present results.

Table 2. Population ratio of *endo/exo* in different solvents

Solvent	Temperature	Ratio (*endo/exo*)
Chloroform	−28 (°C)	1.4
Acetone	−28	1.3
Di-*n*-propyl ketone	−28	1.2
DMSO-water (1:1)	−12	0.93

In a chloroform solution of 2-chloro-*p*-formyltoluidide,[3] the proton-6 chemical shifts were found to be 7.0 and 8.13 ppm in the *exo* and *endo* form respectively, at 10°C and with the R value of 0.5. At 40°C, however, a partial coalescence occurred and the proton-6 signal appeared at 8.10 ppm, lower than the value estimated directly from the two chemical shifts and the R value at 10°C given above. This suggests that the equilibrium was shifted to the *endo* form with an increase in the temperature. In the present case, however, the resonance positions of the formyl protons and of the proton-3 at higher temperatures are almost the same as those evaluated from the R values and the chemical shifts of these protons obtained from the NMR spectra at low temperatures. This suggests a temperature independence of the population ratio of the two rotational isomers.

Kinetic Studies of Intermolecular Hydrogen Bonding in Carboxylic Acids by Means of Ultrasonic Absorption Measurement. I. Fatty Acids

Takayuki SANO, Nobuhide TATSUMOTO, Toshio NIWA, and Tatsuya YASUNAGA

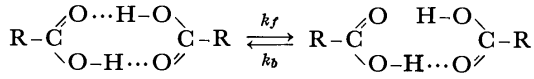
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received November 15, 1971)

The ultrasonic absorptions in *n*-butyric, isobutyric, *n*-valeric, isovaleric, and *n*-caproic acids have been measured in the frequency range from 2.5 to 95 MHz in order to study the relationship between the ultrasonic absorption and the chemical structure of the alkyl group in carboxylic acids. The relaxation absorptions were observed for all the acids with relaxation frequencies in the range of 1.6—8.7 MHz. The kinetic parameters have been calculated on the basis of an assumption that the absorptions are associated with the breakage of one of the two hydrogen bonds in the dimer, as in the case of propionic acid. The values of the heat of reaction, ΔH, were calculated to be 4.7—6.4 kcal per mole of dimer. By an application of the results to Taft's equation, $\log K=\rho^*\sigma^*+sE_s$, it is deduced that the change in the ΔH in a series of monocarboxylic acids is due to variations in the inductive effect of each alkyl group. However, the change in the heat of activation, ΔH^*, can not be explained in terms of the inductive effect.

It is well known that an excess absorption of ultrasound exists in the frequency range from 0.5 to 10 MHz in such liquid monocarboxylic acids as acetic[1,2] and propionic[3,4] acids. As the origin of this absorption, the transition from monomeric to dimeric molecules of carboxylic acid has been assumed.[5]

However, the ultrasonic investigation for acetic acid in various solvents by Piercy and Lamb[6] raises the question of whether the above mechanism for the ultrasonic absorption is reasonable for acetic acid. Furthermore, Tabuchi[7] has suggested that the absorption in acetic acid might be associated with the transition from the cyclic dimer to the open dimer. Also, one of the present authors[4] has concluded that the ultrasonic absorption is associated with a perturbation of the following equilibrium:



from his measurement of the ultrasonic absorption in methyl propionate solutions of propionic acid, and has calculated the kinetic parameters of this reaction.

Hitherto, the ultrasonic study of monocarboxylic acids has been done mainly for acetic and propionic acids. It is interesting to study the changes in the absorption with the increase in the carbon number and with the changes in the alkyl group of carboxylic acids in its structure.

Experimental

A pulse technique[4] was used to measure the ultrasonic absorption in the liquid monocarboxylic acids over the frequency range from 2.5 to 95 MHz. The velocity of the sound was measured by means of an ultrasonic interferometer[8] operated at 3.0 and 5.0 MHz. In order to observed the dependence of the relaxation frequency and the absorption on the temperature, measurements were made in the temperature range from 15 to 30°C for *n*-butyric, isobutyric, *n*-valeric, and isovaleric acids, and from 25 to 45°C for *n*-caproic acid. The relaxation absorption in *n*-caproic acid is relatively small in comparison with the others. The densities were measured with a pycnometer. An adiabatic-type calorimeter was used for the heat-capacity measurements. The chemicals used were all guaranteed grade and were used without further purification.

Results

The ultrasonic absorption spectra in a series of monocarboxylic acids are shown in Figs. 1—6. All the spectra can be represented by a single relaxation formula:

$$\frac{\alpha'}{f^2}=\frac{\alpha}{f^2}-B=\frac{A}{1+(f/f_{\max})^2} \qquad (1)$$

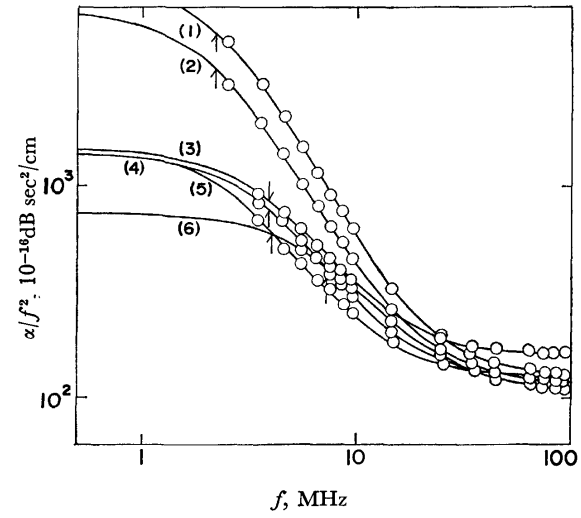


Fig. 1. Ultrasonic absorption spectra in monocarboxylic acids: (1), propionic; (2), butyric; (3), isovaleric; (4), valeric; (5), caproic; and (6), isobutyric acids at 25°C.

a), b), c) The values calculated from H. H. Landolt and R. Bornstein, "Physikalische Chemische Tabellen," Vol. III. Part 3. d) The sound velocities measured at 5 MHz.

$\pm 10\%$ respectively.

If one assumes that the excess absorption in a series of monocarboxylic acids is due to the same type of reaction as in the case of acetic[2] and propionic[4] acids, the general expression for this reaction type is:

$$A \underset{k_b}{\overset{k_f}{\rightleftarrows}} B$$

and:

$$K = \frac{k_f}{k_b} \tag{2}$$

$$2\pi f_{max} = k_f + k_b \tag{3}$$

where K is the equilibrium constant and where k_f and k_b are the forward and backward rate constants respectively. If it is assumed that the volume change in this reaction is zero, the relaxation heat capacities at a constant volume and pressure are represented by the equation:

$$C_p^r = C_v^r = \frac{(\Delta H)^2}{RT^2} \cdot \frac{K}{(1+K)^2} \tag{4}$$

where ΔH is the enthalpy change of reaction; T, the absolute temperature, and R, the gas constant.

The enthalpy change is calculated by means of van't Hoff's isochore:

$$\left(\frac{\partial \ln K}{\partial (1/T)}\right)_p = -\frac{\Delta H}{R} \tag{5}$$

$$K = \exp(-\Delta G/RT) \tag{6}$$

where ΔG is the free energy change of the reaction. Similarly, the temperature dependence of the rate constant is given by:

$$\left(\frac{\partial \ln k}{\partial (1/T)}\right)_p = -\frac{\Delta H^*}{R} \tag{7}$$

The activation free energy is given by the Eyring equation:

$$k = \frac{kT}{h} \exp\left(-\frac{\Delta G^*}{RT}\right) \tag{8}$$

where k is the Boltzman constant; h, the Planck constant, and ΔG^*, the activation free energy. The kinetic parameters, K, k_f, and k_b, and thermodynamic parameters, ΔH and ΔH^*, were calculated from Eqs. (2)—(6) by the same procedure as was used in a previous paper.[4] ΔG and ΔS were calculated by the relationship: $\Delta G = \Delta H - T\Delta S$. The values thus obtained are listed in Table 3. The uncertainties in K, ΔG, ΔH, ΔS, k_b, k_f, ΔH_b^*, and ΔH_f^* are approximately ± 30, ± 20, ± 20, ± 20, ± 5, ± 10, ± 10, and $\pm 20\%$ respectively.

Discussion

As can be seen in Table 3, ΔH increases monotonously with the increase in the carbon number for normal compounds, while it decreases for isocompounds. In order to explain this phenomenon quantitatively from the point of view of the structure of the alkyl group, the following Taft's[9] equation is used:

Table 3. The kinetic parameters for a series of monocarboxylic acids at 30°C

	K (10^{-2})	ΔG (kcal/mol)	ΔH (kcal/mol)	ΔS (cal/deg)	k_b (10^7/sec)	ΔH_b^* (kcal/mol)	k_f (10^5/sec)	ΔH_f^* (kcal/mol)

a), b) The values calculated from data in literatures.[2,4]

9) R. W. Taft, Jr., *J. Amer. Chem. Soc.*, **74**, 2729 (1952).

$$\log K_i = \rho^*\sigma^* + sE_s \quad (9)$$

where K_i is the rate constant or equilibrium constant; σ^*, the polarity parameter, and E_s, the steric parameter. ρ^* and s are proportionality constants and depend only on the type of reaction. The plots of log K against σ^* and E_s are represented in Figs. 7 and 8 respectively, where for the values of σ^* and E_s those found in the literature are used.[9,10] It can be seen in the figures that log K changes linearly with σ^*, while no simple relationship is found between log K and E_s. The value of ρ^* calculated from the plot is 13.8. From this fact and the linearity between log K and ΔH, as can be seen in Fig. 9, it can be deduced that the difference in the ΔH values of the series of monocarboxylic acids is due to variations in the polarity effect of each alkyl group in the molecules. A combination of Figs. 7 and 8 shows that ΔH increases

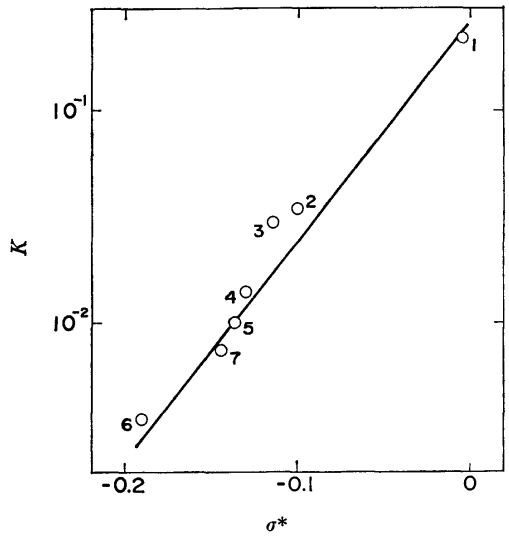

Fig. 7. The plot of ln K against σ^* for a series of carboxylic acids. Hereafter numbers denote the acids as (1), acetic; (2), propionic; (3), butyric: (4), valeric; (5), caproic; (6), isobutyric; and (7), isovaleric acids.

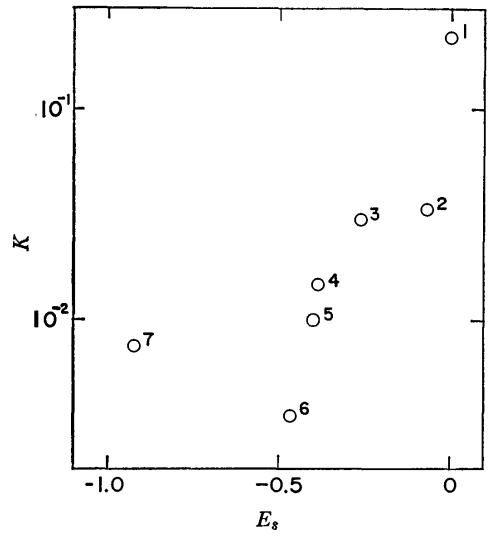

Fig. 8. The plot of ln K against E_s.

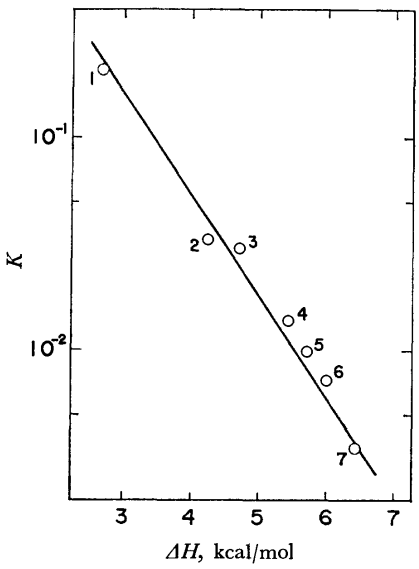

Fig. 9. The plot of ln K against ΔH.

with the strength of the polarity effect, *i.e.*, with the decrease in σ^*. The values of ΔH are in the range of 4.7—6.4 kcal per mole of dimer; this finding is consistent with the fact that these values are those of the breaking of one hydrogen bond, and there is a linear relationship[11] between σ^* and the inductive effect of the alkyl group on the carboxyl group. From these

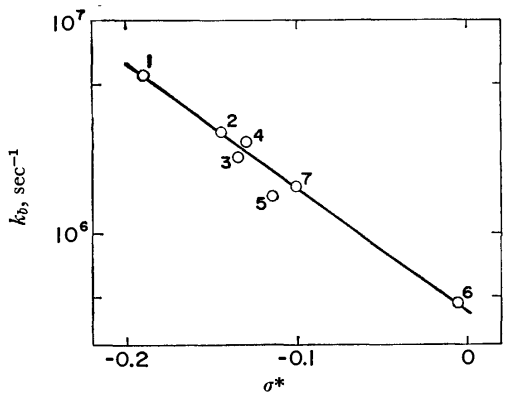

Fig. 10. The plot of ln k_b against σ^*.

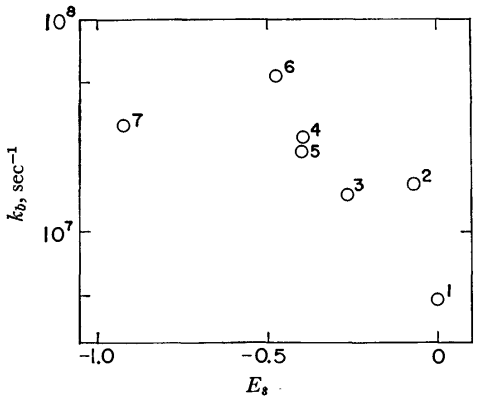

Fig. 11. The plot of ln k_b against E_s.

10) R.W. Taft, Jr., *J. Amer. Chem. Soc.*, **75**, 4538 (1953).

11) M. Chiang and T. Tai, *Scientia Sinica*, **12**, 785 (1963).

results, it can be concluded that the electron density of the carboxyl group increases with the increase in the inductive effect, so the hydrogen bond becomes more stable in the cyclic dimer than in the open dimer.

The relationships between the rate constant and the values of σ^* and E_s, are shown in Figs. 10 and 11, where the plot of $\log k_b$ against σ^* gives a straight line; no such relationship exists between $\log k_b$ and E_s, however the value of ρ^* calculated from the plot is -7.90. The change in ΔH_b^* cannot, however, be ascribed to the polarity effect, as can be seen in Table 3, where there exists no simple relationship between $\log k_b$ and ΔH_b^*.

As can be seen in Table 3, the ΔH_b^* values of acetic and propionic acids are greater than those of other acids. The abnormal ΔH_b^* values of these two acids may be ascribed to the formation of the polymer, as has been suggested by a study[12] of sound velocity and dipole moment. The liquid contains some linear polymer, and some excess energy is required to break the hydrogen bonds of the polymer.

From the above discussion, it may reasonably be concluded that the excess absorptions in the series of monocarboxylic acids are all associated with the perturbation of the equilibrium between the open dimer and the cyclic dimer, and that the cyclic dimer becomes more stable because of the inductive effect of the alkyl group, which increases the electron density in the carboxyl group.

More extensive measurements may be desirable to confirm the inductive effect mentioned above. A study of halogeno carboxylic acids is now in progress; the results will be reported.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2673—2677 (1972)

Kinetic Studies of Intermolecular Hydrogen Bonding in Carboxylic Acids by Means of Ultrasonic Absorption Measurement. II. Halogeno Carboxylic Acids

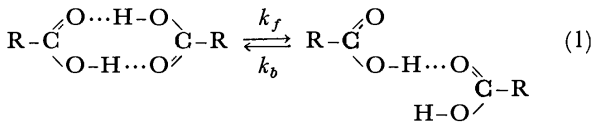
Takayuki SANO, Nobuhide TATSUMOTO, Yukio MENDE, and Tatsuya YASUNAGA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received December 21, 1971)

The ultrasonic absorptions in several halogeno carboxylic acids, such as monochloroacetic, dichloroacetic, trichloroacetic, trifluoroacetic, α-chloropropionic, and β-chloropropionic acids, have been measured in the frequency range from 2.5 to 95 MHz. Excess absorptions were observed in all the acids. The kinetic and the thermodynamic parameters based on the equilibrium between the open dimer and the cyclic dimer were calculated. An application of Taft's equation, $\log K=\rho^*\sigma^*+sE_s$, to the results suggests that neither the equilibrium constant nor the rate constant depends on the polarity effect of the alkyl group, but depends mainly on the steric effect, and that the reaction is controlled not only by the enthalpy change, but also by the entropy change.

In a previous paper[1] the mechanism of the ultrasonic absorption in the fatty acids has been attributed to a perturbation of the equilibrium between the cyclic dimer and the open dimer:



(1)

In view of the kinetic and thermodynamic characteristics based on the above reaction for a series of fatty acids, it has been concluded that the cyclic dimer becomes more stable because of an increase in the electron density in the carboxyl group with an increase in the inductive effect of the alkyl group. Since this conclusion has been deduced from the results for the fatty acids with only the hydrocarbon in the alkyl group, more extensive studies seemed desirable. The present study was undertaken in an attempt to confirm more completely this effect for some halogeno carboxylic acids with the help of ultrasonic absorption measurements. Because some halogeno carboxylic acids such as dichloroacetic acid[2] are occasionally used as the solvents of biopolymers, it seemed worthwhile to measure the ultrasonic absorption in halogeno carboxylic acids in order to understand the more complex biochemical and solvent interaction reactions.

Experimental

A pulse technique[3] was used to measure the ultrasonic absorptions in the liquid halogeno carboxylic acids, such as monochloroacetic, dichloroacetic, trichloroacetic, trifluoroacetic, α-chloropropionic, and β-chloropropionic acids, together with trimethylacetic acid in the frequency range from 2.5 to 95 MHz. The velocity of the sound was measured by an ultrasonic interferometer[4] operated at 3.0 MHz and

by the sing-around method[5] at 1.92 MHz. In order to observe the dependence of the relaxation frequency, the excess absorption, and other physical properties on the temperature, measurements were made at various temperatures over the melting point: monochloroacetic, 66.3, 70, 74, and 78°C; dichloroacetic, 20, 25, 30, 35, and 40°C; trichloroacetic, 65.4, 69.1, 73, and 77°C; trifluoroacetic, 15, 20, 25, and 30°C; α-chloropropionic, 20, 25, 30, 35, and 40°C; β-chloropropionic, 45, 50, 55, and 60°C; and trimethylacetic acids, 40 and 45°C. All the compounds are deliquescent, so the ultrasonic cell was designed to maintain a sample liquid in an inert and dry atmosphere. The densities were measured by a pycnometer, and the heat capacities, by an adiabatic-type calorimeter. The chemicals used were all of a guaranteed grade and were used without further purification.

Results

The ultrasonic absorption spectra for the monochloro-, dichloro-, trichloro-, trifluoro-, trimethylacetic, α-chloropropionic, and β-chloropropionic acids are shown in Fig. 1. In all these acids except the trimethylacetic acid, excess absorptions were observed. The relaxation spectra can all be represented by a single relaxation formula:

$$\frac{\alpha}{f^2} = \frac{A}{1+(f/f_{max})^2} + B \qquad (2)$$

where α is the ultrasonic absorption coefficient, f is the frequency of sound, f_{max} is the relaxation frequency, and A and B are the excess and classical absorptions respectively.

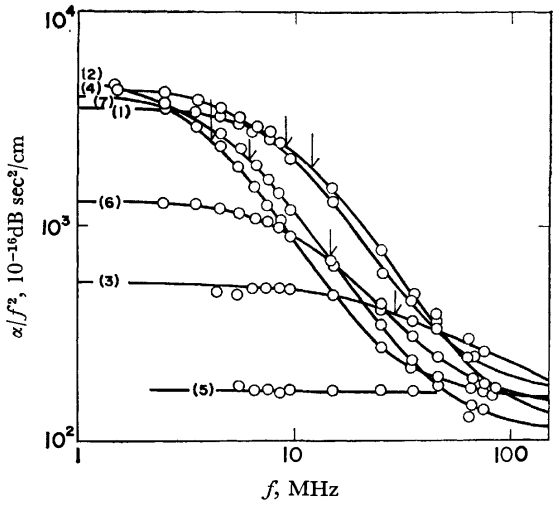

Fig. 1. Ultrasonic absorption spectra in some carboxylic acids: (1): monochloroacetic, 66.3°C; (2): dichloroacetic, 25°C; (3): trichloroacetic, 65°C; (4): trifluoroacetic, 30°C; (5): trimethylacetic, 40°C; (6): α-chloropropionic 25°C; and (7): β-chloropropionic acids, 50°C.

A least-squares computer program is routinely used to evaluate the three parameters, A, B, and f_{max}. The uncertainties in A, B, and f_{max} are approximately ±10, ±5, and ±5% respectively. These values are

333	1.2061	1.1684	10.25	0.555

listed in Table 1. On the other hand, in the trimethylacetic acid the value of α/f^2 remains constant at 165×10^{-16} dB sec^2/cm in the frequency range from 3.5 to 85 MHz, and the temperature dependence of the excess absorption in the trichloroacetic acid can not be measured because of the high relaxation frequency. The other values required for the calculation of the kinetic and thermodynamic parameters (*e.g.*, the sound velocity, u; the density, ρ; the thermal expansion coefficient, l, and the heat capacity at a constant pressure, C_p) are listed in Table 2. The experimental errors in u, ρ, l, and C_p are approximately ±0.01, ±0.05, ±0.5, and $\pm10\%$ respectively.

If the same type of reaction, which does not accompany any volume change, as that reported previously in the case of the fatty acids is considered to be the origin of the excess absorptions in the acid studied in this report, the reaction type can be given by:

$$A \underset{k_b}{\overset{k_f}{\rightleftarrows}} B \tag{3}$$

and the kinetic and thermodynamic parameters can be given by equations:

$$K = \frac{k_f}{k_b} \tag{4}$$

$$2\pi f_{max} = k_f + k_b \tag{5}$$

$$C_v^r = C_p^r = \frac{(\Delta H)^2}{RT^2}\cdot\frac{K}{(1+K)^2} \tag{6}$$

$$K = \exp(-\Delta G/RT) \tag{7}$$

$$\Delta G = \Delta H - T\Delta S \tag{8}$$

$$\frac{\partial \ln (k_i/T)}{\partial(1/T)} = -\frac{\Delta H_i^*}{R} \tag{9}$$

where K is the equilibrium constant, and where k_f and k_b are the forward and backward rate constants respectively. C_v^r and C_p^r are the relaxation heat capacities at a constant volume and a constant pressure respectively. ΔH is the heat of reaction; ΔG, the free energy, and ΔS, the entropy of reaction. k_i represents k_f or k_b, and ΔH_i^* is the heat of activation. The kinetic and thermodynamic parameters were calculated from Eqs. (4)—(9). However, the kinetic values, such as K, k_f, and k_b, cannot be compared directly with those of other cmpounds because the measurements had to be done at various temperatures over the melting point. Consequently, the kinetic parameters at 30°C are estimated by extrapolations of K, k_f, and k_b respectively *vs.* the temperature; they are listed in Table 3. The errors are approximately $\pm20\%$ in K, ΔG, ΔH, and ΔS, ±5 and $\pm10\%$ in k_b and ΔH_b^*, and ±10 and $\pm20\%$ in k_f and ΔH_f^*.

Discussion

As can be seen in Fig. 1, the halogeno carboxylic acids studied in the present paper show an ultrasonic absorption similar with regard to the position of the relaxation frequency and the magnitude of B to that in the fatty acids reported in the previous paper. This suggests that the ultrasonic absorptions in the halogeno carboxylic acids are associated with the same type of reaction as in the fatty acids.

In order to confirm the polarity effect of the alkyl group on Reaction (1), the following Taft's equation was used:

$$\log K_i = \rho_i^*\sigma^* + s_iE_s \tag{10}$$

where K_i is the rate constant or equilibrium constant, where σ^* and E_s are the polarity and steric parameters respectively, where ρ_i^* and s_i are the proportionality constants and depend only on the type of reaction, and where the subscript i represents K or k_b. The plots of $\log K$ against σ^* and E_s are represented in Figs. 2 and

3 respectively, along with that of the fatty acids obtained in the previous report. The values of σ^* and E_s are found in the literature.[6] In Fig. 2, it can be seen that the relationship between log K and σ^* is linear in the case of the fatty acids, but is not linear in that of the halogeno carboxylic acids. With respect to the relationship between log K and E_s in Fig. 3, the halogeno carboxylic acids give a better straight line than the fatty acids. The value of s_K for the equilibrium constant calculated from the plot is 0.954. As to the relationships between log k_b and σ^* and E_s, similar explanations can also be given from Figs. 4 and 5. The value of s_{k_b} for the rate constant is calculated to be -0.869. Therefore, it can be deduced that both K and k_b depend mainly on the steric effect of the alkyl group in halogeno carboxylic acids; this is in contrast with the case of fatty acids.

Moreover, it can be seen in Table 3 that the relationship between log K and ΔH and that between log k_b and ΔH_b^* are not linear. Though the results are unfortunately, inconsistent with our expectations with regard to the behavior of the kinetic values, the difference may be ascribed to the large size of the halogen atom; that is, the substitution of the large halogen atoms for the hydrogen atom in the alkyl group of the acids may lead to an intermolecular steric interaction rather than to an intramolecular electrostatic effect. Because the relationship between log K and ΔS is also not linear, as can be seen in Table 3, it can be deduced that the reaction in the halogeno carboxylic acids is controlled not only by the enthalpy change, but also by the entropy change.

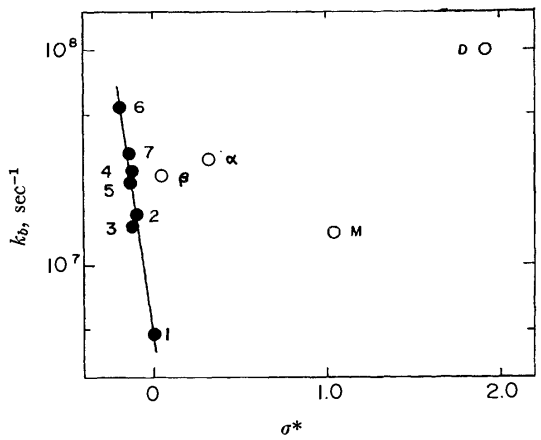

Fig. 4. The plot of ln k_b against σ^*.

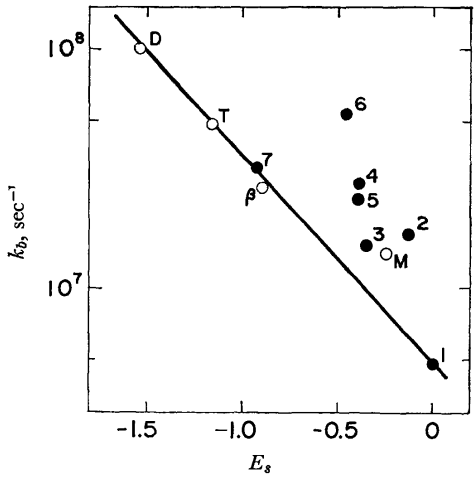

Fig. 5. The plot of ln k_b against E_s.

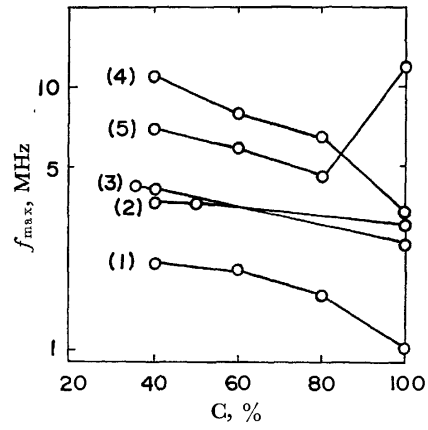

Fig. 6. The plot of the relaxation frequency against volume percent of the some carboxylic acids in dioxane solutions: (1): acetic; (2): propionic; (3): butyric; (4): dichloroacetic; and (5): α-chloropropionic acids.

In order to observe only the abnormal behavior of the relaxation frequency in solutions, ultrasonic absorption measurements were carried out in dioxane solutions of some carboxylic acids, such as acetic, propionic, butyric, dichloroacetic, and α-chloropropionic acids. The results are shown in Fig. 6. In all the acids, the relaxation frequencies shift to the higher-frequency side with a decrease in the concentration; they do this in spite of the existence of a concave point in the case of the α-chloropropionic acid. This fact may support the suggestion that the ultrasonic absorption mechanism in the halogeno carboxylic acids is the same reaction as in the fatty acids. From the above discussion and the quite recent investigations by

6) R. W. Taft, Jr., *J. Amer. Chem. Soc.*, **74**, 2729 (1952); R. W. Taft, Jr., *ibid.*, **75**, 4538 (1953).

Corsaro and Atkinson,[7,8] it is reasonable to conclude that the excess absorptions in the series of carboxylic acids studied in this and previous papers are to be attributed to the perturbation of the equilibrium between the cyclic dimer and the open dimer, and also that the reaction in the case of the halogeno carboxylic acids depends mainly on the steric effect rather than on the polarity effect of the alkyl group, and that it is controlled by both the enthalpy and the entropy changes. While it might be interesting to study the cause of the concave point in the α-chloropropionic acid, visible in Fig. 6, the investigation of such a solvent effect is beyond the scope of this discussion.

Finally, the presence of other excess absorptions is to be expected in the higher-frequency ranges over 100 MHz, because the carboxylic acids studied in this and previous papers all have similar values greater than about 100×10^{-16} dB·sec^2/cm of the classical absorption; B. Thus, the ultrasonic absorption measurements over a wider frequency range, and the interpretation of the overall absorptions, will lead to a final solution of the problem of the ultrasonic absorption in the carboxylic acids.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2677—2683 (1972)

The Self-diffusion of Chloride Ions in Nickel Dichoride Crystallites and an Isotopic Exchange Reaction between Chlorine Gas and the Crystallites

Yoshihiro SENSUI

Institute for Atomic Energy, Rikkyo (St. Paul's) University, Yokosuka

(Received March 10, 1972)

The self-diffusion of chloride ions in the bulk of nickel dichloride crystallites was studied in the temperature range of 180—340°C in a carefully-evacuated vacuum system; the isotopic exchange reaction between gaseous chlorine and the crystallites was also studied. The activation energy for the migration of chloride ions was determined to be 1.01 eV (=23.3 kcal/mol). The exchange reaction proceeded with activation energies of 3.6 and 9 kcal/mol for the active and the less-active part of the surface first layer, 13 and 16 kcal/mol for the active and the less-active one of the second layer, and 21 kcal/mol for the third layer. (These activation energies converge to the value of the self-diffusion in the bulk.) The Θ-rule nearly holds good in the present case.[1]

The correlation between the surface reactivities of solids and the surface-structures is a very interesting theme in the field of surface science. Verwey[2] proposed that on the surface of ionic crystals, ions within the surface first layer change the degree of polarization and are displaced from the normal lattice position, in this way reducing their surface energies. Benson *et al.*[3] and Anderson and Scholz[4] extended this model by taking into consideration the relaxation of the first five layers in the crystal of alkali halides. The results of their calculation show that the several surface layers should be distorted.

The isotopic exchange reaction between crystal and gaseous molecules is one of the simplest surface reactions, and the method of this exchange reaction is very useful in the investigation of the self-diffusion of ions in crystals. Such reactions have been studied in the systems of $NaCl/Cl_2$,[5,6,10,12] KCl/Cl_2,[7,10] $RbCl/Cl_2$,[8] and KBr/Br_2.[9] Harrison and his co-workers[5] have investigated mainly the surface-exchange reaction. Barr *et al.*[9-11] and Laurent and Benard[12] have studied mainly the self-diffusion in the bulk of the crystals, while Takaishi and the present author[6-8] have studied that of chloride ions, along with the surface-exchange reaction, which shows, successively, the expected correlation between the surface structure and its reactivities of NaCl,[6] KCl,[7] and RbCl.[8] However, there have been few studies of higher valent metal halide crystals, except for the self-diffusion study of the $MnCl_2/Cl_2$ system by the present author[13] and

the qualitative studies by Willard and his co-workers.[14]

In this paper, results of a study of the exchange reaction between chlorine gas and nickel dichloride crystallites will be presented as well as the results concerning the self-diffusion of chloride ions in the crystallites. This material was chosen for a reason similar to that in the case of manganese dichloride; that is, it is relatively easy to handle because of its layer structure, its relatively low volatility, and its surface homogeneity, presumed from the results of the krypton adsorption study by Larher[15] and from the electron-microscopic data (Fig. 1).

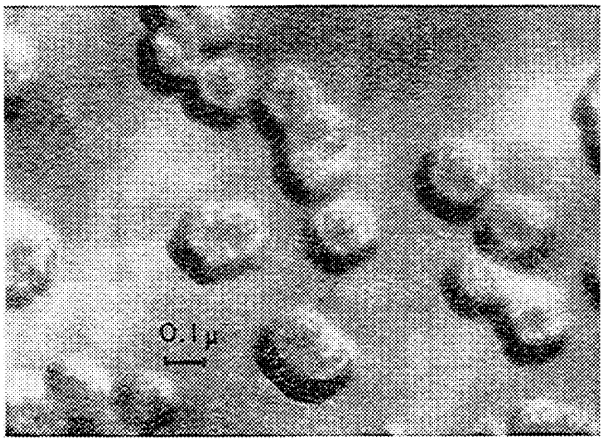

Fig. 1. The external shape of nickel dichloride crystallites used in the present experiment.

Experimental

Procedure. The apparatus used was the same as that described in the previous papers.[6-8] The system was all made of glass, except for two pieces of Teflon stopper in the circulation pump. The sample was dehydrated by baking at 60°C for about 10 hr in a vacuum. Then, the temperature was gradually raised to 200°C over 3 hr and kept at that temperature for about 7 hr. After this pre-baking, the system was sealed off from the main pumping line and thus made grease-free. Baking out at a temperature higher than 200°C was carried out with a Vac-Ion pump, which was isolated when the residual pressure was below 5×10^{-7} torr during the baking of the sample at 340°C.

Chlorine gas of a purity of 99.8%, contained in a glass cylinder (supplied from Takachiho Chemical Co.), was distilled and dehydrated by means of Linde-3A Molecular Sieves. The latter had been baked out prior to use in a vacuum of 5×10^{-7} torr at 400°C. This is a necessary procedure.[7] In the sealed-off vacuum system, purified chlorine gas was introduced, through a breakable seal, into a system containing carefully baked-out radioactive nickel dichloride crystallites. The reaction was followed by measuring the radioactivity of ^{36}Cl in gaseous chlorine, which was circulated by means of a circulation pump made of glass.[15] A thin-wall G.M. counter in a part of the system had a counting efficiency of 3% against 0.714 MeV γ-ray from ^{36}Cl.

Materials. Radioactive nickel dichloride was obtained by the isotopic-dilution method from radioactive hydrochloric acid which had been distilled in a vacuum and from nickel dichloride which had been prepared by a reaction between nickel sponge (Johnson-Matthey's spectrographically-standardised reagent, catalog No. J.M. 891) and distilled hydrochloric acid. The specific radioactivity of the resultant radioactive nickel dichloride was 5.2 μc/g. The precipitates of the radioactive dichloride were prepared by modifing Marshall's method[17] *i.e.*, by adding about 100 parts of distilled ethyl ether to one part of a saturated alcoholic solution of the dichloride. After the supernatant solution had been replaced with ethyl ether, the precipitates were transferred into the vacuum system. The crystallites were obtained by baking them out carefully by means of the procedure described above. The crystallites thus obtained have an even-grained external shape, as is shown in Fig. 1 and by the BET surface area of 26 m^2/g, which agrees with the geometric area calculated from the electron-microscopic data. This means that the crystallites are non-porous and that the roughness-factor of the surface is approximately unity.

Results and Discussion

Self-diffusion of Chloride Ions in the Bulk of the Crystallites. In the crystal of nickel dichloride with a $CdCl_2$ structure, chlorine atoms are arranged in cubic closest-packing, and a nickel atom occupies an octahedral hole made up of chlorine atoms, forming a sandwich-like layer of Cl–Ni–Cl, consisting of two adjacent layers of chlorine atoms with a layer of nickel atoms between them. Since the primary valencies of the nickel and chlorine atoms are satisfied within the sandwich-like layer, there being only van der Waals forces between adjacent layers, this may be regarded as a semi-infinite two-dimensional molecule in a first approximation.[18] However it should be mentioned that there may be some influences of nickel atoms on the configuration of adjacent chlorine layers, because of the cubic close-packed arrangement taking place in nickel dichloride crystals. Therefore, only on the basis of the structure of the crystal, we cannot predict that an anion vacancy migrates predominantly in either direction, either along or beyond the sandwich-like layer in the bulk of the crystal, by exchanging its site with the chlorine atom's. In the following paragraph, the experimental results on the self-diffusion of ^{36}Cl in the bulk of nickel dichloride crystallites will be described in some detail.

The mean length of the shorter sides of the crystallites used was estimated to be 0.06 μ from the electron-microscopic data (*cf.* Fig. 1); this corresponds to a few hundred layers in the direction along the *c*-axis of the crystal. In the present experiments, only the ^{36}Cl in the bulk of the near-surface region diffuses out into the gaseous phase and was measured; the region corresponds to less than 30 layers. Therefore, the diffusion data obtained may be analyzed on the basis of the model of semi-infinite media as a first approximation. For this model, the diffusion equation has the solution;[19]

$$X_g = X_s + 2\alpha(Dt/\pi)^{1/2}$$

where X_g designates the amount of ^{36}Cl diffused out into the gaseous phase after time t; X_s that of ^{36}Cl in the surface region which diffused out into the gaseous phase at the initial stage of the reaction; D, the bulk diffusion constant, and α, the product of the surface area and the initial concentration of ^{36}Cl. Denoting the measured counting rate by C, we obtain;

$$C = K \cdot X_g \text{ and } C_s = K \cdot X_s,$$

where K is the conversion factor. Thus we obtain;

$$C = C_s + \frac{2\alpha}{K}(Dt/\pi)^{1/2}$$

in which the value for C_s cannot be obtained directly from the experiments. The exchange process, it is expected, may be rate-controlled by the bulk-diffusion, and the curve of C against $\sqrt{t}$ may be linear, except in the initial stage. However, there are some ambiguities with regard to the start of the reaction. The measured time t must be corrected; namely, it is replaced by $(t+\delta)$, where the value for δ is determined empirically so as to give a linear curve. The results are given in Fig. 2, which the intersection of the straight line with the ordinate gives the value for C_s.

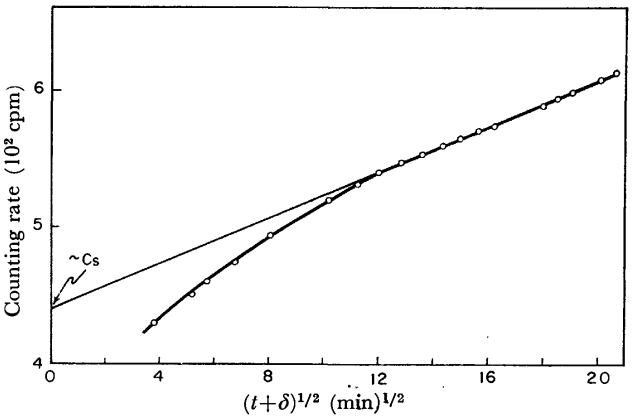

Fig. 2. The plots of C against the square-root of $(t+\delta)$. The data obtained from the specimen II at 180°C.

Next, we suppose that a first diffusion run is carried out at a temperature, T_1, for time t_1, in which the diffusion constant is D_1. If a second run is made at another temperature, T_2, for time t_2, in which the constant is D_2, the total counting rate, C, may be shown by;[19]

$$C = C_s + \frac{2\alpha}{K\sqrt{\pi}}(D_1t_1 + D_2t_2)^{1/2}.$$

This may be extended to further runs and be rewritten as follows;

$$(C - C_s)^2 = \left(\frac{4\alpha^2}{\pi K^2}\right)(D_1t_1 + D_2t_2 + \cdots).$$

The values of $(C-C_s)^2$ thus obtained are plotted against the time in Fig. 3.

The measured points fit well on the straight lines. If the crystallites had a large number of dislocations along which diffusion proceeded much faster, or it concomitant diffusions with different rate constants

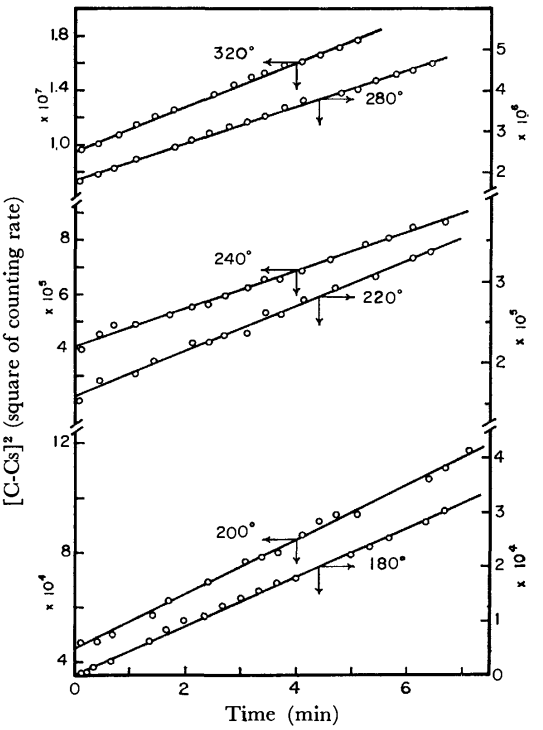

Fig. 3. The plots of $(C-C_s)^2$ against time. All of data in this figure are obtained from the specimen II.

proceeded, complex curves would be obtained; that is, the plots of $(C-C_s)^2$ against the time would not fit on a straight line when the temperature was changed. This is not observed in the present case, and so it may be concluded that the model used is adequately supported experimentally. When the self-diffusion of chloride ions or anion vacancies takes place uniformly both parallel with and perpendicular to the sandwich-like layers in the bulk of the crystallites, the values of C_s correspond to the amount of ^{36}Cl within about five layers which diffused out into the gaseous phase. Moreover if the diffusion has proceeded predominantly in either direction, the value of C_s agrees with the one which corresponds to nine layers. In the case of alkali chlorides, in which the surfaces are distorted remarkably by electrostatic forces,[3] the value of C_s corresponds to five layers or so.[6-8] Since it may generally be regarded that the degree of distortion in the surface region of covalent crystals is smaller than that of the distortion of ionic crystals, the value of C_s which correlates with the surface distortion may not be larger in the former than in the latter. Therefore, it may be concluded that the diffusion in the bulk of nickel dichloride crystallites proceeds uniformly in both of the directions in the temperature range used in the present experiment, 180—340°C. This presumption is consitent with the analytical results of the exchange reaction in the surface region, which will be presented below. From the slopes in Fig. 3, the values of $(4\alpha^2/\pi K^2)D$ can be obtained. The Arrhenius plots of these values are shown in Fig. 4.

The slope in this figure gives the activation energy for the migration of ^{36}Cl, ΔE_d, in the bulk of nickel dichloride crystallites. From this experimental results, we obtain;

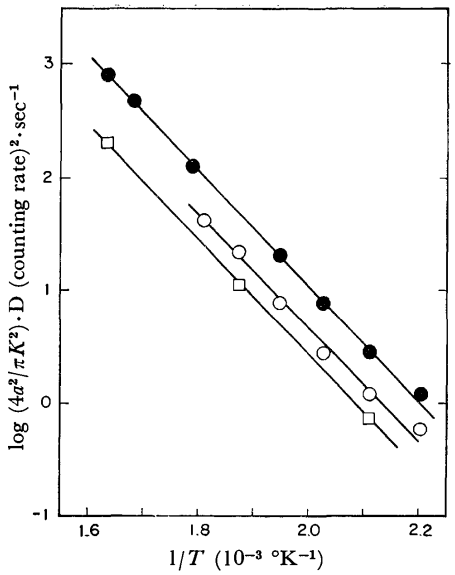

Fig. 4. The Arrhenius plots of apparent self-diffusion rates. ○, ●, and □ refer to different specimens, I, II, and III, respectively.

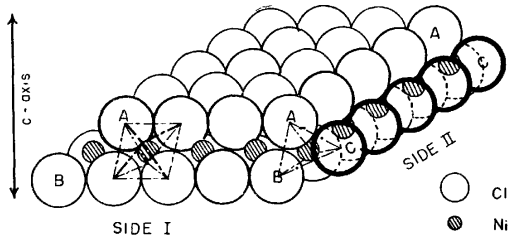
$$D = D_0 \exp(-\Delta E_d/kT),$$

$$\Delta E_d = 1.01 \text{ eV and } D_0 = \sim 3\times 10^{-8} \text{ cm}^2\cdot\text{sec}^{-1}.$$

Both of these values are slightly large in comparison with the corresponding values in the crystallites of manganese dichloride[13] with the same $CdCl_2$-structure, in which $\Delta E_d=0.95$ eV and $D_0=1\times 10^{-8}$ cm$^2\cdot$sec^{-1}.

The diffusion experiments in the present work were carried out in the temperature range of 180—340°C. Since ^{36}Cl in the region deeper than the near-surface region diffused out into the gaseous phase within an hour or so at temperatures higher than 340°C, the data obtained in the condition could not be analyzed on the basis of the model of semi-infinite media. No break in the Arrhenius curve was found in the present case, while one appeared obviously at about 330°C in the case of the manganese dichloride crystallites. This discrepancy may be ascribed to the narrow temperature range in which the present experiment was carried out. Hence, the present work was limited to determining the activation energy and the frequency factor of the migration of ^{36}Cl or an anion vacancy; these values for the formation of an anion vacancy or a pair of an anion and a cation vacancies were excluded.

Exchange Reaction in the Surface Region of the Crystallites. In the bulk of nickel dichloride crystallites, a stoichiometric configuration is satisfied by the octahedral coordination of chlorine atoms around a nickel atom, but on the surface the configuration can not always be satisfied. The electron-micrography of the crystallite shows that the surface of the crystal may be approximately regarded as consisting of two kinds of external planes, which are parallel with and perpendicular to the sandwich-like layers. The configuration of the chlorine atoms in the latter planes can not be satisfied by the octahedral configuration for a reason to be explained below. As a help to explanation, a bird's-eye view of the external side model of the sandwich-like layer[18] is shown in Fig. 5. Side I



Fif. 5. A bird's-eye view of the side-model of the sandwich-like layer in nickel dichloride crystal. Chlorine atoms at the position of *A*, *B*, and *C* take the effective valencies of 1/3, 1/2, and unity, respectively.

in this figure shows a section of the octahedral configuration, in which a nickel atom is co-ordinated with three one-third-effectively-valent chlorine atoms (A) and two half-valent chlorine atoms (B).

On this side, there are no chlorine atoms at the apex positions of the octahedral structures. On the other hand, in the crystal side structure shown on Side II of Fig. 5, a nickel atom occupies a tetrahedral hole made up of an effectively uni-valent chlorine atom (C) and three one-third-valent chlorine atoms (A). It may thus be self-evident that the tetrahedral configuration shown on Side II of Fig. 5 is more stable thermodynamically than the vacant octahedral structure on Side I. Therefore, we may predict that, in the external plane perpendicular to the sandwich-like layer, chlorine atoms are arranged in a distorted tetrahedral configuration. Hence, it may be presumed that there are two kinds of domains in the first layer of the crystal surface. The ratio of these two domain areas can be estimated from the electronmicroscopic data as follows;

$$\frac{\text{(Domain I, perpendicular to the sandwich-layer)}}{\text{(Domain II, parallel with the sandwich-layer)}} = \frac{0.8}{1}.$$

The distortion appearing in the first layer of the surface may influence the configuration of the second layer. Hence, it should be considered that there are two kinds of parts in the second layer of the surface, much as in the first layer.

Below, the exchange reactions in the surface region will be analyzed kinetically on the basis of the conditions described above. The surface of nickel dichloride crystallites is highly reactive for chlorine gas; this situation is similar to that with the crystallites of alkali chlorides—that is, gaseous chlorine exchanges with chlorine atoms in the first layer of the surface, even at −21.2°C, and the exchange reaction between the first and the second layers at room temperature takes place rather gradually, as shown in Fig. 6.

Let C and $2C(s)$ be the counting rate at time t and at saturation respectively. Then, we can calculate the value of $C(s)$ from the surface area of the crystallites and the specific radioactivity of the chlorine atoms, if we assume that all of the ^{36}Cl atoms in the first and second layers are transferred into the gaseous phase. [This assumption is valid, since the chlorine atoms in the gaseous phase are about 500 times more than those in the surface monolayer of the crystallites, and the reverse reaction from the phase to the crystal may be neglected.] The calculated values of $C(s)$ are in

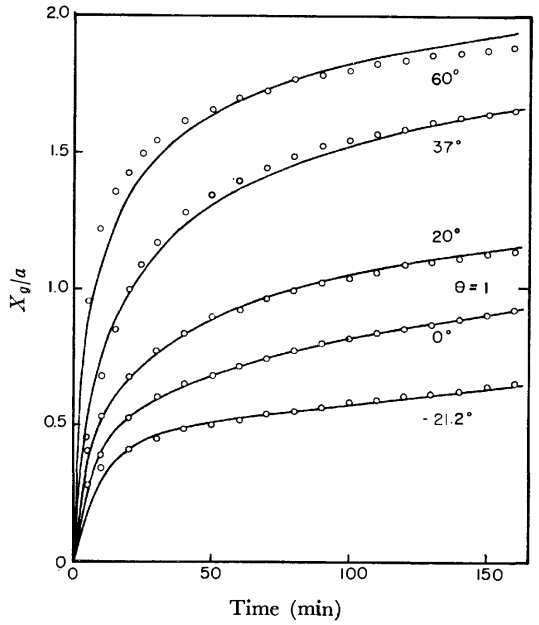


Fig. 6. Counting rates against time curve for the first and the second layer reaction. The line $\theta=1$, designates the monolayer capacity: Solid curves show the values calculated from Eq. (2).

good agreement with those from the measurement of the exchange reaction.

The initial portion of the curve at low temperatures can be analyzed tentatively without taking the second layer into consideration. Now, let us assume that there is a considerable difference between the reactivities of the two domains in the crystal surface. The plots of $\log[1-C/C(s)]$ against the time are shown in Fig. 7. These curves are graphically analyzed in a manner similar to the treatment of the decay of a mixture of radio-isotopes.

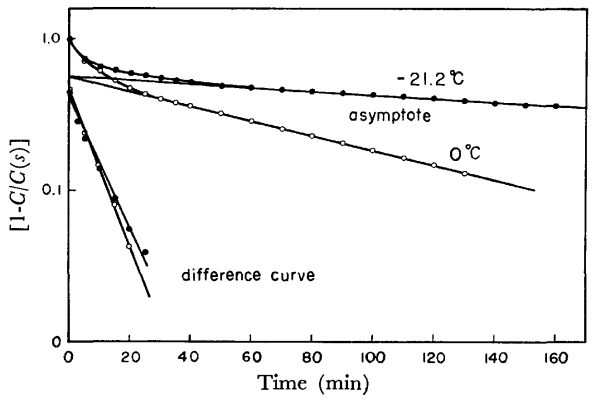

Fig. 7. The plots of log $[1-C/C(s)]$ against time for the reaction in the first and the second layer. The points in the difference curves are calculated from the smoothed experimental curves and the asymptote.

The asymptotes to the tail of the experimental curves give the curves of the relative counting rate against the time referred to the least relative part of the first layer. The difference between the experimental curve and the asymptote is shown as a difference curve, which is approximately linear. The intercepts of the asymptote and the difference curve with the ordinate give the relative values of the two kinds of domain area; the ratio of the active area to the less-active one has the value of 0.78—0.82, in agreement with the ratio estimated from the electron-microscopic data. The best-fitting values of the rate constants for the respective domains, $k_1(1)$ and $k_1(2)$, can be determined from the slopes of the difference curve and the asymptote. The above results indicate that the two-domains model is a good approximation. After the exchange reaction in the first and the second layers were completed at 60°C, the temperature was raised to 80°C, at which point the third-layer exchange reaction proceeded at a slow rate as shown in Fig. 9. The influence of ^{36}Cl in the third layer must be taken into consideration even in the first- and the second-layer exchange reactions at temperatures near 60°C, while the third-layer reaction may proceed at a very slow rate at that temperature.

The approximate reaction scheme is given by;

$$\begin{array}{l} \overset{k_1(1)}{\swarrow} \text{domain(1) of 1st layer} \overset{k_2(1)}{\rightleftharpoons} \text{2nd layer} \overset{k_3}{\rightleftharpoons} \text{3rd layer} \\ \qquad\quad \text{area} \propto a(1) \qquad\quad \text{area} \propto a(1) \qquad\quad \text{area} \propto a(1) \\ \text{gas} \\ \underset{k_1(2)}{\nwarrow} \text{domain(2) of 1st layer} \overset{k_2(2)}{\rightleftharpoons} \text{2nd layer} \overset{k_3}{\rightleftharpoons} \text{3rd layer} \\ \qquad\quad \text{area} \propto a(2) \qquad\quad \text{area} \propto a(2) \qquad\quad \text{area} \propto a(2) \end{array}$$

In this scheme, the reverse reaction from the gaseous phase to the solid is ignored for the reason mentioned above, and it is assumed that the rate constants for the (1) and (2) domains, $k_3(1)$ and $k_3(2)$, have the same value, k_3. The kinetic analysis, then, is given by;

$$\begin{aligned} &dX_g(j)/dt = k_1(j)x_1(j) \\ &dx_1(j)/dt = -k_1(j)x_1(j) - k_2(j)x_1(j) + k_2(j)x_2(j) \\ &dx_2(j)/dt = -k_2(j)x_2(j) + k_2(j)x_1(j) - k_3x_2(j) + k_3x_3(j) \\ &X_g + x_1(j) + x_2(j) + x_3(j) = 3a(j), \end{aligned} \tag{1}$$

and

$$X_g = \sum_{j=1}^{2} X_g(j),\ x_1 = \sum_{j=1}^{2} x_1(j),\ x_2 = \sum_{j=1}^{2} x_2(j),\ x_3 = \sum_{j=1}^{2} x_3(j),$$

$$a = \sum_{j=1}^{2} a(j),$$

where x_n designates the number of ^{36}Cl in the nth layer at time t; a, the number of ^{36}Cl contained in each layer at $t=0$; k_n, the apparent rate constant of the exchange reaction between the $(n-1)$th and the nth layers; the subscript g, the gaseous phase; and (j), the jth kind of domain.

To obtain a solution, an approximation is made;

$$x_3 = a \cdot \exp(-\lambda t),$$

where λ is the effective rate constant for the decrease in x_3. Then, using the boundary condition;

$$X_g(j) = 0, \text{ and } x_1(j) = x_2(j) = x_3(j) = a(j), \text{ at } t = 0,$$

we obtain the solution;

$$\begin{aligned} \frac{X_g(j)}{a(j)} = {} & \frac{k_1(j)}{\rho_+(j)\rho_-(j)}\left\{\frac{k_2(j)k_3}{\lambda} - \rho_+(j) - \rho_-(j) - k_1(j)\right\} \\ & - \frac{k_1(j)k_2(j)k_3}{\lambda[\lambda+\rho_+(j)][\lambda+\rho_-(j)]}\exp(-\lambda t) \\ & - \frac{k_1(j)}{\rho_+(j)[\rho_+(j)-\rho_-(j)]}\left\{\rho_-(j) + k_1(j)\right. \end{aligned}$$

$$-\frac{k_2(j)k_3}{\lambda+\rho_+(j)}\Big\}\exp[\rho_+(j)t]$$
$$-\frac{k_1(j)}{\rho_-(j)[\rho_-(j)-\rho_+(j)]}\Big\{\rho_+(j)+k_1(j)$$
$$-\frac{k_2(j)k_3}{\lambda+\rho_-(j)}\Big\}\exp[\rho_-(j)t]$$

with;

$$2\rho_\pm = -\{[k_1(j)+2k_2(j)+k_3] \pm [k_1(j)^2+4k_2(j)^2+k_3^2-2k_1(j)k_3]^{1/2}\}. \quad (2)$$

By a comparison of Eq. (2) with the experimental curves, the best-fitting values for $k_1(j)$, $k_2(j)$, and k_3 are determined with the aid of an electronic computer. The experimental results are well described by the theory, as is shown in Fig. 6. The Arrhenius plots of $k_1(j)$ and $k_2(j)$ are given in Fig. 8; from them, the activation energies for the exchange reaction can be obtained: 3.6 kcal/mol (=0.16 eV) for the active part of the first layer, 9 kcal/mol (=0.39 eV) for the less-active one, 13 kcal/mol (=0.57 eV) for the active part of the second layer, and 16 kcal/mol (=0.68 eV) for the less-active one.

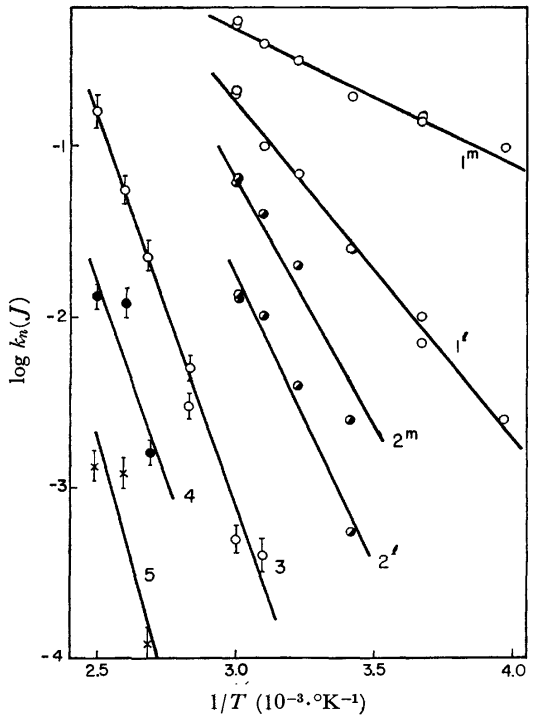

Fig. 8. The Arrhenius plots of the rate constants. The rate constants are given in units of min^{-1}; the numbers in this figure designate the layer's number; the superscripts for number 1 and 2, *m* and *l*, mean the active and the less-active domain, respectively.

In the second-layer exchange reaction, the values of the activation energies are close to each other between the active and less-active parts, and those of the rate constants for the respective parts approach one another with an increase in the temperature. From these results, we may assume that the exchange reaction in the inward layers deeper than the second layer proceeds at rates approximately equal between the two domains. From this point of view, the results of the exchange reaction in these layer may be analyzed as follows.

Since the rate of reaction in the third layer is much lower than that in the second, in analyzing the reaction in the inner layers exceeding the second, it may be assumed that the distribution of ^{36}Cl is in equilibrium between the gaseous phase and the first and second layers. The rates of the reaction in the fourth and fifth layers are similar to the rate in the third; hence, the successive reaction in these layers must be considered. A preliminary analysis of the initial stage of reaction in the third layer showed that the third layer behaves as a uniform one; that is, no remarkable difference in the reactions in the two domains is observed. Thus, the kinetic equation can be given by;

$$dX_g/dt = k_3x_3$$
$$dx_3/dt = -k_3x_3 - k_4x_3 + k_4x_4$$
$$dx_4/dt = k_4x_3 - k_4x_4 - k_5x_4 + k_5x_5, \quad (3)$$

and so on. To obtain a solution, an approximation is made;

$$x_5 = a\cdot\exp(-\gamma t),$$

where γ is an effective rate constant for the decrease in x_5. Then, using the boundary conditions;

$$X_g = 0, \text{ and } x_3 = x_4 = x_5 = a, \text{ at } t = 0,$$

we obtain a solution analogous with Eq. (2);

$$\frac{X_g}{a} = \frac{k_3}{\eta_+-\eta_-}\left\{\frac{k_4k_5}{\gamma}-\eta_+-\eta_--k_3\right\}$$
$$-\frac{k_3k_4k_5}{\gamma(\gamma+\eta_+)(\gamma+\eta_-)}\exp(-\gamma t)$$
$$-\frac{k_3}{\eta_+(\eta_+-\eta_-)}\left\{\eta_-+k_3-\frac{k_4k_5}{\gamma+\eta_+}\right\}\exp(\eta_+t)$$
$$-\frac{k_3}{\eta_-(\eta_--\eta_+)}\left\{\eta_++k_3-\frac{k_4k_5}{\gamma+\eta_-}\right\}\exp(\eta_-t), \quad (4)$$

with;

$$2\eta_\pm = -\{(k_3+2k_4+k_5)\pm(k_3^2+4k_4^2+k_5^2-2k_3k_5)^{1/2}\}.$$

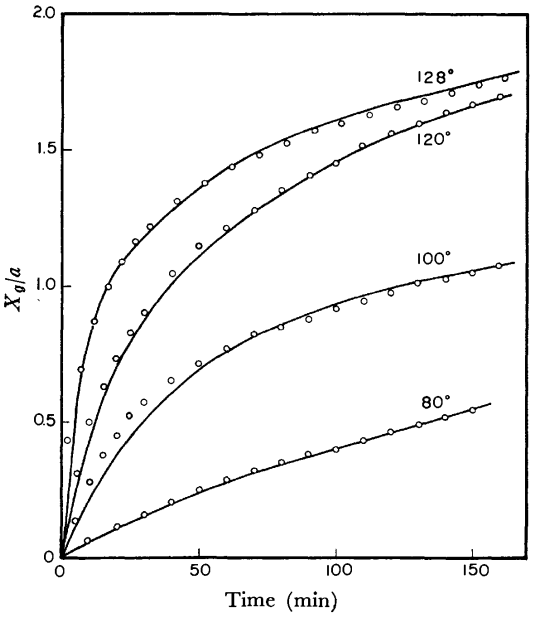

Fig. 9. Counting rates against time curve for the reaction in the third, fourth and fifth layers. Solid curves show the values calculated from Eq. (4).

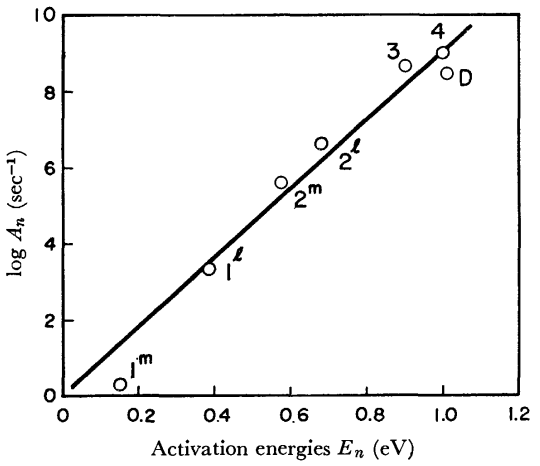

Fig. 10. Linear relationship between log A_n and ΔE_n. A_n is given in the unit of sec^{-1}.

By a comparison of Eq. (4) with the experimental curves obtained, the best-fitting values for k_3, k_4, and k_5 are determined with the aid of a computer. Most of the experimental results are well described by the theory, as is shown in Fig. 9. The Arrhenius plots of k_3, k_4, and k_5 are given in Fig. 8, from which the activation energies for the exchange reaction are obtained: 21 kcal/mol (=0.9 eV) for the third layer and about 23 kcal/mol (=1 eV) for the fourth layer, with some ambiguity.

The actifation energies of the exchange reaction in the surface region converge with that of the self-diffusion in the bulk of nickel dichloride crystallites. This is similar to the previous results on alkali chlorides,[6-8] while the properties of the crystal are remarkably different between nickel dichloride and alkali chlorides.

The relation between the diffusion coefficient, D, and the rate constant, k_d, is given by $D=\frac{1}{2}k_d l^2$, where k_d is the number of jumps per unit time, and l, the distance of a jump. Experssing k_d and k_n in the form $k=A\cdot\exp(-\Delta E/\boldsymbol{k}T)$, we obtain a linear relationship between log A_n and ΔE_n, as is shown in Fig. 10; that is, the Θ-rule holds nearly entirely good in the present case, as in many rate processes.[1]

The present author's sincere thanks are due to Professor T. Takaishi of Rikkyo University for his valuable discussions and to Dr. A. Nakamoto of Rikkyo University for his assistance in the computer calculation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2683—2687 (1972)

Mechanism of Charge-transfer Polymerization. III.[1] Flash Photolysis of *N*-Vinylcarbazole—Chloranil System

Yasuhiko SHIROTA, Kiyoshi KAWAI,* Naoto YAMAMOTO,** Kazuhiro TADA, Tadamasa SHIDA,*** Hiroshi MIKAWA, and Hiroshi TSUBOMURA**

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received February 22, 1972)

Photochemical formation of transient *N*-vinylcarbazole cation and chloranil anion-radicals has been demonstrated by means of flash spectroscopy for the *N*-vinylcarbazole–chloranil–solvent systems. Identification and decay of the species formed by flash illumination are described.

The photochemical reaction of *N*-vinylcarbazole (VCZ) in the presence of an electron acceptor has currently been the subject of great interest. The reaction is complex involving cationic polymerization, cyclodimerization, and in certain cases radical polymerization or copolymerization with an electron-accepting monomer, the reaction course being strongly solvent dependent.[2] For example, in the system VCZ–chloranil(CA), cationic polymerization of VCZ occurs in benzene,[3] while in polar, basic solvents such as acetone, acetonitrile or methanol cyclodimerization of VCZ takes place to form *trans*-1,2-dicarbazylcyclobutane.[2,4] It has been postulated that the reaction proceeds *via* transient VCZ cation-radical formed by the photochemical electron transfer between the donor, VCZ, and an electron acceptor, and the reaction course is explained in terms of the dual reactivity, cationic and radical, of the VCZ cation-radical.[2] However, no direct evidence for the formation of ion-radical intermediates has so far been obtained.

The present study was undertaken to demonstrate the formation of VCZ cation and CA anion-radicals by means of flash spectroscopy for the VCZ–CA–

solvent systems. We reported[5] on the flash photolysis of CA in various solvents, the results of which were utilized for the present analysis. Formation of VCZ cation and CA anion-radicals was confirmed and occurrence of the electron transfer in the photochemical reaction of VCZ in the presence of an electron acceptor has been verified for the first time.[6,7] VCZ cation-radical was confirmed by the radiolytic method established for the selective formation of ion-radicals.

Experimental

Materials. *N*-Vinylcarbazole (VCZ) (Nakarai Chemical Ltd., extra pure grade) was recrystallized twice from methanol, then twice from *n*-hexane and dried *in vacuo* for two or three days at room temperature, mp 65°C. Chloranil (CA) of reagent grade (Wako Pure Chemical Ind. Ltd.) was recrystallized from benzene, then passed through a column of freshly baked calcium carbonate using benzene as an eluent to remove acidic impurities,[8] and then recrystallized twice from benzene, followed by a fractional sublimation *in vacuo*. Acetone was refluxed with potassium permanganate for half a day, dried with calcium sulfate and distilled. Acetonitrile was refluxed over phosphorus pentoxide for 24 hr, distilled and then refluxed over anhydrous potassium carbonate and again distilled immediately before use. Methanol was refluxed with small amounts of sodium metal and distilled. Benzene was purified and dried in the usual way and distilled from sodium wire immediately before use. *sec*-Butyl chloride (*s*-BuCl) (Tokyo Chemical Ind. Co.) was used as received, purity being proved to be good enough for the radiolytic experiment.

Flash Spectroscopy. The concentration ranges of VCZ and CA were 2×10^{-4}—8×10^{-4}M and 1×10^{-4}—2×10^{-4}M, respectively. Freshly prepared solutions were evacuated at 10^{-5} mmHg by several freeze-pump-thaw cycles or bubbled with highly purified nitrogen gas for about 20 min to remove dissolved oxygen, and then poured into a cylindrical silica cell, 1.5 cm in diameter and 20 cm in length. The apparatus is almost the same as that described by Yamamoto *et al.*[9] The transient absorption spectra were obtained photographically with Fuji Neopan SSS film (ASA 200). A combined filter composed of a glass plate and a benzene solution of ethylcarbazole (2×10^{-4}M) was used to cut off the light of wavelength below 350 nm.

Absorption Spectroscopy of γ-Irradiated Rigid Solutions. *N*-Vinylcarbazole in *s*-BuCl was frozen at 77°K to a glassy rigid solution and γ-irradiated at the same temperature (total dose 1.6×10^{19} eV/g). The absorption appearing in the visible to near infrared region was measured with a Cary 14RI spectrophotometer. Further details of the experiment are described elsewhere.[10]

Results and Discussion

N-Vinylcarbazole forms a charge-transfer complex with CA in the ground state (λ_{CTmax} 506 nm, shoulder at 590 nm, in CCl_4). However, in the present experiment no donor-acceptor interaction in the ground state was observed because of the low concentration of the solutions, selective excitation of the acceptor, CA, thus being possible. Absorption of photoenergy by VCZ (*ca.* 2×10^{-4}M) was almost negligible in the wavelength region above 350 nm. When CA was selectively excited by the flash illumination ($h\nu>350$ nm) of a nitrogen-bubbled acetone solution containing 2×10^{-4}M VCZ and 1×10^{-4}M CA at room temperature, a transient absorption spectrum consisting of two band systems was obtained, one with a maximum at 446 nm and a shoulder at 421 nm, and the other a weak, broad band system in the region of wavelength longer than 550 nm (Fig. 1).

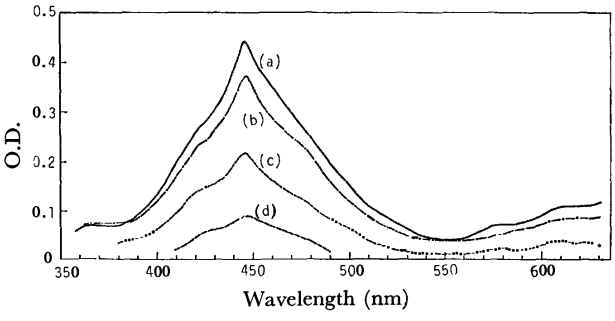

Fig. 1. The absorption spectra of transient species obtained by the flash photolysis of an acetone solution of VCZ (2×10^{-4} M) and CA (1×10^{-4} M). Delay time: (a) 3 μsec (b) 9 μsec (c) 26 μsec (d) 84 μsec. O. D. stands for the optical density.

The former was assigned to CA anion-radical from its identity with the spectrum of the chemically prepared CA anion-radical in acetone.[11] The latter was attributed to VCZ cation-radiacl as the most reasonable counterpart of the CA anion. Its intensity was found to decrease with increasing concentration of VCZ, which suggests the occurrence of the reaction of VCZ cation-radical formed with VCZ monomer. The assignment was substantiated by γ-irradiation of VCZ in *s*-BuCl at 77°K which is known to produce exclusively the solute cation.[10,12] The absorption spectrum of the VCZ cation observed for the irradiated frozen solution is shown in Fig. 2. The authenticity of the spectrum as due to VCZ cation would be supported by the fair agreement of the result of calculation shown by the sticks in Fig. 2. The result was obtained by using a computer program[13] for the SCF-MO calculation of open-shell molecules.[14] The absorption identified with the VCZ cation (Fig. 2) may be compared favorably with the absorption (Fig. 1) at wave-

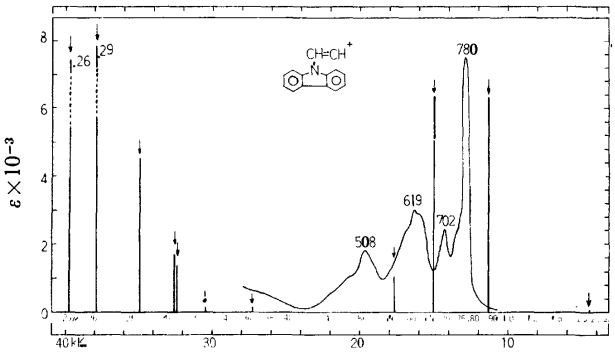

Fig. 2. The absorption spectrum of VCZ cation-radical produced by γ-ray irradiation of VCZ in *s*-BuCl matrix at 77°K. The sticks represent the theoretical spectrum obtained by an SCF-MO calculation for the cation. The left ordinate refers to the molar extinction coefficient of the experimental spectrum while the right refers to the oscillator strength of the theoretical spectrum. The numbers at peak are the wavelengths in unit of nm.

lengths longer than 550 nm (due to the limitation in the film, the absorption beyond 650 nm in Fig. 1 could not be measured).

For comparison with the VCZ–CA system the absorption spectrum obtained by the flash illumination of CA only in acetone solution is shown in Fig. 3. It should be noted that no pure absorption of CA anion-radical was obtained in this case. The *T-T'* absorption of CA appeared in the region 450—550 nm at the delay time of 3 μsec and faded away mostly at 17 μsec, and the bands at *ca.* 440 nm and *ca.* 370 nm which persisted after disappearence of *T-T'* absorption were regarded as due to the mixture of CA semiquinone radical and CA anion-radical.[5] The absorption spectra of CA semiquinone radical and CA anion-radical are similar, but the semiquinone radical has a second band at λ_{max} 357—375 nm,[5] while the anion-radical has none in this region. The absorption spectrum of CA semiquinone radical has been obtained by the flash photolysis of CA in tetrahydrofuran as a result of hydrogen abstraction reaction from the solvent by the excited CA, showing a band at λ_{max} 437 nm with a shoulder at 414 nm and a band at λ_{max} 375 nm.[5] Although a very weak, broad band system was also observed beyond 550 nm even with CA only in acetone solution, it decayed at nearly the same rate as for the triplet state of CA and was assigned to the charge-transfer band between the solvent as a donor and triplet CA as an acceptor. The same phenomenon was found in a benzene solution.[5]

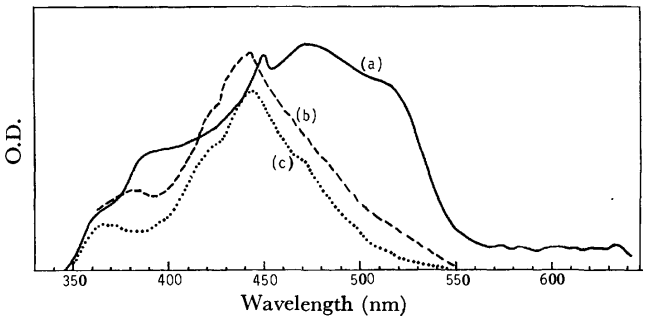

Fig. 3. The absorption spectra of transient species obtained by the flash photolysis of CA (2.3×10^{-4} M) in acetone. Delay time: (a) 3 μsec (b) 17 μsec (c) 56 μsec.

Chloranil anion-radical formed in an acetone solution of VCZ and CA decayed at a diffusion-controlled rate (Fig. 4). A rate constant $k=2.1\times10^{10}$M^{-1}sec^{-1} was obtained by using the molar extinction coefficient $\varepsilon=9\times10^{3}$ reported for CA anion-radical at its abosrption.[10]

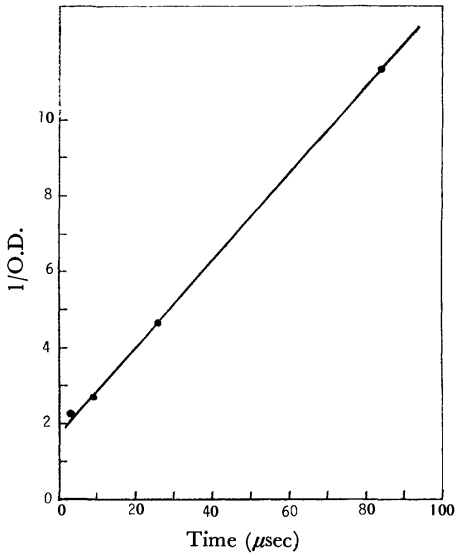

Fig. 4. Plots of second-order kinetics for the decay of CA anion-radical at 446 nm formed in an acetone solution of VCZ (2×10^{-4} M) and CA (1×10^{-4} M).

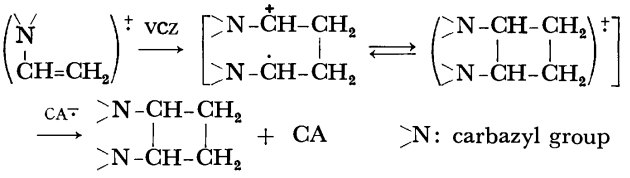
The second-order decay of CA anion-radical indicates a bimolecular recombination between VCZ cation and CA anion-radicals and/or between VCZ dimer cation-radical and CA anion-radical, which is consistent with the proposed mechanism for the cyclodimerization of VCZ,[2,4] if the reaction proceeds under the conditions of the present flash photolysis as in the preparatory scale reaction.



The kinetic observation in an acetone solution may be explained in terms of the following scheme of reactions.

$$VCZ + CA \xrightarrow{h\nu} VCZ^{+\cdot} + CA^{-\cdot} \quad (1)$$

$$VCZ^{+\cdot} + CA^{-\cdot} \xrightarrow{k_1} VCZ + CA \quad (2)$$

$$VCZ^{+\cdot} + VCZ \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} VCZ_2^{+\cdot} \quad (3)$$

$$VCZ_2^{+\cdot} + CA^{-\cdot} \xrightarrow{k_3} VCZ_2 + CA \quad (4)$$

The rate equation of the decay of CA anion-radical is

$$-d[CA^{-\cdot}]/dt = k_1[CA^{-\cdot}]\{[VCZ^{+\cdot}] + (k_3/k_1)[VCZ_2^{+\cdot}]\}, \quad (5)$$

where

$$[VCZ^{+\cdot}] + [VCZ_2^{+\cdot}] = [CA^{-\cdot}] \quad (6)$$

$$[VCZ_2^+]/[VCZ^+][VCZ] = k_2/k_{-2} = K \quad (7)$$

Substituting Eqs. (6) and (7) into (5) we obtain

$$-d[CA^-]/dt = k_1[CA^-]^2\left\{\frac{1+(k_3/k_1)K[VCZ]}{1+K[VCZ]}\right\} = k_1C[CA^-]^2, \quad (8)$$

$([CA^-] \ll [VCZ])$ C: constant

which is the second-order decay equation. The following rate equation is derived from the above scheme of reactions where the process k_{-2} is not considered in Eq. (3), if the rate constant k_1 is assumed to be equal to k_3.

$$-d[CA^-]/dt = k_1[CA^-]^2 \quad (9)$$

If the absorption at longer wavelengths in Fig. 1 is due to the VCZ cation, it should be observed irrespective of solvent. When acetonitrile was used in place of acetone, the solution of VCZ (2.5×10^{-4}M) and CA (1×10^{-4}M) gave the spectrum shown in Fig. 5 which is similar to Fig. 1 and may be interpreted in terms of the formation of VCZ cation and CA anion-radicals. In contrast to the solution containing the two solutes CA only in acetonitrile showed the absorption shown in Fig. 6. This can be attributed to T-T' absorption of CA and the absorption mainly due to the semiquinone radical. No absorption appeared at the wavelength longer than 550 nm.

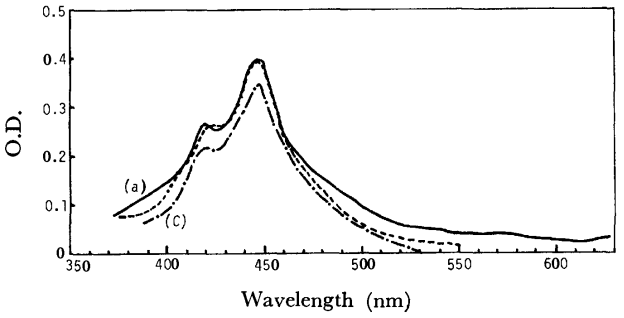


Fig. 5. The absorption spectra of transient species obtained by the flash photolysis of an acetonitrile solution of VCZ (2.5×10^{-4} M) and CA (1×10^{-4} M). Delay time: (a) 4 μsec, (b) 9 μsec, (c) 250 μsec.

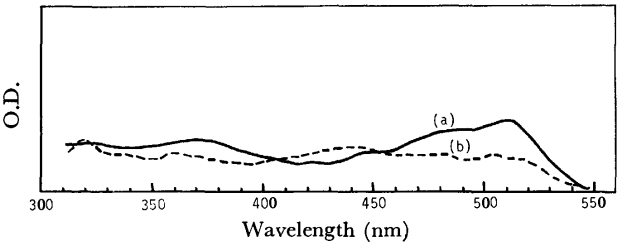

Fig. 6. The absorption spectra of transient species obtained by the flash photolysis of CA (1.4×10^{-4} M) in acetonitrile. Delay time: (a) 3 μsec. (b) 26 μsec.

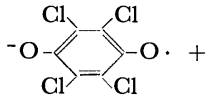
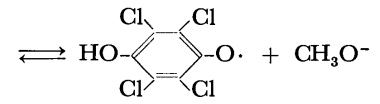
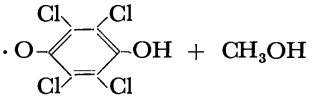
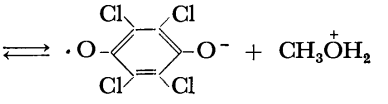
The transient absorption spectrum obtained in methanol is shown in Fig. 7. In methanol the spectrum in the region 400—500 nm differs somewhat in shape from that observed in acetone or in acetonitrile, showing two bands at λ_{max} 426 and 451 nm. The absorption attributable to VCZ cation-radical appeared at a wavelength longer than 550 nm. The absorption bands in the region 400—500 nm are almost the same as those obtained by the flash photolysis of CA only in methanl and interpreted as an admixture of the absorption of CA anion-radical and CA semiquinone radical. The semiquinone radical is suggested to be formed by the protonation of the anion-radical initially formed.





In the flash photolysis of CA only in methanol the spectrum obtained is composed of the T-T' absorption, the absorption of the semiquinone radical and of the anion-radical. No absorption appeared at a wavelength longer than 550 nm (Fig. 8). In this case the initially formed semiquinone radical by the hydrogen abstraction reaction of the excited CA from the solvent dissociates into the anion-radical and is in equilibrium with the latter species.





The acid-base equilibrium between the semiquinone radical and the anion-radical (semiquinone anion) in

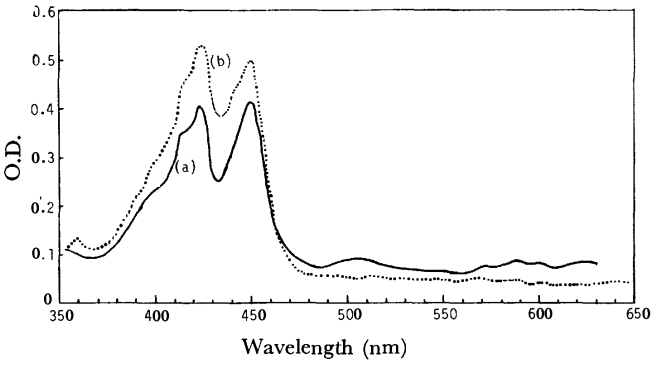


Fig. 7. The absorption spectra of transient species obtained by the flash photolysis of a methanol solution of VCZ (2×10^{-4} M) and CA (1×10^{-4} M). Delay time: (a) 3 μsec (b) 8.5 μsec.

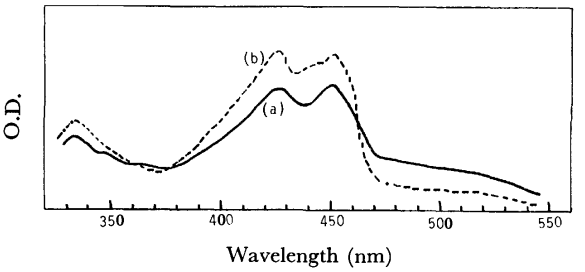

Fig. 8. The absorption spectra of transient species obtained by the flash photolysis of CA (1.8×10^{-4} M) in methanol. Delay time: (a) 3 μsec (b) 16 μsec.

methanol has also been shown by Bridge and Porter[15] in the flash photolysis of duroquinone.

Noticeably, CA anion-radical formed in acetonitrile or in methanol persisted for a much longer time than in acetone under comparable conditions. Details are not available at present and further studies are needed with respect to this point. Flash photolysis of the system VCZ–CA was also carried out in benzene solution, but the absorption bands obtained were very low in intensity and no definite conclusions were reached.

Transient CA anion and VCZ cation-radicals were detected in the VCZ–CA–solvent systmes by selective excitation of the acceptor, while in the absence of VCZ no pure absorption of CA anion-radical was obtained. This confirms the fact that photochemical electron transfer took place between VCZ and the excited CA in polar solvents. This seems to be the first example to demonstrate the occurrence of electron transfer in the photochemical reaction of VCZ in the presence of an electron acceptor.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2687—2692 (1972)

A New Theory of Melting at High Pressures

Hitoshi KANNO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received March 14, 1972)

As an improvement of the significant structure theory, a new partition function of monatomic liquid was derived:

$$Z_l(T, V_l) = \left\{\prod_{i=1}^{3N_v}\left[2\sinh\left(\frac{h\nu_i}{2kT}\right)\right]^{-1}\right\}\left\{\left(\frac{2\pi mkT}{h^2}\right)^{3/2}\frac{eV_f}{N_t}\right\}^{N_t}\exp\left\{-\frac{\Phi_l(V_l)}{kT}\right\}$$

where $3N_v$ and $3N_t$, ($N_v+N_t=N$; Avogadro number), are the numbers of freedom in vibrational and translational motions, respectively, ν_i the i-th normal vibration in the vibrational motion, m the mass of molecule, V_f the free volume of liquid, and $\Phi_l(V_l)$ the configurational potential energy of liquid. Melting of argon at high pressures is successfully interpreted by means of the partition function.

Theoretical interpretations of melting in terms of the partition function have been made by a number of investigators.[1-3] Of the theories suggested, few can give a satisfactory quantitative description of melting. This is connected partly with the confused state of theory of melting and partly with the inadequacy and/or the mathematical difficulty of various proposed partition functions of liquid. A satisfactory interpretation of melting seems to be achieved by the finding of a good partition function for liquid.

Though the significant structure theory of liquid developed by Eyring and his co-workers[4] yields good numerical agreement with experiment for a number of the thermodynamic properties of many types of liquids, Tuerpe and Keeler[5] have shown that it does not give a satisfactory description of melting phenomenon at high pressures. The theory, however, suggests two important facts: (1) the liquid consists of both vibrational and translational degrees of freedom, and (2) the partition function of liquid must be analogous to that of solid near the melting point and to that of gas toward the gas region.

Bearing these concepts in mind it seems worthwhile to investigate the possibility of deriving the partition function of liquid which is applicable to the melting process at high pressures. The purposes of this study are to present a new partition function of liquid differing somewhat from Eyring's one,[4] and to apply it to the melting phenomenon, in particular the melting of argon at high pressures.

Theoretical

Adopting the concept of the significant structure theory[4] that both vibrational and translational degrees of freedom coexist in the liquid state, let us assume that the number of atoms in the vibrational motion is N_v and that the number in the translational motion is N_t ($=N-N_v$, N: Avogadro number). Accordingly the numbers of freedom $3N_v$ and $3N_t$ are distributed between the two motions in the liquid. The significant structure theory also considers that movable holes of mocleular size produced by volume increase accompanying fusion and thermal expansion confer the translational degrees of freedom on some fractions of molecules of the liquid.

5) D. R. Tuerpe and R. N. Keeler, *J. Chem. Phys.*, **47**, 4283 (1967).

If we assume that a hole in liquid moves about as freely as does a molecule in vapor, it is to be expected that a molecule in the translational motion can share the whole excess volume of the liquid. In other words, the molecules in the translational motion are statistically indistinguishable. Consider a molecule in the translational motion in the liquid. It may move randomly from one position into a neighboring hole by producing a hole behind and may be oscillatory there, but another molecule begins to make translational motion by jumping into the hole. So, as a whole, it may be visualized that a hole in the liquid moves freely from one position to another similar to a gas molecule in vapor. This view has been proposed and supported by many theoretical approaches and experimental evidences,[4,6-8] though not without a few objections.[9]

The energy level in the vibrational motion is given by

$$\varepsilon_i = h\nu_i\left(n_i+\frac{1}{2}\right) \tag{1}$$

where ν_i is the normal vibration of the i-th freedom in the vibrational motion, n_i the quantum number specifying vibrational state. The kinetic energy of the particle in the translational motion is

$$\frac{1}{2m}p_j^2 = \frac{1}{2m}(p_{xj}^2+p_{yj}^2+p_{zj}^2) \tag{2}$$

where p_{xj}, p_{yj}, and p_{zj} are, respectively, the x-, y-, and z-components of momentum p_j, and m the mass of molecule. Thus the energy state of the liquid is designated by the quantum numbers n_i ($i=1, 2, \cdots 3N_v$) of normal vibration, momenta p_j ($j=1, 2, \cdots N_l$) of atoms in the translational motion and the configurational potential energy arising from intermolecular forces $\Phi_l(V_l)$. Hence the total internal energy of the system is represented as follows.

$$E_l(V_l, n_i, p_j) = \Phi_l(V_l) + \sum_{i=1}^{3N_v}\left(n_i+\frac{1}{2}\right)h\nu_i + \sum_{j=1}^{N_l}\frac{p_j^2}{2m}. \tag{3}$$

Since the sum of states for one particle in the translational motion is given by

$$z_j = \int_{-\infty}^{+\infty}\int\int\int_{volume}\exp\left(-\frac{p_j^2}{2mkT}\right)\frac{1}{h^3}\mathrm{d}p_{xj}\mathrm{d}p_{yj}\mathrm{d}p_{zj}\mathrm{d}x\mathrm{d}y\mathrm{d}z \tag{4}$$

and the sum of states for the i-th vibrational motion is

$$z_i = \sum_{n_i=0}^{\infty}\exp\left\{-\frac{\left(n_i+\frac{1}{2}\right)h\nu_i}{kT}\right\} = \left\{2\sinh\left(\frac{h\nu_i}{2kT}\right)\right\}^{-1}, \tag{5}$$

the partition function for the liquid composed of N monatomic molecules is

$$Z_l(T, V_l) = \sum_{states}\exp\left\{-\frac{E_l(V_l, n_i, p_j)}{kT}\right\}$$
$$= \left\{\prod_{i=1}^{3N_v}z_i\right\}\frac{1}{N_l!}\left(\prod_{j=1}^{N_l}z_j\right)\exp\left\{-\frac{\Phi_l(V_l)}{kT}\right\}$$
$$= \left\{\prod_{i=1}^{3N_v}\left[2\sinh\left(\frac{h\nu_i}{2kT}\right)\right]^{-1}\right\}$$
$$\times\left\{\left(\frac{2\pi mkT}{h^2}\right)^{3/2}\frac{eV_f}{N_l}\right\}^{N_l}\exp\left\{-\frac{\Phi_l(V_l)}{kT}\right\}, \tag{6}$$

where V_f is the free volume of the liquid.[10] In this calculation it was assumed that each degree of freedom is separable. We also used Stirling's approximation $N_l! = (N_l/e)^{N_l}$ for the factorial $N_l!$ in the denominator of the partition function which arises from the indistinguishability of the particles in the translational motion. The condition for the validity of Eq. (6) is the separability of the internal energy into kinetic (vibrational and translational) and potential parts.

The Helmholtz free energy of the liquid becomes

$$F_l(T, V_l) = -kT\log Z_l(T, V_l)$$
$$= \Phi_l(V_l) + kT\sum_{i=1}^{3N_v}\log\left\{2\sinh\left(\frac{h\nu_i}{2kT}\right)\right\}$$
$$-N_lkT\log\left\{\left(\frac{2\pi mkT}{h^2}\right)^{3/2}\frac{eV_f}{N_l}\right\} \tag{7}$$

There are two efficient approximation methods for the vibrational term in Eq. (7); Debye's approximation[11] and Einstein's.[12] According to the former, the number of modes of vibration in the frequency range from ν to $\nu+\mathrm{d}\nu$ is given by

$$g(\nu) = \frac{9N_v}{\nu_m^3}\nu^2$$

where ν_m is the highest allowed frequency of the vibration of the system. Applying this approximation to the vibrational term in Eq. (7), we get

$$F_l(T, V_l) = \Phi_l(V_l)$$
$$+ 9kN_vT(T/\theta_l)^3\int_0^{\theta_l/T}x^2\log\left\{2\sinh\left(\frac{x}{2}\right)\right\}\mathrm{d}x$$
$$-N_lkT\log\left\{\left(\frac{2\pi mkT}{h^2}\right)^{3/2}\frac{eV_f}{N_l}\right\} \tag{8}$$

where $\theta_l(=h\nu_m/k)$ is the characteristic temperature of liquid. It is expected that θ_l is more strongly temperature dependent than that of solid.

Equation (8) has the same asymptotic behaviour as Eyring's equation:[4] When N_l approaches zero, Eq. (8) gives the Helmholtz free energy of a solid, and when N_v goes to zero, we have the Helmholtz free energy of a real gas.

In principle we can now derive all the thermodynamic properties of liquid from the usual thermodynamic equations, but in order to make further progress it is necessary to know the exact values of N_l (or N_v), θ_l, $\Phi_l(V_l)$, and V_f or their exact forms as functions of T and V_l.

According to the significant structure theory,[4] N_l, N_v, and V_f are represented by

$$N_l = N\left(\frac{V_l-V_s}{V_l}\right)$$

7) H. Eyring, *J. Chem. Phys.*, **4**, 283 (1936).
8) Dan McLachan, Jr., and Ernest G. Ehlers, *J. Geophys. Res.*, **76**, 2780 (1970).
9) J. H. Hildebrand and G. Archer, *Proc. Nat. Acad. Sci. U. S.*, **47**, 1881 (1961).
10) The term "free volume" is used in the free volume theory in a different meaning. In this theory, it is referred to as the sum volume of movable holes in the liquid.
11) P. Debye, *Ann. Physik.*, **39**, 789 (1912).
12) A. Einstein, *ibid.*, **22**, 180 (1970).

$$N_v = N\left(\frac{V_s}{V_l}\right) \tag{9}$$
$$V_f = V_l - V_s$$

where V_s and V_l are the volume of solid at melting point and the volume of liquid, respectively. These relations were derived on the assumption that in one mole of liquid there are $(V_l-V_s)/V_s$ moles of holes of molecular size and that the whole excess volume (the sum of the volumes of the movable holes) is communally utilized by the molecules in the translational motion. If we assume that a hole in the liquid completely surrounded by other molecules moves freely like a gas molecule in a vapor, the effective number of holes (the number of molecules in the translational motion) which behave like a gas molecule is obtained by multiplying the number of holes $N(V_l-V_s)/V_s$ by the probability of molecules occupying the positions around the hole V_s/V_l. The relation (9) are expected to be valid for the liquid forming closed packed crystal or nearly closed packed crystal and for the region not far from melting point. Adopting these relations to our formulation, we obtain the following expression for the Helmholtz free energy of liquid

$$F_l(T, V_l) = \Phi_l(V_l) + 9RT(V_s/V_l)(T/\theta_l)^3\int_0^{\theta_l/T} x^2 \log\left\{2\sinh\left(\frac{x}{2}\right)\right\}dx - RT\left(\frac{V_l-V_s}{V_l}\right)\log\left\{\left(\frac{2\pi mkT}{h^2}\right)^{3/2}\frac{eV_l}{N}\right\} \tag{10}$$

Now let us consider the melting process of monatomic molecule substances such as inert gas elements. From the thermodynamical point of view, fusion takes place when the Gibbs free energies of solid and of liquid intercept each other. This is expressed by the equation

$$F_s(T, V_s) + PV_s = F_l(T, V_l) + PV_l \tag{11}$$

where P is the pressure of the system.

In connection with the equation of liquid we formulated, we employ the partition function of Debye type for the solid phase. The Helmholtz free energy of the solid phase is thus given by

$$F_s(T, V_s) = \Phi_s(V_s) + 9RT(T/\theta_D)^3\int_0^{\theta_D/T} x^2 \log\left\{2\sinh\left(\frac{x}{2}\right)\right\}dx \tag{12}$$

where $\Phi_s(V_s)$ is the configurational potential energy of solid, and θ_D the Debye characteristic temperature of the solid.

The theory of melting is required to be capable of evaluating the temperature of melting, the change of volume and the latent heat of melting from intermolecular potential. In this paper, however, the reverse method is employed to test the applicability of the present model since the adoption of the crude theories for evaluating the values of $\Phi_l(V_l)$ and θ_l may obscure the applicability of Eq. (10).

We choose the entropy change upon fusion and the volumes of solid and liquid at the triple point as adjustable parameters and adjust the characteristic temperature (θ_l) and the configurational potential energy of liquid $\Phi_l(V_l)$ to the condition of Eq. (11) at the triple point. Then with the aid of Eq. (11) we calculate the melting point, entropy change upon fusion, internal energies and entropies of both phases at the pressure P and compare them with experimental data.

From Eq. (10), we get

$$S_l(T,\theta_l) = -\frac{\partial F_l(T,\theta_l)}{\partial T} = -9R\left(\frac{V_s}{V_l}\right)\left(\frac{T}{\theta_l}\right)^3\int_0^{\theta_l/T} x^2\log\left\{2\sinh\left(\frac{x}{2}\right)\right\}dx + 4.5R\left(\frac{V_s}{V_l}\right)\left(\frac{T}{\theta_l}\right)^3\int_0^{\theta_l/T} x^3\coth\left(\frac{x}{2}\right)dx + R\left(\frac{V_l-V_s}{V_l}\right)\log\left\{\left(\frac{2\pi mkT}{h^2}\right)^{3/2}\frac{eV_l}{N}\right\} + \frac{3}{2}R\left(\frac{V_l-V_s}{V_l}\right) \tag{13}$$

and for the solid we obtain

$$S_s(T,\theta_D) = -9R(T/\theta_D)^3\int_0^{\theta_D/T} x^2\log\left\{2\sinh\left(\frac{x}{2}\right)\right\}dx + 4.5R(T/\theta_D)^3\int_0^{\theta_D/T} x^3\coth\left(\frac{x}{2}\right)dx \tag{14}$$

Accordingly, the entropy change on fusion (ΔS_m) is given by

$$\Delta S_m = S_l(T_m,\theta_l) - S_s(T_m,\theta_D) \tag{15}$$

With the aid of Eqs. (13), (14), and (15), and the observed values of V_s, V_l, and θ_D, we can determine the value of θ_l by fitting the calculated ΔS_m to experiment at the triple point. At the triple point of argon (T_m=83.81 K), the observed values of V_s, V_l, and ΔS_m are 24.614,[13] 28.332 ml,[13] and 3.395 cal/mol K,[14] respectively. With the value of θ_D=80 K,[15] Eq. (15) gives the value θ_l of 54.8 K. Determination of $\Phi_l(V_l)$ at the triple point is a straightforward numerical problem: it is solved by utilizing the evaluated values of θ_l and $\Phi_s(V_s)$ and by satisfying Eq. (11). As the value of $\Phi_s(V_s)$ is -1955 cal/mol at the triple point,[16] the value of $\Phi_l(V_l)$ which is found to satisfy Eq. (11) is -1624 cal/mol. In this calculation we can neglect the terms PV_s and PV_l in Eq. (11) as they are small compared to $F_s(T, V_s)$ and $F_l(T, V_l)$ at ordinary pressures.

Next we proceed to consider the melting of argon at high pressures. We cannot now neglect the PV terms in Eq. (11), and several plausible approximations and estimations must be introduced to achieve numerical calculations. At high pressures the pressure effect on $\Phi_s(V_s)$, $\Phi_l(V_l)$, θ_D, and θ_l must be taken into account. For the configurational potential energy of the solid, we use the equation[16]

$$\Phi_s(V_s) = -\frac{z}{2}N\varepsilon\left\{2.4090\left(\frac{N\sigma^3}{V_s}\right)^2 - 1.0109\left(\frac{N\sigma^3}{V_s}\right)^4\right\} \tag{16}$$

13) K. Clusius and K. Weigand, *Z. Physik. Chem.*, **B46**, 1 (1940).

15) K. Clusius, *Z. Physik. Chem.*, **B31**, 459 (1936).
16) R. H. Wentorf, R. J. Beuhler, J. O. Hirschfelder, and C. F. Curtiss, *J. Chem. Phys.*, **18**, 1484 (1950). The values $\varepsilon=165\times10^{-16}$ ergs and $\sigma=3.41\times10^{-8}$ cm obtained by E. Whalley and W. G. Schneider, *J. Chem. Phys.*, **23**, 1644 (1955) were used in numerical calculations.

where z is the number of nearest neighbor molecules, σ and ε are, respectively, the distance and energy characteristics of the system in the 6—12 Lennard-Jones potential, *i.e.*,

$$\phi(r) = 4\varepsilon\left\{\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6}\right\} \tag{17}$$

To obtain the value of $\Phi_l(V_l)$ at the pressure P, we introduce the approximation

$$\Phi_l(V_l) = \left(\frac{V_s}{V_l}\right)A \cdot \Phi_s(V_s) \tag{18}$$

where A is an adjustable parameter and determined to fit the data at the triple point. For the sake of simplicity A is taken to be independent of pressure, *i.e.*, constant. This approximation is based on the facts that the change of configurational potential energy on melting is mainly due to the decrease of the number of nearest neighbor molecules and that in the case of inert gas elements the contribution to the configurational potential energy from the non-nearest neighbor molecules is not so large. Combining the observed values of $\Phi_s(V_s) = -1955$ and $\Phi_l(V_l) = -1624$ cal/mol at the triple point, the value of A is found to be 0.9564.

The Grüneisen law[17] may be used to take account of the pressure effect on the characteristic temperature of both phases:

$$\gamma = -\frac{\partial \log \theta}{\partial \log V} \tag{19}$$

where γ is the Grüneisen parameter and θ the characteristic temperature of the system. If we assume that the Grüneisen parameter is constant, Eq. (19) may be integrated at once to yield

$$\begin{aligned} \gamma_s \log\left(\frac{V_s}{V_s^0}\right) &= \log\left(\frac{\theta_D^0}{\theta_D}\right) \\ \gamma_l \log\left(\frac{V_l}{V_l^0}\right) &= \log\left(\frac{\theta_l^0}{\theta_l}\right) \end{aligned} \tag{20}$$

where θ_D^0 and θ_l^0 are respectively the Debye temperature of solid and the characteristic temperature of liquid at a reference melting point. V_s^0 and V_l^0 are the corresponding volumes of solid and liquid, γ_s and γ_l are the Grüneisen parameters of solid and liquid, respectively. It seems clear that in the case of liquid phase the accuracy of Eq. (20) is not very high.

Although some of these approximations are not rigorous enough for accurate computations, it is expected that they are valid enough to show the main feature of melting phenomenon at high pressures. Once the values of $\Phi_s(V_s)$, $\Phi_l(V_l)$, θ_D, and θ_l are known as functions of volume of the system, we can evaluate the melting point, latent heat of fusion, internal energy of the system at the pressure P with the aid of Eq. (11) and the observed values of V_s and V_l at the melting point corresponding to P.

Calculations and Discussion

The results of calculations together with the experimental data[18] are shown in Table 1. The calculation procedure was follows. At first the values of $\Phi_s(V_s)$, $\Phi_l(V_l)$, θ_D, θ_l, N_t, and V_f were calculated by use of Eqs. (9), (16), (18), and (20), and the observed values of V_s and V_l at the melting point T_m of the pressure P.[18] We adopted the triple point of argon as a reference point. The value of γ_s and γ_l were assumed to be 2.21 and 2.10, respectively. Then substituting these values into Eq. (11), we found the melting temperature of the system at the pressure P, and using this calculated temperature the entropies and the internal energies of both phases were evaluated. Though the value of γ_s was taken from the data (the value of 80 K) summarized by Pollack,[19] the value of γ_l was chosen so as to fit the calculations to the experimental data. The internal energy was calculated by use of the well-known thermodynamic relation

$$E(T) = -T^2\left\{\frac{\partial}{\partial T}\left(\frac{F}{T}\right)\right\} \tag{20}$$

Agreement between calculation and experiment[18] is excellent, but it is interesting to not that all the calculated ΔS_m, $S_l(T_m)$, $S_s(T_m)$, $E_l(T_m)$, and $E_s(T_m)$ values are systematically smaller in their absolute values than the corresponding observed values. This is considered to be in part due to the errors inherent in the various approximations introduced and to the neglect of anharmonic effect of vibrational motions in both solid and liquid. Bridgman[20] also reported the entropy change on fusion of argon at high pressures. The reported values of ΔS_m are 10.31, 8.64, 7.49, 6.64, 6.07, and 5.62 J/mol K at melting temperatures 106.3, 126.4, 144.9, 162.0, 178.0, and 193.1 K, respectively. They are all lower than the corresponding calculated values.

200	$199._5$	2.10	7.9_3	−2816	57.2_2

a) Temperature is in degrees Kelvin (K). Entropies are in joules per mole K (J/mol K) and energies in joules per mole (J/mol).
b) The value of γ_l was chosen so as to give the observed melting temperature at pressure P. The value of γ_s was assumed to be 2.21.

Dugdale and Frank[21] showed that in the case of solid helium the Debye temperature depends only on volume to a first approximation and that the Grüneisen law, *i.e.*, $\gamma_s = -\mathrm{d}\log\theta_D/\mathrm{d}\log V_s$, holds well along the melting curve up to high pressures. By fixing γ_s constant, *i.e.*, $\gamma_s = 2.21$, we can determine the value of γ_l which gives observed melting temperature at P. The variation of γ_l with the increase in pressure is shown in Table 2 along with the entropy change upon fusion, internal energy and entropy of liquid. The fact that γ_l approaches the value of γ_s with the increase in pressure expects that thermodynamic properties of liquid resemble more and more those of solid with the increase in pressure. Although the value of γ_s was fixed constant throughout the calculations, γ_s also varies with volume and temperature.

From Eq. (20), the specific heat of liquid at constant volume is obtained as

Table 3. Specific heat of liquid inert gas element at melting point[a]

Element	Mp	θ_D	ΔH_m	θ_l (Calcd)	$CV_l(T_m,\theta_l)$ (Obsd)	$CV_l(T_m,\theta_l)$ (Calcd)
Ne	24.56	64	80.1	40.3	4.42[a]	4.92
Ar	83.81	80	284.5	54.8	5.50[b] 5.19[c]	5.46
Kr	115.78	63	392.0	44.0	5.38[d]	5.53
Xe	161.37	55	548.5	35.9	—	5.66

a) Melting temperature, θ_D and θ_l are in degrees Kelvin (K), ΔH_m (heat of fusion) is in calories per mole (cal/mol), $CV_l(T_m,\theta_l)$ is in calories per mole K (cal/mol K).
Sources of data: θ_D: K. Clusius, *Z. Phys. Chem.* (Leipzig), **B31**, 459 (1936). ΔH_m, V_s, and V_l: Gerald L. Pollack, *Rev. Mod. Phys.*, **36**, 748 (1964). $CV_l(T_m,\theta_l)$ observed; estimated from a) C. Gladun, *Cryogenics*, **6**, 27 (1966); b) A. Eucken and F. Hauk, *Z. Phys. Chem.*, **134**, 161 (1928); c) C. Gladun and F. Menzel, *Cryogenics*, **10**, 210 (1970); d) C. Gladun, *ibid.*, **11**, 205 (1971).

$$CV_l(T,\theta_l) = \left\{\frac{\partial E_l(T,\theta_l)}{\partial T}\right\}_V$$
$$= 9R\left(\frac{V_s}{V}\right)\left(\frac{T}{\theta_l}\right)^3\int_0^{\theta_l/T}\frac{x^4e^x}{(e^x-1)^2}\mathrm{d}x$$
$$+\frac{3}{2}R\left(\frac{V_l-V_s}{V_l}\right) \tag{21}$$

With the aid of the computed θ_l value, we can evaluate $CV_l(T_m, \theta_l)$. Comparison of the calculated $CV_l(T_m, \theta_l)$ with experiment is given in Table 3 together with the data of other inert gas elements. Though the calculated $CV_l(T_m, \theta_l)$ value deviates systematically from experimental value for all inert gas elements, the agreement is fairly good. The fact that deviation between calculation and experiment becomes larger from krypton (xenon) to neon is attributable to the underestimation of the number of freedom in the translational motion. In other words, Eq. (9) gives a lower value than the actual one for the N_l value. The reason is as follows. From classical theory one would expect the V_s value at 0 K and zero pressure to be equal to $N\sigma^3$. For krypton and xenon this holds within experimental error and for argon this is nearly true, but for neon and helium the actual molar volumes are very much larger than those given by the formula $N\sigma^3$. Accordingly the validity of Eq. (9) is lost in the cases of neon and helium.

We used a most simple form for evaluating configurational potential energy of liquid, but it is to be pointed out that Eq. (18) does not give asymptotic consistency: it does not yield the potential of solid when V_l approaches V_s. However, the good agreement with experiment leads to the conclusion that the approximation is rather adequate for the evaluation of $\Phi_l(V_l)$. Obviously a detailed theoretical study for the accurate calculation of the configurational potential energy of liquid is required to complete the present theory. It seems very likely that development of the

radial distribution function method[22,23] and/or the Monte Carlo method[24,25] will suffice the requirement in near future.

At the present time some ambiguities exist in the present theory, especially in the calculations of $\Phi_l(V_l)$, N_l (or N_v), V_f, θ_l, and γ_l. Neverthless there is little doubt that the partition function of liquid given here will work well for the liquid composed of monatomic molecules. A more detailed application of the partition function is clearly bounded up with a better understanding of the volume and temperature dependencies of $\Phi_l(V_l)$, N_l, V_f, θ_l, and γ_l.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2692—2694 (1972)

On the Change of Electrical Conductivity of Metal on Melting

Hitoshi KANNO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received April 4, 1972)

A partition function of liquid recently proposed by the present author[1] has been applied to the change of the electrical conductivity of metal at melting point. The relation between σ_s/σ_l and θ_D/θ_l is more successfully interpreted by this partition function than that used by Mott.[2]

It was previously reported that a partition function proposed by the author was successfully applied to the melting of argon at high pressures.[1] The partition function of N monatomic liquid is

$$Z_l(T, V_l) = \left\{ \prod_{i=1}^{3N_v} \left[2 \sinh\left(\frac{h\nu_i}{2kT} \right) \right]^{-1} \right\} \times \left\{ \left(\frac{2\pi mkT}{h^2} \right)^{3/2} \frac{eV_f}{N_l} \right\}^{N_l} \exp\left\{ -\frac{\Phi_l(V_l)}{kT} \right\} \quad (1)$$

where N_l and N_v, $(N_l+N_v=N)$, are respectively the numbers of molecules in translational and vibrational motions, ν_i is the normal mode of the i-th vibrational motion, m the mass of a molecule, V_f the free volume of the liquid, and $\Phi_l(V_l)$ the configurational potential energy of the liquid.

It is worthwhile applying the partition function to other systems in order to examine its applicability and validity. The application to liquid metals is described in this paper with special emphasis on the characteristic temperature of liquid (θ_l). Correlation between σ_s/σ_l (σ: electrical conductivity of metal at melting point, and subscripts s and l denote respectively solid and liquid phases) and θ_D/θ_l (θ_D: Debye temperature of a solid metal) is interpreted more successfully by means of the partition function than that used by Mott.[2]

Evaluation of Characteristic Temperature of Liquid

At present there is no well-defined theoretical model to evaluate the mean vibrational frequency of atoms in the vibrational motions in the liquid metal from their interatomic potentials. We adopt the same procedure as given previously[1] to evaluate the characteristic temperature of liquid at melting point.

The Helmholtz free energy of liquid metal is given, by

$$\begin{aligned} F_l(T, V_l) &= -kT \log Z_l(T, V_l) \\ &= \phi_l(V_l) + kT \sum_{i=1}^{3N_v} \log \left\{ 2 \sinh\left(\frac{h\nu_i}{2kT} \right) \right\} \\ &\quad - N_l kT \log \left\{ \left(\frac{2\pi mkT}{h^2} \right)^{3/2} \frac{eV_f}{N_l} \right\} \end{aligned} \quad (2)$$

Applying the Debye approximation to the vibrational part in Eq. (2), and adopting the Eyring presentations[3] for N_l, N_v, and V_f, *viz*

$$\begin{aligned} N_v &= \frac{NV_s}{V_l} \\ N_l &= \frac{N(V_l - V_s)}{V_l} \\ V_f &= V_l - V_s \end{aligned} \quad (3)$$

where V_s and V_l are the volumes of solid at the melting point and of liquid, respectively, we obtain

$$\begin{aligned} F_l(T, V_l) &= \phi_l(V_l) \\ &\quad + 9RT \left(\frac{V_s}{V_l} \right) \left(\frac{T}{\theta_l} \right)^3 \int_0^{\theta_l/T} x^2 \log \left\{ 2 \sinh\left(\frac{x}{2} \right) \right\} dx \\ &\quad - RT \left(\frac{V_l - V_s}{V_l} \right) \log \left\{ \left(\frac{2\pi mkT}{h^2} \right)^{3/2} \frac{eV_l}{N} \right\}, \end{aligned} \quad (4)$$

1) H. Kanno, This Bulletin, **45**, 2687 (1972).

2) N. F. Mott, *Proc. Roy. Soc. Ser.*, *A*, **146**, 465 (1934).

3) H. Eyring, T. Ree, and N. Hirai, *Proc. Nat. Acad. Sci. U. S.*, **44**, 683 (1958); H. Eyring and Mu Shik Jhon, "Significant Liquid Structure", John Wiley & Sons, New York (1969), and references contained therein.

where θ_l is the characteristic temperature of liquid (which corresponds to the Debye temperature of the solid). It should be pointed out that relations (3) are only approximate and are thought to be valid only for the low temperature region not far from melting point and for a close packed substance in its solid phase.

In correspondence to the partition function of liquid, we use the Debye equation for the solid phase

$$F_s(T, V_s) = \Phi_s(V_s) + 9RT\left(\frac{T}{\theta_D}\right)^3 \int_0^{\theta_D/T} x^2 \log\left\{2 \sinh\left(\frac{x}{2}\right)\right\} dx \quad (5)$$

where $\Phi_s(V_s)$ is the configurational potential energy of solid metal and θ_D the Debye temperature.

The entropy change on melting ΔS_m is represented by

$$\Delta S_m = \frac{\Delta H_m}{T_m} = S_l(T_m, V_l) - S_s(T_m, V_s) = -\left\{\frac{\partial F_l(T, V_l)}{\partial T}\right\}_{T=T_m} + \left\{\frac{\partial F_s(T, V_s)}{\partial T}\right\}_{T=T_m} \quad (6)$$

where ΔH_m is the latent heat of fusion, $S_l(T_m, V_l)$ and $S_s(T_m, V_s)$ are the entropies of liquid and solid phases at melting point, respectively.

With the aid of the observed values of θ_D, V_l, V_s, ΔS_m, and Eq. (6), we can determine the characteristic temperature of liquid (θ_l) at melting point by adjusting ΔS_m to give the experimental value.

Calculations and Discussion

The data used for calculations are tabulated in Table 1. Though the values T_m, V_l, V_s, and ΔS_m are in fair agreement in literature, the θ_D values show some difference according to the method (elastic or thermal) and temperature range at which determination was carried out. We used the Debye temperature of about 298 K obtained from specific heat data.[4]

As regards the characteristic temperature of liquid metal, Mott[2] has made an interesting comparison. He showed that the ratio of electrical conductivity of liquid metal to that of solid metal (both measured at melting point) is well correlated to the ratio of the mean frequencies of thermal vibrations of atoms in solid and liquid phases.

The electrical conductivity of solid metal is expressed as[5]

$$\sigma_s = \text{const} \cdot \frac{e^2}{m^*}\left(\frac{\beta}{C_D}\right)^2 \frac{m \cdot \theta_D^2}{V_s T} \quad (7)$$

where β/C_D and m^* (effective mass of electron) represent the magnitude of the binding of the electron to the lattice, e is the charge of electron.

When a metal melts, only a small percentage of volume increase is observed. Experimental evidences[6,7] show that structual configuration of liquid metal just above melting point retains most of the features of solid metal. Thus adopting Mott's hypothesis that electrical conductivity change at melting point is mainly due to the change of the electron scattering with phonon of high energy and utilizing the same formula as Eq. (7) for the electrical conductivity of liquid metal, we may easily derive the following formula

$$\frac{\sigma_s}{\sigma_l} = \left(\frac{\theta_D}{\theta_l}\right)^2 \cdot \frac{V_l}{V_s} \quad (8)$$

In Mott's theory a liquid metal is assumed to consist only of vibrational freedom. He derived the following formula giving the relation between σ_s/σ_l and θ_E/θ by applying the harmonic oscillator model of liquid to the liquid metal at the melting point:

$$\frac{\Delta H_m}{T_m} = 3R \log\left(\frac{\theta_E}{\theta}\right)[+R]^{8)} \quad (9)$$

where θ_E is the Einstein temperature and θ is a characteristic temperature of liquid state which corresponds

8) In Mott's original paper,[2] the term R was omitted. As first suggested by O. K. Rice, *J. Chem. Phys.*, **6**, 476 (1938) and shown by the significant structure theory[3] and the present theory, the communal entropy introduced on melting, which is the cause for the term R in Eq. (9), is in fact much smaller in most actual cases than R.

TABLE 2. COMPARISON OF CALCULATED σ_s/σ_l VALUES WITH OBSERVED CONDUCTIVITY CHANGES

Metal	σ_s/σ_l Observed	σ_s/σ_l Calcd by Mott[a)]	σ_s/σ_l Calcd by this theory

Source of data: Observed values are taken from the tabulated data in Ref. 9.

a) Calculated with Eqs. (8) and (9) using tabulated data in Table 1. In this calculation the term $\boldsymbol{R}$ in Eq. (9) was omitted after Mott.

to the Einstein temperature.

The values of σ_s/σ_l computed from Eqs. (6) and (8) compared with the values obtained by Mott's theory are given in Table 2. We see that the values σ_s/σ_l calculated by Eq. (6) give better agreement to experiment than those deduced from Eq. (9). This might be due to the fact that in Mott's theory all ΔS_m are ascribed to the change of vibrational frequency, neglecting the communal entropy. Actually a part of ΔS_m is caused by the introduction of the partial indistinguishability of the particles upon melting. It should be pointed out that as Eyring's relations for N_t and V_f, *i.e.*, Eq. (3), are not applicable to the open structure metals such as Bi, Sb, and Ga, it is impossible to evaluate the characteristic temperatures of these liquid metals by Eq. (6). The volume of the open structure metal contracts on melting and the σ_s/σ_l values also show anomalous changes.[9)]

9) T. E. Faber, in "The Physics of Metals, I Electrons", edited by J. M. Ziman, Cambridge University Press, (1969), pp. 282—316.

The general agreement of the calculated σ_s/σ_l values with the observed ones indicates that the translational motions of metal atoms in liquid phase and the holes introduced make a negligible contribution to the change of electrical conductivity because of their small fractions in the $3N$ degrees of freedom in the liquid metal just above melting point.

Carlson, Eyring, and Ree[10)] applied the significant structure theory to liquid metals such as Na and Hg to interpret the thermodynamic properties of these metals, including viscosity and self-diffusion. The theory, however, assumes that the mean frequency of thermal vibrations of atoms in liquid phase is the same as that of solid phase. Thus it can not applied to the present problem.

In recent years a new approach has been made for describing the electrical conductivity of liquid metal in terms of the pseudopotential approximation.[11,12)] Although the agreement between theory and experiment is encouraging, quantitative comparison is still premature.

Conclusion

Despite exceptions such as Hg, Ga, Sb, and Bi (some of them are semiconductors in the solid phase but ordinary metals when liquid), it is concluded in conjunction with Mott that most part of the change of electrical conductivity of metal on melting is ascribed to the change of the frequency of thermal vibrations in $3N$ degrees of freedom. The weakness of the liquid model used by Mott (communal entropy problem) was removed in the present model and a better agreement between theory and experiment was obtained.

The author wishes to thank Professor H. Hamaguchi for his kind encouragement.

The Powder ESR Spectra of Some Bis(amino acidato)copper(II) Complexes

Seizo MISUMI, Toshiyuki ISOBE, and Shinkichi KIMOTO

Inorganic Chemistry Laboratory, Faculty of Science, Kyushu University, Fukuoka

(Received December 28, 1971)

Copper(II) complexes with some natural amino acids were prepared, and their powder ESR spectra were measured. The pattern types of the ESR spectra of these Cu(II) complexes with amino acids were classified into four types, and by the pattern type, the *cis*- or *trans*-isomer was estimated.

Many X-ray crystallographic investigations of bis(amino acidato)copper(II) complexes[1-12] have revealed that the amino acids are usually bidentately-coordinated to the metal through the nitrogen (N) of the amino group and the oxygen (O) of the carboxyl group. Though there is the possibility of a *cis*- or *trans*-coordination for a bis-complex, the bis(glycinato)-copper(II) monohydrate reported by Tomita[13] was the first example of the *cis*-configuration. Since then other *cis*-complexes have been found[4,5,8,10] and many bis(amino acidato)copper(II) complexes have been investigated by X-ray crystallography,[1-12] infrared spectra,[14,15] visible diffuse reflectance spectra,[16] and ESR.[17-20]

In this paper, the powder ESR spectra of these complexes will be presented and discussed.

Experimental

Materials. The copper(II) complexes used in this study were as follows: $Cu(gly)_2 \cdot H_2O$-(I), $Cu(gly)_2 \cdot H_2O$-(II), $Cu(L\text{-val})_2$, $Cu(DL\text{-val})_2 \cdot H_2O$, $Cu(L\text{-ile})_2 \cdot H_2O$, $Cu(DL\text{-ile})_2 \cdot H_2O$, $Cu(L\text{-asn})_2$, $Cu(L\text{-arg})_2(NO_3)_2 \cdot 3H_2O$, $Cu(L\text{-trp})_2$, $Cu(L\text{-gln})_2$, $Cu(L\text{-ala})_2$, $Cu(DL\text{-ala})_2$, $Cu(L\text{-ser})_2$, $Cu(L\text{-thr})_2 \cdot H_2O$, $Cu(DL\text{-phe})_2$-(I), $Cu(DL\text{-phe})_2$-(II), $Cu(L\text{-phe})_2$, and $Cu(L\text{-leu})_2$, where the abbreviations used are gly : glycine, val : valine, ile : isoleucine, asn : asparagine, arg : arginine, trp : tryptophane, gln : glutamine, ala : alanine, ser : serine, thr : threonine, phe : phenylalanine, and leu : leucine.

Preparation. The $Cu(gly)_2 \cdot H_2O$-(I) and $Cu(gly)_2 \cdot H_2O$-(II) were prepared by the method of Tomita[13]; the $Cu(L\text{-val})_2$, $Cu(L\text{-ile})_2 \cdot H_2O$, and $Cu(L\text{-gln})_2$, by the method of Neuberg *et al.*[21] from basic $Cu(OH)_2 \cdot CuCO_3$, and the $Cu(DL\text{-val})_2 \cdot H_2O$, $Cu(DL\text{-ile})_2 \cdot H_2O$, $Cu(L\text{-asn})_2$, $Cu(L\text{-trp})_2$, $Cu(L\text{-ala})_2$, $Cu(DL\text{-ala})_2$, $Cu(L\text{-phe})_2$, and $Cu(L\text{-leu})_2$, by the method of Abderhalden and Schnitzler[22] from freshly-prepared $Cu(OH)_2$, while the $Cu(L\text{-arg})_2(NO_3)_2 \cdot 3H_2O$ was prepared by a method similar to that described by Dubois.[23] The $Cu(L\text{-ser})_2$ was prepared by the methods of both van der Helm and Franks[4] and of Abderhalden and Schnitzler[22]; the two complexes thus obtained were identical. The $Cu(DL\text{-phe})_2$-(I) and $Du(DL\text{-phe})_2$-(II) were prepared by the method of Herlinger *et al.*[14] All the ligand molecules were commercially available.

Each molecular formula was determined by elementary analysis and was confirmed by studying the far-infrared spectrum.

Measurements. The ESR spectra (powdered samples) of the complexes were measured at room temperature with a JEOL X-band ESR spectrometer, model JES-ME-3X, equipped with a 100 KHz field modulation unit.

Results and Discussion

1) $Cu(gly)_2 \cdot H_2O$-(I) and $Cu(gly)_2 \cdot H_2O$-(II).

Tomita[13] suggested that bis(glycinato)copper(II) monohydrate was a *cis*- and that dihydrate was a *trans*-complex. However, Yasui and Shimura[16] reported that the *trans*-complex was also a monohydrate, and the same result was obtained in this work. The separation of *cis*- and *trans*-complexes was confirmed by the methods of X-ray analysis,[2] infrared spectrum,[14,15] and visible diffuse reflectance spectrum.[16]

The powder ESR spectra of $Cu(gly)_2 \cdot H_2O$-(I) and $Cu(gly)_2 \cdot H_2O$-(II), checked by means of the infrared spectra, are shown in Fig. 1. It can be seen from Fig. 1 that, while the spectrum of *cis*-$Cu(gly)_2 \cdot H_2O$ is clearly axial in character, that of *trans*-$Cu(gly)_2 \cdot H_2O$ shows a distortion from the usual axial pattern. It is reasonable to expect that the *trans*-complex would display such a rhombic distortion due to the difference in Cu–O and Cu–N bond lengths. The ESR spectrum of *trans*-$Cu(gly)_2 \cdot H_2O$ was measured for the first time.

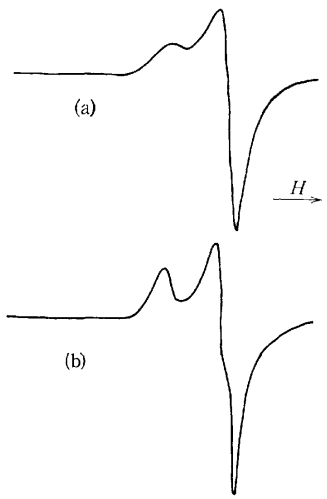

Fig. 1. The powder ESR spectra of *cis*-Cu(gly)$_2$·H$_2$O-(I) (a) and *trans*-Cu(gly)$_2$·H$_2$O-(II) (b).

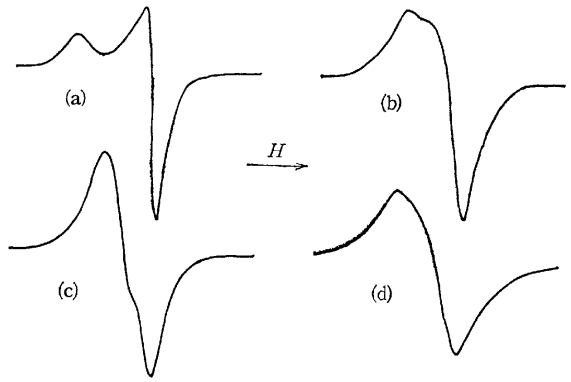

Fig. 2. The different types of the powder ESR spectra.
(a) Cu(L-val)$_2$-type, (b) Cu(L-trp)$_2$-type
(c) Cu(L-thr)$_2$·H$_2$O-type, (d) Cu(L-ala)$_2$-type

Figure 2 shows four typical polycrystalline ESR spectra of bis(amino acidato)copper(II) complexes: (a) Cu(L-val)$_2$, (b) Cu(L-trp)$_2$, (c) Cu(L-thr)$_2$·H$_2$O, and (d) Cu(L-ala)$_2$. Cu(L-val)$_2$, Cu(L-ile)$_2$·H$_2$O, Cu(DL-ile)$_2$·H$_2$O, Cu(L-asn)$_2$, Cu(L-arg)$_2$(NO$_3$)$_2$·3H$_2$O, and Cu(DL-phe)$_2$-(II) belong to the Cu(L-val)$_2$-type; Cu(L-trp)$_2$, Cu(DL-ala)$_2$, Cu(L-gln)$_2$, and Cu(DL-val)$_2$·H$_2$O belong to the Cu(L-trp)$_2$-type, and Cu(L-thr)$_2$·H$_2$O and Cu(L-ser)$_2$ belong to the Cu(L-thr)$_2$·H$_2$O-type, while Cu(L-ala)$_2$, Cu(DL-phe)$_2$-(I), Cu(L-phe)$_2$, and Cu(L-leu)$_2$ belong to the Cu(L-ala)$_2$-type.

The *cis*- and *trans*-complexes determined or estimated in this and other studies[2-5,12,14,16] are summarized in Table 1. The column for the ESR spectra in Table 1 shows the type of the powder ESR spectrum. Figure 2 shows that Cu(L-val)$_2$ gives an axial pattern, while Cu(L-trp)$_2$, Cu(L-thr)$_2$·H$_2$O, and Cu(L-ala)$_2$ give a non-axial pattern (clearly neither rhombic nor isotropic). From Table 1, the complexes of the Cu(L-val)$_2$-type can be found to be all *cis*-complexes except for the result of infrared spectra of Cu(L-val)$_2$.[14] On the other hand, the complexes of the Cu(L-trp)$_2$-type, the Cu(L-thr)$_2$·H$_2$O-type, and the Cu(L-ala)$_2$-type are all found to be *trans*-complexes except for the results of the X-ray analysis of Cu(L-ser)$_2$.[4] Therefore, the complexes of the Cu(L-val)$_2$-type are estimated to be *cis*-complexes, and the complexes of the Cu(L-trp)$_2$-type and the Cu(L-ala)$_2$-type, *trans*-complexes.

Although there is a difference between the results on Cu(L-val)$_2$ by Herlinger *et al.*[14] and those by Yasui and Shimura,[16] it may be believed to be a *cis*-complex on the basis of the above discussion.

According to van der Helm and Franks, Cu(L-ser)$_2$ forms a square pyramidal complex.[4] The four atoms (N_A, N_B, O_{1A}, O_{1B}) are not coplanar, but form a very flattened tetrahedron.[4] This is a complex with a lower symmetry than the other, so it may be supposed that this complex shows a non-axial pattern of the powder ESR spectrum. Only a coplanar *cis*-complex shows an axial pattern, while a non-coplanar *cis*-complex shows a non-axial pattern. Cu(L-thr)$_2$·H$_2$O is found to be the same type.

Bis(DL-phenylalaninato)copper(II) is a complex[14] which has *cis*- and *trans*-isomers, just as bis(glycinato)-copper(II)[13] and bis(L-alaninato)copper(II).[3,8] Cu(DL-phe)$_2$-(I) belongs to the Cu(L-ala)$_2$-type, and Cu(DL-phe)$_2$-(II) belongs to the Cu(L-val)$_2$-type; the

Table 1. Bis (amino acidato) copper (II) complexes determined or estimated by authors and other investigators

	Crystal structure	Infrared spectra[14]	Reflection spectra[16]	ESR spectra
Cu(gly)$_2$·H$_2$O-(I)	*cis*[2]	*cis*	*cis*	(*cis*)
Cu(gly)$_2$·H$_2$O-(II)	—	*trans*	*trans*	(*trans*)
Cu(L-ala)$_2$	*trans*[3]	*trans*	*trans*	L-ala (*trans*)
Cu(L-ser)$_2$	*cis*[4]	—	—	L-thr
Cu(L-ile)$_2$·H$_2$O	*cis*[5]	*cis*	*cis*	L-val (*cis*)
Cu(L-val)$_2$	—	*trans*	*cis*	L-val (*cis*)
Cu(DL-ile)$_2$·H$_2$O	—	*cis*	*cis*	L-val (*cis*)
Cu(DL-phe)$_2$-(II)	—	*cis*	—	L-val (*cis*)
Cu(DL-phe)$_2$-(I)	—	*trans*	—	L-ala (*trans*)
Cu(DL-ala)$_2$	—	*trans*	*trans*	L-trp (*trans*)
Cu(DL-val)$_2$·H$_2$O	—	*trans*	*trans*	L-trp (*trans*)
Cu(L-thr)$_2$·H$_2$O	—	—	*trans*	L-thr
Cu(L-phe)$_2$	*trans*[12]	*trans*	—	L-ala (*trans*)
Cu(L-leu)$_2$	—	*trans*	—	L-ala (*trans*)

former is found to be a *trans*-complex, and the latter, a *cis*-complex, from the results of the powder ESR spectra. These facts agree with those of the other infrared spectral study.[14] Thus, it supports our findings that a *cis*-complex or *trans*-complex found not only for bis(glycinato)copper(II), but also for bis(DL-phenylalaninato)copper(II), could be estimated by ESR. Table 1 shows the good agreement of our study with other studies.[2,3,5,12,14,16]

The geometrical isomers are believed to be classifiable as follows:

$Cu(gly)_2 \cdot H_2O$-(I)	*cis*
$Cu(gly)_2 \cdot H_2O$-(II)	*trans*
$Cu(\text{L-val})_2$	*cis*
$Cu(\text{DL-val})_2 \cdot H_2O$	*trans*
$Cu(\text{L-ile})_2 \cdot H_2O$	*cis*
$Cu(\text{DL-ile})_2 \cdot H_2O$	*cis*
$Cu(\text{DL-phe})_2$-(I)	*trans*
$Cu(\text{DL-phe})_2$-(II)	*cis*
$Cu(\text{L-asn})_2$	*cis*

Studies on the Interaction between Long Chain Alcohols and Alkyl Sulfates. II. Molecular Association between Dodecyl Alcohol and Dodecyl Sulfate of Divalent Metals

Yoshikiyo Moroi, Kinshi Motomura, and Ryohei Matuura
Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka

(Received December 28, 1971)

Molecular interaction between dodecyl alcohol and dodecyl sulfate of divalent metal cations such as Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, and Cu^{2+} was studied by measurement of heat of complex formation, differential thermal analysis and infrared spectroscopy. It was found that magnesium, manganese, cobalt, nickel, and copper dodecyl sulfates formed two or three kinds of complexes with dodecyl alcohol, differing in composition depending on temperature. On the other hand, no evidence of complex formation could be found by these experimental techniques for calcium, strontium and barium dodecyl sulfates, all of which are very small in solubility into water. For the former class of metal dodecyl sulfates the composition of complex was 3.5—4.0 in molar ratio of alcohol to sulfate at temperature below the melting point of alcohol, while it was 5.0—6.0 at temperature above it. The heat of complex formation above the melting point of alcohol was −40——44 kcal/mol-sulfate. Two or three characteristic absorption bands could be found over the range 3200—3500 cm^{-1}, suggesting that the complex formation is due to hydrogen bonding between two components.

Many papers concerning the interaction between long chain alcohols and alkyl sulfates have been published with viewpoints of emulsion and film stabilization due to complex formation and penetration. The results, however, have not been coincident with one another. Recently, Friberg has attempted to interrelate the molecular complexes as emulsion and foam stabilizer with phase diagram of the components;[1-3] in his papers the materials have not been confined to long chain compounds.

In our previous paper, it has been shown that there are two kinds of complexes, I and II, between dodecyl alcohol and sodium dodecyl sulfate, tetradecyl alcohol and sodium tetradecyl sulfate, hexadecyl alcohol and sodium hexadecyl sulfate, differing in the composition ratio of alcohol to sulfate.[4] The complex I was stable at temperature below the melting point of alcohol, the molar ratio of alcohol to sulfate being 0.55—0.63. The complex II was stable at temperature above the melting point of alcohol, its molar ratio being 1.0.

The object of this paper is to extend the previous work to divalent alkyl sulfates and to see the difference between monovalent and divalent cation complexes by the same methods as in the previous paper. Also it is our aim to investigate whether the mechanism of the complex formation could be elucidated by statistical thermodynamics.

The following abbreviations are used.
DOH: Dodecyl Alcohol
$Mg(DS)_2$, $Ca(DS)_2$, $Sr(DS)_2$, $Ba(DS)_2$, $Mn(DS)_2$, $Co(DS)_2$, $Ni(DS)_2$, $Cu(DS)_2$: Magnesium, Calcium, Strontium, Barium, Manganese, Cobalt, Nickel, and Copper Dodecyl Sulfate, respectively.

These are often represented as $M(DS)_2$.
DTA: Differential Thermal Analysis
IR: Infrared Spectroscopy

Experimental

Materials. DOH was the same as described in the previous paper.[4] $M(DS)_2$ was prepared by a double decomposition from divalent metal cation chloride or sulfate and purified sodium dodecyl sulfate (SDS) in aqueous media. The CMC value was 8.13×10^{-3} mol/*l* at 25°C. The precipitate of $M(DS)_2$ formed was purified by repeated recrystallizations from water, and was dried at 125°C for fifteen minutes under a reduced pressure. The purified $M(DS)_2$ did not show any characteristic endothermic peak of SDS at 104°C on a DTA curve. The absorption bands of water could hardly be found in their IR spectra.

The specimens of complexes of DOH and $M(DS)_2$ used for measurements of DTA, IR and heat of complex formation were prepared by the two methods, *i.e.*, the melt method and the crystallization method. These were quite the same as described in the previous paper. Most of these metal dodecyl sulfates were so hygroscopic that all operations were performed in an atmosphere of dried nitrogen gas.

Methods. A Shimadzu X-ray diffractometer (DV-1) with a Geiger counter was employed with a beam exit slit of 0.7 mm. The nickel filtered copper radiation was used in all cases. The apparatus was standardized at angles 28.44° of silicon. The scanning speed was 1 deg/min., and the chart speed was 20 mm/min.

The DTA apparatus and operational condition were the same as those in the preceeding paper.[4] In the present case, two or three endothermic peaks appeared in DTA curves of the complexes even after a long time. As a result, the ratio of alcohol to sulfate in the complex above the melting point of DOH was determined from the composition at which the exothermic peak due to freezing of excess free alcohol disappeared on cooling curve. On the other hand, below the melting point the ratio was determined from the composition at which the endothermic peak due to melting of excess free alcohol disappeared on heating curve. This method is different from the previous one,[4] and the reason will be made clear in the next section.

The IR apparatus and operational condition were the same as those in the preceeding paper[4] except replacing hexachlorobutadiene by Nujol.

The heat of complex formation was measured at 35°C with an Applied Electric Laboratory calorimeter, Model CM-204S1. The samples were so hygroscopic that they were sealed into a glass ampule. On mixing them with DOH the ampule was held in DOH and crushed in it by a small hammer, after having been thermally equilibriated. The sample weight was about 100 mg and DOH used was 50 ml. Sodium dodecyl sulfate, sodium tetradecyl sulfate, and sodium hexadecyl sulfate formed the complexes with their corresponding alcohols which are insoluble in the alcohols, while complexes of $M(DS)_2$ with DOH were very soluble in DOH. Consequently $M(DS)_2$ with DOH were very soluble in DOH. Consequently, the heat of complex formation could not be measured only through mixing the sulfate with the alcohol. Therefore, it was determined by subtracting the heat (ΔHs) evolved by solubilizing the complex into DOH from the heat (ΔHt) evolved by mixing the dried sulfate with DOH with subsequent solubilization of complex.

Results and Discussion

X-ray Diffraction. The characteristic data of $M(DS)_2$ are collected in Table 1. As $Co(DS)_2$, $Ni(DS)_2$, and $Cu(DS)_2$ are so hygroscopic that their characteristics change during operation, the values for these sulfates are those for the compounds with water of crystallization, *i.e.*, $M(DS)_2\cdot nH_2O$. The amounts of water of crystallization for hygroscopic $M(DS)_2$ determined by elementary analysis were identical with those in literature,[5] and the agreement between the calculated and observed values of elementary analysis was good.

Table 1. Results of DTA and X-ray diffraction for $M(DS)_2$

$M(DS)_2$	DTA (°C)		X-ray (Å)
	Dehydration	Transition	Long spacing
$Mg(DS)_2$		120	34.0
$Ca(DS)_2$		83	30.0
$Sr(DS)_2$			36.0
$Ba(DS)_2$		121	33.8
$Mn(DS)_2$		132	32.1
$Co(DS)_2\cdot6H_2O$	56, 85, 110		20.6
$Ni(DS)_2\cdot6H_2O$	57, 72, 85, 101		29.2
$Cu(DS)_2\cdot4H_2O$	44, 118		25.0
NaDS		104	31.6, 39.0

It can be said from this result that the X-ray long spacing of metal sulfates with water of crystallization are shorter than those without water. This fact indicates that the carbon chain axis of sulfates with water is more tilted than those without water.

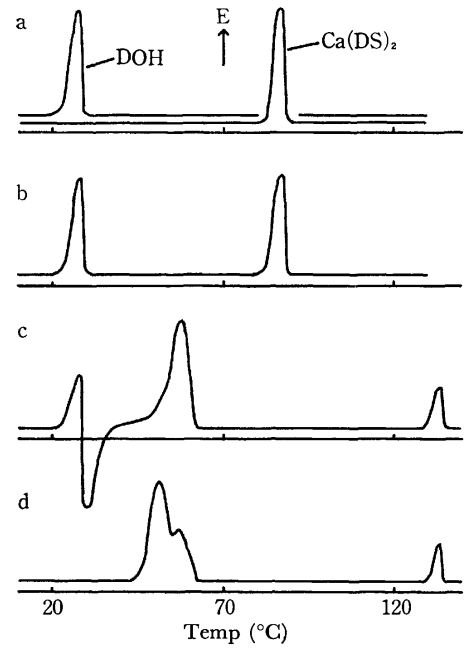

Fig. 1. DTA curves for detecting a complex formation. a: DOH and $Ca(DS)_2$ b: mixture of DOH and $Ca(DS)_2$, c: mixture of DOH and $Mn(DS)_2$, d: $Mn(DS)_2$-DOH complex, E: endothermic

5) R. Matuura and I. Satake, *Yushi*, **16**, 94 (1963).

DTA. The complex formation could easily be detected by DTA technique. The typical examples are shown in Fig. 1. When the mixture of $M(DS)_2$ and DOH in a solid phase is heated in a DTA cell from the temperature below the melting point of DOH to higher temperature, the DTA curve results merely in the superposition of their own DTA curves, unless they form a complex. On the other hand, the mixture which forms a complex shows a sharp exothermic peak in the heating curve just beyond the endothermic peak due to melting of DOH. This exothermic peak is followed by a new endothermic peak which corresponds to the characteristic peak of the complex. This phenomenon indicates that the mixture in solid state cannot undergo a reaction, while the melt of DOH can react with solid $M(DS)_2$ to form a complex accompanying heat evolution.

The sodium sulfate complexes were so stable that they kept up their own state during the operation without showing any peak in a DTA curve due to transition. On the contrary, divalent cation complexes are not so stable and have two or three more endothermic peaks even after being kept at a fixed temperature for a long time. Therefore, it was difficult to assign each endothermic peak to a complex. When the complexes formed above the melting point of DOH are cooled below it, they release the extra DOH at freezing state and transform to the other complexes. These complexes formed below the melting point of DOH are so unstable that they react again with the extra molten DOH on being heated above the melting point of DOH and show the exothermic peak due to complex formation in addition to the characteristic endothermic peak of the complex. However, it was possible, in some cases, to assign the peak to complex L or complex H, with the aid of the measurement of peak area on DTA curve, depending on the temperature at which the complex was kept. Complex L and complex H are complexes which formed below and above the melting point of DOH, respectively. The results of differential thermograms of these complexes are summarized in Table 2. Consequently, differing from the method in the previous paper, the following method was used in this study to determine the composition of the complex. The composition of complex L was determined from the ratio of DOH to $M(DS)_2$ in the state where the endothermic peak due to melting of extra free DOH disappears, and the composition of complex H was determined from the ratio in the state where the exothermic peak due to freezing of extra free DOH disappears. The typical DTA curves of manganese complex are shown in Fig. 1.

Table 2. Characteristic endothermic temperatures of complexes in DTA curves

Metal	Complex L (°C)	Complex H (°C)
Mg	40—43	53—55
Ca	—	—
Sr	—	—
Ba	—	—
Mn	40—41, 46—47	57—58
Co	38—40, 47—50	57—59
Ni	30—33, 38—40	
Cu	40—42, 48—50	

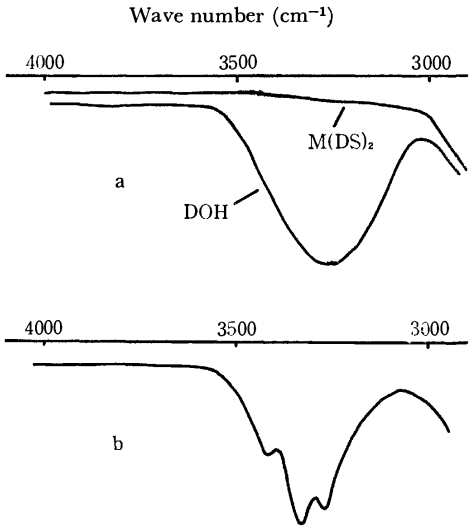

Fig. 2. IR spectra of complex formation. a: DOH and $M(DS)_3$, b: $Mn(DS)_2$-DOH complex

Infrared. Infrared spectroscopy as well as DTA are useful technique for detecting the complex formation. It is shown in Fig. 2 that the spectrum in the hydroxyl stretching region has sharper bands than those of DOH and is composed of two or three absorption bands. These bands, however, are broader in comparison with those of sodium sulfate complex. This might suggest that there are two or three kinds of (slightly diffused) bonding states between $M(DS)_2$ and DOH. The characteristic band region of complexes is the same as that of DOH, indicating that complexes are formed by the hydrogen bonding between two components in a manner similar to DOH. As will be mentioned later, it can also be confirmed from the magnitude of heat of complex formation that the complex formation is mainly due to the hydrogen bonding. The characteristic bands are summarized in Table 3.

Table 3. Characteristic absorption bands of complexes in IR spectra

Metal	Absorption band (cm^{-1})		
Mg	~3310	~3370	~3450
Mn	~3290	~3320	~(3460)
Co	~3280	~3320	~(3480)
Ni	~3290	~3340	~(3420)
Cu	~3200	~3300	

Heat of Complex Formation. As shown in Fig. 3, $M(DS)_2$ reacts with molten DOH to form a complex with heat evolution and then resolves in molten DOH with heat absorption. When particles of larger size, of $M(DS)_2$ were dropped into molten DOH, the rate of resolution is larger than that of complex formation, accompanying net heat absorption. The heat of complex H formation (ΔH_H) is shown in Table 4 together with the results of complex H composition. Complex H used to measure ΔH_S had the composition of $M(DS)_2 \cdot 6DOH$. Even if the ratio of alcohol to sulfate is less than six, the effect of excess DOH on ΔH_S should be

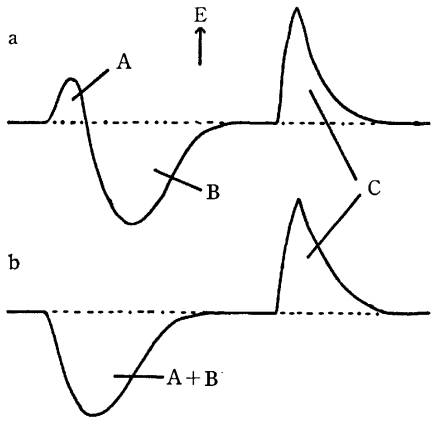

Fig. 3. Diagram of heat of complex formation and dissolution into DOH. a: $M(DS)_2$ in small size, b: $M(DS)_2$ in larger size, A: heat of complex formation, B: heat of dissolution of complex, C: standard heat, E: exothermic

Table 4. Heat of complex formation and composition of complex

Metal	ΔH_H (kcal/mol-sulfate)	Molar ratio of DOH to $M(DS)_2$	
		complex L	complex H
Mg	−41.0±2	3.8—4.0	5.8—6.0
Mn	−40.1±2	3.8—4.0	5.8—6.0
Co	−41.2±2	3.8—4.0	5.0—6.0
Ni	−41.5±2	3.8—4.0	5.0—6.0
Cu	−44.0±2	3.8—4.0	5.5—6.0

negligible because of very little solubilization of complex H in excess DOH. The values of ΔH_H are about −40 kcal/mol-sulfate. These values are five or six times as large as those of sodium sulfate complex formation (7—8 kcal/mol-sulfate). This is consistent with the fact that the ratio of alcohol to sulfate in complex H is 5 to 6, while that of complex II of sodium sulfate is 1.0.

Statistical Thermodynamical Consideration

It seems to be instructive in a further investigation to discuss the complex formation with the viewpoint of statistical thermodynamics. In analogy with the previous paper,[4] this discussion is intended to explain the composition of complexes, namely the molar ratio of alcohol to sulfate in a complex, which is nearly 4 below the melting point of alcohol and nearly 6 above it. As mentioned above, there are two or three complexes in total, differing from the case of sodium sulfates. Furthermore, a divalent metal sulfate has two radicals of alkyl sulfate in a molecule, and then the theoretical treatment comes to be a little more difficult.

The consideration is based on the concept of chapter XI in "mixture" by Guggenheim.[6] We denote alcohol and sulfate by A and B, respectively, and consider a binary mixture containing Nr molecules of alcohol and N molecules of sulfate on a lattice of $N(r+2)$ sites with a coordination number Z, where $M(DS)_2$ is regarded as a dimer and occupies two lattice sites. Since A and B molecules have ZNr and $(2Z-2)N$ contact number, respectively, the total number of intermolecular contact (Q) is given by

$$Q = \frac{ZN}{2}(r+q), \tag{1}$$

where q is defined so that the open chain r-mer containing r elements may have Zq contacts, and then q is in this case equal to $2-2/Z$. The ratios of Q from A and B are denoted by U and V, respectively.

$$U = \frac{r}{r+q} \tag{2}$$

$$V = \frac{q}{r+q} \tag{3}$$

There are four kinds of contacts, A-A, A-B, B-A, and B-B. We denote by $-2X/Z$ the energy for a pair of the same kind of molecules and further define W such that the contribution of A-B contact of configurational energy is

$$-\frac{X'_{A-A}+X'_{B-B}+W}{Z}. \tag{4}$$

What must be emphasized at this point is that the energy for a longitudinal pair should be different from that for a lateral one. Nevertheless, we used $-2X/Z$ as the mean value of them. Consequently, the discussion cannot be given in terms of individual item, but may be limited to the mean values as a whole.

From these definitions, we can construct Table 5 for a complete random distribution. The prime in Table 5 refers to the newly obtained complex, E_c being the total configurational energy.

Table 5. Number of pairs and certain related quantities

Kind of contact	Number of contacts	Energy of all such contacts
A-A	QU^2	$-\frac{2}{Z}\ QU^2X'_{A-A}$
A-B	QUV	$-\frac{1}{Z}\ QUV(X'_{A-A}+X'_{B-B}+W)$
B-A	QVU	$-\frac{1}{Z}\ QVU(X'_{B-B}+X'_{A-B}+W)$
B-B	QV^2	$-\frac{2}{Z}\ QU^2X'_{B-B}$
All	Q	$-\frac{2Q}{Z}\ (UX'_{A-A}+VX'_{B-B}+UVW)=E_c$

E_c can be rewritten as follows;

$$E_c = -N\left(rX'_{A-A}+qX'_{B-B}+\frac{rq}{r+q}W\right) \tag{5}$$

According to definition, the configurational partition function Ω is given by

$$\Omega = \sum \exp(-E_c/kT), \tag{6}$$

where the summation extends over the $g(Nr, N)$ distinguishable configurations. $g(Nr, N)$ is given by

6) E. A. Guggenheim, "Mixtures", ed. by R. H. Fowler, P. Kapitza, N. F. Mott, and E. C. Bullard, Oxford at the Clarendon Press (1952).

$$g(Nr, N) = \left(\frac{Z}{2}\right)^N \frac{(Nr+2N)!}{(Nr)!N!}\left\{\frac{(Nr+Nq)!}{(Nr+2N)!}\right\}^{1/(2-q)} \quad (7)$$

As the configurational free energies of pure substances containing the same number of molecules are $-NrX_{A-A}$ and $-NqX_{B-B}$, the molar free energy of mixing of the sulfate is given by

$$\Delta F_m = -Nr(X'_{A-A}-X_{A-A}) - Nq(X'_{B-B}-X_{B-B}) - \frac{Nrq}{r+q}W - RT\left[\ln 2Z - r\ln\frac{r}{r+2} - 2\ln\frac{2}{r+2} + \frac{1}{2-q} \times\left\{r\ln\frac{r+q}{r+2} + q\ln(r+q) - 2\ln(r+2)\right\}\right], \quad (8)$$

where N is Avogadro's number. Concerning a liquid or solid phase, we can, without serious error, replace internal energy and Helmholtz free energy by enthalpy and Gibbs free energy, respectively. Consequently the molar enthalpy of mixing of sulfate is given by

$$\Delta H = -Nr(X'_{A-A}-X_{A-A}) - Nq(X'_{B-B}-X_{B-B}) - \frac{Nrq}{r+q}W, \quad (9)$$

where we assume that the temperature changes of X'_{B-B}, X_{B-B}, and W are negligible, because of very limited temperature range 20—35°C in this case.

First, when $r=0$, we obtain the equation

$$\Delta H = -Nq(X'_{B-B}-X_{B-B}) \equiv \Delta H_0 \quad (10)$$

The new parameter ΔH_0 is hypothetically equivalent to the heat evolved when a sulfate is transformed into a complex whose lattice sites are all occupied by sulfate molecules.

Second, when $r=r_H$, which is the ratio of DOH to $M(DS)_2$ in complex H, ΔH_H is given by

$$\Delta H_H = -r_H(NX'^H_{A-A} - NX^1_{A-A}) + \Delta H_0 - \frac{Nr_Hq}{r_H+q}W, \quad (11)$$

where $X^1{}_{A-A}$ is the X_{A-A} of liquid alcohol and ΔH_H is equal to the heat of complex H formation measured above the melting point of alcohol.

We may obtain unknown parameters from the ratios of DOH to $M(DS)_2$ in complex L and complex H, imposing conditions consistent with the results on ΔG_m.

For complex L,

$$\frac{\partial \Delta G_{mL}}{\partial r} < 0 \text{ at } r = r_{L1},$$

$$\frac{\partial \Delta G_{mL}}{\partial r} > 0 \text{ at } r = r_{L2}, \quad (12)$$

and $$\Delta G_{mH} < 0 \quad \text{at } r_{L1} < r < r_{L2},$$

where r_{L1} and r_{L2} are lower and upper limit of r_L, respectively.

For complex H,

$$\frac{\partial \Delta G_{mH}}{\partial r} < 0 \text{ at } r = r_{H1},$$

$$\frac{\partial \Delta G_{mH}}{\partial r} > 0 \text{ at } r = r_{H2}, \quad (13)$$

and $$\partial \Delta G_{mH} < 0 \quad \text{at } r_{H1} < r < r_{H2},$$

where r_{H1} and r_{H2} are lower and upper limit of r_H, respectively.

We employed 1, 2, and 3 kcal/mol -$M(DS)_2$ as a reasonable value for ΔH_0, and 22.8 and 15.1 kcal/mol for NX_{A-A} and $NX^1{}_{A-A}$, respectively, according to the previous paper.[4] Thus NW and NX'_{A-A} can be obtained from Eqs. (11), (12), and (13), with Z to be an unknown parameter. A typical example for calculation is shown in Fig. 4 for $Mg(DS)_2$-DOH complex. The results obtained are summarized in Table 6. This shows that the values of NX'_{A-A} are 17—19 and 11—13 kcal/mol for NX'^L_{A-A} and NX'^H_{A-A} respectively.

In the previous paper, NX'_{A-A} was the average of those of complex I and II. On the other hand, in

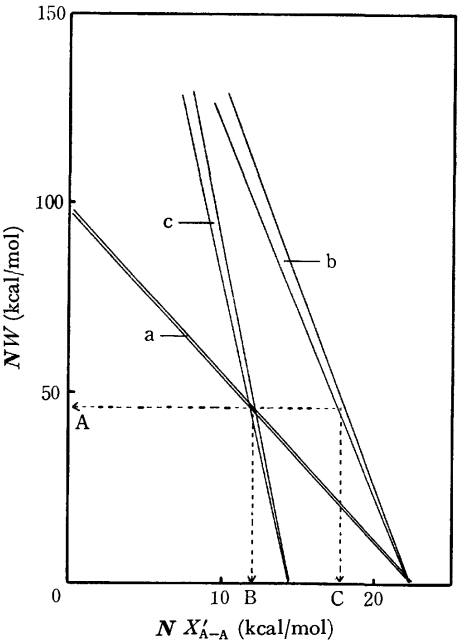

Fig. 4. Calculation of NW and NX'_{A-A} for $Mg(DS)_2$-DOH, $Z=8$. Extents obtained from equations: (a), Eq. (11); (b), Eq. (12); (c), Eq. (13).

Co	17.0±0.3	11.5±0.6	48±2	−35.4± 9
Ni	17.0±0.3	11.5±0.6	48±2	−35.4± 9
Cu	17.5±0.3	11.8±0.3	44±2	−32.3± 9

the present treatment the NX'_{A-A} is separated into NX'^{L}_{A-A} and NX'^{H}_{A-A} for complex L and complex H, respectively. Comparing these values with the previous ones, 14—16 kcal/mol, which is almost equal to the mean value of NX'^{L}_{A-A} and NX'^{H}_{A-A}, we arrive at the conclusion that the state of alcohol in monovalent cation complex is almost equal to that in divalent one.

Using the values of NX'^{L}_{A-A}, the heat of complex L formation can also be calculated with W in complex H also shown in Table 6. Thus, it is found that the absolute value of ΔH_L is smaller than that of ΔH_H and the effect of the alterations of ΔH_0 and Z on unknown parameters is rather small.

What is evident from these results is as follows; $M(DS)_2$ of divalent ion whose sulfate (MSO_4) is rather soluble in water is apt to form a complex with DOH, and *vice versa*.

For Ca, Sr, and Ba dodecyl sulfate, the intermolecular force in a crystal state is so strong that the complex cannot be formed. In other words, their own intermolecular force is stronger than that between $M(DS)_2$ and DOH in a complex state. On the other hand, the intermolecular force of dodecyl sulfate of such metals as Mg, Mn, Co, Ni, and Cu is weaker than that between $M(DS)_2$ and DOH in a complex state and leads to a negative enthalpy change on the complex formation that has a main effect on negative free energy change.

According to the above discussion, the dodecyl sulfate of divalent metals having larger solubility into a water must form a complex with DOH. The composition of it should depend on the metal ion and the temperature.

Oxygen Vacancies in the Perovskite-type Ferrites. II. Mössbauer Effect in the $SrFeO_{2.5}$-$LaFeO_3$ Solid-solution System

Hiroshi YAMAMURA and Ryôiti KIRIYAMA*

National Institute for Research in Inorganic Materials, Kurakake, Sakura-Mura, Niihari-Gun, Ibaraki
**The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka*

(Received December 7, 1971)

The Mössbauer effect was studied for the solid-solution $Sr_{1-x}LaFeO_{2.5+x/2}$ system, prepared by firing in a vacuum. The intensity of the characteristic six absorption lines of the tetrahedral-iron site in the brownmillerite-type phase ($0.0 \leq x \leq 0.20$) was weakened with an increase in the La content because of an increasing incorporation of oxygen, while the Mössbauer parameters remained constant. $SrFeO_{2.5}$ with a brownmillerite-type structure, completely changed into a cubic perovskite-type structure at the composition with $x=0.30$; however, the original absorption peaks for the tetrahedral-iron site still exist even if the intensity is considerably decreased. Moreover, new peaks came out, with Mössbauer parameters different from those for the octahedral- or the tetrahedral-iron sites. On the basis of the values of their Mössbauer parameters, the origin of the new peak can be assigned to the presence of a five-coordinated iron site surrounded by a trigonal bipyramidal polyhedron of oxygen rather than a square pyramidal one. The three kinds of iron site lead to a single octahedral one when most of Sr is replaced with La ($x \geq 0.50$). The oxygen-deficient, perovskite-type phase with a cubic symmetry may be stabilized by the presence of the mixed-coordination scheme of Fe^{3+}, *i.e.*, the octahedral, trigonal bipyramidal, and tetrahedral sites.

In the previous paper,[1] we studied the role of oxygen vacancies in the stabilization of the perovskite-type structure in the $Sr_{1-x}M_xFeO_{3-\delta}$ solid-solution system ($M=Y^{3+}$, La^{3+}, Bi^{3+}, or In^{3+}). The X-ray diffraction measurements indicated that the end member $SrFeO_{2.5}$, which is isostructural with brownmillerite, which has an orthorhombic symmetry, changed to a cubic perovskite-type structure upon the addition of M^{3+} ($0.30 \leq x \leq 0.60$) as a result of a decrease in the concentration of oxygen vacancies. Throughout the previous study, however, we could not visualize the details of an oxygen-deficient structure only by means of X-ray diffractometry. The purpose of the present work is to further clarify the contents of the defect structure with the aid of such Mössbauer spectroscopic information, observed at iron sites, as the coordination state from the surrounding oxygens, the nature of the chemical bonding, and the electric-field gradient.

$LaFeO_3$, being isostructural with $GdFeO_3$ (the space group P_{bnm}-D_{2h}^{16}), consists of four distorted sub-cells,[2] and neutron-diffraction measurements[3] have shown that it has a G-type,[4] spin-ordered antiferromagnetic structure with its Neel temperature at 750°K. The Mössbauer spectrum was first observed by Eibschutz *et al.*[5] to show an isomer shift of +0.32 mm/sec and

an internal magentic field of 519 kOe. On the other hand, MacChesney *et al.*[6] studied the $SrFeO_{3-\delta}$ system, in which $SrFeO_{2.5}$ (prepared by firing in CO_2/H_2) was found to have a brownmillerite-type structure. The Mössbauer spectrum for $SrFeO_{2.5}$ was first reported by Gallagher *et al.*[7] without sufficient discussion. According to the results of Collvile's study, $CaFeO_{2.5}$,[8] being isostructural with $SrFeO_{2.5}$ (the space group P_{cmn}-D_{2h}^{16}), has an orthorhombic symmetry, are containing two types of iron sites, (Fe_I and Fe_{II}), both of which are alternatively drawn up along the *b*-axis. The Fe_I occupies an octahedral site surrounded by 6 O^{2-}, while the Fe_{II} occupies a tetrahedral site surrounded by 4 O^{2-} ions. The crystal lattice with a perovskite-type structure is deformed by the ordering of the oxygen vacancies. The neutron-diffraction measurements[9] revealed that $CaFeO_{2.5}$ also has a G-type antiferromagnetic structure with its Neel temperature at 720°K, where the spins of Fe^{3+} in both the octahedral and tetrahedral sub-lattices all lie along the *c*-axis. Grant,[10] after having studied the Mössbauer effect of $CaFeO_{2.5}$, concluded that the electric-field gradient is axially symmetric, in which the *z*-principal axis is parallel to the crystallographic *b*-axis, and that the large quadrupole splitting both the iron sites arises from the deformation of the corresponding oxygen-octahedron and -tetrahedron.

The Mössbauer effect for the $Sr_{1-x}La_xFeO_{3-\delta}$ system, prepared by firing under a high oxygen pressure, was studied by Shimony *et al.*[11] and by Gallagher *et al.*[12] In their investigation, however, attention was paid only to the mixed valencies of Fe^{3+} and Fd^{4+}, not to the generated lattice defect. On the other hand, only a few studies of the defect structure using Mössbauer spectroscopy have been published. Sawatzky *et al.*[13] determined the extent of the distribution of Fe^{3+} for octahedral and tetrahedral sites in the inverse spinel $CoFe_2O_4$. On the other hand, Elias *et al.*[14] successfully confirmed the occurrence of the tetrahedral Fe^{3+} site due to the presence of iron vacancies even in the wüstite phase ($Fe_{1-x}O$); their results are consistent with the results of the neutron-diffraction study.[15]

Experimental

Preparation of the Samples. The solid-solution samples were prepared by ball milling mixed particles of graduated pure reagents, (α-Fe_2O_3, $SrCO_3$ and La_2O_3) in the desired proportions, and by then firing at 900°C and 1000°C in air for 5 hr. The samples thus obtained were refired at 1100°C in a vacuum ($\sim 10^{-3}$ mmHg) and then cooled to room temperature, while the same degree of vacuum was maintained, after a given firing period. The method of preparation has been described in greater detail in the previous paper.[1]

X-Ray Diffractometry. X-ray powder diffractometry using cobalt-$K\alpha$ radiation was used for the assignment of the structure as well as for the determination of the lattice constant of the specimens.

Measurements and Analysis of Mössbauer Spectra. The Mössbauer spectrum was taken using a spectrometer equipped with 400-channel pulse-height analyzer (a RAH-403 type; Hitachi Co., Ltd.), calibration with either iron foil or α-Fe_2O_3. The source used was cobalt-57, with 14.4 keV γ-radiation, dispersed in either palladium or copper; it was driven at a constant accerelation speed ($\pm$10 mm/sec) for all the measurements at room temperature. The absorbers were prepared by grinding the oxide samples into fine particles and by then evenly spreading them on a square aluminium plate 0.50 mm thick with a circular hole 20 mm in internal diameter; both sides of the powder compact thus molded were sealed with cellophane. The thickness of the powder compact was chosen so that it contained about 15—20 mg of total iron per square centimeter of the cross section. The isomer shifts are given in values relative to metallic iron for all the samples.

The energy levels of magnetic hyperfine splitting between the ground state and first excited one of iron-57 under the presence of an axially symmetric electric-field gradient is given by the following equation:

$$E = -g\mu_n H m_I + (-1)^{|m_I|+1/2}\varepsilon, \qquad (1)$$

where μ_n, H, m_I, and ε are the nuclear magneton, the internal magnetic field, the magnetic quantum number, and the electric quadrupole parameter respectively. Fig. 1 shows

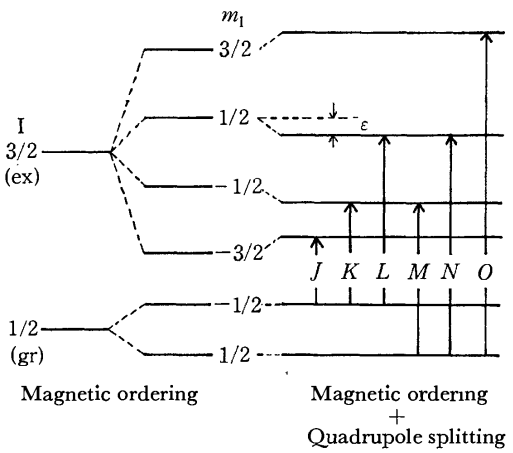

Fig. 1. Energy levels of iron-57 in the Mössbauer spectrum. I, m_I and ε are nuclear spin quantum number, magnetic quantum number of iron-57 and quadrupole parameter, respectively.

diagramatically the energy levels of iron-57. In this figure, each energy level is denoted as *J*, *K*, *L*, *M*, *N*, or *O*, in the order of ascending energy. Therefore, the quadrupole parameter (ε) is given by:

$$\varepsilon = \frac{1}{4}\{(O-N)-(K-J)\}. \qquad (2)$$

On the other hand, an isomer shift (I.S.) closely correlated

with the contribution of *s*-electron density manifests itself as a shift of the nuclear energy levels and, therefore, is given by the following equation:

$$\text{I.S.} = \frac{4}{5}\pi Ze^2R^2\left(\frac{\delta R}{R}\right)\{|\Psi_a(0)|^2-|\Psi_s(0)|^2\} \quad (3)$$

$$= \frac{1}{12}(3J+2K+L+M+2N+3O), \quad (4)$$

where $e|\Psi(0)|^2$ is an expression for the charge density at the nucleus and whose R and δR are, respectively, the ground-state radius of iron-57 and the difference in nuclear radius between the ground-state and the excited-one. The Mössbauer velocity was obtained by multiplying the respective pair peaks, *J*—*O*, *K*—*N*, and *L*—*M*, by the transition probabilities of 3, 2, and 1 respectively.

Results and Discussion

At first, the structural knowledge on the $Sr_{1-x}La_xFeO_{3-\delta}$ solid-solution system obtained by X-ray diffractometry will be briefly described. The content of oxygen vacancies (δ) varies with the content of La (x), as may be understood from the formula. The X-ray powder patterns of the sample with x=0.0—0.20 could be indexed on the basis of a brownmillerite-type structure with orthorhombic symmetry. It is noticeable that the intensity of fairly strong peaks with an even larger k number in Miller indices (*hkl*) (*e.g.*, (161), (080), and (280)) decreased with an increase in x. On the other hand, the respective pair peaks, such as (200)—(002), (240)—(042), and (341)—(143), in the brownmillerite-type phase approached each other with an increase in x, resulting in the appearance of the corresponding peaks of (110), (111), and (211) in the cubic perovskite-phase with a further increase in x.

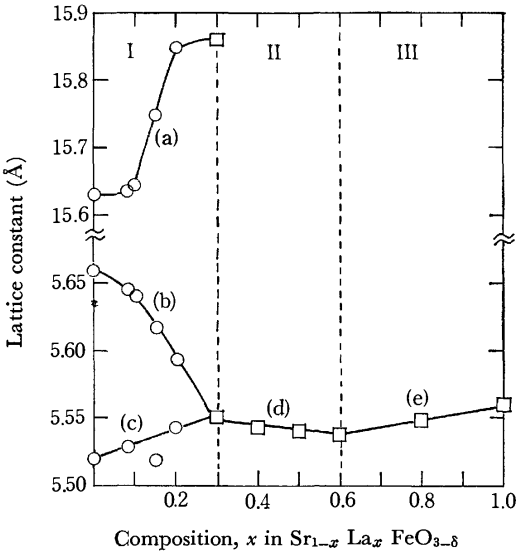

Fig. 2. Lattice constants in the system $Sr_{1-x}La_xFeO_{3-\delta}$ prepared by firing at 1100°C in vacuum: (a), (b), and (c) are the lattice constants of *b*-, *a*- and *c*-axis for the brownmillerite-type orthorhombic phase (region I), respectively and (d) and (e) are the lattice constants for the cubic perovskite-type phase (region II) and pseudocubic $LaFeO_3$-type one (region III).

The rather broad diffraction pattern and no splitting of the peak due to $K\alpha_1$ and $K\alpha_2$ radiation at a high diffraction angle for the cubic perovskite phase in the compositional range of x=0.30—0.60 suggest that the structure is a little random as a result of its vacancies. The lattice constant *versus* the composition is plotted in Fig. 2. In the unit-cell parameter of the brownmillerite-type phase, the *a*-axis decreased rapidly, whereas the *c*-axis increased slowly, with an increase in the La content, the two meeting at x=0.30. In Fig. 2, the lattice constant in the cubic perovskite-type phase is given, for comparison, as a value 2 times the actual lattice constant, a_0.[16] On the other hand, the tendency of the b_0 parameter to increase over the region with x=0.20 resulted in 15.85 Å, which was approximately equal to 15.94 Å ($=a_0\times4\sqrt{2}$).[16] This fact allows us to consider the phase with x=0.20 as a pseudotetragonal structure formed as an intermediate phase during the transformation between the two phases. Over the compositional range of x=0.30—0.60, the cubic perovskite-type structure was preferable; its lattice constant was 3.926 Å at the composition of x=0.30, larger than that of 3.850 Å for $SrFeO_3$ prepared by firing under a high oxygen pressure, after MacChesney *et al.*[6] The lattice constant in the cubic phase decreased linearly with an increase in the contents of La. The further addition of La (x=0.80—1.0) distorted the cubic lattice to a $LaFeO_3$-type structure with an orthorhombic symmetry. Thus, it seems likely that the presence of oxygen vacancies of the solid-solution plays an important role in the stabilization of a perovskite-type structure with cubic symmetry.

The Mössbauer spectrum of $SrFeO_{2.5}$ at room temperature is shown in Fig. 3(a). It is understandable in terms of a couple of six-line patterns arising from types of iron sites having both different magnetic hyperfine splitting and quadrupole splittings. The quadrupole splitting must occur as a result of the destruction of the spherical symmetry built by the surrounding ions around iron, because the Fe^{3+} ion itself is in a spherically symmetrical $^6A_1$ state. Generally, the relation between ΔE_Q, the quadrupole splitting observed above the Neel point, and ε, the quadrupole parameter observed below it, are given by the following equation:

$$\varepsilon = \frac{1}{4}\Delta E_Q(3\cos^2\theta-1), \quad (5)$$

where θ is the angle between the magnetic field and the principal axis of the electric-field gradient. The idea proposed by Grant[10] in his Mössbauer study on $CaFeO_{2.5}$ may be also true for $SrFeO_{2.5}$; that is, the electric-field gradient at both the iron tetrahedral and octahedral sites may be axially symmetric, with the *z*-principal axis parallel to the crystallographic *b*-axis. On the other hand, the antiferromagnetic spins of both the iron sites in $SrFeO_{2.5}$ are supposed to be along the

16) When the lattice constants for the brownmillerite-type phase with an orthorhombic symmetry and for the cubic perovskite-type one are assumed to be a_0, b_0, c_0, and a^* respectively, the relations among them are given by the following equations; $a_0\simeq c_0\simeq 2a^*$ and $b_0\simeq 4\sqrt{2}a^*$.

c-axis. Therefore, Eq. (5) may be simplified to:

$$\varepsilon = -\frac{1}{4}\Delta E_Q \qquad (6)$$

Since the Mössbauer spectra are measured below the Neel point in this work, ΔE_Q can be calculated using the observed values of ε with the aid of Eq. (6). The presently-observed absorption lines are here denoted as J, K, L, M, N, and O in the order of ascending energy, as has been described above, together with additional symbols showing the coordination numbers of the iron sites. Therefore, for example, the third line from the left in the tetrahedral iron site is expressed by 4L (Fig. 3(a)).

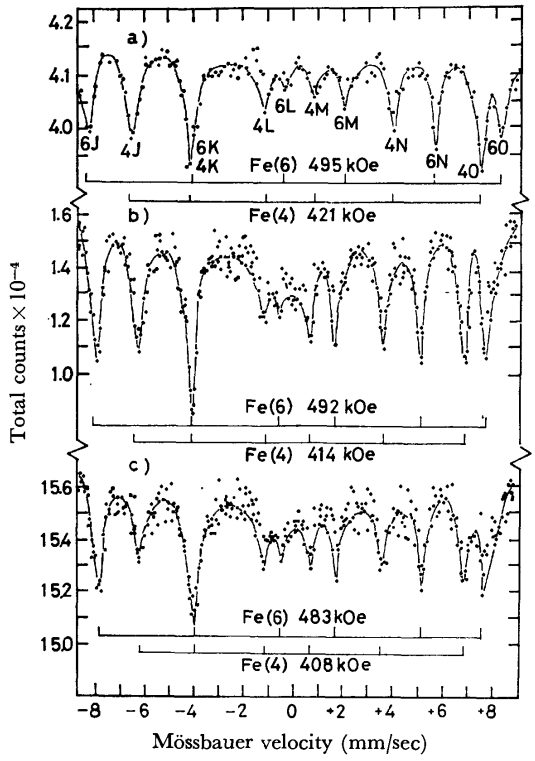

Fig. 3. Mössbauer spectra in the system $Sr_{1-x}La_xFeO_{3-\delta}$ ($0.0 \leq x \leq 0.10$) prepared by firing in a vacuum: a), b) and c) are the spectra for the composition of $x=0.0$, 0.07 and 0.10, respectively. Number in parentheses is coordination number of oxygen.

The Mössbauer parameters of $SrFeO_{2.5}$, *i.e.*, the isomer shifts, quadrupole splittings, and internal magnetic fields, were calculated to be +0.235 mm/sec, +0.391 mm/sec, and 495 kOe for the octahedral iron site, and +0.160 mm/sec, −0.280 mm/sec, and 421 kOe for the tetrahedral one, respectively. The higher velocity of the isomer shift, accompanied by a larger internal magnetic field, for the octahedral site than those for the tetrahedral one may be explained by the contribution of covalency in Fe–O bonding, this being also found in the cases of spinels[17] and garnets.[18] Both the values of the isomer shift indicate that two types of iron in this solid-solution are three valency states.

Accordingly, the relation between the substituted La content and the oxygen one for the solid-solution system in the present study may be presented by x in the composition: $Sr_{1-x}La_xFeO_{2.5+x/2}$.

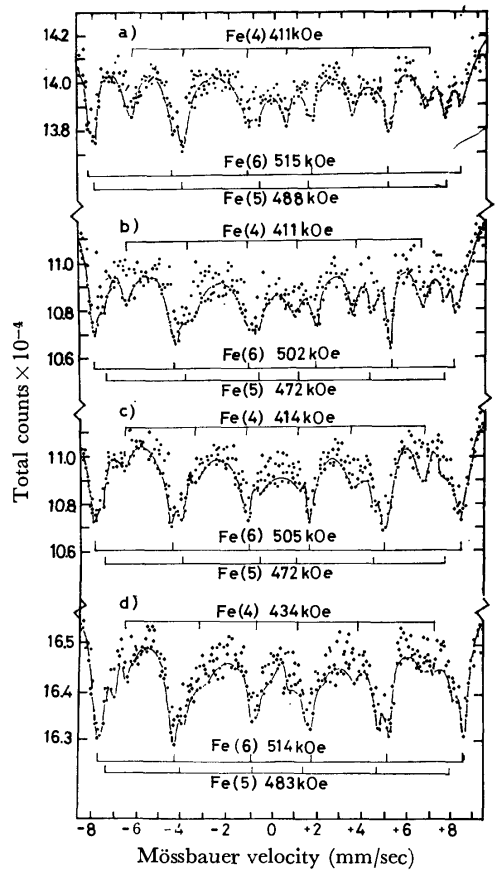

Fig. 4. Mössbauer spectra in the system $Sr_{1-x}La_xFeO_{3-\delta}$ ($0.15 \leq x \leq 0.40$) prepared by firing in a vacuum: a), b), c) and d) are the spectra for the composition of $x=0.15$, 0.20, 0.30 and 0.40, respectively. Number in parentheses is coordination number of oxygen.

The Mössbauer spectra for $x=0.07$ and $x=0.10$ are shown in Fig. 3(b) and 3(c) respectively. The respective intensities of the 4M-, 4N-, and 4O-peaks decreased with an increase in the La content. This fact may be attributed to a change in the coordination state of Fe^{3+} from a tetrahedral site to an octahedral one occurring as a result of the incorporation of oxygen due to La substitution. No change was observed in the values of the internal magnetic field and quadrupole splitting, whereas the isomer shift for the octahedral, Fe^{3+} site had a tendency to move toward the higher-velocity side when the content of Sr decreased in the compositional range from $x=0.0$ to 0.10.

The Mössbauer spectrum for the composition with $x=0.15$ revealed a broad line with an asymmetric form, as is shown in Fig. 4(a). In addition, new absorption lines appeared between the 4O and 6O lines, and between the 4K and 6K lines. This means the appearance of new six lines different from the lines for the octahedral and tetrahedral Fe^{3+} sites. If only the amount of oxygen incorporated by the addition of La controls the change from a tetrahedral site to an

octahedral one, the peak intensity for the tetrahedral site must be only two-thirds that for the octahedral site at the composition of $x=0.15$. Experimental evidence, however, indicated that the intensities for the two sites were nearly equal. The values of the isomer shift, the quadrupole splitting, and the internal magnetic field for the sample with $x=0.15$ were +0.380 mm/sec, +0.109 mm/sec, and 515 kOe for the octahedral site, +0.136 mm/sec, −0.150 mm/sec, and 411 kOe for the tetrahedral site and +0.326 mm/sec, +0.326 mm/sec, and 488 kOe for the new peak, respectively. It is noticeable that the isomer shift and the internal magnetic field for the new peak both fall between those for the octahedtal site and those for the tetrahedral site.

The Mössbauer spectrum for the sample with $x=0.20$, with a pseudotetragonal perovskite-type structure, is shown in Fig. 4(b); three kinds of six absorption line also appear, and a new line appears in the neighborhood of the 6*N* line besides the splitting which has already occurred in the sample with $x=0.15$. The sample with $x=0.30$ revealed an exact cubic perovskite-type structure. According to a discussion on the basis of the crystal structure, the central metal ion in the cubic perovskite-type structure must be surrounded by six oxygen ions. Nevertheless, it is interesting that the presently-observed oxygen-deficient perovskite-type phase with cubic symmetry possesses measurable amount of the tetrahedral iron site and the "X-site" in addition to the octahedral site (Fig. 4(c)).

In the sample with the composition of $x=0.40$ (Fig. 4(d)), the absorption line from the tetrahedral iron site was still recognized even if its intensity was weakened. For the sample with $x=0.50$ (Fig. 5(a)) and $x=0.80$ (Fig. 5(b)), however, broad six line arose only from the octahedral site, in which the half-height width values of the respective line were four times (for $x=0.50$) and two times (for $x=0.80$) the value in $LaFeO_3$ (Fig. 5(c)). In spite of such a situation regarding the intensity of the absorption lines of the octahedral site, little change for that of the tetrahedral site occurred. These facts allow us to say that an increase in the oxygen content in the solid-solution plays no role in the occurrence of change from the tetrahedral site to the octahedral one over the compositional range from $x=0.50$ to $x=1.0$.

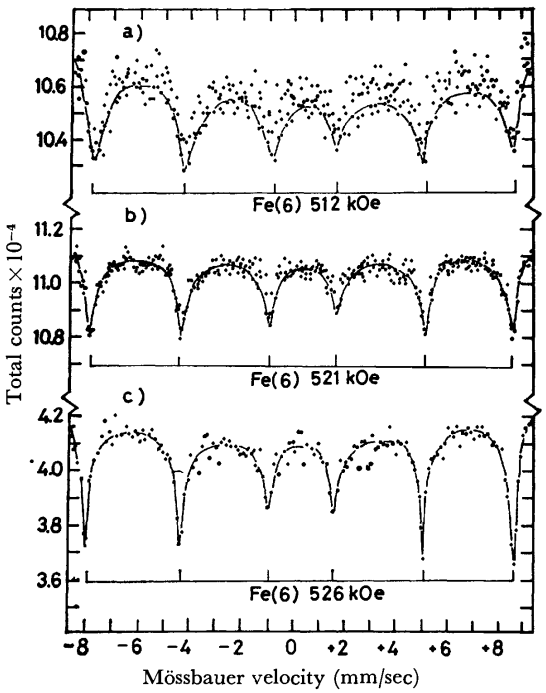

Fig. 5. Mössbauer spectra in the system $Sr_{1-x}La_xFeO_{3-\delta}$ ($0.50 \leq x \leq 1.0$) prepared by firing in a vacuum: a), b), and c) are the spectra for the composition of $x=0.50$, 0.80 and 1.0, respectively. Number in parentheses is coordination number of oxygen.

To clarify the details of the present oxygen-deficient structure, it seems important to discuss the assignment of the unknown peak for "X-iron site" which appeared in all the samples with the composition of $x=0.15$—0.40. The characteristics of the new unknown pattern may be summarized as follows:

(1) The value of the isomer shift falls between that for the octahedral site and that for the tetrahedral site, regardless of the composition.

(2) The value of the internal magnetic field is also between that for the octahedral site and that for the tetrahedral site.

(3) No measurable change in the intensity of the new peak is observed over the entire range of composition of the solid-soltuion presently treated.

(4) The magnitude and the direction of the quadrupole splitting in the brownmillerite-type phase are almost equal to those for octahedral site, the magnitude being decreased considerably in the cubic perovskite-type phase.

The possible origins for the occurrence of the new peaks are as follows:

(1) The presence of a different phase containing Fe^{3+}.

(2) The existence of Fe^{2+} occurring as a result of firing at a fairly high temperature in a vacuum and/or of the substitution of La^{3+}.

(3) The presence of a tetrahedral or octahedral site with an environment slightly different from the brownmillerite-type phase of $SrFeO_{2.5}$.

(4) The presence of Fe^{4+} remained unchanged even under a fairly high degree of vacuum.

(5) The formation of five-coordinated Fe^{3+} as an intermediate during the course of the transformation from a tetrahedral site to an octahedral one.

No different phase containing Fe^{3+} with magnetic ordering, however, was confirmed by either X-ray diffractometry or magnetic measurements. The possibility of (2) and (3) can also be ruled out because the value of the isomer shift is between those for the octahedral and tetrahedral Fe^{3+} sites. On the other hand, Fig. 2 shows that the length of the *b*-axis in the brownmillerite-type structure increased with an increase in the content of incorporated oxygen, suggesting an increase in the over-all coordination number of Fe^{3+}; thus, one more of the possibilities (4) may be ruled out. The most probable reason for the occurrence of the octahedral iron site may be the existence of small amounts of $LaFeO_3$ in the brownmillerite-type phase.

The values of the isomer shift and the internal magnetic field of $LaFeO_3$, however, indicate that it is different from the values for the "X-iron site". The above anomalies in the Mössbauer parameters may be explained by the fifth possibility, that is, the presence of the five-coordinated Fe^{3+}.

Van Loef,[19] in his Mössbauer study of spinels and garnets, suggested that the values of the isomer shifts and the internal magnetic fields have a close relation to the form of oxygen-coordinated polyhedron. The results in the present work support his idea. The possible form of the five-coordinated polyhedron may be a regular trigonal bipyramidal rather than a square pyramidal because of the fairly small quadrupole splitting.

Remarks
C.N.: oxygen coordination number around iron
$H_{int.}$: internal magnetic field
I.S. : isomer shift relative to metallic iron
ε : quadrupole parameter

The Mössbauer parameters obtained in the present work are summarized in Table 1. The isomer shift and the quadrupole splitting for the three types of iron sites against the composition are also plotted in Fig. 6 and 7. The isomer shift for the octahedral Fe^{3+} site increased abruptly with an increase in the concentration of La and then stayed constant over the cubic perovskite-type phase, approaching that of $LaFeO_3$ when the concentration of La increased further. The isomer shift for the tetrahedral site showed a more complicated variation with the composition. It decreased rapidly up to $x=0.20$ and then increased linearly above $x=0.20$, nearly coinciding with the

□: quadrupole splitting for the tetrahedral Fe^{3+} site

expected value for the octahedral site estimated by extraporation to $x=0.50$, where the Mössbauer pattern showed only a broad six-line pattern for the octahedral iron site.

The relation between the quadrupole splitting and the composition seems to be valuable enough to discuss on the basis of crystal symmetry. Though the values of the quadrupole splitting for all the sites over the entire compositional range of $x=0.0$—0.10, in which the brownmillerite-type phase was preferable, are comparable to that of $SrFeO_{2.5}$, they considerably decreased with the progress of the structural transformation from the orthorhombic phase to the tetragonal one, and then show no quadrupole splitting when the cubic perovskite-type is attained. No internal magnetic field dependence on the composition was observed; these values for octahedral, tetrahedral, and trigonal bipyramidal sites were found to be ~510, ~480, and ~410 kOe respectively.

It is necessarily uncommon for the trigonal bipyra-

Fig. 8. Imaginative oxygen-deficient cubic perovskite-type structure in the system $Sr_{1-x}La_xFeO_{3-\delta}$ prepared by firing in a vacuum, where large cation, Sr or La ion is omitted for simplicity. The primitive unit cell is represented in dashed line. Number in parentheses is coordination number of oxygen.

midal polyhedron of oxygen to be present as a result of the absence of oxygen along the direction [110] out of the cubic perovskite-type structure. The imaginative oxygen-deficient cubic perovskite-type structure with octahedral, trigonal bipyramidal, and tetrahedral iron site is shown in Fig. 8. The reported Mössbauer spectroscopic measurements, together with the nuclear ferromagnetic resonance spectroscopic measurements, however, have already indicated that magneto plumbite, $BaFe_{12}O_{19}$, with layer structure, has a trigonal bipyramidal iron site.[20-22] The isomer shift for the trigonal bipyramidal iron site in $BaFe_{12}O_{19}$ was found to be between that for the octahedral site and that for the tetrahedral site, as in the present study. On the other hand, the quadrupole splitting and the internal magnetic field were larger and smaller than the values for both the octahedral and tetrahedral sites. In this case, however, the presence of the five-coordinated iron site may be expected because one of the anion sites is replaced by barium in the $BaFe_{12}O_{19}$.

Wadsley[23] has studied the importance of transition metal-oxygen mixed coordination schemes associated with an anion-deficient phase. Negas and Roth[24] have discussed the stoichiometry and the stability of $SrMnO_{3-\delta}$ from the standpoint of variation in the coordination scheme of the manganese cation and suggested the presence of a trigonal bipyramidal manganese site in addition to a normal octahedral site, without, however, reporting any data on this idea. In summary, it may be shown that the presence of an ion deficiency in the crystal lattice contributes to the change in the coordination number. Accordingly, the traditional thinking that vacancies exist as simple holes is not applicable for an oxygen-deficient perovskite-type structure. This idea may be sometimes true for an oxide solution.

The authors would like to thank Dr. Ri-ichi Kikuchi for allowing them to use the apparatus for the Mössbauer effect at the Radio Isotope Laboratory in the Institute of Scientific and Industrial Research, Osaka University, and Dr. Shin-ichi Shirasaki for his helpful discussion while they were preparing this paper.

Electron Spin Resonance Study of Adduct Formation by Bis(trifluoroacetylacetonato)copper(II) with Phosphorus Donor Ligands

F. LEH and K. M. CHAN*

Air Pollution Research Center, University of California, Riverside, California 92502, U.S.A.

(Received September 6, 1971)

The study of the ESR spectra parameters of bis(trifluoroacetylacetonato)copper(II)-phosphorus complexes in chloroform solution at room temperature and 77°K shows that the g and hyperfine tensors change with the formation of 1 : 1 adduct. Such effect is more clearly exhibited by the parameters $A_{\parallel}$ and $g_{\parallel}$. A correlation is obtained between the spectral data and the basicity of the tertiary phosphine ligands.

High spin divalent transition metal ions usually have strong tendency to form compounds having a coordination number greater than four.[1] For example, the axial ligation of bis(acetylacetonato)copper(II) forms 1 : 1 adduct with heterocyclic bases.[2,3] However, such adduct formation depends on the relative electron withdrawing power of the β-diketones.[4] Successive trifluoromethylation of the acetylacetones will increase their affinity for the copper atom for axial ligation, which has been demonstrated by the formation of 1 : 1 and/or 1 : 2 addition complexes with donor solvent and nitrogen containing chelates by bis(trifluoroacetylacetonato)copper(II)[5] and bis(hexafluoroacetylacetonato)-copper(II).[6,7]

The preparation of the above complexes of σ-type nitrogen containing ligands are well documented, but not for π-type bases. This is primarily due to the fact that copper(II) salts react with tertiary phosphine and are reduced to copper(I) compounds.[8-10] Only recently the preparation of 1 : 1 adduct of bis(hexafluoroacetylacetonato)copper(II) with triphenylphosphine was reported.[11] This paper describes our work in ESR study of 1 : 1 adducts of bis(trifluoroacetylacetonato)copper(II) with tertiary phosphines.

Solvent Effect on Copper Complexes

Antosik *et al.*[12] analysed the effect of the solvent on axial ligations. Based on the ESR spectra of several square planar cupric β-ketoenolates, they concluded that the axial ligation arose from the two-axial dipoles acting on the two axes perpendicular to the plane of cupric complexes. First-order perturbation theory was used to obtain the relationships between the spin-Hamiltonian parameters for the 'isolated' complexes with those for the perturbed complexes. Greater values of the parallel components of the g tensors and numerically smaller values of the parallel components of the hyperfine tensor for the chloroform complexes than that of the corresponding components in the 'isolated' cupric chelates were predicted.

A systematic investigation of the ESR parameter $\langle A \rangle$ of bis(t-butylacetoacetato)copper(II) in different organic solvents such as cyclohexane, carbon tetrachloride, benzene, chloroform, pyridine-cyclohexane mixture, was carried out by Libutti, Wayland, and Garito.[13] Basic solvents, *e.g.* pyridine, caused a large decrease in $\langle A \rangle$ values and an increase in $\langle A \rangle$ values occurred if less coordinating solvents were used. Another study with ESR spectra of bis(acetylacetonato)-copper(II) in various solvents was reported by Adato and Eliezer,[7] and showed that the anisotropy of the nuclear hyperfine interaction tensor varied with different solvents. Such effect was claimed to be better obtained from the hyperfine splitting parameter $A_{\perp}$.

Experimental

Dark green bis(trifluoroacetylacetonato)copper(II)-phosphorus complexes, $Cu(tfac)_2 \cdot PR_3$ (where $PR_3 = (n\text{-}Bu)_3P$, Et_3P, Ph_3P, $PhPMe_2$, Ph_2PMe, $(PhO)_3P$) were prepared by mixing 1 : 1 ratio of bis(trifluoroacetylacetonato)copper-(II) with phosphine in chloroform solution under nitrogen. Bis(trifluoroacetylacetonato)copper(II)-phosphorus complexes are quite stable in vacuum at 0°C, but decompose rapidly when heated over 50°C.

ESR spectra were recorded with a Varian V-4502 EPR spectrometer equipped with a 100-kHz field modulation and control unit (Model V-4560). The g values were measured by comparison with the free radical standard diphenylpicryhydrazyl (DPPH) for which the g_0 value was accurately known to be 2.0036.

Results and Discussion

In chloroform solution, bis(trifluoroacetylacetonato)copper(II)-phosphorus complexes, $Cu(tfac)_2 \cdot PR_3$ ($PR_3 = Et_3P$, $(n\text{-}Bu)_3P$, Ph_2PMe, $PhPMe_2$) exhibit the

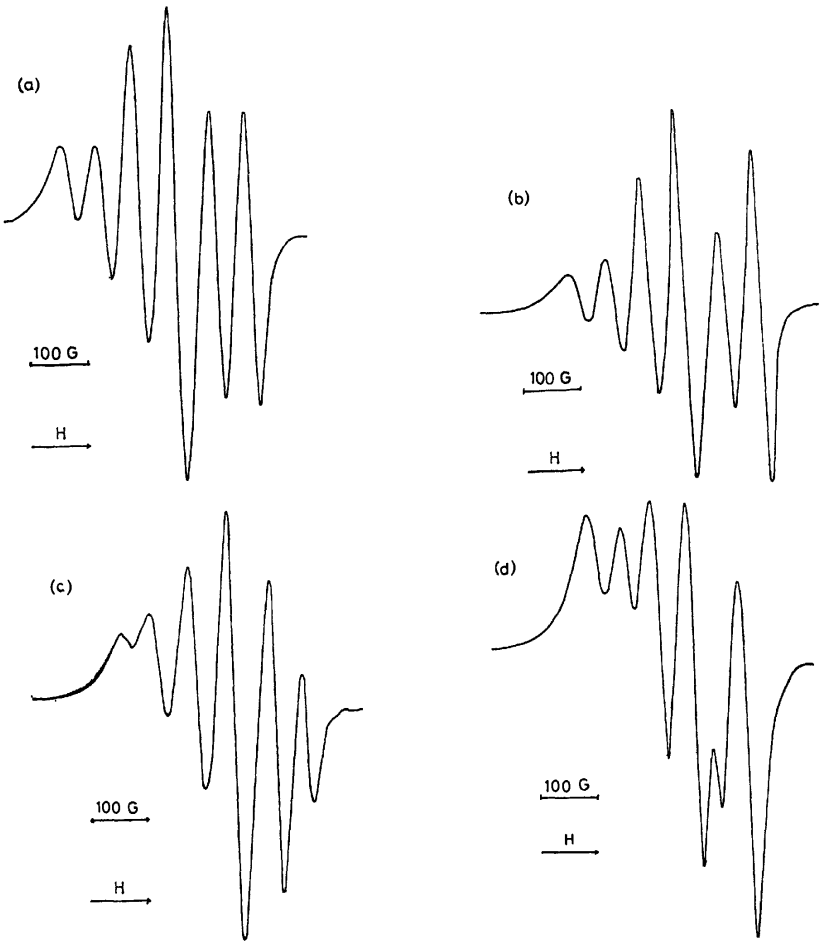

Fig. 1. ESR spectra of bis(trifluoroacetylacetonato)copper(II)-phosphorus complexes at room temperature in chloroform.
(a): triethylphosphine (b): *n*-tributylphosphine
(c): dimethylphenylphosphine (d): diphenylmethylphosphine

ESR spectra as shown in Fig. 1 (a), (b), (c), (d). In a polycrystalline sample, all molecules are assumed to be in an identical environment, and their microcrystalline axes randomly oriented. In a frozen solution spectra (Fig. 2), it is possible to obtain $g_{\parallel}$ and $A_{\parallel}$, and from these values we calculated $g_{\perp}$ and $A_{\perp}$ using the approximate equations $\langle g\rangle = g_{\parallel}/3 + 2g_{\perp}/3$ and $\langle A\rangle = A_{\parallel}/3 + 2A_{\perp}/3$, where $\langle A\rangle$ and $\langle g\rangle$ are obtained in solution assuming that the freezing of the solvent does not change the local crystal field in a manner that would affect the isotropic A and g values.

The spectra of bis(trifluoroacetylacetonato)copper-(II)-phosphorus complexes characterise the interaction of the unpaired electron of Cu(II) (nuclear spin $I=3/2$) with one ^{31}P nucleus ($I=1/2$), this interaction being responsible for the doublet splitting of the four copper lines. Due to the overlapping of $+3/2$ and $+1/2$ hyperfine lines of the one with $-3/2$ and $-1/2$

a) from Ref. 13.

lines of the other, a typical six lines spectra are observed. When the phosphine is triphenylphosphine, the ESR spectra of the complexes in chloroform consist mainly of the unresolved four copper lines, but the greater g and smaller A compared with $Cu(tfac)_2$ imply the axial ligation of phosphorus ligand.[12] From the data in Table 1, we suggest the structure of (1) and (2) as in the following diagram, where the chloroform molecule is linked to the metal *via* one of its chlorines[4] or bonded to a pair of the ligand oxygen atoms *via* hydrogen atom.[16] The evidence for the formation of six coordinate bis adducts in bis(trifluoroacetylacetonato)-copper(II) has been found in other case[5] and bis adducts of square planar Ni(II) complexes are common.[14,15] Observations of the X-band spectra of a series of Cu(II) β-diketonates in chloroform-toluene glasses[12] have shown that the exhibition had twice the number of expected lines. This is due to the formation of weak chloroform complexes with some square planar compounds of copper(II).

Our results indicate that phosphines are better ligands towards bis(trifluoroacetylacetonato)copper(II) than the corresponding phosphites. Since phosphite is better π-bonder and poorer σ-donor than phosphine, it follows that the σ-bonding tendency of a ligand is a predominant factor in determining its reactivity. The data in Table 1 also indicate that in phosphine series, the A_P, decreases with increasing basicity of the ligand in the order $Et_3P > (n\text{-}Bu)_3P > Me_2PPh \gg MePPh_2 \gg PPh_3 > P(OPh)_3$. The relative basicities of the phosphines were measured by Streuli,[17] using nitromethane as a solvent and recording the difference in half-neutralization potentials, ΔHNP, with *N,N'*-diphenylguanidine as a standard. The electron involved in π and σ-bonding between transition metal and phosphine is shifted more toward the phosphorus atom. The highest occupied molecular orbital of the above complexes, which contain an unpaired electron, seems to reflect the general donor-acceptor properties of the ligands.

As predicted from the molecular orbital calculations,[12] the axial ligation results in decreasing separations of ΔE_{xy} and ΔE_{xz}, which yield the differences in the ESR parallel components of the g and hyperfine tensors. The decrease in both $A_\parallel$ and $g_\parallel$ values from bis(trifluoroacetylacetonato)copper(II) to 1:1 phosphine adduct illustrates the coordination effect. Such phenomena were previously attributed to the solvent effect. Dimerization is also expected to reduce the value of hyperfine tensor in a manner similar to the formation of 1:1 adduct. However, in a dimer, two copper(II) ions ($S=1/2$) are coupled together by a dipolar interaction, a singlet ($S=0$) and triplet ($S=1$) state will be formed and the dipolar interaction will cause a separation of the $M_s=1$ and $M_s=0$ levels in zero magnetic field. ESR transitions are observed within the triplet. These will be in either normal or allowed $\Delta M=1$ type centered about a resonance position H_0, and in addition one may find forbidden or $\Delta M=2$ transition occurring at about $H_0/2$. The absence of low field signal in ESR spectrum of bis-(trifluoroacetylacetonato)copper(II)-phosphorus complexes reveals that the changes in ESR parameters can thus be ascribed to differences in the monomer and not to partial dimer.

Attempts to synthesize 1:2 complexes of bis(trifluoroacetylacetonato)copper(II) and phosphine were unsuccessful. The reactions led to the formation of Cu(I) complexes as $Cu(tfac)(PR_3)_2$.

The above experimental evidence indicates the formation of 1:1 adduct of bis(trifluoroacetylacetonato)-copper(II) and tertiary phosphines. Further systematic investigations of interaction between β-diketone transition metal complexes and phosphorus ligands are in progress.

Infrared Spectrum and Normal Vibrations of *N,N*-Dimethylthioacetamide

Arabinda RAY and D. N. SATHYANARAYANA

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore-12, India

(Received February 9, 1972)

Infrared spectrum of *N,N*-dimethylthioacetamide (DMTA) has been recorded in the region 250—4000 cm^{-1}. Normal vibration analysis has been carried out employing Urey-Bradley force field and assignments are made and supported by comparison with related molecules. The complexes of DMTA with cobalt(II), copper(I), and mercury(II) chlorides have been prepared and their infrared spectra recorded. The frequency shifts in metal complexes are in accord with the assignments of C=S and C–N frequencies.

Although the normal vibrations of primary and secondary thioamides have been well investigated,[1,2] no detailed study of tertiary thioamides seems to have been made. It is only recently we made a normal vibration analysis of *N,N*-dimethylthioformamide (DMTF) to know the detailed nature of the vibrations.[3] It was considered worthwhile to study the normal vibrations in the next higher thioamide, *N,N*-dimethylthioacetamide (DMTA). In this paper, the normal coordinate treatment of DMTA employing Urey-Bradley force field (UBF) is reported. The preparation of the complexes of DMTA with the chlorides of cobalt(II), copper(I), and mercury(II) and their infrared spectra are also included. The assignment of the infrared frequencies are discussed by comparison with related molecules and also from frequency shifts in metal complexes.

Experimental

Materials Employed. *N,N*-Dimethylthioacetamide was synthesized by treating "high purity" *N,N*-dimethylacetamide (obtained from National Chemical Laboratory, Poona, India) with phosphorus pentasulphide (Merck) in benzene (A. R. Grade) according to the general procedure of Hofmann.[4] It was repeatedly recrystallized from *n*-hexane. $CoCl_2 \cdot 6H_2O$, $CuCl_2 \cdot 2H_2O$, and $HgCl_2$ were of A. R. Grade quality. Distilled ethanol (99%) was used.

Preparation of Complexes. *Dichlorobis(DMTA) Cobalt-(II)*: It was prepared by mixing ethanol solutions of DMTA and cobalt(II) chloride according to the reported procedure[5] (Found: Co, 17.03; S, 18.66%. Calcd for $CoCl_2 \cdot 2DMTA$: Co, 17.54; S, 19.05%.).

Chloro-(DMTA) Copper(I): An ethanol solution of DMTA was mixed with copper(II) chloride in ethanol, when copper-(II) gets reduced to copper(I) and an yellow precipitate of the cuprous complex was obtained. It was filtered off, washed thoroughly with ethanol followed by carbon disulphide and dried in vacuum (Found: Cu, 31.23; S, 14.90%. Calcd for CuCl·DMTA: Cu, 31.43; S, 15.84%.).

Dichlorotetrakis(DMTA) Mercury(II): The above method was followed for its preparation. The resulting white precipitate was filtered, washed with ethanol and dried in vacuum (Found: Hg, 30.30; S, 18.41%. Calcd for $HgCl_2 \cdot 4DMTA$: Hg, 29.34; S, 18.72%.).

Analysis. The complexes were analysed for metal and sulfur by standard methods.

Infrared Spectra. The infrared spectra of DMTA and its complexes were taken in Nujol mull and KBr pellets on a Carl-Zeiss UR 10 spectrophotometer in the range 4000—400 cm^{-1}, and on a Perkin-Elmer grating spectrophotometer, 521 in the range 400—250 cm^{-1}.

Normal Coordinate Treatment

The molecule DMTA belongs to the point group C_s and its 39 fundamental vibrations are classified as 24 A′ and 15 A″ vibrations. The secular equation of the Wilson's GF matrix was solved for A′ vibrations only, which were of interest in the present study. Further, the six C–H stretching modes were split off for simplification. The internal coordinates are defined in Fig. 1 and the symmetry coordinates are listed in Table 1. The structural parameters were taken from DMTF.[3] The C–C′ bond length was assumed to be 1.54 Å and the angles around carbon, tetrahedral. An IBM computer 360/44 was used.

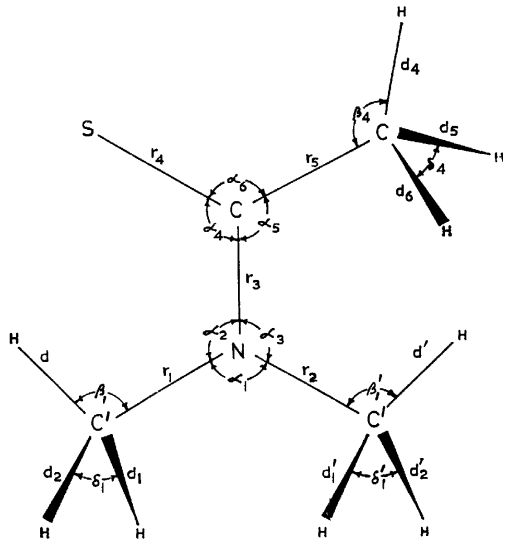

Fig. 1. Internal coordinates for DMTA.

Force Field. It is noteworthy that the UBF has been found to be very effective in the vibrational analysis of thioamide derivatives.[1-3,6] It is for this reason that UBF was chosen for our calculations.

K_{CN}	5.75	$H_{C'NC}$	0.20	$F_{CC'}$	0.55
K_{CS}	3.74	H_{SCN}	0.150	F_{NC}	0.75
K_{CC}	2.85	$H_{C'CN}$	0.390	F_{NS}	1.45
Intramolecular tension (md Å)		$H_{C'CS}$	0.390	F_{SC}	0.60
k_{CCH3}	−0.056	$H_{HC'N}$	0.30	F_{NH}	0.55
k_{NCH3}	−0.050	$H_{HC'(N)H}$	0.425	F_{CH}	0.50
		$H_{HC'C}$	0.255	F_{HH}	0.05
		$H_{HC'(C)H}$	0.410	F'	−0.1F

The initial set of UBF constants were taken from thioacetamide (TAM), *N*-methylthioacetamide (NMTA), and DMTF.[1-3] The force constants were progressively improved by an iterative procedure. Some of the bending force constants in DMTA differ from, and the stretching and repulsion force constants remain nearly the same as those in TAM, NMTA, and DMTF. Thus, the force field appears to be satisfactorily transferrable among related thioamide molecules. The frequency fit is satisfactory except the rocking frequencies which show comparatively large deviations as are usually the case in the UBF. The final set of force constants is given in Table 2.

Results and Discussion

The observed and calculated frequencies along with the assignments from potential energy distribution (PED) are given in Table 3. The infrared frequencies of DMTA and its complexes in the region 250—1800 cm^{-1} and their assignments are presented in Table 4. A brief discussion of the assignment of the frequencies is given below.

C–N and C=S Stretching Modes. From valence bond concept, on coordination of the thiocarbonyl sulfur to metal, the C–N stretching frequency is expected to increase while the C=S stretching frequency show a decrease. The C–N stretching frequency occurring at 1540 cm^{-1} in DMTA increases to 1580 to 1610 cm^{-1} in metal complexes and the increase is apparently related to the metal ion. The C–N stretching frequency has been reported to increase to 1600 cm^{-1} on *S*-methylation as expected.[7] A band at 1560 cm^{-1} in DMTF has a similar assignment.[3]

Two bands at 870 and 656 cm^{-1} have large C=S stretching contribution, about 25% in each case. These frequencies decrease to 862—845 and 652—635 cm^{-1}, respectively, in metal complexes. The decrease in the 870 and 656 cm^{-1} bands is substantial in the case of copper(I) and mercury(II), while it is nominal in the case of cobalt(II). This is understandable since copper(I) and mercury(II) are known to form stronger coordination bonds with sulfur donors than cobalt(II). The 870 and 656 cm^{-1} bands have been found to shift to lower frequencies on "selenation", *i.e.*, in *N,N*-dimethylselenoacetamide,[7] to 834 and 606 cm^{-1}, respectively. Similar downward shift in these two frequencies has been noted on *S*-methylation.[7] These findings support the larger contribution from C=S stretching to 870 and 656 cm^{-1} bands. An earlier assignment[8] of C=S stretching for a band near 1100 cm^{-1} is thus not favoured.

Significant contribution of C=S stretching is seen in the 1284 cm^{-1} band also. This band also shows smaller shift to a lower frequency by 10—15 cm^{-1} in metal complexes except in the cobalt complex.

C'–N and C–C' Stretching Modes. The asymmetric C'–N stretching, unlike in DMTF and DMF[3] (*N,N*-dimethylformamide), is highly coupled and is distributed in the frequencies at 1284, 1130, and 1060 cm^{-1}. The C'–N symmetric stretching has contributions in the 870 and 656 cm^{-1} bands. Their occurrence is comparable with those of DMF and DMTF.[3]

Similarly, the C–C' stretching is highly mixed with other vibrations and has contributions in the frequencies at 1284, 1130, and 656 cm^{-1}. The assignment is comparable to that in NMTA[1] and *N*-methylacetamide.[9] The C–C stretching has been located at 954 cm^{-1} in *N,N*-dimethylacetamide.[10]

Skeletal Bending Modes. The bands at 495 and 444 cm^{-1} are predominantly due to NCS and CCS bending vibrations, respectively. The corresponding bands in thioacetamide have been found[1] at 470 and 380 cm^{-1}. No gradual change in frequencies has been

observed for these bands in complexes, probably because of their possible different structures.

C-CH_3 and N-CH_3 Bending Modes. The symmetric and asymmetric deformations at 1370 and 1470 cm^{-1}, respectively, and the rocking mode at 1020 cm^{-1} for C-CH_3 group compare well with those in related molecules.[1,9,12] Similarly, the symmetric and asymmetric bending modes of the N-CH_3 group are easily located at 1430 and 1470 cm^{-1}, respectively and the rocking modes at 1185 and 1060 cm^{-1}.[9-12]

Frequency Shifts in Metal Complexes. Although cobalt(II) complexes were known earlier,[5] no infrared study concerning DMTA has been reported. The complexes of copper(I) and mercury(II) chlorides are new. The effect of complex formation on C=S and C-N stretching frequencies was pointed out earlier. It is satisfying to note that the expected frequency shifts have been realised. The NCS bending frequency may be expected to show a small increase on coordination to metals. However, this band is nearly stationary, except for 3 cm^{-1} raise in mercury and cobalt complexes. This may be attributed to the complicated nature of coupling in the 495 cm^{-1} frequency and also to the different structures of the complexes.

The authors thank Prof. C. C. Patel, for helpful discussion and encouragement; and Mr. G. Durga Prasad for help in the initial stages of calculation and for preparing the cobalt complex.

Ultrasonic Study of Solute-Solvent Interaction in Aqueous Solutions of Tetraalkylammonium Salts

Fumio HIRATA and Kiyoshi ARAKAWA

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received September 6, 1971)

Ultrasonic velocity of aqueous solutions of tetraalkylammonium chlorides was measured over wide ranges of concentration and temperature in order to study the nature of solute-solvent interactions. Adiabatic compressibility was obtained from the data of sound velocity and density. The results were discussed in terms of the influence of solutes upon the structure of liquid water. It has been shown that Me_4N^+ is a structure breaker, while n-Bu_4N^+ forms a structure or "icebergs" around the cations evidently, and that the ability of iceberg formation begins at n-Pr_4N^+. It was concluded that the icebergs have a more rigid structure than the ice-like structure in bulk water.

Aqueous solutions of tetraalkylammonium salts show abnormal behavior in various physico-chemical properties, such as partial molal volume,[1-3] activity coefficient,[4-6] heat of solution,[7-10] conductance,[11] and viscosity.[12]

The behavior has been discussed mainly in terms of water-hydrocarbon interactions leading to recognition of hydrophobic interactions.

In recent years, the important role of hydrophobic interaction for the maintenance of higher order structure of protein molecules with non-polar side chains in aqueous solutions has become increasingly clear.[13,14]

When hydrocarbon molecules are dissolved in water, the entropy of solution becomes much more negative than in corresponding non-aqueous solutions. On this basis Frank and Evans[15] postulated the formation of "icebergs" around non-polar solute molecules in water.

Recently, Wen and Saito[1] have obtained remarkable results in the measurement of partial molal volume of tetraalkylammonium bromides in aqueous solutions.

A deep minimum appears for the partial molal volume of tetrabutylammonium bromides at about 1 mol/l.

It ascends with rising temperature. For the sake of interpretation, formation of a *clathrate-like structure* of water molecules around tetrabutylammonium cations was suggested.

Frank and Wen,[16] on the other hand, proposed a simple model for the modification of the structure of liquid water caused by the presence of ions.

A tetraalkylammonium cation is regarded as a fairly large spherical ion and a solute with hydrophobic surface. These two factors are supposed to influence the liquid structure of water. It is of interest to study the solute-solvent interaction in aqueous solutions of these salts.

The compressibility obtained from the measurement of sound velocity is determined primarily by intermolecular forces. It is useful to measure sound velocity for the purpose of studying the structural change of liquid water induced by solute molecules.

However, there have been very few studies along this line, except that reported by Conway and Verral which was made over a limited range of temperature at low concentrations[17] and also that by Allam and Lee.[18]

We have, thus, attempted to measure ultrasonic velocity of aqueous solutions of tetraalkylammonium chlorides over wide ranges of concentration and temperature.

Experimental

Samples of tetraalkylammonium chlorides, R_4NCl (R; Me, Et, Bu) were obtained from Wako Pure Chemical Industry Co., Ltd. and tetrapropylammonium chloride from Eastman Organic Chemicals, Rochester, New York. The samples were purified by recrystallization from ethanol-ether mixtures for tetramethylammonium chloride and chloroform-ether mixtures for tetraethylammonium chloride,[1] respectively.

All salts were dried in a vacuum at 60—70°C.

Concentrations of aqueous solutions of these four salts were determined by gravimetric analysis by precipitation with $AgNO_3$. The results agreed with the values calculated from the weight of dried samples before dissolution within small errors.

Sound velocity was measured using a crystal interferometer of the usual type at 3 MHz. The cell used was the same type as that previously described.[19]

Measurements were carried out at temperature from 20 to 35°C. Temperature was controlled within ± 0.05°C.

Density was measured using a pycnometer of the usual type.

Results

Ultrasonic Velocity. The ultrasonic velocity for aqueous solutions of tetraalkylammonium salts at 3 MHz is plotted against temperature and shown in Figs. 1 (a)—(d). We see that it increases linearly with the rise in temperature for tetramethylammonium chloride solutions, but temperature dependency is seen to be reversed at a certain concentration in the case of the other three salts.

Adiabatic Compressibility. Adiabatic compressibility κ_s is obtained from the sound velocity and density of solutions. Values of κ_s for aqueous solutions of tetraalkylammonium chlorides are plotted against temperature in Figs. 2 (a)—(d).

Similarly to sound velocity *vs.* temperature curves, the temperature dependence of κ_s is reversed at a certain concentration for solutions of Et_4NCl, Pr_4NCl, and Bu_4NCl, respectively. The values of κ_s at 25°C for each 1 mol/*l* solution is shown in Fig. 3 as a function of the number of carbon atoms in each salt. It is seen that adiabatic compressibility decreases with the number of carbon atoms and that the temperature dependence is reversed between Et_4NCl and Pr_4NCl.

Discussions

Compressibility in Water. Water is regarded as an equilibrium mixture of two structures such as an *ice-like structure* and a *close packed structure.*[20,21]

Compressibility of liquid water is given by

$$\kappa = \kappa_\infty + \kappa_{relax.}/(1+\omega^2\tau^2) \qquad (1)$$

where κ_∞ is an instantaneous part of compressibility and $\kappa_{relax.}$ a relaxational part of compressibility.[20]

The relaxation time τ corresponding to $\kappa_{relax.}$ is of the order of 10^{-11} sec. The relation $\omega\tau \ll 1$ holds in the present experiment, where ω is the angular frequency. Thus, the adiabatic compressibility obtained is equal to $\kappa_\infty + \kappa_{relax.}$.

With the rise in temperature, κ_∞ increases due to thermal expansion, and $\kappa_{relax.}$ decreases due to thermal rupture of the ice-like structure.

Thus, the decrease of compressibility at temperatures 20—35°C is attributed to the decrease of $\kappa_{relax.}$, which is dominant over the increase of κ_∞.

Structure Breaking Effect of Tetramethylammonium Cations. Compressibility decreases rapidly from pure water to aqueous solutions of tetramethylammoium chloride (Fig. 3). This might be ascribed to three effects: (1) the effect of Cl^- on the structure of water, (2) the decrease of compressibility caused by the introduction of large incompressible cations Me_4N^+, (3) the influence of Me_4N^+ on the structure of the surrounding water.

The difference between partial molal volume, $\bar{V}$, and intrinsic volume, V^0, estimated from crystal radius of

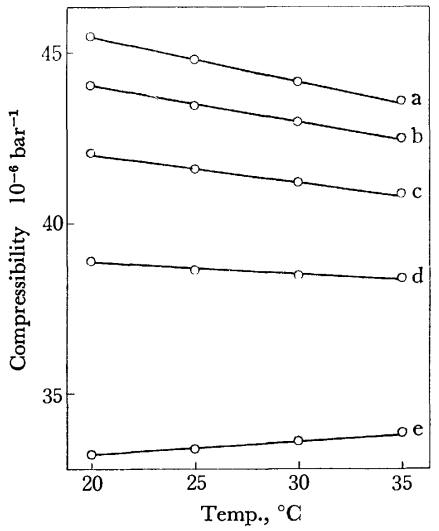

Fig. 2(c). Compressibility of aqueous solutions of tetrapropylammonium chloride. Concn. (M: mol/l) (a) Pure water, (b) 0.10 M, (c) 0.25 M, (d) 0.51 M, (e) 1.01 M.

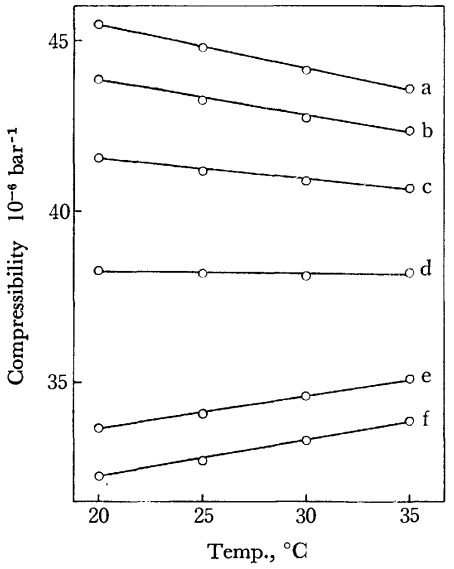

Fig. 2(d). Compressibility of aqueous solutions of tetrabutylammonium chloride. Concn. (M: mol/l) (a) Pure water, (b) 0.08 M, (c) 0.22 M, (d) 0.44 M, (e) 0.88 M, (f) 1.15 M.

ions represents the volume change of water caused by the action of ions. The values of $(V^0\text{-}\bar{V})$ of Cl^- and Me_4N^+ are estimated to be 1.7 and 21.4 cm^3/mol, respectively.[3] The effect of Cl^- is regarded to be negligible as compared with that of Me_4N^+.

Thus, only the contribution from Me_4N^+ might be taken into consideration.

The values of $(V\kappa_s)$ of an 1 mol/l solution of tetramethylammonium chloride is given by

$$V\kappa_s = N_1V_1\kappa_1 + N_2(V^0_{NMe_4^+}\kappa^0_{NMe_4^+} + V^0_{Cl^-}\kappa^0_{Cl^-}) \quad (2)$$

where

V; volume of an 1 mol/l aqueous solution
κ_s; adiabatic compressibility of 1 mol/l aqueous solution
κ_1; average compressibility of solvent water in the solution

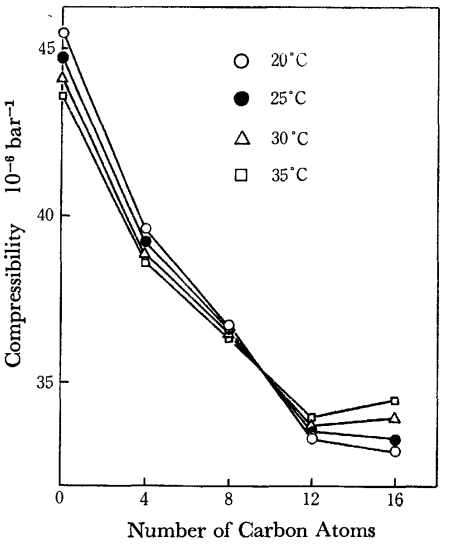

Fig. 3. Compressibility of 1 M aqueous solutions of tetraalkylammonium chlorides as a function of the number of carbon atoms in each salt.

V_1; volume of solvent water in the solution
N_1; number of moles of water in the solution
$V^0_{NMe_4^+}$; intrinsic volume of Me_4N^+
N_2; number of moles of Me_4NCl
$\kappa^0_{NMe_4^+}$; intrinsic compressibility of Me_4N^+
$V^0_{Cl^-}$; intrinsic volume of Cl^-
$\kappa^0_{Cl^-}$; intrinsic compressibility of Cl^-

In this equation, $(V^0_{Cl^-}\kappa^0_{Cl^-})$ is practically zero and can be neglected. Thus we obtain the magnitude of κ_1 by the equation

$$\kappa_1 = \frac{V\kappa_s - N_2V^0_{NMe_4^+}\kappa^0_{NMe_4^+}}{N_1V_1} \quad (3)$$

The intrinsic volume of Me_4N^+, $V^0_{NMe_4^+}$, is estimated with large uncertainty from 90 to 105 cm^3/mol.[1-3,12]

When we use the largest value[22] 105 cm^3/mol for $V^0_{NMe_4^+}$ and the value 3×10^{-6} bar^{-1} for $\kappa^0_{NMe_4^+}$ we find the average compressibility of water in the solution at 25°C to be smaller than the compressibility in pure water at the same temperature.[27] Thus, the sharp decrease of compressibility from pure water to a 1 mol/l aqueous solution of Me_4NCl is primarily ascribed to the structure-breaking effect of Me_4N^+.

22) The value V_{ion} was calculated from the ionic radius in crystal r_x by the equation

$$V^0_{ion} = \frac{4}{3}\pi N_A r_x^3 \quad (N\text{: Avogadro's number})$$

This value is supposed to be too large in the case of Me_4N^+, as compared with reported values of V_{ion}.[1-3,13,23-26]

26) E. Gleuckauf, *Trans. Faraday Soc.*, **61**, 914 (1965).

27) The value of $\kappa_{NMe_4^+}$ has not been determined. It might be estimated to be larger than 3×10^{-6} bar^{-1} which is nearly equal to the value for fused quartz, flint glass, LiCl crystal (*cf.* Cho-onpa Gijutsu Binran (Handbook for Ultrasonic Technique), Nikkan Kogyo Shinbun Co., Ltd. (1966), p. 1325). When $\kappa_{NMe_4^+} \geq 3\times10^{-6}$ bar^{-1}, the value of $\kappa_1 < 44.7_5\times10^{-6}$ bar^{-1} which is the value for bulk water at 25°C.

This conclusion is also supported by the fact that the temperature dependence of compressibility of a 1 mol/l solution of Me_4NCl is smaller than that of pure water (Fig. 3).

Moreover, it is consistent with the results of studies for physico-chemical properties of the solution such as partial molal volume,[1] heat capacity[9], and conductivity.[11]

Iceberg Formation Around Tetrabutylammonium Cations. Several papers have peported that Bu_4N^+ ions form icebergs around themselves.

Wen and Saito[1] stated in 1964 that the structure of icebergs is "*clathrate like*". However, Wen and Hung[8] stated recently that "the nature of structure promotion by hydrocarbons or tetraalkylammonium salts is not well defined". Wicke[28] stated on the basis of NMR data that the icebergs around non-polar solutes have a "rigid" structure involving non-tetrahedral linking of H_2O molecules.

The values of κ_s of 1 mol/l solution of Bu_4NCl increase with rising temperature (Fig. 3).

The amount of icebergs is supposed to decrease with the rise in temperature. Thus, our result supports the idea that the icebergs around Bu_4N^+ cations have a smaller compressibility than bulk water, and that the structure of the icebergs is more rigid than ice-like structure.

The Nature of Icebergs. Conway and Verral discussed the molal adiabatic compressibility of solutes in aqueous solutions of tetraalkylammonium halides at infinite dilution.[17] They calculated the difference of molal values of κ_s at infinite dilution,

$$\phi^0_{K(s),Me,NX} - \phi^0_{K(s),Et,NX},\ \phi^0_{K(s),Et,NX} - \phi^0_{K(s),Pr,NX},\ \textit{etc.}$$

From the difference the contribution from co-anions to the compressibility of solutions was cancelled out.

We have calculated the difference of κ_s for solutions $\kappa_{Me,NCl,1M} - \kappa_{Et,NCl,1M}$, *etc.* at concentration 1 mol/l, and have compared the results with the values of Conway and Verral at infinite dilution (Table 1).

In the case of tetramethylammonium salt, tetraethylammonium salt and tetrapropylammonium salt solutions, the values of the difference at infinite dilution and those at 1 mol/l are nearly the same, but those between tetrapropylammonium salt solutions and tetrabutylammonium salt solutions at infinite dilution are much larger than the values at 1 mol/l.

The effect of solute to surrounding water per mole in the 1 mol/l solution is clearly less than the effect at infinite dilution owing to an overlapping effect (Fig. 4).[29]

Table 1. The difference of molal adiabatic compressibility

This work (10^{-6} bar^{-1} mol^{-1} l)		Conway and Verral (10^{-6} bar^{-1} mol^{-1} l)	
$\kappa_{Me_4NCl,\ 1M} - \kappa_{Et_4NCl,\ 1M}$,	2.6$_3$	$\phi^0_{K(s),\ Me_4NX} - \phi^0_{K(s),\ Et_4NX}$,	2.4
$\kappa_{Et_4NCl,\ 1M} - \kappa_{Pr_4NCl,\ 1M}$,	3.0$_6$	$\phi^0_{K(s),\ Et_4NX} - \phi^0_{K(s),\ Pr_4NX}$,	3.7
$\kappa_{Pr_4NCl,\ 1M} - \kappa_{Bu_4NCl,\ 1M}$,	0.2$_0$	$\phi^0_{K(s),\ Pr_4NX} - \phi^0_{K(s),\ Bu_4NX}$,	10.6

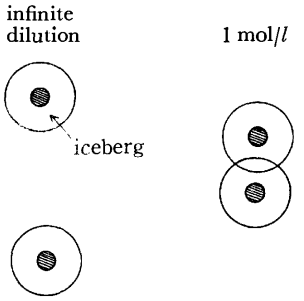

Fig. 4. Overlapping effect of solute-solvent interactions.

The fact that the difference between our data and those of Conway and Verral becomes appreciable (last row, Table 1) supports the idea that the overlapping effect appears typically in Bu_4N^+ ions. This is consistent with the above conclusion.

Dernell and Greyson[30] found that the tetraalkylammonium salts depress the temperature of maximum density of water T_m and the order of the effect increases in sequence $H_4N^+ < Me_4N^+ < Et_4N^+ < Pr_4N^+ < Bu_4N^+ < Am_4N^+$. They concluded that "the water structure-promoting characteristics of the species ordinarily found at room temperature do not manifest themselves in the neighborhood of T_m". Sarma and Ahluwalia,[31] however, rejected the conclusion from their measurements of heats of solution ΔH_s^0.

Heat capacity changes ΔC_p in aqueous solutions of Bu_4NBr, Pr_4NI, and $NaBPh_4$ derived from ΔH_s^0 values show no appreciable change as temperature falls from 30 to 4°C. They suggested that the hydration sheath around non-polar groups is not definitely ice-I-like but rather resembles a Pauling-type clathrate cage or some other polymorphic modification of ice. Our concept of rigid icebergs is consistent with this idea.

Relation between the Ability of Iceberg Formation and Ionic Size. As seen in Fig. 3, a marked difference appears in the temperature dependence of Pr_4NCl, where it is reversed, and the tendency is more remarkable in the solution of Bu_4NCl. Thus, the ability of iceberg formation seems to be appreciable at Pr_4N^+.

This agrees with the results obtained by Lindenbaum[7] from a study of thermodynamic excess functions in which the magnitude of excess enthalpy and entropy for Pr_4NCl solutions are very large in comparison with those for Me_4NCl and Et_4NCl solutions and the trend becomes more marked for Bu_4NCl solution.

On the other hand, several papers state that the behavior of Me_4N^+ differs from that of R_4N^+ (R; Et, *n*-Pr, *n*-Bu).[5,9,32]

This discrepancy may be at least partly ascribed to the difference of the nature of physico-chemical properties treated in those studies.

Our thanks are due to the kind cooperation of Mr. Nobuo Takenaka, Dr. Osamu Kiyohara, and Mr. Keiji Hasegawa.

Induced Optical Activity of Nucleic Acid-Toluidine Blue O Complex

Tomoyasu NAKAMURA and Yasumasa J. I'HAYA
Department of Materials Science, The University of Electro-Communications, Chofu-shi, Tokyo
(Received February 19, 1972)

The absorption, circular dichroism (CD) and optical rotatory dispersion spectra of DNA–toluidine blue O complexes were observed over the visible absorption spectral region. Effect of temperature on CD was examined at the temperatures 6—86°C. For the complex of a low DNA phosphate to dye ratio, the Krönig-Kramers transform was carried out and one positive and four successive negative CD bands were resolved. It is concluded that the shorter wavelength CD bands, one positive and one negative, are due to an exciton splitting of the dye dimers and that the rest may be induced by an asymmetric environment of the DNA deoxyribose residue.

In a previous paper,[1] we reported that the DNA- and RNA-thionine (Th) complexes show Cotton effects in the visible absorption region of the dye and that these Cotton effects may have two origins; one induced from the dye monomers bound to DNA (Optical Activity I) and the other caused by an interaction between the dimerically bound dyes (Optical Activity II). In a preliminary report on the study of the DNA-toluidine blue O (TBO) complexes,[2] we demonstrated that the usual exciton theory fails to predict the longer wavelength Cotton effects of the high *P*/*D* (DNA phosphate residue/dye concentration) complexes. In Optical Activity I, the dye monomers seem to be involved in a complicated interaction with the asymmetric environment due to deoxyriboses of DNA.

The most striking feature of the DNA-TBO complex at low *P*/*D* is the sign of each partial circular dichroism (CD) spectrum, which is completely the reverse of that found in the DNA-acridine orange (AO) complex. On the other hand, the general feature of the CD spectra of the DNA- and RNA-Th complexes resembles that of the DNA-AO complex including their signs.[1] In this paper, we report the absorption spectra and Cotton effects of the DNA-TBO complexes at low as well as at high *P*/*D* values, with particular reference to their temperature dependence. CD band resolution is carried out for the low *P*/*D* complex by means of the Krönig-Kramers transform. It is shown that both effects of exciton splitting and asymmetric field are necessary for inducing the longer wavelength Cotton effects.

Experimental

Commercial calf-thymus DNA (Sigma Type I) and toluidine blue O (3-amino-7-dimethylamino-2-methylphenazathionium chloride) (Merck) were used without further purification. Stock aqueous solutions of DNA and TBO were dessolved in 0.01M phosphate buffer (pH 6.84). Concentration of TBO was chosen to be 5×10^{-5}M. A Jasco ORD/UV-5 recording spectropolarimeter with CD attachment was used. Further experimental details were the same as given previously.[1]

Results

The intensity of the absorption spectrum of TBO in water changes with concentration. According to Rabinowitch and Epstein,[3] the absorption peak appearing at low concentration is called M-band (monomer band) and at high concentration D-band (dimer band). In our experiment, the M-band and the D-band of TBO are located at 637 nm ($\varepsilon=2.9\times10^4$) and 562 nm ($\varepsilon=1.1\times10^4$), respectively. Using the same method as theirs, we obtained the average equilibrium constant for dimerization $K=2.6\times10^{-4}\,l\cdot mol^{-1}$ at room temperature, the value being nearly equal to that of methylene blue.[3]

An analogous change in the visible absorption spectrum of the dye can be seen when DNA is added to the dye solution. This has been reported by Huse, Miyake, and Tsuboi.[4] Apart from a detailed charac-

teristic, the changing profile of the absorption spectrum of DNA-TBO is similar to that of DNA-AO.[5] On the other hand, the optical rotatory dispersion (ORD) and CD spectra of DNA-TBO are quite different from those of DNA-AO.[6-8] The representative CD and ORD spectra of DNA-TBO are shown in Fig. 1 with their CD band components resolved by the Krönig-Kramers transform.[9] At low P/D values, one positive and four successive negative CD bands appear with maxima located at 529, 563, 590, 615, and 645 nm, respectively. They are hereafter referred to as Bands I, II, III, IV, and V. Band V (at 645 nm) is somewhat doubtful. At high P/D values, the positive CD maximum (Band I) disappears and the successive negative CD maxima (Bands II—V) shift a little to the shorter wavelength side, a newly developed positive CD band then coming out at about 650 nm (Fig. 2). The features of CD bands change with both temperature and P/D values (Fig. 3).

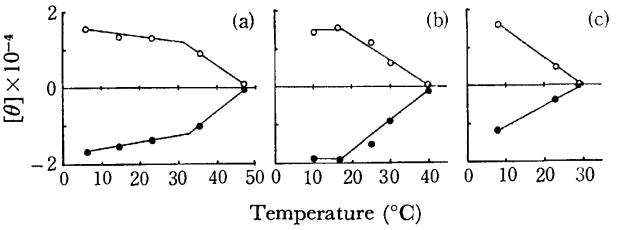

Fig. 4a. Temperature dependence of $[\theta]_{max}$ of DNA-TBO complexes; ○: positive maxima at 520—530 nm, ●: negative maxima at 555—560 nm.
(a): P/D=0.22, (b): P/D=0.46, (c): P/D=0.93

The change in molar ellipticity $[\theta]$ is plotted against temperature in Fig. 4a. It should be noted that the $[\theta]$ values of the positive CD maximum at about 524 nm (Band I) and the negative one at about 560 nm (Band II) diminish linearly with increasing temperature. Furthermore, the $[\theta]$ values of these CD bands do not change very much even at sufficiently low temperature when P/D is considerably low (<0.5), although a slight shift of the whole spectrum to the shorter wavelength side is observed (Fig. 3). It was difficult to observe a positive CD band located at about 650 nm, as the sensitivity of our photomultiplier was very low in the spectral region. The temperature effect of this band, therefore, was not examined. The temperature dependence of the negative CD band of the P/D=2.6 complex is shown in Fig. 4b. The effect of temperature on the absorption curves of TBO dissolved in 0.01 M phosphate buffer is given in Fig. 5a.

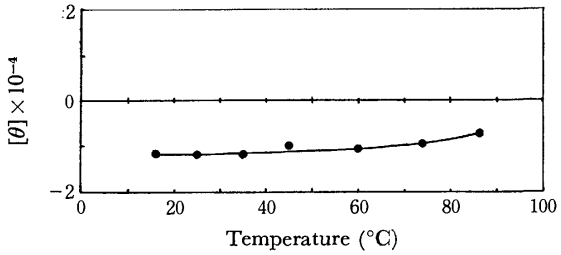

Fig. 4b. Temperature dependence of negative CD maximum (600—604 nm) of DNA-TBO P/D=2.6 complex.

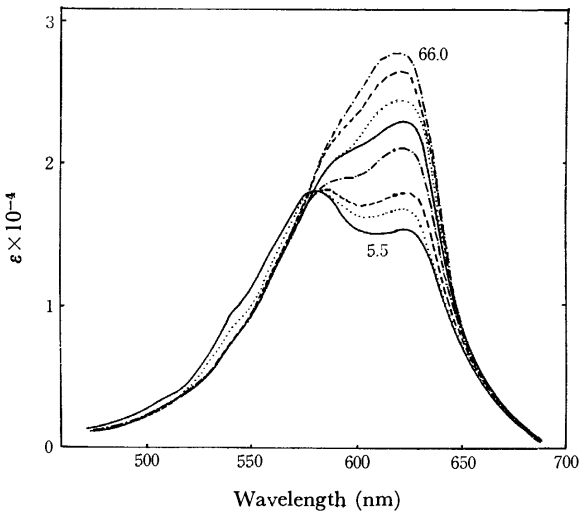

Fig. 5a. Absorption spectrum of TBO in 10^{-2} M phosphate buffer at various temperatures. Concentration of TBO, 5×10^{-5} M. Temperatures, from lower to upper, 5.5, 10, 15, 25.5, 36, 45.5, 56 and 66°C.

Discussion

According to Gardner and Mason,[6] dyes contributing to the optical activity of nucleic acid-dye complexes can be divided into two species, those bound to the nucleic acid helix monomerically and those bound dimerically. In our previous study on the DNA- and RNA-Th complexes, we confirmed the validity of their interpretation.[1] The present study on the DNA-TBO complexes also supports this conclusion. As shown in Fig. 1, the two resolved CD bands located at 529 and 563 nm are of nearly equal ellipticity and have signs opposite to each other (*vide infra*). Moreover, their $[\theta]_{max}$ wavelengths (Bands I and II) correspond to the shoulders, which may be thought to be split absorption bands due to a dye-dye interaction of each absorption spectrum of the complexes taken at various temperatures (Fig. 3).

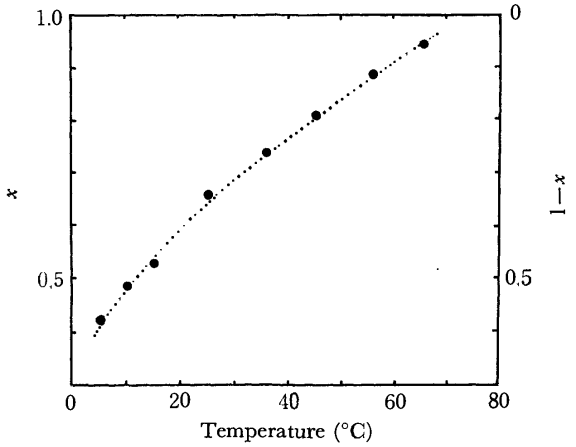

Fig. 5b. Plot of monomer (x) and dimer ($1-x$) fraction of TBO in aqueous solution against temperature.

These facts suggest that the optical activity appearing at 500—550 nm is induced by an exciton interaction in line with the works of Moffitt[10] and of Tinoco.[11] In addition to this, a comparison of the change in the dimer fraction ($1-x$ in Fig. 5b) and that in the maximum values of molar ellipticity with increasing temperature ($[\theta]$ in Fig. 4a) suggests that the intensities of these CD bands depend upon the amount of the dye dimers bound to the DNA helix. The numerical value of molar ellipticity should be constant if there is no conformational change in the dye-dye steric conformation. Actual molar ellipticity should then be evaluated using the concentration of the *dye dimers* bound to the DNA helix at appropriate sites. The actual molar ellipticities for bands I and II located at 529 and 563 nm, respectively, are thus evaluated and listed in Table 1. Here the following assumptions are made: (i) in the temperature range where $[\theta]_{max}$ is constant, there is no free dye[12] and the fraction of the bound dye dimers is constant; (ii) the fractions of monomer and dimer are estimated from the absorption spectrum of the dye in aqueous solution measured at the corresponding temperature.

Assumption (i) seems to be valid since in the temperature range where the $[\theta]$ value is constant (10—16°C for the complex of $P/D=0.46$) the absorption spectrum of the complex does not change its profile very much as seen in Fig. 3. Assumption (ii) is not justified but requisite, since estimation of monomer and dimer fractions from the absorption spectrum of the complex is not possible due to the shift in the absorption spectrum and the strong hyper- and/or hypo-chromisms. In order to evaluate actual $[\theta]$ values under Assumptions (i) and (ii), the dimer fraction of the dye must be estimated at the temperature where slope of the plot $[\theta]_{max}$ *vs.* temperature changes (Fig. 4a).

The rotational strengths for the resolved CD bands are also calculated by means of the relationship[9]

$$R_k \simeq 0.696 \times 10^{-42}\sqrt{\pi}[\theta_k]\frac{\Delta_k}{\lambda_k} \quad (k=\text{I—V})$$

where $[\theta_k]$, Δ_k, and λ_k are the molar ellipticity, the half band width and the wavelength of $[\theta_k]_{max}$ of the k-th CD band, respectively. The results are given in Table 1. The calculated $[\theta]_{max}$ and R for bands I and II are comparable with observed values. The absolute values of R_I and R_{II} are nearly equal to each other within experimental error. This suggests that the optical activity appearing in the neighborhood of 550 nm is due to just one origin as has been stated.

Table 1. Molar ellipticities and rotational strengths for resolved CD bands of DNA-TBO $P/D=0.26$ complex[a]

Band	λ_{max} (nm)	$\lambda_{shoulder}$ (nm)	$[\theta]_{max}\times10^{-4}$ Obsd	$[\theta]_{max}\times10^{-4}$ Calcd	$R\times10^{-40}$cgs Obsd	$R\times10^{-40}$cgs Calcd
I	529.1	~532	1.75	3.85	7.18	15.81
II	563.4	~554	−1.72	−3.78	−6.67	−14.73
III	590.7	~582	−1.05		−2.85

V	645.2	—	−0.6		−1.60	

a) Calculations of $[\theta]_{max}$ and R for Bands III—V have not been carried out since the origins of the bands are not due to the TBO dimers.

Three causes seem to be possible for Bands III, IV, and V. (1) They might be induced from an interaction between the monomerically bound dyes, since the wavelengths of the CD band maxima are located around the monomer absorption band. (2) A contribution from some higher energy levels may induce such successive CD bands as reported by Bush and Brahms in the case of oligonucleotides.[13] (3) They might be induced by an asymmetric environment attributed to the asymmetric carbons of deoxyriboses. It should be noted that for high P/D values a positive CD band located at about 650 nm appears as shown in Fig. 2. Previous results indicated that this band (called M(+)

in reference 2) results from the dye monomers, the type of interaction being probably not of an exciton type.[2] Thus, Bands III—V cannot be attributed to (1) alone, *i.e.* to the monomerically bound dyes.

The maxima of Bands III and IV correspond well with the absorption shoulders of the complex (Table 1). The bands can thus be attributed to a combination of (2) and (3), *i.e.* to vibrational levels of the dye (probably in its dimerically bound state), which become optically active by the influence of the asymmetric carbons of deoxyriboses.

We might conclude as follows. (1) The Cotton effects of the low *P*/*D* complexes in the wavelength region 500—580 nm (Optical Activity II) are induced from an exciton-type interaction between the dye dimers. (2) The Cotton effects of the high *P*/*D* complexes in the wavelength region 620—670 nm (Optical Activity I) result from the dye monomers through the asymmetric perturbation of deoxyriboses. (3) Three negative CD bands developed in the wavelength region 550—650 nm correspond to vibrational components of the dye, which become optically active due to the asymmetric environment of DNA. Characteristics of the DNA-TBO system are the signs of the CD bands of its low *P*/*D* complex, which are opposite to the corresponding CD bands of DNA-AO and DNA-Th complexes. This suggests that the steric conformations of DNA-dye complexes are not always the same, contrary to the conventional interpretation. Since AO, Th, and TBO have a similar molecular framework, there seems to be no big difference between the binding sites of the dye molecules to the DNA helices. The major factor determining the CD band signs, therefore, can not be the whole helical arrangement of the bound dyes but is probably the local arrangement and/or relative orientation of the neighboring dye molecules that form dimers.

Hydrogenation by Cyanocobaltate. II.[1] Mechanisms of the Hydrogenations of 1,3-Butadiene and Isoprene Catalyzed by Pentacyanocobaltate(II) in Aqueous Solution

Takuzo FUNABIKI, Mitsuo MATSUMOTO, and Kimio TARAMA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received January 5, 1972)

Hydrogenations of 1,3-Butadiene and isoprene catalyzed by pentacyanocobaltate(II) have been studied by the measurements of infrared and nuclear magnetic resonance spectra on the reaction solutions and by following the time-courses of the reactions. Infrared spectroscopy has revealed: (1) The aging reaction is promoted by CN^- ion and it hardly occurs at a low CN/Co ratio. (2) In the hydrogenation of butadiene the formation of a σ-but-2-enyl complex at a high CN/Co ratio is very rapid, but that of a *syn*-π-(1-methylallyl) complex at a low CN/Co ratio is generally slow. The rate of the formation of these complexes is affected by the relative concentration of butadiene to $Co(CN)_5H^{3-}$. (3) In the hydrogenation of isoprene a σ-3-methylbut-2-enyl complex is formed regardless of the CN/Co ratio. Nuclear magnetic resonance spectroscopy has confirmed the structures of these complexes and it also showed that the σ-but-2-enyl complex consists of simliar amounts of the *cis*- and *trans*-isomers. The reactions are explained by the mechanisms, in which intermediate complexes in the formation of alk-1-enes and alk-2-enes are the *cis*- and *trans* σ-but-2-enyl and the *syn*-π-(1-methylallyl) complexes in the case of butadiene, and the σ-2- and -3-methylbut-2-enyl and the π-(1,2-dimethylallyl) complexes in the case of isoprene. It is described that the reactivity and the selectivity in the hydrogenation of conjugated dienes are strongly controlled by the steric factor in the transition state.

Pentacyanocobaltate(II) is one of the typical transition metal complexes which hydrogenate conjugated dienes selectively to simple-olefins, and has been studied by many authors.[2] Two mechanisms have been proposed for the selective hydrogenation; the one involves organocobalt complexes as intermediates, and the other free radicals. In the former case it has been found that the selectivity depends on the CN/Co ratio. The hydrogenation of butadiene has been studied in most detail, because the effect of the CN/Co ratio is most remarkable,[3] and the reaction has been interpreted in terms of the following scheme.

$$2Co(CN)_5^{3-} + H_2 \rightleftarrows 2Co(CN)_5H^{3-}$$
$$Co(CN)_5H^{3-} + C_4H_6 \rightleftarrows Co(CN)_5(C_4H_7)^{3-}$$
$$Co(CN)_5(C_4H_7)^{3-} + Co(CN)_5H^{3-} \longrightarrow C_4H_8 + 2Co(CN)_5^{3-}$$

Kwiatek and Seyler[3c,3d] have proposed a mechanism in which σ-but-2-enyl pentacyanocobaltate [I] and π-methylallyltetracyanocobaltate [II] are the intermediates in the formations of 1- and *trans*-2-butenes, respectively. They isolated the complex [I] in an impure solid state and studied its reactivity with $Co(CN)_5H^{3-}$. Although the NMR spectrum observed at 60 MHz was not analyzed completely, [I] was assumed on the analogy with σ-but-2-enyl-π-cyclopentadienyldicarbonyliron. The equilibrium between the complexes [I] and [II] was assumed on the analogy with the equilibrium between σ- and π-allyl complexes which was demonstrated by NMR. This mechanism has been generally accepted, but the lack of any kinetical study would be its greatest defect. Afterwards, Burnett *et al.*,[4] tried kinetical treatments and proposed a mechanism in which the direct intermediate in the formation of 1-butene is not [I] but σ-1-methylprop-2-enyl pentacyanocobaltate [III] on the basis of the hypothesis that the additions of $Co(CN)_5H^{3-}$ to butadiene and intermediate complexes may proceed through a 1,2-addition mechanism. In spite of the detailed discussion, the proposed mechanism was not convincing because the variation of the amount of the intermediate complexes was not followed.

The hydrogenation of isoprene, on the other hand, has not been studied in detail and some complicating results have been reported: The selectivity depends not only on the CN/Co ratio but on the ratio of the concentration of isoprene to cobalt and on the presence of hydrogen.[2,5] No mechanism to explain satisfactorily these results has been proposed.

Recently the present authors have found a novel solvent effect on the selectivity in the hydrogenation of butadiene.[1,6] The formation of *cis*-2-butene, which is hardly observed in aqueous solution, is greatly promoted in the glycerol-methanol or ethylene glycol-water solvent in the presence of excess cyanide ion. In consideration of the solvent effect, it seemed essential to clarify the mechanism in aqueous solution. For this purpose, it is important to discuss on the hydrogenations of butadiene and isoprene at the same time, because the former can give one terminal and two internal olefins, while the latter gives two terminal and one internal olefins. In this paper, mechanisms of these reactions are proposed from the time-courses of the formations of the products and of the complexes including the intermediate complexes, and from the confirmation of the structures of the intermediate complexes. These were performed by the gaschromatographic analysis of gas samples and by the measurements of IR and NMR spectra on the reaction solution without isolating the unstable species.

Experimental

Infrared Spectral Measurements. IR spectra of the reaction solutions were recorded on a JASCO DS-403G spectrophotometer in the 2000—2200 cm^{-1}. To enable the quick and repeated samplings and measurements of the complexes sensitive to air and heat of an infrared ray, a polyethylene cell placed between two plates of rock salt was used. Frequency was accurate to within ± 1 cm^{-1}.[7]

Nuclear Magnetic Resonance Spectral Measurements. NMR spectra of the reaction solutions were recorded in most cases at 100 MHz with a Varian HR-100D spectrometer, but JEOL C-60HL and Varian HR-220 were also used. D_2O was usually used as a solvent, but H_2O was also used to confirm the proportion of the intensity of the bands corresponding to CH_2 and CH_3 groups. Measurements were performed either at room temperature or at 5°C.

Hydrogenation Procedure. The hydrogenation was carried out in a 100 m*l* flask containing a 25 or 50 m*l* solution with a cobalt concentration of 0.2M. Gases in the reaction vessel were circulated through the solution at a flow rate of about 500 m*l* per minute.[1] Gas and aqueous samples picked out by injection syringes were analyzed by glc and IR, respectively. In the case of butadiene, reactions were carried out under three different conditions: (A) In the absence of hydrogen, the reaction of $Co(CN)_5^{3-}$ was started under an atmosphere of butadiene, (B) The reaction of $Co(CN)_5H^{3-}$, which was previously prepared, was started under an atmosphere of butadiene and a small amount of hydrogen, (C) The reaction of $Co(CN)_5^{3-}$ was started under an atmosphere of hydrogen and butadiene. In the case of isoprene, reactions were carried out under the conditions similar to (A) and (B). For the NMR measurements reactions were carried out in 2 m*l* solutions at 0°C.

Results and Discussion

Reactions of Pentacyanocobaltate(II) with Water and Hydrogen. It has been well known that pentacyanocobaltate(II) reacts with water to form hydridopentacyanocobaltate (aging reaction), and the reaction has been explained in terms of the Eq. (1)[8] or (2).[2]

$$2Co(CN)_5^{3-} + H_2O \longrightarrow Co(CN)_5H^{3-} + Co(CN)_5OH^{3-} \quad (1)$$
$$2Co(CN)_5^{3-} + 2H_2O \longrightarrow Co(CN)_5H^{3-} + Co(CN)_5OH_2^{2-} + OH^- \quad (2)$$

As seen in Fig. 1a, the IR spectra of the pentacyanocobaltate(II) solution under an atmosphere of nitrogen at 0°C in the presence of excess cyanide ion (CN/

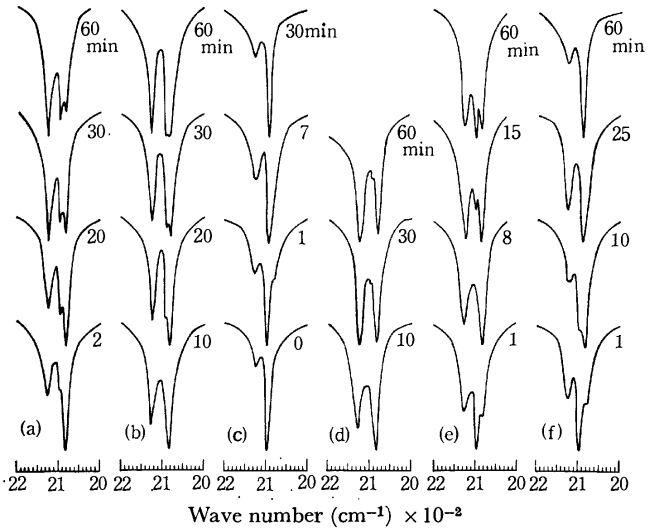

Fig. 1. IR spectra of the reaction solution in H_2O at 0°C in the hydrogenation of butadiene.
(a) Aging reaction at CN/Co=6.0, (b) Under condition (A) at CN/Co=6.0, (c) Under condition (B) at CN/Co=6.0, (d) Under condition (A) at CN/Co=4.5 (e) Under condition (B) at CN/Co=4.5, (f) Under condition (B) at CN/Co=5.0

Co=6.0) showed a gradual decay of the 2082 cm^{-1} band of $Co(CN)_5^{3-}$ in accompany with growths of the 2097 cm^{-1} band of $Co(CN)_5H^{3-}$ and of the band near at 2127 cm^{-1}. In the absence of excess cyanide ion (CN/Co=5.0), however, the reaction was so slow that only a weak shoulder band of $Co(CN)_5H^{3-}$ was observed even after one hour. In the presence of deficient cyanide ion (CN/Co=4.5), the formation of $Co(CN)_5H^{3-}$ was much slower. Although it has been reported that the aging reaction is promoted by alkali metal ions,[8c,9] the addition of KCl to the solution at CN/Co=5.0 had no effect. These results suggest that the cyanide ion rather than the potassium ion is responsible for the promotion of the aging reaction, and that the following reactions take place rather rapidly even at low temperatures in the presence of excess cyanide ion.

$$Co(CN)_5OH^{3-} + CN^- \longrightarrow Co(CN)_6^{3-} + OH^- \quad (3)$$

$$Co(CN)_5OH_2^{2-} + CN^- \longrightarrow Co(CN)_6^{3-} + H_2O \quad (4)$$

It has been supposed that these reactions are very slow at low temperatures,[2,8a] and the band near at 2127 cm^{-1} can not be corresponded exclusively to $Co(CN)_6^{3-}$ because $Co(CN)_5OH_2^{2-}$ shows a similar band, but the above proposals seem to be supported by the following results. (1) From the linear relationship between CN stretching frequencies and the Taft's σ_I function,[7] it is expected that $Co(CN)_5OH^{3-}$ shows the band near at 2110 cm^{-1}. (2) It has been reported that in the visible and ultraviolet spectroscopic study of the aging reaction, the formation of $Co(CN)_6^{3-}$ instead of $Co(CN)_5OH^{3-}$ was observed and it exceeded that of $Co(CN)_5OH_2^{2-}$ except in the initial stage.[8d]

When hydrogen was absorbed by pentacyanocobaltate(II) at 0°C, a strong $Co(CN)_5H^{3-}$ band together with a weak broad band near at 2125 cm^{-1} were observed regardless of the CN/Co ratio (*cf.* Fig. 1c). At 20°C, the $Co(CN)_5^{3-}$ band did not disappear completely, demonstrating that the reaction is reversible and the equilibrium constant depends on the reaction temperature.

Hydrogenation of Butadiene. (i) In the Presence of Excess Cyanide Ion (CN/Co=6.0) at 0°C. Under condition (A), a slow growth of a new band of the complex [I] at 2091 cm^{-1} was observed accompanied by a slow decay of the $Co(CN)_5^{3-}$ band (Fig. 1b). The formation of 1-butene as a main product was very slow but was continuous, reflecting that the aging reaction proceeds under this condition.

Under condition (B), the IR spectral changes as shown in Fig. 1c were observed. In the initial stage of the reaction, the $Co(CN)_5^{3-}$ band appeared in accompany with a decay of the $Co(CN)_5H^{3-}$ band, but both were rapidly replaced by the band of the complex [I]. The formation of butenes (1-(90%), *trans*-2-(8%), *cis*-2-(2%)) was remarkable in the initial stage, but it did not proceed any more after about 15 minutes when the formation of [I] was accomplished.[10]

Under condition (C), the accomplishment of the formation of [I] took place after 45 minutes when the ratio of butadiene to hydrogen was 1/1(vol). Under this condition, the formation of 1-butene was remarkable: 1-(98%), *trans*-2-(1%), *cis*-2-(1%). It appeared that the lower ratio of butadiene to hydrogen was advantageous for the product formation while the higher one was so for the formation of the complex [I]. The $Co(CN)_5H^{3-}$ band was not observed in the course of reaction.

(ii) In the Presence of Deficient Cyanide Ion (CN/Co=4.5) at 0°C. Under condition (A), a weak 2098 cm^{-1} band of the complex [II] barely appeared after 30 minutes, but its growth and a decay of the $Co(CN)_5^{3-}$ band were very slow (Fig. 1d). The yield of butenes (the main product was *trans*-2-butene) was much lower than that in (i), reflecting that the aging reaction hardly proceeds under this condition.

Under condition (B), a rapid decay of the $Co(CN)_5H^{3-}$ band and a growth of the $Co(CN)_5^{3-}$ band were observed in accompany with an initial rapid formation of *trans*-2-butene (1-(14%), *trans*-2-(82%), *cis*-2-(4%)).[10] Different from the mode in (i), the band of [II] appeared after the complete disappearance of the $Co(CN)_5H^{3-}$ band and grew gradually, whereas the $Co(CN)_5^{3-}$ band decayed (Fig. 1e).

Under condition (C), the formation of [II] was greatly affected by the ratio of butadiene to hydrogen and was remarkable at a high ratio. When the ratio was 6/1, a steady growth of the band of [II] and a decay of the $Co(CN)_5^{3-}$ band took place immediately. When the ratio was 1/1, a weak shoulder band of [II] which appeared in the initial stage did not grow, and the strong $Co(CN)_5^{3-}$ band hardly changed. On the other hand, the formation of butenes was more

9) N. K. King and M. E. Winfield, *J. Amer. Chem. Soc.*, **80**, 2060 (1958).

10) The mode of the time courses of the formation of butenes were similar to those at 20°C, which were reported in the previous paper (Ref. 1).

remarkable in the latter than in the former. The composition of butenes (1-, *trans*-2-, *cis*-2-) was: 15%, 84%, 1% in the former and 10%, 89%, 1% in the latter. (In the experiments (i) and (ii), the composition of butenes was nearly constant in the course of reaction.)

(iii) In the Presence of the Stoichiometric Amount of Cyanide Ion (CN/Co=5.0) at 0°C. The relation between the variation of the complexes and the composition of butenes was rather complicated. As seen in Fig. 1f, the IR spectral change under condition (B) was similar to that in Fig. 1c showing the formation of the complex [I], except an initial great growth of the $Co(CN)_5^{3-}$ band. *trans*-2-Butene was the main product as reported[1,3] (1-(12%), *trans*-2-(81%), *cis*-2-(7%) after 10 min.), but a slight increase of 1-butene was observed with the elapse of time (1-(18%), *trans*-2-(76%), *cis*-2-(6%) after 60 min).

Confirmation of the Structures of the Intermediate Complexes in the Hydrogenation of Butadiene. Although Kwiatek and Seyler could not analyze the NMR spectra of the σ-butenyl complex observed at 60 MHz,[3d] the comparison of the NMR spectra measured directly on the reaction solution at 60, 100, and 220 MHz made it possible to reveal that the solution contained two complexes with very similar configurations (Fig. 2). They were assigned to the *cis*- and *trans*-isomers of [I].[11] Although it could not been determined clearly which signal corresponded to each isomer, slightly stronger bands (b and d) may correspond to the *trans*-isomer, because the *trans*-isomer may be more stable than the *cis*-isomer and because $J_{3,4}$ of the *trans*-isomer of the analogous compounds is in most cases smaller than that of the *cis*-isomer. It was also demonstrated that the proportion of the isomers did not depend on the CN/Co ratio so long as an excess cyanide ion was present. It is noteworthy that the proportion of the deuterium atom incorporated into the terminal methyl groups of the complexes prepared in D_2O under an atmosphere of hydrogen varied with the reaction condition. When the enough butadiene was added to the solution of the hydridocomplex under condition (B), one deuterium atom per mole of the complex was incorporated, but when the complex was prepared under condition (C), the proportion decreased greatly. It has been reported that the rate of the H–D exchange between $Co(CN)_5H^{3-}$ and D_2O is certainly very much faster than the addition reaction.[8d,12] A study on this problem is in progress.

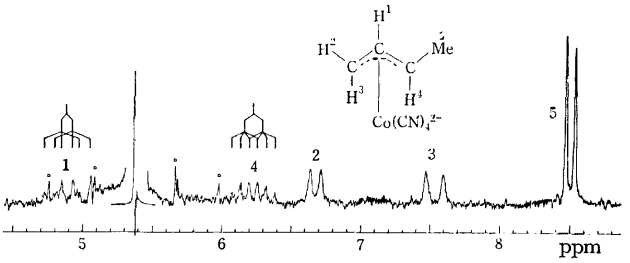

Fig. 3. NMR spectrum of the reaction solution at CN/Co= 4.5 in D_2O in the hydrogenation of butadiene. Observed at 100 MHz and at 5°C.
○, Side band of H_2O.

It has been considered that the complex [II] is too unstable to be observed,[3d] but the IR spectra showed the formation of an intermediate complex in the presence of deficient cyanide ion and made it possible to find an appropriate condition for its formation. The NMR spectrum observed after the separations of the residual $Co(CN)_5^{3-}$ by an addition of $BrCCl_3$ and of precipitates by filteration, revealed that the solution contained only a *syn*-π-(1-methylallyl) complex (Fig. 3).[11] It is noteworthy that an *anti*-complex was not contained. Deuterium atom was not incorporated into the complex in spite of the reaction in the D_2O solvent. It was also demonstrated by IR and NMR that [II] was converted to [I] and *vice versa* by the addition of either the KCN or $CoCl_2$ solution to the solution containing each complex. Chemical shifts and coupling constants are summarized in Table 1.

Hydrogenation of Isoprene. Figure 4 shows the typical results under condition (A) at 30°C with a cobalt concentration of 0.2M ($CoCl_2$=10 mmol) and with 10 mmol of isoprene. It shows clearly the dependence of product compositions on the reaction time and the CN/Co ratio. The results can be considered from

the two different relations; (i) between 2-methyl-1- and 2-methyl-2-butenes, (ii) between 2-methyl-1- and 3-methyl-1-butenes.

(i) Figure 4 shows that 2-methyl-2-butene is produced even in the presence of excess cyanide ion and that the proportion of 2-methyl-1- and -2-butenes is abruptly replaced in the course of reaction. This change took place when green precipitates appeared in the solution and was caused by the abrupt formation of 2-methyl-2-butene in accompany with the stop of the formation of 2-methyl-1-butene (Fig. 5). The time

when the change took place depended on the cyanide ion concentration and on the reaction temperature; the lower the concentration and the higher the temperature, the earlier the change took place. These results may be most reasonably explained by the following. The cyanide ion concentration decreases in the course of reaction owing to the aging reactions (1)—(4) or to the hydrolysis of the cyanide ion, and 2-methyl-2-butene is formed when the cyanide ion becomes deficient.

(ii) The mode of the formation of the two terminal olefins was remarkably different. The formation of 2-methyl-1-butene was always greater than that of 3-methyl-1-butene in an initial stage of the reaction. Although the formation of 3-methyl-1-butene was generally small, it became remarkable in the presence of a large excess cyanide ion. As the aging reaction was promoted by the excess cyanide ion, it was supposed that the increase in the relative concentration of $Co(CN)_5H^{3-}$ to isoprene might promote the formation of 3-methyl-1-butene. This was demonstrated by the result in Fig. 6, in which the effect of the relative concentration of isoprene to cobalt was examined.

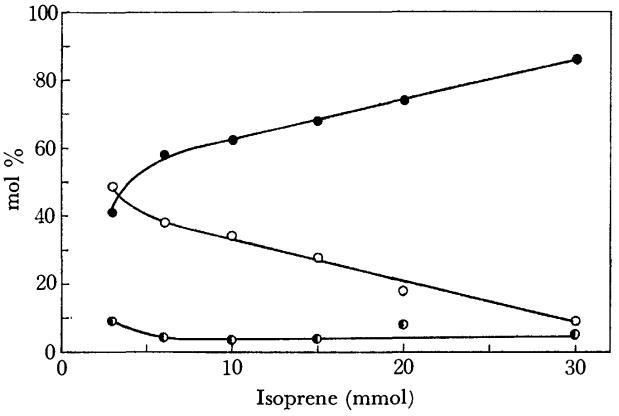

Fig. 6. Effect of the relative concentration of isoprene to $Co(CN)_5^{3-}$ in the hydrogenation of isoprene (Compositions after 3 hr) in H_2O, at 30°C, under condition (A), and with $CoCl_2$=10 mmol.
●: 2-methyl-1-butene, ○: 3-methyl-1-butene,
◐: 2-methyl-2-butene

Under condition (B), the formations of 3-methyl-1-butene at CN/Co=6.0 and of 2-methyl-2-butene at CN/Co=5.0, were greatly promoted. At CN/Co=6.0, the composition of the products (2-methyl-1-, 3-methyl-1-, 2-methyl-2-butenes) was 51%, 33%, 16% after 5 min and it became 2%, 70%, 9% after 20 min, which was maintained subsequently. It is noteworthy that the composition of 3-methyl-1-butene is greater than that of 2-methyl-1-butene. At CN/Co=5.0, the composition (8%, 9%, 83%) was nearly constant throughout the course of reaction.

The IR spectra of the reaction solutions in the presence of excess cyanide ion showed similar changes to the case of butadiene, showing the band of the intermediate complex at 2090 cm^{-1}. At CN/Co=4.5, however, the same band at 2090 cm^{-1} together with the shoulder band of $Co(CN)_5^{3-}$ was observed, contrary to the expectation that a new band may be observed at higher frequencies than 2090 cm^{-1}.

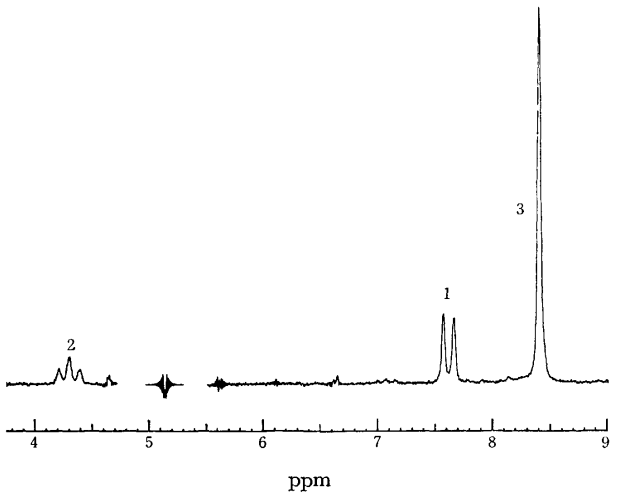

Fig. 7. NMR spectrum of the reaction solution at CN/Co=6.0 in D_2O in the hydrogenation of isoprene. Observed at 100 MHz and 5°C.

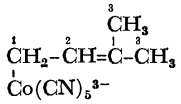
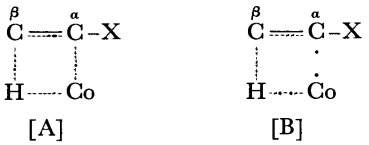


The NMR spectrum observed in the D_2O solution under condition (B) (Fig. 7) demonstrated that the solution at CN/Co=6.0 contained only a σ-3-methyl-but-2-enyl complex [VII],[13] and that the complex at CN/Co=4.5 was not a π-allylic complex but the σ-complex [VII].

Mechanisms of the Hydrogenations of Butadiene and Isoprene in Aqueous Solution. (i) Mechanism of the Initial Interaction of $Co(CN)_5H^{3-}$ with Substrates to form the Intermediate Complexes. In the hydrogenation by other transition metal complexes, the coordination of the substrate at a vacant site on the metal is mostly required, but in the case of pentacyanocobaltate(II) it has been proposed that the hydrogen of the hydridocomplex approaches the positive β-carbon of an activated double bond to form the four-center transition state [A][2,4] or the radical transition state [B].[13,14]



[A] has been proposed on the analogy with the transition state in the formation of $Co(CN)_5H^{3-}$ from $Co(CN)_5^{3-}$ and hydrogen,[4] but the kinetic trends in the addition of $Co(CN)_5H^{3-}$ to α,β-unsaturated compounds indicated that [B] best describes the initial interaction of $Co(CN)_5H^{3-}$ with most activated olefins.[13] The result that substituents on the β-carbon, regardless of their electron-donating (*e.g.* CH_3, CO_2^-)[12,13] or -attracting (*e.g.* C_6H_5)[15] properties, interfere with the reaction of $Co(CN)_5H^{3-}$ with substrates, and that the kinetic trends fail to parallel the stability of $CoC(CH_3)X$ adducts,[13] indicate that steric rather than electronic factors control the initial step and the C···H bonding rather than the C···Co is important in the transition state. Thus, [B] is preferable to [A].

Although it had been supposed that the hydridocomplex adds to activated olefins as though it were polarized Co^+–H^-,[2] it is well assumed from the infrared spectroscopic study that the polarization must be in a slight degree.[7] The view that the atomic hydrogen rather than the anionic hydrogen of $Co(CN)_5H^{3-}$ approaches the β-carbon, is supported by the result that the formation of 3-methyl-1-butene exceeds that of 2-methyl-1-butene in the presence of excess $Co(CN)_5H^{3-}$ in the hydrogenation of isoprene, because radicals approach more readily C^1 than C^4 in

$C^1=C^2-C^3=C^4$ and *vice versa* in the case of anions.[16]

The previous authors have proposed that the 1,2-adduct $CoC(CH_3)X$ is first formed inevitably *via* the transition state [A] or [B] and it isomerizes readily to the more stable 1,4-adduct in the hydrogenation of conjugated dienes,[4,13,14] but the result of the hydrogenation of isoprene suggests that this may not necessarily be the case. Mechanism 1 shows the probable courses for the formation of the intermediate complexes and the products in the hydrogenation of isoprene.

It is well assumed that the rate of the reaction (6) is greater than that of (5), because the formation of 3-methyl-1-butene is greater than that of 2-methyl-1-butene in the presence of excess $Co(CN)_5H^{3-}$, under which condition intermediates are more completely converted to products. Even if the hydrogen atom of $Co(CN)_5H^{3-}$ approaches C^1 more readily than C^4, the mechanism, in which the 1,2-adducts [IV] and [VI] should be first formed, seems to be unfavorable to explain the rate difference, because the tertiary alkyl complex [VI] must be extremely less stable than [IV]. On the base that the thermodynamic stability

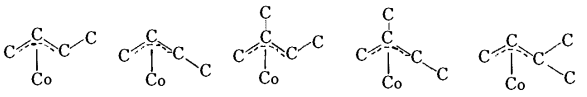
Mechanism 1.

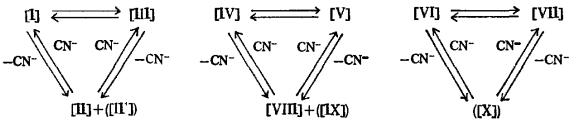
may be in order of [VII]≥[V]>[IV]>[VI] and that the reactions (5) and (6) are reversible, the 1,4-addition mechanism may be probable so long as it is supposed that the C···Co bonding in the transition state is not important. This is supported by the following. From the point of view that the process consists of the radical addition to the radicals, $[C^1{=}\overset{\overset{C}{|}}{C^2}{=}C^3{-}C^4H_3]$ and $[H_3C^1{-}\overset{\overset{C}{|}}{C^2}{=}C^3{=}C^4]$, about the same probability is expected for the addition of Co to C^1 and to C^3 in the reaction (5), but the addition to C^4 must be greater than to C^2 in the reaction (6).[16] Similarly, in the hydrogenation of butadiene, the 1,2- and 1,4-additions seem to have the same probability, but the latter may be predominant on account of the greater stability of the 1,4-adducts.

(ii) Mechanisms of the Conversion of σ-Complexes to π-Allylic Complexes. The complexes [II], [II'], [VIII], [IX], and [X] are the possible π-allylic complexes in the hydrogenations of butadiene and isoprene.



[II] [II'] [VIII] [IX] [X]

The present results that have demonstrated the formation of [II] and the equilibrium between [I] and [II] in the hydrogenation of butadiene are well explained by the mechanism 2, which have originally been proposed by Kwiatek and Seyler.[3c] In the hydrogenation of isoprene, none of [VIII], [IX], and [X] could be observed, but the relation between the 2-methyl-1- and -2-butenes in Fig. 4 indicates that the equilibrium in the mechanism 3 is taking place. [VIII] must be too unstable to have been observed on account of an additional methyl group to [II]. It is well assumed that the formations of [IX] and [X] may be negligible, because they must be less stable than [II']. The observation of the σ-complex [VII] in the deficient cyanide concentration indicates that the equilibrium in the mechanism 4 hardly takes place.



Mechanism 2 Mechanism 3 Mechanism 4

The isomerisation between [I] and [III] or [IV] and [V] may occur *via* the transition states which do not require ligand dissociation.[3c] The equilibrium [I]⇄[III] can explain the formation of similar amounts of the *cis*- and *trans*-isomers of [I] and the independence of the proportion on the CN/Co ratio. It is supposed that *cis*-[I] is slightly less stable than *trans*-[I] and it may be the origin of the selective formation of *cis*-2-butene in the presence of excess cyanide ion in the alcoholic solvents.[1,6]

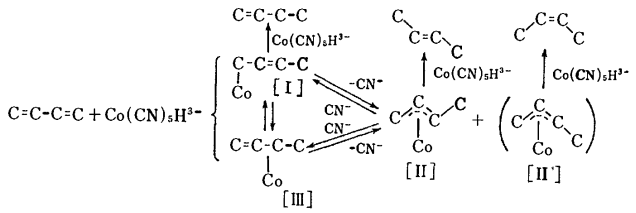
(iii) Mechanisms of the Product Formation. The result that the formation of 2-methyl-1-butene is always greater than that of 3-methyl-1-butene in the initial stage of the hydrogenation of isoprene may arise from that the intermediate for the latter is more stable than that for the former. Although the mechanism in which the 1,2-adducts [IV], [VI] are the direct intermediates for these alk-1-enes may not be excluded only for the reason that [VI] is less stable than [IV], the mechanism seems implausible because the principle proposed in the mechanism[4] can not be applied in general, especially to the radical mechanism. Alternatively, the results are clearly explained by the mechanism in which the 1,4-adducts are the direct intermediates. As described previously, the thermodynamic stability of [V] and [VII] seems similar ([VII] may be slightly more stable than [V] because a methyl group is located at the β-position in [V] and at the γ-position in [VII]). When the hydrogen atom of $Co(CN)_5H^{3-}$ approaches the γ-carbon in [V] or [VII], the steric factor, which controls the initiation step, should control the reactivity. Two methyl groups on the γ-carbon in [VII] must

hinder more strongly the approach of the hydrogen atom of $Co(CN)_5H^{3-}$ than the single methyl group in [V], resulting in the greater kinetic stability of [VII] than [V]. Similarly, [I] should be the direct intermediate for the formation of 1-butene in the hydrogenation of butadiene. The dependence of the rate of the formation of [I] and 1-butene on the ratio of butadiene and hydrogen under condition (C) supports this mechanism. The steric factor can also explain that [VII] is kinetically more stable than [I] despite the thermodynamic stability seems reverse.

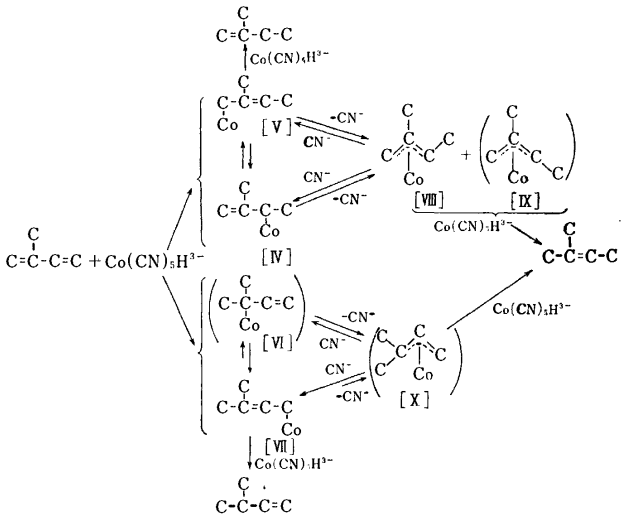
It is evident that the π-allylic complexes [II] and [VIII] are the direct intermediates for *trans*-2-butene and 2-methyl-2-butene, respectively. This is strongly supported by the result that the formations of [II] and of *trans*-2-butene depend greatly on the relative concentration of butadiene and hydrogen under condition (C). The difficulty of the formation of [II] compared with [I] may be attributable to the lower kinetic stability of [II] than [I], because their thermodynamic stability may be similar or reverse. The result at CN/Co=5.0 in the hydrogenation of butadiene is readily understood by this difference of the kinetic stability between these two complexes which must be formed in similar amounts. The difference of the kinetic stability is interpreted in terms of the steric factor. The hydrogen atom of $Co(CN)_5H^{3-}$ can approach more readily [II] than [I] because [II] has an unsubstituted carbon atom. This steric factor explains also that 1-butene is not formed from [II], because the hydrogen of $Co(CN)_5H^{3-}$ can approach the unsubstituted carbon more readily than the carbon substituted by a methyl group.

The explanation by the steric factor can be applied in general to the hydrogenation by pentacyanocobaltate(II) and excludes the mechanism in which the Co···Co bonding is included in the transition state.[4,5b]

In conclusion, the hydrogenations of butadiene and isoprene in aqueous solution are interpreted satisfactorily in terms of the mechanisms 5 and 6, respectively.



Mechanism 5



Mechanism 6

Order of Quencher Participation in Photochemistry. I. Proton Transfer from the Excited *p*-Hydroxybenzophenone in Mixed Solvents of Cyclohexane and Alcohols

Mikio Hoshino and Masao Koizumi

Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai

(Received January 20, 1972)

The change in the absorption spectrum of *p*-hydroxybenzophenone (HOBP) and relative quantum yields Φ_{rel} for the photoreduction of HOBP have been studied in mixed solvents consisting of cyclohexane and four kinds of alcohol. The change in absorption spectrum occurs in two steps with methanol, ethanol, and 2-propanol, suggesting the following equilibria, HOBP+S⇆A, and A+S⇆B (S, alcohol molecule). Φ_{rel} changes in two steps with methanol and ethanol and in one step with 2-propanol and amyl alcohol roughly in line with the spectral change. The changes in Φ_{rel} have been interpreted to be due to the deprotonation of HOBP. $\Phi_{rel}=1/(1+K[S]^n)$ holds for them with $n=5.5$ for 2-propanol and $n=7$ for other alcohols. A linear relation holds between $1/(n-1)\log K$ and Hammett's constant of alkyl group of alcohols, suggesting that the deprotonation tendency depends upon the specific interaction between alcohol molecules. The reactivity of A-species is considered to depend largely on the dielectric nature of the solvent.

We examined Porter and Suppan's mechanism[1,2] for the suppression of the photoreduction of *p*-hydroxybenzophenone (HOBP) in ethanol and obtained additional information.[3] The proton transfer from the excited HOBP, was reconfirmed as a cause for the non-occurrence of the photoreduction. It was found that a hydrogen-bonded species consisting of HOBP and ethanol does not necessarily undergo the ionic dissociation upon excitation. Such a species (A) is formed in cyclohexane when a small amount of ethanol is added, but under such conditions it does not undergo the proton transfer and accordingly it is photoreduced efficiently. This result is consistent with the finding of Matsuyama and Baba that a hydrogen-bonded species of HOBP and $(CH_3)_3N$ in cyclohexane–isopentane–ether (4: 4: 1) exhibits the phosphorescence from molecular $T(n\text{-}\pi^*)$ state at 77°K.[4] For the proton transfer to occur, a certain condition is necessary which is realized at higher ethanol concentrations. With an increase in ethanol concentration, it was suggested from the change of the absorption spectrum that in addition to A another species, perhaps HOBP with two C_2H_5OH attached to OH of HOBP (B) is formed in equilibrium with A. However, the proton transfer was found to occur much more rapidly with the increase of ethanol concentration than the formation of B. Therefore the proton transfer which occurs upon excitation is not directly concerned with the ground state equilibrium suggested by the absorption spectra. In fact, the decrease of the quantum yield of photoreduction with the increase of ethanol concentration caused by the proton transfer, was found to obey the equation

$$\Phi_{rel}=\frac{1}{1+K[\text{ethanol}]^n} \qquad (1)$$

wher $n=7$.

The present paper reports on the previous communication in detail together with results obtained for methanol, 2-propanol and amyl alcohol. The relative quantum yields have been found to be reproduced by Eq. (1) in all cases.

Experimental

A 6W germicidal lamp was employed as a light source of the steady light experiments. Spectral change was measured with a Hitachi ESP-3T spectrophotometer. Apparatus and procedures for the flash experiment are the usual ones employed in our laboratory.

Alcohols and cyclohexane were purified by the usual methods. *p*-Hydroxybenzophenone of G.R. grade of Wako Junyaku was recrystallized three times from aqueous ethanol.

Results

Absorption Spectra of HOBP in the Mixed Solvents of Cyclohexane and Alcohols. The change in absorption spectrum of HOBP in cyclohexane is given in Fig. 1 as a function of the ethanol concentration. With the addition of ethanol the peak located at 272 nm in cyclohexane gradually shifts to longer wavelength. It is seen that the change occurs in two steps, the first

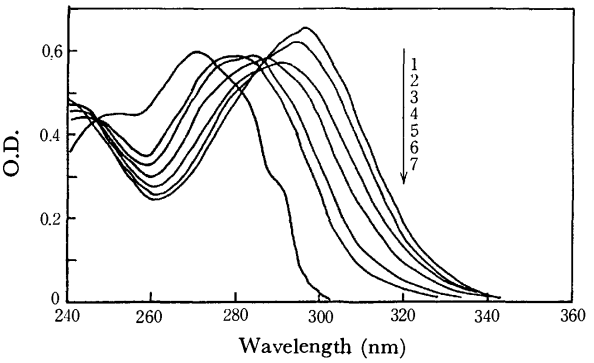

Fig. 1. Spectral change of HOBP in cyclohexane (3.65×10^{-5} M) with the addition of ethanol. Concentration of ethanol; 1) 3.4, 2) 8.5×10^{-1}, 3) 1.7×10^{-1} 4) 8.5×10^{-2}, 5) 3.4×10^{-2}, 6) 1.7×10^{-2}, 7) 0 M (Downward at 300 nm).

step ending at $\sim 3\times10^{-2}$M and the second occurring from 3×10^{-2}M to pure ethanol.

An isosbestic point is not observed in the first step. It appears in the second step, but not so clearly. Taking into account the superposition of the general solvent effect, which obscures the existence of the isosbestic point, one may safely assume the following equilibrium.

$$\text{HOBP} + \text{S} \rightleftarrows \text{A} \qquad \text{A} + \text{S} \rightleftarrows \text{B} \qquad (2)$$

where S denotes an ethanol molecule.

The equilibrium constant of the second step was estimated by the equation

$$(D_\infty - D)K[\text{S}] = D - \varepsilon_A C_0 \qquad (3)$$

which can be derived directly from

$$D = C_A\varepsilon_A + C_B\varepsilon_B \qquad C_A + C_B = C_0$$

$$K = C_B/C_A[\text{S}]$$

D; optical density of HOBP at a given ethanol concentration

D_∞; the optical density in pure ethanol

The plots of $(D_\infty - D)$ [S] against D at two wavelengths are shown in Fig. 2. Their slopes have the same magnitude giving $K = 1.2_3\times10\text{M}^{-1}$.

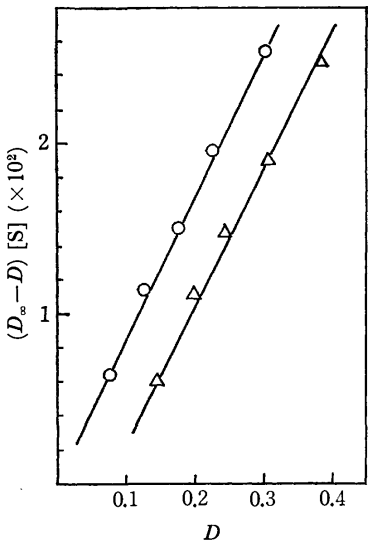

Fig. 2. Examples of the plots of $(D_\infty - D)$ [S] *vs.* D.
○: 310 nm △: 305 nm

The results for methanol, 2-propanol, and amyl alcohol are given in Figs. 3, 4, and 5. In the case of methanol and 2-propanol the change occurs in two steps as in ethanol and so the same type of equilibrium is thought to exist. The above analysis gives for 2-propanol the equilibrium constant for A+S⇄B, $K = 2\times10\text{M}^{-1}$. For methanol, the analysis was not successful. For amyl alcohol the two step change is not so distinguished. The degree of the shift is in the order, methanol>ethanol>2-propanol≈amyl alcohol.

Relative Quantum Yields as a Function of Alcohol Concentration. The spectral change of HOBP in cyclohexane upon irradiation is given in Fig. 6, which shows a gradual and monotonous decrease in optical density. This is due to the following reaction as in the

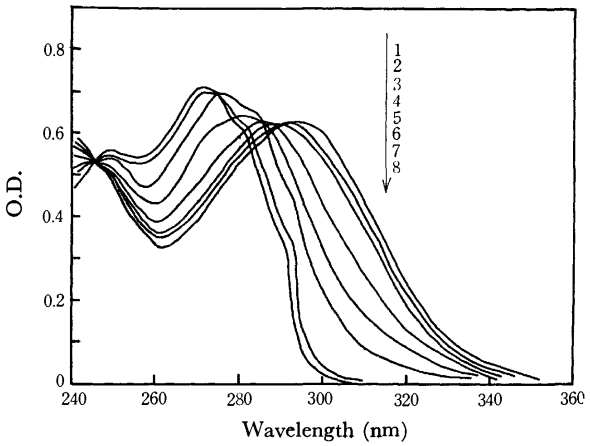

Fig. 3. Spectral change of HOBP in cyclohexane (4.27×10^{-5} M) with the addition of methanol. Concentration of methanol; 1) 1.22×10^{-1}, 2) 9.76×10^{-2}, 3) 6.10×10^{-2}, 4) 4.88×10^{-2}, 5) 4.66×10^{-2}, 6) 3.44×10^{-2}, 7) 1.12×10^{-2}, 8) 0 M (downward at 300 nm).

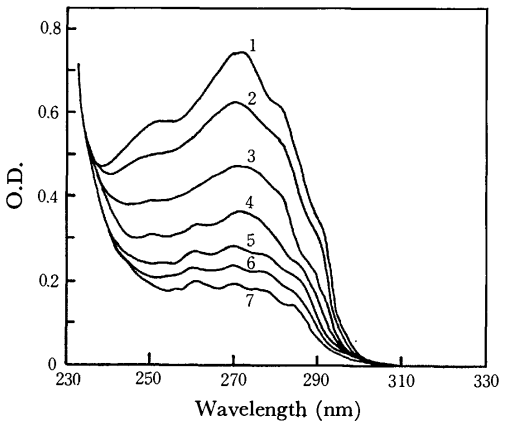

Fig. 6. Spectral change of HOBP in cyclohexane (4.57×10^{-5} M) upon irradiation at 2537 Å. Time of irradiation; 1): 0, 2): 0.5, 3): 1.0, 4): 1.5, 5): 2.0, 6): 2.5, 7): 3.0 min.

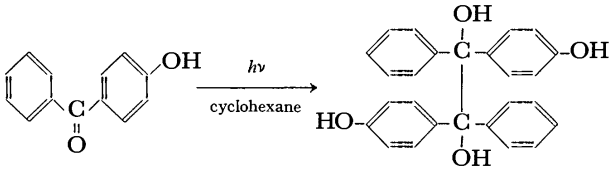
case of benzophenone.[5,6]



The rate was evaluated from the following equation, which takes the inner filter effect of the product pinacol into account.

$$-\frac{dC_A}{dt} = \Phi I_0(1-10^{-D})\frac{D_A}{D}$$

where C_A and D_A are the concentration of HOBP and the optical density due to HOBP, respectively. D is the total optical density experimentally obtained.

Integrating, we get

$$C_A^0 - C_A(t) = \Phi I_0\int_0^t (1-10^{-D})\frac{D_A}{D}dt.$$

By means of the relations

$$C_A^0 - C_A(t) = \frac{\Delta D}{(\varepsilon_A-\varepsilon_B)} \qquad D = D_A + \frac{\varepsilon_B}{(\varepsilon_A-\varepsilon_B)}\Delta D$$

(ε_B, the molar extinction coefficient of pinacol)

we obtain

$$\Delta D/(\varepsilon_A-\varepsilon_B) = \Phi I_0\int_0^t (1-10^{-D})D_A/D\,dt = \Phi I_0\int_0^t Y dt. \quad (4)$$

$\int_0^t Y\,dt$ can be obtained graphically.

An example of the analysis by Eq. (4) is shown in Fig. 7. The appearance of an induction period might be due to the incompleteness of the degassing. The relative quantum yields Φ_{rel} at various ethanol concentrations obtained by the above method are plotted against ethanol concentration in Fig. 8. The decrease of Φ_{rel} seems to occur in two steps, the first step being very small. A remarkable decrease from about 3×10^{-2}M of ethanol can not be reproduced either by Stern-Volmer or Perrin equations. It has been found that the following equation fits the results very well.

5) J. G. Calvert and J. N. Pitts, Jr., "Photochemistry," John Wiley & Sons, New York, (1966), p. 534.

6) A. Schonberg, "Preparative Organic Photochemistry," Springer-Verlag, New York Inc. (1968), p. 206.

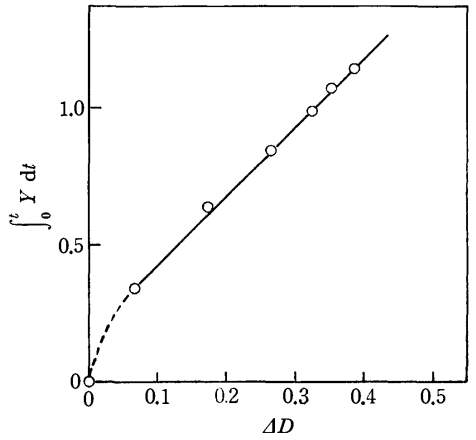


Fig. 7. An example of the plot of $\int_0^t Y\,dt$ *vs.* ΔD. HOBP in cyclohexane (4.57×10^{-5} M).

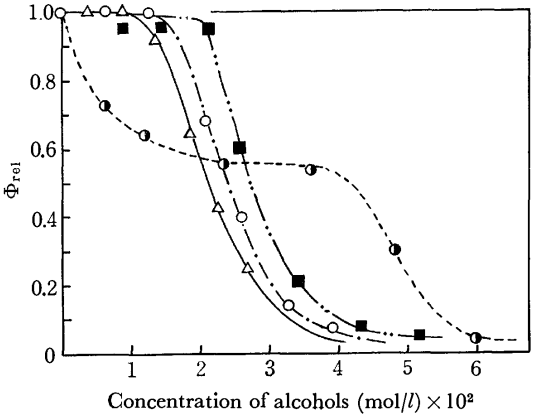

Fig. 8. Dependence of the relative quantum yield for the photoreduction of HOBP upon the concentration of alcohols. ◑: methanol, ○: 2-propanol, ■: ethanol, △: *n*-amyl alcohol.

$$\Phi_{rel} = \frac{1}{1+K[S]^n} \quad (1)$$

Thus by plotting log $(1/\Phi_{rel}-1)$ against log [S], we obtain a good straight line, which gives $n=7$ and $K=8\times10^{10}$. Hereafter the value of the order of quencher participation will be called n. The curve in Fig. 8 is a calculated one. We see from Figs. 1 and 8 that Φ_{rel} decreases very rapidly in the ethanol concentration region where the absorption spectrum begins to turn from species A to B.

The relative quantum yields obtained for 2-propanol, mechanol, and amyl alcohol by the same method of analysis are also given in Fig. 8.

In the case of methanol the results are conspicuous, the change occurring very clearly in two steps. This implies that species A in this case has much lower photoreactivity than that of HOBP itself. The first step seems to come to an end at about 3×10^{-2}M where the concentration of species B greatly predominates judging from the spectral change given in Fig. 3. The result for methanol ensures the reality of the small decrease of Φ in the low concentration region of ethanol.

The dependence of Φ_{rel} on isopropyl and amyl alcohol concentration is reproduced very satisfactorily

by Eq. (1). In the case of methanol, we assumed $\Phi_{rel}=0.58$ as a value at the end of the first step. The quantum yields in the second step were normalized in reference to this value.

The values of K and n and the related quantities are listed in Table 1. Some physical constants which will be referred to later are also included.

Table 1. The values of K and n and the related quantities

	n	K	$C_{1/2}$(M)[a]	DK at 25°C	Viscosity at 20C°
Methanol	7	2.5×10^{9}	4.7×10^{-2}	32.63	0.611
Ethanol	7	8.0×10^{10}	2.5×10^{-2}	24.30	1.19
2-Propanol	5.5	9.86×10^{8}	2.2×10^{-2}	18.3	2.39
Amyl alcohol	7	4.7×10^{11}	$2.0_7\times10^{-2}$	13.9	4.36

a) $C_{1/2}$, the concentration at which Φ decreases by one-half.

Studies on Primary Processes by means of Flash Technique. To obtain better insight into the proton transfer, flash photolysis studies have been performed on the HOBP solution in ethanol, cyclohexane and also in their mixture.

———: O⁻BP prepared chemically

The solution of HOBP 5.6×10^{-5}M in ethanol was subjected to a flash with a power of 80 J/flash. A transient spectrum immediately after the flash is given in Fig. 9. It has a peak at about 350 nm and the spectral shape agrees exactly with that of O⁻BP (alkaline alcoholic solution of HOBP). This is in complete agreement with Porter and Becket's result.[7] The decay obeys the second order with a rate constant of $1.6_2\times10^{9}$M^{-1}sec^{-1} which was evaluated by the use of $\varepsilon=2.25\times10^{4}$ at 340 nm. This value is a little smaller than the diffusion controlled rate constant.

The transient spectrum when 5.1×10^{-5}M HOBP in cyclohexane was subjected to a flash with a power of 150 J/flash is given in Fig. 10. The spectrum resembles very much that of ketyl radical of benzophenone reported by Porter and Wilkinson.[8] The spectrum is observed in the degassed solution but not in the aerated solution. The decay of the ketyl radical is of second order with a rate constant of 1.1×10^{9}M^{-1}sec^{-1}. This value was evaluated with the use of $\varepsilon=1.08\pm0.22\times10^{4}$ at 550 nm obtained from the optical density divided by

the yield of ketyl radical (evaluated from the decrease of HOBP).

The yield of ketyl radical immediately after flashing as a function of the ethanol concentration in cyclohexane is given in Fig. 11. The yield was determined by measuring the optical density of ketyl radical in the long wavelength region where there is no absorption of anion. The decline of the curve becomes prominent at about 2.1×10^{-2}M which is a little smaller than the concentration given in Fig. 8. This may be due to different experimental conditions. The agreement can be said satisfactory. It is concluded that the cause for the quenching of photoreduction occurs prior to the formation of ketyl radical. It is most likely that this is related to deprotonation. It should be added that the rate constant of the disappearance of ketyl radical is scarcely affected by the ethanol concentration.

Discussion and Supplementary Experiments

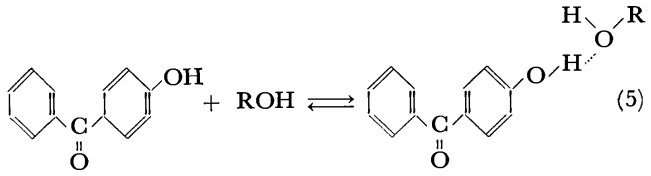
From the results, it is suggested that two types of molecular associates are formed between HOBP and alcohol in cyclohexane. Thus the change in absorption spectrum occurs in two distinct steps in methanol, ethanol, and 2-propanol. The quantum yield of photoreduction also changes in two steps in methanol

7) A. Becket and G. Porter, *Trans. Faraday Soc.*, **59**, 1686 (1963).
8) G. Porter and F. Wilkinson, *ibid.*, **57**, 1686 (1961).

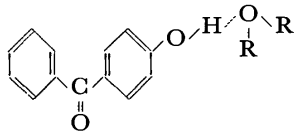
and ethanol.

As regards the change in absorption spectrum the isosbestic point is not always observed, this being due to the superposition of the general solvent effect. Thus for methanol, whose dielectric constant is as large as 32.63, no clear isosbestic point is observed in both the first and second steps.

As regards the first step of the spectral change, it is most likely connected with the formation of a hydrogen-bonded species as follows.



The hypothesis is supported by the absorption spectrum of HOBP in ether shown in Fig. 12 which also gives the spectral change due to the addition of ethanol. It is certain that ether forms a hydrogen bond with HOBP in the following way and a close resemblance



of the absorption spectrum of HOBP in ether to that of species A supports the existence of equilibrium (5). We see from Fig. 12 that the absorption spectrum changes gradually with the increase in ethanol concentration giving no isosbestic point.

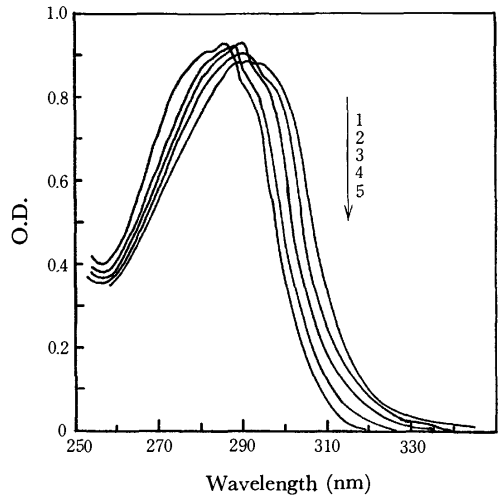


Fig. 12. Spectral change of HOBP in ether (5.50×10^{-5} M) with the addition of ethanol. Concentration of ethanol; 1) 5.1, 2) 3.4, 3) 1.7, 4) 0.85, 5) 0 M (downward at 310 nm).

As regards the second step, a detailed discussion was given on the nature of species B in ethanol-cyclohexane.[3] Some pieces of evidence were presented for the assumption that as long as the spectral behavior is concerned, the second ethanol molecule in species B is attached to the first one bonded to HO and not to the C=O group of HOBP. The present results obtained for other alcohols are also consistent with this view. Furthermore, the equilibrium constants for A+S⇌B are for ethanol and 2-propanol 1.2×10 and 2×10 respectively, which are not incompatible with the association constants of alcohols reported in literature.[9]

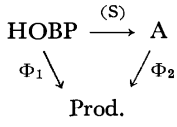
As to the spectral shift, two factors are considered to be important, (a) the general solvent effect represented by DK and (b) the specific interaction between solute and solvent molecules such as hydrogen-bonding. The former is the largest in methanol and decreases in the order ethanol, 2-propanol, amyl alcohol. The latter is considered to become larger from methanol to ethanol, amyl alcohol and to 2-propanol. No clear-cut isosbestic point and a large shift in case of methanol can be ascribed to a large DK. In the case of amyl alcohol for which DK is the smallest, the specific interaction only is an important factor, and this is why the two steps are not so distinctly separated.

The relative quantum yields in the mixed solvents clearly demonstrate that species A does not undergo the eventual deprotonation upon excitation and accordingly it is photoreduced efficiently. This is supported by the fact that HOBP is very efficiently photoreduced in ether.[10] Ether has no hydrogen to be detached as a proton and accordingly a hydrogen-bonded species can be reduced even in pure ether.

Analysis of the experimental results using Eq. (4) leads to the quantum yield of 1.35. This suggests the existence of a similar situation to that for the photoreduction of benzophenone in 2-propanol.[11]

A remarkable exception is methanol; in this case Φ_{rel} of species A is 0.58 with reference to free HOBP. Thus the reactivity of H-bonded species in methanol is about one half that of free HOBP. In the case of ethanol the difference in reactivity between free HOBP and hydrogen-bonded species is very small and in other alcohols there is no measureable difference.

The following analyiss supports the view that the above difference in the case of methanol (and perhaps in ethanol) is attributed to the nature of species A and not related with the transient proton transfer or other kinetic phenomena. On the basis of the following scheme involving equilibrium, HOBP+S⇌A



we obtain

$$\Phi = \frac{\Phi_1+\Phi_2\alpha[S]}{1+\alpha[S]} \qquad (6)$$

where

$$\alpha = \frac{\varepsilon_A}{\varepsilon_f}K, \qquad K = \frac{[A]}{[HOBP][S]}$$

(ε_f and ε_A are molar extinction coefficients of free HOBP and A-Species)

9) N. O. Coggeshall and E. L. Saier, *J. Amer. Chem. Soc.*, **73**, 5414 (1951).

10) The photoreduction of HOBP in ether seems to be somewhat anomalous; upon irradiation, a new absorption spectrum appears in the longer wavelength region in contrast to cyclohexane. This may be due to a trivial side reaction.

11) Φ for the photoreduction of benzophenone in 2-propanol varies from 0.80 to 2 according to the light intensity.[5]

It follows from (6) that

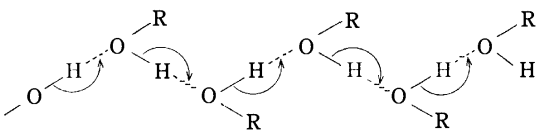
$$\frac{1-\Phi_{rel}}{[S]} = \alpha\Phi_{rel} - \alpha\frac{\Phi_2}{\Phi_1} \qquad (7)$$

In fact the plot of $1-\Phi_{rel}/[S]$ *vs.* Φ_{rel} gives a good straight line and from the slope and intercept we obtain $\Phi_2/\Phi_1 \approx 0.5$ which agrees fairly well with the experimental value.

However, in view of the fact that the specific interaction between ROH and HOBP or the strength of H-bond is the weakest for methanol and ethanol next, the dielectric nature of the solvent is considered to be an important factor for determining the reactivity of H-species. Perhaps the entity consisting of $O\text{-}H\cdots O\langle^{H}_{R}$ group and the surrounding solvation sphere of alcohol molecules may determine the reactivity.

On the other hand, the second step decrease in Φ_{rel} in methanol and ethanol and a single step decrease in other alcohols are considered to be closely related to the deprotonation of HOBP. It is regrettable that the yield of anion could not be examined as a function of ethanol concentration, since the absorption spectrum of anion was superposed by that of ketyl radical which has about ten times absorbance as that of the former. However, the approximate agreement between the two plots, Φ_{rel} and the yield of ketyl radical against [ethanol], implies that the cause of the quenching of photoreduction occurs prior to the formation of ketyl radical. It is very likely therefore, that the phenomenon is related to the proton transfer. Successful analysis by Eq. (1) also supports this view. If the decrease in Φ_{rel} were merely due to the difference in reactivity of species A and B existing in equilibrium, the decrease would not be so steep.

The result where the order of quencher participation (n) is as large as seven might be understood in the following way. For the proton transfer to suppress the reaction, the excited anion O⁻BP produced as a result of deprotonation would be reconverted to the ground state with no chance of recombining with the proton. This may be possible only if a proton transfer occurs from one alcohol molecule to its neighbour in a successive scheme of a relay type as shown below (Grotthus mechanism).



The order of the quencher participation may then be interpreted as the average number of alcohol molecules participating in the proton transfer, required for the quenching of reaction to occur. The result where n is seven for three alcohols except for 2-propanol is also in line with this view.

If such a model is accepted the value of K may be related to the association tendency of alcohol molecules. If one assumes that this tendency is measured by an equilibrium constant of dimerization and the same equilibrium constant for the successive association

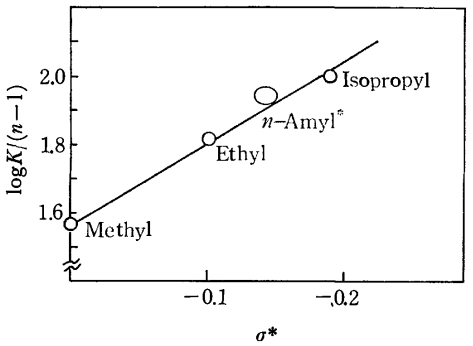


Fig. 13. A plot of log $K/(n-1)$ against σ^*.
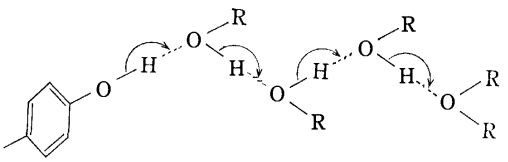
σ^* value of n-amyl is assumed to be −0.130——0.145.

$$k = \frac{[A_2]}{[A]^2} = \frac{[A]^3}{[A_2][A]} = \frac{[A_4]}{[A_3][A]} = \cdots$$

then k is given by $K^{1/n-1}$. In fact, the relation between $\log K/(n-1)$ and the Hammett constant[12] is approximately linear as shown in Fig. 13. That the order of quencher participation is 5.5 for 2-propanol may be due to a large electron releasing power of isopropyl group, which enhances the accepting power of proton.

Thus we might say that the proton transfer efficiency in alcohols is closely related to the specific interaction between alcohol molecules and not to the dielectric nature or the viscosity of the solvent, as was found in Table 1.

It is of interest to add that for Φ_{rel} in the mixed solvent of ether and ethanol, the same type of equation as (1) holds but with $n=3$ and $K=2.8\times10^{-2}$. The smaller values of n and K are reasonable because the proton accepting power is considered to be larger for ether than for ethanol. It is possible that the following structure has a lifetime longer than that of the excited anion O⁻BP.



Thus all the results we obtained are consistently explained by the Grotthus mechanism of proton transfer.

Our thanks are due to Dr. K. Kikuchi for his help in the flash experiments.

On the First Singlet and Triplet Excited States of the Lithium Molecule

Susumu KOHDA,* Kimio OHNO,
and Hiroshi TAKETA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo
General Education Department, Kyushu University, Ropponmatsu, Fukuoka

(Received December 6, 1971)

The first singlet and triplet excited states of Li_2 are studied by the MO and VB methods. As basis, only $1s$ and $2s$ AO's are used. In the MO description, the antibonding MO is more diffuse than the bonding MO and the difference is bigger in $^1\Sigma_u^+$ than $^3\Sigma_u^+$. In the VB description, splitting of the $2s$ orbital in the purely ionic ($^1\Sigma_u^+$) and covalent ($^3\Sigma_u^+$) wave functions does not lead to any energy lowering. An interpretation of this result is suggested. The calculated singlet-triplet separation is compared with previous calculations.

The lithium molecule is the simplest diatomic molecule with inner shells. In this paper, the first singlet and triplet excited states are studied by the molecular orbital (MO) and valence bond (VB) methods.

In conventional MO and VB calculations, only those atomic orbitals (AO's) which are occupied in the ground state of free atoms are usually used as a basis and the same basis is used to describe different excited states as well as the ground state. These conventional MO and VB calculations failed badly in predicting the V-T separation in C_2H_4[1] and the $^3\Sigma_u^- - ^3\Sigma_u^+$ separation in O_2[2]. In order to overcome this difficulty within the framework of the MO method, Huzinaga[3,4] advocated the use of different AO's for bonding and anti-bonding MO's and the view that these AO's could also be different in different states. He applied this idea to C_2H_4 and obtained a much better value for the V-T separation. His anti-bonding MO in the V state is very diffuse and the optimum orbital exponent of $2p\pi$ AO turns out to be as small as 0.2. This remarkable result was confirmed later by Goddard, Hunt, and Dunning,[5] who used a very flexible basis in their calculation. Ohno and Itoh[6,7], on the other hand, had attacked the same problem by the VB method. Their method is characterized by the use of different AO's for a neutral atom and for its positive and negative ions. Although their calculations were approximate, the V-T and $^3\Sigma_u^- - ^3\Sigma_u^+$ separations they obtained were fairly good.

In this work, the first singlet and triplet excitation energies of Li_2 are calculated both by Huzinaga's MO method and by the spirit of Ohno and Itoh's VB method. The aim of the work is not to achieve a numerical accuracy for these excited states but to gain qualitative idea about charcteristics of these states. Thus, only $1s$ and $2s$ Slater-type orbitals are used as the basic AO's. The orbital exponent of $1s$ is fixed at 2.685, which is the potimum value for the neutral Li atom.[8] The internuclear distance is also fixed at the observed value of 5.051 a.u.[9]

Molecular Orbital Treatment

In the MO treatment with the limited basis explained above, the wave functions for the first singlet and triplet excited states are written as

$$\Psi^{MO}(^1\Sigma_u^+) = 1/\sqrt{2}\,[\det|1\sigma_g\overline{1\sigma}_g 1\sigma_u\overline{1\sigma}_u 2\sigma_g\overline{2\sigma}_u| - \det|1\sigma_g\overline{1\sigma}_g 1\sigma_u\overline{1\sigma}_u\overline{2\sigma}_g 2\sigma_u|], \quad (2.1)$$

and

$$\Psi^{MO}(^3\Sigma_u^+) = 1/\sqrt{2}\,[\det|1\sigma_g\overline{1\sigma}_g 1\sigma_u\overline{1\sigma}_u 2\sigma_g\overline{2\sigma}_u| + \det|1\sigma_g\overline{1\sigma}_g 1\sigma_u\overline{1\sigma}_u\overline{2\sigma}_g 2\sigma_u|], \quad (2.2)$$

where spins α and β are associated with the orbitals with out and with a bar, respectively.

Following Huzinaga's procedure, we take the orbital exponents of the $2s$ orbitals used in $2\sigma_g$ and $2\sigma_u$ as two independent variational parameters. They are denoted by δ_g for $2\sigma_g$ and δ_u for $2\sigma_u$. The orbitals $2\sigma_g$ and $2\sigma_u$ are orthogonalized to $1\sigma_g$ and $1\sigma_u$, respectively, by the Schmidt procedure. The latter are constructed from the $1s_a$ and $1s_b$ AO's.

The energy is thus a function of two parameters, *i.e.*, δ_g and δ_u for each state. The results are collected in Table 1. When we use the same AO's in constructing the two MO's $2\sigma_g$ and $2\sigma_u$ (MO2=VB2), the optimum orbital exponents for $^1\Sigma_u^+$ and $^3\Sigma_u^+$ turned out to be close to the optimum value of Li^- and Li, respectively. The latter values are 0.547 for Li^-[10] and 0.637 for Li.[8] This could be expected since when the restriction $\delta_u=\delta_g$ is imposed, the MO functions Eq. (2.1) and Eq. (2.2) are identical with the VB functions which are inoic for $^1\Sigma_u^+$ and covalent for $^3\Sigma_u^+$.

When we use different AO's in different MO's (MO3), the antibonding $2\sigma_u$ becomes more diffuse than the bonding $2\sigma_g$. The degree of splitting is bigger in $^1\Sigma_u^+$ than in $^3\Sigma_u^+$. This is in accord with the observations made by Huzinaga,[11] and

Phillipson and Mulliken[12] on H_2, by Huzinaga[3,4] and Dunning *et al.*[5] on C_2H_4, and by Taketa *et al.* on O_2[13]. However, even the splitting between $2\sigma_g$ and $2\sigma_u$ in $^1\Sigma_u^+$ is smaller than that found in H_2, C_2H_4, and O_2. This is probably connected with the fact that the equilibrium internuclear distance is large in comparison with the radius of the valence orbital in the case of Li_2.

Valence Bond Treatment

In the VB treatment with the limited bais we employed, the wave functions for the first singlet and triplet excited states can be written as

$$\begin{aligned}\Psi^{VB}(^1\Sigma_u^+) = N[&\det|1s_a\overline{1s_a}1s_b\overline{1s_b}2s_a\overline{2s_a}|]\\ &-\det|1s_a\overline{1s_a}1s_b\overline{1s_b}\overline{2s_a}2s_a'|\\ &-\det|1s_a\overline{1s_a}1s_b\overline{1s_b}2s_b\overline{2s_b}'|\\ &+\det|1s_a\overline{1s_a}1s_b\overline{1s_b}\overline{2s_b}2s_b'|],\end{aligned} \tag{3.1}$$

and

$$\begin{aligned}\Psi^{VB}(^3\Sigma_u^+) = N'[&\det|1s_a\overline{1s_a}1s_b\overline{1s_b}2s_a\overline{2s_b}'|\\ &-\det|1s_a\overline{1s_a}1s_b\overline{1s_b}\overline{2s_a}2s_b'|\\ &-\det|1s_a\overline{1s_a}1s_b\overline{1s_b}2s_b\overline{2s_a}'|\\ &-\det|1s_a\overline{1s_a}1s_b\overline{1s_b}\overline{2s_b}2s_a'|].\end{aligned} \tag{3.2}$$

These wave functions correspond to the structures Li^+-Li^- for $^1\Sigma_u^+$ and Li-Li for $^3\Sigma_u^+$ and contain two variational parameters δ_{2s} and δ_{2s}'. All $2s$ orbitals $2s_a$, $2s_b$, $2s_a'$ and $2s_b'$ are orthogonalized to the $1s$ orbitals by the Schmidt procedure.

The energy again becomes a function of two parameters. Contrary to our expectation, the energy minima are found at $\delta_{2s}=\delta_{2s}'=0.582$ for $^1\Sigma_u^+$ and at $\delta_{2s}=\delta_{2s}'=0.647$ for $^3\Sigma_u^+$. When $\delta_{2s}=\delta_{2s}'$, the wave functions in Eqs. (3.1) and (3.2) are identical with those in Eqs. (2.1) and (2.2), respectively, under the restriction $\delta_u=\delta_g$. This means that no improvement over the simple VB function comes about by allowing the wave functions an extra freedom of $\delta_{2s} \neq \delta_{2s}'$. An exactly similar conclusion is reached in the VB treatment of the $^1\Sigma_u^+$ and $^3\Sigma_u^+$ states of H_2 with the two $1s$-type AO's.[14]

In these cases, the wave function is symmetric with respect to the two parameters and the energy must have a extremum at $\delta_{2s}=\delta_{2s}'$ when δ_{2s} and δ_{2s}' change along a line perpendicular to the line $\delta_{2s}=\delta_{2s}'$. The results we have obtained mean that the point where $\delta_{2s}=\delta_{2s}'=0.582$ ($^1\Sigma_u^+$) or 0.647 ($^3\Sigma_u^+$) is a minimum and not a saddle point. This may seem less strange when the valence bond wave functions in Eqs. (3.1) and (3.2) are expressed in the following way:

$$\Psi^{VB}(^1\Sigma_u^+) \propto \Psi^{MO}(^1\Sigma_u^+) + \Psi'^{MO}(^1\Sigma_u^+)$$
$$\Psi^{VB}(^3\Sigma_u^+) \propto \Psi^{MO}(^3\Sigma_u^+) + \Psi'^{MO}(^3\Sigma_u^+)$$

where Ψ^{MO} ($^1\Sigma_u^+$) and $\Psi^{MO}(^3\Sigma_u^+)$ have been given in Eqs. (2.1) and (2.2), respectively, and Ψ'^{MO} has the same functional form as Eq. (2.1) or Eq. (2.2) but δ_{2s} and δ_{2s}' are interchanged in $2\sigma_g$ and $2\sigma_u$. We have seen that the energies of the wave functions Ψ^{MO} ($^1\Sigma_u^+$) and $\Psi^{MO}(^3\Sigma_u^+)$ are quite low. However, $\Psi'^{MO}(^1\Sigma_u^+)$ and $\Psi'^{MO}(^3\Sigma_u^+)$ are expected to have very high energies, since they correspond to an unlikely model in which the bonding MO is diffuse and the anti-bonding MO is tight. The wave functions in Eqs. (3.1) and (3.2) are forced to contain equal amount of Ψ^{MO} and Ψ'^{MO}. This might be the reason why the extra degree of freedom introduced in the VB calculation turns out to be superfluous.

Summary

The calculated singlet-triplet separation is compared with other calculations in Table 1. Unfortunately, the $^3\Sigma_u^+$ state has not been observed. If we take the value of 0.63 eV obtained by the best calculation among the listed as a standard, the separation we obtained is only slightly better than the conventional calculation. However, the modification introduced here makes it clear that the $2\sigma_u$ orbital in the $^1\Sigma_u^+$ state is more diffuse than the $2\sigma_g$ orbital and both of the $2\sigma_u$ and $2\sigma_g$ orbitals in the $^3\Sigma_u^+$ state. It should also be noted that the use of two $2s$-type AO's in the ionic ($^1\Sigma_u^+$) and covalent ($^3\Sigma_u^+$) functions does not lead to any improvement over the conventional treatment.

The authors wish to express their hearty thanks to Professor S. Huzinaga for valuable discussions. Calculation of molecular integrals were carried out on the HITAC 5020E Computer at the University of Tokyo Computing Centre and the rest on the FACOM 270—20 Computer at the Chemistry Department, Hokkaido University.

Thermal Decomposition of Ammonium Salts of Transition Metal Oxyacids. I. Thermogravimetric Analysis of Ammonium Paramolybdate

Il-Hyun PARK*

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received August 5, 1970)

The decomposition of ammonium paramolybdate (APM) has been investigated by using a quartz spring balance in various ambient pressures. APM is decomposed in four or five stages, including a dehydration procedure, depending on the ambient pressures. However, these results do not agree with those of previous reports. This discrepancy may be attributed to the use of a sensitive quartz spring balance, a small amount of a sample, the application of a slow heating rate, or the utilization of DTG curves in the present study. The control of the ambient pressure was effective in investigating the thermogravimetric change in detail, especially in confirming the dehydration reaction. It is also concluded clearly that, in the course of the decomposition process, there is a final decomposition stage which has never been reported. The kinetics of the thermal decomposition was studied. The activation energies of the decomposition of APM under 760 Torr are 38.6, 194.8, 81.9, and 151.2 kcal·mol^{-1} respectively for the first to the fourth stages.

The thermal decomposition of ammonium paramolybdate tetra-hydrate (APM) has been studied by many investigators, and its decomposition process and the intermediates have been reported.[1-9] It was found by thermal analysis that APM decomposes in three stages. However, Rode and Tverdokhlebov reported that it decomposes in four stages, that is, they said there is a dehydration stage of all the hydrated water molecules. They also determined the composition of the intermediates by chemical analysis, by the X-ray diffraction method, *etc.* Their results, however, disagree with each other. Especially, the decomposition temperatures of the first stage and the third stage on their thermogravimetric curves (TGA) and the compositions of the intermediates are not in agreement with each other. This could be due to the differences in the experimental conditions and methods they adopted. Nevertheless, both of them forms a stable substance, $(NH_4)_2O\cdot 4MoO_3$, as a decomposition product up to the second stage.

In the present experiment, the ambient pressure was controlled in order to study the process of the first and third decomposition stages in detail, for about these stages the previous papers were not in agreement. The pressure-control method means to maintain a constant ambient pressure of a desired value during the decomposition.

The gases evolved by decomposition generally diffues slowly from the vicinity of the sample under normal atmospheric pressure, but the diffuse more rapidly when the ambient pressure decreases. As a result, changes in the decomposition process can be expected. If the evolving gases near the sample are continuously eliminated, we can expect to obtain different information.

The experiments were carried out by means of thermogravimetric analysis, using a highly-sensitive quartz spring balance calibrated for thermal agitation, in seven different ambient pressures: 760, 580, 130, 70, 20, 5, and 10^{-3} Torr (*in vacuo*). The final products of decomposition were identified by means of X-ray diffraction.

sample, was hung by means of a fine quartz rod to a quartz spring balance, and the shortening of the helix caused by the decrease in weight was measured by means of a cathetometer. The spring balance had a sensitivity of 0.391 mm/mg with 162 turns, and a maximum load of 1 g, including the weight of the sample crucible (about 0.2 g). The temperature was measured by means of two chromel-alumel thermocouples; one of them was set right under the crucible in the reaction tube in order to measure the decomposition temperature, while the other was set outside of the reaction tube at the same level as the crucible in order to control the heating rate. The control of the ambient pressure was attained by using a liquid nitrogen trap which condensed the evolved gases except a small amount of nitrogen, so that any large change in pressure in the reaction tube was suppressed. The experiments were carried out in a closed system in order to maintain a constant pressure except in the case of 760 Torr.

Samples. The sample was a Merck reagent of an extra pure grade (Germany) and was used without further purification. The sample was powdered to 150—200 mesh. The effect of the particle size on the thermogravimetric change was within the limits of experimental error. Considering the balance sensitivity, the sample weight of 50 mg was used. The final decomposition products in 760 Torr and 10^{-3} Torr were examined by means of the X-ray diffraction method.

Effects of Air Buoyancy and Convection. Before the measurements of the thermogravimetric change, the effects of air buoyancy and convection in the cylindrical decomposition tube must be considered. The temperature change in the spring balance should also be taken into account. Upon a change in temperature the crucible and the crucible with a sample will show an apparent weight change. Therefore, correction is essential in order to obtain an accurate thermogravimetric curve. The factors which cause the apparent weight changes are the air buoyancy, the convection effect in the cylindrical tube, the shape of the crucible, the temperature change in quartz helix, *etc.* In order to determine the above-mentioned correction, the apparent weight change for an inert sample (30 mg) in the crucible in an elevating temperature was measured by means of the apparatus used for the measurement. The correction curves thus obtained are shown in Fig. 2. It may be seen from the figure that the apparent weight increase was observed up to about 200°C regardless of the ambient pressures. The maximum weight increases were found to be about 0.2 mg. Above 200°C, the apparent weight loss was seen up to about 400°C, where the maximum weight loss of about 0.35 mg was observed. The observed weights during the decomposition were thus corrected. Although the corrections are not exact because the weight and volume of the sample change as the decomposition proceeds, the discrepancy is considered to be small and can be disregarded.

Corrections of Temperature. Generally, it is difficult to measure directly the temperature of the sample which hangs from the helix during decomposition. The usual way is to measure the temperature in the furnace near the sample. However, this method often introduces a large error in the decomposition temperature. If the furnace temperature is increased at a constant rate, the temperature of the furnace is usually higher than the decomposition temperature. It is said that this thermal lag is about 3 to 14°C, and that it is approximately proportional to the heating rate.[10] The difference was examined by attaching one thermocouple directly to the sample crucible and the other to the outside of the reaction tube near the sample. The results are shown in Fig. 3. It may be seen from the figure that the difference in temperature decreases as the ambient pressure decreases.

X-Ray Analysis. To identify the final products decomposed from APM at 760 Torr and 10^{-3} Torr, the X-ray analysis was carried out using a Schimadzu recording diffractometer with Cu-$K\alpha$ radiation.

Results and Discussion

Thermogravimetric Analysis. The TGA curves obtained by the thermogravimetric measurements in ambient pressures of 760, 580, 130, 70, 20, 5, and 10^{-3} Torr at a heating rate of 2°C/min are shown in Figs. 4 and 5, while the differential thermogravimetric curves (DTG curves) are shown in Figs. 6 and 7. It may clearly be seen from the curves that APM decomposes in four stages under higher pressures and in five stages under the pressures below 130 Torr. Here, the first stage of the decomposition splits into two stages, although the stable range of the intermediate is not very large. This is different from the results reported by other investigators,[1-9] who considered APM to

10) A. E. Newkirk, *Anal. Chem.*, **32**, 1558 (1960).

decompose in three stages under 760 Torr. Only Rode reported the decomposition in four stages, but his sample was $5(NH_4)_2O \cdot 12MoO_3 \cdot 12H_2O$.

Funaki and Rode reported that all the molecules of the water of hydration are removed during the first decomposition process (Duval, Hegedüs, and Ma did not show the dehydration step). This suggests that the removal of the water of hydration can occur independently of the removal of ammonia, and that the first decomposition process under pressures of 130 Torr or lower corresponds to a part of the dehydration. As will be described in the next paper, the analysis of the gases evolved by decomposition under low pressures confirms this process.

The DTG curve under 70 Torr shows that the maximum of dw/dt in the first decomposition process corresponds to 80°C and that the weight loss at the minimum is 23.5%, which approximately corresponds to three water molecules of APM. That is, the first stage in 70 Torr corresponds to the removal of three water molecules of APM, this is also true under 130 Torr. For the cases of 20 and 5 Torr, the elimination of two molecules of water corresponds to the first decomposition stage. By comparing the first minimum on DTG curves under 20 or 5 Torr with those under 130 or 70 Torr, it is seen that the trough of the former

is deeper than that of the latter. The depth of the trough on the DTG curve is considered to be related to the stability of the intermediate; that is, the height of the trough above the base line indicates the instability of the intermediate. The higher trough means that the intermediate is more unstable, and that two continuous reactions overlap considerably. Accordingly, by comparing Figs. 6 and 7 we can find that the intermediates under 20 or 5 Torr are more stable than those under 130 or 70 Torr. Therefore, it is not unreasonable to suppose that, also under 760 or 580 Torr, the dehydration reaction occurs prior to the removal of ammonium oxide, but the overlap of the two succeeding reactions is so large that the processes can not be observed separately, as they can under lower pressures. Judging from the tendency for the number of removed water molecules to decrease with a decrease in the ambient pressure, it will be expected that more than three water molecules can be removed in the first decomposition stage under 760 or 580 Torr and less than two under 10^{-3} Torr. Ma reported that, under 760 Torr APM begins to evolve ammonia at the temperature of about 120°C. The dehydration becomes rapid at around 115°C, and it is almost complete at 130°C. He concluded that, in the first stage in 760 Torr, four molecules of water are removed at first, and that then some ammonia is removed, without being any step resulting in $2(NH_4)_2O \cdot 5MoO_3$ at about 130°C. Lindqvist[11] showed, by crystallographic investigations, that the four hydrates were not included in the crystal structure of the discrete hepta-molybdate ion, $Mo_7O_{24}^{6-}$. This indicates that the water molecules of hydration exist independently in crystal lattice and that they are bonded with a weak bonding strength. Therefore, they can easily break away with a decrease in the atmospheric pressure before ammonium oxide evolves.

It is seen that both the first minimum under 760 and 580 Torr and the second minimum below 130 Torr on the DTG curve occur at the same temperature of about 160°C. However, the intermediates have different compositions and are comparatively unstable, with no horizontal portions being observed on the TGA curves. Different compositions for the intermediate have been reported by different investigators. Funaki and Rode decided it was a product of mere dehydration. On the other hand, Ma and others obtained the $2(NH_4)_2O \cdot 5MoO_3$ formula, but their TGA curves also suggest a lack of stability. Accordingly, it can be presumed that the intermediates in this region are so unstable that the compositions vary depending on the decomposition conditions.

From the TGA and DTG curves, it may be seen clearly that a stable intermediate, $(NH_4)_2O \cdot 4MoO_3$, is produced under any conditions except under pressures below 20 Torr. This is in good agreement with the conclusions described in the literature. However, even this stable compound could not be recognized in an ambient pressure below 20 Torr. This means that the two succesive reactions overlap very much and that the effect of the ambient pressure is large in the low-pressure range. The temperature range for the existence of this stable compound was around 220—260°C, which is in good agreement with the results reported by other workers.

It is of interest to note that a new intermediate was found at the third decomposition stage under 760 and 580 Torr and at the fourth decomposition stage under below 130 Torr. This stage exists between the stable compounds, $(NH_4)_2O \cdot 4MoO_3$, and the final product, MoO_3, and seems to be fairly stable. It may be seen from the DTG curves that the stable intermediate exists in the temperature range of 315—330°C under any conditions. From the weight loss data, the mole ratios, $(NH_4)_2O/MoO_3$ of this intermediate lie approximately in the range from 0.04 to 0.06. It converts into a final product, MoO_3, through another decomposition stage. According to Ma, the catalytic decomposition of ammonia to hydrogen and nitrogen by MoO_3 occurs at this stage. However, the reaction is not a catalytic decomposition but the oxidation of ammonia by Mo(VI) oxide, for no hydrogen was detected. The TGA data indicates that the weight loss percentage increases as the ambient pressure decreases. In the pressure below 70 Torr, the total weight loss was greater than the theoretical value. For example, under 10^{-3} Torr, the total weight loss percentage was 19.04%, this was 0.57% larger than the theoretical value, and the composition calculated from this value was approximately $MoO_{2.98}$ It seems to be reasonable to assume that the loss of oxygen was mainly due to the oxidation of ammonia. Moreover, the oxygen deficiency of MoO_3 was not observed upon decomposition under pressures above 130 Torr because of the reoxidation by the oxygen in the surrounding atmosphere. This conclusion will be confirmed by the analysis of the evolved gases in the succeeding paper.

From the above discussion, the following can be said to be the processes of the thermal decomposition in 760, 130, and 20 Torr:

760 Torr;

The color of the final product was a deep greenish gray.

$$3(NH_4)_2O \cdot 7MoO_3 \cdot 4H_2O \xrightarrow{90-130^\circ C} \underset{7.8-7.9\%(7.8\%)^{a)}}{5(NH_4)_2O \cdot 14MoO_3} \xrightarrow{175-210^\circ C} \underset{11.1\%(11.1\%)}{(NH_4)_2O \cdot 4MoO_3} \xrightarrow{285-315^\circ C} \underset{17.6\%(17.5\%)}{(NH_4)_2O \cdot 28MoO_3} \xrightarrow{360-395^\circ C} \underset{18.45\%(18.47\%)}{7MoO_3}$$

130 Torr;

The color of the final product was a grayish green.

$$3(NH_4)_2O \cdot 7MoO_3 \cdot 4H_2O \xrightarrow{65-105^\circ C} 3(NH_4)_2O \cdot 7MoO_3 \cdot H_2O \xrightarrow[4.3\%(4.4\%)]{105-145^\circ C} \underset{8.5-9.2\%(9.0\%)}{9(NH_4)_2O \cdot 28MoO_3} \xrightarrow{180-210^\circ C} \underset{11.0-11.1\%(11.1\%)}{(NH_4)_2O \cdot 4MoO_3} \xrightarrow{275-305^\circ C} \underset{16.6\%(16.5\%)}{(NH_4)_2O \cdot 15MoO_3} \xrightarrow{360-400^\circ C} \underset{18.56\%(18.47\%)}{7MoO_3}$$

a) The value of the observed weight-loss percentage, with the theoretical value in parentheses.

11) I. Lindqvist, *Ark. Kemi*, **2**, 325, 349 (1950).

20 Torr;
The color of the final product was a grayish green.

$$3(NH_4)_2O\cdot 7MoO_3\cdot 4H_2O \xrightarrow{50-85^\circ C}$$

$$3(NH_4)_2O\cdot 7MoO_3\cdot 2H_2O \xrightarrow{85-140^\circ C} 2(NH_4)_2O\cdot 7MoO_3$$
3.0—3.2%(2.9%) 9.7—10.4%(10.0%)

$$\xrightarrow{190-210^\circ C} 5(NH_4)_2O\cdot 28MoO_3 \xrightarrow{265-290^\circ C}$$
12.9—13.4%(13.2%)

$$(NH_4)_2O\cdot 15MoO_3 \xrightarrow{360-390^\circ C} 7MoO_3$$
17.3—17.5%(17.2%) 18.73%(18.47%)

The final product decomposed under 760 Torr was a light greenish gray. In the 10^{-3} Torr sample the color changed during decomposition; it was light green at 200°C, a light greenish gray at 250°C, and violet black at the final decomposition temperature.

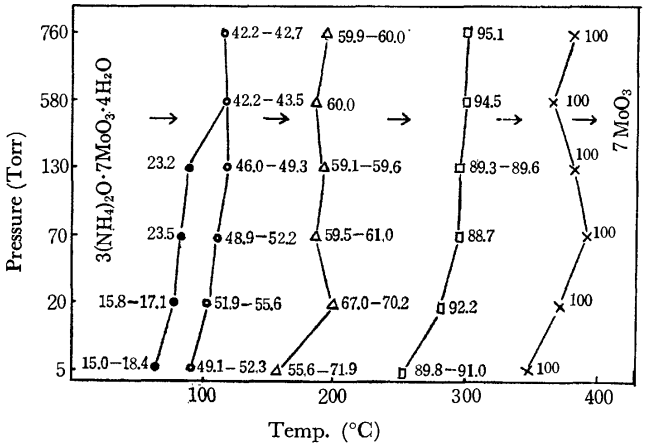

Fig. 8. Relationship between pressure and maximum decomposition temperature and percentage of decomposition.

Figure 8 shows the general relationship between the maximum temperatures of decomposition (corresponding to the peaks of the DTG curves) in various ambient pressures and the weight-loss percentage. The X-ray patterns of the final products (composition, MoO_3) obtained by decomposition are given in Table 1. They show a reasonable agreement with the X-ray patterns for MoO_3 reported in the literature,[12] but the present author could not enough investigate for the lower Mo(VI) oxides with the oxygen-deficient structure.

Reaction Kinetics. The advantages of studying the reaction kinetics from the data obtained under a rising sample temperature are that considerably less experimental data are required than in the isothermal method, and that the kinetics can be continuously probed over the entire temperature range. However, it is necessary to measure the temperature accurately and also to avoid any change in the heating rate by an *endo-* or *exo*-thermic reaction. The latter effect can be avoided fairly well by suing a small amount of the sample. The reaction kinetics using the TGA data has been investigated by a number of workers. Freeman and Carroll[13] obtained the following equation applicable to the sample under heating and examined its applicability:

$$\frac{-\Delta E^*/2.3R\Delta(1/T)}{\Delta \log W_r} = -x + \frac{\Delta \log dw/dt}{\Delta \log W_r}$$

E^*: energy of activation.
R: gas constant.
T: absolute temperature.
x: the order of reaction.
$W_r = W_c - W$
W: total weight loss up to the time t.
W_c: weight loss at the completion of the reaction.

By using a plot of $(\Delta\log dw/dt)/(\Delta\log W_r)$ *vs.* $(\Delta 1/T)/(\Delta\log W_r)$ for each reaction, the activation energy can be calculated. For the purpose of this plot, dw and W_r were determined directly from the TGA values. The straight lines in Figs. 9 and 10 show the decomposition reaction from the first to the fourth stage under 760 Torr. From the slopes of these lines, the activation energies of the decomposition of APM

in 760 Torr were found to be 38.6, 194.8, 81.9, and 151.2 kcal·mol^{-1} respectively from the first to the fourth stage. As has previously been described, there is a dehydration reaction stage in the decomposition process under the pressures below 130 Torr. By using the data obtained from the dehydration reaction, the activation energy was claculated for the dehydration process. Figure 11 shows the plot of $\Delta(1/T)/(\Delta \log W_r)$ *vs.* $(\Delta \log dw/dt)/(\Delta \log W_r)$ for the case of 70 Torr. The activation energy was found from its slope to be 17.3 kcal·mol^{-1}.

The author wishes to express his thanks to Professor Kumasaburo Kodera of Kyoto University for his valuable advice and continuous encouragement throughout this work. He is also grateful to Assistant Professor Norihiko Nakanishi of Kyoto University for his advice for X-ray analysis and to Mr. Isao Kusunoki of Kyoto University for his fruitful discussions and to Mr. Shinkichi Schimidzu for the measurement of TGA.

Thermal Decomposition of Ammonium Salts of Transition Metal Oxyacids. II. The Determination of the Gas Constituents Evolved by Ammonium Paramolybdate Decomposition

Il-Hyun PARK*

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received August 5, 1970)

Gases evolved by the decomposition of ammonium paramolybdate tetrahydrate have been analyzed by means of an omegatron mass spectrometer. Only water molecules of the hydration were eliminated during the first stage of decomposition, and the final stage was not the elimination reaction of ammonia but the oxidation reaction of ammonia by Mo(VI) oxide. Between 150 and 250°C, ammonia and water were evolved in a mole ratio of roughly 2:1, corresponding to the elimination of $(NH_4)_2O$. However, the range is not clear because of the overlap of the elimination of water at the lower limit and that of nitrogen at the upper limit. At higher temperatures, a small amount of NO was observed.

In a previous paper[1] it was described that ammonium paramolybdate tetrahydrate (APM) is decomposed in four stages under 760 Torr and in five stages under below 130 Torr; those results were based on thermogravimetric analyses.

Many published papers have discussed the gases evolved in each stage of decomposition simply on basis of the thermogravimetric analysis curves (TGA curves). It is said that in the first stage, ammonia and water are simultaneously removed as soon as four molecules of water are removed, and no separate stages have been observed in this process. The mole ratio of ammonia to water is 2:1; it corresponds to that of $(NH_4)_2O$. The second and the third decomposition stage are also considered to be the elimination of $(NH_4)_2O$ as ammonia and water.

Ma[2] carried out the analysis of evolved gases by means of an omegatron mass spectrometer and found that nitrogen began to come out around 250°C and reached a maximum around 320°C. He also found that hydrogen was evolved along with the nitrogen; he concluded that both were produced by the decomposition of ammonia on the surface of Mo(VI) oxide. He also measured the amount of evolved ammonia by chemical analysis and found a general agreement with the weight loss. He pointed out that any discrepancy is due to the formation of nitrogen from ammonia. In addition, he reported that water is evolved more than would be theoretically expected from the amount of ammonia. Therefore, it was considered worth while to study the gas evolution by thermal decomposition. Especially, the evolution of nitrogen observed by Ma and the dehydration stage described in the previous paper was confirmed by gas analysis. The present studies were carried out by means of an omegatron mass spectrometer.

Experimental

Apparatus and Procedure. Figure 1 shows a schematic diagram of the apparatus; it was constructed of molybdenum glass and was composed of a fused silica reaction tube coupled with a pressure-measuring device, an omegatron mass spectrometer, and two evacuating systems. The apparatus was bakable at 450°C, and its ultimate vacuum was 1×10^{-8} Torr. The main residual gas was carbon monoxide, accompanied by small amounts of carbon dioxide and water. Between the reaction tube and the omegatron, there was a copper seal metal valve and a capillary leak which reduced the pressure in the reaction tube to below 1×10^{-5} Torr for the operation of the omegatron. A McLeod gauge was used to measure the pressure of the noncondensable gases, while the total pressure of the omegatron system was measured by means of a Bayard-Alpert gauge. The evolving gases were analyzed by means of the omegatron mass spectrometer. The omegatron tube was of Mitsubishi Electric make, simple box type, and was placed in a magnetic field of 4500 gauss. The resonance ion current of the omegatron was measured by means of a Takeda TR-84H vibrating reed electrometer. The temperature of decomposition was measured by means of a chromel-alumel thermocouple.

Measurement of the Evolving Gases. The gases evolved in each decomposition stage were analyzed in the closed system and in the evacuating system. A powdered sample of Merck extra pure grade (50 mg) was placed in the decomposition cell, RC_1, in the case of the closed system. The measurement of the evolved gases was carried out from room temperature (20°C) to 500°C at intervals of 50°C. Usually, after about one hour the pressure of the evolved gases attained a stationary value. Then the gases were

Table 1. Pattern coefficients of various gases

Gases	Mass									
	12	14	15	16	17	18	19	28	32	44
NH_3		1.2	4.2	7.0	100					
H_2O				1.8	21	100	10			
N_2		10						100		
CO	4—5	0.3-0.4		4				100		
CO_2	2			7					0.3	100

introduced into the omegatron through the capillary leak and were analyzed. After the measurements, the remaining gases were evacuated through a metal valve, M_2. After the pressure of the reaction system has attained 1×10^{-5} Torr, the constituents of the residual gases were checked. Then, the temperature of the cell was raised to the next decomposition temperature and the gases evolved were analyzed. The same procedure was repeated up to 500°C.

The observed intensities of the different gas ions were compared in the following way. At pressures lower than 10^{-5} Torr, the relationship of the ion current to the pressure may be represented by the following equation:

$$S \cdot P = i_+/i_-$$

where S is the sensitivity and can be treated much as the sensitivity in the ionization gauge, i_+, the ionic current produced by the electron current, i_-, and P, the pressure. The values of the sensitivity ratio for the ionization gauge for various gases determined by Wagener and Johnson[3] were used in estimating the relative amounts of N_2, H_2O, and CO_2. For the other gases, the relative sensitivities were estimated on the assumption that the sensitivity of the ionization gauge, S, and N_e, the total number of electrons per gas molecule, have a linear relationship.[4] Therefore, for the most important gases, NH_3 and H_2O, the sensitivities are nearly equal. The difference in the conductance of the gas should be considered in exact measurements, but as it is proportional to the square root of the molecular weight and as the main gases measured were ammonia and water, the correction is omitted here.

For the identification of the spectrum, the pattern coefficients of the relevant gases were determined to be as is shown in Table 1. They are in good agreement with Klopfer's[5] results. Hydrocarbons from the greased stop cock which connects the reaction system to the McLeod gauge might cause some trouble in the measurement; for instance, they might react with the sample. Therefore, to confirm whether or not there was any effect, another experiment was carried out by using an evacuating system free from grease vapor. This was carried out below 10^{-6} Torr under continuous evacuation. For this purpose, the sample cell, RC_2, near the omegatron was used. This procedure was carried out in order especially to investigate the gas constituents above 250°C.

Dehydration Process. The measurements were carried out in a closed system under an ambient pressure of 10^{-1} Torr in order to check the elimination of the hydrated molecules prior to the evolution of ammonia, under a low temperature as far as was possible. The evolved gases were measured at intervals of 10°C from room temperature to 100°C.

Oxidation of Ammonia by Molybdenum Oxide. Molybdenum oxides, obtained by the thermal decomposition of APM heated up to 450°C under 760 Torr and under 10^{-3} Torr, were used. The oxide sample was placed in RC_1 and was heated under 10^{-1} Torr ammonia. The gases produced by the reaction for 1 hr were investigated by means of the omegatron at intervals of 50°C from 300 to 500°C. Of course, the evolution of ammonia or nitrogen from the sample itself has previously been examined, but no ammonia or nitrogen was detected.

Results and Discussion

The relative amounts of the gases evolved by thermal decomposition in a closed system are shown in Fig. 2 as a function of the temperature. The mass spectra before and after the production of nitrogen, namely, at 250, 300, and 350°C, are shown in Fig. 3. Gas analysis was carried out at the temperature near the maximum of dw/dt on the DTG curve given in the previous paper. As was reported in that paper, it was assumed, from the results of TGA, that there was a dehydration process under pressures lower than 130 Torr, but its existence should be confirmed by gas analysis. Only Funaki[6] has pointed out the existence of the dehydration process of four molecules of water at 110°C. On the other hand, from the titration of

evolved ammonia, Ma presumed the existence of a dehydration process just before the removal of $(NH_4)_2O$ within the first stage of the decomposition under 760 Torr. In his thermogram, however, the separation of the two processes is not seen. Also, by the present experiment, the separate dehydration process was not observed in the first decomposition process under 760 Torr. Figure 4 shows the limit of dehydration, *i.e.*, the beginning of ammonia evolution in an ambient pressure of 10^{-1} Torr. Under 10^{-1} Torr and below 70°C the peak of $m/e=17$ is considered to be almost entirely the fragment ion of H_2O, and the amount of ammonia is very small. However, at 80°C about one third of the peak may be attributed to ammonia. Therefore, the evolution of ammonia, *i.e.*, the removal of $(NH_4)_2O$, began at about 80°C; below this temperature only water of hydration was released. Thus, the existence of the dehydration stage under 10^{-1} Torr was confirmed. In Table 2, the temperatures at which ammonia began to be released in different ambient pressures are shown. From Table 2, it is clear that the temperature of ammonia production shifts to higher temperatures as the ambient pressure increases and that a part of the water molecules of hydration are removed at the beginning of decomposition, but the removal of the residual water overlaps with that of ammonia. The higher the pressure, the greater is the overlapping of the two procedures. Ammonia exists in the crystal as ammonium ions, and it is released with the water in the composition of $(NH_4)_2O$. Generally, it has been considered that the final product, MoO_3, is produced by the removal of only NH_3 and H_2O, although the analysis of the evolved gas has not been done. Ma analyzed the evolved gases for the first time and found out that, in the stage of the removal of $(NH_4)_2O$, the ratio of NH_3 and H_2O was not 2: 1. However, in the present study, it may be seen in Fig. 2 that the ratio of 2: 1 continued from 150 to 250°C; it is considered that this corresponds to the elimination of $(NH_4)_2O$. It was found by the thermogravimetric analysis that the intermediate obtained by the decomposition at this stage has the composition of $(NH_4)_2O\cdot4MoO_3$; it is an extremely stable compound. The TGA curve shows that this stable compound decomposes above 250°C. According to Figs. 2 and 3, the evolution of ammonia decreased suddenly at 300°C; simultaneously, the peak of $m/e=28$ appeared. This is clearly the peak of nitrogen. It may be seen from Table 3 that the pressure at 300°C measured by the McLeod gauge without a cold trap was below 1/10 of that at 250°C. The value of the total pressure is not very reliable because of the pressure of the condensable water vapor; nevertheless, it is true that the amounts of gases evolved are very small at this temperature.

The total pressure of gas evolved at 350°C again increased to twice that at 300°C and reached a maximum. Hydrogen was not observed at all; the main products at this stage were water and nitrogen, which

was the oxidation product of ammonia with Mo(VI) oxide. However, the amount of water is considerably less than that which should be produced by the oxidation of ammonia. This discrepancy may be explained by the loss of water by adsorption on the inside wall of the glass apparatus, because the total amount of gas evolved was rather small.

The gases evolved at 400°C were mainly nitrogen and carbon dioxide of $m/e=44$, and no ammonia was observed. As the total pressure was very low at this temperature, the amounts of nitrogen and water were very small. Therefore, the thermal decomposition of APM was completed here. The carbon dioxide might be produced by the oxidation of the impurity carbon contained in the sample, or part of it might come from the grease vapor. As for the production of carbon dioxide, Onchi and Kusunoki[7] have reported that, by the thermal decomposition of MoO_3 *in vacuo*, the main gaseous product about 400°C was carbon dioxide, the production of oxygen-deficient oxide is attributable to the reduction by the impurity. The main gases observed at 450 and 500°C were carbon dioxide and carbon monoxide, plus a small amount of NO, $m/e=30$. Nitric oxide might be produced by the further oxidation of ammonia. Oxygen with $m/e=32$ has not observed throughout the decomposition up to 500°C.

····· MoO_3 prepared in air
●: N_2, ○: H_2O, △: NH_3

The experiment in the evacuating system confirmed that the evolution of ammonia, water, and nitrogen was similar to that in the closed system except that the temperature of nitrogen production was shifted to a slightly higher temperature. This fact suggests that the oxidation of ammonia takes place at the moment of its production, or that the collisions with the surface need not be repeated many times, though the produced NH_3 comes in contact with the oxide surface. The results of the oxidation of ammonia by the MoO_3 produced by the thermal decomposition of APM in air or *in vacuo* show that nitrogen was formed about 300°C and that the amount reached its maximum at 350—400°C for both samples (Fig. 5). The tendency of the reaction is similar to the case of APM but the temperature seems to be shifted to a higher value. However, no detailed discussion can be made because of the lack of reproducibility of the data. It was found that the evolution of H_2O came later than the production of N_2. The reason for this may be as follows: when NH_3 was oxidized on the surface of MoO_3, the O-H bond was perhaps produced in a crystal by binding the H of NH_3 and the O of MoO_3, and later, as the temperature rose, this O-H was perhaps eliminated by way of the formation of H_2O. Further examinations are needed to confirm this conclusion on the basis of the reproducibility of the experimental results. Nevertheless, it was proved that the ammonia produced in a crystal is actively oxidized to nitrogen on the surface of MoO_3 or on the interface of the crystal.

The author wishes to express his thanks to Professor Kumasaburo Kodera of Kyoto University for his valuable advice and continuous encouragement throughout the course of this work. He also wishes to thank Assistant Professor Masaru Onchi and Mr. Isao Kusunoki of Kyoto University for their continuing interest and helpful advice.

Thermal Decomposition of Ammonium Salts of Transition Metal Oxyacids. III.[1] Thermogravimetric Analysis of Ammonium Chromate

Il-Hyun PARK*

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received February 1, 1971)

Thermal decomposition of ammonium chromate (AC) and ammonium dichromate (ADC) has been studied by means of TG, DTA, and DTG. It showed four steps in thermal decomposition of AC and three steps in that of ADC. Decomposition product in each step of the thermal decomposition was examined by X-ray diffraction method. From the results of both thermogravimetric analysis and X-ray study, it was concluded that the first decomposition product of AC was ADC, the second was CrO_3 and the final product was Cr_2O_3. The third product gave the X-ray patterns of the mixture of Cr_2O_3 and CrO_3, and the mole ratio of O/Cr in the temperature range for the existence of the product (300—390°C) was 2.1—2.0. The kinetics in the second decomposition step for AC and in the first decomposition step for ADC were studied, giving the values of the energy of activation of 24.2 and 22.4 kcal/mol, respectively.

In a preceding paper of this series,[2] it was reported that molybdenum(VI) oxide formed by thermal decomposition of ammonium paramolybdate oxidized ammonia evolved during the thermal decomposition. It is known that ammonia is oxidized more readily by oxyacids of chromium(VI) than those of molybdenum(VI).

Ammonium chromate decomposes slowly to form ammonium dichromate even at room temperature.[3] It is believed that the thermal decomposition of ammonium dichromate can be described by the following simple reaction:[4]

$$(NH_4)_2Cr_2O_7 \xrightarrow{\Delta} Cr_2O_3 + N_2 + 4H_2O$$

As the results of studies on isothermal decomposition of ADC, however, several authors noticed that ammonia and oxides of nitrogen were present in appreciable quantities amongst the decomposition products.[5-10] They examined the compositions of evolved gases and final solid products. Unfortunately, their results as to the composition of the final solid product were not in complete agreement with each other. All of them except Harbard investigated isothermal decomposition reactions, and Harbard carried out the decomposition experiment by heating ADC in a closed tube, the gas evolved being collected in a gas burette. Kinetics and mechanism of isothermal decomposition of ADC were studied by Taylor *et al.*[10,11] without using thermogravimetric analysis.

The present study has been undertaken to make clear the entire processes of thermal decomposition of AC and ADC by means of thermogravimetric analysis, to determine the composition and structure of each decomposition intermediate and the temperature range for the existence of each decomposition product, and to examine kinetics of the decomposition reactions.

Experimental

Thermogravimetric Analysis (TG). TG was carried out by using the quartz spring balance described in the preceding paper of this series.[2] AC and ADC (extra pure reagents of Nakarai Chemical Co.) were powdered to the size of 170—200 mesh prior to each measurement. A sample of 10 mg was heated at a rate of 2°C/min. The ambient pressure of the decomposition was 760 Torr.

Differential Thermal Analysis (DTA), Thermogravimetric Analysis (TG), and Derivative Thermogravimetry (DTG). By using the automatic recording thermobalance of Cho Balance Co., DTA, TG, and DTG were carried out simultaneously. A sample of 20 mg was heated at a rate of 3.7°C/min in the ambient pressure of 760 Torr, and α-Al_2O_3 was taken as a reference material for DTA.

Decomposition Rate Measurements. The experimental apparatus for decomposition rate measurements was similar to that used for TG under vacuum.[2] The kinetics of decomposition of AC and ADC were followed by use of the quartz spring balance. A sample of 20 mg was used for the determination of decomposition rates. The decomposition product in the first step of the thermal decomposition of AC was obtained by heating AC up to 120°C and annealing it for several hours under 760 Torr.

X-Ray Analysis. X-Ray patterns of the intermediates in each step of the decomposition reactions were obtained with an automatic recording diffractometer of Shimadzu Seisakusho, Ltd. using CuK_α radiation. Each decomposition intermediate for X-ray analysis was prepared by annealing the corresponding product at the respective temperatures for several hours.

Results

Thermogravimetric Analysis. The results for thermal decompositions of AC and ADC obtained under 760

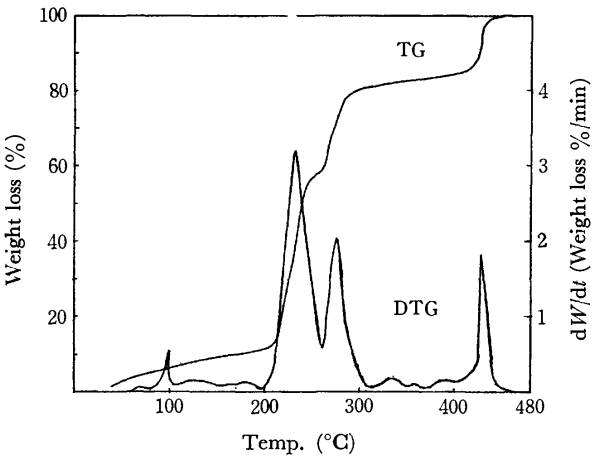

Fig. 2. Thermogravimetric and derivative thermogravimetric curves of ADC (in 1 atm.).

Torr are shown in Figs. 1 and 2, respectively. From these results it is seen that the decomposition of AC proceeds in four steps and that of ADC in three steps. The first step of the decomposition of AC produces an orange-colored ADC, and three succeeding steps of decomposition of AC are similar to the three steps of decomposition of ADC itself.

Differential Thermal Analysis, Thermogravimetric Analysis, and Derivative Thermogravimetry. The results of studies on thermal decomposition of AC and ADC obtained by simultaneous measurement of DTA, DTG, and TG are shown in Figs. 3 and 4. The TG and DTG curves obtained by this method are in good agreement with those obtained by the spring balance method (Figs. 1 and 2). It is seen that the first step of the decomposition of AC is endothermic, whereas the other three steps of the decomposition are exothermic. In this case again the decomposition after the first step of AC is similar to that of ADC itself.

Rate of Decomposition of AC and ADC. About 10—20 min were required for the reaction vessel and reactants to reach a desired constant temperature. The decomposition rates of AC in the second step and those of ADC in the first step were measured at constant temperatures from 180 to 200°C. The rate

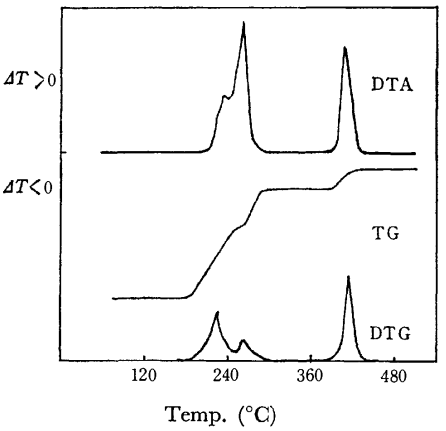

Fig. 4. DTA, TG, and DTG curves of ADC.

determination was followed until the plots of fraction decomposed (α) *vs.* time (t) reached to the end of sigmoid part.

X-Ray Analysis. A sample of AC was heated up to 120°C and annealed for several hours and its X-ray pattern was examined. Another sample of AC was heated up to 240°C and annealed for several hours and its X-ray pattern was examined. The first column-(a) and the third column(c) in Table 1 show the diffraction data of the intermediates prepared by heating AC at 120 and 240°C, respectively. These results are indicated to be almost in agreement with literature values, which are shown in the second (b) and fouth columns(d),[12] respectively. A sample of AC was heated up to 360°C and annealed for several hours, and its X-ray pattern was examined. The results are in the fifth column(e) in Table 1, which represents a pattern entirely different from that of CrO_2,[13] but indicates the presence of both CrO_3 and Cr_2O_3. A sample of AC was heated up to still higher temperature and annealed for several hours to form the final decomposition product, and its X-ray pattern was checked. The final product gave the diffraction data as shown in the sixth column(f), agreeing with those in the literature.[12]

Discussion

Thermal Analysis. The composition of each intermediate of the thermal decomposition was determined, and the temperature range where each intermediate existed was deduced from the TG and DTG curves. The decomposition processes are summarized as follows:

Ammonium chromate:

$$(NH_4)_2CrO_4 \xrightarrow{80\text{—}120^\circ C} (NH_4)_2Cr_2O_7\text{(orange)}\ 17.6\%(17.4\%)^{14)}$$

$$\xrightarrow{200\text{—}230^\circ C} CrO_3\text{(brown)}\ 34.7\%(34.2\%) \xrightarrow{260\text{—}275^\circ C} CrO_2\text{(black)}\ 44.5\%(44.6\%)$$

$$\xrightarrow{400\text{—}435^\circ C} Cr_2O_3\text{(dark green)}\ 49.1\%(50.0\%)$$

Ammonium dichromate:

$$(NH_4)_2Cr_2O_7 \xrightarrow{205\text{—}245^\circ C} CrO_3\text{(brown)}\ 22.0\%(20.6\%) \xrightarrow{260\text{—}285^\circ C}$$

$$CrO_2\text{(black)}\ 32.4\%(33.3\%) \xrightarrow{410\text{—}435^\circ C} Cr_2O_3\text{(dark green)}\ 38.5\%(39.7\%)$$

14) The values are weight loss percentages observed, the theoretical values being included in parentheses.

The values of weight loss percentage observed are consistent with the theoretical values within 1%. DTG curve shows a small weight decrease in ADC prior to the first decomposition step, as shown in Fig. 2. This is considered to be due to the removal of adsorbed water from the crystal surface. The percentage of the weight decrease amounts to about 3.5%.

According to the DTA curve of AC, the endothermic peak appears at $T_{max}=110^\circ C$ and the three exothermic peaks appear at $T_{max}=210$, 255, and 410°C, respectively. These temperatures are in good agreement with the temperatures at $dw/dt=$max. the on DTG curve determined by spring balance measurement.

It was confirmed by thermal analysis that AC decomposes in four steps, and the results of X-ray analysis for the intermediate of each step support the production of the above mentioned compounds. Namely, the first decomposition product from AC at about 120°C is ADC and the second decomposition product formed by heating AC up to 240°C is CrO_3. The product yielded by heating AC up to 360°C corresponds to one having formula of CrO_2 according to the result of weight loss determined by TG, and to the mixture of CrO_3 and Cr_2O_3 according to the X-ray analysis

(Table 1). Thus, the 3.38 Å line might be attributed to CrO_3 and the other strong lines (3.65, 2.67, 2.47, and 1.67 Å) are attributed to Cr_2O_3.

It can be said that an oxide which has the composition of Cr_5O_9 is formed in decomposition of CrO_3 to Cr_2O_3 and this oxide is generally regarded as a double compound of chromium(III) and chromium(VI) oxides, or chromium(III) chromate: $Cr_5O_9=2Cr_2O_3\cdot CrO_3$. The existence of Cr_5O_9 is, however, doubtful. King could not made Cr_5O_9, at least, in the thermal degradation of CrO_3, but he found two non-Daltonide compounds as the intermediates, one of which had 2.6—2.2 and the other 1.9—1.7 atoms of O per atom of Cr.[15] $2Cr_2O_3\cdot CrO_3$ is brown and paramagnetic, CrO_2 is black and both are insoluble in water.[3] On the other hand Taylor[16] has mentioned that CrO_3 melts at 193°C and forms brown chromic chromate ((CrO_2)-$CrO_4=Cr_3O_6$) and liberates oxygen at 250°C,

$$6CrO_3 = 2Cr_3O_6 + 3O_2$$

and on further heating yields chromium sesquioxide.

$$4CrO_3 = 2Cr_2O_3 + 3O_2$$

In the present work, the product obtained when AC was heated up to 360°C showed the composition of CrO_2 and had black color. However, it might be considered that during annealing at 360°C for several hours, some amounts of oxygen was lost by decomposition, a part of which oxidized residual nitrogen compounds or carbon impurity contained in sample, giving lower oxide, Cr_5O_9. Although it has been reported that there are oxides having the various compositions, *e.g.*, Cr_3O_8, Cr_2O_5 *etc.*,[17] none of these have been actually found in this work. The value of the ratio of O/Cr is calculated to be 2.1—2.0 at the temperature range of 300—390°C.

Reaction Kinetics. In order to examine the result of thermal analysis, the decomposition rate of the first step degradation product of AC was compared with that of ADC. Namely, the reaction rates of CrO_3 formation from these samples were measured in isothermal decomposition. The α *vs.* t curves were sigmoid in shape and were analyzed by use of the modified Prout-Tompkins equation:[18]

$$-\ln(1-\alpha) = kt$$

where α is the fraction decomposed in time t and k is the rate constant. The plots of $-\ln(1-\alpha)$ *vs.* t at various temperatures for the decomposition product in the first step of the thermal decomposition of AC and for ADC are shown in Figs. 5 and 6. The results clearly indicate that both reactions follow the unimolecular decay law. Arrhenius plots for the two reactions

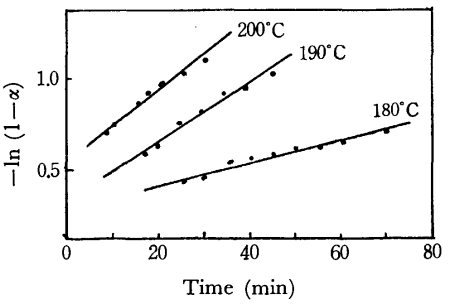

Fig. 5. The plot of $-\ln(1-\alpha)$ *vs.* t for ADC prepared by heating AC up to 120°C.

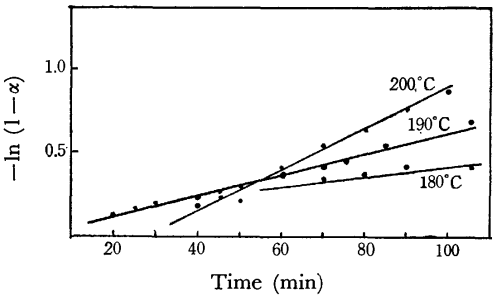

Fig. 6. The plot of $-\ln(1-\alpha)$ *vs.* t for ADC.

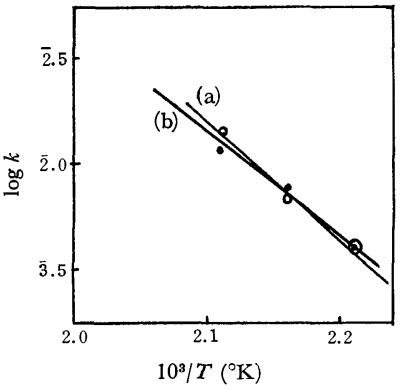

Fig. 7. Arrhenius plots of the rate constants.
(a) in 2nd decomposition step of AC
(b) in 1st decomposition step of ADC

are shown in Fig. 7. From the slopes of these lines, the activation energies of the two reactions are found to be 24.2 and 22.4 kcal/mol, respectively. From these results it may be said that the second step of AC decomposition corresponds to the first step of ADC decomposition, which is in agreement with the conclusion of X-ray analysis.

The author wishes to express his sincere thanks to Professor Kumasaburo Kodera of Kyoto University for his valuable advice and continuous encouragement throughout this work. Thanks are also to be expressed to Assistant Professor Norihiko Nakanishi of Kyoto University for his advice for X-ray analysis and to Assistant Professor Saburo Kako of Kyoto Univeristy for his valuable cooperation for DTA measurement.

Thermal Decompsition of Ammonium Salts of Transition Metal Oxyacids. IV.[1] Determination of Constituents of Gases Evolved in Decomposition of Ammonium Chromate

Il-Hyun PARK*

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received February 1, 1971)

Constituents of gases evolved in thermal decomposition of ammonium chromate and ammonium dichromate have been studied by an omegatron mass spectrometer. From the data of gas analysis, the following conclusions have been obtained. The decomposition of the first step started with proton transfer mechanism and the ratio of NH_3 to H_2O was not 2: 1 at the beginning. The second step corresponded to the formation of N_2, N_2O, and H_2O through oxidation of NH_3 by the chromate anion. The decomposition in the third step was accompanied by the evolution of oxygen molecules. The production of CrO_3 was confirmed by comparing the dissociation pressure of CrO_3 produced in AC decomposition with that of pure CrO_3. The decomposition in the last step corresponded to the process from CrO_2 to Cr_2O_3, with the evolution of O_2, CO_2, and CO.

In the preceding work,[1] the thermograms of ammonium chromate (AC) and ammonium dichromate (ADC) were obtained, and the composition and structure of each intermediate were determined from the results of weight decrease data and X-ray analysis.

The evolved gases in the decomposition of AC have not yet been analyzed but only the gases evolved in ADC decomposition near 200°C have been studied by some investigators. For instance, Simpson *et al.*[2] have reported that N_2, N_2O, and H_2O were the main products in the range of temperature from 180 to 215°C. However, the gas constituents reported by other workers differed from those mentioned above. In this study the evolved gases in the thermal decomposition of AC and ADC by heating them from room temperature up to 500°C were analysed by an omegatron mass spectrometer, in the hope of better interpretation of the thermogram and better understanding of the mechanism of decomposition in each step.

Experimental

Apparatus and procedure for gas analysis were similar to those used in the previous work,[3] except the use of dry ice to remove the hydrocarbon vapor from the stopcock grease. The total pressure was measured by a Pirani gauge. Extra pure reagents of AC and ADC from Nakarai Chemical Co. were used without further purification. Samples used were both powder and crystal grain. The gas analysis was carried out in closed and in evacuating systems up to 500°C, with the intervals of 50°C. The gaseous products were identified by the omegatron, comparing the mass spectrum observed with the standard pattern obtained from pure gases. In addition to the patterns for N_2, H_2O, CO, and CO_2 described in the previous paper,[3] the pattern coefficients for N_2O and O_2 are shown in Table 1.

Table 1. Pattern coefficients of oxygen and nitrous oxide

Gas	Mass No.						
	14	15	16	28	30	32	44
O_2			10—15			100	
N_2O	6	2—3	3	30—45	25—30		100

The decomposition pressure of CrO_3 was measured by similar method to that of Kodera *et al.*[4] Samples of CrO_3 used were either CrO_3 sample prepared in the laboratory or commercially available CrO_3 (extra pure reagent of Nakarai Chemical Co.). The former was prepared by heating AC up to 240°C and keeping it for 20 hr at this temperature during annealing. Color of the product was dark brown. The temperature range of measurement was from 225 to 400°C, and the decomposition of CrO_3 to CrO_2 proceeded at this temperature range.

Results

The Gases Evolved in the Closed System and in Evacuating System. The decomposed gases from AC at room temperature were studied in a closed system. The gases were collected for one hour and used for mass spectrum determination. After the measurement, the system was evacuated again and the same procedure was repeated at the interval of one hour. Percentages of NH_3 and H_2O were determined, as shown in Table 2. Similarly the constituents of decomposed gases from

ADC at 200°C were studied in the closed system at the interval of 30 min. The percentages of NH_3, oxidation products of NH_3 and H_2O, were determined, as shown in Table 3. Percent molar fractions of the evolved gases in the decomposition of AC and ADC at various temperatures are plotted in Figs. 1 and 2,

the laboratory. Constituents of gas evolved were CO_2 with trace of nitrogen compounds. The mass spectrum of gas evolved at 300°C is shown in Fig. 4(a). The peak for $m/e=44$ is mainly due to CO_2^+ (95%) rather than N_2O^+ (5%). The peak for $m/e=28$ is assumed to be due to CO^+ or N_2^+, but from the pattern coefficient[3] it was decided that the peak is due to CO^+.

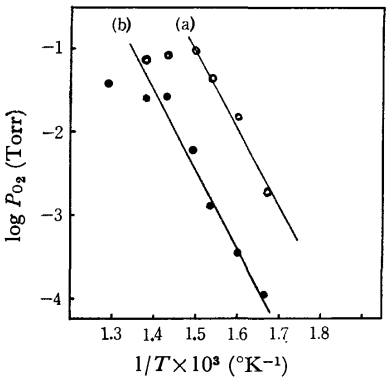

Fig. 5. Dissociation pressure of the prepared CrO_3 (a) and standard CrO_3 (b).

Oxygen is seen at $m/e=32$. The fact that CO_2 is formed is in agreement with the results of Kodera *et al.*[4] on the thermal decomposition of metal oxides *in vacuo*. Below 300°C, oxygen molecules produced might be consumed for the oxidation of nitrogen compounds or carbon impurities. The mass spectrum of gas evolved at 375°C is shown in Fig. 4(b). Main product is O_2 with some amounts of CO and a small amount of CO_2.

For comparison, similar experiments were carried out with the pure CrO_3[5] sample above 325°C. The results are shown in Table 4. The dissociation pressures of the prepared CrO_3 and pure CrO_3 were plotted against $1/T$ in Fig. 5.

Discussion

First Decomposition Step. From the results of thermogravimetric analysis,[1] it was supposed that AC was decomposed to ADC at the first step, two molecules of NH_3 and one molecule of H_2O being eliminated at this step. However, according to the gas analysis by omegatron, as seen in Fig. 1 and Table 2, the theoretical ratio 2: 1 ($=NH_3$: H_2O) in the gaseous phase does not appear until it is heated up to about 90°C, but this ratio is much larger than 2: 1 below 90°C. Namely, the evolution of NH_3 and H_2O does not take place in the form of $(NH_4)_2O$ as in the case of the decomposition of ammonium paramolybdate described in the previous paper,[3] where the ratio of NH_3 to H_2O was always 2: 1. Accordingly, it is considered that the elimination mechanisms of NH_3 and H_2O in the decomposition of ammonium chromate and ammonium paramolybdate differ with each other. Table 2 suggests that NH_3 is eliminated rapidly in the beginning whereas the amount of H_2O evolving gradually increases as the reaction proceeds. In other words, NH_3 is eliminated before H_2O is formed from the crystal in this step, and the following decomposition does not proceed: $2(NH_4)_2CrO_4 \longrightarrow (NH_4)_2Cr_2O_7+2NH_3+H_2O$.

5) This sample was sublimated at 200°C *in vacuo* and was condensed as dark red crystals at the upper part of the reaction cell, while CO_2 gas evolved. The dissociation pressure of CrO_3 at 650°C was 1.3×10^{-3} Torr and green Cr_2O_3 was condensed at the upper part of the reaction cell while the pressure decreases rapidly.

As described by Davies *et al.*[6] on the thermal decomposition of ammonium perchlorate, it is considered that only NH_3 is eliminated at the first step from the crystal by proton transfer mechanism. Thus, the mechanism may be expressed by

$$2(NH_4^+\text{-}CrO_4^{2-}) \rightleftharpoons 2(NH_3\text{-}H\text{-}CrO_4^-) \rightleftharpoons 2(NH_3\text{-}HCrO_4^-)$$
$$\quad\;\; | \qquad\qquad\quad | \qquad\qquad\quad |$$
$$\quad NH_4^+ \qquad\quad NH_4^+ \qquad\quad NH_4^+$$
$$\quad (I) \qquad\qquad (II) \qquad\qquad \Downarrow$$
$$2NH_3(g) \longleftarrow 2NH_3(a)+2NH_4^+HCrO_4^-$$
$$\qquad\qquad\qquad\qquad\qquad\quad \downarrow$$
$$H_2O(g) \longleftarrow H_2O(a)+(NH_4)_2Cr_2O_7$$
$$\qquad\qquad\qquad\qquad\qquad\quad \downarrow$$
$$(NH_4)_2Cr_2O_7,$$

where (a) and (g) indicate adsorbed and gaseous states, respectively.

The reaction begins with the transfer of a proton from NH_4^+ to CrO_4^-. After the proton transfer process is accomplished through a transition state (II), coulombic interaction between NH_3 and $H\text{-}CrO_4^-$ (NH^+) is lost, and NH_3 becomes free to migrate over the surface of the crystal as a mobile adsorbed phase. Then, NH_3(a) will be desorbed, followed by the desorption of H_2O(a). The total pressure showed 7 Torr at 70°C. Therefore the decomposition reaction of the first step takes place at this temperature, where the ratio of NH_3 to H_2O is approximately 2: 1.

Second Decomposition Step. It is seen from Fig. 1 that N_2 and N_2O begin to be evolved at 100°C and the fraction of NH_3 decreases rapidly with increasing temperature. Although the amount of H_2O is large at this temperature, it is less than that produced from oxidation of NH_3 into N_2 and N_2O. It is concluded from the total pressure measurements that the second decomposition step for AC begins at about 150°C. The total pressure increases greatly above this temperature, and amounts to 2.2 Torr at 200°C. At this temperature the evolved gases consist of about 52% N_2O, 21% N_2, 26% H_2O, and NH_3 of less than 1%. Nitrogen content decreases to about 3% at 250°C, while CO_2 begins to be evolved at this temperature. Amounts of CO_2 and N_2O were determined by comparing their pattern coefficients with the corresponding standard ones (Ref. 4 and Table 1). The production of CO_2 is considered to be due to the oxidation of carbon or carbon compounds as impurity in the sample.

The second step in AC decomposition corresponds to the first step for ADC. Many studies have been reported on the ADC decomposition at the temperature range of 180 to 230°C, but these results are not in agreement with each other. Simpson *et al.*[2] have reported that N_2, N_2O, and H_2O were evolved throughout the reaction but free ammonia (10%) was produced at the autocatalytic stage. In the present work, the evolution of NH_3 in the ADC decomposition at 200°C is observed in the beginning but the amount is very

6) J. V. Davies, P. W. M. Jacobs, and A. Russell-Jones, *Trans. Faraday Soc.*, **63**, 1737 (1967).

small as is shown in Table 3. The reason of the discrepancy may be explained by the difference of experimental condition: that is, Simpson used a single crystal as a starting material after evacuation at room temperature and temperature was raised rapidly to 195.5°C, while, in the present work, powdered sample was used and heating rate was rather slower than that adopted by Simpson. The evolution of NH_3 is small, as is shown in Fig. 2. Namely, most of NH_4^+ ions are oxidized from the beginning.

It was concluded from the thermal analysis that CrO_3 are produced by the decomposition of ADC. CrO_3 is a strong oxidizing agent and it is said that hydrogen itself, ammonia and hydrogen sulfide are oxidized by CrO_3.[7] Therefore, NH_3 produced in the crystal will be easily oxidized to form N_2 and N_2O, and consequently Cr(VI) is reduced to lower oxidation state. It is seen that nearly equal amounts of N_2 and N_2O are obtained in evacuating system when the powdered sample is used, as shown in Fig. 3(a), but the amount of N_2 exceeds slightly that of N_2O, when the crystal grain is used, as shown in Fig. 3(b), although the amounts of NH_3 in both cases are quite small as in the case of the closed system. This might be explained by the fact that most of NH_4^+ ions are oxidized as soon as the decomposition proceeds, and the amount of NH_3 which is oxidized after evolution is small. The formation of H_2O continues throughout the decomposition. This is in agreement with Simpson's results. It is expected that Cr(VI) ought to be reduced partly at this step because of the vigorous oxidation of NH_3. However, from the results of X-ray analysis[1] and the measurement of dissociation pressure of CrO_3, it is supported that the product formed in this decomposition step is mainly CrO_3.

Third Decomposition Step. The third step of the decomposition involves the formation of O_2 from the relatively unstable CrO_3. At the temperature near 250°C N_2O and H_2O are the main products and CO_2 is also found. Origin of N_2O and H_2O may be NH_3, NH_2, or N_2 remained in the crystal. The peak of oxygen does not appear at 300°C but appears at 350°C and the amount of CO_2 approaches to 64%. Accordingly the weight decrease at this decomposition step are related to the elimination of O_2, CO_2, H_2O, and N_2O. The evolution of oxygen begins after the production of CO_2 and N_2O are finished, as shown in Figs. 4(a) and 4(b). It seems that oxygen molecules produced by decomposition is consumed for the oxidation of nitrogen compounds and carbon impurities.

Fourth Decomposition Step. The constituents of gases evolved at 400°C are mainly O_2, CO_2, CO, H_2O, and the trace of N_2O. The decomposition takes place between 400 and 450°C as observed in the thermal analysis and the total pressure measurement. The gases evolved at 450°C are mainly O_2, CO, and CO_2 but N_2O is hardly seen. A small amount of NO was observed in this temperature range only when the decomposition was carried out in evacuating system.

Gases Evolved in ADC Decomposition. According to Fig. 2, it is seen that the total pressure at 100°C is very low and the amount of NH_3 is smaller than those of N_2 and N_2O. The first decomposition shows the maximum at about 200°C and the evolved gases are N_2 and N_2O. The formation of O_2 is observed at 400°C.

The author wishes to express his sincere thanks to Professor Kumasaburo Kodera of Kyoto University for his valuable advice and continuous encouragement throughout this work. He is also grateful to Assistant Professor Masaru Onchi of Kyoto University and Mr. Isao Kusunoki of Kyoto University for their helpful advice and discussion for omegatron measurement and to Mr. Tadasi Ito for the measurement by the omegatron.

Kinetics of Multidentate Ligand Substitution Reactions. XIII. Substitution Reactions of 1-(Hydroxy-4-methyl-2-phenylazo)-2-naphthol-4-sulfonic Acid (Calmagite) with Nickel(II)-Glutamate, -Aspartate, -Iminodiacetate, -Nitrilotriacetate and -Diethylenetriamine Complexes and That with the Cobalt(II)-Nitrilotriacetate Complex

Mutsuo KODAMA, Takami SATO, and Sadatsugu KARASAWA
Department of Chemistry, Ibaraki University, Bunkyo, Mito, Ibaraki
(Received January 27, 1972)

The substitution reactions of calmagite with nickel(II)-glutamate, -aspartate, -iminodiacetate, -nitrilotriacetate, and -diethylenetriamine complexes, and that with the cobalt(II)-nitrilotriacetate complex, were studied by employing the stopped-flow technique. In the calmagite reactions with the nickel(II)-glutamate, -aspartate, and -iminodiacetate complexes, the reaction products were found to be mixed-ligand complexes involving calmagite and glutamate, aspartate, or iminodiacetate anions. In these reactions, the 1:2 ratio complex dissociates rapidly into the 1:1 ratio complex first; then, the 1:1 ratio complex reacts slowly with the calmagite anion to form a mixed-ligand complex. From a comparison of the observed rate constant with that estimated on the basis of the proposed reaction intermediate, it was concluded that the latter step proceeds through the outer-sphere complex between the calmagite anion and a 1:1 ratio complex, and that the water-loss from the 1:1 ratio complex is the slowest step. In the cases of the reactions of calmagite with nickel(II)-nitrilotraicetate and -diethylenetriamine complexes, and that with the cobalt(II)-nitrilotriacetate complex, all the reaction invariably gave a metal(II)-calmagite complex with a 1:1 composition, MD^-. These reactions were found to proceed through the completely-deprotonated and divalent calmagite anions.

We have studied a series of substitution reactions of two *o,o'*-dihydroxyazo dyes, Eriochrome Black T (BT) and calmagite, with cobalt(II) and nickel(II)-aminopolycarboxylate complexes.[1,2] The reactions were invariably first-order in the metal(II)-aminopolycarboxylate complex, and gave a metal(II)-dye complex with a 1:1 composition, MD^-. In the present paper, the kinetics of the substitution reactions of calmagite with the nickel(II)-glutamate (Glut), -aspartate (Asp), -iminodiacetate (IDA), -nitrilotriacetate (NTA), and -diethylenetriamine (Dien) complexes, and that with the cobalt(II)-NTA complex, will be dealt with spectrophotometrically. From a comparison of the observed rate constant with that calculated on the basis of the reaction intermediate proposed, the detailed reaction mechanism and the structure of the reaction intermediate will also be discussed.

Experimental

Reagents. The preparation and the standardization of cobalt(II) and nickel(II) nitrate solutions were described in a previous paper.[3] Reagent-grade Glut, Asp, IDA, and NTA were recrystallized from their aqueous solutions by adding pure hydrochloric acid and ethanol. The Dien used in this study was purified by distilling it under reduced pressure. The calmagite was recrystallized from its ethanol solution by employing the Lindstrom-Isaac method.[4] The other reagents were of an analytical reagent grade and were used without further purification.

Apparatus and Experimental Procedures. All the absorption spectra were obtained with a Hitachi ESP-3 pen-recording spectrophotometer. For the measurement of the pH of the sample solution, a Hitachi-Horiba glass electrode pH meter F-5 was used. All the measurenmets were conducted in solutions of a constant ionic strength (0.30) ($NaClO_4$ or KNO_3). The reactions of calmagite with nickel(II)-IDA, -NTA, and -Dien complexes were followed spectrophotometrically at 620 mμ using a Hitachi ESP-3 pen-recording spectrophotometer. The kinetic investigation of the reactions of calmagite with nickel(II)-Glut and -Asp complexes and of that with the cobalt(II)-NTA complex were carried out by using a Hitachi Rapid Scanning Spectrophotometer RSP-2 with a stopped-flow mixing chamber. The experimental procedures were the same as those described previously.[3] In this study, no buffer reagent was used, because free Glut, Asp, IDA, NTA, and Dien have enough buffer capacity to maintain the pH values of sample solutions constant over the entire pH range covered. All the exchange reactions were studied in solutions containing large excesses of complexed and uncomplexed Glut, Asp, IDA, NTA, or Dien over calmagite. Therefore, all the exchange reactions could be treated as pseudo-first-order reactions. Thus, the apparent rate constant of the pseudo-first-order reaction, Kap^+, was obtained from the slope of the linear relation between $\log(A_0-A\infty)/(A-A\infty)$ and the time, t.[3] Here, A_0, A, and $A\infty$ indicate the absorbances of solutions at time $=0$, t, and ∞ respectively.

Results and Discussion

Equilibrium Study. In the cases of nickel(II)-glutamate, -aspartate and -iminodiacetate complexes, the absorbances of the equilibrium mixtures with calmagite were found to increase with an increase in the concentration of uncomplexed glutamate, aspartate or iminodiacetate. In considering that the calmagite anion and the aminopolycarboxylate anions used in this study can act as tridentate ligand in the complex-

formation reaction with the nickel(II) ion, this finiding suggests the possibility of the formation of a mixed-ligand calmagite complex involving the aminopolycarboxylate anion. From the thermodynamic point of view,[5] one can derive Eq. (2) for the following mixed-ligand-complex-formation equilibrium:

$$NiD^- + X^{2-} \overset{K^X_{NiD}}{\rightleftarrows} NiDX^{3-}$$

$$\log \frac{A-A_{NiD}}{A_{NiDX}-A} = \log \frac{K^X_{NiD}}{(\alpha_H)_X} + \log [X]_f \qquad (2)$$

where NiD^-, X^{2-}, and $NiDX^{3-}$ denote the nickel(II)-calmagite complex, the aminopolycarboxylate anion, and the mixed-ligand complex of the nickel(II) ion respectively, where $(\alpha_H)_X$ is the (α_H) value of aminopolycarboxylate, and where $[X]_f$ is the concentration of uncomplexed aminopolycarboxylate, where A_{NiD} is the absorbance of the solution in which all the nickel(II) complex ions are in the form of NiD^-, where A_{NiDX} is that of the solution in which all the nickel(II) complex ions exist in the form of $NiDX^{3-}$, and where A is that of the solution in which NiD^- and $NiDX^{3-}$ coexist. This relation was examined by using some typical experimental data. Typical results obtained for glutamate and aspartate systems are reproduced in Fig. 1. From the $\log [X]_f$ values at $\log (A-A_{NiD})/(A_{NiDX}-A)=0$, the $\log K^X_{NiD}$ values were determined to be 2.8_0 and 3.5_0 for the glutamate and aspartate systems respectively. In a similar way, the K^X_{NiD} value for the IDA system was determined to 4.3_0.

On the other hand, in the cases of the nickel(II)-NTA and Dien systems and of the cobalt(II)-NTA system, the concentrations of uncomplexed NTA and Dien had no effect on the absorption curve of the metal-(II)-calmagite complex, disproving the formation of a mixed-ligand complex involving the NTA anion or Dien.

Kinetic Study. In the kinetic study, although the results will not be shown here, the following facts were found in preliminary experiments:

i) In solutions of a given pH, a given concentration of a metal(II) complex of Glut, Asp, IDA, NTA, or Dien, and a given initial concentration of calmagite, k^+_{ap} is inversely proportional to the concentration of uncomplexed Glut, Asp, IDA, NTA, or Dien.

ii) In solutions of a given pH, a given concentration of uncomplexed Glut, Asp, IDA, NTA, or Dien, and a given initial concentration of calmagite, k^+_{ap} is exactly proportional to the total concentration of a metal(II)-Glut, -Asp, -IDA, -NTA, or -Dien complex.

iii) In solutions of a given pH and given concentrations of uncomplexed and complexed Glut, Asp, IDA, NTA, or Dien, k^+_{ap} is independent of the initial concentration of calmagite.

iv) As is shown in Figs. 2 and 3, in solutions of a given initial concentration of calmagite, and given concentrations of a free Glut, Asp, IDA, NTA, or Dien and its metal(II) complex, k^+_{ap} multiplied by $K_2\cdot[X]_f\cdot(\alpha_H)_D/(\alpha_H)_X$ is a linear function of the concentration of the hydrogen ion and is given by:

$$\frac{k^+_{ap}\cdot K_2[X]_f\cdot(\alpha_H)_D}{(\alpha_H)_X} = k_\alpha + k_\beta\cdot[H^+] \qquad (3)$$

where K_2 and $(\alpha_H)_D$ are the second successive formation constant of a metal(II)-Asp, -Glut, -IDA, -NTA, or -Dien complex and the (α_H) value of calmagite respec-

tively. In considering that, under the present experimental conditions, all the metal(II) ions are considered to exist in the form of MX_2^{2-2m}, the above experimental findings suggest that all the substitution reactions are first-order with respect to the concentration of a metal(II)-Glut, -Asp, -IDA, -NTA, or -Dien complex with a 1:1 composition, and first-order with respect to the concentration of calmagite, and also that the reactions invariably proceed through the completely-deprotonated and divalent calmagite anions, D^{3-} and HD^{2-}. The K_{NID}^{X} values obtained show that the reaction products in the substitution reactions of calmagite with the nickel(II)-Glut, -Asp, and -IDA complexes under the present experimental conditions are given by $NiDX^{3-}$. Therefore, the reaction mechanism for the exchange reactions of calmagite with nickel(II)-Glut, -Asp, and -IDA complexes can be depicted as:

$$NiX_2^{2-} \rightleftharpoons NiX^0 + X^{2-} \quad \text{in a rapid equilibrium}$$

$$NiX^0 + \begin{cases} HD^{2-} \overset{k_{HD}}{\rightleftharpoons} NiDX^{3-} + H^+ \\ D^{3-} \overset{k_D}{\rightleftharpoons} NiDX^{3-} \end{cases} \quad \text{r.d.s. I}$$

For the above reaction, Eq. (3) can be rewritten as:

$$k_{ap}^{+} = 2.303\times\text{log-plot slope} = \frac{[Ni(II)]_t}{(1+K_2'\cdot[X]_f)\cdot(\alpha_H)_D}\left(k_D+\frac{k_{HD}\cdot[H^+]}{K_3^D}\right) \quad (4)$$

From the slopes and intercepts of the straight lines in Fig. 2, the k_{HD} and k_D values for the substitution reactions of calmagite with the nickel(II)-Glut, -Asp, and -IDA complexes were determined; they are listed in Table 1. On the other hand, in the cases of the exchange reactions of calmagite with the nickel(II)-NTA and -Dien complexes, and that with the cobalt(II)-NTA complex, in connection with the experimental facts given above, it can be concluded that the reaction mechanism for these reactions can be formulated as:

$$MX_2^{2-2m} \rightleftharpoons MX^{2-m} + X^{m-} \quad \text{in a rapid equilibrium}$$

$$MX^{2-m} + \begin{cases} HD^{2-} \overset{k_{HD}}{\rightleftharpoons} MD^- + HX^{1-m} \\ D^{3-} \overset{k_D}{\rightleftharpoons} MD^- + X^{m-} \end{cases} \quad \text{r.d.s. II}$$

where X^{m-} means the tervalent NTA anion or completely-deprotonated Dien.

As in the cases of the nickel(II)-Glut, -Asp, and -IDA systems, the k_{HD} and k_D values for these reactions were determined from the slopes and intercepts of the straight lines in Fig. 3. The k_{HD} and k_D values determined are also listed in Table 1.

Table 1. Rate constants (μ=0.30, 25°C)

System	Rate constants, $M^{-1}\,sec^{-1}$	
	k_D	k_{HD}
Ni(II)-glutamate	4.9×10^7	$1.5_8\times10^6$
Ni(II)-aspartate	3.5×10^6	$4.0_5\times10^5$
Ni(II)-iminodiacetate	4.8×10^5	$1.5_2\times10^4$
Ni(II)-nitrilotriacetate	2.5×10^5	$1.6_7\times10^3$
Ni(II)-diethylenetriamine	9.8×10^7	$2.5_0\times10^5$
Co(II)-nitrilotriacetate	6.5×10^5	$2.6_4\times10^5$

We can propose the common water-loss mechanism for the substitution reactions of calmagite with nickel(II)-Glut, -Asp, and -IDA complexes. A nickel(II)-Glut, -Asp, or -IDA complex with a 1:2 composition diffuses first and dissociates rapidly to form an outer-sphere complex with the calmagite anion. Then, a coordinated water molecule dissociates from the nickel(II) complex, NiX^0, and a donor group of the calmagite anion coordinates with the nickel(II) ion at the vacated coordination site. In the above reaction mechanism, the water loss from the nickel(II) complex, NiX^0, is considered to be the rate-determining step. In the above water-loss mechanism, if, in the nickel(II)-Glut, -Asp, and -IDA complex segments of the outer-sphere complexes, the Glut, Asp, and IDA anions are bonded to the nickel(II) ion through two oxygen and one nitrogen atoms, all the rate constants (k_D or k_{HD} values) should be identical, because the difference in the electrostatic and steric effects among these three systems are considered to be negligible. On the other hand, if the outer-sphere complexes have the structure shown by I or II in Fig. 4, the rate constants, k_D and k_{HD},

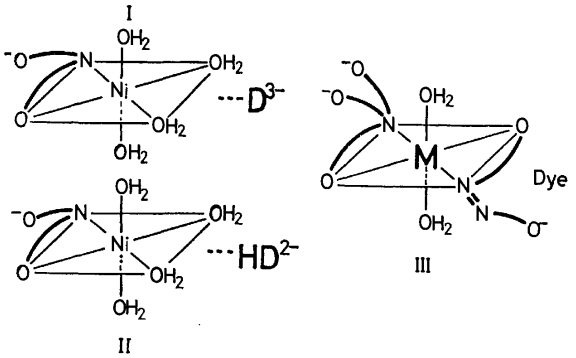

Fig. 4. Reaction intermediates

must be given by Eq. (5):

$$k^{6)} = k^{-H_2O}\frac{K_{Ni-gly}\cdot K_{as}\cdot K_{ele}\cdot K_{st}}{K_{NiX}} \quad (5)$$

where k^{-H_2O} is the rate constant of water-loss from the nickel(II) ion; K_{as}, the association constant of the outer-sphere complex, and K_{Ni-gly}, the stability constant of the nickel(II)-glycinate segment, and where K_{ele} and K_{st} are the electrostatic contribution to the stability of the reaction intermediate and the statistical factor respectively. This relation was examined experimentally. The k_D and k_{HD} values for the glutamate system were calculated to be 1.1×10^7 and $1.1\times10^6 M^{-1}sec^{-1}$ respectively by using $k^{-H_2O}=10^{5.30}$,[7] $K_{Ni-gly}=10^{4.71}$,[8] $K_{as}=10^{1.7}$ or $10^{0.7}$,[9] $K_{ele}=10^{0.5}$, and $K_{st}=1.0$. In consideration of the assumption made in the above calculation, the agreement between the calculated and observed rate constants can be regarded as satisfactory. Equation (5) also shows that k_D and k_{HD} values should be proportioanl to the reciprocal of the stability constant, K_{MX}^{-1}. In Table 2, the relative rate constants and the ratio of K_{MX} are compared. The K_{MX} values used in the estimation of the K_{MX}^{-1} ratio were calculated from the related stability constants in a solution with an ionic strength of 0.10 by using the activity coefficients calculated by means of the Davies equation.[10] Generally, the stability constants reported in the literature are of widely varying accuracy, differing from each other by several tenths of log K units. Considering this, and also the assumption made in the calculation of the activity coefficients, it can be said that the observed ratio agrees, at least semi-quantitatively, with the K_{MX}^{-1} ratio. These findings lend strong support to the above water-loss mechanism proposed for the substitution reactions of the nickel(II)-Glut, -Asp, and -IDA complexes with calmagite.

In the substitution reactions of calmagite with the nickel(II)-NTA and -Dien complexes, and that with the cobalt(II)-NTA complex, the fact that the rate constants are larger than the corresponding dissociation constants can be explained by assuming a reaction mechanism where the reaction proceeds through a mixed-ligand reaction intermediate involving leaving and attacking groups. Here, the dissociation of the leaving group from the reaction intermediate is the rate-determining step. As was discussed in connection with the substituion reaction of diethylenetriaminepentaacetic acid (DTPA) with the nickel(II)-NTA complex in the presence of ethylenediamine,[11] when the calmagite segments in the reaction intermediates of nickel(II)-NTA and -Dien complexes have the same structures, and when the leaving NTA anion and Dien are bonded to the nickel(II) ion through glycinate and ethylenediamine chelate rings respectively, the rate-constant ratio between the nickel(II)-NTA and -Dien complex systems should be 2.2×10^2. As is clear from the data in Table 1, the observed k_D and k_{HD} ratios are 3.9×10^2 and 1.5×10^2 respectively. The agreement between observed and calculated ratios can thus be regarded as satisfactory. Furthermore, if the calmagite reactions of both nickel(II)- and cobalt(II)-NTA complexes have as the reaction intermediate, (III), the rate constant ratio, k_{Co}/k_{Ni}, between the cobalt(II) and Nickel(II) systems should be given by:

$$\frac{k_{Co}}{k_{Ni}} = \frac{k_{Co}^{-gly}}{k_{Ni}^{-gly}}\times\frac{K_{Co-gly}}{K_{Ni-gly}}\times\frac{K_{NiX}}{K_{CoX}}\times\frac{K_{Co-D}}{K_{Ni-D}} \quad (6)$$

where k_M^{-gly}, K_{M-gly}, K_{M-D}, and K_{MX} are the dissociation rate constant of the metal(II)-glycinate complex of a 1:1 ratio, the stability constant of the metal(II)-glycinate complex, the stability constant of the metal(II)-calmagite segment, and the stability constant of the 1:1 ratio metal(II)-NTA complex respectively. From the above relation, the k_{Co}/k_{Ni} value was calculated to be 1.0×10^2, by using the $k_{Co}^{-gly}/k_{Ni}^{-gly}$ value reported by Hammes and Steinfeld[12] and the reported K values ($\mu=0.30$).[13] Here, the cobalt(II)- and nickel(II)-4-(*p*-arsonaphenylazo)-3-hydroxynaphthalene-2,7-disulfonic acid complexes were used as models of the metal(II)-calmagite segments of the mixed-ligand reaction intermediates.[13] The rate constant ratios for the k_D and k_{HD} were 2.5×10^2 and 1.6×10^2 respectively. The calculated ratio is in good agreement with the observed ratio. This agreement also supports the present authors' explanation that the calmagite reactions of cobalt(II)- and nickel(II)-NTA complexes proceed through the reaction intermediate III.

TABLE 2. RATE CONSTANT RATIOS

System	Rate constant ratio		K_{MX}^{-1} ratio
	k_D	k_{HD}	
Ni(II)-glutamate	1.04×10^2	1.04×10^2	5.9×10^2
Ni(II)-aspartate	7.3	26.6	14.1
Ni(II)-iminodiacetate	1.0	1.0	1.0

(Received January 27, 1972)

The kinetics of the substitution reactions of EDTA and EDTA-OH with nickel(II)-EDMA and -Dien complexes were studied using the polarographic technique. The substitution reactions of EDTA and EDTA-OH with the nickel(II)-EDMA complex were found to have a common reaction mechanism. They were first-order with respect to EDTA or EDTA-OH, and also first-order with respect to the nickel(II)-EDMA complex with a 1:1 composition; their reaction mechanism could be formulated as:

$$NiX_2^0 \rightleftharpoons NiX^+ + X^- \quad \text{in a rapid equilibrium}$$

$$NiX^+ + \begin{cases} HY^{1-m} \overset{k_{HY}}{\rightleftharpoons} NiY^{2-m} + HX^0 \\ Y^{m-} \overset{k_Y}{\rightleftharpoons} NiY^{2-m} + X^- \end{cases} \quad \text{r.d.s.}$$

The substitution reactions of EDTA and EDTA-OH with the nickel(II)-Dien complex were also studied under experimental conditions where the reaction could be treated as a pseudo-first-order reaction. The reactions were first-order with respect to the concentration of EDTA or EDTA-OH. However, their reaction rate were independent of the concentrations of the nickel(II)-Dien complex and of uncomplexed Dien. This fact was ascribed to the formation of a stable outer-sphere complex between the nickel(II)-Dien complex with a 1:2 ratio and the EDTA or EDTA-OH anion, through which the substitution reaction proceeds.

Previous papers in this series[1-3] have dealt with substitution reactions involving nickel(II)-iminodiacetate (IDA), aspartate (Asp), -ethylenediaminemonoacetate (EDMA), and -nitrilotriacetate (NTA) complexes. Those reactions have been shown to proceed invariably through a nickel(II) complex of a 1:1 composition, a complex which is in a rapid equilibrium with a 1:2 ratio complex. The substitution reactions of the nickel(II)-EDMA complex with EDTA and EDTA-OH were also found to proceed with the 1:1 ratio nickel(II)-EDMA complex. However, in sharp contrast, the substitution reactions of the nickel(II)-diethylenetriamine (Dien) complex with EDTA and EDTA-OH are zero-order in concentrations of complexed and uncomplexed Dien. In this paper, the substitution reactions of nickel(II)-EDMA and Dien complexes with EDTA and EDTA-OH will be dealt with by employing the polarographic method. The reaction mechanism and the structure of the reaction intermediate also will be discussed in detail.

Experimental

Reagents. The ways of preparing EDMA dihydrochloride and of its purification were described previously.[4] The Dien used in this study was purified twice by distilling it under reduced pressure. The EDTA and EDTA-OH were recrystallized from their aqueous solutions by adding pure HCl and ethanol. The preparation of standard nickel(II) nitrate solution was also described previously.[5] The other reagents were of an analytical-reagent grade and were used without further purification.

Apparatus and Experimental Procedures. The apparatus and the experimental procedures were the same as those described previously.[3] In this study, all the measurements were conducted in solutions of an ionic strength of 0.30 ($NaClO_4$ for the EDMA system, KNO_3 for the Dien system). In the kinetic study of the substitution reaction of the nickel(II)-EDMA complex, no buffer reagent was used, because the free EDMA has enough buffer capacity to maintain the pH values of the solutions constant. In the substitution reactions of the nickel(II)-Dien complex, however, a phosphate buffer mixture was used over the entire pH range convered. All the sample solutions contained large excesses of complexed and uncomplexed Dien over EDTA or EDTA-OH. Therefore, all reactions could be treated as pseudo-first-order reactions.

Results and Discussion

Substitution Reactions of the Nickel(II)-EDMA Complex with EDTA or EDTA-OH. As in the case of the substitution reaction of the nickel(II)-EDMA complex with diethylenetriaminepentaacetic acid (DTPA),[2] provided that the other experimental conditions are kept constant, the apparent pseudo-first-order rate constants, k_{ap}^+s, as determined from the slope of the linear log (i_0/i_t) *vs.* t plot, were i) inversely proportional to the concentration of uncomplexed EDMA, ii) exactly proportional to the total concentration of the nickel(II) ion, and iii) independent of the initial concentration of EDTA or EDTA-OH. Furthermore, the k_{ap}^+ value

multiplied by $K_2\cdot[X]_f\cdot(\alpha_H)_X/[Ni(II)]_t\cdot(\alpha_H)_Y$ was found to be a linear function of the hydrogen-ion concentration and to be given by Eq. (1) (Fig. 1):

$$k_{ap}^{+}\times\frac{K_2\cdot[X]_f\cdot(\alpha_H)_Y}{(\alpha_H)_X\cdot[Ni(II)]_t}=k_\alpha+k_\beta[H^+] \qquad (1)$$

where K_2 is the second successive formation constant of the nickel(II)-EDMA complex; $[X]_f$, the concentration of uncomplexed EDMA; $(\alpha_H)_Y$, the (α_H) value of EDTA or EDTA-OH, and $(\alpha_H)_X$, the (α_H) value of EDMA. As was discussed in connection with the substitution reaction of the nickel(II)-EDMA complex with DTPA,[2] these facts clearly indicate that the substitution reactions of the nickel(II)-EDMA complex with EDTA and EDTA-OH can be depicted as:

$$NiX_2^0 \rightleftharpoons NiX^+ + X^- \quad \text{in a rapid equilibrium}$$

$$NiX^+ + \begin{cases} HY^{1-m} \overset{k_{HY}}{\rightleftharpoons} NiY^{2-m} + HX^0 \\ Y^{m-} \overset{k_Y}{\rightleftharpoons} NiY^{2-m} + X^- \end{cases} \quad \text{r.d.s. I}$$

where Y^{m-} and X^- are completely-deprotonated EDTA or EDTA-OH and EDMA anions respectively. On the basis of the above reaction mechanism, k_{ap}^{+} can be written as:

$$k_{ap}^{+}=\frac{[Ni(II)]_t}{(1+K_2'\cdot[X]_f)\cdot(\alpha_H)_Y}\times\left(k_Y+k_{HY}\cdot\frac{[H^+]}{K_n}\right) \qquad (2)$$

where $[Ni(II)]_t$ and K_n denote the total concentration of the nickel(II) ion and the fourth dissociation constant of EDTA or the third dissociation constant of EDTA-OH respectively. The fact that, in the substitution reaction of EDTA-OH with the nickel(II)-EDMA complex, the $k_{ap}^{+}\cdot K'_2\cdot[X]_f\cdot(\alpha_H)_Y/[Ni(II)]_t$ value is almost constant under the present experimental conditions implies that the reaction proceeds only through its tervalent anion. From the slopes and intercepts of straight lines in Fig. 1, the k_{HY} and k_Y values were determined; they are listed in Table 1. The chloride ion was found to have no effect on the reaction.

Substitution Reactions of the Nickel(II)-Dien Complex with EDTA and EDTA-OH. The substitution reaction of the nickel(II)-Dien complex with EDTA was studied in the pH range from 7.10 to 9.00. At pH's lower than 8.00, a phosphate buffer mixture was used to keep the solution pH constant. However, it had no effect on the rate of the substitution reaction. As in the case of the substitution reaction of the EDMA complex, the k_{ap}^{+} value was independent of the initial concentration of EDTA or EDTA-OH. However, in striking contrast to the findings observed in the substitution reaction of the nickel(II)-EDMA complex, the k_{ap}^{+} value was independent of the concentrations of uncomplexed Dien and of the nickle(II) ions. Considering that, under the present experimental conditions, all the nickel(II) ions exist in the form of NiX_2^{2+},[2] the above findings clearly suggest that the EDTA and EDTA-OH anions form a stable outer-sphere complex with NiX_2^{2+}, only through which the reactions proceed. Furthermore, the k_{ap}^{+} value multiplied by $(\alpha_H)_Y$ was found to be a linear function of the hydrogen-ion concentration, corresponding to the following relation:

$$k_{ap}^{+}\cdot(\alpha_H)_Y=\text{constant}\times[H^+] \qquad (3)$$

Some typical results were reproduced in Fig. 2. From these experimental facts, we can conclude that the EDTA and EDTA-OH reactions with the nickel(II)-Dien complex under the present experimental conditions have the following reaction mechanism, IIa:

Table 1. Rate constants (μ=0.30,25°C)

System	k_Y, $M^{-1}\,sec^{-1}$	k_{HY}, $M^{-1}\,sec^{-1}$
EDTA—Ni(II)-EDMA	1.5×10^3	$3.9_0\times10^2$
EDTA-OH—Ni(II)-EDMA	2.8×10^2	—
EDTA—Ni(II)-Dien	—	$5.2_5\times10^{-2}$
EDTA-OH—Ni(II)-Dien	—	$1.1_8\times10^{-1}$

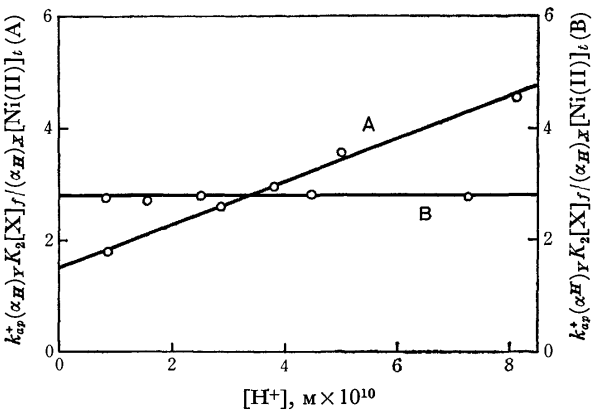

Fig. 1. The plot of $k_{ap}^{+}K_2[X]_f(\alpha_H)_Y/[Ni(II)]_t(\alpha_H)_X$ against the concentration of hydrogen ion.
Total concentration of nickel(II)-ion=10.0 mM
Initial concentration of EDTA or EDTA-OH=0.52 mM
μ=0.30, 25°C
A: EDTA system, $[X]_f$=20.0 mM
B: EDTA-OH system, $[X]_f$=15.0 mM

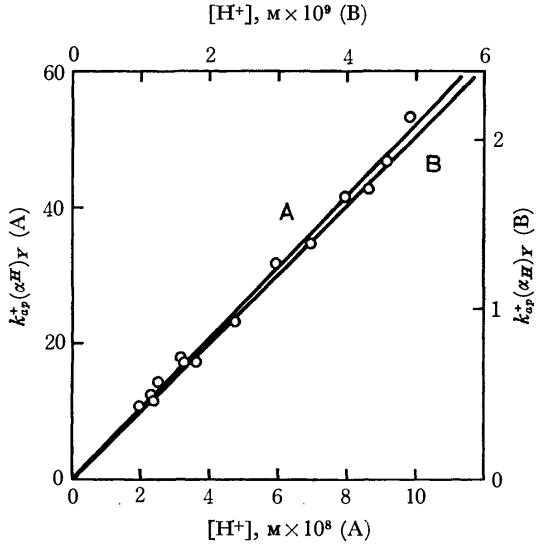

Fig. 2. The plot of k_{ap}^{+} $(\alpha_H)_Y$ against the concentration of hydrogen ion.
Total concentration of nickel(II)-ion=6.0 mM
Initial concentration of EDTA or EDTA-OH=0.52 mM
The concentration of uncomplexed Dien=18.0 mM
μ=0.30, 25°C
A: EDTA system B: EDTA-OH system

$$NiX_2^{2+} + HY^{1-m} \overset{K_{as}}{\rightleftharpoons} NiX_2^{2+} \cdots HY^{1-m} \quad \text{rapid}$$

$$NiX_2^{2+} \cdots HY^{1-m} \overset{k_{HY}}{\rightleftharpoons} NiY^{2-m} + HX^{+} + X^{0} \quad \text{r.d.s. IIa}$$

For the above reaction mechanism, if the formation of the outer-sphere complex, $NiX_2^{2+}\cdots HY^{1-m}$, is complete, k_{ap}^{+} can be written as:

$$k_{ap}^{+} = \frac{1}{(\alpha_H)_Y} \times \frac{k_{HY}\cdot[H^+]}{K_n} \qquad (4)$$

Therefore, from the slope of the linear relations in Fig. 2, the k_{HY} values for the EDTA and EDTA-OH reactions were determined. These values are also listed in Table 1.

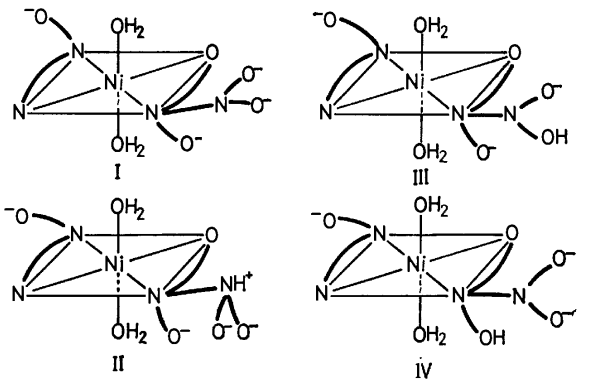

Fig. 3. Reaction intermediates.

As in the case of the substitution reaction of the nickel(II)-EDMA complex with DTPA, if the reaction of the nickel(II)-EDMA complex with EDTA proceeds through the two reaction intermediates (I and II) in Fig. 3, and if the dissociation of the EDMA anion from them is the rate-determining step, on the basis of these reaction intermediates the k_Y and k_{HY} values can be calculated from the $k_c = k_{Ni}^{en} K_{Ni-en} K_{Ni-gly}/K_{NiX}$ relation.[6] Here, k_{Ni}^{en} is the rate constant of the dissociation of the nickel(II)-ethylenediamine complex; K_{Ni-en}, the stability constant of the 1 : 1 nickel(II)-ethylenediamine complex; K_{Ni-gly}, the stability constant of the 1 : 1 nickel(II)-glycinate complex, and K_{NiX}, the stability constant of the 1 : 1 nickel(II)-EDMA complex. The calculated k_Y and k_{HY} values were 1.0×10^3 and 6.4×10^2 respectively. Of course, the electrostatic contribution to the stability of the reaction intermediate and the statistical factor were also taken into account. The nickel(II)-*N*-ethylglycinate complex was used as a glycinate model. The agreement of the observed k_Y and k_{HY} values with the calculated ones can be regarded as satisfactory. The rate constants calculated on the basis of every reaction intermediate other than I and II showed no good agreement with the observed values. Similarly, one of the following two reaction intermediates (III and IV in Fig. 3) would be possible for the substitution reaction of EDTA-OH with the nickel(II)-EDMA complex. The k_{HY} values calculated on the basis of III and IV were 1.6×10^2 and $8.1\times10\,M^{-1}sec^{-1}$ respectively. The former value agreed well with the observed value; this supports the reaction intermediate III.

In the substitution reactions of the nickel(II)-Dien complex, we previously assumed the formation of an outer-sphere complex between NiX_2^{2+} and HY^{1-m} in order to explain the reaction profile. However, it is very hard to believe that two Dien molecules dissociate simultaneously from the nickel(II) ion in the outer-sphere complex. For this reason, the experimental fact that the reaction rate is practically independent of the nickel(II)-Dien complex concentration indicates that the rate-determining step is the dissociation of the first Dien molecule from the nickel(II) ion, which is then followed by the rapid formation of a mixed 1 : 1 : 1 nickel(II), Dien, Y^{m-} complex and the rapid dissociation of the second Dien molecule from it. If the outer-sphere complex is depicted as V, the k_{HY} value can be given by $K_{Ni-L}\cdot K_{st}\times k_{rds}/K_2$. Here, K_2 denotes the second successive formation constant of the nickel(II)-Dien complex; K_{Ni-L}, the stability of the leaving Dien segment, and k_{rds}, the rate constant of the dissociation of the first Dien molecule from the reaction intermediate, V in Fig. 4. By approximating the k_{rds} value to the dissociation rate constant of a 1 : 2 ratio nickel(II)-ethylenediamine complex ($\log k = 0.72$[7]), and K_{Ni-L}, to the second successive formation constant of the nickel(II)-*N*-(2-hydroxyethyl)ethylenediamine complex,[8] the k_{HY} value was calculated to be 8.4×10^{-2} from the above relation. The k_{HY} value obtained experimentally agreed well with this value. To complete the substitution reaction, the above rate-determining step should be followed by the rapid dissociation of the second Dien molecule from the reaction intermediate. By analogy with the substitution reaction of the nickel(II)-Dien complex with DTPA, the latter step would proceed through the following mixed-ligand reaction intermediate (VI), where the dissociation of Dien from it is slow. Here, it must be noted that if

the formation of the reaction intermediate VI is rapid enough, the rate constant calculated on the basis of the reaction intermediate VI should be much larger than the k_{HY} value obtained experimentally. By the common way of calculating the rate constant, the k_{HY} values for the EDTA and EDTA-OH systems were calculated to be 390. This rate constant, large compared with the observed k_{HY} value, shows that the IIa reaction mechanism can reasonably be rewritten as:

$$NiX_2^{2+} + HY^{1-m} \overset{K_{as}}{\rightleftharpoons} NiX_2^{2+} \cdots HY^{1-m} \quad \text{in a rapid equilibrium}$$

$$NiX_2^{2+} \cdots HY^{1-m} \overset{k_{HY}}{\rightleftharpoons} NiXY^{2-m} + HX^{+} \quad \text{r.d.s. IIa}$$

$$NiXY^{2-m} \rightleftharpoons NiY^{2-m} + X^{0} \quad \text{rapid}$$

The formation of a mixed-ligand complex of the nickel(II) ion involving both Dien and the EDTA or EDTA-OH anion as a reaction product could be disproved spectrophotometrically. In order to ascertain the formation of an outer-sphere complex between NiX_2^{2+} and the EDTA or EDTA-OH anion, a conductometric investigation was also carried out. However, it could provide no experimental evidence justifying the formation of an outer-sphere complex. Since the K_{as} value predicted from the Fuoss equation[9] is not large enough for the completion of the outer-sphere complex formation, it may be assumed that the internal hydrogen-bond formation between the HY^{1-m} anion and the free nitrogen atom of coordinated Dien plays an important role in the stabilization of the outer-sphere complex.

The substitution reaction of the cobalt(II)-Dien complex with EDTA was also studied. However, it proceeds so rapidly that we could not determine its rate or reaction mechanism by the present polarographic technique.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2764—2767 (1972)

The Extraction and Spectrophotometric Determination of Titanium(IV) with Tiron[1]

Yoshinobu WAKAMATSU* and Makoto OTOMO**

*Department of Industrial Chemistry, Hachinohe Technical College, Hachinohe-shi, Aomori

**Department of Synthetic Chemistry, Nagoya Institute of Technology, Showa-ku, Nagoya-shi

(Received March 13, 1972)

A method has been described for the spectrophotometric determination of titanium(IV), which is based on the extraction of the titanium(IV)-Tiron chelate into *n*-butanol in the presence of 1,3-diphenylguanidinium salt. The extracted species containing titanium, Tiron, and diphenylguanidine in a molar ratio 1:2:4, has an absorption maximum at about 385 nm. The maximum extraction is obtained when the pH of the initial aqueous phase is controlled to about 3.0 to 4.0. Beer's law is obeyed up to 25 μg titanium per 10 m*l* of *n*-butanol. The molar absorptivity of the extracted species is 1.4×10^4 at 385 nm. Molybdenum(VI) and chelating agents interfere with the determination of titanium.

As is well known, Tiron, disodium salt of 1,2-dihydroxybenzene-3,5-disulfonic acid, forms water soluble chelates with many metal ions and has been used as a colorimetric reagent for several metal ions,[2-6] or as a masking agent[7] or a metallochromic indicator[8] in complexometric titrations. Recently, Busev *et al.*[9] applied the reagent to the selective extraction-spectrophotometric determination of molybdenum (VI), on the basis of the extraction of the ion-association complex formed between the molybdenum-Tiron chelate and 1,3-diphenylguanidinium cation. A similar method was also applied to the determination of iron(III).[10]

Because of its superior extraction efficiency, 1,3-diphenylguanidinium salt has recently been used in many analytical procedures with advantage. In our previous works, the anionic metal-chelates of Methylthymol Blue,[11,12] Xylenol Orange[13] or Indoferron[14-16] have been extracted into suitable organic solvents in

the presence of 1,3-diphenylguanidinium chloride. The extraction mechanisms of the ion-association complexes thus formed have also been investigated by a spectrophotometric method. The present paper will describe the spectrophotometric determination of titanium(IV), which is based on the extraction of the titanium-Tiron-1,3-diphenylguanidinium association complex into *n*-butanol. The extracted species, containing titanium, Tiron and diphenylguanidine in a molar ratio 1:2:4, has an absorption maximum at 385 nm and the molar absorptivity of about 1.4×10^4. By this method, up to 25 μg of titanium can be determined within the experimental error.

Experimental

Reagent. About 0.01 M titanium(IV) solution was prepared by dissolving the hydrolysis products of titanium tetrachloride in 6 N sulfuric acid and diluting with distilled water. The resultant solution was standardized by the complexometric titration.[17] A working standard solution was prepared by diluting the above solution with distilled water to a desired concentration.

A 5×10^{-2} M Tiron solution was prepared by dissolving the Dotite Tiron in distilled water without further purification.

A 0.5 M 1,3-diphenylguanidinium chloride (DPG-Cl) stock solution was prepared by dissolving 1,3-diphenylguanidine (Guaranteed Reagent, Tokyo Kasei Co., Ltd.) in calculated amounts of hydrochloric acid and diluting with distilled water.

All other chemicals used were of guaranteed reagent quality.

Apparatus. The absorbance measurements were made with a Hitachi Model 124 recording-spectrophotometer with 10-mm quartz cells and a Hitachi Model EPU-2A spectrophotometer with 10-mm glass cells. The shaking was done with an Iwaki Model V-D shaker with a time switch. The pH measurements were made with a Toa Denpa Model HM-5A glass electrode pH meter.

Standard Procedure. To a sample solution containing up to 25 μg of titanium in a 50 m*l* separating funnel were added 2 m*l* of a 5×10^{-2} M Tiron solution and 10 m*l* of a 0.1 M DPG-Cl solution which had been adjusted to pH 3.6 with monochloroacetic acid and sodium acetate solutions. The solution was diluted with water to 20.0 m*l* and shaken for 5 min. with 10.0 m*l* of *n*-butanol. The absorbance of the organic phase was then measured at 385 nm using a reagent blank as the reference.

Results and Discussion

Absorption Spectra. The absorption spectra of the association complex extracted into *n*-butanol are shown in Fig. 1, along with that of the reagent blank. At any pH values examined, the absorption maximum of the extracted species is found at about 385 nm. The extracted species was stable for at least several hours.

The Effect of pH. The effect of pH of the aqueous phase on the extraction was examined. The results are shown in Fig. 2. The maximum extraction is reached at pH 3.0 to 4.0 when the association complex is extracted into *n*-butanol from the aqueous solution containing 9.6 μg titanium, 5.0×10^{-3}M Tiron and 1.3×10^{-1}M DPG-Cl. This pH range is shifted to 3.3 to 4.0 for 19.2 μg titanium.

Tiron: 5.0×10^{-3} M, DPG-Cl: 0.13 M, Ti: I; 9.6 μg, II; 19.2 μg, III; 0.

The Effect of the Tiron Concentration. The effect of the Tiron concentration on the extraction was investigated by varying the Tiron concentration, while other variables being held constant. The absorbance

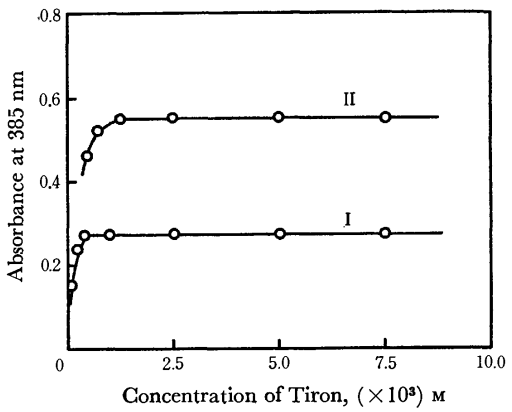

Fig. 3. Effect of Tiron concentration on the extraction of Ti(IV)-Tiron-DPG.
pH: 3.6, DPG-Cl: 0.13 M, Ti: I; 9.6 μg, II; 19.2 μg

17) K. Ueno, "Chelatometric Titration (In Japanese)", Nankodo, Tokyo (1965), p. 315.

of the organic phase was constant when the Tiron concentration in the initial aqueous phase was more than 2.0×10^{-3}M, as is shown in Fig. 3.

The Effect of the DPG-Cl Concentration. The absorbance of the organic phase remained essentially constant provided that the DPG-Cl concentration of the initial aqueous phase was more than about 9.0×10^{-2}M. The titanium-Tiron chelate could not be extracted into the organic phase in the absence of DPG-Cl. The absorbance of the organic phase was not affected by further addition of DPG-Cl at least up to 0.2M.

The Effect of the Shaking Time. The shaking time was varied from 0.5 to 30 min. It was found that shaking for 3 min sufficed; for safety, a shaking time of 5 min was selected. The aqueous phase after one extraction was colorless,indicating that only one extraction is needed for complete extraction of the association complex.

Choice of Solvent. The titanium-Tiron-DPG association complex can be extracted into such aliphatic alcohols as *n*-butanol, isobutyl alcohol and *n*-amyl alcohol, but not into hydrocarbons, halogenated hydrocarbons, esters and ketones. *n*-Butanol was chosen as the solvent which gave the highest absorbance.

Calibration Curve. A calibration curve for the determination of titanium was prepared under the optimum conditions. A good linear relationship was obtained over the concentration range 0 to 25 μg of titanium per 10 m*l* of *n*-butanol. The molar absorptivity of the extracted species was approximately 1.4×10^4 at 385 nm. This value is about 1.4 times as high as that obtained by the direct reaction in aqueous solution without DPG-Cl. The proposed method is comparable in sensitivity with the Xylenol Orange[18] or the chromotropic acid method.[19]

The Effect of Diverse Ions. Separate tests were made to elucidate the interference of various cations as well as that of anions on the determination of titanium. The results are summarized in Tables 1 and 2. Molybdenum(VI) interfered at all concentrations investigated, giving positive errors. Iron(III) up to about 10-fold excess did not interfere with the determination when nitrilotriacetic acid (NTA) (2×10^{-3}M) was added as a masking agent before extraction. The interference of the larger amounts of iron(III) may be prevented by addition of a suitable reducing agent. Of the anions tested, chloride, nitrate, sulfate, and phosphate ions, even at high concentrations, did not interfere with the determination. However, chelating agents such as ethylenediaminetetraacetic acid (EDTA) and cyclohexanediaminetetraacetic acid (CyDTA) interfered seriously, giving negative errors.

The Composition of the Extracted Species. The composition of the extracted species was studied by a graphical method, in which all the equilibrium concentrations and distribution ratios were estimated by measuring the absorbances of the organic or aqueous phases at suitable wavelengths.

In Fig. 4, log (distribution ratio of Tiron, D_{Tiron}) is plotted against log (DPG-Cl concentration in the organic phase/chloride ion concentration in the aqueous phase, $[\text{DPG-Cl}]_0/[\text{Cl}^-]$), the Tiron and the hydrogen ion concentrations being kept constant. The slope of straight line portion shows that the ratio Tiron: DPG is 1: 2. Considering the acid dissociation constants ($K_{\text{OH},1}$ and $K_{\text{OH},2}$) of Tiron, it is reasonable to say that Tiron is combined with two DPG cations through its two sulfonate groups to give an extractable neutral species, $H_2R(DPG)_2$.

The number of moles of Tiron in the titanium-Tiron-DPG association complex was determined by plotting log (distribution ratio of titanium, D_{Ti}) against log

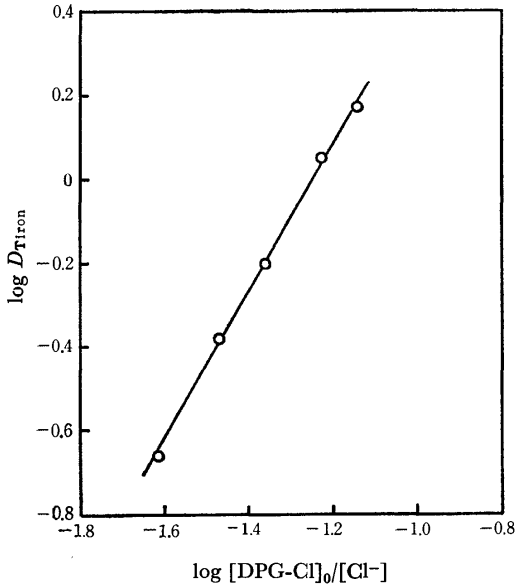

Fig. 4. Relationship between log D_{Tiron} and log [DPG-Cl]$_0$/[Cl$^-$] for the Tiron-DPG system.
Tiron: 5.0×10^{-4} M, pH: 3.6

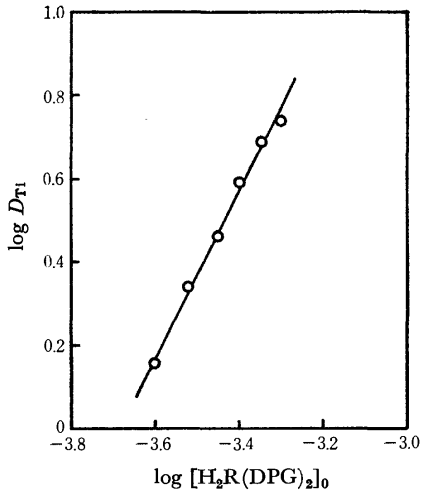

Fig. 5. Relationship between log D_{Ti} and log [$H_2R(DPG)_2$]$_0$ for the Ti(IV)-Tiron-DPG system.
Ti: 2.0×10^{-5} M, pH: 3.6

(Tiron-DPG concentration in the organic phase, [$H_2R(DPG)_2$]$_0$); all other variables were kept constant. The slope of 1.8 (Fig. 5) indicates that two molecules of Tiron combines with one atom of titanium. Evidently the composition of the extracted species is Ti: Tiron: DPG=1:2:4.

The pH dependence of the extraction was then examined by plotting log D_{Ti} against pH value of the aqueous phase. The curves shown in Fig. 6 indicates

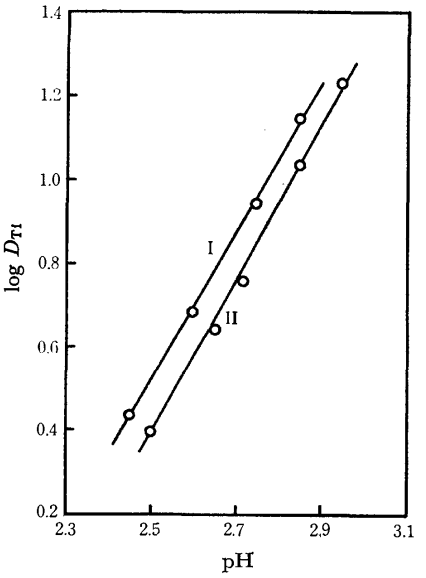

Fig. 6. Relationships between log D_{Ti} and pH for the Ti(IV)-Titon-DPG system.
Tiron: 5.0×10^{-3} M, DPG-Cl: 0.13 M, Ti: I; 1.0×10^{-5} M, II; 2.0×10^{-5} M

that two protons are concerned with the extraction process.

Since titanium(IV) exists predominantly as TiO^{2+} under the experimental conditions,[20] it may be assumed that the original complex is an anionic titanyl(IV)-Tiron species, $TiO(HR)_2^{4-}$, which combines with four DPG cations to form a neutral ion-association complex. From the foregoing observations, it seems natural that the extraction equilibrium expression is given in the simplest form

$$TiO^{2+} + 2[H_2R(DPG)_2]_0 \rightleftarrows [TiO(HR)_2(DPG)_4]_0 + 2H^+$$

and that the distribution ratio of titanium is therefore expressed by

$$\log D_{Ti} = \log [TiO(HR)_2(DPG)_4]_0/[TiO^{2+}] = \log K + 2\log [H_2R(DPG)_2]_0 + 2pH$$

where K is a constant including the acid dissociation constants of Tiron, the distribution coefficients of DPG-Cl, $H_2R(DPG)_2$, and $TiO(HR)_2(DPG)_4$, the formation constants of $H_2R(DPG)_2$ and $TiO(HR)_2(DPG)_4$, and the equilibrium constant of the reaction between titanium and Tiron.

The authors wish to thank Miss Tomiko Takebe for her laboratory work.

Cobalt(II) and -(III) Complexes of 1,5-Dialkylpentane-2,4-diones[1]

Isao YOSHIDA, Hiroshi KOBAYASHI, and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka

(Received April 22, 1972)

Based on the spectral studies in visible, ultraviolet as well as in infrared regions, the dimeric octahedral structure was proposed for bis(heptane-3,5-dionato)cobalt(II) monohydrate, $[Co(DNPM)_2 \cdot H_2O]$, bis(nonane-4,6-dionato)cobalt(II) monohydrate, $[Co(DNBM)_2 \cdot H_2O]$, bis(2,8-dimethylnonane-4,6-dionato)cobalt(II) monomethanolate, $[Co(DIVM)_2 \cdot CH_3OH]$, and bis(tridecane-6,8-dionato)cobalt(II) monomethanolate, $[Co(DNCM)_2 \cdot CH_3OH]$. The dimeric chelates of the type $[CoL_2 \cdot B]$, where B represented water or methanol, were stable in solid state, however, they freed the base B to form a tetrahedral monomeric complex in non-donating solvents. A red-pink solution of the cobalt(II) chelates were oxidized spontaneously in the period of a few days to give a green solution of cobalt(III) chelates of type $[CoL_3]$. Cobalt(III) chelates of 2,6-dimethylheptane-3,5-dione (DIBM) and 2,2,6,6-tetramethylheptane-3,5-dione (DPVM) in addition to the above ligands were synthesized and their spectra were discussed in comparison with the corresponding cobalt(II) chelates.

It has been well established by X-ray crystallography that anhydrous bis(pentane-2,4-dionato)cobalt(II), $Co(AA)_2$, existed as a tetramer in solid state, in which four octaheral units attached face-to-face and edge-to-edge linearly.[2] However, molecular weight determinations in non-donating solvents such as carbon tetrachloride or benzene indicated that the degree of polymerization varied between 1.3 and 3.5, and that the depolymerization proceeded with decreasing concentration.[3] The spectral characteristics of $Co(AA)_2$ in such solvents also indicated the reversible interconversion between an octahedral oligomer and a tetrahedral monomer. The spectrum of the highly diluted solution of $Co(AA)_2$ in non-donating solvents, is quite similar to that of bis(2,2,6,6-tetramethylheptane-3,5-dionato)cobalt(II), $Co(DPVM)_2$, which is known as a mononuclear tetrahedral complex.[4]

A unique tetrahedral structure of $Co(DPVM)_2$ among the cobalt(II) β-diketone chelates, is understood to be due to the steric hindrance of the terminal *t*-butyl groups which are bulky enough to prevent the association of mononuclear species in solid state as well as in solution state.[3,4] The similar effect was also observed in the case of bis(2,2,6,6-tetramethylheptane-3,5-dionato)-nickel(II), $Ni(DPVM)_2$, which is known to be a square planar mononuclear complex.[5-7]

In this respect, it is of great interest to investigate the effect of alkyl substitution at 1- and 5-carbon of pentane-2,4-dione upon the property of resulting complexes. In the previous paper, we reported on the nickel chelates of some 1,5-dialkyl-pentane-2,4-diones with terminal alkyl groups of various bulkiness and proposed an octahedral dimeric structure based on the spectral studies.[8]

This paper is to report on the syntheses and the structural studies of cobalt(II) and -(III) chelates of the following six pentane-2,4-dione analogues: heptane-3,5-dione (or dipropionylmethane, DNPM), nonane-4 6-dione (or di-*n*-butyrylmethane, DNBM), 2,6-dimethylheptane-3,5-dione (or diisobutyrylmethane, DIBM), 2,8-dimethylnonane-4,6-dione (or diisovalerylmethane, DIVM), 2,2,6,6-tetramethylheptane-3,5-dione (or dipivaloylmethane, DPVM), and tridecane-6,8-dione (or di-*n*-caproylmethane, DNCM).

Experimental

Preparation of Compounds. Details of the syntheses and the properties of 1,5-dialkyl-pentane-2,4-diones were described in the previous paper.[8]

Cobalt(II) chelates were prepared by the following general procedure. To a solution containing 1.5 g (0.005 mol) of cobalt(II) nitrate hexahydrate in 20 m*l* of aqueous methanol, was added a solution of 0.01 mol of the ligand in 5 m*l* of methanol. Then, 6 m*l* of 1.5 M aqueous sodium hydroxide was added with vigorous stirring to the mixture, from which a red-pink complex precipitated immediately along with a small amount of green precipitate. The red-pink cobalt(II) chelate was much less soluble in cold methanol than the green cobalt(III) chelate, and was readily separated by fractional dissolution in cold methanol. The cobalt(II) chelate was recrystallized from methanol as fine blood-red needles. Of the ligands investigated in the present work, attempts to prepare the DIBM and DPVM chelates were unsuccessful. The results of elemental analysis and the composition of the chelates, which were successfully synthesized, are summarized in Table 1.

Cobalt(III) chelates were prepared by the following method.[9] A suspension of 1.72 g of cobalt(II) carbonate (0.003 mol) and 0.01 mol of a ligand in 50 m*l* of water was heated at about 95°C. Then, 24 m*l* of 10% hydrogen peroxide was added dropwise to the hot mixture under effective stirring over a period of 1 hr. At the end of the reaction, the mixture was cooled to the room temperature and the dark green reaction product was extracted with 100—200 m*l* of benzene. After evaporating the solvent from the clear extract until dryness under reduced pressure, the green solid residue was recrystallized from an appropriate solvent.

Most of the ligands afforded crystalline cobalt(III) chelates, while DNBM and DNCM gave green oily chelates, which eventually had to be purified by a column chromatography. The crude oil was dissolved in a mixture of methanol and ether, and was passed through alumina and silica gel columns, of both 10 cm length, successively. The pure oily chelates were obtained from the eluates by evaporating the solvent. The results of elemental analysis, compositions, solvents for recrystallization as well as appearances of the chelates are summarized in Table 2.

Measurements. All solvents used in the spectral studies were of reagent grade, and were dried and distilled by the standard method prior to use.

Solid reflectance spectra were measured on a Hitachi EPU-2A spectrophotometer with a diffuse reflectance attachment. Absorption spectra in visible and ultraviolet regions were measured with Hitachi EPS-2 and Hitachi 124 spectrophotometers respectively. Infrared absorption spectra were measured with a JASCO-DS-403G spectrophotometer.

Results and Discussion

Reflectance and Absorption Spectra in Visible Region. The result of elemental analyses of the cobalt(II) chelates, with an exception of pentane-2,4-dionate, agrees well with a molecular formula of $CoL_2 \cdot B$, where L and B represent β-diketonate anion and water or methanol respectively. Interestingly, DNPM and DNBM chelates were obtained as a monohydrate while DIVM and DNCM chelates as a monomethanolate. While the above compositions seem to suggest a pentacoordinate structure, the reflectance spectra on solid samples, which are shown in Fig. 1 and Table 3, are very similar to those of bis(pentane-2,4-dionato)-cobalt(II) dihydrate or tetrameric anhydrous bis-(pentane-2,4-dionato)cobalt(II), both being known to

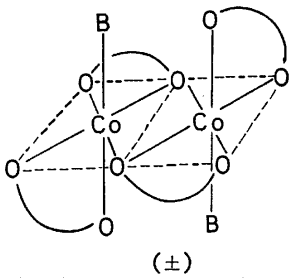
be octahedral hexacoordinate.[2,10] In the wave number range higher than 8.3 kK, two peaks can be observed at about 20 and 8.3 kK, which are assignable to the transitions of $^4T_{1g}(P) \leftarrow {}^4T_{1g}(F)$ and $^4T_{2g}(F) \leftarrow {}^4T_{1g}(F)$ respectively.[11]



(±)

Proposed dimeric structure on the mono-base adduct complexes of bis(1,5-dialkyl-pentane-2,4-dionato)cobalt-(II).

Thus, in order to satisfy these requirements, it is reasonable to assume that the chelates are of dimeric structure, in which two octahedral CoL_2B units are jointed together by two bridging oxygens as shown in the structure (I). This structure may be indirectly supported by the similar dimeric structure which has been assigned to bis(pentane-2,4-dionato)cobalt(II) monohydrate by the X-ray diffraction study.[12] We have also proposed the similar structure for bis(1,5-dialkyl-pentane-2,4-dionato)nickel(II) monohydrate.[8]

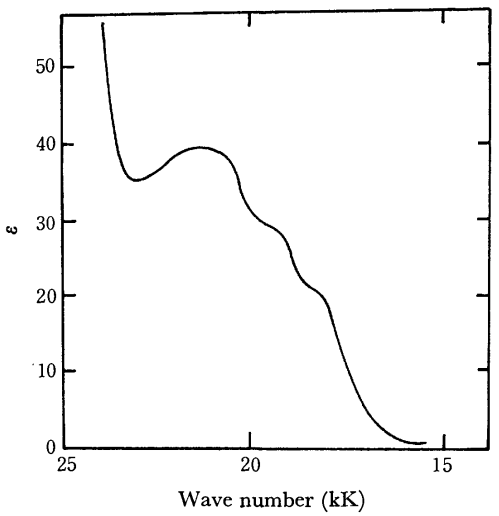


Fig. 2. The pyridine solution spectrum of the $Co(DNPM)_2 \cdot H_2O$ at room temperature.

The blood-red cobalt(II) chelates could dissolve easily into pyridine affording a pink solution. The absorption peaks of the cobalt(II) chelates in pyridine are summarized in Table 3. A typical example is shown in Fig. 2, in which three absorption peaks are observed at 21.1, 19.5, and 18.5 kK respectively, and the spectrum can be referred to an octahedral cobalt-(II) chelate.[10,11,13] Accordingly, the dimeric chelate must be cleaved therein to afford the monomeric octahedral *trans* bis-pyridine adducts.[13,14]

It has been known that the alkyl substitution on the 3-carbon of pentane-2,4-dione leads to the metal complex being a weaker Lewis acid,[15,16] and a similar effect may also be expected on the 1,5-dialkyl substitution on pentane-2,4-dione. The decrease in the acidity of CoL_2 unit may weaken the axial ligation by a base such as pyridine. Resulting elongation of the bond along z-axis leads to lowering the symmetry of octahedral pyridine adducts, and eventually to increase the absorption intensity. There may also operate the steric interaction between pyridine molecule and cobalt-(II) chelate. In our previous paper on the copper(II) complexes of 1,5-dialkyl-pentane-2,4-diones, we proposed that the terminal alkyl groups extended above or below of the xy-plane of copper(II) chelates.[17] If it is also true in this case, the elongation of the bond along z-axis may be more pronounced on the chelates with more bulky alkyl substituents. Thus, the combined inductive and steric effects of alkyl substituents may be responsible for the increase of the absorption intensity. The fact that the extent of increase in molar absorptivity is parallel to the bulkiness of alkyl substituents, positively favors our proposal.

On the other hand, absorption spectra of the present

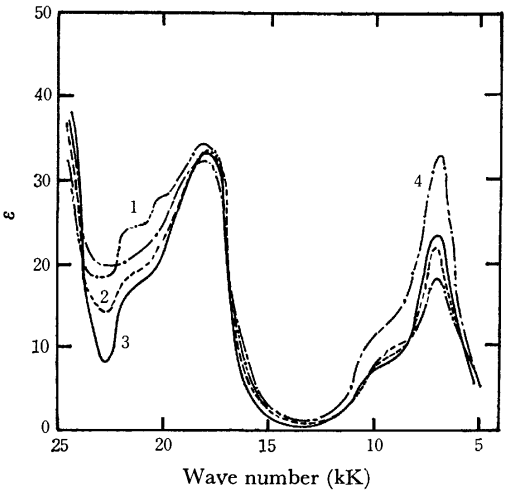

Fig. 3. The absorption spectra of $Co(DNPM)_2 \cdot H_2O$ in chloroform:
(1): 0.02 M, (2): 0.01 M, (3): 0.005 M (14°C), (4): 0.02 M (46°C).

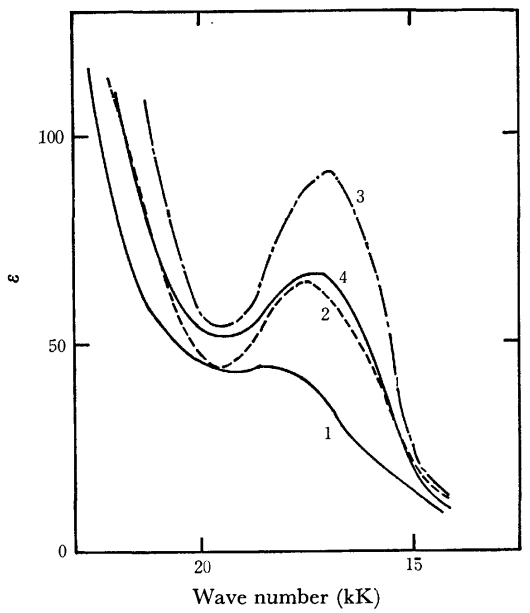

Fig. 4. The absorption spectra of coblat(II) chelates in toluene, measured at 24 hr after dissolution:
(1): $Co(DNPM)_2 \cdot H_2O$, (2): $Co(DNBM)_2 \cdot H_2O$, (3): $Co(DIVM)_2 \cdot CH_3OH$, (4): $Co(DNCM)_2 \cdot CH_3OH$. Absorption coefficient was evaluated from the above structures.

complexes in non-donating solvents are quite different from the reflectance spectra of solid samples or the absorption spectra of pyridine solutions. As an example, Fig. 3 shows the absorption spectra of $Co(DNPM)_2 \cdot H_2O$ in chloroform in a range of concentration and of temperature. The spectral characteristics in dilute solution are very much similar to that of $Co(DPVM)_2$, which is known as a monomeric tetrahedral complex.[4] Two absorption peaks at 18.0 and 7.0 kK may be assigned to $^4T_1(P) \leftarrow {}^4A_2$ and $^4T_1(F) \leftarrow {}^4A_2$ transitions, respectively.[18] These spectral features due to a tetrahedral structure are enhanced with decreasing the chelate concentration and with elevating temperature.

It is clear, therefore, that the dimeric 1:1 base adduct dissociates into a corresponding monomeric tetrahedral cobalt(II) complex and a free base in equilibrium in a chloroform solution as shown in Eq. (1).

$$[CoL_2 \cdot B]_2 \rightleftarrows 2[CoL_2] + 2B \qquad (1)$$

As expected, the bulkiness of the alkyl substituents on the ligands seems to favor the abundance of the monomeric form in the equilibria in solution phases. However, no quantitative study was undertaken owing to an undesirable oxidative side reaction, which will be described below.

Finally, the solutions of the present complexes in non-donating solvents gradually change their color from red-pink to green. Figure 4 shows the absorption spectra of such solutions measured at 24 hr after dissolution in toluene. It is interesting to note that the rate of the color change is parallel to the bulkiness of the alkyl substituents on the ligands. Thus, after 24 hr, the solution of $Co(DIVM)_2 \cdot CH_3OH$ is of an intense green color, while that of $Co(DNPM)_2 \cdot H_2O$ still remains in a pale-pink color. However, after one week standing at room temperature, the solution of cobalt(II) chelates changed to green color completely and their spectra were superimposable to those of the corresponding cobalt(III) chelates which were synthesized in separate routes. The spectral data of the cobalt(III) chelates are summarized in Table 4. Accordingly, these cobalt(II) chelates were oxidized spontaneously to cobalt(III) chelates, and the relative easiness of oxidation was again in parallel with the bulkiness of the alkyl substituents. As the oxidation proceeded even in the atmosphere of nitrogen, some redox reaction must have occurred in this system. However, further detailed investigation was not undertaken to elucidate the reaction mechanism.

Table 4. Spectral characteristics of cobalt(III) chelates in visible and ultraviolet regions

Chelate	Peak (kK) and molar absorptivity (mol^{-1} l cm^{-1}) in visible region (in carbon tetrachloride)		in ultraviolet region (in cyclohexane)			
$Co(AA)_3$	16.7	(144)	—	—	—	—
$Co(DNPM)_3$	16.8	(152)	38.4	(35500)	43.5	(40000)
$Co(DNBM)_3$	16.9	(157)	38.2	(35500)	43.2	(39500)
$Co(DIBM)_3$	16.9	(176)	38.0	(37500)	43.2	(43000)
$Co(DIVM)_3$	16.9	(153)	37.9	(37500)	43.1	(42000)
$Co(DPVM)_3$	17.0	(182)	37.9	(39000)	43.1	(43500)
$Co(DNCM)_3$	16.9	(158)	38.0	(36000)	43.1	(39000)

Absorption peaks of the cobalt(III) chelates, as shown in Table 4, shift slightly to higher energy side with increasing bulkiness of the alkyl substituents, probably due to the increased basicity of the ligands.

Ultraviolet Absorption Spectra. Tetrameric octahedral bis(pentane-2,4-dionato)cobalt(II) is known to dissociate to form a monomeric tetrahedral complex in non-donating solvents,[3] showing a single absorption peak at 292 nm in a diluted chloroform solution, for example.[19] On the other hand, the octahedral mono-

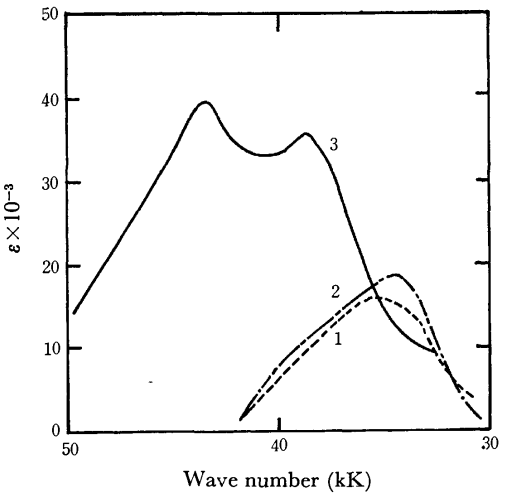

Fig. 5. Typical UV absorption spectra of cobalt(II) and -(III) chelates:
(1): $Co(DNPM)_2 \cdot H_2O$ in methanol, (2): $Co(DNPM)_2 \cdot H_2O$ in cyclohexane, (3): $Co(DNPM)_3$ in cyclohexane.

meric species of bis(pentane-2,4-dionato)cobalt(II), regardless of the kind of bases or donating solvents, always gave rise to an absorption peak at around 280 nm.

Concerning the present complexes also, as summarized in Fig. 5 and Table 5, the mono-solvent adducts shows a single absorption peak at 288—291 nm region upon dissolved in cyclohexane to a high dilution. Combined with the result of the visible spectral studies, these complexes are considered to exist as tetrahedral monomeric species in cyclohexane. On the other hand, the spectra of these complexes in methanol exhibit a single absorption peak at 282—283 nm region, which indicates the predominance of the solvent coordinated octahedral species, again being consistent with the visible spectral observations. Thus, in the ultraviolet absorption spectra of bis(pentane-2,4-dionato)cobalt-(II) and its analogues, such extent of difference in wave number may be utilized as a criterion in discriminating their coordination structures. The cobalt-(III) chelates, $Co(III)L_3$, show two UV absorption peaks in a much shorter wavelength region as shown in Table 4, and can be readily distinguished from those of the cobalt(II) chelates.

Infrared Absorption Spectra. A sharp, relatively strong ν_{OH} band is observed in a region of 3350—3360 cm^{-1} on each of the monohydrate complexes in nujol mull. The corresponding peak appears at a higher frequency region in non-donating solvents such as carbon tetrachloride or chloroform as summarized in Table 6. The ν_{OH} band shifts to a higher wave number region with the decreasing chelate concentration, approaching to that of free water molecule at 3710 cm^{-1}. This result suggests that the interaction between the coordinated water and the chelated cobalt(II) ion becomes weaker in non-donating solvents than in solid state, being in good agreement with the result of visible and ultraviolet spectral studies.

The monomethanol adducts show a ν_{OH} band at 3550—3540 cm^{-1}, appearing at a little lower wave number region than that of the free ν_{OH} band of primary alcohol (3640 cm^{-1}). The result again suggests the interaction between methanol and the chelated cobalt-(II) ion.

As stated previously, when the hydrated cobalt(II) chelates were recrystallized from methanol, DIVM and DNCM chelates came out as monomethanol adducts, while DNPM and DNBM chelates as monohydrates. Therefore, DIVM and DNCM chelates accept methanol as a second ligand in preference to

water. Although it seems contradictory that DIVM and DNCM chelates accepts a weaker base such as methanol in preference to a stronger base such as water, the result could be explained by the hydrophobic repulsion by non-polar alkyl substituents against polar water molecule, if one remind that DIVM and DNCM have more bulky alkyl substituents than those of DNPM and DNBM.

There is still remained to be elucidated a question why the alkyl substituents on the 1- and 5-positions of pentane-2,4-dione favors the formation of a dimeric form of the mono-solvent adduct in their cobalt(II) as well as nickel(II) complexes[8] rather than forming a mononuclear bis-adduct octahedral complex as observed in the parent pentane-2,4-dionates. However, this tendency may partly be ascribed to the mutual repulsion between solvent molecules and alkyl substituents, and partly to the increased basicity of coordinated carbonyl oxygen atoms which could eventually coordinate to the neighboring cobalt(II) or nickel(II) complex unit by forming the oxygen bridged binuclear complex.

Stable Paramagnetic Species in Natural Strontium Sulfate Crystals

Toshio MATSUZAKI, Morio SETAKA, V. V. GROMOV,* and Takao KWAN
Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo
(Received November 22, 1971)

Natural strontium sulfate crystals were found to show complex ESR spectra without any special irradiation. The spectra were classified into three groups, A, B, and C; the thermal and photochemical behavior of each group was distinguished from that of the others. It was proposed that Group B originates from SO_3^- radicals, and Groups A and C were tentatively interpreted as due to lattice defects (F-center and V-center).

γ-Irradiated single crystals of potassium sulfate have been reported to give rise to stable paramagnetic species at room temperature,[1,2] and their physical and chemical nature was the object of interest with regard to the mechanism of electron transfer in the crystal.[3]

Recently we have found that some *natural* strontium sulfate crystals contain stable paramagnetic species even without any special irradiation. In the present paper we shall report the ESR characteristics of these paramagnetic species, with special attention paid to their assignments as well as to their thermal and photochemical behavior.

Experimental

Material. The strontium sulfate samples, produced in the USSR were subjected to ESR investigations, the numbering and the localities of production are shown below.

No	Localities	No	Localities
2	Fergana	5	Central Russia
3	North Caucasus	6	South Caucasus
4	North Fergana	7	Turkmenistan

These $SrSO_4$ samples were seemingly crystalline and transparent to a certain extent, and all gave rise to complex ESR spectra at room temperature. Only the No. 4 sample was subjected to detailed investigations because of its less irregular form. The X-Ray analysis of the No. 4 sample has, in fact, shown that it is a twin crystal. An emmission spectro-chemical analysis of the sample showed that it contains some alkali and alkaline earth metals as impurities: (Mg(+), Ca(###), Ba(##), Na(−), K(+), and Rb(−)), where (−) indicates the absence of metals and (+), (##) and (###) the relative abundance.

Apparatus and Procedure. The ESR measurements were made at room temperature with a JEOL-P-10-type spectrometer, using a microwave frequency of the X-band with 100kHz field modulation. The ESR spectra were taken at every 5° rotation around the three principal axes of an orthogonate (X,Y,Z) of the crystal. The g-values were calculated by using a standard signal of manganese dispersed in MgO powder, which had previously been calibrated with a DPPH signal.

The effects of annealing and photoirradiation on the paramagnetic species were monitored by means of an ESR spectrum observable at the fixed position of the sample crystal. The sample was heated in an electric furnace for 30 minutes at every 50°C from room temperature up to 350°C. Photoirradiations of the sample were carried out by means of a low-pressure mercury lamp (Ushio Denki Co., 200 W). γ-Irradiations (5×10^5 rad/hr from ^{60}Co) were also performed, and the results were compared qualitatively with the results of the photoirradiations.

The parallel surfaces of the sample used made it possible to measure the UV absorption spectra ranging from 210 to 700 mμ, and also the thermal effects on the UV spectra.

Results and Discussion

A typical ESR spectrum for the *virgin* $SrSO_4$ sample (No. 4) fixed at a certain position in the microwave cavity is shown in Fig. 1. The spectrum appeared to be characterized by a number of resonance lines,

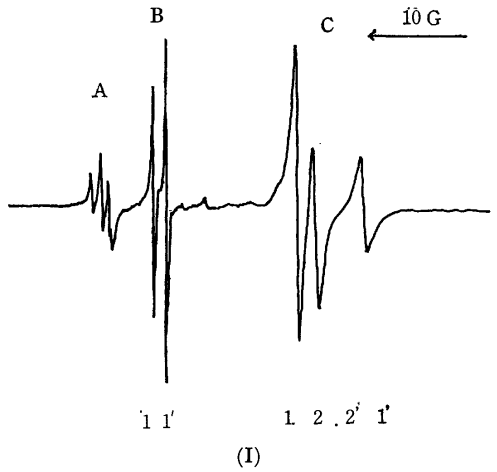

Fig. 1. A typical ESR spectrum of the natural $SrSO_4$ crystal.

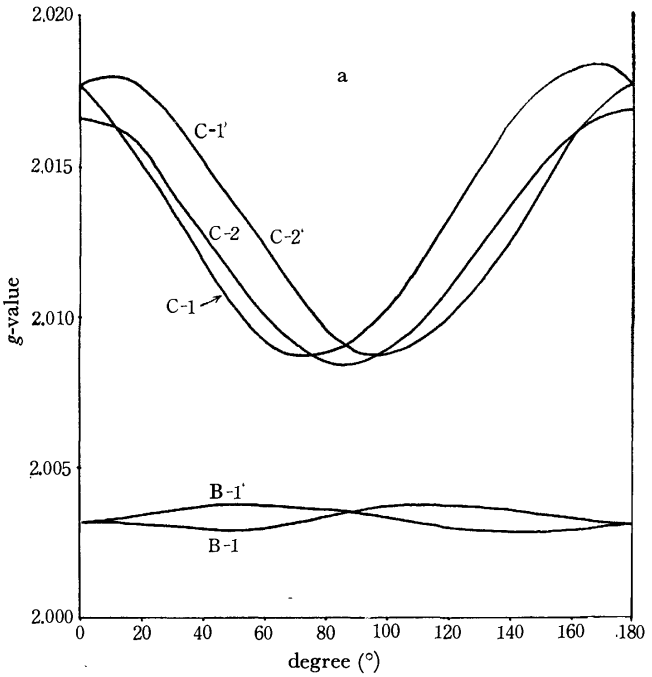
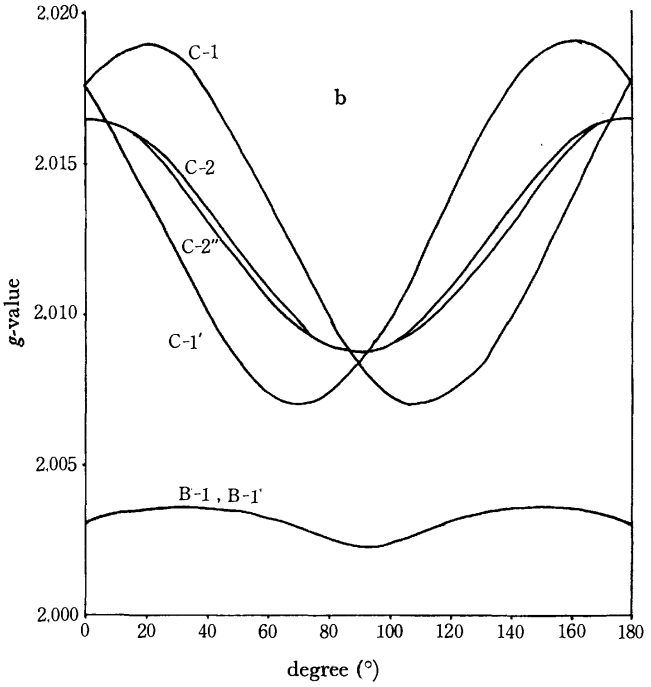
probably due to different paramagnetic species. However, the lines may be classified for convenience into three groups, A, B, and C, from the higher to the lower magnetic field respectively as is illustrated in Fig. 1.

Group A was usually a minor one in the spectrum. Group B consisted of two resonance lines of a similar shape (designated as B-1 and B-1′ respectively), and Group C, probably of four lines (C-1 and C-1′, C-2 and C-2′). Figures 2a, b, and c show, respectively, the changes in the g-factors of these spectral lines when the sample crystal was rotated around its three axes (X, Y, Z). The principal g-values, calculated from the g-factor dependence, are shown in Table 1.

TABLE 1

Signal	g_1	g_2	g_3
A		1.9965—2.0018	
B-1	2.0041	2.0033	2.0021
B-1′	2.0041	2.0033	2.0021
C-1	2.0194	2.0094	2.0064
C-1′	2.0192	2.0091	2.0069
C-2	2.0167	2.0090	2.0082
C-2′	2.0166	2.0090	2.0082





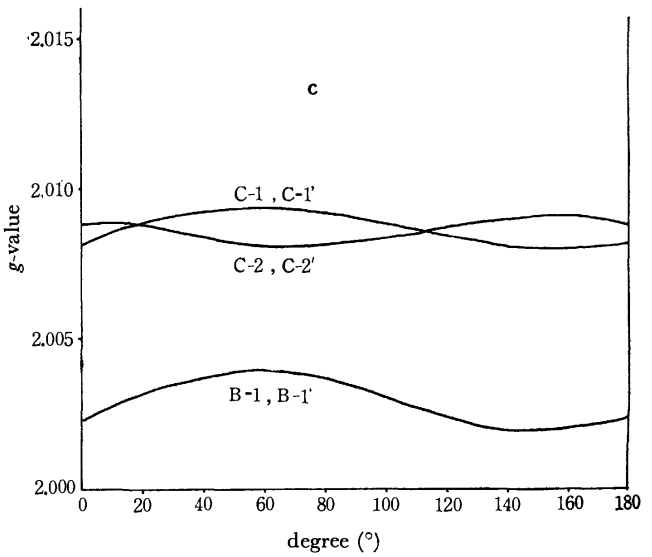


Fig. 2. a. b. c.
Angular dependence of g-factors of B and C signals around X, Y, and Z axes.

As is shown in Table 1, the principal g-values of the *paired* lines, such as B-1 and B-1′, C-1 and C-1′, and C-2 and C-2′, nearly coincided with each other, suggesting that the pair of signals is due to a common paramagnetic species and that the signals differ in their direction in the crystal in harmony with their twin characters, as revealed by X-ray analysis. The angular variation of the g-factor for Group A, consisting of several resonance lines, appeared to be rather complicated and did not permit us to derive any general trend. However, their g-values were all less than that

of a free spin (1.9965—2.0018).

We shall discuss the origin of each Group. First, the fact that the g-values of Group A were slightly less than that of a free spin suggests that Group A originates from electrons trapped at anion vacancies of F-centers rather than from hole defects in the $SrSO_4$ crystal; the g-values of F-centers in alkali halide crystals have been reported by many workers to be the results of negative g-shifts.[4] However, since g-values alone are not very informative, it is hard at present to identify the species corresponding to Group A without ambiguity.

The principal g-values of B-1 and B-1′ were isotropic and were close to that of a free spin (2.0041, 2.0033, 2.0021). It has already been reported by one of the present authors[1] that the γ-irradiated single crystals of K_2SO_4 give two kinds of ESR spectra; one is highly anisotropic, while the other is characterized by an almost isotropic g-tensor, with the principal g-values of 2.0033, 2.0033, and 2.0023. Accordingly, the two spectra were assigned to SO_4^- and SO_3^- respectively. Thus, on the basis of that report, the paramagnetic species corresponding to Group B are attributed to SO_3^- radicals rather than SO_4^- radicals.

The formation of O_3^- radicals has also been proposed for γ-irradiated single crystals of K_2SO_4.[5] The reported g-values (2.139, 2.0127, and 2.0102) for O_3^- radicals do not seem, however, to correspond to those of any Group. Also, the principal g-values for the SO_2^- produced in some ionic crystals have been reported to be 2.012, 2.0082, and 2.0037.[6] The g-values for our paramagnetic species are, again, distinguished from those of SO_2^-. Consequently, the origin of Group C seems to be associated with some lattice defects in the crystal rather than with sulfur- or oxygen-containing radicals.

The effects of thermal annealing on our paramagnetic species were investigated in order to support our assignments (Fig. 3). Group B was most stable on heating and did not decay until 350°C. Such a thermal stability has also been reported with SO_3^- in a γ-irradiated K_2SO_4 crystal;[3] this would support our assignment for the B signal.

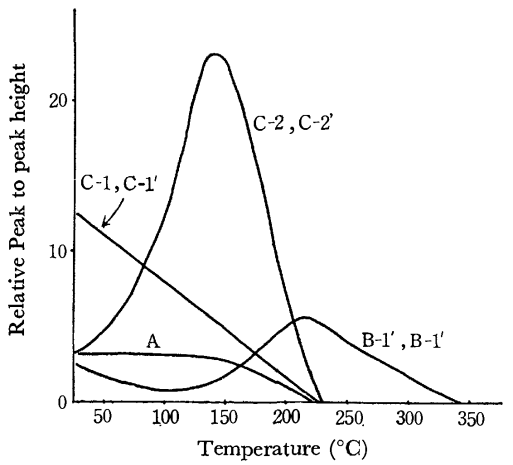

Fig. 3. Effects of thermal annealing on A, B, C signals.

Both the A and C groups were less stable on annealing; they nearly disappeared around the temperature of 200°C. However, it was rather surprising to note that the intensity of C-2 and C-2′ *increased* to a remarkable extent below 150°C, while the C-1 and C-1′ decreased monotonously within the temperature range studied. This phenomenon may suggest that the C-1 species can be distinguished from the C-2 species, even if the two species collapse at almost the same temperature. An inspection of the two annealing curves might lead one to presume that the C-1 paramagnetic center collapses upon heating by reaction with some other defects in the crystal, thus giving rise to another paramagnetic C-2 center.

As has already been mentioned, all the ESR signals (Fig. 1) disappeared completely when the crystal was heated to 350°C. However, some signals were restored upon UV irradiation. For example, when a highly-annealed sample, hence one showing no ESR signal, was irradiated with UV light at room temperature for less than 10 min, only the Group C signals were reproduced, while γ-irradiation for five hours showed a full recovery of all the signals, together with some additional signals. Thus, the C signal is considered to be quite sensitive to UV light as well as to heating as compared with the B singal.

UV absorption measurements of the sample crystal have shown that there exist two broad but distinct absorption bands around 250 and 550 mμ. In particular, the absorption band at 250 mμ was found to be unstable to heating; it disappeared completely at 200°C, quite in parallel with the ESR intensity of Group C upon annealing. All the results can be explained naturally if Group C is assumed to be associated with some labile crystal defects.

In recent years many types of color centers have been found, in particular in alkali halide crystals, and explained in terms of a variety of crystal defects. For example, the V- and F-centers in a potassium chloride crystal have been assumed to give two optical absorption bands[7] near the two wavelengths, 250 and 550 mμ, mentioned above with respect to our sample. Thus, the optical absorption at 250 mμ for the sample is likely to be associated with a color center such as a V-center, although further investigations will be required to confirm the assignments.

The authors are indebted to Professor Yoichi Iitaka for his X-ray analyses of the samples investigated in the present work. One of the authors (V.V.G) gratefully acknowledges the financial support from the Academy of Sciences of the USSR, which made it possbile for him to stay in Japan.

Chemical Behavior of Carbon in High-purity Silicon in the Dissolution and Fusion of the Matrix

Tadashi NOZAKI, Yoshihiro MAKIDE, Yoshifumi YATSURUGI,*
Yoshiyuki ENDO,* and Nobuyuki AKIYAMA*
The Institute of Physical and Chemical Research, Wako-shi, Saitama

(Received December 4, 1971)

The behavior of carbon in high-purity silicon in the dissolution and fusion of the matrix was studied by the ^{11}C-tracer technique. Silicon samples containing ^{11}C, either atomistically dispersed or mainly coagulated as SiC, were prepared. In alkali dissolution, no loss of ^{11}C was observed, and carbon originally dispersed in silicon was found to behave in a similar way to colloidal carbon under subsequent treatments. By $HF-HNO_3-KIO_4$ dissolution and succeeding $KMnO_4$ treatment, the dispersed carbon was oxidized almost quantitatively but the SiC coagulates were not completely decomposed. In alkali fusion a part of ^{11}C was lost. By fusion with $Pb_3O_4-B_2O_3$, carbon in both states was converted into CO_2. The results suggest a possible application of activation analysis to the measurement of the coagulation degree of carbon in high-purity silicon.

The behavior of a trace impurity element in the dissolution or fusion of a high-purity matrix has not yet been fully studied. We have examined the chemical behavior of carbon in semiconductor silicon in the decomposition of the matrix by means of radio-tracer technique. The results are given in this paper.

The following facts are known about carbon in silicon: (1) the solubility in solid silicon is slightly less than 3 ppm at the melting point, and carbon with a concentration above the solubility is coagulated as SiC;[1] (2) carbon is soluble up to 35 ppm in liquid silicon at the melting point, and in the solidification of carbon-saturated silicon slightly over 90% of the carbon coagulates into SiC;[1] (3) commercial semiconductor silicon usually contains from 30 ppb to 2 ppm of carbon;[1] and (4) carbon atoms dissolved in solid silicon occupy substitutionally the lattice points of the silicon crystal.[2]

As a radio-tracer, $^{11}C(\beta^+, T_{1/2}=20.3\text{ m})$ was used because it can be measured more easily and more precisely than ^{14}C by the scintillation counting of annihilation radiation. The excitation function and thick target yield for the $^{11}B(p,n)^{11}C$ reaction are known.[3,4] A sufficient activity of ^{11}C is easily produced by the proton bombardment of B_2O_3.

Experimental

Sample Preparation. The cyclotron at the Institute of Physical and Chemical Research was used for the proton bombardment, with the proton energy set at about 13 MeV. Three kinds of ^{11}C-containing samples were prepared by the following methods. (1) A silicon wafer doped with 50 to 100 ppm of boron was bombarded (a few μA beam, 20 min). After being left for 40 min for the ^{30}P formed by the $^{30}Si(p, n)^{30}P$ reaction to decay, the wafer was treated with a mixture of HF and HNO_3 to remove the surface contamination. (2) A B_2O_3 target was placed in a glass vessel with an aluminum foil window and bombarded with protons (about 10 μA beam, several minutes). A noticeable portion of the ^{11}C was evolved from the target as oxides and carried with a helium stream to the next room, where it was caught in a liquid-nitrogen trap after being passed through a dry-ice trap. About 50 mCi of carrier-free $^{11}CO_2$ was thus collected. A portion (about 1 g) of a semiconductor silicon rod, 1 cm in diameter and 5 cm long, sustained in an evacuated quartz tube was fused by radio-frequency heating, and the $^{11}CO_2$ was introduced into the tube. After being kept molten for a few minutes, the silicon was left to cool, and its surface layer was removed by etching. The silicon sample thus obtained contained a millicurie level of ^{11}C. (3) The process was similar to that in (2), but the silicon melt was brought into contact with a small amount of graphite powder or CO_2 gas.

The ^{11}C atoms in the sample prepared by Method (1) can occupy a higher-energy site in the silicon crystal since it has received the nuclear recoil energy in its nascent stage. Samples obtained from (1) and (2) contain the carbon homogeneously dispersed atomistically. The sample obtained from (3) contains coagulates of SiC. The carbon content of the samples prepared by each method was as follows: Method (1), 0.5—1 ppm; Method (2), 100—500 ppb; Method (3), 10—30 ppm of the coagulated carbon together with about 3 ppm of the dispersed carbon.

Dissolution and Fusion. The silicon matrix was decomposed by the following treatments: (a) dissolution in alkaline solutions, (b) dissolution in $HF-HNO_3$ solutions, (c) fusion with NaOH and $NaOH-NaNO_3$, and (d) fusion with $Pb_3O_4-B_2O_3$. About 0.5 g of the sample was used for each treatment. In most cases the products were treated with various reagents.

(a) The sample was pulverized and added to a NaOH solution (5 mol/*l*, 25 m*l*). When the dissolution reaction subsided, the mixture was gently heated to boil. Water was occasionally added to keep the volume of the solution almost constant. The sample was also subjected to a similar treatment with a NaOH solution (5 mol/*l*) containing $NaNO_3$ (2 mol/*l*), $KMnO_4$ (0.5 mol/*l*) or CrO_3 (0.5 mol/*l*) and with a Na_2O_2 solution (2.5 mol/*l*). In the absence of $KMnO_4$ or Na_2CrO_4, the silicon was dissolved within 30 min.

(b) The sample in small plates or blocks was added to a mixture of HF (46%, 15 m*l*) and HNO_3 (60%, 15 m*l*). The silicon was dissolved in 10 min with heat evolution. The $HF-HNO_3$ mixture containing KIO_4 (3 g) was also

used to accelerate dissolution.

(c) The sample was coarsely pulverized and added in small portions to NaOH (15 g) or a mixture of NaOH (10 g) and $NaNO_3$ (5 g) kept just above their melting points. Since the reaction was highly exothermic, the rate could not be controlled.

(d) A mixture of the pulverized sample, Pb_3O_4 (30 g) and B_2O_3 (6 g) was put into a Vycor-glass tube, and heated under an oxygen stream by a town gas-oxygen flame, first gently and then violently. The fusion was completed within 5 min, leaving a pale yellow glassy matter with globules of metallic lead when cooled. The oxygen stream was led to an Ascarite column after being passed through an I_2O_5–H_2SO_4–SiO_2 column in order to confirm the quantitative recovery of the ^{11}C.

For acidification of the resulting alkaline solution, HCl (1:1), H_2SO_4 (1:2) or HNO_3 (1:1) was added, in about twice the stoichiometrical amount for the neutralization of the alkali used. The cake of the alkali fusion was treated with the acids diluted further twice. In some cases, $KMnO_4$ (3 g) or CrO_3 (3 g) was added to the mixture, which was then boiled for 5 min. For collection of the suspending colloidal particles in the solution, fine powder (50 mg) of quartz or charcoal was stirred into the solution and precipitated with the particles by centrifugation. For dissolution of the precipitated hydrated silicon oxide, HF (46%, 5 m*l*) was added to the mixture.

Radioactivity Measurement. Annihilation radiation from the sample was measured by a scintillation counter with a single channel analyzer. In order to confirm the radiochemical purity of the original samples, the γ-ray spectrum and decay curve were measured; no radio-nuclide other than ^{11}C was found. Before and after each treatment, the radioactivity of the sample was measured from outside the vessel. Care was taken to keep the counting efficiency constant.

Since the original silicon contained a high-level activity of ^{11}C, the sample was placed at least 30 cm apart from the scintillator, thus making the counting efficiency almost insensitive to a small variation in the sample position. When the sample lost most of its ^{11}C activity, it was placed close to the scintillator, and the efficiency was calibrated by a resin-covered ^{22}Na standard source inserted in the center of a non-radioactive replica of the sample. In order to stop the positrons completely and to make the self-absorption constant, the silicon sample before the dissolution or fusion was sandwiched between polystyrene or iron plates with such a thickness as to give almost the same absorption as the self-absorption in the sample after the treatment. The effect of volume change caused by the addition of acid was corrected by insertion of a polystyrene plate beneath the sample in the measurement before the addition.

Results and Discussion

The results for the silicon sample containing only the atomistically dispersed carbon are given in Fig. 1. No significant difference in the behavior of ^{11}C was observed between the samples prepared by Methods (1) and (2).

In the alkali dissolution, no loss of ^{11}C was observed and the behavior of ^{11}C was not affected by the addition of $NaNO_3$ or Na_2O_2. In the presence of $KMnO_4$ or K_2CrO_4 the dissolution did not proceed smoothly, probably because the silicon surface was covered with oxides of manganese or chromium. We see from

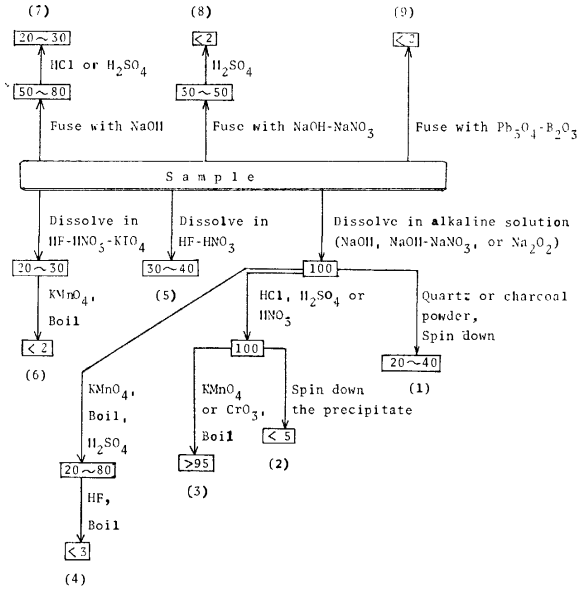

Fig. 1. Behavior of homogeneously dispersed carbon. Fraction of ^{11}C remaining in the reaction mixture (%). Figures in the parentheses are the treatment number in the text.

Treatments 1, 2, and 3 (Fig. 1) that the carbon in the alkaline solution was not dissolved as carbonate or any other soluble compound but turned into colloidal particles. The solution contained Na_2CO_3 in a quantity sufficient for a carrier of $^{11}CO_3^{2-}$. In order to examine whether CO_2 was evolved quantitatively by acidification of the solution, a solution containing $Na_2{}^{11}CO_3$ and Na_4SiO_4 was prepared and acidified; the evolution was almost quantitative, although a small fraction (less than 10%) of ^{11}C sometimes remained even after the solution was boiled. The results of Treatments 2 and 3 suggest that the carbon was held in the precipitate of hydrated silicon oxide formed by the acidification of the alkaline silicate solution. In Treatment 4 (Fig. 1), the fraction of ^{11}C remaining after the addition of H_2SO_4 varied remarkably depending mainly on the stirring efficiency and other conditions at the moment of addition. When the boiling in Treatment 4 before the acidification was prolonged, no noticeable difference in the remaining fraction of ^{11}C was found. It can thus be deduced that the oxidation of carbon by $KMnO_4$ was slow in the alkaline solution but made fast by the acidification, after which, however, hydrated silicon oxide soon precipitated embracing the carbon and thus preventing oxidation. When HF was added, the silicon oxide was dissolved and the carbon was rapidly oxidized. Treatment 6 (Fig. 1) also shows the effectiveness of the $KMnO_4$ oxidation in acid solution. The inefficiency of the oxidation in the alkaline solution might be due to the covering of the carbon suspension with hydroxides or carbonates of impurity elements in the reagents.

After the alkali fusion (Treatments 7 and 8, Fig. 1) the fraction of the ^{11}C remaining is found to depend markedly on the vigorousness of the fusion reaction—the more vigorous the reaction, the less the fraction remaining. The effect of $NaNO_3$ as oxidizing agent

was clearly observed in the alkali fusion.

Either by the dissolution in $HF-HNO_3-KIO_4$ and subsequent $KMnO_4$ treatment or by the $Pb_3O_4-B_2O_3$ fusion, the dispersed carbon was oxidized almost quantitatively. Thus either procedure could be used for the separation of ^{11}C in the activation analysis of carbon in silicon by means of the $^{12}C(^3He,\alpha)^{11}C$ reaction. A procedure for the activation analysis using Treatment 6 was given in detail.[5] In order to facilitate the complete oxidation of the carbon, however, it is recommended to use a larger quantity (10 g) of $KMnO_4$ than that given previously (1 g).[5] Treatment 9 (Fig. 1) was developed and has been used by Engelmann and co-workers.[6] From our experience in this treatment, a part of the carbon was likely to be incorporated in lead drops formed from Pb_3O_4 not being oxidized easily unless oxidation was completed rapidly. In our determination, we pulverize the sample, mix it with $Pb_3O_4-B_2O_3$ powder, and heat the mixture in a Vycor-glass tube with a town gas-oxygen flame.

The behavior of the coagulated carbon in the above two treatments are shown in Fig. 2. The sample contained also dispersed carbon. The entire carbon was decomposed by $Pb_3O_4-B_2O_3$ fusion. In the dissolution with $HF-HNO_3-KIO_4$ followed by treatment with $KMnO_4$, the decomposition of the coagulated carbon was incomplete. It is certain that the more perfect the crystal structure of the SiC coagulates, the less complete the decomposition into CO_2. In the activation analysis of carbon by the $^{12}C(^3He,\alpha)^{11}C$ reaction, a part of the ^{11}C formed in the coagulates is driven out of them by the nuclear recoil effect and converted into $^{11}CO_2$ by means of the $HF-HNO_3-KIO_4-KMnO_4$ treatment. Thus in this case, the fraction of ^{11}C converted depends also on the grain size of the coagulates.

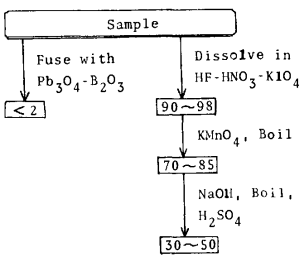

Fig. 2. Behavior of coagulated carbon.
Fraction of ^{11}C remaining in the reaction mixture (%).

TABLE 1. SENSIBILITY OF THE THREE METHODS FOR THE DIFFERENT PHYSICAL STATES OF CARBON IN SILICON

Method		Homogeneously dispersed carbon	Coagulated carbon
Activation analysis	$Pb_3O_4-B_2O_3$ fusion (or nondestructive)	+	+
	$HF-HNO_3-KIO_4-KMnO_4$ dissolution	+	±
Infrared spectrophotometry		+	−

The three methods for the determination of carbon in semiconductor silicon are given in Table 1. The nondestructive activation analysis (the first method) can be applied only to carbon-doped silicon. The fraction of the coagulated carbon determined as carbon by the second method is dependent on the state of the coagulates, namely, the grain size and the perfectness of the crystal structure. We have obtained the calibration curve for infrared spectrophotometry (the third method) using various semiconductor silicon samples analyzed for carbon by the activation analysis.

Therefore, by the use of all the three methods or two of them, it is now possible to get information on the physical state of carbon in silicon, though high accuracy is often needed in the determinations. Actually, when silicon samples of relatively high carbon contents were kept at 1300°C for many hours, the infrared-active carbon contents decreased gradually without any significant change in the results obtained by the second method.

We would like to express our thanks to members of the Cyclotron Operation Group of the Institute of Physical and Chemical Research for their help in the bombardment.

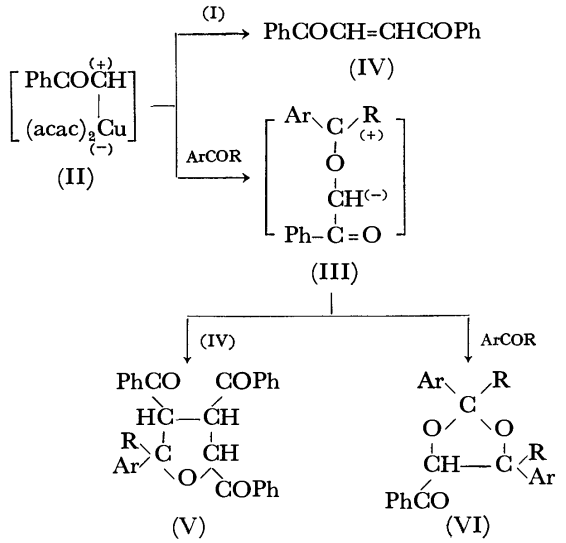
(Received January 17, 1972)

The copper chelate-catalyzed decomposition of *o*-methoxycarbonyl-α-diazoacetophenone was carried out in benzene. The reaction gave a dimer of a carbonyl ylide intermediate. The intermediate was trapped with dipolarophiles such as *trans*-dibenzoylethylene, ethyl fumarate, isoprene and dimethyl acetylenedicarboxylate, yielding 1,3-dipolar adducts in a stereospecific and stereoselective manner. Similar results were obtained in the catalytic decomposition of *o*-(*n*-butoxycarbonyl)-α-diazoacetophenone. The configuration of adducts and the mechanism of the reaction are discussed.

Carbonyl ylide has been reported as an intermediate in the cycloaddition of some oxiranes having electron attracting group-s to olefinic and acetylenic dipolarophiles.[2] The formation of carbonyl ylide is also expected in the reaction of carbene with carbonyl compound. However, very few example-s were found in the literature.[3] In a previous paper,[1a] we showed that the copper chelate catalyzed reaction of α-diazoacetophenone (I) with aromatic carbonyl compounds such as benzaldehyde and acetophenone gave the corresponding tetrahydrofurans (V) and dioxolanes (VI) accompanied by some by-products derived from benzoylcarbenes, and that the mechanism of the reaction could be explained by assuming a carbonyl ylide intermediate (III), produced by the reaction of a ketocarbene-copper chelate complex, copper carbenoid (II) with carbonyl compounds (Scheme 1).



Scheme 1.

This paper deals with the copper chelate-catalyzed decomposition of substituted α-diazoacetophenones having methoxycarbonyl group at *ortho*-position.

Results and Discussion

Catalytic Decomposition of o-*Methoxycarbonyl-α-diazoacetophenone (VII) in Benzene.* The bis(acetylacetonato)-copper-catalyzed decomposition of VII was carried out in benzene at 80°C under nitrogen. The reaction gave X as the principal product, which had a similar structure to that obtained by Zimmerman and Simkin[4] in the photochemical reaction of 2,3-epoxy-2-methyl-3-phenylindanone. The IR spectrum of X showed a streching vibration band of carbonyl group at 1712 cm^{-1} and an absorption band of newly formed ring-ether linkages at 1285 and 1260 cm^{-1}, and showed no carbonyl streching vibration band of ester group of the starting diazo compound. Ullman and Milks[5] have obtained an another type of dimer yielded by the 1,3-dipolar cycloaddition of benzopyrilium oxide to carbonyl group of indenone oxide in the thermal reaction of 2,3-diphenylindenone oxide. Ullman-type structure of our reaction product (X) may be ruled out by the absence of characteristic IR absorption bands of dioxolane[1a] in the region of 1100—1000 cm^{-1}. The failure of the isolation of indenone oxide (IXd) may support the structure Xa because Xb is the adduct of IXd and IXb.

Since none of the Wolff rearrangement products and formal dimers of *o*-methoxycarbonyl-benzoylcarbene were obtained during the reaction, one reasonable mechanism involves forming of a ketocarbene-copper chelate complex (VIII), a copper carbenoid, followed by the formation of a carbonyl ylide intermediate (IX), and a head-to-tail dimerization (Scheme 2).

This intermediate (IX) seems to be produced intramolecularly by electrophilic attack of carbenoid-carbon on carbonyl oxygen at *ortho*-position, contrary to the case of intermolecular reaction of a copper-carbenoid with methyl benzoate.[1a] Facilities for the formation of carbonyl ylide (IX) may be attributed to that the carbonyl group of *o*-substituent is close to the carbenoid

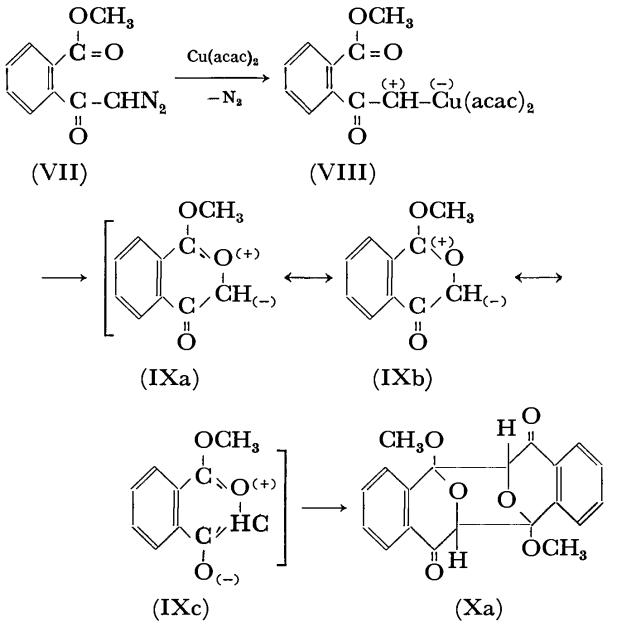
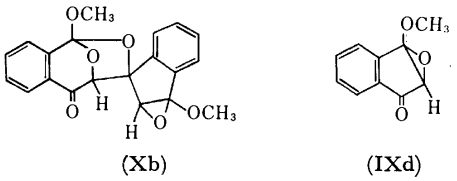
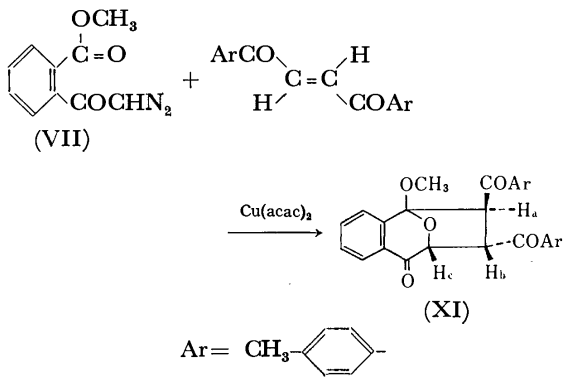


Scheme 2.



carbon atom (neighboring group participation), and that the newly created ring of IX is stabilized owing to the contribution of its canonical formula-e (IXa, IXb, and IXc). The contribution of IXc to the intermediate seems to be smaller than that of carbonyl ylide structure (IXa), because the color of the reaction mixture does not show the red color of benzopyrilium oxide,[5] but main-tain-s blue color of copper chelate during the reaction.

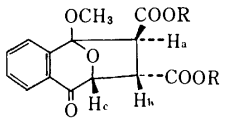
Reaction of o-Methoxycarbonyl-α-diazoacetophenone (VII) with Unsaturated Compounds. In order to investigate the reactivities of the carbonyl ylide toward dipolarophiles, the copper chelate-catalyzed decomposition of VII was carried out in the presence of unsaturated compounds. In the presence of *trans*-bis(*p*-methylbenzoyl)ethylene, the reaction gave an adduct (XI) in 75% yield. No cyclopropane derivatives, which would be formed by the reaction of the copper-carbenoid with the ethylenic compound, were recognized by the precise investigation of IR and NMR spectra of the reaction products. The coupling constants of NMR spectrum



of XI show that H_a and H_b seems to be oriented in *trans*-configuration judging from its small value of $J_{a,b}=2.0$ Hz, whereas H_b and H_c to be in *cis*-configuration ($J_{b,c}=6.0$ Hz) from the analogy to the stereochemistry fo pyrrolidine system.[6]

The results indicate that the addition of IX to the ethylenic compound may be stereospecific, and that the reaction may proceed through a concerted ($_\pi 4_s + _\pi 2_s$) type of cycloaddition according to the Woodward-Hoffman rule.[7]

In a similar manner, the dipolar intermediate (IX) was trapped with diethyl and dimethyl fumarates to give adducts, XII and XIII, in yields of 59 and 70%, respectively.

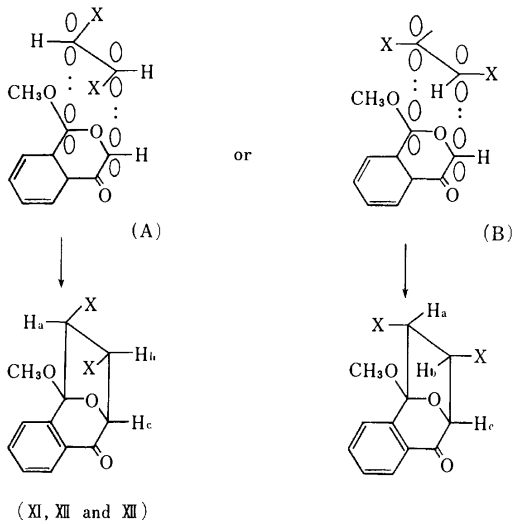


(XII) R: C_2H_5
(XIII) R: CH_3

The NMR spectra showed that the configurations concerning with H_a, H_b, and H_c of XII and XIII are quite same to that of XI.

Two kinds of transition states A and B, may be possible in the addition of IX to the ethylenic compounds (Scheme 3). The one (A) gives an adduct in which H_b and H_c are oriented in *cis*-configuration, whereas the other (B) leads to an adduct in which H_b and H_c are in *trans*-configuration. The fact that H_b and H_c of the adducts (XI, XII, and XIII) are oriented in *cis*-configuration indicates that the addition will take stereoselectively through A, owing to the overlapping of π-electrons of IX with those of acyl group of ethylenic compounds and/or to the repulsion of methoxy group of IX against acyl group of the ethylenic compounds.

The reaction of VII with dimethyl maleate seems to be remarkably slower than that with dimethyl fumarate,



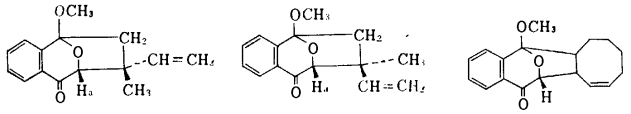
Scheme 3.

6) a) J. W. Lown and K. Matsumoto, *Can. J. Chem.*, **48**, 2215 (1970). b) R. Huisgen, W. Scheer, G. Szeimies, and H. Hube, *Tetrahedron Lett.*, 397 (1966).

7) R. B. Woodward and R. Hoffman, "The Conservation of Orbital Symmetry" Academic Press Inc, Weinheim (1970).

because the reaction of VII with a mixture of maleate and fumarate (99: 1), which contained almost equimolecular amount of dimethyl fumarate to VII, gave only an adduct (XIII) of IX to dimethyl fumarate in 70% yield. Dimethyl fumarate was found to be consumed completely during the reaction by the gas chromatographic analyses of recovered substrate.

In the presence of isoprene, two stereoisomeric adducts, XIV and XV, were obtained in yields of 34 and 43%, respectively. The NMR spectra show that the H_a of XV is deshielded by 0.14 ppm in comparison with that of XIV owing to π-electrons of the ethenyl group. The results indicate that the isoprene reacts with the carbonyl ylide (IX) by 1,2-addition to give XIV and XV. Cyclooctadiene-1,3 also reacted with IX to afford a 1: 1 adduct in a 18% yield, whose structure was assumed to be XVI by the similarity to the reaction with isoprene.

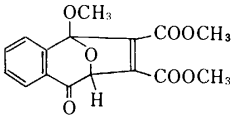


(XIV) (XV) (XVI)

Methyl acrylate, *trans*-methyl crotonate, crotonaldehyde, acrylonitrile, and crotononitrile gave also cycloaddition products in high yields (60—90%).[8]

However, *cis*- and *trans*-stilbenes, maleic anhydride, chalcone and norbornadiene gave no cycloaddition products, although the reason is not clear. In these cases, the dimer (X) was obtained in 40—50% yield.

In the presence of dimethyl acetylenedicarboxylate, the reaction gave XVII as an adduct in 70% yield.



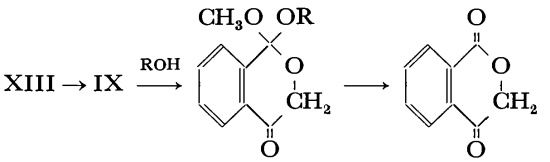
(XVII)

Similar results were obtained in the reaction of *o*-(*n*-butoxycarbonyl)-α-diazoacetophenone (VII′) as is shown in Table 1.

Table 1. Reaction of *o*-(*n*-butoxycarbonyl)-α-diazoacetophenone with dipolarophiles

Dipolarophile		Adduct Yield (%)	Adduct Mp (°C)
C_6H_5CO, H / C=C / H, COC_6H_5	(XI′)	92	91—92
$H_3COOC-C\equiv C-COOCH_3$	(XVII′)	80	oil

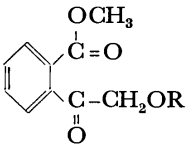
The Catalytic Decomposition of o-*Methoxycarbonyl-α-diazoacetophenone (VII) in Protic Solvents.* The copper chelate-catalyzed decompositions of VII were carried out in protic solvents such as ethyl alcohol and dioxane-water. The reaction gave isochromanedione-1,4 (XVIII) in yields of 40—50%, without any insertion products (XIX) of the ketocarbene to O–H bond of ethyl alcohol and water. The formation of XVIII



(XVIII)

Scheme 4.

gives another support to the intermediacy of carbonyl ylide (IX) as is shown in Scheme 4.



(XIX)

These results mentioned above suggest that the copper carbenoid (VIII) converts preferentially to give a carbonyl ylide intermediate (IX), followed by 1,3-dipolaraddition to unsaturated compounds.

Experimental

All melting and boiling points are uncorrected. The IR spectra were measured on a Hitachi Infrared Spectrometer, model EPI-S2. The NMR spectra were recorded at 60 Mc with a Varian Associates model A-60 Spectrometer, using tetramethylsilane as an internal standard.

Materials. o-*Alkoxycarbonyl-α-diazoacetophenones* were prepared starting from alkyl hydrogen phthalate according to the method of Hodson.[9]

o-*Methoxycarbonyl-α-diazoacetophenone*, mp 62.0—62.3°C. IR (KBr): 2200 (-N≡N), 1725 (ester C=O), 1605 (diazoketone C=O), 1370, and 740 cm^{-1} (Ph).

Found: C, 58.88; H, 3.89; N, 13.61%. Calcd for $C_{10}H_8O_3N_2$: C, 58.82; H, 3.95; N, 13.72%

o-(n-*Butoxycarbonyl*)-α-*diazoacetophenone*, oil, partially decomposes on standing at room temperature. IR (KBr); 2200 (-N≡N), 1725 (ester C=O), 1610 (diazoketone C=O), 1350, and 735 cm^{-1} (Ph).

Catalytic Decomposition of VII in Benzene. A solution of 2.0 g (0.01 mol) of VII and 0.05 g (1.9×10^{-4} mol) of $Cu(acac)_2$ in 50 m*l* of benzene was heated at 80°C under an atmosphere of nitrogen. The color of the reaction mixture turned dark-brown with an evolution of almost theoretical amount of nitrogen. After the reaction was over, the catalyst was separated by filtration and the solvent was removed by distillation. The residue was fractionated by silicagel chromatography (solvent: benzene) and a colorless crystalline product was obtained accompanied by a small amount of unknown solid. The structure of the crystalline product (X) was determined by elemental analyses and IR and NMR spectra after repeated crystallization from benzene-*n*-heptane, mp 233—235°C, yield 0.48 g (27%). IR (KBr): 1712 (ring C=O), 1285, 1260, 1237 (ring C=O and C–O–C), and 1052 cm^{-1} (C–O-CH_3)[10] NMR ($CDCl_3$): 1.7—2.7 (m, 8H, Ph), 5.08 (s, 1H, methyne-H), 5.62 (s, 1H, methyne-H), 6.30 (s, 3H, OCH_3), and 6.54 τ (s, 3H, OCH_3).

Found: C, 68.05; H, 4.32%. Calcd for $C_{20}H_{16}O_6$: C, 68.18; H, 4.58%.

8) The detail will be published elsewhere.

9) D. Hodson, G. Holt, and D. K. Wall, *J. Chem. Soc., C*, 971 (1970).

10) No absorption band of ester group was observed.

Reaction of VII and VII' with Ethylenic Compounds. A solution of VII or VII' (0.01 mol) in 50 ml of benzene was added dropwise to a solution of $Cu(acac)_2$ (1.9×10^{-4} mol) and an unsaturated compound (0.01 mol) in 100 ml of benzene on stirring at 80°C under the atmosphere of nitrogen. The reaction products were separated by silica gel chromatography and were identified by elemental analyses and IR and NMR spectroscopy.

In the reaction of VII with trans-*bis*(p-*methylbenzoyl*)*ethylene*, a white crystalline product (XI), mp 193.0—194.0°C, was obtained without any other detectable by-products, yield 3.50 g (83%). IR (KBr): 1710 (ring C=O), 1280, 1240 (ring C–O–C), 1065 (C–O-CH_3), 833, and 772 cm^{-1} (Ph). NMR ($CDCl_3$): 1.7—2.8 (m, 12H, Ph), 4.65 (d, 1H, Hc), 4.93 (d, 1H, Ha), 5.26 (dd, 1H, Hb), 6.32 (s, 3H, OCH_3), and 7.54 τ (s, 6H, CH_3). $J_{a,b}=2.0$ Hz, $J_{b,c}=6.0$ Hz.

Found: C, 76.53; H, 5.47%. Calcd for $C_{28}H_{24}O_5$: C, 76.35; H, 5.49%.

In the reaction of VII' with trans-*dibenzoylethylene*, a white crystalline adduct (XI'), mp 91.0—92.0°C, was isolated, yield 4.18 g (92%). IR (KBr): Nearly same to above concerning with characteristic bands. NMR ($CDCl_3$): 1.7—3.3 (m, 14H, Ph), 4.75 (d, 1H, Hc), 5.10 (d, 1H, Ha), 5.40 (dd, 1H, Hb), 6.0—6.25 (m, 2H, OCH_2), 8.0—9.0 (m, 4H, CH_2), and 9.10 τ (broad s, 3H, CH_3). $J_{a,b}=1.9$ Hz, $J_{b,c}=5.8$ Hz.

Found: C, 76.78; H, 5.76%. Calcd for $C_{29}H_{26}O_5$: C, 76.63; H, 5.77%.

In the reaction of VII with diethyl fumarate, an adduct (XII), mp 36.5—37.0°C, were obtained, yield 2.05 g (59%). NMR ($CDCl_3$): 1.7—3.0 (m, 4H, Ph), 5.20 (d, 1H, Hc), 5.73 (q, 2H, OCH_2), 6.02 (d, 1H, Ha), 6.12 (q, 2H, OCH_2), 6.40 (s, 3H, OCH_3), 6.52 (dd, 1H, Hb), 8.65 (t, 3H, CH_3), and 8.90 τ (t, 3H, CH_3). $J_{a,b}=1.8$ Hz, $J_{b,c}=5.8$ Hz. IR (KBr): 1735 (ester C=O), 1710 (ring C=O), 1288, 1232 (C–O–C), and 760 cm^{-1} (Ph).

Found: C, 61.76; H, 5.52%. Calcd for $C_{18}H_{20}O_7$: C, 62.06; H, 5.79%.

In the reaction of VII with dimethyl fumarate, a crystalline product (XIII), mp 110.5—111.0°C, was obtained, yield 2.25 g (70.3%). NMR ($CDCl_3$): 1.7—3.3 (m, 4H, Ph), 4.98 (d, 1H, Hc), 6.10 (d, 1H, Ha), 6.52 (dd, 1H, Hb), 6.20 (s, 3H, OCH_3), 6.40 (s, 3H, OCH_3), and 6.55 τ (s, 3H, OCH_3). $J_{a,b}=1.7$ Hz, $J_{b,c}=6.0$ Hz. IR (KBr): 1735 (ester C=O), 1710 (ring C=O), 1287, 1233 (ring C–O–C), 980, and 760 cm^{-1} (Ph).

Found: 59.86; H, 4.84%. Calcd for $C_{16}H_{18}O_7$: C, 60.00; H, 5.04%.

In the reaction of VII with isoprene, two kinds of liquid products (XIV and XV), were isolated in yields of 0.78 and 0.98 g (34 and 43%), respectively. IR (neat) of XIV: 1700 (C=O), 1635 (C=C), 1290 (ring C–O–C), 1050 (C–O-CH_3), and 765 cm^{-1} (Ph). NMR ($CDCl_3$) of XIV: 1.9—2.8 (m, 4H, Ph), 4.7—5.8 (m, 3H, CH=CH_2), 6.55 (s, 3H, OCH_3), 8.13 (s, 1H, methyne-H), 6.6—8.4 (m, 2H, CH_2), and 8.57 τ (s, 3H, CH_3).

Found: C, 73.41; H, 6.45%. Calcd for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%. IR (neat) of XV: The same above. NMR ($CDCl_3$) of XV: 1.9—2.8 (m, 4H, Ph), 4.7—5.8 (m, 3H, CH=CH_2), 6.55 (s, 3H, OCH_3), 8.32 (s, 1H, methyne-H), 6.6—8.4 (m, 2H, CH_2), and 8.55 τ (s, 3H, CH_3).

Found: C, 73.56; H, 6.35%. Calcd for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%.

In the reaction of VII with cyclooctadiene-1,3, a liquid product (XVI) and unidentified oil (XVI') were obtained in yields of 0.49 g (18.4%) and 0.16 g, respectively. IR (neat) of XVI: 1700 (ring C=O), 1300, 1250 (ring C–O–C), 1060 (C-OCH_3), and 770 cm^{-1} (Ph). NMR ($CDCl_3$) of XVI: 1.7—2.7 (m, 4H, Ph), 4.0—5.5 (m, 2H, CH=CH), 6.50 (s, 3H, OCH_3), and 6.6—9.3 τ (m, 11H, CH and CH_2).

Found: C, 75.87; H, 7.12%. Calcd for $C_{18}H_{20}O_3$: C, 76.03; H, 7.09%.

IR (neat) of XVI': 1700 (ring C=O), 1290, 1250 (ring C–O–C), 1060 (C-OCH_3), 770, and 740 cm^{-1} (Ph). NMR ($CDCl_3$) of XVI': 1.7—3.2 (m, 8H, Ph), 4.0—5.5 (m, contaminated with a trace of XVI), 6.55 (d, 6H, OCH_3), and 6.7—9.3 τ (m, 12H, CH and CH_2).

Reactions of VII and VII' with Acetylenic Compounds. The reactions were carried out in similar manner as described above.

In the reaction of VII with dimethyl acetylenedicarboxylate, a liquid product (XVII) was obtained, yield 2.11 g (70.3%). NMR ($CDCl_3$): 1.9—2.7 (m, 4H, Ph). 4.50 (s, 1H, methyne-H), singlets at 6.17, 6.30 and 6.47 τ (9H, OCH_3). IR (neat): 1725 (ester C=O), 1715 (ring C=O), 1660 (C=C), 1270 (ring C–O–C) and 760 cm^{-1} (Ph).

Found: C, 60.45; H, 4.31%. Calcd for $C_{16}H_{14}O_7$: C, 60.38; H, 4.43%.

In the reaction of VII' with dimethyl acetylenedicarboxylate, an oily product (XVII') was isolated, yield 2.99 g (80%). NMR ($CDCl_3$): 2.0—2.7 (m, 4H, Ph), 4.60 (s, 1H, methyne-H), 6.1—6.4 (q, 2H, OCH_2), 6.20 (s, 6H, OCH_3) and 8.1—9.15 τ (m, 7H, CH_2 and CH_3). IR (neat): 1725 (ester C=O), 1715 (ring C=O), 1660 (C=C), 1260 (ring C–O–C) and 760 cm^{-1} (Ph).

Catalytic Decomposition of VII in Protic Solvents. The catalytic decomposition of VII (2 g, 0.01 mol) in 150 ml of a mixed solvent of dioxane and water (5:1) was carried out as mentioned above. A white crystalline product (XVIII), 101.0—102.5°C, was obtained, yield 0.81 g (50%). IR (KBr): 1725 (ring C=O), 1280, 1140 (ring C–O–C) and 763 cm^{-1} (Ph). NMR ($CDCl_3$): 1.6—2.3 (m, 4H, Ph) and 4.90 τ (s, 2H, CH_2).

Found: C, 66.38; H, 3.51%. Calcd for $C_9H_6O_3$: C, 66.67; H, 3.73%.

The same product (XVIII) was isolated in the reaction in ethyl alcohol (yield; 0.72 g, 44%).

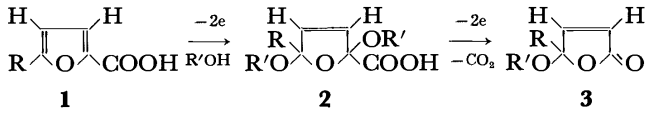
Anodic Reaction of 2-Furoic Acids. II. Electrolysis of Methyl 5-Acetyl-2-furoate and Its Homologous in Protic Solvents

Sigeru TORII, Hideo TANAKA, and Tsutomu OKAMOTO
Department of Industrial Chemistry, Okayama University, Okayama
(Received January 17, 1972)

Anodic oxidation of methyl 5-acetyl-2-furoate **4** in methanol leads to ring-opened diesters **8** and **9**, and lactone **10** in addition to methyl 5-acetyl-2,5-dimethoxy-2,5-dihydro-2-furoates **7**. Formation of **8**, **9**, and **10** can be rationalized as arising from **7**. On the other hand, oxidation of methyl 5-methoxy- and 5-bromo-2-furoates, **5** and **6**, also give **9** and **10**. The reactions involve initial production of cationic intermediates **13** and **15**, which are readily solvolized to give **8**, **9**, and **10**. A mechanism of the formation of the intermediates **13** from **5**, **6**, and **7** is discussed.

Recently a review[1] describing an anodic oxidation of 2-acetylfuran in methanol in the presence of sulfuric acid suggested that the corresponding 2,5-dimethoxy-2,5-dihydrofurans was isolated in low yield, but details on isolation and on structural assignment of the reaction products have not been described. Apparently little attention has been paid to the fate of the acetyl group attached to the furan ring under this oxidation conditions.

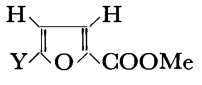
In the previous investigation on anodic oxidation of 5-alkyl-2-furoic acids in protic media,[2] we found that the oxidation of the furan ring and the carboxy group on the anode electrode proceeded stepwise as shown in the following scheme.



1 **2** **3**

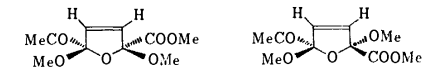
R=Alkyl R′=Me, Ac

Our interest in the anodic reaction of more complex 2-furoic acids led us to investigate the oxidation of methyl 5-acetyl-2-furoate **4**[3] and the related compounds **5** and **6** on the electrode. We wish here to report on studies concerning anodic reaction of **4**, **5**, and **6** as well as detail structures of the products.

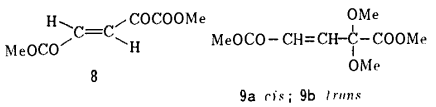


4 Y = MeCO
5 Y = MeO
6 Y = Br

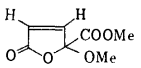
Thus, **4** was electrolyzed in methanol containing concentrated sulfuric acid and lithium perchlorate under constant current using two platinium foil electrodes. Details of the experimental conditions together with results are shown in Table 1. The products were generally a mixture of **7a**, **7b**, **8**, **9a**, and **10**, however in runs 1 and 2 the major product was **9a**. In the experiment 3 an increase of the formation of ketoester **8** and lactone **10** was found to be caused by addition of a small amount of water. In the earlier stage of the reaction as shown in run 4, prominent proportion of **7a** and **7b** among the constituents of the



7a **7b**



8 **9a** *cis*; **9b** *trans*

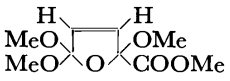


10

product was observed.

The results obtained in run 5 clearly showed that electrolysis of a mixture of **7a** and **7b** separated from the reaction products (run 4) gave **8**, **9**, and **10**, indicating that compounds **7a** and **7b** should be a precursor of the products.

Similar reaction fashions were observed (see Table 2) when methyl 5-bromo- and 5-methoxy-2-furoates, **5**[4] and **6**,[4] were electrolyzed in the almost same conditions as the cases of **4** and **7**, since oxidations of **5** and **6** gave principally **9** and **10**. Analytical specimen of these compounds were isolated by preparative vpc.



11

Electrolytic methoxydation of **6** has been attempted by several groups[5] and they assigned the incorrect structure **11** for the compounds **9**. They visualized the attack of methoxy group to the oxidized furan ring to yield trimethoxy derivative **11**, since anodic methoxydation of furan derivatives are known to afford 2,5-dimethoxy-2,5-dihydrofurans.[2,6] However, the

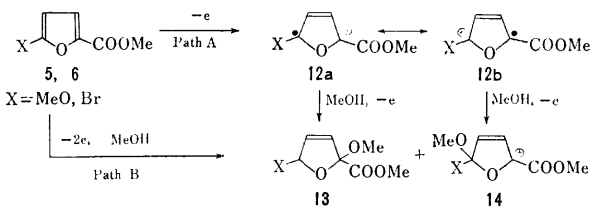
ring opened structures of **8**, **9a**, and **9b** are now distinctly established by NMR spectra as shown in Table 3.

The NMR spectra of **9a** and **9b** had singlet bands at τ 6.73 (6H) and 6.68 (6H), respectively, ascribable to geminal methoxy groups and two bands at τ 6.19—6.29 regions due to the protons (6H) attached to carbomethoxy groups. The structure of **11** instead of **9** should be rejected, since NMR signals due to the methoxy groups of **11** would be expected to be magnetically nonequivalent by the influence of the carbonyl group, being observed upon **19**,[2] but the signals at τ 6.73 can account for the above assignment. The isomer **9b** had a typical AB type signals at τ 3.22 and 3.62 (J_{AB}=15.7 Hz) due to *trans* olefinic protons, in well agreement with the pattern observed in **8**, whereas the *cis* isomer **9a** had a singlet band appearing at τ 3.93 (2H, olefin), in agreement with values observed in 2,5-dihydrofuran derivatives **7** and **19** in Table 3. The carbonyl absorption bands of **9a** and **9b** assigned to the ester groups contiguous to dimethyl acetal carbon atoms were observed at 1762—1763 cm^{-1}.

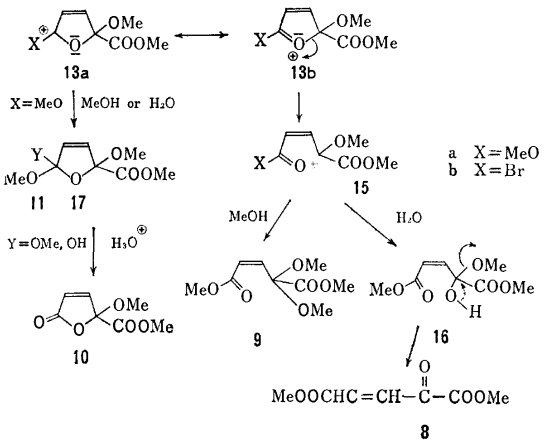
The structure of butenolide **10** was confirmed by its infrared spectrum; 1810, 1785, and 1766 cm^{-1} (unsaturated lactone and ester carbonyls), by its NMR spectrum; τ 2.72 (d, 1H), 3.65 (d, 1H), 6.14 (s, 3H), and 6.54 (s, 3H), and by its microanalyses.

A plausible mechanism for the transformation of **5** and **6** by the anodic oxidation to **9** and **10** *via* intermediates **13** or **14** are shown in Schemes 1, 2, and 3. In fact, the same two electron oxidation, which is considered to involve cation radical or dication intermediates (path A and path B), has been shown by the results from electrolyses of furans and furoic acids.[1,2,6b,7] As shown in Scheme 2, it is possible that the intermediates **13a** and **13b** would be subjected to solvolysis to give **9** and **10** *via* **11** and **15**. However, it must be noted that **13** (X=Br) does not give any appreciable amount of **10** in vpc. This reveals that the intermediate **15b** derived from **13** (X=Br) should be generated more readily in contrast to **15a** (X=MeO).

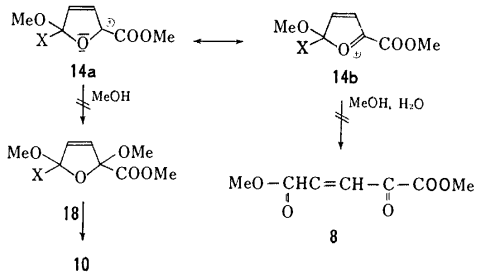
Most of our endeavour to isolate the key intermediates **11** and **17** failed. On the other hand, it must be mentioned that relatively high terminal voltage and presence of water were effective in producing **10**. The precise mechanism of the formation of **10** is not



Scheme 1



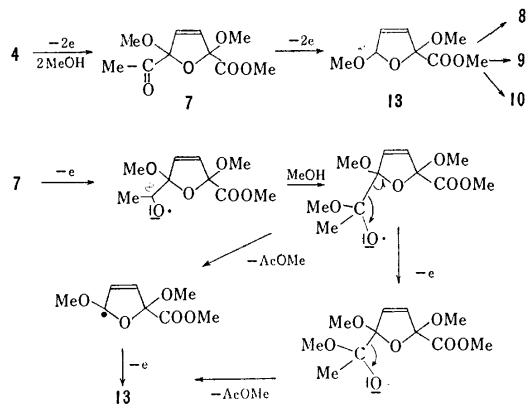
Scheme 2



Scheme 3

certain, but the most likely explanation for the formation of **10** is that it results from methanolysis or hydrolysis of **13a** *via* **17**, probably in an acid-catalyzed hydrolysis *in situ* or during after treatment.

As illustrated in Scheme 3, the intermediates **14a** and **14b** (X=Br), if formed, would be expected to afford **8**, **18**, and **10** by the attack of the solvents. The results from the experiments 9 and 10 shown in Table 2 suggest that the absence of **8** and **18** reveals a probability of the presence of **13** rather than **14**.



Scheme 4

In the course of the conversion of **7** to **8**, **9**, and **10**, the intermediate **13** is supposed to play an important role, but it is not easy to elucidate its behavior. A tentative mechanism of the conversion of **7** to **13** is depicted in Scheme 4. Any change could not be observed in its constituent on vpc, when a mixed solution of **7** in methanol in the presence of catalytic

7) S. Arita, Y. Takahashi, and K. Takeshita, *Kogyo Kagaku Zasshi*, **72**, 2289 (1969); K. Yoshida and T. Fueno, This Bulletin, **42**, 2411 (1969); C. K. Mann and K. K. Barnes, "Electrochemical Reactions in Nonaqueous Systems," Marcel Dekker, Inc., N. Y. (1970), p. 157.

amount of sulfuric acid was stirred for 5 hr without passing electric current. This demonstrates that removal of the acetyl group from **7** would be assisted by electrolysis, however, little is known of anodic oxidation on carbonyl function except for aroyl derivatives[8] and adduct of bisulfite.[9] Concerning the elimination of acetyl group from **7**, a further detailed mechanism could not be discussed on the basis of our present results.

The isomerization of the *cis* isomer **9a** to the *trans* **9b** occurred when the bromide **6** was electrolyzed. Addition of ammonium bromide to the runs 1 and 2 in Table 1 resulted in the production of **9b**. In both cases, liberation of bromine was encountered. This seems to implicate a catalyst of the **9a**→**9b** isomerization in the electrolytic media.

Experimental[10]

Ethyl 5-Acetyl-2-furoate **4**.[3] An improved method. To a solution of methyl 2-furoate (50.4 g, 0.4 mol) and acetic anhydride (20.4 g, 0.2 mol) in benzene (188 m*l*), anhydrous stannic chloride (104 g, 0.4 mol) was added at −5—0°C with stirring. The mixture was stirred for 7 hr at room temperature and then treated with 50 m*l* of 20% aqueous hydrochloric acid. The organic layer was extracted with benzene and the extract was shaken with aqueous sodium bicarbonate and aqueous sodium chloride. Distillation of the extract, after removal of the solvent, gave 13.3 g of oily material, bp 90—110°C (1 mmHg). The distillate was once dissolved in benzene and washed with aqueous sodium carbonate followed by aqueous sodium chloride. Evaporation of the solvent gave 10 g of crystalline **4** (yield 45%), mp 99—100°C from methanol (lit,[3] mp 101—102°C).

Anodic Oxidation of Methyl 5-Acetyl-2-furoate **4**. *Apparatus*: A cell used in this electrolysis is depicted in Fig. 1. The inside beaker (cathode compartment) fitted with a condenser, a cathode, a thermometer, a stirrer, and a drying tube was immersed in an anode vessel. The outside beaker (Anode compartment) fitted with an anode electrode, a thermometer, a stirrer, and a drying tube was immersed in a water bath. Electrodes were two platinium foils (1.5×2.0 cm^2). Current was controlled manually.

The reaction conditions and results are summarized in Table 1. A typical electrolysis procedure (Exp. 1) is indicated as follows: a solution of lithium perchlorate (6 g) in methanol (130 ml) containing 0.3 g of conc. sulfuric acid was poured into both the compartments. In the anode compartment, **4** (1.0 g) was charged and electrolyzed under a constant current of 0.5 A at 27—28°C for 5 hr with tirring. Then the electrolyzed solution in the anode compartment was

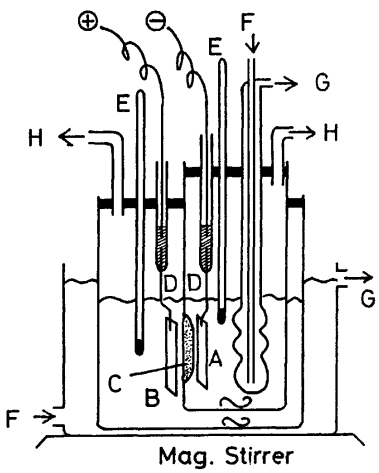


Fig. 1. Electrolysis cell. A: Cathode, B: Anode, C: Glass filter, D: Hg pool, E: Thermometer, F: Cooling water inlet, G: Cooling water outlet, H: $CaCl_2$ Tube

concentrated *in vacuo*. The residue was taken up in ether, and the solution was washed with aqueous sodium bicarbonate and sodium chloride, and dried over anhydrous sodium sulfate. Evaporation of the solvent gave 0.99 g of crude liquid product. The yield of the products was estimated by vpc and the results are listed in Tables 1 and 2. Isolation of main constituents was carried out by preparative vpc: **7a** (*cis*): n_D^{20} 1.4528, n_D^{25} 1.4511. 9) M. Oyama and M. Ohno, *ibid.*, **1966**, 5201.

10) All melting and boiling points are uncorrected. Preparative gas chromatography was accomplished with a partially modified Yanagimoto GCG-550T unit, using a column (4ϕ, 3 m long) packed with 10% SE-30 on Celite 545, 80—100 mesh, and H_2 (20 m*l*/min) as a carrier gas at 140°C. The retention times of the products are shown in Table 4. Infrared spectra were determined by a Hitachi EPI-S2 spectrophotometer. NMR spectra were obtained on a Japan Electron Optics Laboratory spectrometer (JNM-C-60) in deuterochloroform with TMS as an internal reference. Microanalyses were carried out by Miss M. Harada of this Laboratory.

in the manner described previously. Vpc analysis of the product showed the presence of **7a**, **7b**, **8**, **9a**, and **10** (Table 1). Structural assignment of each constituents were performed by comparing their IR spectra with those of the corresponding authentic compounds.

Methyl 5-Bromo-2-furoate ***6***. Methyl 5-bromo-2-furoate **6** was prepared by the method of Amstutz *et al.*,[4d] mp 63—65°C from methanol (lit,[4c] mp 62.5—63.5°C).

Methyl 5-methoxy-2-furoate ***5***. To a solution of sodium (2 g, 0.087 atom) and sodium iodide (0.1 g) in 100 m*l* of absolute methanol, **6** (7.2 g, 0.035 mol) was added. After refluxing for 4 hr the solvent was removed under diminished pressure. The residue was dissolved in ether and washed with aqueous sodium chloride. Evaporation of the solvent followed by distillation gave 2.5 g of methyl 5-methoxy-2-furoate **5**: bp 78—79°C (1 mmHg) (yield 41%), mp 51—52°C from *n*-hexane (lit,[4c] mp 51—53°C).

Anodic oxidation of methyl 5-bromo-2-furoate ***6***. Electrolysis was carried out in the same manner described previously.[2] The reaction conditions along with the results are listed in Table 2. The reaction mixture was neutralyzed with methanolic sodium methoxide (Na 0.2 g/MeOH 20 m*l*). After evaporation of the solvent *in vacuo*, the residue was treated in the usual manner to give 0.9 g of crude oil whose constituents were analyzed by vpc and the results are shown in Tables 2 and 4. IR and NMR spectra of **9a** were identical with those of the specimen obtained by the above paragraph. Physical data of **9b** are as follows: n_D^{20} 1.4532, n_D^{25} 1.4513. IR (liq. film) 3000 (=C–H), 1762, 1732 (ester C=O), 1663 (C=C), 1440, 1310, 1260, 1170, 1090, 1050, 1013, 980, 942, 930, 910, 866, and 808 cm^{-1}. NMR (see Table 3).

Found: C, 49.80; H, 6.57%. Calcd for $C_9H_{14}O_6$: C, 49.54; H, 6.47%.

Electrolysis of Methyl 5-Methoxy-2-furoate ***5***. A solution of **5** (1.0 g) in methanol (30 m*l*) containing conc. sulfuric acid (0.1 g) was electrolyzed in the manner described in preceding paragraph (Table 2). Structural assignment of the products was carried out by vpc analyses and in comparison of their IR spectrum with that of the corresponding authentic specimen.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2787—2790 (1972)

Reaction of Vinylic Radicals with Oxygen[1]

Naoto WADA and Katsumi TOKUMARU[2]

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo, 113

(Received January 11, 1972)

Thermal decomposition of *trans*-α-phenylcinnamoyl peroxide and *t*-butyl *trans*- and *cis*-α-phenylperoxycinnamates and photolyses of 1,1-diphenyl-2-iodoethylene and 1,1,2-triphenyl-2-iodoethylene were carried out in benzene under oxygen and their products were determined. The intermediate vinylic radicals, on reaction with oxygen, undergo oxidative cleavage and dioxygenation of their unsaturated bonds. As an example, 1,2-diphenylvinyl radicals give benzaldehyde together with benzoin.

Much effort has been made to investigate the reaction of alkyl radicals with oxygen and to elucidate the products and reaction mechanism.[3] Aryl radicals have also been shown to react with oxygen giving phenolic products, though a detailed mechanism is not yet fully understood.[4] The reaction of vinylic radicals with oxygen has not been investigated much but one of us showed that *trans*-cinnamoyl peroxide and α-methylcinnamoyl peroxide, on thermal and photochemical decomposition in benzene or carbon tetrachloride under oxygen, gave benzaldehyde together with benzoic acid among the products through the oxidative cleavage of the intermediate styryl or 1-methyl-2-phenylvinyl radicals with oxygen as shown below.[5]

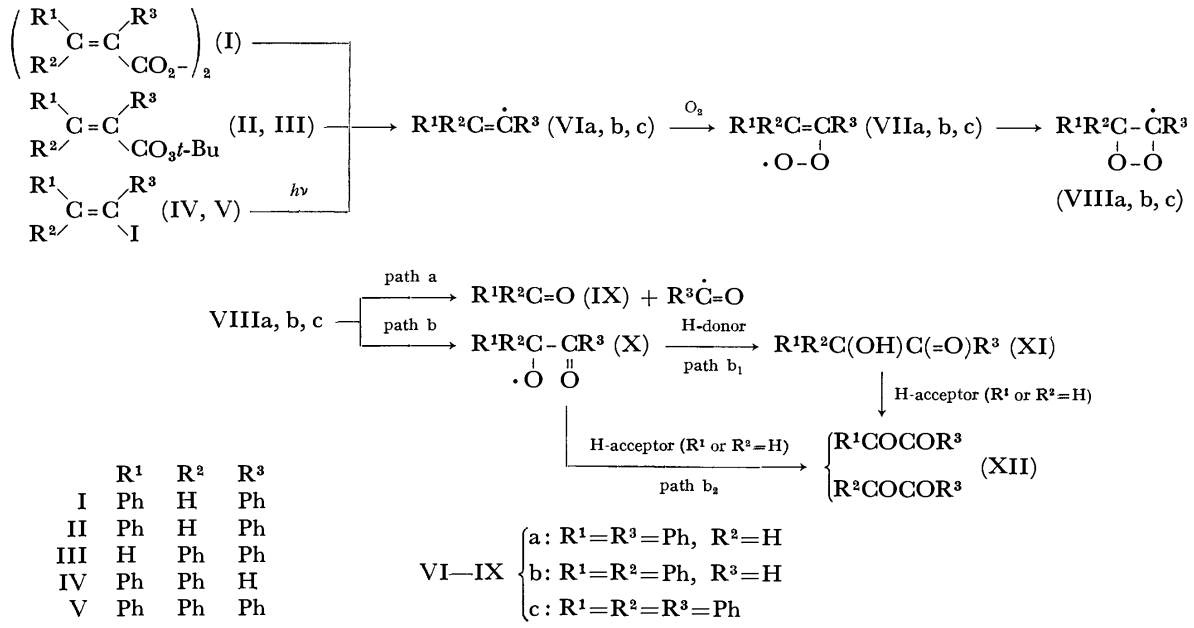
a) Initial concentration: 0.03—0.05M. b) *t*: *trans*; *c*: *cis*; n.d.: detected but not determined. c) Reaction conditions show method of decomposition, temperature and atmosphere. T: thermal decomposition; P: photolysis with a low pressure (160 W) mercury lamp.



Scheme 1.

cis-α-phenylperoxycinnamate (III) carried out under oxygen in benzene afforded benzaldehyde (12% or 19% from II or III, respectively) and benzil (15% or 19% from II or III, respectively). Benzoin (3%) and benzoic acid along with diphenylacetylene (15%) were also found among the products from II.

Irradiation of 1,1-diphenyl-2-iodoethylene (IV) or 1,1,2-triphenyl-2-iodoethylene (V) in benzene in a stream of oxygen at room temperature with a low pressure mercury lamp afforded benzophenone (54% and 34% from IV and V, respectively).

The results are summarized in the table. In view of the generation of 1,2-diphenylvinyl radicals from the peroxidic sources, I, II, and III,[6] and the formation of 1-propyl-1-butenyl radicals from the photolysis of 4-iodo-3-heptene,[7] formation of the oxidation products can be attributed to the reaction of the intermediate vinylic radicals with oxygen. This might proceed as in the following scheme.

6) N. Wada, K. Tokumaru, and O. Simamura, This Bulletin, **44**, 1112 (1971).

7) R. C. Neuman, Jr. and G. D. Holmes, *J. Org. Chem.*, **33**, 4317 (1968).

Vinylic radicals (VI) generated from suitable sources react with oxygen to afford vinylperoxy radicals (VII), which subsequently cyclize to give 2,3-dioxetanyl radicals (VIII).[5] These radicals are either decomposed into carbonyl compound (IX) and acyl radicals (path a), or converted into α-ketoalkoxy radicals (X) (path b), which abstract hydrogen atoms from the reaction medium to give α-ketoalcohol (XI) (path b_1) or lose hydrogen atoms to give α-diketone (XII) (path b_2). Path a proposed previously[5] is supported by the formation of benzaldehyde, benzoic acid or benzophenone. Path b is proposed herewith on the basis of the production of benzoin and benzil from the decomposition of I, II, and III under oxygen.

Production of benzil at the expense of benzoin from the peroxyesters II and III might be due to the high reactivity of *t*-butoxy radicals to abstract hydrogen atom from benzoin or from the α-ketoalkoxy radical (X). A low yield of deoxybenzoin (3%) from I seems to occur with no participation of oxygen, on taking account of its formation from I decomposed under nitrogen,[6] although its path is ambiguous at the present time. The absence of α-ketoalcohol among the products from the irradiation is undoubtedly attributable to its further labile photolysis into aroyl and α-hydroxyaralkyl radicals[8] followed by their reaction with oxygen:

$$ArRC(OH)C(=O)Ar \xrightarrow{h\nu} ArC\dot{O} + ArR\dot{C}OH$$

Postulation of 2,3-dioxetanyl radicals as an intermediate undergoing facile cleavage is supported by the recent findings on 1,2-dioxetane (XIII), which was actually prepared and shown to decompose readily into two carbonyl components.[9]

$$R^1R^2C(-O-O-)CR^3R^4\ (XIII) \longrightarrow R^1R^2CO + R^3R^4CO$$

($R^1=R^2=R^3=Me$, $R^4=H$;[9a] $R^1=R^3=OEt$, $R^2=R^4=H$;[9b] $R^1=R^2=R^3=R^4=OMe$[9c])

1-Oxa-2-azacyclobutene-2 (XIV) was also proposed to be an intermediate during the course of the reaction of unsubstituted vinyl radicals with nitric oxide in gas phase and facilely decompose into formaldehyde and hydrogen cyanide.[10]

$$H_2C=\dot{C}H + NO \longrightarrow H_2C=CH(-O-N=) \longrightarrow$$

$$H_2C(-O-)CH(-N=)\ (XIV) \longrightarrow H_2CO + HCN$$

Irradiation of IV in benzene under nitrogen afforded 1,1,4,4-tetraphenyl-1,3-butadiene (11%), 1,1-diphenylethylene (5%) and diphenylacetylene (trace). A large amount of the starting material was recovered. In contrast, in the irradiation of the same iodide in a slow stream of oxygen under the same conditions as above, no starting iodide was recovered and iodine was liberated in 78% yield. The results suggest that the presence of oxygen, by capturing the vinylic radicals, prevents their reactions with iodine atoms or with molecular iodine returning to the starting iodide.

$$Ph_2C=CHI\ (IV) \longrightarrow Ph_2C=\dot{C}H\ (VIb) + I\cdot$$

$$Ph_2C=\dot{C}H + O_2 \longrightarrow Ph_2C=CHOO\cdot \longrightarrow \text{Products}$$

$$Ph_2C=\dot{C}H + I\cdot\ (\text{or } I_2) \longrightarrow Ph_2C=CHI\ (\text{or } +I\cdot)$$

Formation of 1,1,4,4-tetraphenyl-1,3-butadiene might be due to either dimerization of the intermediate vinylic radicals (VIb) or addition of the radical (VIb) to IV followed by elimination of an iodine atom.

$$2Ph_2C=\dot{C}H \longrightarrow Ph_2C=CH-CH=CPh_2$$

$$Ph_2C=\dot{C}H\ (VIb) + Ph_2C=CHI\ (IV) \longrightarrow$$

$$Ph_2C=CH-\dot{C}HI-CPh_2 \longrightarrow Ph_2C=CH-CH=CPh_2 + I\cdot$$

It should be pointed out that the absence of the products which would result from the substitution of the vinylic radicals on benzene, *viz.*, 1,1,2-triphenylethylene from I, II, III, or IV, or 1,1,2,2-tetraphenylethylene from V, indicates a low reactivity of the vinylic radicals towards aromatic substitution, in contrast to aryl radicals, which also belong to sp^2-hybridized σ-radicals and effectively undergo aromatic substitution.[11]

Experimental

Materials. *trans*-α-Phenylcinnamoyl peroxide (I), *t*-butyl *trans*- (II) and *cis*-α-phenylperoxycinnamate (III) were prepared as described before.[6] 1,1-Diphenyl-2-iodoethylene (IV) and 1,1,2-triphenyl-2-iodoethylene (V) were prepared according to literature.[12,13]

Thermal Decomposition of I, II, and III under Oxygen. One to three grammes of I, II, or III in 300 ml of benzene was placed in a 300—500 m*l* three-necked round-bottomed flask fitted with a gas inlet tube, a stopper and a reflux condenser. The mixture was kept in a slow stream of oxygen in a thermostat at a specified temperature for 8—70 hr until the peroxide was completely decomposed.

Photolyses of IV and V under Oxygen or Nitrogen. About 1 g of IV or V was irradiated in 100 m*l* of benzene for 20—24 hr with an immersion-type 160 W low pressure mercury lamp in a slow stream of oxygen or nitrogen.

Product Analysis. Determination of iodine liberated from the irradiation run was carried out by titration of an aliquot of the reaction mixture with a standard sodium thiosulphate solution.

For determination of the organic products the reaction mixture was shaken with 5% aqueous sodium carbonate. However, the reaction mixture from the photolysis was shaken with 5% aqueous sodium thiosulphate to remove iodine prior to the extraction with the carbonate. The alkaline layer was acidified with 5% hydrochloric acid, shaken with ether to remove acids and the extract was treated with diazomethane and the resulting methyl benzoate or α-phenylcinnamate was determined by vpc using Ucon Oil as a liquid phase. The benzene layer was dried over anhydrous sodium sulphate, and benzene was distilled off. The residue was subjected to chromatography on alumina and vpc using silicon oil or Ucon Oil as a liquid phase.

The authors' thanks are due to Professor O. Simamura for his encouragement throughout this work.

The Nuclear Magnetic Resonance Study of Several *o*-Disubstituted Benzenes

Michio KONDO

Central Research Laboratories, Sankyo Co., Ltd., Hiromachi 1-chome, Shinagawa-ku, Tokyo

(Received November 10, 1971)

The nuclear magnetic resonance spectra of six *o*-disubstituted benzenes containing a carbonyl group have been analyzed. The chemical shifts of the proton-6, adjacent to the carbonyl group, show a solvent dependence, indicating changes in the intramolecular interactions between the two *ortho* substituents.

It is known that the protons adjacent to the substituents in *o*-disubstituted benzenes often have chemical shifts differing by more than 0.1 ppm from the values estimated from a simple additive rule.[1] Interactions between the two substituents adjacent to each other must be responsible for these discrepancies. In some cases, the interactions fix the orientation of either one or both of the substituents. Fixing the substituent with a large magnetic anisotropy at one orientation markedly affects the chemical shifts of the *ortho* protons. In acetanilide, for example, the chemical shifts of the *ortho* protons depend to a great extent on whether the rotation about the bond connecting the amide nitrogen with the aromatic carbon atom is free or restricted.[2] Acetanilides, which have a substituent at the 2-position capable of forming intramolecular hydrogen bonds with the amide proton, exhibit deshielding, to a great extent, of the aromatic proton at C_6.[2]

The fixed orientation of some substituents into the plane of the ring often induces rather large long-range couplings between the substituents and particular ring protons.[3]

In this paper, the author will show that a difference in the carbonyl orientation through the intramolecular hydrogen bonding is responsible for the large difference between the chemical shifts of the proton-6 in *N*-methyl salicylamide and *N*-methyl-*o*-methoxy benzamide. Furthermore, the chemical shifts of the ring proton-6 in these compounds are very similar in dimethyl sulfoxide, which is known as a powerful solvent for disrupting the intramolecular and intermolecular hydrogen bonds of solute molecules.[4,5]

Experimental

The acids and esters used were commercial products. The amides were prepared by reacting the corresponding esters with an equimolar amount of methylamine (40% aqueous solution) in methanol at room temperature for a week. The solvent, the non-reacted ester, and the amine were distilled out under reduced pressures. The *N*-methyl salicylamide was purified by recrystallization from cyclohexane; mp 87.5—88.0°C. The *N*-methyl-*o*-methoxy benzamide was purified by distillation under reduced pressure; bp 148—150°C/4 mmHg.

The NMR spectra were obtained on a Varian A-60D spectrometer. Tetramethylsilane was used as the internal standard. A scale expansion of the recorder chart of 2 Hz/cm was used for determining the ring-proton resonances. The relative positions among the ring-proton signals were read with an accuracy of ± 0.05 Hz. The simulation of the NMR spectra was carried out by means of an electronic computer, CDC 3600, using an iterative computer program, LAOCON 3.[6] With very few exceptions, all the peaks observed were in accord with the calculated peaks within 0.1 Hz.

Results and Discussion

The chemical shifts of the ring protons are summarized in Table 1. The chemical shifts reported for methyl salicylate in carbon tetrachloride[7] are almost uniformly located at fields higher by about 10 Hz than the present results. This is a general tendency when comparing the spectra of aromatic compounds dissolved in carbon tetrachloride and chloroform.

Dimethyl Sulfoxide Solutions. Interestingly, in dimethyl sulfoxide the chemical shifts of the ring protons at any given position are very similar for all the compounds studied. This is reasonable since, supposedly, the substituent variation in the present case has only a minor influence on the ring protons' electronic environment, provided that there are no special interactions between the two *ortho* substituents. In dimethyl sulfoxide, as is well known, the intermolecular interactions between solute and solvent molecules are preferred to intramolecular hydrogen bonds. Therefore, no special intramolecular interactions can be expected between the two substituents. Dimethyl sulfoxide molecules may interact with the hydroxyl or amide protons through the formation of intermolecular hydrogen bonds.[5] This kind of interaction shifts these resonances to lower fields. This expectation was actually realized (not listed in Table 1). The disruption of the intramolecular hydrogen bonds results in an increased freedom of movement of the substituents, probably a free rotation around the C_{ring}–CO bond, which would result in an averaing of the shielding effects of the carbonyl group on the ring proton-6. This may be the reason why the proton-6 chemical shift in all the compounds is nearly the same in dimethyl sulfoxide.

Consistent with this is the disruption of the intramolecular hydrogen bonds for methyl salicylate and other *ortho*-substituted phenols dissolved in dimethyl sulfoxide, as is suggested by the fact that the relative chemical shifts of OH in *ortho*-substituted phenols in dimethyl sulfoxide solutions are linearly-related to those for *para*-substituted phenols.[8]

Chloroform Solutions. In chloroform, on the other hand, the intramolecular interactions through hydrogen bonding may be expected to take place in some of the compounds studied, but not in others.

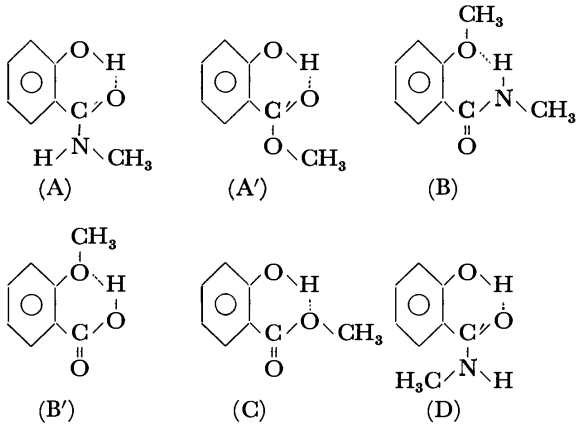
The proton chemical shifts of the compounds V, for which there is no possibility of intramolecular hydrogen bonding even in a chloroform solution, are very similar in both solvents, chloroform and dimethyl sulfoxide.

From the arguments given above, it appears that the chemical shift of the proton-6 is about 470 Hz from TMS when there are no special interactions between the two *ortho* substituents. From this point of view, the chemical shift of the ring proton-6 of *N*-methyl salicylamide in chloroform is considered to be strongly shielded. This suggests a certain interaction between the two substituents. The present author ascribes this remarkable shielding effect to the orientation fixing of the amide group through the intramolecular hydrogen bonding between phenolic hydroxyl proton and the carbonyl oxygen in the amide group, as is shown in A. A low-field resonance of the phenolic hydroxyl proton (744 Hz) is consistent with the argument described above. It is known that the resonance of phenolic hydroxyl protons is observed at about 270 Hz

7) R. Freeman and N. S. Bhacca, and C. A. Reilly, *J. Chem. Phys.*, **38**, 293 (1963).

8) M. T. Tribble and J. G. Traynham, *J. Amer. Chem. Soc.*, **91**, 379 (1969).

when they are free[9] and is shifted to lower fields when intramolecular hydrogen bonds are formed.[10,11] The phenolic hydroxyl protons of salicylaldehyde[11] and methyl salicylate[7] were observed at 665.5 and 641.7 Hz respectively. Unfortunately, however, no long-range coupling was observed between the phenolic hydroxyl proton and the ring proton-4 in *N*-methyl salicyalmide.



On the other hand, the ring proton-6 resonances of *o*-methoxy benzoic acid and *N*-methyl-*o*-methoxy benzamide were observed at very low fields, lower by about 20 Hz than the average value described in the preceding section. In these two compounds, the intramolecular hydrogen bonds give rise to planar molecules like B, where the carbonyl group is fixed in the molecular plane in quite a different way from that in A. In B, the proton-6 can be expected to be subjected to a strong electric field due to the carbonyl group and to resonate at lower fields. In the case of 2,5-dimethoxy acetanilide, where a strong effect of the carbonyl group could also be expected, the proton-6 resonance was found at 487 Hz.[2d] The amide proton resonance of *N*-methyl-*o*-methoxy benzamide was found at about 467 Hz, lower by about 60 Hz than that of *N*-methyl salicylamide, probably because of the intramolecular hydrogen bond.

Interestingly enough, the proton-6 resonates at about an average field in the case of methyl salicylate, although an intramolecular hydrogen-bond formation like A is expected to occur in this compound in chloroform; thus, the proton-6 could be expected to resonate at about the same field as that of *N*-methyl salicylamide. This unexpectedly low field resonance may be interpreted in terms of: (i) a considerable contribution by molecules of the C structure, or (ii) an electric-field deshielding exerted by the lone-pair electrons on the ester oxygen atom in A'. The IR study of methyl salicylate in carbon tetrachloride gave no evidence regarding any contribution of the C structure.[12] Therefore, the first interpretation can be ruled out.

The proton-6 of salicylaldehyde has been reported to resonate at 442.811 Hz from TMS.[11] This observation is consistent with the second explanation given above.

Ōki *et al.*[13] studied the conformations of several esters and concluded that the *s-trans* configuration is the exclusive one. Therefore, the A' structure is considered to be the most stable one for methyl salicylate. In this geometrical arrangement, the lone-pair electron cloud of the oxygen atom in the ester group exerts a strong electric field on the proton-6, inducing a pronounced deshielding effect.

Benzene Solutions. Benzene is known as a representative solvent which has a special effect on the proton chemical shifts of compounds with a carbonyl group.[14] A similar effect has been reported for some amides.[15]

According to these results, the ring proton-6 of *N*-methyl salicylamide would be expected to shift to higher fields when dissolved in benzene if the molecular structure assumed is A. This expectation is the case, as is shown in Table 1. By contrast, for *N*-methyl-*o*-methoxy benzamide the proton-6 resonance would be expected to remain unchanged or to shift to lower fields, provided that the molecular structure assumed is B. Actually, however, the resonance signal of the proton-6 was observed at a lower fields and that of the proton-3 shifted to higher fields. These observations prove the correctness of the structural assignments given above.

Furthermore, a consideration of van der Waals' repulsion for *N*-methyl salicylamide gives preference to the A structure over D, where the amide hydrogen lies *cis* to the carbonyl group with respect to the amide bond, N–CO, because of the strong repulsion expected between the methyl group and the proton-6 in the latter structure.

On the other hand, no remarkable benzene shift was observed for the proton-6 in the II and IV compounds. In the case of the latter, the flexibility of the carbomethoxy group, *i.e.*, the free rotation around the C_{ring}–CO bond, may be an important factor in interpreting this observation. In the former compound, the lone-pair electrons on the ester oxygen atom would prevent the benzene molecules from access to the proton-6.

Spin-spin Coupling. The results are presented in Table 2. None of the coupling constants varies significantly in changing the solvent. Furthermore, no appreciable variation in any of the coupling constants is observed from compound to compound. These observations are reasonable, because the change in the substituents of these compounds seems to cause only a weak perturbation in the ring moiety.

Previous empirical efforts to interpret substituent effects on proton-proton couplings have involved a

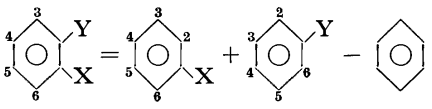
correlation with the substituent electronegativity, E_x. Castellano and Sun[16] observed a definite trend of coupling values with E_x in a study of a number of monosubstituted benzenes. J_{23} and J_{26} were found to increase, and J_{24} and J_{25} to decrease, with E_x, and it was suggested that the inductive effect of the substituent was the principal factor involved. Fraser,[17] on the other hand, from a consideration of the J_{ortho} values in a series of monosubstituted derivatives, concluded that the π-contributions to J were at least as important as the inductive effect. Some other studies have been done in establishing a qualitative correlation between J and E_x for disubstituted benzenes.[18-22]

If a simple additivity rule can be applied to the H-H coupling constants, the following equations can give estimates for the coupling constants of *o*-disubstituted benzenes.



$$J_{34}(XY) = J_{34}(X) + J_{23}(Y) - J_o$$
$$J_{35}(XY) = J_{35}(X) + J_{24}(Y) - J_m$$
$$J_{36}(XY) = J_{36}(X) + J_{25}(Y) - J_p$$
$$J_{45}(XY) = J_{45}(X) + J_{34}(Y) - J_o$$
$$J_{46}(XY) = J_{46}(X) + J_{35}(Y) - J_m$$
$$J_{56}(XY) = J_{56}(X) + J_{45}(Y) - J_o$$

where J_o, J_m, and J_p stand for the *ortho*-, *meta*-, and *para*-coupling respectively between two ring protons of unsubstituted benzene.

From the above equations, one can calculate the 51 J_o's, 34 J_m's, and 17 J_p's, using the coupling constants of the present compounds and monosubstituted benzenes.[23,24] The averaged values are 7.46, 1.30, and 0.67 for J_o, J_m, and J_p respectively. These values are in good agreement with the experimental values.[25]

Reaction of α-Halosulfoxides with Amines[1]

Tatsuo NUMATA and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshiku, Osaka

(Received March 3, 1972)

When optically active bromomethyl *p*-tolyl sulfoxide was treated with sodium methylmercaptide or sodium ethoxide, optically active α-substituted methyl *p*-tolyl sulfoxides were obtained in good yields. By contrast, reaction with secondary amines produced achiral *p*-toluenesulfenamides, methylenediamines, and amine hydrobromides in nearly quantitative yields. The reaction with an amine is presumed to proceed through the initial nucleophilic substitution at α-carbon of the sulfoxide to form aminomethyl *p*-tolyl sulfoxide, followed by rearrangement to the corresponding sulfenate, and subsequent attack of the amine at the sulfur atom of the sulfenate to form the final product. Meanwhile, a facile interconversion of alkoxymethyl *p*-tolyl sulfoxide and corresponding sulfenate was also observed.

α-Halosulfoxides have become useful in the synthesis of various derivatives of sulfoxides. As a typical example,[2] α-epoxysulfoxide can be readily synthesized by the reaction of α-chlorosulfoxide with ketone in the presence of base. However, the nucleophilic substitution reactions of α-chloroalkyl sulfoxides are known to take place slowly.[3]

Recently, Ogura and Tsuchihashi[4] reported that this reaction proceeds through an S_N2 process with inversion of configuration at the α-carbon atom of an α-chloroalkyl sulfoxide.

For convenient synthesis of optically active α-substituted methyl aryl sulfoxides, however, this reaction is the shortest route, and hence we examined in detail the reaction of a more reactive and optically active bromomethyl *p*-tolyl sulfoxide with various nucleophiles.

Results and Discussion

When bromomethyl *p*-tolyl sulfoxide (**1**) was treated with CH_3S^-, $C_6H_5S^-$, CH_3O^-, and $C_2H_5O^-$, the corresponding α-substituted methyl *p*-tolyl sulfoxides were obtained in good yields (Eq. (1)).

$$\underset{\underset{\text{O}}{\downarrow}}{\text{Tol-S-CH}_2\text{Br}} + \text{X}^- \longrightarrow \underset{\underset{\text{O}}{\downarrow}}{\text{Tol-S-CH}_2\text{-X}} \qquad (1)$$

1

$X^-=CH_3S^-$, $C_6H_5S^-$, CH_3O^-, $C_2H_5O^-$
Tol=*p*-$CH_3C_6H_4$

Further, in the reaction of optically active bromomethyl *p*-tolyl sulfoxide with CH_3S^- and $C_2H_5O^-$, the corresponding optically active α-substituted methyl sulfoxides were obtained in good yields, and the starting optically active α-bromosulfoxide was also readily synthesized by bromination of optically active methyl *p*-tolyl sulfoxide with *N*-bromosuccinimide (NBS), bromine and pyridine in dichloromethane. The optical rotations of these sulfoxides are summarized in Table.

Table Optical rotation[a] of Tol-$\overset{*}{S}$(O)-CH_2-X

X	H	Br	SCH_3	OC_2H_5
$[\alpha]_D$	+201.0	+176.7	+193.3	+229.5
(*c*,*l*)	(1.00,1)	(1.05,1)	(1.04,1)	(0.83,1)

a) measured in benzene at 20°C

The data in this Table indicate that the configuration of the sulfoxide is little affected by α-bromination of the sulfoxide or by displacement reaction at the α-carbon atom of the sulfoxide.

However, in the reaction of optically active bromomethyl *p*-tolyl sulfoxide (**1**) with secondary amines (**2**), achiral *p*-toluenesulfenamides (**3**) were produced quantitatively, instead of forming optically active aminomethyl *p*-tolyl sulfoxides.

These reactions occurred when bromomethyl sulfoxide (**1**) was heated at 70°C for 1—2 hr with excess amine (**2a—c**) in benzene under nitrogen atmosphere, and *p*-toluenesulfenamide (**3a—c**), methylenediamine (**4a—c**) and amine hydrobromide (**5a—c**) were obtained in nearly quantitative yields (Eq. (2)).

$$\underset{\underset{\text{O}}{\downarrow}}{\text{Tol-S-CH}_2\text{-Br}} + 4\text{RR'NH} \xrightarrow{70^\circ} \text{Tol-S-N-RR'} + \text{RR'NCH}_2\text{NRR'} + \text{RR'NH}\cdot\text{HBr} + \text{H}_2\text{O} \qquad (2)$$

1 **2a—c** **3a—c** **4a—c** **5a—c**

a) R, R'=morpholino
b) R, R'=piperidino
c) R=R'=C_2H_5

This reaction was little affected by the solvent used, since the reaction in acetonitrile or ethanol proceeded smoothly in a similar fashion under the same condition in benzene to form the same products (**3**, **4**, **5**).

The physical and spectroscopic properties of sulfenamides (**3a—c**) are identical with those of authentic samples synthesized by the reaction of *p*-toluenesulfenyl chloride with the corresponding amines.

When chloromethyl *p*-tolyl sulfoxide (**6**) was allowed to react with morpholine (**2a**) in chlorobenzene, sulfenamide (**3a**), methylenediamine (**4a**), and amine hydrochloride were formed in nearly quantitative yields, as in the case of bromomethyl sulfoxide (**1**), though a somewhat more drastic condition was necessary. Similarly, chloromethyl methyl sulfoxide (**7**) was

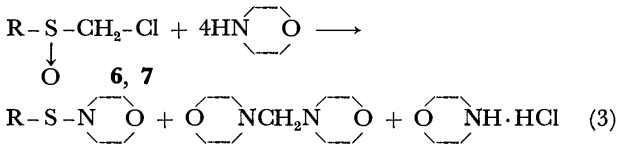
found to react with morpholine (**2a**) a little more readily, and methanesulfenomorpholide (*N*-methylthiomorpholine) was also obtained quantitatively (Eq. (3)).



(3)

6) R=*p*-$CH_3C_6H_4$
7) R=CH_3

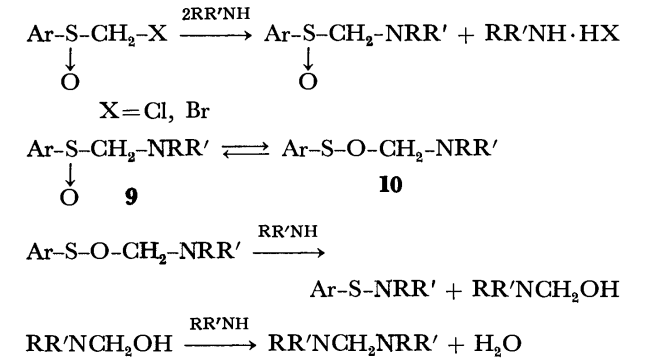
This reaction is influenced markedly by the steric requirement around the α-carbon atom of the sulfoxide, since when α-bromoethyl phenyl sulfoxide (**8**) with excess morpholine was heated in refluxing benzene for 50 hr, benzenesulfenomorpholide was produced in only 40% yield, accompanying with the formation of diphenyl disulfide (15%), while the starting sulfoxide was recovered in 40%. The formation of diphenyl disulfide is presumed to be due to the thermal decomposition of the sulfenamide produced *via* a homolytic pathway.

In the reaction of **1** or **7** with primary amine (*i.e.*, *n*-butylamine, cyclohexylamine, and aniline), *p,p'*-ditolyl disulfide or dimethyl disulfide was formed as main products in 50—80% yields. This appears to be related to the thermal instability of the sulfenamides formed.[5]

As for the stoichiometry, four molar equivalents of amine per one equimolar amount of the α-bromosulfoxide were necessary to complete the reaction according to Eq. (2).

When a solution of an equimolar mixture of the sulfoxide (**1**) and morpholine (**2a**) was heated at 70°C for 5 hr, **3a**, **4a**, and **5a** were formed in 21, 20, and 24% yields, respectively, and the starting sulfoxide (**1**) was recovered in 73%. This means that an intermediate of this reaction would be very reactive and cannot be isolated.

Based on the stoichiometry of the reaction, the following reaction scheme may be suggested:



From the order of the reactivities of α-halosulfoxides (**1**, **6**, **7**, **8**) with morpholine, the reaction is presumed to proceed through the initial nucleophilic substitution at the α-carbon atom of the sulfoxide to form incipiently α-aminomethyl *p*-tolyl sulfoxide (**9**), followed by rearrangement to the sulfenate (**10**). Subsequent attack of an amine at the sulfur atom of the sulfenate (**10**) to afford the sulfenamide and aminomethanol would probably be very rapid. Aminomethanol thus formed would undergo condensation with the amine to afford methylenediamine and water.

Although the sulfenyl ester was not detected in this work, it may be reasonable to postulate that the conversion of the sulfoxide (**9**) to the sulfenyl ester (**10**) is facilitated because of the electron-releasing amino group at the α-carbon.

The reaction between the sulfenate (**10**) and an amine to form the sulfenamide would be very facile, though the reactions of the sulfenate with nucleophiles have little been studied.[6] While aminomethyl *p*-toluenesulfenate (**10**) is not available to test this pathway because of the difficulty in synthesis of this compound, a slightly more stable ethoxymethyl *p*-toluenesulfenate than aminomethyl sulfenate has been prepared and this was found to react readily with morpholine at room temperature to give *p*-toluenesulfenomorpholide quantitatively.

This interpretation for the α-halosulfoxides-amine reaction may also be supported by the observation that substituted ethoxymethyl (or methoxymethyl) *p*-toluenesulfenate is formed in the equilibrium when the corresponding ethoxymethyl (or methoxymethyl) *p*-tolylsulfoxide (which has another effective electron-releasing group at α-carbon) was heated under high vacuum. Meanwhile, the reverse conversion of this sulfenate to the sulfoxide is also found to occur readily by dissolving of the sulfenate in nonpolar aprotic solvents such as chloroform.[7]

Such a rearrangement is known in allyl aryl sulfoxides and aryl benzyl sulfoxides.[8]

A somewhat analogous formation of sulfenamides in the reaction of allyl or α-naphthylmethyl aryl sulfoxides with piperidine, apparently *via* the prior rearrangements of the sulfoxides to the sulfenates, was reported recently by Abbott and Stirling.[9]

Experimental

Materials. *Optically Active Methyl* p-*Tolyl Sulfoxide* was prepared by the method of Mislow[10] in which (−)menthyl (−)*p*-toluenesulfinate was reacted with methylmagnesium iodide in ether. mp 75°C, $[\alpha]_D$ +201.0° (*c*=1.00, benzene) Lit,[10] mp 73—74°C, $[\alpha]_D$ +145.5° (*c*=2, acetone).

Optically Active Bromomethyl p-*Tolyl Sulfoxide* (*1*) was prepared by bromination of optically active methyl *p*-tolyl sulfoxide with bromine, *N*-bromosuccinimide (NBS), and pyridine in dichloromethane in 80% yield, according to the procedure

developed by Tsuchihashi.[11] The sulfoxide obtained was recrystallized from cyclohexane. mp 88—89°C, $[\alpha]_D$ +176.7° (c=1.05, benzene), ν_{SO} (KBr) 1044 cm^{-1}, NMR ($CDCl_3$) δ=2.53 (3H, s), 4.50 (2H, AB quartet, J=11 Hz, Δ_{AB}= 8.3 Hz), 7.74 (4H, m).

Optically Active Methylthiomethyl p-*Tolyl Sulfoxide* was prepared by the reaction of optically active bromomethyl *p*-tolyl sulfoxide with sodium mercaptide in 50% CH_3CN-H_2O at room temp. for 2 hr in 90% yield. The sulfoxide obtained was recrystallized from cyclohexane. mp 42—44°C, $[\alpha]_D$ +193.3° (c=1.04, benzene), ν_{SO} (KBr) 1038 cm^{-1}, NMR ($CDCl_3$) δ=2.35 (3H, s), 2.59 (3H, s), 3.96 (2H, s), 7.82 (4H, m) Found: C, 53.92; H, 5.72%. Calcd for $C_9H_{12}OS_2$: C, 53.96; H, 6.04%.

Optically Active Ethoxymethyl p-*Tolyl Sulfoxide* was prepared by the reaction of optically active bromomethyl *p*-tolyl sulfoxide with sodium ethoxide in ethanol at 70° for 5 hr in 85% yield. The sulfoxide obtained was purified by preparative TLC (silica gel) with chloroform as eluent. $[\alpha]_D$ +229.5° (c=0.83, benzene), ν_{SO} (neat) 1050 cm^{-1}, NMR ($CDCl_3$) δ=1.33 (3H, t, J=7 Hz), 2.56 (3H, s), 4.07 (2H, quartet J=7 Hz), 4.64 (2H, s), 7.80 (4H, m) Found: C, 60.72; H, 7.06%. Calcd for $C_{10}H_{14}O_2S$: C, 60.57; H, 7.12%.

Chloromethyl p-*Tolyl Sulfoxide* (**6**) was prepared by the chlorination of methyl *p*-tolyl sulfoxide, which was synthesized by bromine-oxidation of methyl *p*-tolyl sulfide in usual manner,[12] with *N*-chlorosuccinimide (NCS) and pyridine, according to the procedure developed by Tsuchihashi.[13] The sulfoxide obtained was recrystallized from ether-hexane. mp 60.0—61.0°C (lit:[14] mp 61.5—62°C).

Bromomethyl p-*Tolyl*, *Methylthiomethyl* p-*Tolyl*, *Methoxymethyl* p-*Tolyl*, *and Ethoxymethyl* p-*Tolyl Sulfoxides* were prepared by the same way used for synthesis of the corresponding optically active compounds as mentioned above.

Bromomethyl isomer, mp 63.0—64.0°C (lit,[11] mp 63°C); methylthiomethyl isomer, mp 61.0—61.5°C; methoxymethyl isomer, ν_{SO} (neat) 1049 cm^{-1}, NMR ($CDCl_3$) δ=2.40 (3H, s), 3.65 (3H, s), 4.38 (2H, s), 7.45 (4H, m).

Phenylthiomethyl p-*Tolyl Sulfoxide* was prepared by the reaction of bromomethyl *p*-tolyl sulfoxide with sodium thiophenoxide in ethanol at 70°C for 4 hr in 84% yield. The sulfoxide obtained was recrystallized from benzene-hexane. mp 51—52°C, ν_{SO} (KBr) 1042 cm^{-1}, NMR (CCl_4) δ=2.35 (3H, s), 4.12 (2H, s), 7.52 (9H, m) Found: C, 63.79; H, 5.08%. Calcd. for $C_{14}H_{14}OS_2$: C, 64.09; H, 5.38%.

α-Bromoethyl Phenyl Sulfoxide (**8**) was prepared by the bromination of ethyl phenyl sulfoxide with bromine, NBS and pyridine in 69% yield. bp 129—130°C/0.5 mmHg, ν_{SO} (neat) 1056 cm^{-1}, NMR ($CDCl_3$) δ=1.90 (3H, d, J=7 Hz), 4.87 (1H, quartet J=7 Hz), 7.69 (5H, m). Found: C, 41.35; H, 3.68%. Calcd for C_8H_9OSBr: C, 41.22; H, 3.89%.

Chloromethyl Methyl Sulfoxide (**7**) was prepared by the chlorination of dimethyl sulfoxide with NCS in the presence of K_2CO_3 according to the procedure of Tsuchihashi.[13] bp 66—68°C/1 mmHg, (lit,[13] 90°C/4 mmHg).

p-*Toluenesulfenamides* (**3**) were synthesized by the reaction of *p*-toluenesulfenyl chloride, which was synthesized by the method described in the text book,[15] with corresponding excess amines in dichloromethane.

p-Toluenesulfenodiethylamide, bp 67°C/1 mmHg; *p*-toluenesulfenomorpholide, bp 100°C/0.5 mmHg; *p*-toluenesulfenopiperidide bp 98°C/0.8 mmHg (Lit[9] 90°C/0.3 mmHg).

Methanesulfenomorpholide was prepared by the reaction of methanesulfenyl chloride, which was synthesized from the reaction of dimethyl disulfide with dry chlorine gas according to the procedure of Mislow,[8a] with excess morpholine in dichloromethane. bp 79°C/24 mmHg. (lit,[16] 48—49°C/ 5 mmHg).

Dimorpholino Methane (**4a**) was synthesized by condensation of morpholine and formaline according to the procedure of Harradence.[17] bp 120°C/23 mmHg (lit,[17] 139—140°C/29 mmHg).

Amines used were purified by twice distillation under nitrogen atmosphere.

Reaction of α-Haloalkyl Aryl Sulfoxides with Amines. *i*) *α-Bromosulfoxide with Secondary Amine*: α-Bromosulfoxide (0.5—1 g) was heated at 70°C for 1—2 hr with an excess amine (1—3 g) in dry benzene (5—10 cc) under nitrogen atmosphere until the spot of sulfoxide in thin layer chromatography (tlc) analysis disappeared and amine hydrobromide salt precipitated. After collecting the precipitated amine hydrobromide salt and evaporation of solvent and excess amine *in vacuo*, the oily residue was separated by preparative tlc (silica gel) to afford the sulfenamide and methylenediamine in 90—96% yields.

ii) *α-Chlorosulfoxide with Morpholine*: α-chlorosulfoxide (0.5 g) was heated at 120°C for 2.5 hr to complete the reaction with morpholine (1 g) in dry chlorobenzene (5 cc). Method of work up and product analysis are described above.

Reaction of Chloromethyl Methyl Sulfoxide with Morpholine. The sulfoxide (1 g) was heated at 70°C for 8 hr with morpholine (5 g) in benzene (20 cc). After collecting amine hydrochloride precipitated, fractional distillation of the reaction mixture under reduced pressure gave first benzene and unchanged morpholine, and subsequently the fraction of methanesulfenomorpholide (79°C/24 mmHg), and the final fraction of dimorpholino methane (120°C/23 mmHg).

Conversion of Ethoxymethyl p-*Tolyl Sulfoxide to Sulfenate* The sulfenate was produced as a distillate by rapid vacuum distillation of the sulfoxide using a micro-distillation apparatus in 70—80% yield. bp 100—110°C/1.5 mmHg, IR (neat) 1150, 1120, 920, 800 cm^{-1}.

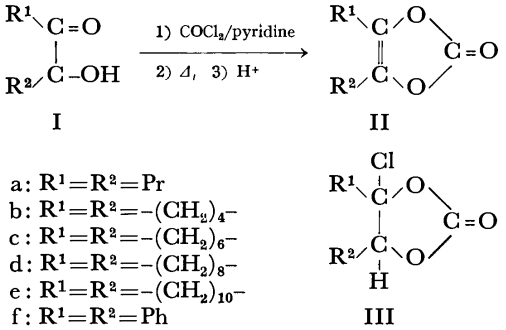
The Photochemistry of 4,5-Disubstituted 1,3-Dioxolen-2-ones

Tamejiro HIYAMA, Shinsaku FUJITA, and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto
(Received January 31, 1972)

The benzene-sensitized photoreaction of 4,5-dipropyl- (IIa) and 4,5-tetramethylene-1,3-dioxolen-2-one (IIb) in isopropyl alcohol gives two reduction products, *cis*- (V) and *trans*-4,5-disubstituted 1,3-dioxolan-2-one (VI). The irradiation of octa- (IId) and decamethylene-bridged vinylene carbonate (IIe) results in transannular hydrogen atom transfer from a methylene group to the olefinic bond and a subsequent recombination affording three tricyclic products, IX, X, and XIX. An examination of the stereochemistry of the products has indicated the participation of a diradical intermediate.

1,3-Dioxolen-2-ones (vinylene carbonates) are useful synthetic intermediates.[1] Recent reports have dealt with their photochemical dimerization[2] as well as with their cycloaddition reaction to olefins[3] and acetylenes.[4] We first wanted to obtain a general method for the preparation of 4,5-disubstituted derivatives, and then we proceeded to examine the photochemical behavior[5] of the derivatives.

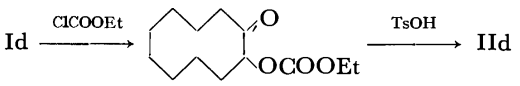
Preparation of 4,5-Disubstituted 1,3-Dioxolen-2-ones. The known route to vinylene carbonates consisted of the chlorination of ethylene carbonates and a subsequent dehydrochlorination.[6] Vinylene carbonates are carbonic acid esters of ene-diols which are tautomeric with acyloins.[7] The treatment of an acyloin (I) with phosgene in the presence of pyridine afforded monochlorinated ethylene carbonate, III. The direct distillation of III caused a thermal dehydrochlorination, thus giving a crude vinylene carbonate, II (Scheme 1).



Scheme 1.

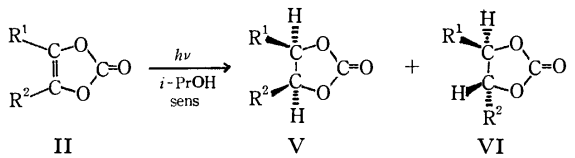
As the NMR spectrum showed contamination by exocyclic isomer(s), the crude carbonate, II, was converted to a pure form by heating a mixture dissolved in xylene with *p*-toluenesulfonic acid. The resulting II showed satisfactory NMR signals (no olefinic protons).

The carbonate, IId, was also prepared by the ethoxycarbonylation of sebacoin (Id) with ethyl chloroformate followed by treatment with *p*-toluenesulfonic acid in boiling xylene (Scheme 2).



Scheme 2.

Photoreduction. The UV irradiation of IIa in isopropyl alcohol containing a benzene sensitizer afforded *cis*-4,5-dipropyl-1,3-dioxolan-2-one (Va) and its *trans* isomer (VIa), along with two dimers of IIa and acetone pinacol. The ratio of Va/VIa was determined by gas chromatography (GC) to be 8 : 92, (Scheme 3). The structures of the products were established by comparison with authentic samples prepared by the esterification of *meso*- and *dl*-4,5-octanediol[8] with phosgene.



Scheme 3.

On the other hand, the UV irradiation of IIa in acetone gave only two kinds of dimers. The stereochemistry of the dimers was not examined.

The tetramethylene derivative, IIb, gave two saturated products, Vb and VIb (19% yield, 89: 11), upon irradiation in isopropyl alcohol–benzene. In the absence of hydrogen donors, IIb resisted the photoreaction.

The hexamethylene derivative, IIc, behaved differently and gave only a dimer upon irradiation both in acetone and in isopropyl alcohol–benzene.

Since the photoreaction of II required the presence

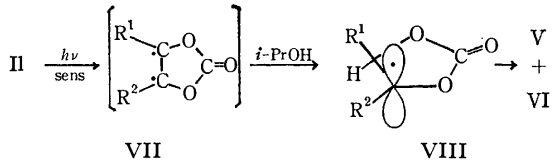
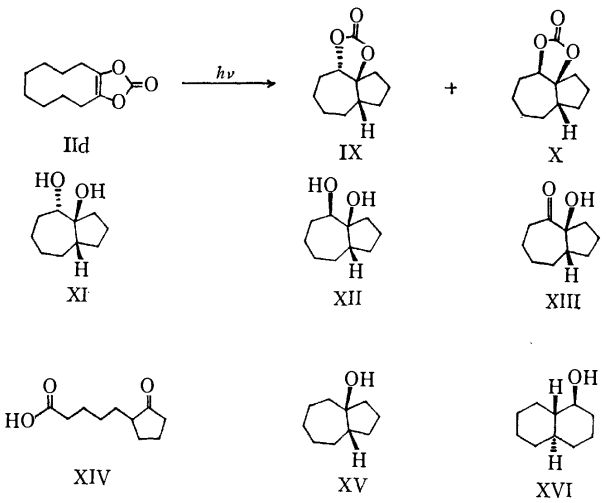
8) The compound was obtained by sodium borohydride reduction of butyroin, followed by chromatographic separation. See J. Wiemann, G. Dana, Sa-Le-Thi-Thuan, and M. Brami, *Compt. Rend.*, **258**, 3724 (1964).

of triplet sensitizers,[2] such as acetone and benzene, the reaction must involve the triplet state of the olefinic functional group as a diradical. The photochemical behavior of the ene-diol carbonate moiety of II may be understood in the same way as the photoreduction of cyclopentenes.[9] The triplet state, VII, abstracts a hydrogen atom from isopropyl alcohol to produce the VIII radical stabilized by the adjacent oxygen atom. This then yields a mixture of ethylene carbonate isomer (V and VI), in which the thermodynamically more stable one predominates (Scheme 4).



Scheme 4.

Intramolecular Hydrogen Abstraction. The irradiation of IId in acetone gave no dimers, but a mixture of novel tricyclic stereoisomers, IX and X, in a 71% yield. As the separation of the two isomers failed, the mixture was hydrolyzed to the *vicinal* diols, XI and XII (Scheme 5). The ratio of XI/XII was determined by GC as 85: 15. The separation of the two diols was accomplished by preparative thin-layer chromatography (plc).



Scheme 5.

The structure and stereochemistry of XI and XII were established as follows. Since the oxidation of XI and XII by *N*-bromosuccinimide (NBS)[12] gave the same ketol, XIII, the diols should have the same ring system and ring fusion. The absorption of XIII at 1700 cm^{-1} implied that the ring including the carbonyl group was medium-sized. The glycol cleavage of XI and XII with periodate-permanganate[13] afforded ε-(2-ketocyclopentyl)valeric acid (XIV).[14] Hence, both XI and XII were established to have a bicyclo-[5.3.0]decane structure. The *cis*-ring fusion of the photoproducts was determined by the fact that the half-tosylation of a mixture of XI and XII, followed by reduction with lithium aluminum hydride or sodium borohydride, afforded *cis*-bicyclo[5.3.0]decane-1-ol (XV), along with *trans,trans*-α-decalol (XVI).[15] The formation of the latter can be ascribed to the base catalyzed rearrangement of the half-tosylate,[16] followed by the reduction of the resulting *trans*-α-decalone. In fact, the treatment of the half-tosylate of XI and XII with sodium methoxide in methanol afforded *trans*-α-decalone.

The reduction of XIII with sodium bis(2-methoxyethoxy)aluminum hydride (VSH) yielded XI almost exclusively. On the basis of Cram's rule,[17] the *trans*-configuration of the *vicinal* hydroxyl groups of XI was established, and consequently XII turned out to be its *cis*-diol isomer. Thus, XI and XII were concluded to be *cis*-bicyclo[5.3.0]decane-*trans*-1,2-diol and its *cis*-diol isomer respectively. The transannular photoreaction of IId proceeded even in isopropyl alcohol upon benzene sensitization, and neither reduction products nor dimers were detected among the products.

An inspection of the Dreiding models of IId suggests that the hydrogen atom on the C-6 in the excited state[18] resides closest to the C-1 (XVII) and that the abstraction of H_A by the C-1 radical probably occurs *via* seven-membered cyclic transition state. A subsequent recombination[19] of the resulting diradical, XVIII, may account for the preference for IX.

The decamethylene derivative, IIe, proved to be rather less reactive than IId. The irradiation of an

9) It has been well known that acyclic and large ring olefins undergo the *cis-trans* isomerization (Ref. 10) upon triplet sensitization, and that four- or five-membered cyclic olefins are reduced by hydrogen abstraction of the double bond (Ref. 11).

16) Similar rearrangements have been reported previously. For example, see a) G. Büchi, W. Hofheinz, and J. V. Paukstelis, *J. Amer. Chem. Soc.*, **91**, 6473 (1969). b) C. A. Grob, H. R. Kiefer, H. Lutz, and H. Wilkens, *Tetrahedron Lett.*, **1964**, 290. c) E. J. Corey, R. B. Mitra, and H. Uda, *J. Amer. Chem. Soc.*, **85**, 362 (1963).

17) D. J. Cram and K. R. Kopecky, *ibid.*, **81**, 2748 (1959).

18) A carbon-carbon double bond is well known to be twisted in its triplet state, see Ref. 10, p. 137.

19) Recombination of a diradical is known to occur with retention of the configuration at the radical centers separated by intervening one methylene, whereas it proceeds with partial inversion if the radical centers are separated by three or more methylenes. See C. G. Overberger and J. Anselme, *J. Amer. Chem. Soc.*, **84**, 869 (1962). The absence of *trans*-fused bicyclo[5.3.0]decanes in the photoproducts suggest that the recombination of the diradical XVIII precedes any conformational change. The reason is not clear yet, but may be explained by assuming fast spin-inversion at the radical center (C-10) adjacent to a hetero atom.

Table 1. Physical properties of 1,3-dioxolen-2-ones. II

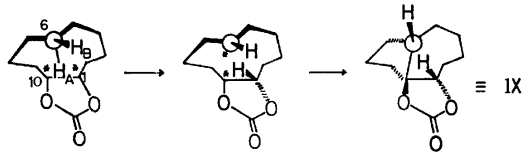
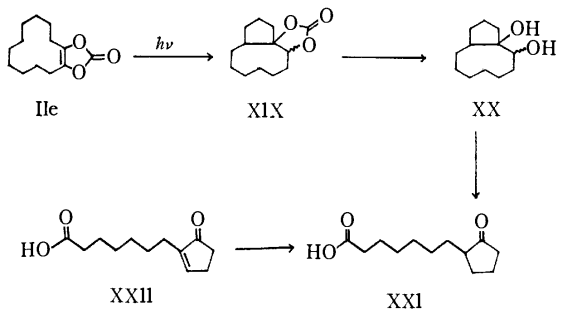


Scheme 6.

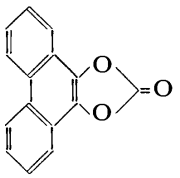
acetone solution of IIe yielded XIX in a 49% yield, along with a recovery of IIe (21%) (Scheme 7). The presence of the stereoisomers was not excluded, as no satisfactory separation of the isomers was accomplished. Alkaline hydrolysis gave the *vicinal* diol, XX, which was then subjected to Rudloff oxidation to afford 7-(2-ketocyclopentyl)heptanoic acid (XXI). IR bands of the keto acid appeared at 1737, and 1708 cm^{-1}, characteristic of a five-membered ketone and a carboxylic acid respectively. An authentic sample of XXI was obtained by the hydrogenation of the unsaturated derivative (XXII).[20] Consequently, the structure of XIX was established to be bicyclo[7.3.0]-dodecane-1,2-diol. The stereochemistry of the *vicinal* hydroxyl groups and the mode of the ring fusion were not examined.



Scheme 7.

20) J. F. Bagli, T. Bogri, R. Deghenghi, and K. Wiesner, *Tetrahedron Lett.*, **1966**, 465. We are heartily grateful to Dr. Bagli for his kindness of sending us the sample of XXII.

The diphenylvinylene carbonate, IIf, was recovered unchanged upon irradiation in cyclohexane, whereas the photoreaction of IIf in the presence of iodine gave a phenanthrene derivative, XXIII, in a 77% yield.



XXIII

Experimental

All the temperatures are uncorrected. The infrared spectra were recorded on a Shimadzu spectrophotometer IR-27-G; the ultraviolet spectra, on a Hitachi EPS-2 spectrometer; the nuclear magnetic resonance spectra, on a JEOL-60-H spectrometer, and the mass spectra, on a Hitachi RMU-6L spectrometer.

Preparation of I. *General Procedure*: To a solution of an acyloin (50 mmol) in benzene (60 m*l*) and pyridine (90 m*l*), a mixture of a 30% toluene solution (55 g) of phosgene (167 mmol) and benzene (80 m*l*) was added, drop by drop, at 0°C; the mixture was then stirred overnight. After dilution with *n*-hexane (300 m*l*), the precipitated pyridinium chloride was filtered off. The filtrate was washed twice with water (100 m*l*) and dried over anhydrous potassium carbonate. The evaporation of the solvent *in vacuo* and subsequent distillation gave a mixture of II and its isomer(s). The distillate was dissolved in a xylene mixture (*ca.* 80 m*l*), after which the solution was heated to reflux for 24 hr in the presence of *p*-toluenesulfonic acid (*ca.* 1 g). Neutralization with pyridine, filtration, and distillation gave II. The yields and physical properties are summarized in Table 1.

4,5-Diphenyl-1,3-dioxolen-2-one (IIf). This was prepared much as has been described above. Distillation at 140—150°C/0.15 mmHg gave IIf in a 61% yield; it then crystallized; mp 71—73°C (lit,[7] 74—76°C (*n*-hexane)). IR (KBr): 1820, 1695, 1208, 1068, 995, 727, 692 cm^{-1}. MS: *m/e* (relative abundance) 238 (M^+, 3), 165 (13), 152 (5), 105 (100), 77 (64).

4,5-Octamethylen-1,3-dioxolen-2-one (IId). An Alternate Procedure. Ethyl chloroformate (6 ml, 63 mmol) was added, drop by drop, to a solution of sebacoin (5.10 g, 30 mmol) in pyridine (30 ml) at room temperature, after which stirring was continued for 1 hr. The mixture was then diluted with *n*-hexane (100 ml), and the precipitated pyridinium chloride was filtered off. The solvents were evaporated *in vacuo* to yield ethyl 2-ketocyclodecyl carbonate quantitatively. IR (neat): 1750, 1728, 1260, 1010 cm^{-1}.

The unsymmetrical carbonate was directly mixed with *p*-toluenesulfonic acid (0.59 g, 3.4 mmol) in xylene (150 ml), and the whole was heated to reflux. After one day *p*-toluenesulfonic acid (1.18 g, 6.8 mmol) was added; the heating was then continued for another day. The acid was then neutralized with pyridine, and the precipitated salts were filtered off. Evaporation and distillation gave IId (3.97 g, 67%); bp 123—126°C/3 mmHg. The oil solidified and was recrystallized from *n*-hexane (see Table 1).

UV Irradiation of IIa in Acetone. A solution of IIa (1.14 g, 67 mmol) in acetone (50 ml) was placed in a quartz tube and irradiated with a 200-W high-pressure mercury lamp externally for 62 hr. The subsequent evaporation of the excess acetone *in vacuo* gave a crude solid (*ca.* 1.5 g), which was then recrystallized from *n*-hexane–ether–ethyl acetate to yield a dimer (0.05 g); mp 225—226°C. IR (Nujol): 1810, 1100, 1035 cm^{-1}. NMR ($CDCl_3$): δ 0.8—2.3 (m). MS: *m/e* (relative abundance) 171 (16), 170 ($M^+/2$, 100), 141 (30), 83 (18), 71 (25), 69 (8), 55 (22), 43 (66). Found: C, 63.6; H, 8.3%. Calcd for $C_{18}H_{28}O_6$: C, 63.5; H, 8.3%.

The mother liquid was subjected to chromatography on a silica gel column. Elution with benzene gave another crop of the crystalline dimer (0.18 g, totally, a 20% yield). Further elution gave an oily dimer (0.87 g, 76%); bp 100—110°C (bath temperature)/0.2 mmHg. IR (neat): 1810, 1212, 1131, 1032 cm^{-1}. NMR (CCl_4): δ 0.8—2.3 (m). MS: *m/e* (relative abundance) 170 ($M^+/2$, 28), 169 (11), 141 (21), 83 (20), 71 (59), 55 (43), 43 (100). Found: C, 63.5; H, 8.8%. Calcd for $C_{18}H_{28}O_6$: C, 63.5; H, 8.3%.

UV Irradiation of IIa in Isopropyl Alcohol–benzene. A mixture of IIa (1.12 g, 66 mmol), isopropyl alcohol (50 ml), and benzene (1 ml) was irradiated as has been described above for 5 days. Subsequent evaporation and distillation at 120—140°C/20 mmHg gave acetone pinacol (0.4 g). Further distillation (110°C/0.8 mmHg) gave a mixture of Va and VIa (0.22 g, 19%). The GC (High Vacuum Silicone Grease on Celite 545, 10%, 2 m) of the mixture revealed that the Va/VIa ratio was 8:92. Each component was separated by preparative GC (Silicone SE 30 on Chromosorb W, 30%, 1 m); the mass and infrared spectra and retention time on the GC were identical with those of the respective authentic samples (*vide infra*).

cis-*4,5-Dipropyl-1,3-dioxolan-2-one (Va).* Pyridine (2 ml) was added, drop by drop, at 0°C to a mixture of *meso*-4,5-octanediol (0.30 g, 2 mmol), benzene (10 ml), and a 30% phosgene solution in toluene (1.5 g). Stirring was continued overnight. A subsequent work-up gave Va quantitatively, bp 85—90°C (bath temperature)/3 mmHg. IR (neat): 1810, 1095, 1030 cm^{-1}. NMR (CCl_4): δ 0.8—2.1 (m, peak at δ 1.03 and 1.65, 14H, methyls and methylenes), 3.7—4.5 (m, 2H, CH–O). MS: *m/e* (relative abundance) 129 (M^+-43, 3), 128 (M^+-44, 1), 98 (4), 86 (9). 85 (11), 71 (16), 67 (26), 57 (68), 56 (61), 55 (53), 43 (84), 41 (100). Found: C, 62.9; H, 9.4%. Calcd for $C_9H_{16}O_3$: C, 62.8; H, 9.4%.

trans-*4,5-Dipropyl-1,3-dioxolan-2-one (VIa).* This was prepared much as above from *dl*-4,5-octanediol; it formed an oil; bp 105—110°C (bath temperature)/3 mmHg. IR (neat): 1802, 1180, 1030 cm^{-1}. NMR ($CDCl_3$): δ 0.8—2.2 (m, peak at δ 0.95 and 1.55, 14H, methyls and methylenes), 4.5—5.0 (m, 2H, CH–O). MS: *m/e* (relative abundance) 129 (4), 128 (3), 99 (5), 86 (10), 85 (12), 71 (28), 67 (36), 57 (78), 43 (100), 41 (98). Found: C, 62.9; H, 9.4%. Calcd for $C_9H_{16}O_3$: C, 62.8; H, 9.4%.

UV Irradiation of IIb in Isopropyl Alcohol–benzene. A mixture of IIb (0.42 g, 3 mmol), isopropyl alcohol (15 ml), and benzene (0.5 ml) was irradiated for 5 days. A subsequent GC of the mixture showed the presence of Vb and VIb, along with the recovered IIb. The separation of Vb and VIb was performed by preparative GC. The IR and mass spectra and retention times on the GC of both products were identical with those of the authentic samples. The yield of Vb and VIb was estimated by GC to be 13%, and the Vb/VIb ratio was determined to be 89:11.

cis- *and* trans-*4,5-Tetramethylene-1,3-dioxolan-2-one (Vb and VIb).*[21] These were prepared from *cis*- and *trans*-cyclohexane-1,2-diol much as has been described in the preparation of Va and VIa. The *cis* isomer, Vb, exhibited IR (neat): 1800, 1205, 1162, 1135, 1030 cm^{-1}. NMR ($CDCl_3$): δ 1.2—2.2 (m, 8H, methylenes), 4.5—5.0 (m, 2H, methines). The *trans* isomer, VIb, exhibited IR (Nujol): 1795, 1190, 1150, 1100, 1058, 1040 cm^{-1}. NMR ($CDCl_3$): δ 1.0—2.5 (m, 8H, methylenes), 3.8—4.3 (m, 2H, methines).

UV Irradiation of IIc. The irradiation of IIc (1.40 g, 8.3 mmol) in acetone for 6 days, and subsequent concentration and chromatography on a silica-gel column gave crystals (0.62 g, 44%); mp 268°C (acetonitrile-ethyl acetate (1:1)). IR (Nujol): 1805, 1190, 1050 cm^{-1}. NMR ($CDCl_3$): δ 0.8—2.8 (m, peak at δ 1.45, methylenes). MS: *m/e* (relative abundance) 168 ($M^+/2$, 61), 140 (9), 129 (14), 95 (35), 84 (62), 67 (48), 59 (76), 55 (89), 43 (100), 41 (73). Found: C, 64.1; H, 7.1%, MW (cryoscopic method) 325. Calcd for $C_{18}H_{24}O_6$: C, 64.3; H, 7.2%, MW 336.

The irradiation of IIc (1.01 g, 6 mmol) in isopropyl alcohol (18 ml) and benzene (1 ml) for 4 days, followed by the separation of the products by chromatography on a silica-gel column, gave the dimer in a 45% yield.

UV Irradiation of IId. An acetone solution (30 ml) of IId (1.00 g, 5.1 mmol) was irradiated for one day, then concentrated and subjected to chromatography on a silica-gel column. Elution with benzene gave the recovered IId (0.03 g) and an inseparable mixture of IX and X (0.71 g, 71%); bp 130—135°C/3 mmHg. IR (neat); 1800, 1175, 1160, 1028 cm^{-1}. NMR (CCl_4): δ 0.8—2.5 (m, peak at δ 1.80, 15H, methylenes and methine), 4.2—4.8 (m, 1H, CH–O). MS: *m/e* (relative abundance) 196 (M^+, 8), 152 (17), 124 (24), 110 (28), 109 (26), 97 (49), 95 (40), 84 (92), 81 (67), 67 (85), 55 (98), 41 (100). Found: C, 67.2; H, 8.0%. Calcd for $C_{11}H_{16}O_3$: C, 67.3; H, 8.2%.

Hydrolysis of IX and X. A mixture of IX and X (1.33 g, 6.8 mmol) was added to a solution of potassium hydroxide (1.5 g) dissolved in water (40 ml) and ethanol (40 ml). The whole was stirred for 6.5 hr at room temperature. The ethanol was then evaporated *in vacuo*, and residue was extracted with chloroform. The subsequent evaporation of the solvent and the purification of the residue by chromatography on a silica-gel column gave a mixture of XI and XII (0.83 g, 72%). The recrystallization of the mixture gave XI; mp 82—83°C (acetone). IR (Nujol): 3400, 1065, 1010, 910 cm^{-1}. NMR ($CDCl_3$): δ 0.8—2.3 (m, peak at δ 1.65, 15H, methylens and methine), 2.43 (s, 2H, OH), 3.2—3.8 (m, 1H, CH–O). MS: *m/e* (relative abundance) 170 (M^+, 6), 152 (9), 123 (15), 111 (17), 97 (100), 84 (66), 67 (29), 55 (41). Found:

21) P. Brown and C. Djerassi, *Tetrahedron*, **24**, 2949 (1968).

C, 70.5; H, 10.6%. Calcd for $C_{10}H_{18}O_2$: C, 70.5; H, 10.7%.

The plc of the mother liquid gave XII: bp 100—105°C/0.15 mmHg. IR (neat): 3480, 1085, 1035, 920 cm^{-1}. NMR ($CDCl_3$): δ 0.8—2.4 (m, 15H, methylenes and methine), 2.55 (s, 2H, OH), 3.0—3.7 (m, 1H, CH-O). MS: *m/e* (relative abundance) 170 (M^+, 12), 152 (12), 123 (15), 111 (34), 97 (100), 84 (70), 67 (33), 55 (50). Found: C, 70.5; H, 10.7%. Calcd for $C_{10}H_{18}O_2$: C, 70.5; H, 10.7%.

Oxidation of XI with NBS. A mixture of XI (0.14 g, 0.8 mmol), acetone (10 m*l*), water (1 m*l*), NBS (0.20 g, 1.1 mmol), and acetic acid (5 drops) was stirred overnight at room temperature. Subsequent work-up and purification by plc gave the ketol, XIII (0.07 g, 50%); bp 100°C (bath temperature)/3 mmHg. IR (neat): 3460, 1700, 1137 cm^{-1}. NMR ($CDCl_3$): δ 0.8—2.7 (m, peak at δ 1.75 and 2.25, methylenes and methine), 2.78 (s, 1H, OH). MS: *m/e* (relative abundance) 168 (M^+, 25), 150 (11), 124 (26), 111 (100), 98 (68), 97 (67), 83 (39), 78 (40), 55 (50). Found: C, 71.0; H, 9.6%. Calcd for $C_{10}H_{16}O_2$: C, 71.4; H, 9.6%.

Oxidation of XII with NBS. This was perfomed as has been described above. The IR and mass spectra and the retention time on GC were identical with those obtained by the oxidation of XI.

Reduction of XIII with VSH. A benzene solution of VSH (72 wt%, 0.5 m*l*) was added, drop by drop, to XIII (0.02 g, 0.12 mmol) in benzene (10 m*l*), and then the mixture was stirred overnight. A subsequent work-up gave diol (0.03 g, quantitative). The spectrum and retention time on the GC were identical with those of XI.

Periodate-permanganate Oxidation of XI and XII. To a mixture of XI and XII (0.36 g, 2.1 mmol), *t*-butyl alcohol (30 m*l*), potassium carbonate (0.10 g), and water (20 m*l*), we added an aqueous solution (50 m*l*) of sodium metaperiodate (2.60 g), potassium permanganate (0.05 g), and potassium carbonate (0.10 g) at room temperature; the mixture was then stirred for 3 hr. Extraction with chloroform and concentration gave the crude keto acid (XIV) (0.29 g, 78%). IR (neat): 3600—2400, 1735, 1710, 1200, 1155 cm^{-1}. MS: *m/e* (relative abundance) 184 (M^+, 4), 129 (14), 97 (16), 84 (100), 69 (24), 55 (50), 41 (58). The oxime melted at 121—124°C (lit,[14] 124—125.5°C). The semicarbazone melted at 192—193°C (lit,[14] 195—196°C).

Conversion of XI and XII to XV and XVI. A mixture of XI and XII (0.10 g, 0.6 mmol) and *p*-toluenesulfonyl chloride (0.12 g, 0.6 mmol) was treated with pyridine (5 m*l*) at room temperature, and stirring was continued overnight. A subsequent work-up gave the half-tosylate of XI and XII (0.15 g). IR (neat): 3420, 1170, 890 cm^{-1}.

The reduction of the half-tosylate with lithium aluminum hydride[22] or sodium borohydride[23] was performed according to the reported procedure. The GC of the mixture revealed the presence of XV as well as XVI, which was separated by preparative GC. The XVI alcohol showed IR (neat): 3380, 1140, 1035, 1015 cm^{-1}. MS: *m/e* (relative abundance) 154 (M^+, 7), 136 (100), 121 (35), 111 (33), 95 (55), 94 (58), 81 (50), 67 (83), 55 (60), 41 (73).

The attempted separation of XV was unsuccessful, but its formation was proven by comparing the retention times on two different GC columns (Dowfax 9N9, 10%, 2 m, and High Vacuum Silicone Grease, 10%, 2 m) with those of an authentic sample[24] which had been prepared by the hydroboration[25] of $\Delta^{1(7)}$-bicyclo[5.3.0]decene.[26] The XV alcohol thus obtained showed IR (neat): 3360, 1010 cm^{-1}. MS: *m/e* (relative abundance) 154 (M^+, 2), 136 (43), 121 (32), 97 (50), 95 (59), 81 (60), 67 (88), 55 (80), 41 (100).

UV Irradiation of IIe. The irradiation of IIe (4.29 g, 19 mmol) in acetone (60 m*l*) for 11 days and subsequent chromatography on a silica-gel column gave IIe (0.90 g, 21%) (elution with *n*-hexane–benzene (1:1)). Further elution with *n*-hexane–benzene (1:3) gave XIX (2.12 g, 49%). IR (neat): 1800, 1255, 1039 cm^{-1}. NMR (CCl_4): δ 1.2—2.8 (m, peak at δ 1.63, 19H, methylenes and methine), 4.0—4.7 (m, 1H, CH-O). MS: *m/e* (relative abundance) 224 (M^+, 9), 180 (3), 151 (6), 137 (6), 123 (14), 111 (24), 98 (66), 84 (52), 81 (49), 67 (63), 55 (100). Found: C, 69.5; H, 9.0%. Calcd for $C_{13}H_{20}O_3$: C, 69.6; H, 9.0%.

Hydrolysis of XIX. A mixture of XIX (2.12 g, 9.4 mmol), potassium hydroxide (2 g), water (40 m*l*), and ethanol (60 m*l*) was stirred overnight. A subsequent work-up gave crude XX (1.28 g, 69%). Recrystallization from *n*-hexane gave white needles; mp 90.4—91.6°C. IR (Nujol): 3360, 1094, 1015 cm^{-1}. NMR (CCl_4): δ 0.7—2.7 (m, 19H, methylenes and methine), 3.2—4.0 (m, 3H, CH-O and OH). MS: *m/e* (relative abundance) 198 (M^+, 10), 180 (4), 139 (12), 125 (27), 111 (19), 97 (93), 84 (100), 67 (57), 55 (90). Found: C, 72.7; H, 11.3%. Calcd for $C_{12}H_{22}O_2$: C, 72.7; H, 11.2%.

Oxidation of XX. This was performed much as has been described in the oxidation of XI and XII; it afforded XXI in an 86% yield. IR (neat): 3700—2300, 1737, 1708, 1410, 1250, 1200, 1155 cm^{-1}. MS: *m/e* (relative abundance 212 (M^+, 2), 163 (4), 123 (5), 109 (5), 97 (14), 84 (100), 83 (20), 69 (15), 55 (30). The semicarbazone melted at 169—171°C.

Hydrogenation of XXII. A mixture of XXII (0.13 g, 0.62 mmol) and Raney Nickel (*ca.* 0.1 g) in ethanol (10 m*l*) was stirred under a hydrogen atmosphere for a day. The subsequent filtration of the catalyst and concentration gave XXI quantitatively. The semicarbazone melted at 170—172°C.

UV Irradiation of IIf. A solution of IIf (2.5 g, 10.5 mmol) and iodine (0.2 g) in cyclohexane (75 m*l*) was irradiated for 7 days. The precipitates of XXIII (1.92 g, 77%) were collected by filtration and recrystallized from benzene to afford needles; mp 178—179°C. IR (KBr): 1840, 1805, 1622, 1605, 1120, 1045, 1024, 910, 740, 712 cm^{-1}. NMR ($CDCl_3$): δ 7.5—8.2 (m, 6H), 8.4—8.9 (m, 2H). MS: *m/e* (relative abundance) 236 (M^+, 80), 180 (44), 164 (100), 152 (28). UV (*n*-hexane): λ_{max} (log ε) 248 (5.72), 255 (5.82), 269 (4.95), 280 (4.67), 292 (4.86), 305 (5.12). Found: C, 76.1; H, 3.2%. Calcd for $C_{15}H_8O_3$: C, 76.3; H, 3.4%.

The Phenolysis of Tetrahydrolinalyl and 2-Octyl Systems. The Rates, Steric Courses, and Product Distributions

Kunio OKAMOTO and Tomomi KINOSHITA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received March 6, 1972)

As tertiary and secondary systems with optical activity, tetrahydrolinalyl (methylethylisohexylcarbinyl) chloride or *p*-nitrobenzoate and 2-octyl *p*-toluenesulfonate have been selected, and their titrimetric and polarimetric rate constants (k_t and k_p) for S_N1 phenolyses have been measured in the presence of triethylamine (or sodium phenoxide) in 50 wt% phenol-benzene. At higher amine (or phenoxide) concentrations, the k_t and k_p coincide with each other for tetrahydrolinalyl chloride (at 25.0°C) or *p*-nitrobenzoate (at 100.0°C), and also for 2-octyl tosylate (at 75.0°C), exhibiting the typical features of the S_N1 solvolysis rate constant. In the absence of the amine (or sodium phenoxide), the k_t diminishes to show a gap between the k_p and the k_t, indicating the occurrence of an ion-pair return in the phenolysis for both systems. Under the same reaction conditions as those of the rate measurement, tetrahydrolinalyl chloride and *p*-nitrobenzoate yield the phenyl ether, with a predominant racemization accompanied by some net inversion of the configuration, whereas 2-octyl tosylate gives 2-octyl phenyl ether, *o*-, and *p*-2-octylphenols, with a net inversion of the configuration accompanied by a slight racemization. These steric results indicate that phenol can be considered as a typical solvolytic solvent. The product distributions have been assessed for the reactions of 2-octyl chloride (200°C) and of tetrahydrolinalyl chloride (25.0°C) with the molecule of phenol under the S_N1 phenolysis conditions, by extrapolating the product composition curves to a zero concentration of the phenoxide. For both systems, the phenol molecule is predominantly *O*-alkylated (74 and 99% respectively), accompanied by minor amounts of *C*-alkylation. In contrast to the phenol reaction, the phenoxide ion undergoes more *C*-alkylation (42 and 50% respectively).

Our previous studies of the phenolytic reactivity with regard to optically-active substrates have concentrated upon the optically-active 1-phenylethyl system;[1] the phenolysis of this system proceeded to yield 1-phenylethyl phenyl ether with a partially-retained configuration. This is not a standard result for the steric course of the solvolysis, since the solvolyses of such simple *sec*- and *tert*-alkyl (or aralkyl) systems have generally been reported to give a product with a partially-inverted onfiguration.[2] Therefore, we considered it of interest to examine whether the solvolysis of simple optically-active systems other than the 1-phenylethyl system would proceed with a retention of the configuration in the phenolic solvent or not; we selected the 2-octyl and the tetrahydrolinalyl (methylethylisohexylcarbinyl) systems, which are readily available and which also have been reported to give partially-inverted products in common solvolytic solvents[3] other than phenol.

Our results show that, in contrast to the 1-phenylethyl system, the phenolysis for both systems proceeds with a net inversion of the configuration—a standard result expected of the typical S_N1 solvolysis of a simple optically-active system. We will also report on the distributions of the phenolysis products in both systems.

Results and Discussion

The S_N1 *Characteristics of the Phenolyses of 2-Octyl and Tetrahydrolinalyl Systems.* The titrimetric and polarimetric rate constants (k_t and k_p) in a 50 wt% phenol-benzene solvent were measured in the presence of variable concentrations of triethylamine (or sodium phenoxide) on 2-octyl chloride at 175.0 and 200.0°C or on the *p*-toluenesulfonate at 75.0°C, and on tetrahydrolinalyl (methylethylisohexylcarbinyl) chloride at 25.0°C or on the *p*-nitrobenzoate at 100.0°C. Satisfactory first-order kinetic behavior, expected of a typical S_N1 reaction, was observed for each of the k_t's and k_p's; the results are tabulated in Table 1.

The effects of the triethylamine (or sodium phenoxide) concentrations upon the k_t and the k_p values in the phenolyses of 2-octyl tosylate and tetrahydrolinalyl *p*-nitrobenzoate are illustrated in Figs. 1 and 2 respectively. It is immediately obvious that the k_t's for the tetrahydrolinalyl *p*-nitrobenzoate (or chloride) are almost independent of the amine (or the phenoxide) concentrations; this is a typical kinetic feature of the S_N1 solvolysis (see also Table 1).

From Figs. 1 and 2 it is also evident that, at a zero concentration of the base, there exists a gap between the k_p and k_t values (*i.e.*, $k_p > k_t$) in the case of 2-octyl tosylate, and most probably in the case of tetrahydrolinalyl *p*-nitrobenzoate as well; these results indicate that the S_N1 phenolyses for these systems proceed with some "ion-pair" return.

The gap between the k_p and k_t values has already been observed in the phenolysis of 1-phenylethyl chloride.[4] However, in marked contrast to the 1-phenylethyl system, in which the gap actually widens as the

a) Sodium phenoxide was used instead of triethylamine. b) THL=Tetrahydrolinalyl; OPNB=*p*-Nitrobenzoate.

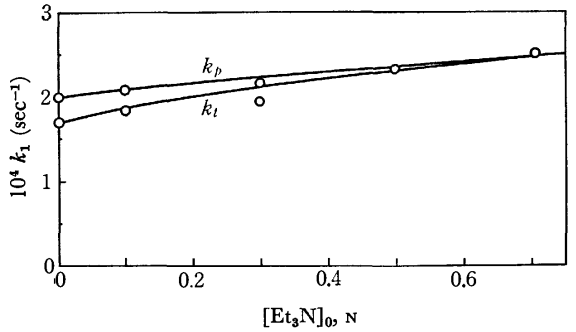

Fig. 1. Effect of the added triethylamine upon the first-order rate constants for the phenolysis of 2-octyl tosylate in 50 wt% phenol-benzene solvent at 75.0°C.

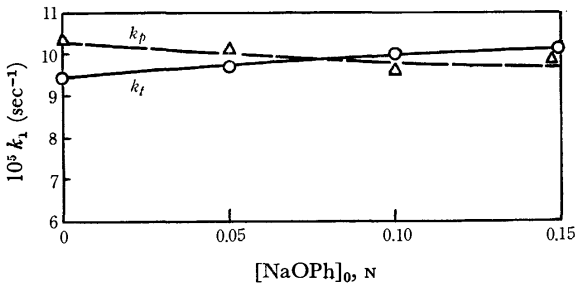

Fig. 2. Effect of the added sodium phenoxide upon the first-order rate constants for the phenolysis of tetrahydrolinalyl *p*-nitrobenzoate in 50 wt% phenol-benzene solvent at 100.0°C.

concentration of the base increases, in the 2-octyl and tetrahydrolinalyl systems the gap virtually disappears with an increase in the amine concentrations (see Figs. 1 and 2). The coincidence in the k_p and k_t values (within the limits of experimental error) suggests that the consumption rate (k_2[PhOH]+k_2'[PhO$^-$] in Eq. (1)) of the ion-pair intermediate becomes far greater than the return rate (k_{-1} in Eq. (1)) at higher amine or phenoxide concentrations, and that the return phenomena virtually disappear as the amine or the phenoxide concentration increases.

These kinetic features can be expressed by the following reaction scheme, which contains a single ion-pair intermediate; the observed rate constant can be expressed by Eq. (1):

$$RX \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [R^+ \cdots X^-] \xrightarrow{k_2[PhOH]+k_{2'}[PhO^\ominus]} \text{Phenolysis products}$$

$$k_{obs.} = \frac{k_1(k_2[PhOH]+k_{2'}[PhO^\ominus])}{k_{-1}+k_2[PhOH]+k_{2'}[PhO^\ominus]} \quad (1)$$

For the acetolysis of 2-octyl tosylate, a similar reaction scheme with a single ion-pair intermediate has already been proposed by Streitwieser *et al.*[3a,b] Thus, providing that the above scheme applies to these phenolyses, from the data illustrated in Figs. 1 and 2 and from Eq. (1) the k_{-1}/k_2 ratio can be estimated to be 0.925(M) for the phenolysis of 2-octyl tosylate at 75.0°C and 0.467(M) for that of the tetrahydrolinalyl system at 100.0°C.

The Steric Courses of the Phenolyses of 2-Octyl Tosylate and of Tetrahydrolinalyl Chloride and p-*Nitrobenzoate.* The phenolyses of optically-active 2-octyl tosylate were carried out at 75.0°C in 50 wt% phenol–benzene for one and for ten half-lives. By the chromatography on silica gel, from the reaction mixtures we isolated the

a) The maximum rotations for the relevant optically active compounds in this Table are shown in Table 3. b) The rotations for a neat sample at 21—25°C in a 1-dm tube. c) See text; ethy 2-octyl ether, which was obtained by the SN2 ethanolysis of the unchanged ROTs, possessed $[\alpha]_D$ −14.9°, and α% 91.2 (with respect to ROTs). d) A net steric course. e) See text; the calculated α% on the basis of the optical purity of tetrahydrolinalool, from which the starting chloride was prepared, amounts to 3.62%; the α%, calculated on the basis of the maximum rotation[11)] for tetrahydrolinalyl chloride, amounts to 3.21%.

elimination product in a 50—60% yield; this product was composed of 1-, *cis*-2-, and *trans*-2-octenes. From the subsequent eluents, the substitution products (2-octyl phenyl ether, *o*-, and *p*-2-octylphenols) were separated in a 40—60% yield. The configuration of each product was predominantly inverted, and the degree of racemization was quite small. The details of the results are tabulated in Table 2.

The inversion with some racemization is a standard result for the steric course of the solvolysis of a simple secondary alkyl system;[2)] similar stereochemical outcomes for the 2-octyl systems have been observed in acetic acid[3a,b)] and aqueous dioxane[3c,d)] solvents.

The phenolysis of tetrahydrolinalyl chloride, when conducted at 25.0°C in the 50 wt% phenol-benzene solvent for 10 half-lives, yielded a 86.2% yield of decenes (a mixture of 4 isomers), a 13.6% yield of tetrahydrolinalyl phenyl ether, and small amounts of *o*- and *p*-tetrahydrolinalylphenols (0.15 and 0.017% yields respectively); the configuration of the phenyl ether was inverted, with some racemization. Since we have no information about the extent of racemization during the retentive conversion of tetrahydrolinalool to tetrahydrolinalyl chloride, we can not estimate the optical purity of the starting chloride thus prepared nor, consequently, the exact degree of racemization for the phenyl ether in the course of the phenolysis. However, if we assume that the retentive chloride formation by thionyl chloride proceeds with a low degree of the racemization, as is observed in the case of optically-active 1-phenylethyl alcohol,[5)] we may expect that the tetrahydrolinalyl chloride phenolysis proceeds with a predominant racemization, with some net inversion.

Tetrahydrolinalyl *p*-nitrobenzoate, $[\alpha]_D^{21.0}$ −0.925°, was prepared from tetrahydrolinalool, $\alpha_D^{23.5}$ −0.43°, and *p*-nitrobenzoyl chloride in pyridine. The phenolysis of the *p*-nitrobenzoate was carried out at 100.0°C in the 50 wt% phenol-benzene solvent for 10 half-lives; it yielded a 85% yield of decenes (a mixture of 4 isomers), a 12.5% yield of tetrahydrolinalyl phenyl ether, and a small amount of *C*-alkylated phenols (less than a 0.5% yield). From the values of the maximum rotations of the *p*-nitrobenzoate and the phenyl ether (see Table 3), it was estimated that the phenolysis proceeded with a 83.8% racemization, accompanied by a net 16.2% inversion.

An inversion of the configuration with some racemization has been typically observed in the solvolyses of simple *tert*-alkyl systems, *e.g.*, in the solvolyses of tetrahydrolinalyl chloride in 80% aqueous acetone and methanol solvents,[3e)] in the methanolysis of methylethylisobutylcarbinyl hydrogen phthalate,[6)] and in solvolyses of methylethylphenylcarbinyl chloride,[7)]

p-nitrobenzoate,[8] and hydrogen phthalate[8] in acetic acid,[8] methanol,[7,8] ethanol,[7] 80% aqueous ethanol,[7] and 75% aqueous dioxane.[7]

In conclusion, these steric results for both systems indicate that the phenolic solvent can be considered as a typical solvolytic solvent.

The Absolute Configurations and the Maximum Rotations for 2-Octyl Phenyl Ether, Tetrahydrolinalyl Phenyl Ether, and o- *and* p-*2-Octylphenols.* Optically-active compounds of the titled phenolysis products, the absolute configurations and maximum rotations of which are not yet known, were prepared from, or derived to, a known, optically-active compound by following the reaction schemes described below. The configurations and the rotations thus established are tabulated in Table 3, along with those of the relevant optically-active compounds. Using the values shown in Table 3, the net steric courses and extents of inversion (α%) in the course of the phenolyses have been estimated; they are tabulated in Table 2.

(*S*)-(+)-2-Octyl *p*-toluenesulfonate was treated with sodium phenoxide in dimethylformamide at 75.0°C for 20 hr. Since the reaction proceeds by means of the S_N2 mechanism, the (−)-2-octyl phenyl ether thus obtained was determined to possess the (*R*)-configuration.[9] The maximum rotation (Table 3) was calculated from the known rotation[3a] of 2-octyl tosylate:

$$(S)\text{-}(+)\text{-2-Oct-OTs} \xrightarrow[\text{in DMF}]{\text{NaOPh}} (R)\text{-}(-)\text{-2-Oct-OPh}$$

Optically-active *o*- and *p*-2-octylphenols, obtained by the acidic rearrangement of optically-active 2-octyl phenyl ether, were subjected to permanganate oxidation[10] in acetone. From the specific rotations of the optically-active 2-methyloctanoic acid[11] thus obtained, the maximum rotations of (*R*)-(−)-*o*-2-octylphenol and (*R*)-(−)-*p*-2-octylphenol were estimated (Table 3):

$$(R)\text{-}(-)\text{-}o\text{-2-Oct-C}_6\text{H}_4\text{OH} \xrightarrow[\text{in acetone}]{\text{KMnO}_4} (R)\text{-}(-)\text{-2-Me-Octanoic Acid}$$

$$(R)\text{-}(-)\text{-}p\text{-2-Oct-C}_6\text{H}_4\text{OH} \xrightarrow[\text{in acetone}]{\text{KMnO}_4} (R)\text{-}(-)\text{-2-Me-Octanoic Acid}$$

(*S*)-(−)-Methylethylisohexylcarbinol (Tetrahydrolinalool, THL-OH), with a somewhat lower rotation, was converted to potassium tetrahydrolinalate in benzene; then the potassium salt was treated with an excess of bromobenzene. The maximum rotation of the (*S*)-(−)-tetrahydrolinalyl phenyl ether thus obtained was calculated on the basis of the maximum rotation of tetrahydrolinalool[12] (Table 3):

$$(S)\text{-}(-)\text{-THL-OH} \xrightarrow[\text{in benzene}]{K} (S)\text{-THL-OK} \xrightarrow{\text{PhBr}} (S)\text{-}(-)\text{-THL-OPh}$$

The Product Distribution for the Phenolyses of 2-Octyl and Tetrahydrolinalyl Chlorides. The composition of the phenolysis product after ten half-lives was determined by gas chromatography, using diphenyl ether as the internal standard. Each phenolysis was conducted with a sodium phenoxide/substrate ratio higher than 10 in order to keep the base concentration approximately invariant during the phenolysis.

In Table 4 the effect of the sodium pheoxide concentration upon the product composition is presented for the phenolyses of 2-octyl and tetrahydrolinalyl chlorides in the 50 wt% phenol-benzene solvent at 200.0 and 25.0°C respectively; it is also illustrated in Figs. 3 and 4.

The product composition for the tetrahydrolinalyl system is approximately invariant, despite the wide variation in the concentration of the phenoxide ion. In contrast to this system, in the 2-octyl system the olefin % decreases with an increase in the phenoxide concentration.

Since, in the reaction media, there exist two species of nucleophiles, *viz.*, the phenol molecule and the

b) Distribution % for the substitution products.

phenoxide ion, it is of interest to assess the product distribution for each species.

We can, first, estimate the product distribution for the reaction of the phenol molecule with the ion-pair intermediate by extrapolating the composition lines in Figs. 3 and 4 to a zero concentration of the phenoxide ion. The results are tabulated in Table 5, along with the distribution % for the phenolysis of 1-adamantyl chloride, which has previously been estimated by the same procedure.[13]

Secondly, providing that the phenol molecule and the phenoxide ion competitively attack the ion-pair intermediate at the product-formation step, and that the concentrations of the phenol molecule and the phenoxide ion are actually invariant during the reaction, we can assess the product distribution ($r_{i,x}$, *vide infra*) for the phenoxide-ion reaction, by using Eq. (2), which expresses the relationships between the observed product composition (*viz.*, $r_{obs.,\ olefin}$, $r_{obs.,\ ether}$, $r_{obs.,\ ortho}$, and $r_{obs.,\ para}$) and the estimated product distributions for the phenol reaction (*viz.*, $r_{m,\ olefin}$, $r_{m,\ ether}$, $r_{m,\ ortho}$, and $r_{m,\ para}$) or for the phenoxide reaction (*viz.*, $r_{i,\ olefin}$, $r_{i,\ ether}$, $r_{i,\ ortho}$, and $r_{i,\ para}$). The details for the derivation of Eq. (2) have been reported previously.[13]

$$\mathrm{RX} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{Ion-pair intermediate} \xrightarrow{k_2[\mathrm{PhOH}]} \underset{r_{m,ether}}{\mathrm{ROPh}} + \underset{r_{m,ortho}}{o\text{-}\mathrm{RC_6H_4OH}} + \underset{r_{m,para}}{p\text{-}\mathrm{RC_6H_4OH}} + \underset{r_{m,olefin}}{\text{Olefins}}$$

$$\text{Ion-pair intermediate} \xrightarrow{k_2'[\mathrm{PhO}^\ominus]} \underset{r_{i,ether}}{\mathrm{ROPh}} + \underset{r_{i,ortho}}{o\text{-}\mathrm{RC_6H_4OH}} + \underset{r_{i,para}}{p\text{-}\mathrm{RC_6H_4OH}} + \underset{r_{i,olefin}}{\text{Olefins}}$$

$$\frac{(r_{obs,x}-r_{m,x})}{([\mathrm{PhO}^\ominus]/[\mathrm{PhOH}])} = -\left(\frac{k_2'}{k_2}\right)r_{obs,x} + \left(\frac{k_2'}{k_2}\right)r_{i,x} \qquad (2)$$

In Eq. (2), x denotes olifin, ether, *ortho*, or *para*. Since we have already established the values for $r_{obs.,\ x}$, $r_{m,x}$, and ($[\mathrm{PhO}^\ominus]/[\mathrm{PhOH}]$), we can estimate the values for $r_{i,x}$ and k_2'/k_2 by a graphical method.[13] In Table 5 the results of the estimation of $r_{i,x}$ for 2-octyl chloride and tetrahydrolinalyl chloride are presented, along with the previously-reported values for 1-adamantyl chloride.[13]

From Table 5 it is immediately obvious that, for each substrate, the proportion of *O*-alkylation (the phenyl ether formation) is greater in the case of the phenol reaction than in the case of the phenoxide reaction. This indicates that the ambident phenol molecule reacts more selectively with the ion-pair intermediate than does the ambident phenoxide ion, which reacts more rapidly and, therefore, less selectively. The rapidness of the phenoxide reactions is reflected in the k_2'/k_2 rate ratio (27—7800), shown in Table 5.

It is also evident from Table 5 that the proportions of *O*-alkylation in the phenol-molecule reaction diminish in this sequence: tetrahydrolinalyl>1-adamantyl>2-octyl chlorides. It has been established in the case of 1-phenylethyl chloride[14] that the proportion of *O*-alkylation in the phenol-molecule reaction is virtually independent of the reaction temperature. If this is the case also in the phenolyses of these chlorides, the above-mentioned sequence of the proportions for *O*-alkylation on the phenol molecule will be independent of the temperature. Consequently, the sequence may indicate that the stabilization of the ion-pair intermediate in the tetrahydrolinalyl system contributes substantially to the enhanced tendency to undergo *O*-alkylation; this seems to be relevant, with the observation that the S_N1-like reaction of methyl iodide with silver nitrite predominantly yields the *O*-alkylation product, unlike the S_N2 reaction with sodium nitrite.[15]

For the phenoxide reaction there appears to be no simple correlation between the stability of the ion-pair intermediate and the structural sequence (*viz.*, 1-Ad>2-Oct>THL) for the *O*-alkylation proportions on the phenoxide ion; this sequence remains to be accounted for.

As has been mentioned above, the three substrates, 2-octyl, 1-adamantyl, and tetrahydrolinalyl chlorides, all undergo phenolysis to yield predominantly inversive, completely retentive, and substantially racemic phenyl ethers; it seems difficult to find a correlation between these steric outcomes and the sequence of the proportions of *O*-alkylation.

Rearrangement of the Phenyl Ether in the Medium of the Phenolysis. Since it is well known that the *sec*- and *tert*-alkyl phenyl ethers readily undergo a rearrangement to give *o*- and *p*-alkylphenols in the presence of an acidic catalyst,[16] the possibility of a rearrangement for 2-octyl phenyl ether and tetrahydrolinalyl phenyl ether even in the slightly acidic solvent phenol can not be eliminated. However, we detected no *o*- or *p*-alkylated phenols in the reaction mixtures when these phenyl ethers were subjected to a rearrangement in 50 wt% phenol–benzene for more than ten half-lives of the phenolysis at, respectively, 200 and 25°C. Consequently, all of the *o*- and *p*-alkylated phenols found in these phenolysis products are not produced as a result of the rearrangement of the phenyl ether, but are directly produced from the ion-pair intermediate in each phenolysis.

Experimental[17]

Materials. 2-Octyl chloride[18] and optically-active 2-octyl *p*-toluenesulfonate[19] were prepared in the usual

manners. The resolution of 2-octanol was perfomed according to the method of Kenyon.[20] Optically-active tetrahydrolinalyl *p*-nitrobenzoate (mp 39.5—40.1°C (cor.)) (see Tables 2 and 3) was prepared from tetrahydrolinalool[12] and *p*-nitrobenzoyl chloride in pyridine (*vide infra*) Optically-active tetrahydrolinalyl chloride[21] was prepared from tetrahydrolinalool.[12] Sodium phenoxide was prepared by refluxing a toluene solution of phenol with sodium metal. The other organic reagents employed were of an analytical reagent grade and were fractionated just prior to use. Titration with a Karl Fischer reagent indicated the water content of phenol to be less than 10^{-2} M.

Product Isolation. *The Phenolysis of 2-Octyl Tosylate (75°C)*: To 146 m*l* of a 1:1 (by wt.) mixture of phenol and benzene containing triethylamine (2.20 m*l*; 0.101 M), there was added optically-active 2-octyl *p*-toluenesulfonate (4.290 g, 0.01510 mol; $\alpha_D^{22.6}$ +5.195±0.015°, 1 dm, neat). The reaction mixture was kept at 75.0±0.1°C for 24 hr (about 10 half-lives). The mixture was then diluted with 300 m*l* of ether, and washed successively with 10% aqueous sodium hydroxide (100 m*l*×5) and 10% aqueous sodium chloride (100 m*l*×5) to make it neutral to pH indicator paper. The ethereal solution, dried with magnesium sulfate, was concentrated by distillation; a part (3.74 wt%) of the residual liquid was examined by gas chromatography. The remainder was evapolated, and then separated by column chromatography on silica gel (60 g). The column was eluted successively with *n*-hexane, *n*-hexane-benzene (1:1 by vol.), benzene, benzene-ether (97:3 by vol.), and ether. The fractions eluted with *n*-hexane–benzene gave 2-octyl phenyl ether (681 mg; bp 130—135°C/4.0 mmHg; 21.9% yield; the same infrared spectrum as in an authentic sample; $\alpha_D^{21.0}$ −10.05± 0.02°, 0.5 dm, neat). The fractions eluted with benzene gave *o*-2-octylphenol (99.8 mg; bp 138—145°C/4.0 mmHg; 3.21% yield; the same infrared spectrum as in an authentic sample; $[\alpha]_D^{21.4}$ −2.17±0.15° (*c* 12.9, benzene)). The fractions eluted with benzene-ether gave *p*-2-octylphenol (64.7 mg; bp 140—145°C/4.0 mmHg; 2.17% yield; the same infrared spectrum as in an authentic sample; $[\alpha]_D^{22.0}$ +4.69± 0.05° (*c* 72.3, benzene)).

The Phenolysis of Tetrahydrolinalyl Chloride (25°C). A 1:1 (by wt.) mixture (94.5 m*l*) of phenol and benzene, containing triethylamine (1.48 m*l*; 0.1030 M), was prepared and kept at 25.0±0.1°C for 1 hr. To the phenolic solvent, optically-active tetrahydrolinalyl chloride (2.000 m*l*, 1.703 g; 0.00965 mol; bp 55.0—59.5°C/4.0 mmHg; $\alpha_D^{25.8}$ +0.50± 0.02°, 1 dm, neat) was then added. The reaction mixture was maintained for 1.5 hr (about 11 half-lives). After the working-up described above, an oily material (0.3668 g) was chromatographed on alumina (30 g). The fractions eluted with *n*-hexane gave tetrahydrolinalyl phenyl ether (0.1693 g; bp 145—150°C/4.0 mmHg; 7.51% yield; $\alpha_D^{22.3}$ +0.20±0.02°, 1 dm, neat; IR (CCl_4) 2950, 1590, 1490, 1460, 1220, 1140, and 700 cm^{-1}; NMR (CCl_4) δ 2.85 (m, 5H) and 8.85 (m, 21H)).

Found: C, 81.96; H, 11.40%. Calcd for $C_{16}H_{26}O$: C, 82.00; H, 11.18%.

The Phenolysis of Tetrahydrolinalyl p-*Nitrobenzoate (100°C).* Optically-active tetrahydrolinalyl *p*-nitrobenzoate (3.0345 g; 0.00989 mol; mp 39.5—40.1°C (corr.); $[\alpha]_D^{16.0}$ −0.925± 0.011° (*c* 26.5, benzene)) was dissolved in 97 m*l* of a 1:1 (by wt.) mixture of phenol and benzene, containing sodium phenoxide (0.0993 M). After 24 hr (about 10 half-lives) at 100.0±0.1°C, the solution was treated in the usual way. A residual liquid (1.1055 g) was separated by thin-layer chromatography on silica gel to give tetrahydrolinalyl phenyl ether (0.2905 g; bp 145—150°C/4.0 mmHg; 12.5% yield; $\alpha_D^{16.5}$ +0.635±0.005°, 0.5 dm, neat).

Kinetic Measurements. *Titrimetric Rate Constant (k_t).* The previous procedure was followed.[22] For the runs of the tetrahydrolinalyl chloride phenolysis at 25°C, 1.000 m*l* aliquots were removed at intervals from 20 m*l* of the reaction mixture placed in a glass-stoppered flask. For the phenolyses of 2-octyl chloride, 2-octyl tosylate, and tetrahydrolinalyl *p*-nitrobenzoate at 200, 75, and 100°C respectively, the usual sealed-ampoule (1.000 m*l*) technique was employed. The diminution of the base concentrations was followed by titration with standard perchloric acid (0.05 N) in acetic acid, using crystal violet as the indicator. For the phenolysis of tetrahydrolinalyl chloride, carried out in the absence of a base, a 1 m*l* glass-stoppered flask was used. In this case, the free space was filled with liberated HCl in the course of the phenolysis. Therefore, after a specified length of time, the flask, filled with a 1 m*l* reaction mixture, was immersed and opened in a large quantity of cold acetic acid used as a stop-solvent. The increase in the HCl concentration was followed by titration with standard sodium acetate in acetic acid. All the rate data were treated graphically, plotting log $a/(a-x)$ against the time. In each case the reaction was followed to at least 70% completion; a smooth linear relationship was obtained. Infinity titers were determined after at least ten half-lives. The rate data are shown in Figs. 1 and 2 and in Table 1.

Polarimetric Rate Constant (k_p). For the phenolysis of 2-octyl tosylate, the usual sealed-ampoule (5 m*l*) technique was employed. Each ampoule, after having been kept at the reaction temperature for a specified time, was cooled and the reaction mixture was immediately transfered into a 2 dm polarimeter tube. The optical rotation was measured at room temperature. For the phenolysis of tetrahydrolinalyl *p*-nitrobenzoate, the observation of the optical rotation of a reaction mixture was impossible because of the low optical rotation of the reaction mixture. Therefore, the measurement was carried out by the use of another method as follows. After a specified reaction time, to 100 m*l* of the reaction mixture we added a large quantity of cold ether. The cold ethereal solution was promptly washed with cold 10% aqueous NaOH and then with cold 10% aqueous NaCl, and dried (Na_2SO_4); most of the solvent was subsequently removed by rotary-evaporation. To the residual liquid, benzene was added to make a 2.00 m*l* solution. The specific rotation of the benzene solution was determined. Thus, the rotations for two specified reaction times were treated graphically and a smooth first-order linear relationship was obtained. The data for the k_p's are shown in Figs. 1 and 2 and Table 1.

Product-distribution Analysis by Gas Chromatography. To several mg of 2-octyl chloride (or tetrahydrolinalyl chloride) with diphenyl ether (an internal standard), placed in a 12 m*l* ampoule, there was added 10 m*l* of a phenol-benzene (1:1 by wt.) solvent containing a specified amount of sodium phenoxide (or triethylamine). The sealed ampoule was kept at the reaction temperature for 10 half-lives. The reaction mixture was then diluted with 20 m*l* of ether, washed with 10% aqueous Na_2CO_3 and 10% aqueous NaCl, dried with $MgSO_4$, and distilled to leave 6—8 m*l* of the residual liquid, which was then analysed by glc using a 2 m×3 mm column with Apiezon Grease on Neopak 1A at 200°C.

22) K. Okamoto, H. Yamada, I. Nitta, and H. Shingu, This Bulletin, **39**, 299 (1966).

Rearrangement of the Phenyl Ethers. The usual sealed-ampoule technique was employed. To several mg of 2-octyl phenyl ether (or tetrahydrolinalyl phenyl ether), which contained diphenyl ether as an internal standard and which was placed in a 2 ml ampoule, we added 1 ml of a phenol–benzene (1:1 by wt.) mixture. The ampoule was kept at the same temperature as that of the chloride phenolysis for the 10 half-lives. The analysis was performed by glc using a 2 m×3 mm Apiezon Grease column at 200°C.

Syntheses of Optically-active Authentic Samples (cf. Table 3). *(R)-(−)-2-Octyl Phenyl Ether.* (*R*)-(−)-2-Octyl phenyl ether was prepared from (*S*)-(+)-2-octyl tosylate and sodium phenoxide under S_N2 reaction conditions. The reaction in DMF was determined to be a 2nd-order reaction, with k_2 3.58×10^{-3} (sec^{-1} M^{-1}) at 75.0°C. (*S*)-(+)-2-octyl tosylate (2.8467 g, 0.01001 mol; $\alpha_D^{22.6}$ +5.195±0.015°, 1 dm, neat), prepared from (*S*)-(+)-2-octanol $\alpha_D^{23.1}$ +7.27±0.02°, 1 dm, neat), was dissolved in 97.0 ml of DMF containing sodium phenoxide (2.44 g, 0.0210 mol). After 20 hr at 75°C, the mixture was treated as has been described above; the residual liquid was separated by column chromatography on basic alumina to give 2-octyl phenyl ether (1.461 g; bp 130—135°C/4.0 mmHg; 71.0% yield; $\alpha_D^{21.5}$ −22.95±0.01°, 1 dm, neat)

(S)-(−)-Tetrahydrolinalyl Phenyl Ether. A mixture of (*S*)-(−)-tetrahydrolinalool (3.160 g; 0.0200 mol; bp 54.0—59.5°C/5.0 mmHg; $\alpha_D^{23.5}$ −0.43±0.02°, 1 dm, neat) and potassium metal (0.78 g; 0.020 mol) in dry benzene (50 ml) was refluxed for 8 hr; the mixture then became homogeneous. To the mixture, bromobenzene (15.98 g; 0.200 mol) was added. The reaction mixture was then refluxed for an additional 14 hr. After the addition of ether (200ml), the mixture washed with 10% aqueous NaCl (100 ml×4) and dried with $MgSO_4$. The ethereal solutions was concentrated; the residual liquid was chromatographed on alumina. The fractions eluted with *n*-hexane and with benzene gave tetrahydrolinalyl phenyl ether (0.544 g, 0.00232 mol; bp 140—145°C/4.0 mmHg; 11.6% yield; $\alpha_D^{24.2}$ −5.53±0.03°, 1 dm, neat). The fractions eluted with ether and with ethanol gave unchanged tetrahydrolinalool (2.37 g; 75.0% recovery; $\alpha_D^{20.8}$ m0.42±0.02°, 1 dm, neat).

(S)-(−)-Tetrahydrolinalyl p-*Nitrobenzoate.* The usual method for the preparation of optically-active 1-phenylethyl *p*-nitrobenzoate[23] was modified for the preparation of tetrahydrolinalyl *p*-nitrobenzoate. A mixture of (*S*)-(−)-tetrahydrolinalool (4.07 g; 0.0257 mol; bp 54.0—59.5°C/5.0 mmHg; $\alpha_D^{23.5}$ −0.43±0.02°, 1 dm, neat) and *p*-nitrobenzoyl chloride (4.88 g; 0.0263 mol) in pyridine (12 ml) was stirred at 30.0—31.6°C for 5 hr in order to make it homogeneous. The mixture was then treated in the usual way to give (*S*)-(−)-tetrahydrolinalyl *p*-nitrobenzoate (6.55 g; 83.0% yield; mp 39.5—40.1°C (corr.); $[\alpha]_D^{21.0}$ −0.925±0.011° (*c* 26.5, benzene); IR (CCl_4) 3000, 1790, 1380, 1340, 1230, 1150, 1080, and 700 cm^{-1}; NMR (CCl_4) δ 1.3 (m, 21H) and 8.2 (d, 4H)).

Found: C, 66.43; H, 8.33%. Calcd for $C_{17}H_{25}NO_4$: C, 66.42; H, 8.20%.

Oxidation of 2-Octylphenols. Optically-active (−)-*o*- and (+)-*p*-2-octylphenols were prepared by the rearrangement (in the presence of *p*-toluenesulfonic acid, 100°C, 21 hr) of (*R*)-(−)-2-octyl phenyl ether ($\alpha_D^{20.5}$ −23.78±0.01°, 1 dm, neat) in phenol-benzene (1:1 by wt.). The optically-active *o*- and *p*-2-octylphenols thus were oxidized to 2-methyloctanoic acid according to the procedure of Hart and Eleuterio.[24] To a solution of *o*-2-octylphenol (1.94 g; 0.00943 mol; $[\alpha]_D^{24.1}$ −0.31±0.09° (*c* 56.5, benzene)) in acetone (200 ml), we added potassium permanganate (10.3 g, 0.0652 mol) in distilled water (750 ml) at 10—15°C. The mixture was then stirred for 2 hr and acidified with 6 N sulfuric acid, and the manganese dioxane thus precipitated was dissolved by the addition of sodium bisulfite. The mixture was extracted with 10% aqueous $NaHCO_3$ (100 ml×4), and the extracts were acidified with 6 N H_2SO_4 (100 ml) and then extracted with benzene (100 ml×4). The benzene solution was dried with $MgSO_4$. After the solvent had been removed by rotary-evaporation, the residual oil was distilled *in vacuo* to give 2-methyloctanoic acid (0.339 g, 22.8% yield; bp 98.4—111.5°C/2.0 mmHg; $[\alpha]_D^{16.8}$ −1.12±0.07° (*c* 28.5, *n*-heptane)). Since this conversion proceeds with the maintenance of the configuration of the assymmetric carbon atom, the configurations of 2-methyloctanoic acid and *o*-2-octylphenol should be identical. Thus, the specific rotation of optically-pure (*R*)-(−)-*o*-2-octylphenol may be estimated to be −4.56° (in benzene) on the basis of the value for optically-pure (*R*)-2-methyloctanoic acid, −16.4° (in *n*-heptane).[11] In the same manner, from (+)-*p*-2-octylphenol (2.64 g, 0.0128 mol; $[\alpha]_D^{24.1}$ +1.70±0.26° (*c* 26.5, benzene)) (+)-2-methyloctanoic acid (0.0477 g, 2.3% yield; bp 106.0—111.2°C/0.8 mmHg; $[\alpha]_D^{24.6}$ +4.25±0.19° (*c* 10.3, *n*-heptane)) was obtained. The specific rotation of optically-pure (*S*)-*p*-2-octylphenol can, therefore, be estimated to be +6.57° (in benzene).

The authors wish to express their thanks to Mr. Osamu Makino for his technical assistance.

Friedel-Crafts Aralkylation. II.[1] The $AlCl_3 \cdot CH_3NO_2$-catalyzed Phenethylation of Benzene and Toluene with 2-Arylethyl Chlorides in a Nitromethane Solution

Makoto Ichii

Institute for Chemical Research, Kyoto University, Gokasho, Uji, 611

(Received October 18, 1971)

The rates of $AlCl_3 \cdot CH_3NO_2$-catalyzed phenethylations of benzene (50°C) or toluene (25°C) with 2-arylethyl (ring-substituted phenethyl) chlorides were measured in homogeneous nitromethane solutions. The reactions are first-order in the aromatic component, first-order in the phenethyl chloride, and second-order in aluminum chloride. Substituent effects in the phenethyl chlorides give linear relationships with Hammett's σ constants. A displacement mechanism involving a nucleophilic attack by the aromatic substrate on the phenethyl chloride-catalyst system is proposed for the reactions. Competitive phenethylations of benzene and toluene were also carried out at 50°C. Both the isomer distribution and the relative reactivity of toluene to benzene are affected by the ring-substituents, the effects of which are correlated closer with the substrate selectivity. These results suggest that the transition state in the rate-determining step for the phenethylations is in nature an (oriented) π complex rather than a σ complex.

The Friedel-Crafts alkylation reaction of aromatics with primary alkyl halides continues to present various interesting problems. In particular, there are arguments as to the structure of the activated complex in the rate-determining step for the reaction.[2]

In the previous paper,[1] we reported the kinetics of the $AlCl_3 \cdot CH_3NO_2$-catalyzed phenethylation of benzene and toluene with 2-phenylethyl chloride and suggested the displacement mechanism for the reaction.

In this paper, we will describe a study of the aralkylations (phenethylations) of benzene and toluene with 2-arylethyl chlorides using the $AlCl_3 \cdot CH_3NO_2$ complex as the catalyst in nitromethane solutions; we will thus attempt to elucidate the nature of the transition state in the rate-determining step and the effect of ring-substituents on the reaction rates and the isomer distributions. Electron-donating substituents tend to decrease the electron deficiency of the reaction center in an aralkylating agent, while electron-withdrawing substituents tend to increase it. Thus, it is possible to correlate the electrophilicity of the substituting agent with the selectivity by changing its electrophilicity systematically, while keeping the other factors constant.

Results and Discussion

The phenethylation reactions in homogeneous nitromethane solutions can easily be followed kinetically, and they are considered to be free from consecutive isomerization. Proof of the non-isomerizing conditions is given clearly by the experimental fact that the phenethylation of benzene with 2-(*m*-tolyl)- or 2-(*p*-tolyl)-ethyl chloride yielded no isomer mixture of 1-phenyl-2-tolylethanes.

The rates of noncompetitive phenethylations of benzene (50°C) or toluene (25°C) with substituted phenethyl chlorides ($XC_6H_4CH_2CH_2Cl$) were measured under the same conditions. The mole ratio of benzene: $XC_6H_4CH_2CH_2Cl$: aluminum chloride in the solution was 5.6: 1: 1, and that of toluene: $XC_6H_4CH_2CH_2$-Cl: aluminum chloride was 4.7: 1: 1. Unfortunately, it was impossible to determine the reaction rates with 2-(*p*-nitrophenyl)ethyl chloride, since the reactions were too slow to be measured under the above conditions. It needed severe conditions (*e.g.*, using more than equimolar quantities of the catalyst to the chloride without nitromethane) to bring about *p*-nitrophenethylation, accompanied by side reactions.

During the course of the reactions, small amounts of by-products (di- or higher phenethylated and 1, 1-diarylethane-type rearranged products, and polymers resulting from the reactions between the aralkylating agents) were detected by gas chromatography and spectroscopic methods. In the early stages of the reactions, however, they are negligible and it is convenient to assume that only monoalkylation takes place under the present experimental conditions. Therefore, for all systems, pseudo-second-order plots were obtained, assuming that:

$$\frac{d[\text{product}]}{dt} = k_{obs}[\text{aromatic}][XC_6H_4CH_2CH_2Cl] \quad (1)$$

The obtained results are summarized in Table 1. A second-order dependence on the catalyst concentration was found (when the concentration of the catalyst was reduced to one half, the values of k_{obs} with benzene for X=*p*-CH_3O, *p*-CH_3, and *p*-Cl were 2.65×10^{-3}, 1.43×10^{-3}, and 2.73×10^{-4} respectively), as in the previous investigation with 2-phenylethyl chloride (X=H).[1] Thus, the reactions are second-order with respect to the catalyst; that is, $k_{obs}=k_4[AlCl_3]^2$, where k_4 is the overall fourth-order rate constant.

In order to clarify the mode in which a substituent group exerts its effect upon the reaction rate, the results in Table 1 are plotted against the substituent constants. Fairly good correlations with Hammett's σ constants were obtained (Fig. 1). The apparent reaction constants, ρ, calculated by the method of least squares,[3] are -1.71 ($r=0.940$) for the reaction with

a) Initial concentration, $[AlCl_3]=0.400$mol/*l*. b) The description of the isomer distributions of the products is omitted, because they are almost identical to those obtained in the competitive reactions described later. c) See Ref. 1.

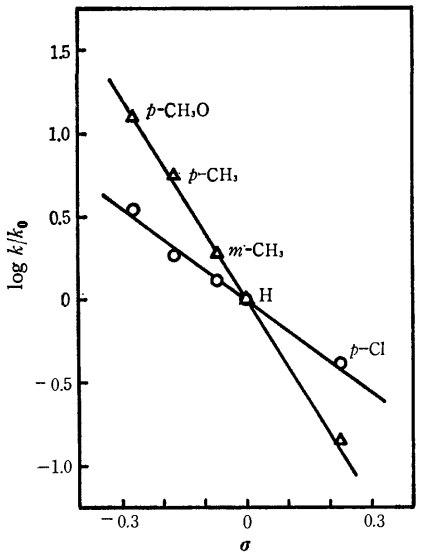

Fig. 1. Hammett plots for the $AlCl_3 \cdot CH_3NO_2$-catalyzed phenethylation of benzene (○) at 50°C or toluene (△) at 25°C with $XC_6H_4CH_2CH_2Cl$.

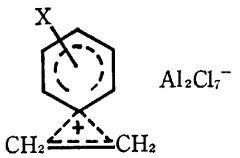
benzene and −3.72 (r=0.942) for toluene. The linear relationships with Hammett's σ, but not with Brown's σ^+ constants, suggest that the rate-determining step does not involve a phenonium ion-type intermediate (**1**) as an electrophile.[4] If any neighboring aryl



1

participation takes place, much larger substituent effects would be observed through a resonance interaction between the substituent and the reaction site, and then the reaction rates might be correlated with Brown's σ^+ constants. This is not true for the present phenethylation. Thus, the present results are more consistent with a displacement mechanism involving a rate-determining nucleophilic attack by the aromatic substrate on the phenethyl chloride-dimeric aluminum chloride system (Eq. (4)).[5] The transition state in

$$XC_6H_4CH_2CH_2Cl + AlCl_3\text{–}CH_3NO_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} XC_6H_4CH_2CH_2Cl\text{–}AlCl_3 + CH_3NO_2 \quad (2)$$

2

$$\mathbf{2} + AlCl_3\text{–}CH_3NO_2 \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} XC_6H_4CH_2CH_2\overset{\delta+}{\text{—}}\overset{\delta-}{Cl}\cdots Al_2Cl_6 + CH_3NO_2 \quad (3)$$

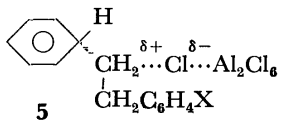
3

$$\mathbf{3} + C_6H_6 \xrightarrow{k_3} \text{(arenium ion)}\ H,\ CH_2CH_2C_6H_4X\ \ Al_2Cl_7^- \quad (4)$$

4

$$\mathbf{4} \rightleftharpoons \text{(C}_6\text{H}_5\text{)}\text{–}CH_2CH_2C_6H_4X + HCl + Al_2Cl_6 \quad (5)$$

the rate-determining step may be represented as an oriented π-complex(**5**):[6,7]



5

From the proposed mechanism, we can obtain the appropriate rate expression by using the steady-state approximation and by assuming that $k_{-1}, k_{-2} \gg k_1, k_2, k_3$:

$$\text{rate} = \frac{k_1k_2k_3}{k_{-1}k_{-2}}[XC_6H_4CH_2CH_2Cl][C_6H_6][AlCl_3\text{–}CH_3NO_2]^2 \quad (6)$$

This is in substantial agreement with Eq. (1).

The value of k_{obs} includes the k_1/k_{-1} and k_2/k_{-2} terms, the equilibrium constants for the formation of **3**. It seems reasonable to consider that the obtained ρ-value is determined largely by the preceding equilibria, especially by the k_1/k_{-1} term.[5] This explains the rather large negative ρ-values. Therefore, the substituent effects on the rate-determining step may be small. This means that the extent of the C–Cl bond cleavage has a great effect on the reactivity. In the case of the *p*-NO_2 group, little formation of **3** may take place. It appears that the group becomes much more electron-withdrawing than an ordinary one

a) See Ref. 1. b) Mole ratio of reactants, aromatics: *p*-$NO_2C_6H_4CH_2CH_2Cl$:$AlCl_3$=37:1:2, without nitromethane. The k_T/k_B value seems to be influenced by the transalkylation of the products. The isomeric 1-(*p*-nitrophenyl)-2-tolylethanes were not separable by gas chromatography.

through complex formation with aluminum chloride.[8)]

Competitive phenethylations of benzene and toluene at 50°C were also carried out by treating equimolar amounts of aromatic components in nitromethane solutions. The mole ratio of aromatics: $XC_6H_4CH_2CH_2Cl$ catalyst was always 10:1:1 unless otherwise noted. In the course of the reaction, the isomer distribution and the rate of toluene relative to benzene were found to remain almost unchanged. The average values of the relative rates and isomer distributions, together with the partial rate factors for substitution, are summarized in Table 2. The competitive reaction with 2-(*p*-nitrophenyl)ethyl chloride was unsuccessful so long as it was conducted in a nitromethane solution.

The data of Table 2 reveal the most significant effects of substituents on the relative rates and the isomer distributions. That is, both substrate and positional selectivities are affected by changing the electrophilicity of the reagent. However, the effects are more remarkable in the former selectivity. The electron-donating substituents tend to increase the relative rate, k_T/k_B; at the same time they tend to decrease the amount of the *meta*-isomer, as reflected by the increasing ratio of the partial rate factors for the *para*- and *meta*-positions of toluene, p_f/m_f, shown at the last column in Table II. On the other hand, the electron-withdrawing substituents decrease both the k_T/k_B and p_f/m_f ratios. In other words, a more stable and, hence, weaker electrophile has higher substrate and positional selectivities. The formation of the nonionized intermediate (**3**) with a electron-withdrawing substituent is difficult. However, once it is formed, it is highly energetic and reacts with benzene or toluene, discriminating slightly between them and at the same time slightly between the *ortho*- or *para*- and the *meta*-positions in toluene. Hence, it is possible to correlate the electrophilicity of the substituting agent with its

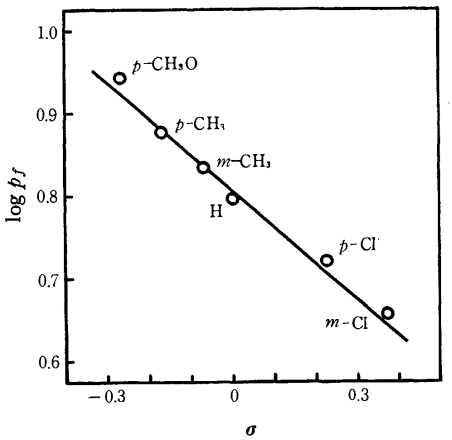

Fig. 2. Relationship between log p_f and Hammett's σ.

selectivity. In fact, as is shown in Fig. 2, a plot of the log p_f *versus* the substituent constant indicates a simple relationship between these quantities. The p_f-value is utilized as the measure of the substrate selectivity in order to eliminate any possible complications from steric factors. On the other hand, no simple relationship[9)] exists between the electrophilicity and the positional selectivity as reflected in the p_f/m_f ratio, although the latter actually depends on the former. These observations and the low k_T/k_B ratios suggest that the transition state in the displacement step should be regarded as an (oriented) π complex rather than as a σ complex.[2)]

Recently, Olah suggested that the position of the transition state in electrophilic aromatic substitutions is not a fixed one, but can be changed from a late one resembling the intermediate (σ complex) to an early one resembling the starting material (π complex).[2c)] According to this proposal, our present work provides good examples of early transition states. In substitutions where the rate-determining transition state is of a π-complex nature, the transition states of the subsequent σ-complex formation (leading to positional selectivity) appear relatively early on the reaction coordinate. In this case, the role of the methyl group in toluene in stabilizing the σ complex becomes less

8) In above discussions, little reference was made concerning the possibility of the aryl migration from β- to α-carbon atom. It was found that the ethylation with $^{14}CH_3CH_2Cl$ in excess benzene (R. M. Roberts, G. A. Ropp, and O. K. Neville, *J. Amer. Chem. Soc.*, **77**, 1764 (1955)) or with $^{14}CH_3CH_2F$ in nitromethane solution (A. Natsubori and R. Nakane, *J. Org. Chem.*, **35**, 3372 (1970)) gave practically no rearranged product. Rearrangement studies for the present phenethylations are in progress.

9) L. M. Stock and H. C. Brown, *Advan. Phys. Org. Chem.*, **1**, 35 (1963).

important with an increase in the electrophilicity of the reagent, and the higher proportion of *meta*-substitution is observed with a stronger electrophile. Consequently, the substrate selectivity is influenced directly by the electrophilicity of the substituting agent, which has relatively less effect on the positional selectivity.

Experimental

Materials.[10] The benzene, toluene, and 2-phenylethyl chloride (**6**) were commercial products of the highest available purity. They were further purified by distillation. The nitromethane was purified as has been described by Olah *et al.*[11] The preparation of 1,2-diphenylethane (**7**), 1-phenyl-2-tolylethanes (**8**), and 1,2-ditolylethanes (**9**) has been previously reported.[12] The 2-arylethanols were prepared as has been described in the literature.[13,14] They were converted to the corresponding chlorides by treatment with thionyl chloride. 2-(*p*-Anisyl)ethyl chloride (**15**); bp 98°C/4.5 mmHg (lit,[15] bp 90—92°C/2 mHg). 2-(*o*-Tolyl)ethyl chloride (**11**); bp 83—84°C/6 mmHg. 2-(*m*-Tolyl)ethyl chloride (**12**); bp 78—79°C/5 mmHg. 2-(*p*-Tolyl)ethyl chloride (**13**); bp 72—74°C/3 mmHg. 2-(*m*-Chlorophenyl)ethyl chloride (**14**); bp 91—92°C/3 mmHg. 2-(*p*-Chlorophenyl)ethyl chloride (**15**); bp 89—90°C/2 mmHg (lit,[16] bp 82—83°C/3 mmHg) 2-(*p*-Nitrophenyl)ethyl chloride (**16**) was obtained by the nitration of 2-phenylethyl chloride; mp 48.2—48.5°C (lit,[17] mp 48—49°C). Monosubstituted bibenzyls were prepared by treating the appropriate 2-arylethyl chloride with benzene in the presence of aluminum chloride. 4-Methoxybibenzyl (**17**); mp 54—56°C (lit,[18] mp 55—58°C). 3-Chlorobibenzyl (**18**); bp 130—131°C/2 mmHg (lit,[19] bp 148°C/3 mmHg). 4-Chlorobibenzyl (**19**); mp 47—48°C (lit,[19] mp 49°C). 4-Nitrobibenzyl (**20**); mp 68°C (lit,[20] mp 70—71°C). Non-contaminated isomer mixtures of 1-(*p*-anisyl)- (**21**), 1-(*m*-chlorophenyl)- (**22**), 1-(*p*-chlorophenyl)- (**23**), and 1-(*p*-nitrophenyl)-2-tolylethanes (**24**) were prepared by treating the appropriate 2-arylethyl chloride with toluene in the presence of aluminum chloride. Each isomer of **21**, **22**, and **23** was identified by a comparison of the infrared spectra (*o*-, 750—765 cm^{-1}, *m*-, 775—780 cm^{-1}; *p*-, 805—815 cm^{-1}) and gas chromatograms in a manner similar to that described previously.[21] Commercial aluminum chloride was sublimed before use.

Kinetic Measurements. Molar solutions in nitromethane of aluminum chloride and 2-arylethyl chloride were prepared. 20.0 m*l* of the catalyst solution and 10.0 m*l* of aromatic hydrocarbon (benzene or toluene) were placed in a 100 m*l*, three-necked flask equipped with a reflux condenser, a thermometer, and a stopcock. The flask was then placed in a constant-temperature bath (50 ± 0.1°C for benzene or 25 ± 0.1°C for toluene) and magnetically stirred. 20.0 m*l* of the 2-arylethyl chloride solution, maintained at the reaction temperature, was syringed through the stopcock into the flask. A small portion (2.0 m*l*) of the reaction mixture was drawn out from time to time with a calibrated syringe. Each sample was quenched with ice-water, washed with a small amount of water, dried over anhydrous sodium sulfate, and analyzed by gas chromatography. Each run consisted of at least 5 points, and the pseudo-second-order rate constant was determined graphically. The values obtained were corrected by blank experiments.

Competitive Phenethylations. A mixture (20.0 m*l*) of equimolar amounts of benzene and toluene was phenethylated in a nitromethane solution at 50°C in the same manner as has been described above. The samples were taken out periodically and analyzed by gas chromatography.

Analytical Procedure. The analyses were carried out with a Hitachi Perkin-Elmer model F6D gas chromatograph employing Golay-type capillary columns and a hydrogen flame ionization detector. For the determination of **6**, **7**, and **8**, a BDS-90 Golay column (length, 90 m; *i.d.*, 0.50 mm; coated with the butanediol succinate polyester) was used with a column temperature of 155°C and a nitrogen carrier-gas pressure of 1.0 kg/cm^2; for **8**, **9**, **11**, **12**, and **13**, 160°C and 1.2 kg/cm^2; for **10**, **17**, and **21**, 165°C and 1.5 kg/cm^2; for **14**, **15**, **18**, **19**, **22**, and **23**, 160°C and 1.5 kg/cm^2. Under these conditions, the isomer separation was complete. For the determination of **16**, **20**, and **24**, a Q-45 Golay column (length 45 m; *i.d.*, 0.50 mm, coated with Apiezon L) was with a column temperature of 170°C and a carrier-gas pressure of 1.5 kg/cm^2. In this case, however, the isomers of **24** were not separable. After the determination of the relative response data, the mol % were calculated from the areas of individual peaks by the internal standard method. The accuracy of measurements was found to be within the limit of a $\pm3.0\%$ relative error, based on analyses of mixtures of known composition.

The author is grateful to Professor S. Kunichika, Dr. S. Oka, Dr. J. Hayami, and Mr. T. Sugiyama for their helpful discussions.

10) All of the boiling and melting points are uncorrected. The structure of the authentic samples prepared was confirmed by infrared and NMR spectra. The infrared spectra were measured with a Hitachi EPI-S2 Spectrophotometer and the NMR spectra with a Varian T-60 Spectrometer.

Aroyl Arenesulfonyl Peroxides IV. The Mechanism of Carboxy-inversion of Benzoyl *p*-Toluenesulfonyl Peroxide[1]

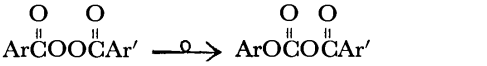
Ryuki HISADA, Hiroshi MINATO, and Michio KOBAYASHI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo

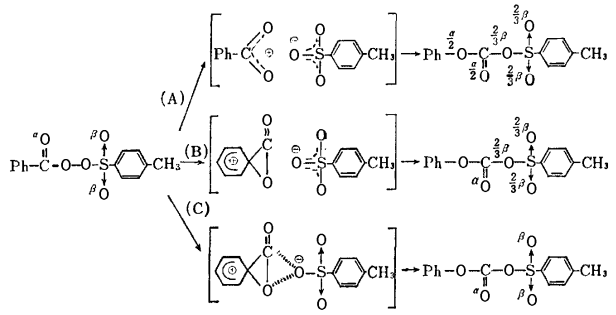
(Received December 13, 1971)

Benzoyl *p*-toluenesulfonyl peroxide (BTP) with ^{18}O-labeled carbonyl oxygen and ^{18}O-labeled sulfonyl oxygen were prepared. They were decomposed in benzene in the presence or in the absence of trifluoroacetic acid,and the phenyl *p*-toluenesulfonyl carbonate (PTC)-^{18}O produced was isolated and analyzed. It was found that the carbonyl oxygen-18 of BTP was retained as the carbonyl oxygen of PTC, whereas the sulfonyl oxygen-18 of BTP was equilibrated with the peroxidic oxygen. The mechanism of the carboxy-inversion was discussed.

The thermal decompositions of symmetrical and asymmetrical acyl (aroyl) peroxides *via* the carboxy-inversion process are well documented.[2] It is known that the asymmetrical acyl (aroyl) peroxides rearrange to the corresponding anhydrides more readily than symmetrical peroxides. Therefore, the acyl sulfonyl



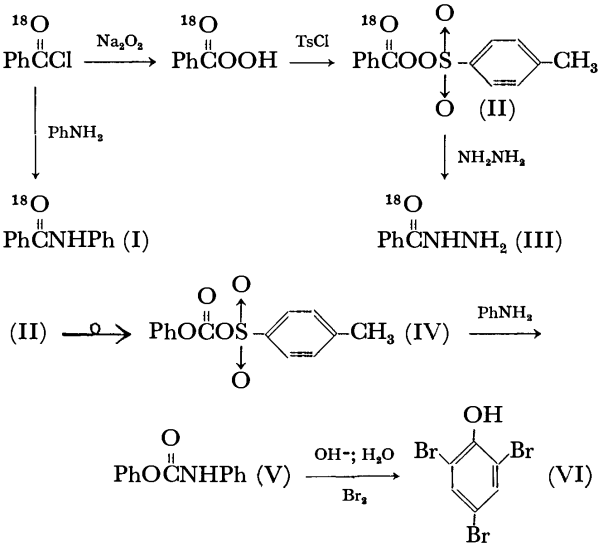
peroxides are expected to rearrange to the mixed anhydrides more easily than the diacyl peroxides. Razuvaev, Likhterov, and Etlis[3] reported that the decomposition of benzoyl alkanesulfonyl peroxides in benzene gave phenyl alkanesulfonyl carbonates in 83% yield. In the previous papers[4,5] from our laboratories, we have reported that benzoyl *p*-toluenesulfonyl peroxide (BTP) and *p*-chlorobenzoyl *p*-toluenesulfonyl peroxide rearrange to phenyl *p*-toluenesulfonyl carbonate (PTC) (48% yield), and *p*-chlorophenyl *p*-toluenesulfonyl carbonate (42% yield), respectively. Plausible mechanisms for this rearrangement are the followings.



In order to establish the mechanism, the rearrangement of BTP to PTC has been investigated by the ^{18}O-labeling technique, and the results will be described in this paper.

Results and Discussion

BTP[carbonyl-^{18}O] and BTP[sulfonyl-^{18}O] were prepared and decomposed in benzene either in the presence or in the absence of trifluoroacetic acid. Yields of the carboxy-inversion product, PTC, were 43—48% in benzene and 67—71% in benzene-trifluoroacetic acid. The PTC produced from the decomposition of BTP-[carbonyl-^{18}O] was converted, by the reaction with aniline, to phenyl phenylcarbamate and *p*-toluenesulfonic acid. The phenyl phenylcarbamate obtained was hydrolyzed to phenol, which was then converted into 2,4,6-tribromophenol. The ^{18}O-contents of compounds I—VI in the following scheme were determined.



The results obtained are summarized in Table 1. Table 1 shows that practically all the carbonyl oxygen-18 of BTP is retained in the carbonyl oxygen of PTC, and that the rearrangement of BTP to PTC does not go through a state in which the carbonyl oxygen and the peroxidic oxygen of BTP are scrambled.

From *p*-toluenesulfonyl chloride-^{18}O the BTP[sulfonyl-^{18}O] was prepared, and the oxygen-18 contents of VII—XIII were determined.

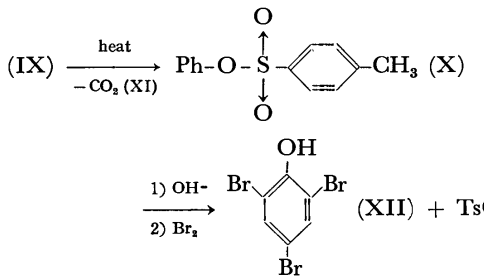
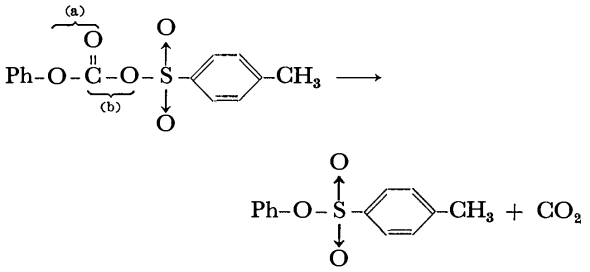
a) Experimental error in two measurements for the same sample was ±0.02 excess atom %.
b) In benzene-trifluoroacetic acid. c) In benzene. d) Calculated on the assumption that the carbonyl oxygen is not equilibrated with the peroxidic oxygen.





In order to determine the distribution of oxygen-18 in the sulfonyl oxygen and the ether oxygen in IX, one has to find some reactions with which these two kinds of oxygen can be distinguished. Reactions of IX with hydrazine or sodium methoxide were attempted, but they did not attack the sulfonyl sulfur atom. The method which met the requirements was the pyrolysis of neat IX at 230°C.

However, the mechanism of the pyrolysis of IX must be established. There are two possible modes of decarboxylation from IX. If the pyrolysis occurs according to process (a), the carbon dioxide evolved should contain no oxygen-18 regardless of whether or not the sulfonyl oxygen and the peroxidic oxygen of VIII were scrambled during the rearrangement.

The results of the ^{18}O analyses of VII—XIII are

Table 2. The ^{18}O-contents in BTP[sulfonyl-^{18}O] and related compounds[a] (excess atom % oxygen-18)

		Run 1		Run 2	
		Found	Calcd[b]	Found	Calcd[b]
TsCl-^{18}O	(VII)	0.81	(0.81)	0.76	(0.76)

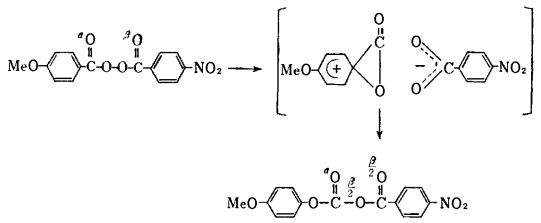
CO_2	(XI)	0.32	0.27	0.27	0.25
$Br_3C_6H_2OH$	(XII)	0.03	0	0.04	0
$H_3C-C_6H_4-SO_3H$	(XIII)	0.36	0.36	0.35	0.34

a) Experimental error in two measurements for the same sample was ±0.02 excess atom %.
b) Calculated on the assumption that two sulfonyl oxygens are completely equilibrated with one peroxidic oxygen.

shown in Table 2. Since the carbon dioxide contains excess oxygen-18, process (a) is rejected, and thus it has been established that the thermal decarboxylation of arenesulfonyl aryl carbonates occurs according to process (b).

Since the hydrolysis of aryl arenesulfonates proceeds with S–O cleavage instead of C–O cleavage, no excess ^{18}O-incorporation in XII indicates that no excess ^{18}O in the phenoxy oxygen in IX and X. The ^{18}O-contents in IX, X, and XI show that during the rearrangement of VIII to IX two sulfonyl oxygens and one peroxidic oxygen of VIII are completely scrambled.

These findings reject mechanism (A), and probably mechanism (C) as well. It is possibe that the sulfonyl oxygen-18 atoms are completely retained during the carboxy-inversion process and then, prior to the decarboxylation, completely scrambled when the mixed anhydride was heated up to 230°C. However, the decarboxylation proceeds with the S–O bond cleavage, whereas the scrambling requires the C–O bond cleavage. It seems less likely that *both* the C–O bond and the S–O bond of the mixed anhydride are cleaved upon heating. Therefore, the rearrangement of aroyl arenesulfonyl peroxides to aryl arenesulfonyl carbonates probably proceeds through a state similar to that shown in mechanism (B). Mechanism (B) is similar to the mechanism proposed for the rearrangement of *p*-methoxybenzoyl *p'*-nitrobenzoyl peroxide.[6,7]



Experimental

Preparation of Peroxybenzoic Acid[carbonyl-^{18}O]. Benzoyl chloride [carbonyl-^{18}O] was prepared according to the method of Denney and Denney.[7] Peroxybenzoic acid[carbonyl-^{18}O] was prepared according to the procedure of Vilkas[8] by use of benzoyl chloride[carbonyl-^{18}O] and sodium peroxide with some modification. Peroxybenzoic acid[carbonyl-^{18}O] was extracted from the aqueous layer with dichloromethane, and the dichloromethane solution was used for preparation of BTP[carbonyl-^{18}O].

Preparation of BTP[carbonyl-^{18}O] or BTP[sulfonyl-^{18}O]. BTP[carbonyl-^{18}O] or BTP[sulfonyl-^{18}O] was prepared, according to the method used for the preparation of the unlabeled BTP,[3] by using peroxybenzoic acid[carbonyl-^{18}O] and *p*-toluenesulfonyl chloride, or peroxybenzoic acid and *p*-toluenesulfonyl chloride [sulfonyl-^{18}O], respectively.

Decomposition of BTP[carbonyl-^{18}O] or BTP[sulfonyl-^{18}O]. A solution of 4.39 g (15 mmol) of BTP[carbonyl-^{18}O] in 150 m*l* of benzene, or 2.64 g (9 mmol) of BTP[sulfonyl-^{18}O] in 120 m*l* of benzene in the presence of trifluoroacetic acid (5 mol/mol BTP) was decomposed under the conditions described previously.[4] Phenyl *p*-toluenesulfonyl carbonate (PTC) was isolated by elution chromatography on a silica gel column (Wako Gel Q 22), and then recrystallized from ether; mp 64—65°C.

Reaction of PTC with Aniline. To 1.33 g (4.6 mmol) of PTC dissolved in 30 m*l* of dichloromethane was added 0.93 g (10 mmol) of freshly distilled aniline. The reaction mixture was refluxed for 30 min, washed with water, dilute hydrochloric acid and water, successively, and dried over anhydrous magnesium sulfate. Solvent was evaporated under reduced pressure and phenyl phenylcarbamate obtained was recrystallized from carbon tetrachloride; yield, 850 mg (87%); recrystallized three times from carbon tetrachloride; mp 124—125°C (lit,[9] 126°C).

Hydrolysis of Phenyl Phenylcarbamate. A mixture of phenyl phenylcarbamate (626 mg), sodium (850 mg), water (15 m*l*) and ethanol (10 m*l*) was refluxed for 2 hr. The ethanol was evaporated under reduced pressure, and then water and ether were added to the residue. The aqueous layer was washed with ether twice, and neutrallized with hydrochloric acid. Phenol isolated was converted by bromine water into 2,4,6-tribromophenol; 850 mg (88%); purified by sublimation twice, mp 94—95°C (lit,[10] 95°C).

Pyrolysis of PTC. In a vessel connected with a gas buret, 1.00 g of PTC was placed. After the atmosphere was replaced with nitrogen, the vessel was heated gradually to 230°C and kept at this temperature until about 60 m*l* of carbon dioxide was evolved. The brownish reaction mixture obtained was dissolved in benzene, washed with water, and dried over anhydrous magnesium sulfate. After the benzene was removed under reduced pressure, the residue was chromatographed on a silica gel column. Phenyl *p*-toluenesulfonate isolated (223 mg, 26.5%) was twice recrystallized from *n*-hexane, mp 95°C (lit,[11] 95—96°C).

Hydrolysis of Phenyl p-*Toluenesulfonate.* A mixture of phenyl *p*-toluenesulfonate (172 mg), sodium hydroxide (276 mg), dioxane (3 m*l*) and water (4 m*l*) was sealed in an ampoule and heated at 94°C for 100 hr. After dioxane was removed under reduced pressure, water was added to the mixture. The aqueous layer was acidified with hydrochloric acid and the phenol formed was extracted with ether. *p*-Toluenesulfonic acid remaining in the aqueous layer was converted to its *S*-benzylisothiuronium salt (235 mg, 91%) which was recrystallized three times from water, mp 180—181°C (lit,[12] 181—182°C). Phenol obtained from the ether layer was converted to 2,4,6-tribromophenol; 171 mg (75%); purified by sublimation, mp 94—95°C.

Reaction of BTP[carbonyl-^{18}O] with Anhydrous Hydrazine. A solution of 0.90 g of BTP[carbonyl-^{18}O] in 25 m*l* of anhydrous benzene was added drop by drop to a mixture of 1.0 g of anhydrous hydrazine and 5 m*l* of benzene at 2°C with stirring. After the addition was over, benzene and unreacted hydrazine were removed under reduced pressure. Benzhydrazide produced (250 mg, 61%) was recrystallized three times from ether, mp 112.5—113°C (lit,[13] 112.5°C).

Determination of Oxygen-18 Contents. All the samples were converted to carbon dioxide according to the method of Rittenberg and Ponticorvo[14] for determination of the ^{18}O-contents. The ^{18}O-contents were determined by use of a Hitachi RMU-6E Type Mass Spectrometer.

Photolyses of Alkyl Sulfinates and Sulfites[1)]

Michio KOBAYASHI, Hiroshi MINATO, Yoshiko MIYAJI, Takuji YOSHIOKA, Koji TANAKA, and Koichi HONDA*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo

(Received February 15, 1972)

Methyl, ethyl, *n*-butyl, *n*-octyl, benzyl, and allyl *p*-toluenesulfinates were photolyzed in *n*-hexane or without solvent. The products analyses indicate that the photolyses of these esters involve the fission of ArSO–OR bond, producing a sulfinyl radical and an alkoxy radical. In the case of the allyl ester, isomerization to the corresponding sulfone took place to some extent. When optically active *l*-menthyl *l*-*p*-toluenesulfinate was irradiated, its optical activity decreased fairly quickly while very little photolysis was observed. This photo-racemization was ascribed to the reversible formation of sulfinyl radical and menthyloxy radical. When di-*n*-butyl sulfite was photolyzed, the products found were explained by assuming the initial formation of *n*-butoxysulfinyl radical and *n*-butoxy radical. When *n*-butyl chlorosulfite was photolyzed, the products found indicate the initial fission of the S–Cl bond instead of the S–O bond.

Concerning the photochemistry of organo-sulfur compounds, many reports have been published.[2)] However, no papers have been published concerning the photo-reactions of sulfinic acids and their esters. Since alkyl arenesulfinates show a fairly strong absorption at about 250 nm due to $n \rightarrow d\pi$ transition,[3)] they are expected to undergo photolyses.

In connection with our investigations on sulfinyl, sulfonyl, and sulfonyloxy radicals, photolyses of some sulfinic esters have been studied, and the results will be described in this paper.

Results and Discussion

A. Photolyses of Alkyl p-*Toluenesulfinates.* Methyl, ethyl, *n*-butyl, *n*-octyl, benzyl, and allyl *p*-toluenesulfinates without or with *n*-hexane as solvent were degassed in quartz vessels, and then photolyzed at room temperature. Gaseous products formed were identified and quantitatively determined by mass-spectrometry or gas chromatography. Low-boiling products were distilled together with the solvent. The compounds in the residue and the distillate were identified and quantitatively determined.

Table 1 shows the UV absorption maxima of various sulfinates.

Table 2 shows the results of photolysis of ethyl *p*-toluenesulfinate. When a degassed solution of ethyl *p*-toluenesulfinate in *n*-hexane (0.27 mol/*l*) was irradiated for 9 hr, the gaseous products obtained were found to be CO (50.6), CH_4 (22.2), H_2 (16.9), C_2H_4 (4.6), C_2H_6 (3.5), C_3H_8 (1.3), and C_3H_6 (1.0%).

The decomposition of ethyl *p*-toluenesulfinate can be ascribed to its absorption at 250 nm, because a) no decomposition was observed in dark in 120 hr at room temperature, and b) more than 95% of the ester was recovered after irradiation with a high pressure mercury lamp in a Pyrex vessel for 147 hr.

Table 3 shows the results of photolysis of methyl *p*-toluenesulfinate in *n*-hexane.

Formation of methyl *p*-toluenesulfonate is in contrast with the results in the ethyl ester. No contamination

0.34	(192)[a]	0	0	0	0	0

a) A blank experiment with no irradiation at room temperature. No change was observed in its NMR spectrum. b) A sulfone of unknown structure, in weight %; mp 100—104.5°C: C, 66.28, 66.14%; H, 6.47, 6.52%. c) Polymeric sulfone of unknown structure, in weight %.

of the initial methyl sulfinate with *p*-toluenesulfonic acid or methyl *p*-toluenesulfonate was confirmed by the IR and NMR spectroscopy. When the solvent was removed from the reaction mixture under reduced pressure at room temperature, the NMR spectrum of the residue showed a signal ascribable to CH_3 of $TsOCH_3$ at 3.7 ppm (s), indicating that $TsOCH_3$ is present in the reaction mixture and is not produced during chromatography and other subsequent treatments.

Table 4 shows the results of photolysis of *n*-butyl *p*-toluenesulfinate in *n*-hexane. The reactivity of the butyl ester is much lower than that of the ethyl ester. The mass spectrum of the gaseous and low-boiling products shows peaks at *m/e* 92, 91, 79, 78(M), 77, 64, 56, 52, 51, 44, 39, 29, and 28, indicating the presence of some toluene.

Table 5 shows the results of photolysis of *n*-octyl *p*-toluenesulfinate in *n*-hexane.

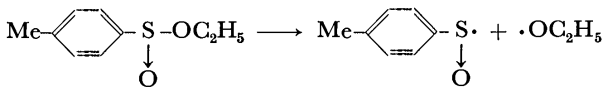
These data show that alkyl *p*-toluenesulfinates with longer alkyl groups are less prone to undergo photolysis.

Table 6 shows the results of photolysis of allyl *p*-toluenesulfinate. When the mixture was irradiated longer, the yield of allyl *p*-tolyl sulfone decreased and that of polymeric sulfone increased. Cope, Morrison, and Field[4] reported thermal rearrangement of allyl benzenesulfinate to allyl phenyl sulfone upon heating at 100°C for 24 hr. No occurrence of such thermal rearrangement under our conditions was confirmed by a blank experiment in dark. It was also confirmed that allyl *p*-tolyl sulfone (0.02M in *n*-hexane, degassed) showed almost no change in its NMR spectrum upon irradiation for 113 hr with a high pressure mercury lamp.

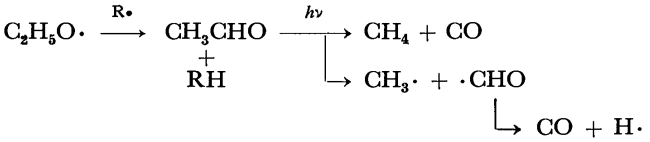
When a degassed solution of benzyl *p*-toluenesulfinate (3.6 mmol) in *n*-hexane (30 m*l*) was irradiated for 192 hr with a high pressure mercury lamp, an absorption at 257 nm disappeared and a new absorption appeared at 243 nm. A weak absorption was observed at 290 nm. Analysis of the reaction mixture revealed the presence of 47 mol% of $C_7H_7SO_2SC_7H_7$, 27.4 mol% of benzaldehyde, and 2 mol% of dibenzyl. Thin layer chromatography showed the presence of some di-*p*-tolyl disulfide.

These results show that when alkyl *p*-toluenesulfinates are irradiated, the SO–O bonds are broken. The photolysis of the ethyl ester is shown as follows.

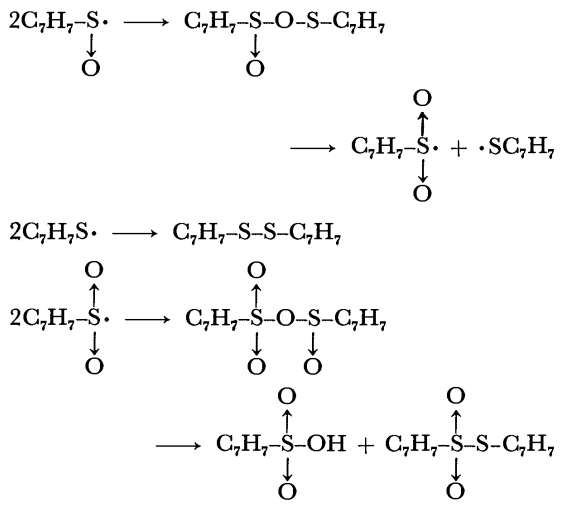
4) A. C. Cope, D. E. Morrison, and L. Field, *J. Amer. Chem, Soc.*, **72**, 59 (1950).



A part of the alkoxy radicals reacts with the sulfinyl radicals, yielding acetaldehyde, which undergoes further photolysis according to the scheme reported in the literature.[5]

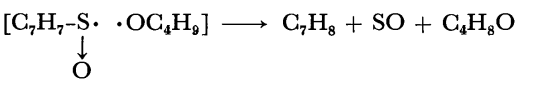


The products arising from the sulfinyl radicals are $C_7H_7SO_2SC_7H_7$, $C_7H_7SSC_7H_7$, and $C_7H_7SO_3H$. Formation of these products can be explained by the following scheme.

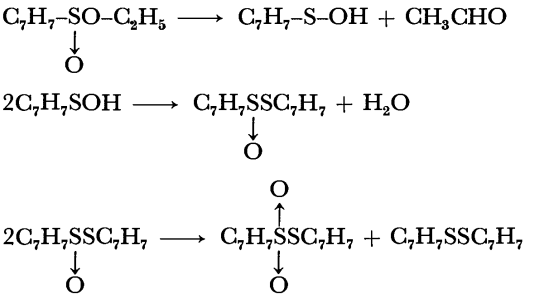


Formation of $ArSO_3H$, $ArSO_2SAr$, and ArSSAr from $ArSO_2$ have been reported by da Silva Correa and Waters.[6]

The mass-spectrometric analysis of the products of the photolysis of *n*-butyl *p*-toluenesulfinate showed the presence of toluene; this finding suggests the occurrence of the following process in cage.



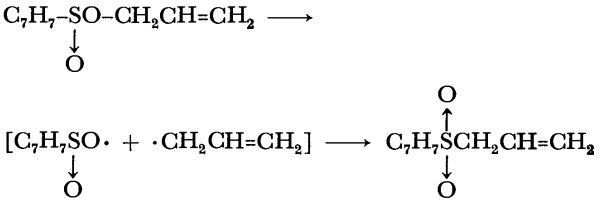
The following non-radical scheme is conceivable for the photolysis of alkyl *p*-toluenesulfinates.



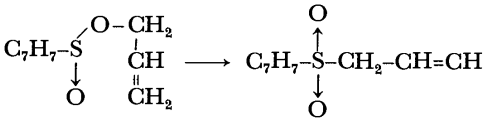
This scheme requires the formation of $ArSO_2SAr$ and ArSSAr in equal amounts. However, the yield of $ArSO_2SAr$ was much greater than that of ArSSAr in all the cases. The results of the photoracemization to be described later also favor the homolytic scheme.

When a degassed solution of ethyl *p*-toluenesulfinate-[sulfinyl-^{18}O] (excess ^{18}O, 0.37 atom%) in *n*-hexane (0.30M) was irradiated at room temperature for 114 hr and the ^{18}O content of the *p*-tolyl *p*-toluenethiolsulfonate isolated was analyzed, it was found to contain 0.54 excess ^{18}O atom%. If only the O–C bond is cleaved, the ^{18}O content of the thiolsulfonate must be equivalent to that of the sulfinate. The result of this experiment shows that the SO–O bond is cleaved by photolysis, though not exclusively.

In the case of the allyl ester, photo-isomerization to allyl *p*-tolyl sulfone took place to some extent. It requires the SO_2–C bond cleavage, which can be rationalized in terms of the stability of allyl radical.

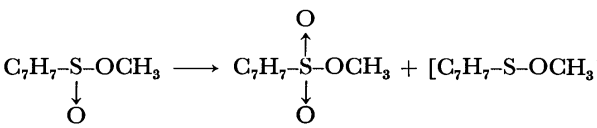


However, in the case of benzyl *p*-toluenesulfinate, no benzyl *p*-tolyl sulfone was detected and much benzaldehyde (a product of the SO–O bond cleavage) was found. Therefore, it is possible that the allyl ester is the only exceptional case and the photoisomerization proceeds by a cyclic process shown below.



It has been reported that thermal isomerization of the allyl ester occurs *via* reversible dissociation to allyl cation and a sulfinate anion,[7] whereas benzyl *p*-toluenesulfinate does not isomerize thermally to the corresponding sulfone.[8]

In the case of methyl *p*-toluenesulfinate, photodisproportionation took place to some extent, yielding methyl *p*-toluenesulfonate.



Photochemical oxygen transfer has been observed in the case of dimethyl sulfoxide,[9] but in sulfinate esters this is the only example.

In an attempt to determine whether a triplet or a singlet excited state is involved in photolyses of sulfinates, degassed solutions of ethyl *p*-toluenesulfinate (1.5 mmol) in *n*-hexane (30 m*l*) with or without a

$[\alpha]_D^{EtOH}$ −186.42°	(4)[b)]	—	$[\alpha]_D^{CH_2Cl_2}$ +28.38°	(100)[b)]

a) Solvent is *n*-hexane, unless otherwise stated.
b) A blank experiment performed in dark without irradiation.

quencher (piperylene, 3.2 mmol) were irradiated by a high pressure mercury lamp in quartz vessels at room temperature for 105 hr. After the volatile components were removed under high vacuum at room temperature, the residues were dissolved in $CDCl_3$, and their NMR spectra were determined. It was found that in the presence of piperylene almost no thiolsulfonate was formed whereas in the absence of piperylene a considerable amount of thiolsulfonate was formed. However, since piperylene itself appeared to undergo some photopolymerization or addition in the presence of ethyl *p*-toluenesulfinate, no definite conclusion was obtained.

B. Photo-racemization of Sulfinate Esters. As shown in Table 1, λ_{max} and log ε of alkyl *p*-toluenesulfinates do not vary with the chain lengths of the alkyl groups, whereas the photolyses of these esters take place to much lesser extent when alkyl groups have longer chain lengths. A possible explanation for these phenomena is that internal return of the sulfinyl radicals and alkoxy radicals takes place in cage and this internal return takes place more easily when alkoxy groups are larger and less prone to diffuse away. If this is the case, irradiation of optically active sulfinate esters must result in photo-racemization.

$$\underset{\text{optically active}}{R-\overset{*}{S}(=O)-OR'} \xrightarrow{h\nu} [R-S(=O)\cdot \cdot OR'] \longrightarrow \underset{\text{racemic}}{R-S(=O)-OR'}$$

When a degassed solution of *l*-menthyl *l*-*p*-toluenesulfinate in *n*-hexane was irradiated with a high pressure mercury lamp at room temperature and then the solvent was removed under reduced pressure at room temperature, the optical activity of the residue was much smaller than that of the initial ester, as shown in Table 7. Very little photolysis is expected to take place during such a short time of irradiation. In order to exclude the possibility of apparent decrease of optical activity of the ester by the contamination of optically inactive decomposition products, the residual ester was converted to phenyl *p*-tolyl sulfoxide by reaction with phenylmagnesium bromide in ether and the optical activity of the sulfoxide was determined.

It is remarkable that considerable racemization took place by irradiation for a short time during which no appreciable photolysis was observed.

Photo-racemization of sulfoxides has been studied fairly extensively.[10)] Racemization of optically active benzhydryl *p*-toluenesulfinate has been studied in acetic acid, and ascribed to reversible dissociation to sulfinate anion and diphenylcarbonium ion. Rates of internal return of the ion pair to the sulfinate ester are approximately equal to those of isomerization to the sulfone.

$$(+)\text{-}C_7H_7\text{-}S(=O)\text{-}OCHPh_2 \rightleftharpoons [C_7H_7\text{-}S(=O)\text{-}O^{\ominus}\ {}^{\oplus}CHPh_2]$$

$$C_7H_7\text{-}S(=O)\text{-}CHPh_2 \qquad (-)\text{-}C_7H_7\text{-}S(=O)\text{-}OCHPh_2$$

Under our experimental conditions, extensive racemization took place while very little photolysis occurred and no sulfone was observed. Therefore, this photo-racemization should not be ascribed to the reversible dissociation to sulfinate anion and menthyl cation, but rather to the reversible formation of sulfinyl radical and menthyloxy radical.

C. Photolyses of Di-n-butyl Sulfite and n-Butyl Chlorosulfite. Since the photolyses of sulfinate esters were found to involve homolysis of the S-O bond, photolyses of di-*n*-butyl sulfite was investigated.

In contrast with alkyl *p*-toluenesulfinates, dialkyl sulfites show no absorption maxima in the ordinary ultraviolet region, and consequently photolysis proceeded rather slowly.

After neat liquid of di-*n*-butyl sulfite was degassed and irradiated by a high-pressure mercury lamp at room temperature for 31 hr, the gaseous portion of the products was analyzed by gas chromatography, and was found to be CO (26.5), H_2 (37.4), SO_2 (16.4), 1-butene (1.67), butane (0.086), propane (0.84), propene (0.24), ethylene (2.96), ethane (0.17), methane (0.65) (the sum of the hydrocarbons, 6.62), N_2 (14.9), and O_2 (4.32%).

Gas-chromatographic analysis of the liquid products showed that *n*-butanol (14 mol/100 mol ester) and *n*-butyraldehyde (1.7 mol%; confirmed by its 2,4-dinitrophenylhydrazone).

These results indicate that the SO-O bond of the sulfite is cleaved first. The products found can he rationalized by the scheme shown in the next page.

As another compound containing the sulfinyl group, *n*-butyl chlorosulfite was photolyzed. Since this compound has a UV absorption maximum at 230—235 nm, photolysis proceeds fairly rapidly. When neat liquid

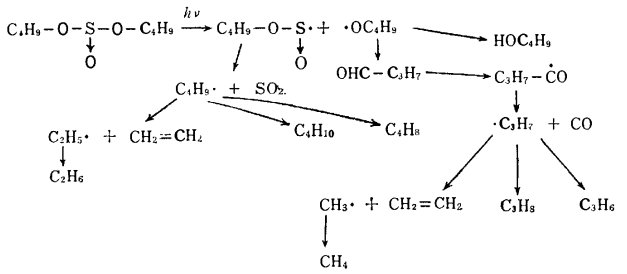
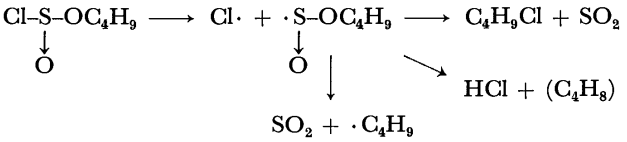
11) E. Ciuffarin, M. Isola, and A. Fava, *ibid.*, **90**, 3594 (1968).



n-butyl chlorosulfite (75 mmol) was degassed and irradiated with a high-pressure mercury lamp at room temperature for 7.5 hr, n-C_4H_9Cl (2.0 mmol), HCl (0.5 mmol), SO_2 (0.35 mmol), and some $(n\text{-}C_4H_9O)_2SO$ were found as the products. These results indicate that the bond initially cleaved is not the SO–O bond but the S–Cl bond.



Experimental

Materials. Alkyl *p*-toluenesulfinates were prepared by condensation of *p*-toluenesulfinic acid and an alcohol in the presence of dicyclohexylcarbodiimide with or without solvent (dichloromethane).[12] Methyl ester, bp 78—79°C/1.5 mmHg; ethyl, 78°C/6×10^{-3} mmHg; butyl, 110—114°C/6×10^{-3} mmHg; octyl, 112°C/5×10^{-3} mmHg; allyl, 79—81°C/2×10^{-3} mmHg; benzyl, mp 48°C.

Photolyses of p-*Toluenesulfinates.* Neat ester or its solution in *n*-hexane (spectroscopic grade, 0.3—1.0 M) was placed in a quartz vessel and completely degassed. Then the vessel was irradiated with a 1 kW high-pressure or 30 W low-pressure mercury lamp. During the irradiation some solids began to appear on the wall. After the irradiation, the reaction mixture was frozen with liquid nitrogen, and the gaseous products were pumped out with a Töpler pump and analyzed by gas chromatography (molecular sieve column). In some cases these gaseous products were subjected to mass-spectrometric analysis. The remaining mixture was evaporated at room temperature under high vacuum, and the NMR spectrum of the residue was taken. Then the residue was analyzed by elution chromatography (Florisil, silca gel, or alumina column) and gas chromatography. *p*-Toluenesulfonic acid was extracted with water, and determined quantitatively as its *S*-benzylisothiuronium salt.

Photolysis of Ethyl p-*Toluenesulfinate-[sulfinyl-*^{18}*O]*. *p*-Toluenesulfinic acid was heated in $D_2{}^{18}O$ (^{18}O, 1.5 atom %) and converted to $C_7H_7S^{18}O_2D$, which was then allowed to react with ethanol and dicyclohexylcarbodiimide. Into 20 ml of *n*-hexane, 1.1 g (6.0 mmol) of the ethyl *p*-toluenesulfinate-[sulfinyl-^{18}O] thus produced was dissolved. The solution was degassed and then irradiated with a 1 kW high-pressure mercury lamp for 144 hr at room temperature. The reaction mixture was evaporated at room temperature under high vacuum, and the residue was chromatographed on a Florisil column, and the thiolsulfonate was isolated.

Photo-racemization of l-*Menthyl* l-p-*Toluenesulfinate.* *l*-Menthol and *p*-toluenesulfinic acid was allowed to react in the presence of dicyclohexylcarbodiimide in dichloromethane.[12] The diastereomeric menthyl ester mixture obtained was treated with hydrogen chloride in the presence of tetramethylammonium chloride, and the crystals of the *l-l* ester were obtained.

A solution of this *l-l* ester (1.0 g) in *n*-hexane (38 ml) was degassed and irradiated by a 1 kW high-pressure mercury lamp for 1—21 hr. After the optical activity of the solution irradiated was determined, the solvent was removed at room temperature under high vacuum. The residue was dissolved in ether, and converted to phenyl *p*-tolyl sulfoxide by reaction with ethereal phenylmagnesium bromide.

*Photolysis of Di-*n*-butyl Sulfite.* Di-*n*-butyl sulfite (bp 118—120°C/21 mmHg) (14.8 g; 76.2 mmol) was degassed in a quartz vessel, and irradiated with a 1 kW high-pressure mercuty lamp for 31 hr. The gaseous products collected with a Töpler pump was analyzed by gas chromatography.

Photolysis of n-*Butyl Chlorosulfite.* *n*-Butyl chlorosulfite (85—87°C/46 mmHg) (75 mmol) was degassed, and irradiated with a 1 kW high-pressure mercury lamp for 7.5 hr. The gaseous and low-boiling products were collected in a liquid-nitrogen trap by vacuum distillation, and dissolved in water. The amount of HCl was determined by titration, and that of SO_2 was determined after it was converted to sulfuric acid by H_2O_2. The amounts of *n*-butyl chloride and di-*n*-butyl sulfite were determined by gas chromatography.

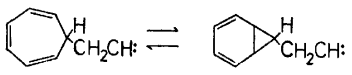
β-(2,4,6-Cycloheptatrien-1-yl)ethylcarbene. The Synthesis of 9-Substituted Bicyclo[4.2.1]nona-2,4,7-trienes and 9-Substituted Barbaralanes[1]

Haruki TSURUTA, Katsuhiko KURABAYASHI, and Toshio MUKAI
Department of Chemistry, Faculty of Science, Tohoku University, Sendai
(Received December 22, 1971)

The thermal decomposition of sodium salt of (2,4,6-cycloheptatrien-1-yl)acetaldehydes tosylhydrazone (**4**, **6**, and **8**) afforded 9-substituted bicyclo[4.2.1]nona-2,4,7-triene (**9**, **11**, and **14**) and 9-substituted barbaralane (**10**, **12**, and **15**). In the case of **8**, products containing two nitrogen atoms (**17** and **18**) were isolated. The structure and the photochemical reaction of **17** provided strong support for the intermediacy of the tetracyclo[4.3.0.$0^{2,9}$.$0^{5,7}$]-nona-3-ene (**37**) derivative for the formation of the bicyclo[4.2.1]nona-2,4,7-triene derivatives. The difference in energy surface between C_9H_{10} and $C_{10}H_{10}$ hydrocarbons was discussed.

The intramolecular addition of carbene to an isolated double bond has been a useful tool in synthesizing strained compounds. Recently, the application of this reaction to compounds with conjugated double bonds has received considerable attention. However, these reactions tend to afford complicated products, because an originally-formed strained intermediate easily rearranges into more stable compounds under these reaction conditions. For example Jones[2] and Masamune[3] investigated the thermal and photochemical decomposition of bicyclo[6.1.0]nona-2,4,6-triene-9-carboxaldehyde tosylhydrazone and reported the formation of seven and six products respectively. Similarly, the thermal decomposition of bicyclo[5.1.0]octa-2,4-diene-8-carboxaldehyde tosylhydrazone afforded four products.[2,4] We chose to study the reaction of β-(2,4,6-cycloheptatrien-1-yl)ethylcarbene (**1**) in order to see how the terminal carbene reacts intramoleculary to a conjugated triene or to a conjugated diene of the norcaradiene valence isomer (**2**). It also seemed of



(**1**) (**2**)

interest to investigate the thermal stability of the expected highly strained intermediates.

Results

When sodium salt of (2,4,6-cycloheptatrien-1-yl)-acetaldehyde tosylhydrazone (**4**) was heated in dry dioxane at 90—95°C, two kinds of C_9H_{10} hydrocarbon were obtained. The major liquid product (yield= 16%) (M=118) was identified as bicyclo[4.2.1]nona-2,4,7-triene (**9**) by a comparison of its NMR and IR spectra with those of an authentic sample.[5] The catalytic reduction of **9** in ether afforded a known bicyclo[4.2.1]nonane (mp 95°C).[6]

The minor crystalline compound (**10**; yield=4%) shows a very characteristic NMR spectrum containing four symmetrical groups of peaks with relative intensities of 2:4:2:2 (Table 1). This spectrum is in good agreement with that of tricyclo[3.3.1.$0^{2,8}$]nona-3,6-diene (barbaralane).[7,8] A comparison of the NMR data with those of known bridged homocycloheptatrienes shown in Table 1 indicate that H_a-absorption tends to shift to a lower field, while H_b and H_c tend to shift to a higher field, with an increase in the number of the bridged methylene. One of the reasons for this phenomenon may be a change in the anisotropic

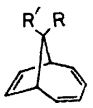
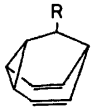
effect[9] of the three-membered ring.

The heating of the sodium salt of α-(2,4,6-cycloheptatriene-1-yl)propionaldehyde tosylhydrazone (**6**) in dry dioxane at 75°C afforded two hydrocarbons. The major oil (yield=22%) was shown to be a mixture of **11a** and **11b** in a 2: 1 ratio, based on the area of the methylproton signal at τ 9.10 and 9.33 and of isolated olefinic-proton peaks at 4.85 and 4.97. Although the separation of the mixture was difficult, a reduced product which was obtained after the uptake of three equivalents of hydrogen could be separated into two sorts of $C_{10}H_{18}$. However, it remains uncertain which is the predominant product between **11a** and **11b**. The structure of the minor component (yield=5%) is consistent with 9-methylbarbaralane (**12**) judging from the NMR spectrum (Table 1).



(**9**): R=R′=H
(**11a**): R=H, R′=CH_3
(**11b**): R=CH_3, R′=H



(**10**): R=H

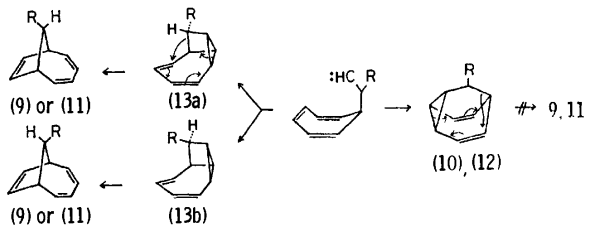
The formation of barbaralane derivatives can be explained in terms of the intramolecular addition of the carbene to the C_4–C_5 bond in the cycloheptatriene nucleus, whereas that of bicyclo[4.2.1]nona-2,4,7-triene is rather surprising. One possible path is as follows. A highly-strained intermediate (**13**), formed by the addition of the carbene to the C_2–C_3 olefinic bond, rearranges to **9** and/or **11** by way of bond cleavage and migration, as is depicted in Scheme 1. As an alternative path, the rearrangement in barbaralane derivatives (**10** and **12**) shown by the arrow is pertinent, but the control experiment eliminated this possibility. The attempted thermolysis of barbaralane **10** under the same conditions as in the decomposition of **4** resulted in the complete recovery of **10**. Assuming the strained compound **13** to be an intermediate, the formation of *syn*- and *anti*-9-methyl bicyclo[4.2.1]nona-2,4,7-triene is understandable, because a small substituent such as hydrogen or methyl will not cause any significant difference in nonbonding interaction between **13a** and **13b**. However, when the substituent, R, is larger than hydrogen or methyl, the ratio of *syn*- and *anti*-**11** will change considerably because the nonbonding



Scheme 1.

interaction of R with the rest of the molecule is heavier in **13b** than in **13a**. The phenyl derivative (R=Ph) was chosen for study next in order to confirm this point.

The thermolysis of the sodium salt of α-phenyl-α-(2,4,6-cycloheptatrien-1-yl)acetaldehyde tosylhydrazone (**8**) was carried out similarly; a three hydrocarbons (**14**, **15**, and **16**) in addition to two nitrogen-containing products (**17** and **18**) were thus formed. The structural elucidation of the main hydrocarbon (**14**, yield=33%) is based on a comparison of the spectral data with that of **9**. The geometry of the phenyl group at the C_9-position was determined in the following way. In the NMR spectrum of **14**, the signal ascribed to C_9-hydrogen appears as a singlet at τ 7.18, suggesting that the bond angle between the bridgehead proton and the C_9-proton is nearly 90°. An inspection of the model of **14** shows that the bond angles between *syn*-H_9 and H_1 and between *anti*-H_9 and H_1 are 90 and 30° respectively. The value calculated on the basis of the Karplus equation ($J_{syn\text{-}H_9,H_1}\approx 0$, $J_{anti\text{-}H_9,H_1}=6.0$ Hz) is in good agreement with the observed value for **14**, in which the phenyl group is located at the *anti*-position relative to the conjugated diene. Contrary to the case of methyl derivatives, it should be noted that only one stereoisomer **14** was selectively formed; this is in accord with the mechanistic discussion described in Scheme 1.

The NMR spectrum of (**15**, yield=3%) involves three groups of peaks, as is shown in Table 1, in addition to the peaks due to phenyl protons. Thus, compound **15** was identified as 9-phenylbarbaralane. The methin proton signal at the C_9-position bearing the phenyl group shifts downfield to overlap with the two protons at C_1 and C_5. The third crystalline hydrocarbon (**16**, yield=2%) was an aromatic compound; its structure was established to be 2-phenylindene by a comparison of its spectra and melting point with those of an authentic specimen.[12]

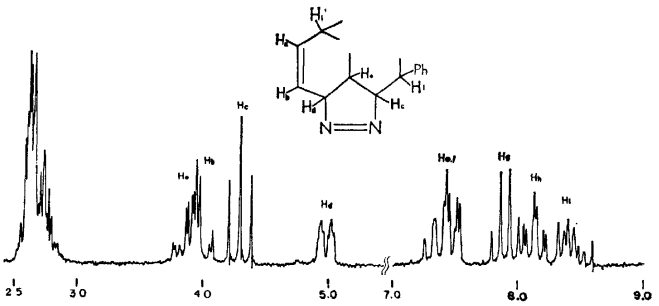


Fig. 1. NMR Spectrum of **17** in $CDCl_3$ (100 MHz).

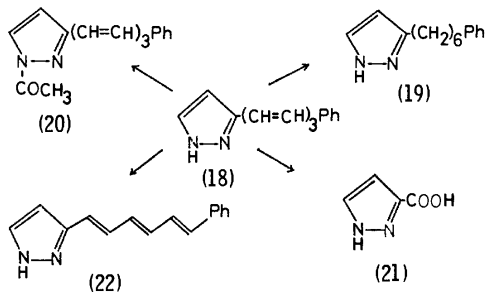
Compound **17**, with a formula of $C_{15}H_{14}N_2$ (M=222), has no bands ascribable to NH and NH_2 groups in the IR spectrum, but the absorption band at 1534 cm^{-1} as well as the UV maximum (340 nm, ε 240) suggested the presence of an azo function. The NMR spectrum exhibits complex peaks (Fig. 1). All nine protons except the phenyl protons are in different circumstances; each proton is named alphabetically from downfield to upfield. It seems reasonable to assign H_c and H_d to

9) K. Tori and K. Kitahonoki, *J. Amer. Chem. Soc.*, **87**, 386 (1965).
10) H. E. Zimmerman and G. L. Grunewald, *ibid.*, **88**, 183 (1966).
11) R. Merényi, J. F. M. Oth, and G. Schröder, *Chem. Ber.*, **97**, 3150 (1964).
12) N. Campbell and E. Ciganek, *J. Chem. Soc.*, **1956**, 3834.

the protons adjacent to an azo group. Generally, under these circumstamces the methin proton appears in a fairly low field.[13-15] A decoupling experiment clarified the relationship between all the protons and led to the partial structure shown in Fig. 1. Irradiation on H_d affected the signals of three protons, H_a, H_b, and H_e. The signals due to H_a and H_b changed into a quartet (J=10.5, 4.5 Hz) and a doublet (J=10.5 Hz) respectively, while H_e, overlapped with H_f, turned into an apparent quartet (J=8.7, 7.0 Hz). Synchronous irradiation on both H_c and H_d made H_e a doublet (J=7.0 Hz), and H_f an apparent split doublet (J=2.0 Hz). Additional simultaneous irradiation on both H_e and H_f altered H_c to a sharp singlet and H_d to a finely-split singlet. Finally, H_i changed into a triplet upon irradiation on H_a. Three opened bonds of the partial structure in Fig. 1 are joined to build a three-membered ring and 7-phenyl-9,10-diazatetracyclo-[6.2.1.$0^{4,6}$.$0^{5,11}$]undeca-2,9-diene is assigned for **17**. The coupling constant (4.5 Hz) between H_a and H_i seems compatible with the reported values which were observed between a three-membered ring proton and an olefinic proton in bicyclo[4.2.1]heptene[16] and tricyclo[2.2.2.$0^{2,7}$]octene.[17] The chemical shifts and coupling constants of **17** are summarized in the Experimental section. Additional support for the structure was obtained from the photochemical behavior of **17** and from a mechanistic consideration of the reaction path which will be discussed later.

A nitrogen-containing product (**18**, yield=25%) (M=222) has the same formula as **17**. The NMR spectrum shows a very complicated multiplet between τ 2.4 and 3.9 containing two sets of doublets at 2.46 and 3.59 (J=2.0 Hz). The catalytic reduction of **18** over 10% Pd-C in ethanol afforded an oily product **19** after the uptake of three equivalents of hydrogen. In the NMR spectrum of **19**, the AB doublet still remains at τ 2.63 and 4.07 (J=2.0 Hz), whereas the complex signals of olefinic protons disappear and instead new two signals due to methylenic protons appear at τ 7.42 (4H, broad quartet) and 8.61 (multiplet, 8H). The signals at τ 7.42 can be ascribed to the methylene protons adjacent to the aromatic ring. The IR spectrum of **18** showed a strong hydrogen-bonded NH absorption at 3175—2883 cm^{-1}. In the NMR spectrum of monoacetate **20**, the AB doublet was observed at τ 3.53 and 1.83 (J=2.9 Hz), suggesting that the original peaks at τ 2.46 in **18** suffered from shielding by the acetyl group and shifted downfield such as to τ 1.83, whereas the other peaks remained unchanged in nearly the same field.[18] Another piece of evidence that **18** is a 3-substituted pyrazole derivative was given by oxidation with potassium permanganate, in which case pyrazole-3-carboxylic acid (**21**) was obtained.[19] When a solution of **18** in benzene containing iodine was heated under reflux, an isomer (**22**) was formed. In the IR spectrum of **22**, a strong peak appeared at 1005 cm^{-1} (*trans*-CH=CH), while the originally-observed peak at 746 cm^{-1} (*cis*-CH=CH) disappeared. Furthermore, the UV spectrum of **22** is very similar to that of *trans, trans, trans*-1,6-diphenyl-1,3,5-hexatriene,[20] suggesting the presence of the same triene system. On the basis of these data, compound **18** was identified as 1-phenyl-6-(3-pyrazolyl)-1,3,5-hexatriene, in which at least one double bond has a *cis*-configuration.



Discussion

A possible mechanistic pathway for the formation of all the products from the thermal decomposition of **8** is depicted in Scheme 2. Of the two nitrogen-containing products, the tetracyclic compound **17** is obviously produced from the norcaradiene valence isomer **24** by the 1,3-dipolar addition of a diazomethane counterpart to one of the double bonds. Another possible structure **17a** was ruled out on the basis of the decoupling experiment in the NMR spectrum. The formation of the pyrazole derivative **18** can be explained by assuming an intermediate of a tetracyclic azo compound **29**, which is derived by the 1,3-dipolar addition of a diazomethane counterpart to the C_2–C_3 bond in **23**, followed by the cleavage of the four-membered ring of **29** and by subsequent aromatization. The driving force for this reaction may be ascribed to release from the strain as well as to the stabilization arising from the formation of the full conjugated compound linked by two aromatic groups.

On the other hand, two pathways are possible for the formation of **14**. The divalent carbon in **25** may be added to the C_2–C_3 bond, giving a highly-strained intermediate **27**, which may then be immediately relieved from the strain in the manner described in Scheme 1 to afford **14**. An alternative route is that the carbene center in the norcaradiene isomer **26** is added to the C_2–C_3 bond[21,22] to form a tetracyclic intermediate **28**, which then easily gives rise to **14** by

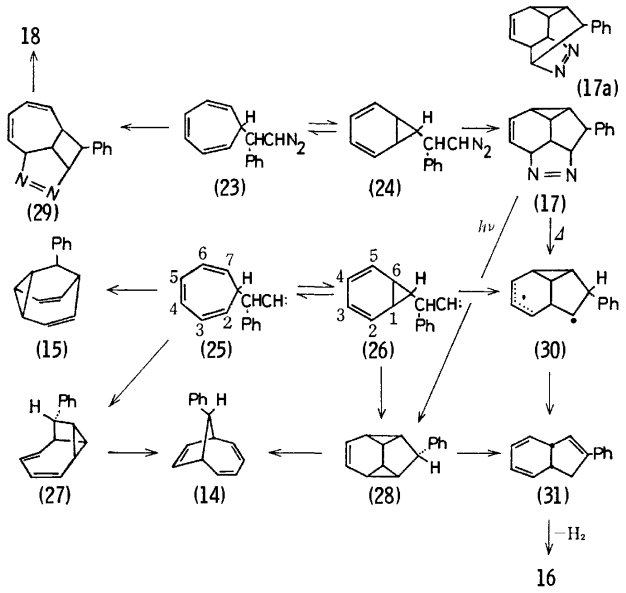
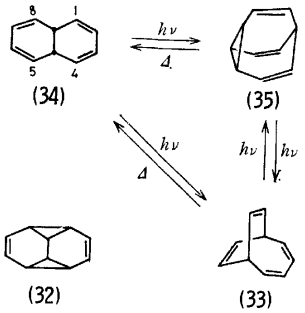
the retro-Diels-Alder reaction.[23,24] In both routes the stereochemistry of the phenyl group in **14** can be satisfactorily explained by assuming that the phenyl group is on the less-crowded side to avoid a nonbonding repulsion. The fact that **14** was produced in a 43% yield by the irradiation of **17** with Pyrex-filtered light strongly supports the latter pathway (**26**→**28**→**14**).



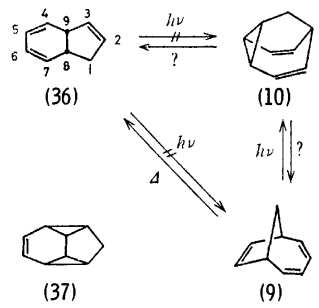
Scheme 2.

At this stage, it is of interest to compare the energy surface of C_9H_{10} hydrocarbons with that of $C_{10}H_{10}$ hydrocarbons. A part of the chemistry of the $C_{10}H_{10}$ hydrocarbons,[25] which have been extensively studied, is displayed in Scheme 3. The corresponding chemistry of the C_9H_{10} hydrocarbons, which are derived from the $C_{10}H_{10}$ hydrocarbons in Scheme 3 by the replacement of the etheno group with a methylene bridge, is depicted in Scheme 4.

A few years ago, Cannell[5] studied the photoreaction of **9** in acetone, in which case a (2+2)π cyclization of the conjugated diene moiety took place to give *exo*-(**38**) and *endo*-tricyclo[4.2.1.$0^{2,5}$]nona-3,7-diene (**39**). The repetition of the photolysis of **9** using a low-pressure



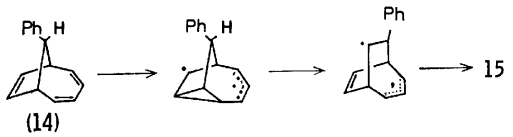
Scheme 3.



Scheme 4.

lamp without any sensitizer in dioxane resulted in the formation of four kinds of photoproducts and the recovery of a small amount of **9**. Although we confirmed two of the products to be **38** and **39** on the basis of their reported NMR spectra,[5] neither vpc nor NMR peaks due to **10** could be detected in the photoproducts.

The sensitized photoreaction of this system provided different results. When the photolysis of **14** was carried out in benzene using benzophenone as a sensitizer, **15** was formed as a single product. This transformation is in sharp contrast to the direct irradiation described above and may be characterized in terms of a di-π-methane cyclization, as is shown below. This reaction corresponds to the photoreaction of bicyclo[4.2.2]deca-2,4,7,9-tetraene (**33**) to bullvalene (**35**), as is shown in Scheme 3.[26]



The thermal transformation of **9** to *cis*-8,9-dihydroindene (**36**) was recently found by Berson *et al.*[27] This is formally similar to the thermal conversion of **33** into 9,10-dihydronaphtalene (**34**), but the mechanism is different. The intermediate from **33** to **34** was proved to be tetracyclo[4.4.2.$0^{2,10}$.$0^{5,7}$]deca-3,8-diene (**32**) on the basis of a deuterium-labeling experiment,[28] while the conversion of **9** into **36** proceeds through an unsymmetric tricyclic intermediate (**40**). If a step-by-step mechanism is involved in the transformation of **33** to **34**, the cleavage of a three-memberd ring of **32** will afford a stable diallylradical, which will then force the subsequent fission of another three-membered ring and will be stabilized by the formation of two sets of conjugated diene **34**. On the other hand, the tetracyclic compound **28**, which is formed *via* the intramolecular Diels-Alder cyclization of **14**, can not afford such a stable radical; instead, it may give a rather unstable homoallyl or 1,3-diradical **30**. Moreover, it must be accompanied by a hydrogen shift to form a *cis*-8,9-dihydroindene derivative. Thus, **28**, even if formed, tends to return to **14** or, at a high temperatures,

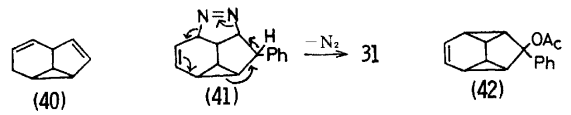
to follow the homodienyl hydrogen migration path to give dihydroindene (**31**).[27] The formation of **31** through a diradical, followed by a 1,2-hydrogen migration, or through a concerted 1,9-hydrogen shift ($_{\pi}2_s+_{\sigma}2_s+_{\sigma}2_s+_{\sigma}2_s+_{\sigma}2_s$), as is shown in **41**, was illustrated in the thermolysis of the diazo compound **17**. The refluxing of **17** in diglyme in air gave **16** in a 49% yield. The yield of **16**, however, dropped to 5% when the thermolysis was carried out in a nitrogen atmosphere, and instead 2-phenyl-8,9-dihydroindene **31** (mp 56—58°C) was formed in a 51% yield. The structure identity of **31** was based on the NMR spectrum, consisting of four groups of peaks at τ 2.72 (m, 5H), 4.00 (m, 1H), 4.36 (m, 4H), and 6.0—7.7 (m, 4H), and on its rapid interconversion into 2-phenylindene when left standing in air. Because of the existence of a thermally-labile diazo group, the heating of **17** easily releases nitrogen to give an energy-



(40) (41) (42)

rich diradical intermediate **30**, which then affords **31** by 1,2-hydrogen migration (Scheme 2). The possibility that **31** was formed by the thermal rearrangement of initially-formed nonatriene **14**[27] could be precluded by control experiments. The nonatriene **14** was very stable and was recovered not only under the pyrolytic condition of **17** in refluxing diglyme, with or without an oxidizing reagent, but also upon pyrolysis in a flow system by passing it through a column containing glass helics preheated at 400°C. However, when **28** has a leaving group such as the acetyl group at the C_8-position such as **42**, the thermal conversion into 2-phenylindene becomes facile.[29]

The irradiation of **36** was performed by Vogel *et al.*[30] and by Schwartz,[31] in each case, *trans*-8,9-dihydroindene was obtained as the main product. This *trans*-formation was explained in terms of a disrotatory ring closure of the intermediate, *cis, cis, trans, cis-* or *cis, cis, cis, trans*-cyclononatetraene, formed from the dihydroindene **36** by a conrotatory ring opening. Neither **9** nor **10** was found in the photolysate. The bond formation between C_1 and C_8 and between C_4 and C_5 in **34** leads to tetracyclodecadiene **32** and takes place without a hydrogen shift (Scheme 3), whereas the hydrogen shift from the methylene group is essential to derive a tetracyclic intermediate such as **37** from **36** (Scheme 4). Therefore, in the photoreaction of **36**, a fission at the C_8–C_9 bond or $(2+2)\pi$ cycloaddition in the diene moiety is preferable to the cyclization leading to **37**. However, if *cis*-8,9-dihydroindene is highly substituted and if the ring opening to the corresponding cyclononatetraene causes steric hindrance, the bonding not only between C_3 and C_4, but also between other positions, becomes possible, depending on the nature of the sbustituents.[32] In these cases, no barbaralane or bicyclo[4.2.1]nona-2,4,7-triene derivatives were characterized. Although the photochemical and thermal reaction of **10** have not been well documented, Daub and Schleyer reported the acetone-sensitized conversion of tricyclo[3.2.2.$0^{2,4}$]nona-6,8-diene into **10**[22] and described that **10** is not stable under photolytic conditions.

In any event, these results add some information on the difference between the energy surfaces of C_9H_{10} and $C_{10}H_{10}$ hydrocarbons. Studies of the thermal and photochemical behavior of C_9H_{10} groups, especially that of barbaralane, are now in progress in this laboratory.

Experimental

All the melting points and boiling points are uncorrected. Vpc was carried out on Hitachi K-53 (analytical), Hitachi KGL-2B, and Willkins (A-700) (preparative) instruments. The IR and NMR spectra were taken on Shimadzu IR-27 and Varian 60A or 100A spectrometers respectively. The mass and UV spectra were recorded on Hitachi RUM-6D and Hitachi EPS-3 spectrometers respectively.

Preparation of (2,4,6-Cycloheptatrien-1-yl)acetaldehyde Tosylhydrazone (4). To a solution of tosylhydrazide (17.3 g, 0.93 mol) dissolved in a 3:1 mixture of ethanol and water, (**3**) (12.5 g, 0.93 mol) was added, drop-by-drop at room temperature, to produce white crystals (27.4 g, 98%). White needles from ethanol; bp 130°C (d).

Found: C, 63.61; H, 5.96; N, 9.05%. Calcd for $C_{16}H_{18}N_2O_2S$: C, 63.56; H, 6.00; N, 9.27%. IR (KBr): 3226, 1597, 1361, 1326, 1163, 747, 714 cm^{-1}. NMR ($CDCl_3$): τ 2.18 (m, 2H), 2.72 (m, 3H), 3.40 (m, 2H), 3.90 (m, 2H), 5.03 (m, 2H), 7.49 (m, 2H), 7.61 (s, 3H), 8.17 (m, 1H).

Thermal Decomposition of 4. Formation of Bicyclo[4.2.1]-nona-2,4,7-triene (9) and Tricyclo[3.3.1.$0^{2,8}$]nona-3,6-diene (10) (barbaralane). A suspension of 47% sodium hydride (5.1 g, 0.1 mol) in dry dioxane (5 ml) was added to a solution of **4** (20 g, 0.66 mol) in dioxane (130 ml). The suspension of the sodium salt was then heated at 90—95°C under a stream of nitrogen. The evolution of nitrogen ceased after one hour and left crystals of sodium *p*-toluenesulfinate (11 g). The filtrate was diluted with petroleum ether (bp 40—60°C) and washed well to remove the dioxane. The organic layer was extracted with a 40% aqueous silver nitrate solution, which was then decomposed by 28% aqueous ammonia (*ca.* 100 ml). It was extracted with petroleum ether, washed with water, dried (Na_2SO_4), and evaporated to give yellowish-orange oil (5 g), which was subsequently passed through a column containing alumina (B.G.I). Elution with petroleum ether (bp 40—60°C) afforded a colorless oil (1.0 g, 20%) which consisted of two components in a ratio of 4:1 and which was separated on a preparative vpc column (3 m × 1/4″ 10% Carbowax at 120°C). The oily product corresponding to the shorter retention time and to the main component was **9**.

Found: C, 91.34; H, 8.78%. Calcd for C_9H_{10}: C, 91.47; H, 8.53%. IR (neat): 3021, 1642, 732, 679 cm^{-1}. UV (cyclohexane nm ε) 259 (2710), 268 (2460), 278 (1360). NMR (CCl_4): τ 4.12 (m, 4H), 4.87 (m, 2H), 6.92 (bd, J=

11.3 Hz, 1H), 8.07 (t×d, J=11.3, 6.2 Hz, 1H), 8.71 (d, J=11.3 Hz, 1H).

The second product was established to be **10**; mp 39—40°C.

Found: C, 91.08; H, 8.48%. Calcd for C_9H_{10}: C, 91.47; H, 8.53%. IR (CCl_4): 3030, 2915, 1678, 1616, 1381 cm^{-1}.

A solution of **10** (10 mg) in dioxane was heated under reflux and monitored by vpc. No other peaks except **10** appeared after heating for 116 min.

Catalytic Reduction of ***9***. A solution of **9** (118 mg, 1 mmol) dissolved in ether (10 m*l*) was catalytically reduced over an Adams catalyst (10 mg) at the temperature of ice water. It consumed three equivalents of hydrogen (72.3 m*l*, calcd 67.2 m*l*) after 138 min. The filtration of the catalyst and the evaporation of the ether left 117 mg of crystals; mp 90—93°C. Sublimation afforded bicyclo[4.2.1]nonane; mp 94—95°C.

Found: C, 86.96; H, 13.00%. Calcd for C_9H_{16}; C, 87.02; H, 12.98%. NMR (CCl_4): τ 7.8—9.3 (m).

*Preparation of α-(2,4,6-Cycloheptatrien-1-yl)propionaldehyde Tosylhydrazone (****6****).* Morphorinoenamine of propionaldehyde (27 g, 0.212 mol) was added, drop by drop and at room temperature, to a solution of tropyliumfluoroborate (41.5 g, 0.233 mol) in water (500 m*l*). The solution was stirred for two hours and then extracted with ether. The extracts were washed with water, dried (Na_2SO_4), and evaporated to leave 24.7 g (78.5%) of **5**: bp 86—87°C/0.8 mmHg.

Found: C, 80.94; H, 8.27%. Calcd for $C_{10}H_{12}O$: C, 81.04; H, 8.16%. IR (neat): 3012, 2817, 1724, 746, 709 cm^{-1}. NMR (CCl_4): τ 0.36 (d, J=2.0 Hz, 1H), 3.37 (m, 2H), 3.80 (m, 2H), 4.80 (m, 2H), 7.33 (d×q×d, J=7.5, 7.0, 2.0 Hz, 1H), 8.08 (m, 1H), 8.85 (d, J=7.0 Hz, 3H).

Into a solution of tosylhydrazide (11.2 g, 0.06 mol) in a mixture of ethanol and water (3:2) (260 m*l*), **5** (7.7 g, 0.052 mol) was stirred at room temperature. The filtration of the deposited white crystals yielded 15.5 g (94%) of the deposited white crystals yielded 15.5 g (94%) of the tosylhydrozone **6**. Needles from ethanol; mp 129—130°C.

Found: C, 64.56; H, 6.50; N, 8.89%. Calcd for $C_{17}H_{20}N_2O_2S$: C, 64.54; H, 6.37; N, 8.86%. IR (KBr): 3226, 1600, 1362, 1325, 1167, 751, 710 cm^{-1}. NMR ($CDCl_3$): τ 1.88 (bs, 1H), 2.14 (m, 2H), 2.68 (m, 2H), 2.87 (d, J=6.4 Hz, 1H), 3.38 (m, 2H), 3.92 (m, 2H), 4.98 (m, 2H), 7.33 (m, 1H), 7.57 (s, 3H), 8.50 (m, 1H), 8.89 (d, J=7 Hz, 3H).

Thermal Decomposition of ***6****. Formation of 9-Methylbicyclo[4.2.1]nona-2,4,7-triene (****11****) and 9-Methyltricyclo[3.3.1.0^{2,8}]nona-3,6-diene (****12****).* Sodium salt, prepared from 10 g of **6**, in dioxane (120 m*l*) was subjected to decomposition at 75—80°C. A subsequent workup similar to the decomposition of **4**, without extraction with a silver nitrate solution, produced 5 g of a crude oil, which was then passed through a column of alumina. Elution with petroleum ether (bp 40—60°C) yielded 1.35 g (27%) of a colorless oil, which was a mixture of **11** and **12** in a ratio of 9:2 (based on the area of the vpc peak). Preparative vpc (10 mm×1 m 20% DOP at 70°C) separated **11** (shorter retention time) and **12**. NMR of **11** (CCl_4): τ 4.10 (m, 8H), 4.85 and 4.97 (m, combined area 4H), 7.0—7.5 (4H), 7.6—8.5 (4H), 9.10 and 9.33 (d, J= 7.0 Hz, combined area 6H).

A solution of **11** (205 mg, 1.5 mmol) in ether (5 m*l*) was hydrogenated over 10% prereduced Pd-C (25 mg) at the temperature of ice-water. It absorbed three equivalents of hydrogen (104.8 m*l*, calcd 104.2 m*l*) after 170 min. The catalyst was removed, and the filtrate was evaporated to give 210 mg of a colorless oil, which was separated by preparative vpc (10 mm×1 m 20% DOP at 80°C). A colorless oil was eluted first.

Found: C, 87.09; H, 13.03%. Calcd for $C_{10}H_{18}$: C, 86.88; H, 13.12%. NMR (CCl_4): τ 7.8—8.9 (m, 15H), 9.12 (d, J=7.0 Hz, 3H). Then were eluted colorless, sublimable needles; mp 117—118°C.

Found: C, 86.79; H, 12.83%. Calcd for $C_{10}H_{18}$: C, 86.88; H, 13.12%. NMR (CCl_4): τ 7.7—8.6 (m, 15H), 8.95 (d, J=7.0 Hz, 3H).

*Preparation of α-Phenyl-α-(2,4,6-cycloheptatrien-1-yl)acetaldehyde Tosylhydrazone (****8****).* β-Ethoxystyrene (3.07 g, 0.021 mol) was dropped into a solution of tropyliumfluoroborate (7.3 g, 0.040 mol) in water (90 m*l*) at room temperature and stirred overnight. The separated oil was extracted with ether, and the extract was washed with water, dried (Na_2SO_4), and evaporated to give an orange oil. Distillation (bp 134—135°C/1.5 mmHg) yielded 4.1 g (95%) of the acetaldehyde **7**, which crystallized on standing. Colorless crystals from *n*-hexane; mp 55—57°C.

Found: C, 85.37; H, 6.78%. Calcd for $C_{15}H_{14}O$: C, 85.68; H, 6.71%. IR (neat): 3021, 2817, 1724, 760, 747, 701 cm^{-1}. NMR (CCl_4): τ 0.5 (d, J=2.6 Hz, 1H). 2.84 (m, 5H), 3.43 (m, 2H), 3.95 (m, 2H), 4.92 (m, 2H), 6.23 (d×d, J=11.0, 2.6 Hz, 1H), 7.47 (m, 1H).

To a solution of tosylhydrazide (10.2 g, 0.055 mole) dissolved in a mixture of ethanol and water (8:13) (210 m*l*), **7** (10 g, 0.048 mol) in ethanol (20 m*l*) was added, drop by drop and at room temperature, to form white crystals. Filtration afforded 15.5 g (87%) of **8**; mp 163—165°C. Needles from ethanol; mp 165.5—166°C.

Found: C, 69.69; H, 6.09; N, 7.58%. Calcd for $C_{22}H_{22}N_2O_2S$: C, 69.82; H, 5.86; N, 7.40%. IR (KBr): 3226, 1597, 1364, 1325, 1167, 747, 705 cm^{-1}. NMR ($CDCl_3$): τ 1.88 (bs, 1H), 2.20 (m, 2H), 2.80 (m, 8H), 3.36 (m, 2H), 3.87 (m, 2H), 5.01 (m, 2H), 6.24 (d×d, J=11.5, 7.0 Hz, 1H), 7.58 (s, 3H), 7.86 (m, 1H).

Thermal Decomposition of ***8****. Formation of* ***14****,* ***15****,* ***16****,* ***17****, and* ***18****.* A suspended sodium salt, prepared from 10 g of **8**, in dioxane (130 m*l*) was heated at 80—83°C and then treated as in the work-up described in connection with the formation of **11** and **12**. A crude red oil (4.7 g) was then separated using alumina-column chromatography. The product eluted first with petroleum ether (bp 40—60°C) was a colorless oil (1.7 g, 36%) whose vpc (20% DC-11 at 200°C) showed that it was a mixture of **14** and **15** in a ratio of 11:1. The petroleum ether solution of the mixture, upon cooling at −60°C, left erystals (mp 36—38°C), which, on sublimation, afforded **14** as colorless prisms; mp 39—41°C.

Found: C, 93.02; H, 7.38%. Calcd for $C_{15}H_{14}$: C, 92.74; H, 7.26%. IR (neat): 3030, 2933, 1605, 982, 794, 725, 699 cm^{-1}. UV (cyclohexane nm ε) 255 (2200) (sh), 261 (2480) (sh), 264 (2190). 271.5 (2370), 283 (1490) (sh), NMR (CCl_4): τ 2.93 (s, 5H), 3.65—4.35 (m, 4H), 4.83 (m, 2H), 6.90 (d, J=6.5 Hz, 2H), 7.18 (s, 1H).

The petroleum ether-benzene (2:1) mixture eluted yellow crystals (mp 150—156°C) (116 mg), which were subsequently recrystallized from ethanol to give **16** (95 mg, 2%) as colorless scales; mp 165—166°C.

Subsequent elution with ether afforded **17**; mp 91—93°C (410 mg). Colorless needles from cyclohexane-ethanol (10:1) (330 mg, 7%); mp 93—94°C.

Found: C, 80.84; H, 6.48; N, 12.66%. Calcd for $C_{15}H_{14}N_2$: C, 81.05; H, 6.35; N, 12.60%. IR (KBr): 3040, 2907, 1642, 1600, 1534, 1490, 1449, 930, 750, 725, 696 cm^{-1}. UV (MeOH nm ε) 260 (1080, sh), 269 (660, sh), 340 (240). $J_{1,11}$=8.0, $J_{2,3}$=10.5, $J_{3,4}$=4.5, $J_{4,5}$=7.5, $J_{4,6}$=8.0, $J_{5,6}$=7.0, $J_{5,11}$=7.0, $J_{6,7}$=2.0 and $J_{7,8}$=$J_{8,11}$=8.7 Hz.

Finally, an ether–ethanol mixture (9:1) eluted **18**; mp 125—130°C (1.3 g). Colorless needles from benzene; mp 133—134°C (1.18 g 25%).

Found: C, 81.25; H, 6.53; N, 12.52%. Calcd for $C_{15}H_{14}N_2$, C, 81.05; H, 6,35; N, 12.60%. IR (KBr): 3175—2888; 987, 746 cm^{-1}. UV (MeOH nm ε) 260 (7080), 340 (46710).

Reactions of 1-Phenyl-6-(3-pyrazolyl)-1,3,5-hexatriene ***18****. Acetate.* Acetylation was accomplished on the treatment of **18** with acetylchloride in pyridine. Pale yellow small scales from ethanol; mp 137—138°C (80%).

Found: C, 77.33; H, 6.31; N, 10.33%. Calcd for $C_{17}H_{16}N_2O$: C, 77.25; H, 6.10; N, 10.60%. IR (KBr): 3040, 1736, 986, 787, 751, 691 cm^{-1}. UV (MeOH nm ε) 235 (7150), 348 (63250), 364 (48870) (sh).

Catalytic Reduction. A solution of **18** (504 mg, 2.3 mmol) in ethanol (50 m*l*) was reduced over prereduced 10% Pd-C (50 mg). After the uptake of three equivalents of hydrogen (160 m*l*, calcd 152 m*l*), the filtration of the catalyst, followed by the evaporation of the filtrate, yielded a pale yellow oil (516 mg); bp 175—178°C/3 mmHg.

Found: C, 78.36; H, 8.81, N, 11.88%. Calcd for $C_{15}H_{20}N_2$: C, 78.90; H, 8.83, N, 12.27%. IR (neat): 3195, 3096, 2907, 2841, 1458, 936, 749, 700 cm^{-1}.

Oxidation with Potassium Permanganate. A solution of **18** (333 mg, 1.5 mmol) dissolved in acetone (50 m*l*) and water (200 m*l*) was refluxed for eight hours with potassium permanganate (10.7 g, 0.068 mol). The excess potassium permangnate was then decomposed by the addition of methanol and the manganese dioxide deposited was washed with hot water. The combined filtrate was concentrated to *ca.* 50 m*l*, neutralized with 6N HCl, and extracted with ether. The extract was washed with water, dried (Na_2SO_4), and evaporated to yield benzoic acid (84 mg, 63%). The acidic filtrate, from which the benzoic acid had been removed, was continuously extracted with ether, which was then evaporated to afford pyrazole-3-carboxylic acid (mp 208°C) (d) (96 mg, 78%). Colorless needles from water; mp 213°C; identified by a comparison of the IR spectra and by a mixed-melting-point determination with an authentic sample.[19]

IR (KBr): 3534, 3322, 3145, 1712, 1445, 770 cm^{-1}. NMR (D_2O): τ 2.13 (d, J=2.5 Hz, 1H), 3.03 (d, J=2.5 Hz, 1H).

Isomerization. A solution of **18** (222 mg, 1 mmol) in benzene (6 m*l*) was refluxed for five hours in the presence of iodine (22 mg). On cooling, yellow crystals (mp 186—191°C) (205 mg, 92%) were filtered. Pale yellow scales from benzene, mp 201—203°C.

Found: C, 80.60, H, 6.54; N, 12.27%. Calcd for $C_{15}H_{14}N_2$: C, 91.05; H, 6.35; N, 12.60%. IR (KBr): 3236, 3049, 2976, 1495, 1005, 933, 770, 751, 691 cm^{-1}. UV (MeOH nm ε) 240 (9550), 344 (74300), 361 (56500). NMR (DMSO-d_6): τ 2.38—3.98 (m).

Reactions of ***17****. Thermolysis. a)* An anhydrous diglyme (1 m*l*) solution of **17** (50 mg) was refluxed for six hours *in air*. The subsequent addition of ether, which has been washed with water and dried (Na_2SO_4), followed by the removal of the solvent, gave 46 mg of yellow crystals. The crude crystals were purified by alumina-column chromatography. Petroleum ether (bp 40—60°C)-benzene (2:1) eluted colorless **16**, mp 165—166°C (21 mg, 49%). *b)* The above reaction was carried out *in a nitrogen atmosphere* using 226 mg of **17** in diglyme (2 m*l*); it yielded a pale yellow oil (117 mg) which was then passed through a column of alumina. Colorless crystals (mp 49—55°C) (100 mg, 51%) were eluted with petroleum ether. Colorless needles from ethanol, mp 56—58°C; those needles were converted into **16** on standing in air and were assigned to **31**. IR (KBr): 3021, 2841, 1493, 1443, 754, 718, 686 cm^{-1}.

Petroleum ether–benzene (9:1) eluted colorless crystals (30 mg) (mp 161—164°C), which were recrystallized from ethanol to yield 10 mg (5%) of **16**. Finally we eluted 38 mg of colorless crystals; mp 173—182°C. Colorless needles from benzene; mp 185—186°C (29 mg, 15%); their structure was not identified.

Found: C, 92.32; H, 7.42%. Calcd for $C_{15}H_{14}$: C, 92.74; H, 7.26%. IR (KBr): 3021, 2882, 1597, 1493, 1443, 866, 753, 726, 687 cm^{-1}.

Photolysis. A solution of **17** (130 mg) dissolved in dioxane was irradiated for one hour through a Pyrex filter using a Toshiba H 400-p high-pressure lamp. The photolysate was diluted with ether, and then washed with water, dried (Na_2SO_4), and evaporated to yield a pale yellow oil (96 mg). Alumina-column chromatographic separation afforded 44 mg (43%) of **14** on elution with petroleum ether and 10 mg of **17** on elution with benzene ether (9:1).

Photolysis of ***9****.* A solution of **9** (3.5 g, 29.7 mmol) dissolved in anhydrous dioxane and placed in a quartz cell was irradiated for 72 hr using a 6 W low-presssure lamp (Ushio-UM6). Dilution with water was followed by the addition of petroleum ether (bp 40—60°C). The organic layer was washed well with water to remove the dioxane and then dried over Na_2SO_4. The evaporation of the solvent left a pale yellow oil (2.9 g), whose vpc (3 mm×1 m 5% DOP at 120°C) showed five peaks with a ratio of 4: 7.5: 5:1: 11.5 in the order of the retention time; it was submitted to preparative vpc (10 mm×3 m PEG 4000 at 100°C). The oil eluted first (area 4) involved five groups of peaks at τ 3.81 (s, 2H), 3.95 (bs, 2H), 7.66 (bs, 4H), 8.47 (bd, J=8.5 Hz, 1H), and 8.75 (bs, 1H), and was proved to **38** on the basis of the reported data.[5] Secondly, a colorless oil was obtained. Its NMR spectrum contained six groups of peaks, at τ 4.15 (s, 2H), 4.25 (t, J=2.0 Hz, 2H), 7.05 (bd, J=3.8 Hz, 2H), 7.43 (m, 2H), 8.13 (bd, J=8.5 Hz, 1H) and 8.50 (bd, J=8.5 Hz, 1H); it was identified as **39**. Besides **38**, **39**, and **9** (area 1), two kinds of oily products (area 5 and 11.5) were obtained, but their structures were not characterized.

Sensitized Photolysis of ***14****. Formation of 9-Phenylbarbaralane* ***15****.* A solution of **14** (58 mg, 0.3 mmol) and benzophenone (309 mg, 1.7 mmol) dissolved in benzene (5 m*l*) was irradiated through a Pyrex filter using Rayonet MGR-black light. The progress of the reaction was monitored on vpc (3 mm×1 m 5% SE-30 at 170°C), and the peak due to **14** disappeared after 5 hr of irradiation. The benzene was removed and the residue was subjected to preparative tlc separation and developed by a mixture of *n*-hexane–benzene (1:2) to afford **15** (27 mg) from R_f=0.91. IR (neat): 3030, 2940, 2875, 1618, 1602, 1492, 1450, 794, 735, and 694 cm^{-1}.

Heterocycles Structurally Influenced by a Side Chain. II.[1] 7-Phenacylxanthopterins and 6-Phenacylisoxanthopterins[2]

Yasuo IWANAMI and Taketsugu SEKI*
Sasaki Institute, Kanda-Surugadai, Tokyo
(Received November 11, 1971)

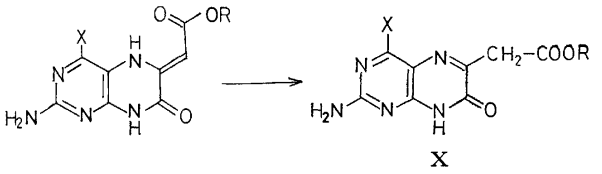
Phenacyl derivatives of two naturally-occurring pteridines and their 4-amino analogues (III and V) have been synthesized for their structural study. Since these compounds are obtained by the condensation of ethyl benzoylpyruvates (II) with tri- or tetraaminopyrimidine (I), a carbon-nitrogen double bond, which is adjacent to the phenyl group of the side chain, may be expected in the ring (-N=C-CH_2-CO-Ph). However, their NMR spectra show that the double bonds of all the products are displaced onto the side chain (-NH-C=CH-CO-Ph), the carbonyl of which is hydrogen-bonded with the secondary amino group thereby formed. This form of V makes striking contrast to alkyl isoxanthopterin-6-acetates (X), in which the corresponding double bond remains undisplaced. The intermediate products of V (IV) and V were hydrolyzed with acid or alkali into 6-methylisoxanthopterin (VI) and benzoic acids (VII).

When a side chain with a β-carbonyl group is introduced into nitrogen heterocycles at a position adjacent to the nitrogen atom, the carbon-nitrogen double bond of the ring is often displaced onto the side chain.[1] This displacement is likely to be facilitated by an intramolecular hydrogen bonding between the carbonyl and the secondary amino group of the ring thereby formed. One of our early reports[3] was the first presenting evidence for the fixation of the enamine form, which is illustrated below:

Imine form Enamine form

It is said that the imine form rather than the enamine form is predominant in imine-enamine tautomerism when hydrogen is present on the nitrogen atom.[4,5] However, the enamines reported[6] on by our laboratory are stable under ordinary conditions in spite of the presence of hydrogen.

During the course of further studies, many examples of similarly-fixed enamines in condensed[1,3,6,7] and noncondensed[3,6,7] heterocycles of five-,[7] six-,[1,3,6,7] and seven-membered[7] rings, and also in simpler alkyl β-aminoacrylates,[8] have been encountered. Interestingly, however, a structural resemblance is not always followed by such a fixation of the enamine form. Indeed, reverse is the case in alkyl isoxanthopterin-6-acetates and their 4-amino analogues (X), which exist in the imine form, as we recently reported.[9] It appears that the imine forms of these compounds are also fixed unless otherwise dissolved in a protic solvent.[9]



X

X=O or NH
R=CH_3 or C_2H_5

Consequently, we were particularly interested in whether or not the phenacyl derivatives of xanthopterin and isoxanthopterin exist in the enamine forms. We will now describe the synthesis and characterization of the phenacyl derivatives of these two naturally-occurring pteridines (originally found in butterfly wings), all of which are new compounds.

The condensation of 2,5,6-triamino-4-hydroxypyrimidine (Ia) with ethyl p-substituted benzoylpyruvate (or the corresponding acid in some cases) (II) under acidic conditions gave 7-(p-substituted phenacyl)xanthopterin (III), but in an ammoniacal solution it afforded an intermediate product (IV), which was then cyclized to 6-(p-substituted phenacyl)isoxanthopterin (V) in the presence of sulfuric acid. The 4-amino analogues of these three types of products (III, IV, V; X=NH_2) could be obtained by the reaction of 2,4,5,6-tetraaminopyrimidine (Ib) instead of Ia. The position of the phenacyl groups in V was confirmed by the fact that V was hydrolyzed into 6-methylisoxanthopterin (VI) and the corresponding benzoic acid (VII). A similar hydrolysis proceeded with the intermediate product (IV).

All these phenacylpteridines (III and V) were sparingly soluble or practically insoluble in the usual solvents, but could be dissolved into concentrated sulfuric acid. Thus, the NMR spectra of these com-

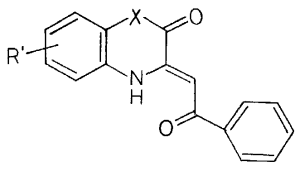
pounds were determined in sulfuric and deuteriosulfuric acid. 7-(*p*-Methylphenacyl)xanthopterin (IIIb), for example, exhibits no signal between 7.19 and 0 ppm (δ scale) except for a singlet at 2.60 ppm due to the methyl group which is attached to the benzene ring of IIIb. Therefore, IIIb does not involve methylene ($-CH_2-$) in its structure. Instead, it contains a methine (=CH-) group, which is revealed by a singlet at 7.19 ppm. The bands in the lowest field, *ca.* 8.3 ppm, must be due to the protons *ortho* to the electron-withdrawing carbonyl group. This, in turn, indicates that the carbonyl group does not exist as an enol in IIIb. Since the enol double bond is thus absent, the above methine can be assigned to another double bond, which is derived by the migration of the carbon-nitrogen double bond of the ring onto the side chain.

The NMR data obtained on the samples of the other analogues, III and V, are similar with those of this one, IIIb. It is, therefore, fitting to call them by the more practical expression "7-(*p*-methylphenecylidene)-7,8-dihydroxanthopterin" (IIIb) and so on. This type of partial structure of III and V is exactly the same as that of 3-phenacyl-2(1*H*)-quinoxalinones (VIII, X=NH) and 3-phenacyl-2*H*-1,4-benzoxazin-2-ones (VIII, X=O), which have been shown to exist in the "phenacylidene" structure (*i.e.*, the enamine form) both in solution and in crystalline states, as reported in a preceding paper.[1]

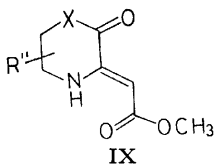


VIII

X=O or NH
R'=H, CH_3, Cl, or Benzo

In the case of VIII, an amino proton gave rise to a band in the lowest field (13.88—12.02 ppm), giving evidence of its participation in the intramolecular hydrogen bonding. In the present study, however, we could not observe the corresponding signal. The signal of the amino proton is probably overlapped with that of the solvent (11.38 ppm). Moreover, sulfuric acid is not a proper solvent for the NMR spectra of the intermediate (IV). Although IV exhibited an olefinic proton signal, this might be due to the methine of V, which could be derived from dehydration with sulfuric acid. Finally, we found that dimethyl sulfoxide-d_6 dissolved IV as well as III and V to a certain extent at a high temperature (175°C). In this solvent, the products, IIIb, IVb, and Vb, for example, gave methine proton signals at 6.54, 5.88, and 5.90 ppm respectively, in addition to the aromatic *ortho* protons around 8 ppm. This also supports the enamine structures of these three types of products.[10,11]

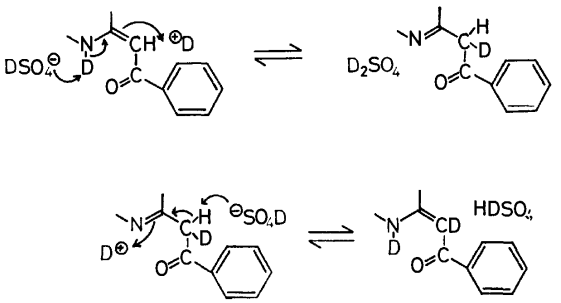
Returning to the NMR spectra in the sulfuric-acid solvent system, the profile of the spectrum of IIIb in sulfuric acid-d_2 was not the same as that in sulfuric acid. The methine proton signal disappeared in sulfuric acid-d_2. This accounts for the deuterium exchange. The exchange mechanism would be a concerted reaction,[9] similar to that proposed for VIII in trifluoroacetic acid-d[1] and to that for the compounds with the general formula of IX,[6] as is illustrated below:



IX

X=O or NH
R''=Benzo or H

In trifluoroacetic acid, VIII exists in an equilibrium mixture of four forms, including not only the imine-enamine tautomers but also the keto-enol tautomers of a phenacyl moiety.[1] However, III, IV, and V, all possessing the same phenacyl group, gave no spectral indications of the keto-enol tautomers. There was thus a most impressive contrast between the products of this study and VIII, in spite of their structural resemblance. Therefore, the deuterium exchange mechanism of III, IV, and V is more closely related to that of IX,[6] which does not have a phenacyl substituent, and they must be essentially the same:



One of the possible exchange mechanisms

There is another striking contrast between V and alkyl isoxanthopterin-6-acetates (X).[9] Both of these compounds are 6-substituted derivatives of isoxan-

10) Since the spectra of VIII in this solvent are essentially the same (the enamine type) between 35 and 175°C, and since the spectra of X are also the same (the imine type), in this temperature range, we assume that the present products exist in the enamine form not only at 170° but also at lower temperatures.

11) The IR spectra of III, IV, and V are not so informative because of their complicated bands.

Table 1. Electronic absorption maxima of the products

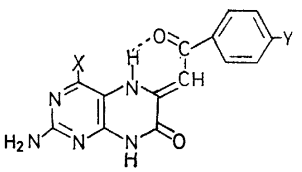
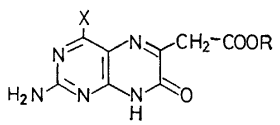
thopterin, but they are different from each other in their existing forms; *i.e.*, V exists in the enamine form, and X in the imine form.



V



X

The replacement of an alkoxyl group in X by a phenyl group into V makes an extension of the conjugated system in the enamine form to include the benzene ring, so that the form is stabilized.[12]

None of the products, III, IV, or V, melt below 300°C. The maxima of the electronic absorption spectra of these products in 0.1N sodium hydroxide are listed in Table 1.

The NMR spectra show that the present products exist in the enamine form. The signals of the corresponding imine form do not appear in our results. The only indication of its existence was given when the spectra were measured in sulfuric acid-d_2. In other words, the fact that the methine proton signal disappeared upon deuterium exchange was interpreted to indicate the presence of the imine form[14] in a trace amount. The previous observations on VIII and IX indicated that the methine proton siganl of VIII in dimethyl sulfoxide-d_6 did not disappear when deuterium oxide was added (*i.e.*, exclusively in the enamine form), and that of IX in methanol-d_4 also remained unaffected; besides, the enamine structures of VIII and IX were fixed even in the crystalline state, as was proved by the IR spectroscopy. In a protic solvent like trifluoroacetic acid, however, VIII and IX have been shown to exist as an equilibrium mixture of imine and enamine tautomers,[15] because both methylene (imine) and methine (enamine) proton signals were observed, and were removed in trifluoroacetic acid-*d*. On the bases of these observations, we deduce that the present products, III, IV, and V, are fixed in the enamine structure unless dissolved in a protic solvent like sulfuric acid.

12) This is probably not the only factor in inducing the enamine form. The influence of phenyl substitution in the present comparison, however, would be similar to that of benzoylacetone (89.2% enolized) in contrast to ethyl acetoacetate (8.0% enolized).[13]

13) J. March, "Advanced Organic Chemistry: Reactions, Mechanisms, and Structure," McGraw-Hill Book Co., New York (1968), p. 60.

14) The other interpretation would be a similar migration and return of the double bond *via* its immonium ion, as was illustrated in a previous paper,[9] (this mechanism is at present indistinguishable from the concerted reaction already mentioned) or the direct ionization of the methine hydrogen (carbanion formation).

15) Many examples of NMR spectra which separately indicate both forms of keto-enol tautomers, and of imine-enamine tautomers[1,6,16] as well, are known. This suggests that, when either one of the forms is shown solely in the spectrum, the other form is improbable or exists in a very small amount, beneath the lebel of detection, rather than that the rapid interconversion (indistinguishable by a NMR spectrometer) of two (or more) forms gives rise to a spectrum of an appearently single form. In the latter case, it is most probable that all the signals of protons taking part in the interconversion fall into a single peak, together with that of solvent acid, at a moderate temperature, because hydroxyl or amino proton exchanging with the solvent proton rapidly constitutes one signal joined together.

16) L. Merlini, W. von Philipsborn, and M. Viscontini, *Helv. Chim. Acta*, **46**, 2592 (1963).

Even in this acid, the compounds mostly exist in the enamine form, as has already been mentioned.

Besides the physicochemical observations, we made a study of the biological effects of the products, III, IV, and V. Of these compounds, some of the IV compounds were shown to stimulate the cell growth of several microorganisms. The most active substance was 2,6-diamino-4-hydroxypyrimid-5-ylamino(*p*-hydroxyphenacylidene)acetamide (IVe). This compound remarkedly enriched the cell mass of *Escherichia coli*, *Clostridium butyricum*, *Candida utilis*, and *Rhodotorula glutinis* to two- or three-fold that of the control cultures.[17]

Experimental

The NMR spectra were determined on a Hitachi H-60 spectrometer, while the electronic absorption were taken on a Hitachi 124 spectrophotometer. All the melting points are uncorrected.

Ethyl (p-Substituted Benzoyl)pyruvates (IId, g, g').[18-20] Ethyl *p*-bromobenzoylpyruvate (IId) (yield 68%); colorless needles; mp 60.5—61.5°C.

Ethyl *p*-carboxybenzoylpyruvate (IIg) (53%); colorless needles; mp 126—128°C.

Found: C, 58.97; H, 4.36%. Calcd for $C_{13}H_{12}O_6$: C, 59.09; H, 4.58%.

p-Ethoxycarbonylbenzoylpyruvic acid (IIg'). Ethyl *p*-ethoxycarbonylbenzoylpyruvate, prepared from *p*-ethoxycarbonylacetophenone and diethyl oxalate in a 45% yield, was hydrolyzed with a mixture of 10% sulfuric acid and acetic acid (2: 1) to give IIg' as colorless crystals (40%); mp 150—151°C.

Found: C, 55.68; H, 4.85%. Calcd for $C_{13}H_{12}O_6 \cdot H_2O$: C, 55.32; H, 5.00%.

7-Phenacylidene-7,8-dihydroxanthopterin (IIIa).[21] Into a warmed (*ca.* 50°C) suspension of 2,5,6-triamino-4-hydroxypyrimidine (IIa) sulfate (2.4 g) in water (50 m*l*), a solution of ethyl benzoylpyruvate (Ia) sodium salt (3.6 g) in 1N acetic acid (100 m*l*) was dropped with stirring, and then the temperature of the reaction mixture was gradually raised to 100°C. The mixture, which started to turn a deep orange with the formation of reddish precipitates, was refluxed for 1.5 hr, and then left to stand overnight at room temperature with continuous stirring. The crystals thus deposited were collected on a funnel, and washed well with water and ethanol. The crude product (2.4 g) was recrystallized from dimethyl sulfoxide to give IIIa as orange crystals; mp>300°C.

Found: C, 52.83; H, 4.65; N, 22.63%. Calcd for $C_{14}H_{11}O_3N_5 \cdot H_2O$: C, 53.33; H, 4.16; N, 22.22%.

7-(p-Methylphenacylidene)-7,8-dihydroxanthopterin (IIIb).[21] In to a warmed (*ca.* 50°C), a solution of IIb (1.9 g) in ethanol (50 m*l*) was dropped with stirring. The reaction mixture was gradually heated, and then refluxed for 1.5 hr to give an orange precipitate. After the mixture had been left to stand overnight at room temperature with stirring, the deposited crystals were collected on a funnel, and washed with water and ethanol. The crude product (1.4 g) was repeatedly recrystallized from dimethyl sulfoxide to give IIIb as orange-yellow crystals; mp>300°C.

Found: C, 54.47; H, 4.20; N, 21.36%. Calcd for $C_{15}H_{13}O_3N_5 \cdot H_2O$: C, 54.71; H, 4.59; N, 21.27%.

7-(p-Chlorophenacylidene)-7,8-dihydroxanthopterin (IIIc).[21] In a manner similar to that used in the preparation of IIIb, the crude product of IIIc (1.4 g) was obtained from Ia sulfate (1.2 g) and IIc (2.1 g). The product was recrystallized from dimethyl sulfoxide to afford IIIc as yellow prisms; mp>300°C.

Found: C, 50.46; H, 3.12; N, 20.95%. Calcd for $C_{14}H_{10}O_3N_5Cl$: C, 50.71; H, 3.02; N, 21.11%.

7-(p-Bromophenacylidene)-7,8-dihydroxanthopterin (IIId). The crude product of IIId (2.8 g) from Ia sulfate (1.2 g) and IId sodium salt (2.4 g) was recrystallized from dimethyl sulfoxide to give IIId as yellow prisms; mp>300°C.

Found: C, 44.42; H, 2.83; N, 18.33%. Calcd for $C_{14}H_{10}O_3N_5Br$: C, 44.71; H, 2.66; N, 18.61%.

7-(p-Cyanophenacylidene)-7,8-dihydroxanthopterin (IIIf). The crude product of IIIf (0.75 g) from Ia sulfate (0.96 g) and IIf sodium salt (1.2 g) was recrystallized from dimethyl sulfoxide to afford IIIf as brownish red crystals; mp>300°C.

Found: C, 51.10; H, 3.77; N, 23.76%. Calcd for $C_{15}H_{10}O_3N_6 \cdot 3/2H_2O$: C, 51.60; H, 3.72; N, 24.06%.

7-(p-Carboxyphenacylidene)-7,8-dihydroxanthopterin (IIIg). The crude product of IIIg (2.0 g) from Ia sulfate (1.8 g) and IIg (2.0 g) was recrystallized from dimethyl sulfoxide to give IIIg as brownish red crystals; mp>300°C.

Found: C, 48.49; H, 4.05; N, 18.63%. Calcd for $C_{15}H_{11}O_5N_5 \cdot 3/2H_2O$: C, 48.91; H, 3.83; N, 19.02%.

7-Phenacylidene-2,4-diamino-6(5H)-pteridinone (IIIa').[21] Into a suspension of 2,4,5,6-tetraaminopyrimidine (Ib) sulfate (1.4 g), a hot solution of IIa sodium salt (2.4 g) was dropped with stirring. The reaction mixture was then heated to 100°C for 2 hr, and thereafter maintained at pH 1—2. After the mixture had stood overnight, the precipitated crystals were collected by filtration. The crude product, IIIa' (0.8 g), was purified by reprecipitation. The crystalls were dissolved in a minimum amount of concentrated sulfuric acid, and then water was added into the solution chilled in an ice bath to give IIIa' as brownish red crystals; mp> 300°C.

Found: C, 50.65; H, 4.03; N, 24.74%. Calcd for $C_{14}H_{12}O_2N_6 \cdot 1/3H_2SO_4 \cdot 1/3H_2O$: C, 50.19; H, 4.01; N, 25.09%.

7-(p-Methylphenacylidene)-2,4-diamino-6(5H)-pteridinone (IIIb').[21] The crude product of IIIb' (1.4 g) from Ib sulfate (1.4 g) and IIb sodium salt (1.7 g) was recrystallized from dimethyl sulfoxide to give IIIb' as yellow crystals; mp>300°C.

Found: C, 56.41; H, 4.87; N, 26.68%. Calcd for $C_{15}H_{14}O_2N_6 \cdot 1/2H_2O$: C, 56.44; H, 4.70; N, 26.32%.

7-(p-Hydroxyphenacylidene)-2,4-diamino-6(5H)-pteridinone (IIIe'). The crude product of IIIe' (1.0 g) from Ib sulfate (1.4 g) and IIe sodium salt (3.2 g) was recrystallized from dimethyl sulfoxide to give IIIe' as orange crystals; mp>300°C.

Found: C, 50.63; H, 4.41; N, 25.42%. Calcd for $C_{14}H_{12}O_3N_6 \cdot H_2O$: C, 50.91; H, 4.27; N, 25.45%.

7-(p-Cyanophenacylidene)-2,4-diamino-6(5H)-pteridinone (IIIf'). The crude product of IIIf' (1.3 g) from Ib sulfate (1.4 g) and IIf sodium salt (1.8 g) was recrystallized from dimethy sulfoxide to give IIIf' as brownish red crystals; mp>300°C.

Found: C, 53.97; H, 4.09; N, 28.86%. Calcd for $C_{15}H_{11}O_2N_7 \cdot 3/4H_2O$: C, 53.81; H, 3.76; N, 29.29%.

2,6-Diamino-4-hydroxypyrimid-5-ylamino (phenacylidene) acet-

amide (IVa). Into a suspension of Ia sulfate (2.0 g) in water (50 ml), 1N ammonium hydroxide (50 ml) was added to alkalize it at about pH 8. A solution of IIa (1.7 g) in ethanol (20 ml) was then dropped with stirring into the suspension, the color of which had turned violet, during a course of about 30 min at room temperature; the pH was maintained by adding 1N ammonium hydroxide. The color of the reaction mixture then became gradually reddish-brown. After the IIa had all been dropped, the mixture was stirred more. In a little while, fine brown crystals began to deposit on the bottom of the reaction vessel. Stirring was continued overnight. The precipitated crystals were collected on a glass filter, and washed successively with 1N sulfuric acid, water, and ethanol. The crude product of IVa sulfate (1.0 g) was recrystallized from dimethy sulfoxide to give yellowish-brown crystals; mp>300°C.

Found: C, 49.66; H, 3.86; N, 24.62%. Calcd for $C_{14}H_{14}O_3N_6 \cdot 1/4H_2SO_4$: C, 49.63; H, 4.31; N, 24.81%.

2,6-Diamino-4-hydroxypyrimid-5-ylamino(p-methylphenacylidene)-acetamide (IVb). In a manner similar to that used in the preparation of IVa, the crude product of IVb (0.9 g) was obtained from Ia sulfate (2.0 g) and IIb (1.8 g). The IVb sulfate was recrystallized from dimethyl sulfoxide to afford IVb as dark yellow crystals; mp>300°C.

Found: C, 52.02; H, 4.47; N, 24.06%. Calcd for $C_{15}H_{16}O_3N_6 \cdot 1/5H_2SO_4$: C, 51.78; H, 4.75; N, 24.16%.

2,6-Diamino-4-hydroxypyrimid-5-ylamino(p-hydroxyphenacylidene)-acetamide (IVe). The crude product (1.6 g) from Ia sulfate (2.4 g) and IIe (2.4 g) was recrystallized from dimethyl sulfoxide to afford IVe as reddish-brown crystals; mp>300°C.

Found: C, 47.22; H, 4.13; N, 23.67%. Calcd for $C_{14}H_{14}O_4N_6 \cdot 3/2H_2O$: C, 47.05; H, 4.79; N, 23.52%.

2,6-Diamino-4-hydroxypyrimid-5-ylamino(p-carbamoylphenacylidene)acetic Acid (IVg'). The crude product (1.4 g) from Ia sulfate (1.8 g) and IIg (2.0 g) was dissolved in 1N sodium hydroxide, and the resulting solution was poured into warm 3N hydrochloric acid. The reprecipitation was repeated three times to give IVg' as dark red crystals; mp>300°C.

Found: C, 46.87; H, 3.93; N, 21.45%. Calcd for $C_{15}H_{12}O_5N_6 \cdot 3/2H_2O$: C, 47.00; H, 3.94; N, 21.93%.

Ethyl 2,4,6-Triaminopyrimid-5-ylamino(phenacylidene) acetate (IVe'). The crude product (0.3 g) obtained by the condensation of Ib sulfate (2.4 g) with IIa (2.2 g) in an ammoniacal solution of pH 7.7 was washed successively with a 1:1 mixture of dimethyl sulfoxide and 50% sulfuric acid, water, and ethanol on a glass filter, and was then recrystallized from dimethyl sulfoxide to give IVe' as reddish-brown crystals; mp>300°C.

Found: C, 45.92; H, 4.42; N, 20.05%. Calcd for $C_{16}H_{18}O_4N_6 \cdot 1/2H_2SO_4 \cdot 1/2H_2O$: C, 46.16; H, 4.84; N, 20.18%.

6-Phenacylidene-5,6-dihydroisoxanthopterin (Va).[21] The The crude product of IVa (1.0 g) was dissolved in a minimum amount of concentrated sulfuric acid. The dark-colored solution was gradually heated to 60°C. After it had been left to stand overnight at room temperature, water was added to the solution chilled in an ice bath; this step was then repeated to give Va(0.5 g) as yellowish-brown crystals; mp> 300°C.

Found: C, 46.46; H, 3.82; N, 18.89%. Calcd for $C_{14}H_{11}O_3N_5 \cdot 1/2H_2SO_4 \cdot H_2O$: C, 46.15; H, 3.87; N, 19.22%.

6-(p-Methylphenacylidene)-5,6-dihydroisoxanthopterin (Vb).[21] In a similar manner, the product, IVb (0.8 g), obtained from Ia sulfate (2.0 g) and IIb (1.8 g) was cyclized in the presence of concentrated sulfuric acid, and was then recrystallized from dimethyl sulfoxide to give Vb as dark orange crystals; mp>300°C.

Found: C, 54.89; H, 4.17; N, 21.15%. Calcd for $C_{15}H_{13}O_3N_5 \cdot H_2O$: C, 54.71; H, 4.59; N, 21.27%.

6-(p-Chlorophenacylidene)-5,6-dihydroisoxanthopterin (Vc).[21] The crude product (1.4 g) from Ia sulfate (2.0 g) and IIc (2.0 g) was recrystallized for hot dimethyl sulfoxide, in which cyclization probably took place, to give Vc as dark yellow crystals; mp>300°C.

Found: C, 50.28; H, 3.23; N, 20.57%. Calcd for $C_{14}H_{10}O_3N_5Cl \cdot 1/4H_2O$: C, 50.04; H, 3.15; N, 20.85%.

6-(p-Bromophenacylidene)-5,6-dihydroisoxanthopterin (Vd). The crude product (1.0 g) form Ia sulfate (2.4 g) and IId (3.0 g) was recrystallized from hot dimethyl sulfoxide to afford Vd as dark yellow crystals; mp>300°C.

Found: C, 44.97; H, 3.03; N, 18.87%. Calcd for $C_{14}H_{10}O_3N_5Br$: C, 44.71; H, 2.66; N, 18.61%.

6-(p-Hydroxyphenacylidene)-5,6-dihydroisoxanthopterin (Ve).[21] The crude product (2.1 g) from Ia sulfate (2.4 g) and IIe (2.3 g) was purified by reprecipitation from a cencentrated sulfuric acid solution to give Ve sulfate as yellow crystals; mp>300°C.

Found: C, 41.25; H, 3.50; N, 16.51%. Calcd for $C_{14}H_{11}O_4N_5 \cdot H_2SO_4$: C, 40.87; H, 3.18; N, 17.03%.

6-(p-Carboxyphenacylidene)-5,6-dihydroisoxanthopterin (Vg). The crude product (0.7 g) from Ia sulfate (0.8 g) and IIg (1.0 g) was reprecipitated from a dimethyl sulfoxide solution by adding water to give Vg as orange-red crystals; mp> 300°C.

Found: C, 48.30; H, 4.23; N, 18.41%. Calcd for $C_{15}H_{11}O_5N_5 \cdot 2H_2O$: C, 47.75; H, 4.01; N, 18.56%.

Hydrolysis of V and IV. A suspension of Ve (0.6 g) 2N sodium hydroxide (30 ml) was refluxed for 30 min, and then left standing to cool. The precipitate thereby formed was removed by filtration. The filtrate was acidified with 6N hydrochloric acid. The yellow crystals thus precipitated were collected on a funnel and washed repeatedly with ethanol. The crystals were dissolved into 1/2N sodium hydroxide, and then 2N hydrochloric acid was dropped into the solution to reprecipitate it. The purification step was repeated three times to afford 6-methylisoxanthopterin (VI) (0.2 g). The UV spectrum was identical with that previously reported.[22] Found: N, 36.69%.

From the combined ethanol extracts, the solvent was removed *in vacuo*; the residue was recrystallized from a mixture of ethanol and ether to give *p*-chlorobenzoic acid (VIIc); mp 243°C, undepressed on admixture with a commercial sample. The identity was also proved by UV spectroscopy.

Found: C, 53.67; H, 3.47%.

A suspension of Vc (0.5 g) in 6N hydrochloric acid (200 ml) was refluxed for 28 hr. The undissolved meterials were removed by filtration while the reaction mixture was still hot. The filtrate was then concentrated under reduced pressure, and the residue was repeatedly extracted with ether. The remaining crystals (0.2 g) were purified according to the above reprecipitation. The identity of the VI thereby formed with the corresponding product in the above alkaline hydrolysis and that of the VIIc obtained from the combined ether extracts with a commercial sample were proved by UV spectroscopy.

A suspension of VIe (0.5 g) in 2N sodium hydroxide (40 ml) was refluxed for 3 hr. After acidification followed by evaporation *in vacuo*, the residue was washed ethanol. The crystals were similarly purified to give VI, which was spectroscopically identical with the sample. The *p*-hydroxybenzoic acid (VIIe) obtained from the combined extracts

was identified by a mixed-melting-point determination (mp 213—214°C) and UV spectroscopy.

The other compounds belonging to IV or V (both X=OH) behaved similarly under hydrolysis, as evidenced by the UV spectra of the hydrolysates.

Grateful acknowledgment is made to Miss Nobu Maruta for a part of the elementary analysis; to Mr. Takeshi Inagaki, Nitto Chemical Industry Co., for many NMR spectra; to Dr. Tetsuo Maruyama, JEOL Co., for NMR spectra at an elevated temperature, and to Mr. Jun-etsu Seo and Mr. Atsuo Norose for their valuable technical assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2834—2836 (1972)

1,2: 8,9-Dibenzo-3,10-bisdehydro[14]annulene-5,12-dione

Takashi KOJIMA, Yoshiteru SAKATA, and Soichi MISUMI*
The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka
(Received March 13, 1972)

An annelated[14]annulenedione (V) was prepared by the Castro reaction of cuprous salt of *o*-iodocinnamoylacetylene (IV) in order to examine the aromatic character of the inner fourteen membered ring. The NMR spectra of V in arsenic trichloride and deuterotrifluoroacetic acid suggest that significant downfield shift of the inner protons H_B is due to a paramagnetic ring current arising from polarization of two carbonyl groups in the inner ring, compared with the spectra of a reference compound VI.

A series of fully conjugated monocyclic monoketone, so-called annulenone, are predicted to be aromatic or non-aromatic owing to polarization of carbonyl group provided they contain $(4n+3)$ membered ring or $(4n+1)$ membered ring, respectively. Recently, several annulenones, *e.g.*, 4,9-methano[11],[1] [13],[2a] [15],[2b] and [17][2c] annulenone derivatives, have been synthesized in order to confirm this prediction. On the other hand, as in the case of annulenes, an effect of annelation on aromatic character of annulenone has been explored in a few annelated annulenones, dibenzo-[9],[3] 6,7-benzo-4,9-oxido[11],[4a] 4,7: 10,13-dioxido-[15],[4b] and 2,5: 8,11: 14,17-trioxido[17][4c] annulenones, indicating the delocalization of π-electrons through condensed benzene or furan nuclei.

For the purpose of comparison with the properties of the annelated annulenones, we attempted to examine the effect of annelation on conjugated cyclic diketone or annulenedione.[5] In this paper we wish to report the synthesis and properties of 1,2: 8,9-dibenzo-3,10-bisdehydro[14]annulene-5,12-dione (V). It is expected that this $(4n+2)$ membered ring compound is non-aromatic by virtue of polarization of two carbonyl groups and thereby represents a paramagnetic ring current.

Results and Discussion

Synthesis. *o*-Iodocinnamaldehyde (II) was obtained by the reaction of *o*-iodobenzaldehyde with acetaldehyde in anhydrous alcohol at room temperature in 40% yield.[6] The cinnamaldehyde II was treated with ethynyl magnesium bromide[7] in dry tetrahydrofuran to produce an ethynyl carbinol III in a yield of 74%. Oxidation of the carbinol III with active manganese dioxide[8] in carbon tetrachloride at 0°C yielded crude ethynyl *o*-iodostyryl ketone (IV) which gave red cuprous salt in 86% yield by treatment with Ilosvay reagent. Dry cuprous salt of IV was subjected

to the Castro reaction[9] in anhydrous *N,N*-dimethyl formamide at 120°C to give cyclic dimolecular product, 1,2 : 8,9-dibenzo-3,10-bisdehydro[14]annulene-5,12-dione (V), of fairly thermostable and lemon yellow needles in 1.2% yield. The structure of the annulene-dione V was confirmed by elemental analysis and IR, NMR, and Mass spectra. Styryl phenylethynyl ketone (VI) was obtained through the Castro reaction of cuprous salt of cinnamoyl acetylene with iodobenzene as a reference compound for the synthesis and NMR spectrum of V.

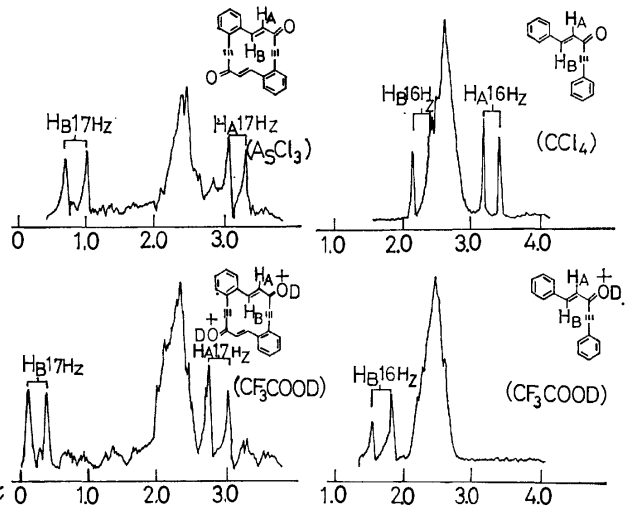

Fig. 1. The NMR spectra of V and VI (60 MHz, TMS)

Table 1. The chemical shifts (τ) of V and VI

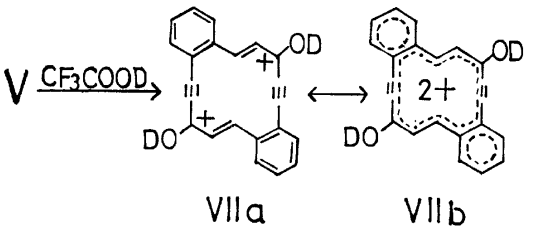
	Solvent	H_B	BzH	H_A
V	$AsCl_3$	0.81	~2.4~	3.14
	CF_3COOD	0.22	~2.3~	2.88
VI	CCl_4	2.27	~2.6~	3.31
	CF_3COOD	1.68	~2.5~	~2.5~

NMR Spectra. The NMR spectra of V and VI are shown in Fig. 1 and Table 1. The spectrum of V was measured in arsenic trichloride and in deutero-trifluoroacetic acid because of poor solubility in the usual organic solvents, while VI gave no distinct spectrum owing to instability in the former medium. The chemical shift of inner protons H_B in V are at considerably lower field ($\Delta\delta$: *ca.* 1.5 ppm) than that of proton H_B in VI, in contrast to somewhat same position of both protons H_A in V and VI. A difference in the chemical shifts in different solvents is *ca.* 0.1 ppm between arsenic trichloride and carbon tetrachloride.[10] The extent to which the shift of the protons H_B in V is affected by shielding effects of the π-electron systems (-C≡C-, -C=C-, and >C=O) and electric field effect of carbonyl group other than a styryl phenylethynyl ketone moiety in V was estimated according to the McConnell equation (1)[11] and the Buckingham equation (2),[12] respectively, to be about −0.7 ppm at most. It is interesting that the protons H_B in V appear

$$\Delta\sigma = \Delta\chi \sum_{i=1} \frac{1}{3R^3}(1-3\cos^2\theta) \quad (1)$$

$$\Delta\sigma = -2\times 10^{-12}E_z - 10^{18}E^2 \quad (2)$$

at considerably lower field beyond the combined effect of both effects above-stated. The inner fourteen membered ring of V is considered as a twelve π-electron system, *i.e.*, a $4n\pi$ ring system of the Hückel rule, through the polarization of two carbonyl groups. So the inner ring system may reveal a paramagnetic ring current and thereby may show downfield shift of the inner protons. Accordingly, the marked downfield shift of the protons H_B in V described above can be accounted for by a total effect of the paramagnetic ring current and the other effects, mainly by the former.



It is expected that when V is protonated, the inner protons H_B may indicate the signal at further lower field by way of additional paramagnetic ring current of the inner ring as depicted by VIIa and VIIb. This prediction was, in fact, realized with the chemical shift in deuterotrifluoroacetic acid as is shown in Table 1 and Fig. 1. In contrast to the chemical shift of the inner proton, the outer protons H_A and the benzenoid protons show little difference in the chemical shift, compared with ones in arsenic trichloride. It is most likely due to internal compensation of the paramagnetic ring current with an effect of positive charge. This postulate is possibly supported by marked down field shifts of both protons H_A and H_B of VI in deuterotrifluoroacetic acid by comparison with the chemical shifts in carbon tetrachloride.

Experimental

All melting points are uncorrected. The electronic, infrared, NMR, and mass spectra were measured on Hitachi ESP-3T, Jasco DS-402G, Hitachi R-20, and Hitachi RMU-7, respectively.

1-o-Iodophenyl-1-penten-4-yn-3-ol (III). To an ethynylmagnesium bromide[7] solution prepared by introduction of acetylene into ethylmagnesium bromide (from 6.9 g, 0.29 g-atom of magnesium and 30 g, 0.28 mol of ethyl bromide) in dry tetrahydrofuran added dropwise *o*-iodocinnamaldehyde[6] (II, 50 g, 0.19 mol) in dry tetrahydrofuran (100 ml) under ice cooling and stirring. After stirring at room temperature overnight, the reaction mixture was poured into a cooled aqueous solution saturated with ammonium chloride to decompose the Grignard complex. The aqueous layer was extracted with ether and the combined organic solution was washed with water and dried over magnesium sulfate.

After evaporating organic solvent, the residue (57 g) was subjected to high vacuum distillation to give pale yellow oil (45 g, 83% yield) of the ethynyl carbinol III, bp 135—137°C/3×10^{-2} mmHg.

IR(neat): 3300 (s, ν_{OH}), 3250 (s, $\nu_{\equiv CH}$), 2200 (w, $\delta_{C\equiv C}$),960 (s, $\delta_{trans\ CH=CH}$), and 750 cm^{-1} (s, *o*-substituted benzene). NMR (CCl_4): τ 2.18—3.31 (m, 4H, aromatic), 3.04 (d, J= 15 Hz, 1H, olefin), 3.91 (dd, J=5, 15 Hz, 1H, olefin), 4.45 (m, 1H, methine), 6.52 (broad, 1H, OH), 7.45 (d, J=2 Hz, 1H, acetylene). Found: C, 46.29; H, 3.00; I, 45.02. Calcd for $C_{11}H_9OI$: C, 46.49; H, 3.19; I, 44.67.

o-Iodocinnamoylacetylene (IV). A suspension of active manganese dioxide[8] (100 g) in a carbon tetrachloride (500 m*l*) solution of above carbinol III (10 g, 36 mmol) was stirred under ice-cooling for 1.5 hr. After filtration and washing sufficiently with acetone, the combined filtrate and washings were evaporated in vacuum. Dark red residual solid (8.2 g) was used to prepare cuprous salt as it is because of difficult purification. A small amount of crude sample was extracted with ether and recrystallized from petroleum ether to give yellow plates of the ketone IV, mp 70—71°C.

IR (Nujol mull): 3210 (m, $\nu_{\equiv CH}$), 2100 (s, $\nu_{C\equiv C}$), 1630 (s, $\nu_{C=O}$), 979 (m, $\delta_{trans\ CH=CH}$), 765 cm^{-1} (m, *o*-substituted benzene). NMR (CCl_4): τ 1.92 (d, J=16 Hz, 1H, olefin.), 2.16—3.10 (m, 4H, arom.), 3.44 (d, J=16 Hz, 1H, olefin), 6.70 (s, 1H, acetylene). Found: C, 46.95; H, 2.33; I, 44.62. Calcd for $C_{11}H_7OI$: C, 46.83; H, 2.50; I, 44.98.

1,2:8,9-Dibenzo-3,10-bisdehydro[14]annulene-5,12-dione (V). To a solution of Ilosvay's reagent was added a solution of above-stated crude ketone IV (9 g, 31 mmol) in ethanol (100 m*l*) and acetone (50 m*l*) to give immediately red precipitate of cuprous salt. The cuprous salt was filtered, washed with water, ethanol, and ether, successively, and dried in vacuum at room temperature, 9.5 g (86% yield).

Dry cuprous salt (5.0 g, 15 mmol) in dry *N,N*-dimethyl formamide (150 ml) was heated with stirring at 120°C under nitrogen for 8 hr. After cooling the reaction mixture was poured into water and extracted with benzene. The organic layer was wahsed with water, dried over magnesium sulfate, and evaporated in vacuum. The residual solid dissolved in benzene was filtered through silica gel with benzene and ether–benzene (1: 99). After evaporating the solvent, crude solid was triturated with benzene and recrystallized from same solvent with active charcoal to give lemon yellow needles of the annulenedione V, mp>500°C, 27 mg (1.2% yield).

IR (Nujol mull): 2200 (s, $\nu_{C\equiv C}$), 1630 (s, $\nu_{C=O}$), 975 (m, $\delta_{trans\ CH=CH}$), 765 cm^{-1} (m, *o*-substituted benzene). UV (THF): λ_{max} (ε), 217 (35400), 304 nm (42200); Mass, *m/e* 308 (M^+). Found: C, 85.74; H, 3.77. Calcd for $C_{22}H_{12}O_2$: C, 85.70; H, 3.92; mol wt 308.

Styryl Phenylethynyl Ketone (VI). Styryl ethynyl carbinol[7] prepared by ethynylation of cinnamaldehyde was oxidized with active manganese dioxide in carbon tetrachloride to give cinnamoyl acetylene. Cuprous salt of this acetylenic ketone was subjected to the Castro reaction with iodobenzene in pyridine to yield a ketone VI, mp 72—73°C (lit,[13] 69—70°C).

(Received March 16, 1972)

Several benzo- and/or naphtho-derivatives of triptycene were prepared in a manner of addition reaction of dehydronaphthalene (XIII) or a new type of aryne, dehydroanthraquinone (XVI) generated from 3-amino-anthraquinone-2-carboxylic acid (XV), with a few acenes. The absorption bands in longer wavelength region of their UV spectra and the chemical shift of bridgehead protons in their NMR spectra led to a conclusion that the spectra of those annelated triptycenes are elucidated in terms of a superposition and a sum of magnetic effects of separated component chromophores, respectively, and thereby indicate a negligible existence of the across-space π-electron interactions, if any, among three aromatic nuclei.

Triptycene (II) is an interesting, rigid cage molecule having a higher order of symmetry (D_{3h}). Since the first synthesis by Bartlett and his co-workers,[1] this unique geometry of the molecule has attracted numerous investigators for studies of spectral properties. Thus an electronic interaction of three separated benzene nuclei in this molecule has early been considered to contribute significantly on the electronic spectrum, because σ-type overlap of $2p\pi$ orbitals was anticipated as in the case of parent compound, barrelene (I).[2] Many efforts have so far been done for examination of such σ-type interactions.[3] However, most of observed spectra of triptycene and its derivatives were

found to be explained in terms of a sum of three benzenoid chromophores and not of the interaction among those chromophores. Present authors also reported that the electronic spectra of several chloro-substituted triptycenes could be interpreted by a superposition of three benzenoid chromophores.[4]

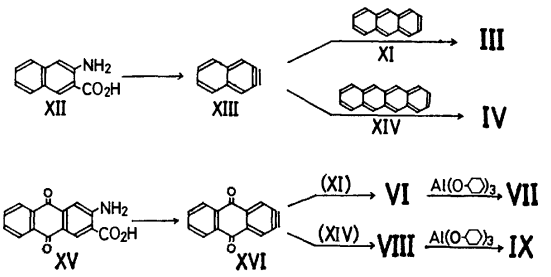
On the other hand, there have been interesting investigations that CD spectra of a number of optically active triptycene derivatives were consistent with an explanation of interactions among electric transition moments of benzenoid chromophores[5] and that a triplet state arising from photoexcitation of tribenzotriptycene (V) was located in any one of naphthalene nuclei at 20°K, but delocalized among three naphthalene nuclei at 77°K.[6]

A stepwise annelation or condensation with additional aromatic nuclei to the triptycene molecule is of great interest in connection with the interaction in question. Since the spectral properties of condensed aromatic nuclei as naphthalene and anthracene have been well investigated, it is expected, from the examination of electronic absorption and emission spectra, that such annelated derivatives of triptycene may afford valuable informations about the intramolecular across-space interactions. In addition, it appears that they are appropriate systems for a study of magnetic anisotropies of containing aromatic nuclei because of their rigid structures.

Literature search revealed that there have been only two annelated derivatives (III[7] and V[6]) of triptycene containing naphthalene ring as condensed aromatic nucleus. In the present paper we wish to report the synthesis and spectral properties, electronic and NMR, of several triptycene derivatives (III—IX) including naphthalene, anthracene, and anthraquinone nuclei.

Results and Discussion

Synthesis. Since triptycene was prepared by the Diels-Alder reaction of anthracene with benzyne, various triptycene derivatives have generally been synthesized through the addition reaction of arynes. In the present investigation triptycene derivatives were



also prepared in a manner of aryne reaction except tribenzotriptycene (V) which was obtained by the addition reaction of 1,4-dihydronaphthalene-1,4-oxide with pentacene, followed by dehydration with acetic anhydride.[6] The synthesis of mono- and di-benzotriptycenes (III and IV) was carried out by the reaction of anthracene (XI) and tetracene (XIV) with an aryne, 2,3-dehydronaphthalene (XIII), generated from 3-amino-2-naphthoic acid (XII) according to Friedman,[7] in 11 and 25% yields, respectively. In order to obtain two triptycene derivatives (VII and IX) containing anthracene nucleus, a reaction path *via* reduction of phthaloyl derivatives, VI and VIII, was chosen in the present study because 2,3-dehydroanthracene corresponding to XIII might be difficult to generate for a reason of its self-condensation. The phthaloyl derivatives VI and VIII were obtained by the reaction of anthracene and tetracene with a new aryne, 2,3-dehydroanthraquinone (XVI), generated from 3-aminoanthraquinone-2-carboxylic acid (XV), in 24 and 29% yields, respectively. The aryne precursor XV was prepared *via* five steps from toluene in good yield according to the procedure of Hosoda.[8] The quinone derivatives VI and VIII were reduced by the Meerwein-Pondorf-Verley reaction using aluminum tri(cyclohexyl oxide)[9] to give two anthracene derivatives in 35% of VII and 29% yield of IX, respectively. All the triptycene derivatives (III—IX) are thermally stable and kept without any change for a long time. The addition reaction of tetracene was carried out in a nitrogen atmosphere and with degassed solvent, otherwise it would result in yielding mainly an oxidative product, tetracene quinone, instead of regular addition compounds IV and VIII.

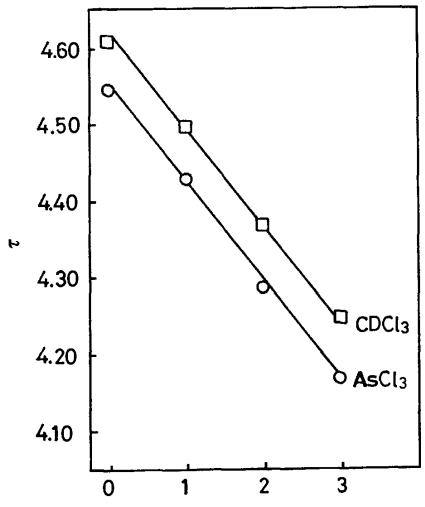

Fig. 1. Relation between the chemical Shifts of bridgehead protons of benzo-derivatives (III—V) and the number of naphthalene nuclei in deuterochloroform and arsenic trichloride.

Nuclear Magnetic Resonance Spectra. Table 1 shows the chemical shift of bridgehead protons of triptycene and some annelated triptycenes (III—IX) in arsenic trichloride and/or in deuterochloroform, because VI, VIII, and IX are sparingly soluble in the latter solvent. The chemical shifts of bridgehead protons in triptycene (II) and mono-, di-, and tri-benzotriptycenes (III, IV, and V) afford straight lines when plotted against number of naphthalene nuclei as is shown in Fig. 1. The figure reveals that the slope of the lines remains nearly constant even if the solvent is changed from deuterochloroform to arsenic trichloride and that the resonance positions of the bridgehead protons regularly shift to lower field by average 0.13 ppm along with the increase of the number of naphthalene nuclei. This finding seems to be accounted for in terms of additional ring current effect of naphthalene nuclei introduced stepwise into the triptycene molecule and therefore to substantiate the Schaefer's conclusion[10] about non-existence of "round-the-barrel" current in the triptycene molecules. In other words, the difference in the chemical shifts of bridgehead protons may be represented by a difference in the magnetic anisotropies of contained aromatic nuclei.

Thus, the chemical shifts $\Delta\sigma_1$ and $\Delta\sigma_2$ of the bridgehead protons in triptycene (II) and benzotriptycene (III) are expressed as follows:

$$\Delta\sigma_1 = 3\Delta\sigma_b + \Delta\sigma_0 \quad (1)$$

$$\Delta\sigma_2 = 2\Delta\sigma_b + \Delta\sigma_n + \Delta\sigma_0' \quad (2)$$

where $\Delta\sigma_b$ and $\Delta\sigma_n$ are chemical shifts due to ring current of a benzene nucleus and a naphthalene one, and $\Delta\sigma_0$ and $\Delta\sigma'_0$ are chemical shifts caused by various effects, *i.e.* the electric field, the van der Waals, the solvent, the electron density effects and so on, other than the ring current in II and III, respectively.

In a series of similarly constructed compounds the anisotropic effects of particular C–C and C–H bonds and the other effects are generally approximated to be equal, *i.e.* $\Delta\sigma_0=\Delta\sigma'_0$. From Eqs. (1) and (2):

$$\Delta\Delta\sigma = \Delta\sigma_1 - \Delta\sigma_2 = \Delta\sigma_b - \Delta\sigma_n \quad (3)$$

Eq. (3) implies that the difference ($\Delta\Delta\sigma$) in the chemical shifts of the bridgehead protons in triptycene and benzotriptycene can be represented as a difference in ring current effects of a benzene nucleus and a naphthalene one. Since $\Delta\sigma_b$ and $\Delta\sigma_n$ are the chemical shifts only due to magnetic anisotropy of ring current in each aromatic nucleus, they should be correlated with the McConnell equation[11] assuming that a center of the anisotropy is situated at the center of each benzene ring (Eqs. (4) and (5)). Thus, in the case of naphthalene nucleus two centers of the anisotropy are placed at the center of each benzene ring:

$$\Delta\sigma_b = -\frac{\Delta\chi(1-3\cos^2\theta_1)}{3R_1^3} \quad (4)$$

$$\Delta\sigma_n = -\left\{\frac{\Delta\chi'(1-3\cos^2\theta_2)}{3R_2^3} + \frac{\Delta\chi'(1-3\cos^2\theta_3)}{3R_3^3}\right\} \quad (5)$$

where R_n is a distance between a bridgehead proton and a center of each benzene ring, $\Delta\chi$ and $\Delta\chi'$ are the vectors which represent the anisotropies due to the ring currents of benzene ring and each benzene component in naphthalene nucleus, respectively, and θ is an angle between a line represented as R and $\Delta\chi$ or a main axis of each benzene, *i.e.* $\theta=90°$ in this case. Jonathan[12] calculated some ratios of ring current intensities of condensed aromatic nuclei to benzene ring as is shown in Table 2; *e.g.* for naphthalene nucleus, Eq. (6) are assumed.

$$\Delta\chi' = 1.1\Delta\chi \quad (6)$$

From Eqs. (3), (4), (5), and (6):

$$\Delta\Delta\sigma = -\frac{\Delta\chi(1-3\cos^2\theta_1)}{3R_1^3} + \frac{1.1\Delta\chi(1-3\cos^2\theta_2)}{3R_2^3} + \frac{1.1\Delta\chi(1-3\cos^2\theta_3)}{3R_3^3} \quad (7)$$

The observed value of $\Delta\Delta\sigma$ (-0.13×10^{-16}) and the values of the distances, $R_1=3.5$, $R_2=3.4$, and $R_3=5.5$ Å which are measured on the geometry drawn by reference to X-ray analysis,[13] are substituted in Eq.

(7). A calculated value of the magnetic anisotropy of benzene, $\Delta\chi = -33 \times 10^{-30}$ cm^3/mol, is good agreement with the Craig's value[14] ($\Delta\chi = -31 \times 10^{-30}$ cm^3/mol) obtained by substracting a sum of Pascal's constants[15] from the observed value of magnetic susceptibility of benzene.

Using the value of $\Delta\chi$ calculated above and the ring current intensity of each benzene ring in Table 2, the chemical shifts of bridgehead protons in the triptycene derivatives containing anthracene nucleus, VII and IX, are calculated to be τ 4.39 and 4.30, respectively. Those values were found to be well compatible with the observed values of VII and IX, τ 4.40 and 4.27 in arsenic trichloride.

Consequently, it was found that the application of Jonathan's values and the assumption which the various effects other than ring current, $\Delta\sigma_0$ and $\Delta\sigma_0'$, are approximated to be equal were valid for study on magnetic anisotropies and relative intensities of ring currents in this system.

Electronic Spectra. The electronic absorption spectra of the annelated triptycenes above-stated are shown in Figs. 2, 3, and 4 and in Table 3.

It has been pointed out from the spectrum of triptycene that the electronic interaction among three separated benzene nuclei in the molecule would not be so large in spite of the presumption of significant overlaps among those π-electron systems.[3] If the strong interaction between naphthalene nuclei in benzo-derivatives of triptycene, III, IV, and V, is expected to occur, the spectra of dibenzo- and tribenzo-

triptycenes should reveal longer wavelength shifts of absorption maxima than that of monobenzotriptycene. However, Fig. 2 and Table 3 exhibit that the longest wavelength bands of these triptycene derivatives appear at nearly the same position. Similar phenomena are observed at longer wavelength region of VII and IX in Fig. 3 and of VI and VIII in Fig. 4. In addition, absorption bands of benzonaphtho-triptycene IX in

Benzo-naphtho-(IX)	λ		233		269	283[a]	309	323.5	340.5	357.5	376
	ε		81200		130000	75000	4010	5100	6310	8040	5300

a) shoulder.

longer wavelength region more than 300 nm are compared with a sum of those of benzotriptycene III and naphthotriptycene VII in Table 3 as follows:

IX: λ_{max} nm (ε) 309(4010), 323.5(5100), 340.5(6310), 357.5(8040), and 376(5300)

III+VII: λ_{max} (ε) 310(3300), 324(5500), 339(6400), 356(8430), and 375(5900)

An excellent agreement between observed and calculated values of wavelength and intensity of absorption bands demonstrates additivity or superposition of component chromophores on the spectra of the annelated triptycenes.

On the other hand, absorption bands other than the longest wavelength bands of three benzo-derivatives, III, IV, and V, show a few features as follows: a) broadening of all the absorption bands with increasing number of naphthalene nuclei, especially of the bands at 270—290 nm (Fig. 2), b) differences in position of B_b bands (220—260 nm) in contrast to nearly the same position of L_a bands (260—300 nm) and L_b bands (300—330 nm) (Fig. 2), c) the intensity of L_b bands per naphthalene chromophore is in order of III<IV<V, but the intensity of L_a bands in order of III>V>IV (Table 3).

A **plausible elu**cidation may be put on these spectral changes. When two of the same chromophores, which are fixed closely with each other, interact slightly, the exciton theory[16] is applicable to this system just as molecular aggregate in crystal system which shows unambiguous shift and splitting of absorption bands due to interaction among the component chromophores. Thus, the phenomenon a) above-stated is explainable with the splitting of degenerated levels —Davydov splitting— due to exciton interaction as well as in the other phenomena b) and c).

The spectra of VII and IX, containing anthracene nucleus, in concentrated sulfuric acid were changed with time as shown in Fig. 5. The formation of cation radical of anthracene itself in that medium was demonstrated by ESR measurement[17] and by the fact that the position of the longest wavelength maximum of

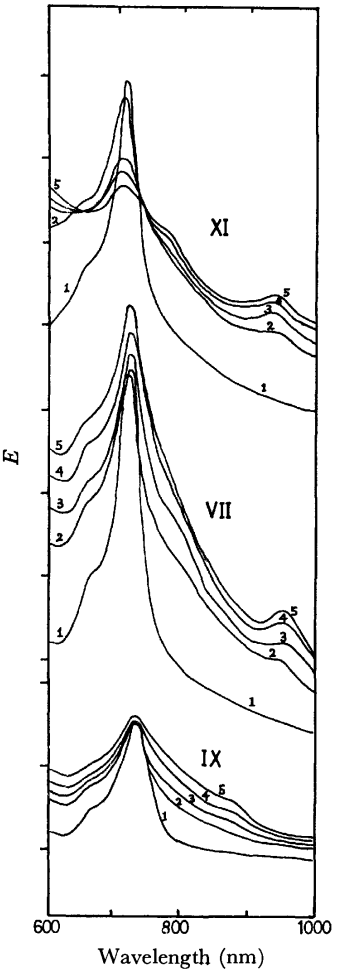

Fig. 5. The electronic spectra of cation radicals of anthracene (XI), naphthotriptycene (VII), and benzo-naphthotriptycene (IX) in conc. sulfuric acid at 15°C: curve 1, 45 min after dissolution; curve 2, 165 min; curve 3, 285 min; curve 4, 405 min; curve 5, 525 min.

16) M. Kasha, H. R. Rawls, and M. Ashraf El-Bayoumi, "Molecular Spectroscopy VIII," Butterworth, London, 1965 and references cited there on.

17) H. Kon and M. S. Blois, Jr., *J. Chem. Phys.*, **28**, 743 (1958); S. I. Weissman, E. de Boer, and J. J. Conradi, *ibid.*, **26**, 963 (1957).

the cation radical coincided with that of the anion radical of anthracene, an alternant hydrocarbon, in absorption spectra.

The cation radicals of the triptycene derivatives VII and IX show the longest wavelength absorption bands at longer wavelength region only by 10 and 20 nm, respectively, than that of anthracene itself. It indicates that there is weak interaction among the aromatic nuclei in triptycene radicals in contrast to an increase of interaction in the anion radical of [2.2]paracyclophane.[18] However, the maxima at 720—730 nm of the cation radicals of VII and IX remain unchanged with time, while the intensity of the maximum of anthracene radical decreases rapidly with time and falls to half after 10 hr. This phenomenon is possibly interpreted partly by stabilization due to delocalization of the cation radical in VII and IX, and mainly by stabilization due to protecting effect of bulky π-electron cloud in benzene and naphthalene nuclei.

Experimental

All melting points are uncorrected. The IR and UV spectra were obtained on a JASCO autorecording spectrometer DS-402G and on a Hitachi ESP-3T, respectively. The molecular weights were determined with a Hitachi mass spectrometer RMU-7 and/or with Knauer vapour pressure osmometer. The NMR spectra were measured on a Hitachi Perkin-Elmer R-20 spectrometer (60 M) using TMS as an internal standard. A frequency counter was used to measure the frequency separation between signals.

Materials. Tetracene was synthesized from tetralin and phthalic anhydride *via* 3 steps in 3.3% of over-all yield according to Fieser.[19] Pentacene was prepared by reduction of pentacene-6,13-dione, which was obtained from phthaldehyde and cyclohexane-1,4-dione in a 65% yield, with aluminum tri(cyclohexyl oxide).[20]

Triptycene (II). The synthesis of triptycene was carried out according to the procedure of Fieser[21] in a 42% yield, mp 262.0—262.5°C (lit, 255°C).

Benzotriptycene(III). III was prepared by the reaction of anthracene with 2,3-dehydronaphthalene (XIII), generated from 3-amino-2-naphthoic acid (XII) and isoamyl nitrite, in tetrahydrofuran according to the procedure of Friedman,[7] 11% yield, mp 263.5—265.0°C (lit, 257—258°C).

Dibenzotriptycene (IV). To a mixture of tetracene (1.0 g, 4.3 mmol) and 3-amino-2-naphthoic acid (2.1 g, 11 mmol) in dioxane (500 m*l*) was dropwise added a solution of isoamyl nitrite (10 m*l*, 75 mmol) in dioxane (50 m*l*) for 2 hr at 70°C with stirring in nitrogen atmosphere. After the addition, the reaction mixture was stirred for 30 min at 80°C. Colorless solid obtained by evaporating the solvent under reduced pressure was chromatographed on alumina (150 g). Early benzene fractions (200 m*l*) were collected and the solvent was removed *in vacuo*. The residue was re-chromatographed on silica gel (30 g) in each 100 m*l* fraction using the following solvents: petroleum ether (100 m*l*) and then petroleum ether–carbon tetrachloride (1: 1, 750 m*l*). From the third fraction was obtained 19 mg of white solid, which was recrystallized from acetone to give colorless needles, mp 213.5—214.5°C, of 5,12-dihydrotetracene (lit,[22] mp 212°C). NMR (in $CDCl_3$): τ 5.93 (s, 4H, methylene), 2.1—2.9 (m, 10H, aromatic).

The residue obtained from 4—9th fractions was recrystallized from ethanol to give 582 mg (37.5% based on tetracene) of pure IV, mp 277—280°C. Found: C, 94.98, H, 4.98%; mol wt, 354 (mass spectrometry). Calcd for $C_{28}H_{18}$: C, 94.88, H, 5.12%; mol wt 354. IR (KBr-disk): 890 (s), 882 (s), 739 (s), 562 (s), 477 (s) cm^{-1}.

Tribenzotriptycene (V). According to the procedure of Wittig,[6] the reaction of pentacene with 1,4-dihydronaphthalene-1,4-oxide, followed by treatment of the adduct with hydrochloric acid in acetic anhydride, afforded 28% yield of tribenzotriptycene (V), mp 386.5°C (lit,[6] 387—389°C). The IR spectrum of the compound is completely superimposable on the reported one.

Phthaloyltriptycene (VI). To a stirred mixture of 3-aminoanthraquinone-2-carboxylic acid (1.5 g, 6 mmol) and anthracene (3.2 g, 18 mmol) in dioxane (400 m*l*) was added dropwise a solution of isoamyl nitrite (34 m*l*) in dioxane (58 m*l*) over a period of two hours at 70°C and the mixture was stirred at 85°C for 30 min. After removal of the solvent the residue was chromatographed on alumina (250 g). From benzene fractions 555 mg (24.1%) of V was obtained. Recrystallized from ethyl acetate, mp 341—344°C. Found: C, 87.32; H, 4.23%; mol wt, 384 (mass spectrometry), 413 (vapour pressure osmometry). Calcd for $C_{28}H_{16}O_2$: C, 87.48; H, 4.20%; mol wt, 384. IR (KBr-disk): 1665 (s), 1352 (m), 1324 (s), 1300 (s), 951 (m), 734 (m), 709 (m) cm^{-1}.

Phthaloyl-benzotriptycene (VIII). Through the procedure described for VI, the synthesis of VIII was carried out with 3-aminoanthraquinone-2-carboxylic acid (XV) and tetracene (XIV), except the use of degassed dioxane as a solvent. Chromatography on alumina using benzene gave a 29% yield of VIII. Recrystallized from ethyl acetate, mp 352.0—352.5°C. Found: C, 88.20; H, 4.00; mol wt, 434 (mass spectrometry). Calcd for $C_{32}H_{18}O_2$: C, 88.46; H, 4.18%; mol wt, 434. IR (KBr-disk): 1670 (s), 1659 (s), 1592 (s), 1325 (s), 1300 (s), 954 (m), 742 (m), 714 (m) cm^{-1}.

Naphthotriptycene (VII). A mixture of VI (260 mg, 0.7 mmol) and aluminum tri(cyclohexyl oxide)[9] (3 m*l*) in cyclohexanol (1.5 m*l*) was refluxed for 48 hr. The mixture was poured into water and was stirred for one hour. It was extracted with benzene and the extract was washed with aqueous calcium chloride solution and then water and dried over calcium chloride. Removal of the solvent *in vacuo* gave 83 mg (35%) of VII, which was recrystallized from cyclohexane to give colorless leaflets, mp 287—288°C. Found: C, 94.78; H, 5.02%; mol wt, 354 (mass spectrometry), 349 (vapour pressure osmometry). Calcd for $C_{28}H_{18}$: C, 94.88; H, 5.02%; mol wt, 354. IR (KBr-disk): 907 (m), 733 (s), 625 (s) cm^{-1}.

Benzo-naphtho-triptycene (IX). The reduction of VIII was carried out in a manner similar to that described for VII. Recrystallization of the crude material (yield 33%) from ethyl acetate afforded pure IX as pale yellow columns, mp 295.5—296.0°C. Found: C, 94.98; H, 4.87%; mol wt, 405 (mass spectrometry), 403 (vapour pressure osmometry). Calcd for $C_{32}H_{20}$: C, 95.02; H, 4.98%; mol wt, 404.5. IR (KBr-disk): 902 (m), 887 (m), 882 (m), 736 (s), 629 (m), 572 (m), 511 (m), 473 (m), 459 (m) cm^{-1}.

Studies on Aminosugars. XXIX. The Synthesis of 3′-*O*-Methylkanamycin[1,2]

Hamao UMEZAWA, Tsutomu TSUCHIYA, Ryujiro MUTO,* and Sumio UMEZAWA*

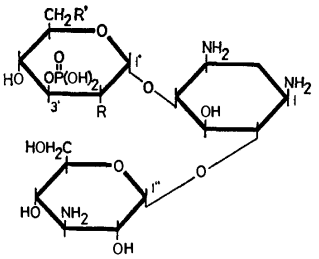
Institute of Microbial Chemistry, Shinagawa-ku, Tokyo

**Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo*

(Received May 11, 1972)

6-*O*-(3-Amino-3-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine, previously synthesized, was masked with ethoxycarbonyl, isopropylidene, and benzyl groups to give 6-*O*-(2-*O*-benzyl-3-deoxy-3-ethoxycarbonylamino-4,6-*O*-isopropylidene-α-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyl-2-deoxystreptamine, which was condensed with 6-azido-2,4-di-*O*-benzyl-6-deoxy-3-*O*-methyl-α-D-glucopyranosyl chloride by a modified Koenigs-Knorr reaction to give a mixture of α,α- and α,β-diglycoside compounds. Hydrogenation of the azido group and removal of the masking groups gave a mixture of 3′-*O*-methylkanamycin and its diastereomer. The 3′-*O*-methylkanamycin was devoid of antibacterial activity.

Recently, Umezawa and co-workers[3] have clarified the mechanism of the resistance of resistant bacteria in patients to kanamycins and streptomycin, and it was found that these resistant bacteria produce enzymes which inactivate these antibiotics. In the case of kanamycins, 3′-hydroxyl groups are phosphorylated (Fig. 1) by the enzymic reaction and, in the case of streptomycin, the 3-hydroxyl group of *N*-methyl-L-glucosamine moiety is adenylylated[4] by ATP or phosphorylated.[5] It was also proved that resistant *Pseudomonas aeruginosa* to kanamycin produces a similar enzyme[6] which phosphorylates kanamycin from ATP to give kanamycin-3′-phosphate. Furthermore, studies[6] on the substrate specificity of the phosphorylating enzyme using a variety of aminoglycosides showed that



Kanamycin A 3′-phosphate: R=OH, R′=NH_2
Kanamycin B 3′-phosphate: R=NH_2, R′=NH_2
Kanamycin C 3′-phosphate: R=NH_2, R′=OH

Fig. 1.

the whole kanamycin structure is not required for the enzymic reaction and that only 4-*O*-glycosyl-2-deoxystreptamine is required for the enzymic reaction, whereas 3-amino-3-deoxy-D-glucose (3AG) moiety is not involved in binding of the antibiotics with the enzyme.

The above mentioned phosphorylation resistance mechanism suggested that variation of the surroundings of C-3 in the aminosugar moiety attached to C-4 of deoxystreptamine of kanamycins may lead to derivatives that are not susceptible to phosphorylation by the enzyme and active against the resistant bacteria. Our initial approach to such a derivative was the total synthesis of 3′-*O*-methylkanamycin and 3′-deoxykanamycin.

The synthesis has been accomplished by the condensation of 6-azido-2,4-di-*O*-benzyl-6-deoxy-3-*O*-methyl-α-D-glucopyranosyl chloride (**7**) with a masked derivative (**12**) of 6-*O*-(3-amino-3-deoxy-α-D-glucopyranosyl)-2-dexoystreptamine. In this synthesis, we tried to use an azido derivative of glucose for the condensation with an aglycone.

An anomeric mixture of methyl 3-*O*-methyl-D-glucopyranoside (**2**) was prepared by acidic methanolysis of 1,2: 5,6-di-*O*-isopropylidene-3-*O*-methyl-D-glucose[7] (**1**) and the anomers (**2a**, **2b**) were separated by resin column chromatography using Dowex 1×2. The procedure for the separation of the anomers was found to be more convenient than an alternative method[8] through a 4,6-*O*-benzylidene derivative. Preferential tosylation of **2a** and **2b** gave 6-*O*-tosylated product (**3a**, **3b**) in about 60% yields, respectively, and their structures were confirmed by NMR spectra. The tosyl group of **3a** and **3b** was displaced by an azido group with sodium azide in dimethyl formamide (DMF) to give 6-azido derivatives (**4a**, **4b**). Benzylation of **4a** with benzyl chloride and potassium hydroxide in DMF gave 2,4-di-*O*-benzylated derivative (**5a**) in a yield of 82%.

An anomeric mixture of **2** was led to an anomeric mixture of **5** in a yield of 50%, which was hydrolyzed

1) A part of this paper was read by S. Umezawa at Symposium of New Natural Product Syntheses, the 23rd International Congress of Pure and Applied Chemistry at Boston, U.S.A., July 28, 1971; A short communication was reported: S. Umezawa, T. Tsuchiya, R. Muto, Y. Nishimura, and H. Umezawa, *J. Antibiotics*, **24**(4), 274 (1971).

2) The numbering of the kanamycin structure was followed by that described in the following paper: T. Kobayashi, T. Tsuchiya, K. Tatsuta, and S. Umezawa, *ibid.*, **23**(5), 225 (1970).

with hydrochloric acid and acetic acid in aqueous methanol to give 6-azido-2,4-di-*O*-benzyl-6-deoxy-3-*O*-methyl-D-glucopyranose (**6**), mp 112—113°C, $[\alpha]_D^{20}$ +108° (*c* 0.9, acetone). Expectedly,[9] in this reaction, the β-anomer (**5b**) was found to be more readily hydrolyzed than the α-anomer (**5a**). Chlorination of **6** with thionyl chloride gave the desired 6-azido-2,4-di-*O*-benzyl-6-deoxy-3-*O*-methyl-α-D-glucopyranosyl chloride (**7**), mp 33—35°C, $[\alpha]_D^{15}$ +184° (*c* 1.1, acetone). The α-anomeric configuration of the chlorine atom was confirmed by the NMR spectrum and optical rotation of **7**.

On the other hand, a partially masked derivative of 6-*O*-(3-amino-3-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine was prepared. Previously in the total syntheses of kanamycins,[10] we prepared a suitably masked derivative of this glycoside and this derivative was expected to be usable again for the present synthesis, however, in the present synthesis, we turned hopefully to use an *N*-ethoxycarbonyl derivative instead of the carbobenzoxy derivative.

Treatment of 6-*O*-(3-amino-3-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine with ethyl chloroformate in aqueous acetone in the presence of sodium carbonate gave tri-*N*-ethoxycarbonyl derivative (**8**) in a 82% yield. Isopropylidenation of **8** with 2,2-dimethoxypropane in the presence of *p*-toluenesulfonic acid at about 40°C afforded a di-*O*-isopropylidene derivative (**9**) in a 84% yield. Benzylation of **9** with benzyl chloride in the presence of barium oxide and barium hydroxide in DMF afforded the benzyl derivative (**10**), which, on deacetonation by treatment with 80% aqueous acetic acid, afforded 6-*O*-(2-*O*-benzyl-3-ethoxycarbonylamino-3-deoxy-α-D-glucopyranosyl)-*N*,*N*'-diethoxycarbonyl-2-deoxystreptamine (**11**), mp 149°C, $[\alpha]_D^{15}$ +77° (*c* 1, pyridine). Controlled isopropylidenation of **11** by treatment with 2,2-dimethoxypropane at 0°C for three hours successfully afforded the desired mono-*O*-isopropylidene derivative (**12**), mp 263°C, $[\alpha]_D^{20}$ +54° (*c* 1, pyridine), in a 60% yield. The orientation of the isopropylidene group in **12** was confirmed by the tritylation of **12** and **11**. When **11** which contains a primary hydroxyl group was tritylated with trityl chloride in pyridine, the product showed the characteristic color-reaction of a trityl derivative when sprayed with sulfuric acid on tlc, while **12** underwent no tritylation by the same procedure. In this connection, we would like to mention about the characteristic feature of the isopropylidene groups in the NMR spectra of the above mentioned compounds. When the NMR spectra of **10** and **12** were compared, it was found that methyl signals ascribable to the 4,5-*O*-isopropylidene group of deoxystreptamine moiety appeared at $\tau\sim8.6$, whereas those of 4,6-*O*-isopropylidene group of 3AG moiety appeared separately at $\tau\sim8.6$ and ~8.7. This clear-cut separation of signals was recognizable only in DMSO-d_6 and not in pyridine-d_5.

In the next place, the monoisopropylidene derivative (**12**) was condensed with the glycosyl chloride (**7**). In analogy to the previous studies on the total syntheses of kanamycins,[10] the condensation was effected by use of mercuric cyanide and Drierite in dioxane-benzene under an extremely anhydrous condition. The product was chromatographed on a silica gel column, affording the desired condensation product (**13**), mp 226°C $[\alpha]_D^{15}$ +92.6° (*c* 0.4, chloroform), in a 14% yield. Expectedly, **13** showed, in the NMR spectrum, the methyl signals of the isopropylidene group separated at τ 8.75 and 8.63, indicating that the group is attached at C-4,6 of the 3AG moiety in conformity with the above-mentioned observation.

Finally, **13** was treated with aqueous acetic acid to remove the isopropylidene group, hydrogenated over palladium black to remove the benzyl groups and treated with barium hydroxide to hydrolyze the *N*-ethoxycarbonylamino groups, affording an anomeric mixture of the 6-*O*-(3-amino-3-deoxy-α-D-glucopyranosyl)-4-*O*-(6-amino-6-deoxy-3-*O*-methyl-D-glucopyranosyl)-2-deoxystreptamine (**14**), mp 167—169°C, $[\alpha]_D^{15}$ +106° (*c* 0.5, water), in a 55% yield. Although paper chromatography of **14** with *n*-butanol–pyridine–water–acetic acid (6:4:3:1) showed a single spot by ninhydrin coloration, the NMR spectrum of **14** showed approximately 0.5 proton of the equatorial H-1 of 6-amino-6-deoxy-3-*O*-methyl-D-glucose moiety at τ 4.63 as doublet ($J\sim3$ Hz), indicating that **14** was an anomeric mixture of a ratio about 1:1.

The position of attachment of 6-amino-6-deoxy-3-*O*-methyl-D-glucosyl moiety to the 2-deoxystreptamine was demonstrated by the periodate oxidation of **14**. The survival of deoxystreptamine in the hydrolyzate of the oxidation mixture was shown by paper chromatography with ninhydrin indicating that the glycosidation did not occur at the C-5 of 2-deoxystreptamine, but at the C-4.

The 3'-*O*-methylkanamycin (**14**) showed no inhibition to *S. aureus*, *E. coli*, *Pseudomonas aeruginosa*, *Mycobacterium* 607 at 100 μg/ml in a nutrient agar, but inhibited *B. subtilis* PCI 219 at 25 μg/ml. It showed partial inhibition of *E. coli* carrying R factor at 100 μg/ml. As reported in the succeeding paper, 3'-deoxykanamycin exhibits a strong antibacterial activity in the similar strength as kanamycin. 3'-*O*-Methyl group was suggested to hinder the binding of 3'-*O*-methyl kanamycin with bacterial ribosomes, because it showed almost no inhibition of poly phenylalanine synthesis on poly U-ribosome system.

Experimental

Infrared spectra (IR) were recorded with a Perkin-Elmer Infrared Spectrophotometer. Nuclear magnetic resonance (NMR) spectra were obtained with a Varian A-60 spectrometer. Tetramethylsilane was used as the internal standard.

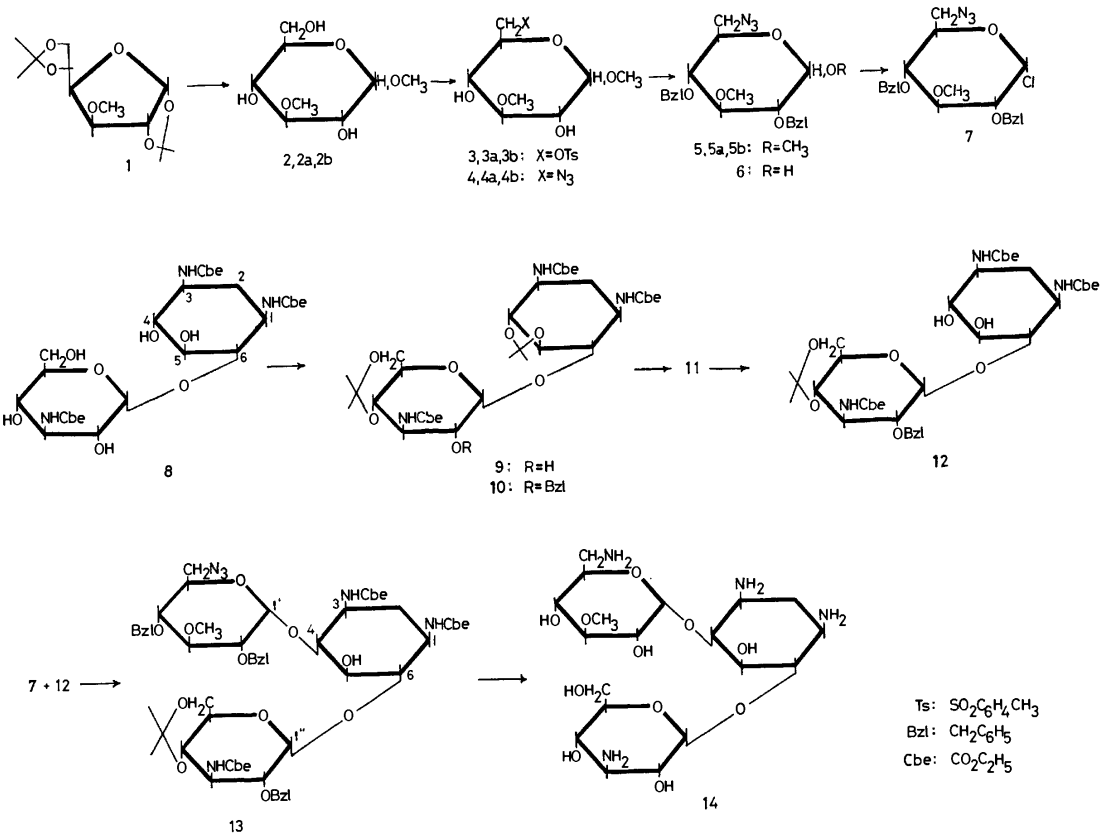

Chart 1.

Thin layer chromatography (tlc) was performed on silica gel and the spots were visualized with sulfuric acid. Paper chromatography was performed on Toyo-Roshi paper No. 50 and the spots were detected with 0.5% ninhydrin in pyridine and heating to 110°.

*Methyl 3-O-Methyl-α-D-glucopyranoside (**2a**) and its β-anomer (**2b**).* A solution of **1** (5.1 g) in methanolic 1% hydrochloric acid (120 m*l*) was refluxed for 7 hr and coevaporated with benzene. The residue was dissolved in methanol and the solution was neutralized with Amberlite IRA 400 (OH form), treated with charcoal and evaporated to give a syrup (3.51 g, 91%). On tlc (acetone–ethyl acetate 3:2), the product showed a single spot (*Rf* 0.6), indicating no contamination with the starting material (R_f 1.0). The syrup (2.76 g) was then chromatographed on a column of Dowex 1×2 (OH form, 400 m*l*) with water. After the first fraction (400 m*l*) was discarded, the eluate was cut into 10 g each. α-Anomer (**2a**) was eluted between tube Nos. 10—17 and β-anomer (**2b**) between Nos. 20—35. Evaporation of the former gave a syrup (1.42 g, 47%) which, on storage, crystallized in needles, mp 80—82°C (lit,[8] 80—81°C), $[\alpha]_D^{25}$ +161° (*c* 1.4, acetone) (lit, +164°); IR (KBr): 840 cm^{-1} (type 2a).

Found: C, 46.30; H, 8.02%. Calcd for $C_8H_{16}O_6$: C, 46.15; H, 7.75%.

Evaporation of the latter fraction gave a syrup (0.98 g, 32%), $[\alpha]_D^{25}$ −33° (*c* 0.8, acetone) (lit [8] −26°); IR 885 cm^{-1} (type 2b).

Found: C, 46.34; H, 7.80%.

*Mthyl 3-O-Methyl-6-O-tosyl-α-D-glucopyranoside (**3a**).* To an ice-cold solution of **2a** (1.42 g) in dry pyridine (28 m*l*, dried over fused sodium hydroxide), tosyl chloride (2 g) was added and the solution was allowed to stand in a refrigerater for 5 hr. After a few drops of water was added, the solution was concentrated. The residue was dissolved in chloroform (200 m*l*) and the solution was washed successively with 5% potassium bisulfate solution, water, saturated sodium bicarbonate solution and water, dried over sodium sulfate and evaporated, giving a syrup. Tlc (ethyl acetate) showed that the syrup contained three components of R_f 0.93 (ditosylated product), 0.61 (**3a**, major) and 0.17 (**2a**). The syrup was then chromatographed on silica gel column (70 g) with ethyl acetate. The ditosylated product was eluted between 160—190 m*l* and **3a** between 240—370 m*l*. The latter fraction was evaporated and the residue was dissolved in benzene. Addition of petroleum ether gave a solid (1.48 g, 60%), mp 100—103°C, $[\alpha]_D^{15}$ +107° (*c* 1, acetone); IR (KBr): 1360, 1170 cm^{-1} ($\nu_{a.s}$ and ν_s SO_2, respectively).

Found: C, 49.98; H, 6.37; S, 8.64%. Calcd for $C_{15}H_{22}O_8S$: C, 49.71; H, 6.12: S, 8.85%.

NMR (in $CDCl_3$): τ 7.54 (3H s, the methyl of a tosyl group), 6.61 (3H s, C(1)-OCH_3), 6.35 (3H s, 3(C)-OCH_3), 6.1—6.8 (4H, m H-2,3,4,5), 5.70 (2H d, H-6,6′; This shows that 6-OH was tosylated. Corresponding signals are not recognized in **2a** and **4a**), 5.33 (1H d, H-1), 2.05—2.75 (4H, AB quartet-like pattern, J~8 Hz, tosyl); $J_{1,2}$ 3 Hz, $J_{5,6}$′ ~$J_{5,6}$′ ~3 Hz.

*Methyl 3-O-Methyl-6-O-tosyl-β-D-glucopyranoside (**3b**).* Compound **2b** (0.98 g) was treated likewise as in the case of **2a** and the product (**3b**) was recrystallized from benzene-petroleum ether to give crystals (1.0 g, 59%), mp 132—133°C, $[\alpha]_D^{15}$ −13.6° (*c* 1.1, acetone).

Found: C, 49.91; H, 6.34; S, 8.99%. Calcd for $C_{15}H_{22}O_8S$: C, 49.71; H, 6.12; S, 8.85%.

*Methyl 6-Azido-6-deoxy-3-O-methyl-α-D-glucopyranoside (**4a**) and its β-Anomer (**4b**).* The anomeric mixture of methyl 3-*O*-methyl-D-glucopyranoside (**2**) was tosylated likewise as described in the case of **3a**, and the product (5.0 g) was dissolved in dry DMF (dried over calcium hydride and supernatant layer was used without distillation). After addition of sodium azide (1.8 g), the mixture was refluxed

for 1 hr. The resulting brown solution was filtered and the filtrate was evaporated with several additions of toluene to remove the remaining DMF. The syrupy residue was dissolved in ethyl acetate and the solution was passed through a short column of silica gel (15 g) with the same solvent; the fraction containing the products (**4a** and **4b**) was collected and evaporated to give a pale yellow syrup (3.14 g, 98%), which had the same R_f-value with that of **3a** or **3b** (R_f 0.61 with ethyl acetate, 0.6 with ethyl acetate–benzene 5: 1 and 0.8 with methyl ethyl ketone), however, the infrared spectrum of the syrup showed no absorption of sulfonyl group but showed that of an azide group (2100 cm^{-1}), indicating that the reaction was completed. Anomers (2.05 g) were separated by chromatography on a column of Dowex 1×2 (OH form, 33×450 mm) with water. After the first fraction (400 m*l*) had been discarded, the eluate was cut into 10 g each. The α-anomer was eluted between tube Nos. 22—28 and the β-anomer between Nos. 34—48. Evaporation of the former afforded a solid (0.56 g), which was recrystallized from benzene to give colorless crystals (0.51 g), mp 88—89°C, $[\alpha]_D^{20}$ +129° (*c* 1, acetone); IR (KBr): 2100 (N_3), 845 cm^{-1} (type 2a).

Found: C, 41.39; H, 6.61; N, 18.30%. Calcd for $C_8H_{15}O_5N_3$: C, 41.20; H, 6.48; N, 18.02%.

Evaporation of the latter fraction followed by recrystallization from benzene gave colorless crystals (0.56 g), mp 110—111°C, $[\alpha]_D^{20}$ −87° (*c* 1, acetone); IR (KBr): 2100 (N_3), 885 cm^{-1} (type 2b).

Found: C, 41.51; H, 6.73; N, 17.89%.

These α- and β-anomers (**4a** and **4b**) were identical with those prepared from the anomerically pure tosylated compounds (**3a** and **3b**), respectively.

*Methyl 6-Azido-2,4-di-*O*-benzyl-6-deoxy-3-*O*-methyl-α-*D*-glucopyranoside (5a) and its β-anomer (5b).* To an ice-cold solution of **4a** (207 mg) in dry DMF (4 m*l*), powdered potassium hydroxide (590 mg) and benzyl chloride (0.6 m*l*) were added in turn and the mixture was stirred for 30 min. at room temperature. Tlc (benzene–methyl ethyl ketone 25: 1) of the reaction mixture showed that the starting material (**4a**, R_f 0) disappeared and **5a** (R_f 0.55) appeared as a sole product. Filtration followed by evaporation gave a syrup, which was coevaporated with toluene several times. The resultant syrup was dissolved in chloroform and the solution was washed with water, dried over sodium sulfate, and evaporated to give a solid (302 mg, 82%), which gradually crystallized on storage, mp 59—61°C, $[\alpha]_D^{15}$ +111° (*c* 1, acetone); IR (KBr): 2100 (N_3), 840 (type 2a; 735, 690 cm^{-1} (phenyl).

Found: C, 64.20; H, 6.58; N, 10.07%. Calcd for $C_{22}H_{27}O_5N_3$: C, 63.90; H, 6.58; N, 10.16%.

Likewise, from the β-anomer (**4b**, 282 mg) **5b** was obtained as needles (392 mg, 79%), mp 62—65°C, $[\alpha]_D^{15}$ +1.7° (*c* 0.9, acetone); IR (KBr): 2100 (N_3), 885 (type 2b); 745, 695 cm^{-1} (phenyl).

Found: C, 64.11; H, 6.94; N, 10.06%.

*6-Azido-2,4-di-*O*-benzyl-6-deoxy-3-*O*-methyl-D-glucopyranose (6)* To an anomeric mixture of **5** (8.12 g) in acetic acid (46 m*l*), 2N hydrochloric acid in 50% aqueous-methanol (15.5 m*l*) was added and the solution was refluxed for 3 hr. Tlc (benzene–methyl ethyl ketone 15: 1) of the reaction mixture showed that the solution contained four components of R_f 0.76 (**5b**), 0.71 (**5a**), 0.5 (**6**), and 0. Evaporation *in vacuo* followed by coevaporation with toluene gave a syrup (2.86 g), which was then chromatographed on a column of silica gel (100 g) with benzene–methyl ethyl ketone (15: 1). After the first fraction (160 m*l*) was discarded, the eluate was cut into 5 g each. A mixture of **5a** and **5b** (rich in **5a**) was eluted between tube Nos. 3—10 and **6** between Nos. 16—35. Evaporation of the latter fraction gave a syrup (1.19 g), which was recrystallized from benzene–petroleum ether to give **6** (1.15 g), mp 112—113°C, $[\alpha]_D^{20}$ +108° (*c* 0.9, acetone; final value); IR (KBr): 3380, 2100; 750, 740, 697 cm^{-1}.

Found: C, 63.36; H, 6.52; N, 10.52%. Calcd for $C_{21}H_{25}O_5N_3$: C, 63.14; H, 6.31; N, 10.52%.

The former fraction was evaporated to give a syrup (1.18 g), which could again be used for hydrolysis to **6**.

When the reaction period exceeded the limit of 3 hr, the product was observed to increase in the undesirable product of R_f 0, decreasing the yield of **6**. NMR of **6** (in $CDCl_3$): τ 6.32 (3H, s, OCH_3), 5.26 (2H s, one of methylenes of benzyls), 5.13 and 5.37 (2H AB quartet; another methylene of benzyls; *J* 11 Hz).

*6-Azido-2,4-di-*O*-benzyl-6-deoxy-3-*O*-methyl-α-*D*-glucopyranosyl Chloride (7).* A solution of **6** (5.0 g) in thionyl chloride (55 m*l*) was allowed to stand for 1 hr at room temperature. Tlc (benzene–methyl ethyl ketone 30: 1) of the reaction mixture showed that the starting material (**6**, R_f 0.15) disappeared and **7** (R_f 0.82) appeared as a main product. Evaporation of the solution followed by coevaporation with toluene gave a syrup, which was then chromatographed on a column of silica gel (90 g) with benzene. The fraction containing **7** (500—800 m*l* portion) was evaporated and the resultant syrup (3.2 g, 61%) crystallized to needles after 2 weeks storage. Mp 33—35°C, $[\alpha]_D^{15}$ +184° (*c* 1.1, acetone).

Found: C, 60.18; H, 6.05; N, 9.85; Cl, 8.78%. Calcd for $C_{21}H_{24}O_4N_3Cl$: C, 60.36; H, 5.79; N, 10.06; Cl, 8.48%.

NMR (in $CDCl_3$): τ 6.20—6.62 (5H, m, H-2,3,4,6,6′), 6.30 (3H s, OCH_3), 5.90 (1H doublet of triplets, H-5), 5.28 (2H s, $C\underline{H}_2C_6H_5$), 5.12 and 5.36 (2H AB quartet, *J* 11 Hz, $C\underline{H}_2C_6H_5$), 3.98 (1H d, H-1), 2.64 and 2.60 (5H singlets, phenyl of benzyls); $J_{1,2}$ 3.2 Hz, $J_{4,5}$ 9.0 Hz, $J_{5,6}=J_{5,6'}\sim3$ Hz.

*N,N′-Diethoxycarbonyl-6-*O*-(3-deoxy-3-ethoxycarbonylamino-α-*D*-glucopyranosyl)-2-deoxysterptamine (8).* To a solution of 6-*O*-(3-amino-3-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine (3AD) (5.52 g) and anhydrous sodium carbonate (5.30 g) in water (55 m*l*), acetone (55 m*l*) was added with vigorous stirring and to the suspension, ethyl chloroformate (5.8 g) was added all at once. An almost clear solution was soon formed with evolution of gas, after that precipitates appeared. Regardless of precipitation, agitation was continued for 18 hr at room temperature. Tlc (benzene–methyl ethyl ketone 4: 1) of the reaction mixture showed a single spot (R_f 0.4). After addition of 2N hydrochloric acid (22 m*l*), the reaction mixture was evaporated *in vacuo*. The residue was then suspended in DMF (200 m*l*), filtered from an insoluble matter and the filtrate was evaporated with several additions of toluene. The resultant residue was dissolved in DMF (40 m*l*) and worked up again as above. The desalted residue was boiled with ethanol (150 m*l*) for a while, cooled, and the insoluble product was taken by filtration; 7.50 g (82%), mp>250°C, $[\alpha]_D^{20}$ +64° (*c* 1, DMF); IR (KBr): 1695 (amide I), 1545 cm^{-1} (amide II).

Found: C, 47.01; H, 7.12; N, 7.83%. Calcd for $C_{12}H_{37}O_{13}N_3$: C, 46.75; H, 6.91; N, 7.79%.

*N,N′-Diethoxycarbonyl-6-*O*-(3-deoxy-3-ethoxycarbonylamino-4,6-*O*-isopropylidene-α-*D*-glucopyranosyl)-4,5-*O*-isopropylidene-2-deoxystreptamine (9).* To a solution of well dried **8** (973 mg) in dry DMF (dried over calcium hydride), dehydrated *p*-toluenesulfonic acid (30 mg, dried *in vacuo* at 100°C in the presence of P_2O_5) and 2,2-dimethoxypropane (1.4 m*l*) were added, and the mixture was allowed to stand for 5 hr at 40°C. Tlc (benzene–methanol 3: 1) of the reaction mixture showed that **8** (R_f 0.37) had completely been consumed and the main product (**9**, R_f 0.74) appeared, being accompanied

by a trace of mono-isopropylidene product (R_f 0.54). After treatment with Amberlite IRA-400 (OH form, 2 ml) resin, the mixture was filtered and the filtrate was evaporated with several additions of toluene to give a thick syrup (1.06 g). Purification was accomplished by dissolving the syrup in methanol–ethanol (1:1) with subsequent addition of petroleum ether; a colorless solid (940 mg, 84%), mp 237—238°C, $[\alpha]_D^{20}$ +41° (*c* 1, pyridine); IR (KBr): 1705, 1540, 1310 (isopropyl), 845 cm^{-1} (type 2a).

Found: C, 52.23; H, 7.55; N, 6.81%. Calcd for $C_{27}H_{45}O_{13}N_3$: C, 52.33: H, 7.32; N, 6.78%.

NMR (in DMSO-d_6): τ 8.85 (9H t, *J* 7 Hz, $CH_2C\underline{H}_3$), 8.70 (3H s, one of methyls of 4,6-*O*-isopropylidene group), 8.61—8.63 (9H singlet-like pattern, other methyls of isopropylidene groups).

*6-O-(2-O-Benzyl-3-deoxy-3-ethoxycarbonylamino-4,6-O-isopropylidene-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-4,5-O-isopropylidene-2-deoxystreptamine (**10**).* To a mixture of **9** (102 mg), powdered barium oxide (62 mg) and powdered barium hydroxide octahydrate (123 mg) in DMF (2 ml), benzyl chloride (0.14 ml) was added and the suspension was agitated vigorously for 1 hr at room temperature. Tlc (benzene–methanol 5: 1) of the reaction mixture showed that the starting material (R_f 0.52) disappeared and instead, a new spot (**9**, R_f 0.70) appeared. The suspension was filtered with the aid of chloroform (20 ml) and the filtrate was evaporated with several additions of toluene. The chloroform solution of the resultant residue was washed with saturated sodium bicarbonate solution, then with water, dried over sodium sulfate and concentrated. Addition of petroleum ether afforded a colorless solid (112 mg, 96%), which was recrystallized from methanol, mp 286°C, $[\alpha]_D^{20}$ +47° (*c* 1, pyridine); IR (KBr): 1695, 1545, 1375, 845; 735, 700 cm^{-1}.

Found: C, 57.20; H, 7.44; N, 5.81%. Calcd for $C_{34}H_{51}O_{13}N_3$: C, 57.53; H, 7.24; N, 5.92%.

NMR (in DMSO-d_6): τ 8.98 (3H t, *J* 7 Hz, $CH_2C\underline{H}_3$), 8.85 (6H t, *J* 7 Hz,$CH_2C\underline{H}_3$), 8.74 (3H s, isopropylidene), 8.63 (9H s, isopropylidene), 2.77 (5H s, phenyl).

*6-O-(2-O-Benzyl-3-deoxy-3-ethoxycarbonylamino-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2-deoxystreptamine (**11**).* A suspension of **10** (3.36 g) in 80% aqueous acetic acid (100 ml) was heated for 10 min at 80°C. Tlc (benzene–methanol 5: 2) of the solution showed that the starting material (**10**, R_f 0.80) disappeared and instead, **11** (R_f 0.58) appeared as a sole product. The solution was evaporated with several additions of toluene-methanol. The resultant residue was dissolved in methanol, and the solution was treated with Amberlite IRA-400 (OH form), then with active charcoal. Concentration of the solution to about 100 ml followed by cooling gave a colorless crystals (2.58 g, 87%), mp 149°C, $[\alpha]_D^{15}$ +77° (*c* 1, pyridine); IR (KBr): 3340, 1690, 1545 cm^{-1}.

Found: C, 53.15; H, 6.93; N, 6.53%. Calcd for $C_{28}H_{43}O_{13}N_3$: C, 53.41; H, 6.88; N, 6.67%.

*6-O-(2-O-Benzyl-3-deoxy-3-ethoxycarbonylamino-4,6-O-isopropylidene-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2-deoxystreptamine (**12**).* To an ice-cold solution of well dried **11** (1.76 g, 2.8 mmol) in dry DMF (35 ml, dried over calcium hydride), dehydrated *p*-toluenesulfonic acid (24 mg) and 2,2-dimethoxypropane (1.46 g, 14 mmol) were added and the mixture was allowed to stand for 3 hr at 0°C. Tlc (benzene–methanol 5: 1) of the reaction mixture showed that three components, namely, **10** (R_f 0.66), **11** (R_f 0.30) and **12** (R_f 0.54, major) were contained. After treatment with methanol-washed Amberlite IRA-400 (OH form), the mixture was filtered and the filtrate was evaporated with several additions of toluene to give a colorless powder (1.8 g). Since the powder had only very limited solubility against the solvent systems tested, several attempts to separate the components by column chromatography, however, were unsuccessful. The suspension of the powder (1.8 g) in benzene (60 ml) was refluxed for 15 min, cooled and filtered. Tlc showed that the benzene-insoluble material (1.50 g) contained **11** and **12**. The insoluble material was treated with warm chloroform and an insoluble part was removed. The chloroform-soluble portion (1.28 g) was then dissolved in dioxane (15 ml) and the solution was diluted with petroleum ether (100 ml) to give pure **12** (1.12 g, 60%), mp 263°C, $[\alpha]_D^{20}$ +54° (*c* 1, pyridine); IR (KBr): 3340, 1695, 1545, 1375; 750, 690 cm^{-1}.

Found: C, 55.12; H, 7.14; N, 6.15%. Calcd for $C_{31}H_{47}O_{13}N_3$: C, 55.60; H, 7.07; N, 6.27%.

NMR (in DMSO-d_6): τ 8.95 (3H, t, *J* 7 Hz, $CH_2C\underline{H}_3$), 8.84 (6H, t, *J* 7 Hz, $CH_2C\underline{H}_3$), 8.72 (3H s, isopropylidene), 8.61 (3H s, isopropylidene), 2.63 (5H, s, phenyl).

*Tritylation of **12** and **11**.* To a solution of **12** (one mol. equiv.) in pyridine, trityl chloride (2 mol. equiv.) was added and the solution was allowed to stand for 4 days at 27°C. Tlc (benzene–methanol 5: 1) of the reaction mixture showed that the starting material (**12**) was left unchanged throughout the reaction. On the other hand, by the same tritylation as mentioned above, the deacetonated compound **11** (R_f 0.30) was changed to a derivative which had R_f 0.56 and showed the characteristic yellow coloration on spraying sulfuric acid on tlc, indicating the presence of trityl group. These facts indicated that, in the compound **12**, the isopropylidene group is not attached to the deoxystreptamine moiety, but to C-4,6 positions of the 3-amino-3-deoxyglucose moiety.

*4-O-(6-Azido-2,4-di-O-benzyl-6-deoxy-3-O-methyl-D-glucopyranosyl)-6-O-(2-O-benzyl-3-deoxy-3-ethoxycarbonylamino-4,6-O-isopyropylidene-α-D-glucopranosyl)-N,N′-diethoxycarbonyl-2-deoxy streptamine (**13**).* Solvents used in this reaction were thoroughly dried as follows: purified dioxane was refluxed with sodium metal for 1 hr just before use and the supernatant layer was used; purified benzene was dried over $LiAlH_4$ overnight and the supernatant layer was used.

To a mixture of **12** (558 mg, 1 mol. equiv.), mercuric cyanide (836 mg) and freshly prepared Drierite (800 mg) in dry dioxane (6 ml), a solution of **7** (455 mg, 1.3 mol. equiv.) in dry benzene (6 ml) was added and the mixture was heated under vigorous stirring for 5 hr at 100—105°C in a pressure bottle. During the reaction period, absorption of the moisture from the air was avoided strictly, otherwise the yield of **13** become very poor with the formation of undesirable compound (R_f 0.58) mentioned below. The reaction mixture was poured into a saturated sodium bicarbonate solution with stirring and the product was extracted with chloroform. After dried over sodium sulfate, the chloroform solution was concentrated and diluted with petroleum ether to give a colorless powder (500 mg). Tlc (benzene–methanol 5: 1) of the product showed the presence of at least four components: The desired product (**13**, R_f 0.68, major), a deacetonated product (R_f 0.58) and the starring materials **12** (R_f 0.54) and **7** (R_f 1.0; **6** will also be included). The powder was chromatographed, without delay, on a column of silica gel (50 g) with benzene–methanol–ammonia saturated methanol[11] (5: 0.75: 0.25) and the fraction containing **13** (85—110 ml portion) was evaporated to dryness. The residue was treated with dioxane–petroleum ether to give a colorless solid (119 mg, 14%), mp 226°C, $[\alpha]_D^{15}$ +92.6° (*c* 0.4, $CHCl_3$); IR (KBr): 2100, 1700, 1535, 1370; 740, 695 cm^{-1}.

Found: C, 59.23; H, 6.78; N, 8.11%. Calcd for $C_{52}H_{70}$-

11) Since the silica gel is somewhat acidic and was found to cause the hydrolysis of the isopropylidene group, a small quantity of ammonia was added to the developer.

$O_{17}N_6$: C, 59.42; H, 6.71; N, 8.00%.

NMR (in DMSO-d_6): τ 8.94 (3H t, J 7 Hz, $CH_2C\underline{H}_3$), 8.86 (6H, t, J 7 Hz, $CH_2C\underline{H}_3$), 8.75 (3H s, isopropylidene), 8.63 (3H s, isopropylidene), 2.72, 2.73, 2.76 (5H, singlets, phenyl).

*6-O-(3-Amino-3-deoxy-α-D-glucopyranosyl)-4-O-(6-amino-6-deoxy-3-O-methyl-D-glucopyranosyl)-2-deoxystreptmine (**14**).*
A suspension of **13** (212 mg) in 80% aqueous acetic acid (4 m*l*) was heated at 80°C for 5 min. The resultant solution was evaporated with several additions of toluene to give a solid (200 mg), which had a R_f-value of 0.58 (by tlc with benzene–methanol 5: 1) and, in its NMR spectrum (in DMSO-d_6), showed no signals corresponding to an isopropylidene group. Other clear signals were: τ 8.95 (3H t, J 7 Hz, $CH_2C\underline{H}_3$), 8.83 (6H t, J 7 Hz, $CH_2C\underline{H}_3$), 2.61, 2.62, 2.65 (each 5-proton singlet, phenyl of benzyls). A methoxyl signal was not clear by being superimposed with other signals.

The solid was then suspended in a mixture of water (4.3 m*l*) and methanol (7 m*l*), and after the addition of a few drops of acetic acid, the mixture was hydrogenated with freshly prepared palladium black and hydrogen under pressure (30 lb/sq. inch) at 45°C for 2 hr. Water (5 m*l*) was added and the reaction was continued for additional 10 hr. The resultant solution was filtered and the filtrate was evaporated to give a solid (~100 mg), which had a R_f-value 0.26 on tlc with benzene–methanol (1: 2). Its infrared spectrum showed no absorption of azide (2100 cm^{-1}) and benzyl groups (~700 cm^{-1}) but showed the absorptions of amide groups (1700, 1550 cm^{-1}). By NMR spectroscopy (in D_2O), it showed also no aromatic peaks (τ 2—3). Other clear signals were: τ 8.78 (3H t, J 7 Hz), 8.74 (6H t, J 7 Hz), 4.84 (1H d, J ~3 Hz, H-1 of 3AG moiety), 4.62 (approximately 0.5 proton doublet, J ~ 3 Hz, H_{eq}-1 of 6-amino-6-deoxy-D-glucose moiety).

The solid (100 mg) was then heated with 10% solution of barium hydroxide octahydrate (5 m*l*) at 100°C for 7 hr, and then neutralized with sulfuric acid. The resultant precipitate was removed by filtration and the filtrate was concentrated. The residue was chromatographed on a column Dowex 1×2 (OH form, 10×100 mm) with water. Ninhydrin-positive fractions were collected and evaporated to give a crystalline product (**14**); 55 mg (55%), mp 167—169°C, $[\alpha]_D^{15}$ +106° (*c* 0.5, water). By paper chromatography with *n*-butanol–pyridine–water–acetic acid (6:4:3:1), it showed single spot of R_{fKM}[12] 2.2.

Found: C, 46.20; H, 7.47; N, 11.00%. Calcd for $C_{14}H_{38}O_{11}N_4$: C, 45.78; H, 7.68; N, 11.24%.

NMR (in D_2O): τ 6.37 (3H s, OCH_3); this singal is absent in the NMR of kanamycin; 4.95 (1H d, J ~3 Hz), 4.63 (~0.5 H d, J ~3 Hz). The whole pattern was closely resemble to that of kanamycin free base.

Bioassay. The anomeric mixture (approximately 1:1) of 3′-*O*-methylkanamycin (**14**) only inhibited the growth of *Bacillus subtilis* PCI 219 completely at a dilution 25 mcg/m*l*, but showed no inhibition against several kinds of strains such as *M. pyogenes* var. *aureus* 209P, *E. coli* K-12, *K. pneumoniae*, *Ps. aeruginosa*, *Mycobacterum* 607 and *M. phlei*, respectively, at 100 mcg/m*l* in nutrient agar.

The authors wish to thank Dr. Masa Hamada and members of the Institute of Microbial Chemistry for bioassay and Mr. Saburo Nakada for the elemental analysis. The authors also wish to thank Messrs. Hisamasa Abe and Kohei Watanabe for their techinical assistance.

12) R_f-value relative to kanamycin, which is taken as 1.

**Institute of Microbial Chemistry, Shinagawa-ku, Tokyo*

(Received May 11, 1972)

3′-Deoxykanamycin has been totally synthesized from 6-*O*-(2-*O*-benzyl-3-deoxy-3-ethoxycarbonylamino-4,6-*O*-isopropylidene-α-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyl-2-deoxystreptamine and 6-azido-2,4-di-*O*-benzyl-3,6-dideoxy-α-D-*ribo*-hexopyranosyl chloride. It has been found that the 3′-deoxykanamycin has strong antibacterial activity not only against common bacteria but also against kanamycin-resistant bacteria.

In a preceding paper[3] we described the synthesis of 3′-*O*-methylkanamycin as an initial approach to an active kanamycin derivative against resistant bacteria. However, the derivative was found to be inactive. The lack of activity is thought to be due to the presence of the *O*-methyl group at C-3′ hindering its binding to bacterial ribosome. Consequently, we undertook to replace the 3′-hydroxyl group by hydrogen, namely the synthesis of 3′-deoxykanamycin.

The synthesis has been accomplished by the condensation of 6-azido-2,4-di-*O*-benzyl-3,6-dideoxy-α-D-

1) A part of this paper was read by S. Umezawa at Symposium of New Natural Product Syntheses, the 23rd International Congress of Pure and Applied Chemistry at Boston, U.S.A., July 28, 1971.

2) Short communication: S. Umezawa, T. Tsuchiya, R. Muto, Y. Nishimura, and H. Umezawa, *J. Antibiotics*, **24**, 274 (1971).

3) H. Umezawa, T. Tsuchiya, R. Muto, and S. Umezawa, This Bulletin, **45**, 2842 (1972).

ribo-hexopyranosyl chloride (**10**) with masked derivative[3] (**11**) of 6-*O*-(3-amino-3-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine (3AD).

The starting material, methyl 4,6-*O*-benzylidene-3-deoxy-α-D-*ribo*-hexopyranoside (**1**) was prepared from methyl 4,6-*O*-benzylidene-2,3-di-*O*-tosyl-α-D-glucopyranoside and lithium aluminium hydride according to a modified procedure[4] of the method of Vis and Karrer.[5] Debenzylidenation of **1** in aqueous acetic acid gave methyl 3-deoxy-α-D-*ribo*-hexopyranoside (**2**). Preferential tosylation of **2** followed by acetylation gave a 6-*O*-tosyl-2,4-di-*O*-acetyl derivative (**3**) in a yield of 39%. The tosyl group of **3** was then displaced by an azide group with sodium azide in DMF giving a 6-azide derivative (**4**) in a yield of 76%. Deacetylation of **4** followed by benzylation with benzyl bromide and barium oxide-barium hydroxide octahydrate in DMF gave a 6-azido-2,4-di-*O*-benzyl derivative (**6**) in a yield of 81%. The NMR spectrum of **6** showed the following coupling constants: $J_{2,3_{ax}}=J_{3_{ax},4}=J_{3_{eq},3_{ax}}$ ~11 Hz and these values indicated that **6** had a ribopyranoside structure. The retension of configuration in **6** showed that the displacement of the tosyl group of **3** by azide ion occured at C-6, indicating preferential tosylation occured at C-6 of 2. Hydrolysis of **6** by refluxing with hydrochloric acid in water-methanol-acetic acid gave 6-azido-2,4-di-*O*-benzyl-3,6-dideoxy-D-*ribo*-hexopyranose (**7**) in a yield of 75%. The high yield of the hydrolysis product (**7**) is noteworthy, since hydrolysis of glycosidic bond of a 2-*O*-benzylated glycoside is generally fairly slow[6] and the prolonged reaction causes the decomposition lowering the yield. The high yield of **7** may be ascribed to the absence of any substituents at C-3, causing an easy approach of hydrogen ion to the anomeric center. Chlorination of **7** with cold thionyl chloride gave a syrup of the desired 6-azido-2,4-di-*O*-benzyl-3,6-dideoxy-α-D-*ribo*-hexopyranosyl chloride (**10**) in a yield of 61%. The α-anomeric configuration of the chloride atom was confirmed by the NMR spectrum, in which H-1_{eq} resonated at τ 3.83 (J 3.5 Hz) and no other signals ascribable to H-1 were observed.

Since, as described above, the yield of the step of the preferential tosylation of **2** was low, an alternative method was searched. Treatment of **1** with *N*-bromosuccinimide according to the method of Hanessian[7] gave methyl 4-*O*-benzoyl-6-bromo-3,6-dideoxy-α-D-*ribo*-hexopyranoside (**8**) in a yield of 85%. Displacement of the bromine atom with an azide ion in DMF proceeded smoothly and the corresponding 6-azido derivative (**9**) was obtained in a yield of 81%. Removal of the benzoyl group gave a derivative identical with **5** (methyl 6-azido-3,6-dideoxy-α-D-*ribo*-hexopyranoside) prepared by the former route. Thus the new route was proved to be superior to the former.

The condensing partner, 6-*O*-(2-*O*-benzyl-3-deoxy-3-ethoxycarbonylamino-4,6-*O*-isopropylidene-α-D-glucopyranosyl)-*N*,*N*'-diethoxycarbonyl-2-deoxystreptamine (**11**) has been prepared by the method described in a preceding paper[3] starting from 3AD. Condensation of **10** with **11** was carried out in a strictly anhydrous condition as described in a preceding paper.[3] The solution of **10** and **11** in dry benzene-dioxane (3:1) was refluxed for 15 hr in the presence of mercuric cyanide and Drierite and the main condensation product, 4-*O*-(6-azido-2,4-di-*O*-benzyl-3,6-dideoxy-α-D-

6) See, for example, P. W. Austin, F. E. Hardy, J. G. Buchanan, and J. Baddiley, *J. Chem. Soc.*, **1965**, 1419; R. Gigg and C. D. Warren, *ibid.*, **1965**, 2205.

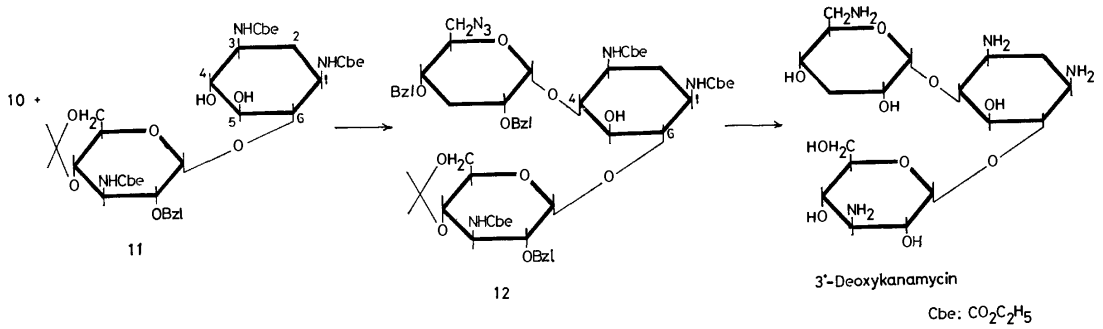

Chart 2.

ribo-hexopyranosyl)-6-*O*-(2-*O*-benzyl-3-deoxy-3-ethoxycarbonylamino-4,6-*O*-isopropylidene-α-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyl-2-deoxystreptamine (**12**) was isolated by column chromatography in a yield of 25%. The structural proof of the product was obtained by its elemental analysis, infrared and NMR spectra, confirming the presence of an azide, three *O*-ethyls, three benzyls, and an isopropylidene group. The sharp melting point, the chromatographycal homogeneity and the high positive rotation ($[\alpha]_D^{20}=+97°$, *c* 0.9, pyridine) indicated that the product was in a highly pure state and had 4-*O*-α-D-glycoside configuration. In the NMR spectrum, the signals assignable to the anomeric proton (H-1′) were not clear, overlapping with other signals.

The condensation product (**12**) was then deacetonated with 80% acetic acid and the azido group was reduced with Raney nickel and hydrogen to an amino group. The product was *N*-acylated with ethoxycarbonyl chloride and debenzylated with palladium black and hydrogen to give the tetra-*N*-ethoxycarbonyl derivative. Since the reduction of an azido group with consecutive removal of benzyl groups with palladium black sometimes[8] causes the damage[9] of the amino group liberated, the amino group was acylated in advance of the debenzylation. Finally, de-*N*-acylation followed by column chromatography with Amberlite CG50 and 0—0.3N ammonia yielded 3′-deoxykanamycin, manely, 6-*O*-(3-amino-3-deoxy-α-D-glucopyranosyl)-4-*O*-(6-amino-3,6-dideoxy-α-D-*ribo*-hexopyranosyl)-2-deoxystreptamine, $[\alpha]_D^{20}+146°$ (*c* 0.2, water).

3′-Deoxykanamycin thus synthesized showed[2] antibacterial activity in the similar strength as kanamycin and moreover, it showed inhibition against resistant *E. coli* carrying R factor, resistant *Staphylococci*, and *Pseudomonas aeruginosa*. This result is in accord with expectation based on the resistant mechanism.

Experimental

Infrared spectra (IR) were recorded with a Perkin-Elmer Infrared Spectrophotometer. Nuclear magnetic resonance (NMR) spectra were recorded with a Varian A-60D spectrometer. Tetramethylsilane was used as the internal standard. Thin layer chromatography (tlc) was performed on silica gel and the spots were visualized with sulfuric acid. Paper chromatography was performed on Toyo-Roshi paper No. 50 and the spots were detected with 0.5% ninhydrin in pyridine and heating to 110°C.

Methyl 3-Deoxy-α-D-ribo-hexopyranoside (2). A solution of **1** (1.59 g) in aqueous acetic acid (1:2, 50 m*l*) was heated at 100°C for 10 min. The solution was evaporated and the residue was treated with water and ether. After the ether layer was discarded, the aqueous solution was filtered, evaporated and coevaporated with toluene to give a syrup, 1.00 g, $[\alpha]_D^{20}+124°$ (*c* 1, water) (lit,[10] $+125.1°$ (*c* 2.3, water)).

Methyl 2,4-Di-O-acetyl-3-deoxy-6-O-tosyl-α-D-ribo-hexopyranoside (3). To a cold (−10°C) solution of **2** (1.61 g) in dry pyridine (75 m*l*), *p*-toluenesulfonyl chloride (1.81 g) was added and the mixture was stirred at the temperature for 3 hr and allowed to stand at 0°C overnight. Tlc (ethyl acetate) of the reaction mixture showed three spots corresponding to **2** (R_f 0.21), the monotosyl derivative (R_f 0.55, major) and the ditosyl derivative (R_f 0.93). Acetic anhydride (5.6 m*l*) was added and the mixture was allowed to stand at room temperature overnight. The solution was evaporated and the residue was extracted with chloroform. The solution was washed with water, dried over sodium sulfate and evaporated to give a syrup (3.47 g). Tlc (benzene–ethyl acetate 6:1) of the syrup showed three spots of R_f 0.34, 0.45 (major) and 0.57. The syrup was chromatographed on a column of silica gel (100 g) with benzene–ethyl acetate (5:1) and the fraction containing **3** (360—510 m*l*, R_f 0.45) was evaporated to give a syrup, 1.47 g (39%), $[\alpha]_D^{18}+108°$ (*c* 1, $CHCl_3$).

Found: C, 52.07; H, 5.92; S, 7.58%. Calcd for $C_{18}H_{24}O_9S$: C, 51.91; H, 5.81; S, 7.70%.

NMR (in $CDCl_3$): τ 8.00 and 7.94 (both 3H singlets, OAc), 8.3—7.7 (2H m, H-3,3′), 7.56 (3H s, CH_3Ph), 6.68 (3H s, OCH_3), 6.35—6.0 (1H m, H-5?), 6.0—5.7 (2H m, H-6,6′?), 5.6—5.15 (3H m; the signal pattern in this area was quite resemble with that of **4** at τ 5.5—5.0. Therefore these signals could be assigned to H-1,2 and 4.

Methyl 2,4-Di-O-acetyl-6-azido-3,6-dideoxy-α-D-ribo-hexopyranoside (4). A mixture of **3** (0.98 g) and sodium azide (1.6 g) in dry DMF (40 m*l*, dried over calcium hydride) was stirred at 145°C for 1.5 hr. The resulting yellow solution was filtered, evaporated, and coevaporated with toluene to give a syrup. Tlc (benzene–ethyl acetate 6:1) of the syrup showed two spots of R_f 0.55 (major, **4**) and 0.45 (**3**), the former being orange when sprayed with sulfuric acid. Chromatography with silica gel (100 g) and the same solvent system gave a pale yellow syrup, 0.51 g (76%), $[\alpha]_D^{18}+121°$C (*c* 1, $CHCl_3$); IR: 2100, 1745, 1445, 1370 cm^{-1}.

Found: C, 46.07; H, 6.03; N, 14.65%. Calcd for $C_{11}H_{17}N_3O_6$: C, 45.99; H, 5.97; N, 14.62%.

8) Y. Nishimura, T. Tsuchiya, and S. Umezawa, This Bulletin **44**, 2521 (1971).

9) Use of fresh palladium black prepared just before use also is of importance, as described in the preceding paper.[3]

10) E. J. Hedgley, W. G. Overend, and R. A. C. Rennie, *J. Chem. Soc.*, **1963**, 4701.

NMR (in $CDCl_3$): τ 8.00 and 7.97 (both 3H singlets, OAc), 8.4—7.5 (2H m, H-3.3′), 6.74 (2H d, J 5 Hz, H-6,6′), 6.58 (3H s, OCH_3), 6.16 (1H quintet, J 5,5 and ~10 Hz, H-5), 5.5—5.0 (3H m, H-1,2,4); $J_{4,5}$~10 Hz, $J_{5,6}=J_{5,6'}$ 5Hz. Comparison of the signal pattern of **3** and **4** showed that the H-6,6′ protons which appeared in **4**, as a doublet at τ 6.74, resonated at τ 5.85 in **3**, indicating the presence of a 6-*O*-tosyl group in **3**.

*Methyl 6-Azido-3,6-dideoxy-α-*D*-ribo-hexopyranoside (5).*

a) From 4: To a solution of **4** (0.51 g) in methanol (10 m*l*), a piece of sodium metal was added and subsequent procedures were carried out in a usual manner; a pale yellow syrup, 0.30 g (84%), $[\alpha]_D^{18}$ +142° (*c* 1, $CHCl_3$); IR: 3420 (s), 2960, 2100 (sharp), 1450, 1280, 1150, 1050, 1015, 970, 910, 840, 755 cm^{-1}.

Found: C, 41.45; H, 6.53; N, 20.49%. Calcd for $C_7H_{13}N_3O_4$: 41.37; H, 6.45; N, 20.68%.

NMR (in $CDCl_3$): τ 6.47 (3H s, OCH_3), 5.30 (1H d, J 3.5 Hz. H-1),

b) From 9: A solution of **9** in methanol was treated likewise as described above. Yield 97%.

*Methyl 6-Azido-2,4-di-O-benzyl-3,6-dideoxy-α-*D*-ribo-hexopyranoside (6).* To a solution of **5** (0.57 g) in DMF (12 m*l*), powdered barium oxide (2.2 g) and powdered barium hydroxide octahydrate (4.6 g) were added and to the suspension, benzyl bromide (5 m*l*) was stirred in dropwise under vigorous stirring at room temperature and the mixture was agitated overnight. Chloroform (80 m*l*) was added and the mixture was filtered through a layer of celite. The filtrate was evaporated and coevaporated with toluene to give a syrup, which showed four spots of R_f 0.80 (**6**, major), 0.20 (slight), 0.05 (slight) and 0 (slight) on tlc with benzene–ethyl acetate (10: 1). The syrup was chromatographed on a short column of silica gel (30 g) with the same solvent system and the fraction containing **6** was collected and evaporated to give a pale yellow syrup, 0.87 g (81%), $[\alpha]_D^{19}$ +90° (*c* 1, $CHCl_3$); IR: 2100, 735, 700 cm^{-1}.

Found: C, 65.84; H, 6.49; N, 10.99%. Calcd for $C_{21}H_{25}N_3O_4$: C, 65.78; H, 6.57; N, 10.96%.

NMR (in $CDCl_3$): τ 8.10 (1H q, J ~11 Hz, H_{ax}-3), 7.69 (1H sextet, J 4.5, 4.5, and 11 Hz, H_{eq}-3), 6.56 (3H s, OCH_3), 6.9—6.0 (5H m, H-2,4,5,6,6′), 5.58 and 5.38 (each 1H doublet (J 11.5 Hz) forming an AB quartet centered at 5.48, C(2?) $OC\underline{H}_2C_6H_5$), 5.40 (2H s, C(4?)$OC\underline{H}_2C_6H_5$), 5.28 (1H d, J 3.5 Hz, H-1), 2.65 and 2.62 (both 5H singlets, $OCH_2C_6\underline{H}_5$).

*6-Azido-2,4-di-O-benzyl-3,6-dideoxy-*D*-ribo-hexopyranose (7).* To a solution of **6** (0.51 g) in acetic acid (18 m*l*), 2N hydrochloric acid in 50% aqueous methanol (6 m*l*) was added and the solution was refluxed for 1.5 hr. After neutralization with sodium hydrogen carbonate, the solution was filtered, and the filtrate was evaporated to give a residue. The chloroform solution of the residue was washed with water, dried over sodium sulfate and evaporated to give a syrup, which, on tlc with benzene–ethyl acetate (10:1), showed three spots of R_f 0.80 (**6**, minor), 0.40 (**7**, major) and 0.0. The syrup was chromatographed on a short column of silica gel with the same solvent system and the fraction containing **7** was collected and evaporated to give a pale yellow syrup, 0.37 g (75%), $[\alpha]_D^{18}$ +75° (*c* 1, $CHCl_3$; the final value); IR: 2100, 740, 700 cm^{-1}.

NMR (in $CDCl_3$): The whole pattern of **7** was fairly resemble to that of **6**. However an anomeric proton appeared at τ 4.75 (J 3.5 Hz) in the strength of approximately 0.55 proton. Hence, **7** will be an anomeric mixture of approximately α:β-anomer 55: 45 at least in chloroform solution.

Found: C, 64.90; H, 6.61; N, 11.12%. Calcd for $C_{20}H_{23}N_3O_4$: C, 65.02; H, 6.28; N, 11.38%.

*Methyl 4-O-Benzoyl-6-bromo-3,6-dideoxy-α-*D*-ribo-hexopyranoside (8).* To a solution of **1** (19.6 g) in dry carbon tetrachloride (500 m*l*), *N*-bromosuccinimide (14.4 g) and barium carbonate (30 g) were added and the mixture was refluxed for 1.5 hr. The resulting yellow solution was filtered and the filtrate was washed with 2% sodium hydrogen carbonate solution and with water, dried over sodium sulfate, and evaporated to give a syrup, 21.7 g (85%), $[\alpha]_D^{18}$ +169° (*c* 1, $CHCl_3$); R_f 0.54 on tlc with benzene–ethyl acetate (1: 1) (**1**, R_f 0.45); IR (KBr): 3430, 1725, 710 cm^{-1}.

Found: C, 48.98; H, 4.92; Br, 23.47%. Calcd for $C_{14}H_{17}O_5Br$: C, 48.71; H, 4.97; Br, 23.15%.

NMR (in $CDCl_3$); τ 8.13 (1H, q, J 11.5 Hz, H_{ax}-3), 7.56 (1H sextet, J 5,5 and 11.5 Hz, H_{eq}-3), 6.45 (3H s, OCH_3), 6.8—5.8 (4H m), 5.22 (1H d, J 3.5 Hz, H-1), 5.03 (1H octet, J 5,10 and 11.5 Hz, H-4), 2.8—1.8 (5H m, typical for benzoyl protons).

*Methyl 6-Azido-4-O-benzoyl-3,6-dideoxy-α-*D*-ribo-hexopyranoside (9).* To a solution of **8** (9.5 g) in dry DMF (180 m*l*), sodium azide (9.0 g) was added and the mixture was stirred at 140°C for 1.5 hr. Tlc (benzene–ethyl acetate 1: 1) showed that **8** and **9** had an identical R_f value, but they were distinguished each other by the difference in coloration. After filtration, the solution was evaporated and the residue was dissolved in chloroform. The solution was washed with water, dried over sodium sulfate and evaporated to give a syrup. To remove color impurities, the solution of the syrup in benzene–ethyl acetate (1: 1) was passed through a short column of silica gel with the aid of the same solvent system and the fraction containing **9** was evaporated to give a pale yellow syrup, 6.90 g (81%), $[\alpha]_D^{18}$ +189° (*c* 1, $CHCl_3$); IR: 3440, 2100, 1725, 710 cm^{-1}.

Found: C, 54.95; H, 5.75; N, 14.01%. Calcd for $C_{14}H_{17}N_3O_5$: C, 54.71; H, 5.58; N, 13.68%.

*6-Azido-2,4-di-O-benzyl-3,6-dideoxy-α-*D*-ribo-hexopyranosyl Chloride (10).* To ice-cold thionyl chloride (5 m*l*), **7** (197 mg) was added gradually and the solution was allowed to stand in the cold for 1 hr and then at room temperature overnight. The solution was coevaporated with dry toluene *in vacuo* and the residue was dissolved in dry benzene. The solution was passed through a short column of silica gel (3 g), which was preactivated at 120°C *in vacuo* for 5 hr before use. The eluate containing **10** was collected and evaporated to give a pale yellow syrup, 125 mg (61%), $[\alpha]_D^{20}$ +170° (*c* 1, $CHCl_3$); R_f 0.5 on tlc with benzene (**7**, R_f 0); IR: 2930, 2870, 2100 (sharp, N_3), 1500, 1460, 1370, 1350, 1290, 1110 (s), 1000, 895, 740 (s), 700 cm^{-1}.

Found: C, 62.14; H, 5.98; N, 11.07; Cl, 9.61%. Calcd for $C_{20}H_{22}N_3O_3Cl$: C, 61.93; H, 5.72; N, 10.83; Cl, 9.14%.

NMR (in $CDCl_3$): τ 8.12 (1H q, J ~11.5 Hz, H_{ax}-3), 7.58 (1H sextet, J ~5, ~5, and ~12 Hz, H_{eq}-3), 6.8—5.8 (5H m, H-2,4,5,6,6′), 5.53 and 5.40 (both 1H doublets (J 11.5 Hz) forming an AB quartet centered at 5.46, C(2?) $OC\underline{H}_2C_6H_5$), 5.43 (2H s, C(4?) $OC\underline{H}_2C_6H_5$), 3.83 (1H d, J 3.5 Hz, H-1), 2.68 and 2.65 (both 5H singlets, $OCH_2C_6\underline{H}_5$).

*4-O-(6-Azido-2,4-O-di-O-benzyl-3,6-dideoxy-α-*D*-ribo-hexopyranosyl)-6-O-(2-O-benzyl-3-deoxy-3-ethoxycarbonylamino-4,6-O-isopropylidene-α-*D*-glucopyranosyl)-N,N′-diethoxycarbonyl-2-deoxystreptamine (12).* A mixture of **10** (400 mg, 1.6 mol and freshly prepared Drierite (1.5 g) in strictly dried[3] benzene–dioxane (3: 1, 16 m*l*) was refluxed for 30 min and to the mixture, **11**[3] (450 mg, 1 mol) and dried mercuric cyanide (0.57 g) were added. The mixture was refluxed for 6 hr. Mercuric cyanide (0.57 g) was added and the mixture was again refluxed for 6 hr. The procedure was repeated once again. The resulting reaction mixture was poured into a saturated sodium hydrogen carbonate

solution with stirring and the product was extracted with chloroform. After dried over sodium sulfate, the chloroform solution was evaporated to give a syrup (0.9 g). Tlc (chloroform–acetone 5: 1) of the syrup showed six spots of R_f 0.02 (**11**), 0.58, 0.49 (major, **12**), 0.47. 0.31, and 0.9 (**10** and **7**). The syrup was chromatographed on a column of alumina (E. Merck, neutral, 60 g) with chloroform–acetone (5: 1) initially, and after **10** and **7** (both, R_f 0.9) had been eluted (42—88 m*l*), with ethanol. The ethanol eluate was evaporated to give a solid (0.49 g), which contained all components cited above other than **10** and **7**. The solid was then chromatographed on a column of silica gel (Wako gel, 50 g) with chloroform–acetone (5: 1). Compound **12** (R_f 0.49, 250 mg, 36%), a mixture of **12** and the substance having R_f 0.47 (0.10 g), a mixture of the substance having R_f 0.47 and 0.3 (0.06 g) and the substance having R_f 0.31 (0.08 g) were eluted in this order in the fractions of 187—287, 287—400, 400—500, and 500—700 m*l*, respectively. Compound **12** was recrystallized from a mixture of ethanol–acetone (1:1) containing a small amount of ammonia: 170 mg (25%), mp 263—264°C, $[\alpha]_D^{20}$ +97° (*c* 0.9, pyridine); IR (KBr): 3360, 2940, 2110 (N_3), 1705 (amide I), 1545 (amide II); 1075, 1045, 860, 780, 745, 700 cm^{-1}.

Found: C, 59.79; H, 6.76; N, 7.91%. Calcd for $C_{51}H_{68}N_6O_{16}$: C, 59.98; H, 6.71; N, 8.28%.

NMR (in pyridine-d_5): τ 8.90, 8.87, and 8.85 (each 3H s, $CH_2C\underline{H}_3$), 8.57 and 8.54 (each 3H s, isopropylidene), 2.4—2.7 (15H m, phenyl).

*6-O-(3-Amino-3-deoxy-α-D-glucopyranosyl)-4-O-(6-amino-3,6-dideoxy-α-D-*ribo*-hexopyranosyl)-2-deoxystreptamine (3′-Deoxykanamycin).* A suspension of **12** (82 mg) in aqueous acetic acid (1: 4, 2 m*l*) was heated at 90°C for 5 min. Tlc (chloroform–acetone 5: 1) of the resulting solution showed that **12** (R_f 0.85) had disappeared and a deacetonation product (R_f 0.07) appeared. The solution was poured into water and the precipitates were filtered to give a solid (79 mg). The solid was dissolved in hot ethanol–dioxane (5: 1, 12 m*l*) and the solution was hydrogenated with Raney nickel (T-4) and hydrogen under pressure (50 *l*b/sq. inch) at 42°C for 3 hr. The reaction mixture was filtered and the filtrate was evaporated to give a solid (60 mg), which had an R_f value 0.22 on tlc with benzene–ethanol (5: 1) (the starting material, R_f 0.75). Its infrared spectrum showed no absorption corresponding to an azide (~2100 cm^{-1}).

To a suspension of the solid in aqueous acetone (1: 1, 3 m*l*), anhydrous sodium carbonate (70 mg) and ethoxycarbonyl chloride (36 mg) were added and the mixture was stirred at room temperature for 30 min, whereupon, on tlc with benzene–ethanol (5: 1), the starting material (R_f 0.22) disappeared and a product (R_f 0.71) appeared. The resulting solution was evaporated *in vacuo* and the residue was extracted with chloroform. The chloroform solution was washed with water, dried over sodium sulfate and evaporated to give a solid (53 mg).

The solid was dissolved in hot aqueous ethanol (1: 8, 9 m*l*) and, after addition of a few drops of acetic acid, the solution was hydrogenated with palladium black and hydrogen under pressure (50 *l*b/sq. inch) at 30°C for 12 hr. The reaction mixture was filtered and evaporated to give a solid (39 mg), which gave R_f 0 on tlc with benzene–ethanol (5:1). Its NMR spectrum showed no absorption peaks corresponding to benzyl protons.

The solid was then heated with 1N barium hydroxide solution at 90°C for 9 hr and the solution was neutralized with carbon dioxide. After filtration, the solution was evaporated *in vacuo*. The residue was dissolved in water to give a slightly turbid solution, which was filtered and evaporated. To remove barium carbonate thoroughly, the procedure was repeated untill a clear solution was obtained. Colorless solid, 24 mg. Paper chromatography (Toyo Roshi No. 50) of the solid with *n*-butanol–pyridine–water–acetic acid (6:4:3:1) showed that the solid was composed mainly of 3′-deoxykanamycin ($R_{f\text{kanamycin}}$ 2.2) being accompanied with a slight amount of 2-deoxystreptamine and by-products (R_f 0). The solid was then chromatographed with a column of Amberlite CG50 (NH_4^+ form, 5.5×55 mm); water (30 m*l*), 0.05N (70 m*l*) and 0.1N ammonia (100 m*l*) eluted impurities. Subsequent development with 0.3 N ammonia eluted 3′-deoxykanamycin in 99—135 m*l* fraction, colorless solid, 10 mg (27%). It was recrystallized from water–acetone, $[\alpha]_D^{20}$ +146° (*c* 0.2, H_2O).

Found: C, 46.10; H, 7.70%. Calcd for $C_{18}H_{16}H_4O_{10}$: C, 46.14; H, 7.75%.

Proofs for the Structure of 3′-Deoxykanamycin. *a) By Periodate Oxidation*: 3′-Deoxykanamycin (1.0 mg) was dissolved in 10% sodium periodate solution (0.09 m*l*) and the solution was allowed to stand at room temperature for 12 hr. After addition of ethylene glycol (0.09 m*l*), an equal volume of concentrated hydrochloric acid with that of the solution was added and the solution was heated at 90°C for 1 hr. Paper chromatography with *n*-butanol–pyridien–water–acetic acid (6:4:3:1) showed the presence of 2-deoxystreptamine. Parallel to this experiment, kanamycin and neomycin were treated likewise and it was shown that kanamycin gave 2-deoxystreptamine, whereas neomycin did not give it.

b) By Hydrolysis: A solution of 3′-deoxykanamycin in 6N hydrochloric acid was heated at 90°C for 40 min. Paper chromatography with the above-mentioned solvent-system of the resulting solution showed the presence of 2-deoxystreptamine and 3-amino-3-deoxy-D-glucose. Other products could not be clearly discerned because of diffusion of the spots.

The authors wish to thank Mr. Saburo Nakada for the elemental analysis and to Mr. Yasuhiro Ito for his technical assistance.

Improved Solid-Phase Synthesis of Tryptophan-Containing Peptides. I. Use of Hydrogen Chloride in Formic Acid as a Reagent for the Cleavage of *t*-Butyloxycarbonyl Group[1]

Motonori OHNO, Sadaji TSUKAMOTO, Satoru MAKISUMI, and Nobuo IZUMIYA

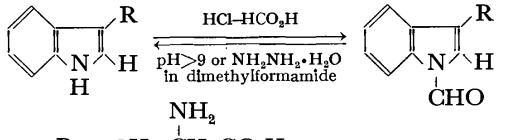
Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka

(Received May 22, 1972)

An improved method has been described for the solid-phase synthesis of tryptophan-containing peptides. Hydrogen chloride in formic acid has been introduced as a reagent for the cleavage of the *t*-butyloxycarbonyl group owing to the stableness of tryptophan and N^{t}-formyltryptophan in this system. The effectiveness of the new reagent has been demonstrated in the synthesis of the tryptophan-containing heptapeptide, lysylalanylglycylleucylglycyltryptophylleucine.

The usefulness of the solid-phase synthesis of polypeptides has been documented in the syntheses of a number of biologically active peptides[2] and of proteins.[3] This quick technique has also been becoming a valuable tool in the syntheses of enzymic fragments involved in noncovalently bonded, active complexes and their analogs as an approach to understanding of protein structure and function relationships, as exemplified in bovine pancreatic ribonuclease A[3a,4] and staphylococcal nuclease.[5] It is well known, however, that tryptophan in the peptide chain growing on the polymer support undergoes oxidation during treatment with hydrogen chloride in acetic acid or dioxane for the cleavage of the *t*-butyloxycarbonyl (Boc) group[2,3] that is usually employed as an α-amino protecting group in the solid-phase peptide synthesis. In such cases, sulfhydryl reagent such as β-mercaptoethanol (EtSH)[6] or dithiothreitol[3b] has been used as a scavenger to protect tryptophan from oxidative destruction.

Bubbling of hydrogen chloride into a solution of tryptophan[7] or its derivatives (including even enzymes) in formic acid results in formylation of the indole nitrogen (N^{t}) and this formyl group can be removed in a weakly alkaline medium.[8]



$R = -CH_2-CH(NH_2)-CO_2H$ etc.

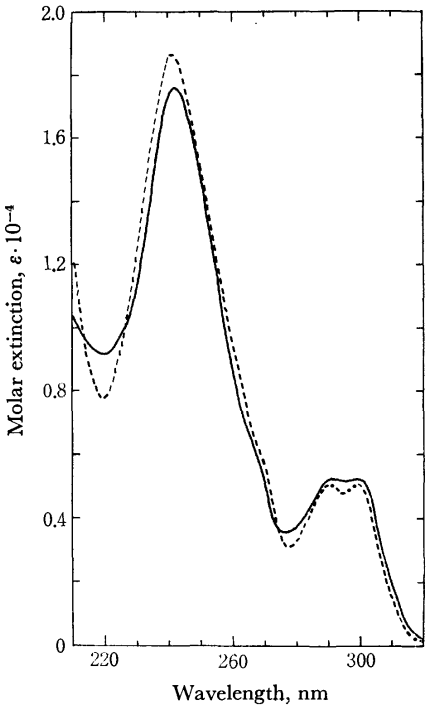


Fig. 1. Ultraviolet absorption spectra of N^{t}-formyltryptophan hydrochloride (——) in water and N^{α}-acetyl-N^{t}-formyltryptophan methyl ester (------) in methanol.

The UV absorption spectra characteristic of N^{t}-formyltryptophans are shown in Fig. 1. On the high-voltage paper electrophoresis (pH 2.08) of a solution of tryptophan dissolved in 0.1—1N hydrogen chlordie in formic acid, no band other than those of tryptophan and N^{t}-formyltryptophan has been detected even after a prolonged standing of the solution, showing the stability of the two indole derivatives in this system. The degree of transformation of tryptophan into N^{t}-formyltryptophan depends on concentration of hydrogen chloride and the time keeping in solution. No reaction occurred upon treatment of N^{t}-formyltryptophans with a large excess of anhydrous triethylamine in dimethylformamide. The formyl group, however, has been cleaved by dissolving N^{t}-formyltryptophans in dimethylformamide containing a 20—30 fold molar excess of hydrazine hydrate and standing for 48 hr. The thin-layer chromatographic studies using α-Boc-aspartic

acid β-benzyl ester showed that a 1.2—2.0 fold molar excess of hydrogen chloride (0.1N) in formic acid cleaves the Boc group as rapidly as with a 20-fold molar excess of hydrogen chloride (1N) in acetic acid. These observations led us to examine hydrogen chloride-formic acid as a reagent for cleavage of the Boc group in the solid-phase synthesis of tryptophan-containing peptides.

Since removability of the Boc group in the heterogeneous system such as solid-phase synthesis would not be expected to be the same level as in the homogeneous solution system and it is true, the more excess amount of hydrogen chloride than that required for complete cleavage in the solution system should be used.

In the preliminary experiments in which the syntheses of H-Lys-Ala-Gly-Trp-Leu-OH and H-Ala-Gly-Lys(ε-Tfa)-Gly-Trp-Leu-OH (Tfa: trifluoroacetyl) have been made by using hydrogen chloride-formic acid, it was clearly indicated through the UV absorption spectra and the electrophoretic behaviors of the products that the reagent was quite effective in protecting tryptophan from oxidative destruction. We report here, as a typical example, the details of the solid-phase synthesis of the heptapeptide, H-Lys-Ala-Gly-Leu-Gly-Trp-Leu-OH, using the new deblocking method.

The heptapeptide was built up by the usual manner[2,3] starting from Boc-leucyl resin and using a 6-fold molar excess of hydrogen chloride (0.1N) in formic acid. ε-Amino group of lysine was protected with benzyloxycarbonyl (Z) group. In parallel, two peptides with the same sequence were constructed on the resins using 1N hydrogen chloride in acetic acid in the presence and absence of EtSH (2%). Halves of the three protected peptidyl resins [**1a** (*via* HCl-HCOOH), **1b** (*via* HCl-AcOH-EtSH), and **1c** (*via* HCl-AcOH)] were cleaved by hydrazine hydrate in dimethylformamide as described.[9] In order to remove nonpeptide substances derived from the resin, the three products of Boc-Lys(ε-Z)-Ala-Gly-Leu-Gly-Trp*-Leu-$NHNH_2$[10] [**2a** (*via* HCl-HCOOH), **2b** (*via* HCl-AcOH-EtSH), and **2c** (*via* HCl-AcOH)] were reprecipitated from the methanolic solutions by addition of ethyl ether-petroleum ether (1:2 v/v). The other halves of **1a** and **1b** were treated with anhydrous hydrofluoric acid in the presence of anisole,[11,12] and the peptide produced *via* HCl-HCOOH was further treated with 0.1N aqueous piperidine to remove the N^{i}-formyl group attached to a part of tryptophyl residue since this group is resistant to anhydrous hydrofluoric acid (see Experimental section): the two completely deblocked heptapeptides [**3a** (*via* HCl-HCOOH) and **3b** (*via* HCl-AcOH-EtSH)] were obtained.

The UV absorption spectrum of **2a** (Fig. 2) was virtually identical with that of Z-tryptophan except that a trough in the 240—250 nm region showed somewhat greater absorption and was shifted to the red by 2 nm. This indicates that **2a** has been contaminated to only a minor extent by oxidized species. Extinction coefficients of **2b** and **2c** at 282 nm were respectively 1.34 and 1.45 times as large as that of **2a**. Such enhancement of the extinction at 282 nm should be ascribed to oxidation of the indole chromophore although what types of products formed has so far been unknown.

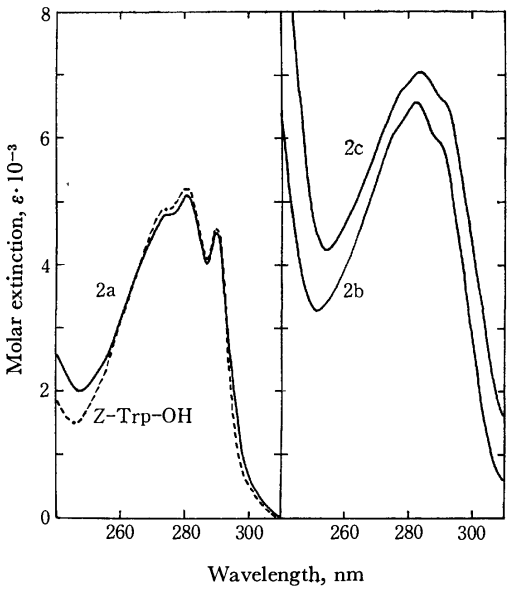

Fig. 2. Ultraviolet absorption spectra of the protected peptide hydrazides, **2a**, **2b**, and **2c**, and Z-tryptophan in methanol.

Figure 3 shows gel-chromatographic patterns of **3a** and **3b** on a Sephadex G-25 column. **3b** gave a complex profile owing to its heterogeneity. To ascertain whether the major peak from **3a** is due only to pure peptide, **3a** was treated with a 10-fold molar excess of 2-nitro-4-carboxyphenylsulfenyl chloride (NCPS-Cl)[13,14] in 80% formic acid and the modified peptide was chromatographed on the same column. Since the peptide containing 2-thio-(2-nitro-4-carboxyphenyl)-tryptophan[14] reveals an increased adsorptivity on the gel than the unmodified,[15] it is apparent from the delayed and shifted elution profile of the modified peptide that the original peptide in the major peak from **3a** involved only pure tryptophyl residue. This was further confirmed from the observation that the modified peptide from the major peak fractions gave exactly the same spectrum as that of 2-thio-(2-nitro-4-carboxyphenyl)-tryptophan and gave a single band upon thin-layer chromatography. Comparison of the two elution diagrams before and after reaction of **3b** with NCPS-Cl indicates that **3b** contains unchanged tryptophan to a small extent.

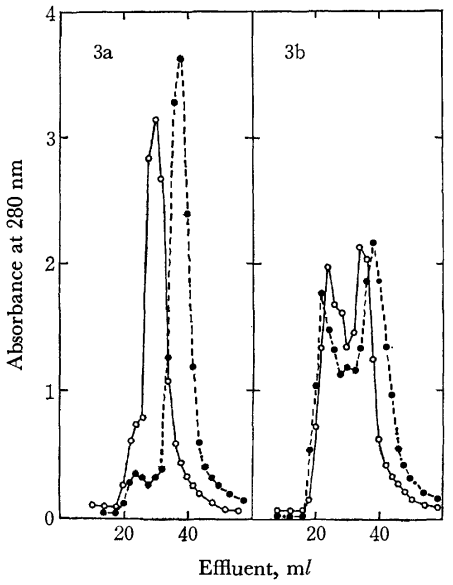

Fig. 3. Elution diagrams of the peptides, **3a** (6 mg) and **3b** (6 mg), on a Sephadex G-25 column (0.9×60 cm) before (○—○) and after (●·····●) modification with NCPS-Cl; solvent, 10% acetic acid. The details are described in the Experimental section.

Use of hydrogen chloride-formic acid for the cleavage of the Boc group in the solid-phase synthesis is worthy of attention in such a remarkable suppression of tryptophan oxidation. This merit of the reagent is due possibly to the reductive nature of formic acid. Since formylation of the indole nitrogen stabilizes the indole nucleus against oxidation, use of N^{α}-Boc-N^{i}-formyltryptophan in the solid-phase synthesis is under investigation and will be the subject of future publication.

Experimental

Melting points are uncorrected. UV spectra were taken with a Hitachi spectrophotometer EPS-3T or a Shimadzu UV-200 spectrophotometer equipped with a U-125MU recorder. Optical rotations were measured with a Yanagimoto polarimeter OR-20. Thin-layer chromatographies were performed on Merck silica gel G using either ethyl acetate–methanol (2:1 v/v) (solvent 1) or *n*-butanol–acetic acid–water (4:1:5 v/v, upper layer) (solvent 2) as the developing solvent. Paper electrophoreses were carried out under the following condition: paper, Whatman 3MM (57 cm length); solvent, 0.24N formic acid (pH 2.08); voltage gradient, 48 V/cm; period, 90 min. In this condition all amino acids and peptides in the present experiments moved to the cathode. Substances were detected by spraying ninhydrin (0.2% solution in 80% ethanol) or a modified Ehrlich reagent (0.5% solution of *p*-dimethylaminocinnamaldehyde in 0.5N hydrochloric acid). Amino acid analyses of peptides were carried out on samples that had been hydrolyzed with constant boiling hydrochloric acid for 24 hr in evacuated, sealed tubes at 110°C, and were recorded on a Hitachi amino acid analyzer KLA-3A.

Boc-Leucine, glycine, alanine, valine, and tryptophan were prepared by the reaction of each amino acid with Boc-azide[16] or purchased from the Protein Research Foundation (Osaka). α-Boc-ε-Z-Lysine and α-Boc-ε-Tfa-lysine (mp 101—102°C, lit,[17] 103°C) were prepared by the reaction of ε-Z-lysine[18] and ε-Tfa-lysine[19] with Boc-azide. Z-Tryptophan was prepared from Z-Cl[20] and tryptophan by the Schotten-Baumann procedure. 2-Thio-(2-nitro-4-carboxyphenyl)-tryptophan [λ_{max} in 10% acetic acid 260 (log ε 4.29), 282 (log ε 4.33), and 355 nm (log ε 3.65)] was prepared from 2-nitro-4-carboxyphenylsulfenyl chloride and tryptophan as reported.[14] Chloromethylated copolystylene-divinylbenzene (2%) resin (1.3 mmol/g, 100—200 mesh) was obtained from the Protein Research Foundation (Osaka). Formic acid (analytical grade, 98—100%) was purchased from the Merck Co. and used without purification. Acetic acid was refluxed over potassium permanganate and distilled. Concentration of hydrogen chloride in formic acid or acetic acid was based on the weight of hydrogen chloride absorbed per unit volume of the solvent, or determined by the Volhard titration. The other solvents for the solid-phase synthesis were purified by the appropriate procedures.

Formylation of Tryptophans. Dried hydrogen chloride was bubbled into a solution of tryptophan (7.0 g) in formic acid (100 ml) at room temperature. At suitable intervals aliquotes of the solution were diluted with water for recording UV spectra. After the absorbance at 298 nm reached maximum (about 3 hr), the solvent was removed *in vacuo* with slight warming. N^{i}-Formyltryptophan hydrochloride crystallized by addition of ethyl ether to the syrup. Crystals were collected and washed with ethyl ether, 9.20 g (100%), mp 218°—220°C, $[\alpha]_D^{23}$ −4.7° (*c* 1.91, water).

Found: C, 53.60; H, 4.99; N, 10.42. Calcd for $C_{12}H_{12}O_3N_2 \cdot HCl$: C, 53.64; H, 4.88; N, 10.43%.

α-Acetyltryptophan methyl ester (0.30 g) was treated by the same way as described above, and the syrup was taken into ethyl acetate that was washed with water, dried over sodium sulfate and evaporated. Crystallization of the residue by addition of petroleum ether gave 0.28 g (85%) of N^{α}-acetyl-N^{i}-formyltryptophan methyl ester; mp 102—104°C, $[\alpha]_D^{23}$ +21.0° (*c* 1.64, methanol).

Found: C, 62.10; H, 5.76; N, 9.68. Calcd for $C_{15}H_{16}O_4N_2$: C, 62.49; H, 5.59; N, 9.72%.

N^{i}-Formyltryptophans are nonfluorescent under UV lamp and negative to the modified Ehrlich reagent.

Paper Electrophoresis of a Solution of Tryptophan Dissolved in 0.1—1N Hydrogen Chloride in Formic Acid. As a typical experiment, 30 mg of tryptophan was dissolved in 5 ml of 0.4N hydrogen chloride in formic acid and the solution was allowed to stand at room temperature. At suitable intervals aliquotes of the solution were taken and subjected to paper electrophoresis. No band other than those of tryptophan and N^{i}-formyltryptophan has been detected even after 100 hr. The ratio of the latter to the former increased with time. Under the lower or higher concentration of hydrogen chloride than that of the example, transformation of tryptophan into N^{i}-formyltryptophan took place in slower or faster rate. It should be noted that the mobilities of tryptophan and N^{i}-formyltryptophan under the condition mentioned above are 15 and 12 cm, respectively.

Stability of N^{i}-Formyltryptophans. a) Anhydrous Triethylamine: N^{α}-Acetyl-N^{i}-formyltryptophan methyl ester (10 mg) was dissolved in 1 ml of dimethylformamide containing

0.14 ml of anhydrous triethylamine. At suitable intervals aliquotes of the solution were taken and evaporated *in vacuo* to dryness. The residues were dissolved in ethanol and their UV spectra were recorded. No change has been observed in the starting spectrum even after standing for 24 hr.

b) Anhydrous Hydrofluoric Acid: In the reaction vessel of the type described by Sakakibara *et al.*,[11] N^i-formyltryptophan hydrochloride (10 mg) was treated with anhydrous hydrofluoric acid (2 ml) in the presence of anisole (0.1 ml) at 0°C for 1 hr.[11,12] After removal of anhydrous hydrofluoric acid *in vacuo* at room temperature, the residue was taken into 10% acetic acid. An aqueous solution was shaken with ethyl ether and lyophilized. The dried powder exhibited the typical N^i-formyltryptophan spectrum. On paper electrophoresis, mobility of a ninhydrin-positive but modified Ehrlich reagent-negative band was the same as that of the authentic N^i-formyltryptophan hydrochloride.

Hydrazinolytic Removal of Formyl Group from N^i-Formyltryptophans. N^α-Acetyl-N^i-formyltryptophan methyl ester (10 mg) was dissolved in 0.5 ml of dimethylformamide containing 0.05 ml of hydrazine hydrate and the solution was allowed to stand at room temperature. At suitable intervals aliquotes of the solution were diluted with ethanol for recording spectra. The complete indole spectrum was obtained after 48 hr.

Boc-Leucyl Resin. To 4.0 g of chloromethylated copolystylene-divinylbenzene (2%) resin (1.3 mmol of Cl/g), were added 34 ml of anhydrous ethanol containing 1.38 g (5.5 mmol) of Boc-leucine and 0.77 ml (5.5 mmol) of triethylamine. The mixture was refluxed for 72 hr with continuous stirring. The resin was filtered, rinsed repeatedly with ethanol and with methylene chloride, and dried *in vacuo*. Amino acid analysis of the resin indicated the leucine content to be approximately 0.20 mmol/g.

Boc-Lys(ε-Z)-Ala-Gly-Leu-Gly-Trp-Leu-resins (**1a**, **1b**, and **1c**).* Boc-leucyl resin (0.5 g) was placed in a reaction vessel of the type described by Merrifield for repeated deblocking, rinsing and coupling procedure. For the synthesis of **1a**, the following cycle was used for stepwise addition of the appropriate Boc-amino acid. The resin was rinsed with formic acid (three 6 ml portions), shaken for 30 min in 0.1N hydrogen chloride in formic acid (6 ml), rinsed with formic acid (three 6 ml portions), with anhydrous ethanol (three 6 ml portions) and with dimethylformamide (three 6 ml portions), shaken for 10 min in 10% triethylamine in dimethylformamide (two 6 ml portions), rinsed with dimethylformamide (three 6 ml portions) and with methylene chloride (three 6 ml portions). The resin was then suspended in 6 ml of methylene chloride containing a 4-fold molar excess of the appropriate Boc-amino acid and shaken for 15 min. Equimolar *N,N'*-dicyclohexylcarbodiimide was added in 1 ml of methylene chloride and shaking was continued overnight. The coupling steps were terminated by rinsing with methylene chloride (three 7 ml portions) and with anhydrous ethanol (three 6 ml portions). For the syntheses of **1b** and and **1c**, formic acid and 0.1N hydrogen chloride in formic acid were replaced by acetic acid and 1N hydrogen chloride in acetic acid, and EtSH (2% by volume) was added to the acid mixture in the case of **1b**.

Boc-Lys(ε-Z)-Ala-Gly-Leu-Gly-Trp-Leu-$NHNH_2$ (**2a**, **2b**, and **2c**).* To each suspension of **1a**, **1b**, and **1c** (0.40 g each) in 3.5 ml of dimethylformamide, were added 0.4 ml of 100% hydrazine hydrate and the mixture were shaken for 2 days at room temperature. The dimethyformamide solutions were separated by filtration and the resins were rinsed several times with dimethylformamide. The combined filtrates were evaporated *in vacuo* nearly to dryness. The hydrazides solidified upon the addition of water and were filtered and washed with water. The hydrazides were dissolved in methanol and the insoluble substances were filtered off. The filtrates were evaporated to a small volume and a mixture of ethyl ether and petroleum ether (1:2 v/v) was added. The crystalline products were filtered off: **2a**, 74 mg (86% yield of **2b**), mp 198—200°C, $[\alpha]_D^{20}$ −28° (*c* 0.165, methanol), $R_f(1)$ 0.91; **2b**, 86 mg, mp 189—191°C, $[\alpha]_D^{20}$ −22° (*c* 0.158, methanol), $R_f(1)$ 0.91;[21] and **2c**, 78 mg, mp 181—184°C, $[\alpha]_D^{20}$ −13° (*c* 0.205, methanol), $R_f(1)$ 0.91.[21] Amino acid analysis of **2a**: Lys, 0.97; Ala, 1.00; Gly, 1.85; Leu, 2.06. Amino acid analysis of **2b**: Lys, 1.00; Ala, 1.00; Gly, 2.09; Leu, 2.20. Amino acid analysis of **2c**: Lys, 1.12; Ala, 1.00; Gly, 2.14; Leu, 2.25. The UV absorption spectra were taken in the methanolic solutions (see Fig. 2). Elemental analysis was carried out only on **2a**.

Found: C, 57.98; H, 7.52; N, 15.13. Calcd for $C_{49}H_{73}N_{11}O_{11}\cdot H_2O$: C, 58.23; H, 7.29; N, 15.26%.

H-Lys-Ala-Gly-Leu-Gly-Trp-Leu-OH (**3a** and **3b**).* **1a** (0.2 g) was treated with 4—5 ml of anhydrous hydrofluoric acid for 1 hr at 0°C in the presence of anisole. After removal of anhydrous hydrofluoric acid *in vacuo*, the peptide cleaved was extracted with two 5 ml portions of 10% acetic acid. The aqueous solution was shaken with ethyl ether and lyophilized to afford 35 mg of a white powder. The UV spectrum of the product in 0.1N sodium hydroxide was virtually identical with that of tryptophan in the same solvent except for somewhat greater absorption in the 240—250 nm region. The above white powder was dissolved in 0.1N aqueous piperidine, and the solution was allowed to stand at room temperature for 10 min and lyophilized, to give **3a** as a white residue. **1b** (0.2 g) was treated by the same way as for **1a** except for treatment with 0.1N piperidine, to afford 49 mg of **3b** as a light brown powder. Its UV spectrum was similar to that of **2b** in Fig. 2. Amino acid analysis of **3a**: Lys, 0.98; Ala, 1.00; Gly, 1.90; Leu, 2.10. Amino acid analysis of **3b**: Lys, 0.96; Ala, 1.00; Gly, 2.10; Leu, 1.92.

Reaction of H-Lys-Ala-Gly-Leu-Gly-Trp-Leu-OH (**3a** and **3b**) with 2-Nitro-4-carboxyphenylsulfenyl Chloride (NCPS-Cl) and Sephadex G-25 Column Chromatographies of the Modified Peptides.* To a solution of 6 mg of **3a** in 2 ml of 80% formic acid, was added 16 mg of NCPS-Cl and the solution was stirred for 4 hr at room temperature and lyophilized. The dried residue was scratched with five 2 ml portions of acetone containing 2% concentrated hydrochloric acid in order to remove the excess reagent. The yellow peptide was separated by centrifugation from the acetone solution and dissolved in water, and the solution was lyophilized. The dried peptide was dissolved in 0.2 ml of 10% acetic acid and chromatographed on a Sephadex G-25 column (0.9×60 cm) equilibrated with the same solvent (Fig. 3). The elution was monitored by absorption at 280 nm. The spectra of the major peak fractions were exactly the same as that of 2-thio-(2-nitro-4-carboxyphenyl)-tryptophan. The unmodified peptide (**3a**) was chromatographed on the same column and its elution pattern was compared with that of the modified peptide (Fig. 3). The modified peptide recovered from the major peak fractions gave a single band on thin-layer chromatography, $R_f(2)$ 0.45, and on paper electrophoresis (mobility, 12.5 cm) and its amino acid analysis gave the ratio: Lys, 1.00; Ala, 1.00; Gly, 1.92; Leu, 1.98. **3b** (6 mg) was treated with 16 mg of NCPS-Cl and the modified peptide was chromatographed by the same manner as described above, and its elution diagram was compared with that of **3b** (Fig. 3).

21) When 47% hydrobromic acid was sprayed to cleave the Boc-group, the spot colored brown.

The Reaction of Elemental Sulfur with Organic Compounds. IV. The Reactions of *N*-Arenesulfonylsulfilimine and Sulfoximine with Sulfur and Diaryl Disulfide[1]

Shigeru OAE, Yoshiyuki TSUCHIDA, Kenji TSUJIHARA, and Naomichi FURUKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshiku, Osaka

(Received February 28, 1972)

The reactions of elemental sulfur and diaryl disulfide with the compounds bearing a semipolar S→N linkage were investigated. Elemental sulfur was found to react with *N*-arenesulfonylsulfilimine and sulfoximine affording the corresponding sulfide and the sulfoxide respectively. Diaryl disulfide also was found to undergo similar reactions with these compounds. In the reaction of diaryl disulfide with *N*-arenesulfonylsulfilimine, *N,N*-bis(arylthio)arenesulfonamide was obtained as a main product besides the corresponding sulfide. The mechanisms of these reactions are discussed.

In the course of our studies on the reactions of elemental sulfur and disulfide, we have shown that compounds bearing a semipolar linkage, such as sulfoxides,[2-4] sulfones,[2,4-6] and pyridine *N*-oxides,[7] are reduced to the corresponding sulfides or pyridines by treatment with either sulfur or diaryl disulfide. As an extension of these works we have investigated the reactions of *N*-arenesulfonylsulfilimine and sulfoximine, which are isoelectronic nitrogen analogs of sulfoxide and sulfone, respectively, with both elemental sulfur and diaryl disulfides. This paper will describe the reactions in detail.

Results and Discussion

Reactions of N-*arenesulfonylsulfilimine with Sulfur and Diaryl Disulfide.* When a mixture of one mole-equivalent diphenyl-*N*-*p*-tosylsulfilimine (I) and one atom-equivalent elemental sulfur was heated in refluxing chlorobenzene, diphenyl sulfide was obtained in *ca.* 50% yield. Similarly diphenyl disulfide also reduced I to afford diphenyl sulfide in an almost quantitative yield under a similar reaction condition. In the latter reaction, besides diphenyl sulfide, *N,N*-bis(phenylthio)-*p*-toluenesulfonamide (IIa) was isolated in 28% yield from the product mixture (Eq. (1)). The compound

$$\underset{\underset{\text{N-Ts}}{\downarrow}}{\text{PhSPh}} + \text{PhSSPh} \longrightarrow \text{PhSPh} + \underset{\underset{\text{Ts}}{|}}{\text{PhSNSPh}} \qquad (1)$$

I IIa

Ts=-$SO_2C_6H_4CH_3$-*p*

IIa gives the characteristic IR and NMR spectra and satisfactory analysis of carbon, hydrogen, and nitrogen. In Table 1 the results of the reactions of a few other sulfilimines with disulfides are shown. The relatively small yields of II were attributable to thermal instability of II. In fact, thermal decomposition of IIa took place readily at about 160°C to give diphenyl disulfide and dark colored substance (Eq. (2)).

$$\text{IIa} \longrightarrow \text{PhSSPh} + \text{dark colored substance} \qquad (2)$$

Reactions of Sulfoximine with Sulfur and Diaryl Disulfide. When a mixture of one mole-equivalent diphenyl sulfoximine (III) and one atom-equivalent elemental sulfur was heated at *ca.* 160°C, a dark red colored solution was obtained. From this solution diphenyl sulfoxide was separated in an almost quantitative yield through column chromatography. Diphenyl disulfide was found also to react with III to give diphenyl sulfoxide in *ca.* 86% yield. These results were tabulated in Table 2 together with the results of the reactions of methyl *p*-tolyl sulfoximine.

III

Mechanism of the Reactions of N-*arenesulfonylsulfilimine with Sulfur and Diaryl Disulfide.* *N*-Sulfonylsulfilimines are weak bases[8] and behave as effective nucleophiles,[9] while diaryl disulfide is susceptible to nucleophilic attack.[10] Therefore the initial step of the reaction (1) is considered to be the nucleophilic attack of the negatively charged nitrogen atom of the sulfilimine on the sulfur atom of the S-S bond, forming the sulfonium salt (IV). The subsequent step is presumed to be the homolytic cleavage of the N-S bond of IV to give radical cation of diphenyl sulfide and the amino radical (V) for the following two reasons, (A) and (B). (A) It is known that radical cations can be formed readily from such similar compounds as diaryl sulfide, thianthrene, and phenoxathiin.[11] Moreover, those sulfilimines which are presumed to give the stable radical cations such as thianthrene, phenoxathiin, and dibenzothiophene *N*-tosylsulfilimines actually were found to react with the disulfide very

readily (Table 1). However dialkyl or alkyl aryl sulfilimines, which would not give stable radical cation, did not react or reacted very little. These observations seem to suggest that a radical cation species is involved in the course of the reaction. (B) A strong ESR absorption was observed during the course of the reactions (1) and (2). The spectrum (Fig. 1) clearly indicates that the amino radical V was formed, and which may be considered to be a relatively stable radical species.

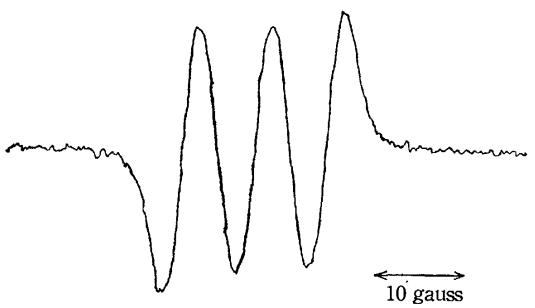

Fig. 1. ESR spectrum of $\cdot N(SPh)SO_2C_6H_4CH_3$-*p*.

In the following scheme the most likely reaction pathway is shown.

The reaction of the sulfilimine with elemental sulfur is considered to proceed through a similar route.

Mechanism of the Reactions of Sulfoximine with Sulfur and Diphenyl Disulfide. Sulfoximine is known to be basic,[12] therefore the following ionic pathway involving the nucleophilic attack of the sulfoximine on sulfur atom of diphenyl disulfide seems to be the most conceivable (Eq. (5)).

Experimental

Materials. Diaryl disulfides were prepared from the corresponding aryl mercaptans by iodine or nitric acid ($(p\text{-}ClC_6H_4S)_2$) oxidation. $(C_6H_5S)_2$ mp 61°C (lit, 61.5°C[13]), $(p\text{-}CH_3C_6H_4S)_2$ mp 46°C (lit, 45.5°C[14]), $(p\text{-}CH_3OC_6H_4S)_2$ mp 43—44°C (lit, 44—45°C[15]), $(p\text{-}ClC_6H_4S)_2$ mp 70—71°C (lit, 73°C[16]).

N-p-Tosylsulfilimines were prepared from the corresponding sulfides and chloramine-T according to the usual procedure.[17] *N*-Benzenesulfonylsulfilimine was prepared similarly from the corresponding sulfide and chloramine-B. (Ts= $-SO_2C_6H_4CH_3$-*p*, B=$-SO_2C_6H_5$). $(CH_3)_2S(:NTs)$ mp 157°C (lit, 157—157.5°C,[17]) $PhS(:NTs)CH_3$ mp 129—130°C (lit, 129—130°C[17]), $Ph_2S(:NTs)$ mp 112°C (lit, 111—112°C[17]), $Ph_2S(:NB)$ mp 120°C, dibenzothiophene(:NTs) mp 169°C (Found: C, 64.06; H, 4.33; N, 3.81%. Calcd for $C_{19}H_{15}NO_2S_2$: C, 64.59; H, 4.25; N, 3.97%), thianthrene(:NTs) mp 166—167°C (Found: C, 59.58; H, 4.04; N, 3.46%. Calcd for $C_{19}H_{15}NO_2S_3$: C, 59.22; H, 3.90; N, 3.64%), phenoxathiin(:NTs) mp 169°C (Found: C, 61.38; H, 4.04; N, 3.74%. Calcd for $C_{19}H_{15}NO_3S_2$: C, 61.79; H, 4.06; N, 3.79%).

Sulfoximines were prepared by the hydrolysis of corresponding *N-p*-tosylsulfoximines with conc. sulfuric acid according to the method used by Bentley and Whitehead.[18] $Ph_2S(:O)(:NH)$ mp 102.5°C (lit, 102—102.5°C[12]), $p\text{-}CH_3C_6H_4S(:O)(:NH)CH_3$ mp 71°C (lit, 71—72°C[12]).

*The Reaction of Elemental Sulfur with Diphenyl-*N-p-*tosylsulfilimine.* Diphenyl-*N-p*-tosylsulfilimine (I), 0.71 g (0.002 mol) and 0.064 g (0.002 g atom) of sulfur was dissolved in 5 ml of chlorobenzene and the mixture was refluxed for about 24 hr. The product obtained was analyzed by thin layer and gas liquid chromatographies, and diphenyl sulfide was obtained as the main product. The yield of the sulfide was determined by gas liquid chromatography as *ca.* 50%.

The Reaction of Diaryl Disulfide with N-*Sulfonylsulfilimine.* Diphenyl disulfide, 0.436 g (0.002 mol) and 0.71 g (0.002 mol) of I was dissolved in 5 ml of chlorobenzene and refluxed for about 40 min until the color of the solution turned to dark red. After the solvent was evaporated a dark red tarry product mixture was obtained. The product was separated by column elusion chromatography through silica gel packed column, and diphenyl sulfide was obtained quantitatively with *n*-hexane as eluent, and subsequently *N,N*-bis(phenylthio)-*p*-toluenesulfonamide (IIa) was obtained with toluene as eluent. The crude IIa was recrystallized from absolute ethanol and colorless needles (mp 97.5—98°C) were obtained (0.276 g, 28%). This was the general procedure applied also for the other runs. The yields of II are shown in Table 1 while mp, IR, NMR, and CH analysis data are shown below. IIa mp 97.5—98°C. Found: C, 58.97; H, 4.49; N, 3.75%. Calcd for $C_{19}H_{17}NO_2S_3$: C, 58.91; H, 4.39; N, 3.62%. IR (cm^{-1}, KBr): ν_{SO_2} 1345 and 1160, ν_{S-N} 875. NMR ($CDCl_3$): 2.40 (s, 3H), 7.00—8.00 (m, 14H). IIb mp 94.5°C. Found: C, 60.43; H, 5.10; N, 3.33%. Calcd for $C_{21}H_{21}NO_2S_3$: C, 60.72; H, 5.06; N, 3.37%. IR (cm^{-1}, KBr): ν_{SO_2} 1345 and 1170, ν_{S-N} 835. NMR ($CDCl_3$): 2.52 (s, 6H), 2.59 (s, 3H), 7.30—8.30 (m, 12H). IIc mp 92.5°C. Found: C, 56.56; H, 4.63; N, 3.15%. Calcd for $C_{21}H_{21}NO_4S_3$: C, 56.38; H, 4.70; N, 3.13%. IR (cm^{-1}, KBr): ν_{SO_2} 1340 and 1160, ν_{S-N} 850. NMR ($CDCl_3$): 2.45 (s, 3H), 3.87 (s, 6H), 6.70—8.00 (m, 12H). IId mp 111—112°C. Found: C, 50.05; H, 3.38; N, 3.10%. Calcd for $C_{19}H_{15}Cl_2NO_2S_3$: C, 50.00; H, 3.29; N, 3.07%. IR (cm^{-1}, KBr): ν_{SO_2} 1350 and 1170, ν_{S-N} 850. NMR ($CDCl_3$): 2.55 (s, 3H), 7.20—8.10 (m, 12H), IIe mp 80.5°C. Found: C, 57.58; H, 4.05; N, 3.78%. Calcd for $C_{18}H_{15}NO_2S_3$: C, 57.91; H, 4.02; N, 3.75%. IR (cm^{-1}, KBr): ν_{SO_2} 1350 and 1170, ν_{S-N} 880. NMR ($CDCl_3$): 7.20—8.20 (m, 15H). IIf mp 92°C. Found: C, 59.51; H, 4.89; N, 3.37%. Calcd for $C_{20}H_{19}NO_2S_3$: C, 59.85; H, 4.74; N, 3.49%. IR (cm^{-1}, KBr): ν_{SO_2} 1350 and 1165, ν_{S-N} 880. NMR ($CDCl_3$): 2.31 (s, 6H), 7.00—8.00 (m, 13H).

The Reaction of Elemental Sulfur with Sulfoximine. Diphenyl sulfoximine (III), 0.217 g (0.001 mol) and 0.032 g (0.001 g atom) of sulfur was placed in a glass tube, and was heated in an oil bath maintained at *ca.* 160°C for 15 min. The red colored product was treated with column chromatography on silica gel. As a main product diphenyl sulfoxide (0.200 g) was obtained in an almost quantitative yield. The same procedure was found to be applied to the reactions of methyl *p*-tolyl sulfoximine with elemental sulfur.

The Reaction of Diphenyl Disulfide with Sulfoximine. Diphenyl disulfide, 0.218 g (0.001 mol), and diphenyl sulfoximine, 0.217 g (0.001 mol) was dissolved in 5 ml of *o*-dichlorobenzene and refluxed for about 5 hr. As a main product diphenyl sulfoxide was obtained in *ca.* 86% yield (0.174 g) by column elusion chromatography on silica gel. The same procedure could be applied to the reaction of methyl *p*-tolyl sulfoximine with diphenyl disulfide.

The Reaction of Diphenyl Disulfide with Dimethyl or Methyl Phenyl N-p-*Tosylsulfilimines.* The reaction of dimethyl-*N-p*-tosylsulfilimine with diphenyl disulfide did not proceed after 15 hr heating in refluxing chlorobenzene and the reactants were recovered. Methyl phenyl *N-p*-tosylsulfilimine was also treated with the disulfide under the same condition, however the reaction proceeded very little.

Thermal Decomposition of IIa. *o*-Dichlorobenzene solution of IIa was heated for *ca.* 1 hr at 160°C. From the dark colored product mixture diphenyl disulfide was obtained as a purely separable substance by chromatography through a silica gel column.

ESR Measurement. In a quartz sample tube 1 mm in diameter was placed the *o*-dichlorobenzene solution of IIa. The spectrum was recorded at 160°C with JES-ME-3X spectrometer. An identical spectrum was observed in the course of the reaction of I with diphenyl disulfide.

Optical Resolution of Aspartic Acid by Using Copper Complexes of Optically Active Amino Acids*

Kaoru HARADA and Wung-wai Tso

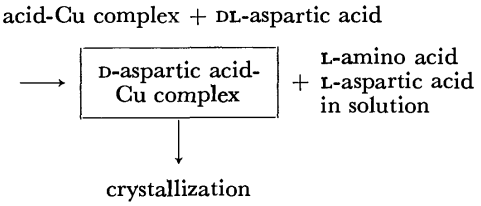
Institute for Molecular and Cellular Evolution and Department of Chemistry, University of Miami, 521 Anastasia Avenue, Coral Gables, Florida 33134, U.S.A.

(Received September 28, 1971)

Optical resolution of DL-aspartic acid by using copper complexes of L-alanine, D-alanine, L-glutamic acid, D-glutamic acid, and L-proline in aqueous solution is described. In this investigation the effects of (1) the concentration of reactants and (2) the ratio of the optically active amino acid to racemic aspartic acid in the reaction mixture were studied.

Studies have been made[1,2] on the optical resolution of racemic aspartic acid by the use of enzymatic and also diastereomeric chemical methods. Several methods have been reported for the optical resolution of racemic aspartic acid or a racemic aspartic acid copper complex. Racemic aspartic acid was optically resolved by employing optically active amines[3] and by seeding a supersaturated solution of DL-aspartic acid with ammonium formate.[4,5] Racemic aspartic acid copper complex was resolved easily by seeding with either an L- or D-aspartic acid copper complex.[6] Racemic aspartic acid copper complex was partially resolved by using biopolymers such as cotton or wool.[7] It was found that a supersaturated solution of racemic aspartic acid copper complex was spontaneously resolved into partially optically active L-aspartic acid copper complex.[8] Several investigations of the utilization of metal chelate compounds for optical resolution of racemic amino acids have been reported.[9,10,11]

The optical resolution of DL-aspartic acid by adding a solution of DL-aspartic acid to solutions of the copper complexes of D- or L-alanine, D- or L-glutamic acid, or L-proline was reported.[12] The mixture was allowed to stand for 24 hr to crystallize the aspartic acid copper complex. The optically active aspartic acid copper complex that crystallized had a configuration opposite to the optically active amino acid used in the reaction. This simple procedure for the resolution of racemic aspartic acid yielded 90—100% optically active D- or L-aspartic acid. The phenomenon was explained as a stereoselective ligand exchange reaction.[12] This paper reports the effects of (1) the concentration of reactants and (2) the ratio of the optically active amino acid to racemic aspartic acid on the resolution of racemic aspartic acid.



L-Alanine (0.01, 0.02, and 0.03 mol) was treated with copper carbonate for preparation of the solution (50 m*l*) of L-alanine copper complex. Racemic aspartic acid (0.01, 0.02, and 0.03 mol) in 100 m*l* of water was added to each of the solutions of L-alanine copper complex. Since the crystallization of the aspartic acid copper complex depended on the composition and concentration of the reaction mixture, the crystallization was carried out from several hours to 24 hr. The crystals were then collected by filtration (1st crop). The filtrate was allowed to stand longer (24—72 hr) for the 2nd crop of crystals of the aspartic acid copper complex to grow. The results of resolution of racemic aspartic acid by using L-alanine copper complex are summarized in Table 1.

We see that in reactions A-1, B-2, and C-3, the total amount of aspartic acid copper complex increased as the concentration of the reaction mixture was increased. Figure 1 shows the amount of crystalline aspartic acid copper complex normalized to 0.01 mole racemic aspartic acid. For the 1st crop of crystals, the maximum crystallization occurred when the molar ratio of L-alanine to DL-aspartic acid was about 1.5. The total amount of crystalline complex (1st and 2nd crops) was almost constant when the molar ratio of L-alanine to DL-aspartic acid exceeded 1.5. Figure 2 shows the optical purity of aspartic acid obtained from the 1st and 2nd crops as a function of the molar ratio of L-alanine to DL-aspartic acid. The aspartic acid from the 1st crop was always of the D-configuration; whereas, the configuration of aspartic acid from the 2nd crop depended upon the molar ratio of L-alanine to DL-aspartic acid. When the molar ratio was less than 1, the 2nd crop of crystals had a D-configuration as in the 1st crop. On the other hand, when the molar ratio was greater than 1, the 2nd crop of crystals had an L-configuration. The sharp inversion of configuration in the 2nd crop of

crystals is interesting and might be understood by taking into account the amount of DL-aspartic acid in the reaction mixture.

Figure 3 shows the results of a similar optical resolution of DL-aspartic acid by using L-proline copper complex. The amount of crystalline aspartic acid copper complex is normalized to 0.01 mole racemic aspartic acid. The curves are similar to those in Fig. 1. The 1st crop shows a maximum at a molar ratio of about 2. The total amount of crystalline complex reaches a plateau at a molar ratio of 2. Figure 4 shows the optical purity of aspartic acid obtained from the 1st and 2nd crops as a function of the molar ratio of L-proline to DL-aspartic acid. The aspartic acid from the 1st crop always had a D-configuration; whereas, the aspartic acid from the 2nd crop had a D-configura-

tion when the molar ratio of L-proline to DL-aspartic acid was less than 0.9. The aspartic acid had an L-configuration when the molar ratio was greater than 1. The curves are similar to those in Fig. 2. Figure 5 shows the amount of crystalline aspartic acid copper complex and optical purity of aspartic acid obtained by prolonged crystallization for up to 7 days. In this experiment, the molar ratio of L-proline to DL-aspartic acid was 1. As the degree of crystallization increased, the optical purity of the aspartic acid decreased rapidly.

Figure 6 shows the results of the optical resolution of DL-aspartic acid by using L- or D-glutamic acid copper complex. Optically active glutamic acid copper complex gave the highest stereospecific resolution of DL-aspartic acid. Figure 6a shows the optical purity of aspartic acid obtained from the 1st and 2nd crops as a function of the molar ratio of L-glutamic acid to DL-aspartic acid. The aspartic acid from the first crop shows a maximum optical purity when the molar ratio of L-glutamic acid to DL-aspartic acid was 1. In comparison, the optical purity of the aspartic acid from the 2nd crop is high throughout. Figure 6b shows almost the same results by using D-glutamic acid.

The optical resolution of racemic aspartic acid using several copper complexes of optically active amino acids was explained by a stereoselective ligand exchange mechanism and subsequent preferential crystallization.[9] However, attempts to observe the possible stereoselective ligand exchange by the absorption spectrum and the mutarotation of the reaction mixture were unsuccessful. These observations together with the rapid rate of ligand exchange in copper complexes suggest that the proposed stereoselective ligand exchange may not represent the mechanism of these reactions.

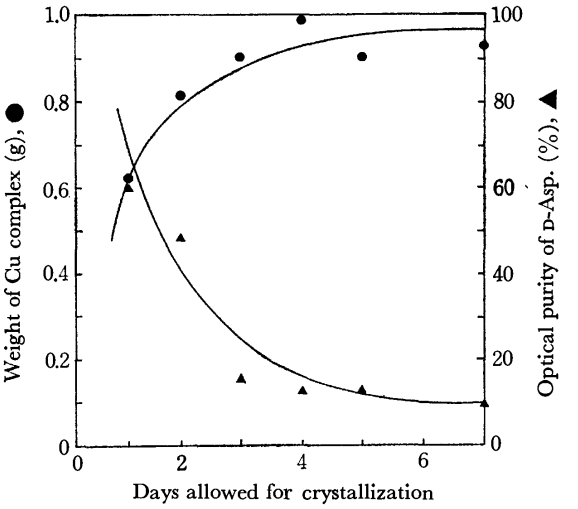

Fig. 5. Weight of aspartic acid copper complex and optical purity of aspartic acid *versus* days allowed for crystallization. (Cu complex prepared from 0.01 mol L-Pro and 0.01 mol DL-Asp in 150 m*l* H_2O)

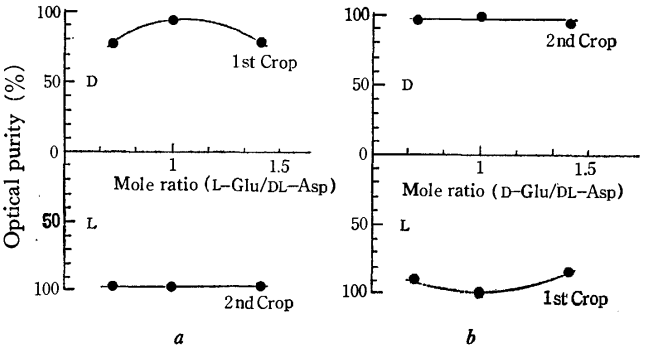

Fig. 6. Optical purity of aspartic acid *versus* mole ratio; a: L-glutamic acid copper complex was used; b: D-glutamic acid copper complex was used.

Experimental

Copper Complex of Optically Active Aspartic Acid (Reaction A-1). L-Alanine (0.89 g, 0.01 mol; Mann Research Laboratories, Inc.; $[\alpha]_D^{25} = +14.3°$ in 6N HCl) was boiled gently with 5.0 g of copper carbonate (Baker Analytical Grade) in 50 m*l* of water for five minutes. The excess of copper carbonate was removed by filtration under reduced pressure. DL-Aspartic acid (1.33 g, 0.01 mol; Mann assayed grade) in 100 m*l* of hot water was added through filter paper to the filtrate. The solution was kept at room temperature for 1 day without agitation. The crystallized D-aspartic acid copper complex, 0.48 g, was collected by filtration. The filtrate was allowed

to stand an additional two days for further crystallization. L-Rich aspartic acid copper complex, 0.51 g, was obtained.

Other amino acids used were L-proline ($[\alpha]_D^{20}=-51.8°$, 0.5N HCl), L-glutamic acid ($[\alpha]_D^{20}=+31.5°$, 6N HCl), and D-glutamic acid ($[\alpha]_{20}^{D}=-31.5°$, 6N HCl).

Preparation of Free Aspartic Acid. The optically active aspartic acid copper complexes were dissolved by heating in 30 to 50 m*l* of 7% acetic acid. The copper ion in each solution was removed by precipitation with hydrogen sulfide. After the precipitation was complete, a small amount of activated charcoal was added to the solution and the solution was cooled to room temperature. The mixture was then filtered and the filtrate was evaporated to dryness under reduced pressure. The aspartic acid was weighed and its specific rotation was measured without further purification.

Some of the optically active preparations of aspartic acid contained a trace to a small amount of the other optically active amino acid used in the resolution reaction (L-ala, L-pro, L- and D-glu). The impurities were detected by paper chromatography. The small amounts of impurities could be eliminated easily by one recrystallization from 25 volumes of water. The optical purity of aspartic acid was measured without recrystallization, since such a purification procedure would cause considerable fractionation of partially optically active aspartic acid. All the optical rotation measurements were carried out by the use of a Rudolph Model 80 polarimeter with a PEC-101 photometer at 25°C using a 10 cm cell.

Polymerization of Vinyl Monomers in the Presence of Surface Active Agents. II. The Rate of Polymerization of Methyl Methacrylate

Teruzo ASAHARA, Manabu SENŌ, Shinsaku SHIRAISHI, and Yoshikazu ARITA

Institute of Industrial Science, University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received January 22, 1972)

The polymerization of methyl methacrylate in the presence of sodium tetrapropylenebenzenesulfonate(ABS) in an aqueous system without any ordinary initiators was examined kinetically. The rate of polymerization of methyl methacrylate is dependent on the initial concentrations of methyl methacrylate and ABS, and expressed by the equation:

$$R_p \propto [\mathrm{ABS}]^{0.37}[\mathrm{MMA}]^{0.32}$$

The apparent activation energy of the polymerization is about 3 kcal/mol. It was confirmed by electron microscopic observation that the number of polymer molecules is in the same order as that of the micelle particles in the polymerization system.

We reported previously on the polymerization of methyl methacrylate (MMA) in the presence of anionic surface active agents such as alkylbenzenesulfonate (ABS) in an aqueous system without any ordinary initiators. This system gave a stable emulsion of poly(MMA) with an unusually high molecular weight in a good yield.[1)]

In this paper, the results of a kinetic study of the polymerization of MMA in the presence of ABS in an aqueous system will be described.

Experimental

Materials. Methyl methacrylate and sodium tetrapropylenebenzenesulfonate (ABS) were purified according to the method described previously.[1)] Diphenylpicrylhydrazyl (DPPH) of G.R. grade was used without further purification.

Determination of the Rate of Polymerization. 100 g of deionized water and a desired amount of ABS were placed in a four-necked, flat bottomed 100 m*l* flask equipped with a condenser, a dropping funnel, a nitrogen inlet tube and a rubber stopper. The mixture was then preheated at a prescribed reaction temperature for 40 min, a slow stream of nitrogen being introduced into the mixture. MMA was then added through the dropping funnel and allowed to polymerize. About 2 g of the reaction mixture was withdrawn by a syringe and accurately weighed at regular time intervals. The weighed sample was poured into 10 m*l* of methanol in order to precipitate the polymer formed, which was collected by filtration, washed with methanol, dried at 60°C under a vacuum and weighed. The rate of polymerization was determined from the weight of the precipitate.

Determination of Number of Particles. Particle size determination was carried out on a sample of about 1 g which was withdrawn from the reaction mixture and diluted with 10 times as much water containing 0.01% of hydroquinone which was used to minimize further change. The diluted sample was deposited onto the collodion substrates in the form of minute droplets of approximately 2 micron in radius. The specimen was shadow-cast with carbon, and the electron micrographs were taken with a JEM-5Y electron microscope of magnification 9800 at 80 kV. The surface average dia-

1) T. Asahara, M. Senō, S. Shiraishi, and Y. Arita, This Bulletin, **43**, 3895 (1970).

meters of particles were obtained on 50—100 particles in an enlarged (×2) photograph using a Scale Lupe of magnification 5. The number of particles was calculated from the volume average diameter and the density of particles which was approximated to be 1.0.

Measurement of the Generated Radicals. 50 m*l* of water or an organic solvent (THF or ethyl acetate), 0.3 g of ABS, and 1 m*l* of MMA or ethyl acetate, each containing 5.0 mg of DPPH, were placed in an apparatus as shown in Fig. 1. If the mixture was not a clear solution, a few drops of octaoxyethylene nonylphenyl ether were added as a solubilizer. The mixture was shaken well and subsequently frozen in a liquid nitrogen bath. It was then brought to a vacuum below 10^{-3} Torr in order to degas, and then allowed to melt. This freeze-thaw procedure was repeated three times to attain complete degassing. The degassed mixture was then heated in an oil bath at 80±0.2°C and the absorption of each sample at 530 mμ was measured at regular time intervals.

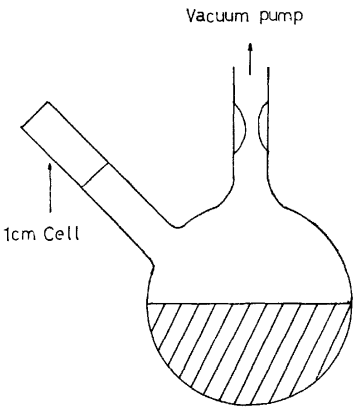

Fig. 1. Apparatus for measurement of generated radicals.

Results and Discussion

We found[1] that MMA polymerized readily in the presence of an anionic surface active agent in water without any ordinary initiators. The mechanism of the polymerization, however, has not been clarified yet. A kinetic approach to the polymerization was attempted and the relationship between the rate of polymerization and the initial monomer concentration or the ABS concentration was investigated. The quantity of the free radicals generated in the reaction system was also measured spectrometrically by using DPPH in order to obtain information on the initiation mechanism of the polymerization.

For a case of usual emulsion polymerization, Smith and Ewart presented the following equation for the rate of polymerization:[2]

$$R_p = k_p[\mathrm{M}]/N/2, \quad (1)$$

where k_p is the rate constant of the propagation reaction, [M] is the monomer concentration in the particles which is supposed to remain constant until the excess monomer droplets disappear in the system, and N is the number of particles. Thus R_p is dependent only on N. Smith and Ewart also pointed out that the relationship between N and the concentration of emulsifier was as follows:

$$N = k(\mathrm{CsAs})^{3/5}(\rho/\mu)^{2/5} \quad (2)$$

where As is the surface area of a particle, Cs is the concentration of the emulsifier present, ρ is the rate of generation of radicals, μ is the rate of volume increase of the particles and k is a constant with value 0.37—0.57.

Their theory, however, cannot be applied to our reaction system, in which R_p depends on the initial monomer concentration $[\mathrm{M}]_0$, which is defined as an apparent molarity calculated from the composition in the initial reaction mixture. A plot of log R_p against log $[\mathrm{M}]_0$ is found to be linear as shown in Fig. 2. The relationship can be expressed by the equation:

$$R_p \propto [\mathrm{M}]_0^{0.32}$$

The result may imply that the monomer concentration in the particles does not remain constant in the present reaction system.

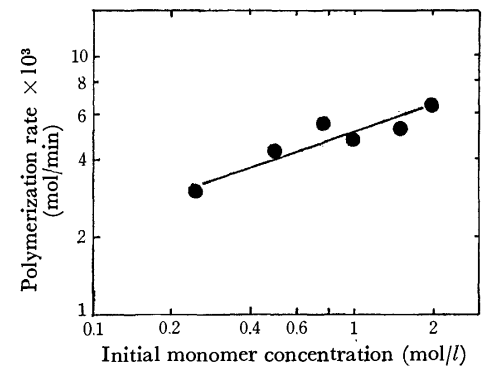

Fig. 2. Dependence of polymerization rate (mol/min) on initial monomer concentration (mol/*l*).
ABS 0.3 g/100 g of water, 80°C, under nitrogen atmosphere. Slope of line 0.32.

While Smith and Ewart also showed that the value of R_p was proportional to 0.6th power of the concentration of the emulsifier, Lee and Longbottom[3] have proposed the following equation:

$$R_p \propto [\mathrm{Cs}]^{0.18-0.55}$$

The rate of polymerization of our system depends on the concentration of ABS. As seen from Fig. 3, the relation between R_p and [Cs] is given by

$$R_p \propto [\mathrm{Cs}]^{0.37}$$

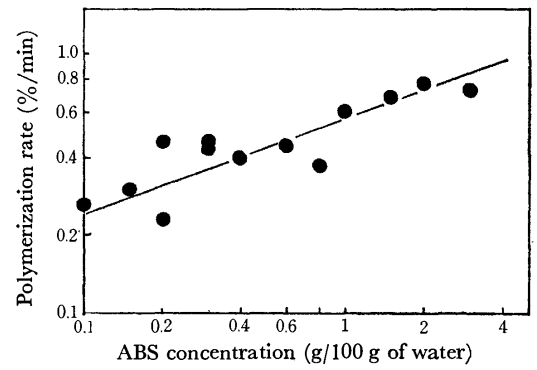

Fig. 3. Dependence of polymerization rate (%/min) on ABS concentration.
MMA 10 g, 80°C, under nitrogen atmosphere. Slope of line 0.37.

2) W. V. Smith and R. H. Ewart, *J. Chem. Phys.*, **16**, 592 (1948).

3) P. I. Lee and H. M. Longbottom, *J. Appl. Polym. Sci.*, **14**, 1377 (1970).

The rate of polymerization was measured at temperatures 70—100°C and the results are shown in Table 1. The activation energy of the overall polymerization reaction is about 3 kcal/mol. This value is very small compared to the values reported hitherto for the radical polymerization of MMA. The polymerization rate decreased at 100°C. This might be due to the increase of the rate of termination reaction or the reduced stability of particles caused by boiling of the reaction mixture. The induction period decreased with an increase of reaction temperature, but an estimation of the activation energy of the initiation reaction from the period was not successful.

The average degree of polymerization of the poly(MMA), DP, was obtained from the intrinsic viscosity measurement[1] and the result is plotted against the initial monomer concentration and the ABS concentration (Figs. 4 and 5). The DP is almost independent of both ABS and $[M]_0$. It tends to increase slightly with a rise in reaction temperature, presumably because the rate constant of the propagation increases with an increasing temperature (Table 1). In every case, DP is very high as we have emphasized.[1] It might be explained as follows: The number of generated radicals is very small, radicals rarely exist simultaneously in the same particle and the termination by radical coupling hardly takes place.

This is rationalised by a comparison of the number of polymer molecules formed with that of the polymer particles. The number of polymer molecules was calculated from polymer yields and molecular weight.

Table 1. Effect of reaction temperature on polymerization rate and DP

Reaction temperature (°C)	Polymerization rate (mol/min)	DP
70	4.42×10^{-3}	5.48×10^{-4}
80	4.59	5.90
85	4.39	5.50
90	6.05	6.80
100	5.38	6.31

MMA 10 g; water 100 g; ABS 0.3 g under nitrogen atmosphere.

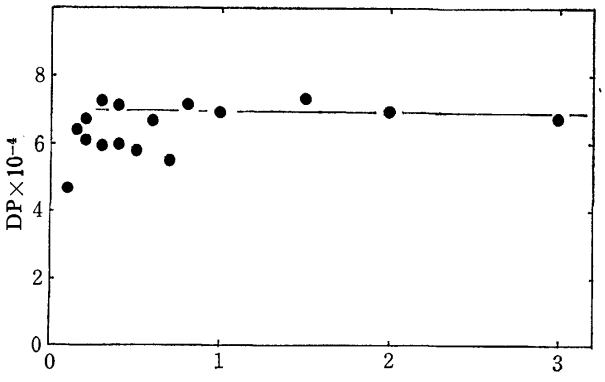

Fig. 4. Dependence of DP on ABS concentration.
MMA 10 g, 80°C, 2 hr, under nitrogen atmosphere.

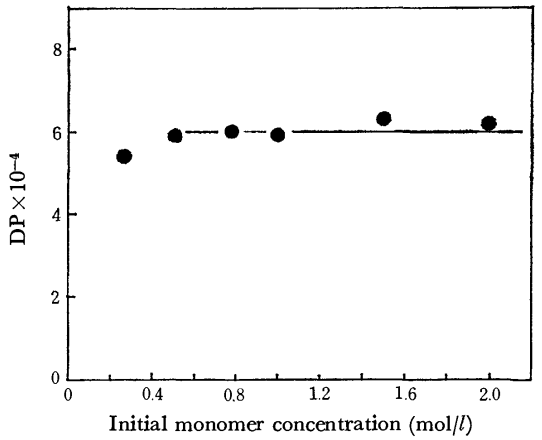

Fig. 5. Dependence of DP on initial monomer concentration.
ABS 0.3 g, water 100 g, 80°C, 2 hr, under nitrogen atmosphere.

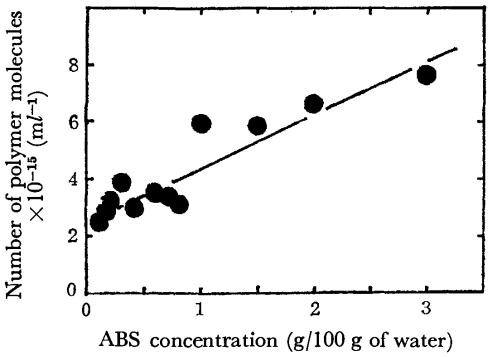

Fig. 6a. Dependence of number of polymer molecules on ABS concentration.

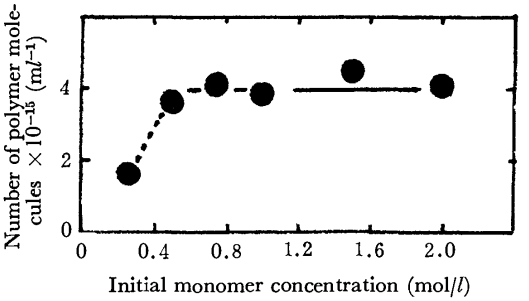

Fig. 6b. Dependence of number of polymer molecules on initial monomer concentration.
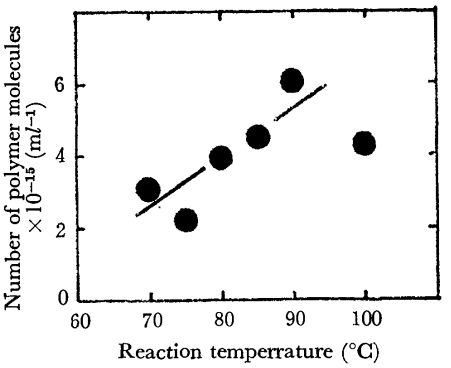
ABS 0.3 g, water 100 g, 80°C, 2 hr, under nitrogen atmosphere.



Fgi. 6c. Dependence of number of polymer molecules on reaction temperature.
ABS 0.3 g, MMA 10 g, water 100 g, 2 hr, under nitrogen atmosphere.

The effects of the concentrations of ABS and monomer and of the reaction temperature on the number of polymer molecules are shown in Figs. 6a, b, and c. The number of polymer molecules increased with the increasing concentration of ABS and increasing reaction temperature, but was not affected by the concentration of monomer in the concentration range above 0.5 mol/*l*. We see from the results that the generated radicals increased with the increasing concentration of ABS and temperature.

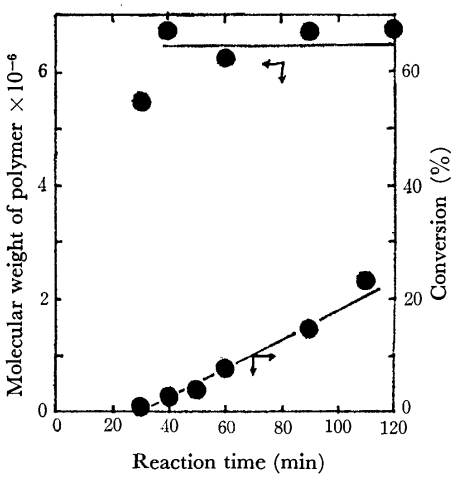


Fig. 7. Dependence of molecular weight of polymer on reaction time.
MMA 50 g, ABS 2.5 g, water 500 g, 80°C, under nitrogen atmosphere.

When a steady state was reached (Fig. 7), direct determination of particle size was attempted with an electron microscope. The samples were prepared under the conditions; reaction time 30, 60, and 120 min, the ABS concentration 1 g and 3 g per 100 g of water.

The results are shown in Fig. 8 and Table 2. The result in Table 2 shows that the particle size is in the relatively narrow range 300—400 Å independent of the concentration of ABS and the reaction time. The maximum particle size is 1000—1200 Å and the particles which are supposed to be generated newly were observed at every reaction time. The number of polymer particles per unit volume is about 1×10^{15}, which is in the same order as the number of polymer molecules calculated above. Since poly(MMA) scatter electrons poorly and give electron micrographs of a low contrast, we used the shadow-casting with carbon.

Table 2. Particle size of MMA latices

ABS (g)	Reaction time (min)	Average diameter (Å)	Number of polymer particles (ml^{-1})	Number of polymer molecules[a] (ml^{-1})
1	30	414

Fig. 8. Electron micrographs of MMA latices. The samples are at reaction time; 30 min (a), 60 min (b), 120 min (c). ABS 1 g/100 g water. (×19600).

It may be presumed that the polymerization in particles proceeds in a similar way to that in bulk polymerization. Thus the relation between the degree of polymerization and the initial monomer concentration can be represented by the equation:

$$DP = k_p/\{k_t[P\cdot]/[M]+k_{tr}\}$$

where k_p, k_t, and k_{tr} are rate constants of propagation, termination and chain transfer to monomer, respectively, and [P·] and [M] are concentration of growing radical and monomer in the particle, respectively.

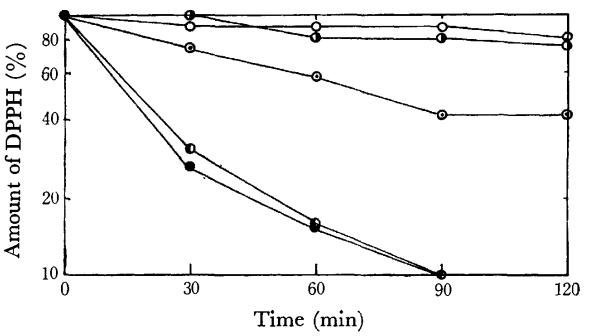

Fig. 9. Time changes of disappearance of DPPH in various system.
◐ H_2O 50 m*l*; ABS 0.3 g; MMA 1 m*l*; DPPH 5 mg
⊙ THF 50 m*l*; ABS 0.3 g; MMA 1 m*l*; DPPH 5 mg
◑ THF 50 m*l*; ABS none; MMA 1 m*l*; DPPH 5 mg
● H_2O 50 m*l*; ABS 0.3 g; ethyl acetate 1 m*l*; DPPH 5 mg
○ ethyl acetate 50 m*l*; ABS 0.3 g; ethyl acetate 1 m*l*; DPPH 5 mg

The ratio [P·]/[M] can be regarded as negligibly small from the results in Table 2. Thus $DP \simeq k_p/k_{tr}$ which is constant. In fact, DP is independent of monomer concentration as shown in Fig. 5, which gives $k_p/k_{tr}=6\times10^4$.

Measurement of the generated radicals was carried out by using DPPH as a radical scavenger in MMA or ethyl acetate. The absorption of DPPH in the presence of water or organic solvents was measured at 530 mμ with a spectrophotometer. As shown in Fig. 9, when an organic solvent such as THF or ethyl acetate was used instead of water, the amount of DPPH remained almost constant. In an aqueous system, in spite of the presence of MMA, the absorption of DPPH decreases markedly in intensity in the presence of ABS. These results are seen to reflect a specific role of the interface, and are consistent with the fact that a surfactant shows the surface activity only in an aqueous medium.

Thus, it is plausible that the polymerization is initiated at the surface of the micelle particles.

The authors are indebted to Mr. Shigeki Shiozawa for his technical assistance.

Model Reactions for the Biosynthesis of Thyroxine. XIX. The Formation of a Thyroxine Precursor by Photooxidation of 4-Hydroxy-3,5-diiodophenylpyruvic Acid in Organic Solvents[1-3]

Kanji OMURA, Akira NISHINAGA, and Teruo MATSUURA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received January 20, 1972)

Photooxidation of 4-hydroxy-3,5-diiodophenylpyruvic acid (I) in methanol was found to yield a hydroperoxide (IV). This hydroperoxide reacted anaerobically with 3,5-diiodotyrosine (II) to form thyroxine (III). A photoproduct, presumably IV, apparently accelerated the oxidation of I. Methanol, among several organic solvents, was found to be the best solvent for the photooxidation. Similar oxidations with 4-hydroxy-3-iodo-5-methoxyphenylpyruvic acid (V) and 4-hydroxyphenylpyruvic acid (VI) showed that the rate of oxidation decreased in the order I>V>VI. A product of the photooxidation of I, probably the hydroperoxide IV, also acts as an accelerator in the photooxidation of the desiodo analog VI of I.

A nonenzymic model reaction for the biosynthesis of thyroxine was reported by Meltzer and Stanaback,[4] who showed that autoxidation (pH 7.5) of 4-hydroxy-3,5-diiodophenylpyruvic acid (I) in the presence of 3,5-diiodotyrosine (II) yields thyroxine (III) in moderate yield. Nishinage *et al.*[5] have demonstrated that the reaction takes place in two distinct phases: the enolic form of I is first autoxidized to a hydroperoxide (IV), which then reacts with II to form III in an over-all yield of up to ~40%. Oxygen was found to be required only in the first step, but not in the second.[5]

Structural requirements for the autoxidation of I in aqueous media were found to be the existence of I in its enolic form and the dissociation of the phenolic proton. A solution of I in an organic solvent does not consume oxygen.[6] In organic solvents I exists in its enolic form,[5] but the phenolic hydroxyl is undissociated. This observation prompted us to investigate the photooxidation of I by oxygen in organic solvents. This paper also includes some results obtained in similar photooxidations (sensitized or unsensitized) of two analogs of I, *viz.* 4-hydroxy-3-iodo-5-methoxyphenyl-

Results and Discussion

Photooxidation of I. A solution of I in methanol was irradiated at ~5°C with a 100 W high-pressure mercury lamp of Pyrex housing. Oxygen was bubbled through the solution during the irradiation until the absorption of oxygen was nearly quantitative (0.93 mol/mol of I). The solution contained the hydroperoxide IV as shown by the isolation of the diol acid VII after reduction of the photolysate with sodium borohydride. The yield of VII was 57% (based on I). The identity of VII was confirmed by direct comparison with the previously described diol acid VII.[5] Treatment of the photolysate with 3,5-diiodotyrosine (II), described previously,[5] gave thyroxine (III) in 18.6% yield (also based on I). Treatment of a methanolic solution of I with oxygen in the dark, followed by treatment with II yielded no thyroxine (III). It can therefore be concluded that dissociation of the phenolic proton of I, a prerequisite for the autoxidation in aqueous media (pH 7.5),[5] is not required for the photooxidation in methanol.

9	Same+1.1 mM rose bengal	45	0.23	1.1

a) A solution of I (2.3 mmol) in a solvent (100 ml) was irradiated at ~5°C with light above 2800 Å under oxygen-bubbling.
b) Irradiated at 22°C.
c) Not determined.

The photochemical conversion of I to IV is an additional example of the resemblance betweeen certain photochemical and biological oxidations.[7] It is similar to the photooxidation of other enolic compounds.[7b,8] Moreover, it provides a new synthetic route to thyroxine.

Solvent Effect on the Photooxidation of I. The effect of solvents on the oxygen consumption of I under irradiation and on the formation of III after treatment of the photolysate with II are shown in Fig. 1 and Table 1. The best yield of III was obtained in methanol at ~5°C (Exp. 1). At room temperature the yield was decreased (Exp. 2). A similar decrease in yield with increased temperature had been observed previously in the autoxidation in an aqueous medium at pH 7.4.[6] It should be noted that the photooxidation in methanol is apparently an auto-catalytic reaction, since the maximam rate was reached only after about 10—15 min (Fig. 1). A similar phenomenon was also observed in the autoxidation of I in an aqueous medium,[5] where a radical chain reaction is believed to occur. In the case of the photooxidation, however, it probably can be attributed to an accelerating effect of the reaction product (IV) (see below). In acetone the rate of the reaction, without any induction period, was higher than with methanol. Acetone, however, seems to promote also the decomposition of the reaction product (IV), as suggested by the lower yield of III (Exp. 4). In tetrahydrofuran induced oxidation of the solvent appears to occur, since the yield of III was low in spite of the absorption of an excess of oxygen (Exp. 6). The slower rate of oxidation in pyridine can be attributed to the absorption of the incident light by the solvent (Exp. 7). It must be assumed that even in this case, the thermally[5] and presumably photochemically unstable hydroperoxide IV is formed, but then destroyed during the long period of irradiation. Consequently, no thyroxine (III) could be isolated in this case after treatment of the reaction mixture with

diiodotyrosine (II). Oxygen was hardly absorbed in boric acid solution (pH 4.5) on irradiation (Exp. 8), while facile absorption was observed in the autoxidation of I in boric acid–NaOH (pH 7.5).[5] The addition of boric acid to methanol did not alter the extent of oxygen uptake or the yield of thyroxine (III) (Exp. 3).

Accelerating Effect of the Hydroperoxide IV in Methanol. As mentioned above, the conversion of I into IV in methanol is slow at first, but becomes faster with time. A possible explanation for this is a photochemically initiated radical-chain reaction, since similar phenomena can often be found in many autoxidation reactions, including that of I itself,[5] which are believed to proceed *via* a radical-chain mechanism.

An intermittent irradiation experiment seemed, however, to exclude this possibility, since no oxygen uptake was observed during the interruption of irradiation (Fig. 2). Upon resumption of the irradiation the rate of oxygen uptake became the same value which had been reached prior to the interruption of the irradiation. An alternative explanation for the sigmoid shape of the oxygen uptake curve would be an accelerating effect exerted by the photoproduct, presumably the hydroperoxide IV or by one of its degradation products. This possibility was supported by a photooxidation experiment with I in the presence of the hydroperoxide IV which was supplied in the form of a freshly photooxygenated solution of I (Fig. 3). In

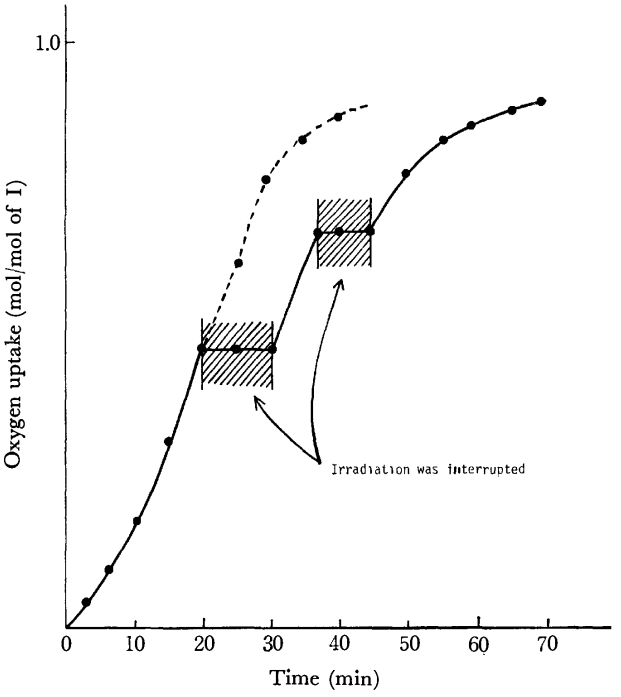

Fig. 2. Intermittent irradiation (>2800 Å) of I (2.3 mmol) in methanol (90 m*l*) at 25°C. ----Intermittent irradiation, ——uninterrupted irradiation.

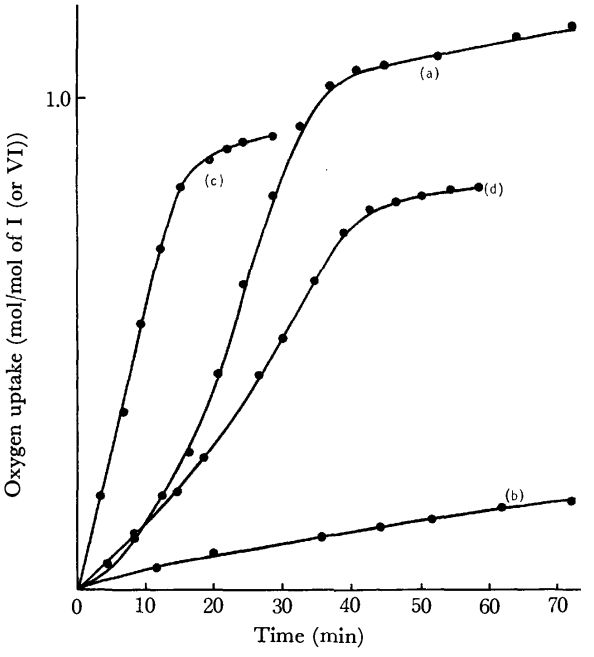

Fig. 3. Effect of the photooxidation product of I on the oxygen uptake of I (1.16 mmol) or VI (1.16 mmol) on irradiation (>2800 Å) in methanol (100 m*l*) at ~2°C. (a) I alone, (b) VI alone, (c) I added to a freshly photooxygenated solution (oxygen uptake 100%) of I (1.16 mmol), (d) VI added to a freshly photooxygenated solution (oxygen uptake 100%) of I (1.16 mmol).

this case the rate of oxygen uptake was maximal even at the initial stage of the reaction. The accelerating action of a photooxygenated solution of I is even more strikingly illustrated by the acceleration of the photooxidation of the desiodo analog of I, 4-hydroxyphenylpyruvic acid (VI), which by itself undergoes only very slow photooxidation (Fig. 3, see also below). The hydroperoxide IV is the main product (~60%) of the oxidation of I, and neither 4-hydroxy-3,5-diiodobenzaldehyde nor 2,6-diiodobenzoquinone, known as degradation products of IV,[5] had an appreciable accelerating effect.

The mechanism of the acceleration remains to be elucidated. The generation of singlet oxygen by the interaction of the excited IV with triplet oxygen[9] seems improbable since the photooxidation of 2,5-dimethylfuran was insufficiently sensitized by the hydroperoxide IV, and addition of a small amount of rose bengal, a typical sensitizer for generating singlet oxygen, had little effect on the photooxidation of I.

Sensitized and Unsensitized Photooxidation of V and VI. Photooxidations were also carried out with 4-hydroxy-3-iodo-5-methoxyphenylpyruvic acid (V) and 4-hydroxyphenylpyruvic acid (VI) in methanol in the presence or in the absence of a sensitizer. As shown in Fig. 4, the unsensitized oxygenation of V was slower than that of I. The slowest absorption of oxygen was observed in the case of the desiodo analog VI. The photooxidation of these acids was faster in acetone than in methanol, but the order of the reaction rates was again I>V>VI. Rose bengal was also found to accelerate the photooxidation of V and VI (Figs. 5 and 6). In each case the rate of oxygen consumption increased with increased sensitizer concentration. It should, however, be noted that the amount of rose bengal used was larger than that usually required for a typical photosensitized oxidation. Addition of a small amount of rose bengal, which is sufficient to sensitize the photooxidation of an olefinic compound, had only a weak sensitizing effect.

It may be therefore assumed that the mechanism of the rose bengal-sensitization of the photooxidations described in this respect is different from the usual

(a) Rose bengal (1.1 mmol), (b) rose bengal (0.32 mmol), (c) rose bengal (0.032 mmol), (d) without rose bengal, (e) rose bengal (1.1 mmol) alone (without VI).

Table 2. Photooxidation of V and VI in methanol[a)]

Exp No.	Compound	Rose bengal added (mmol)	Irradiation time (min)	Oxygen uptake (mol/mol of substrate)	Peroxide[b)] (%)	Thyroxine analogs[c)] (%)
10	V	—	120	0.90	—[d)]	X (trace)
11	V	0.12	35	0.57	—[d)]	X (1.3)
12	VI	—	60	0.12	—[d)]	—[d)]
13	VI	0.16	35	0.50	12	—[d)]
14	VI	1.1	35	0.80	40	—[d)]

a) A solution of V (2.3 mmol) or VI (4.6 mmol) in methanol (100 m*l* or 220 m*l*, respectively) was irradiated (>2800 Å) at ~2°C under oxygen-bubbling.
b) Estimated by iodometric titration.
c) Isolated after the photolysate was treated with II (see Experimental).
d) Not determined.

photosensitized oxidation, involving singlet oxygen and the triplet sensitizer, in which self-quenching occurs at higher concentrations of the sensitizer resulting in a slower reaction rate. Additional support for this assumption is provided by the finding that the rate of photosensitized oxidation of 2,6-di-*t*-butylphenol, where singlet oxygen is believed to be involved at least in part,[10] decreases with increased sensitizer concentration (Fig. 7).

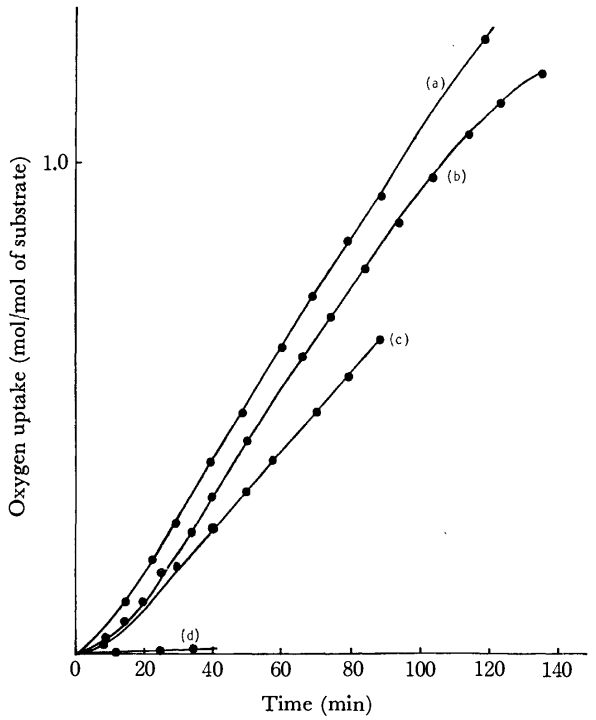

Fig. 7. Oxygen uptake by irradiation (>2800 Å) of 2,6-di-*t*-butylphenol (1.16 mmol) in the presence of various amounts of rose bengal in methanol (90 m*l*) at ~2°C. (a) Rose bengal (0.032 mmol), (b) rose bengal (0.32 mmol), (c) rose bengal (1.1 mmol), (d) without rose bengal.

The structure of the products of the photosensitized oxidation of V and VI has not yet been elucidated. The formation of a hydroperoxide (VIII or IX, analogs of IV) cannot be excluded, since irradiation of VI in the presence of rose bengal yielded a product capable of oxidizing iodide to iodine and the photolysate of V gave a thyroxine analog (X) on reaction with 3,5-diiodotyrosine (II), although in low yield (Table 2).

Experimental

Materials. 4-Hydroxy-3,5-diiodophenylpyruvic acid was purchased from Osaka Lanoratory of Synthetic Organic Chemicals. 4-Hydroxy-3-iodo-5-methoxyphenylpyruvic acid[11] and 4-hydroxyphenylpyruvic acid[12] were prepared according to the described methods. The solvents were freshly distilled before use.

Oxygen Uptake Experiments. A solution was irradiated using a 100W high-pressure mercury lamp with a Pyrex cooling jacket (ice-water). The reaction vessel was immersed in ice-water. During irradiation oxygen was bubbled through the solution in a closed circulating system equipped with a circulation pump and the consumption of oxygen was determined manometrically. In order to assure a constant irradiation level, the lamp was turned on at least 10 min before the start of the experiment while the solution was shielded from the light. The reaction was started by removal of the shield.

A. Photooxidation of 4-Hydroxy-3,5-diiodophenylpyruvic Acid (I) in Methanol. A solution of I (2.0 g) in methanol (200 m*l*) was irradiated at ~5°C for 70 min. During this period 97 m*l* of oxygen was absorbed. Iodometric titration of an aliquot (20 m*l*) of the light brown photolysate showed that liberated iodine was corresponding to 59% peroxide content. An aliquot (60 m*l*) was treated with sodium borohydride (3.0 g) at 0—36°C under nitrogen-bubbling. The mixture was acidified with dilute HCl and extracted with ether. The ether layer was dried over anhydrous Na_2SO_4 and evaporated to dryness. Vpc analysis of the residue after trimethylsilylation[13] (stationary phase, silicone DC on celite; temperature, 250°C; carrier gas, hydrogen) indicated the presence of 0.36 g of glycol VII (58%). The glycol was isolated as colorless needles by means of preparative tlc on silica gel (toluene-ethyl formate-formic acid, 5:4:1); 110°C with foaming. An authentic sample[5] had the same mp and identical mobility on tlc.

The remaining photolysate (120 m*l*) was deoxygenated by nitrogen-bubbling (10 min, ~2°C), then quickly added to a solution of 3,5-diiodotyrosine (II, 6.0 g) in 0.2M borate buffer (500 m*l*, pH 7.8, ~2°C) with nitrogen-bubbling, during

which time the solution was permitted to warm up to room temperature. The reaction mixture was worked up as previously described.[5] A colorless precipitate (0.40 g) of thyroxine (III), identical with authentic sample, was obtained.

Other experiments with I are summarized in Table 1, Figs. 1, 2, 3, and 4.

B. Photooxidation of 4-Hydroxy-3-iodo-5-methoxyphenylpyruvic Acid (V) in Methanol (Table 2-Exp. 11). A solution of V (0.78 g) and rose bengal (0.1 g) in methanol (200 m*l*) was irradiated for 35 min at ~2°C. The oxygen-consumption was 33 m*l*. The photolysate was treated with II (6.0 g) in 0.2M borate buffer (500 m*l*, pH 7.7) under nitrogen and worked up. 3,5,3′-Triiodo-5′-methoxythyronine (X) (21 mg), identical with authentic sample,[11] was obtained.

Other experiments with V are summarized in Table 2, Figs. 4 and 5.

C. Photooxidation of 4-Hydroxyphenylpyruvic Acid (VI) in Methanol (Table 2-Exp. 12—14). A solution of VI (0.84 g) in methanol (200 m*l*) in the presence of various amounts of rose bengal was irradiated under oxygen at ~2°C. The photolysate, when added to a solution of KI in dilute acetic acid, liberated iodine, was iodometrically titrated for peroxide analysis.

Other experiments with VI are summarized in Figs. 3, 4, and 6.

(Received February 2, 1972)

The structure and configuration of rishitinol (**2**), isolated from tuber tissues of white potatoes (*Solanum tuberlosum*×*S. demissum*) infected by an incompatible race of *Phytophtora infestans*, were deduced from spectral and chemical data and confirmed by the synthesis of its recemate. 5,8-Dimethyl-1-tetralone-3-carboxylic acid (**13**) prepared from 2,5-dimethylbenzyl chloride was esterified, reduced, and then dehydrated to the dihydronaphthalene derivative (**20**), which was converted into the oxyisopropyl derivative (**21**). The hydroboration of **21** followed by hydrogen peroxide oxidation afforded a multi-component mixture, from which *dl*-rishitinol (**25**= *dl*-**2**) was isolated along with isomeric glycols (**22**—**24**).

A few years ago we reported on the isolation[2] and structure elucidation[3] of an antifungal norsesquiterpene alcohol, rishitin (**1**), from tuber tissues of white potatoes (*Solanum tuberlosum*×*S. demissum*) infected by an incompatible race of *Phytophtora infestans*. Since the isolation of rishitin qualified as "phytoalexin," efforts have been made to isolate the alcohol and its closely related compounds from diseased plants of various species of the *Solanum* family in search of its biological significance as well as the biogenetic route.[4-8]

Recently we isolated a new sesquiterpene alcohol (**2**), designated as rishitinol, from the diseased white potato tubers and reported on the structure as well as the total synthesis of its racemic form.[9] The details of the studies are given in this paper.

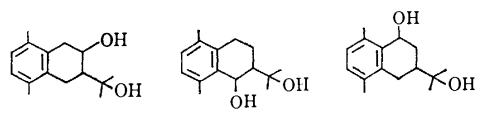
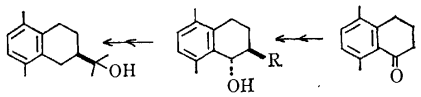
The sesquiterpene alcohol **2** was isolated as follows. The tuber slices of diseased white potatoes (8.5 kg) were treated by the reported procedure[2] to yield "the hexane-soluble fraction" (24.5 g). This on column chromatography over silicic acid afforded two relevant fractions, one (10.5 g) eluted with hexane containing the compound in question and the other eluted with hexane–acetone (92: 8) being more polar and rishitin-rich. The former was chromatographed over silicic acid and celite, and the resulting ether eluate, after removal of acidic substances, was rechromatographed over alumina. A rishitinol-rich fraction (180 mg) eluted with ether–methanol was further purified by thin layer chromatography (tlc) on silica gel and recrystallized to yield rishitinol **2** (50 mg), mp 128—129°C and $[\alpha]_D$ +47° (chloroform), in pure state.

Compound **2** was analyzed for $C_{15}H_{22}O_2$, which was confirmed by the mass spectrum (*m/e* 234, M^+). The UV, IR, and NMR spectral data revealed the presence of the following structural units: one tetra-substituted benzene with two vicinal hydrogens [λ_{max} 263 mμ (ε 280); ν_{max} 3070, 1600, 810, and 804 cm^{-1}; τ 7.81 and 7.75 (each 3H, singlet), and 3.10 (2H, singlet)]; two *tertiary* methyl groups (τ 8.65 and 8.54 (each 3H, singlet)]; *secondary* and *tertiary* hydroxy groups [ν_{max} 3300 cm^{-1}; τ 7.25 (2H, broad singlet, disappeared on addition of deuterium oxide) and 5.30 (1H, broad singlet W_H=7 Hz)]. Compound **2** resisted acetylation under the usual conditions and oxidation with periodic acid. All the results together with the co-existence of rishitin in the same plant suggest that rishitinol would be represented either by (planar) structure **2a**, **2b**, or **2c**. Since these structures are regarded to be of hydroxyoccidol, we first intended to prepare *dl*-occidiol[10] (**3**) in anticipation of the effectiveness of the NMR spectrum of **3** for structural determination and the availability of the synthetic intermediates of **3** for the preparation of **2b**.



2a **2b** **2c**



3 **5** R=$COOC_2H_5$ **4**
6 R=$C(OH)(CH_3)_2$

The synthesis of *dl*-occidol was carried out by a slight modification of the procedure by Hirose and Nakatsuka,[10a] starting with *p*-xylene and succinic anhydride *via* tetralone (**4**)[11] and oxyester (**5**). The resulting *dl*-occidol exhibited two six-proton singlets due to the gem-dimethyl and aromatic methyl protons, as shown in Table 1 in which the chemical shifts of relevant protons are summarized. In view of the large difference (0.11 ppm) in the chemical shift between two gem-dimethyl groups of **2**, this spectral pattern (*cf.*, Table 1) indicated that another hydroxyl group of **2** would hinder the presumed free rotation of the oxyisopropyl group and probably be located at one of the adjacent carbons. The possibility of structure **2c** would therefore be excluded. The synthetic intermediate **5** was then treated with methyl magnesium iodide to give glycol **6**. The relative configuration of the hydroxyl and oxyisopropyl groups in **6** was tentatively assigned to *trans*, because, in the NMR spectra of **5** and **6**, the proton on carbon bearing the hydroxyl group appeared as a doublet at τ 4.78 and 4.75 with coupling constants of 7 and 5 Hz, respectively. Glycol **6**, while it possessed the same molecular formula as **2**, differed definitely from **2**. On the basis of the large deshielding effect (0.24 ppm) caused by the hydroxyl group at the carbon adjacent to the benzene ring on the aromatic methyl protons, it was inferred that rishitinol would be formulated most favorably as **2a**.

As a synthetic approach to **2a**, 5,8-dimethyl-2-tetralone (**7**) was first prepared, starting from the corresponding 1-tetralone (**4**) and using a method analogous to that of the conversion of 1-tetralone into 2-tetralone.[12] However, the attempted formylation of **7** with methyl formate and sodium methoxide failed, forming a multi-component mixture. The one-step synthesis[13] of 5,8-dimethyl-2-tetralone-3-carboxylate was next undertaken but also failed; treatment of 2,5-dimethylphenylacetyl chloride with ethyl acrylate in the presence of aluminum chloride resulted in the formation of an intractable tarry material.

The synthesis of rishitinol was finally achieved as follows. 5,8-Dimethyl-4-oxo-1,2,3,4-tetrahydro-2-naphthoic acid (**13**) was first prepared in a manner analogous to the synthetic procedure of the corresponding 5,8-demethyl derivative by Haworth *et al.*[14] Alkylation of ethyl sodioacetoacetate with 2,5-dimethylbenzyl chloride[15] (**8**) produced the 2,5-dimethylbenzyl derivative (**9**), which was again treated with sodium in ethanol and then refluxed with ethyl chloroacetate to give acetylbenzylsuccinate (**10**) in 34% yield from **8**. In accordance with the structure **10**, the NMR spectrum exhibited signals due to an acetyl and two carbethoxy methyl protons. Further treatment of **10** with 2N sodium hydroxide under reflux effected both hydrolysis and removal of the acetyl group to yield 2,5-dimethylbenzylsuccinic acid (**11**) which on heating with acetic anhydride formed the corresponding anhydride (**12**) in 68% yield from **10**. The structure was supported by the IR absorption bands due to an acid anhydride group. The Friedel-Crafts cyclization of **12** led to the formation of a 2: 1 mixture of 5,8-dimethyl-1-tetralone-3-carboxylic acid (**13**) and its isomeric acid (**14**) containing a hydrindanone skeleton in 70% yield. They were separated by fractional recrystallization. While **13** showed an absorption maximum due to the carbonyl

group in a six-membered ring, **14** showed one due to the group in a five-membered ring. The UV and NMR spectra of both compounds also supported the assigned structures. In view of the fact that Haworth's cyclization with the demethyl derivative of **12** resulted in the isolation of only 1-tetralone-3-carboxylic acid,[14] it would be noticeable that compound **14** was formed in a considerable yield. Apparently the present result would be derived from large steric hindrance against the six-membered ring rather than the five-membered[16] caused by one of the aromatic methyl groups. Tetralone **13** was then converted with hydrogen chloride in ethanol into the corresponding ethyl ester (**15**) in 70% yield.

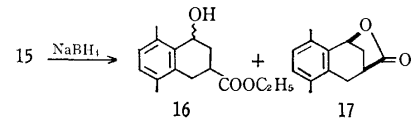
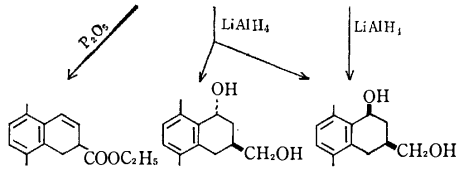
14

The reduction of the ketoester **15** with sodium borohydride in ethanol produced a mixture of hydroxy esters (**16**) and γ-lactone (**17**), which were isolated by column chromatography in 61 and 30% yields, respectively. Hydroxy esters (**16**) gave only one spot on tlc. However, on treatment with lithium aluminum hydride **16** formed a 1 : 1 mixture of two glycols, which were separated by preparative tlc to give a glycol (**18**), mp 125—127°C, and a glycol (**19**), mp 111—113°C, in 35 and 35% yields, respectively. The relative configuration of the hydroxyl and the carbethoxyl groups of these glycols was made by the formation of the *cis*-glycol **18** on reduction of the γ-lactone **17** with the *cis*-configuration at the carbons in question. **16** was thus, subjected to dehydration with phosphorus pentoxide. The reaction proceeded smoothly to give dihydronaphthalene derivate (**20**) in 70% yeild.

As a final step of the synthesis, an attempted hydration of dihydronaphthalenes by hydroboration followed by hydrogen peroxide oxidation[17] gave no fruitful result. Ester **20** was then converted into the oxyisopropyl derivative (**21**) in 53% yield by treatment with methylmagnesium iodide. Compound **21** showed the UV spectrum in good accord with the structure and also displayed an NMR spectrum resembling closely that of occidol **3** except for signals due to olefinic protons.



16 **17**



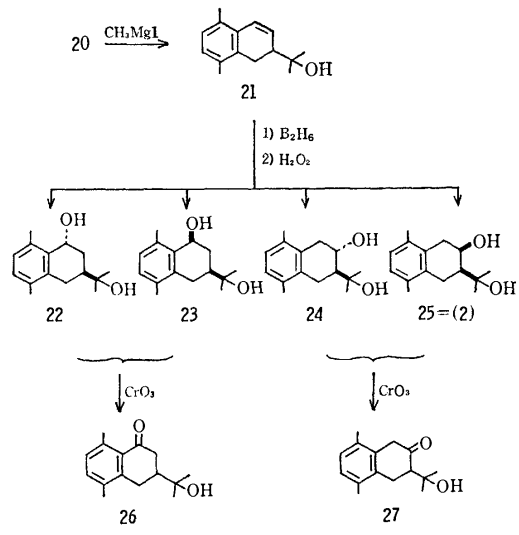
20 **19** **18**

Hydroboration of the olefin **21** folowed by oxidation with hydrogen peroxide afforded a multi-component mixture, which was separated roughly into three fractions by column chromatography over silica gel. The least mobile fraction obtained in 27% yield showed two spots on tlc. However, on purification by preparative

16) *Cf.*, R. T. Arnold and P. N. Craig, *J. Amer. Chem. Soc.*, **72**, 2728 (1950), and their previous papers.

17) G. Zweifel and H. C. Brown, "Organic Reactions," Vol. 13, John Wiley & Sons, Inc., London and New York (1963), p. 27.

tlc followed by recrystallization, it afforded only one 1-hydroxytetralin derivate (**22**) in 18% yield. However, the Jones oxidation[18] of both the pure alcohol **22** and the residue left on isolation of **22** produced the same 1-tetralone derivative (**26**) indicating the presence of an epimeric alcohol (**23**). The relative configurations of **22** and **23** were assigned to *trans* and *cis* on the basis of the appearance of the proton at C_1 of **22** as a triplet with J of 3 Hz at τ 5.10, since it is not probable that both the hydroxyl and oxyisopropyl groups would assume axial conformations. The middle fraction obtained in 26% yield was subjected to acetylation. The product was separated by preparative tlc to give monoacetate (**24a**) and the unreacted glycol (**25**) in 10 and 6% yields, respectively. **24a** on hydrolysis with alkali readily afforded glycol (**24**). As expected, both glycols **24** and **25** were oxidized with the Jones reagent to yield the same 2-tetralone derivative (**27**). The NMR spectra of these alcohols, consistent with the structures, made it possible to assign *trans* and *cis* configurations to the glycols **24** and **25**, respectively; the proton at C_2 of **24** appeared as a multiplet with W_H of 25 Hz centered at τ 6.50, while that of **25** as a broad singlet with W_H of 7 Hz at τ 5.24.



Compound **25** has now been identified as a racemate of rishitinol by comparison of the UV, IR, NMR, and mass spectra as well as tlc. In view of the absolute configuration of rishitin[3] and occidol,[10b] rishitinol would also possesses the β-oriented oxyisopropyl group. Hence rishitinol is represented most favorably by structure **2**.

Experimental

The melting points were measured in open capillaries and uncorrected. The optical rotations, UV and IR spectra were taken in chloroform, 99% ethanol and Nujol, respectively, unless otherwise stated. The NMR spectra were recorded in deuterochloroform at 60 and/or 100 MHz, tetramethylsilane being used as an internal standard. The following abbreviations were used in the NMR spectra. "s singlet, d doublet, t triplet, q quartet, b broad, and m multiplet." Thin layer chromatography (tlc) was carried out over silica gel of Merck G, and column chromatography over silica gel of Mallinckrodt A.R. 100 mesh or alumina of Merck Active I, neutral.

Isolation of Rishitinol (2). Tuber slices of the R_1 cultivar Rishiri (White potato, *Solanum tuberosum*×*S. demissum*) (60 kg), inoculated with an incompatible race of *Phytophthora infestans* (Mont.) d By, were dried (8.5 kg), homogenized, extracted, and separated in the same manner as that reported previously.[1] The resulting "hexane-soluble fraction"[1] (24.5 g) contained rishitin (**1**) and rishitinol (**2**). This fraction was chromatographed over silica gel (150 g) and celite (70 g), using hexane and hexane-acetone as eluents and separated roughly into two parts, one (10.5 g) eluted with hexane and the other eluted with hexane-acetone (92:8) and rishitin-rich (tlc). The former, less polar, was then rechromatographed over silica gel (100 g) and celite (30 g), using hexane, benzene, chloroform, ether, and ether–methanol as eluents. The yellow oil (5.9 g) obtained from the ether eluates was dissolved again in ether and shaken with 5% aqueous sodium carbonate to remove acidic components. The remaining ether solution was washed with water, dried, and evaporated to leave a neutral substance (3.1 g). This was again chromatographed over alumina (60 g), using hexane, hexane–benzene, benzene, benzene–ether, ether, and ether–methanol as eluents. The eluate from ether–methanol (99:1) gave a crystalline material (180 mg) on trituration with hexane, which showed a single spot on tlc (R_f=0.63, chloroform–ether, 1:1) and was collected by filtration. This was recrystallized twice from hexane to give pure rishitinol (**2**) (50 mg), mp 128—129°C, $[\alpha]_D$ +47°; mass, *m/e* 234 (M^+); IR, ν_{max} 3070, 1600, 810, and 804 cm^{-1}; UV. λ_{max} 263 mμ (ε 280); NMR, τ 8.65, 8.54, 7.81 and 7.75 (each 3H, s), 8.25 (1H, m), 7.25 (2H, br s, disappeared on addition of deuterium oxide), 7.05 (4H, m), 5.30 (1H, br s W_H= 7 Hz,) and 3.10 (2H, s).

Found: C, 76.88; H, 9.46%. Calcd for $C_{15}H_{22}O_2$: C, 76.37; H, 9.51%.

Rishitinol **2** was treated with acetic anhydride (0.3 m*l*) and pyridine (0.2 m*l*) at room temperature for 2 days. After the usual work-up, the starting material was recovered unchanged.

A solution of **2** (10 mg) in ethanol (10 m*l*) was added to a solution of sodium metaperiodate (15.6 mg) in water (18 m*l*) and acetic acid (2 m*l*), and the mixture was then diluted to 30 m*l* with water and allowed to stand at room temperature. A part (5 m*l*) of the solution was taken out three times at intervals of a day and titrated with a 0.0115 N sodium thiosulfate solution after addition of 2 m*l* of 0.1 N potassium iodide; 0.32, 0.29 and 0.25 moles of the metaperiodate were consumed in each run.

Ethyl 1-Hydroxy-5,8-dimethyl-1,2,3,4-tetrahydro-2-naphthoate (5). A solution of methyl 5,8-dimethyl-1-oxo-1,2,3,4-tetrahydro-2-naphthoate[10a] (10 g), mp 75—76°C, in ethanol (45 m*l*) was treated with a solution of sodium borohydride (2.2 g) in ethanol (75 m*l*) in the same manner as that of Hirose and Nakatsuka.[10a] The resulting oily product showed two spots and chromatographed over silica gel (120 g) and celite (40 g), using benzene, benzene–chloroform, and chloroform as eluents. Fractions eluted with benzene–chloroform gave a crude sample of **5** (3.7 g), which on trituration with hexane yielded a crystalline material, showing a single spot. Fractions eluted with chloroform afforded a brown oil (3.8 g), which was a mixture of **5** and, probably, its carbomethoxy

18) A. Bowers, T. G. Halsall, E. R. H. Jones, and A. J. Lemin, *J. Chem. Soc.*, **1953**, 2548.

homologue[19] (checked by tlc). The above crystalline substance was recrystallized from hexane for analysis to give **5** (2.1 g), mp 65—66°C; mass, *m/e* 248 (M^+); IR, ν_{max} 3360 and 1720 cm^{-1}; NMR, τ 8.68 (3H, t, J=7 Hz, $COOCH_2C\underline{H}_3$), 7.80 and 7.56 (each 3H, s, $C\underline{H}_3$ at C_5 and C_8), 5.75 (2H, q, J=7 Hz, $COOC\underline{H}_2CH_3$), 4.79 (1H, br s, $\underline{H}$ at C_1) and 3.03 (2H, s, $\underline{H}$ at C_6 and C_7).

Found: C, 72.48; H, 8.24%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

2-(1-Hydroxy-5,8-dimethyl-1,2,3,4-tetrahydro-2-naphthyl)propan-2-ol (6). A solution of the hydroxy ester **5** (200 mg) in dry ether (10 m*l*) was added to the Grignard solution prepared from magnesium (75 mg) and methyl iodide (450 mg) in dry ether (7 m*l*) at room temperature. After being left at the same temperature for 20 hr, the mixture was treated with a saturated ammonium chloride solution (20 m*l*) and extracted with ether. Evaporation of ether gave a brown residue (150 mg) which was separated into two portions by preparative tlc (solvent, ether). The more mobile portion (80 mg) was identified as the unreacted ester (**5**) by tlc and the mixed melting point method. The less mobile one, showing a single spot, was extracted with acetone–methanol from the plates and gave **6** (60 mg) which resisted crystallization and further purification. However, its NMR spectrum was in good accord with the structure; τ 8.69 and 8.50 (each 3H, s, $(C\underline{H}_3)_2COH$), 7.80 and 7.56 (each 3H, s, $C\underline{H}_3$ at C_5 and C_8), 4.75 (1H, d, J=5 Hz, $\underline{H}$ at C_1) and 3.02 (2H, s, *H* at C_6 and C_7).

dl-*Occidol (3).* Compound **19** (954 mg), dissolved in a 2:1 mixture (40 m*l*) of ethanol and acetic acid was hydrogenated over Adams platinum (500 mg as $PtO_2 \cdot H_2O$) at room temperature for 1 hr, when almost one mole of hydrogen was absorbed. The reaction was further continued for 7 hr. After removal of the catalyst and the solvent, the residue was dissolved in ether. The ethereal solution was washed with a sodium carbonate solution and water, dried, and evaporated to leave a crystalline material (800 mg), which was recrystallized from hexane to give **3**, mp 102—103°C; UV, λ_{max} 266 mμ (ε 200); NMR, 8.70 (6H, s), 7.80 (6H, s) and 3.10 (2H, s).

Found: C, 82.43; H, 9.97%. Calcd for $C_{15}H_{22}O$: C, 82.51; H, 10.16%.

2,5-Dimethylbenzyl Chloride (8). A mixture of *p*-xylene (500 m*l*), paraformaldehyde (32 g), and zinc chloride (40 g) was heated at 70°C for 15 min and then cooled to 50°C. Dry hydrogen chloride was passed into the mixture for 30 min at 50—60°C. After the whole mixture was washed with water, 5% sodium bicarbonate, and water successively, the xylene solution was separated, dried and distilled to give compound **8** (71 g), bp 88—90°C/5 mmHg (lit,[14] bp 105°C/15 mmHg).

Ethyl Aceto-2,5-dimethylbenzylacetate (9). The chloride **8** (140 g) was added slowly to an ethanol solution of ethyl sodioacetoacetate preparaed from sodium (20.8 g), ethanol (250 ml), and ethyl acetoacetate (234 g). The mixture was then refluxed for 6 hr, when sodium chloride precpitated was removed by filtration. The filtrate was concentrated and distilled *in vacuo* to yield a pale yellow oil (**9**) (167.4 g), bp 169—173°C/5 mmHg; IR, ν_{max} 1735 and 1720 cm^{-1}.

Ethyl α-Aceto-α-2,5-dimethylbenzylsuccinate (10). Compound **9** (167 g) was treated with sodium (15.4 g) dissolved in ethanol (200 m*l*), and mixed with ethyl chloroacetate (87.4 g). The whole mixture was worked up in the same manner as mentioned above. The product (**10**), oil, bp 185—198°C/5 mm Hg, showed spectra consistent with the assigned structure; IR, ν_{max} 1735 and 1705 cm^{-1}; NMR, τ 8.80 and 8.83 (each 3H, t, J=8 Hz, $COOCH_2C\underline{H}_3$), 7.77 (9H, s, CH_3CO and aromatic CH_3), and 5.90 and 5.93 (each 2H, q, J=8 Hz, $COOC\underline{H}_2CH_3$).

2,5-Dimethylbenzylsuccinic Acid (11). A suspension of the succinate **10** (261 g) in 2 N sodium hydroxide (1.2 *l*) was refluxed for 26 hr and poured onto a mixture of ice and hydrochloric acid. The resulting precipitates were collected, washed with water, and recrystallized from methanol to afford **11** (138 g); mass, *m/e* 236 (M^+); IR, ν_{max} 3300 and 1705 cm^{-1}. It turned gradually brown and then dark brown at 160—170°C, but did not melt below 240°C.

2,5-Dimethylbenzylsuccinic Anhydride (12). The acid **11** (80.5 g) was refluxed with acetic anhydride (161 g) for 30 min. The reaction mixture was worked up as usual and crude crystalline anhydride was recrystallized from carbon tetrachloride to afford **12** (69 g) mp 80—83°C; IR; ν_{max} 1865 and 1785 cm^{-1}.

5,8-Dimethyl-4-oxo-1,2,3,4-tetrahydro-2-naphthoic Acid(13) and 4,7-Dimethyl-1-indanone-2-acetic Acid (14). The anhydride **12** (7.4 g) was added slowly under stirring to aluminum chloride (10 g) suspended in nitrobenzene (35 m*l*) under cooling by an ice-bath. The cold mixture was stirred at the temperature for 1 hr and at room temperature overnight, and poured onto a mixture of ice and hydrochloric acid. The aqueous mixture was then subjected to steam distillation to remove nitrobenzene, and extracted with chloroform. On removal of the solvent the chloroform solution afforded a reddish residue (5.5 g), which was purified by column chromatography on silica gel (150 g) and celite (15 g). Fractions eluted with benzene–acetone (1:1—1:4) gave a crystalline mass, which was recrystallized from benzene to give **13** (4.9 g), fine needles, mp 127—131°C. This was recrystallized from the same solvent for analysis to give **13** (2.8 g), plates, mp 135—137°C; UV, λ_{max} 254 (log ε 4.07) and 305 mμ (log ε 3.34); IR, ν_{max} 3280, 1705, and 1665 cm^{-1}; NMR, τ 7.70 and 7.40 (each 3H, $C\underline{H}_3$ at C_5 and C_8), 7.00 (5H, m), 2.96 and 2.78 (each 1H, d, J=9 Hz, $\underline{H}$ at C_6 and C_7) and −0.80 (1H, s, $COO\underline{H}$).

Found: C, 71.71; H, 6.39%. Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47%.

The mother liquors obtained on the above recrystallizations were combined and evaporated to leave a crystalline residue, which was recrystallized repeatedly from benzene to give **14** (1.1 g), mp 113—115°C; IR, ν_{max} 3150, 1705, and 1695 cm^{-1}; NMR, τ 7.70 and 7.40 (each 3H, s), *ca.* 7.0 (5H, m), 2.96 and 2.81 (each 1H, d, J=10 Hz) and −1.04 (1H, s).

Ethyl 5,8-Dimethyl-4-oxo-1,2,3,4-tetrahydro-2-naphthoate (15). The naphthoic acid **13** (20.5 g) was esterified with 5% ethanolic hydrogen chloride under reflux for 5 hr and gave a crystalline ester, which was recrystallized from hexane to yield **15** (16.2 g), mp 74—76°C; IR ν_{max} 1735 and 1670 cm^{-1}; NMR, τ 8.76 (3H, t, J=7 Hz, $COOCH_2C\underline{H}_3$), 5.85 (2H, q J=7 Hz, $COOC\underline{H}_2CH_3$), 7.71 and 7.41 (each 3H, s), *ca.* 7.0 (5H, m), and 2.98 and 2.86 (each 1H, AB q, J=10 Hz).

Ethyl 4-Hydroxy-5,8-dimethyl-1,2,3,4-tetrahydro-2-naphthoate (16) and 5,8-Dimethyl-1,2,3,4-tetrahydro-2,4-naphthalenecarbolactone (17). A solution of the naphtoate **15** (8 g), in ethanol (155 m*l*) was reduced with sodium borohydride (1.8 g) in ethanol (50 m*l*) under cooling in an ice-bath for 3 hr. The product consisted of two components (tlc), which were separated by column chromatography over silica gel (200 g), using benzene, benzene–ether and ether as eluents; one was eluted from benzene–chloroform (19:1—1:5) and the other

19) This substance, which had been reported to be methyl ester,[10a] was apparently a mixture of the methyl ester and ethyl ester **5**, since the result of elemental analysis did not agree with the calculated value for $C_{14}H_{18}O_3$.

from benzene–chloroform (1:6—1:1). The former was recrystallized from benzene to give lactone **17**, (2.4 g), mp 129—131°C; IR, ν_{max} 1765 cm^{-1}; NMR, τ 7.84 and 7.62 (each 3H, s), 4.30 (1H, d, J=6 Hz) and 3.00 (2H, s).

The latter was obtained as colorless oil which showed a single spot but proved to be a mixture of two C_4-epimers formulated as (planar) structure **16** from the NMR spectral data; τ 8.76 and 8.71 (total 3H, t, J=8 Hz, $COOCH_2C\underline{H}_3$) 7.80 and 7.60 (each 3H, s, $C\underline{H}_3$ at C_5 and C_8), 5.89 and 5.78 (total 2 H, q, J=8 Hz, $COOC\underline{H}_2CH_3$), and 3.03 (2H, s, $\underline{H}$ at C_6 and C_7).

cis-1-Hydroxy-3-hydroxymethylene-5,8-dimethyl-1,2,3,4-tetrahydronaphthalene (18) and its Isomer (19). To a solution of the hydroxy ester (**16**, 176 mg) in dry ether (20 m*l*) was added slowly an ether solution (5 m*l*) of lithium aluminum hydride (50 mg) under stirring at room temperature. After being left for 20 hr, the reaction mixture was worked up as usual to leave an amorphous product (143 mg) showing two spots on tlc. This was subjected to preparative tlc (ether) to give two crystalline glycols. The less polar glycol was recrystallized from hexane containing methanol to give the *cis* isomer (**18**, 51 mg), mp 125—127°C, and the more polar the *trans* isomer (**19**, 52 mg), mp 111—113°C (from ether). The *cis* isomer was also obtained in 70% yield from lactone **17** under the same conditions as above.

The *cis* glycol (**18**, 54 mg) was acetylated with acetic anhydride–pyridine (1:1, 1.2 m*l*) at room temperature for 24 hr. The reaction mixture was worked up as usual and gave the diacetate (41 mg), oil, showing a single spot on tlc; IR, ν_{max} 1730, 1240, and 810 cm^{-1}; NMR, τ 7.97 and 7.94 (each 3H, s, $OCOC\underline{H}_3$), 7.79 (6H, s, $C\underline{H}_3$ at C_5 and C_8), 5.88 (2H, d, J=7.5 Hz, $C\underline{H}_2OCOCH_3$), 3.99 (1H, double t, J=5, 5 and 0.5 Hz, $\underline{H}$ at C_1), and 3.02 (2H, s, $\underline{H}$ at C_6 and C_7).

The diacetate of *trans* isomer **19** was also obtained in 54% yield, oil; IR, ν_{max} 1727, 1240 and 810 cm^{-1}; NMR, τ 7.95 and 7.93 (each 3H, s), 7.79 (6H, s), 5.86 (2H, d, J=5 Hz), 3.88 (1H, t, J=3 Hz) and 2.95 (2H, s).

Ethyl 5,8-Dimethyl-1,2-dihydro-2-naphthoate (20). An epimeric mixture of the hydroxynaphthoates (**16**, 10.4 g) dissolved in dry benzene (25 m*l*) was dehydrated with phosphorus pentoxide (7.5 g) suspended in dry benzene (17 m*l*) in the manner described before. The reaction mixture was worked up as usual and purified by chromatography over silica gel (250 g) and celite (50 g) to give dihydronaphthoate **20** (6.8 g), oil, showing a single spot; IR ν_{max} 1735 cm^{-1}; UV, λ_{max} 260 mμ (log ε 3.90).

2-(5,8-Dimethyl-1,2-dihydro-2-naphthyl)propan-2-ol (21). A solution of the naphthoate (**20**, 2.9 g) in dry ether (15 m*l*) was subjected to the Grignard reaction by the same procedure as that for conversion of **5**, using the reagent prepared from magnesium (1.2 g) in ether (10 m*l*) and methyl iodide (9.0 g) in ether (20 m*l*). The reaction gave a crude alcohol (2.2 g) which was chromatographed over alumina (80 g). The eluate from benzene-chloroform (3:2—5:7) gave crystalline material on trituration with benzene. The crystals were recrystallized from benzene to yield **21** (1.6 g), needles, mp 46—48°C; UV, λ_{max} 260 mμ (log ε 4.04); IR, ν_{max} 3360 cm^{-1}; NMR, τ 8.80 (6H, s, $(C\underline{H}_3)_2COH$), 7.80 and 7.77 (each 3H, s), 4.01 (1H, double d, J=10 and 4 Hz, $\underline{H}$ at C_3), 3.37 (1H, double d, J=10 and 2 Hz, $\underline{H}$ at C_4) and 3.20 (2H, s).

Hydroboration of Compound 21. Into a stirred solution of the alcohol **21** (1.45 g) in dry tetrahydrofuran (35 m*l*) was passed diborane, prepared from sodium borohydride (1.0 g) dissolved in diglyme (5 m*l*) and boron trifluoride etherate (6 m*l*) dissolved in diglyme (4 m*l*), for 1 hr at room temperature under nitrogen. The mixture was then diluted with water and made alkaline with 3 N sodium hydroxide (5 m*l*). To the alkaline solution was added dropwise 30% hydrogen peroxide (6.5 m*l*), and the whole mixture was stirred at 35—50°C for 1 hr and then extracted with ether. The ether solution was washed with a saturated sodium chloride solution, dried, and evaporated to give a multi-component (1.35 g) which was separated into three fractions by chromatography over alumina (38 g). The most mobile fraction eluted with benzene–chloroform (4:1—3:2) gave the unreacted alcohol **21** (0.45 g). The niddle fraction eluted with benzene–chloroform (1:1) afforded a colorless oil (0.4 g), consisting meinly of two components and the least mobile eluted with benzene–chloroform (2:3) did a two other components mixture (0.43 g).

2-(trans-1-Hydroxy-5,8-dimethyl-1,2,3,4-tetrahydro-3-naphthyl)propan-2-ol (22) and its cis-*1-Hydroxy Isomer (23).* The least mobile fraction was further purified by preparative tlc using ether. A component showing a slightly smaller R_f value than that of rishitinol (**2**) was extracted with acetone–methanol. Removal of the solvent gave an amorphous substance which crystallized partially on trituration with benzene. The crystalline mass (**22**, 270 mg) was recrystallized from the same solvent and melted at 142—143°C; NMR, τ 8.72 and 8.75 (each 3H, s), 7.82 and 7.60 (each 3H, s), 5.10 (1H, t, J=3 Hz) and 3.05 (2H, s). The mother liquors obtained on removal of **22** were evaporated *in vacuo* to leave an amorphous residue (68 mg) showing almost the same IR spectrum as **22**. Examination of the residue by tlc indicated the presence of **22** and another component, the latter not being isolated in pure state even through its acetyl derivative. However, the component proved to be compound **23**, an epimer at C_4 of **22**, since both pure **22** and crude **23** on oxidation with the Jones' reagent afforded the same 1-tetralone derivative **26**, oil, in the same yield (70%); IR, ν_{max} 3420 and 1665 cm^{-1}.

2-(trans-2-Hydroxy-5,8-dimethyl-1,2,3,4-tetrahydro-3-naphthyl)-propan-2-ol (24) and its cis-*2-Hydroxy Isomer 25=dl 2).* The foregoing middle fraction, obtained from hydroboration products of **21**, was oxidized with the Jones' reagent to give 2-tetralone devative (**27**) (IR, ν_{max} 1705 cm^{-1}) as a single product, indicating the components to be 2-hydroxy tetralin derivatives. They were separated by acetylation; treatment of the fraction (390 mg) with acetic anhydride–pyridine (1:1, 4 m*l*) at room temperature for 24 hr afforded an oily mixture (353 mg). This was purified by preparative tlc using chloroform–ether (1:1) to yield an unacetylated, crude crystalline substance (90 mg), mp 127—129°C, and an oily acetate (**29a**, 180 mg); IR, ν_{max} 3360 and 1730 cm^{-1}; NMR, τ 8.75 (6H, s), 7.91 (3H, s, $OCOC\underline{H}_3$), 7.84 and 7.80 (each 3H, s), *ca.* 7.0 (6H, m), 4.80 (1H, m, W_H=25 Hz, $C\underline{H}OAc$) and 3.15 (2H, s). Hydrolysis of the acetate (**24a**) in refluxing 1 N methanolic potassium hydroxide afforded a glycol, which was crystallized from hexane to give compound **24** (39 mg), mp 127—128°C; IR, ν_{max} 3300 cm^{-1}; NMR, τ 8.65 (6H, s), 7.84 (6H, s), *ca.* 6.5 (1H, br m, W_H=25 Hz, $C\underline{H}OH$) and 3.10 (2H, s); R_f=0.60 (chloroform–ether, 1:1) and 0.32 (chloroform–ether, 4:1).

The crude crystalline glycol was recrystallized from hexane to afford compound **25** (25 mg), mp 127—129°C; mass, *m/e* 234 (M^+); UV, λ_{max} 265 mμ (ε 300); NMR, τ 8.65 and 8.54 (each 3H, s), 7.82 and 7.75 (each 3H, s), 5.30 (1H, br s, W_H=7 Hz) and 3.05 (2H, s); R_f=0.63 (chloroform–ether, 1:1) and 0.28 (chloroform–ether, 4:1). The compound was confirmed to be a racemic form of rishitinol (**2**) in all respects (NMR, IR, UV, and mass spectra and tlc).

2-(5,8-Dimethyl-3,4-dihydro-2-naphthyl)propan-2-ol (29). To a cooled and suspended mixture of phosphorus pentoxide

(1.6 g) in dry benzene (6 m*l*) was added a solution of compound **5** (3.7 g) in dry benzene (18 m*l*) under stirring, and the mixture was stirred at 0°C for 5 hr. The cold mixture was then poured into water and extracted with ether. After being washed with water and dried, the ether solution was evaporated to leave a crystalline material which, on recrystallization from ethanol, yielded ethyl 5,8-dimethyl-3,4-dihydro-2-naphthoate (3 g), mp 53—54°C; IR, ν_{max} 1695 and 1620 cm^{-1}; NMR, τ 8.64 (3H, t, J=7 Hz), 7.73 and 7.62 (each 3H, s), 5.74 (2H, q, J=7 Hz), 3.06 (2H, s) and 2.28 (1H, s).

Found: C, 78.05; H, 7.68%. Calcd for $C_{15}H_{18}O_2$: C, 78.23; H, 7.88%.

The naphthoate (2.3 g) was subjected to the Grignard reaction under the same conditions as for compound **6**. The reaction mixture was worked up as usual and gave an oily product (2.2 g), which was chromatographed over alumina (45 g) using hexane and benzene as eluents. Fractions eluted with benzene afforded a colorless oil (**29**) (2.0 g), showing a single spot; IR, ν_{max} 3360 cm^{-1}; NMR, τ 8.58 (6H, s), 7.78 and 7.70 (each 3H, s) and 3.33 (1H, s).

Found: C, 83.22; H, 9.42%. Calcd for $C_{15}H_{20}O$: C, 83.28; H, 9.32%.

*2-(1,2-Dihydroxy-5,8-dimethyl-1,2,3,4-tetrahydro-2-naphthyl)-propane (**30**).* *dl*-Occidol (**3**, 105 mg) was heated with 90% formic acid (1 g) on a water-bath for 1 hr, and the mixture was cooled and diluted with ether. The ether solution was washed with 5% sodium carbonate and water, dried, and evaporated to give an oily product. While this dehydratd product showed a single spot on tlc, it was found to consist of a few unsaturated compounds by examination of the NMR spectrum. This was therefore used for the subsequent reaction without further purification. Osmium tetroxide (80 mg) was added to a solution of oil (52 mg) in dry ether (3 m*l*) and pyridine (0.08 m*l*) under stirring at room temperatute. The mixture immediately turned dark violet and dark brown osmate esters deposited after 5 min. After being left for 2 days, the whole mixturs was evaporated under reduced pressure and the residual osmate ester was decomposed by reflux with a mixture of sodium sulfite (600 mg) and 50% aqueous ethanol (100 m*l*) for 2 hr. After filtration of black precipitates deposited, the filtrate was diluted with water and extracted with ether. Evaporation of the dried extract followed by trituration of the residue with hexane afforded a crystalline product, which was recrystallized from the same solvent to give pure **30** (18 mg), mp 85—86°C; NMR, τ 9.09 (3H, d, J=7 Hz), 8.09 (3H, J=7 Hz), 7.79 and 7.57 (each 3H, s), 5.25 (1H, br s, W_H=6 Hz) and 3.02 (2H, s).

Found: C, 76.63; H, 9.44%. Calcd for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%.

The authors are grateful to Mr. Norio Sato for the preparation of raw materials, to Mr. Shigezo Shimokawa for the measurement of NMR, to Miss Masako Takahashi for that of mass spectra, and to Misses Hiroko Kakizaki and Motoko Sato for microanalyses.

Studies of Acyl and Thioacyl Isocyanates. IX.[1] The Cycloaddition Reactions of Benzoyl and Thiobenzoyl Isocyanates with Anils

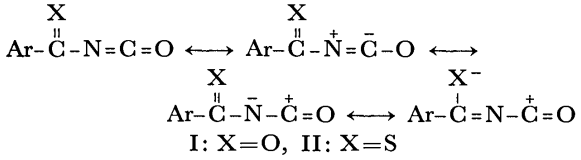
Otohiko TSUGE and Shuji KANEMASA

Research Institute of Industrial Science, Kyushu University, Higashi-ku, Hakozaki, Fukuoka 812

(Received March 17, 1972)

Thiobenzoyl isocyanates react with benzylidenanilines, benzylidenalkylamines and dianils to yield the corresponding mono- and bis(4+2) cycloadducts. Benzoyl isocyanates do not react with benzylidenanilines, but they are easily added to benzylidenebenzylamine to give the (4+2) cycloadducts in good yields. Cycloaddition of these isocyanates to anils is dependent upon the basicity of the nitrogen atom of C=N bond. Neither benzoyl isocyanates nor thiobenzoyl isocyanates are added to the C=C bond of cinnamylidenanilines, but they react with the C=N bond to afford the (4+2) cycloadducts.

The 1,4-dipolar contribution of benzoyl (I) and thiobenzoyl isocyanates (II) is manifest in cycloaddition reactions as evidenced by their dimerization[2] and reactions of carbodiimides.[3]



I: X=O, II: X=S

We have therefore undertaken to expand the cycloaddition reactions of these isocyanates with various compounds having a C=N bond. A preliminary report was given on the cycloaddition reaction of I and II with some benzylidenamines.[4]

Investigation was made to prepare new heterocycles, and obtain information on the differences between the reactivities of I and II in cycloaddition reactions. This paper deals with the cycloaddition to benzylidenamines, dianils and cinnamylidenanilines.

a) Reaction conditions: at room temperature for 5 min. b) All the compounds melted with decomposition. c) NMR ($CDCl_3$) δ ppm: 3.78 (3H, singlet, OCH_3), 6.18 (1H, singlet, >CH), 6.78—8.20 (14H, multiplet, aromatic protons). d) NMR ($CDCl_3$) δ ppm: 3.79 (3H, singlet, OCH_3), 6.16 (1H, singlet, >CH), 6.78—8.18 (14H, multiplet, aromatic protons). e) Reaction conditions: at room temperature for 5 hr.

Results and Discussion

Reactions with Benzylidenamines. No reaction of benzoyl isocyanates (I) with benzylidenanilines (III) took place even in xylene under reflux, but thiobenzoyl isocyanates (II) reacted easily with anils IIIa—IIIg at room temperature to afford the corresponding 1:1 adducts IVa—IVg in good yields.

IVa—g

The structures of IV were deduced to be the (4+2) cycloadducts, 2*H*-1,3,5-thiadiazin-4(3*H*)-ones, on the basis of their spectral data. The yields, physical properties and results of elemental analyses of IV are given in Table 1.

IVe was easily hydrolyzed with hydrochloric acid to *N*-(*p*-methoxyphenyl)-*N'*-thiobenzoylurea (V), identical with an authentic sample prepared from IIa and *p*-anisidine. This supports the proposed structure for IV.[5]

V

As shown in Table 1, the yield of IV is affected by the nature of substituent R^3 but hardly at all by that of R^2, from the fact that IIa reacted easily with *p*-nitrobenzylidenaniline (IIId) to give IVf while it took 5 hr for IIa to disappear with benzylidene-*p*-nitroaniline (IIIe). Addition of IIa to *p*-nitrobenzylidene-*p*-nitroaniline (IIIf) did not take place even under forced conditions (90—100°C, 1 hr).

On the other hand, benzoyl isocyanates (I) as well as II reacted easily with benzylidenebenzylamine (VIa) at room temperature, forming (4+2) cycloadducts VII in excellent yields. Similarly, the (4+2) cycloadduct was obtained from IIa and benzylidene-*n*-propylamine (VIb) and -cyclohexylamine (VIc). The structures of VII were confirmed by their spectral data and elemental analyses. The yields, physical properties and results of elemental analyses of VII are given in Table 2.

a) Reaction conditions: at room temperature for 5 min. b) All the compounds are colorless needles. c) All the compounds melted with decomposition. d) NMR ($CDCl_3$) δ ppm: 0.92 (3H, triplet, $-(CH_2)_2-CH_3$), 1.4—2.0 (2H, multiplet, $-CH_2-CH_2-Me$), 3.11, 4.05 (each 1H, double triplet, $-CH_2-Et$), 5.85 (1H, singlet, >CH), 7.15—8.1 (10H, multiplet, aromatic protons). e) NMR ($CDCl_3$) δ ppm: 0.9—2.2 (10H, multiplet, CH_2), 4.4—5.0 (1H, broad signal, ), 5.97 (1H, singlet, >CH), 7.2—8.1 (10H, multiplet, aromatic protons).

mixture of bis(4+2) cycloadduct IXa and *N,N′*-dibenzoylcarbamoylethylenediamine X. As bis(4+2) cycloadduct IXa was rather unstable and decomposed during recrystallization to give X, the crystals were washed with benzene and then diethyl ether to obtain almost pure IXa, mp 131—132.5°C (decomp.), whose IR spectrum showed that the bands are due to $\nu_{C=O}$ and $\nu_{C=N}$ at 1680, 1665, and 1615 cm^{-1}. However, the NMR spectrum could not be determined because of decomposition of IXa in solution. Signals appeared at δ 3.78, 4.0 (each CH_2), 6.2 (NH), 6.9 (CH), 7.2—8.05 (aromatic protons), 8.32 (NH), and 10.05 ppm (CHO) in the NMR spectrum in deuteriochloroform ($CDCl_3$); this indicates that IXa was partially hydrolyzed to X and benzaldehyde. Hydrolysis of IXa with hydrochloric acid in ethanol afforded Xa, mp 270.5°C (decomp.), in a good yield.

The reactions of IIa with VIIIa and with hydrobenzamide (VIIIb) afforded the corresponding bis(4+2) cycloadducts IXb and IXc, even when equimolar amounts of IIa and VIII were used. The yields for the 2:1 molar ratio (Ia or IIa to VIII),

physical properties and results of elemental analyses of IX are given in Table 3.

In the reaction with VIIIb, two isomers IXc-1 (high melting) and IXc-2 (low melting) were formed. Their IR spectra were very similar and the NMR spectra supported the (4+2) cycloadduct structures.[6]

TABLE 3. BIS-2*H*-1,3,5-THIA (OXA) DIAZIN-4(3*H*)-ONES IX[a]

	X	R	Yield (%)	Mp (°C)	IR, cm^{-1} $\nu_{C=O}$	IR, cm^{-1} $\nu_{C=N}$	Microanalysis (%) Found C	H	N	Calcd C	H	N

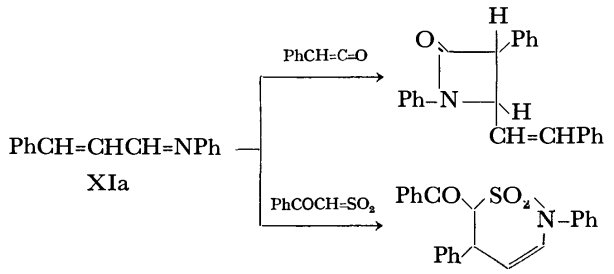
IXc-2	S	PhCH	67	186	1660	1637	71.39	4.38	8.52	71.14	4.52	8.97

a) Reaction conditions: I or II/VIII (2/1 molar ratio), at room temperature for a few minutes. All the compounds are colorless needles.

6) Although it is conceivable that IXc-1 and IXc-2 are stereoisomers resulting from the configurations of 6- and 6′-phenyl groups in the 1,3,5-thiadiazine rings and from the conformation of the methine carbon atom between both rings, their stereochemistry is not clear.

Reaction with Cinnamylidenanilines. Very few investigations of cycloaddition to cinnamylidenaniline (XIa) have been reported. Pfleger and Jäger[7] proposed an addition reaction of phenylketene to XIa of the Diels-Alder type, but Sakamoto and Tomimatsu[8] analyzed the structure of the same reaction product and showed that it is the (2+2) cycloadduct, β-lactam. Recently,[9] we found that the reaction of benzoylsulfene with XIa gives an adduct of the Diels-Alder type. It thus seemed of interest to investigate the reaction of I or II with cinnamylidenanilines.



Under various conditions, the reaction of Ia with XIa gave resinous materials exclusively. However, IIa reacted easily with XIa at room temperature to afford a good yield of crystalline 1 : 1 adduct XIIa.

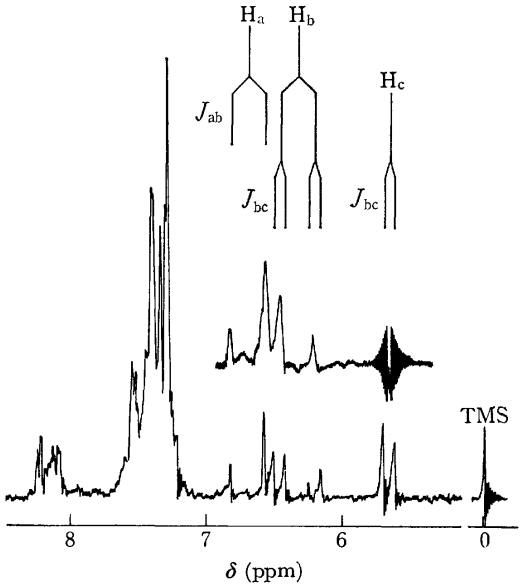


Fig. 1. NMR spectrum of XIIa.

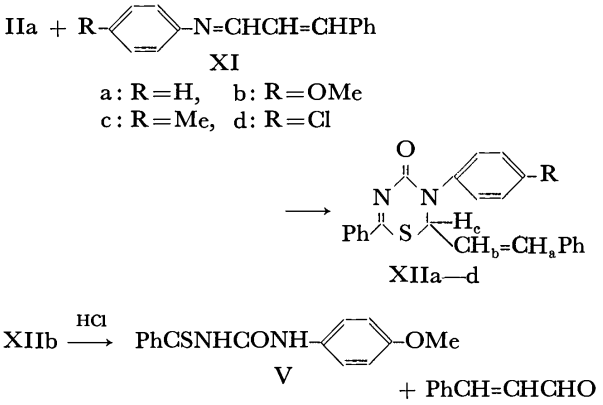
The IR spectrum of XIIa was very similar to that of IVa and showed the characteristic band assignable to the CH=CH (*trans*) linkage at 976 cm^{-1}. The NMR spectrum (Fig. 1) exhibited two olefinic protons H_a and H_b, and methine proton H_c at δ 6.76 (1H, doublet with J_{ab}=15.8 Hz), 6.38 (1H, double doublet with J_{ab}=15.8 and J_{bc}=5.2 Hz, changed to a doublet with J_{ab}=15.8 Hz when irradiated at δ 5.70 ppm) and 5.70 ppm (1H, doublet with J_{bc}=5.2 Hz), besides aromatic protons.

The value of the ethylenic coupling constant of the β-lactam obtained from phenylketene and XIa has been reported to be 17 Hz,[8] and that of *trans*-cinnamaldehyde, the starting material of XIa, is 16.2 Hz.[10] Thus it is apparent that XIIa is the (4+2) cycloadduct of IIa to the C=N bond in XIa, 3,6-diphenyl-2-*trans*-styryl-2*H*-1,3,5-thiadiazin-4(3*H*)-one.



Similar reactions of IIa with cinnamylidenanilines XIb—XId gave the corresponding (4+2) cycloadducts XIIb—XIId. Finally, XIIb was easily hydrolyzed with hydrochloric acid to urea V and cinnamaldehyde, providing additional support for the proposed structure. The yields, physical properties, results of elemental analyses, and spectral data of XII are given in Tables 4 and 5, respectively.

Table 4. 3,6-Diaryl-2-*trans*-styryl-2*H*-1,3,5-thiadiazin-4(3H)-ones XII

Experimental

All melting points are uncorrected. The IR spectra were measured as KBr pellets on a Nippon Bunko IR-S spectrophotometer; the NMR spectra were determined at 60 MHz on a Hitachi R-20 NMR spectrometer with TMS as an internal reference.

Materials. Benzoyl isocyanates (Ia—Id) were prepared by the method reported previously.[2] Thiobenzoyl isocyanates (IIa—IIc):[11] A solution of 1.0 g of 2-phenyl-,[12] 2-*p*-methoxyphenyl-[12] or 2-*p*-chlorophenylthiazoline-2,4-dione[12] in 10 m*l* of xylene was heated at 120°C, giving a reddish violet solution of II which was used *in situ*. This solution is referred to as the standard solution of II.

Anils were prepared from the corresponding aldehyde and amine. Benzylidenaniline (IIIa), mp 54°C (lit,[13] mp 53.5°C); *p*-methoxybenzylidenaniline (IIIb), mp 61°C (lit,[14] mp 58—59°C); benzylidene-*p*-anisidine (IIIc), mp 73—74°C (lit,[15] mp 72°C); *p*-nitrobenzylidenaniline (IIId), mp 93°C (lit,[16] mp 93°C); benzylidene-*p*-nitroaniline (IIIe), mp 118°C (lit,[17] mp 117—118°C); *p*-nitrobenzylidene-*p*-nitroaniline (IIIf), mp 199°C (lit,[18] mp 198.5°C); benzylidenebenzylamine (VIa), bp 200—201°C/18 mmHg (lit,[19] bp 205°C/20 mmHg); -*n*-propylamine (VIb), bp 101—102°C/16 mmHg (lit,[20] bp 208—210°C/744 mmHg); -cyclohexylamine (VIc), bp 154°C/18 mmHg (lit,[21] bp 136°C/16 mmHg). Dibenzylidenethylenediamine (VIIIa), mp 54°C (lit,[22] mp 53—54°C); hydrobenzamide (VIIIb), mp 110°C (lit,[23] mp 110°C). Cinnamylidenaniline (XIa), mp 109°C (lit,[22] mp 109°C); -*p*-anisidine (XIb), mp 118—119°C (lit,[24] mp 119°C); -*p*-toluidine (XIc), mp 82°C (lit,[25] mp 83°C); -*p*-chloroaniline (XId), mp 106—107°C (lit,[24] mp 107°C).

General Procedure for the Reaction of I or II with III and/or VI. A solution of equimolar amounts of I or II and III or IV in xylene was stirred at room temperature for a few minutes, during which time the reaction was completed. Filtration and recrystallization of crystals gave the corresponding (4+2) cycloadducts. The yields, physical properties, and results of elemental analyses of (4+2) cycloadducts IV and VII are given in Tables 1 and 2, respectively.

Hydrolysis of (4+2) Cycloadduct IVe. A solution of 0.3 g of IVe in 20 m*l* of methanol containing 2 m*l* of concentrated hydrochloric acid was stirred at 50°C for 5 min during which time it turned into a clear yellow solution. The solution was evaporated *in vacuo* to leave a residue which was washed with diethyl ether. Recrystallization of the ether-insoluble yellow crystals from ethanol gave 0.13 g (57%) of *N*-(*p*-methoxyphenyl)-*N'*-thiobenzoylurea (V), mp 178—179°C (decomp.) (lit,[26] mp 179°C (decomp.)), which was identical with the authentic sample prepared from IIa and *p*-anisidine. From the ether-washings, benzaldehyde was identified as its 2,4-dinitrophenylhydrazone.

Reaction of Ia with Dibenzylidenethylenediamine (VIIIa). A solution of 1.25 g of Ia and 1.0 g of VIIIa in 20 m*l* of dry benzene was stirred at room temperature for 10 min, and then filtered to give 1.85 g of solid whose IR spectrum indicated it to be a mixture of bis(4+2) cycloadduct IXa and *N,N'*-dibenzoylcarbamoylethylenediamine (X). The crystals were washed with benzene and then diethyl ether to leave colorless crystals, mp 131—132.5°C (decomp.), which were subjected to microanalysis without further purification.

The washings were evaporated *in vacuo* to leave X which corresponds to the hydrolyzed product of IXa.

A solution of 0.5 g of IXa in 20 m*l* of ethanol containing 2 m*l* of concentrated hydrochloric acid was stirred at 50°C for a few minutes, and the colorless crystals were filtered. Recrystallization from acetic acid afforded 0.28 g (84%) of X, mp 270.5°C (decomp.), as colorless prisms.

Found: C, 61.32; H, 4.96; N, 15.80%. Calcd for $C_{18}H_{18}N_4O_4$: C, 61.01; H, 5.12; N, 15.81%.

IR cm^{-1}: 3290 (NH), 1697, 1665 (C=O).

NMR (trifluoroacetic acid (CF_3COOH)) δ ppm: 3.88 (4H, broad signal, CH_2), 7.4—8.1 (10 H, multiplet, phenyl protons), 9.5, 10.0 (each 2H, broad signal, NH).

Reaction of IIa with Hydrobenzamide (VIIIb). When 0.8 g of VIIIb was added to the standard solution of IIa at room temperature, colorless crystals deposited immediately. Filtration gave 0.5 g (30%) of (4+2) cycloadduct IXc-l, which was washed with hot benzene and then subjected to microanalysis because of its insolubility in ordinary organic solvents.

NMR (CF_3COOH) δ ppm: 6.62 (1H, singlet, CH), 6.9—8.3 (22H, multiplet, two methine and 20 aromatic protons).

The xylene filtrate was evaporated *in vacuo* to leave a viscous oily substance, which solidified on trituration with petroleum ether. Recrystallization from benzene–petroleum ether (bp 45—65°C) gave 1.12 g (67%) of isomeric (4+2) cycloadduct IXc-2 as colorless needles.

NMR (carbon tetrachloride) δ ppm: 6.28 (1H, singlet, CH), 6.8—7.8 (22H, multiplet, two methine and 20 aromatic protons).

Similarly, the reaction of the standard solution of IIa with 0.62 g of VIIIa at room temperature for 5 min gave (4+2) cycloadduct IXb, which on recrystallization from

ethanol afforded 1.2 g (75%) of colorless needles.

NMR (CF_3COOH) δ ppm: 3.6—4.3 (4H, multiplet, CH_2), 6.63 (2H, singlet, CH), 7.5—8.2 (20H, multiplet, aromatic protons).

The physical properties and results of elemental analyses of IX are given in Table 3.

Reaction of IIa with Cinnamylidenanilines (XI). When an equimolar amount of XI was added to the standard solution of IIa, crystals were formed immediately. Filtration and recrystallization afforded the corresponding (4+2) cycloadduct XII.

Hydrolysis of (4+2) Cycloadduct XIIb. A solution of 0.3 g of XIIb in 20 m*l* of methanol containing 4 m*l* of concentrated hydrochloric acid was stirred at 50°C for 5 min during which time it turned into a clear yellow solution. The solution was evaporated *in vacuo* to leave a residue which was washed with diethyl ether and then ethanol. Recrystallization from ethanol afforded 0.11 g (52%) of urea V, mp 178—179°C (decomp.).

This research was supported financially in part by a grant from the Ministry of Education. The authors would like to express their thanks to Visiting Professor J.-P. Anselme, University of Massachusetts, Boston, for reading the manuscript.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2882—2884 (1972)

Oxidative Coupling of Aminonaphthols

Yoshimori OMOTE, Yasuomi TAKIZAWA, and Noboru SUGIYAMA
Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo
(Received December 8, 1971)

The oxidative coupling of three aminonaphthols by manganese(III) tris(acetylacetonate) was examined. The products from 5-amino-2-naphthol were enol-acetylacetonylidene-1-(6-hydroxynaphthyl)-imine (**1**) and 2,2′-dihydroxy-5,5′-diamino-1,1′-binaphthyl (**2**); those from 8-amino-2-naphthol were 4-(acetylacetone-3″-yl)-7,7′-dihydroxy-1,1′-azonaphthalene (**3**) and enol-acetylacetonylidene-7-hydroxy-1-naphthylimine (**4**); the product from 5-amino-1-naphthol was enol-acetylacetonylidene-4-hydroxy-1-naphthylimine (**5**).

We reported on the synthesis of a DOPA dimer[1] and Swan and Chapman reported on that of other DOPA dimers.[2] The compounds are of interest with respect to possible intermediacy of DOPA melanogenesis. Piattelli *et al.*[3] isolated several dimers of catechol from its oxidation products. The melanin precursor is very susceptible to oxidation making it difficult to regulate its oxidation to afford a specific dimer.

It is known that 2,3-dihydroxynaphthalene is dimerized into 2,2′,3,3′-tetrahydroxy-1,1′-binaphthyl by oxidative coupling using iron(III) alum,[4] and that 2,2′-dihydroxy-1,1′-binaphthyl is prepared by the oxidative coupling of 2-naphthol with manganese(III) tris(acetylacetonate).[5]

This suggests the possibility of controlling oxidation of phenolic compounds by selecting proper substrate, oxidant, solvent, and temperature. The results of investigation of the oxidative coupling of aminonaphthols are given. They are interesting as models of melanin precursors and also of practical importance as modification of hair dyes.[6]

Results and Discussion

Three available aminonaphthols were chosen as substrates. Oxidation was carried out under conditions suitable for oxidative coupling to give specific dimers. In order to do so, several known methods[5,7] recommended for the oxidative coupling of phenols were compared with the use of 2-naphthol as a reference. Manganese(III) tris(acetylacetonate) (MTA) shows the best result (Table 1).

TABLE 1. OXIDATION PRODUCTS FROM 2-NAPHTHOL AND 5-AMINO-2-NAPHTHOL WITH SEVERAL OXIDANTS

Oxidant	Oxidation products			
	(2-Naphthol)		(5-Amino-2-naphthol)	
	Dimer	Polyer*	Dimer	Polymer[a]
O_2/OH^- [8]	+	+	−	++
$K_3Fe(CN)_6$[9,10]	+	+	−	++
$FeCl_2$[11]	+	+	−	++
$VOCl_3$[7]	++	−	−	+
MTA[5]	++	−	++	−

a) Polymer: The products were black tar and did not dissolve in any solvents.

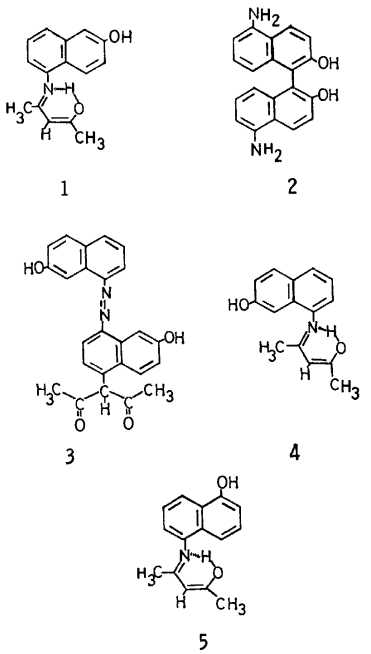
Aminonaphthols were oxidized with MTA in acetonitrile at 80°C under nitrogen atmosphere. From 5-amino-2-naphthol two products were obtained. One product with R_f 0.39 and mp 185°C was proved to have the structure **1** because the NMR spectrum in $CDCl_3$ of the substance showed the peaks at δ 2.15 (s, methyl 3H), 5.3 (s, methine 1H), 7.1—7.9 (m, naphthalene 6H), 9.9 (broad, phenolic 1H, disappeared with D_2O), and 12.8 (s, enol 1H, disappeared with D_2O). Both elemental analyses and mass spectrum also fit the structure **1**. The other product with R_f 0.17 and mp 230°C showed the peaks at δ 3.0 (s, aromatic amine 4H), 5.05 (broad s, phenolic 2H) and 6.3—8.0 (m, naphthalene 10H) in the NMR spectrum in acetone-d_6. This revealed the structure **2**, which was also supported by elemental analyses and mass spectrum.

In case of the oxidative coupling of 6-amino-2-naphthol, binaphthyl-type dimer was not obtained, but a 1,1′-azonaphthalene-type dimer (**3**) was obtained accompanied by enol-acetylacetonylidene-hydroxynaphthylimine (**4**). The structure **3** is in accord with the NMR spectrum in $CDCl_3$ which showed the peaks at δ 1.75 (two s, two methyl 6H), 1.7 (broad, phenolic 2H, disappeared with D_2O), 3.2 (s, methine 1H), and 6.2—7.8 (m, naphthalene 11H).



The UV spectrum of **3** also supports azonaphthalene structure showing λ_{max}(EtOH) at 255, 262 (sh), 315, 390, 409, and 514 nm. Recently Stead[12] reported on the formation of 2,8,8′-trihydroxy-1,1′-azonaphthalene-3,6,3′,6′-tetrasulfonic acid from the coupling of diazotized 1-amino-8-hydroxynaphthalene-3,6-disulfonic acid. It is interesting that a similar 1,1′-azonaphthalene is directly obtained by the oxidative coupling of an aminonaphthol.

The oxidative coupling of 5-amino-1-naphthol gave neither C–C coupling product like **2**, nor N–N coupling product like **3**, but afforded C–N coupling product between 5-amino-1-naphthol and acetylacetone from MTA. The structure of C–N coupling product is proposed as **5**. Spectral proofs of structure **4** and **5** are as follows. The NMR spectrum in $CDCl_3$ of **4** showed signals at δ 1.85 (s, 3H), 2.15 (s, 3H), 2.70 (broad, 1H), 5.30 (s, 1H), 7.10—7.90 (m, 6H), and 12.5 (s, 1H), and that of **5** showed signals at δ 1.9 (s, 3H), 2.2 (s, 3H), 5.3 (s, 1H), 6.9—7.5 (m, 6H), 9.1 (broad, 1H), and 12.6 (s, 1H).

Table 2. Linking of oxidative coupling of aminonaphthols

Coupling			C–C	+ (**2**)	—	—
N–N	—	+ (**3**)	—
C–N	+ (**1**)	+ (**4**)	+ (**5**)

The mark (○) shows a position which will be radical rich by resonance when naphthoxy radical is formed. The mark (□) shows a position where electron density is large because of the electron releasing effect of amino group. The mark (+) means positive reaction and the product is shown by a number in ( ).

The results of the oxidative coupling of three aminonaphthols are summarized in Table 2. In the case of 5-amino-2-naphthol, the C–C coupling is possible because the inductive effect of amino group will increase radical density at *ortho* position to hydroxyl group. In the case of 8-amino-2-naphthol, however, the C–C coupling at *ortho* position is prevented by steric hindrance of amino group, affording the N–N coupling product. In the case of 5-amino-1-naphthol, *ortho* position to hydroxyl group is not active enough to dimerize, only the C–N coupling product being obtained. The C–N coupling product between amino group and acetylacetone of MTA is formed in every case.[13]

Experimental

Enol-acetylacetonylidene-1-(6-hydroxynaphthyl)imine (1). 5-Amino-2-naphthol (0.79 g) was added to a solution of acetonitrile (30 ml) containing manganese(III) tris(acetylacetonate) (MTA) (2.11 g) under atmosphere of nitrogen. The mixture was stirred and kept under reflux at 80°C overnight. The solvent was then evaporated under reduced pressure. The concentrated product was examined by tlc (silica gel, benzene–ethyl acetate, 2: 1, v/v), two spots being observed at R_f 0.39 and 0.17. A portion (0.5 g) of the crude product was purified by silica gel column chromatography using the mixture of benzene and ethyl acetate (2: 1, v/v). The first fraction having R_f 0.39 gave a pale yellow solid which was recrystallized from benzene–ethyl acetate as pale yellow needles, mp 185°C (0.16 g). IR (KBr): 3100, 2900, 1630, 1600, 1500, 1430, 1420, 1300, and 900 cm^{-1}. MS (*m/e*): 241 (M^+).

13) K. Kaeriyama, This Bulletin, **43**, 1511 (1970).

Found: C, 74.71; H, 6.23; N, 5.84%. Calcd for $C_{15}H_{15}O_2N$: C, 74.66; H, 6.27; N, 5.81%.

2,2'-Dihydroxy-5,5'-diamino-1,1'-binaphthyl (2). Evaporation of the second chromatographic fraction of the preceding experiment gave a gray solid which was reprecipitated from benzene–ethyl acetate to give grayish powder (0.2 g), mp 230°C (decomp.).

IR: (KBr) 3370, 3300, 1620, 1590, 1510, 1429, 930, and 810 cm^{-1}. MS (*m/e*): 316 (M^+).

Found: C, 75.73; H, 5.36; N, 8.88%. Calcd for $C_{20}H_{16}O_2N_2$: C, 75.93; H, 5.10; N, 8.86%.

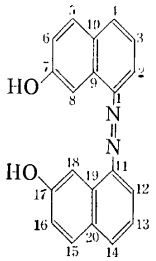
4-(Acetylacetone-3"-yl)-7,7'-dihydroxy-1,1'-azonaphthalene (3). A mixture of 8-amino-2-naphthol (0.8 g), acetonitrile (40 m*l*) and MTA (2.1 g) was treated in the same way as described above. The first elution of column chromatography gave red powder (0.21 g) which was reprecipitated from benzene, mp 251—252°C (decomp.). IR (KBr): 3400, 2900, 1705, 1685, 1655, 1625, 1590, 1320, and 830 cm^{-1}.

Found: C, 73.20; H, 4.94; N, 6.88%. Calcd for $C_{25}H_{20}O_4N_2$: C, 72.80; H, 4.89; N, 6.79%.

Enol-acetylacetonylidene-7-hydroxy-1-naphthylimine (4). The second fraction of the preceding chromatography gave a pale yellow solid which was recrystallized from benzene–ethyl acetate as pale yellow needles (0.04 g), mp 179—180°C. IR (KBr): 3400, 3100, 2900, 1620, 1600, 1550, 1320, 1250, and 1220 cm^{-1}.

Enol-acetylacetonylidene-4-hydroxy-1-naphthylimine (5). A mixture of 5-amino-1-naphthol (0.8 g), acetonitrile (40 m*l*) and MTA (2.5 g) was treated in the same way as described above. Only one product could be obtained. It was purified by column chromatography and recrystallization from ethyl acetate to give pale yellow needles (0.14 g), mp 187—188°C. IR (KBr): 3000, 2800, 1625, 1600, 1550, 1420, 1380, and 820 cm^{-1}. MS (*m/e*): 241 (M^+).

Calculation of S_R of 7,7'-Dihydroxyazonaphthalene. In order to determine the position of acetylacetonyl group in compound **3**, it was assumed that **3** was formed by the reaction of 7,7'-dihydroxyazonaphthalene radical and MTA. Parameters and superdelocalizability (radical) were as follows.



$$\alpha_{\dot{N}} = \alpha + 0.5\beta$$

$$\alpha_{\dot{O}} = \alpha + 2.0\beta$$

$$\beta_{NC} = 0.8\beta$$

$$\beta_{OC} = 0.8\beta$$

$$\beta_{NN} = 1.0\beta$$

Position No.	S_R(R)	Position No.	S_R(R)
1	0.9087	6	0.8887
2	1.0925	7	0.8859
3	0.8684	8	1.0129
4	1.1790	9	0.7690
5	1.0282	10	0.7129

The value of S_R(R) shows that position No. 4 will be most active in radical reaction.

The authors wish to thank Dr. Osamu Kikuchi, Department of Chemistry, Tokyo Kyoiku University, for HMO calculations.

The Synthesis and Stereochemistry of 2,3-Ferrocenocyclopentenone

Tamio SHIRAFUJI, Akio ODAIRA, Yasusi YAMAMOTO, and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Yosida, Kyoto

(Received February 29, 1972)

An optical isomer of 2,3-ferrocenocyclopentenone (X) has been synthesized from methyl (1*S*) (−)-2-hydroxymethylferrocenecarboxylate *via* a six-step synthesis. The absolute configuration of (−)-X has been confirmed by a comparison of its CD and ORD curves with those of the corresponding ferrocene homologs previously recorded. The mass spectrum of X is also discussed.

The asymmetric induction achieved in the lithiation of (*S*)(+)-(*N*-α-pipecolylmethyl)ferrocene (I)[1] has opened a synthetic route to chiral 1,2-disubstituted ferrocene derivatives, such as methyl (1*S*)(−)-2-hydroxymethylferrocenecarboxylate (III). Schlögl and his co-workers have established the absolute configuration of ferrocene derivatives in their study of ferrocene chirality.[2] They prepared 2,3-ferrocenocyclohexenone and several substituted 2,3-ferrocenocyclopentenones, but not the parent compound (X). The conventional

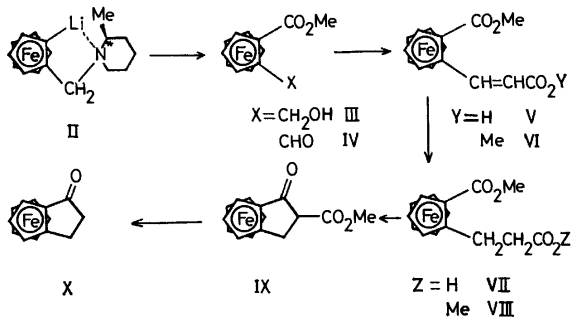
cyclization of ferrocenylpropionic acid preferentially gives the heteroannularly-bridged ketone.[3,4] We now wish to report on a successful synthetic approach to this ketone (X) in its optically-active form (*cf.* Scheme 1).



Scheme 1

The oxidation of (1*S*)(−)-III with MnO_2 gave methyl (−)-2-formylferrocenecarboxylate (IV). The subsequent Knoevenagel-Doebner condensation of the aldehyde (−)-(IV) with malonic acid gave the acid (−)-V. The catalytic hydrogenation of (−)-V with PtO_2, followed by esterification with diazomethane, afforded the diester (−)-VIII. The Dieckmann-type cyclization of the diester (−)-VIII with NaH in tetrahydrofuran gave the *β*-ketoester (IX),[5] which was then treated with dilute KOH to furnish the ketone (−)-X.

The ORD and CD curves of (−)-VI, (−)-VIII, and (−)-X were very similar to those of (1*S*)(−)-III of a known configuration,[1] as is shown in Figs. 1 and 2. Thus, every product obtained in each step of this synthetic route possesses the (1*S*,2*R*)-configuration.

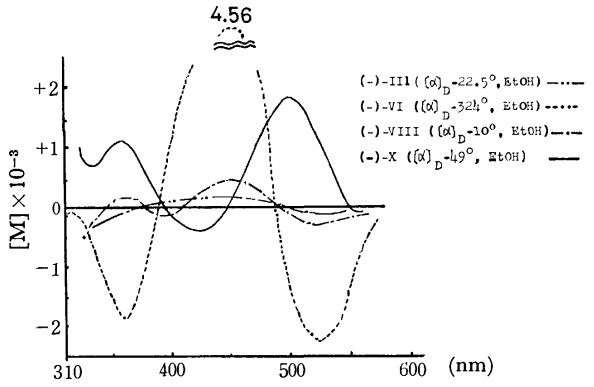


Fig. 1. ORD of III, VI, VIII, and X.

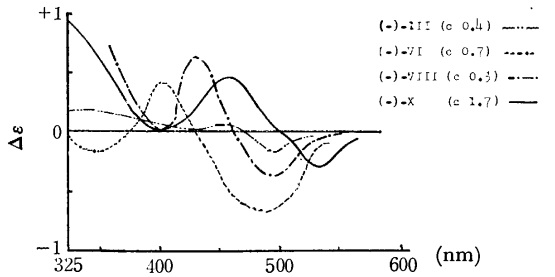

Fig. 2. CD of III, VI, VIII, and X (EtOH).

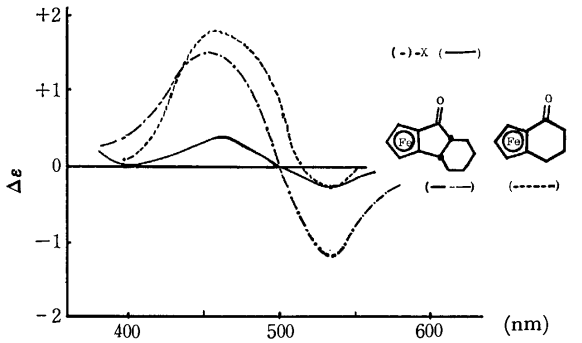

Fig. 3. CD of (−)-X and its homologs so far reported.

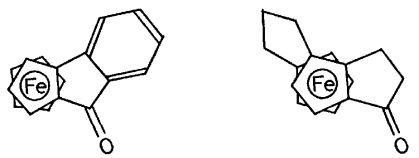
Furthermore, the CD curve of (−)-X in the region of the 300—600 nm ferrocene band area was similar to that of the ferrocenocyclohexenone of the (1*S*)-configuration[2g] and had the opposite sign of those of the substituted ferrocenocyclopentenones of the (1*R*)-configuration[2a,d,e] (see the following Scheme and Fig. 3).



CD value:
Δε −3.50 (485 nm, EtOH)

CD value:
Δε −1.30 (490 nm, EtOH)

On the basis of these facts, it was confirmed that the absolute configuration of (−)-X is (1*S*,2*R*).[6]

Finally, it should be added that the mass spectrum of the ketone (X) now synthesized exhibited an intense peak at *m/e* 212. The exact mass of this peak (212.027) showed that decarbonylation had occurred instead of the loss of ethylene.[8] The cleavage accounts for the metastable peak at *m/e* 187 (see Fig. 4).

8) This result is coincident with the fragmentation of 1-indanone (90% decarbonylation, 10% loss of ethylene). See: J. H. Bowie, *Aust. J. Chem.*, **19**, 1619 (1966).

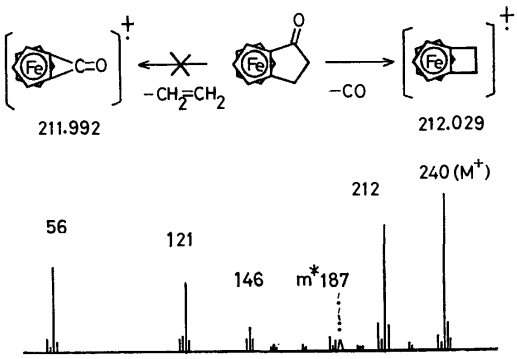

Fig. 4. Mass spectrum of ketone X.

Experimental

All the melting points and the boiling points are uncorrected. The microanalyses were performed at the Elemental Analyses Center of Kyoto University. The IR spectra were recorded on a Shimadzu IR-27-G spectrophotometer, and the mass spectra, on a Hitachi RMU-6L spectrometer. The NMR spectra were taken in a $CDCl_3$ or CCl_4 solution at 60 MHz on a JEOL C-60-H spectrometer; the chemical shifts are given in ppm from a TMS internal standard. The NMR signals are designated as *s* for a singlet, *d* as a doublet, *t* as a triplet, and *m* as a multiplet. The optical rotations were measured using a cell 1 or 5 cm in length at room temperature (20°C), and *c* is given in g/100 m*l*. The ORD and CD spectra were recorded on a JASCO ORD-5 spectropolarimeter in a EtOH solution (*c* in mg/m*l*), with a cell 1 cm long. The UV spectra were taken in EtOH on a Hitachi EPS-2 recording spectrophotometer. Column chromatography was carried out on Sumitomo activated alumina unless otherwise stated. The purity of every product was checked on tlc (Merck Aluminiumoxid G).
