The Mössbauer Effect in Ethyltin Halides and Related Compounds

Noriyuki WATANABE and Eiji NIKI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received September 12, 1970)

The Mössbauer spectra for ethyltin halides and related compounds (Et_4Sn, SnX_4 (X=Cl,Br, I), Et_3SnX, Et_2SnX_2 (X=Cl, Br, I), $EtSnI_3$) were obtained. The replacement of ethyl groups by halogen atoms made the isomer shifts more positive relative to the tetraethyltin precursor. These results may be explained in terms of the rehybridization theory that the *s*-character of a central atom tends to concentrate in orbitals directed toward electropositive substituents. A suggestion that the compounds of $RSnX_3$ type show smaller quadrupole splittings than the R_3SnX compounds is made and discussed in terms of the rehybridization in the orbitals of the tin atom and in terms of bond ionicity.

The ^{119}Sn-Mössbauer parameters in organotin compounds provide some useful information about the nature of the chemical bond formed by the tin atom. Among them, the isomer shift depends on the *s*-electron density at the tin nucleus. Changes in the electron density at the tin nucleus arise primarily through changes in the valence 5*s*-electrons, but other valence 5*p*- and 5*d*-electrons can shield 5*s*-electrons from the tin nucleus.[1a] An increase in the isomer shift corresponds to an increase in the *s*-electron density at the tin nucleus.[1b] Alkyl- and aryltin halides show positive isomer shifts compared to the corresponding tetraalkyl- and tetraaryltin.[1a,2-5] These findings on isomer shifts cannot be interpreted only in terms of polarization due to the electronegativity of the bonding halogen atoms. Stöckler and Sano have made a plausible suggestion that the tin *d*-orbital electron donated to the halogen atom may antishield the tin nucleus from the *s*-electron.[4] In the present study, similar results for ethyltin halides were obtained. Further, diethyltin dihalides showed an obvious dependence of the isomer shift on the halogen atoms. These results may be interpreted in terms of both the rehybridization of tin valence orbitals and the polarization due to the bonding halogen atoms. Very large quadrupole splittings were observed for triethyltin halides and diethyltin dihalides, whereas for ethyltin triiodide the splitting was drastically reduced. The fact that the compounds of $RSnX_3$ type (X=halogen or pseudohalogen, R=alkyl or aryl group) show smaller quadrupole splittings than the R_3SnX compounds will be discussed in terms of the rehybridization in the valence orbitals of the tin atom and in terms of bond ionicity.

Experimental

The compounds used in the present study were prepared by published procedures.[6,7] All of the triethyltin halides and ethyltin triiodide were purified by fractional distillation at a reduced pressure. The diethyltin dihalides were washed with ether and dried at a reduced pressure. The elemental analyses of C and H gave almost completely satisfactory results. The ^{119m}Sn-Mössbauer spectra were taken using a constant acceleration electromagnetic driver previously reported on.[8] The source was $Pd^{119m}Sn$, containing about 0.2 mCi ^{119m}Sn. The source was operated at room temperature, while the absorbers were cooled with liquid nitrogen in a cryostat previously reported on.[8] The velocity scale has been calibrated by the isomer shifts of β-Sn and SnO_2. The isomer shifts of β-Sn and SnO_2 are +1.11 and −1.58 mm/sec respectively with respect to $Pd^{119m}Sn$.

Results and Discussion

The Mössbauer parameters for ethyltin halides and related compounds are presented in Table 1. The Mössbauer spectra of Et_4Sn, Et_3SnCl, and Et_2SnCl_2 are shown in Fig. 1. The dependences of the isomer shifts on halogen atoms bonding to tin and on their number are shown in Fig. 2. Parish and Platt reported the quadrupole splittings of Et_nSnX_{4-n} (n=1, 2, 3, X=Cl, Br, I), with the exception of $EtSnI_3$ but their results do not agree with ours.[9] On the other hand, Bryuchova *et al.* presented quadrupole splittings and

isomer shifts consistent with our results for Et_3SnBr and Et_2SnI_2; that is, they reported that Et_3SnBr and Et_2SnI_2 showed the quadrupole splittings of 3.45 and 3.21 mm/sec and isomer shifts of −0.48 and −0.33 mm/sec relative to α–Sn, which could be converted to shifts of +0.12 and +0.27 mm/sec respectively relative to PdSn.[10]

Isomer Shift. Ethyltin halides showed more positive isomer shifts than did tetraethyltin. The isomer shifts in dihalides were more positive than those in monohalides. These results indicate that the *s*-electron density at the tin nucleus increase with an increase in the isomer shifts; $Et_4Sn < Et_3SnX < Et_2SnX_2$. Similar results for alkyl- and aryltin halides have been reported.[2-5] It may seem that the electron-withdrawing abilities of halogen atoms should decrease the 5*s*-electron density at the tin nucleus. Moreover, the 5*p*-electrons, which can shield 5*s*-electrons from the tin nucleus, may be decreased in the same way, but the decrease in the 5*p*-electron cannot compensate for the decrease in the 5*s*-electron density at the tin nucleus.[11] Hence, these results on isomer shifts cannot be interpreted only in terms of polarization due to the electronegativity of the halogen atoms. Stöckler and Sano have interpreted these results in terms of the deshielding by the tin *d*-orbital participated in $d\pi$–$p\pi$ bonding with halogen atoms.[4] However, the way in which the *d*-electron deshields the *s*-electron from the tin nucleus is ambiguous. Devooght *et al.* suggested that all the halides, with the exception of trimethyltin halides, could be tetracoordinated monomers.[12] The far-infrared spectra obtained in this study for ethyltin halides with neat samples sandwiched between CsI plates or nujol mulls showed the same Sn–C stretching frequencies as that in a previously-reported cyclohexane solution, in which ethyltin halides were tetrahedral monomers.[13] Bent proposed the following theory on the basis of the effects of the orbital hybridization and the electronegative substituents on the bond angles, bond lengths, and other physical properties.[14] He mentioned that the *s*-character of a central atom tends to be concentrated in orbitals directed toward electropositive substituents. This rule can explain our findings on the isomer shifts. That is, the *s*-character in tin valence orbitals is concentrated in the orbitals toward the more electropositive ethyl groups (in general, alkyl groups), while the *p*-character is concentrated in the orbitals directed to the electronegative halogen atoms. Moreover, the bonds directed to halogen atoms are more ionic due to their electronegativity. The increased ionicity in an orbital with a predominant *p*-character leads to an increase in the *s*-electron density at the tin nucleus due to decreased shielding by the *p*-electron. For triethyltin halides, the dependence of the isomer shifts on the bonding halogen atoms is not evident. However, it is obvious for diethyltin dihalides, in the case of which it coincides with the order of halogen electronegativity. Therefore, it may be assumed that the rehybridization effect is predominant

for triethyltin halides, while, for diethyltin dihalides, the polarization effect due to the electronegativity of halogen atoms is comparable to the rehybridization effect.

Quadrupole Splitting. The quadrupole splittings for mono- and dihalides increased in the order; iodides<bromides<chlorides. These results are consistent with the observations previously published.[2-5,9,10] The splitting of ethyltin triiodide was drastically reduced. Similar results for trihalides have been reported in several pairs of compounds. Stöckler and Sano reported that the splittings for $(C_6H_5)_3SnCl$ and $C_6H_5SnCl_3$ were 2.46 and 1.80 mm/sec respectively, while for $(CH_3)_3SnBr$ and CH_3SnBr_3 they were 3.28 and 1.91 mm/sec respectively.[4] Moreover, Gassenheimer and Herber reported similar results for alkyltin pseudohalides[15] (for $(C_4H_9)_3SnSCN$ and $C_4H_9Sn(SCN)_3$, 3.88 and 1.46 mm/sec, respectively). Consequently, it seems to be a general rule that the compounds of the $RSnX_3$ type (X=halogen or pseudohalogen, R=alkyl or aryl group) show smaller quadrupole splittings than the compounds of the R_3SnX type in cases where these compounds are monomeric. This can be understood if we consider the field gradient at the tin nucleus in the following model. From the fact previously mentioned, we assume a C_{3v} symmetry around the tin atom for $RSnX_3$. The four valence hybrid orbitals of the tin atom are as follows;

$$\begin{aligned}
\varphi_1 &= C_R\varphi_s + (1-C_R^2)^{1/2}\varphi_{p(z)} \\
\varphi_2 &= C_X\varphi_s + (1-C_X^2)^{1/2}(\varphi_{p(z)}\cos\alpha - \varphi_{p(x)}\sin\alpha) \\
\varphi_3 &= C_X\varphi_s + (1-C_X^2)^{1/2}(\varphi_{p(z)}\cos\alpha + \frac{1}{2}\varphi_{p(x)}\sin\alpha \\
&\quad - \frac{\sqrt{3}}{2}\varphi_{p(y)}\sin\alpha) \\
\varphi_4 &= C_X\varphi_s + (1-C_X^2)^{1/2}(\varphi_{p(z)}\cos\alpha + \frac{1}{2}\varphi_{p(x)}\sin\alpha \\
&\quad + \frac{\sqrt{3}}{2}\varphi_{p(y)}\sin\alpha) \qquad (1)
\end{aligned}$$

where α is the angle between the direction of the tin-carbon bond (z axis) and that of the tin-halogen bonds, where φ_s and φ_p are the tin valence $5s$ and $5p$ orbitals, and where C_X and C_R are the s-character of the hybrid orbitals directed to alkyl group and to the halogen atoms respectively. From the orthogonality of φ_1 with φ_2, we obtain;

$$\cos^2\alpha = \frac{C_R^2C_X^2}{(1-C_R^2)(1-C_X^2)} \qquad (2)$$

and from the orthogonality of φ_3 with φ_4, we obtain;

$$C_X^2 = \frac{1-3\cos^2\alpha}{3\sin^2\alpha} \qquad (3)$$

The four molecular orbitals are;

$$\begin{aligned}
\psi_1 &= \frac{\varphi_1 + i_R\varphi_R}{(1+i_R^2)^{1/2}} \\
\psi_j &= \frac{\varphi_j + i_X\varphi_X}{(1+i_X^2)^{1/2}}, \quad j = 2, 3, 4 \qquad (4)
\end{aligned}$$

where φ_R and φ_X are the valence atomic orbitals of carbon and halogen, and where i_R and i_X are their characters in the appropriate molecular orbitals.

The field gradient, $(V_{zz})_j$, due to electrons in the molecular orbital, ψ_j, is given by the expectation value of the field gradient operator, H_q ($H_q = \frac{3\cos^2\theta-1}{r^3}$);

$$(V_{zz})_j = 2\langle\psi_j|H_q|\psi_j\rangle \qquad (5)$$

The contribution of ψ_1 is;

$$(V_{zz})_1 = 2\frac{1-C_R^2}{1+i_R^2}V_{p(z)} \qquad (6)$$

where $V_{p(z)} = \langle\varphi_{p(z)}|H_q|\varphi_{p(z)}\rangle$ and $\langle\varphi_s|H_q|\varphi_{p(z)}\rangle = 0$, neglecting the two-center integral, $\langle\varphi_R|H_q|\varphi_R\rangle$, $\langle\varphi_{p(z)}|H_q|\varphi_R\rangle$, *etc.* as too small.

The contribution of $p(z)$ electrons in the molecular orbitals, ψ_2, ψ_3, and ψ_4, is;

$$\sum_{j=2}^{4}(V_{zz})_j = 6\frac{1-C_X^2}{1+i_X^2}V_{p(z)}\cos^2\alpha \qquad (7)$$

Moreover, the contributions of the $p(x)$ and $p(y)$ electrons in ψ_2, ψ_3, and ψ_4 are;

$$\sum_{j=2}^{4}(V_{xx})_j = 3\frac{1-C_X^2}{1+i_X^2}V_{p(x)}\sin^2\alpha \qquad (8)$$

and;

$$\sum_{j=2}^{4}(V_{yy})_j = 3\frac{1-C_X^2}{1+i_X^2}V_{p(y)}\sin^2\alpha \qquad (9)$$

where $V_{p(x)} = \langle\varphi_{p(x)}|H_q|\varphi_{p(x)}\rangle$, *etc.*

If it is assumed that all of the $5p_x$, $5p_y$, and $5p_z$ orbitals have the same radial functions, the next equation is obtained:

$$V_{p(x)} = V_{p(y)} = -\frac{1}{2}V_{p(z)} \qquad (10)$$

Consequently, the total field gradient, V_{zz}, is:

$$V_{zz} = 2V_{p(z)}\left[\frac{1-C_R^2}{1+i_R^2} + 3\frac{1-C_X^2}{1+i_X^2}\left(\frac{3\cos^2\alpha-1}{2}\right)\right]$$

By introducing (2) and (3) into the above equation, we obtain:

$$\begin{aligned}
V_{zz} &= V_{p(z)}[(1-C_R^2)(1+I_R) - (1-C_R^2)(1+I_X)] \\
&= (1-C_R^2)(I_R-I_X)V_{p(z)} \qquad (11)
\end{aligned}$$

where the bond ionic characters, I_X and I_R, are expressed as:

$$I_X = \frac{1-i_X^2}{1+i_X^2}, \quad I_R = \frac{1-i_R^2}{1+i_R^2}. \quad (I_X<0,\ I_R>0,\ |I_X|>|I_R|)$$

An analogus calculation for R_3SnX yields:

$$V_{zz}(R_3SnX) = (1-C_X'^2)(I_X'-I_R')V_{p(z)} \qquad (12)$$

where C'_X is the coefficient included in one of the tin valence orbitals for R_3SnX, ($\varphi'_1 = C'_X\varphi_s + (1-C'_X{}^2)^{1/2}\varphi_{p(z)}$) and where I'_X and I'_R are the bond ionic characters for R_3SnX ($I'_X<0$, $I'_R>0$, $|I'_X|>|I'_R|$).

By combining (11) with (12), we obtain:

$$\frac{V_{zz}(RSnX_3)}{V_{zz}(R_3SnX)} = -\frac{(1-C_R^2)(I_X-I_R)}{(1-C_X'^2)(I_X'-I_R')} \qquad (13)$$

Since the rehybridization theory can be applied to $RSnX_3$ as well as to R_3SnX, it may be assumed that $C_R^2 > 1/4$ for $RSnX_3$ and $C_X'^2 < 1/4$ for R_3SnX. (This is exactly what Bent's rehybridization theory predicts.)

15) B. Gassenheimer and R. H. Herber, *Inorg. Chem.*, **8**, 1120 (1969).

Moreover, it is reasonable that we consider $|I'_X|>|I_X|$. For example, this consideration may be supported by the fact that the replacement of hydrogen by the more electronegative chlorine for chloromethanes, CH_nCl_{4-n}, makes the C–Cl bond less ionic.[16] As more direct evidence, we find, from the n.q.r. data for $(n\text{-}C_4H_9)_n\text{-}SnCl_{4-n}$ (n=0, 1, 2), that the replacement of chlorine atoms by buthyl groups leads to an increase in the ionic character in the Sn–Cl bond.[17] Other support is found in the recent calculation of orbital populations in aryltin chlorides.[18] Moreover, since I_R and I'_R are small compared to I_X and I'_X, $(I_X-I_R)/(I'_X-I'_R)\fallingdotseq I_X/I'_X$.[18] Therefore, it can be concluded that $|V_{zz}(RSnX_3)|<|V_{zz}(R_3SnX)|$ and that the more electronegative the substituents, X, the larger the field gradient, V_{zz}, for R_3SnX.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 4—7(1972)

The X-Ray Emission Spectra of the Compounds of Third-period Elements. II. The *K* Spectra of Phosphorus in Compounds

Yoshihito TAKAHASHI

Government Industrial Development Laboratory, Hokkaido Higashi-Tsukisamu, Sapporo

(Received February 5, 1971)

On sixteen compounds of phosphorus, the wavelength shifts of the $K\alpha_{1,2}$ lines and the fine structures of the $K\beta$ band of the phosphorus emission spectra were measured. For the oxygen compounds, the relationship between the intensity ratio of the $K\beta'$ line and the energy shift of the $K\alpha_{1,2}$ lines was found to be expressed by a straight line similar to that found for sulfur and chlorine compounds. In the spectra of the oxyacids and their salts, the intensity ratio of the satellite line which is observed between the $K\beta_1$ and $K\beta'$ lines is proportional to the number of the hydroxyl groups in a molecule. The appearance of this line seems to be attributable to the covalent bond between a third-period atom and a non-ionized atom. In the $K\beta$ spectrum of triphenyl phosphite, the strong satellite line at the highest energy site seems to have a nature similar to those found in sulfite, chlorate, and phosphorus trichloride.

Previously, we have studied the nature of the satellite line $K\beta'$ which is observed on the longer-wavelength side of the $K\beta_1$ line of sulfur and chlorine in many kinds of oxygen compounds, and have found that the relationship between the ratio of the integral intensity of the $K\beta'$ line to the total intensity of the $K\beta$ line (we call it the intensity ratio of the $K\beta'$ line) and the energy shift of $K\alpha_{1,2}$ lines (it relates to the effective charges of the atom in a molecule[1,2]) can be expressed by straight line similar to those for the oxygen compounds of both sulfur and chlorine. From these facts, it has been suggested that the appearance of the $K\beta'$ line is due to the transfer of valence electrons from the third-period atom to the bonded oxygen atoms in the molecule, and that its intensity is related to the nature of the ligand atoms rather than to the kind of third-period atom.[3,4]

In order to check the general truth of these facts as regards all the third-period elements, the P$K\beta$ spectra of various phosphorus compounds have been measured. Although the data on the P$K\alpha_{1,2}$ lines have been already reported by Yao and Holst,[5] and more recently by Nikolaev *et al.*,[6] new measurements are now made for several compounds.

Experimental

The spectra were measured on the same apparatus as that descrived in a previous work.[4] A flat germanium analyzing crystal ((111) plane, $2d$: 6.53272 Å) was also used. The wavelength values of the P$K\alpha_{1,2}$ lines on each compound were measured, using the fourth-order reflection of the Cu$K\alpha_1$ line (corresponding to 6.16200 Å) as the standard; they were then converted to the value of the energy shift from the value of red phosphorus. The spectra of P$K\beta$ were obtained using the step-by-step method as in the previous work. However, in the case of phosphorus trichloride, in order to avoid the oxydation of the material during the measurements, the spectrum was obtained by the chart-recording method (one running time was 12 min), and the average of the three runs was taken. The background was measured at the 5.90 Å position. The separation of the $K\beta$ spectrum into several component peaks was attempted, taking the P$K\beta_1$ peak of anhydrous sodium phosphate as the standard shape.

Results and Discussion

The P$K\beta$ spectra measured are shown in Fig. 1. We named the component peaks as is shown in Fig. 1, *i.e.*, A($K\beta'$), B, C($K\beta_1$), C', and D, counting from the longer-wavelength side. The structure of the spectrum of red phosphorus was so complicated that the separation into component peaks was not attempted for this substance. The characteristic values of the $K\alpha_{1,2}$ and $K\beta$ lines for each compound are summarized in Table 1.

——: regression line relating to the oxygen-compounds of sulfur and chlorine, $y=0.25x+0.02$.
------: anticipated line relating to the compounds of chlorine ligand.

The relationship between the $K\beta'$ intensity ratio and the energy shift of the $K\alpha_{1,2}$ lines found in the oxygen compounds and chlorides of phosphorus (mark ○ and △, respectively) is shown in Fig. 2. Although the points for the oxygen compounds are scattered in some extent, it may be concluded that they lie on a straight line similar to that found in the oxygen compounds of sulfur and chlorine. To speak more exactly, the points for the oxysalts of phosphorus drop on the upper side of the line, while those for the molecular oxygen compounds (phosphorus pentoxide P_2O_5, triphenyl phosphate $(\phi O)_3PO$, *etc.*) lie on the lower side. The points for phosphorus pentachloride and phosphorus trichloride deviate much from the line (mark △). It might be presumed that the latter points lie on another line, having a larger gradient. From this fact, it seems that the gradient of the line in the Fig. 2 is related not to the kind of third-period atom in the molecule, but to the kind of ligand atom.

In the $K\beta$ spectra of the oxygen compounds of sulfur and chlorine, and in those of the oxysalts of phosphorus, the energy difference between A and C was measured to be about 14 eV. However, in the case of the molecular oxygen compounds of phosphorus (P_2O_5, $(\phi O)_3PO$, *etc.*), the energy difference between A and C is about 12 eV, and there is a strong C' peak separated about 5 eV from the C peak on the higher-energy side. On the other hand, in the $K\beta$ spectra of the chlorides

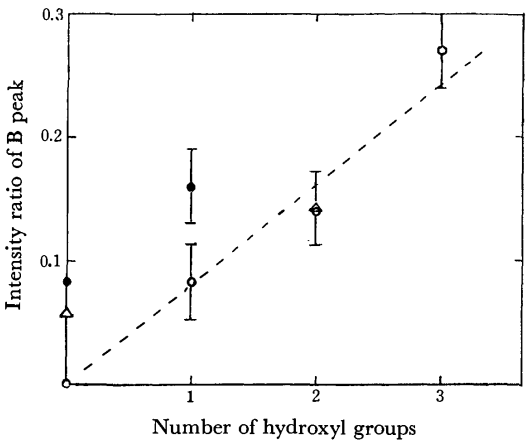

Fig. 3. The relationship between the intensity ratio of B peak and the number of hydroxyl groups in the oxyacids and their salts.
○: phosphoric acid (sodium salt)
△: phosphorous acid (sodium salt)
●: hypophosphorous acid (sodium salt)
We supposed that hypophosphorous acid was monobasic, in this Figure. We did not adupt the B′ peak, but adupted only the B peak on the intensity ratio of hypophosphorous acid.

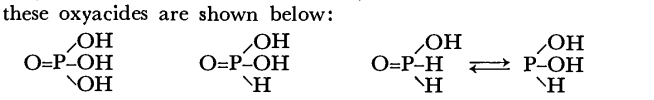
of phosphorus, the energy differece between A and C was about 8.5 eV. The difference in these two cases may be compared with the difference in the gradients of the two lines in Fig. 2.

As in the case of the sulfur compounds, in which the B peak is observed in the $K\beta$ spectrum of such molecular compounds as dimethyl sulfone and the N,N-derivative of sulfoneamide,[3] the B peak is also observed in the molecular compounds of phosphorus, such as phosphorus pentoxide, triphenyl phosphate, and phosphorus pentachloride. In addition, in the oxysalts and oxyacids of phosphorus, the intensity of the B peak is proportional to the number of hydroxyl groups in the molecule.[7] In the spectrum of anhydrous sodium phosphate, which does not have a hydroxyl group, the B peak is, as expected, not observed. This relationship is shown in Fig. 3. Considering the position of the points for phosphite and hypophosphite in the figure, it seems that the P–H bond of these compounds slightly affects the appearance of the B peak. The appearance of the B peak seems to be attributable to the covalent bond between a third-period atom and a non-ionized atom, such as P–OH, P–OC, and P–OP. On sodium pyrophosphate, $[^{=}O_3P\text{–}O\text{–}PO_3^{=}]\cdot 4Na^+$, which involves only one such covalent bond per phosphorus atom, the B peak intensity ratio is close to the value in disodium hydrogenphosphate, and while on sodium metaphosphate, $^{-}O_2P\langle^{O\text{–}PO_2^{-}}_{O\text{–}PO_2^{-}}\rangle O\cdot 3Na^+$, which has two such covalent bonds per phosphorus atom, the ratio is close to the value in sodium dihydrogenphosphate. Further, on phosphorus pentoxide (dimer), in which there are one and a half such covalent bonds per phosphorus atom, the value of the ratio is conformable to the number of the covalent bond (see Table 1).

The D peak, as has been mentioned in a previous work, was markedly observed in the S$K\beta$ spectra of sulfite and sulfoxides and in the Cl$K\beta$ spectrum of chlorate.[3,4] As for the phosphorus compounds, a remarkable D peak is also observed in the spectrum of phosphorus trichloride. Generally, it seems that the remarkable D peak is observed in the $K\beta$ spectrum of the compound in which the third-period atom has one lone pair, such as $SO_3^{=}$, ClO_3^{-}, SF_4,[9] and PCl_3. The phosphorus atom of triphenyl phosphite $(\phi O)_3P$ also has one lone pair, so the appearance of the remarkable D peak in the spectrum can be anticipated. The D peak in the $K\beta$ spectrum measured (Fig. 1m) seems to correspond to the D peak of the sulfite or the phosphorus trichloride in view of the position and the intensity of the peak. That is, the peak appears in nearly the same position as the D peak of the phosphorus trichloride, and the peak separation between A and D in the spectrum of Fig. 1m, about 21 eV, corresponds to that between A and D for the sulfite, 21 eV, and to that for the chlorate, 20 eV. The intensity ratios of the D peak to the total $K\beta$ line in these compounds (0.29, 0.19, and 0.14 for triphenyl phosphite, phosphorus trichloride, and sodium sulfite, respectively) are larger than in other compounds.

The C′ peak is observed in the spectra of phosphorus pentoxide, triphenyl phosphate, and triphenyl phosphite. This peak can be distinguished from the D peak as a result of the difference in the position of the C′ peak (5.790—5.800 Å) from that of the D peak (5.783—5.787 Å). For example, in the spectrum of triphenyl phosphite, both D and C′ peaks are observed, and they can be distinguished, as is shown in Fig. 1m.

7) To make the matter clearer, the chemical structures of these oxyacides are shown below:



phosphoric acid, (tribasic) phosphorous acid, (dibasic) hypophosphorous acid, (monobasic)

in which dibasic inorganic hypophosphites are not present.[8]

8) "Mellor's Comprehensive Treatise on Inorganic and Theoretical Chemistry," Vol. VIII, (1962), p. 873.

9) In the S$K\beta$ spectrum of sulfur tetrafluoride, the intensity ratio of the D peak is 0.13, the peak separation between the D and C peaks is 7.2 eV, and that between the C and A peaks is 18.5 eV.[10]

Spectra of Anions in Pure Iodine Melt and Iodine Solution Containing Tellurium

Kazuhiko ICHIKAWA and Mitsuo SHIMOJI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received February 27, 1971)

The absorption spectra in the ultraviolet and visible region were measured as a function of the temperature for pure molten I_2 and for I_2+Te solutions. The two peaks found at about 305 and 370 mμ can be attributed to the I_3^- ion. These peaks increase with the addition of Te indicating an increase in the concentration of the I_3^- ion. This result is consistent with the previous interpretation of the conductivity of molten I_2 containing Te. The ionization potential of I_3^- can be estimated to be about 3.1 eV on the basis of a cyclic analysis using the model of Stein and Treinin which was developed for anion spectra in aqueous solutions. The temperature shift of the absorption energy can also be interpreted in terms of the same model. The heat change for the $I_2(g)+I(g)=I_3(g)$ reaction is estimated as -48.0 kcal·mol^{-1}.

In a previous paper[1] we have described our finding on the electrical conductivity of molten I_2+Te solutions, and pointed out that, in the I_2-rich region, the triiodide ion, I_3^-, probably resulting from some chemical reactions, may contribute largely to the electrical conduction.

This paper will report on the absorption spectra of the same solutions in the ultraviolet and visible regions. The experimental results confirm the presence of the I_3^- ion in these solutions and are discussed in terms of the theory given by Platzman and Franck[2] and modified by Stein and Treinin[3] for anion spectra in aqueous solutions.

Experimental

Materials. The tellurium used was 99.9999% pure. Guaranteed reagent-grade I_2 was dried at room temperature under a vacuum in order to remove the surface water and was purified by sublimation *in vacuo* at about 50°C.

Apparatus and Procedure. The absorption spectra in the ultraviolet and visible regions (230—700 mμ) were measured for the pure I_2 liquid and I_2+Te solutions. Measurements of diffuse reflectance spectra were carried out with a Beckman DK-2A ratio recording spectro-photometer. The quartz-drum-cell containing the sample, in which a fine powder phase was made of the guaranteed reagent-grade aluminum oxide, was sealed off under a vacuum. The observed temperature range was limited to below 200°C because of the limited temperature-supporting capacity of this spectrometer. The diffuse reflectance obtained for a given wavelengh was transformed to the optical density in arbitary units by means of the Kubelka-Munk equation.[4]

Results

The absorption bands of the I_2+Te solutions at several concentrations and temperatures are plotted in Fig. 1. All the absorption spectra show two peaks with a charactristic spacing at about 305 and 370 mμ. Their optical densities increase with the addition of Te,

although the wavelengths of the peaks are almost unchanged. Above about 150°C the optical density decreases and the band width increases with the temperature. Table 1 shows the two absorption maxima in the molten I_2 and I_2+4 at.% Te systems at 150°C. The energy separation between these two band maxima is very small, with a range of only about 0.6×10^4 cm^{-1}. In Fig. 2 the temperature dependence of the $h\nu_{max}$ of the longer wavelength band in the pure I_2 liquid is recorded. The straight line gives $dh\nu_{max}/dT=-7.3$ cm^{-1} deg^{-1}.

Discussion

In our previous work,[1] the considerable increase in the conductivity of molten I_2, upon the addition of 0.1—4 at.% Te was interpreted in terms of a charge-transport mechanism, and the formation of the triiodide ion I_3^-, resulting from the $I_2+I^-\longrightarrow I_3^-$ reaction, was suggested. The existence of the I_3^- ion is now confirmed by the absorption maxima found at 305 and 370 mμ, as is shown in Fig. 1 and Table 1, in which the other data for the CsI_3,[5] $KI+I_2$[6] aqueous solutions and the $KI+I_2$[7] solid solutions are also cited. The two peaks of the absorption spectra suggest a doublet splitting of some kind in the electronic states of the I_3 molecule.

The magnitude of $h\nu_{max}$ and its temperature shift, $dh\nu_{max}/dT$, obtained here will be discussed using the theory of Stein and Treinin,[3] which accounts for the anion spectra in aqueous solutions in terms of the charge-transfer-to-solvent mechanism.[2,3,8-10] Since the solvent structure in their theory is approximated only by a dielectric continuum with a static dielectric constant, D_s, the formula proposed by them may be used for systems other than the aqueous solution. Thus, the absorption energy of the solvated I_3^- ion may be written, using Stein and Treinin's notation, by:

$$h\nu_{max}=E_x-L_x+\frac{e^2}{r_0}\left(\frac{1}{2}+\frac{1}{2D_{op}}-\frac{1}{D_s}\right)-\frac{e^2}{2\bar{R}_e}\left(1-\frac{1}{D_{op}}\right)-\left(\frac{\pi^2me^4}{2h^2}\right)\left(\frac{1}{D_{op}}-\frac{1}{D_s}\right)^2 \quad (1)$$

The value of the apparent radius, r_o, of the cavity in the continuous medium can be determined from the relation $r_o\cong\alpha r_c$,[3] where r_c is the crystallographic radius and where α is a constant with a value of about 1.275. The value of r_c for I_3^- is taken as 3.51 Å from the crystallographic data of CsI_3,[11] by using the method of Gray and Waddington[12] for the calculation of the effective radius of N_3^-. The energy change associated with the non-thermodynamic dissolution of the I_3 molecule, $-L_x$, is roughly taken as $-3\Delta H_e/2$ by considering the dispersion forces. Here, ΔH_e[13] is the heat of evaporation of liquid I_2. The average distance of the excited electron from the center, $\bar{R}_e$, is calculated using the hydrogen-like wave function in the Coulomb force field due to the effective charge of the Landau type.

Table 2. Ionization potential E_x of I_3 evaluated by means of eq. (1) energies in 10^4 cm^{-1}

	150°C molten I_2	Room temperature		
		aq. CsI_3	aq. $KI+I_2$	crystal $KI+I_2$
E_x	2.41	2.60	2.60	2.60
D_{op}	2.73	1.78	1.78	2.69
D_s	13.0	78.5	78.5	4.94
L_x	0.607	0.483	0.483	0.758

The values of the optical dielectric constant D_{op} and those of D_s for the liquids are referred to "Gmelins Handbuch der anorganischen Chemie" **8**, Jod, Verlag Chemie, Berlin (1933) p. 85, 649. and **5**, Sauerstoff, Verlag, Weinheim, (1963) p. 1550, 1591, and those for the crystal are taken from N. F. Mott and R. W. Gurney, "Electronic Processes in Ionic Crystals," Clarendon Press, Oxford (1940), p. 12.

No data have been obtained so far for the value of the ionization potential of the I_3^- ion, E_x. Therefore, the value shown in Table 2 is evaluated on the basis of Eq. (1) using the experimental $h\nu_{max}$ values. Similar calculations were also made for CsI_3 and $KI+I_2$ aqueous solutions and for the KI crystal containing I_2, where it is assumed that the values of $-L_x$ are 3/2 of the heats[13,14] of solution of I_2 into the respective solvents. The calculated E_x values in Table 2 are almost constant, ranging only $(2.4-2.6)\times10^4 cm^{-1}$, despite the differences in the parameters of the respective solvents.

No quantitative calculations have been performed for the I_2+Te solutions, because no observed values of D_s in this system are available. The resemblance in the positions of the absorption maxima reported in Fig. 1 and Table 1, however, suggests the applicability of the same model for the extremely I_2-rich melts. In other words, the parameter values (for r_o, D_s, D_{op}, L_x, *etc.*) in the molten I_2 containing a small amount of Te below 4 at.% may not be very different from those in pure I_2. Further, the increase in the optical densities of the peaks (Fig. 1) upon the addition of Te and the decrease upon the raising of the temperature indicate an increase in the concentration of the I_3^- ion. These facts are consistent with the conclusion in the conductivity work[1] that the enthalpy change in the I_3^- formation must be negative, because the I_3^- concentration decreases with an increase in the temperature in these I_2-rich liquids.

Theoretically, the temperature shift can be written by a differentiation of Eq. (1) with respect to the temperature. The contribution from the temperature change in D_s and D_{op} is, at most, -1 $cm^{-1}deg^{-1}$, which is much smaller than the experimental value of -7.3

$cm^{-1}deg^{-1}$. The term of dL_x/dT can be calculated from the value of the heat capacity of the I_3^- ion in the excited state, $C_p(I_3(I_2)_n^-)$. The heat-capacity effect in the gaseous state practically vanishes[10] in these cyclic calculations, for its effect appears in the processes of both the ion removal and the radical solvation (*e.g.*, in the terms of E_1 and E_2 in Eq. (6) in the paper of Stein and Treinin,[3] from which Eq. (1) in this paper is obtained). $C_p(I_3(I_2)_n^-)$ is roughly taken as 3/2 of the heat capacity of the I_2 molecule in the liquid state. dr_o/dT is evaluated from the $\alpha dr_c/dT$ relation using the density data.[15] Thus, for pure I_2 the calculated $dh\nu_{max}/dT$ value of $-8.7\ cm^{-1}deg^{-1}$ is in fair agreement with the experimental value of $-7.3\ cm^{-1}deg^{-1}$ (Fig. 2). This temperature shift may also be interpreted alternatively in terms of the vibrational effect[10] of the solvated molecules.

In a simpler model, proposed by Smith and Symons,[8] the temperature effect is explained by considering only the change in the excited state, which is approximated as a state of a free particle in a spherical box. Adopting $E_x=2.41\ cm^{-1}deg^{-1}$ from Table 2 and $h\nu_{max}=26990\ cm^{-1}$, we get 10.2 Å for the radius, r_o*, of the spherical box in their model. However, such a free-electron-like behaviour in the box may be difficult to correlate with any physical property of the ion, as was pointed out by Stein and Treinin.[3]

The heat of formation of triiodide molecules in the gaseous state has not previously been reported. However, the heat of reaction, $\Delta H_r(I_3^-(aq))$, for the equilibrium in aqueous solutions[16]:

$$I_2(aq) + I^-(aq) \rightleftharpoons I_3^-(aq) \qquad (2)$$

has been well investigated, and the heats[14] of hydration of the iodine molecule and ion, *i.e.*, $\Delta H_h(I_2)$ and $\Delta H_h(I^-)$, are konwn. Further, the ionization potential of the I^- ion, $E_x(I^-)$,[9] has been established, the heat of hydration of the I_3^- ion can be estimated theoretically by means of Born's equation,[17] and the semiempirical value of the ionization potential of the I_3^- ion, $E_x(I_3^-)$, is shown in Table 2 of this paper. Thus, if we use $\Delta H_r(I_3^-(aq))=-4.7\ kcal\cdot mol^{-1}$, $\Delta H_h(I_2)=-9.5$, $\Delta H_h(I)=-72.1$, $\Delta H_h(I_3^-)=-39.3$, $E_x(I^-)=72.5$, and $E_x(I_3^-)=71.5$, the heat of reaction, $\Delta H_r(I_3(g))$, for the reaction:

$$I_2(g) + I(g) = I_3(g) \qquad (3)$$

can be given by $-48.0\ kcal\cdot mol^{-1}$. This calculated result suggests that the I_3 molecule is stable in the gaseous phase, as is observed in the mass spectra.[17]

We are indebted to Professor Y. Matsunaga, in whose laboratory the measurements of the absorption spectra were made. We also wish to thank Professors K. Ohno and Y. Matsunaga for their helpful discussions. One of us (K.I.) is grateful for a grant from the Sakkokai Foundation.

A MO-theoretical Study of the Catalytic Activity of Onium Compounds in the Liquid-phase Oxidation

Katsutoshi OHKUBO and Hirokazu KANAEDA

Department of Synthetic Chemistry, Kumamoto University, Kurokami-machi, Kumamoto

(Received March 3, 1971)

A theoretical study with the extended Hückel method augmented by *d*-orbitals was undertaken in order to elucidate the relation between the electronic structures of various onium compounds and their catalytic activities in the liquid-phase oxidation of hydrocarbons. There were several findings. Firstly, the differences in the catalytic activities of the carbonium, ammonium, and oxonium compounds are ascribed to those in the AO populations of the p_z-orbitals on their central atoms. Secondly, the distinguished activities of sulfonium and phosphonium compounds were well explained by the partially-occupied sulfur or phosphorus 3*d*-orbitals, in which the d_{xz} (or d_{yz}) orbital is utilized most effectively for the interaction with the $(1\pi_g)_z$–orbital of O_2. Finally, the relatively low activities of arsonium and telluronium compounds are ascribed to the vacant and diffused 4*d* or 5*d* orbitals, while the appreciable activity of the selenonium compound is caused by the partial electron-occupancy of the $4d_{xz}$ (or $4d_{yz}$) orbital of the central selenium.

The catalyst in the liquid-phase oxidation of hydrocarbons has been widely investigated from the viewpoints of both theory and technology. Among several oxidation catalysts, such as transition metal compounds[1] (including chelates[2] and complexes[3]) and halogen compounds[4] (involving ammonium salts[5]), ammonium salt-catalysts exhibit some especially interesting features in their catalytic behavior because they show little activity for the promotion of the oxidation reaction, even though the ammonium cation possesses the counter anion of perchlorate[5] or tetrafluoroborate,[6] and also because the difference in the substituents attached to the central nitrogen has an influence upon the catalytic activity. Our own previous studies[7,8] of the catalytic activities of several onium compounds demonstrated that the activity was affected directly by the differences in the onium central atoms and immediately by those in the structures of the counter anions and the substituents. That is, sulfonium and phosphonium salts involving the lower vacant 3*d*-orbitals (strictly speaking, the partially-occupied 3*d*-ones) were found most effective, and it was shown that the larger the alkyl group attached to the central atom, the higher the catalytic activity. As for the counter anions, phosphate, sulfate, *etc.* are more active than halides. These experimental phenomena are directly connected with the catalytic activation of molecular oxygen, as was suggested by our spectroscopic[9] and theoretical[10,11] investigations concerning the possible interaction between the catalyst and O_2.

In this paper, we will attempt to clarify the correlation between the electronic structures of onium compounds and their catalytic activities in the liquid-phase oxidation of hydrocarbons, such as cumene and α-pinene. For example, the catalytic activity of several onium tetrafluoroborates has been found to be in approximately the following order: carbonium<ammonium<oxonium, silyl<phosphonium≃sulfonium, arsonium≃telluronium<selenonium. Extended Hückel molecular orbital (EHMO) calculations were performed on these onium compounds.

Method of Calculation

The extended Hückel method (EHMO) proposed by Hoffmann[12] was adopted to the calculations of $(CH_3)_3CCl$, $(CH_3)_4NCl$, $(CH_3)_3OCl$, $(CH_3)_3SiCl$, $(CH_3)_4PCl$, $(CH_3)_3SCl$, $(CH_3)_4AsCl$, $(CH_3)_3SeCl$, and $(CH_3)_3TeCl$. Methyl derivatives of onium compounds were taken for mathematical convenience. The geometries used for the calculations are illustrated in the figures of this paper.

The orbital exponents and the Coulomb integrals ($H_{\mu\mu}$) were supplied by Clementi[13] and Jaffè,[14,15] respectively. Especially, the $H_{\mu\mu}$ value of the oxygen 2*p*-orbital was obtained from the atomic ground-state ionization potential[14] ($H_{\mu\mu}$(O 2*p*)$=-13.61$ eV). The $H_{\mu\mu}$ values of the *d*-orbitals of S, P, As, Se, and Te were -7.00,[16] -6.53, -5.00, -4.00, and -4.00 eV respectively. The resonance integrals ($H_{\mu\nu}$) were evaluated by the Wolfsberg-Helmholtz approximation[17]:

$$H_{\mu\nu} = 0.875(H_{\mu\mu}+H_{\nu\nu})S_{\mu\nu}$$

Results and Discussion

Electronic Structures of Second-row Onium Compounds. It is necessary at first to assume the molecular structures of carbonium, ammonium, and oxonium compounds under the present experimental conditions. In view of the propeller-like D_3 symmetry of the triphenylcarbonium cation[19] and the ionic property of these compounds, it is plausible to assume planar C_{3v} structures for the trimethylcarbonium and trimethyloxonium cations.[20] On the basis of the above discussion, the EHMO calculations were performed for $(CH_3)_3CCl$ and $(CH_3)_3OCl$ at the ionic distances of C–Cl and O–Cl (2.66 and 3.5 Å respectively). The valence-electron distributions of the above compounds are shown in Fig. 1. In regard to the structure of $(CH_3)_4NCl$, two representative configurations can be considered: one of them takes the C_{4v} symmetry of the ammonium cation, while the other takes the T_d symmetry. The two distinct electronic structures of $(CH_3)_4NCl$ are indicated in Fig. 2.

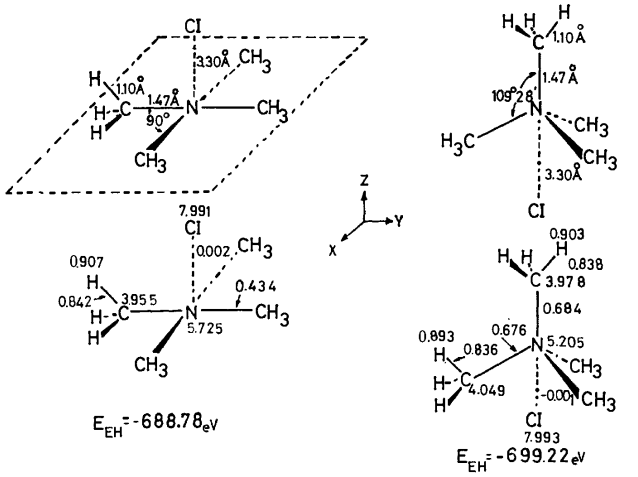

Fig. 2. Valence electron distributions and total energies of the two representative structures of $(CH_3)_4NCl$.

The catalytic activities of the second-row onium compounds were not remarkable as compared with sulfonium and phosphonium compounds. This may be ascribed to their inoic character, which reflects the small or negative overlap population between the cation and the anion (see M_{A-Cl} in Table 1), considering that the considerable covalency of the bond between the cation and the anion contributes directly to the partial electron-occupation of the lowest unoccupied (LU) central-atom orbital, which can then be utilized for the interaction with the $1\pi_g$-orbitals of O_2.

It is necessary here to discuss the order of the activity, carbonium<ammonium<oxonium, in hydrocarbon oxidations. In the case of carbonium and oxonium catalysts, the interaction between the catalyst and the $(1\pi_g)_z$-orbital of O_2 takes place in the direction of the p_z-orbital of the central atom from the opposite side of the counter anion, since, in such a mode of interaction, an overlapping of the orbitals but no steric hindrance can be expected. The above discussions lead to an assumption that the partially-occupied carbon p_z-orbital (the LU orbital of $(CH_3)_3CCl$) and the nonbonding oxygen p_z-orbital (the highest occupied (HO) orbital of $(CH_3)_3OCl$) play an important role in the interaction with the $(1\pi_g)_z$-orbital of O_2. That is, the AO population of the HO level on the p_z-orbital of the central atom ($N_{HO}(Z_A)$) is closely related to the catalytic activity, because the activity results from the electron-donor property of the onium cation.[8] In the case of the ammonium catalyst, the interaction between the p_z-orbital of the ammonium cation and the $(1\pi_g)_z$-orbital of O_2 is sterically hindered to some extent by the substituents attached to the central nitrogen. The values of $N_{HO}(Z_A)$ and the AO population of the central atom ($N(Z_A)$) are listed in Table 1. The order of the above values is in agreement with the catalytic activity as defined by the maximum reaction rate (R_{max}).

Electronic Structures of Third-row Onium Compounds. The EHMO calculations were carried out on the electronic structures of onium compounds possessing third row-atoms, *i.e.*, silyl, phosphonium, and sulfonium compounds. The silyl compound was taken as a com-

parison. As to the molecular structure of the sulfonium compound, the planar C_{3v} symmetrical sulfonium cation gave the most stable configuration of the trimethylsulfonium compounds.[20] The structures of silyl and phosphonium compounds have, however, thus far remained obscure. There are two possible representative configurations for each of the cations, silyl and phosphonium: for the former, one is the planar C_{3v} symmetrical silyl cation and the other is the C_{3v} symmetrical silyl compound,[21] while for the latter, the one is the C_{4v} symmetrical phosphonium ion and the other is the T_d symmetry of the phosphonium compound. Figures 3 and 4 show the configurations of these compounds and the electronic structures, together with the total energies (E_{EH}). $(CH_3)_3SiCl$ would take the C_{3v} symmetry, although the Si–Cl bond may be lengthened to some extent in hydrocarbons involving such polar oxidation

products as alcohols and hydroperoxides.

Among the onium compounds utilized for the liquid-phase oxidation catalysts, phosphonium and sulfonium compounds exhibit the most remarkable activity. The extraordinary activities of these compounds are due to the catalytic activation of molecular oxygen by means of their partially occupied *d*-orbitals, in which the d_{xz} or the d_{yz} is the most preferable orbital for the interaction with the $(1\pi_g)_x$-orbital of O_2.[10,11] Moreover, the mode of the interaction has been discussed in detail in Refs. 8, 10, and 11. This partial occupancy of the sulfur or phsophorus *d*-orbitals is not only due to the somewhat covalent nature of the bond between the onium cation and the counter anion, but also to the *d*–π interactions between the carbon *p*-orbitals of the substituents and the *d*-orbitals. Some aspects of these features mentioned above can be explained by the orbital contours of $(CH_3)_3SCl$ illustrated in Figs. 5 and 6.

In conclusion, the order of the catalytic activity, silyl<phosphonium<sulfonium, can be well explained by the small AO population of the p_z-orbital of the silyl compound and the almost identical AO populations of the *d*-orbitals (indicated by N_d in Table 2) of phosphonium and sulfonium compounds. It is necessary here to mention that, in the case of the sulfonium compound, the nonbonding sulfur p_z-orbital at the HO MO may contribute to some extent to the increase in the electron-donor property of the compound, while the nonbonding or electron-rich *p*-orbitals can not be expected in the case of the phosphonium compound.

Electronic Structures of Fourth- or Fifth-row Onium Compounds. The onium compounds discussed in this section are arsonium, selenonium, and telluronium compounds. In regard to the structures of selenonium and telluronium compounds, they would take the planar C_{3v} symmetrical cations much like the sulfonium compound. On the other hand, two distinct structures can be considered for the arsonium compound; one takes the C_{4v} symmetrical ligand plane of the arsonium ion, while the other takes the T_d symmetrical arsonium ion. Perhaps, the latter configuration is more plausible. The

TABLE 3. RELATION BETWEEN ELECTRONIC STRUCTURES OF FOURTH AND FIFTH ROWS ONIUM COMPOUNDS AND THE CATALYTIC ACTIVITIES

valence electron distributions of $(CH_3)_3SeCl$, $(CH_3)_3TeCl$, and $(CH_3)_4AsCl$ are shown in Figs. 7 and 8.

The relatively low catalytic activities of these compounds as compared with sulfonium and phosphonium compounds may be attributed to the diffused $4d$ or $5d$ orbitals of the central atoms. Especially, the arsonium compound and the telluronium compound indicate negative N_d values for the AO populations of their d-orbitals. On the other hand, the appreciable activity of the selenonium compound results from the partial-occupied selenium d_{xz} or d_{yz} orbital. The order of the activity, arsonium$\simeq$telluronium$<$selenonium, can be well explained by that of the N_d values indicated in Table 3.

The molecular structures of the onium compounds discussed in this paper will be treated in more detail in a succeeding report.

Most of the calculations were carried out on FACOM 230.60 computer at the Computer Center of Kyushu University, but some of them were done at the Computer Center of Kyoto University.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 15—19(1972)

Measurements of the Vapor and Dissociation Pressures of Potassium Sulfate and Carbonate at High Temperatures

Tetsuo KOSUGI

Hitachi Research Laboratory, Hitachi Ltd., Kuji-Machi, Hitachi, Ibaraki

(Received March 8, 1971)

The dissociation reactions of potassium sulfate and potassium carbonate were determined using a quadrupole-type mass spectrometer with a Knudsen-cell-type ion source. The vapor and dissociation pressures of potassium sulfate and the dissociation pressure of potassium carbonate were obtained, by the use of the Knudsen effusion method at temperatures from 900 to 1700°K, as follows:

$$\log P = -1.253 \times 10^4\left(\frac{1}{T}\right) + 7.724 \quad (K_2SO_4)$$

$$\log P_d = -3.275 \times 10^4\left(\frac{1}{T}\right) + 20.83 \quad (K_2SO_4)$$

$$\log P_d = -1.135 \times 10^4\left(\frac{1}{T}\right) + 9.257 \quad (K_2CO_3)$$

The equilibrium constants of the dissociation reaction were estimated from the above data and from those of Kröger and Stratmann:[1]

$$\log K_p = -6.94 \times 10^4\left(\frac{1}{T}\right) + 38.8 \quad (K_2SO_4)$$

$$\log K_p = -1.38 \times 10^4\left(\frac{1}{T}\right) + 9.80 \quad (K_2CO_3)$$

An easily ionizable material (seed) must be added to the combustion products of fuels to achieve a sufficient degree of ionization of the gases in a magneto-hydrodynamic (MHD) generator. The problem of seed recovery in open-cycle MHD power plants is of critical importance for the successful economic realization of MHD power generation. In general, the seed used for open-cycle MHD power generation is a potassium compound. Hart *et al.*[2] suggested that the potassium compounds which were contained in exhaust gases from the MHD generator were potassium sulfate and potassium carbonate when a sulfur-contained fuel was used.

Unfortunately, the physical and chemical properties of the potassium compounds are not yet clear because of their strong reactivity at high temperatures. Therefore, a seed-recovering technique has not been established.

This paper will give experimental data on the dissociation reactions and some thermodynamic constants of potassium sulfate and potassium carbonate at high temperatures.

Experimental

Mass Spectrometric Studies. Apparatus: Details of the mass spectrometer used have been described in a previous paper.[3] The Knudsen cell, made of Pt-5%Rh alloy, was heated with a tantalum heater. The temperature of the cell was measured with a calibrated Pt/Pt-13%Rh thermocouple at the bottom of the cell.

The vapor effusing from the Knudsen cell entered directly into the ionization chamber, which was mounted on top of

the analyzer tube. In the ionization chamber, neutral atoms and molecules were bombarded with electrons of controlled energy and thus ionized. A secondary electron multiplier was used for ion detection. The out-put of this multiplier was amplified and recorded.

Materials: A special grade of potassium compound was used. Impurities in the powder were checked by means of emission spectroscopy. The results of qualitative analysis showed a trace of Na and no evidence of As, Ca, Mg, Pt, Fe, Al, Sn, Ag, Cu, and Pb. Further sample purification was not carried out.

Preparation of the Sample: The method of sample preparation was the same as given in a previous paper.[3]

After preparation, the cell was cooled to below 50°C. Then, the ion intensity of each dissociaton product was measured by means of the mass spectrometer at each experimental temperature. Then peaks at masses 32, 39, 48, 64, and 94 were attributed to O_2^+, K^+, SO^+, SO_2^+, and K_2O^+ respectively for the potassium sulfate on the basis of the detected mass number and the atomic construction of the sulfate. On the other hand, the peaks at masses 12, 16, 28, 39, 44, and 94 for the carbonate were associated with C^+, O^+, $CO,^+$ K^+, CO_2^+, and K_2O^+ respectively. Throughout these experiments, no potassium-oxygen compounds other than K_2O were observed. SO_3 was also not observed from the potassium sulfate.

The product $(I_x^+ \cdot T)$ is proportional to the partial pressure of the species x,[4] where I_x^+ is the measured ion intensity. Thus, the thermal dissociation reaction was discussed on the basis of the relation between $\log(I_x^+ \cdot T)$ and $1/T$. The vapor and dissociation pressures were measured independently of the results of the mass-spectrometric studies.

The values of $\log(I_x^+ \cdot T)$ *vs.* $1/T$ are shown in Fig. 1 for the sulfate and in Fig. 2 for the carbonate.

As is obvious from Fig. 1, the chemical species marked O_2^+, SO_2^+, and K_2O^+ showed the same temperature dependency. In the case of the carbonate, CO^+, K^+, CO_2^+, and K_2O^+ exhibited similar slopes, as is shown in Fig. 2.

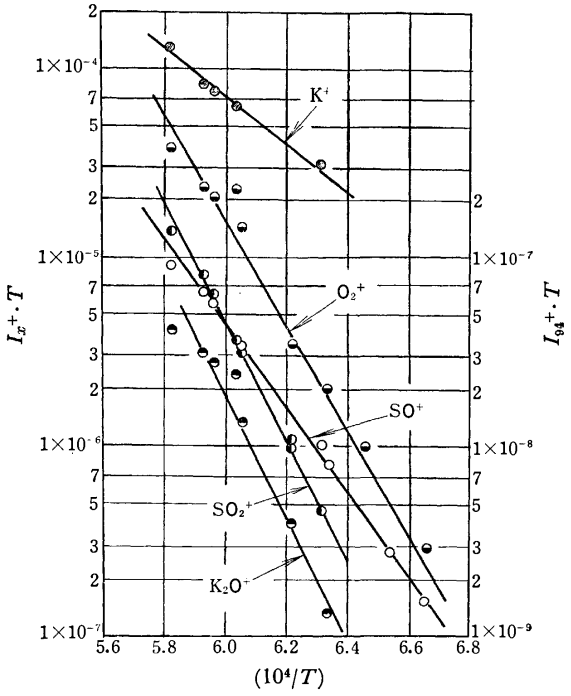

Fig. 1. Plots of $I_x^+ \cdot T$ *vs.* $1/T$ for thermal dissociation products of potassium sulfate.

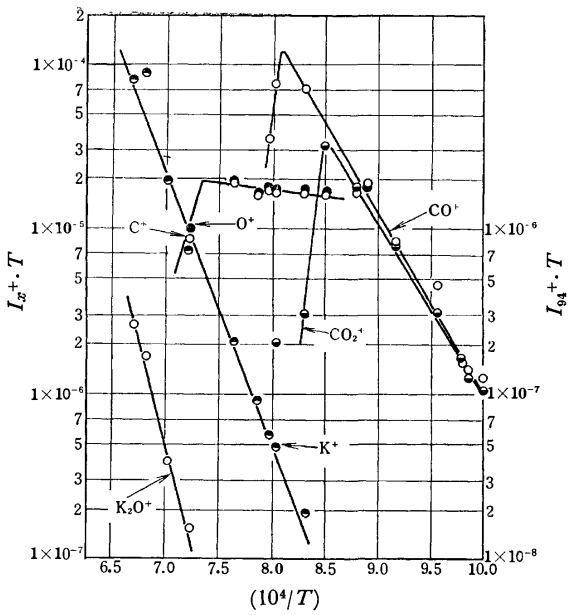

Fig. 2. Plots of $I_x^+ \cdot T$ *vs.* $1/T$ for thermal dissociation products of potassium carbonate.
(x=molecular weight)

It should be noted that the thermal dissociation reaction of the carbonate is effected completely below 1,250°K and that the temperature dependencies of C^+, and O^+ are very slight.

Effusion-rate Measurements by Knudsen Method. The cell was made of Pt-5%Rh alloy; the orifice diameter was 0.5 mm, and the thickness of the orifice was 0.25 mm. The inner diameter of the cell was 9.5 mm.

The effusion weight of the sample was calculated as the weight change in the cell before and after each run, because the evaporation rate of the platinum was very small (*ca.* 1×10^{-11} g/cm²/sec at 1,700°K).[5] The cell weight was measured to be about 0.01 mg by means of a semi-micro-balance.

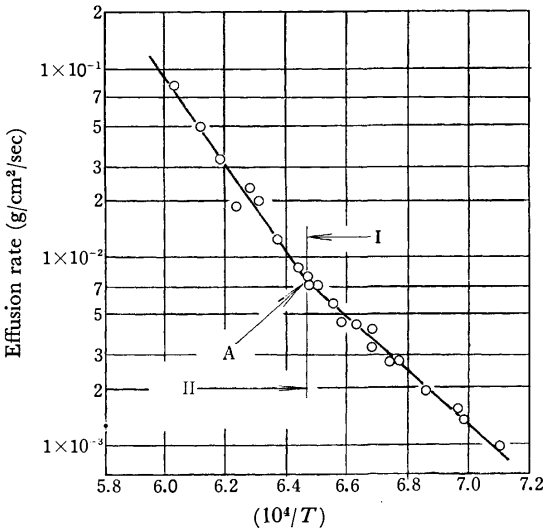

Fig. 3. Plots of effusion rate *vs.* $1/T$ of K_2SO_4.

5) H. A. Jones, I. Langmuir, and D. H. J. Mackey, *Phys. Rev.*, **30**, 201 (1927). See T. Okada and R. Goto, "Hakkinzoku to Kogyoteki Riyo," Sangyo Tosho, Tokyo (1956), p. 91.

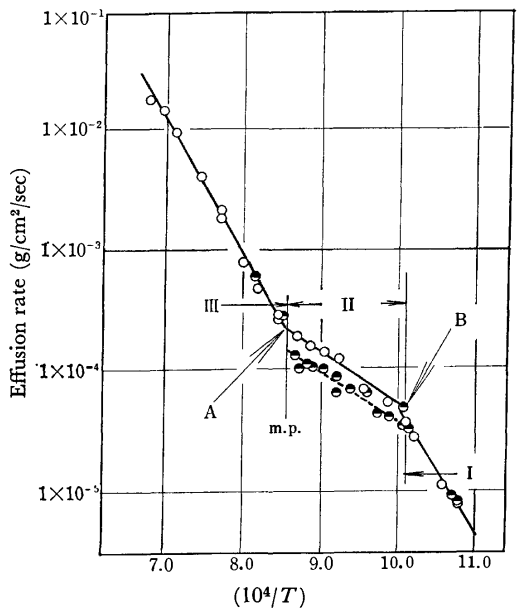

Fig. 4. Plots of effusion rate *vs.* $1/T$ of K_2CO_3.

In the precise calculation of the effusion rate, the orifice area change caused by the thermal expansion of the cell material must be calibrated. However, as the thermal expansion of platinum at 1,700°K is about 1.5%,[6] the orifice-area change was disregarded and a value measured at room temperature was used in this experiment. The preparations of the samples and cell were described previously.[7,8]

The effusion rates of the sulfate and carbonate are plotted in Figs. 3 and 4 as log G *vs.* $1/T$ where G is the effusion rate. It was obvious that the effusion rate of the sulfate showed a temperature-dependency change at Point A and that the slope of the curve in the higher temperature region (II) was larger than that in the lower temperature region (I).

The effusion-rate change of the carbonate was very complicated compared with that of the sulfate. The effusion rate was changed by the maximum degassing temperature in the (II) region indicated in Fig. 4.

Discussion

Thermal Dissociation Reaction of the Samples. The detected species will be generated by several reactions for example, as primary thermal dissociation reaction products of the sample, consecutive reaction products of the above primary reaction products might be detected. Therefore, it is impossible to conclude that all the detected species are generated from the primary dissociation reaction of the sample or that those species indicating larger ion intensities were the primary dissociation products.

Thus, the identification of the primary dissociation products was made by a comparison of the heats of formation of all the species in this study.

Now, let us assume the following primary dissociation reaction:

$$ABC \longrightarrow A + B + C \qquad (1)$$

In this reaction, the heat of formation of A, B, and C species must be equal to the heat of dissociation of the starting material, ABC. Therefore, the slopes of the relations of $\log(I_A^+ \cdot T)$, $\log(I_B^+ \cdot T)$, and $\log(I_C^+ \cdot T)$ *vs.* $1/T$ should be equal. From this point of view, chemical species as O_2, SO_2, and K_2O were assumed to be the primary dissociation products of potassium sulfate (from Fig. 1).

Then, the dissociation reaction of the sulfate can be estimated as:

$$K_2SO_4 \longrightarrow K_2O + SO_2 + \frac{1}{2}O_2 \qquad (2)$$

Regarding the carbonate the species which have the same slope in Fig. 2 are K, K_2O, CO, and CO_2. Of these, the potassium atoms indicate the same temperature dependency as was observed for the sulfate shown in Fig. 5. In addition, the heat of formation of the potassium atom is very close to that of the K_2O molecules, from the following reaction:

$$2K + \frac{1}{2}O_2 \longrightarrow K_2O \qquad (3)$$

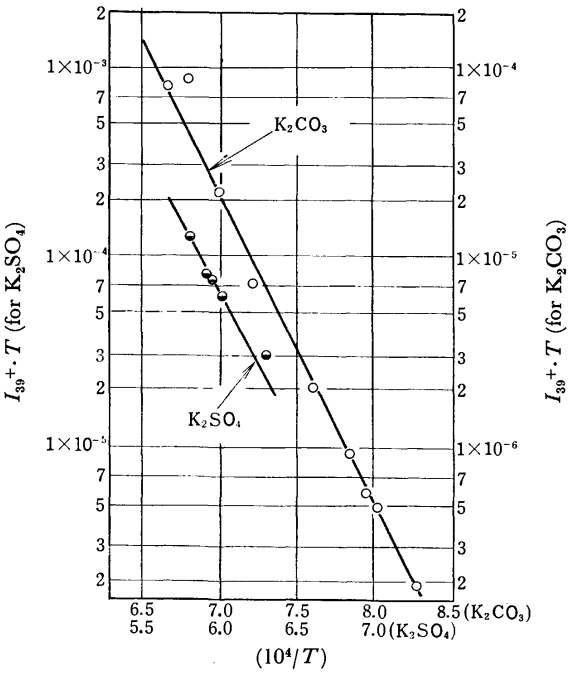

Fig. 5. Plots of $I_{39}^+ \cdot T$ *vs.* $1/T$ for K^+ in K_2SO_4 and K_2CO_3.

Therefore, it can be considered that the potassium atoms are produced by thermal dissociation of the potassium oxide in the two samples. On the basis of the above discussion and the mass balance between the starting material and the dissociation products, the thermal dissociation reaction of the carbonate was estimated as follows:

$$K_2CO_3 \longrightarrow K_2O + CO_2 \qquad (4)$$

Recently, a mass spectrometric study of the dissociation reaction of alkali metal compounds was reported by Ficalora *et al.*[9] They proposed the following dissociation reaction for the sulfate on the basis of a com-

6) J. W. Edwards, R. Speiser, and H. L. Johnston, *J. Appl. Phys.*, **22**, 424 (1951).

parison of the measured ion intensities:

$$K_2SO_4 \longrightarrow 2K + SO_2 + O_2 \quad (5)$$

In this study, however, the heat of formation of a potassium atom was different from that of the SO_2 and O_2 molecules shown in Fig. 1. This implies that the potassium atom differs from the SO_2 and O_2 molecules in its formation mechanism. The generation mechanism of a potassium atom should, then, be considered as a dissociation product of K_2O molecules as has been described above.

Kellogg[10] proposed that the dissociation reaction of sodium sulfate porceeded as:

$$Na_2SO_4 \longrightarrow Na_2O + SO_3 \quad (6)$$

However, it is difficult to consider that the dissociation reaction of potassium sulfate proceeds in that way for the following two reasons:

1) Sulfur trioxide was not detected in this study. In addition, it is considered, from the above description, that sulfur dioxide might be one of the true primary dissociation products.

2) It was estimated, on the basis of a previous report,[11] that sulfur trioxide was not stable in this experimental temperature range, and that only sulfur dioxide was present.

On the basis of the above considerations, Eqs. (5) and (6) can be said not to be adequate for indicating the dissociation mechanism of potassium sulfate.

Vapor and Dissociation Pressures. Potassium Sulfate: The relationship of log G *vs.* $1/T$ should be linear if the dissociation reaction is not observed. The experimental results for the sulfate, however, show a change in the slope at Point A (*ca.* 1,555°K) in Fig. 3. The slope is steeper in the higher-tempearture region. It is estimated that the main effused species are changed near Point A; *i.e.*, the primary dissociation products are only detected by the mass spectrometer above 1,555°K.

Therefore, it is assumed that the measured G value consists of two components: the K_2SO_4 molecules (G_1) and all the dissociation products (G_2). Thus, we assumed the measured G value to be:

$$G = G_1 + G_2 \quad (7)$$

where:

$$\log G_1 = -A\left(\frac{1}{T}\right) + B$$

$$\log G_2 = -C\left(\frac{1}{T}\right) + D$$

$$G_2 = G_3 + G_4 + G_5$$

$$G_1 = G(K_2SO_4)$$

$$G_3 = G(K_2O)$$

$$G_4 = G(SO_2)$$

$$G_5 = G(O_2)$$

A, B, C, D: constants

These constants were calculated by least-means-square method from the measured G values using a computor (HITAC-5020F). The resulting values were 1.220×10^4 for A, 5.638 for B, 3.245×10^4 for C, and 18.36 for D. The vapor pressure equation derived from G_1 using the Knudsen equation[12] for the sulfate is, then:

$$\log P = -1.253\times10^4\left(\frac{1}{T}\right) + 7.724 \text{ (Torr)} \quad (8)$$

The average heat of vaporization in the experimental temperature range is estimated to be 57.3 ± 8.6 kcal/mol, and the entropy of vaporization at the melting point (1,342°K) is estimated to be 42.7 ± 6.4 e.u. from the extrapolation of the vapor-pressure equation.

The vapor-pressure data measured in this experiment were in good agreement with the data of Nettleton *et al.*[13] obtained from the evaporation-rate measurement of a droplet of the sulfate melted under several atmospheric conditions. However, they disagree with the data reported by Kröger and Stratmann.[1]

The dissociation pressure of the sulfate was estimated by using the G_2 values and the ideal gas equation; it can be represented by the following equation:

$$\log P_d = -3.275\times10^4\left(\frac{1}{T}\right) + 20.83 \text{ (Torr)} \quad (9)$$

The average heat of dissociation was 150 ± 22.5 kcal/mol. The vapor and dissociation pressures are shown in Fig. 6, together with the published data.

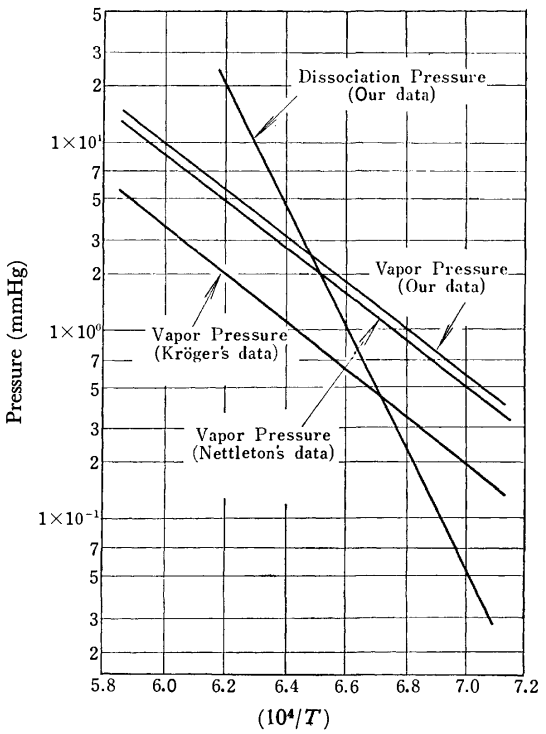

Fig. 6. Vapor and dissociation pressure of K_2SO_4.

Potassium Carbonate: From the results of the mass-spectrometric study and Wöhler's report,[14] it should be considered that the major effusing vapors are dissociation products of the sample throughout the experimental-temperature range.

10) H. H. Kellogg, *Trans. Met. Soc.*, AIMT **230**, 1622 (1964).
11) F. Hals, L. Keefe, and A. E. Bindari, An ASME publication 64-WA/ENER-5 (1964).
12) A. N. Nesmeyanov, Edited by Gray, "Vapor Pressure of the Chemical Elements," Elsevier Publishing Company (1963).
13) M. A. Nettleton and E. Raask, *J. Appl. Chem.*, **17**, 18 (1967).
14) L. Wöhler, *Z. Elektrochem.*, **11**, 836 (1905).

From a previous discussion,[8] it can be considered that the slope in the (I) region of Fig. 4 depends mainly on the activation energy of Eq. (4).

Then, the true effusion rate of the primary dissociation products of the carbonate was calculated from the measured effusion rate at the lowest experimental temperature (925°K) and the temperature dependency of the CO_2 molecule obtained from the mass-spectrometric experiment.

The relationship of the effusion rate and the temperature, assuming that there was no reaction between the sample vapor and the cell, was:

$$\log G = -1.105 \times 10^4\left(\frac{1}{T}\right) + 6.989 \qquad (10)$$

where:

$$G = G(K_2O) + G(CO_2)$$

Thus, the dissociation pressure of the carbonate was estimated to be:

$$\log P_d = -1.135 \times 10^4\left(\frac{1}{T}\right) + 9.257 \text{ (Torr)} \qquad (11)$$

using the method described for the sulfate. The average heat of dissociation in the experimental temperature range was found to be 51.9 ± 8.1 kcal/mol. The dissociation pressure is shown in Fig. 7 along with the data reported by Kröger and Stratmann,[1] measured by the same method as the present data, and the data of Howarth and Turner,[15] measured by the static method. All the data agree well.

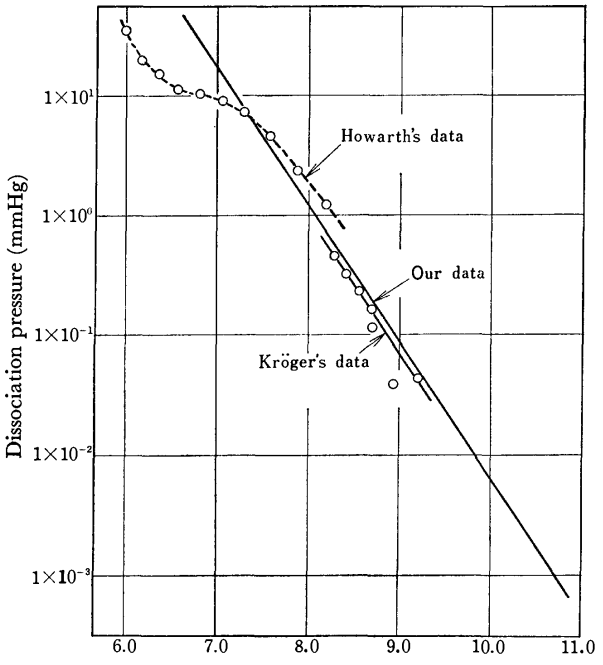

Fig. 7. Dissociation pressure of K_2CO_3.

Equilibrium Constants of The Dissociation Reaction. From the above discussion, the equilibrium constants of the two samples can be said to be:

$$K_p(K_2SO_4) = P(K_2O)\cdot P(SO_2)\cdot P(O_2)^{1/2}\cdot P(K_2SO_4)^{-1} \qquad (12)$$

$$K_p(K_2CO_3) = P(K_2O)\cdot P(CO_2)\cdot P(K_2CO_3)^{-1} \qquad (13)$$

For the sulfate, the relation between the measured dissociation pressure and the partial pressure of each dissociation product is:

$$P_d = P(K_2O) + P(SO_2) + P(O_2) \qquad (14)$$

Therefore, $K_p(K_2SO_4)$ is expressed as follows, using the measured vapor and dissociation pressures:

$$\log K_p(K_2SO_4) = -6.94 \times 10^4\left(\frac{1}{T}\right) + 38.8 \text{ (atm}^{1.5}\text{)} \qquad (15)$$

$K_p(K_2CO_3)$ can be calculated by the same method; however, vapor pressure of the carbonate could not be obtained in the present work. Consequently, the vapor-pressure data of Kröger and Stratmann[1] were used for $P(K_2CO_3)$. The following relation was thus estimated:

$$\log K_p(K_2CO_3) = -1.38 \times 10^4\left(\frac{1}{T}\right) + 9.80 \text{ (atm)} \qquad (16)$$

Both relations are shown in Fig. 8.

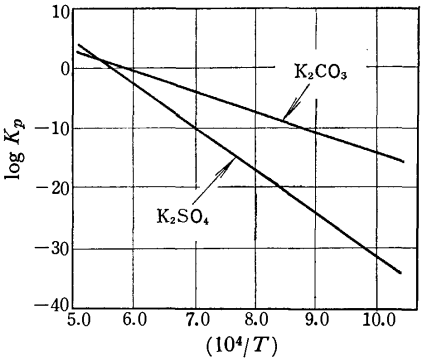

Fig. 8. Equilibrium constants of dissociation reaction.

A part of this work was sponsored by the Ministry of International Trade and Industry of Japan.

The useful suggestions of Dr. K. Shinriki and Dr. N. Kawashima of this laboratory are greatly appreciated.

Studies of Rare Earth Oxyfluorides in the High-temperature Region

Koichi NIIHARA and Seishi YAJIMA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received March 29, 1971)

The behavior of the rhombohedral LnOF and the tetragonal $Ln_4O_3F_6$ at high temperatures was investigated by differential thermal analysis and the high-temperature X-ray diffraction technique. In the case of the rare earth oxyfluorides, LnOF (Ln=La, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu, and Y), the high-temperature transition rhombohedral⇄cubic was observed by means of DTA and a high-temperature X-ray camera. The heat of transformation from rhombohedral to cubic was obtained by means of DTA. The transition temperatures and the heat of transformation, ΔH, shift to higher temperatures and to greater values respectively as the atomic numbers of the rare earth elements increase, although there are some anomalies. One endothermic peak was observed for the rare earth oxyfluorides, $Ln_4O_3F_6$, from Sm to Lu. On the other hand, no peak was observed up to 1300°C for La, Pr, Nd, and Y. The behavior of the peak temperature of DTA against the atomic number for $Ln_4O_3F_6$ is similar to that for LnF_3; this indicates a transformation from an orthorhombic to a hexagonal structure.

In the system of LnF_3–Ln_2O_3, three forms of rare earth oxyfluorides have been reported.[1-9] The relations between these rhombohedral, tetragonal and cubic forms have not, however, been known at all. According to our previous study[10] of the rare earth oxyfluorides (Sm through Lu), the rhombohedral pahses, LnOF, have the stoichiometric composition and the tetragonal phases, $Ln_4O_3F_6$, have the comparatively large nonstoichiometric composition range. The third cubic phases, with a fluorite-type structure, were observed in the SmOF–$Sm_4O_3F_6$ region after quenching from a high temperature, but in the other system the cubic phases were not identified by a similar procedure. The variety of structures reported for the rare earth oxyfluorides suggests that a study of the structures at high temperatures would be fluitful. In particular, based on Zachariasen's structure analysis[3] employing the order-disorder of the anion, it was hoped that the order-to-disorder transition could be observed by means of the high-temperature X-ray technique. In this paper, the behavior of the rhombohedral LnOF and the tetragonal $Ln_4O_3F_6$ at high temperatures was investigated by means of differential thermal analysis and the high-temperature X-ray technique.

Experimental

Materials. Many rare earth oxides[11] (La_2O_3, Pr_6O_{11}, Nd_2O_3, Sm_2O_3, Eu_2O_3, Gd_2O_3, Tb_4O_7, Dy_2O_3, Ho_2O_3, Er_2O_3, Tm_2O_3, Yb_2O_3, Lu_2O_3, and Y_2O_3) were separated from a crude rare eath mixture in this laboratory by the ion-exchange method, using the EDTA solution as the solvent. The rare earth oxides obtained by this method were >99.9% pure.

The anhydrous lanthanon trifluorides, LaF_3 through LuF_3, were prepared as has previously been described.[10]

The rare earth metals[12] were prepared by the calcium reduction of LnF_3 according to the following reaction:

$$2LnF_3 + 3Ca = 2Ln + 3CaF_2$$

The metals obtained by this method were >99.5% pure.

Sample Preparation. All the rhombohedral LnOF and tetragonal $Ln_4O_3F_6$ rare earth oxyfluorides, except for Pr and Tb, were prepared as has previously been described.[10] In the cases of Pr and Tb, the oxyfluorides were prepared by the hydrolic heating of the fluorides in an atmosphere with a relatively high humidity, or by the following chemical reactions:

$$3Pr_6O_{11} + 11PrF_3 + 4Pr = 33PrOF \quad (1)$$

$$3Pr_6O_{11} + 22PrF_3 + 4Pr = 11Pr_4O_3F_6 \quad (2)$$

$$3Tb_4O_7 + 7TbF_3 + 2Tb = 21TbOF \quad (3)$$

$$3Tb_4O_7 + 14TbF_3 + 2Tb = 7Tb_4O_3F_6 \quad (4)$$

The mixture of oxide, metal, and fluoride, weighed in a stoichiometric composition, was melted in a platinum boat. The chemical analyses were performed by igniting to the oxide.

High-temperature X-ray Diffraction. High-temperature X-ray diffraction patterns were obtained by means of a Rigaku Denki high-temperature X-ray diffraction camera mounted a X-ray diffractometer. The mounted samples were placed in the camera, which was then evacuated. The pressure at the inlet in the camera was found to be less than 5×10^{-4} mmHg, but either oxidation or hydrolysis occurred when samples were heated above 800—1000°C. Because of this problem, the high-temperature phases of the tetragonal oxyfluorides, $Ln_4O_3F_6$, were not identified.

Differential Thermal Analysis. The DTA apparatus consisted of a platinum-wound furnace, a sample chamber, and a microvolt recorder. The sample holder consisted of a 25-mm-diameter nickel rod, in which two symmetrical, 7.9-mm-diameter, 19.2-mm-deep sample wells were drilled. The rare earth oxyfluoride placed in a platinum sample chamber with the same geometry as the sample wells was

Table 1. The lattice parameter of the rhombohedral LnOF and the tetragonal LnOF of Pr, Tb, and Lu

Ln in LnOF and $Ln_4O_3F_6$	Lattice parameter			
	LnOF		$Ln_4O_3F_6$	
	a in Å	α in degree	a in Å	c in Å
Pr	7.018±0.002	33.05±0.05	5.710±0.004	5.758±0.003
Tb	6.751±0.004	33.09±0.03	5.575±0.003	5.491±0.003
Lu	6.536±0.002	33.05±0.02	5.482±0.002	5.308±0.003

placed in one well, and Al_2O_3 in the other.

The standard conditions for each DTA run were a 950—1000-mg portion of the sample and a heating rate of 2.5°C/min in a vacuum or in an inert gas atmosphere. The Pt-Pt·Rh thermocouples were used for the temperature measurement. The calibration data indicate an error of ±3°C at 600°C.

The DTA apparatus was calibrated for the heat-of-transformation studies by the use of compounds with a known heat of decomposition or transformation in a temperature range not far from that under study. The calibration compounds were $CuSO_4 \cdot 5H_2O$, SiO_2, and $BaCO_3$. The heat of transformation obtained could be reproduced to within ±7%.

Experimental Results

Sample Preparation. The X-ray diffraction data showed that all of the rhombohedral LnOF and tetragonal $Ln_4O_3F_6$ rare earth oxyfluorides, except for Ce and Pm, from La to Lu had an isostructure with the previously-reported rhombohedral and tetragonal forms[10] respectively. The results of chemical analyses and the lattice parameters for Pr, Tb, and Lu are summarized in Table 1 and Table 2. The preparation of Pr and Tb oxyfluorides by the hydrolysis technique resulted in mixed products of the rhombohedral and tetragonal oxyfluorides. In general, hydrolysis was found to be unsatisfactory since the extent to which the reaction proceeded could not be controlled.

Table 2. Metal content of LnOF and $Ln_4O_3F_6$ for Pr, Tb, and Lu

Ln in LnOF and $Ln_4O_3F_6$	LnOF		$Ln_4O_3F_6$	
	obsd%	calcd%	obsd%	calcd%
Pr	79.55	80.10	77.50	77.65
Tb	81.42	81.95	79.24	79.69
Lu	83.31	83.33	81.05	81.20

High-temperature X-ray Diffraction. In the case of the LnOF (Ln=La, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu, and Y) rare earth oxyfluorides, the high-temperature rhombohedral⇄cubic transition was observed by the high-temperature X-ray camera. It was found, from the relative-intensity measurements of the X-ray diffraction, that the high-temperature phase had a fluorite-type structure and that the rhombohedral⇄cubic transition was reversible. The X-ray patterns of LaOF at 25, 450, and 550°C are shown in Fig. 1. The lattice parameters of LaOF and NdOF were determined over the temperature range of 25—700°C. It can be seen from Fig. 2 that the unit cell volume varied continiously with the temperature in the regions of the rhombohedral and cubic forms respectively, and that it increased abruptly at the transition temperatures. The extrapolated values of the volume differences of the two phases at the transition temperature are 0.80 Å^3 and 0.65 Å^3 for LaOF and NdOF respectively.

Differential Thermal Analysis. Differential thermal analyses (DTA) were made of both the rhombohedral LnOF and the tetragonal $Ln_4O_3F_6$ of the rare earth oxyfluorides of La through Lu. In the cases of the rhombohedral oxyfluorides, the DTA curves exhibited one endothermic peak up to 1250°C. Since all of the DTA curves were quite similar to each other, only two of them are reproduced in Fig. 3. It can be seen from Fig. 1—3 that the endothermic peak temperatures of DTA correspond to the transition temperatures of rhombohedral⇄cubic. From these results, it can be concluded that all of the LnOF rare earth oxyfluorides transform from the rhombohedral structure to the fluorite-type structure. In Table 3 we list the temperatures of the DTA peaks for the rhombohedral oxyfluorides. The DTA peaks against the atomic numbers are plotted in Fig. 4. As may be shown from Fig. 4, the peak temperatures shift to higher temperature as the atomic numbers increase, that is, as the ionic radii of the rare earth ion decrease, although there are several anomalies.

Y	560	—

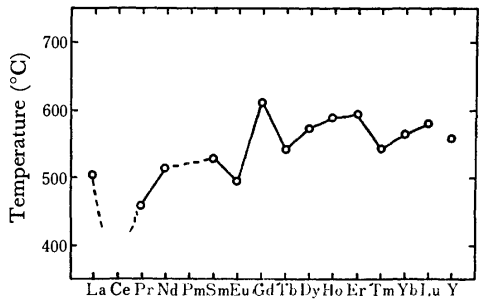

Fig. 4. DTA peak temperature of rare earth oxyfluorides LnOF as a function of atomic number.

The DTA results for the $Ln_4O_3F_6$ oxyfluorides are summarized in Table 3. One endothermic peak was observed for Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, and Lu, but no peak was observed at all up to 1250°C for La, Pr, Nd, and Y. Two of these DTA curves are reproduced in Fig. 3. The variation in the DTA-peak temperature for the $Ln_4O_3F_6$ oxyfluorides are plotted as a function of the atomic number of the rare earth element in Fig. 5. The efforts to identify the high-temperature phase of the tetragonal oxyfluorides, $Ln_4O_3F_6$, using the high-temperature X-ray technique beyond the DTA peak temperatures were not successful because of the oxidation of samples and the inaccuracy of the diffraction patterns. The high-temperature phases could not be observed by quenching techniques, either.

(●: The transition temperature of orthorhombic to hexagonal LnF_3 as a function of atomic number)

The Heat of Transformation from Rhombohedral to Cubic Structure for LnOF. Under specific experimental conditions, DTA can be used to determine the heat of transformation by the integration of the differential curve peak. From the theories of Speil[13] and others[14,15] the area of curve peak is:

$$\text{peak area} = \int_{t_1}^{t_2} \theta dt = \frac{\Delta HM}{g\lambda}$$

14) M. J. Vold, *Analyst. Chem.*, **21**, 683 (1949).
15) S. L. Boersma, *J. Amer. Ceram. Soc.*, **38**, 281 (1955).

where t_1 and t_2 are the temperature limits of the peak, θ is the differential temperature, ΔH is the heat of transformation, M is the mass of the reactive sample present, λ is the thermal conductivity of sample, and g is a constant dependent on the furnace and sample-holder geometry. In practice, the apparatus is calibrated by studying the reaction of known thermal effects. In this manner, the constants, g and λ, are evaluated. Table 4 gives the heat of transformation from rhombohedral to cubic for LnOF and the values of the ionic radii. The heat of transformation, ΔH, is plotted as a function of the atomic number of the rare earth element in Fig. 6. As is shown by Fig. 6, ΔH shifted to higher values as the atomic number of the rare earth ion increased, although there were several anomalies.

Discussion

All of the rare earth oxyfluorides, LnOF, were observed to be transformed from a rhombohedral to a fluorite-type structure in the temperature region of 450—600°C. It is considered that this transition is due to the order-disorder of the anion: the rhombohedral oxyfluorides,[3] LnOF, result from a complete ordering of the oxygen and fluorine atoms into a distinct site in the unit cell, while the fluorite-type phase results from a statistical distribution of oxygen and fluorine. The transition temperature observed in thermal analyses do not follow the smooth trend so characteristic of lanthanide compounds. However, the phase-transition temperatures in $LnNbO_4$ and $LnTaO_4$ increase as the ionic radii decrease at first and then become relatively constant beyond Gd.[16] The data presented in this paper seem to show a similar phenomenon.

The heat of transformation from a rhombohedral to a fluorite-type structure is 1.8—3.8 kcal/mol. On the other hand, the heats of transformation of cubic to monoclinic Eu_2O_3[17] and of cubic to hexagonal Pr_2O_3[17] are about 4.3 and 1.0 kcal/mol respectively. It can be seen that the values of the heat of transformation from a rhombohedral to a fluorite-type structure are as large as those of the heat of transformation of rare earth sesquioxides, Ln_2O_3. The ΔH of rhombohedral to cubic LnOF shifts to higher values as the atomic number of the rare earth ion increases, although there are some anomalies. This trend is the same as that for the heat of decomposition of rare-earth sulphate and oxysulphate.[18] The ΔH for Pr and Tb is much lower than the other values. A possible explanation of the anomalies for Pr and Tb is that PrOF and TbOF form a solid solution with either oxides or the fluorides. As has previously been reported,[10] all the rhombohedral phases, LnOF, except for Pr and Tb have a stoichiometric composition, and no nonstoichiometric composition range exists in any of the systems. The method of preparing PrOF and TbOF is different from that of other rare earth oxyfluorides. In this method, the stoichiometry of PrOF and TbOF could not be determined by metal analyses alone because the oxides of Pr and Tb have a comparatively large nonstoichiometric composition range at high temperatures,[19] although the oxides of all the rare earths except Pr and Tb have the stoichiometric composition $LnO_{1.500}$.[20] The ions of Pr and Tb are comparatively easy to convert into tetravalent ions relative to other rare earth ions. Judging from this fact, it is possible that the rhombohedral phase for Pr and Tb may be stable for nonstoichiometries, $LnO_{1\pm x}F_{1\pm y}$, and that a small variation in stoichiometry could effect a large change in the transformation of rhombohedral to cubic LnOF.

The efforts to determine the cause of an endothermic peak $Ln_4O_3F_6$ from Sm to Lu were unsuccessful. As is shown in Fig. 5, the variation in the peak temperature of DTA against the atomic number is quite similar to that of the transition temperature of rare earth trifluorides from orthorhombic to hexagonal LnF_3.[21] It is reasonable to consider that the crystal structures are different between the A region and the B region. This point is still open to question, though, and further work is called for.

The Kinetics and Mechanism of the Photo-oxidation of *N,N'*-Diphenyl-*p*-phenylenediamine. Electron-transfer from the Upper Excited Singlet State to Oxygen

Haruo SHIZUKA, Yasuyoshi SAWAGURI, and Toshifumi MORITA

Department of Chemistry, Gunma University, Kiryu, Gunma

(Received April 26, 1971)

The photo-oxidation of *N,N'*-diphenyl-*p*-phenylenediamine (DPPD) has been studied spectrophotometrically. The quantum yield for the diimine formation, Φ, in aerated cyclohexane at 2537 Å and 20°C did not change with variations of the irradiation time, the concentration of DPPD, or the light intensity. However, the Φ values increased, as did the decrease in the fluorescence quantum yields, as the excitation energies increased. The dissolved oxygen had the optimum concentration (1.2×10^{-4}M), giving the maximum value of Φ in aerated cyclohexane at 2537 Å, and none of the product, the diimine, was obtained in the degassed system. When about 0.13M of ethanol or methanol was added to aerated cyclohexane, the maximum value of Φ was measured, and the addition of a highly-polar solvent, acetonitrile or H_2O, decreased regularly in Φ. On the basis of these results, it can be said that the photo-oxidation of DPPD originates from the Franck-Condon state of the upper excited singlet state, $^1(RH_2)_n$. It seems that, in the primary processes of the reaction, the electron transfers take place from the Franck-Condon state of $^1(RH_2)_n$ directly to the oxygen molecule ($^3\sum_g^-$) and to the solvent, resulting in a trapped electron which immediately jumps into the oxygen molecule. Then, the $(RH_2)^+O_2^-$ ion pair may be formed, and subsequently the intermediate, $(RH_2)^+O_2^-$, may be converted to the product or the starting materials. The dissolved oxygen and the polar solvents are responsible for the electron-transfer processes, but they deactivate the ion pair, resulting in the decrease in Φ.

It is known that aromatic amine derivatives give rise photochemically to many interesting reactions, such as photoionization, photocyclization, rearrangement, photo-oxidation, and decomposition.

The photoionizations of aromatic amines can be classified as follows: (1) The photo-ionization in a polar solvent *via* the singlet exciplex formed by the interaction between the lowest excited singlet state of the amines (the electron donor) and the ground state of the electron acceptor, or *vice versa*, was originally shown by Leonhardt and Weller.[1] Similar results for organic donor-acceptor systems have been reported by Tsubomura *et al.*[2,3] and by Koizumi *et al.*[4,5] The exciplex formation has been extensively studied by Mataga *et al.*[6–10] and by Weller *et al.*[11,12] (2) The photo-ionization in a rigid matrix at the temperature of nitrogen by a two-step excitation *via* the lowest triplet states of the amines has been well accomplished by several workers[2,13–16] since the pioneering work of Lewis and Lipkin.[17] The photo-ionization in fluid media by the two-step excitation *via* the lowest triplet states has also been studied by means of a flash technique.[2,18–20] (3) It has been reported by Potashnik *et al.* that the photo-ionization may occur through a CT triplet state of an electron-donor-acceptor pair in a polar matrix.[21] (4) Of course, the direct photo-ionization is induced by excitation energies larger than those of the ionization potentials of the molecules.

The photocyclization of diphenylamines has been preliminarily reported by Bowen and Eland,[22] and by Linschitz *et al.*[23] The reaction mechanism of the photocyclization of diphenylamines has been kinetically studied by Shizuka *et al.*[24]: the photo-cyclization of

diphenylamines originates from the lowest triplet state, and subsequently the triplet transient leads to the formation of the intermediate, M (11,12-dihydrocarbazole, whose two central hydrogens are in the *cis*-configuration), competing with the triplet deactivation processes; then M converts to the corresponding carbazoles, with and without oxygen, or to the ground state of the original substance.

The photo-Fries rearrangements of benzene derivatives (acetanilide, phenylacetate, *N*-acetyl diphenylamine, *N*-acetyl carbazole, *etc.*) in the liquid phase occur *via* the predissociative intersystem crossing $^3\sigma_0$-(N–C)←$S_1(\pi\pi^*)(^1B_2)$ or $^3\sigma_0$(O–C)←$S_1(\pi\pi^*)(^1B_2)$, thus forming the pair radicals; these radicals recombine efficiently in a solvent cage into the original substance and *ortho*- and *para*-isomers, as has been studied by Shizuka *et al.*[25] In general, the predissociation of the benzene derivative occurs at a β-bond *via* the $^1B_2$ state.[25] The photolysis of hydrazobenzene[26] also occurs *via* the predissociative intersystem crossing $^3\sigma_0$(N–H)←$S_1(\pi\pi^*)$, involving the β-bond fission of the benzene derivative and subsequent disproportionation between *N,N'*-diphenylhydrazyl radicals, giving, as products, azobenzene and the starting material. If oxygen is dissolved in the system, the radical intermediate reacts with oxygen, thus forming azobenzene and the HO_2 radical. A similar photo-decomposition of acetanilide in the vapor phase may occur *via* the predissociation at the β-bond, as has been reported by Shizuka and Tanaka.[27]

Recently, the flash photolysis of aniline derivatives in various solutions has been studied by Hori, Itoi, and Tsubomura.[28] The initial yield of the cation formed in an oxygenated solution is proportional to the intensity of the flash light, indicating that the photo-ionization is a one-photon process; they suggested that the charge-transfer states are formed between the aromatics and the oxygen molecule, either by direct excitation or *via* the interaction of excited anilines and the ground state of oxygen, and the charge-transfer states then lead to the solvated cations and anions in highly-polar solvents.

The photo-oxdiation of *N,N'*-diphenyl-*p*-phenylenediamine (DPPD) has been predicted by Linschitz *et al.*[29] However, little mechanistic work has yet been reported. In addition to the photochemical processes described above, several processes in the photo-oxidation of DPPD have been considered: the reaction of the lowest excited singlet state of DPPD with the ground state of oxygen ($^3\Sigma_g^-$), the reaction of the ground state of DPPD with the singlet oxygen ($^1\Delta_g$),[30] and an electron transfer from the upper excited singlet state of DPPD to the ground state of oxygen. Furthermore, it is unknown whether or not the photochemical reaction of DPPD is accompanied by a photocyclization similar to that of diphenylamine.

This paper will report in some detail on the kinetics and mechanism of the photo-oxidation of DPPD.

Experimental

Materials. The *N,N'*-Diphenyl-*p*-phenylenediamine (DPPD) and *N*-cyclohexyl-*N'*-phenyl-*p*-phenylenediamine (CPPD) were Seiko Chem. Co., Ltd., reagent-grade products and were purified by repeated recrystallizations from ethanol and from ligroin respectively. The corresponding diimines, prepared by the chromic-acid oxidation of DPPD or CPPD in glacial acetic acid,[31] were recrystallized several times from ethanol and cyclohexane. The photoproducts were identified by UV and IR spectroscopy and by thin-layer chromatography. The cyclohexane was a Tokyo Kasei Co. G.R.-grade product; it was purified by passing it through a silica-gel column and by distillation. The acetonitrile was a Tokyo Kasei Co. G.R.-grade product; it was dried over calcium chloride, refluxed repeatedly over phosphorus pentoxide until no color appeared on the oxide, distilled into freshly-fused potassium carbonate, distilled from it, and finally fractionally distilled.[32] The ethanol and methanol were Kanto Chemical Co. G.R.-grade products and were used without further purification.

Light Source and Actinometry. A low-pressure mercury resonance lamp with a Vycor glass filter was used as the 2537 Å radiation source, while a xenon lamp (an Ushio 150 W UXL-150D-SS), equipped with a diffraction grating, was used as the 2400—3200 Å range radiation source. The diffraction grating admitted only a narrow band of light wavelengths (±70 Å). Actinometry was carried out using a ferric oxalate solution.[33] The fluorescence quantum yields of DPPD and CPPD were obtained by comparison with the relative fluorescence intensity of naphthalene, whose fluorescence quantum yield is 0.21 in ethanol.[34]

Degassing Procedure and Measurement of the Oxygen Concentration. The solution was thoroughly degassed on a high-vacuum line by the freeze-pump-thaw method. The concentration of dissolved oxygen was adjusted by flushing with nitrogen at room temperature, and was determined by the method of Munck and Scott.[35]

Analysis. The amounts of the photoproducts (diimines) were determined spectrometrically. The ultraviolet and visible absorption spectra were measured by Hitachi 139 and 124 spectrophotometers. The fluorescence and phosphorescence spectra were taken with a Hitachi MPF-2A fluorescence spectrophotometer. The μ-second flash apparatus was an ordinary one.

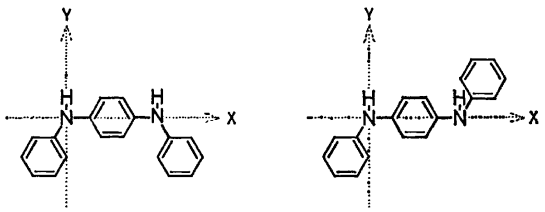
Method of Calculation

The π electronic structure of DPPD was studied by the variable β, γ procedure of the semiempirical SCF–MO method in combination with singly-excited CI calculation. The parameters were taken to be as was proposed by Nishimoto and Forster.[36] The one-center repulsion integrals, $\gamma_{\mu\mu}$, were estimated from the corresponding valence-state ionization potentials (I_μ) and electron affinities (A_μ) by the Pariser-Parr approximation.[37] The values of I_μ and A_μ were found in the paper of Hinze and Jaffé.[38] The two-center electron-repulsion integrals, $\gamma_{\mu\nu}$, were estimated by the use of the Nishimoto-Mataga approximation.[39] The corresponding bond-order (P)/bond-length (r) relations[36] are $r_{CC}(\text{Å}) = 1.517 - 0.180P$ for C–C bonds and $r_{CN}(\text{Å}) = 1.451 - 0.180P$ for C–N bonds. The two-center core-resonance integrals, $\beta_{\mu\nu}$, were evaluated by the Nishimoto-Forster approximation.[36] The geometries of DPPD were assumed to be as follows:

Geometries of DPPD



cis-form. *trans*-form.

The C–C and C–N bond lengths were assumed to be 1.39 and 1.38 Å respectively. All the bond angles were assumed to be 120°. The computation was carried out by means of a HITAC 5020E located at the Computer Center, The University of Tokyo.

Results

(1) Absorption and Emission Spectra. In order to study the behavior of DPPD in electronically-excited states, the absorption and emission spectra of DPPD were measured. Figure 1 shows the absorption and emission spectra of DPPD. Several quantities for the electronically-excited states of DPPD and those calcu-

lated by the semiempirical SCF–MO–CI method are summarized in Table 1. In the case of CPPD, similar results were obtained.

(2) Quantum Yields for the Diimine Formations. Aerated solutions of DPPD and CPPD are stable at room temperature for several hours. Therefore, the amounts of the corresponding diimines produced by thermal reactions can be neglected.

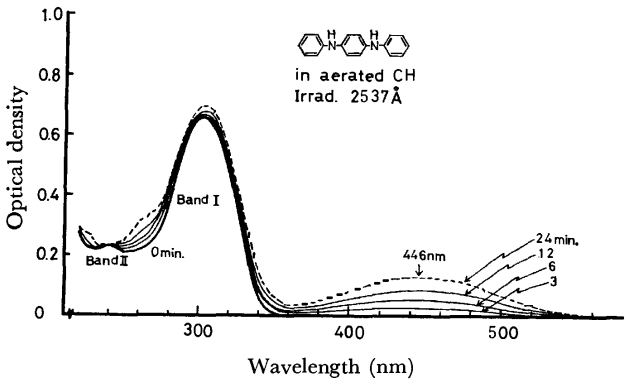

Fig. 2. Spectral change of DPPD in aerated cyclohexane upon irradiation with the 2537 Å light. Numbers refer to time at measurement in minutes.

The spectrum of the aerated cyclohexane solution of DPPD changed upon irradiation with the 2537 Å light, as is shown in Fig. 2. A new band with a maximum at 446 nm appeared; the spectral change showed the formation of *N,N'*-diphenyl-*p*-quinonediimine (DPI). The photoproduct was separated by column chromatography and was identified by UV and IR spectroscopy and by thin-layer chromatography. The photo-oxidation of CPPD also occurred in aerated cyclohexane. However, no photochemical diimine formation was observed in the degassed system in either case, and no photocyclization such as that of diphenylamines took place in the photochemical reactions of DPPD and CPPD. Table 2 shows the molar extinction coefficients of the diimines.

Table 2. The molar extinction coefficients of the diimines

Substance	Solvent	λ_{max} nm	$\varepsilon_{max}(\times 10^{-4})$ $l\,mol^{-1}cm^{-1}$
 (DPI)	CH	304	2.83
		446	0.63
	EtOH	304	2.71
		443	0.67
(CPI)	CH	296	2.84
		428	0.30

Where CH and EtOH denote cyclohexane and ethanol respectively, and, where CPI denotes *N*-cyclohexyl-*N'*-phenyl-*p*-quinonediimine.

The quantum yields for the product formation (Φ^{λ}) were measured spectrophotometrically. Figure 3 shows the quantum yields for DPI formation under various conditions at 2537 Å. The quantum yields in aerated cyclohexane did not change with any variations in the

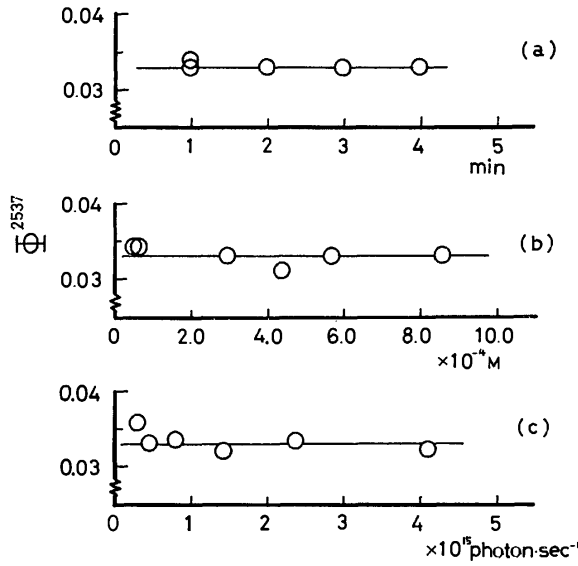

Fig. 3. Dependence of quantum yields for DPPD in cyclohexane solutions at 2537 Å and 20°C: (a) on irradiation time with initial concentration of 5.6×10^{-4}M, (b) on concentration, (c) on light intensity.

irradiation time, the concentration of DPPD, or the light intensity. However, the effects of the excitation wavelength, dissolved oxygen, and polar solvents on Φ^{λ} were measured. Similar results were obtained in the case of CPPD. The quantum yields (Φ_0^{2537}) of DPPD and CPPD in aerated cyclohexane at 2537 Å and 20°C were 0.033 and 0.041 respectively.

(3) Effects of the Excitation Wavelength on the Quantum Yields for the Product Formation (Φ^{λ}) and on the Fluorescence Quantum Yields ($\Phi^{\lambda}{}_f$). The dependence of the excitation wavelength (3200—2400 Å) on Φ^{λ} and $\Phi^{\lambda}{}_f$ in aerated cyclohexane at 20°C was measured using a xenon lamp with a diffraction grating filter. The results are shown in Fig. 4. The Φ^{λ} values increased as a function of the excitation energy. In contrast, the $\Phi^{\lambda}{}_f$ values decreased gradually as the excitation energy increased. The $\Phi^{\lambda}{}_f$ values became constant in the 3000—3200 Å range, where scarcely any photo-oxidation took place.

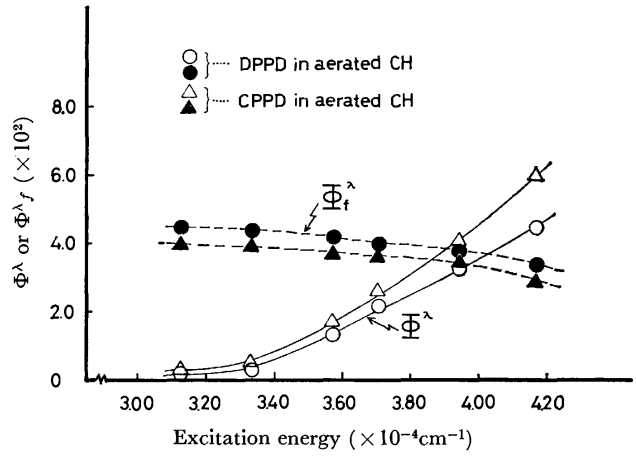

Fig. 4. Dependence of quantum yields Φ^{λ} for the diimine formation and of fluorescence quantum yields $\Phi^{\lambda}{}_f$ on excitation energy in aerated cyclohexane at 20°C.
○: Φ^{λ} of DPPD ●: $\Phi^{\lambda}{}_f$ of DPPD
△: Φ^{λ} of CPPD ▲: $\Phi^{\lambda}{}_f$ of CPPD

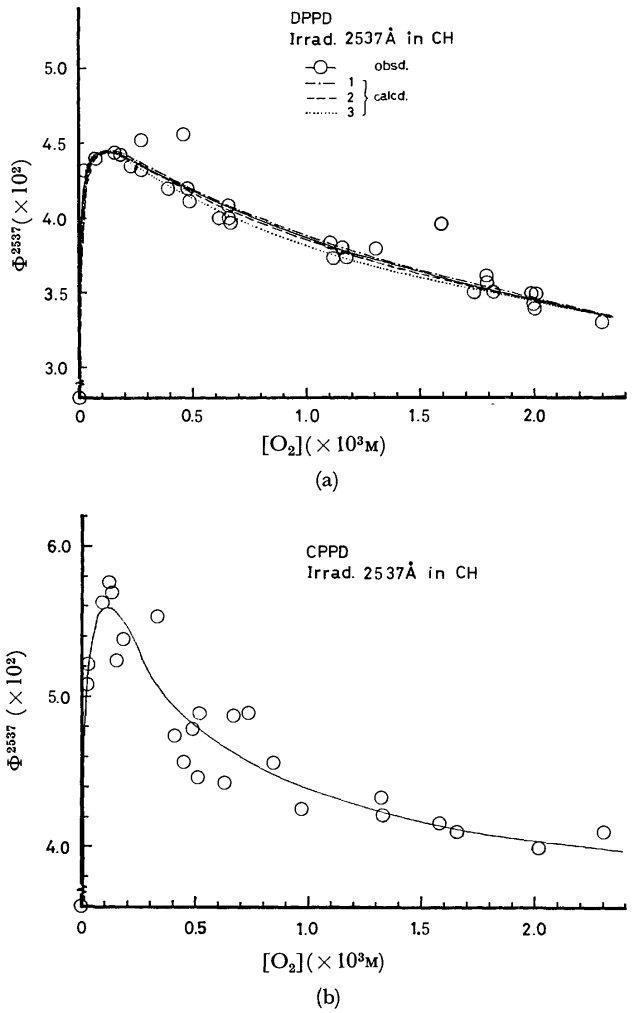

Fig. 5. Dependence of quantum yields Φ^{2537} on oxygen dissolved in cyclohexane at 2537 Å and 20°C: (a) for DPPD; -○- observed values, (1)—(3) calculated values. See Table 4. (b) for CPPD; -○- observed values.

(4) Effect of Dissolved Oxygen on Φ^{2537}. The dependence of dissolved oxygen on Φ^{2537} in cyclohexane at 2537 Å and 20°C was measured by the method described above. The results are shown in Fig. 5(a) and (b). The Φ^{2537}_{max} value of DPPD (0.044) was measured at $[O_2]=1.2\times10^{-4}$M. This shows that the dissolved oxygen has the optimum concentration (1.2×10^{-4}M), giving the maximum value of Φ^{2537} in the photo-oxidation of DPPD. The oxygen effect on the Φ^{2537} of DPPD was in good accordance with the simulation calculated kinetically, as will be discussed later. Similar experimental results were obtained in the case of CPPD, as is shown in Fig. 5(b).

(5) Effects of the Addition of Polar Solvents on Φ^{2537}. The effects of polar solvents on Φ^{2537} in the aerated system at 2537 Å and 20°C were measured. The mixed solvents used were prepared by the addition of a small amount of polar solvents to cyclohexane, except in the case of H_2O. The polar solvents used were ethanol, methanol, acetonitrile, and H_2O. Figure 6 shows the dependence of the relative quantum yields ($\Phi^{2537}/\Phi^{2537}_0$) on the addition of polar solvents to cyclohexane in the aerated system at 2537 Å and 20°C. The photo-oxidation of DPPD was considerably affected by the addition of a small amount of polar solvents to cyclohexane. When about 0.13M of ethanol or methanol was added to cyclohexane, the maximum value of $(\Phi^{2537}/\Phi^{2537}_0)_{max}$ was measured.

In the cyclohexane and ethanol system, the addition of ethanol increased the Φ^{λ} values; the values then decreased gradually, passing through the maximum value ($\Phi^{2537}_{max}=0.050$) at [EtOH]=0.13M. However, the addition of a highly polar solvent, acetonitrile or H_2O, immediately decreased those values, as is shown in Fig. 6.

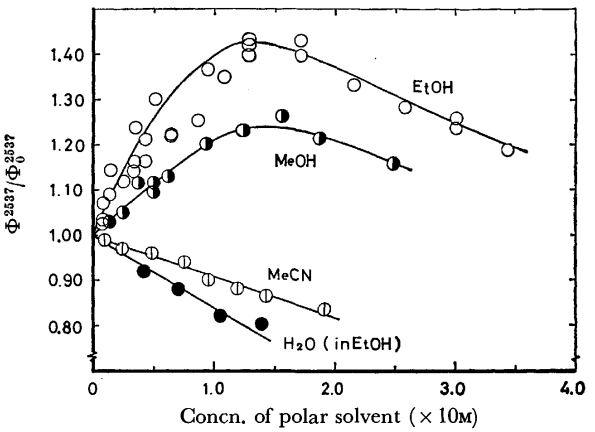

Fig. 6. Effects of the addition of polar solvents on Φ^{2537} for DPPD at 2537 Å and 20°C, where EtOH, MeOH, and MeCN denote ethanol, methanol, and acetonitrile. A small amounts of polar solvents, except H_2O, added to aerated cyclohexane, and in the case of H_2O the aerated EtOH solution was used.

Figure 7 shows the excitation-wavelength effect on the Φ^{λ} of DPPD in the mixed solvent (cyclohexane and ethanol). At every excitation wavelength, similar results were obtained, as is shown in Fig. 7.

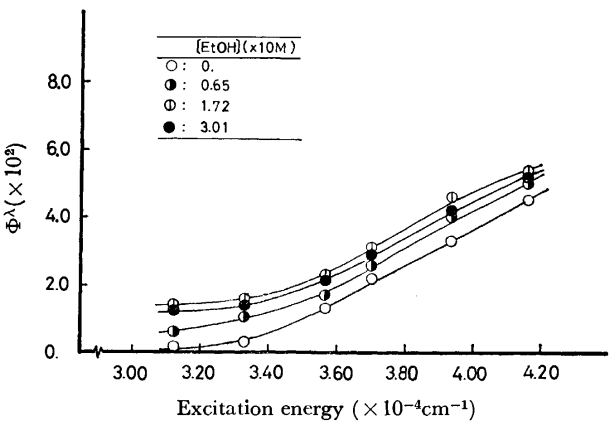

Fig. 7. Dependence of quantum yield Φ^{λ} for DPPD on excitation energy in the mixed solutions of cyclohexane and ethanol.

On the other hand, no intermediate of the photo-oxidation in aerated and degassed cyclohexane or in ethanol was observed by a μ-second flash technique.

Discussion

The results on the excitation-wavelength, dissolved-oxygen, and polar-solvent effects on the quantum yields

of the reaction and the fluorescence can be accounted for by the following schemes:

$$RH_2 + h\nu \xrightarrow{I_a} {}^1(RH_2)_n \quad (0)$$

$${}^1(RH_2)_n \xrightarrow{k_1} {}^1(RH_2)_1 \quad (1)$$

$${}^1(RH_2)_n + O_2 \xrightarrow{k_2'} RH_2^+ \cdots O_2^- \xrightarrow{k_2'} (RH_2)^+O_2^- \quad (2)$$

$${}^1(RH_2)_n + CH \xrightarrow{k_3'} RH_2^+ + e_{solv}^{CH} \xrightarrow{k_{3e}[O_2]}$$

$$\downarrow k_{3q}$$

$$RH_2 + CH$$

$$RH_2^+ + O_2^- + CH \xrightarrow{k_{3p}} (RH_2)^+O_2^- + CH \quad (3)$$

$${}^1(RH_2)_n + EtOH \xrightarrow{k_4'} RH_2^+ + e_{solv}^{EtOH} \xrightarrow{k_{4e}[O_2]}$$

$$\downarrow k_{4q}$$

$$RH_2 + EtOH$$

$$RH_2^+ + O_2^- + EtOH \xrightarrow{k_{4p}} (RH_2)^+O_2^- + EtOH \quad (4)$$

$$(RH_2)^+O_2^- \xrightarrow{k_5} R + (H_2O_2) \quad (5)$$

$$(RH_2)^+O_2^- \xrightarrow{k_6} RH_2 + O_2 \quad (6)$$

$$(RH_2)^+O_2^- + O_2 \xrightarrow{k_7} RH_2 + 2O_2 \quad (7)$$

$$(RH_2)^+O_2^- + EtOH \xrightarrow{k_8} RH_2 + O_2 + EtOH \quad (8)$$

$${}^1(RH_2)_1 \xrightarrow{k_s} RH_2 \quad (9)$$

$${}^1(RH_2)_1 \xrightarrow{k_f} RH_2 + h\nu_f \quad (10)$$

$${}^1(RH_2)_1 \xrightarrow{k_{isc}} {}^3(RH_2) \quad (11)$$

$${}^1(RH_2)_1 + O_2 \xrightarrow{k_d} RH_2 + O_2 \quad (12)$$

$${}^3(RH_2) \xrightarrow{k_t} RH_2 \quad (13)$$

$${}^3(RH_2) \xrightarrow{k_p} RH_2 + h\nu_p \quad (14)$$

$${}^3(RH_2) + O_2 \xrightarrow{k_d} RH_2 + O_2 \quad (15)$$

where RH_2, ${}^1(RH_2)_1$, ${}^1(RH_2)_n$, and ${}^3(RH_2)$ are the ground state, the lowest excited singlet state, the upper excited singlet state, and the lowest triplet state of *p*-phenylenediamines (DPPD and CPPD) respectively, where R is the diimine, where f and p denote the fluorescence and the phosphorescence respectively, where e_{solv}^{CH} and e_{solv}^{EtOH} denote solvated electrons trapped by CH and by EtOH respectively, where CH and EtOH are cyclohexane and ethanol respectively, and where λ denotes the excitation wavelength.

The effects of the excitation wavelength on Φ^λ and $\Phi^\lambda{}_f$ show that the photo-oxidation of *p*-phenylenediamines originates from the upper excited singlet state, ${}^1(RH_2)_n$. Furthermore, it seems, considering the continuously increasing and decreasing of Φ^λ and $\Phi^\lambda{}_f$ shown in Fig. 4, that the primary processes of the reaction occur from the Franck-Condon state of the upper excited singlet state. Thus, the primary processes of the reaction have very high rate constants, $\sim 10^{11}$ sec^{-1}; the rate constants of the processes should be comparable

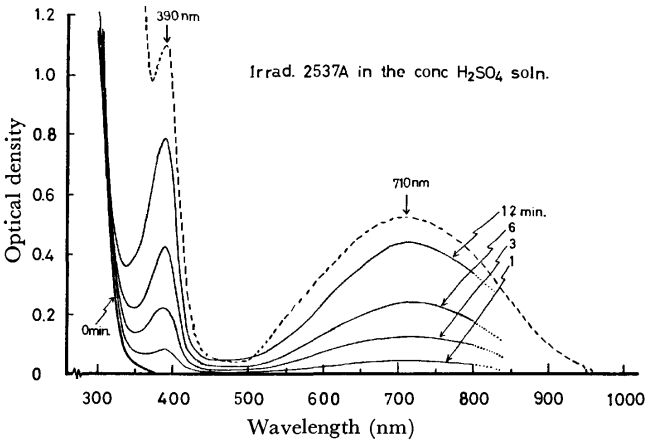

Fig. 8. The spectral change of DPPD upon irradiation with the 2537 Å light in the mixed solution of ethanol and H_2SO_4 in proportions 2 : 1 at 20°C. Numbers refer to time at measurement in minutes. The broken line denote the absorption spectrum for the cation radical RH_2^+ as has been reported by Linschitz *et al.*[29,40]

to those of the internal conversion, ${}^1(RH_2)_n \rightarrow {}^1(RH_2)_1$, whose rate constants are of the order of 10^{12}—10^{13} sec^{-1}. These processes can be accounted for by the ionization processes; one is the long-range electron-transfer process from ${}^1(RH_2)_n$ to the ground state of $O_2({}^3\Sigma_g^-)$, while the other is the electron-transfer process from ${}^1(RH_2)_n$ to the solvent. Polar solvents such as ethanol promote the latter process, since the electron-trapping ability in a polar solvent is larger than that in a nonpolar solvent.[2,14] In addition to this, the polar solvents dissolve the intermediate in the reaction, resulting in a decrease in Φ^{2537} as shown in Fig. 6. Therefore, it seems that the intermediate is an ion pair $(RH_2)^+O_2^-$ formed by the processes described in Eqs. (2)—(4). This assumption is supported by the fact that the spectrum of DPPD in the concd. H_2SO_4 solution at 2537 Å and 20°C was the same as that of the corresponding cation radical, as is shown in Fig. 8. The UV-V absorption spectrum of the DPPD cation radical has been reported by Linschitz *et al.*[29,40] The ESR absorption spectrum of the cation radical in acetic acid has also been measured.[40] In an acidic solution, the cation radical is very stable. Of course, in a highly polar solvent, no ion pair $(RH_2)^+O_2^-$ is formed because of the high dielectric constant. The photoionization processes in the photo-oxidation of DPPD and CPPD differ from that of the Weller-type ionization.[1] The Weller-type photoionization occurs through the exciplex $(DA)^*$ formed by the interaction between the lowest excited singlet state of the donor and the ground state of the acceptor, or *vice versa*, in a highly polar solvent. The electron transfer between oxygen and aromatic anilines *via* the exciplex formation has been proposed by Hori, Itoi, and Tsubomura;[28] they have also shown that the photoionization is mainly a single-photonic process. In the present work, the electron transfer occurs from the Franck-Condon state of the upper excited state ${}^1(RH_2)_n$. Since Φ^{2537} is not dependent

40) H. Linschitz, J. Rennert, and T. M. Korn, *J. Amer. Chem. Soc.*, **76**, 5839 (1954).

on the light intensity (Fig. 3(c)), the photoionization is a single-photonic process.

The possibility of a predissociative β-bond fission (N–H bond), such as that of hydrazobenzene,[26] can be disregarded, since the reactive state of DPPD was not the lowest excited singlet state, but the upper excited singlet state, since the Φ^{2537} values did not depend on the light intensity, and since no diimine formation was observed in the degassed system. The possibility that complex formation between DPPD and O_2 in the ground states is responsible for this photo-oxidation was shown to be unlikely by the fact that the spectral intensities and the positions of the aerated solution were identical with those of the degassed solution.

From the steady-state approximation, the following equations are obtained:

$$\frac{d[(RH_2)^+O_2^-]}{dt} = k_2^\lambda[^1(RH_2)_n][O_2] + (k_{3p}+k_{4p})[RH_2^+][O_2^-] - (k_5+k_6+_7[O_2] + k_8[EtOH])[(RH_2)^+O_2^-] = 0 \quad (16)$$

$$[(RH_2)^+O_2^-] = \frac{k_2^\lambda[^1(RH_2)_n][O_2]+(k_{3p}+k_{4p})[RH_2^+][O_2^-]}{k_5+k_6+k_7[O_2]+k_8[EtOH]} \quad (16')$$

$$\Phi^\lambda = \frac{d[R]/dt}{I_a} = \frac{k_5[(RH_2)^+O_2^-]}{I_a} = \left\{\frac{k_2^\lambda[O_2]+\frac{k_3^\lambda[CH]k_{3e}[O_2]}{k_{3e}[O_2]+k_{3q}[RH_2^+]}+\frac{k_4^\lambda[EtOH]k_{4e}[O_2]}{k_{4e}[O_2]+k_{4q}[RH_2^+]}}{k_1+k_2^\lambda[O_2]+k_3^\lambda[CH]+k_4^\lambda[EtOH]}\right\} \times \frac{k_5}{k_5+k_6+k_7[O_2]+k_8[EtOH]} \quad (17)$$

where:

$$[^1(RH_2)_n] = \frac{I_a}{k_1+k_2^\lambda[O_2]+k_3^\lambda[CH]+k_4^\lambda[EtOH]}$$

$$[RH_2^+] = \frac{\{k_3^\lambda[CH]+k_4^\lambda[EtOH]\}[^1(RH_2)_n]}{k_{3q}[e_{solv}^{CH}]+k_{4q}[e_{solv}^{EtOH}]+(k_{3p}+k_{4p})[O_2^-]}$$

$$[O_2^-] = \frac{\{k_{3e}[e_{solv}^{CH}]+k_{4e}[e_{solv}^{EtOH}]\}[O_2]}{(k_{3p}+k_{4p})[RH_2^+]}$$

$$[e_{solv}^{CH}] = \frac{k_3^\lambda[CH][^1(RH_2)_n]}{k_{3e}[O_2]+k_{3q}[RH_2^+]}$$

and

$$[e_{solv}^{EtOH}] = \frac{k_4^\lambda[EtOH][^1(RH_2)_n]}{k_{4e}[O_2]+k_{4q}[RH_2^+]}$$

If [EtOH]=0, Eq. (17′) is derived from Eq. (17).

$$\Phi^\lambda = \left\{\frac{k_2^\lambda[O_2]+\frac{k_3^\lambda[CH]k_{3e}[O_2]}{k_{3e}[O_2]+k_{3q}[RH_2^+]}}{k_1+k_2^\lambda[O_2]+k_3^\lambda[CH]}\right\}\frac{k_5}{k_5+k_6+k_7[O_2]} = \left\{\frac{a^\lambda[O_2]+\frac{b^\lambda c[O_2]}{c[O_2]+1}}{1+a^\lambda[O_2]+b^\lambda}\right\}\frac{1}{1+d+e[O_2]} \quad (17')$$

where:

$$a^\lambda = \frac{k_2^\lambda}{k_1}, \quad b^\lambda = \frac{k_3^\lambda}{k_1}[CH], \quad c = \frac{k_{3e}}{k_{3q}[RH_2^+]}$$

$$d = \frac{k_6}{k_5}, \text{ and } e = \frac{k_7}{k_5}$$

On the other hand, the fluorescence quantum yield, Φ^λ_f, is given by:

$$\Phi_f^\lambda = \frac{k_1}{k_1+k_2^\lambda[O_2]+k_3^\lambda[CH]}\cdot\frac{k_f}{k_s+k_f+k_{isc}+k_d[O_2]} \quad (18)$$

Scarcely any photo-oxidation of DPPD occurred upon irradiation with the 3200 Å light, as is shown in Fig. 4. Therefore, Eq. (19) holds approximately:

$$\Phi_f^{3200} = \frac{k_f}{k_s+k_f+k_{isc}+k_d[O_2]} \quad (19)$$

where $k_1 \gg k_2^{3200}+k_3^{3200}[CH]$. The relative fluorescence quantum yield, $\Phi_f^{3200}/\Phi^\lambda_f$, is obtained from Eqs. (18) and (19):

$$\frac{\Phi_f^{3200}}{\Phi_f^\lambda} = 1+\frac{k_2^\lambda[O_2]+k_3^\lambda[CH]}{k_1} = 1+a^\lambda[O_2]+b^\lambda \quad (20)$$

where $[O_2]=2.3\times10^{-3}$M.[24] The $\Phi_f^{3200}/\Phi^\lambda_f$ values are listed in Table 3.

Table 3. The $\Phi_f^{3200}/\Phi_f^\lambda$ values of DPPD in aerated cyclohexane

Excitation wavelength Å	Excitation energy eV	$\Phi^\lambda\times10^2$	$\Phi_f^{3200}/\Phi_f^\lambda$
2400	5.17	4.5	1.33
2537	4.88	3.3	1.19_3
2700	4.59	2.2	1.12
2800	4.43	1.33	1.07
3000	4.13	0.28	1.02
3200	3.87	0.18	1.00

The following values can be estimated:

$$a^{2537}[O_2]+b^{2537} = 0.19_3 \quad (21)$$

where $[O_2]=2.3\times10^{-3}$M. Then, the simulation of Φ^{2537} as a function of $[O_2]$ was carried out using Eqs. (17′) and (21).

The (Φ^{2537}_{calcd}) values of DPPD are in accordance with those obtained experimentally, as is shown in Fig. 5(a). The appropriate values of the a^{2537}, b^{2537}, c, d, and e parameters are listed in Table 4. From the results of the calculations, the two rates, $k_2^{2537}[O_2]$ and $k_3^{2537}[CH]$, in the electron-transfer processes (Eqs. (2) and (3)) can be said to be nearly equivalent in aerated cyclohexane, where $[O_2]=2.3\times10^{-3}$M, and at 2537 Å, because the $(2.3\times10^{-3}a^{2537})/b^{2537}$ ratio is approximately equal to unity.

Table 4. The appropriate values of the parameters

No. of plot in Fig. 5 (a)	$a^{2537}\times10^{-1}$	$b^{2537}\times10$	$c\times10^{-5}$	d	$e\times10^{-3}$
1	3.35	1.16	3.00	1.22	1.12
2	4.20	0.96_5	3.00	0.86_5	1.28
3	5.04	0.77	3.00	0.51_1	1.44

Thus, Eq. (22) is obtained:

$$k_2^{2537} = 4\times10^3 k_3^{2537} \quad (22)$$

If n molecules of oxygen are randomly distributed around a DPPD molecule in a certain volume, V, the radius ($\bar{r}$) between the DPPD molecule and the nearest-neighbor oxygen molecule can be evaluated by the following equation, derived by Yamamoto, Nakato, and

Tsubomura:[41]

$$\bar{r} = (V/2\pi n)^{1/3}$$

or
$$\bar{r} = 6.42[O_2]^{-1/3}\text{Å} \quad (23)$$

The calculated $\bar{r}$ value is 49 Å in aerated cyclohexane ($[O_2]=2.3\times10^{-3}$M) at 2537 Å and 20°C. The large $\bar{r}$ value shows the long-range electron transfer from the Franck-Condon state of the $^1(RH_2)_n$ state to dissolved oxygen. The rate constant of the long-range electron transfer, k_2^{2537}, is very much larger than that of the electron transfer to the solvent (cyclohexane), as is shown in Eq. (22).

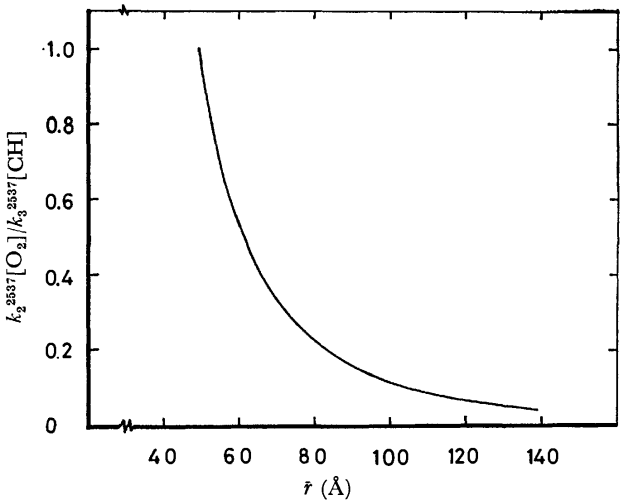

Fig. 9. The ratio k_2^{2537} $[O_2]/k_3^{2537}[CH]$ as a function of $\bar{r}$.

The plot of the $k_2^{2537}[O_2]/k_3^{2537}[CH]$ ratio as a function of $\bar{r}$ is shown in Fig. 9. It can be understood that the $k_2^{2537}[O_2]/k_3^{2537}[CH]$ values significantly decrease as the $\bar{r}$ values increase. The dissolved oxygen in cyclohexane acts as an electron-trapping center in the primary processes of the photo-oxidation and also deactivates the intermediate $(RH_2)^+O_2^-$, as is shown in Eq. (7). In the electron-transfer processes from $^1(RH_2)_n$ to the solvents, it may be assumed that the $^1(RH_2)_n$ species ejects an electron to the solvents and that subsequently the electron is trapped by the dissolved oxygen, as is shown in Eqs. (3) and (4). Scarcely any photooxidation of DPPD in aerated cyclohexane occurred upon irradiation with the 3200 Å light, which corresponds to the shoulder of the absorption Band I in Fig. 1. The absorption Band I is comprised of several singlet-singlet transitions, as is shown in Table 1, where the calculated data for the *cis*-form are almost the same as those for the *trans*-form. Although the reactive state can not be assigned exactly, the photo-ionization processes described above apparently take place from the upper excited singlet state, $^1(RH_2)_n$. In the secondary processes of the reaction, it seems that the $(RH_2)^+O_2^-$ ion pair is converted to the corresponding diimine (Eq. (5)). This transformation probably involves an intramolecular proton transfer process:

$$(RH_2)^+O_2^- \longrightarrow (RH)(HO_2) \longrightarrow R + H_2O_2 \quad (24)$$

The H_2O_2 formation was identified by iodometry.

Finally, a schematic energy diagram of the photooxidation of DPPD and CPPD is shown in Fig. 10. The detailed reaction schemes can be written as in Eqs. (0)—(15).

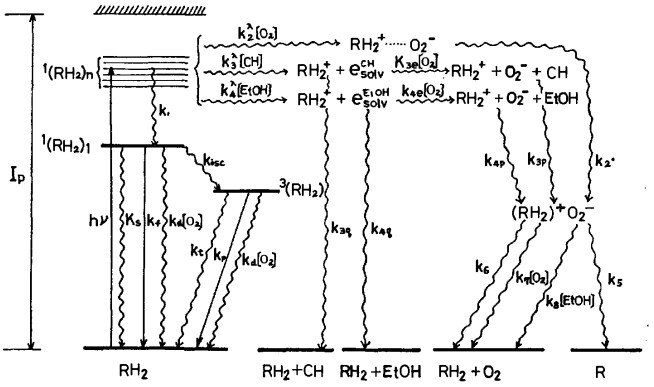

Fig. 10. Schematic energy state diagram for the photooxidation of DPPD.

The authors wish to thank Professors Ikuzo Tanaka and Yuji Mori of the Tokyo Institute of Technology for their very helpful discussions of this paper.

Calculation of Infrared Band Intensities of Various Chlorinated Ethanes

Kazutoshi TANABE and Shinnosuke SAËKI

Government Chemical Industrial Research Institute of Tokyo, Honmachi, Shibuyaku, Tokyo

(Received May 8, 1971)

Infrared absorption intensities of fundamental bands of three molecular species, CH_3CCl_3, CD_3CCl_3 in the vapor phase, and C_2Cl_6 in dilute solution in carbon disulfide have been measured. From the intensity data of four kinds of chlorinated ethanes C_2H_6, C_2D_6, CH_3CCl_3, CD_3CCl_3, the least number of common intensity parameters has been determined using the least squares method. Intensities of C_2Cl_6 calculated using the determined values of intensity parameters have been compared with the observed intensities in solution. It has proved that for almost all electro-optical parameters, it is possible to determine values commonly applicable to various chlorinated ethanes, while for μ_{CH} and $\delta\mu_{CH}/\delta r_{CH}$, it is not possible to find commonly applicable values, as in the case of chlorinated methanes.

In our previous paper,[1] infrared band intensity data of thirteen kinds of chlorinated methanes, from methane to carbon tetrachloride, were interpreted in terms of common intensity parameters as few as possible. The least squares method was applied to determine values of those parameters to obtain the best fit between observed and calculated intensities. As a result, for most of the electro-optical parameters, values commonly applicable to all chlorinated methanes could be determined, while for the two parameters μ_{CH} and $\delta\mu_{CH}/\delta r_{CH}$, it was not possible to find commonly applicable values.

In this study, in order to examine whether similar trends are also found in other cases, the molecular series of chlorinated ethane have been investigated, using the same technique as in the previous study. Molecular species treated in this study are C_2H_6, C_2D_6; CH_3CCl_3, CD_3CCl_3; C_2Cl_6, all having three-fold symmetry axis.

As compared with the case of chlorinated methanes, the treatment of ethane series requires many more electro-optical parameters in calculation. For example, several parameters associated with C–C bonds such as μ_{CC} or $\delta\mu_{CC}/\delta r_{CC}$ have to be taken into account, from the intensity expression based on the theory. Consequently, computative process is more complex and more time-consuming. However, it is of much interest to examine how the values of parameters change from chlorinated methanes to ethanes.

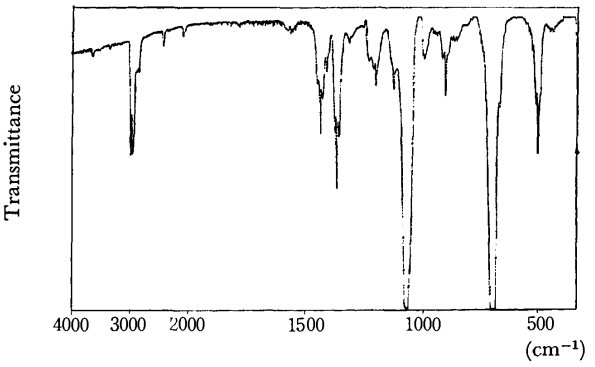

Fig. 1. Vapor phase spectrum of CH_3CCl_3.

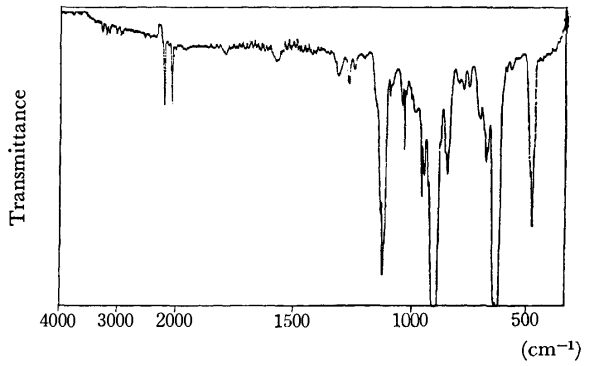

Fig. 2. Vapor phase spectrum of CD_3CCl_3.

Experimental

Infrared absorption intensities of fundamental bands of three molecular species CH_3CCl_3, CD_3CCl_3 in the vapor phase and C_2Cl_6 in dilute carbon disulfide solution were measured in a range 4000—600 cm^{-1} using a Perkin-Elmer Model 421 grating spectrophotometer combined with a digital data recorder.[2] Intensities for bands below 600 cm^{-1} were roughly estimated by inspection from observed spectra measured using Perkin-Elmer Model 225 and 180 spectrophotometers. Deuterated methyl chloroform CD_3CCl_3, supplied from Merk Sharp & Dohm of Canada Limited, was used without further purification. Observed spectra of CH_3CCl_3 and CD_3CCl_3 in the vapor phase are shown in Figs. 1 and 2. Methods and instrumental conditions were almost the same as described in the previous papers.[1,3]

Results and Discussion

In order to estimate the absolute band intensity, and to obtain the **L**-matrix necessary for computing the band intensity, the assignment of fundamental bands has to be determined definitely. Concerning the ethane species, C_2H_6 and C_2D_6, the frequency and intensity data are all obtained from literatures[4-13]

where band assignments are correctly made. These data are summarized in Table 1.

As for methyl chloroform CH_3CCl_3, several authors reported frequency data and made a tentative assignment of fundamental bands. The observed bands are considered to be correctly assigned therein, except for the C–C stretching vibration. To this mode, diffrent frequencies, 1075,[14] 1068,[15] 1012,[16] 1007,[17] 977,[18] 867,[19] and 714 cm^{-1},[20] were assigned by different authors. The last two values seem inappropriately low as compared with the C–C stretching frequencies in similar molecules: 995 in C_2H_6, 972 in CH_3CH_2Cl, 1052 in *trans*-CH_2ClCH_2Cl, 1027 in *gauche*-CH_2ClCH_2Cl, and 975 in C_2Cl_6. In particular, the band at 714 cm^{-1} should be assigned to the C–Cl degenerate stretching mode.

The vapor phase spectrum observed in the region 1500—400 cm^{-1} is shown in Fig. 3. The strongest band at 1100—1070 cm^{-1} shows a very complex band envelope, which is undoubtedly assigned to the CH_3 rocking vibration (species E). On the other hand, the C–C stretching mode is expected to show a P, Q, R

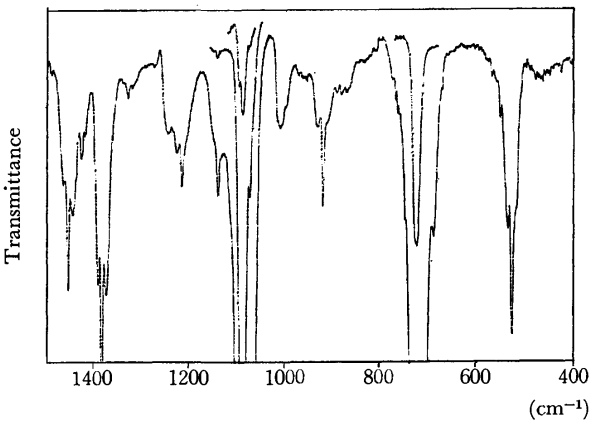

Fig. 3. Vapor phase spectrum of CH_3CCl_3 in a region 1500—400 cm^{-1}.

band envelope similar to the CH_3 symmetric stretching (at 2951 cm^{-1}) or symmetric deformation band (at 1386 cm^{-1}) of the same symmetry species A_1. Although no observed band may be assigned to the C–C stretching mode with certainty, the band observed at about 1010 cm^{-1} has been tentatively assigned to this mode, after Cleveland *et al.* (1012 cm^{-1}),[16] or Karplus and Halford (1007 cm^{-1}).[17]

As for deuterated methyl chloroform CD_3CCl_3, no previous data on vibrational frequencies and intensities have been reported. Most of fundamental bands for this molecule have been assigned by referring to those of CH_3CCl_3, or taking into account band profiles observed in the vapor phase. The C–C stretching frequency could not be determined in like manner, hence its band has been assigned by referring to the frequency product rule for the isotopic species CH_3CCl_3 and CD_3CCl_3, as given in Table 2. Although there may be some ambiguity in assigning the fundamental frequencies only on the basis of observed spectrum, the observed values listed in Table 3 have been adopted as the tentative assignment. Taking into account the fact that not the harmonic frequencies but the observed frequencies are employed for the product rule in Table 2, the observed values listed are considred to satisfy the rule, hence the band assignment for these species might be correctly made.

Table 2. Frequency product rule for CH_3CCl_3 and CD_3CCl_3

	Theoretical	Observed
A_1	$\left(\frac{m_H^2 \times M_D}{m_D^2 \times M_H}\right)^{1/2} = 0.5060$	$\prod_{i=1}^{5} \frac{\nu_{obsd}^i(D)}{\nu_{obsd}^i(H)} = 0.5233$
E	$\left(\frac{m_H^3 \times M_D \times I_D}{m_D^3 \times M_H \times I_H}\right)^{1/2} = 0.3725$	$\prod_{i=7}^{12} \frac{\nu_{obsd}^i(D)}{\nu_{obsd}^i(H)} = 0.3812$

the chlorinated ethanes treated here, have been determined using the least squares method from fifty-five observed frequencies. Calculated normal frequencies are given in Table 3, compared with the observed values, and the converged values of the LSFF constants are in Table 4, where asterisks indicate the constants fixed at zero in the least squares calculation.

Agreement between calculated and observed frequencies is satisfactory on the whole, and the converged values of the LSFF constants seem appropriate. The frequencies assigned tentatively for the C–C stretching vibration of methyl chloroforms CH_3CCl_3 and CD_3CCl_3 are represented with the above LSFF constants to a reasonable extent, thus the above band assignment could be considered acceptable.

Infrared band intensities of fundamental bands of three molecular species CH_3CCl_3, CD_3CCl_3, and C_2Cl_6, estimated on the basis of such band assignment, are listed in Table 5. The intensity sum rule proposed by Crawford[21] gives the results shown in the same table. It can be deduced from this result that these intensity data are reliable and accurate for calculation.

For computing the band intensity of chlorinated ethanes, parameters other than those used for chlorinated

A_{obsd} in CH_3CCl_3, CD_3CCl_3 is in the vapor phase, and A_{obsd} in C_2Cl_6 is in dilute solution of carbon disulfide.

methanes have to be introduced into the calculation based on the valence-optical theory.[22,23] These parameters are for example, the ones associated with the C–C bond, such as μ_{CC}, or $\delta\mu_{CC}/\delta r_{CC}$. Furthermore, if parameters due to the long-range methyl-methyl group interaction such as $\delta\mu_{CH}/\delta r_{CH}$ (where μ_{CH} and r_{CH} are attached to different carbon atoms, respectively) are taken into account, the total number of the electro-optical parameters becomes too large as compared with the number of available intensity data. In order to determine values for intensity parameters from the observed data, reduction of the unknown parameters is necessary, and for this purpose, those parameters which might be expected to have rather small values, such as the above $\delta\mu_{CH}/\delta r_{CH}$, are neglected.

Intensity parameters determined in calculation based on these considerations are twenty-four as follows:

(a) for C–H bond; μ_{CH}, $\delta\mu_{CH}/\delta r_{CH}$, $\delta\mu_{CH}/\delta r'_{CH}$, $\delta\mu_{CH}/\delta r_{CC}$, $\delta\mu_{CH}/\delta\alpha_{HCH}$, $\delta\mu_{CH}/\delta\alpha'_{HCH}$, $\alpha\mu_{CH}/\delta\alpha_{HCC}$, $\alpha\mu_{CH}/\delta\alpha'_{HCC}$,

(b) for C–Cl bond; μ_{CCl}, $\delta\mu_{CCl}/\delta r_{CCl}$, $\delta\mu_{CCl}/\delta r'_{CCl}$, $\delta\mu_{CCl}/\delta r_{CC}$, $\delta\mu_{CCl}/\delta\alpha_{ClCCl}$, $\delta\mu_{CCl}/\delta\alpha'_{ClCCl}$,, $\delta\mu_{CCl}/\delta\alpha_{ClCC}$, $\delta\mu_{CCl}/\delta\alpha'_{ClCC}$,

(c) for C–C bond; μ_{CC}, $\delta\mu_{CC}/\delta r_{CC}$, $\delta\mu_{CC}/\delta r_{CH}$, $\delta\mu_{CC}/\delta r_{CCl}$, $\delta\mu_{CC}/\alpha_{HCH}$, $\delta\mu_{CC}/\delta\alpha_{HCC}$, $\delta\mu_{CC}/\delta\alpha_{ClCCl}$, $\delta\mu_{CC}/\delta r_{ClCC}$.

These twenty-four parameters have been adjusted using the least squares method from the thirty-three data, that is, the thirty-two intensity data of C_2H_6, C_2D_6, CH_3CCl_3, CD_3CCl_3, and the permanent dipole moment of the methyl chloroform molecule.[24] The computative process is the same as in the previous papers, and the molecular constants used are given in Table 6.

∠ClCCl		109°	108°14′

Bond lengths are in (Å).

Because of the sign ambiguity inherent in intensity studies, several converged sets of intensity parameters are obtained, as in our previous cases. Although it is desirable to repeat the least squares calculation by changing the starting values of parameters in various ways to find out the most acceptable set with the smallest residual, such repetative computations are time-consuming and could not be carried out. Hence, first, the parameters were classified into the following three groups: (1) these common to chlorinated methanes, (2) those considered to be less important and to have small values, and (3) those considered to be more important and to have significant values. And as the starting values of the parameters, the values already determined were adopted for the first group, zero values were assumed for the second group, and various with changes of signs were tested for the third group. After more than fifteen starting sets of parameters have been tested, several sets have been obtained for converged values of the least squares calculation, and the set with the smallest residual among those has been considered to be most acceptable.

a) For C_2Cl_6, A_{obsd} is measured in solution of carbon disulfide, and should not be compared directly with A_{calcd}.

Band intensities thus calculated in terms of twenty-four parameters (Calcd I) are listed in Table 7, compared with the observed values, where intensities of C_2Cl_6 have been calculated using the determined values of parameters as described above. Agreement between calculated and observed values is satisfactory on the whole, but considerable disagreement is found in several bands,

22) L. A. Gribov and E. M. Popov, *Opt. Spectry.*, **12**, 304 (1962).
23) L. A. Gribov, "Intensity Theory for Infrared Spectra of Polyatomic Molecules," Consultants Bureau (1964).
24) R. H. Wiswall and C. P. Smyth, *J. Chem. Phys.*, **9**, 356 (1941).

This is the same situation as in the case of the chlorinated methanes reported in our previous paper.[1] That is, intensities for bands associated with the C–Cl bonds are well represented in terms of the above parameters, while in some bands associated with the C–H or C–D bonds, the calculated intensities are very much lower than the observed values. The disagreement in the CH_3 or CD_3 degenerate stretching in ethanes and rocking bands in methyl chloroforms is especially remarkable.

In order to revise such deficiency, it will be necessary to adjust some parameters separately for each molecules. In the case of chlorinated methanes treated in our previous paper,[1] similar disagreements in calculated intensities of some bands were encountered, and in order to get over such difficulties, two parameters μ_{CH} and $\delta\mu_{CH}/\delta r_{CH}$ were separately adjusted for each molecule. As a result, it has been proved that these two parameters may really be effective and sensitive in interpreting the observed intensities. And it has also been found that the adjustment of parameters other than μ_{CH} or $\delta\mu_{CH}/\delta r_{CH}$ was not effective for the satisfactory explanation of observed intensities. Therefore, in order to fit the calculated intensities of the $CH_3(CD_3)$ degenerate rocking bands of CH_3CCl_3 (CD_3CCl_3) to the observed values, it is considered effective to assign different values to μ_{CH} for ethanes and methyl chloroforms, and in order to resolve large discrepancies in the $CH_3(CD_3)$ degenerate stretching band intensities of ethanes, it is considered effective to assign different values to $\delta\mu_{CH}/\delta r_{CH}$. It may be considered less effective to adjust other parameters for resolving the discrepancies in intensities.

Hence, next calculation based on these considerations has been carried out using the least squares method to adjust the twenty-six parameters, of which μ_{CH} and $\delta\mu_{CH}/\delta r_{CH}$ are assumed to take different values for ethanes and methyl chloroforms (Calcd II). The calculated intensities are given in Table 7, compared with the observed values and the calculated values obtained in Calcd I. It is seen that the agreement is much improved and large discrepancies in the CH_3 (CD_3) degenerate stretching and rocking band intensities are successfully resolved in this calculation. The value 93 of the residual, sum of weighted deviations, in Calcd II is much smaller than the value 1416 in Calcd I. This shows that the average difference between observed and calculated intensities in Calcd II is about twice as large as the experimental errors of the intensity measurement.

As mentioned in Experimental, since the vapor phase spectrum of C_2Cl_6 was not observed because of its very low pressure, the band intensities were measured in solution of carbon disulfide. Therefore, the calculated intensities for C_2Cl_6 listed in Table 7 correspond to the intensities to be measured in the vapor phase, and should not be compared with the intensities observed in solution which are also shown in parentheses in Table 7 only as the information.

In Table 8, converged values and their standard deviations in most acceptable sets are given for intensity parameters for Calcd I and II. Parameters with asterisks in the table are fixed at zero in the least squares calculation. Among these parameters, μ_{CC} may probably have some finite value especially in the case of CH_3CCl_3. However, its value can by no means be determined here because too many parameters are taken in this case. Therefore the values determined for the other parameters should be considered to be valid only under the postulation of negligence of μ_{CC}. Although this is indeed a very disagreable ambiguity, this is inevitable at the present stage of such intensity studies. In the treatment of many other molecules, it will be probable to obtain experimental facts which give us a clearer knowlegde about μ_{CC}.

TABLE 8. CONVERGED VALUES AND THEIR DEVIATIONS OF INTENSITY PARAMETERS (D, or D/Å)

Parameter	Calcd (I)	Calcd (II)
μ_{CH} (C_2H_6)	0.28 (0.04)	0.35 (0.02)
μ_{CH} (CH_3CCl_3)		0.49 (0.05)
μ_{CCl}	−1.47 (0.05)	−0.93 (0.98)
$\mu_{CC}(CH_3CCl_3)$	0.00*	0.00*
$\delta\mu_{CH}/\delta r_{CH}$ (C_2H_6)	0.57 (0.06)	0.88 (0.01)
$\delta\mu_{CH}/\delta r_{CH}$ (CH_3CCl_3)		0.28 (0.04)
$\delta\mu_{CH}/\delta r'_{CH}$	0.33 (0.03)	0.17 (0.01)
$\delta\mu_{CH}/\delta r_{CC}$	0.00*	0.00*
$\delta\mu_{CH}/\delta\alpha_{HCH}$	0.27 (0.06)	0.38 (0.02)
$\delta\mu_{CH}/\delta\alpha'_{HCH}$	0.00*	0.00*
$\delta\mu_{CH}/\delta\alpha_{HCC}$	−0.00 (0.03)	0.04 (0.01)
$\delta\mu_{CH}/\delta\alpha'_{HCC}$	0.00*	0.00*
$\delta\mu_{CCl}/\delta r_{CCl}$	−2.33 (0.30)	−2.28 (0.25)
$\delta\mu_{CCl}/\delta r'_{CCl}$	−0.16 (0.22)	−0.19 (0.20)
$\delta\mu_{CCl}/\delta r_{CC}$	0.00*	0.00*
$\delta\mu_{CCl}/\delta\alpha_{ClCCl}$	1.36 (0.46)	1.85 (0.66)
$\delta\mu_{CCl}/\delta\alpha'_{ClCCl}$	0.00*	0.00*
$\delta\mu_{CCl}/\delta\alpha_{ClCC}$	0.70 (0.67)	1.24 (0.39)
$\delta\mu_{CCl}/\delta\alpha'_{ClCC}$	1.97 (0.39)	1.50 (0.65)
$\delta\mu_{CC}/\delta r_{CC}$	0.86 (0.10)	0.86 (0.09)
$\delta\mu_{CC}/\delta r_{CH}$	−0.18 (0.04)	0.02 (0.04)
$\delta\mu_{CC}/\delta r_{CCl}$	−0.15 (0.22)	−0.15 (0.22)
$\delta\mu_{CC}/\delta\alpha_{HCH}$	0.00*	0.00*
$\delta\mu_{CC}/\delta\alpha_{HCC}$	0.20 (0.02)	0.06 (0.04)
$\delta\mu_{CC}/\delta\alpha_{ClCCl}$	0.00*	−0.00 (0.00)
$\delta\mu_{CC}/\delta\alpha_{ClCC}$	0.30 (0.20)	0.33 (0.21)

Asterisks indicate the parameters fixed at zero in the least squares calculation.

It can be deduced that in Calcd II, a slight difference in converged values for μ_{CH} of ethanes and of methyl chloroforms is found but this is the very reason for the successful explanation of the CH_3 (CD_3) degenerate rocking band intensities in these molecules. That is, μ_{CH} is a very sensitive parameter to interpret the band intensity, and consequently, it has proved that it is not possible to find out a value commonly applicable to ethanes and methyl chloroforms for this parameter.

A similar situation is also found in the derivative $\delta\mu_{CH}/\delta r_{CH}$. The fact that some difference in $\delta\mu_{CH}/\delta r_{CH}$ for ethane and methyl chloroform obtained in Calcd II is quite similar to the chlorinated methanes,[1] hence, assigning different values to this parameter for each molecule is necessary for a successful explanation of the CH_3 (CD_3) degenerate stretching band intensities of these molecules.

Some comment has to be made here with respect to the significance of the converged values of the intensity parameters as listed in Table 8. As mentioned in our previous papers[1,3] as well as pointed out by Gribov himself,[25] the valence-optical theory used here has an essential disadvantage which seems to be almost fatal. Too many electro-optical parameters have to be taken into account, and furthermore, due to the fact that they always appear in forms of linear combinations in intensity expressions, individual value of each parameter can not be determined. This is attributed to an assumption that a molecular dipole moment is decomposed as a vector sum of bond dipole moments, in interpreting the band intensity data in terms of intensity parameters.

If one takes a viewpoint in which significant or meaningful quantities are derived from the infrared intensity data, such decomposition is certainly broken down, and one relies upon the treatment as in the serial works by Crawford and his collaborators. In their treatment, the infrared intensity data are interpreted in terms of parameters which are derivatives of the molecular dipole moment with respect to various symmetry coordinates. However, analyses in their studies are restricted within different isotopic species of a certain molecule, and infrared intensity data of various molecules can not be interpreted with their approach. Because the intensity parameters used in their analysis are chracteristic of a molecule as a whole and cannot be transferred among various molecules since both μ and S_i in $(\delta\mu/\delta S_i)$ (where μ is a molecular dipole moment and S_i is the i-th molecular symmetry coordinate) are quantities inherent to a framework of a molecule as a whole.

If one attempts to interpret the intensity data of different molecules in terms of the least number of common parameters, such parameters have to be associated with the bond property. Because the conception of "bond" is most natural and general for chemists in considering some properties of various kinds of different molecular species. In the classical "bond moment hypothesis" used in the previous infrared studies, all bond moments are assumed to depend only on the variation of their own bond lengths. On this basis, many calculations have been carried out for bond moments and their derivatives with respect to the stretching of their bonds, using the experimental results of the band intensities. However, with this approximation, it was very often encountered that different sets of values were obtained for bond moments and/or bond derivatives from sets of the band intensities belonging to different symmetry species, and that the vector sum of bond moments was not equal to the total permanent dipole of the molecule. This fact suggests that this approximation is too rough to explain the observed intensities.

Taking into account the dependence of a bond dipole on the variation of its neighboring internal coordinates, Gribov *et al.* pointed out the necessity of introducing the moment derivatives with respect to some neighboring internal coordinates. This improvement is quite reasonable from the viewpoint of the necessary variation in electron distribution with the displacements of atoms in vibration. This valence-optical theory is an extension of the classical bond moment hypothesis which is designated as the zero-order approximation of the valence-optical theory according to Gribov. That is, in addition μ_i and $\delta\mu_i/\delta r_i$ determined in the classical theory, more electro-optical parameters $\delta\mu_i/\delta r_j$ and $\delta\mu_i/\delta\alpha_{jkl}$ are to be determined using the observed band intensity data. As mentioned above, those parameters cannot be obtained individually, but merely their linear combinations can be determined from the intensity calculations as a disadvantage of this theory.

The form of the linear combinations in which the parameters take part, is dependent on the framework of the molecule as a whole, and is different from molecule to molecule. Hence, if the assumption that the electro-optical parameters may take the same values independent of the molecular species is accepted, some of the parameters are to be determined by solving simultaneous equations of linear combinations of the parameters. Values thus determined for the parameters are qualified to explain the observed intensity data of various different molecules. The converged values given in Table 8 implies such significance, although they still depend on values at which undeterminable parameters should be fixed. Since no unambiguous answer can be given to the question which parameters among several undeterminable parameters should be fixed at what values, it is reasonable to fix less important parameters at zero, using some chemical intuition or taking into account the potential energy matrix element.[1,3] Therefore it is concluded that the converged values in Table 8 are necessary and sufficient to interpret the infrared intensity data of ethanes and methyl chloroforms. And, even though the above parameters μ_{CH} and $\delta\mu_{CH}/\delta r_{CH}$ may also be linearly combined with some other parameters and only values of those linear combinations may be determined definitely, it is considered to be very probable that these two parameters may really be effective and sensitive in interpreting the band intensity data, as was already experienced in the case of chlorinated methanes.[1]

For several parameters common to the chlorinated methanes and ethanes, results are summarized in Table 9. This shows clearly the above conclusion that in

Table 9. Parameters common to chlorinated methanes and ethanes (D, or D/Å)

Species	μ_{CH}	$\frac{\delta\mu_{CH}}{\delta r_{CH}}$	μ_{CCl}	$\frac{\delta\mu_{CCl}}{\delta r_{CCl}}$
CH_4	0.95	0.54		
CH_3Cl	0.59	0.34		
CH_2Cl_2	0.13	0.10	−1.32	−2.86
$CHCl_3$	0.09	−0.06		
CCl_4				
C_2H_6	0.35	0.88		
CH_3CCl_3	0.49	0.28	−0.93	−2.28
C_2Cl_6				

Results for chlorinated methanes are taken from Set (A) in Table 9 of Ref. 1, and for ethanes, from Calcd II in Table 8 of this paper.

25) L. A. Gribov, *Opt. Spectry.*, **25**, 53 (1968).

order to explain the band intensity data of various chlorinated ethanes as well as methanes in terms of as few common intensity parameters as possible,, most parameters may take common values transferable to various molecular species, but it is not possible to find out commonly applicable values for the two parameters μ_{CH} and $\delta\mu_{CH}/\delta r_{CH}$ for the various chlorinated methanes and ethanes. Furthermore, this may suggest that bond properties in the C–H bonds in these molecules vary from one to another much more than in C–Cl bonds. These conclusions might be confirmed by the quantum-chemical approach such as the CNDO techniques.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 38—42(1972)

Study of Grinding Reaction of the System of Fine Particle Silica and Basic Zinc Carbonate by X-Ray Silicon K-Emission Band Spectra[1]

Muneyuki MOTOYAMA and Genzo HASHIZUME
Industrial Research Institute of Hyogo Pref., Suma-ku, Kobe

(Received May 17,1971)

Usefulness of X-ray emission spectrometry was demonstrated in a study of the grinding reaction of the system of fine particle silica and basic zinc carbonate. Si$K\alpha$ bands of the ground mixtures shifted toward the lower energy side relative to that of the fine particle silica, whearas Si$K\beta$ bands toward the opposite side. These band shifts were regarded as a measure of the reaction progress. The Si$K\beta$ band shift was shown more distinctly than the $K\alpha$ band shift and explained as come from a decrease in the *s*-character of the bond caused by the chemical bonding of the zinc atom with the fine particle silica. The $K\beta$ band shift was also correlated with the destabilization energy relative to the fine particle silica after C. G. Dodd and G. L. Glen. The band shifts indicated that the final product of this grinding reaction was amorphous zinc silicate-like compound. The correspondence of the X-ray band shifts with the infrared spectral shifts was also shown.

Solid structures of materials are distorted by a mechanical treatment such as grinding, rolling, or crushing.[2] This sort of structural distortions gives samples physicochemical activities and, when mixtures of more than two chemicals are subjected to such a mechanical treatment, chemical reactions occur in some cases.[3] The chemical state of each species in the ground mixture is not easily known. It can hardly be measured whether some species become chemically bounded or not.

X-Ray emission and absorption spectra originate in electronic process, so that, to a first approximation, they are not affected by physical states and reflect electronic structures of materials. Many studies have been made of the chemical effects on the X-ray spectra, particularly for third-period elements such as magnesium, aluminum, and silicon.[4] This paper describes an experimental application of X-ray emission spectra to studying amorphous ground mixtures of fine particle silica and basic zinc carbonate. A correspondence of the X-ray method with infrared spectroscopic method is also shown.

Experimental

Materials and Grinding Procedure. Basic zinc carbonate was used in commercial grade. The samples of fine particle silica named Nipsil VN-3, Carplex #1120 and Aerosil were obtained from Nihon Silica Co. Ltd., Shionogi Seiyaku Co. Ltd., and Degussa Inc., respectively. Some properties of these kinds of silica were shown in Table 1. Amorphous zinc silicate was obtained from Kantoo Chemical Co., Ltd. Crystalline zinc silicate was prepared by heating amorphous zinc silicate for two hours at 950°C in an electric furnace. A mixture of 3 g of the basic zinc carbonate and 2 g of the fine particle silica was dry-ground in an automatic mortor for a desired time. The grinding process was monitored with the X-ray diffraction diagram of basic zinc carbonate in the ground mixture.

TABLE 1. SOME PROPERTIES OF FINE PARTICLE SILICA

Fine particle silica	Particle size Å	Specific surface area m^2/g	pH
Nipsil VN-3	160	240	6.2
Carplex #1120	100	110	10.5
Aerosil	200	200	4.0

Apparatus and Measurements. A Rigakudenki Geigerflex fluorescent X-ray spectrometer equipped with a type D9C constant potential X-ray generator and with a type KG5 goniometer was used for the X-ray emission measurements.

The chromium target of Philips PW2164 X-ray tube operated at 50 kV and 40 mA was used for the excitation. The silicon K-emission spectra were analyzed with a flat crystal of EDDT cut for its (020) plane ($2d$=8.808 Å). The detector was a cylindrical gas flow proportional counter with a 2 μ thick polypropyrene film, where counting gas was a 90% argon-10% methane mixture and a voltage of 1920 V was applied. A pulse height analyzer was used for improving peak-to-background ratios. The X-Ray chamber was kept vacuum of less than 10^{-2} mmHg during the measurements. Two Soller collimators were used. Each of the entrance collimator of 100 mm long and the receiving collimator of 30 mm long had a 0.15 mm vane spacing. The band profiles of the silicon K-emission spectra were measured by counting X-ray intensities at every 1/100° (2θ) for $K\alpha$ and 5/100° (2θ) for $K\beta$ band. Instrumental drifts including that by a temperature change were monitored by measuring a standard fine particle silica for every five samples.

The X-ray diffraction diagrams were recorded with a Geigerflex X-ray diffractometer. Nickel-filtered copper $K\alpha$ line excited at 40 kV and 10 mA was used with a scanning speed of 1° (2θ) per min, a divergence slit of 1°, and a receiving slit of 3 mm.

Infrared spectra were measured with a spectrometer type DS-403G (Japan Spectroscopic Co., Ltd.) equipped with grating monochrometers. The ground products were suspended in liquid paraffin and held between two potassium bromide plates for the measurements.

Results

The X-ray diffraction diagrams of the ground mixtures are shown in Fig. 1 in which diffraction peaks corresponded to those for basic zinc carbonate. The crystalline structure of the basic zinc carbonate seems distorted with an increase of grinding time, and the ground mixture becomes wholly amorphous after about 300 hours' grinding. In the early stages of the grinding treatment, however, the intensities of the diffraction peak at 35.9° (2θ) increase as shown in Fig. 2. But it is not evident that these changes of the diffraction diagrams are correlated with some grinding reactions. The X-ray diffraction diagrams may not give further information about any grinding reactions.

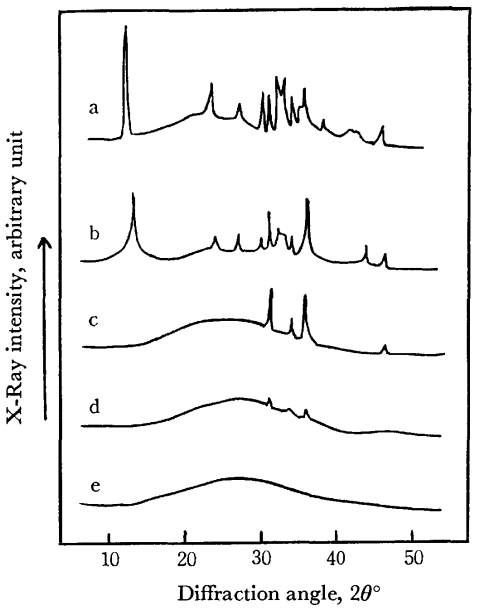

Fig. 1. X-ray diffraction diagrams of the ground mixtures of the fine particle silica and the basic zinc carbonate. Diagrams from a to e correspond to the grinding times for 0, 24, 90, 300, and 600 hr, respectively.

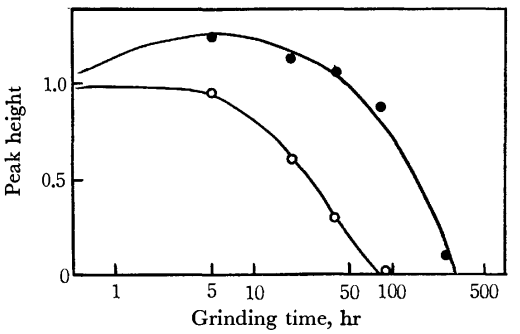

Fig. 2. Variation of diffraction peaks with the grinding time. The peak heights are the relative value to a non-treated mixture of the fine particle silica and the basic zinc carbonate.
●: Peak at 35.9° (2θ)
○: Peak at 12.4° (2θ)

X-Ray Emission Spectra. The Si K-emission spectra of the fine particle silica and the zinc silicate are shown in Fig. 3. In these spectra, both the $K\alpha$ and the $K\beta$ bands are normalized in such a way that each maximum is made as taking a uint intensity. When compared with those for the fine particle silica, the $K\alpha$ band of the zinc silicate shifts toward the lower energy side, whearas the $K\beta$ band toward the higher energy side. Any differences among the K-emission spectra of Nipsil VN-3, Aerosil and, Carplex # 1120 were not observed in this experiment. A satellite band, $K\beta'$, at the lower energy side of the main $K\beta$ band also shifted, but its intensity was too weak to be studied. Although the $K\alpha$ band was also accompanied by some satellite bands, the resolving power of the instrument was not satisfactory and it was difficult to determine their pre-

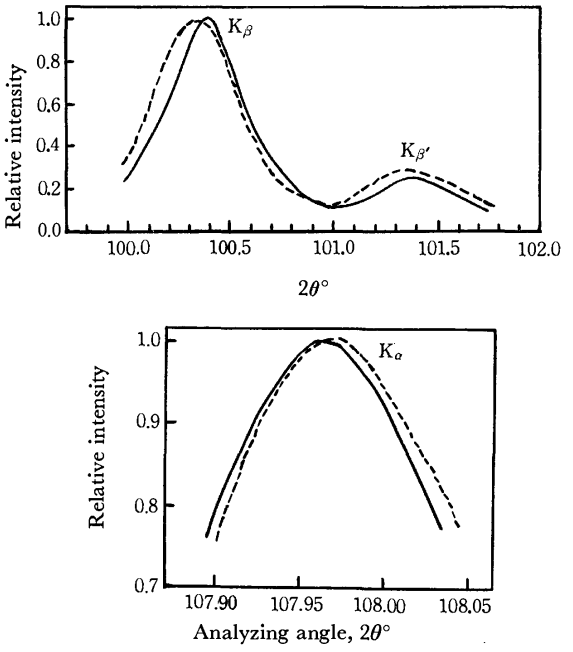

Fig. 3. Silicon K-emission spectra: Solid and dashed lines show spectra of fine particle silica and zinc silicate, respectively. The peak heights are normalized.

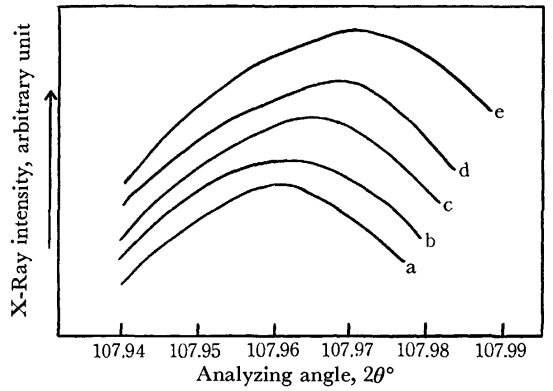

Fig. 4. Variation of Si$K\alpha$ bands of the ground mixtures of the fine particle silica and the basic zinc carbonate with the grinding treatment. Spectra from a to e correspond to the grinding times of 0, 46, 93, 160, and 610 hr, respectively.

cise band profiles and positions. Therefore, only the main $K\alpha$ and $K\beta$ bands were used for the present study.

The $K\alpha$ bands of the ground mixtures measured at the various stages of the grinding treatment are shown in Fig. 4 in which the peak maxima are illustrated. The shifts of the $K\alpha$ band of the ground mixture from that of the fine particle silica are expressed in electron volts and plotted against the grinding time as shown in

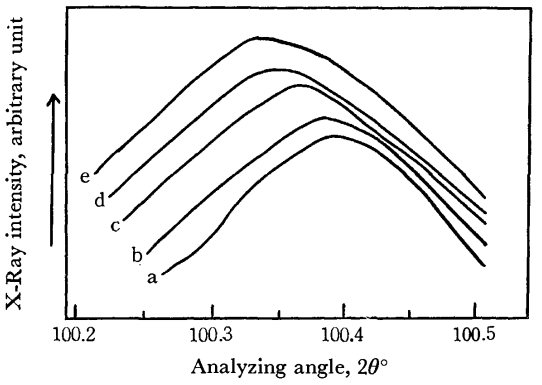

Fig. 6. Variation of Si$K\beta$ bands of the ground mixtures of the fine particle silica and the basic zinc carbonate with the grinding treatment. Spectra from a to e correspond to the grinding time of 0, 46, 93, 160, and 610 hr, respectively.

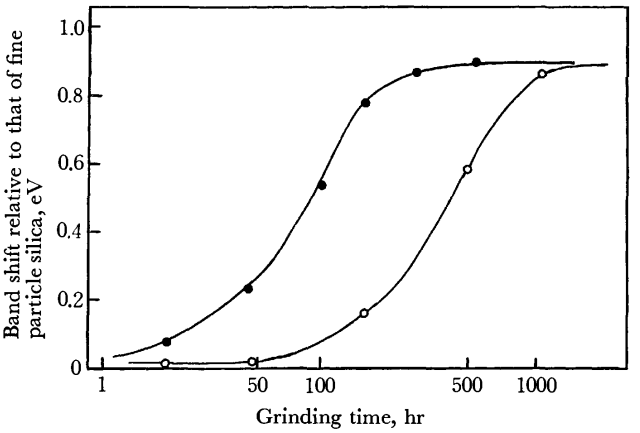

Fig. 7. Si$K\beta$ band shifts with the grinding treatment.
●: System of Nipsil VN-3 or Aerosil and basic zinc carbonate
○: System of Carplex #1120 and basic zinc carbonate

Fig. 5. The $K\alpha$ band shifts are not so large that each electron volt value plotted lacks accuracy. However, a distinct difference can be seen in the reactivities of Nipsil VN-3 or Aerosil and Carplex #1120. This fact would become more evident in the measurement of the Si$K\beta$ bands showing relatively large spectral shifts.

Figure 6 shows the Si$K\beta$ bands of the ground mixtures near the peak maxima measured at the various stages of the grinding treatment. A plot of the spectral shifts against the grinding time is also shown in Fig. 7 in which the $K\beta$ band shifts are increased about one order of magnitude compared with the $K\alpha$ band shifts. Figure 7 indicates that the grinding reaction of Nipsil VN-3 or Aerosil with the basic zinc carbonate proceeds for about 300 hr. Thereafter, the rates of this reaction become very small and finally not appreciable after about 500 hr. On the other hand, Carplex #1120 reacts quite late as the final state is obtained with more than 1,000 hr of the grinding treatment.

Infrared Spectra. Infrared spectrometry also provided useful information about the grinding reaction. This is demonstrated in Fig. 8. With increasing the grinding time, the stretching absorption band of Si–O

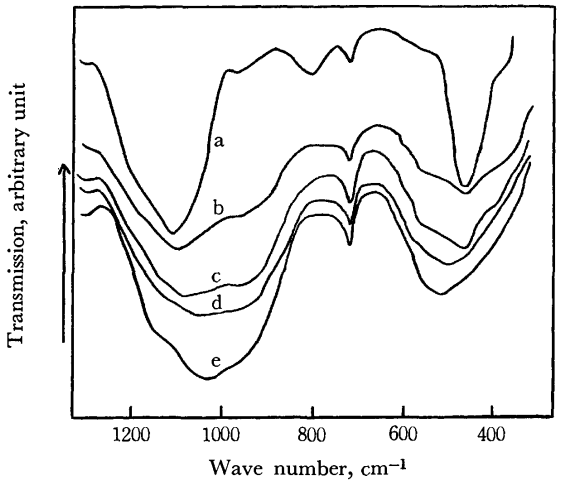

Fig. 8. Infrared spectra of the ground mixtures of the fine particle silica and the basic zinc carbonate. Spectra from a to e correspond to the grinding time of 0, 46, 93, 166, and 610 hr, respectively.

bond shifts toward the lower energy side and the bending one toward the opposite side. Although this figure represents the reaction system of Nipsil VN-3 and the basic zinc carbonate, the same was true for the case of the other samples of the fine particle silica.

Discussion

White and Gibbs found a correlation between the mean Si–O bond lengths of various silicate minerals and their Si$K\beta$ band shifts from the Si$K\beta$ band of quartz.[5] They used quartz as a standard sample for the determination of wavelength shifts, whereas fine particle silica was used for the same purpose in the present measurement. However no differences in wavelength of the Si$K\beta$ bands were observed between the fine particle silica and quartz in the present measurement, so that values of Si$K\beta$ band shifts in their report may be regarded as in the same scale as in the present study.

Thus the variation of the mean Si–O bond length can be correlated with the time of the grinding treatment as shown in Fig. 9, in which their data were adopted in such a way that the linear correlation coefficient should be 0.85.[5] The mean Si–O bond length is also correlated with the mean coordination number of oxygen as reported by Brown and Gibbs.[6] The increase in the oxygen coordination number corresponds to the less s-character in a bond as a result of the withdrawal of the electrons on oxygen when zinc atom comes to make a chemical bond with silica.

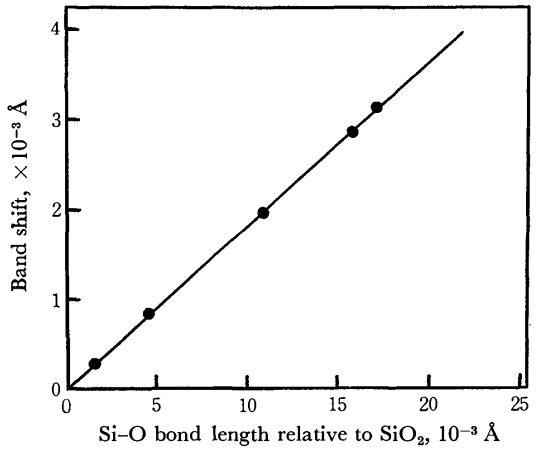

Fig. 9. Relation between Si$K\beta$ band shifts and Si–O bond lengths of the ground mixtures of the fine particle silica and the basic zinc carbonate. A correlation coefficient is 0.85 after White and Gibbs.[5]

The situation is also reflected in the infrared absorption spectra, because an increase in the oxygen coordination number causes a variation in O–Si–O bond angle. The bending absorption bands shift toward the higher energy side with increasing the grinding time in Fig. 8. If the zinc atoms are, in fact, chemically bound with the oxygen atoms in silica, the shifts in the infrared absorption bands may be compared with those in the Si$K\beta$ X-ray bands. Although the infrared absorption band in Fig. 8 is composed of more than two single bands, its absorption position in wave number was, for convenience, graphically determined as shown in Fig. 10. Figure 11 is a plot of the shifts in the bending absorption bands relative to the fine particle silica against those of the Si$K\beta$ bands. A linear relationship is evident between the two spectroscopic measurements. This suggests that these variations in the individual spectrum result from the same chemical effects as mentioned above.

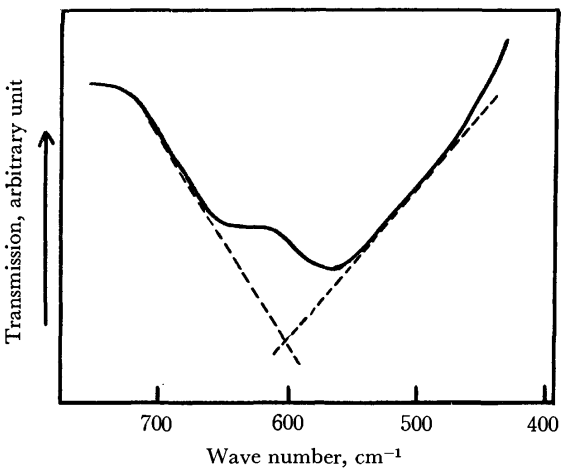

Fig. 10. Graphical method for the determination of infrared band position. Wave number at which two dashed lines intersect is adopted, for convenience, as a band position.

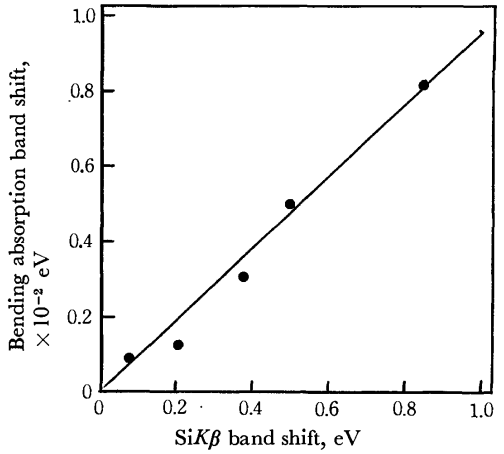

Fig. 11. Relation between X-ray Si$K\beta$ band shifts and infrared bending absorption band shifts relative to that of fine particle silica.

Cauchois[7] and Fischer[8] assumed the Si$K\beta$ bands of the oxides of magnesium, aluminum, and silicon to be due to the crossover transitions which originate from the anion or oxygen and terminate in the metal ion. Their assumption gives a relatively easy interpretation of the influence of zinc atoms on the Si–O bond. As the zinc atoms come to make chemical bonds with the oxygen atoms which are nearly tetrahedrally coordinated around the silicon atom, the Si–O bond will

become more ionic. This increase in ionic character corresponds to a decrease in the *s*-character of Si–O bond, which causes the Si$K\beta$ bands to shift toward the higher energy side. The interpretation of the $K\alpha$ band shifts are perhaps more complicated because the band shifts are so small that only a slight change in the 1*s* orbital of silicon influences the band shifts.

a) Relative to Nipsil VN-3 or Aerosil

Another estimation was given by Dodd and Glen[9] that the Si–O bond is stable in the structure of α-quartz, the Si$K\beta$ band of which appears in the lowest energy position of all the silicate structures. Thus the Si$K\beta$ band shift of a certain silicate toward the higher energy side from that of α-quartz is a measure of the degree of Si–O bond destabilization relative to the Si–O bond of α-quartz. This estimation is readily accepted as a measure of the grinding reaction process, because it is not difficult to consider that the ground products are in metastable higher energy states in the sense of chemical bonding. The destabilizations of the ground mixtures relative to the fine particle silica were thus calculated from the X-ray shifts in Table 2 together with those of the synthetic amorphous zinc silicate and the crystalline zinc silicate. This table indicates that the final state in the ground product may result in amorphous zinc silicate and further reaction does not occur by the more grinding treatment. This phenomenon discriminates the grinding reaction or, more generally, the mechanical treatment from the ordinary thermal reaction in which the entire rearrangement of each species take place and the final crystalline product is

Crystalline zinc silicate	0.0263	7.15

a) The precision of the measured values should be taken as better than two significant figures, although three are reported in this column.

obtained. This is summarized schematically in Fig. 12.

Further information is obtained with the changes of the Si$K\beta$ band width which are shown in Table 3. The half widths of the crystalline and amorphous zinc silicate are broader than that of the fine particle silica. However, the Si$K\beta$ band widths of the ground mixtures rapidly approach to that of the amorphous zinc silicate whose width is broader furthermore than that of the crystalline zinc silicate. It is notable that, even in the early stages of the grinding reaction, considerable band broadening occurs. On the other hand, considerable band shifts can not be seen in these stages as indicated in Fig. 5 and Fig. 7. Thus even in the early stages of the grinding treatment, chemical reaction may occur to a considerable extent, and with increasing the grinding time, the reaction more thoroughly. Hence the grinding reaction in the early stages of the treatment differs merely in the extent and not in the quality from that of the last stage of the treatment. The Si$K\alpha$ bands did not show so distinct a change in the band widths as seen in the $K\beta$ bands.

Roughly speaking, the changes in the X-ray diffraction diagram correspond to the progress in the grinding reaction described by means of Si*K*-emission spectral shifts in the cases of Nipsil VN-3 and Aerosil but not in the case of Carplex #1120. The surface acidity is critical to the difference of the reactivities of these three kinds of fine particle silica, as seen from Table 1.

Conclusion

The X-ray Si*K* spectra gave useful information about the grinding reaction in which the products are usually amorphous. The $K\beta$ band shifts changed depending on the grinding time which caused the corresponding decrease in the *s*-character in the Si–O bonds. The band shifts indicated that the final product in the reaction between the fine particle silica and the basic zinc carbonate was amorphous zinc silicate-like compound which was in a metastable higher energy state relative to the fine particle silica. The infrared spectra also provided useful information about this reaction but the X-ray spectroscopic method was superior to the former because the latter gave direct reflections of electronic structures.

Re-absorption Effect of Charge-Transfer Fluorescence by the Excited Electron Donor-Acceptor Complex

Hiroshi MASUHARA and Noboru MATAGA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received May 19, 1971)

It has been shown that excited electron donor-acceptor (EDA) complexes of *s*-tetracyanobenzene (TCNB) with benzene or toluene can be produced quite densely when excited with a giant pulse laser and that there arises a remarkable re-absorption of the charge-transfer (CT) fluorescence by the excited EDA complexes. We have investigated in detail the re-absorption effect by examining the dependence of the CT fluorescence spectra on the direction of observation, the decay function of the fluorescence, the effect of the concentration of solution as well as the effect of the exciting light intensity on it. The excited singlet-singlet (S_n←S_1) absorption spectra have been obtained by analyzing the re-absorption effect. Since the CT fluorescence spectra are broad and have no structure, the fluorescence can work as a good light source for the absorption spectral measurement.

The nsec flash photolysis has been made possible by using a giant pulse laser as an exciting light source. The absorption spectra of short-lived transient species such as excited singlet state of aromatic molecules produced by excitation with the laser in solution have been determined with some intense flash lamps of short duration. Novak and Windsor used laser-induced sparks in O_2 and Xe gases as spectroflashes and an image-converter camera as a detection apparatus.[1] Porter and Topp used some scintillators as a spectroflash.[2] On the other hand, there are some difficulties in the kinetic analysis of processes in nsec time region. As an example, strong fluorescence spectra caused by the laser excitation often overlap the absorption bands of excited singlet states and the signal to noise ratio in the photoelectric measurement is rather large. Such difficulties have been removed to some extent by applying a Xe flash lamp[2] or a pulsed Xe lamp as a monitoring light source.[3,4]

Recently, we have found a characteristic hollow in time-resolved fluorescence spectra of EDA complexes of TCNB, which is due to the re-absorption of CT fluorescence by excited complex. The S_n←S_1 absorption spectra of TCNB-benzene and TCNB-toluene complexes have been obtained by analyzing the re-absorption.[5] Since the CT fluorescence spectra of TCNB complexes are rather broad and have no structure, the fluorescence can work as a good light source for the absorption spectral measurement. In the present paper, results of investigations concerning the dependence of the CT fluorescence on the direction of observation, fluorescence decay function, effect of the solute concentration as well as the effect of exciting light intensity on the re-absorption of CT fluorescence, will be reported and a theoretical estimation of the re-absorption effect will be given.

Experimental

We used a Q-switched ruby laser (Japan Electron Optics, JLR-02A) with an output of *ca.* 1.5 J. An exciting light pulse of 347 nm was produced through the ADP frequency doubler with conversion efficiency of *ca.* 8%. The output of a 347 nm pulse was measured with a ballistic thermopile TRG model 100 (HADRON). Fluorescence spectra and fluorescence decay curves were observed with a Nalumi R21 spectrograph and an RCA 1P28 photomultiplier. A Tektronix 585 A synchroscope was triggered by a signal from a Hewlett-Packard 5082-4220 photodiode which receives a scattered laser pulse. Fluorescence was observed from the side of the cuvett opposite the laser excitation (rear observation) as well as from a direction perpendicular to the excitation (side observation). The ordinary fluorescence measurement was made with an Aminco-Bowman spectrophotofluorometer. All the chemicals were the same as used before.[5] Solutions were degassed carefully by the usual method.

Results and Discussion

Since the population of the excited EDA complex in the case of laser excitation is much larger than that in ordinary spectrophotometric measurement, there arises strong re-absorption of the CT fluorescence by the excited complex. The following features of the CT fluorescence were found in the case of TCNB-benzene and TCNB-toluene complexes.[5,6] (1) A characteristic hollow appears at about 460 nm in the time-resolved fluorescence spectra at an earlier stage of decay (0—50 nsec). It can be obtained by plotting the fluorescence intensities at various stages of decay. (2) At about 460 nm, the decay curve of the fluorescence is not exponential but has a peculiar shape, while the decay curves are nearly exponential at other wavelengths. Time-resolved fluorescence spectra and typical decay curves are shown in Figs. 1 and 2. They can be ascribed to re-absorption of CT fluorescence by the high density excited state produced by the laser excitation. We have carried out a quantitative estimation of the re-absorption effect as follows.[7]

Spatial Distribution of Excited EDA Complexes. The

7) In relation to the S_n←S_1 absorption spectra of TCNB complexes, only the final Eqs. (5), (6), (9), (10) were given without any detailed account in Ref. 5.

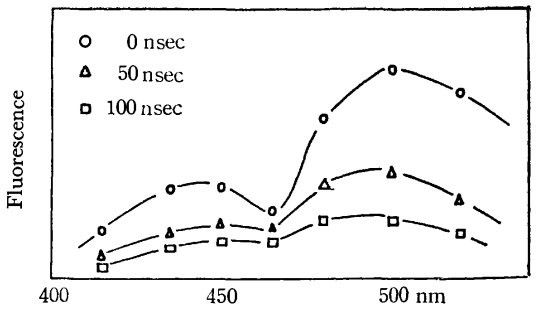

Fig. 1. The time-resolved fluorescence spectra of TCNB-benzene complex in the case of rear observation. $\varepsilon_{g\lambda}c_g=0.8$. In the present paper (Figs. 1, 5, and 7), 0 nsec is used to indicate the time when the concentration of excited complex is the maximum (taken from Ref. 6).

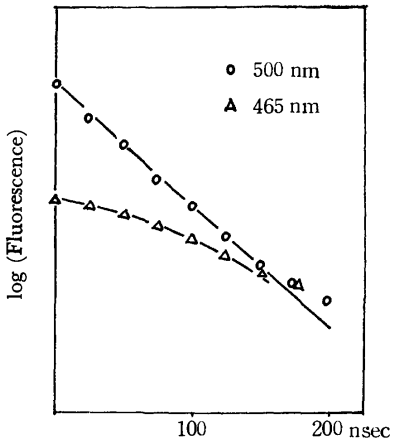

Fig. 2. Observed (○, △) and calculated (——) fluorescence decay curves of TCNB-benzene complex in the case of rear observation. $\varepsilon_{g\lambda}c_g=0.8$ (taken from Ref. 6).

distribution of fluorescent EDA complexes is expected to be proportional to $\Phi_{\lambda 0}10^{-\varepsilon_{g\lambda}c_g x}$, where $\Phi_{\lambda 0}$ is the intensity of 347 nm pulse which is exciting exclusively the CT band of TCNB complexes; x is the distance from the front face of the cell in cm; $\varepsilon_{g\lambda}$ and c_g are the molar extinction coefficient at 347 nm and the concentration of EDA complex in the ground state, respectively. In the present work $\varepsilon_{g\lambda}c_g$ is *ca.* 1.0. However, a deviation of distribution from $\Phi_{\lambda 0}10^{-\varepsilon_g c_{g\lambda} x}$ can be expected, since the high intensity excitation often leads to saturation of absorption in the front part of the sample. We have examined this question by photographing the fluorescing sample cell from a direction perpendicular to the excitation.[8] The obtained film blackening is given in Fig. 3, which shows an approximate linear relation between log I(flourescence intensity) and x. Consequently, it is appropriate to assume that the distribution of the excited EDA complex is proportional to $\Phi_{\lambda 0}10^{-\varepsilon_{g\lambda}c_g x}$.

The distribution of the re-absorbing EDA complex is of course the same as that of the fluorescent EDA complex. The concentration of the excited complex in M, c_e, is given by

8) The authors wish to express their thanks to Prof. Shunji Kato of Osaka University for his helpful discussion on this problem.

$$c_e(x) = s\Phi_{\lambda 0}10^{-\varepsilon_{g\lambda}c_g x} \quad (1)$$

where s is a proportionality constant.

Dependence of Fluorescence on the Direction of Observation. In the case of rear observation, since differential fluorescence intensity I_x emitted from the thin layer between x and $x+dx$ can be re-absorbed by the thin layer between y and $y+dy$, the following equation can be obtained.

$$dI_x = -\mu(y)I_x dy \quad (2)$$

where y is the distance from x to the back of the cell in cm and $\mu(y)$ is the absorption coefficient at y. A schematic model for the present analysis is shown in

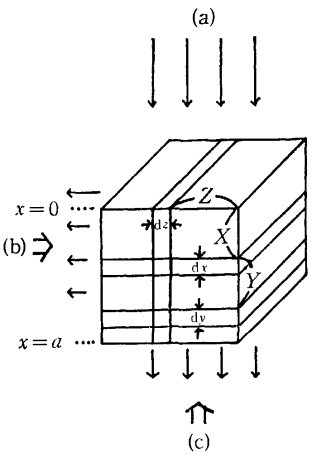

Fig. 4. A schematic model for analysis of the re-absorption of CT fluorescence by excited complex itself.
(a) excitation (b) side observation (c) rear observation.

Fig. 4. Although μ is independent of y in the usual treatment, it is a function of y in the present case and can be written as

$$\mu(y) = \varepsilon_{e\lambda'}c_e(x+y) = \varepsilon_{e\lambda'}s\Phi_{\lambda 0}10^{-\varepsilon_{g\lambda}c_g x}10^{-\varepsilon_{g\lambda}c_g y} \quad (3)$$

where $\varepsilon_{e\lambda'}$ is the molar extinction coefficient of the $S_n \leftarrow S_1$ band at λ' (the wavelength at which the fluorescence is observed). Putting Eq. (3) into Eq. (2) and integrating Eq. (2) with respect to y, the differential fluorescence intensity I_x observed at the back of the cell is given as follows.

$$I_x(y=a-x) =$$
$$10^{-\varepsilon_{g\lambda}c_g x}10^{\log q}10^{\varepsilon_{e\lambda'}s\Phi_{\lambda 0}(10^{-\varepsilon_{g\lambda}c_g a}-10^{-\varepsilon_{g\lambda}c_g x})/\varepsilon_{g\lambda}c_g} \quad (4)$$
$$Q = \rho\Omega\Phi_{\lambda 0}F_\lambda(\lambda')\varepsilon_{g\lambda}c_g/4\pi n^2$$

where ρ, Ω, $F_\lambda(\lambda')$, and n represent reflective index on the surface of the cell, solid angle in which the fluorescence is observed, fluorescence quantum yield observed in the wavelength range $\lambda'\sim\lambda'+d\lambda'$, and refractive index of solvent, respectively. Since we are observing the sum of the differential fluorescence intensities, I_x must be integrated with respect to x from 0 to a. Consequently the fluorescence intensity at λ' in the side opposite the excitation is given as follows.

$$d\Phi'(\lambda') = \int_0^a I_x dx d\lambda'$$
$$= \rho\Omega F_\lambda(\lambda')\varepsilon_{g\lambda}c_g(1-10^{\varepsilon_{e\lambda'}s\Phi_{\lambda 0}(10^{-\varepsilon_{g\lambda}c_g a}-1)/\varepsilon_{g\lambda}c_g})$$
$$\times d\lambda'/4\pi n^2\varepsilon_{e\lambda'}s \quad (5)$$

For notation in these equations, we refer to Förster's treatment.[9] When the excitation intensity $\Phi_{\lambda 0}$ is weak, Eq. (5) is reduced to the usual Eq. (6).[9]

$$d\Phi'(\lambda') = \rho\Omega\Phi_{\lambda 0}F_\lambda(\lambda')(1-10^{-\varepsilon_{g\lambda}c_g a})d\lambda'/4\pi n^2 \quad (6)$$

In the present case, the excitation intensity $\Phi_{\lambda 0}$ is determined to be *ca.* 1.7×10^{17} photons,[10] $\varepsilon_{g\lambda}c_g$ is adjusted to be 1.0, a is 1 cm, and s is calculated to be 2×10^{-21}, assuming the re-absorption extinction coefficient of $S_n\leftarrow S_1$ band at 462 nm $\varepsilon_{e\lambda'}$ to be 10^4. The re-absorption of several tens % of the fluorescence at 460 nm is expected from the estimation by Eqs. (5) and (6) with these values. It is in good agreement with our result.

In the case of side observation, the differential fluorescence intensity I_x can be re-absorbed in the layer between z and $z+dz$. Thus, we have

$$dI_x = -\varepsilon_{e\lambda'}c_e(x)I_x dz \quad (7)$$

The equation is in the same form as the usual Lambert-Beer equation. The fluorescence intensity in the case of side observation is given as follows.

$$d\Phi'(\lambda', x) =$$
$$\rho\Omega F_\lambda(\lambda')\varepsilon_{g\lambda}c_g(1-10^{-a\varepsilon_{e\lambda'}s\Phi_{\lambda 0}10^{-\varepsilon_{g\lambda}c_g x}})d\lambda'/4\pi n^2\varepsilon_{e\lambda'}s \quad (8)$$

where one should note the x-dependence of the fluorescence intensity. Numerical estimation by means of Eq. (8) indicates that at $x\sim0$ cm a re-absorption of several tens % of fluorescence arises as in the case of rear observation, while no appreciable re-absorption effect will be observed at $x\sim1.0$ cm. The results shown in Fig. 5 are in good agreement with this numerical estimation.

9) Th. Förster, "Fluoreszenz Organischer Verbindungen," Vandenhaeck und Ruprecht, Götingen, 1951. p. 35.

10) In Ref. 5 effective excitation intensity $\Phi_{\lambda 0}$ was assumed to be 10^{16} photons per pulse. However, no change of the results in Ref. 5 is required since there was a numerical mistake in calculating s, which cancelled out an error in value. There arises some ambiguity in estimating effective concentration of the excited EDA complex, which is required for calculating s, since the distribution of the excited complex is not uniform. In the present work s was obtained assuming the concentration of the excited complex as $(1.7\times10^{17}/\pi r^2\times a\times6.03\times10^{23})\times10^{-x}$M, where r is an effective diameter of a 347 nm pulse.

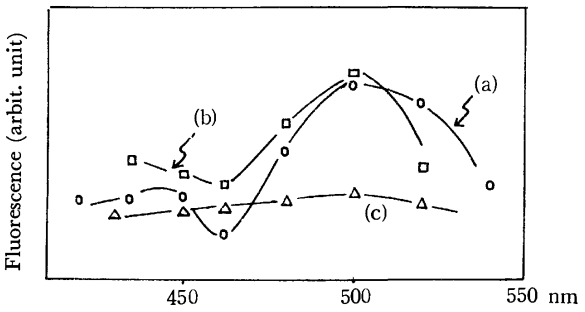

Fig. 5. The fluorescence spectra of TCNB-benzene system (t$\sim$0 nsec) obtained in the case of side observation. $\varepsilon_{g\lambda}c_g=0.8$.
(a) $x\sim0$ cm (b) $x\sim0.5$ cm (c) $x\sim1.0$ cm

Fluorescence Decay Function.[11] Since the coefficients of re-absorption as well as fluorescence follow the exponential decay, the following can be easily derived in the case of rear observation:

$$d\Phi'(\lambda', t) =$$
$$\rho\Omega F_{\lambda 0}(\lambda')\varepsilon_{g\lambda}c_g(1-10^{\varepsilon_{e\lambda'}s_0\Phi_{\lambda 0}e^{-t/\tau}(10^{-\varepsilon_{g\lambda}c_g a}-1)/\varepsilon_{g\lambda}c_g})$$
$$\times d\lambda'/4\pi n^2\varepsilon_{e\lambda'}s_0 \quad (9)$$

where τ is fluorescence lifetime, and $F_{\lambda 0}$ and s_0 satisfy the following equations, respectively.

$$F_\lambda = F_{\lambda 0}e^{-t/\tau}$$
$$s = s_0 e^{-t/\tau} \quad (10)$$

The simulated curves obtained by means of Eq. (9), using the value of lifetime obtained from the fluorescence decay at 500 nm, are given in Fig. 2. One can see a good agreement between experimental and simulated curves. In the case of side observation at $x\sim0$ cm the same nonexponential decay of the fluorescence at λ' as indicated by Eq. (9) is expected, while little deviation of fluorescence decay from the exponential function will occur at $x\sim1.0$ cm. As shown in Fig. 6, the simulated curves can reproduce the experimental ones satisfactorily.

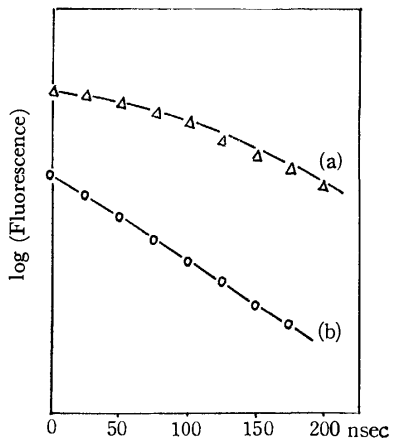

Fig. 6. Observed (○, △) and calculated (——) fluorescence decay curves of TCNB-benzene system at 465 nm in the case of side observation. $\varepsilon_{g\lambda}c_g=0.8$.
(a) $x\sim0$ cm (b) $x\sim1.0$ cm

11) The effect of absorption by excited singlet state as well as triplet state on fluorescence decay function was mentioned in Ref. 2.

Effect of the Concentration of Solution on Re-absorption. Since the CT fluorescence is re-absorbed by the excited EDA complex the characteristic hollow in the fluorescence spectra as well as the nonexponential decay of fluorescence might not be observable under low concentration of the excited complex. The excitation of a low concentration solution of the EDA complex with a laser pulse of moderate intensity as well as low intensity excitation of a solution of mederate concentration will produce excited EDA complexes of rather low concentration. A comparison of the time-resolved fluorescence spectra between solutions of moderate and low concentrations is given in Fig. 7, where the excitation light intensity was moderate and side observation was performed. A characteristic hollow is observed only in the case of rather high concentration solution.

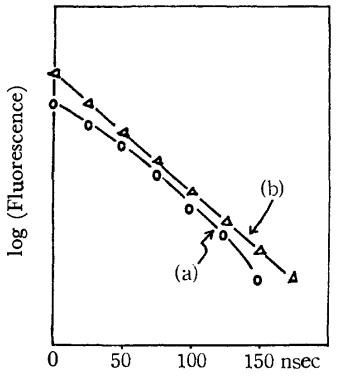

Fig. 8. Effect of the excitation light intensity on the re-absorption. TCNB-benzene system, $\varepsilon_{g\lambda}c_g=0.8$.
Intensity; (a) normal laser excitation (b) 0.3% of the normal value.

Effect of Exciting Light Intensity on Re-absorption. The excitation intensity was varied by neutral filters composed of wire gauzes. The dependence of decay function at 462 nm on the exciting light intensity is given in Fig. 8. When the exciting light intensity was reduced to 0.3% of the normal value (1.7×10^{17} photons/pulse), the observed fluorescence decay was almost exponential.

The $S_n\leftarrow S_1$ Absorption Spectra. From the above results, it is confirmed that a characteristic hollow in the fluorescence spectra of earlier stage of decay and the nonexponential decay at about 460 nm are due to the re-absorption of the fluorescence by the excited singlet state of the EDA complex. Consequently, we can obtain the $S_n\leftarrow S_1$ absorption spectra by comparing the fluorescence spectra observed by an Aminco-Bowman spectrophotofluorometer and those observed by laser excitation. The result in the case of TCNB-benzene complex is given in Fig. 9. For the absorption spectral measurement of the excited complex, the fluorescent light can work as a good light source, the duration of which is the same as the lifetime of the objective transient. Thus, it is concluded that this method is useful for obtaining $S_n\leftarrow S_1$ absorption spectra.

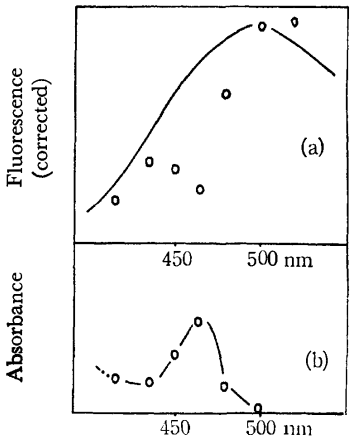

Fig. 9. Fluorescence spectra and $S_n\leftarrow S_1$ absorption spectra of TCNB-benzene complex. $\varepsilon_{g\lambda}c_g=0.8$ (taken from Ref. 6).
(a) Fluorescence spectra measured by laser excitation (○) and by Aminco-Bowman spectrophotofluorometer (—).
(b) $S_n\leftarrow S_1$ absorption spectra.

The conditions necessary for the absorption spectral measurement by this method might be as follows; (1) The optical density at λ can be adjusted to be *ca.* 1.0. (2) The fluorescence and the $S_n\leftarrow S_1$ absorption spectra overlap each other to some extent. (3) The fluorescence lifetime is in the same order as the duration of an exciting pulse, although in order to identify the lifetime of the re-absorbing species with that of the fluorescent one the lifetime of fluorescence must be longer than the duration of the 347 nm pulse. We have a few critical experimental results concerning the above conditions. We have studied the $S_n\leftarrow S_1$ spectra of TCNB-mesitylene complex by the present re-absorption method. However, no appreciable re-absorption was observed, but we were able to measure the $S_n\leftarrow S_1$ spectra of this complex by the nsec flash photolysis method.[6,12] Since the fluorescence lifetime is 43 nsec,[13] which satisfies the condition (3), no observation by the present re-absorption method can be ascribed to the poor overlapping between fluroescence and the $S_n\leftarrow S_1$ absorption spectra. Concerning condition (3), the fluorescence lifetime of TCNB-benzene complex was adjusted by saturating the solution with air. The re-absorption of CT fluorescence was observed in the case

12) H. Masuhara and N. Mataga, The Symposium on Molecular Structures, Kyoto, 1971.
13) T. Kobayashi, K. Yoshihara, and S. Nagakura, The Symposium on EDA Complexes, Osaka, 1970, Preprint.

of this complex, where the shape of the fluorescence light pulse was almost the same as that of the exciting pulse and the apparent lifetime was several nsec. Thus, condition (3) is valid.[14]

Related Problems. When the re-absorption of CT fluorescence by the excited complex itself occurs, higher excited states of the complex will be produced. The rate equation for these processes can be written as

$$\frac{dE}{dt} = -aE - fE + \beta cE^* \tag{11}$$

$$\frac{dE^*}{dt} = \alpha fE - cE^* \tag{12}$$

where E and E^* are concentrations of fluorescent and higher excited states, a and c represent the rate constants of the unimolecular decay of E and E^*, respectively, and f is the rate constant of the re-absorption of CT fluorescence. The notations α and β are the yields of corresponding processes. Since f is proportincal to E, these equations are similar to those used in analyzing the lifetime shortening of exciplexes through bimolecular interaction.[15] In this paper the higher excited state is assumed to return to the fluorescent state through radiationless degradation. Problems on the higher excited states of TCNB complexes as well as those on the interactions of excited complexes through re-absorption of CT fluorescence by the excited complex will be solved with progress of laser experiments.

The authors thank Mr. N. Tsujino for his assistance in the experimental work.

14) The $S_n \leftarrow S_1$ spectra of 1,12-benzperylene-*N*,*N*-dimethylaniline heteroexcimer have been observed in this laboratory. This heteroexcimer is an another good example which satisfies conditions (1)—(3).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 47—51(1972)

Acidic Property and Catalytic Activity of TiO_2·ZnO

Kozo Tanabe, Chijiko Ishiya, Isao Matsuzaki, Ichiro Ichikawa, and Hideshi Hattori
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo
(Received May 21, 1971)

A new type of mixed metal oxide TiO_2·ZnO was prepared by either heterogeneous or homogeneous co-precipitation and the acidic property was measured by *n*-butylamine titration and by observation of infrared spectra of adsorbed pyridine. It was found that TiO_2·ZnO containing about 7 or 57% of ZnO shows a very large acid amount of 0.5—0.9 mmol/g and a fairly high acid strength of $H_0 \leqq -3$, the acid sites being both Brönsted and Lewis type and the acid sites of high strength created by heterogeneous precipitation. The catalytic activity and selectivity of TiO_2·ZnO were found very high for the hydration reaction of ethylene. The catalyst was active also for the alkylation of phenol by methanol and gave only monoalkylated products.

Metal oxides such as SiO_2·Al_2O_3, SiO_2·MgO, SiO_2·ZrO_2, Al_2O_3·B_2O_3, and Al_2O_3·MgO are known to be solid acid catalysts, each of which contains either SiO_2 or Al_2O_3, both essential constituents of natural clay minerals. The oxides have been extensively used as useful catalysts for various acid-catalyzed reactions in the field of petroleum chemistry. However, not much work has been done on other combinations of oxides, which might show surface acidity and catalytic acitvity, and we have initiated a systematic study on mixed metal oxides which do not contain any clay mineral component. The present paper reports the acidic property and catalytic activity of TiO_2·ZnO, a new combination of metal oxides. Each of TiO_2 and ZnO was previously reported to have only weak acidic property,[1,2] but the combination shows large acid amount and high acid strength as well as high catalytic activity.

Experimental

Preparation of Catalysts. Titanium oxide, zinc oxide, and TiO_2·ZnO of various compositons were prepared respectively by heating titanic acid, zinc hydroxide and the mixtures in air at 200—500° for 3 hr. Titanic acid, zinc oxide and their mixtures were prepared as follows.

1) Titanic Acid; 62.6 m*l* of $TiCl_4$ was dissolved into 120 m*l* of distilled water cooled by ice. To this was added 240 m*l* of distilled water in which 3 m*l* of concd. HCl and 156 g of $(NH_4)_2SO_4$ had been dissolved. The solution was boiled on a water bath for 1 hr and 110 m*l* of 28% ammonia water was added to form the precipitate of titanic acid H_4TiO_4, pH of the solution being 6.67. After the solution had been heated further for 1 hr, the precipitate was filtered off and washed thoroughly with distilled water until no anions of chloride and sulfate were detected in the washing. The precipitate was dried at 90° for 1—2 days.

2) Zinc Hydroxide: A precipitate was formed by adding 56 m*l* of 28% ammonia water into 100 m*l* of water containing 46.9 g of $ZnCl_2$, the final pH of the solution being found to be 6.27. The precipitate was washed and dried as in 1).

Table 1. Conditions for preparation of co-precipitated mixtures 2 and 3

	Co-precipitated mixture 2	Co-precipitated mixture 3
Solution I	137 g $ZnCl_2$ dissolved in 100 m*l* H_2O	261 g $ZnCl_2$ dissolved in 100 m*l* H_2O
Solution II	4 m*l* conc. HCl+210 g $(NH_4)_2SO_4$ in 322 m*l* H_2O	0.4 m*l* conc. HCl+21.0 g $(NH_4)_2SO_4$ in 32 m*l* H_2O
Solution III	84 m*l* $TiCl_4$ in 161 m*l* cooled H_2O	8.4 m*l* $TiCl_4$ in 16.1 m*l* cooled H_2O
Aqueous NH_3	198 m*l*	270 m*l*
Final pH	6.02	7.04

3) Co-precipitated Mixtures 1,2,3,4, and 5 of Titanic Acids and Zinc Hydroxides: Co-precipitated mixture 1 was prepared as follows. 14.0 g of $ZnCl_2$ was dissolved in 30 m*l* of water. 398 g of $(NH_4)_2SO_4$ and 7.6 m*l* of concd. HCl were dissolved in 600 m*l* of water. These were added to 160 m*l* of a solution prepared by dissolving $TiCl_4$ in 306 m*l* of water cooled by ice. The solution was heated on a water bath for 1 hr and 337 m*l* of 28% ammonia water was added to form co-precipitates of the mixture, the final pH of the solution being 7.08. After the solution was heated further for 1 hr, the precipitate was filtered off and washed thoroughly with distilled water until no anions of chloride and sulfate were detected in the washing. It was then dried at 90° for 1—2 days. Weight% of ZnO in the calcined mixture was calculated to be 6.7.

Co-precipitated mixtures 2 and 3 were prepared by adding 28% ammonia water to mixtures of solutions I, II, and III heated on a water bath for 1 hr (see Table 1), and by treating the co-precipitated mixture in a similar way to that for 1. Weight % of ZnO in 2 and 3 was 57.4 and 96.2, respectively.

Co-precipitated mixture 4 was prepared as follows. A cooled solution prepared by dissolving 10 m*l* concd. HCl and 150 g of $(NH_4)_2SO_4$ in 300 m*l* H_2O was added to a cooled mixture of two solutions, one 15.07 g $ZnCl_2$ in 50 m*l* H_2O and the other 69 m*l* $TiCl_4$ in 132 m*l* H_2O. After stirring 150 m*l* of ammonia was added and the solution was then treated in a similar way to that for 1. The final pH of the solution was 7.3. Weight % of ZnO was 15.2.

In the preparation of co-precipitated mixtures 1—3, two thirds of the added ammonia was poured at once and the remaining portion dropwise until the pH of the solution became approximately 7. For 4, all the ammonia was added gradually. The concentration of ammonium hydroxide ion differs locally during the formation of precipitates, *i.e.*, precipitates are formed in a heterogeneous concentration of hydroxide ion. Co-precipitated mixture 5 was prepared by homogeneous precipitation using urea instead of ammonia.[3] By this method, precipitates are formed from homogeneous solution of hydroxide ion, since urea decomposes to give ammonium hydroxide at elevated temperatures according to the formulas.

$$(NH_2)_2CO + H_2O \rightleftharpoons 2NH_3 + CO_2$$
$$NH_3 + H_2O \rightleftharpoons NH_4OH$$

Two solutions, one prepared by dissolving 26.9 m*l* $TiCl_4$ in 51 m*l* H_2O, and the other 5.3 g $ZnCl_2$ in 25 m*l* H_2O, were put into a 5 *l* beaker and the solution was diluted with water to make the volume 5 *l*. 97.2 g of urea was then added and the solution was stirred, the pH being 2. When the solution was heated at 95—98°C for 10—20 min, a fine colloidal and elastic precipitate was formed gradually. The solution was heated further for 2—3 hr until the pH of the solution became approximately 7. The precipitate was filtered off, washed with water until no anions of chloride and sulfate were detected in the washing and then dried at 120—150°C for 1—2 days. The weight % of ZnO was 13.9. All reagents used were of guaranteed grade from Wako Pure Chemical Co.

X-Ray Diffraction. The powder pattern of each specimen was obtained with an X-ray diffractometer ADG-301 DIFF PET, Toshiba electric Co. with filtered Cu$K\alpha$ radiation. The specimen was scanned between 10 and 65° (2θ).

Measurement of Surface Area and Acidic Property. Surface areas of TiO_2, ZnO, and No. 1 and 3 samples of TiO_2·ZnO which were calcined at 200—500° were determined by applying the BET method to the adsorption isotherm of nitrogen at −196°.

The acid amounts and strengths of catalysts were measured by titrating the 100—200 mesh powder suspended in benzene with 0.1N *n*-butylamine benzene solution, using neutral red ($pK_a=6.8$), methyl red (4.8), 4-phenylazo-1-naphthylamine (4.0), *p*-dimethylaminoazobenzene (3.3), benzeneazodiphenylamine (1.5), dicinnamalacetone (−3.0) or benzalacetophenone (−5.6) as indicators.

The Brönsted and Lewis acidity was determined by observing the infrared spectra of pyridine adsorbed on catalyst surface. The catalyst was heat-treated in a glass tube at various temperatures for 3 hr in air and the glass tube was sealed off. Immediately after the tube had been opened, it was connected to a vacuum apparatus and evacuated to 10^{-5} mmHg for 30 min at room temperature. Pyridine (about 2 mmHg) was then introduced and adsorbed for 10 min. After removing the excess of pyridine by evacuating at 100°C for 30 min, 3 mg of the sample was mixed with 200 mg of KBr powder and pressed into tablets of 12 mm diameter using a pressure of approximately 40000 psi. The spectrum in the 1400—1600 cm^{-1} region was measured using a Hitachi EPI-2 infrared spectrophotometer.

Measurement of Catalytic Activity. Hydration of ethylene was carried out by circulating a mixture of ethylene and water vapor (molar ratio:20) through 2 g of TiO_2·ZnO catalyst at 200°C. The ethanol formed was analyzed with a gas chromatograph using a column of silicon DC 550 on celite.

Alkylation of phenol by methanol was carried out by means of the usual flow method at 400°C. The products were analyzed by a gas chromatograph using a column of polyethylene glycol on celite.

Results and Discussion

Acidic Properties and Structures. Acid amounts at various acid strengths of TiO_2, ZnO, and samples 1—3 of TiO_2·ZnO calcined at various temperatures are given in Tables 2 and 3. Titanium oxides calcined at 400—500°C and zinc oxide at 400°C showed an acid strength of $H_0 \leqq +1.5$, which was never observed in their commercial products calcined at any temperature.[1,2] The effects of ZnO content on the acidities of TiO_2·ZnO calcined at 300 and 400°C are shown in Figs. 1 and

a) End point of titration was not clear. Anthraquinone of $pK_a = -8.2$ did not show its acidic color on the surface.

we see that the acid amounts at various acid strengths become large when TiO_2·ZnO contains about 7 or 57% of ZnO. The acidities of the mixed oxides containing about 96% of ZnO are small when they are calcined at 300°C, but their acid amounts at $H_0 \leqq 3.3$ and 1.5 increase greatly when calcined at 400°C. In both cases of Figs. 1 and 2, fairly strong acid sites of $H_0 \leqq -3.0$ appear only when about 7 or 57% of ZnO is contained in the catalyst. This fact and a comparison of the specific surface areas of TiO_2·ZnO containing

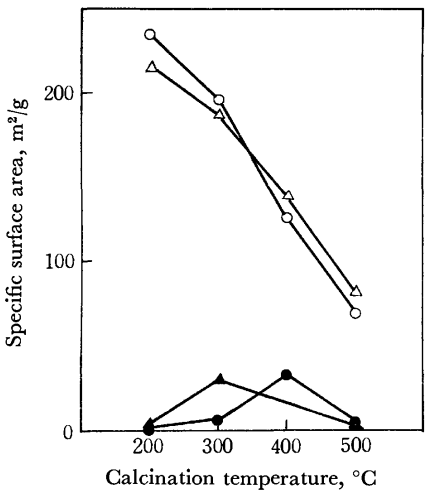

Fig. 3. Change in surface area of TiO_2 (-△-), ZnO (-▲-) sample 1 (-○-), and sample 3 (-●-) on calcination temperature.

7% of ZnO with those of TiO_2 alone (Fig. 3) indicate that the observed large amount and high strength of acid sites of TiO_2·ZnO are not due to the increase of specific surface area. Since the actual amount of surface acid in a given H_0 range is given by the difference between acid amounts at pK_a's of the two indicators bracketing that H_0 range, it may be said that the characteristic of acidity distribution of TiO_2·ZnO containing about 7 or 57% of ZnO calcined at 200—500°C is a fairly large acid amount in the range of acid strength, $H_0 \leqq -3.0$ (in some cases, $H_0 \leqq -5.6$), and of TiO_2·ZnO containing about 96% of ZnO calcined at above 400°C is a very large acid amount in the range of acid strength, $-3.0 < H_0 \leqq 1.5$ (Figs. 1—2 and Table 3).

The effects of calcination temperature on the acidities are given in Tables 2 and 3. The maximum acid amount of sample 1 was observed when calcined at 300°C and that of 3 at 400°C. The acidity change in 2 is shown in Fig. 4. It should be noted that methyl red behaves anomalously on the surface of TiO_2·ZnO (57% ZnO); the acid amounts measured by using methyl red of $pK_a = 4.8$ were found in all cases to be

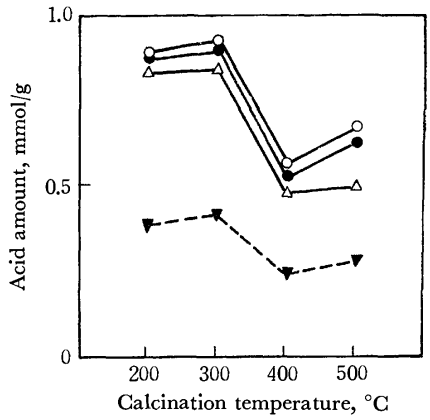

Fig. 4. Dependence of acid amount of sample 2 on temperature.
(-○-): $H_o \leqq 3.3$, (-●-): $H_o \leqq 1.5$, (-△-): $H_o \leqq -3.0$, (-▼--): $H_o \leqq 4.8$

lower than those measured by indicators having lower values of pK_a, as is shown by a dotted line in Fig. 4.

The acidity of 4 containing 15% of ZnO prepared by a slightly modified method is compared with that of 5 containing the same amount of ZnO prepared by using urea where acid amount was plotted against acid strength (Fig. 5). The acid strength of 4 is higher than that of 5, the latter having no acid sites of $H_0 \leqq -3.0$. However, the acid amount in the range of $-3 < H_0 \leqq 6.8$ is found much larger in 5 than in 4, about 0.6 mmol/g and 0.02 mmol/g, respectively. Thus, it might be said that the heterogeneous precipitation method using aqueous ammonia creates strong acid and the homogeneous method using urea relatively weak acid sites.

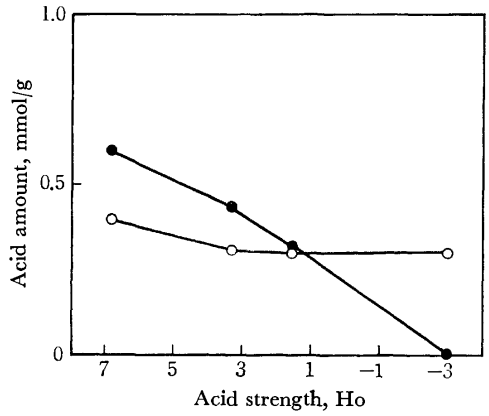

Fig. 5. Comparison of acidic property of TiO_2·ZnO prepared by heterogeneous precipitation method sample 4 (-○-) with that by homogeneous precipitation method sample 5 (-●-).

The infrared spectra of pyridine adsorbed on TiO_2·ZnO and samples 1 and 3 of TiO_2·ZnO calcined at 200—500°C are shown in Figs. 6 and 7. Since it is known that the band of coordinately bonded pyridine appears at 1445—1460 cm^{-1} on the surface of various solid acids, and that of pyridinium ion at around 1530—1540 cm,[-1 4-8] the band near 1540 cm^{-1} in Fig. 6

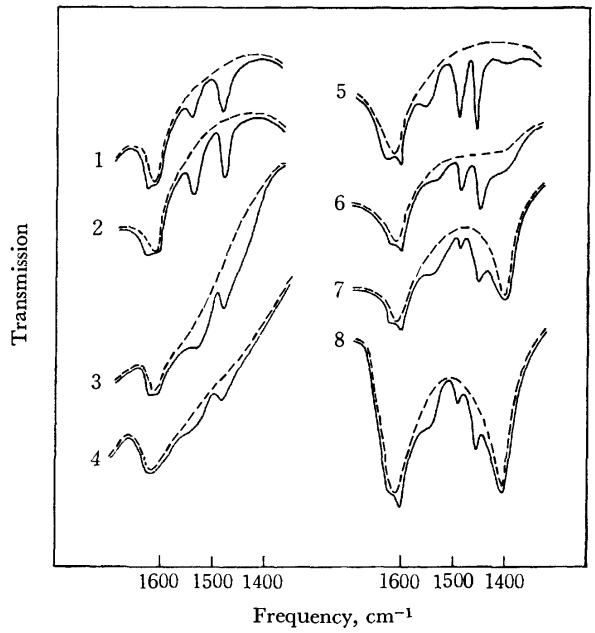

Fig. 6. Infrared spectra of pyridine adsorbed on TiO_2 (1—4) and sample 1 (5—8) calcined at various temperatures. Calcined temperatures are 500 (1,5), 400 (2,6), 300 (3,7), and 200°C (4,8)

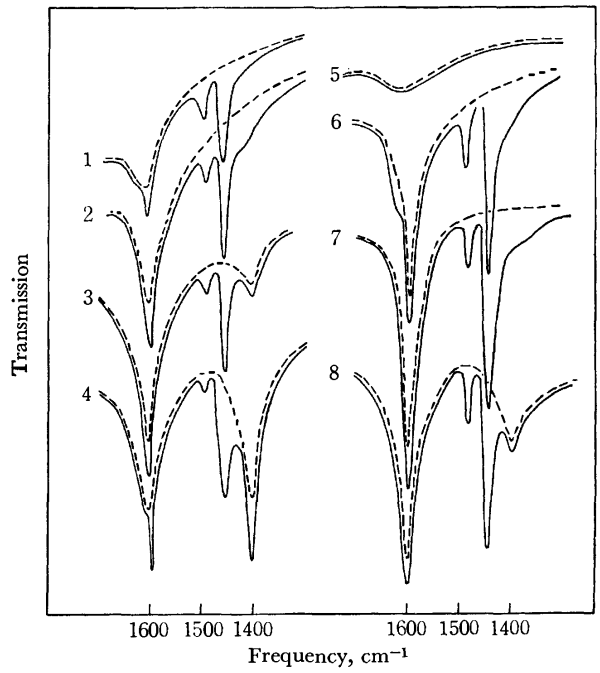

Fig. 7. Infrared spectra of pyridine adsorbed on sample 3 (1—4) and ZnO (5—8) calcined at various temperatures. Calcined temperatures are 500 (1,5), 400 (2,6), 300 (3,7), and 200°C (4,8)

has been assigned to the band due to pyridinium ion formed on Brönsted acid site and that at 1450 cm^{-1} in Figs. 6 and 7 due to coordinately bonded pyridine on Lewis acid site. Thus, TiO_2 has only Brönsted acid

4) E. P. Parry, *J. Catalysis*, **2**, 371 (1963).
5) M. R. Basila, T. R. Kantner, and K. H. Rhee, *J. Phys. Chem.*, **68**, 3197 (1964).
6) J. W. Ward, *J. Catalysis*, **9**, 225 (1967).
7) B. V. Liengme and W. K. Hall, *Trans. Faraday Soc.*, **62**, 3229 (1966).

sites and ZnO only Lewis acid sites, though the latter disappear when calcined at 500°C. Sample 1 of TiO_2·ZnO has both Brönsted and Lewis acid sites, while 3 has only Lewis acid sites. The Lewis acid sites of both samples do exist even when calcined at 500°C.

The band at 1485 cm^{-1} appears commonly on both Brönsted and Lewis acid sites. The bands near 1600 cm^{-1} observed in all samples before adsorption of pyridine are considered due to the adsorbed water molecules and/or coordinately bonded ammonia which are retained even after calcination. The bands near 1400 cm^{-1} observed in 1 and 3 and ZnO calcined below 400, 300, and 200°C, respectively, are those of the ammonium ion retained after calcination at relatively low temperature. The infrared spectra of ammonium sulfate used for the preparation of oxides give only the band at 1400 cm^{-1}, but TiO_2 prepared by using ammonium sulfate shows no band. This indicates that ammonium sulfate is not retained on the surface and therefore does not cause the observed acidic property.

A survey of the structure of TiO_2·ZnO by X-ray diffraction shows that sample 2 is entirely amorphous. Sample 1 showed only a pattern of the rutile type and sample 3 only a pattern of hexagonal ZnO, no pattern of the spinel structure being found. However, the structure of acid sites of TiO_2·ZnO is not clear at present.

Catalytic Activity. Since TiO_2·ZnO containing about 7% of ZnO (sample 1) was found to show fairly high acidity, its catalytic activity was tested for the hydration reaction of ethylene and the alkylation of phenol with methanol which are known to be catalyzed by the usual solid acids. Hydration reaction of ethylene over sample 1 of TiO_2·ZnO calcined at 400°C, was carried out at 200°C. The result is shown in Fig. 8, where the catalytic activities of nickel sulfate calcined at 300°C[9] and phosphoric acid mounted on celite[9] for the reaction under the same reaction conditions are also shown for comparison. The activity of the new TiO_2·ZnO catalyst is higher than that of nickel sulfate and solid phosphoric acid which are well-known catalysts for olefin hydration. Since the acid strength of acid sites effective for ethylene hydration is reported to be $H_0 \leqq -3$ in the case of various metal sulfate catalysts,[9] the observed high activity of TiO_2·ZnO catalyst is considered to be due to the fact that the catalyst has a large acid amount at $H_0 \leqq -3$ as shown in Table 3.

(-△-) Catalyst: 17 g of H_3PO_4 on celite, Reaction temp.: 220°C

The selectivity of this catalyst was also high, only ethyl alcohol being formed, although diethyl ether or acetaldehyde is usually formed when the catalysts of high acid strength ($H_0 \leqq -8.2$) such as SiO_2·Al_2O_3 and Al_2O_3·B_2O_3 are used.[9]

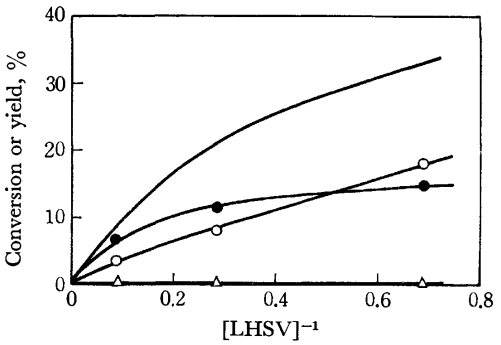

Fig. 9. Alkylation of phenol by methanol catalyzed by TiO_2·ZnO.
Reaction temp.: 400°C, total conversion (——), yield of *o*-cresol (-●-), *m*- and *p*-cresol (-○-), anisol (-△-)

The activity and selectivity of sample 1 of TiO_2·ZnO for alkylation of phenol with methanol are shown in Fig. 9. The conversion was about 33% at $LHSV^{-1}$ 0.7 and only monoalkylated phenols were obtained. The cause of selectivity and reaction kinetics are being studied in comparison with various known acidic catalysts.

Gas-Phase Charge-Transfer Complexation of Carbonyl Cyanide as Acceptor

Takayuki FUENO and Yoshiro YONEZAWA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received May 27, 1971)

Charge-transfer complexations of carbonyl cyanide with furan, tetrahydrofuran, diethyl ether, and their sulfur homologs have been investigated in gaseous phase at temperatures 22—82°C. Thermodynamic data showed that the complexations are enthalpy-controlled in the temperature range studied and that the complexes formed from *n*-donors are fairly strongly bound. Both the transition and bonding energies could be interpreted in terms of the usual two-state resonance model. It has been deduced that the spatial arrangements of the components do not greatly differ for the various donors studied, despite the difference in precise nature of the bondings involved.

Intermolecular interactions leading to the formation of "charge-transfer (CT)" complexes have been attracting increasing interests of both physical and organic chemists.[1] Studies have recently been conducted in gaseous phase, which have served to disclose the role of solvents in the CT complexations formerly observed in condensed phases. The gas-phase CT complexations studied so far include those with iodine,[2-8] sulfur dioxide,[9] tetracyanoethylene,[6,10,11] and carbonyl cyanide[12,13] as electron acceptor.

From a particular interest in the role of molecular complexation in the kinetics of some gas-phase reactions,[14,15] we investigated the bonding character of the gas-phase CT complexes of carbonyl cyanide, $(CN)_2CO$. This compound was chosen as acceptor because of relative unfamiliarity with respect to its structure and reactivity. The donor compounds here investigated are furan, tetrahydrofuran, diethyl ether and their sulfur homologs, *i.e.*, a series of C_2XC_2-type compounds with X=O or S. Carbonyl cyanide, being highly electron-deficient at its carbonyl carbon atom, gives fairly strong complexes with some of the donor molecules studied. Nonetheless, it has been found that the usual assumption of weak complexation is still valid for characterizing the present CT interaction systems.

Experimental

Materials. Carbonyl cyanide was synthesized from tetracyanoethylene according to the method of Linn, Webster, and Benson.[16] It was distilled under reduced pressure in an all-glass apparatus and stored in a reservoir which was screened from sunlight and cooled with Dry Ice-methanol.

Furan, thiophene, tetrahydrofuran, tetrahydrothiophene, diethyl ether, and diethyl sulfide were all purchased and purified by drying and distillation.

Apparatus and Procedure. The apparatus used is diagrammatically shown in Fig. 1. The absorption cell made of cylindrical quartz is 2 cm in diameter and 10 cm in light-path length. The side arm of the absorption cell has a sampling part for donors and two capillary parts, S_1 and S_2, for sealing off. The volumes of the absorption cell and of the glass tube between sealing-off points were measured before the absorption cell was connected with the vacuum line. The sampling part for donors consists of a glass tube stoppered with silicone gum and tightened with stainless steel fittings having a hole for a microinjector. The whole apparatus maintained vacuum under 10^{-3} mmHg.

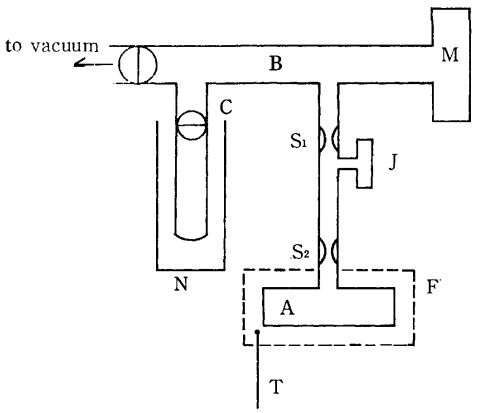

Fig. 1. Apparatus used for the gas-phase complexation measurements.
A, absorption cell; B, auxiliary tube; C, reservoir; M, oil manometer; F, electric heater; J, sampling part; T, thermocouple; N, liquid N_2 vessel; and S_1, S_2, seal-off parts

Gaseous mixtures of carbonyl cyanide and donor were prepared by the following method. The carbonyl cyanide vapor was metered into the evacuated absorption cell, using an oil manometer. The absorption cell was sealed off at capillary point S_1 from the vacuum line. While carbonyl cyanide in the absorption cell was condensed in the cell cooled with Dry Ice-methanol, liquid donor was introduced into the sampling part by use of a 25-μl microinjector. The cell was then sealed off at capillary point S_2. The concentration of carbonyl cyanide was calculated from its vapor

pressure and the predetermined cell volume, assuming that the vapor is an ideal gas. Concentrations of donor vapors were also calculated from the weight of the liquid samples and cell volume. The absorption cell was covered with a heat jacket whose temperature was read with a thermocouple. Spectral measurements were carried out at varying temperatures between 22 and 82°C.

Absorption spectra of gaseous mixtures were recorded on a Shimadzu-MPS-50L spectrophotometer. The spectrophotometric equation which can be applied to this study is[17]

$$\frac{c_a c_b}{d-d_0} = \left(c_a + c_b - \frac{d-d_0}{\varepsilon-\varepsilon_0}\right)\frac{1}{\varepsilon-\varepsilon_0} + \frac{1}{K_c(\varepsilon-\varepsilon_0)} \quad (1)$$

where c_a and c_b are the initial concentrations of carbonyl cyanide and donor, respectively; ε and d_0 are the extinction coefficients of the complex and free carbonyl cyanide, respectively; d is the absorbance per unit length; d_0 is $\varepsilon_0 c_a$; and K_c is the equilibrium constant of complex formation. c_a was varied from 1.1 to 2.3 mM, and c_a from 1.4 to 9.3 mM.

In evaluating ε and K_c from Eq. (1), we adopted the method of Lang.[18] An approximate value of ε was obtained by solving an appropriate pair of simultaneous equations based on Eq. (1). The values of $c_a c_b/(d-d_0)$ obtained from measurements at various c_a and c_b were then plotted against the values of $c_a+c_b-(d-d_0)/(\varepsilon-\varepsilon_0)$. From the slope calculated by the least squares method, a better value of ε was obtained. The procedure was repeated until the resulting value of ε coincided with the assumed. Usually, two iterations sufficed for the present purpose. The values of K_c at various temperatures were calculated from Eq. (1) by use of the ε value finally obtained. In the temperature range studied, ε of each complex did not vary appreciably with temperature.

Results

Figure 2 shows the absorption spectra of gaseous CT complexes of carbonyl cyanide with a series of donors at 62°C. The intensities of absorption increased (decreased) with the lowering (rising) in temperature and were essentially reproducible at temperatures between 22 and 82°C. This indicates that the complexes can exist in equilibrium with the free donor (D) and acceptor (A) species. Above 90°C, however, the absorbance in the shorter-wavelength region tended to show a gradual decrease with the elapsing time, indicating the occurrence of an irreversible reaction.

Prochorow *et al.*[19] investigated the absorption spectrum of carbonyl cyanide in both gaseous phase and

n-hexane solution and attributed the weak absorption with vibrational structure appearing in the 260—400 nm region to the symmetry forbidden n-π^* transition of the carbonyl group. The extinction coefficient at the absorption maximum $\lambda_{max}=330$ nm was reported to be 3.0 $M^{-1}cm^{-1}$. The vibrational structure of carbonyl cyanide remains clearly in the CT complexes with furan (Fu) and thiophene (Th). It is also discernible in the complexes with tetrahydrothiophene (THT) and diethyl sulfide (DES), but absent in the tetrahydrofuran (THF) and diethyl ether (DEE) complexes.

Table 1 summarizes the spectral and thermodynamic data of the CT complexes observed. Prochorow and Tramer[13] have already reported that the gaseous CT complex of carbonyl cyanide with DEE has $\lambda_{max}=$ 262 nm, $\varepsilon\simeq65$ $M^{-1}cm^{-1}$ and $K_c\simeq45$ M^{-1} at an unspecified temperature. The ε value we obtained is about half as great as theirs, but the K_c values observed in both studies are in rough accord with each other.

Figure 3 gives a plot of the wavenumbers of the CT band maxima, $\bar{\nu}_{max}$, against the ionization potentials I_D of donor compounds. For the sake of reference, the points for benzene, toluene, and *p*-xylene[13] have been included. The points including those of the benzene derivatives fit approximately the simple theoretical formula[20,21]

$$h c\bar{\nu}_{max} = I_D - C_1 + \frac{C_2}{I_D - C_1} \qquad (2)$$

with $C_1=5.7$ eV and $C_2=2.5$ $(eV)^2$.

Inspection of the equilibrium data given in Table 1 indicates that the K_c values of saturated donors are appreciably greater than those of unsaturated donors. The K_c values of the sulfur compounds are uniformly greater than those of the corresponding oxygen homologs. The results are in agreement with those found for the gas-phase CT complexes of iodine as acceptor.[2,4,6] The CT complexations here observed may be characterized by the relatively large equilibrium constants K_c for some donors and the correspondingly large enthalpy change of complexation, $-\Delta H°$.

In Fig. 4, the observed values of $\Delta H°$ are plotted against the values of $\Delta S°$. Although errors inherent to these thermodynamic quantities are too large to permit any quantitative considerations, it does appear that an extrathermodynamic relationship[22] holds between the $\Delta H°$ and $\Delta S°$ values observed. The "isokinetic" temperature as determined from the slope is *ca.* 435°K. The results indicate that the relative complexation abilities of the series of donor compounds here investigated are enthalpy-controlled in the temperature range studied.

Discussion

The observed dependence of $\bar{\nu}_{max}$ on I_D (Fig. 3) confirms that the absorption bands in question are essentially due to the intermolecular charge transfer transitions. The constants C_1 and C_2 appearing in Eq. (2) are given by[20,21]

$$C_1 = E_A - E_C + W_0 \qquad (3)$$

and

$$C_2 = 2\beta^2 \qquad (4)$$

where E_A is the electron affinity of the acceptor; E_c is the Coulombic energy involved in the ionic state, D^+A^-; W_0 is the van der Waals interaction energy of the no-bond state, DA; and β is the exchange interaction between the two extreme states.

If the simple two-state resonance model, on which

22) J. E. Leffler and E. Grundwald, "Rates and Equilibria of Organic Reactions," John Wiley, New York, N .Y. (1963), Chapter 9.

Eq. (2) is based, is also an adequate description of the bondings in the present complexations, then the binding energy should be given approximately by just a half the second term of Eq. (2)[23]:

$$\Delta E_R = C_2/2(I_D - C_1) \quad (5)$$

Substitution of the spectroscopically determined values of C_1=5.7 eV and C_2=2.5(eV)^2 into Eq. (5) gives ΔE_R=8.7(Fu), 8.7(Th), 6.6(THF), 9.9(THT), 7.2 (DEE), and 11.1(DES) kcal mol^{-1}. Although the values of ΔE_R thus calculated are all in order-of-magnitude agreement with the observed heats of complexation (Table 1), one can hardly see any quantitative correlation between these two sets of data.

One possible reason for the absence of correlation between ΔE_R and $\Delta H°$ might be sought in the premise that the C_1 and C_2 values can be assumed to be constant for the different types of donor compounds. Some of the donors studied in this work are unsaturated compounds which should fall in the category of the so-called π-donors (Fu and Th), while others are saturated n-donors (THF, THT, DEE, and DES). There is no justification for expecting the bonding characters of these two types of donors in complexes to be nearly the same.

In order to find logical consistency, we have solved Eqs. (2) and (5) simultaneously with respect to C_1 and C_2. The results are listed in Table 2.

Table 2. Values of C_1 and C_2[a]

Donor	C_1, eV	C_2, (eV)^2
Furan	5.3	1.0
Thiophene	5.3	1.9
Tetrahydrofuran	6.0	2.9
Tetrahydrothiophene	6.2	2.9
Diethyl ether	5.3	1.7
Diethyl sulfide	6.2	3.0

a) Calculated from the experimental vaules of ν_{max} and $\Delta H°$ through Eqs. (2) and (5).

Although no quantitative significance should be attached to the C_1 and C_2 values thus derived, it is worth noting that the π-donors take C_1=5.3 eV and C_2=1.4 (eV)^2 on the average, while three n-donors (THF, THT, and DES) possess values centered on C_1=6.1 eV and C_2=2.9 (eV)^2. The case of DEE is apparently closer to the π-donor case, which might be accidental. The values C_1=5.7 eV and C_2=2.5 (eV)^2 obtained from Fig. 3 should be taken merely as the averages of these individual values.

That the n-donors have greater values of C_1 and C_2 than the π-donors can best be reconciled by assuming that the former are complexed with $(CN)_2CO$ at an intermolecular distance somewhat shorter than in the case of the latter. In the present π-donor complexes it is likely that the component molecules are located on two parallel planes as in most π-donor-π-acceptor complexes. Taking the interplanar distance in our π-donor complexes to be the same (3.50 Å) as in crystalline naphthalene-TCNE[24] and assuming the W_0 to be negligibly small, we obtain E_A=1.2 eV for $(CN)_2CO$. This value of E_A in turn gives the intermolecular distance of *ca.* 3.0 Å for the n-donor-$(CN)_2$-CO complexes, a not unreasonable distance.

The constant C_2=2.9 (eV)^2 reduced for the present n-donor-$(CN)_2CO$ interactions is perhaps the greatest of the values hithero recorded.[1] For such a large C_2 value, the usual assumption of weak complexes would no longer be reliable, and thus both Eqs. (2) and (5) would need to be modified accordingly. Nevertheless, in view of the approximate nature of the present treatment, we may be satisfied for the present with such semiquantitative arguments as presented above on the basis of the assumption of weak complexation.

Discussion so far has been based on the assumption that charge transfer is the only cause of intermolecular bonding energies. However, Dewar and Thompson[25] argued that charge transfer is not generally the main factor responsible for the intermolecular bondings in donor-acceptor complexes. Lippert, Hanna, and Trotter[26] theoretically demonstrated that the Coulombic, induction, dispersion, charge-transfer, and exchange-repulsion energies all contribute to the total binding energies of the aromatic-TCNE as well as aromatic-halogen complexes.

Charge transfer spectra certainly provide no direct evidence for dominancy of the role of charge transfer in intermolecular bondings. Nonetheless, cases do exist in which the relative complexation abilities of donors can be interpreted in terms of charge transfer alone.[27,28] We thus consider the simple charge-transfer description to be useful in certain cases, occasionally providing good estimates of the bonding energies. Implicit in this view is the fact that the charge-transfer energy can be in line with the total bonding energy for structurally analogous complexes. If the contribution of the various other stabilizing factors happens to be counterbalanced by the intermolecular exchange repulsion, the role of charge transfer may even be regarded as a dominant factor of the bondings.

Despite the above complexity of the bonding character, the observed thermodynamics of complexation manifests a simple feature. The isokinetic relationship holding between $\Delta H°$ and $\Delta S°$ would imply an apparent thermodynamic uniformity of the complexation, irrespective of the precise nature of the bondings involved. This may not be quite a fortuitous result, if the spatial arrangements of the components are similar (*i.e.*, all parallel planes) for the various donors studied.

23) Both Eqs. (2) and (5) may be considered to be correct, only if $2C_2/(I_D-C_1)^2$ is small enough as compared with unity. For the sake of simplicity, we assume that this requirement is fulfilled here.

ESR Investigation of Copper Ions on Several Kinds of Cation Exchange Resins

Kayoko UMEZAWA and Takeo YAMABE
Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo
(Received June 1, 1971)

Copper ions on several kinds of cation exchange resins were investigated by means of ESR spectroscopy. It was found that the motion of copper ions is restricted in the network of the ion exchange resin, and that the mobility of copper ions is closely connected with the chemical interaction of the copper ions with the fixed ionic groups of the resins. The mobility of copper ions is in the order of; on the sulfonic group>on the phosphonic group>on the carboxylic group>on the iminodiacetate group. This sequence is the reverse of the selectivity for the copper ion. The effect of the water molecules involved in ion exchange resins is also considered, and the copper species on each ion exchange resin are assumed.

It is interesting to investigate the physico-chemical properties of hydrated ion-exchange resin by NMR, ESR, and IR measurements, because it can be considered as a concentrated electrolyte solution. Studying the behavior of ion-exchange resin may also be helpful in making clear the behavior of a concentrated electrolyte solution.

With this in view, Zundel *et al.*[1] investigated in detail by infrared measurements the water molecules involved in ion exchange resins, and several recent reports have been concerned with the water molecules in ion exchange resins, which were investigated by the NMR technique.[2]

However, only a few studies using ESR measurements have been reported.[3] By ESR measurements, although the measurable ions are limited in such substances as Cu(II), Mn(II), VO(II), and Fe(III), the behavior of ions on ion exchange resin can be directly observed instead of the water molecules.

In this paper, we will describe the results of the investigation of copper ions on several kinds of cation exchange resins by ESR measurements. The bonding of copper ions with fixed ionic groups, the mobility of the copper ions, and the effect of water molecules will be discussed. It will be concluded that the mobility of copper ions with fixed ionic groups, and that water molecules also influence the mobility of copper ions and the bonding of copper ions when copper ions are exchanged on ion exchange resin of either the sulfonic- or phosphonic-acid type.

Experimental

Materials. Cation exchange resins used were as follows, Dowex 50W X-2, 4, 8, and 16(sulfonic-acid-type cation exchange resin), Amberlite IRC 50(carboxylic-acid-type cation exchange resin), and Dowex A-1 (chelating ion-exchange resin containing an iminodiacetate group). These ion exchange resins were conditioned by the usual method.

Preparation of Samples. Wet ion exchange resin/10 m*l*, Na form was equilibrated with 20 m*l* of a copper nitrate solution of 10^{-3} mol/*l* for 24 hr, then it was collected by filtration, washed thoroughly with distilled water, and kept in a desiccator in which the relative humidity was 100%.

Measurements. A Japan Electron Optics Co., Ltd. ESR spectrometer model JES. ME 3X was used at room temperature or at 77°K. The modulation frequency was 100 kHz, and the modulation width was 5 gauss.

Results and Discussion

The ESR line shape of copper ions on each ion exchange resin showed a well-resolved spectrum at 77°K, suggesting that the copper ions were homogeneously dispersed. Moreover, at room temperature, the ESR line consists of an asymmetric single line or a line consisting of $g_{//}$ and $g_{\perp}$ components. This suggests that the motion of copper ions was affected. It was found that the motion of copper ions was affected by the fixed ionic groups and also by the amount of water in the ion exchange resins.

(1-1) The Influence of the Amount of Water in the Ion Exchange Resins on the Motion of Copper Ions. Figure 1 shows the influence of the amount of water in Dowex 50 W on the ESR line shape of copper ions. The ESR spectrum shows an asymmetric single line, not a symmetric one, when the ion exchange resin is full of water. With the decrease in the amount of water in the ion exchange resin, the ESR spectra show $g_{//}$ and $A_{//}$ components. The change in these spectra is very similar to that in the spectra of copper ions obtained by Kneubühl[4] in glycerin. He discussed the influence of the viscosity of the solvent on the motion of copper ions and showed that the increase in viscosity causes a slower Brownian motion, resulting in the ESR spectra with $g_{//}$ and $A_{//}$ components of copper ions. This suggests that the decrease in the amount of water in ion exchange resin causes a slower Brownian motion of copper ions on ion exchange resin. In other words, the decrease in the amount of water from the network of the ion exchange resin results in an increase in the microscopic viscosity and a large correlation time, τ_c.

Figure 2 shows the effect of the DVB (divinylbenzene) content in the resin on the Brownian motion. It shows

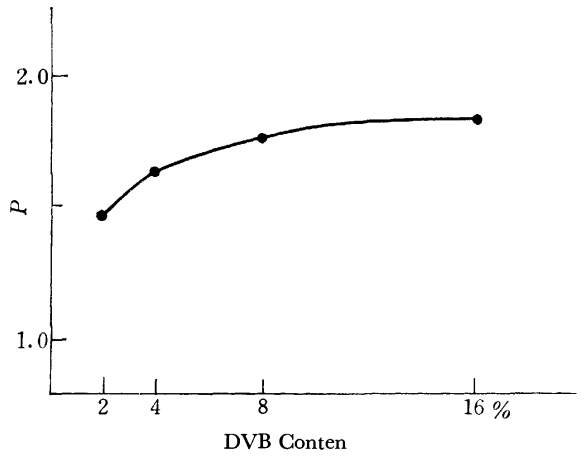

Fig. 2. Influence of DVB content on the motion of copper ion sorbed on Dowex 50W.

that the Brownian motion becomes slower with the increase in the DVB content. P indicates the ratio of the half maximum line width in the lower magnetic field to that in the higher magnetic field.[5] When P is equal to unity, the movement of copper ions is as fast as in an aqueous solution, while when P is larger than unity, the movement is slower than in an aqueous solution. The amount of copper ions sorbed was about 0.02 mmol/m*l* ion exchange resin. In this concentration range, the influence of dipolar interaction or electron exchange interaction is negligible. There are several points to be considered with regard to the effects of the increase in DVB content—the decrease in the amount of water in the ion exchange resin per unit of volume or per unit of weight, the increase in the number of sulfonic groups per unit of volume, and the decrease in the average pore diameter of the network. This last effect, however, seems to have little influence on the motion of copper ions, since the average pore diameter is about 16.9 Å for the ion exchange resin containing 15% of DVB,[6] this value is sufficiently large for the

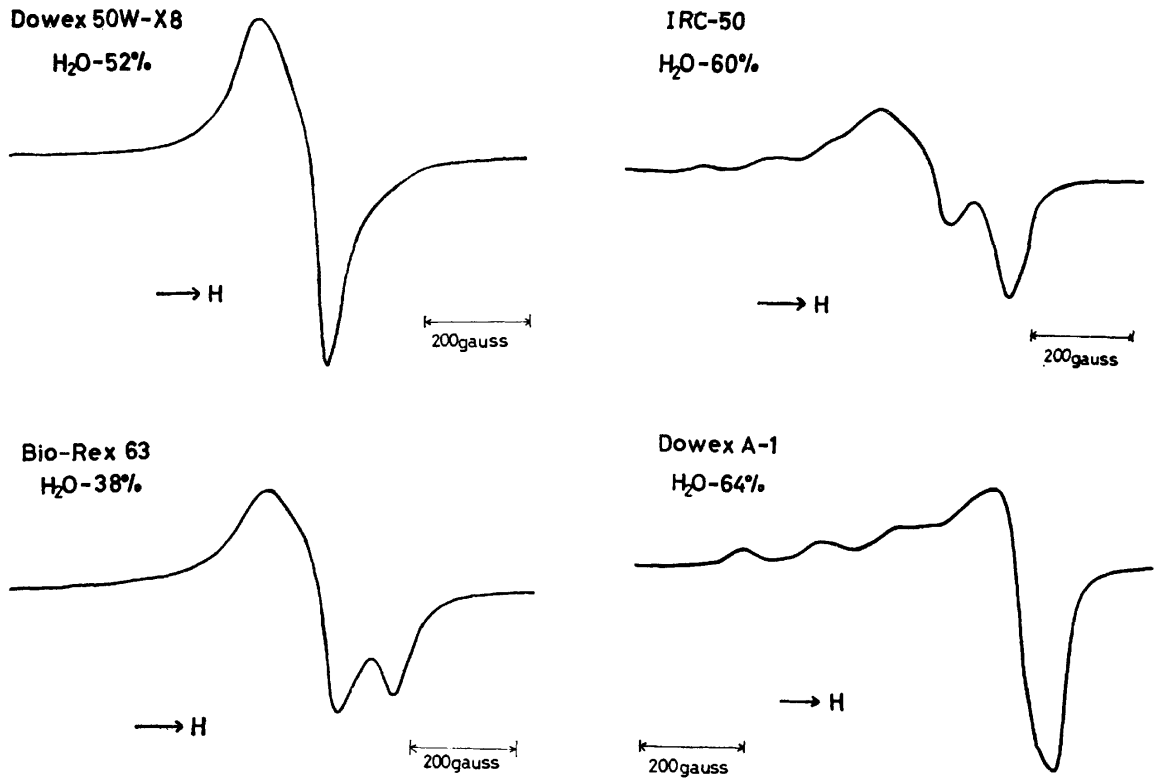

Fig. 3. ESR spectra of copper ions sorbed on various kinds of ion exchange resins at room temperature. The arrows show the absorption signal of Mn^{2+} as standard.

copper ion radius. On the other hand, the other two factors are important, because the decrease in the amount of water is responsible for the slow Brownian motion of copper ions mentioned above, and because the increase in the number of sulfonic groups causes the increase in the amount of counter ions per unit of weight or per unit of volume of the ion exchange resins. The latter results in the decrease in the number of water molecules per cation; therefore, the copper ions are tightly attached to the sulfonic groups. A similar result was obtained by Creekmore and Reilley.[2b] They observed line broadening of the NMR spectra of Na^+ on Dowex 50 W.

(1-2) Influence of Fixed Ionic Groups on the Motion of Copper Ions on Ion Exchange Resins. Figure 3 shows the line shape of the copper ion on various ion exchange resins, which were equilibrated with a relative humidity of 100% at room temperature. The amount of copper ions sorbed was about 0.02 mmol/m*l* ion exchange resin. As can be seen from the figure, the motion of copper ions sorbed is affected more strongly by the kind of fixed ionic group than by the amount of water in the resin. For example, Dowex A-1, containing about 64% of water, shows $g_{//}$ and $A_{//}$ components in its ESR spectrum, suggesting a very slow motion, while Dowex 50W, containing about 52% of water, shows an asymmetric single line spectrum and no $g_{//}$ and $A_{//}$ components. From this comparison, it can be said that the mobility of copper ions decreases in the order of; on the sulfonic group>on the phosphonic group>on the carboxylic group>on the iminodiacetate group. This sequence is the reverse of the selectivity of copper ions. In other words, the stronger the chemical interaction of a fixed ionic group with copper ions, the slower the Brownian motion of the copper ions. This will be discussed in detail in the following section (2). In the higher concentration region of copper ions, we also observed the influence of the difference in the mobility of copper ions on the ESR line shape. In the iminodiacetate group, the line shape changed little except for a little line broadening, even in the higher concentration region of copper ions, while in sulfonic groups P approached to unity with increase in the copper ion concentration, as

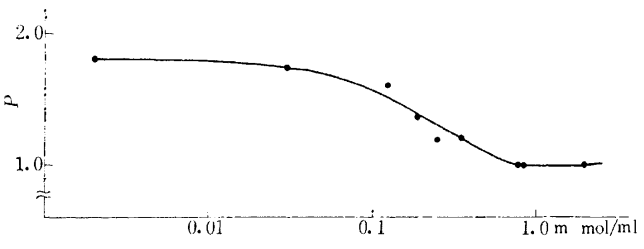

Fig. 4. Concentration dependence of copper ions on P.

is shown in Fig. 4. This difference can be interpreted as follows. As the mobility of copper ions on sulfonic groups is less restricted in the network of ion exchange resin, copper ions can interact with each other by collision in the higher concentration region of copper ions. Therefore, the asymmetry due to a slow Brownian motion in the lower concentration region is averaged out by such strong interaction as electron exchange, resulting in a symmetric single line of the ESR spectrum.

Furthermore, a narrowing of the line width was observed. When P is equal to unity, the line width, ΔH_{pp}, was 110 gauss a value which was consistent with that reported as the exchange narrowed line width by Fujiwara and Hayashi.[7] On the other hand, in iminodiacetate groups, the mobility of copper ions is too restricted for copper ions to move around; therefore, an increase in copper ions only causes dipolar interaction, resulting in line broadening.

Zinc-doped Copperacetate-monohydrate[c]	2.344	2.052 2.082	147	

All *g*- and *A*-values were obtained at 77°K and amount of copper ion sorbed was about 0.02 mmol/m*l* ion exchange resin.

a) ion exchange resin was dehydrated in vacumm at 10^{-3} mmHg for 24 hr at room temperature, at 50°C and at 100°C, but it was not observed the influence of dehydration temperature on *g*- and *A*-values.

b) see Ref. 10.

c) see Ref. 11.

(2) Copper Species on Each Ion Exchange Resin. Table 1 shows the *d–d* band absorption maxima and the *g*- and *A*-values of copper ions on hydrated ion exchange resins and on dehydrated ones. The values for hydrated ion exchange resins agree well with those obtained by Cohen and Heitner-Wirguin.[3c] They assumed that the copper species on hydrated Dowex 50W was $[Cu(H_2O)_6]^{2+}$ on the bases of a comparison of the *g*-values and *d–d* band absorption maxima of the aqueous solution of $[Cu(H_2O)_6]^{2+}$ with those of copper ions on Dowex 50W.[3b] However, as can be seen from Table 1, the *g*-values increased and the $A_{//}$ value decreased when Dowex 50W was dehydrated in a vacuum at 10^{-3} mmHg for 24 hr.[8] These changes may be due to a decrease in the coordination number of the water molecules around the copper ions. In Table 2, there are listed the *g*- and *A*-values of copper ions in H_2O-ethyleneglycol, those of copper *p*-toluenesulfonic acid in H_2O and those of copper polystyrene sulfonic acid in H_2O; almost all were the same and coincided well with those of copper ions on hydrated Dowex 50W. In the media of sulfuric acid, however, the *g*-vaulues of copper ions increased slightly and the *A*-value decreased with the increase in the coordination of sulfuric acid. This can be interpreted as being due to the decrease in the number of water molecules around copper ions as a result of dehydration by sulfuric acid. This tendency of change in *g*- and *A*-values was consistent with the results on copper ions on hydrated and dehydrated Dowex 50W. Similar results were obtained by Zundel and Murr[9] by studying the infrared spectra. They concluded that, when the resin was hydrated, the copper ion was $[Cu(H_2O)_6]^{2+}$, and that when it was dehydrated, the copper ions was $[Cu(H_2O)_4]^{2+}$. It is difficult to estimate the coordination number of water molecules from the ESR data, but it seems reasonable, in view of the Jahn-Teller effect, to assume that the coordination number of water molecules decreases from six to four upon dehydration. As is well known, as a result of the Jahn-Teller effect one copper ion interacts with four ligands more strongly than with the other two ligands. Therefore, two among six water molecules coordinated with the copper ion are rather easily dehydrated. Similarly, copper ions on Bio-Rex 63 are $[Cu(H_2O)_6]^{2+}$ when hydrated and $[Cu(H_2O_4)]^{2+}$ when dehydrated. These results suggest that the sulfonic and phosphonic groups interact with copper ions only by means of electro-static force. Moreover the difference in the mobility of copper ions may be due to the difference in the charge number of the fixed ionic groups. The sulfonic group is one minus ion, while the phosphonic group can be two minus.

Table 2. *g*- AND *A*-VALUES OF COPPER ION VARIOUS FROZEN SOLUTION AT 77°K

	Volume Ratio of Solvent	$g_{//}$	$g_{\perp}$	$A_{//}$ $\times 10^{4}$ cm^{-1}

$Cu(NO_3)_2$-*p*-toluenesulfonic acid/water		2.383	2.091	133
$Cu(NO_3)_2$-polystyrenesulfonic acid/water		2.413	2.085	133
$Cu(NO_3)$/water-sulfuric acid	5:1	2.40	2.08	145
	1:5	2.44	2.10	123
	1:10	2.48	2.10	104
	1:500	2.48	2.10	98

Concentration of copper ion was about 10^{-3} mol/*l*.

The *g*- and *A*-values of copper ions on Amberlite IRC 50, which were not influenced by dehydration, suggest a strong interaction of copper ions with the carboxylic group. The form of the copper species can be assumed to be $[Cu(OOC\text{–}R)_2]_2$, $(H_2O)_4Cu\langle^{OOC\text{–}R}_{OOC\text{–}R}$, or $R\text{–}C\langle^{O}_{O}\ Cu\ ^{O}_{O}\rangle C\text{–}R$. Cohen and Heitner-Wirguin found a strong IR absorption at 1650 cm^{-1} and attributed it to COO–M groups; they also found broad absorption maxima usually found for octahedral copper carboxylates, at 14300 cm^{-1}. They proposed the second form for copper species on IRC 50.[3c] However, the data obtained by them strongly suggest that copper ions form chelate bonding with carboxylic groups, but

7) S. Fujiwara and H. Hayashi, *J. Chem. Phys.*, **43**, 23 (1965).

8) A new ESR signal always appeared at about 3360 gauss; the same magnetic field as in the absorption of DPPH, after the dehydration of the ion exchange resin. This will be reported elsewhere in more detail.

9) G. Zundel and A. Murr, *Z. Phys. Chem.*, **54**, 59 (1967).

give weak evidence of coordination by four water molecules. We propose the last form for it for the following reasons. First, it should be noted that copper ions on the carboxylic group exists as a monomer, not a dimer, which is the first form, although copper ions generally form a dimer with acetic acid and other fatty acids. The *g*- and *A*-values have already been obtained for copper acetate monohydrate,[10] which is a dimer form, and zinc-doped copper acetate monohydrate,[11] X-ray-[12] or γ-ray-[13] irradiated copper acetate monohydrate, which are monomer forms.[14] Moreover, the ESR spectrum of copper ions on the carboxylic group showed only a doublet spectrum and the *g*- and *A*-values are consitent with those of the monomer form, Second, no influence of dehydration on *g*- and *A*-values was observed, and these was a restricted motion of copper ions; these facts suggest that water molecules have little influence on the bonding or mobility of copper ions. If one copper ion is surrounded by four water molecules as Cohen *et al.* proposed, the copper ion is mobile, as are copper ions on the sulfonic group, by the rapid exchange of water molecules from coordination sphere to the outer sphere; furthermore, two of the water molecules around the copper ion are unstable upon dehydration, and the dehydration will cause a change in the *g*- and *A*-values. As has been mentioned above, however, the *g*- and *A*-values changed little upon dehydration. Therefore, the second form can be ruled out; only the $R\text{–}C\langle^{O}_{O}\,Cu\,^{O}_{O}\rangle C\text{–}R$ model can well explain these results.

The copper ion on Dowex A-1 was discussed in detail by Cohen and Heitner-Wirguin;[3c] they assumed that the iminodiacetate group acts as a trivalent ligand when the copper ion is sorbed from a neutral solution. Considering the coincidence of our *g*- and *A*-values with those obtained by them, the small influence of the dehydration on the *g*- and *A*-values, the very slow motion of the copper ion, our results agree well with theirs.

One of the authors (K. U.) wishes to thank Dr. Shinsaku Shiraishi and Mr. Nobuharu Takai in this Institute and Dr. Tomi Sugimoto for their many helpful discussions and suggestions.

14) Strictly speaking, copper acetate monohydrate does not change its dimer form upon X-ray or γ-ray irradiation or by dopetion by zinc ions. However, the elctronic exchange interaction between copper ions disappears and the elctronic behavior of the copper ion is that of a monomer.

Electron Spin Resonance Studies of Bis(acetylacetonato)copper(II) Adsorbed on X-Type Zeolite. I. Interaction with Ammonia and Aniline

Yoshio YAMADA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received June 7, 1971)

The interaction of bis(acetylacetonato)copper(II) ($Cu(acac)_2$) adsorbed on X-type zeolite of the sodium form and on silica gel with ammonia and aniline was investigated by ESR. The magnetic and bonding parameters for $Cu(acac)_2$ on the surfaces indicate that the axial-ligand field about the copper on the surfaces is similar to that in a toluene solution. This finding implies that the copper in $Cu(acac)_2$ does not interact strongly with these surfaces. However, it was deduced from the change in the spectrum at higher temperatures that the quasi-π-electrons in $Cu(acac)_2$ interact with the electrostatic field arising from the cations on the zeolite. When ammonia or aniline was introduced, the bonding characters of the complex altered significantly. It was found, from the variation in the parameters, that the axial-ligand field about the complex strengthens and that an adduct is formed. Furthermore, a spectral line at $g=2.004$, which was observed only for $Cu(acac)_2$ on the zeolite in the presence of aniline, was considered to be due to a cation radical formed by an electron transfer from the aniline to the complex.

The ESR spectra of copper(II) complexes have been measured in the liquid and frozen solution states by several authors.[1-5] However, very little work has been done as yet on the complexes in the adsorbed state.[6,7] If a copper complex is adsorbed on a solid surface, it can be expected that the interaction of the complex with the surface will alter the bonding character of the complex.

In this paper, the stability of bis(acetylacetonato)-copper(II) in the adsorbed state and the effect of am-

monia or aniline on the adsorbed complex are studied in order to estimate the variation in the bonding character of the complex and in order to examine the interaction with the surface. In the following paper, the reaction of the complex with pyridine will be described on the basis of the interaction with the surface. The purpose of these works is to obtain information on the characteristic reactions taking place on the surface and on the structure of the complex formed on it. In this connection, these studies may contribute to our understanding of heterogeneous catalytic reactions involving complexes.

Experimental

Materials. An X-type zeolite of the sodium form (Linde Lot No. 1380019, Molecular Sieve 13X powder) free from any binder and silica gel was used as the adsorbent. The method of preparation of silica gel has already been described in a preceding paper.[8] The bis(acetylacetonato)-copper(II)($Cu(acac)_2$) was prepared according to the method in the literature[9] and was purified by recrystallization from chloroform. The ammonia and aniline were repeatedly distilled under a vacuum prior to use. The former was synthesized by the ordinary method, while the latter was obtained commercially.

Procedures. The zeolite was heated in a vacuum for 5 hr at 500°C. The amount of $Cu(acac)_2$ (0.88 mg in 1 m*l* of chloroform per 0.25 g of the zeolite) was adjusted so that all of the complex molecules entered the cages of the zeolite in the ratio of one molecule to *ca.* 20 cages. The chloroform solution of $Cu(acac)_2$ was introduced to the zeolite through a breakable seal. Note should be taken of the procedure that the zeolite was cooled before the introduction of the solution in order to prevent the $Cu(acac)_2$ from decomposing by the heat of adsorption. After the chloroform had been eliminated under a vacuum, the complex adsorbed on the zeolite was exposed, at room temperature, to ammonia at a pressure of 100 Torr or to aniline vapor, and then the ESR spectra were measured with a Japan Electron Optics Laboratory JES-3BS-X type ESR spectrometer, equipped with a 100kc field-modulation unit. The g value was determined by comparison with the value for DPPH, 2.0036.

Results and Discussion

The ESR spectrum of $Cu(acac)_2$ adsorbed on the X-type zeolite is shown in Fig. 1 (a). It can be considered, from the well-resolved lines of this spectrum, that the complex molecules are sufficiently remote from one another. When a Molecular Sieve 3A was used as the adsorbent, only a broad singlet spectrum was observed. The absence of structure seems to be ascribable to the dipole-dipole interaction among the complex molecules. From the difference between these spectra, the complex molecules may be deduced to be included in the cages of the X-type zeolite.

If the complex takes a structure with a completely axial symmetry, the spectrum at the perpendicular g component ($g_\perp$) should consist of four lines as a result

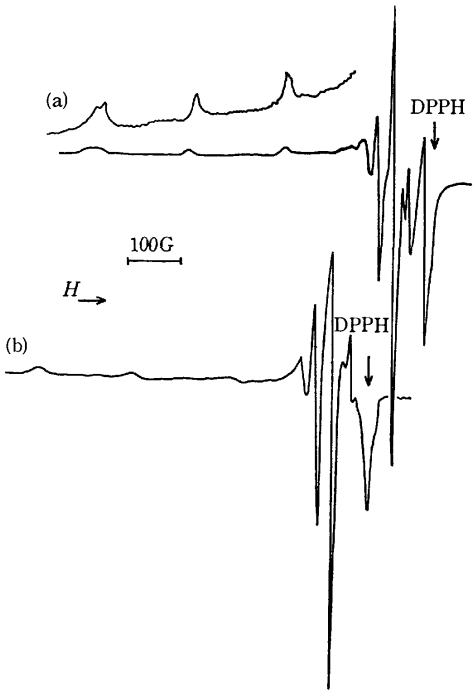

Fig. 1. ESR spectra of $Cu(acac)_2$ (a) on NaX zeolite and (b) on silica gel at 77°K.

of the coupling between an electron spin and a nuclear moment ($I=3/2$) of copper, neglecting the isotope of its nucleus.[10] However, a few unexpected peaks, which had also been observed in the frozen solution,[2] were found, as can be seen in Fig. 1 (a). Recently, these extra peaks have been analyzed on the basis of a theoretical consideration.[11] According to this theory, the observed peaks seem to be due not only to the separation of $g_\perp$ components, g_x and g_y, because of the deviation from axial symmetry, but also to angular anomalies and to transitions with $m_I>0$ caused by electric quadrupole effects.

When the complex was adsorbed on silica gel, a spectrum similar to that on the zeolite was observed

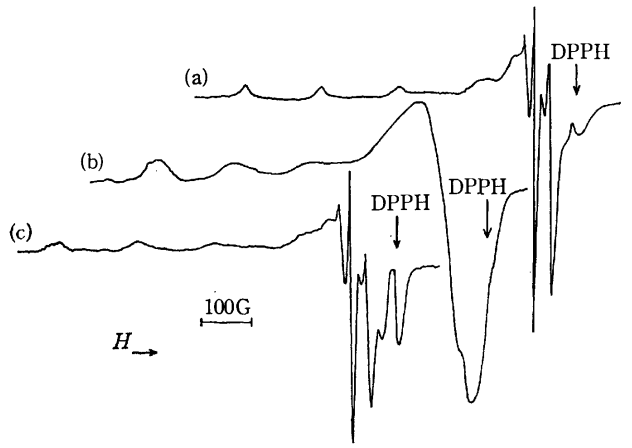

Fig. 3. Spectra of $Cu(acac)_2$ (a) on NaX zeolite (b) on silica gel in the presence of aniline at 77°K, and (c) 77°K after sample (a) was left for a few days at room temperature.

(Fig. 1 (b)). The extra peaks in the $g_\perp$ region are not clearly discernible, as may be seen in Fig. 1 (b), because of the linewidth broadening. The spectra shown in Figs. 2 (a) and (b) were obtained when ammonia was introduced, at a pressure of 100 Torr, to $Cu(acac)_2$ on the zeolite and the silica gel respectively, and then the samples were heated at 80°C. The original spectrum was replaced by an ill-resolved one in each case. On the other hand, the well-resolved spectrum shown in Fig. 3 (a) appeared on the exposure of the $Cu(acac)_2$ on the zeolite to aniline vapor. A weak singlet at $g=2.004$ behaved differently from the other signals in the variation of the temperature and the microwave power. A detailed discussion of the singlet will be presented later. The magnetic parameters determined from these spectra are listed in Table 1, along with those from the spectrum of $Cu(acac)_2$ in a toluene solution.[12]

In order to discuss the nature of the copper-ligand bonding in terms of these experimental parameters, the bonding parameters were calculated by a molecular orbital theory.[1,13] That is, α^2, which is a measure of the covalency of in-plane σ-bonding between a copper $3d$ orbital and the ligand orbitals, can be written in the

Table 1. Magnetic parameters

	$g_{\parallel}$	$g_\perp$	$\lvert A_{\parallel}\rvert \times 10^4 cm^{-1}$	$\lvert A_\perp\rvert \times 10^4 cm^{-1}$

first approximation:

$$A_{\parallel} = P\left[-\alpha^2\left(\frac{4}{7}+\kappa_0\right)+(g_{\parallel}-2.002)+\frac{3}{7}(g_\perp-2.002)+0.04\right] \quad (1)$$

where $P=0.036$ cm^{-1} and where κ_0 is the Fermi contact term for the free cupric ion and is nearly equal to 0.43, according to Kivelson and Neiman.[1]

The value of β_1^2, which is a measure of the covalency of the in-plane π-bonding, was evaluated from the equation:

$$g_{\parallel} - 2.002 = -8\rho[\alpha\beta_1 - \alpha'\beta_1 S - \alpha'(1-\beta_1^2)^{1/2}T(n)/2] \quad (2)$$

where $\rho=\lambda_0\alpha\beta_1/\Delta E_{xy}$ and where $T(n)$ has the value of 0.220 for the β-keto enolate chelates. The spin-orbit coupling constant for the free cupric ion, λ_0, is -828 cm^{-1}. On account of the difficulty in observing the absorption spectra, the energy difference between E_{xy} and $E_{x^2-y^2}$ is approximately set as the constant value of 15000 cm^{-1}. The normalization of the in-plane σ-bonding orbital yields:

$$\alpha^2 + \alpha'^2 - 2\alpha\alpha' S = 1, \quad (3)$$

where S, the overlap integral, is equal to 0.076 for the β-keto enolate complexes. By the use of Eqs. (1), (2), and (3), the values of the bonding parameters, that is, α^2, β_1^2, and α'^2, were calculated; the results are summarized in Table 2.

Table 2. Bonding parameters

	α^2	α'^2	β_1^2
$Cu(acac)_2$ in $C_6H_5CH_3$	0.82	0.25	0.73
$Cu(acac)_2$ on SiO_2	0.86	0.21	0.72
$Cu(acac)_2$ on zeolite	0.85	0.22	0.75
$Cu(acac)_2$ on SiO_2–NH_3	0.83	0.24	0.71
$Cu(acac)_2$ on zeolite–NH_3	0.83	0.24	0.79
$Cu(acac)_2$ on SiO_2–$C_6H_5NH_2$	0.80	0.27	0.91
$Cu(acac)_2$ on zeolite–$C_6H_5NH_2$	0.82	0.25	0.89

Prior to the consideration of the bonding character, the stability of the complex on the surfaces was examined. The intensity of the spectrum of $Cu(acac)_2$ adsorbed on the zeolite gradually decreased and the linewidth became broader as the temperature was raised. The spectrum disappeared near 90°C. The broadening of the spectral lines can be explained in terms of the decomposition of the complex; the cupric ion thus produced interacts more strongly with the surface than that in the complex does. On the other hand, a small decrease in the intensity was observed up to *ca.* 200°C for $Cu(acac)_2$ on silica gel. It, therefore, may be considered that the especially active sites on the zeolite play an important role in the decomposition of the complex. Abramov *et al.*[14] studied the IR spectra of benzene adsorbed on zeolites and interpreted the various shifts of some bands in the IR spectra as being caused by the interaction of the π-electron of the benzene molecule with the electrostatic field of the cations on the walls of the cavities in the zeolites. An

14) V. N. Abramov, A. V. Kiselev, and V. I. Lygin, *Zh. Fiz. Khim.*, **37**, 1156 (1963).

essentially similar interaction can be expected for the quasi-π-electrons in $Cu(acac)_2$ adsorbed on the zeolite. As can be seen in Table 2, the in-plane π-bonding for $Cu(acac)_2$ on the zeolite is somewhat more ionic than that for the complex on silica gel. This may be interpreted as follows: the symmetry of the complex lowers slightly as a result of the interaction of the quasi-π-electrons in the complex with the electrostatic field from the cations on the zeolite, and the copper atom is no longer coplanar to the four chelating oxygen atoms.

It is well known that the magnetic parameters of copper complexes depend largely upon the kind of solvent.[12] This arises from the differences in the basicity of the solvent molecules, one or two of which coordinate to the complex along the axis normal to the molecular plane. When apical ligands coordinate to the cupric ion, *i.e.*, when the axial-ligand field strengthens, the values of $g_{//}$ increase, while those of $|A_{//}|$ decrease.[5,15] On the basis of this rule and the results shown in Table 1, the axial field can be said to be weak in the adsorbed state as well as in a toluene solution, where none of the solvent molecules coordinates to the complex as an apical ligand.[12] Consequently, it seems reasonable to consider that the copper atom in the complex does not interact strongly with the surface.

When ammonia or aniline is introduced to $Cu(acac)_2$ on the zeolite or silica gel, the $g_{//}$ value increases and the $|A_{//}|$ value decreases, except for $Cu(acac)_2$ on silica gel in the presence of ammonia. According to the above rule, these facts may indicate that the adsorbed molecule coordinates as an apical ligand. Since such basic molecules have a strong donating ability, their equatorial coordination should be weakened by back-donation, resulting in an increase in α^2. Nevertheless, this phenomenon was not seen on the introduction of ammonia or aniline. This unexpected result may be attributable to the use of the Fermi contact term, κ_0, as a constant in the calculations. It has been indicated[16] that the axial coordination of the electron-donating molecule increases the charge density in the 4*s* orbital, thereby reducing the promotion of the unpaired electron to the 4*s* orbital and causing a decrease in κ_0. Hence, this conflict can be removed in terms of the decrease in κ_0. From the above discussion, it can be concluded that the introduction of aniline or ammonia to $Cu(acac)_2$ on the zeolite, and that of aniline to $Cu(acac)_2$ on silica gel, bring about the axial-ligand field, leading to the formation of the adduct, though the circumstances of the complex are not clear for the system of $Cu(acac)_2$-ammonia on silica gel. Furthermore, when we take into account the finding that the copper atom in the complex interacts more strongly with ammonia or aniline than with the surface, it seems likely that the complex has such a structure that the copper atom is located above the plane containing the four chelating oxygen atoms. These oxygen atoms may interact with the surface hydroxy groups.

When $Cu(acac)_2$ adsorbed on the zeolite in the presence of aniline was allowed to stand for a few days at room temperature, the spectral line at $g=2.004$ in Fig. 3 (a) grew considerably, whereas the other lines arising from the complex slightly decayed (Fig. 3 (c)). The saturation curves for microwave power of the former line and of the latter lines were recorded according to the methods described by Bloembergen and Wang.[17] It was found from the curves that the former line easily saturates with microwave power. These results suggest that there is a possibility of the formation of a cation radical by the electron transfer from aniline to $Cu(acac)_2$. The ionization potential of aniline, which was measured by the photoionization method, is 7.7 eV.[18] This value is quite low.

When the temperature of the system was raised, the intensity of the signal due to the cation radical increased remarkably and became constant near 130°C. From the increase in the radical concentration, it may be deduced that the mixing of the lone-pair orbital with an orbital of the copper atom occurs to a greater extent as a result of the strong interaction between the copper atom and the aniline molecule at elevated temperatures, and that it accelerates the electron transfer. The formation of radical was observed in the solution containing aniline.

The effect of the zeolite on aniline in the absence of $Cu(acac)_2$ was examined in an additional experiment. When aniline was adsorbed on the zeolite, a weak line, probably due to the cation radical, was observed at the same position as above, but its intensity did not increase at higher temperatures. It can be concluded from these facts that the cation radical formed in the system of $Cu(acac)_2$-aniline on the zeolite arises mainly from the electron transfer and partly from some other mechanism.

The author wishes to express his hearty thanks to Professor Masaji Miura and Dr. Akinori Hasegawa for their valuable discussions and encouragement throughout this work.

Electron Spin Resonance Studies of Bis(acetylacetonato)copper(II) Adsorbed on X-Type Zeolite. II. The Substitution Reaction of Ligands with Pyridine

Yoshio YAMADA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received June 7, 1971)

The interaction of bis(acetylacetonato)copper(II) ($Cu(acac)_2$) adsorbed on X-type zeolite of the sodium form with pyridine was investigated by means of ESR. When a pyridine vapor was introduced to $Cu(acac)_2$ on the zeolite, the spectral lines of the perpendicular g component for $Cu(acac)_2$ were replaced by those consisting of a superhyperfine structure, which arises from the ligand nitrogen atoms. The observed spectrum was assigned to $[Cu(pyridine)_4]^{2+}$. Such a characteristic substitution reaction of $Cu(acac)_2$ with pyridine was not, however, observed on silica gel nor in ordinary solvents. It is pointed out, on the basis of these results and of the considerations described in a preceding paper, that the reaction involves the following mechanism: the interaction of quasi-π-electrons in $Cu(acac)_2$ with an electrostatic field originating from the cation on the zeolite lowers the stability of $Cu(acac)_2$, and the complex is attacked by two adsorbed pyridine molecules and two pyridinium ions which are formed by the combination with protons on acid sites, resulting in the substitution reaction. In addition, $[Cu(pyridine)_4]^{2+}$ was produced on other cation-exchanged zeolites and silica-alumina. The substitution reaction was also found when α-, β-, or γ-picoline was used instead of pyridine.

The interaction of adsorbed bis(acetylacetonato)-copper(II) ($Cu(acac)_2$) with the surface and the effect of ammonia and aniline on the complex were studied in the preceding paper (hereafter to be designated as part I). With regard to the interaction with pyridine, we[1] have recently reported that a ligand-substitution reaction occurs on the introduction of pyridine to $Cu(acac)_2$ adsorbed on the zeolite. Yokoi *et al.*[2] have found a substitution reaction with pyridine in the solution of bis(ethylacetoacetato)copper(II) or bis(salicylaldehydrato)copper(II). They have pointed out, however, that $Cu(acac)_2$ brings about no substitution reaction with pyridine in a chloroform solution. It is known, with respect to $Cu(acac)_2$ and other copper(II) β-diketone chelate complexes, that some heterocyclic bases coordinate to the complex as one or two apical ligands in ordinary solvents, such as chloroform or toluene, and that an adduct is formed.[2-6] Therefore, in order to explain the difference between the reactivity of the complex on the surface and that in solution, a reaction mechanism is proposed on the basis of the influence of the surface, and, at the same time, the assignment attempted in the short communication[1] is reconsidered in the present work.

Experimental

The X-type zeolite of the sodium form (NaX zeolite) is the same as that used in part I. The cation-exchanged zeolites, NH_4X (NH_4X may not be a precise representation, because ammonia gas is released from NH_4X zeolite by the evacuation at 500°C and protons are considered to be present on the surface.), LiX, and CaX, were prepared from the original NaX zeolite by the conventional method.[7] The amount of the sodium ion exchanged was determined by means of atomic-absorption spectroscopy. The percentage of the exchanged cation was 96.1, 86.0, or 94.4 for NH_4X, LiX, or CaX respectively. Silica-alumina (alumina content *ca.* 40%) was synthesized from ethyl orthosilicate and aluminum isopropoxide. GR-grade pyridine was further purified by distillation under a vacuum. The IR spectra were obtained using a Hitachi EPI-S2 spectrophotometer. The preparation of the other samples and the procedure of the measurements have been described in part I.

Results and Discussion

The Formation of $[Cu(pyridine)_4]^{2+}$ on NaX Zeolite. When $Cu(acac)_2$ adsorbed on NaX zeolite was exposed to pyridine vapor at room temperature, the spectrum presented in Fig. 1 (a) was observed. This spectrum differs remarkably at the perpendicular g component ($g_\perp$) from that due to $Cu(acac)_2$ on the zeolite, which has been shown in Fig. 1 (a) of part I. The variation in the spectrum suggests the conversion of $Cu(acac)_2$ into another complex. When the sample was allowed to stand for a few days at room temperature, the relative intensities of the spectral lines at the $g_\perp$ component changed slightly. However, as can be seen from Figs. 1 (a) and (b), they altered considerably after the sample had been heated at 100°C and the excess pyridine had been removed. These results show that the formation of the new complex is slow at room temperature, but is accelerated by heating. The spectrum in Fig. 1 (b) consists of many lines with a coupling constant of 16 gauss; this value was determined from the splitting between lines at the central part of the $g_\perp$ component. Figure 1 (c) shows a K-band spectrum in the $g_\perp$ region, which is remarkably broad in contrast to that at the

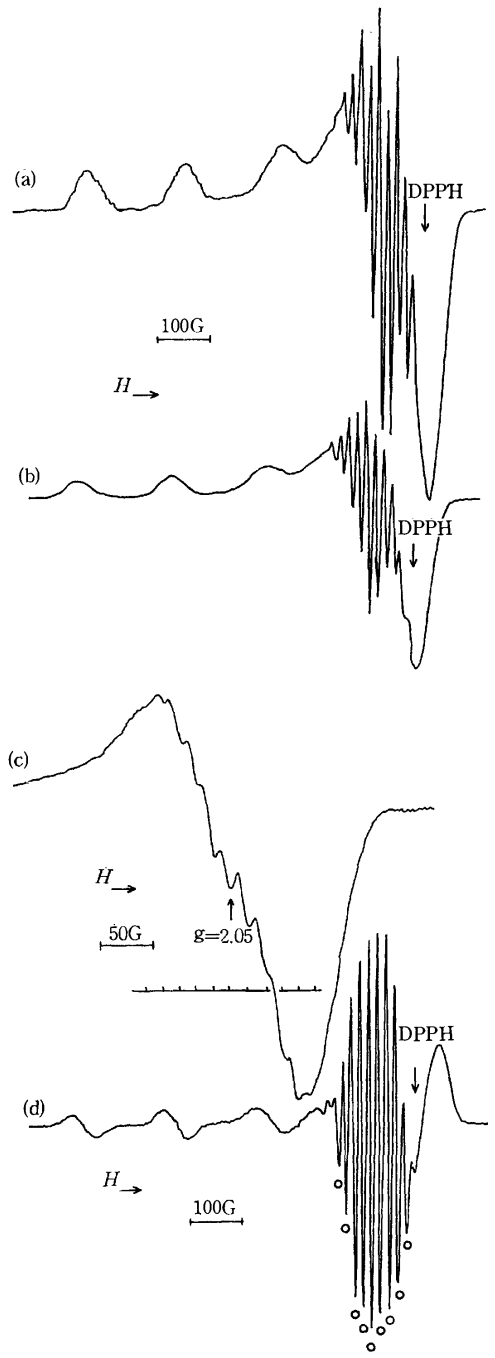

Fig. 1. (a) ESR spectrum of $Cu(acac)_2$ on NaX zeolite in the presence of pyridine at 77°K, (b) spectrum measured at 77°K, after sample (a) was heated at 100°C and excess pyridine was removed, (c) K-band spectrum of sample (a) at 77°K, and (d) second derivative X-band spectrum of sample (b) at 77°K.

X-band. Nevertheless, the observed spectrum consists of lines with a nearly equal splitting of about 16 gauss. Therefore, the separation of $g_\perp$ components, g_x and g_y, due to the deviation from axial symmetry can be disregarded and the value of the coupling constant determined from the X-band spectrum is confirmed.

The superhyperfine (shf) structure arising from the coupling with the nitrogen nucleus of pyridine contributes to the observed spectral lines at the $g_{//}$ component. Therefore, the shf structure should be observed on each of the four lines constituting the parallel hyperfine (hf) structure from the copper atom. Unfortunately, the resolved shf structure in the $g_{//}$ region could not be found, even on the second derivative spectrum (Fig. 1 (d)), but the linewidth of the individual hf structure showed a considerable broadening compared with that for $Cu(acac)_2$ on the zeolite. In a short communication,[1] it has been concluded, on the basis of the 11 lines observed at the $g_\perp$ component, that two of the four oxygen atoms originally coordinating to the cupric ion are replaced by two pyridine molecules. However, an ambiguity remains in this assignment, because the complexity of the spectrum caused by angular anomalies,[8] the electric quadrupole interaction of copper, and the isotope of copper makes it difficult to determine exactly the number of the lines at the $g_\perp$ component. In addition, the number of the lines depends not only on the number of pyridine molecules coordinating to the cupric ion, but also on the ratio of the splitting constant of the copper nucleus to that of the ligand nitrogen nucleus. Since the isotropic hf structure was not observed for this system, it was impossible to determine the perpendicular hf coupling constant of the copper nucleus. Thus, no assignment for the complex can be made. However, the second derivative spectrum shown in Fig. 1 (d) is similar to that for a complex formed in the pyridine - chloroform solution of $CuCl_2$ at 77°K.[9] Moreover, the values of the magnetic parameters obtained from the spectrum of Fig. 1 (b), *i.e.*, $A_{//}$ and $g_{//}$, correspond to those for the complex, in which four pyridine molecules coordinate to the cupric ion in a methanol solution.[10] The intensities of the nine lines at the central part shown in Fig. 1(d) are remarkably stronger than those of the other parts. These lines are represented by circles.

Gersmann and Swalen[9] have reported that the value of the perpendicular hf coupling constant from the copper nucleus is negligibly small in the spectrum observed for $CuCl_2$ in pyridine - chloroform. The same result has also been obtained for $[Cu(pyridine)_4]^{2+}$ in methanol.[10] Hence, assuming that these results can be applied in the present case, the nine intense peaks may be considered to be due only to a shf structure arising from the coupling with four equivalent nitrogen atoms, whereas the weak remaining peaks in the $g_\perp$ region may originate from angular anomalies,[8] the transition with $m_I > 0$ due to the electric quadrupole interaction, and the isotopes of copper. These results and considerations lead to the conclusion that the four chelating oxygens of $Cu(acac)_2$ on the zeolite are replaced by four pyridine molecules after the introduction of pyridine, resulting in the formation of a new complex, $[Cu(pyridine)_4]^{2+}$. The substitution reaction was also suggested by the IR measurements; the absorption band at 1580 cm^{-1} for $Cu(acac)_2$ on the zeolite, which has been assigned to the stretching of chelating carbonyl groups,[11] disappears with the adsorption of pyridine.

TABLE 1. MAGNETIC AND BONDING PARAMETERS OF THE COPMLEXES ON SILICA GEL AND NaX ZEOLITE

	$\lvert A_{//}\rvert \times 10^4\text{cm}^{-1}$	$\lvert A_{\perp}\rvert \times 10^4\text{cm}^{-1}$	$g_{//}$	$g_{\perp}$	α^2	α'^2	β_1^2
$Cu(acac)_2/SiO_2$	195	28	2.253	2.055	0.86	0.21	0.72
$Cu(acac)_2$-pyridine/SiO_2	166	43	2.311	2.050	0.83	0.24	0.90
$Cu(acac)_2$/NaX zeolite	190	31	2.264	2.043	0.85	0.22	0.75
$[Cu(pyridine)_4]^{2+}$/NaX zeolite	196	—	2.254	2.052	0.86	0.22	0.74

The values of the magnetic parameters determined from the spectra of Fig. 1 (b) and of the bonding parameters, calculated using Eqs. (1), (2), and (3) of part I, are listed in Table 1. The observed $|A_{//}|$ value of $[Cu(pyridine)_4]^{2+}$ on the zeolite is larger than that of $Cu(acac)_2$. The result can be explained in terms of the fact that the strong coordination of pyridine along the equatorial axis accompanies an increase in covalent character, that is, the promotion of the unpaired electron to the 4*s* copper orbital, and brings about a positive contribution to the $|A|$ value.[12,13] A similar result has been obtained in the case of copper phthalocyanine[14] or copper tetraphenylporphine,[15] in which the cupric ion is coordinated with four ligand nitrogen atoms. The in-plane σ-bonding of these complexes is known to be highly covalent. Thus, $[Cu(pyridine)_4]^{2+}$ is considered to exhibit a considerably covalent character in the copper-nitrogen σ-bonding. However, an unexpected increase in α^2 was obtained (Table 1). This can be interpreted as being caused by the fact that a constant value of κ_0 is used in the calculation of α^2, as has been described in part I.

On the other hand, the value of α'^2 can also be evaluated from the observed shf coupling constant of the nitrogen atoms, independent of the hf coupling constant due to the copper nucleus. The relations between α'^2 and the shf coupling constants are expressed by the following two formulas:[16]

$$A_{//}^{N} = \left(\frac{\alpha'}{4}\right)^2 (2\gamma\beta_0\beta_N)\left[-\frac{8\pi}{9}|\rho_s(0)|^2 + \frac{8}{15}\langle r_p^{-3}\rangle\right] \quad (1)$$

$$A_{\perp}^{N} = \left(\frac{\alpha'}{4}\right)^2 (2\gamma\beta_0\beta_N)\left[-\frac{8\pi}{9}|\rho_s(0)|^2 - \frac{1}{15}\langle r_p^{-3}\rangle\right] \quad (2)$$

where $A_{//}^{N}$ and $A_{\perp}^{N}$ are the shf coupling constants in the directions of the N–Cu–N axis and perpendicular to it respectively, where $|\rho_s(0)|^2$ is the 2*s* electron density at the nitrogen nucleus; r_p, the radius of the 2*p* nitrogen orbital; γ, the gyromagnetic ratio of the ^{14}N nucleus, being set as 0.4036; β_0, the Bohr magneton, and β_N, the nuclear magneton. Maki and McGarvey[16] have calculated $|\rho_s(0)|^2 = 33.4\times10^{24}\text{cm}^{-3}$ for the 2*s* function and $\langle r_p^{-3}\rangle = 21.1\times10^{24}\text{cm}^{-3}$ for the 2*p* function. By the substitution of the parallel shf coupling constant observed at the $g_{\perp}$ component of the copper, $A_{//}^{N} = 15.3\times10^{-4}\text{cm}^{-1}$, into Eq. (1), $\alpha'^2 = 0.40$ was obtained. Even if the experimental errors are taken into account, this value is still considerably different from that calculated from α^2. This deviation seems to be responsible for the overestimation of α^2 described above. The large parallel shf coupling constant indicates that the copper-nitrogen bond is strong and highly covalent. This result is consistent with that derived from the hf coupling constant of the copper atom.

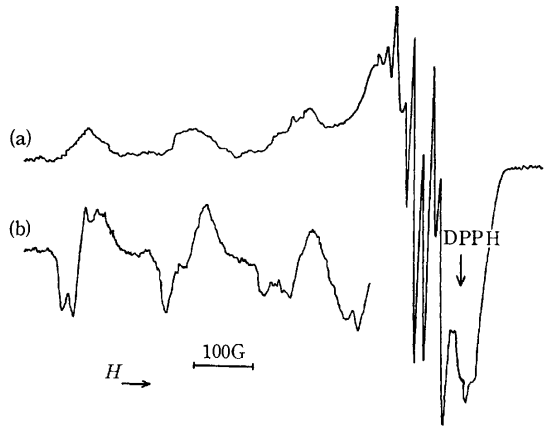

Fig. 2. (a) First and (b) second derivative spectra of $Cu(acac)_2$ on NaX zeolite in the presence of γ-picoline, measured at 77°K after the sample was heated at 80°C.

The Substitution of $Cu(acac)_2$ on the Zeolite with Picoline. When α-, β-, or γ-picoline was used instead of pyridine, the spectra obtained were similar to that observed in the case of pyridine. Figure 2 (a) shows a typical spectrum. The shf structure due to $[Cu(picoline)_4]^{2+}$ is also seen on this spectrum, but the intensity ratio of each peak is irregular. The second derivative spectrum in the $g_{//}$ region of Fig. 2 (a) was measured (Fig. 2 (b)). By taking into account the finding that two sets of hf structure are observed in the $g_{//}$ region, two species of the complex are thought to be formed on the zeolite. Hence, it may be deduced that the irregularity is caused by the superposition of the spectra due to the two molecular species. The stability of these complexes lowers in the sequence of γ-, β-, α-picoline; the intensity of the spectrum decreases near 110, 130, and 140°C for the complexes of $[Cu(\alpha\text{-picoline})_4]^{2+}$, $[Cu(\beta\text{-picoline})_4]^{2+}$, and $[Cu(\gamma\text{-picoline})_4]^{2+}$ respectively. On the other hand, $[Cu(pyridine)_4]^{2+}$ is stable even at 150°C. From these results, the stability of these complexes may be considered to be responsible for the differences in the structure arising from the position of the methyl group and in the interaction with the surface.

The Interaction of $Cu(acac)_2$ with Pyridine on the Various Surfaces. Figures 3, 4, and 5 show the spectra recorded after the introduction of pyridine to $Cu(acac)_2$

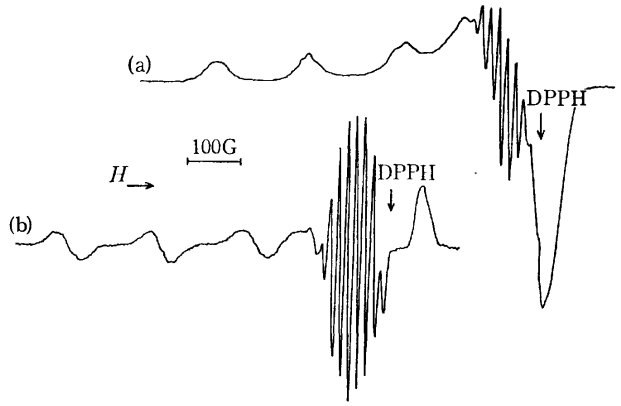

Fig. 3. (a) First and (b) second derivative spectra of $[Cu(pyridine)_4]^{2+}$ on LiX zeolite at 77°K.

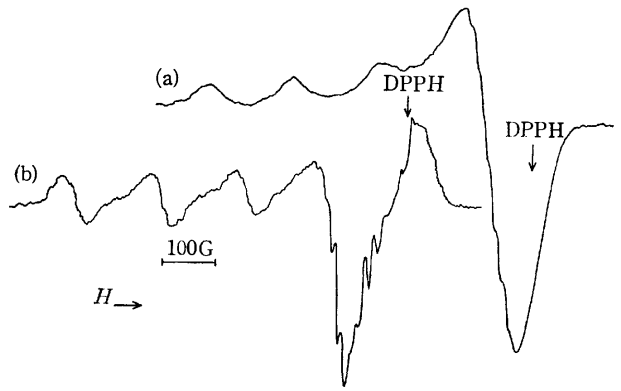

Fig. 4. (a) First and (b) second derivative spectra of $[Cu(pyridine)_4]^{2+}$ on NH_4X zeolite at 77°K.

adsorbed on LiX, NH_4X, and CaX zeolites respectively. In the case of LiX zeolite, the shf structure in the $g_\perp$ region is discernible in the first derivative spectrum. On the other hand, for the complex on NH_4X or CaX zeolite, the structure is hardly observed in the first derivative because of the linewidth broadening, but it becomes appreciable in the second derivative (Figs. 4 (b) and 5 (b)). All of these spectra have the same shf coupling constant in the $g_\perp$ region as that for the spectrum of $[Cu(pyridine)_4]^{2+}$ on NaX zeolite. Therefore, $[Cu(pyridine)_4]^{2+}$ must be produced also on these zeolites. Moreover, not only on these zeolites, but on

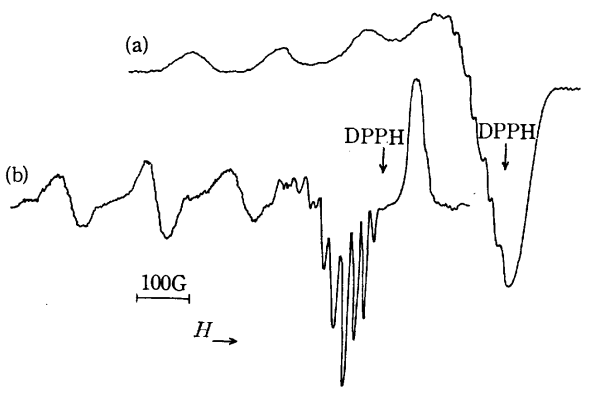

Fig. 5. (a) First and (b) second derivative spectra of $[Cu(pyridine)_4]^{2+}$ on CaX zeolite at 77°K.

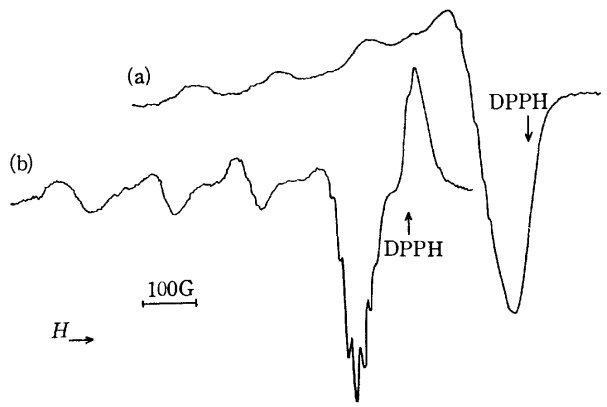

Fig. 6. (a) First and (b) second derivative spectra of $[Cu(pyridine)_4]^{2+}$ on silica-alumina at 77°K.

silica-alumina, the formation of $[Cu(pyridine)_4]^{2+}$ can be recognized from the second derivative spectrum in Fig. 6 (b).

When $Cu(acac)_2$ on silica gel was exposed to pyridine vapor, a spectrum which is remarkably different from that of $[Cu(pyridine)_4]^{2+}$ formed on NaX zeolite appeared, as can be seen in Fig. 7. The magnetic and bonding parameters determined from the spectrum in

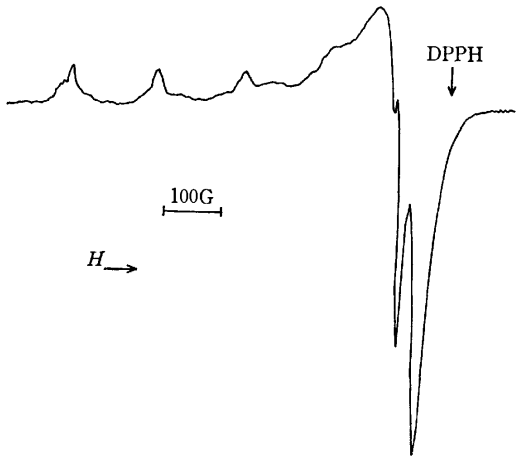

Fig. 7. Spectrum of $Cu(acac)_2$ on silica gel in the presence of pyridine at 77°K.

Fig. 7 are summarized in Table 1. The value of $|A_{//}|$ decreases, but the value of $g_{//}$ increases, in striking contrast to the variation in the parameters of the spectrum observed on NaX zeolite. This means that an adduct is formed, as has been described in part I. Therefore, it can be concluded that such a substitution reaction as observed on the zeolites does not occur on silica gel. This conclusion is predictable from the findings presented in part I; since $Cu(acac)_2$ on silica gel is stable even at 180°C, it is considered that the interaction of quasi-π-electrons in $Cu(acac)_2$ with the surface is weak.

The Mechanism for the Formation of $[Cu(pyridine)_4]^{2+}$. Though the characteristic substitution reaction was not observed in ordinary solvents,[1] the coordination of pyridine along the molecular plane was found in the solution of ethanol - water at pH$\leqq$3. It has already been reported that the following reaction takes place in the

aqueous ethanol solution at a low pH:[17]

$$Cu(acac)_2 + H^+ \rightleftarrows [Cu(acac)]^+ + \text{acetylacetone}$$

Accordingly, the proton may participate also in the substitution reaction on NaX zeolite.

As has been described in part I, the magnetic parameters of the complex on the zeolite are similar to those in toluene. In addition, an IR absorption band due to the stretching of the chelating carbonyl group is observed for $Cu(acac)_2$ on zeolite. Therefore, it is unnecessary to consider that, before the introduction of pyridine, $Cu(acac)_2$ dissociates into Cu^{2+} and two acetylacetone molecules through interaction with NaX zeolite.

Ward[18] has shown, by means of the IR spectra, that NaX zeolite dehydrated fully at 500°C has no detectable Brönsted and Lewis acids, while Watanabe and Habgood[19] have detected the Brönsted acid sites by heating the zeolite under a vacuum at temperatures between 150 and 200°C. Since chloroform contains a trace amount of water,[20] there is a further possibility that the water associated with cation-deficient centers produces the Brönsted-acid sites. Hence, it is thought that the Brönsted-acid sites combine with the adsorbed pyridine molecules to form pyridinium ions. On the other hand, as has been described in part I, the quasi-π-electrons in $Cu(acac)_2$ interact with the electrostatic field of the cations on zeolites and the complex becomes unstable. Consequently, it can be concluded that two pyridine molecules and two pyridinium ions attack the unstable complex and substitute themselves for the acetylacetone molecules.

When the zeolite was exposed to pyridine vapor and $Cu(acac)_2$ was then adsorbed on the zeolite, only a faint, broad singlet spectrum was observed, showing that the substitution reaction did not occur. This may be due to the facts that the acid sites are poisoned by the pyridine molecules and that the electrostatic field from the sites is screened. From the results, it seems reasonable to consider that the stability of the complex is not lowered significantly because the interaction of the complex with the zeolite is weakened by the preadsorption of pyridine.

In conclusion, the substitution of the ligands in $Cu(acac)_2$ with pyridine molecules was found to occur on various zeolites and silica-alumina, but not on silica gel and in ordinary solvents. The complex formed on the zeolites and silica-alumina was identified as $[Cu(pyridine)_4]^{2+}$ on the basis of the various results and considerations. This reaction was interpreted in terms of both the instabilization of $Cu(acac)_2$ caused by the interaction of the quasi-π-electrons in $Cu(acac)_2$ with the electrostatic field of the cations on zeolites, and the attack of two pyridine molecules and two pyridinium ions. Such a substitution reaction was also observed on NaX zeolite using α-, β-, or γ-picoline instead of pyridine, though the complexes produced were less stable than $[Cu(pyridine)_4]^{2+}$.

The author wishes to express his hearty thanks to Professor Masaji Miura and Dr. Akinori Hasegawa of Hiroshima University for their valuable discussions. Special thanks are also due to Assistant Professor Koichi Itoh of Osaka University for his generous permission to use the ESR spectrometer with a K-band.

The Dehydrogenation of Amines by Molten Metal Catalysts[1]

Kiyohisa Okano, Yasuo Saito, and Yoshisada Ogino
Department of Chemical Engineering, Faculty of Engineering, Tohoku University, Aramaki Aoba, Sendai
(Received June 7, 1971)

In order to investigate the catalytic activity of molten metal, experiments were carried out using the dehydrogenation of *n*-butylamine, benzylamine, and cyclohexylamine as test reactions. The molten zinc catalyst was thus found to show specially high activities and selectivities in all test reactions. The activity of the molten gallium catalyst for the dehydrogenation of *n*-butylamine was also considerable. However, the selectivity of this catalyst was somewhat lower than that of the molten zinc catalyst, and considerable amounts of dibutylamine were produced at lower reaction temperatures. The other molten metals were found to be almost inactive. That is, Pb, Cd, Sn, and Bi were inactive, while Tl and In were only slightly active.

The present authors have undertaken a systematic study of the catalysis of liquid metals and have found that some liquid metals, such as zinc and indium, efficiently dehydrogenate methanol,[2] *n*-butanol,[3] *iso*-butanol,[3] and *sec*-butanol.[3] Further studies of the dehydrogenation of the other alcohols, including cyclohexanol and benzyl alcohol, are now proceeding.

Although the details of the mechanism of the catalysis by the liquid metal have not yet been clarified, it is assumed that the interaction between lone-pair electrons around the oxygen atom of alcohol causes the dehydrogenation of alcohol. By extending this idea, it can be expected that the dehydrogenation of amine is catalyzed by the liquid metal. The present work has been undertaken to confirm this expectation.

Experimental

Catalysts. The liquid zinc (Zn-L) was mainly used as a catalyst in the present work. However, in some cases, other liquid metals, *i.e.* In-L, Tl-L, Ga-L, Pb-L, Cd-L, and Bi-L, were also examined.

Reactants. The *n*-butylamine, benzylamine, and cyclohexylamine were obtained commercially. They were of the highest quality among the available reagents.

Activity Test. The method of the activity test was similar to that described in previous papers.[2,3] The reaction products were analyzed mainly by gas chromatography, but the results were supplemented by chemical analysis and by infrared spectroscopic analysis.

Results and Discussion

Dehydrogenation of n-*Butylamine.* According to the experimental results, Zn-L and Ga-L showed considerably high catalytic activities for the dehydrogenation of *n*-butylamine. The activities of In-L and Tl-L were too low to be measured accurately, and Pb-L, Sn-L, Cd-L, and Bi-L were inactive. Therefore, only the details of the activities of Zn-L and Ga-L will be presented below.

Catalytic Activity of Zn-L for the Dehydrogenation of n-*Butylamine.* The experimental results showed that the catalytic activity of Zn-L persisted for a long period (more than 10 hr). The gaseous products were mainly hydrogen, and the contents of methane, ethane, and ethylene were very small. The main liquid product was *n*-butyronitrile (II). In addition to the main product, a small amount of a liquid by-product was also detected on the gas-chromatographic chart. The retention time of this peak agreed with that of the product of the following reaction[4]:

$$CH_3CH_2CH_2CH_2NH_2 + CH_3CH_2CH_2CHO \longrightarrow CH_3CH_2CH_2CH{=}N{-}CH_2CH_2CH_2CH_3 + H_2O$$

Thus, the by-product was identified as Schiff's base, *i.e.* $CH_3CH_2CH_2CH{=}N{-}CH_2CH_2CH_2CH_3$ (III). The infrared spectra shown in Fig. 1 support this view. The absorption peak appearing at 1660 cm^{-1} indicates the presence of a $-\overset{|}{C}{=}N-$ group.

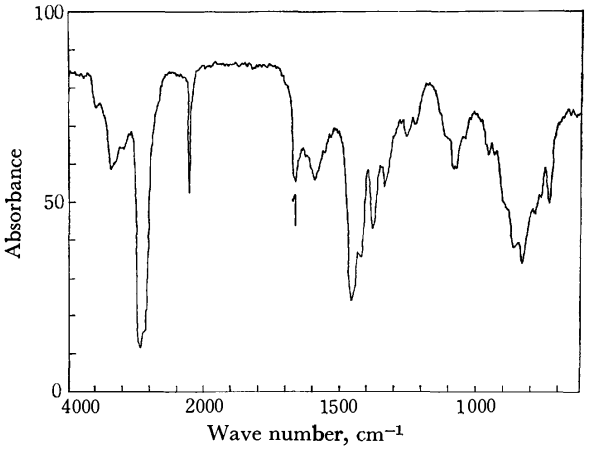

Fig. 1. Infrared spectra of the liquid products obtained by dehydrogenating *n*-butylamine in the presence of the Zn-L catalyst.

1) Studies on Catalysis by Molten Metal. III.

2) Y. Saito, A. Miyamoto, and Y. Ogino, *Kogyo Kagaku Zasshi*, **74**, No. 8, 1521 (1971).

3) K. Kashiwadate, Y. Saito, A. Miyamoto, and Y. Ogino, This Bulletin, **44**, 3004 (1971).

4) The procedures for obtaining Schiff's base (III) (*i.e. N*-butyliden-*n*-butylamine) by a reaction such as that described in the text had been reported by K. N. Campbell *et al.* (*J. Amer. Chem. Soc.*, **66**, 82 (1944)), and by C. W. C. Stein *et al.* (*ibid.*, **64**, 2569 (1942)). In the present research, the products of this reaction was distilled in a nitrogen stream. The isolated material showed a definite boiling point of 142—143°C, which agreed well with the literature values of 141—145°C. Therefore, the isolated material may be identified as *N*-butylidene-*n*-butylamine and may be used as a standard material for the gas-chromatographic analysis, which was carried out under the following conditions: column; 20% PEG20M+10% KOH on cellite 2.25 m, carrier gas; He 8.10 ml/min, temperature; 80°C.

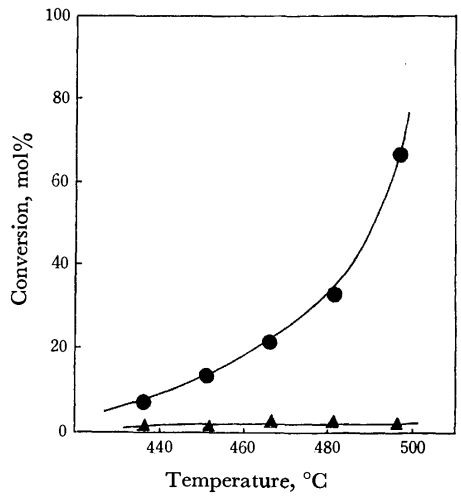

Fig. 2. The temperature dependency of the catalytic activity of Zn-L for the dehydrogenation of *n*-butylamine:
—●— conversion to *n*-butyronitrile, —▲— conversion to Schiff's base. (Zn 70 g, Feed 0.089 mol/hr).

The conversion-*vs*-temperature relation is shown in Fig. 2. As can be seen in this figure, the conversion of *n*-butylamine to *n*-butyronitrile increased steeply with the increase in the reaction temperature, whereas the conversion to Schiff's base increased only a little.

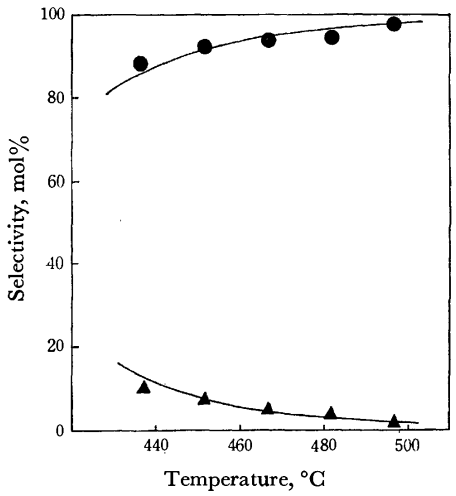

Fig. 3. The temperature dependency of the selectivity of the Zn-L catalyst in the dehydrogenation of *n*-butylamine:
—●— for *n*-butyronitrile, —▲— for Schiff's base. (Zn 70 g, Feed 0.089 mol/hr).

The selectivity-*vs*-temperature relation is shown in Fig. 3. It can be seen in this figure that, with an increase in the reaction temperature, the selectivity for the formation of *n*-butyronitrile increased, while the selectivity for the formation of Schiff's base decreased. Further, it must be noted that the selectivity of the Zn-L catalyst for the formation of nitrile was generally high and that an especially high selectivity (~100%) was obtainable at high reaction temperatures (~500°C).

According to Dolgow,[5] Schiff's base can be regarded as an intermediate product in the catalytic hydrogenation of nitrile. Therefore, the same base may be produced by the reverse reaction, *i.e.*, the dehydrogenation of amine. Presumably, the primary product of the dehydrogenation would be aldimine, *i.e.*, $CH_3CH_2CH_2CH{=}NH$ (I), which is unstable and which can easily be subjected to further dehydrogenation to form nitrile (II). In addition, the aldimine (I) may react with *n*-butylamine to form Schiff's base in the following way:

$$\underset{\text{I}}{CH_3CH_2CH_2CH{=}NH} + CH_3CH_2CH_2CH_2NH_2 \longrightarrow \underset{\text{III}}{CH_3CH_2CH_2CH{=}N\text{-}CH_2CH_2CH_2CH_3} + NH_3$$

Thus, the over-all reaction scheme for the Zn-L catalyzed dehydrogenation of *n*-butylamine may be expressed as follows:

$$n\text{-butylamine} \xrightarrow[\text{Zn-L}]{-H_2} \text{aldimine (I)} \xrightarrow[\text{Zn-L}]{-H_2} n\text{-butyronitrile (II)}$$

$$\text{aldimine (I)} \xrightarrow[\text{Zn-L}]{+n\text{-butylamine}} \text{Schiff's base (III)} + \text{ammonia}$$

According to this reaction scheme (the parallel formation of II and III), when the total conversion of *n*-butylamine reaches zero, the concentrations of both II and III should be extraporated to values which are larger than 0% and smaller than 100%. As can be seen in Fig. 4, the experimental results supported this expectation. If II is consecutively formed *via* III the concentration of II should be extraporated to 0% and the concentration of III should be extraporated to 100%.

Catalytic Activity of Ga-L for the Dehydrogenation of Butylamine. As can be seen in Fig. 5, Ga-L showed a persistent activity for the dehydrogenation of *n*-butylamine. As in the dehydrogenation by the Zn-L catalyst, the main gaseous product was hydrogen, but very small amounts of methane, ethane, and ethylene were also

Relations between the reaction time and the activity of the Ga-L catalyst for the dehydrogenation of *n*-butylamine: -○- total conversion, -●- selectivity for *n*-butyronitrile, -▲- selectivity for dibutylamine, -■- selectivity for Schiff's base. (Ga 40 g, Feed 0.089 mol/hr, Temperature 500°C).

produced. On the other hand, the liquid product[6] contained considerable amounts of dibutylamine, $(CH_3CH_2CH_2CH)_2NH$ (IV), in addition to *n*-butyronitrile (II) and Schiff's base (III).

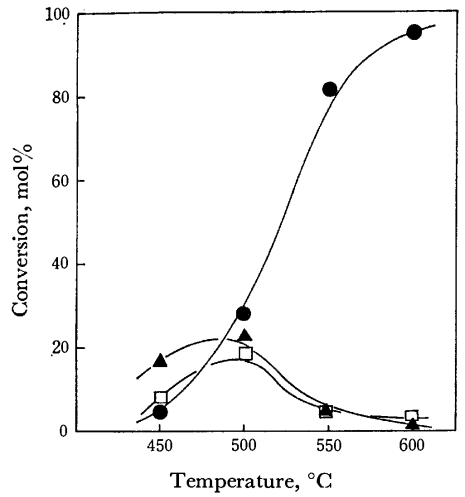

Fig. 6. The temperature dependency of the catalytic activity of the Ga-L catalyst: -●- conversion to *n*-butyronitrile, -▲- conversion to dibutylamine, -□- conversion to Schiff's base. (Ga 40 g, Feed 0.089 mol/hr).

The temperature dependency of the catalytic activity of Ga-L is given in Fig. 6. At lower reaction temperatures, the conversion to nitrile (II) was rather low and the conversion to Schiff's base (III) or the conversion to dibutylamine (IV) was found to be high. However, the conversion to nitrile (II) increased steeply with the increase in the reaction temperature, whereas the conversion both to Schiff's base (III) and to dibutylamine (IV) decreased markedly with the increase in the reaction temperature. Thus, the selectivity for the formation of *n*-butyronitrile (II) increased steeply with the increase in the reaction temperature and reached ~95% at a temperature of 600°C.

As can be seen in Fig. 6, the curve which expresses the relation between the reaction temperature and the conversion of *n*-butylamine to Schiff's base (III) is nearly parallel with the curve which expresses the relation between the reaction temperature and the conversion to dibutylamine (IV). This means that the formation of III is intimately related to the formation of IV. Further information about this point was obtained by plotting each of the fractions, III/III+IV and IV/III+IV, against the conversion of *n*-butylamine to III+IV. As can be seen in Fig. 7, th eIII/III+IV fraction approaches unity, while the IV/III+IV fraction approaches zero, as the conversion is reduced to zero. These facts indicate that IV is formed consecutively from III.

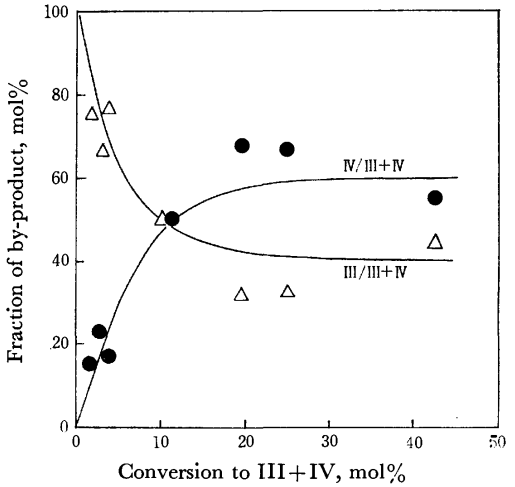

Fig. 7. Relations between the conversion of *n*-butylamine to by-products (dibutylamine and Schiff's base) and the respective fraction of each component in the by-products obtained in the presence of the Ga-L catalyst: -△- fraction of Schiff's base, -●- fraction of dibutylamine. (Ga 40 g, Feed 0.089 mol/hr).

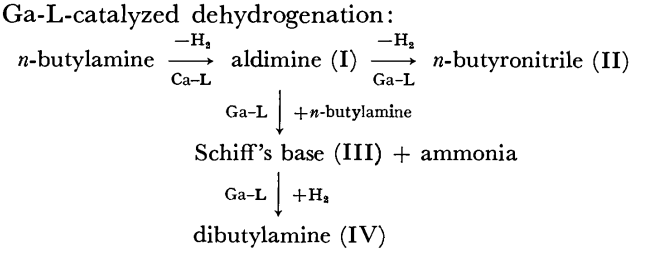
The above-mentioned features of the Ga-L-catalyzed dehydrogenation of *n*-butylamine are somewhat different from those of the Zn-L-catalyzed dehydrogenation, which were described in the previous section; the following reaction scheme[7] seems to be applicable to the Ga-L-catalyzed dehydrogenation:



6) Ammonia was also detected, in addition to negligibly small amounts of ethylamine, diethylamine, *n*-propylamine, dipropylamine, acetonitrile, propionitrile, and acrylonitrile. These materials were also found in the products obtained by the use of the Zn–L catalyst.

7) W. S. Brey *et al.* (*Ind. Eng. Chem.*, **51**, 1031 (1959)) dehydrogenated butylamines by using an alumina catalyst and obtained dibutylamine, *N*-butylidenbutylamine, and some other compounds. They proposed a reaction scheme. However, because of the complicated product distribution, their reaction scheme was more complex than the present one.

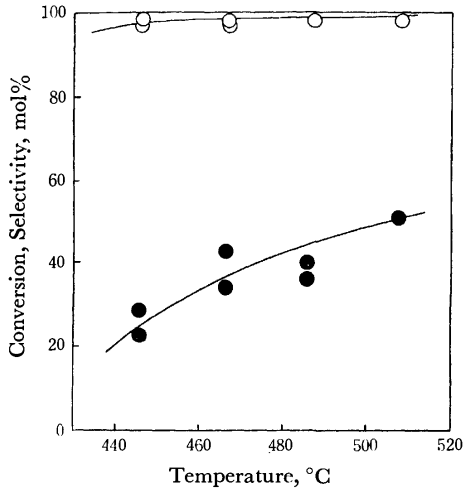


Fig. 8. The temperature dependencies of the catalytic activity and the selectivity of the Zn-L catalyst for the dehydrogenation of benzylamine: -●- total conversion, -○- selectivity for the formation of benzonitrile. (Zn 50 g, Feed 0.068 mol/hr).

Dehydrogenation of Benzylamine. In the dehydrogenation of benzylamine, only Zn-L was used as a catalyst. As can be seen in Fig. 8, Zn-L showed catalytic activity in the dehydrogenation of benzylamine. The reaction products were mainly hydrogen and benzonitrile, and the selectivity of the dehydrogenation was nearly 100% under the present experimental conditions. Thus, the over-all reaction may be expressed simply by:

$$C_6H_5CH_2NH_2 \xrightarrow{\text{Zn-L}} C_6H_5CN + 2H_2$$

Dehydrogenation of Cyclohexylamine. Also in this reaction, only Zn-L was used as a catalyst. According to the experimental results, cyclohexylamine decomposed and evolved hydrogen and ammonia, together with very small amounts of cyclohexene, cyclohexane, and a trace of unidentified compound. The mole ratio of hydrogen to ammonia was nearly 1 : 1. Further, the liquid products gave the infrared spectra shown in Fig. 9. This figure shows the presence of the $-\overset{|}{C}=N-$ group in the the liquid products.

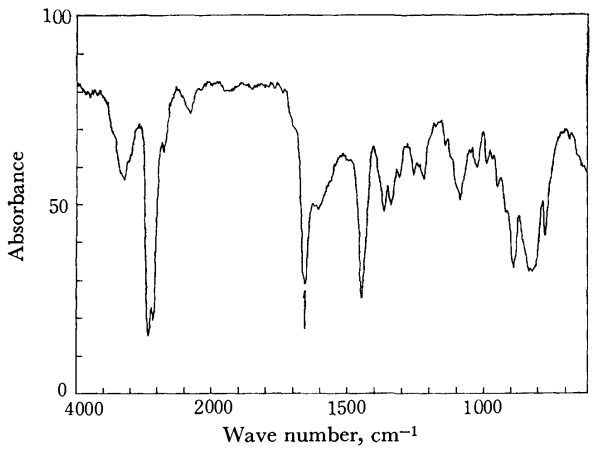

Fig. 9. Infrared spectra of the liquid products obtained by dehydrogenating cyclohexylamine in the presence of the Zn-L catalyst.

Thus, it was suspected that the dehydrogenation product (V) was *N*-cyclohexylidencyclohexylamine, which had been obtained by Pasek *et al.*[8] in the cyclohexylamine decomposition over alumina. To confirm this suspicion, *N*-cyclohexylidencyclohexylamine was prepared by the procedure reported by Pasek *et al.*[8] and properties of this compound were compared with those of the dehydrogenation product. That is, the reaction product (V′) of the following reaction:

was isolated by means of distillation in a nitrogen stream at a pressure of 20 mmHg. Further, the dehydrogenation product (V) was also isolated by distillation. Then, the properties of V′ and V were compared. The results were as follows; i) both V′ and V crystallized at a given temperature of 26°C and boiled at 132°C (20 mmHg), and ii) the gas-chromatographic retention time[9] of V agreed well with that of V′. These facts indicate that the dehydrogenation product (V) is *N*-cyclohexylidencyclohexylamine. Considering these facts, the over-all reaction may be expressed as follows;

(1)

In the present work, the reaction (1) was assumed to be the main reaction and the conversion of cyclohexylamine was calculated on the base of this scheme. The results are given in Fig. 10.

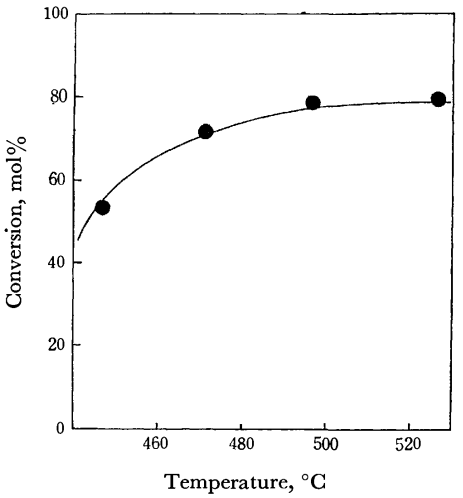

Fig. 10. The temperature dependency of the catalytic activity of the Zn-L catalyst for the dehydrogenation of cyclohexylamine. (Zn 50 g, Feed 0.072 mol/hr).

Presumably, the primary reaction is a dehydrogenation of cyclohexylamine to ketimine, *i.e.*, $C_6H_{10}NH$ (VI). However, because of the high reactivity of this compound, a further reaction between this compound and cyclohexylamine occurs. Therefore, it is not unlikely that the compound (VI) was not detected.

8) J. Pasek, J. Tyrpekl, and M. Machova, *Collect. Czech. Chem. Commun.*, **31**, 4108 (1966).

9) Except for the temperature (135°C), the conditions of the gas-chromatographic analysis were identical with those described in the foot note of the previous section.

Summary

The present work has demonstrated that some liquid metals catalyze the dehydrogenation of amine. Especially, the high activity and the high selectivity of the Zn–L catalyst must be noted. The dehydrogenation of amine by solid catalysts has been said to be difficult,[5] and it has been considered that specially-prepared catalysts[10] are necessary for the selective dehydrogenation of amine. On the contrary, the liquid metal catalysts can be prepared without difficulty. Therefore, the use of the liquid-metal catalyst seems to give a useful tool not only for a scientific study of the dehydrogenation of amine, but also for the industrial dehydrogenation of amine.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 73—77(1972)

Interaction between Phenothiazine Triplet State with Several Electron Acceptors

Teiki IWAOKA, Hiroshi KOKUBUN, and Masao KOIZUMI
Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai

(Received June 14, 1971)

As an extension of the previous paper (This Bulletin, **44**, 341 (1971)) which proposed the formation of a certain charge transfer complex between triplet phenothiazine (PTH^T) and oxygen or dimethylisophthalate, the similar donor-acceptor interaction has been studied between PTH^T and several other acceptors such as dimethylterephthalate (DMTP), nitrobenzene, dinitrobenzene, and terephthalonitrile in deaerated ethanol solutions. In case of DMTP, studies have been made also in cyclohexane. It has been established that all the acceptors except nitrobenzene attack PTH^T with the diffusion controlled rate constant and that in ethanol they give rise to free radical ions and/or solvent shared ion-pair. In cyclohexane, however, no transient species other than triplet has been detected.

Donor and acceptor interaction in the singlet excited state of aromatic compounds has been studied extensively since the discovery of exciplex by Leonhardt and Weller.[1] But very few researches have been reported on the analogous phenomena related with the triplet states of aromatic compounds. As far as we know, Beens and Weller's work[2] on the formation of C-T complex between the triplet state of pyrene and terephthalonitrile, is the only one so far reported. One reason why such investigations are few may be due to the higher ionization potential of the triplet state as compared with that of the singlet excited state, which makes it difficult for such an interaction to occur specifically in the triplet state but not in the ground state. It is expected that for the interaction analogous to the exciplex formation to occur in the triplet state, the ionization potential of donor should be very low or the singlet and triplet energy difference is small. Indeed it has been reported that in some dyestuffs for which S*- and T-levels are close with each other, reactions such as $D^T+D \longrightarrow D^+ + D^-$ or $D^+ + O_2 \longrightarrow D^+ \cdots O_2^-$ really occur.[3]

In the previous paper,[4] we have found that the triplet state of phenothiazine (PTH) with a low ionization potential of 6.9 eV[5] interacts with weak electron acceptors such as oxygen and dimethylisophthalate and forms transiently a certain type of C-T complex. In case of oxygen, an ultimate product was a neutral radical of PTH while the initial compounds were recovered in case of dimethylisophthalate. This paper reports the interaction of triplet PTH with several other electron acceptors.

Experimental

Materials. Dimethylterephthalate was recrystallized three times from G. R. grade ethanol. Nitrobenzene of G. R. grade from Wako Junyaku was used without further purification. *p*-Dinitrobenzene was recrystallized twice from G. R. grade ethanol. Terephthalonitrile was recrystallized from methanol and was sublimed *in vacuo*. Cyclohexane of E. P. grade of Wako Junyaku was shaken with the mixture of fuming sulfuric acid and conc. sulfuric acid (1:1) six times, washed with the aqueous solution of potassium permanganate and then shaken with the aqueous NaOH solution three times. After being washed with water five times, it was kept in contact with metallic sodium for one day and then distilled over sodium metal renewed.

Procedures. Apparatus and procedures for the flash experiment are the usual ones employed in our laboratory. A suitable combination of filters (plate glass, Toshiba-glass filters, UVD-25, VB-40, VB-48, PV-43, *etc.*) was used in the flash apparatus in order to excite only phenothiazine.

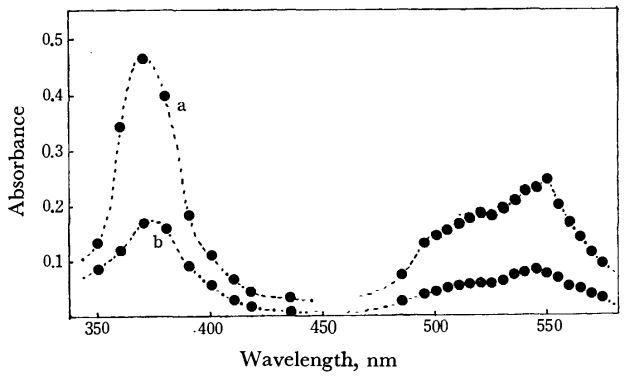

Fig. 1. Transient absorption spectra obtained upon flashing the degassed ethanol solutions of PTH-DMTP;
[PTH]=8.0×10^{-5}M, [DMTP]=1×10^{-4}M
a, immediately after flashing
b, 300 μsec after flashing

Results and Discussion

Interaction between PTH^T and Dimethylterephthalate (DMTP). The electron affinity of DMPT is expected to be a little larger than that of dimethylisophthalate. Figure 1 shows the transient spectrum when the degassed ethanol solution of DMTP (1×10^{-4}M) and PTH (8×10^{-5}M) is flashed. The spectrum resembels that of DMTP radical anion produced when the tetrahydrofuran solution of DMTP is treated with sodium.[6] A little swell in the region 500~520 nm might be due to the PTH cation which should be produced simultaneously. It may be due to the small absorbance that the radical cation is not clearly discerned. The spectrum in Fig. 1 strongly suggests that contrary to dimethylisophthalate, the free radical ion or solvent-shared ion-pair is produced in this system. The decay of the absorbance at 550 nm is of the first order with the same rate constant independent of the DMTP concentration at least when the concentration is lower than 1.0×10^{-5}M. However in case that [DMTP] is 2.5×10^{-5}M or 1.0×10^{-4}M, the early part of the decay is appreciably larger though the latter part decays almost with the same rate constant as that in the lower concentration of DMTP. Table 1 gives the decay constants for the later stage at various DMTP concentrations. Figure 2 shows the change of absorbance with time at different DMTP concentrations. In spite of such situations in the decay curves, the transient spectra in the early and later stages practically coincide, which suggest strongly the coexistence of the free radical ions and the solvent-shared ion-pair. It is reasonable that the latter decays as the first order while the former does in the second order, and the second order decay becomes negligible as the concentration of free ion becomes low.

Table 1. First order decay constants (at the later stage) of the intermediate at various DMTP concentrations (sec^{-1})

[DMTP]	Wavelength, nm		
	380	555	470
1×10^{-4}	3.1×10^{3}	2.2×10^{3}	
2.5×10^{-5}		2.6×10^{3}	2.9×10^{3}
1.0×10^{-5}		2.3×10^{3}	
5.0×10^{-6}	2.6×10^{3}	2.8×10^{3}	2.8×10^{3}
2.5×10^{-6}		2.5×10^{3}	
7.0×10^{-7}		3.1×10^{3}	

6) T. Kowata and M. Koizumi, This Bulletin, **42**, 3352 (1969).

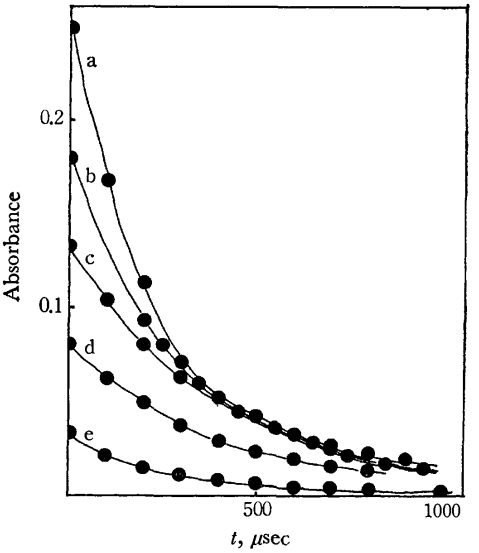

Fig. 2. Change of transient absorption with time at different DMTP concentrations observed at 550 nm.
[PTH]=8.0×10^{-5}M
DMTP concentartion is as follows:
a, 1.0×10^{-4}M b, 2.5×10^{-5}M c, 1.0×10^{-5}M
d, 2.5×10^{-6}M e, 7.5×10^{-7}M

Figure 3 shows the decay of T–T absorption and the rise of absorption at 550 nm. It is clearly seen that these processes occur simultaneously, and this suggests that the 550 nm species is mainly produced from the interaction of triplet PTH and DMTP. Figure 4 gives the decay constant of PTH^T as a function of [DMTP]. From the slope, the rate constant for PTH^T+DMTP $\xrightarrow{k_1}$ is evaluated as $1.4\times10^{9}M^{-1}sec^{-1}$. Figure 5 shows the absorbance at 550 nm immediately after flashing, which is the measure of the yield of transient species, plotted against [DMTP].

Assuming the following scheme

$$^3PTH + DMTP \xrightarrow{k_r} (PTH^+\cdots DMTP^-)$$

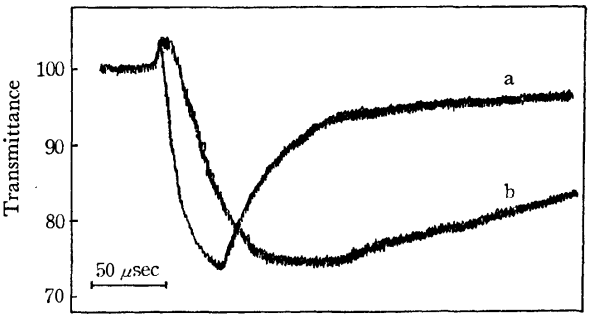

Fig. 3. Change in the transmittance at 470 nm and 550 nm on oscilloscope.
a, 470 nm b, 550 nm

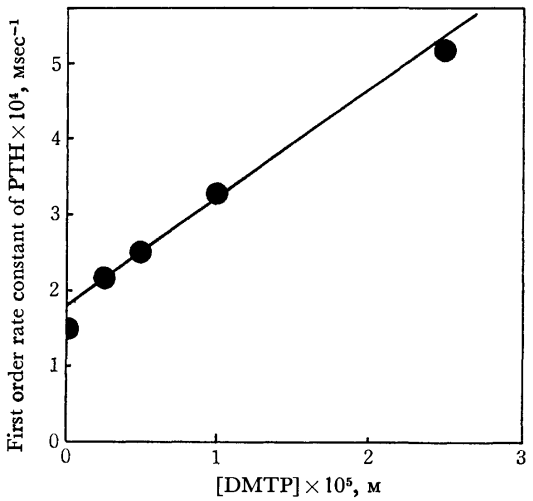

Fig. 4. Dependence of the apparent first order rate constant of phenothiazine triplet state upon the concentration of dimethylterephthalate.
[PTH]=8.0×10⁻⁵M

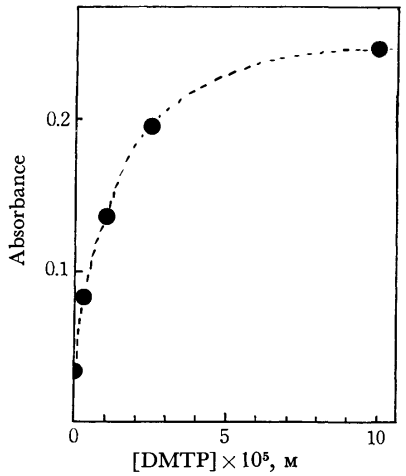

Fig. 5. Plot of the absorbance at 550 nm, immediately after flashing against [DMTP].

$$^3\text{PTH} + \text{DMTP} \xrightarrow{k_q} \text{PTH} + \text{DMTP}$$

$$^3\text{PTH} \xrightarrow{k_d} \text{PTH}$$

and by taking into account the constancy of [PTH] and the flash intensity, the following relation can easily be derived.

$$[\text{PTH}^+\cdots\text{DMTP}^-] = [^3\text{PTH}] \times \frac{k_r[\text{DMTP}]}{k_d + (k_r + k_q)[\text{DMTP}]}$$

If the above scheme holds, the plot $1/[\text{PTH}^+\cdots\text{DMTP}^-]$ *vs.* $1/[\text{DMTP}]$ should be linear. Figure 6 shows that this holds very satisfactorily.

In case of cyclohexane used as a nonpolar solvent, no transient spectrum other than T–T absorption is observable. The decay of T–T absorption increases with the increase in [DMTP] as shown in Fig. 7. From this plot, the rate constant k_1 for $^3\text{PTH}+\text{DMTP} \xrightarrow[\text{in } C_6H_{12}]{k_1}$ is evaluated as $k_1 = 1.3\times10^9\,\text{M}^{-1}\text{sec}^{-1}$.

Interaction of Nitrobenzene and p-*Dinitrobenzene with PTH*^{T}. The addition of 1×10^{-4}M of nitrobenzene

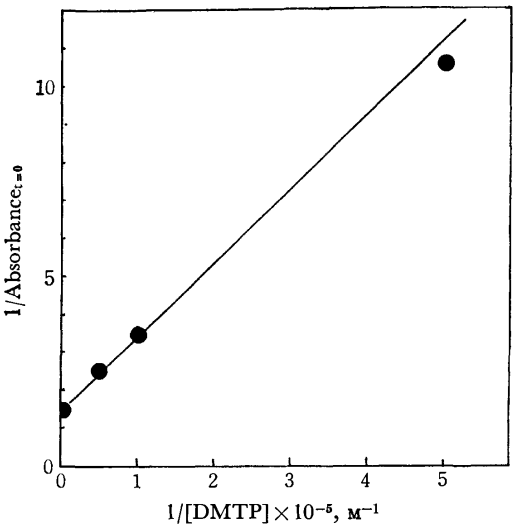

Fig. 6. Plot of 1/Absorbance (at 550nm)$_{t=0}$ against 1/[DMTP].
[PTH]=8.0×10⁻⁵M

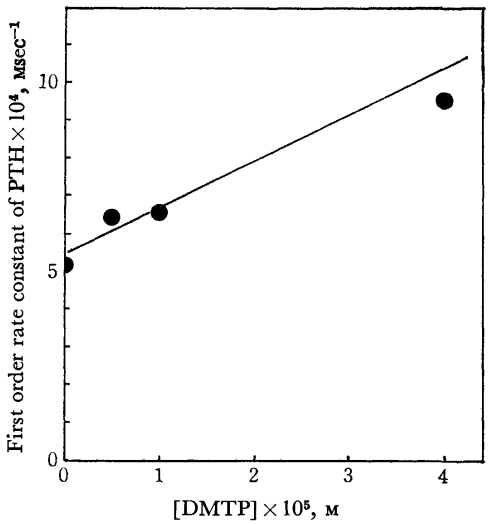

Fig. 7. Dependence of the decay rate of phenothiazine triplet state upon the concentration of dimethylterephthalate in cyclohexane. [PTH]=8.0×10⁻⁵M

(NB) to the deaerated ethanol solution of PTH did not affect the yield of T–T absorption of PTH appreciably. There was no other transient species detected. The decay constant of PTH^T was $4—5\times10^4\,\text{M}^{-1}\text{sec}^{-1}$ as compared with 1.5×10^4 in the absence of NB. Hence the rate constant k_1 for $\text{PTH}^T+\text{NB}\longrightarrow\text{PTH}+\text{NB}$ is estimated to be $\lesssim10^8\,\text{M}^{-1}\text{sec}^{-1}$.

In case of 10^{-2}M *p*-dinitrobenzene (DNB), the strongest acceptor in our experiment,[7] no T–T absorption was observed and the transient spectrum perhaps due to radical cation (PTH^+) was observed in addition to the absorption of radical anion (DNB^-). For 10^{-6}M—10^{-5}M DBN, only the absorption of anion

7) Electron affinity of DNB is estimated to be about 1.7 eV according to R. Foster and P. Hanson, *Biochem. Biophys. Acta*, **112**, 482 (1966). Judging from the absorption spectrum, it is plausible that C-T complex is formed already in the ground state.

radical (DNB^-) was obtained as shown in Fig. 8.[8] It decays according to second order from initial to final, which suggests its existence as free radical anion. Figure 9 shows the dependence of triplet decay upon the DNB concentration. The rate constant k_r for $PTH^T + DNB \xrightarrow{k_r}$ was estimated to be $1.7 \times 10^9 M^{-1}sec$. Dependence of the absorption of DNB anion radical at 630 nm on the concentration of triplet PTH clearly showed the formation of the former by the reaction between DNB and PTH^T.

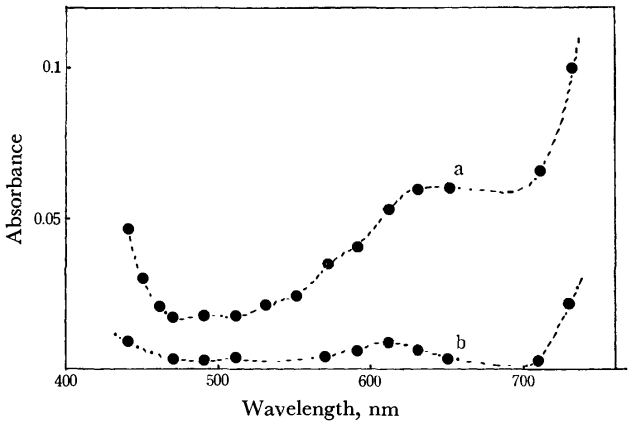

Fig. 8. Transient absorption spectra obtained upon flashing the degassed ethanol solutions of PTH-DNB.
[PTH] $=8.0 \times 10^{-5}$ M, [DNB] $=3 \times 10^{-5}$ M
a, immediately after flashing

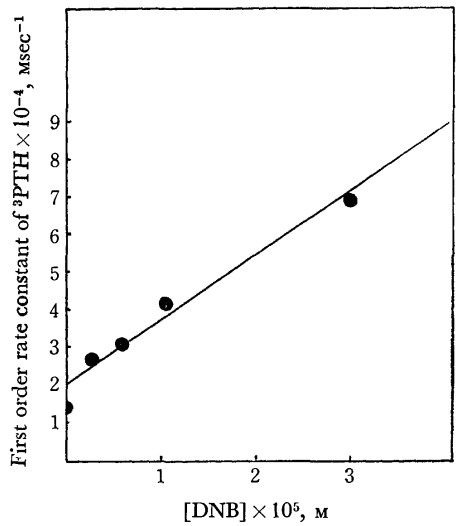

Fig. 9. Dependence of the apparent first order rate constant of phenothiazine triplet state upon the concentration of dinitrobenzene. [PTH] $=8.0 \times 10^{-5}$ M

Interaction of Terephthalonitrile (TPN) with PTH^T. Figure 10 shows the transient spectra of ethanol solutions of 1×10^{-5} M PTH containing TPN of two different concentrations. A short-lived absorption at

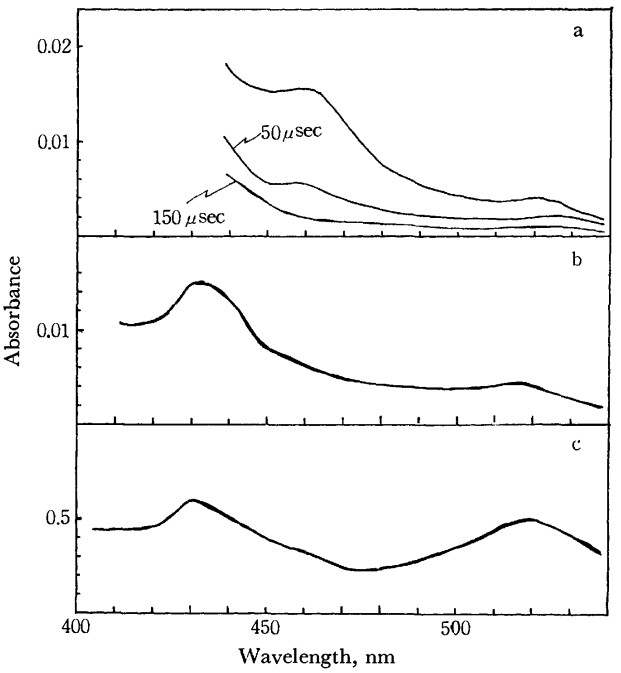

Fig. 10. Transient absorption spectra obtained upon flashing the degassed ethanol solutions of PTH-TPN.
[PTH] $=8.0 \times 10^{-5}$ M
a, [TPN] $=1.0 \times 10^{-5}$ M b, [TPN] $=1.0 \times 10^{-4}$ M
c, Spectrum of the anion radical of terephthalonitrile in tetrahydrofuran.[9]

450—460 nm in Fig. 10a is due without doubt to T–T absorption. In case [TPN] is 1.0×10^{-4} M, T–T absorption does not appear, as shown in Fig. 10b. Figure 10c is the spectrum of $TPN^{\cdot -}$ in tetrahydrofuran obtained by sodium-treatment, as reported by Ishitani and Nagakura.[9] The relative peak height at 430 nm in Fig. 10b is appreciably larger than in Fig. 10c. This suggests the superposition of another species in this region.[10] It was really found that the decay at

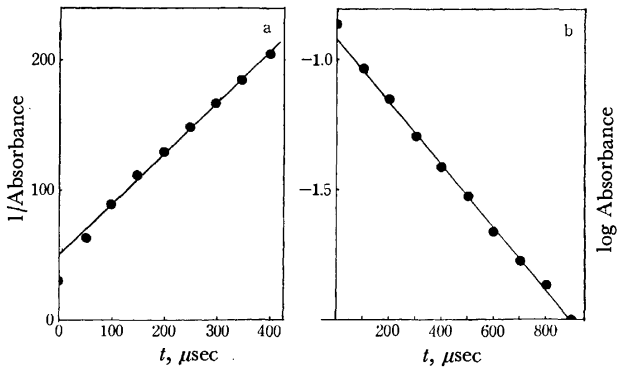

Fig. 11. Second order decay at 520 nm (free TPN^-) and first order decay at 430 nm ($PTH^+ - TPN^-$).
a, 520 nm b, 430 nm

8) According to the referee's unpublished result, the absorption spectrum of DNB radical anion has no peak at ~610 nm clearly seen on curve b. In fact there is no sign of its existence on curve a. The 610 nm peak might be due to some unknown by-product produced secondarily from DNB radical anion.

9) A. Ishitani and S. Nagakura, *Theor. Chim. Acta*, **4**, 236 (1966).

10) According to the referee, TPN radical anion has no absorption in the wavelength region longer than 500 nm only having a peak at ~430 nm; he attributes the peak at 520 nm reported in Ref. 9 to some unknown by-product. If this is true, the peak in question observed in Fig. 10b may be due to the phenothiazine radical cation.

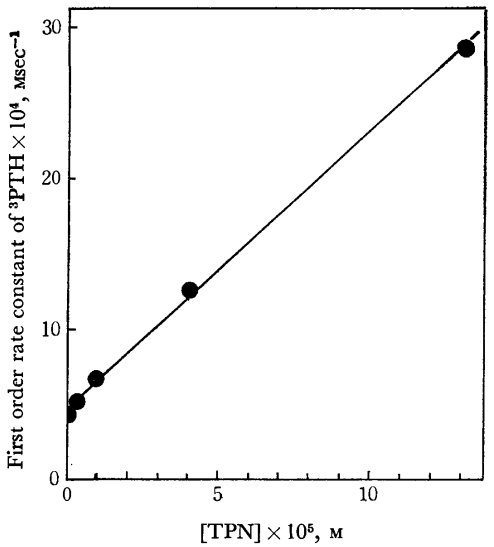

Fig. 12. Dependence of the apparent first order rate constant of phenothiazine triplet state upon the concentration of terephthalonitrile; [PTH] $=8.0 \times 10^{-5}$M.

520 nm in Fig. 10b is of second order as indicated in Fig. 11a and the peak may be attributed to the free TPN^-. The decay at 430 nm on the other hand, obeys the first order as shown in Fig. 11b, and is independent of [TPN]. It is reasonable to consider that free radical ion and the solvent shared ion-pair are produced simultaneously and decay rather independently with each other.

As shown in Fig. 12, the decay of T–T absorption is linearly related with [TPN], and from the slope the rate constant for $PTH^T + TPN \longrightarrow$ is evaluated as $2.0 \times 10^9 M^{-1}sec^{-1}$.

General Discussion. Although the results of the present investigation are still preliminary, we can draw some conclusions from them. First, the electron acceptors with the values of electron affinity larger than 0.7—0.9 eV quench the triplet PTH with almost the rate constant controlled by diffusion irrespective of the solvent polarity. Secondly, the molecular mechanism for triplet quenching is not the T–T energy transfer, because the T-levels of all the present acceptors are higher than that of PTH. It is due, as verified in the present investigation, to various types of donor-acceptor interaction.

In non-polar solvents no transient species other than triplet are observable. Perhaps transient species produced has too short a life time as to be captured by the ordinary flash technique. In polar solvents formations of C-T complex, ion-pair, and the free ions depend on the electron affinity of the acceptor and on the solvent polarity. However, the detailed feature of these donor-acceptor interaction in the triplet state phenothiazine awaits further systematic studies.

Thanks are due to the referee's presentation of his unpublished absorption spectra of DNB and TPN radical anions.

Transient Species Obtained by the Flash Photolysis of Chloranil in Various Solutions

Kiyoshi KAWAI,* Yasuhiko SHIROTA,** Hiroshi TSUBOMURA,*** and Hiroshi MIKAWA**

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received June 17, 1971)

Transient absorption spectra have been obtained by the flash photolysis of chloranil in various organic solvents. In trichlorotrifluoroethane, two T-T′ absorption systems of chloranil were obtained with well-resolved vibrational structures. In tetrahydrofuran, on the other hand, absorption spectra mostly consist of semiquinone radical formed by the hydrogen abstraction from solvent. In benzene and in acetone, the first T-T′ absorption system was much more diffuse and was accompanied by a weak, broad absorption at longer wavelength ($\lambda >$ 550 nm) which might be assigned to a charge transfer absorption from triplet chloranil as acceptor and the solvent molecule as donor. In acetone and in methanol, it has also been found that there is an equilibrium between semiquinone radical and semiquinone anion.

Porter and his co-workers obtained transient absorption spectra by the flash photolysis of quinones and assigned them to semiquinone radicals, semiquinone anions, and relatively short-lived triplet quinones (quinones in the lowest triplet state).[1] Recently, Kemp and Porter[2] illuminated a degassed ethanol solution of chloranil with a nitrogen laser and obtained the transient absorption spectrum of triplet chloranil with a maximum at about 500 nm. The triplet chloranil is expected to have a larger electron affinity than in

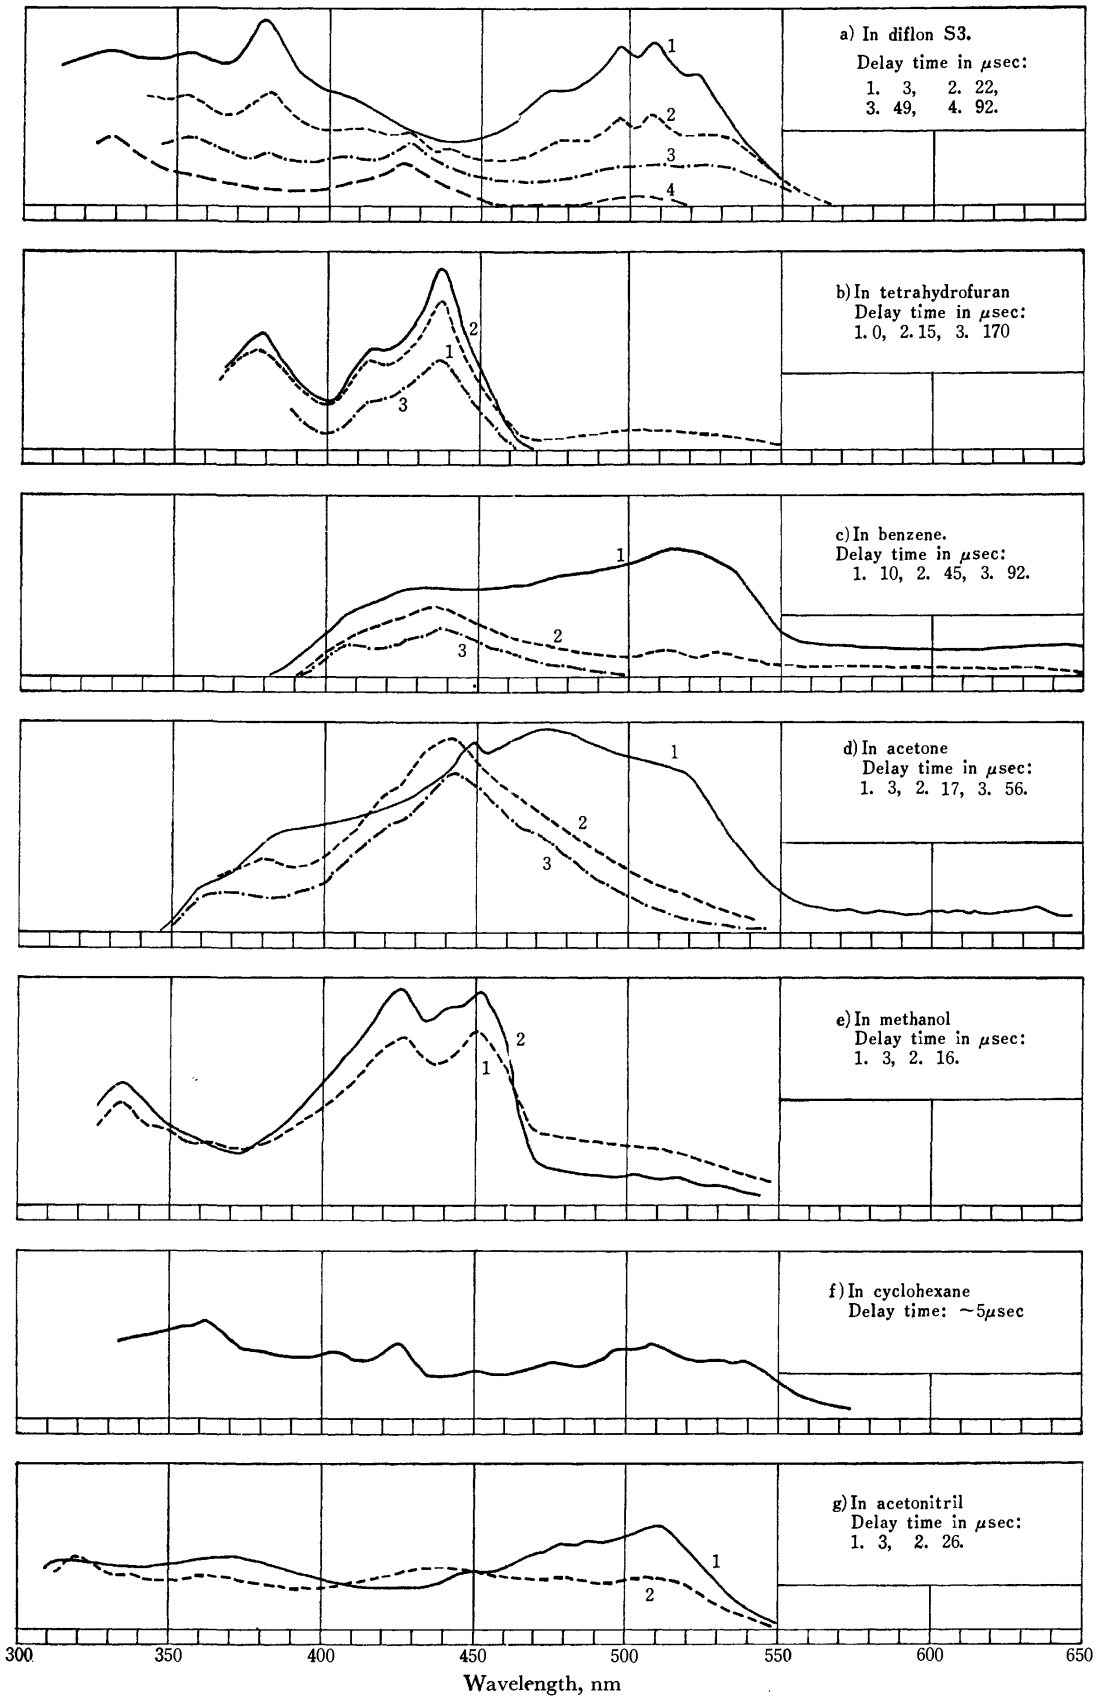

Fig. 1. Absorption spectra of transient species obtained by the flash photolysis of chloranil in various solvents.

the ground state, and might have specific interactions with solvents having electron-donating properties. We have carried out detailed investigations on the T-T′ spectra of chloranil using various solvents in order to obtain evidence on any such donor-acceptor interactions, and also on the chemical properties of semiquinones formed photo-chemically.

Experimental

Materials. Chloranil was purified by recrystallization from benzene, passing through a calcium carbonate column, and further recrystallization from benzene. Trichlorotrifluoroethane (Diflon S3), a commercial product from Daikin Kogyo Co., Ltd. and which may be a mixture of isomers, was shaken with sulfuric acid, neutralized, dried with calcium chloride and distilled with a Widmer column. Acetone was refluxed with potassium permanganate for half a day, dried with calcium sulfate and distilled. Tetrahydrofuran was refluxed overnight with potassium hydroxide, distilled, refluxed with sodium wire again and then distilled. Benzene was shaken with sulfuric acid, neutralized, dried with calcium chloride, refluxed with sodium wire and then distilled with a Widmer column. Methanol was refluxed overnight on sodium wire and then distilled. Acetonitrile was purified by passing through an alumina column, refluxed with calcium hydride and then distilled.

Methods. Concentrations of the solutions of chloranil used in the experiment were mostly in the range $1—3\times 10^{-4}$M. Solutions were bubbled with highly purified nitrogen gas so as to purge dissolved oxygen, and then poured in a cylindrical silica cell 1.5 cm in diameter and 20 cm in length. The apparatus used for the flash spectroscopic measurements is mostly the same as that described in an earlier paper.[3]

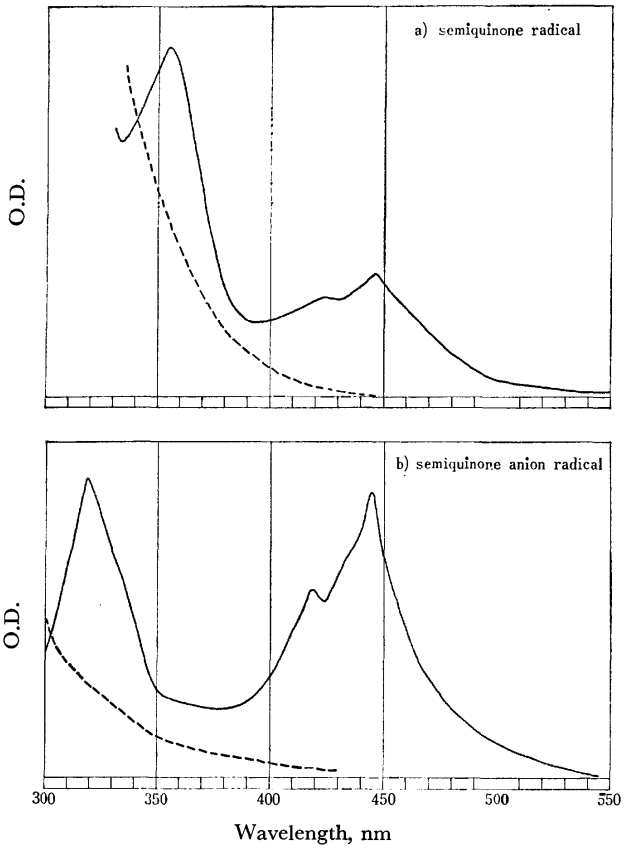

Fig. 2. Absorption spectra of the semiquinone radical and semiquinone anion chemically produced from chloranil.
a) ------ Absorption of chloranil in α-methyltetrahydrofuran at 77°K.
—— The same, after irradiation with a high pressure mercury lamp.
b) ------ Absorption of chloranil in degassed tetrahydrofuran.
—— The same, after contact with sodium-potassium alloy.

Results

The transient spectra obtained by the flash photolysis of chloranil in various solvents are shown in Fig. 1, a)—g). For the sake of comparison, the spectrum of semiquinone radical obtained by the photolysis of chloranil in an α-methyltetrahydrofuran matrix at 77°K is shown in Fig. 2 a), and that of the semiquinone anion obtained by the reduction of chloranil in tetrahydrofuran with sodium-potassium alloy in Fig. 2 b).

The spectra obtained in trichlorotrifluoroethane (Diflon S3) is shown in Fig. 1 a). The solvent was used for the purpose of obtaining pure T-T′ absorption spectrum of chloranil, for it was expected to be inert to excited chloranil, especially with the hydrogen-abstraction reaction. There is a band system at around 500 nm with four apparent vibrational sub-bands at 522, 507, 497, and 473 nm, and a second eminent one with a principal maximum at 379 nm. Both these two systems may be assigned to the T-T′ transitions of chloranil, since they could not be detected in the solution saturated with oxygen. The general characteristics of the first 500 nm system coincide also with those of the T-T′ spectrum reported by Kemp and Porter in an ethanol solution, though the resolution in their spectrum is a little poorer than ours. They did not measure the T-T′ spectrum in the region below 450 nm, while our results give the second system lying below 400 nm. We have also determined the life time of the triplet state (decay of these bands) to be *ca.* 30 μsec.

Besides these T-T′ absorptions, a minor transient band centered at 425 nm was obtained which persists for a longer time than the triplet state. The spectrum is like that of the semiquinone radical mentioned later, and is tentatively assigned to a radical () formed by the abstraction of chlorine atom from the solvent.

The spectra obtained in tetrahydrofuran is shown in Fig. 1 b). The main feature at around 430 nm is quite like that of the first band-system of the semiquinone radical (Fig. 2 a)), though the former is shifted to the blue by about 10 nm. The semiquinone anion radical has a similar band system at the same region. However, the semiquinone radical has a band at 357 nm, while semiquinone anion lacks it. The presence of a band at around 375 nm in the spectra of Fig. 1 b) seems to indicate that the semiquinone radical is the main product formed by flash photolysis. This is also in harmony with the fact that the α-hydrogen of tetrahydrofuran is easily abstracted.[4]

3) N. Yamamoto, Y. Nakato, and H. Tsubomura, This Bulletin, **39**, 2603 (1966).

The weak absorption appearing in the 500 nm region is ascribable to the T-T′ absorption. The absorption decays in a few microseconds, indicating a rapid hydrogen abstraction in the triplet state. It was also found that the semiquinone radical was formed even in an aerated tetrahydrofuran solution (containing oxygen). This indicates that the hydrogen abstraction occurs at least partly at the singlet excited state of chloranil. In aerated ethanol, no semiquinone radical was formed.

The spectra obtained from the flash photolysis of benzene solutions in the range $\lambda>320$ nm are shown in Fig. 1 c). At the delay time of 10 μsec, a broad spectrum was obtained with the principal peak at 516 nm, which is assigned to the first T-T′ system. It decays quickly, and another system ascribable to the semiquinone radical appears at a longer delay time. It is generally believed difficult to abstract a hydrogen atom from benzene. However, our present results have revealed that a hydrogen abstraction can occur from benzene.[5] It is to be noted that the T-T′ spectrum in the case of benzene solution is much more broad and structureless than that in Diflon S3. There is also a broad, weak absorption beyond 550 nm, which decays at nearly the same rate as the triplet state. Transient spectra obtained for a number of solutions containing both benzene and Diflon S3 (Fig. 3) show that the absorption intensity in the 550 to 650 nm region, relative to that of the first T-T′ system, increases obviously with the increase in the benzene content. This seems to indicate strongly that a new absorption system is found which arises from the interaction of benzene and triplet chloranil.

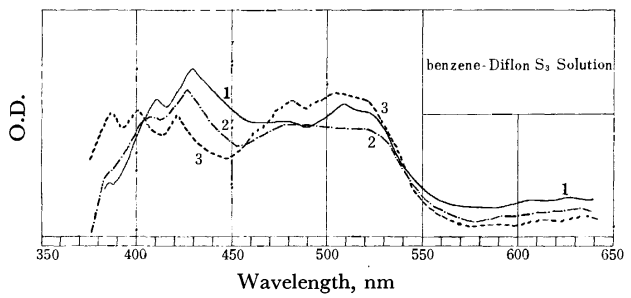

Fig. 3. Absorption spectra of transient species obtained by the flash photolysis of chloranil in a mixture of trichlorotrifluoroethane (Diflon S3) and benzene, at a delay time of 15 μsec. The volume ratio, Diflon S3/benzene for each curve, is given below:
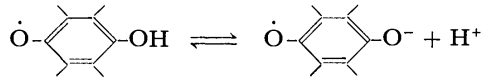
1) 3/7 2) 7/3 3) 9/1

The transient spectra obtained for the acetone solutions is shown in Fig. 1 d). In this case, the flash excitation was carried out in the region $\lambda>330$ nm by use of a combination filter system composed of a glass plate and an aqueous solution of sodium nitrate. Absorption in the region 450—550 nm appearing at the delay time of 3 μsec fades out mostly at 17 μsec and a new system appears at about 440 nm. The former (450—550 nm) may be assigned to the T-T′ spectrum of chloranil from its wavelength and decay time, while the latter does not exactly fit into the spectrum of either semiquinone radical or semiquinone anion but can be explained by assuming that the two species are mixed, indicating that the semiquinone radical formed in the first place by the flash undergoes ionic dissociation and is in the following acid-base equilibrium in acetone.



The situation is quite similar to the photolysis product of hydroquinone in neutral or acid solutions.[6] In the acetone solution, a broad absorption is also found beyond 550 nm, which may most probably be interpreted as an absorption arising from the interaction between triplet chloranil and acetone similar to the case of benzene solutions.

In methanol, the transient spectra (Fig. 1e)) can be interpreted as an assembly of the T-T′ absorption and the absorption by semiquinone radical and semiquinone anion. The bands at 426 and 451 nm decay in the first order kinetics with different decay constants.

The transient spectra obtained in cyclohexane showed bands ascribable to the T-T′ and the semiquinone radical absorption (Fig. 1 f)). Those in acetonitrile show the T-T′ absorption and the absorption mostly ascribable to the semiquinone radical (Fig. 1 g)).

The peak wavelengths of the transient spectra obtained in various solvents and their assignments are summarized in Table 1.

TABLE 1. THE PEAK WAVELENGTHS OF TRANSIENT ABSORPTION SPECTRA OBTAINED BY THE FLASH PHOTOLYSIS OF CHLORANIL IN VARIOUS SOLVENTS IN nm

Transient Species	Triplet Chloranil	Semiquinone Radical	Semiquinone Anion
Diflon S3	522, 507, 497, 473; 410, 379	425	
Cyclohexane	539, 507, 495, 474	425, 403	
Benzene	516	436, 408	
THF	~500	437, 415, 377	
Acetone	520, 503; 471	(441, 420, 365)[a]	
Methanol	~500	426	451
Acetonitril	510, 487, 479; 372	(440, 319)[a]	

a) Strongly overlapped.

Discussion

From the results, a considerable influence of solvents can be seen on the first T-T′ system in various solvents, especially in such electron-donating solvents as benzene and acetone. In these solvents, the first T-T′ system is much more diffuse than others. It is of particular interest that there are broad absorptions in the range $\lambda>$ 550 nm, which seem to be charge transfer bands with the solvent molecule as donor and triplet chloranil as

4) It is suggested that the discrepancy between the peak wavelength of the first band system in Fig. 2 a) and that in Fig. 1 b) may be attributed to differences in solvent and temperature.

5) Rubin *et al.* reported a hydrogen abstraction reaction from benzene by excited phenanthraquinone. M. B. Rubin and Z. Neuwirth-Weiss, *Chem. Commun.*, **1968**, 1607.

6) K. Kimura, K. Yoshinaga, and H. Tsubomura, *J. Phys. Chem.*, **71**, 4485 (1967).

acceptor. Quite independently, Briegleb and Schuster recently reported a few cases of absorption spectra of triplet pyromellitic dianhydride at 77°K showing similar bands and assigned them to charge transfer absorption from solvent to triplet pyromellitic dianhydride.[7]

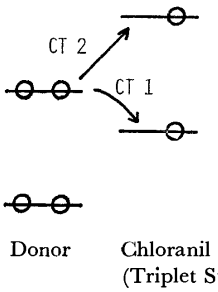


Fig. 4. Diagram indicating charge transfer between donor and triplet chloranil.

It is a delicate problem to determined whether the lowest triplet state of chloranil is (n-π^*) or (π-π^*). Shcheglova *et al.* found an emission spectrum from chloranil in a hexane (9 vol)-toluene (1 vol) solution and concluded that it arises from the lowest triplet (π-π^*) state at 17200 cm^{-1} above the ground state,[8] where π and π^* are the highest filled and lowest vacant π-MO, respectively. Thus, a charge transfer can occur from the highest filled MO of the donor (solvent) to the π-MO of chloranil, leading to a charge transfer band at very long wavelength regions (CT 1 in Fig. 4). The transition energy for a charge transfer absorption can be given approximately by the equation

$$h\nu_{CT} = I_D - E_A - e^2/r_{DA} + \Delta, \quad (1)$$

where I_D and E_A are the ionization energy of donor and the electron affinity of acceptor, r_{DA} is the distance between donor and acceptor, and Δ is a term collecting all other minor contributions. For an ordinary benzene-chloranil complex, the charge transfer band has $\lambda_{max}=$ 335 nm, which corresponds to $h\nu_{CT}$ of 3.7 eV.[9] The electron affinity of chloranil in the lowest triplet state can be given by

$$E_A{}^T = E_A + W_T - W_G$$

where W_T and W_G are the energies of the triplet and ground state, respectively. Using the value derived by Shcheglova (17200 cm^{-1}=2.1 eV), we obtain for the complex between benzene and triplet chloranil

$$h\nu'_{CT} = I_D - E_A - (W_T - W_G) - e^2/r_{DA} + \Delta, \quad (2)$$

If it is assumed that r_{DA} and Δ are the same for both complexes, then from (1) and (2), we obtain

$$h\nu'_{CT} = 1.6\ eV \equiv 780\ nm.$$

This value seems to be in harmony with our experimental result, especially when one takes account of the resonance splitting between the upper and lower states which seems to be somewhat larger than the splitting for the ordinary chloranil-benzene complex. But further investigations seem to be necessary for the elucidation of the nature of the lowest triplet state of chloranil, and the weak, long-wavelength absorption found in the present work.

Partial Pressures of Strontium and Strontium Oxide over Strontium Oxide Heated on Platinum

Mitsuru ASANO, Yutaka YAMAMOTO, Noriaki SASAKI, and Kenji KUBO

Institute of Atomic Energy, Kyoto University, Uji, Kyoto

(Received June 18, 1971)

A quadrupole mass filter was used to determine the partial pressures of Sr(g) and SrO(g) over strontium oxide heated on a platinum-ribbon filament. The ion currents of $^{88}Sr^+$ and $^{88}Sr^{16}O^+$ were measured while the filament temperature was continuously increasing at a heating rate of about 14°C/min; the calculations of the partial pressures were carried out by the integral method for Sr(g) and by the sensitivity-calibration method for SrO(g). The data are represented by:

$$\log P_{Sr(g)}(\text{atm}) = 6.633 - \frac{2.536\times 10^4}{T}$$

in the temperature range of 1643—1851°K, and by:

$$\log P_{SrO(g)}(\text{atm}) = 6.707 - \frac{2.793\times 10^4}{T}$$

in the 1747—1850°K range. From the values of the partial pressures, the dissociation energy of strontium oxide was determined to be $D_0°(SrO)=96.2\pm 0.9$ kcal/mol by the third-law treatment and $D_0°(SrO)=102\pm 5$ kcal/mol by the second-law treatment.

Many studies have been carried out on the nature of vapor species from strontium oxide heated on various materials, such as platinum,[1-3] tungsten,[4-5] molybdenum,[4] and alumina.[7] Using mass-spectrometric techniques, Aldrich,[1] Bickel and Holroyd,[2] and Pelchowitch[3] have observed that, in the strontium oxide-platinum system, the main vaporization products are free strontium atom, plus small amounts of the strontium oxide molecules, and that no reactions occur between strontium oxide and platinum. However, the partial pressures of Sr(g) and SrO(g) could not be determined, since no sensitivity calibration of their mass spectrometers was done. Drowart *et al.*[4,5] have measured the relative ion intensities of the vapor products produced by the reactions of alkaline earth oxides with a tungsten Knudsen cell or molybdenum cell, and determined the dissociation energy of alkaline earth oxides and the stabilities of the gaseous tungstates, tungstites, molybdates, and molybdites of alkaline earths. Recently, the present authors[6] measured the partial pressures of Sr(g), SrO(g), $SrWO_4$(g), and $SrWO_3$(g) over the solid products produced by the reactions between strontium oxide and a tungsten-ribbon filament. Porter *et al.*[7] also measured the partial pressure of SrO(g) in equilibrium with the solid placed in an alumina Knudsen cell only at the temperature of 2100°K.

Hitherto, the vapor pressure over strontium oxide heated on a platinum filament have all[8,9] been determined on the assumption that SrO(g) is the only gaseous species, although experimental evidence to justify this assumption has never been published.

In the present work, a quadrupole mass filter was used to determine the partial pressures of Sr(g) and SrO(g) over strontium oxide heated on a platinum-ribbon filament. The ion currents of $^{88}Sr^+$ and $^{88}Sr^{16}O^+$ were measured while the filament temperature was continuously increasing at a constant rate; the partial pressures were calculated by the integral method for Sr(g) and by the sensitivity-calibration method for SrO(g). Moreover, from the values of the partial pressures, the dissociation energy of strontium oxide was determined by third-law and second-law treatments.

In a conventional integral method,[10] the ion currents are ordinarily measured at a fixed temperature or by varying the temperature step by step for a proper interval, while in the present work the currents were measured under the above conditions, since the measurements were carried out with a very small sample.

The vaporization of strontium oxide supported on various materials is of interest in the physics and chemistry concerned with the phenomena of the thermal emissions of electrons and ions.

Experimental

The platinum-ribbon filament used to hold the strontium oxide was 0.75 mm wide and 0.025 mm thick (H. Cross. Co.) and was kept straight with the aid of a tungsten spring, even at high temperatures.

Strontium nitrate was used to prepare strontium oxide on the filament. Reagent-grade strontium nitrate was

purified by the carbonate method and was crystallized out from a nitrate solution. Using a micro syringe, 1 μl of strontium nitrate solution containing 20.30 μg of strontium was placed on the central part of the filament for a length of about 3 mm and dried under an infrared lamp. After it had then been set in a vacuum chamber, the filament was slowly heated by an externally-programmed DC power supply driven by a motor of an adjustable speed; the strontium nitrate was thus thermally decomposed to strontium oxide. Then, the filament was further heated at a rate of about 14°C/min, and the partial pressures of the gaseous species vaporized from the strontium oxide on the platinum filament were measured by means of a NEVA NAG 510H quadrupole mass filter equipped with a secondary electron multiplier.

A collimated gaseous beam originating from strontium oxide was ionized in an ionization chamber by low-energy electrons (13 eV), so the fragmentation of SrO(g) to Sr^+ and O was assumed to be negligible.

The filament holder was devised so as to move back and forth; this mechanism was used as a shutter.

A schematic diagram of the arrangement of the experimental apparatus is shown in Fig. 1.

The filament temperature was measured with a Leed and Northrup 8632C optical pyrometer by sighting the back side of the filament, on which strontium oxide was applied, through a prism; the readings were corrected for the emissivity of the platinum filament and the transmission coefficients of the prism and the glass window of the vacuum chamber. If an appreciable thermal gradient existed throughout the sample, the results might be seriously in error. Under the present conditions, however, the error seems to be negligible because of the very small sample.

The background pressure in a vacuum chamber was maintained at less than 2×10^{-8} Torr with an ion pump during all the experiments.

The basic data of the present work are the ion-current measurements of $^{88}Sr^+$ and $^{88}Sr^{16}O^+$ made with a continuosly-increasing temperature at a heating rate of about 14°C/min. The upper temperature limit was dictated by the amount of the sample, and the lower limit, by the ion-detection ability of the mass filter.

The resolution of a quadrupole mass filter varies automatically throughout mass scanning, so that the sensitivity varies with the mass number. The mass filter used in this study was designed to maintain a constant relation between sensitivity and resolution. Consequently, for a given resolution, the ion current is quantitatively proportional to the number of ionizable gaseous atoms. To obtain this relation, the ion currents of the M/e=28, 44, 71, 85, and 109 peaks were measured as a function of the resolution. The resolution is here defined as $M/\Delta M$, where M is the mass number and where ΔM is the half-width of the ion peak in amu. The relations for the five ion species are shown in Fig. 2, where the slopes are constant. In the present work, the resolution was kept high enough to measure the ion currents of Sr^+ and SrO^+, usually higher than 130.

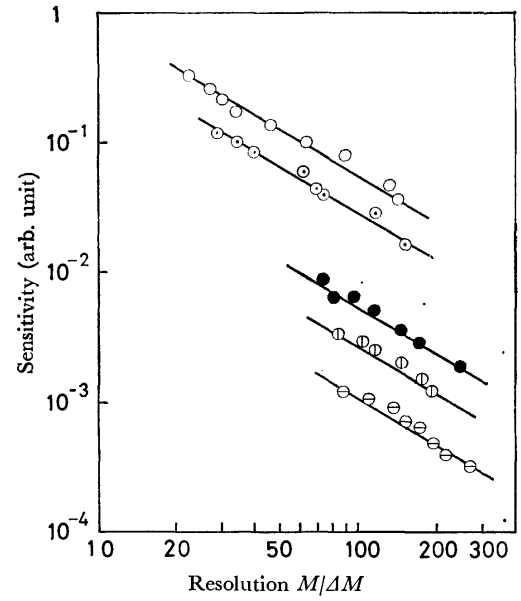

Fig. 2. Relation between sensitivity and resolution. M/e= 28 ⊙, 44 ○, 71 ●, 85 ◑, and 109 ⊖.

The background ions of the same mass number as the interesting species resulted from the residual gases in a vacuum chamber. However, the effect of the background was practically negligible at higher temperatures, since the ion intensities of Sr^+ and SrO^+ were much greater than the residual gas ions.

Method for Determining Partial Pressures

The determination of the vapor pressures of solid materials with a mass spectrometer has been carried out by two methods, namely, the sensitivity-calibration method[10–12] and the integral method.[10,11] In the

11) W. A. Chupka and M. G. Inghram, *J. Phys. Chem.*, **59**, 100 (1955).
12) J. Drowart, G. DeMaria, R. P. Burns, and M. G. Inghram, *J. Chem. Phys.*, **32**, 1366 (1960).

latter method, a known amount of sample is completely vaporized out and the ion intensity is integrated over the period of time required to vaporize the entire sample. Knowing the whole amount of sample vaporized and making use of the vaporization equation, the vapor pressure of the sample is calculated. The modified integral method was used to calculate the partial pressure of Sr(g).

The total number of gaseous atoms (or molecules), z_{tot}, vaporized from the sample is given by:

$$z_{tot} = a\int_0^{t_{end}} z\mathrm{d}t \tag{1}$$

where z is the number of gaseous atoms vaporized per unit of time per unit of area, where a is the vaporization area, and where t_{end} is the time after which the sample is completely vaporized out. The ion current, I^+, is given by the following relation:

$$I^+ = C\frac{(E-I)\sigma\gamma S_1 S_2}{\bar{v}}z \tag{2}$$

where C is the factor for instrument geometry, E is the energy of the impact electron, I is the ionization potential of the element (or compound), σ is the maximum ionization cross section of the gaseous species, γ is the isotopic abundance ratio for the ionized gaseous species, S_1 is the efficiency of the electron multiplier, S_2 is the sensitivity of the mass filter, and $\bar{v}$ is the average velocity of the gaseous atoms.

From Eqs. (1) and (2), the following equation is obtained:

$$z_{tot} = \frac{a}{C(E-I)\sigma\gamma S_1 S_2}\int_0^{t_{end}} I^+\bar{v}\mathrm{d}t \tag{3}$$

Since, in the present work, the ion currents are measured with a continuously increasing temperature at a constant rate, the $\bar{v}$ is given as a function of the time:

$$\bar{v} = \sqrt{\frac{8RT_t}{\pi M}} \tag{4}$$

where $\boldsymbol{R}$ is the gas constant and where T_t is the sample temperature at time t. Substituting for $\bar{v}$, Eq. (3) becomes:

$$z_{tot} = K\int_0^{t_{end}} I^+\sqrt{T_t}\mathrm{d}t \tag{5}$$

where:

$$K = \frac{a}{C(E-I)\sigma\gamma S_1 S_2}\sqrt{\frac{8R}{\pi M}}$$

Similarly, the number of gaseous atoms, $z_{\Delta t}$, vaporized in the time interval between t_1 and t_2, during which the temperature increases from T_1 to T_2, is given by:

$$z_{\Delta t} = K\int_{t_1}^{t_2} I^+\sqrt{T_t}\mathrm{d}t \tag{6}$$

Taking the ratio of Eqs. (5) and (6):

$$\frac{z_{\Delta t}}{z_{tot}} = \frac{W_{\Delta t}}{W_{tot}} = \frac{\int_{t_1}^{t_2} I^+\sqrt{T_t}\mathrm{d}t}{\int_0^{t_{end}} I^+\sqrt{T_t}\mathrm{d}t} \tag{7}$$

where W_{tot} is the whole amount of the sample and where $W_{\Delta t}$ is the amount vaporized in the time interval $\Delta t = t_2 - t_1$. The graphical integrals in Eq. (7) are shown in Fig. 3, where the experimental data for only the Sr^+ ion current are given against the time, together with the temperature. The whole area under the curve of $I^+\sqrt{T_t}$ corresponds to W_{tot}, and the oblique line part area, to $W_{\Delta t}$. Consequently, the rate of the vaporization of atoms vaporized per unit of time per unit of area, m, is obtained from the following equation:

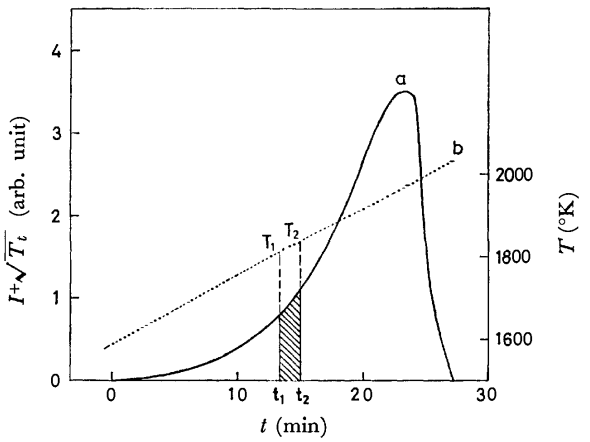

Fig. 3. Graphical representation for the integrals in Eq. (7).
(a) $I_{Sr}{}^+\sqrt{T}$ and (b) temperature.
Whole area under the curve (a) is corresponded to the integral of the denominator and oblique line part area to the numerator in Eq. (7).

$$m = \frac{W_{\Delta t}}{a\Delta t} = \frac{W_{tot}}{a\Delta t}\frac{\text{oblique-line part of Fig. 3}}{\text{whole area of Fig. 3}} \tag{8}$$

For the vaporization from an open surface, the vapor pressure, P, at the average temperature of $\bar{T}=(T_1+T_2)/2$ in the time interval of Δt can be calculated by the Langmuir equation[13]:

$$P = m\sqrt{\frac{2\pi R\bar{T}}{M}} \tag{9}$$

assuming the vaporization coefficient to be unity. Then, for a series of time intervals, the vapor pressures are successively calculated in the same manner, until the amount of sample decreases and the rate of vaporization does not give the pressure corresponding to the temperature.

When a vaporization occurs in only one vapor species the above procedure can be applied to the measurement of the vapor pressure without any correction. In the case of the vaporization of strontium oxide on the platinum filament, however, the strontium-containing vapors consists of a predominant amount of Sr(g) and a small amounts of SrO(g), as is shown in Fig. 4, where the experimental data for the Sr^+ and SrO^+ ion currents from their vapors are given. Consequently, in the present work the SrO^+ ion current was first converted into an imaginary strontium ion current, $I^+_{Sr}(imag)$, which was equivalent to I^+_{SrO}; then, by using the sum of the actual and the imaginary strontium ion currents, $I^+_{Sr}(sum)=I^+_{Sr}+I^+_{Sr}(imag)$, the integral of the denominator in Eq. (7) was carried out. In this case, Eqs. (8) and (9) become:

13) L. Langmuir, *Phys. Rev.*, **2**, 329 (1913).

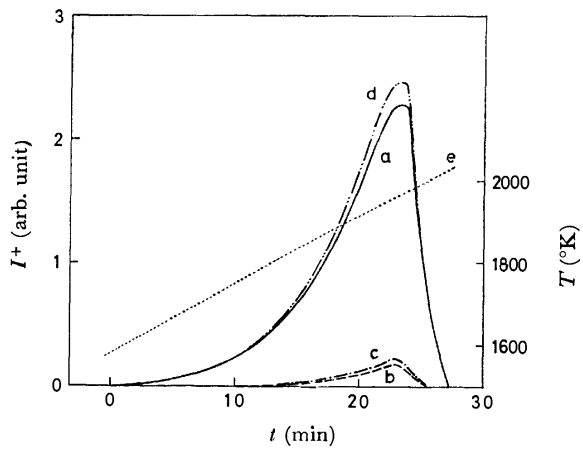

Fig. 4. Experimental data for I^+_{Sr} and I^+_{SrO} against time, together with I^+_{Sr} (imag) and I^+_{Sr}(sum).
(a) —— I^+_{Sr}, (b) ---- I^+_{SrO}, (c) -·- I^+_{Sr} (imag) equivalent to I^+_{SrO}, (d) —·— I^+_{Sr} (sum)$=I^+_{Sr}+I^+_{Sr}$ (imag), and (e) ------ temperature.

$$m_{Sr} = \frac{W_{Sr} \text{ in SrO}}{a\Delta t} \frac{\int_{t_1}^{t_2} I^+_{Sr}\sqrt{T_t}\,dt}{\int_0^{t_{end}} I^+_{Sr}(\text{sum})\sqrt{T_t}\,dt} \tag{10}$$

and:

$$P_{Sr} = m_{Sr}\sqrt{\frac{2\pi RT}{M_{Sr}}} \tag{11}$$

respectively. The values of I^+_{Sr} (imag) and I^+_{Sr} (sum) are also shown in Fig. 4.

The conversion of I^+_{SrO} into I^+_{Sr} (imag) was carried out as follows. When SrO(g) is vaporized from strontium oxide, the current of the strontium oxide ion is given from Eq. (2):

$$I^+_{SrO} = C\frac{(E-I_{SrO})\sigma_{SrO}\gamma_{SrO}S_{1SrO}S_{2SrO}}{\bar{v}_{SrO}}z_{SrO}$$

$$= k\frac{(E-I_{SrO})\sigma_{SrO}\gamma_{SrO}S_{1SrO}S_{2SrO}\sqrt{M_{SrO}}}{\sqrt{T}}z_{SrO} \tag{12}$$

where $k=C\sqrt{\pi/8R}$.
Similarly, for the imaginary strontium ion:

$$I^+_{Sr}(\text{imag}) = k\frac{(E-I_{Sr})\sigma_{Sr}\gamma_{Sr}S_{1Sr}S_{2Sr}\sqrt{M_{Sr}}}{\sqrt{T}}z_{Sr}(\text{imag}) \tag{13}$$

Now, if the $^{88}Sr^+$ and $^{88}Sr^{16}O^+$ are measured, the following relations hold:

$$z_{SrO} = z_{Sr}(\text{imag}) \tag{14}$$

and:

$$\gamma_{SrO} = \gamma_{Sr} \tag{15}$$

Consequently, from Eqs. (12) and (13):

$$I^+_{Sr}(\text{imag}) = \frac{(E-I_{Sr})\sigma_{Sr}S_{1Sr}S_{2Sr}\sqrt{M_{Sr}}}{(E-I_{SrO})\sigma_{SrO}S_{1SrO}S_{2SrO}\sqrt{M_{SrO}}}I^+_{SrO} \tag{16}$$

That is, the amount of I^+_{SrO} at a given temperature can be converted into the I^+_{Sr}(imag) using Eq. (16).

For the calculation of the partial pressure of SrO(g), the sensitivity-calibration method was employed. Here, the partial pressure of Sr(g) was used as a reference; that is:

$$P_{SrO} = \frac{I^+_{SrO}(E-I_{Sr})\sigma_{Sr}S_{1Sr}S_{2Sr}T_{SrO}}{I^+_{Sr}(E-I_{SrO})\sigma_{SrO}S_{1SrO}S_{2SrO}T_{Sr}}P_{Sr} \tag{17}$$

In the mass-spectrometric Knudsen effusion technique, silver has been widely used as a reference material, since silver vaporizes almost entirely in the form of monoatomic gases and the vapor pressure is well known. However, in the present condition of free vaporization from an open surface, it is difficult to use an outer reference such as silver.

The values of the ionization potentials for strontium and strontium oxide were taken from Drowart[4] to be $I_{Sr}=5.7$ and $I_{SrO}=6.1$ eV, while the relative maximum ionization cross section for strontium was taken from Mann[14] to be $\sigma_{Sr}=8.88$ and the cross section for strontium oxide was obtained, by summing the values for the constituent atoms, as $\sigma_{SrO}=10.19$. The efficiency of the electron multiplier for the mass dependence, S_1, was corrected by a factor of the reciprocal of the square root of the mass number, taking into account the so-called mass effect.[15] Moreover, the sensitivity of the mass filter, varying with the resolution, S_2, was corrected from the constant slope of the lines in Fig. 2. As the time interval, Δt, 1 min was taken for all calculations.

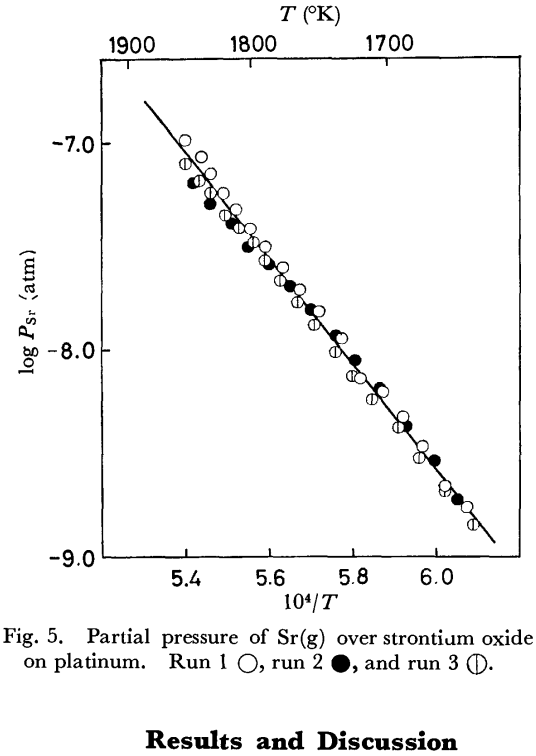

Fig. 5. Partial pressure of Sr(g) over strontium oxide heated on platinum. Run 1 ○, run 2 ●, and run 3 ⓘ.

Results and Discussion

1. Partial Pressure of Sr(g). The partial pressures of Sr(g) over strontium oxide heated on a platinum filament are shown in Fig. 5. The line drawn by the least-squares treatment of the data follows this equation:

$$\log P_{Sr}(\text{atm}) = 6.633 - \frac{2.536\times10^4}{T} \tag{18}$$

in the temperature range of 1643—1851°K. Moreover, from the slope of the line the heat of the vaporization of Sr(g)[16] was calculated to be 116 ± 2 kcal/mol at the

14) J. B. Mann, *J. Chem. Phys.*, **40**, 1646 (1967).
15) W. Ploch and W. Walcher, *Rev. Sci. Instrum.*, **22**, 1028 (1951).
16) This value corresponds to the partial molar enthalpy of the vaporization of Sr(g) from SrO(g).

experimental temperatures. Here, the uncertainty is the standard deviation for the least-squares fit.

As will be described later, the partial pressure of Sr(g) is more than an order of magnitude greater than that of SrO(g). Consequently, it may be observed that the total vapor pressures over strontium oxide obtained by Moore *et al.*,[8] and by Claassen and Veenemans,[9] assuming SrO(g) to be the only gaseous species, are approximately equivalent to the partial pressure of Sr(g) if the consideration of a factor of $\sqrt{M_{Sr}/M_{SrO}}$ is made for their values. The agreement between the observed partial pressure of Sr(g) and their total vapor pressures is extremely good.

In the experiments of Moore *et al.* and of Claassen and Veenemans, the vaporization took place in sealed-off tubes, so the Sr(g) vaporized from the heated sample to the cold collector wall could readily recombine with the released oxygen. Thus, even though strontium oxide was found in the collected products on the wall, the calculations should be carried out for each vapor species of Sr(g) and SrO(g) by the aid of mass analysis.

Bickel and Holroyd[2] have described that the temperature dependence of the Sr^+ ion current is at first seemingly irreproducible. However, the sample passes through a series of changes as the temperature is cycled, and eventually equilibrium conditions are reached on the platinum filament, where reproducible data can be obtained. They have also determined the heat of the vaporization of Sr(g) from the slopes of the lines obtained by plotting the log Sr^+ ion current against the reciprocal of the temperature; they found it to be 164 kcal/mol in the initial state, and 60 kcal/mol for the higher-temperature range and 138 kcal/mol for the lower in the final state. However, Aldrich[1] has observed that the vaporization process of strontium oxide heated on platinum is reproducible without any particular care, and from similar plots of his data he obtained the heat of the vaporization of Sr(g) as 144 kcal/mol over the full temperature range investigated. In the present work, where the measurements were carried out with a continuously increasing temperature, the Sr^+ and SrO^+ ion currents were satisfactorily reproducible in all runs.

Further, the heat of the vaporization of SrO(g) has been obtained by Moore *et al.*, from their data on the total vapor pressure, to be 126.6 kcal/mol, while Blewett,[17] from the data of Claassen and Veenemans,[9] found it to be 117 kcal/mol. Again, these values are approximately equivalent to the value for Sr(g). The agreement of the heats of the vaporization of Sr(g) determined by many workers is poor.

2. Partial Pressure of SrO(g). The partial pressures of SrO(g) vaporized congruently from strontium oxide on platinum are shown in Fig. 6. The line represents the least-squares fit of the data of three runs and is given by the following equation:

$$\log P_{SrO}(\text{atm}) = 6.707 - \frac{2.793\times10^4}{T} \qquad (19)$$

in the temperature range of 1747—1850°K. Moreover, the heat of the vaporization of SrO(g) was calculated to be 128±2 kcal/mol at the experimental temperatures.

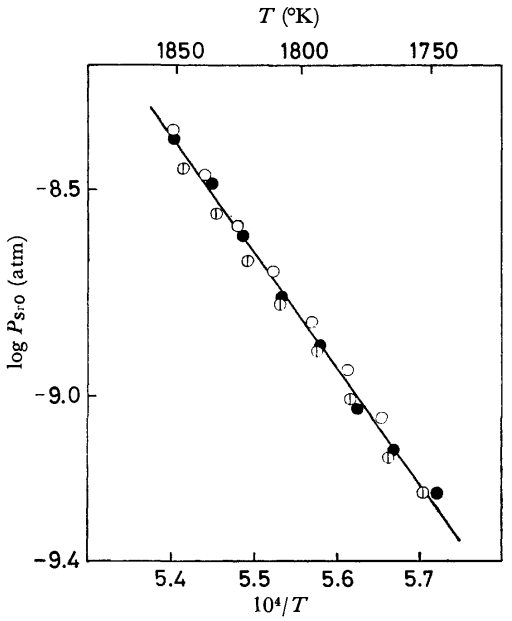

Fig. 6. Partial pressure of SrO(g) over strontium oxide heated on platinum. Run 1 ○, run 2 ●, and run 3 ⦶.

Here again, the uncertainty given is the standard deviation for the least-squares fit.

The measurements for the vapor pressure and for the heat of vaporization of SrO(g) have been carried out by Porter *et al.*[7] only at the temperature of 2100°K, using a mass-spectrometric Knudsen effusion method with an alumina cell. The vapor pressure of 2.5×10^{-7} atm for SrO(g), obtained by extrapolating the line in Fig. 6 to 2100°K, may be seen to be in conflict with the value of 3.8×10^{-8} atm estimated by Porter *et al.* at this temperature; also, the heat of vaporization, 135±3 kcal/mol, corrected to 298°K, is in poor agreement with their value of 155.1 kcal/mol at 298°K. These discrepancies seem to be due to the difference in the supporting materials for strontium oxide and/or the uncertainty as to their experimental error for the single measurement at 2100°K.

The reactions between strontium oxide and platinum have been studied thermodynamically by Moore *et al.*[8] Their results indicate that strontium oxide and platinum do not react in such a manner as to form free Sr(g), and at the same time they do not produce any compounds containing strontium and platinum. In the present work, no high-mass compounds resulting from a reaction between strontium oxide and platinum were detected, although some Pt^+ ions were observed at the highest temperature.

3. Dissociation Energy of Strontium Oxide. For the experimental determination of the dissociation energy of strontium oxide, it is necessary to measure the partial pressures of Sr(g), SrO(g), and oxygen in the present system. The mass spectra of O^+ and O_2^+ ions exhibited a more indistinct shutter effect than those of the Sr^+ and SrO^+ ions did, so the partial pressure of oxygen was calculated from the following relation:

$$P_O(\text{atm}) = \sqrt{\frac{M_O}{M_{Sr}}}P_{Sr}(\text{atm}) = 0.4273P_{Sr}(\text{atm}) \qquad (20)$$

assuming that the oxygen atoms were vaporized by an

17) J. P. Blewett, *J. Appl. Phys.*, **10**, 668 (1939).

equivalent amount of Sr(g) at a given temperature. If oxygen molecules are assumed to be in equilibrium with Sr(g) and SrO(g), half of the dissociation energy of the oxygen molecule must be considered in the calculations.

The free-energy function for SrO(g) was calculated from the usual statistical mechanical equations[18] by using the data of the vibration frequency of strontium oxide, $\omega=653.5\ cm^{-1}$ [19]; the interatomic distance, $r=1.921$ Å[19], and the electronic states, $^3\Sigma$ and $^3\Pi$, lying about $10870\ cm^{-1}$ above the ground state, $X^1\Sigma$.[4] The values calculated are $-(G_T^\circ-H_0^\circ)/T=60.4$(1500°K), 60.9 (1600°K), 61.4(1700°K), 61.9(1800°K), 62.4(1900°K), and 62.8(2000°K) in cal/mol deg respectively. The free-energy functions for Sr(g) and O(g) were taken from Margrave.[20]

By combining the free-energy functions of SrO(g), Sr(g), and O(g) with the free-energy change for the following reaction:

$$SrO(g) = Sr(g) + O(g) \qquad (21)$$

the dissociation energy was calculated to be $D_0^\circ(SrO)=96.2\pm0.9$ kcal/mol. Moreover, a least-squares fit to the second-law treatment for the equilibrium constant of the same reaction gave $D_{1800}^\circ(SrO)=103\pm5$ kcal/mol, which became $D_0^\circ(SrO)=102\pm5$ kcal/mol when corrected to 0°K by using the heat capacities of SrO(g), Sr(g), and O(g). Here, the heat capacity of SrO(g) was calculated by the use of the kinetic theory.[21]

In general, the analysis of the data by third-law treatment is considered superior to that using the second law because each data point is independent of the other.

The dissociation energy of strontium oxide has been determined by various methods, that is, mass-spectrometric measurements by the Langmuir method and the Knudsen effusion method, total vapor-pressure measurements, spectrometric measurements, and theoretical calculations. In Table 1, the values determined in this work are shown together with the literature values. The values obtained by the present mass-spectrometric Langmuir method agree, within the limits of experimental error, with those obtained by the Knudsen method except for the low value reported by Porter *et al.*,[7] As for this low value, Drowart *et al.*[4] have explained it by saying that SrO(g) vaporized from an alumina Knudsen cell, thus leading to the formation of a compound, $(SrO)_{1\text{-}4}Al_2O_3$ in the condensed phase; they derived $D_0^\circ(SrO)=105$ kcal/mol by adding the heat of the formation of the $SrO\cdot Al_2O_3$ compound, -19 kcal/mol, to the value obtained by Porter *et al.* However, it is less easy to explain the low value calculated from the data for all the gas-phase reactions of Eq. (21), since this equilibrium should be independent of the solid-phase composition.

a) Third law treatment.
b) Second law treatment.
c) Calculation from the data of Ref. 8.
d) Ion model.
e) Internuclear potential function with three parameters, *i.e.*, equilibrium bond distance, force constant, and anharmonicity constant.
f) Internuclear potential function with five parameters, *i.e.*, in addition to above three parameters, vibrational-rotational coupling constant and one constant of 1.065.

As may be seen in Table 1, the values obtained by the spectrometric method[24-28] are systematically higher than those obtained by the mass-spectrometric method. This discrepancy is presumably due to the uncertainties of the measurements of the flame temperature and its gradient by the spectrometric method, and the defference in principle between the spectrometric and the thermochemical values.

The value calculated by the ionic model[29] is in fair agreement with those experimental determined, whereas the values obtained by the internuclear potential functions[30] deviate markedly from the other values.

The authors wish to express their thanks to Professor S. Magari of the Institute of Atomic Energy, Kyoto University, for his valuable suggestions and discussions.

Viscous Properties of Liquid Oligotrifluorochloroethylene

Naosato Yoshida and Shuichi Hamada

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received June 18, 1971)

The viscosities of fractionated liquid oligotrifluorochloroethylene were measured in the molecular-weight range from 820 to 2100 at temperatures ranging from 40 to 120°C. While the relationships between log η and log M_n were regarded as being approximately linear in the molecular-weight range smaller than 1090, and their slopes were much larger than unity, a considerable deviation from the approximately linear relationship was observed in the molecular-weight range larger than 1090. The temperature dependence of the viscosities was well explained in terms of the WLF equation under the present experimental conditions. The large slope in the range of the linear relationship may be caused because the reciprocals of the free-volume fractions, $1/f$, increase remarkably with an increase in the molecular-weight. The free-volume per cubic centimeter, F, contributed by chain-ends increased abruptly with an increase in the molecular-weight in the range smaller than about 1200.

In a previous paper,[1] it was reported that the slope of the log η-log M_n relationship for oligotrifluorochloroethylene was much larger than unity in the molecular-weight range from 820 to 1090; a similar behavior in oligostyrene and oligoisobutylene has also been reported by Fox and Flory[2,3] and by Uchida and Hata.[4]

In this work, the dependence of the viscosity on the molecular-weight will be discussed in connection with the free-volume.

Experimental

Materials. Daifloil's No. 20, 50, 100, and 200, which were obtained from the Daikin Kogyo Company, were used as the samples of oligotrifluorochloroethylene. The acetone-soluble part was fractionated in the manner described in our previous paper,[1] while the acetone-insoluble part was fractionated according to whether it was soluble or insoluble in benzene or carbon tetrachloride. The number-average molecular-weight of the oligotrifluorochloroethylene thus fractionated was estimated by cryoscopic and ebullioscopic methods, using benzene and carbon tetrachloride respectively as the solvents.

Procedure. The melting point, T_m, of the sample crystallized was estimated by a dilatometric method. Beforehand, a rough melting point, T_m', of the sample was estimated by a capillary method in order to obtain the crystallization temperature of the sample fractionated. A suitable amount of the sample was crystallized in a container of the dilatometer by allowing it to stand for about 30 hr at a temperature of $(7/9)\,T_m'$. The samples were considered to crystallize sufficiently, since sharp X-ray patterns were observed even with samples obtained by quenching. The sample thus crystallized was sealed in a dilatometer containing mercury. The dilatometer was kept at $T_m' - 20°$ for 30 min to establish a thermal equilibriun, and then it was heated slowly at a heating rate of 0.05°C/min. The melting point was estimated graphically from the specific volume-temperature relationship.

The viscosities and the densities of the liquid samples were measured with an Ubbelohde-type viscometer and a dilatometer respectively in the manner described in a previous paper;[1] they were determined at given temperatures in the range from 40 to 120°C with an accuracy of ± 0.01°C in thermostated baths filled with water or silicone oil.

Results

Melting Points of Oligotrifluorochloroethylene. Table 1 shows the melting points of the samples fractionated in the molecular-weight range from 1200 to 3800.

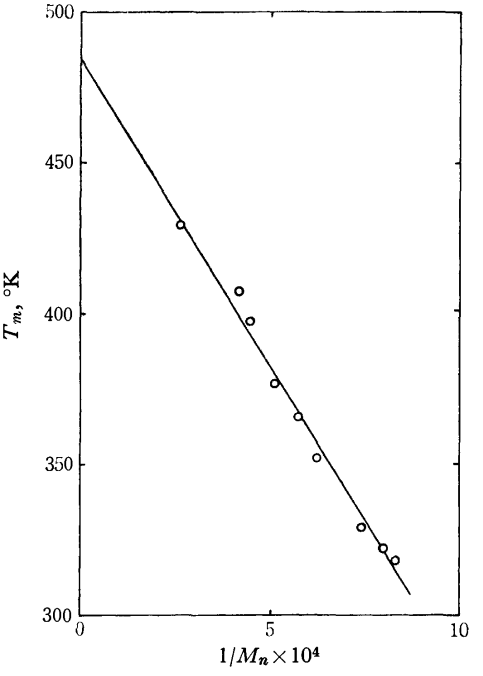

Fig. 1. Relationship between T_m and $1/M_n$.

Table 1. Melting points of oligotrifluorochloroethylene

M_n	1200	1250	1350	1600	1750	1950	2250	2400	3800
T_m, °K	317	321	328	351	365	376	397	407	429

Figure 1 shows the relationship between the melting point, T_m, and the reciprocal of the number-average molecular-weight, $1/M_n$. The linear relationship between T_m and $1/M_n$ can be expressed as follows:

$$T_m = 485 - 2.10 \times 10^5/M_n \qquad (1)$$

Table 2. Viscosities of oligotrifluorochloroethylene

M_n	Viscosities η, poise								
	40°C	50°C	60°C	70°C	80°C	90°C	100°C	110°C	120°C
820	6.39	2.93	1.51	0.855	0.521				
860	10.78	4.71	2.33	1.26	0.730	0.451			
870	18.81	6.68	3.16	1.64	0.916	0.547			
890		9.16	4.23	2.15	1.19	0.698			
1010		29.53	12.28	5.68	2.99	1.63			
1030			16.60	7.59	3.77	2.01	1.14		
1050			21.21	9.49	4.63	2.43	1.36		
1070			23.20	10.39	5.05	2.64	1.47		
1090			26.23	11.66	5.64	2.93	1.62		
1200				24.94	11.20	5.44	2.83		
1600					49.25	22.55	11.14		
2100							23.88	12.20	6.60

The melting point, T_m^0, of a high-polymeric trifluorochloroethylene is expected to be 485°K from the linear relationship. This value is nearly equal to that of polytrifluorochloroethylene, 497°K, as reported by Hoffman and Weeks.[5,6]

Viscosities of Oligotrifluorochloroethylene. The viscosities of the liquid samples fractionated are given in Table 2.

Though the results in the molecular-weight range smaller than 1090 have been reported in the previous paper,[1] they were reexamined for this work.

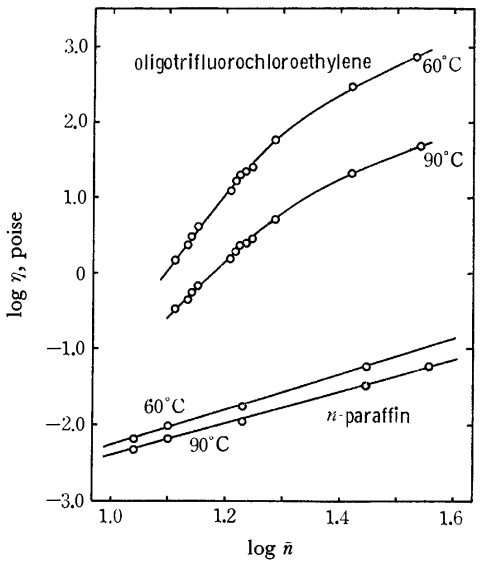

Fig. 2. Chain-length dependence of viscosity.
(The viscosity values for oligotrifluorochloroethylene in the molecular-weight range larger than 1200 at 60°C, and those in the molecular-weights of 820 and 2100 at 90°C were calculated by using WLF equation, respectively.)

Figure 2 shows the relationships between log $\bar{n}$ and log η at 60 and 90°C in the chain-length range from 12.8 to 34.8; the chain-length, $\bar{n}$, shows the number of carbon atoms in the skeleton of oligotrifluorochloroethylene and *n*-paraffin molecules. An expression, $\bar{n}$, was taken in order to compare the dependence of the viscosities of oligotrifluorochloroethylene on the chain-length with those for *n*-paraffin. While an approximately linear relationship was obtained between log η and log $\bar{n}$, *i.e.*, between log η and log M_n, in the molecular-weight range smaller than 1090, as was reported in the previous paper,[1] the linear relationship did not hold in the molecular-weight range larger than 1090. On the contrary, in the case of *n*-paraffin[7,8] log η varied linearly with log$\bar{n}$ in the chain-length range from 5 to 64 (the molecular-weight range from 72.15 to 899.68). The slopes of the linear part were much larger than those found in the usual lower-molecular-weight chain polymers, and they rose remarkably with an increase in the temperature.[1]

Temperature Dependence of Viscosities. The shift factor, a_T, based on an arbitrary fixed temperature, T_0, obeyed well the WLF equation,[9] reported in the previous paper.[1] From the linear relationship between $(T-T_0)/\log a_T$ and $(T-T_0)$, the WLF parameters, C_1^0 and C_2^0, were estimated in the molecular-weight range from 820 to 2100. Table 3 shows C_1^0 and C_2^0 at the fixed temperature of 70°C and their products, $C_1^0C_2^0$.

The apparent activation energy, E_a, for the viscous flow was estimated from the following equation:[6]

Table 3. Values of C_1^0, C_2^0, and $C_1^0C_2^0$ at 70°C

M_n	C_1^0	C_2^0	$C_1^0C_2^0$
820	3.50	146.2	511.9
860	4.13	158.8	655.8
870	4.55	164.6	749.7
890	4.61	161.8	744.8
1010	5.76	180.1	1037.1
1030	5.95	179.9	1069.7
1050	6.09	179.7	1094.9
1070	6.27	184.3	1155.6
1090	6.34	185.0	1173.2
1200	7.03	187.1	1314.7
1600	7.51	185.4	1392.0
2100	7.70	179.9	1385.6

$$E_a = 2.303C_1^0C_2^0RT^2/(C_2^0+T-T_0)^2 - RT + \alpha RT^2 \quad (2)$$

where R and α are the gas constant and the thermal-expansion coefficient of the liquid sample respectively.

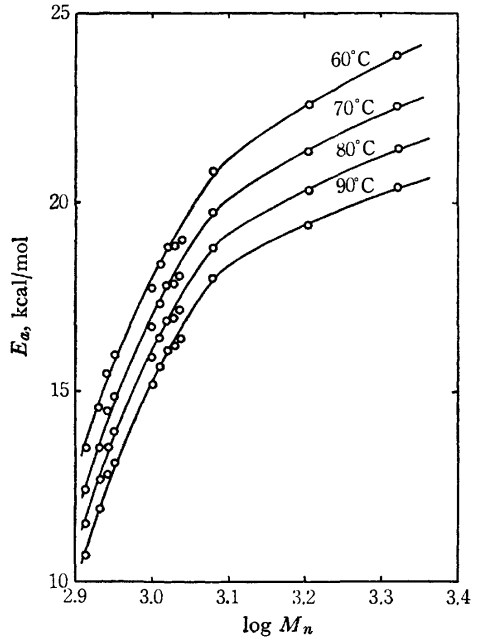

Fig. 3. Dependence of apparent activation energy for viscous flow on log M_n.

Figure 3 shows the dependence of E_a on log M_n. Though the values of E_a increased with an increase in the molecular-weight, they were quite large in comparison with those found in the usual lower-molecular-weight oligomers without branched chains.[10]

Discussion

According to Doolittle,[7,11] the viscosity is related to free-volume fraction by the following equation:

$$\ln \eta = \ln P + Q(1/f_T) \quad (3)$$

where P and Q are empirical constants; where f_T is the free-volume fraction at T, and where the parameter, Q, is regarded as being approximately unity.[12] The reciprocal of the free-volume fraction, $1/f_T$, at a given temperature, T, was calculated from the following equation in conjunction with the WLF equation:

$$1/f_T = 2.303C_1^0C_2^0/(C_2^0+T-T_0) \quad (4)$$

The dependence of $1/f_T$ on the molecular-weight, M_n, and the number of carbon atoms, $\bar{n}$, in the skeletons of oligotrifluorochloroethylene and n-paraffin molecules at given temperatures is shown in Fig. 4. The parameters, C_1^0 and C_2^0, for n-paraffin were estimated from the results reported by Doolittle[7] by the manner used in the case of oligotrifluorochloroethylene. The reciprocal of the free-volume fraction, $1/f_T$, varied considerably with $\bar{n}$ in the case of oligotrifluorochloroethylene; this is in contrast with the case of n-paraffin, as is shown

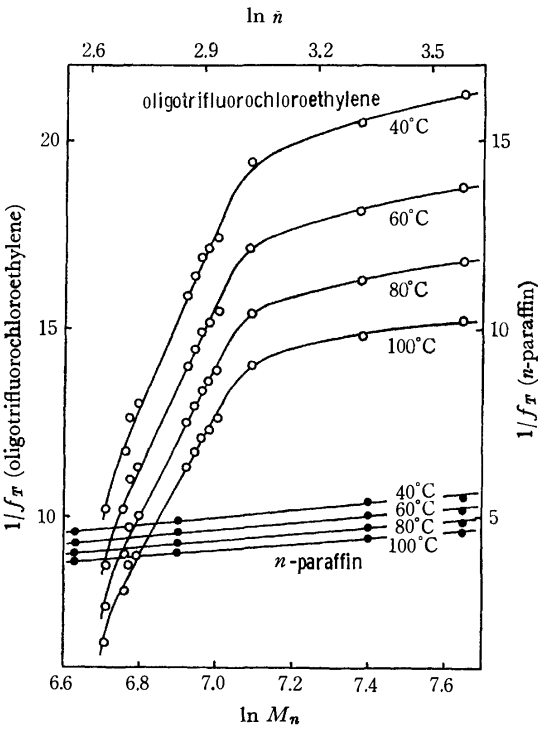

Fig. 4. Relationship between ln M_n and $1/f_T$.

in Fig. 4. While linear relationships between $1/f_T$ and log M_n were obtained in the molecular-weight range from 860 to 1200, considerable deviations from the linear relationships were observed in the molecular-weight range larger than 1200. In the molecular-weight range from 860 to 1200, the relationship between $1/f_T$ and ln M_n is expressed as follows:

$$1/f_T = \ln h + k \ln M_n \quad (5)$$

The slopes, k, were much larger than unity, and they decreased with an increase in the temperature, as is shown in Table 4.

Table 4. Slopes, k, of the linear relationship

Temp., °C	40	60	80	100
k	23.8	22.0	20.0	18.8

The free-volume fraction, f_T, at T is expressed by the following equation:

$$f_T = f_g + \alpha_f(T-T_g) \quad (6)$$

where f_g is the free-volume fraction at T_g, and α_f, its thermal-expansion coefficient. The thermal-expansion coefficient, α_f, of the free-volume fraction is expressed as $1/2.303C_1^0C_2^0$. Figure 5 shows the relationships between α_f and $\bar{n}$ for oligotrifluorochloroethylene and n-paraffin. The α_f values of oligotrifluorochloethylene increased remarkably as the $\bar{n}$ values decreased in the range of $\bar{n}$ smaller than approximately 20; they reached a constant value, 3×10^{-4}°C^{-1}, above an $\bar{n}$ value of 20, though the α_f values for n-paraffin scarcely changed at all.

The glass-transition temperatures, T_g, of the fractionated oligotrifluorochloroethylenes were deduced from their melting points, because the measurement of the glass-transition temperature was difficult because of a tendency toward easy crystallization. The ratio be-

11) A. K. Doolittle and D. B. Doolittle, *J. Appl. Phys.*, **28**, 901 (1957).
12) F. Bueche, *J. Chem. Phys.*, **24**, 418 (1956).

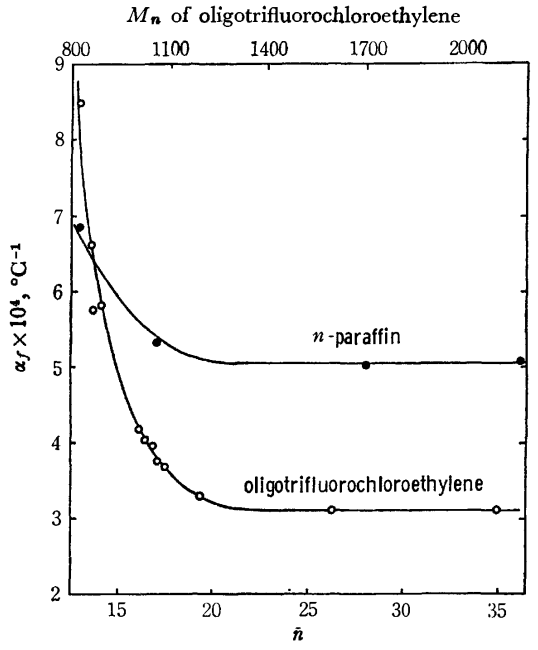

Fig. 5. Relationship between α_f and $\bar{n}$.

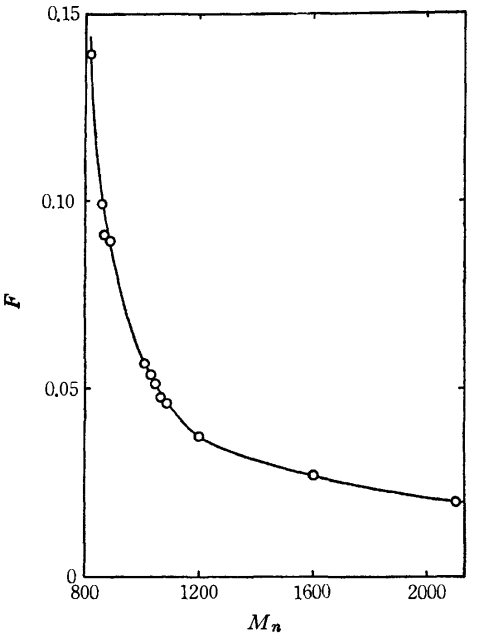

Fig. 6. Relationship between chain-end free volume per cc, F, and M_n at 52°C.

tween the glass-transition temperature and the melting point, T_g/T_m, for polytrifluorochloroethylene was reported to be 0.654 by Hoffman and Weeks.[5,6] This ratio was nearly equal to the value, 0.667, found in usual asymmetric polymers.[13] By the use of this value, 0.667, found in usual asymmetric polymers.[13] By the use of this value in the oligomer range, the relationship between the T_g and the M_n of oligotrifluorochloroethylene can be expressed from the relationship of $T_g/T_m=0.654$ and Eq. (1) as follows:

$$T_g = 317 - 1.37 \times 10^5/M_n \quad (7)$$

Thus, the glass-transition temperature, T_g, of oligotrifluorochloroethylene is considered to rise remarkably as the molecular-weight increases in the oligomer range.

Accordingly, the free-volume fraction, f_T, in the molecular-weight range below 1200 ($\bar{n}=20$) is considered to vary remarkably with the effects of both an abrupt decrease in α_f and a remarkable rise in T_g with an increase in the molecular-weight. The free-volume fractions, f_T, were related only to the variation in T_g depending on the molecular-weight above 1200, because the thermal-expansion coefficient, α_f, of the free-volume was nearly constant.

Bueche[14] pointed out that the chain-ends of the polymer would contribute a certain amount to the total free-volume of the system, because each chain-end would necessarily possess more free-volume than that of a continuous chain. If the free-volume contributed by a chain-end is designated as θ, the total amount of free-volume per cubic centimeter, F, contributed by chain-ends can be expressed as follows:

$$F = \theta(2\rho N/M_n) \quad (8)$$

where ρ is the polymer density, and N, the Avogadro number. Further, the glass-transition temperature, T_g, in relation to the free-volume contributed by chain-ends, was expressed as follows:

$$T_g = T_g^0 - (2\rho N\theta/\alpha_f)(1/M_n) \quad (9)$$

where T_g^0 is the glass-transition temperature of high-polymeric polymer. From Eqs. (7) and (9), the F and the θ values for polytrifluorochloroethylene are given by the following equations:

$$F = 1.37 \times 10^5\alpha_f/M_n \quad (10)$$

$$\theta = 1.37 \times 10^5\alpha_f/2\rho N \quad (11)$$

where α_f is the function of the molecular-weight, as is shown in Fig. 5.

Table 5 shows the free-volume, θ, contributed by a chain-end in the molecular-weight range from 820 to 2100 at 52°C (the glass-transition temperature of polytrifluorochloroethylene[5,6]), when ρ is regarded as approximately 1.9. The θ values decreased with an increase in the molecular-weight up to about 1200.

Figure 6 shows the relationship between the free-volume, F, contributed by chain-ends and the molecular-weight at 52°C. The F value increased abruptly with a decrease in the molecular-weight below about 1200.

The Microwave Spectrum of Dimethyl Sulfone

Shuji SAITO and Fumio MAKINO
Sagami Chemical Research Center, Sagamihara, Kanagawa
(Received June 24, 1971)

The microwave spectra of normal and ^{13}C-isotopic species of dimethyl sulfone have been investigated, and the rotational constants of both species have been determined. The following r_0-structural parameters have been determined: r(C–S)$=1.777\pm0.006$ Å, r(S–O)$=1.431\pm0.004$ Å, $\angle$CSC$=103°17'\pm10'$, and $\angle$OSO$=121°1'\pm15'$, assuming that r(C–H)$=1.091$ Å and $\angle$HCH$=109°34'$. The variations in the structural parameters among the related alkyl sulfides, alkyl sulfoxides, and alkyl sulfones have been discussed. The dipole moment has been determined to be $\mu=4.432\pm0.041$ D along the b axis. This value is consistent with the results of a bond-moment calculation based on the dipole moment of dimethyl sulfoxide.

Recently, ethylene episulfone, $(CH_2)_2SO_2$[1], has been subjected to a microwave spectroscopic study; we have found an r_0 structure characterized by a long C–C bond (1.590 Å) and rather short C–S bonds (1.731 Å). These distinct features have been considered to arise from the ring strain. Dimethyl sulfone, $(CH_3)_2SO_2$, may be a typical molecule with no ring strain, corresponding to ethylene episulfone. In fact, the structural comparison mentioned above was made with reference to the structure of dimethyl sulfone, which was determined by X-ray crystallography, not by microwave spectroscopy. Sands[2] reported that r(C–S) $=1.78$Å, a little shorter than the distance of the normal single C–S bond, r(S–O)$=1.44$ Å, $\angle$CSC$=103°$, and $\angle$OSO$=117.9°$, slightly smaller than the $\angle$OSO angle for the normal sulfone group. To make the situation clear, it may be desirable to compare the structure of ethylene episulfone with those of simple alkyl sulfones as accurately determined by microwave spectroscopy. Feairheller and Katon[3] observed the infrared and Raman spectra for dimethyl sulfone with detailed frequency assignments; they pointed out that this molecule is roughly an accidental spherical top. A normal-coordinate analysis of dimethyl sulfone was carried out by Carter, Freeman, and Henshall.[4] There have been a few reports on the dipole moment for this molecule as studied by the dielectric-constant method.[5–7]

In this paper we wish to report the results of the determination of the molecular structural parameters and the dipole moment for dimethyl sulfone from its microwave spectrum.

Experimental

The dimethyl sulfone sample used was obtained from the Tokyo Kasei Kogyo Co. A ^{13}C-enriched sample (6 at. % of ^{13}C) was prepared by oxidizing ^{13}C-enriched dimethyl sulfide with potassium permanganate.[8] The enriched dimethyl sulfide was formed by the reaction[9] of sodium sulfide on methyl iodide enriched to about 6 at. % of ^{13}C. The spectra were observed with a 110-kHz Stark-modulation microwave spectrometer.[10] As the vapor pressure of dimethyl sulfone was about 0.02 mmHg at about 20°C, all the measurements were carried out at room temperature. A high-precision dc-voltage power supply (Fluke, Model 415B) was used in the Stark-effect measurements.

Microwave Spectrum

Most of the measurements were made using a recorder, because the spectral lines were all weak. The assignment of the spectral lines for the normal species was performed by observing the Stark effect on each transition. The frequencies of the observed transitions are listed in Table 1. The rotational constants for the normal species were determined by a least-squares fitting of the lowest ten transitions. The centrifugal distortion effect was discarded in the analysis, because only low-J transitions were observed. Although the ^{13}C-enriched sample was used, it was difficult to assign the spectral lines of the ^{13}C species. This is because the expected frequency regions for low-J transitions of the ^{13}C species were densely covered with other strong lines. Observation had to be made very carefully of the Stark effect for each candidate line and of its relative intensity in the natural sample and in the ^{13}C-enriched sample. A simple relation between the moments of inertia, $\Delta I=I_c-(I_a+I_b)$, was also helpful for the assignment, because it remains essentially unchanged for the isotopic substitution of the atoms in the CSC plane. Ten observed transitions of the ^{13}C species are listed in Table 2. Most of them were used to calculate the rotational constants. The observed rotational constants and moments of inertia are given in Table 3. The three rotational constants thus obtained differ from one another only by a few hundred megahertz, so the dimethyl sulfone molecule is a nearly accidental spherical-top, as has been pointed out by Feairheller and Katon.[3] Table 3 also shows that the ΔI's for the normal species and the ^{13}C species agree very well. This indicates that the effect of zero-point vibrations can be disregarded.

Table 2. Observed rotational transitions of ^{13}C-enriched dimethyl sulfone (MHz)

Transition	ν_{obs}[a]	$\nu_{obs}-\nu_{calc}$[c]

b) $\Delta I=I_c-(I_a+I_b)$.

Dipole Moment

The second-order Stark effect was measured for six transitions, as is shown in Table 4. The electrode spacing was calibrated using the $J=1\leftarrow0$ transition of OCS.[11] From the Stark coefficients, the dipole moment along the b axis was determined to be 4.432± 0.041 D, where the error quoted was 2.5 times the standard deviation. This value is in agreement with the values ($\mu=4.25$—4.26 D) obtained by the dielectric-constant measurements.[5-7]

Table 4. Stark coefficients and dipole moments of dimethyl sulfone

Transition		$\Delta\nu/E^2_{obs}$[a]	μ_{obs}(D)
$2_{20}-1_{11}$	$M=1$	2.536×10^{-4}	4.484

$\mu=\mu_b=4.432\pm0.041$D[b]			

a) Values in MHz (V/cm)$^{-2}$.
b) Error is 2.5 times the standard deviation.

Structure

Dimethyl sulfone has six independent structural parameters. Among them, it is hard to determine the two parameters related to methyl groups without information on the deuterated species. As has been discussed in the cases of ethylene episulfoxide[10] and ethylene episulfone[1], it may be reasonable to assume that the structure of the methyl groups for dimethyl sulfone is the same as that of dimethyl sulfide[12]: r(C–H) $=1.091$ Å and $\angle$HCH$=109°34'$. The remaining four structural parameters, the C–S and S–O bond distances and the $\angle$CSC and $\angle$OSO bond angles, were determined by fitting to the three moments of inertia for the normal species and I_a for the ^{13}C species; this choice of moments of inertia was found to be the most suitable for determining the four structural parameters. The results are

Table 6. Observed and calculated moments of inertia (amuÅ^2)

	Observed	$I_{obs}-I_{calc}$ [a]
Normal species		
I_a	108.961	0.000
I_b	117.654	0.000
I_c	120.987	0.000
^{13}C species		
I_a	109.721	0.000
I_b	119.766	−0.001
I_c	123.859	0.001

a) Based on the structure given in Table 5.

given in Table 5. The uncertainties estimated are due to the experimental uncertainties of the rotational constants and the assumption regarding the methyl groups. The moments of inertia for dimethyl sulfone are calculated using the structure thus obtained; they are compared with the observed values in Table 6. The agreement between them is good.

Discussion

As the comparison in Table 7 shows, the structure of dimethyl sulfone obtained by Sands[2] is in good agreement with our results except for the value of the ∠OSO angle. The ∠OSO angle of 121°1′ which was obtained by this work seems quite reasonable for the ∠OSO angle of alkyl sulfone compounds.

k) The mean value of 1.41 Å and 1.44 Å.

For the purpose of comparison, the four main structural parameters of several related compounds are also listed in Table 7. The C–S bond of dimethyl sulfone is shorter than those of dimethyl sulfide[12] and dimethyl sulfoxide.[13] On the other hand, the C–S bond of ethylene episulfone[1] is distinctly shorter than that of dimethyl sulfone, but, contrary to the case of ethylene episulfone, the C–S bonds of other ring compounds, ethylene episulfide[14] and ethylene episulfoxide,[10] are slightly longer than those of the corresponding compounds, dimethyl sulfide and dimethyl sulfoxide respectively. The former fact means that the sulfone group has a strong electron withdrawing force, resulting in the decrease of the C–S bond distances. The latter fact suggests that the ring strain has some effect on the structures of ring compounds. The behavior of the ring strain can be understood by comparing the ∠CSC bond angles listed in Table 7. The ∠CSC angle of dimethyl sulfone is appreciably wider than those of dimethyl sulfide and dimethyl sulfoxide, so the corresponding ring compound, ethylene episulfone, suffers from severe ring strain. The unusually short C–S bonds of ethylene episulfone may be formed by the combined effects of the weakened long C–C bond and the migration of electrons from the C–C bond to the C–S bonds caused by the strong electron-withdrawing force of the sulfone group. The variation in the ∠CSC bond angle among alkyl sulfides, alkyl sulfoxides, and alkyl sulfones can be explained by the degree of the *s*-character of the C–S bond, which itself depends on the oxidation state of the sulfur atom. However, another point remains to be discussed why the C–S bond distances of ethylene episulfide and ethylene episulfoxide increase slightly, contrary to the case of ethylene episulfone. It is difficult to say why this is so, but it may be said that both the ring strain and the electron-withdrawing force around the sulfur atom in ethylene episulfide and ethylene episulfoxide are so weak that the ring-structures depend on a balance between the two forces. It must be noted that the S–O bond distance and the ∠OSO bond angle of the sulfone group are nearly constant, regardless of the structure of the alkyl group.

Finally, it is interesting to divide the dipole moment of dimethyl sulfone into the C–S and S–O bond moments. When the C–S and S–O bond moments are assumed to be 1.47 D and 2.70 D respectively, values which are derived from the moment of dimethyl sulfoxide,[13] the dipole moment of dimethyl sulfone can be estimated to be 4.47 D. This agrees with the observed value, 4.432 D, given in Table 4. In the same way, the dipole moment of ethylene episulfone can be calculated to be 4.36 D by using the C–S and S–O bond moments of ethylene episulfoxide.[10] The observed value for ethylene episulfone is 4.41 D.[1]

The authors would like to thank Professor Yonezo Morino for his helpful discussions.

Low-Frequency Raman Spectra and Phase Transition of the 1,2-Dichloroethane Crystal

Akira OZORA, Tsugito NAKAGAWA, and Mitsuo ITO
Department of Chemistry, Faculty of Science, Tohoku University, Sendai
(Received July 1, 1971)

In order to study the phase transition of 1,2-dichloroethane crystal at 177°K, the low-frequency Raman spectra were measured at various temperatures, and normal coordinate analysis was carried out. It was found that the phase transition is of rotational type in which the librational motion of the molecule about the axis passing through two chlorine atoms of the molecule changes into a nearly free rotation about the same axis.

Introduction

It is well-known that 1,2-dichloroethane in gas and liquid phases consists of two rotational isomers of *gauche*- and *trans*-forms, but only the *trans*-form is stable in the solid.

The 1,2-dichloroethane crystal has a phase transition at 177°K, on which a number of investigations have been made. According to the X-ray diffraction studies by Lipscomb *et al.*[1,2] both high[1] and low temperature phases[2] (hereafter referred to as crystals I and II, respectively) are monoclinic, the space group C_{2h}^5-$P2_1/c$ with two molecules in a unit cell, and have very similar cell dimensions. The positions of the carbon atoms could readily be identified for crystal II, but not for crystal I. The chlorine atoms were located at nearly the same positions in both phases (Table 1). They concluded that a nearly free rotational motion of the molecule about the axis passing through the two chlorine atoms takes place in crystal I.

TABLE 1. CRYSTAL STRUCTURES OF 1,2-DICHLOROETHANE

Crystal I	Crystal II
monoclinic	monoclinic
$Z=2$	$Z=2$
$C_{2h}^5-P2_1/c$	$C_{2h}^5-P2_1/c$
$a=5.04$ Å	$a=4.66$ Å
$b=5.56$ Å	$b=5.42$ Å
$c=8.00$ Å	$c=7.88$ Å
$\beta=109°30'$	$\beta=103°30'$
x(C)=—	x(C)=0.099
y(C)=—	y(C)=0.003
z(C)=—	z(C)=0.094
x(Cl)=0.303	x(Cl)=0.318
y(Cl)=0.279	y(Cl)=0.278
z(Cl)=0.074	z(Cl)=0.084
at 223°K	at 133°K

In this paper, we report a new evidence available from the low-frequency Raman spectra supporting Lipscomb's conclusion about the nature of the transition.

Experimental

1,2-Dichloroethane was obtained from Junsei Pure Chemical Co., and distilled twice in a vacuum. The Raman spectra were obtained with a Narumi model 750Z-1200 double monochromator. The 6328Å line from He-Ne gas laser was used as an exciting light. An S-20 photomultiplier followed by a photon counting system was employed for detection of the spectra. The optical arrangement for laser Raman measurements is the same as described previously.[3] Temperature control of the sample was made by regulating flow speed of dry nitrogen gas cooled with liqudid nitrogen. Accuracy of temperature was estimated to be ±3°C.

Results

From the crystal structure of 1,2-dichloroethane,nine optical active lattice vibrations are expected, of which three are of translational lattice modes ($2A_u+B_u$) active only in the infrared spectrum. The remaining six are of rotational lattice modes ($3A_g+3B_g$) active only in the Raman spectrum.

Table 2. Observed raman frequencies of the lattice vibrations of the 1,2-dichloroethane crystal (cm^{-1})

Crystal I			Crystal II					
235°K	217°K	197°K	172°K	150°K	127°K	114°K	77°K	4.2°K
33	37	40	47	49	51	52	54	56
			—	—	—	72	74	74
62	65	69	72	74	76	77	79	80
			101	107	109	112	117	121

The Raman spectra of the lattice vibrational region at various temperatures between 4.2°K and 235°K are shown in Fig. 1, and the observed frequencies are summarized in Table 2. Four Raman lines were observed in crystal II, although some bands were not resolved at high temperatures.

The highest frequency line at 110 cm^{-1} is probably due to A_g rotational lattice mode around the axis of the least moment of inertia of the molecule nearly coinciding with the direction connecting the two chlorine atoms of the molecule. Weak intensity of this line may be explained by this assignment as a result of small anisotropy of the molecular polarizability around the Cl–Cl axis. Fairly strong intensities and low frequencies of the other lines suggest that they are assigned to rotational modes around the molecular axes perpendicular to the Cl–Cl axis. We assigned tentatively the strong lines at 52 and 77 cm^{-1} at 114°K to the A_g mode and the weaker line at 72 cm^{-1} to the B_g mode.

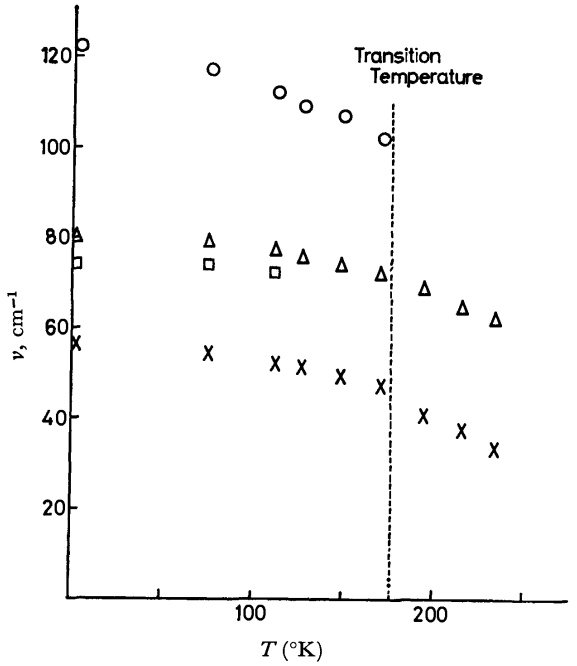

Fig. 2. Effects of temperature on frequencies of lattice vibrational Raman lines.

It should be emphasized that existence of the weak band at 110 cm^{-1} was clearly recongnized even at a temperature just below transition point. However, the weak band is hardly seen as soon as it is transformed into crystal I, while good correspondence is observed for the other lines between the two phases. Figure 2 shows the effect of temperature on the Raman frequencies. The effect is rather large for the highest frequency Raman line of 110 cm^{-1} and it amounts to 20 cm^{-1} between 4.2°K and 172°K as compared with about 10 cm^{-1} for the other lines. We see that smooth curves can be drawn for the Raman lines commonly observed in both phases with no discontinuity at transition point. On the other hand, width of these lines shows discontinuity at transition point as seen in Fig. 3, where the line widths are plotted against temperatures.

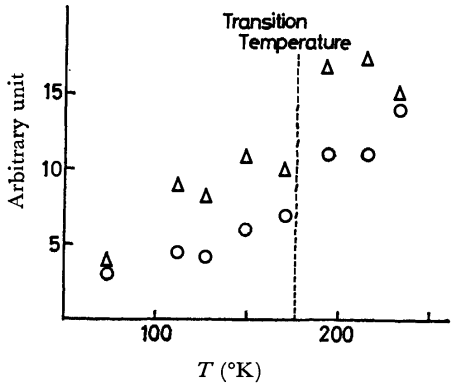

Fig. 3. Effects of temperature on widths of lattice vibrational Raman lines (Plots are given for the Raman lines commonly observed in crystals I and II at about 70 cm^{-1} (△) and 50 cm^{-1} (○)).

Normal Coordinate Calculation

The normal coordinate calculation of the lattice vibrations was carried out for crystal II according to the GF matrix method developed by Shimanouchi *et al.*[4,5] in a rigid body approximation. The approximation may be valid for the Raman active lattice vibrations of the *g* species, since the lowest frequency intramolecular vibration of the *g* species of the molecule which may interact with the *g* lattice vibrations comes out at about 300 cm^{-1} and is well separated from the highest frequency lattice vibrations. The fact that the lowest frequency intramolecular vibration varies within 3 cm^{-1} in the transformation from liquid to the crystal[6] also supports the approximation.

The crystal structure of 1,2-dichloroethane at 133°K is shown in Fig. 4. The positions of hydrogen atoms were located by assuming the C–H distance of 1.08 Å and the ∠CCH and ∠HCH of 109°28′. The principal axes of the moment of inertia of the molecule are also shown in Fig. 4. U and V axes lie in the ClCCCl plane

and the U axis makes an angle of 1°24′ with the line connecting the two chlorine atoms. The W axis is perpendicular to the U and V axes and coincides with the C_2 symmetry axis of the molecule.

For the intermolecular potential, we assumed the atom-atom interaction potential in the form

$$V(r) = A \exp(-Br) - Cr^{-6},$$

where r is the interatomic distance and A, B, C are constants characteristic of the type of atom pair. Usefulness of this type of potential in calculation of the lattice vibrations of molecular crystals was demonstrated on many occasions.[7]

Three sets of constants proposed by Williams, Kitaigorodsky and Bartell-Crowell[8] for the three types of atom pairs, C–C, C–H, and H–H (hereafter referred to sets I, II, and III, respectively) were used to calculate the lattice frequencies in combination with the Cl–Cl potential obtained by Hill.[9] The set of constants proposed by Dashevsky[10] was also used (hereafter it is referred to set IV). The four sets of constants are listed in Table 3. The constants for C–Cl and H–Cl were taken as geometric mean of the corresponding pairs of identical atoms for A and C, and as arithmetic mean for B.

The atom-atom interactions were assumed for all the atom pairs whose interatomic distances are less than 5.0, 4.0, 5.5, 4.5, 5.0, and 5.0 Å for C–C, H–H, Cl–Cl, C–H, C–Cl, and H–Cl, respectively Further inclusion of the atom pairs beyond these limits have

little effect on the calculated frequencies.

The calculated frequencies obtained with the four sets of potentials are given in Table 4, together with the observed frequencies. It is seen that the Dashevsky's potential (set IV) shows fairly good agreement between the observed and calculated frequencies, while the other sets give higher calculated frequencies. The 1,2-dichloroethane crystal involves fairly short Cl–Cl and Cl–H distances, and slight changes in their interatomic potentials have a large effect on the calculated frequencies. When the force constants for these two atom pairs are compared, it was found that the force constant-interatomic distance curves for Cl–H differ a great deal between set IV and the other sets especially in the short distance range, while the Cl–Cl curves are very similar to each other. The difference in the Cl–H curves must be ascribed to difference in the H–H potentials, since we assumed the parameters for Cl–H to be geometric and arithmetic means of the Cl–Cl and H–H parameters. The force constant curves for H–H are compared in Fig. 5. It is seen that the curve obtained from Dashevsky's potential differs considerably from the others. This is probably the principal reason for the difference in the calculated frequencies between set IV and the others[11].

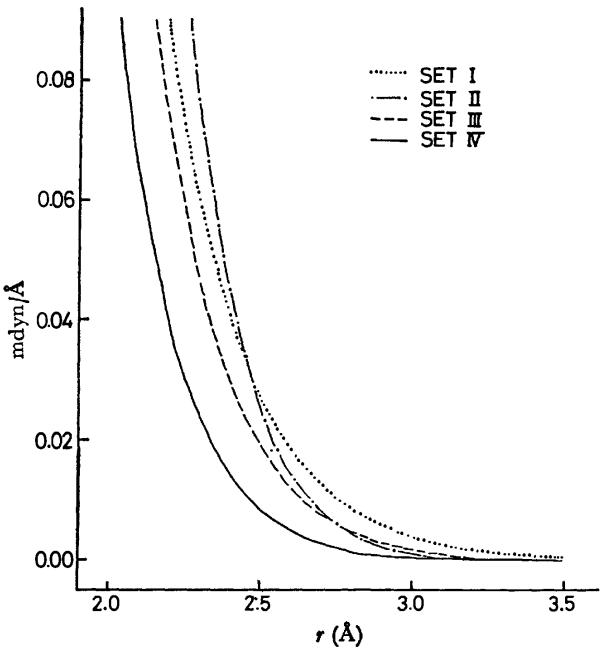

Fig. 5. Force constant curves for H–H.

In the last column of Table 4, approximate vibrational modes calculated with Dashevsky's potential are given. It is noted that the highest frequency vibrations $\nu_1(A_g)$ and $\nu_6(B_g)$ may be described approximately as due to rotational oscillations around the U axis. The situation is the same also in the vibrational modes obtained with other potentials.

Nature of the Phase Transition

Main differences between the Raman spectra of crystals I and II may be summarized as follows: the $\nu_1(A_g)$ line of 110 cm^{-1}, which is weak but distinctly observed in crystal II, is hardly recognized in crystal I, and the widths of all the Raman lines change abruptly at transition temperature.

On the other hand, normal coordinate calculation showed that $\nu_1(A_g)$ (and also $\nu_6(B_g)$) of crystal II is mainly due to the rotational oscillation around the U axis, which almost coincides with the line connecting the two chlorine atoms of the molecule.

The results strongly suggest that the phase transition of the 1,2-dichloroethane crystal at 177°K is a transition in which the rotational oscillational motion about the Cl–Cl axis of the molecule changes into a nearly free rotational motion about the same axis and *vice versa*, supporting the conclusion obtained by Lipscomb *et al.* from their X-ray studies. The $\nu_1(A_g)$ line of crystal II is stilll broad even at 4.2°K, and its band width increases with increase of temperature more rapidly than that of other lines. This implies that the molecular rotational oscillation about the U axis is fairly easy even at very low temperatures, and the oscillational amplitude rapidly increases up to the transition point where a nearly free rotation of the molecule takes place.

11) In the calculation of lattice vibrations of naphthalene and anthracene crystals, the observed frequencies are fairly well reproduced with the potentials given by Kitaigorodsky and Bartell-Crowell, while considerably lower and higher frequencies are calculated with the potentials given by Dashevsky and Williams, respectively.

Exact Classical-Mechanical Calculation of the Translational-Vibrational Energy Transfer of Energized Anharmonic Diatomic Molecules

Okitsugu KAJIMOTO and Takayuki FUENO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received July 2, 1971)

The exact classical-mechanical calculation of the translational-vibrational energy transfer of diatomic molecules was extended to collisions between inert gas and anharmonic oscillator of varying initial vibrational energy. The systems investigated were H_2–He, N_2–Ar, and I_2–Ar. It was found that, at lower vibrational levels, the transitions in both upward and downward directions become more efficient with an increase in the initial vibrational energy of molecules. In a high vibrational energy region, however, vibrational deactivation reaches a maximum and then diminishes as the initial vibrational energy approaches the dissociation threshold. The results illuminate the essence of a "bottleneck" to vibrational energy flow involved in the activation process of bimolecular dissociation of diatomic molecules.

Several workers[1-9] have developed theories on the kinetics of diatomic molecules (and the three-body atomic recombination as the reverse reaction) coupled with molecular vibrational relaxation. Their theories all show that dissociation kinetics should receive a sizable draw-back effect from the limited rates of vibrational activation of molecules, the overall reaction being a process proceeding under vibrational non-equilibrium. Details of the non-equilibrium kinetics should essentially be subject to the vibrational transition probabilities of reacting molecules in their collisions with heat-bath molecules.

However, it is an extremely cumbersome problem to evaluate such probabilities for an anharmonic oscillator energized up to its dissociation threshold. In this high-energy region, the vibrational levels are in general not only densely spaced but also poorly definable because of the coupling between vibrational and rotational degrees of freedom. This constitutes an unsurmountable obstacle to an otherwise successful adaption of the concept of vibrational ladder climbing to the overall kinetics of bimolecular dissociations.

One way to overcome the difficulty is to consider the reaction in question as a process of energy flow, by assuming the vibrational energy to be indiscrete. In principle, the diffusion theory presented by Keck and Carrier[10] and the energy-band theory proposed by Rice[11] are both along this line. In this work we treat the average vibrational energy, $\Delta\varepsilon$, which could be gained or lost by Morse oscillators of arbitrary internal energy on their single collision with an inert gas molecule.

It should be noted that the vibrational energy increment, when calculated for an oscillator of relatively low internal energy, should be related, in its classical limit, to the quantum-mechanical vibrational transition probability, P_{ij}, through $P_{ij}=\Delta\varepsilon/(\varepsilon_i-\varepsilon_j)$, where ε_i and ε_j are the energies of the discrete vibrational levels i and j, respectively. Although a number of theoretical procedures (classical, semiclassical or quantum) have been given for such calculations in the literature,[12] any procedure assuming complete separability between the translational and vibrational motions is of little use for our purpose. Separability is justifiable only when the maximum displacement of an oscillating atom from its equilibrium position is considered to be sufficiently small compared with the range size of interaction between the atom and an incident sphere, which is certainly not the case for an energized anharmonic oscillator. Benson and Berend[13] were the first to calculate the $0\rightarrow1$ transition probabilities of diatoms under *mutual* interaction with the incident atom during a collision; exact collision trajectories were obtained by numerical integration of the classical equations of motion for the colinear system. An analogous "exact" classical-mechanical procedure has been used by Kelley and Wolfsberg[14] in order to calculate the energy transferred between harmonic oscillators and inert atoms. A quantum-mechanical version of these "exact" treatments was presented by Secrest and Johnson,[15] who calculated several lower-level transition probabilities of diatoms as a function of incident energy.

In the present paper, we have adopted the exact classical-mechanical procedure to calculate the energy transfer of Morse oscillators as a function of the initial vibrational energy of oscillators as well as the initial relative translational energy of the collision system. The main part of this paper will be bisected. The first half deals with the transition probabilities between lower vibrational levels. The exact quantum-mechanical results of Secrest and Johnson are used as a

standard for comparison. The latter half deals with the energy transfer of energized anharmonic oscillators. Some important features of the mechanism of bimolecular dissociation of diatomic molecules are shown by comparison of the resulting energy transfer with that of harmonic oscillators.

Method of Calculation

The calculation is based on the classical colinear collision model. The coordinate system is as defined in Fig. 1; a Morse-type molecule BC is struck by an atom A.

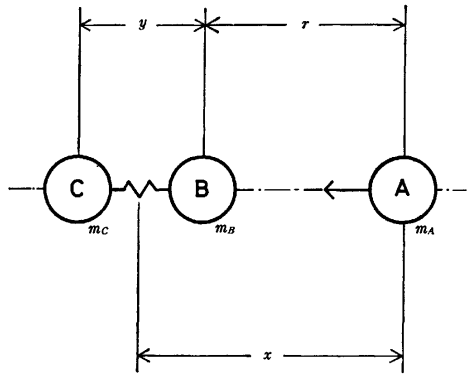

Fig. 1. The colinear collision model and its coordinate system.

The potential of the Morse oscillator is defined by

$$U(y) = D\{\exp[-a(y-y_e)]-1\}^2 \quad (1)$$

The potential acting between the colliding atoms A and B is assumed to be given by the Lennard-Jones 6—12 function:

$$V(r) = 4D_L[(r_L/r)^{12}-(r_L/r)^6] \quad (2)$$

where

$$r = x - ym_C/(m_B+m_C) \quad (3)$$

and m_B and m_C are the masses of atoms B and C respectively. In addition to the above potentials, the harmonic potentials and exponential repulsion potentials were also used for $U(y)$ and $V(r)$, whenever appropriate.

$$U(y) = \frac{1}{2}k(y-y_e)^2 \quad (4)$$

$$V(r) = A\exp(-r/L) \quad (5)$$

The total Hamiltonian of the collision system is expressed by

$$H = \frac{p_x^2}{2m} + \frac{p_y^2}{2\mu} + U(y) + V(x,y) \quad (6)$$

where p_x and p_y denote the momenta with respect to the ordinate variables x and y, respectively, and m and μ are the reduced masses of the collision system and the oscillator, respectively.

$$m = m_A(m_B+m_C)/(m_A+m_B+m_C) \quad (7)$$

$$\mu = m_Bm_C/(m_B+m_C) \quad (8)$$

Hamilton's equations of motion were solved numerically on a digital computer (NEAC 2200) with the aid of the Runge-Kutta-Gill procedure. The initial position of an incoming atom was so selected as to be large enough to render the initial interaction potential $V(x,y)$ negligibly small. The same criterion was applied for terminating the computations. The time step used for integration was 0.5×10^{-16} sec, which proved to be sufficiently small to warrant energy conservation.

For a given vibrational energy ε of the oscillator and a given translational energy E of the incident atom, the energy increment $\Delta\varepsilon$ of the oscillator was calculated as the function of the initial phase angle ϕ of the oscillator. Each initial phase was determined by dividing the period of oscillation into equal time increments. The corresponding initial bond length and momentum were calculated by use of the analytical solution of the internal motion of the Morse oscillator.[16] $\Delta\varepsilon$ was directly evaluated from the difference between the vibrational energies of the oscillator before and after the collision. The $\Delta\varepsilon$ values thus obtained were smooth functions of ϕ, as shown in Fig. 2.

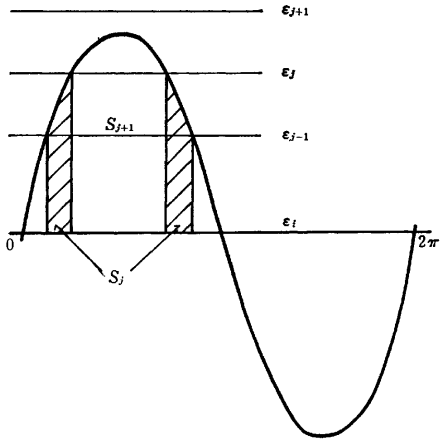

Fig. 2. Definitions of $\Delta\varepsilon_{i\to j}$ and the exact classical transition probability $P_{i\to j}$.

The average energy gain of the oscillator on a collision can be evaluated simply by integrating the $\Delta\varepsilon(E, \varepsilon, \phi)$ over the region where it is positive, and by dividing the results by 2π.

$$\Delta\varepsilon_{act}(E,\varepsilon) = \frac{1}{2\pi}\int_{\Delta\varepsilon>0}\Delta\varepsilon(E,\varepsilon,\phi)\mathrm{d}\phi \quad (9)$$

Likewise, the average energy loss, $\Delta\varepsilon_{deact}$, can be derived from $\Delta\varepsilon(E, \varepsilon, \phi)$ in the region where $\Delta\varepsilon<0$.

In cases where the initial vibrational energy is not very large, Eq. (9) should be related with the quantum-mechanical transition probability. Suppose the collision energy is relatively low, so that the maximum value of $\Delta\varepsilon(E, \varepsilon, \phi)$ for fixed E and ε is small compared with the energy difference between adjacent vibrational levels. The average energy gain of the oscillator which was initially at the i-th level, can then be expressed by

$$\Delta\varepsilon_{i\to i+1}(E) = \frac{1}{2\pi}\int_{\Delta\varepsilon>0}\Delta\varepsilon(E,\varepsilon_i,\phi)\mathrm{d}\phi \quad (10)$$

The transition probability $P_{i\to i+1}(E)$ can be defined as $\Delta\varepsilon_{i\to i+1}(E)$ divided by the energy difference be-

16) N. B. Slater, *Nature*, **180**, 1352 (1957).

tween the i-th and the $(i+1)$-th levels, *viz.*,

$$P_{i\to i+1}(E) = \Delta\varepsilon_{i\to i+1}(E)/(\varepsilon_{i+1}-\varepsilon_i) \qquad (11)$$

$P_{i\to i-1}(E)$ can be obtained through an analogous procedure, except that $\Delta\varepsilon_{i\to i-1}(E)$ is calculated from $\Delta\varepsilon(E, \varepsilon, \phi)$ in the region where $\Delta\varepsilon<0$.

On the high-energy collisions, however, the computed energy gain or loss exceeds the energy difference between adjacent levels (see Fig. 2), so that $\Delta\varepsilon_{i\to j}(E)$ should be properly defined so as to include the jumps over more than one quantum. The main problem is how $\Delta\varepsilon$ should be related with these various quantum jumps.

We here propose a working hypothesis that $\Delta\varepsilon$ can be partitioned into various $\Delta\varepsilon_{i\to j}$'s according to the relevant range of phase angles. That is, just as the activation and deactivation were discriminated according to the range of the phase angles which rendered the calculated $\Delta\varepsilon$ positive or negative, the various quantum jumps are considered to be properly characterized by the phase angle ranges which make such multi-step jumps possible on a single collision. Equation (10) can then be extended into a more general form

$$\Delta\varepsilon_{i\to j}(E) = \frac{1}{2\pi}\int_{\varepsilon_j-\varepsilon_i>\Delta\varepsilon>\varepsilon_{j-1}-\varepsilon_i} \Delta\varepsilon(E, \varepsilon_i, \phi)\mathrm{d}\phi \qquad (12)$$

where $j=i+1, i+2,\cdots\cdots$. For deactivation, the corresponding expression will be as follows:

$$\Delta\varepsilon_{i\to j}(E) = \frac{1}{2\pi}\int_{\varepsilon_{j+1}-\varepsilon_i>\Delta\varepsilon>\varepsilon_j-\varepsilon_i} \Delta\varepsilon(E, \varepsilon_i, \phi)\mathrm{d}\phi \qquad (13)$$

where $j=i-1, i-2,\cdots\cdots$. The transition probabilities are given by

$$P_{i\to j}(E) = \Delta\varepsilon_{i\to j}(E)/(\varepsilon_j-\varepsilon_i) \qquad (14)$$

for either of the activation and deactivation processes. Plausibility of the above hypothesis can only be judged from its outcomings given in the following section.

Vibrational Transitions at Lower Levels

Before discussing the characteristic behavior of the energy transfer of energized molecules, we examine the reliability of the transition probabilities derived for lower levels. Let us compare the exact classical transition probabilities with those obtained by the approximate methods and by the exact quantum-mechanical calculations. In their exact quantum-mechanical theory, Secrest and Johnson[15] assumed a harmonic oscillator model struck by an atom through an exponential repulsion potential. In order to facilitate comparison, we have used the same collision model and potential parameters. Other approximate probabilities based on the classical,[17] semiclassical,[18] and quantum (distorted wave)[19] methods were also evaluated for the same model. The collision systems studied were H_2–He, N_2–Ar, and I_2–Ar. Both the intramolecular and intermolecular potential parameters used are listed in Table 1.

Table 1. Parameters for the harmonic-exponential-repulsion potential models

System	Harmonic potential[a]		Collision potential[b]
	k, 10^4g/sec^2	y_e, Å	L, Å
H_2–He	57.494	0.7413	0.1576
N_2–Ar	229.43	1.0975	0.2041
I_2–Ar	17.202	2.667	0.2400

a) $U(y)=1/2\,k(y-y_e)^2$. k was evaluated from ω_e by use of the equation $k=(2\pi c\omega_e)^2\mu$, where c is the velocity of light and μ is the reduced mass of the oscillator. ω_e was taken from G. Herzberg, "Molecular Spectra and Molecular Structure I. Spectra of Diatomic Molecules," van Nostrand Reinhold Co., New York (1950).

b) $V(r)=A\exp(-r/L)$. A was taken to be equal to the initial translational energy E. L is evaluated from collision diameter σ by use of the equation $L=\sigma_{A\text{-}B}/17.5$ (K. F. Herzfeld and T. A. Litovitz, "Absorption and Dispersion of Ultrasonic Waves," Academic Press, New York (1959)). σ was taken from J. O. Hirschfelder *et al.*, "Molecular Theory of Gases and Liquids," Wiley, New York (1967).

H_2–He system. The values of $P_{0\to1}(E)$ calculated by the various methods as the functions of the initial translational energy of the incident atom are compared in Fig. 3. The approximate classical-, semicalssical-, and quantum-mechanical solutions all give $P_{0\to1}$ values exceeding unity at energetic collisions, whereas both the exact solutions give values which seem reasonable. The latter two solutions are in essential agreement with each other. In the lower collision energy region, however, the exact classical results are somewhat greater than those of the quantum-mechanical calculations.

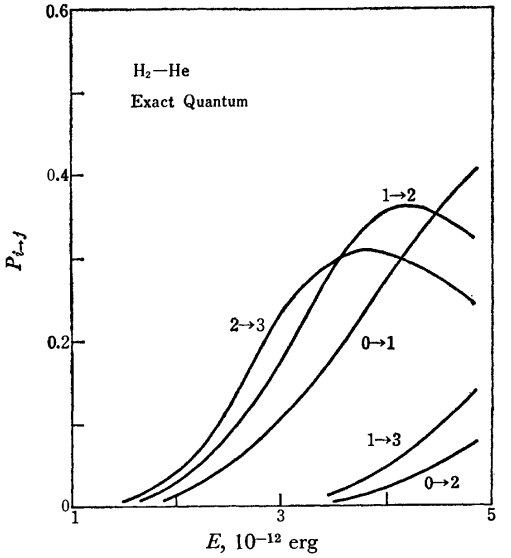

Fig. 5. Exact quantum transition probabilities of a harmonic H_2 molecule colliding with an He atom as functions of incident energy.

TABLE 2. DETAILED BALANCINGS OF THE $P_{i\to j}$ VALUES CALCULATED FOR THE H_2–He SYSTEM

Method	Transition probability	
	$P_{0\to1}$ ($E=3.0\times10^{-12}$ erg)	$P_{1\to0}$ ($E=2.17\times10^{-12}$ erg)
Semiclassical	0.60	0.19
Quantum(DW)	0.35	0.35
Exact Quantum	0.11	0.11
Exact Classical	0.20	0.20
	$P_{1\to2}$ ($E=3.0\times10^{-12}$ erg)	$P_{2\to1}$ ($E=2.22\times10^{-12}$ erg)
Semiclassical	1.21	0.41
Quantum(DW)	0.70	0.70
Exact Quantum	0.18	0.18
Exact Classical	0.29	0.30

a) $\varepsilon_1-\varepsilon_0=0.83\times10^{-12}$erg
b) $\varepsilon_2-\varepsilon_1=0.78\times10^{-12}$erg

shows that the general features of the numerical results reached from the two methods agree fairly well.

One criterion for testing the soundness of the theoretical procedure can be brought about from the microscopic reversibility relationship, which demands that $P_{1\to0}$ at an incident energy E be equal to $P_{0\to1}$ at the energy $E+(\varepsilon_1-\varepsilon_0)$. Table 2 presents a part of such tests. The exact classical method is seen to be at least as good as the quantum-mechanical methods.

N_2–Ar system. The $P_{0\to1}(E)$ values calculated by the various methods are shown in Fig. 6. Here also, the results of the exact quantum-mechanical calculations and those of exact classical calculations closely resemble each other. Although the approximate theories again give too high values of $P_{0\to1}(E)$ for energetic collisions, the differences between the approximate and exact calculations are not as great as those in the case of the H_2–He system, provided the probabilities are compared in the range of ε between 2×10^{-12} and 4×10^{-12}erg.

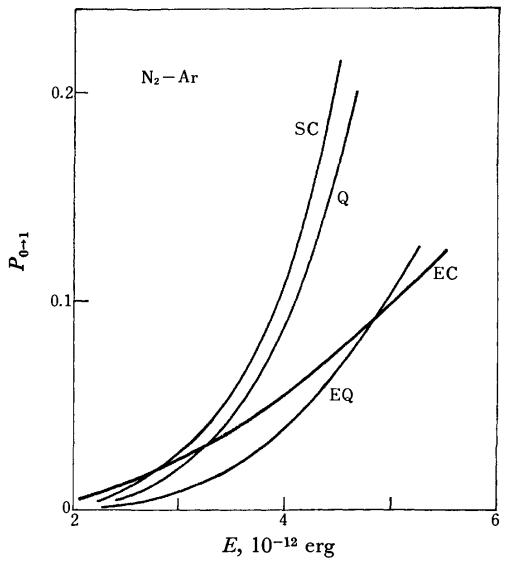

Fig. 6. The 0→1 transition probability of a harmonic N_2 molecule on its collision with an Ar atom as a function of incident energy.
SC, semiclassical[18]; Q, quantum(DW)[19]; EC, exact classical; EQ, exact quantum[15]

The calculations showed that the 1→2 and 2→3 transition probabilities are nearly two- and threefold the 0→1 probability, respectively. This is to be expected, since nitrogen is recognized as the least anharmonic oscillator, to which the well-known Landau-Teller formula,[20] $P_{i\to i+1}=(i+1)P_{0\to1}$, could be applied at lower levels.

I_2–Ar system. Iodine molecules have a very shallow potential and a small vibrational quantum, and the transition probabilities are relatively great even at lower vibrational levels. The first excited vibrational level of iodine molecule lies only 0.035×10^{-12}erg above the ground state. Comparing this value with 0.04×10^{-12}erg, the RT value at 300°K, one may expect that the 0→1 transition probability will be large

20) L. Landau and E. Teller, *Physik. Z. Sowjet Union*, **11**, 18 (1937).

even at room temperature. This in turn implies that at higher temperatures the multi-quantum transition might be more efficient than the 0→1 transition. As an example, the average energy transferred at the collision of $E=0.87\times10^{-12}$erg (the corresponding temperature being as high as 5000°K) is about 0.2×10^{-12}erg, which corresponds to the 0→6 transition.

Several transition probabilities calculated for the I_2–Ar system by the exact classical method are shown in Fig. 7. It may be seen that the 0→1 transition probability reaches its maximum at a collision energy of 0.3×10^{-12}erg and then gradually decreases. The 0→2 transition becomes significant around this energy, attains its maximum at 0.4×10^{-12}erg, and then is replaced by the 0→3 transition.

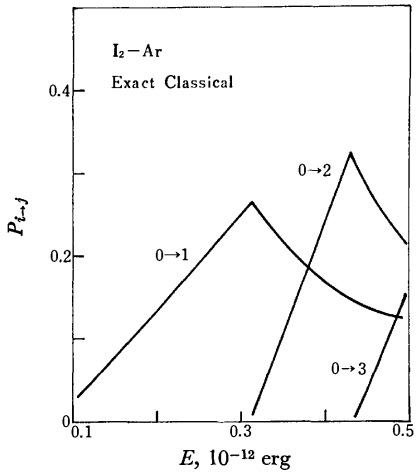

Fig. 7. Exact classical transition probabilities of a harmonic I_2 molecule colliding with an Ar atom as functions of incident energy.

In the case of iodine molecule, one significant transition from a given level is liable to be replaced quickly by another as the incident energy increases. Moreover, the level spacings are so dense that the transition probabilities of each level lose their meaning. Therefore, $\Delta\varepsilon$ will be a more convenient measure of the energy transfer even in the room temperature region.

Energy Transfer in the Higher Vibrational Energy Region

We have extended the exact classical-mechanical calculations to the energy transfer of vibrationally activated diatomic molecules. The collision system consists of a Morse oscillator and an atom interacting with it through the Lennard-Jones potential, a collision model which is more realistic for energized molecules. The systems investigated are H_2–He and I_2–Ar. Various potential parameters used are summarized in Table 3. A harmonic oscillator model was also used for the sake of comparison. Both oscillator models lead to the same results only at lower vibrational levels.

H_2–He system. As an illustrative example, typical trajectories of an atom and a Morse oscillator are shown in Fig. 8. The solid lines represent the motions of an oscillator initially at the 12-th vibrational level

Table 3. Parameters for the Morse-Lennard-Jones potential models

System	Morse Potential[a]			Collision Potential[b]	
	D, 10^{-12} erg	a, Å^{-1}	y_e, Å	D_L, 10^{-12} erg	r_L, Å
H_2–He	7.602	2.284	0.7413	0.002633	2.759
N_2-Ar	15.88	2.452	1.0975	0.01357	3.576
I_2–Ar	2.495	1.546	2.667	0.0465	4.20

a) $U(y)=D\{\exp[-a(y-y_e)]-1\}^2$. Parameters were taken from G. Herzberg, "Molecular Spectra and Molecular Structure I. Spectra of Diatomic Molecules," van Nostrand Reinhold Co., New York (1950).

b) $V(r)=4D_L[(r_L/r)^{12}-(r_L/r^6)]$. Parameters were taken from J. O. Hirschfelder *et al.*, "Molecular Theory of Gases and Liquids," Wiley, New York (1967).

and of an atom colliding with the incident energy of 0.5×10^{-12}erg (the corresponding temperature being *ca.* 3620°K). The trajectories of an atom and an oscillator initially at the ground vibrational level are given by broken lines. The amplitude of the energized oscillator is so large, about 1.5 Å at the 12-th level, which is 8 times greater than that of the ground state oscillator, that the assumption $|\Delta y|\ll L$ used in the approximation does not hold. The time duration for the maximum extension is much more prolonged in the energized H_2, thus facilitating its excitation on collision. These facts clearly indicate the necessity of adopting exact treatments, if reliable results are to be obtained for energized diatomic molecules.

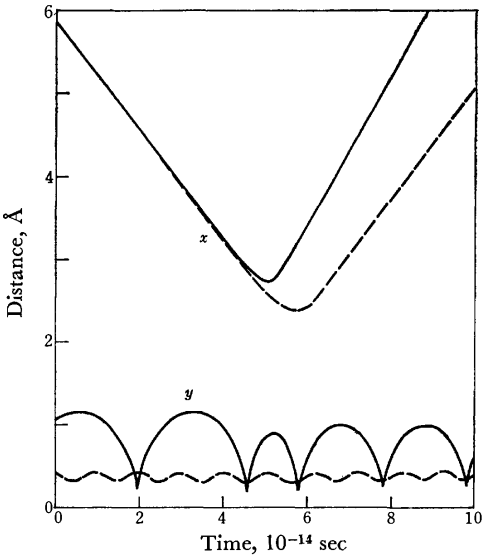

Fig. 8. Trajectories for collisions between a Morse H_2 molecule and an He atom with the incident energy fixed at 0.5×10^{-12} erg.
The initial vibrational levels of H_2 are the 0th (------) and the 12th (——).

The phase-averaged $\Delta\varepsilon$ is calculated for each level for various collision energies ranging from 0.51×10^{-12} to 5.62×10^{-12}erg. Figure 9 shows the results obtained for $E=2.02\times10^{-12}$erg. For the E value chosen, the energy transferred in either of the upward and downward directions increases at first with the level height, and the downward transitions tend to dominate over

the upward transitions, except for the 0-th level. Above the 9-th level, however, the energy transferred downward gradually decreases with the level height, until it becomes overshadowed by that for the upward transition, which is capable of leading to dissociation. The higher levels must then be kept depopulated below their thermal-equilibrium populations during the course of overall dissociation reaction.

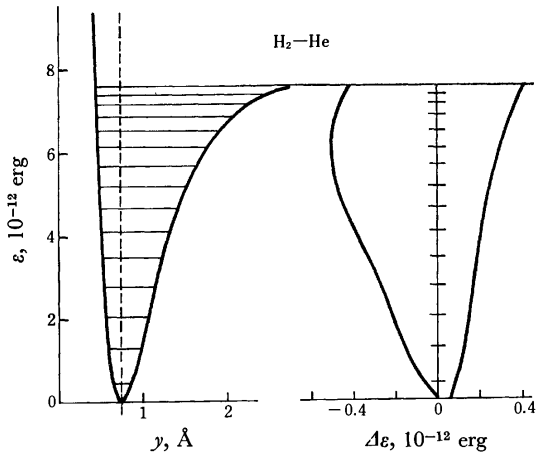

Fig. 9. The average energy change of a Morse H_2 molecule in collision with an He atom as a function of initial vibrational energy. The incident energy is fixed at 2.02×10^{-12} erg.

I_2–Ar system. Dependence of the vibrational energy increment $\Delta\varepsilon$ on the initial vibrational energy of the oscillator is shown in Fig. 10. The features of energy transfer are similar to those noted for the H_2–He system. Occurrence of the maximal deactivation in the vicinity of the threshold region is even more marked than in the H_2–He system.

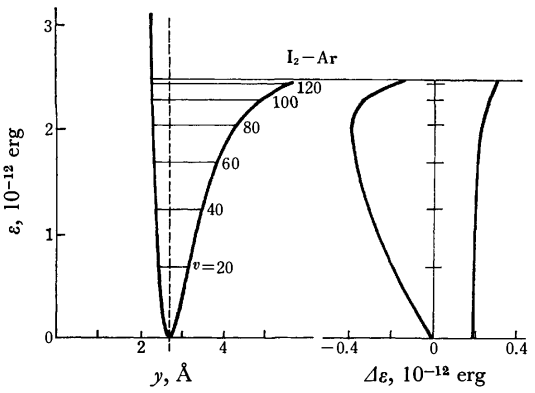

Fig. 10. The average energy change of a Morse I_2 molecule in collision with an Ar atom as a function of initial vibrational energy. The incident energy is fixed at 0.87×10^{-12} erg.

For the sake of comparison, calculations were also carried out for the hypothetical harmonic iodine molecule colliding with an argon atom of $E=0.87\times10^{-12}$erg. The results are shown in Fig. 11, where it is apparent that no such maximal efficiency for deactivation shows up; the deactivation becomes more efficient monotonously with an increase in the initial vibrational energy, and always exceeds the efficiency of activation except in the very low vibrational energy region.

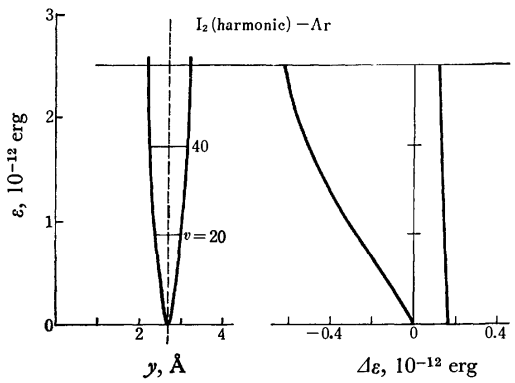

Fig. 11. The average energy change of a harmonic I_2 molecule in collision with an Ar atom as a function of initial vibrational energy. The incident energy is fixed at 0.87×10^{-12} erg.

The effects of the variation of the Morse parameter a on the energy transfer were also examined for a fixed collision energy of $E=0.87\times10^{-12}$erg. The results are shown in Fig. 12. The a values chosen were 1.0 and 3.0 which should be compared with the most plausible value 1.546 for the I_2–Ar system. A larger a corresponds to a greater anharmonicity.[21] The main feature of the results for a large a is the decrease in efficiency of the upward transitions for molecules of low vibrational energy together with the uniform diminution in efficiency of the downward transitions. The former would act to retard the activation of stable molecules, while the latter would accelerate the dissociation of vibrationally excited molecules to continuum. The net result is

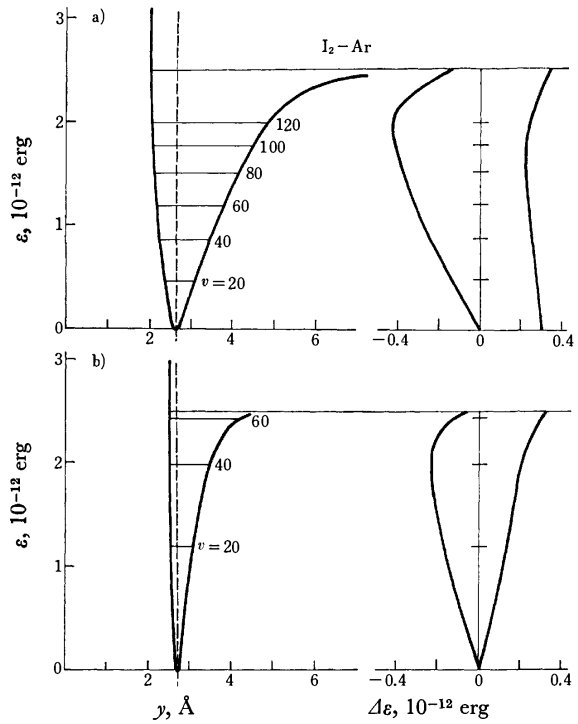

Fig. 12. Effects of the vibrational anharmonicity on the energy change of I_2 in collision with Ar.
a) $a=1.0$ Å; b) $a=3.0$ Å

21) This can be readily verified by expanding the Morse potential function with respect to $(y-y_e)$:

$$D\{\exp[-a(y-y_e)]-1\}^2 = Da^2(y-y_e)^2 \times[1-a(y-y_e)+(7/12)a^2(y-y_e)^2+\cdots]$$

that the depopulation of energized molecules will be more conspicuous for diatoms of greater vibrational anharmonicity.

Discussion

From the results we conclude that Morse oscillators are subjected to a maximal extent of vibrational deactivation in the region just beneath the dissociation threshold. The conclusion has an important bearing on the dissociation-recombination kinetics of diatomic molecules in inert gas.

In dissociation, the molecules energized up to the threshold would tend to get excited still more or dissociated on a collision with a heat-bath molecule, whereas the molecules of low internal energy would be provided with far less opportunity of getting excited. As a result, the energized molecules would be kept depopulated below their thermal distribution, thus effecting a considerable lowering in dissociation rate. This is exactly what we have as an image for the non-equilibrium kinetics of dissociation processes.[3] The region of the maximal deactivation efficiency can then be taken as a "bottleneck" to a normal upward flow of vibrational energy.

By the same token, the highly energized molecules formed by recombination of atoms would be over-populated on one hand, and would still retain a good deal of chance to get redissociated on the other. Once the energized molecules have passed through the bottleneck, they are all subjected to deactivation to stable molecules. The net effect is again a lowering in the rate of downward flow because of the presence of the bottleneck, if it is not too narrow. This could be regarded as a physical basis of the steady-flow assumption[5] which was invoked in order to account for the kinetics of the molecular recombinations of iodine and bromine atoms. However, if the bottleneck is very narrow because of a great anharmonicity of the molecule formed, it will play a critical role in controlling the rate of energy flow. The steady-state assumption will then be considerably in error, and the net rate will be decreased anomalously as in the case of fluorine.[22]

We have not attempted to consider the energy increments averaged over the thermal distribution of collision energies, E. Neither was the energy flow considered explicitly in relation with the reaction rates. Nevertheless, the $\Delta\varepsilon(E, \varepsilon)$ calculated for energized molecules is useful for understanding the kinetic feature of dissociation and recombination. The presence of a bottleneck in these reactions (viewed as energy flow phenomena) can be visualized more clearly than ever before, from an inspection of $\Delta\varepsilon(E, \varepsilon)$ calculated for anharmonic diatomic molecules.

The Physical Properties of the Anion Radical Salts Derived from 3,5,3′,5′-Tetrachloro-4,4′-diphenoquinone and 3,5,3′,5′-Tetrabromo-4,4′-diphenoquinone[1]

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received July 3, 1971)

The anion radical salts derived from 3,5,3′,5′-tetrachloro-4,4′-diphenoquinone and 3,5,3′,5′-tetrabromo-4,4′-diphenoquinone were prepared. The absorption spectra in solution and the solid-state spectra were examined in order to study the solid-state properties characteristic of the anion radical salts. The measurements of the static magnetic susceptibilities and the electrical resistivities were also useful for this purpose. These physical properties were found to be based on the charge-transfer interaction between the anion radical molecules. It was suggested that, in these solid anion radical salts, the anion radical molecules might be stacked by a unique face-to-face arrangement in groups of two or an infinite number of molecular systems.

The solid-state properties of the anion radical salts of various halogen-substituted *p*-benzoquinones have been reported in a previous paper.[2] The present paper will describe some anion radical salts of the halogen-substituted 4,4′-diphenoquinones with diamagnetic counter cations (see Fig. 1). The electron spin resonance (ESR) spectra of these crystalline salts have already been examined by Matsunaga.[3]

In general, solid ion radical salts have been a matter of great interest, because the ion radical molecules form, in themselves, a plane-to-plane stacking into columns so as to make a large overlap between their half-filled molecular orbitals.[4] In this case, any individual radi-

Fig. 1. The anion radical salts of (a) 3,5,3′,5′-tetrachloro-4,4′-diphenoquinone (TCDQ) and (b) 3,5,3′,5′-tetrabromo-4,4′-diphenoquinone (TBDQ). M^+ represents a diamagnetic counter cation.

cal molecule interacts through charge transfer most strongly with one or two other radicals. Much knowledge concerning the mutual charge-transfer interaction has been accumulated by measuring the solid-state spectra, the magnetic susceptibilities, and the electrical conductivities.[5-11] The purpose of the present paper is to apply these physical methods to the anion radical salts derived from 3,5,3′,5′-tetrachloro-4,4′-diphenoquinone (TCDQ) and 3,5,3′,5′-tetrabromo-4,4′-diphenoquinone (TBDQ). We shall examine how the charge-transfer interaction between the anion radicals contributes to the solid-state properties of these anion radical salts. The properties of these compounds are interesting in comparison with those previously-investigated properties of the halogen-substituted *p*-benzoquinone anion radical salts.[2]

Materials

3,5,3′,5′-Tetrachlorobiphenyl-4,4′-diol was made by the chlorination of biphenyl-4,4′-diol (Eastman Kodak Co., white-label grade) suspended in acetic acid, while 3,5,3′,5′-tetrabromobiphenyl-4,4′-diol was similarly made by the bromination of biphenyl-4,4′-diol.[12] The TCDQ and TBDQ[13] were obtained by the oxidation of 3,5,3′,5′-tetrachlorobiphenyl-4,4′-diol and 3,5,3′,5′-tetrabromobiphenyl-4,4′-diol respectively with fuming nitric acid.[12] They were purified by treating them with chloroform.

The following four anion radical salts were prepared according to the method of Matsunaga[14]: Na^+ $TCDQ^{\cdot-}$, K^+ $TCDQ^{\cdot-}$, Na^+ $TBDQ^{\cdot-}$, and K^+ $TBDQ^{\cdot-}$. In this method, the anion radical salts were made by the one-electron reduction of the corresponding quinones with alkali metal iodides in an acetone solution.

The Absorption Spectra in Solution

In order to characterize the solid-state spectra of these anion radical salts, it will be necessary to compare them with the absorption spectra of the salts dissolved in solution; therefore, we will examine the spectra in this section. The absorption spectra in solution were measured at room temperature, using a Beckman DK-2A spectrophotometer at concentration of the order of 10^{-5} mol/*l*. Since the anion radical salts are soluble only with difficulty in an acetone solution, it was difficult to determine the values for the molar extinction coefficients.

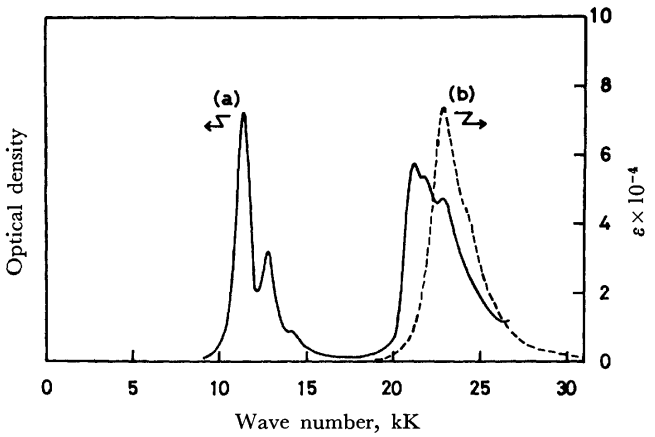

Fig. 2. The absorption spectra of (a) Na^+ $TCDQ^{\cdot-}$ in acetone solution and of (b) neutral TCDQ in ethylene dichloride solution.

The TCDQ Anion Radical Salts. The aborption spectrum of Na^+ $TCDQ^{\cdot-}$ in an acetone solution is reproduced in Fig. 2, together with that of neutral TCDQ in an ethylene dichloride solution. The absorption spectrum of neutral TCDQ has an absorption peak at 23.0 kK with the molar extinction coefficient of 7.33×10^4 and a shoulder around 24.2 kK, while that of the anion radical salt has low-energy absorption peaks at 11.4 kK, 12.9 kK, and 14.2 kK, and a high-energy band with some vibrational structures at 21.2 kK, 21.8 kK, and 22.9 kK. This anion radical salt in solution appears greenish yellow, and it is quite stable at room temperature. The spectrum is not changed when the counter cation of the salt is replaced by the potassium cation. Since the concentration is so dilute, the salt seems to be completely dissociated in the solution. The spectrum obtained is that of the anion radical

13) Generally speaking, stable anion radicals are made from strong electron-acceptor molecules. Both TCDQ and TBDQ molecules are strong electron acceptors. In order to investigate their electron-accepting properties, the charge-transfer complexes of TCDQ and TBDQ with such donors as aromatic hydrocarbons were examined in an ethylene dichloride solution. The absorption spectra of the complexes were measured at room temperature. The complex of pyrene with TCDQ showed the maximum position of the charge-transfer band at 14.2 kK, while the complex of pyrene with TBDQ showed it at 13.6 kK. Let us compare these results with the charge-transfer absorption of the pyrene-7,7,8,8-tetracyanoquinodimethane complex, where the absorption maximum of the first charge-transfer band has been reported to be located at 13.7 kK. For a common donor, the variation of the charge-transfer energies of the complexes arises mostly from the difference in the electron affinities of the acceptors. Therefore, if the value of 1.7 eV for the electron affinity of 7,7,8,8-tetracyanoquinodimethane is chosen as a reference, the electron affinities of TCDQ and TBDQ can be estimated to be 1.6_4 eV and 1.7_1 eV respectively. Fig. 3. The absorption spectra of (a) Na^+ $TBDQ^-$ in acetone solution and of (b) neutral TBDQ in ethylene dichloride solution.

monomer,[15] because the counter cations of the salts are simple alkali metal cations.

The TBDQ Anion Radical Salts. The absorption spectrum of Na^+ $TBDQ^-$ in an acetone solution is given in Fig. 3, together with that of neutral TBDQ in an ethylene dichloride solution. The absorption spectrum of neutral TBDQ has an absorption peak at 22.4 kK with the molar extinction coefficient of 7.40×10^4, and a shoulder around 23.5 kK, while that of the anion radical salt has low-energy absorption peaks at 11.4 kK, 12.9 kK, and 14.2 kK, and a high-energy band with some vibrational structures at 21.3 kK, 21.8 kK, and 22.9 kK.[15] The spectroscopic features of Na^+ $TBDQ^-$ were found to be very similar to those for Na^+ $TCDQ^-$. Therefore, it can be said that the electronic states of the 4,4′-diphenoquinone anion radicals are scarcely affected even though the chlorine substituents are replaced by the bromine substituents.

The Solid-State Spectra

In general, it is interesting to examine the solid-state spectra of ion radical salts if the charge-transfer interaction between the ion radicals takes place in the solid state. In this case, the solid-state spectra are known to be different from the monomer spectra of the ion radicals in solution and to show the intermolecular charge-transfer band in the low-energy region.[2,7-11] In this section, we will apply this method to the solid TCDQ and TBDQ anion radical salts by measuring the diffuse reflection spectra.

The diffuse reflection spectra were recorded on a Beckman DK-2A spectroreflectometer in the range from 4.0 kK to 30.8 kK at room temperature. In order to avoid cation exchange between the salt and the diluent, the sodium salts were ground and diluted with sodium chloride, while the potassium salts were similarly treated with potassium bromide. The solid-state spectra were then obtained by plotting the diffuse reflection spectra using the Kubelka-Munk equation, $f(R)=(1-R)^2/2R$, in which R is the reflectance.

The TCDQ Anion Radical Salts. These crystalline anion radical salts are dark blue and are quite stable at room temperature. The solid-state spectrum of Na^+ $TCDQ^-$ (Fig. 4, Curve a) shows a low-energy band at 6.6 kK and high-energy bands at 15.5 kK and 26.2 kK.[16] Theses pectroscopic features were found to be quite different from those of the monomer spectrum of the TCDQ anion radical in solution. The band at 6.6 kK appears in the low-energy region, where the anion radical monomer does not absorb. This band is broad without vibrational structures, and the intensity is strong. It cannot be assigned to the charge-transfer transition from the anion radical to the counter cation, since its maximum position is scarcely shifted when the counter cation of the salt is replaced (see below). Although, at present, no experimental data on the charge-transfer absorption in the dimer of the anion radicals are available for purposes of comparison, the low-energy band at 6.6 kK seems to be attributable to the charge-transfer transition between the anion radicals in the solid state. In this case, the TCDQ anion radicals will be stacked closely enough together for the half-filled molecular orbitals to make a large overlap, and the π-π transitions of the monomer will be much perturbed in the field of the other anion radicals. This is shown as appreciable blue-shifts of the high-energy bands at 15.5 kK and 26.2 kK for the solid-state spectrum of Na^+ $TCDQ^-$, compared to the monomer absorptions of the TCDQ anion radical at 11.4 kK and 21.2 kK respectively.

The solid-state spectrum of K^+ $TCDQ^-$ (Fig. 4, Curve b) shows a low-energy band at 6.7 kK and high-energy bands at 15.3 kK and 25.4 kK. The locations and the intensities of these bands were found to coincide well with those for Na^+ $TCDQ^-$. Therefore, the situation of the solid state of K^+ $TCDQ^-$ seems to be

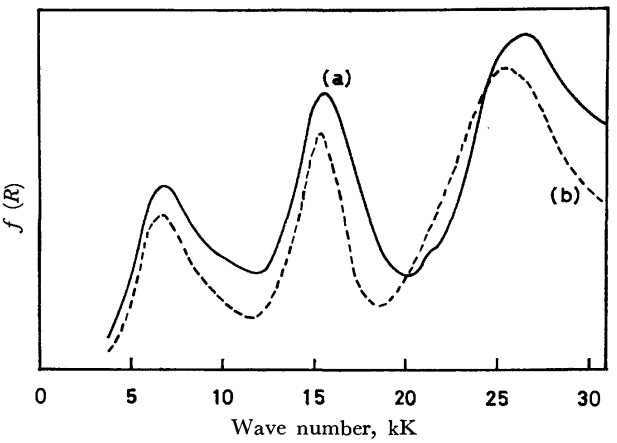

Fig. 4. The solid-state spectra of (a) Na^+ $TCDQ^-$ and (b) K^+ $TCDQ^-$.

15) The monomer spectrum of the 4,4′-diphenoquinone anion radical was found to be very similar to that of the benzidine cation radical. Concerning the π-electron systems, the 4,4′-diphenoquinone anion radical seems to be, in spite of the opposite electric charge, isoelectronic to the benzidine cation radical. See H. Matsusaka and K. Suzuki, paper presented at the 19th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1966.

16) The monomer spectrum and also the solid-state spectrum of the 4,4′-diphenoquinone anion radical salt were found to be very similar to those of the cation radical salt of benzidine bromide, respectively. The solid-state spectrum of the benzidine bromide shows a low-energy charge-transfer band at 6.7 kK and high-energy bands at 15.6 kK and 26.0 kK. See Refs. 7 and 15.

very analogous to that of Na^+ $TCDQ^{\cdot-}$.

The TBDQ Anion Radical Salts. These crystalline anion radical salts are also dark blue and are quite stable at room temperature. The solid-state spectrum of Na^+ $TBDQ^{\cdot-}$ (Fig. 5, Curve a) is composed of a low-energy band at 6.5 kK and high-energy bands at 15.1 kK and 25.5 kK.[16] These spectroscopic features were again found to be quite different from those of the monomer spectrum of the TBDQ anion radical in solution, but they were very similar to those of the solid-state spectrum of Na^+ $TCDQ^{\cdot-}$. Therefore, the low-energy band at 6.5 kK can also be assigned to the charge-transfer transition between the anion radicals in the solid state, while the high-energy bands at 15.1 kK and 25.5 kK can be assigned to the shifted bands of the monomer absorptions at 11.4 kK and 21.3 kK respectively. The electronic structures of the solid 4,4'-diphenoquinone anion radical salts are scarcely affected even though the chlorine substituents are replaced by the bromine substituents.

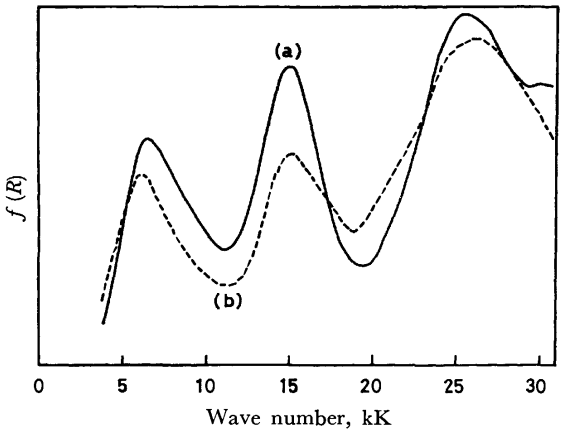

Fig. 5. The solid-state spectra of (a) Na^+ $TBDQ^{\cdot-}$ and (b) K^+ $TBDQ^{\cdot-}$.

K^+ $TBDQ^{\cdot-}$ gives a solid-state spectrum (Fig. 5, Curve b) comprising a low-energy charge-transfer band at 6.2 kK and high-energy bands at 15.2 kK and 25.8 kK. The locations and the intensities of these bands are coincident with those for the corresponding bands in Na^+ $TBDQ^{\cdot-}$. Therefore, the charge-transfer interactions in these two solid substances appear to be very much alike in manner.

The Magnetic Susceptibilities

It has been well established that the charge-transfer interaction between the ion radicals leads to a marked decrease in the paramagnetic susceptibilities of the ion-radical salts.[2,6-9]. The charge-transfer interaction is known to stabilize the antiferromagnetic state where the spins associated with the ion radicals are antiparallel. Hence, we will attempt to measure the static magnetic susceptibilities for the TCDQ and TBDQ anion radical salts.

The magnetic susceptibilities of the anion radical salts and the neutral TCDQ and TBDQ were measured by the Gouy method. All the measurements were made at room temperature under an atmospheric pressure. The susceptibility balance was calibrated by referring to distilled oxygen-free water, for which the susceptibility was taken to be -0.720×10^{-6} emu/g at room temperature.

Na^+ $TCDQ^{\cdot-}$. Although the TCDQ anion radical molecule possesses an unpaired electron, the magnetic susceptibility of Na^+ $TCDQ^{\cdot-}$ at 18°C was found to be diamagnetic. Its value was experimentally determined to be $-(143\pm3)\times10^{-6}$ emu/mol, while the value for the neutral TCDQ was determined to be $-(142\pm1)\times10^{-6}$ emu/mol. The value for the neutral TCDQ was used for the diamagnetic susceptibility of its anion radical, since the skeleton of the neutral TCDQ is very similar to that of its anion radical. By making the correction for the diamagnetism of the counter cation, the diamagnetic susceptibility of Na^+ $TCDQ^{\cdot-}$ was estimated to be $-(147\pm1)\times10^{-6}$ emu/mol. The paramagnetic susceptibility of Na^+ $TCDQ^{\cdot-}$ was evaluated by subtracting the diamagnetic susceptibility from the observed magnetic susceptibility. The paramagnetic susceptibility was thus determined to be as small as $(4\pm4)\times10^{-6}$ emu/mol; this value corresponds only to $(0.3\pm0.3)\%$ of the free-spin paramagnetism. This marked disappearance of the paramagnetism can be understood in terms of the antiferromagnetic spin exchange interaction between the unpaired electrons on the TCDQ anion radicals. Although it is not clear, at present, whether the spin exchange interaction can be described by the singlet-triplet model or by the linear chain Heisenberg model, the antiferromagnetic spin exchange interaction in this salt seems to be as large as 0.1—0.2 eV. At any rate, it is certain that the charge-transfer interaction between the anion radicals makes a significant contribution to the antiferromagnetic spin exchange interaction.

Na^+ $TBDQ^{\cdot-}$. The magnetic susceptibility of Na^+ $TBDQ^{\cdot-}$ at 18 °C was also found to be diamagnetic. Its value was experimentally determined to be $-(155\pm2)\times10^{-6}$ emu/mol, while the value for neutral TBDQ was determined to be $-(174\pm1)\times10^{-6}$ emu/mol. In a way similar to the case of Na^+ $TCDQ^{\cdot-}$, the paramagnetic susceptibility of Na^+ $TBDQ^{\cdot-}$ was estimated to be $(24\pm3)\times10^{-6}$ emu/mol by subtracting the diamagnetic susceptibility of $-(179\pm1)\times10^{-6}$ emu/mol. The magnitude of this paramagnetic susceptibility, although it is rather larger than that of Na^+ $TCDQ^{\cdot-}$, is much less than that of the free-spin paramagnetism. Except for a slight decrease in the antiferromagnetic spin-exchange interaction in Na^+ $TBDQ^{\cdot-}$, the magnetic state of Na^+ $TBDQ^{\cdot-}$ appears to be similar to that of Na^+ $TCDQ^{\cdot-}$.

The Semiconductivities

Among the organic semiconductors, ion radical salts are known to exhibit particularly high electrical conductivities.[5] These electrical properties are based on a unique face-to-face stacking of the ion radical molecules in the solid state.[4] In this respect, it seemed that it would be interesting to examine the semiconductive properties of the TCDQ and TBDQ anion radical salts.

The electrical resistivity and its variation when the

temperature ranged from 15 °C to 90°C were measured with the DC method. The anion radical salts have been available only as small crystals, excluding the possibility of single-crystal measurements. Hence, the measurements were performed with the sample powder under a compression of 5.4×10^2 kg per cm^2 between stainless steel electrodes in a Teflon cylinder.

For all of these compounds, a good linear relationship was obtained when the logarithm of the resistivity was plotted against the reciprocal of the absolute temperature. Therefore, the resistivity (ρ) was described by:

$$\rho = \rho_0 \exp(E/kT), \quad (1)$$

where E is the activation energy for conduction. For the TCDQ and TBDQ anion radical salts, the data on the specific resistivity at room temperature and the value of E are collected in Table 1. Table 1 shows that these values are scarcely affected when the substituents of the anion radicals or the counter cations now under investigation are replaced.

Table 1. The electrical resistivity data on the TCDQ and TBDQ anion radical salts

Compound	ρ at 20°C (Ωcm)	E[a)] (eV)
Na^+TCDQ^-	2.0×10^4	0.24
K^+TCDQ^-	3.3×10^4	0.24
Na^+TBDQ^-	3.2×10^3	0.22
K^+TBDQ^-	8.7×10^4	0.27

a) The activation energy for conduction.

These anion radical salts were found to be highly conductive. This implies the arrangement of a face-to-face stacking of the anion radical molecules in these solid salts. It is interesting to see that the specific resistivities of these anion radical salts are as low as those of the 7,7,8,8-tetracyanoquinodimethane (TCNQ) anion radical salts, in which the specific resistivities of Na^+ $TCNQ^-$ and K^+ $TCNQ^-$ have been reported to be 1×10^5 Ω cm and 1×10^4 Ω cm respectively at room temperature.[5)]

Discussion

The above-mentioned characteristics in the solid-state spectra, the magnetic susceptibilities, and the electrical resistivities clearly indicate that the strong charge-transfer interaction between the anion radical molecules takes place in the TCDQ and TBDQ anion radical salts. Therefore, the anion radical molecules are expected to form, in themselves, a place-to-plane stacking into columns so as to make a large overlap between their half-filled molecular orbitals; this feature of the crystal structure has also been found in a number of other ion radical salts.[4)] The charge-transfer absorption characteristic of the solid-state spectra should be ascribed to the transition of the $<\cdots Q^-Q^-Q^-Q^-\cdots>$ $\rightarrow<\cdots Q^-Q^0Q^2-Q^-\cdots>$ type, where Q^- denotes a 4,4′-diphenoquinone anion radical molecule. However, a question still remains whether the intermolecular interaction is to be described predominantly by pair-by-pair or by a linear chain column composed of an infinite number of anion radical molecules. In the former case, the interaction is approximately confined to the dimer of the anion radicals, while, in the latter case, one individual anion radical interacts equally strongly with two others. In this respect, a further study of the X-ray diffraction will be required to determine by which arrangement the TCDQ and TBDQ anion radicals are stacked in the present solid salts.

Finally, we have to compare the results on the TCDQ and TBDQ anion radical salts with those previously determined for the anion radical salts of various halogen-substituted *p*-benzoquinones.[2)] The charge-transfer interaction in the halogen-substituted *p*-benzoquinone anion radical salts is largely affected not only by the kinds of the halogen substituents in the anion radical molecules, but also by the species of the counter cations. In the case of the potassium cation, the interaction of the salt is markedly decreased compared to that of the sodium salt. Moreover, the charge-transfer interaction is decreased when the substituted chlorine for the anion radical molecule is replaced by bromine. In contrast to these halogen-substituted *p*-benzoquinone anion radical salts, it is noteworthy that the manner of the charge-transfer interaction in the TCDQ and TBDQ anion radical salts does not depend practically on the kinds of the halogen substituents in the anion radical molecules or on the species of the counter cations now under investigation.

The Photochemical Decomposition of Ethylamine as Studied by Means of the Electron Spin Resonance

Yashige KOTAKE, Mitsuo ONO, and Keiji KUWATA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received July 5, 1971)

The photochemical decomposition of ethylamine at low temperatures was studied using ultra-violet light of various wavelengths (120—400 nm), and the photochemical reactions were examined. The initial stage of the decomposition is the release of the hydrogen atom by far ultra-violet light. As the decomposition proceeds, the effective wavelengths for the succeeding reactions become longer. The final products of the decomposition are the methyl radical and other diamagnetic species. The effects of the matrix and the counter ion on the reaction are also discussed.

In the field of radiation chemistry, alkylamines have been investigated intensively as hole-trap reagents.[1] Because most alkylamines have their optical absorption peaks in the far ultra-violet (FUV) region, the peaks being assigned as n-σ^* excitations, photochemical study by direct photolysis with FUV light is difficult. Wood *et al.* reported that, upon X-ray irradiation, many alkylamines decompose into π-radicals with the structure of $RCHNH_2$.[2-4] This π-radical converts into the $RCH{=}\dot{N}$ radical after a short UV-irradiation.

Richerzhagen and Volman[5] irradiated ethylamine in an adamantane matrix with mercury resonance lines (184, 253 nm). Both X-ray and UV studies indicate complex reactions, however, and the mechanism of its decompositions is not clear. Also, the effective wavelength of the radiation has not been specified.

By selecting the light source well, the primary and succeeding processes of the decomposition can be observed selectively. The control of the matrix is also informative for the study of the reaction mechanism.

In this study, the photochemical decomposition of ethylamine was investigated by means of selective illumination. The primary process of the photochemical decomposition of ethylamine was the elimination of an α proton, much as in the case of X-ray irradiation. The primary process was affected strongly by its counter ion and the state of the matrix.

Experimental

Materials. The ethylamine used was obtained by the dehydration of 70% aqueous solution by potassium hydroxide. An especially purified sample was obtained by the neutralization and dehydration by KOH of an aqueous solution of ethylamine hydrochloride of a guaranteed grade.

Aqueous solutions of different concentrations were prepared by the volumetric dilution of pure ethylamine. The amino group was deuterated by the exchange reaction of heavy water with the ethylamine in the solution.

Irradiation. FUV light from a hydrogen (~120 nm) or a mercury (~180 nm) discharge lamp which was excited by microwave discharge was irradiated in the sample through a LiF window *in vacuo*. The apparatus for the irradiation has been reported elsewhere.[6] The sample was deposited on the outside of the quartz coldfinger cooled with liquid nitrogen and was thought to be amorphous.

UV light and near UV light from a 1-kW high-pressure mercury arc were irradiated using Toshiba UVD-1B and UVD-25 filters respectively. Samples were placed in quartz or spectrosil tubes, evacuated several times, and then irradiated at the temperature of liquid nitrogen. These samples, when cooled to 77°K, became polycrystalline.

Temperatures higher than −150°C were obtained by mixing isopentane and liquid nitrogen and by putting the irradiated samples into the mush.

Results and Discussion

FUV Irradiation. Amorphous pure ethylamine, which consists of FUV (120—180 nm) irradiated for 1 hr, gives the ESR spectrum shown in Fig. 1A.

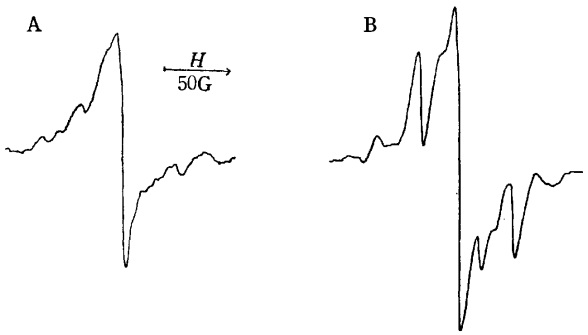

Fig. 1. A: ESR spectrum of FUV irradiated ethylamine at 77°K. B: UV (240 nm) re-irradiated to A.

This unresolved spectrum, which spreads over 70 gauss, is assigned to the $CH_3\dot{C}HNH_2$ radical. Wood and Lloyd[4] identified the $CH_3\dot{C}HNH_2$ radical by the X-ray irradiation of ethylamine in an adamantane matrix and obtained $a_{H\alpha}=15.3$, $a_{H\beta}=20.2$, $a_{HN}=4.9$, and $a_N=4.9$ gauss. The envelope of the spectrum is consistent with these assignments. The poor resolution of the spectrum may be attributed to the fact that the sample is amorphous and that other radicals may also exist. The poor resolution also prevented the detection of the deuterium substitution effect of amino hydrogen.

UV Irradiation. By the subsequent irradiation of UV light (~240 nm) for 2 or 3 min, the FUV-irradiated sample gave another radical, the spectrum of which is shown in Fig. 1B. This spectrum shows, in addition to the spectrum of the CH_3CHNH_2 radical, a comparatively sharp doublet with a separation of 79 gauss. By further irradiation by UV light the methyl radical was also produced.

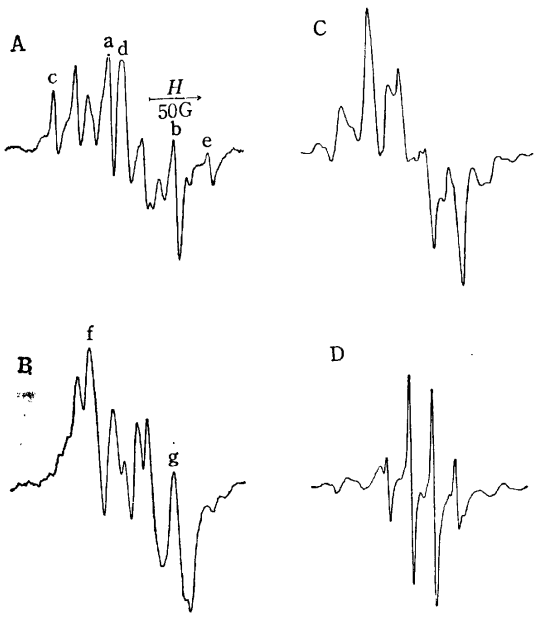

Fig. 2. ESR spectra of UV (240 nm) irradiated ethylamine at 77°K. A: 100% B: added trace of water C: 75 vol % aqueous solution D: 30 vol% aqueous solution.

Aqueous Solution of Ethylamine. The ESR spectra of several kinds of aqueous solutions of ethylamine observed after a 1 hr irradiation of UV light (240—400 nm) are shown in Fig. 2. In concentrated ethylamine solutions, the spectra show complex features (Fig. 2A), indicating the conversion of the primarily-produced radicals. However, the most striking feature of this spectrum is the sharp 64G doublet, marked a, b, and the 87G triplet of the methylene imino radical,[7,8]

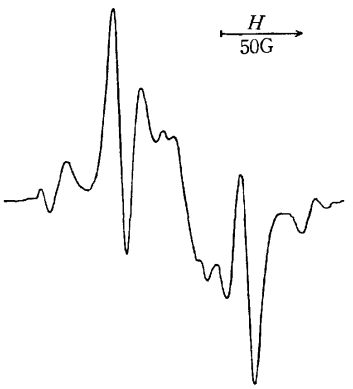

Fig. 3. ESR spectrum of UV (240 nm) irradiated ethylamine 75 vol % aqueous solution at 77°K which is observed at −150°C ($CH_3\dot{C}H{=}\dot{N}$ radical).

marked c, d, and e. Also another unidentified radical exists in this spectrum. By irradiating UV light, ethylamine containing a trace of water gives the spectrum shown in Fig. 2B. Instead of the 64G sharp doublet peak, the 79G sharp doublet peaks are revealed (f, g). By increasing the amount of water, a methyl radical was observed with the 79G doublet (Fig. 2C, 2D).

The spectra shown in Fig. 2C changed to Fig. 3 when the sample was warmed to −150°C. At this temperature, the methyl radical disappeared, and only the radical which shows the 79G doublet survived. This radical may be assigned to the ethylidenimino (CH_3-$CH{=}\dot{N}$) radical. Many investigators[2-5,9,10] have observed this radical in the solid and liquid phases, and it has an isotropic hydrogen splitting of 79—80 gauss. In this study, the radical shown in Fig. 3 shows no deuterium-substitution effect of amino hydrogen. This 79-gauss doublet agrees with the radical produced by the UV irradiation following the FUV irradiation of ethylamine.

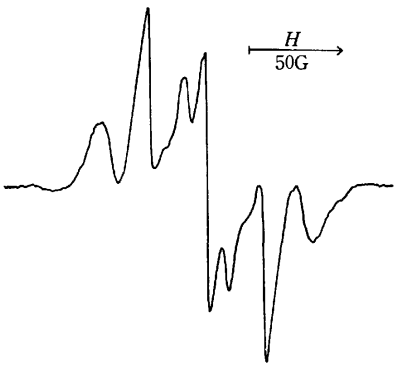

Fig. 4. ESR spectrum of UV (240 nm) irradiated ethylamine hydrochloride at 77°K ($\dot{C}H_2CH_2NH_3^+Cl^-$ radical).

Ethylamine Hydrochloride. Ethylamine hydrochloride gives the spectrum shown in Fig. 4 upon irradiation with UV light longer than 240 nm at 77°K. In the spectra of Fig. 4, the splitting of both side lines is 64G; this coincides with the a and b lines of Fig. 2A. This spectrum is very similar to the spectrum obtained for FUV- and UV-irradiated *n*-propanol.[6] In the case of *n*-propanol, this was assigned to the CH_2–CH_2–CH_2–OH radical, while the radical from irradiated ethylamine hydrochloride can be assigned to the CH_2–CH_2–NH_3^+–Cl^- radical. Taniguchi *et al.*[11] observed this radical in the flow system of an aqueous solution of ethylamine with hydrogen peroxide and $TiCl_3$, and they reported $a_{H\alpha}=26.6$, $a_{H\beta}=22.7$, and $a_N=5.1$ gauss. These coupling constants satisfactorily explain the spectrum of Fig. 4.

Mechanism of Decomposition. The radical species generated by the photolysis show absorption maxima of progressively longer wavelengths as the decomposition proceeds. Ethylamine has its optical absorption peak in the far ultraviolet region; CH_3CHNH_2, at 240—400 nm, and $CH_3C\dot{H}{=}N$, at wavelengths longer than

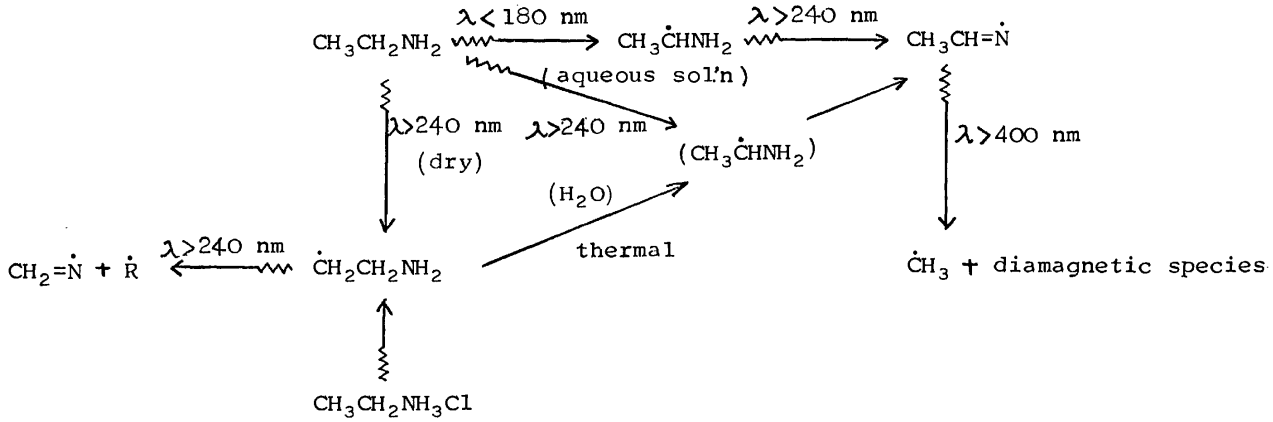

Fig. 5. Photochemical reaction scheme of ethylamine.

400 nm. The ethylidenimino radical decomposes into the methyl radical and other diamagnetic species upon irradiation with light longer than 400 nm. This fact indicates that the precursor of the methyl radical formed in the aqueous solution of less than a 75 vol % of ethylamine is the ethylidenimino radical.

Wood *et al.*[2] reported that several alkylamines gave no ESR signal upon UV irradiation unless the sample had previously been X-ray irradiated. Though alkylamines have their optical absorption peaks in the FUV region, they usually gave tailing absorptions in the UV region, and prolonged irradiation gives products with poor quantum yields. All the features of the photochemical reaction sequence are shown in Fig. 5.

The slightly different primary product for each sample may be attributed to the difference in the trapping states of the radicals. In addition, in the case of ethylamine hydrochloride the strong counter ion of chlorine may interfere with the secondary photochemical decompositions. The role of the water molecule seems to be mainly to affect the rigidity of the matrix. Also, it isolates the amine molecule and promotes the unimolecular decomposition. The dependence of the matrix state on the amount of water is exemplified by the result that the methyl radical in an ethylamine aqueous solution of less than 30% disappeared at about −100°C, while in a 75% solution it disappeared at −150°C.

Molecular Vibrations and Force Fields of Alkyl Sulfides. II. Infrared Spectra of $CH_3S(CH_2S)_nCH_3$ ($n=0-3$)

Masaru OHSAKU, Yuji SHIRO,* and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received July 12, 1971)

Infrared spectra recorded in the liquid and solid states of dimethyl sulfide, CH_3SCH_3, bis(methylthio)methane, $CH_3SCH_2SCH_3$, bis(methylthiomethyl) sulfide, $CH_3SCH_2SCH_2SCH_3$, and bis[(methylthio)methylthio]methane, $CH_3SCH_2SCH_2SCH_2SCH_3$, are reported. For the $CH_3SCH_2SCH_3$ species, the gaseous spectra were also recorded. For these molecules, the observed bands were assigned to the fundamental modes of the vibrations with reference to those of reported analogous-structure molecules. The existence of the rotational isomers of the last three compounds was postulated. The regularity of the wave number of the fundamentals obtained and the intensity change in some of the bands for this series of compounds were discussed. The frequency shift in the liquid-solid phase transition was also described for a few bands.

The vibrational analysis of dimethyl sulfide, CH_3SCH_3, has been reported elsewhere.[1-4] For bis(methylthio)methane, $CH_3SCH_2SCH_3$, and bis(methylthiomethyl) sulfide, $CH_3SCH_2SCH_2SCH_3$, Welti and Whittaker[5] have reported an infrared treatment. Complete assignments, however, were not made. For bis[(methylthio)methylthio]methane, $CH_3SCH_2SCH_2SCH_2SCH_3$, we have not found any vibrational treatment reported up to 1970. In the first paper of this series,[4] we determined the molecular force fields of dimethyl sulfide. However, we could not obtain complete experimental results with the low-resolution instrument we used. Therefore, we recorded the spectra of dimethyl sulfide a new. On the molecular series of $CH_3S(CH_2S)_nCH_3$ ($n=0-3$), some correlations may exist between those vibrational spectra and the degree of n. Rotational isomerism is also expected in the molecular species of $n=1-3$. From this point of view, we have investigated the infrared spectra of this series: $CH_3S(CH_2S)_nCH_3$ ($n=0-3$). This paper will treat the vibrational interpretation of polythiomethylene.

Experimental

Materials. The dimethyl sulfide was commercially obtained (Tokyo Kasei Co., Tokyo) and distilled in a vacuum over phosphorus pentoxide before use. The other materials used in the infrared recording were prepared according to the method reported by Fehér and Vogelbruch.[6]

Bis(methylthio)methane
found bp 149—150°C/760 mmHg, 44°C/14 mmHg; purity (above 99%)
lit.[5-6] bp 148—150°C/760 mmHg, 45°C/14 mmHg

Bis(methylthiomethyl) Sulfide
found bp 106°C/5 mmHg; purity (above 98%)
lit.[5-6] bp 100—103°C/3.5 mmHg, 113°C/13 mmHg

Bis[(methylthio)methylthio]methane
found bp ~135°C/1—2 mmHg, mp 17.0°C; purity (above 90%)
lit.[6] bp 117.5°C/0.7 mmHg, mp 17.2°C

The purity of all the samples was estimated by means of gas chromatography. The infrared spectra were measured in the liquid and solid states in the range of 4000—200 cm^{-1} with a Perkin-Elmer Model 621 Spectrophotometer equipped with KBr and CsI cells. The liquid spectra of dimethyl sulfide were recorded at a temperature slightly above its melting point. The other materials were recorded at room temperature (*ca.* 22°C). For the $CH_3S(CH_2S)_nCH_3$ ($n=1-3$) series the infrared spectra in CS_2 and CH_3NO_2 solutions were also recorded (1400—600 cm^{-1}). The solid spectra were obtained with a conventional cell which was cooled by liquid nitrogen. The spectrum of the solid film was recorded before and after annealing near the melting point. The gaseous spectra of $CH_3SCH_2SCH_3$ were also investigated in the 850—600 cm^{-1} region at temperatures of 26—129°C. The wave numbers thus obtained were calibrated by the use of bands of indene and polystyrene. The frequency of the obtained spectra has measured with an estimated accuracy of ± 1 cm^{-1} at 2000—400 cm^{-1} and with an accuracy of ± 2 cm^{-1} at 4000—2000 cm^{-1}; the accuracy of the 400—200 cm^{-1} region may be within 5 cm^{-1}. The $\sim$ sign in Tables 2—4 shows that the wave number of its band was poorly estimated.

Vibrational Assignment

The assignments of the observed bands were made on the basis of those of dimethyl sulfide,[1-4] monochloromethyl methyl sulfide,[7] (methylthio)methanethiol,[8] polymethylene disulfide,[9] and 1,3,5-trithiane.[10]

Dimethyl Sulfide. The assignments are summarized in Table 1. The annealed spectra are more finely resolved than the liquid spectra. We compared the spectra of liquid and solid states, and found that a new band, which was not observed in the liquid spectra, appeared in the C–H stretching, CH_3 degenerate deformation, and CH_3 rocking regions, in the solid state.

a) Above 3000 cm^{-1} and 2800—1500 cm^{-1} regions are omitted.

Dimethyl sulfide has a C_{2v} symmetry. However, if the site symmetry of C_{2v} does not remain in the solid state, the forbidden bands may appear. Moreover, one each of C–H stretching, CH_3 degenerate deformation, CH_3 rocking, and torsional vibrations belong to the A_2 species. In the spectral region we treated, the former three bands are expected. This sufficiently coincident with the observed result that only three bands belonging to the A_2 vibrations appeared in the solid state, in addition to the bands in the liquid state. The obtained wave numbers closely agreed with the calculated wave number of the previous normal coordinate treatment.[4)] Thus, these observations lead to the findings that the site symmetry of the dimethyl sulfide molecule changes to C_2 or C_s in the solid state and that the new bands can be assigned to the A_2 mode. In the spectra obtained in the solid state, unannealed or annealed, seven bands were observed in the 2900 cm^{-1} region. Among these bands the overtone bands of the CH_3 degenerate deformation vibrations may be confused; they are hardly distinguishable from each other. In the annealed spectra around 1400 cm^{-1}, we obtained four bands, at 1448, 1432, 1428, and 1421 cm^{-1}. Among these bands, the band at 1428 cm^{-1} is assigned to the CH_3 degenerate deformation vibration of the A_2 species. In the region around 1300 cm^{-1}, two bands were obtained finely in the solid film. In our previous paper,[4)] we considered that these CH_3 symmetrical deformation bands overlapped each other with a low resolution of the spectrometer. For the CH_3 rocking region, we obtained three bands in the liquid, and four bands in the solid, film. The band at 952 cm^{-1} appeared only in the solid film. This band corresponds well to the band (960—950 cm^{-1}) obtained from the Pd and Pt complex of dimethyl sulfide.[11)] As for the weak band obtained at 909 cm^{-1} (liquid), we previously identified it as an impurity band. Scott and El-Sabban treated[12)] the normal coordinate treatment and identified it as the sum-combination of the A_2 torsional and B_1 C–S stretching vibrations. Allkins and Hendra treated[3)] the vibrational spectra of CH_3XCH_3 spectral series (X=S, Se, and Te) and identified it as the fundamental. If the band around 900 cm^{-1} of CH_3SCH_3 is the sum-combination, the sum-combination for CH_3SeCH_3 and CH_3TeCH_3 would not be observed in this region. However, in the expected region, the corresponding band due to the fundamental was reported.[3)] Thus, the band around 900 cm^{-1} is not to be considered as a sum-combination, but can be assigned to a rocking fundamental. For the C–S stretching region, a couple of the bands were obtained, at 744 and 693 cm^{-1}, in the annealed state. Below 400 cm^{-1} the skeletal deformation bands can be expected. The weak band at 275 cm^{-1} may be assigned to the skeletal deformation vibration.

Bis(methylthio)methane. The obtained infrared data of bis(methylthio)methane are summarized in Table 2. The annealed spectra are well resolved in the C–H stretching, CH_3 degenerate deformation, and CH_3 rocking regions. The bands around 2950 cm^{-1} may due to the C–H stretching vibrations. In this region the overtone bands of the CH_3 degenerate deformation fundamentals may be present. As for the CH_3 degenerate deformation, the bands obtained around 1430 cm^{-1} may be assigned. For the region 1400—1100 cm^{-1}, the CH_2 bending, CH_3 symmetrical deformation, CH_2 wagging, and the CH_2 twisting vibrations are expected. The medium band obtained at 1387 cm^{-1} and the very strong band at 1203 cm^{-1} in the liquid spectra separate into two components upon crystallization. This splitting may be attributed to the crystal field effect or to the imperfection annealing. Around 960 cm^{-1} two bands appeared in the liquid state and three bands in the crystalline state. The liquid-solid phase transition shift of this region is fairly large. The bands obtained in this region may be due to the CH_3 rocking vibrations. A rather puzzling feature of the spectra is the infrared band of a weak intensity at 874 cm^{-1}. It seems too high for a CH_2 rocking fundamental and too low for a CH_3 rocking fundamental; we can not explain reasonably. For the C–S stretching region, 760—600 cm^{-1}, we observed seven bands, including three shoulder bands, in the liquid state. This molecule has four C–S stretching vibrational freedom for one conformation. Actually, in the solid state, four bands appeared. For the skeletal deformation region, 400—200 cm^{-1}, we obtained nine very weak and fairly broad bands in the liquid state.

Bis(methylthiomethyl) Sulfide. The obtained spectra of an annealed film of bis(methylthiomethyl) sulfide were well resolved. The infrared data we obtained are summarized in Table 3. The molecule has two methylene groups and six C–S bonds. The obtained spectra of bis(methylthiomethyl) sulfide are more complicated than those of bis(methylthio)methane. However, the spectral features in the 3000—1300 cm^{-1} region are similar to those of bis(methylthio)methane. The bands which appeared around the 1200 and 1150 cm^{-1} regions are to be assigned to the CH_2 wagging and twisting vibrations respectively. As for the CH_3 rocking region, two bands appeared in the liquid state. In the crystalline state, three sharp bands were obtained, at 969, 961, and 955 cm^{-1}. To the CH_2 rocking vibrations, two bands at 844 and 780 cm^{-1} in the solid state are assigned. The bands around 700 cm^{-1} may due to the C–S stretching vibrations. In this region, seven bands, including three shoulder bands, appeared in the liquid state. In the crystalline film, five bands of them are retained, their intensities changed. In the region 400—200 cm^{-1}, the skeletal deformation vibrations

twisting vibrations respectively. The bands obtained around 970 cm^{-1} may be due to the rocking vibrations of the terminal CH_3 groups. The strong shoulder band of the liquid state at 960 cm^{-1} decreases in its intensity in the solid state. Three bands of the CH_2 rocking vibrations are expected for this molecule. Actually, four bands appeared in the liquid state, at 858, 820, 785, and at 763 cm^{-1}, and in the annealed film, three bands appeared, at 866, 811 and at 760 cm^{-1}. The C–S stretching vibrations are obtained around 700 cm^{-1}. We obtained eight bands in the liquid state (740, 731, 712, 700, 687, 663, 651, and 640 cm^{-1}) and five bands in the crystalline state (742, 729, 701, 665, and 654 cm^{-1}). In the region 400—200 cm^{-1}, seven bands appeared in the liquid state.

Discussion

The existence of the rotational isomer of the series of the compounds discussed above may be investigated by means of studying the spectra in the region of the CH_2 rocking, C–S stretching, and the skeletal deformation

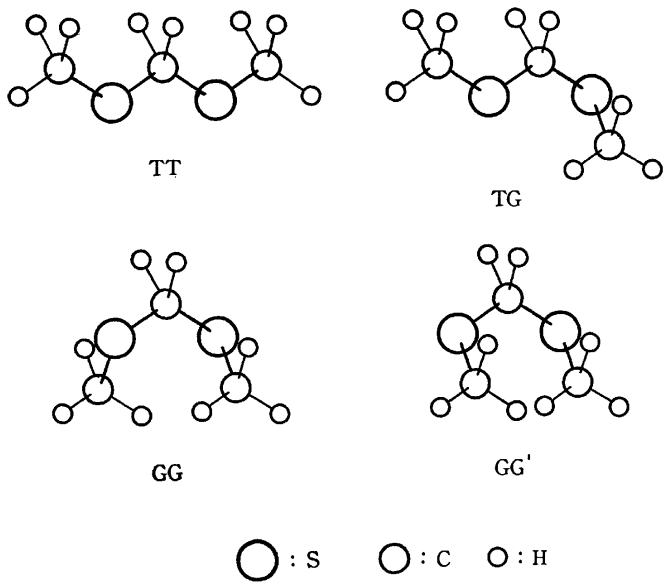

Fig. 1. Structures and conformations of bis(methylthio)methane.
T=*Trans*, G=*Gauche*.

vibrations. Among these vibrations, the ones which were sufficiently covered in the spectral range we treated are the CH_2 rocking and C–S stretching vibrations. On bis(methylthio)methane, one CH_2 rocking and four C–S stretching bands can be expected. Actually, two CH_2 rocking and seven C–S stretching bands appeared in the liquid-state spectra. In bis(methylthiomethyl) sulfide, two CH_2 rocking and six C–S stretching bands can be expected. We obtained five CH_2 rocking and eight C–S stretching bands in the liquid spectra. In the case of bis[(methylthio)methylthio]methane, treatment is above only with difficulty. In this molecule, three CH_2 rocking and eight C–S stretching vibrations can be expected; we observed four CH_2 rocking and eight C–S stretching bands in the liquid state.

On bis(methylthio)methane, four conformations (TT, TG, GG, and GG') may be supposed on theoretical, as is shown in Fig. 1. We revealed the existence of the rotational isomers by means of a comparison between the spectra of the liquid and solid states, since some bands of the liquid spectra disappeared in the solid state. Moreover, in order to confirm the existence of the rotational isomers, we attempted to investigate the temperature dependence of the band intensity of the gaseous state in the 850—600 cm^{-1} region on $CH_3SCH_2SCH_3$. The wave numbers of the gaseous bands we obtained are summarized in Table 5, together with the corresponding wave numbers of the liquid and solid spectra. From the gaseous envelopes obtained at different temperatures, we found that the intensity change was not large enough to determine the energy differences between and/or among the rotational isomers. Therefore, in order to observe the wave number change due to the rotational angles, we have made a normal coordiante treatment of $CH_3SCH_2SCH_3$ with four conformations: TT, TG, GG, and GG', using the Urey-Bradley force field. The details of the normal coordinate treatment will be reported in a separate paper.[13]

a) Not appeared in the solid state.

13) M. Ohsaku, Y. Shiro, and H. Murata, to be published.

The computed wave numbers of the C–S stretching vibrations are listed in Table 6. As is shown in Table 6, the calculated wave number changes with the skeletal conformations. The bands which disappeared in the solid state may be identified as fundamentals. Among the four conformations, the GG′ form might have a higher energy than the other forms. Therefore, three conformations remain: TT, TG, and GG. We, at present, can not venture to decide how many conformations (two or three) may exist in the liquid or gaseous state with stability. However, from only these data, we can not deny that these three conformations coexist in either the liquid or gaseous state. In the solid state, this molecule may have one conformation. In the case of bis(methylthiomethyl) sulfide and bis-[(methylthio)methylthio]methane, a large number of conformations can be expected. The situation is difficult in studying the longer molecules. The difficulty

in the recognition of the rotational isomer will be reported separately in connection with the normal coordinate treatment of this series of compounds.

The observed frequencies for the spectral series studied, $CH_3S(CH_2S)_nCH_3$ (n=0—3), are graphically summarized in Fig. 2. Figures 3 and 4 show the band shapes thus obtained in relation to the CH_3 and CH_2 groups (annealed). Tables 7 and 8 show the infrared frequencies of the terminal CH_3 groups and the internal CH_2 groups obtained in the crystalline state. The C–H stretching region shows no definite tendency in either the liquid or solid state. The frequency of the CH_3 degenerate deformation and the CH_3 symmetrical deformation bands obtained in the liquid state changes little from dimethyl sulfide to bis[(methylthio)methylthio]methane. However, the frequency obtained in the annealed state shows a little irregularity. The spacing of two CH_3 symmetrical deformation bands also shows a little irregularity. The CH_2 bending, wagging, and the twisting vibrations constantly shifted to a lower frequency region with increase in the molecular chain length. The frequency difference among CH_3 rocking bands becomes small hyperbolically with an increase in the chain length. This shows that the intramolecular interaction of methyl groups between the two ends rapidly decreases with an increase in the chain length. We observed the CH_2 rocking vibrations in the wider range around 800 cm^{-1}. It is interesting that, in the annealed spectra, the central band at 811 cm^{-1} of bis-[(methylthio)methylthio]methane has nearly the same frequency of that of bis(methylthio)methane (808 cm^{-1}), and that the spacings between their bands and their side bands are nearly the same width on both sides (55 and 51 cm^{-1}). For the C–S stretching region, the bands obtained are gradually complicated with an increase in the molecular chain. However, a couple of more intense bands appeared at nearly the same wave number in any case; that is, in the liquid spectra the intense bands were 742 and 691 cm^{-1}, 746 and 694 cm^{-1}, 742 and 700 cm^{-1}, and 740 and 700 cm^{-1} for dimethyl sulfide, bis(methylthio)methane, bis-(methylthiomethyl) sulfide, and for bis[(methylthio)-

methylthio]methane respectively.

The intensities of various fundamentals are of interest. That is, the intensities of fundamentals arising from CH_3 groups, *i.e.*, the CH_3 degenerate deformation, CH_3 symmetrical deformation, and the CH_3 rocking fundamentals, decrease, while on the other hand, the intensities of the fundamentals arising from CH_2 groups, *i.e.*, the CH_2 bending, CH_2 wagging, CH_2 twisting, and the CH_2 rocking fundamentals, increase with an increase in the chain length.

The relations of the obtained wave numbers will be discussed in detail by the aid of the normal coordinate treatment analysis. The results of the normal coordinate treatment of the molecules described in this paper will be reported separately.[13]

Conclusion

The infrared spectra of the $CH_3S(CH_2S)_nCH_3$ (n=0—3) series obtained in the liquid and solid states have been assigned. For the last three molecules, the rotational isomer can be expected. On the $CH_3SCH_2SCH_3$ molecular species, the existence of more than two conformations was confirmed in the liquid or gaseous states by two procedures: a) a comparison between the liquid and solid spectra, and b) a normal coordinate treatment. Moreover, in the solid state, the species $CH_3SCH_2SCH_3$ would be one conformation. We tried to ascertain the temperature dependence of the gaseous envelopes. However, the differences by which to determine the energy difference based on the rotational isomer were not obtained. It seems that some regularities stay in the fundamentals of this series thus obtained: $CH_3S(CH_2S)_nCH_3$ (n=0—3).

The authors wish to express their gratitude to Assistant Professor Michiro Hayashi of Hiroshima University for his encouragement throughout this work. One of the authors (M. O.) is largely indebted to the foundation of the Kumura Syogakukai (Teijin Co., Tokyo).

Charge-transfer Interaction and Chemical Reaction. IV. Reactions of *para*-Substituted Derivatives of Aniline with Chloranil

Takashi NOGAMI,* Keitaro YOSHIHARA,** and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo

(Received July 20, 1971)

Interactions of chloranil with *p*-phenylenediamine, *N,N*-dimethyl-*p*-phenylenediamine, and *N,N,N',N'*-tetramethyl-*p*-phenylenediamine were studied by measuring visible and ultraviolet absorption spectra at various temperatures between 77°K and 300°K. In an ether-isopropyl alcohol (3:1) mixed solvent, the *p*-phenylenediamine- and *N,N*-dimethyl-*p*-phenylenediamine-chloranil systems were led to the substitution reaction through the outer complex and the ionic species as reaction intermediates. In ethyl ether, the *p*-phenylenediamine- and *N,N*-dimethyl-*p*-phenylenediamine-chloranil systems were found to yield the inner complex and the substituted species through the outer complex, respectively. In the *N,N,N',N'*-tetramethyl-*p*-phenylenediamine-chloranil system, the inner complex was found to be formed *via* a clustering of the outer complexes.

The interactions between aromatic amines and chloranil were found to be classified into the following three types: (a) the charge-transfer (outer or inner) complex is formed between an electron donor and an acceptor and no further reaction proceeds; (b) the substitution reaction occurs through the outer and inner complexes; (c) the substitution reaction occurs through the outer complex and ionic species. The difference in the reactivities between *meta*-substituted derivatives of aniline and *ortho*- and *para*-substituted ones was explained by taking the π-electron density on the amino group into account.

In previous papers of this series,[1] the reactions of several aromatic amines with chloranil were studied from the viewpoint of charge-transfer interaction. Detailed studies were made of the reactions of chloranil with aniline,[1a] 1,3,5-triaminobenzene,[1b] and *m*-phenylenediamine.[1d] In these three systems, the substitution reactions were found to occur through the outer and inner complexes as the reaction intermediates. A detailed kinetic study was made of the third case by measuring the formation and decay curves of the inner complexes, and the potential energy curves of the reactions were determined experimentally. Substitution reactions of a similar mechanism were found to occur for the systems including chloranil and several *meta*-substituted derivatives of aniline (*m*-anisidine, *m*-aminophenol, *N,N*-dimethyl-*m*-phenylenediamine, *N,N,N',N'*-tetramethyl-*m*-phenylenediamine, and 1-methyl-2,4,6-triaminobenzene).

On the other hand, another type of reactions were found for systems containing *ortho*- or *para*-substituted derivatives of aniline and chloranil. The main purposes of the present study are to clarify the mechanism for the interaction of chloranil with *p*-substituted anilines and to obtain information on the effect of the position of the substituted group upon the reaction mechanism. For these purposes, we took *p*-phenylenediamine (PD), *N,N*-dimethyl-*p*-phenylenediamine (DMPD), and *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) as electron donors. Furthermore, the classification of the reactions between chloranil and various aromatic amines is described on the basis of the π-electron density on the amino group by comparing the *meta*-substituted derivatives of aniline with *ortho*- and *para*-substituted ones.

Experimental

Materials. PD, DMPD, and TMPD were purified by vacuum sublimation. Chloranil was purified by repeated recrystallizations from acetone.

Measurements. A Cary recording spectrophotometer model 14 M was used for the measurements of electronic absorption spectra, a quartz cell with a 1-cm light path length being used. The donor and acceptor solutions, which were separately prepared, were mixed with each other immediately before the absorption measurements at low temperatures. For the measurements at low temperatures, a sample cell was immersed in a quartz dewar vessel designed for the spectroscopic measurements and was cooled with cold nitrogen gas. The temperature was regulated by nitrogen-flow velocity.

Results and Discussion

Reaction of PD with Chloranil. We studied the interaction of chloranil with PD, DMPD, and TMPD using ethyl ether and ether-isopropyl alcohol (3:1) as solvents. First of all, let us describe the results for the PD-chloranil system in ethyl ether.

After mixing the ethyl ether solutions of PD and chloranil at a low temperature (the concentrations of PD and chloranil in the final solution were 6.7×10^{-4}M and 3.3×10^{-4}M, respectively), the change in the absorption spectra was measured. The 785 and 390 nm bands assigned to the outer complex[2] appear at first and decrease in intensity with increasing temperature. After the solution was kept at room temperature for a few hours, a blue species gradually precipitated. The absorption spectra of the precipitate, which was mea-

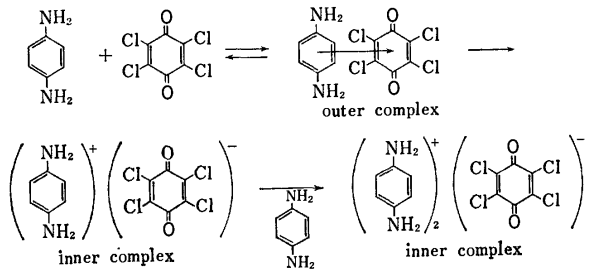
2) This assignment was made from the relation between the peak position of the charge-transfer absorptions observed with the chloranil complexes and the ionization potentials of several electron donors.

sured by coating the powdered sample on a glass plate by a stainless steel spatula,[3] were found to consist of the absorption bands of the 2:1 (PD: chloranil) complex (380, 590, and 670 nm) plus the charge-transfer absorption band of the 1:1 complex (850 nm).[4] The elemental analysis data of the precipitate show that it is a mixture of about 90% of the 2:1 complex and about 10% of the 1:1 complex. These two complexes show an ESR signal.[4] This indicates the formation of ion pair type complexes which may be denoted by inner complexes. From the above-mentioned experimental facts, the reaction mechanism of the system under consideration may be represented as follows:



Next, let us turn to the PD-chloranil system in an ether-isopropyl alcohol (3:1) mixed solvent. After mixing the solutions of PD and chloranil in the mixed solvent (the concentrations of PD and chloranil in the final solution were 6.7×10^{-4}M and 3.3×10^{-4}M, respectively) at 193°K, the temperature dependence of the absorption spectrum was measured; the results are shown in Fig. 1. At first, the absorption bands of the outer complex appear; then they decrease in intensity with the increasing temperature. With the decrease in the bands due to the outer complex, new bands due to the PD cation monomer (500 and 465 nm) and dimer (605 nm)[5] appear with the isosbestic points at 430 and 640 nm. This fact shows that the outer complex directly converts into the cation monomer and dimer.

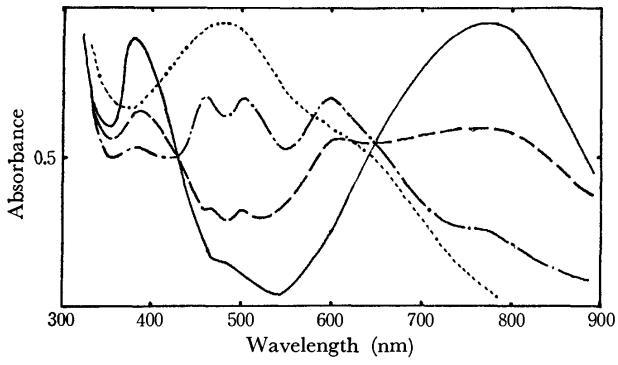


Fig. 1. The absorption spectra of the PD—chloranil system in an ethyl ether-isopropyl alcohol (3:1) mixed solvent; [PD]$=6.7\times10^{-4}$M, [chloranil]$=3.3\times10^{-4}$M.
—— The absorption spectrum measured immediately after mixing at 193°K; the spectrum of the outer complex.
– – – The absorption spectra measured at 225°K; the spectra of the outer complex and of the PD cation monomer and dimer.
– • – The absorption spectra measured at 235°K; the spectra of the PD cation monomer and dimer.
····· The absorption spectrum measured at room temperature; the spectrum of the final reaction product.

The ionic specimens do not cause succeeding reactions at temperatures lower than 230°K. When the solution is recooled from 230°K to 193°K, the absorption bands of the outer complex and cation dimer always increase in intensity and those of the cation monomer disappear. However, the outer complex bands do not completely recover the initial absorbance at 193°K.

The absorption bands due to the chloranil anion (426 and 455 nm)[6] can not be detected, probably because the concentration of the chloranil anion is rather low and its absorption band may be covered by those of the outer complex, the PD cation monomer, and a final reaction product.

By raising the temperatures of the solution to room temperature, the absorption bands due to the outer complex and to the PD cation monomer and dimer disappear in a few minutes; thereafter, those due to the final reaction product (460 and 630 nm) gradually increase the intensity for a few hours. The elemental analysis of the reaction product corresponds to $C_{18}H_{14}Cl_2N_4O_2$[7] and indicates that it is 2,5-dichloro-3,6-di-*p*-aminoanilino-*p*-benzoquinone.

In order to clarify whether the PD cation monomer and dimer exist as reaction intermediates in the main reaction path or only in the side reaction, the time dependences of the absorption spectra of the PD cation and final reaction product were measured in the temperature range from −15°C to 0°C[8]; the result is shown in Fig. 2. The absorption band of the PD cation at 450—500 nm is covered by that of the final reaction product; therefore, the vibrational structure of the former band is smeared out with the latter band as the reaction proceeds. From Fig. 2, we can obtain[9]

6) R. Foster and T. J. Thomson, *Trans. Faraday Soc.*, **58**, 860 (1962).

7) The PD—chloranil system in ethyl ether-isopropyl alcohol (3:1) mixed solvent. Found: C, 54.16; H, 4.21; Cl, 17.58; N, 15.81%. Calcd for $C_{18}H_{14}Cl_2N_4O_2$: C, 55.52; H, 3.59; Cl, 18.25; N, 14.39%. The DMPD—chloranil system in ethyl ether. Found: C, 58.43; H, 5.00; Cl, 16.28; N, 12.07%. Calcd for $C_{22}H_{22}Cl_2N_4O_2$: C, 59.32; H, 4.94; Cl, 15.95; N, 12.58%. The DMPD—chloranil system in ethyl ether-isopropyl alcohol (3:1) mixed solvent. Found: C, 59.24; H, 4.88; Cl, 15.56; N, 12.55%. Calcd for $C_{22}H_{22}Cl_2N_4O_2$: C, 59.32; H, 4.94; Cl, 15.95; N, 12.58%. The agreement between the found and the calculated is not good for the PD—chlornail system in the mixed solvent. The discrepancy may be due to the difficulty in removing the 1:1 substitution product and other impurities and also to their hygroscopic property. We tried to separate each product by chromatography and other methods, but we did not succeed mainly because of very small solubility of the precipitate.

8) Because of the difficulty of keeping the temperature constant, we measured the absorption spectra without controlling the temperature.

9) The absorption intensities at 630 and 500 nm were measured at some time intervals determined by the wavelength scanning speed. Since the reaction is rather fast, we can not ignore the absorption intensity change which occurs during the intervals. Therefore, in the analysis of the experimental results, we made a suitable correction for this change.

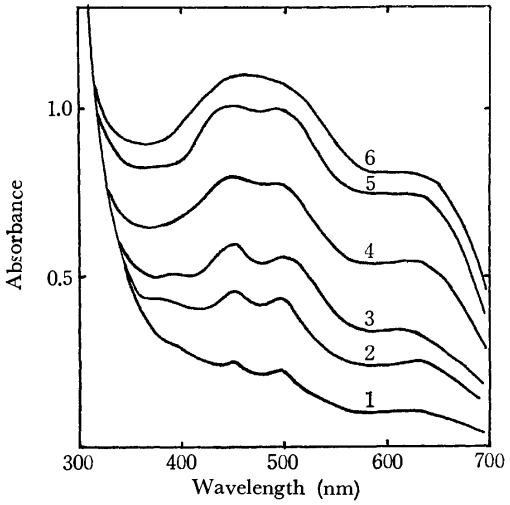

Fig. 2. The time dependence of the absorption spectrum of the PD—chloranil system in an ether-isopropyl alcohol (3: 1) mixed solvent; [PD]$=5.0\times10^{-4}$M, [chloranil]$=2.5\times10^{-4}$M. Curves 1, 2, 3, 4, 5, and 6 are, respectively, the spectrum measured at 3, 7, 11, 19, 40, and 73 min after the mixing of the donor and acceptor solutions at -15°C. The temperature increased gradually from -15 to 0°C during the measurements.

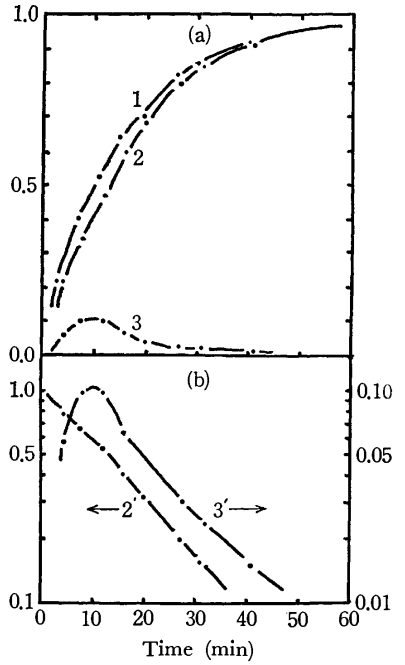

Fig. 3. The time dependence of the absorption intensities of the PD cation and the reaction product derived from the curves shown in Fig. 2. (a); the ordinate is I_{500}/I_{500}^{max}, I_{630}/I_{630}^{max}, and $I_{500}/I_{500}^{max}-I_{630}/I_{630}^{max}$ for curves 1, 2, and 3, respectively: (b); the ordinate is $(I_{630}^{max}-I_{630})/I_{630}^{max}$ and $I_{500}/I_{500}^{max}-I_{630}/I_{630}^{max}$ for curves 2′ and 3′, respectively. The left- and right-hand side ordinates are concerned with curves 2′ and 3′, respectively.

the time dependences of the absorption intensities at 500 and 630 nm (I_{500}/I_{500}^{max} and I_{630}/I_{630}^{max}, respectively), as shown in Fig. 3[10]. Here, I_{500} and I_{630} denote the absorption intensities at 500 and 630 nm, respectively; the superscript "max" means that the corresponding quantity is the value at the final stage of the reaction.

I_{500} is concerned with both the PD cation and the reaction product, but I_{630} with only the reaction product.[10] Therefore, we can obtain an information about the time dependence of the absorption intensity of the PD cation by calculating the $I_{500}/I_{500}^{max}-I_{630}/I_{630}^{max}$ value at each time. Curves 1, 2, and 3 in Fig. 3(a) represent the time dependences of the values, I_{500}/I_{500}^{max}, I_{630}/I_{630}^{max}, and $I_{500}/I_{500}^{max}-I_{630}/I_{630}^{max}$, respectively. In Fig. 3(b), the time dependence of $[I_{630}^{max}-I_{630}]/I_{630}^{max}$ is compared with that of $[I_{500}/I_{500}^{max}-I_{630}/I_{630}^{max}]$. The two curves in Fig. 3(b) are almost parallel to each other after 15 min. This means that the decreasing rate of the PD cation is almost equal to the increasing rate of the reaction product. Therefore, the PD cation undoubtedly takes part in the main reaction path as an intermediate and plays an important role in the reaction of PD with chloranil in an ether-isopropyl alcohol (3: 1) mixed solvent. Although the details of the mechanism are not clear, it seems probable that the reaction proceeds through the interaction between the chloranil anion and the PD cation (or its dimer).

Reaction of DMPD with Chloranil. The ether solution containing DMPD and chloranil shows absorption bands due to the outer complex at 815 and 390 nm[2] at 193°K. With the increasing temperature, the intensities of these bands decrease and absorption bands due to a final reaction product which appear at 460 and 670 nm increase in intensity. The elemental analysis of the reaction product corresponds to $C_{22}H_{22}Cl_2N_4O_2$,[7] indicating that it is 2,5-dichloro-3,6-di-*p*-dimethylaminoanilino-*p*-benzoquinone. The infrared absorption measurements also support this identification.[11] No reaction intermediate could be detected between the outer complex and the final reaction product. Two reaction mechanisms are conceivable in this solvent, *i.e.*, a substitution reaction through the outer and inner (σ) complexes and one through the outer complex and ionic species. If the former is the case, the reaction mechanism of the system under consideration is phenomenologically similar to that of the aniline-chloranil system[1a] in the sense that we can not detect spectrophotometrically the inner complex through which the reaction may be expected to proceed. From only the above experimental facts, we can not conclude which of these two reactions actually occurs.

In an ether-isopropyl alcohol (3: 1) mixed solvent, the reaction of DMPD with chloranil is similar to that of the PD-chloranil system in the same solvent because, in both systems, the substitution reaction occurs through the outer complex and such ionic species as the donor cation, which exists in an equilibrium between the monomer and the dimer. Figure 4 shows the change in the absorption spectrum with the progress of the reaction of DMPD with chloranil. The cation dimer and monomer have absorption maxima at 670 nm and at 523 and 570 nm,[5] respectively. The final reaction product which has absorption bands at 460 and 670 nm was identified as 2,5-dichloro-3,6-di-*p*-dimethylaminoanilino-*p*-benzoquinone by an elemental analysis.[7] The absorption bands due to ionic species

10) The temperature is high enough to disregard the absorption due to the PD cation dimer at 605 nm.

11) One band of the N-H stretching mode was observed at 3180 cm^{-1}.

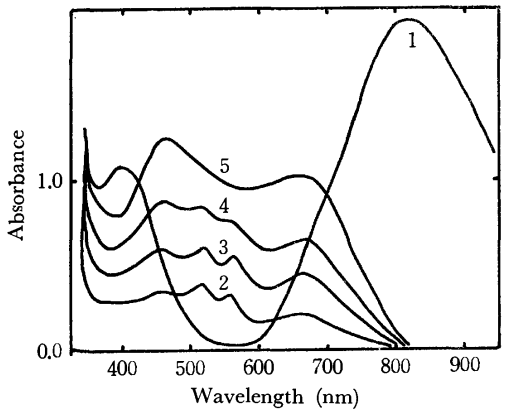

Fig. 4. The absorption spectra of the DMPD-chloranil system in an ether-isopropyl alcohol (3: 1) mixed solvent; [DMPD] $=5.0\times10^{-4}$M, [chloranil] $=2.5\times10^{-4}$M. Curve 1, is the absorption spectrum measured at 198°K; the spectrum of the outer complex. Curves 2, 3, 4, and 5 are the spectra measured at 17, 28, 45, and 129 min after the mixing at 253°K. During the measurements, the temperature increased from 253 to 273°K.

disappear almost completely at room temperature a few minutes after the mixing and those due to the final reaction product gradually increase. No reaction intermediate was found between the ionic species and the final reaction product.

Interaction of TMPD with Chloranil. The temperature and concentration dependencies of this system were investigated by studying the electronic absorption spectra in an ethyl ether-isopropyl alcohol (3: 1) mixed solvent. The system showed two different kinds of complexes. One of them is greenish yellow and exhibits an absorption peak at 830 nm. This band was identified by Foster and Thomson as the CT band of the outer complex.[6] The other is reddish-brown and

b) [D] denotes the concentration of TMPD in the unit of 10^{-3} M.

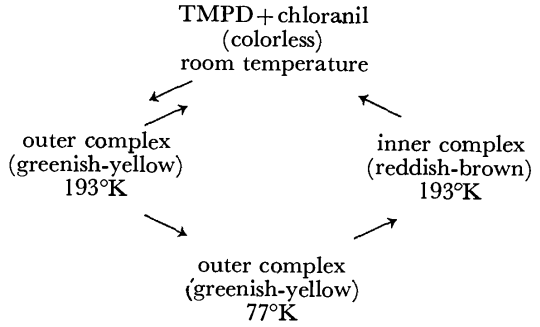
has absorption peaks at 1100, 635, 520, and 434 nm. The 1100 nm band corresponds to a reverse CT band ($D\cdot A\leftarrow D^+A^-$) of the inner (ion-pair or ionic EDA) complex observed by Sato, Kinoshita, Sano, and Akamatu for the solid TMPD-chloranil complex.[12]

We studied the behaviors of these two specimens in solutions of various concentrations of the components by measuring their absorption spectra at room temperature, 193°K, and 77°K; as an example, the temperature dependence of the spectrum observed with the solution consisting of 1.25×10^{-4}M TMPD and 1.0×10^{-3}M chloranil is shown in Fig. 5.[13] The results obtained for the solutions containing various concentrations of the components are classified and tabulated in Table 1. In this table, A,B,C,D, and E denote the following phenomena: A: Immediately after mixing the TMPD and chloranil solutions at room temperature, the outer complex is formed and is gradually converted into the inner complex which precipitates as a reddish-brown crystal. At this stage, the outer and inner complexes coexist in the solution. B: The solution is green at room temperature because of the outer complex formation. The inner-complex formation starts by lowering the temperature of the solution to 193°K and the solution turns reddish-brown without a precipitate. The solution becomes green again by raising its temperature. C: Only the outer complex is formed in the temperature range from room temperature to 193°K, and the inner-complex formation starts at 77°K. D: The component molecules which are almost completely free at room temperature start to form the outer complex at 193°K. This pro-

12) Y. Sato, M. Kinoshita, M. Sano, and H. Akamatu, This Bulletin, **43**, 2370 (1970).
13) The concentrations of D and A in this solution correspond to class D in the classification of Table 1.

cess is reversible. By raising the solution temperature to 193°K after having once lowered it to 77°K, the inner complex is formed. By raising the temperature further, the solution returns to the initial stage at room temperature. E: Only the outer complex is formed in the range from 193°K to 77°K; the inner complex is not formed.

The present results of the outer-complex formation are reasonable and can be explained by the equilibrium-shift toward the outer-complex formation caused by the lowering of the temperature. The results concerning the inner complex, though rather complicated, suggest that its formation can not occur unless the outer-complex concentration exceeds some limited value. This seems to show that the inner-complex formation needs environmental cooperation, in particular, that there must be a clustering of donor-acceptor pairs before the inner-complex formation begins.[14] In this connection, phenomenon D is particularly interesting as showing the following color cycle with the temperature:



The colorless solution at room temperature turns greenish-yellow at 193°K; the color becomes deeper by decreasing the temperature to 77°K. The solution changes from greenish-yellow to reddish-brown by raising the temperature from 77°K to 193°K.[15] By raising further the temperature, the solution returns to the initial colorless state. The color cycle occurs regardless of the lowering and raising rates of the temperature and can be repeated many times.

In order to investigate the process from the outer complex to the inner complex, we measured the change in the scattering light intensity with the time, using a He–Ne gas laser as the light source. After keeping a cell containing the solution of TMPD and chloranil in the mixed solvent (the concentrations of TMPD and chloranil were 1.25×10^{-4}M and 5.0×10^{-4}M, respectively, corresponding to D in Table 1) to 77°K, we set it in a dewar vessel designed for the optical measurement and started the measurement of the scattering light intensity as soon as possible.

The inner complex is formed as the temperature of the solution is raised by acetone of room temperature surrounding the cell in the dewar vessel; thereafter, it dissociates into its component molecules. Corresponding to the change in the inner-complex concentration

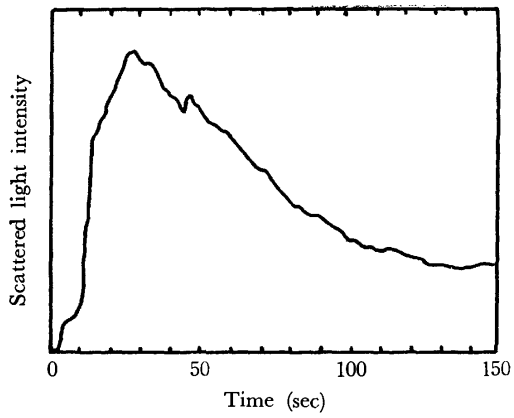


Fig. 6. The time dependence of the scattered light intensity measured for the solution containing TMPD and chloranil in an ethyl ether-isopropyl alcohol (3: 1) mixed solvent, [TMPD]$=1.25\times10^{-4}$M, [chloranil]$=5.0\times10^{-4}$M. With the rapid temperature rising from 77°K to room temperature, the scattered light intensity increases and decreases corresponding to the formation and decay of the inner complex, respectively.

with the time, the scattering light intensity changes, as is shown in Fig. 6. Briefly speaking, the time-change of the scattering light intensity shown in this figure is parallel to that of the concentration of the inner complex. This seems to support the view that the clustering of the outer complexes is related to the formation of the inner complex.[16] As pointed out by Mulliken,[17] a potential barrier between the outer and inner complexes may be expected to decrease with the increase in the polarity of the environment caused by the clustering.

A similar phenomenon was observed when we used ethyl ether as the solvent instead of an ethyl ether-isopropyl alcohol (3: 1) mixed solvent. Furthermore, both solvents are not enough polar to dissociate the inner complex between TMPD and chloranil into the ions, although the system is known to ionize in such a polar solvent as a chloroform-ethanol (1: 1) mixed solvent.[18]

Classification of Interactions of Aromatic Amines with Chloranil. On the basis of the results described in previous papers[1a–1d] and in the present paper, the interactions of various aromatic amines with chloranil in ethyl ether and in an ethyl ether-isopropyl alcohol (3: 1) mixed solvent can be classified as in Table 2. In this classification, the interactions are briefly divided into three classes, (a), (b), and (c), and each of the first two is further divided into two subclasses.

(a) The charge-transfer complex is stable and no further reaction proceeds. This class is divided further into two subclasses.

(a1) Only the outer complex is formed.

$$D + A \rightleftarrows D\cdot A$$

(An example of D in this subclass is diphenylamine)

14) Mulliken presented a similar view for the formation of NH_4^+ Cl^- crystal from NH_3+HCl gases (R. S. Mulliken, *J. Phys. Chem.* **56**, 801 (1952)).

15) This process is irreversible.

16) The details of the light-scattering experiment will be published in a forthcoming paper.

17) R.S. Mulliken, *J. Phys. Chem.*, **56**, 801 (1952).

18) I. Isenberg and S. L. Baird, *J. Amer. Chem. Soc.*. **84**, 3803 (1962).

Table 2. Ionization potentials of aromatic amines, maximum wavelengths of CT absorptions of their complexes with chloranil, and their chemical reactivities with chloranil

Amine	I_p[a] (eV)	λ_{CT} (nm)	Classification of reaction
Diphenylamine	7.1	655	a1
Aniline	7.69[b]	556	b1
o-Toluidine	7.7	555	b1
m-Toluidine	7.50[b]	555	b1
p-Toluidine	7.4	600	b1
o-Anisidine	7.6	568	—
m-Anisidine	7.6	567	b2
p-Anisidine	7.3	616	—
o-Aminophenol	7.6	567	—
m-Aminophenol	7.5	580	b2
p-Aminophenol	7.5	578	—
o-PD[c]	6.9	710	c
m-PD	7.0	680	b2
p-PD	6.8	785	a2, c[d]
1,3,5-Triaminobenzene	7.1	660	b2
1-Methyl-2,4,6-triaminobenzene	7.0	680	b2
N,N-dimethylaniline[e]	7.2	650	c
N,N-dimethyl-*m*-phenylenediamine	7.0	680	b2
DMPD	6.5	815	b1 or c, c[f]
N,N,N',N'-tetramethyl-*m*-phenylenediamine	—	g)	b2
TMPD	6.5	830	a2

a) Estimated from the absorption peak positions of the corresponding outer complexes with chloranil except for aniline and *m*-toluidine.
b) F. I. Vilesov, *Soviet Phys. Usp.*, **6**, 888 (1964).
c) In the *o*-phenylenediamine–chloranil system, the outer complex was found to produce some ionic species as reaction intermediates, although the ionic species and the final reaction product are not yet identified.
d) The a2 and c were found in ethyl ether and in an ethyl ether-isopropyl alcohol (3:1) mixed solvent, respectively.
e) In *N,N*-dimethylaniline–chloranil system, the outer complex ionizes into the *N,N*-dimethylaniline cation and the chloranil anion, and thereafter, the cation produces crystal violet as a final product in acetonitrile. J. W. Eastman, G. Engelsma, and M. Calvin, *J. Amer. Chem. Soc.*, **84**, 1339 (1962). Similar reaction processes were found by us in ethyl ether or in an ethyl ether-isopropyl alcohol (3:1) mixed solvent.
f) The b1 or c and c were found in ethyl ether and in an ethyl ether-isopropyl alcohol (3:1) mixed solvent, respectively.
g) The absorption spectrum of the outer complex has not been measured.

(a2) Both outer and inner complexes are formed.

$$D + A \rightleftarrows D\cdot A \longrightarrow D^+A^-$$

(An example of D in this subclass is TMPD)

(b) The substitution reaction proceeds through the outer and inner complexes.

$$D + A \rightleftarrows D\cdot A \longrightarrow D^+A^- \cdots \longrightarrow P$$

This class is also phenomenologically divided into two subclasses.

(b1) The inner complex is too unstable to be observed by electronic absorption measurements. Aniline is an example of D in this subclass.[1a]

(b2) The inner complex can be observed by electronic absorption measurements. *m*-Phenylenediamine is an example of D in this subclass.[1d]

(c) The reaction proceeds through the outer complex and the ionic species as the reaction intermediates.

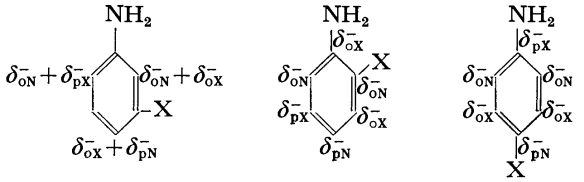
$$D + A \rightleftarrows D\cdot A \longrightarrow D^+ \text{ (or } D_2^{2+}) + A^- \cdots \longrightarrow P$$

(An example of D in this class is PD in an ethyl ether-isopropyl alcohol (3:1) mixed solvent)[19]

In the above classification, D, A, D·A, D^+A^-, D^+, D_2^{2+}, A^-, and P represent aromatic amine, chloranil, the outer complex, the inner complex, the aromatic amine cation, its dimer, the chloranil anion, and the final product, respectively.

Stability of the Inner Complex. In a previous paper[1d], we pointed out that there exists a parallel relationship between the electron-donating abilities of the *meta*-substituent groups in *meta*-derivatives of aniline and the stabilities of their inner complexes with chloranil. For instance, the inner complex formed between *m*-phenylenediamine and chloranil exists about two hours at room temperature, while the complex with *m*-anisidine lasts only a few seconds. The inner complex can not be observed for the system including chloranil and toluidine which has a weaker electron-donating substituent at the *meta*-position than does *m*-anisidine. This fact was explained[1d] on the basis of the reasonable expectation that the nonbonding electron density on the nitrogen atom of the amino group increases with the electron-donating ability of the *meta*-substituent. From the same point of view, we shall consider the difference in stability between the inner complexes of chloranil with *meta*-substituted anilines and *ortho*- or *para*-substituted anilines.

From Table 2 we can deduce the general tendency that aniline derivatives having the electron-donating substituent(s) at the *meta*-position can form such stable inner complexes as can be detected spectroscopically as intermediates in the substitution reactions. As is clearly seen from the following figure in which the electron-density increments on the carbon atoms at the *ortho*- and *para*-positions of the substituent group (s= X or NH_2) are designated by δ^-_{os} and δ^-_{ps}, respectively, in the case of the *meta*-substituted derivatives of aniline, both the amino group and the *meta*-substituent group act to increase the π-electron densities on the three carbon atoms (*ortho* and *para* carbon atoms) by their electron migration effect, while in the case of *ortho*- and *para*-substituted derivatives of aniline, the π-electron densities on all six carbon atoms increase almost equally



by the same effect. This means that, in the former case, the electron migration effect of the amino group

19) The contribution of A^- to this type of reaction is not certain.

is hindered to a greater extent by that of the *meta*-substituent group; therefore, the nonbonding electron density on the amino group is greater than in the latter case. Since the electron-donating ability of aromatic amines in the case of the inner-complex formation may be considered to increase with an increase in the nonbonding electron density on the nitrogen atom of the amino group, the *meta*-substituted derivatives of aniline may be expected to form more stable inner complexes with chloranil than do the *ortho*- and *para*-substituted derivatives.

The ionization potentials (I_p's) of the aromatic amines used as electron donors and the observed peak positions, (λ_{CT}), of the CT bands of the corresponding outer complexes with chloranil are also tabulated in Table 2. Neither the I_p's nor the λ_{CT}'s exhibit any tendency characteristic of the aniline derivatives with an electron-donating substituent(s) at the *meta*-position of the amino group. This may be reasonable, because they are mainly connected with the donor ability of the π-electrons on the benzene ring, while the inner-complex formation is connected with that of the nonbonding electrons of the amino group.

We should like to express our sincere gratitude to Dr. Tomihiko Ohsawa, The Institute of Physical and Chemical Research and Dr. Nobuharu Takai, The Institute of Industrial Science, The University of Tokyo, for their help in the purification of the reaction products.

The Infrared Spectra and the Antiferroelectric Phase Transition of Copper Formate Tetrahydrate

Jiro HIRAISHI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received July 23, 1971)

The infrared spectra of copper formate tetrahydrate are measured in the frequency region from 4000 to 24 cm^{-1} at various temperatures. This compound is known to undergo an antiferroelectric phase transition at −37.7°C. The bands due to the librational and translational modes of the crystalline water molecules in the antiferroelectric phase are quite different from those in the paraelectric phase, while no appreciable differences between the spectra in the two phases are observed for other bands. Those facts agree with the results obtained by the crystallographic study, which show that the ordering of the orientation of the water molecules occurs at the phase transition. The similarity of the librational and the translational modes of the water molecules to those of ice is also discussed.

Solid copper formate tetrahydrate, $Cu(HCOO)_2 \cdot 4H_2O$, undergoes an antiferroelectric phase transition at −37.7°C, and the transition temperature shifts to −27.7°C, when the crystalline water is deuterated.[1-3] The crystal structure of the paraelectric phase (above the transition temperature) was determined by means of X-ray diffraction by Kiriyama, Ibamoto, and Matsuo[4] and by means of neutron diffraction by Okada, Cromer, and Almodovar[5]; they found the space group of the crystal to be $P2_1/a$—C_{2h}^5, with two formula units per unit cell. The crystal consists of alternative layers, one of copper formate and one of crystalline water, parallel to the *ab* plane. The orientation of the crystalline water molecules is disordered; this disorder is similar to that observed in ice.[5] Okada *et al.* suggested that a two-dimensional ordering of the orientation of the water molecules occurs at the phase transition. Turberfield[6] studied the crystal structure of $Cu(HCOO)_2 \cdot 4D_2O$ by means of neutron diffraction at temperatures ranging from 4.2 to 253°K and concluded that the ordering process at the transition temperature involves a cell doubling along the *c* axis. The ordered structure of the crystalline water molecules in the antiferroelectric phase was studied by means of deuteron magnetic resonance by Soda and Chiba.[7,3] They proposed that the ordered layer of the water molecules has a 2-fold screw axis symmetry. The corresponding space group is $P2_1/n$. The structures of the copper formate and of the disordered and ordered water molecules layers are shown in Figs. 1 and 2 respectively.

The infrared spectra of the compound were measured by Kuroda and Kubo.[9] They analyzed the bands due to the copper formate layer, assuming a planar model of the space group $P4/mbm$—D_{4h}^5. The librational modes of the crystalline water molecules were observed in the frequency region from 800 to 500 cm^{-1} [9]. The translational modes of the water molecules, expected to

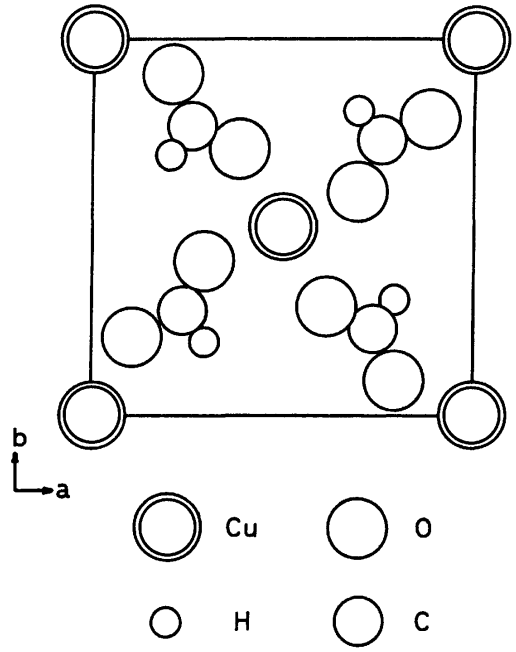

Fig. 1. Structure of the copper formate layer.[5]

appear in the frequency region lower than 350 cm^{-1}, were not yet measured. They assigned the CH stretching, the CO_2 asymmetric stretching, the CO_2 symmetric stretching, the CH in-plane and the CH out-of-plane bending, and the CO_2 scissoring vibrations to the bands at 2910, 1562, 1384, 1366, 1050, and 834 cm^{-1} respectively. In the present work, the infrared spectra of the solid in the frequency region from 4000 to 24 cm^{-1} are measured at various temperatures, as the librational and the translational modes of the water molecules are expected to give some information about the phase transition. The spectrum above 1000 cm^{-1} is not discussed in the present paper, because our results do not differ from those obtained by Kuroda and Kubo.[9]

Experimental

The sample was prepared by the method reported by Okada *et al.*[5] Single crystals grown from an aqueous solution were crushed to prepare Nujol mull for the infrared absorption measurements. The crystalline water was deuterated by keeping the powdered sample in a desiccator with heavy water for a few weeks. As the compound reacts with potassium bromide, plates of Ge, KRS-5, and polyethylene were used for the measurement of the spectra. The infrared spectra were usually recorded on JASCO model 402-G (from 4000 to 400 cm^{-1}), Hitachi model EPI-L (from 700 to 200 cm^{-1}), and Hitachi model FIS-1 (from 500 to 60 cm^{-1}) grating spectrophotometers. A Hitachi model FIS-21 single-beam grating spectrophotometer of the Cryogenic Center, University of Tokyo, was also used for the measurement in the frequency region from 180 to 24 cm^{-1}. The temperature was measured with a copper constantan thermocouple, which was inserted into the plates through a small hole. The temperatures shown in the figures were measured within an accuracy of $\pm 2°K$ for the measurement of the frequency region of the librational modes and within an accuracy of $\pm 1°K$ for the measurement of the frequency region of the translational modes.

Results and Discussion

(1) Temperature Dependency of the Spectra. The infrared spectra in the frequency region from 1000 to

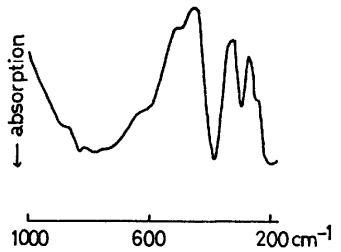

Fig. 3. Infrared spectra in the frequency region from 1000 to 180 cm^{-1} of $Cu(HCOO)_2 \cdot 4H_2O$ at room temperature.

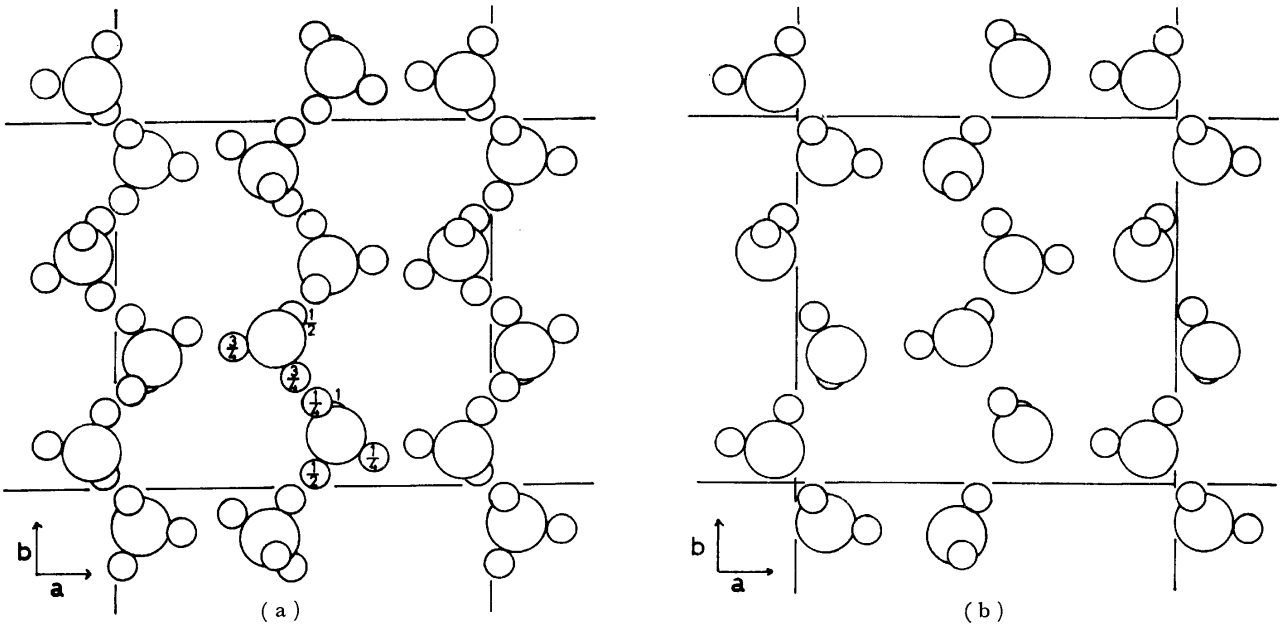

Fig. 2. Structure of the H_2O layers (a) in the paraelectric phase[5] and (b) in the antiferroelectric phases.[8] The large and the small circles represent the oxygen and the hydrogen atoms of water molecules, respectively. The number on small circles indicates the statistical weight of each hydrogen atom.

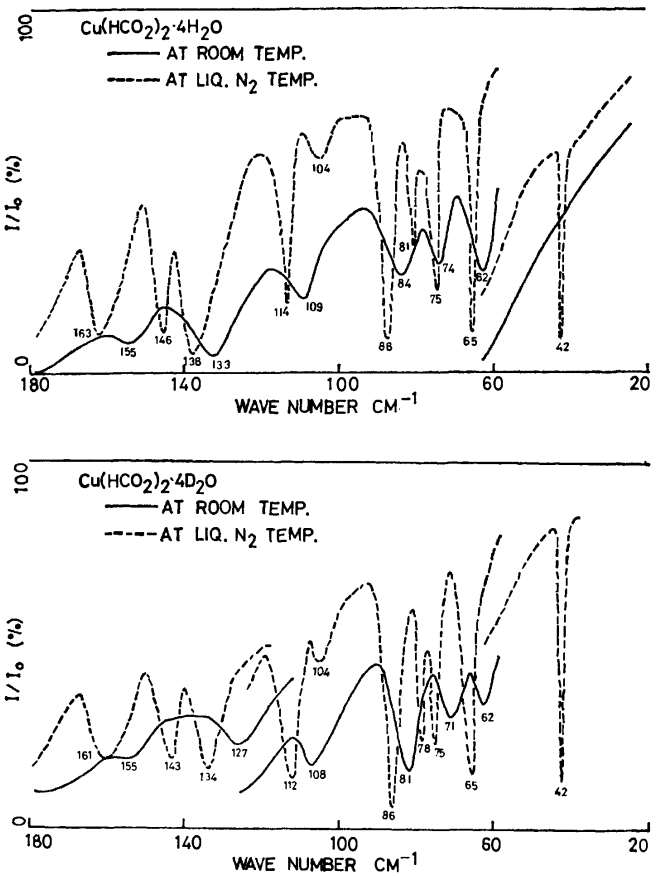

Fig. 4. Far infrared spectra in the frequency region from 180 to 24 cm^{-1} of $Cu(HCOO)_2 \cdot 4H_2O$ and $Cu(HCOO)_2 \cdot 4D_2O$ (70—80% of the crystalline water is deuterated) at room and liquid nitrogen temperatures.

180 cm^{-1} of $Cu(HCOO)_2 \cdot 4H_2O$ are shown in Fig. 3. The spectra below 180 cm^{-1} at room temperature and the temperature of liquid nitrogen for $Cu(HCOO)_2 \cdot 4H_2O$ and $Cu(HCOO)_2 \cdot 4D_2O$ are also shown in Fig. 4. The spectra at low temperatures in the frequency region from 700 to 450 cm^{-1} and below 180 cm^{-1} are quite different from those at room temperature. Spectral change in the librational and the translational modes of crystalline water upon temperature depression has been observed for several salts, such as $CuCl_2 \cdot 2H_2O$[10] and $Li_2SO_4 \cdot H_2O$,[11] although no phase-transition phenomenon has been reported for these compounds. In order to confirm that the spectral change observed in copper formate tetrahydrate arises from the antiferroelectric phase transition, the spectra were recorded at various temperatures in the frequency region from 700 to 450 cm^{-1} and from 90 to 60 cm^{-1}. The results, shown in Figs. 5 and 6, indicate that the spectral change occurs at the transition temperature. The discontinuity in the spectra with the temperature depression found in the bands due to the translational and the librational modes of the crystalline water molecules (see the later discussion of the assignment) is not found in the bands due to the formate group and the H_2O stretching and the bending vibrations. These

facts agree with the finding obtained by other methods—that the crystalline water molecules are connected with the antiferroelectric phase transition.

(2) The Librational Modes of the Crystalline Water Molecules. The broad band covering the frequency region from 900 to 450 cm^{-1} in Fig. 3 was assigned to the H_2O librational modes by Kuroda and Kubo.[9] This assignment was confirmed by the deuteration of the crystalline water, on which the broad band shifted to the lower frequency region around 550 cm^{-1} and left the CO_2 scissoring vibration band at 834 cm^{-1}. The disordered structure of the crystalline water in the paraelectric phase, shown in Fig. 2a, is somewhat similar to that found in ice.[5] The infrared and Raman spectra of ice were measured by Whalley *et al.*[12] The librational bands of ice I, which has an disordered structure, form a broad band covering the frequency region from 1000 to 400 cm^{-1}, while those of ice II and III give a good deal of a fine structure below 700 cm^{-1}. They explained that this fine structure arose from the ordering of the hydrogen atoms in ice II and III because of the disappearance of the fine structure in partially-deuterated ice II or III. The librational band of ice I is similar to that of the crystalline water of the formate in the paraelectric phase; those of ice II and III are also similar to that of the formate in the antiferroelectric phase. The spectra of the librational modes of the partially-deuterated crystalline water molecules of the formate below the transition temperature do not give such a fine structure as is observed for the ordinary water molecules of the formate. These facts indicate that the transition from the paraelectric to the antiferroelectric phase involves the ordering of the orientation of the crystalline water molecules, as was pointed out by a crystallographic study.[5]

(3) The Spectra below 400 cm^{-1}. The vibrations which are expected to appear below 400 cm^{-1} can be classified into three groups. The first group, A, includes the vibrations due to the copper formate layer, except for the intramolecular vibrations of the HCO_2 group and three acoustic modes of the layer. In the paraelectric phase, these vibrations are classified as $6a_g+8a_u+6b_g+7b_u$; that is, fifteen vibrations are infrared active. The second group, B, includes the translational modes of the crystalline water molecules, except for three acoustic modes of each layer. There are 42 modes ($11a_g+10b_g+11a_u+10b_u$) in the antiferroelectric phase. The rest of the vibrations (Group C) are due to the acoustic modes of each layer. There are three modes for the paraelectric phase (a_u+2b_u) and nine for the antiferroelectric phase ($a_g+3a_u+2b_g+3b_u$), except for three acoustic modes of the crystal.

The number of the bands observed below 400 cm^{-1} is much less than expected. It is not the purpose of the present paper to assign all the observed bands. We may say, at least, that most of the bands below 180 cm^{-1} can be assigned to the vibrations of group B, because the translational vibrations of water molecules in ice are located in this frequency region,[12] and that most of the bands below 180 cm^{-1} of the formate shift more or less to the lower frequency region on the deuteration of the crystalline water molecules, as is shown in Fig. 4. The following discussion may explain the difference between the spectra below 180 cm^{-1} in the para- and the antiferroelectric phases. Whalley and Bertie discussed the vibrational spectra of orientationally-disordered crystals.[12a] Their conclusion was that all the translational lattice vibrations of the orientationally-disordered crystal can be active in both the Raman and infrared spectra. They analyzed the translational vibrations of ice I,[12b] considering that the features in the

12) a) J. E. Bertie and E. Whalley, *J. Chem. Phys.*, **40**, 1637, 1646 (1964). b) *ibid.*, **46**, 1271, 1264 (1967). c) M. J. Taylor and E. Whalley, *ibid.*, **40**, 1660 (1964). d) J. E. Bertie, H. J. Labbe, and E. Whalley, *ibid.*, **49**, 775 (1968).

infrared spectrum correspond to similar features in the density of states of the lattice vibrations. The far infrared spectra of ice I show a very broad band with a sharp maximum at 229.2 cm^{-1} and several shoulder bands, while the spectra of ice II show sharp maxima at 237.1, 186.4, 151.4, 136.1, and 106.5 cm^{-1}, plus a few shoulder bands.[12d] Makita and Seo measured the dielectric constant of the formate and reported the relaxation time to be 10^{-6}—10^{-7} sec,[13] which is much larger than the period of the translational lattice vibrations of the crystalline water molecules (10^{-11}—10^{-12} sec). That is, the orientation of the water molecules of the formate is disordered during the period of the translational lattice vibrations of the water molecules. Accordingly, all of the translational lattice vibrations, not only with the wave vector $k\sim0$, but also with $k\neq0$, are infrared active in the paraelectric phase. In the antiferroelectric phase, the structure is ordered and the ordinary selection rule of the symmetry C_{2h} holds for the infrared absorption.

Figure 7 shows the vibrational modes of Group C. The interatomic distances of Cu–O_W (2.38 Å) and H_W–O_F (1.88 Å) are about the same as the distances of Cu–O_F (2.00 Å) and the H_W–O_W hydrogen bond (1.72—1.90 Å) respectively,[5] where O_W, H_W, and O_F represent the oxygen and hydrogen atoms of the water molecule and the oxygen atom of the formate group respectively. This indicates that the interaction between the copper formate and the crystalline water layers are similar to the interaction between the copper and the formate group, or to that between the water molecules, so that the bands due to the vibrations, ν_b and ν_e in Fig. 7 can be expected not to appear below

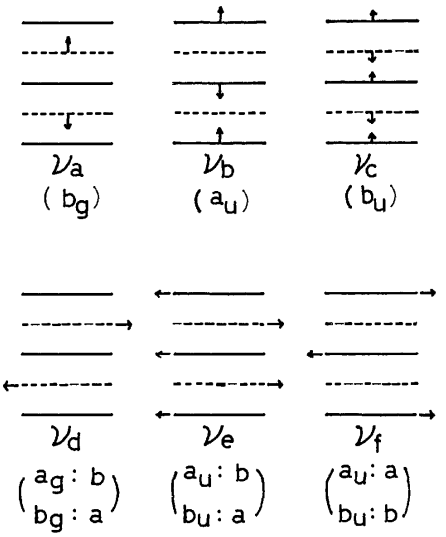

Fig. 7. Vibrations due to the acoustic modes of each layer in the antiferroelectric phase. Bravais unit cell consists of four layers, two of copper formate layer (solid line) and two of H_2O layer (dashed line). Symmetry species of each vibration is given in parenthesis. a_g: b represents that symmetry species of the vibration, the displacement coordinate of which is along b axis, is a_g.

100 cm^{-1}. The bands due to ν_e and ν_f are expected to have lowest frequency. ν_f is active in the antiferroelectric phase, but inactive in the paraelectric phase, because the wave vector of the vibration is zero in the former phase, but π in the latter phase. It can be concluded from the above considerations that the band at 42 cm^{-1}, which appears only in the antiferroelectric phase, may be assigned to ν_f, and the band at 62 cm^{-1} to ν_e.

Heat Capacity of Ammonium Chloride between 8 and 300 K

Hideaki CHIHARA and Minoru NAKAMURA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka

(Received August 16, 1971)

Heat capacity of NH_4Cl was measured between 8 and 300 K with an adiabatic calorimeter. The low-temperature limit of the Debye temperature is 352 K and its high-temperature limit in the harmonic approximation is 285 K. The λ transition point T_λ is 242.502±0.004 K with the heat of transition 1168 J mol^{-1} and the entropy of transition 5.00 JK^{-1} mol^{-1}. It is very close to the first-order transition. From the analysis of the heat capacity between 242 and 300 K, an extra contribution to the heat capacity that amounts to 11.5 JK^{-1} mol^{-1} at 300 K is extracted and explained by a simple model which assumes an additional type of order-disorder in the arrangment of NH_4 ions above T_λ. The energy difference between the parallel and the antiparallel pairs of NH_4 ions is estimated to be 1.46 kJ mol^{-1} from the low-temperature tail of the heat capacity anomaly near T_λ.

Ammonium chloride undergoes a diffuse phase transition at 242.5 K (hereafter designated by T_λ) and an abrupt phase transition at 457.6 K (hereafter designated by T_c). Detailed experimental and theoretical investigations[1] have been made concerning the lower phase transition at T_λ.[2-8] It is generally agreed that this transition is associated with disordering of ammonium ions between two possible orientations. Such mechanism has been established by experiments on the neutron diffraction[9] and infrared absorption[2,3] on single crystals of NH_4Cl as well as ND_4Cl.

Heat capacity measurements have been reported by many investigators[10-13] particularly below room temperature and they are fully analyzed in the paper by Sakamoto.[8] The earlier measurements, however, were not sufficiently closely spaced to reveal the shape of the heat capacity anomaly in the vicinity of T_λ. We have undertaken the precision measurements of the heat capacity between 8 and 300 K using an adiabatic calorimeter and found the results suggesting that T_λ is merely the starting point of the higher temperature transition at T_c.

Experimental

Material. Ammonium chloride (Yashima Chemicals Co., stated purity 99.9%) was recrystallized from aqueous solution and purified further by vacuum sublimation.

Calorimeter. The cryostat and calorimeter used for the present study is a modification of the one described earlier.[14] To employ larger amount of specimen, the larger calorimeter vessel (gold) and the larger adiabatic shield were newly machined, the refrigerant container being the same as before. Helium exchange gas was used to aid in the attainment of the equilibrium within the calorimeter, its amount corresponding to less than 1 Torr at room temperature. The correction to the solid heat capacities due to dissociative vaporization of NH_4Cl in the calorimeter was negligibly small even at room temperature.[15]

Temperature scales. The working thermometer above 11 K was a Leeds & Northrup platinum thermometer calibrated at the U. S. National Bureau of Standards; This was based on 1948 International Temperature Scales. A carbon resistor (Allen-Bradley, 1/8 W, 10Ω at room temperature) was used for the region below 11 K. It was calibrated by comparison with the platinum thermometer *in situ* at five different temperatures between 11 and 21 K. The results of comparison were fitted to the Clement-Quinell formula in the form

$$\log R + \frac{K}{\log R} = A + \frac{B}{T} \qquad (1)$$

for the purpose of extrapolation below 11 K. The calibration was carried out immediately after each series of measurements. The primary heat capacity values reported in the present paper are based on this temperature scale.

Since there was no fixed points below 11 K, the resulting temperature scale may be in error below about 6 K. After the experiments were concluded, the carbon scale was reexamined by comparing the carbon resistance with ^4He vapor pressure at 4.2 K in addition to the five comparisons above 11 K. The carbon scale was found to depend to a small extent on whether or not the fixed point at 4.2 K was included in the determination of the constants in Eq. (1). Further, an additional term, $C/(\log R)^2$, on the left-hand side of Eq. (1) improved the fitting of the equation. The probable error in the heat capacity values that arises from this type of uncertainty in the temperature scale were estimated to be about 10% at 4.0 K, 7.5% at 5 K, 2.5% at 6 K, 1.7% at 7 K, and 0.3% at 10 K in the present case. In view of rather large uncertainties below 8 K, the measured points below 8 K will be omitted from Table 1.

Results

Measured values of the heat capacity are given in Table 1 and the smoothed values at rounded temperatures in Table 2. Curvature corrections were not applied, but may be computed from Table 1 since each series is result of continuous measurements. In the transition region, the temperature was constant at worst to within 5/10000 K when equilibrium has been reached and the smallest temperature rise in a single heating was about 2/100 K; the maximum error in $E/\Delta T$ that comes from the smallness of ΔT was therefore about 5%.

The present results are compared in Fig. 1 with previously published results of Simon,[10] Simon, Simson, and Ruhemann,[11] and Ziegler and Messer.[12] More recent unpublished measurements by Stephenson[13] above 19 K agree more satisfactorily with the present measurements. Fractional deviations from our smoothed values are compared in Table 3.

The temperature T_λ was determined from the point of maximum slope in the enthalpy *vs.* temperature graph as 242.502±0.004 K. The heat of transition was evaluated by estimating 'normal' heat capacity curve as indicated in Fig. 1. It was 1168 J mol^{-1} and the corresponding entropy of transition was 5.00 JK^{-1} mol^{-1} or 0.601 R where R is the gas constant. Table 4 is the comparison of different measurements.

Conversion of C_p to C_v

One of the crucial procedure in the analysis of experimental heat capacities is the conversion of C_p to C_v. Very rarely, reliable values of thermal expansion coefficient and isothermal compressibility are available over a sufficiently wide temperature range. We plotted available data of the molar volume on a large graph paper and found that the data by Staveley *et al.*[16] Lawson,[17] Hüllsmann-Biltz,[18] and Vegard-Hillesund[19] are mutually consistent below T_λ whereas those by Dinichert[20] and Adenstadt[21] deviate con-

siderably in the opposite directions. We then adopted the temperature of 150 K as the reference temperature to fix C_p–C_v because the effect of the transition is barely seen at this temperature.

The adiabatic compressibility χ_S at 150 K was calculated from an extrapolation of Garland's values on c_{11} and c_{44} and it was converted to the isothermal compressibility χ_T by using the formula

$$\chi_T = \chi_S + (V\alpha^2 T/C_p) \quad (2)$$

where V is the molar volume, α the volume expansion coefficient, and T the absolute temperature. The reference values at 150 K were thus $V=33.806$ cm^3 mol^{-1}, $\alpha=1.005\times10^{-4}$K^{-1}, $C_p=53.58$JK^{-1}mol^{-1}, $\chi_S=3.8596\times10^{-7}$ cm^{-2} N^{-1}, and $\chi_T=3.9551\times10^{-7}$ cm^{2}N^{-1}. These values give

$$C_p - C_v = \frac{V\alpha^2 T}{\chi_T} = 1.294\text{JK}^{-1}\text{mol}^{-1}$$

at 150 K. Because few experimental determinations have been reported of α and χ below 150 K, an approximate formula

$$C_p - C_v = AC_p^2 T \quad (3)$$

was applied below 150 K, where the value of A was fixed as 3.004×10^{-6} mol J^{-1} so as to reproduce the correction at 150 K. Between 150 and 230 K, we adopted Lawson's length data[17] and normalized them so that they become consistent with the molar volume at 273.2 K (34.826 cm^3), thus estimating the values of α which are shown in Fig. 2. χ_S was derived from the measured elastic constants.[23] Above T_λ, Sakamoto's calculated values[8] of α and Garland's χ_S values were used to obtain the C_p–C_v correction. The results of such computations and the estimated C_v values are listed in Table 5.

Low-temperature Heat Capacities

The low-temperature C_v was converted to the equivalent Debye temperature Θ_D^C for six degrees of freedom per unit cell after the contributions[2,3] of the intra-ionic vibrations at 1403 cm^{-1} (triply degenerate) and 1683 cm^{-1} (doubly degenerate) and of librations of ammonium ions at 391 cm^{-1} (triply degenerate, below T_λ) have been subtracted from C_v. The plot of Θ_D^C *vs* temperature (Fig. 3) shows a shallow minimum around

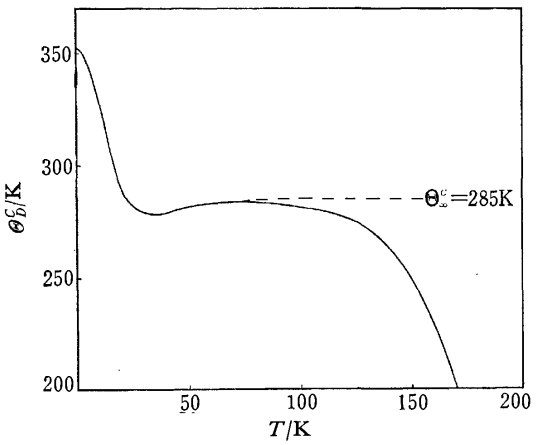

Fig. 3. Equivalent Debye temperature of ammonium chloride based on C_v for $6N$ degrees of freedom.

35 K with Θ_D^C (min)=279 K. The Debye temperature at the high temperature limit in the harmonic approximation was estimated to be Θ_∞^C=285 K corresponding to the Debye cut-off frequency of 198 cm^{-1} or 5.9×10^{12} Hz. This cut-off frequency is in good agreement with that obtained from the analysis of coherent inelastic scattering results for ND_4Cl.[24] The cut-off frequency is not affected by the deuterium substitution. The limiting low-temperature Θ_0 was obtained from the plot of C_vT^{-3} against T^2 at 352 ± 6 K.

High-temperature Heat Capacities

Inspection of Fig. 3 shows that Θ_D^C tends to decrease above 100 K. Because the intra-ionic and the libra-

tional contributions in the harmonic approximation have been subtracted from C_v which was used in deriving Θ_D^C, the descending trend of Θ_D^C must be due either to onset of the phase transition and/or to some anharmonic effect.

To visualize the behavior near T_λ, the 'rotational' part of C_v, defined by

$$C_R = C_v - C_i - C_D(285\,\mathrm{K}) \tag{4}$$

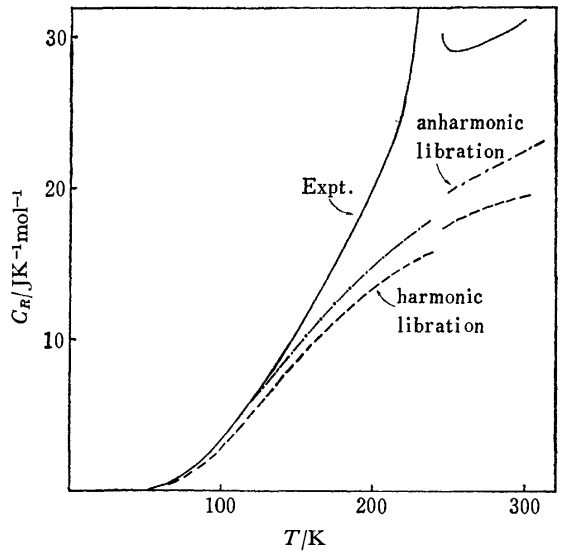

Fig. 4. Rotational contribution to the molar heat capacity.

was calculated, were C_i is the heat capacity due to intra-ionic vibrations and C_D (285 K) is the Debye heat capacity corresopnding to Θ_∞^C. The results are shown in Fig. 4. In the same figure, a curve is drawn that corresponds to the harmonic libration of NH_4^+ ions (391 cm^{-1} for $T<T_\lambda$ and 359 cm^{-1} for $T>T_\lambda$). The use of Einstein heat capacity for the libration mode may be justified by the flatness of the dispersion relation observed by the inelastic neutron scattering experiments.[5] It is apparent that the harmonic libration model can account for C_R only up to about 130 K where C_R begins to curl up rapidly. Such deviation may be taken as indicating on-set of the order-disorder transition, but what seems to be abnormal is the large discrepancy between C_R and the harmonic librational heat capacity above T_λ which amounts to as great as 11.5 J K^{-1} mol^{-1}. The existence of this extra heat capacity was already pointed out by Sakamoto[8] although his estimate was somewhat smaller (8.95 J K^{-1} mol^{-1} at 298.15 K) than ours. We shall now examine some possibilities that could account for the extra contribution.

a) Anharmonic Librations. Woessner and Snoden[6] derived a value of 19.7 kJ mol^{-1} ($T<200$ K and $T<T_\lambda$) for the activation energy of the reorientation of ammonium ions from their measurements of the NMR spin-lattice relaxation time. Since the activation energy is only eight times as large as the average thermal energy of a single ammonium ion at 300 K, the anharmonic contribution to the librational heat capacity could be significant.

If we assume the potential energy of an ammonium ion of the form

$$V(\phi) = \frac{1}{2}V_0(1-\cos n\phi)$$
$$= c\phi^2 + f\phi^4 + \cdots \tag{5}$$

where V_0 is the barrier height and ϕ is the angle of rotation, the anharmonic Einstein heat capacity then becomes[25]

$$\frac{c_v}{R} = \frac{c_v^h}{R} - \frac{3}{2}\frac{fRT}{c^2} + \cdots \tag{6}$$

Equation (6) is also plotted in Fig. 4 by the dot-dash curve. It still falls short of the C_R values. The situation is almost the same if we use Eq. (5) and calculate the heat capacity of a triply degenerate hindered rotor with the help of Pitzer-Gwinn's tables.[26] Recently, Garland and Weiner[27] introduced a more anharmonic potential function that can account for the optical spectra.[1] However, the use of their energy level scheme (with $\omega=391$ cm^{-1} and $x=29$ cm^{-1}) gave too small a heat capacity, only 16.6 J K^{-1} mol^{-1} to be compared with 19.6 J K^{-1} mol^{-1} obtained at 300 K in the harmonic approximation.

b) Subsidiary Minima in the Potential Energy. At the upper transition point (T_c), NH_4Cl is transformed into NaCl type of structure probably because the reorientation rate of NH_4 cations becomes progressively larger at higher temperatures, finally reaching a point where the molecular field an NH_4 cation sees is made effectively spherical. The shape of the heat capacity curve near T_c is such that the heat capacity drops abruptly at T_c by as much as about 22.5 J K^{-1} mol^{-1} (5.38 cal K^{-1} mol^{-1}). If the transition were simply associated with the change from reorientation to nearly free rotation of NH_4 cations, the heat capacity drop would be about $^3/_2 R$ or 12.5 J K^{-1} mol^{-1}, about half of the decrease found experimentally. The sum of contributions 76 J K^{-1} mol^{-1}, Debye lattice heat capacity 25 J K^{-1} mol^{-1}, C_p—C_v correction *ca.* 30, rotation of NH_4 cations 12.5, and internal vibrations of NH_4 8.6, roughly account for the observed heat capacity, *ca.* 81 J K^{-1} mol^{-1}, immediately above T_c. The fact that the distance (3.27 Å) between the nearest N and Cl atoms is equal to the sum (3.29 Å) of the ionic radii also suggests that ammonium ions undergo almost free rotation above T_c. This in turn will indicate that there must be some extra contribution to the heat capacity below T_c. Therefore, the observed heat capacity contains such extra persistently between T_λ and T_c.

To interpret the extra contribution to the heat capacity we shall assume a simple model in which ammonium ions can assume additional type of disorder other than the one that is responsible for the transition at T_λ. Below T_λ the NH_4 cations are rather rigidly held in one of the two possible orientations but as the complete disorder is attained immediately above T_λ,

25) A. J. E. Foreman and A. B. Lidiard, *Phil. Mag.* **8**, 97, (1963).

the ions will execute a kind of rattling motion as a result of frequent reorientational motion. The lowest potential barrier over which an NH_4 ion can reverse its orientation will be such that the ion is rotated through about 60° around one of its N–H bond (threefold axis) and then 60° around the axis perpendicular to the bond. The first type of rotation will lead the ion to a shallow minimum of the potential energy—here, three hydrogen bonds are broken but they are replaced by electrostatic attraction between hydrogen and chloride ions. At such an intermediate orientation, the remaining N–H···Cl⁻ hydrogen bond will become shortened giving rise to eightfold position of the N atom, slightly displaced from (½½½) toward one of the eight neighboring chloride ions. If we now assume that those subsidiary eight minima have energy ε relative to the principal minima, we shall obtain a Schottky type anomaly in the heat capacity, *i.e.*

$$C_{\mathrm{Sch}} = \frac{N\varepsilon^2}{kT^2}\frac{g_0}{g_1}\frac{\exp(\varepsilon/kT)}{[1+(g_0/g_1)\exp(\varepsilon/kT)]^2} \qquad (7)$$

where $g_0=2$ and $g_1=8$ for the model proposed. Equation (7) is plotted in Fig. 5 for $g_0/g_1=1/4$, $\varepsilon=7.5$ kJ mol^{-1}. The maximum of C_{Sch} was fixed at 300 K as Sakamoto's analysis suggested the existence of a broad maximum here. At 300 K, Eq. (7) gives 10.36 J K^{-1} mol^{-1} whereas the experimental extra heat capacity is 11.50 J K^{-1} mol^{-1} if we assume harmonic librational modes or 8.57 J K^{-1} mol^{-1} if we assume Eq. (5) for the potential energy function. The agreement with Eq. (5) appears satisfactory in the absence of reliable estimates for the anharmonicity. Our measurements of the heat capacity did not extend beyond 300 K and therefore Eq. (5) would not deserve more detailed fitting at present. However, the existence of large extra heat capacities between T_λ and T_c is beyond doubt and they must be associated with some additional degrees of freedom in the crystal. We have proposed a possible interpretation here which may have consequences in other properties of NH_4Cl at high temperatures, *e.g.* inelastic neutron scattering, Raman spectra, and dielectric dispersion.

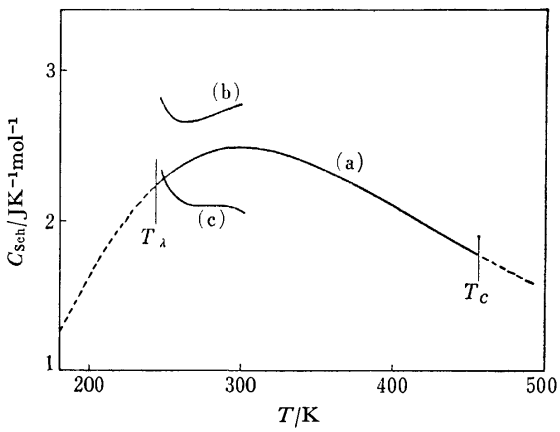

Fig. 5. Schottky heat capacity [Eq. (7)]. Comparison with 'experimental' estimates of the anomalous heat capacity above T_λ. Curve a: theoretical calculation for $g_0/g_1=1/4$, $\varepsilon=7.5$ kJ mol^{-1}, Curve b: estimate based on the harmonic libration model, Curve c: estimate based on the anharmonic libration model.

A similar type of anomaly was reported[28] in the case of stoichiometric AgI, in which case positional disorder of Ag cations were assumed to explain an anomalously large heat capacity after it has transformed to the α form at 150°C.

Anomaly Associated with the λ Transition

Garland and Schumaker[29] confirmed a good correlation between the intensity of the 1444 cm^{-1} infrared band and the anomalous part of the heat capacity using Stephenson's unpublished results. Since our results agree satisfactorily with Stephenson's heat capacities, we shall not attempt to repeat the analysis but merely point out that the transition is very close to the first order transition as may be inferred from Series XI, Table 1.

The Energy to Reorient an NH_4 ion in the Ordered Matrix

It is possible to estimate the energy required to rotate an NH_4^+ ion through 180° from the low temperature tail of the λ transition. Assuming that the number of NH_4^+ in the wrong orientation n is very small compared with the total number of the ions N, we have

$$\frac{n}{N} = \exp(s/k)\exp(-\varepsilon/kT) \qquad (8)$$

where ε is such energy and the anomalous heat capacity ΔC is given by

$$\Delta C = \frac{1}{T^2}\cdot\frac{\varepsilon^2}{k}e^{s/k}e^{-\varepsilon/kT} \qquad (9)$$

in an analogous way to the case of vacancy formation.[30]

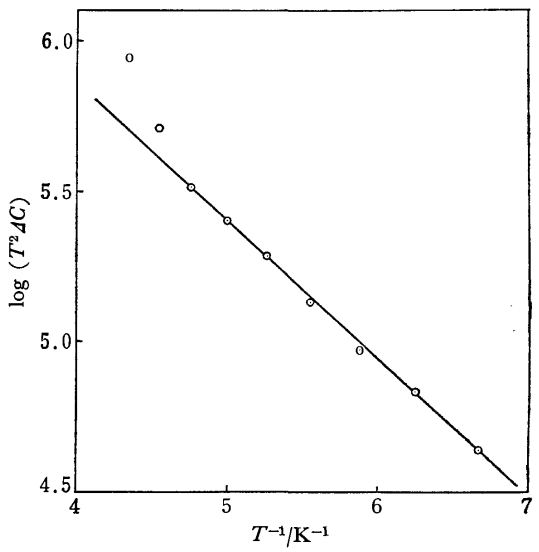

Fig. 6. Evaluation of the energy to reorient an NH_4 cation in almost perfectly ordered lattice.

28) C. M. Perrott and N. H. Fletcher, *J. Chem. Phys.* **48**, 2143, 2681 (1968).
29) C. W. Garland and N. E. Schumaker, *J. Phys. Chem. Solids*, **28**, 799 (1967).
30) R. H. Beaumont, H. Chihara, and J. A. Morrison, *Proc. Phys. Soc.* (London), **78**, 1462 (1961).

ΔC was evaluated as the difference between C_R and C_{lfb} in Fig. 4 and a plot is made of log $(T^2\Delta C)$ *versus* $1/T$ in Fig. 6. A good straight line is obtained between 150 and 210 K, the slope of which gives $\varepsilon=8.77$ kJ mol^{-1}. The deviation of the points for 220 and 230 K is due to rapid increase of the heat capacity in the transition region. Eq. (8) then reads

$$\frac{n}{N} = 5.32 \exp(-1055/T) \tag{10}$$

which leads to a value of $n/N=0.035$ at 210 K. The magnitude of ε (8.77 kJ mol^{-1}) corresponds to the difference in energy between six parallel pairs and six antiparallel pairs; the energy difference between one parallel and one antiparallel pair is then 1.46 kJ mol^{-1}, about 3/4 of kT_λ (=2.02 kJ mol^{-1}).

The authors would like to thank Mr. Tooru Atake for assistance during the measurements. They also express gratitude to Professor Stephenson of Massachusetts Institute of Technology for sending them his unpublished heat capacity values. Discussions with Dr. Nobuo Nakamura of Osaka University were very fruitful to whom their thanks are due.

Polarographic Catalytic Waves of Titanium(IV) Chelates of EDTA and Related Compounds

Hiroko KANEKO and Takeo OZAWA
Electrotechnical Laboratory, Tanashi, Tokyo
(Received July 29, 1970)

In the presence of the chlorate ion, the electrode reaction of the various titanium(IV)-chelates is followed by a cyclic process, *i.e.*, an electrochemical reduction of electroactive species generated continuously by coupled chemical oxidation. The reaction rate constant of the regeneration is determined from the ratio of the limiting current observed by the DC polarographic method in the presence of the chlorate ion to that determined without it, and it is calculated using Koutecky's equation. The complex-forming agent decreases the wave height of the catalytic waves of titanium(IV) chelates, and a clear dependency of the height of the catalytic waves on the dissociation constants of the titanium chelates is found. The catalytic wave heights of the titanium(IV) chelates decrease in the order of oxalic acid, NTA, EDTA-OH, EDTA, and CyDTA; the dependency on the stability seems to be the reverse. The logarithm of the dissociation constant is in a linear relation with the logarithm of the catalytic current. The mechanism is discussed on the basis of the above-mentioned facts.

The reduction of titanium(IV) in the presence of the chlorate ion is an example of the type of behavior in which the original depolarizer is regenerated by the reaction of the primary product with a certain component of the solution. These catalytic waves of titanium(IV) in various solutions were investigated.[1-3] The DC polarographic behaviors of the titanium(IV) ion in an ethylenediamine tetraacetate(EDTA)s olution[4] and in a cyclohexanediamine *N,N,N',N'*-tetraacetate(CyDTA) solution[5] have already been investigated, and the compositions and stability constants of titanium(IV) complexes and the mechanism of the electrode reaction have been determined.

Though it is supposed that, in the presence of a chelating agent, the regeneration rate of titanium(IV) might become considerably slow, no investigation of it has yet been reported. In the present paper, the effects of these EDTA-like agents on the regeneration of titanium(IV) by the chlorate ion are investigated, and the rate constants of the regeneration reactions of some titanium(IV) chelates are calculated by the use of Koutecky's equation.[6] The complex-forming agent decreases the wave height of the catalytic wave of the titanium(IV) chelate, and a clear dependency of the height of the catalytic waves on the dissociation constants of titanium chelates is found.

Experimental

Reagents. All the solutions used were prepared from analytical reagent-grade chemicals. Titanium metal (spongy one) was dissolved in dilute sulfuric acid and oxidized by a small amount of dilute warm nitric acid, after which the solution was standardized by visual chelatometric titration with EDTA as the titrant. The solutions of the complex-forming reagents, EDTA, CyDTA, *N*-(2-hydroxyethyl)-ethylenediamine *N,N',N'*-triacetic acid (EDTA-OH), nitrilo-triacetic acid (NTA), and oxalic acid (OX), were prepared from commercial analytical-grade chemicals and were standardized by visual titration with a zinc solution and with a Eriochrome Black T solution as the indicator.

Apparatus. Polarographic current-voltage cruves were

obtained with a Yanagimoto P8 series polarograph, model P8-DPR. A three-electrode system is utilized in this instrument, and the potentials are measured at intervals of a few seconds with an electrodehammer which also dislodges the mercury drop. The capillary employed for the DME measurements had a capillary constant ($m^{2/3}t^{1/6}$) of 1.14 in 0.1 mol/*l* sulfuric acid (open circuit), where m is the flow of electrode mercury per second and where t is the drop time.

The pH of the solution was measured immediately after the measurements of the current-voltage curve by means of a Toa HM-5A pH meter equipped with a glass electrode.

Procedure. The measurements were carried out in solutions containing 0.96 mmol/*l* of titanium(IV), 0.1 mol/*l* of oxalic aicd, and 0.05 mol/*l* of potassium chlorate; the concentrations of chelating agents in the solutions were 5, 10, 20, and 50 mmol/*l*. All the solutions were de-aerated with nitrogen gas for 10 min before the polarogram was obtained. During the course of the measurement, a nitrogen atmosphere was maintained over the solution in the cell. The temperature of the solutions was kept at 25.0°C within a variation of ±0.1°C by using a thermostat. The polarogram of the above-mentioned solution was recorded after recording the wave of the solution of the same composition without potassium chlorate.

Results

The rate constants, k, of the regeneration reactions of some titanium chelates are calculated as follows:

$$\begin{array}{ccc} \text{Ti (IV)} + e & \longrightarrow & \text{Ti (III)} \\ \uparrow & & \downarrow \\ \overbrace{\text{ClO}_3^-} & & \overbrace{k} \end{array} \qquad (1)$$

In the case of $i_l/i_d > 2.5$ and $i_l \ll {}_x i_d$, the equation for the total limiting current can be derived from the approximate expression of Koutecky:[6]

$$i_l/i_d = 1 + 0.815\sqrt{kCt} \qquad (2)$$

where i_l and i_d indicate the kinetic current of the catalytic reaction and the diffusion current respectively; where i_t is the sum of i_l and i_d; k, the rate constant of the regeneration reaction of titanium(IV); C, the concentration of the oxidizer; ${}_x i_d$, the hypothetical diffusion current which would be observed for the reduction of all the chlorate ions, and t, the drop time. Equation (2) holds only when the complex-forming agent and the oxidizer exist in a large excess over the titanium(IV) in the solution. In the case of $i_l/i_d > 2.5$, if the relation betwen i_l/i_d and $C^{1/2}$ is linear, the rate of the catalytic reaction of the regeneration of titanium(IV) is rapid and the decrease in the concentration of the oxidizer can be neglected.

When i_l/i_d is plotted against the square root of the concentration of the chlorate ion, the rate constant, k, of the regeneration reaction of titanium(IV) can be obtained from the slopes of these linear plots, provided that the polarographic waves of titanium chelate in the solution without the chlorate ion can be observed. Actually, the polarographic waves of titanium chelates in the solution without the chlorate ion are observed with solutions containing 20 mmol/*l* of EDTA, EDTA-OH, and CyDTA, 50 mmol/*l* of NTA, and 0.1 mol/*l* of oxalic acid respectively at pH 1.

In Fig. 1, the wave height divided by the root of h_0 is plotted against the mercury height, where h_0 is the mercury height corrected for back pressure. It can be inferred that the limiting current of titanium chelate in the solution without the chlorate ion is the diffusion current. This inference is also derived from the temperature coefficient (1.4%/°C) of the wave of the EDTA-OH titanium-chelate (Fig. 9).

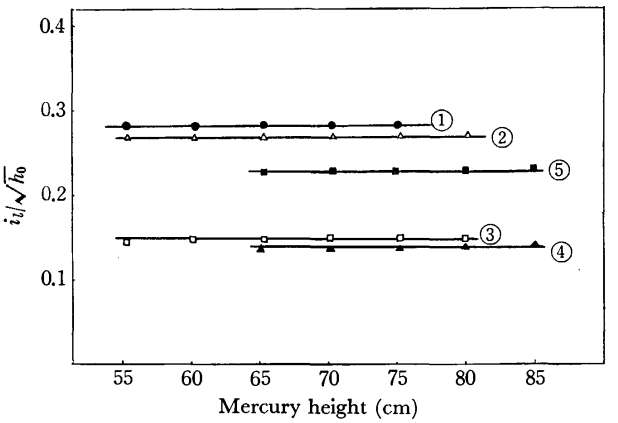

Fig. 1. The effect of mercury height on the diffusion current. 1, OX; 2, NTA; 3, EDTA-OH; 4, EDTA; 5, CyDTA.

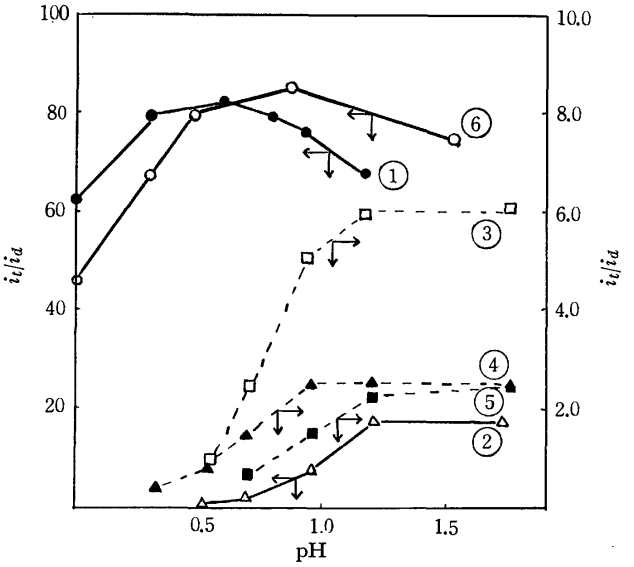

Fig. 2. The effect of pH on i_l/i_d. 1, OX; 2, NTA; 3, EDTA-OH; 4, EDTA; 5, CyDTA; 6, nothing.

Then, the dependencies of the i_l/i_d ratio on the pH of the solution and on the concentration of the chelating agents were observed. In Fig. 2, the dependencies of the i_l/i_d ratio on the pH are shown, where the concentration of the chelating agents is 5 mmol/*l*, except for oxalic acid and NTA, whose concentrations are 0.1 and 0.02 mol/*l*. As is shown in Fig. 2, the dependency is negligible in the range of pH larger than 1.2, except for the solution containing oxalic acid and that without any chelating agent. The large variations observed in the latter cases seem to be due to the low stabilities of the complexes. All the measurements hereafter are made by controlling pH within an accuracy of ±0.1. The effect of the pH on the half-wave potential of the catalytic wave is shown in Fig. 3.

The effect of the concentration of the chelating

agents is shown in Fig. 4, where the concentration of titanium(IV) is 0.94 mmol/*l* and where that of chlorate is 0.05 mol/*l*. At concentrations higher than 0.01 mol/*l*, the dependency of the i_l/i_d ratio on the concentration is low for EDTA-OH and CyDTA; the dependency for EDTA might be similar because its properties are similar to those of CyDTA, while a large dependency is found for the solution containing NTA, where the dependency seems to be negligible for the range higher than 0.05 mol/*l* and where the precipitation is found in the NTA solution in the range over 0.07 mol/*l*. This large dependency might be caused by the co-existence of the complex ion containing a single NTA molecule and that complex ions containing NTA molecules. The second wave found for the NTA chelate mentioned below is presumably other evidence of this. Hereafter, the concentration of NTA will be controlled at 0.05 mol/*l*, and that of oxalic acid at 0.1 mol/*l*.

The diffusion current of the titanium(IV)-EDTA-OH chelate solution increases as the temperature increases, and its temperature coefficient is 1.4%/°C. However, the catalytic current is in a nonlinear relationship with the temperature (Fig. 5).

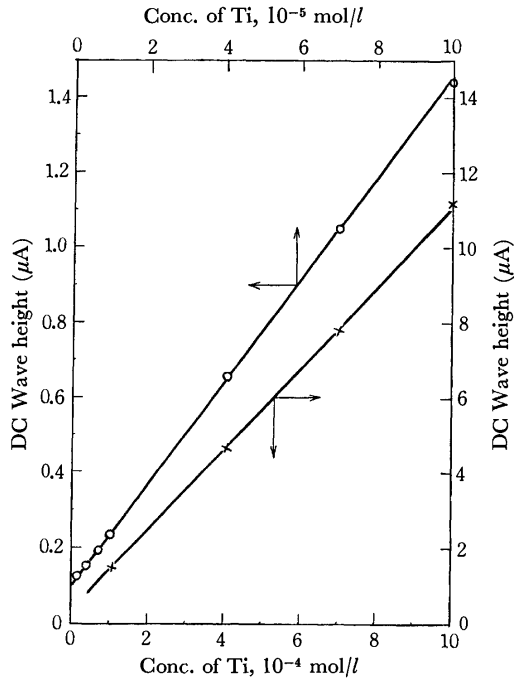

Fig. 6. Calibration curves of the catalytic wave of titanium-EDTA-OH chelate.
pH: 1.2, EDTA-OH: 0.02M, $KClO_3$: 0.05M.

As is shown in Fig. 6, a linear relationship is found between the concentration of titanium(IV)-EDTA-OH and their catalytic current in the presence of 0.05 mol/*l* potassium chlorate over the range from 1×10^{-6} mol/*l*, to 1×10^{-3} mol/*l* of titanium(IV).

In Fig. 7, the values of i_l/i_d at the drop time of 3.0 sec and at pH 1.0 ± 0.1 are plotted against the square root of the concentration of the total chlorate ion. The catalytic wave height of titanium chelates decreases in the order of oxalic acid, NTA, EDTA-OH, EDTA, and CyDTA. Straight lines can be drawn through

the plots, as is seen in Fig. 7, and the intercepts are 1; these facts are in accordance with Eq. (2). The rate constant of the regeneration can be obtained, since $(i_l/i_d-1)/0.815\sqrt{Ct}$ equals $\sqrt{k}$. The rate constants thus obtained are shown in Figs. 8A and 8B, where the variations in the rate constant with *the drop time* and with *the concentation of the oxidizer* are shown. Here the rate constants, k, in the case of the regeneration of EDTA-Ti(IV) and CyDTA-Ti(IV) are the apparent ones, because the values of i_l/i_d are less than 2.5. As is clearly seen in these figures, there is no variation; these results are in good agreement with Eq. (2). The average values are tabulated in Table 1. For the solution of the titanium-NTA complex, two catalytic waves are observed; the first one is shown in Figs. 7 and 8 and is tabulated in Table 1. Since the values of i_l/h_0 against the mercury height for

presence of titanium(IV) ions. Therefore, the rate constant in this case, in Table 1, is the apparent rate constant of the regeneration of titanium(IV), and it seems that the actual rate is more rapid than the apparent one.

On the other hand, the value of k obtained, using 0.1 mol/l of oxalate, 0.2 mol/l of sulfuric acid, 10^{-3} mol/l of titanium chloride, and 0.008—0.256 mol/l of potassium chlorate solutions, by Koryta[7] is 5.3×10^4 l/mol·sec, and that obtained, using 0.2 mol/l of oxalate, 3.36 mmol/l of the titanium(IV) ion, and 0.06—0.08 mol/l of potassium chlorate solutions, by Smith,[8] are both 2.5×10^4 l/mol·sec. Tanaka *et al.*[3] obtained 2.1×10^4 l/mol·sec using 0.2 mol/l of oxalate, 1×10^{-3} mol/l of the titanium(IV) ion, and 0.07—0.15 mol/l of sodium chlorate solutions at pH 1.07. The value of k in titanium(IV)-oxalic acid obtained by the present authors is in good agreement with the value obtained by Koryta, though his values are generally somewhat greater than our values, and with those obtained by Smith and by Tanaka *et al.*, though their values are somewhat less than our value. The difference might be caused by the difference in pH and the concentration of the oxalate, as may be seen in Fig. 2.

Discussion

As is shown in Figs. 7, 8, and Table 1, the values of i_t/i_d vary according to the kind of chelating agent, and they seem to be in an order the reverse of that of the dependency on the stability of the titanium chelates. In Fig. 9, the i_t values of various titanium (Ti-CyDTA, Ti-EDTA, Ti-EDTA-OH, Ti-NTA, and Ti-OX) are plotted against the logarithms of their stability constants, where the stability constants of titanium-oxalic acid reported by Babco *et al.*,[9] of titanium-EDTA reported by Pecsok *et al.*,[4] of titanium-CyDTA and titanium-EDTA-OH to be reported elsewhere soon by one of the present authors,[5,10] and of titanium-NTA obtained by the same procedure are used. There is a linear relationship between the logarithms of the reciprocal of the dissociation constants and those of catalytic currents of the chelates. The following empirical equation is obtained, by the method of the least squares, between the current and the stability constant of the titanium(III) complex, pK_3.

$$\log i_t = \text{const.} - 0.08\text{p}K_3 \qquad (3)$$

A similar clear linear dependency of the catalytic current on the dissociation constant of the complex of titanium(IV), pK_4, is also found; the empirical equation obtained by the same procedure is as follows.

$$\log i_t = \text{const.} - 0.1\text{p}K_4 \qquad (4)$$

On the other hand, a more simple relationship can be found between the rate constant of the regeneration tabulated in Table 1 and the logarithum of the ratio of the dissociation constant of the titanium(IV) complex to that of the titanium(III) complex; *i.e.*, k is proportional to the logarithms of the ratio of the dissociation constant over the pH range from 1.2 to 1.8 except in the case of oxalic acid. This is shown in Fig. 10(a), as is the empirical equation obtained by using all plots;

$$\log k = -0.1 + 1.4\log K_4/K_3 \qquad (5)$$

where K_4 and K_3 are the dissociation constant of the titanium(IV) complex and that of the titanium(III) complex respectively. Here, the rate constants, k, in the case of the regeneration of EDTA-Ti(IV) and CyDTA-Ti(IV) are the apparent ones because these values of i_t/i_d are less than 2.5.

Thus, the problem to be solved is which one of these three empirical equations is the fundamental one. The confusion is caused by the facts that i_t is roughly proportional to i_t/i_d and that log K_4/K_3 is also in a

10) The stability constants of the 1:1 chelates of Ti(III)-EDTA-OH, Ti(III)-CyDTA, Ti(III)-NTA, TiO(II)-EDTA-OH, TiO(II)-CyDTA, and TiO(II)-NTA at pH 1.5±0.1 obtained by one of the present authors are 17.7, 23.8, 13.6, 19.7, 24.3, and 15.4, respectively.

roughly linear relation with pK_4 or pK_3. If Eq. (3) is the true fundamental equation, the mechanism that titanium(III) ions formed by the dissociation of the titanium(III)-chelates are oxidized by the chlorate ions is supported, because the rate of oxidation may depend directly on the concentration of the titanium(III) ion, which in turn depends on the rate of dissociation of the complex, if the dissociation is a rate-determining process, or which, in turn, depends on the stability constant of the complex, if the oxidation is a rate-determining one. This type of effect of the complex is widely observed.[11] However, there are some difficulties in explaining the exponent of 0.08 and the relation of i_t and pK_3. Besides, since the rates of the dissociation of some metal complexes of EDTA and CyDTA are low, they should be in relation not with the stability constants, but with the dissociation rates. The mechanism seems to be implausible.

If the mechanism by which the titanium(III)-chelate complexes are directly oxidized by the chlorate ions is the true mechanism:

$$\begin{array}{l} \text{Ti(III)-Y} + \text{Oxid.} \longrightarrow \text{Oxid.} \cdots \text{Ti} \cdots \text{Y} \\ \qquad\qquad\qquad\qquad\qquad\quad \downarrow \\ \text{Ti(IV)-Y} + \text{Red.} \longleftarrow \text{Red.} \cdots \text{Ti} \cdots \text{Y} \end{array} \qquad (6)$$

Equation (5) is directly related to the rule of the linear free energy relation (LFER, Brönsted-Horiuchi-Polanyi-Hammett's rule),[12] since $\log K_4/K_3$ is the difference in the free energies of the product and the reactant of regeneration. As may be seen in Figs. 2 and 4, i_t/i_d depends on the pH and on the concentration of the chelating agents. Hence, the rate constants are also dependent on these parameters. However, except the case of oxalate, the rate constants in Fig. 10 are obtained in the range where i_t/i_d is scarcely dependent on these parameters and where only a single type of complex exists for each chelating agent.[5] On the other hand, it seems that two or more types of complexes, *e.g.*, the complexes with the chelating agent and one with other components of the solution, can exist in the region where i_t/i_d depends on the parameters; therefore, $\log K_4/K_3$ is not equal to the difference in the free energies of the product and the reactant of the regeneration. The scattering of the data in Fig. 10 is caused partly by these effects. As has been mentioned above, since two waves are observed for the NTA complex, there is a possibility of the coexistence of two different type of complexes. The first wave may be due to the complex of titanium with a single molecule of NTA, while K_3 and K_4 are apparent equilibrium constants among two more types of complexes. Therefore, there are some questions of including the plot of the NTA complex, and also of including the plot of the oxalate complex for the reason mentioned above. If we omit their two plots, a less-scattered relation can be obtained, as is shown by Line(b) in Fig. 10(b), and the empirical equation is:

$$\log k = -0.05 + 1.0 \log K_4/K_3 \qquad (7)$$

The relation is very clear and simple, the mechanism is in accordance with the postulation of Vlcek,[13] and a similar mechanism has also been reported for other complexes.[14] However, K_4 is not the dissociation constant of the titanim(IV) complex but that of the titanyl complex. The process of the oxidation of the titanium(III) complex consists of the process of the oxidation of the titanium(III) ion and the hydrolysis of the titanium(IV) ion to the titanyl ion, and the rate of oxidation observed may be that of the titanium(III) complex to the titanyl complex.

Since the reactions are complicated, no conclusion supported by clear, direct evidence can be obtained, but the mechanism would be elucidated if similar reactions were observed for other ion-complexes.

Electric Conduction and Density of Condensed Phosphoric Acids and Their Mixtures with Sulfuric Acid

Akitane AKIYAMA, Tsuyoshi SUZUKI, and Takashi SAJI

Department of Electrochemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received January 22, 1971)

The electrolytic conductivities and densities of condensed phosphoric acids have been measured in the P_2O_5 concentration range from 55% to 80% at 55.0, 70.0, and 90.0°C. Assuming the proton jump mechanism through the hydrogen bond network of H_2O and H_3PO_4, the molar conductance was calculated and found to be constant in the P_2O_5 concentration range between 60% and 76%. The investigation has been extended to the mixtures of condensed phosphoric acids and concentrated sulfuric acid. The complex formation of $[H_4PO_4^+ \cdot HSO_4^-]$ and $[H_3O^+ \cdot HSO_4^-]$ has been suggested in the mixture.

The physical and chemical characteristics of condensed phosphoric acid (abbreviated as CPA) have been studied by a number of investigators.[1] However, the mechanism of the electric conduction in CPA still remains unclarified. The conduction should be closely related to the physico-chemical structure of CPA. This paper deals with the relation between the electric conduction and physico-chemical structure of CPA in relation concentrated sulfuric acid and its mixtures with CPA.

Studies have been made on the density[2-6] and electric conduction[7,8] of CPA, but the results do not coincide. The discrepancy can be ascribed to the difference in experimental procedures. Since the chemical composition and purity of an electrolyte affect density and conduction, the so-called "reorganization" of CPA[9] cannot be overlooked. The effect of reorganization of CPA on density and electrolytic conductivity has not so far been investigated except for anhydrous orthophosphoric acid[14,16] and we have therefore, examined it first. The measurements of electrolytic conductivity and density were undertaken over a wide range of P_2O_5 concentrations.

Some interesting information on the relation between the physico-chemical structure and electric conduction of CPA has been obtained by means of the concept of "molar conductance."

Experimental

The two conductivity cells used in this work were the same type as the one designed by Jones for precision measurements.[12] The electrodes were flat platinum disks (15 mm in diameter) not platinized, since a platinized platinum electrode undergoes corrosion in CPA. The cell constants were 4.72 and 11.97 cm^{-1}. The cell was placed in a constant temperature bath containing silicone oil. The measurements were carried out at 55, 70, and 90°C ±0.02°C. The curve, linear extrapolation to the infinite frequency of the measured resistance *versus* (frequency)$^{1/2}$, was constructed. The resistance at the infinite frequency can be considered to be free from impedance caused by electrode reactions.

The density measurement was carried out by weighing a calibrated silica cylinder (11.6 mm in diameter and 57 mm in length). The silica cylinder was suspended with a thin platinum wire from one end of an analytical balance and submerged in a liquid to be tested.

CPA was prepared as follows.

(1) Reagent grade phosphorus pentoxide was sublimated in iron pipes[10] in an oxygen atmosphere at 800°C in order to remove organic impurities and lower phosphorus oxides such as PO_2, P_2O_3, and P_4O_6.

(2) The purified P_2O_5 was then dissolved in reagent grade phosphoric acid by heating in a glassy carbon beaker.

(3) The concentration of CPA was determined by means of potentiometric titration.[11]

Results

Crystalline orthophosphoric acid is regarded to be H_3PO_4.[13] Upon fusion, a small portion of H_3PO_4 is converted into pyrophosphoric acid by self-dehydration and a part becomes triphosphoric acid. This process is called reorganization. The reorganization of orthophosphoric acid has been found to be accompanied by a decrease in conductance.[14] Crystalline phosphoric acid prepared by fractional freezing method[15] was reexamined first. It was melted just before the experiment and the conductivity was measured at 55, 70, and 90°C as a function of time. The conductivity decreased with time and reached a steady value, which can be considered to be the conductivity of the equilibrated mixture of $H_{n+2}P_nO_{3n+1}$ (n=0, 1, 2,···). The time required to reach the equilibrated CPA was about one hour at 90°C and about 30 hours at 55°C.

The rate of self-hydration or dehydration is so high at a high temperature that CPA heat-treated at 200°C for one hour can be regarded as an equilibrated mixture of $H_{n+2}P_nO_{3n+1}$ (n=0, 1, 2, ···). The mixture was quenched in to a refrigerator and transferred into the conductivity cell. The conductivity of quenched CPA was then measured as a function of time at 55, 70, and 90°C. No change in the conductance was observed, that is, no change in the composition of CPA could be detected. It might be assumed from the result that the equilibrium constants of the self-hydration and dehydration reactions in a CPA were independent of temperature within experimental accuracy. All CPA's used in the following experiments were heat treated at 200°C for one hour.

The electrolytic conductivities *versus* P_2O_5 concentration are shown in Fig. 1. The conductivity decayed linearly with increasing concentration down to about 72% and then a rapid decrease was observed. The P_2O_5 concentration of 72% corresponds to the stoichiometrically pure orthophosphoric acid. This result coincides with those reported by other workers.[8,6]

The densities *versus* P_2O_5 concentration are shown in Fig. 2. Tye results agreed with those reported by Ferr.[4]

CPA can be considered to be a mixture of H_2O, H_3PO_4 $H_4P_2O_7$,···$H_{n+2}P_nO_{3n+1}$ in the concentration range used in this experiment. In order to introduce the concept of "molar conductance," it was assumed first that the main conducting components in the CPA are H_2O and H_3PO_4 and that both H_2O and H_3PO_4 behave as equally effective species for the electric

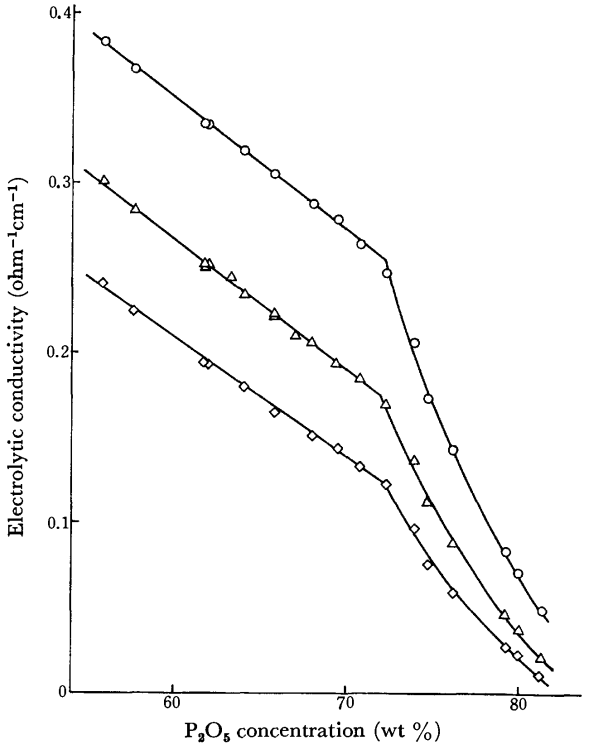

Fig. 1. Electrolytic conductivity of CPA.
Temp: 55°C (◇), 70°C (△), and 90°C (○).

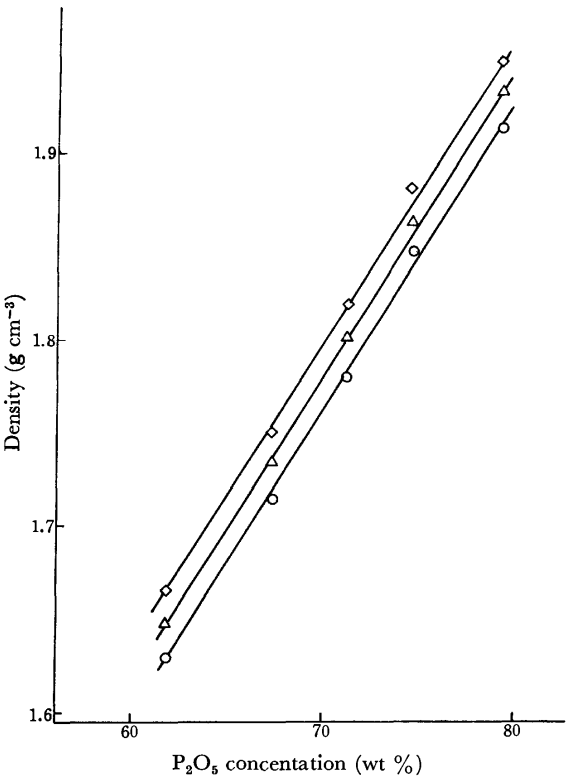

Fig. 2. Density of CPA. Temp.: 55°C (◇), 70°C (△), and 90°C (○).

conduction of CPA. The molar conductance (Λ) of CPA, therefore, can be calculated from electrolytic conductivity (κ) and the density (ρ) by means of the following equation:

$$\Lambda = \kappa\sum\chi_i M_i/\rho(\chi_{H_2O}+\chi_{H_3PO_4}) \quad (1)$$

where χ_i is the mole fraction of the ith component of the molecular weight of M_i and χ_{H_2O} and $\chi_{H_3PO_4}$ are the

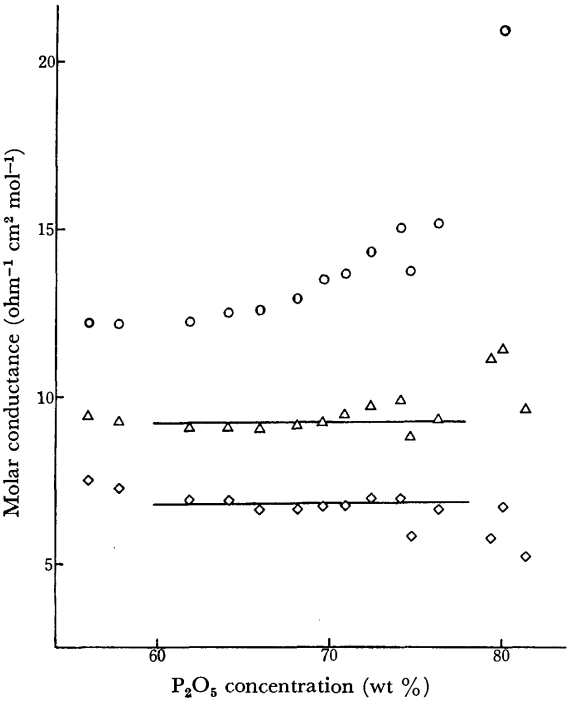

Fig. 3. Molar conductance of CPA.
Temp: 55°C (◇), 70°C (△), and 90°C (○).

16) N. N. Greenwood and A. Thompson, *J. Chem. Soc.*, **1959**, 3485.

mole fractions of H_2O and H_3PO_4, respectively. They are given from the analytical data by Huhti and Gartaganis.[17] The calculated molar conductances are plotted against the P_2O_5 concentration in Fig. 3. It was noted that the molar conductances of CPA at 55 and 70°C are constant in the concentration range between 60% and 76%.

Concentrated sulfuric acid was mixed with CPA's of 61.8, 66.8, 70.8, 74.8, and 79.3%, respectively. The electrolytic conductivities of the five mixtures at 55°C are plotted in Fig. 4 against the weight percentages of CPA's, and the densities in Fig. 5. Measurements were carried out at 70 and 90°C. The results were very similar to those for 55°C. It was noted that the electrolytic conductivities of mixtures were far from additive as compared to those of CPA and H_2SO_4.

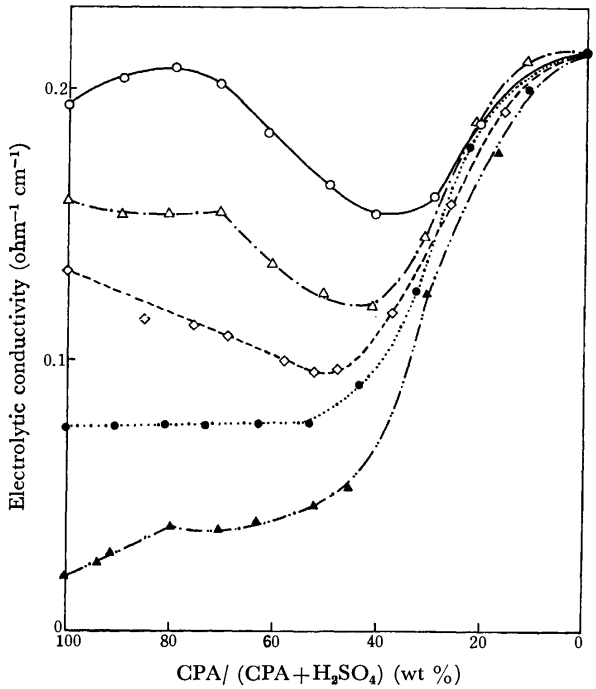

Fig. 4. Electrolytic conductivity of CPA-H_2SO_4 mixtures. 100% CPA's are of P_2O_5 concentrations of 61.8% (○), 66.8% (△), 70.8% (◇), 74.8% (●), and 79.3% (▲).

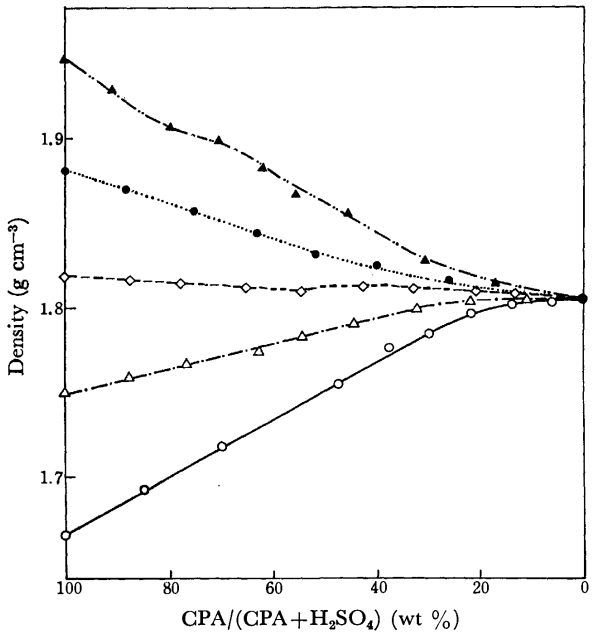

Fig. 5. Density of CPA-H_2SO_4 mixtures. Symbols are same as Fig. 4.

The molar conductance of CPA-H_2SO_4 mixture was introduced in a similar way to that of CPA. H_2O and H_3PO_4 as well as H_2SO_4 are assumed to be conducting components, and they behave as equally effective species on the electric conduction. Then, Eq. (1) becomes

$$\Lambda = \kappa\sum\chi_i M_i/\rho(\chi_{H_2O}+\chi_{H_3PO_4}+\chi_{H_2SO_4}) \quad (2)$$

The molar conductances of mixtures at 55°C are plotted in Fig. 6 against the molar composition rate R which is represented by

$$R = (\chi_{H_2O}+\chi_{H_3PO_4})/(\chi_{H_2O}+\chi_{H_3PO_4}+\chi_{H_2SO_4}) \quad (3)$$

The 79.3% CPA mixture was excluded in the figure since the discrepancy from the straight line in Fig. 3 was so remarkable that the assumption on the electric conduction of CPA does not hold for CPA of high P_2O_5 concentrations. It is particularly noteworthy in Fig. 6 that a minimum was observed at the R value of 0.5.

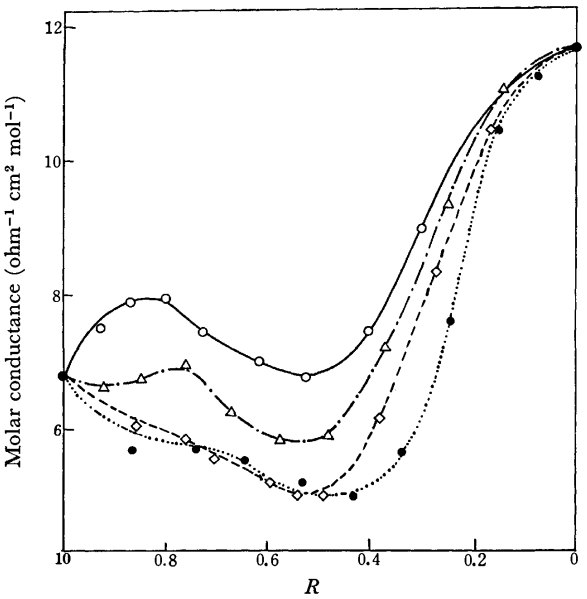

Fig. 6. Molar conductance of CPA-H_2SO_4 mixtures. Symbols are same as Fig. 4.

Discussion

CPA: The mechanism of electric conduction in condensed phosphoric acid as well as in anhydrous sulfuric acid has been investigated.[16,18] It was confirmed that the characteristic features of these acids are the self-dissociation into ionic products and their ability to conduct electricity by proton-jump. There are a number of ionic species in CPA such as H_3O^+,

17) A. L. Huhti and P. A. Gartaganis, *Can. J. Chem.*, **34**, 785 (1956).

18) N. N. Greenwood and A. Thompson, *J. Chem. Soc.*, **1959**, 3475.

$H_4PO_4^+$, $H_2PO_4^-$, $H_3P_2O_7^-$. Greenwood and Thompson[16] assumed that $H_2PO_4^-$ was the only conductive species with proton-jumps. They explained that the sharp drop in κ at about 72% P_2O_5 was due predominantly to the decrease in the concentration of anomalously conductive $H_2PO_4^-$ ions. All the previous discussions on the conduction mechanism of concentrated acids were based on an ion which has a high mobility by proton-switch conduction. In this investigation, however, the electrolytic conductivity and density data of CPA are handled on the basis of the length of hydrogen bond networks along which protons can be transferred; it was assumed that the hydrogen bond network leading to a high proton conductivity in CPA was constructed by H_2O and H_3PO_4. The "molar conductance" term which is defined by Eq. (1) has been introduced. When Λ was plotted against the cencentration of CPA, Λ at 55° and 70°C could be considered to be constant in the concentration range from 60% to 76% P_2O_5 (Fig. 3). This might indicated that our assumption of Eq. (1) is reasonable; the electric conduction of CPA (60%—76% P_2O_5) occurs by proton-jumps through the hydrogen bonds of H_2PO_4 and H_2O, and by the following rotation of these molecules. The constant value of Λ also seems to show that both H_2O and H_3PO_4 bahave as equally effective species on electrical conduction. Condensed phosphoric acids of higher molecular weights such as pyrophosphoric acid and triphosphoric acid do not play important roles in the conduction of CPA in this concentration range because the massiveness inhibits the rotation of molecule after a proton-jump. The discrepancy of Λ's from a streight line at 90°C can be attributed to the additional contribution of pyrophosphoric acid to the conduction, since it seems that the rotation of a massive molecule becomes more favorable at higher temperatures. The discrepancy of Λ's from straight lines at low P_2O_5 concentrations of CPA can be assumed to be due to the ionic conduction by hydrated H^+ and ionized phosphoric acids.

We assumed that H_2O as well as H_3PO_4 is electrical conductive species, whereas Greenwood *et al.*[16] concluded that H_3O^+ could not be considered as conductive species since H_3O^+ was unlikely to take part in the hydrogen bonded structure of CPA. The conclusion by Greenwood was made by the analogy of the behavior of H_3O^+ in sulfuric acid. The structure of CPA, however, is considered to be a more complicated hydrogen bridge system containing mobile protons as current-carrying species. The Raman spectroscopy and other physico-chemical properties of anhydrous H_3PO_4 were studied by Simon and his co-workers.[13,15] It was suggested that there are free mobile protons which are not located at a fixed PO_4 group. Mobile protons were also found within the hydrogen bonded structure of water and ice by Eigen and Mayer.[19] It seems, therefore, to be reasonable to assume that H_2O is a conductive species in CPA.

It is interesting that the molar conductance of CPA does not depend upon the ratio of H_2O to H_3PO_4. This shows either that the number of mobile protons as well as mobility do not change with the change of the ratio of H_2O to H_3PO_4, or that the increase of mobility and the decrease of number mobile protons occur at the same rate with the change in the concentration of CPA. This is still an open question.

The reorganization rate of orthophosphoric acid could be calculated by use of the assumption. Suppose α mol% of orthophosphoric acid is converted into pyrophosphoric acid. The electrolytic conductivity of pure orthophosphoric acid (κ_0), which is the initial conductivity, changes to conductivity (κ_0) of the reorganized phosphoric acid mixture according to the equation

$$\kappa_e = \kappa_0(1-\alpha/100). \quad (4)$$

The reorganization rate calculated by this equation was 6.6 mol% at 70°C, and coincided with 6.38 mol% obtained by means of paper chromatography.[17]

CPA-H_2SO_4 Mixtures: The idea of the hydrogen bond network of H_2O and H_3PO_4 assumed for CPA is extended for CPA-H_2SO_4 mixtures. Upon calculation of the molar conductance for the mixtures, it was assumed that H_2SO_4 plays a part in the network of H_2O and H_3PO_4 as an equally effective species of conduction. Variation of the molar conductance in Fig. 6 show that the mixture is complicated. The complication also could be predicted from the that the electrolytic conductivity was far from the additivity of that of CPA and H_2SO_4. Reorganization of CPA by the addition of H_2SO_4 can not be neglected; however, in following discussion, the mole fractions of H_2O, H_3PO_4, and H_2SO_4 are calculated by assuming that no reorganization reaction of CPA occurs upon mixing with H_2SO_4. The most interesting result is that there exists a minimum in the molar conductance for R value of 0.5, where the molar ratio of $[H_2O+H_3PO_4]$ to $[H_2SO_4]$ was unity, as seen in Fig. 6. The minimum suggests the complex formation between H_3PO_4 and H_2SO_4 as well as between H_2O and H_2SO_4, such as $[H_4PO_4^+ \cdot HSO_4^-]$ and $[H_3O^+ \cdot HSO_4^-]$. It seems to be reasonable to assume such complex formation because H_2SO_4 has been found to be a strong mono-protonic acid in CPA.[20] It can be concluded that the length of hydrogen bonding reduced by complex formation, resulting in a decrease in the molar conductance of pure CPA or pure H_2SO_4 by mixing.

The ionic conduction plays a role in the electric conduction of a CPA of low P_2O_5 concentration. The addition of H_2SO_4 into a CPA of low concentration caused the increase in the molar conductance up to the R value of 0.8. This can be explained by the increase of conductive ions by mixing H_2SO_4 with CPA of low concentration.

An inflection point exists in the electrolytic conductivity curve and the density curve at a high P_2O_5 concentration CPA of 79.3%. The weight % of CPA at the inflection was 80% for the electrolytic conductivity curve and 70% for the density curve. The mechanism of electric conduction in the pure CPA of 79.3% is still unknown.

(Received June 5, 1971)

[Cu(allyl alcohol)(H_2O)]ClO_4 (abb. Cu(all)$(H_2O)ClO_4$), [Cu(allyl alcohol)$_2(H_2O)$]ClO_4 (abb. Cu(all)$_2$-$(H_2O)ClO_4$), [Cu(2-methylallyl alcohol)(H_2O)]ClO_4 (abb. Cu(meth)$(H_2O)ClO_4$) and [Cu(*cis*- and *trans*-2-butenyl alcohol)$_2$ (H_2O)]ClO_4 (abb. Cu(*cis*-and *trans*- but$_2$ $(H_2O)ClO_4$) were synthesized. It was shown by means of equivalent conductance that Cu(all)$(H_2O)ClO_4$ is a strong electrolyte of uni-uni valent in acetone. The molecular weight of Cu(all)$(H_2O)ClO_4$ obtained from measurements of the direct vapor-pressure depression of acetone showed that the complex is monomeric. The C=C stretching band of the allylic alcohol shifts by about 100 cm^{-1} to the lower frequency side upon coordination. The chemical shifts of the vinyl protons in these complexes shift by about 0.5—1 ppm to the higher frequency side than those of free alcohols. It was concluded that the allylic alcohol coordinates to the copper atom through both the double bond and the oxygen atom. The equilibrium constant corresponding to Cu(*trans*-but)$^+_2(H_2O)ClO_4$+2*cis*-2-butenyl alcohol=Cu(*cis*-but)$^+_2(H_2O)ClO_4$+2*trans*-2-butenyl alcohol in 2-butenyl alcohol was estimated to be 9.82 at 25°C and the enthalpy change was estimated to be −3.13 kcal/mol.

Manahan[3] found that two potentials corresponding to Cu(II)=Cu(I)+e and Cu(I)=Cu(0)+e are observed in aqueous solutions containing allyl alcohol. However only one potential corresponding to Cu(II)=Cu(0)+2e is observed in the absence of allyl alcohol. Further data concerning the dependence of the reduction potential on the concentrations of copper(II) and allyl alcohol were explained on the basis of the formation of the copper(I)-allyl alcohol complex with a mole ratio of one to one and with a formation constant of $5.02\times10^4 mol^{-1}\,l$. The isolation of the complex, however, has not been successful.

Previously we synthesized crystalline complexes of allyl alcohol[4] and some related compounds[5,6] with copper(I) chloride. It was then established that allyl alcohol coordinates to the copper(I) atom with both the double bond and the oxygen atom, and that this complex is a dimer with a double chloro bridge. However, the dissociation vapor pressures of these complexes are fairly large and they easily decompose to the original unsaturated ligands and copper(I) chloride. From the fact that one of the decomposition products, copper(I) chloride, is stabilized by the chloro bridges with the formation of a tetrahedral configuration, this instability is presumably enhanced by the high donating power and by the bridging potential of the chloride ligand. Now we have synthesized the copper(I) perchlorate-allylic alcohol complexes with molar ratios of one to one and one to two with expectation of obtaining stable complexes, but the former was rather explosive.

Experimental

Materials. The copper(II) perchlorate hexahydrate was prepared from copper(II) hydroxide and a 60% aqueous solution of perchloric acid and was recrystallized from ethyl acetate. The allyl alcohol, 2-methylallyl alcohol and 2-butenyl alcohol were used after distillation. The acetone used for the measurements of the molecular weight and the electric conductance was purified in the usual manner[7] and distilled *in vacuo*.

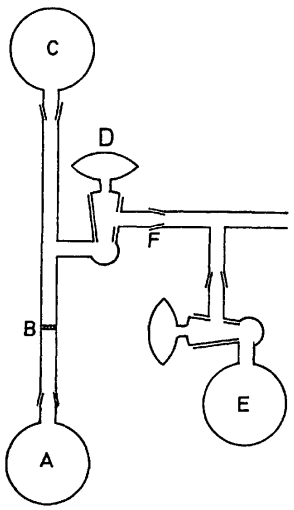

Fig. 1. The ampoule system for the synthesis of the copper(I) perchlorate complexes with allylic alcohols.

Synthesis of Cu(all)$(H_2O)ClO_4$. The ampoule system employed for the synthesis of the complex is illustrated in Fig. 1. Copper(II) perchlorate hexahydrate (100—200 mg), copper metal and a stirring bar were placed in an ampoule A. Allyl alcohol was then transferred from another ampoule E and the stopcock D was closed. The solution was stirred magnetically till the blue color of copper(II) faded and it became colorless. Then the apparatus was inverted at the taper joint F so that the solution could be filtered through the

sintered glass B into yet another ampoule C. The solvent was then transferred into E by vacuum distillation. In the course of the transfer of the alcohol, colorless crystals were formed. The complex was obtained as a white powder by further drying.

After the complex was weighed, the ligand was freed by the addition of aqueous ammonium chloride. All the allyl alcohols were collected together with the water by the vacuum distillation of the aqueous solution. It was determined by means of gas chromatographic and IR assay that the volatile materials were composed of water and allyl alcohol. The quantity of allyl alcohol was determined by bromination as has been described previously.[4] The nonvolatile material was dissolved in aqueous ammonia and analyzed for copper electrolytically and for the perchlorate ion as a nitron adduct.

Found: Cu, 26.1; C_3H_6O, 24.7; ClO_4, 41.7%. Calcd for $Cu(C_3H_6O)(H_2O)ClO_4$: Cu, 26.6; C_3H_6O, 24.7; ClO_4, 41.7%. Further, the water was detected in the IR spectra and the mole ratio of water to allyl alcohol was estimated to be unity on the basis of the NMR assay.

Synthesis of $Cu(all)_2(H_2O)ClO_4$. A small quantity of allyl alcohol was distilled into the ampoule C containing $Cu(all)(H_2O)ClO_4$, and then the complex was dissolved completely (Fig. 1). The excess of alcohol was distilled back to the E ampoule by means of a difference of temperature of between 20.5°C (the mp of acetophenone) and 0°C, the complex was thus obtained as colorless and transparent crystals. When the temperature of the ampoule C was higher by several degrees, the complex was decomposed to $Cu(all)(H_2O)ClO_4$; when it was lower by several degrees, the complex was not dried because of its high solubility in allyl alcohol. The complex was analyzed as has been described above.

Found: Cu, 21.5; C_3H_6O, 40.0; ClO_4, 34.8%. Calcd for $Cu(C_3H_6O)_2(H_2O)ClO_4$: Cu, 21.4; C_3H_6O, 39.2; ClO_4, 33.4%.

Synthesis of $Cu(meth)(H_2O)ClO_4$ and $Cu(but)_2(H_2O)ClO_4$. $Cu(meth)(H_2O)ClO_4$ was synthesized and analyzed much as in case of $Cu(all)(H_2O)ClO_4$.

Found: Cu, 25.3; C_4H_8O, 28.5; ClO_4, 40.6%. Calcd for $Cu(C_4H_8O)(H_2O)ClO_4$: Cu, 25.3; C_4H_8O, 28.5; ClO_4; 39.3%. The presence of the 1:2 complex of 2-methyl-allyl alcohol was suggested on the basis of the IR spectra, but its isolation was difficult.

$Cu(but)_2(H_2O)ClO_4$ was obtained and analyzed much as in the case of $Cu(all)(H_2O)ClO_4$.

Found: Cu, 20.5; C_4H_8O, 44.3; ClO_4, 31.2%. Calcd for $Cu(C_4H_8O)_2(H_2O)ClO_4$: Cu, 19.0; C_4H_8O, 44.4; ClO_4, 30.6%. We failed to obtained the one to one 2-butenyl alcohol complex.

Equivalent Conductance. The equivalent conductance of $Cu(all)(H_2O)ClO_4$ in acetone was measured at 25.0°C with a cell modified only enough to make it possible to operate it in a vacuum using the Yanagimoto conductivity outfit, Model MY-7. The results are listed in Table 1.

Table 1. Equivalent conductances of $Cu(all)(H_2O)ClO_4$ in acetone (at 25.0°C)

0.02003	118.3

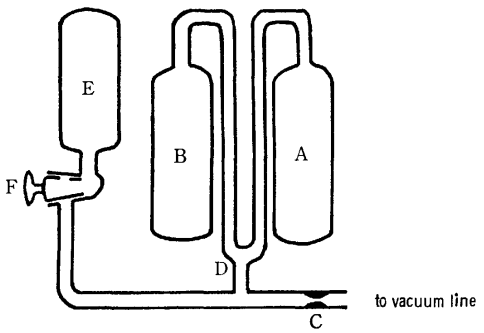

Fig. 2. The apparatus used for the direct measurements of depressions of vapor pressures.

Molecular Weight Measurement. The molecular weight of $Cu(all)(H_2O)ClO_4$ was determined by direct measurements of the vapor-pressure depressions of acetone. The apparatus used is illustrated in Fig. 2. The complex was prepared and dried completely in the A ampoule. Carefully degassed acetone was transferred from the vacuum line to A and B at the same time and the apparatus was sealed off at C. Mercury charged in E was transferred to D through the stopcock F. The difference in the vapor pressure between the pure solvent and the acetone solution of the complex was measured at a constant temperature by the U-type mercury manometer formed at D. The value of Dreisbach[8] was referred to be estimating the vapor pressures of acetone in this study. The estimated values are in good agreement with our measurement; for instance, the 263 mmHg measured at 28.5°C agrees with the 263 mmHg evaluated from Ref. 8. The results are listed in Table 2.

Table 2. The data to obtain the molecular weight of $Cu(all)(H_2O)ClO_4$ in acetone

	Sample 1	Sample 2	
Concn. (wt. %)	2.92	3.01

Vapor press. of acetone (mmHg)[a]	266	209	279
Mol. wt.	151	145	153
	average 150		

a) Evaluated from $\log P = 7.19038 - 1233.4/(t-230)$

Gas Chromatography. The *cis*- and *trans*-isomers of 2-butenyl alcohol were separated by the use of gas chromatography under the following conditions: PEG 1500/siliconized Celite; temperature, 110°C; column, 4.5 mm in od × 3.5 m; carrier gas, hydrogen, 30 ml/min. The ratio of the isomers was evaluated from the average value of five measurements.

IR Spectra. The infrared absorption spectra were measured with a Hitachi infrared spectrophotometer EPI-2. The sprctra of $Cu(all)_2(H_2O)ClO_4$ and $Cu(but)_2(H_2O)ClO_4$ were measured by the use of both a sodium chloride cell and a polyethylene film, since these complexes easily exchange the anion. All the samples were prepared in nitrogen atmospheres.

NMR Spectra. The samples for NMR measurements were prepared in the vacuum system and the spectra were measured with a 60 MHz spectrometer, model JNM 3H60 of the Japan Electron Optics Laboratory, Ltd.

Results and Discussion

The present investigation has been undertaken to synthesize stable complexes of allylic alcohols with copper(I) perchlorate; however the complexes obtained were slightly unstable. For instance, when a methanol solution of Cu(all)$(H_2O)ClO_4$ was kept standing at room temperature it became turbid forming copper(I) oxide within a few days. The decomposition rate of the complex increased markedly upon heating. The solid complex heated under a vacuum exploded at around 200°C. A further accidental explosion occurred when it was treated with a spatula of stainless steel in a nitrogen atmosphere.

Cu(all)$(H_2O)ClO_4$ and Cu(meth)$(H_2O)ClO_4$. The NMR spectra of allyl alcohol and its complex are shown in Fig. 3. Table 3 shows the data of the NMR spectra of allylic alcohols and their complexes.

The spectra of allyl groups are very complex.[9] The NMR spectra of the complex of allylic alcohol are also so complex that the chemical shifts and coupling constants of the vinyl protons were difficult to determine. However, it is clear that the chemical shifts of the protons attached to the saturated carbons are affected little by coordination, and that the chemical shifts of the vinyl protons shifted by 0.5—1 ppm to a higher field. These shifts can be explained as being mostly due to a decrease in the double bond character upon coordination, and the small shift of methylene protons to a higher field is consistent with the decrease in the electron density of the double bond.

It is found that the intensity ratio of $(OH+R_1)$: (R_2+R_3): CH_3 of Cu(all)$(H_2O)ClO_4$ is 4:2:2; this is consistent with the composition obtained from elementary analysis, $Cu(CH_2=CHCH_2OH)(H_2O)ClO_4$. A similar intensity ratio was observed in the case of the 2-methylallyl alcohol complex.

The NMR spectra of neat 2-methylallyl alcohol are essentially the same as those of 2-methylallyl alcohol in deuterated methanol solutions. Because the OH proton signal overlaps with one of the vinyl proton signals, the NMR spectra of 2-methylallyl alcohol was used to distinguish between the absorptions of the OH group and the vinyl proton.

Table 4. The C=C stretching bands of allylic alcohols and their complexes with copper(I) perchlorate

	ν(C=C) cm^{-1}
Allyl alcohol	1646
Cu(all)$(H_2O)ClO_4$	1538
Cu(all)$_2(H_2O)ClO_4$	1537
2-Methylallyl alcohol	1657
Cu(meth)$(H_2O)ClO_4$	1579
trans-2-Butenyl alcohol	1673
Cu(*trans*-but)$_2(H_2O)ClO_4$	1558
cis-Butenyl alcohol	1654
Cu(*cis*-but)$_2(H_2O)ClO_4$	1540

The frequencies of the C=C stretching bands of both the free and the coordinated allylic alcohols are listed in Table 4. The IR spectra of the complexes with allylic alcohols closely resemble those of copper(II) perchlorate and free alcohols except for the C=C stretching bands. The C=C stretching bands of the ligands are shifted by about 110 cm^{-1} to the lower frequency side by coordination. This shift indicates a decrease in the electron density of the double bond and is consistent with the decrease in shielding observed in the NMR spectra. The shift in the copper(I) perchlorate complex is considerably larger than that in the copper(I) chloride complex (95 cm^{-1}) and suggests a stronger coordination as expected.

It has been reported[10] that the Cl-O stretching

9) L. M. Jackman, "Application of Nuclear Magnetic Rsonance Spectroscopy in Organic Chemistry," Pergamon Press, London (1959).

10) B. J. Hathaway and A. E. Underhill. *J. Chem. Soc.*, **1961**, 3091.

absorption of the perchlorate ion at around 1100 cm^{-1} is split into three or four peaks and is shifted to the lower frequency side by coordination. No absorption bands of the complexes in this region split and differ from those of copper(II) perchlorate hexahydrate.

The equivalent conductances of the one to one complex of allyl alcohol listed in Table 1 were plotted against the roots of the concentrations and the conductance at an infinite dilution, 195, was obtained by extrapolation. This value is close to those of lithium halides and potassium iodide in acetone[11] suggesting that the complex is a strong electrolyte of uni-uni valent.

The equivalent conductance at 25.7°C of a 30.1% solution of $Cu(all)(H_2O)ClO_4$ in acetone was found to be 40. This value is quite small as compared with the conductance at an infinite dilution, showing a small activity coefficient together with the presence of nondissociated species at this concentration. As Table 2 shows, the molecular weight of the complex in acetone is about 150. Because the formula weight of the complex in acetone is 237, the molecular weight of the completely dissociated complex is 119. From this fact, it can be concluded that the complex is monomeric and that the somewhat large molecular weight may be due to the presence of the undissociated complex in acetone.

It is difficult to obtain direct evidence showing the coordination of the oxygen atom of allylic alcohols to the copper atom. We failed to isolate similar complexes with alkene such as ethylene, propene and butenes. This failure suggests that the coordination ability of simple monoolefins is too weak for them to form stable complexes and that the allylic alcohol chelates to copper(I) *via* both the double bond and oxygen atom.

There is some evidence of coordination of the water to the copper(I) ion. Firstly, as has been described above, $Cu(all)(H_2O)ClO_4$ dissolved in alcohols or ketones forms Cu(I) oxide slowly. This implies that the dissociation constant of the proton of the water molecule coordinated to the copper(I) ion is larger than that of free water. Secondly, at room temperature the water molecule can not be removed under a vacuum of 10^{-3} mmHg. Furthermore, the complex does not lose its water molecule on treatment with 2,2-dimethoxypropane. It seems that the water is removed before an explosion.

$Cu(all)_2(H_2O)ClO_4$ and $Cu(but)_2(H_2O)ClO_4$. The NMR spectrum of $Cu(all)_2(H_2O)ClO_4$ could not be measured because it dissociates rapidly into the one to one complex and allyl alcohol in solution.

The NMR data of the complex of 2-butenyl alcohol are listed in Table 3. As Fig. 4 shows, commercial 2-butenyl alcohol is composed of *cis*- and *trans*-isomers in a ratio of about one to three. The complex prepared from the commercial alcohol, however, had nearly the same amounts of the *cis*- and *trans*-isomers. The vinyl protons of both isomers shift to the lower frequency side by about 0.5 ppm from the parent vinyl proton upon coordination; the intensity ratio of the protons is consistent with the $[Cu(C_4H_8O)_2(H_2O)]ClO_4$ composition (Fig. 4 and Table 3).

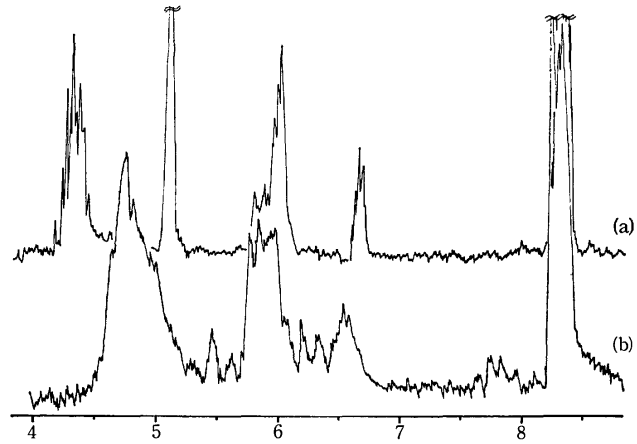

Fig. 4. The NMR spectra of commercial 2-butenyl alcohol and $Cu(but)_2ClO_4$ (b) in CD_3OD.

The IR spectra of the one to two complexes are similar to those of the one to one complexes (Table 4), and they show no absorption due to the free double bond. Therefore, both double bonds may coordinate to copper(I). The oxygen atoms of alcohols may coordinate to copper(I) just as in $Cu(all)(H_2O)ClO_4$. It is not clear from the present data whether the water molecule coordinates or not.

*The Equilibrium between the Cu(*cis*-but)$_2(H_2O)ClO_4$ and Cu(*trans*-but)$_2(H_2O)ClO_4$.* As has been described above, the mole ratio of *cis*-isomers to *trans*-isomers in the complex is greater than that in the original alcohol. Copper(I) chloride is soluble in 2-butenyl alcohol, suggesting the formation of a copper(I) chloride-2-butenyl alcohol complex similar to the copper(I) chloride-allyl alcohol complex.[4] When 2-butenyl alcohol was added to an excess of powdered copper(I) chloride and was then collected by vacuum distillation, it was found that the early fractions were rich in the *trans*-isomer while the later fractions were rich in the *cis*-isomer. These facts show that the *cis*-2-butenyl alcohol coordinates more easily to copper(I) chloride than does the *trans*-alcohol. On the basis of these findings, we tried to evaluate the difference in the stabilities of the complexes of these isomers.

It is known that the vapor pressure of *trans*-butene is rather close to that of the *cis*-isomer. For instance, the vapor pressures of the former and the latter at 0°C are 660 and 730 mmHg respectively.[12] The smallness of the difference may reflect the isomers of 2-butenyl alcohol. In fact, when 2-butenyl alcohol was collected by vacuum distillation, no difference in the composition of the isomers was found between the early and the final fractions. It was confirmed that the complex does not catalyze the isomerization of 2-butenyl alcohol.

Now the following equilibrium and equilibrium constant can be assumed:

$$2C + CuT_2(H_2O)^+ = 2T + CuC_2(H_2O)^+ \quad (1)$$

11) L. G. Savedoff, *J. Amer. Chem. Soc.*, **88**, 664 (1966).

12) D. R. Stull, *Ind. Eng. Chem.*, **39**, 517 (1947).

$$K = \frac{[T]^2[CuC_2(H_2O)^+]}{[C]^2[CuT_2(H_2O)^+]} \quad (2)$$

where C and T represent *cis*- and *trans*-2-butenyl alcohol respectively. It was ascertained that all the copper(II) used is reduced to the copper(I) complexes. The α_0 and α fraction are defined by:

$$\alpha_0 = [T]_0/[C]_0 \quad (3)$$

$$\alpha = [T]/[C] \quad (4)$$

where $[T]_0$ and $[C]_0$ are the concentrations of *trans*- and *cis*-2-butenyl alcohol respectively before the preparation of the complex, while [T] and [C] are those of *trans*- and *cis*-2-butenyl alcohol after the preparation of the complex. The following relations are obtained:

$$[C]_t = [C] + 2[CuC_2(H_2O)^+] \quad (5)$$

$$[T]_t = [T] + 2[CuT_2(H_2O)^+] \quad (6)$$

$$[Cu]_t = [CuC_2(H_2O)^+] + [CuT_2(H_2O)^+] \quad (7)$$

where the subcript "t" represents the total concentration of each species. The β fraction is defined by Eq. (8). Equation (9) then results, since no isomerization occurs.

$$\beta = [C]_t/[C]_0 \quad (8)$$

$$[T]_t/[T]_0 = \beta \quad (9)$$

The following relations are derived from Eqs. (3)—(9):

$$[CuC_2(H_2O)^+] = \{2[Cu]_t + (\alpha-\alpha_0)\beta[C]_0\}/2(\alpha+1) \quad (10)$$

$$[CuT_2(H_2O)^+] = \{2\alpha[Cu]_t + (\alpha-\alpha_0)\beta[C]_0\}/2(\alpha+1) \quad (11)$$

Substitution in Eq. (2) results in:

$$K = \alpha^2\{2[Cu]_t + (\alpha-\alpha_0)\beta[C]_0\}/\{2\alpha[Cu]_t - (\alpha-\alpha_0)\beta[C]_0\} \quad (12)$$

If the ratio of *cis*-2-butenyl alcohol to the *trans*-isomer in the vapor phase is equal to that in the liquid phase, α and α_0 should be the ratio of the isomers of the starting 2-butenyl alcohol measured in the vapor phase and after the preparation of the complex respectively.[13]

In this experiment, we prepared the copper(I) complex in pure 2-butenyl alcohol and collected small portions of the solvent ($\sim$10 μl) by vacuum distillation in order to determine α_0 and α. The results are listed in Table 5.

The temperature dependence of the equilibrium constant was determined. Figure 5 shows the plot of log$K$ *versus* $1/T$. The enthalpy change corresponding to Eq. (1) was evaluated as -3.13 kcal/mol from the gradient.

Muhs and Weiss[14] determined the equilibrium constants of silver-olefin complexes by the use of ethylene glycol solutions of silver nitrate as the liquid phase of gas chromatographic column. These reactions are expressed by:

$$\text{olefin} + AgNO_3 = \text{olefin}\cdot AgNO_3$$

In the case of 2-butene, the ratio of the equilibrium constants of *cis*- and *trans*- is 3.9 at 40°C. The ratios of most olefins fall around 4. These values must be squared in order to be compared with the present data. The value of K at 40°C is estimated to be 7.1 by the extrapolation of the straight line in Fig. 5. The value for copper(I) is rather similar to that of silver(I) though the former is smaller. The stability of *cis*-2-butenyl alcohol compared to that of the *trans*-isomer may be attributed to the relief of the inner strain of the *cis*-isomer by coordination.

Table 5. The equilibrium constant for the reaction of Eq.(1)[a] (at 30.1°C)

Concn. (mol/kg sol)		*trans*-Isomer / *cis*-Isomer	Equilibrium constant, K
2-Butenyl alcohol	Cu(I)	at vapor phase	
6.13	2.44	4.25	8.00
7.67	1.94	3.85	8.27
8.69	1.61	3.53	7.95
9.40	1.39	3.38	8.03
			av. 8.06

a) The ratio of *trans*- to *cis*-isomer of starting 2-butenyl alcohol is 2.53.

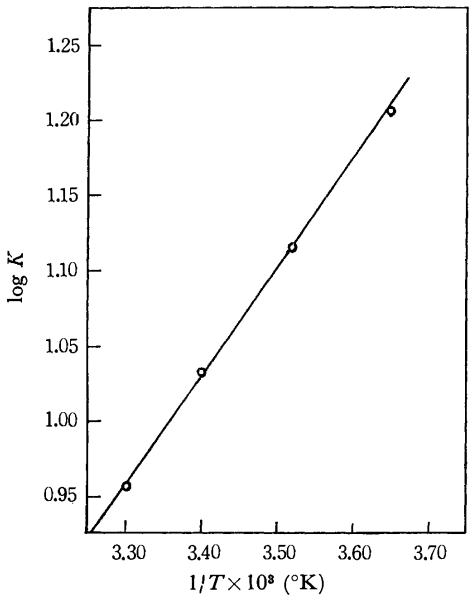

Fig. 5. The temperature dependencies of the formation constant, K.

The authors wish to thank Professor Shinichi Kawaguchi of Osaka City University for his valuable advice and encouragement.

13) Here we assumed that the fractions, α_0 and α, in liquid phase are equal to those of gas phase. However, if the *trans*- and *cis*-2-butenyl alcohol have their vapor pressures, Pt and Pc, respectively, and obey Raoult's law, then α_0 and α in Eq. (12) are represented as $(Pt/Pc)\alpha_0$(gas) and $(Pt/Pc)\alpha$(gas), respectively, where α_0(gas) and α(gas) are the fractions in gas phase corresponding to them in liquid phase.

Reactions of Tris(acetylacetonato)manganese(III) and Bis(acetylacetonato)-manganese(II) with Ethylenediamine and Other Primary Amines

Yoshinori NISHIKAWA, Yukio NAKAMURA, and Shinichi KAWAGUCHI*

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received June 10, 1971)

Tris(acetylacetonato)manganese(III) reacts with ethylenediamine (L_2) and other primary amines (L) in organic solvents at room temperature producing $Mn(acac)_2L_2$. The same Mn(II) complexes were also prepared quantitatively by reactions of $Mn(acac)_2(H_2O)_2$ with amines. Besides the usual hexa-coordinate monomeric complex, allylamine gave a dimeric compound $[Mn(acac)_2(CH_2=CHCH_2NH_2)]_2$, which is the first example of the binuclear manganese(II) complex of acetylacetone. The stoichiometry of the redox reaction between $Mn(acac)_3$ and ethylenediamine was established and discussed in connection with the initiation mechanism of vinyl polymerization.

In previous papers, reactions of acetylacetone chelates of copper(II),[1] beryllium,[2] and aluminum[3] with bromine in dichloromethane have been reported to result in different kind of products. Similar reactions of the corresponding cobalt(III),[4] cobalt(II),[5] nickel(II),[6] manganese(III), and manganese(II) complexes are now under investigation. In the course of these studies it was noticed that primary alkylamines react with tris(acetylacetonato)manganese(III) producing amine adducts of bis(acetylacetonato)manganese(II). The same compounds have also been derived from the latter manganese(II) chelate by direct reactions with the corresponding amines.

Dwyer and Sargeson[7] synthesized bis(acetylacetonato)diamminemanganese(II) and similar adducts of 2,2′-bipyridine and 1,10-phenanthroline either by substitution reactions between bases and sodium tris(acetylacetonato)manganate(II), or by direct addition reactions between bases and bis(acetylacetonato)manganese(II). Graddon and Mockler[8] also prepared mono- and bis-adducts of pyridine derivatives with the manganese(II) chelate by reactions of bis(acetylacetonato)diaquomanganese(II) with the heterocyclic bases. However, corresponding alkyl amine adducts have not been reported as yet.[9]

As to the redox reactions, tris(acetylacetonato)manganese(III) has been reduced by phenylhydrazine[10] and 2,6-xylenol[11] but has not been reduced by biguanide,[12] picolinic acid or 8-hydroxyquinoline.[13] The present paper reports on the redox reactions between tris(acetylacetonato)manganese(III) and several aliphatic amines, and also on the characterization of manganese(II) complexes produced.

Experimental

Materials. Tris(acetylacetonato)manganese(III),[14] bis(acetylacetonato)manganese(II)[15] and bis(acetylacetonato)-diaquomanganese(II)[15] were synthesized by the methods of Charles (Found for $Mn(C_5H_7O_2)_3$: Mn, 15.59; C, 51.15; H, 5.98%. Found for $Mn(C_5H_7O_2)_2$: Mn, 21.85; C, 47.21; H, 5.58%. Found for $Mn(C_5H_7O_2)(H_2O)_2$: Mn, 19.09; C, 41.68; H, 6.29%). Bis(acetylacetone)ethylenediimine was also prepared according to the literature[16] and recrystallized twice from water (Found: C, 64.39; H, 9.02; N, 12.54%).

Methallylamine was prepared by ammonolysis of methallyl chloride.[17] In an autoclave 96 m*l* of methallyl chloride (1 mol), 500 g of 28% aqueous ammonia (8 mol) and 140 g of ammonium chloride (2.5 mol) were allowed to react at 80—90°C for about 30 min under a pressure of 10 kg/cm^2. Then an aqueous solution of 160 g of sodium hydroxide was added to the mixture and methallylamine was extracted with ether and purified by fractional distillation. Found: C, 66.41; H, 12.63%. *trans*-Crotylamine was also synthesized according to the similar method. Found: C, 67.07; H, 12.81%.

Commercial ethylenediamine, propylamine and allylamine were distilled over metallic sodium. Allylamine was allowed in advance to stand over potassium hydroxide for one day in the cold. Diethyl ether was dried with calcium chloride and distilled over sodium. Benzene and *N,N*-dimethylformamide (DMF) were also purified by the standard methods.[18]

Redox reactions. The reaction between ethylenediamine and tris(acetylacetonato)manganese(III) was performed in a

three-necked flask equipped with a burette and a glass tube containing calcium chloride. To an ethereal solution of the manganese(III) complex (*ca.* 0.3 g) was added dropwise an ethereal solution of three times as many moles of ethylenediamine with magnetic stirring. Agitation was continued further after mixing of reactant solutions was finished. After about half an hour a precipitate of ivory color began to separate, but it took about one week before intense black-brown color of the starting solution disappeared indicating completion of the reaction. Then the precipitate was filtered and submitted to the elemental analysis. The filtrate was divided into three portions and contents of acetylacetone, ethylenediamine and total nitrogen were determined.

Analyses. Manganese content in each solid sample was determined gravimetrically as the sulfate after decomposition of the compound with nitric acid.

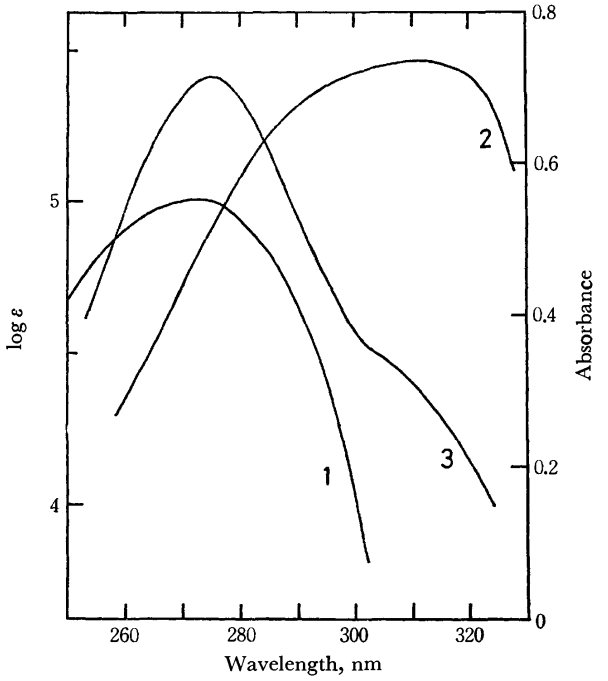

Fig. 1. Ultraviolet absorption spectra of acetylacetone (curve 1, left ordinate), bis(acetylacetone)ethylenediimine (curve 2, left ordinate), and a filtrate from the redox reaction between tris (acetylacetonato)manganese(III) and ethylenediamine (curve 3, right ordinate) in ether.

The filtrate from the above redox reaction contained the liberated acetylacetone, the excess ethylenediamine, produced bis(acetylacetone)ethylenediimine, and the decomposition products of ethylenediamine. The ultraviolet absorption spectrum of this solution is shown in Fig. 1 together with those of acetylacetone and bis(acetylacetone)ethylenediimine. Ethylenediamine does not absorb light in this region and its decomposition products may not either. Thus the absorption spectrum of the solution was analysed on the assumption that it is due to acetylacetone and bis(acetylacetone)ethylenediimine, and the total amount of acetylacetone freed in this redox reaction was determined.

Another aliquot of the filtrate solution was acidified with dilute sulfuric acid and freed of solvent under reduced pressure. The residue was dissolved in water and neutralized with a dilute solution of sodium hydroxide. An aqueous solution of sodium rhodizonate was added in excess to this solution producing a violet precipitate of one to one salt of ethylenediamine with rhodizonic acid. The gravimetric determination of ethylenediamine by this method was tested in advance employing a known amount of the amine, and the accuracy was proved to be more than 99%.

The third aliquot of the filtrate solution was placed in a 500 m*l* Kjeldahl flask, to which potassium sulfate (10 g), selenium (0.2 g) and concentrated sulfuric acid (25—30 m*l*) were added. The mixture was carefully heated by an infrared irradiation to vaporize ether almost completely, and then the total nitrogen content was measured according to the usual Kjeldahl method.

Syntheses of Mixed Complexes of Manganese(II). To prevent oxidation of manganese(II) the following preparations were all performed in an atmosphere of nitrogen employing deoxygenated solvents.

Bis(acetylacetonato)ethylenediaminemanganese(II): Two methods were employed. (i) About 3 g of tris(acetylacetonato)manganese(III) was dissolved in DMF, to which a DMF solution of three times as many moles of ethylenediamine was added. After about 30 min an ivory precipitate began to separate, which was recrystallized from DMF resulting in pale yellow crystals: mp around 150°C (dec). Found: Mn, 17.55; C, 45.83; H, 7.08; N, 8.63%. Calcd for Mn(acac)$_2$en=$C_{12}H_{22}O_4N_2Mn$: Mn, 17.54; C, 46.00; H, 7.09; N, 8.94%.

(ii) Bis(acetylacetonato)diaquomanganese(II) was allowed to react with an equimolar amount of ethylenediamine in DMF. A pale yellow precipitate appeared at once in an almost quantitative yield, and was recrystallized from DMF. Found: M, 17.51; C, 46.10; H, 7.14; N, 9.15%.

Thus, the same compound was obtained in these two types of reactions as evidenced by results of the elemental anaysis and infrared spectra. The corresponding complex containing deuterated ethylenediamine was prepared by the following method. Ethylenediamine-d_4 was prepared by repeated fractional distillations from heavy water solutions and characterized by means of NMR spectra. To a solution of 0.3 g of anhydrous bis(acetylacetonato)manganese(II) in 10 m*l* of DMF containing a few drops of heavy water was added ten drops of ethylenediamine-d_4 and allowed to react for a while with frequent shaking. Bis(acetylacetonato)(ethylenediamine-d_4)manganese(II) was produced as a pale yellow precipitate, filtered and washed with DMF containing a small quantity of heavy water.

Bis(acetylacetonato)bis(allylamine)manganese(II): This compound was also prepared by the following two methods. (i) About 2 g of tris(acetylacetonato)manganese(III) was dissolved in 200 m*l* of ether, to which more than ten times as many moles of allylamine was added. A precipitate began to appear after a while, but the mixture was stirred for one or two days. Pale yellow needles were obtained after recrystallization from ether. Found: Mn, 15.11; C, 52.16; H, 7.57; N, 7.98%. Calcd for Mn(acac)$_2$(CH_2=$CHCH_2NH_2$)$_2$ = $C_{16}H_{28}O_4N_2Mn$: Mn, 14.96: C, 52.31; H, 7.68; N, 7.63%. If about six times as many moles of allylamine is employed, a mixture of bis- and mono-adducts of allylamine with bis(acetylacetonato)manganese(II) is obtained.

(ii) An ethereal solution of twice as many moles of allylamine was added to a suspension of bis(acetylacetonato)diaquomanganese(II) (3 g) in ether. Immediately appeared a pale yellow fuzzy precipitate, which was recrystallized from ether. Found: C, 52.12; H, 7.63; N, 7.30%. Infrared spectra of this specimen were identical with those of the product from the above redox reaction.

Bis(acetylacetonato)allylaminemanganese(II): When an ethereal solution of equimolar allylamine was added to an ethereal suspension of bis(acetylacetonato)diaquomanganese(II) (2.5 g), a fuzzy precipitate appeared at first, but changed gradually to a powder. Pale yellow crystals were obtained

by recrystallization from ether. Found: C, 50.25; H, 6.86; N, 4.10%. Calcd for $Mn(acac)_2(CH_2{=}CHCH_2NH_2)$ = $C_{13}H_{21}O_4NMn$: C, 50.33; H, 6.82; N, 4.51%.

Bis(acetylacetonato)bis(propylamine)manganese(II): The reaction between tris(acetylacetonato)manganese(III) and propylamine in ether gave pale yellow needles. Found: Mn, 15.09; C, 51.64; H, 8.62; N, 7.45%. Calcd for $Mn(acac)_2(C_3H_7NH_2)_2 = C_{16}H_{32}O_4N_2Mn$: Mn, 14.79; C, 51.75; H, 8.69; N, 7.54%. The same complex was also produced by the reaction of propylamine with bis(acetylacetonato)-diaquomanganese(II) in ether. Found: Mn, 14.97; C, 51.71; H, 8.63; N, 7.50%. Even when an equimolar amount of propylamine was allowed to react with the manganese(II) complex, the one to one adduct was not produced but the bis(amine)-adduct was obtained exclusively.

Bis(acetylacetonato)bis(methallylamine)manganese(II) was prepared by the reaction of bis(acetylacetonato)diaquomanganese(II) with methallylamine in ether in the mole ratio of one to two and recrystallized from ether. Found: Mn, 13.91; C, 54.55; H, 8.23; N, 7.25%. Calcd for $Mn(acac)_2(CH_2{=}C(CH_3)CH_2NH_2)_2 = C_{18}H_{32}O_4N_2Mn$: Mn, 13.89; C, 54.68; H, 8.16; N, 7.08%.

*Bis(acetylacetonato)bis(*trans*-crotylamine)manganese(II)* was also prepared in a similar reaction. Found: Mn, 13.71; C, 54.80; H, 8.20, N, 7.07%. Either of these allylic amines did not give the mono(amine)-adduct even in reactions at the reactants mole ratio of one to one.

Measurements. Ultraviolet absorption spectra were measured by means of a Hitachi spectrophotometer model EPS-2. Infrared absorption spectra in the 4000—650 cm^{-1} region were measured with a Hitachi infrared spectrophotometer EPI-2, and those in 700—200 cm^{-1} with a Hitachi grating infrared spectrophotometer EPI-L. Magnetic susceptibilities were measured at room temperature by the Gouy method with a Shimadzu magnetic balance employing hexaamminechromium(III) chloride as a reference substance. Diamagnetic corrections were calculated from Pascal's constants. Thermogravimetric analysis was performed using a thermo-spring-balance C-282 of Hamada Denki Seisakusho, Ltd. under reduced pressure. The rate of temperature elevation was fixed at 30°C/hr for the ethylenediamine complex and at 20°C/hr for allylamine and propylamine complexes. Molecular weight was determined by the cryoscopic method in benzene in a deaerated vessel to prevent oxidation of the manganese(II) complexes and also with a vapor-pressure osmometer of Toa electronics, Ltd. employing ether as a solvent and tris(acetylacetonato)aluminum as a reference substance.

Results

Properties of Bis(acetylacetonato)ethylenediaminemanganese-(II). A novel mixed ligand complex bis(acetylacetonato)ethylenediaminemanganese(II) was prepared either by a redox reaction between tris(acetylacetonato)manganese(III) and ethylenediamine, or by a substitution reaction of bis(acetylacetonato)diaquomanganese(II) with the amine. Infrared absorption spectra of the compound in the higher frequency region are composed of those due to the acetylacetonate ligand and also those due to coordinated ethylenediamine. Characteristic bands due to the diamine ligand are listed in Table 1 which were assigned by reference to literatures[19] and also to the deuteration effects. As

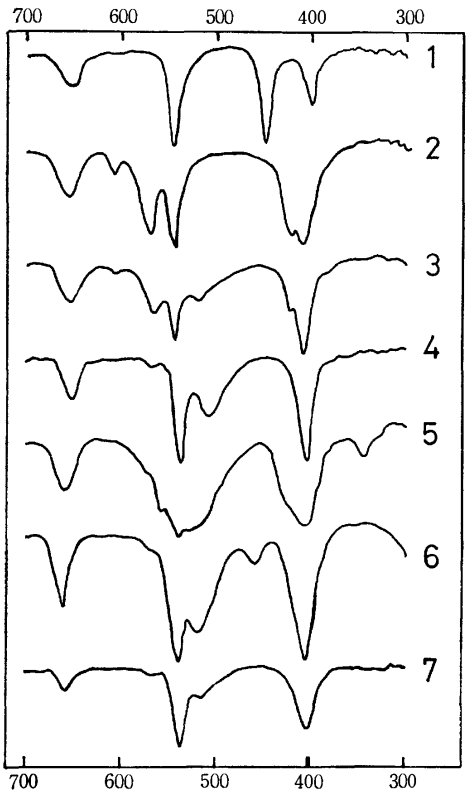

Fig. 2. Infrared spectra in the 700—300 cm^{-1} region of bis(acetylacetonato)manganese(II) and amine adducts in Nujol mull: 1, $Mn(acac)_2$; 2, mono(allylamine)-adduct; 3, bis(allylamine)-adduct; 4, bis(propylamine)-adduct; 5, bis(methallylamine)-adduct; 6, bis (*trans*-crotylamine)-adduct; 7, ethylenediamine-adduct.

shown in Fig. 2, infrared absorption spectrum of bis(acetylacetonato)manganese(II) in the 700—300 cm^{-1} region consists of a broad band around 650 cm^{-1} and three strong peaks at 543, 449, and 399 cm^{-1}. Dismukes, Jones, and Bailar interpreted the spectrum in terms of coupling of metal-oxygen vibrational modes with three low-frequency vibrational modes of the acetylacetonate anion.[20] The strong peak at 449 cm^{-1} was not ob-

20) J. P. Dismukes, L. H. Jones, and J. C. Bailar, Jr., *J. Phys. Chem.*, **65**, 792 (1961).

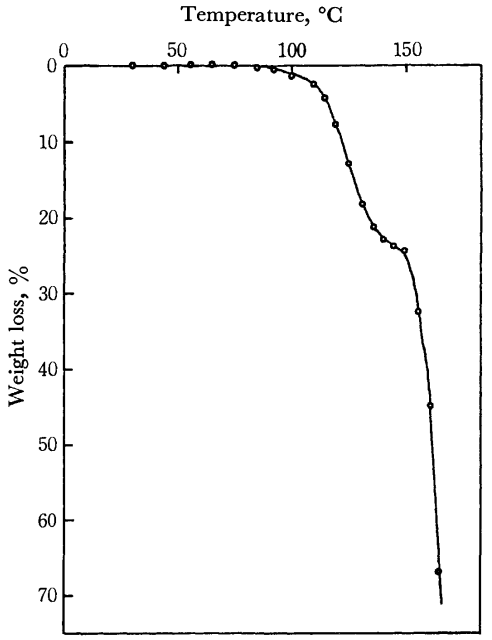

Fig. 3. Thermogravimetric analysis of bis(acetylacetonato)-ethylenediaminemanganese(II) *in vacuo*. The rate of temperature elevation was fixed at 30°C/hr.

served in the spectrum of the ethylenediamine adduct. It may be due to the structural change from trimeric $Mn(acac)_2$[8] to monomeric $Mn(acac)_2en$. Weak bands at 572 and 516 cm^{-1} in the latter spectrum may be assigned to the metal-nitrogen stretching.

Thermogravimetric analysis, as shown in Fig. 3, indicates that bis(acetylacetonato)ethylenediaminemanganese(II) begins to decompose at around 95°C liberating ethylenediamine, which was trapped at −78°C. The ethylenediamine was transformed to the hydrochloride and identified by the elemental analysis and infrared spectra.[21] Sudden decrease of weight at temperatures above 150°C is due to sublimation of the decomposition residue, which was identified as bis-(acetylacetonato)manganese(II) by the elemental analysis and infrared spectra. The weight loss below 150°C amounts to 24% exceeding the calculated value of 19.2% for the ethylenediamine content in this adduct. This discrepancy seems to be caused by partial sublimation of the residual bis-chelate. When a sample was kept at 100°C *in vacuo*, the weight decreased more slowly and reached a constant weight after 6 hr. The weight loss in this case was 22.0% and still higher than the calculated ethylenediamine content.

Molecular weight of $Mn(acac)_2en$ could not be measured on account of insolubility in ether, benzene, and other solvents suitable for the measurement, but it could be presumed to be monomeric from analogy with the bis(allylamine)-adduct which will shortly be described. Magnetic moment of this compound was determined to be 6.08 B.M. by the Gouy method at room temperature. This value is so close to the value of 5.91 B.M. estimated by the spin-only equation that high-spin octahedral configuration of manganese(II) may be proposed for this compound.

Other Primary Amine Adducts with Bis(acetylacetonato)manganese(II). Bis(acetylacetonato)bis(amine)manganese(II) complexes were also prepared by the two types of reactions just as in the case of the ethylenediamine adduct. The 1 : 1 amine adduct was obtained only in a 1 : 1 reaction between bis(acetylacetonato)manganese-(II) and allylamine. Even when other primary amines such as propylamine, methallylamine and *trans*-crotylamine were allowed to react with $Mn(acac)_2$ in the mole ratio of one to one, the bis(amine)-adducts were produced exclusively.

TABLE 2. THE NH STRETCHING AND NH_2 BENDING FREQUENCIES OF SEVERAL PRIMARY AMINES AND THEIR ADDUCTS WITH BIS(ACETYLACETONATO)MANGANESE(II) TOGETHER WITH THE C=C STRETCHING FREQUENCIES OF ALLYLIC COMPOUNDS

a) Free amines as neat liquid and metal complexes in Nujol.

Table 2 summarizes infrared frequencies of NH stretching and NH_2 bending vibrations of these primary amines and their adducts, and those of C=C stretching in allylic amines. The NH stretching frequencies of amine adducts are shifted remarkably to the lower frequency side indicating coordination of amine groups to the metal. Close resemblance of infrared spectra in the lower frequency region as shown in Fig. 2 suggests that the bis-adducts of primary monoamines take the *cis* configuration as is the case for the ethylenediamine adduct. The C=C stretching frequencies of adducts of allylamine and its derivatives show no appreciable shifts from those of free ligands implying non-participation of the C=C group in coordination.

Magnetic moments of allylamine, bis-allylamine and bis-propylamine adducts are 5.97, 6.08, and 6.14 B.M.,

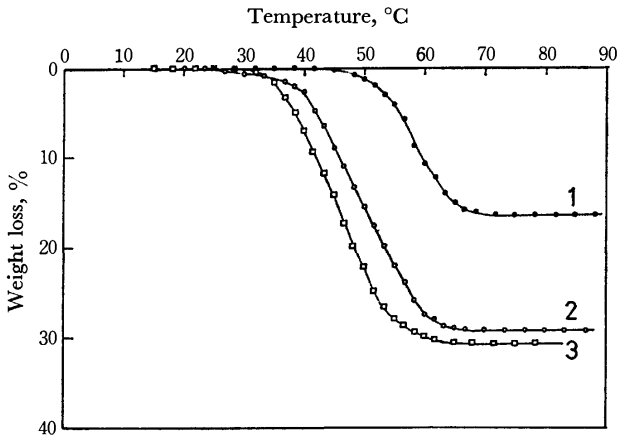

Fig. 4. Thermogravimetric curves for decompositions of amine adducts with bis(acetylacetonato)manganese(II). Curve 1, mono(allylamine)-adduct; curve 2, bis(allylamine)-adduct; curve 3, bis(propylamine)-adduct.

Table 3. Results of thermogravimetric analysis of amine adducts with bis(acetylacetonato)-manganese(II)

Compound	Beginning of decomposition (°C)	Weight loss (%)	Calcd amine content (%)
$Mn(acac)_2en$	95	22.0	19.2
$Mn(acac)_2(AllNH_2)$	45	16.4	18.4
$Mn(acac)_2(AllNH_2)_2$	25	29.1	31.1
$Mn(acac)_2(PrNH_2)_2$	30	30.7	31.8

respectively, indicating that they are all high-spin complexes. Results of thermogravimetric analysis of these compounds are shown in Fig. 4 and Table 3. Allylamine and propylamine adducts decomposed at much lower temperatures than the ethylenediamine adduct did. Thus the weight became constant below 70°C in each case since sublimation of the decomposition residue did not start at these lower temperatures even *in vacuo*.

The volatile product was identified as the free amine, and the decomposition residue as bis(acetylacetonato)-manganese(II) in either case. The observed weight loss in these compounds is close to the calculated amine content, respectively. The higher temperature of decomposition of the ethylenediamine complex seems to reflect its higher thermodynamic stability, compared with bis-adducts of monoamines. However, the trend is independent of the negative shift observed for the N–H stretching frequencies, and might be understood in terms of the entropy effect in the diamine chelate.

The decomposition pressure of the bis(allylamine) complex is higher than that of its mono-adduct and the former compound changes to the latter by prolonged evacuation even at room temperature. The results of molecular weight determination shown in Table 4 indicate that the bis(allylamine) complex is monomeric both in benzene and ether, but the mono(allylamine) complex is dimeric in ether. The latter compound is less soluble in benzene and did not allow the cryoscopic measurement.

Table 4. Molecular weights of allylamine adducts with bis(acetylacetonato)manganese(II)

Compound	Calcd	Found in benzene[a)]	Found in ether[b)]
$Mn(acac)_2(AllNH_2)$	310		580
$Mn(acac)_2(AllNH_2)_2$	367	350	350

a) Cryoscopy
b) Vapor pressure osmometry

Stoichiometry of the Redox Reaction between Tris(acetylacetonato)manganese(III) and Ethylenediamine. A precipitate formed by the reaction between tris(acetylacetonato)manganese(III) and ethylenediamine was identified as bis(acetylacetonato)ethylenediaminemanganese(II) by the elemental analysis and infrared spectra. Since this compound is insoluble in ether at all, the filtrate could be used for the analysis of the excess ethylenediamine, total nitrogen, and liberated acetylacetone as described in the Experimental section.

Table 5. Products of a reaction between tris-(acetylacetonato)manganese(III) and ethylenediamine in ether

	No. of mols	Mol ratio
Reactants employed:		
$Mn(acac)_3$	8.31×10^{-4}	1
ethylenediamine	24.93×10^{-4}	3
Ppt. produced:		
$Mn(acac)_2en$	8.47×10^{-4}	1.02
Contained in the filtrate:		
acetylacetone	6.32×10^{-4}	
bis(acac)ethylenediimine	1.01×10^{-4}	
total acetylacetone	8.34×10^{-4}	1.00
total ethylenediamine	9.30×10^{-4}	1.12
total nitrogen	27.8×10^{-4} g·atom	

As summarized in Table 5 the manganese(II) complex was produced quantitatively. Liberated acetylacetone was also equimolar to the complex, indicating that no appreciable decomposition of the acetylacetonate ligand occurred in this redox reaction. Since 2.493 mmol of ethylenediamine was employed and 0.847 mmol was found as coordinated in the Mn(II) complex, the remaining 1.646 mmol might be expected to exist in the solution. However only 0.930 mmol of ethylenediamine was found in the filtrate existing both as the free diamine and the diimine. Thus 0.716 mmol of the amine must be considered to have been decomposed. Total nitrogen contained in the filtrate was not 2×1.646 mg·atom but only 2.78 mg·atom. These results suggest that ethylenediamine was consumed in reducing Mn(III) to Mn(II). Oxidized products of the amine have not yet been characterized, but some volatile product(s) corresponding to 0.51 mg·atom of nitrogen must have escaped from the reaction mixture during a long period reaction. Thus the over-all redox reaction between tris(acetylacetonato)manganese-(III) and ethylenediamine can be represented by the following equation.

$$Mn(acac)_3 + 2en = Mn(acac)_2en + acacH + \text{decomposition products of en} \quad (1)$$

Discussion

Bis(acetylacetonato)bis(allylamine)manganese(II) was ascertained to be monomeric in benzene and ether. Molecular weights of other bis(monoamine) and ethylenediamine complexes have not been determined, but it may be presumed by analogy that they are all monomeric six-coordinate complexes. Allylamine is quite specific in forming the 1:1 adduct which is dimeric in ether and in crystals, too.[22] It is worth noting that the mono-allylamine-adduct is more stable than the bis(allylamine)-adduct while similar mono-adducts of propyl-, methallyl-, and crotyl-amines can not be obtained.

Graddon and Mockler[8] found that 1:1 adducts of pyridine and 4-methylpyridine with bis(acetylacetonato)-manganese(II) are both monomeric in benzene and proposed five-coordinate structures for these complexes. On the contrary the present 1:1 adduct of allylamine is dimeric and a six-coordinate structure must be considered. As evidenced by the IR data, the ethylenic group of allylamine is not involved in coordination to the metal, and the amine molecule acts as a unidentate ligand. Thus the acetylacetonate groups are considered to take the role of bridging ligands as depicted in Fig. 5. This structure is analogous to that given to dimeric bis(acetylacetonato)aquocobalt(II) by Cotton and Elder,[23] and is the first example of the dimeric manganese(II) complex containing acetylacetonate groups as bridging ligands. It is not certain at the present stage of investigation why propylamine and other monoamines can not assume similar structures, but will be clarified by the X-ray studies now in progress.[22]

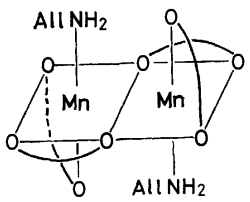

Fig. 5. A proposed structure of dimeric bis(acetylacetonato)-allylaminemanganese(II).

Tris(acetylacetonato)manganese(III) is known as one of the most effective initiators of free-radical polymerization of vinyl monomers.[24] Recently Bamford and Ferrar found that propylenediamine and other donor additives stimulate the radical initiation quite markedly in the polymerizations of styrene, methyl methacrylate and acrylonitrile initiated by Mn(acac)$_3$.[25] The first step of the redox reaction must be coordination of an amine molecule to the manganese(III) metal in such a fashion as represented by Eq. (2), since the outer-sphere electron transfer seems

$$Mn^{III}(acac)_3 + en \longrightarrow (acac)_2Mn^{III}\langle^{acac}_{en} \quad (2)$$

less probable. Succeeding steps may be either (3) or (5). If an electron is transferred from the coordinated

$$(acac)_2Mn^{III}\langle^{acac}_{en} \longrightarrow Mn^{II}(acac)_2 + C_5H_8O_2 + (en-H)\cdot \quad (3)$$

$$Mn^{II}(acac)_2 + en \xrightarrow{fast} Mn^{II}(acac)_2en \quad (4)$$

$$(acac)_2Mn^{III}\langle^{acac}_{en} \longrightarrow Mn^{II}(acac)_2en + C_5H_7O_2\cdot \quad (5)$$

$$C_5H_7O_2\cdot + en \xrightarrow{fast} C_5H_8O_2 + (en-H)\cdot \quad (6)$$

amine to the metal and the acetylacetonate anion dissociates as a molecule abstracting a proton from neighboring ethylenediamine, there will result the deprotonated ethylenediamine radical (Eq. 3). The product Mn(acac)$_2$ is labile and will add an excess molecule of ethylenediamine quite easily (4) as shown in this paper. On the other hand if an electron is delivered by an acetylacetonate ligand, an acetylacetone radical will be produced (5).

Uehara *et al.*[26] reported that pyridine, α,α'-lutidine, and piperidine accelerated polymerization of styrene, methyl methacrylate, and vinyl acetate initiated by Mn(acac)$_3$, and that polystyrene prepared in the Mn(acac)$_3$-py system showed the carbonyl stretching band at round 1700 cm^{-1} but no absorption due to the pyridine ring. By means of tracer experiments Bamford and Ferrar[27] also disclosed that in the vinyl polymerization initiated by Mn(acac)$_3$ and propylenediamine or dimethyl sulfoxide, each growing radical carried one acetylacetonate residue, but fragments derived from the additives were incorporated in the polymer only to a minor extent. These results indicate unequivocally that the process (5) occurred in the main. As described already acetylacetone molecules are recovered quantitatively in the reaction between Mn(acac)$_3$ and ethylenediamine in the absence of vinyl monomers. The succeeding step (6) must proceed rapidly in advance to spontaneous degradation of the acetylacetone radical.

A grant given to Nakamura by Fuji Photo Film Co., Ltd. is gratefully acknowledged. The authors also thank Mr. J. Gohda for the elemental analyses.

(Received June 18, 1971)

A series of new kinds of mixed cobalt(III) complexes, *trans*(O,X)-[Co(X)(aminoacidato)(diethylenetriamine)]Y, have been prepared and characterized by visible and ultraviolet, circular dichroism, and proton magnetic resonance spectroscopy for X=CN^-, NO_2^-, and Cl^-; aminoacid=glycine, α-aminoisobutyric acid, L-alanine, L-valine, L-threonine, and L-proline; and Y=Br^-, Cl^-, or ClO_4^-. The proton magnetic resonance spectra of the cyano mixed complexes show the existence of new conformational isomers, *endo* and *exo* forms, which concern the ligand CN^- and the hydrogen atom attached to the central nitrogen atom of the meridionally coordinated diethylenetriamine ligand.

In the course of preparative studies of mixed cyano cobalt(III) complexes,[1-3] we have obtained a group of new cyano-diethylenetriamine cobalt(III) complexes with various aminoacids, including optically active ones.[4] In order to characterize these complexes, we have also prepared analogous complexes in which cyanide ion is replaced by a chloride or a nitrite ion. This paper reports the preparation of such complexes and their structures as determined by visible and ultraviolet, circular dichroism, and proton magnetic resonance spectroscopy. A short communication was given on the existence of a couple of novel isomers of the new cyano-diethylenetriamine cobalt(III) complex ion.[5]

Experimental

Ligands and Starting Materials. Diethylenetriamine, glycine, α-aminoisobutyric acid, L-alanine, L-proline, L-valine, and L-threonine were obtained from Wako Pure Chemicals, and used without further purification.

$[Co(NO_2)_3dien]$,[6] $[CoCl_3dien]$,[6] and *trans*-$[Co(CN)(SO_3)(NH_3)_4]$[7] were prepared according to the methods described in literature.

Preparation of the Complexes. All *trans*(O,X)-monoacido-aminoacidato-diethylenetriamine-cobalt(III) complexes (X=CN^-, NO_2^-, or Cl^-) were prepared as follows.

Method 1) *trans*-$[Co(CN)(SO_3)(NH_3)_4] \xrightarrow{dien}$ an intermediate complex (not isolated) $\xrightarrow{concd.\ HBr}$ $Co(CN)(OH_2)(dien)Br_2 \xrightarrow{amH,\ NaOH}$ *trans*(O, CN)-$[Co(CN)(am)(dien)]^+$ (in water)

Method 2) *trans*(O, Cl)-$[Co(Cl)(am)(dien)]^+ \xrightarrow{KCN}$ *trans*(O,CN)-$[Co(CN)(am)(dien)]^+$ (in DMSO)

Method 3) $[CoCl_3dien] \xrightarrow{amH,\ NaOH}$ *trans*(O, Cl)-$[Co(Cl)(am)(dien)]^+$ (in water)

Method 4) $[CoCl_3dien] \xrightarrow{amH,\ NaOH,\ NaNO_2}$ *trans*(O, NO_2)-$[Co(NO_2)(am)(dien)]^+$ (in water)

Method 5) $[Co(NO_2)_3dien] \xrightarrow{amH,\ NaOH}$ *trans*(O, NO_2)-$[Co(NO_2)(am)(dien)]^+$ (in water)

trans*(O,CN)-[Co(CN)(gly)(dien)]*$Br\cdot 3H_2O$. *Method 1*: To a suspension of 35 g of *trans*-$[Co(CN)(SO_3)(NH_3)_4]\cdot 2H_2O$ in 250 m*l* of water was added 15.5 g of diethylenetriamine. Upon heating at 70—80°C for 2 hr with occasional stirring, the starting complex dissolved nearly completely with evolution of ammonia gas. The resulting brown solution was filtered, and the filtrate was concentrated to about 60 m*l* at 60°C under reduced pressure. The sticky solution was treated wtih 100 m*l* of concd. hydrobromic acid, cooled in an ice bath overnight and filtered. The brown solution was warmed at 75°C for about 4 hr until the color turned deep red and was then filtered. To the filtrate was added 400 m*l* of water and an appropriate amount of methanol and acetone. A crude complex, precipitated on cooling was filtered off, washed with methanol, air-dried and recrystallized from water by adding methanol and acetone. Elemental analysis showed the composition $Co(CN)(OH_2)(dien)Br_2$.

Found: C, 16.13; H, 4.81; N, 15.53%. Calcd for $C_5H_{15}N_4OCoBr_2$: C, 16.41; H, 4.13; N, 15.31%. The complex turns from pale rose to testaceous by storing in a vacuum desiccator or by heating. Such a color change might be due to the dehydration of coordinated water followed by the anation of bromide ion. Further study was not made.

To a warm aqueous solution (50—60°C, 50 m*l*) containing 7.3 g of $Co(CN)(OH_2)(dien)Br_2$ was added slowly an aqueous solution (50 m*l*) containing 1.5 g of glycine and 0.56 g of sodium hydroxide. The solution was warmed at 75°C with occasional stirring until the color changed from dark red

to yellow brown, and then concentrated to about 15 m*l* at about 60°C and cooled. Orange yellow crystalline powder precipitated was filtered off, washed with methanol and air-dried. The aqueous solution of this product was passed through a column (3×30 cm) containing cation exchange resin Dowex 50W-X8 in hydrogen ion form. The column was washed with water and the adsorbed yellow band was eluted with 4% aqueous solution of lithium bromide. The desired complex was eluted first, followed by $[Co(CN)(glyH)_2(dien)]^{2+}$. Each fraction was checked by its visible absorption spectrum. The fractions containing the desired complex were collected and concentrated at 60°C under reduced pressure. A yellow complex, *trans*(O,CN)-$[Co(CN)(gly)(dien)]Br\cdot 3H_2O$ was precipitated by adding methanol, filtered off, washed with water-methanol and methanol and air-dried. The complex was recrystallized from water by adding methanol.

An orange complex $[Co(CN)(glyH)_2(dien)]Br_2\cdot 3H_2O$ was obtained from the fractions eluted later.

Found: C, 20.26; H, 5.46; N, 15.72%. Calcd for $C_9H_{29}N_6O_7CoBr_2$: C, 19.57; H, 5.29; N, 15.22%. The complex which contains two neutral unidentate glycine is less soluble in water than *trans*(O,CN)-$[Co(CN)(gly)(dien)]Br\cdot 3H_2O$.

Method 2: Four grams of *trans*(O,Cl)-$[Co(Cl)(gly)(dien)]ClO_4$ was ground thoroughly and suspended in 30 m*l* of dimethylsulfoxide (DMSO) with mechanical stirring, and 1 g of potassium cyanide was added. The color of the solution changed from reddish violet to orange and a yellowish orange product precipitated. This was filtered off as rapidly as possible and was dissolved in 0.47% hydrobromic acid. The solution was poured on a column containing cation exchange resin Dowex 50W-X8 in hydrogen ion form. The column was washed with water and the adsorbed band was eluted with an aqueous solution containing 20 m*l* of 47% hydrobromic acid and 30 g of lithium bromide in 1000 m*l* of water. A pure complex was obtained from the eluate by the same way as in Method 1.

trans*(O,CN)*-$[Co(CN)(am)(dien)]Br\cdot xH_2O$ (am=α-aibut, L-ala, L-pro, L-val, and L-thr)

The complexes were prepared by Method 1) as for the glycine complex using α-aibutH, L-alaH, L-proH, L-valH and L-thrH instead of glyH.

trans*(O,Cl)*-$[Co(Cl)(gly)(dien)]ClO_4$. *Method 3*: An aqueous solution (30 m*l*) containing 1.5 g of glycine and 0.56 g of sodium hydroxide was added to a suspension of 5.4 g of $[CoCl_3dien]$ in 30 m*l* of warm water (40°C) with mechanical stirring. This was warmed at 65°C until the $[CoCl_3dien]$ dissolved nearly completely, and then filtered. The filtrate was passed through a column containing the same kind of resin as in Method 1. By elution with 3% aqueous solution of sodium perchlorate, the column gave many bands with different colors. The desired complex was obtained from the brownish-violet band eluted first. The brownish-violet eluate was concentrated at 50°C under reduced pressure and cooled. Pure crystals precipitated were filtered off, washed with ice water, water-methanol and methanol, and air-dried.

trans*(O,Cl)*-$[Co(Cl)(am)(dien)]ClO_4\cdot xH_2O$ (am=L-ala, L-pro, L-val, and L-thr)

The complexes were obtained from $[CoCl_3dien]$ and L-alaH, L-proH, L-valH, and L-thrH by Method 3) as for the glycinato complex.

trans*(O,NO$_2$)*-$[Co(NO_2)(gly)(dien)]Cl\cdot H_2O$ *Method 4*: A mixture containing 5.4 g of $[CoCl_3dien]$, 1.5 g of glycine and 0.56 g of sodium hydroxide in 50 ml of water was warmed at 50°C for an hour, and filtered. 1.3 g of sodium nitrite was added to the filtrate and the resulting solution was concentrated to about 25 m*l* at 80°C, filtered and cooled. Brownish-yellow crystals were precipitated by adding 10 m*l* of concd. hydrochloric acid under cooling in an ice bath. They were filtered off, washed with ice water, water-methanol and methanol, and air-dried. The complex was recrystallized from hot water or water-methanol.

Method 5: The complex was also prepared from $[Co(NO_2)_3dien]$ (3.8 g), glycine (1.5 g), sodium hydroxide (0.56 g) and a small amount of activated charcoal, using a method similar to Method 4.

trans*(O,NO$_2$)*-$[Co(NO_2)(am)(dien)]Cl\cdot xH_2O$ (am=α-aibut, L-ala, L-val, L-pro, and L-thr)

The complexes were prepared from $[CoCl_3dien]$ or $[Co(NO_2)_3dien]$ and α-aibutH, L-alaH, L-proH, L-valH, and L-thrH according to the method for the glycinato complex.

a) Prepared according to Method 1. b) Prepared according to Method 2.

Results of the chemical analyses of all the new complexes are given in Table 1.

Measurements. Visible and ultraviolet absorption spectra were obtained with a Beckman DU spectrophotometer and a Hitachi EPS-3 recording spectrophotometer. The circular dichroism (CD) curves were recorded with a Model ORD/UV-5 spectrophotometer of Japan Spectroscopic Co. Proton magnetic resonance (PMR) spectra were obtained with a Varian A-60 spectrometer in deuterium oxide, with sodium tetramethylsilane (NaTMS) as an internal reference. All spectral measurements were carried out at room tempertaure.

Results and Discussion

Configuration of the Complexes. As Fig. 1 shows, the first absorption bands of the cyano complexes exhibit no sign of splitting and the absorption curves have a pattern very similar to those of *trans*(O,CN)-[Co(OH$_2$)(CN)en$_2$]$^{2+}$ and *trans*(O,CN)-[Co(OH)(CN)-en$_2$]$^+$ reported in the previous paper.[1] The chloro complexes, on the other hand, give the first absorption bands split into two components at *ca.* 18000 and *ca.* 22000 cm^{-1}. Such a splitting is expected for only the complex in which chloride ion takes the position *trans* to the oxygen atom of amino-acidato group. The *trans*(O,Cl) structure of the chloro complex has been confirmed by a recent X-ray analysis on the [Co(Cl)-(gly)(dien)]ClO$_4$.[8] We thus conclude that all the cyano and chloro complexes we prepared have the structure of *trans*(O,X) type (X=CN$^-$ or Cl$^-$). The data of absorption spectra are summarized in Table 2.

The absorption spectra of the nitro complexes provide no definite information on the structure, but their CD curves are very similar to those of the cyano complexes as is seen in Fig. 2. Thus, it is concluded that the nitro complexes also take the *trans*(O,NO$_2$) structure. This conclusion has been confirmed by X-ray analysis on *trans*(O,NO$_2$)-[Co(NO$_2$)(gly)(dien)]Cl·H$_2$O.[9]

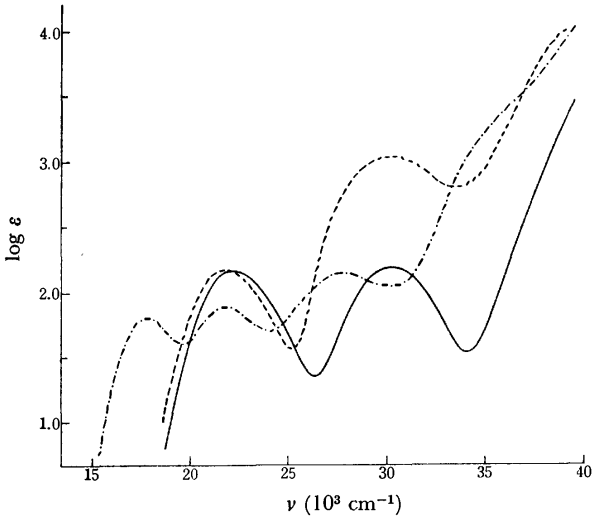

Fig. 1. Absorption spectra of *trans*(O,X)-[Co(X)(gly)(dien)]$^+$ ions in water:
—— CN$^-$, - - - NO$_2^-$, —·— Cl$^-$

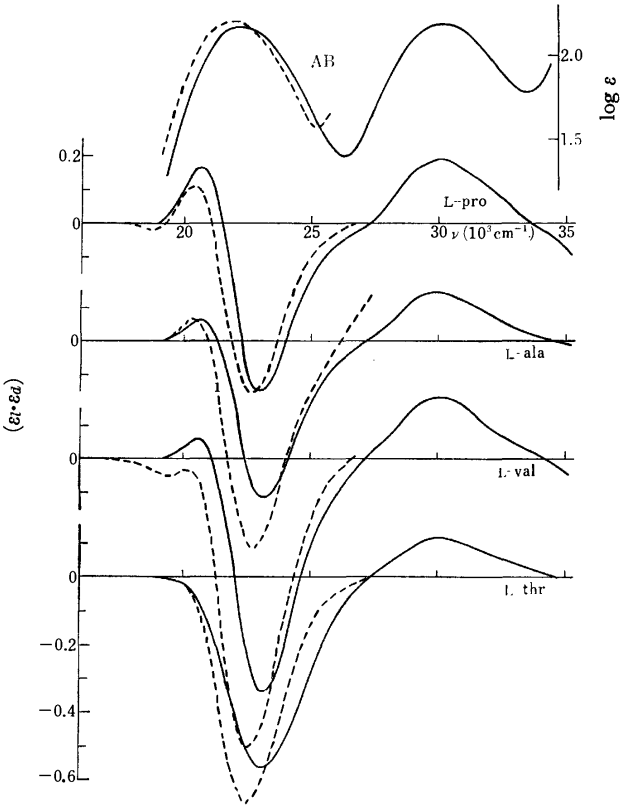

Fig. 2. Absorption(AB) and CD curves of *trans*(O,X)-[Co(X)-(L-am)(dien)]$^+$ ions in water:
—— CN$^-$, - - - NO$_2^-$.

PMR spectra of the complexes in deuterium oxide also support the *trans*(O,X) structure (X=CN$^-$, Cl$^-$, and NO$_2^-$). In the deuterium oxide solutions, hydrogen atoms of the amino groups were deuterated rapidly. Legg and Cooke[10] reported that the ethylene signals of dien coordinated meridionally in Co(III) complexes showed a rather sharp peak in the 181—187 cps region (60 MHz), while those of facially coordinated dien gave broad and complicated peaks in the 156—190 cps region. As Fig. 3 and Table 3 show, the present complexes exhibit sharp signals characteristic of the meridionally coordinated dien in the 179—186 cps region.

Further evidence for the *trans*(O,X) structure can be seen in the CD spectra of the complexes in the region of the first absorption band. Since the complex *trans*-(O,X)-[Co(X)(L-am)(dien)]$^+$, has no configurational chirality around the cobalt(III) ion, the CD in the region of the *d–d* transitions can be brought about by the vicinal effect of the coordinated L-amino-acidato group. Figure 2 shows the CD spectra of the cyano and nitro complexes in the region of the first and second absorption bands. The pattern and magnitude of these CD curves correspond to those of the complexes of the type [Co(NH$_3$)$_4$(L-am)]$^{2+}$,[11] indicating that the present dien complexes have no configurational chirality. This in turn suggests that the dien group in the

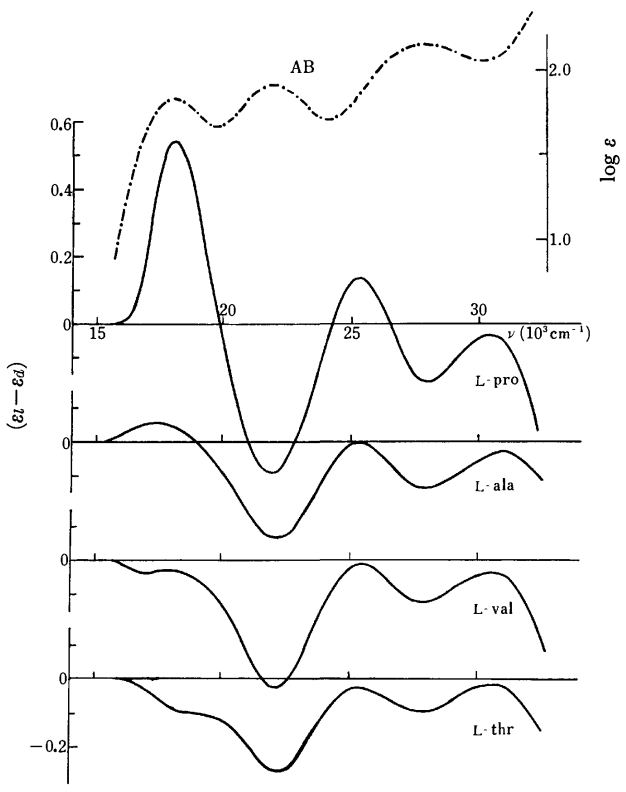

Fig. 4. Absorption (AB) and CD curves of *trans*(O,Cl)-[Co(Cl)(L-am)(dien)]$^+$ ions in water.

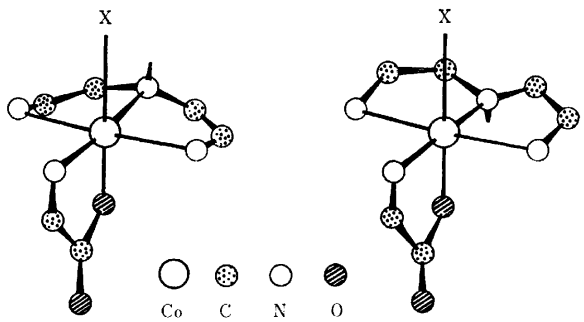
present complexes takes a meridional coordination.

Figure 4 shows that the chloro complexes give CD curves differing somewhat from those of the cyano or nitro complexes in the region of the *d–d* absorption bands. Such a difference may be attributed to the larger splitting of the first absorption band of the chloro complex than those of the cyano or nitro complex.[1)]

Conformational Isomerism. As Fig. 3-a shows, *trans*(O,CN)-[Co(CN)(gly)(dien)]$^+$, prepared from [Co(CN)$(SO_3)(NH_3)_4$] by Method 1, gives two kinds of methylene signals due to the glycinato chelate at 210.5 and 213.5 cps. Similarly, *trans*(O,CN)-[Co(CN)(L-ala)-(dien)]$^+$ and *trans*(O,CN)-[Co(CN)(α-aibut)(dien)]$^+$ show two kinds of methyl signals at 86.5 and 87.5, and at 84.2 and 86.0 cps, respectively (Fig. 3-f and 3-i). On the other hand, the corresponding chloro (Fig. 3-e) and nitro (Fig. 3-d) complexes show only one kind of methylene or methyl signal due to the amino-acidato chelate.

The appearance of the two kinds of methylene or methyl signals in the cyano-aminoacidato complexes can be attributed to the existence of two isomers such as shown in Fig. 5. We refer to them as *endo*(X,NH) form and *exo*(X,NH) form in this paper. Such an isomerism is originated from a puckering structure of the dien group and produces a remarkable difference in the direction of the hydrogen atom attached to the central nitrogen atom of dien. As Fig. 5 shows, the direction of this hydrogen atom of the *endo*(X,NH)



endo (X, NH) form *exo* (X, NH) form

Fig. 5. Two isomers of *trans*(O,X)-[Co(X)(gly)(dien)]$^+$.

isomer is toward the ligand X, while that of the *exo*-(X,NH) isomer toward the oxygen atom of amino-acidato chelate.

In order to confirm the existence of such isomers, we prepared another sample of *trans*(O,CN)-[Co(CN)(gly)-(dien)]$^+$ from *trans*(O,Cl)-[Co(Cl)(gly)(dien)]$^+$, which gave only one methylene signal in its PMR spectrum, according to Method 2. The cyano complex thus prepared gives an identical electronic absorption spectrum with that of the sample prepared from *trans*-[Co-(CN)$(SO_3)(NH_3)_4$], but its PMR spectrum exhibits only one methylene signal. As Fig. 3-b shows, this signal coincides with one of the two signals observed for the sample prepared by Method 1. The result strongly supports the existence of two stable isomers of *endo* and *exo* forms, in the cyano complex. It is not possible to correlate the chemical shift of methylene or methyl signal with the structure of these isomers at present. However, the complexes *trans*(O,Cl)-[Co(Cl)(gly)(dien)]ClO_4[8] and *trans*(O,NO_2)-[Co(NO_2)-(gly)(dien)]$Cl\cdot H_2O$[9] were determined to have the *endo* form by X-ray analysis. Consequently, the *trans*-(O,CN)-[Co(CN)(gly)(dien)]$^+$ prepared from the *trans*-(O,Cl)-[Co(Cl)(gly)(dien)]$^+$ can be assigned to the *endo*(CN,NH) form, since complete isomerization to the *exo* form during synthesis from the *endo* form seems to be very unlikely. The methylene signal of this cyano complex coincides with the higher field component of the doublet observed for the mixture of two cyano isomers prepared from [Co(CN)$(SO_3)(NH_3)_4$].

The isomerization reaction between the *endo* and the *exo* isomers is expected to take place relatively easily in an alkaline solution, since the reaction may involve deprotonation of the secondary amine of the dien group. In fact, the *trans*(O,CN)-[Co(CN)(gly)(dien)]$^+$ which gave only one methylene signal showed two kinds of methylene signals on being treated with aqueous hydroxide (pH 10, 60°C, 6 hr), as shown in Fig. 3-c.

The present isomerism would be attributed to the coordination of X on either of the non-equivalent sides of the N_4 plane involving the puckered rings of dien.[5] Hence, this kind of isomerism can not be substantiated in such complexes as [Co$(NO_2)_3$(dien)],[12] in which both sides of the N_4 plane are occupied by the same NO_2^- ions.

A similar isomerism was found by Gainsford and House[13] for [Co(Cl)(en)(dien)]$^{2+}$ (en=ethylenediamine).

The authors wish to express their thanks to Prof. Kazuo Saito, Tohoku University, for his encouragement throughout this work.

Rapid Solvent Extraction and Direct Spectrophotometric Determination of Lead(II) with 1,1,1-Trifluoro-4-(2-thienyl)-4-mercaptobut-3-en-2-one

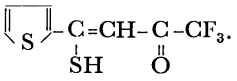
S. B. Akki and S. M. Khopkar

Department of Chemistry, Indian Institute of Technology, Bombay-76, India

(Received April 19, 1971)

The thio derivative of 2-thenoyltrifluoroacetone 1,1,1-trifluoro-4-(2-thienyl)-4-mercaptobut-3-en-2-one (STTA) is used for the simultaneous extraction and direct colorimetric determination of lead. About 100 μg of lead is quantitatively extracted, at pH 6.5, with 10 m*l* of 0.0020M STTA-CCl_4 as a bright orange colored complex, which can be measured spectrophotometrically at 480 nm. The system conforms to Beer's law over the concentration range of 1—40 μg/m*l* of lead(II). The color of the complex is stable for 60 hr. Lead can be quantitatively extracted and determined in the presence of a number of ions. The method is made selective by using some sequestering agents and carrying out selective extractions with mesityl oxide. The procedure is found to be suitable for the analysis of lead in gun metal and solder.

Thiothenoyltrifluoroacetone (1,1,1-trifluoro-4-(2-thienyl)-4-meracptobut-3-en-2-one) was used for the solvent extraction of several transition elements.[1] Lead also forms bright orange colored complex with this reagent around pH 6.5 which can be measured spectrophotometrically at 480 nm. The above reagent shall for the sake of brevity be assigned the symbol STTA indicating that it is a monosulphur substituted derivative of thenoyltrifluoroacetone commonly known as TTA. It has structural formula as:



The various β-diketones used as extractants for lead are acetylacetone,[2] benzoylacetone, dibenzoylmethane,[3] and thenoyltrifluoroacetone.[4] Extraction with acetylacetone was not quantitative, while that with dibenzoylmethane or benzoylacetone was possible only in alkaline media. Extraction with thenoyltrifluoroacetone needed high reagent anion concentration. Several other chelating agents[5] such as oxine, oximes, cupferron, azonaphthols, dithizone, neutral organophosphorus compounds were used for the extraction of lead to little advantage.

The method proposed by us is simple and rapid, and it affords clean-cut separation of lead from other ions. The method is sensitive and applicable at tracer concentrations. It is also found to be applicable to the analysis of lead in alloys such as gun metal or solder.

Experimental

Apparatus and Reagents. A type Cϕ4 quartz spectrophotometer with 10 mm matched cells; Cambridge pH meter; Wrist action flask shaker. 1,1,1-Trifluoro-4-(2-thienyl)-4-mercaptobut-3-en-2-one (STTA) was synthesised from 2-thenoyltrifluoroacetone (Fluka, A. G.) by the procedure of Berg and Reed.[6] About 0.0020M reagent in carbon tetrachloride was utilised. The reagent was always preserved in a refrigerator.

A stock solution of lead nitrate was prepared by dissolving about 1.6 g of lead nitrate (May and Baker, England) in 1 *l* of distilled water containing 0.01% nitric acid. The solution was standardised gravimetrically as the chromate[7] and was found to contain 1 mg of lead per m*l*. The dilute solution containing 100 μg/m*l* of lead was prepared by ten fold dilution.

A buffer solution of pH 6.5 was prepared by dissolving 77 g of ammonium acetate in water, acidified with acetic acid to pH 6.5, and diluted to 1 *l*.

General Procedure. An aliquot of lead nitrate solution (containing about 100 μg of lead) was taken. It was treated with 10 m*l* of buffer solution of pH 6.5 and then diluted with water to 25 m*l*. For the study of extraction as a function of pH, the buffer solution was not added except when pH 6.5 was required. In such cases the pH of lead nitrate solution was adjusted to the desired value with 0.01N nitric acid and 0.01N ammonium hydroxide, the pH meter being used and then the solution was diluted as above. For the study of the effect of diverse ions, the solution containing the foreign ion under investigation was added prior to the buffer solution. The aqueous solution was then transferred into a 250 m*l* separatory funnel. It was extracted for 10 min, on a wrist action flask shaker, with 10 m*l* of 0.0020M STTA solution in carbon tetrachloride. The solution was allowed to settle and separate into two layers. The bright orange colored organic phase was withdrawn in a 10 m*l* volumetric flask. It was then measured at 480 nm against the reagent blank. The amount of lead was then computed from the calibration curve.

Results and Discussion

Absorption Curve. The absorption spectrum of a solution of lead(II)-STTA complex (lead$=4.33\times10^{-4}$M) extracted at pH 6.5 is illustrated in Fig. 1; the reagent blank being used as a reference solution. The spectrum of the reagent blank against carbon tetrachloride is also given. The bright orange lead(II) chelate solution shows maximum difference in absorbance, between itself and the reagent blank at 480 nm.

Table 1. Extraction of lead(II)-STTA complex as a function of pH
Pb(II)=100 μg; 0.0020M STTA-CCl_4

pH	Extraction (%E)	Distribution ratio (D)
0.5	10.6	0.30
1.0	10.6	0.30
1.5	10.6	0.30
2.0	14.8	0.44
2.5	19.1	0.59
3.0	23.4	0.76
3.5	23.4	0.76
4.0	29.8	1.06
4.5	29.8	1.06
5.0	63.8	4.41
5.5	74.5	7.31
6.0	93.6	36.56
6.1	95.0	47.50
6.2	97.9	116.50
6.3	97.9	116.50
6.4	100.0	∞
6.5	100.0	∞
6.6	100.0	∞
6.7	97.9	116.50
6.8	85.1	14.17
6.9	85.1	14.17
7.0	85.1	14.17
7.5	85.1	14.17
8.0	85.1	14.17
8.5	63.8	4.41
9.0	48.9	2.40

The curve steadily falls and the absorbance of the complex becomes negligible beyond 600 nm. The reagent blank itself has strong absorbance till 460 nm and falls beyond this wavelength. Thus all the absorbance measurements were performed at 480 nm. The absorptivity at 480 nm is 4.803×10^2, calculated on the basis of lead content of 4.83×10^{-4}M, with an absorbance of 0.235 at 480 nm, when 1 cm cell was used.

Extraction as a Function of pH. The liquid-liquid extraction behaviour of lead(II)-STTA system was studied in the pH range of 0.5—9.0. The extraction is quantitative at pH of 6.4—6.6 (Table 1, Fig. 3). Beyond this pH the extraction decreases and becomes negligible at pH 9.0. Therefore, all extractions were carried out at pH 6.5 using the acetate buffer to facilitate rapid quantitative extractions.

Table 2. Applicability of Beer's law

Lead (II) taken, μg	Absorbance		
	475 nm	480 nm	490 nm
10	0.055	0.065	0.060
25	0.110	0.110	0.095
50	0.135	0.135	0.120

400	0.650	0.650	0.600

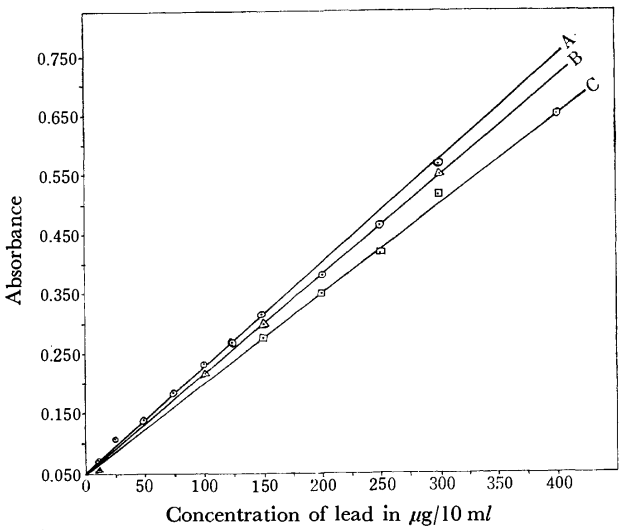

Fig. 2. Beer's law curve. pH=6.5
A=480 nm, B=475 nm, C=490 nm

Beer's Law Curve. Different amounts of lead(II) were taken and extracted at pH 6.5 as above. Their corresponding absorbances were measured at various wavelengths, *viz.* 475, 480, and 490 nm, to observe how colored system holds in the Beer's law (Table 2, Fig. 2). The Pb(II)-STTA system conforms to Beer's law over the concentration range of 1—40 μg of lead per m*l* at 480 nm.

Stability of Coloration. The absorbance of Pb(II)-STTA complex was measured at intervals of 0, 0.5, 1, 2, 3, 6, 12, 24, 48, 60, 72, and 96 hr. The absorbance is stable up to 60 hr, beyond which it undergoes about

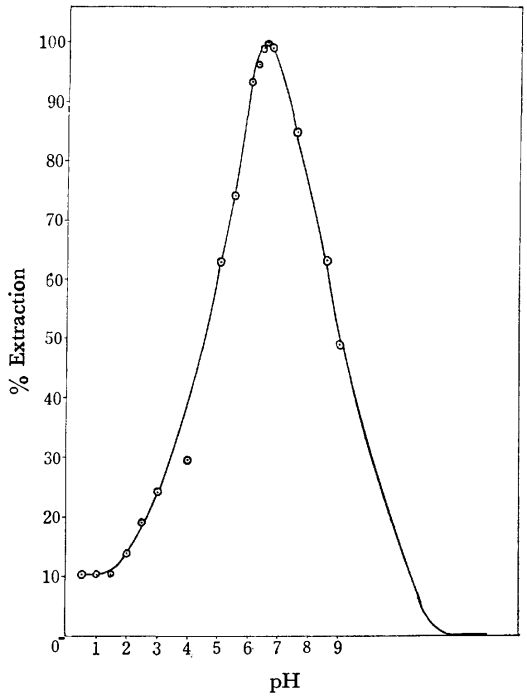

Fig. 3. Extraction as the function of pH.

4% decomposition. It is recommended therefore to measure the absorbance of the complex within 60 hr of extraction.

Reagent Concentration. With other factors being constant, the concentration of STTA was varied from 5.0×10^{-4}M to 2.0×10^{-3}M. The results in Table 3 indicate that the optimum reagent concentration is 10 m*l* of 2.0×10^{-3}M. Similarly, the absorbance is essentially constant with higher reagent concentration *e.g.* 3.0×10^{-3}M or 4.0×10^{-3}M. Extraction is incomplete with dilute solution of the reagent *viz.* 5.0×10^{-4}M, 1.0×10^{-3}M. The variation in volume of 2.0×10^{-3}M reagent showed that 10 m*l* of this reagent is quite adequate for quantitative extraction of lead.

Table 3. Effect of reagent concentration
(100 μg of Pb(II) after extraction with 0.0020 M STTA-CCl_4 at pH 6.5 gives an absorbance of 0.235±0.010 in 10 m*l* of solution.)

STTA concentration (M) $\times 10^{-3}$	STTA added (m*l*)	Absorbance at 480 nm
0.5	10	0.120
1.0	10	0.180
1.5	10	0.230
2.0	10	0.235
3.0	10	0.245
4.0	10	0.245
2.0	15	0.190
2.0	7.5	0.185
2.0	5.0	0.185

Diverse Ions. The effect of the presence of several ions on the extraction behaviour of lead was studied (Table 4). The tolerance limit was set at the amount required to cause ±2.0% error in the lead recovery. It was observed that the alkaline earths, alkali metals, fluoride, tartrate, ascorbate etc. are tolerated in the ratio of 1: 50; while thallium(III), aluminium, beryllium, arsenite, cyanide, sulphite, thiocyanate, malonate, citrate are tolerated in the ratio of 1: 10. Some elements form characteristic colored complexes with the reagent and show interferences. They are mercury, cadmium, palladium, noble metals, cobalt, nickel, and

cerium. However, the interference of ions such as antimony, rhodium, and thorium can be eliminated by using masking agents, while alkali fluoride can mask interferences due to aluminium, manganese and germanium. In addition, the process of selective extraction[5] with mesityl oxide (4-methyl-3-pentene-2-one) can eliminate interferences due to iron(III), chromium(III), molybdenum(VI), vanadium(V), and rhenium(VI), (Table 4). The interference due to copper or zinc can be similarly removed by prior extraction with acetylacetone,[3,8] or with 8-hydroxyquinoline-chloroform,[9,10] respectively.

Separation of Lead from Gun Metal. 0.692 g of gun metal was dissolved in concentrated nitric acid. Tin was removed as metastannic acid and it was determined gravimetrically. The filtrate was evaporated to dryness. The residue was dissolved in water and made up to 1 *l*. One milliliter of the diluted solution was then taken and adjusted to pH 2.5, and extracted with (10 $\times$5) m*l* of 0.1 M acetylacetone-benzene solution to remove copper.[3,8] The aqueous phase was then adjusted to pH 4.5 and extracted with (10$\times$3) m*l* of 0.01 M oxine-chloroform to remove zinc.[9,10] Finally the aqueous phase containing lead was taken and mixed with 10 m*l* of acetate buffer of pH 6.5, and extracted with 10 m*l* of 0.0020 M STTA in carbon tetrachloride. The bright orange colored Pb(II)-STTA complex was measured spectrophotometrically at 480 nm. The percentage of lead was found to be 4.90, 4.98, and 4.96 as against 5.0%.

Separation of Lead from Solder. About 0.5 g of the solder was dissolved in minimum volume of concentrated nitric acid. Tin was then removed as the insoluble residue of metastannic acid. The filtrate was evaporated to dryness, extracted with water and made up to 1 *l*. Two milliliters of this diluted solution was taken and mixed with 5% citric acid to complex antimony. Then 10 m*l* of buffer solution (pH 6.5) was added, and lead was extracted with 10 m*l* of 0.0020 M STTA-carbon tetrachloride and measured at 480 nm. The percentage of lead was found to be 58.2, 59.3, and 60% as against 59.5%.

Recommended Procedure and Precision. Take an aliquot of the solution containing 10—400 μg of lead in a separatory funnel. Add 10 m*l* of buffer solution of pH 6.5 to and shake it for 10 min with 10 m*l* of 0.0020 M STTA-carbon tetrachloride solution. Allow the layers to settle. Separate the aqueous layer into the beaker and organic layer into 10 m*l* volumetric flask. Then measure the absorbance of bright orange colored lead-(II)-STTA complex at 480 nm against the reagent blank. Calculate the lead concentration from the calibration curve.

In six runs with 100 μg of lead(II) the absorbance found was 0.235$\pm$0.010. The standard deviation was $\pm$1.2%.

Table 5. Accuracy data

Lead taken μg	Absorbance at 480 mμ	Lead found μg	% Error
30	0.115	30	0
40	0.125	41	2.0
60	0.170	62	3.3
110	0.250	112	2.0
175	0.360	175	0
275	0.525	273	3.5
		Av. Error = $\pm$1.8%	

Different amounts of lead(II) were taken and determined by the recommended procedure. The results (Table 5) are accurate to within $\pm$1.8%. Thus the proposed method has fairly good precision and accuracy within $\pm$1.8%. The total operation for each run requires only 25—30 min. The sensitivity of the method by Sandell's definition is 0.5 μg/cm^2 per m*l* of solution.

The Preparation of Bis(dimethylglyoximato)nitrosylcobalt(II) and its Conversion into the Nitro Complex

Motonori TAMAKI, Isao MASUDA, and Koichiro SHINRA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita

(Received June 21, 1971)

The preparation of diamagnetic $Co^{II}(dmgH)_2NO$ (dmgH=dimethylglyoximato monoanion) is reported. The complex shows the IR absorption band of NO at 1641 cm^{-1}, indicating a neutral NO ligand in the complex. The IR and electronic spectra are consistent with the structure of the penta-coordinate, the square-pyramidal configuration of the complex. In the presence of oxygen and water, the complex is oxidized rapidly ($NO \rightarrow NO_2^-$, $Co(II) \rightarrow Co(III)$) and converted into $Co^{III}(dmgH)_2NO_2 \cdot OH_2$. During the reaction, a complex formulated as $[Co^{II}(dmgH)_2NO \cdot OH_2][Co^{III}(dmgH)_2NO_2] \cdot 2H_2O$ is obtained. It is considered that, in the complex, the Co(II) is bound with the Co(III) through a NO bridge. The assignments of the IR spectra have been made using ^{15}NO and $^{15}NO_2$.

Thus far, many transition metal nitrosyl complexes have been prepared.[1] The low-spin Co(II) complexes with square-planar configurations are known to bind NO, thus forming diamagnetic, penta-coordinate Co(II) complexes with square-pyramidal configurations, such as CoAE(NO), CoSalen(NO), and $Co(dtc)_2(NO)$.[2,3] Recently, Schrauzer and Windgassen isolated planar $Co(dmgH)_2$,[2,4] with a magnetic moment of 1.70 B.M.

In this paper, the preparation and properties of $Co^{II}(dmgH)_2NO$ will be described. Of the transition-metal nitrosyl complexes with the same type of structure, the present complex is anomalous in that it is oxidized easily to form the nitro-Co(III) complex, $Co^{III}(dmgH)_2NO_2 \cdot OH_2$.

Experimental

Preparation of the Complexes. Bis(dimethylglyoximato)-nitrosylcobalt(II), $Co^{II}(dmgH)_2NO$; Complex I: a) $Co(CH_3COO)_2 \cdot 4H_2O$ (2.5 g) was dissolved in 30 m*l* of methanol, and the solution was saturated with NO at 0°C. Into this solution we stirred, drop by drop, dimethylglyoxime (2.3 g) suspended in 60 m*l* of ethanol. Bubbling NO into the solution for about 2 hours resulted in the precipitation of a black compound. The NO dissolved in the solution was driven off by nitrogen, then the precipitates were collected on a filter and washed with a small amount of water under a nitrogen stream. Three grams of a black, crystalline complex, I, were thus obtained.

Found: Co, 18.30; C, 29.91; H, 4.77; N, 21.69%. Calcd for $CoC_8H_{14}N_5O_5$: Co, 18.46; C, 30.10; H, 4.43; N, 21.95%. The same complex was obtained in a similar way in an acetone solution.

b) One gram of $Co(dmgH)_2$[3] was dissolved in 80 m*l* of methanol, and then NO was bubbled into the solution for about one hour with ice cooling, by which time the solution turned a brownish-black. After the remaining NO had been expelled with nitrogen, the solution was concentrated to 20 m*l* *in vacuo* at 50°C, thus leaving a crystalline precipitate of a brownish-black color. Yield: 0.5 g. The complex was proved to be identical with the complex I by a study of its IR spectral data.

Complex II: One gram of the complex I was quickly dissolved in 1 *l* of ether at room temperature, then the undissolved complex was filtered off. When the complex stood in air for a few minutes, yellowish-brown needles (complex II) were precipitated. Yield: 0.7 g.

Found: Co, 16.60; C, 27.08; H, 4.82; N, 19.51%. Calcd for $Co_2C_{16}H_{34}N_{10}O_{14}$: Co, 16.64; C, 27.12; H, 4.85; N, 19.78%. The complex II is soluble in methanol, tetrahydrofuran, and acetonitrile, but it is, unlike the complex I, sparingly soluble in benzene and insoluble in chloroform and ether.

The complex II was also obtained from a dichloromethane solution. One gram of the complex I was dissolved in 200 m*l* of dichloromethane, after which the solution was allowed to stand in air for about 24 hours (the solution had been concentrated to about 50 m*l*). Yellowish-brown needles, 0.7 g were thus separated. Elementary analysis and IR spectrum indicated the compound to be identical with the complex II obtained from ether solution.

Found: Co, 16.70; C, 27.22; H, 4.81; N, 19.84%. Calcd for $Co_2C_{16}H_{34}N_{10}O_{14}$: Co, 16.64: C, 27.12; H, 4.85; N, 19.78%.

Bis(dimethylglyoximato)nitroaquocobalt(III), $Co^{III}(dmgH)_2NO_2 \cdot OH_2$. One gram of the complex II was dissolved in a mixture of 150 m*l* of acetone and 10 m*l* of water. The solution was refluxed at 70—80°C for 10 hours, and then evaporated to 10 m*l* *in vacuo* to leave a brown precipitate (complex III). Yield: 0.8 g. This complex could be recrystallized from acetone.

Found: Co, 16.65; C, 27.34; H, 4.54; N, 20.00%. Calcd for $CoC_8H_{16}N_5O_7$: Co, 16.68; C, 27.20; H. 4.58; N, 19.83%. The complex III is soluble in methanol and acetonitrile, but insoluble in chloroform, ether, and benzene. The molecular weight, determined in an acetonitrile solution at 37°C by means of a Vapor Pressure Osmometer, was 341, corresponding to the value of 353 calculated on the basis of the above formula.

The complex III was also separated from an acetone solution of the complex II when it stood in air for two days.

The results of elementary analysis and the IR and UV spectral data agreed with those obtained for the same com-

pound prepared by Tschugaeff.[5]

^{15}NO-, and $^{15}NO_2$-Substituted Complexes. The (^{15}NO)-complex I was synthesized similarly by using ^{15}NO, generated from $K^{15}NO_3$ (97%).[6] The (^{15}NO)($^{15}NO_2$)-complex II and the ($^{15}NO_2$)-complex III were obtained from the (^{15}NO)-complex I. (^{15}NO)-complex I; Found: C, 29.01; H, 4.58; N, 21.92%. Calcd: C, 30.01; H, 4.42; N, 22.18%.

(^{15}NO)($^{15}NO_2$)-complex II; Found: C, 26.84; H, 4.38; N, 19.02%. Calcd: C, 27.12; H, 4.85; N, 19.78%.

($^{15}NO_2$)-complex III; Found: C, 27.33; H, 4.57; N, 19.91%. Calcd: C, 27.13; H, 4.56; N, 20.05%.

Measurements. The IR spectra were measured in Nujol or in hexachlorobutadiene, with a Hitachi 225 grating spectrometer for the 4000—200 cm^{-1} region and a JASCO IR-G spectrometer for the 4000—400 cm^{-1} region. The thermogravimetric analysis was carried out by using a Rigaku-denki thermobalance at a heating rate of 2°C/min under a nitrogen stream. The magnetic susceptibilities were measured at room temperature by the Gouy method. A nickel chloride solution was used as the calibrant. The electronic absorption spectra were obtained with a Hitachi EPS-3 spectrophotometer.

Results and Discussion

Complex I. The elementary analysis shows that the complex I has a composition corresponding to $Co(dmgH)_2NO$. The physical and chemical data, to be discussed below, agree with a structure where NO is bound axially to the central metal ion of the planar $Co^{II}(dmgH)_2$. As is seen in the IR spectrum in Fig. 1, $Co(dmgH)_2NO$ shows an absorption band at 1641 cm^{-1} which can be assigned to the NO stretching frequency.[7] The NO band observed in this region has been discussed as an indication of the neutral NO ligand in the complexes.[3a] Upon replacing the NO ligand with ^{15}NO, this band shifts to 1615 cm^{-1} (Fig. 1 and Table 1). Besides the above band, the bands at 575 cm^{-1} and 540 cm^{-1} are also observed to shift slightly to lower wave numbers. The IR spectral feature of $Co(dmgH)_2NO$ in the 1600—700 cm^{-1} region resembles that of the planar, metal complexes including dimethylglyoximato, such as $Ni^{II}(dmgH)_2$,[8] $Cu^{II}(dmgH)_2$,[9] and $[Co^{III}(dmgH)_2LL'](L,L'=Cl$ and/or $NH_3)$.[9]

The electronic absorption spectrum of the complex measured in a chloroform solution is presented in Fig. 2. The spectrum shows an absorption band at 20×10^3 cm^{-1} with $\log\varepsilon \fallingdotseq 2.8$. This band may be com-

parable to the band which has been taken as an indication of the square-pyramidal configuration of the complex, as in the cases of CoAE(NO),[3a] CoSalen(NO),[3a] or RCoSalen (R=C_2H_5 and C_6H_5),[10] though the assignment of these transitions has not yet been clarified. The diamagnetic property of the present complex is consistent with the above spectral data, both IR and electronic. Thus, this evidence has led us to propose a square-pyramidal configuration for the $Co(dmgH)_2NO$ complex.

As has been described in the Experimental part, $Co(dmgH)_2NO$ is easily converted into the complex III, which can be formulated as $Co(dmgH)_2NO_2\cdot OH_2$. The molecular weight, 341, determined in acetonitrile, is consistent with this formula. The electronic spectra in an aqueous solution and the IR spectrum are identical with those of $Co^{III}(dmgH)_2NO_2\cdot OH_2$,[11] which has been synthesized by Tschugaeff[5] in a different way. Four IR absorption bands, which are characteristic of the nitro group in the complexes,[12] $\nu_{as}(NO_2)$, $\nu_s(NO_2)$, $\delta(ONO)$, and $\rho_w(NO_2)$ are assigned for the complex III at 1453, 1321, 819, and 618 cm^{-1} respectively (Fig. 3 and Table 1). The above assignments have been confirmed by the shifts of the bands to a lower frequency upon replacing the $^{15}NO_2$. It is worth noticing that the band for $\rho_w(NO_2)$ can clearly be assigned by ($^{15}NO_2$)-substitution indicating that the NO_2 group coordinates through nitrogen.[13]

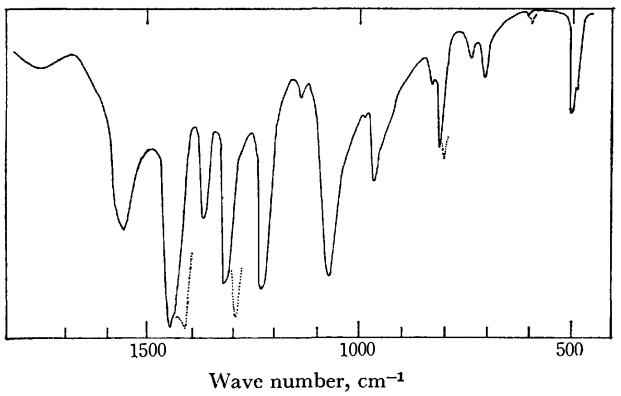

Fig. 3. IR spectra of $Co^{III}(dmgH)_2NO_2\cdot OH_2$ (——) and $Co^{III}(dmgH)_2$ ($^{15}NO_2$)$\cdot OH_2$ (·····) in Nujol.

Conversion of NO into NO_2^-. It has been extensively studied how, in a series of six-coordinate Co(III) complexes including the NO_2 ligand, such as $[Co^{III}(NH_3)_5NO_2]Cl_2$, NO_2 exists as ONO^- in an alkaline solution and as NO_2^- in an acid solution.[14] This isomerization proceeds reversibly depending on the pH of the solution. As for the NO^+ ligand, it has been found, in the case of $[Fe^{II}(CN)_5NO]^{2+}$, that the NO^+ ligand is converted into ONO^- in an alkaline solution.[15,16] Recently, Godwin and Meyer reported the NO^+ ligand of $[Ru^{II}(bipy)_2(NO)X]^{2+}$ (X=Cl, Br) reacts with the hydroxide ion in an aqueous solution to form NO_2^-.[17] As far as the neutral NO ligand is concerned, no report has been presented dealing with the conversion of NO into ONO^- or NO_2^-, though many of the nitrosyl complexes have been synthesized where NO has been considered to be formally neutral.[3,18]

As has been described in the Experimental section, $Co^{II}(dmgH)_2NO$ (I) is very unstable in water and is rapidly oxidized to $Co^{III}(dmgH)_2NO_2\cdot OH_2$(III). As may be seen in Fig. 2, the electronic spectrum of the complex I in an aqueous solution (curve 1) is quite different from that in chloroform (curve 2), but it is very close to the spectrum of the complex III in water (curve 4). These spectral data are thought to show that the conversion of the complex I into III takes place almost quantitatively. An oxygen-free, aqueous solution which was prepared by using a high vacuum line showed no absorption band at around 20×10^3 cm^{-1}. Upon exposing this solution to air, the solution came to show an absorption curve which is similar to the curve 1.

It may be said, from the above results, that, in an oxygen-free, aqueous solution, the complex I no longer preserves its penta-coordinate configuration and that both water and oxygen are consumed in the conversion reaction of the complex I to III.

Table 2. The ν(NO) of the nitrosyl complexes (cm^{-1})

	a (in Nujol mull)	*b* (in CH_2Cl_2)	*b*−*a*
$Co(dmgH)_2NO$	1641	1705	64
$Co(dmgH)_2(^{15}NO)$	1615	1680	65
CoSalen(NO)	1624	1666	42
CoAE(NO)	1654	1650	−4
CoBE(NO)	1635	1653	18

An aqueous solution of the complex I shows acid: pH =4.35 for 2×10^{-3} M, implying that the conversion reaction includes the addition of the OH^- anion to the NO ligand, as in the case of the reaction of $[Fe^{II}(CN)_5NO]^{2+}$ forming $[Fe^{II}(CN)_5ONO]^{4+}$ in an alkaline solution.[15] As may be seen from Table 2, the NO stretching frequency of the complex I observed at 1641 cm^{-1} in Nujol shifts to 1705 cm^{-1} in CH_2Cl_2 solution; this shift is considerably larger than those observed for other nitrosyl complexes with similar structures. These data are considered to reflect a larger polarization, as $(Co^{II})^{\delta-}$—$(N=O)^{\delta+}$ in the present complex, which may facilitate the OH^- addition, as is shown in Scheme (I).

$$(Co^{II})^{\delta-}-(NO)^{\delta+} + OH^- \longrightarrow \left[Co^{II}-N\begin{matrix}O\\ \diagdown OH\end{matrix}\right]^- \longrightarrow Co^{III}-NO_2 + H^+ \qquad (I)$$

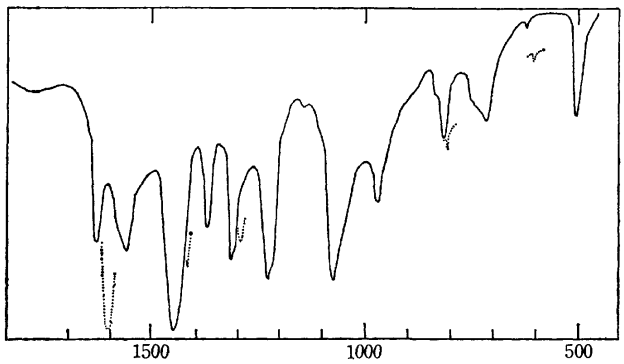

Fig. 4. IR spectra of $[Co^{II}(dmgH)_2NO\cdot OH_2]$ $[Co^{III}(dmgH)_2NO_2]\cdot 2H_2O$ (——) and $[Co^{II}(dmgH)_2(^{15}NO)\cdot OH_2][Co^{III}(dmgH)_2(^{15}NO_2)]\cdot 2H_2O$ (·····) in Nujol.

Complex II. This compound was separated as a crystalline precipitate during the conversion of the complex I into the complex III in an ether solution. The complex II is diamagnetic, and the results of elementary analysis are in fair agreement with the $Co_2(dmgH)_4NO\cdot NO_2\cdot 3H_2O$ composition. In the thermogravimetric analysis curve for the complex II, the weight loss of about 8.5% observed between 145—165°C is thought to correspond to the loss of three water molecules in the complex. Unlike the complex I, the complex II is insoluble in chloroform and ether. The complex exhibits the characteristic bands for both NO_2 and NO, as may be seen in Fig. 4 and Table 1. Each of the four bands for NO_2 is observed at almost the same frequency as for the complex III; the NO band is found to be slightly shifted to a lower frequency than in the complex I. These facts can hardly be understood without proposing that both the NO_2 and NO groups are involved in the complex. Thus, the structure of the complex II seems to include either a Co—Co bond or an NO bridge. The possible formation of a Co—Co bond by the interaction between Co(II) complexes with a low-spin d^7 configuration has been reported for $[Co^{II}(dmgH)_2B]_2$ where B is pyridine, aquo or triphenylphosphine.[4, 19] However, in the case of a diamagnetic complex such as $Co(dmgH)_2NO$, it is difficult to expect a similar Co—Co bond. With respect to the complexes with bridging NO, it has been reported that the NO band is observed at about 1500 cm^{-1} for $(C_5H_5)_3Mn(NO)_3$ and $[C_5H_5Cr(NO)_2]_2$.[20] The fact that the present complex shows the NO band at 1628 cm^{-1}, only slightly shifted to a lower frequency than that (1641 cm^{-1}) of the complex I, does not indicate clearly the existence of a bridging NO group. A very weak interaction through the NO group may be supposed to take place in the complex II.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 174—178(1972)

Thermal Properties of Copper(II) Chelates of Some 1,5-Alkylpentane-2,4-diones[1)]

Isao YOSHIDA, Yoshitsugu OONO, Hiroshi KOBAYASHI, and Keihei UENO
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka

(Received June 26, 1971)

Thermally stable and low melting copper(II) chelates of β-diketones have been synthesized as follows; bis(heptane-2,4-dionato)copper(II), mp 172°C; bis(nonane-4,6-dionato)copper(II), mp 162°C; bis(5-ethylheptane-2,4-dionato)copper(II), mp 72°C; bis(3-ethylnonane-4,6-dionato)copper(II), mp 50°C; bis(3,7-diethylnonane-4,6-dionato)copper(II), mp 58°C. Their thermal characteristics including enthalpy and entropy of fusion, have been discussed in relation with the molecular structure of the copper chelates.

In relation to our research project on the application of zone-melting technique to the systems containing metal chelate compounds,[2-6)] we have been interested in the metal chelates which melt at relatively low temperature without decomposition. It has been known that the introduction of alkyl groups on 1 and/or 5 positions of 2,4-pentanedione results in the lowering of melting point of the corresponding metal chelates.[7-10)] However, no systematic investigation on this respect have been appeared in literatures. This paper is to report on the results of the investigation on the thermal properties of copper(II) chelates of 1-

and/or 5-ethyl-substituted 2,4-pentanedione.

The ligands chosen in this study are heptane-2,4-dione (Etacac), nonane-4,6-dione (EtacacEt), 5-ethylheptane-2,4-dione (Et_2acac), 3-ethylnonane-4,6-dione (Et_2acacEt), 3,7-diethylnonane-4,6-dione (Et_2acacEt_2). The measurements of absorption spectra in visible as well as infrared region, the differential thermal analyses, the differential scanning calorimetric analyses, and the determination of melting point and molecular volume have been carried out on the 1:2 copper(II) chelates of the above ligands, and the relationship between the structure of the chelates and their thermal properties was discussed.

Experimental

Syntheses of Ligands. The ligands except Et_2acacEt and Et_2acac have been reported in the literatures, and they were synthesized by the condensation of corresponding ketone and ester in the presence of sodium amide. The ligands obtained were; Etacac (bp 67.5—70°C/20 mmHg),[11] EtacacEt (bp 101—102°C/20 mmHg),[8] and Et_2acacEt_2 (81—82°C/1.8—1.9 mmHg).[12]

The new ligands, Et_2acac and Et_2acacEt, were also synthesized in a similar manner to those described above, from 3-ethyl-2-pentanone and ethyl acetate for Et_2acac, and from 2-pentanone and phenyl 2-ethylbutyrate for Et_2acacEt. While the former was separated as pure ligand (bp 77°C/10 mmHg), the latter was not obtained as a pure form from the reaction mixture, and therefore the reaction product was directly converted into copper(II) chelate, which was eventually purified as copper chelate.

All these ligands were characterized in the form of copper(II) chelates by elemental analyses as shown in Table 1.

Preparation of Copper(II) Chelates. The copper(II) chelates of acac, Etacac, and EtacacEt were easily prepared by shaking stoichiometric amount of aqueous cupric acetate and the ligand, and the precipitated chelate was recrystallized from ethanol.

The copper(II) chelate of Et_2acac was prepared by the similar manner to the above procedure, but was obtained as dark violet oily product which crystallized after standing for a few hours. It was recrystallized from 80% ethanol to afford blue sticks. The chelate of Et_2acacEt_2, which was prepared by the similar manner, was also a dark violet oily product which slowly crystallized during 24 hours. If the ligand was not pure enough, the crystallization could hardly be observed. The crude chelate was recrystallized from 90% ethanol to afford blue sticks.

The copper(II) chelate of Et_2acacEt was prepared from the crude ligand and aqueous cupric acetate as described in the previous section. The crude copper chelate, which was obtained as a blue green oily product, was extracted with hexane. The hexane solution was washed successively with water and a saturated sodium bicarbonate solution. After evaporating hexane, blue oily residue was kept standing in a dish to afford a violet crystalline mass which was eventually purified by repeated precipitation from ethanol solution with water. No condition and solvent for the recrystallization of this chelate could be found.

The molecular formula and the analytical data of the chelates are summarized in Table 1.

Table 1. The molecular formula and the analytical results of the copper(II) chelates investigated

Chelate	Molecular formula	Elemental analysis Found C%	Found H%	Calcd C%	Calcd H%
$Cu(acac)_2$	$C_{10}H_{14}O_4Cu$	45.89	5.63	45.91	5.35
$Cu(Etacac)_2$	$C_{14}H_{22}O_4Cu$	52.90	6.99	52.90	6.98
$Cu(EtacacEt)_2$	$C_{18}H_{30}O_4Cu$	57.82	8.17	57.81	8.09
$Cu(Et_2acac)_2$	$C_{18}H_{30}O_4Cu$	57.83	8.23	57.81	8.09
$Cu(Et_2acacEt)_2$	$C_{22}H_{38}O_4Cu$	61.21	8.89	61.44	8.91
$Cu(Et_2acac Et_2)_2$	$C_{26}H_{46}O_4Cu$	64.12	9.65	64.23	9.54

Apparatus and Procedure. Melting points were observed on a micro-hot-stage with a Yanagimoto micro melting point apparatus (model MP-S2) which was calibrated with a standard sample.

Densities of the copper(II) chelate were determined by the standard procedure using a 3—4 m*l* picnometer. The volume of immersion liquid displaced by a known weight of a finely powdered solid chelate was measured at 25±0.1°C. The molecular volume was then calculated by deviding the molecular weight by density. The result is summarized in Table 2.

The heat of fusion was determined with a Perkin-Elmer Model DSC-18 differential scanning calorimeter. The differential thermal analysis was carried out on a Rigakudenki Thermoflex-8001 with a 3—5 mg sample sealed in an aluminum capsule at a heating rate of 3°C/min, using alumina as a reference, either in air or in nitrogen atmosphere.

The thermodynamic characteristics of the copper(II) chelates are summarized in Table 3.

The infrared spectra were measured with a JASCO Model DS-403G grating spectrophotometer on the samples in KBr pellet, and the absorption spectra in visible region were measured with a Hitachi Model 124 recording spectrophotometer.

Results and discussion

DTA Study. In order to evaluate the thermal stability of the copper chelates, the differential thermal analysis (DTA) was carried out on the samples in air as well as in nitrogen atmosphere. The results are given in Fig. 1. The DTA curves except for $Cu(acac)_2$, are characterized with a sharp endothermic peak A. The endothermic peak (A) temperature was found to be in good agreement with the melting point of the respective copper chelate which was determined by the micro-hot-stage method (Table 3).

The repeated DTA measurement on the same sample up to the temperature 15°C above the melting point of the chelate, did not show any change of the endothermic temperature. This implies that the peak is not due to the decomposition, but purely due to the fusing process. This was also confirmed by the comparison of the infrared spectra of the samples before and after the DTA run, which were found to be exactly superimposable.

The samples of $Cu(Etacac)_2$, $Cu(Et_2acacEt)_2$, and $Cu(Et_2acacEt_2)_2$ did not show any change in the

12) E. H. Man, F. W. Swamer, and C. R. Hauser, *ibid.*, **73**, 901 (1951).

endothermic peak area and peak temperature as well as the sample weight during the repeated runs. On the other hand, $Cu(Etacac)_2$ decreased its sample weight and the peak area. The change can be ascribed to the slow sublimation or vaporization of the sample during the heating process.

As to $Cu(Et_2acac)_2$, a single endothermic peak at 71°C splitted into two peaks at 65°C and 70°C after the first run, however the sample weight and peak area remained constant during the repeated runs. As the twin peaks did not change after the second run, this may be related with a kind of phase transition accompanied with the fusing process.

The endothermic peak B at higher temperature in nitrogen atmosphere is related with the decomposition of the samples, while the complicated exothermic peaks in air at the same temperature range being related with the oxidative decomposition of the samples.

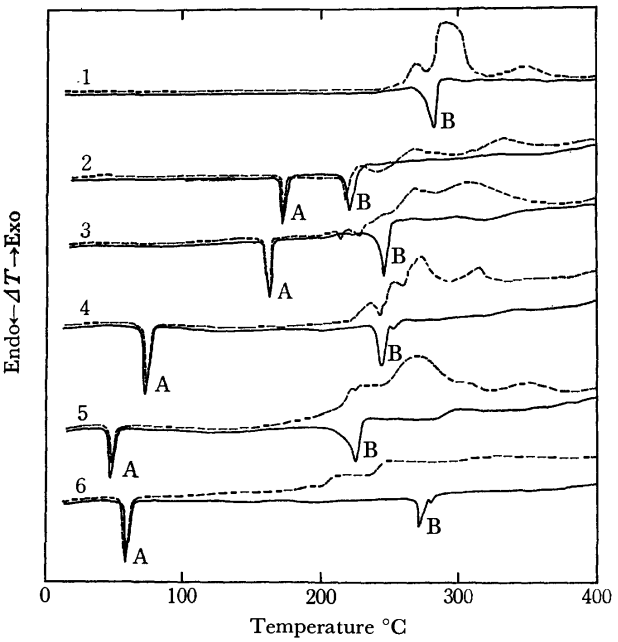

Fig. 1. DTA curves of the copper (II) chelates heated in nitrogen atmosphere (——) and in air (·····).
1. $Cu(acac)_2$ 2. $Cu(Etacac)_2$ 3. $Cu(EtacacEt)_2$
4. $Cu(Et_2acac)_2$ 5. $Cu(Et_2acacEt)_2$ 6. $Cu(Et_2acacEt_2)_2$

The thermal stability of copper chelates, roughly estimated by the decomposition peak temperature, increases in the order of $Cu(Et_2acacEt)_2 < Cu(Etacac)_2 < Cu(Et_2acac)_2 < Cu(EtacacEt)_2 < Cu(Et_2acacEt_2)_2 < Cu(acac)_2$. In general, the copper chelates of the symmetric ligands are more stable than those of the unsymmetric ligands, and the melting point becomes lower with increasing number of terminal ethyl groups on the ligand. Thus, the temperature range where the molten chelate is stable, is widest for $Cu(Et_2acacEt_2)_2$ and becomes narrower in the order of $Cu(Et_2acacEt)_2$, $Cu(Et_2acac)_2$, $Cu(EtacacEt)_2$, and $Cu(Etacac)_2$. Finally, the chelate of non-ethylated ligand, $Cu(acac)_2$, can not exist as molten state.

Spectral Study. As shwon in Table 4, the infrared absorption bands due to the stretching mode of C=C and C=O bonds in the chelate ring do not shift significantly from one chelate to another. The result suggests that the introduction of ethyl groups on 1 and/or 5 positions of pentane-2,4-dione does not affect appreciablly the bond strengths in the chelate ring of bis(pentane-2,4-dionato)copper(II).

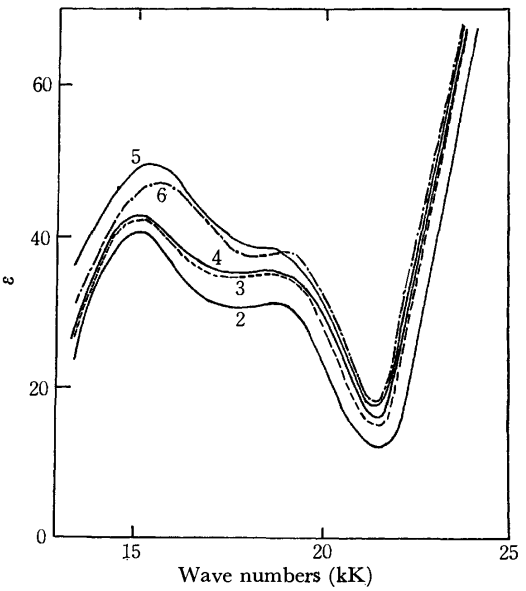

Fig. 2. Visible absorption spectra of copper(II) chelates in carbon tetrachloride at room temperature.
2. $Cu(Etacac)_2$ 3. $Cu(EtacacEt)_2$ 4. $Cu(Et_2acac)_2$
5. $Cu(Et_2acacEt)_2$ 6. $Cu(Et_2acacEt_2)_2$

The visible absorption spectra of the copper chelates in carbon tetrachloride are shown in Fig. 2. The spectra are characterized with two peaks at about 15000 cm^{-1} and 17500 cm^{-1} which shift very little with the kind of ligand, and the spectra are very similar to that of bis(pentane-2,4-dionato)copper(II) which is known to take a tetra-coordinate square planar structure. The similarity of visible absorption spectra regardless of the kind of ligands indicates that the introduction of ethyl groups on the terminal methyl carbon of the ligands does not cause any intramolecular steric hindrance which may results in the change in the symmetry of square planar coordination structute. The construction of molecular model also proved that the terminal ethyl groups did not cause any steric repulsion between the opposing two ligands in the chelate molecule. Furthermore, the molecular model suggested that the terminal ethyl groups fixed into rather restricted spaces with least steric interaction with the chelate ring, so that the ethyl groups could not rotate freely but extend above or below the *x-y* plane of the copper chelate.

The molecular volume of the chelate increases with the increasing number of ethyl groups introduced into the ligand as shown on the fourth column in Table 2. However, the increase of molecular volume per ethyl group increases as the complexity of the chelated ligand increases as indicated on the fifth column of Table 2. This tendency may be attributed to the mutual interaction of ethyl groups, as the increment should be unchanged if there is no interaction between the ethyl groups. As to the question of whether the interaction of ethyl groups is intramolecular one or

$Cu(acac)_2$	$-Cu(EtacacEt)_2$	127.8	32.0	6.8
$Cu(EtacacEt)_2$	$-Cu(Et_2acacEt_2)_2$	155.7	38.8	

intermolecular one, the latter seems to be true from the following observations. First, there operates no steric interaction between the terminal ethyl groups within the ligand molecule or of opposing two ligands in the copper(II) chelate, as proved by the molecular model. Secondly, the extent of the contribution of additional ethyl groups to the increase of molecular volume of less complicated ligands remains almost the same as visualized in Table 5. If the interaction between the ethyl groups within the same ligand does exist, the value on the last column in Table 5 should increase with increasing degree of interaction. Additionally, molecular volume of $Cu(EtacacEt)_2$ and of $Cu(Et_2acac)_2$ are nearly equal (Table 2).

It has been shown that the visible absorption spectra of bis(pentane-2,4-dionato)copper(II) in chloroform (15000 cm⁻¹ and 18000 cm⁻¹) changed into single band in pyridine (15200 cm⁻¹). According to Ortolano,[13] of the two absorption bands in chloroform, a band at 18000 cm⁻¹ is assigned to a transition of d_{xy}—d_{z^2}. When the chelate is dissolved in a strongly coordinating solvent such as pyridine, this band receives a bathochromic and hypsochromic change and emerges into the parent band resulting in a broad band at 15200 cm⁻¹ region, the reason for which is explained as the coordination of pyridine molecule to the central copper ion along the *z*-axis.

The similar spectral change was observed on the copper chelates investigated in this study, when they were dissolved in pyridine and in 2,6-lutidine. The results are summarized in Table 6. In contrast to

Table 6. Characteristic visible absorption bands of copper(II) chelates in various solvents

13) L. L. Funck and T. R. Ortolano, *Inorg. Chem.*, **7**, 567 (1968).

the spectra in pyridine, where the frequency of absorption maxima remained almost unchanged for all chelates, those in 2,6-lutidine were broader in band width and showed rather wide variation in the frequencies. The latter spectra may be understood to be an intermediate stage of coordination of solvent molecule to the copper(II) ion, where the band due to d_{xy}—d_{z^2} transition does not completely emerge into the parent band, resulting in the broadening and the apparent bathochromic shift of the parent band. If it is the case, the extent of bathochromic shift of a bond near 15300 cm^{-1} in 2,6-lutidine from that in pyridine, can be used as a measure of estimating the intensity of interaction between the solvent molecules and the chelated copper(II) ion. In other words, the greater is the shift of the band between the two solvents, the weaker is the coordination of solvent molecules to the chelated copper(II) ion. As shown in Table 6, the order of decreasing intensity of interaction between 2,6-lutidine and the copper ion is $Cu(Etacac)_2 > Cu(EtacacEt) > Cu(Et_2acac)_2 > Cu(Et_2acacEt)_2 > Cu(Et_2acacEt_2)_2$. This order is in accordance with the shielding effect of ethyl groups introduced on 1- and/or 5-carbon of pentane-2,4-dione, if one assume that the terminal ethyl groups extend above or below of the *xy* plane of copper(II) chelate as discussed above.

Refering to the thermodynamic characteristics on the fusion of copper(II) chelates, it is noticed that the melting point of the chelate is dependent upon ΔH_f term rather than ΔS_f term. The monotonous decrease of the enthalpy of fusion with the increasing number of terminal ethyl groups introduced on the ligand, is understood to be due to the increase of intermolecular distance as suggested by the molecular volume, and also due to the increasing shielding effect by the terminal ethyl groups.

It is also noticed that ΔS_f decreases as ΔH_f decreases with an exception of $Cu(Et_2acac)_2$. Such parallel change of ΔS_f and ΔH_f can be often found in a series of hydrocarbon compounds. The change of entropy of fusion may be explained mainly in terms of the difference in crystal structure, if one remined that the structure of the chelate ring is found to be almost the same for all ligands and that the terminal ethyl groups are conceivably fixed in rather restricted spaces. Thus the difference of ΔS_f can be understood to be mainly due to the difference in ordering of the chelate molecules in the crystalline state.

As to the copper chelates of unsymmetric ligands, there is a possibility that the solid chelate is a mixture of *cis*- and *trans*-isomers, which may result in the lowering of melting point, lower than the expected value for one of the isomers. This effect must be most prominent for $Cu(Et_2acac)_2$, because the ligand is most unsymmetric. Thus, values of the thermodynamic parameters for $Cu(Et_2acac)_2$ do not fit in the general tendency of those of other chelates.

As discussed above, the melting point of bis(pentane-2,4-dionato)copper(II) lowers with the increasing number of ethyl groups introduced on 1- and/or 5-position. Although the result can be discussed semiquantitatively by the spectroscopic evidences as well as the thermodynamic data, the crystal structure data are needed for the more quantitative discussion of the melting point of these metal chelates.

DSC measurements were carried out by courtesy of Professors T. Oyama and K. Takamizawa, to whom the authors are thankful. They are also grateful to the Ministry of Education for a grant-in-aid for scientific research.

Isomerism of the Metal Complexes containing Multidentate Ligands. I. Geometric and Optical Isomers of the Bis(diethylenetriamine)-cobalt(III) Ion[1]

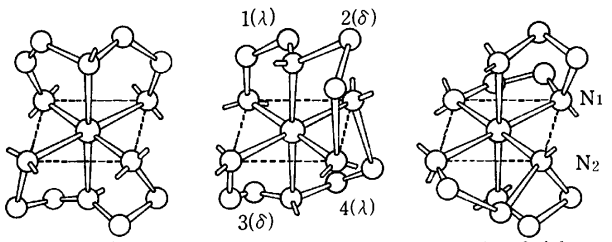
Yuzo Yoshikawa and Kazuo Yamasaki

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received July 15, 1971)

Three possible isomers of bis(diethylenetriamine)cobalt(III) halide were isolated by column chromatography on ion-exchange cellulose and Sephadex, and the *mer*- and *u-facial* isomers were completely resolved by column chromatography on SE-Sephadex. These isomers were studied by electronic, infrared, and PMR spectroscopy, and the absolute configuration of the *u-facial* isomer was assigned on the basis of the circular dichroism spectrum.

The cobalt(III) complex of diethylenetriamine (abbreviated as dien), $[Co(dien)_2]X_3$, was first described by Mann[2] in 1934. Later Brigando *et al.*[3] and also Schmidtke[4] measured the absorption spectrum in the visible and ultraviolet regions, and Basolo *et al.*[5] determined the rate of proton exchange of this complex. These authors, however, did not refer to the possible isomers of this complex, and it is not certain which isomer was used for these investigations. The complex, $[Co(dien)_2]X_3$ can exist in three geometric isomers, as is shown in Fig. 1; the isomerism has been discussed by several authors,[6–10] but the isomers have never been isolated and characterized. In a previous paper[11] we have reported the resolution of one of the isomers of this complex by column chromatography on P-cellulose. The details of the isolation and characterization of all three isomers will be described in the present paper.



(a) *s-facial* (b) *mer* (c) *u-facial*

Fig. 1. Three geometric isomers of $[Co(dien)_2]^{3+}$. The hydrogen atoms of the $-CH_2-$ groups are not shown. The figure 1 (c) represents the configuration of the $(+)_{589}$-*u-facial* isomer. The configuration of $(+)_{589}$-$[Co(penten)]^{3+}$ is the same with 1(c), the N_1 and N_2 atoms being linked by an ethylene group.

Experimental

1.1. Measurements. All the measurements were carried out at 25°C. The electronic absorption, optical rotatory dispersion (ORD), and circular dichroism (CD) spectra were measured by means of a JASCO ORD/UV-5 and a JASCO J-20 spectrometer, using quartz cells 1, 5, and 10 mm thick. The intensities of the ORD and CD spectra were checked using those of $(+)_{589}$-$[Co(en)_3]Br_3 \cdot H_2O$, $[M]^{25}_{589} = 602°$,[12] and $\Delta\varepsilon_{490} = +1.89$[13,14] as references. The infrared spectrum (4000—650 cm^{-1}) was measured with a JASCO-402G infrared spectrophotometer by using Nujol and hexachlorobutadiene mulls, and the far-infrared spectrum (700—200 cm^{-1}), with a Hitachi EPI-L spectrophotometer by using Nujol mulls. The PMR spectrum in deuterated dimethylsulfoxide was determined using a JEOL model C-60H spectrometer with tetramethylsilane(TMS) as the reference, the concentration used being 20 wt%.

1.2. Ligand. Commercially-available diethylenetriamine was further purified by vacuum distillation.

1.3. Synthesis of the Isomers. The complex was prepared as mixtures of isomers by the following four methods.

Method A: Cooled diethylenetriamine (7.7 g) was dissolved in 30 m*l* of cold water, and to this solution 14 g of $K_3[Co(CO_3)_3] \cdot 3H_2O$[15] was added in small portions with vigorous stirring. The mixture was kept at 0—3°C during the reaction for about one hour. One gram of active charcoal was then added and stirring was continued for 5 hr. After the solution had been kept at 0°C overnight, 100 m*l* of ice water and then 25 m*l* of concentrated hydrobromic acid were slowly added under cooling (5—10°C). After the evolution of carbon dioxide, the active charcoal was filtered off and the filtrate was evaporated to half the volume. The crystallized yellowish needles were filtered, recrystallized from water, washed with aqueous ethanol (1:1), and dried in air. The yield of the complex bromide, which was named the isomer A, was about 1 g. The above reaction mixture contained three isomers, and the formation ratio was found to be: *s-facial*: *u-facial*: *mer* = 16:25:59 by separation on an SE-Sephadex column and by subsequent spectrophotometric determination (*cf.* 1.4).

Method B: To 50 g of $[CoBr(NH_3)_5]Br_2$ suspended in 400 m*l* of water, 2 g of active charcoal was added, and then 30 g of diethylenetriamine was slowly added in about one hour. Ammonia was evolved, and then the stirring was continued for 24 more hours at 25°C. The charcoal was then filtered off, and the filtrate was evaporated to half its volume under reduced pressure. Large amounts of ethanol and diethyl ether were then added until the precipitation was complete. The yellowish-brown powder thus obtained was filtered and washed several times with 1-butanol and once with diethyl ether, and then dried in air. The yield was 65.5 g. This product is a mixture of three isomers with the formation ratio of *s-facial: u-facial: mer*=7:30:63, which was determined by separation on an SE-Sephadex column as has been described above.

Method C: A mixture of isomers was also obtained by adding diethylenetriamine to a cobalt chloride solution in the presence of active charcoal and by then oxidizing the reaction mixture with air or hydrogen peroxide. This method gave almost the same results as the method B.

Method D: To 2 m*l* of diethylenetriamine, 0.8 g of finely ground *mer*-$[CoCl_3(dien)]$[7] was added. The mixture was well triturated for about 20 min in an ice-bath, and then the the excess diethylenetriamine was thoroughly washed away with 1-butanol. The remaining solid was dissolved in a small amount of water, and the isomers were separated by column chromatography as has been described in 1.4. The product obtained contained only the *u-facial* and *mer* isomers in the ratio of 8:92. This preparative method is not an equilibrium one, but was used for confirming the configurational assignment of the *mer* (the isomer C).

1.4. Separation of the Isomers. Since the separation of three isomers by the conventional fractional crystallization technique was unsatisfactory and laborious, a chromatographic method using ion-exchange Sephadex[16] and cellulose was developed. The SE-Sephadex used was a product of Pharmacia, Sweden, with a particle size of 40—120 μ and an ion-exchange capacity of 2.3 ± 0.3 meq/g. A mixture of the isomers obtained by one of the above methods, A, B, C, or D, was poured on an SE-Sephadex column (diameter, 3.0 cm; length, 120 cm) and eluted with a 0.15 M sodium $(+)_{589}$-tartrate solution at the rate of 1.2—1.4 m*l* per minute. Three completely-separated bands were thus obtained. The fastest moving complex was named A; the middle one, B, and the slowest one, C. The isomer A is the same as the one which is least soluble among the products obtained by the method A. Three isomers, A, B, and C, were found by experiments to be described in the later sections, to be *s-facial*, *u-facial*, and *mer* isomers respectively. Eluted fractions of the isomer B were optically active, indicating a partial resolution. Consequently, the isomer B was identified as the *u-facial* isomer. An example of the separation experiment is shown in Fig. 2.

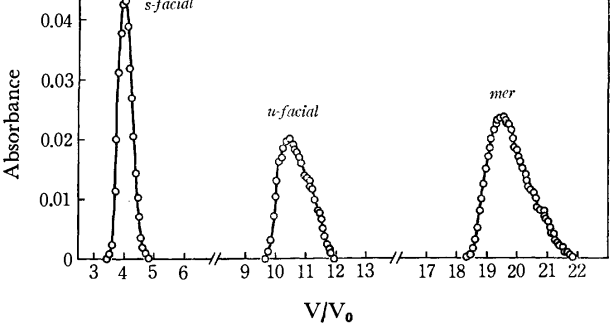

Fig. 2. Elution curves of an equimolecular (0.02 mmol) mixture of three isomers of $[Co(dien)_2]^{3+}$. Eluent: 0.15M sodium $(+)_{589}$-tartrate solution. The horizontal axis shows the volume ratio of the effluent *versus* the bed volume of the column.

The isomers could also be separated on a P-cellulose column (100 cm long), using 1-butanol saturated with water as the solvent, and a mixture of 1-butanol, concentrated hydrochloric acid, and water in a ratio of 200:15:15 as the eluent. First, the *mer*, then *s-facial*, and lastly *u-facial* isomers were eluted. Each isomer was back-extracted into the water phase, which was then evaporated to dryness. The chlorides thus obtained were recrystallized from water, washed quickly with an equal mixture of water and ethanol, and then dried in air.

The bromides of the *mer* and *u-facial* isomers were prepared by passing the respective chlorides through an ion-exchange resion column of the bromide form. The *s-facial* bromide was obtained as the least soluble isomer by the method A. The *mer* iodide was obtained by converting the chloride on an ion-exchange resin column of the iodide form. The *u-facial* and *s-facial* iodides were precipitated when potassium iodide was added to solutions of the *u-facial* and *s-facial* chlorides respectively.

1.5. Resolution of the u-Facial *and* Mer *Isomers.* The chromatographic method using SE-Sephadex described in 1.4 was also applied, with minor modifications, to the complete resolution of the *u-facial* and *mer* isomers. When eluted by a sodium $(+)_{589}$-tartrate solution, the adsorbed *u-facial* isomer was not clearly separated into two bands, but the initial and last several fractions indicated an almost complete resolution. The use of a 0.3 M sodium antimony $(+)_{589}$-tartrate solution instead of a sodium $(+)_{589}$-tartrate solution caused the two bands corresponding to $(+)_{589}$ and $(-)_{589}$ antipodes to be completely separated in the column. The fast-moving band corresponds to the $(+)_{589}$-antipode with the CD value of $\Delta\varepsilon_{502}=+0.98$ and the molar rotation of $[M]_{589}=+211°$ (*cf.* Fig. 3). The optically-active complexes, both $(+)_{589}$ and $(-)_{589}$, have the same chemical composition, $[Co(dien)_2]\cdot Cl_3\cdot H_2O$, while the racemic complex has two moles of water of crystallization.

The resolution of the *mer* isomer was first carried out by Searle and Keene[17] by the conventional fractional crystallization of the diastereoisomers. The chromatographic method used in the resolution of the *u-facial* isomer has been successfully applied by us to the resolution of the *mer* isomer as well. The *mer* isomer adsorbed on a column of SE-Sephadex was eluted by a 0.3 M sodium antimony $(+)_{589}$-tartrate solution. First $(+)_{589}$ and then $(-)_{589}$ antipodes were eluted with complete separation. The effluents thus obtained were diluted five times, and then they were again adsorbed on columns of SE-Sephadex. After the columns had been washed with 0.01 N hydrochloric acid, each antipode was eluted with 1 N NaCl containing 0.01 N HCl. To the effluents, potassium hexacyanocobaltate(III) was added. The sparingly soluble yellowish crystals thus obtained were suspended in 0.01 N HCl with an ion-exchange resin (Dowex 1X8) in the chloride form. After the solution had been stirred for 2 hours, the resin was filtered off. The filtrate which contained the optically-active chloride was again

passed through a column of Dowex (chloride form) to ensure its conversion into the chloride, and then it was evaporated to dryness. The resulting chloride was dissolved in water and precipitated by adding ethanol. The rotation observed for $(+)_{589}$-*mer*-$[Co(dien)_2]Cl_3$ has its maximum at 484 mμ with the value of $[M]_{589}=-658°$ (*cf* Fig. 4). The half-time of the racemization of the aqueous solution is about 4 weeks at room temperature.

Results and Discussion

2.1. Chemical Compositions. The three isomers have the chemical compositions shown in Table 1; they have been characterized by a study of their infrared, electronic, and PMR spectra.

Table 1. Chemical composition of the isomers

Complex	Elemental analyses (Calcd value)			
	Co	Halogen	N	H_2O
s-facial $[Co(dien)_2]Cl_3\cdot H_2O$	15.05 (15.12)	27.08 (27.30)	—	4.58% (4.62)
$[Co(dien)_2]Br_3$	11.58 (11.67)	47.41 (47.47)	16.70 (16.64)	
$[Co(dien)_2]I_3$	9.29 (9.12)	58.93 (58.94)	— —	
u-facial $[Co(dien)_2]Cl_3\cdot 2H_2O$[a]	14.38 (14.46)	25.88 (26.09)	—	8.78 (8.84)
$[Co(dien)_2]Br_3\cdot H_2O$	11.25 (11.27)	45.87 (45.87)	16.29 (16.07)	3.53 (3.44)
$[Co(dien)_2]I_3\cdot H_2O$	8.91 (8.88)	57.27 (57.33)	— —	2.60 (2.71)
mer $[Co(dien)_2]Cl_3\cdot 2\frac{1}{2}H_2O$	14.03 (14.14)	25.13 (25.53)	— —	10.81 (10.81)
$[Co(dien)_2]Br_3\cdot 2H_2O$	10.74 (10.89)	44.07 (44.31)	15.65 (15.53)	7.10 (6.67)
$[Co(dien)_2]I_3\cdot \frac{1}{2}H_2O$	8.94 (9.00)	58.25 (58.39)	— —	1.17 (1.38)

a) Optically active antipodes, both $(+)_{589}$ and $(-)_{589}$, have one mol of water of crystallization.

The isomer B has been proved to have the *u-facial* structure by its resolution into optical antipodes. The *mer* isomer is also resolvable, but its optical activity is less stable than that of the *u-facial* isomer.[17] The *s-facial* isomer cannot be resolved because it has a center of symmetry. The X-ray crystal analysis of *s-facial*-$[Co(dien)_2]Br_3$ has recently been carried out by Saito *et al.* This complex cation has a center of symmetry with an approximate C_{2h} symmetry.[18]

The distinction between *mer* and *s-facial* isomers was made by studying the PMR spectrum. The preparative method D also afforded additional evidence for the meridional structure of the isomer C.

2.2. Circular Dichroism Spectrum. The structure of the two complex ions, $[Co(dien)_2]^{3+}$ and $[Co(penten)]^{3+}$, are closely related; they are different only in that a fifth chelate ring joining the two secondary nitrogen atoms is present in the latter (*cf.* Fig. 1). Therefore, the absolute configuration of $[Co(penten)]^{3+}$ may give a clue to the elucidation of that of the *u-facial*-$[Co(dien)_2]^{3+}$. The X-ray crystal analysis of $(+)_{589}$-$[Co(en)_3]^{3+}$ [19] and $(+)_{589}$-$[Co(penten)]^{3+}$ [20] showed that both ions have the same *Λ* configuration in terms of the IUPAC nomenclature.[21] The absolute configuration of the latter ion has also been assigned on the basis of the stereospecificity of the methylated penten.[22]

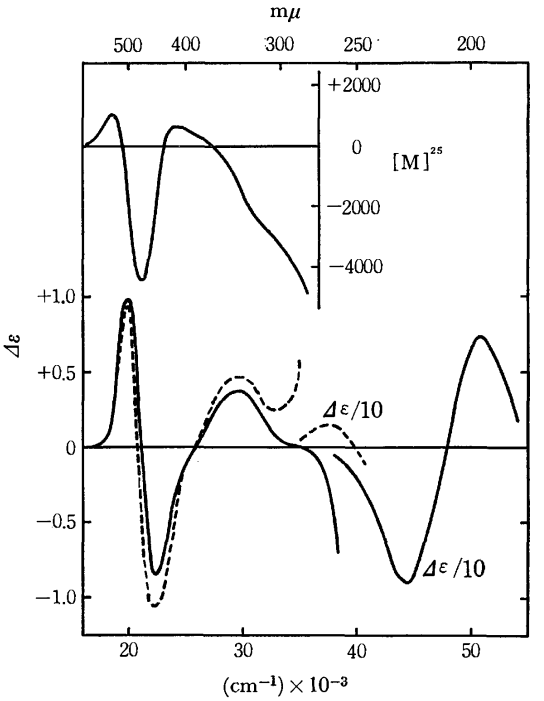

Fig. 3. Optical rotatory dispersion (upper curve) and circular dichroism (lower curve) spectra of $(+)_{589}$-*u-facial* $[Co(dien)_2]Cl_3$;——in water and·····in 0.2M Na_2SeO_3.

The relationship between the absolute configuration and the CD spectrum of $(+)_{589}$-$[Co(en)_3]^{3+}$ has been well established. This complex has a major positive band and a minor negative band at a lower and a higher frequency in the region of the octahedral $^1A_{1g}\rightarrow T^1_{1g}$ absorption, the area of these CD bands being diminished and enhanced respectively by the addition of selenite or phosphate ions.[23,24] The same relationship holds also for $(+)_{589}$-$[Co(penten)]^{3+}$.[22] The ORD and CD curves of $(+)_{589}$-*u-facial*-$[Co(dien)_2]^{3+}$ are shown in Fig. 3. The CD spectrum shows a lower-energy positive ($\Delta\varepsilon=+0.98$, 19900 cm^{-1}) and a higher-energy negative ($\Delta\varepsilon=-0.84$, 22500 cm^{-1}) component in the region of the first ligand-field band. Further, another positive component ($\Delta\varepsilon=+0.37$, 29900 cm^{-1}) exists in the region of the second band, and intense negative and positive components ($\Delta\varepsilon=-9.0$, 44400 cm^{-1} and $\Delta\varepsilon=+7.4$, 50700 cm^{-1}) in the region of the charge-transfer band. Since the sign and magnitude of the

CD bands of $(+)_{589}$-*u-facial*-$[Co(dien)_2]^{3+}$ are similar to those of $(+)_{589}$-$[Co(en)_3]^{3+}$ and $(+)_{589}$-$[Co(penten)]^{3+}$, it may be concluded that these three complexes have the same absolute configuration, *Λ*, those of the dien and penten complexes being shown in Fig. 1.

Further, from a consideration of the sign of the CD band in the charge-transfer region,[25] each five-membered chelate ring can be presumed to have the conformation shown in Fig. 1. The X-ray determination of the absolute configuration of the $(+)_{589}$-*u-facial*-$[Co(dien)_2]^{3+}$ is now under way by Prof. Y. Saito, University of Tokyo. Both the ring-pairing method[26] and the octant rule[27] support the absolute configuration proposed here.

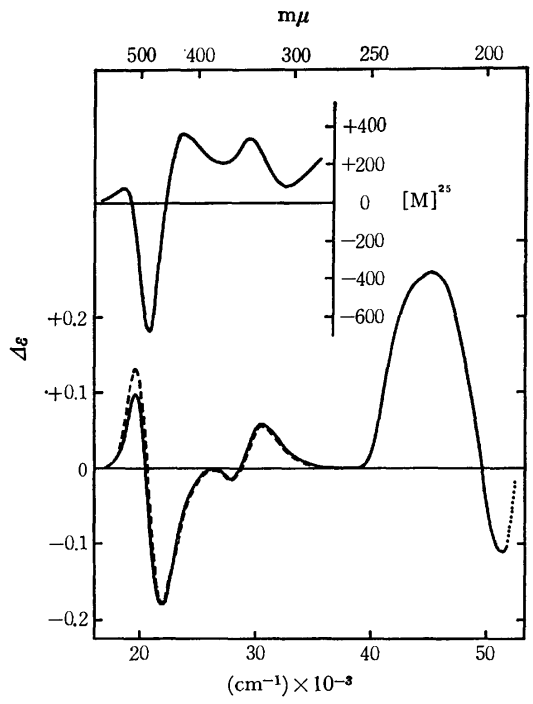

Fig. 4. Optical rotatory dispersion (upper curve) and circular dichroism (lower curve) spectra of $(+)_{589}$-*mer*-$[Co(dien)_2]Cl_3$; ——in water and ·····in 0.2M Na_2SO_4.

In Fig. 4 the ORD and CD curves of the $(+)_{589}$-*mer*-$[Co(dien)_2]Cl_3$ are shown. The CD spectrum has peaks split into two in the regions of the $^1A_{1g} \rightarrow {}^1T_{1g}$ ($\Delta\varepsilon = +0.096$, 19500 cm^{-1}; $\Delta\varepsilon = -0.181$, 21900 cm^{-1}) and $^1A_{1g} \rightarrow {}^1T_{2g}$ ($\Delta\varepsilon = -0.014$, 27800 cm^{-1}; $\Delta\varepsilon = +0.057$, 30700 cm^{-1}) transitions; these are much less intense than those of the $(+)_{589}$-*u-facial* isomer. In the charge-transfer region, a CD peak with a weak intensity is observed. The $(-)_{589}$-antipode shows an identical CD spectrum with the opposite sign. In 0.2 M sodium sulfate, the intensity of the lower-energy band in the first absorption region is enhanced, while the other peaks are affected very little. Sodium sulfate is used because sodium selenite commonly used accelerates the racemization because of the increase in the pH. The optically-active *mer* isomer is stable only in the pH region lower than 6.

In the structure of the *mer* isomer shown in Fig. 1, both the skew chelate pairs, 1,3 and 2,4 have the *Λ* (*δ*, *λ*) configuration, while the pairs, 2,3 and 1,4 have the *Λ*(*δ*, *δ*) and *Λ*(*λ*, *λ*) configurations respectively. This isomer, therfore, has, as a whole, an equal number of *Λ* and *Λ* configurations, and *δ* and *λ* conformations. Thus, the dissymmetric effects seem to be cancelled out. Nevertheless, CD peaks, though very weak, are observed; they may be due to the integration of the three different configuraions and conformations mentioned above.

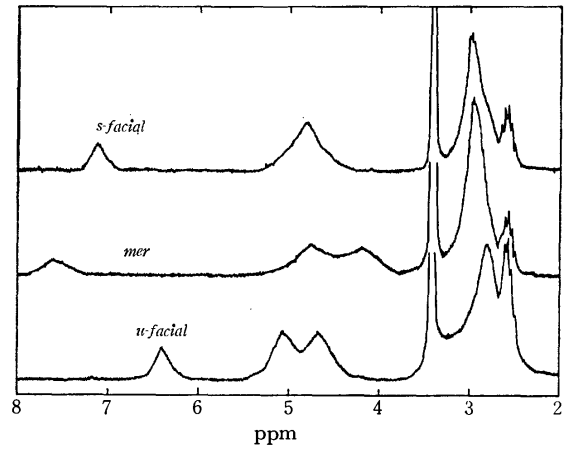

Fig. 5. PMR spectra of *s-facial* (curve 1,) *mer*(curve 2) and *u-facial* (curve 3) isomers of $[Co(dien)_2]I_3$ in deuterated DMSO.

2.3. *PMR Spectrum.* Figure 5 shows the PMR spectra of the three isomers taken in deuterated dimethylsulfoxide. The isomer A shows broad signals at *δ* 4.80 and 7.12 (intensity ratio 4: 1); the isomer C at *δ* 4.18, 4.75, and 7.60 (intensity ratio 2: 2: 1), and the isomer B, at *δ* 4.68, 5.08, and 6.40 (intensity ratio 2: 2: 1). From the intensities, the siganls at *δ* 4.0—5.5 are assigned to the protons in NH_2 groups, and those in the lower field, to the protons in NH groups, both of which are broadened by the quadrupole relaxation of the ^{14}N nucleus.[28]

The signal at *δ* 3.4 is due to water remaining in the solution, and that at *δ* 2.5—2.6, to residual CH_3 groups in the deuterated solvent. Further, the signals of methylene groups appear at *δ* 2.7—3.0. As is clear from the structures shown in Fig. 1 the NH_2 signals for the *mer* and *u-facial* isomers should be split into two, while only one signal can be expected for the *s-facial* isomer.

In the *s-facial* isomer, the NH_2 groups are equivalent, while the other two isomers have unequivalent sets of two NH_2 groups. The observed results agree with the expectation, and so the isomer A is identified as *s-facial*. The signal due to two equivalent NH groups of the *u-facial* isomer should be in the highest field because the two central nitrogen atoms may be displaced from the

octahedral positions by large non-bonded interactions around them, while that of the *mer* isomer should be in the lowest fields (*cf.* 2.4). On the basis of these results, the isomer A, B, and C are identified as *s-facial*, *u-facial*, and *mer* respectively. Yoneda *et al.*[29] reported the PMR spectrum of $[Co(dien)_2]Cl_3$ in trifluoroacetic acid without referring to the isomerism. Judging from the reported spectrum, their sample seems to be the *mer* isomer.

2.4. Electronic Absorption Spectrum. The absorption spectra of the three isomers in the region 18000—52500 cm^{-1} are shown in Table 2 and Fig. 6. By stereochemistry the *mer* isomer is more distorted from a regular octahedron than the other two. Consequently, it may reasonably be concluded that the distortion of the ligand molecule makes the Co–N(secondary) bond length shorter than the Co–N(primary) bond length, and that two terminal nitrogen(primary) atoms are considerably displaced from the apices of a regular octahedron. This expected difference in bond lengths has been found by X-rays for several complexes, as shown in Table 3.

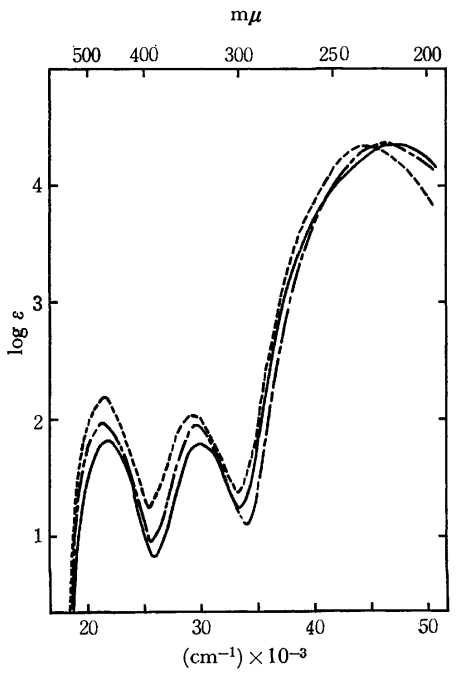

Fig. 6. Absorption spectra of three isomers of $[Co(dien)_2]Cl_3$ in water; —— *s-facial*, ····· *mer* and -·-*u-facial*.

Table 3

Complex	M-NH	M-NH_2	Ref.
mer-$[Co(NO_2)gly(dien)]Cl \cdot H_2O$	1.91Å	1.94Å	30
mer-$[CoCl(gly)(dien)]ClO_4$	1.94	1.99	30
mer-$[Ni(dien)_2]Cl_2 \cdot H_2O$	2.05	2.16	31

If the conformational structure (δ,λ) of each chelate ring is not taken into consideration, the *s-facial* isomer can be said to have a center of symmetry,[18] while the other two have none, and the structures of the latter two may deviate considerably from an octahedron. This expectation agrees with the intensity of the *d–d* absorption bands shown in Table 2. On the other hand, the first ligand field bands, which are observed at 21800, 21600, and 21500 cm^{-1} for *s-facial*, *mer*, and *u-facial* isomers respectively, reveal that the ligand field is highest for the *s-facial* isomer and lowest for the *u-facial* isomer. In spite of the strained structure, the *mer* isomer has a higher ligand field than the *u-facial* isomer. Presumably it contributes to this result that the Co–N(secondary) bond in the *mer* isomer is appreciably stronger than the others. The above result is consistent with the PMR results.

By comparing the absorption bands reported by Brigando[3] and Schmidtke[4] with those of the present investigation, we find that the sample used by Brigando seems to be a mixture of the *mer* and *u-facial* isomers, while that of the latter investigator is the *mer* isomer.

2.5. Infrared Spectra. Recently Schmidtke and Garthoff[32] studied in detail the infrared spectra of the geometric isomers of mono(diethylenetriamine)

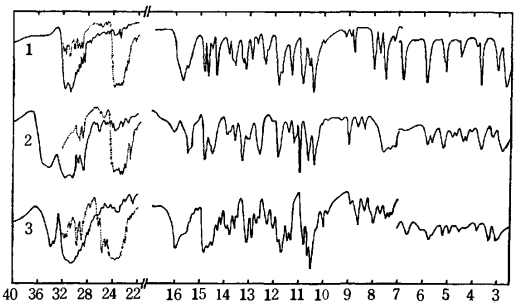

Fig. 7. Infrared spectra of *s-facial* (curve 1), *mer* (curve 2), and *u-facial* (curve 3) isomers of $[Co(dien)_2]Br_3$. ····· deuterated complexes.

32) H. H. Schmidtke and D. Garthoff, *Inorg. Chim. Acta*, **2**, 357 (1968).

complexes of Rh(III), Cr(III), and Co(III), and concluded that the *facial* and *meridional* isomers can be distinguished by different spectral features. Buckingham and Jones[33] have also studied the infrared spectra of isomers of diacido(triethylenetetramine)cobalt(III) complexes. On the basis of these results, and also of those of ethylenediamine complexes, the infrared spectra of $[Co(dien)_2]Br_3$ are assigned. The spectra in the region 4000—300 cm^{-1} are shown in Fig. 7.

In all three isomers the NH stretching vibrations observed at 3200—3000 cm^{-1} shift to 2400—2250 cm^{-1} on deuteration, with the ratio of $\nu_{NH}/\nu_{ND}=1.33$—1.34. The frequency of these vibrations is highest for the *u-facial*, medium for the *mer*, and lowest for the *s-facial* isomers. For the *mer* isomer, a medium strong band appears at 2848 cm^{-1} and this shifts to 2128 cm^{-1} on deuteration ($\nu_{NH}/\nu_{ND}=1.35$), while the other two show only very weak bands in this region. Therefore, this band may be characteristic of the *mer* isomer, and it can tentatively be assigned to the NH stretching vibration of the secondary amine.

The absorption bands at 1610—1550 cm^{-1} shift on deuteration to 1220—1150 cm^{-1} with the ratio of $\nu_{NH}/\nu_{ND}=1.32$—1.36; therefore, they are identified as antisymmetric NH_2 bending vibrations. The *mer* isomer showed a larger splitting in the same region; it may be due to the two unequivalent NH_2 groups. In the region lower than 600 cm^{-1}, the bands due to ring deformation and those related to the Co–N bonds coupled with them are observed. Generally the *s-facial* isomer shows fewer and sharper bands than the other two, as is to be expected from its higher symmetrical structure.

A near-infrared band of HDO was used to study the kinetics of proton exchange[34] in these three isomers; it was found that the NH group exchanged protons faster than the NH_2 group of the ligand and that, further, the rate of the exchange of the NH group of the *mer* isomer is largest among the three isomers.[35] This fact is consistent with the position of the NH signal of the *mer* isomer in the lowest magnetic field (*cf.* 2.3).

The authors appreciate the experimental contribution of Mr. A. Imai in the early stage of the present investigation. A part of the expenses was met by a Grant-in-Aid of the Ministry of Education.

The Analytical Application of Sulfur Analogues of β-Diketones. I. The Extraction Spectrophotometric Determination of Cobalt(II) with 1,1,1-trifluoro-4-(2-thienyl)-4-mercaptobut-3-en-2-one (STTA)

Takaharu HONJYO and Toshiyasu KIBA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa, Ishikawa Prefecture

(Received July 26, 1971)

The solvent extraction of cobalt(II) with 1,1,1-trifluoro-4-(2-thienyl)-4-mercaptobut-3-en-2-one (abbreviated as STTA) in cyclohexane has been investigated, and a new spectrophotometric method for the determination of minute amounts of cobalt has been developed on the basis of the results obtained in the extraction study. When a sample solution the pH of which had been adjusted to 6.0—6.5 with hydrochloric acid or sodium hydroxide solution was shaken with a 10^{-3}M STTA organic solution, the extraction of cobalt(II) proceeded rapidly and quantitatively. The amount of cobalt up to 8 ppm in the final organic phase could be determined by measuring the absorbance at 480 or 490 nm against the reagent blank. All other interferring ions, such as Hg(II), Cu(II), Ni(II), Pb(II), Zn(II), and Fe(III), extractable together with cobalt(II) could be stripped out of the organic phase by shaking it with 1—12M hydrochloric acid, while cobalt remained in the organic phase as it was. After this treatment, the organic phase was shaken with an aqueous buffer solution of pH 9—11; thereby, the excess of the reagent was released to a great extent from the organic phase into the aqueous solution. The cobalt-STTA chelate was then the only one existing in the organic phase; therefore, the sensitivity and the selectivity of the method increased so much that a few ppb of cobalt(II) could be determined precisely by measuring the absorbance of the final organic phase at 360 nm against the reagent blank. In this work, the apparent mole ratio of STTA to cobalt in the complex formation was estimated to be 4: 1, and the molar absorption coefficients of the chelate in cyclohexane were found to be 4970000 (at 360 nm), 13200 (at 450 nm), 6500 (at 480 nm), and 5500 (at 490 nm) respectively. Anions, such as oxalate and citrate, as well as EDTA interfered with this extraction. By the recommended procedure, cobalt of a few ppb in an analytical-grade reagent of nickel nitrate hexahydrate could be determined.

Thenoyltrifluoroacetone (abbreviated as TTA) is a well-known chelating agent useful for the solvent extraction and for the colorimetric determination of various metal ions.[1] One of its substituents, monothiothenoyltrifluoroacetone (1,1,1-trifluoro-4-(2-thienyl)-4-mercaptobut-3-en-2-one, abbreviated as STTA), in which one oxygen atom of TTA is replaced with sulfur, has stimulated the interest of many investigators because of its chemical and physical behaviors. Because of the difficulty of its preparation, however, this attractive reagent has not been extensively investigated. However various monometric monothio-derivatives of β-diketones have appeared in the past seven years thanks to the efforts of Chaston *et al.*,[2,3] Uhlemann and Müller,[4] Berg and Reed,[5] and Yokoyama, *et al.*,[6] and many energetic investigations of the coordinative properties of the metal chelates are now under way. Among these reagents, STTA has been found to form its chelates with transition elements, each of them having a specific color and the attribute of being extracted with organic solvents.[5,7,8] Taking advantage of this behavior, the extraction spectrophotometric determination of copper,[9] palladium,[10] and mercury,[11,12] with STTA and the use of the isotope-dilution method for mercury[13] with monothio-dibenzoylmethane have been tried. Nevertheless, the chemical properties of monothio-derivatives of β-diketones and their metal chelates have not yet been reported in detail. The present authors aimed to investigate the extraction behavior of STTA chelates of various metals, and, as a first step, attempted to prepare the STTA reagent by their own method, based on the report by Berg and Reed.[5] After preliminary experiments, the STTA was found to react with the divalent cobalt ion to form a complex of extreme stability. The present paper will describe the extraction-spectrophotometric method for the determination of cobalt with STTA in cyclohexane. The method seems to be more sensitive and selective for cobalt than other methods consisting of synergistic solvent extraction and spectrophotometry, *i.e.*, with benzoyltrifluoroacetone in the presence of tri-*n*-octylphosphine oxide.[14]

Experimental

Apparatus. The visible and ultraviolet absorption spectra were obtained with a Hitachi EPU-2A type spectro-

photometer with 1-cm quartz cells. Radioactivity counting was done with a Kobe Kogyo NaI (Tl) well-type scintillation counter, Model PS-400, connected to a transistorized scaler, Model SA-250. A Hitachi-Horiba glass electrode pH meter, Model M-3, was employed for the pH measurement. A Iwaki shaking machine, type KM, was used for the agitation of the aqueous and organic phases in the solvent extraction. The melting point of the prepared STTA was measured with a Yanagimoto Micro Melting-point Apparatus, Model MP-J2. The infrared absorption spectra were obtained by the nujol method with a Japan Spectroscopic Infrared Spectrophotometer, Model DS 301.

Materials. A stock solution of cobalt(II) was prepared by dissolving a definite amount of cobalt(II) chloride hexahydrate of a guaranteed grade in distilled water, and it was standardized by EDTA titration, using MX as an indicator.[15] The concentration of the solution was estimated to be 0.97×10^{-3} M. The STTA was synthesized in the authors' laboratory by the following procedure, which was based on the method reported by Berg and Reed: the starting substance, TTA, was first stored in a desiccator containing silica gel in order to dry it satisfactorily. Anhydrous ethanol was prepared by adding 5 g of metallic sodium to 500 m*l* of commercial-reagent-grade ethanol (99.5%), by heating it under reflux for 5 to 8 hr, and by then distilling the alcohol. Hydrogen sulfide gas from a steel bomb (from Seitetsu Kagaku Co.) was introduced into a washing bottle containing distilled water dried through a glass tube containing anhydrous calcium chloride, and thereafter passed into the reaction vessel. Hydrogen chloride gas was generated by dropping concentrated sulfuric acid onto solid sodium chloride of a suitable amount in a distillation flask under occasional heating; the gas evolved was introduced from the outlet tube of the flask into a washing bottle containing concentrated hydrochloric acid, and then into another one containing concentrated sulfuric acid. After having been dried well, the hydrogen chloride gas was also passed into the reaction vessel. The dehydration of these three materials, ethanol, hydrogen sulfide, and hydrogen chloride, might lead a worker to a successful synthesis of STTA. This vital part of the process has, however, not been described, not even by Berg and Reed;[5] therefore, if one works according to their procedure, the result might fail. The synthesis in this work was done by a method modified by the present authors as follows. Into a 500-m*l* flask with four necks, 5 to 10 g of TTA and 150 to 200 m*l* of the dehydrated ethanol were put through the large central neck of the flask, and then the vessel was cooled to 0°C in an ice bath. The dried hydrogen chloride gas was introduced through the first slender neck into the vessel in order to saturate the gas in it. The dried hydrogen sulfide gas was then passed through the second slender neck into the reaction vessel for 3 to 4 hr under occasional shaking. Here the third slender neck was useful for letting the gases out under slow suction. The content of the vessel began to turn dark red even after the passing of hydrogen sulfide gas for only about thirty minutes, but the passing of the gas was continued for 3 to 4 more hr in order to complete the reaction. The dark red solution thus obtained was poured over ice in a beaker; the red precipitate of STTA began gradually to appear as the ice melted. The product was separated from the solution by filtration, washed with an appropriate amount of water and dried by sucking the air through the filter and finally on the silica gel in a desiccator. The dried substance was submitted to its recrystallization from the dehydrated ethanol and further purified by repeating the recrystallization twice or thrice. The purified STTA was sealed in a brown-colored bottle in a nitrogen atmosphere and stored in a refrigerator kept at 5°C. The reagent when stored in this manner was quite stable during the storage for as long a time as two years or more, but once it was placed in the air, it slowly turned dark by oxidation. The synthesis was repeated seven times; all were successful when the described procedure was followed exactly. The STTA purified by the recrystallization from dehydrated ethanol showed a melting point of 60—70°C, but the material insufficiently purified or incompletely dried showed a melting point lower than that. The STTA in cyclohexane showed its absorption maximum at 365 nm and a molar absorption coefficient of 1.90×10^{4}. The characteristic absorption frequencies and their assignments were as follows: 1623 (ref. 1612,[3] 1620[5]) ν (C=O); 1260 (ref. 1260,[3] 1258[5]) μ (C=S); 817 (ref. 817,[3] 819[5]) μ (C=S)+δ(C–H). The stock solution of STTA prepared by dissolving the reagent in cyclohexane so as to be 10^{-3}—10^{-2} M was stored in a brown-colored bottle placed in a refrigerator to avoid its decomposition before use. A dilute reagent solution has a yellow color, and the concentrated solution, a red color. The concentration of the reagent was checked from time to time by measuring the absorbance at 350—450 nm. The cyclohexane was purified by distillation, and the chloroform, by washing it successively with a dilute sodium hydroxide solution, water, dilute hydrochloric acid, and three portions of water, and by finally distilling it. Thenoyltrifluoroacetone of a guaranteed reagent grade was purchased from the Dojindo Research Laboratory Co., Ltd., and was used as a starting substance for the synthesis of STTA after drying the commercial reagent in a desiccator containing silica gel. All the other reagents were of a reagent grade and were employed without further purification.

Procedure. An aqueous solution containing cobalt(II) ions was made to have 0.1 M acetic acid (in the acidic region) or 0.1 M boric acid (in the basic region), and its pH was adjusted to a desired value. Ten milliliters of this solution and 10 m*l* of 10^{-3} M STTA in cyclohexane were put together in a 30-m*l* glass-stoppered centrifuge tube and agitated by means of a mechanical shaker for 15—30 min at room temperature (25—29°C). After the separation of the two phases by centrifugation, the amount of cobalt(II) in the cyclohexane was determined by measuring the absorbance at 480 or 490 nm. The extractability of cobalt(II) was also determined by using a ^{60}Co tracer and by counting the radioactivity in both phases with a NaI (Tl) scintillation counter. The pH of the aqueous phase was checked again after each extraction.

Results and Discussion

Absorption Spectra. The absorption spectra of STTA in cyclohexane and those of the extracted cobalt(II)-STTA chelate are shown in Fig. 1. The absorption curve of the chelate has its maximum at 450 nm, but the absorbance of the reagent blank is remarkably large around this wavelength. The measurement of the absorbance of the chelate was, therefore, performed at 480 or 490 nm.

Effect of pH. The effect of the pH on the extractability of cobalt(II) of 10^{-4}M with 10^{-3} M STTA in cyclohexane was examined; the results are shown in Fig. 2 in terms of the absorbance of the chelate. A complete and quantitative extraction is found to be accomplished in the pH region between 5.5 and 7.5. The decrease in the distribution in the basic region may be due to

the increasing solubility of STTA into the aqueous phase, since a yellow color appears in the aqueous beyond pH 6.0. This gradually turns yellowish red with an increase in the pH, while the original color of the reagent in the organic phase fades little by little. Some yellow deposit of an unknown composition is observed in the aqueous phase at pH 9.0.

Effect of Organic Solvents. STTA was dissolved in various organic solvents to make various 10^{-3}M STTA solutions, and the extraction of ^{60}Co in concetrations lower than 10^{-10}M was performed with these organic solutions. Among cyclohexane, benzene, carbon tetrachloride, chloroform, and methyl isobutyl ketone, cyclohexane was found to be the most excellent solvent to extract cobalt in the lower pH region, as can be seen in Fig. 3. In the lower pH region, hydroxo-complexes of many metals are not formed; therefore, serious interference can be avoided spontaneously. This is the reason for our preferring cyclohexane as a solvent in this study. The distribution of cobalt from a 10^{-4}M solution was found to be somewhat lower than that of radioactive cobalt in a trace amount. This might be attributed to the decrease in the effective concentration of STTA in the organic phase caused by the consumption of the reagent during the chelate formation and also to the time-lag needed to reach the extraction equilibrium.

Effect of the Reagent Concentration. The extraction of cobalt from a 10^{-4}M aqueous solution with cyclohexane containing STTA of varying concentrations was done; the absorbance of the organic phase is given in Fig. 4 in terms of the initial concentration of STTA in cyclohexane. The results show that it is enough to keep the

concentration of STTA four times that of cobalt in order to achieve the quantitative extraction of the metal.

Effect of Shaking Time. The extractability of 10^{-4}M cobalt with 10^{-3}M STTA in cyclohexane at pH 6.0 is given in Fig. 5 as a function of the shaking time. The quantitative result is attained in about ten minutes of shaking.

Effect of the Volume of the Aqueous Solution. When the volume of the organic phase of 10^{-3}M STTA in cyclohexane was kept at 10 m*l*, when that of the aqueous phase was varied from 10 m*l* to 100 m*l*, and when the absorbance of the organic phase was measured at 480 nm after every extraction, almost the same absorbance was obtained in each case, as is shown in Fig. 6. Therefore, the volume of the initial aqueous solution seems to have no effect on the extraction recovery of cobalt, even at a ten-fold volume of the organic phase.

Stability of the Extracted Chelate. By measuring the absorbance of the cobalt-STTA chelate in cyclohexane at 480 nm at long intervals, the brown color

of the chelate was found to be quite stable; it showed no change in the absorbance for several weeks. The extraction was carried out in natural daylight and also in the dark, but no differences in the distribution as in the absorbance could be found between the two cases.

Back-extraction of the Chelate from the Organic Phase. The back-extraction of the extracted chelate was attempted by shaking the organic phase with hydrochloric acid of from 1 to 12M for thirty minutes. It was found that the back-extraction of cobalt did not occur at all. On the other hand, when the organic phase was shaken with an aqueous buffer solution of pH 9.0—11.0, the excess of the STTA reagent was almost entirely transferred into the aqueous solution, leaving only the cobalt-STTA in the organic phase. Thus, by the above two treatments, other interferring ions could be stripped out and the excess of the STTA be back-washed from the organic phase; therefore, the spectrophotometric determination of cobalt might be more sensitive and selective. This can be readily seen in Fig. 7, in which the absorbance of the organic phase after shaking with aqueous solutions of varying pH values, one at 480 nm when cobalt-STTA is present and another at 440 nm when only STTA is present, are shown together for the sake of comparison. The

Aqueous phase 10 m*l*. Shaking time: 30 min.
—●— Co-STTA, —○— reagent blank.

STTA in the organic phase is found to begin to transfer itself into the aqueous phase at pH 6.0; it completely dissolves into the aqueous solution of pH above 9.5. On the other hand, the cobalt-STTA remains in the organic phase, as before. The absorbance of this cobalt-STTA could keep its value constant for at least several hours. The absorption spectra of the cobalt-STTA chelate remaining in the organic phase after back-washing with an aqueous solution of pH 9 and pH 11 are shown in Fig. 8, in which the reagent blank is found to have remarkably decreased, particularly at pH 11, without any effect on the STTA chelate. Thus, when the uncombined STTA was removed from the organic phase, the quantitative determination of cobalt could be extended to the order of ppb in the final organic phase.

Recommended Procedure and Working Curve. From the experimental results described above, a useful procedure for cobalt could be developed as follows. From 10 to 100 m*l* of an aqueous sample solution, the pH of which had been adjusted at 6.0—6.5 with 0.1M acetic acid and 0.1M sodium hydroxide, was put in a 30—300 m*l* glass-stoppered centrifuge tube or separating funnel, and 10 m*l* of 10^{-3}M STTA cyclohexane solution was then added into the vessel. The content was agitated by a mechanical shaker for 15 to 30 min at room temperature (25—29°C). After

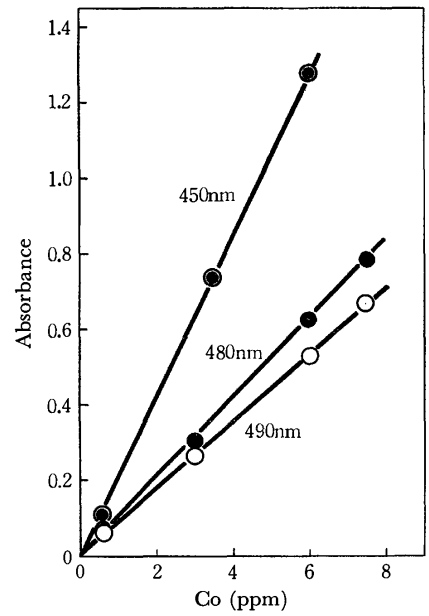

Fig. 9. Working curves for cobalt(II) at different wavelength.

Organic phase: 10 m*l* of 10^{-3}M STTA-cyclohexane.
Shaking time: 15—30 min.

the lower aqueous phase had been separated off, the remaining organic phase was shaken again with 1M hydrochloric acid and then with a buffer solution of pH 9.0—11.0. After centrifugation, the organic phase was taken out to determine its absorbance at 450, 480, or 490 nm arbitrarily against the reagent blank. The analytical working curves prepared at each wavelength are shown in Fig. 9, in which it is found that Beer's law is obeyed up to 8 ppm of cobalt in the final organic solution and in which the molar absorption coefficients are found to be 13200 (at 450 nm), 6500 (at 480 nm), and 5500 (at 490 nm).

Effect of Diverse Ions. The effect of foreign ions on the determination of cobalt according to the above procedure is noted in individual cases in Table 1. Mercury(II), Pb(II), Cu(II), Ni(II), Zn(II), and Fe(III) could form their extractable, colored complexes with STTA and, therefore, interfered with the spectrophotometric detemination of cobalt(II) if they could not be removed from the organic phase. However, when the organic phase containing the chelates of these metals was shaken with hydrochloric acid of 1.0—12M for thirty minutes, all these ions other than cobalt could be readily back-extracted into the acid. This fact was examined by the tracer method and by the colorimetric method to make sure that the separation was complete. On the other hand, these metal ions existing in the original sample solution consume the STTA reagent, being competitive with the formation of cobalt-STTA, and therefore hinder the extraction of the latter. When a large amount of these other ions are present a larger amount of the reagent should be employed to permit the complete extraction of all the metal ions. The back-extraction with hydrochloric acid could remove all the metal ions other than cobalt from the organic phase; this process seemed indispensable for the purpose. Strange to say, the cobalt-

In each case 57.2 μg of cobalt(II) was taken in 10 ml of the aqueous solution of pH 6.0—6.5 and extracted with 10 ml of 10^{-3} M STTA-cyclohexane.

STTA chelate was scarcely back-extracted from cyclohexane, even with 1—12M hydrochloric acid, 70% perchloric acid, and 18M sulfuric acid as well as an aqueous buffer solution of pH 9—13, each after one hour's shaking. The chelate could, however, be back-extracted to the extent about 15% with 1.0M sodium hydroxide after thirty minutes' shaking and to the extent about 10% and 90% under shaking with concentrated nitric acid for thirty and sixty minutes respectively. With concentrated sulfuric acid, all the cobalt was transferred immediately from the organic phase into the acid accompanying the decomposition of the organic matter.

Some Aspects of the Nature of Co-STTA. As has been described above, the cobalt-STTA once formed in the extraction system is remarkably stable. At pH 6.5, all of the cobalt in the aqueous solution was extracted into the organic phase (as is shown in Fig. 2), while a small amount of the STTA reagent was back-extracted into the aqueous phase under the same contitions (as is shown in Fig. 7). The absorbance of the extracted cobalt-STTA was examined in terms of the mole ratio of STTA to cobalt; the absorbance was found to become constant in the region above the 4:1 ratio, as is shown in Fig. 4. This confirms that the apparent mole ratio of STTA to cobalt in the complex formation was 4:1. Similar investigations have been done for Co(II)-1-nitroso-2-naphthol,[16,17] Co(II)-dithizone,[18,19] and Co(II)-monothio-dibenzoylmethane.[6,20]

In all cases involving the present study, it may be assumed that the original cobalt could no longer be present as divalent, but must be trivalent or something else after its chelate formation. A detailed report concerning the composition of this stable cobalt-STTA will be presented in the near future.

Application of the Recommended Method. The extraction spectrophotometric procedure for cobalt recommended by the present authours will find extensive application for various purposes. First of all, the method has been applied to the determination of a minute amount of cobalt in a nickel nitrate reagent of the guaranteed analytical grade. The recovery of cobalt was ascertained at the same time by employing a radioactive tracer, $^{60}Co(<10^{-10}M)$; it was found to be 97.4—98.4% from an aqueous solution of $10^{-4}M$ nickel(II). The results obtained are shown in Table 2, while the practical analysis of a trace amount of cobalt in nickel nitrate of an analytical grade gives the data shown in Table 3. In the latter case, the recovery of cobalt was checked by using ^{60}Co in order to confirm the spectrophotometric data. In this case, when a minute amount of cobalt is to be determined, the absorbance of cobalt-STTA at 360 nm is preferred. As is shown in Fig. 8, when the organic phase was back-washed with a solution of pH 11.0, the proper absorption spectra of cobalt-STTA appeared distinctly since the reagent blank was reduced to an almost indetectable value. Therefore, as little as 5.89 ppb of cobalt(II) in a sample aqueous solution could be determined by using a 10 m*l* of the initial solution and by measuring the absorbance of the final organic phase as being 0.482, corresponding to $0.97\times10^{-7}M$ Co-STTA. The molar absorption coefficient of Co-STTA was found to be 4970000 at 360 nm. In the determination of a trace amount of cobalt in the nickel nitrate reagent, a working curve was prepared at 360 nm for cobalt of 0.6 to 60 ppb in the final organic phase; each measured absorbance was adopted to this working curve, and the amount of cobalt was evaluated. The results after three experiments are shown in Table 3; the standard deviation is also estimated to be 0.004%.

A part of the expense for the experiment has been defrayed from a grant given by the Ministry of Education, to which the authors' thanks are due.

Substituent Effect of Dipole and Dipolarophile in the Reaction of Nitrones with *N*-(Substituted phenyl)maleimides

Yosio IWAKURA, Keikichi UNO, Suck-Ju HONG, and Tatsuhiko HONGU

Department of Synthetic Chemistry, Faculty of Engineering, Tokyo University, Bunkyo-ku, Tokyo

(Received May 4, 1971)

The reactions of *C*-(*p*-substituted phenyl)-*N*-(*p*-substituted phenyl)nitrones with *N*-(*p*-substituted phenyl)maleimides were carried out in THF to give both *trans*- and *cis*-isoxazolidines. The formation ratios of *trans*- to *cis*-isoxazolidines (I_T/I_C) were determined by the NMR spectra of the cycloadduct mixtures. Though the values of I_T/I_C varied with the electronic characters of the substituents, R_1, R_2, and R_3, they were always found to be larger than unity.

In an earlier paper[1] from this laboratory we have reported on the configuration of the cycloadduct of nitrone with *N*-phenylmaleimide. In order to investigate the substituent effect of dipole and dipolarophile in the reactions of nitrones and *N*-phenylmaleimides, we have studied the reactions of nitrones having the substituents R_1 in *C*-phenyl and R_2 in *N*-phenyl groups both at the *p*-positions, with *N*-phenylmaleimide having the substituent R_3 at the *p*-position. We have found that the ratios of *trans*- to *cis*-isoxazolidines in the

cycloadduct mixtures varied with the electronic character of the substituents, R_1, R_2, and R_3. The ratios of *trans*- to *cis*-isoxazolidines were determined directly by the NMR spectra of the cycloadduct mixtures. Detailed results are described in the present paper.

Results and Discussion

The reactions of *C*-phenyl-*N*-(*p*-substituted phenyl) nitrones with *N*-(*p*-substituted phenyl)maleimides were carried out in anhydrous THF to give cycloadducts in quantitative yields. In agreement with earlier work,[1] the formations of *trans*- and *cis*-isoxazolidines were observed. The melting points and analytical data of *trans*- and *cis*-isoxazolidines obtained are summarized in Table 1 with the ratios of *trans*- to *cis*-isoxazolidines in the cycloadduct mixtures.

The NMR spectra of the cycloadduct mixture (run 4-B) obtained without any purification are shown in Fig. 1. Signals of each isomers were assigned as shown in the figure according to the previous paper.[1]

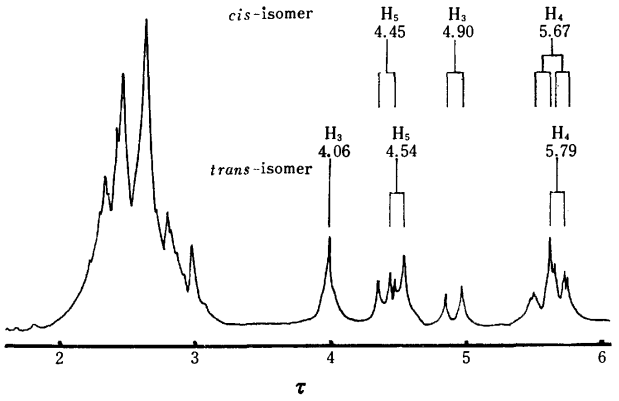

Fig. 1. The NMR spectra of cycloadduct mixture (run 4-B) in DMSO-d_6.

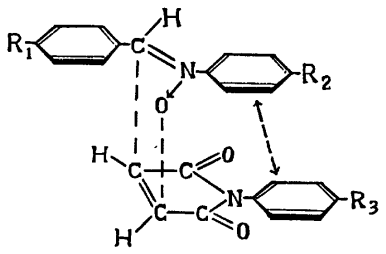
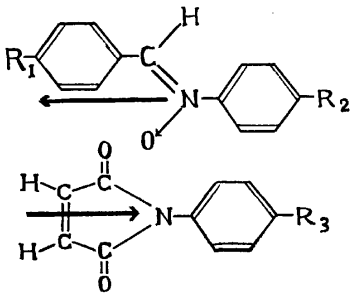
As shown in Fig. 1, proton signals at *C*-3 of isoxazolidine rings appear to be a singlet and doublet according to *trans*- and *cis*-isoxazolidines, respectively, without any overlap. Accordingly, the ratio of *trans*- to *cis*-isoxazolidines (I_T/I_C) can be directly obtained from the NMR spectral comparison, and the values of I_T/I_C thus obtained are summarized in Table 1.

The value of I_T/I_C for every 1,3-dipolar cycloaddition reaction was found to be >1, indicating that the formation of *trans*-isoxazolidine is more favorable than *cis*-isomer. Assuming the reaction of nitrone with *N*-phenylmaleimide by one step mechanism,[2] $I_T/I_C>1$ reveals that addition reaction of nitrone with *N*-phenylmaleimide would proceed favorably through the above transition state as shown in Scheme 1.



Scheme 1

For establishing such a favorable transition state of the addition reaction in the present investigation, it is necessary that the dipole moments of both reaction species, dipole and dipolarophile, should orient to the arrow-signed direction as shown in Scheme 2.



Scheme 2

If the substituent R_1 of nitrone is an electron withdrawing group, the greater dipole moment is anticipated, *i.e.*, the formation of *trans*-isoxazolidine would be predominant. Eventually higher value of I_T/I_C is obtained.

Figure 2 shows the relation between the electronic characters of R_1 and the values of I_T/I_C from Table 1. An approximately linear relation appeared to exist between the Hammett σ value of R_1 and the value of log I_T/I_C. Increasing the negativities of the substituents R_1, the greater values of I_T/I_C were obtained. Such experimental facts seem to support strongly above mentioned assumptions.

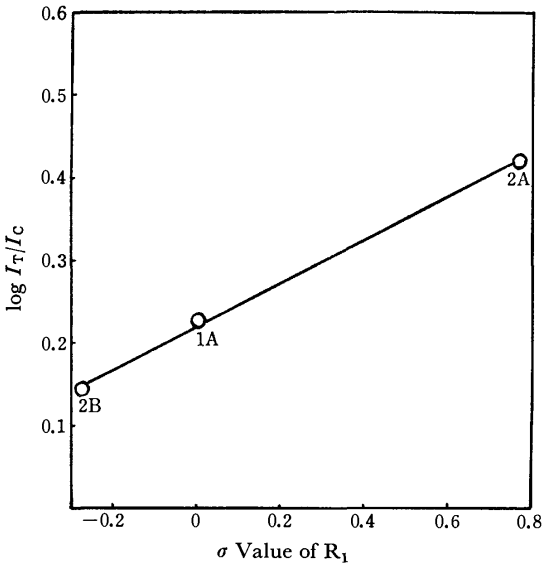


Fig. 2. The relation between the Hammett σ value of R_1 and the log I_T/I_C.
R_2=H; R_3=H.

The magnitudes of dipole moments of *N*-phenylmaleimides may depend on the electronic characters of R_3 in *p*-substituted *N*-phenylmaleimides. There are also fairly good relationships between the Hammett σ values and the values of log I_T/I_C as shown in Fig. 3.

In the series of the substitutents (R_2=H, CH_3, and

t-Bu) on *N*-phenyl group of nitrone, the greater electronegativities of the substituents, the greater values of I_T/I_C were obtained. These results may also appear to be consistent with that the dipole-dipole interaction between dipole and dipolarophile would influence on the formation ratios of *trans*- to *cis*-isoxazolidines. But when R_2 is Cl, the results are reversed, *i.e.*, with increase in the electro-negativities of R_3, the smaller values of I_T/I_C were obtained.

If the above mentioned assumptions are reasonable, we may draw a conclusion tentatively that the dipole moment of nitrone having the substituent, R_2=Cl, should orient to the reverse direction to those of nitrones having the substituents, R_2=H, CH_3, and *t*-Bu. Considering that Cl is an electron-withdrawing group, such a possible dipole orientation of a nitrone having Cl as R_2 can not be denied. We can point out one more additional possible consideration as an influencing factor on the configurations of *trans*- and *cis*-isoxazolidines in the present work. As shown in Scheme 1, at the transition state in 1,3-dipolar cycloaddition of nitrone with *N*-phenylmaleimide *N*-phenyl group of nitrone exists near enough to *N*-phenyl group of *N*-phenylmaleimide. In this event, the affinity between *N*-phenyl group of nitrone and *N*-phenyl group of *N*-phenylmaleimide may affect on the values of I_T/I_C. This explanation is in accordance with the fact that $I_T/I_C>1$ was always obtained as shown in Table 1. The τ values of the protons of *N*-phenyl group of nitrone having Cl as R_2, shifted to lower values than those of other nitrones as shown in Table 2. Such a fact may indicate clearly that the electron density of *N*-phenyl group of nitrone having Cl as R_2, is being much lowered. Accordingly, the affinity between *N*-phenyl group of *N*-phenylmaleimide having electron-donating R_3 and *N*-phenyl group of nitrone would exert to give the results as indicated in Fig. 3.

The relations between the Hammett σ values of R_2 and the values of log I_T/I_C are shown in Fig. 4.

In the series of the reaction of nitrone with *N*-phenylmaleimide having NO_2 as R_3, the greater electro-

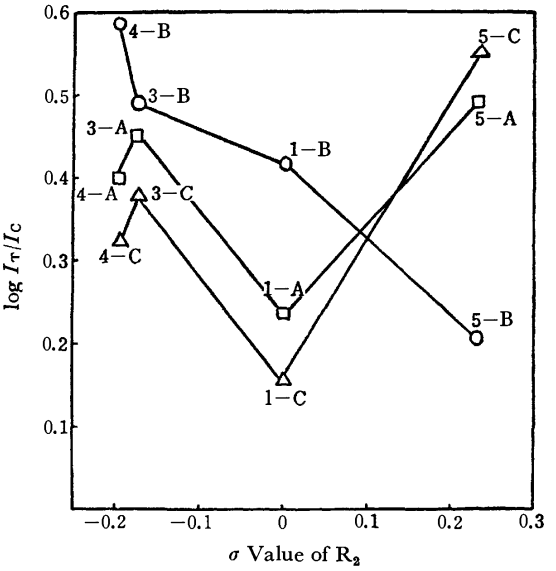

Fig. 4. The relation between the Hammett σ values of R_2 and the log I_T/I_C.
R_1=H; R_3: □=H, ○=NO_2, △=OCH_3

negativities of R_2, the greater values of I_T/I_C were obtained but not linearly. But as shown in Fig. 4, in the case of R_2=H and CH_3, the results obtained were different, *i.e.*, nitrone having no substituent on *N*-phenyl group gave the smallest value of I_T/I_C. Nitrones having either electron donating or withdrawing group on *N*-phenyl group gave the greater values of I_T/I_C.

As we have already pointed out on the explanations of Figs. 2 and 3, the value of I_T/I_C may be influenced by following two factors: (1) dipole orientation of the dipole and dipolarophile; (2) affinity between *N*-phenyl group of nitrone and *N*-phenyl group of *N*-phenylmaleimide. When affinity between *N*-phenyl group on nitrone and *N*-phenyl group of *N*-phenylmaleimide is small, (1) will be a main factor governing the value of I_T/I_C. The results shown in Fig. 4 may not be inconsistent with this explanation. In Fig. 4, if the Hammett σ value of R_2 is positive, (2) might be assumed as a governing factor for the I_T/I_C, but if the σ value of R_2 is negative, (1) will become important. When (1) is a predominant factor governing the value of I_T/I_C, *p*-substituent of *N*-phenyl group of nitrone would come near to *N*-phenyl group of phenylmaleimide. It will be reasonably explained that the decrease of the value of I_T/I_C, in the case of *t*-Bu, is due to the steric hindrance of bulky group.

We have proceeded explanations on the results obtained in the present work, on the basis of one step addition mechanism. Further studies are under progress.

Experimental

Materials. A typical example of *C*-phenyl-*N*-(*p*-*t*-butylphenyl)nitrone was prepared in the following manner. Nitration of *t*-butylbenzene was carried out by the procedure of Ketcham.[3] The oily product, *p*-nitro-*t*-butylbenzene was obtained in 80% yield (bp, 108.5—110°C/5 mmHg), identified by the IR spectrum. Then *p*-nitro-*t*-butylbenzene was reduced to hydroxylamine by zinc dust in 65% yield by the usual manner, mp 89.5—90°C.

Found: C, 72.57; H, 8.89; N, 8.32%.

Calcd for $C_{10}H_{15}ON$: C, 72.69; H, 9.15; N, 8.48%.

The mixture of equimolar amounts of *p*-*t*-butylphenylhydroxylamine and benzaldehyde in ethanol was refluxed for three hrs. Recrystallization three times from *n*-hexane afforded white needles, *C*-phenyl-*N*-(*p*-*t*-butylphenyl)-nitrone (mp, 117—119°C) in 71% yield.

Found: C, 80.31; H, 7.39; N, 5.40%.

Calcd for $C_{17}H_{19}ON$: C, 80.57; H, 7.56; N, 5.53%.

Other nitrones, were prepared in over 70% yields by the procedure of Wheeler *et al.*[4] Their melting points were as follows: R_1=H, R_2=H, 112—113°C (lit, 114°C);[4] R_1=H, R_2=CH_3, 123°C (lit. 123°C);[4] R_1=H, R_2=Cl, 174—175°C (lit, 174°C)[5], 181°C)[4]. *N*-phenylmaleimides, R_3, were synthesized by the procedure of Searle.[6] Their melting points were as follows: R_3=H, 90—91°C (lit, 90—91°C);[6] R_3=NO_2, 167°C (lit, 167—168°C);[6] R_3=OCH_3, 146°C. The last product was a new compound and gave following analytical data.

Found: C, 64.98; H, 4.46; N, 6.89%. Calcd for $C_{11}H_9O_3N$: C, 65.69; H, 4.46; N, 6.89%.

NMR Spectra. The NMR spectra were measured in DMSO-d_6 solution (concentration: about 10% solution of the sample by weight) at room temperature with Japan Electron Optics C-60 spectrometer (60 MHz). Tetramethylsilane was used as an internal reference.

The Synthesis and Asymmetric Adsorption of an Optically-active Basic Polymer Starting from L-Proline

Tetsushi YAMASHITA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received April 9, 1971)

N-Prolyl-*p*-aminostyrene was synthesized by the reaction of *N*-carboxy-L-proline anhydride with *p*-aminostyrene phosphate. This optically-active basic monomer was then copolymerized wtih *N*,*N*′-bis(*p*-vinylphenyl)-adipamide to give a basic polymer. Similar basic polymers were also obtained, starting from other α-amino acids, through this procedure. Of these polymers, the polymer involving L-proline was used for the chromatographic resolution of the phthalamidic acid derivatives of DL-phenylalanine, DL-valine, and DL-phenylglycine. The polymer resolved partially DL-*N*-(*o*-carboxybenzoyl)phenylalanine.

There have been many reports[1-5] concerning the use of synthetic optically-active basic polymers as adsorbents for the chromatographic resolution of racemates.

Most such polymers have been synthesized by the method in which an optically-active group is introduced into an optically-inactive "reactive polymer"[6] (*e.g.*, chloromethylated polystyrene[2-5] and polymethacroyl chloride[1]).

On the other hand, we[7] previously reported several optically-active basic polymers synthesized by a different method, which involves either the hydrazinolysis or hydrogenolysis of the neutral copolymers composed of *N*-(*N*-phthaloyl or *N*-tosyl-α-amino acyl)-*p*-aminostyrene and *N*,*N*′-diacroylhexamethylenediamine. However, this synthetic method has two limitations.

The first limitation is that this method cannot be applied to imino acids or to the α-amino acids with *s*-alkyl, acetoxyl, and/or indole groups. The second one is the difficulty of removing completely the *N*-blocking group from the polymer; the optimum yield of the dephthalization of the polymer upon treatment with hydrazine hydrate was below 60%.

This article will describe the procedure of synthesizing directly the optically-active basic monomers by

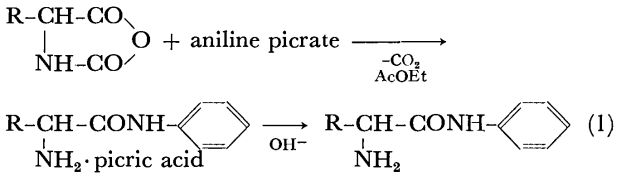
the use of several *N*-carboxy-α-amino acid anhydrides and *p*-aminostyrene phosphate.

Wessley and John[8] reported a synthetic procedure of α-amino acid anilides in which aniline picrate was allowed to react with some *N*-carboxy-α-amino acid anhydrides (Eq. (1)).



(1)

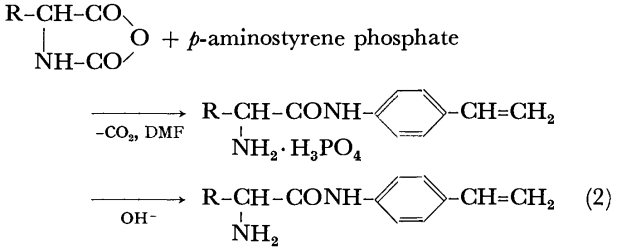
In this reaction, they nicely utilized the difference between the pK_a's of aniline and the resulting anilide, the former being an aromatic amine, and the latter, aliphatic. The picric acid formed a salt with the anilide, whose pK_a is higher than that of the aniline. The salt formation also prevented any further reaction between the still-remaining *N*-carboxy-α-amino acid anhydride and the resulting anilide.

If *N*-carboxy-α-amino acid anhydride is allowed to react with a similar salt of *p*-aminostyrene in lieu of aniline, *N*-(α-amino acyl)-*p*-aminostyrene should be obtained as an optically-active basic monomer.

The synthesis of the monomer was attempted with several salts of *p*-aminostyrene with acids of different pK_a's.

When the salt of a weak acid, such as acetic acid or formic acid, was used, the amine formed was not stabilized as a salt, but it attacked successively the unreacted *N*-carboxy-α-amino acid anhydrides to give only a polyamide. *p*-Aminostyrene hydrochloride polymerized itself, to poly-*p*-aminostyrene, while the salt of *p*-toluenesulfonic acid gave a small amount of the monomer, accompanied mostly by complex by-products.

When the phosphate or picrate was allowed to react with *N*-carboxy-α-amino acid anhydride, the synthesis of the monomer was successful, especially in the former case (Eq. (2)).



(2)

Table 1 shows the physical data on the monomers synthesized by the above procedure.

Table 1. Monomers derived from α-amino acids

Methionine	Oil	−55($CHCl_3$)	76

8) F. Wessley and M. John, *Monatsch. Chem.*, **48**, 1 (1927).

In order to obtain an insoluble basic polymer suitable as a chromatographic sorbent, the monomers were copolymerized with some crosslinking agents [divinyl benzene, *N*,*N*′-diacroylhexamethylenediamine,[7] *N*,*N*′-bis(*p*-vinylphenyl)adipamide].

N,*N*′-bis(*p*-vinylphenyl)adipamide was found to be especially useful among these crosslinking agents.

The homogeneous copolymerization of monomer with *N*,*N*′-bis(*p*-vinylphenyl)adipamide was performed, by the use of azo-bis-isobutyronitrile as an initiator, in tetrahydrofuran under refluxing conditions.

Of these polymers, the polymer from L-proline was subjected to hydrolysis in order to examine whether or not racemization occurred during the synthesis. The crude proline obtained after hydrolysis was purified as the picrate. No apparent racemization was detectable from the observed value of the optical rotation of the proline freed from the picrate with aniline.[9]

The chromatographic resolutions of phthalamidic acid derivatives of DL-phenylalanine, DL-valine, and DL-phenylglycine by means of this proline polymer were attempted. As eluent solvents, 10^{-3}, 10^{-4}, and 10^{-5}N aqueous ammonia were used successively.

When DL-*N*-(*o*-carboxybenzoyl)phenylalanine was eluted chromatographically with 10^{-5}N aqueous ammonia, the observed value of the specific rotation for the first fraction was $[\alpha]_D = -18°$ (optical purity, 33%).

The results of the resolution of DL-*N*-(*o*-carboxybenzoyl)phenylalanine eluted with 10^{-4}N aqueous ammonia are given in detail in Table 2.

Table 2. Result of resolution of ammonium salt of DL-*N*-(*o*-carboxybenzoyl)phenylalanine with proline polymer

Fraction No.	Weight (mg)	*c*	α_D	$[\alpha]_D$(°)	α_{546}	$[\alpha]_{546}$(°)
1	13.5	0.45	−0.070	−15	−0.090	−20

35—74	3.0	0.10	+0.010	+10	+0.012	+12
last fraction	45.0	1.50	+0.105	+ 7	+0.120	+ 8

In the case of the elution of DL-*N*-(*o*-carboxybenzoyl)-valine with 10^{-4}N aqueous ammonia, the fraction at the earliest stage of the elution showed only an unreliable, low specific rotation.

As was indicated in the previous paper[10] concerning acidic polymers, the substrate involving a benzyl group was more efficiently resolved than that with an isopropyl group in the corresponding moiety of the molecule.

The parallel result in the present study seems quite interesting.

DL-*N*-(*o*-carboxybenzoyl)phenylglycine was less stable than the two above-mentioned substrates under the basic condition; it was, however, found that this sub-

9) G. J. Cox and H. King, *J. Biol. Chem.*, **84**, 533 (1929).

10) T. Yamashita and N. Nakamura, This Bulletin, **43**, 1809 (1970).

strate unfortunately suffered from hydrolysis during the elution despite the expected resolution.

In the optical resolution of the racemates of amino acids, amino acid derivatives, and mandelic acid by means of synthetic optically-active polymers[5,6,10,11] derived from the starting materials of the L-configuration, it has been reported that these polymers are apt to adsorb the substrates of the L-configuration more strongly than those of the D-configuration.

In the present work, the *N*-(*o*-carboxybenzoyl)-phenylalanine of the L-configuration was also more adsorptive, on the L-polymer, than that of the D-configuration.

However, further experimentation and consideration are necessary to explain this observation fully.

Experimental

The Synthesis of p-*Aminostyrene Phosphate.* When 98% phosphoric acid (23 g) in ethanol (35 m*l*) was added to an ether solution of *p*-aminostyrene[12] obtained by the reduction of *p*-nitrostyrene[13] (34 g) with an aluminum amalgam, a white solid salt separated. The solid was collected on a filter, washed with ethanol and ether, and dried in a vacuum desiccator. Yield, 72%. mp 138—140°C.

The salt in a sealed tube was stable for a long period in a refrigerator.

The Syntheses of N-*Carboxy-α-amino Acid Anhydrides.* All of the *N*-carboxy-α-amino acid anhydrides except that of L-cystine[14] were prepared by the phosgenation procedure.[15-18]

The Synthesis of the L-*Proline Monomer.* *p*-Aminostyrene phosphate (0.1 mol) was dissolved, in small portions, in a solution of *N*-carboxy-L-proline anhydride (0.1 mol) in anhydrous dimethylformamide; the evolution of CO_2 gas thus occurred. The solution was then allowed to stand for 2—3 days at room temperature. The end point of the reaction was confirmed by the absence of the spot of *p*-aminostyrene on a silica-gel thin-layer chromatogram [benzene-ethyl formate-methanol (5:4:1) and 95% ethanol-28% aqueous ammonia (4:1) as solvents.]

The dimethylformamide was distilled off from the solution under reduced pressure below 40°C. The residue was decomposed with aqueous sodium bicarbonate, and then extracted with chloroform or ethyl acetate. The extract was washed with water, dried over anhydrous sodium sulfate, and evaporated to dryness under reduced pressure.

The *N*-prolyl-*p*-aminostyrene was recrystallized from ethyl acetate-petroleum ether to give needles; mp 100—102°C, $[\alpha]_D^{20}$ −62° (*c* 0.5, AcOEt). IR (cm^{-1}): 3200—3400 (NH amide and amine), 1670 (C=O), 990, 910 (–CH=CH_2), 835 (*p*-substitution). Found: C, 72.60; H, 7.31; N, 12.80%. Calcd for $C_{13}H_{16}N_2O$: C, 72.19; H, 7.46; N, 12.95%.

The monomers starting from some other α-amino acids were prepared by procedures similar to that desribed above.

The Synthesis of N,N′-*Bis(*p-*vinyl phenyl)adipamide.* Adipic acid dichloride[19] (0.05 mol) was added, under external cooling with ice water, to an ether solution of *p*-aminostyrene (0.1 mol) and pyridine (0.1 mol) to separate a white, solid material. After standing overnight at room temperature, the solid was collected on a filter, washed with water and ethanol, and then dried in a vaccum desiccator. The *N,N′*-bis(*p*-vinylphenyl)adipamide was recrystallized from ethanol or tetrahydrofuran. Yield, 75%. mp 240°C dec.. IR (cm^{-1}): 3350 (NH), 1655 (C=O), 990, 905 (–CH=CH_2), 840 (*p*-substitution). Found: C, 75.64; H, 7.26; N, 7.65%. Calcd for $C_{22}H_{24}N_2O_2$: C, 75.83; H, 6.94; N, 8.04%.

Copolymerization. A mixture of *N*-prolyl-*p*-aminostyrene (0.01 mol) and *N,N′*-bis(*p*-vinylphenyl)adipamide (0.01 mol) in anhydrous tetrahydrofuran (100—120 m*l*) was stirred, after the addition of a small amount of azo-bis-isobutyronitrile, under reflux for 30—40 hr. The copolymer precipitated as a white powder; it was filtered and then washed thoroughly with dimethylformamide, methanol, and tetrahydrofuran successively. Yield, 60%.

The copolymers containing α-amino acids other than L-cystine were also obtained by procedures similar to that described above. The cystine monomer was polymerized in anhydrous benzene without the addition of any cross-linking agent. The exchange capacities of these polymers, determined by using 0.1 N hydrochloric acid, were as follows: proline, 1.5 *meq*/g; tryptophan, 1.0 *meq*/g; methionine, 0.72 *meq*/g; cystine, 3.64 *meq*/g.

Isolation of Proline from the Hydrolysates of the Polymer Starting from L-*Proline.* The proline copolymer was hydrolyzed and proline was isolated according to the ordinary procedure[9,20] for the isolation of L-proline from protein hydrolysates. The polymer was boiled in 5 N hydrochloric acid for 10 hr under reflux and filtered. The filtrate was decolorized with charcoal and evaporated *in vacuo* to dryness. Picric acid was added to the residue dissolved in ethanol, and the resulting picrate was recrystallized from water. mp 150°C. Free proline was isolated from the picrate after decomposition with aniline by the usual method.[9] mp 219—221°C dec. (from ethanol-ether). $[\alpha]_D^{20}$ −84.5° (*c* 1, in water). Lit,[20] $[\alpha]_D^{20}$ −86° in water.

The Syntheses of Substrates. The substrates were obtained by the ordinary method,[21] in which *N*-phthaloyl-α-amino acids were treated with aqueous alkali.

DL-*N*-(*o*-carboxybenzoyl)phenylalanine, mp 180—182°C. $[\alpha]_D$ +67°, $[\alpha]_{546}$ +80° (*c* 1, 0.5N aqueous ammonia) in L-form. The ammonium salt of the L-configuration, mp 178—182°C. $[\alpha]_D$ +56° (*c* 0.51, 10^{-4}N aqueous ammonia), +54° (*c* 0.52, 10^{-5} N aqueous ammonia).

DL-*N*-(*o*-carboxybenzoyl)valine, mp 164—166°C. $[\alpha]_D$ +12°, $[\alpha]_{546}$ +12° (*c* 1, 0.1 N aqueous ammonia) in L-form.

DL-*N*-(*o*-carboxybenzoyl)phenylglycine,[21] mp 185—188°C. $[\alpha]_D$ +101 (*c* 2, acetone) in L-form.

The ammonium salt of DL-*N*-(*o*-carboxybenzoyl)phenylalanine was prepared by the addition of tetrahydrofuran or acetone to a solution of the acid in aqueous ammonia. The ammonium salts of the other acids failed to crystallize.

Column Chromatography. A proline copolymer (45 g) suspended in a sufficient volume of water was poured into a column (2 cm in diameter; 150 cm in length; the final length

of the packed polymer was *ca.* 80 cm). The ammonium salt of DL-*N*-(*o*-carboxybenzoyl)phenylalanine (200 mg), dissolved in *ca.* 10 m*l* of 10^{-4} N aqueous ammonia, was adsorbed on the upper zone of the sorbent; then was eluted with the same solvent at room temperature. The flow rate of the solvent was *ca.* 6 m*l*/hr under atmospheric pressure; 12.50 m*l* portions of the eluent were collected automatically. Each of the eluents showed only a single spot on a silica-gel thin-layer chromatogram, the R_f value being in agreement with that of authentic *N*-(*o*-carboxy-benzoyl)phenylalanine. Acetic acid-*n*-butanol-water (1:1:1), 95% ethanol-28% aqueous ammonia(4:1), and benzene-ethyl formate-methanol (5:4:1) were used as the solvents. The concentration of the substrate in each fraction was estimated by UV absorption by using a Hitachi EPS-2-photometer. When the observed concentration was too low to determine the optical rotation, 10—30 consecutive fractions were combined and concentrated under reduced pressure. The last fraction was eluted with 0.1 N aqueous ammonia. The optical rotation of the evaporated residue was determined in 10^{-4}N aqueous ammonia by means of a Rex-automatic polarimeter. The chromatographic resolution of the other two racemates were also carried out by a procedure similar to that described above.

The Syntheses and Reactions of Sulfenyl-substituted Sulfonium Ylides

Yosio HAYASI and Hitosi NOZAKI

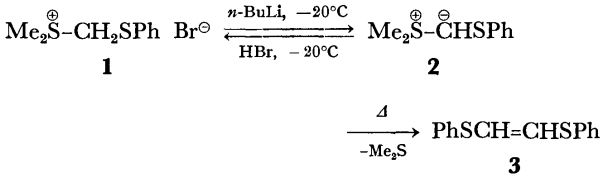
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto

(Received April 24, 1971)

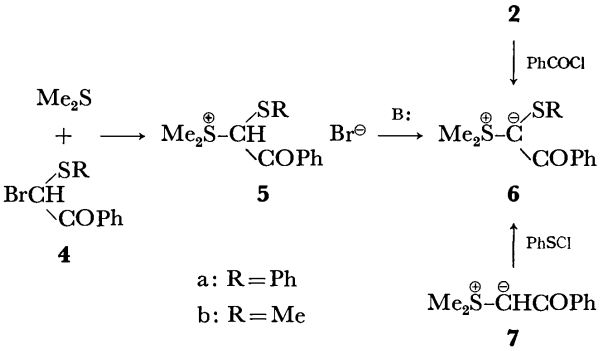
Unstable dimethylsulfonium (phenylthio)methylide (**2**) is prepared in a THF solution from the corresponding sulfonium salt by treating it with *n*-butyllithium. Sulfenyl-substituted stable phenacylides **6a** and **6b** are obtained in three ways. The ylide **6a** decomposes at 120°C in benzene to give (E)-**9**, the dimer of benzoyl(phenylthio)carbene. In contrast, the heating of **6a** in ethanol affords ethanolysis products (**11**, **12**) and ethyl benzoate. The alkylation of **6a** and **6b** with trimethyl- and triethyloxonium fluoroborate gives the vinylsulfonium salt **13**. The ylide **2** reacts with (Z)- and (E)-1,2-dibenzoylethylene and with diethyl fumarate to give cyclopropanes, **15** and **16** respectively.

Sulfonium ylides are often stabilized by the introduction of an electron-withdrawing group or groups on the ylide carbon, such groups as COR, COOR, and SO_2R.[1] Herewith we report on the syntheses and reactions of sulfenyl-substituted sulfonium ylides,[2] as no precedent of this class has yet appeared. The sulfenyl group should effectively delocalize the negative charge by using a 3*d* orbital of the sulfur atom.[3] Incidentally, the cleavage of the ylide bond gave rise to sulfenylcarbenes, whose behavior was also investigated.[5]

Dimethylsulfonium (phenylthio)methylide (**2**) was obtained as a solution in tetrahydrofuran (THF) upon the treatment of the sulfonium salt **1** with *n*-butyllithium. The solution was stable at lower temperatures, as after 1 hr of standing at −20°C **2** was reconverted quantitatively into the sulfonium salt **1** by the addition of hydrogen bromide. The concentration of the ylide solution under reduced pressure below room temperature afforded (Z)-1,2-bis(phenylthio)ethylene (**3a**, 27% yield) and its (E) isomer (**3b**, 43% yield).



When dimethyl sulfide was allowed to react with phenacyl bromides **4a** and **4b**, two sulfonium salts, **5a** and **5b** respectively, were obtained as highly hygroscopic crystals. The treatment of **5a** and **5b** with sodium hydride in THF gave two crystalline ylides, **6a** and **6b** respectively.



The ylide **6a** was also obtained by two alternative methods: the treatment of dimethylsulfonium phe-

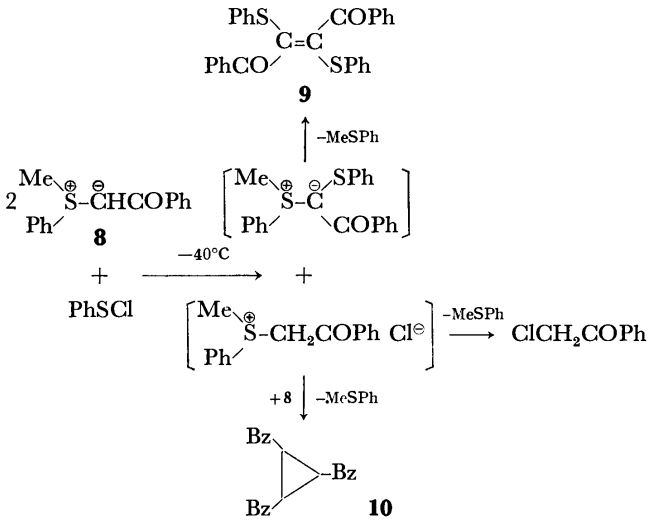
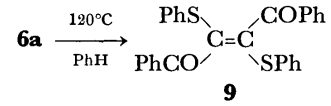
nacylide (**7**)[7] with benzenesulfenyl chloride, and that of **2** with benzoyl chloride. The "ylide carbonyl" IR band of **6a** and **6b** appeared in the same region as that of **7**, whereas the UV absorption experienced a blue shift of *ca.* 20 nm upon the introduction of the sulfenyl group into **7** (see Experimental section). Apparently the sulfenyl group delocalizes the ylide negative charge by utilization of the 3*d* orbital of the sulfur atom.[8]

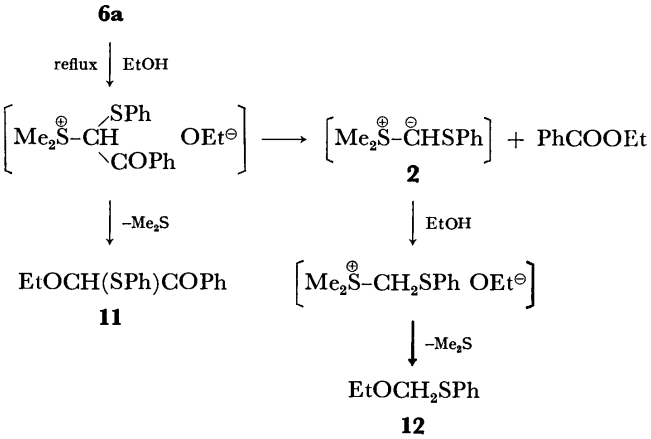
In contrast to the reaction of the ylide **7**, that of two mole equivalents of methylphenylsulfonium phenacylide (**8**)[9] with benzenesulfenyl chloride gave a complex mixture, which consisted of (E)-1,2-dibenzoyl-1,2-bis(phenylthio)ethylene (**9**, 13%), thioanisole (122%), α-chloroacetophenone (50%), and (E)-1,2,3-tribenzoylcyclopropane (**10**, 20%), plus a remainder of unknown substances.



The ylides **6a** and **6b** have been found to serve as precursors of benzoyl(phenylthio)carbene.[10] The ylide **6a** was stable in boiling benzene, but decomposition took place at 120°C to yield (E)-1,2-dibenzoyl-1,2-bis(phenylthio)ethylene (**9**). The analytical and spectral data supported the constitution given, while the (E)-configuration was deduced on the basis of its IR spectrum, which showed a conjugated carbonyl absorption band at 1665 cm^{-1}.[11]



The prolonged heating of **6a** in boiling ethanol afforded α-ethoxy-α-(phenylthio)acetophenone (**11**, 23%), ethyl benzoate (19%), and phenylthiomethyl ethyl ether (**12**, 12%). The olefin **9** and the compound originating from the Wolff rearrangement of benzoyl(phenylthio)carbene could not be detected. A possible scheme of the reaction is shown below:



The photolytic decomposition of **6a** was carried out in some solvents, but no single product was isolated.

The treatment of the ylides **6a** and **6b** with trimethyl- and triethyloxonium tetrafluoroborate resulted in O-alkylation, giving vinylsulfonium salts, **13** (Table 1), instead of an S-alkylated product. The oily sulfonium tetrafluoroborates (**13a**: R=Ph, R′=Me and **13c**: R=R′=Me) were converted to crystalline tetraphenylborates (**14a** and **14c**) by treatment with sodium tetraphenylborate. The structure of these vinylsulfonium salts was confirmed by the results of analyses and by the spectral data. Especially, the NMR spectrum of **14c** showed three peaks of methyl protons at δ 2.07 (–SMe), 2.83 (>S⊕–Me), and 3.50 (O–Me) ppm; they supported the structure of **14** and, therefore, that of **13**:

a) In acetone-d_6 solution with TMS as a reference.
b) In $CDCl_3$ solution with TMS as a reference.
c) In DMSO-d_6 solution with sodium 3-(trimethylsilyl)propanesulfonate as a reference.

In view of the well known reaction[13] of dimethylsulfonium methylide with electron-deficient olefins or carbonyl compounds, we have examined the possible reactions of **2** with such substrates. However, benzophenone failed to react with **2** at −20°C, whereas both benzaldehyde and *p*-nitrobenzaldehyde actually reacted with **2** to afford a very complex mixture which could not be characterized.

When (E)-1,2-dibenzoylethylene was allowed to react with **2** in THF, *r*-1,*t*-2-dibenzoyl-*t*-3-(phenylthio)-cyclopropane (**15**) was obtained in a 27% yield as the sole product. The assignment of the indicated configuration is based on the NMR spectral data of the corresponding sulfone, **16** (see Experimental section).

The reaction of **2** with (Z)-1,2-dibenzoylethylene gave the same stereoisomer, **15**, in a 53% yield. Analogously, the treatment of **2** with diethyl fumarate afforded diethyl *t*-3-(phenylthio)-*r*-1,*t*-2-cyclopropanedicarboxylate (**17**) in a 51% yield; its oxidation led to the sulfone **18**. The given configuration was also based on the NMR spectral data, in which the ethyl protons were obviously nonequivalent. The preference for the (E) configuration of **15** and **17** may be ascribed to the intermediacy of the betaines, **19**.

Expectedly, the ylide **6a** did not react with (E)-1,2-dibenzoylethylene and diethyl maleate under reflux in THF.

Experimental

All the melting and boiling points are uncorrected. The microanalyses were performed at the Elemental Analyses Center of Kyoto University. The NMR spectra were taken with JEOL C-60H and Varian ME-100 spectrometers, and the chemical shifts are reported in δ values relative to the TMS internal standard unless otherwise stated. The abbreviations s, t, q, and m refer to singlet, triplet, quartet, and multiplet respectively. The UV absorption spectra were taken in 95% EtOH on a Shimadzu MPS-50L spectrometer.

Preparation of Dimethyl(phenylthiomethyl)sulfonium Bromide (1). A solution of bromomethyl phenyl sulfide[14] (7.0 g, 34.4 mmol) and dimethyl sulfide (2.6 g, 42.0 mmol) in dry acetone (50 m*l*) was stirred at 0°C for 24 hr. The resulting precipitates were collected by filtration, washed with dry acetone, and dried in a vacuum desiccator to afford very hygroscopic crystalline solids **1** (8.0 g, 88%); mp 69—70°C (dec.). NMR (DMSO-d_6): 3.12 (s, 6H), 5.41 (s, 2H), 7.2—7.9 (m, 5H). Found: C, 40.7; H, 5.0%. Calcd for $C_9H_{13}BrS_2$: C, 40.8; H, 4.9%.

Preparation of Dimethylsulfonium (Phenylthio)methylide (2). To a suspension of **1** (2.65 g, 10.0 mmol) in THF (150 m*l*), a solution of *n*-butyllithium (10 mmol) in *n*-hexane (14.7 m*l*) was added in one portion at −20°C under nitrogen, after which the mixture was stirred for five min. Thus we obtained a pale yellow solution of dimethylsulfonium (phenylthio)-methylide (**2**). After standing for 1 hr at −20°C, the solution was treated with HBr gas. The resulting precipitates melted at 69—70°C (mixed mp 69°C) and showed an IR spectrum identical with that of an authentic sample of **1**.

The Decomposition of Dimethylsulfonium (Phenylthio)methylide (2). The solution of **2** in THF (50 m*l*), prepared by the treatment of **1** (2.65 g, 10.0 mmol) with a solution of *n*-butyllithium (10.0 mmol) in hexane (14.7 m*l*) at −20°C, was allowed to warm up to room temperature. The reaction mixture was then concentrated under reduced pressure at 0—5°C to afford a crude oil, which was submitted to chromatography on an alumina column with *n*-hexane. The initial eluate was (E)-1,2-*bis*(phenylthio)ethylene (**3b**, 0.52 g, 43%); mp 61—62°C (from EtOH) (lit.[15] mp 62°C). IR (KBr): 924 cm^{-1}; NMR (CCl_4): 6.44 (s, 2H), 7.0—7.4 (m, 10H). The second one was (Z)-1,2-bis(phenylthio)ethylene (**3a**; 0.33 g, 27%): mp 30.5—31°C (lit,[15] mp 31.5°C). NMR (CCl_4): 6.41 (s, 2H), 7.0—7.4 (m, 10H).

α-Bromo-α-(phenylthio)acetophenone (4a)[16] was prepared by the treatment of α-(phenylthio)acetophenone with bromine in the presence of a catalytic amount of aluminum chloride in dry ether at 0°C.

Preparation of Dimethyl[α-(phenylthio)phenacyl]sulfonium Bromide (5a). A solution of **4a** (20 g, 66 mmol) and an excess of dimethyl sulfide in dry acetone was stirred at 0°C for 5 hr. The resulting precipitates were filtered, washed with dry acetone, and dried over P_2O_5 in a vacuum desiccator to afford hygroscopic crystals **5a** (19 g, 78%), mp 76—78°C (dec.). IR (Nujol): 1675, 1290 cm^{-1}; NMR ($CDCl_3$): 2.07 (s, 6H), 6.42 (s, 1H), 7.2—8.1 (m, 10H). Found: C, 52.3; H, 4.7%. Calcd for $C_{16}H_{17}BrOS_2$: C, 52.0; H, 4.6%.

Preparation of Dimethyl[α-(methylthio)phenacyl]sufonium Bromide (5b). To a solution of α-(methylthio)acetophenone (8.3 g, 50 mmol) in dry benzene (200 m*l*) under nitrogen, we added sodium hydride (2.4 g, a 50% dispersion in mineral oil, 50 mmol) in one portion at 0°C. After the evolution of hydrogen gas had ceased, bromine (8.0 g, 50 mmol) was

13) E. J. Corey and M. Chaykovsky, *J. Amer. Chem. Soc.*, **87**, 1353 (1965).

16) W. Groebel, *Chem. Ber.*, **92**, 2887 (1959).

added dropwise to the reaction mixture at the same temperature. The mixture was stirred for an additional 5 min and then filtered in order to remove the NaBr. After an excess of dimethyl sulfide had been added to this filtrate, the mixture was stirred at 0°C for 5 hr. The resulting precipitates were filtered, washed with dry acetone, and dried over P_2O_5 under reduced pressure to afford hygroscopic salt **5b** (11.0 g, 72%), mp 92—93°C (dec.); this product was subjected to the following reaction without further purification. IR (Nujol): 1673, 1278 cm^{-1}; NMR ($CDCl_3$): 2.14 (s, 3H), 2.33 (s, 6H), 6.44 (s, 1H), 7.2—8.1 (m, 5H). Found: C, 42.6; H, 4.7%. Calcd for $C_{11}H_{15}BrOS_2$: C, 43.0; H, 4.9%.

Preparation of Dimethylsulfonium α-(Phenylthio)phenacylide (6a). (a) To a solution of **5a** (17.0 g, 46 mmol) in THF (250 m*l*) cooled with an ice-water bath, we added NaH (2.2 g, 50% dispersion in mineral oil, 46 mmol) in one portion. The reaction mixture was stirred until the evolution of hydrogen had subsided. Filtration followed by concentration gave a crystalline solid substance, which was recrystallized from benzene to afford **6a** (11.0 g, 85%), mp 135—136°C. IR (KBr): 1530, 1335 cm^{-1}; λ_{max}^{EtOH} 247 (log ε 4.07), 282 (3.84) nm; NMR ($CDCl_3$): 2.64 (s, 6H), 7.1—7.9 (m, 10H). Found: C, 67.0; H, 5.5%. Calcd for $C_{16}H_{16}OS_2$: C, 66.6; H, 5.6%.

(b) To a solution of **7** (18.0 g, 100 mmol) in THF (300 m*l*), we added, drop by drop, a solution of benzenesulfenyl chloride (7.2 g, 50 mmol) in THF (50 m*l*) under nitrogen at −20°C. After being stirred for an additional 4 hr at the same temperature, the reaction mixture was allowed to warm to room temperature, diluted with water, and extracted with $CHCl_3$. The extract was dried ($MgSO_4$) and concentrated *in vacuo*. The residual solid was recrystallized from benzene to afford **6a** (12.5 g, 87%), mp and mixed mp 135—136°C. Its identity was further confirmed by a study of its IR spectrum.

(c) To a solution of **2** in THF (150 m*l*), prepared by the treatment of **1** (2.65 g, 10.0 mmol) with *n*-BuLi, we added, drop by drop, a solution of benzoyl chloride (0.70 g, 5.0 mmol) in THF (5 m*l*) under nitrogen at −20°C. After being stirred for an additional hour, the reaction mixture was allowed to warm up to room temperature under stirring. Work-up then afforded **6a** (1.00 g, 72%); mp and mixed mp 135—136°C.

Preparation of Dimethylsulfonium α-(Methylthio)phenacylide (6b). A mixture of **5b** (10.0 g, 32.6 mmol) and NaH (1.56 g, 50% dispersion in mineral oil, 32.6 mmol) in THF (250 m*l*) was stirred at 0°C under nitrogen for 5 hr. The reaction mixture was then filtered, and the filtrate was concentrated under reduced pressure. The recrystallization of the residue from petroleum ether (bp 30—50°C) and THF (1:1) afforded **6b** (6.1 g, 83%); mp 85—86°C. IR (KBr): 1485, 1340 cm^{-1}; λ_{max}^{EtOH} 280 (log ε 3.83); NMR ($CDCl_3$): 1.96 (s, 3H), 2.66 (s, 6H), 7.1—7.9 (m, 5H). The compound decomposed slowly on standing at room temperature on exposure to air. Found: C, 58.1; H, 6.4%. Calcd for $C_{11}H_{14}OS_2$: C, 58.4; H, 6.2%.

Reaction of Methylphenylsulfonium Phenacylide (8) with Benzenesulfenyl Chloride. A solution of benzenesulfenyl chloride (2.89 g, 20 mmol) in THF (30 m*l*) was added to a solution of **8** (9.68 g, 40 mmol) in THF (250 m*l*) at −40°C under nitrogen. The mixture was stirred for an additional 8 hr at the same temperature and then filtered. The filtrate was concentrated, and the residual oil was chromatographed on a Florisil column. Elution with hexane gave thioanisole (3.03 g, 122%) and α-chloroacetophenone (1.54 g, 50%). Elution with benzene gave **9** (1.16 g, 13%), mp and mixed mp 173.5—174°C. Final elution with chloroform yielded (E)-1,2,3-tribenzoylcyclopropane (**10**, 1.30 g, 20%), mp and mixed mp 213—214°C.[17]

Thermolysis of 6a in Benzene. A solution of **6a** (2.2 g, 7.8 mmol) in dry benzene (100 m*l*) was heated in a sealed glass tube at 120°C for 3 hr. After the solvent had been removed, the residue was chromatographed (silica gel, benzene) to afford **9** (0.34 g, 10%), mp 173.5—174°C (from benzene). λ_{max}^{EtOH} 212 (log ε 4.63), 256 (4.52) nm; IR (KBr): 1665, 1240 cm^{-1}; NMR ($CDCl_3$): 7.0—8.0 (m). The parent peak in the mass spectrum was observed at *m/e* 452. Found: C, 74.6; H, 4.4%. Calcd for $C_{28}H_{20}O_2S_2$: C, 74.3; H, 4.5%.

Thermolysis of 6a in Ethanol. A solution of **6a** (1.1 g, 3.9 mmol) in 100% EtOH (100 m*l*) was heated to reflux for 22 hr. After the evaporation of the solvent, ether was added to the residual oil (0.83 g). The resulting precipitates were collected and found to be **6a** (0.14 g). The filtrate was concentrated, and the residual oil was subjected to chromatography on a silica gel column. Elution with hexane gave phenylthiomethyl ethyl ether (**12**, 0.08 g, 12%), which was found to be identical with an independently synthesized specimen upon a comparison of their IR and NMR spectra and retention times on glc. Elution with hexane and benzene (2:1) gave ethyl benzoate (0.11 g, 19%). A final elution with benzene gave α-ethoxy-α-(phenylthio)acetophenone (**11**) as an oil (0.24 g, 23%). IR (neat): 1693, 1274, 1098 cm^{-1}; NMR ($CDCl_3$): 1.32 (t, 3H, $J_{AX}=J_{BX}=$ 7.2 Hz), 3.70 (1H, $J_{AB}=9.0$ Hz, $J_{AX}=7.2$ Hz), 4.07 (1H, $J_{AB}=9.0$ Hz, $J_{BX}=7.2$ Hz), 5.40 (s, 1H), 7.1—8.1 (m, 10H). Found: C, 70.7; H, 5.8%. Calcd for $C_{16}H_{16}O_2S$: C, 70.6; H, 5.9%.

Preparation of Phenylthiomethyl Ethyl Ether (12). An authentic sample was prepared as follows. To an EtOH (150 m*l*) solution of sodium thiophenoxide prepared from thiophenol (29.0 g, 26.4 mmol) and an equivalent amount of sodium (6.1 g, 26.4 mmol), we added, drop by drop, chloromethyl ethyl ether (25.0 g, 26.4 mmol) at 0°C. The reaction mixture was then extracted with ether. The removal of the solvent *in vacuo*, followed by distillation at 114—125°C/15 mmHg, afforded a mixture of **12** and chloromethyl ethyl ether (45:55). Purification by preparative glc (10% SE 30 on Chromosorb W) yielded **12**. IR (neat): 1077 cm^{-1}; NMR (CCl_4): 1.20 (t, 3H), 3.62 (q, 2H), 4.92 (s, 2H), 7.0—7.6 (m, 5H). Found: C, 64.5; H, 7.2%. Calcd for $C_9H_{12}OS$: C, 64.3; H, 7.2%.

Photolysis of 6a. A solution of **6a** (3.0 g, 10.5 mmol) in 100% EtOH (350 m*l*) was irradiated by means of a 200-W high-pressure mercury arc (Pyrex filter) for 30 hr. Crystalline precipitates were then collected and found to be sulfur (0.42 g). The evaporation of the solvent afforded an intractable oil.

Reaction of 6a with Trimethyloxonium Tetrafluoroborate. A mixture of **6a** (1.7 g, 5.9 mmol) and trimethyloxonium tetrafluoroborate (1.3 g, 8.8 mmol) in dry CH_2Cl_2 (20 m*l*) was stirred at room temperature under nitrogen for 24 hr. After the evaporation of the solvent, the residual oil was washed with ether to afford **13a** as an insoluble oil (1.47 g). The crude oil was taken up in deionized water (20 m*l*) and treated with sodium tetraphenylborate (1.6 g, 4.7 mmol) to precipitate **14a** (0.97 g, 33%); mp 143—145°C (dec.) (from acetone-water). Found: C, 78.8; H, 5.9%. Calcd for $C_{41}H_{39}BOS_2$: C, 79.1; H, 6.0%.

Reaction of 6a with Triethyloxonium Tetrafluoroborate. A mixture of **6a** (1.0 g, 3.5 mmol) and triethyloxonium tetrafluoroborate (1.0 g, 5.3 mmol) in CH_2Cl_2 (20 m*l*) was stirred at room tempeature for 24 hr. The evaporation residue was then dissolved in ethanol; the subsequent cautious addition of ether to the solution at 0°C resulted in the precipita-

17) G. Maier, *ibid.*, **95**, 611 (1962).

tion of pure crystals of **13b** (0.79 g, 56%); mp 89—94°C (dec.). Found: C, 53.5; H, 5.2%. Calcd for $C_{18}H_{21}BF_4OS_2$: C, 53.5; H, 5.2%.

The treatment of **13b** (0.28 g, 0.7 mmol) with sodium tetraphenylborate (0.24 g, 0.7 mmol) in deionized water (10 m*l*) afforded **14b** (0.41 g, 92%); mp 165—167°C (from acetone-water). Found: C, 79.3; H, 6.7%. Calcd for $C_{42}H_{41}BOS_2$: C, 79.2; H, 6.5%.

*Reaction of **6b** with Trimethyloxonium Tetrafluoroborate.* A mixture of **6b** (2.26 g, 10.0 mmol) and trimethyloxonium tetrafluoroborate (1.48 g, 10.0 mmol) in CH_2Cl_2 (20 m*l*) was stirred at 0°C for 20 hr. Work-up then afforded **13c** as an oil (2.15 g). The treatment of the crude oil with sodium tetraphenylborate (2.36 g, 6.9 mmol) in a mixture of CH_2Cl_2 (40 m*l*) and water (30 m*l*) afforded a crystalline solid, **14c** (1.72 g, 31%); mp 174—175°C (from acetone-water). Found: C, 77.2; H, 6.6%. Calcd for $C_{36}H_{37}BOS_2$: C, 77.1; H, 6.7%.

*Reaction of **2** with (E)-1,2-Dibenzoylethylene.* To a solution of **2** in THF (150 m*l*), prepared by the treatment of **1** (2.65 g, 10.0 mmol) with *n*-butyllithium at −20°C, we added, drop by drop, solution of (E)-1,2-dibenzoylethylene (2.30 g, 9.7 mmol) in THF (50 m*l*). After being stirred for an additional hour at the same temperaure, the reaction mixture was allowed to warm up to room temperature; it was then diluted with water and extracted with chloroform. The chloroform solution was dried ($MgSO_4$) and concentrated, and the residual oil was chromatographed on a silica gel column. Elution with a mixture of benzene and hexane (3:1) afforded *r*-1, *t*-2-dibenzoyl-*t*-3-(phenylthio)-cyclopropane (**15**, 0.96 g, 27%); mp 113.5—114°C (from PhH-hexane). IR (KBr): 1660, 1336, 1208, 1010 cm^{-1}; NMR (CCl_4): 3.40—3.76 (m, 3H), 6.9—8.0 (m, 15H). Found: C, 76.8; H, 5.2%. Calcd for $C_{23}H_{18}O_2S$: C, 77.1; H, 5.1%.

*Reaction of **2** with (Z)-1,2-Dibenzoylethylene.* To a solution of **2** in THF (150 m*l*), prepared by the treatment of **1** (1.92 g, 7.3 mmol) and *n*-BuLi (7.3 mmol) at −50°C under nitrogen, we added, drop by drop, a solution of (Z)-1,2-dibenzoylethylene (1.52 g, 6.4 mmol) in THF (40 m*l*). After being stirred for an additional hour at the same temperature, the reaction mixture was allowed to warm up to room temperature. Work-up then afforded **15** (1.21 g, 53%) (mp and mixed mp 113.5—114°C), which was identical with the above sample.

*Oxidation of **15**.* A solution of **15** (0.09 g, 0.3 mmol) and 30% H_2O_2 (*ca.* 5 m*l*) in AcOH (10 m*l*) was stirred at room temperature for 4 days. The reaction mixture was then diluted with water, neutralized with aqueous $NaHCO_3$ and extracted with $CHCl_3$. After drying ($MgSO_4$), the solution was concentrated to afford *r*-1,*t*-2-dibenzoyl-*t*-3-phenylsulfonylcyclopropane (**16**, 0.10 g, 100%); mp 188—189°C (from benzene). IR (KBr): 1676, 1318, 1270, 1220, 1151 cm^{-1}; NMR ($CDCl_3$): 3.47 (q, 1H, J_{AC}=6.0 Hz, J_{AB}=10.2 Hz), 3.81 (q, 1H, J_{BC}=6.0 Hz, J_{AB}=10.2 Hz), 4.42 (t, 1H, J_{AC}=J_{BC}=6.0 Hz), 7.1—8.2 (m, 15H). Found: C, 70.9; H, 4.8%. Calcd for $C_{23}H_{18}O_4S$: C, 70.8; H, 4.7%.

*Reaction of **2** with Diethyl Fumarate.* To a solution of **2** in THF (150 m*l*), prepared from **1** (2.65 g, 10.0 mmol) and *n*-BuLi (10.0 mmol) at −20°C under nitrogen, we added, drop by drop, a solution of diethyl fumarate (1.55 g, 9.0 mmol) in THF (15 m*l*). After the reaction mixture had then been stirred for 1 hr at the same temperature, it was allowed to warm up to room temperature. Work-up then afforded diethyl *t*-3-(phenylthio)-*r*-1,*t*-2-cyclopropanedicarboxylate (**17**, 1.34 g, 51%); bp 125—126°C/0.05 mmHg. An analytically-pure sample was obtained by preparative GLC (30% High Vacuum Silicone Grease on Celite 535, 220°C). IR (neat): 1729, 1328, 1255, 1172, 1025 cm^{-1}; NMR (CCl_4): 1.15 (t, 3H), 1.31 (t, 3H), 2.30—3.10 (m, 3H), 3.98 (q, 2H), 4.08 (q, 2H), 6.8—7.3 (m, 5H). Found: C, 61.5; H, 6.3%. Calcd for: $C_{15}H_{18}O_4S$: C, 61.2; H, 6.2%.

*Oxidation of **17**.* A solution of **17** (0.31 g, 1.1 mmol) and 30% H_2O_2 (*ca.* 15 m*l*) was heated at 70°C for 12 hr with stirring. Subsequent work-up and chromatography (silica gel column, benzene) afforded diethyl *t*-3-phenylsulfonyl-*r*-1,*t*-2-cyclopropanedicarboxylate (**18**, 0.32 g, 90%) as an oil. This oil solidified on standing at room temperature for several months, mp 60—61.5°C. IR (neat): 1730, 1370, 1320, 1265, 1180, 1150, 1019, 1030 cm^{-1}; NMR (CCl_4): 1.30 (t, 3H), 1.33 (t, 3H), 2.43—3.10 (m, 3H), 4.16 (q, 2H), 4.23 (q, 2H), 7.2—8.0 (m, 5H). Found: C, 54.9; H, 5.6%. Calcd for $C_{15}H_{18}O_6S$: C, 55.2; H, 5.6%.

*Attempted Reaction of **6a** with (E)-1,2-Dibenzoylethylene and Diethyl Fumarate.* A solution of **6a** (1.2 g, 4.3 mmol) and (E)-1,2-dibenzoylethylene (1.0 g, 4.3 mmol) in THF (100 m*l*) was heated under reflux for 6 hr. A work-up then resulted in a complete recovery of the starting materials. The similar treatment of **6a** (1.44 g, 5.0 mmol) and diethyl maleate (0.86 g, 5.0 mmol) also resulted in a complete recovery of the starting materials.

C-C Bond Fission in Carboxamides. Kinetic Studies on Alkaline Hydrolysis of Substituted α-Nitroisobutyranilides

Hiroteru SAYO, Hidenobu OHOMORI, Tsuneji UMEDA, and Masaichiro MASUI

Faculty of Pharmaceutical Sciences, Osaka University, Toyonaka, Osaka-fu

(Received May 4, 1971)

Alkaline hydrolysis of substituted α-nitroisobutyranilides, trichloroacetanilide and trifluoroacetanilide was studied kinetically at various hydroxyl ion concentrations in 10% aqueous dioxane. The formation of phenylcarbamate ion as an intermediate was confirmed on hydrolysis of the α-nitroisobutyranilides and trichloroacetanilide but not trifluoroacetanilide. All the substituted α-nitroisobutyranilides except the *p*-nitro derivative were found to undergo C–C bond fission exclusively. Trichloroacetanilide and the *p*-nitro derivative of α-nitroisobutyranilide underwent both C–C and C–N bond fission. The mechanism of C–C bond fission in the hydrolysis of α-nitroisobutyranilides was explained on the basis of the solvent isotope effect as a fast reversible addition of a hydroxyl ion followed by a rate-determining decomposition of the tetrahedral addition intermediate to form a phenylcarbamate ion and a carbanion.

Alkaline hydrolysis of anilides containing strongly electron attracting groups in the acylic part of the molecule has been studied extensively by many workers, but the only reaction pathway so far proposed is C–N bond fission to give carboxylate anion and aniline as primary products.

The only exception to this pathway is that deduced from the brief description of Eriksson and Holst[1] of a distinct odour of phenyl isocyanide and formation of chloride ion during the alkaline hydrolysis of trichloroacetanilide, but these authors did not discuss the origin of these compounds.

Previously we found an unusual C–C bond fission besides the usual C–N bond fission during studies on alkaline hydrolysis of α-nitroisobutyramide[2] and trichloroacetanilide,[3] and showed the origin of phenyl isocyanide and chloride ion in the latter case.

The present work was on alkaline hydrolysis of substituted α-nitroisobutyranilides to examine C–C bond fission in the alkaline hydrolysis of carboxamides. Use of substituted anilides facilitated studies on the effect of structural change on the hydrolysis and provided much information on the mechanism of the reaction.

Experimental

Materials. α-Nitroisobutyranilides were prepared by condensation of α-nitroisobutyryl chloride, obtained by a known method,[4] with appropriate anilines in dichloromethane at 0°C in the presence of potassium carbonate. They were recrystallized from appropriate solvents. The results of analyses are shown in Table 1. Trichloroacetanilide[5] and trifluoroacetanilide[6] were prepared by a known method and gave the expected analytical values. Deuterium oxide (99.75% D_2O) and NaOD (in 99.75% D_2O) were obtained from Merck and Co., Inc. The inorganic compounds used were of reagent grade.

Apparatus. Spectroscopic measurements were carried out with a Shimadzu, type QV-50, spectrophotometer. A Metrohm pH-meter, type E-300B, with a combined electrode was used for pH measurements.

Kinetic Measurements. Kinetic measurements were made spectrophotometrically at 50±0.02°C in 10% (V/V) aqueous dioxane unless otherwise specified. The ionic strength of the reaction mixture was adjusted to 0.9 by addition of potassium chloride except for $[OH^-]>0.9$M. The initial concentration of anilides was in the range 10^{-3} to 10^{-4}M. The concentration of sodium hydroxide was estimated with sulfamic acid. In a typical run, a volume of about 85 m*l* of sodium hydroxide solution, with the desired amount of potassium chloride, was put into a 100 m*l* volumetric flask and warmed to 50±0.02°C in a water bath. A volume of 10 m*l* of anilide in dioxane and the necessary amount of sodium hydroxide solution to make up the volume, both at 50°C, were added to the flask. The resulting mixture was quickly shaken, and then stood in the bath. At appropriate intervals 0.50 m*l* of the solution was pippetted into 5 m*l* of 1N HCl and the absorbance due to unreacted anilide was measured. The rate constant of the reaction was obtained graphically using the usual pseudo-first order kinetic treatment. The absorption maxima of the anilides used are shown in Table 1. With the *m*-nitro derivative, the absorption of *m*-nitroaniline overlaps that of the anilide in acidic solution, so the above method was not applicable. Hence *m*-nitroaniline was converted into its diazonium salt in 1N-HCl solution, and the absorption of this salt at 540 mμ was followed. *m*-Nitrophenylcarbamic acid was rapidly converted into *m*-nitroaniline under these condition and hence the amount of diazonium salt observed corresponded to the sum of the amounts of aniline and phenylcarbamic acid present in the reaction mixture.

Phenylcarbamate ion in the reaction mixture was separated and determined by the method of Christenson.[7] The rate of decomposition of phenylcarbamate ion (k_6 in Table 4) was measured with phenyl isocyanate.

Acid Dissociation Constants. pK_a values for the α-nitroisobutyranilides were determined from the change in the absorbance with pH. Stock solutions of an anilide were mixed with appropriate buffers and the absorbances of the anilide in its undissociated form were measured at its λ_{max} shown in Table 1. Error due to the time lapse between mixing and reading the absorbance was corrected by extrapolation of values to zero time.

Results

Hydrolysis of Substituted α-Nitroisobutyranilides. The rate of hydrolysis of all α-nitroisobutyranilides used was first-order in the anilide at constant hydroxyl ion concentration. The final products were 2-nitropropane aci-ion, substituted aniline and carbonate ion. The observed pseudo-first-order rate constant, k_{obs}, approaches a limiting value with increase in hydroxyl ion concentration, as shown in Fig. 1 and Table 2. These limiting values, k_{limit}, are also summarized in Table 2. A similar phenomenon was observed by Erikson and Holst on hydrolysis of trichloro- and trifluoroacetanilide.[1] The effect of the initial concentration on k_{obs} was examined with concentrations of 2×10^{-4} to 8×10^{-4}M of unsubstituted α-nitroisobutyranilide at a hydroxyl ion concentration of 0.9M and μ=0.9: no effect was observed. Change in ionic strength between 0.9 and 3.6 had no effect on k_{obs} for hydrolysis of the same anilide at a hydroxyl ion concentration of 0.9M. Substituted phenylcarbamate ion was detected by the method of Christenson[7] in the reaction mixture during the hydrolysis, and its concentration increased with time, up to a maximum, and then decreased slowly towards zero at infinite time. A typical example of the hydrolysis of unsubstituted α-nitroisobutyranilide is shown in Fig. 2. The time when the phenylcarbamate ion reaches its maximum concentration is given in Table 3, as t_{max}, with the relative concentration of phenylcarbamate ion at this time. The maximum concentration of phenylcarbamate ion increased with the concentration of hydroxyl ion.

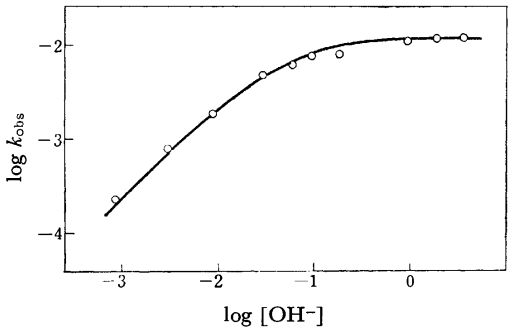

Fig. 1. Plot of log k_{obs} against log [OH⁻] in the alkaline hydrolysis of α-nitroisobutyranilide. The line is calculated from Eq. (16) and parameter values in Table 2.

a) $[C]_{max}$ represents the concentration of phenylcarbamate ion at $t=t_{max}$; $[A_0]$ is the initial concentration of total anilide.

Acid Dissociation Constants. The acid dissociation constants of α-nitroisobutyranilides are summarized in Table 2. A plot of the acid dissociation constants for substituted α-nitroisobutyranilides against the Hammett σ values was linear with $\rho=+1.19$ (figure not shown). With the *p*-nitro derivative, use of the σ^- value fitted the line better.

Decomposition of Phenylcarbamate Ion. In aqueous alkaline solution phenyl isocyanate is rapidly transformed to phenylcarbamate ion, and the latter decomposes gradually to give aniline and carbonate ion.[7,8] The rate of the decarboxylation reaction was measured at 50—70°C. The pseudo-first-order rate constants are summarized in Table 4.

Table 4. Pseudo-first-order rate constants for the decomposition of phenylcarbamate ion k_6 at 50°C

$[OH^-]$, M[a]	1.9	0.9	0.18	0.09	0.009
10^3k_6, min^{-1}	3.31	6.50	8.56	11.8	35.0

a) $\mu=0.9$ except for $[OH^-]>0.9$ M, containing 10% (v/v) dioxane.

Hydrolysis of Trichloro- and Trifluoroacetanilide. Table 2 also shows data for the hydrolysis of trichloro- and trifluoroacetanilide. The rates obtained at 25°C are in fairly good agreement with those reported previously.[1] A considerable amount of phenylcarbamate ion was obtained on hydrolysis of trichloroacetanilide, and the amount increased to a maximum as in the case of α-nitroisobutyranilides (Table 3). Thus it seems that the reaction pathway for the hydrolysis of trichloroacetanilide is comparable to that of α-nitroisobutyranilides. However, with trifluoroacetanilide, the concentration of phenylcarbamate ion was very low during the run and so no maximum was observed.

8) E. Mohr, *J. Prakt. Chem.*, [2] **73**, 177 (1906); C. Naegeli, A. Tyabji, L. Conrad, and F. Litwan, *Helv. Chim. Acta*, **21**, 1100 (1938).

Table 5. Rate constants k_{obs} and activation parameters for the hydrolysis of anilides $RCONHC_6H_5$, $[OH^-]=0.9$M, $\mu=0.9$

Temp. (°C)		R: $Me_2C(NO_2)$	CCl_3	CF_3
10^3k_{obs}, min^{-1}	25		10.0	33.7
	35		27.0	85.0
	50	10.8	117	291
	60	28.7		
	70	80.6		
E_a, kcal/mol		21.8	18.9	16.4
$\Delta S^{\neq}$, e.u.		−10.5	−14.7	−20.5

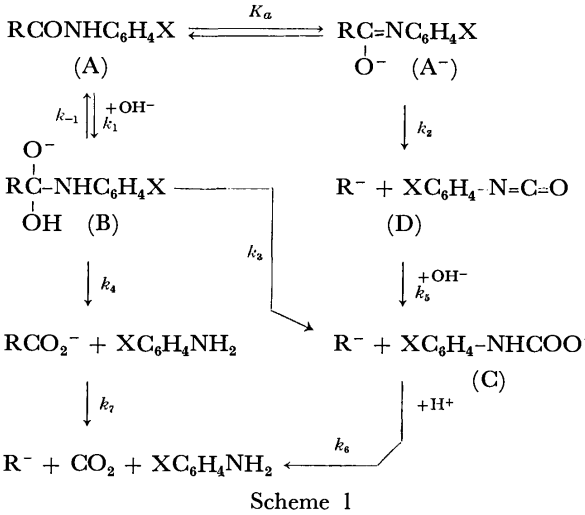
The rate of aniline formation was essentially the same as that of disappearance of anilide. The results suggest that a C–C bond fission similar to that with trichloroacetanilide scarcely occurs during hydrolysis of trifluoroacetanilide.

Activation Parameters. The activation parameters for the hydrolysis of α-nitroisobutyranilide, trichloroacetanilide and trifluoroacetanilide are shown in Table 5. They were obtained at a hydroxyl ion concentration of 0.9M, where the observed pseudo-first-order rate constant is very close to its limiting value, k_{limit}.

Solvent Isotope Effect. Solvent isotope effects on the hydrolysis of α-nitroisobutyranilide, trichloroacetanilide and trifluoroacetanilide were examined at a hydroxyl ion concentration of 1.8M, where $k_{obs}=k_{limit}$ was valid for each of these compound. The $k_{obs}(H)/k_{obs}(D)$ ratio was 1.10 ± 0.07 for α-nitroisobutyranilide, 1.33 ± 0.06 for trifluoroacetanilide and 1.39 ± 0.04 for trichloroacetanilide.

Discussion

Formation of phenylcarbamate ion as an intermediate and other results suggest the following reaction pathway for the hydrolysis of α-nitroisobutyranilides:



Scheme 1

(The possibility that step k_3 involves a term catalyzed by hydroxyl ion cannot be excluded at this point.

This will be discussed later.) A similar step to that involving formation of phenyl isocyanate (D) as an intermediate has been demonstrated in the hydrolysis of carbamic acid esters.[7] Assuming that B is in a steady state, the observed pseudo-first-order rate constant (k_{obs}) for the disappearance of total anilide is given by Eq. (1).

$$k_{obs} = \frac{K_w}{K_a+a_H}\left(\frac{k_1k_3}{k_{-1}+k_3+k_4} + \frac{k_1k_4}{k_{-1}+k_3+k_4}\right) + \frac{k_2K_a}{K_a+a_H} \quad (1)$$

where K_a is the dissociation constant defined in Eq. (2), K_w is the ionic product of water, and a_H is the activity of hydronium ion.

$$K_a = \frac{[A^-]a_H}{[A]} \quad (2)$$

The conversion of phenyl isocyanate into phenylcarbamate ion has been reported to be very rapid in alkaline solution,[7,8] and hence D can also be considered to be in a steady-state. The rate of the change in C is given by Eq. (3).

$$\frac{d[C]}{dt} = \lambda[A_0]e^{-k_{obs}t} - k_6[C], \quad (3)$$

where $$\lambda = \frac{K_w}{K_a+a_H}\cdot\frac{k_1k_3}{k_{-1}+k_3+k_4} + \frac{k_2K_a}{K_a+a_H} \quad (4)$$

and $[A_0]$ is the initial concentration of total anilide, so that

$$[C] = \frac{\lambda[A_0]}{k_{obs}-k_6}(e^{-k_6t}-e^{-k_{obs}t}). \quad (5)$$

We now define t_{max} as the time for C to reach its maximum concentration, and $[C]_{max}$ as the concentration of C at this time. When $t=t_{max}$, then $d[C]/dt=0$ is valid. Substituting [C] from equation (5) in equation (3) and solving about t_{max} gives Eq. (6).

$$t_{max} = \frac{\ln k_{obs} - \ln k_6}{k_{obs}-k_6} \quad (6)$$

The t_{max} calculated in Table 3 was obtained using experimental values of k_{obs} (Table 2), k_6, measured separately (Table 4),[9] and Eq. (6). The good agreement between the observed and calculated values substantiates the above equations.

From Eq. (3)

$$\lambda[A_0]e^{-k_{obs}\cdot t_{max}} - k_6[C]_{max} = 0$$

$$\lambda = k_6\frac{[C]_{max}}{[A_0]}e^{k_{obs}\cdot t_{max}} \quad (7)$$

Thus the value of λ can be calculated from experimental values. By subtracting Eq. (4) from Eq. (1), we obtain Eq. (8).

$$k_{obs} - \lambda = \frac{K_w}{K_a+a_H}\cdot\frac{k_1k_4}{k_{-1}+k_3+k_4}. \quad (8)$$

As shown in Table 3, the values of $k_{obs}-\lambda$ for the substituted α-nitroisobutyranilides are essentially zero within the limits of experimental error except with the *p*-nitro derivative. This strongly suggests that the hydrolysis of these compounds proceeds exclusively through pathways involving phenylcarbamate ion as an intermediate, that is, k_1 or k_4 is negligible. If $k_4\simeq 0$, Eq. (1) can be reduced to Eq. (9). (As will be discussed later, the experimental results obtained were not explained successfully when $k_1\simeq 0$).

$$k_{obs} = \frac{K_w}{K_a+a_H}\frac{k_1k_3}{k_{-1}+k_3} + \frac{k_2K_a}{K_a+a_H} \quad (9)$$

From Eq. (9)

$$\frac{k_1k_3K_w}{k_{-1}+k_3} + k_2K_a = k_{obs}(K_a+a_H) \quad (9')$$

Table 6. Values of $k_{obs}(K_a+a_H)$ for the hydrolysis of α-nitroisobutyranilide at various hydroxyl ion concentrations at 50°C

$[OH^-]$, M	3.6	1.8	0.9	0.09	0.054	0.009	0.0009
$10^{14}k_{obs}(K_a+a_H)$, M·min^{-1}	1.90	1.88	1.80	1.77	1.84	1.97	1.95

As shown in Table 6, the value of $k_{obs}(K_a+a_H)$ does not change with hydroxyl ion concentration within the limits of experimental error, and hence the left hand side of Eq. (9') can also be regarded as constant. Since mechanistically k_1, k_{-1}, and k_2 should be constants, two possibilities may be considered. First, k_3 does not contain a term dependent on hydroxyl ion concentration; that is, k_3 is also a constant. If this is not the case, $k_3 \gg k_{-1}$ should be true to make the term constant. In Eq. (9) the first term represents the rate constant for disappearance of total anilide through the tetrahedral intermediate (B), and the second term that for disappearance through phenyl isocyanate (D). It is difficult to decide which step is predominant, but solvent isotope effects should afford a clue to this problem. Tobias and Kézdy have reported a method for determining whether carbanions are intermediates in the hydrolysis of esters with labile α protons.[10] This method would be applicable in the present case.

In the pH region where $K_a \gg a_H$ Eq. (9) can be simplified to Eq. (10).

$$k_{obs} = k_{limit} = \frac{K_w}{K_a}\cdot\frac{k_1k_3}{k_{-1}+k_3} + k_2 \quad (10)$$

If only step k_2 is operative,

$$k_{obs} = k_2$$

Since no proton transfer is involved in this step, it is expected that $k_{obs}^{H_2O}/k_{obs}^{D_2O}=1$.[10] On the other hand, if step k_3 is actually operative, the observed isotope effect should be

$$k_{obs}^{H_2O}/k_{obs}^{D_2O} = (k^{H_2O}/k^{D_2O})(K_w^{H_2O}/K_w^{D_2O})(K_a^{D_2O}/K_a^{H_2O}), \quad (11)$$

where $k=k_1k_3/(k_{-1}+k_3)$.

The values of $K_w^{H_2O}/K_w^{D_2O}$ and $K_a^{H_2O}/K_a^{D_2O}$ at 50°C were estimated by the method of Swain, Kuhn and Schowen[11] to be 5.8 and 3.05, respectively. The

9) k_6 is the pseudo-first-order rate constant for the decomposition of phenylcarbamic acid and varies with hydroxyl ion concentration in a complicated manner. No further investigation was carried out, since the absence of information on the detailed nature of k_6 would not affect the conclusion.

10) P. S. Tobias and F. J. Kézdy, *J. Amer. Chem. Soc.*, **91**, 5171 (1969).

11) C. G. Swain, D. A. Kuhn, and R. L. Schowen, *ibid.*, **87**, 1553 (1965).

value of $K_w^{H_2O}/K_w^{D_2O}$ at 25°C estimated by the same method is 6.75, which is in good agreement with the reported value of 6.67 ($K_w^{D_2O}/K_w^{H_2O}=0.15$).[12] This seems to substantiate the above assumptions. Using these values and Eq. (11), we get

$$k_{obs}^{H_2O}/k_{obs}^{D_2O} = 1.9(k_1^{H_2O}/k_1^{D_2O}) \quad (12)$$

where $k_3 \gg k_{-1}$, and another Eq. (13) where $k_{-1} \gg k_3$.

$$k_{obs}^{H_2O}/k_{obs}^{D_2O} = 1.9\times(k_1k_3/k_{-1})^{H_2O}/(k_1k_3/k_{-1})^{D_2O} \quad (13)$$

It has been reported that an inverse isotope effect is involved in a process in which hydroxyl ion attacks a carbon atom, and the expected maximum isotope effect in such a process should be 1.7^{-1}.[13] Equation (12) is, then

$$k_{obs}^{H_2O}/k_{obs}^{D_2O} = 1.9/1.7^{\beta} \quad (14)$$

where β represents the degree of bond formation in the transition state, that is $0 \leqq \beta \leqq 1$.[11] As discussed above step k_3 does not involve a term catalyzed by hydroxyl ion when Eq. (13) holds, and hence no solvent isotope effect is expected as in step k_2. Thus Eq. (13) becomes

$$k_{obs}^{H_2O}/k_{obs}^{D_2O} = 1.9/1.7 \fallingdotseq 1.12 \quad (15)$$

The observed solvent isotope effects were 1.33 and 1.39 for trifluoroacetanilide and trichloroacetanilide, respectively. On hydrolysis of these two anilides, at the lyoxide ion concentration used in this study the attack of hydroxyl ion on the anilide was shown to be rate-determining.[1] The observed values are in the range expected from Eq. (14). In the hydrolysis of trichloroacetanilide, therefore, the possibility of phenylcarbamate ion being produced through step k_2 seems unlikely. If it is not the case, the observed solvent effect should be smaller than that for trifluoroacetanilide, because more than one third of the whole reaction proceeds through phenylcarbamate ion.

The solvent isotope effect observed in the hydrolysis of α-nitroisobutyranilide at a lyoxide ion concentration of 1.8M was 1.10, which is very close to the value expected from Eq. (15). The results strongly suggest that the hydrolysis of α-nitroisobutyranilide mainly proceeds through the tetrahedral addition intermediate (B), and the rate of decomposition of this intermediate to phenylcarbamate ion is slower than that of liberation of hydroxyl ion to give the original anilide, that is, $k_{-1} \gg k_3$.

The value of activation entropy, $\Delta S^{\ddagger} = -10.5$ eu., also seems to support this view. In the hydrolysis of carbamic acid esters, those hydrolyzed *via* a reaction pathway with an isocyanate intermediate like step k_2 in Scheme 1, have positive $\Delta S^{\ddagger}$ values, and those having negative $\Delta S^{\ddagger}$ values have been stated to be hydrolyzed *via* a tetrahedral addition intermediate.[7] The $\Delta S^{\ddagger}$ values of several of the latter esters are less negative than that of α-nitroisobutyranilide. If step k_2 in Scheme 1 actually operates in the hydrolysis of α-nitroisobutyranilide, the value of $\Delta S^{\ddagger}$ should be positive. The possibility that the reaction occurs *via* both pathways, k_2 and k_3, is not completely eliminated, but it seems extremely likely that step k_2 is not the main pathway.

From the above discussion Eq. (9) may be reduced to Eq. (16).

$$k_{obs} = \frac{K_w}{K_a + a_H} \cdot \frac{k_1k_3}{k_{-1}}. \quad (16)$$

Using the values of k_{limit} (Table 2), K_a (Table 2), and K_w, the value of k_1k_3/k_{-1} is calculated to be 0.347 min^{-1} for the hydrolysis of α-nitroisobutyranilide. The solid line in Fig. 1 is calculated from Eq. (16) and these values. This calculated line agrees well with the observed rate constants.

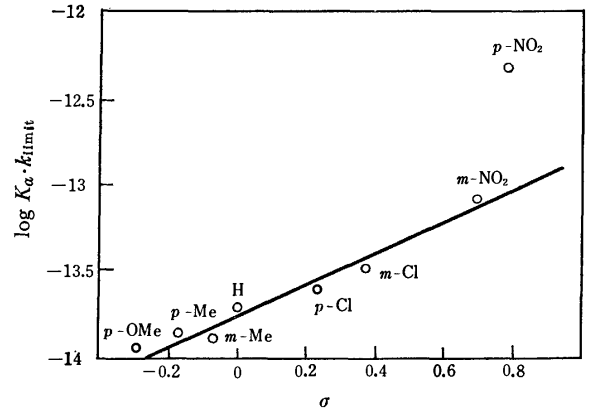


Fig. 3. Plot of $k_{limit} \cdot K_a$ against σ.

A plot of the value $k_1k_3K_w/k_{-1}$ ($=k_{limit} \cdot K_a$) for the substituted α-nitroisobutyranilides against Hammett σ values was essentially linear with $\rho=0.83$ (Fig. 3) except for the *p*-nitro derivative. The upward deviation observed with this anilide was reduced when the σ^- value was used. However, it is doubtful whether this treatment is adequate in the present case. Since the value of $k_{obs}-\lambda$ for the *p*-nitro derivative (Table 3) is more than half that of k_{obs} at 0.9M hydroxyl ion concentration, a considerable amount of C–N bond fission, that is normal hydrolysis, occurs in the hydrolysis. This fact seems compatible with the observed deviation in Fig. 3. In the hydrolysis of substituted acetanilide, the *p*-nitro derivative reacts appreciably faster than the rate predicted from the rates observed with other anilides, and thus a new mechanism was introduced to interpret the hydrolysis of anilides with strongly electron withdrawing substituents on the phenyl ring.[14] The C–N bond in the *p*-nitro derivative of α-nitroisobutyranilide must be activated by the *p*-nitro group more than that in other derivatives, and hence normal hydrolysis becomes possible to some extent.

It is interesting to compare the results obtained with trifluoroacetanilide, trichloroacetanilide and α-nitroisobutyranilide. In the hydrolysis of the trifluoro-derivative, no C–C bond fission was observed, that is the reaction was normal. With the trichloro-derivative, the ratio of C–C bond fission to C–N bond fission is more than one third. With the α-nitroisobutyr-deriv-

atives, the reaction proceeds exclusively through C–C bond fission except with the *p*-nitro-derivative. A similar phenomenon was observed in studies on the formation of a tetrahedral addition intermediate of ethyl acetate derivatives.[15] The addition compound from ethyl trichloroacetate was found to decompose *via* C–C bond fission to give ethyl carbonate, whereas that from ethyl trifluoroacetate did not.

The value of activation energy for the decarboxylation of the carboxylic acids shown in Table 7 are interesting. The order of facility of C–C bond fission coincides with that observed in the present study. It seems clear from the above considerations that C–C bond fission increases with stability of the carbanion formed.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 208—213 (1972)

Studies of the Synthesis of Furan Compounds. XXVI.[1] The Reaction of 5-Nitro-2-furimidoylhydrazine with Acid Anhydrides[2]

Ichiro HIRAO, Yasuhiko KATO, and Hiromichi TATEISHI

Laboratory of Organic Synthesis, Department of Chemical Engineering, Kyushu Institute of Technology, Tobata-ku, Kita-kyushu

(Received May 10, 1971)

Reactions between 5-nitro-2-furimidoylhydrazine (I) and acetic or propionic anhydride (or the corresponding acids) under various conditions afforded 5-methyl- (II) and 5-ethyl-2-(5-nitro-2-furyl)-1,3,4-oxadiazole (IV) and 5-methyl- (III), 5-ethyl- (IX), 1-acetyl-5-methyl- (VII), 1-propionyl-5-ethyl- (VIII), 1-propionyl-5-methyl- (X), and 1-acetyl-5-ethyl-3-(5-nitro-2-furyl)-1,2,4-triazole (XI) respectively. The treatment of I with acetic and propionic anhydride in refluxing benzene or tetrahydrofuran gave 1-acetyl- (V) and 1-propionyl-2-(5-nitro-2-furimidoyl)-hydrazine (VI) respectively. Compounds, VII, VIII, X, and XI were also prepared by the cyclization of V with propionic anhydride and by that of VI with acetic anhydride in dioxane. The structures of the products were discussed on the basis of the spectral data.

In continuation of our previous report on the preparation of several 5-nitro-2-furyl-heterocycles by the cyclization of 5-nitro-2-furimidoylhydrazine (I) with bifunctional compounds,[3] this paper will deal with the preparation of acyl (or without acyl)-(5-nitro-2-furyl)-5-alkyl-1,2,4-triazoles by the reaction of I with acid anhydries under various reaction conditions, and with the determination of the position of the acyl group in the triazole nucleus on the basis of the reactions of the acyl derivatives of I with acetic and propionic anhydrides.

Results and Discussion

Atkinson and Polya reported the synthesis of 1-methyl (or phenyl)-3-phenyl-1,2,4-triazole by the reaction of the corresponding 1-substituted 2-benzimidoylhydrazine with formic acid,[4] while Atkinson *et al.* reported that of 3-amino-5-alkyl (or aryl)-1,2,4-triazoles from an aminoguanidine salt and the appropriate organic acid in the presence of a small amount of nitric acid.[5] In a similar manner, when I was heated in glacial acetic acid, two products, II and III, were obtained. Compound II was identified as the 2-(5-nitro-2-furyl)-5-methyl-1,3,4-oxadiazole by an admixture-test and by a comparison of its IR spectrum with that of an authentic specimen,[3] while III was confirmed to be 3-(5-nitro-2-furyl)-5-methyl-1,2,4-triazole on the basis of the analytical and spectral data. The similar treatment of I with propionic acid afforded only one product, 2-(5-nitro-2-furyl)-5-ethyl-1,3,4-oxadiazole (IV) (Scheme 1).

1-Acetyl-(V) and 1-propionyl-2-(5-nitro-2-furimidoyl)-

hydrazine (VI) were obtained by treating I with acetic and propionic anhydrides respectively in refluxing benzene or tetrahydrofuran. However, I afforded 1-acetyl-3-(5-nitro-2-furyl)-5-methyl-1,2,4-triazole (VII) and 1-propionyl-3-(5-nitro-2-furyl)-5-ethyl-1,2,4-triazole (VIII) when heated in large excesses of acetic and propionic anhydride respectively. Compounds VII and VIII were similarly obtained from, respectively, V and acetic anhydride, and VI and propionic anhydride.

When heated in water, VII afforded III, and VIII provided 3-(5-nitro-2-furyl)-5-ethyl-1,2,4-triazole (IX),

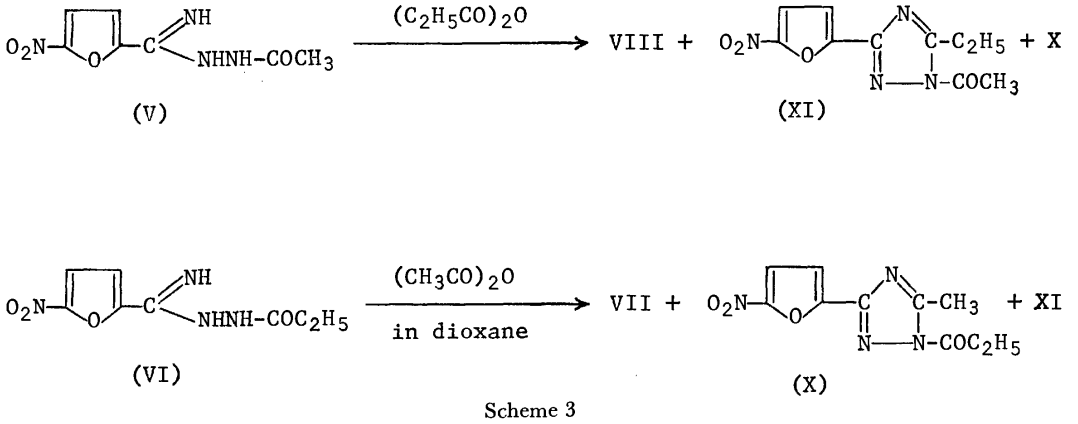
a) TMS was used as the internal standard. b) HMDS was used as the internal standard. c) Two protons of the furan ring were overlapped and showed a singlet. d) The CH_3 and $COCH_3$ protons appeared the same field and formed a singlet.

both in almost quantitative yields. III was reverted to VII by heating it in acetic anhydride, and IX, to VIII in propionic anhydride. 1-Propionyl-5-methyl- (X) and 1-acetyl-5-ethyl-3-(5-nitro-2-furyl)-1,2,4-triazole (XI) were obtained by the treatment of III with hot propionic anhydride, and by the treatment of IX with hot acetic anhydride, whereas X and XI reverted to III and IX respectively upon heating with water. Furthermore, X was converted into VII, and also VIII into XI, by heating them with acetic anhydride. These results show that the acyl group on a nitrogen of the triazole nucleus could be replaced easily be an acyl group of the acid anhydride employed (Scheme 2).

The IR spectra showed a characteristic wide ammonium absorption in the 3010—2550 cm^{-1} region for III, and in the 3150—2800 cm^{-1} region for IX. This fact, as has been discussed previously,[3] suggests that both III and IX contribute to an intermolecular association because of the hydrogen transfer between two adjacent molecules. Neither the spectrum of III nor that of IX showed the C=O stretching absorption which was observed at 1680 cm^{-1} in the spectra of compounds V and VI. In the finger-print region, III had a sharp band at 1058 cm^{-1} due to a methyl rocking vibration, and IX contained three absorptions, at 1062, 1048, and 842 cm^{-1}. The 1048 cm^{-1} band is assigned to the CH_3 rocking vibration, and the 1062 and 842 cm^{-1} bands to the C–H wagging motion of the $-C_2H_5$ group.

On comparing the IR spectra of the four acyl compounds (VII, VIII, X, and XI), all of them were found to show a strong absorption band, VII at 1736, VIII at 1738, X at 1759, and XI at 1754 cm^{-1} due to the C=O stretching vibration. The weak to medium bands due to the C–H stretching motion in VII, VIII, X, and XI appeared in the 3000—2800 cm^{-1} region. In the finger-print regions, the band assignable to the CH_3 rocking mode in VII was observed at 1091 cm^{-1} and also in X at 1089 cm^{-1}. In the compound VIII, the 1084, 1060, and 828 cm^{-1} bands, and in XI, the 1085, 1060, and 830 cm^{-1}, bands might be assignable much as in the mother compound, IX. Two strong bands and a weak one appeared at 962, 646, and 727 cm^{-1} respectively in VII; the corresponding ones at 962, 646, and 723 cm^{-1} in XI were assigned to a $-COCH_3$ group introduced, while the bands due to the $-COC_2H_5$ motion in VIII are observed as a weak band at 964 cm^{-1} and a strong one at 943 cm^{-1}, while those in X are observed at 965 and 943 cm^{-1}.

The NMR spectra in DMSO-d_6 supported the structures of III, VII, VIII, IX, X, and XI presented above. As is shown in Table 1, the chemical shifts of the ring methyl or methylene protons of VII, VIII, X, and XI shifted to a lower magnetic field than those of III or IX upon the introduction of an acetyl or propionyl group. This indicates that the acyl group may be introduced into the vicinal nitrogen atom next to the existing alkyl group. The NMR spectra of X and XI in DMSO-d_6 were different from those in trichloroacetic acid (Table 1). Both the acetyl protons and the methylene protons of a propionyl group are more subject to the solvent effect than are the methyl and methylene protons attached to the triazole ring, and their chemical shifts shifted to a higher magnetic field. The C_4-proton of the furan nucleus was very subject to the solvent effect and revealed the signal together, with that of the C_3-ptoton



Scheme 3

at 7.23 ppm of hexamethyldisiloxane (HMDS); accordingly, the signals were observed as a singlet.

On the treatment of VI with a large excess of acetic anhydride in dioxane at 95—100°C for 1 hr, a mixed product was obtained. The components were successfully resolved by treating the mixture with hot ligroin. The ligroin-insoluble part was confirmed to be VII on the basis of the analytical and spectral data. From the ligroin solution, a crystalline powder (XII) (mp 103—105°C) was obtained. The results of an elemental analysis of XII was in good accordance with the calculated value for $C_{10}H_{10}N_4O_4$ (X or XI). Subsequent crystallization from ligroin raised the melting point to 112—114°C, but the results of the elemental analysis were unchanged. In addition, the IR spectrum of XII did not agree with that of X or XI, and it had bands at 980, 955, 725, and 645 cm^{-1}, indicating the presence of both acetyl and propionyl groups. The NMR spectrum as is shown in Fig. 1a, revealed signals at (δ from TMS in DMSO-d_6) 1.26 (q, J=7.5 Hz), 2.74 (s), *ca.* 2.95—3.35 (m), 7.42 (d, J=4.0 Hz), and 7.80 (d, J=4.0 Hz), with relative intensities of 3:3:2:1:1. However, when measured in trichloroacetic acid, the NMR spectrum (Fig. 2b) varied remarkably and showed signals at (δ from HMDS) 0.82 (t, J=7.5 Hz), 1.16 (t, J=7.5 Hz), 1.86 (s), 2.15 (q, J=7.5 Hz), 2.62 (s), 2.94 (q, J=7.5 Hz) and 7.23 (s) (the signal intensity ratio; 0.58: 0.93: 0.92: 0.40: 0.58: 0.62: 1). Considering these data, it was concluded that XII was obviously a mixture of X and XI, and that the component ratio (X:XI) was 39:61 (on the basis of the NMR intensity ratio).

The similar treatment of V with propionic anhydride also produced three compounds, VIII, X, and XI, in the proportion of 1: 0.8: 0.6.

A modern representation of the structure of 1,2,4-triazole takes cognizance of the imino hydrogen atom not being attached to any of the nitrogen atoms, but rather existing as a charged atom closely bound by a negatively-charged triazole nucleus stabilized by resonance.[6] The substitution reaction upon the imino

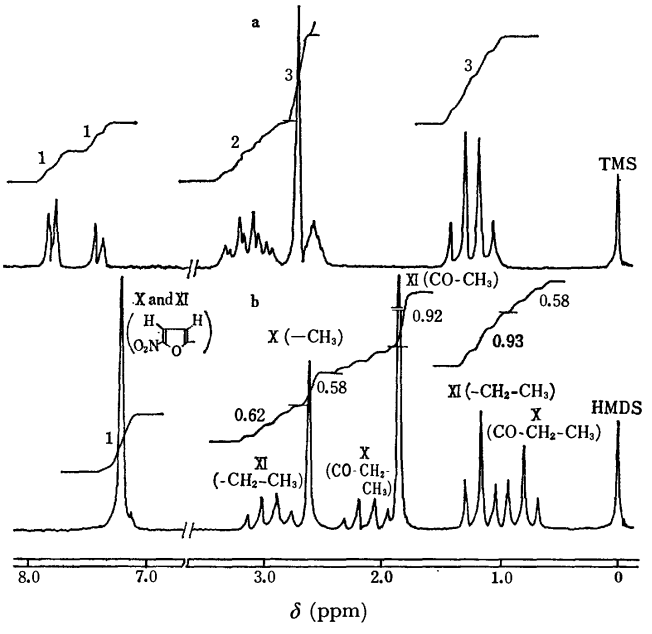


Fig. 1. NMR spectra of XII (mixture of X and XI).
a: measured in DMSO-d_6 at 24°C
b: measured in CCl_3COOH at 70°C

nitrogen of triazole could, then, give three isomeric *N*-substituted derivatives (1-, 2-, and 4-substituted derivatives). In this investigation, none of the isomeric acetyl or propionyl derivatives were isolated, but only a sort of product was obtained in each type of derivative. It is very difficult to determine the position of an acyl group substituted on the triazole nucleus, fortunately, however, we could confirm the formation of XI from the reaction of V with propionic anhydride and from that of X from VI and acetic anhydride by studying the NMR spectra. Consequently, it seems reasonable to conclude that the position of the introduced acyl group of VII, VIII, X, and XI is the vicinal nitrogen atom, far from the 5-nitro-2-furyl group, as has been discussed above.

Experimental

All the melting and decomposition points are uncorrected. The elemental analyses were performed on a Yanagimoto C. H. N. Corder, MT-2 type. The infrared absorption spectra (IR) were measured in potassium bromide discs on a Hitachi grating infrared spectrophotometer, Model EPI-G3.

6) K. T. Potts, *Chem. Rev.*, **61**, 87 (1961). The π-electron densities for 1,2,4-triazole were published in the following literature: a) L. E. Orgel, T. L. Cottrell, W. Dick, and L. E. Sutton, *Trans. Faraday Soc.*, **47**, 113 (1951). b) M. R. Atkinson and J. B. Polya, *J. Chem. Soc.*, **1954**, 3319. c) S. Basu, *Proc. Natl. Inst. Sci. India*, **21A**, 173 (1955).

The nuclear magnetic resonance spectra (NMR) were determined by means of a Nihon-Denshi NMR spectrometer, JNM C-60HL (60 MHz). The spectra were measured in DMSO-d_6 at 24°C with tetramethylsilane (TMS) as the internal standard, and in trichloroacetic acid at 70°C with hexamethyldisiloxane (HMDS) as the internal standard; the chemical shifts are expressed in δ-values.

2-(5-Nitro-2-furyl)-5-methyl-1,3,4-oxadiazole (II) and 3-(5-Nitro-2-furyl)-5-methyl-1,2,4-triazole (III). 5-Nitro-2-furimidoylhydrazine[7] (I) (3 g, 17.6 mmol), glacial acetic acid (50 m*l*), and nitric acid (5 drops) were heated under reflux for 2 hr. After cooling, water (100 m*l*) was added and the mixture was extracted with ether (500 m*l*). The ether extracts were washed with water and dried over anhydrous sodium sulfate. After the concentration of the extracts, the residue was treated with hot benzene (50 m*l*) and the insoluble product was filtered off while hot. Thus, the crude material of III was obtained as an ochreous powder; mp 232—234°C; 0.7 g. Recrystallization from water gave yellow needles; mp 243—244°C. The yield was 0.6 g (17.5%).

Found: C, 43.05; H, 2.95; N, 28.55%. Calcd for $C_7H_6N_4O_3$ (III): C, 43.29; H, 3.09; N, 28.86%.

On cooling of the benzene filtrate, a yellow-ochre powder (0.5 g) was obtained; mp 138—148°C. Crystallization from ethanol afforded pale yellow needles; mp 153—154°C. Yield, 0.3 g (8.7%).

Found: C, 43.54; H, 2.35; N, 21.92%. Calcd for $C_7H_5N_3O_4$ (II): C, 43.07; H, 2.56; N, 21.53%.

This product was identified as the 1,3,4-oxadiazole (II) by an admixture-test and by a comparison of the IR spectrum with that of an authentic specimen.[3]

2-(5-Nitro-2-furyl)-5-ethyl-1,3,4-oxadiazole (IV). A mixture of I (1 g, 5.8 mmol), propionic acid (20 m*l*), and nitric acid (3 drops) was refluxed for 2 hr. Work-up as above afforded 0.3 g (24.4%) of IV, mp 182—183°C, as yellow needles (recrystallized from benzene-ligroin).

Found: C, 46.30; H, 3.36; N, 20.20%. Calcd for $C_8H_7N_3O_4$: C, 45.93; H, 3.35; N, 20.10%.

1-Acetyl- (V) or 1-Propionyl-2-(5-nitro-2-furimidoyl)hydrazine (VI). Acetic or propionic anhydride (each 20 mmol) was added slowly to a stirred solution of I (3.4 g, 20 mmol) in 100 m*l* of benzene (or 70 m*l* of tetrahydrofuran). The mixture was then stirred vigorously at room temperature for 1 hr. After cooling, the product was filtered and recrystallized from methanol. V; orange-yellow cylinders; mp 211—212°C decomp. Yield, 3.96 g (93.3%).

Found: C, 39.98; H, 3.73; N, 26.74%. Calcd for $C_7H_8N_4O_4$ (V): C, 39.62; H, 3.77; N, 26.42%.

VI; orange-yellow needles; mp 216—217°C decomp. Yield, 4.18 g (92.5%).

Found: C, 42.82; H, 4.48; N, 24.77%. Calcd for $C_8H_{10}N_4O_4$ (VI): C, 42.47; H, 4.42; N, 24.78%.

If the recrystallization was achieved from water, V was obtained as its semi-hydrate of yellow needles; mp 210°C.

Found: C, 38.52; H, 4.11; N, 25.31%. Calcd for $C_7H_8N_4O_4 \cdot \frac{1}{2}H_2O$: C, 38.01; H, 4.07; N, 25.34%.

1-Acetyl-3-(5-nitro-2-furyl)-5-methyl-1,2,4-triazole (VII).

From I and Acetic Anhydride: A solution of I (3.4 g, 20 mmol) in 50 m*l* of acetic anhydride was stirred at room temperature for 1 hr and then heated under reflux for an additional hour. On cooling, the separated product was collected and washed with benzene to afford 3.4 g (72%) of VII (mp 210—213°C) as pale yellow needles. Recrystallization from acetone gave pale yellow needles; mp 211—212°C.

Found: C, 45.73; H, 3.39; N, 23.72%. Calcd for $C_9H_8N_4O_4$: C, 45.76; H, 3.39; N, 23.73%.

From V and Acetic Anhydride: A mixture of V (2.12 g, 10 mmol) and acetic anhydride (30 m*l*) was refluxed for 1 hr. Subsequent work-up as above afforded 1.85 g (78.4%) of pale yellow needles. Mp 211—212°C; undepressed upon admixture with a sample prepared by the above method.

From the Acetylation of III: Compound III (1.94 g, 10 mmol) was covered with acetic anhydride (20 m*l*) and heated under reflux for 1 hr. The excess acid anhydride was then removed *in vacuo*, and the residue was recrystallized from acetone to give 1.9 g (80%) of VII as pale yellow needles, mp 210—211°C. This product was found to be identical with VII by a mixed-melting-point determination and by a comparison of the IR spectrum with that of an authentic sample.

1-Propionyl-3-(5-nitro-2-furyl)-5-ethyl-1,2,4-triazole (VIII).

From I and Propionic Anhydride: This was prepared in the same way as was VII, but using propionic anhydride (50 m*l*). The resulting solution was taken to dryness *in vacuo*, and the residue was crystallized from ligroin to give 2.9 g (55%) of VIII as pale brown granules; mp 78—79°C.

Found: C, 49.75; H, 4.48; N, 20.92%. Calcd for $C_{11}H_{12}N_4O_4$: C, 50.00; H, 4.54; N, 21.21%.

From VI and Propionic Anhydride: VI (2.26 g, 10 mmol) and propionic anhydride (20 m*l*) were heated together under reflux for 1 hr. The excess acid anhydride was removed *in vacuo*, and the oily residue was solidified by cooling, washed with ether, and then dried. Thus, 1.8 g of the crude product were obtained; mp 69—72°C. Subsequent recrystallization from ligroin gave 1.46 g (55.3%) of pale yellow granules; mp 78—79°C. This product was found to be identical with VIII by a mixed-melting-point determination.

From the Acylation of IX with Propionic Anhydride: The procedure outlined above for VII was followed using IX (2.08 g, 10 mmol) and propionic anhydride (20 m*l*). A work-up as above afforded 1.85 g (70%) of pale brown granules melting at 80—81°C. The product was shown to be the same as above by a study of its IR spectrum and by its failure to depress the melting point when mixed with a sample prepared by the above method.

1-Propionyl-3-(5-nitro-2-furyl)-5-methyl-1,2,4-triazole (X).

The procedure outlined above for VII was employed using III (0.97 g, 5 mmol) and propionic anhydride (25 m*l*). Work-up as above gave 1.03 g (82.3%) of pale yellow cylinders; mp 148—149°C (from ligroin).

Found: C, 48.12; H, 4.08; N, 22.62%. Calcd for $C_{10}H_{10}N_4O_4$: C, 48.00; H, 4.00; N, 22.40%.

1-Acetyl-3-(5-nitro-2-furyl)-5-ethyl-1,2,4-triazole (XI).

The procedure outlined above for VII was followed using IX (1.04 g, 5 mmol) and acetic anhydride (40 m*l*). A work-up as above then afforded 1.09 g (87.6%) of XI as pale yellow needles which melted at 119°C.

Found: C, 48.11; H, 4.11; N, 22.29%. Calcd for $C_{10}H_{10}N_4O_4$: C, 48.00; H, 4.00; N, 22.40%.

Hydrolyses of VII, VIII, X, and XI. Five mmol of acyl-triazole (VII, VIII, X, or XI) were heated in 100 m*l* of water under reflux for 1 hr. On cooling, the hydrolyzed product (III or IX) was separated as pale yellow needles; the needles were filtered, washed with a small amount of cold water, and then dried. The yield were almost quantitative. Recrystallization was achieved from water when the purity was unsatisfactory. IX; pale yellow needles; mp 179—181°C.

Found: C, 46.45; H, 3.80; N, 26.67%. Calcd for $C_8H_8N_4O_3$ (IX): C, 46.15; H, 3.85; N, 26.95%.

Reaction of VIII or X with Acetic Anhydride. Acetic anhydride (30 m*l*) and the propionyl-triazole VIII (or X)

7) Y. Kato and I. Hirao, *Bull. Kyushu Inst. Technol.*, No. 15, 57 (1965).

(5 mmol) were heated together under reflux for 1 hr. On cooling or concentration, a crude product was obtained; it was then recrystallized from ligroin (acetone) to afford pure XI (or VII) in a 66% (69%) yield.

Reaction of VI with Acetic Anhydride in Dioxane. A mixture of VI (2.26 g, 10 mmol), acetic anhydride (10.2 g, 0.1 mol), and dioxane (50 m*l*) was heated at 100°C for 1 hr. The solvent and acid anhydride were removed *in vacuo*, and the residue was heated in ligroin (100 m*l*) under reflux. The insoluble material was filtered while hot and recrystallized from acetone to afford VII as pale yellow needles, which melted at 211—212°C and which weighed 0.4 g (17%). This was identical in its IR spectrum with an authentic sample of VII.

On the concentration of the mother filtrate, a light yellow, crystalline product was obtained. Mp 103—105°C; the yield was 1.35 g.

Found: C, 48.34; H, 3.71; N, 22.73%. Calcd for $C_{10}H_{10}N_4O_4$ (X and XI): C, 48.00; H, 4.00; N, 22.40%.

Recrystallization from ligroin raised the melting point to 112—114°C, but the value of the elemental analysis was unchanged. This product was identified as a mixture of X and XI by a study of its IR and NMR spectra. However, the resolution of X and XI could not be achieved by solvents or solvent pairs. The compound ratio (X: XI) was determined to be 39: 61 on the basis of the NMR intensity ratio of the methyl and acetyl proton (in CCl_3COOH).

Reaction of V with Propionic Anhydride. A mixture of V (2.12 g, 10 mmol) and propionic anhydride (20 m*l*) was heated under reflux for 1 hr. A work-up as above afforded 0.65 g of pale yellow crystals (mp 108—110°C) as the first precipitate from the ligroin solution.

Found: C, 48.36; H, 4.12; N, 22.41%. Calcd for $C_{10}H_{10}N_4O_4$ (X and XI): C, 48.00; H, 4.00; N, 22.40%.

This substance was confirmed to be a mixture of X and XI on the basis of its IR and NMR spectra. The compound ratio was determined to be X: XI=8: 5 by the NMR method, using trichloroacetic acid as the solvent.

The ligroin filtrate was concentrated *in vacuo*, and the residue was crystallized from petroleum ether to give 0.53 g (20%) of VIII as pale yellow granules; mp 79—80°C. The melting point of this compound was not depressed upon admixture with an authentic sample of VIII.

The authors are indebted to Mr. T. Hayakawa and Mr. T. Shiraishi for their help in the experimental work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 213—215(1972)

Syntheses of 1,2-Dithiole Derivatives[1]

Akiko CHINONE, Kozo INOUYE, and Masaki OHTA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 21, 1971)

Sulfurization of 1,3-diarylpropanetrione (**1**) with hydrogen sulfide and hydrogen chloride afforded a mixture of 4-hydroxy-3,5-diaryl-1,2-dithiolium chlorides (**3**) and 3,5-diaryl-1,2-dithiolium chlorides (**4**). Treatment of a mixture of **3a** and **4a** with triethylamine in alcohol gave anhydro-4-hydroxy-3,5-diphenyl-1,2-dithiolium hydroxide (**5a**) and the 4-substituted product (**6**). Sulfurization of dibenzoyldibromomethane yielded 3,5-diphenyl-1,2-dithiolium bromide. Reactions of **5a** with picric acid and acetic anhydride in the presence of perchloric acid were carried out.

Sulfurization of 1,3-diphenylpropanetrione (**1a**) with hydrogen sulfide and hydrogen chloride in a mixture of chloroform and ethanol afforded a crude product, from which a mesoionic compound **5a** (anhydro-4-hydroxy-3,5-diphenyl-1,2-dithiolium hydroxide) was obtained by treatment with triethylamine.[2] Schönberg[3] reported recently that the reaction of potassium ethyl xanthogenate with 1,1,3,3-tetrabromo-1,3-diphenylacetone gave the same compound as **5a** which is regarded as a valence isomer of 1,3-diphenylpropane-1,3-dithione-2-one (**2**). In this report, we wish to describe our results on the sulfurization products in detail. Further examination of the crude sulfurization product of **1a** revealed that the product was composed of two components, **3a** and **4a**. Since the mixture was not separable by recrystallization and detection by tlc was unsuccessful, the mixture was subjected to further reaction without separation. Structures of **3a** and **4a** were confirmed as stable perchlorates **7** and **8** by treating the mixture with perchloric acid or silver perchlorate. They were identical with those reported by Schönberg[3] and Leaver.[4] Dehydrohalogenation of the mixture with triethylamine in ethanol afforded a mixture of a mesoionic compound **5a** and 3-ethoxy-3,5-diphenyl-1,2-dithiole (**6a**). The latter was prepared by the reaction of 3,5-diphenyl-1,2-dithiolium perchlorate with sodium ethoxide.[5] 3-Methoxy derivative (**6b**) was obtained when the mixture was treated with triethylamine in methanol. When the mixture was treated with pyridine in methanol, **5a** and unreacted **4a** were obtained. This result shows that **4a** is convertible to **6** only in the presence of a strong

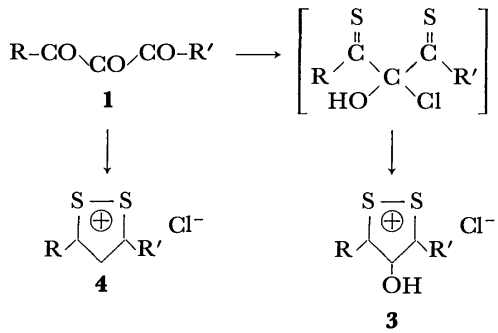
base. In a similar way, sulfurization of 1-(*p*-methoxyphenyl)-3-phenylpropanetrione (**1b**) gave two products, **3b** and **4b**. As in the case of sulfurization of **1a**, **3b**, and **4b** could not be separated by recrystallization. Treatment of the mixture of **3b** and **4b** with triethylamine in methanol gave a mesoionic compound **5b**, but the methoxy-substituted product corresponding to **6** was not isolated. The IR spectrum of **5b** was similar to that of **5a** in the region 1500—1400 cm^{-1} due to the CO group and dithiole ring. In UV spectra of **5b**, a hypsochromic shift was observed as in the case of **5a**,[3] as shown below.

UV SPECTRA OF **5b**

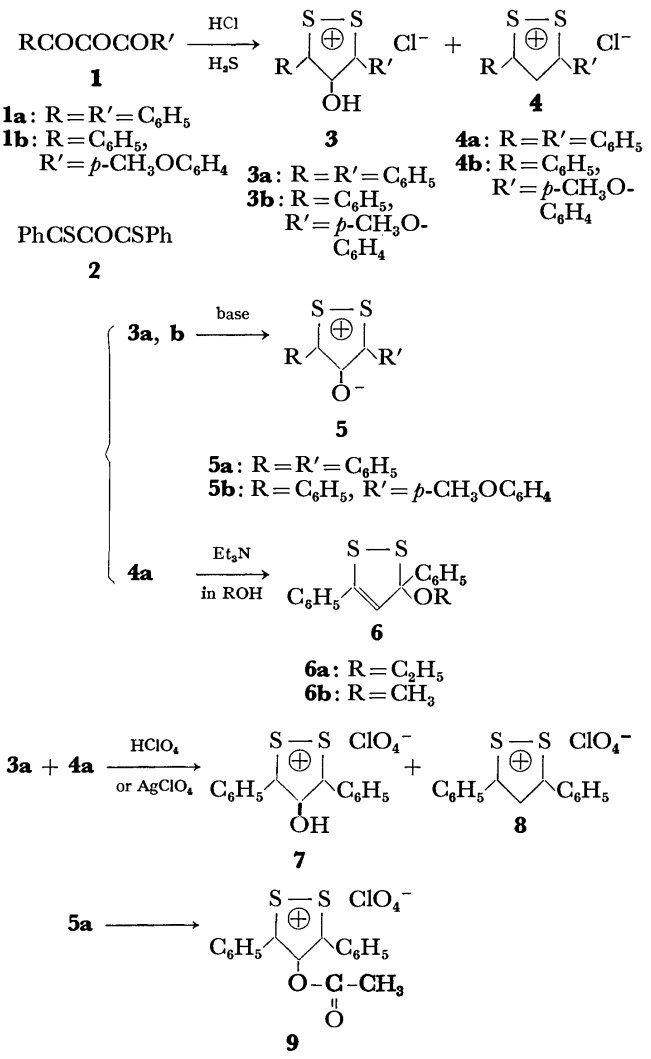
Solvent	λ_{max}(mμ)	log ε
Benzene	586	4.12
Pyridine	574	4.38
DMF	574	4.36
Acetonitrile	558	4.11

Sulfurization of 1-methyl-3-phenylpropanetrione did not afford the aimed product. Under the same conditions, dibenzoyldibromomethane was subjected to sulfurization to give 3,5-diphenyl-1,2-dithiolium bromide, which was converted into perchlorate **8** by treating with silver perchlorate.

The mechanism for the formation of **3** and **4** from **1** could be explained *via* a chlorohydrin intermediate and the reduction with hydrogen sulfide during the course of the reaction.



The reaction of 1,2-dithiolium salts without hydroxyl group at its 4-position has been extensively studied.[4-6] It is known that the 3- and 5-positions of 1,2-dithiole show high reactivity toward nucleophilic reagents.[5,6] Treatment of **5a** with acetic anhydride and perchloric acid yielded the *O*-acetyl derivative **9**, which showed an absorption peak at 1790cm^{-1} due to the C=O group in its IR spectrum. This is consistent with the fact that the CO bond of **5a** is highly polarized as shown in its IR spectrum, in which the CO group showed absorption peak at 1495 cm^{-1}. Methylation of **5a** with methyl iodide was not successful and resulted in the recovery of the starting material. The picrate of **5a** was obtained by treatment with picric acid. Reaction of **5a** with aniline gave a product which was recrystallized from ethanol to give dark blue needles with a mp of 168—170° C. The results of elementary analysis and molecular weight measurement (304 in DMF) indicate that the molecular formula is $C_{21}H_{15}SN$. It was assumed to be 3,4,5-triphenylisothiazole from its IR spectrum and NMR spectrum. Reaction of **5a** with dry ammonia in refluxing methanol afforded a product which was recrystallized from benzene or ligroin to give colorless needles with a mp of 102—105°C, $C_{15}H_{11}NSO$, which is most likely to be 4-hydroxy-3,5-diphenylisothiazole from its elementary analysis and spectral data. Reaction of **5a** with a dipolarophile such as dimethyl acetylenedicarboxylate, tolane or phenyl isocyanate did not give the adduct and resulted in the recovery of the starting material.



Experimental

Sulfurization of 1,3-Diphenylpropanetrione. To a solution of 100 g of 1,3-diphenylpropanetrione in 200 m*l* of chloroform, 1400 m*l* of ethanol was added. Into the solution, dry hydrogen chloride and hydrogen sulfide were bubbled for 1.5 hr under ice cooling, and then hydrogen sulfide was bubbled at room temperature for further 5.5 hr. During the course of bubbling, the color of the solution turned from yellow to reddish brown. After the solution was kept to stand for 2 days at room temperature, precipitates contaminated with sulfur were filtered off and the filtrate was concentrated *in vacuo* at 40—50°C. Ether was added to the residue to give a crude mixture of **3a** and **4a**. When the mixture was re-

6) G. Duguay and H. Quiniou, *Bull. Soc. Chim. Fr.*, **1970**, 1918.

crystallized from acetonitrile, two forms of crystal separated out, silky crystals melting at about 200°C (dec.) and needles melting at about 110°C (dec.). We could not find a suitable solvent for fractional crystallization.

Sulfurization of 1-(p-Methoxyphenyl)-3-phenylpropanetrione. Dry hydrogen chloride was bubbled into 90 m*l* of methanol under ice cooling until the volume of the methanol solution became 110 m*l*, to which a solution of 1-(*p*-methoxyphenyl)-3-phenylpropanetrione (5g) in 20 m*l* of chloroform was added. Dry hydrogen sulfide was bubbled into the solution for 3.5 hr with stirring under ice cooling. After the solution was kept to stand for 2 days at room temperature, precipitates were filtered off and the filtrate was concentrated *in vacuo* at 40—45°C. Ether was added to the residue to give a mixture of **3b** and **4b**, which partially melted at about 120°C (dec.) and 190°C (dec.), but the mixture could not be separated analytically pure by recrystallization.

Sulfurization of Dibenzoyldibromomethane. Dibenzoyldibromomethane was dissolved in 50 m*l* of chloroform, to which 300 m*l* of ethanol was added. Dry hydrogen chloride and hydrogen sulfide were bubbled into the solution for 2 hr at room temperature with stirring. After the solution was kept to stand for 2 days at room temperature, percipitates containing sulfur were filtered off and filtrate was concentrated *in vacuo* at 40—50°C. Recrystallization from ethanol afforded reddish yellow needles with a mp of 190—200°C, yield 5 g (54%). Although the value of elementary analysis was not satisfactory, the structure of this product was assigned to be 3,5-diphenyl-1,2-dithiolium bromide by treatment with silver perchlorate to give the perchlorate **8**.

Reaction of Sulfurization Products with Base. i) To a solution of a mixture (57 g) of **3a** and **4a** in 500 m*l* of ethanol, 19 g of triethylamine was added dropwise. After being stirred for 1 hr, precipitates were collected (filtrate was treated as described in ii)), washed with ether repeatedly, and recrystallized from acetic acid, DMF, or pyridine to give dark brown needles with a mp of 240—241°C (dec.), yield 21 g (41%).

Found: C, 66.48; H, 3.89; S, 23.40%. Calcd for $C_{15}H_{10}OS_2$: C, 66.67; H, 3.73; S, 23.68%.

ii) The filtrate obtained as described in i) was concentrated in a vacuum. The residue was washed with water and recrystallized from acetonitrile to give 3-ethoxy-3,5-diphenyl-1,2-dithiole, yield 15 g (29%), as pale yellow needles with a mp of 68—69°C.

iii) To a solution of a mixture (22 g) of **3a** and **4a** in methanol was added 7 g of triethylamine, and precipitates were filtered off and washed with ether, and the ether and filtrate were combined and concentrated *in vacuo*. The residue was washed with ether and recrystallized from methanol to give **6b** as yellow needles with a mp of 83—84°C, yield 9 g (42%).

Found: C, 63.52; H, 4.64; S, 21.90%. Calcd for $C_{16}H_{14}O_2S_2$: C, 63.52; H, 4.64; S, 21.20%. VU: λ_{max}^{MeOH} mμ(log ε) 227 (4.18), 345 (2.55). NMR: τ($CDCl_3$) 2.40—2.82 (m, 10H), 4.10 (s, 1H), 6.49 (s, 3H).

Reaction of 5a with Acetic anhydride in the Presence of Perchloric Acid. To a solution of 0.27 g of **5a** in acetic anhydride, 0.3 g of 70% perchloric acid was added dropwise with stirring under ice cooling. Ether was added to the reaction mixture to give orange crystals, which were recrystallized from methanol yielding **9** as orange needles with a mp of 174—176°C; yield 0.38 g (92%).

Found: C, 49.41; H, 3.41; S, 15.50%. Calcd for $C_{17}H_{13}O_6S_2Cl$: C, 49.45; H, 3.15; S, 15.52%.

Picrate of 5a. A mixture of picric acid and **5a** (0.13 g) in benzene was stirred at room temperature for 30 min. Precipitates were collected and recrystallized from methanol to give the picrate of **5a** as orange plate with a mp of 245—246°C.

Found: C, 50.73; H, 2.71; N, 8.45; S, 12.76%. Calcd for $C_{21}H_{13}N_3O_8S_2$: C, 50.50; H, 2.61; N, 8.42; S, 12.83%. IR: 3500—3200, 1560, 1440—1400, 1350 cm^{-1}.

Reaction of 5a with Aniline. After treating 0.35 g of **5a** in 30 m*l* of refluxing aniline for 3 hr, excess aniline was removed by filtration and methanol was added to the residue. Precipitates were collected and recrystallized from ethanol to give dark blue needles with a mp of 168—170°C, yield 0.36 g (88%).

Found: C, 80.78; H, 4.01; N, 4.41; S, 9.99%. Calcd for $C_{21}H_{15}SN$: C, 80.51; H, 4.79; N, 4.47; S, 10.22%.

Reaction of 5a with Ammonia. Ammonia was bubbled into a refluxing solution of **5a** (1.0 g) in 60 m*l* of methanol for 1.5 hr. After cooling, precipitates were filtered off and the filtrate was concentrated to give a crude product. Recrystallization from benzene or ligroin afforded colorless needles with a mp of 102—105°C.

Fould: C, 71.29; H, 4.57; N, 5.75; S, 12.40%. Calcd for $C_{15}H_{11}NSO$: C, 71.15; H, 4.35; N, 5.53; S, 12.65%.

Hydrogenation and Hydrogenolysis. XIV.[1] The Hydrogenation of Ethyl *p*-Tolyl Ether over Platinum Metal Catalysts[2]

Shigeo NISHIMURA, Masayoshi URAMOTO, and Tetsuo WATANABE

Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Koganei-shi, Tokyo

(Received May 28, 1971)

The hydrogenation of ethyl *p*-tolyl ether (**1**) in ethanol has been studied with five unsupported platinum metals as catalysts, mainly with the purpose of estimating the yields of ethyl 4-methyl-1-cyclohexenyl ether (**2**) formed as intermediate. Except for ruthenium catalyst, the hydrogenation of **1** in ethanol was accompanied by the formation of acetal **3**, ketone **4** and alcohol **5** which seem to be related to the formation of **2**. The amounts of **2** and the related compounds which were desorbed from the catalyst surface have been estimated to be 32—33% for Ru, 32—34% for Rh, 72—76% for Pd, 3.7% for Ir and 4.7% for Pt, by application of both kinetic and extrapolation methods. A good agreement was obtained between the results from the two methods. The proportion of hydrogenolysis increased for the catalyst metals in the order Pd$<$Ru$\ll$Rh$<$Ir$<$Pt. With platinum catalyst a noticeable amount of toluene was formed along with methylcyclohexane. The hydrogenation of ethyl 4-methyl-3-cyclohexenyl ether (**6**), one of the other intermediates of the hydrogenation of **1**, has also been studied in ethanol. Hydrogenolysis occurred extensively with palladium and rhodium catalysts, but much less with ruthenium, iridium and platinum catalysts. The hydrogenation route of **1** and its relation to hydrogenolysis and stereochemistry of hydrogenation of **1** are discussed with reference to the formation and hydrogenation of its intermediates.

The study of catalytic hydrogenation of aromatic compounds with reference to formation of their hydrogenation intermediates has been the subject of recent investigations.[3-6] The stereochemistry of hydrogenation of aromatic compounds has been discussed on the basis of the results of the hydrogenation of their intermediates.[3,4b-d] In most cases, the amount of intermediates detectable during the course of hydrogenation is rather small, which makes it difficult to estimate the real yields of the intermediates formed on the catalyst surface and to interpret the course of hydrogenation quantitatively.[3] However, in some cases, the rate of hydrogenation of intermediates is low and these might accumulate in considerable amount during the course of hydrogenation, as with phenols,[4] where the intermediate cyclohexanones are usually hydrogenated rather slowly and the estimation of the yields of the ketones can be made quantitatively.[4d,7] In other cases, the intermediates formed on the catalyst surface are transformed into the derivatives which are hydrogenated only slowly, or they may give products which differ from those resulting from the simple hydrogenation of parent aromatic compounds. Such cases are known, for example, in the hydrogenation of aniline in acetic acid over some platinum metals where considerable amounts of *N*-phenylcyclohexylamine accumulate as intermediate[5] and in the hydrogenation of benzene with platinum or rhodium catalyst in the presence of hydrogen fluoride where the formation of phenylcyclohexane became as much as 25% by weight of the hydrogenation products.[6]

We carried out the hydrogenation of ethyl *p*-tolyl ether (**1**) in ethanol over five platinum metals. The main purpose was to estimate the yields of the enol ether **2** formed as the intermediate, the hydrogenation of which was also studied in detail and reported in the preceding paper.[1] The hydrogenation of **1** in ethanol is accompanied by the formation of the acetal **3** which probably results from the addition of ethanol to the enol ether **2** formed on the catalyst surface. The extent of the acetal formation might depend on the nature of catalyst metals.[1] Since the rate of hydrogenation of the acetal is always lower than that of the enol ether, its formation may be advantageous for an estimation of the yield of the enol ether intermediate. The hydrogenation was studied at 25 or 50°C under the atmospheric pressure of hydrogen. The hydrogenation of ethyl 4-methyl-3-cyclohexenyl ether (**6**) was also studied, since **6** may be one of the other intermediates which are susceptible to desorption from the catalyst surface on hydrogenation of **1**. It is also of interest to observe the behavior of **6**, a homoallyl ether, towards hydrogenolysis.

Experimental

Materials. Ethyl *p*-tolyl ether (**1**) was prepared according to the procedure of Vogel[8] by the reaction of ethyl iodide with sodium *p*-methylphenoxide in absolute ethanol. Bp 82°C/17 mmHg.

Ethyl 4-methyl-3-cyclohexenyl ether (**6**) was prepared by the dehydration with iodine of 4-ethoxy-1-methyl-1-cyclohex-

b) Given by 100×mol (**2**+**3**+**4**+**5**)/mol (100−1).

anol which was obtained by the addition of methylmagnesium iodide to 4-ethoxycyclohexanone. Bp 170°C; n_D^{20} 1.4530. The structure of **6** was confirmed by the NMR spectrum obtained on a JNM-C-60HL spectrometer (Japan Electron Optics Laboratory, Co.) at 60 MHz: τ 4.75 (1H, m, vinyl proton), 6.52 (2H, q, $OC\underline{H}_2CH_3$), 6.30—6.75 (1H, m, C$\underline{H}$ adjacent to oxygen), 7.5—8.5 (6H, broad m, saturated ring protons other than at C-1), 8.36 (3H, s, 4-$C\underline{H}_3$), 8.82 (3H, t, $OCH_2C\underline{H}_3$).

Catalysts. Unsupported ruthenium, rhodium, palladium, iridium and platinum catalysts were prepared by the methods descibed in the preceding paper.[1)]

Solvent. The S. S. G. ethanol of the Wako Pure Chemical Industries was further dehydrated by refluxing with sodium metal and diethyl phthalate.[9)]

Hydrogenation. The substrate (0.2 m*l*) was hydrogenated as usual with 25—50 mg of the catalyst in 10 m*l* ethanol at 25 or 50°C under the atmospheric pressure of hydrogen. The catalyst was shaken with hydrogen for about 10 min before the addition of the substrate.

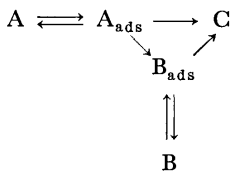
Analysis of Reaction Mixture. The reaction mixture was taken into a microsyringe through a silicone rubber stopper during the course of hydrogenation and subjected to gas chromatography. For most analyses a column of 10% PEG 20M on Chromosorb W (3 mm×3.75 m) was used at the temperature programmed in 2°C/min for 36—100°C and in 4°C/min for 100—160°C. Under these conditions, the peaks of unsaturated ethers **2** and **6** were not separated. Since in most cases the amount of **6** in the reaction mixture was extremely small, the peak corresponding to **2** and **6** was regarded to be that of **2**. When separation of **2** and **6** was needed, a column consisting of PEG 20M and Apiezon L was used. However, complete separation of the reaction mixture was also difficult even with this column. Accordingly, a complete analysis of the reaction mixture was carried out by superposing the two gas chromatograms obtained using the two columns described above.

Results

*Hydrogenation of **1** with Ruthenium Catalyst.* Table 1 shows the change in composition of the reaction mixture during the hydrogenation of **1** with ruthenium catalyst in ethanol at 25°C. A noteworthy feature of the ruthenium-catalyzed hydrogenation is that the enol ether **2**, formed as intermediate, is hydrogenated to saturated ether **7** with little formation of acetal **3**. This result was not unexpected as addition of ethanol to **2** occurred only very slowly during the hydrogenation of **2** with ruthenium catalyst in ethanol.[1)] In Fig. 1 the varying amounts of **2** and **3** during the course of hydrogenation are plotted *versus* the conversion of **1**. The maximum amount was 12.0% at 67.4% conversion of **1**. The amount of intermediates desorbed from the catalyst surface can be calculated by means of the following equation (deduced on the reaction scheme shown below)[10)] to be 32.6% [f=0.326 in Eq. (1)].[11)]

$$C_B = \frac{f}{K-1}(C_A - C_A^K) \qquad (1)$$

C_A: concentration of aromatic compound A when the initial concentration of A is unity.
C_B: concentration of intermediate B when the initial concentration of A is unity.
f: fraction of A that leaves the catalyst surface as B during hydrogenation.
K: a constant which depends on the relative reactivity of A and B.



The amount can also be obtained by extrapolating the varying selectivity for formation of **2** and **3** during

9) L. F. Fieser, "Experiments in Organic Chemistry," 3rd Ed., Heath and Company, Boston (1955), p. 285.

10) Equation (1) is obtained by assuming that the hydrogenation is of first order and the function of hydrogen is the same, for A and B. For the derivation, see Ref. 7 which deals with the case where A is all transformed into C through the intermediate B and the establishment of adsorption-desorption equilibria is fast. It was shown by de Boer and van der Borg that Eq. (1) is also widely applicable to other cases [J. H. de Boer and R. J. A. M. van der Borg, *Actes Congr. Intern. Catal.*, 2e, *Paris*, 1960, p. 919 (Editions Technip, Paris, 1961)].

11) Approximate values of f and K can be obtained from the maximum concentration of B, $(C_B)_{max}$, and the corresponding concentration of A, $(C_A)_m$, using the following relations obtained by differentiating Eq. (1) with respect to C_A and putting the resulting expression equal to zero:

$$(C_A)_m = K^{1/1-K};\ (C_B)_{max} = f \times K^{K/1-K}$$

The values of f and K thus obtained were corrected graphically to represent the experimental results better throughout the course of hydrogenation.

hydrogenation to the initiation, as also shown in Fig. 1. By this method we obtain a 32% yield of **2** and **3** which is in excellent accord with the value obtained above by the kinetic method. Detectable amounts of the intermediate **6** were very small, the maximum amount being only 0.8% in 32% conversion of **1** (see Fig. 1). Application of Eq. (1) to the change in the amount of **6** during hydrogenation gives the amount of **6** which leaves the catalyst surface to be 6%. The *cis/trans* ratio of saturated ether **7** formed decreases during the course of hydrogenation from 6.3 at an initial stage to 2.9 at an almost complete hydrogenation. The degree of hydrogenolysis is rather small with ruthenium catalyst (9.6%), but somewhat greater than that with palladium catalyst.

Hydrogenation of **1** *with Rhodium Catalyst.* Table 2 indicates the change in composition of the reaction mixture during hydrogenation of **1** with rhodium catalyst in ethanol at 25°C. It is seen that the intermediates accumulate mostly as acetal **3** along with small amounts of enol ether **2** and ketone **4**. The ketone **4** probably is the product of the hydrolysis of **2** or **3** during hydrogenation, in spite of the fact that carefully dehydrated solvent was used. It is noteworthy that **2**, **3**, and **4** formed are scarcely hydrogenated during the hydrogenation of **1** and their sum increases almost linearly with the conversion of **1** (Fig. 2). By assuming that **3** and **4** were all formed through **2** which was produced on the catalyst surface, the amount of **2** which left the catalyst surface as itself or its derivatives can be calculated to be 32% by means of Eq. (1) (Fig. 2). Application of the extrapolation method gives a 34% yield of **2** and related compounds, as also shown in Fig. 2. When the amount of unreacted **1** approaches almost zero, hydrogenation of the accumulated intermediates seems to begin and the main product is the alcohol **5**, as indicated by a definite increase of **5** over saturated ether **7** and methylcyclohexane (Table 2).[12] The *cis/trans* ratio of **7** formed is very high at the initial stage, but decreases to about 10 towards the end of hydrogenation. Hydrogenolysis occurs rather extensively with rhodium catalyst (about 45% at 58.1% conversion of **1**) and constitutes the most important hydrogenation pathway of **1**.

Hydrogenation of **1** *with Palladium Catalyst.* **1** was hydrogenated at 50°C in ethanol, the results being shown in Table 3. The main intermediates are acetal **3** and ketone **4** and they are hydrogenated further to give ether **7** as the major product. Change in the sum of **2**, **3**, and **4** during hydrogenation is shown in Fig. 3. The amount of **2** and the related intermediates which left the catalyst surface was estimated to be 72% by the kinetic method. The value of 76% was obtained for that amount by the extrapolation method (Fig. 3). Alcohol **5** was formed only slightly with palladium catalyst although the ketone was produced in considerable amount during the course of hydrogenation. This might be due to the fact that with palladium catalyst in ethanol ketone **3** is hydrogenated mostly to give **7**, rather than alcohol **5**.[13] The *cis/trans* ratio of ether **7** formed is about 8 at initial stages of hydrogenation and then increases gradually to about 14 towards later stages. It is to be noted that the yield of *cis*-ether is the greatest with palladium catalyst among the platinum metals investigated. Another noteworthy feature of the palladium-catalyzed hydrogenation is that hydrogenolysis occurred only to the extent of 5.3% which is smaller than any of those obtained by the other platinum metals.

12) The alcohol was also the main product of hydrogenation of acetal **3** with rhodium catalyst in ethanol.[1)]

○ : Concentration of enol ether **2** and related compounds in the reaction mixture.

Hydrogenation of ***1*** *with Iridium Catalyst.* Table 4 shows the results of the hydrogenation of **1** in ethanol at 50°C with iridium as a catalyst. The iridium-catalyzed hydrogenation is characteristic in that the detectable amount of **2**, **3**, **4**, and **5** is extremely small, their sum being less than 1% at maximum. The amount of **2** and related compounds was estimated to be 3.7% by the extrapolation method as shown in Fig. 4. The *cis*/*trans* ratio of **7** formed decreases slightly during hydrogenation from about 10 to 6.4. Hydrogenolysis occurred more extensively than with rhodium (59% at 54.1% conversion of **1**) and a small amount of toluene (1.1% at 35.4% conversion of **1**) was formed along with methylcyclohexane.

b) Given by mol 100 × mol(**8**+**9**)/mol(**7**+**8**+**9**)

are given in Table 5. The formation of acetal **3** and related compounds is small, although they are hydrogenated only with difficulty and increases almost linearly with hydrogenation. The amount of **2** and the related compounds was estimated to be 4.7% by the extrapolation method as shown in Fig. 5. The *cis*/*trans* ratio of ether **7** formed was 9.9 near the end of hydrogenation and it did not vary much during hydrogenation. It is noticeable that of the platinum metals investigated hydrogenolysis occurred to the greatest extent with platinum (about 63%). The platinum-catalyzed hydrogenation is also characteristic in that a noticeable amount of toluene is formed along with methylcyclohexane (about 4% at 72.5% conversion) and the toluene formed is hydrogenated rather slowly in the presence of **1**.[14] By applying Eq. (1) to the change in the amount of toluene during hydrogenation, the amount which left the surface was estimated to be 9.5% [f=0.095, K=0.9 in Eq. (1)].

Hydrogenation of **6** *with Platinum Metal Catalysts.* Table 6 summarizes the results of the hydrogenation of **6** in ethanol with the five platinum metals as catalysts. It is seen that hydrogenolysis occurs rather extensively with palladium and rhodium catalysts, but not so with ruthenium, iridium and platinum catalysts. In general, the *cis*-ether is formed in larger amounts than the *trans*-ether.[15]

Discussion

It is seen that the results of estimation of enol ether **2** and related compounds by the kinetic and extrapolation methods were in good agreement. Thus the amount of enol ether and related compounds which leaves the catalyst surface during hydrogenation has been estimated to be 32—33% for ruthenium, 32—34% for rhodium, 72—76% for palladium, 3.7% for iridium and 4.7% for platinum. If we assume that acetal, ketone and alcohol are all formed through enol ether **2**, the values obtained above are considered to show the amount of **2** which left the catalyst surface. Since it is not certain whether these values indicate the real yields of the enol ether intermediate formed on the catalyst surface, they might be considered to be the minimum values of the amount of the intermediate formed in hydrogenation of **1**.[17]

Table 7. Amount of enol ether or ketone intermediate which leaves the catalyst surface during the course of hydrogenation of ethyl *p*-tolyl ether or *p*-cresol

Catalyst	Amount of the intermediate, mol %	
	Enol ether in hydrogenation of ethyl *p*-tolyl ether	Ketone in hydrogenation of *p*-cresol[a]
Ru	33,[b] 32[c]	60[b]
Rh	32,[b] 34[c]	54[b]
Pd	72,[b] 76[c]	100[b]
Ir	— 3.7[c]	20[b]
Pt	— 4.7[c]	—[d]

a) Data from Ref. 4d and Y. Takagi, *Sci. Pap. Inst. Phys. Chem. Res.* (Tokyo), **64**, 39 (1970).
b) Estimated by kinetic method.
c) Estimated by extrapolation method.
d) Not estimated accurately. The maximum amount of ketone detected was only 2—2.5%.

When the present results are compared with those obtained previously on the ketone intermediate formed in hydrogenation of *p*-cresol (Table 7), it is obvious that there exists a common tendency in the selectivity of the catalyst metals for the formation of the intermediates, although the yield of enol ether is always smaller than that of ketone over the same metal. Thus, the palladium-catalyzed hydrogenation of **1** proceeds to a greater part through enol ether as intermediate, and *p*-cresol is hydrogenated quantitatively *via* the ketone intermediate over the same metal. Ruthenium and rhodium catalysts are very similar in the way they give nearly the same yield of enol ether or ketone in hydrogenation of **1** or *p*-cresol. Both iridium and platinum catalysts are characteristic in that detectable amounts of the intermediates are small in hydrogenation.

The extent of hydrogenolysis also depends on the nature of the catalyst metals and increases in the order

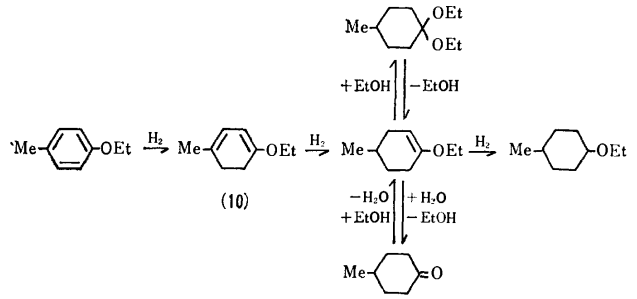
14) Formation of toluene in as much as 21% was observed in hydrogenation of ethyl *m*-tolyl ether with platinum catalyst under the same conditions as for the hydrogenation of **1** (the results presented at the 23rd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1970).

15) It should be noted that 1,4-dimethylcyclohexene is reported to give the product of much smaller *cis*/*trans* ratios (1.56, 0.39, 1.33 for Rh, Pd, Pt catalysts, respectively, in acetic acid at 25°C and 1 atm).[16]

16) A. S. Hussey, T. A. Schenach, and R. H. Baker, *J. Org. Chem.*, **33**, 3258 (1968).

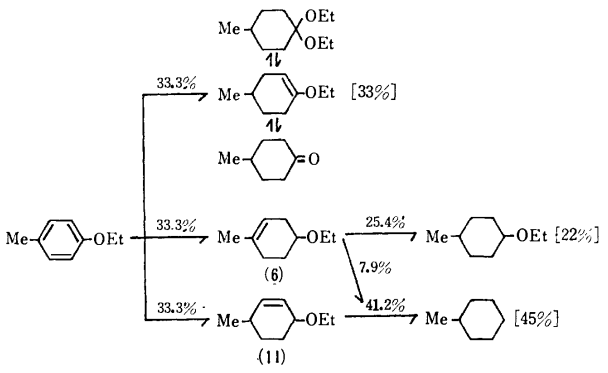
17) Acetal formation is adventageous for the estimation of enol ether formed on the catalyst surface. As an example, the largest amount of enol ether **2** during hydrogenation was only 1.2% at 35.4% conversion on hydrogenation of **1** with rhodium catalyst in *t*-butyl alcohol in which an acetal is not formed.

Pd<Ru≪Rh<Ir<Pt. The very small amount of hydrogenolysis observed with palladium catalyst suggests that the yields of the allyl and homoallyl ether intermediates are also small, because these ethers are expected to be susceptible to extensive hydrogenolysis in further hydrogenation when produced on the catalyst surface (Table 6). This is in line with the fact that the enol ether intermediate is formed in a large yield, since enol ether is known to be hydrogenolyzed only to a slight extent with palladium catalyst.[1] The hydrogenation of **1** over palladium catalyst is fairly stereospecific, the *cis*-ether being formed in a selectivity of 93%. This result may also be related to the production of enol ether or acetal in large yield since they are known to give the saturated ether of a high *cis*/*trans* ratio.[1,18] Thus, it is suggested that the predominant hydrogenation route of ethyl *p*-tolyl ether over palladium catalyst will be the one shown in Scheme 1. The selective hydrogenation of the dihydro intermediate **10** to the enol ether **2** can be expected from similar examples.[19]



Scheme 1. Hydrogenation pathway of ethyl *p*-tolyl ether with palladium catalyst in ethanol.

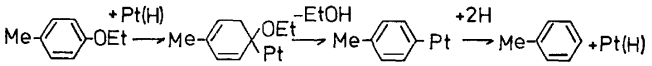
It is of interest that the selectivity of ruthenium and rhodium catalysts for the formation of the enol ether intermediate is similar, and its estimated yield is very close to the value 33.3% based on the assumption that all tetrahydro derivatives of **1** are formed in equal probability. This assumption was proposed by Siegel and his coworkers[3a] for an explanation of the results of stereochemistry of the hydrogenation of isomeric xylenes with platinum catalyst. If the other two tetrahydro intermediates, the allyl and homoallyl ethers (**11** and **6**), are also produced equally in 33.3% yield according to the above assumption and the allyl ether is assumed to be hydrogenolyzed completely over rhodium catalyst, we can calculate the amount of hydrogenolysis which will occur in hydrogenation of **1**, using the value in Table 6 for the homoallyl ether. Thus the proportion of hydrogenolysis over rhodium catalyst may be evaluated to be 41.2% as shown in Scheme 2. It is seen that the value obtained experimentally (45%) is fairly close to the calculated one. Over ruthenium



Scheme 2. Hydrogenation pathways of ethyl *p*-tolyl ether over rhodium catalyst in ethanol: figures in parentheses indicate the observed composition of the reaction mixture.

catalyst, the hydrogenation pathways leading to the tetrahydro derivatives may be similar to those given in Scheme 2. The small amount of hydrogenolysis over this catalyst will probably be due to its poor activity towards the hydrogenolysis of the allyl and homoallyl ethers.

The large extent of hydrogenolysis taking place with iridium and platinum catalysts must result from the formation of the allyl and enol ether intermediates, because the homoallyl ether **6** is hydrogenolyzed only to a small extent over these metals (see Table 6). With platinum the hydrogenolysis of **1** to give toluene is also responsible for the extensive hydrogenolysis. It was shown that enol ether **2** is extensively hydrogenolyzed with platinum catalyst in ethanol.[1] Since **1** is also considered to be an enol type ether, this type of hydrogenolysis is also expected to occur according to the mechanism suggested for the hydrogenolysis of **2** as shown in Scheme 3.[1] On the other hand, the saturated ether **7** formed with platinum catalyst on hydrogenation of **1** may be supposed to be formed mostly through the homoallyl ether intermediate.



Scheme 3. Hydrogenolysis of ethyl *p*-tolyl ether with platinum catalyst.

With respect to the stereochemistry of hydrogenation of **1**, the fairly high stereospecificity of palladium catalyst has been discussed. Among the other platinum metals, rhodium and platinum catalysts also give the saturated ether of rather high *cis*/*trans* ratio, as compared with the hydrogenation of *p*-xylene.[20] This is probably due to the fact that homoallyl ether **6** gives the saturated *cis* isomer in much greater yield than does 1,4-dimethylcyclohexene in the hydrogenation with these catalysts.[21] A lower yield of saturated *cis*-ether with ruthenium catalyst can also be explained in relation to the stereochemistry of hydrogenation of the intermediate unsaturated ethers, since both **2** and **6** give a saturated ether of rather small *cis*/*trans* ratio (1.45 for **2** and 3.0 for **6**).

18) Hydrogenation of ethyl *m*-tolyl ether in ethanol with palladium catalyst gives *trans*-ether predominantly. Similarly, 3-methylcyclohexanone diethyl acetal as well as the enol ethers derived from it also give the *trans*-ether predominantly under the same conditions (the results partly presented at the 23rd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1970).

19) a) J. M. Bell, R. Garrett, V. A. Jones, and D. G. Kubler, *J. Org. Chem.*, **32**, 1307 (1967). b) W. S. Johnson, *J. Amer. Chem. Soc.*, **78**, 6278 (1956).

20) Hydrogenation of *p*-xylene with rhodium and platinum catalysts in isopropyl alcohol at 25°C under 1 atm gave the product of *cis*/*trans* ratio 2.4 and 2.3, respectively (unpublished results). *Cf.* also Ref. 3a.

Phytosterols and Triterpenes in the Roots of the "Kidney Bean" (*Phaseolus vulgaris* L.)[1]

Nobukatsu KATSUI, Hajime MATSUE, Tomohiko HIRATA, and Tadashi MASAMUNE
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

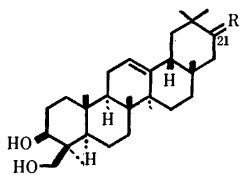
(Received May 20, 1971)

In connection with the studies of hatching substances for soybean cyst nematodes, the neutral fraction of the roots of the "kidney bean" (*Phaseolus vulgaris* L.) has been examined. It was found that phytosterols and triterpenes exist in the roots of plants.

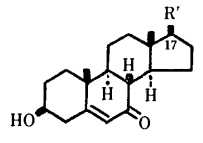
Recently the hatching of eggs and larval emergence from the soybean cyst nematode (*Heterodera glycines*) has been found to be stimulated by root diffusates of several host plants.[2] Among the host plants, soybean (*Glycine Max* Merrill) has been studied extensively and reported to contain γ-sitoserol (clionasterol), stigmasterol, and soyasapogenols-A~E[3,4] as its neutral components. On the other hand, root diffusates of the "kidney bean" (*Phaseolus vulgaris* L.) are known to be more active for the hatching,[2] but no paper on the components of this plant seems to have been published. Accordingly, in connection with studies on the relevant hatching substances, we have examined the neutral fraction of the "kidney bean".

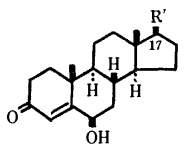
The dried powdered roots of the "kidney bean" were percolated with water and then extracted with methanol, after removal of the aqueous solution which was active for the hatching. The methanol extracts were subjected to column and thin layer chromatography as well as fractional recrystallization to isolate and identify triterpenes and phytosterols. The results deserve some comment.

(1) Compound II, $C_{32}H_{48}O_5$, was presumed to be a 21-dehydro derivative of I on the basis of mass, IR, and NMR spectra. In fact, compound I was transformed *via* its acetonide to 21-dehydrosoyasapogenol-B,



I R=-----OH, -H
II R=O





IV R′=R¹
V R′=R²

VI R =R¹
VII R′=R²

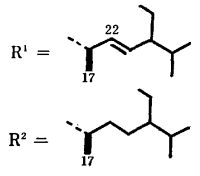


Table 1. Triterpenes and phytosterols[a] in the roots of the "kidney bean"

	Compound	Mp (°C)	Yield (%)	$[\alpha]_D$	Ref.
I	Soyasapogenol-B[b]	259—261	0.005	+89°	3
II	Soyasapogenol-E	249—250	0.0013	+34°	4
III	Stigmast-5-en-3β-ol (β-sitosterol)	141—142	0.003

mp 247—248°C and $[\alpha]_D+32°$, which was identical with II. As a compound corresponding to the above structure, Willner *et al.*[4] obtained a triterpene, soyasapogenol-E, from soybean. While their compound is amorphous and its crystalline derivatives, acetonide and diacetate, differ slightly from ours in physical constants, we consider that II should be assigned soyasapogenol-E.

(2) Occurrence of phytosterols IV, V, VI, and VII is a noticeable fact in the sense that these compounds appear to have been isolated newly from natural source. The latter two compounds, hitherto unknown, involve 6β-hydroxy-Δ^4-3-ketone structure, and the former two contain a ketonic group at C_7.[8] In view of the fact that no detectable amount of stigmast-5-en-3β-ol (VIII, stigmasterol) could be found, it would be certain that these four sterols, at least IV and VI, are not artifacts formed by air oxidation[6] or microbiological oxidation[9] during the course of isolation.

Experimental

The melting points are uncorrected. The optical rotations, UV and IR spectra were measured in chloroform, 99% ethanol, and Nujol, respectively, unless otherwise stated. The NMR spectra were recorded at 60 and/or 100 MHz in deuterochloroform, TMS being used as an internal standard, unless otherwise stated. The abbreviations "s, d, t, q, br, and m" in the NMR spectra denote "singlet, doublet, triplet, quartet, broad, and multiplet," respectively. Thin layer chromatography (tlc) was carried out on silica gel (Merck G), using benzene-ether 5: 1 (solvent A) or chloroform-ether 1: 1 (B). Column chromatography was carried out over silica gel (Mallinckrodt A.R. 100 mesh).

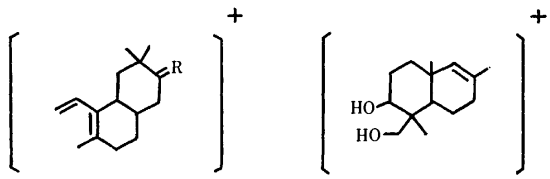
Extraction of Roots of the "Kidney Bean" (Phaseolus vulugaris L.). The dried, powdered roots (22 kg) were percolated with water (3×100 *l*) and, after removal of the aqueous solution, extracted with methanol (2×125 *l*). The extracts were concentrated to about 20 *l in vacuo* and extracted continuously with chloroform to give resinous material (124 g), which was treated with *n*-hexane. The hexane-insoluble materials (97 g) were redissolved in chloroform and washed with 2N sodium hydroxide solution and then 1N hydrochloric acid. The neutral substances (16 g) thus obtained were chromatographed over a mixture of silica gel (250 g) and celite (100 g), using *n*-hexane, benzene, chloroform, and ether, successively. Elution with benzene gave an oily, complex mixture (3.3 g, probably esters), which was not examined further. Elution with chloroform afforded phytosterols (2.2 g) and a mixture of ketones (4.4 g), and that with ether crude soyasapogenol-B (4.3 g).

β-Sitosterol (III). The phytosterol mixture was crystallized from methanol to give crude β-sitosterol (0.90 g), mp 126—130°C, which on recrystallization from methanol afforded III (0.54 g), colorless plates, mp 141—142°C in pure state.

The mother liquors were treated with bromine to check the presence of stigmasterol (VIII), but no crystalline substance corresponding to its tetrabromide[10] was obtained.

Soyasapogenol-B (I). The crude soyasapogenol-B was recrystallized repeatedly from methanol to give I (1.1 g), mp 253—254°C, in pure state, which gave green color by the Lieberman-Burchards test. This was recrystallized from methanol to yield an analytical sample (0.99 g), mp 259—261°C and $[\alpha]_D+89°$ (*cf.* Ref. 3c); mass, *m/e* 458 (M^+), 234 (base peak, IX), 224 (X), and 219 (IX−Me);[11] IR, ν_{max} 3300, 1388, 1379, and 845 cm^{-1}; NMR (deuteropyridine), δ 0.99, 1.08, and 1.23 (each 3H, s), 1.28 (6H, s), 1.56 (3H, s), and 3.73 (3H, br m). This compound was identical (mixed mp, tlc, mass, IR, and NMR spectra) with authentic specimens donated by Professors C. Djerassi[12] and O. Jeger.[3b]

Found: C, 78.36; H, 10.94%. Calcd for $C_{30}H_{50}O_3$: C, 78.55; H, 10.99%.



IX R=OH, H
XI R=O

X

Compound I (51 mg) was acetylated with acetic anhydride (1 m*l*) and pyridine (1 m*l*) at room temperature for 24 hr to give the triacetate (Ia, 55 mg), colorless prisms, mp 176—177°C from methanol and $[\alpha]_D+80°$ (*cf.* Ref. 3c); mass, *m/e* 584 (M^+), 276 and 261; IR, ν_{max} 1724 cm^{-1}; NMR, δ 0.83 and 0.91 (each 3H, s), 1.00 (9H, s), 1.04 and 1.16 (each 3H, s), 2.03 (6H, s, OAc), 2.06 (3H, s, OAc), 4.14 and 4.38 (each 1H, ABq $J=12$ Hz, CH_2OAc), 4.62 (2H, br m, 2 CH-OAc) and 5.25 (1H, br t $J=4.5$ Hz, H at C_{12}) (*cf.* Ref. 13).

Found: C, 74.02; H, 9.40%. Calcd for $C_{36}H_{56}O_6$: C, 73.90; H, 9.65%.

Soyasapogenol-E (II). The mixture of ketones was rechromatographed over a mixture of silica gel (80 g) and celite (20 g) using chloroform as solvent, and separated into four fractions. The first fraction gave a brown-red oil (1.3 g, probably esters), which was not examined further. The second yielded a mixture of ketones (0.97 g), which was submitted to separation. The next fraction afforded crude soyasapogenol-E (1.7 g), and the last fraction was proved to contain I (0.17 g) as a main component by tlc (solvent B).

Crude soyasapogenol-E was recrystallized from methanol to give colorless needles (260 mg), mp 233—234°C, which on recrystallizations from methanol afforded an analytical sample of II (80 mg), mp 249—250°C (amorphous[4]) and $[\alpha]_D+34°$; mass,[11] *m/e* 456 (M^+) and 232 (base peak, XI); IR, ν_{max} 1705 cm^{-1}; NMR, δ 0.86, 0.89, and 0.92 (each 3H, s), 0.98 (6H, s), 1.20 and 1.23 (each 3H, s), 3.36 (2H, br CH_2-OH), 4.33 (1H, br CHOH), and 5.29 (1H, br H at C_{12}) (*cf.* Ref. 4).

Found: C, 78.93; H, 10.76%. Calcd for $C_{30}H_{48}O_3$: C, 78.89; H, 10.51%.

The second crops (70 mg), obtained from the mother liquor on recrystallizations of II, gave the diacetate (IIa, 50 mg),

mp 243—244°C and $[\alpha]_D$+21° (*cf.* Ref. 4); mass, *m/e* 540 (M^+) and 232; IR, ν_{max} 1706, 1740, and 1745 cm^{-1} (*cf.* Ref. 4); NMR, δ 0.87 (3H, s), 0.98, 0.99, and 1.01 (total 15H, each s), 1.20 (3H, s), 2.01 and 2.03 (each 3H, s, OAc), 4.16 and 4.32 (each 1H, ABq J=12 Hz, CH_2OAc), 4.52 (1H, dd J= 7.5 and 2.5 Hz, CHOAc), and 5.26 (1H, br d J= 5 Hz, H at C_{12}) (*cf.* Ref. 4). Compound IIa was reconverted into II by hydrolysis under the same conditions as those[4] reported.

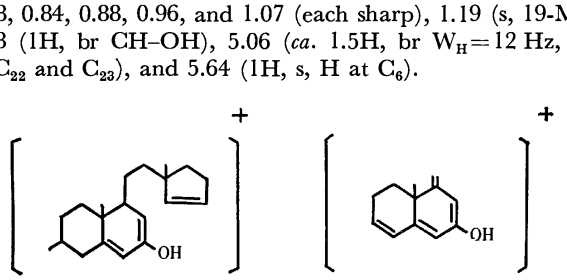
Found: C, 75.08; H, 9.72%. Calcd for $C_{34}H_{52}O_5$: C, 75.51; H, 9.69%.

Soyasapogenol-B (I, 786 mg) dissolved in a 4: 1 mixture (10 m*l*) of chloroform and ether was passed through a column of silica gel (Wakogel Q-23), freshly washed successively with methanol, acetone, and *n*-hexane, using *n*-hexane containing 8% acetone. The eluate was recrystallized from methanol to give the acetonide (Ib, 500 mg), mp 177—178°C and $[\alpha]_D$+111° (*cf.* Ref. 3c); IR, ν_{max} 3430, 1150, 1100, 1080, 1052, and 1025 cm^{-1}; NMR, δ 0.88, 0.90, 0.99, 1.03, 1.11, 1.15, 1.20, 1.35, and 1.40 (each 3H, s), 3.35 (2H, br), 4.03 (1H, br d J=10 Hz), and 5.25 (1H, br).

Compound Ib (450 mg) in pyridine (10 m*l*) was oxidized with chromic anhydride (530 mg) in pyridine (4 m*l*) at room temperature for 20 hr under stirring. The product was treated with water and ether, and the ether solution afforded amorphous keto-acetonide (495 mg). This was converted into crystalline glycol on heating with methanol, which was recrystallized from methanol to give II (300 mg), mp 246—248°C and $[\alpha]_D$+32°. This compound and its diacetate, mp 243—244°C and $[\alpha]_D$+24°, were identical with the corresponding natural specimens.

Stigmasta-5,22-dien-3β-ol-7-one (IV) and Stigmast-5-en-3β-ol-7-one (V). A mixture of ketones (970 mg), the second fraction obtained on rechromatography, was triturated with methanol to give crystalline material (340 mg), which was separated into two fractions (150 and 65 mg) by preparative tlc (chloroform: ether 3 : 1). Recrystallization of the former from ethanol afforded crystal A (IV and V, 80 mg), and that of the latter crystal B (VI and VII, 50 mg), each showing a single spot on tlc (solvent A).

Crystal A had mp 144—146°C and $[\alpha]_D$−80°; mass, *m/e* 428 (M^+), 426 (M^+), 410, 408, 396, 383, 314, 287 (base peak, XII), and 174 (XIII);[14] UV, λ_{max} 238 mμ (ε 16000); IR, ν_{max} 3360 and 1675 cm^{-1}; NMR, δ 0.69 (s, 18-Me), 0.74, 0.78, 0.84, 0.88, 0.96, and 1.07 (each sharp), 1.19 (s, 19-Me), 3.58 (1H, br CH–OH), 5.06 (*ca.* 1.5H, br W_H=12 Hz, 2H at C_{22} and C_{23}), and 5.64 (1H, s, H at C_6).



XII XIII

XIV XII−H_2O

Crystal A (50 mg) was converted into the acetate, which on preparative tlc (benzene: chloroform 2 : 1) followed by trituration with acetone afforded a sample (35 mg) showing a single spot, mp 176—179°C and $[\alpha]_D$−102°; mass, *m/e* 410 (M^+–AcOH), 408 (M^+–AcOH), 396, 365, and 269 (base peak, XIV) and 174; UV, λ_{max} 238 mμ (ε 15000); IR, ν_{max} 1740 and 1670 cm^{-1}; NMR, δ 0.68 (3H, s, 18-Me), 0.75, 0.79, 0.86, 0.89, 0.97, and 1.08 (each sharp), 1.18 (3H, s, 19-Me), 2.00 (3H, s, OAc), 4.68 (1H, br CH-OAc), 5.08 (1.3H, t J=6 Hz, 2H at C_{22} and C_{23}), and 5.68 (1H, s, H at C_6).

Attempted purifications of crystal A [preparative tlc over silica gel (benzene: *n*-hexane 1: 1), over silica gel containing silver nitrate, or over alumina or bromination followed by debromination] failed and only repeated recrystallization from methanol effected isolation of IV (10 mg from 80 mg of A) in pure state, which had mp 138—140°C and, after drying, 160—162°C and $[\alpha]_D$−78°; mass, *m/e* 426 (M^+), 408, 383, 287 (XII), and 269 (XIV); UV, λ_{max} 238 mμ (ε 16000); IR, ν_{max} 3360 and 1675 cm^{-1}; NMR, δ 0.69 (s, 18-Me), 0.83 (t J=7 Hz, 29-Me), 0.83 (d J=6 Hz, 26- and 27-Me), 1.00 (d J=7 Hz, 21-Me), 1.19 (s, 19-Me), 3.60 (1H, br CH–OH), 5.08 (2H, br t J=5 Hz, 2H at C_{22} and C_{23}), and 5.65 (1H, s, H at C_6). This compound was identified as IV by direct comparison with an authentic sample.

Found: C, 81.54; H, 10.84%. Calcd for $C_{29}H_{46}O_2$: C, 81.63; H, 10.87%.

A 2: 1 mixture of synthetic samples IV and V had mp 144—146°C and $[\alpha]_D$−81°, and that of the respective acetates mp 176—179°C and $[\alpha]_D$−101°. The former and the latter mixtures revealed mass, UV, IR, and NMR spectra, superimposable over the corresponding spectra of crystal A and its acetate, respectively.

Stigmasterol acetate (VIIIa) and β-sitosterol acetate (IIIa) were oxidized[8a] to give the respective 7-oxo derivatives (IVa), mp 183—184°C (*cf.* Refs. 5 and 6a) and $[\alpha]_D$−103° (*cf.* Ref. 6a); mass, *m/e* 408, 365, 297, and 269 (base peak); UV, λ_{max} 238 mμ (ε 15000); IR, ν_{max} 1740 and 1670 cm^{-1}; NMR, δ 0.69 (3H, s, 19-Me), 0.83 (t J=7 Hz, 29-Me), 0.83 (d J= 7 Hz, 26- and 27-Me), 1.02 (d J=7 Hz, 21-Me), 1.21 (s, 19-Me), 2.02 (3H, s, OAc), 4.63 (1H, br CH–OAc), 5.02 (2H, br t J=5.5 Hz, 2H at C_{22} and C_{23}), and 5.61 (1H, s, H at C_6), and (Va), mp 174—176°C and $[\alpha]_D$−95° (*cf.* Ref. 7); mass, *m/e* 410, 396, and 174 (base peak); UV, λ_{max} 238 mμ (ε 15000); IR, ν_{max} 1740 and 1670 cm^{-1}; NMR, δ 0.69 (3H, s, 18-Me), 0.86 (d J=6 Hz, 21-, 26-, and 27-Me), 0.88 (t J= 7 Hz, 29-Me), 1.22 (s, 19-Me), 2.06 (3H, s, OAc), 4.67 (1H, br CH–OAc), and 5.70 (1H, s, H at C_6).

The resulting 7-oxo-compounds (IVa and Va) were saponified[6a] to yield the respective alcohols IV and V. Compound IV had mp 138—140°C (from methanol) and mp 158—160°C (after drying at 90°C) (154°C[5] and 130—135°C[6a]) and showed $[\alpha]_D$−78° (−113°[5]). Compound V had mp 128—130°C and $[\alpha]_D$−85° (144—145°C and −116°[7]); mass, *m/e* 428, 410, 396, and 174 (base peak); UV, λ_{max} 238 mμ (ε 16000); IR, ν_{max} 3380 and 1675 cm^{-1}; NMR, δ 0.68 (3H, s, 18-Me), 0.82 (d J=6 Hz, 21-, 26-, and 27-Me), 0.85 (t J=7 Hz, 29-Me), 1.19 (s, 19-Me), 3.63 (1H, br CH–OH), and 5.70 (1H, s, H at C_6).

Stigmasta-4,22-dien-6β-ol-3-one (VI) and Stigmast-4-en-6β-ol-3-one (VII). Crystal B (50 mg) had mp 210—213°C and $[\alpha]_D$+16°; mass, *m/e* 428 (M^+) and 426 (M^+); UV, λ_{max} 238 mμ (ε 16000); IR, ν_{max} 3400, 1680, 1035, and 1010 cm^{-1}; NMR, δ 0.76 (s, 18-Me), 0.81, 0.84, 0.87, 0.91, 0.98, and 1.09 (each sharp), 1.39 (3H, s, 19-Me), 4.34 (1H, br s W_H=5 Hz, CH–OH), 5.12 (1H, br t J=5 Hz, 2H at C_{22} and C_{23}), and 5.80 (1H, s, H at C_4). This crysatal resisted further purification.

Treatment of crystal B (43 mg) with acetic anhydride (0.4 m*l*) and pyridine (0.4 m*l*) gave its acetate, amorphous, showing $[\alpha]_D$+21°; mass, *m/e* 470, 468, 428, 426, and 149 (base peak); UV, λ_{max} 237 mμ (ε 15000); IR, ν_{max} 1740 and 1680 cm^{-1}; NMR, δ 0.76 (s, 18-Me), 0.84, 0.88, 0.90, 0.98, and 1.09 (each sharp), 1.28 (3H, s, 19-Me), 2.02 (3H,

14) S. Sasaki, "Interpretation of Mass Spectra," Hirokawa Publishing Co., Tokyo (1965), p. 172.

s, OAc), 5.09 (1H, br t J=5 Hz, 2H at C_{22} and C_{23}), 5.40 (1H, br t J=3 Hz, CH–OAc), and 5.91 (1H, s, H at C_4) (*cf.*, NMR spectrum[15] of cholest-4-en-6β-ol-3-one).

These spectral data suggest crystal B to be a 1:1 mixture of VI and VII. In fact, a 1:1 mixture of synthetic samples of VI and VII, had mp 209—212°C and $[\alpha]_D$+15°, and the corresponding acetate, amorphous, showed $[\alpha]_D$+23°. These synthetic alcohol and acetate mixtures exhibited the mass, UV, IR, and NMR spectra superimposable over the corresponding spectra of crystal B and its acetate, respectively.

Preparation of VI and VII. To a solution of stigmasterol (VIII, 2.40 g) in benzene (11 m*l*) and acetic acid (10 m*l*) was added sodium bichromate (1.5 g as hydrate) in acetic acid (5 m*l*) at room temperature (*cf.* Ref. 16). The mixture was stirred at room temperature overnight and, after addition of ethanol (*ca.* 10 m*l*), diluted with water (50 m*l*), and then extracted with ether (50 m*l*). The ether solution was washed with a 5% sodium bicarbonate solution and then with water, dried and evaporated to leave amorphous residue. This was purified by chromatography over silica gel (100 g), using a 10:1 mixture of chloroform and ether, and it gave a crude sample of VI (1.1 g), mp 198—203°C, showing a single spot on tlc. Recrystallization from ethanol afforded a pure sample, mp 210—212°C and $[\alpha]_D$+8°; mass, *m/e* 426; UV, λ_{max} 238 mμ (ε 16000); IR, ν_{max} 1680 and 1620 cm^{-1}; NMR, δ 0.77 (3H, s, 18-Me), 1.39 (s, 19-Me), 4.33 (1H, br s W_H=6 Hz, CH–OH), 5.11 (2H, br t J=5 Hz, 2H at C_{22} and C_{23}), and 5.79 (1H, s, H at C_4).

Found: C, 81.25; H, 10.99%. Calcd for $C_{29}H_{46}O_2$; C, 81.63; H, 10.84%.

Compound VI was converted into the acetate (VIa), mp 107—109°C (from *n*-hexane) and $[\alpha]_D$+16°; mass, *m/e* 468, 426, and 149 (base peak); UV, λ_{max} 238 mμ (ε 15,000); IR, ν_{max} 1740, 1680, and 1620 cm^{-1}; NMR, δ 0.77 (3H, s, 18-Me), 1.29 (s, 19-Me), 2.02 (3H, s, OAc), 5.12 (2H, br t J=5 Hz, 2H at C_{22} and C_{23}), 5.40 (1H, br s W_H=5 Hz, CH–OAc), and 5.90 (1H, s, H at C_4).

Found: C, 79.50; H, 10.15%. Calcd for $C_{31}H_{48}O_3$; C, 79.43; H, 10.32%.

Compound VII (1.49 g) was likewise obtained from β-sitosterol (III, 2.2 g) in crude state and had mp 188—194°C. Recrystallization from ethanol gave a pure sample, mp 211—213°C and $[\alpha]_D$+29°; mass, *m/e* 428; UV, λ_{max} 238 mμ (ε 16000); IR, ν_{max} 1680 and 1620 cm^{-1}; NMR, δ 0.76 (3H, s, 18-Me), 1.39 (s, 19-Me), 4.31 (1H, br s W_H=6 Hz, CH–OH), and 5.79 (1H, s, H at C_4).

Found: C, 81.48; H, 11.37%. Calcd for $C_{29}H_{48}O_2$: C, 81.25; H, 11.29%.

An acetate (VIIa) of VII was obtained only in amorphous state and showed $[\alpha]_D$+27°; mass, *m/e* 470, 428, and 149; UV, λ_{max} 238 mμ (ε 15000); IR, ν_{max} 1740, 1680, and 1620 cm^{-1}, NMR, δ 0.77 (3H, s, 18-Me), 1.29 (s, 19-Me), 2.02 (3H, s, OAc), 5.39 (1H, br s W_H=5 Hz, CH–OAc), and 5.90 (1H, s, H at C_4).

Found: C, 79.35; H, 10.50%. Calcd for $C_{31}H_{50}O_3$: C, 79.10; H, 10.71%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 226—229(1972)

The Syntheses of 5-Azidotropolones and Their Electrophilic, Nucleophilic, and Thermal Reactions[1]

Takashi TODA, Hiroshi HORINO, and Tetsuo NOZOE
Department of Chemistry, Faculty of Science, Tohoku University, Katahiracho-ni-chome, Sendai

(Received June 2, 1971)

Several 5-azidotropolones were synthesized by the reaction of sodium azide with tropolone diazonium salts which has been prepared from the corresponding 5-aminotropolones. Most of the 5-azidotropolones thus obtained were stable except for the 4-alkyl derivatives. Their electrophilic substitution reactions took place at their 3- and 7-positions, and also their hydroxyl groups behaved like those of other tropolones. 5-Azidotropolone methyl ether did not react with aromatic amines, but it did with aliphatic amines and guanidine to give 2-aminotropone derivatives and 1,3-diazaazulene derivative. The thermolysis of 5-azidotropolone and its methyl ether afforded 5-aminotropolone and its methyl ether respectively; however, 5-azido-4-phenyltropolone gave indolo[3,2-*d*]tropolone.

Recently, organic azido-compounds have been investigated by many researchers because of their interesting properties.[2] However, azido derivatives of tropolones have not been known until recently; only 2-, 3-, and 4-azidotropones[3–5] and 2-azido-5-nitrotropone[6] have been synthesized, and their properties have been investigated very recently.

Azidotropolones are expected to form nitrene intermediates by photolysis or thermolysis, or by the formation of heterocyclic troponoid compounds and other

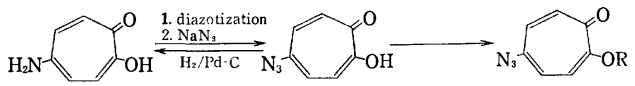
interesting properties in the case of the azido groups. This prompted us to investigate azidotropolones; in this report, we will present our findings on the syntheses, chemical properties, and thermolysis of 5-azidotropolones.

Azidotropones were synthesized from hydrazinotropone with sodium nitrite or from halotropones with sodium azide.[3-6] However, the synthesis of hydrazino derivatives of tropolones and the direct replacement of halogen derivatives of tropolone by sodium azide were difficult. On the other hand, the reaction of sodium azide with diazonium salts of 5-aminotropolones[7] afforded the corresponding azidotropolones in fairly good yields.

The structure of those compounds was established as follows; the azido compound (IIa) obtained from 5-aminotropolone (I) shows strong absorption bands at 3280 cm^{-1} (tropolones' OH group),[8] at 2130 cm^{-1} (N_3),[9] and at 870 and 851 cm^{-1} (two adjacent hydrogens of troplones).[8] The catalytic reduction of IIa gave 5-aminotropolone in a good yield. Therefore, IIa is 5-azidotropolone.

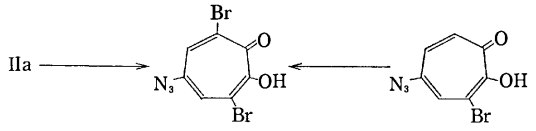


I IIa IIIa: R=Ac
b: R=Me
c: R=Ts

Also, IIa gave a sodium salt, a copper complex, and an acetate (IIIa), a methyl ether (IIIb), and a tosylate (IIIc). These properties are parallel with those of other tropolones.

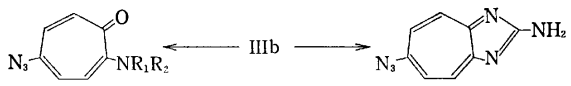
Other 5-azidotropolones, possessing different functional groups at the 3- and 4-positions on the tropolone nucleus, were synthesized by an analogous method; they are shown in Table 1. These azido compounds show spectral properties analogous with those of IIa; however, the introduction of azido groups did not cause any special change in their spectral properties.

As a typical electrophilic substitution reaction, the bromination of IIa was investigated. The bromination of IIa and IIb gave the same 3,7-dibromo derivative (IVa), while 5-azido-3-phenyltropolone (IId) gave the corresponding 7-bromo derivative. Unlike the cases of the electrophilic reactions of phenyl azides,[10] the results showed that this substitution occurred at the 3- and 7-positions, just as in other 5-substituted tropolones and that the azido group did not affect the direction of the brominations.



IVa IIb

2-Amino-5-azidotropone derivatives, (Va) and (Vb), and 2-amino-6-azido-1,3-diazaazulene (VI) were obtained by the reaction of IIIb with aliphatic amines and with guanidine respectively. The properties of IIIb are parallel with those of tropolone methyl ethers.[11] However, no reactions with aromatic amines occurred; presumably, the electron-releasing effect of the azido group[10] and the weak nucleophilicity of the aromatic amines[12] are responsible for this. It is interesting that 5-azidotropolone is stable toward amines, though 2-azido-5-nitrotropone gives 2-aminotropone derivatives by its direct displacement of the azido group with amines.[6]



Va: R_1=Et, R_2=H
b: R_1=R_2=Et VI

Although 2-azidotropones are thermaly unstable and readily loose nitrogen to form ring-cleavage substances, all the 5-azidotropolones except 4-alkyl derivatives are fairly stable entities.

However, when IIa and its methyl ether IIIb were heated in ethylene glycol, 5-aminotropolone and its methyl ether[13] were obtained in 50 and 25% yields respectively; also some intractable resinous substances were formed.

It is known that decomposition of azido compounds in protic solvents affords the corresponding amino compounds, but the yields are rather poor.[2] The reason for the fairly good yield of 5-aminotropolone is as follows; the tropolonyl nitrene formed during the thermolysis has the resonance formula represented below. The nitrene intermediate is stabilized by the contribution of those resonances and lives rather stably until the formation of 5-aminotropolone by hydrogen abstraction from the solvent.

Benzenoid azido compounds, which possess good substituents at the ortho-position of the azido group,

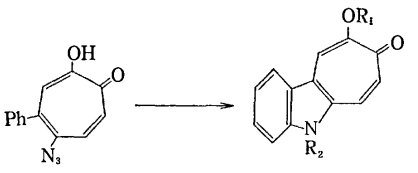
and aliphatic azido compounds, which possess suitable chains, afford five- or six-membered hetero-cyclic compounds.[2] The thermolysis of 5-azido-4-phenyltropolone in ethylene glycol gave an acidic substance in a 50% yield. The IR and UV spectra of this compound are similar to those of indolo[2,3-*d*]tropone.[14] Thus, the structure of VIIa can be said to be indolo[3,2-*d*]tropolone (9-hydroxycycloheptatrieno[*b*]indol-8(5*H*)-one). The spectral evidence of its diacetate (VIIb), methyl ether (VIIc), and an acetate of VIIc (VIId) also support this conclusion.



IIe

VIIa: $R_1=R_2=H$
b: $R_1=R_2=Ac$
c: $R_1=Me$, $R_2=H$
d: $R_1=Me$, $R_2=Ac$

4-Alkyl-5-azidotropolones (IIf and IIg) are very unstable and could not be obtained in an analytically pure state. This unstability and the formation of complex tarry substances of 4-alkyl-5-azidotropolones suggest that hydrogens of alkyl groups, especially those of the isopropyl group, are abstracted by azido groups, which form nitrene intermediates. The alkyl radicals formed gave complex resultants by means of intra- or inter-molecular reactions. However, no clear substances were obtained.

Experimental[15]

5-Azidotropolone (IIa). A solution of 5.0 g of 5-amino-tropolone I in 150 m*l* of 6N sulfuric acid was treated with 2.77 g of sodium nitrite in 25 m*l* of water. The resulting solution was stirred, drop by drop, into a solution of 2.84 g of sodium azide in 20 m*l* of water at −6——9°C. After the mixture had been allowed to stand overnight at room temperature, 5.53 g of the brown precipitates (IIa) were collected and recystallized from ethanol; mp 140°C (dec.). The residue was extracted with ethyl acetate and dried, and the solvent was removed to afford 0.03 g of the additional IIa.

Found: C, 52.04; H, 3.18; N, 25.44%. Calcd for $C_7H_5O_2N_3$: C, 52.07; H, 2.42; N, 25.10%. λ_{max}^{MeOH}, mμ (log ε); 242 (4.20), 355 (3.49), 425 (3.54 sh).

5-Azido-3-bromotropolone (IIb). A solution of 200 mg of 5-amino-3-bromotropolone in a mixture of 4 m*l* of dioxane and 1 m*l* of 18N sulfuric acid was treated with a solution of sodium nitrite in 0.3 m*l* of water. After standing for 20 min, the resulting solution was stirred, drop by drop, into an aqueous solution of 73 m*l* of sodium azide at −5——8°C. It was then allowed to stand at room temperature for about 5 hr. Subsequent dilution with 30 m*l* of water gave a precipitate, which was then collected and recrystallized from ethanol to yield 112 mg of IIb; mp 117°C (dec.).

Found: C, 34.73; H, 1.63; N, 17.35%. Calcd for $C_7H_4O_2N_3Br$: C, 35.32; H, 1.92; N, 16.80%. λ_{max}^{MeOH}, mμ (log ε); 260 (4.22), 351 (4.07), 410 (3.62 sh).

The following substituted 5-azidotropolones were prepared in the same way as above. The data of the analyses and some physical properties are as follows.

5-Azido-3-methyltropolone (IIc). Mp 100°C, from methanol.

Found: C, 54.21; H, 4.08; N, 23.47%. Calcd for $C_8H_7O_2N_3$: C, 54.23; H, 3.98; N, 23.72%. $\lambda_{m\mu}^{MeOH}$, mμ (log ε); 242 (4.23), 345 (4.07).

5-Azido-3-phenyltropolone (IId). Mp 115°C (dec.), from methanol.

Found: C, 65.49; H, 3.71; N, 16.93%. Calcd for $C_{13}H_9O_2N_3$; C, 65.26; H, 3.79; N, 17.57%. λ_{max}^{MeOH}, mμ (log ε); 229 (4.11), 256 (4.05), 285 (3.98), 356 (3.90), 405 (3.70).

5-Azido-4-phenyltropolone (IIe). Mp 122°C (dec.), from methanol.

Found: C, 65.44; H, 3.97; N, 16.93%. Calcd for $C_{13}H_9O_2N_3$: C, 65.26; H, 3.79; N, 17.57%. λ_{max}^{MeOH}, mμ (log ε) 229 (4.15), 267 (4.21), 356 (4.18), 402 (3.85).

5-Azido-4-methyltropolone (IIf). Mp 135°C (dec.). λ_{max}^{MeOH} mμ (log ε), 228 (4.15), 346 (4.03).

5-Azido-4-isopropyltropolone (IIg). Mp 109°C (dec.).

5-Azizo-2-acetoxytropone (IIIa). One hundred mg of 5-azidotropolone IIa were allowed to stand overnight in a solution of pyridine (1.5 m*l*) and acetic anhydride (1.5 m*l*). Subsequent heating on a water bath for 10 min and evaporation *in vacuo* produced 117 mg of IIIa; mp 117°C (dec.), recrystallized from ethanol.

Found: C, 52.68; H, 3.44; N, 20.48%. Calcd for $C_9H_7O_3N_3$: C, 52.89; H, 3.43; N, 20.68%. ν(KBr); 2130 cm^{-1}.

5-Azido-2-methoxytropone (IIIb). An ethereal solution of diazomethane was added, drop by drop, to 90 mg of IIa dissolved in a cold mixture of 20 m*l* of ethyl acetate and 8 m*l* of ether until there was no coloration by a ferric chloride test. After it had then stood overnight, the solution was evaporated to dryness *in vacuo* thus giving 170 mg of yellow IIIb; mp 110°C (dec), recrystallized from a mixture of benzene and cyclohexane.

Found: C, 54.66; H, 3.85; N, 23.36%. Calcd for $C_8H_7O_2N_3$: C, 54.85; H, 3.88; N, 23.06%. λ_{max}^{MeOH}, mμ (log ε); 226 (4.17), 343 (4.15), ν(KBr); 2130 cm^{-1}.

5-Azido-2-tosyloxytropone (IIIc). To a solution of 100 mg of IIa in 1.5 m*l* of pyridine, 100 mg of *p*-toluenesulfonyl chloride was added at once, upon which the reaction occurred exothermically. After the mixture had stood for a night, further addition of 140 mg of the reagent led to a negative ferric chloride test. The solution was then poured into 30 m*l* of water and acidified succesively with 6N hydrochloric acid to yield 140 mg of IIIc; mp 136°C (dec), recrystallized from ethanol.

Found: C, 53.28; H, 3.68; N, 12.80%. Calcd for $C_{14}H_{11}O_4N_3$: C, 53.00; H, 3.50; N, 12.25%. ν (KBr); 2130 cm^{-1}.

5-Azido-3,7-dibromotropolone (IVa). *1) Bromination of IIa*: Into a solution of 100 mg of IIa and 110 mg of sodium acetate in 2 m*l* of acetic acid, 220 mg of bromine in 0.3 m*l* of acetic acid was stirred for 12 min. The product was collected and filtered to give 160 mg of IVa, which was recrystallized from ethanol; mp 119°C (dec.). The residue was concentrated under reduced presure without heating to yield 41 mg of the additional IVa. The filtrate was diluted with water and then extracted with chloroform; this procedure afforded 40 mg of a paste after the evaporation of the solvent. The paste was chromatographed over a paper treated with phosphoric acid; this showed only one spot, the same as IVa.

Found: C, 26.16; H, 1.35; N, 12.75%. Calcd for $C_7H_3O_2N_3Br_2$: C, 26.19; H, 0.94; N, 13.09%. λ_{max}^{MeOH}, mμ (log ε);

14) J. Shin, D. Sc. thesis of Tohoku University, March, 1958.
15) All the melting points are uncorrected.

264 (4.27), 355 (3.90), 420 (3.43), 456 (3.36).

2) Bromination of IIb: An acetic acid solution of 80 mg of bromine was added to a mixture of 100 mg of IIb and 40 mg of sodium acetate in 2 m*l* of acetic acid. The solution was then treated as above. This gave 87 mg of IVa, which showed no melting-point depression on admixture with the product obtained in 1); also, their IR spectra are superimposable.

5-Azido-7-bromo-3-phenyltropolone (IVb). IVb was prepared in the way described above and recrystallized from ethanol; mp 117.5°C (dec.).

Found: C, 49.58; H, 2.78; N, 12.83%. Calcd for $C_{13}H_8O_2N_3Br$: C, 49.10; H, 2.53; N, 13.21%. ν (KBr); 3235, 2140, 2105 cm^{-1}.

Catalytic Reduction of IIa. A solution of IIa (100 mg) in 30 m*l* of ethyl acetate was shaken with 30 mg of 10 per cent palladium on carbon in a hydrogen atomosphere. The catalyst was then removed, and the filtrate was concentrated to give 73 mg of yellow crystals. Recrystallization from a mixture of benzene and ethyl acetate made its mp 181°C; it was identified as 5-aminotropolone by a mixed-melting-point determination with an authentic sample.

Reaction of IIIb with Aromatic Amines. 1) A mixture of 100 mg of IIIb and 100 mg of *o*-phenylenediamine dissolved in 4 m*l* of absolute ethanol was heated to reflux for 2 hr. It was then evaporated to yield 84 mg of IIIb; mp 105—107°C, identified by thin-layer chromatography and admixture with the starting material.

2) A mixture of 100 mg of IIIb and 64 mg of *p*-toluidine in absolute ethanol was boiled for 2 hr. The same treatment as above gave 85 mg of IIIb; mp 109—110°C.

5-Azido-2-ethylaminotropone (Va). A solution of 200 mg of IIIb was dissolved in a mixture of 3 m*l* of ethanol and a 70% aqueous solution of monoethylamine. After standing for two days, the solution was diluted with water, neutralized with 2N hydrochloric acid, and then extracted with ethyl acetate to give 180 mg of a red oil. Treatment of it with 230 mg of picric acid in ethanol afforded 365 mg of yellow crystals which was recrystallized from ethanol; mp 128—129°C (dec.).

Found: C, 43.13; H, 3.02; N, 23.47%. Calcd for $C_{15}H_{13}O_8N_7$: C, 42.97; H, 3.12; N, 23.39%. ν (KBr); 2100 cm^{-1}.

5-Azido-2-diethylaminotropone (Vb). Two hundred mg of IIIb were dissolved in a mixture of 1 m*l* of diethylamine and 2 m*l* of absolute ethanol. After having stood overnight, the solution was evaporated; water was added, and then it was acidified with 2N hydrochloric acid. It was extracted with ethyl acetate, evaporated, and then chromatographed over silica gel to give a reddish oil (56 mg) and the recovered IIIb (180 mg). λ_{max}^{MeOH}, mμ; 255, 382, 437. ν (KBr); 2130 cm^{-1}.

A picrate of this oil was obtained by treatment with an alcoholic solution of picric acid; mp 112—113°C (dec.), from ethanol.

Found: N, 21.92%. Calcd for $C_{17}H_{17}O_8N_7$: N, 21.90%. ν (KBr); 2100 cm^{-1}.

2-Amino-6-azido-1,3-diazaazulene (VI). To a solution of guanidine hydrochloride (142 mg) and sodium (35 mg) in absolute ethanol (2 m*l*), IIIb (220 mg) was added and it was stirred for a night. The yellow precipitate thus formed (132 mg) was collected and recrystallized from ethanol. No clear melting point was observed, but it decomposed gradually.

Found: C, 51.45; H, 3.63; N, 44.50%. Calcd for $C_8H_6N_6$: C, 51.61; H, 3.25; N, 45.14%. λ_{max}^{MeOH}, mμ (log ε); 224 (4.19), 253 (4.25), 376 (3.87). ν (KBr); 3050, 2120, 1675, 844, 826 cm^{-1}.

Thermolysis of 5-Azidotropolone. A suspension of IIa (500 mg) in ethylene glycol (5 m*l*) was heated under a nitrogen atomosphere. It became a solution at about 105°C and bubbled at 115—130°C. After gas evolution had ceased, the solvent was removed by suction and the residue was extracted with hot ethanol. The evaporation of this solution and recrystallization from benzene gave 126 mg of yellow crystals (mp 179—180°C), which were identified with I by a mixed-melting-point determinations with an authentic sample. The subsequent treatment of this filtrate with a saturated alcoholic solution of picric acid gave 90 mg (mp 226°C (dec.)) of 5-aminotropolone picrate.[16]

Thermolysis of 5-Azido-2-methoxytropone. A suspension of IIb (300 mg) in ethylene glycol (3 m*l*) was heated under a nitrogen atmosphere. The nitrogen gas began to bubble about at 115—125°C. The solution was then concentrated under reduced pressure and extracted with hot methanol to afford 70 mg of a yellow oil, which was then crystallized with a saturated alcoholic solution of picric acid; mp 220°C, from ethanol. This picrate was identified with 5-amino-2-methoxytropone picrate[13] by a mixed-melting-point determination with an authentic sample.

Thermolysis of 5-Azido-4-phenyltropolone. A solution of IIe (350 mg) in ethylene glycol (4 m*l*) was heated under a nitrogen atmosphere. It bubbled at 115—120°C. After gas evolution had ceased, the solution was poured into 20 m*l* of water and then extracted with chloroform; this procedure afforded 150 mg of yellow crystals of indolo[3,2-*d*]tropolone (VIIa). Recrystallization from ethanol made its mp 240—241°C (dec.).

Found: C, 74.02; H, 4.64. N, 6.42%. Calcd for $C_{13}H_9O_2N$: C, 73.92; H, 4.30; N, 6.63%. λ_{max}^{MeOH}, mμ (log ε); 243 (4.44), 260 (4.10 sh), 300 (4.24 sh), 325 (5.55), 364 (4.04 sh), 405 (3.96), 426 (3.98). ν (KBr); 3080, 840, 773, 746 cm^{-1}.

Methyl Ether (VIIb) of VIIa. A solution of VIIa (200 mg) in methanol (16 m*l*) was treated with ethereal diazomethane cooled in an ice-bath. After it has been allowed to stand for 8 hr, yellow needles which precipitated were collected and recystallized from ethanol; mp 266—267°C.

Found: C, 73.92; H, 5.10; N, 5.62%. Calcd for $C_{14}H_{11}O_2N$: C, 74.65; H, 4.92; N, 6.22%. λ_{max}^{MeOH}, mμ (log ε); 241 (4.37), 254 (4.23 sh), 325 (4.45), 363 (4.02), 309 (3.97), 417 (3.95). ν (KBr); 3095, 1625 cm^{-1}.

N,O-*Diacetate (VIIc) of VIIa.* A solution of VIIa (50 mg) and acetic anhydride (0.3 m*l*) in pyridine (0.7 m*l*) was refluxed for 5 min. The solution was then poured into water to afford colorless crystals (50 mg) ,which were recrystallized from ethanol; mp 203°C.

Found: C, 69.40; H, 4.64; N, 4.71%. Calcd for $C_{17}H_{13}O_4N$: C, 69.14; H, 4.44; N, 4.74%. λ_{max}^{MeOH}, mμ (log ε); 235 (4.42), 324 (4.38), 348 (4.22 sh), 380 (4.48). ν (KBr); 1765, 1701 cm^{-1}.

N-*Acetyl Methyl Ether (VIId) of VIIa.* A solution of VIIa (55 mg) and acetic anhydride (0.4 m*l*) in pyridine (0.8 m*l*) was heated on a water bath for 30 min and then refluxed for 1 min. The solution was poured into water, neutralized with 2N hydrochloric acid, and extracted with chloroform. The extract was concentrated to yield a yellow powder (56 mg), which was recrystallized from ethanol; mp 206—207°C.

Found: C, 71.27; H, 5.07; N, 5.41%. Calcd for $C_{16}H_{13}O_3N$: C, 71.90; H, 4.90; N, 5.24%. λ_{max}^{MeOH}, mμ; 240, 256, 325, 378, 397. ν (KBr); 1670 cm^{-1}.

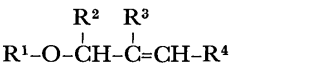
Palladium-catalyzed Exchange of Allylic Groups of Ethers and Esters with Active Hydrogen Compounds. II.[1]

Kuniyuki TAKAHASHI, Akihisa MIYAKE, and Go HATA
Basic Research Laboratory, Toray Industries, Inc., Tebiro, Kamakura
(Received June 4, 1971)

The allylic compounds (I), R^1–O–R (R=allylic groups, R^1=Ph, Me, $PhCH_2$, MeCO), react with active-hydrogen compounds such as phenols, alcohols, carboxylic acids, primary and secondary amines and active methylene compounds, to give allylic derivatives of the active-hydrogen compounds by an intermolecular exchange of the allylic groups of I with the atom to which the active hydrogens are bonded in the presence of palladium catalysts. Allyl and substituted-allyl ethers are more reactive than the corresponding carboxylates. In the reactions of methyl and benzyl ethers, it is necessary to add phenol to obtain the exchange products in fairly good yields. Bis(triphenylphosphine)palladium chloride plus sodium phenoxide, palladium acetate plus triphenylphosphine, and zerovalent palladium complexes such as tetrakis(triphenylphosphine)palladium and (maleic anhydride)bis(triphenylphosphine)palladium are effective catalysts.

It has been reported that the vinyl group of ethers and esters exchanges with various active-hydrogen compounds such as phenols, alcohols and carboxylic acids in the presence of mercury salts[2,3] or palladium salts.[4] Mercury acetate also catalyzes the exchange of an allyl group of allyl ethers with a hydroxyl group of alcohols.[5] Sabel and his coworkers have reported[4] on the exchange reaction of an allyl group between allyl acetate and propionic acid by $PdCl_2$·NaCl-$CH_3CH_2CO_2Na$ catalyst system.

Recently a new type of palladium catalyzed dimerization of 1,3-dienes completed by the addition of active-hydrogen compounds such as alcohols, phenols, amines, carboxylic acids and active methylene compounds, has been found.[6-9] Smutny found[10] that the palladium complexes, which catalyzed the reaction of phenol with butadiene to the formation of 1-phenoxy-2,7-octadiene, degradated the resulting ether to phenol and 1,3,7-octatriene. The degradation reaction seems to proceed through an allylic intermediate by the insertion of the palladium atom to the C–O bond of the ether. If such an intermediate exists, the intermediate is expected to react with active-hydrogen compounds to afford 2,7-octadienyl derivatives of the corresponding active-hydrogen compounds. In fact, the reaction of 1-phenoxy-2,7-octadiene with methyl acetoacetate gave the expected products. A further research has led to the finding that allylic compounds (I) react with active-hydrogen compounds in the same way



I

R^1=Ph, CH_3, $PhCH_2$, CH_3CO
R^2=H, $CH_2CH_2CH_2CH{=}CH_2$
R^3=H, CH_3
R^4=H, CH_3, $CH_2CH_2CH_2CH{=}CH_2$

to give allylic derivatives of the active hydrogen compounds by the intermolecular exchange of the allylic groups of the allylic compounds to the atom to which the active-hydrogen is bonded. This type of reaction is applied to alcohols, phenols, carboxylic acids, and primary and secondary amines. The same type of exchange reactions of allylic group has been reported independently by Atkins and his coworkers.[11] We reported a part of these reactions in a preliminary communication.[1] The present paper describes the reactions in detail.

An active and easily available catalyst is prepared by mixing dichlorobis(triphenylphosphine)palladium (II) and sodium phenoxide. The combination of palladium acetate and triphenylphosphine, and zerovalent palladium phosphine complexes such as tetrakis(triphenylphosphine)palladium(0) and (maleic anhydride)bis(triphenylphosphine)palladium(0) are also effective catalysts. Platinum catalysts such as the combination of dichlorobis(triphenylphosphine)platinum(II) and sodium phenoxide, and tetrakis(triphenylphosphine)platinum(0) also showed catalytic activity, but the activity of the platinum catalysts was smaller than that of palladium catalysts. It is noted that all of the catalysts are also effective for the dimerization reaction of 1,3-dienes in the presence of active hydrogen compounds.[6-9] The reactions proceeded as shown in the following equation. Only small amounts of the branched products(III) were normally observed.

The reaction products were confirmed by elemental analysis, molecular weight measurement, and IR and NMR spectral measurement or by comparison with authentic samples.[6-10]

C_8H_{13}=$-CH_2CH=CH(CH_2)_3CH=CH_2$, C_3H_5=$-CH_2CH=CH_2$

Reaction of Allyl and Substituted-allyl Phenoxide. The reaction of methyl acetoacetate with 1-phenoxy-2,7-octadiene in the presence of dichlorobis(triphenylphosphine)palladium(II) and sodium phenoxide at 85°C gave methyl 2-acetyl-4,9-decadienoate(IIa) and methyl 2-acetyl-2-(2,7-octadienyl)-4,9-decadienoate (IIb), in 84 and 7% yields, respectively, besides phenol. These products are also formed by the reaction of methyl acetoacetate with 1,3-butadiene in the presence of the palladium catalyst.[9]

1-phenoxy-2-propene similarly reacted with methyl acetoacetate in the presence of $PdCl_2(Ph_3P)_2$ and sodium phenoxide to give methyl 4-acetyl-4-pentenoate (IIc) and methyl 2-acetyl-2-allyl-4-pentenoate(IId) in 18 and 47% yields, respectively. The catalytic activity of the combination of $PdCl_2(Ph_3As)_2$ and sodium phenoxide is slightly smaller than that of $PdCl_2(Ph_3P)_2$ and sodium phenoxide.

Allyl and substituted-allyl phenoxide also reacted with substituted phenols, alcohols, amines and carboxylic acids in the presence of the palladium or platinum catalyst to give corresponding allylic derivatives. Results of the reactions of allyl and substituted allyl phenoxide with active hydrogen compounds are summarized in Table 1.

In the reactions of 1-phenoxy-2,7-octadiene with amines, neither branched products, 1-vinyl-5-hexenylamines, nor 1,3,7-octatriene were detected. The formation of diallylpiperadine could be confirmed in the reaction of 1-phenoxy-2-propene with piperadine. In the reaction of 1-phenoxy-2,7-octadiene with cyclohexylamine and aniline, *N*-(2,7-octadienyl)-cyclohexylamine and -aniline, (IIe) and (IIf), were formed.

The reaction of 1-phenoxy-2-propene with *p*-chlorophenol and with *p*-cresol afforded the corresponding exchange products (IIh) and (IIi) in 26 and 41% yields, respectively. The reaction mixture of 1-phenoxy-2-propene and *p*-cresol was confirmed to consist of 1-phenoxy-2-propene, *p*-cresol, 1-(*p*-methylphenoxyl)-2-propene (IIi) and phenol as expected, while in the reaction mixture of 1-phenoxy-2-propene and *p*-chlorophenol an unidentified product was observed besides four expected components.

Results of the reactions of alcohols with phenoxyoctadienes consisting of 1-phenoxy-2,7-octadiene(92%) and 3-phenoxy-1,7-octadiene(8%) in the presence of dichlorobis(triphenylphosphine)palladium(II) and sodium phenoxide are summarized in Table 2. The reaction of methanol with the phenoxyoctadienes gave a mixture of IIj(93%) and IIIj(7%) in an 89% yield. Formation of a small amount of 1,3,7-octatriene was observed. The reactivity of methanol was much

a) Reaction conditions: $PdCl_2(Ph_3P)_2$ 0.05 mmol, PhONa 0.5 mmol, Phenoxyoctadiene 5.05 g (0.025 mol) and benzyl alcohol 0.05 mol, 85°C

b) C_5H_9=$-CH_2CH_2CH_2CH=CH_2$

greater than that of ethanol, isopropyl alcohol and benzyl alcohol. The reaction of isopropyl alcohol gave only 1,3,7-octatriene in a 13% yield. It seems that the acidity of alcohol has a large effect on the reactivity. A similar tendency has been observed in the dimerization of 1,3-butadiene in the alcohols by the palladium catalyst.[7)]

The reaction of the phenoxyoctadienes with benzyl alcohol by the $PdCl_2(Ph_3P)_2$-PhONa catalyst was studied as a function of time. The result is shown in Table 3. The products, IIk and IIIk, were formed in 58 and 2% yields, respectively. This shows that the ratio of 3-phenoxy-1,7-octadiene to 1-phenoxy-2,7-octadiene changed from 0.09 to 0.24 in ten minutes after the beginning of the reaction with the formation of 1,3,7-octatriene. This indicates the rearrangement of 1-phenoxy-2,7-octadiene to 3-phenoxy-1,7-octadiene with the catalyst. The initial formation of 1,3,7-octatriene was rapid. However, the amount of the triene decreased gradually. The decrease seems to be due to the consumption of 1,3,7-octatriene for the formation of its adducts by the reaction of the triene with benzyl alcohol. Vpc showed an unidentified peak near that of 1-benzyloxy-2,7-octadiene.

Results of the reactions of benzyl alcohol with phenoxyoctadiene by several palladium and platinum catalysts are shown in Table 2. Platinum catalysts and a mixture of palladium acetate and triphenylphosphine are also effective, but a combination of palladium chloride and sodium phenoxide did not show any catalytic activity. Apparently, the reaction by tetrakistriphenylphosphine complexes of Pd(0) and Pt(0) gives a larger amount of 1,3,7-octatriene than bistriphenylphosphine complexes of Pd(II) and Pt(II), and the reaction by the platinum catalysts affords a much larger amount of the branched product (IIIk) than the palladium catalysts. The allyl group of 1-phenoxy-2-propene also migrated to benzyl alcohol in the presence of $PdCl_2(Ph_3P)_2$ and sodium phenoxide to give 1-benzyloxy-2-propene (III) in an 82% yield.

The reaction of the phenoxyoctadienes consisting of 1-phenoxy-2,7-octadiene(92%) and 3-phenoxy-1,7-octadiene(8%), with acetic acid in the presence of palladium acetate and triphenylphosphine proceeded to give octadienyl acetate(IIm) and (IIIm) in 32 and 6% yields based on the phenoxyoctadienes, respectively, and a small amount of 1,3,7-octatriene. The reaction in dimethylformamide as a solvent proceeded more smoothly to give IIm and IIIm in 40 and 16% yields, respectively.

Easy fission of the allylic carbon-oxygen bond is shown by the reversibility of the above reaction. It is interesting to note that the reverse reaction using a 74:26 mixture of IIm and IIIm resulted in a predominant formation of 1-phenoxy-2,7-octadiene (ratio of the linear to the branched 97:3).

$$PhOCH_2CH=CH(CH_2)_3CH=CH_2 \underset{PhOH}{\overset{CH_3COOH}{\rightleftharpoons}} CH_3CO_2CH_2CH=CHCH_2CH_2CH_2CH=CH_2 \quad \text{IIm}$$

$$+ CH_3CO_2CH(CH=CH_2)CH_2CH_2CH_2CH=CH_2 \quad \text{IIIm}$$

Benzoic acid reacted similarly with the phenoxyoctadienes in the presence of palladium acetate and triphenylphosphine to afford a 70:30 mixture of octadienyl benzoate (IIn) and (IIIn) in a 60% yield.

Reaction of Allyl and Substituted-allyl Alkoxides. 1-Phenoxy-2,7-octadiene reacts readily with active hydrogen compounds in the presence of palladium catalysts to give 2,7-octadienyl derivatives of the active hydrogen compounds. However, 1-alkoxy-2,7-octadienes such as 1-methoxy-2,7-octadiene and 1-benzyloxy-2,7-octadiene did not react with amines and active methylene compounds under similar conditions. It was found, however, that the alkoxyoctadienes react with phenol to give 1-phenoxy-2,7-octadiene and alcohols, and that the reaction is reversible although the equilibrium exists between the alkoxyoctadienes and phenol. The reaction of the benzyloxyoctadienes(a 97:3 mixture of IIk and IIIk) with phenol by the $PdCl_2(Ph_3P)_2$-sodium phenoxide catalyst gave an 86:14 mixture of 1-phenoxy-2,7-octadiene and 3-phenoxy-1,7-octadiene in a 7% yield. The reaction of methoxyoctadienes with phenol afforded phenoxyoctadienes in a 3% yield.

The results suggest that the presence of phenol makes it possible for the reaction of the alkoxyoctadienes with amines and active methylene compounds to give the corresponding octadienyl derivatives of the active hydrogen compounds through the two successive exchanges of the octadienyl group, as shown by the following equation.

$$R'\text{-}O\text{-}C_8H_{13} + Ph\text{-}OH \rightleftharpoons PhO\text{-}C_8H_{13} + R'\text{-}OH$$
$$PhO\text{-}C_8H_{13} + R''\text{-}H \longrightarrow R''\text{-}C_8H_{13} + PhOH$$

$R'=CH_3$, $C_6H_5CH_2$
R''-H = active hydrogen compounds
C_8H_{13} = 2,7-octadienyl group

The reaction of the benzyloxyoctadiene with piperidine in the presence of phenol and a palladium catalyst gave the expected octadienyl piperidine. The reaction is applicable to 1-alkoxy-2-alkenes. The reaction of 1-benzyloxy-2-propene with methyl acetoacetate in the presence of the palladium catalyst and phenol afforded methyl 2-acetyl-4-pentenoate and methyl 2-acetyl-2-(2-propenyl)-4-pentenoate. The results are summarized in Table 4. The reaction was much slower than that of 1-phenoxy-2-propene with methyl acetoacetate.

The reaction of 1-(2-propenyloxy)-2,7-octadiene with piperidine proceeded to give two products, *N*-(2,7-octadienyl)piperidine and *N*-(2-propenyl)piperidine, in 12 and 24% yields, respectively, which shows that the reactivity of the propenyl group is larger than that of the octadienyl group.

Reaction of Allyl and Substituted-allyl Carboxylates. As described, 2,7-octadienyl acetate and benzoate react with phenol in the presence of the palladium catalysts to afford 1-phenoxy-2,7-octadiene. The same type of reaction occurred between 2-propenyl acetate and active hydrogen compounds such as phenol, carboxylic acids, alcohols, amines and active methylene compounds. Results of the reactions of allyl and substituted-allyl carboxylates with the active hydrogen compounds are summarized in Table 5. The reactions proceed usually much more slowly than those of 1-phenoxy-2-propene and its derivatives, but the reaction with amines proceeds at a moderate rate.

Experimental

Reagents. $PdCl_2(Ph_3P)_2$,[12] $PdCl_2(Ph_3As)_2$,[13] $Pd(OAc)_2$,[14] $Pd(Ph_3P)_4$,[12] $Pd(Ph_3P)_2$(maleic anhydride),[15] $PtCl_2(Ph_3P)_2$[16] and $Pt(Ph_3P)_4$[16] were prepared by previously reported methods.

Methyl acetoacetate, 2-propenyl acetate and all the phenols, alcohols, amines and carboxylic acids were purified by distillation. 1-Phenoxy-2,7-octadiene,[8] 1-alkoxy-2,7-octadienes[7] and 2,7-octadienyl carboxylates[17] were prepared by the reaction of 1,3-butadiene with phenol, alcohols and carboxylic acids, respectively, in the presence of the palladium catalyst. 1-Phenoxy-2-propene,[18] 1-phenoxy-2-methyl-2-propene[18] and 1-phenoxy-2-butene[18] were prepared by the reactions of phenol with allyl chloride, methallyl chloride and crotyl chloride, respectively, in the presence of potassium carbonate. 1-Benzyloxy-2-propene was prepared by the reaction of benzyl alcohol with 1-phenoxy-2-propene in the presence of $PdCl_2(Ph_3P)_2$ and sodium phenoxide. All the reactions were carried out under argon atmosphere.

Reaction of 1-Phenoxy-2-propene with Methyl Acetoacetate. A

18) W. M. Iaver and W. F. Filbert, *J. Amer. Chem. Soc.*, **58**, 1388 (1936).

mixture of 0.05 mol of methyl acetoacetate, 0.1 mol of 1-phenoxy-2-propene, 0.05 mmol of $PdCl_2(Ph_3P)_2$ and 0.5 mmol of sodium phenoxide was stirred at 85° for 8.5 hr under argon atmosphere. The reaction mixture was subjected to distillation and the ratio of the products was determined by vpc. The product consisted of IIc(2.8 g, 18%) and IId(4.6 g, 47%). The yields were calculated on the basis of 1-phenoxy-2-propene. IIc, IR(neat)cm^{-1}: 1745 and 1722(keto ester), 1646, 995 and 922(–CH=CH_2). NMR(CCl_4) τ: 7.86(s, CH_3CO–), 7.47(t, J=7.0 Hz, =C–CH–C), 6.50(t, J=7.0 Hz, C–CH–CO), 6.34(s, CH_3O–) and 4.06—5.05(m, olefinic protons). IId, IR(neat)cm^{-1}: 1744 and 1714(keto ester), 1644, 993 and 921(CH_2=CH–). NMR(CCl_4)τ: 7.97(s, CH_3CO–), 7.46 (d, J=7.0 Hz, =C–CH_2–C), 6.34(s, CH_3O) and 4.22—5.03 (m, olefinic protons).

Reaction of 1-Phenoxy-2,7-octadiene with Cyclohexylamine. A mixture of 0.05 mol of 1-phenoxy-2,7-octadiene, 0.1 mol of cyclohexylamine, 0.1 mmol of $PdCl_2(Ph_3P)_2$ and 1.0 mmol of sodium phenoxide was stirred at 85° for 2 hr to give IIe (10.4 g, 69%). IR(neat)cm^{-1}: 1644, 991 and 911(CH_2=CH–), 968(*trans*-CH=CH–). NMR(CCl_4) τ: 9.24(s, –NH), 7.5—8.9(m, –$(CH_2)_3$– and cyclo-C_6H_{11}), 6.84(d, J=4.0 Hz, N–CH_2–C=) and 4.01—5.12(m, olefinic protons).

Reaction of 1-Phenoxy-2-methyl-2-propene with Diethylamine. A mixture of 0.05 mol of 1-phenoxy-2-methyl-2-propene, 0.1 mol of diethylamine, 0.1 mmol of $PdCl_2(Ph_3P)_2$ and 0.5 mmol of sodium phenoxide was stirred at 85° in a 100 m*l* autoclave for 1 hr to give *N*-(2-methyl-2-propenyl)diethylamine (5.6 g, 89%). IR(neat)cm^{-1}: 1654 and 893(CH_2=C<), NMR(CCl_4) τ: 9.03(t, J=7.0 Hz, CH_3–C–N–), 8.30 (s, CH_3–C=), 7.53(q, J=7.0 Hz, C–CH_2–N–), 7.14(s, –N–CH_2–C=) and 5.18—5.25(C=CH_2).

Reaction of 1-Phenoxy-2-propene with p-*Cresol.* A mixture of 0.025 mol of 1-phenoxy-2-propene, 0.025 mol of *p*-cresol, 0.05 mmol of $PdCl_2(Ph_3P)_2$ and 0.5 mmol of sodium phenoxide was stirred at 85°C for 3 hr to afford IIi(1.5 g, 41%). Unreacted 1-phenyl-2-propene(1.3 g, 40%) was recovered.

Reaction of Phenoxyoctadiene with Benzyl Alcohol. A mixture of 0.025 mol of the phenoxyoctadiene(92% 1-phenoxy-2,7-octadiene and 8% 3-phenoxy-1,7-octadiene), 0.05 mol of benzyl alcohol and 0.05 mmol of $Pd(Ph_3P)_4$ was stirred at 85°C for 2.5 hr to give 1,3,7-octatriene(1.1 g, 41%), IIk(1.3 g, 24%) and IIIk(0.6 g, 11%). IIk IR(neat)cm^{-1}: 1666 and 1640 (C=C), 991 and 908(–CH=CH_2) and 970(*trans* –CH=CH–). NMR(CCl_4) τ: 7.8—8.7(6H, m, =C–$CH_2CH_2CH_2$–C=), 6.13 (2H, d, J=5.5 Hz, –O–CH_2–C=), 5.58(2H, s, Ph–CH_2–O–), 4.0—5.2(5H, m, olefinic protons) and 2.67(5H, s, C_6H_5–). IIIk IR(neat)cm^{-1}: 1644, 991, 922, and 915(CH_2=CH–). NMR(CCl_4) τ: 7.8—8.7(6H, m, –$CH_2CH_2CH_2$–C=), 6.3(1H, m, –O–CH), 5.67 and 5.33(2H, two d, J=12.0 Hz, C_6H_5–CH_2–O–), 3.9—5.4(6H, m, olefinic protons) and 2.67(5H, s, C_6H_5–).

Reaction of Phenoxyoctadiene with Benzoic Acid. A mixture of 0.05 mol of the phenoxyoctadienes(92% 1-phenoxy-2,7-octadiene and 8% 3-phenoxy-1,7-octadiene), 0.1 mol of benzoic acid, 0.1 mmol of $Pd(OAc)_2$, 0.25 mmol of triphenylphosphine and 10 m*l* of dimethylformamide was stirred at 85°C for 24 hr. The product consisted of IIn(4.9 g, 42%), IIIn(2.1 g, 18%) and a trace amount of 1,3,7-octatriene. The unreacted phenoxyoctadienes(3.8 g) were recovered. IIn, IR(neat)cm^{-1}: 1720(ester), 1672 and 966(*trans* –CH=CH–), 1643, 988, and 907(CH_2=CH–). NMR(CCl_4) τ: 8.25—8.75 (2H, m, –CH_2–C–C=), 7.70—8.15(4H, m, =C–CH_2–C–CH_2–C=), 5.28(2H, d, J=6.5 Hz, –O–CH_2–) and 3.9—5.25(5H, m, olefinic protons). IIIn, IR(neat)cm^{-1}: 1720(ester), 1644, 990, 922(sh), and 916(CH_2=CH–). NMR(CCl_4) τ: 7.7—8.8 (6H, m, –$CH_2CH_2CH_2$–) and 3.85—5.25(7H, m, –O–CH– and olefinic protons).

Reaction of 1-Methoxy-2,7-octadiene with Methyl Acetoacetate. A mixture of 0.05 mol of 1-methoxy-2,7-octadiene, 0.1 mol of methyl acetoacetate, 0.1 mmol of $PdCl_2(Ph_3P)_2$, 1.0 mmol of sodium phenoxide and 0.05 mol of phenol was stirred at 85°C for 16 hr to give IIa in a 74% yield. IR(neat)cm^{-1}: 1748 and 1724(>C=O), 1644(C=C), 992 and 911(–CH=CH_2) and 971(*trans* –CH=CH–). NMR(CCl_4) τ: 8.61(2H, m, –C–CH_2–C–), 8.04(4H, m, =C–CH_2–C–CH_2–C=), 7.88(3H, s, –CO–CH_3), 7.55(2H, t, J=7.0 Hz, =C–CH_2–C–CO=), 6.51 (1H, t, J=7.0 Hz, –C–CH–CO–), 6.34(3H, s, –O–CH_3) and 3.98—5.16(5H, m, olefinic protons).

Reaction of 1-(2-Propenyloxy)-2,7-octadiene with Piperidine. A mixture of 0.025 mol of 1-(2-propenyloxy)-2,7-octadiene, 0.05 mol of piperidine, 0.1 mol of $PdCl_2(Ph_3P)_2$, 1.0 mmol of sodium phenoxide and 0.025 mol of phenol was stirred at 85°C for 20 hr and at 110°C for 16 hr. The product consisted of *N*-(2,7-octadienyl)piperidine(0.6 g, 12%) and *N*-(allyl)piperidine(0.75 g, 24%). *N*-(Allyl)piperidine showed the following spectral characteristics. IR(neat)cm^{-1}: 1643, 993, and 915(CH_2=CH–). NMR(CCl_4) τ: 8.52 and 7.70(protons of piperidine ring), 7.13(2H, d, J=7.0 Hz, N–CH_2–) and 3.8—5.1(3H, m, olefinic protons).

Reaction of Octadienyl Acetate with Propionic Acid. A mixture of 0.025 mmol of octadienyl acetate(74% 2,7-octadienyl acetate and 26% 1-vinyl-5-hexenyl acetate), 0.05 mol of propionic acid, 0.05 mmol of $Pd(OAc)_2$, 0.2 mmol of triphenylphosphine and 5 m*l* of dimethylformamide was stirred at 85°C for 15 hr. The product consisted of 1,7-octadienyl propionate(1.7 g, 37%), 1-vinyl-5-hexenyl propionate(0.6 g, 13%) and a trace amount of 1,3,7-octatriene.

Reaction of Octadienyl Acetate with Aniline. A mixture of 0.025 mol of the octadienyl acetate(74% 2,7-octadienyl acetate and 26% 1-vinyl-5-hexenyl acetate), 0.05 mol of aniline, 0.05 mmol of $PdCl_2(Ph_3P)_2$ and 0.5 mmol of sodium phenoxide was stirred at 85°C for 1 hr. To the reaction mixture 10 m*l* of water was added, and the organic layer was extracted with ether to give *N*-(2,7-octadienyl)aniline (4.5 g, 89%).

Studies of Benzoylsulfene. V.[1] The Reaction of Benzoylsulfene with Enamines

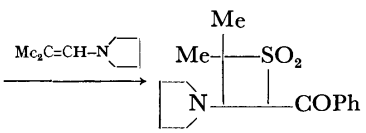
Otohiko TSUGE, Sumio IWANAMI, and Shigeru HAGIO[2]
Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka
(Received June 9, 1971)

The reaction of benzoylmethanesulfonyl chloride with enamines derived from cyclohexanone in the presence of triethylamine has been studied. The chloride reacted with 1-(1-morpholino)- and 1-(1-piperidino)cyclohexene in the presence of triethylamine, affording the corresponding acyclic sulfones. On the other hand, the reaction of the chloride with 1-(1-pyrrolidinyl)cyclohexene gave 2-benzoylmethanesulfonylcyclohexanone and 2,3-dibenzoyl-2,3,4,5,6,7-hexahydrothianaphthene 1,1-dioxide. The latter compound, whose structure corresponded to the compound derived from the 2:1 adduct of benzoylsulfene and the enamine with the elimination of sulfur dioxide and pyrrolidine, reacted with hydrazine hydrate to give 1,4-diphenyl-5*a*,6,7,8,9,9*a*-hexahydrothianaphtheno[2,3-*d*]-pyridazine, which was then transformed into 3,4,6-triphenylpyridazine.

In general, sulfenes ($RCH{=}SO_2$) generated *in situ* from aliphatic sulfonyl chlorides and triethylamine (NEt_3) react with enamines derived from aldehydes and cyclic ketones to give four-membered cyclic sulfones. Examples are the additions of methanesulfonyl chloride to 2-methyl-1-pyrrolidinyl-1-propene[3] and 1-(1-morpholino)cyclohexene[4] in the presence of NEt_3, which gave the corresponding thiethane 1,1-dioxides.

However, the study concerning the reaction of benzoylmethanesulfonyl chloride (I) with an enamine in the presence of NEt_3 has not been extended beyond that of Opitz,[5] who reported that the reaction of benzoylsulfene ($PhCOCH{=}SO_2$), generated from I and NEt_3, with 2-methyl-1-pyrrolidinyl-1-propene gave the four-membered cyclic sulfone, whose structure corresponded to the (2+2) cycloadduct of benzoylsulfene to the enamine.

$$\underset{\text{I}}{PhCOCH_2SO_2Cl} \xrightarrow[NEt_3]{-HCl} [PhCOCH{=}SO_2]$$



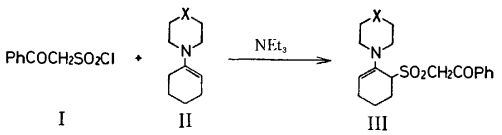
In previous papers, the reactions of I with anils[6] and carbodiimides[7] in the presence of NEt_3 were investigated and it was found that the corresponding (4+2) and/or (2+2) cycloadducts of benzoylsulfene to the C=N bond were formed. These facts indicate that benzoylsulfene is more reactive than usual sulfenes ($RCH{=}SO_2$) and that, in the cycloaddition reaction benzoylsulfene behaves as a 1,2- or 1,4-dipole.

We plan to develop the cycloaddition reactions of benzoylsulfene with various compounds. In the present paper we wish to report on the reaction of benzoylsulfene with enamines derived from cyclohexanone, which unexpectedly led to the formation of acyclic sulfones and an abnormal product.

Results and Discussion

The reaction of benzoylmethanesulfonyl chloride (I) with equimolar amounts of 1-(1-morpholino)cyclohexene (IIa) and NEt_3 in dioxane at room temperature for 1.5 hr gave a crystalline compound, IIIa, mp 135°C (decomp.), in a 61% yield, besides triethylammonium chloride in a quantitative yield. The results of elemental analysis and the molecular weight (M^+ *m/e* 349) of IIIa were consistent with the expected 1:1 adduct of benzoylsulfene and IIa. The IR spectrum of IIIa exhibited characteristic bands ascribed to the $\nu_{C=O}$ and $\nu_{C=C}$ at 1685 and 1640 cm^{-1} respectively. On the other hand, the NMR spectrum in deuteriochloroform ($CDCl_3$) showed signals at τ 5.5 (1H, $\geqslant$C<u>H</u>, multiplet), 5.13 and 4.63 (each 1H, $-SO_2-C\underline{H}_2-COPh$, doublet, J= 15 Hz), and 4.56 (1H, =C<u>H</u>–, triplet, J=3.7 Hz), besides signals of cyclohexenyl- and morpholino-methylene protons and of phenyl protons.

On the basis of these spectral data and the following chemical transformations, it seems reasonable to conclude that IIIa is 6-benzoylmethanesulfonyl-1-(1-morpholino)cyclohexene.



I II III

a: X=O, b: X=CH_2

The hydrolysis of IIIa with dilute hydrochloric acid gave 2-benzoylmethanesulfonylcyclohexanone (IV), mp 103°C (decomp.), in an almost quantitative yield; its structure was confirmed by the spectral studies as well as by the elemental analysis. Furthermore, IIIa reacted with I in the presence of NEt_3 to afford 1,3-di(benzoylmethanesulfonyl)-2-(1-morpholino)cyclohexene (V), mp 152.5—153°C (decomp.), which was subsequently hydrolyzed to 2,6-di(benzoylmethanesulfonyl)-cyclohexanone (VI), mp 141—142°C, in a 37% yield. The structures of V and VI were established on the basis of the spectral studies and of the elemental analyses.

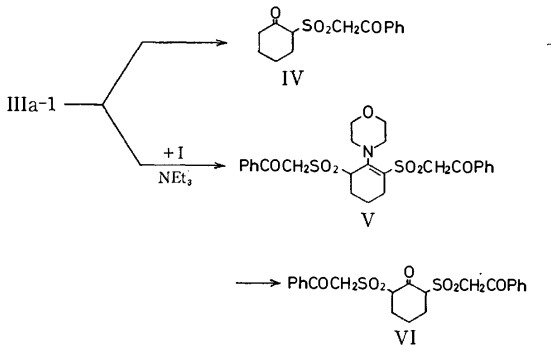
The mass spectrum of IIIa was also in harmony with the proposed structure.



A similar reaction of I with 1-(1-piperidino)cyclohexene (IIb) in the presence of NEt_3 gave 6-benzoylmethanesulfonyl-1-(1-piperidino)cyclohexene (IIIb), mp 151°C (decomp.), in a 61% yield.

On the other hand, I reacted with 1-(1-pyrrolidinyl)-cyclohexene (IIc) under similar conditions to give IV and a novel product, VII, mp 183°C (decomp.), in 11 and 22% yields respectively.

The compound VII was assumed, as a result of the spectral studies and the elemental analysis as well as the chemical transformations, to be 2,3,4,5,6,7-hexahydro-2,3-dibenzoylthianaphthene 1,1-dioxide. The molecular formula ($C_{22}H_{20}O_4S$) of VII was in agreement with that of the compound derived from a 2:1 adduct of benzoylsulfene and IIc upon the elimination of sulfur dioxide and pyrrolidine. It is obvious that VII contains two benzoyl groups in the molecule, because the hydrolysis of VII with methanolic sodium hydroxide afforded two moles of benzoic acid per mole of VII, and the IR spectrum of VII showed characteristic bands at 1670 ($\nu_{C=O}$), 1300 and 1130 cm^{-1} (ν_{SO_2}). In the mass spectrum, the parent ion peak (M^+) appeared at *m/e* 380, together with major peaks at *m/e* 316 (M^+-SO_2), 211 (316^+-PhCO), 106 (211^+-PhCO) and 105 ($PhCO^+$).

The NMR spectrum of VII is illustrated in Fig. 1. As is shown in Fig. 1, two methine protons appeared at τ 4.48 (1H, doublet with J=5.5 Hz) and 4.20 (1H, multiplet, changed to a doublet with J=5.5 Hz when irradiated at τ 7.6 (2H, quasi-equatorial protons at the 4- and 7-positions)) respectively.

Furthermore, VII reacted with hydrazine hydrate to give 1,4-diphenyl-5*a*,6,7,8,9,9*a*-hexahydrothianaphtheno[2,3-*d*]pyridazine (VIII), mp 198°C (decomp.), in a quantitative yield. The structure of VIII was confirmed by the spectral studies and elemental analysis as well as by the chemical transformation. The NMR spectrum of VIII in $CDCl_3$ showed a multiplet (2H, two methine protons) at τ 6.35; this fact seems to exclude the possibility of an alternate structure, VIII', for VIII.

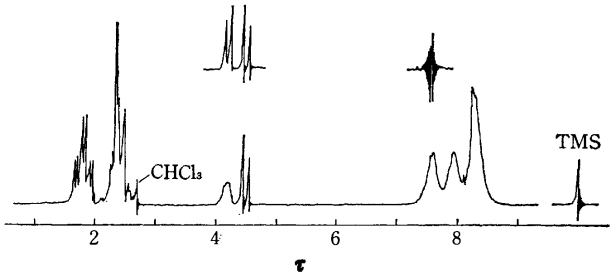


Fig. 1. NMR spectrum of VII in $CDCl_3$.

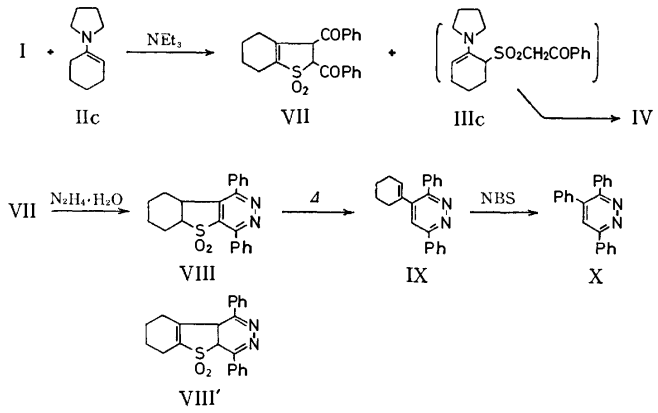

The thermal decomposition of VIII at 210°C gave 4-(1-cyclohexenyl)-3,6-diphenylpyridazine (IX), mp 160°C, whose structure was established by the spectral studies and by the transformation to 3,4,6-triphenylpyridazine (X) in a 33% yield. The treatment of IX with *N*-bromosuccinimide in carbon tetrachloride afforded X, mp 176°C (lit,[8] mp 176—177.5°C), which was identical with an authentic sample prepared by the reported method.[8]

Incidentally, the formation of IV in the reaction of I with IIc may be illustrated by the hydrolysis of the initially-formed 6-benzoylmethanesulfonyl-1-(1-pyrrolydinyl)cyclohexene (IIIc).

It is known that, in the reaction of sulfonyl chlorides with enamines in the presence of NEt_3, the formation of acyclic sulfones is favored by increasing the substitution at the α-carbon of the sulfonyl chloride and also of the enamine.[9] Recently, Looker[10] found that the additions of methanesulfonyl and arenesulfonyl chlorides to 1,3-diphenyl-2-(1-pyrrolidinyl)propene in the presence of NEt_3 gave the corresponding acyclic sulfones, and suggested that the acyclic sulfones were formed by the ring opening of the initially-formed cyclic sulfones.

The reaction of methanesulfonyl chloride with IIa gave the four-membered cyclic sulfones, as was mentioned at the beginning of this paper, while phenylmethanesulfonyl chloride reacted with IIc to afford, on hydrolysis, 2-phenylmethanesulfonylcyclohexanone, which was assumed to be derived from 1-phenylmethanesulfonyl-2-(1-pyrrolidinyl)cyclohexene.[10]

It is, then, of interest to form acyclic sulfones III and/or the hexahydrothianaphthene VII *via* the reaction of benzoylsulfene with II.

Although the exact course of the reaction of benzoylsulfene with II is not clear, the formation of the betaine intermediate by a two-step sequence (the formation of a betaine intermediate, followed by proton transfer)

8) R. A. Carboni and R. V. Lindsey, Jr., *J. Amer. Chem. Soc.*, **81**, 4342 (1959).

seems more reasonable than that through the ring opening of a cyclic sulfone. On the other hand, the formation of VII may be explained if the further addition of benzoylsulfene to the betaine intermediate and the subsequent elimination of both sulfur dioxide and pyrrolidine are assumed.

Experimental

All the melting points are uncorrected. The IR spectra were measured in KBr disks, while the NMR spectra were recorded on a 60 MHz Hitachi R-20 NMR spectrometer, using TMS as the internal reference. The mass spectra were obtained on a Hitachi RMS-4 mass spectrometer, using a direct inlet and an ionization energy of 70 eV.

Materials. Benzoylmethanesulfonyl chloride (I), mp 88°C (lit,[11] mp 87.5—88.2°C), was prepared according to the method of Truce and Vriesen.[11] 1-(1-Morpholino)- (IIa), bp 105—107°C/10 mmHg (lit,[12] bp 113—114°C/12 mmHg), 1-(1-piperidino)- (IIb), bp 107—109°C/13 mmHg (lit,[13] bp 108.5/12 mmHg) and 1-(1-pyrrolidinyl)cyclohexene (IIc), bp 87—88°C/3 mmHg (lit,[13] bp 110—111°C/12 mmHg) were prepared from cyclohexanone and the corresponding amines.

Reaction of I with IIa in the Presence of NEt_3. To a solution of 1.7 g (0.01 mol) of IIa and 1.0 g (0.01 mol) of NEt_3 in 10 m*l* of dioxane, a solution of 2.2 g (0.01 mol) of I in 40 m*l* of dioxane was added, drop by drop, at room temperature over a period of 30 min while the mixture was being stirred. After the reaction mixture had been stirred at the same temperature for 1 hr, triethylammonium chloride precipitated in a quantitative yield was removed by filtration. The filtrate was evaporated *in vacuo* to leave a residue, which was crystallized on trituration with methanol. Recrystallization from methanol gave 6-benzoylmethanesulfonyl-1-(1-morpholino)cyclohexene (IIIa) mp 135°C (decomp.), as colorless prisms. Yield, 2.2 g (61%).

Found: C, 61.90; H, 6.73; N, 3.97%. Calcd for $C_{18}H_{23}O_4NS$: C, 61.88; H, 6.64; N, 4.01%.

NMR ($CDCl_3$): τ 6.7—8.4 (10H, C<u>H</u>$_2$ in cyclohexenyl ring and –C<u>H</u>$_2$–N–C<u>H</u>$_2$–, multiplet), 6.38 (4H, –C<u>H</u>$_2$–O–C<u>H</u>$_2$–, triplet), 5.5 (1H, >C<u>H</u>, multiplet), 5.13, 4.63 (each 1H, –SO_2–C<u>H</u>$_2$–COPh, doublet, J=15 Hz), 4.56 (1H, =C<u>H</u>–, triplet, J=3.7 Hz), 2.3—2.55 (3H,  , multiplet), 1.8—2.1 (2H,  , multiplet). Mass: *m/e* 349 (M^+), 285 (M^+–SO_2), 268 (285$^+$–OH), 180 (285$^+$–PhCO), 167 (285$^+$–PhCOCH), 166, 165, 164, 163, 120 ($PhCOCH_3^+$), 105 ($PhCO^+$), 86  , 77 (Ph^+).

A similar reaction of I with IIb in the presence of NEt_3 gave 6-benzoylmethanesulfonyl-1-(1-piperidino)cyclohexene (IIIb), mp 151°C (decomp.), as colorless prisms in a 61% yield.

Found: C, 65.68; H, 7.50; N, 4.00%. Calcd for $C_{19}H_{25}O_3NS$: C, 65.69; H, 7.25; N, 4.03%.

IR: cm^{-1} 1685 ($\nu_{C=O}$), 1640 ($\nu_{C=C}$), 1300, 1115 (ν_{SO_2}). NMR ($CDCl_3$): τ 6.1—8.9 (16H, C<u>H</u>$_2$ in rings, multiplet), 5.5 (1H, >CH, multiplet), 4.8—5.3 (2H, –SO_2–C<u>H</u>$_2$–COPh, multiplet), 4.6 (1H, =C<u>H</u>–, broad triplet), 2.3—2.6 (3H,  , multiplet), 1.8—2.0 (2H, , multiplet). Mass: *m/e* 347 (M^+), 283 (M^+–SO_2), 178 (283$^+$–PhCO), 165 (283$^+$–PhCOCH), 164, 163, 120 ($PhCOCH_3^+$), 105 ($PhCO^+$), 84 , 77 (Ph^+).

Hydrolysis of IIIa. After a suspension of 100 mg of IIIa in 6 m*l* of 1N aqueous hydrochloric acid had been stirred at room temperature for 1 hr, the crystals were collected by filtration, washed with water, and then dried; yield, 75 mg (93%). Recrystallization from methanol gave 2-benzoylmethanesulfonylcyclohexanone (IV), mp 103°C (decomp.), as colorless prisms.

Found: C, 59.95; H, 5.82%. Calcd for $C_{14}H_{16}O_4S$: C, 59.99; H, 5.75%. IR: cm^{-1} 1710, 1680 ($\nu_{C=O}$). NMR ($CDCl_3$): τ 7.2—8.4 (8H, CH_2 in cyclohexanone ring, multiplet), 5.55 (1H, >CH, double doublet, J=6 and 8 Hz), 1.9—2.6 (5H, phenyl protons, multiplet). Mass: *m/e* 280 (M^+), 216 (M^+–SO_2), 215, 188 (216$^+$–CO), 161 (M^+–$PhCOCH_2$), 120 ($PhCOCH_3^+$), 105 ($PhCO^+$), 77 (Ph^+).

Similarly, 100 mg of IIIb were hydrolyzed with hydrochloric acid to afford 74 mg (92%) of IV.

Reaction of IIIa with I in the Presence of NEt_3. To a stirred solution of 2.2 g of IIIa and 0.6 g of NEt_3 in 20 m*l* of dioxane, a solution of 1.4 g of I in 30 m*l* of dioxane was added, drop by drop, at room temperature over a period of 30 min. After the reaction mixture had been stirred at the same temperature for 30 min, triethylammonium chloride (0.85 g, 96%) was removed by filtration. The filtrate was evaporated *in vacuo* to leave a residue, from which IIIa (1.1 g, 48%) was separated when it was treated with 10 m*l* of methanol. The methanol filtrate was allowed to stand overnight to afford 1.1 g (37%) of 1,3-di(benzoylmethanesulfonyl)-2-(1-morpholino)cyclohexene (V), which, on recrystallization from methanol, gave colorless prisms, mp 152.5—153°C (decomp.).

Found: C, 58.93; H, 5.76; N, 2.93%. Calcd for $C_{26}H_{29}O_7NS_2$: C, 58.75; H, 5.50; N, 2.63%. IR: cm^{-1} 1680 ($\nu_{C=O}$), 1610 ($\nu_{C=C}$), 1300, 1120 (ν_{SO_2}). NMR ($CDCl_3$): τ 6.0—8.5 (14H, C<u>H</u>$_2$ in cyclohexenyl and morpholino ring, multiplet), 5.18, 5.32 (each 1H, –SO_2–C<u>H</u>$_2$–COPh, doublet, J=17.5 Hz), 4.70, 5.11 (each 1H, –SO_2–C<u>H</u>$_2$–COPh, doublet, J=14.5 Hz), 5.10 (1H, >CH, multiplet), 1.8—2.6 (10H, phenyl protons, multiplet). Mass: *m/e* 349 (M^+–$PhCOCH{=}SO_2$).

Hydrolysis of V. A suspension of 0.3 g of V in 15 m*l* of methanol was refluxed with 0.5 m*l* of concentrated hydrochloric acid for 3 hr. The reaction mixture was then evaporated *in vacuo* to leave crystals, which, on recrystallization from a benzene-petroleum benzine (bp 45—60°C) mixture, gave 0.23 g (95%) of 2,6-di(benzoylmethanesulfonyl)cyclohexanone (VI), mp 141—142°C, as colorless prisms.

Found: C, 56.99; H, 4.54%. Calcd for $C_{22}H_{22}O_7S_2$: C,

57.14; H, 4.80%. IR: cm^{-1} 1712 ($\nu_{C=O}$), 1680 ($\nu_{C=O}$), 1310, 1125 (ν_{SO_2}). NMR ($CDCl_3$): τ 7.0—8.2 (6H, $C\underline{H}_2$ in cyclohexanone ring, multiplet), 5.3 (2H, $\geq C\underline{H}$, multiplet), 5.05 (4H, $-SO_2-C\underline{H}_2-COPh$, singlet), 1.9—2.7 (10H, phenyl protons, multiplet).

Reaction of I with IIc in the Presence of NEt_3. The reaction of 2.2 g of I with 1.5 g of IIc in the presence of 1.0 g of NEt_3 in dioxane was carried out in a manner similar to that used in the reaction of IIa, and then triethylammonium chloride was removed by filtration. The filtrate was evaporated *in vacuo* to leave a residue, which was crystallized on trituration with methanol. Filtration and recrystallization from methanol gave 0.37 g (22%) of 2,3-dibenzoyl-2,3,4,5,6,7-hexahydrothianaphthene 1,1-dioxide (VII), mp 183°C (decomp.), as colorless needles.

Found: C, 69.47; H, 5.36%. Calcd for $C_{22}H_{20}O_4S$: C, 69.46; H, 5.30%.

The compound IV was obtained from the filtrate; yield, 0.3 g (11%).

Hydrolysis of VII. A solution of 0.4 g of VII in 30 m*l* of methanol was stirred with 1 m*l* of 1N aqueous sodium hydroxide at room temperature for 12 hr. The reaction mixture was evaporated *in vacuo*, and then a residue was extracted with benzene and water. The water extract was neutralized with hydrochloric acid, giving 0.21 g of benzoic acid, while from the benzene-extract an unidentified substance was obtained in a trace amount.

1,4-Diphenyl-5a,6,7,8,9,9a-hexahydrothianaphtheno[2,3-d]pyridazine (VIII). After a solution of 0.11 g of VII in 30 m*l* of methanol had been stirred with three drops of 80% hydrazine hydrate at room temperature for 3 hr, filtration afforded yellow crystals. Recrystallization from methanol gave 90 mg (83%) of VIII, mp 198°C (decomp.), as yellow needles.

Found: C, 69.95; H, 5.42; N, 7.38%. Calcd for $C_{22}H_{20}O_2N_2S$: C, 70.20; H, 5.36; N, 7.44%. IR: cm^{-1} 1312, 1135 (ν_{SO_2}). Mass: *m/e* 376 (M^+), 312 (M^+-SO_2).

Thermal Decomposition of VIII. After the thermal decomposition of 350 mg of VIII had been carried out at 210°C for 10 min, the product was extracted with hot ligroin (bp 60—85°C). The ligroin-extract was evaporated *in vacuo* to leave a residue, which, on recrystallization from benzene, gave 4-(1-cyclohexenyl)-3,6-diphenylpyridazine (IX), mp 160°C, as yellow prisms. Yield, 96 mg (33%).

Found: C, 84.40; H, 6.29; N, 8.71%. Calcd for $C_{22}H_{20}N_2$: C, 84.58; H, 6.45; N, 8.97%. NMR ($CDCl_3$): τ 7.5—8.7 (8H, $C\underline{H}_2$, multiplet), 4.0 (1H, $=C\underline{H}-$, multiplet), 1.6—2.8 (11H, phenyl protons, multiplet). Mass: *m/e* 312 (M^+), 308 (M^+-2H_2), 283 (M^+-N_2-H).

3,4,6-Triphenylpyridazine (X). A mixture of 200 mg of IX and 200 mg of *N*-bromosuccinimide in 100 m*l* of carbon tetrachloride was refluxed with a trace amount of benzoyl peroxide for 20 hr. After the reaction mixture had been concentrated *in vacuo*, the precipitated crystals were washed with a dilute aqueous sodium hydrogensulfide solution and then water. The insoluble substance was chromatographed on silica gel, using chloroform as the eluent, to afford 30 mg (15%) of crystals. Recrystallization from ethanol gave colorless prisms of X, mp 176°C (lit,[8] mp 176—177.5°C), which was identical with an authentic sample prepared by the reported method.[8]

Stereochemical Studies of Monoterpene Compounds. XIII.[1] The Conformational Analysis of the Acetyl Group of 4-Methyl-10-nor-8-oxomenthols by Circular Dichroism

Takayuki Suga and Satoru Watanabe

Department of Chemistry, Faculty of Science, Hiroshima University, Higahisenda-machi, Hiroshima

(Received June 14, 1971)

The conformational analysis of the acetyl group of a stereoisomeric pair of 4-methyl-10-nor-8-oxomenthols was made by means of the temperature-dependent circular dichroism. (1R:3S:4R)-(+)-4-Methyl-10-nor-8-oxoneomenthol (**1**) exhibited a double-humped Cotton effect at a low temperature. This phenomenon seems to indicate the existence of a conformational equilibrium among **1b**, **1c**, and **1d**, but not **1a**. On the other hand (1R:3R:4R)-(−)-4-methyl-10-nor-8-oxomenthol (**3**) exhibited an inversion in the sign of the Cotton effect when the solvent and the temperature were changed. This phenomenon was interpreted in terms of the conformational equilibrium among **3a**, **3b**, and **3c**. These phenomena were interpreted in terms of the competition of the steric factor and the intramolecular hydrogen bonding.

The temperature-dependent circular dichroism (CD) has been found useful for investigating the rotational conformation of the 17-acetyl group of 20-ketosteroids.[2-4] We have previously studied[5] the rotational conformation of the acetyl group of an epimeric pair of 10-nor-8-oxomenthols. In order now to investigate the influence of the C-4 methyl group on the conformation of the acetyl group, the conformational analysis of (1R: 3S: 4R)-(+)-4-methyl-10-nor-8-oxoneomenthol (**1**), (1R: 3R: 4R)-(−)-4-methyl-10-nor-8-oxomenthol

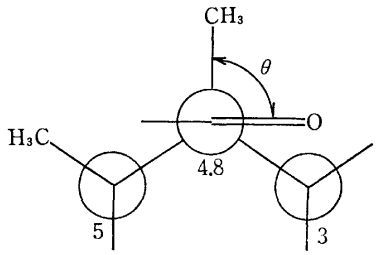
Results and Discussion

4-Methyl-10-nor-8-oxomenthols (**1**) and (**3**) were prepared from (1R : 3S : 4S)-(+)-4-methylneoisopulegol and (1R : 3R : 4S)-(−)-4-methylisopulegol respectively by ozonization. The configuration of the isopulegol derivatives was assigned according to Brewster's benzoate rule.[6] Thus, the configuration of the-4-methyl-10-nor-8-oxomenthols was determined to be as is shown by **1** and **3**.

Throughout the following discussion of the conformational analysis, the conformation of the C-4 acetyl group has been assumed to be equatorial for the following reasons: (a) the compounds, **1** and **3**, with equatorial acetyl group are energetically more stable by 0.5 and 2.0 kcal/mol respectively than the axial isomers on the basis of the $-\Delta G^\circ$ value,[7] although the stabilization energy of the hydrogen bonding is not involved in this value. (b) The nuclear magnetic resonance spectra indicated the C-3 proton of compounds **1** and **3** in carbon tetrachloride to be equatorial and axial respectively. (c) The C-4 acetyl group of the acetates, **2** and **4**, was proved to be equatorial



5

by studying the nuclear mangnetic resonance spectrum.

As is shown in Fig. 1, the conformational energy of the acetyl group of compounds **1** and **3** around the C(4)—C(8) bond was estimated by using the energy functions given for our previous calculation of 10-nor-8-oxomenthols,[5] where θ corresponds to a dihedral angle of the Newman projection (5). The sign of the Cotton effect shown was predicted by an examination of the model[8] for each conformer, according to the octant rule.[9] The conformers with θ=120, 240, or 360° may be preferred to both compounds, **1** and **3**. This is supported by the speculation[10,11] that the carbonyl group would eclipse the C–C bond in its equilibrium position. In the calculation of the energy, the energy function of the intramolecular hydrogen bonding between the hydroxyl and the carbonyl groups has not been considered. However, the energy of hydrogen bonding should affect the preference of the rotational conformation of the acetyl group. The **1b** and **3b** conformers may be stabilized by hydrogen bonding. However, if intramolecular hydrogen bonding is obstructed by such a factor as polar solvents, the electrostatic interaction between the hydroxyl lone-pair electrons and the carbonyl π and/or lone-pair electrons may destabilize the bonded conformers, (**1b**) and (**3b**). This would, then, cause the occurence

1d

of unstable conformers, (**1a**) and (**1c**), and (**3a**) and (**3c**). According to the octant rule,[9] the **1b**, **3a**, and **3b** conformers should exhibit a positive Cotton effect, while the (**1c**) and (**3c**) conformers should exhibit a negative one. On the other hand, the **1a** conformer may not show any Cotton effect at all.

(1R : 3S : 4R)-(+)-4-Methyl-10-nor-8-oxoneomenthol (1). The CD curves of the compound (**1**) showed a positive Cotton effect regardless of the solvent polarity (Fig. 2), although the maximum position and the molecular ellipticity exhibited a remarkable difference when the solvent was changed from a nonpolar to a polar one. The weak positive Cotton effect in the polar solvents may be attributable to the **1d** conformer rather than to **1a**, while the strong one in the nonpolar

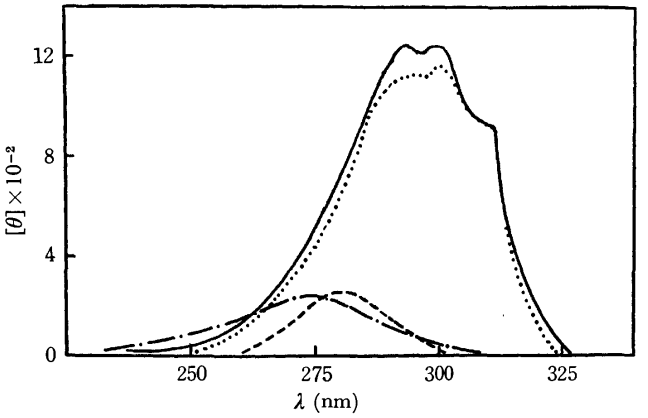

Fig. 2. CD curves of (1R:3S:4R)-(+)-4-methyl-10-nor-8-oxoneomenthol (**1**) in selected solvents at +25°C: ····· in CCl_4, —— in isooctane, —·— in MeOH, and - - - in DMSO.

media may be attributable to the bonded conformer (**1b**). The attribution of this weak positive Cotton effect to the **1d** conformer in place of the **1a** conformer may here be justified by the apperance of the positively-rotating conformer (**1d**) as a result of the interaction between the hydroxyl and the methyl groups in the **1a** conformer. The intramolecularly-hydrogen-bonded conformer (**1b**) is preferred in the nonpolar solvents, whereas the nonbonded conformer (**1d**) is preferred in the polar ones. This was supported by the infrared spectrum in the carbon tetrachloride solution, which exhibited a free hydroxyl band at 3623 cm^{-1} (ε=28), along with two peaks, at 3580 (ε=32) and 3535 cm^{-1} (ε=20), due to the interacted hydroxyl group[12] between the π-electrons of the carbonyl and the hydroxyl groups and between the lone-pair electrons of the hydroxyl groups and the carbonyl oxygen respectively.

The variable-temperature CD curves of the compound (**1**) in EPA (Fig. 3) showed a double-humped Cotton effect at −192°C. The positions of the re-

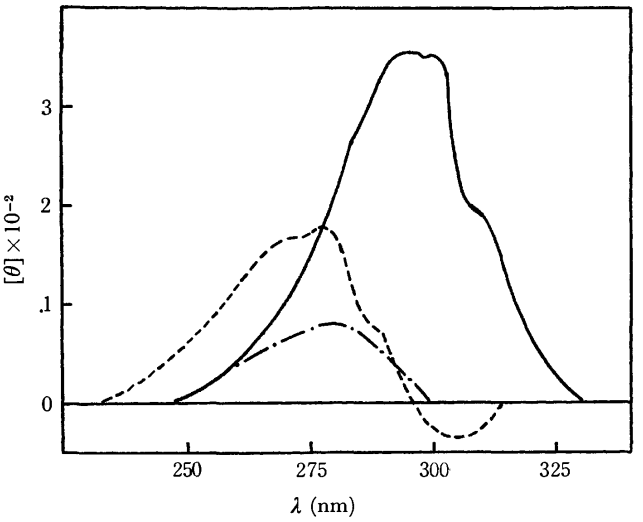

Fig. 3. CD curves of (1R:3S:4R)-(+)-4-methyl-10-nor-8-oxoneomenthol (**1**) in EPA: —— at +25°C, —·— at −74°C, and ····· at −192°C.

12) T. Shishibori, *J. Sci. Hiroshima Univ., Ser. A-II*, **32**, 125 (1968).

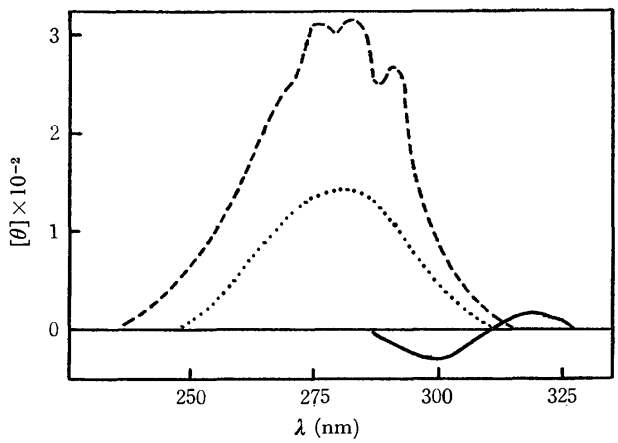

Fig. 4. CD curves of (1R:3S:4R)-(+)-4-methyl-10-nor-8-oxomenthyl acetate (**2**) in EPA: —— at +25°C, ····· at −127°C, and - - - at −190°C.

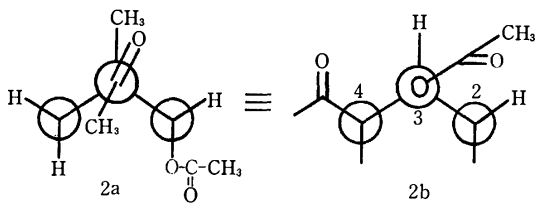
spective extremes differ by nearly 25 nm. The positive maximum observed at the same position as in the case of other polar solvents at room temperature was attributed to the **1d** conformer, whereas the negative one was attributed the **1a** conformer. The strong positive maximum at 25°C contrasted with that at −192°C, showing the similarity to the position in the case of nonpolar solvents at 25°C, but the rotational strength was slightly weakened. This positive Cotton effect curve implied a preference for the **1b** conformer at 25°C in EPA. A similar phenomenon was also observed in the variable-temperature CD curves in the MI solvent. Consequently, these results, together with the conformational energy in Fig. 1, seem to indicate the existence of a conformational equilibrium among **1b**, **1c**, and **1d**. The positively-rotating hydrogen-bonded conformer (**1b**) is preferred at room temperature, whereas the nonbonded conformers (**1c**) and (**1d**) are preferred at low temperatures. On the other hand, the acetate (**2**) in EPA exhibited only the positive Cotton effect at −190°C (Fig. 4), in contrast with the parent compound (**1**) under the same conditions. The replacement of the hydroxyl group with the acetoxy one made the positively-rotating conformation (**2a**) preferred at low temperatures because of the increase in the electrostatic interaction between the acetoxy and the carbonyl groups. At low temperatures, the frozen staggerd conformation[3] (**2b**) may be considered to prescribe the orientation of the lone-pair electrons of this group. Accordingly, the **2a** conformation with about θ=0—30° would be preferred because of the strengthened interaction due to the orientation of the electrons.

(1R : 3R : 4R)-(−)-4-Methyl-10-nor-8-oxomenthol (3). The CD curves of the oxomenthol (**3**) exhibited a



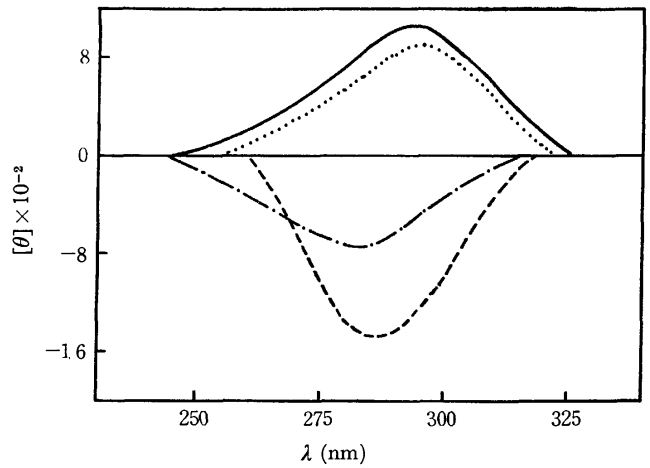


Fig. 5. CD curves of (1R:3R:4R)-(−)-4-methyl-10-nor-8-oxomenthol (**3**) in selected solvents at +25°C: ····· in CCl_4, —— in isooctane, —·— in MeOH, and - - - in DMSO.

positive Cotton effect in isooctane and carbon tetrachloride, and a negative one in methanol and dimethyl sulfoxide (Fig. 5). Such an inversion of the sign of the Cotton effect upon the change of the solvent can be ascribed to the conformational alteration of the acetyl group among **3a**, **3b**, and **3c**. For the compound **3**, the **3a** conformer with θ=0° may be expected because of the absence of the steric interaction between the methyl (of the acetyl group) and the hydroxyl groups; this is in contrast with the **1a** conformer to be expected for the compound **1**. In a nonpolar medium at a room temperature, the positively-rotating conformer (**3b**) with θ=120° is implied to be dominant because of the stabilizing intramolecular hydrogen bonding. This is further supported by the infrared spectrum, which exhibited a weak free hydroxyl band at 3620cm^{-1} (ε=21), along with two peaks at 3575 (ε=35) and 3530 cm^{-1} (ε=20) due to the intramolecularly-interacting hydroxyl group between π-electrons of the carbonyl and the hydroxyl groups and between lone-pair electrons of the hydroxyl group and the carbonyl oxygen respectively. In polar solvents at room temperature, the negatively-rotating conformer (**3c**) with θ=240° is interpreted as preferred becasue of the losses of the stabilization energy due to hydrogen bonding and, consequently, because of the destabilizing electrostatic repulsion between the carbonyl and the hydroxyl groups. This idea is supported by the solvent- and temperature-dependent CD curves of the acetate (**4**), which inherently possesses no ability of intramolecular hydrogen bonding but which does possess the ability to have an electrostatic repulsion between the carbonyl and the acetoxy groups. The CD curves of the acetate exhibited only a negative Cotton effect in both nonpolar and polar solvents. The rotational strength of the Cotton effect increased exceedingly in proportion as the temperature was lowered from −74 to −190°C in EPA. Accordingly, the acetate (**4**) exists predominantly in a negatively-rotating and energetically-favorable conformation, with θ=about 240°.

The CD curves of the compound (**3**) in EPA at low temperatures (at −74 and −180°C) exhibited a

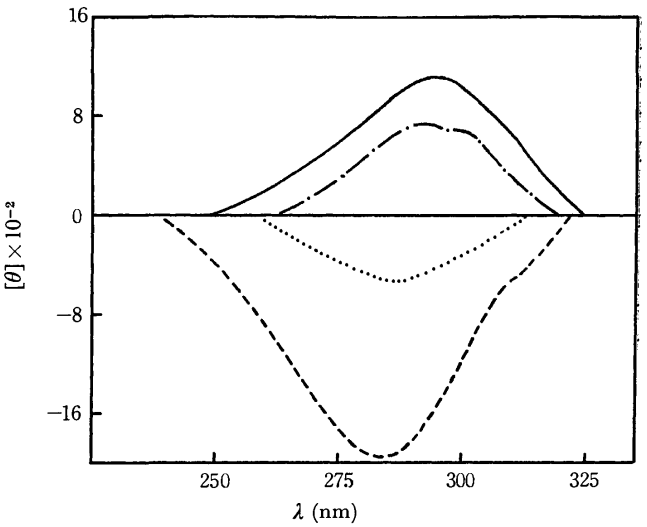

Fig. 6. CD curves of (1R:3S:4R)-(−)-4-methyl-10-nor-8-oxomenthol (**3**) in MI: —— at +25°C, −·− at −74°C, ····· at −127°C, and − − − at −186°C.

strong negative Cotton effect, in contrast with the curve at 25°C, whereas the curves in MI showed a positive Cotton effect at 25 and −74°C and a negative one at lower temperatures, as is shown in Fig. 6. This inversion in the sign of the Cotton effect with the change in the temperature is very similar to the phenomenon observed upon changing the solvent. The inversion of the sign was interpreted as an indication of the increase in the nonbonded conformer at the sacrifice of the bonded conformer with a lowering of the temperature. Thus, at lower temperatures in both polar and nonpolar media, the **3c** conformer, with $\theta=240°$, should be preferred. Our interpretation of such phenomena of the compound (**3**) can be understood after due consideration of the explanation given of the CD curve of 2-oxo-1-*p*-menthanol,[13] which exhibits such an inversion of the sign from a positive Cotton effect to a negative one at lower temperatures. The decrease in the rotational strength for the positive CD curves of the compound (**3**) in decalin at both higher and lower temperatures suggested also that the hydrogen-bonded conformer (**3b**) would be diminished with an increase in the population of the nonbonded conformers by being kept out of room temperature.

Thus, it was concluded that the presence of the C-4 methyl group remarkably alters the conformational preference of the acetyl side-chain of 4-methyl-10-nor-8-oxomenthols in comparison with that of 10-nor-8-oxomenthols.[5] The presence of the C-4 methyl group decreases the population of the conformer when $\theta=180°$, whereas the absence of this group increases the conformer when $\theta=150$—$210°$. These results were very consistent with a prediction judging from the calculated energy function.

Experimental

Measurements. The CD curves were measured on a Japan Spectroscopic Co., Ltd., automatically-recording spectropolarimeter, Model ORD/UV-5, equipped with a circular dichroism attachment. The low- and high-temperature CD curves were obtained by the use of the same spectrometer, using low- and high-temperature CD cells designed and constructed by the present authors. The EPA solvent was composed of ether-isopentane-ethanol in the ratio of 5: 5: 2 by volume. The MI solvent was composed of methylcyclohexane-isopentane in the ratio of 1: 3 by volume.

The IR spectra in the hydroxyl-stretching region were measured with a Perkin-Elmer Model 621 Grating Infrared spectrometer at 25°C. A sodium chloride absorption cell (10 mm long) was used; the concentration of the solution was 0.005 mol/*l*.

(1R: 3S: 4S)-(+)-4-Methylneoisopulegol and (1R: 3R: 4S)-(−)-4-Methylisopulegol. (−)-Methylisopulegone (bp 69—70°C/8 mmHg; n_D^{25} 1.4682; d_4^{25} 0.9231; $[\alpha]_D^{25}-139.18°$ (neat); the semicarbazone derivative, mp 201—202°C) was synthesized by the methylation of (+)-pulegone (81—82°C/5 mmHg; n_D^{25} 1.4843; d_4^{25} 0.9303; $[\alpha]_D^{25}+23°$ (neat)) following the method in the literature,[14] and then it was reduced with lithium alminum hydride in dry ether to two isomeric alcohols. The configuration of the alcohols was identified as (1R: 3S: 4S)-(+)-4-methyl-neoisopulegol, 62.0—63.0°C/3 mmHg; n_D^{25} 1.4735; d_4^{25} 0.9204; $[\alpha]_D^{25}+54.32°$ (neat); the 3,5-dinitrobenzoate derivative, mp 142—143°C, $[\alpha]_D^{25}+59.24°$ (*c* 0.00211, $CHCl_3$), and (1R: 3R: 4S)-(−)-4-methylisopulegol, 63.0—64.5°C/3 mmHg; n_D^{25} 1.4776; d_4^{25} 0.9192; $[\alpha]_D^{25}-1.67°$ (neat); the 3,5-dinitrobenzoate derivative, mp 107°C, $[\alpha]_D^{25}-29.66°$ (*c* 0.00236, $CHCl_3$), by applying Brewster's benzoate rule.

(1R: 3S: 4R)-(+)-4-Methyl-10-nor-8-oxoneomenthol (1). The ozonization of (1R: 3S: 4S)-(+)-4-methyl-neoisopulegol gave (1R: 3S: 4R)-(+)-4-methyl-10-nor-8-oxoneomenthol (**1**): mp 69.5°C; $[\alpha]_D^{25}+57.46°$ (*c* 0.1514, MeOH); NMR ($CDCl_3$), >CH–C<u>H</u>$_3$ 0.92 ppm (doublet, $J=6.0$ Hz, 3H), –C–CH_3 1.15 (singlet, 3H), O=C–CH_3 2.15 (singlet, 3H), >C<u>H</u>–OH 4.0 (broad singlet, 1H), >CH–O<u>H</u> 2.79 (broad singlet, 1H); ν_{max}^{Nujol} 3503 cm^{-1} (OH), 1690 (C=O), 1352 ($-COCH_3$); λ_{max}^{MeOH} 282 nm ($\varepsilon=30.32$), $\lambda_{max}^{Isooctane}$ 288 (32.94); mass spectrum, *m/e* 170 (M^+); CD (max) in decalin (*c* 0.154): $[\theta]_{295}^{+150°}$ +549, $[\theta]_{292}^{+74°}$ +922, $[\theta]_{301}^{+25°}$ +922, $[\theta]_{293}^{+25°}$ +1093, $[\theta]_{300}^{+25°}$ +1111, $[\theta]_{293}^{-74°}$ +634, $[\theta]_{301}^{-74°}$ +617, $[\theta]_{324}^{-74°}$ −137, MI (*c* 0.15): $[\theta]_{293}^{+25°}$ +1350, $[\theta]_{301}^{+25°}$ +1350, $[\theta]_{295}^{-74°}$ +901, $[\theta]_{300}^{-74°}$ +801, $[\theta]_{270}^{-192°}$ +313, $[\theta]_{297}^{-192°}$ −128.

The acetate (2): The acetylation of (**1**) with acetic anhydride in the presence of pyridine afforded the acetate (**2**): mp 60.5°C; $[\alpha]_D^{25}+66.96°$ (*c* 0.134, MeOH); NMR (CCl_4) >CH–C<u>H</u>$_3$ 0.89 ppm (doublet, $J=5.5$ Hz, 3H), –$\underset{|}{C}$–CH_3 1.09 (singlet, 3H), O=$\underset{|}{C}$–CH_3 1.92 and 1.96 (each singlet, 6H), >CH–O– 5.09 (singlet, 1H); ν_{max}^{Nujol} 1730, 1374 cm^{-1} (acetate), 1708 (C=O), 1350 (methyl ketone); λ_{max}^{MeOH} 280 nm ($\varepsilon=31.55$), $\lambda_{max}^{isooctane}$ 281 (31.29); CD (max) in CCl_4 (*c* 0.4362): $[\theta]_{292}^{+25°}$ −92, in MeOH (*c* 0.4544): $[\theta]_{282}^{+25°}$ −20, $[\theta]_{315}^{+25°}$ +22, in isooctane (*c* 0.4018): $[\theta]_{300}^{+25°}$ −48.

(1R: 3R: 4R)-(−)-4-Methyl-10-nor-8-oxomenthol (3). BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 245—247(1972)

Studies on Nucleosides and Nucleotides. II. Selective Acylation of 5′-Hydroxyl Group of Thymidine[1]

Oyo MITSUNOBU, Junji KIMURA, and Yoshiyuki FUJISAWA

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Megurisawa-cho, Setagaya-ku, Tokyo

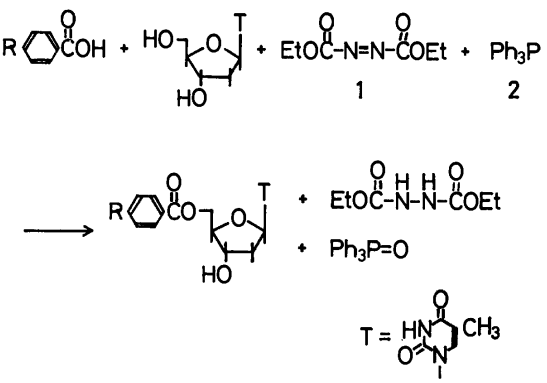
(Received June 15, 1971)

Treatment of thymidine and either acetic acid or benzoic acid with diethyl azodicarboxylate (**1**) and triphenylphosphine (**2**) in dioxane afforded 5′-*O*-acetyl or 5′-*O*-benzoylthymidine along with a trace of 3′,5′-di-*O*-acylated product. When thymidine and benzoic acid or *p*-substituted benzoic acids were allowed to react with **1** and **2** in hexamethylphosphoric triamide(HMPA), the corresponding 5′-*O*-aroylthymidines were selectively obtained. The aroyl groups having electron-withdrawing substituents were much more readily removed than those having electron-releasing groups under mild alkaline conditions.

For the chemical synthesis of nucleotides and oligonucleotides, the hydroxyl groups of sugar moiety should be appropriately protected prior to phosphorylation. Of many blocking groups examined so far, triarylmethyl groups have been widely used because they can be introduced predominantly to 5′-hydroxyl group of nucleosides and removed under acidic conditions. It is known, however, that alkali-labile protecting groups are superior to acid-labile ones for the synthesis of oligonucleotides.[2] Thus acyl groups are used as alkali-labile groups for the protection of the hydroxyl functions as well as amino functions. There are few reports, however, of the selective acylation of 5′-hydroxyl groups of nucleosides.

In a previous paper,[3] we have reported that the 5′-hydroxyl groups of thymidine and uridine were predominantly phosphorylated by means of dibenzyl hydrogen phosphate, diethyl azodicarboxylate (**1**) and triphenylphosphine (**2**). It is of interest to apply this procedure to the selective acylation of 5′-hydroxyl groups of nucleosides.

Acylation of Thymidine. Thymidine was allowed to react with equimolar amounts of acetic acid, **1** and **2** in dioxane at 60°C for 3 hr. The thymidine remaining insoluble disappeared as the reaction proceeded and 5′-*O*-acetylthymidine was isolated in a 55.2% yield by silica gel column chromatography.[4] Differing from the case of phosphorylation of thymidine, a trace of 3′,5′-di-*O*-acetylthymidine was also isolated. Similarly, the reaction of thymidine with benzoic acid, **1** and **2** led to the formation of 5′-*O*-benzoylthymidine in isolated yield of 78.0%. A trace of 3′,5′-di-*O*-benzoylthymidine was also formed.



Since thymidine was found to be sufficiently soluble in hexamethylphosphoric triamide (HMPA), further experiment was carried out using HMPA as the solvent. When a solution of thymidine and **2** in HMPA was

treated with benzoic acid and **1** at room temperature, 5′-*O*-benzoylthymidine was formed in yield of 74.0% and 25.0% of thymidine was recovered as determined by paper chromatography. It is noteworthy that no 3′,5′-di-*O*-benzoylthymidine could be detected by thin layer chromatography (tlc) of the reaction mixture. By a similar way, 5′-*O*-*p*-nitrobenzoyl-, 5′-*O*-*p*-cyanobenzoyl-, 5′-*O*-*p*-methoxybenzoyl- and 5′-*O*-*p*-toluylthymidine were obtained. The results are summarized in Table 1.

As shown in Table 1, benzoic acid derivatives having electron-withdrawing groups gave higher yields of the corresponding 5′-*O*-aroylthymidines than those having electron-releasing groups. 5′-*O*-Aroylthymidine could be isolated by silica gel column chromatography.

Thymidine is soluble in HMPA, while triphenylphosphine oxide formed precipitated nearly quantitatively and could be readily removed by filtration. Although HMPA is known to form complexes with protic acids,[5] no disturbing influence on the present reaction was observed. HMPA is, therefore, a suitable solvent for the present purpose in spite of its high boiling point.

Generally, acid chlorides, acid anhydrides or aryl carboxylates react with 5′-hydroxyl group as well as 3′(2′)-hydroxyl group of nucleosides to give both 5′-*O*-acylated and 3′(2′),5′-poly-*O*-acylated compounds.[6,7] As an example, *p*-nitrobenzoylation of unprotected thymidine (5 mmol) by means of *p*-nitrobenzoyl chloride (5.5 mmol) in pyridine resulted in the formation of 5′-*O*-*p*-nitrobenzoylthymidine (55%) and 3′,5′-di-*O*-*p*-nitrobenzoylthymidine (18%).[8] Thus, the present method might be convenient for the selective formation of 5′-*O*-aroylthymidine.

Acylation of alcohols by means of carboxylic acids, **1** and **2** may proceed through quaternary phosphonium salts, **3** and **4**, *e.g.*, may involve activation of alcohols rather than carboxylic acids.[9] Acylating and carboxylating reagents having bulky groups predominantly gave corresponding 5′-*O*-protected nucleosides.[10] Thus, it would be reasonable to postulate that the selective formation of 5′-*O*-aroylthymidines by the present method is due to steric hindrance of three phenyl groups around the positively charged phosphorus atom in the intermediate **3**.[3]

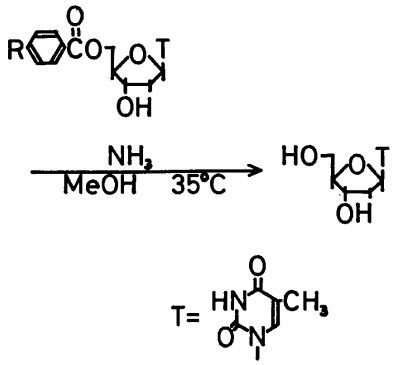
raphy. As expected,[11] the nature of the *p*-substituents affected the rate of solvolysis; the aroyl groups having electron-withdrawing substituents were much more readily removed than those having electron-releasing groups. The time(hr) required for the complete dearoylation was as follows: *p*-NO_2, 1.0; *p*-CN, 1.5; H, 8.0; *p*-CH_3O, 22; *p*-CH_3, 23.



The results indicate that the acylation of thymidine by means of carboxylic acids, **1** and **2** provides a convenient and selective method available for the preparation of 5′-*O*-acylthymidines.

Experimental

Methods. Paper chromatography was carried out by the ascending technique using Toyoroshi No. 51A paper. The solvent used was *n*-butanol-2NHCl (5: 1). The R_f values of different compounds are listed in Table 1. Estimation of the yields of 5′-*O*-aroylthymidines formed by the reaction in HMPA was carried out spectrophotometrically after elution of spots from paper chromatograms. The spots and appropriate blank areas of the paper were eluted after it was cut into small pieces by soaking in 0.1N hydrochloric acid for 1 day at 37°C in sealed vessels, the contents of the vessels being shaken occasionally. The extracts were measured by a Hitachi EPS-3T recording spectrometer.

Thin layer chromatographic plates were prepared using silica gel PF_{254} (E. Merck) and developed with $CHCl_3$: CH_3CN=1: 1. Silica gel (Wakogel C-300) was used for column chromatography.

Commercial thymidine was dried at 80—90°C over phosphorus pentoxide. Diethyl azodicarboxylate[12] and *p*-toluic acid[13] were prepared by known procedures. Other commercial reagents and solvents were purified and dried by ordinary procedures.

11) On alkaline hydrolysis of 5′-*O*-acyl-2′,3′-isopropylidenuridine, the order of reactivity is $CF_3CO>CCl_3CO>CH_2ClCO>CH_3CO$. F. Cramer, H. P. Bär, H. J. Phaese, W. Sänger, K. H. Scheit, G. Schneider, and J. Tennigkeit, *Tetrahedron Lett.*, **1963**, 1039.

13) W. F. Tuley and C. S. Marvel, "Organic Syntheses," Coll. Vol. III, p. 822.

Preparation of 5′-O-Acetylthymidine. Acetic acid (180 mg, 3×10^{-3} mol) and diethyl azodicarboxylate (522 mg, 3×10^{-3} mol) in dioxane (5 m*l*) were added to a mixture of thymidine (726 mg, 3×10^{-3} mol) and triphenylphosphine (786 mg, 3×10^{-3} mol) in dioxane (5 m*l*) at 60°C under stirring. Stirring was continued for 3 hr and the solution was concentrated. The residue was applied to silica gel column (3.2×70 cm). Elution with ethyl acetate afforded diethyl hydrazodicarboxylate in the first fraction, a trace of 3′,5′-di-*O*-acetylthymidine in the next fraction and 5′-*O*-acetylthymidine in the third fraction. 5′-*O*-Acetylthymidine was obtained by evaporating and crystallizing the residue from ethyl acetate, 55.2% (470 mg). It melted at 153—154°C (lit,[6a] mp 150°C). Found: C, 50.67; H, 5.72; N, 10.34%. Calcd for $C_{12}H_{16}N_2O_4$: C, 50.70; H, 5.63; N, 9.86%.

Similarly, the reaction of benzoic acid (366 mg, 3×10^{-3} mol) with equimolar amounts of thymidine, diethyl azodicarboxylate and triphenylphosphine was carried out in dioxane. Elution with acetonitrile afforded a trace of 3′,5′-di-*O*- benzoylthymidine (mp 154—156°C: Found: C, 63.41; H, 5.02; N, 6.03%. Calcd for $C_{24}H_{22}N_2O_7$: C, 64.00; H, 4.89; N, 6.22%) and a 75.1% (780 mg) yield of 5′-*O*-benzoylthymidine, mp 171—172°C recrystallized from benzene-ethyl acetate. Found: C, 58.72; H, 5.09; N, 8.23%. Calcd for $C_{17}H_{18}N_2O_6$: C, 58.96; H, 5.20; N, 8.09%.

Preparation of 5′-O-Aroylthymidines. General Procedure. A mixture of triphenylphosphine (1×10^{-3} mol) and thymidine (1×10^{-3} mol) in HMPA (1 m*l*) was stirred with exclusion of moisture and a solution of carboxylic acid (1×10^{-3} mol) and diethyl azodicarboxylate (1×10^{-3} mol) in HMPA (1 m*l*) was added over a period of 1 hr at room temperature. Stirring was continued for 5 hr and the mixture was then kept standing overnight at room temperature. After removal of triphenylphosphine oxide (nearly quantitative yield) by filtration, the filtrate was concentrated to a sirup under reduced pressure. The residue was dissolved in dry methanol and the solution was adjusted to exactly 100 m*l* to determine the amounts of the 5′-*O*-aroylthymidine formed and the thymidine unreacted by means of paper chromatography. Methanol was then removed and the residue was chromatographed over silica gel to isolate the product. Elemental analyses and physical properties of 5′-*O*-aroylthymidines thus isolated are summarized in Table 2.

Isolation of 5′-O-p-Methoxybenzoylthymidine. The residue obtained by the removal of methanol was applied to silica gel column (2.2 cm×50 cm), and eluted with a mixture of chloroform-acetonitrile (1: 1) giving a 54.5% yield of 5′-*O*-*p*-methoxybenzoylthymidine. This was purified by recrystallization from methanol.

Solvolysis of 5′-O-Aroylthymidine. 5′-*O*-Aroylthymidine (30 mg) was dissolved in methanolic ammonia (10 m*l*, saturated at room temperature) and stirred at 35°C. The reaction was monitored by paper chromatography and tlc. Time required for the 5′-*O*-aroylthymidines to disappear was as follows; 5′-*O*-*p*-nitrobenzoylthymidine, 1.0; 5′-*O*-*p*-cyanobenzoylthymidine, 1.5; 5′-*O*-benzoylthymidine, 8.0; 5′-*O*-*p*-methoxybenzoylthymidine, 22; 5′-*O*-*p*-toluylthymidine, 23 hr.

The Reaction of Hydrosilanes with Chlorosilanes in the Presence of Grignard Reagents. A New Method of Silicon-Silicon Bond Formation

Akira Hosomi and Hideki Sakurai
Department of Chemistry, Faculty of Science, Tohoku University, Sendai
(Received June 15, 1971)

A new method has been developed for the formation of a silicon-silicon bond. Hydrosilanes having at least one phenyl or one trimethylsilyl group on a silicon atom were subjected to reaction with chlorosilanes to give unsymmetrically substituted disilanes in the presence of secondary or tertiary Grignard reagent which was inert to both chlorosilanes and hydrosilanes. The method was extended to the preparation of benzyl, allyl, and alkylsilanes.

Chemistry of organopolysilanes has recently become a subject of growing interest.[1] In investigations of organopolysilanes, it is frequently desirable to prepare unsymmetrically substituted organodisilane compounds. For this the Wurtz-type condensation between the two different kinds of halosilanes may be employed. However, it does not necessarily give the desired compound selectively unless one of the two halosilanes makes a stable silylalkali metal bond.[2]

It was reported that cyclohexylmagnesium bromide was also effective for the condensation of halosilanes.[3] A silyl Grignard reagent, "Ph_3Si–MgX", formed by the interaction between triphenylchlorosilane and cyclohexylmagnesium bromide was assumed as an intermediate. This was further coupled with another chlorosilane to form a new silicon-silicon bond. The presence of magnesium metal gave rise to more favorable results.[4] Some symmetrically substituted disilanes have been also obtained by the action of magnesium metal upon chlorosilanes[5] where an intermediacy of the "Si–MgX" compound formed directly from magnesium and the chlorosilane was presumed.

We have investigated the reaction of various hydrosilanes with sterically hindered Grignard reagents, such as isopropylmagnesium chloride in tetrahydrofuran (THF), primarily in the hope of preparing a stable silyl Grignard reagent. Although the convincing evidence of its formation was not available, some unsymmetrically substituted disilanes were obtained in good yield by adding chlorosilane to the reaction mixture.

Results and Discussion

An appropriate hydrosilane was added to a solution of Grignard reagent from *sec*- or *tert*-alkyl halides in THF and was heated to reflux. Trimethylchlorosilane was then added to the reaction mixture and the mixture was heated to reflux under nitrogen. After work-up, an unsymmetrically substituted disilane was obtained as a result of the condensation between hydrosilane and chlorosilane. The products were identified by comparing their retention times on gas chromatography and IR and NMR spectra with those of authentic samples.

$$\equiv Si^1\text{–}H + \equiv Si^2\text{–}Cl \xrightarrow{RMgX} \equiv Si^1\text{–}Si^2\equiv + MgXCl + RH$$

It has been shown that the introduction of an alkyl group into silicon took place in the reaction of hydrosilanes with Grignard reagents derived from primary alkyl halides,[6] and thus the sterically hindered Grignard reagent formed from *sec*- or *tert*-alkyl halides was employed. It has been also established that *sec*- or *tert*-Grignard reagents give no substitution product in the reaction with trialkylchlorosilanes.[7]

The results are summarized in Table 1. It is interesting to note that the presence of an aromatic or an organosilyl group on silicon in a hydrosilane is apparently necessary for the condensation, just as in the formation of "silyl Grignard reagents,"[3,5] or silyl alkali metal compounds[2] from chlorosilanes. These groups may play a role in the stabilization of the negative charge, which would develop on the silicon atom of "silyl Grignard reagents." If hydrosilanes were converted into chlorosilanes under the present reaction conditions, the reaction may be trivial, since coupling of chlorosilanes by means of Grignard reagents is known. However, the fact that no such conversion of hydrides into chlorides really occurred was verified by several control experiments; for example, after a hydrosilane was heated at reflux with the starting alkyl halide or chlorosilane in the presence of magnesium metal, magnesium salts, or alkyl Grignard reagents, no traces of the corresponding chlorosilane could be detected.

The yields are independent of the presence of magnesium in the reaction mixture. However, the effect of solvent is very significant. Thus, although disilanes were not obtained in diethyl ether, the reaction took

place smoothly in more basic solvents such as hexamethylphosphoramide (HMPA) or especially in THF. However, the formation of δ-hydroxybutylsilane due to the cleavage of THF by magnesium salts[5a,8] causes the lowering of the yields, competing with the condensation between Si–H and Si–Cl.

It would be of interest to assume the intermediacy of the "silyl Grignard reagent" in this reaction. However, hydrolysis with deuterium oxide after heating hydrosilanes and Grignard reagent in THF gave no deuterium-containing product.

The reaction was extended to the preparation of benzyl, allyl, and alkylsilanes.

$$Ph_nMe_{3-n}SiH + RX + i\text{-}PrMgCl \longrightarrow Ph_nMe_{3-n}SiR + MgXCl + C_3H_8$$

$$RX = PhCH_2Cl,\ CH_2=CHCH_2Cl,\ MeI,\ n\text{-}BuI$$

Results are shown in Table 1. All the products were separated by preparative GLC and identified by NMR. NMR data are given in Table 2.

8) D. Wittenberg, D. Aoki, and H. Gilman, *ibid.*, **80**, 5933 (1958).

Experimental

Alkyl chlorides were prepared from the corresponding alcohols by known methods. Triphenylsilane, diphenylsilane, and pentamethyldisilane were prepared by reduction with lithium aluminum hydride of the corresponding chlorosilanes. Diphenylmethylsilane was prepared by partial phenylation of methyldichlorosilane with phenylmagnesium chloride. All physical constants and GLC analyses confirmed the purity of the materials.

Typical Runs of Condensation. a) The Reaction of Diphenylmethylsilane with Trimethylchlorosilane: From a dropping funnel diphenylmethylsilane (2.5 g, 0.0125 mol) was added to the Grignard reagent prepared from isopropyl chloride (15.7 g, 0.20 mol) and magnesium (4.8 g, 0.20 mol) in THF in a three-necked flask. After refluxing for one hour, trimethylchlorosilane (22 g, 0.20 mol) was added to this solution, and additional refluxing was continued for 10 hr. By GLC analysis of the reaction mixture 1,1-diphenyltetramethyldisilane (1.32 g, 0.0049 mol) and diphenylmethylsilane (1.04 g, 0.0052 mol) were detected. After hydrolysis, however, an additional product identified to be δ-hydroxybutyldiphenylmethylsilane (0.44 g, 0.0016 mol), was obtained. It had n_D^{20}

1.5685 (lit,[8] 1.5693, 1.5688). These products were separated by preparative glc and characterized by IR and NMR spectra and by the known physical constants.

b) The Reaction of Diphenylmethylsilane with Benzylchloride: By means of essentially the same procedure, diphenylmethylbenzylsilane (1.00 g, 0.00344 mol), mp 64°C was obtained from diphenylmethylsilane (2.5 g, 0.0125 mol) and benzyl chloride (2.50 g, 0.020 mol). The product was separated by glc.

An Attempt of Detection of a Silyl Grignard Reagent. In a three-necked flask were refluxed isopropylmagnesium chloride and diphenylmethylsilane for 20 hr in THF. After quenching with deuterium oxide, the product was separated by preparative glc. The silicon-deuterium bond in the compound could not be characterized by IR, NMR or mass spectra.

An Attempted Redistribution between Diphenylmethylsilane and Trimethylchlorosilane Catalyzed by Magnesium Bromide. Diphenylmethylsilane (2.5 g, 0.0125 mol) was heated with stirring in THF for 6 hr in the presence of magnesium bromide prepared *in situ* from magnesium (3.6 g, 0.15 mol) and 1,2-dibromoethane (9.4 g, 0.0125 mol). Diphenylmethylbromosilane was not detected by careful examination by glc. Trimethylchlorosilane (10.8 g, 0.1 mol) was then added to the mixture, which was heated for 4 hr. glc examination revealed that neither diphenylmethylchlorosilane nor 1,1-diphenyltetramethyldisilane was formed.

We are indebted to Tokyo Shibaura Electric Co., Ltd., for a gift of chlorosilanes.

Ring Expansion through a 1,3-Acyl Rearrangement. Reactions of Cyclic Sulfonium Ylides with Acetylenic Compounds[1]

Moriaki HIGO, Takeshi SAKASHITA, Minoru TOYODA, and Teruaki MUKAIYAMA

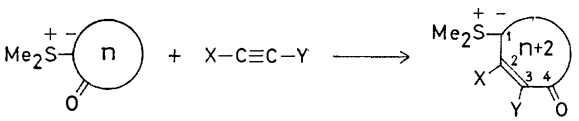
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 17, 1971)

Ring expansion of cyclic sulfonium ylides with acetylenic compounds was investigated. It was found that a six-membered cyclic sulfonium ylide (I) gave eight-membered ring expansion products (IIIa—e) in high yields under mild conditions on treatment with acetylenic compounds (IIa—e) in dimethyl sulfoxide. In a similar manner, the reactions of five- and seven-membered cyclic sulfonium ylides with II afforded ring expansion products (XIa) and (IXa—c). The ring expansion was considered to proceed through an intramolecular 1,3-acylrearrangement. It was found that, when the reaction of I and IIa was carried out in benzene, an intermediate bicyclic sulfonium betaine (VIIa) was obtained as yellow precipitates. The properties and reactions of VIIa were investigated. It was shown that the ring expansion product IIIa gave cyclooctenone derivatives (XIIa—c) by the reaction with some nucleophiles. IIIa was found to give diene esters (XIII, R=acyl) and diene ethers (XIII, R=alkyl) upon reaction with acyl and alkyl halides.

It was found[2] that 3,4-furandicarboxylic acid derivatives were produced by the reactions of sulfonium ylides with dimethyl acetylenedicarboxylate through a 1,3-acyl rearrangement.

This paper deals with a new ring expansion of cyclic sulfonium ylides by two carbon atoms[3] by the reactions with acetylenic compounds through an intramolecular 1,3-acyl rearrangement.



(I) (n=6) (II) (III) (n=6)
(VIII) (n=7) (IX) (n=7)
(X) (n=5) (XI) (n=5)

When a six-membered cyclic sulfonium ylide, *i.e.*, dimethylsulfonium-2-oxocyclohexylide (I) was treated with dimethyl acetylenedicarboxylate (IIa) in dimethyl sulfoxide (DMSO), an exothermic reaction soon took place and a ring expansion product, dimethylsulfonium-2,3-dicarbomethoxy-4-oxo-2-cyclooctenylide (IIIa) was obtained in quantitative yield. The IR spectrum of IIIa showed strong absorptions at 1726, 1627, and 1528 cm^{-1}. The absorption at 1726 cm^{-1} can be attributed to the unsaturated ester carbonyl and those at 1627 and 1528 cm^{-1} to the ester and ketone carbonyl, respectively, both conjugated with the ylide carbanion.[2,4,5] Based upon IR, NMR, and UV spectra, IIIa was found to have the structure of a sulfonium ylide stabilized by a conjugated system.[2,4] The ylide IIIa gave a sulfonium salt (IVa) with 2,4,6-trinitrobenzenesulfonic acid (TNBS-H) in quantitative yield.

The NMR spectrum of IVa showed a low field peak

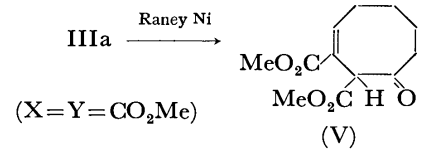
TNBS-H (IV)

at δ=12.80 attributable to a partially enolated α-proton[6] in the β-keto ester system. It is thus obvious that IVa exists in the form of a vinylsulfonium salt rather than that of an allylsulfonium salt.

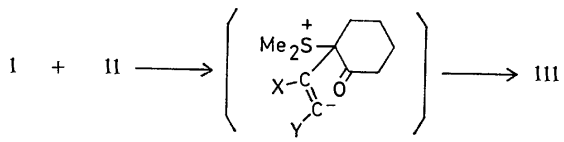
The structure of IIIa, the ring expansion product, was firmly supported by the fact that IIIa was desulfurized by Raney nickel to afford 2,3-dicarbomethoxy-4-oxocyclooctene (V) in 50% yield, identical with an authentic sample.[7]



(V)

In a similar manner, when ethyl phenylpropiolate (IIb), benzoylphenylacetylene (IIc), dibenzoylacetylene (IId), and methyl propiolate (IIe) were treated with I, the corresponding ring expansion compounds (IIIb—e) were obtained in good yields. Similarly, IIIb—e afforded TNBS salts (IVb—e). In the cases of asymmetric acetylenes IIb,c,e, the NMR spectra of IVb,c,e, indicate that more electron attracting groups, *i.e.*, carboalkoxy and benzoyl groups, are attached to C_3 of III. The reaction of I with phenylacetylene, however, did not occur even after prolonged stirring for several days at room temperature. The results are summarized in Table 1.

It is reasonable to consider that the reaction of I with II proceeds through an intermediate betaine (VI), which is transformed into III by way of the intramolecular 1,3-migration of the acyl group.[8] The chemical driving force of the reaction is probably due to the enhanced stability of III over I gained from the extended conjugation formed by acyl migration. Perhaps severe steric interaction prevented further cyclization of III to a bicyclofuran ring by means of intramolecular nucleophilic displacement accompanied with elimination of dimethyl sulfide.



(VI)

In order to elucidate acyl migration mechanism, the effect of the solvents in the reaction of I with IIa was investigated. Solvents such as *N*,*N*-dimethylformamide (DMF), acetonitrile and tetrahydrofuran (THF) also afforded IIIa in 24, 55, and 25% yields, respectively. The results indicate that DMSO is the most suitable as solvent for the reaction. On the other hand, when the reaction of I and IIa was carried out in benzene, IIIa was not formed and yellow precipitates were obtained. The precipitates melted at 90—100°C, resolidified above this temperature and decomposed at 165°C. It was also found that the precipitates were easily transformed into IIIa by heating at 90°C for several minutes or merely dissolving into polar solvents, even into chloroform. Their limited solubility in benzene and facile

conversion into IIIa in polar solvents precluded measurements of NMR and UV spectra. In view of the above facts, however, it seems most reasonable to assume that the precipitates are a bicyclic sulfonium betaine having [4.2.0]bicyclooctene structure (VIIa), a valence isomer of IIIa.

VIIa ⟶ IIIa

In order to have further proof for the structure VIIa, prevention of a facile ring opening of VIIa, which might be caused by electron migration from the oxygen anion to the bicyclo ring system, was attempted by means of alkylation[9] of the anion. However, alkylation of VIIa with triethyloxonium fluoborate resulted in the ring opening and the product was the same as that formed from IIIa and the alkylating reagent.

It was established that the ring expansion of a seven-membered cyclic sulfonium ylide, dimethylsulfonium-2-oxocycloheptylide (VIII) also occurred upon reaction with IIa giving dimethylsulfonium-2,3-dicarbomethoxy-4-oxo-2-cyclononenylide (IXa) in 87% yield.

Similarly, the reactions of VIII with IIb,c afforded the ring expansion products (IXb,c) in good yields under mild conditions. The results are listed in Table 2.

In the case of a five-membered cyclic sulfonium ylide (X), X was prepared *in situ* from the corresponding sulfonium salt on treatment with *n*-butyllithium because of an unsuccessful isolation of X. X was immediately allowed to react with IIa to afford a ring expansion product (XIa) in 52% yield.

The ring expansion of eight- and twelve-membered cyclic sulfonium ylides, however, has not yet been successful.

The reactions of the ring expansion product IIIa were investigated with the expectation that IIIa, being a reactive sulfonium ylide, would become a potential synthetic intermediate.

It was shown that IIIa gave cyclooctenone derivatives (XIIa—c) by displacement reactions with some nucleophiles accompanied with elimination of dimethyl sulfide. When IIIa was allowed to react with benzenethiol, 1-phenylthio-2,3-dicarbomethoxy-4-oxocyclooctene (XIIa) was obtained in 80% yield with evolution of dimethyl sulfide. The structural assignment was made on the basis of elemental analysis and IR and NMR[6] spectra.

In a similar manner, cyclooctenone derivatives (XIIb—d) were obtained in excellent yields when IIIa was allowed to react with ethanethiol, hydrogen cyanide or methanol. The results are shown in Table 3.

IIIa + R–H $\xrightarrow{-Me_2S}$ 
(XII)

On the other hand, the reactions of IIIa with several

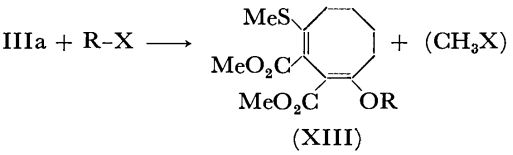
active methylene compounds, such as acetylacetone and ethyl malonate, in various solvents resulted only in the formation of 1-methylthio-2,3-dicarbomethoxy-4-oxocyclooctene (XII, R=MeS) in 23—74% yields.

The reactions of IIIa with electrophilic reagents were also investigated. It was found that IIIa gave diene esters (XIII, R=acyl) and diene ethers (XIII, R=alkyl) on treatment with acyl and alkyl halides. Acylation and alkylation were found to occur exclusively on the oxygen atom.[10] The results are recorded in Table 4.



(XIII)

It should be noted that the reactions of cyclic sulfonium ylides I, VIII and X with II in DMSO afforded the ring expansion (by two carbon atoms) products III, IX, and XI through the 1,3-acyl rearrangement in high yields under extremely mild conditions. The cyclic sulfonium ylide III, having a reactive sulfonium group, was found to be an important intermediate for the syntheses of various cyclooctane derivatives with cyclohexanone as a starting material.

Experimental

All the experiments were carried out in atmosphere of nitrogen. Melting points are uncorrected. NMR spectra were measured in $CDCl_3$ unless otherwise stated with tetramethylsilane as internal standard.

Preparation of Cyclic Stable Sulfonium Ylides. Dimethylsulfonium-2-oxocyclohexylide (I) was newly prepared from dimethyl-2-oxocyclohexylsulfonium fluoborate in 80% yield by the action of aqueous sodium hydroxide in a mixture of chloroform and saturated aqueous potassium carbonate.

In a similar manner, seven-, eight-, and twelve-membered cyclic stable sulfonium ylides were obtained in good yields from the corresponding fluoborate or methylsulfate. The cyclic ylides gave sulfonium salts with 2,4,6-trinitrobenzenesulfonic acid (TNBS-H)[11] in quantitative yields. The results are listed in Table 5.

Reaction of Dimethylsulfonium-2-oxocyclohexylide (I) with Dimethyl Acetylenedicarboxylate (IIa)[12] *in Dimethyl Sulfoxide (DMSO).* When a solution of IIa (1.42 g, 10 mmol) in 15 m*l* of dry DMSO was added dropwise to a solution of I (1.58 g, 10 mmol) in DMSO with stirring at 18°C, an exothermic reaction soon took place and yellow precipitates of dimethylsulfonium-2,3-dicarbomethoxy-4-oxo-2-cyclooctenylide (IIIa) were deposited. After being stirred for an hour, IIIa was filtered and washed well with dry benzene. Dilution of the filtrate with 1 *l* of dry ether gave additional 0.99 g of IIIa. The total yield was 2.99 g (100%). Mp 166.5—167.5°C (dec). IR (KBr): 1726, 1627, 1528 (C=O) and 1575 (C=C) cm^{-1}. NMR (DMSO-d_6): δ 1.3—2.3 (8H, m, C_4H_8), 2.94 (6H, s, $Me_2\overset{+}{S}$), 3.33 (3H, s, MeOCO) and 3.64 (3H, s, MeOCO) ppm. UV: λ_{max}^{EtOH} 280 (ε 9,800) and 368 (ε 4,900) mμ.

In a similar manner, reactions of I with ethyl phenylpropiolate (IIb),[13] benzoylphenylacetylene (IIc),[14] dibenzoylacetylene (IId),[15] and methyl propiolate (IIe)[16] afforded the corresponding ring expansion compounds (IIIb—e). The yields and the properties are summarized in Table 1.

Reaction of IIIa with 2,4,6-Trinitrobenzenesulfonic Acid (TNBS-H). An equimolar amount of TNBS-H was added to a solution of IIIa in methanol at room temperature and dimethyl-2,3-dicarbomethoxy-4-oxo-1-cyclooctenylsulfonium 2,4,6-trinitrobenzenesulfonate (IVa) was obtained instantly in quantitative yield. Mp 202.0°C (dec) (recrystallized from methanol).

Similarly, reactions of IIIb—e with TNBS-H afforded the corresponding 2,4,6-trinitrobenzenesulfonates (IVb—e) quantitatively. The results are also shown in Table 1.

Desulfurization of IIIa with Raney Nickel. A mixture of IIIa (0.87 g, 2.9 mmol) and large excess of Raney nickel (W-4)[17] in 20 m*l* of water and 15 m*l* of ethanol was heated at 90—100°C for 8.5 hr. After removal of precipitates from the hot reaction mixture by centrifugal separation, the solution was evaporated to give 2,3-dicarbomethoxy-4-oxocyclooctene (V), 0.35 g (50%), mp 75.0—76.0°C (purified by sublimation). Found: C, 59.69; H, 6.90%. Calcd for $C_{12}H_{16}O_5$: C, 59.99; H, 6.71%. The melting point was not depressed by admixture with an authentic sample prepared by the method of Brannock *et al.*[7] The IR spectra of both samples are identical.

a) Anion of starting salt. b) Decomposition point. c) 2,4,6-Trinitrobenzenesulfonate.
d) Not isolated. e) Methylethylsulfonium-2-oxocyclododecylide.

Reaction of I with IIa in Benzene. *1) Isolation of Bicyclic Sulfonium Betaine (VIIa)*: A solution of IIa (0.71 g, 5 mmol) in 15 m*l* of dry benzene was added over a period of 25 min at 10°C to a suspension of I (0.79 g, 5 mmol) in 30 m*l* of dry benzene. After stirring for 2 hr, the resulting bright yellow precipitates (VIIa), 0.93 g (62%), were filtered, washed and dried at reduced pressure. IR (KBr): 1710, 1677, and 1532 cm^{-1}. VIIa melted at 90—100°C, resolidified above this temperature and decomposed at 165°C. When VIIa was heated at 90°C for several minutes, its IR spectrum became identical with that of IIIa.

2) Alkylation of VIIa with Triethyloxonium Fluoborate.[18] When VIIa was allowed to react with triethyloxonium fluoborate at room temperature for 6 hr, dimethyl-2,3-dicarbomethoxy-4-ethoxy-1,3-cyclooctadienylsulfonium fluoborate was produced in quantitative yield. Mp 147—148°C (Methanol). Found: C, 45.92; H, 5.88; S, 7.94%. Calcd for $C_{16}H_{25}BF_4O_5S$: C, 46.17; H, 6.06: S, 7.69%. IR (KBr): 1727, 1709, 1681, and 1590 cm^{-1}. NMR: δ 1.43 (3H, t, Me–CH_2, J=4.5 Hz), 1.9—2.8 (8H, m, C_4H_8), 3.13 (6H, s, $Me_2\overset{+}{S}$), 3.65 (3H, s, MeOCO), 3.78 (3H, s, MeOCO), and 6.20 (2H, q, Me–CH_2–O, J=4.5 Hz) ppm.

The same sulfonium fluoborate was obtained by the reaction of IIIa with triethyloxonium fluoborate.

Reaction of Dimethylsulfonium-2-oxocycloheptylide (VIII) with II. When VIII was treated with IIa—c in DMSO in the same manner as described above for the reaction between I and II, the corresponding ring expansion products (IXa—c) were obtained. Reactions of IXa—c with TNBS-H gave 2,4,6-trinitrobenzenesulfonates (IXa—c·TNBS-H) in quantitative yields. The results are listed in Table 2.

Reaction of Dimethylsulfonium-2-oxocyclopentylide (X) with IIa. To a solution of dimethyl-2-oxocyclopentylsulfonium 2,4,6-trinitrobenzenesulfonate[19] (2.19 g, 5 mmol) and IIa (0.71 g, 5 mmol) in 10 m*l* of dry DMSO, a solution of *n*-butyllithium (5 mmol) in 6 m*l* of *n*-hexane was added *via* hypodermic syringe over a period of an hour with occasional cooling. After stirring for 2 hr, TNBS-H (5 mmol) was added to the reaction mixture. Addition of methanol gave crystalline dimethyl-2,3-dicarbomethoxy-4-oxo-1-cycloheptenylsulfonium 2,4,6-trinitrobenzenesulfonate (XIa·TNBS-H), mp 194°C (dec) (methanol), in 52% yield. Found: C, 39.34; H, 3.80; N, 7.44; S, 10.79%. Calcd for $C_{19}H_{21}N_3O_{14}S_2$: C, 39.38; H, 3.63; N, 7.25; S, 11.05%.

Reaction of IIIa with Benzenethiol. When a mixture of IIIa (0.300 g, 1 mmol) and benzenethiol (0.110 g, 1 mmol) in 15 m*l* of dry benzene was stirred at room temperature, the crystals of IIIa gradually disappeared to give an almost clear solution after 6 hr. Stirring was continued overnight and the solvent was removed under reduced pressure. The resulting viscous oil was chromatographed over silica gel. Elution with ether-petroleum ether (1: 1) gave 1-phenylthio-2,3-dicarbomethoxy-4-oxocyclooctene (XIIa), mp 118.5—119.5°C (*n*-hexane), in 80% yield. Further elution with the same mixture afforded 1-methylthio-2,3-dicarbomethoxy-4-oxocyclooctene (XII, R=MeS) in 18% yield.

In a similar way, reactions of IIIa with ethanethiol, hydrogen cyanide and methanol gave 1-substituted-4-oxocyclooctene derivatives(XIIc—d) in high yields without concomitant formation of XII(R=MeS). In the case of hydrogen cyanide, the reaction was carried out with twofold excess of hydrogen cyanide generated *in situ* from potassium cyanide and acetic acid. The yields, melting points, NMR spectra and analytical values of XIIa—d are shown in Table 3.

Reaction of IIIa with Acetylacetone. A solution of IIIa (0.300 g, 1 mmol) and acetylacetone (0.100 g, 1 mmol) in 10 m*l* of dry DMSO was heated at 90—100°C for 18 hr. The reaction mixture was poured into ice-water and worked up with ether to give a semi-crystalline viscous oil which was chromatographed over silica gel. Elution with methylene chloride afforded 1-methylthio-2,3-dicarbomethoxy-4-oxocyclooctene (XII, R=MeS) in 23% yield, mp 124—125°C (*n*- or *c*-hexane). Found: C, 54.69; H, 6.47; S, 11.10%. Calcd for $C_{13}H_{18}O_5S$: C, 54.54; H, 6.34; S, 11.18%. IR (KBr): 1703, 1650, 1618, and 1553 cm^{-1}. NMR: δ 1.2—2.85 (8H, m, C_4H_8), 3.37 (3H, s, MeS), 3.68 (3H, s, MeOCO), 3.70 (3H, s, MeOCO), and 12.67 (1H, s, CO–CH–CO_2Me) ppm.

Similarly, reactions of IIIa with diethyl malonate, malononitrile, ethyl acetoacetate, dibenzoylmethane and trifluoroacetylacetone in various solvents such as DMSO, DMF, acetonitrile, methylene chloride, THF, dioxane or benzene also gave XII (R=MeS) in 23—74% yields.

Reaction of IIIa with Benzoyl Chloride. When a mixture of I (0.310 g, 1.03 mmol) and benzoyl chloride (0.149 g, 1.05 mmol) in 15 m*l* of dry benzene was stirred at room temperature, the yellow crystals of IIIa gradually disappeared. After being stirred overnight, the solvent was evaporated to give a viscous oil which was chromatographed over silica gel. 1-Methylthio-2,3-dicarbomethoxy-4-benzoyloxy-1,3-cyclooctadiene (XIIIa), mp 138.5—139.5°C, was obtained in 68%

19) The sulfonium salt was prepared from dimethyl sulfide, 2-bromocyclopentanone and silver 2,4,6-trinitrobenzenesulfonate.[11]

yield by elution with ether-petroleum ether (2: 3). NMR (DMSO-d_6): δ 1.1—2.9 (8H, m, C_4H_8), 2.40 (3H, s, MeS), 3.42 (3H, s, MeOCO), 3.47 (3H, s, MeOCO) and 7.4—8.1 (5H, m, C_6H_5) ppm.

In a similar way, the reactions of IIIa with acetyl chloride, methyl iodide and benzyl bromide afforded the corresponding diene ester (XIIIb) and diene ethers (XIIIc, d). The results are recorded in Table 4.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 255—258(1972)

Structure and Reactivity of Organic Ions in Gas-Phase Radiolysis. III. The Benzenonium Ions Formed by the Reactions of CH_5^+ and $C_2H_5^+$ Ions from Methane with *o*-Xylene[1]

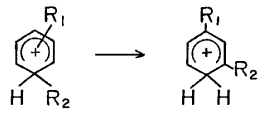
Yukio YAMAMOTO, Setsuo TAKAMUKU, and Hiroshi SAKURAI

The Radiation Laboratory, The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

(Received June 18, 1971)

The gas-phase radiolysis of mixtures of *o*-xylene and excess methane has been studied at room temperature as a function of methane pressure and the added NO and NH_3 in order to investigate the reactions of CH_5^+ and $C_2H_5^+$ ions from methane with *o*-xylene. It has been suggested that the proton transfers from these ions to *o*-xylene result in the isomerization to *m*-xylene *via* an intermediate σ complex, dimethylbenzenonium ion, and that a part of the $C_2H_5^+$ ions is added to *o*-xylene leading to the formation of two isomers of dimethylethylbenzene. The proposed mechanism of the methane-sensitized isomerization of *o*-xylene to *meta* isomer has been supported by the observation that both *m*-xylene-d_0 and *m*-xylene-d_1 were formed in the radiolysis of a mixture of *o*-xylene and methane-d_4. The isotope effect (k_H/k_D) on the proton loss from the dimethylbenzenonium ion was roughly estimated to be 1.8 ± 0.4. Group migration of intermediate σ complexes was discussed.

In previous studies,[2-5] it was reported that, in the gas-phase radiolysis of toluene, ethylbenzene, and *m*-xylene, $C_7H_7^+$ ions,[6] formed from these alkylbenzenes, react with the parent alkylbenzene molecules to produce the corresponding benzylated alkylbenzenes, alkyldiphenylmethanes.[7] The products predominantly consisted of such isomers as are benzylated at a *meta* position to the resident alkyl groups. It has also been reported that, in the gas-phase radiolysis of a mixture of propane with benzene or toluene, the isopropylation of the aromatics by $C_3H_7^+$ ions from propane was observed, and in the case of toluene the isopropylation occurred mainly at a *meta* position at higher pressures of toluene.[1] Attention was paid to the mechanism of these electrophilic aromatic substitution reactions in the gas phase in order to explain the observed isomer distribution of the products, which is in contrast to that known in analogous liquid-phase reactions such as the Friedel-Crafts reactions.[8] We have proposed a mechanism involving an isomerization process of intermediate σ complexes, benzenonium ions,[1,3] where R_1 and R_2 show the resident



I II

and attacking alkyl groups, respectively. Thus, it has been suggested that the primarily formed complex I easily isomerizes to the more stable one II, which is most effectively stabilized by the inductive effect of alkyl groups, since in the gas phase it exists as a free ion with a certain internal energy. We have extended the study of this type of reaction, which proceeds through benzenonium ion intermediate, especially in order to investigate its intramolecular rearrangement.

In the high pressure mass spectrometry of methane, it has been reported that the major product ions at higher pressures are CH_5^+ and $C_2H_5^+$ ions, which comprise approximately 90% of the total ionization.[9] The ions are unreactive with methane but highly reactive with some kinds of additives such as ammonia, water, and aromatic hydrocarbons.[10,11] Munson and Field reported that these ions react with several aromatic hydrocarbons to yield predominantly protonated aromatic ions along with a relatively small amount of ethyl ion adducts.[11] The present investigation deals with the reactions of these benzenonium ions expected to

be also formed in the gas-phase radiolysis of mixtures of *o*-xylene and excess methane.

Experimental

Materials. *o*-Xylene obtained from Wako Pure Chem. Indust. Co. was purified by the usual method. After distillation using a 1 m column packed with stainless helices, the purity determined gas chromatographically by means of flame-ionization detection was more than 99.9%. The purified *o*-xylene was dried over sodium, degassed, and stored in a high vacuum line. Methane-h_4 and methane-d_4, obtained from Takachiho Shoji Co. and Merck and Dohme of Canada, respectively, were also stored in the vacuum line, after several trap-to-trap distillations. These samples were thoroughly dried by passing through sodium mirrors prior to use. Ammonia and nitric oxide, both obtained from Takachiho Shoji Co., were also purified by several trap-to-trap distillations.

Procedures. Experimental procedures were almost the same as those reported previously.[1] Irradiation was carried out in Pyrex cylinders approximately 120 m*l* in volume with γ rays from a 5000 Ci ^{60}Co source at room temperature. The dose rate and the dose were 3.7×10^{15} eV/hr·μmol and 2.6×10^{17} eV/μmol, respectively, for *o*-xylene. The products were analyzed by gas chromatography using a combination of Bentone 34 (3 m) and Apiezon L (3 m) and a flame-ionization detector. The column temperatures were 100 and 140°C for the products with retention times less and more than that of *o*-xylene, respectively. The isotopic distribution of *m*-xylene formed in the radiolysis of a mixture of *o*-xylene and methane-d_4 was determined using a directly coupled gas chromatograph-mass spectrometer (Hitachi RMS-4 mass spectrometer) at an ionizing potential of 80 eV.

Results and Discussion

All the radiolysis experiments were performed at the same pressure of *o*-xylene, 3.3 ± 0.2 mmHg. The *G* values were calculated on the basis of the energy absorbed by *o*-xylene. The *G* values of the products of the gas-phase radiolysis of a mixture of *o*-xylene and methane in the presence and absence of a radical scavenger, nitric oxide, together with those of the radiolysis of pure *o*-xylene are presented in Table 1.[12] The dependence of the product yields on methane pressure is shown in Figs. 1 and 2. When excess methane was added to *o*-xylene, the *G* values of *m*-xylene, *o*-ethyltoluene, and 1,2,3- and 1,2,4-trimethylbenzenes appreciably increased, and 1,2-dimethyl-3-ethylbenzene and 1,2-dimethyl-4-ethylbenzene were newly formed. The yields of these products increased with increasing methane pressure. Among these products, *o*-ethyltoluene and two isomers of trimethylbenzene were appreciably reduced by the addition of NO (Table 1). Thus, it is suggested that these products are mainly formed by the reactions of radicals from methane with *o*-xylene as follows.

$$R\cdot + (CH_3)_2C_6H_4 \longrightarrow RH + CH_3C_6H_4CH_2\cdot \quad (1)$$

$$CH_3C_6H_4CH_2\cdot + CH_3\cdot \longrightarrow CH_3C_6H_4CH_2CH_3 \quad (2)$$

$$CH_3\cdot + (CH_3)_2C_6H_4 \longrightarrow (CH_3)_3C_6H_3 + H \quad (3)$$

1,2-Dimethyl-3-ethylbenzene	0	0.40	0.51
1,2-Dimethyl-4-ethylbenzene	0	1.03	1.18

a) The mol ratio of added NO to methane was about 0.07.

12) In a previous study of the gas-phase radiolysis of pure *o*-xylene, it was reported that benzocyclobutene is also formed with a *G* value of 0.08 at a *o*-xylene pressure of 4.7 mmHg [K. E. Wilzbach and L. Kaplan, *Advances in Chemistry Series*, No. 82, American Chemical Society, Washington, D. C., (1968), p. 134]. However, the yield of this product could not be determined under the analytical conditions of this study. The yields of other liquid products in these studies are in good agreement with each other.

where R· shows any radical or a hydrogen atom formed from methane. On the other hand, *m*-xylene and two isomers of dimethylethylbenzene were not so much affected by the added NO, indicating that the methane-sensitized isomerization and ethylation of *o*-xylene are nonradical processes.

It might be expected that the major ionic reactions in the primary process of the gas-phase radiolysis of mixtures of *o*-xylene and excess methane are the proton transfer from the CH_5^+ and $C_2H_5^+$ ions and the addition of the $C_2H_5^+$ ions to *o*-xylene as follows.

$$CH_4 \xrightarrow{\sim\sim} CH_5^+, C_2H_5^+ \qquad (4)$$

$$CH_5^+ \text{ (or } C_2H_5^+) + \text{C}_8\text{H}_{10} \longrightarrow \text{C}_8\text{H}_{11}^+ + CH_4 \text{ (or } C_2H_4) \qquad (5)$$

IIIa

$$C_2H_5^+ + \text{C}_8\text{H}_{10} \longrightarrow \text{C}_{10}\text{H}_{15}^+ \qquad (6)$$

IVa

In solution chemistry it is known that the acid-catalyzed isomerization of *o*-xylene results in the exclusive formation of *m*-xylene.[13] Such a result is similar to that of the methane-sensitized isomerization of *o*-xylene. Thus, the methane-sensitized isomerization might be attributed to an acid-catalyzed reaction where the CH_5^+ and $C_2H_5^+$ ions act as Brønsted acids to *o*-xylene. Ethylation of *o*-xylene might also be considered to be an electrophilic substitution reaction by the $C_2H_5^+$ ions analogous to the benzylation and isopropylation of aromatics.[1-5]

It has been reported that the CH_5^+ and $C_2H_5^+$ ions from methane are highly reactive with NH_3 though unreactive with NO[10]

$$CH_5^+ \text{ (or } C_2H_5^+) + NH_3 \longrightarrow NH_4^+ + CH_4 \text{ (or } C_2H_4) \qquad (7)$$

Thus, it may be expected that a competition would occur between reactions (5) and (6) and reaction (7)

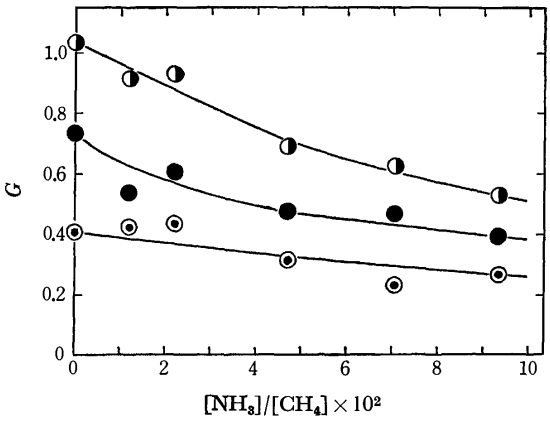

Fig. 3. Effect of added NH_3: ●, *m*-Xylene; ⊙, 1,2-Dimethyl-3-ethylbenzene; ◑, 1,2-Dimethyl-4-ethylbenzene.

13) H. C. Brown and H. Jungk, *J. Amer. Chem. Soc.*, **77**, 5579 (1955).

in the *o*-xylene-methane-NH_3 system. The effect of added NH_3 on the yields of *m*-xylene and two isomers of dimethylethylbenzene was studied from this point of view at a methane pressure of 51.1 mmHg, and the result is shown in Fig. 3. It was observed that the *G* values of these products decreased apparently with increasing NH_3 concentration, while those of *o*-ethyltoluene and two isomers of trimethylbenzene, formed by radical reactions, were not appreciably affected by the added NH_3. Thus, it seems reasonable to conclude that the methane-sensitized isomerization and ethylation of *o*-xylene are initiated by reactions (5) and (6), respectively, and the subsequent reactions may be considered to be as follows.

IIIa → IIIb → IIIc

IIIc → IIId $\xrightarrow{-H^+}$ m-Xylene

IVa → IVb or IVc

IVb or IVc $\xrightarrow{-H^+}$ Dimethylethylbenzene

where the primarily formed intermediate σ complexes IIIa and IVa have certain excess internal energies because of the exothermicities of reactions (5) and (6), and are easily isomerized to the more stable σ complexes IIId and IVb or IVc, respectively. The mechanisms are identical with those of the acid-catalyzed isomerization of *o*-xylene in solution and of the benzylation and isopropylation of aromatics in gas-phase radiolysis.[1,3] The loss of a proton from the intermediate σ complexes to produce the neutral products may be considered to be due to the proton transfer from these complexes to *o*-xylene molecules or to other species with higher proton affinities existing in the radiolytic system.[1,3]

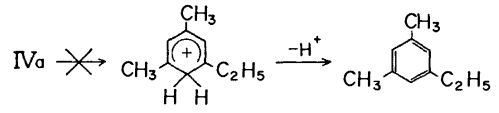
As is shown in Figs. 1 and 2, the dependence of the *m*-xylene yield on methane pressure differed from those of two isomers of dimethylethylbenzene; the sensitization effect on the formation of *m*-xylene was appreciably reduced at higher pressures of methane, while the yields of dimethylethylbenzenes increased almost linearly with methane pressure. Such a deviation of the plot of the *m*-xylene yield against methane pressure from linearity could be explained by a selective consumption of the CH_5^+ ions by the radiolysis products from methane; it has been reported that in the high pressure mass spectrometry of methane containing a small amount of ethane, which is the most abundant hydrocarbon product in the gas-phase radiolysis of methane,[14] the

14) See for example, K. Yang and P. J. Manno, *ibid.*, **81**, 3507 (1959).

CH_5^+ ions rapidly decrease with increasing pressure, while the $C_2H_5^+$ ions somewhat increase.[15]

The activation energy of the acid-catalyzed isomerization of *o*-xylene in solution has been estimated to be 22.8 kcal/mol;[13] it may be considered that the analogous reaction in the gas phase requires the same order of activation energy. The reaction heats of the protonation of benzene by the CH_5^+ and $C_2H_5^+$ ions have been calculated to be -32 and $+3$ kcal/mol, respectively,[11] although those for *o*-xylene are not known. Since the methyl inductive effect would result in a higher proton affinity of *o*-xylene than that of benzene, the protonation of *o*-xylene by the CH_5^+ ion may be considered to be exothermic with more than 32 kcal/mol. Thus, it seems also correct to conclude that the protonation of *o*-xylene by the CH_5^+ ions results in the isomerization to *m*-xylene; the overall reaction is exothermic. However, it is not at present possible to decide whether the $C_2H_5^+$ ions contribute to the isomerization of *o*-xylene as well as the CH_5^+ ions or not.

In these experiments of the gas-phase radiolysis of mixtures of *o*-xylene and methane, 1,3-dimethyl-5-ethylbenzene was not detected. This indicates that the migration of the resident methyl groups of *o*-xylene does not occur in the transition state of the ethylation of *o*-xylene by the $C_2H_5^+$ ions, in spite of the fact that it gives the most stable σ complex of the dimethylethylbenzenonium ions as follows.



This finding could probably be explained in terms of the activation energy of the methyl migration and the excess internal energy of the intermediate complex IVa.

In order to obtain further information about the mechanism of the methane-sensitized isomerization in gas-phase radiolysis, the radiolysis of a mixture of *o*-xylene and methane-d_4 was examined at a methane-d_4 pressure of 51.4 mmHg, and the mass spectrum of the produced *m*-xylene was measured and compared with that of authentic *m*-xylene-d_0, both of which are shown in Fig. 4. The *G* value of *m*-xylene in this experiment was 0.81, and no difference in the product formation was observed between the experiments using methane-d_0 and methane-d_4. The mass spectra shown in Fig. 4 indicate that both *m*-xylene-d_1 and *m*-xylene-d_0 were formed in the radiolysis of the mixture of *o*-xylene and methane-d_4.[16] The mechanism proposed above is supported by this result; the deuterium ion transfer from the CD_5^+ and $C_2D_5^+$ ions to *o*-xylene yields the benzenonium ion containing a deuterium atom which, after the methyl migration, loses a proton or a deuterium ion to give *m*-xylene-d_1 or *m*-xylene-d_0, respectively. The ratio of *m*-xylene-d_1 to *m*-xylene-d_0 was calculated to be 2.0 ± 0.2 from the relative intensities of the ions with mass 91, 92, and 93 of these mass spectra. The calculation was based on the assumption that the *m*-xylene-d_1, which contains the deuterium in the aromatic ring, yields the mass 91 and 92 ions with the relative yields of 11 and 89%, respectively.[17] An estimation of the isotope effect (k_H/k_D) on the proton loss from the intermediate σ complex IIId is possible on the basis of the following assumptions: (a) In the radiolysis of the mixture of *o*-xylene and methane-d_4, *m*-xylene is formed by the direct energy absorption of *o*-xylene with the same *G* value as in the direct radiolysis of *o*-xylene, 0.19 (Table 1). (b) The increase of *m*-xylene by the addition of methane-d_4 to *o*-xylene is exclusively attributed to the reactions of the CD_5^+ and $C_2D_5^+$ ions with *o*-xylene. (c) In the transition state of the methane-sensitized isomerization of *o*-xylene, a rapid hydrogen migration occurs around a ring of the intermediate σ complex, and the deuterium is statistically distributed among the five possible positions attached to the ring carbons before the loss of a proton or a deuterium ion.[18] The value of k_H/k_D obtained in this way was 1.8 ± 0.4.

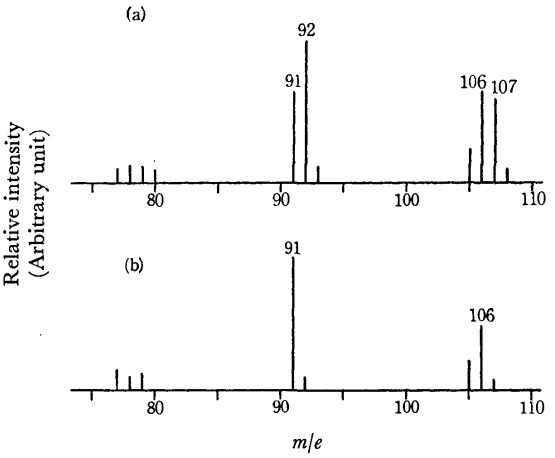


Fig. 4. Partial mass spectra of (a) the *m*-xylene formed in the gas-phase radiolysis of an *o*-xylene-CD_4 mixture and (b) authentic *m*-xylene-d_0.

The most interesting result obtained in this study is that the ionic species formed from methane by γ irradiations react with *o*-xylene to produce *m*-xylene *via* an intermediate σ complex, and this reaction is identical with the acid-catalyzed isomerization of *o*-xylene in solution. This conclusion was strongly supported by the isotopic distribution of the *m*-xylene, formed in the gas-phase radiolysis of a mixture of *o*-xylene and methane-d_4.

We wish to thank Mr. Tamotsu Yamamoto and Mr. Tomikazu Sawai in the Radiation Laboratory for assistance in the γ irradiations.

15) M. S. B. Munson and F. H. Field, *J. Amer. Chem. Soc.*, **87**, 3294 (1965).

16) The mass spectra indicate that no other *m*-xylene containing more than one deuterium atom was formed; the *m*-xylene-d_1 was not formed by a hydrogen-deuterium exchange reaction on the produced *m*-xylene-d_0.

17) H. M. Grubb and S. Meyerson, "Mass Spectrometry of Organic Ions," ed. by F. W. McLafferty, Academic Press, New York (1963), p. 453.

18) This assumption seems to be reasonable on the basis of the following reports: a) Rapid hydrogen migration around the ring of benzenonium ions has been observed in acidic solutions of aromatic hydrocarbons. See for example, G. A. Olah, R. H. Schlosberg, D. P. Kelly, and Gh. D. Mateescu, *J. Amer. Chem. Soc.*, **92**, 2546 (1970). b) In the high pressure mass spectrometry of methane containing a small amount of 1-methyl-4-isopropylbenzene, the result has been accounted for by rapid hydrogen migration (see Ref. 11).

Linear Conjugated Systems Bearing Aromatic Terminal Groups. VI. Syntheses and Electronic Spectra of 6,6′-Dichrysenylpoly-ynes

Shuzo AKIYAMA and Masazumi NAKAGAWA

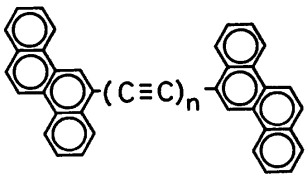
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received June 18, 1971)

6,6′-Dichrysenylpoly-ynes (I_n, $n=1$—6) have been synthesized and their electronic spectra were measured. It was found that the bathochromic shifts of the longest-wavelength absorption peaks (λ_{max}) along with an increase in the number of acetylenic bond (n) were proportional to $n^{1.6}$ ($\lambda_{max}=5.8\,n^{1.6}+394$ nm).

In previous papers we reported that new linear relationships between the longest-wavelength absorption maxima (λ_{max}) and the xth power of the number of acetylenic bond (n) [$\lambda_{max} \infty n^x$] hold in various kinds of diarylpoly-ynes (II_n[1], III_n[2], IV_n[3], V_n[3], VI_n[4], VII_n[4], and $VIII_n$[4]) (Fig. 1). It was shown that the value of x is dependent on the nature of terminal groups as well as on the position of linking of polyacetylene chain.

In order to get further information on the role of aromatic terminal groups in the photoexcitation of diarylpoly-ynes, 6,6′-dichrysenylpoly-ynes (I_n) have been synthesized. The present paper deals with the syntheses and spectral regularity of I_n.



I_n

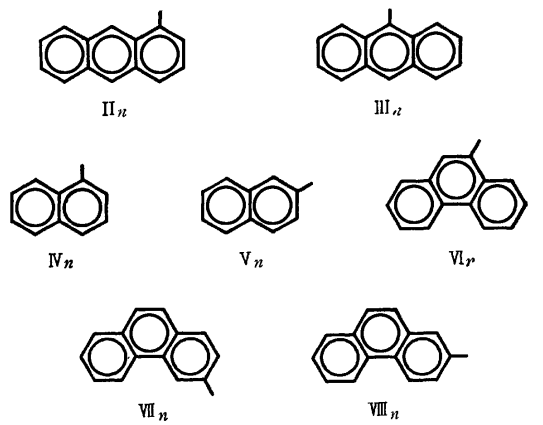

Fig. 1. The terminal groups (R) of diarylpoly-ynes [R(C≡C)$_n$R].

ylene (I_1) by means of an intramolecular Wittig reaction has been reported[5] together with other diarylacetylenes.

Acetyl-[6] and formyl derivatives (IX and XI) were used as starting materials for the syntheses of 6,6′-dichrysenylpoly-ynes (I_n, n=2—6). 6-Chrysenecarboxaldehyde (XI) was obtained in a good yield by chromium trioxide-pyridine oxidation of hydroxymethyl derivative (X).[7] The reaction sequence adapted for the preparation of I_n is a general method which had been established to be useful for the syntheses of various types of diarylpoly-ynes.[1-4]

6,6′-Dichrysenylpoly-ynes (I_1—I_6) were found to be fairly stable. It was observed that I_n is less soluble in common organic solvents as compared with other diarylpoly-ynes. I_2 and I_6 in particular were found to be the least soluble materials. Upon recrystallization from toluene, the solvent persistently incorporated into the crystals of diacetylene (I_2) and tetraacetylene (I_4), and the solvent of crystallization of I_4 (1 mol) could not be removed *in vacuo* even at elevated temperature.

The color of crystals, decomposition points and IR absorptions due to $\nu_{C\equiv C}$ are summarized in Table 1. The highest wave number of $\nu_{C\equiv C}$ was observed in the spectrum of tetraacetylene (I_4), as in the case of II$_n$[1], diphenyl- and dimethylpoly-ynes.[8] Like other series

Table 1. Physical properties of I_n

n	Color of crystals	Decomposition point (°C)	$\nu_{C\equiv C}$ (cm^{-1})

of diarylpoly-ynes, the absorption intensities of the most intense peaks in $\nu_{C\equiv C}$ bands seem to increase with the increase in the length of poly-yne chain. The IR spectra of I_n are shown in Fig. 2.

Electronic Spectra. The absorption curves and electronic spectral data of I_n are shown in Fig. 3 and Table 2. The L_b band of chrysene could not be observed in the spectra of I_n, due presumably to its coalescence with the L_a band which is shifted to a longer wavelength by interaction with polyacetylenic chromophore.

Chrysene can be regarded as benzophenanthrene. Thus, the 6-position in chrysene corresponds to either 3- or 9-position of phenanthrene. Actually, 6,6′-dichrysenylpoly-ynes (I_n) exhibit closely related electronic spectra with those of 3,3′- and 9,9′-diphenanthrylpoly-ynes.[4] The characteristic of the spectrum of chrysene could not be observed even in the spectra of a lower member of I_n just as in the case of diphenanthrylpoly-ynes. Like the spectra of other diarylpoly-ynes, the pronounced vibrational fine structure in the long-wavelength absorption band exhibits characteristic features of the spectra of I_n. The magnitude of red shift of the longest-wavelength maximum (λ_{max}) increases gradually with an increase in the number of n (11, 17, 21, 22, and 24 nm).

Table 3. Spacing of vibrational fine structure

n	1	2	3	4	5	6
Spacing (cm^{-1})	—	2050	1890	2300	1970	1870

As is shown in Table 3, the highest wave number of spacing between the longest-wavelength vibrational subband and the next longest-wavelength one was observed in the spectrum of tetraacetylene (I_4), which corresponds to the fact that the highest wave number of $\nu_{C\equiv C}$ is also observed in I_4.[9]

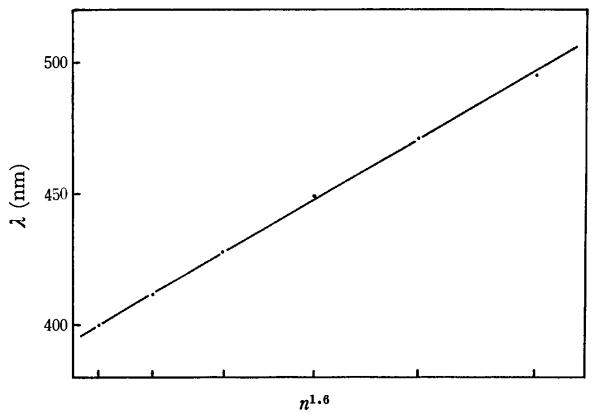

Fig. 4. Linear relationship between λ and $n.^{1.6}$

The plots of longest-wavelength absorption maxima (λ_{max}) against $n^{1.6}$ gave an excellent straight line as illustrated in Fig. 4. The linear relationship could be expressed by the following empirical formula:[10]

$$\lambda_{max} = 5.8n^{1.6} + 394 \text{ nm (in toluene)}.$$

The observed and calculated values of λ_{max} are listed in Table 4.

Table 4. Observed and calculated values of λ_{max} (nm)

Experimental

All melting points are uncorrected. The electronic spectra were obtained on a Hitachi EPS-3T Spectrophotometer at room temperature. The infrared spectra were measured with a Hitachi EPI-2 Infrared Spectrophotometer by KBr-disk method. Evaporation of solvent and concentration of solution were performed under reduced pressure.

6-Chrysenecarboxaldehyde (XI). A solution of X (14.30 g, 0.056 mol)[7] in pyridine (120 m*l*) was added to a chilled solution of chromium trioxide (18.0 g, 0.18 mol) in pyridine (250 m*l*). The mixture was shaken in an ice-salt bath for 30 min, and then for 45 min at room temperature. The reaction mixture was poured into water (2 *l*). The resulting precipitate was filtered, washed with water and dried to give a brown powder. The powder was extracted with benzene (500 m*l*) using a Soxhlet type extractor. The extract was passed through a short column of alumina (15 g). Concentration of the filtrate (up to *ca.* 30 m*l*) gave faint yellow cubes (12.30 g, 86%, mp 164—166°C). Recrystallization of this material three times from benzene gave analytical sample with mp 165—166°C.

Found: C, 88.91; H, 4.66%. Calcd for $C_{19}H_{12}O$: C, 89.04; H, 4.72%. IR: 1690 (C=O) cm^{-1}.

6-Ethynylchrysene (XII). Chlorination of 6-Acetylchrysene (XI): A mixture of 6-acetylchrysene (XI, 27.0 g, 0.1 mol),[6] phosphorus pentachloride (22.9 g, 0.11 mol) and benzene (150 m*l*) was refluxed for 75 min. The volatile material was removed under reduced pressure and the residue was placed for several hours in an evacuated desiccator containing potassium hydroxide. Light brown crystalline mass obtained was subjected to the subsequent reaction.

Dehydrochlorination of the Chloride: The crude chloride in tetrahydrofuran (100 m*l*) was added over a period of 20 min at −70°C to a suspension of sodium amide (from sodium, 9.2 g, 0.4 g-atom) in liquid ammonia (500 m*l*). After 3 hr the ammonia was allowed to evaporate, and then a saturated solution of ammonium chloride was added to the reaction mixture. The organic solvent was distilled off and the residue was collected by filtration and washed with water. The benzene extract of the residue (800 m*l*) was passed through a short column of alumina (80 g). Concentration of the filtrate resulted in yellow cubes, mp 176—178°C (dec.), 24.0 g (96%). A solution of the crude crystals in petroleum ether (bp 60—80°C) was passed through a thin layer of alumina. Crystals obtained by concentrating the filtrate were recrystallized from methanol to afford colorless cubes (mp 182°C (dec.)), which gave yellow silver and yellow cuprous acetylides.

Found: C, 94.89; H, 4.79%. Calcd for $C_{20}H_{12}$: C, 95.21; H, 4.79%. UV: $\lambda_{max}^{benzene}$ (log ε) 282 (4.97), 301.5 (3.93), 315 (4.10), 329 (4.33), 344 (4.35) nm. IR: 3280 (≡CH) cm^{-1}.

6,6′-Dichrysenyldiacetylene (I_2). A mixture of 6-ethynyl-

9) Detailed discussion on the spacing and the $\nu_{C\equiv C}$ will be given elsewhere.

10) The linear relationship between λ_{max} and n^x in various diaryl-poly-ynes could be explained in terms of HMO based on a modified bond-alternation approximation.

chrysene (XII, 0.070 g, 0.28 mmol), cupric acetate monohydrate (0.70 g), pyridine (20 ml) and methanol (5 ml) was stirred for 2 hr at 50°C. The reaction mixture was cooled. The insoluble material was collected by filtration and washed with methanol and water successively, yielding light yeollw fine crystals in a quantitative yield (dec. p>330°C). This was recrystallized from toluene to give yellow cubes (dec. p>330°C). Elemental analysis of the cryatals revealed that the substance contained solvent of crystallization, which could be removed by heating the crystals at 100°C for several hr under reduced pressure (2×10^{-3} mmHg).

Found: C, 95.35; H, 4.52%. Calcd for $C_{40}H_{22}$: C, 95.59; H, 4.41%.

6-Chrysenyl-2-propyn-1-ol (XIII). A solution of 6-formylchrysene (XI, 6.15 g, 0.024 mol) in tetrahydrofuran (200 ml) was added to an ice-cooled solution of ethynylmagnesium bromide (from magnesium, 1.80 g, 0.075 g-atom and ethyl bromide, 8.20 g, 0.075 mol) in tetrahydrofuran (35 ml). After having been stirred overnight at room temperature, the reaction mixture was decomposed by adding a saturated ammonium chloride solution. The organic layer was separated, and dried. Concentration of the solution (up to *ca.* 10 ml) gave an oily material, which was mixed with benzene (20 ml). Crystals deposited on warming the mixture were washed with a small amount of benzene to yield light brown fine crystals, mp 170—173°C, 5.98 g (88%).

Found: 89.15; H, 5.03%. Calcd for $C_{21}H_{14}O$: C, 89.33; H, 5.00%. IR: 3100—3400 (O–H), 3290 (≡CH), 1060 (C–O) cm^{-1}.

1,6-Di(6-chrysenyl)-1,6-dihydroxy-2,4-hexadiyne (XIV). A mixture of 6-chrysenyl-2-propyn-1-ol (XIII, 3.00 g, 0.011 mol), cuprous chloride (1.4 g), ammonium chloride (1.0 g) and acetone-methanol (1: 1, 80 ml) was vigorously stirred at room temperature under an atmosphere of oxygen at a slightly elevated pressure. After being stirred overnight, the precipitate deposited was collected by filtration and dissolved in tetrahydrofuran. Insoluble material was removed by filtration and the filtrate was passed through a short column of alumina (8 g). The crystals, 1.62 g (54%), obtained by evaporating the solvent were recrystallized from dioxane to give faint yellow needles (dec. p *ca.* 160°C). Elemental analysis indicates that the crystals contain 1 mol of dioxane as a solvent of crystallization.

Found: C, 84.96; H, 5.14%. Calcd for $C_{42}H_{26}O_2\cdot C_4H_8O_2$: C, 84.90; H, 5.27%. IR: 3600—3100 (O–H), 1065 (C–O) cm^{-1}.

6,6'-Dichrysenyltriacetylene (I_3). *Formation of XV*: A solution of thionyl chloride (0.21 g, 1.8 mmol) and pyridine (0.14 g, 1.8 mmol) in tetrahydrofuran (5 ml) was added to a solution of glycol (XIV, 0.337 g, 0.6 mmol) in tetrahydrofuran (15 ml) over a period of 15 min at −20°C, and the mixture was then shaken for 30 min. The reaction mixture containing chloride (XV) was subjected to the following reaction without isolation.

Dehydrochlorination of dichloride (XV): To a vigorously stirred suspension of sodium amide (from sodium, 0.46 g, 0.02 g-atom) in liquid ammonia (90 ml), the solution of dichloride (XV) was added in one portion at −70°C. After 30 min, ammonium chloride (2.5 g) was added and the ammonia was allowed to evaporate. After the organic solvent had been removed, a small amount of water was added to the residue. The insoluble material was collected and washed successively with water, a small amount of ethanol and benzene, and then dissolved in hot toluene (350 ml). The hot solution was passed through a short column of alumina (13 g). On cooling the filtrate to room temperature, I_3 crystallized out as yellow needles (dec. p *ca.* 295°C, 0.147 g, 47%). Analytical specimen was prepared by recrystallization from toluene.

Found: C, 95.94; H, 4.20%. Calcd for $C_{42}H_{22}$: C, 95.79; H, 4.21%.

1-(6-Chrysenyl)-2-butyn-1,4-diol (XVI). A solution of aldehyde (XI, 5.1 g, 0.02 mol) in tetrahydrofuran (200 ml) was added to an ice-cooled solution of Grignard derivative of propargyl alcohol in tetrahydrofuran (70 ml), which had been prepared from magnesium, 2.88 g, 0.12 g-atom, ethyl bromide, 13.1 g, 0.12 mol and propargyl alcohol, 3.36 g, 0.06 mol. The mixture was allowed to stand overnight, then a saturated aqueous solution of ammonium chloride was added to the reaction mixture. The organic layer separated was dried and concentrated. The residue was treated with a small amount of hot benzene to cause crystallization. The crystals (mp 193—197°C, 5.54 g, 89%) were recrystallized from ethanol-benzene to give colorless fine crystals (mp 197—198°C).

Found: C, 84.27; H, 5.19%. Calcd for $C_{22}H_{16}O_2$: C, 84.59; H, 5.16%. IR: 3600—3100 (O–H), 1040—1000 (C–O) cm^{-1}.

6-Butadiynylchrysene (XVIII). *Preparation of XVII*: A solution of thionyl chloride (3.22 g, 0.027 mol) in tetrahydrofuran (10 ml) was added over a period of 15 min to a solution of glycol (XIV, 2.00 g, 6.4 mmol) and pyridine (2.13 g, 0.027 mol) in tetrahydrofuran (40 ml) at −10°C. After the mixture had been stirred for further 2 hr at room temperature, crushed ice was added, and extraction was carried out with benzene (100 ml). The extract was washed with an aqueous solution of sodium hydrogen carbonate, and dried. The solvent was removed to yield an oily material which solidified on standing.

Dehydrochlorination of dichloride (XVII): The crude XVII in tetrahydrofuran (15 ml) was treated with sodium amide (from sodium, 1.0 g, 0.44 g-atom) in liquid ammonia (100 ml) for 1 hr at −70°C. The reaction mixture was worked up as usual. The product was repeatedly digested with petroleum ether (bp 60—80°C, total 600 ml). The filtrate obtained by passing the extract through a thin layer of alumina (3.5 g) was concentrated to yield XVIII as faint yellow crystals, 1.138 g (34%). The butadiynyl compound (XVIII) was found to be extremely unstable, and readily turned into an insoluble deep green substance. XVIII gave orange-yellow silver and deep yellow cuprous acetylides.

UV: $\lambda_{max}^{\text{petroleum ether}}$ 357 (L_a), 375 (L_b) nm.

6,6'-Dichrysenyltetraacetylene (I_4). The yellow crystalline powder (0.180 g, 50%) obtained by the cupric acetate oxidation [cupric acetate monohydrate (2.5 g), methanol (5 ml) and pyridine (50 ml), 1 hr at 50°C] of XVIII (0.360 g, 1.3 mmol) was digested with boiling toluene (350 ml). The hot extract was percolated through a short column of alumina (10 g). On standing the filtrate, I_4 containing 1 mol of solvent of crystallization was obtained as deep yellow fine needles (dec. p *ca.* 250°C, 0.096 g, 27%). It was found that the solvent could not be removed upon heating to 60°C for 24 hr under reduced pressure (2×10^{-3} mmHg).

Found: C, 95.38; H, 4.62%. Calcd for $C_{44}H_{22}\cdot C_7H_8$: C, 95.30; H, 4.70%.

3-(6-Chrysenyl)-prop-2-ynal (XIX). To an ice-cooled solution of isopropylmagnesium bromide (from magnesium, 1.92 g, 0.08 g-atom and isopropyl bromide, 10.8 g, 0.088 mol) in tetrahydrofuran (50 ml) was added, over a period of 15 min, a solution of 6-ethynylchrysene (XII, 10.08 g, 0.04 mol) in the same solvent (250 ml) under stirring. The mixture was refluxed for 1 hr, and dimethylformamide (18 ml) was added under cooling with an ice-salt bath. After the mixture had been stirred for 4 hr at 30°C, 5% sulfuric acid (600 ml) was

added under vigorous agitation, after which benzene (500 m*l*) was added and then stirring was continued overnight. The mixture was extracted with benzene (500 m*l*). The extract was washed with a saturated solution of sodium hydrogen carbonate, and dried. The solvent was removed to afford yellow crystals. The crystals were washed with a small amount of benzene-cyclohexane (1: 1), thus yielding light orange-yellow needles (8.11 g, 72%). This was recrystallized twice from benzene-cyclohexane (1: 1) to yield XIX as orange-yellow needles, mp 160—161°C (dec.).

Found: C, 89.70; H, 4.36%. Calcd for $C_{21}H_{12}O$: C, 89.98; H, 4.32%. IR: 2830, 2730 (CHO), 2175 (C≡C), 1655 (C=O) cm^{-1}.

1-(6-Chrysenyl)-1,4-pentadiyn-3-ol (XX). The reaction of ethynylmagnesium bromide with XIX (5.60 g, 0.02 mol) according to the procedure used for XIII afforded XX as yellow fine crystals, mp *ca.* 140°C (dec.), 3.51 g (62%). This substance was recrystallized twice from ethyl acetate to yield pure XX, mp 152—154°C (dec.).

Found: C, 89.68; H, 4.56%. Calcd for $C_{23}H_{14}O$: C, 90.17; H, 4.61%. IR: 3600—3100 (OH), 3300 (≡CH), 2220, 2100 (C≡C), 1023 (C–O) cm^{-1}.

6,6'-Dichrysenylpentaacetylene (I_5). Oxidative Coupling of Chrysenylpentadiynol (XX): The product obtained by the Glaser reaction [cuprous chloride (1.00 g), ammonium chloride (0.90 g), methanol (80 m*l*) and oxygen] of XX (2.50 g, 8.2 mmol) was dissolved in tetrahydrofuran (100 m*l*). The solution was percolated through a thin layer of alumina (3 g). Concentration of the filtrate afforded a viscous brown oil which crystallized on treatment with a small amount of benzene (0.90 g, 36%). Repeated recrystallization of this substance from tetrahydrofuran or dioxane gave slightly impure material whose IR spectrum was in accord with that expected for XXI.

Chlorination of XXI: According to the procedure used in the preparation of XV, glycol (XXI, 0.305 g, 0.5 mmol) was treated with a solution of thionyl chloride at −30°C. The reaction mixture containing XXII was immediately subjected to the following reaction.

Dehydrochlorination of XXII: Dehydrochlorination of XXII with sodium amide (from sodium, 0.20 g, 8.4 mg-atom) was performed according to the method used for I_3. I_5 was obtained as light orange fine needles (dec. p *ca.* 230°C, 31 mg, 11% based on crude XXI). The second crop of I_5 (15 mg, 5%) was obtained from the mother liquor.

Found: C, 96.05; H, 3.82%. Calcd for $C_{46}H_{22}$: C, 96.14; H, 3.86%.

1-(6-Chrysenyl)-2,5-hexadiyn-1,4-diol (XXIII). A solution of 6-formylchrysene (XI, 6.15 g, 0.024 mol) in tetrahydrofuran (200 m*l*) was added to a stirred and ice-cooled solution of the Grignard derivative of 2,4-pentadiyn-3-ol[11] (from alcohol, 2.65 g, 0.033 mol and ethylmagnesium bromide in tetrahydrofuran, 100 m*l*). The mixture was stirred overnight at room temperature. The reaction mixture was hydrolyzed by the addition of a saturated solution of ammonium chloride. The aqueous layer was extracted with benzene. Viscous oily material obtained by concentration of the combined organic layer was warmed with benzene (30 m*l*) to cause crystallization. The crude material was recrystallized from ethyl acetate-benzene to afford light brown powder (4.50 g, 56%). This was used without further purification in the subsequent reaction. A small portion of the crude material was dissolved in dioxane and passed through a thin layer of alumina. The crystals obtained by concentrating the filtrate were redissolved in ethyl acetate and chromatographed on alumina to result in pure XXIII as colorless needles, mp 197—199°C (dec.).

Found: C, 85.19; H, 4.75%. Calcd for $C_{24}H_{16}O_2$: C, 85.69; H, 4.79%.

The second crop obtained from the mother liquor was colorless needles, mp 165—170°C. (Found: C, 85.40; H, 4.83%). The two stereoisomeric kinds of crystal gave almost the same IR spectra. IR: 3600—3100 (O–H), 3300 (≡CH), 2100 (C≡C), 1035 (C–O) cm^{-1}.

6-Chrysenyltriacetylene (XXV). Chlorination of XXIII: According to the procedure used for XVII, XIII (2.02 g, 6 mmol) in a mixture of tetrahydrofuran (30 m*l*) and pyridine (1.42 g, 18 mmol) was converted into XXIV on treatment with thionyl chloride (2.14 g, 18 mmol) in tetrahydrofuran (5 m*l*) at −15°C. Crude XXIV obtained as a brown oily material was used without further purification in the subsequent reaction.

Dehydrochlorination of XXIV. The procedure used for XVII was applied to XXIV. Since the triacetylene (XXV, Faint yellow fine needles, UV: $\lambda_{max}^{petroleum\ ether}$ 379 nm) was found to be extremely unstable, a petroleum ether solution was used in the following reaction.

6,6'-Dichrysenylhexaacetylene (I_6). A mixture of the solution of triacetylene (XXV), cupric acetate monohydrate (2.0 g) and pyridine (50 m*l*) was concentrated to *ca.* 30 m*l* *in vacuo* and pyridine (50 m*l*) and methanol (5 m*l*) were added. Stirring was continued overnight at room temperature. The insoluble material was collected and washed with ethanol and then with water. Crude hexaacetylene (I_6), thus obtained, brick red crystalline powder (0.440 g, 24% based on diol, XXIII), was digested with hot toluene (350 m*l*), and the hot extract was percolated through a short column of alumina (7 g). Pure I_6, orange-red needles, dec. p. *ca.* 150°C was obtained on standing the filtrate.

Found: C, 96.17; H, 3.77%. Calcd for $C_{48}H_{22}$: C, 96.30; H, 3.70%.

Modified Clemmensen Reductions of Keto Groups to Methylene Groups

Masaaki TODA, Mikio HAYASHI, Yoshimasa HIRATA, and Shosuke YAMAMURA*

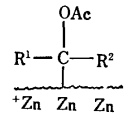
Chemical Institute, Nagoya University, Chikusa-ku, Nagoya

**Faculty of Pharmacy, Meijo University, Showa-ku, Nagoya*

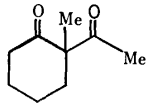
(Received June 24, 1971)

A modified Clemmensen reduction is described for the conversion of keto-groups into methylene groups by using active zinc powder in common organic solvents and acetic anhydride saturated with hydrogen chloride; the scope and limitations of these new reduction systems are also discussed.[1]

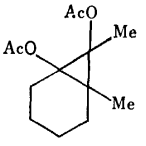
In a previous paper,[2] we reported a useful method for the conversion of isolated keto-groups into methylene groups using active zinc powder in acetic anhydride saturated with hydrogen chloride under very mild conditions (0°C, 2—6 hr). Furthermore, it has been suggested that the easy reductions of keto-groups to methylene groups are attributable to the formation of an acyl cation from acetic anhydride and hydrogen chloride, and that the acetoxyorganozinc compound is a likely intermediate (I). In fact, the treatment of the β-diketone (II) with Zn–Ac_2O–HCl has been known to afford the corresponding diacetoxycyclopropane (III) in a high yield.[3] However, attempts to reduce cholestan-3-one to cholestane with active zinc powder in Ac_2O-*p*-TsOH (or BF_3 etherate) under various conditions proved unsuccessful.



(I)



(II)



(III)

In the above experiments we were able to do such zinc reductions by using common organic solvents saturated with hydrogen chloride instead of acetic anhydride. When treated with active zinc powder in diethyl ether saturated with hydrogen chloride (0°C, 1 hr), cholestan-3-one afforded the corresponding reduction product, cholestane, in a high yield. Other solvents were also used; the results, summarized in Table 1, indicate that diethyl ether is much better for the modified Clemmensen reduction than the other solvents. These zinc reductions, which must be carried out under anhydrous conditions, take place more easily than the usual Clemmensen reduction. The mechanism of the former seems, however, to be essentially the same as that of the Clemmensen reduction.[4]

In view of the high reactivity of these reduction systems (Zn–HCl–Ac_2O (or Et_2O)), zinc reductions of α-substituted, α,β-unsaturated, and aryl ketones were carried out (Table 2).

TABLE 1. ZINC REDUCTIONS IN COMMON ORGANIC SOLVENTS SATURATED WITH HYDROGEN CHLORIDE

Ketone	Solvent	Product	Yield (%)
Cholestan-3-one	Ac_2O	Cholestane	87[a]
	Et_2O	Cholestane	89[b]
	Tetrahydrofuran	Cholestane	44[b]
	Benzene	Cholestane	64[b]
		3-Chlorocholestane	21
	n-Hexane	Cholestane	57[b]
		3-Chlorocholestane	8
Androstan-3,17-dione	Ac_2O	Androstane	66[c]
		17β-Acetoxyandrostane	26
	Et_2O	Androstane	75[b]

a) At 0°C for 2 hr. b) At 0°C for 1 hr. c) At 0°C for 6 hr.

TABLE 2. ZINC REDUCTIONS OF α-SUBSTITUTED, α,β-UNSATURATED, AND ARYL KETONES

Ketone	Product	Yield (%)
2α-Bromocholestan-3-one	Cholestane	86[a], 85[b]
	3-Acetoxycholest-2-ene	8[a]
α-Acetoxycholestan-3-one[c]	Cholestane	90[a], 79[b]
	Enol acetates	2[a],[d]
3β,5α-Diacetoxy-7α-bromocholestan-6-one	3β-Acetoxycholestane	73[e]
3β,17α-Diacetoxypregn-5-en-20-one	3β-Acetoxypregn-5-ene	62[e]
Cholest-1-en-3-one	Cholestane	30—32[a], 88[b]
	3-Acetoxycholest-2-ene	24—10[a]
	Cholestan-3-one	30—40[a]
Cholest-4-en-3-one	Cholestane	48[b]
	Coprostane	40[b]
Methyl β-benzoyl propionate	Methyl γ-phenyl butyrate	45[a], 41[b]
Indanone	Indane	22[a], 42[b]

a) In acetic anhydride saturated with HCl (0°C, 2 hr).
b) In diethyl ether saturated with HCl (0°C, 1 hr).
c) A mixture of 2α- and 4α-acetoxycholestan-3-ones (1:1).
d) A mixture of 3-acetoxycholest-2 and 3-enes.
e) In acetic anhydride saturated with HCl (0°C, 6 hr).

In particular, the reductions of α-halo- and α-acetoxy-oxo-steroids with active zinc powder in diethyl ether saturated with hydrogen chloride are expected to afford the following reduction products: an olefin (IV), an acetate (or halide) (V), and a completely reduced compound (VI). In the case of the (Zn–Ac_2O–HCl) reduction system, two more reduction products (VII and

VIII) are expected in addition to the three above compounds (IV, V, and VI). In our experiments, modified Clemmensen reductions of α-acetoxy and α-halo-cholestan-3-one afforded a mixture of cholestane (86—90%) and 3-acetoxycholest-2-ene (2—8%) with Zn–Ac_2O–HCl, and only cholestane (79—85%) with Zn–Et_2O–HCl. In these reactions, the first step is probably the same as in usual zinc reductions in acetic acid or aqueous mineral acid leading to the formation of an enolate anion. Therefore, the ketonization of the enolate anion and the subsequent protonation take place much faster than an attack of the acyl cation on the oxygen atom of the enolate anion.[5] The resulting cholestan-3-one is converted into cholestane as usual. In the cases of α,β-unsaturated ketones, results considerably different from those obtained with the α-substituted ketones were obtained. When treated with active zinc powder in acetic anhydride saturated with hydrogen chloride, cholest-1-en-3-one gave a mixture of three reduction products (cholestane (32—30%), 3-acetoxycholest-2-ene (24—10%) and cholestan-3-one (30—40%)). The completely reduced product, cholestane, is probably formed through the cyclopropoxide or enolate anion. Furthermore, both cholestan-3-one and 3-acetoxycholest-2-ene (VII) may be derived from an intermediate of the corresponding acetoxycyclopropane structure (IX), an intermediate which seems to be converted into cholestan-3-one in the course of isolation. Recently, Elphimoff-Felkin and Sarda[6] have reported that the α,β-unsaturated ketones with a phenyl group afford the corresponding acetoxycyclopropanes when treated with Zn–Ac_2O–HCl. Accordingly, it can be expected that the completely reduced product can be obtained in a high yield by using active zinc powder in diethyl ether saturated with hydrogen chloride. In fact, the reduction of cholest-1-en-3-one to cholestane was successfully achieved by the use of the above-mentioned reduction system under mild conditions. Cholest-4-en-3-one was also converted into a mixture of cholestane and coprostane in a high yield. Zinc reductions of aryl ketones were also carried out under the same conditions.[7] However, these reductions are not always better in yields than usual Clemmensen reductions of aryl ketones except under mild conditions (0°C, 1 hr), since undesirable dimerization reactions seem to take place between two anion radical intermediates, which are much more stabilized by the aryl group than is the anion radical from such an isolated ketone as cholestan-3-one.

Experimental

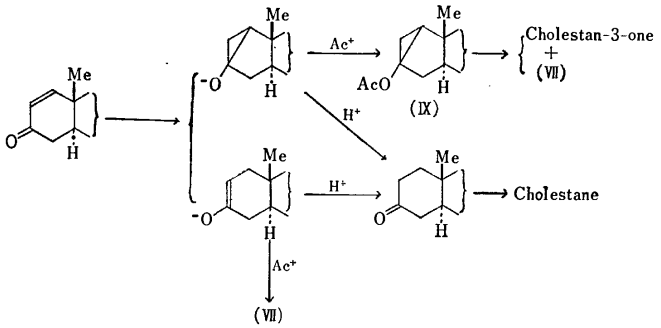
The melting points were determined on a micro hot-stage. The infrared spectra were recorded in KBr or film with a JASCO IR-S spectrophotometer.

Preparation of Active Zinc Powder. Commercial zinc powder (Kishida Chemical Co., *ca.* 300 mesh) was activated by washing it well with 2% hydrochloric acid according to a previously-described procedure (see Ref. 2). The zinc powder thus obtained was used immediately.

General Procedure for the Zinc Reduction. Cholestan-3-one was dissolved in diethyl ether saturated with hydrogen chloride at 0°C, and then active zinc powder was slowly stirred into the resulting solution. After being stirred at 0°C for 1 hr, the reaction mixture was poured into large amounts of ice water. Then, the aqueous solution was made basic with sodium carbonate and extracted thoroughly with diethyl ether. The extracts were dried over anhydrous Na_2SO_4; the solvent was then removed under reduced pressure to give a pale yellow oil, which was chromatographed on silica gel (Mallinckrodt, 100 mesh) (25 g) and eluted with benzene to afford colorless crystals of cholestane (mp 77.5—79°C). The yields of cholestane varied with the quantity of zinc powder, as the chart shows below.

Cholestan-3-one (mg)	Zn (g)	Et_2O (m*l*)	Yield (%)
500	5.0	75	89
500	1.25	12.5	84
500	0.50	10	85
500	0.25	10	56

According to the above-mentioned procedure or the previously-reported procedure,[2] zinc reductions of α-substituted, α,β-unsaturated and aryl ketones were carried out (see Tables 1 and 2); the reduction products were carefully separated by



5) The enol acetate (VII) is stable for the (Zn-Ac_2O-HCl) reduction system.

6) M. I. Elphimoff-Felkin and P. Sarda, *Tetrahedron Lett.*, **1969**, 3045.

7) The reaction mixture spontaneously turned brown when active zinc powder was added to the solution.

silica-gel chromatography (Mallinckrodt, 100 mesh), using benzene as the eluant, except for a mixture of cholestane and coprostane.[8] When experiments were carried out in a large scale, the reduction procedure was further modified as follows.

In a 500-m*l*, three-necked, round-bottomed flask fitted with a sealed mechanical stirrer, a gas inlet tube, and a Y-tube fitted with a low-temperature thermometer and a calcium chloride tube, we placed 250 m*l* of dry diethyl ether which had been cooled in a dry ice-acetone bath to −10——15°C; then dry hydrogen chloride gas was bubbled in with slow stirring. After about 45 min, 10 g of cholestan-3-one were dissolved, with stirring, in the above solution below −15°C. To the ethereal solution we then added 12.3 g of activated zinc powder at about −20°C over a period of 2—3 min, and then the temperature of the reaction solution was elevated to −5°C. Stirring was continued for 2 hr, keeping the reaction temperature between 0——4°C. Finally, the reaction mixture was cooled to −15°C, slowly poured into large amounts of ice, and then worked-up as usual to give 8.2—8.9 g of cholestane. mp 78—79°C.

All the reduction products were found to be identical with the known compounds by a study of their mps, IR, and mass spectra.

8) The relative ratio of the two reduction products was determined by studying their peak areas on a gas-liquid chromatogram (SE-30 (5%); 250°C, N_2; flame-ionized detector).

The authors are grateful to Professor T. Goto, Nagoya University, for providing some α-acetoxy-oxosteroids.

The Epoxidation of Homoallylic Alcohols and the Formation of Sesquiterpene Diols

Shosuke YAMAMURA, Masanobu IGUCHI, Masatake NIWA, and Yoshimasa HIRATA*

Faculty of Pharmacy, Meijo University, Showa-ku, Nagoya

**Chemical Institute, Nagoya University, Chikusa-ku, Nagoya*

(Received June 24, 1971)

The epoxidation of homoallylic alcohols was effected with *m*-chloroperbenzoic acid in ether, and the resulting epoxides were reduced with lithium aluminum hydride to the corresponding diols. Particularly in the cases of calameone and isocalamendiol, the exocyclic double bond at the C_3-position was attacked by the peroxy-acid from the side opposite to the axial hydroxyl group at the C_5-position.

In the course of structural studies of calameone (I), a sesquiterpen-diol isolated from *Acorus calamus* L. (Japanese name "Shyobu"), we obtained some interesting results.

In the cases of homoallylic alcohols generally, a peroxy-acid attacks the double bond from the same side as the hydroxyl group.[1] On the other hand, the double bond can be attacked by the same reagent from the opposite side when a methoxyl group is used instead of the hydroxyl group in the same system.[1] In fact, the dehydrated compound (II), which had been obtained from isocalamendiol (III),[2] was treated with *m*-chloroperbenzoic acid and then reduced with lithium aluminum hydride to afford a mixture of calameone (I) and a new isomer (IV), the structure of which was proposed on the basis of a reaction mechanism analogous to that of calameone (I).[1,3] We could further make a configurational isomer (V) at the C_3-position as follows. When treated with *m*-chloroperbenzoic acid in ether, isocalamendiol (III) did not give a β-epoxide (VI), but an α-isomer (VII), in a 98% yield. Furthermore, the dehydration of VII was effected with $POCl_3$-pyridine to give, in a 48% yield, a dehydrated epoxide (VIII). Finally, the reduction of VIII with lithium aluminum hydride afforded the new diol (V), the structure of which was elucidated by a comparison of the NMR spectra of these four sesquiterpen-diols (see Table 1). In the NMR spectra of the compounds

TABLE 1. NMR SIGNALS OF SESQUITERPEN-DIOLS

Compound	*i*-Pr	$-\dot{C}Me-OH$	$-\dot{C}=CH_2$
Calameone	δ 0.90 (6H, d, J=6.8 Hz)	δ 1.13 (3H, s)	δ 4.80 (1H, br.s)
			4.89 (1H, br.s)
Isocalamendiol (III)	0.90 (3H, d, J=7.0 Hz)	1.22 (3H, s)	4.80 (1H, br.s)
	0.93 (3H, d, J=7.0 Hz)		4.89 (1H, br.s)
Compound (IV)	0.93 (6H, d, J=6.5 Hz)	1.12 (3H, s)	4.68—5.00 (2H, br.m)
Compound (V)	0.88 (3H, d, J=6.9 Hz)	1.21 (3H, s)	4.77 (1H, br.s)
	0.91 (3H, d, J=6.9 Hz)		4.95 (1H, br.s)

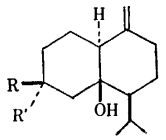
(VI) (VII) (VIII)



(IX) R=H, R'=Me
(X) R=Me, R'=H

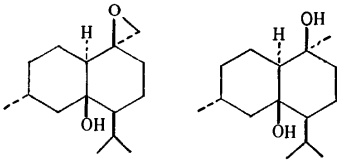
We made further experiments using three different compounds (I, IX, and X), which had already been synthesized from isocalamendiol (III).[2,3] The epoxidation of the (IX) compound, which has an equatorial methyl group at the C_3-position, with *m*-chloroperbenzoic acid gave the expected β-epoxide (XI) in a 76% yield; this substance has then reduced with lithium aluminum hydride to afford a known compound (XII).[3] In the case of the (X) compound, which has an axial methyl group at the C_3-position, we can expect the formation of an α-epoxide analogous to that of isocalamendiol (III). However, the treatment of X with the same peroxy-acid gave a β-isomer (XIII) in an 88% yield; this isomer was also reduced with lithium aluminum hydride to afford a known compound (XIV).[3] On the other hand, in the case of calameone (I), an α-epoxide (XV) was obtained in an almost quantitative yield; its structure was determined by a comparison of the NMR spectra of five epoxides (VII, VIII, XI, XIII, and XV) (see Table 2): the NMR signal of XV, which can be attributed to the methylene protons on the epoxide-ring, is very similar to those of compounds VII and VIII in its chemical shift as well as its coupling constant.

The present studies indicate that such a peroxy-acid as *m*-chloroperbenzoic acid attacks the double bond,

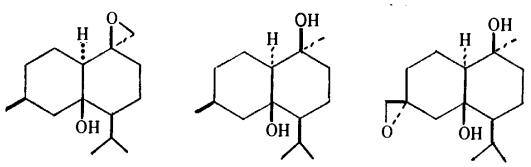
Table 2. NMR signals of several epoxides

Compound	Methylene-protons on the epoxide-ring
VII	δ 2.60 (2H, s)
VIII	2.60 (2H, s)
XI	2.38 (1H, d, J=4.3 Hz), 2.81 (1H, d, J=4.3 Hz)
XIII	2.37 (1H, d, J=4.2 Hz), 2.83 (1H, d, J=4.2 Hz)
XV	2.63 (2H, s)

as usual, from the same side as the hydroxyl group in homoallylic alcohols which are not sterically hindered (in II and IX), whereas different results have been obtained in the cases of calameone (I) and isocalamendiol (III), as has been described above. Probably, interaction between the peroxy-acid and the homoallylic hydroxyl group at the C_5-position can be prevented by the axial tertiary methyl group at the C_9-position (in III). In the case of I, such an interaction may also be sterically hindered by the 9β-hydroxyl group or prevented by the formation of hydrogen bonding between the two axial hydroxyl groups at the C_5 and C_9-positions. Finally, the epoxidation of the compound (X), which has an axial secondary methyl group at the C_3-position, did not afford the expected α-epoxide, but the β-epoxide (XIII). Probably, the axial secondary methyl group at the C_3-position is easily moved from the normal position so as not to interrupt such an interaction between the peroxy-acid and the hydroxyl group, as compared with the case of the tertiary methyl group in III.



(XI) (XII)



(XIII) (XIV) (XV)

Experimental

All the melting-points are uncorrected. The IR spectra were recorded on a Hitachi-215 spectrophotometer. The NMR spectra were taken on Varian A-60 and Nihondenshi JNM-60H (60 MHz) spectrometers, using $CDCl_3$ as the solvent, unless otherwise stated. Only prominent peaks are cited. The chemical shifts are given in ppm relative to the internal TMS. The coupling constants are given in Hz (s: singlet; d: doublet; t: triplet; q: quartet; m: multiplet). The mass spectra were obtained on a Hitachi RMU-6D mass spectrometer operating with an ionization energy of 70 eV. Column chromatography was carried out on neutral alumina

(Katayama Co. Ltd., 150—250 mesh).

Epoxidation of Isocalamendiol (III). A solution of isocalamendiol (810 mg) and *m*-chloroperbenzoic acid (705 mg) in abs. ether (30 m*l*) was heated under reflux for 3 hr and then cooled to room temp. After the decomposition of the excess peroxy-acid with 10% aq. Na_2SO_3 (10 m*l*), the ethereal solution was washed with 5% aq. $NaHCO_3$ (5 m*l*×2) and then satu. aq. NaCl, and dried over Na_2SO_4. The subsequent removal of the solvent gave white crystals (835 mg). Recrystallization from *n*-hexane gave white needles; mp 100—101°C; ν_{max}^{KBr} 3520 and 3400 cm^{-1}; δ 0.90 (6H, d, J=6.3 Hz), 1.29 (3H, s) and 2.60 ppm (2H, s); *m/e* 236 (M^+-18) (Found: C, 70.70; H, 10.31%. $C_{15}H_{26}O_3$ requires: C, 70.83; H, 10.3 %).

Dehydration of Epoxy-isocalamendiol (VII). Into a solution of epoxy-isocalamendiol (296 mg) in abs. pyridine (10 m*l*), we slowly stirred a solution of $POCl_3$ (1 m*l*) in abs. pyridine (3 m*l*) at − 16°C. The reaction solution was further stirred for 30 min, and then at 15°C for 2 hr. The reaction solution was then poured into large amounts of ice and extracted with ether. The ether extract was washed well with satu. aq. NaCl and dried over anhydrous Na_2SO_4. The subsequent removal of the solvent gave a pale brown oil, which was chromatographed on alumina (7 g) and eluted with pet. ether-ether (1: 1) to leave a colorless oil (175 mg). This oil was dissolved in *n*-hexane and then allowed to stand at 0°C to give 135 mg of white crystals; mp 61.5—62.5°C (from *n*-hexane); ν_{max}^{KBr} 3560, 3450 br., 1642, 895, and 885 cm^{-1}; δ 0.87 (3H, d, J=6.8 Hz), 0.90 (3H, d, J=6.8 Hz), 2.60 (2H, s), 4.68 (1H, br. s), and 4.90 ppm (1H, br. s); *m/e* 236 (M^+) (Found: C, 76.22; H, 10.56%. $C_{15}H_{24}O_2$ requires: C, 76.22; H, 10.24%).

Reduction of Dehydrated Epoxide (VIII) with Lithium Aluminum Hydride. Lithium aluminum hydride (10 mg) was added to a solution of dehydrated epoxide (130 mg) in abs. ether (20 m*l*), and then the mixture was stirred at room temp. for 2 hr. After the decomposition of the excess lithium aluminum hydride with satu. aq. ether, the reaction solution was washed with 20% aq. potassium sodium tartarate. The ether solution was washed with satu. aq. NaCl and then dried over anhydrous Na_2SO_4. The subsequent removal of the solvent gave 130 mg of white crystals; mp 112.5—114°C (from *n*-hexane); ν_{max}^{KBr} 3450 sh., 3380 br., 3090, 1650, and 895 cm^{-1}; δ 0.88 (3H, d, J=6.9 Hz), 0.91 (3H, d, J=6.9 Hz), 1.21 (3H, s), 4.77 (1H, br. s), and 4.95 ppm (1H, br. s); *m/e* 238 (M^+) (Found: C, 75.90; H, 10.97%. $C_{15}H_{26}O_2$ requires: C, 75.58; H, 11.00%).

Epoxidation of the Equatorial Sec. Methyl Olefin (IX). A solution of IX (102 mg) and *m*-chloroperbenzoic acid (95 mg) in abs. ether (8 m*l*) was heated under reflux for 3 hr; then it was worked up as usual to give a white solid, which was chromatographed on alumina (2.5 g) and eluted with pet. ether-ether (3: 1) to afford 83 mg of white crystals; mp 91.5—92.5°C (from *n*-hexane); ν_{max}^{KBr} 3570 cm^{-1}; δ 0.88 (3H, d, J=6.0 Hz), 0.92 (3H, d, J=6.9 Hz), 0.93 (3H, d, J=6.9 Hz), 2.38 (1H, d, J=4.3 Hz), and 2.81 ppm (1H, d, J=4.3 Hz); *m/e* 238 (M^+) (Found: C, 75.21; H, 11.15%. $C_{15}H_{26}O_2$ requires: C, 75.58; H, 11.00%).

Reduction of the Epoxide (XI) with Lithium Aluminum Hydride. Lithium aluminum hydride (4 mg) was stirred into a solution of the epoxide (49 mg). The reaction solution was stirred at room temp. for 2 hr and then worked up as usual to give 49 mg of white crystals (mp 133—134°C (from *n*-hexane)) which were completely identical with an authentic sample of dihydrocalameone (XII) (mp and IR spectrum).

Epoxidation of the Axial Sec. Methyl Olefin (X). A solution of X (340 mg) and *m*-chloroperbenzoic acid (320 mg) in abs. ether (10 m*l*) was refluxed for 3 hr and then worked up as usual to give a colorless oil, which was chromatographed on alumina (8.5 g) and eluted with pet. ether-ether (2: 1) to give 322 mg of white crystals; mp 61—62.5°C (from *n*-hexane); ν_{max}^{KBr} 3580 and 3450 br. cm^{-1}; δ 0.90 (3H, d, J=6.9 Hz), 0.94 (3H, d, J=6.9 Hz), 1.13 (3H, d, J=7.0 Hz), 2.37 (1H, d, J=4.2 Hz), and 2.83 ppm (1H, d, J=4.2 Hz); *m/e* 238 (M^+) (Found: C, 75.30; H, 11.21%. $C_{15}H_{26}O_2$ requires: C, 75.58; H, 11.00%).

Reduction of the Epoxide (XIII) with Lithium Aluminum Hydride. Lithium aluminium hydride (10 mg) was stirred into a solution of XIII (77 mg) in abs. ehter (10 m*l*). The reaction solution was further stirred at room temp. for 2 hr and then worked up as usual to give 100 mg of white needles, mp 123—124°C (from *n*-hexane), which were completely identical with an authentic sample of the isomer (XIV) of dihydrocalameone (mp and IR spectrum).

Epoxidation of Calameone (I). A solution of calameone (68 mg) and *m*-chloroperbenzoic acid (60 mg) in abs. ether (5 m*l*) was heated under reflux for 3 hr and then worked up as usual to give a crystalline solid; this solid was then chromatographed on neutral alumina (1.5 g) and eluted with chloroform to give 65 mg of white crystals; mp 96—98°C (from *n*-hexane); ν_{max}^{KBr} 3370 br. cm^{-1}; δ 0.91 (6H, d, J=6.8 Hz), 1.16 (3H, s), 1.63 (2H, s), 3.12 (1H, s, OH), and 4.44 ppm (1H, s, OH); *m/e* 254 (M^+) (Found: C, 70.78; H, 10.45%. $C_{15}H_{26}O_3$ requires: C, 70.83; H, 10.30%).

The authors wish to thank Miss E. Naoi, Meijo University, for the elemental analysis.

Syntheses of Benzo[5,6]cyclohept[1,2-*b*]indol-6-ones

Kameji YAMANE and Kunihide FUJIMORI

Department of Chemistry, Faculty of Science, Shinshu University, Matsumoto

(Received June 25, 1971)

The monoarylhydrazones(IIa—c) of benzocycloheptene-5,6-dione (I) underwent Fischer indolization to form 11,12-dihydrobenzo[5,6]cyclohept[1,2-*b*]indol-6-ones (IIIa—c). The treatment of IIIa—c with *N*-bromosuccinimide gave the benzoindolotropone derivatives (Va—c). Va, Vc, and VI afforded a dibromo compound (VII) on treatment with bromine in acetic acid.

Previous investigations in this area have dealt almost exclusively with syntheses of indolotropones[1] and indolotropolones.[2-4] The present paper will report on the syntheses of benzotropone derivatives fused with the indole ring.

Results and Discussion

When benzocycloheptene-5,6-dione (I) was treated in ethanol or acetic acid with an equivalent amount of phenylhydrazine, hydrochloride of *p*-tolylhydrazine, or *p*-bromophenylhydrazine, monoarylhydrazones (IIa—c) were obtained. IIa—c underwent Fischer indolization in acetic acid in the presence of zinc chloride or concd. hydrochloric acid to form 11,12-dihydrobenzo[5,6]cyclohept[1,2-*b*]indol-6-ones (IIIa—c). IIIa and IIIb were also prepared by the reaction of I with phenyl- or *p*-tolylhydrazine hydrochloride in acetic acid.

The dione (I) or monophenylhydrazone (IIa) gave IV, the phenylhydrazone of IIIa, on treatment with an excess of phenylhydrazine in acetic acid, but IIIa did not give the compound (IV). It can be presumed that bisphenylhydrazone was first formed, and that the Fischer indolization occurred smoothly under these conditions, although the bisphenylhydrazone could not be isloated.

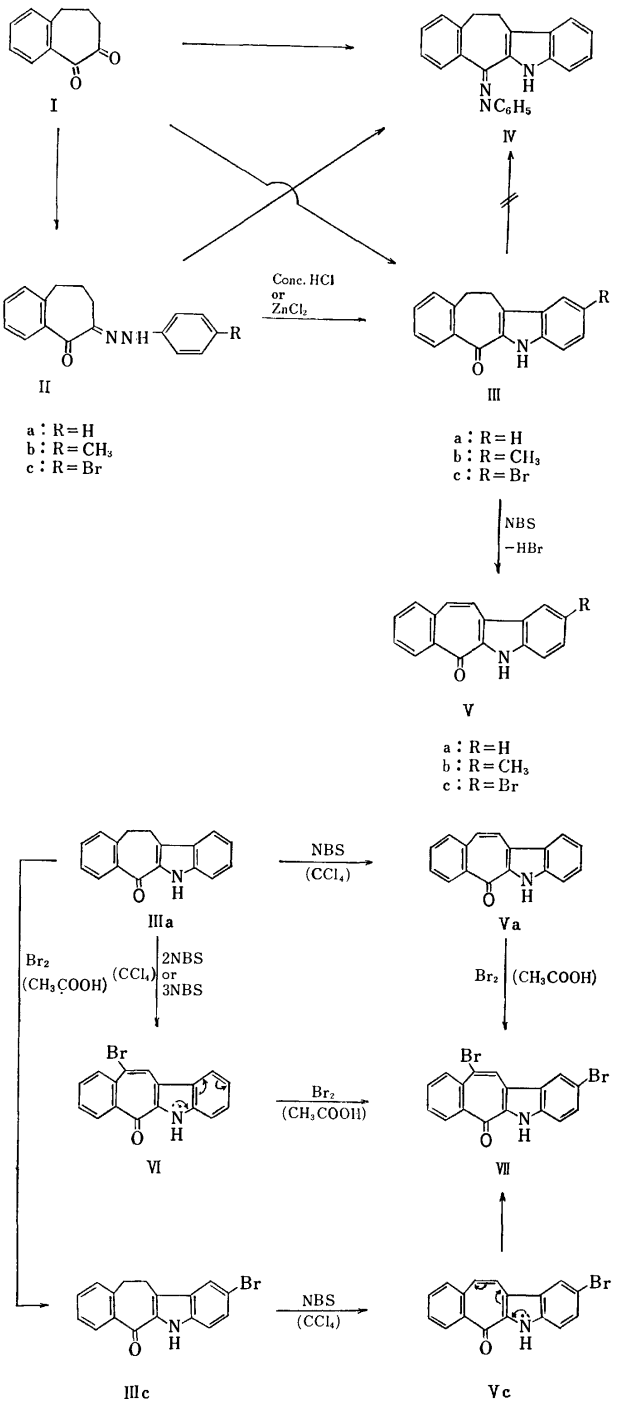
The treatment of IIIa—c with *N*-bromosuccinimide resulted in dehydrogenation, thus formed the benzoindolotropone derivatives (Va—c) in good yields; however, the treatment of IIIa with bromine in acetic acid gave the monobromo compound (IIIc). The reaction of IIIa with two or three molar equivalents of *N*-bromosuccinimide afforded the monobromo compound (VI), which is isomeric with Vc.

The bromination of Va in acetic acid gave the dibromo compound (VII), which was also prepared by the reaction of Vc or VI with bromine in acetic acid.

Furthermore, the *N*-benzyl derivative was obtained by the reaction of IIIa with benzyl chloride.

The ultraviolet spectra of Va—c and VI were more complex than those of IIIa—c.

The infrared spectra of Va—c and VI showed olefinic C–H stretching absorption at 3100—3000 cm^{-1}. In contrast with IIIa—c, Va—c, and VI indicated the absence of paraffinic C–H stretching absorption bands in the 3000—2800 cm^{-1} region. The N–H and C=O stretching absorption bands of Va—c and VI appeared



1) T. Nozoe, Y. Kitahara, and J. Shin, unpublished works.
2) M. Mühlstädt and W. Treibs, *Ann.*, **608**, 38 (1957).
3) T. Nozoe, H. Horino, and T. Toda, *Tetrahedron Lett.*, **1967**, 5349.
4) M. Mühlstädt and H. Lichtmann, *J. Prakt. Chem.*, **312**, 466 (1970).

in regions about 60—65 cm^{-1} and 60—62 cm^{-1} lower than those of IIIa—c respectively. It can, therefore, be concluded that Va—c and VI are the dehydro products of IIIa—c.

As Va—c and VI were only slightly soluble in common organic solvents, the NMR spectra could not be measured. In the NMR spectra of III, four methylene protons appeared as a singlet at τ 6.7.

Experimental

All the melting points were determined in a liquid bath and are uncorrected. The IR spectra were run as KBr tablets on a Hitachi Model EPI-G spectrophotometer. The UV absorption spectra were measured in ethanol on a Hitachi spectrophotometer Model 124. The NMR measurements were carried out on a JEOL Model JNM-4H-100 spectrometer in deuterochloroform as the solvent, with tetramethylsilane as the internal standard.

Benzocycloheptene-5,6-dione Monophenylhydrazone (IIa). *a)* A mixture of I (0.5 g) and phenylhydrazine (0.3 g) in ethanol (6 m*l*) was refluxed for 2 hr on a water bath. After cooling, the separated crystalline material was collected and recrystallized from ethanol as orange needles (0.3 g, 39%); mp 111—112°C. Found: C, 77.24; H, 6.11; N, 10.61%. Calcd for $C_{17}H_{16}ON_2$: C, 77.24; H, 6.14; N, 10.60%.

b) The reaction of I with an equivalent amount of phenylhydrazine in acetic acid afforded orange needles, mp 111°C, which are also obtained when using 2.5 molar amounts of phenylhydrazine in *n*-butyl alcohol; these needles showed no depression in mp on mixed fusion with monophenylhydrazone (IIa).

*Benzocycloheptene-5,6-dione Mono-*p*-tolylhydrazone (IIb).* A mixture of I, *p*-tolylhydrazine hydrochloride, and sodium acetate in ethanol was treated by a method similar to that described above. Orange needles (44%); mp 160—161°C. Found: C, 77.39; H, 6.42; N, 10.08%. Calcd for $C_{18}H_{18}ON_2$: C, 77.68; H, 6.51; N, 10.06%.

*Benzocycloheptene-5,6-dione Mono-*p*-bromophenylhydrazone (IIc).* This was obtained by a method similar to that used for IIb; it was recrystallized from ethanol to give orange yellow needles (54%); mp 160—161°C. Found: C, 59.68; H, 4.38; N, 8.19%. Calcd for $C_{17}H_{15}ON_2Br$: C, 59.48; H, 4.41; N, 8.16%.

*11,12-Dihydrobenzo[5,6]cyclohept[1,2-*b*]indol-6-one (IIIa).* *a)* To a solution of IIa (0.5 g) in acetic acid (15 m*l*) we added zinc chloride (0.4 g) or concd. hydrochloric acid (a few m*l*); the mixture was then refluxed for 4 hr in an oil bath. After cooling, the reaction mixture was diluted with water, and the resulting material was collected and recrystallized from ethanol to give yellow needles (0.45 g, 96%); mp 185—186°C. IR(KBr): ν NH 3305 cm^{-1}, ν conjugated C=O 1612 cm^{-1}, 1586 cm^{-1}. UV: λ_{max} (EtOH): 253 mμ (log ε 4.15), 338 mμ (log ε 4.32). NMR (in $CDCl_3$): τ 1.8—3.0 (multiplet, 8H), τ 6.74 (singlet, 4H). Found: C, 82.58; H, 5.31; N, 5.99%. Calcd for $C_{17}H_{13}ON$: C, 82.57; H, 5.30; N, 5.67%.

b) A suspension of I (0.5 g) and phenylhydrazine hydrochloride (0.5 g) in acetic acid (5 m*l*) was refluxed for 3 hr in an oil bath. After cooling, the reaction mixture was diluted with water, and the resulting material was collected and recrystallized from ethanol to give yellow needles (0.43 g, 61%); mp 185—186°C.

*2-Methyl-11,12-dihydrobenzo[5,6]cyclohept[1,2-*b*]indol-6-one (IIIb).* *a)* A mixture of IIb (0.12 g), zinc chloride (0.4 g), and acetic acid (6 m*l*) was treated as in IIIa a). Yellow needles (0.09 g, 82%); mp 174—176°C.

b) A mixture of I (0.5 g), *p*-tolylhydrazine hydrochloride (0.46 g), and acetic acid (5 m*l*) was treated as in IIIa. Yellow needles (0.47 g, 63%); mp 174—175°C. IR(KBr): ν NH 3306 cm^{-1}, ν conjugated C=O 1611 cm^{-1}, 1590 cm^{-1}. UV: λ_{max} (EtOH): 254 mμ (log ε 4.18), 345 mμ (log ε 4.37). NMR (in $CDCl_3$) τ 1.8—3.0 (multiplet, 7H), τ 6.76 (singlet, 4H), τ 7.53 (singlet, 3H). Found: C, 82.75; H, 5.70; N, 5.48%. Calcd for $C_{18}H_{15}ON$: C, 83.05; H, 5.82; N, 5.38%.

*2-Bromo-11,12-dihydrobenzo[5,6]cyclohept[1,2-*b*]indol-6-one (IIIc).* *a)* A mixture of IIc (0.3 g), zinc chloride (0.6 g), and acetic acid (10 m*l*) was treated by a method similar to that described above. Light yellow needles from ethanol (0.25 g, 86%); mp<230°C. UV: λ_{max} (EtOH): 257 mμ (log ε 4.06), 336 mμ (log ε 4.32). IR(KBr): νNH 3310 cm^{-1}, ν conjugated C=O 1613 cm^{-1}, 1585 cm^{-1}. Found: C, 62.59; H, 3.67; N, 4.11%. Calcd for $C_{17}H_{12}ONBr$: C, 62.59; H, 3.71; N, 4.30%.

b) Into a solution of IIIa (0.2 g) in acetic acid (35 m*l*), bromine (0.16 g) in acetic acid (5 m*l*) was stirred; the mixture was then stirred for 3 hr at room temperature. The separated material was collected by filtration and recrystallized from acetic aicd as yellow micro needles (0.23 g, 88%); mp>230°C. The needles were found to be identical with the product which was obtained by Method a).

Phenylhydrazone of IIIa (IV). *a)* A mixture of I (0.5 g) and phenylhydrazine (1.25 g) in acetic acid (10 m*l*) was refluxed for 4 hr. After cooling, the separated material was recrystallized from ethanol as yellow micro needles (0.43 g, 44%); mp 237—238°C. IR(KBr): νNH 3390 cm^{-1}, 3340 cm^{-1}. Found: C, 81.87; H, 5.62; N, 12.66%. Calcd for $C_{23}H_{19}N_3$: C, 81.87; H, 5.68; N, 12.45%.

b) A mixture of IIa (0.2 g) and phenylhydrazine (0.12 g) in acetitic acid (6 m*l*) was refluxed for 3 hr. After cooling, the separated material was recrystallized from ethanol as yellow micro needles (0.14 g, 54%); mp 237—238°C. Their mp was not depressed on admixture with IV, which was obtained by Method a).

*Benzo[5,6]cyclohept[1,2-*b*]indol-6-one (Va).* To a solution of IIIa (0.3 g) in carbon tetrachloride (30 m*l*), NBS (0.22 g) and benzoyl peroxide (0.06 g) were added; then the mixture was refluxed for 3 hr on a water bath. After cooling, the separated material was collected by filtration. The treatment of this with a small amount of chloroform gave an insoluble material which was then recrystallized from acetic acid as yellow micro needles (0.3 g, *ca.* 100%); mp >270°C. IR(KBr): νNH 3243 cm^{-1}, ν conjugated C=O 1581 cm^{-1} (medium), 1558 cm^{-1} (strong), 1533 cm^{-1} (shoulder). UV: λ_{max} (EtOH): 233 mμ (log ε 4.41), 295 mμ (log ε 4.53), 327 mμ (log ε 4.29). Found: C, 83.55; H, 4.34; N, 5.85%. Calcd for $C_{17}H_{11}ON$: C, 83.24; H, 4.52; N, 5.71%.

*2-Methylbenzo[5,6]cyclohept[1,2-*b*]indol-6-one (Vb).* A mixture of IIIb (0.15 g), NBS (0.10 g), benzoyl peroxide (0.06 g), and carbon tetrachloride (30 m*l*) was treated as in the case of Va. Yellow needles from chloroform (0.11 g, 81%); mp>270°C. IR(KBr): νNH 3251 cm^{-1}, ν conjugated C=O 1582 cm^{-1} (medium), 1550 cm^{-1} (strong), 1532 cm^{-1} (shoulder). UV: λ_{max} (EtOH): 235 mμ (log ε 4.46), 296 mμ (log ε 4.56), 336 mμ (log ε 4.36). Found: C, 83.38; H, 4.96; N, 5.40%. Calcd for $C_{18}H_{13}ON$: C, 83.37; H, 5.05; N, 5.40%.

*2-Bromobenzo[5,6]cyclohept[1,2-*b*]indol-6-one (Vc).* This was prepared from IIIc (0.2 g), NBS (0.13 g), benzoyl peroxide (0.04 g), and carbon tetrachloride (40 m*l*) by a method similar to that used for Vb. Yellow micro needles (0.18 g, 90%); mp >270°C. IR(KBr): νNH 3262 cm^{-1}, ν conjugated C=O 1575 cm^{-1} (medium), 1555 cm^{-1} (strong), 1533 cm^{-1}

(weak). UV: λ_{max} (EtOH): 252 mμ (log ε 4.40), 284 mμ (log ε 4.57), 328 mμ (log ε 4.38). Found: C, 63.33; H, 3.03; N, 4.30%. Calcd for $C_{17}H_{10}ONBr$: C, 62.98; H, 3.11; N, 4.32%.

Bromo Compound (VI). To a solution of IIIa (0.2 g) in carbon tetrachloride (20 m*l*), NBS (0.30 g) and benzoyl peroxide (0.06 g) were added, and then the mixture was refluxed for 3 hr on a water bath. After cooling, the separated material was collected by filtration. This was dissolved in chloroform and purified by passing through a silica gel column. The eluate gave yellow needles (0.12 g, 46%); mp >270°C. IR(KBr): νNH 3254 cm^{-1}, ν conjugated C=O 1581 cm^{-1} (shoulder), 1559 cm^{-1} (strong), 1551 cm^{-1} (shoulder). UV: λ_{max} (EtOH): 237 mμ (log ε 4.34), 299 mμ (log ε 4.43), 332 mμ (log ε 4.31). Found: C, 62.99; H, 2.94; N, 4.16%. Calcd for $C_{17}H_{10}ONBr$: C, 62.98; H, 3.11; N, 4.32%.

Dibromo Compound (VII). *a)* Into a solution of Va (0.1 g) in acetic acid (25 m*l*), bromine (0.15 g) in acetic acid (5 m*l*) was stirred, and then the mixture was stirred for 3 hr at room temperature. The separated material was collected by filtration and recystallized from acetic acid as yellow micro needles (0.14 g, 85%); mp >270°C. IR(KBr): νNH 3249 cm^{-1}, ν conjugated C=O 1601 cm^{-1} (weak), 1571 cm^{-1} (shoulder), 1560 cm^{-1} (strong), 1541 cm^{-1} (shoulder). Found: C, 50.76; H, 2.25; N, 3.67%. Calcd for $C_{17}H_9ONBr_2$: C, 50.76; H, 2.25; N, 3.48%.

b) This was prepared from VI (0.1 g) and bromine (0.1 g) in acetic acid (160 m*l*) by a method similar to that used for VII a). Yellow micro needles (0.1 g, 83%); mp >270°C. This showed an infrared spectrum identical with that of VII a).

c) A mixture of Vc (0.05 g), bromine (0.05 g), and acetic acid (150 m*l*) was treated as in the case of VII a). Yellow micro needles (0.06 g, *ca.* 100%); mp >270°C. This showed an infrared spectrum identical with that of VII a).

N-*Benzyl Derivative (VIII).* A mixture of IIa (0.15 g) and potassium (0.02 g) in dry toluene (10 m*l*) was stirred for 10 hr at room temperature. The unreacted potassium was filtered off. Benzyl chloride (0.10 g) was added to the filtrate, and the mixture was refluxed for 3 hr in an oil bath. After the reaction mixture had then cooled, we added water to it. After the insoluble material had been removed by filtration, the toluene layer was dried and the solvent was evaporated. The residue was dissolved in benzene and purified by passing it through an alumina column. Yellow needles from ethanol (trace); mp 131—131.5°C. IR(KBr): ν conjugated C=O 1618 cm^{-1} (strong), 1588 cm^{-1} (medium). Found: C, 85.59; H, 5.76; N, 4.00%. Calcd for $C_{22}H_{19}ON$: C, 85.43; H, 5.68; N, 4.15%.

The authors wish to express their thanks to Professor Emeritus Tetsuo Nozoe of Tohoku University for his kind guidance and to Mr. Hidekichi Nakajima for his cooperation in this work.

The Kinetics and Mechanism of the Reactions of *N*-Sulfinylanilines with Formic Acid

Fukiko YAMADA, Tomihiro NISHIYAMA, and Toshiharu EMI

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka

(Received August 9, 1971)

We have examined the kinetics of the reactions between *N*-sulfinylanilines and formic acid. The reactions follow this rate equation; rate=k[R–C_6H_4–NSO][HCOOH]. The kinetic runs were made over a wide temperature range (40—90°C) in order to obtain the values of the activation energy. The values for the reactions of *N*-sulfinylaniline, *N*-sulfinyl-*p*-toluidine, and *N*-sulfinyl-*p*-chloroaniline with formic acid are 14.6, 15.1, and 10.1 kcal/mol respectively. The reaction mechanism is discussed by means of their NMR spectral data.

In 1932, Carré and Libermann reported that carboxylic acids react with *N*-sulfinylaniline to form the corresponding anilides:[1]

$$C_6H_5NSO + RCOOH \longrightarrow C_6H_5NHCOR + SO_2$$

Recently, Smith and King re-examined the above reaction.[2] They presented the possibility that a trace of either thionyl chloride, or hydrogen chloride, or traces of both, might be present as an impurity in *N*-sulfinylaniline and that one of these impurities might have been acting as the catalyst. In consequence, the following mechanism was postulated by them;

$$C_6H_5NSO + 3HCl \longrightarrow C_6H_5NH_2 \cdot HCl + SOCl_2$$

$$RCOOH + SOCl_2 \longrightarrow RCOCl + SO_2 + HCl$$

$$C_6H_5NH_2 \cdot HCl + RCOCl \longrightarrow C_6H_5NHCOR + 2HCl$$

They concluded that the steps involved in the reaction of *N*-sulfinylaniline with carboxylic acids are correctly described by the above sequence, in which both aniline hydrochloride and thionyl chloride are intermediates. The reaction was shown to require the presence of hydrogen chloride.

On the other hand, some recent reports from this laboratory have described the reactions of *N*-sulfinylanilines with alkene oxides[3,4] and the general structures of the reaction products, the oxathiazolidines, as determined by means of their NMR[4] and mass spec-

tra.[5] In these circumstances, it became of interest to study the reactivity of *N*-sulfinylanilines in relation to formic acid. The present paper is concerned with the kinetics of the reactions of *N*-sulfinylanilines with formic acid carried out in the absence of the catalysts, that is, in the absence of both hydrogen chloride and thionyl chloride. The reaction mechanism is also discussed.

Experimental

Measurements. All the melting points are uncorrected. The NMR spectra were obtained at 60 MHz with a Japan Electron Optics Model JNM 3H-60 spectrometer at room temperature. The chemical shifts are reported in ppm downfield from the internal TMS (δ). A constant-temperature bath was employed; it was equipped with an immersion heating element that afforded a temperature control of ± 0.1°C.

Materials. *N*-Sulfinylaniline, *N*-sulfinyl-*p*-toluidine, and *N*-sulfinyl-*p*-chloroaniline were prepared and purified by the reported method.[6] No hydrogen chloride or thionyl chloride was left in the *N*-sulfinylanilines. These facts were confirmed by using both gas chromatography and the NMR method. The formic acid was of an analytical grade and was dried for several days over anhydrous copper sulfate and filtered, after which the filtrate was distilled under reduced pressure.

Kinetic Procedure. In a 3-necked, 30-m*l* flask equipped with a gas inlet and output tubes and an addition funnel, we placed *N*-sulfinylaniline (0.05 mol). In a typical second-order run, about a twofold excess of formic acid was added rapidly to start the reaction. The flask was swirled in order to mix the reactants and was then kept at a constant temperature. A constant flow of dry nitrogen gas was introduced into the reaction mixture throughout the reaction (2.0—4.5 *l*/hr). Nitrogen was passed through the reaction flask to sweep the sulfur dioxide evolved into 80 m*l* of water in the absorption bulbs; at the end of a sufficient period, 5 or 10 min, the bulbs were disconnected and exchanged for other bulbs using a three-way stopcock. In each run, a 10-m*l* portion was withdrawn from the aqueous solution; we then added a known excess of an iodine solution (0.1N) and determined the amount of the excess by back titration with standard sodium thiosulfate. The rate of sulfur dioxide's release was obtained by this method. The conversion of *N*-sulfinylaniline based on the initial concentration can, therefore, be obtained by means of the measurement of the sulfur dioxide evolved. The rate constants given in the table are the averages of two or more determinations.

Reaction-products Criterion. The crystals were obtained in almost quantitative yields by the reactions of *N*-sulfinylanilines with formic acid and did not show any melting-point depression when the products were mixed with authentic samples of the corresponding *p*-substituted formanilides; formanilide, mp and mmp 46.0—47.5°C; *N*-*p*-tolylformamide, 50.0—50.4°C, and *N*-*p*-chlorophenylformamide, 99.0—99.8°C. The analytical results of these compounds coincided with those of the authentic compounds.

Results and Discussion

The rate of the reaction of *N*-sulfinylanilines with formic acid was followed by the iodine titration of the sulfur dioxide evolved. The results gave good second-order rate constants for all the runs, and the points obtained fell on good straight lines (Fig. 1):

$$\text{rate} = k[\text{R-C}_6\text{H}_4\text{-NSO}][\text{HCOOH}]$$

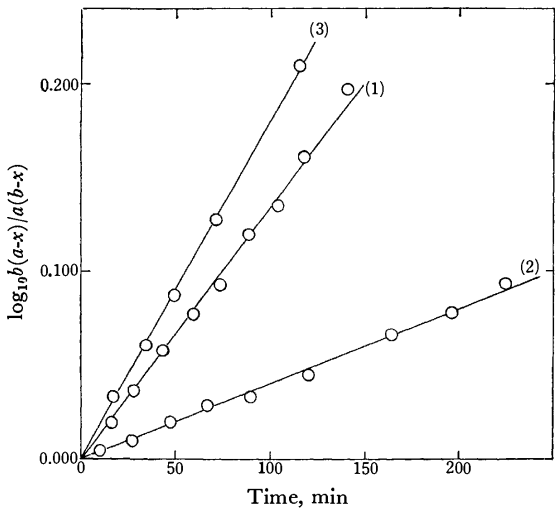

Fig. 1. The second-order plots for the reaction of *N*-sulfinylanilines with formic acid at 60°C. *a* and *b* are the initial concentrations of formic acid and *N*-sulfinylanilines, respectively.
(1) *N*-sulfinylaniline, 5.03 mol/*l*; formic acid, 13.03 mol/*l*. conversion 48.4%.
(2) *N*-sulfinyl-*p*-toluidine, 5.98 mol/*l*; formic acid, 10.86 mol/*l*. conversion 34.7%.
(3) *N*-sulfinyl-*p*-chloroaniline, 5.17 mol/*l*; formic acid, 10.92 mol/*l*. conversion 54.0%.

TABLE 1. THE RATE CONSTANTS AND THE VALUES OF THE ACTIVATION ENERGY FOR THE REACTION OF *N*-SULFINYLANILINES WITH FORMIC ACID

Temp. C°	*N*-Sulfinylaniline $k\times10^4$, *l*/mol·min	*N*-Sulfinyl-*p*-toluidine $k\times10^4$, *l*/mol·min	*N*-Sulfinyl-*p*-chloroaniline $k\times10^4$, *l*/mol·min
40	—	—	2.9
50	1.5	0.9	4.8
60	3.6	1.8	7.2
70	7.3	4.0	12.3
80	12.2	6.6	—
90	16.1	9.4	—
E, kcal/mol	14.6	15.1	10.1

Table 1 shows the rate constants of the reactions of *N*-sulfinylanilines with formic acid at various temperatures, along with the values of the activation energy as evaluated from the slopes of the Arrhenius plots. The data given in Table 1 clearly indicate that *N*-sulfinyl-*p*-chloroaniline reacted faster with formic acid than did *N*-sulfinylaniline, as expected, and also faster than *N*-sulfinyl-*p*-toluidine. The reaction is facilitated by the introduction of an electron-attracting substituent into the phenyl group, but is retarded by that of an electron-releasing substituent.

Observation of the Reaction Process using NMR. The spectrum of *N*-sulfinylaniline in carbon tetrachloride exhibits the two-proton and three-proton multiplets due to the ring proton in the regions of 7.93—8.10 and 7.45—7.58 ppm respectively (Fig. 2). In the reaction

6) A. Michaelis and R. Herz, *Ber.*, **23**, 3480 (1890).

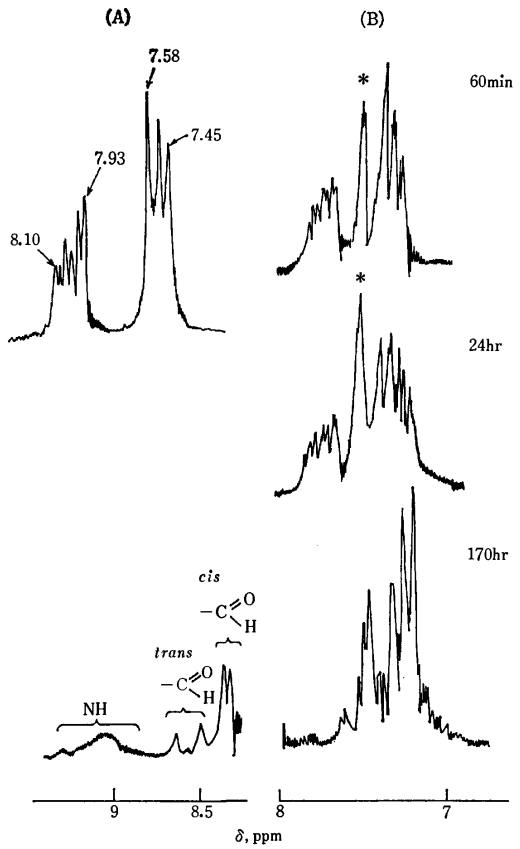

Fig. 2. The NMR spectrum of *N*-sulfinylaniline in CCl_4 (A) and changes of the NMR spectra with reaction time (B). Asterisks indicate the peak at 7.73 ppm.

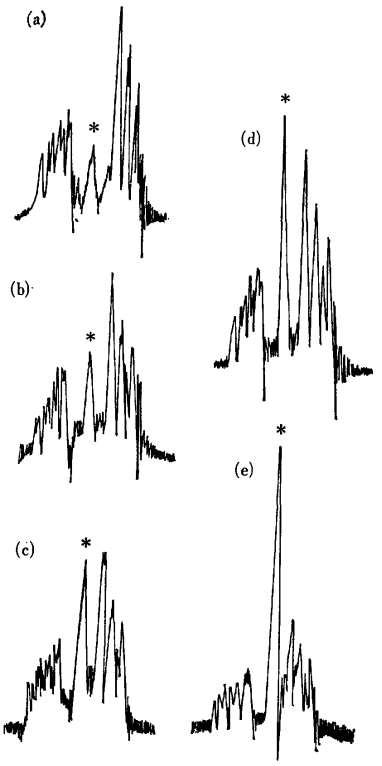

Fig. 3. The NMR signals of the ring protons of the reaction mixtures of *N*-sulfinylaniline with formic acid under various concentrations at 40°C for 60 min, molar ratios of *N*-sulfinylaniline to formic acid; (a) 1:4.3, (b) 1:5.5, (c) 1:7.6, (d) 1:11.1, and (e) 1:17.6. The spectra are not necessarily on exactly the same scale. Asterisks indicate the peak at 7.73 ppm.

of a fivefold excess of formic acid with *N*-sulfinylaniline at 25°C, a new single peak immediately appears at 7.73 ppm (60 min). After the mixture has stood 24 hr, the peak was intensified. These signals changed with the reaction time. Of these signals, the three-proton signal changed most remarkably as a result of the overlapping of the ring-proton signal of the reaction product. The peak at 7.73 ppm increased and then decreased gradually. When the reaction was over, the two-proton signal disappeared; these NMR signals were changed to those of formanilide (170 hr).

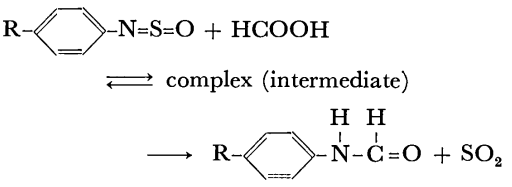
Figure 3 shows the NMR spectra of the reaction mixtures at different concentrations. After a mixture has stood for 60 min at 40°C, the peak at 7.73 ppm shows various intensities. This fact indicates that the intensive changes at the 7.73 ppm peak depend on the molar ratios of *N*-sulfinylaniline to formic acid under these experimental conditions.

Table 2. Chemical shifts in different solvents (1.70 mmol/ml)

Compound	Solvent	Chemical shifts, δ, ppm					
		Ring proton				New peak	Methyl
N-Sulfinyl-aniline	HCOOH	7.49—8.08				7.73	—
	CCl_4	7.45—8.10				—	—
N-Sulfinyl-*p*-toluidine	HCOOH	7.28	7.41	7.80	7.93	7.54	2.47
	CCl_4	7.22	7.35	7.84	7.97	—	2.62
N-Sulfinyl-*p*-chloroaniline	HCOOH	7.41	7.57	7.84	8.00	7.70	—
	CCl_4	7.40	7.55	7.87	8.02	—	—

The chemical shifts of *N*-sulfinylanilines in both formic acid and carbon tetrachloride are shown in Table 2. No new peak, such as the peak at 7.73 ppm, was observed in the carbon tetrachloride solutions. Peaks at 7.73, 7.54, and 7.70 ppm could, however, be observed in the formic acid solutions.

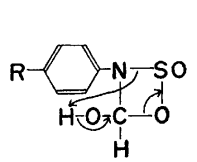
Probable Mechanism. The results presented above indicate that the reactions proceed by the following pathway:



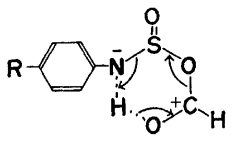
The reaction is initiated by the interaction between a sulfur atom of the –N=S=O group and a carbonyl oxygen of formic acid. Thus, the molecules can form a 1:1 complex; this step is probably rate-determining and is followed by the step yielding anilides and sulfur dioxide. The rates of the reactions in the 40—90°C temperature range showed a second-order dependence on the concentrations of the reactants. When *N*-sulfinylanilines react with more than fourfold excesses of formic acid or at low temperatures, below 40°C, new peaks were observed in their NMR spectra (in Table 2). It can, therefore, be suggested that the peaks indicate the existence of the intermediate in each reaction,

The new chemical shifts appeared as a result of the formation of the intermediates. The NMR spectrum of aniline formate in formic acid shows a single peak at 7.53 ppm, a slightly higher shift than that of the above intermediates. Aniline formate is also well-known as an intermediate of the reaction of aniline with formic acid.

There are ample examples in the literature to show that *N*-sulfinyl compounds form four-membered intermediates *via* the cycloaddition of the reactants. For example, Kresze and Albrecht[7,8] reported that the reactions of *N*-sulfinyl compounds with carbonyl compounds were transformations analogous to a Wittig reaction in which the carbonyl oxygen is replaced by the R–N= or RSO_2–N= group and the sulfur dioxide is eliminated. On the other hand, we have easily prepared the 2-oxo-3-aryl-1,2,3-oxathiazolidines, that is, five-membered heterocyclic compounds, by the cycloadditions of *N*-sulfinylanilines to alkene oxides.[3,4] From these facts, the four-membered ring structure seems to be less stable than the five-membered ring structure. In these circumstances, we propose a four or six-membered heterocyclic structure as an intermediate as follows:



four-membered intermediate



six-membered intermediate

At the present time, the four-membered ring-activated complex and the six-membered ring-activated complex are entirely compatible with the above experimental data.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 274—279(1972)

The Reaction between Hydrocarbon and Hydrogen Sulfide in Silent Electrical Discharge. I. The Reaction of Ethylene or Propylene with Hydrogen Sulfide

Yoshiharu NISHIMURA[1] and Kazuaki KAWAMOTO

Institute of Commodities, Faculty of Economics, Kagawa University, Takamatsu

(Received August 6, 1971)

In order to examine the possibility of the direct introduction of the sulfhydryl radical into ethylene or propylene and that of the telomerization by means of a silent discharge, the mixture of ethylene or propylene and hydrogen sulfide was discharged in an ozonizer. (1) With ethylene and hydrogen sulfide, the main products were ethyl mercaptan, *n*-butyl mercaptan, and ethylene dithioglycol. Besides these compounds, the reaction products were confirmed to be diethyl sulfide, *s*-butyl, *n*-hexyl, *n*-propyl, and isopropyl mercaptans, and gaseous products. (2) With propylene and hydrogen sulfide, on the other hand, *n*-propyl mercaptan, di-*n*-propyl sulfide, isopropyl mercaptan, and 1,2-propylene dithioglycol were obtained as the main products. Besides these compounds, there were diisopropyl sulfide, ethyl and *n*-butyl mercaptans, 4-methyl-1-pentene, 2,3-dimethylbutane, 1,5-hexadiene, 2-methylpentane, 1-hexene, *n*-hexane, and gaseous products. The maximum yield of the liquid products was obtained when ethylene or propylene and hydrogen sulfide were mixed in approximately the ratio of 1:1. Judging from the relative concentration of each compound in the reaction products, it may be said that vinyl, ethyl, and sulfhydryl radicals in the reaction system of ethylene and hydrogen sulfide, and 2-methylvinyl, isopropenyl, propyl, allyl, isopropyl, and sulfhydryl radicals in the reaction system of propylene and hydrogen sulfide, are the main intermediates.

The oxidation of hydrocarbons by a silent electrical discharge has been studied by Sugino *et al.*[2] and by Tsutsumi *et al.*[3]

In previous papers,[4] the reaction between hydrocarbon (cyclohexane, ethylene, and propylene) and hydrogen cyanide in a silent discharge was studied. When a mixed gas of ethylene and hydrogen cyanide was discharged in an ozonizer under atmospheric pressure, acrylonitrile could be prepared in one step. Besides this compound, the formation of telomers, such as ethyl, *n*-butyl, and *n*-hexyl cyanides, was also observed. Moreover, the reactions of ethylene with 2-propanol and with carboxylic acid under a silent dis-

charge have been reported by Hiraki.[5]

The direct synthesis of mercaptan and sulfide from olefin and hydrogen sulfide has been reported by many investigators. Vaughan and Rust[6] found that the photo-chemical addition of hydrogen sulfide to olefinic bonds took place very readily, giving mixtures of the corresponding mercaptans and sulfides. The radiation-induced addition of hydrogen sulfide to propylene to give *n*-propyl mercaptan and di-*n*-propyl sulfide has been investigated by Sugimoto *et al.*[7] The X-ray initiated free-radical addition of hydrogen sulfide to fluoroethylenes has been reported by Harris and Stacey.[8]

Losanitsch[9] reported that when a mixture of ethylene and hydrogen sulfide was subjected to a silent electrical discharge, ethyl mercaptan and the polymer of thioaldehyde ($(C_2H_4S)_6$) were obtained. However, no detailed study of the reaction of propylene with hydrogen sulfide under a silent discharge has yet been reported.

The present study was undertaken to find out whether the mercaptan and the sulfide are obtained by the reaction of ethylene or propylene with hydrogen sulfide under a silent discharge, to check whether or not a telomerization occurs under the present reaction conditions, and, at the same time to ascertain the mechanism of this reaction. In this research, the silent discharge was carried out in a Siemen ozonizer for 6 hr, using a voltage of 12 kilovolts. The direct introduction of a sulfhydryl radical into hydrocarbon was observed.

Experimental

Materials. The ethylene and propylene were purchased from the Nihon Sekiyu Kagaku Co., Ltd. (Kawasaki) and the Takachiho Chemicals Co. (Tokyo) respectively, and the hydrogen sulfide, from the Seitetsu Chemicals Co. (Osaka). These materials were used without further purification. No impurity was found in these reagents by gas-chromatographic analysis. (Columns of activated charcoal, acetonylacetone, dimethylsulfolane, and silica gel were used.)

Apparatus. The silent discharge reactor system used in this study is shown in Fig. 1. (1) Helium, hydrogen sulfide, and ethylene or propylene coming from the bomb were passed over calcium chloride (A). (2) The molar ratios of the ethylene or propylene and the hydrogen sulfide were roughly determined by means of a manometer (B), and the quantitative analysis of the mixed gas in this experiment was performed by gas chromatography. (A column of silica gel was used.) (3) The reservoirs (C) were filled with a mixture of ethylene or propylene and hydrogen sulfide. (4) The mixed gas was circulated by means of a pump (D) at the rate of 2 *l*/min. (5) The outside (a) of the discharge tube (E) was filled with water, and the inner tube (b), with a 3% $CuSO_4$ solution. (6) The discharge tube (E) used was a Pyrex tube 45 cm in effective length, 3.5 cm in outside diameter, and with a space gap of 0.25 cm. (7) The electrical energy was supplied by a 15-kV transformer (F).

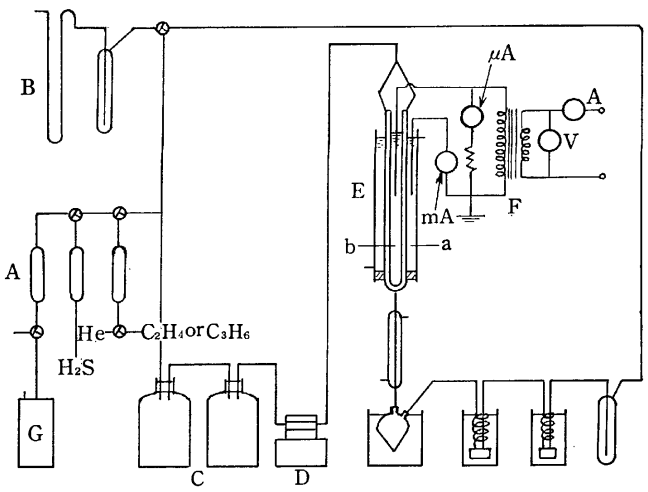

Fig. 1. Apparatus.

Procedure. In order to exclude the oxygen, the pressure in the system was reduced by means of a vacuum pump (G), and the oxygen was completely replaced by helium. In the presence of a small quantity of air, a great deal of a tarry yellow deposit was formed on the glass wall. A mixture of ethylene or propylene and hydrogen sulfide, at the molar ratio shown in Tables 1 and 3, was then put into the system. The volume of the system was 49.0 *l*. The mixed gas was made homogeneous by using a pump (D) for 30 min and was then passed through the discharge tube at a regular velocity of 2 *l*/min for the period of the reaction. A current of 60 cycles was passed through a voltage regulator; the voltage was stepped up by a transformer to give the required value. The products coming out of the discharge tube were condensed by passing them through a condenser; then they were collected by being passed through two traps cooled to −45°C by acetone-dry ice. The liquid products were analyzed by the method described below, while the non-condensable gases were analyzed by gas chromatography at intervals of 20 min. The pressure in the system during the period of the reaction was measured at intervals of 20 min.

Identification and Analysis of the Reaction Products. The liquid products obtained by the reaction between ethylene or propylene and hydrogen sulfide were identified by comparing their retention times on the gas chromatogram with those of authentic samples. (Columns of tricresyl phosphate, dinonyl phthalate, and Silicone DC-550 were used.) In addition, the reaction products were fractionally distilled, and the constituents of the fraction were identified by observing the formation of the derivatives.[10] Ethyl mercaptan was obtained in a fraction boiling at 33—36°C. From this fraction, 2,4-dinitrophenyl thioether, mp 114—115°C, and the 3,5-dinitrobenzoyl thioester, mp 61—62°C were obtained. The fraction boiling at 90—93°C was confirmed to consist mainly of diethyl sulfide by transforming it into the diethyl sulfone,[11] mp 73—74°C. Furthermore, the infrared spectrum of this fraction agreed with that of the authentic diethyl sulfide. *n*-Butyl mercaptan, obtained as a fraction boiling at 96—100°C, was converted into its 2,4-dinitrophenyl thioether and the 3,5-dinitrobenzoyl thioester, the melting points of the derivatives being 65—66°C and 48—49°C respectively. The ethylene dithioglycol was obtained in a fraction boiling at 144—146°C. Upon gas-chromatographic analysis, this frac-

tion showed the same retention time as that of authentic ethylene dithioglycol. The infrared spectrum of this fraction agreed with that of the authentic specimen.

The liquid products obtained by the reaction between propylene and hydrogen sulfide were identified by the following method. The fraction boiling at 56—60°C consisted of isopropyl mercaptan, which was identified by transforming it into the 2,4-dinitrophenyl thioether, mp 94—94.5°C, and the 3,5-dinitrobenzoyl thioester, mp 83—84°C. *n*-Propyl mercaptan was present in a fraction boiling at 65—68°C. From this fraction, the 2,4-dinitrophenyl thioether, mp 80—81°C, and the 3,5-dinitrobenzoyl thioester, mp 51—52°C were obtained. Di-*n*-propyl sulfide, obtained as a fraction boiling at 140—143°C, and 1,2-propylene dithioglycol (bp 148—154°C) showed the same retention times on the gas chromatogram as those of the authentic reagents, furthermore, the infrared spectra of these fractions agreed with those of the authentic specimens. The liquid hydrocarbon products listed in Table 4 were identified by the use of squalane, *β,β'*-oxydipropionitrile, tricresyl phosphate, and dimethylsulfolane columns.

These derivatives showed no depression of their melting points when mixed with authentic specimens. The gaseous products, obtained by the reaction between ethylene or propylene and hydrogen sulfide, were also analyzed by gas chromatography. (Columns of activated charcoal, tricresyl phosphate, a mixture of molecular sieve 13 X and hexamethylphosphoramide, acetonylacetone, and dimethylsulfolane were used.) The gaseous products could not be determined quantitatively. The quantitative analysis of the liquid products in this experiment was performed by gas chromatography.

Results and Discussion

The results obtained by running ethylene with hydrogen sulfide in an ozonizer under the conditions described in Table 1 are summarized in Table 2. Further, by running propylene with hydrogen sulfide under the conditions listed in Table 3, a large number of compounds were obtained. The compositions of those compounds which have been identified are summarized in Table 4. The percentage of the compounds shown in these tables does not necessarily represent the maximum yield, but is an average of three experiments under constant operating conditions. However, the fluctuation in the yields of the compounds obtained in repeated experiments was less than 1 per cent. A small amount of air was found to reduce the liquid products.

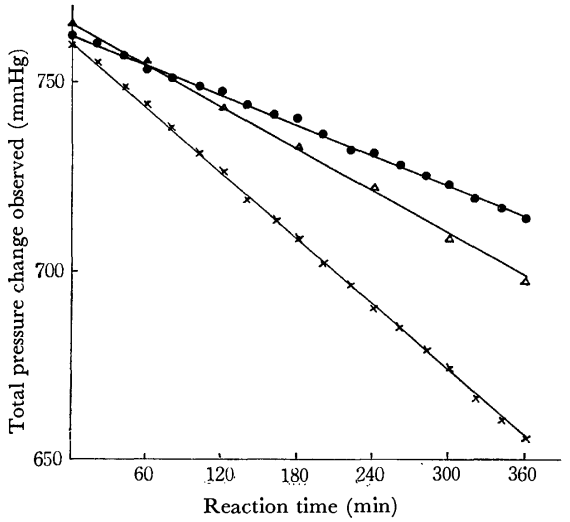
Air apparently acts as a free radical scavenger to retard this chain reaction. The gaseous products given by the reaction of ethylene and hydrogen sulfide consisted of hydrogen, methane, ethane, acetylene, propane, propylene, *n*-butane, 1-butene, and 1,3-butadiene. In the cases of propylene and hydrogen sulfide, the gaseous products were found to be hydrogen, methane, ethane, ethylene, acetylene, propane, methylacetylene, and allene.

Influence of the Molar Ratio of Ethylene to Hydrogen Sulfide on the Yield. In order to check the molar-ratio effects on the discharge reaction of ethylene and hydrogen sulfide, the reaction was carried out with various ratios of the ethylene to the hydrogen sulfide, as is shown in Table 1. As may be seen from Table 2, the yield of the reaction product depends upon the molar ratio of the ethylene and the hydrogen sulfide; the maximum yield of liquid products was obtained when they were mixed in the ratio of approximately 1 : 1. However, the distribution of the products depends on the molar ratio of the reactants as follows: (1) The yield of ethylene dithioglycol increased at high ratios of hydrogen sulfide to ethylene. (2) On the other hand, the *n*-butyl mercaptan and diethyl sulfide decreased with an increase in the ratio of hydrogen sulfide to ethylene. (3) The yield of ethyl mercaptan, though the molar ratio of ethylene and hydrogen sulfide changed, was approximately constant. Ethyl, *n*-butyl, and *n*-hexyl mercaptans seem to be formed by the telomerization between ethylene and hydrogen sulfide. However, the formation of *n*-octyl mercaptan (1 : 4 telomer) and one-to-five or more products could not be observed by gas-chromatographic analysis. The total pressure in the reaction system was measured at intervals of 20 min; the results are shown in Fig. 2.



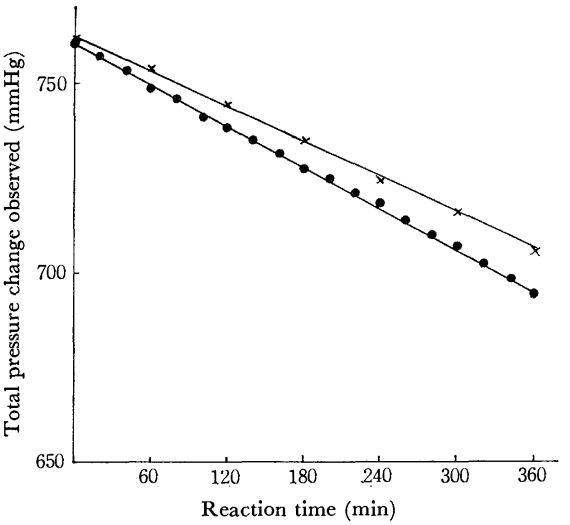
● : Experiment No. 1 △ : Experiment No. 5
× : Experiment No. 3

Fig. 2. Relation between total pressure in reaction system and time of reaction. (Reactants: C_2H_4 and H_2S)

As may be seen from this graph, the total pressure decreased linearly with the progress of the reaction time, in spite of the molar ratios of ethylene and hydrogen sulfide. A proportional relation was found between the velocity of the reduced pressure in the reaction system and the yield of the reaction product; that is, it has been found that increasing the velocity of the reduced pressure increases the amount of the reaction product. In addition, the ratio of the consumption of ethylene to hydrogen sulfide was found, from gas analysis, to be kept constant during the period of the reaction.

The Reaction between Propylene and Hydrogen Sulfide. When a mixture of propylene and hydrogen sulfide was allowed to react in a silent discharge, a large number of products (summarized in Table 4) were obtained. As is shown in Table 4, the conversion efficiency (grams of reaction product per grams of propylene and hydrogen sulfide used $\times 100$) depends upon the ratio of propylene to hydrogen sulfide; it has been found that the maximum yield of the liquid product was obtained when the mixed components of the reactant were approximately in the ratio of 1 : 1, that, in the 1 : 1 ratio, the addition products, such as *n*-propyl mercaptan and isopropyl mercaptan, were obtained in high yileds, while such sulfides as di-*n*-propyl sulfide and diisopropyl sulfide decreased with an increase in the ratio of hydrogen sulfide to propylene, and that, on the other hand, the yield of 1,2-propylene dithioglycol increased at high ratios of hydrogen sulfide to propylene. The formation of allyl mercaptan could not be observed by gas-chromatographic analysis. The yield of *n*-propyl mercaptan was higher than that of isopropyl mercaptan. Therefore, the addition followed an anti-Markownikoff rule. This rule was observed in both the photo-chemical addition[6] and the radiation-induced addition[7] of hydrogen sulfide to propylene. The nature of the discharge-induced addition appears to be similar to that of these additions. Figure 3 shows how the total pressure in the reaction system changes during the period of the silent discharge. In the cases of propylene and hydrogen sulfide, the same results as in the case of ethylene were obtained.

The Mechanism of the Formation of the Main Products Obtained by the Reaction of Ethylene and Hydrogen Sulfide.



● : Experiment No. 8
× : Experiment No. 9

Fig. 3. Relation between total pressure in reaction system and time of reaction. (Reactants: C_3H_6 and H_2S)

It was reported by Egloff *et al.*[12] that the radical from ethylene in the electrical discharge was a vinyl radical, and that it was produced by breaking a carbon-hydrogen bond. Tsutsumi[13] reported that the vinyl radical was obtained by two molecular processes,[14] as is shown below. One of the present authors reported that the formation of acrylonitrile by the reaction of ethylene with hydrogen cyanide in the silent discharge may be observed by a combination of the vinyl radical and the cyano radical.[4] It has been reported by Hiraki[5] that the formation of the methyl vinyl ketone by a reaction between ethylene and methyl acetate in a silent discharge may be due to the combination of the vinyl radical and acetyl radical. Gorden and Ausloos[15] reported that the vacuum-ultraviolet photolysis of ethylene led essentially to three types of processes, as is indicated below.[16]

The mechanism of the formation of ethyl mercaptan, *n*-butyl mercaptan, ethyl dithioglycol, and diethyl sulfide by the reaction of ethylene with hydrogen sulfide may be represented as follows: The first step is the vibrational excitation of the ethylene molecule and the hydrogen sulfide molecule by electron impact,[17] while the second step consists of both (1) the reaction of the excited ethylene molecule with a normal ethylene molecule to give the vinyl radical and the ethyl radical,[14] and(2) the decomposition of the excited molecules to give the vinyl radical, the sulfhydryl radical, and the hydrogen atom. Ethyl mercaptan may be formed by three paths: (1) the combination of the ethyl radical (obtained by two molecular processes) and the sulfhydryl radical, (2) the reaction of the sulfhydryl radical with ethylene, and then the addition of a hydrogen atom to the $\dot{C}H_2$-CH_2SH radical so formed, and (3) the formation of vinylthiol[18] or ethylene sulfide[19] by the combination of the vinyl radical and the sulfhydryl radical, and then the addition of hydrogen atoms to the compounds thus obtained. The formation of acetylene, 1,3-butadiene, and 1-butene may show the existence of the vinyl radical. Further, it seems that ethane, *n*-butane, and 1-butene are obtained by the use of the ethyl radical. The formation of *n*-butyl mercaptan may be presented as follows:

$$CH_2{=}CH_2 + \cdot SH \longrightarrow \dot{C}H_2{-}CH_2SH$$

$$CH_2{=}\dot{C}H + \cdot SH \longrightarrow CH_2{-}CH_2 \quad (\text{S bridge})$$

$$CH_2{-}CH_2\ (\text{S bridge}) + H_2S \longrightarrow \dot{C}H_2{-}CH_2SH + \cdot SH$$

$$\dot{C}H_2{-}CH_2SH + C_2H_4 \longrightarrow \dot{C}H_2{-}(CH_2)_3SH$$

$$\dot{C}H_2{-}(CH_2)_3SH + H_2S \longrightarrow CH_3{-}(CH_2)_3SH + \cdot SH$$

Ethyl dithioglycol may be formed by the addition of the sulfhydryl radical to the $\dot{C}H_2$–CH_2SH radical. The formation of diethyl sulfide may proceed by two paths: (1) the reaction between vinylthiol or ethylene sulfide and the hydrogen atom, the addition of the $CH_3CH_2S\cdot$ radical thus obtained to ethylene and then the reaction of the $CH_3CH_2SCH_2\dot{C}H_2$ radical and the hydrogen atom, and (2) the reaction of the ethyl mercaptan, once formed, with ethylene to give the diethyl sulfide.[20]

The Mechanism of the Formation of the Main Products Obtained by the Reaction of Propylene and Hydrogen Sulfide. The formation of the main products obtained by the reaction of propylene and hydrogen sulfide in a silent discharge is thought to proceed by a mechanism similar to that proposed for the reaction between ethylene and hydrogen sulfide. The process consists of both (1) the reaction of the excited propylene molecule with a normal propylene molecule to give 2-methylvinyl, isopropenyl, allyl, propyl, and isopropyl radicals,[21] and (2) the decomposition of the excited propylene or hydrogen sulfide to give 2-methylvinyl, isopropenyl, allyl,

12) C. L. Thomas, C. Egloff, and J. C. Morell, *Chem. Rev.*, **28**, 1 (1941).

13) S. Tsutsumi, *Kagaku Kogyo*, **16**, 623 (1965).

14) $CH_2{=}CH_2 + e^* \longrightarrow CH_2{=}CH_2^* + e$
$CH_2{=}CH_2^* + CH_2{=}CH_2 \longrightarrow CH_2{=}\dot{C}H + CH_3\dot{C}H_2$

15) R. Gorden, Jr., and P. Ausloos, *J. Chem. Phys.*, **47**, 1799 (1967).

16) $C_2H_4^* \longrightarrow C_2H_2 + H_2$
$C_2H_4^* \longrightarrow C_2H_3 + H$
$C_2H_4^* \longrightarrow C_2H_2 + 2H$

17) Although ion-molecular process are possible in some electron-impact reactions, in the present case this process does not seem to be the main path, judging from the results presented by Devins *et al.*, Inoue,[2] and Egloff *et al.*[12] The present reaction is presumed to be mostly a radical reaction. (J.C. Devins and M. Burton, *J. Amer. Chem. Soc.*, **76**, 2618 (1954).)

18) Stacey *et al.* reported the preparation of vinylthiols by the X-ray-initiated addition of hydrogen sulfide to mono- and disubstituted acetylenes at room temperature, and it has been reported by Oae that vinylthiol is more stable than thioaldehyde. (F. W. Stacey and J. F. Harris, Jr., *J. Amer. Chem. Soc.*, **85**, 963 (1963); S. Oae, "Chemistry of Organic Sulfur Compounds," Kagakudojin, Kyoto (1968), p. 103.)Strausz *et al.* found that irradiation by a medium-pressure mercury arc lamp of mixtures of hydrogen sulfide and acetylene or methylacetylene in quartz reaction cells at −78° C gave good yields of vinyl mercaptan and 2-methylvinyl mercaptan respectively. (O. P. Strausz, T. Hikida, and H. E. Gunning, *Can. J. Chem.*, **43** (3), 717 (1965).)

19) It was reported by Strausz *et al.* that, when a photo-chemical reaction between ethylene or propylene and carbonyl sulfide was carried out, the corresponding vinylthiols, such as vinyl mercaptan, methylvinyl mercaptan, and propenethiol, and the corresponding cyclic compounds, such as ethylene sulfide, and propylene sulfide, were formed. Furthermore, they reported that the following steps must be considered for the primary reaction:

$$S(^1D) + \text{olefin} \longrightarrow \begin{cases} [C{-}C]^{**} \ (\text{S bridge}) \\ [C{=}C{-}SH]^{**} \\ S(^3P) + \text{olefin}^* \\ [C{=}C{-}CH_2{-}SH]^{**} \end{cases}$$

(O. P. Strausz and H. E. Gunning, *J. Amer. Chem. Soc.*, **84**, 4080 (1962); H. A. Wiebe, A. R. Knight, O. P. Strausz, and H. E. Gunning, *ibid.*, **87**, 1443 (1965).)

20) The free radical addition of thiols to olefin under irradiation with gamma rays has been investigated by Fontijn and Spinks, and by Araki. They found that the corresponding sulfides were formed as the main products. (A. Fontijn and J. W. J. Spinks, *Can. J. Chem.*, **35**, 1384, 1397, 1410 (1957); K. Araki, *Nippon Kagaku Zasshi*, **81**, 807 (1960).) It has been reported by Bach that the processes induced by the discharge reaction are similar to those induced by radiolysis. (N. Bach, *Chem. Eng. Progr.*, **51**, 478 (1955).)

21) $CH_2{=}CH{-}CH_3 + e^* \longrightarrow C_3H_6^* + e$
$C_3H_6^* + CH_2{=}CH{-}CH_3 \longrightarrow$

$$\begin{cases} \dot{C}H{=}CH{-}CH_3 \\ CH_2{=}\dot{C}{-}CH_3 \\ CH_2{=}CH{-}CH_2\cdot \end{cases} + \begin{cases} CH_3{-}CH_2{-}CH_2\cdot \\ CH_3{-}\dot{C}H{-}CH_3 \end{cases}$$

and sulfhydryl radicals, and a hydrogen atom.[22] The formation of *n*-propyl mercaptan may be represented by the same mechanism as the formation of ethyl mercaptan in the case of ethylene. In the case of the reaction between propylene and hydrogen sulfide, vinylthiols ($CH_3CH{=}CHSH$ and $CH_3C(SH){=}CH_2$) or propylene sulfide ($CH_3{-}CH\overset{S}{\diagdown\!\diagup}CH_2$) may be formed by the combination of the 2-methylvinyl radical or the isopropenyl radical and the sulfhydryl radical.

Isopropyl mercaptan may be formed by two paths: (1) A hydrogen atom adds preferentially to the terminal carbon atom of propylene to form the isopropyl radical,[23] and the radical thus produced yields isopropyl mercaptan. (2) This compound is obtained by the addition of hydrogen atoms to vinylthiols or propylene sulfide.

The dimeric products, such as 4-methyl-1-pentene, 2,3-dimethylbutane, 2-methylpentane, 1,5-hexadiene, 1-hexene, and *n*-hexane, may be formed by a recombination reactions between propyl, isopropyl, and allyl radicals.

22) $C_3H_6^* \longrightarrow \begin{cases} \dot{C}H{=}CH{-}CH_3 \\ CH_2{=}\dot{C}{-}CH_3 \\ CH_2{=}CH{-}CH_2\bullet \end{cases} + \bullet H$

$H_2S^* \longrightarrow \bullet SH + \bullet H$

23) Moore reported that, when the mercury-photosensitized hydrogenation of propylene was carried out over a range of temperatures from 30 to 200°C, a hydrogen atom was added to the terminal carbon atom of propylene to form the isopropyl radical. (W. J. Moore, *J. Chem. Phys.*, **16**, 916 (1948).)

NOTES

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 280—281(1972)

The Mass Spectra of *N,N'*-Diarylpiperazines

Fukiko YAMADA, Yasuyoshi FUJIMOTO, and Tomihiro NISHIYAMA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka

(Received January 6, 1971)

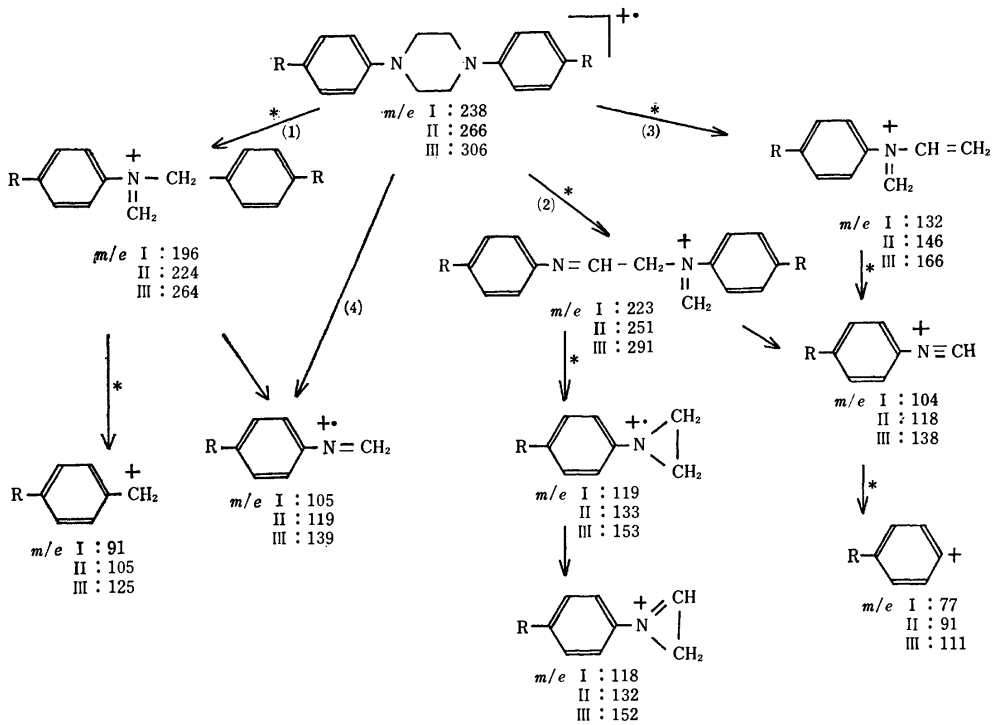
In a previous paper, we reported on the preparation of *N,N'*-diarylpiperazines, which have a substituent, a *p*-methyl or *p*-chloro group, on the benzene ring.[1] Mass spectrometric data will now be reported for *N,N'*-diphenylpiperazine (I, R=H), *N,N'*-di-*p*-tolylpiperazine (II, R=CH_3), and *N,N'*-di-*p*-chlorophenylpiperazine (III, R=Cl). By the use of metastable-ion measurements, the major fragmentation pathways of the three compounds, I, II, and III, have been deduced.

The mass spectral data of the compounds are shown

Table 1. Mass spectral data of the compounds, I, II, and III

Compound I			Compound II			Compound III		
m/e	Ion composition[a]	Rel. int. (%)	*m/e*	Ion composition	Rel. int. (%)	*m/e*	Ion composition	Rel. int. (%)
238	$C_{16}H_{18}N_2$	79	266	$C_{18}H_{22}N_2$	89	306	$C_{16}H_{16}N_2Cl_2$	57
223	$C_{15}H_{15}N_2$	14	251	$C_{17}H_{19}N_2$	26	291	$C_{15}H_{13}N_2Cl_2$	3
196	$C_{14}H_{14}N$	10	224	$C_{16}H_{18}N$	13	264	$C_{14}H_{12}NCl_2$	6
132	$C_9H_{10}N$	40	146	$C_{10}H_{12}N$	49	166	C_9H_9NCl	39
119	C_8H_9N	21	133	$C_9H_{11}N$	29	153	C_8H_8NCl	12
105	C_7H_7N	100	119	C_8H_9N	100	139	C_7H_6NCl	100
104	C_7H_6N	39	118	C_8H_8N	34	138	C_7H_5NCl	41
91	C_7H_7	19	105	C_8H_9	23	125	C_7H_6Cl	16
78	C_6H_6	11	92	C_7H_8	23	111	C_6H_4Cl	26
77	C_6H_5	53	91	C_7H_7	60			

a) The high-resolution mass spectra of these compounds gave correct composition of all ions mentioned in the table, within the error of ±5 millimass units.



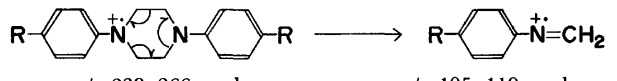
* Asterisks denote the processes for which metastable transitions were observed.

Scheme 1. The major fragmentation paths of the compounds.

1) F. Yamada, T. Nishiyama, M. Kinugasa, and M. Nakatani, This Bulletin, **43**, 3611 (1970).

in Table 1, while the major fragmentation paths are shown in Scheme 1.

The molecualr ions produce a prominent peak and are usually the second most abundant ion in the spectra of the compounds. The base peaks are at masses 105, 119, and 139 respectively, and are due to $R-C_6H_4N-CH_2^{+}\cdot$. These ions result from the elimination of the $R-C_6H_4\dot{C}H_2$ radical from the intermediate ion, $(R-C_6H_4)_2\overset{+}{N}CH_2CH_2$, (Path 1 in Scheme 1) or from the retro-Diels-Alder decomposition of the molecular ion (Path 4). This decomposition will be a dominating process in the formation of the $R-C_6H_4\overset{+\cdot}{N}CH_2$ ion:

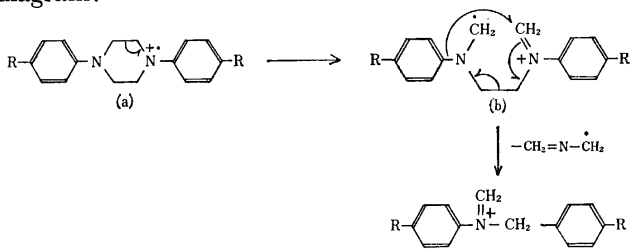


m/e 238, 266, and 306 → *m/e* 105, 119, and 139

In the case of Compound I, the metastable transition indicates that the above ion can also be formed by another route, one which involves the loss of C_2H_2 from the $C_9H_9N^{+}\cdot$ ion with the mass of 131. Thus, the fragmentation pathways of I are rather more complex than those of II and III. However, all three compounds, I, II, and III, give very similar pathways, as is shown in Scheme 1.

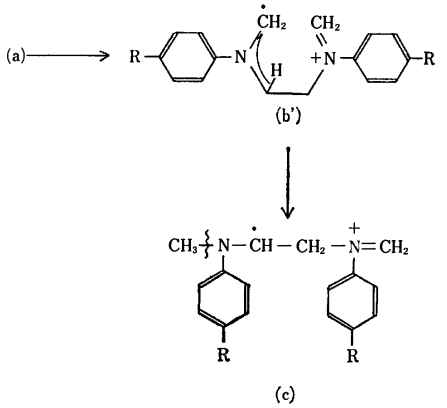
The metastable transitions and exact mass measurements indicate the following results.

Path (1), Giving m/e 196, 224, and 264. These fragments are generated directly from the molecular ion by the loss of a C_2H_4N radical. The probable fragmentation mechanism is indicated by the following diagram:



m/e 196, 224, and 264

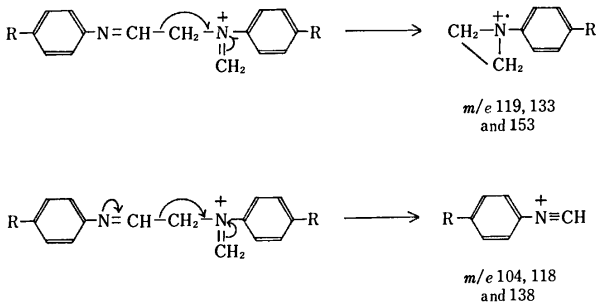
The ring cleavage of the molecular ion as in **a** and the subsequent rearrangement with the transfer of the *N*-bonded aryl group, as is shown in **b**, afforded the fragment ion.



Path (2), Giving m/e 223, 251, and 291. These ions are produced from the molecular ion by the loss of the respective methyl radicals.

The rearrangement with the transfer of a hydrogen atom, as is shown in **b'**, followed by the loss of the species from **c**, gives the fragment ions.

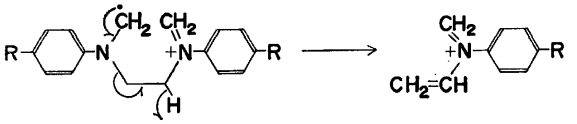
The ions at the masses of 119, 133, and 153 can be formed by the loss of the $R-C_6H_4NCH$ radical from *m/e* 223, 251, and 291 respectively, while the ions at *m/e* 104, 118, and 138 may also be formed by the expulsion of the $R-C_6H_4NC_2H_4$ fragment from the same point of origin. It is thought that this fragmentation process is due to a one- or two-electron shift, as is shown below:



m/e 119, 133 and 153

m/e 104, 118 and 138

Path (3), Giving m/e 132, 146, and 166. These ions are produced by the loss of the $R-C_6H_4NCH_3$ radicals from the respective molecular ions.



m/e 132, 146, and 166

As has been described above, in the mass spectra of the three compounds, I, II, and III, there are four principal modes of fragmentation of the molecular ion:

(1) Aryl rearrangement (Path 1)
(2) Loss of a methyl radical (Path 2)
(3) Loss of a $R-C_6H_4NCH_3$ radical (Path 3), and
(4) retro-Dieles-Alder decomposition (Path 4).

This fragmentation behavior of the compounds resembles that of piperazine and its derivatives,[2] but the M−1 ions were not observed, as expected, in the *N,N'*-diarylpiperazines.

Experimental

The high-resolution mass spectra were obtained with a Japan Electron Optics Co., Ltd., JMS-O1SG mass spectrometer. Accurate mass values were obtained from the photoplate by means of a JMA-1C Automatic Data analyzer. The metastable-ion transitions were determined by scanning the accelerating voltage, as has been described in the literature.[3]

The Formation Constants of Some Metal Thiobenzoato- and Thioacetato-Complexes in Dioxane-Water Solvent

Akira OUCHI, Toshio TAKEUCHI, Yoshiaki TAKAHASHI, and Mitsuhisa NAKATANI

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received January 27, 1971)

Recently the metal complexes of sulfur-containing ligands have been actively studied and many papers have been published. However, only a few data about their stability in the solution state have been obtained because of their low solubilities in water or their instabilities in a solution due to solvolytic decomposition.

Monothiocarboxylic acid is one of the most interesting sulfur-containing ligands, and solid metal complexes of monothio-benzoic acid have recently been synthesized and investigated by several authors.[1-3] Although they are insoluble in water, some of them are soluble in a 60% dioxane-water solution. Therefore, it seemed that it would be interesting to obtain their formation constant data.

The nickel(II), cobalt(II), manganese(II), zinc(II), and iron(II) complexes of thiobenzoic acid as well as thioacetic acid were investigated. When the copper(II) salt was mixed with the thiocarboxylic acid, an insoluble copper(I) complex has precipitated immediately. In the run using cadmium(II) salt, the equilibrium was not obtained even after it had stood 2 hr; after that turbidity was observed in the solution. Consequently, the formation constants of neither copper(II) nor cadmium(II) complexes were obtained.

Experimental

Materials. The 1,4-dioxane was a G. R. reagent of the Wako Chemical Co., Ltd., and was used after being purified according to the directions of Riddich and Toops.[4] The thiobenzoic acid and thioacetic acid used were G. R. reagents of the Tokyo Kasei Chemical Co., Ltd., while the other chemicals used were G. R. reagents of the Wako Chemical Co., Ltd.; they were used without any further purification.

General Procedure. The techniques employed were those of Calvin.[5] A Toa Denpa Co. model HA-5A pH meter, a glass electrode, and a saturated calomel electrode were used. All the measurements were made at 30.0±0.1°C. Each run was repeated 4 times, and the average values were used for the calculations.

The Measurement of the Acid-dissociation Constants. 30 ml of dioxane, 5 mmol of potassium nitrate, and 1 mmol of thiocarboxylic acid were diluted to 50 ml with water.[6] The sample was titrated with a 1.000N sodium hydroxide standard aqueous solution. From the reading of the pH meter of the half-neutralized point (B), the pK_D (where K_D is the acid dissociation constant) was obtained by the Uitert's equation, $pK_D=B+(\log U_H^0+\log 1/\gamma)$ (where U_H is a conversion factor obtained by the diagram of the authors).[7]

The Measurement of Formation Constants of the Complexes. 30 ml of dioxane, 4 mmol of potassium nitrate, 1 mmol of nitric acid, 0.1 mmol of metal nitrate (the sulfate was used in the cases of iron(II) salt), and 1 mmol of the ligand were mixed and diluted to 50 ml with water. The sample solution was left in a thermostat bath more than 3 hr in order to attain the equilibrium state. The titration of the sample was done over a 6 hr period after the dissociation in order to avoid the effect of the decomposition of the solute.

No precipitation was found during the ($n<2$) process. The calculation of the formation constants was done as has been described by Calvin,[5] Uitert,[7-9] and Goldberg.[10]

Results and Discussion

A typical run of the data and the results of the calculation are shown in Table 1. The acid dissociation constants obtained and the formation constants of their complexes are shown in Table 2.

Generally, the thiobenzoates are slightly more stable than the thioacetates of the corresponding metals.

TABLE 1. TITRATION OF 60% DIOXANE-WATER SOLUTION OF NICKEL NITRATE (2.00×10^{-2}M), THIOBENZIOC ACID (2.00×10^{-2}M), POTASSIUM NITRATE (8.00×10^{-3}M), AND NITRIC ACID (2.00×10^{-3}M) WITH STANDARD AQUEOUS SOLUTION OF SODIUM HYDROXIDE (1.00N)

NaOH (ml)	B	$\bar{n}$	p(Ch$^-$)
1.050	3.96	0.54	4.30
1.100	4.20	1.00	4.09
1.150	4.40	1.44	3.91
1.200	4.65	1.91	3.69

B: Reading of the pH meter standardized with aqueous buffer.
(Ch$^-$): Mole concentration of the monovalent chelate anion Ch$^-$.
$\bar{n}$: The number of the coordinated ligand molecules per one metal ion.

5) M. Calvin and K. W. Wilson, *J. Amer. Chem. Soc.*, **67**, 2003 (1945).
6) As the sample was titrated with a sodium hydroxide aqueous solution, each calculation was carried out using the U_H^0 (conversion factors) and values of each dioxane concentration, assuming that the total volume was obtained by the addition of the two. In these regions, the difference of $(U_H^0+\log 1/\gamma)$ per 1% difference in the dioxane concentration is about 0.02. In Table 2, the concentration of dioxane is abbreviated to 60%, even though the precise values at 60% are expected to be in the range of ±0.02.

Table 2. The dissociation constants and the formation constants of metal complexes of thiobenzoic acid and thioacetic acid in 60% dioxane[6] at 30°C

	Thiobenzoic acid		Thioacetic acid	
	$\log K_1$	$\log K_2$	$\log K_1$	$\log K_2$
H	-7.3_4		-7.6_1	
Mn(II)	4.1	3.5	4.1	3.5
Fe(II)	4.3	3.8	4.2	3.8
Co(II)	4.3	3.9	4.0	3.5
Ni(II)	4.3	3.9	4.1	3.6
Zn(II)	5.4	4.5	4.8	4.1

The formation constants of manganese(II), iron(II), nickel(II), and cobalt(II) were almost all the same, but that of the zinc(II) complex was a little higher, when the ligand acid was the same. According to Savant,[1] in the nickel(II) and zinc(II) complexes of thiobenzoic acid, the ligand acts as the bidentate and coordinates to the central metal *via* oxygen as well as *via* the sulfur atom of the ligand. Although the complexes of some of the metals used in this experiment have not yet been obtained in the solid state, they are expected to be in almost a very similar form in the solution. These complexes may be solvetad by dioxane, as in the case of pyridine adduct shown by Melson.[2] In the calculations, however, it is assumed that the thiocarboxylic acid will coordinate far more strongly than dioxane. According to Yamasaki,[11] the formation constants of nickel(II) and zinc(II) benzoate in an aqueous solution are slmost the same. On the other hand, Yamasaki,[12] Leussing,[13] and Freiser[14] have reported that zinc(II) makes a more stable complex than does nickel(II) when the ligand bonds to the central metal with charged sulfur.

Therefore, from these results, it seems that the sulfur atom of the thiocarboxylato complexes of these metals is likely to bond to the central metal even in a solution.

The authors wish to thank Professor Yukichi Yoshino and their colleagues for their helpful discussions.

An NMR Study of Metal Complexes Containing Acetylacetone and Related Compounds. II. The Preparation and Structure of Mixed Cobalt(III) Complexes Containing Acetylacetone and Amino Acids

Yuki Fujii and Toshio Ejiri

Department of Chemistry, Ibaraki University, Bunkyo-cho, Mito, Ibaraki

(Received May 7, 1971)

Many reports have been published on the NMR spectra of tris-type β-diketonatocobalt(III) complexes.[1-3] Recently, bis-type acetylacetonatocobalt(III) complexes have also been prepared. Their NMR spectra have been studied and their geometrical isomers assigned.[4-8]

In this paper, we will report the preparations of mixed cobalt(III) complexes containing one molecule of the acetylacetone anion and two molecules of the amino acid anion, and will discuss the relation between the structures of mono-type acetylacetonatocobalt(III) complexes and their NMR spectra.

Experimental

Preparation of the Complexes. *1)* cis(N)cis(O)-*Bisglycinatoacetylacetonatocobalt(III) Monohydrate*, cis(N) cis (O)-[*Co(gly)$_2$(acac)*]·H_2O *(I)*: Sodium dinitrobisacetylacetonatocobalt (III)[4] (8.0 g, 0.014 mol) was dissolved in 200 m*l* of water, and then methanol (40 m*l*), glycine (2.0 g, 0.027 mol) neutralized with potassium hydroxide (0.86 g) in 30 m*l* of water, and activated charcoal (2.0 g) were added to the solution in this order. The mixture was heated at about 70°C for ten minutes, the activated charcoal was filtered off, and the filtrate was concentrated to about 40 m*l*; the trisacetylacetonatocobalt(III) thus deposited was then filtered off. When acetone (100 m*l*) was added to the filtrate, reddish-purple crystals were separated out. They were subsequently recrystallized from 33% acetone. Yield, about 1.5 g (32%). Found: C, 35.23; H, 5.65; N, 9.00%. Calcd for $C_9H_{15}CoN_2O_6\cdot H_2O$: C, 35.07; H, 5.57; N, 9.09%.

2) cis(N)trans(O)-*Bisglycinatoacetylacetonatocobalt(III) Monohydrate*, cis(N)trans(O)-[*Co(gly)$_2$(acac)*]·H_2O *(II)*: Trisacetylacetonatocobalt(III) (3.6 g, 0.01 mol) was dissolved in 200 m*l* of methanol. Glycine (1.5 g, 0.02 mol) neutralized with potassium hydroxide (1.2 g) in 50 m*l* of water and

activated charcoal (1.0 g) were added, and the mixture was heated at about 60°C for fifteen minutes. The activated charcoal was then filtered off, and the filtrate was concentrated to about 30 ml by evaporating the solvent under reduced pressure. When acetone (100 ml) was added to the solution, reddish-purple crystals were separated out. (These crystals were a 1: 2 mixture of *cis(N)cis(O)* and *cis(N)trans(O)* isomers.) The crystals were dissolved in 50 ml of water, and the solution was concentrated slowly by evaporating the solvent to about 25 ml. When the solution was allowed to stand for a day, only the *cis(N)trans(O)* isomer was separated out. The crystals were subsequently washed with water and methanol. Yield, about 0.5 g (15%). Found: C, 35.12; H, 5.37; N, 9.25%. Calcd for $C_9H_{15}CoN_2O_6 \cdot H_2O$: C, 35.07; H, 5.57; N, 9.09%.

3) cis(N)trans(O)-*Bis*-L-*alaninatoacetylacetonatocobalt(III) Dihydrate*, cis(N)trans(O)-$[Co(\text{L-}ala)_2(acac)] \cdot 2H_2O$ *(III)*: This complex was prepared by the same method as was the complex I. Yield, about 2.0 g (40%). The reaction between trisacetylacetonatocobalt(III) and L-alanine also gave only the *cis(N)trans(O)* isomer. Yield, about 1.2 g (33%). Found: C, 37.35; H, 6.68; N, 7.89%. Calcd for $C_{11}H_{19}CoN_2O_6 \cdot 2H_2O$: C, 37.29; H, 6.56; N, 7.91%.

4) Potassium Bis(acetylacetoneglyciniminato)cobalt(III) Tetrahydrate, trans(N)-$K[Co(acacgly)_2] \cdot 4H_2O$ *(IV)*: A solution of 19.5 g of cobalt(II) chloride hexahydrate in 20 ml of water was added to a solution of 12 g of acetylacetone neutralized with potassium hydroxide (6.6 g) and 17.8 g of glycine in 100 ml of water. The mixed solution was oxidized with a hydrogen peroxide solution and then warmed at 50—60°C for one hour. The solution was concentrated under reduced pressure to a volume of 30 ml; the trisacetylacetonatocobalt(III) and potassium chloride thus deposited were then filtered off. When the resulting solution was cooled to 0°C, reddish-brown crystals were separated out. They were recrystallized from water. Yield, about 4.0 g (10%). Found: C, 35.23; H, 5.52; N, 5.94%. Calcd for $C_{14}H_{18}CoN_2O_6 \cdot 4H_2O$: C, 35.00; H, 5.47; N, 5.83%.

Measurements. The IR spectra were recorded with a Hitachi EPI-S2 infrared abosrption spectrophotometer by using the potassium bromide disk. The visible and ultraviolet abosorption spectra were measured with a Hitachi EPS-3 spectrophotometer in water. The NMR spectra were recorded with a Hitachi R-20 spectrometer (60 MHz) at 35°C. The spectra were measured with about a 5—10% solution of deutrated water by using NaTMS as the internal reference.

Results and Discussion

Infrared Absorption Spectra. The main bands of the IR spectra are listed in Table 1. All the complexes show an asym. ν_{COO} band between 1630 and 1680 cm^{-1}, and $\nu_{C=C}$ and $\nu_{C=O}$ (and $\nu_{C=N}$ for the complex IV) bands between 1500 and 1570 cm^{-1}. Thus, we can conclude that all the carboxylate groups of the amino acid in Complexes I to IV are coordinated to the cobalt(III) ion,[9] and also that the acetylacetonate anions are chelated to the cobalt(III) ion.[10] Complexes I, II, and III give the bands of ν_{NH_2} and δ_{NH_2}, but Complex IV does not. Therefore, in the case of Complex IV, the formation of the Schiff-base between acetylacetone and glycine is confirmed.

Table 1. Infrared absorption spectra (in cm^{-1})

Complex	NH_2 str.	COO asym. str.	NH_2 bend.	C=C str.	C=O str.
I	3260 3140	1675 1640	1586	1566	1512
II	3280 3150	1670 1640	1586	1565	1515
III	3250	1665 1637	1595	1567	1525
IV		1630		1592	1502 (C=N str.)

Table 2. Visible and ultraviolet absorption spectra (in $c/s \times 10^{-13}$)

Complex	ν_{max} (log ε)	ν_{sh} (log ε)	ν_{max} (log ε)
I	55.6 (2.19)	78.8 (2.37)	92.2 (3.61)
II	56.7 (2.22)	78.8 (2.46)	92.0 (3.59)
III	57.1 (2.02)	78.8 (2.30)	92.0 (3.57)
IV	47.5 (1.77) (sh), 57.4 (2.47)		90.6 (3.97)

Electronic Absorption Spectra. The numerical values of the electronic absorption spectra are listed in Table 2. The first abosrption bands of Complexes I, II, and III appear at about 56×10^{13} c/s, and their positions are nearly equal to those of the bisglycinatooxalatocobalt(III) complexes.[11] Since the first bands of Complexes I, II, and III show no splitting, these complexes can be assigned to the *cis(N)*-form structure.

Complex IV, on the other hand, shows a split first absorption band; therefore, a *trans(N)*-form structure can be assigned to this complex.

NMR Spectra. The NMR spectra of the complexes are shown in Figs. 1 and 2, while their numerical values are listed in Table 3.

From these NMR spectra, it can be concluded that Complexes I and II have *cis(N)cis(O)* and *cis(N)trans(O)* forms respectively. Moreover, it can be concluded that Complex III has the *cis(N)trans(O)* form. In the cases of the bisglycinatocobalt(III) complexes, it is confirmed that the *cis(N)cis(O)* isomer shows a CH_2 signal constructed of two peaks, while the *cis(N)trans(O)* isomer gives one peak.[11] Also it is shown that the difference between the *cis(N)cis(O)* and *cis(N)trans(O)* structures is more clearly distinguished by the methyl signals of the acetylacetonate group.

Complex IV shows one C=CH, one CH_2, and two CH_3 peaks with relative intensities of 1: 2: 3: 3. This

Table 3. PMR spectra (in τ)

Complex	C=CH	CH_2		CH_3(acac)	
I	4.22	6.45 6.65		7.71 7.92	
II	4.30	6.34		7.92	
III	4.25	5.91 6.03 6.15	CH(ala)	7.93 8.43 8.55	CH_3(ala)

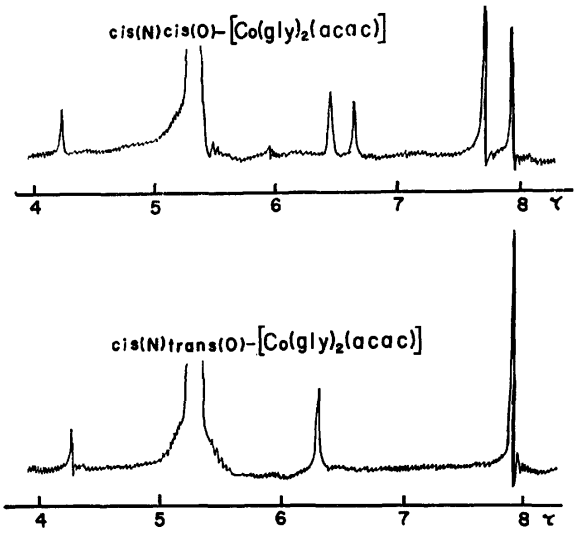

Fig. 1. PMR spectra of the complexes.

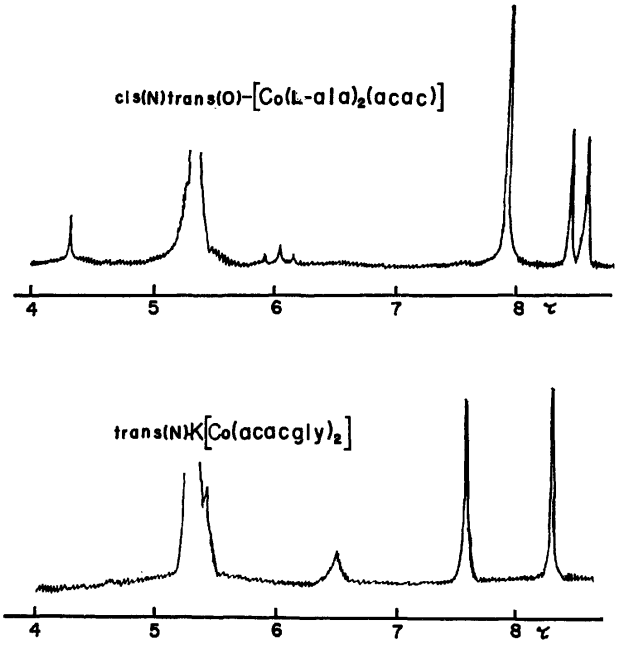

Fig. 2. PMR spectra of the complexes.

spectral pattern clearly implies that Complex IV is a Schiff-base complex in which acetylacetone and glycine are condensed. This fact has also been confirmed by studying the IR spectrum. It is assumed that the formation of the schiff-base complex may be the cause of the difficulty of preparing the *trans(N)cis(O)* isomer.

The El Reaction of Menthyl and Neomenthyl Tosylates in Aprotic Solvents

Masatomo NOJIMA, Masakatsu YOSHIMURA, and Niichiro TOKURA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita

(Received May 11, 1971)

The El reaction has been studied, especially in protic solvents, in relation to the S_N1 reaction.[1] In contrast to the insistence of Ingold[2] that the intermediates of the S_N1 and El reactions were the same, and that there was no solvent effect upon the ratio of the afforded olefin and the replaced product, Winstein[3] established that an elimination from the intimate ion pair occurred in the solvent with a low ionizing power:

$$RX \rightleftharpoons R^{\oplus}X^{\ominus} \rightleftharpoons R^{\oplus}//X^{\ominus} \overset{Y^{\oplus}}{\rightleftharpoons} RY + X^{\ominus}$$

$$\downarrow \text{intimate ion pair} \qquad \downarrow \text{solvent separated ion pair}$$

olefin olefin

Chart 1

We examined the El reactions of menthyl and neomenthyl tosylates in dimethylsulfoxide (DMSO), dimethylformamide (DMF), acetonitrile, methylene chloride, and 1,2-dichloroethane respectively in hopes of clarifying the effects of the aprotic solvents upon the rates and to obtain insight into the mechanism of this reaction.

The first-roder rate constants are tabulated in Table 1, along with the derived values of the thermodynamic quantities, the enthalpy and entropy of activation, ΔH^{*} and ΔS^{*}. Although no linearity between the rates and the dielectric constants of the solvents was observed, the rate increased as the dielectric constants of the solvent increased. These results may be explained as follows: the use of solvents with high dielectric constants is advantageous for the ionization and dissociation of the substrate.[4]

The rate ratios between neomenthyl and menthyl tosylates in various solvents are summarized in Table 2. It has been suggested that the hydrogen participation in the ionization step of neomenthyl tosylate contributes to the large acetolysis rate ratio between neomenthy

AcOH	59

and menthyl tosylates.[5] The rate ratio in the reaction in DMF was 150, while in methylene chloride it was 22. These results suggest that the hydrogen paticipation does not play an important role, at least in the reaction in methylene chloride.

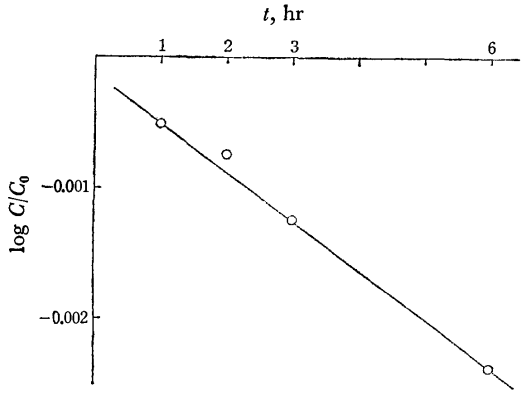

Fig. 1. Isomerization of I to II.
C_0: initial concentration of I. C: concentration of I at time t.

An isomeric change in the configuration of the substrate was found in the reaction in DMF. The E1 reaction of menthyl tosylate in DMF at 75°C, followed by the reduction of the reaction mixture by lithium amide, led to the isolation of neomenthol, olefins, and menthol. From the relationship of log C/C_0 to the reaction time (Fig. 1), the rate of the isomerization of menthyl tosylate to neomenthyl tosylate was estimated to be 2.38×10^{-7} sec^{-1}, which is one order of magnitude smaller than the rate of the olefin formation (2.10×10^{-6} sec^{-1}). The neomenthyl derivative was not detected in the reaction mixtures obtained by reactions in any other solvents except DMF.

Experimental

Materials. DMSO and DMF were purified by drying them over calcium hydride, and they were distilled under diminished pressure. Acetonitrile was purified by the method of Coetzee *et al.*[6] Methylene chloride and 1,2-dichloroethane was dried over calcium chloride and distilled. Menthyl tosylate was obtained by following the method of Winstein;[4] mp 92.2—93.3°C (lit, 93.5—94.0[4]). Neomenthyl tosylate was prepared from neomenthol with tosyl chloride; mp 62.5—63.9°C[7] (lit, 63.0—63.5°C).

Kinetic Procedure. The rates were measured by using glass tubes which could be closed by means of a polyethylene cap. The thermostats were of a conventional design and maintained the temperature within±0.05°C. The reaction mixtures were prepared from the known weight of a solute and from the solvent volumetrically. The reactions were followed by withdrawing ampoules from the thermostat at suitable intervals and by titrating them with a sodium acetate-methanol solution, using bromophenol blue as the indicator.

The Reaction in DMF. The reaction of menthyl tosylate (300 mg) was performed in the presence of two equivalent moles of lutidine in 20 m*l* of the solvent at 75°C. The reaction mixture was poured into ice water, extracted by petroleum ether, and dried over anhydrous sodium sulfate. After the evaporation of the solvent, the reaction mixture was reduced with five equivalent moles of lithium amide in ammonia at 70°C for 4 hr. The reaction mixture was hydrolysed by aq. hydrochloric acid, extracted by ether, and dried over anhydrous sodium sulfate. After the evaporation of the solvent, the products were analyzed by means of a Hitachi K-53 vpc apparatus, equipped with a flame-ionization detector on a PEG 6000 column operated at 180°C.

The Reduction of Menthyl Tosylate.[8] Into a lithium amide-ammonia solution prepared by dissolving 0.8 g (0.05 mol) of lithium in 100 m*l* of ammonia, we added 1.6 g (0.005 mol) of menthyl tosylate dissolved in 10 m*l* of ether. After four hours methanol was added and the mixture was extracted with ether. Then the reaction mixture was treated and analyzed as has been described above; only menthol was present.

The Jacobsen Reaction and the Acid-Catalyzed *Ortho-para* Interconversion of Iodoanisoles and Iodophenetoles

Hitomi SUZUKI and Michie YOSHIDA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received June 1, 1971)

o-Iodoanisole and *p*-iodoanisole are unstable when brought into contact with sulfuric acid and readily undergo disproportionation to yield 2,4-diiodoanisole.[1] Similarly behave both *o*- and *p*-iodophenetoles, giving 2,4-diiodophenetole in a high yield. Such intermolecular iodo migration is usually referred to as the Jacobsen reaction. When a small amount of *o*- or *p*-iodoanisole is dissolved in sulfuric acid, an intense dark brown color develops, which persists over a period of many days. Dilution of the solution with acetic acid or water, however, causes disappearance of this color and the formation of the iodoanisolesulfonic acid. The deep-colored solution has the iodinating power, but the diluted colorless solution has not. In contrast, *m*-iodoanisole is merely sulfonated to give *m*-iodoanisolesulfonic acid, and the solution neither becomes colored nor possesses the iodinating property.

Several inorganic iodo compounds are known, when dissolved in sulfuric acid, to give deep-colored solutions which contain stable positive iodine (I_3^+ or I_5^+) or multivalent iodine (IO^+ or IO_2^+), and possess the strong iodinating power.[2] In this connection, it seems interesting to examine the intermediate species which is responsible for such an easy intermolecular transfer of the iodine atom in the Jacobsen reaction of iodoanisoles. Being brought into solution, *o*- or *p*-iodoanisole develops at first green, then yellow color, which gradually deepens to yellow brown, and finally to dark brown or black. Within several hours after preparation, both solutions from *o*- and *p*-iodoanisole showed the same ultraviolet absorption (λ_{max}, 205, 227, 238—239 *sh*,[3] 281, 410 *sh*, and 438 nm), and this spectral pattern remained unchanged for days. When a bsaic hydrocarbon such as mesitylene was added to these systems, decoloration soon took place and the formation of iodomesitylene was observed at the time of the disappearance of characteristic color. With a weaker base such as *o*-dichlorobenzene or sterically crowded 1,2,4,5-tetraisopropylbenzene, however, such decoloration was not observed. The solution diluted with acetic acid or water contained neither elementary iodine nor iodic acid, so the possible role of the positive iodine or the multivalent iodine for these coloration was ruled out. The spectral pattern of the above solutions differs from the spectra of the any known inorganic iodo compounds dissolved in sulfuric acid,[2] but resembles the spectrum which is superposition of the spectra of anisolesulfonic acid and the benzenonium complex[4] (Fig. 1). Thus the absorption band in the visible region is thought to be due to the stable σ-complex (for example, I) formed by the addition of sulfur trioxide and stabilized through the conjugative delocalization of positive charge by methoxyl group. Then, the intermolecular transfer of iodine atom would probably proceed through the nucleophilic attack of a more basic substrate upon the iodine atom of this intermediate (Scheme 1).

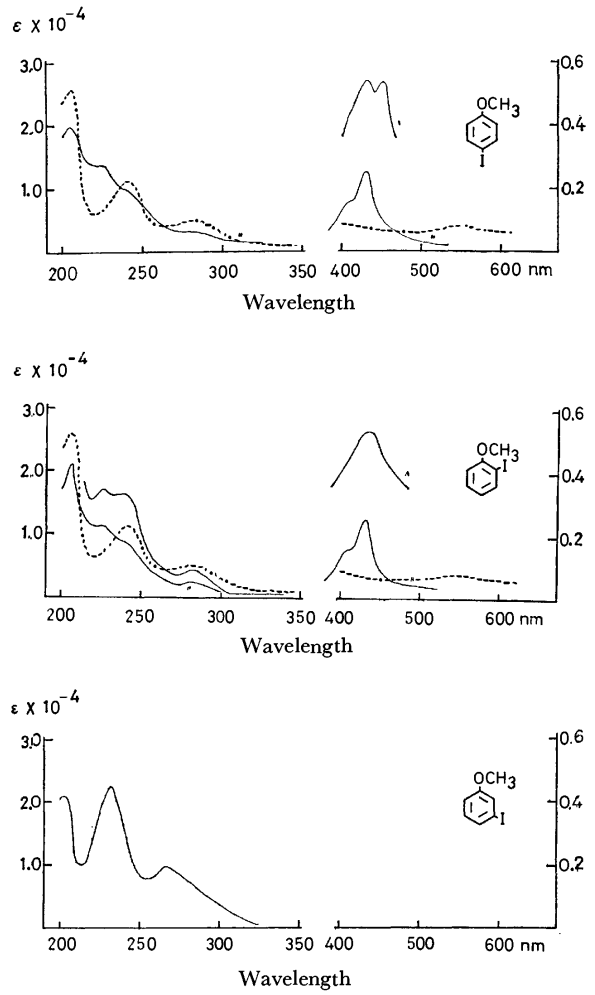

Fig. 1. Absorption curves of iodoanisoles in concentrated sulfuric acid.
Solid line: A. Immediately after dissolution.
B. Several hours later.
Dotted line: After a month's standing.

Intermolecular iodo migration is of some synthetic value. Polyalkylbenzenes can be successfully iodinated by the transfer of iodine atom from *o*-iodoanisole on

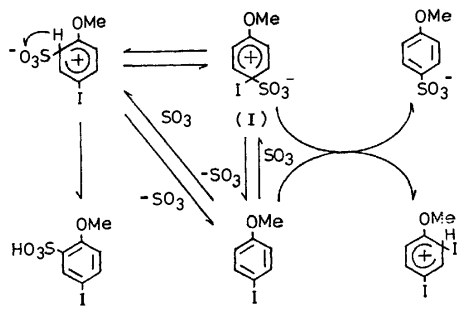

Scheme 1

addition of sulfuric acid.[5] Isomer distribution of the iodination products obtained by the crossed Jacobsen reaction of *o*-iodoanisole with toluene, ethylbenzene, isopropylbenzene, and *t*-butylbenzene is summarized in Table 1. The results clearly indicate the electrophilic nature and the bulkiness of the attacking species.

TABLE 1. ISOMER DISTRIBUTION OF THE PRODUCTS OBTAINED BY THE CROSSED JACOBSEN REACTION OF *o*-IODOANISOLE WITH SOME ALKYLBENZENES

Alkylbenzene	Isomer distribution (%)			
	ortho	*meta*	*para*	1/2 *ortho*-*para* ratio
Toluene	59	a)	41	0.72
Ethylbenzene	41	1	58	0.35
Isopropylbenzene	22	2	76	0.14
t-Butylbenzene	4	0	96	0.02

a) Not determined due to ill resolution from *o*- and *p*-isomers.

Interestingly, *o*- and *p*-iodoanisoles were found to be interconversible in the presence of small amounts of sulfuric acid. This facile isomerization was carried out, agitating the light petroleum solution of each isomer with about 10% weight of sulfuric acid for several hours at room temperature. The relative amount of both isomers in the equilibrium mixture varied to some extent depending on the experimental conditions employed, but the *p*-isomer was always predominant ($o/p=0.32$—0.43). In no case, *m*-isomer was detected, which excludes the intramolecular 1,2-shift process of the isomerization. The present observation is probably the first example of the protogenic acid-catalyzed isomerization of haloanisoles.[6]

The reaction probably involves deiodination and the concurrent rapid reiodination *via* the intermediate I. The interconversion might also be formulated as the intramolecular rearrangement of iodine atom from ortho to para and *vice-versa* through the π-complex. However, the mechanism which involves the iodination of iodoanisoles to 2,4-diiodoanisole, followed by displacement of either one of iodine atoms in the latter seems less probable, since the diiodoanisole was found to be comparatively stable under the same condition.

The reasonable explanation for the lack of iodine migration in *m*-iodoanisole is that the electrophilic attack could hardly occur at the *m*-position where the iodine atom occupies owing to the unfavorable positional condition relative to the methoxyl group, as a result the detachment of the iodine atom as positively-charged species is depressed and *m*-iodoanisole is merely converted to sulfonic acid. The absence of disproportionation with the iodo compounds bearing electron-attracting group[7] or bulky group[8] is probably due to either the difficulty of the formation of the intermediate ion such as I, or the steric hindrance to the S_N2 type intermolecular iodine transfer. Similar disproportionation was observed during the acid hydrolysis of some *o*-iodoacetanilides, which will be described elsewhere.

Experimental

Iodoanisoles (*o*, bp 113—114°C/14 mmHg; *m*, bp 113—114°C/16.5 mmHg; *p*, mp 50—51°C) and iodophenetoles (*o*, bp 126—127°C/16 mmHg; *p*, mp 28—29°C, bp 133—134°C/19 mmHg) were prepared from the corresponding anisidines and phenetidines, respectively. Ultraviolet spectra were measured in 98% sulfuric acid solutions on a Hitachi EPS-300 spectrophotometer and a Shimadzu QV-50 spectrophotometer. The product analysis was performed on a Hitachi Model 063 gas chromatograph using a capillary column coated with Apiezon Grease L.

Jacobsen Reaction of Iodoanisoles and Iodophenetoles. A typical procedure is as follows: A mixture of *o*-iodophenetole (12.4 g) and sulfuric acid (10 g) was stirred at room temperature for 2 hr. The dark thick mixture was diluted with excess of water and the oily precipitate was extracted with ether. The ethereal solution was evaporated and the residue was passed over a column of alumina. Elution with light petroleum, followed by recrystallization from the same solvent gave 2,4-diiodophenetole as white prisms, mp 46—47°C. Yield, 7.7 g (82%). *p*-Iodophenetole gave the same product in somewhat less yield. IR (Nujol): 799, 871, 925, 1042, 1113, 1149, 1242, and 1278 cm^{-1}: PMR (CCl_4): 8.54 (Me, t, $J=7.2$ Hz), 6.00 (CH_2O, q, $J=7.2$ Hz), 3.55 (Aromatic H, d, $J=8.8$ Hz), 2.54 (Aromatic H, q, $J=8.8$ and 1.8 Hz), and 2.03 τ (Aromatic H, d, $J=1.8$ Hz).

Found: C, 25.94; H, 2.19%. Calcd for $C_8H_8I_2O$: C, 25.70; H, 2.16%.

Similarly, *o*- and *p*-iodoanisole gave 2,4-diiodoanisole, mp 68—69°C, in 75—76% yield. IR (Nujol): 800, 872, 1037, 1146, 1187, 1245, 1263, and 1278 cm^{-1}: PMR (CCl_4): 6.14 (MeO, s), 3.48 (Aromatic H, d, $J=8.4$ Hz), 2.48 (Aromatic H, q, $J=8.4$ and 2.4 Hz), and 1.99 τ (Aromatic H, d, $J=2.4$ Hz).

Found: I, 70.73%. Calcd for $C_7H_6I_2O$: I, 70.52%.

5) H. Suzuki, T. Sugiyama, and R. Goto, This Bulletin, **37**, 1858 (1964).

6) Iodophenetoles have been shown to behave similarly. There are several instances known in which the apparent intramolecular bromine shift has been observed during the demethylation of bromoanisoles in the presence of hydrobromic acid. However, these results rather belong to the well-documented isomerization of bromophenols. *Cf.* G. R. Pettit and D. M. Piatak, *J. Org. Chem.*, **25**, 721 (1960), and other papers cited therein.

Reaction of Iodobiphenyls and Iodonaphthalenes with Concentrated Sulfuric Acid. Attempted Extension of the Jacobsen Reaction to Polycyclic Systems

Hitomi SUZUKI and Naotaka YAMAMOTO

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

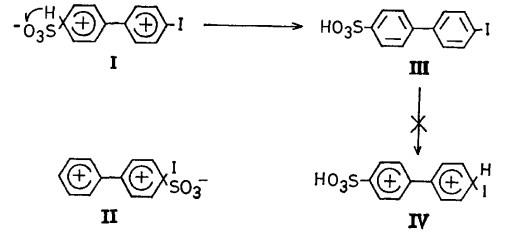
(Received June 1, 1971)

In contact with concentrated sulfuric acid, aromatic iodo compounds undergo disproportionation to give higher iodo derivatives. The reaction has been known as the Jacobsen reaction,[1] but its synthetic possibility has received little attension. In some previous papers,[2] we have reported that such disproportionation of aromatic iodo compounds can be used for one-step preparation of certain polyiodobenzene derivatives, which otherwise require lengthy laborious procedure to obtain. Now the reaction has been attempted to extend to the titled polycyclic iodo compounds with the initial aims to define the scope of its synthetic utility as well as to obtain, if possible, previously unknown higher iodo derivatives. Only several triiodo and tetraiodobiphenyls have so far been recorded in literature.[3] No data have been appeared on the preparation of polyiodonaphthalenes containing more than three iodine atoms, with the exception of a recent note that a trace amount of 1,2,3-triiodo and 1,2,3,4-tetraiodonaphthalene was formed in the photolysis of *o*-bis(iodoethynyl)benzene.[4] No product from the sulfonation of the titled compounds seems to have been adequately characterized before.

Treatment of 1-iodonaphthalene with excess of sulfuric acid at room temperature, followed by dilution with water gave a small amount of reddish-brown pasty solid, chromatography of which on alumina using light petroleum as eluant gave a small amount of 1,4-diiodonaphthalene. Yield was usually below 5% and most part of the starting material went into solution as sulfonic acid. The amount of sulfuric acid relative to iodo compound could be varied over a wide range without any significant improvement on the yield of the diiodo product. The change in temperature from room temperature up to 70°C had no effect on the results. Some elementary iodine was liberated at elevated temperature. From the aqueous part, a sulfonic acid was obtained and identified as 4-iodonaphthalene-1-sulfonic acid by comparison with the authentic specimen. On similar treatment, 2-iodonaphthalene was readily sulfonated to give a mixture of sulfonic acids in which 7-iodonaphthalene-1-sulfonic acid and 6-iodonaphthalene-2-sulfonic acid were the main components, the former being predominant. No disproportionation product could be obtained.

4-Iodobiphenyl reacted with sulfuric acid more readily than did 1-iodonaphthalene, giving some 4,4′-diiodobiphenyl as disproportionation product. Yields varied from nearly zero to 8% depending on the conditions employed. Most part of the starting material was converted to sulfonic acid. Similar treatment of 2- and 3-iodobiphenyls merely gave 4′-sulfonic acids. The orientation of sulfo group in these acids was established through the conversion to iodobiphenylsulfonamides, followed by the reductive removal of iodine atom with aqueous ammonia and zinc dust leading to 4-biphenylsulfonamide. Since iodine atom would deactivate the ring in which it is located, the sulfo group has probably entered at the most reactive 4′-position of another ring.

Although the above results delimit the possible use of the Jacobsen reaction for the preparation of the higher iodo compounds, they still seem to provide some information to understand the process of iodine transfer. A sulfur trioxide will add to the substrate to form either the complex I in which the hydrogen atom at the attacking site may migrate to oxygen to give a sulfonic acid III, or the complex II in which the iodine atom may be transferred to the second molecule *via* S_N2 attack on the iodine atom to yield a higher iodo compound. This interpretation is consistent with the findings that only 1-iodonaphthalene and 4-iodobiphenyl which have the iodine atom at the most favorable position for electrophilic attack under go disproportionation. Since the sulfonic acids derived from these compounds are stable in contact with sulfuric acid, a role of the protonated sulfonic acid IV as a possible iodinating species is less probable. 2-Iodonaphthalene will direct the bulky sulfo group to 6 and 8-positions, while 2- and 3-iodobiphenyls are subject to the preferential attack at 4′-position of the unsubstituted ring. Therefore, the inability of these compounds to undergo rearrangement is attributed to the unfavorable structural condition for electrophilic attack at the position where iodine atom occupies.



As a parallel study to disproportionation, some effort has been made to iodinate iodobiphenyls and iodo-

a) Principal peaks in 650—2000 cm^{-1} region.

naphthalenes with iodine-periodic acid[5] in order to obtain the reference compounds as well as to know the substitution pattern in these systems. So far, very little information is available on the direct iodination of these compounds except 4-iodobiphenyl, which has been readily converted to 4,4′-diiodobiphenyl in the presence of iodine and suitable oxidizing agent.[6]

1-Iodonaphthalene underwent slow iodination to give mainly 1,4-diiodonaphthalene with a little of 1,5-diiodo isomer. 2-Iodonaphthalene reacts quite slowly to give a mixture of diiodonaphthalenes in a low yield, and infrared spectrum of which proved the major component to be 2,6-diiodonaphthalene. Appreciable amounts of amorphous substances are formed as by-product. None of these diiodonaphthalenes could be iodinated further.

The direct iodination of iodobiphenyls took place more readily than did iodonaphthalenes. 2-Iodobiphenyl gave a mixture of diiodobiphenyls, while 3-iodobiphenyl yielded a diiodobiphenyl and a triiodobiphenyl, relative ratio of these products depending on the amounts of the reagent and length of reaction time. Electrophilic substitution in biphenyl has been known to occur mainly at 4 and 4′-positions, since the transition states are stabilized most effectively when attacking species is attached to these positions. Thus, the major products which would result from the iodination of 2-iodobiphenyl are thought to be 2,4′- and 2,4-diiodobiphenyls, while the products from 3-iodobiphenyl can be formulated as 3,4′-diiodobiphenyl and 3,4,4′-triiodobiphenyl, respectively. 4-Iodobiphenyl gave only 4,4′-diiodobiphenyl in high yield. The iodine atom could not be introduced into 2 or 2′-position even with the use of large excess of the reagent under the conditions employed.

Experimental

Authentic iodonaphthalenesulfonic acids and diiodonaphthalenes were mostly obtained by replacement of amino group in aminonaphthalenesulfonic acid or naphthylamine by iodine, respectively. Infrared spectra were measured in KBr disc, unless otherwise stated, with a JASCO DS-402G spectrophotometer.

General Procedure for the Jacobsen Reaction. A typical procedure is as follows: 1-Iodonaphthalene (5 g) and sulfuric acid (10 g) were placed in a small stoppered flask and then stirred magnetically at 20—30°C for 5 hr. The mixture was diluted with water and the oily solid (*ca.* 0.4 g) was extracted with light petroleum and chromatographed on alumina using the same solvent as eluant. Colorless prisms (0.3 g, mp 85—110°C)[7] were obtained from early eluates and identified as

7) Some isomeric impurity, possibly 1,5-diiodonaphthalene, might be responsible for the wide melting range of the disproportionation product.

1,4-diiodonaphthalene by infrared spectral comparison with the authentic sample (lit,[8] mp 109—110°C). IR: 743, 775, 808, 942, 1129, 1239, and 1378 cm^{-1}.

Found: I, 67.0%. Calcd for $C_{10}H_6I_2$: I, 66.8%.

The aqueous part was carefully neutrallized with sodium carbonate and the precipitated sodium sulfonate was collected by filtration, dried, and treated with phosphorus pentachloride to give *4-iodonaphthalene-1-sulfonyl chloride*, which was recrystallized from carbon tetrachloride and melted at 123—124°C. On heating with aqueous ammonia, the chloride was converted into *4-iodonaphthalene-1-sulfonamide*, mp 211—213°C.

Physical properties of sulfonyl chlorides and sulfonamides obtained from the reaction of iodonaphthalenes and iodobiphenyls are summarized in Table 1.

Iodination of Iodobiphenyls. Iodine (10.2 g) was added to a mixture of 2-iodobiphenyl (14 g), periodic acid dihydrate (4.56 g), and 80% acetic acid (120 m*l*) containing small amount of sulfuric acid as catalyst, and the mixture was stirred at 70—80°C for 6 hr. Upon cooling, an oily deposit was taken up into light petroleum, washed with aqueous sodium hydrogen sulfate to remove the unchanged iodine, dried, and distilled under reduced pressure to give diiodobiphenyl (19.1 g) as a pale yellow syrup, bp 164—165°C/2 mmHg, which was presumably a mixture of *2,4'- and 2,4-diiodobiphenyls*, the former being predominant. IR: 752, 820, 998, and 1006 cm^{-1}. Found: C, 35.3; H, 2.0%. Calcd for $C_{12}H_8I_2$: C, 35.5; H, 2.0%.

By a similar procedure, 3-iodobiphenyl gave *3,4'-diiodobiphenyl* (mp 75—77°C, IR: 771, 827, and 1003 cm^{-1}. Found: C, 35.4; H, 2.0%. Calcd for $C_{12}H_8I_2$: C, 35.5; H, 2.0%), together with some *3,4,4'-triiodobiphenyl* (mp 114—116°C, IR: 800, and 995 cm^{-1}. Found: C, 27.5; H, 1.6%. Calcd for $C_{12}H_7I_3$: C, 27.1; H, 1.3%). 4-Iodobiphenyl gave *4,4'-diiodobiphenyl* (mp 210—211°C, IR (Nujol), 802, 996, and 1068 cm^{-1}. Found: C, 35.1; H, 1.8%. Calcd for $C_{12}H_8I_2$: C, 35.5; H, 2.0%).

Iodination of Iodonaphthalenes. 2-Iodonaphthalene (5.1 g) mixed with 80% acetic acid (30 m*l*) containing small amount of sulfuric acid as catalyst was treated with iodine (2.6 g) and periodic acid dihydrate (1.14 g) at 70—80°C for 20 hr. The reaction proceeded quite slowly and gave a dark pasty solid, which was taken up into light petroleum-benzene mixture and passed over a column of alumina to yield a low-melting solid substance (*ca.* 3.2 g) from early eluates and fine needles (0.3 g) from later eluates. The former was mainly composed of the unchanged starting material with a little of diiodonaphthalene. The latter product crystallized from ethanol as fine leaflets, mp 210—213°C, had the formula $C_{10}H_6I_2$ and was identified as impure 2,6-diiodonaphthalene on the basis of its high melting point (lit,[9] 203—204°C) and similarity of its infrared spectrum to 2,6-dichloronaphthalene. IR (Nujol): 813, 837, and 888 cm^{-1}. Found: C, 32.9; H, 1.7; I, 66.0%. Calcd for $C_{10}H_6I_2$: C, 31.5; H, 1.6; I, 66.8%.

Similar iodination of 1-iodonaphthalene led mainly to 1,4-diiodonaphthalene with some 1,5-diiodo isomer. The reaction was slow, but polymeric substance was not formed so much.

The Synthesis of Methyl 2,4,6-Tri-*O*-benzyl-α-D-glucopyranoside

Shinkiti KOTO, Yuko TAKEBE, and Shonosuke ZEN

School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo

(Received June 12, 1971)

In synthetic carbohydrate chemistry, the partially benzylated derivative of sugar is, in general, used as an important intermediate.[1] This paper will deal with a facile method of preparing a new, partially-benzylated derivative of D-glucopyranose, methyl 2,4,6-tri-*O*-benzyl-α-D-glucopyranoside (I), directly from methyl α-D-glucopyranoside by means of a controlled benzylation.[2] Methyl α-D-glucopyranoside was very carefully heated below 110°C in benzyl chloride in the presence of sodium hydride (3.3 molar equiv.) to give a mixture of partially- as well as fully-substituted products. After chromatographic separation, the main product, I, was obtained as a distillable oily product with a high reproducible yield; it was fully characterized as crystalline *p*-nitrobenzoate and *p*-phenylazobenzoate. The results of the elemental analysis and the $\varepsilon_{258.5}^{\text{ethanol}}$ value[2] of I indicated the existence of three benzyl groups. The position with a free hydroxyl group was determined by the methylation; *i.e.*, I was converted into the known methyl 4,6-*O*-benzylidene-3-*O*-methyl-α-D-glucopyranoside[3] and 1,2,4,6-tetra-*O*-benzoyl-3-*O*-methyl-β-D-glucopyranose[4] respectively. Thus, the 3-OH of I was unsubstituted.

The high reactivity of the 6-OH and 2-OH of α-D-glucopyranoside compared with that of others is frequently observed[5] and has led to successful preparations of the 2,6-di-*O*-substituted derivative. By the way, the difference between the reactivity of 3-OH and that of 4-OH is usually small, and their order is rather variable according to circumstances. In certain cases, however, a significantly lower reactivity of 3-OH has been reported;[6] the present result may be another example of this.

After the hydrolysis of I, 2,4,6-tri-*O*-benzyl-1,3-di-*O*-

p-nitrobenzoyl-α-D-glucopyranose (VI) was obtained as fine crystals.

Experimental

Tlc was carried out by the use of Silica Gel G (Merck). The silica gel used for the column chromatography was the product of the Kanto Chemical Co. The PMR spectra were measured with Varian S-60T in $CDCl_3$, with TMS as the internal standard. The melting points were determined by means of a Yanagimoto micro-melting-point apparatus; uncorrected values are given. The specific rotation was measured in a 1-dm tube by means of an Atago Polux apparatus in $CHCl_3$ at 25±3°C.

Methyl 2,4,6-Tri-O-benzyl-α-D-glucopyranoside (I). A suspension of methyl α-D-glucopyranoside (5.0 g; 26 mmol) and sodium hydride (*ca.* 50% dispersion; 2.7 g; 2.2 molar equiv.) in freshly-distilled benzyl chloride (26 g; 8 molar equiv.) was cautiously heated at 104—105°C (the oil bath was maintained below 110°C) with very efficient stirring (magnetic) under anhydrous condition. When, after 1.5—2.5 hr, a sharp rising of the reaction temperature and a violent evolution of hydrogen gas began, the oil bath was removed at once and the reaction vessel was immersed in a cold-water bath. After the evolution of the gas had ceased, the vessel was carefully heated at 104—105°C for 2 hr. During the reaction, the mixture became a porous mass, and then it turned into a thin slurry. After cooling to room temperature, another portion of sodium hydride (1.5 g; 1.1 molar equiv.) was added to the mixture; the reaction was then continued at the same temperature overnight. The cooled mixture was filtered through a bed of Hyflo Super-Cel. The filtrate and the washings were combined and evaporated on a boiling-water bath under reduced pressure. A yellow sirup (17 g) was chromatographed on a column of SiO_2 (350 g), eluting it with a mixed solvent of benzene and 2-butanone (20: 1). The order of elution was as follows: a mixture of the dispersion oil, the remaining benzyl chloride and other non-carbohydrate by-products, the tetrasubstituted product, and the main product, I (7.4 g; 62%). I was used directly for the further reactions.

When the original benzylation reaction was continued with additional benzyl chloride (5 g) and sodium hydride (2 g) at 125°C, the perbenzylated glucoside[2] was formed quantitatively.

Methy 2,4,6-Tri-O-benzyl-3-O-methyl-α-D-glucopyranoside (V). I (2.0 g) was heated with methyl iodide (1.1 m*l*) in DMF (3.3 m*l*) in the presence of BaO (1.5 g) at 70—80°C for 3 hr.[7] A brief chromatography gave thin, colorless oil of V.

Methyl 4,6-O-Benzylidene-3-O-methyl-α-D-glucopyranoside. V was hydrogenated quantitatively by the use of palladium on carbon (5%) in methanol and then treated with benzaldehyde in the presence of $ZnCl_2$. Tlc showed the complete exhaustion of the hydrogenated material. Long needles (from diisopropyl ether; 84%). Mp 152—153°C, $[\alpha]_D^{24}$ 118.4° (*c* 2.5, $CHCl_2CHCl_2$). [Lit,[3] mp 150—151°C; $[\alpha]_D^{14}$ 119.5° (*c* 1.6, $C_2H_2Cl_4$)]. The PMR spectrum showed the benzylidene tertiary proton as a singlet at δ 5.56. (Found: C, 61.23; H, 6.91%.)

1,2,4,6-Tetra-O-benzoyl-3-O-methyl-β-D-glucopyranose. The above-mentioned hydrogenolyzed product was hydrolyzed with hot dilute hydrochloric acid and then subjected to neutralization, evaporation, and ordinary benzoylation. Colorless crystals (from methanol; 85%). Mp 203—204°C, $[\alpha]_D^{25}$ 2.5° (*c* 3.9, $CHCl_3$). The authentic sample had a mp of 200—202°C and $[\alpha]_D^{27}$ value of −2.3° (*c* 4.2, $CHCl_3$). [Lit,[4] mp 198—199°C; $[\alpha]_D$ 3.6° (*c* 4.94, $CHCl_3$)]. The mixed mp was 200.5—203.5°C. The IR (KBr) and PMR spectra of the two compound were superimposable. (Found: C, 68.25; H, 4.94%).

2,4,6-Tri-O-benzyl-1,3-di-O-p-nitrobenzoyl-α-D-glucopyranose (VI). I (1.03 g) was heated with aqueous mixed acid prepared from glacial acetic acid (11 m*l*) and sulfuric acid (2N, 2.9 m*l*) for 80 min on a boiling-water bath. After the addition of sulfuric acid (2N, 2.3 m*l*), the mixture was further heated for 9 hr. After neutralization, an oily product (1.27 g) was fractionated on a column of SiO_2 (20 g; benzene: 2-butanone=5: 1). After the recovery of the unchanged mate-

7) R. Kuhn, H. H. Baer, and A. Seeliger, *Ann. Chem.*, **611**, 236 (1958).

rial (0.44 g; 43%), a hydrolyzed product was eluted in a yield of 0.37 g (37%). This was treated with excess *p*-nitrobenzoyl chloride in pyridine. The crude residue thus obtained (95%) was crystallized with diethyl ether.

Spectral Data: I, ν_{max}^{film} (cm^{-1}): 3490, 3460 (OH), 3090, 3070, 3030, 3010, 1955, 1875, 1810, 1720, 1603, 1584, 1145, 739, 699 (benzyl); δ (ppm): 2.40 (1H, broad, exchangeable with D_2O; 3-OH), 3.37 (3H, singlet; *O*-CH_3), 3.43 (1H, quartet; H-2, $J_{1,2}=4.0$ Hz, $J_{2,3}=8.0$ Hz), 4.13 (1H, quartet; H-3, $J_{3,4}=10.0$ Hz). The Synthesis of Silacyclopentane Derivatives

Tsunao ARAKI, Daiyo TERUNUMA, and Toshio FUSE

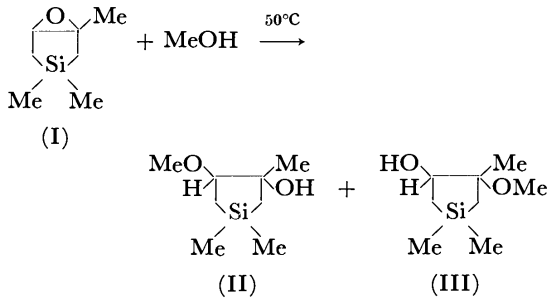
Department of Applied Chemistry, Faculty of Science and Engineering, Saitama University, Urawa

(Received June 22, 1971)

In the course of our studies of the reaction and polymerization of silacyclopentanes and -pentenes, 6-oxa-3-sila-1,3,3-trimethylbicyclo[3.1.0]hexane(I)[1], 1,3,3-trimethyl-3-silabicyclo[3.1.0]hexane(V), and 1,1,3-trimethyl-1-silacyclopentane(VI) were synthesized. Some of the reactions of I and the hydrogenation reaction of 1,1,3-trimethyl-1-silacyclopentene-3(IV)[2] were investigated.

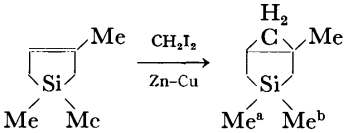
Results and Discussion

Because of its high strain in the epoxy ring, I was found to be very reactive; the addition of even a small amount of aluminum chloride to I caused a violent reaction, giving a solid polymer. Furthermore, I was found to react with methanol at 50°C giving a mixture of new compounds, 1,1,3-trimethyl-4-methoxy-1-silacyclopentane-3-ol(II) and its isomer, 1,1,3-trimethyl-3-methoxy-1-silacyclopentane-4-ol(III).



(I) (II) (III)

Under the same reaction conditions, other alcohols, such as ethanol, 1-propanol, and 1-butanol, and alkyl amines, such as methylamine and diethylamine, did not react with I. This lowering of the reactivity toward amines, in contrast with that of ordinary epoxy groups, may be explained in terms of the enhanced basisty of the carbon atomes next to oxygen caused by the electron-releasing effect of the CH_3Si- group. Now, we wish to report another successful synthesis of a new bicyclosilacyclopentane derivative, *i.e.*, 1,3,3-trimethyl-3-silabicyclo[3.1.0]hexane(V). This compound was synthesized by the method of carbene addition using the Simmons-Smith reagent.[3] The structural assignment was accomplished by the analysis of the IR and NMR spectra (IR spectrum; $-CH_2-$ in the cyclopropane ring, 3050 cm^{-1}; its skeletal vibration, 1010 cm^{-1}; NMR spectrum; the two singlets at τ=9.90 and 9.95 for (CH_3^a) (CH_3^b)Si- show that the silacyclopentane ring remains intact).



(IV) (V)

Another new compound, 1,1,3-trimethyl-1-silacyclopentane(VI) was also synthesized by hydrogenating IV in the presence of the Pd–C catalyst. In this reaction, when *n*-hexane was used as the solvent hydrogenation proceeded successfully and VI was obtained, but when

methanol was used in place of *n*-hexane, only a ring-opening product, dimethylisopentylmethoxysilane(VII), was found in the reaction mixture. It was also observed that when a small amount of water was present in the solvent, diisopentyltetramethyldisiloxane(VIII) was formed as a by-product. The structural assignment for VIII was found by comparing its IR and NMR spectra with those of an authentic sample prepared from isopentylmagnesium bromide and dimethyldichlorosilane.

More detailed studies of the reaction of silacyclopentane derivatives are in progress.

Experimental

The NMR spectra were measured by means of a Varian A-60 spectrometer, using tetramethylsilane as the internal standard. The infrared spectra were obtained on a Shimadzu IR-27C spectrophotometer.

Preparation of 1,1,3-trimethyl-1-silacyclopentene-3(IV). A mixture of 34 g (0.5 mol) of isoprene and 64.5 g (0.5 mol) of dimethyldichlorosilane in 80 m*l* of tetrahydrofuran was added to 23 g (1 g atom) of a sodium dispersion in 120 m*l* of tetrahydrofuran over a 3-hr period at 30—35°C (external cooling) under a nitrogen atmosphere. After stirring for 20—25 hr at room temperature, filtration and distillation gave 18.0 g of IV; 28.5% yield; bp 123°C.

Epoxidation of IV. To a solution of 24 g (0.172 mol) of perbenzoic acid in 300 m*l* of chloroform, 20 g (0.157 mol) of IV was added over a 3-hr period at 5—7°C. After maintaining the reaction mixture at 5°C for 48 hr, benzoic acid and the excess perbenzoic acid were extracted with 200 m*l* of N sodium hydroxide. The chloroform solution was washed with two 100-m*l* portions of water and then dried. The removal of the solvent under reduced pressure at room temperature, followed by the frational distillation of the residue, gave 15.6 g of I; 64% yield; bp 60—62°C/34 mmHg, n_D^{25} 1.4442.

Reaction of I with Methanol. Five grams (35.2 mmol) of I and 5.5 g (171.9 mmol) of methanol were placed in a round-bottomed flask. The mixture was maintained for 5 hr at 50°C with stirring. The subsequent fractional distillation of the resulting mixture gave 3.7 g of the product; 60.7% yield; bp 85—90°C/20 mmHg. The H^1 NMR spectrum showed $SiCH_3$ singlets at τ 9.88 and 9.87, a complex multiplet for CH_2 at *ca.* 8.8—9.5, a singlet for C–CH_3 at 8.89, one for O–CH_3 at 6.89, and a quartet for C–H at 6.17. Two hydroxy H^1 peaks, at 7.1 and 8.3, indicate that *tert*-(II) and *sec*-(III) alcohols are present in the product.

Attempts to React I with Other Alcohols. I was reacted with ethanol, 1-propanol, and 1-butanol under the same reaction conditions as were used in the case of methanol. In every case, vapor-phase chromatographic analysis (3m, Thermal-3, 147°C) showed that I and the alcohol remained unchanged in the resulting mixture.

Attempts to React I with Amines. a) Methylamine was introduced into 1 g of I for 5 hr at 50°C. The vpc analysis of the resulting mixture indicated that the reaction did not occur.

b) A mixture of 1 g (7.0 mmol) of I and 2.5 g (34.2 mmol) of diethylamine was maintained for 5 hr at 50°C. The vpc analysis of the resulting mixture indicated that the reaction did not occur.

Preparation of 1,3,3-trimethyl-3-silabicyclo[3.1.0]hexane(V). A mixture of 8 g (0.0635 mol) of IV and 25 g (0.0933 mol) of methylene iodide in 50 m*l* of ethyl ether was refluxed in the presence of 6.5 g of Zinc-Copper couple for 24 hr with stirring. The ether solution was then decanted from the unreacted couple, washed with two 10 m*l* portions of a saturated aqueous ammonium chloride solution, and then dried over anhydrous magnesium sulfate. Fractional distillation gave 2.9 g of V; 33.1% yield; bp 35—36°C/17 mmHg. Found: Si, 20.4%. Calcd for $C_8H_{16}Si$: Si, 20.1%.

Hydrogenation of IV. General Procedure: Ten grams (0.0793 mol) of IV were hydrogenated in a catalytic hydrogenating apparatus in 50 m*l* of the four solvents described below using 0.5 g of palladium charcoal as the catalyst, at room temperature and under atmospheric pressure. The hydrogen uptake was almost theoretical in the case of each solvent. After the removal of the solvent, fractinal distillation gave the following compounds:

1) in the dry *n*-hexane solvent; 9.0 g of VI, bp 120—123°C, n_D^{20} 1.4345. Found: Si, 21.9%. Calcd for $C_7H_{16}Si$: Si, 22.0%.
2) in dry methanol: 10.2 g of VII, bp 60—62°C/80 mmHg, n_D^{20} 1.4120. Found: Si, 17.2%. Calcd for $C_8H_{20}OSi$: Si, 17.6%.
3) in *n*-hexane containing a small amount of water: VI and VIII (bp 120°C/20 mmHg, n_D^{20} 1.4282, Found: Si, 20.1%. Calcd for $C_{14}H_{34}OSi_2$: Si, 20.5%) were obtained. The yields of VI and VIII varied with the amount of water added.
4) in methanol containing a small amount of water: VII and VIII were obtained. The yields of VII and VIII varied with the amount of water added.

Preparation of an Authentic Sample of Diisopentyltetramethyldisiloxane. Isopentylmagnesium bromide prepared from 15.1 g (0.1 mol) of isopentyl bromide and 2.91 g (0.12 g atom) of magnesium in 50 m*l* of ether was stirred into 12.9 g (0.1 mol) of dimethyldichlorosilane in 20 m*l* of ether. The reaction mixture was heated at reflux for 2 hr, and then 30 m*l* of dilute hydrochloric acid were added. The ether layer was dried, subsequent distillation gave 4.8 g of diisopentyltetramethyldisiloxane; 35% yield. Its boiling point and IR and NMR spectra are consistent with those of VIII.

The authors wish to thank Dr. H. Nohira for his many helpful discussions and the Shinetsu Kagaku Co. for providing the dimethyldichlorosilane.

Tautomerism in 1-Arylazo-2-naphthols as Studied by Fluorescence

Yoshio MATSUNAGA and Masaaki SHIMANE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received July 10, 1971)

Earlier we examined the diffuse reflection spectra of sixteen 1-arylazo-2-naphthols[1] diluted with sodium chloride and concluded that the azo and hydrazone tautomers coexist in this solid, two-component system.[2] In many cases, the spectra were found to be markedly modified by elevating the temperature. These changes were thermally reversible and were attributed to the movement of the tautomeric equilibrium. A few years ago, Rau studied the fluorescence of hydroxyazo compounds, mostly at 77°K, and concluded that the hydrazone tautomer is the emitting species.[3] Solid 1-phenylazo-2-naphthol was noted by him to be weakly fluorescent at room temperature. Therefore, the examination of the fluorescence in our samples seemed to be a useful means of checking the validity of our earlier conclusions.

The samples of 1-arylazo-2-naphthols diluted with sodium chloride were those used in our previous work.[2] The fluorescence spectra were recorded on a Hitachi Model MPF-2A spectrophotometer. The samples, packed into quartz capillaries, were examined at room temperature and also at the temperature of liquid nitrogen. The wavelength of the exciting light, selected on the basis of experiments on the excitation-dependence of the fluorescence spectra, was 400 or 470 mμ. It is well known that fluorescence spectra are usually mirror-images of the corresponding absorption spectra when plotted on a frequency scale. Unfortunately, the present spectra are located in the region where the sensitivity of the detector decreases drastically; therefore, the attempts at calibration were not successful. In spite of this shortcoming, it is certain that the peak with the longest wavelength in the reflection spectrum arises from the hydrazone tautomer.

Whether or not the samples at a concentration of 1% are fluorescent is summarized in Table 1. Six among the sixteen examined are not fluorescent; however, the following three become fluorescent when diluted more: the *p*-NO_2 derivative at a concentration of 0.1%, and the *p*-Cl and *o*-OH derivatives at 0.01%. In the last column of Table 1, we show which is the major tautomer in the samples diluted with sodium chloride. This information, obtained from the temperature-dependence of the reflection spectra, is cited from one of our earlier works.[2] There is a fairly good parallelism between the detection of fluorescence at 1% and the presence of an appreciable amount of the hydrazone tautomer. The only exceptions are the *o*-OH and *p*-NO_2 derivatives mentioned above. The detection at 0.1 or 0.01% is in accordance with one of our conclusions that the higher the degree of dilution, the more molecules in the hydrazone form. In the case of the *p*-NO_2 derivative, a reexamination of the reflec-

TABLE 1. THE DETECTION OF FLUORESCENCE IN 1-ARYLAZO-2-NAPHTHOLS DILUTED WITH SODIUM CHLORIDE

Substituent	Concentration		Major tautomer[a]

a) Determined by the temperature-dependence of the reflection spectra with the samples diluted with sodium chloride, see Ref. 2.

b) The azo tautomer may be the major one when the concentration is high.

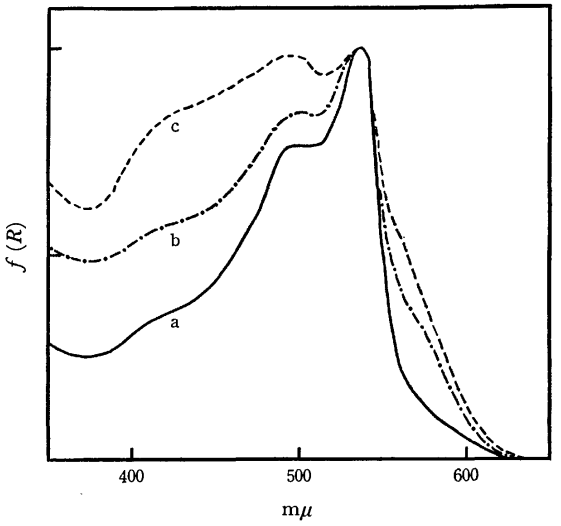

Fig. 1. Diffuse reflection spectra of 1-(*p*-nitrophenylazo)-2-naphthol diluted with sodium chloride at a concentration of 1%; (a) stored for one day after the temperature-dependence measurement, (b) after storage over one year, (c) prepared by grinding at room temperature only. The maximum is arbitrarily taken as 1.00 in each spectrum.

1) This designation is used throughout this paper for convenience; it is not intended to define the structure. The substituents are on the phenyl ring.

2) C. Dehari, Y. Matsunaga, and K. Tani, This Bulletin, **43**, 3404 (1970).

3) H. Rau, *Ber. Bunsenges. Phys. Chem.*, **72**, 637 (1968).

tion spectra revealed that a large change occurred at a concentration of 1% during prolonged storage at room temperature. As is shown in Fig. 1, the sharp peak appearing at 538 mμ is relatively strong when examined one day after the temperature-dependence measurement, but was much weaker after storage for one year. A sample prepared by grinding at room temperature gives the spectrum shown by Curve c. Thus, the hydrazone tautomer of this derivative seems to be less stable than we thought earlier. However, the peak is dominant at concentrations of 0.1 and 0.01% even after storage for nearly two years. It must be noted that the absence of fluorescence cannot be considered as an indication of the absence of the hydrazone tautomer. Nevertheless, fluorescence is not detected at a 1% dilution in most of the cases where the azo tautomer is the major one. All the compounds which are fluorescent at a concentration of 1% are also fluorescent without dilution with sodium chloride. In such cases, it is very likely that the two tautomeric forms exist together, even in crystals.

Cooling brings about a marked increase in the intensity of the fluorescence at the short-wavelength end of the spectrum. In the cases of 1-phenylazo-2-naphthol and the *m*-Cl derivative, the appearance of a fine structure is noted. With the *m*-Me, *p*-Me, *m*-MeO, and *m*-NO_2 derivatives, the change in the relative intensity is so great that the low-temperature fluorescence seems to be shifted to the short-wavelength side by 15—20 mμ.

The authors wish to express their thanks to Professors Hiroaki Baba and Koichi Yagi for permission to use the spectrophotometers.

The Reaction of Ethyl Acetoacetate with Benzonitrile in Liquid Ammonia

Noboru SUGIYAMA, Makoto YAMAMOTO, Susumu KOBAYASHI, and Choji KASHIMA

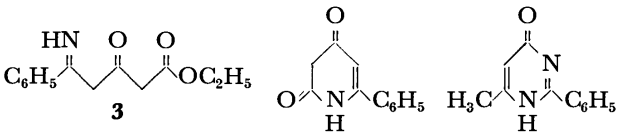
Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received July 14, 1971)

It is well known that β-diketones[1,2] and β-keto-esters[3,4] condense with an electrophile in the presence of bases in liquid ammonia.

In a previous paper,[5] we reported that acetylacetone condensed with benzonitrile in the presence of alkali amide in liquid ammonia to give 4(1*H*)-pyridone. As one of our series of studies of the syntheses of heterocycles, the present paper will describe the reaction of ethyl acetoacetate (**1**) with benzonitrile (**2**) in liquid ammonia.

If the reaction of **1** with **2** proceeds as the reaction of acetylacetone with **2**, the reaction product may be expected to be 2,4-dioxo-6-phenyl-1,2,3,4-tetrahydropyridine (**4**). However, the reaction of **1** with an equimolar amount of **2** in the presence of twice as many moles of sodium amide in liquid ammonia resulted in the formation of 10% of ethyl 5-amino-3-oxo-5-phenyl-4-pentenoate (**3**), 5.0% of **4**, and 33% of 4-oxo-6-methyl-2-phenyl-1,4-dihydropyrimidine (**5**). The structures of **3**, **4**, and **5** were supported by the spectral data. Compounds **4** and **5** were identified by a direct comparison with authentic samples.[6,7] Since **3** was converted to **4** in liquid ammonia or in ether in the presence of sodium amide, **3** is considered to be an intermediate of the formation of **4** from **1** and **2**. Compound **4** was also formed by heating **3** over 150°C.



3 **4** **5**

Fig. 1

When the reaction was carried out with a molar ratio of **1**, **2**, and sodium amide of 1 : 1 : 3, the yields of the reaction procduts, based on **1**, were 52.5% of **5** and 20% of **3**, plus a trace of **4**.

It has been reported that **2** is converted into benzamidine[8] in the presence of the amide ion, and that benzamidine and **1** condense to a pyrimidine derivative in the presence of sodium ethoxide in ethanol.[7] This fact suggests that the amide anion attacks the compound **2** to give benzamidine in liquid ammonia, and that benzamidine then condenses with **1** to yield **5**.

The condensation reaction at the terminal methyl group is considered to be initiated by the formation of a dianion by the abstraction of two protons from the methyl and methylene groups of β-diketone. The methyl proton of **1** is less acidic than that of acetylacetone or benzoylacetone.[4] When sodium amide was reacted on **1**, the monoanion of **1** is predominant, this monoanion reacts with **2** to give **5** (Scheme 1). When potassium amide is used instead of sodium amide, the

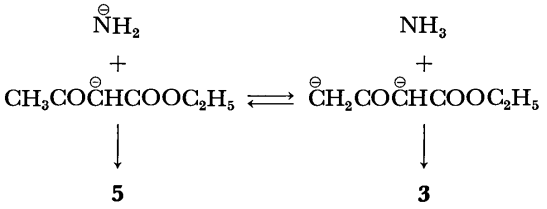

Scheme 1

dianion of **1** is predominant because the ability of dianion formation of potassium amide is a little higher than that of sodium amide in liquid ammonia.[5,9] The dianion reacted with **2** to give **3**. Actually, the yield of **3** increased to 43%, as is listed in Table 1.

Table 1. The products of the reaction of **1** with **2**

Amide	n[a]	Reaction time (hr)	Product (%)		
			3	**4**	**5**
$NaNH_2$	2	2.5	10	5.0	33
$NaNH_2$	3	2.5	20	trace	53
KNH_2	2	2.5	43	trace	3.8
KNH_2	2	5.0	32	15	3.7

a) Molar ratio, **1**:**2**: amide = 1:1:n

The extension of the reaction time leads to an increase in the yield of **4**. This fact suggests that the initially-formed **3** has been converted to **4** by the residual amide ion in liquid ammonia.

This is a simple and convenient method for the synthesis of a compound of the **4** type, because the only method for synthesizing **4** previously reported (F. Arndt *et al.*[6]) is very complicated.

Experimental

Ethyl 5-amino-3-oxo-5-phenyl-4-pentenoate (3). To a solution of 0.1 mol of sodium amide in about 300 m*l* of liquid ammonia in a three-necked flask, we added, drop by drop, 0.05 mol (6.5 g) of **2** in 30 m*l* of anhydrous ether. After this mixture had been stirred for 1 hr, 0.05 mol (5.2 g) of **1** in 30 m*l* of anhydrous ether was added. The dark gray color of the solution soon turned to a brownish green. After being stirred for an additional 2.5 hr, the reaction mixture was neutralized with solid ammonium chloride. The liquid ammonia was evaporated rapidly in a water bath, and 100 m*l* of ether was added. The resulting ethereal suspension was shaken with 2N hydrochloric acid to dissolve the inorganic salts. The acidic aqueous layer was separated and again extracted with fresh ether. The two ether layers were combined and dried over anhydrous sodium sulfate, and the ether was evaporated under reduced pressure. The residue was chromatographed on a silica-gel (Merk 7734, 0.05—0.2 mm) column with a benzene-ethyl acetate (4: 1 v/v) mixture. A fraction which showed a brown color in a ferric chroride test was collected and evaporated to afford **3** (1.17 g, 10%) as an orange oil.

Found: C, 66.50; H, 6.63; N, 5.99%. Calcd for $C_{13}H_{15}NO_3$: C, 66.93; H, 6.48; N, 6.01%. IR(liquid film): 3400 (νNH), 1730 (νC=O, ester carbonyl), 1610 (νC=N) and 695 cm^{-1} (phenyl). UV: λ_{max}^{EtOH} 242 (ε 9390) and 328 nm (ε 17000). NMR(in CCl_4): δ 1.21 (t, 3H, methyl protons), 3.20 (s, 2H, C-2 methylene protons), 4.05 (q, methylene protons of the ester group), 5.32 (s, 1H, C-4 enolic olefin proton), 6.37 (broad, 1H, non-hydrogen bonded NH), 7.40 (m, 5H, aromatic protons), and 9.80 (braod, 1H, hydrogen bonded NH).

The compound **3** was not distilled because of its easy conversion by heat. By heating at 150—170°C for 30 min, about 46% of the **3** was converted into **4**.

After the compound **3** was obtained, **5** was eluted with benzene-ethyl acetate (2: 1 v/v) from the same column. Yield, 0.48 g (5.2%).

2,4-Dioxo-6-phenyl-1,2,3,4-tetrahydropyridine (4). After adjusting the pH to 4—5, the aqueous layer was allowed to stand at room temperature for two hours. The resulting precipitate was collected and then treated with hot acetone. The acetone-insoluble solid was collected and recrystallized from hot pyridine to give **4** as a white solid; 0.47 g (5.0%); mp 312—314°C (lit, 315—318°C[6]). IR(KBr): 3100 (νNH), 1645 (νC=O, conjugated ketone) and 695 cm^{-1} (phenyl). UV: λ_{max}^{EtOH} 308 nm (ε 10300).

4-Oxo-6-methyl-2-phenyl-1,4-dihydropyridine (5). When the hot acetone solution obtained above was cooled, compound **5** was separated as colorless needles. Yield, 2.58 g (28%); mp 215—216°C (lit, 218—221°C[7]).

Found: C, 71.15; H, 5.43; N, 14.92%. Calcd for $C_{11}H_{10}N_2O$: C, 70.95; H, 5.41; N, 15.05%. IR(KBr): 3175 (νNH), 1670 (νC=O, conjugated ketone) and 690 cm^{-1} (phenyl). UV: λ_{max}^{EtOH} 240 (ε 17300) and 293 nm (ε 11200). NMR(in $CDCl_4$): δ 2.38 (s, 3H, methyl protons), 6.28 (s, 1H, olefin proton), 7.52 (m, 3H, aromatic protons), and 8.20 (m, 2H, aromatic protons).

The Condensation Reactions of 1 with 2 under Various Conditions. The condensation reactions of **1** with **2** were carried out by using potassium amide, instead of sodium amide, and were also carried out by changing the molar ratio of amide to **1** and to **2** and/or by changing the reaction time. The results are listed in Table 1.

The Cyclization of 3 to 4. *a*) A solution of 122 mg of **3** in 5 m*l* of anhydrous ether was added to 50 m*l* of liquid ammonia containing 35 mg of sodium amide. The mixture was stirred for two hours and then neutralized with 60 mg of solid ammonium chrolide. After the evaporation of the ammonia, the residue was acidified with 30 m*l* of dilute hydrochloric acid; the resulting white precipitate was collected by filtration. Yield, 74 mg (76%). This compound was identified by comparing its spectral data with those of an authentic sample of 2-phenyl-4,6-dihydroxypyridine.

b) To 80 m*l* of anhydrous ether there were added 30 mg of sodium amide and 100 mg of **3** in 20 m*l* of anyhdrous ether. The solution was then stirred at room temperature for two hours. The **4** was identified by comparison with an authentic sample by means of thin-layer chromatography.

Rotational Isomerism in Ethylmethylsilane

Michiro HAYASHI, Keiichi OHNO, and Hiromu MURATA
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received July 27, 1971)

Although many experimental data have been accumulated concerning rotational isomerism, a number of molecules have not yet been studied. In this note, we will deal with the vibrational spectra of ethylmethylsilane in relation to the rotational isomerism.

Experimental

The samples of ethylmethylsilane and its deuterated species ($CH_3CH_2SiD_2CH_3$) were prepared as follows. Methyltrichlorosilane was treated by an ethyl Grignard reagent, and the product ($CH_3CH_2SiCl_2CH_3$) was reduced with $LiAlH_4$ or $LiAlD_4$ respectively.[1]

The infrared spectra in the region from 4000 to 200 cm^{-1} were recorded with Perkin-Elmer instruments (model 621 and 521) and Hitachi instruments (EPI-L and FIS-3). For the measurements in the crystalline state, the vapor of the sample was directly condensed on CsI plate in a cell cooled with liquid nitrogen in a vacuum and was then annealed several times in order to keep the sample from being in the supercooled liquid state. The method was also extended to measurements in the liquid state at about 19°C, since the boiling point of the sample is rather low for measurements using the usual technique.

Results and Discussion

According to the reported vibrational assignments for similar molecules, such as dimethylsilane[2] and ethylsilane,[3] CCSi deformation, SiH_2 rocking, twisting, wagging, Si–C symmetric, and asymmetric stretching modes would be expected in the regions around 300, 467(389), 591 (472), 643(558), 659(636), and 728(700) cm^{-1} respectively, where the frequencies in parentheses indicate the expected frequencies for the deuterated species.

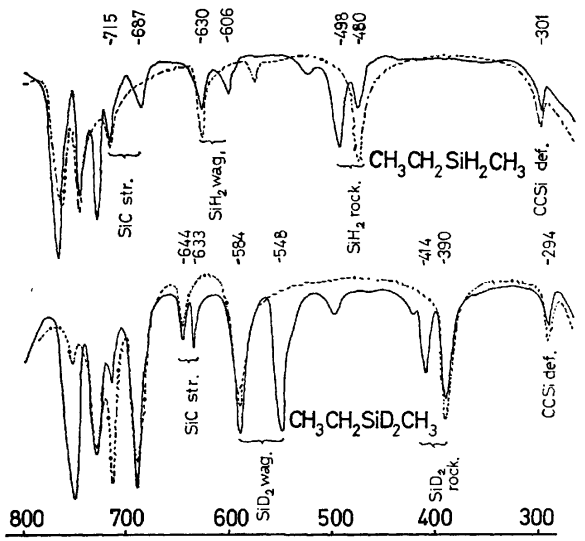

Fig. 1. The infrared spectra of ethylmethylsilane and its deuterated species; —— in the liquid state (19°C), ····· in the crystalline state.

As is shown in Fig. 1, in the region from 700 to 300 cm^{-1}, too many spectra exist there to be an unique molecular form, and some of the spectra vanish in the crystalline state. These facts provide us with evidence of the existence of rotational isomers in the liquid state. The assignments of the observed spectra can easily be found for this region; some are shown in Fig. 1.

The SiH_2 wagging mode and one of the Si–C stretching modes for the parent species are found at frequencies slightly different from those for dimethylsilane. However, this can be understood if these modes originally have nearly equal frequencies and are strongly coupled in ethylmethylsilane, while the corresponding modes in dimethylsilane are separated because of the symmetry of the molecule.

In the gaseous state, the resolution of the spectra becomes worse because of the broad envelopes of the unresolved rotational fine structures.

However, for the deuterated species, the SiD_2 rocking mode is seen as doublets like those in the liquid state; this is considered to be definite evidence of the existence of the rotational isomers in the gaseous state.

As for the parent species, careful measurements with a higher resolution give weak Q branches of the bands at 479 and 498 cm^{-1} over the broad band envelope; these correspond to the bands assigned to the SiH_2 rocking modes in the liquid state. Therefore, the isomers also exist in the parent species. The molecular forms of the isomers would be the *trans* and the *gauche* forms, as in the case of 1,2-dihalogenoethane.

One of the present authors (M.H.) has actually found the *trans* form in the gaseous state by microwave spectroscopy,[4] but he could not find the other form, since the observed microwave spectra were too weak for him to make definite assignments of the transitions for the *gauche* form at the temperature of dry ice.

As usual experimental techniques, such as solvent-effect measurements of the vibrational spectra, seem to be invalid for the determination of the molecular forms of ethylmethylsilane, normal vibration calculations for the skeletal vibrations were attempted regarding ethylmethylsilane as a four-body problem and using a set of force constants which had been obtained from the observed skeletal vibration frequencies of methylsilane,

ethylsilane, and dimethylsilane.

However, the observed skeletal frequencies of ethylmethylsilane could not be reasonably reproduced by this over-simplified treatment. Therefore, at present, we cannot conclude whether or not one of the isomers is in the *gauche* form and which isomer persists in the crystalline state.

The authors wish to express their thanks to Professor Tatsuo Miyazawa of Osaka University and to the staff of his research group for allowing us to use their instruments and for their technical assistance.

On the Role of the Quadrupole-quadrupole Interaction in the Molecular Arrangements in Crystalline Benzene

Masao HASHIMOTO and Taro ISOBE

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai

(Received August 2, 1971)

It has been said that, in a typical aromatic crystal, quadrupole-quadrupole interaction makes only a negligible contribution to the lattice energy[1-3] and the equilibrium molecular orientation. On the other hand, Kihara[4-6] indicated, after using his molecular models, which simulate magnetically the electric multipoles of actual molecules, that the structure of a molecular crystal corresponds to a minimum of the electrostatic energy between the molecules when the molecules have simple shapes and sufficiently strong electric multipoles. We cannot, therefore, neglect the quadrupole-quadrupole interaction energy against the van der Waals dispersion energy, because only the relative smallness of the former against the latter does not generally justify the discarding of the former.

The crystal packing problem of benzene has been discussed by several authors[1-3,7-8] in terms of the intermolecular potential functions. These authors calculated the dependency of the potential energy of this crystal with respect to the class of the structural variation, in which the molecules are rotated in only small angles from the equilibrium structure, with a preservation of the space-group symmetry. They have obtained a successful explanation in terms of the van der Waals dispersion energy only. However, in principle, we must start to consider the molecular packing problem in two interacting molecules; we must calculate the most stable relative arrangement of the two molecules when the intermolecular distance is known, and then construct the whole crystal from this pair. This is related to the phenomena of condensation and crystallization.

Calculation and Results

One of the two molecules is set on the point of the origin of the cartesian coordinate, while the position of the other is expressed by $P(\theta,\theta',\varphi,\varphi',\gamma,R)$, as is shown in Fig. 1.

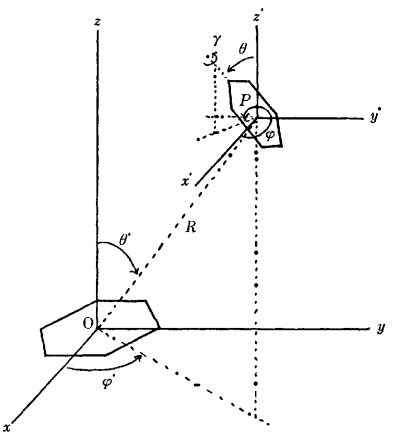

Fig. 1. Geometrical representation of two benzene molecules in interaction.

The intermolecular potential, $v(R)$, is expressed by the sum of the interatomic potentials, $v(r_j)$, as follows:

$$v(R) = \sum_j v(r_j) = \sum_j (b_j \exp(-c_j r_j) - a_j/r_j^6), \qquad (1)$$

where the summation, j, is extended to all pairs of atoms in the two molecules. The three parameters, a_j, b_j, and c_j, were derived from Bartell's function in a way fully described in the text (*cf.* Table 1).[9] A part of the potential energy surface obtained is indicated

TABLE 1. PARAMETER SET

	a_j	b_j	c_j
C···C	298.0	237.0×10^3	4.32

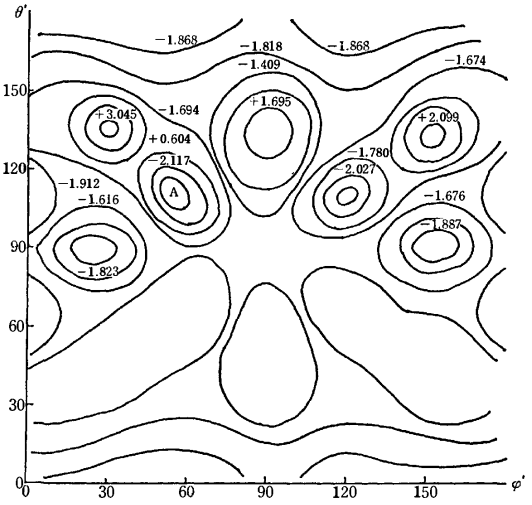

Fig. 2. θ'-φ' energy surface between two benzene molecules. The values in the figure are the minimum with regard to θ, φ, and γ and expressed in kcal/mol unit.

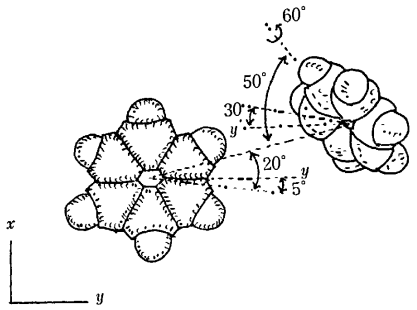

Fig. 3. The most stable orientation of two benzene molecules when R=5.13Å.

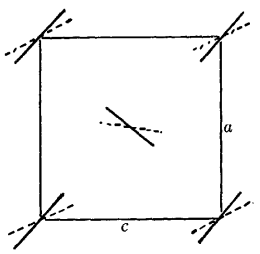

Fig. 4. Diagram of the crystal structure of benzene projected down the b-axis. —— : experimental; ····· our calculation.

in Fig. 2, where R is set at 5.13 Å, the shortest intermolecular distance in the benzene crystal at −3°C. The relative molecular orientation corresponding to the A position in Fig. 2 is indicated in Fig. 3. The corresponding packing in the crystal is indicated by the dashed line in Fig. 4. Thus, it can be observed in Fig. 4 that the molecular packing derived from the two molecules is not consistent with the experimental one, indicating that other types of intermolecular force are acting in addition to the van der Waals interaction.

There are two types of such intermolecular forces. One is the non-additive contribution to Eq. (1), but this is small because of the relatively higher symmetry of the benzene molecules.[10] The other is the quadrupole-quadrupole interaction. The benzene molecules have quadrupole moments[11] perpendicular to the molecular plane:

$$q_{//} = -(5.6\pm2.8)\times10^{-26}\ \text{cm}^2\ \text{e.s.u.}$$

The quadrupole-quadrupole interaction is expressed as follows:

$$\begin{aligned} Q_{ab} = {} & 3qq'[1-5(\cos^2\theta+\cos^2\theta')+17\cos^2\theta\cos^2\theta' \\ & +2\sin^2\theta\sin^2\theta'\cos^2(\varphi-\varphi') \\ & +16\sin\theta\sin\theta'\cos\theta\cos\theta'\cos(\varphi-\varphi')]/4R^5. \end{aligned} \quad (2)$$

Here, the q's are the observed quadrupole moments of the benzene molecule and the θ's and φ's are correlated to the θ's, φ's, and γ in Fig. 1.

The most favourable relative arrangement of two quadrupoles can easily be calculated to be the one in which the molecular planes make a 90° angle. This is almost entirely consistent with the experimental molecular arrangement in the crystal.[12]

Thus, it is necessary, in studying the molecular packing in the benzene crystal, to introduce the quadrupole-quadrupole interaction. The calculated quadrupole-quadrupole interaction energy is −0.95——0.86 kcal/mol at the equilibrium arrangement; this value is attractive.

All the numerical calculations in this paper were done at Computer Center of Tohoku University, using a NEAC 2200 model 700—500 Computer system.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 301(1972)

The Nucleophilic Cyclopropylation of the Condensed Aromatic Ring with Sulfonylcarbanion

Hitosi NOZAKI, Tetuya NISIMURA, and Yasusi YAMAMOTO

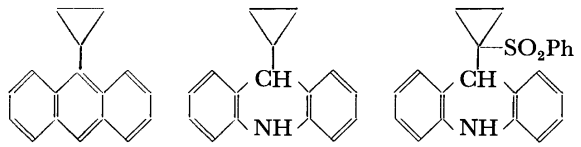
Department of Industrial Chemistry, Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received August 17, 1971)

The nucleophilic methylation of aromatic nuclei has been attained by the action of methylsulfinylcarbanion[1] or dimethyloxosulfonium methylide[2] upon condensed ring hydrocarbons, benzopyridines, or nitrobenzenes. We previously reported that the nucleophilic alkyl-substitution can be effected by the action of sulfonyl-carbanions[3] on anthracene and acridine in hexamethyl-phosphoric triamide (HMPA) as a solvent. We now wish to report a one-step introduction of the cyclopropyl group in anthracene and acridine by means of a sulfonylcarbanion which had been prepared from cyclopropyl phenyl sulfone[4] and sodium hydride in HMPA.

The reaction with anthracene gave 9-cyclopropyl-anthracene (I) (79%). In contrast to the methylation by means of methylsulfinylcarbanion and phenylsulfonylcarbanion, 9,10-dicyclopropylated product was not obtained. The structure of I was supported by its NMR, IR, and mass spectra as well as by the results of elemental analysis.

The treatment of acridine with this carbanion gave 9-cyclopropylacridane (II) (25%) besides a considerable amount of a crystalline, insoluble solid.[5] Phenanthrene, quinoline, or isoquinoline did not react with this carbanion.



I II III

The cyclopropylated product may be ascribed to the nucleophilic attack of the carbanion on the aromatic ring, followed by a concerted hydride shift and the elimination of the sulfinate anion. This route has previously been proposed in the cases of the methylation by means of methylsulfinylcarbanion[1a] and phenylsulfonyl-carbanion.[3b] On the other hand, 9-cyclopropylacridane seems to be attributable to the decomposition of transient 9-(1-phenylsulfonylcyclopropyl)acridane (III), as 9-(1-phenylsulfonylethyl)acridane is the sole isolable product of the reaction of acridine with the carbanion derived from ethyl phenyl sulfone.[3b]

Experimental

All the mps are uncorrected. The microanalyses were performed by Mrs. Kiyoko Fujimoto of this department. The NMR spectra were taken on a 60 MHz instrument (JEOL C-60 H spectrometer) in deuteriochloroform with tetramethylsilane as the internal standard. The mass spectra were obtained on a Hitachi RMU-6L spectrometer.

Reaction of Anthracene with a Carbanion. A carbanion solution was prepared under N_2 from sodium hydride (0.48 g, 20 mmol) and cyclopropyl phenyl sulfone (3.64 g, 20 mmol) in HMPA (30 m*l*) at 60—70°C for 2 hr. To this, a solution of anthracene (1.78 g, 10 mmol) dissolved in HMPA (20 m*l*) was added, and the reaction mixture was stirred at 90°C for 23 hr. Work-up followed by recrystallization (EtOH) then gave 9-cyclopropylanthracene (I) (1.71 g, 79%); mp 133—134°C. IR (Nujol): 1030 cm^{-1} (cyclopropane ring). MS: 218 (M^+). NMR ($CDCl_3$): δ 0.60—0.95 and 1.25—1.60 (m, 4H, methylenes of cyclopropane), 2.15—2.65 (m, 1H, methine of cyclopropane), and 7.25—8.95 (m, 9H, aromatic protons).

Found: C, 93.3; H, 6.5%. Calcd for $C_{17}H_{14}$: C, 93.5; H, 6.5%.

Reaction of Acridine with a Carbanion. A carbanion solution prepared from sodium hydride (0.48 g, 20 mmol) and cyclopropyl phenyl sulfone (3.64 g, 20 mmol) was allowed to react with acridine (1.79 g, 10 mmol) at 70°C for 15 hr. The reaction mixture was treated with water and extracted with benzene. The evaporation of benzene *in vacuo* and subsequent treatment with ether gave a crystalline solid. The structure of this solid could not be confirmed, as the attempted purification of this solid failed. Meanwhile, the chromatography of the dissolved part in ether on a silica-gel column gave 9-cyclopropylacridane (II) (0.56 g, 25%). The product, II, showed a mp of 122—124°C. IR (Nujol): 3350 cm^{-1} (NH). MS: 221 (M^+). NMR ($CDCl_3$): δ 0.25—0.75 (m, 4H, methylenes of cyclopropane), 0.75—1.00 (m, 1H, methine of cyclopropane), 3.38 (d (J=8 Hz), 1H, benzylic proton), and 6.65—7.75 (m, 9H, aromatic protons and NH).

Found: C, 86.6; H, 6.8%. Calcd for $C_{16}H_{15}N$: C, 86.8; H, 6.8%.

SHORT COMMUNICATIONS

Stereoselective Reactions of Some Anions Derived from 1,3,5-Trithianes

Michio FUKUNAGA, Kazutaka ARAI, Hiizu IWAMURA, and Michinori ŌKI
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo
(Received August 23, 1971)

While we were studying the base-catalyzed reactions of 1,3,5-trithiane derivatives, Hartmann and Eliel[1] recently reported on the stereoselective protonation and methylation of 2-lithio-1,3-dithiane derivatives. Although the system we have been studying is a little different from the one reported by Hartmann and Eliel, the results are so similar that we feel it is timely to report our independent findings on the 1,3,5-trithianes.

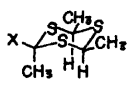
The H-D exchange of the ring-protons of *trans*-2,4,6-trimethyl-1,3,5-trithiane (**1**) was performed in *t*-butyl alcohol-*d* in the presence of alkali *t*-butoxide, and the reaction rate was followed by NMR spectroscopy. The rate of the exchange of the equatorial proton of the compound was found to be 40 times faster[2] than that of the axial, showing the relative ease of the exchange at the equatorial position.

More striking results were obtained with *cis*-2,4,6-trimethyl-1,3,5-trithiane (**2**), which gave a negligible exchange rate under conditions that were convenient for measuring the rate of **1**. Under more severe conditions, the rate of the exchange of the ring-proton of **2** was found to be 550 times lower than that of the axial proton of compound **1**; the rate ratio is now 22000 to 1 when those of the equatorial proton of **1** and the ring-proton of **2** are compared.[3]

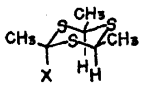
The reaction proceeded with retention of configuration. Thus, **1** gave no *cis* isomer containing deuterium as far as NMR spectra showed. Similarly, no *trans* isomer with D was found upon treating compound **2** with *t*-butoxide in *t*-butyl alcohol-*d*.

Quenching the lithio derivatives with H_2O or D_2O provides another stereoselective reaction of the trithianes. Thus, the treatment of either **1** or **2** with butyllithium, followed by quenching with water, gave a 96:4 mixture of **1** and **2**, whereas quenching with deuterium oxide afforded *r*-2-deuterio-2,*cis*-4,*cis*-6-trimethyl-1,3,5-trithiane (**3**).

The preferential reaction at the equatorial position of 1,3,5-trithiane derivatives is not confined to the protonation. We believe that the carbonation is also stereoselective and that only the equatorial isomer is obtained. The treatment of either *cis*- or *trans*-2,4,6-trimethyl-1,3,5-trithiane (**1** or **2**) with equimolar butyllithium in ether-tetrahydrofuran, followed by carbonation with carbon dioxide, produced the identical carboxylic acid (**4**) [mp 137—138.5°C NMR($CDCl_3$) δ: 1.59 (6H, d), 2.07 (3H, s), 4.39 (2H, q), 8—9 (1H, s)]. When this carboxylic acid was treated with an acid catalyst such as BF_3 etherate, a mixture was obtained which contained an isomer (**5**) [mp 135—135.5°C NMR($CDCl_3$) δ: 1.55 (6H, d), 1.78 (3H, s), 4.69 (2H, q), ~10 (1H, s)] as a major component. Since it is well known that, in trithiane derivatives, the proton signals of the equatorial position appear in a higher magnetic field than the axial counterpart,[4] compound **4** may be assigned to the equatorial isomer.

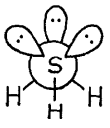


1: X=H
3: X=D
4: X=CO_2H

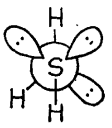


2: X=H
5: X=CO_2H

A possible cause of the stereoselectivity of the above reactions may be mentioned. Since a quantum mechanical study[5] has suggested that the most stable conformation of the $HSCH_2^-$ ion is **6** rather than **7**, the anion lone-pair equatorial conformation which is analogous to conformation **6** will be favored over the anion lone-pair axial. The preferential attack from the equatorial side can be explained on this ground.



6



7

It seems difficult to explain why the H-D exchange proceeds with a high retention of configuration on the basis of the above-mentioned results. However, the data on the rates of H-D exchange now available to us conform with the relative population of the H-equatorial isomer. The results suggest that the reaction occurs solely at the H-equatorial conformation. The detail will be published elsewhere.

Gas Chromatography of Rare Earth Pivaloyltrifluoroacetone Adducts with Tri-*n*-butyl Phosphate and Tri-*n*-octylphosphine Oxide

Kei UTSUNOMIYA and Tsunenobu SHIGEMATSU
Institute for Chemical Research, Kyoto University, Uji, Kyoto
(Received September 2, 1971)

Recently the rare earth chelates with 1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedione[1] and pivaloyltrifluoroacetone (HPTA)[2,3] have been successfully gas chromatographed. It was shown that gas chromatography following the solvent extraction could be applied for the separation and determination of rare earth elements. The synergic extraction of rare earth ions was thoroughly studied using β-diketones and some organic phosphorus compounds. The high extractability was concluded to be caused by adduct formation. Thus, if the adduct compounds can be eluted, an interesting problem on the gas chromatography of rare earth metal complexes might be presented. In this paper, we wish to describe the gas chromatography of the adduct compounds of europium(III), erbium(III), and lutetium(III) with HPTA and tri-*n*-butyl phosphate (TBP), or with HPTA and tri-*n*-octylphosphine oxide (TOPO).

Five milliliters of an aqueous solution containing rare earth ions (0.01—0.1 mM in the concentration) and sodium acetate (0.2M), having the desired pH (finally pH 5.2—5.3), was shaken with 5 m*l* of benzene solution containing HPTA (0.1M) and TBP (0.1M), or HPTA (0.1M) and TOPO (0.1M), and 10—50 μl of the extract was then employed for gas chromatography. The $pH_{1/2}$ values of the extraction of europium and lutetium are 4.13 and 3.59 with HPTA only, 3.21 and 2.42 with HPTA and TBP, and 2.17 and 1.88 with HPTA and TOPO, respectively. The extracted species in the synergic extraction are $Eu(PTA)_3 \cdot 2TBP$, $Eu(PTA)_3 \cdot 2TOPO$, $Lu(PTA)_3 \cdot TBP$, and $Lu(PTA)_3 \cdot TOPO$. Typical chromatograms of europium complexes extracted are shown in Fig. 1. The retention times (min) obtained under the same conditions as described in Fig. 1 are as follows: europium, 4.4 and 5.5 with the HPTA extract,[4] 4.2 with the HPTA-TBP extract, and 7.2 with the HPTA-TOPO extract; erbium, 3.8, 4.2, and 6.6; lutetium, 2.9, 4.0, and 6.4. The sharp peaks favor the determination of each rare earth element. However, the fact that the separation factors become lower than in the case of the rare earth β-diketonates themselves, makes it unsuitable for the separation. The chromatograms of the synergic extracts which seem favorable for the determination differ a great deal from those of the tris-chelates, and the retention times of the former are generally greater except for europium-HPTA-TBP. This suggests that the adduct compounds can be eluted. For the europium-HPTA-TBP and europium-HPTA-TOPO extracts, the acetone solution of the eluted materials shows fluorescence with the same spectrum as that of the extracted benzene solution. The presence of TBP or TOPO in the eluted complexes is confirmed by comparing the IR spectra of the effluent with those of the tris-chelate, TBP, and TOPO. The results indicate that the rare earth-PTA adducts with TBP and TOPO can be gas-chromatographed without decomposition. Reproducible linear relationships are obtained between the detector response and the original concentration of aqueous europium(III) solution over the range 0.04—0.1 mM in the HPTA-TBP extraction, and 0.01—0.1 mM in the HPTA-TOPO extraction.

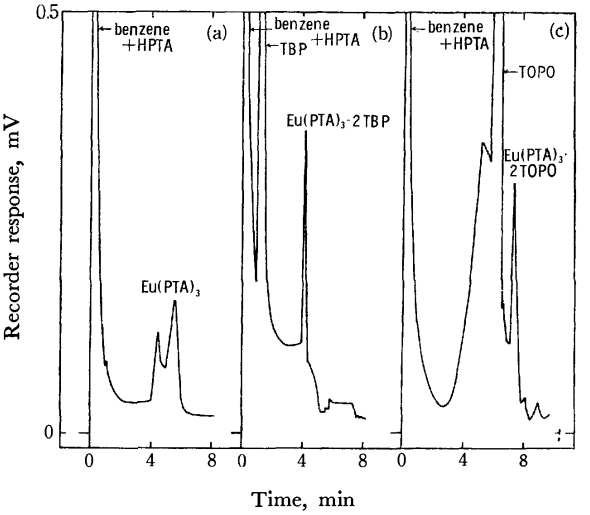

Fig. 1. Gas chromatograms of the extracts of europium(III) with (a) HPTA, (b) HPTA-TBP, and (c) HPTA-TOPO. (a) 152 μg Eu in solvent (50 μl), (b) 91 μg Eu in solvent (50 μl), and (c) 76 μg Eu in solvent (25 μl). Conditions: column, 75 cm × 3 mm i.d. stainless steel; column packing, 5% OV-101 on Chromosorb W AW DMCS (80—100 mesh); column temp., programmed from 150 to 300°C at 20°C/min; helium flow rate, 110 m*l*/min at 150°C. Detector: thermal conductivity detector, 150 mA.

Catalyst Isotope Effect in *n*-Butene Isomerization Catalyzed by Metal Sulfates

Makoto Misono and Yukio Yoneda

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received September 13, 1971)

We have reported that rate and selectivity increase monotonously with the acid strength of catalyst in the isomerization of *n*-butene catalyzed by metal sulfates.[1] The results were explained on the basis of the relative rate of proton transfer between catalyst and butene. If the proton transfer is involved in the reaction, it would be expected that (i) over deuterated catalysts, deuterium atoms are incorporated preferentially into the isomerized butenes, and (ii) isomerization proceeds more slowly over deuterated catalysts than normal catalysts (catalyst isotope effect). Preferential deuteration (i) was reported by Ozaki and Kimura for some solid acids.[2] However, catalyst isotope effect (ii) does not seem to have been reported in solid-acid catalysis so far, although it was reported that perdeuterobutene reacted 1.3—1.8 times more slowly than normal butene over silica-alumina.[3]

We observed catalyst isotope effect (ii), in addition to preferential deuterium incorporation (i), in the case of butene isomerization catalyzed by aluminum and magnesium sulfates supported on silica gel (Al-S and Mg-S). The extent of consumption of catalytically active deuteron on the catalyst surface could be examined by the measurement of the deuterium content of butenes.

Reaction apparatus was a closed circulating system (124 cc) connected to a conventional vacuum-line. Catalysts were first evacuated for 1 hr at 100°C in the system and then equilibrated three times with H_2O or D_2O vapor at 70°C. Further equilibration had no effect on the reaction. A catalyst pre-equilibrated with H_2O is denoted by H-catalyst and that with D_2O by D-catalyst. They were evacuated for 1 hr at 70°C, prior to reaction. Reaction temperature was 60±0.5°C. Butene pressure was 10—15 cmHg. Repeated runs on the same catalyst after the same treatment gave sufficiently reproducible results for Mg-S (±3%) and for Al-S (±10%). The rate obviously decreased upon deuteration of Mg-S and the original activity was recovered by re-equilibration with H_2O. The change was much smaller for Al-S. The ratio of the conversion of *cis*-2-butene over H-Mg-S to that over D-Mg-S at the same reaction time is plotted against the latter in Fig. 1. Extrapolation of this ratio to zero conversion gives an isotope effect of 1.7±0.2. A similar effect was also observed for 1-butene isomerization. The rapid decrease in ratio during the course of the reaction may be due to the substitution of deuteron by a more active proton. A slower decrease observed in an experiment with low butene pressure is in accord with this view. The ratio of two isomerized products from *cis*-2-butene (*trans*/1) was 10% lower over D-catalyst (D-Mg-S and D-Al-S), probably reflecting a secondary isotope effect. There was little change in *cis*/*trans* ratio from 1-butene upon deuteration of the catalyst.

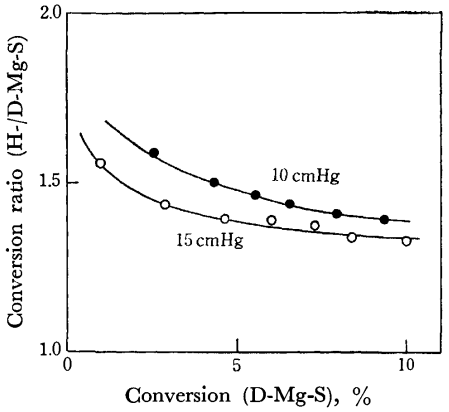

Fig. 1. The ratio of conversion of *cis*-2-butene over normal magnesium sulfate supported on silica gel (H-Mg-S) to that over deuterated magnesium sulfate (D-Mg-S) at 60°C.
Butene pressure: 10 cmHg (●), 15 cmHg (○)

Table 1. Composition of products in the isomerization of *cis*-2-butene over deuterated Mg-S and Al-S at 60°C

		Composition (%)	Isotopic composition (%)[a]	
			d_0	d_1
Mg-S	1-	0.9	38	62
	trans-	0.6	44	56
	cis-	98.5	99.5	0.5
Al-S	1-	3.6	39	61
	trans-	11.9	46	54
	cis-	84.5	91	9

a) Multi-deuterated species observed in small amounts were neglected.

The results of mass spectrometric analysis of the products are given in Table 1. Preferential incorporation of deuterium atoms into isomerized products was obvious. The results show that proton transfer was involved in the reaction and that it was the origin of the observed isotope effect. The fractions of the deuterated products are shown to be only 50—60% and should be compared with the rapid decrease of the conversion ratio in Fig. 1. If the energy profile of the reaction is considered,[4] the observed isotope effect may be regarded as that in the step of proton addition to butene. The reason for the weak effect with a strong acid such as Al-S is now under investigation.

The Reaction of Disodium Tetracarbonylferrate(−II) with Phthaloyl Dichloride. The Formation of Biphthalidylidene

Take-aki MITSUDO, Yoshihisa WATANABE, Masato TANAKA, Kazuo YAMAMOTO, and Yoshinobu TAKEGAMI

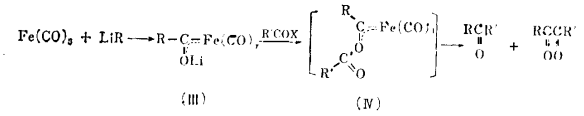
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received September 16, 1971)

Previously we reported that acyl halides react with disodium tetracarbonylferrate(−II) (I) to give the acyl tetracarbonylferrates (II), which are then hydrolyzed to the corresponding aldehydes in high yields.[1]

$$\underset{\text{(I)}}{Na_2Fe(CO)_4} + RCOCl \longrightarrow \underset{\text{(II)}}{Na^+[RCOFe(CO)_4]^-} \xrightarrow{H^+} RCHO$$

On the other hand, Sawa and his co-workers[2] reported that lithium acyltetracarbonylferrates (III), which are prepared from $Fe(CO)_5$ and organolithium compounds, react with acyl halides to give ketones and/or α-diketones. It is strongly suggested that the reaction proceeds *via* the aryl- or alkylacyloxycarbene iron complex (IV):

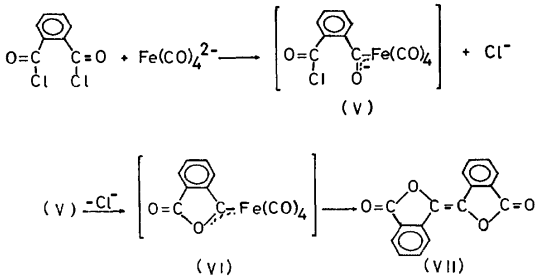


(III) (IV)

In this communication we wish to report that $Fe(CO)_4^{2-}$ reacts with phthaloyl dichloride to give biphthalidylidene possibly *via* the cyclic carbene iron complex.

The reaction was carried out as follows. Into $Na_2Fe(CO)_4$[3] (11 mmol) in tetrahydrofuran, we added 1.6 m*l* (11 mmol) of phthaloyl dichloride with stirring at −40°C under argon. After 1 hr, the mixture was warmed to 40°C and stirred for 2 hr. Then the solvent was distilled off and the residue was washed with water, 6N HCl, water again, and then ethyl ether. The orange-yellow precipitate (0.81 g) thus obtained was recrystallized twice form chloroform to give yellow biphthalidylidene (0.33 g). Yield, 23%. Mp 340—341°C (339—341°C[4]). Found: C, 72.25; H, 3.17%; mol wt (mass) 264. Calcd for $C_{16}H_8O_4$: C, 72.73; H, 3.05%; mol wt 264.22. IR(KBr): 3085 (ν_{C-H}), 1785 ($\nu_{C=O}$), 1605, 1590, 1478 (benzene ring), 1190 (ν_{C-O}), 758 (*o*-disubstituted benzene) cm^{-1}. UV: $\lambda_{max}^{CH_3CN}$ mμ (log ε); 221(4.35), 226(4.38), 257(4.09), 293(4.02), 304(4.07), 356(4.39). These spectra are identical with those of *trans*-formed biphthalidylidene reported previously.[4]

The reaction mechanism is not completely clear at the present time, but a plausible reaction scheme may be presented. First, $Fe(CO)_4^{2-}$ attacks one of the acyl halide groups in phthaloyl chloride to give an acyl carbonylferrate (V). Then the oxygen atom of the acyl group attached to the iron attacks another acyl carbon atom nucleophilically to form a lactonic carbene carbonyliron complex (VI),[5] which then decomposes thermally to biphthalidylidene (VII). Fischer reported that the pyrolysis of a phenylalkoxycarbene-chromium complex gives the dimer of the carbene ligand.[6]



(V) (VI) (VII)

It should be noted that it may be difficult to form the cyclic carbene complex by the reaction of organolithium compounds with metal carbonyls and that two carbene ligands are introduced into this product, biphthalidylidene. In contrast to the present results, only one ligand is introduced into the products in the reaction of lithium tetracarbonylferrate (III) with acyl halide.[2] Further studies of the reaction mechanism are required to explain the difference between these reactions.

The reaction of diacyl halides with metal dianion complexes, $M(L)_n^{2-}$, can possibly be utilized for the preparation of other organic compounds or cyclic carbene metal complexes. We are now investigating these reactions; the results will be published in the near future.

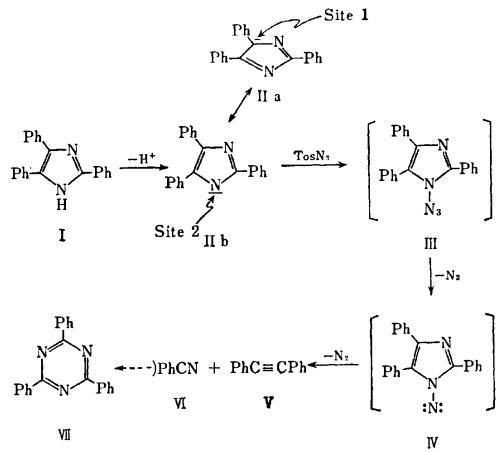
An Unusual Ring Expansion of Lophine to 2,4,6-Triphenyl-s-Triazine

K. SAKAI and J.-P. ANSELME*

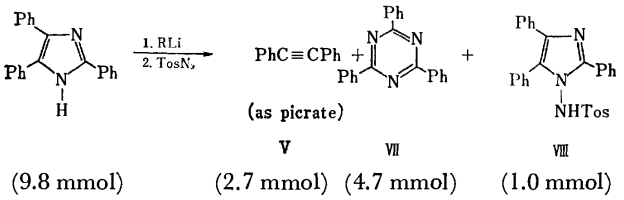
Department of Chemistry, University of Massachusetts, Boston, Mass. 02116, U.S.A.

(Received September 6, 1971)

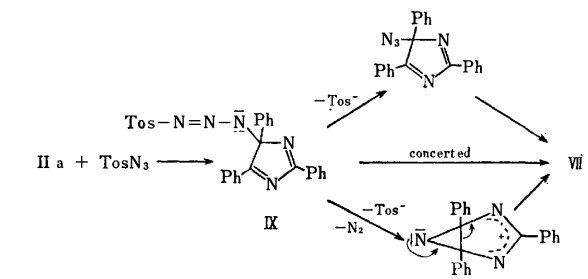
The paucity of *N*-amino imidazoles suitable for our investigation of the fragmentation of *N*-azolylnitrenes[1] prompted us to attempt the generation of these *N*-nitrenes directly *via* the *N*-azides. It has already been shown that in principle all *three* nitrogen atoms of *p*-toluenesulfonyl azide (tosyl azide) can be transferred (*azido transfer* reaction) to anions of secondary amines or imines. Although this reaction has been realized with imines,[2] difficulties arose when side-reactions became the major paths of these experiments.[2,3] These facts notwithstanding, it was anticipated that with the appropriate substrates, *N*-azidation should be possible. The ready availability of 2,4,5-triphenylimidazole (I) prompted us to explore this possibility, particularly since its anion (IIb) is symmetrical with respect to attack of tosyl azide at nitrogen (site 1); since azidation at carbon (site 2) would result in the formation of a non-aromatic ring, it was anticipated that this might favor the formation of the *N*-azide.



The anion of lophine (II), prepared by the reaction of lophine with one equivalent of methyllithium in tetrahydrofuran, was treated with a two-fold excess of tosyl azide and the reaction mixture was then heated under reflux for 12 hr; vigorous evolution of nitrogen was observed. The reaction mixture was quenched by the addition of water and the organic products were separated by chromatography on alumina. From 20.2 mmol of lophine, there was obtained 4.7 mmol of 2,4,6-triphenyl-*s*-triazine (VII), 2.7 mmol of tolan (as its picrate) and 1.0 mmol of *N*-tosylamino lophine (VIII), in addition to 10.4 mmol of unreacted lophine. Our original assumption was that the triazine arose by trimerization of benzonitrile,[4] one of the primary fragmentation products. On that basis, the yield of benzonitrile (as the triazine) would be over 160% and this coupled with the abnormally low yield of the tolan prompted us to question the fragmentation path as the source of the triazine. If the yield of tolan is taken as the extent to which fragmentation (assuming 100% conversion)[5] was responsible for triazine, then 6.1 mmol of lophine anion was converted to 3.8 mmol of triazine by another route.



(9.8 mmol) (2.7 mmol) (4.7 mmol) (1.0 mmol)



The results obtained can only be rationalized in terms of an attack of tosyl azide at carbon followed by generation of the azide or more likely a concerted ring expansion of the primary addition product (IX) perhaps *via* the highly stabilized bicyclic betaine; bond reorganization would then lead to the observed 2,4,6-triphenyl-*s*-triazine. To our knowledge, this is the first report of a nitrene ring expansion of this type of a five- to a six-membered aromatic heterocycle.[6]

The data obtained show that attack by tosyl azide at carbon is favored by almost 2 to 1 over attack at nitrogen and the ring expansion reaction proceeds in about 64% yield.

4) We have determined that benzonitrile trimerizes to the triazine under the reaction conditions.

5) The serendipitous formation of VIII allowed us to ascertain that the fragmentation gave the triazine and diphenylacetylene in 48 and 60% yields respectively. *N*-Tosylaminolophine (VIII) was stable under the reaction conditions. The results of the fragmentation will be reported at a later date.

The Fragmentation of an *N*-Pyrryl Nitrene from the Oxidation of 6-Amino-1,4,5,7-tetramethylpyrrolo[3,4-*d*]pyridazine

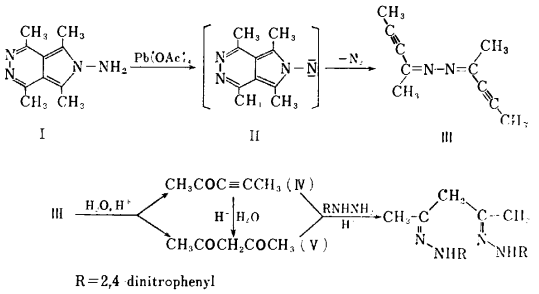
K. SAKAI and J.-P. ANSELME*

Department of Chemistry, University of Massachusetts, Boston, Mass. 02116, U.S.A.

(Received September 28, 1971)

While pyrryl *N*-nitrenes do not undergo fragmentation,[1,2] those *N*-nitrenes derived from 1,2,4- and 1,2,3-triazoles,[2,3] tetrazoles,[3] imidazoles,[4] and 1- and 2-benzotriazoles[5] lose elemental nitrogen with formation of the corresponding triply bonded species. We now report evidence which suggests that fragmentation can be a reaction path for some pyrryl *N*-nitrenes.

When a solution of 6-amino-1,4,5,7-tetramethylpyrrolo[3,4-*d*]pyridazine (I)[6] was heated with lead tetraacetate under reflux for 3 hr, nitrogen was generated in about 36% yield. From the very dark brown reaction mixture, a crude semi-solid was obtained which exhibited a medium intensity band at 2035 cm^{-1} (shoulder at 2075 cm^{-1}) and a strong absorption at 1735 cm^{-1}. Treatment of this crude product with 2,4-dinitrophenylhydrazine under acidic conditions gave the bis-(2,4-dinitrophenyl)hydrazone of acetylacetone, mp 209—212°C, identical in all respects with an authentic sample. When the oxidation was carried out overnight at room temperature, the yield of nitrogen was about 22%. Addition of solid sodium carbonate to the dark reaction mixture, followed by removal of the solids and mild acidic hydrolysis of the filtrate, gave a 16% yield of acetylacetone. Its infrared spectrum was superimposable upon that of an authentic sample; its bis-(2,4-dinitrophenylhydrazone) was also identical in all respects to an authentic sample.



The isolation of acetylacetone coupled with the evolution of nitrogen suggests that, in contrast to the *N*-nitrenes derived from pyrroles and carbazoles,[1,2] the *N*-nitrene (II) generated from I underwent fragmentation to the extent of ~36%. The primary fragment (III) might be expected to be somewhat unstable to the conditions of the reaction and to be hydrolyzed at least partially to 3-pentyne-2-one (IV) which would then presumably be hydrated to acetylacetone; alternatively, IV could give the bis-hydrazone by direct reaction with 2,4-dinitrophenylhydrazine.

The formation of large amounts of dark products suggests that the *N*-nitrene (II) undergoes further reactions *without* expulsion of nitrogen. The occurrence of the fragmentation path in this case may be the result of synergistic effect of two factors, namely the incorporation of the pyrrole ring in a quinoid structure[5] and secondly, the electron withdrawing effect of the two nitrogen atoms of the pyridazine ring which possibly weakens the "backbone" bond[8] sufficiently so that fragmentation can occur.

The CuCl : 1,1-Diphenyl-2-picrylhydrazyl Free Radical Complex

F. LEH and J.K.S. WAN
Department of Chemistry ,Queen's University, Kingston, Ontario, Canada
(Received May 4, 1971)

Although copper ion and hydrazine form a complex readily,[1] none of the disubstituted hydrazines has shown any evidence of complex formation.[2] The reactions of DPPH with copper acetylacetonates[3] and with ferrous ions[4] have been reported. These brief communications are concerned only with the rate of the *apparent* disappearance of free DPPH as monitored by its characteristic visible absorption at 527 mμ, and it was not certain what the nature of the reaction was. The present preliminary report describes the reaction of 2,2-diphenyl-1-picrylhydrazine ($DPPH_2$) and the 1,1-diphenyl-2-picrylhydrazyl radical (DPPH) with Cu(I)Cl and the characterization of the new copper free radical complex formed. Both the $DPPH_2$ and the DPPH reactions lead to the identical solid CuCl:DPPH paramagnetic complex which is remarkably stable. The presence of an unpaired electron in the DPPH ligand may contribute to the donor ability of the molecule to form a metal complex.

The brown solid complex CuCl:DPPH has been prepared *via* different methods involving the reactions of either DPPH with CuCl or $DPPH_2$ with $CuCl_2$ in suitable solvents. The complex can be recrystallized from chloroform and ether and melts with decomposition at 176—178°C. Results of the elementary analysis and molecular weight determinations are consistent with the 1:1 ratio CuCl:DPPH complex. When the complex was dissolved in dilute nitric acid in the presence of Ag^+ ion, gentle heating of the solution regenerated the free DPPH radicals which could be seen readily by the appearance of the characteristic purple color (527 mμ). Prolonged heating resulted in further protonation of DPPH to give the hydrazine. The complex was also found to be unstable in strong acids.

The IR spectrum of the complex in the region 600—4000 cm^{-1} is similar to that of DPPH. The UV-visible absorption spectrum of the complex is, however, distinctly different from that of free DPPH. The characteristic visible absorption band at 527 mμ in the uncomplexed DPPH free radical is probably due to the picryl ring having appreciable delocalized unpaired spin and the second band at ~330 mμ is ascribed to the diphenylamino moiety. The new complexed DPPH absorption spectrum retains the band at ~319 mμ but the visible band at 527 mμ disappears. This suggests that the coordination of Cu^+ ion is probably *via* the picryl ring:

In acid solutions, the complex is not stable; the Cu^+ is oxidized to the Cu^{2+} state and thelig and DPPH is liberated thus regenerating the visible absorption band at 527 mμ.

The oxidation state of copper in the paramagnetic free radical complex was studied by electron spin resonance. The ESR spectrum of the polycrystalline complex shows a single symmetrical line with $g=2.002$. For comparison the Cu(II) complex $Cu^{2+}(N_2H_4)_2(HSO_4^-)_2$ was prepared[1] and its powder ESR spectrum gives the characteristic anisotropic Cu(II)lines. When the CuCl:DPPH complex was dissolved in a degassed benzene solution, a five-line ESR spectrum with additional poorly resolved hyperfine structures resembling a DPPH spectrum, was observed. Since the ESR spectrum of DPPH in a degassed benzene solution is very complicated and has not yet been analysed in detail, it is not practical to speculate on assignments of the CuCl:DPPH spectrum based on some poorly resolved structure. However, ESR spectra of free radical complexes with metal chlorides have been observed with hyperfine couplings assigned to the metal and the chlorine nuclei.[5] γ-Irradiation of the complex CuCl:DPPH in solid state leads to a weak ESR spectrum having the appearance of the paramagnetic Cu^{2+} ion. Detailed investigation of the radiation damage of copper complex is in progress. Based on the ESR results, the copper ion in the solid complex CuCl:DPPH is thought to be in the +1 state. Complementary chemical evidence also showed that the chloride ligand is tightly bound to the copper, characteristic of Cu(I) compounds.

The high resolution PMR spectra of the complex CuCl:DPPH in deuterated acetone or chloroform solvents taken at various temperatures, showed resonance absorptions due to two different groups of protons with intensities in the ratio of 5:1. The large absorption centered at ~538 cps is assigned to the protons on the unsubstituted phenyl rings while the other small absorption at ~435 cps is due to the protons on the picryl ring. In the spectrum of uncomplexed DPPH, the spin delocalization on the picryl ring renders the NMR absorption of the protons on the picryl ring too broad for detection. When the DPPH is complexed to the copper ion *via* the picryl ring, the coordination probably twists the picryl ring more out of the plane of the unpaired electron orbital thus reducing the probability of delocalization and sharpening the picry proton peaks for observation. An X-ray study has shown[6] that in the solid DPPH the picryl ring and the other two phenyl rings are not coplanar with the hydrazine backbone. Thus the observed resonance due to the picryl protons in the complex agrees with the optical absorption evidence suggesting the coordination *via* the picryl ring.

Electronic Spectra and Structures of Organic π-Systems. III. Electronic Spectra of Nitrocyclopentadienide Anion and Formylcyclopentadienide Anion[1]

Zen-ichi Yoshida, Tsunetoshi Kobayashi*, and Akihiko Konishi

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto

(Received February 8, 1971)

The electronic spectra of sodium nitrocyclopentadienide and sodium formylcyclopentadienide have been measured in several solvents. The electronic states of these compounds have been calculated by variable integrals methods I and II (modified Pariser-Parr-Polpe method). The longest wave-length strong absorption band of nitrocyclopentadienide (304 mμ) or formylcyclopentadienide (280 mμ) in isooctane has been assigned to the superimposed band of two intramolecular chage-transfer transitions from the five-membered ring to the nitro or formyl group. Agreement between the calculated and observed transition energies in isooctane is satisfactory.

Among nonbenzenoid aromatic systems the $(CH)_{4n+1}$ ring system having $(4n+2)\pi$ electrons is expected to have interesting electronic characteristics. Cyclopentadienide anion ($n=1$) is the most typical one of this system. However, no detailed investigations have been carried out on the electronic spectra and structures of substituted cyclopentadienide anions. This paper deals with the electronic states of nitro- and formylcyclopentadienide anions.

Experimental

Materials. Sodium nitrocyclopentadienide was prepared by Thiele's[2] method. Sodium formylcylopentadienide was prepared by the method of Hafner and his co-workers.[3] Since the latter compound is quite unstable in atmosphere, treatment was carried out in a nitrogen dry box.

Measurements. Ultraviolet-visible spectra were measured by a Hitachi Model EPS-3T spectrophotometer in isooctane, ether, methanol, water, and acetonitrile.

Results. The ultraviolet-visible spectra of sodium nitrocyclopentadienide and sodium formylcyclopentadienide are shown in Fig. 1. The peak wavelengths are summarized in Table 1.

The ultraviolet and visible spectra of sodium nitrocyclopentadienide in water have been reported also by Kerber and Chick.[4]

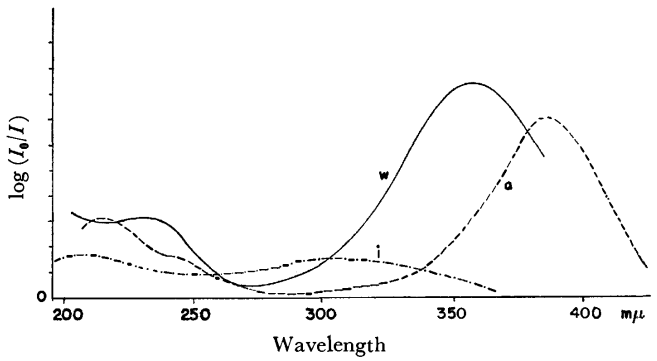

Fig. 1a. Ultra-violet and visible spectra of sodium nitrocyclopentadienide.
Solvents: water (w), acetonitrile (a), and isooctane (i).

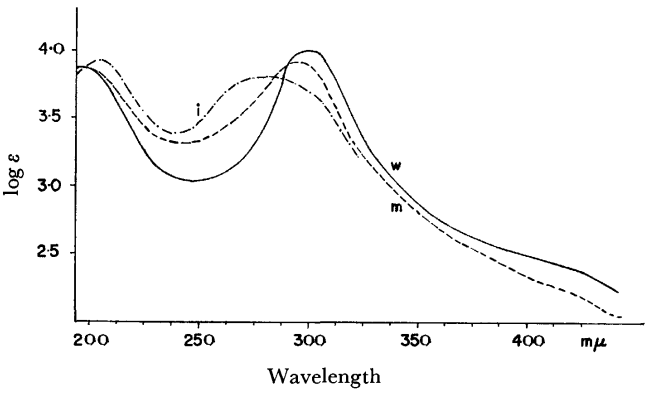

Fig. 1b. Ultra-violet and visible spectra of sodium formylcyclopentadienide.
Solvents: water (w), methanol (m), and isooctane (i).

Theoretical

Methods. The variable integrals methods, VI/1, VI/2/only NNβ, and VI/2/allβ are used.[5] Only the nearest-neighbour β's are taken into consideration in the VI/2/only NNβ, and VI/1 methods while in the VI/2/allβ method all the β's are.

Numberings of the atomic orbitals are shown in Fig. 2. The structures of these molecules are assumed to be as shown in Fig. 2 with reference to the crystallographic data of nitro- and formyl compounds.[6,7] The five-membered rings are assumed to be regular pentagons, and the C–C bond lengths of the pentagons to be 1.40 Å.

The necessary parameters W_p's, α_p's, and $\bar{\alpha}_p$'s are summarized in Table 2.

For the sake of simplicity the variable integrals are reevaluated only in the first five and ten iteration steps of SCF procedures of the VI/1 method and the VI/2 method, respectively.

Table 2. Parameters

	W_p (eV)	α_p	$\bar{\alpha}_p$
C^+	−11.16	3.8379	3.3697
N^{2+}	−28.71	4.2949	3.7631
O^+	−17.28	3.6357	3.0593

All the singly excited configurations are taken into account in the configuration interactions.

Results. The SCF eigenvalues and eigenvectors given by the VI/2/only NNβ method are shown in Table 3. The π-electron densities and bond orders are given in Table 4, and the calculated $^1\pi^*$–$^1\pi$ transition energies in Table 5 together with the observed values.

Discussion

The β's given by the VI/1 method are on the whole similar to those given by the VI/2 method. The VI/1, VI/2/only NNβ, and VI/2/allβ methods give similar SCF eigenvalues and eigenvectors in the case of nitrocyclopentadienide anion, but slightly different eigenvectors in the case of formylcyclopentadienide anion.

The π-electron densities and bond orders given by these methods resemble each other as shown in Table 4. It is presumed that the contribution of the canonical formula or to the ground state of each anion is large. It may be anticipated that in

a) The transition denoted i-j refers to a one-electron excitation from orbital i to virtual orbital j. The second column gives the CI coefficient of the configuration i-j.

b) In isooctane.

the ground states the five-membered rings are not regular pentagons but slightly bond alternated pentagons in which the C_2–C_3 and C_4–C_5 bonds are slightly shorter than the C_1–C_2, C_1–C_5, and C_3–C_4 bonds.

As is seen in Table 1, the first band ($\sim$300 mμ in isooctane) of nitrocyclopentadienide shows a remarkable red shift by the change of solvent from isooctane to acetonitrile, *viz.*, the energy of this band decreases with the increase in the dielectric constant of the solvent. Thus the band is presumed to be due to the transitions to the excited states with dipolemoments larger than those of the ground state. On the other hand the cyclopentadienide ring is an electron donating group and the nitro group a strong electron accepting group. Thus the first band is also expected to be composed of intramolecular charge-transfer transitions associated with electron transfer from the five-membered ring to the nitro group. As is seen in Table 5 the VI methods explain that this band is composed of two transitions ($^1A_1$, $^1B_2$) associated with electron transfer from the five-membered ring to the nitro group.

From our calculation, the 201 mμ band of nitrocyclopentadienide anion observed in isooctane is expected to be composed of at least two transitions. The fact that this band reveals a shoulder when the solvent is changed from isooctane to acetonitrile may support this interpretation.

The agreement between the calculated and observed transition energies in isooctane is satisfactory in the case of nitrocyclopentadienide (Table 5).

In the case of formylcyclopentadienide the 280 mμ band observed in isooctane is also shifted to 311 mμ by the change of solvent from isooctane to acetonitrile, *viz.*, this band shows a large red shift when the dielectric constant of the solvent increases. Thus the band is expected to be composed of transitions to the excited states with dipole moments larger than those of the ground state. On the other hand, our calculations also explain that this band can be composed of two intramolecular charge-transfer bands caused by electron migration from the five-membered ring to the formyl group (Table 5).

The band around 200 mμ of formylcyclopentadienide shows only a slight solvent shift by the change of solvent from a polar to a nonpolar solvent. This band is predicted to be composed of two transitions localized in the five-membered ring. The prediction is in line with the experimental data.

The longest wavelength weak band around 430 mμ of formylcyclopentadienide can be assigned to a π^*-n transition because it shows a blue shift when the solvent is changed from an aprotic to a protic solvent.

As is seen in Table 5 the argeement between the calculated and observed transition energies in isooctane is satisfactory also in case of formylcyclopentadienide. On the whole the effect of sodium cation on electronic spectra of nitro- and formylcyclopentadienide can be neglected in the calculations.

In conclusion the variable integrals methods[5] give a satisfactory explanation of the electronic spectra of both compounds chosen in this study.

The calculations have been carried out on a HITAC 5020 E computer at the Computer Centre of the University of Tokyo.

Electronic Spectra and Structures of Organic π-Systems. IV. Electronic Spectra of Nitropyrroles

Zen-ichi YOSHIDA, Tsunetoshi KOBAYASHI*, and Hidenori YAMADA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto

(Received February 8, 1971)

The electronic spectra of 2-nitropyrrole and 3-nitropyrrole have been measured in various solvents and compared with the values calculated by the variable integrals method II. Agreement between the observed and the calculated transition energies is satisfactory. From eigenvectors of both nitropyrroles, the localization of molecular orbitals to the moiety of molecule has been discussed. The π-electon densities and π-bond orders of both molecules have also been calculated.

We have proposed a new type of modified Pariser-Parr-Pople method, the variable integrals method II, which contains no arbitrary adjusting parameters and needs no guess work in estimating a set of suitable parameters to calculate the electronic spectra of the molecule in question. The method was applied to various kinds of molecules with great success.[1,2]

The electronic spectra of 2-nitropyrrole and 3-nitropyrrole were measured in various solvents and the results were compared with the calculated values.

Experimental

Materials. Nitration of pyrrole was carried out according to Rinkes[3] and needle crystals with mp 60—62°C were obtained. They were dissolved in a benzene-ether (1 : 1) mixture and chromatographed on a silica gel column. Elutions gave substance (I), mp 65°C, as golden yellow coloured needles from carbon tetrachloride (Found: C, 43.03; H, 3.30; N, 24.98; O, 28.42%. Calcd for $C_4H_4N_2O_2$: C, 42.86; H, 3.59; N, 24.99; O, 28.56%, and substance (II), mp 101—102°C, from benzene as yellow crystals (Found: C, 43.02; H, 3.86; N, 25.01; O, 28.60%. Calcd for $C_4H_4N_2O_2$: C, 42.86; H, 3.59; N, 24.99; O, 28.56%). The mass spectrum of each compound showed a parent peak of $m/e=112$. The compounds were identified as monomers of nitropyrroles. There has been some confliction[3-5] concerning the structural identification of nitropyrroles. For instance Safonova and coworkers[4] have reported the mp of 2-nitropyrrole as 55°C and that of 3-isomer to be 64°C. The substance with mp 101°C obtained by the decarboxylation of 4-nitropyrrole-2-carboxylic acid was regarded as a dimer of nitropyrrole.[5] On the other hand, Morgan and Morrey[6] reported that the substances with mp 65—66°C and mp 99—101°C are 2-nitropyrrole and 3-isomer, respectively, and the substance with mp 63—64°C is a mixture of two isomers.

In order to investigate molecular electronic spectra, there should be no ambiguity about the position of the substituent. Thus we confirmed the position of nitro-group by the following infrared method. The infrared spectra of nitropyrroles I and II were measured in carbon tetrachloride on a JASCO DS-402G spectrophotometer. Nitropyrrole I shows three peaks in the NH stretching region at a high concentration. The three peaks at 3470 cm^{-1}, 3390 cm^{-1}, and 3265 cm^{-1} are assigned to the free ν_{N-H}, the intramolecular hydrogen bonded ν_{N-H}, and the intermolecular hydrogen bonded ν_{N-H}, respectively. The peak at 3265 cm^{-1} disappears on dilution. On the other hand, nitropyrrole II shows two peaks in the NH stretching region. The two peaks at 3493 cm^{-1} and 3385 cm^{-1} are regarded as the free and the intermolecular hydrogen bonded N-H stretching vibrations,

respectively. The peak at 3385 cm^{-1} disappears on dilution. Thus it was concluded that nitropyrrole I is 2-nitropyrrole and nitropyrrole II 3-isomer.

Measurements. Ultraviolet and visible spectra were obtained with a Hitachi Model EPS-3T spectrophotometer, in *n*-hexane, tetrahydrofuran, acetonitrile, methanol, and water.

Results. The ultraviolet and visible absorption spectra of the compounds in several solvents are shown in Fig. 1. The peak wavelengths of these spectra are summarized in Table 1. Morgan and Morrey[6] have reported the λ_{max} and ε_{max} of these compounds observed in *n*-hexane and methanol. They are consistent with our results, although the spectra around 200 mμ have not been measured.

Theoretical

Method. The variable integrals method II was used.[1,2] The molecular structures of nitropyrroles are assumed as shown in Fig. 2 using the structural data of pyrrole[7] and *p*-nitroaniline.[8] Numberings of the atomic orbitals are also given in Fig. 2.

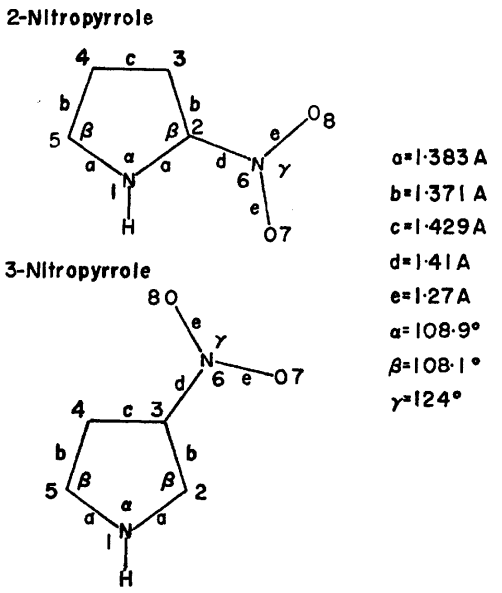

Fig. 2. Assumed structures of nitropyrroles.

7) B. Bak, D. Christensen, L. Hansen, and J. Rastrup-Andersen, *J. Chem. Phys.*, **24**, 720 (1956).

8) J. Donohue and K. N. Trueblood, *Acta Crystallogr.*, **9**, 960 (1956).

Results and Discussion

The SCF eigenvalues and eigenvectors of nitropyrroles are shown in Table 2. The molecular orbitals ψ_5 and ψ_8 of 2-nitropyrrole, and ψ_3, ψ_5, and ψ_7 of 3-nitropyrrole are mainly localized on pyrrole ring, and the molecular orbitals ψ_4's of both nitropyrroles are almost localized in nitro-groups. The other molecular orbitals are delocalized over both pyrrole and nitro-groups.

The π-electron densities and bond orders are summarized in Table 3. In the ground state the charges of about −0.11 *e* and −0.09 *e* are transferred from pyrrole group to nitro-group in 2- and 3-nitropyrroles, respectively.

The calculated transition energies are summarized in Table 4 with the observed ones in *n*-hexane.

In the case of 2-nitropyrrole the calculated 5.354 eV and 6.457 eV transitions are in good agreement with the observed values. From the CI coefficients we see that the 4.327 eV transition is the so-called intramolecular chage-transfer transition associated with electron migration from pyrrole group to nitro-group. This is consistent with the observed large solvent effect on the longest wavelength band. The 4.729 eV transition is contributed from a charge-transfer configuration, a local excitation configuration in nitro-group and a back charge-transfer configuration associated with electron transfer from nitro-group to pyrrole group. The corresponding band seems to be hidden by the other stronger bands. The 5.354 eV transition is contributed from a charge-transfer configuration, a local excitation configuration in nitro-group and a local excitation configuration in pyrrole group. The 6.457 eV transition is mainly contributed from a localized excitation configuration in pyrrole group.

The observed values are those in *n*-hexane.

a) The transition denoted by *i-j* refers to a one-electron excitation from orbital *i* to virtual orbital *j*. The second column gives the CI coefficient of the configuration *i-j*.

b) Observed values in tetrahydrofuran.

In the case of 3-nitropyrrole the caluclated transition energies are in good agreement with the observed values. The calculated 5.252 eV transition has the character of the so-called intramolecular charge-transfer transition associated with electron migration from pyrrole group to nitro-group. The 4.658 eV and the 4.962 eV transitions are the transitions contributed from charge transfer configurations and back charge-transfer configurations. The 6.136 eV band is the local transition in pyrrole ring. In line with this theoretical interpretation, the corresponding observed band showed no appreciable solvent shift.

In conclusion we found that the variable integrals method II is useful for the systems treated in this paper.

The calculation was carried out on a HITAC 5020 E computer at the Computer Centre of the University of Tokyo.

Electronic Spectra and Structures of Organic π-Systems. V. SCFMO Calculations of Some Fulvenes and Fulvalenes with the Variable Integrals Methods[1)]

Zen-ichi YOSHIDA and Tsunetoshi KOBAYASHI*

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University

(Received February 8, 1971)

The electronic states of fulvene, 6-vinylfulvene, 6-aminofulvene, 6,6-dialkoxyfulvene, 6-amino-6-alkoxyfulvene, heptafulvene, 8-vinylheptafulvene, sesquifulvalene, and fulvalene have been investigated with the variable integrals methods. The effect of bond alternation is taken into account in the SCF procedure. Agreement between the calculated and observed transition energies is satisfactory.

The variable integrals methods I and II[2)] are applied to fulvene, 6-vinylfulvene, 6-aminofulvene, 6,6-dialkoxyfulvene, 6-amino-6-alkoxyfulvene, heptafulvene, 8-vinylheptafulvene, sesquifulvalene, and fulvalene in order to check the applicability of these methods. The effect of bond alternation is taken into consideration in the SCF procedure. Agreement between the calculated transition energies and the observed ones is satisfactory.

Methods of Calculation

Methods I and II (VI/2/only NNβ) were described in the previous papers.[2)]

In order to introduce the effect of bond alternations, the bond lengths between two adjacent atoms are re-evaluated by the following formulas in each iteration step of the SCF procedures.

$$\text{VI/1} \qquad l_{CC} = 1.515 - 0.177\,P \qquad (1)$$

$$l_{CO} = 1.367 - 0.177\,P \qquad (2)$$

$$l_{CN} = 1.453 - 0.177\,P \qquad (3)$$

$$\text{VI/2} \qquad l_{CC} = 1.515 - 0.177\,P \qquad (4)$$

$$l_{CO} = 1.371 - 0.177\,P \qquad (5)$$

$$l_{CN} = 1.454 - 0.177\,P \qquad (6)$$

Formulas (1)—(6) are obtained on the assumption that bond lengths depend linearly on bond orders. The coefficients of formuals (1) and (4) are obtained using ethylene and benzene as reference standards. Formulas (2) and (5) are obtained with formaldehyde as the standard, and (3) and (6) with pyridine. The difference between double bond length and single bond length of sp^2-hybridized atom is assumed to be equal to that of sp^2-hybridized carbon atom, *viz.*, 0.177 Å.

For the sake of simplicity the variable parameters are reevaluated only in the first five iteration steps of SCF procedures.

In order to check the applicability of formulas (1)—(6), the above methods have been applied also to *trans*-butadiene, *trans*-acrolein, *p*-dimethoxybenzene, benzoic acid, and acetanilide.

For the sake of brevity the numberings of the atomic orbitals in the molecules are given in Fig. 1. The

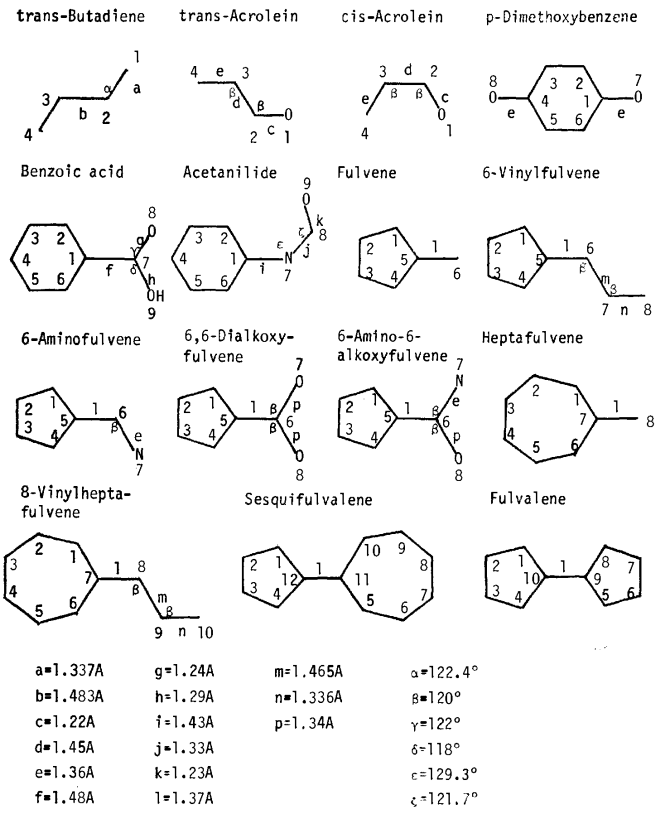

Fig. 1. Assumed structures and numbering systems of molecules.

starting molecular dimensions[3)] are assumed as in Fig. 1, the five-, six-, and seven-membered rings being taken to be regular polygons, the C–C bond lengths of pentagons and heptagons to be 1.40 Å and the C–C bond lengths of benzene rings 1.397 Å.

All the singly excited configurations are taken into account in the configuration interactions.

Results and Discussion

The π-electron densities are given in Table 1, and π-bond orders and the calculated final bond lengths in Table 2 together with the observed bond lengths.[3] The bond lengths of 6,6-dimethylfulvene observed by Norman and Post[4] are also shown in the column for fulvene in Table 2. The calculated $^1\pi^*$–$^1\pi$ electronic transition energies are given in Table 3.

trans-*Butadiene*, *Acrolein*, p-*Dimethoxybenzene*, *Benzoic Acid, and Acetanilide.* Agreement between the finally used bond lengths and the observed ones, and that between the finally calculated bond lengths and the observed ones is good, as shown in Table 2. On the whole both methods give similar γ_{pq}-values and β_{pq}-values in these systems, and similar π-electron

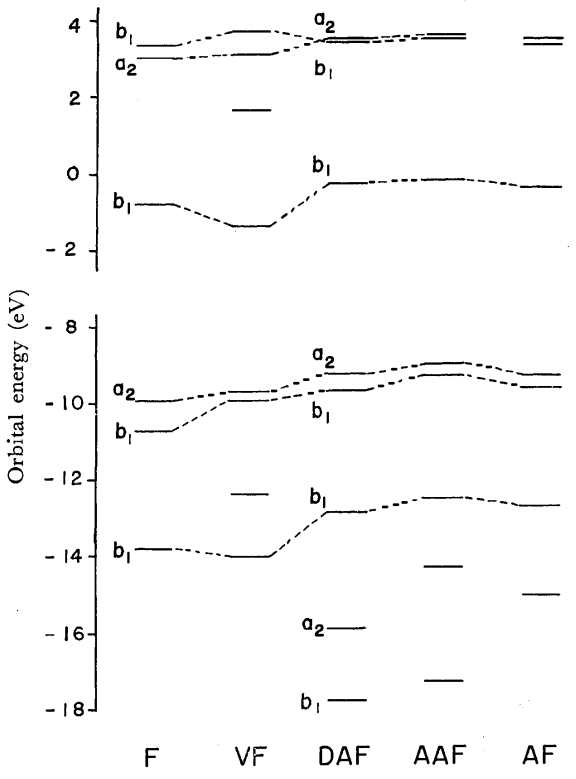

Fig. 2. Correlation diagram for fulvene derivatives with the variable integrals method I.
(F: Fulvene; VF: 6-Vinylfulvene; DAF: 6,6-Dialkoxyfulvene; AAF: 6-Amino-6-alkoxyfulvene; AF: 6-Aminofulvene.)

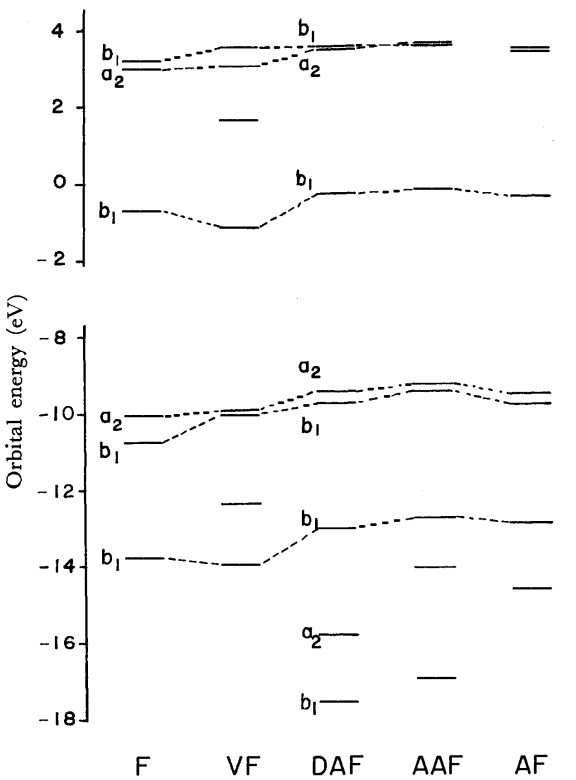

Fig. 3. Correlation diagram for fulvene derivatives with the variable integrals method II.
(F: Fulvene; VF: 6-Vinylfulvene; DAF: 6,6-Dialkoxyfulvene; AAF: 6-Amino-6-alkoxyfulvene; AF: 6-Aminofulvene.)

densities and bond orders (Tables 1 and 2). Agreement between the calculated transition energies by both methods and the observed ones is excellent (Table 3). These results suggest that formulas (1)—(6) can be safely used.

Fulvenes and Fulvalenes. The final parameters or the Coulomb repulsion integrals, γ_{pq}'s, bond lengths, l_{pq}'s, and core resonance integrals, β_{pq}'s, used by both methods are similar to each other except for some cases. In the case of fulvene the finally used bond lengths are in good agreement with the observed bond lengths of 6,6-dimethylfulvene.

The SCF eigenvalues and the eigenvectors given by both methods resemble each other on the whole. The molecular orbitals for fulvene and its derivatives may be approximately correlated as shown in Figs. 2 and 3 for the VI/1 and VI/2 methods, respectively. The correlation diagrams given by the two methods are alike. The lowest occupied orbital of 6-aminofulvene and the two lowest occupied orbitals of 6,6-dialkoxyfulvene or 6-amino-6-alkoxyfulvene are mainly localized on the 6-substituents.

The π-charge densities calculated by both methods are similar to each other (Table 1). The π-bond orders and bond lengths calculated by both methods also resemble each other on the whole (Table 2). The calculated bond lengths of fulvene are in adequate agreement with the bond lengths for 6,6-dimethylfulvene observed by Norman and Post[4] by X-ray crystallographic examination. Both methods reproduce well the bond alternation in the five-membered ring of fulvene. From the table, it is anticipated that slight bond alternations may be present in the five-membered and seven-membered rings of these systems as in fulvene.

The dipolemoment of fulvene calculated by the VI/1 method is 1.231 D and that by the VI/2 method 1.084 D. These values are in good agreement with the observed value (1.1 D) by Thiec and Wiemann[10] in benzene solution. On the other hand the dipolemoment observed by Brown and coworkers[17] by the microwave method is 0.44 D.

The observed transitions are tentatively assigned as in Table 3. Agreement between the calculated transition energies and the observed ones is satisfactory on the whole. The longest wavelength transitions in fulvene, 6-vinylfulvene, 6-aminofulvene, 6,6-diethoxyfulvene and 6-amino-6-ethoxyfulvene are clearly the intramolecular charge-transfer transitions caused by electron transfer from the five-membered rings to the branches.

In conclusion the variable integrals methods I and II are applicable also to these systems.

The calculation was carried out on a HITAC 5020E computer at the Computer Centre of the University of Tokyo.

An MO-Theoretical Study of the Decomposition of Hydroperoxides by Sulfonium Compounds and Some Nucleophiles

Katsutoshi OHKUBO and Hirokazu KANAEDA

Department of Synthetic Chemistry, Kumamoto University, Kurokami-machi, Kumamoto

(Received March 3, 1971)

The decomposition reactions of hydroperoxides (ROOH) by sulfonium compounds or some nucleophiles (sulfides, phosphites, and transition metal ions) were treated by the extended Hückel method, augmented by the use of *d*-orbitals. We obtained serveral findings. First, ROOH was more reactive to nucleophiles and was energetically more stable than $(ROOH)_2$. Second, the order of the ability for the ROOH decomposition, sulfonium compounds $\gg$ sulfides $>$ phosphites $\geq$ thiophene, was in good agreement with that of the AO populations of the nonbonding lone pair orbitals of the above compounds. Third, the distinguished ability of the sulfonium compound may be attributed to the contribution of the partially-occupied sulfur *d*-orbitals, in particular, the lowest unoccupied d_{z^2}-orbital; in the ROOH decomposition, these orbitals interact with the lowest unoccupied antibonding $p\sigma$-orbital of the O-O in ROOH at the O_β atom in the direction of the O-O axis. Finally, it was concluded that the sulfur *d*-orbitals contribute to the long-range interaction ($S\text{-}O_\beta > 3.0$ Å) between ROOH and sulfonium compounds.

The thermal[1] and catalytic[2] decompositions of hydroperoxides have been widely investigated by taking notice of the decomposition mechanism. Some chemical properties of hydroperoxides have thus been unveiled such as the kinds of homolytic or heterolytic decomposition products,[1-3] the bond-dissociation energies of the oxygen-oxygen bond[4,5] (including those of alkoxyl radicals[6]), and the association of hydroperoxides.[7,8] On the other hand, some theoretical studies of the electronic structures of hydroperoxides can be found in Refs. 9, 10, and 11, and more recently in Ref. 12. These studies suggest that most hydroperoxides possess the lowest unoccupied antibonding $p\sigma$-type-orbital of the O–O bond and that the bond can easily be cloven by nucleophiles such as low-valent metal ions,[13,14] sulfides[15] and phosphites.[16]

In our previous paper,[17] which referred to the remarkable ability of sulfonium compounds in the catalytic decomposition of hydroperoxides, a presumption was made that the partially occupied d_{z2} and/or d_{xz} (or d_{yz}) orbitals[18,19] play an important role in the scission of the O–O bond as follows:

$$ROOH + R'_3SCl \rightarrow \left[\begin{array}{c} \overset{\alpha}{O}\text{—}\overset{H}{O}\cdots SR'_3\cdots Cl \\ R \qquad \beta \end{array} \right] \rightarrow RO\cdot + \cdot OH + R'_3SCl$$

(R, R' = alkyl or aryl)

The electron transferred from the sulfonium part to the O–O bond through the sulfur *d*-orbitals increases the antibonding character of the O–O bond and promote the scission.

The present study intends to elucidate the role of the *d*-orbitals of sulfonium compounds in the catalytic decomposition of hydroperoxides, comparing their role with those of the nonbonding lone pair orbitals of sulfides and phosphites.

Methods of Calculation

Four systems were investigated in this work: (a) hydroperoxides, ROOH (R=H, CH_3, C_2H_5, *n*-C_3H_7, *n*-C_4H_9, *t*-C_4H_9, and $C_6H_5C(CH_3)_2$), (b) dimeric hydroperoxides $(ROOH)_2$ (R=H, CH_3, and *t*-C_4H_9), (c) trimethylsulfonium chloride ($(CH_3)_3SCl$) and some nucleophiles ($(CH_3)_2S$, $(C_6H_5)_2S$, $(CH_3O)_3P$, and $(C_2H_5O)_3P$, and (d) the interaction of CH_3OOH with $(CH_3)_3SCl$, $(CH_3)_2S$ or $(CH_3O)_3P$. In the case of (d), CH_3OOH was used for the simplicity of computation.

The orbital exponents and the Coulomb integrals ($H_{\mu\mu}$) were supplied by Clementi[20] and Jaffé[21,22] respectively. Especially, the $H_{\mu\mu}$ values of the oxygen

$2p$-orbital and the sulfur $3d$-orbital were taken to be -13.61 eV and -7.00 eV[23] respectively. The resonance integrals ($H_{\mu\nu}$) were evaluated by the Wolfsberg-Helmholtz approximation[24]:

$$H_{\mu\nu} = 0.875(H_{\mu\mu}+H_{\nu\nu})S_{\mu\nu}$$

where $S_{\mu\nu}$ is the overlap integral between AO's.

The orbital contour diagrams were calculated by the use of Slater's AO functions.[26]

Experimental

The decomposition reaction of cumene hydroperoxide was carried out in the following way: cumene hydroperoxide (22.5 mmol) in cumene (50 ml) was vigorously stirred in the presence of sulfonium chloride or a nucleophile (a sulfide, a phosphite, or a transition metal salt), mainly at 80°C for 4.0 hr. Then, the reaction mixture was pipetted out and submitted to analyses of the decomposition products, acetophenone (AP), dicumyl peroxide (DCP), α-cumyl alcohol (CA), and the residual cumene hydroperoxide (CHP). The analytical treatment was carried out in accordance with the method mentioned previously.[17]

Results and Discussion

Electronic Structures of Hydroperoxides. Before discussing the interaction between hydroperoxides (ROOH) and sulfonium compounds (R'_3SCl), the electronic structures of the former should be reviewed. ROOH is characterized by its lowest unoccupied (LU) antibonding $p\sigma$-type O–O bond. Considering that the atom population of the O_β in $RO_\alpha O_\beta H$ is larger than that of the O_α, as is indicated in Fig. 1, such nucleophiles as sulfides and phosphites will interact with ROOH from the O_β side in the direction of the O–O axis.[12] In the case of sulfonium compounds, the interaction will occur between the d-orbitals of the central sulfur and the O–O $p\sigma$-orbital in the same way mentioned above, perhaps because substituents of the sulfonium compound (named R′) sterically hinder the approach of the compound from the O_α side.[17] The characteristic nature of the O–O bond in ROOH is reflected in the orbital contour diagrams for the LU MO of ROOH (R=CH_3) (see Fig. 2).

It is of interest here to discuss which structure of ROOH, monomer or dimer, is energetically more plausible. The total energies listed in Table 1 demonstrated that the ROOH monomer is preferable for the structure of ROOH, especially at low concentrations of the hydroperoxide. In regard to the reactivity of ROOH to nucleophilic reagents, the partial AO bond population of the O–O in the LU MO ($1/2N^{LU}_{p\sigma}$) can be utilized as a reactivity index since the O–O bond is mainly conposed of the $p\sigma$-orbital of the O–O (see Table 1). The value of $1/2N^{LU}_{p\sigma}$ in Table 1 suggests that ROOH is more reactive than $(ROOH)_2$. On the basis of the above discussions, the

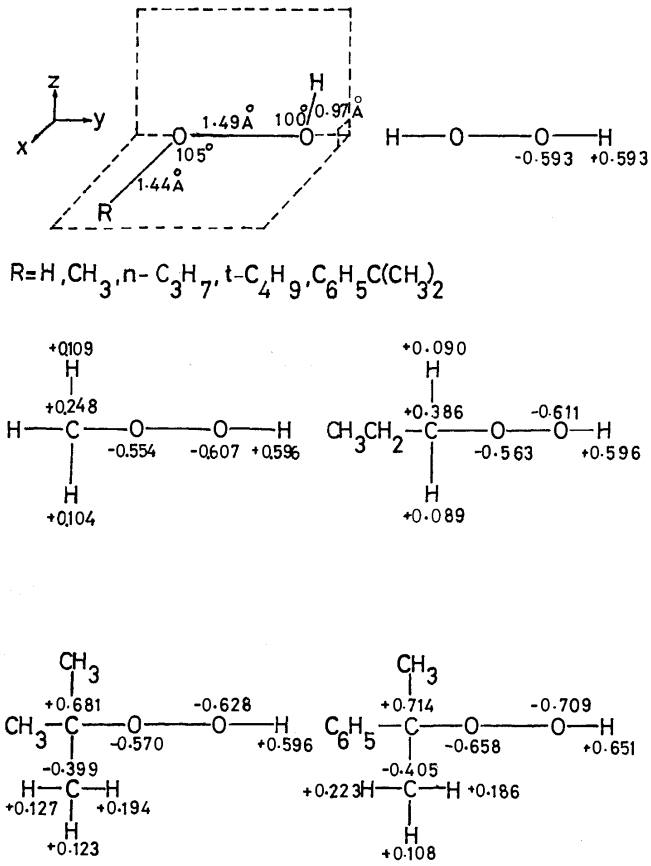

Fig. 1. Atomic charges of some hydroperoxides.

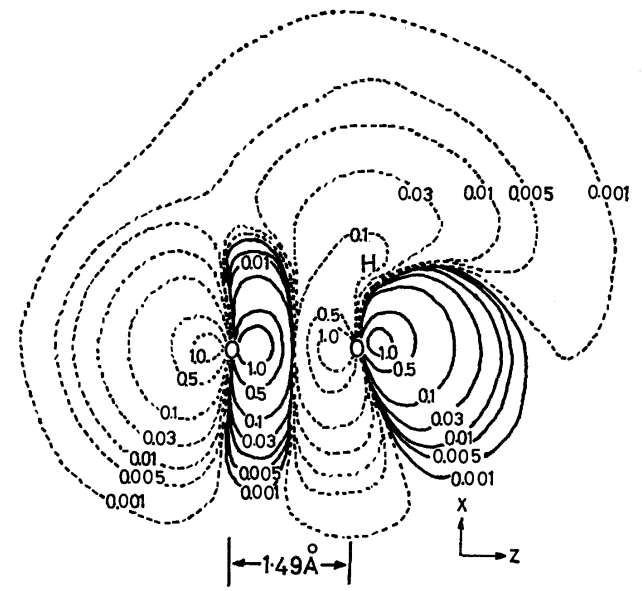

Fig. 2. Orbital contour of CH_3OOH in the LU MO. (the solid and broken lines stand for the positive and negative MO signs, respectively.)

monomer structure of ROOH seems to be the more plausible structure from the standpoints of both the energetic stability and the reactivity to nucleophiles.

Decomposition of Cumene Hydroperoxide by Sulfonium Compounds and Some Nucleophiles. It is of interest also to discuss the abilities of sulfonium compounds and some nucleophiles with regard to the decom-

position of ROOH. Table 2 lists the experimental data obtained from the decomposition reaction of cumene hydroperoxide. Except for transition metal ions, the order of the ability with regard to the ROOH decomposition (estimated from the amount of the hydroperoxide decomposed) was as follows: triphenylsulfonium chloride ≫ diphenylsulfide > triphenylphosphite > trimethylphosphite > triethylphosphite ≃ thiophene. Considering that the ability would be reflected in the AO population of the nonbonding orbital (N_{nbo}) of the central sulfur or phosphorus, in particular, that in the highest occupied (HO) MO ($1/2N_{nbo}^{HO}$), the order of the values of N_{nbo} or $1/2N_{nbo}^{HO}$ listed in Table 3 is in agreement with that of the ability mentioned above. In sulfonium chloride and thiophene, the contribution of the partially-occupied sulfur d-orbitals to the ROOH decomposition should be taken into consideration (this will be discussed, in detail in the later part of this paper).

In regard to the catalytic decomposition of ROOH by the low-valent transition metal ions, the order of the

Values in parentheses stand for the AO populations of the sulfur d_{z^2} orbtal.

ability with regard to the ROOH decomposition: Co(II)>Ni(II)>Fe(II), can be well explained by its parallelism with the energy required for the electron-releasing from the *d*-orbitals of the transition-metal ion to the O–O $p\sigma$-orbital: Co(II) (7.84 eV)[26]>Ni(II) (9.24 eV)[26]>Re(II) (11.00 eV).[27]

The Interaction between ROOH and the Sulfonium Compound or Some Nucleophiles. First, it is necessary to mention the electronic structure of the sulfonium compound. The ASMO SCF calculations on $(CH_3)_3SCl$[28] supported the planar C_{3v} symmetrical sulfonium cation and suggested a suitable location of the counter chloride (S–Cl=3.5 Å) from the energetic point of view. As has already been mentioned, the sulfonium chloride is characterized by its partially-occupied sulfur *d*-orbitals (see Fig. 3), and the remarkable ability of the compound with regard to the ROOH decomposition as compared with those of sulfides or phosphites

Table 4. Changes in the N_{nbo} of $(CH_3)_3SCl$ and some nucleophiles and the M_{OO} of CH_3OOH due to the interaction

Compound	N_{nbo}	M_{OO}
$(CH_3)_2S$	1.993	
$(CH_3O)P$	1.298	0.361
$(CH_3)_3SCl$	1.981	
	(d_{z^2}=0.068)	
	(d_{xz}=0.142)	
$(CH_3)_2S$[a]	0.622	0.329
$(CH_3O)_3P$[a]	1.129	0.350
$(CH_3)_3SCl$[b]	1.955	
in Type I	(d_{z^2}=0.052)	0.249
$(CH_3)_3SCl$[b]	1.501	
in Type II	(d_{xz}=0.061)	0.266

a) The distance between the O_β in $CH_3O_\alpha O_\beta H$ and the S in $(CH_3)_2S$ (or the P in $(CH_3O)_3P$) was 2.0 Å.
b) The distance between the O_β and the central S was 3.0 Å.

is the result of the contribution of this sulfur *d*-orbitals (especially, the d_{z^2}-orbital) to the interaction with the LU antibonding O–O $p\sigma$-orbital in ROOH. This is consistent with the change in the values of N_{nbo} and the bond population of the O–O (M_{OO}) recorded in Table 4, where two distinct modes of interaction between CH_3OOH and $(CH_3)_3SCl$, *i.e.*, Type I and Type II, are taken into consideration (see Fig. 4); in Type I, the interaction mainly occurs between the sulfur d_{z^2}-orbital of the former and the O–O $p\sigma$-orbital of the latter, while in Type II, the sulfur d_{xz}-orbital interacts predominantly with the $p\sigma$-orbital. In view of the smaller value of M_{OO} in Type I at S–O_β=3.0 Å as compared with that of M_{OO} in Type II, the stronger interaction can be expected by Type I. This long-range interaction between CH_3OOH and $(CH_3)_3SCl$ supports the role of the sulfur *d*-orbital in the catalytic decomposition of hydroperoxides, as can be seen from Fig. 5.

The major portions of the present calculations were carried out on a FACOM 230.60 computer at the Computer Center at Kyushu University while a part of them were done at Kyoto University.

The Adsorption of Polyvinylpyrrolidone at the Mercury/Solution Interface

Tadashi YOSHIDA, Tetsuya OHSAKA, and Shoji TANAKA

Applied Electrochemical Laboratory, Graduate School of Science and Engineering, Waseda University, Nishi-Okubo, Shinjuku-ku, Tokyo

(Received March 13, 1971)

The adsorption of polyvinylpyrrolidone (PVP), known as a water-soluble polymer, at the electrolyte/DME interface was examined by observing the differential capacity *vs.* the time relation, under conditions where the adsorption process was mainly controlled by diffusion. In the case of a relatively low bulk concentration and a short adsorption time, the adsorption rate of PVP at −500 mV(SCE) was controlled almost wholly by the diffusion of the adsorbate to the DME. The relation between the time required to attain the saturated adsorption and the bulk concentration was explained approximately by the Koryta equation, based on the linear diffusion. PVP showed no tendency to form multi-layers within the range of bulk concentrations and adsorption times observed. The maximum surface concentration of PVP decreased almost linearly with the increase in its mean molecular weight. The number of constitutive segments adsorbed per unit of area to form a monolayer at the interface was almost constant, independent of the mean molecular weight. The activation energy for the diffusion was found to be *ca.* 4.7 kcal/mol. On the basis of the results obtained, the configuration of PVP adsorbed at the interface was discussed.

Many water-soluble organic polymers are adsorbed strongly at the interface, and it takes some time to attain an adsorption equilibrium when the adsorption rate is mainly diffusion-controlled in a relatively dilute solution.[1-3]

Polyvinylpyrrolidone (PVP),[4] prepared first by Reppe, has characteristic properties of a good solubility, a strong adsorbability, protective colloid action, *etc.*[5] Some papers[6] on the properties of PVP in an aqueous solution have been published, and Jehring[2] computed the maximum surface concentration (Γ_m) of PVP dissolved in a potassium chloride solution by means of AC polarography. In the present paper, the adsorption of PVP will be investigated by observing the differential capacity in detail for the purposes of examining the diffusion behaviour of PVP in solution and discussing its configuration when adsorbed at the interface.

Experimental

Electrodes and Test Cell. The dropping mercury electrode (DME) was used, and the flow rate (m) and drop time (t_d) of DME were as follows: $m=1.10—1.60\times10^{-4}$ g/sec, $t_d=ca.$ 30 sec/drop. The counter electrode was a cylindrical platinum net with a sufficiently large surface. The electrode potential was referred to the saturated calomel electrode (SCE). The test cell and all parts of the mercury dropping equipment with a capillary, made of Pyrex glass except for the capillary, were connected tightly with ground glass joints without rubber stoppers, and the opening of capillary, prepared from a Molybdenum glass tube, was treated suitably with a tungsten carbide cutter.

Materials. Mercury was distilled twice *in vacuo* after having been treated in the usual way. Four kinds of chemical-grade PVP prepared by BASF were used without further purification; their mean molecular weights ($\bar{M}$) were 10000, 26000, 37000, and 750000 respectively. All the solutions were prepared from guaranteed or purified reagents and triply-distilled water.

Differential-capacity Measurements. A precise impedance bridge of the transformer-connection type, equipped with a cathode-ray oscilloscope detector, was employed. The bridge was fed from the CR-type oscillator, where the sinusoidal wave of 1 kHz was adjusted by an attenuator so as to take an input voltage of *ca.* 10 mV_{p-p}. A cylindrical platinum net, installed around a mercury drop, served as a counter electrode for the DC potentiostatic polarization of the test electrode and for the impedance measurements. On the assumption of a series-equivalent circuit of resistance and capacitance, the differential capacity at the mercury/solution interface was determined synchronously with a certain balance time from the beginning of drop growth. The measurements were conducted in an atmosphere of purified nitrogen.

Theoretical

Adsorption Behavior in the Diffusion-controlled Process. On the assumption of an adsorption process controlled simply by semi-infinite linear diffusion, the surface concentration (Γ_t) of adsorbates on a mercury drop at a certain growth time, t, can be given by the well-known Koryta equation (1),[7] derived from the Ilković formula:

$$\Gamma_t = 0.736 D^{1/2} a t^{1/2} \quad (1)$$

where Γ_t is expressed in mol/cm², and t, in sec, and where D and a are the diffusion coefficient of adsorbates in cm²/sec and its bulk concentration in mol/cm³

respectively. According to Frumkin,[8] the relation between the differential capacity and the surface coverage (θ) is written as follows:

$$C = C_{\theta=1}\theta + C_{\theta=0}(1-\theta) \quad (2)$$

where $C_{\theta=1}$ and $C_{\theta=0}$ are the differential capacities per unit of area at $\theta=1$ and $\theta=0$ respectively. Assuming $\theta=\Gamma_t/\Gamma_m$, we obtain from Eqs. (1) and (2):

$$C = C_{\theta=0} - K a t^{1/2} \quad \text{for } t<t_m \quad (3)$$

where $K=0.736(C_{\theta=0}-C_{\theta=1})D^{1/2}\Gamma_m{}^{-1}$

Γ_m and t_m are the maximum surface concentration of the adsorbates and the time required to attain the saturated adsorption respectively. Equation (3) holds only in the case of $t<t_m$ where the adsorption is diffusion-controlled. On the other hand, in the case of $t\gg t_m$, where the adsorption equilibrium is always attainable and where $\theta=1$:

$$C = C_{\theta=1} \quad \text{for } t\gg t_m \quad (4)$$

It is shown by Eq. (3) that, if t is kept constant, C changes linearly with a, while if a is constant, C varies linearly with $t^{1/2}$. Γ_m can be computed from the experimental data by means of Eq. (3) if the value of D is given. At 25°C, the surface area A_t (cm^2) of a mercury drop at its growth time, t, is given by the mercury flow rate, m, as:

$$A_t = 0.85m^{2/3}t^{2/3} \quad (5)$$

Therefore, the observed differential capacity, C_E (μF), is written as follows from Eqs. (3), (4), and (5):

$$C_E = CA_t = 0.85C_{\theta=0}m^{2/3}t^{2/3} - 0.85Km^{2/3}a\,t^{7/6} \quad \text{for } t<t_m \quad (6)$$

$$C_E = C_{\theta=1}A_t = 0.85C_{\theta=1}m^{2/3}t^{2/3} \quad \text{for } t\gg t_m \quad (7)$$

Application of Koutecký-type Equation.[9] The deviation from the Koryta equation can be explained by the Koutecký equation, in which Γ_t is given by Eq. (8), including the supplementary term based on the spherical diffusion:

$$\Gamma_t = 0.736D^{1/2}a\,t^{1/2}(1+3.47D^{1/2}m^{-1/3}t^{1/6}) \quad (8)$$

The (9) and (4)′ relations are obtained from Eq. (8) instead of from the (3) and (4) formulae:

when $t<t_m$, $C = C_{\theta=0} - K a t^{1/2}(1+3.47D^{1/2}m^{-1/3}t^{1/6})$ (9)

if $t\gg t_m$, $C = C_{\theta=1}$ (4)′

Results

Differential-capacity vs. Potential Curves. Figure 1 shows the differential capacity *vs.* potential curves in 1 N sulfuric acid solutions containing PVP ($\bar{M}=10000$) of various concentrations under a fixed balance time, t_B. Relations similar to those in Fig. 1 can be obtained with various t_B values under a fixed value of a instead of t_B. In Fig. 1, the peak due to the ad- or desorption of PVP is found at a noble potential of *ca.* 75 mV(SCE), whereas no peak is given at the less noble side within the potential range observed, and the differential capacity decreases

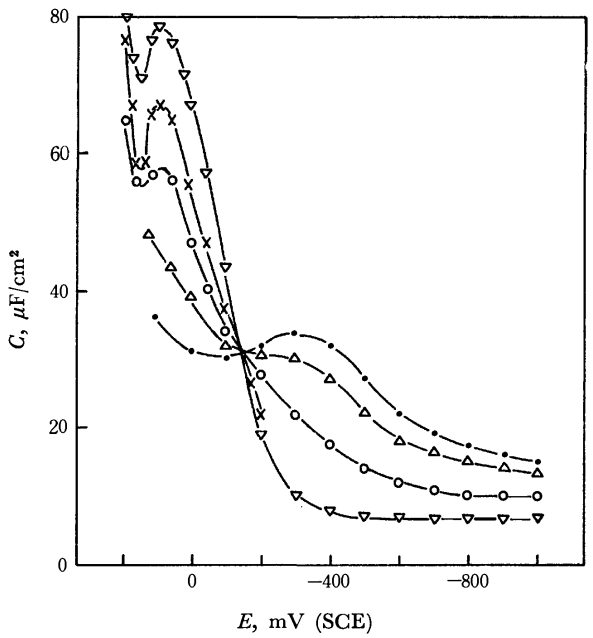

Fig. 1. Differential capacity *vs.* potential curves.
30.0°C, t_B (balance time)=15 sec, 1 N sulfuric acid+PVP ($\bar{M}=10000$); (—·—: PVP 0 mg/*l*, —△—: 5 mg/*l*, —○—: 10 mg/*l*, —×—: 20 mg/*l*, —▽—: 50 mg/*l*)

on the less noble side, while it increases in the peak potential region with an increasing a (or t_B value). The dependence of the capacity on t_B may be understood in terms of the diffusion-controlled adsorption, where the adsorbed PVP increases with the time. Furthermore, it is found that the minimum differential capacity, (C_{min}), due to the adsorption equilibrium or saturation is nearly constant independent of the value of a or t_B within the less noble potential range, while the peak potential is practically independent of the value of a or t_B.

Adsorption attains to its equilibrium or saturation at *ca.* −500 mV(SCE) near the zero-charge potential of mercury upon a reasonable increase in a (or t_B), as may be seen in Fig. 1. Therefore, the interfacial behaviour of PVP will be discussed in most cases at −500 mV(SCE), where the saturated absorption is always attained.

Observed Capacity vs. Time Curves. Figure 2 shows examples of C_E-t curves at −500 mV(SCE) in 1 N sulfuric acid solutions with various values of the concentration of PVP ($\bar{M}=750000$).

In Fig. 2, the C_E for the saturated adsorption with PVP or for the blank solution may be seen to increase with $t^{2/3}$ or A_t [*cf.* Eq. (5) or (7)]. In the diffusion-controlled process [*cf.* Eq. (6)], C_E-t curves are depressed with a, and each curve has a tendency to coincide with the saturated adsorption curve. Diagrams analogous to Fig. 2 were always obtained with PVP's of various $\bar{M}$ values, where for instance, the depression of C_E by the PVP of $\bar{M}=10000$ was about three times that by the PVP of $\bar{M}=750000$ under given a and t_B values.

Oscillograms Observed with a PVP Solution. The oscillograms obtained by the impedance bridge are

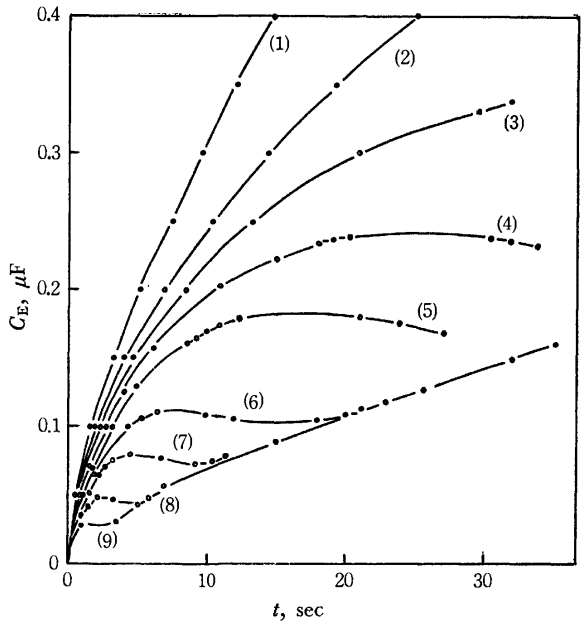

Fig. 2. Observed differential capacity *vs.* time curves.
Observed at −500 mV (SCE), 20.5°C, 1 N sulfuric acid (1) 1 N sulfuric acid+PVP ($\bar{M}$=750000), (2) PVP 15 mg/*l*, (3) 30 mg/*l*, (4) 40 mg/*l*, (5) 50 mg/*l*, (6) 75 mg/*l*, (7) 100 mg/*l*, (8) 150 mg/*l*, (9) 200 mg/*l*

of a simple X type in the case of a blank solution, while they reveal distorted figures in the presence of PVP. Typical cases are shown in Photo. 1 and Fig. 3, where remarkable distortions of figures are revealed in the transient course from the diffusion-controlled process to the saturated adsorption. The oscillograms in Photo. 1 were obtained in a 1 N sodium sulfate solution containing 25 mg/*l* PVP. A figure corresponding to Photo. 1 is shown in Fig. 3, where the three values of the bridge capacitance adjusted

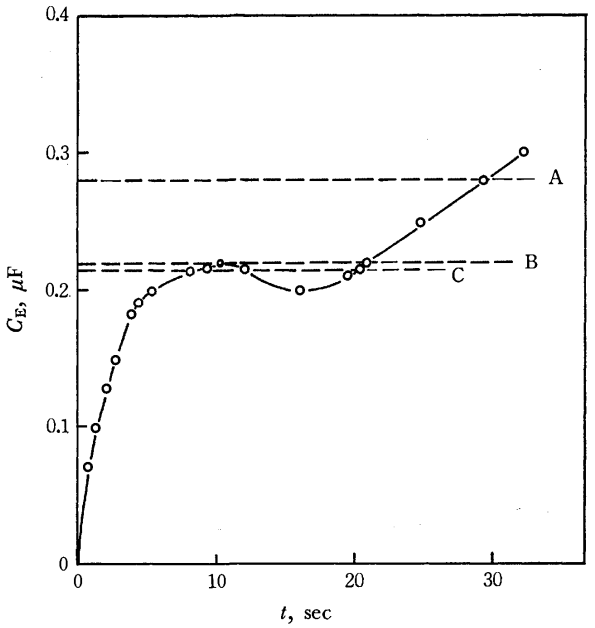

Fig. 3. Observed differential capacity *vs.* time curve connected with Photo. 1.
Observed at −500 mV (SCE), 20.5°C, 1 N sodium sulfate +PVP ($\bar{M}$=10000) 25 mg/*l*, adjusted capacitance; (A: 0.280 μF, B: 0.220 μF, C: 0.215 μF)

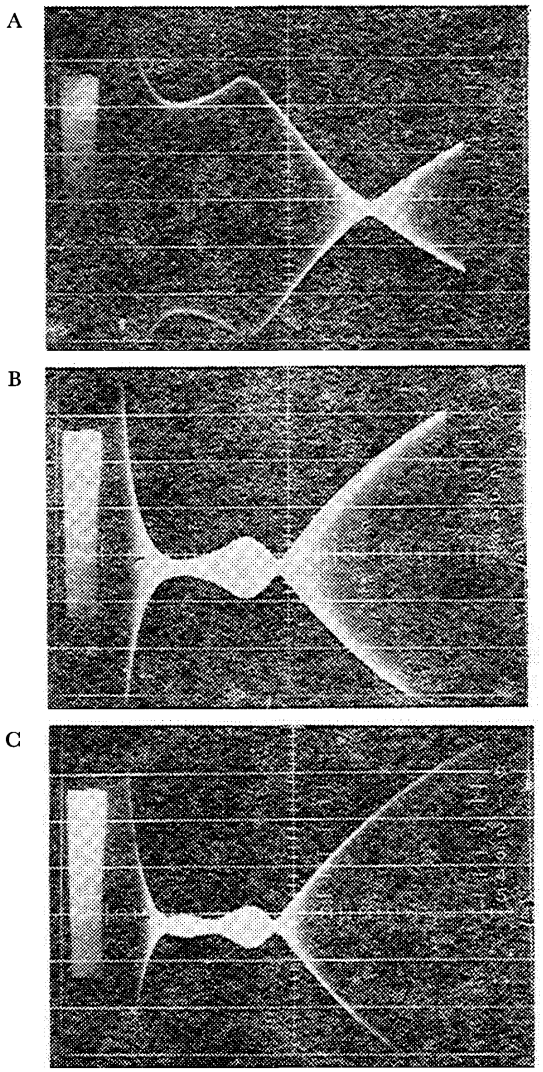

Photo. 1. Oscillograms for the bridge balance.

are given by dashed lines. Figure 3, showing 1 N sodium sulfate solution, is similar to Fig. 2, showing 1 N sulfuric acid solution. In the case of "C" in Photo. 1, three balance times (t_B) are given, as to be expected from the three points of intersection in the order. It may be considered that the first two balance times are attributable to the diffusion-controlled processes, whereas the last one is due to the saturated adsorption. Similarly, the first and second t_B values for the "B" case in Photo. 1 or Fig. 3 may be due to the diffusion-controlled process and to the saturated adsorption respectively. Next, the balance time related to the "A" case in Photo. 1 or Fig. 3 may be due to the saturated adsorption, while the preceding distortion of the oscillogram is to be expected from the shape of the C_E-t curve in Fig. 3. A figure similar to that in Photo. 1 can be obtained from such data as are shown in Fig. 3 on the assumption that the input admittance due to the unbalanced bridge is approximately proportional to the voltage found on the screen to the detector.

Temperature Dependence of C vs. t Curves. Figure

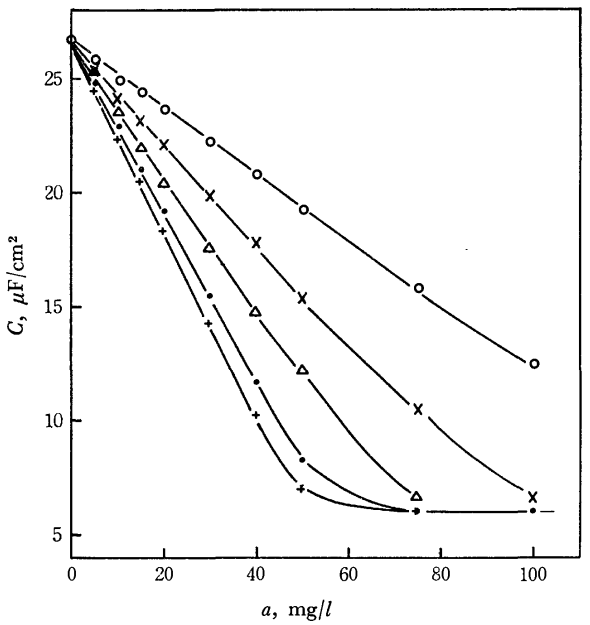

Fig. 6. Differential capacity *vs.* bulk concentration curves. Observed at −500 mV (SCE), 20.5°C, 1 N sulfuric acid+PVP ($\bar{M}$=750000); (—○—: t_B=4 sec, —×—: 9 sec, —△—: 16 sec, —·—: 25 sec, —+—: 30 sec)

4 shows the temperature dependence of the C_E-t curves observed in a 1 N sulfuric acid solution containing PVP ($\bar{M}$=10000) of 20 mg/*l*.

In Fig. 4, the difference between the two curves at 20 and 60°C is nearly negligible in the case of a blank solution. For the solution containing PVP, the time required to attain the saturated adsorption is about 25 sec at 20°C, and it decreases as the temperature rises. The saturated adsorption curves vary somewhat with the temperature, but the differences among them are so small that they are negligible within the temperature range from approximately 20 to 60°C.

Discussion

Application of the Koryta Equation. The variation in the differential capacity, C, with the drop-growth time, t, or with the bulk concentration, a, is expressed by Eq. (3) in the diffusion-controlled process, where $t<t_m$. As may be seen from Figs. 5 and 6 related to the PVP of $\bar{M}$=750000, C decreases linearly with $t^{1/2}$ or a, as to be expected from Eq. (3); it attains a constant value in each case at a certain values of t or a, as to be expected from Eq. (4). The constancy of C shows that the saturated adsorption is achieved. The more a or t_B increases, the steeper the slope of the curve becomes, as may be seen in Figs. 5 and 6. The curves in Figs. 5 and 6 always consist of two linear portions. It is possible to find the time t_m or the bulk concentration, a_m, necessary to attain Γ_m under a certain value of a or t_B from the intersection of these two lines.

It may be concluded that PVP is adsorbed to form the monolayer at the interface, since the minimum differential capacity (C_{min}) observed in the saturated adsorption range is approximately constant independent of a or t (the drop growth or balance time), as may be seen in Fig. 5 or 6.

Saturation Time related to Concentration. The Koryta equation (1) may be modified as follows:

$$\left.\begin{aligned} &\log t_m = -2\log a + K' \\ \text{or:}\quad &\\ &\log t = -2\log a_m + K' \end{aligned}\right\} \qquad (10)$$

where $K'=2\log[\Gamma_m/(0.736D^{1/2})]$

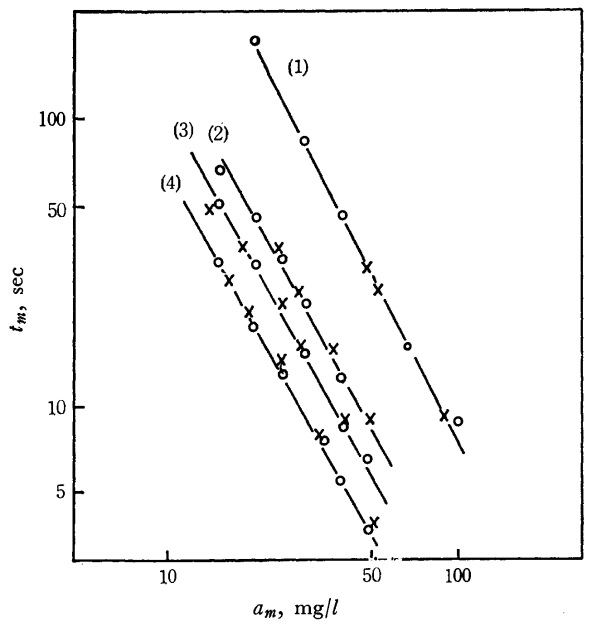

Fig. 7. Time required to attain the saturated adsorption *vs.* bulk concentration curves.
Observed at −500 mV (SCE), 20.5°C, 1 N sulfuric acid+PVP solutions, —o—: derived from C-$t^{1/2}$ curves, - × -: derived from C-a curves, (1): PVP: $\bar{M}$=750000, (2): 37000, (3): 26000, (4): 10000

In Fig. 7, typical plots of $\log t_m$ *vs.* $\log a$ and $\log a_m$ *vs.* $\log t$ are derived from Figs. 5 and 6 with four kinds of PVP. Each plot in Fig. 7 reveals an approximately straight line with a slope deviating by *ca.* −5% from the expected value of −2. Moreover, t_m at a certain definite value of a becomes longer with an increase in the mean molecular weight, as may be seen from Fig. 7; this tendency may result from the lowering of the diffusion coefficient due to the increase in $\bar{M}$.

Reexamination of the Use of the Koryta Equation. Typical C-$t^{1/2}$ and C-a plots based on the Koryta equation are shown in Figs. 5 and 6 with the PVP of $\bar{M}$=750000, the K value in Eq. (3) can be calculated from the slope of each curve. Γ_m can be obtained from the value of K if the diffusion coefficient is known. However, the value of K obtained from the curves in Fig. 5 or 6 shows a slight dependence on a or t_B, *i.e.*, the values of K obtained from the curves in Fig. 5 slightly decreases with an increase in a, while the value derived from the curves in Fig. 6 slightly rises with t_B. Therefore, Γ_m is computed by means of the mean value of K based on the values of the diffusion coefficient[10] as estimated by the Stokes-Einstein equation or experimentally obtained. The dependence of K on a or t_B may be attributable to the variation in the diffusion coefficient with the concentration, or to the effect of the supplementary term of the Koutecký type given in Eq. (9), which was deduced on the basis of the spherical diffusion under a constant Γ_m value, independent of a.

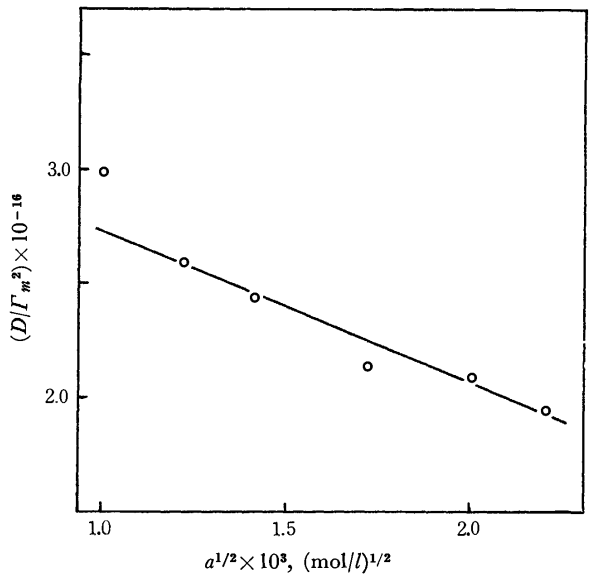

Fig. 8. Concentration dependence of diffusion coefficient for PVP.
Observed at −500 mV (SCE), 20.5°C, 1 N sulfuric acid+PVP ($\bar{M}$=10000) solutions

Friedman *et al.*[12] found a linear relation between the diffusion coefficient and the square root of the bulk concentration for some organic substances (*e.g.*, dextrose, sucrose). An example of the (D/Γ_m^2) *vs.* $a^{1/2}$ plot is shown in Fig. 8, where (D/Γ_m^2) has been calculated from the K derived from the slope of the (C *vs.* $t^{1/2}$) relation at a given a of PVP ($\bar{M}$=10000). As may be seen from Fig. 8, (D/Γ_m^2) shows an approximately linear dependence on the square root of the concentration of PVP. The linear relationship between (D/Γ_m^2) and $a^{1/2}$ in Fig. 8 suggests that the dependence of K on a is attributable to the variation in the diffusion coefficient with a to a certain extent.

A slight deviation of the (D/Γ_m^2)-$a^{1/2}$ relation from linearity may be expected on the basis of the Koutecký equation, in which the effect of the spherical diffusion is taken into consideration. In Eq. (9), the slope of C *vs.* a relation shows $-Kt^{1/2}(1+3.47D^{1/2}m^{-1/3}t^{1/6})$ instead of $-Kt^{1/2}$ in the Koryta Equation (1). The value of K obtained on the basis of the Koryta Equation (1) should be modified to $K(1+3.47D^{1/2}m^{-1/3}t^{1/6})$ in the case of the spherical diffusion, which may be expected to increase with the time. In fact, the value of K obtained from the C-a curve by means of the Koryta equation increases slightly with t_B as has previously been stated.[13]

In short, the variation in the K derived from the Koryta equation may be attributed to the concentration dependence of the diffusion coefficient or to the effect of the spherical diffusion. The deviation of

10) The values of the diffusion coefficient of PVP in the literature[6] as estimated by the Stokes-Einstein equation and as observed with the hanging mercury electrode,[11] are 10.3×10^{-7} cm²/sec for $\bar{M}$=10000, 7.3×10^{-7} for $\bar{M}$=26000, 5.1×10^{-7} for $\bar{M}$=37000, and 1.2×10^{-7} for $\bar{M}$=750000.

11) This Bulletin, to be published.

12) L. Friedman and P. G. Carpenter, *J. Amer. Chem. Soc.*, **61**, 1745 (1939).

13) In the case of $\bar{M}$=10000, for example, the K values derived from the Koryta equation were 1.98×10^9, 2.07×10^9, and 2.19×10^9 for t_B=4, 8, and 16 sec respectively.

the slope by *ca.* −5% from the expected value of −2 in Fig. 7 may be explained by the change in the diffusion coefficient or the effect of the spherical diffusion discussed above. It should be noted that the Koryta equation is approximately applicable to the present system within an error of 10%.

Temperature Dependence of the Diffusion Coefficient. The temperature dependence of the C_E-t relation is shown in Fig. 4 for the case with a 1 N sulfuric acid solution containing 20 mg/l of PVP ($\bar{M}$=10000), and a linear relation is obtained by plotting log [D_T/$D_{(273+20)}$] to T or $1/T$,[14] where the value of (D_T/$D_{(273+20)}$] is derived from the [(t_m at T°K)/(t_m at 273+20°K)] ratio with the Koryta equation at a given a on the assumption that Γ_m is constant independent of T under the present conditions. The temperature coefficient (α) of the diffusion coefficient and the activation energy (Q) of the diffusion are found to be about 0.025 and 4.7 kcal/mol respectively for the present case. The value of Q mentioned above may be reasonable for the diffusion process of PVP ($\bar{M}$=10000).

Configuration of PVP at the Interface. By plotting log Γ_m against log $\bar{M}$ for four kinds of PVP, we obtain an approximately linear relation with a slope of nearly −1, as shown in Fig. 9. From this linear relation, $\bar{M}\Gamma_m$=const. can be obtained; this means that $\bar{P}/S$ is constant, where $\bar{P}$ is the degree of polymerization or the number of segments, and S, the area of the electrode surface occupied by 1 mol of the adsorbed molecule, that is, $S=\Gamma_m^{-1}$. Consequently, it follows that the adsorbed number of the constitutive segment related to PVP at the interface is constant, independent of $\bar{M}$, and that the value of $\bar{P}$ per unit of area can be estimated from Fig. 9 to be *ca.* 4.0×10^{14} seg./cm^2.

The geometrical form of the dissolved PVP molecule in the bulk of the solution was assumed to be a randomly-coiled polymer chain or a revolving ellipsoid.[6] It seems, in the present case, that the geometrical form of PVP in the bulk of the solution may be close to a sphere consisting of a randomly-coiled chain, since the D of PVP, derived from the Stokes-Einstein relation assuming a spherical form, is approximately consistent with the value observed.[11]

Nevertheless, the spherical form of PVP assumed for the diffusion process cannot explain the fact that the minimum differential capacity observed for PVP differs little from that given by the common organic compound of a non-polymer or from that observed for *N*-vinyl-2-pyrrolidone,[14] which is a component monomer of PVP. Therefore, it may be assumed that the adsorbed PVP at the interface takes a configuration of a spread or flatten form of the chain instead of the spherical form. Moreover, consistent with the above conclusion, the adsorbed number of constitutive segments per unit of area is nearly constant, independent of the $\bar{M}$, as has been mentioned previously.

Monolayers of Poly(methyl acrylate) Saponified Partially in Homogeneous and Heterogeneous Systems

Seiichiro HIRONAKA* and Kenjiro MEGURO

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received April 14, 1971)

Poly(methyl acrylate) prepared by radical polymerization of methyl acrylate was saponified partially in acetone-water mixtures (5 : 2 and 100 : 1 by volume), using sodium hydroxide as the catalyst. Saponification in an acetone-water mixture of a 5 : 2 ratio by volume proceeded in a homogeneous state, but the reaction solution of a 100 :1 ratio by volume was in a white-turbid state, in which saponification proceeded in a heterogeneous state. The properties of the monolayers of polymers saponified in different states were studied at the air/water interface by measuring the surface pressure. The limiting areas obtained on distilled water for each polymer saponified in these two systems decreased linearly with an increase in the degree of saponification. However, the monolayers of polymer saponified in a homogeneous system were more stable on sodium chloride solution than those obtained in a heterogeneous system, and gave the limiting areas on solutions above 5% corresponding with the theoretical values calculated from the areas per methyl acrylate and acrylic acid residue and the degree of saponification. This can be explained by the fact that some of the hydrophilic parts of the saponified polymers submerged into the water phase were squeezed out onto the water surface by the salting out effect. On the other hand, those values obtained in a heterogeneous system neither corresponded to the theoretical values nor gave reproducible areas at high concentrations. These facts may be due to the differences in the states of the saponified polymers.

There have been many studies of the hydrolysis of polymers. In particular, a few studies concerned with the hydrolysis of polyacrylate have been reported. Loecker and Smets reported the hydrolysis of copolymers of methacrylic acid and methyl methacrylate in acid-buffered solution.[1] Sakurada *et al.* studied the saponification of poly(methyl acrylate) in binary mixtures of various compositions of water-acetone and reported the effects of solvent on the rate of saponification.[2]

However, studies of the hydrolysis of polymers from the two-dimensional point of view have been scare. Previously, we ourselves investigated the monolayer properties of partially-saponified poly *n*-butyl acrylate at the air/water interface.[3] The relationship between the surface properties and the degree of saponification was discussed.

In the present work, we partially saponified poly(methyl acrylate) with sodium hydroxide in mixtures of different compositions of water-acetone (in homogeneous and heterogeneous systems) and studied the properties of the monolayers of those polymers. The saponification reactions of polymer in homogeneous and heterogeneous systems will be discussed on the basis of the two-dimensional behavior of the polymer when the polymer was spread on water and sodium chloride solutions.

Experimental

Sample Polymers. Methyl acrylate was obtained from Toagosei Co., Ltd. The inhibitor was removed by washing it with 5% sodium hydroxide aqueous solution and distilled water. Methyl acrylate was then purified by distillation under reduced nitrogen atmosphere after having been dehydrated with silicon dioxide. Poly(methyl acrylate) was prepared by radical polymerization in benzene at 50°C under a flow of nitrogen gas, α,α'-azobisisobutyronitrile being used as the inhibitor. After the reaction, this benzene solution was added to a large excess of methanol and the polymer was obtained as precipitate. The polymer thus obtained was purified by repeated precipitation from its acetone solution into a large excess of methanol. The average molecular weight of this polymer was found to be about 659000 by the measurement of the viscosity.

Poly(methyl acrylate) was saponified in a transparent and homogeneous solution of an acetone-water mixture (5 : 2 by volume), with sodium hydroxide as the catalyst, at 50°C until sodium hydroxide was consumed.[3] Saponification in a heterogeneous system was carried out under the same conditions except that the mixture had a different composition of acetone-water (100 : 1 by volume) and except that the reaction solution was a white-turbid suspension of polymer. These saponified polymers for each system were obtained by changing the amount of sodium hydroxide. These polymers were purified by repeated precipitation from their acetone solution into water and methanol. Saponification was confirmed by studying the infrared spectra and by elementary analyses. The degrees of saponification (mol%) of these polymers were calculated by putting the analytical values of carbon as determined by the elementary analyses into Eq. (1), they are listed in Table 1.

$$\frac{c\left(\frac{100-X}{100}\right)+d\frac{X}{100}}{a\left(\frac{100-X}{100}\right)+b\frac{X}{100}}\times 100 = C(\%) \qquad (1)$$

where X is the degree of saponification; a and b are the apparent molecular weights of a methyl acrylate and of an acrylic acid residue respectively; c and d are the weights of carbon in a methyl acrylate and an acrylic acid residue respectively; C (%) is the analytical value of carbon.

Surface-pressure Measurements. The surface pressure-area isotherms were obtained with a modified Wilhelmy-type film balance. The film balance was enclosed in the

chamber adjusted to 20±0.2°C. The distilled water used as the substrate showed a pH of 5.0—6.0. The water in the trough was kept at 20.0±0.2°C by circulating the water from the thermostat bath. Sample polymers were spread on the distilled water and sodium chloride solutions with an "Agla" microsyringe. A mixture of acetone-benzene (1 : 1 by volume) was used as the spreading solvent. Thirty mixutes were allowed for the solvent to evaporate before compression was started. The rate of compression was 7.5 cm²/min.

The surface-pressure measurements were repeated for all polymers at least several times; the results were reproducible within the limits of experimental error.

Results and Discussion

The surface pressure-area isotherms on distilled water for poly(methyl acrylate) and polymers saponified in homogeneous and heterogeneous systems are shown in Figs. 1 and 2. The limiting areas obtained for all the saponified polymers of both systems were smaller than that of poly(methyl acrylate) (Figs. 1 and 2); their theoretical values were calculated as follows.

With the use of the limiting areas of 21.5 Å per methyl acrylate residue and 22.0 Å per acrylic acid residue reported by Crisp,[4,5] the theoretical area (A_t) of the saponified polymer, when all the residues of the polymer were oriented on the water surface, without the hydrophilic parts submerged into the water, was calculated by the following equation:

$$A_t = 21.5\left(1-\frac{X}{100}\right)+22.0\frac{X}{100} \qquad (2)$$

where X is the degree of saponification (mol%).

If the limiting area of the saponified polymer is the sum of the areas of the hydrophilic and hydrophobic parts (acrylic acid and methyl acrylate residues), the measured areas should correspond to the theoretical values calculated by Eq. (2). However, the limiting areas obtained from Figs. 1 and 2 were smaller than the theoretical values and decreased linearly with an increase in the degree of saponification (Fig. 3). The observed decreases in the limiting areas suggest the possibility of some of their hydrophilic parts submerging into the water phase in the compressed state of the films.

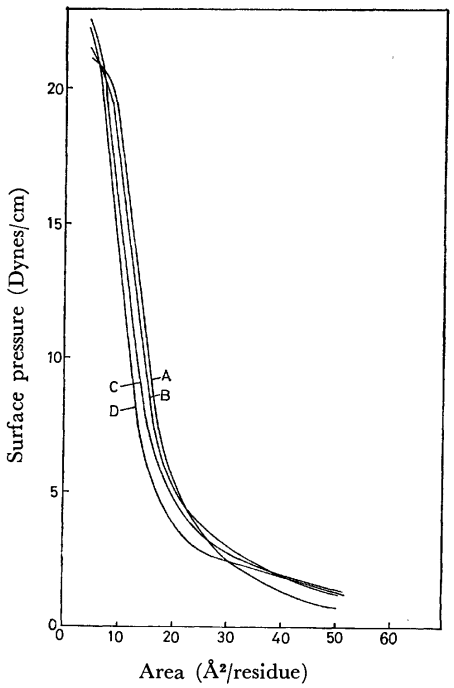

Fig. 1. The surface pressure-area isotherms on distilled water for poly(methyl acrylate) and its saponified polymers in homogeneous system. A-poly(methyl acrylate); B-13.93 mol% saponified polymer; C-24.16 mol% saponified polymer; D-48.34 mol% saponified polymer.

Previously, we investigated the monolayer properties of partially saponified poly *n*-butyl acrylate[3] and discussed them. Saponified polymer monolayers on sodium chloride solution expanded more than those on water. Their limiting areas increased as the salt concentration was increased. The limiting areas obtained on salt solutions above a certain concentration corresponded well to the theoretical values as calculated from the areas per butyl acrylate and per acrylic acid residue. One explanation of this is that the submerged hydrophilic residues of the saponified polymers were forced out of the water phase onto its

surface *via* the salting out effect.

Figure 4 shows the effect of the salt concentration on the surface pressure-area isotherms for the 48.34 mole% saponified polymer obtained in a homogeneous system. Figure 5 shows the plots of the limiting areas obtained for each saponified polymer *vs.* the concentration of sodium chloride. These curves approached nearly horizontal straight lines on salt solutions above 5%. The extrapolated values of these portions to a zero concentration of sodium chloride were in good agreement with the theoretical values within the limits of experimental error, as Table 2 shows. The agreement suggests that the monolayers of the saponified polymers spread completely on salt solutions above about 5%.

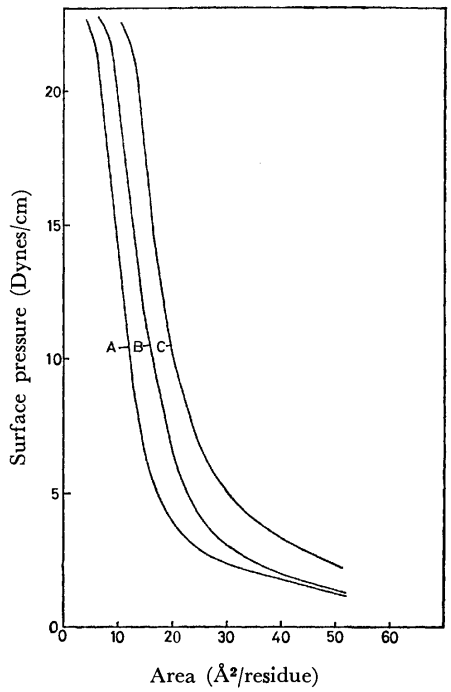

Fig. 4. The surface pressure-area isotherms of 48.34 mol% saponified polymer in homogeneous system on distilled water-(A); 2%-(B); and 5—10% sodium chloride solution-(C).

Also, the ratios of the portion submerging into the water phase and the portion remaining on it were estimated from the theoretical and observed values of the limiting areas in Fig. 3.[3] These ratios showed a good linearity against the degree of saponification. In the present work, this linearity was confirmed to hold (in Fig. 6). It can be suggested that the saponification of poly(methyl acrylate) in a homogeneous system proceeds evenly.

On the other hand, the monolayers of polymers

saponified in a heterogeneous system were confirmed to be unstable on salt solution as compared with those in a homogeneous system. Furthermore, the films of these substances had a tendency to show similar linear plots only in the range of low concentrations, as is shown in Fig. 7, and the extraploated values did not agree with the theoretical ones. In the range of higher concentrations above 2.5—4%, the films were less stable than those at low concentrations and were not reproducible, giving much larger limiting areas than the theoretical ones.

The monolayers of polymers saponified under different conditions showed the different two-dimensional behaviors. This may be due to the difference in the saponified states of the polymers. Probably, saponification in a homogeneous solution of the polymer proceeded evenly.

On the other hand, the results obtained for polymers saponified in a heterogeneous system suggest that the states of saponification of the polymers are not steady. Perhaps polymers may be either those saponified in block or mixtures of saponified and unsaponified polymers. If they are mixtures, their monolayers should give the behaviors of the mixed monolayers. Their monolayers, however, did not give the same surface pressure-area isotherms as the mixed monolayers. Therefore, saponification presumably proceeds in block and the saponified polymers consist of both those saponified in block and those not saponified at all.

The unstability and the further expansion of the monolayers of the saponified polymers on salt solutions above 2.5—4% suggest that the parts saponified in block were salted out strongly, exposing many neighboring carboxylates at the water surface. This resulted in an expansion of the monolayer, which was favored by the repulsion between $-COO^-$ ions formed by their dissociation.

The effect of the pH on the monolayers was further examined by adding hydrochloric acid and sodium hydroxide into the water phase, but the films of polymers obtained in both the homogeneous and heterogeneous systems were hardly affected below pH 6, while they expanded a little in the pH range of 8—9.

In conclusion, on distilled water the monolayers of polymers saponified under different conditions showed the same tendency for the limiting areas to decrease

linearly with the increase in the degree of saponification (Fig. 3); the results obtained on salt solutions suggested the difference in the saponified states of polymers detectable by the differences in the stabilities and the reproducibilities of the limiting areas. Further, the submergence theory held good only for polymers saponified in a homogeneous system. A linear relation was obtained by assuming the submergence theory, by assuming, that is, that some of the hydrophilic groups of the saponified polymers submerge into the water phase and are squeezed out of it by the salting out effect. This fact suggests that, while some of the hydrophilic groups are easily submerged into the water phase by compressing the films, one or two hydrophilic groups of both sides of the saponified portions are next to hydrophobic anchors, such as methyl acrylate residues, and remain on the water surface.

On the basis of the above discussion, it may be suggested that studies of the monolayers are of use in connection with the saponification reaction of polymers.

The Effect of Pressure on the Sol-Gel Transformations of Macromolecules[1)]

Keizo SUZUKI, Yoshihiro TANIGUCHI, and Toshishige ENOMOTO

Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto

(Received April 30, 1971)

The effect of pressure on the gelation of macromolecules, such as gelatin, polyvinyl alcohol, and methyl cellulose, was investigated in order to clarify which binding forces contribute to their gel formations. The values for ΔH and ΔV accompanying the gel formation were calculated from the Eldrige-Ferry's plot and the Clausius-Clapeyron equation respectively. The values for ΔH and ΔV in the gel fromations of gelatin and polyvinyl alcohol are both negative, while those in methyl cellulose are both positive. From the thermodynamical considerations, it has been found that the formation of hydrogen bonds results in negative values of ΔV and ΔH, while that of hydrophobic bonds results in positive values of ΔV and ΔH. Therefore, it may be assumed that the main binding forces in the gelations of gelatin and polyvinyl alcohol may be attributed to hydrogen bonds, and that those in methyl cellulose may be attributed to hydrophobic bonds, at least up to 6000 atm.

Gelations may be classified into three types according to the signs of enthalpy of gelation, ΔH; endothermic ($\Delta H>0$), exothermic ($\Delta H<0$), and athermal ($\Delta H=0$). In each case, there are reversible and irreversible sol-gel transformations. In the present experiment, the non-athermal reversible sol-gel systems are investigated. In reversible gelations, weak binding forces, such as the van der Waals type, hydrophobic bonds, hydrogen bonds, and ionic bonds, are considered to be mainly responsible for the gelation.

In investigating the pressure effect on gelation, it seems worthwhile to classify gelation from the point of view of the volume changes in gel formation, ΔV. The pressure effect can be predicted from the sign of ΔV. That is, the gelation in which ΔV is negative is prompted by hydrostatic compression, while in the gelation in which ΔV is positive, the pressure retards the gel formation.

From the thermodynamical data obtained in the appropriate model systems in which hydrogen bonds or hydrophobic bonds are involved, it has been found that the formation of hydrogen bonds results in negative values of ΔV and ΔH,[2,3)] while that of hydrophobic bonds results in positive values of ΔV and ΔH.[4)] Therefore, we can expect that the pressure will prompt the gel formation in which hydrogen bonds are concerned predominantly, while the pressure will retard the gel formation in which hydrophobic bonds are concerned predominantly.

In the present experiment, gelatin, polyvinyl alcohol, and methyl cellulose were used as samples; the binding forces which are concerned in gel formation will be discussed on the basis of the results of the pressure effect on gel formations.

Experimental

Samples. The gelatin was purchased from the Difco Lab. Co., the polyvinyl alcohol (M. W. 2700) was donated by the Kurashiki Rayon Co. and the methyl cellulose (M.W. 3400, 30.3% methoxyl) was obtained from the Japan Synthetic Chemicals Co., The water used was deionized through an ion-exchange column. These polymer solutions were not buffered.

Sol-Gel Transformation Measurement. The method for the determination of the sol-gel transformation was as follows. The solution was charged into a syringe-type cell, the inner diameter of which was about 10 mm. The cell was set in a high-pressure vessel, and the system was hydrostatically compressed for 10 or 20 min at the desired temperature. As soon as the pressure was released, the state of the system was checked to see if the ball (the diameter of which was 3 mm) inserted in the cell moved or not. In the cases of gelatin and polyvinyl alcohol, the compression was started at the sol state because the gels are formed by compression. The mean value of the lowest pressure at which

the ball did not move and the highest pressure at which the ball did move was considered to be the sol-gel transition pressure. In the case of methyl cellulose, the gel formed at 1 atm was compressed, because the gel melts by compression. The difference between the highest and the lowest pressure was usually about ±50—100 atm.

Results

Figure 1 shows a sol-gel phase diagram of gelatin at various concentrations. The phase above each curve is a sol phase, while the phase below each curve is a gel phase. It can be seen in this figure that the gelation of gelatin is prompted by raising the pressure. The phase diagram of polyvinyl alcohol in Fig. 2, shows that the pressure favors the gel formation. The curves of the concentrations of 13.35 wt% and 15.24 wt% coincide with each other completely, and above a certain pressure the gel is always formed, whatever the temperature.

Figure 3 shows a sol-gel phase diagram of methyl cellulose at various concentrations. In this figure, the phase above the curve is a gel phase, and the phase below the curve is a sol phase. The methyl cellulose gel is melted by compression; *i.e.*, pressure retards the gel formation of methyl cellulose. This behavior is quite different from that of the two other gels discussed above.

Discussion

Figure 4 shows the relation between the logarithm of the gelatin concentration, c, and the reciprocal of the absolute temperature of sol-gel transformation at each pressure according to the plot of Eldrige and

Ferry.[5] The linear relationship is also applicable to polyvinyl alcohol and methyl cellulose except for the higher concentrations in polyvinyl alcohol. The heat of reaction, ΔH, for the formation of the cross-links in gel is calculated from the slope of Fig. 4 according to the following formula;[5] $\log c = \Delta H/(2.303 RT) + \text{constant}$. The calculated ΔH values are tabulated in Table 1, together with those of polyvinyl alcohol and methyl cellulose.

The volume changes in gel formation were calculated from the relation of Clausius-Clapeyron, $dP/dT = \Delta H/T\Delta V$, assuming that the sol-gel transfor-

mation of these macromolecules can be treated as a phase transition. In Table 2, these values are listed. It can be found from Tables 1 and 2 that the gel formations in gelatin and polyvinyl alcohol are exothermic (*i.e.*, ΔH is negative) and are accompanied by a volume decrease and that the gelation in methyl cellulose is endothermic (*i.e.*, ΔH is positive) and is accompanied by a volume increase.[6]

As has already been explained in the introduction, when the values of ΔH and ΔV are both negative, hydrogen bonds contribute predominantly to the gel formation, while when the values of ΔH and ΔV are both positive, hydrophobic bonds contribute predominantly to the gel formation. Therefore, it may be assumed that the main binding forces in both gelatin and polyvinyl alcohol gels originate in hydrogen bonds, while in methyl cellulose hydrophobic bonds are mainly responsible for the gel formation.

The changes in ΔH and ΔV for gelatin at each pressure are different from those of polyvinyl alcohol. That is, the absolute values of ΔH and ΔV for gelatin increase with an increase in the pressure, while those of polyvinyl alcohol decrease. Therefore, we may assume that the mechanism for the gelation of gelatin is different in detail from that of polyvinyl alcohol. In methyl cellulose, (Fig. 3), the ΔV values tend to change in sign from positive to negative above 6000 atm. From these facts, it may be assumed that both hydrophobic and hydrogen bonds are concerned with the gel formation in the case of methyl cellulose, and that, with an increase in the pressure, the contribution of hydrogen bonds surpasses the contribution of hydrophobic bonds.

The Temperature Dependence of the Fractionation of Tritiated Water in an Equilibrium between Crystalline Alum and Its Aqueous Solution

Haruhiko TANAKA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received May 14, 1971)

The temperature dependence of the fractionation of tritiated water (HTO) was examined during the crystal growth of alum from its tritiated aqueous solution. When the ratios of the mole fractions of HTO in the water of crystallization to that of the mother liquid, S, at various temperatures are compared, the following order is established:

$$S_{19.90} \approx S_{29.50} > S_{36.52} > S_{41.95} > S_{47.43} > S_{53.70} \approx S_{69.50},$$

where the suffixes represent the crystallization temperatures, and where $S_{19.90}=0.975$ and $S_{69.50}=0.949$. The concept of the hydration of ions developed recently was applied to the problem of the crystal growth from the solution. Two kinetic parameters, such as the relaxation time of the aluminum ion for entering the surface, τ_c, and that of the hydrated aluminum ion, $Al(OH_2)_6^{3+}$, for the exchange of the water with bulk water, τ_e, were taken into account to explain the fractionation. A surface-diffusion mechanism was suggested as essential in the crystal growth of alum from the solution. The activation free energy for the crystal growth from an unstirred solution was found to be 18.17 kcal/mol, a value which was in good agreement with the value given by Bennema.

Tritium has some advantages over deuterium for examining hydrogen isotope effects. However, the fractionation of tritium in a hydrated crystal in equilibrium with its aqueous solution had scarcely been studied before the results on several hydrated crystals were reported.[1,2] Moreover, the temperature dependence of the fractionation of heavy water has been examined neither by the use of deuterated water nor by that of tritiated water. In this connection, it seemed that it would be quite interesting to study the fractionation of tritium during the crystallization of an inorganic hydrate at various temperatures.

It has been pointed out in a previous report[2] that tritium-fractionation should be useful in the study of phase equilibria between hydrated crystals and their aqueous solutions. Such a study seems to have increasing significance in connection with the recent development of the ionic process in an aqueous solution, particularly with regard to the hydration of various ions. It has become possible to examine the mechanism of the crystal growth of inorganic hydrates from their aqueous solution, as well as the kinetics of the deposition of the hydration water of cations from the solution, in the light of tritium fractionation.

Recently, Fiat and Connick[3] have obtained the kinetic parameters of the hydrated aluminum ion in an aqueous solution by the use of the ^{17}O-NMR technique over a wide range of temperatures. Samoilov[4] has investigated the hydration of alkali metal ions in detail and found that the potassium ion diffuses in an aqueous solution without any hydration water. In addition, the crystal growth of alum from a very slightly supersaturated solution has been studied extensively by Bennema,[5,6] who measured the growth rate as a function of the relative supersaturation of the mother liquid. He concluded from his study that the crystal growth probably occurs by means of a surface-diffusion mechanism originally proposed by Burton *et al.*[7] As he pointed out himself, however, much study remains to be done before a sound theory of crystal growth from an aqueous solution can be worked out.

Potassium aluminum sulfate dodecahydrate, $KAl(SO_4)_2 \cdot 12H_2O$, has been chosen for the present study aiming at the elucidation of the mechanism of crystal growth from an aqueous solution. For this purpose, it seemed that it would be interesting to study the fractionation of tritiated water by slowly growing crystals from a tritiated aqueous solution at various temperatures. Another purpose of the present study is to discuss the behavior of water during the crystal growth from an aqueous solution, behavior which has not been clarified by any other study.

Experimental

Potassium aluminum sulfate dodecahydrate obtained from a commercial source was purified by recrystallization. The solvent was twice-distilled water which contained a trace of tritiated water (*ca.* 1.5×10^{-8} mol/*l*). The single crystals of the hydrated salt were obtained from a very slightly supersaturated solution at constant temperatures of 19.90°, 29.50°, 36.52°, 41.95°, 47.43°, 53.70°, and 69.50°C under unstirred conditions.[8] A seed crystal was obtained from the same solution as that used for the succeeding crystal growth. The form of the small seed crystal was nearly octahedral; the (111) face was well-developed in comparison

with the other faces. The fluctuation of the temperature of the mother liquid was within ±0.02°C in a well-stirred thermostat. The rate of the evaporation of the solvent was so slow that only about 2 g of the well-developed (octahedral) single crystal of the salt was obtained in a week from a large amount of the mother liquid. The relative supersaturation of the mother liquid was kept below *ca.* 1.2×10^{-2} during each crystal growth.

Water from both the mother liquid and the single crystal was recovered by heating them in a stream of nitrogen gas until no further dehydration was observed. The tritium content in the water of crystallization was then compared with that in the corresponding mother liquid by an analysis of the activity of tritium. The activity was measured with a liquid scintillation counter (Packard Tri-Carb), using the scintillant described in a previous paper.[1]

Results and Discussion

The separation factor, S, for the equilibrium between solid and liquid phases can be given as follows in the case of a very low concentration of the relevant isotope (HTO in this case):

$$S = N_s/N_l,$$

where N_s and N_l are the mole fractions of HTO in the solid and liquid phases respectively. Table 1 gives the separation factor, S, together with the net counts per minute (cpm),[9] which are proportional to the amount of HTO, and the value of pH and the maximum relative supersaturation of the mother liquid during the crystal growth.

It may be seen that a considerable dilution of HTO occurs in the solid phase for the whole range of crystallization temperatures. The separation factors apparently decrease with an increase in the temperature in the 29.50°—53.70°C range, implying that more dilution of HTO in the hydrated crystal occurs at higher temperatures. On the other hand, no change in dilution can be seen within the limits of experimental error between 19.90° and 29.50°C or between 53.70° and 69.50°C.

Calculation of the Minimum Separation Factor, S. It has been reported in a previous paper[1] that HTO should be diluted in the crystal of inorganic hydrates during the growth from a solution, if free water behaves according to a surface-diffusion mechanism in which a growth unit essentially diffuses along the crystal surface before integrating into the kink.[7] On the contrary, the value of S has been calculated to be unity when the crystal growth follows a volume-diffusion mechanism; there is a direct integration from the solution into the kink without any surface diffusion.[5] It can thus be assumed here that free water should crystallize from the solution to give the water of crystallization in $KAl(SO_4)_2\cdot12H_2O$ by the surface-diffusion mechanism, since HTO was found to be diluted during the crystal growth of the salt.

Assuming an equilibrium between the free water in the solution and that on the crystal surface, the rate of the integration of the free water into the crystal, R, can be expressed as follows:[1]

$$R = \alpha C_0 \Omega N_0 (kT/2\pi m)^{1/2}(\sigma^2/\sigma_1)\tanh(\sigma_1/\sigma), \quad (2)$$

where

α=correction factor,
C_0=retarding factor,
Ω=volume of a growth unit,
N_0=equilibrium concentration of growth units per ml of the solution,
k=Boltzmann's constant,
T=absolute temperature,
m=mass of a growth unit,
σ=relative supersaturation, and
σ_1=parameter.

The R_{HTO}/R_{H_2O} ratio is thus obtained in the case of the crystal growth by the surface-diffusion mechanism, recognizing that all the factors other than m are independent of the hydrogen isotope:[1]

$$R_{HTO}/R_{H_2O} = (m_{H_2O}/m_{HTO})^{1/2} = 0.949, \quad (3)$$

where R_{HTO}/R_{H_2O} is the ratio of the integration of HTO to that of H_2O molecules into the crystal and where m_{H_2O}/m_{HTO} is the mass ratio of H_2O to HTO molecules. It follows from Eq. (3) that the minimum value of S (or the maximum dilution of HTO in the crystal) is equal to 0.949. This value was derived by assuming

that the fractionation of the isotope results, if at all, only from the free water and, practically speaking, not from the hydration water of the cation.

Free Water in the Aqueous Solution. In the aqueous solution of alum, there are three hydrated ions: $K(OH_2)_p^+$, $Al(OH_2)_6^{3+}$, and $SO_4(H_2O)_q^{2-}$. The hydration number of the aluminum ion has been determined exactly,[10] while those of other ions are ambiguous at this stage. As will be seen, however, the result may be independent of the hydration numbers of K^+ and SO_4^{2-} ions, *i.e.*, p and q. It is improbable that the hydrated aluminum ion, $Al(OH_2)_6^{3+}$, is subject to dehydration in the solution as are the hydrated cations studied in a previous paper,[1] since $Al(OH_2)_6^{3+}$ is rather stable; the order of its lifetime was found to be 7.5 sec at room temperature.[3]

It can be assumed here that the apparent free water molecules may result from the hydration water when the relaxation time needed for $Al(OH_2)_6^{3+}$ to integrate into the crystal surface, τ_c, is longer than that needed for the hydrated ion to exchange its hydration water with bulk water, τ_e. This assumption may be explained by examining a given water molecule rather than the aluminum ion. That is, a given hydration water molecule of Al^{3+} is liberated during the integration into the crystal surface if $\tau_c > \tau_e$. The resulting hydration water of $Al(OH_2)_6^{3+}$ also exchanges with a free water molecule on the surface during the integration into the kink, since the sphere can reside on the surface over the interval of τ_c or a little longer.[6] The water molecules of $Al(OH_2)_6^{3+}$ which integrate into the kink from the surface are thus assumed to result from the originally free water on the surface. On the other hand, half of the hydration water may be taken statistically to come from free water molecules on the surface when τ_c is equal to τ_e.

The hydration of the sulfate ion is supposed to be generally negligible. As for the hydration of the potassium ion, a recent concept by Samoilov[4] may be properly referred to in the present case. According to him, the potassium ion diffuses in a solution without any accompanying hydration water. It follows from the preceding argument that the estimation of the fraction of the free water which plays an important role in the crystal growth can be deduced from the hydration of the aluminum ion.

τ_e of the Aluminum Ion. The relaxation time for the exchange of the hydration water with bulk water has been extensively studied by a number of methods. Although only the order of magnitude of the lifetime of the species, $Al(OH_2)_6^{3+}$, had previously been reported, the exact value has recently been found using a ^{17}O-NMR technique by Fiat and Connick.[3] The measurement was carried out over a wide range of temperatures and the activation free energy for the exchange and the relaxation time were both derived. The lifetime of the $Al(OH_2)_6^{3+}$ species is reproduced in Fig. 1 as a function of the reciprocal of the absolute temperature.

Estimation of the Value of τ_c. The relaxation

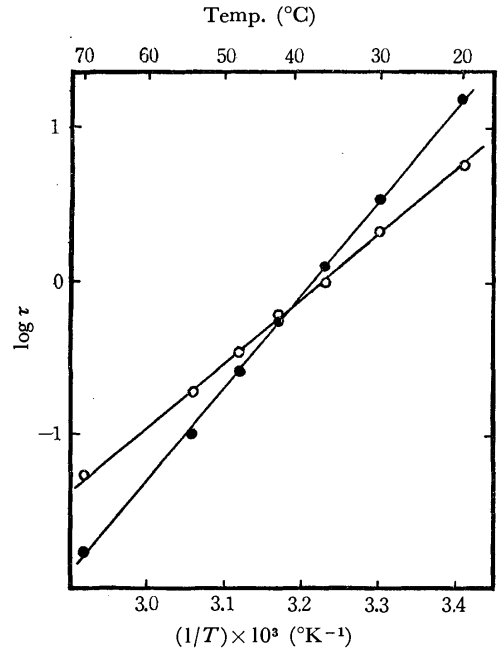

Fig. 1. Plots of τ_c and τ_e *vs.* $1/T$.
● τ_e calculated from Ref. 3.
○ τ_c calculated in terms of Eq. (4) using the value of E_{sf}, 18.2 kcal/mol.

time of the aluminum ion for integrating into the crystal surface, τ_c, can be represented by the equation:[6]

$$\tau_c = (h/kT)\exp(E_{sf}/kT), \quad (4)$$

where E_{sf} is the activation free energy of the ion for integrating into the crystal surface. It seems impossible at this stage to determine the value of E_{sf} accurately, since only the total activation energy for the crystal growth, E_t, can be obtained from the relation between the growth rate, R, and the temperature at a constant relative supersaturation, σ. However, the value of E_{sf} may be nearly equal to that of E_t or a little smaller, if the activation free energy of the aluminum ion for integrating into the kink from the surface, E_k, is relatively small. That is, it is possible to obtain the value of E_{sf} experimentally if the surface-diffusion mechanism is essential in which the integration of the cation into the surface is the rate-determining step. An energy diagram for the

10) H. W. Baldwin and H. Taube, *J. Chem. Phys.*, **33**, 206 (1960); R. E. Connick and D. N. Fiat, *ibid.*, **39**, 1349 (1963).

integration of the cation from the solution into the crystal is shown in Fig. 2.

On the other hand, the value of E_{sf} can also be estimated from a R-σ relation in which the growth rate, R, is expressed as a function of the relative supersaturation, σ, at a constant temperature. According to Bennema, the rate of the crystal growth of $KAl(SO_4)_2 \cdot 12H_2O$ from a well-stirred solution is given in the case of the surface-diffusion mechanism as follows:[6]

$$R = \beta C_0 \Omega (kT/h) \Lambda N_0 \{\exp(-E_{sf}/kT)\} (\sigma^2/\sigma_1) \tanh(\sigma_1/\sigma), \quad (5)$$

where β is a retarding factor and Λ is the thickness of the adsorption layer. He has thus estimated the value of E_{sf} to be 14.0 kcal/mol at 40°C in the case of a stirred solution. The value may, however, have some ambiguity at this stage due to the adjustable parameters, C_0 and Λ.

In the case of an unstirred solution, the following equation may hold:

$$E_{sf} = 14.0 + E_d, \quad (6)$$

where E_d is the activation free energy of the aluminum ion for diffusion in the solution. Equation (6) seems possible, for the activation processes of the cation for the diffusion and the integration into the surface should occur simultaneously. Accordingly, the value of E_{sf} becomes 18.2 kcal/mol in the case of an unstirred solution, assuming the value of E_d to be 4.2 kcal/mol, as was given by Eyring.[11] Neglecting the temperature dependence of the value of E_{sf}, it becomes possible to obtain the value of τ_c using Eq. (4) over the temperature range of 19.90°—69.50°C. Figure 1 shows the values plotted against the reciprocal of the absolute temperature.

Calculation of the Value of S. From the relation between τ_c and τ_e, the separation factor, S, can be calculated at a given temperature, taking account of Eq. (3). Since τ_e is larger than τ_c at 19.90°, 29.50°, and 36.52°C, as may be seen from Fig. 1, the aluminum ion should enter the crystal surface, accompanying the hydration water; that is, the species of the growth units are K^+, $Al(OH_2)_6^{3+}$, SO_4^{2-}, and H_2O for the crystal growth of alum. Assuming for the moment that the hydration water of $Al(OH_2)_6^{3+}$ is not subject to any fractionation of HTO from the bulk water, the value of S at 19.90°, 29.50°, and 36.52°C is calculated to be 0.975 as follows:

$$S = (6 \times 1.000 + 6 \times 0.949)/12 = 0.975. \quad (7)$$

At 41.95°C, τ_c is equal to τ_e. This means that the number of the hydration water of the cation, which integrates into the surface, is reduced to half of the preceding value; *i.e.*, the apparent species of the growth units may become K^+, $Al(OH_2)_3^{3+}$, SO_4^{2-}, and H_2O. The value of S is calculated as follows: $S = (3 \times 1.000 + 9 \times 0.949)/12 = 0.963$. The implication of the assumption that $\tau_c = \tau_e$ at 41.95°C seems quite important in that the value of E_{sf} (or the value of τ_c) can be determined rather exactly in terms of Eq. (4) if the value of τ_e is known, as is the case with the present study. It may be noted here, however, that the evaluated τ_c value may be a little ambiguous, as was pointed out before. As will be shown later, it is more reasonable to assume the reverse, that the $\tau_c = \tau_e$ equation holds when the observed value becomes 0.963.

At a higher temperature, the cation should integrate into the crystal surface apparently, without the hydration water, as was discussed before, because the $\tau_c > \tau_e$ relation holds in this case. It follows that all of the water of crystallization in alum should come from free water molecules, so the value of S becomes 0.949, as may be seen from Eq. (3).

At temperatures around 41.95°C, *i.e.*, at 36.52°C and 47.43°C, however, the separation factors are unlikely to take the extreme values of 0.975 and 0.949 respectively, because both τ_c and τ_e values should have some distribution and so should overlap to some degree. Accordingly, it is necessary to take account of the apparent loss of half of the hydration water of $Al(OH_2)_6^{3+}$ at 36.52°C. As a result, the apparent species of a growth unit for the aluminum ion at 36.52°C becomes $Al(OH_2)_m^{3+}$ with $3 < m < 6$. Similarly, the apparent species at 47.43°C can be given by $Al(OH_2)_n^{3+}$ with $0 < n < 3$. It follows that the separation factors, S, at 36.52° and 47.43°C are, at this stage, calculated to be in the ranges of 0.975—0.963 and 0.963—0.949 respectively. This also means that the apparent species of the growth unit changes continuously into the dehydrated aluminum ion, Al^{3+}, from the $Al(OH_2)_6^{3+}$ species with an increase in the temperature in the range of 29.50°—53.70°C, which thus leads to a continuous decrease in the value of S from 0.975 to 0.949 as the dehydration proceeds.

It should be noted here that the above treatment for the apparent dehydration of the species, $Al(OH_2)_6^{3+}$, is statistically true. The calculated value of S is given in Table 2, together with the values of τ_c and τ_e, and the apparent species of growth units. It seems worthwhile noting that the observed values are in good agreement with the calculated ones.

Factors Which May Influence the Value of S. It is well known that an aqueous solution of alum gives an acidic solution because a hydrolysis of the $Al(OH_2)_6^{3+}$ species occurs in the solution, a hydrolysis which is represented by a reaction such as:

$$Al(OH_2)_6^{3+} + H_2O \rightleftarrows Al(OH_2)_5(OH)^{2+} + H_3O^+.$$

It is thus necessary to obtain the concentration ratio of the tritiated hydronium ion, H_2TO^+, to the tritiated water, HTO. The T_3O^+ and HT_2O^+ species can be neglected as a source of tritium, since the mother liquid used contains a trace amount of HTO.

Salomon[12] has calculated the equilibrium constant of the reaction:

$$H_2O + H_2TO^+ \rightleftarrows HTO + H_3O^+,$$

to be 1.051 at 25°C. Therefore, the concentration

TABLE 2. CALCULATED SEPARATION FACTOR, S_{cal}, THE VALUES τ_c AND τ_e, AND APPARENT SPECIES OF GROWTH UNITS IN THE CRYSTAL GROWTH OF ALUM

Temp. (°C)	τ_c (sec)	τ_e (sec)	Apparent species of growth units	S_{cal}[c]
19.90	5.7	15.7	K^+, $Al(OH_2)_6^{3+}$, SO_4^{2-}, and H_2O	0.975 (0.971)
29.50	2.1	3.4	K^+, $Al(OH_2)_6^{3+}$, SO_4^{2-}, and H_2O	0.975 (0.971)
36.52	1.0_0	1.2_4	K^+, $Al(OH_2)_m^{3+}$ [a], SO_4^{2-}, and H_2O	$\begin{cases}<0.975\ (0.971)\\ >0.963\end{cases}$
41.95	0.6_3	0.6_0	K^+, $Al(OH_2)_3^{3+}$, SO_4^{2-}, and H_2O	0.963
47.43	0.3_6	0.2_7	K^+, $Al(OH_2)_n^{3+}$ [b], SO_4^{2-}, and H_2O	$\begin{cases}<0.963\\ >0.949\end{cases}$
53.70	0.2	0.1	K^+, Al^{3+}, SO_4^{2-}, and H_2O	0.949
69.50	5.4×10^{-2}	1.7×10^{-2}	K^+, Al^{3+}, SO_4^{2-}, and H_2O	0.949

a) $3<m<6$
b) $0<n<3$
c) The value corrected considering the species, $Al(OH_2)_5(HTO)^{3+}$, is given in parentheses.

ratio of H_2TO^+ to HTO in the solution is calculated to be *ca.* $[H_3O^+]/55.6$, where $[H_3O^+]$ refers to the concentration of H_3O^+. It follows that the H_2TO^+ species need not be considered as a source of tritium if $[H_3O^+]<10^{-1}$ gram ion/*l*. In the present study, the pH value of the mother liquid is larger than 1.85, so only HTO molecules have to be considered in calculating the value of *S*.

As for the crystal growth at 19.90° and 29.50°C, the $Al(OH_2)_6^{3+}$ species has been found to integrate into the crystal surface, accompanying the hydration water, as has been discussed before. Therefore, the $Al(OH_2)_5(HTO)^{3+}$ species should be taken into consideration in this case. The more tritiated species, *e.g.*, $Al(OH_2)_4(HTO)_2^{3+}$ are negligible, since the concentration of HTO is extremely low in the present case. Assuming the identical behavior of the species, $Al(OH_2)_5(HTO)^{3+}$, with a free water molecule in fixing into the crystal from the solution, the value of the separation factor for the species is estimated to be *ca.* 0.993 in terms of Eq. (2). The fractionation, if any, of HTO in the hydration water of the cation from bulk water is disregarded at this stage, which may lead to a little ambiguity in the calculation of *S*.

Mechanism of the Crystal Growth and the Fractionation of HTO. Since the $\tau_c=\tau_e$ relation is established when the species of a growth unit for the aluminum ion becomes $Al(OH_2)_3^{3+}$, as has been described above, the value of E_{sf} may be deduced in terms of Eq. (4), using the known value of τ_e.[3] The value of E_{sf} at 41.95°C is thus estimated to be *ca.* 18.17 kcal/mol in the case of an unstirred solution. It is interesting that the activation free energy for the exchange of the water in $Al(OH_2)_6^{3+}$ with bulk water, E_{ex}, becomes equal to the value of E_{sf} at this temperature, as may be seen from the equation:[13]

$$\tau_e = (h/kT)\exp(E_{ex}/kT). \quad (8)$$

The $E_{ex}=E_{sf}$ condition is important in that it is difficult to obtain the value of E_{sf} experimentally as well as theoretically, while the value of E_{ex} can be determined experimentally.

The mean displacement of the growth unit on the surface, x_s, can be estimated approximately, since the value of the activation free energy necessary for leaving the surface, E_{sl}, is nearly equal to the value of E_{sf}. The value of x_s for the aluminum ion is obtained in terms of the expression:[6]

$$x_s = a\exp\{(E_{sl}-E_{sd})/2kT\}, \quad (9)$$

where a is the shortest distance between neighboring growth units in the crystal and where E_{sd} is the activation free energy for the diffusion of the growth unit from one equilibrium position to a neighboring one on the surface. The value of E_{sd} is assumed to be *ca.* 7 kcal/mol according to Bennema,[5] so the value of x_s can be estimated to be *ca.* $7.6\times10^3\,a$. This implies that the cation diffuses over a wide range of the surface before integrating into the kink, because $x_s\gg a$. It follows that the surface-diffusion mechanism should play an essential role in the integration of the cation into the crystal, since the $x_s\gg a$ relation is a necessary condition for integration by means of this mechanism. This also implies that the integration of the cation into the surface should be the rate-determining step; therefore, the value of E_k is relatively small in comparison with the value of E_{sf} (*cf.* Fig. 2).

Accordingly, the crystal of alum should grow by the surface-diffusion mechanism, assuming that the rate of integration of the aluminum ion determines the overall growth mechanism. This assumption is supported by the facts that alum necessarily crystallizes from a slightly supersaturated solution in a stoichiometric way and that the cation has the lowest relaxation time for integrating into the crystal. The preceding discussion may be regarded as another argument for the mechanism of the crystal of alum which has been suggested by Bennema.[5,6] It may be concluded from the present study that isotopic fractionation in phase equilibria is largely influenced by the crystal-growth mechanism and the system of ions and water. The determination of the isotopic fractionation during the crystal growth of hydrated salts from a slightly supersaturated solution should thus contribute to an understanding of the growth mechanism and/or the system of the aqueous solution.

The author wishes to express his gratitude to Professor Hisao Negita of this University for his stimulating discussions and suggestions throughout this work. Thanks are also due to Dr. Osamu Yamamoto for his help in analysing the activity of tritium.

Strain Gauge Electromicrobalance for Surface Tension Measurement[1)]

Masakatsu KOSHINUMA, Akio NAKAMURA, Tsutomu SEIMIYA, and Tsunetaka SASAKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Tokyo

(Received June 3, 1971)

Two types of apparatus using an unbonded strain gauge of a cantilever type for the measurement of surface tension were constructed. One is a sensitive electromicrobalance equipped with an extended arm attached to the cantilever of the strain gauge. The apparatus proved suitable as a surface balance in a completely closed system. By this apparatus, the measurement of surface tension ranging from 0 to 74 dyn/cm is possible with the accuracy of ±0.10 dyn/cm. The other type was constructed by connecting the sensing lever of strain gauge to the arm of a torsion balance with a strip of phosphor bronze. This device together with a counterbalance on the opposite side of the arm also proved to be useful as a tensiometer. Accuracy of this apparatus was a little better than that of the extended arm type balance, although a larger space is required. Both apparatus are inexpensive, easy to construct and simple to operate, and are suitable for the self-recording of time dependence of surface tension or weight change in general with sufficient accuracy. Equations proposed for the time dependence of surface tension of surfactant solution were checked by using the strain gauge tensiometer of the extended arm type.

The Wilhelmy type surface tensiometer is known to give reliable values of surface tension[2)] and is considered to be the best method for the measurement of surface tension, particularly of surfactant solutions where aging is inevitable.[3)]

We previously devised a self-recording tensiometer using torsion balance and differential transformer as a transducer which converts a small vertical displacement of hanging glass plate into an electrical output for recording.[4)] Although the electrical output from the differential transformer was larger than that from a strain gauge of direct loading, skill is required for preparing a good working spiral spring to support the transformer core. In addition, unsteady actions of transformer and oscillator reduced the accuracy of the measurement.

In the present study, the differential transformer was replaced by a strain gauge to improve the performance of the torsion balance. Although surface tension measurements using strain gauge have already been reported,[5-7)] some of them lack detailed descriptions of the apparatus while others turn out to be inapplicable for the self-recording of time dependence of surface tension. Therefore, a self-recording strain gauge tensiometer of a torsion balance type was first constructed. In this apparatus a sensing lever of the strain gauge was connected by a phosphor bronze strip to a fixed point on the arm of the torsion balance and response of the torsion balance due to the action of surface tension was converted into the electrical output which operates a recorder. This apparatus has proved more accurate and sensitive than the former one.[8)]

However, for an accurate measurement of the surface tension of solutions, evaporation of solute or solvent from the solution should be prevented, since slight evaporation frequently produces a profound change in surface concentration[9)] and surface tension. Therefore, the space over the surface of liquid for the measurement should be minimized. The torsion balance is not suitable for this purpose, since a large space is required. A spring balance was constructed but was unfavorable because of its size and sensitiveness towards the temperature change.[10)]

A cantilever strain gauge of extended arm type was finally devised which turned out to be satisfactory for the surface tension measurement of aqueous solution, since it is compact and easy to set in a small chamber together with the solution to be measured. The apparatus proved to be insensitive to temperature and moisture.

By using this apparatus, the time dependence of surface tension of aqueous surfactant solution was measured, uninfluenced by evaporation of the solution and contamination from the surrounding atmosphere, and applicability of various equations proposed for calculating such dependence was checked.

Experimental

Construction of Surface Tensiometer. Strain Gauge: The strain gauge used was of unbonded and cantilever type (UL-120, *Shinko Communication Industry Co., Ltd., Japan*). Its maximum output is ±4 mV for permissible load of ±2 g. A maximum input of 4 volt was supplied from D. C. voltage stabilizer (NA-112, *Nippon Stabilizer Co., Ltd., Japan*). Output voltage from the strain gauge was properly attenuated, biassed with mercury cell, and was recorded by using a 1 mV full scale recorder (*Hitachi* QPD 33, *Hitachi Ltd.*,). A block diagram of the whole electrical setup is shown in Fig. 1 for tensiometer of the extended arm type.

Strain Gauge Tensiometer of Torsion Balance Type. The apparatus is shown in Fig. 2 in which S is the strain gauge, C, a counterbalance, P, a hanging plate ($20\times20\times0.02$ mm, 300 mg), and D, a magnetic dumper. A tungsten torsion wire of the torsion balance T was 0.22 mm in diameter and 60 mm in length, at the center of which a beam of 230 mm in length was fixed at a point 80 mm from its end. The sensing lever of the strain gauge was connected with the beam at a fixed point on it with a strip of phosphor bronze B ($20\times1\times0.07$ mm). Magnification of the force due to surface tension could be varied by shifting the point of connection of phosphor bronze with respect to the arm. The counterbalance was attached to the opposite side of the arm to offset the weight of the hanging plate and, if necessary, a part of the force due to the surface tension. By this means, together with the electrical attenuation of ouptut and the proper choice of the bias voltage, the range and sensitivity of the balance could be controlled according to the requirement of the experiment. In the present study phosphor bronze was fixed at a point 125 mm from the end of the arm as shown in Fig. 2. This increased the output of strain gauge six times the value of direct loading.

The performance of the apparatus is shown in Table 1. Sensitivity and accuracy are a little better than those of the former apparatus as shown in the table. The apparatus was adjusted so that the surface tension of 73 dyn/cm corresponded to about 1.8 g load of the strain gauge. The apparatus was used under two different conditions. In the first case, the output due to surface tension was so attenuated that 73 dyn/cm corresponded to the full scale of the recorder. In the second case, the output from the strain gauge was applied through the bias voltage to the recorder without electrical attenuation so that the full scale of the recorder covered a range from X_1 to X_1+25 dyn/cm, X_1 being varied between 0 and 55 dyn/cm. Temperature change of several degrees did not affect the surface tension, since the temperature dependence of output (Fig. 3) was found to be 9.05×10^{-6} mV/mg·deg and this corresponded to 0.002 dyn/cm·deg.

Strain Gauge Tensiometer of Extended Arm Type. Figure 4 shows the arrangement of a tensiometer of the extended arm type together with the liquid for measurement and the apparatus for conditioning the chamber containing them. In this apparatus, an extended arm E of thin glass rod, 330 mg in weight was attached to the cantilever of strain gauge S. The effective length of the arm was 93 mm. The tensiometer was fixed to the side column of the chamber. The weight of the Wilhelmy plate P, ($20\times15\times0.02$ mm, 250 mg) was chosen to be the sum of the force due to the surface tension of water (about 73 dyn/cm), and the weights of arm and plate are brought near the limit of a permissible load of the strain gauge. By this arrangement, the weight ranging from 0 to 300 mg could be measured with the accuracy of ±0.4 mg. This corresponds to the surface tension of 0 to 74 ± 0.1 dyn/cm for the plate of 40 mm in horizontal perimeter as shown in Table 1.

For surface tension measurement, a clean glass plate was hung from the arm and the chamber was closed after being flushed with humidified nitrogen (Fig. 4). The liquid then was slowly introduced from the reservoir R into the vessel V until its surface just touched the lower end of the hanging plate P. The vertical force due to the surface tension acting on the plate was converted into an electrical output and recorded through the bias voltage. The recorder was so adjusted that 50 dyn/cm corresponded to a

full scale, and the surface tension ranging from X_2 to X_2+50 dyn/cm could be measured, X_2 being varied between 0 and 24 dyn/cm.

Neither the hysteresis due to the load nor the effect of moisture was observed during the course of 24 hr measurement in both types of tensiometers.

Measurement of Time Dependence of Surface Tension and Equilibrium Surface Tension

Surface tension was measured for a 5.4×10^{-6} mol/l aqueous solution of hexaoxyethylene dodecyl ether (homogeneous) by using the extended arm strain gauge tensiometer, at 25°C. The results are shown in Fig. 5. Water used for preparaing the solution was distilled from acid permanganate, then alkaline permanganate solutions and finally distilled without permanganate in borosilicate flasks. Surface tension showed a relatively long aging extending over about 20 hr until it attained an equilibrium. Since measurements were carried out in a closed vessel, evaporation was completely eliminated and the system was free from comtamination from the surrounding atmosphere. Thus the observed changes are considered to be proper to the solution and the data obtained are pertinently for checking the validity of various equations proposed for the time dependence of surface tension of surfactant solution or the equations for obtaining an equilibrium surface tension. Table 2 shows the equilibrium surface tension values calculated from the following empirical equations with various ranges of observed surface tension *vs.* time values.

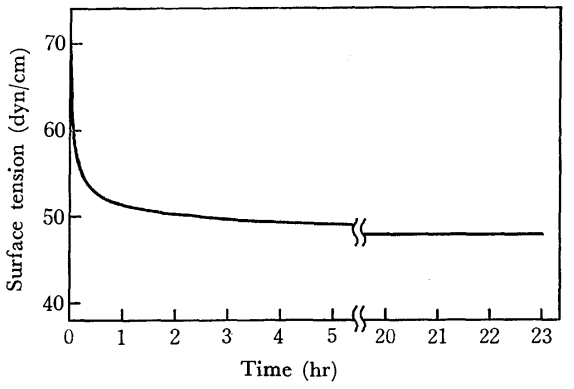

Fig. 5. Surface tension of aqueous hexaoxyethylene dodecyl-ether (at 25°C, 5.4×10^{-6} mol/l).

$$\sigma_t = \sigma_\infty + a/t + b/t^2$$
$$\text{or, } \sigma_t + t(d\sigma_t/dt) = \sigma_\infty - b/t^2 \quad (1)^{11}$$
$$\sigma_t = \sigma_\infty + (\sigma_0-\sigma_\infty)\exp(-\alpha t)$$
$$\text{or, } \sigma_t = (-1/\alpha)(d\sigma_t/dt)+\sigma_\infty \quad (2)^{12}$$
$$\sigma_0 - \sigma_t = (\sigma_0-\sigma_\infty)/(c/\sqrt{t}) + 1 \text{ or,}$$
$$1/(\sigma_0-\sigma_t) = 1/(\sigma_0-\sigma_\infty) + \{c/(\sigma_0-\sigma_\infty)\}(1/\sqrt{t}) \quad (3)^{13}$$

In these equations, σ_t, σ_0, and σ_∞ denote the surface tension of solution at time t, $t=0$ and $t=\infty$ respectively, and α, a, b, and c constants.

It is seen in Table 2 that, as regards the extrapolated equilibrium values of surface tension σ_∞ obtained from the σ-t values of longer time range (0.5—5 hr), Eq. (1) is found to give the best value, being the nearest to the equilibrium value obtained after 20 hr. Since σ_∞ obtained by using σ-t values of shorter and earlier time range is not reliable, the agreement of σ_∞ obtained from Eq. (3) and σ-t values of 5—25 min range is considered to be accidental. Thus, Eq. (1) is recommended here as an empirical formula, but 4 hr measurement is necessary in order to obtain a reliable value of equilibrium surface tension.

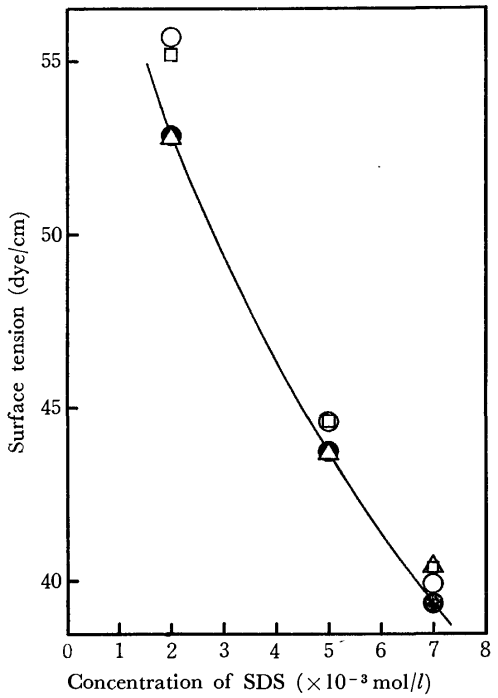

Fig. 6. Calculated and observed equilibrium surface tension.
○: Eq. (1), □: Eq. (2), △: Eq. (3), ● and —: Observed value.

Surface tension was further measured for aqueous solutions of ionic surfactant, sodium dodecyl sulfate, and the validity of the above three equations was checked for three different concentrations. The results are shown in Fig. 6 together with the equilibrium value (solid line) observed after 20 hr. The values of σ_∞ were calculated from σ-t curve of 0.5—4 hr range. We see that the difference between the observed and calculated σ_∞ decreased with increasing concentration and decreasing time dependence of surface tension in the case of Eqs. (1) and (2), while the relation is reverse in the case of Eq. (3). The general tendency is such that the observed equilibrium values of surface tensions to be equal or smaller than the values calculated from these equations.

Table 2. Calculated and observed equilibrium surface tension

	Surface tension (dyn/cm)				
	5—25 min	0.5—2 hr	2—4 hr	0.5—5 hr	After[a] 20 hr
Eq. (1)	50.8	49.3	47.9	47.6	47.8
Eq. (2)	50.8	49.5	48.5	48.8	
Eq. (3)	47.8	46.9	47.3	46.9	

a) Equilibrium surface tension measured for 5.4×10^{-6} mol/l aqueous solution of hexaoxyethylene dodecyl ether at 25°C.

It is concluded from the above observations that the applicability of these equations may differ for different solutions, and a common equation applicable for all systems cannot be obtained. This is quite natural since these equations are empirical, and it is difficult to derive a theoretical equation predicting the change of surface tension with time, because the mechanisms of surface aging may differ for different solutions which are not clear at present, although some explanations have been proposed.[14]

However, from the practical view point Eq. (3) seems convenient since a linear plot is applicable. But also in this case, a 4 hr measurement of surface tension completely free from evaporation and contamination seems desirable for calculation of a reliable value of equilibrium surface tension.

Adsorption of Sodium and Calcium Dodecyl Sulfates at the Surface of Their Aqueous Solutions

Jun SASAKI, Kazuo TAJIMA, and Tsunetaka SASAKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received June 8, 1971)

Adsorption of sodium dodecyl sulfate (NaDS) and calcium dodecyl sulfate ($Ca(DS)_2$) at the aqueous surface was measured by a radiotracer method using tritium labelled compounds at constant ionic strength of 1×10^{-2} and 7.5×10^{-3} adjusted by the addition of NaCl and $CaCl_2$, respectively. The adsorbed amounts increased with increasing concentration of dodecyl sulfates in both cases, and approached saturation values of 3.65×10^{-10} mol/cm^2 at 25°C for NaDS and 3.8×10^{-10} mol/cm^2 at 55°C for $Ca(DS)_2$. The amounts calculated from surface tension data by applying the Gibbs adsorption isotherm were confirmed to be in good agreement with the values directly measured. The adsorbed amounts of chloride ion, generally assumed to be zero, were confirmed to be negligible in the concentration region from zero up to critical micelle concentration.

Numerous investigations have been reported on the study of surface active substance at air-solution interface with the purpose of examining the applicability of the Gibbs adsorption isotherm under various conditions.[1-5] However, there are only a few discussions based on the direct measurement of surface excess, especially for well defined plane aqueous surface.[5-8]

In the previous studies,[6,8] the Gibbs adsorption isotherm $-d\gamma=nRT\Gamma d\ln a$ was confirmed to hold for the adsorption from aqueous solution of NaDS with $n=2$ for salt free solution, and with $n=1$ for the solution containing excess salt. Several workers have studied the adsorption of ionic surfactant solution at constant ionic strength[2,4,9,10] and eliminated activity coefficients from the Gibbs adsorption isotherm.

In the present study, we have carried out direct measurements of adsorbed amounts of tritiated NaDS and $Ca(DS)_2$ at aqueous interface, and at constant ionic strength by a radiotracer method. Measurements of surface tension were also carried out under the same conditions. From the results the validity of the Gibbs adsorption isotherm at constant ionic strength was checked.

Experimental

Materials. Sodium dodecyl-2,3-t_2 sulfate (TNaDS) was prepared as previously reported.[11] Dodecan-2,3-t_2-1-ol used for the preparation was confirmed to be chemically and radiochemically pure by radiogaschromatography. Calcium dodecyl-2,3-t_2 sulfate ($TCa(DS)_2$) was also synthesized in the same manner as TNaDS from dodecan-2,3-t_2-1-ol, except for the neutralization of dodecyl sulfuric acid by $Ca(OH)_2$. Both surfactants were carefully recrystallized from ethanol and subjected to Soxhlet extraction using ethyl ether for 48 hr to remove unreacted tritiated dodecanol and other surface active impurities. Specific activity of the substances obtained was 16 Ci/mol. Both surfactants were further confirmed to be free from surface active impurities as judged from the absence of minimum in surface tension *vs.* concentration curves. Triply distilled water was used.

Procedure. Ionic strengths of TNaDS and $TCa(DS)_2$ solutions used were kept constant at 1.0×10^{-2} and 7.5×10^{-3} respectively, by diluting 1.0×10^{-2} mol/l TNaDS with NaCl solution of the same concentration and 2.5×10^{-3} mol/l $TCa(DS)_2$ with $CaCl_2$ solution of the same concentration. Radioactivity of tritiated dedecyl sulfate solution was meas-

ured by using a gas-flow GM counter[13] equipped with a thin film (polycarbonate) window as shown in Fig. 1. A counter tube A can be raised or lowered by the rack and pinion device B. Surfactant solution was contained in a polyethylene cell C, 70 mm in diameter. The distance constant to 0.70±0.02 mm by means of electrical contact of the aqueous surface with the point of a needle F fixed to the GM tube. To avoid the effect of carbon dioxide from the surrounding atmosphere, nitrogen gas, well humidified by passing through a glass tube of 6 m in length packed with wet glass wool was slowly introduced and allowed to leak from the chamber D. During the course of measurement, gas flowing was stopped in order not to disturb the solution surface. The whole apparatus was placed in a thermostated glove box filled with humidified nitrogen gas.

After standing both the cell and dodecyl sulfate solution for about 30 min in the glove box, 25 m*l* of the solution was poured into the cell. Radioactivity of the aqueous solutions of TNaDS and $TCa(DS)_2$ was measured at 25±1°C and 55±1°C, respectively. The temperature was chosen several degrees above each Krafft point. Measurements were continued until equilibrium steady counting was obtained. Radioactivity due to the bulk of solution was measured over the surface of tritiated dodecanol dissolved in non-radioactive dodecanol as in the preceeding method[6] and was subtracted from the total radioactivity to give the radioactivity due to adsorption. To convert the radioactivity thus obtained to the amount of adsorbed surfactant, known amount of tritiated stearic acid of 9.0 Ci/mol in specific activity was spread on aqueous solution of 0.1 N H_2SO_4 using the same cell, and the surface count was measured at 25°C and 55°C for TNaDS and $TCa(DS)_2$, respectively. From the inclination of the straight line of count rate *vs.* spread amount multiplied by the ratio of specific activity of tritiated stearic acid to that of tritiated dodecyl sulfate, a conversion factor (mol cm^{-2} cpm^{-1}) was obtained. The surface count rate obtained by subtracting bulk count rate from the count rate over the aqueous solution was converted to surface excess Γ_{D^-} by multiplying it with the conversion factor. Surface tension was measured by the drop volume method applying the Harkins and Brown correction, and by the Wilhelmy plate method, both under the same conditions as in the case of the adsorption measurement.

Results and Discussion

Adsorption. The observed amounts of adsorption Γ_{D^-} were plotted against concentration C for TNaDS and $TCa(DS)_2$ as shown by open circles in Figs. 2 and 3, respectively, The value of Γ_{D^-} for TNaDS rapidly increased with increasing concentration of TNaDS and approched a saturation value of $\Gamma_{D^-}=3.65\times10^{-10}$ mol/cm^2 at the concentration of 2.5×10^{-3} mol/*l*. However, above critical micelle concentration (CMC), it gradually decreased with increasing TNaDS concentration. At the concentration of 1×10^{-2} mol/*l*, where the concentration of NaCl became zero, Γ_{D^-} decreased to 3.09×10^{-10} mol/cm^2, which is in good agreement with the former Γ_{D^-} value of the saturation amount of adsorption for the same system measured by the sheet scintillation counter[6] as shown in Fig. 2. Coincidence of both

—: calculated value

results obtained by two different methods of measurement for the same solution shows sufficient reliability of both methods and the absolute value of adsorbed amount obtained. The decrease of Γ_{D^-} above CMC is a direct indication of the effect of decrease of ionic strength or the decrease of NaCl concentration with nearly constant concentration of single dodecyl sulfate ions.[8] Thus, the increase of adsorption of dodecyl sulfate ion due to the addition of NaCl is distinct in a wide range of concentration as shown in Fig. 2. Adsorbed amount from aqueous solution of $TCa(DS)_2$ was also measured for the whole range of concentration up to CMC. It also increased rapidly with increasing concentration and arrived at a saturation value of $\Gamma_{D^-}=3.8\pm0.7\times10^{-10}$ mol/cm^2 at the concentration of 5×10^{-4} mol/*l*, which was roughly equal to the saturation value for TNaDS. Adsorption isotherm for $TCa(DS)_2$ showed fluctuation which might be due to the fluctuations of the count rate. This is inevitable since the absorption coefficient of air space between surface of the solution and window of the GM counter becomes unsteady owing to the incomplete saturation of the space with water vapor at elevated temperature. Gradual contamination of the thin film of the GM counter by radioactive substance, presumably dodecanol produced by hydrolysis of $TCa(DS)_2$ at high temperature, was also observed during the measurement. Radioactivity due to this

13) T. Seimiya, K. Sekine, and T. Sasaki, *J. Sci. Instr.*, **42**, 906 (1956).

contamination was subtracted as background count rate. The water vapor absorbed and permeating through the thin film might have some influence upon the count rate observed. However, it turned out to be negligible in the present experiment.

Surface Tension. Figure 4 shows the surface tension *vs.* concentration curve for the aqueous solution of TNaDS measured by the drop volume and Wilhelmy plate methods. The surface tension obtained by the drop volume method is seen to agree with that obtained by the self-recording Wilhelmy plate method. This differs from the general tendency of the former being somewhat larger. This is due to the rapid attainment of steady surface tension exhibited by the surfactant solution in the presence of added neutral salt. The surface tension of aqueous solution of $TCa(DS)_2$ measured by the Wilhelmy plate method is shown in Fig. 5. In this case, 2 — 3 hr was required to attain equilibrium even in the presence of neutral salt, presumably due to the low concentration of both the surfactant and added salt.

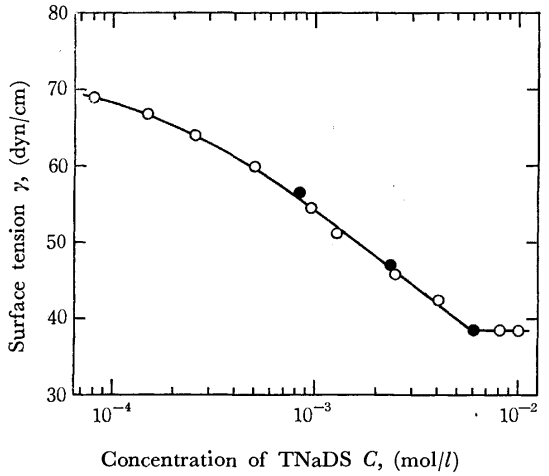

Fig. 4. Surface tension *vs.* concentration of TNaDS solution (25°C).
○: drop volume method
●: Wilhelmy plate method

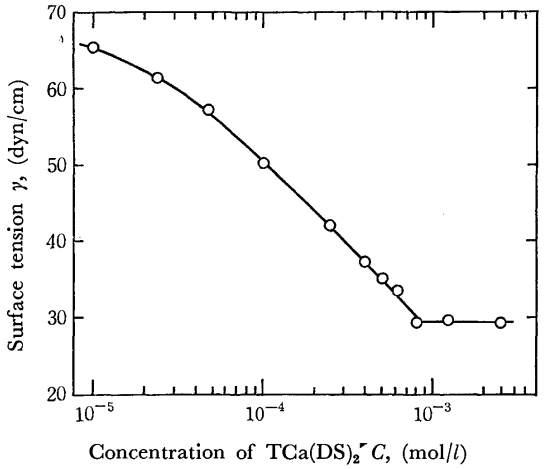

Fig. 5. Surface tension *vs.* concentration of $TCa(DS)_2$ solution (55°C).

Gibbs Adsorption Isotherm. In the present system, where the concentration of hydrogen ion is taken as constant, the Gibbs adsorption isotherm is given by

$$-\frac{d\gamma}{RT} = \Gamma_{D^-}d\ln C_{D^-}f_{D^-} + \Gamma_{M^{n+}}d\ln C_{M^{n+}}f_{M^{n+}} + \Gamma_{Cl^-}d\ln C_{Cl^-}f_{Cl^-}, \quad (1)$$

where f's express activity coefficients, and subscripts D^-, M^{n+}, and Cl^- denote dodecyl sulfate ion, n-valent counter ion and chloride ion, respectively. Activity coefficients of the ions in aqueous solution drop for constant ionic strength and Eq. (1) is reduced to

$$-\frac{1}{RT}\left(\frac{d\gamma}{d\ln C_{D^-}}\right)_I = \Gamma_{D^-} - \Gamma_{Cl^-}\frac{C_{D^-}}{C_{Cl^-}}, \quad (2)$$

where subscript I indicates the constancy of ionic strength. The value of $\Gamma_{D^-}-\Gamma_{Cl^-}(C_{D^-}/C_{Cl^-})$ was calculated with this equation by graphically evaluating $d\gamma/d\ln C_{D^-}$ from γ *vs.* $\ln C_{D^-}$ plot shown in Fig. 4. The results for TNaDS are shown by a solid line in Fig. 2. Satisfactory agreement of calculated value with independently observed Γ_{D^-} might give the experimental evidence that $\Gamma_{D^-}-\Gamma_{Cl^-}(C_{D^-}/C_{Cl^-})$ is essentially equal to Γ_{D^-}, and $\Gamma_{Cl^-}=0$.[12] This confirms the view that the Gibbs adsorption isotherm can be applied in the form

$$-\frac{1}{RT}\left(\frac{d\gamma}{d\ln C_{MD_n}}\right)_I = \Gamma_{D^-} \quad (3)$$

in the concentration region from zero up to CMC for the TNaDS solutions containing a neutral salt with common counter ion at constant ionic strength. Thus it might be concluded that the counter ion of added neutral salt is not adsorbed regardless of the amount added in the solution as is actually indicated, and Eq. (1) is valid without the term $\Gamma_{Cl^-}d\ln C_{Cl^-}f_{Cl^-}$. It is worth noting that although $\Gamma_{Cl^-}=0$ can readily be anticipated from a theoretical viewpoint and this assumption has been adopted by many investigators,[1,4,14] experimental confirmation is not satisfactory. So, the conclusion obtained is significant. Schwuger,[9] in his study of adsorption of divalent metal tetradecyl sulfate at constant ionic strength, neglected the term $\Gamma_{Cl^-}(C_{D^-}/C_{Cl^-})d\ln C_{Cl^-}$ assuming that salt is added in excess. Actually, however, neither was the salt in excess nor the ratio C_{D^-}/C_{Cl^-} small at CMC. It is because of the term Γ_{Cl^-} being zero at any concentration of added salt that the above calculation is justified. Schwuger insisted that at CMC the addition of salt under constant ionic strength has no effect on surfactant adsorption. However, the enhancing effect of salt on the adsorption amount of surfactant is evident as shown in Fig. 2. On close inspection, a small but distinct increase can be observed also in his Γ_{D^-}'s caused by the addition of salt at constant ionic strength, in accordance with our results.

Adsorption of $TCa(DS)_2$ was calculated from Eq.

14) E. J. W. Verwey and T. Th. G. Overbeek, "Theory of the Stability of Lyophobic Colloids," Elsevier, Amsterdam (1948), p. 22.

(3) by applying the data of the surface tension curve shown in Fig. 5. The values of Γ_{D^-} were plotted against the concentration of $TCa(DS)_2$ with a solid line in Fig. 3. Allowing for the experimental error mentioned above, Eq. (3) can also be applied to the adsorption at aqueous surface of $TCa(DS)_2$ solution. The results of the present study also confirmed experimentally the applicability of the Gibbs adsorption isotherm in the form of Eq. (3) for divalent metal dodecyl sulfate from zero concentration up to CMC. It is inferred also in this case that non-adsorption of co-ion in deriving Eq. (3) is not an assumption but the experimental fact, and Eq. (2) without the Γ_{Cl^-} term is safely applicable as is generally believed.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 351—355 (1972)

On the Viscosities of Mixtures of Oligotrifluorochloroethylene and *n*-Heptadecane

Naosato YOSHIDA and Shuichi HAMADA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received June 18, 1971)

The viscosities, η_m, of mixtures of oligotrifluorochloroethylene and *n*-heptadecane were expressed as follows: $\eta_m=[(1-\Phi_R)-n(1-\Phi_R)]\eta_H+[\Phi_R+n(1-\Phi_R)]^2/[\Phi_R/\eta_R+n(1-\Phi_R)/\eta_H]$, where Φ_R is the volume fraction of the oligotrifluorochloroethylene in the mixture; η_R and η_H, the viscosities of oligotrifluorochloroethylene and *n*-heptadecane respectively, and n, a parameter. The two components were considered to be comparatively well compatible with each other, because the parameter, n, was small (here about 0.1). The free-volume fractions, f_T, of the mixed systems, as calculated from the WLF parameters, were larger than those calculated by assuming a simple additivity between those of the two components. This effect is considered to be caused by the mitigation of physical interactions among oligotrifluorochloroethylene molecules, which are dispersed by *n*-heptadecane as good compatibility is achieved between the two components.

The viscoelastic properties of a mixture of polymers depend on the ratio of the components and on their mixing state.[1] If two components are completely compatible with each other, the mixed system behaves, for example, like a random copolymer with only a glass-transition temperature which is a function of the monomer ratio.[2] Such a compatible system has been obtained, for example, by blending polyvinyl chloride and butadiene-acrylonitrile rubber within a certain volume fraction range of the components.[3] On the contrary, a mixed system of two incompatible or poorly compatible components, such as is observed in ordinary cases, gives properties consistent with those of the original components. If the two components are slightly compatible with each other, they partially dissolve one another according to the natures of the components and the manner of mixing.

In this work, the viscosities of mixtures of oligotrifluorochloroethylene and *n*-heptadecane were studied in connection with their compatibility and free-volume fractions.

Experimental

Materials. Daifloil No. 50, which was obtained from the Daikin Kogyo Company, was used as the sample of oligotrifluorochloroethylene. The oligotrifluorochloroethylene was fractionated by the manner described in our previous paper.[4] Fractionated oligotrifluorochloroethylene samples with the number-average molecular weights of 910, 950, and 1000, which were estimated by the cryoscopic method, were used as polymer components in the mixed systems. A guaranteed-grade *n*-heptadecane, which was obtained from the Kanto Kagaku Company, was used without further purification. The mixed samples of oligotrifluorochloroethylene and *n*-heptadecane were prepared in the following manner: the two components were mixed well together with benzene in various proportions, and then the benzene was removed by vacuum distillation from the mixture at temperatures from 30 to 50°C.

The volume fractions of oligotrifluorochloroethylene in the mixed samples are shown in Table 1.

Procedure. The viscosities and the densities of the liquid samples were measured with an Ubbelohde-type viscometer and a dilatometer respectively in the manner described in the previous paper.[4] The measurements were carried out in the temperature range from 30 to 70°C, with an accuracy of ±0.01°C, in a thermostated water bath.

Results and Discussion

The viscosities of oligotrifluorochloroethylene, *n*-heptadecane, and mixed samples are listed in Table 2-a and 2-b.

Mixing Model for Mixtures of Oligotrifluorochloroethylene and n*-Heptadecane.* The mixing states of oligotrifluorochloroethylene and *n*-heptadecane in the samples have been discussed, on the basis of the dependence of their viscosities on the volume fractions

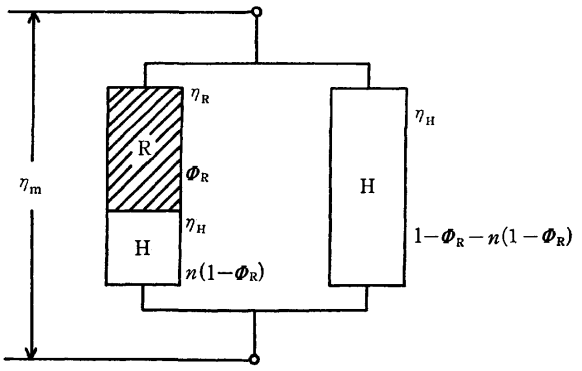
of oligotrifluorochloroethylene, by using the mixing theory proposed by Takayanagi.[5,6] As a consideration of the "R in H" type parallel-model as Fig. 1 shows, the viscosities, η_m, of mixtures of oligotrifluorochloroethylene and n-heptadecane can be expressed as follows:[5]

$$\eta_m = [(1-\Phi_R)-n(1-\Phi_R)]\eta_H+[\Phi_R+n(1-\Phi_R)]^2/[\Phi_R/\eta_R+n(1-\Phi_R)/\eta_H] \quad (1)$$

where the subscripts R and H denote oligotrifluorochloroethylene and n-heptadecane respectively, and where n is a parameter which indicates the degree of contribution of the series element in the parallel-model. The values of the viscosities at 50°C, as calculated by Eq. (1), are shown by solid curves in Fig. 2. The observed values, which are shown by fllled circles in Fig. 2, agree well with those calculated by assuming the "R in H" type parallel-model when is nearly equal to 0.1. These mixed systems were considered to be comparatively well compatible under suitable conditions because of the small value of n, *i.e.*, the smaller contribution of the series element.

5) M. Takayanagi, *Kobunshi*, **10**, 289 (1961).
6) E. Shiraki and G. Okamoto, *Kogyo Kagaku Zasshi*, **65**, 148 (1962).



R: Oligotrifluorochloroethylene
H: *n*-Heptadecane

Fig. 1.

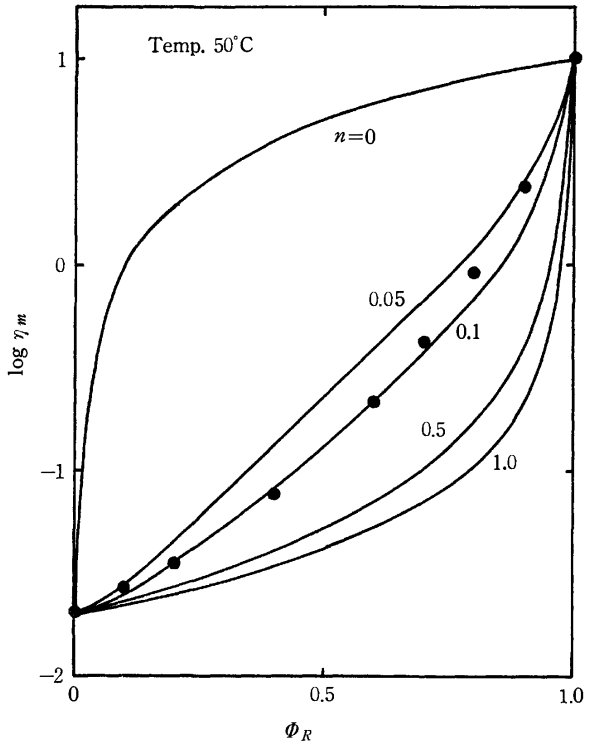


Fig. 2. Relationship between log η_m and Φ_R.

This conclusion was supported by the facts that it was difficult to separate the two components into two phases and that the η_m values did not change even when measured after 2 months, providing the conditions were suitable. A slight deviation of the observed values from the solid line (n is 0.1) in the volume fraction range larger than 0.7 is considered to be caused by the change in the degree of compatibility between the two components.

The η_m/η_H ratio of the viscosities of the mixture and *n*-heptadecane can be expressed by rewriting Eq. (1) as follows:

$$\eta_m/\eta_H = (1-\Phi_R) + [\Phi_R{}^2\eta_R + n\Phi_R(1-\Phi_R)(2\eta_R-\eta_H)]/[\Phi_R\eta_H + n(1-\Phi_R)\eta_R] \quad (2)$$

When the volume fraction, Φ_R, is small and when n is nearly equal to 0.1, η_m/η_H can be approximately expressed as follows:

$$\eta_m/\eta_H = 1+\Phi_R+\Phi_R{}^2/n(1-\Phi_R) \quad (3)$$

because $\eta_R \gg \eta_H$, and $n(1-\Phi_R) \gg \Phi_R\eta_H/\eta_R$. With the assumption of $n=\Phi_R f(\Phi_R)$, the following relationship is obtained:

$$\eta_m/\eta_H = 1 + \Phi_R + \Phi_R/(1-\Phi_R)f(\Phi_R) \simeq 1 + a\Phi_R + b\Phi_R{}^2 \quad (4)$$

where a and b are parameters. Figure 3 shows the relationship between $(\eta_m/\eta_H-1)/\Phi_R$ and Φ_R at 50°C and at volume fractions, Φ_R, smaller than 0.2. The linear relationship was found to be as follows: $(\eta_m/\eta_H-1)/\Phi_R=2.5+5.6\Phi_R$. Similar relations have been found for dilute solutions of polymers.[7-10]

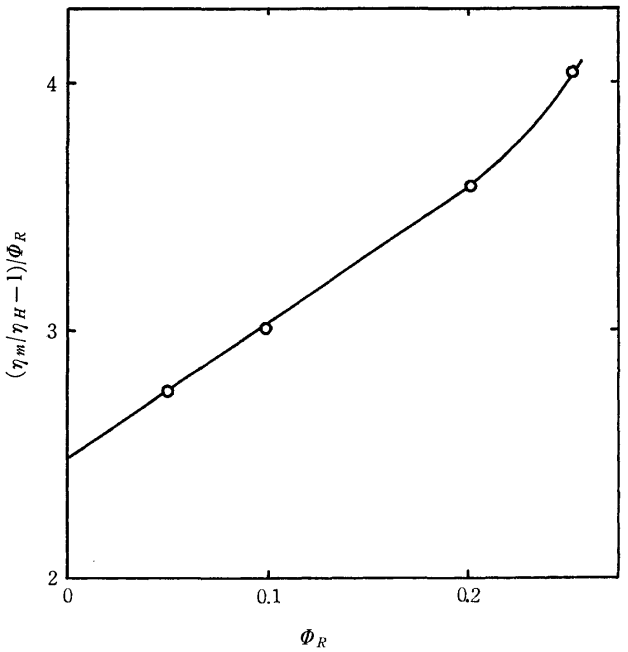

Fig. 3. Relationship between $(\eta_m/\eta_H-1)/\Phi_R$ and Φ_R at 50°C.

Temperature Dependence of Viscosities. Figure 4 shows the relationships between $(T-T_0)$ and $(T-T_0)/\log a_T$. The shift factor, a_T, which was expressed by $\eta\rho_0 T_0/\eta_0\rho T$, was calculated on the basis of an arbitrary fixed temperature, T_0. The linear relationships made it clear that the temperature dependence of the viscosities of the mixed samples could be well explained by the WLF equation.[11] The WLF parameter, $C_1{}^0$ and $C_2{}^0$, were estimated on the basis of T_0 from the linear relationships between $(T-T_0)$ and $(T-T_0)/\log a_T$ in Fig. 4.

The free-volume fraction, f_0, at T_0 and its thermal-expansion coefficient, α_f, were expressed by $1/2.303C_1{}^0$ and $1/2.303C_1{}^0C_2{}^0$ respectively. Table 3 shows the free-volume fractions, f_T, at 30°C and their thermal-expansion coefficients, α_f.

If physical interactions between n-heptadecane and oligotrifluorochloroethylene molecules or phases do not exist at all, the volume, V, and the free-volume, v_f, of the mixture may be given by simple additivity as follows:[12]

$$V = V_R + V_H \tag{5}$$

$$v_f = v_{f,R} + v_{f,H} \tag{6}$$

and $$f = v_f/(V_R+V_H) = \Phi_R f_R + (1-\Phi_R) f_H \tag{7}$$

where V_R and V_H are the substantial volumes of oligotrifluorochloroethylene and n-heptadecane in the mixture, and where $v_{f,R}$ and $v_{f,H}$ are the respective free-volumes of the components. Therefore, the temperature dependence of the free-volume fraction, f_T, at T is expressed as follows when the physical interactions do not exist at all:

$$f_T = \Phi_R[f_{0,R}+\alpha_{f,R}(T-T_0)] + (1-\Phi_R) \times [f_{0,H}+\alpha_{f,H}(T-T_0)] \tag{8}$$

12) T. Horino, Y. Ogawa, Y. Soen, and H. Kawai, *J. Appl. Polym. Sci.*, **9**, 2261 (1965).

where $f_{0,R}$ and $f_{0,H}$ are the respective free-volume fractions of oligotrifluorochloroethylene and n-heptadecane at T_0, and $\alpha_{f,R}$ and $\alpha_{f,H}$, their respective thermal-expansion coefficients.

Figure 5 shows the dependence of the free-volume fractions, f_T, of the mixture at 30°C on the volume fractions of oligotrifluorochloroethylene with the molecular weight of 910. The broken line shows

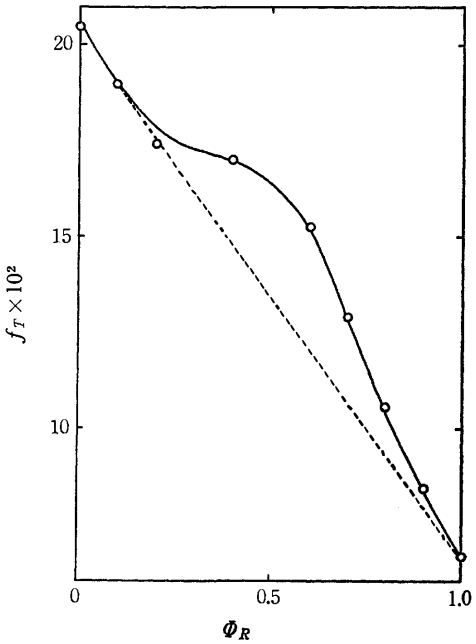

Fig. 5. Relationship between f_T and Φ_R at 30°C.

the relationship calculated by means of Eq. (7). The free-volume fractions, f_T, were larger than those obtained by assuming a simple additivity between the two components. Thus, some physical interactions between the two kinds of molecules or phases are considered to exist. In view of the physical interactions, the free-volume fraction, f_T, of a mixture is generally given by the following equation:

$$f_T = \Phi_R\beta_R(p,T,\Phi_R)f_{T,R} + (1-\Phi_R)\beta_H(p,T,\Phi_R)f_{T,H} \tag{9}$$

where the β's are interaction parameters, and p, the internal pressure induced by one phase on the other due to the difference between the thermal-expansion coefficients of the two phases. The free-volume fractions, f_T, varied abnormally at Φ_R values of about 0.2.

Molecular-weight Dependence of the Viscosities of the Mixture. Figure 6 shows the dependence of the viscosities of the mixtures on the molecular weights of oligotrifluorochloroethylene at 50°C. At molecular weights ranging from 910 to 1000, linear relationships were observed between $\log \eta_m$ and $\log M_n$. The slopes of the linear relationships were much larger than unity, and they decreased with a decrease in the volume fraction, Φ_R.

Figure 7 shows the dependence of the reciporcals of the free-volume fractions, $1/f_T$, on the molecular weights of the oligotrifluorochloroethylene in the mixtures. The reciprocals of the free-volume fractions,

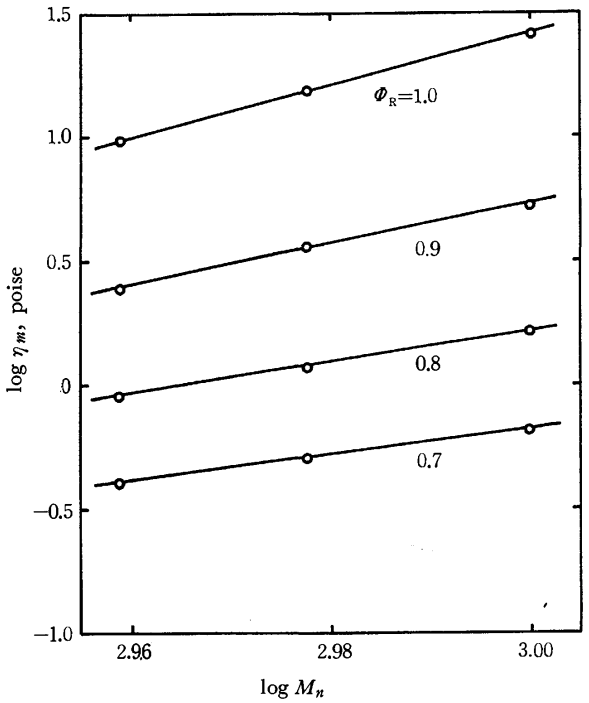

Fig. 6. Dependence of viscosity on molecular weight at 50°C.

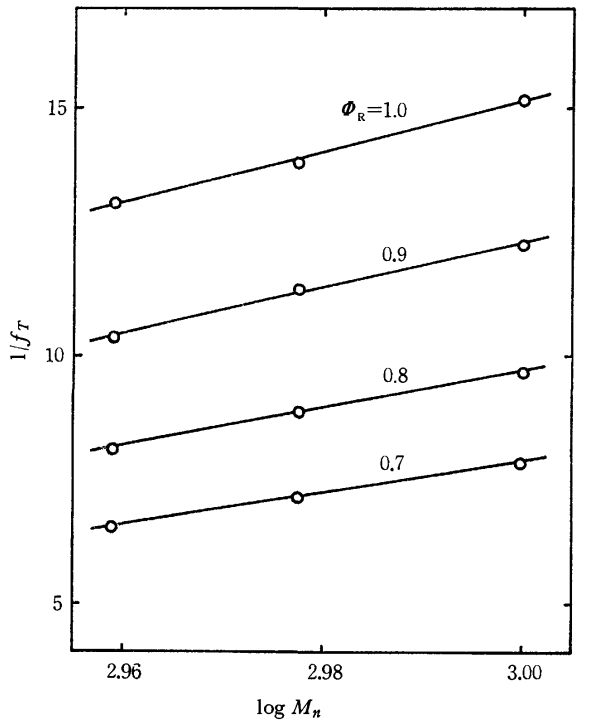

Fig. 7. Relationship between $1/f_T$ and log M_n at 50°C.

$1/f_T$, varied linearly with log M_n. The slopes of the linear relationships were much larger than unity,

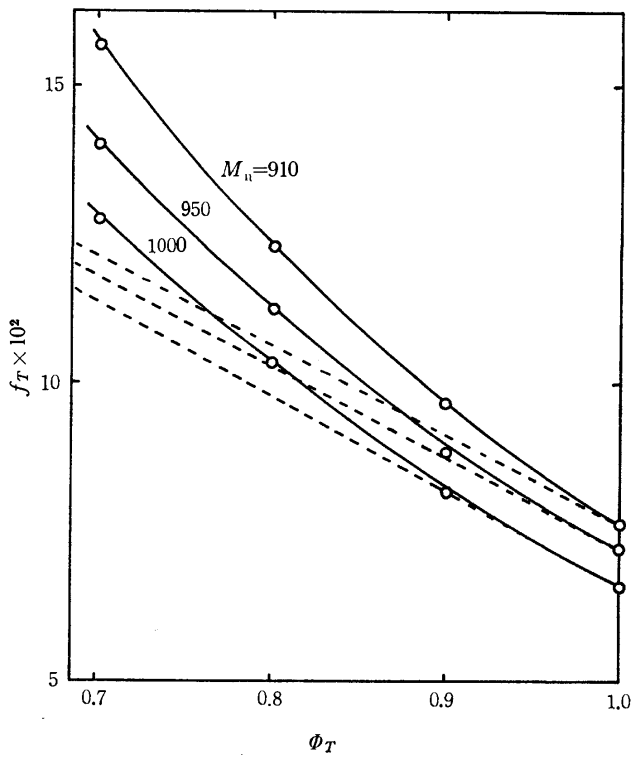

Fig. 8. Dependence of free volume fraction on Φ_T at 50°C.

and they varied with the volume fractions, Φ_R, as did those of log η_m-log M_n relationships.

Figure 8 shows a plot of the free-volume fraction, f_T, against the volume fraction, Φ_R, at 50°C. The broken lines shows the relationships calculated by Eq. (7). The estimated free-volume fractions, f_T, of the mixtures were larger than those calculated by Eq. (7), and the deviation from the calculated values increased with a decrease in the volume fraction, Φ_R, and with a decrease in the molecular weight. A negative effect on the physical interaction among oligotrifluorochloroethylene molecules is implied by the results, because the *n*-heptadecane molecules are considered to disperse among the oligotrifluorochloroethylene molecules and to obstruct the physical interaction among them. The viscosities of liquid oligotrifluorochloroethylene are larger than those of usual chain-polymers with the same chain-lengths.[4,13] Judging from the results shown in Fig. 8, strong interactions may be considered to exist. It has been suggested that these intermolecular actions are a result of the polarization of molecules induced by electronegative atoms or groups bound on the chain-skeletons.[3]

Study of Dielectric Relaxation Mechanism and Mutual Viscosity in Some Aromatic Compounds

N. K. MEHROTRA, T. C. PANT, and M. C. SAXENA
Physics Department, Lucknow University, Lucknow, India
(Received October 23, 1970)

Relaxation time and mutual viscosity of seven substituted benzenes, *p*-toludine, *o*-nitroaniline, 2,4-dichloroanisole, 2,3-dichloroanisole, 2,5-dichloronitrobenzene, 3,4-dichloronitrobenzene, and 4-chloro-1,3-dinitrobenzene have been determined in the 3.13 cm (9585 MHz) microwave region, and at three different temperatures 20, 30, and 40°C. Correlation of mutual viscosity with relaxation time leads to the conclusion that the mutual viscosity is a better representation of the resistance to the rotation of the individual solute molecule.

Investigation of dielectric relaxation in a number of organic compounds shows wide disagreement between the observed values of relaxation time and those calculated using the Debye equation.[1] This discrepancy can be explained if in the Debye equation we use a mutual viscosity parameter η_{12} representing the interaction between both solute and solvent molecules, instead of solvent viscosity η_1. The expression for the coefficient of mutual viscosity η_{12} as proved by Hill[2] is given by:

$$\eta_m\sigma_m = x_1^2\eta_1\sigma_1 + x_2^2\eta_2\sigma_2 + 2x_1x_2\eta_{12}\sigma_{12} \quad (1)$$

where η_m, η_1, and η_2 are the coefficients of viscosity of the solution, solvent and solute, respectively, and the quantities σ represent the average intermolecular distances.

On rearrangement Eq. (1) yields

$$\frac{(\eta_m\sigma_m - x_1^2\eta_1\sigma_1)}{x_2^2\sigma_2^2} = \eta_2 + 2(x_1/x_2)\cdot(\sigma_{12}/\sigma_2)\eta_{12} \quad (2)$$

This equation represents a straight line and its slope gives mutual viscosity η_{12}.

It is interesting to note that an expression involving mutual viscosity η_{12} was also proposed by Vaughan and his co-workers.[3] The results obtained using this expression are in good agreement with those obtained using Hill's equation. Their equation in the present notation is

$$\eta_m = x_1^2\eta_1 + x_2^2\eta_2 + 2x_1x_2\eta_{12} \quad (3)$$

which yields on rearrangement, the relation

$$\frac{(\eta_m - x_1^2\eta_1)}{x_2^2} = \eta_2 + 2x_1/x_2\cdot\eta_{12} \quad (4)$$

The slope of this straight line gives the mutual viscosity.

A good approximation of the relation between the viscosity and relaxation-time was suggested by Kalman and Smyth,[4] who found that the equation

$$\tau = \frac{c'}{T}\eta^{\alpha} \quad \text{where} \quad \alpha = \Delta H\tau/\Delta H\eta$$

gives very satisfactory results over a small temperature range. We have used this equation for a comparative study.

The free energies of activation for the process of dipole orientation and viscous flow have also been calculated using Eyring's equation.[5,6]

Experimental

Chemicals. All the compounds used are of pure quality, obtained from Messrs British Drug House. Purest quality analar benzene obtained from Messrs B.D.H. was distilled before use.

The dielectric constant ε' and the loss factor ε'' were measured using the standing wave technique of Roberts and Von Hippel[7] and its subsequent simplification by Dakin and Works.[8] The estimated accuracies in the measurements of ε' and ε'' were $\pm1\%$ and $\pm5\%$, respectively. The relaxation time was then determined using the concentration variation method of Gopala Krishna.[9]

Viscosities were measured to an accuracy of $\pm2\%$ with a Hoppler precision viscometer. This method requires the determination of time of fall of a glass or metal ball between two marks in a glass tube filled with a liquid with known density. Viscosity η_m of the liquid is calculated using the relation

$$\eta_m = F(S_K - S_F)K \quad (5)$$

where F is the time of fall of the ball in seconds, S_k is the specific gravity of the ball, S_F is the specific gravity of the liquid, and K is the ball constant (=0.009495).

Results and Discussion

Table 1 contains the values of relaxation time τ, mutual viscosity η_{12}, and ratios $T\tau/\eta$, $T\tau/\eta_{12}$ and $T\tau/\eta\alpha$. The values of the relaxation times and molar activation energy parameters at different temperatures are given in Table 2.

The relaxation time of *p*-toluidine is found to be smaller than that of *o*-nitroaniline. This can be explained on the basis that the intramolecular rotation of the $-NH_2$ group is comparatively less hindered by the $-CH_3$ group at the para position than by the $-NO_2$ group at the ortho position in the latter molecule. Further, the variation of relaxation time is in accordance with the

variation of their molecular volumes. 2,3-Dichloroanisole exhibits a larger relaxation time than 2,4-dichloroanisole, although the size of the two molecules is the same. This can be explained by considering the fact that both molecules contain $-OCH_3$ group at the ortho position, which is capable of intramolecular rotation round its bond with the benzene ring. The rotation of $-OCH_3$ group experiences greater steric hindrances due to the neighbouring chloro groups in 2,3-dichloroanisole than in 2,4-dichloroanisole, resulting in a greater relaxation time in the former molecule.

It is observed from the table that the relaxation time of 2,5-dichloronitrobenzene is smaller than that of 3,4-dichloronitrobenzene, which can be concluded from the consideration that the volume swept out for dipole orientation by the former molecule is also smaller. The largest relaxation time of 4-chloro-1,3-dinitrobenzene among all other compounds investigated can be attributed to its biggest size and the strong polarity of the $-NO_2$ groups.

It is apparent from Table 1 that the ratio increases with the rise of temperature for nearly all the compounds investigated. This is not in conformity with the Debye theory which requires the ratio to be constant for small change of temperature. The anomaly is explained if η_{12} the mutual viscosity of the solute and solvent is used instead of solvent viscosity η_1. The variation in the values of ratios $T\tau/\eta_{12}$ and $T\tau/\eta\alpha$ at different temperatures is negligibly small and this leads us to conclude that either η_{12} or η_1^{α} gives a more convincing account of the resistance confronted by the individual solute molecules during the process of rotation.

The values of the average mutual viscosity η_{12} as determind from Eq. (4) of Vaughan and co-workers are almost equal to those obtained using Hill's equation (2). This is because the form of the two equations is very nearly the same. We have determined the values of η_{12} for chlorobenzene using Eqs. (2) and (4). For chlorobenzene in benzene, Eq. (2) gives 0.74, while Eq. (4) gives 0.73. This indicates a fairly good agreement in the values of η_{12} obtained using the two equations.

The free energies of activation for dipole orientation and viscous flow are found to increase with the rise of temperature while the relaxation time decreases. An explanation is furnished from the consideration that with the rise of temperature, thermal agitation increases, resulting in the increase of the activation energies. Similar results have also been concluded by Shukla and Coworkers[10] for some substituted benzaldehydes. The negative value of the entropy of activation found for most of the compounds investigated indicates that there are fewer configurations possible in the activated state and for these configurations the activated state is more ordered than the normal state. A comparison of the activation energies for the viscous flow using solvent viscosity η_1 and mutual viscosity η_{12} show that $\Delta F_{\eta_{12}}$ is a better representation of the potential barriers offering inner friction to the rotating molecules.

The higher values of ΔF_η as compared to $\Delta F\tau$ indicate that while the process of dipole orientation involves only the rotation of the molecules, the process of viscous flow involves both rotation and translation. Similar results were observed earlier in the case of substituted pyridines.[11]

Self-Diffusion of Chloride Ions in Manganese Dichloride Crystallites

Yoshihiro SENSUI

Institute for Atomic Energy, Rikkyo (St. Paul's) University, Yokosuka

(Received June 19, 1971)

The self-diffusion of chloride ions in the powdery crystals of manganese dichloride was studied in the temperature range of 200—420°C by the use of the isotopic-exchange method. The activation energies for self-diffusion were determined to be 0.95 and 1.6 eV in a lower and a higher temperature region respectively. From these, the activation energy for the migration of chloride ions and the formation energy of an anion vacancy or a pair of an anion and a cation vacancy were deduced.

The method of the isotopic-exchange reaction between gaseous molecules and ionic crystals is very useful to the investigation of the self-diffusion of ions in crystals. By this method, the self-diffusion of halide ions in alkali halide crystals has been investigated by several workers[1-5] Laurent and Benard[1] and Barr *et al.*[2-4] have studied mainly the diffusion in the bulk of the crystals, while Takaishi and the present author have studied that of chloride ions in the bulk of sodium chloride and rubidium chloride crystallites, along with the surface exchange reaction[5]. There have, however, been few studies of higher valent metal halide crystals, except for the qualitative studies by Willard and his co-workers.[6-8]

In the present work, the self-diffusion of chloride ions in manganese dichloride crystallites was investigated as a first step in the study of a series of higher valent metal chlorides; we chose this material because it is relatively easy to handle because of its layer structure, its low volatility, and presumed surface homogeneity. Larher studied the adsorption of krypton on several kinds of crystallites with $CdCl_2$-type structures and concluded that their surface were very homotattic.[9] Manganese dichloride, which he did not study has the same structure and may be presumed to have a homotattic surface on the basis of the electron microscopic data (Fig. 1).

Experimental

The apparatus and technique for measuring the self-diffusion of chloride ions by the isotopic-exchange method were described in previous papers.[5] The diffusion measurements were carried out on five specimens of powdery crystals.

Radioactive manganese dichloride was prepared in the form of an aqueous solution from radioactive hydrochloric acid distilled in a vacuum and manganese dichloride (Merks G.R.-reagent, Item No. 5927) by the isotopic-dilution method. In the resultant radioactive chloride, the ratio of ^{36}Cl to Cl was 5.3×10^{-4}.

Anhydrous crystallites of radioactive manganese dichloride were prepared by modifying Marshall's method,[10] *i.e.*, by pouring 100 m*l* of distilled ethyl ether into about 2 m*l* of an anhydrous ethanol solution of manganese dichloride and then baking the precipitate at 420°C for 6 hr in vacuum (3×10^{-7} Torr) prior to the experiment. An electronmicrograph of the anhydrous specimen is shown in Fig. 1. The characteristic layer structure appeared even in the external shape of the crystallites.

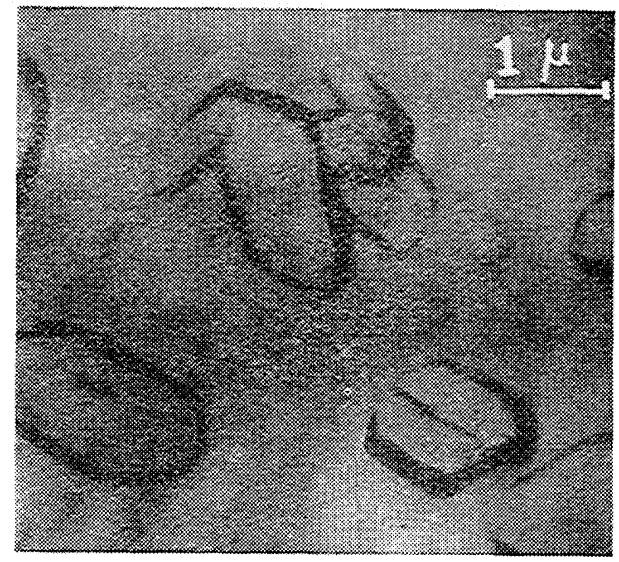

Fig. 1. The external shape of the manganese dichloride crystallites used in the present experiment.

Results and Discussion

Manganese dichloride melts at 650°C and begins to sublime at about 450°C in a vacuum. Therefore, the anion-diffusion measurements were carried out in the temperature range between 200 and 420°C.

At the initial stage of the reaction, only chloride ions near the surface region participate. Accurate data with manganese dichloride were not obtained in this stage, in contrast with the case of alkali chlorides, but it was concluded that the reaction proceed at a high rate. At the later stage, the reaction may be rate-controlled by the bulk-diffusion process. The mean length of the shorter edge of the layer-structural crystallites is estimated from the electronmicroscopic

data to be about 0.5 μ (*cf.* Fig. 1). This length corresponds to a few thousand layer in the direction of the *c*-axis of the crystal. In the present experiments, only the ^{36}Cl ions in the bulk of the near-surface gaseous phase; *i.e.*, amounts corresponding to less than 50 layers were counted. Therefore, the diffusion data obtained may be analyzed on the basis of the model of semi-infinite media. For this model, the diffusion equation has the solution;[11]

$$X_g = X_s + 2\alpha(Dt/\pi)^{1/2}$$

where X_g designates the number of ^{36}Cl ions diffused out into the gaseous phases after time t; X_s, that of the ^{36}Cl ions in the surface region which diffused out into the gaseous phase at the initial stage of the reaction; D, the bulk diffusion constant; and α, the product of the surface area and the initial concentration of ^{36}Cl. Denoting the measured counting rate by C, we obtain;

$$C = K \cdot X_g$$

and;

$$C_s = K \cdot X_s$$

where K is the conversion factor. Thus, we obtain;

$$C = C_s + \frac{2\alpha}{K} \cdot \left(\frac{Dt}{\pi}\right)^{1/2}$$

in which the value for C_s cannot be obtained directly from experiments. The exchange process may be expected to be rate-controlled by the bulk-diffusion, and the curve of C against $\sqrt{t}$ may be linear, except at the initial stage. However, there are some ambiguties as to the start of the reaction. The measured time, t, must be corrected; that is, t is replaced by $(t+\delta)$, where the value of δ is determined empirically so as to give a linear curve. The results are given in Fig. 2, in which the intersection of the straight line with the coordinate give the value of C_s.

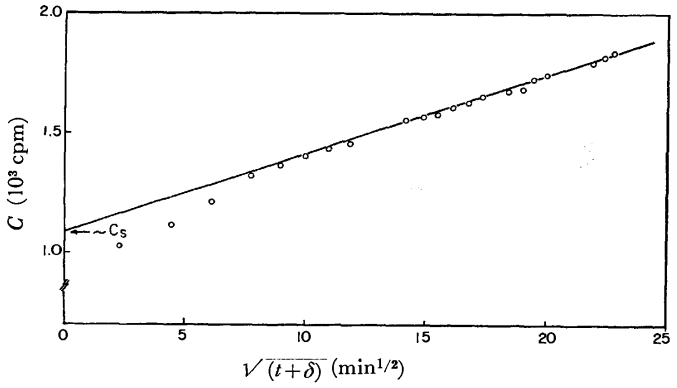

Fig. 2. The plots of C against the square-root of $(t+\delta)$. The data are obtained from the specimen IV at 200°C.

Next, let us suppose that a first diffusion run is made for time t_1 at a temperature T_1 at which the diffusion constant is D_1. If a second run is made for t_2 at a different temperature T_2 (the constant is new D_2), the total counting rate, C, may be shown to be;[11]

$$C = C_s + \frac{2\alpha}{\sqrt{\pi} \cdot K} \cdot (D_1 t_1 + D_2 t_2)^{1/2}.$$

11) A. B. Lidiard and K. Tharmalingam, *Discuss. Faraday Soc.*, **28**, 64 (1959).

This may be extended to further runs and rewritten as follows;

$$(C - C_s)^2 = \frac{4\alpha^2}{\pi K^2} \cdot (D_1 t_1 + D_2 t_2 + \cdots).$$

The values of $(C-C_s)^2$ thus obtained are plotted against the time in Fig. 3. The measured points lie well on the straight lines. If the crystallites contained a lot of dislocations along which diffusion proceeded much faster, complex curve be obtained; that is, the plots of $(C-C_s)^2$ against the time should not fall a straight line when the temperature is changed. This is not the present case, and so it may be concluded that the present model is adequately supported experimentally.

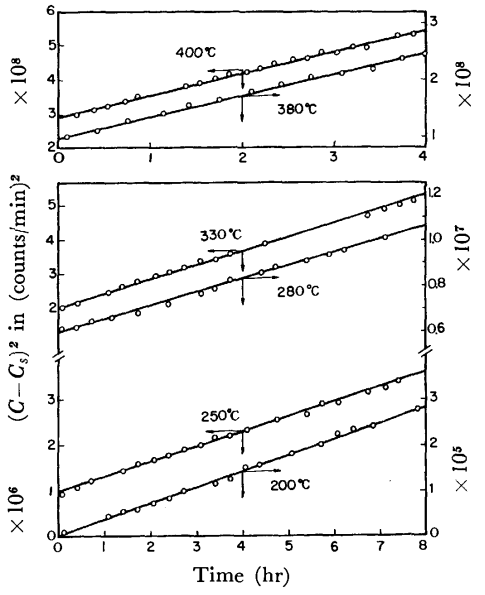

Fig. 3. The plots of $(C-C_s)^2$ against time. All data in this figure are obtained from the specimen IV.

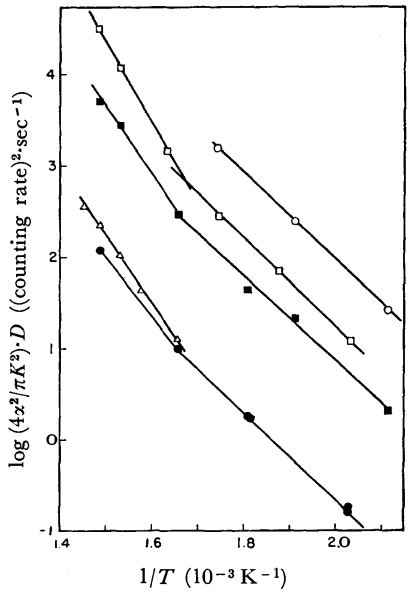

Fig. 4. The Arrhenius plots of apparent self-diffusion rates. ○, ●, □, ■, and △ refer to different specimens, I, II, III, IV, and V respectively.

From the slopes of $(C-C_s)^2$ against the time, the values of $(4\alpha^2/\pi K^2)\cdot D$ can be obtained. The Arrhenius plots of these values are shown in Fig. 4, in which all the curves have break at about 330°C and two kinds of slopes are found. The temperature of the break-point is considerably lower than in the case of alkali chlorides.[1-3] The slope in the lower-temperature region in Fig. 4 gives the activation energy, ΔE, for the migration of ^{36}Cl ions, while that in the higher-temperature region gives $(\Delta E+\Delta W)$, where ΔW denotes the formation energy of an anion vacancy, or a half of that of an anion and a cation vacancy. The values for the activation energies of all the specimens are given in Table 1. The absolute value of D depends on the surface area of the specimen, which was not controlled in the present experiment. Hence, it was possible to determine with confidence only the activation energy in the diffusion process, not the frequency factor. However, if crude estimation from the electronmicroscopic data are used for the surface area of the sample, values, 2×10^{-3} cm^2 sec^{-1} and 1×10^{-8} cm^2 sec^{-1}, are given to the frequency factors corresponding to the formation of a vacancy and the migration of ^{36}Cl respectively. Both of these values are small in comparison with the corresponding values[5] in the crystallites of alkali chlorides, but they are not unreasonable.

Table 1. The value of activation energy for each specimen

Specimen	ΔE (eV)	$\Delta E+\Delta W$ (eV)
I	0.95	
II	0.95	
III	0.96	1.77
IV	0.95	1.50
V		1.58
Average	0.95	1.6

The author's sincere thanks are due to Professor Dr. T. Takaishi of Rikkyo (St. Paul's) University for his valuable discussions.

The Photo-decomposition of 1-Azidopyrene in the Benzene Solution

Tsuguo YAMAOKA,
Department of Printing, Faculty of Engineering, Chiba University, Chiba
Hiroshi KASHIWAGI, and Saburo NAGAKURA
The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received June 25, 1971)

1-Nitrenopyrene (Py-N) was produced by the photo-decomposition of 1-azidopyrene (Py-N_3) in the benzene solution at 77°K and at room temperature. At 77°K, Py-N was found to be stable, and its electronic absorption and ESR spectra were measured. The result shows that its ground state is triplet and the fine structure constant, D, is equal to 0.73 cm^{-1}. At room temperature, 1-nitrenopyrene was found to be converted easily into 1,1′-*trans*-azopyrene (*trans*-Py-N=N–Py) in the oxygen-free benzene solution and into 1-nitropyrene (Py-NO_2) in addition to Py-N=N-Py in the oxygen-containing benzene solution. The decay process of Py-N as a reaction intermediate and the formation processes of the reaction products were studied by the flash-photolysis technique, and from an analysis of the results, the rate constants at 23°C were determined to be 2.1×10^9 $l mol^{-1} sec^{-1}$ and 1.4×10^3 sec^{-1} for 2Py–N→*trans*-Py–N=N–Py and for Py–N+O_2→Py-NO_2, respectively.

Nitrenes produced by the photo-decomposition of the corresponding azides are known to be triplet in their ground states.[1-3] Most of the measurements on the nitrenes have hitherto been made in rigid solutions at low temperature;[4-8] studies of them in fluid solutions are few in number.

The flash-photolysis experiment has demonstrated that they exist as transient intermediates in several photochemical reactions of organic azides.[9-11] In particular, Reiser *et al.*[11] studied kinetically three types of reactions of nitrenes, recombination, hydrogen abstraction from a solvent, and reaction with an azido group, taking 1-nitrenonaphthalene, 4,4′-dinitrenobiphenyl, and 1-nitrenoanthracene.

In the present paper, we studied the electronic absorption and ESR spectra of a new nitrene, 1-nitrenopyrene (hereafter to be abbreviated to Py-

N), and also its decay process in a benzene solution. We adopted this nitrene as a suitable research subject for the following reasons. Firstly, the photodecomposition quantum yield of the parent azide, 1-azidopyrene(Py-N_3), is very large. Secondly, since the absorption peaks characteristic of Py-N_3, Py-N, and a main final product appear at 360 nm, 415 nm, and 500 nm, respectively, we can easily distinguish the components from one another and can easily follow the reaction process.

Experimental

1-Azidopyrene was prepared by treating the 10% hydrochloric acid solution of 1-aminopyrene with aqueous sodium nitrite and srdium azide solutions below 5°C. The precipitation separated by the filtration of the solution was purified by the aid of a column chromatograph of active alumina.

Commercially-available benzene of a GR grade was purified by shaking it with concentrated sulfuric acid, water, an aqueous sodium hydroxide solution, an aqueous potassium permanganate solution containing sodium hydroxide, and water. The benzene thus treated was dehydrated by calcium chloride and thereafter by sodium metal, and finally it was distilled.

In the present study, the nitrene was prepared in both rigid and fluid benzene solutions. The rigid solution of the parent azide in benzene was illuminated by a 500 W mercury lamp at 77°K. The ESR spectrum of the nitrene thus prepared was measured by a JES ME 3X type spectrometer (X-band, 100 KHz modulation). Since the rigid benzene solution is somewhat opaque for cracking, its electronic absorption spectrum was measured by the aid of the special technique developed by Shibata.[12] Actually, the spectrum was measured by a Shimadzu MPS type spectrophotometer at the Institute of Physical and Chemical Research, an apparatus constructed especially to make possible the application of his method.

The preparation of the nitrene from a fluid benzene solution containing Py-N_3 and the measurement of its electronic absorption spectrum were made by the aid of a flash photolysis apparatus (32 Joule, duration time of 20 μsec) at the Institute of Physical and Chemical Research,[13,14] a cylindrical quartz sample cell 10 cm long and 1 cm in diameter being used. The electronic absorption spectrum was photographed at several stages before and after the flash photolysis.

The decay curve of a transient intermediate and the rise curve of the final product, Py-N=N-Py, in a benzene solution at room temperature were recorded at their peak wavelengths by the aid of an R106 photomultiplier and an oscilloscope.

Final products were separated by the aid of a column chromatography of active alumina, and each component was identified by an elemental analysis, by studying the mass spectrum, and, if possible, by comparing the electronic spectrum, the infrared spectrum, and the gas chromatogram with those of an authentic sample.

The oxygen-free solution, if necessary, was prepared by the freeze-thaw technique.

Results and Discussion

Electronic and ESR Spectra of Irradiated Py-N_3 in the Rigid Benzene Solution at 77°K. The electronic absorption and ESR spectra were measured at 77°K with the benzene solution of Py-N_3 (2.7×10^{-4} mol/l) irradiated by a 500W mercury lamp; the results are shown in Figs. 1 and 2, respectively.[15]

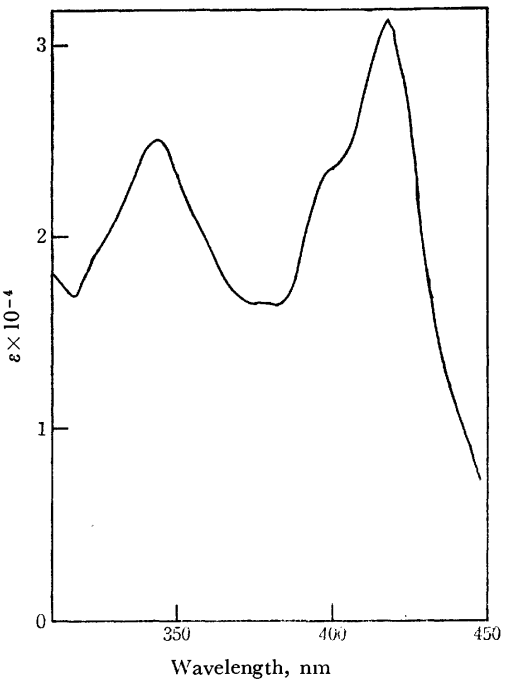

Fig. 1. The electronic absorption spectrum of Py-N in benzene at 77°K.

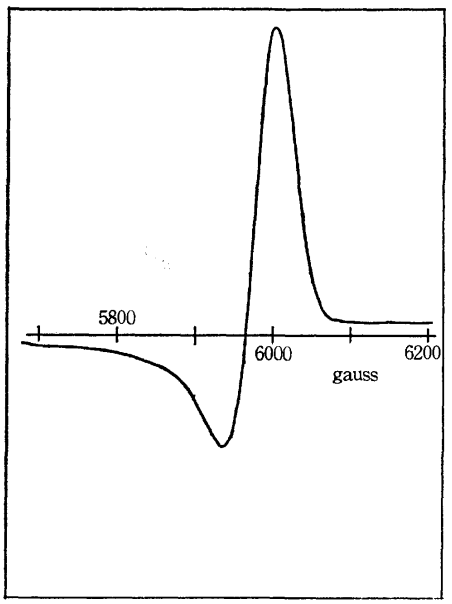

Fig. 2. The ESR spectrum of Py-N in benzene at 77°K.

15) We observed another weak absorption band at 694 nm with a molar extinction coefficient of ~1500 in addition to the strong absorption bands shown in Fig. 1. In the present paper, however, we are concerned with only the strong bands.

The main feature of the ESR spectrum shown in Fig. 2 is that a single, rather broad line appears in a high field (5980 G). This feature is similar to that of the spectra observed for other ground-state triplet nitrenes[1,3] with quite large D and quite small E values. This means that the ESR spectrum shown in Fig. 2 and, therefore, the electronic absorption spectrum shown in Fig. 1 are due to the triplet Py-N. The D value of Py-N was found to be 0.73 cm^{-1} on the reasonable assumptions that $E=0$ and that $g=g_e=2.0023$.[16]

Flash Photolysis of Py-N_3 in Benzene. Figure 3 shows the microphotometer curves of photographs obtained by the flash photolyis of the oxygen-free benzene solution of Py-N_3 ($\sim 1\times10^{-5}$ mol/l). Curves (a), (b), and (c) in this figure are the spectra of the solution taken before, 20 μsec after, and a few minutes after the flash excitation, respectively. Since curve (b) is identical with the spectrum of Py-N shown in Fig. 1, it is evident that Py-N is produced as a transient intermediate in the photoreaction of Py-N_3 in the oxygen-free benzene solution.

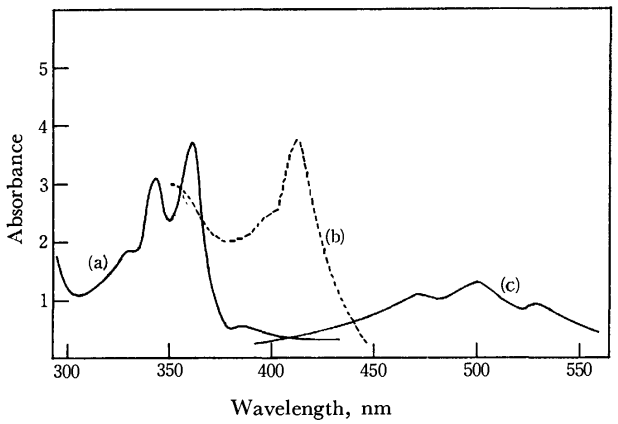

Fig. 3. The microphotometer traces of the absorption spectra measured by the aid of the flash photolysis technique with Py-N_3 in the oxygen-free benzene solution at room temperature.
(a): before a flash irradiation
(b): 20 μsec after a flash
(c): a few minutes after a flash

A final product was isolated from the solution by the aid of the active alumina-column chromatography technique. From the infrared spectrum, and also from a consideration of the electronic absorption spectrum to be described below, the final product was identified with 1,1′-*trans*-azopyrene (abbreviated hereafter to *trans*-Py-N=N-Py).

By stationary irradiation by a mercury lamp of Py-N_3 in an oxygen-free benzene solution at room temperature, we obtained two final products, dark-red and reddish-yellow crystals which were separated from each other by the aid of the active alumina-column chromatography technique in the dark.[17] The elemental analysis of the dark red sample[18] and the mass spectra[19] and infrared spectra[20] of both products show that they have the same chemical composition, Py-N=N-Py. The reddish-yellow crystal is easily converted into the dark red one by warming it from room temperature to ~100°C or by exposing it to sunlight. From these facts, it may be surmised that they are *trans*- and *cis*-Py-N=N-Py. The electronic absorption spectra observed for the dark-red and reddish-yellow samples are shown by curves (a) and (b) in Fig. 4, respectively. In view of the general feature of the electronic absorption spectra that the strongest band of the *trans*-isomer is stronger and appears in a longer-wavelength side than that of the *cis*-isomer, curve (a) in Fig. 4 is due to *trans*-Py-N=N-Py.[21] Since curve (c) in Fig. 3 is identical with this curve, the final product obtained by the flash irradiation of the oxygen-free benzene solution of Py-N_3 is identified with *trans*-Py-N=N-Py.

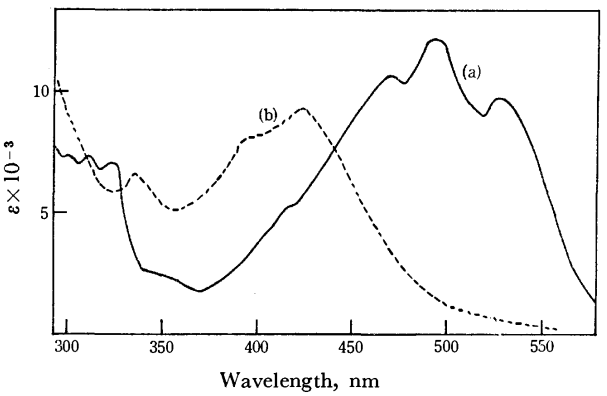

Fig. 4. The electronic absorption spectra of azopyrene.
(a): *trans*-azopyrene
(b): *cis*-azopyrene

The microphotometer curves of photographs obtained by flash photolysis measurements for Py-N_3 ($\sim 1\times10^{-5}$ mol/l) in oxygen-containing benzene solutions are shown in Fig. 5. Curves (a), (b), and (c) in this figure are spectra observed for the solution before, 20 μsec after, and a few minutes after the flash excitation, respectively. Curve (b) in Fig. 5

16) Observed slight broadening in the ESR spectrum of Py-N shows that E is non-zero but is very small. The previously reported E values of nitrenes do not exceed 0.01 cm^{-1}.[3] Therefore, the D value of Py-N may be evaluated by assuming $E=0$ cm^{-1}. Wasserman *et al.* (E. Wasserman, L. C. Snyder, and W. A. Yager, *J. Chem. Phys.*, **41**, 1763 (1964)) could reproduce well by simulation the observed ESR spectrum of methylsulfonylnitrene taking $g=2.0023$. Generally speaking, triplet states of organic molecules have the g value close to 2.0023.

17) Toluene was used as a developing agent. After removing undecomposed Py-N_3, the dark red and reddish yellow parts of the column were cut. The products were extracted by tetrahydrofuran, recrystallized from toluene, washed by toluene and ethyl ether, and finally dried *in vacuo*. All these processes were done in the dark.

18) Found: C, 88.31; H, 4.15; N, 6.59%. Calcd for $C_{32}H_{18}N_2$ (Py-N=N-Py): C, 89.28; H, 4.21; N, 6.51%. A discrepancy between the found and calculated values for carbon may be due to a very small amount of water contained in the sample.

19) Both isomers show a mass spectrum with a signal corresponding to molecular weight of 430.

20) The N=N stretching vibrations were observed for these two isomers in nujol mull.

is identical with the spectrum of Py-N given in Fig. 1. Therefore, we can conclude that Py-N is a transient intermediate in the photoreaction of Py-N_3 also in the oxygen-containing benzene solution.

In the case of the oxygen-containing benzene solution, we isolated two final products by the aid of column chromatography of active alumina. These procucts were identified with *trans*-Py-N=N-Py and 1-nitropyrene (Py-NO_2); the former was confirmed by comparing its electronic spectrum with that of *trans*-Py-N=N-Py given in Fig. 4(a), and the latter by comparing its electronic and infrared absorption spectra and its gas chromatogram with those of the authentic sample. Curve (c) in Fig. 5 consists of the absorption peaks due to *trans*-Py-N=N-Py given by curve (c) in Fig. 3 and the 400-nm peak of Py-NO_2.

Kinetic Study of the Reaction Process. From the identification of the transient intermediate and the final products, the following reaction mechanisms may applied to for the photoreaction of Py-N_3 in benzene:

for the oxygen-free benzene solution:

$$\text{Py-N}_3 \xrightarrow[\text{fast}]{h\nu} \text{Py-N} + \text{N}_2 \tag{1}$$

$$\text{Py-N} + \text{Py-N} \xrightarrow{k_2} \text{Py-N=N-Py} \tag{2}$$

for the oxygen-containing benzene solution:

$$\text{Py-N}_3 \xrightarrow[\text{fast}]{h\nu} \text{Py-N} + \text{N}_2 \tag{1'}$$

$$\text{Py-N} + \text{Py-N} \xrightarrow{k_2'} \text{Py-N=N-Py} \tag{2'}$$

$$\text{Py-N} + \text{O}_2 \xrightarrow{k_3} \text{Py-NO}_2 \tag{3}$$

From Eq. (2), the following equation can be derived for the oxygen-free benzene solution:

$$k_2 t = \frac{1}{x} - \frac{1}{a} \tag{4}$$

where a and x are the concentrations of Py-N at the start of reaction (2) and at the reaction time, t, respectively, and k_2 is the rate constant for reaction (2). By replacing x and a by A_0 and A, respectively, the latter being the absorbances of Py-N observed at the start of the reaction and at the reaction time t, we can obtain the following equation:

$$k_2 t = \frac{\varepsilon L}{A} - \frac{\varepsilon L}{A_0} \tag{4'}$$

Here, L is the length of the sample cell, and ε is the molar extinction coefficient of Py-N at an appropriate wavelength. In actuality, A, A_0, and ε were measured at 415 nm. The ε value at this wavelength was determined to be 3.0×10^4 from the electronic spectrum of Py-N shown in Fig. 1.

In view of the fact shown by Eq. (2) that one Py-N=N-Py molecule is produced from two Py-N entities, the following equation concerning the concentration of the final product can be obtained:

$$k_2 t = \frac{\varepsilon' L}{2(A'_\infty - A')} - \frac{\varepsilon' L}{2A'_\infty} \tag{4''}$$

where A'_∞ and A' are the absorbances of *trans*-azopyrene at the final stage and at the reaction time t, respectively, and ε' is the molar extinction coefficient of *trans*-azopyrene. These quantities were measured at 470 nm, and ε' at this wavelength was determined to be 1.1×10^4 from the spectrum of the authentic sample shown in Fig. 4(a).

For the oxygen-containing benzene solution, equations similar to Eqs. (4), (4'), and (4'') hold approximately at the initial stage of the reaction. At the stage of the reaction latter than $t\sim400$ μsec, the process shown by Eq. (3) becomes predominant. Since the concentration of oxygen in the solution is $\sim10^{-2}$ mol/l,[22] much larger than that of Py–N ($\sim10^{-5}$ mol/l), the following equations can be derived from Eq. (3):

$$\log x' = \log a' - k_3' t' \tag{5}$$

$$k_3' t' = \log A_0'' - \log A'' \tag{5'}$$

where t' is the reaction time, the origin of which is shifted by ~600 μsec from that of t, a', and x' are the concentrations of Py–N at $t'=0$ and at the reaction time t', respectively, and the corresponding absorbances are shown by A_0'' and A'', respectively. Furthermore, $k_3'=k_3[O_2]$, the concentration of oxygen dissolved in the solution at room temperature being represented by $[O_2]$.

For the purpose of confirming the above mechanism, the kinetic measurements were made for the reaction intermediate, Py–N, and also for the reaction products.

In the case of the photo-decomposition in an oxygen-free benzene solution, the time-dependences of the spectral intensities of Py–N at 415 nm and of Py–N=N–Py at 470 nm were measured by the photometric method until 1 msec after the flash irradiation. The result is shown in Fig. 6.

The plots of $(1/A)$ against t give a straight line, as is shown in Fig. 6(a). This means that Eq. (4') holds well for the oxygen-free benzene solution. From the

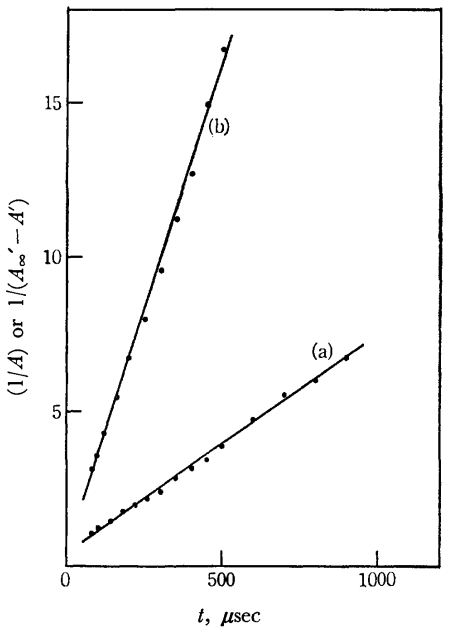

Fig. 6. The time-dependences of the absorption intensities of Py-N and Py-N=N-Py observed for the flash-irradiated Py-N_3 in the oxygen-free benzene solution at 23°C.
(a): $(1/A)$-t plots
(b): $1/(A'_\infty - A')$-t plots

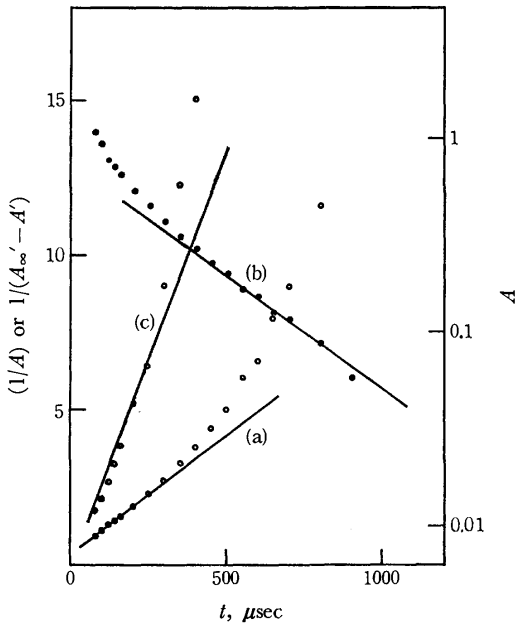

Fig. 7. The time-dependencies of the absorption intensities of Py-N and Py-N=N-Py observed for the flash-irradiated Py-N_3 in the oxygen-containing benzene solution at 23°C.
(a): $(1/A)$-t plots
(b): $\log A$-t plots
(c): $1/(A'_\infty - A')$-t plots

slope of the line, k_2 is determined to be $(2.1\pm0.2)\times 10^9 l\cdot\text{mol}^{-1}\text{sec}^{-1}$ at 23°C. The plots of $1/(A_\infty'-A')$ against t shown in Fig. 6(b) also give a straight line satisfying Eq. (4″), and the rate constant, k_2' is determined from its slope to be $(1.9\pm0.2)\times 10^9 l$ mol^{-1} sec^{-1} at 23°C. This value obtained from the formation velocity of Py–N=N–Py coincides, within the limits of experimental error, with the rate constant obtained from the decay velocity of Py–N. The above-mentioned facts lead to the conclusion that the mechanism given by Eqs. (1) and (2) is satisfied for the photo-decomposition of Py–N_3 in an oxygen-free benzene solution.

Let us turn to the oxygen-containing benzene solution. A decrease in the absorbance, A, with the time was observed at 415 nm for Py–N in this solution; the result is shown in Fig. 7. Curves (a) and (b) in this figure show the $(1/A)$ *vs.* t and $(\log A)$ *vs.* t plots, respectively. These curves indicate that the decrease in A with time is of the second order at the earlier stage of the reaction and of the first order at the stage later than 600 μsec after the flash illumination. The former satisfies Eq. (4) with $k_2'=(2.1\pm0.2)\times 10^9$ l $\text{mol}^{-1}\text{sec}^{-1}$ and the latter Eq. (5) with $k_3'=(1.4\pm 0.2)\times 10^3\ \text{sec}^{-1}$.[23] According to Eq. (2′), the reaction product, *trans*-azopyrene, is formed parallel with the decay of Py–N. This formation process was also followed by measuring A' at 470 nm, and the $1/(A_\infty'-A')$ values were plotted against t; the result is shown by curve (b) in Fig. 7. This curve shows that the formation process follows Eq. (2′) with $k_2=(1.7\pm0.2)\times 10^9\ l\cdot\text{mol}^{-1}\text{sec}^{-1}$. This value agrees, within the limits of experimental error, with the value obtained from the time-dependence of A. The above facts support the reaction mechanism given by Eqs. (1′), (2′), and (3) for the photo-decomposition of Py–N_3 in the oxygen-containing benzene solution.

We should like to express our thanks to Dr. Masashi Imamura and Dr. Akira Kira, The Institute of Physical and Chemical Research, for their kindness in permitting us to use the flash-photolysis apparatus and for many valuable discussions. We are also greatly indebted to Dr. Kazuo Shibata and Dr. Teruo Ogawa, The Institute of Physical and Chemical Research, for their kindness in measuring the absorption spectra of the opaque benzene solutions at the liquid nitrogen temperature.

23) We also tried to obtain the rate constant for the oxygen-containing benzene solution of Py–N_3 according to another analytical method. From Eqs. (2′) and (3), we obtain

$$-\frac{dx}{dt} = k_2'x^2 + k_3'x \qquad \text{(a)}$$

From Eq. (a), the following relations can be derived

$$\frac{k_2'}{k_3'} + \frac{1}{x} = \left(\frac{k_2'}{k_3'} + \frac{1}{a}\right)e^{k_3't} \qquad \text{(b)}$$

or

$$\frac{1}{A} = \frac{1}{\varepsilon L}\left(\frac{k_2'}{k_3'} + \frac{1}{a}\right)e^{k_3't} - \frac{k_2'}{\varepsilon L k_3'} \qquad \text{(b′)}$$

Firstly we evaluated the value of k_3' according to Eq. (5′) and Fig. 7(b). Using this value of k_3', we plotted $1/A$ against $\exp(k_3't)$ and obtained a straight line, the intercept and the slope of which gave k_2'. The value was determined to be $2.15\times 10^9\ l\cdot\text{mol}^{-1}\text{sec}^{-1}$ and $2.08\times 10^9\ l\cdot\text{mol}^{-1}\ \text{sec}^{-1}$, respectively. Both agree with the values obtained from Eqs. (4′) and (4″): But we could not determine precisely a, the initial concentration of Py–N immediately after a flash, from the slope of this straight line. This is because k_2'/k_3' is much greater than $1/a$.

The Exchange Reaction of Deuterium with the Hydroxyl Groups of Zeolite Catalysts

Toshinobu IMANAKA, Yasuaki OKAMOTO, Kazunori TAKAHATA, and Shiichiro TERANISHI

Osaka University, Department of Chemical Engineering, Faculty of Engineering Science, Toyonaka, Osaka

(Received June 28, 1971)

In order to estimate the reactivity of each hydroxyl group, the exchange reaction of deuterium with the hydroxyl groups on the surfaces of the HX, HY, and CaHX zeolites and aerosil was investigated kinetically by an infrared method. The hydroxyl groups appearing at 3660 cm^{-1} on the HX and HY zeolites were more readily exchanged with deuterium than were the other hydroxyl groups on the two zeolites. However, in the case of the CaHX, the order of activities of each hydroxyl group changed with the pressure of deuterium. The rate equation for the reaction is expressed by a Langmuir-type equation. This fact indicates the homogeneity of each hydroxyl group on zeolite. It was found that adsorbed water and carbon dioxide catalyzed the exchange reaction. Furthermore, a compensation effect between the apparent activation energies and the frequency factors occurs in this reaction.

The existence of hydroxyl groups on the surface of zeolite has been shown by infrared spectroscopy.[1-3] The reactivity of a particular hydroxyl group has been estimated from the strength of the interaction with adsorbed olefins,[4,5] bases,[6] and cumene for the HY catalyst.[7] These results show that the hydroxyl group observed at 3650—3640 cm^{-1} is more active than that in the 3550—3540 cm^{-1} region. In this paper, the exchange reaction of deuterium with the hydroxyl groups on the surfaces of zeolites was studied kinetically in order to estimate the reactivity of each hydroxyl group by means of an infrared method. The infrared method has been shown by Carter *et al.*[8] to be useful for investigating the reactivity of a particular hydroxyl group on the surface, as distinct from measuring the overall rate of the exchange of deuterium with a surface hydroxyl group. However, in the kinetic treatment of a reaction, the apparent rate constant, and the adsorption equilibrium constant, and the reactivity of the hydroxyl group must be discussed in terms of the true rate constant.

By the infrared method, Pimentel *et al.*[9] and Eishens and Pliskin[10] have reported the exchange reactions of surface hydroxyl groups on silica gel, and Fry and his co-workers[11] have treated them in some detail. As for alumina, Peri and Hannan[12] have investigated them qualitatively, and Carter *et al.* have studied the reaction kinetically.

The effects of adsorbed water on the reactions catalyzed by zeolites have been reported by many investigators.[13] In the exchange reaction of deuterium with the hydroxyl groups on the zeolite catalyst, similar effects are also found. We found that adsorbed carbon dioxide accelerates its reaction rate. Furthermore, a compensation effect is observed in this reaction; the occurrence of this effect is discussed.

Experimental

Materials. The 13X, 10X, and NaY zeolites were of a commercial grade. The HX, CaHX, and HY zeolites were prepared from their sodium or calcium forms by conventional cation exchange procedures using analytical-grade NH_4Cl. The degree of ion exchange was determined by flame-photometric analysis. In both HX and HY zeolites, 75% of the calcium ions were exchanged. The silica/alumina ratios are 1.4, 1.2, and 2.5 for HX, CaHX, and HY respectively, according to chemical analysis. The aerosil was of a commercial grade. The deuterium used for the exchange reactions had a stated purity of 99.5%.

Procedure. Disks, transparent to infrared radiation, were prepared by pressing the zeolites between polished stainless steel plates to about 10 ton/cm^2. The thickness varied between 7 and 10 mg/cm^2. The platelets were then placed in an IR cell and slid from the salt windows to the center of the IR cell, where they could be heated. The cell can be used in conjunction with a conventional high-vacuum system, and the sample can be treated with gases at any desired temperature. Spectra were taken at room temperature using a Hitachi grating spectrometer. Potassium bromide windows were used on the cell.

The experiments reported in this paper were performed as follows. The disks of HX, HY, CaHX, and aerosil were heated at 300, 400, 350, and 500°C respectively for 14—16 hr under a vacuum of 10^{-5} mmHg in the IR cell. After evacuation, the sample was cooled to room temperature under a vacuum, and the infrared spectrum was recorded. Then, the sample was heated to a reaction temperature and deuterium was introduced. After the desired time had elapsed, sample was cooled to room temperature and the spectrum was again recorded. This procedure was then repeated.

The reaction temperatures were 260—300°C, 280—300°C, 300—330°C, and 400—450°C for HX, HY, CaHX, and

aerosil respectively.

In order to investigate the effect of adsorbed water on the exchange reaction, a small amount of water was added to the system as follows. A trace of adsorbed water was added to the sample by evacuation under a vacuum of 10^{-3} mmHg for 6 hr. Then, the exchange reaction was carried out by adding pure deuterium. In order to add more water to the sample, the reaction was carried out by introducing deuterium containing a small amount of water after the samples had been treated under such conditions.

Mixtures of carbon dioxide and deuterium gas were also placed in contact with the sample in order to study the effects of adsorbed carbon dioxide on the reaction.

Results and Discussion

Typical infrared spectra obtained at room temperature for the sample studied, before and after exposure to deuterium for varying periods of time, are shown in Figs. 1a and 1b. For example, in the original spectrum of the HX zeolite, before exposure to deuterium three different bands due to surface hydroxyl groups were observed. These bands appeared at wave numbers of 3745, 3660, and 3560 cm^{-1}. After exposure to deuterium, additional bands due to OD groups were observed at 2752, 2697, and 2635 cm^{-1}. The wave numbers of the OH groups due to exchange reactions are summarized in Table 1.

Table 1. Wave numbers of OH and OD groups

Sample	Wave number of OH group cm^{-1}	Wave number of additional OD group, cm^{-1}
HX	3745	2752
	3660	2697
	3560	2635
HY	3660	2690
	3548	2622
CaHX	3660	2693
	3595	2659
	3566	2633
aerosil	3755	2760

The reactivity of each hydroxyl group is qualitatively as follows. In the case of the HX zeolite, the OH group occurring at 3660 cm^{-1} is exchanged more readily with deuterium than are the other OH groups under the present experimental conditions. The lowest-frequency OH group (3560 cm^{-1}) has a subsequent activity, while the highest one (3745 cm^{-1}) is most inactive. Although the difference in activities between them is not very great, the OH group observed at 3660 cm^{-1} is 1.5—2 times more active than that at 3745 cm^{-1}. In the case of the HY zeolite, the OH group occurring at 3660 cm^{-1} is a little more active than that at 3548 cm^{-1}. These facts correspond to those estimated from the strength of the interaction with olefins, bases, and aromatics.[12] However, the behavior of the surface hydroxyl groups on the CaHX zeolite is more complecated than in the case with the HX and HY zeolites. When the pressure of deuterium is lower than about 15 cmHg, the OH group observed at 3566 cm^{-1} has the highest activity, that at 3660 cm^{-1} has the next highest one, and that at 3595 cm^{-1} has the lowest one. When the pressure is higher than about 20 cmHg, however, the OH group occurring at 3595 cm^{-1} is more active than those at 3660 and 3566 cm^{-1} which have nearly the same reactivity. The surface OH group on aerosil (3755 cm^{-1}) is much more difficult to exchange than those of the zeolites used. This paper is mainly concerned with the OH groups occurring at 3660 cm^{-1} on HX, HY, and CaHX, and that occurring at 3755 cm^{-1} on aerosil.

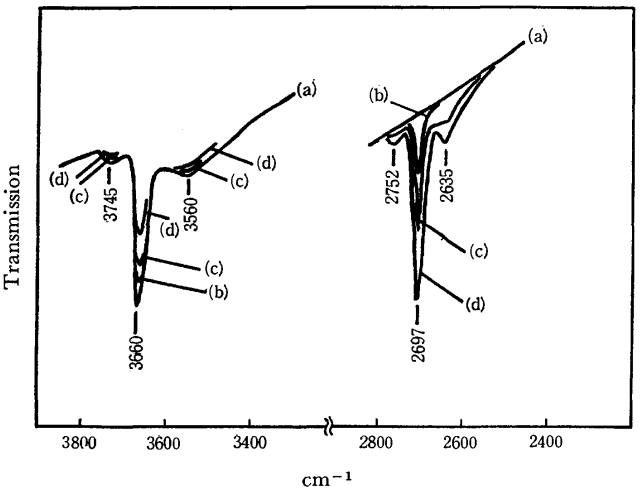

Fig. 1a. Typical infrared spectra of HX as a function of time of treatment with D_2 (13.95 cmHg) at 180°C: (a), 0; (b), 1; (c), 3; (d), 7 hr.

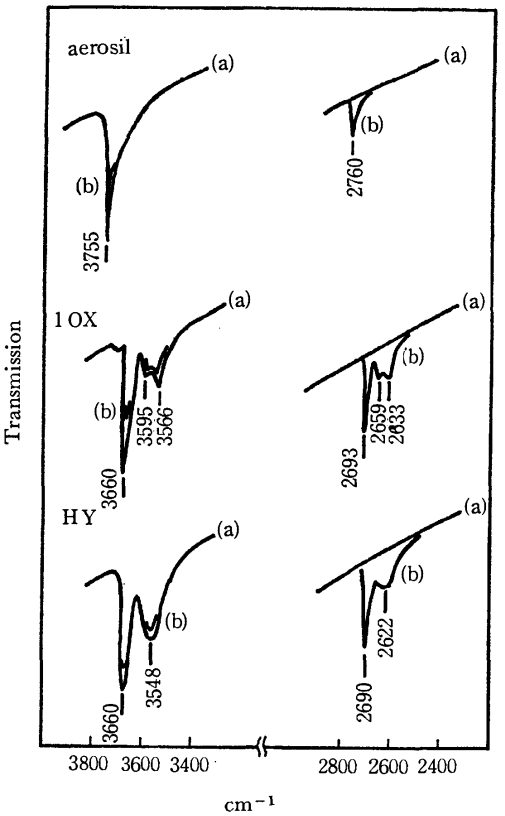

Fig. 1b. Typical infrared spectra of OH and OD groups on HY, CaHX, and aerosil: (a), before exposure to D_2; (b), after exposure to D_2.

If deuterium is adsorbed on the zeolite surface in a Langmuir-type reaction, and the exchange reaction occurs between adsorbed deuterium and hydroxyl groups, the rate equation can be expressed as follows;

$$-\mathrm{d(OH)}/\mathrm{d}t = k\theta\mathrm{(OH)} \quad (1)$$

$$\theta = KP/(1+KP) \quad (2)$$

Therefore,

$$-\mathrm{d(OH)}/\mathrm{d}t = kKP/(1+KP)\mathrm{(OH)} \quad (3)$$

where (OH) is the concentration of surface hydroxyl groups; θ, the coverage of deuterium; k, the rate constant; K, the adsorption equilibrium constant of deuterium; and P, the pressure of deuterium. However, in our experiments, when sliding the samples from the salt windows to the center of the IR cell, the absolute concentration of the hydroxyl group, that is, (OH) in Eq. (3), could not be measured reproducibly. Therefore, Eq. (3) must be transformed into the following equations

$$-\mathrm{d}\ln\mathrm{(OH)}/\mathrm{(OH)_0}/\mathrm{d}t = kKP/(1+KP) \quad (4)$$

$$\mathrm{(OH)_0} = \mathrm{(OH)} + \mathrm{(OD)} \quad (5)$$

where (OD) is the concentration of OD groups and where $(OH)_0$ is the sum of the concentrations of OH and OD groups, that is, the concentration of OH groups before exposure to deuterium. Only $(OH)/(OH)_0$ can be measured in our experiments. Recently it has been reported that the extinction coefficients of OH and OD groups are equal; therefore, the concentrations of OH and OD groups can be represented by their optical densities. Figures 2 and 3 show that the rate equation of the exchange reaction can be expressed by Eq. (4) or (3). That is, each hydroxyl group is considered to be homogeneous. However, for η-alumina, Carter and his co-workers[8] have reported a rate expression which indicates a surface heterogeneity in the alumina. This difference seems to be ascribable to the purity of η-alumina and/or to the crystallinity of zeolite.

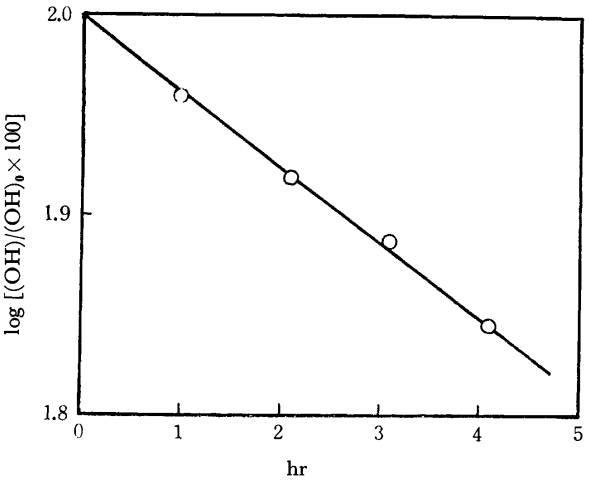

Fig. 2. Exchange of D_2 with the hydroxyl group (HX 3660): reaction pressure; 6.47 cmHg, reaction temperature; 300°C.

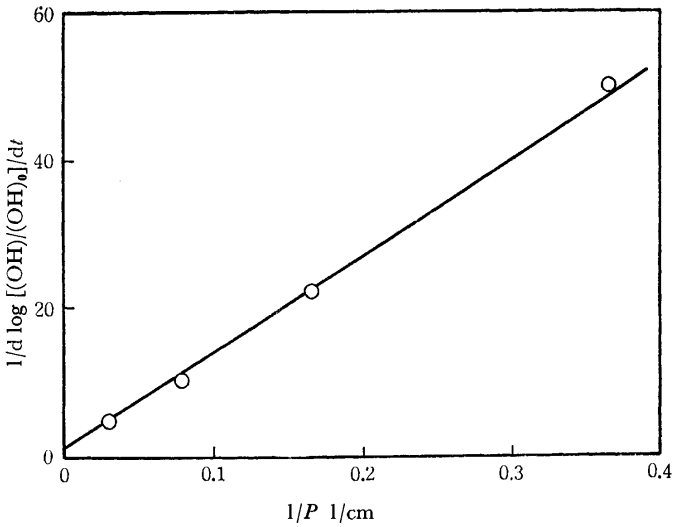

Fig. 3. Langmuir plot of exchange reaction of HX 3660: reaction temperature; 300°C, pressure; cmHg.

From Eq. (4), the rate constant, k, and the adsorption equilibrium constant, K, can be calculated. When the reaction pressure is low, the apparent rate constant, k, can be represented by kK according to Eq. (6):

$$-\mathrm{d(OH)}/\mathrm{d}t = kKP/(1+KP)\mathrm{(OH)}$$
$$= kKP\mathrm{(OH)} \quad (\text{when } KP \ll 1)$$
$$\equiv k'P\mathrm{(OH)} \quad (6)$$

Here, the values of the apparent activation energy, E_a, the frequency factor, A, the activation entropy, ΔS_a, the heat of adsorption, ΔH_a, and the entropy of adsorption, ΔS_a, are calculated from the temperature dependencies of k, k', and K. These values are summarized in Table 2.

The apparent activation energies for the exchange reaction of deuterium with hydroxyl groups have been reported by many investigators. The only value of E_a for a particular OH group, that is, the OH group occurring at 3785 cm^{-1} on η-alumina,[7] is 7—12 kcal/mol. Hall and his co-workers[14,15] have evaluated E_a by measuring the overall rate of exchange for

TABLE 2. KINETICAL CONSTANTS OF EXCHANGE REACTION

OH group	E_a (kcal/mol)	ln A	ΔH_a (kcal/mol)	ΔS_a (e.u.)	$\Delta H^{\neq}$ (kcal/mol)	$\Delta S^{\neq}$ (e.u.)

silica gels (22—23 kcal/mol), γ-alumina (6 kcal/mol) and silica-alumina (8—10 kcal/mol). For the HY zeolite, the value of E_a has been shown to be 20—30 kcal/mol by Imai.[16] The E_a values in Table 2 can not be compared directly with their values, but they seem to be appropriate.

The adsorption heats of the deuterium of the HX and HY zeolites are very large in comparison with those on Na-13(2.06 kcal/mol) and Ca-13(2.49 kcal/mol).[17] They may be explained in terms of the interaction between the electrostatic field of the sodium ion and deuterium. Furthermore, the values of ΔH_a are calculated from the temperature dependence of K in Eq. (4); therefore, they are the values for active deuterium only. Since the values of Na-13Y and Ca-13Y, have, however, been obtained by measuring adsorption isotherms, they are average values of active and non-active deuterium. In the case of the CaHX zeolite, the calcium ions retained in it are considered to exist on the S_1 site only. Therefore, the exchange reaction with the hydroxyl group observed at 3660 cm^{-1} may not be influenced by calcium ions. This is confirmed by the following facts. The OH group occurring at 3660 cm^{-1} on a CaHX zeolite consisting of about 65% of calcium ions is exchanged more readily than that on a CaHX zeolite consisting of 42% calcium ions. Moreover, it has been reported[18] that the activity of the isomerization of *n*-hexane on calcium containing type-Y zeolite catalysts greatly increases when more than 40% of the sodium ions are replaced by calcium ions these facts agree with the effect of calcium ions on the exchange reaction. In the case of aerosil, the heat of adsorption is compatible with that measured on silica.[19]

The adsorption entropies of deuterium on HX and HY are very large. If a deuterium molecule adsorbs on the surface and migrates with two freedoms of translation, the value of the adsorption entropy must be about −9 e.u. Therefore, it is considered that deuterium molecule adsorbed on the HX and HY zeolites migrates in the only defined region, interacting with the cations.

In the case of the CaHX zeolite, however, the adsorption entropy is a degree of free migration. Hence, the deuterium molecule on the CaHX zeolite, which reacts with the surface hydroxyl group of 3660 cm^{-1}, is considered to migrate over a wide region without interacting with the calcium ions in the S_1 sites.

It is found that the small of water adsorbed on the zeolites catalyzes the exchange reaction of deuterium with the surface hydroxyl groups. The rate equation is expressed by Eq. (1) when the amount of adsorbed water is small. The k, k', and K values for the HX zeolite in the presence of adsorbed water are shown in Table 3. In the case of Condition A, the sample was evacuated at 300°C for 6 hr under a vacuum of 10^{-3} mmHg before exposure to pure deuterium. In the case of Condition B, after the sample has been treated under the same conditions as in A, it was placed in contact with the deuterium which contains a small amount of water. The apparent rate constant, k', increases monotonously as the amount of adsorbed water is increased; that is, the exchange rate increases with an increase in the amount of adsorbed water. However, the rate constant, k, has a maximum value. This fact can be explained as follows. The exchange reaction of hydroxyl groups with D_2 is very fast in comparison with that with deuterium. When the amount of adsorbed water is very small, the reaction is accelerated by the exchange reaction between the proton of the water molecule and the deuteron of the deuterium molecule. When the water content is increased, however, water molecules shield the electrostatic field of the cations and, consequently, deactivate the deuterium molecule. The two opposite roles of adsorbed water give the rate constant a maximum value. The increase in K may be explained in terms of the interaction between deuterium and water. The catalytic effect of adsorbed water is more complex than is initially apparent.

Table 3. Effect of adsorbed water on exchange reaction

	No adsorbed water	A	B
k' (1/hr)	1.42×10^{-2}	1.75×10^{-2}	0.113
k (1/hr)	1.50	2.18	0.730
K (1/cmHg)	9.45×10^{-3}	8.03×10^{-3}	0.155

It is found that carbon dioxide also influences the exchange reaction. A typical reaction is shown in

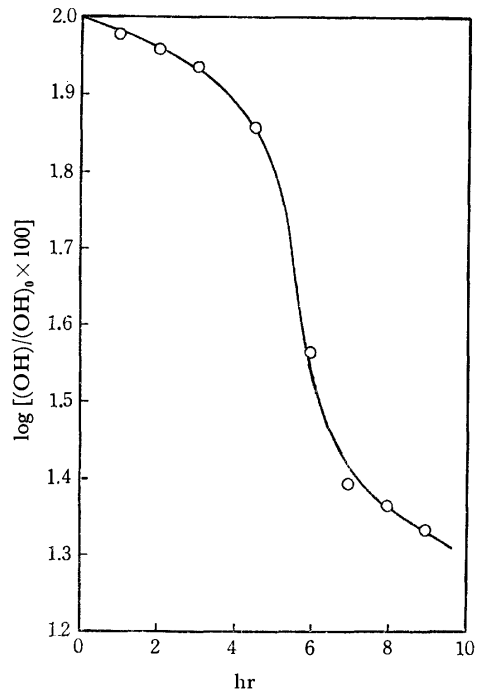

Fig. 4. Effect of carbon dioxide on exchange reaction of HX 3660: reaction temperature; 280°C, pressure of CO_2; 1.34 cmHg, pressure of D_2; 2.08 cmHg.

Fig. 4. The rate equation cannot be expressed by Eq. (1) or (2) in this case. The reaction rate gradually becomes fast and then slows down with the progress of the exchange reaction. The decrease in the rate is not due to a opposite reaction, because a large excess of deuterium is present during exchange reactions. The effect of carbon dioxide may be interpreted in terms of the interaction between deuterium and carbon dioxide, and in terms of the competitive adsorption of two gases.

A compensation effect is found in this reaction. Figure 5 shows the relation between E_a and $\ln A$. The linear relations between ΔS_a and ΔH_a, and also between $\Delta S^{\ddagger}$ and $\Delta H^{\ddagger}$ hold. Generally, k is considered to be variable in a series of reactions. Therefore, the compensation effect may result from compensatory relations of both k and K. When the apparent rate constant is expressed by kK, a normal compensation effect occurs; when it is expressed by k/K, an anti-compensation effect can occur under specific conditions.

With regard to the detailed mechanism of the exchange, the information presently available is not sufficient to establish it with any certainty. It is conceivable, however, that a proton of the hydroxyl group interacts with an adsorbed deuterium molecule, forms a triatomic intermediate, and removes a HD molecule, with the consequent formation a OD group.

Conclusions

The hydroxyl groups occurring at 3660 cm^{-1} on HX and HY zeolites were more readily exchanged with deuterium than were the other hydroxyl groups on the two zeolites. However, in the case of CaHX, the order of activities of each hydroxy group was changed with the pressure of deuterium; this fact is considered to be ascribable to the effect of calcium ions.

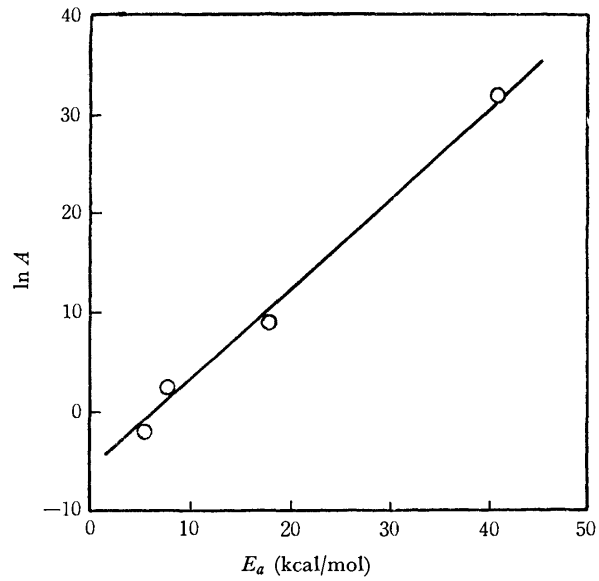

Fig. 5. Compensation effect.

The rate equation for the reaction is expressed by a Langmuir-type equation. This fact indicates the homogeneity of each hydroxyl group on zeolites, contraty to the case with η-alumina. The adsorbed water and carbon dioxide catalyzed the exchange reaction. The adsorbed water accelerates the reaction by the exchange reaction between the proton of the water molecule and the deuteron of the deuterium molecule, but it also shields the electrostatic field, with a consequent deactivation of adsorbed deuterium.

It was found that the compensation effect holds for k, k', and K in this exchange reaction. In general, this effect may result from the existence of the compensatory relation between the entropy and the enthalpy.

Abnormal Hyperfine Splitting in the ESR Spectra of $\alpha,\alpha,\gamma,\gamma$-Tetraphenylallyl-type Organic Stable Free Radicals[1)]

(Received July 3, 1971)

The ESR spectra of $\alpha,\alpha,\gamma,\gamma$-tetraphenylallyl radical have been first observed. An abnormal ESR hyperfine splitting of this radical has been compared with the ESR hyperfine splitting of other tetraphenylallyl-type radicals; it can be explained very well by introducing the idea of a twisted-allyl model of the molecule.

The history of an organic stable free radical, $\alpha,\alpha,\gamma,\gamma$-tetraphenylallyl(TPA), dates from 1923, when Ziegler published the synthetic method.[2)] Observed in the course of the investigation of the magnetic properties of organic stable free radicals, the electron spin resonance(ESR) spectrum of TPA reveals an unusually large hyperfine splitting of the proton adjacent to the β-position of the allyl group, compared with the results of the familiar theoretical calculation of the spin-density distribution.[3)]

The spectrum of $\alpha,\alpha,\gamma,\gamma$-bisdiphenyleneallyl(BDA) also exhibits an exceptionally large hyperfine splitting of the corresponding proton. ESR studies of the hyperfine structures of $\alpha,\alpha,\gamma,\gamma$-bisdiphenylene-$\beta$-phenylallyl(BDPA),[4,5)] BDA,[4,6)] $\alpha,\alpha,\gamma,\gamma$-bisdiphenylene-$\beta$-methylallyl(BDMA),[3)] and $\alpha,\alpha,\gamma,\gamma$-bisdiphenylene-$\beta$-azoallyl(BDAA)[7)] have already been reported by several authors, but not that of TPA; moreover, no systematic explanation of the relation between the hyperfine coupling constant of the β-position and the framework of the allyl group of these radicals has ever been given.

In the present paper, the ESR spectra of BDA and BDAA were remeasured carefully, and that of TPA was measured for the first time in diluted solutions. A possible explanation was also presented, one based on the model that $2p_z\pi$-*orbitals* of the three carbons in the allyl group of the radicals will twist one another by a certain angle with respect to the two C-C bonds. The validity of this model was examined by comparing the proton hyperfine coupling constant of TPA with those of other tetraphenylallyl-type radicals (Fig. 1).

Experimental

The samples were prepared following the process described in Refs. 2, 7, and 8. For the observation of the ESR spectra the solvents were well purified, dehydrated, and degassed by the usual methods.[9)] An aqueous solution of peroxylamine disulfonate was used as the standard, and the value of 13.00 gauss was taken for the nitrogen coupling constants.[10)] The hyperfine coupling constants were usually determined by taking the average values of two or three spectra. All the ESR spectra were obtained with a JES-ME3X-type spectrometer of the JEOL Co., equipped with a 100-kHz field modulation. The experimentally-obtained hyperfine coupling constants were then compared with the spectra reconstructed using the ESR spectrum simulator.

Results

Tetraphenylallyl. One of the observed spectra of TPA is shown in Fig. 2.

The spectrum consisted of two groups, which split further into about thirty hyperfine lines. The analysis of the hyperfine structure of the observed spectra revealed that one proton adjacent to the β-position of the allyl group (A_β^H), the eight-phenyl protons at the *ortho*-positions (A_o^H), the eight-phenyl protons at the *meta*-positions (A_m^H), and the four-phenyl protons at the *para*-positions (A_p^H) are attributable to the hyperfine structures. As a result of the reconstruction of the observed spectra by means of the ESR spectrum simulator, the proton hyperfine coupling constants for each solvent were determined to be as is shown in Table 1.

T.H.F.[b]	8.95	1.20	0.70	2.10
Ethanol	8.75	1.35	0.65	1.95

a) Diethylamine b) Tetrahydrofuran

The temperature dependence of the coupling constant (A_β^H) in the THF solution is shown in Fig. 3 as a function of the temperature. In these ESR spectra, it can be noticed that the A_β^H changes rather markedly than the others, A_o^H, A_m^H, and A_p^H.

Bisdiphenyleneallyl. The ESR hyperfine structure of BDA in diluted CS_2 solution was observed by Kuhn and Neugebauer[4] and Hausser.[6] The spectrum of BDA in a diluted CS_2 solution measured at 20°C is shown in Fig. 4.

In Table 2, the hyperfine coupling constants of the protons of BDA are also tabulated.

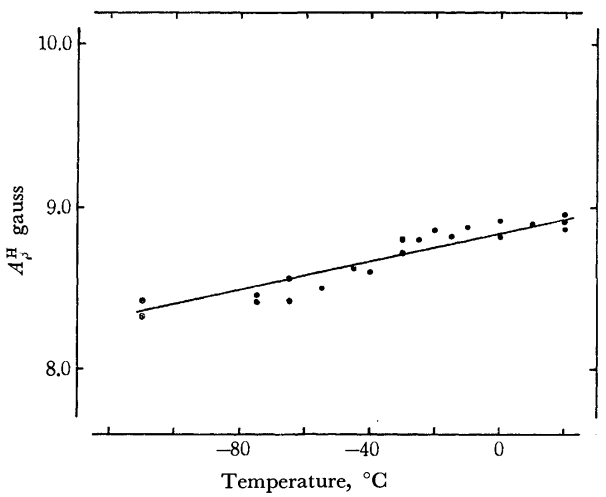

Fig. 3. Temperature dependence of the coupling constant A_β^H of TPA in THF.

Bisdiphenyleneazoallyl. Although the ESR hyperfine structure of BDAA in a diluted benzene solution has already been observed by Kuhn and Neugebauer[7] they did not analyze the spectrum in detail. In this investigation, the ESR spectra were investigated in several organic solvents at 20°C (Fig. 5) and analyzed in detail.

Reconstructing the observed spectra by the ESR spectrum simulator, the hyperfine coupling constants for nitrogen, and each ring proton were determined, as is shown in Table 3.

From the observed ESR spectra of these tetraphenylallyl-type radicals, it can be concluded that the four phenyl groups or two biphenylene groups are equivalent.

Discussion

The theoretical spin densities on each carbon position were enumerated by means of McLachlan's Molecular Orbital method,[11] and also by means of the odd alternant method[12] in the case of TPA. The coupling constants calculated by means of McConnell's relation are also shown in Table 4.

Table 4 indicates that the observed hyperfine coupling constants of the ring protons are in fair agreement with the calculated hyperfine coupling constants. This coincidence indicates the validity of McLachlan's calculation. It should be noted, however, that in TPA and BDA the theoretical hyperfine coupling constants of β-protons are too small to account for the experimentally-determined hyperfine coupling constants; this is in contrast to the close agreement between the observed and the calculated values about the ring protons.

In the ESR spectra of the allyl radical, Fessenden and Schuler[13] have observed three different hyperfine coupling constants due to protons, $A_\beta^H=4.06$ gauss, $A_{\alpha,\gamma}^H=13.93$ gauss, and $A_{\alpha,\gamma}^H=14.83$ gauss. One of them (A_β^H) is a hyperfine coupling constant of the proton adjacent to C_β; it is in satisfactory agreement with the predicted value,[14] on condition that the allyl radical has *sp*² *hybrid orbitals* where the configuration angle of C_α-C_β-C_γ is 120° and that the $2p_z\pi$-*orbitals* of each carbon situated in a C_α-C_β-C_γ plane are parallel. The substitution of phenyl groups for four hydrogen atoms attached to the end carbons, C_α and C_γ, which is the case with TPA, may affect the $2p_z\pi$-*orbital* configuration of the allyl group. The most probable situation is that the allyl group is twisted at an angle of φ, as in Fig. 6, because of the steric effect of the phenyl groups. Assuming this twisted model about the allyl group, the $2p_z\pi$-*orbitals* of C_α and C_γ will result in a nonzero spin density at the proton adjacent to C_β, as is shown in Fig. 7.

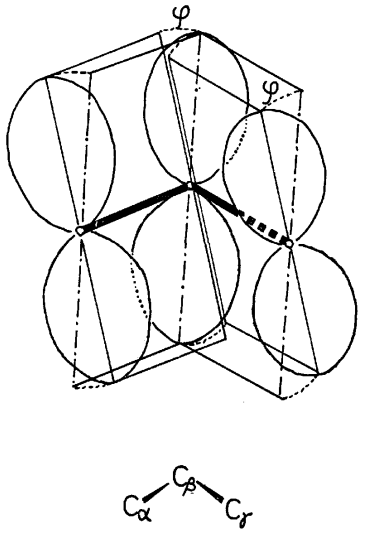

Fig. 6. Twisted allyl model.
$2p_z$ *orbitals* of C_α and C_γ are twisted along the C_α-C_β and C_β-C_γ bonds.

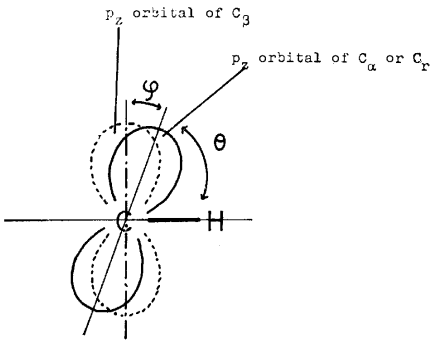

Fig. 7. Relation of the proton adjacent to C_β with $2p_z\pi$-*orbital* of C_α or C_γ.

An interaction between the spin densities of C_α or C_γ and the proton adjacent to C_β can be described by the following relation[15]:

$$A'^H_\beta = (4+50\cos^2\theta)(\rho_{C\alpha}+\rho_{C\gamma}).$$

If the allyl group of TPA or BDA is twisted as in Fig. 6, the experimentally-obtained coupling constant of the proton adjacent to C_β can be estimated by

Calculated coupling constants are obtained using the formula

$A^{H}_{CH}=Q^{H}_{CH}\cdot\rho_{C_1}$ $\qquad Q^{H}_{CH}=-23.0$

a) Each phenyl group is rotated by 10° as that of triphenyl methyl and allyl group is also twisted by 28°.
b) Allyl group is twisted by 37°.
c) Methyl protons.
d) $A^{H}_{C-CH_3}=Q^{H}_{C-CH}\cdot\rho_{C-CH_3}$ $\qquad Q^{H}_{C-CH_3}=+25.0$
e) $A^{N}=Q_1\cdot\rho_N+Q_2\cdot\sum\rho_{C_1}$ ρ_{C_1}s are the spin densities of nuclei attached to the nitrogen. $Q_1=+30.9$, $Q_2=-2.$[19]

the following equation:

$$A^{H}_{\beta} = \frac{Q^{H}_{CH}\cdot\rho_{C\beta} + A'^{H}_{\beta}}{Q^{H}_{CH}\cdot\rho_{C\beta} + (4+50\cos^2\theta)(\rho_{C\alpha}+\rho_{\gamma})}.$$

In the case of TPA, using $\rho_{C\alpha}=\rho_{C\gamma}=+0.251$, $\rho_{C\beta}=-0.063$, $Q^{CH}_{H}=-23.0$ gauss, and $\theta=62°$, A^{H}_{β} becomes 9.05 gauss. In other words, if the twisted angle is assumed to be 28°, A^{H}_{β} will become about 8.90 gauss, which is the most suitable value in this case. Similarly, the twisted angle is estimated to be 37° in the case of BDA. The twisted allyl model mentioned above can easily be applied to the other tetraphenylallyl-type radicals.

For the BDMA, the experimentally-measured hyperfine coupling constants of $A^{H}_{CH_3}$ are close to the theoretically calculated values, as is shown in Table 4. This fact can also be explained by this model, as is shown in Fig. 8, assuming $\rho_{C\alpha}=\rho_{C\gamma}=+0.260$, $\rho_{C\beta}=-0.087$, $Q^{H}_{C\text{-}CH_3}=+25.0$ gauss, and $Q^{H}_{C\text{-}C(CH_3)}=0.85$ gauss;[16] thence, $A^{H}_{CH_3}$ becomes 2.62 gauss or 1.74 gauss.[17] Hence, the protons of the methyl group adjacent to C_β are considerably far apart from C_α or C_γ compared with the proton attached directly to C_β. Consequently, the contribution of $\rho_{C\alpha}$ or $\rho_{C\gamma}$ to the spin density on the methyl proton is negligibly small. On the other hand, the nitrogen nucleus of BDAA is placed at a nodal plane of the $2p_z\pi$-*orbital* of C_α or C_γ. Therefore, the hyperfine coupling constants of nitrogen (A^{N}_{β}) will not be affected directly by the spin density on C_α or C_γ.

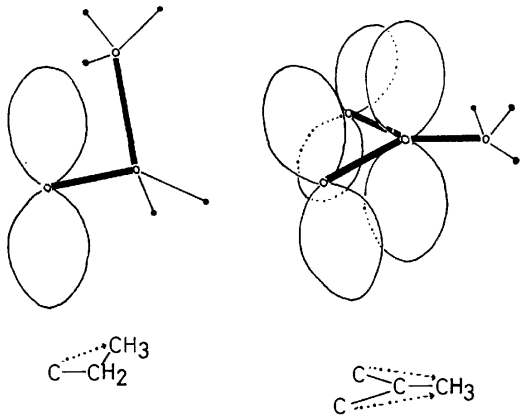

Fig. 8. Twisted allyl model for BDMA.

In addition, the temperature dependence of the coupling constant (A^{H}_{β}) of TPA can also be explained as follows: at high temperatures a vigorous wagging of the allyl group of the TPA molecule will cause the $2p_z\pi$-*orbitals* of C_α and C_γ to come nearer to the proton adjacent to C_β; thence, A^{H}_{β} will become larger, while, at low temperatures, the situation will be reversed.

In order to interpret magnitude of the C_β-proton splitting, a torsion of the phenyl rings from the molecular plane was taken into account at first. However, the spin density of C_β was, at most, the same as that of the allyl radical (the hyperfine coupling constant of the proton adjacent to C_β is only 4.06 gauss[13]). The observation of unusually large splitting of the C_β-proton in TPA or BDA can not be interpreted by means of this mechanism. The other possible explanation is that the configuration angle of C_α–C_β–C_γ is larger than a normal configuration angle of 120° because of the repulsive interaction of phenyl or biphenylene groups. Fraenkel calculated the variation in Q^{H}_{CH} with the bond angle, taking into account the σ-π interaction of the C–H bond.[18] In view of his calculations, the configuration angle of C_α–C_β–C_γ in tetraphenylallyl-type radicals must be smaller than 120°, but this is not plausible in view of the structures of tetraphenylallyl-type radicals.

Conclusion

The abnormal hyperfine coupling constants that have been observed in TPA and BDA could be explained very well, using the method of anisotropic hyperfine interaction. Therefore, in view of the ESR spectra series of these tetraphenylallyl-type radicals, those spectra can be understood by introducing the idea of the twisted allyl model.

The authors wish to thank Professor Kazuhiko Ishizu for his helpful discussion and Mr. Hideo Hasegawa and Mr. Koichi Kubo for the treatment using the ESR spectrum simulator.

17) $A^{H}_{C\text{-}CH_3}=Q^{H}_{C\text{-}CH_3}\cdot\rho_{C\beta}+Q^{H}_{C\text{-}C(CH_3)_3}(\rho_{C\alpha}+\rho_{C\gamma})$ The sign of $Q^{H}_{C\text{-}C(CH_3)_3}$ has not been defined. If the signs of $Q^{H}_{C\text{-}CH_3}$ and $Q^{H}_{C\text{-}C(CH_3)_3}$ are identical, $A^{H}_{C\text{-}CH_3}$ will be 2.62 gauss; if the signs are the opposite, $A^{H}_{C\text{-}CH_3}$ will be 1.74 gauss.

Some Physico-chemical Properties of Vanadium Oxide Supported on Silica or γ-Alumina[1)]

Satohiro YOSHIDA, Toshikatsu IGUCHI, Shingo ISHIDA,* and Kimio TARAMA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received July 6, 1971)

The interactions between vanadium(V) oxide and carriers were investigated in the vanadium oxide catalysts supported on silica and γ-alumina by measuring X-ray diffraction patterns, ESR spectra, solubilities into 0.3 N ammoniacal solutions and reduction rates by benzene. A part of vanadium oxide on the carriers was insoluble in an ammoniacal solution, while unsupported vanadium oxide was easily soluble, and the reduction rates of the catalysts were remarkably affected by the carriers and the vanadium oxide contents. ESR spectra revealed that the vanadium oxide was stabilized by interaction with carriers as a square pyramidal one (VO_5) and a tetrahedral one (VO_4) on the surfaces of γ-alumina and silica, respectively. Massive vanadium(V) oxide crystals grew on these interacted layers with the increase of the oxide contents.

Vanadium oxide has been extensively used as a main catalyst in gas phase oxidation of hydrocarbons and extensive studies have been carried out on its catalytic action.

We also studied the vanadium oxide catalysts especially from the view point of structural chemistry.[2)] Our works mainly dealt with unsupported vanadium catalysts. In the cases of practical catalysts, however, vanadium oxides are generally supported on carriers such as silica and alumina with high surface area. It is known that these carriers have a profound effect on the activities of catalysts.

It is important to elucidate the action of the main component of the supported catalysts. Nevertheless, very few fundamental research works on this problem have been carried out for vanadium oxide catalysts.[2b,3)]

In the present work, some physico-chemical properties of vanadium oxide supported on silica or γ-alumina have been investigated by measuring X-ray diffraction patterns, ESR spectra, solubilities into ammoniacal solutions and reduction rates by benzene vapor in order to clarify the state of vanadium ions in the supported catalysts.

Experimental

Materials. *Silica*: Ethyl silicate purified by distillation three times was hydrolyzed in a water-ethanol mixture at the boiling point. The gel obtained was washed, dried and calcinated at 500°C for 5 hr in dried air stream and was ground to powder of less than 100 mesh.

Alumina: γ-Alumina was obtained by hydrolysis of aluminum isopropoxide, followed by calcination at 650°C for 3 hr, and ground to powder of less than 100 mesh.

Catalysts: Vanadium oxide catalysts supported on silica or γ-alumina were prepared by impregnation of the carrier into an ammoniacal solution of ammonium methavanadate, followed by drying at 110°C and calcination at 500°C for 5 hr in dried air stream. The amount of supported vanadium oxide was analyzed by the usual oxidation-reduction titration method after dissolution of the catalyst into sulfuric acid. Catalysts thus obtained are summarized in Table 1, the vanadium oxide contents being calculated by assuming that vanadium oxide existed as vanadium pentoxide.

Dissolution into an Ammoniacal Solution: The catalyst containing *ca.* 1 g of vanadium oxide was impregnated into 300 m*l* of 0.3 N ammoniacal solution for 24 hr at room temperature. Under this treatment the isolated massive vanadium oxide was easily soluble. Thus, the residue vanadium oxide was regarded to be chemically interacting with the carrier.

Reduction by Benzene Vapour: Reduction rates of vanadium oxide on carriers were determined by measuring the weight loss of the catalysts in a flow of benzene-nitrogen gas by a Shimadzu MTB 50 micro-thermanobalance. Nitrogen gas was saturated with benzene at 2, 5, and 10°C with a flow rate of 30 cc/min and reduction temperatures were in the range 380—450°C.

Results

X-Ray Diffraction. Diagrams of the X-ray diffraction of catalysts are shown in Fig. 1. The catalysts containing more than 20% vanadium oxide on both silica and γ-alumina carriers exhibited diffraction lines due to vanadium(V) oxide (abbreviated as V_2O_5), while those containing less than 10% showed no distinct lines. As a whole, the diffraction lines became intense with the increase of the vanadium oxide content. By precise inspection of the diffraction lines due to V_2O_5 in catalysts, the interplaner spacing of (001) planes (the strongest line) of the catalysts supported on silica (group S) was the same as that of unsupported V_2O_5, while the spacing of the catalysts supported on γ-alumina (group A) was slightly shorter than that of group S. The diffraction lines in the range of high diffraction angle were clearer in group S than in group A.

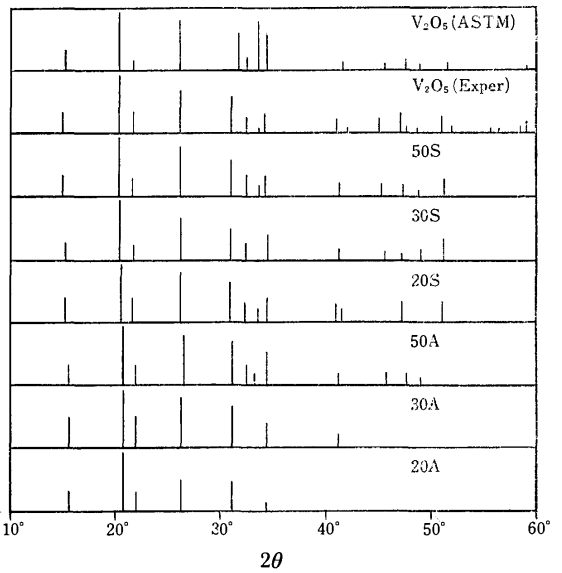

Fig. 1. Diagrams of X-ray diffration of catalysts. Refer to Table 1 for symbols.

Treatment by Ammoniacal Solutions. The residual amount of vanadium oxide in catalysts after treatment with a 0.3 N ammoniacal solution are shown in Table 2 together with the coloration of samples. Generally the amount of the residual vanadium oxide in group A was greater (2—4%) than in group S (1.5—3%). As shown in Table 1, group A had a tinge of green showing existence of a small amount of low-valent vanadium ions and the tone of this color was deepened after treatment with ammoniacal solutions.

Reduction Rates by Benzene Vapour. In the case of the reduction of unsupported V_2O_5 by hydrogen, the change of the weight loss of catalysts caused by reduction consisted of the following three processes as reported by Matsuura.[4] (1) The autocatalytically accelerating process in the initial step of the reduction, (2) the steady reduction process and (3) the retarding process.

In process (2), the weight of the catalysts decreased almost linearly with reduction time and reached the value corresponding to the average composition of

vanadium oxide V_2O_4. In process (3), the vanadium oxide on carriers was further reduced from vanadium (IV) oxide to vanadium(III) oxide. The gradient of the linear relation in process (2) was adopted in this paper as the measure of the rate of reduction expressed as weight loss (mg) per unit time (minute) and unit mass of vanadium oxide (mg) contained in the starting samples. Dependence of the reduction rates on the vanadium oxide contents and the vapour pressures of benzene in the feeds are shown in Figs. 2 and 3, respectively. It is clear that the rate of reduction decreased with the decrease of the vanadium oxide content of the catalysts. For the same content of the oxide, the reduction rates were faster for group S than for group A. Figure 3 shows that the reduction rates are proportional to the first order of the vapor pressure of benzene.

The characteristics of the rate of reduction were maintained in the range of reduction temperatures 380—450°C. The apparent activation energies of the reduction ΔE determined from the variation of the rates with reduction temperature are shown in Table 3. The activation energies varied with carriers and vanadium oxide contents.

It was observed that ΔE of group A tended to be larger than that of group S.

The crystalline structures of the reduced samples with the composition V_2O_4 were examined by X-ray diffraction. The sample of unsupported V_2O_5 reduced under the same conditions was composed of two kinds of structures, *i.e.*, the rutile type V_2O_4 and the intermediate "B" named by Sata *et al.*[5,6] In the cases of

the supported catalysts, only the latter was observed.

ESR Spectra of Catalysts. The evacuated samples of group A exhibited the characteristic ESR spectra with hfs due to $^{51}V(IV)$ in distorted square pyramidal coordination[3,7] and the resolution of hfs became clear with the decrease of vanadium oxide content. In the cases of group S the spectra changed considerably with the vanadium oxide content. While a broad doublet line was observed for 50S and 30S, spectra with not well-resolved hfs over a very broad absorption line were observed for catalysts containing less than 20% vanadium oxide. Typical examples of the spectra are shown in Fig. 4.

When the catalysts were treated with 0.3 N ammoniacal solution, group A exhibited almost the same spectra as 5A in Fig. 4, but group S exhibited only broad absorption lines.

treatment with an ammoniacal solution and dampening are shown in Fig. 5.

Discussion

The results obtained indicate that in the supported vanadium oxide catalysts, vanadium oxide is not only dispersed on the carriers with high surface area, but also interacted chemically with the carriers.

Characteristic Behavior of Vanadium Oxide on Carriers. The main features of the results could be summarized as follows. 1) A tinge of green colour and considerable intensity of ESR spectrum of the supported vanadium oxide suggested that tetravalent vanadium ions (V^{4+}) existed in a larger amount in the supported catalysts than in unsupported V_2O_5 (the amount of V^{4+} in V_2O_5 has been estimated to be about 0.6 atom %.[8]).

2) On the carriers, vanadium oxide insoluble in 0.3 N ammoniacal solution existed and the amount was greater in group A than in group S.

3) Both rutile type V_2O_4 and the intermediate "B" were produced in the course of the reduction of unsupported V_2O_5, but rutile type V_2O_4 was not produced in the case of the supported catalysts.

4) The supported samples were more stable against reduction by benzene vapour than unsupported V_2O_5. The tendency was remarkable especially for the samples supported on γ-alumina.

The reduction rates of vanadium oxide catalysts by benzene followed the "parabolic law" which indicates the rate determining step is the diffusion process of oxygen ions within crystals at rather low temtemperature (327°C).[2b,9] In the present research, however, the rate of reduction was proportional to time, that is, of zeroth order with respect to the amount of unreduced vanadium oxide and was proportional to the vapour pressure of benzene. This seems to indicate that the diffusion process of oxygen ions within the crystal is fast enough for the reduction process and the rate determining step of reduction is the uptake of oxygen from vanadium oxide surface by gaseous benzene or adsorbed benzene with low coverage.

If this is the case, the rate would be controlled mainly by the bond strength of oxygen-vanadium ions on the surface. The results obtained reveal that the carriers, especially γ-alumina, affect the bond strength of oxygen-vanadium ions on the surface of vanadium oxide.

Structure of Vanadium Oxide Supported on γ-alumina. Experiments of the reduction and dissolution in 0.3 N ammoniacal solutions of group A showed that considerable interaction between vanadium oxide and γ-alumina took place during the course of preparation, while X-ray diffraction indicated that the vanadium oxide on the γ-alumina was essentially V_2O_5 with a small modification and no special new compounds were formed. The question whether new compounds were formed or not should depend on further investigations since X-ray diffractometry was not useful for samples containing less than 10% V_2O_5. However, such compounds do not seem to be formed because the ESR spectra of 20A and 5A were essentially the same.

The ESR spectra of group A indicated the existence of square pyramidal vanadium oxide (VO_5) which resembled the (VO_5) unit in V_2O_5 crystal.[10] The well-resolved hfs observed for catalysts of low concentration of vanadium showed that unpaired electrons of vanadium(IV) ion were isolated from each other. Thus (VO_5) might be stabilized in an isolated state on the γ-alumina by chemical interaction. For the catalysts of high concentration of vanadium, the ESR spectra were distorted due to interaction of electrons by the possible formation of a small $(VO_5)_n$ network. The massive V_2O_5 crystal observed by X-ray diffraction would be formed by accumulation of vanadium oxide over $(VO_5)_n$ networks.

Structure of Vanadium Oxide Supported on Silica. Although silica has a larger surface area than γ-alumina, X-ray diffraction indicated that the crystal of V_2O_5 developed on silica better than on γ-alumina and the interspacing of the lattice planes was the same as that of pure V_2O_5. The rate of reduction of 50S was almost the same as that of unsupported V_2O_5.

These results show that on silica the same crystal phase exists as pure V_2O_5, when the vanadium oxide content is high. However, the fact that 50S and 30S did not produce rutile type V_2O_5 during the course of reduction by benzene indicated that the crystal phase was slightly perturbed by silica.

In the case of the catalysts of low concentration of vanadium oxide, the ESR spectra were composed of not well-resolved hfs and differ from those of group A.

10) A. Bystrom, K. A. Wilhelmi, and O. Brotzen, *Acta Chem. Scand.*, **4**, 1119 (1950).

However, the characteristics of square pyramidally coordinated V(IV) ions was observed when samples were dampened as shown in Fig. 5. It is known that tetrahedrally coordinated V(IV) ions could not be detected by ESR at room temperature.[3] From these facts, the spectra could be assigned to distorted square pyramidally coordinated V(IV) ions $(VO_5)'_n$. The spectrum of 20SN which was obtained by treatment of 20S with a 0.3 N ammoniacal solution was broad singlet and changed to a spectrum characteristic of square pyramidal (VO_5) by dampening (Fig. 5).

From these effects of dampening, the broad absorption line of 20SN does not seem to be produced by dipole-dipole interaction of unpaired electrons, but might be assigned to tetrahedrally coordinated V(IV) ions (VO_4) with short spin-lattice relaxation time.

Thus vanadium oxide would be stabilized on silica surface as (VO_4) at first, followed by the formation of $(VO_5)'_n$ and V_2O_5 with the increase of the vanadium oxide content.

Thus, the structure of vanadium oxide on silica or γ-alumina could be represented schematically as in Fig. 6.

In conclusion, it was found that these carriers interacted chemically with vanadium oxide and affected its structure and that $(VO_5)_n$ which contained square pyramidal VO_5 interacted with γ-Al_2O_3 was more stable against reduction by benzene than $(VO_5)'_n$ which comprised distorted $(VO_5)_n$ and tetrahedral VO_4 on SiO_2.

Monolayers of Poly-γ-benzyl-L-glutamate *N*-Alkylamides

Asahi SUZUKI*

Department of Biology, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received July 17, 1971)

To elucidate the effect of long alkyl chains on the surface properties of polypeptides, various poly-γ-benzyl-L-glutamate (PBLG) hexylamides or dodecylamides with different degrees of polymerization were synthesized and their monolayers were examined. PBLG-alkylamides with a low degree of polymerization form expanded-type monolayers on water and their surface pressure-area (π-A) curves have two plateaus. The lower plateau in the π-A curve is not seen in the curves of PBLG-alkylamides with a degree of polymerization of more than 10. The lower plateau in the π-A curve is due to the behavior of the terminal alkyl groups. The effect of temperature on the properties of monolayers was examined. Structures formed in the monolayers were discussed.

From studies on the relation between surface pressure and surface viscosity, it was concluded[1] that the monolayer of poly-γ-benzyl-L-glutamate (PBLG) of low molecular weight is of an expanded type. This was done by comparing polypeptides of rather high molecular weight. The work dealt with the properties of monolayers of low molecular weight PBLG which has a long alkyl chain at its terminal. Ikeda *et al.*[2] discussed to what extent hydrogen bonds between peptides and the van der Waals force between alkyl chains of long chain alkyl amides of poly-α-amino acids contribute to micelle formation in water. It is of interest to see how the van der Waals force between alkyl chains and hydrogen bonds between peptides act in monolayers of polypeptide derivatives, because PBLG-alkylamides are water-insoluble and form monolayers on water.

For this purpose, *n*-hexyl and *n*-dodecyl groups were introduced into polypeptides with different degrees of polymerization. Monolayers of these polymers seemed suitable for studies on the factors making a monolayer stable and on the structures formed in monolayers.

Experimental

A long chain alkylamide of poly-γ-benzyl-L-glutamate was prepared by polymerization of *N*-carboxy-γ-benzyl-L-glutamate anhydride, mp 93°C, in dioxane using hexylamine or dodecylamine as an initiator.[3] The molar ratio of anhydride to initiator, [A]/[I], was varied from 5 to 25 to obtain samples of PBLG-dodecylamide with different degrees of polymerization. The [A]/[I] ratios of the PBLG-hexylamide series were 7, 14, 21, and 28.

The degree of polymerization of polymers was estimated by anhydrous titration of terminal amino groups.[4] Polymers were dissolved in acetic acid and titrated with perchloric acid using methylviolet as an indicator. The activity of perchloric acid was determined by titration with γ-benzyl-L-glutamic acid. The average degrees of polymerization estimated by the titration of amino end groups were approximately equal to the molar ratios of anhydride to initiator: all the ratios of the average degree of polymerization to the [A]/[I] ratio were between 0.9 and 1.2. The polymers were not fractionated into a monodisperse system, so the degrees of polymerization were taken as the [A]/[I] values. In this paper, the [A]/[I] value is given as a suffix *e.g.* PBLG-hexylamide-7 has a value of 7.

Dichloroacetic acid was distilled twice under reduced pressure before use. Benzene was distilled three times. Potassium chloride was heated for about 3 hr at its partial melting temperature.

Polymers were spread at an air/water interface using a conventional Langmuir trough (50.0×14.5×0.9 cm) and their surface properties were measured by means of automatic recording systems.[5] The hanging plate method was employed for measuring surface pressure, the rotatory surface viscometer for surface viscosity and the vibrating electrode method for surface potential.

Polymers were dissolved in a mixture of dichloroacetic acid and benzene (1 : 4, by volume) and spread on water using a micrometer syringe (Alfa, Takara). Potassium chloride was added to the aqueous phase at a concentration of 1 mM to stabilize surface potential. Temperature was controlled by circulating water at constant temperature through a coiled glass tube at the bottom of the trough.

Results and Discussion

The surface pressure (π) and surface viscosity (η) *vs.* surface area (A) curves for the series of PBLG-hexylamide at 20°C are shown in Fig. 1. PBLG-hexylamide-7 has an unusual π-A curve which is of a very expanded type and has two plateaus at surface pressures of 7.8 and 10.0 dyn/cm. The π-A curves of PBLG-hexylamides other than PBLG-hexyl-7 became more condensed as the degree of polymerization increased and their π-A curves had a single plateau at an area of 0.5 m²/mg. Surface viscosity could be detected in monolayers of polymers with a high degree of polymerization when the area was large. Areas where surface viscosities were first detected were distrubuted in the region of the plateaus of the π-A curves.

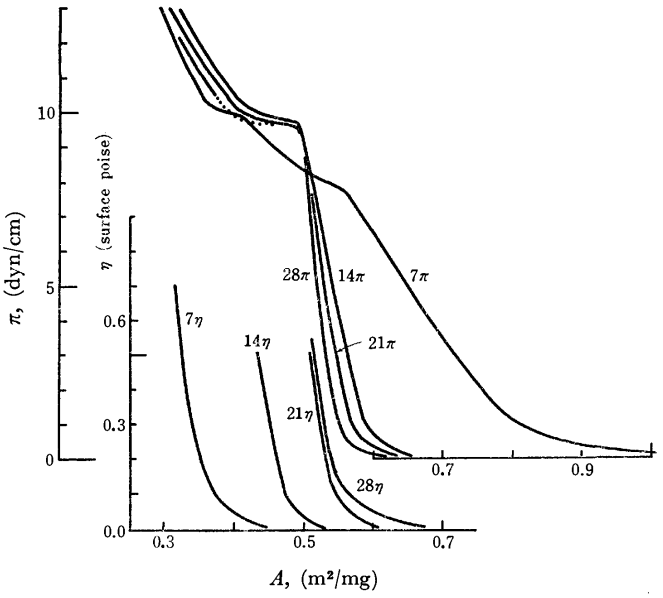

Fig. 1. Variation of the surface properties of PBLG-hexylamide series on water at 20°C.
The degree of polymerization is noted on each curve.

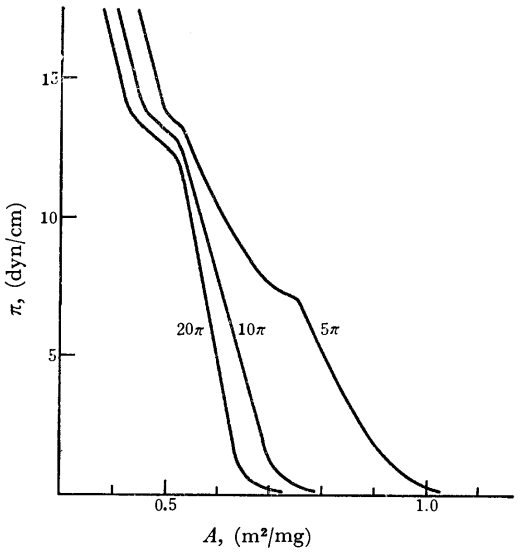

Fig. 2. Variation of π-A curves of PBLG-dodecylamide series on water at 20°C.
The degree of polymerization is noted on each curve.

The π-A and η-A curves of the PBLG-dodecylamide series at 20°C are shown in Fig. 2. There are two plateaus at π=7.2 and 13.0 dyn/cm in the π-A curve of PBLG-dodecylamide-5. The π-A curves of the PBLG-dodecylamide series become a more condensed type with increase in the degree of polymerization. The π-A curves of this series have higher plateaus in the area of 0.55 m²/mg. The surface pressure corresponding to the beginning of the higher plateau varied with the degree of polymerization, but those of the end of the plateau were all at the same pressure of 14.6 dyn/cm.

The temperature dependence of the π-A curve of PBLG-hexylamide-7 is given in Fig. 3. The surface pressure of the lower plateau of the π-A curve does not change appreciably with temperatue but the

33	7.8	9.5

Fig. 3. Temperature dependence of the π-A curves for PBLG-hexylamide-7 on water.
The critical surface pressure π_p related to the plateaus are shown in the figure.

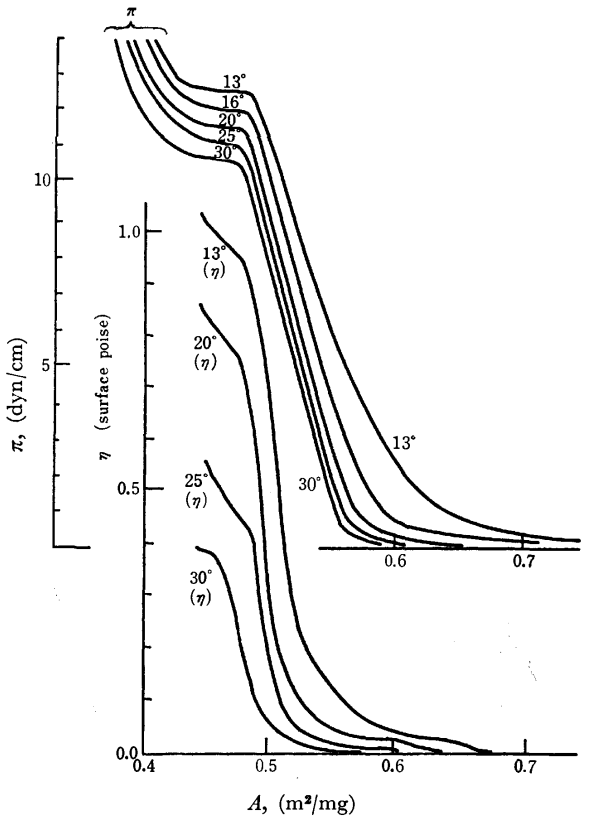

Fig. 4. Temperature dependence of the π-A and η-A curves for PBLG-dodecylamide-10 on water.

surface area corresponding to the beginning of the plateau became smaller with increasing temperature. Both the surface pressure and area of the higher plateau varied with temperature. Temperature had similar effects on the π-A curve of PBLG-dodecylamide-5. Variation of π-A curves of PBLG-dodecylamide-10 with temperature is shown in Fig. 4. The surface pressure corresponding to the higher plateau decreases at high temperature.

The surface moment *vs.* area curves of the PBLG-dodecylamide series are shown in Fig. 5. The surface moment was calculated by the Helmholtz equation $\mu=\Delta VA/4\pi$, assuming that the area occupied by a terminal alkylamine residue is similar to that occupied by an amino acid residue. Since the limiting area of an amino acid residue has been found to be 22 Å^2 in a monolayer of PBLG[1,6] and that of dodecylamine 20.5 Å^2,[7] the above assumption is probably true for a closely packed film.

The smallest area showing the maximum surface moment corresponds to the lower plateau of the π-A curve with PBLG-dodecylamide-5 and also to the area where the surface pressure becomes detectable with PBLG-dodecylamide-10 and PBLG-dodecylamide-20. In an area smaller than that of the plateau, the μ-A curves decrease linearly. In the region from the smallest area showing the maximum surface moment to the area where the surface moment begins to decrease linearly, the plot of μ against A is curved. Assuming that molecules in a monolayer remain in the same conformation when the surface moment is constant, the conformations of the polypeptides seem to remain the same until the surface pressure becomes about 1 dyn/cm, except for PBLG-dodecylamide-5 and PBLG-hexylamide-7 which remain in the same conformations until the lower plateaus are reached. In the region where the plot is curved, the terminal groups contribute considerably to the surface moment since the surface moment varies more for polypeptides of low molecular weight. This suggests that reorientation of terminal groups of polypeptides in associated with decrease in the surface area in this region.

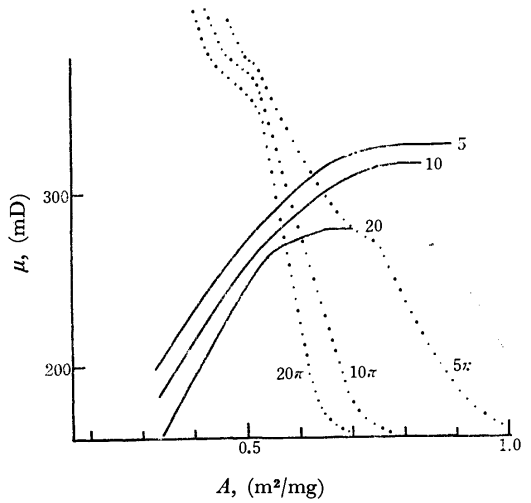

Fig. 5. Surface moment *vs.* area curves for PBLG-dodecylamide series.
The degree of polymerization is noted on each curve.
The π-A curves are shown by dotted lines.

6) S. Ikeda and T. Isemura, This Bulletin,. **34**, 416 (1961).
7) N. K. Adam, *Proc. Roy. Soc.* (London), **A103**, 687 (1923).

Two components of surface moment, due to a peptide and to a terminal group, were estimated from the maximum surface moment, as μ(peptide)$=266\pm29$ and μ(terminal)$=450-1100$ mD. The μ value (peptide) is in accord with that of 265 mD obtained for a monolayer of PBLG.[1,6] The μ value(terminal) varied greatly with polymers. This might be due to complicated factors, such as ionization of these groups.

A hydrocarbon chain should influence the properties of monolayers of polymers of low molecular weight, so the π-A curves of PBLG-hexylamide-7 and PBLG-dodecylamide-5 were compared. The π-A curve of PBLG-hexylamide-7 was found to be more expanded than that of PBLG-dodecylamide-5. The π-A curves of monolayers of PBLG reported previously[1,6] had only one plateau corresponding to the higher plateau observed in this work. This suggests that the lower plateau is due to the terminal alkyl chains. This is supported by the finding that the lower plateau disappeared as the ratio of alkyl groups to peptides became smaller with increase in the degree of polymerization. It seems likely that as the interaction between hexyl groups is smaller than that of dodecyl groups the monolayer of PBLG-hexylamide-7 is more expanded than that of PBLG-dodecylamide-5. The surface pressure related to the lower plateau, which is independent of the temperature, is 7.8 dyn/cm for PBLG-hexylamide-7 and 7.2 dyn/cm for PBLG-dodecylamide-5. Langmuir[8] formulated the interaction between hydrocarbon chains as a function of the number of carbon atoms. Since the polypeptides used in this work have hydrocarbon chains in both their terminals and their side chains, quantitative analyses of their interaction are difficult. The surface pressure at the higher plateau was 10 dyn/cm for PBLG-hexylamide-7 at 20°C and 13 dyn/cm for PBLG-dodecylamide-5 at 20°C, and decreased with increasing temperature.

Surface viscosities become detectable at areas corresponding to the higher plateaus in the π-A curves. It has been reported[9,10] that the surface viscosity of polypeptides is due to the formation of hydrogen bonds between polypeptides. This suggests that hydrogen bonds are formed between peptides in the monolayers when the area corresponds to the higher plateau.

From the shape of the π-A curves obtained with this series of polypeptides, it seems likely that the changes occurring in the monolayers are as follows: (1) molecules in the monolayers become aggregated by the van der Waals force between hydrocarbon chains, (2) reorientation of hydrocarbon chains occurs in the region of the lower plateau, (3) molecules combine by formation of hydrogen bonds between peptide parts of the molecule and (4) reorientation of the side chains of amino acid residues occurs in the region of the higher plateau. The polymers may come in contact with each other by interaction of hydrocarbon chains and the interaction might be too weak to cause any detectable surface viscosity at an area larger than that of the lower plateau. The surface properties of monolayers of PBLG were explained by Yamashita and Yamashita[11] in relation to conformation of the polypeptide. If the conformational change of the oligopeptide studied in this work is considered, it may be related to the higher plateau. Examination of the infrared spectra of the PBLG-dodecylamide series in solid film indicated that low molecular weight PBLG-dodecylamide in the solid film predominantly had β-structure.[12] The conformation of polypeptides in solid films might be related to the π-A curves, as suggested by Yamashita and Yamashita. However, at present information available for further discussion is still insufficient.

12) Solid films for the examination of infrared spectra were prepared from solutions in chloroform on silver chloride plates. Infrared spectra were recorded with a Perkin-Elmer Spectrophotometer, model 221, using a sodium chloride prism. The existence of the α-helical or β-structure is deduced from the absorption bands of amide I and II of polypeptides.

Geometrical Structures of Excited States of Conjugated Molecules: Benzene, Naphthalene, Azulene, and Heptalene

Yuichi FUJIMURA, Hiroyuki YAMAGUCHI, and Takeshi NAKAJIMA

Department of Chemistry, Tohoku University, Katahira-cho, Sendai

(Received July 19, 1971)

A semiempirical SCF CI MO method used in combination with the variable bond-length technique, which has proved to be quite successful in predicting the ground-state geometrical structures of conjugated molecules, has been applied with modifications suitable to their excited states. The values of the parameters appearing in the expression of the resonance integral were adjusted so as to reproduce both the absorption and fluorescence spectra of benzene. The lower three singlet states ($^1B_{2u}$, $^1B_{1u}$, and $^1E_{1u}$) and the lowest triplet state ($^3B_{1u}$) of benzene, the lower two singlet states ($^1B_{1u}$ and $^1B_{2u}$) of naphthalene, the lower two singlet states ($^1B_2$ and $^1A_1$) of azulene, and the lowest singlet state of heptalene are examined. It is predicted that the $^1B_{1u}$ and $^3B_{1u}$ states of benzene have the antiquinoidal and quinoidal conformations of the D_{2h} symmetry respectively, and that the symmetry of the lowest singlet state of heptalene is higher than that (C_{2h}) of the ground state.

The prediction of the geometrical structures, that is, of the C–C bond distances of conjugated hydrocarbons, has long been one of the major problems in π-electron theories. For the ground states of benzenoid hydrocarbons, it has been well recognized that the molecular symmetry is always that suggested by superposition with an equal weight of the equivalent Kekulé-type resonance structures, and that the bond orders calculated using molecular orbital methods, assuming the full molecular-symmetry, yield the theoretical C–C bond lengths, which are themselves in good agreement with the experimental values.

On the other hand, it was somewhat amazing to discover that the ground states of certain nonbenzenoid hydrocarbons (*e.g.*, heptalene) and open-shell or charged π-electron systems (*e.g.*, the cyclopentadienyl radical or the benzene positive ion) do not adopt the fully-symmetrical nuclear arrangement to be expected on the basis of the conventional resonance theory, but, rather, a less symmetrical conformation in which the nuclei have been displaced to a certain degree.[1] These nuclear distortions, accompanied by a molecular-symmetry reduction, have now been well interpreted as due to the Jahn-Teller or pseudo-Jahn-Teller effects.[1,2]

Another interesting case of such bond distortion concerns the electronically-excited states. It has been known, for example, that the ESR line shapes of the lowest triplet state ($^3B_{1u}$) of benzene are not those which would be expected from a molecule with at least a trigonal symmetry.[3] The geometrical structures of the excited states of a conjugated molecule are, in general, different from that of the ground state, the difference being reflected primarily in the band shapes of the electronic spectrum. For example, the UV spectrum of heptalene shows a very long absorption tail throughout the visible region,[4] which probably indicates that the geometrical structure of the first excited state is greatly different from that of the ground state. Furthermore, information on the geometrical structures of excited states is quite useful in understanding the inducing and accepting modes of the intramolecular radiationless transitions.[5,6]

It is the purpose of this paper to propose, on the basis of the semiempirical SCF LCAO MO theory, a computational method of determining the molecular symmetries and C–C bond distances for the electronically-excited states of conjugated molecules and to examine the geometrical structures of the lower excited states of benzene, naphthalene, azulene, and heptalene.

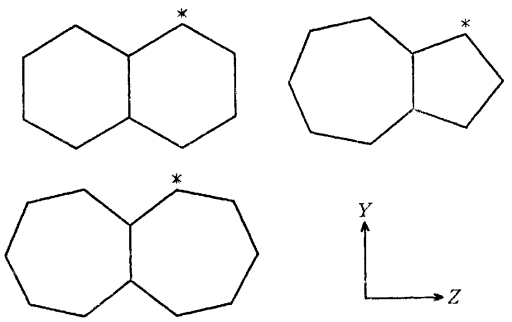

Fig. 1. Numbering of atoms and choice of axes. Carbon atoms are numbered consecutively, starting with the starred atom and proceeding in a clockwise fashion along the periphery.

Method of Calculation

The method used in predicting the energetically most favorable symmetry group and the C nuclear arrangement for an electronically-excited state of a conjugated molecule which is assumed to be planar is a modified version of the semiempirical SCF CI MO method used in combination with the variable bond-length technique, which has proved to be quite successful in predicting the ground-state geometrical

structures of a variety of conjugated molecules.[7,8]

Assuming a certain C nuclear arrangement for a conjugated molecule, we carry out the SCF CI MO calculation in the framework of the Pariser-Parr-Polpe approximation.[9,10] Using the wavefunction for an excited state obtained after the inclusion of the configuration mixing all the singly-excited states, we then calculate the C–C bond length for the excited state by the aid of a suitable bond-order—bond-length relationship (*vide infra*). The new C nuclear arrangement is taken as the geometrical structure for the next SCF MO calculation, and the process is repeated until the convergence of the C–C bond lengths for the excited state is reached. As the starting geometrical structures for the iterative calculation, we take all the possible distorted structures in which C–C bond lengths are distorted so that the set of displacement vectors may form a basis for an irreducible representation of the full symmetry group of the molecule.[11,12]

If the self-consistency of the geometrical structure is achieved at two or more different nuclear arrangements, the total energies should be compared with each other in order to determine which one is the energetically most favorable. The total energy of a conjugated molecule is assumed to be the sum of the π-electron energy and the σ-core energy, which may itself be regarded as the sum of the independent contributions from the C–C σ-bonds. Further, for the reduced distance variation, the individual contribution of the σ-bonds may safely be approximated by the quadratic function of the bond-distance variation:

$$E_\sigma = \sum_{\mu<\nu} \frac{k}{2}(\Delta r_{\mu\nu})^2 \tag{1}$$

where k is the force constant for an sp^2 hybridized C–C σ-bond. The value of k used in the present calculations is 714 kcal mol^{-1} Å^{-2}.[13]

It has now been well established[14] that if the total energy of a conjugated hydrocarbon is written as the sum of the π-electron energy, as calculated using a Hückel approximation, and the σ-bond energy, as approximated by Eq. (1), then the minimization of the total energy with respect to the bond-length variations yields a linear relationship between the bond length, r, and the bond order, p:

$$r_{\mu\nu} = r_0 - ap_{\mu\nu} \tag{2}$$

where r_0 is the length for an sp^2–sp^2 C–C single bond and where $a=2\beta'/k$, β' being the first derivative of the resonance integral.

Recently, Julg[15] has shown that the inclusion of electron repulsions in calculating the π-electron energy by the use of the Pariser-Parr-Pople-type semiempirical SCF MO formalism leads to the following relationship between the bond order and the bond length:

$$r_{\mu\nu} = r_0 - ap_{\mu\nu} + bp^2_{\mu\nu} \tag{3}$$

where $b=\gamma'/2k$ and where γ is the Coulomb repulsion integral between neighboring atoms. The b/a ratio being of the order of 0.1 for the bond distance of 1.34 Å, which corresponds to $p=1$, we may safely neglect the p^2 term in Eq. (3) for the longer bond distances with the lower p values. Further, by minimizing the excited-state total energy with respect to the bond-distance variations, Julg[15] has demonstrated that the same linear relationship between p and r that is appropriate for the ground state holds approximately even for both singlet and triplet excited states. In this paper, we adopt, as the bond-order—bond-length relationship for use in excited states, Eq. (2) with $r_0=1.520$ Å and $a=0.186$,[8] the parameter values giving the ground-state bond lengths, which are in good agreement with the experimental values. Miller and Murrell[16] have proposed the following formula for predicting the excited-state bond lengths of conjugated molecules:

$$\Delta r_{\mu\nu} = -0.228\ \Delta p_{\mu\nu} \tag{4}$$

This formula gives $r_0=1.55$ Å, which seems to be somewhat exaggerated as the length for the sp^2–sp^2 C–C single bond.

The one-center repulsion integral for carbon, given as I_c-A_c, is taken to be 11.16—0.03 eV. The two-center repulsion integrals are calculated using the Mataga-Nishimoto formula.[17] The resonance integrals, $\beta_{\mu\nu}$ (in units of eV), are evaluated using the following formula:

$$\beta_{\mu\nu} = -2.38\ \exp[(1.397-r_{\mu\nu})/A] \tag{5}$$

where the pre-exponential factor has been determined so as to reproduce the experimental excitation energies of benzene. On the other hand, the value of A, on which depend sensitively the geometrical structures of conjugated molecules, cannot be determined by reference to the excitation energies of benzene. In this paper, the value of A is adjusted so as to reproduce the emission energy of the fluorescence from the lowest singlet excited state ($^1B_{2u}$) in benzene. Using the experimental emission energy, 4.44 eV[18] we thus obtain $A=0.30$ Å.

Results and Discussion

Benzene. The geometrical structures of the lower three singlet excited states, $^1B_{2u}$, $^1B_{1u}$, and $^1E_{1u}$, and the lowest triplet state, $^3B_{1u}$, are examined. As the starting bond distortions for iterative calculation, we adopt carbon-stretching symmetry coordinates

TABLE 1. CARBON-STRETCHING SYMMETRY COORDINATES FOR BENZENE

Mode	Symmetry coordinate[a]
a_{1g}	$S_1=\frac{1}{\sqrt{6}}(\Delta r_{12}+\Delta r_{23}+\Delta r_{34}+\Delta r_{45}+\Delta r_{56}+\Delta r_{61})$
b_{2u}	$S_{14}=\frac{1}{\sqrt{6}}(\Delta r_{12}-\Delta r_{23}+\Delta r_{34}-\Delta r_{45}+\Delta r_{56}-\Delta r_{61})$
e_{2g}	$S_{8a}=\frac{1}{\sqrt{12}}(\Delta r_{12}-2\Delta r_{23}+\Delta r_{34}+\Delta r_{45}-2\Delta r_{56}+\Delta r_{61})$
	$S_{8b}=\frac{1}{\sqrt{2}}(\Delta r_{12}-\Delta r_{34}+\Delta r_{45}-\Delta r_{61})$
e_{1u}	$S_{19a}=\frac{1}{\sqrt{2}}(\Delta r_{12}-\Delta r_{34}-\Delta r_{45}+\Delta r_{61})$
	$S_{19b}=\frac{1}{\sqrt{12}}(\Delta r_{12}+2\Delta r_{23}+\Delta r_{34}-\Delta r_{45}-2\Delta r_{56}-\Delta r_{61})$

a) The plus and minus signs indicate the bond shortening and lengthening, respectively. For the numbering of symmetry coordinates, see E. B. Wilson, *Phys. Rev.*, **45**, 706 (1934).

belonging to a_{1g}, b_{2u}, e_{2g}, and e_{1u} irreducible representations of the D_{6h} point group (Table 1). Further, if a certain carbon-stretching symmetry coordinate and its countertype, in which the bond-length variations are reversed, are not equivalent (*e.g.*, S_{8a}), these two bond distortions should be differentiated as the starting geometry.

As for the lowest singlet excited state ($^1B_{2u}$), it turned out that all the starting bond distortions converge into a unique hexagonal nuclear arrangement with the C–C bond length longer by 0.031 Å than that in the ground state. By applying the Franck-Condon principle to the experimental intensity distribution in the 2600 Å band system of benzene, Craig[19] has found the value of 0.037 Å for the increase in the C–C distance associated with the lowest singlet transition, $^1B_{2u}\leftarrow{}^1A_{1g}$. The predicted increase in bond length is in fairly good agreement with this experimentally-estimated value. The $^1B_{2u}$ state should, in principle, suffer pseudo-Jahn-Teller distortions upon coupling with the closely-spaced $^1B_{1u}$ *via* the a_{2g} vibration and upon coupling with the $^1E_{1u}$ state *via* the skeletal bending modes corresponding to the symmetry coordinate, S_6, of the e_{2g} symmetry.[20] However, the a_{2g} vibration has no influence on the C skeletal arrangement, and the bending displacements, S_6, should cause a change in the small $\beta_{\mu\nu}$ value (zero in the P–P–P approximation) between non-neighboring C atoms.

In case of the lowest triplet state ($^3B_{1u}$), the starting nuclear displacements belonging to a_{1g} and b_{2u} representations converge into a hexagonal conformation with the C–C bond length equal to 1.430 Å, while those belonging to the e_{2g} and e_{1u} representations lead to two D_{2h} conformations; one of these is the quinoidal form (I), and the other, the antiquinoidal form (III) (Fig. 2). As for the symmetry displacements of the e_{2g} symmetry, S_{8a} and its countertype bring about the antiquinoidal and quinoidal forms respectively, while S_{8b} and its countertype lead to the other two equivalent quinoidal forms. In Fig. 2 are shown the bond lengths of these equilibrium conformations, together with their relative total energies. The quinoidal form is more stable than the antiquinoidal form by 0.07 eV, the latter being the metastable quilibrium conformation corresponding to the saddle point of the energy surface. The passage from one of the quinoidal conformations, by way of the antiquinoidal saddle points, to the other two equivalent quinoidal conformations may be caused by the e_{2g} vibration.[1,3,21]

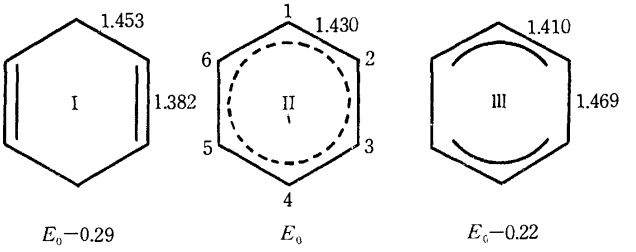

Fig. 2. Predicted equilibrium configurations for the lowest $^3B_{1u}$ excited state of benzene (bond lengths in Å and energies in eV).

In recent years various kinds of experimental studies of the geometry of the $^3B_{1u}$ state of benzene have been attempted. Electron spin resonance experiments by de Groot and van der Waals[3] have indicated that, in solid matrices, the electron-spin distribution in the $^3B_{1u}$ state is far from hexagonal. The study of the phosphorescence spectra of various partly-deuterated benzenes in a C_6D_6 host crystal at 4.2°K by Nieman and Tinti[22] led to the conclusion that the symmetry of the $^3B_{1u}$ state is lower than D_{3h}. The $^3B_{1u}\leftarrow{}^1A_{1g}$ absorption spectrum in benzene vapor mixed with oxygen was studied by King and Pinnington,[23] who concluded that the upper state is of the D_{2h} symmetry. Recently Goncalves and Hutchison[24] studied the electron nuclear double-resonance spectrum of benzene in C_6D_6 single host crystals and suggested that the $^3B_{1u}$ state has an antiquinoidal structure rather than a quinoidal one. It should be noted, however, that, in the experiments in the crystalline or glassy matrix, the degradation of the local D_{6h} symmetry might be due to an environmental effect.

It has been reported that the photochemical reaction of benzene derivatives to Dewar benzene occurs through the $^3B_{1u}$ state.[25–27] To determine the most favorable conformation for the photochemical isomerization, we

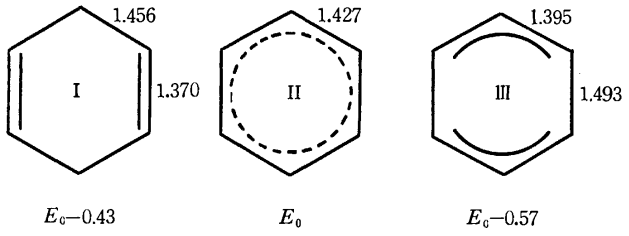

Fig. 3. Predicted equilibrium configurations for the lowest $^1B_{1u}$ excited state of benzene (bond lengths in Å and energies in eV).

examined the nonneighbor 1—4 and 2—5 bond orders of the three conformations, I, II, and III. The predicted 1—4 and 2—5 bond orders of I and III are 0.155 and −0.299, and −0.193 and 0.028, respectively. The predicted 1—4 bond orders of II is −0.057. From the above results, it can be concluded that the most favorable conformation for the reaction in the $^3B_{1u}$ state is I.

For the second singlet state ($^1B_{1u}$), three equilibrium conformations, hexagonal, quinoidal, and antiquinoidal, are obtained. The situation is similar to that predicted for the $^3B_{1u}$ state, except that the relative energies of I and III are interchanged and that the bond length of the unstable hexagonal structure is slightly shorter than that for the $^3B_{1u}$ state (Fig. 3). In the third excited state ($^1E_{1u}$), all the starting distortions lead to the same hexagonal structure, that obtained for the lowest singlet-excited state.

It is well known that the $^1B_{1u}$ state is subjected to the pseudo-Jahn-Teller interaction with the $^1E_{1u}$ state through vibrations of the e_{2g} symmetry[1,21,28] and that the $^1B_{1u}\leftarrow{}^1A_{1g}$ transition is vibronically induced by these vibrations.[29,30] On the other hand, no Jahn-Teller coupling effects are expected to be exhibited at the lowest vibronic level of the $^1E_{1u}\pi^*\leftarrow\pi$ excited state.[31] The results of a recent experimental study by Katz *et al.*[31] of the absorption spectra of benzene and deuterated benzenes in solid rare-gas matrices are in agreement with these predictions. It seems that our results are all consistent with these findings.

Naphthalene. Since the energy difference between the first ($^1B_{1u}$) and second singlets ($^1B_{2u}$) is comparatively small, it may be expected from the symmetry rule[32-34] that the two states will interact strongly with each other through the normal displacement of the b_{3g} symmetry and will suffer a symmetry reduction. Thus, the symmetry groups and the bond lengths for the energetically most favorable nuclear arrangements of the two states were examined. For the two states, the starting bond distortions belonging to the irreducible representations, a_g, b_{3g}, b_{1u}, and b_{2u}, of the full symmetry group, D_{2h}, are taken as the starting bond distortions for iterative calculation. It turns out that, in the two states, all the starting bond distortions converge into a unique self-consistent set of bond lengths corresponding to D_{2h}. The calculated bond lengths of both the states are listed in Table 2 and compared with the experimental values of the ground state.

It is well known that a change in symmetry manifests itself on electronic excitation itself by the appearance of progressions in vibrations which, with respect to the covering symmetry of the ground state, are nontotally symmetrical.

Craig *et al.*[35] have studied the $^1B_{1u}\leftarrow{}^1A_g$ absorption spectrum in naphthalene vapor and shown that such progressions are not found in this absorption band. They have concluded that naphthalene belongs to the D_{2h} symmetry group in the $^1B_{1u}$ electronic state as in the ground state, and that its dimensions are little changed on excitation. The results of Craig *et al.*[35] are in good agreement with the present results.

Table 2. Geometrical structures for various states of aromatic hydrocarbons

Molecule	State	Bond length (Å)					
Napthalene		1—2	1—10	2—3	5—10		
	$^1B_{1u}$	1.399	1.421	1.430	1.457		
	$^1B_{2u}$	1.427	1.417	1.382	1.427

The bond-length changes for excitation to the $^1B_{2u}$ state are calculated by Miller and Murrell,[16] who used Eq. (4) in the framework of the ASMO CI method. The results of these authors are in good agreement with the present ones. By using the predicted bond length changes, they have calculated the intensity of a vibrational progression, which gives a good agreement with the experimental results.

We can draw an important conclusion from the considerations stated above that, on excitation to both the states, there is no change in the symmetry of the molecule.

Azulene. It has been confirmed that azulene does not fluorescence from the lowest singlet ($^1B_2(1)$) state, but instead emits from the second excited singlet ($^1A_1(2)$).[36,37] From this fact, it can be expected that the geometry of the $^1B_2$ (1) state may be considerably deformed compared with that of the ground state ($^1A_1$ (1)). It seemed that it would be interesting to apply the present method to both the excited states.

The starting C-C bond distortions, which are assumed to be inplane, belonging to two irreducible representations, a_1 and b_2, of the full symmetry group, C_{2v}, are taken as the starting ones. Table 2 lists the calculated structures of the $^1B_2$ (1) and $^1A_1$ (2) states, along with the experimental structure of the ground state. For the $^1B_2$ (1) state, the predicted geometrical structure has the C_{2v} symmetry. An analysis of the absorption spectra in the 7000 Å band indicated that azulene retains the C_{2v} symmetry in the $^1B_2$ (1) state.[38] The central bond in the $^1B_2$ (1) state becomes drastically shorter than that in the ground state. In naphthalene, the changes in the bond lengths upon the $^1B_{1u}\leftarrow{}^1A_g$ excitation of naphthalene are comparatively small, so that vibrational frequencies of the upper state can be correlated with those of the ground state. However, a drastic change in the central bond-length of the $^1B_2$ (1) state in azulene would lead to a large variation in the vibrational frequencies of this state. In fact, Hunt and Ross[38] have reported that it is difficult to correlate the vibrational frequencies of the $^1B_2$ (1) state with those of the ground state.

For the $^1A_1$ (2) state, the predicted geometrical structure has the C_{2v} molecular symmetry. McHugh and Ross[39] calculated the structure of the state based on Hückel molecular orbitals with configuration interaction. There are considerable differences between their results and ours in the bond length of the periphery of the molecule. While the C-C bond lengths in the periphery of the molecule are smoothed out in their results, there is a moderate double-bond fixation in the periphery in our results.

From a consideration of the above geometrical structures and the large electronic energy gap[40] between the $^1B_2$ (1) and $^1A_1$ (2) states, it is possible to give a qualitative explanation of the anomalous emission of azulene. The drastic geometrical change in the central bond between the ground and the $^1B_2(1)$ states will lead their two potential surfaces to intersect in the vicinity of the equilibrium point of the $^1B_2$ (1) state. As a result of the intersection, a direct relaxation to the ground state may be the dominant process in the electronic relaxation from the $^1B_2$ (1) state. On the other hand, the bond-length changes in the $^1A_1$ (2) state are moderate, so that the potential surface of the $^1A_1$ (2) state will not intersect with the other potential surfaces ($^1B_2$ (1), $^1A_1$ (1)) in the vicinity of the equilibrium point of the $^1A_1$ (2) state. The large energy gap between the $^1B_2$ (1) and $^1A_1$ (2) states (that is, the small Franck-Condon factors) will cause the nonradiative transition to the lower $^1B_2$ (1) state to be negligibly small. From the above considerations, it can be thought that azulene is emitted from the $^1A_1$ (2) state.

Heptalene. The SCF calculations show that the starting bond distortion, belonging to the b_{3g} representation (that is, alternation), which converges into the geometry of the symmetry group, C_{2h}, in the ground state does not give rise to a symmetry reduction in the lowest excited state; that is, the lowest excited state exhibits no bond alternation. Furthermore, our calculations predict that bond distoritions belonging to b_{1u} and b_{2u} representations do not result in a symmetry reduction, either all the possible starting distortions produce a unique set of bond lengths belonging to the point group D_{2h}. The predicted bond lengths are summarized in Table 2.

The above results may easily be explained on the basis of the symmetry rule[32-34] from the energy-level arrangement in the heptalene molecule with the D_{2h} symmetry. The excitation energies from the ground state to the $^1B_{3g}$, $^1B_{1u}$, and $^1B_{2u}$ states are 0.26, 2.68, and 3.37 eV respectively, and the E_2—E_1 and E_3—E_1 energy gaps are too large to give rise to pseudo-Jahn-Teller distortions in the lowest excited state.

The geometrical structure of the lowest excited state predicted above perhaps gives one of the reasons for the appearance of a long absorption tail in the long-wave length side of the first absorption band in heptalene.[4]

The Effects of the Crystal-structural Transformation on the Chemical Behavior of ^{64}Cu Recoil Atoms in α-Copper Phthalocyanine

Hiroshi KUDO

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken.

(Received July 19, 1971)

The Stage-II annealing process of ^{64}Cu recoil atoms in neutron-irradiated α-copper phthalocyanine was carefully examined. The isothermal annealing curve above 270°C showed anomalous inflection point. It was found that the Stage-II annealing process of the α-crystal consisted of a "normal" monotonous annealing process and a "delayed" process caused by the crystal-structural transformation. The results of a kinematic analysis suggested that the fluctuation of the matrix and the change in the crystalographic factors due to the structural transformation play a triggering role in the delayed annealing reaction.

Despite a number of studies of the annealing reaction of ^{64}Cu recoil atoms in neutron-irradiated copper phthalocyanine,[1-12] the details of the mechanism of the reaction do not appear to have been completely elucidated. Yoshihara and Ebihara[9] found striking effects of the crystal structure on the thermal annealing of the ^{64}Cu recoil atoms produced by (n, γ) and (γ,n) reactions. The recoil atoms in the irradiated β-copper phthalocyanine were very easily annealed, while those in the α-crystal were relatively insensitive. The thermal annealing process could be separated into two stages in both the α- and β-crystals; Stage I below 200°C and Stage II above 250°C.

β-Copper phthalocyanine is the most stable crystal modification, and its crystal structure has been reported in detail by Robertson.[13] At least two other crystal forms, designated as the α- and γ-form, have been characterized by a study of their X-ray powder diffraction patterns and by infrared or visible spectroscopy.[14-21] The α-modification (a metastable crystal) is converted into the β-form by treating it in various organic suspension media, by sublimating it *in vacuo*, or simply by heating it above 250°C.[22-27]

It is known that the behavior of the recoil atom in solids depends on such crystallographic factors as the surface activities, the grain size, and the concentration of defects.[12,28] These factors will inevitably be affected by the crystal-structural transformation. An investigation of the effect of the crystal-structural transformation on the thermal annealing process can be expected to give further information on the chemical fate of the ^{64}Cu recoil atoms in neutron-irradiated α-copper phthalocyanine, especially for the Stage-II annealing process. This effect has, however, attracted little attention during the study of the annealing process in α-copper phthalocyanine.[9]

The aim of the present work is to investigate the effect of the crystal-structural transformation on the Stage-II annealing of ^{64}Cu recoil atoms in neutron-irradiated α-copper phthalocyanine. In fact, the isothermal annealing curve above 270°C showed an anomalous inflection point, while no anomaly was observed in the curve below 250°C. The results are discussed in terms of the crystal-structural transformation during the thermal treatment.

Experimental

Target Materials. α-Copper phthalocyanine from Dai-nihon Ink and Chemicals Inc. was carefully purified by recrystallization from sulfuric acid. β-Copper phthalocyanine was obtained by heating the α-crystal for 5 hr at 300°C. The X-ray powder diffraction pattern, the electron micrograph, and the thermogram of the materials were recorded.

Irradiation. The neutron irradiation of copper Phthalocyanine was performed at the temperature of dry ice (−78°C) for 10 sec by means of a pneumatic tube in the nuclear reactor, JRR-2, of the Japan Atomic Energy Research Institute. The thermal neutron flux at the irradiation position was 5.5×10^{13} n/cm²/sec, and the γ-ray dose rate was about 10^8 R/hr.

Chemical Separation and Radioactivity Measurements. The analytical technique consisted of the dissolution of the target and the separation of the radioactive products by a method described in the literature.[9] After irradiation, the target was dissolved in cold sulfuric acid (<0°C). The solution was slowly poured into a mixture of ice and water to prevent any exchange reaction provoked by a sudden rise of the temperature. The precipitate of copper phthalocyanine was filtered out, and the radioactivity of ^{64}Cu both in the precipitate and in the filtrate was measured by a Baird Atomic single-channel γ-ray spectrometer connected to the NaI(Tl) crystal (well type, 1.75″$\phi\times$2″).

Thermal Annealing. The irradiated sample was heated in a constant-boiling bath with an accuracy of ±0.5°C (<200°C) or in an electric furnace with its temperature controlled within ±1% (>200°C). No thermal decomposition in a gross amount was observed at any temperature.

Results and Discussion

Figure 1 shows the carefully observed isothermal annealing curves of ^{64}Cu recoil atoms in neutron-irradiated α-copper phthalocyanine. As has been described in Ref. 9, the annealable portion in Stage I (below 200°C) is very small, so the State-II process (above 250°C) appears predominant in this system. One can find anomalies in the annealing curves. The isothermal annealing curve of Stage II has an inflection point which moves to the left on the time axis with an increase in its temperature.

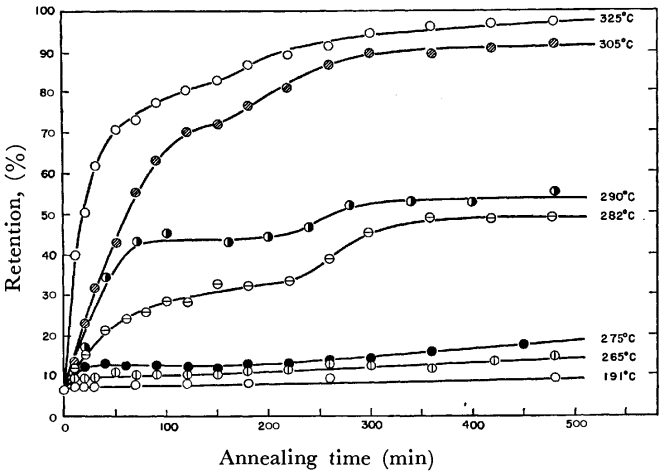

Fig. 1. Isothermal annealing curves of ^{64}Cu recoil atoms in the neutron irradiated α-copper phthalocyanine.

Figure 2 illustrates the isothermal annealing curves of β-copper phthalocyanine. The neutron irradiation and the thermal treatment were carried out under the same condition as those used for the α-crystal. Figure 2 clearly shows the difference between two annealing curves. The annealing process of the β-crystal shows a normal monotonous curve, whereas

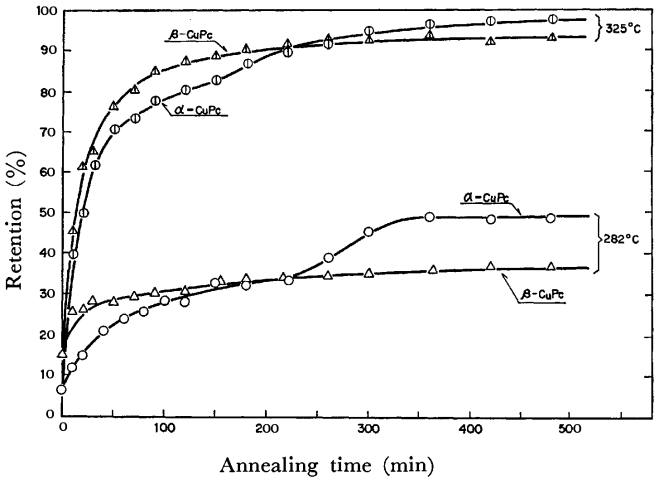

Fig. 2. Comparison of the isothermal annealing curves between α- and β-copper phthalocyanine.

the curve of the α-crystal is not so simple. It can also be pointed out that, although the rate of the annealing reaction of the α-crystal seems somewhat slower than that of the β-crystal at the beginning, the curve for the former reaches a plateau higher than that of the latter, showing a rapid rise around the inflection point. One may attribute these results to the superimposing effect of the crystal-structural transformation in the Stage-II annealing.

The annealing process of the α-crystal appears to consist of the "normal" monotonous annealing process and the "delayed" process which is to be ascribed to the structural transformation. An attempt was made to decompose the curve into two components by assuming that the normal annealing curve can be represented by the first-order rate law. Figure 3 presents two components of the isothermal annealing process of ^{64}Cu recoil atoms in α-copper phthalocyanine. The solid and dotted lines represent the normal annealing process (Component 1) and the other process (Component 2) respectively. Although the magnitude of the annealable portion is not large, the factors determining the features of the curve will hopefully supply

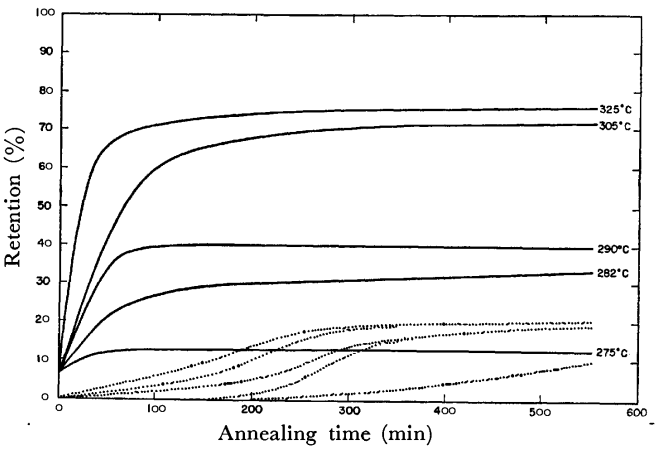

Fig. 3. Two components of the isothermal annealing process in α-copper phthalocyanine; the solid line is the "normal" process (the component 1) and the dotted line is the "delayed" process (the component 2).

information on the mechanism of the delayed annealing process.

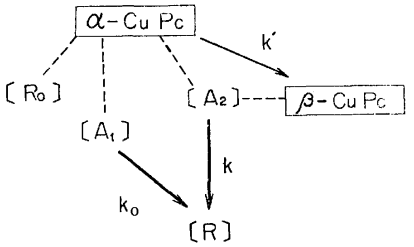
A kinematic analysis was undertaken, with special attention being paid to the delayed annealing process. It was found that the following equations could explain all the features of the annealing reaction:

$$[R] = [C_1] + [C_2], \quad (1)$$

where: $$[C_1] = [A_1]\{1 - \exp(-k_0 t)\} \quad (2)$$

and $$[C_2] = [A_2]/\{1 + 1/a \exp(-kt)\}. \quad (3)$$

Here, [R] is the experimentally-observed value of retention; $[C_1]$, $[A_1]$, and k_0 are the retention, the annealable portion, and the rate constant associated with the normal annealing process; $[C_2]$, $[A_2]$, and k are the corresponding quantities of the other process, and a is a parameter. The mechanism proposed above is depicted schematically in Fig. 4, where k' is the rate constant of the structural transformation of α-copper phthalocyanine to the β-form.



Eig. 4. The possible schematic explanation of annealing process in α-copper phthalocyanine.

As is illustrated in Fig. 5, the curve calculated by the use of Eq. (3) with appropriate values of the a parameter and the k rate constant can satisfactorily explain the delayed annealing reaction. Equation (3) has been derived in the sense of an autocatalytic reaction[29] by assuming that the crystal-structural transformation plays a catalytic role in the course of the delayed process. The parameter a in Eq. (3) determines the induction period, τ, of the delayed process and is closely related to the concentration ratio of the β-modification to the α-crystal in the target under heat treatment. The magnitude of the parameter a becomes smaller with a decrease in the temperature.

The slope of the linear part of the delayed annealing process depends principally on the value of k. The value of k estimated based on the proposed mechanism was found to be of the same order of magnitude as the value of k' associated with the structural transformation of α-copper phthalocyanine. This may indicate that the delayed process is evoked by the crystal-structural transformation.

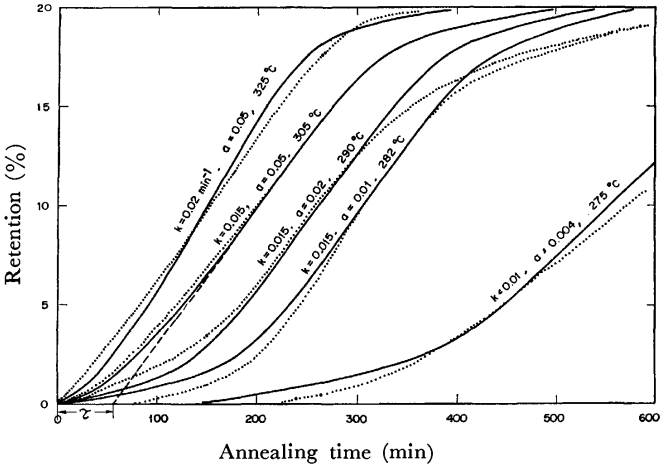


Fig. 5. The calculated curve of the delayed annealing process in α-copper phthalocyanine; the dotted line is the calculated curve and the solid line is the component 2 in Fig. 3.

It is known[30] that the nucleation of a β-particle in a pure α-crystal occurs in the earlier stage of the crystal-structural transformation. After nucleation has begun, the transformation enters the growth stage, the rate of which is controlled by the diffusion process. The electron-micrographic observation revealed that these processes were also involved in the α–β structural transformation of copper phthalocyanine.[31] Consequently, the delayed annealing reaction may be interpreted in terms of the spontaneous fluctuation of the matrix and the change in the crystalographic factors, such as the surface activity and the concentration of defects, due to the structural transformation. These factors probably play a triggering role in the delayed annealing reaction.

The Chemical Behavior of ^{64}Cu Recoil Atoms in the Mixed System of Copper Phthalocyanine and Metal-free Phthalocyanine

Hiroshi KUDO

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken

(Received August 9, 1971)

In order to elucidate the effect of the crystal structure on the chemical behavior of ^{64}Cu recoil atoms in copper phthalocyanine, the author studied the mixed system of copper and metal-free phthalocyanine. It was found that the initial retention increased both in the mixed crystal and in the mixed-disk target. The addition of metal-free phthalocyanine sensitized the target to the thermal annealing reaction, and the rate of the reaction in the mixed crystal was faster than that in the unmixed crystal. The electron acceptor in the target was also found to increase the initial retention. The results were discussed in terms of the electrical properties of the target, which were changed by the change in the spatial arrangement of the molecules.

For the neutron-irradiated copper phthalocyanine, it has already been reported that the chemical consequence of ^{64}Cu recoil atoms depends greatly on the the crystal structure of the target.[1] The initial retention of the β-crystal yielded a higher value than that of the α-crystal. The results have been discussed in terms of the mobility of the recoil atom; *e.g.*, the channeling effect in the crystal depends upon the geometrical configuration of molecules. However, this does not seem the only possible explanation of the difference in the initial retentions in copper phthalocyanine. The intermolecular force and the physical properties of the crystal should inevitably change as the geometrical configuration of the molecules changes. In order to obtain further information leading to a solution of the problem, we studied the mixed system of copper and metal-free phthalocyanine.

Copper phthalocyanine, like other phthalocyanines, shows semiconductivity,[2-6] and the property of its crystal surface necessarily has a significant effect on the fate of the recoil atom. Metal-free phthalocyanine mixed with the target is expected to cause a change in the electrical properties of copper phthalocyanine.[7] It has also been reported[8] that magnesium phthalocyanine disks coated with a film of air-oxidized tetramethyl-*p*-phenylenediamine (TMPD) show a photovoltaic effect, while magnesium phthalocyanine alone exhibits no photovoltaic effect. The addition of chloranil to the surface of films of metal-free phthalocyanine has been found to produce charge carriers in the dark, to increase the quantum yield for the production of charge carriers in the light, and to increase the lifetime of the charge carrier.[9] Interest in the above facts has led to an investigation of the effect of the electron acceptor or the donor in the target.

Experimental

Materials. α-Copper phthalocyanine from Dainihon Ink and Chemicals was carefully purified by recrystallization from sulfuric acid. β-Copper phthalocyanine was obtained by suspending the α-crystal in benzene at 80°C for 2 hr. The α-crystal of metal-free phthalocyanine was prepared from cadmium phthalocyanine by demetallation in a sulfuric acid solution;[10] it was then sublimated *in vacuo* to obtain the β-crystal. The mixed crystal of copper and metal-free phthalocyanine (α-form) was prepared by dissolving appropriate quantities in concentrated sulfuric acid and by then pouring the solution into a large quantity of a mixture of ice and water.[7] The crystal modification of the target material was determined by means of a Philips Norelco X-ray diffractometer, using copper K_α radiation.

For the mixed-disk sample, appropriate quantities of copper and metal-free phthalocyanine were mixed in powder form and then pressed into disk ($\sim$50 mg/cm^2) under a pressure of 100 kg/cm^2. Chloranil from Dai-ichi Pure Chemicals was recrystallized from acetone. *N,N,N',N'*-Tetramethyl-*p*-phenylenediamine dihydrochloride (TMPD), a product of a guaranteed reagent grade from Tokyo Kasei, was used without further purification.

Irradiation. The neutron irradiation of the target was performed at the temperature of dry ice (−78°C) for 10 sec in the nuclear reactor, JRR-2 (thermal neutron flux ϕ_{th}: 5.2×10^{13} n/cm^2/sec) or for 30 sec in the JRR-3 (ϕ_{th}: 2.0×10^{13} n/cm^2/sec). The γ-ray dose rates of the reactors were 1.2×10^8 R/hr and 1×10^8 R/hr respectively.

Chemical Separation and Radioactivity Measurements. The analytical method used here was virtually identical with that described previously.[1] The irradiated target was dissolved in cold sulfuric acid (<0°C), and then the solution was poured into a mixture of ice and water. The precipitate of copper phthalocyanine was then filtered out. The radioactivity of ^{64}Cu in both the precipitate and the filtrate was measured by means of a Baird Atomic single-channel γ-ray spectrometer connected to a NaI(Tl) crystal (well type, 1.75″$\phi\times$2″).

Chloranil and the TMPD did not interfere with the course of the chemical separation.

Thermal Annealing. The irradiated mixed crystal was heated in a constant-boiling bath with an accuracy of ±0.5°C (<200°C) or in an electric furnace with the temperature

controlled within ±1% (>200°C). No thermal decomposition in a gross amount was observed at any temperature.

Results

Prior to the study of the chemical behavior of the recoil atom in the mixed system of copper and metal-free phthalocyanine, the effect of pressing the crystal in the disk was examined. As is shown in Fig. 1, no discrepancy was observed between the untreated and the pressed targets. The initial retentions of both the pressed target and the untreated one were 5.5% for the α-crystal and 13.5% for the β-crystal.

Figure 2 shows the initial retention of the ^{64}Cu recoil atoms obtained in both the mixed crystal and the mixed disk of α-copper phthalocyanine as a function of the concentration of metal-free phthalocyanine

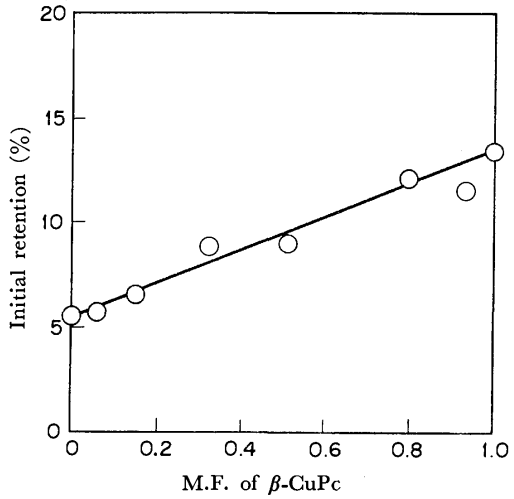

Fig. 1. The initial retention of ^{64}Cu recoil atoms in the mixed disk target of α- and β-copper phthalocyanine. (All samples were pressed under the pressure of 100 kg/cm².)

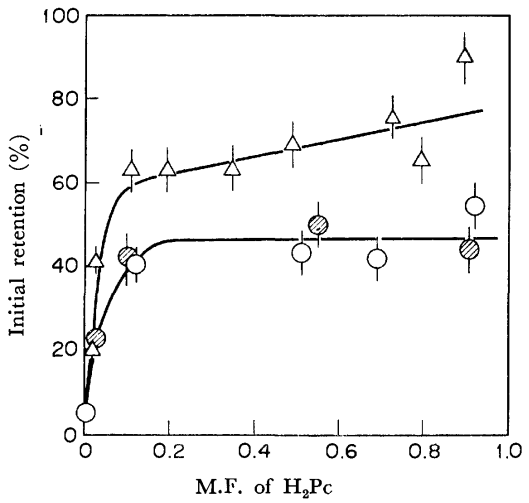

Fig. 2. The initial retention of ^{64}Cu recoil atoms in α-copper phthalocyanine (α-CuPc) mixed with metal-free phthalocyanine (H_2Pc): ○, the mixed crystal (α-form); ◍, the mixed disk with α-H_2Pc; △, the mixed disk with β-H_2Pc.

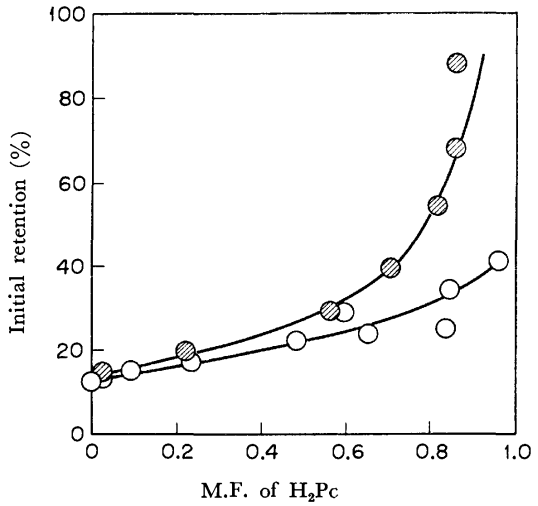

Fig. 3. The initial retention of ^{64}Cu recoil atoms in β-copper phthalocyanine mixed with metal-free phthalocyanine: ○, the mixed disk with α-H_2Pc; ◍, the mixed disk with β-H_2Pc.

in the target. Figure 3 shows the results for β-copper phthalocyanine. Although the shapes of the curves in these figures are not all the same, the initial retention increases in every case in which metal-free phthalocyanine is added. The mixture with the β-form of metal-free phthalocyanine shows a higher value than the mixture with the α-form of metal free phthalocyanine. This tendency is consistent with the finding that the initial retention for β-copper phthalocyanine is larger than that for the α-crystal.

A disk of α-copper phthalocyanine (100 mg/cm²) was irradiated in close contact with a disk of metal-free phthalocyanine in the fashion illustrated in Fig. 4. A disk of α-copper phthalocyanine was attached to a disk (100 mg/cm²) of metal-free phthalocyanine under pressure (Case (a)) or was pressed between two disks (50 mg/cm²) of metal-free phthalocyanine (Case (b)). The initial retentions obtained were 16.8±2.5% and 20.8±3% respectively. These values are clearly higher than those obtained in the unmixed α-crystal.

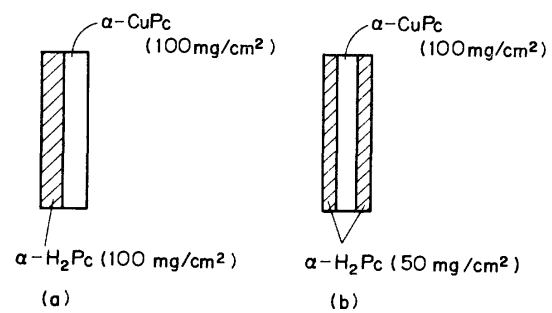

Fig. 4. The cross section of the contact disk target.

The thermal annealing process was studied for the mixed crystal. Figures 5 and 6 show the isothermal annealing curves of ^{64}Cu recoil atoms in the target which contain 0.04 M.F. and 0.53 M.F. of metal-free phthalocyanine respectively. In comparison

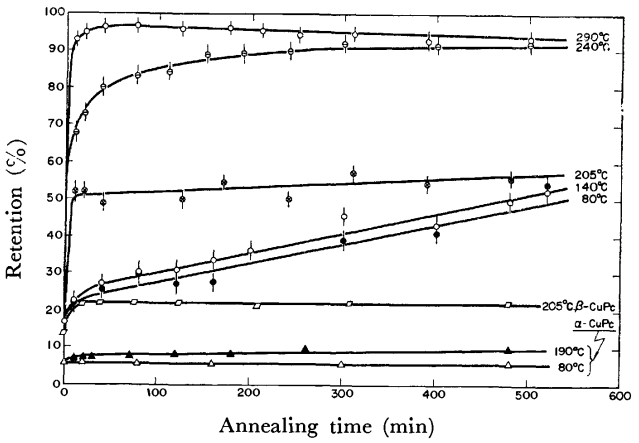

Fig. 5. The isothermal annealing curves for the mixed crystal which contains 0.04 M.F. of metal-free phthalocyanine.

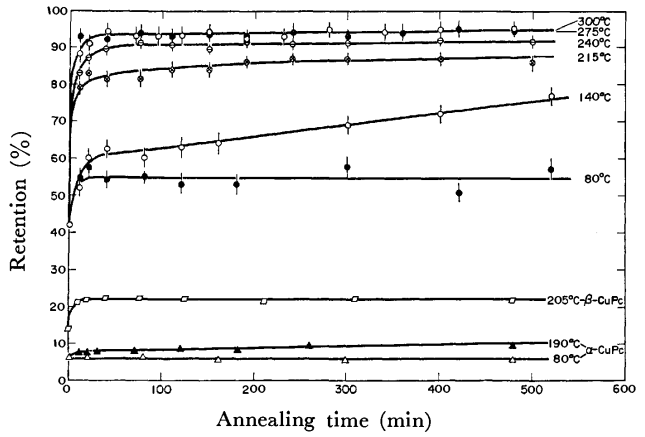

Fig. 6. The isothermal annealing curves for the mixed crystal which contains 0.53 M.F. of metal-free phtha o-cyanine.

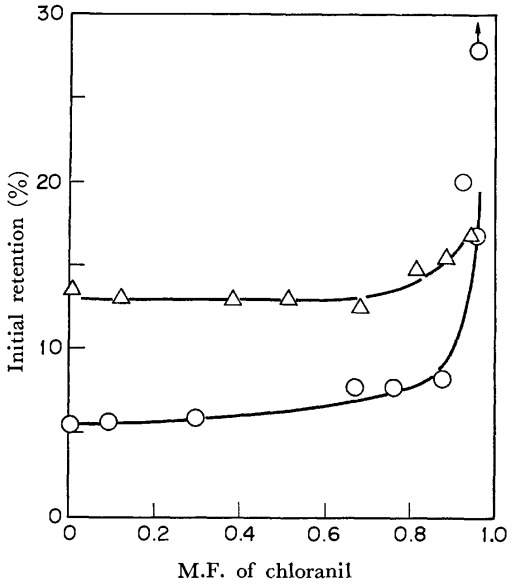

Fig. 7. The effect of chloranil added to copper phthalocyanine on the initial retention of ^{64}Cu recoil atoms. ○, α-crystal; △, β-crystal.

with the curves obtained for the unmixed α-crystal,[1,11] it is clear that, contrary to the case of the unmixed α-crystal, the reaction in the mixed crystal is completed below approximately 250°C. In contrast with the small annealable portion, ΔR, of Stage I (<200°C) in the unmixed crystal, the ΔR in the mixed crystal was very large, even below 200°C. As may be seen in Fig. 5, the retention at 80°C reached a higher value in the mixed crystal, whereas the thermal annealing reaction at the same temperature hardly proceeded at all in the unmixed α-crystal.

The addition of chloranil, as an electron acceptor, to the solid target of copper phthalocyanine was found to increase the initial retention of ^{64}Cu recoil atoms. The results are presented in Fig. 7. When the TMPD was added to the target as an electron donor, no effect on the initial retention was observed.

Discussion

The results presented in Fig. 2 are of great interest. The initial retention increases abruptly in the region of low concentrations of the added metal-free phthalycyanine, the value reaching a plateau in the region above 0.1 M.F. It can also be pointed out that the results obtained with the mixed-disk target of α-copper phthalocyanine with the α-crystal of metal-free phthalocyanine is virtually identical with that obtained in the mixed crystal.

Metal-free phthalocyanine should be distributed homogeneously in the lattice of the mixed crystal, so that it should be possible for the recoil atom to encounter the metal-free molecule in proportion to the concentration of metal-free phthalocyanine. If the recoil atom meets metal-free phthalocyanine in the course of its movement, it may enter the central position of the molecule, thus forming ^{64}Cu-phthalocyanine, since metal-free phthalocyanine has no central metal and two hydrogen atoms in the central space are easily replaced with divalent copper.[5,6] This should lead to an increase in the initial retention.

In the case of the mixed disk target, however, metal-free phthalocyanine may be expected to be mixed rather heterogeneously with copper phthalocyanine. The size of each particle is estimated to be of the order 0.1 μ. Considering the maximum recoil range of ^{64}Cu recoil atoms produced by the ^{63}Cu(n,γ)^{64}Cu reaction in copper phthalocyanine (the order of some tens of Å), it is less probable that the recoil atom interacts directly with metal-free phthalocyanine. Nevertheless, similar results were obtained in the mixed crystal and in the mixed-disk target. From these results, it seems reasonable that metal-free phthalocyanine added to the target indirectly affects the course of the determination of the chemical fate of the recoil atom. The indirect contribution of metal-free phthalocyanine may be supported further by the fact that the initial retention increases when the disk of α-copper phthalocyanine is irradiated in contact with the disk of metal-free phthalocyanine. On the basis of these data, it is possible to say that

11) H. Kudo, This Bulletin, **45**, 389 (1972).

the chemical consequence of the recoil atom strongly depends either on the physical properties of the crystal or on the reaction taking place in the neighborhood of the crystal surface.

As is shown in Figs. 5 and 6, the addition of metal-free phthalocyanine sensitizes the target to the thermal annealing reaction; the annealable portion, ΔR, of Stage I increases remarkably. This may be explained in the same manner as the increase of the initial retention, by assuming that the Stage-I annealing process reflects the initial recoil reaction.[1,12] It is also instructive to note that the rate of the thermal annealing reaction in the mixed crystal, especially at 205°C in the target containing 0.04 M.F. of metal-free phthalocyanine, is faster than that of the unmixed α-crystal. The faster rate of the reaction may be attrubuted to the reaction of the recoil atom at the crystal surface.

Thus, the property of the crystal surface of the phthalocyanine complex may be supposed to play a significant role in determining the chemical behavior of the recoil atom. This is also supported by the results presented in Fig. 7. The addition of chloranil as an electron acceptor to the copper phthalocyanine disk was found to increase the initial retention, although the TMPD, an electron donor, did not appear to affect the initial retention. The results indicate that an electron transfer from copper phthalocyanine to chloranil may have a strong effect on the behavior of the recoil atom.

The conductivity of the α-crystal of metal-free phthalocyanine has been reported[13,14] to be approximately ten times, in special cases more nearly 10^5 times, greater than that of the β-crystal. The values of the energy intervals, based on the band-theory model, of the β-crystals of several metal phthalocyanines lie between 1.5 and 1.7 eV.[15] A much lower value, 0.5 eV, has been reported for the energy interval of the α-crystal.[14] The charge transport in the complex has been explained by an out-of-plane interaction of π-electrons of the conjugated ring structure of the phthalocyanine with the antibonding orbitals of nitrogen atoms in the molecules above and below it.[16] Since the interaction takes place at the distance of the nearest approach of adjacent molecules, the molecular dimensions and the arrangement are important factors in determining the electrical conductivity in the solid. That is, the change in the spatial arrangement of molecules causes a change in the electrical properties of the target and may affect the chemical behavior of the recoil atom in the target.

In the present study of the chemical behavior of ^{64}Cu recoil atoms in the mixed system of copper and metal-free phthalocyanine, the electrical property of the target was suggested to be one of the most significant factors, although it is difficult to conclude at present what parameter of the electrical properties plays a role in determining the chemical fate of the recoil atom. As was mentioned in the last paragraph, the electrical property depends on the spatial arrangement of the molecules. This may lead to an understanding of the crystal-structure dependence of the initial retention in copper phthalocyanine. That is, the channeling effect and also the electrical property of the target might be factors which determine the chemical behavior of the recoil atom.

Calculation of Optical Rotational Strength by Means of Various Types of Molecular Orbitals

Akira IMAMURA, Tsuneo HIRANO,* Chikayoshi NAGATA, and Teiji TSURUTA*

Biophysics Division, National Cancer Center Research Institute, Chuo-ku, Tokyo

**Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Bunkyo-ku, Tokyo*

(Received July 26, 1971)

The optical rotational strengths of the methyl derivatives of cyclohexanone were calculated by means of various types of molecular orbitals, which were converted from those used in the CNDO/2 method. One of them is represented as a Sla ter-basis atomic orbital transformed from molecular orbitals on a CNDO basis by using the overlap matrix. Another was obtained only by modifying the normalization coefficient of the molecular orbitals. From the results, the two-center matrix elements in the calculation of rotational strengths was found to be not negligible, hence, the above-mentioned transformation was indicated to be indispensable. Good agreement with the experimental results was found for the transformed molecular orbitals, especially for those with a modification of the normalization coefficient. The theoretical grounds for these transformations are discussed. The formulae for the matrix elements of the gradient operator which are necessary for the calculation of the rotational strength are given in the appendix.

Recently, several studies of the calculation of the rotational strength by means of molecular orbital theories have been published. Pao and Santry first calculated the rotational strength of methyl-substituted cyclohexanones by the CNDO method,[1] neglecting all the two-center matrix elements.[2] Although only a few experimental data are available, the calculated values agree fairly well with the experimental results. On the other hand, the extended Hückel method[3] was applied to the same molecule, without neglecting the two-center matrix element, by Gould and Hoffmann.[4] Their results seem to be slightly too large.[5] They also calculated the rotational strength of the skewed butadiene chromophore by Pariser-Parr-Pople π-electron-only SCF calculation, with configuration interaction in order to emphasize the importance of the configurational mixing. The rotational strength of the skewed glyoxal at various rotational angles was also calculated[6] by the extended Hückel and CNDO methods, with and without configuration interactions, and with and without the inclusion of two-center matrix elements. This gives the correct sign of the rotational strength for the various α-diketones which were substituted for the skewed glyoxal as a model compound. However, the absolute value of the rotational strength depends remarkably upon the approximations used, that is, whether it is the extended Hückel method or the CNDO method, with or without configuration mixings, and with or without inclusion of two-center integrals. Similar calculations using the Pariser-Parr-Pople method were carried out for skewed butadiene and acrolein by Cheong *et al.*[7] For more complex molecules, the coupled oscillator theory[8] or the method of the composite molecule[9] was employed to find good agreement with the experimental results.

Although the molecular orbital approach to the calculation of the rotational strength is significantly used at present, the quantitative agreement between the calculated and observed values is not always satisfactory. In connection with this, various approximations used in the above calculation should be investigated. For example, the extended Hückel method includes all the overlap integrals; hence, the inclusion of the two-center integrals used for the calculation of the rotational strength is consistent with the approximation of the extended Hückel method However, as is well known, this method is not appropriate for the calculation of polar molecules because of the neglect of the electron-electron repulsion terms. On the other hand, the CNDO method can be expected to give a reasonable wave function for polar molecules, while the inclusion of two-center integrals for the rotational strength is in conflict with the complete neglect of the differential overlap.

In the present investigation, the rotational strength for a few methyl derivatives of cyclohexanone for which experimental data are available were calculated in the CNDO/2 method.[1] The molecular orbital obtained by means of the CNDO/2 method was transformed to that of the Slater-basis set in order to overcome the conflict between the inclusion of two-center integrals in the calculation of the rotational strength and the complete neglect of the differential overlap. The procedure used for the transformation of the molecular orbital from the CNDO basis to the Slater basis will be described in detail in the following section. The rotational strengths thus calculated are in good agreement with the experimental data. The

difference between the rotational strengths calculated as the CNDO basis and as the Slater basis will be considered in connection with the nature of the atomic basis used in the molecular orbital. Moreover, theoretical grounds for the transformation of the molecular orbitals will be discussed.

Method

Molecular Orbitals. The molecular orbitals employed for the calculation of the rotational strengths were calculated by the CNDO/2 method.[1] The parameters included in the method were the same as those proposed by Pople *et al.*[1] The molecular orbitals thus obtained were transformed to those on the Slater basis in the following way: the molecular orbitals on the CNDO basis were assumed to be represented by the orthogonalized atomic basis defined by Löwdin;[10] hence, the atomic orbitals on the CNDO basis can be represented as an appropriate linear combination of Slater-type atomic orbitals effected by the transformation, so that the atomic orbitals on the CNDO basis are orthogonal with each other. The reverse transformation was already carried out by Pople *et al.* in order to compare the results obtained by the use of the CNDO method with those obtained by the use of the non-empirical method.[1] By making use of Pople's notation, the Slater basis set of atomic orbitals, ϕ', is given as;

$$\phi' = \phi S^{1/2} \tag{1}$$

where ϕ is the CNDO-basis set of atomic orbitals and where S is the overlap matrix calculated by use of the Slater-type atomic orbitals.

Another conversion of molecular orbitals was carried out as the assumption that the ratio of the coefficient in a given molecular orbital remains unaltered, while the corresponding normalizing coefficient of the molecular orbital was calculated including the overlap integrals, which were obtained as if the atomic orbital on the CNDO basis were a Slater-type atomic orbital. Therefore, the new coefficient of the atomic orbital can be obtained by dividing the old one by the normalizing coefficient. For occupied orbitals, the new coefficient is usually less in magnitude than the old one because of the bonding character of the orbitals, but the reverse is true for vacant orbitals because of their antibonding character. The physical meanings of these transformations are given below, along with the results calculated for the rotational strength.

Calculation of the Optical Rotational Strength. The optical rotational strength of the molecule, **R**, can be calculated as follows[11]

$$\mathbf{R} = Im\{\langle\Psi_o|\boldsymbol{\mu}|\Psi_e\rangle\cdot\langle\Psi_e|\mathbf{m}|\Psi_o\rangle\} \tag{2}$$

where Ψ_o and Ψ_e are wave functions of the ground and the excited states respectively, and where $\boldsymbol{\mu}$ and **m** are the electric and magnetic moment vectors respectively. In order to avoid the origin dependence of the rotational strength,[12] the matrix element of the electric dipole moment is converted into the dipole velocity formalism, as has already been done by Hoffmann *et al.*,[4]

$$\langle\psi_i|\mathbf{r}|\psi_j\rangle = \frac{\hbar^2}{m}\langle\psi_i|\nabla|\psi_j\rangle/(E_j - E_i) \tag{3}$$

where ψ_i denotes an i-th molecular orbital, and E_i, its energy. By making use of Eqs. (2) and (3), the reduced rotational strength, $[R_{ij}]$, for the $i\rightarrow j$ transition, in which an electron in the i-th molecular orbital is excited to the j-th molecular orbital, is given by Eq. (4);

$$[R_{ij}] = \frac{-7313}{E_j - E_i}\langle\psi_i|\nabla|\psi_j\rangle\cdot\langle\psi_j|\mathbf{r}\times\nabla|\psi_i\rangle, \tag{4}$$

where energy is represented in eV units, and the gradient operator, in Å units. In the LCAO MO approximation, the matrix element included in Eq. (4) can be expanded into those between atomic orbitals. Therefore,

$$\langle\psi_i|\nabla|\psi_j\rangle = \sum_r\sum_s C_{ir}C_{js}\langle\chi_r|\nabla|\chi_s\rangle, \tag{5}$$

$$\langle\psi_j|\mathbf{r}\times\nabla|\psi_i\rangle = \sum_r\sum_s C_{jr}C_{is}\langle\chi_r|\mathbf{r}\times\nabla|\chi_s\rangle, \tag{6}$$

where the molecular orbital, ψ_i, is represented as in Eq. (7), using the atomic orbital χ_r:

$$\psi_i = \sum_r C_{ir}\chi_r. \tag{7}$$

Calculation of the Matrix Element between Atomic Orbitals. The problem now is to calculate the matrix elements between atomic orbitals. One-center integrals will be considered first. The one-center integrals necessary for the calculation are the gradient and the magnetic moment integrals. These integrals have already been given in a previous paper;[2] hence, only the results will be indicated in this paper, with slight modifications. For a gradient operator, the following equations are obtained by using Slater-type atomic orbitals;

$$\int\chi_{2s}\nabla_x\chi_{2px}d\tau = -\int\chi_{2px}\nabla_x\chi_{2s}d\tau = \frac{1}{\sqrt{3}\,a_0}\frac{(\delta_1\delta_2)^{5/2}}{(\delta_1+\delta_2)}(24\delta_1 - 8\delta_2) \tag{8}$$

where a_0 is the Bohr radius and where:

$$\chi_{2s} = \frac{1}{\sqrt{3\pi}}\left(\frac{\delta_1}{a_0}\right)^{5/2} r\exp\left(-\frac{\delta_1}{a_0}r\right), \tag{9}$$

$$\chi_{2px} = \frac{1}{\sqrt{\pi}}\left(\frac{\delta_2}{a_0}\right)^{5/2} x\exp\left(-\frac{\delta_2}{a_0}r\right). \tag{10}$$

If the $2s$ and $2p$ orbitals have the same Slater exponent, Eq. (8) becomes simpler (Eq. (11)):

$$\int\chi_{2s}\nabla_x\chi_{2px}d\tau = -\int\chi_{2px}\nabla_x\chi_{2s}d\tau = \frac{\delta}{2\sqrt{3}\,a_0}, \quad (\delta=\delta_1=\delta_2). \tag{11}$$

It is apparent that the same formulae are given for the matrix elements between $2s$ and $2py$ or $2pz$ atomic orbitals and that the matrix elements between $2p$ orbitals and those between $1s$ orbitals should vanish because of their symmetrical properties. It should be mentioned that when the matrix element is re-

10) P. O. Löwdin, *J. Chem. Phys.*, **18**, 365 (1950).

12) A. Moscowitz, "Modern Quantum Chemistry," Vol. 3, ed. by O. Sinanoğlu, Academic Press, New York (1965), p. 31.

presented in atomic units, a_0 (Bohr radius) in the denominator of Eqs. (8) and (11) is unnecessary.

The one-center matrix elements for the magnetic-moment operator can be rewritten as follows:

$$\int \chi_r(\mathbf{r}\times\nabla)\chi_s d\tau = \mathbf{R}_A \times \int \chi_r \nabla \chi_s d\tau + \int \chi_r(\mathbf{r}_A\times\nabla)\chi_s d\tau, \tag{12}$$

where $\mathbf{R}_A$ is the position vector of the atom, A, to which the χ_r and χ_s atomic orbitals belong, and where $\mathbf{r}_A\times\nabla$ is the magnetic moment operator on the A atom. The second term of the right-hand side of Eq. (12) can be calculated by using the following equations:

$$\left.\begin{aligned}
&(\mathbf{r}_A\times\nabla)\chi_{1s}=0\\
&(\mathbf{r}_A\times\nabla)\chi_{2s}=0\\
&(\mathbf{r}_A\times\nabla)\chi_{2px} = \mathbf{j}\chi_{2pz} - \mathbf{k}\chi_{2py}\\
&(\mathbf{r}_A\times\nabla)\chi_{2py} = \mathbf{k}\chi_{2px} - \mathbf{i}\chi_{2pz}\\
&(\mathbf{r}_A\times\nabla)\chi_{2pz} = \mathbf{i}\chi_{2py} - \mathbf{j}\chi_{2px}
\end{aligned}\right\}, \tag{13}$$

where **i**, **j**, and **k** are the unit vectors in the x, y, and z directions. By combining Eq. (12) with Eq. (13) and Eq. (8) or Eq. (11), all kinds of one-center matrix elements for the magnetic-dipole operator can easily be calculated.

The two-center integrals will be considered next. For the calculation of the two-center matrix elements for the gradient operator, two atoms are assumed to be located on the local coordinate Z axis at the distance of R from one another, as is shown in Fig. 1.

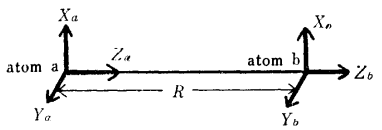

Fig. 1. Local coordinate system.

Then, the matrix elements between the two atomic orbitals on each atom are classified for calculation into several groups according to their symmetrical character, that is, the σ and π characteristics along the Z axis for the atomic orbitals and the gradient operator. The calculation of these matrix elements is followed by the transformation of the coordinate to obtain the matrix element between the atomic orbitals whose coordinates, x, y, and z are defined in the whole molecule. The formulae for the transformation have already been given in the paper by Suzuki *et al.*[13] In Table 1, the equations for the transformation are given; they can be applied by making use of the direction cosines of the local Z-axis with respect to the x, y, z-coordinate system. The two-center gradient matrix elements in the local coordinate can be calculated by using the prolate spheroidal coordinate system, as has already been done by Ehrenson and Phillipson.[14] In this paper, the formulae, which will be given in the appendix, are represented in terms of A and B functions, which are the auxiliary functions frequently used for the calculation of the overlap integrals.[15]

For the calculation of the two-center matrix elements for the magnetic moment operator, the displacement of the origin of the coordinate is necessary, as is shown in the following equation:

$$\int \chi_r(\mathbf{r}\times\nabla)\chi_s d\tau = \mathbf{R}_A \times \int \chi_r \nabla \chi_s d\tau + \int \chi_r(\mathbf{r}_A\times\nabla)\chi_s d\tau \tag{14}$$

where $\mathbf{R}_A$ is the position vector of the atom, A, to which the atomic orbital, χ_s, belongs, and where $\mathbf{r}_A\times\nabla$ is the operator centered on the A atom. The first term of Eq. (14) is easily obtained, since the values of the matrix element for the gradient operator have been calculated in the preceeding step. The second term converts to the calculation of the overlap integrals for p orbitals, but vanishes for s orbitals, according to Eq. (13).

The matrix elements between atomic orbitals thus calculated are substituted into Eqs. (5) and (6) to obtain the rotational strength of the molecules. In order to check the numerical values of these matrix elements, the following equations, which are valid for both the one-center and two-center integrals, should be useful:

$$\int \chi_r \nabla_k \chi_s d\tau = -\int \chi_s \nabla_k \chi_r d\tau \tag{15}$$

TABLE 1. FORMULAE FOR THE TRANSFORMATION OF TWO-CENTER GRADIENT INTEGRALS

$(s|\nabla_i|s) = \gamma_i(S|\nabla_Z|S)$
$(s|\nabla_i|p_i) = \gamma_i^2(S|\nabla_Z|P_Z) + (1-\gamma_i^2)(S|\nabla_X|P_X)$
$(p_i|\nabla_i|s) = \gamma_i^2(P_Z|\nabla_Z|S) + (1-\gamma_i^2)(P_X|\nabla_X|S)$
$(s|\nabla_i|p_j) = \gamma_i\gamma_j\{(S|\nabla_Z|P_Z) - (S|\nabla_X|P_X)\}$
$(p_j|\nabla_i|s) = \gamma_i\gamma_j\{(P_Z|\nabla_Z|S) - (P_X|\nabla_X|S)\}$
$(p_i|\nabla_i|p_i) = \gamma_i[\gamma_i^2(P_Z|\nabla_Z|P_Z) + (1-\gamma_i^2)\{(P_Z|\nabla_X|P_X) + (P_X|\nabla_Z|P_X) + (P_X|\nabla_X|P_Z)\}]$
$(p_i|\nabla_j|p_j) = \gamma_i[(1-\gamma_j^2)(P_Z|\nabla_X|P_X) + \gamma_j^2\{(P_Z|\nabla_Z|P_Z) - (P_X|\nabla_Z|P_X) - (P_X|\nabla_X|P_Z)\}]$
$(p_i|\nabla_j|p_i) = \gamma_j[(1-\gamma_i^2)(P_X|\nabla_Z|P_X) + \gamma_i^2\{(P_Z|\nabla_Z|P_Z) - (P_Z|\nabla_X|P_X) - (P_X|\nabla_X|P_Z)\}]$
$(p_i|\nabla_i|p_j) = \gamma_j[(1-\gamma_i^2)(P_X|\nabla_X|P_Z) + \gamma_i^2\{(P_Z|\nabla_Z|P_Z) - (P_Z|\nabla_X|P_X) - (P_X|\nabla_Z|P_X)\}]$
$(p_i|\nabla_j|p_k) = \gamma_i\gamma_j\gamma_k\{(P_Z|\nabla_Z|P_Z) - (P_Z|\nabla_X|P_X) - (P_X|\nabla_Z|P_X) - (P_X|\nabla_X|P_Z)\}$

i or j or k denotes one of x or y or z. Small letter indicates the atomic orbitals defined in the coordinate of the whole molecule, and large letter the local coordinate in which the Z axis coincides with the line combining two atoms (Fig. 1). γ_i is the direction cosine of the Z axis with respect to the coordinate system x, y and z defined in molecule.

15) R. S. Mulliken, C. A. Rieke, D. Orloff, and H. Orloff, *J. Chem. Phys.*, **17**, 1248 (1949).

$$\int \chi_r(\mathbf{r}\times\nabla)_k\chi_s d\tau = -\int \chi_s(\mathbf{r}\times\nabla)_k\chi_r d\tau, \quad (16)$$

where k denotes either the x, y, or z component of the operator. These equations can easily be proved by using integration by parts. Therefore, Eqs. (17) and (18) can also be obtained:

$$\langle\psi_i|\nabla_k|\psi_j\rangle = -\langle\psi_j|\nabla_k|\psi_i\rangle \quad (17)$$

$$\langle\psi_i|(\mathbf{r}\times\nabla)_k|\psi_j\rangle = -\langle\psi_j|(\mathbf{r}\times\nabla)_k|\psi_i\rangle. \quad (18)$$

In our test calculation, the numerical values for the matrix elements were checked against those in Ref. 6, where the numerical values of the z component of the magnetic moment operator of glyoxal are given together with the coordinates of the atoms. It was also confirmed that the rotational strength thus calculated does not vary with the transformation of the coordinate and the displacement of the origin of the coordinate.

Results and Discussion

In Table 2, the calculated rotational strengths of the methyl derivatives are listed for various methods, together with the experimental values. The coordinates of the atoms used for the calculation are the same as those in Ref. 2. By any method, fairly good agreement with the experimental values is found. However, the calculations with only one-center integrals give too large values for 7-, 13-dimethyl cyclohexanone. In other words, the neglect of the two-center integrals results in a large effect on the value of the rotational strength. Therefore, it should be concluded that the rotational strength has to be calculated by the inclusion of two-center integrals, even in the CNDO method.

Theoretically speaking, the molecular orbital employed for the calculation of the rotational strengths including the two-center matrix elements should not be the molecular orbital calculated in the approximation of the complete neglect of the differential overlap, that is, by the CNDO method. In order to overcome this difficulty, the molecular orbitals obtained by the CNDO method were converted to those on the Slater basis or those with a modification of the normalization coefficient described in the previous section. The bonding parameters, β, in the CNDO method were originally determined by corresponding the non-empirically calculated molecular orbitals with those on the Slater basis, which were converted from those on the CNDO basis for diatomic molecules.[1] In this sense, the molecular orbitals on the Slater basis by the CNDO method seem to be appropriate for the calculation of the rotational strength by procedure including two-center matrix elements. However, it should be emphasized that the atomic orbital on the CNDO basis should have a considerable mixing of Slater-type atomic orbitals other than that of the atom considered if the atomic orbital on the CNDO basis is assumed to be the orthogonalized atomic orbital proposed by Löwdin and if the overlap integrals between Slater-type atomic orbitals are relatively large. On the other hand, the bonding parameters are appropriate for diatomic molecules. Therefore, the Slater-type atomic orbitals converted from those on the CNDO basis may not correspond to the Slater-type atomic orbitals used in non-empirical calculations for large molecules. This may be the reason why the rotational strengths calculated by using the molecular orbital on the Slater basis are slightly different from the experimental values.

Table 2. Rotational strengths of methyl derivatives of cyclohexanone for n-π^* transition[a)]

Method \ Molecule		7-, 13- CH_3 cyclohexanone	7-, 8-, 13- CH_3 cyclohexanone
CNDO basis	total	+1.65	+7.26
	one-center[b)]	+4.95	+3.64

	one-center[b)]	—	—
Experimental[16)]		+1.8	+6.7
Extended Hückel[4)]		+11.06	+12.72

a) The rotational strengths are calculated by using the value of 4 eV for the n-π^* excitation energy.
b) The rotational strength with the one-center matrix element only.
c) CNDO normalized is the method in which the molecular orbital is normalized by using overlap integrals.

Another approach to the calculation of rotational strengths is to use the molecular orbital in which the normalization coefficient is recalculated by including overlap integrals, while the ratio of the coefficients of atomic orbitals in a molecular orbital is assumed to be the same as that in the CNDO method, as has been mentioned in the previous section. Even in this method, there are some faults, one of which is the fact that the molecular orbitals in the CNDO method are calculated in an approximation and with a complete neglect of the differential overlap, contrary to the inclusion of overlap integrals in the recalculation of the normalization coefficient. This discrepancy can be overcome if the ratio of the coefficients of the atomic orbitals in a molecular orbital does not depend upon either the inclusion or neglect of the differential overlap in the CNDO calculation, which cannot be theoretically proved. Another fault included in this method is the non-orthogonality, that is, the molecular orbitals obtained by a modification of the normalization coefficient are usually not orthogonal with each other. However, if the molecular orbitals have different symmetries, even incompletely different ones, such as in the n-π^* transition in methylcyclohexanones, this orthogonality between molecular orbitals is approximately retained. Generally speaking, this non-orthogonal character may not have serious effects on the rotational strength, since the bonding character for occupied orbitals and the antibonding character for vacant orbitals give rise to relatively small overlap integrals between occupied and the vacant orbitals, although the contribution of this overlap term

16) H. Moffitt and A. Moscowitz, *J. Chem. Phys.*, **30**, 648 (1959).

may not be negligible in some cases. At any rate, as may be seen in Table 2, this molecular orbital with a modification of the normalization coefficient seems to give a remarkably good agreement with the experimental results.

In connection with the modification of the molecular orbitals in the CNDO method, we would like to mention that the calculation of the rotational strength with only a one-center matrix element is not always consistent with the approximation in the CNDO method, contrary to the discussion given in a previous paper.[2] The reason for this is that the atomic orbital on the CNDO basis, which can be considered to be the orthogonalized atomic orbital proposed by Löwdin, usually gives non-vanishing two-center matrix elements for the gradient and the magnetic moment operators, even if the corresponding overlap integral vanishes. This is probably supported by the fact that the rotational strengths with only one-center matrix elements calculated by the CNDO molecular orbital (first row of Table 2) are considerably different from those with both one- and two-center matrix elements calculated by the molecular orbitals on the Slater basis (third row of Table 2).

In conclusion, the rotational strengths calculated by the molecular orbitals in the CNDO method with a modification of the normalization coefficients have been found to be in excellent agreement with the experimental result. However, the validity of this treatment must be extensively investigated for various molecules, although the lack of the experimental values of the rotational strength makes it impossible to do so in the present investigation.

Numerical calculations were carried out on the HITAC 5020E Computation Center of the University of Tokyo and on the HITAC 8300 Computer at the National Cancer Center.

Appendix

Formulae of the two-center matrix elements for the gradient operator. As is shown in Fig. 1, the Z axis directs from the a atom to the b atom. R is the distance between a and b atoms in Å units, while P and t are given by the following equation:

$$P = \frac{R}{2a_0}(\delta_a+\delta_b) \tag{A-1}$$

$$t = \frac{\delta_a-\delta_b}{\delta_a+\delta_b} \tag{A-2}$$

where a_0 is the Bohr radius and where δ_a and δ_b are the Slater exponents of the two atomic orbitals, a and b. The auxiliary functions, A_k and B_k, are defined as usual:[15]

$$A_k(P) = \int_1^\infty x^k e^{-Px}dx \tag{A-3}$$

$$B_k(Pt) = \int_{-1}^1 x^k e^{-Ptx}dx. \tag{A-4}$$

The formulae of various types of matrix elements for the gradient operator are given below:

$$(1S_a|\nabla_Z|1S_b) = -\frac{P^4}{4R}(1-t^2)^{3/2}(1-t)$$
$$[A_2B_1+A_1(B_2-B_0)-A_0B_1]$$

$$(2S_a|\nabla_Z|1S_b) = -\frac{P^5}{8\sqrt{3}R}(1-t^2)^{5/2}$$
$$[A_3B_1+A_2(2B_2-B_0)+A_1(B_3-2B_1)-A_0B_2]$$

$$(1S_a|\nabla_Z|2S_b) = \frac{\delta_b}{8\sqrt{3}a_0}P^4(1-t^2)^{3/2}(1-t)$$
$$[-A_3B_1+A_2B_0+A_1B_3-A_0B_2]$$
$$+\frac{P^4}{4\sqrt{3}R}(1-t^2)^{3/2}(1-t)$$
$$[A_2B_1+A_1(B_2-B_0)-A_0B_1]$$

$$(2P_{Za}|\nabla_Z|1S_b) = -\frac{P^5}{8R}(1-t^2)^{5/2}[A_3B_2+A_2B_3$$
$$-A_1B_0-A_0B_1]$$

$$(1S_a|\nabla_Z|2P_{Zb}) = \frac{\delta_b}{4a_0}P^3(1-t^2)^{3/2}(A_2B_0-A_0B_2)$$
$$-\frac{P^5}{8R}(1-t^2)^{3/2}(1-t)^2[A_3B_2+A_2$$
$$\times(B_3-2B_1)+A_1(B_0-2B_2)+A_0B_1]$$

$$(2P_{Xa}|\nabla_X|1S_b) = -\frac{P^5}{16R}(1-t^2)^{5/2}[A_3(B_0-B_2)$$
$$+A_2(B_1-B_3)+A_1(B_2-B_0)+A_0(B_3-B_1)]$$

$$(1S_a|\nabla_X|2P_{Xa}) = \frac{\delta_b}{4a_0}P^3(1-t^2)^{3/2}(A_2B_0-A_0B_2)$$
$$-\frac{P^5}{16R}(1-t^2)^{3/2}(1-t)^2[A_3(B_0-B_2)$$
$$+A_2(B_1-B_3)+A_1(B_2-B_0)+A_0(B_3-B_1)]$$

$$(2S_a|\nabla_Z|2S_b) = \frac{\delta_b}{48a_0}P^5(1-t^2)^{5/2}[A_3(B_0-B_2)$$
$$+A_1(B_4-B_2)+B_1(A_2-A_4)+B_3(A_2-A_0)]$$
$$+\frac{P^5}{24R}(1-t^2)^{5/2}[A_3B_1+A_2(2B_2-B_0)$$
$$+A_1(B_3-2B_1)-A_0B_2]$$

$$(2P_{Za}|\nabla_Z|2S_b) = -\frac{\delta_b}{16\sqrt{3}a_0}P^5(1-t^2)^{5/2}$$
$$[B_2(A_0+A_4)-A_2(B_0+B_4)]$$
$$+\frac{P^5}{8\sqrt{3}R}(1-t^2)^{5/2}$$
$$\times[A_3B_2+A_2B_3-A_1B_0-A_0B_1]$$

$$(2S_a|\nabla_Z|2P_{Zb}) = \frac{\delta_b}{8\sqrt{3}a_0}P^4(1-t^2)^{3/2}(1+t)$$
$$(A_3B_0+A_2B_1-A_1B_2-A_0B_3)$$
$$-\frac{P^6}{16\sqrt{3}R}(1-t^2)^{5/2}(1-t)$$

Spin Relaxation Effects on the ESR Spectrum of Gaseous Oxygen Atoms

Mamoru JINGUJI, Yuji MORI, and Ikuzo TANAKA

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo

(Received July 7, 1971)

The linewidths of the single-quantum transitions of $O(^3P_1)$ and $O(^3P_2)$ in gaseous diluents, such as oxygen molecules and an inter gas, are measured with an ESR spectrometer of a usual type. The cross sections calculated from the pressure broadening are given. With regard to the multiple-quantum transitions in the Zeeman sublevels of $O(^3P_2)$, the dependence of the linewidths on the pressure is duscussed. The spin-lattice relaxation time, T_1, for the single-quantum transitions of $O(^3P_1)$ or $O(^3P_2)$ is evaluated by employing the standard power saturation technique, and the effectiveness of an inert gas on T_1 is studied. The spin-lattice relaxation between the Zeeman sublevels of the O atom is caused by the coupling between the orbital momentum and the electron-spin state upon collision. With regard to the multiple-quantum, the relaxation mechanism is also studied. Finally, we study the relationship between the spin-lattice relaxation time, T_1, and the corresponding probabilities of $\Delta M_J = \pm 1$, $\Delta M_J = \pm 2$, $\Delta M_J = \pm 3$, and $\Delta M_J = \pm 4$ transition induced by collisions.

Recently studies of spin-relaxation phenomena in the gas phase with two different experimental techniques of ESR spectroscopy have been reported for S-state atoms. One is the measurement of the spin-lattice relaxation time, T_1, for the N atom by Brown and Brennen.[1] They noticed that the N atoms in the N_2 diluent have a long spin-lattice relaxation time and interpreted their data in terms of a lack of equilibration in the portion of the flow tube in the external magnetic field up to the cavity. On the other hand, Westenberg and deHaas[2] have obtained T_1 for the H atom by employing the standard power saturation technique; they have found that O_2 is effective in shortening T_1. We have now investigated the spin relaxation phenomena between Zeeman sublevels of O atoms. It is well known that the ground state of the O atom is ^3P, which is split into three states, $^3P_0$, $^3P_1$, and $^3P_2$, by the spin-orbit interaction. We observed the two absorption lines of the $^3P_1$ state and the four lines of the $^3P_2$ state at a low microwave power level and at a low pressure with the usual ESR technique. At lower pressures, we observed the spectra of the multiple-quantum transitions[3] at the expected position for the $^3P_2$ state with a higher microwave power.

In order to obtain the spin-lattice relaxation time for the single-quantum transition between Zeeman sublevels, we employed the standard power saturation technique formulated theoretically by Westenberg and deHaas.[2] This technique was extended to the measurement of T_1 in the multiple-quantum transitions. From the saturation studies of the four lines of the $^3P_2$ state, it was found that the relative absorption intensity of the two-quantum transition to the single-quantum transition is dependent on the pressure. A decrease in the pressure caused this relative intensity to change from a value of about 1/3 to a value of about 6. Since the spin-lattice relaxation in the gas phase is caused by the collision of the O atom with the oxygen molecule, these data show that the intensity of the multiple-quantum transi-

1) R. L. Brown and W. Brennen, *J. Chem. Phys.*, **47**, 4697 (1967).

3) C. C. McDonald, *ibid.*, **39**, 3159 (1963).

tions is correlated with the spin relaxation phenomena. We measured the spin-lattice relaxation time for the single-, two-, and three-quantum transitions. An interpretation has been given of the dependence of T_1 on the pressure, and for the collisional relaxation mechanism in the gas phase. The analysis indicated that the values of T_1 for the single-, two-, and three-quantum transitions were of the order of 10^{-7}—10^{-6} sec in our system, and that, at any pressure, T_1 increased in this order. Then we investigated the variation in T_1 for the single-quantum transition of $O(^3P_2)$ in inert gas diluents, He, Ne, Ar, Kr, and Xe. The measurement of T_1 yielded the following cross sections for the spin-lattice relaxation: $\sigma_{O-He}=9.9$ Å^2, $\sigma_{O-Ne}=8.5$ Å^2, $\sigma_{O-Ar}=12$ Å^2, $\sigma_{O-Kr}=21$ Å^2, $\sigma_{O-Xe}=25$ Å^2, and $\sigma_{O-O_2}=33$ Å^2. It is concluded that the spin-lattice relaxation in O atoms is caused mainly by collisions between the O atom and inert gases through the strong spin-orbit coupling. Finally, we will discuss the relationship between the transition probabilities and the spin-lattice relaxation, using the experimental values of T_1 for the single-, two-, and three-quantum transitions.

Experimental

A JES-3BSX ESR spectrometer with a cylindrical TE_{011} mode cavity was used; the cavity frequency was about 9170 MHz. The magnetic field was modulated sinusoidally at a rate of 100 kHz, and the modulation amplitude was 28 mG. The loaded Q of the cavity was 2840. In order to obtain the spin-lattice relaxation time, the absolute value of microwave power was measured by a means of a thermister. The power (in gauss squared) of the microwave magnetic field, averaged over time and over the volume of the sample in the cavity, was estimated in the manner outlined by Poole.[4]

The flow of oxygen in the quartz tube, 10 mmϕ, was discharged in a cavity powered by a microwave generator (2450 MHz, 100 W) 50 cm upstream from the center of the ESR cavity. The measurements were carried out at total pressures from 0.02 to 0.3 Torr in order to obtain well-resolved spectra.

Theoretical

(i) The Single-quantum Transitions. Westenberg and deHaas[2] assumed that the homogeneous, unsaturated lineshape was Lorentzian, and they derived a general expression for the complex susceptibility in which the imaginary part represents the absorption of energy. Then, using Wahlquist's treatment,[5] they derived the following relation, which is convenient for saturation studies:

$$\left(\frac{H_1S_s}{H_{1R}S}\right)^{2/3}=\frac{0.53}{(2\mu^2T_1T_2/\hbar^2)^{1/3}H_{1R}{}^{2/3}}+0.53(2\mu^2T_1T_2/\hbar^2)^{2/3}H_{1R}{}^{4/3}\left(\frac{H_1{}^2}{H_{1R}{}^2}\right) \quad (1)$$

where μ^2 is the square of the absolute value of the transition matrix element in the direction of the microwave magnetic field, where $H_1{}^2$ is the average value of the microwave power in the sample, and where $H_{1R}{}^2$ is the absolute reference power of 1.54×10^{-4} G. S is the peak-to-peak amplitude, and S_s is the maximum value of S.

(ii) The Multiple-quantum Transitions. The theory of the multiple-quantum transitions was developed by Hughes and Geiger.[6] From their theory, we can expect that the intensities of the two- and three-quantum transitions will be proportional to the square and cube of the microwave power respectively. This relation is confirmed by the experimental results. There is experimental evidence that the lineshape of the two-quantum transition is adequately approximated by the Lorentzian lineshape, *i.e.*;

$$f(H-H_0)=\frac{\gamma T_2{}^*/\pi}{1+\gamma^2T_2{}^{*2}(H-H_0)^2},$$

where $T_2{}^*$ is a measure of the inverse observed linewidth. It is very closely connected with the area and the peak value of the lineshape. For the two-quantum transitions, we derived theoretically the following equation from the analogy of the single-quantum transitions, considering the dependence of the transition on the microwave power

$$\left(\frac{H_1{}^2S_s}{H_{1R}{}^2S}\right)^{2/3}=\frac{0.53}{(2\mu^2T_1T_2{}^*/\hbar^2)^{1/3}H_{1R}{}^{4/3}}+0.53(2\mu^2T_1T_2{}^*/\hbar^2)^{2/3}H_{1R}{}^{8/3}\left(\frac{H_1{}^2}{H_{1R}{}^2}\right)^2 \quad (2)$$

μ^2 in Eq. (2) is the square of the absolute value of the matrix element for the two-quantum transition, which is different from that of the single-quantum transition as given by Hughes and Geiger.[6] In the case of the three-quantum transitions, the following equation is also derived, where μ^2 is the square of the absolute value of the matrix element for the three-quantum transition, and where $T_2{}^{**}$ is a measure of the inverse observed linewidth:

$$\left(\frac{H_1{}^3S_s}{H_{1R}{}^3S}\right)^{2/3}=\frac{0.53}{(2\mu^2T_1T_2{}^{**}/\hbar^2)^{1/3}H_{1R}{}^{6/3}}+0.53(2\mu^2T_1T_2{}^{**}/\hbar^2)^{2/3}H_{1R}{}^{12/3}\left(\frac{H_1{}^2}{H_{1R}{}^2}\right)^3 \quad (3)$$

In Eqs. (2) and (3), $H_{1R}{}^2$ is an absolute reference power at the sample, the values of which are 9.7×10^{-4} and 7.5×10^{-3} G^2 respectively.

Results and Discussion

(i) Linewidth. Collision with any species perturbs the M_J levels by way of coupling between the orbital momentum and the electron spin state, and causes line broadening. For the O atom, the linewidth, ΔH_{msl}, is governed by the collision frequency; thus, ΔH_{msl} is proportional to the total pressure, by analogy with simple kinetic theory. The plots of ΔH_{msl} *vs.* the total pressure, shown in Fig. 1, all give

straight lines. For the $^3P_1$ state, the linewidths of the $M_J=-1\rightarrow0$ and $M_J=0\rightarrow1$ lines were equal to each other. For the $^3P_2$ state, the linewidths of the $M_J=-2\rightarrow-1$ and $M_J=1\rightarrow2$ lines were equal to each other, and the $M_J=-1\rightarrow0$ and $M_J=0\rightarrow1$ lines were also equal. Thus, the $M_J=-1\rightarrow0$ line of $O(^3P_1)$ and the $M_J=-2\rightarrow-1$ and $M_J=-1\rightarrow0$ lines of $O(^3P_2)$ were used for the width measurement, shown in Fig. 1. The cross sections for the line broadening were calculated for each line of the single-quantum transitions from the data in Fig. 1. The slopes of these linear plots give the values of the cross sections, $\sigma_{O(^3P_2)-O_2}=30.1$ Å^2 and $\sigma_{O(^3P_1)-O_2}=27.7$ Å^2, which are somewhat smaller than the value, $\sigma_{O-O_2}=37$ Å^2, obtained for the $M_J=-1\rightarrow0$ line of $O(^3P_1)$ by Westenberg and deHaas.[2]

The linewidths of the multiple-quantum transitions were noticeably smaller than those of the single-quantum transitions, as is to be expected from the theory of the multiple-quantum transitions.[6] The linewidths of the two- and three-quantum transitions are plotted against the total pressure, together with those of the single-quantum transitions, in Fig. 1. In the case of the two-quantum transition, the plots of the $M_J=-2\rightarrow0$ and $M_J=-1\rightarrow1$ lines are shown in Fig. 1, since the linewidths of the $M_J=-2\rightarrow0$ and $M_J=0\rightarrow2$ lines were equal to each other. In the case of the three-quantum transitions, the linewidths of the $M_J=-2\rightarrow1$ and $M_J=-1\rightarrow2$ lines were also equal; thus, the plots of the $M_J=-2\rightarrow1$ line are shown in Fig. 1. The apparent cross sections for the two- and three-quantum transitions are calculated from the slopes of the linear plots in Fig. 1 to be σ_{O-O_2} 14.6 Å^2 (two-quantum transition) and $\sigma_{O-O_2}=9.4$ Å^2 (three-quantum transition). These cross sections for the two- and three-quantum transitions are nearly 1/2 and 1/3 of those for the single-quantum transitions respectively. These relations coincide with that derived theoretically by Hughes and Geiger.[6]

In order to examine the pressure broadening, we added various inert gases, He, Ne, Ar, Kr, and Xe, as perturbers, keeping the partial pressure of oxygen constant at 0.048 Torr. Then, the variation in the linewidth of the $M_J=-1\rightarrow0$ line of $O(^3P_2)$ was measured; the plots of ΔH_{msl} *vs.* the pressure of inert gases are shown in Fig. 2. The slopes of these linear plots give the cross sections for the line-broadening collision. The values obtained are $\sigma_{O-He}=10.1$ Å^2, $\sigma_{O-Ne}=12.4$ Å^2, $\sigma_{O-Ar}=20.1$ Å^2, $\sigma_{O-Kr}=24.2$ Å^2, and $\sigma_{O-Xe}=28.2$ Å^2. The line-broadening cross sections obtained in this paper are larger than those obtained from the kinetic theory.

(ii) Relaxation Time. S-state atoms, which have no orbital angular momentum in the ground electronic configuration, have a long spin-lattice relaxation time, T_1, in the gaseous state. For N atoms, in the N_2 diluent, or for H atoms in the H_2 diluent, therefore, the saturation of ESR absorption by the atoms can be easily observed at a low microwave power, even at a high diluent pressure.[7] On the other hand, the observation of the saturation phenomena on O atoms in the $^3P_2$ and $^3P_1$ states needs a reduced oxygen diluent pressure and an increased microwave power.

By employing Eq. (1), the T_1 values for six single-quantum transitions of $O(^3P_1)$ and $O(^3P_2)$ are obtained from the saturation data. The plots of $(H_1/H_{1R}\cdot S_S/S)^{2/3}$ against the relative power (H_1^2/H_{1R}^2) at oxygen pressures from 0.02 to 0.3 Torr are shown in Fig. 3 for $O(^3P_2)$. The $(H_1/H_{1R}\cdot S_S/S)^{2/3}$ *vs.* (H_1^2/H_{1R}^2) plots for both $O(^3P_1)$ and $O(^3P_2)$ at a constant pressure of 0.139 Torr are also shown in Fig. 4 for the sake of comparison. These plots give linear lines with slopes of $0.53\ \{(2\mu^2T_1T_2/\hbar^2)^{2/3}H_{1R}^{4/3}\}$ and intercepts of $0.53/\{(2\mu^2T_1T_2/\hbar^2)^{1/3}H_{1R}^{2/3}\}$. It is possible to evaluate $T_1\cdot T_2$ from the value of either slopes or intercept. The values of $T_1\cdot T_2$ obtained in these two different ways almost coincided with each other. Since the lineshapes of the absorption spectra are

Lorentzian at low modulation amplitudes and at a low microwave power, we can use the well-known relation $T_2=2/(\sqrt{3}\gamma\Delta H_{msl})$, where γ is $g\mu_B/\hbar$. Using this relation, we can calculate T_2, and then determine T_1 from the value of $T_1\cdot T_2$. These values are summarized in Table 1. In the case of inert-gas diluents, we calculated T_1 from the saturation data in the same manner. The values of T_1 thus obtained are summarized in Table 2. In order to obtain information on the relaxation mechanism, the plots of the reciprocal of T_1 *vs.* the total pressure for O_2 and inert-gas diluents are shown in Figs. 5 and 6 respectively. Especially, all of the plots of the inert-gas diluents were obtained from the saturation data on the $M_J=-2\rightarrow-1$ line of $O(^3P_2)$. Using the kinetic theory, the cross sections for the spin-lattice relaxation are calculated from the slopes of the linear portion in Figs. 5 and 6. The resulting cross sections are $\sigma_{O-He}=9.9$ Å^2, $\sigma_{O-Ne}=8.5$ Å^2, $\sigma_{O-Ar}=12.1$ Å^2, $\sigma_{O-Kr}=20.6$ Å^2, $\sigma_{O-Xe}=24.7$ Å^2, and $\sigma_{O-O_2}=33.3$ Å^2. Figure 7 shows plots of the cross sections against the atomic numbers of the inert gases, which serve as convenient indices. The figure also contains similar plots of the elastic scattering cross sections for collisions between electrons and the inert-gas atoms. The cross sections for the spin-lattice relaxation are about 6 times larger, but the sequence of the cross sections appears to be the same in both cases. A similar effect has been observed in the case of M_J mixing induced by potas-

sium-inert gas atomic collisions.[8] It is probable between the orbital momentum and the electron-spin state by collision.

(iii) Multiple-quantum Transition. Observations of the multiple-quantum transitions for O atoms have been reported by Hughes and Geiger[6] and by McDonald.[3] Recently, Atherton and Cook[9] have discussed the lineshapes of the multiple-quantum transitions of $O(^3P_2)$, and Schindler and Tiedemann[10] have studied, both experimentally and theoretically, the change in the line intensities of the multiple-quantum transitions with the microwave power.

At a microwave power level of about 0.2 mW, only single-quantum transitions were detected. As the the power increased, the single-quantum transitions

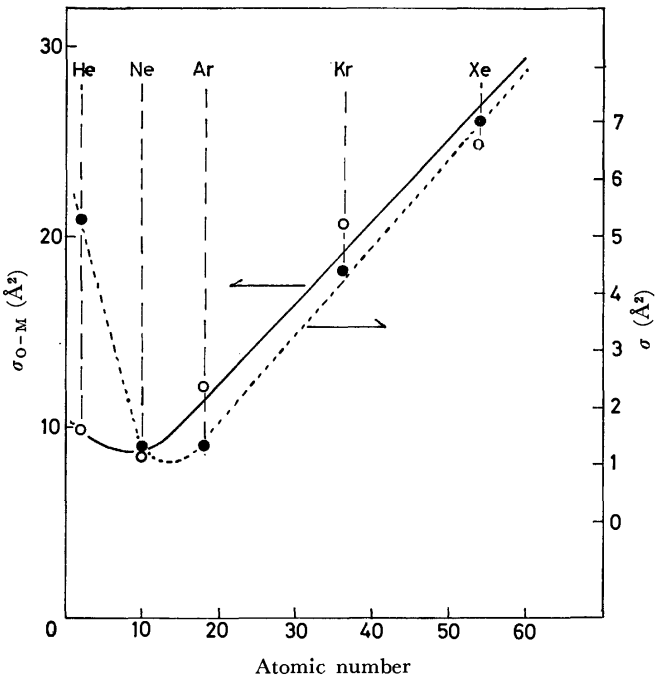

Fig. 7. For comparison of the cross sections (○) for the spin-lattice relaxation with the elastic scattering cross section (●).

showed saturation broadening, and, between each two lines of the four single-quantum transitions of $O(^3P_2)$, the two-quantum transitions appeared and increased in intensity. They became predominant in the spectrum at a microwave power level of about 2.5 mW. A further increase in power produced three-quantum transitions between the two-quantum transition lines, while the single-quantum transitions vanished in the noise level and the two-quantum transitions showed a saturation broadening. At about 20 mW, the three-quantum transitions gave the strongest lines in the spectrum. Finally, between the three-quantum transition lines, the four-quantum transition could be detected at about 100 mW. Thus, by virtue of the different saturation properties of the various transitions, all the possible multiple-quantum transitions for $O(^3P_2)$ can be observed. It is interesting to measure the spin-lattice relaxation time, T_1, of the multiple-quantum transitions, since the saturation property is closely related with the spin-lattice relaxation phenomena.

Extending the treatment employed to measure T_1 for the single-quantum transitions, we tried to obtain for the multiple-quantum transitions from Eqs. (2) and (3), which were derived theoretically. The plots of $(H_1^2/H_{1R}^2 \cdot S_S/S)^{2/3}$ *vs.* $(H_1^2/H_{1R}^2)^2$ for the two-quantum transitions, and those of $(H_1^3/H_{1R}^3 \cdot S_S/S)^{2/3}$ *vs.* (H_1^2/H_{1R}^3) for the three-quantum transitions, are shown in Figs. 8 and 9 respectively. Using Eqs. (2) and (3), we can obtain $T_1 \cdot T_2^*$ and $T_1 \cdot T_2^{**}$ from the slopes of these linear plots in Figs. 8 and 9. We can determine T_2^* and T_2^{**} from the observed linewidths of the two- and three-quantum transition lines, and then calculate T_1 from the values of $T_1 \cdot T_2^*$ and $T_1 \cdot T_2^{**}$. The values of T_1 obtained for the two- and three-

TABLE 3. EFFECTS OF PRESSURE OF T_1 FOR THE TWO- AND THREE-QUANTUM TRANSITION IN O_2 DILUENT

Total pressure (Torr)	Two-quantum transition $M_J=-2\rightarrow0$ (μsec)	Two-quantum transition $M_J=-1\rightarrow1$ (μsec)	Three-quantum transition $M_J=-2\rightarrow1$ (μsec)
0.018	1.75	1.74	2.44
0.048	1.62	1.55	2.05
0.084	1.27	1.24	1.89
0.114	1.21	1.16	1.83
0.139	1.02	0.99	1.65
0.159	0.97	0.95	1.40
0.209	0.88	0.84	1.26
0.225	0.77	0.73	1.05
0.270	0.65	0.65	0.89
0.315	0.62	0.57	0.84

quantum transitions are summarized in Table 3. It is found that the values of T_1 for the single-, two-, and three-quantum transitions decrease in that order. In order to examine the relaxation mechanism, we have plotted $1/T_1$ *vs.* the pressure in Fig. 10. The plots are linear except at low pressures, and the dependence of $1/T_1$ on the pressure is in the same sequence for the two- and three-quantum transitions as for the single-quantum transition. From the data in Fig. 10, the values of the apparent cross sections for the spin-lattice relaxation are found to be $\sigma_{O-O_2}=18.0$ Å^2 (two-quantum transition) and $\sigma_{O-O_2}=14.0$ Å^2 (three-quantum transition), which are smaller than $\sigma_{O-O_2}=33.3$ Å^2 of the single-quantum transition for $O(^3P_2)$.

In order to examine the relaxation mechanism in Zeeman sublevels, we derived the relationship between the transition probabilities induced by collisional interaction and the spin-lattice relaxation time (*cf.* the Appendix). From these relationships, the following results can be expected. In the case of the single-quantum transition, the T_1 values of the $M_J=-2\rightarrow-1$ and $M_J=1\rightarrow2$ lines are equal to each other, while those the $M_J=-1\rightarrow0$ and $M_J=0\rightarrow1$ lines are also equal. In addition, the T_1 value of the former pair is smaller than that of the latter. In the case of the two-quantum transition, the T_1 values of the $M_J=-2\rightarrow0$ and $M_J=0\rightarrow2$ lines are equal to each other, and T_1 of this pair has a smaller value than that of the $M_J=-1\rightarrow1$ line. In the case of the three-quantum transition, the T_1 values of the $M_J=-2\rightarrow1$ and $M_J=-1\rightarrow2$ lines are also equal. These results, expected from the Appendix, are in fair qualitative agreement with the experimental results (Tables 1 and 3). As the Appendix shows, the four transition probabilities can be estimated using the values of T_1 for the single-, two-, and three-quantum transitions obtained experimentally. Under these experimental conditions, the $W_1 \gg W_2 > W_3 > W_4$ relation can be expected. Assuming that the values of W_3 and W_4 are negligibly small, the values of W_1 and W_2 can be calculated from the values of T_1 obtained in the pressure range from about 0.2 to 0.3 Torr by the method of least-squares. The average value of W_2/W_1 is 0.0339

in this pressure range, which shows roughtly that the relaxation may be carried out step-by-step; *i.e.* the single-quantum relaxation mainly occurs even in the case of the miltiple-quantum transition.

Appendix

The corresponding probabilities of the $\Delta M_J=\pm1$, ±2, ±3, and ±4 transitions between five Zeeman sublevels ($M_J=-2$, -1, 0, 1, 2) of the $^3P_2$ states induced by the collisions O of atoms with oxygen molecules are $W_{\pm1}$, $W_{\pm2}$, $W_{\pm3}$, and $W_{\pm4}$ respectively, assuming that the sublevels are approximately equally spaced. We suppose that the populations of the substates are N_{-2}, N_{-1}, N_0, N_1, and N_2. In a thermal equilibrium, the steady-state populations obey Boltzmann's law; this requires that the probabilities for transitions up and down be in the ratios of:

$$\begin{aligned}\frac{W_{+1}}{W_{-1}} &= \exp(g\beta H/\boldsymbol{k}T)\\ \frac{W_{+2}}{W_{-2}} &= \exp(2g\beta H/\boldsymbol{k}T)\\ \frac{W_{+3}}{W_{-3}} &= \exp(3g\beta H/\boldsymbol{k}T)\\ \frac{W_{+4}}{W_{-4}} &= \exp(4g\beta H/\boldsymbol{k}T)\end{aligned} \tag{A-1}$$

Since $g\beta H \ll \boldsymbol{k}T$, we can satisfy these conditions by taking:

$$\begin{aligned}W_{\pm1} &= W_1\left(1 \pm \frac{1}{2}\frac{g\beta H}{\boldsymbol{k}T}\right)\\ W_{\pm2} &= W_2\left(1 \pm \frac{g\beta H}{\boldsymbol{k}T}\right)\\ W_{\pm3} &= W_3\left(1 \pm \frac{3}{2}\frac{g\beta H}{\boldsymbol{k}T}\right)\\ W_{\pm4} &= W_4\left(1 \pm \frac{2g\beta H}{\boldsymbol{k}T}\right)\end{aligned} \tag{A-2}$$

By way of example, we will try to obtain the relationship between the transition probabilities and T_1 for the two-quantum transition ($M_J=-1\rightarrow1$). We consider the initial conditions:

$$\begin{aligned}&N_{-2} = N+2n_0,\ N_{-1} = N+n,\ N_0 = N,\\ &N_1 = N-n,\ N_2 = -2n_0\end{aligned} \tag{A-3}$$

with a small n value, where n_0 is the equilibrium value of n. The time evolution of n obeys the following differential equations:

$$\begin{aligned}\frac{dn}{dt} &= -(W_{+1}+W_{-3}+W_{-2}+W_{-1})(N+n)\\ &\quad + W_{+2}(N-n)+W_{+1}N+W_{+3}(N-2n_0)\\ &\quad + W_{-1}(N+2n_0)\\ -\frac{dn}{dt} &= -(W_{+3}+W_{+2}+W_{+1}+W_{-1})(N-n)\\ &\quad + W_{-2}(N+n)+W_{-1}N+W_{+1}(N-2n_0)\\ &\quad + W_{-3}(N+2n_0)\end{aligned} \tag{A-4}$$

Substituting the probabilities from (A-2), we find that:

$$\frac{dn}{dt} = (2W_1+2W_2+W_3)(n_0-n). \tag{A-5}$$

The spin-lattice relaxation time is:

$$\frac{1}{T_1} = (2W_1+2W_2+W_3). \tag{A-6}$$

In the same manner, we can get the following relation between the transition probabilities and T_1 for the single-, two-, three-, and four-quantum transitions.

(i) single-quantum transition

$$\begin{aligned}M_J = -2\rightarrow-1 \quad & \frac{1}{T_1} = \frac{1}{2}(5W_1+2W_2+2W_3+W_4)\\ M_J = -1\rightarrow0 \quad & \frac{1}{T_1} = \frac{1}{2}(6W_1+3W_2+W_3)\\ M_J = 0\rightarrow1 \quad & \frac{1}{T_1} = \frac{1}{2}(6W_1+3W_2+W_3)\\ M_J = 1\rightarrow2 \quad & \frac{1}{T_1} = \frac{1}{2}(5W_1+2W_2+2W_3+W_4)\end{aligned}$$

(ii) two-quantum transition

$$\begin{aligned}M_J = -2\rightarrow0 \quad & \frac{1}{T_1} = \frac{1}{2}(3W_1+5W_2+W_3+W_4)\\ M_J = -1\rightarrow1 \quad & \frac{1}{T_1} = (2W_1+2W_2+W_3)\\ M_J = 0\rightarrow2 \quad & \frac{1}{T_1} = \frac{1}{2}(3W_1+5W_2+W_3+W_4)\end{aligned}$$

(iii) three-quantum transition

$$\begin{aligned}M_J = -2\rightarrow1 \quad & \frac{1}{T_1} = \frac{1}{2}(3W_1+2W_2+4W_3+W_4)\\ M_J = -1\rightarrow2 \quad & \frac{1}{T_1} = \frac{1}{2}(3W_1+2W_2+4W_3+W_4)\end{aligned}$$

(iv) four-quantum transition

$$M_J = -2\rightarrow2 \quad \frac{1}{T_1} = (W_1+W_2+W_3+2W_4)$$

Semiconducting Anion-radical Salts Derived from 3,3′5,5′-Tetrahalo-*p*-diphenoquinones[1)]

Yoshio MATSUNAGA and Yoshihiro NARITA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received August 2, 1971)

3,3′,5,5′-Tetrachloro- and 3,3′,5,5′-tetrabromo-*p*-diphenoquinones were found to form series of complex anion-radical salts of the $M^+(Q_2)^-$ or $M^+_2(Q_3)^{2-}$ type with various onium cations. These complex salts are dark-colored, almost black in many cases, and show electronic absorptions extending into the rock-salt region. In addition, bluish green-colored simple salts could be isolated with a few cations. The complex salts exhibit electrical resistivities in orders from 10 to 10^4 ohm cm at room temperature. Neither the pattern due to the quinone molecule nor that due to the semiquinone ion is present in their vibrational spectra. A single carbonyl stretching vibration band appears around 1600 cm^{-1}, intermediate between that in the quinone and that in the semiquinone salt.

A new class of electrically-conducting organic compounds formed from various cations and the anion-radical of 7,7,8,8,-tetracyanoquinodimethane (TCNQ) was synthesized by Melby *et al.* about ten years ago.[2-4)] The composition of the anion-radical salts is represented by $M^+(TCNQ)_n^-$, where M^+ is a cation. Naturally, the value of n is 1 in many cases, but for some cations n was found to have multiple values such as 1 and 2, or 1 and 1.5. The complex salts with higher values of n tend to exhibit a lower electrical resistivity than the simple salt, $M^+(TCNQ)^-$.[5)] Since the work of Melby *et al*, the physical properties of the TCNQ anion-radical salts, especially the electrical, magnetic, and optical properties of the complex salts, have been quite extensively studied; however, only relatively few data have been published for new complex ion-radical salts,[6-14)] and far less even for those derived from compounds other than TCNQ.

Goan *et al.* have reported that *p*-chloranil forms molecular complexes with cobaltocene and nickelocene in a mole ratio of donor-to-acceptor of 1 : 2.[15)] The presence of these complexes has been subsequently confirmed by Brandon *et al.* and also by Watanabe *et al.*[16,17)] Their electrical resistivities have been found in the range from 10^4 to 10^6 ohm cm.[17,18)] On the basis of the vibrational spectra, these complexes may be better characterized as complex anion-radical salts containing onium cations. During the course of their work on pentalene derivatives, Le Goff and Lacount obtained a purple-black tetrabutylammonium anion-radical salt of the tetracyanodimethane derivative of dibenzopentalenoquinone. Its composition happened to be $M^+_2(Q_3)^{2-}$. Unfortunately, no resistivity has been reported for this complex salt.[19)] 9-Dicyanomethylene-2,4,7-trinitrofluorene (DTF) was prepared by Mukherjee and Levasseur some years ago. All the anion-radical salts with cations such as methyltriethylammonium, *N*-methyl-quinolinium, methyltriphenylphosphonium, and methyltriphenylarsonium ions have been reported to have the composition of $M^+(DTF)^-$.[20)] Dupuis and Néel have extended the work on the anion-radical salts of DTF and also prepared those of its tetranitro analog. Among the combinations with nineteen cations examined, the only complex (1 : 2) salt was obtained by the reaction between 1,2,3-trimethylbenzimidazolium iodide and DTF.[21)] Here again, the complex salt is much more conducting than the corresponding simple salt. They have observed 50 ohm cm for the 1 : 2 salt and 10^6 ohm cm for the 1 : 1 salt.[22)] A possible complex cation-radical salt has been found in the system of iodine-semiquinoid phenothiazine bromide. The minimum resistivity observed at the composition of $(phenothiazine)_2^+(Br_2I)^-$ is about 4 ohm cm.[23)] Thus, apart from the above-mentioned TCNQ anion-radical salts, our

knowledge of complex ion-radical salts is very fragmentary and scanty. Therefore, it seemed that it would be very interesting to find out whether or not quinones, common electron acceptors which can be as strong as TCNQ and DTF if appropriately selected, can form series of complex anion-radical salts with various onium cations. As the alkali salts of 3,3',5,5'-tetrahalo-*p*-diphenosemiquinones are known to be quite stable,[24,25] the parent quinones were our first choice.

Experimental

Materials. The examples of the anion-radical salts cover only a part of the compounds prepared in this work. However, they illustrate all of the various preparative procedures which we employed.

Tetrahalo-p-*diphenoquinones*: *p*-Biphenol was prepared by the decomposition of tetrazotized benzidine, as has been described by Hirsch, and then halogenated following the procedures reported by Magatti.[26,27] Oxidation to the quinones was carried out in glacial acetic acid by the addition of fuming nitric acid or in carbon tetrachloride with oxides of nitrogen.[28,29] Hereafter, tetrachloro- and tetrabromo-*p*-diphenoquinones will be abbreviated as TCDQ and TBDQ respectively.

Na^+TCDQ^-: Earlier this salt was prepared by the oxidation of tetrachloro-*p*-biphenol dissolved in an aqueous solution of sodium hydroxide with the ferricyanide ion.[25] In the present work, TCDQ was reduced by grinding with an excess of sodium iodide in the presence of acetone. The green crystalline powder was then thoroughly washed with acetone.

(Di-n-propylammonium)$_2$(TCDQ)$_3$: By treating a mixture of 100 mg of powdered TCDQ and 65 mg of di-*n*-propylammonium iodide with acetone, the reddish violet color of the quinone was changed quickly into the black of the anion-radical salt. The yield was 95%. The same product was obtained by the reaction of di-*n*-propylammonium iodide with a mixture of TCDQ and Na^+TCDQ^- suspended in acetonitrile. The complex salt is a purple-black crystalline powder. Found: C, 49.3; H, 4.0; Cl, 36.0%. Calcd for $2C_6H_{16}N\cdot 3C_{12}H_4Cl_4O_2$: C, 49.3, H, 3.8, Cl, 36.4%.

Tetraethylammonium (TCDQ)$_2$: A mixture of 98 mg of TCDQ and 76 mg of tetraethylammonium iodide was added to 20 m*l* of acetone, after which the solution was stirred for a half hour at room temperature. The purple-black solid was collected on a filter and dried in a vacuum desiccator. The yield was 55 mg. Found: C, 49.8; H, 3.6; Cl, 36.5%. Calcd for $C_8H_{20}N\cdot 2C_{12}H_4Cl_4O_2$: C, 49.6; H, 3.7; Cl, 36.6%.

Ferricinium (TCDQ)$_2$: Ferrocene (0.36 g (2 mmol)) was dissolved in 100 m*l* of acetone, and then pulverized TCDQ (1.28 g (4 mmol)) was added. After 5 minutes stirring, the black product was filtered and washed with acetone. The yield was 1.15 g. Found: C, 49.4; H, 2.1; Cl, 34.4%. Calcd for $C_{10}H_{10}Fe\cdot 2C_{12}H_4Cl_4O_2$: C, 49.2; H, 2.2; Cl, 34.4%. The following attempt to prepare the simple salt resulted in the formation of the above-mentioned complex salt. Ferricinium triiodide (2.27 g (4 mmol)) and Na^+TCDQ^- (1.04 g (3 mmol)) were mixed in 50 m*l* of acetonitrile. The suspension was stirred for one hour. Found, C 48.9, H 2.4, Cl, 33.6%. The quinone required for the formation of the complex salt was apparently supplied by the oxidation of the $TCDQ^-$ ion with air during the process of preparation.

Cobalticinium (TCDQ)$_2$: Cobalticinium triiodide, 1.71 g (3 mmol), TCDQ, 0.97 g (3 mmol), and Na^+TCDQ^-, 1.05 g (3 mmol) were mixed in 50 m*l* of acetonitrile. After the mixture had been stirred for a half hour, the black product was filtered and washed with acetone. The yield was 1.8 g. Found: C, 48.1; H, 2.1; Cl, 33.9%. Calcd for $C_{10}H_{10}Co\cdot 2C_{12}H_4Cl_4O_2$: C, 49.0; H, 2.2; Cl, 34.0%.

Tetra-n-*propylammonium TBDQ*: A portion of 150 mg (0.3 mmol) of powdered TBDQ was stirred for one hour with 120 mg tetra-*n*-propylammonium iodide in 20 m*l* of acetone. The bluish-green precipitate was washed with benzene, in which the salt is not soluble. The yield was 130 mg. Found: C, 42.0; H, 4.8; Br, 45.9%. Calcd for $C_{12}H_{28}N\cdot C_{12}H_4Br_4O_2$: C, 42.0; H, 4.7; Br, 46.6%. The corresponding TCDQ salt could be prepared by employing benzene instead of acetone as the reaction medium, but it was found to be too unstable to be examined further.

N-Methyl-acridinium TBDQ: Powdered TBDQ (150 mg (0.3 mmol)) was stirred for 40 min at room temperature with *N*-methyl-acridinium iodide (135 mg (0.5 mmol)) in 30 m*l* of acetone. The green crystalline powder was then filtered. Found: C, 44.7; H, 2.5; Br, 45.9%. Calcd for $C_{14}H_{12}N\cdot C_{12}H_4Br_4O_2$: C, 45.0; H, 2.3; Br, 46.0%.

(N-Methyl-acridinium)$_2$(TBDQ)$_3$: A portion of 100 mg (0.2 mmol) of pulverized TBDQ and one of 50 mg (0.15 mmol) of *N*-methyl-acridinium iodide were ground together and then stirred with 30 m*l* of acetonitrile for a half hour. The violet crystalline solid was filtered and washed with the solvent. The yield was 60 mg. Found: C, 41.0; H, 2.2; Br, 48.9%. Calcd for $2C_{14}H_{12}N\cdot 3C_{12}H_4Br_4O_2$: C, 40.7, H, 1.9; Br, 50.8%.

p-*Phenylenediamine (TBDQ)$_2$*: *p*-Phenylenediamine and TBDQ in a mole ratio of 1 : 2 were added to benzene. After stirring for 15 min, the black product was filtered and washed with benzene. Found: C, 33.0; H, 1.8; N, 3.2; Br, 57.0%. Calcd for $C_6H_8N_2\cdot 2C_{12}H_4Br_4O_2$: C, 32.5; H, 1.5; N, 2.5; Br, 57.7%.

Cobalticinium (p-chloranil)$_2$: Cobalticinium triiodide (1.14 g (2 mmol)), *p*-chloranil (0.49 g (2 mmol)), and K^+-(*p*-chloranil)$^-$ (0.57 g (2 mmol)) were mixed in 50 m*l* of acetone and then stirred for a half hour. The brownish-yellow crystalline product was filtered and washed with acetone. Found: C, 38.9; H, 1.9; Cl, 41.4%. Calcd for $C_{10}H_{10}Co\cdot 2C_6Cl_4O_2$: C, 38.8; H, 1.5; Cl, 41.8%.

Measurements. The electrical resistivities, ρ, at room temperature were examined by a voltage-current method employing a cell similar to that designed by LaFlamme.[30] In some cases, a gradual increase in the resistivity was observed on standing; therefore, the measurements were carried out immediately after drying in a vacuum. The temperature-dependence was measured by a potential-probe method only for some highly-conducting salts. The activation energy for semiconduction, E, was calculated from $\rho=\rho_0\exp(E/kT)$.

The electronic spectra of the solid salts were recorded by means of a Beckman DK-2A spectrophotometer with the aid of a reflectance attachment, and the vibrational spectra, as Nujol mineral oil mulls by means of a Jasco IR-G infrared spectrophotometer. The procedure in the former measurements was described in detail in our previous paper.[23]

Results and Discussion

Syntheses. The interaction between pyrene and TCDQ (TBDQ) dissolved in chloroform generates a charge-transfer absorption, the maximum of which is located at 13.8 (13.6) kK. This value can well be compared with that of 13.7 kK given by the pyrene complex of tetracyanoethylene (TCNE) and that of 13.1 kK given by the complex of TCNQ dissolved in the same solvent. In other words, the present quinones are electron-acceptors as strong as those famous π-acids. Therefore, it is quite understandable that the quinone molecule oxidizes the iodide ion to free iodine and takes up the electron to form the semiquinone ion.

The major synthetic routes to the present anion-radical salts may be classified into the following three.

Method 1: As has been mentioned above, the iodide serves as the electron source for the formation of the semiquinone ion. This is the most general route for the preparation of both simple and complex salts.

Method 2: The complex salt is prepared by the metathesis of the triiodide and NaTCDQ (NaTBDQ) in the presence of TCDQ (TBDQ). If the quinone is omitted, the amount required for the formation of the complex salt is provided by the oxidation of the semiquinone ion with air in the process of stirring.

Method 3: When the cation source is given as a strong electron-donor, the salt may be prepared by oxidation-reduction, as exemplified by the synthesis of the ferricinium $(TCDQ)_2$. Despite the excess of the electron-donor, the reduction of TCDQ is limited to that which can be stabilized in the form of the complex salt.

With most of the onium cations, M^+, the quinones form only complex anion-radical salts represented by the formulas $M(TCDQ)_2$ or $M_2(TCDQ)_3$ and $M(TBDQ)_2$ or $M_2(TBDQ)_3$. All the complex salts are dark-colored-brown, violet, or black depending upon the kind of cation. When heated, most of the TCDQ salts show color-changes due to decomposition in the temperature-range of 150 to 180°C, while the TBDQ salts show changes in the range from 130 to 170°C. The treatment of TCDQ with tetra-*n*-propylammonium iodide gave a bluish-green product which was too unstable to be analysed. This is the only possible simple TCDQ salt observed in our experiment except those with alkali metal cations. Simple TBDQ salts could be isolated with five cations, namely, tetra-*n*-propylammonium, *N*-methyl-acridinium, *N*-methyl-lepidinium, *N*-methyl-, and *N*-ethyl-isoquinolinium cations. They are green or bluish green, as is the sodium salt. Among the above-mentioned cations, *N*-methyl-acridinium also gives a complex anion-radical salt. So far this is the only combination to be found which forms both simple and complex salts.

Electrical Resistivities. As is summarized in Tables 1 and 2, resistivity values in the range of 10^2—10^3 ohm cm are typical of most of the simple and complex salts examined here. The highest resistivity is exhibited by the simple TBDQ salt of tetra-*n*-propylammonium; however, no appreciable difference is observed in the pair of the simple and complex TBDQ salts of *N*-methyl-acridinium. The TBDQ salts tend to be slightly more conductive than the TCDQ salts. Thus, the TCDQ salts exhibiting resistivities about 100 ohm cm or less include only the following three; the complex salts of cobalticinium, ferricinium, and *p*-phenylenediamine cations. On the other hand, the corresponding complex TBDQ salts and four others, which contain *n*-Pr_2EtNH, *n*-Pr_3NH, Me_3PhN, and Et_3PhN cations, are as conducting as the TCDQ salts mentioned above.

In the study of the tetra-*n*-alkylammonium TCNQ salts, Kusakawa and Akashi have shown that the cation size influences the electrical resistivity as much as by a factor of 10^6.[13] Although the space effects observed in the present work are not large, we can point out some trends. The following orders may be noted in the series of the TCDQ complex salts: quinolinium> *N*-*n*-propylquinolinium, *N*-methyl-isoquinolinium> *N* - ethyl - isoquinolium> *N* - *n* - propyl-isoquinolinium, and *N*-methyl-acridinium< *N*-ethyl-acridinium. When ammonium ions are employed, the effects are more pronounced in the series of the TBDQ salts. The resistivity decreases in this order of the cations: $Pr_2NH_2 > Pr_2MeNH > Pr_2EtNH > Pr_3NH$. Similarly, $Et_3NH > Et_4N$ and $Me_3PhN > Et_3PhN$. The last order is reversed in the TCDQ salts.

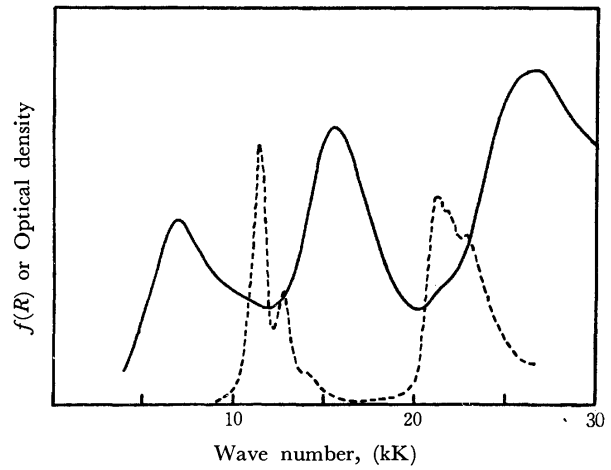

Fig. 1. Electronic spectra of Na^+TCDQ^- in the solid state (——) and in an acetone solution (----).

Electronic Spectra. As is shown in Fig. 1, the solid-state spectrum of NaTCDQ bears no resemblance to that of the salt dissolved in acetone. The solution spectrum comprises bands at 11.3 and 12.7, a shoulder at 14.0, and a strong band with some vibrational structures around 21 kK. It must be noted that this spectrum is very similar to that of the benzidine cation-radical cited in Fig. 2. The latter has bands at 11.6 and 13.1, a shoulder at 14.3, and a strong band around 21.6 kK.[31] Figure 2 presents

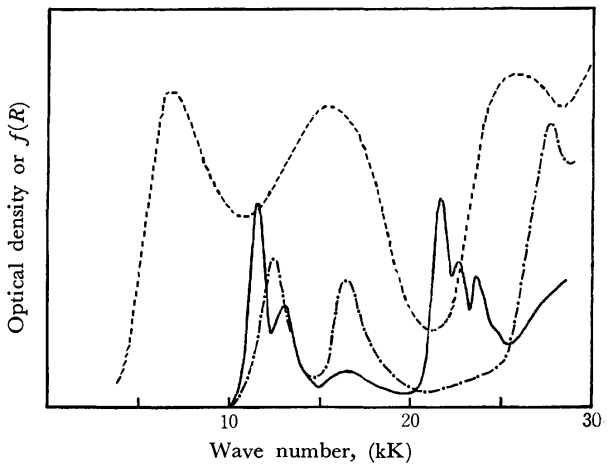

Fig. 2. Electronic spectra of benzidine bromide in an ethanolic solution at room temperature (——) and at low temperature (—·—·—) taken from Ref. 31, and the solid-state spectrum (----) taken from Ref. 32.

the solid-state spectrum of the benzidine bromide, which is very different from the spectra of not only the monomeric but also the dimeric forms of the cation-radical. Considering also the magnetic property, we concluded earlier that the univalent diamine cations in solid benzidine bromide is in a strong, more-than-by-pairs interaction.[32] The solid NaTCDQ shows a solid-state spectrum consisting of three bands located at 6.8, 15.5, and 26.4 kK. Again, this spectrum is very much like that of the benzidine bromide in the solid state. The latter spectrum, shown in Fig. 2, has three bands, at 6.7, 15.5, and 25.8 kK. Therefore, it seems to be quite certain that the anion-radicals in the solid NaTCDQ are also in a strong, more-than-by-pairs interaction. In accordance with this view, a relatively low resistivity, 10^3 ohm cm, is observed for this simple salt.

The spectrum of the solid NaTBDQ presented in Fig. 3 is composed three bands, at 6.2, 15.6, and about 27 kK, and is close to that of the solid NaTCDQ mentioned above. On the other hand, the simple bluish-

green TBDQ salt of tetra-*n*-propylammonium exhibits a resistivity as high as 10^7 ohm cm and a solid-state spectrum bearing no resemblance to that of the NaTBDQ. The bands in the spectrum of this ammonium salt are located at 11.5, 15.2, and 24.5 kK. This spectrum seems to correspond well to those of the dimeric form of the benzidine cation-radical: 12.4, 16.4, and 28 kK, as measured in a cold ethanolic solution (see Fig. 2), and 11.5, 15.2, and about 27 kK, as measured with colored acid clays moistened with benzene.[31,33] Thus, the anion-radicals here appear to be essentially in a pair-by-pair interaction. This speculation is consistent with the observed high resistivity.

The spectra of the simple and complex *N*-methyl-acridinium TBDQ salts are presented in Fig. 4. The simple salt exhibits a resistivity of 10^3 ohm cm, which can be well compared with that of NaTBDQ. However, their electronic spectra are different from each other. The *N*-methyl-acridinium salt shows a low-energy band at 5.6 kK, a little lower than that of the corresponding band of the sodium salt. In addition, the presence of an extra band at 10.5 kK must be noted. It is very likely that the interaction of the anion-radicals in this salt is also more-than-by-pairs, but in a mode somewhat different from that in NaTBDQ. The complex *N*-methyl-acridinium salt shows a spectrum consisting of four bands in the infrared and visible regions. The low-energy band appears at 4.2 kK, the limit of our spectrophotometer. The other three are located at 11.0, 18.2, and 24—28 kK. It is rather surprising to see that this spectrum is very much like that of the complex TCNQ salt of *N*-methyl-acridinium. The latter salt, with a composition of 1 : 2, exhibits four bands, located at <4, 11.2, 17.8, and 27.5 kK.[34] The spectra of most of the complex TCDQ (TBDQ) salts are more or less similar to the one shown in Fig. 4.

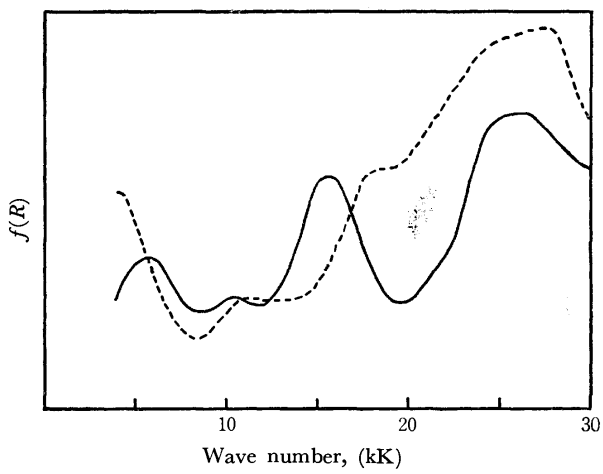

Fig. 4. Diffuse reflection spectra of *N*-methyl-acridinium-TBDQ, the simple salt (——) and the complex salt (----).

Four more examples of the spectra of the complex TCDQ salts are presented in Figs. 5 and 6. In the

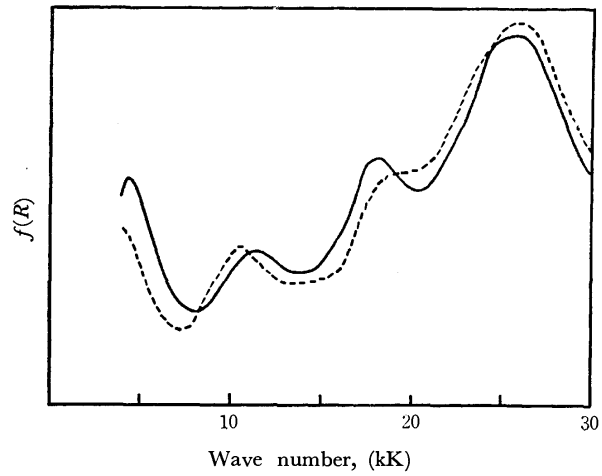

Fig. 5. Diffuse reflection spectra of the complex TCDQ salts containing ethyldi-*n*-propylammonium ion (——) and cobalticinium ion (----).

cases shown in Fig. 5, the cations are quite different in nature and the compositions of the salts are not the same; however, all the patterns are very similar to one another. Absorption bands appear at 4.4, 11.4, 17.8, and 25.6 kK in the ethyldi-*n*-propylammonium salt and at <4, 10.5, 19.0, and 25.8 kK in the cobalticinium salt. On the other hand, the spectra of the TCDQ salts containing cations of the same nature, but exhibiting resistivities different by a factor of two hundred, are compared in Fig. 6. The less-conducting dark-brown-colored quinolinium salt shows bands at 6.4, 20.0 and 27.6 kK. Here, it seems that the weak second band is located around 15 kK, but is hidden by the strong third one. By the introduction of the *N*-*n*-propyl group, the bands are shifted to the low-energy side; that is, they appear at 4.3, 12.8, 18.5, and 27.4 kK. As a result, the salt is violet. In each combination of the salts shown in Figs. 5 and 6, it may be pointed out that the lower the resistivity, the less the energy of the first absorption band. However, such a tendency is only roughly observed in the other cases (see Tables 1 and 2).

34) Y. Iida, *ibid.*, **42**, 637 (1969).

For comparison with the complex anion-radical salts derived from TCDQ and TBDQ, the electronic spectra of the solid cobaltocene (*p*-chloranil)$_2$ and nickelocene (*p*-chloranil)$_2$ are shown in Fig. 7. The close agreement between these two suggests that the pattern is essentially determined by the interaction between *p*-chloranil and its anion-radical. Because of the presence of a wide, relatively transparent region, these salts are only lightly colored. However, it must be added that the presence of such a region is not characteristic of the complex salts. The simple sodium salt of *p*-chloranil, where the anion-radicals are supposed to be in a strong interaction, is known to exhibit absorption bands at 11.6 and 26.5 kK.[35] Compared with this, all the spectra of the complex salts are shifted to the low-energy side; the maxima of the strong bands in the cobalticinium salt are found at 5.6 and 22.2 kK.

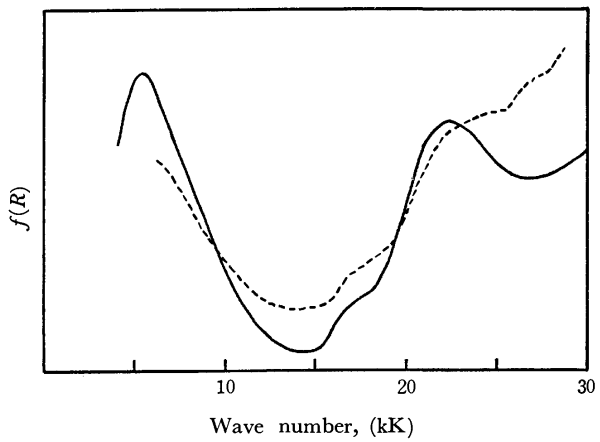

Fig. 7. Diffuse reflection spectra of cobaltocene (*p*-chloranil)$_2$ (——) and nickelocene (*p*-chloranil)$_2$ (----).

Vibrational spectra. It has been established that the vibrational spectrum of the semiquinone ion is markedly different from that of the parent quinone.[34,36] In Fig. 8, the spectrum of TCDQ is compared with that of its simple sodium salt. Instead of the normal carbonyl stretching vibration of TCDQ at 1640 cm^{-1}, a strong absorption band is observed 1530 cm^{-1} in the semiquinone salt. As the wavenumber of the carbonyl mode is known to be mainly determined by the bond order,[37-40] the observed shift can be attributed to the acceptance of one extra electron into the antibonding level of the TCDQ molecule. As a result, the carbonyl bonds more or less lose their double-bond character and the rings lose their quinoid structure. This change over the whole molecule leads to the drastic difference in the vibrational spectrum between the quinone and the

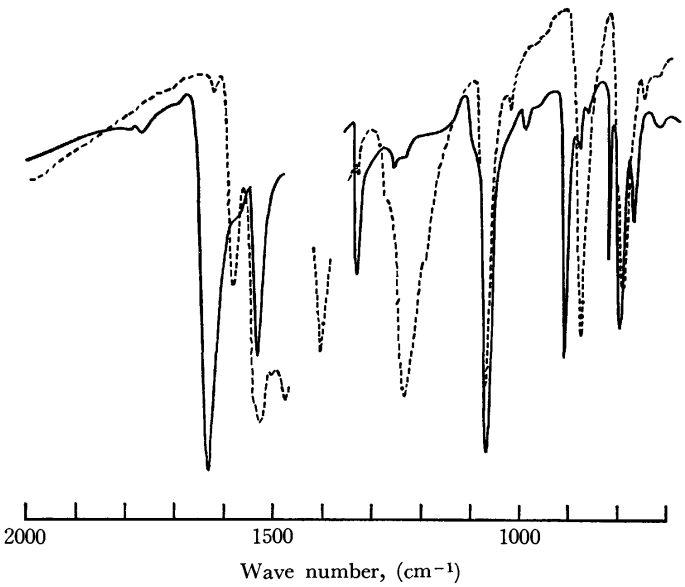

Fig. 8. Vibrational spectra of TCDQ (——) and Na$^+$TCDQ$^-$ (----).

semiquinone ion. Besides a large shift of the carbonyl stretching band, the appearance of a strong broad band at 1240 cm^{-1} must be considered as an indication of the reduction. Moreover, the shift of the band from 910 to 880 cm^{-1} and the replacement of a triplet around 800 cm^{-1} by a strong singlet must be noted.

The spectrum of the complex ethyldi-*n*-propylammonium TCDQ salt bears some resemblance to the spectrum of TCDQ and also that of the semiquinone salt. That is, the presence of bands at 1410, 1250, and 880 cm^{-1} is characteristic of the semiquinone ion. On the other hand, the triplet around 800 cm^{-1} may be ascribed to the original quinone. However, no strong broad band to be assigned to the carbonyl stretching vibration is observed at the wavenumber

corresponding to either that in the quinone or that in the semiquinone ion. A rather narrow band appears at 1610 cm^{-1}. The complex TCDQ salts of di-*n*-propyl-ammonium and methyldi-*n*-propylammonium show spectra similar to this. The spectra of most of the complex TCDQ salts are different from those mentioned above. For example, the spectrum of the cobalticinium salt is shown in Fig. 9. Bands at 860, 1010, and 1410 cm^{-1} form the spectrum of the cation. Here again, we see neither the pattern due to the quinone molecule nor that due to the semiquinone ion. A single broad carbonyl band appears at 1610 cm^{-1}. This wavenumber is intermediate between that in the the quinone, 1640 cm^{-1}, and that in the semiquinone salt, 1530 cm^{-1}. On the basis of this observation, we may conclude that the negative charge is equally shared by the two molecules of the quinone. If so, the quinone molecules in the afore-mentioned three ammonium salts may not be exactly equivalent to each other. The resistivity values seem to have no direct relation with the type of the vibrational spectrum, for the highest value among the complex TCDQ salts is 2×10^5 ohm cm in the quinolinium salt, and the lowest, 24 ohm cm in the ferricinium salt. Their spectra are all of the same type. In all the complexs TCDQ salt, the carbonyl stretching-vibration band is found in the range from 1605 to 1625 cm^{-1} regardless of the composition. This is rather surprising because the formal change per quinone molecule is a half in the 1 : 2 salt and two-thirds in the 2 : 3 salt. Actually, rough estimates derived from a comparison of the red shift of the carbonyl mode in the complex salts with the shift found in the sodium salt are no larger than one-third. The location of the band appearing at 1070 cm^{-1}, in the quinone is hardly affected by the reduction; however, a splitting of as much as 10—25 cm^{-1} is observed in the salts containing some ammonium ions and mostly heterocyclic cations.

The spectrum of TBDQ has a strong carbonyl band at 1630 cm^{-1}. In the simple salts, this band is shifted to the low-energy side by 80—100 cm^{-1}, depending upon the kind of cation. Figure 10 presents the spectra of the simple and complex *N*-methyl-acridinium salts. Here, the carbonyl stretching bands are found at 1545 and 1595 cm^{-1} respectively. The strong broad band located around 1250 cm^{-1} is characteristic of the salts, and it is not observed before the reduction. In the other complex TBDQ salts, the band due to carbonyl stretching appears in the range from 1595 to 1615 cm^{-1}, again regardless of the composition. As in the series of the TCDQ salts, this band is rather weak and narrow in some ammonium salts. Although the band located at 1020 cm^{-1} in the spectra of Fig. 10 apparently corresponds to the 1070 cm^{-1} band in TCDQ, no splitting is observed in any complex TBDQ salts.

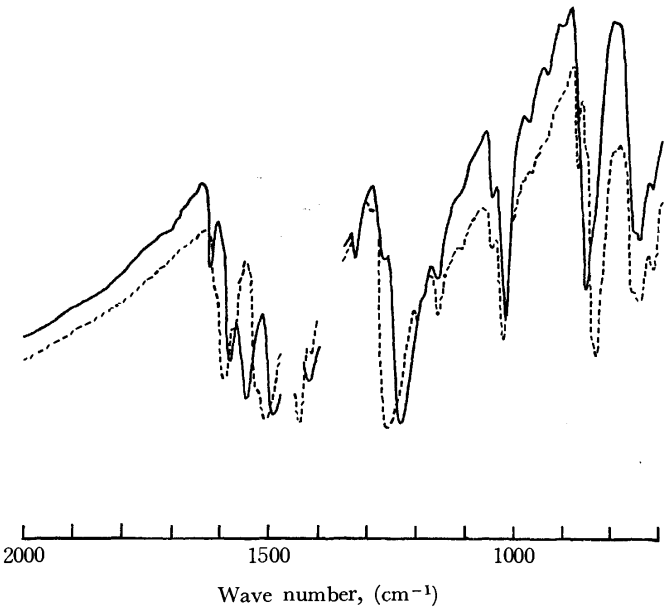

Fig. 10. Vibrational spectra of *N*-methyl-acridinium-TBDQ, the simple salt (——) and the complex salt (----).

Lastly, we wish to emphasize that quinones, if suitably selected, can form series of complex anion-radical salts with various onium cations as well as TCNQ does. Work to prepare a new series of complex anion-radical salts is now in progress using 2,3-dicyano-1,4-naphthoquinone.

The work at Hokkaido University was supported by a grant-in-aid from the Ministry of Education, to which the authors' thanks are due.

Studies of Helical Aggregates of Molecules. III. The Bivalent Metal Soaps of Optically Active 12-Hydroxyoctadecanoic Acid

Taro TACHIBANA, Kazuko KAYAMA, and Hideko TAKENO
Department of Chemistry, Ochanomizu University, Bunkyo-ku, Tokyo

(Received August 20, 1971)

The bivalent metal soaps of optically-active 12-hydroxyoctadecanoic acid were found to crystallize out in the form of twisted fibers from aqueous or anhydrous ethanol solutions. Most soaps of this class produced both right-handed and left-handed fibers from the same specimen, more of the latter in the case of the D-enantiomer. An enantiomorphic relationship of the sense of twist was clearly demonstrated by using both enantiomers of the Ca soap. Under a high-resolution electron microscope, it was observed on the Sr soap that Sr atoms are arranged in lines along the fiber axis with a periodicity of 33—40 Å, showing that the hydroxyoctadecanoate chains of the soap molecules are aligned approximately parallel to the width of the fiber. The twisting of the soap fibers was associated with the layer structure characteristic of soap.

The present work represents an extension of previous studies[1,2] of the sense of twist of helical aggregates of optically active 12-hydroxyoctadecanoic acid and its alkali metal soaps. Some bivalent metal soaps also have been found to form twisted fibers.[3] However, since it had been seen that some soaps of this class, *e.g.*, the Mg soap, produce the right-handed fibers only on some occasions and the left-handed fibers only on other occasions, it was difficult to draw definite conclusions as to the sense of twist of these soap fibers from a small number of experiments. Therefore, experiments have been carried out repeatedly under various conditions.

Generally, the bivalent metal soaps are liable to decompose and release their free acid with a rise in the temperature. For this reason, the crystalline aggregates were allowed to separate out from the C_2—C_8 fatty alcohols into which the soaps are to some extent dissolved without decomposition at temperatures below 100°C. Some soaps thus produced fibrous aggregates, while other soaps, such as the Sr, Ni, and Pb soaps, separated out, in the most part, as amorphous aggregates. Fortunately, we have found that the latter soaps also produced well-developed and twisted fibers when separated out from an alcohol solution containing water. Thus, for the bivalent metal soaps also, it became possible to obtain reliable information about the sense of twist of the soap fibers.

Experimental

The purification of D-12-hydroxyoctadecanoic acid (hereafter abbreviated as "D-acid") from a commercial product has been described previously.[1] The bivalent metal soaps of this acid were prepared by methathesis, at 50°C in aqueous ethanol, between the Na soap and chlorides or sulfates of the corresponding metals. The soaps thus obtained were washed with distilled water, then with ethanol, and finally with acetone, and well dried over P_2O_5 at room temperature. Gravimetric analysis demonstrated that the soaps, which are listed in Table 1, were all the disoaps with the formula of $Me(C_{18}H_{36}O_3)_2$. The water of crystallization was measured by thermogravimetry. The X-ray diffraction patterns, the infrared absorption spectra, and the differential thermographs were also investigated.

To obtain the soap fibers, the soap sample was dispersed into an alcoholic solvent under ultrasonic irradiation and then heated on a water bath. After the excess has been filtered off, the hot solution were allowed to cool to room temperature with stirring. Thus, the Ca and Cd soaps gelled at room temperature, while the other soaps separated out as flocculates or precipitates from the solution. The samples of the Hg and Mn soaps, which are susceptible to thermal decomposition, were carefully treated at a temperature lower than 50°C.

In certain cases, the soap fibers were produced by neutralizing the D-acid in a hydrocarbon solvent, Nujol, with an aqueous solution of the hydroxide of the corresponding metal at a certain high temperature and by then allowing the hot solution to cool to room temperature with stirring. The Nujol solution became grease at room temperature. It was confirmed by infrared analysis that the grease contained no free acid. On the other hand, when the grease was obtained by cooling the Nujol solution in which the soap samples had previously been dissolved at a high temperature (100—160°C), it was demonstrated by infrared analysis that a part of the soap samples was decomposed and free acid was released.

The procedure for observing the aggregates by means of an electron microscope was described in a previous paper.[1]

Results and Discussion

1) Characteristics of the Bivalent Metal Soaps. Since no data on the bivalent metal soaps of 12-hydroxyoctadecanoic acid have yet been described in the literature, some of them are given, together with the data for stearate soaps reported by Matsuura[4] in Table 1. One can see some characteristics of the hydroxyoctadecanoate soaps by comparing them with the stearate soaps.

i) Water of crystallization: With regard to the water of crystallization the hydroxyoctadecanoate soaps are similar to the corresponding stearate soaps.

ii) The infrared absorption spectra: Two infrared absorption bands are found at about 1400 cm^{-1} and 1550 cm^{-1}, they are due to the symmetric and asymmetric stretching vibrations respectively of the carbox-

a), b) Numerical values in parentheses represent those for the corresponding soaps of stearic acid.[4]

ylate ion. Matsuura[4] pointed out that the latter band is broadened or split into two or more bands in the hydrated stearate soaps. However, this splitting of the band was observed for all of the hydroxyoctadecanoate soaps used here, whether hydrated or not.

iii) The X-ray diffraction patterns: The hydroxyoctadecanoate soaps show a long spacing of around 49 Å, this is almost the same value as that of the corresponding stearate soaps, as is shown in Table 1. This value corresponds approximately to double the length of the hydroxyoctadecanoate chain, meaning that the hydroxyoctadecanoate soaps have a layer structure such as that established in the crystal structure of fatty acid and its soaps. It is also common to both the hydroxyoctadecanoate and stearate soaps that the Zn soap gives an abnormally low value of long spacing. It can also be pointed out that the hydrated soaps generally show higher values in the long spacing than do the unhydrated soaps.

The short spacing, which is associated with the interchain distance, is generally broader in the hydroxyoctadecanoate soaps than in the corresponding stearate soaps. The Mn, Ni, and Cu hydroxyoctadecanoates exhibited a diffraction pattern composed of diffuse bands, thus indicating low crystallinity. Here these results will not be taken into consideration further; the present paper will deal mainly with the sense of twist of the soap fibers.

2) The Form of the Aggregates. It was found that the bivalent-metal soaps of the D- (or L-) acid do not always form fibrous aggregates, but produce twisted fibers under appropriate conditions.

Typical electron micrographs are presented in Figs. 1 and 2. These photographs were made to show the same direction as that of the twist of the specimen.

The size and form of the fibrous aggregates and their sense of twist were characteristic of the individual soap under certain conditions. For example, when separated out from ethanol, the Mg soaps produced fibers of a reasonably uniform width of 0.03 μ, while the Sr, Mn, Cu, Cd, Hg, and Pb soaps often produced two types of fibers at the same time: (i) thin fibers of about 0.03 μ wide, with a small pitch of twist, and (ii) ribbons of large dimensions and with a large pitch of twist. The Zn soap precipitated from ethanol in a form of platelets, with a trace of twisted fibers (right-handed and left-handed fibers). This fact may be associated, in some manner, with the abnormally low value of the X-ray long spacing of this soap.

The bivalent metal soaps often produced both right-handed and left-handed fibers at the same time in ethanol. Which type of twisted fibers was more abundant, depended on the solvent used. The Ca soap (D-form) alone exhibited a behavior different from the other soaps in that it produced exclusively the right-handed fibers, not only from alcohols, but also from Nujol. In this connection, the Ca soap showed the same behavior as the Li soap.

3) Enantiomorphic Relationship for the Helical Sense. The relationship between the two enantiomers was previously established for the fibers of the free D- (or L-) acid and of its alkali metal soaps[1] and for the fibers of synthetic polypeptides.[5] As the same relationship can also be expected for the bivalent metal soaps, it was examined by the use of the Ca soap. The fibers from the Ca soap of the D-acid showed a right-handed twist, while those from that of the L-acid showed a left-handed twist, regardless of the solvent used. The Ca soap of the DL-acid (racemic form) gave amorphous precipitates. These micrographs are shown in Figs. 1a, b, and c. Thus it was also demonstrated, for the Ca soap, that the sense of twist in the helical aggregates is primarily associated with the optical isomerism. However, other bivalent metal soaps of the one enantiomer often produced both right-handed and left-handed fibers from the same solution. The same phenomenon was previously observed with the Na and K soaps.[1] This shows that some factors obscure the effect due to the asymmetry of molecule.

4) Solvent Effect on the Sense of Twist. Solvent effects have already been reported for the fibers of the free D- (or L-) acid and of its Li soap, the twist of which showed a one-handed sense in the C_2—C_4 alcohols

5) T. Tachibana and H. Kambara, *Kolloid-Z. Z. Polym.*, **219**, 40 (1967); this paper reports that enantiomorphism is found between helical aggregates of the D-isomer and the L-isomer of poly-γ-benzyl glutamate. Thereafter, we have found the same result with poly-γ-methyl (ethyl, *n*-propyl, or *i*-propyl) glutamate. These polypeptides also gave right-handed fibers for the D-enantiomer and left-handed fibers for the L-enantiomer.

and both senses in longer alkyl chain alcohols. For the Mg and Cd soaps also, an effect was found similar to that observed with the Li soap. The Mg soap of the D-acid produced predominantly the left-handed fibers from alcohols, while produced predominantly the right-handed fibers from Nujol. On the other hand, the Cd soap produced both right-handed and left-handed fibers from alcohols at the same time, though the fraction of the right-handed fibers increased with the length of the alkyl chain in a series of normal fatty alcohols, and right-handed fibers were exclusively produced from Nujol. It is interesting to note that, with regard to the sense of twist, polar or hydroxy solvents such as alcohols have effects contrary to those of such non-polar solvent as Nujol. This is not due to a difference in the crystalline phase between the soap crystal from alcohols and that from Nujol, since the samples from both solvents gave the same X-ray diffraction patterns. Accordingly, the solvent effect observed here can be regarded as a result of a crystal habit. Probably the polar-nonpolar structure of the soap crystal is associated with the observed effect. The possibility of a solvent effect due to an optically active solvent such as optically active amyl alcohol, was examined in the Ca soap, but no effect was observed.

5) The effect of Water. It was found that the presence of water in alcohols greatly influences the form of the soap aggregates. The Ca soap produced the twisted fibers from anhydrous ethanol, as is shown in Fig. 1a, but it produced only platelets from aqueous ethanol. However, the Sr, Ni, and Pb soaps, which were precipitated mostly as amorphous aggregates from anhydrous alcohols, produced a large number of twisted fibers from aqueous ethanol containing 5%(v/v) water (Figs. 2a, f, and 1). These fibers developed greatly with an increase in the water content, so that the sense of twist was more clearly observed with such fibers. However, the Pb soap from aqueous ethanol gave wider and larger ribbons, in which the twist was little observed. On the other hand, the Zn, Ba, and Cd soaps showed little effect of water on the form of the soap aggregates. An infrared spectral examination showed that the Ca, Sr, and Ba soaps recovered from aqueous ethanol were hydrated salts.

The water effect was observed also when the soaps were crystallized out from Nujol. For example, the Mg, Sr, and Ba soaps yielded fibers twisted a little from Nujol containing no water, but well-developed fibers were obtained when the metal soaps were prepared by neutralizing the D-acid in Nujol with an aqueous solution of the corresponding bivalent metal salts or when soaps previously prepared were dissolved into Nujol containing a certain amount of water at a high temperature. In these experiments, it was necessary to choose the most appropriate temperature.

Previously, Birdsall *et al.*[6] observed in a commercial Ca tallowate-minral oil grease, that the soap fibers were present only when a sufficient amount of water had been incorporated into the grease from which the fibers are formed. In this case, the soap crystallized out was of a hydrated form. These results evidently indicate that water in alcohols or Nujol plays some role in developing the soap crystal as a fibrous form. However, in the case of the hydroxyoctadecanoate soaps, the anhydrous soaps also produced the twisted fibers, as has already been described. Therefore, the twisting is not specific to the hydrated soap. Probably water aids in the development of soap fibers during the crystal growth.

6) Aging Effect. It was observed that the soap fibers changed their form when allowed to stand in the solution from which the fibers had been produced; the Cu soap gave left-handed thin fibers and right-handed wide ribbons immediately after it was separated out from ethanol, but the right-handed ribbons were found predominantly in the aged precipitate; the Ni soap produced a globular aggregates as the initial precipitate, and left-handed fibers from the aged precipitate.

The presence of water in ethanol was found to promote the change of the form of the aggregate; the Sr soap produced left-handed thin fibers and non-twisted ribbons as the initial precipitate, and non-twisted wider ribbons alone after sufficient aging (see Figs. 2a and b); the Pb soap initially produced left-handed fibers, and ribbons after aging. These changes were accelerated by increasing the water content in ethanol.

The Ca and Cd soaps often yielded such large twisted fibers that they were visible under an optical microscope. Such fibers were prepared by crystallizing these soaps out from aqueous ethanol and by then evaporating the solvent very slowly. The sense of twist for the large fibers was the same as that in the thin fibers previously observed by means of an electron microscope.

TABLE 2. THE SENSE OF TWIST IN THE FIBERS FROM BIVALENT METAL SOAPS OF D-12-HYDROXY-OCTADECANOIC ACID

Soap	The sense of twist solvent		
	ethanol	aqueous ethanol	Nujol
Mg	l	l	r & (l)
Ca	r	platelet	r
Sr	(l)	l	(r) & (l)
Ba	(l)	platelet	(r) & l
Mn	r & l		
Ni	(l)	(r) & l	
Cu	r & l	(r) & l	
Zn	(r) & (l)	(r) & l	
Cd	r & l	(r) & l	r
Hg	r & l	l	
Pb	(r) & (l)	l	

r: right-handed twist; l: left-handed twist.
(r) or (l) means the presence of a trace of the corresponding twist.

6) D. H. Birdsall and B. B. Farrington, *J. Phys. & Colloid Chem.*, **52**, 1415 (1948).

7) General Remarks on the Sense of Twist. The sense of twist of the soap fibers is summarized in Table 2. From this table, one can see a tendency for the bivalent metal soaps of the D-hydroxyoctadecanoate to favor, more or less, the formation of the left-handed fibers. The same tendency has also been found for all the alkali metal soaps except for the Li soap. This is considered to be a reflection of molecular asymmetry in the sense of twist of the soap fibers. However, it is characteristic of the bivalent metal soaps that both types of twisted fibers are, except in the case of the Ca soap, produced from the same specimen, although which type is predominant depends on the solvent used.

8) Fine Structure of Fibers. The observation of the structure of soap fibers by high-resolution electron microscopy was made using the Sr soap, which is comparably heat-resistant. The specimens were prepared by allowing a drop of the aqueous ethanol solution to dry on a micro-plastic grid for electron microscopy. The micrographs were photographed at an instrumental magnification of 100,000 X in a JEM-100B electron microscope without further treatment. Twisted thin fibers (width, 0.01 μ) and comparably large ribbons (width, about 0.1 μ) were found; the fine structure could be observed in the latter. Figure 3 shows a typical micrograph, in which striations are seen running parallel to the lengths of the fibers. The spacing of these striations is 33—40 Å, which approximates to the long spacing value of 47.5 Å derived from the X-ray diffraction patterns of the soap. Taking into account the uncertainty of the instrumental magnification, this indicates that Sr atoms all arranged in lines along the fiber axis with a periodicity of about 40 Å, and that the hydroxyoctadecanoate chains of the soap molecules all aligned approximately parallel to the width of the fibers. This is in accord with the observations on Na laurate fibers made by Camp and Shuttleworth[7] and on Ca soap fibers made by Bird and Rooney.[8]

The thickness of the ribbon was too thin to be estimated, probably being less than 50 Å. We observed a considerable disordered part where the striations were not seen on the surfaces of the ribbon; the ribbon consisted of a crystalline region and an amorphous region. From such a fine structure, it is presumed that each surface of a ribbon involves polar groups and non-polar alkyl chains of the hydroxyoctadecanoate molecules, and that the thin sides of it consist of polar groups alone or of non-polar groups alone, depending upon the polarity of the solvent from which the ribbons have been separated. One might expect that such thin ribbons would tend to twist themselves or to associate with one another as the result of the free energy requirement. In fact, the electron micrographs demonstrate that the structure is made up of two or more individual fibers twisted about one another. A similar structure is also encountered in twisted fibers of optically non-active soaps such as Na myristate and Ca tallowate. In these cases, both right-handed and left-handed fibers were observed. On the other hand, it has been established by the X-ray diffraction study that the crystal structure of long chain fatty acid and its salt is composed of alternately ionic layers and hydrocarbon layers, stacked on one another. These facts suggest that the twisting of the soap fibers results from the layer structure characteristic of soap. The one-handed twist of thin fibers composed of optically-active molecules is due to the asymmetry of the fiber structure itself.

In this series of studies, an enantiomorphic relationship in helical aggregates has been clearly demonstrated for 12-hydroxyoctadecanoic acid and its Li and Ca soaps. Other soaps of this acid produced both right-handed and left-handed fibers from the one enantiomer and, then, one of them was more or less predominant: the fibers from the univalent and bivalent metal soaps of the D-acid are inclined to twist to the left. This result is evidence that the sense of twist in the macrohelix is determined by the molecular asymmetry. Since biological fibers often exhibit a one-handed twist, it may be suggested that, in this case also, molecular asymmetry may play a role in determining the sense of twist at any stage of the fiber formation.

These studies were supported by a Scientific Research Grant from the Ministry of Education.

The Polymorphism and Physical Properties of the 1,6-Diaminopyrene-*p*-chloranil and Related Molecular Complexes[1)]

Shigeo KOIZUMI and Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received September 2, 1971)

The 1,6-diaminopyrene-*p*-chloranil complex is dark blue when crystallized from chloroform and brown when crystallized from benzene. These two substances are distinctly different in X-ray diffraction, electronic spectrum, vibrational spectrum, and also electrical resistivity. The brown form, the resistivity of which is about 10^5 ohm cm, can be transformed into a third form, exhibiting only a few ohm cm, by compression in the presence of benzene or some other aromatic solvents. Dimorphic forms are also found with the complexes of trichloromonobromo- and dichlorodibromo-*p*-benzoquinones. One of these forms is of a similar nature to the dark blue-colored *p*-chloranil complex. The other form is brown. Only the brown form is obtainable for the complexes of monochlorotribromo-*p*-benzoquinone and *p*-bromanil. All the brown complexes except that of *p*-chloranil are similar and exhibit resistivities of the order of 10^3 ohm cm. In addition, black products exhibiting resistivities of several ohm cm can be prepared by using acetone as the solvent with 1,6-diaminopyrene and tetrahalo-*p*-benzoquinones. Contrary to the afore-mentioned complexes, no definite composition can be assigned to these low-resistivity products.

A large number of molecular complexes formed by interaction between organic electron-donors and acceptors have been examined for semiconductivity and related electronic properties in the past two decades. Among them, the 1,6-diaminopyrene-*p*-chloranil complex seemed to be particularly interesting because of the following reasons: 1) It has been well established that crystal complexes are rather sharply divided into two groups, namely, non-ionic and ionic complexes.[2-4)] Furthermore, the complexes with electrical resistivities of 10^6 ohm cm or less have been shown to be ionic.[5)] The 1,6-diaminopyrene-*p*-chloranil and related molecular complexes were the only exceptions to this rule known before our recent work on benzidine complexes.[6)]

2) The resistivity values recorded for the *p*-chloranil complex are scattered over a wide range, 10^3—10^4 ohm cm for the pressed polycrystalline samples and 10^5—10^9 ohm cm in the three directions of the single crystal.[7-9)] In a preliminary report, one of the present authors suggested that these scattered values can be correlated with the polymorphic forms.[10)]

3) The brown form of the *p*-chloranil complex can be transformed into a new form with a resistivity of only a few ohm cm if compressed with a small amount of benzene.[10)]

Previously we presented a way of demonstrating the effects of the size and shape of the component molecules on the electronic structure of crystal complexes.[11)] The diagram proposed there revealed that the 1,6-diaminopyrene-*p*-chloranil is located near the border line between non-ionic and ionic complexes of this donor. Moreover, the tetramethylbenzidine-*p*-chloranil complex, which exhibits a resistivity of 10^6 ohm cm, is near the above-mentioned location in the diagram. Thus, non-ionic complexes seem to exhibit relatively low electrical resistivities only when their charge-transfer absorptions are in an exceptionally low energy region. Guided by this working hypothesis, we have prepared several non-ionic complexes of benzidine and its derivatives with resistivities of 10^3—10^5 ohm cm.[6)] An examination of the electronic properties of the 1,6-diaminopyrene-*p*-chloranil and related complexes in more detail was highly desirable in order to verify the above-mentioned hypothesis. As the existence of some polymorphic forms has been noted, such a study would provide an excellent chance of demonstrating the importance of the stacking of the component molecules as one of the factors determining the electronic properties of molecular complexes. Furthermore, we were very much interested in the possibility of obtaining low-resistivity complexes without the process of compression.

Experimental

Materials. The *p*-chloranil, 2,5-dichloro-, and 2,6-dichloro-*p*-benzoquinones, and the *o*-chloranil were commercially obtained. The other component compounds were prepared following the procedures described in the references cited: 1,6-diaminopyrene,[12)] trichloromonobromo-*p*-benzoquinone,[13)] 2,5-dichloro-3,6-dibromo-*p*-benzoquinone,[14)] 2,6-dichloro-3,5-dibromo-*p*-benzoquinone.[14)] monochlorotribromo-*p*-benzoquinone,[15)] *p*-bromanil,[16)] 2,3-dichloro-

p-benzoquinone,[17] and *o*-bromanil.[18]

The complexes were crystallized when hot solutions of the components were mixed. For example, a solution of 1,6-diaminopyrene (0.70 g) in 350 m*l* of hot chloroform was added to a solution of *p*-chloranil (0.73 g) in 150 m*l* of hot chloroform. Dark blue crystals were filtered out and washed with the solvent. The yield was 0.85 g. Calcd for $C_{16}H_{12}N_2 \cdot C_6Cl_4O_2$: C, 55.3; H, 2.5; N, 5.9; Cl, 29.7%. Found: C, 55.2; H, 2.4; N, 6.1; Cl, 29.4%. When a solution of the quinone (1.48 g) in 150 m*l* of hot benzene was added to a solution of 1,6-diaminopyrene (1.40 g) in 700 m*l* of the same solvent, brown needles appeared on cooling. The yield was 1.70 g. Found: C, 55.9; H, 2.9; Cl, 28.7%. The *p*-bromanil complex was brown when similarly prepared from both chloroform and benzene. Calcd for $C_{16}H_{12}N_2 \cdot C_6Br_4O_2$: C, 40.3; H, 1.8; N, 4.3; Br, 48.8%. Found: C, 40.6; H, 2.0; N, 4.7; Br, 49.5% for a preparation from chloroform. C, 40.3; H, 1.9; N, 4.4; Br, 48.1% for a preparation from benzene.

When acetone was used as the solvent, the product showed various compositions depending upon the conditions of preparation, *e.g.*, the ratio of the donor to the acceptor employed and their concentrations. The following examples show two extremes in the combination of 1,6-diaminopyrene and *p*-chloranil. The diamine (0.46 g) dissolved in 20 m*l* of acetone was added to 1.48 g of *p*-chloranil in 80 m*l* of hot acetone. The mixture was kept overnight in a stoppered flask, and then the black crystalline deposits were filtered. The yield was 0.43 g. Found: Cl, 16.2% (No. 1 in Table 3). An acetone solution containing 1,6-diaminopyrene and *p*-chloranil in a mole ratio of 1 : 3 was evaporated to dryness at room temperature. The free *p*-chloranil in the deposits was removed by extraction with benzene using a Soxhlet apparatus. The remaining sample was analysed. Found: C, 46.8; H, 2.1; N, 4.6; Cl, 36.3; O, 8.6% (No. 2 in Table 3). One preparation of the 1,6-diaminopyrene-*p*-bromanil crystallized from acetone had the following composition: C, 36.8; H, 1.8; N, 2.9; Br, 53.4% (No. 9 in Table 3).

Measurements. The X-ray measurements were made with a Toshiba recording X-ray diffractometer, Model ADG-301, using filtered copper radiation. The electronic spectra of the crystal complexes were recorded on a Beckman DK-2A spectrophotometer, and the vibrational spectra, on a Jasco IR-G infrared spectrophotometer, both as Nujol mineral oil mulls. The resistivities were measured with a Yokogawa Wheatstone bridge, Type 2768, employing a cell similar to that designed by LaFlamme.[19] During the measurements, the samples were compressed by applying a pressure of about 0.8 kilobars. The temperature was adjusted in the range from room temperature to 100°C using a heating tape wrapped around the cell and with the aid of a Chino temperature-indicating controller.

Results and Discussion

The 1 : 1 Complexes. *p*-Chloranil and trichloromonobromo- and dichlorodibromo-*p*-benzoquinones form dark blue-colored complexes with 1,6-diaminopyrene in chloroform. As they are green when pulverized, hereafter "green form" will be used to designate them. All the quinones give brown-colored

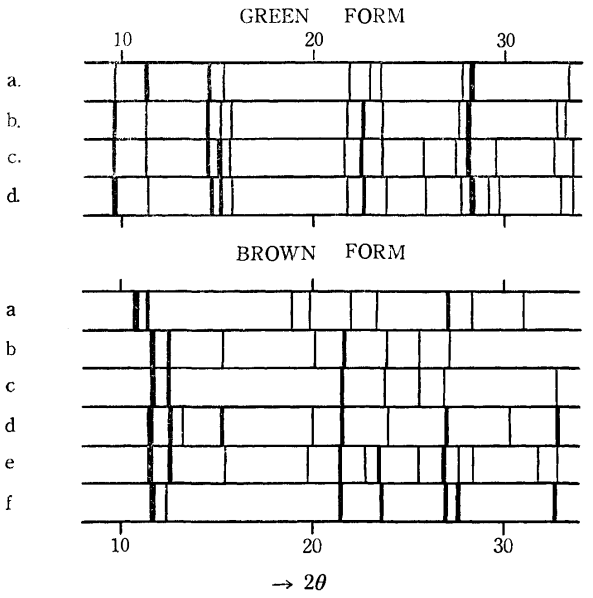

Fig. 1. X-Ray diffraction patterns of the 1,6-diaminopyrene complexes with (a) *p*-chloranil, (b) trichloromonobromo-*p*-benzoquinone, (c) 2,5-dichloro-3,6-dibromo-*p*-benzoquinone, (d) 2,6-dichloro-3,5-dibromo-*p*-benzoquinone, (e) monochlorotribromo-*p*-benzoquinone, and (f) *p*-bromanil.

complexes if mixed with 1,6-diaminopyrene in benzene. The same brown-colored *p*-chloranil complex can be crystallized from the following solvents; toluene, xylene, mono- and *o*-di-chlorobenzenes. The green form is transformed into the brown form when recrystallized from benzene. With monochlorotribromo-*p*-benzoquinone and *p*-bromanil, the brown forms are crystallized even from chloroform. The X-ray diffraction patterns are schematically presented in Fig. 1. The patterns given by all the green forms are similar to each other. However, the brown form of the *p*-chloranil complex is apparently different from the others; hereafter, the latter will be called "the brown form of the second type." Thus, the existence of polymorphic forms in the present complexes is evident. As will be described in the following paragraphs, the difference between the green and brown forms and also that within the brown forms are markedly reflected in their physical and chemical properties. Although only the complexes with *p*-chloranil and *p*-bromanil were analysed, the other complexes mentioned above are doubtlessly of a 1 : 1 composition, also.

The measurements of the electronic spectra of the complexes of *p*-chloranil and *p*-bromanil have been attempted by Kronick *et al.*[20] In their measurements the specimens were ground with potassium bromide and pressed into disks. The absorption spectra obtained by them in the range from about 14 to 40 kK showed the complexes to be mostly radical-ion salts. For instance, the mole fractions of the ionic component of the *p*-chloranil complex was estimated to be as high as 0.90. As was pointed out in our previous paper, the vibrational spectrum is in contradic-

tion with their characterization.[5] Therefore, we examined the electronic spectra of the present complexes by measuring the diffuse reflectance in the range from 6 to 30 kK of the specimens diluted with sodium chloride or naphthalene.[10] Contrary to the spectra presented by Kronick *et al.*, ours showed strong absorptions extended into the near-infrared region. As the charge-transfer absorption of the *p*-chloranil complex is located at 9.9 kK in chloroform and at 8.8 kK in toluene, our observation seemed to be consistent with the view that the complexes are non-ionic. Nevertheless, all the spectra, especially those of the brown forms, contained an extra band appearing at 14 kK. This location can well be compared with a band in the spectrum of 1,6-diaminopyrene monobromide reported in our previous work.[21] The intensity was increased by prolonged grinding, and also by storage; therefore, the cation-radical may be supposed to be formed in these processes. Apparently the discrepancy between the spectra presented by Kronick *et al.* and ours arises from the instability of the complexes ground with potassium bromide. In the present work, we attempted various methods to prevent the appearance of the band at 14 kK. The measurements as Nujol mineral oil mulls was found to be the best from this standpoint. However, with this technique it is not possible to estimate how large the light scattering is or how it depends on the wavenumber, because then the specimens absorb light over the entire measurable range. The apparent spectra newly-obtained for the *p*-bromanil complex and the green and brown forms of the *p*-chloranil complex are shown in Fig. 2. The green form withstands grinding better than the brown form. Consequently, we see that the spectrum of the green form of the *p*-chloranil complex is in essential agreement with that previously measured by the diffuse-reflection method. The spectrum of the brown form is very much improved by the present technique. The absorption maximum of the low-energy band is located around 7 kK. This value is lower by about 2 kK than the energy of the charge-transfer band of this complex dissolved in toluene, from which this form can be crystallized. On the other hand, the low-energy band in the green form appears at exactly the same place as the charge-transfer band of the complex dissolved in chloroform. The overall patterns of these two are similar, and both are certainly of charge-transfer complexes. However, a shoulder on the low-energy side of the absorption band in the visible region is observed only in the spectrum of the brown form, not in that of the green form. Very recently Amano *et al.* presented the crystal spectra of diaminopyrene complexes.[22] In their spectrum of the brown-colored *p*-chloranil complex, there is no charge-transfer band in the near-infrared region. This serious disagreement has yet to be explained. The *p*-bromanil complex, the representative of the brown forms of the second type, shows a spectrum similar to that of the brown-colored *p*-chloranil complex.

As has been reported previously, the vibrational spectrum of the brown form of the *p*-chloranil complex is well approximated by the superposed spectra of the compounds.[5] The green forms and the brown forms of the second type give similar spectra, indicating that they are also non-ionic. However, the patterns in

the region between 1500 and 1700 cm^{-1} are very characteristic of each form. For example, Fig. 3 presents the spectra of the complexes of *p*-chloranil and *p*-bromanil. In the spectrum of the brown-colored *p*-chloranil complex, the bands at 1500, 1595, and 1625 cm^{-1} may be assigned to the donor, and those at 1560 and 1680 cm^{-1}, to the acceptor. The carbonyl stretching band is shifted to 1655 cm^{-1} in the spectrum of the green form. The *p*-bromanil complex gives the highest energy band in this region at 1655 cm^{-1}, but its intensity is markedly weaker than that of the band at 1625 cm^{-1}. Thus, the deviation from the superposed spectrum in the above-mentioned region is appreciable in both the green forms and brown forms of the second type. This observation indicates that the mode of intermolecular interaction is somewhat different in these forms.

The electrical resistivities of compressed polycrystalline samples of the complexes obey the usual exponential law;

$$\rho = \rho_0 \exp(E_a/kT),$$

where ρ is the resistivity, ρ_0 is a constant, and E_a is the activation energy for semiconduction. As has been found in many semiconductors, the value in the high-temperature range is often larger than that in the low-temperature range. For example, the results of the measurements of the complexes of *p*-chloranil, trichloromonobromo-*p*-benzoquinone, and *p*-bromanil are plotted in Fig. 4. The data on all the complexes are listed in Table 1. Kronick and Labes grew their single crystal of the *p*-chloranil complex from chloroform and obtained the following resistivities at 25°C in three directions: 10^5, 10^6, and 10^9 ohm cm.[9] Considering the solvent employed by them, these values may be compared with our value for the green form. The present result agrees reasonably well with the geometric mean of the values observed by Kronick and Labes. In addition, the activation energy in one of the three directions reported by them, 0.19 eV, is in good agreement with our value for the high-temperature range. As may be noted in Table 1, the values of the resistivity and the activation energy in the green forms of the other three complexes are similar to those of the *p*-chloranil complex.

After careful drying, the brown-colored *p*-chloranil complex exhibits a resistivity of the order of 10^5 ohm cm, as is listed in Table 1. This value can be quickly decreased by compression in the presence of benzene. Even a trace of the solvent remaining in the sample can result in a lowering of the resistivity to 10^3—10^4 ohm cm, the values reported by earlier workers.[7,8] If the amount of the solvent is enough, *e.g.*, a few drops per gram, a resistivity as low as a few ohm cm can be achieved. Not only benzene but also the following aromatic liquids were found to be more or less effective in effecting the transformation; toluene, xylene, chlorobenzene, *o*-dichlorobenzene, dimethylaniline, nitro-

TABLE 1. ELECTRICAL PROPERTIES OF THE 1,6-DIAMINOPYRENE COMPLEXES

Acceptor	Form	Resistivity at 20°C (ohm cm)	E_a (eV)[a]
p-Chloranil	Green	1.3×10^6	0.14, 0.20
	Brown	2.7×10^5	0.11, 0.14
Trichloromonobromo-*p*-benzoquinone	Green	9.7×10^5	0.14, 0.17
	Brown (II)	3.3×10^3	0.10, 0.12
2,5-Dichloro-3,6-dibromo-*p*-benzoquinone	Green	3.3×10^6	0.15, 0.19
	Brown (II)	4.0×10^3	0.12, 0.13
2,6-Dichloro-3,5-dibromo-*p*-benzoquinone	Green	2.3×10^6	0.14, 0.16
	Brown (II)	1.3×10^4	0.11
Monochlorotribromo-*p*-benzoquinone	Brown (II)	2.4×10^3	0.10
p-Bromanil	Brown (II)	2.3×10^3	0.10

a) The first value is for the low-temperature range, and the second for the high-temperature range.

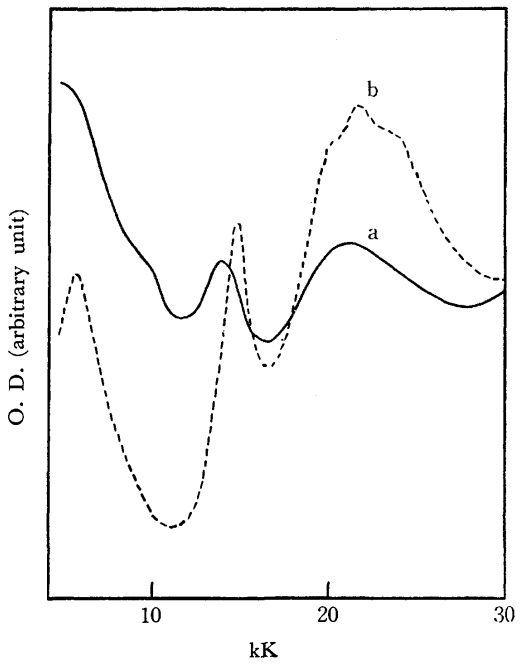

Fig. 5. Electronic spectra of (a) the low-resistivity form of the *p*-chloranil complex and (b) 1,6-diaminopyrene monobromide.

benzene, and pyridine. Contrary to the green and brown forms, which are stable up to about 160°C, the low-resistivity form is not very stable, even at room temperature. After storage for several years, a resistivity of about 100 ohm cm was recorded. The electronic spectrum is shown in Fig. 5, along with that of 1,6-diaminopyrene monobromide measured by the same technique. The absorption in the near-infrared region is appreciably stronger than that in the visible region, and it is shifted to the low-energy side compared with those in the green and brown forms. This behavior seems to be consistent with its low-electrical resistivity, as was noted at the beginning of this paper.

The presence of some diaminopyrene cation-radicals indicated by the peak at 14.0 kK must be mentioned. In the process of the transformation, the complex is compressed; therefore, the pellet produced must be crushed for further examination. As was mentioned earlier, this final step is possibly accompanied by the formation of the cation-radical. The presence of a fair amount of the cation-radical may correlate with the low resistivity, as has been suggested by Kronick *et al*;[20] however, it must be pointed out that the low resistivity can be observed before the crushing. As may be expected from the electronic spectrum shown in Fig. 5, this form shows a strong absorption in the rock-salt region. The vibrational pattern in the above-mentioned characteristic region consists of bands at 1500, 1530, 1580, and 1635 cm^{-1}. If the last one arises from the carbonyl-stretching vibration, it is shifted to the low-energy side as much as 50 cm^{-1}. This unusually large shift may indicate that the crystal structure allows an appreciable contribution of the dative structure to the ground state. It may be suggested that the low-resistivity form has an electronic structure which is intermediate between non-ionic and ionic.

All the brown-colored complexes of the second type exhibit resistivities of the order of 10^3 ohm cm. This value is in accordance with that reported for the *p*-bromanil complex by Labes *et al.*[7] They are stable under compression in the presence of benzene as well as the green forms of the complexes of *p*-chloranil and

Table 2. Classification of the 1 : 1 complexes

Solvent	Halogen atoms on quinonone molecule				
	Cl_4	Cl_3Br	Cl_2Br_2[a]	$ClBr_3$	Br_4
Chloroform	Green form Resistivity 10^6 ohm cm				Brown from (II) 10^3 ohm cm
Benzene	Brown form 10^5 ohm cm		Brown form of (II) Resistivity 10^3 ohm cm

12	2,5-Dichloro-*p*-benzoquinone	Evaporation	2 : 3	10^4
13	2,6-Dichloro-*p*-benzoquinone	Evaporation	2 : 3	10^5
14	*o*-Chloranil	Evaporation	2 : 3	10^4
15	*o*-Bromanil	Evaporation	2 : 3	10^4

trichloromonobromo- and dichlorodibromo-*p*-benzoquinones. The classification of these 1 : 1 complexes, based on X-ray diffraction and physical properties, is summarized in Table 2. It is interesting to note that the kind of polymorphic form is entirely governed by the number of chlorine (or bromine) atoms on the quinone molecule. The large difference in the optical and electrical properties found in these polymorphic forms shows the importance of the stacking of the component molecules as one of the factors determining the electronic properties of these complexes.

The Non-stoichiometric Complexes.[23] 1,6-Diaminopyrene dissolves well in acetone; therefore, we attempted the preparation of the complexes in acetone in order to avoid the use of a large amount of the solvent. Surprisingly, the complexes prepared in acetone are of an entirely different nature from the 1 : 1 complexes described above. They show no definite composition. The complexes were prepared by crystallization from acetone or by the evaporation of the acetone solution to dryness. The second process was performed by lefting the solution stand in a good hood without heating. As may be seen in Table 3, a low resistivity can be achieved over a fairly wide range of composition (*e.g.*, see Nos. 1 and 2). Although the compositions of Nos. 2 and 9 do not exactly correspond to any simple ratio of the donor to the acceptor, both of them are not far from the calculated values for a mole ratio of 2:3: C, 49.9; H, 2.0; N, 4.7; Cl, 35.5; O, 8.0%, and C, 34.6; H, 1.4; N, 3.2; Br, 55.3%, respectively. Therefore, for the quinones other than *p*-chloranil, the evaporation was carried out only at this mole ratio. It must be added that the complex prepared by the evaporation of an acetone solution to dryness cannot be homogeneous. The composition of No. 1 is markedly different from the ratio of the diaminopyrene to the *p*-chloranil initially dissolved into the solvent. When the solvent is evaporated, the composition of the deposit is expected to vary according to the changes in the mole ratio and also in the concentration. Moreover, we can expect the presence of some decomposition products in the samples made by this method. These two factors may explain the observed difference in resistivity between the samples made by crystallization and those made by evaporation (compare Nos. 9 and 10). In Table 3 we can see that only tetrahalo-*p*-benzoquinones give low-resistivity complexes with 1,6-diaminopyrene in this solvent.

23) The resistivities in this section were measured on compressed pellets by a four-probe method using an A. & M. Fell Model B resistivity test rig and a Keithley Model 502 milliohmmeter.

The authors wish to express their thanks to Dr. Toshio Yokokawa for the use of the X-ray diffractometer.

The Second CMC of the Aqueous Solution of Sodium Dodecyl Sulfate. I. Conductivity

Masaji MIURA and Michiko KODAMA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received September 3, 1971)

The conductivity studies of the aqueous solution of sodium dodecyl sulfate (SDS) over the concentration range of 0—0.12 M revealed that there exists a so-called 2nd critical micelle concentration (CMC) at about 65 mM in addition to the 1st CMC at 8.3 mM. The 2nd CMC was greatly influenced by additives; sodium chloride lowered the 2nd CMC, whereas organic substances, such as dodecyl alcohol and *n*-hexane, raised it. Moreover, the specific conductivity-concentration curve of the pure SDS solution broke upward at the 2nd CMC, and its slope increased in the presence of sodium chloride, while it bent toward the concentration axis in the presence of a certain amount of dodecyl alcohol or *n*-hexane. These facts may afford a clue for explaining the micelle structure above the 2nd CMC.

It has been known that, in surfactant solutions, in addition to an initial critical micelle concentration (1st CMC), there occurs a change in the properties of surfactant solutions at a concentration above the 1st CMC, which is usually called the 2nd CMC.

Several works have been done on the 2nd CMC. Tyuzyo *et al.*[1-3] have found a method of estimating the 2nd CMC from the viscosity data. Ekwall and his co-workers[4-9] measured the density, viscosity, and vapor pressure of an aqueous sodium caprylate solution over a wide concentration range above the 1st CMC and discussed the change in the micelle structure. Rovins *et al.*[10] have investigated the 2nd CMC by measuring the viscosity and light-scattering of aqueous solutions of 2-dodecylaminoethanol salts. In our

laboratory we measured the conductivity and viscosity of the Aerosol-OT solution,[11] the conductivity, sound velocity, and viscosity of sodium dodecyl sulfate (SDS) solution,[12] and the fluorescence spectrum of acridine orange which was added to an SDS solution;[13] the presence of the 2nd CMC was ascertained in these systems. Thus, it has been revealed by various methods that the 2nd CMC exists in surfactant solutions. However, how the shape and size of the micelle vary at the 2nd CMC is still little known.

It is well known that the impurity of an electrolyte or non-electrolyte which is present in a surfactant solution lowers the 1st CMC and increases the micelle size. It can be expected, therefore, that the 2nd CMC may also be greatly influenced by such impurities.
